Stability Yields Sublinear Time Algorithms for Geometric Optimization in Machine Learning

Hu Ding 

School of Computer Science and Technology,
University of Science and Technology of China, Anhui, China

Abstract

In this paper, we study several important geometric optimization problems arising in machine learning. First, we revisit the Minimum Enclosing Ball (MEB) problem in Euclidean space \mathbb{R}^d . The problem has been extensively studied before, but real-world machine learning tasks often need to handle large-scale datasets so that we cannot even afford linear time algorithms. Motivated by the recent developments on beyond worst-case analysis, we introduce the notion of stability for MEB, which is natural and easy to understand. Roughly speaking, an instance of MEB is stable, if the radius of the resulting ball cannot be significantly reduced by removing a small fraction of the input points. Under the stability assumption, we present two sampling algorithms for computing radius-approximate MEB with sample complexities independent of the number of input points n . In particular, the second algorithm has the sample complexity even independent of the dimensionality d . We also consider the general case without the stability assumption. We present a hybrid algorithm that can output either a radius-approximate MEB or a covering-approximate MEB, which improves the running time and the number of passes for the previous sublinear MEB algorithms. Further, we extend our proposed notion of stability and design sublinear time algorithms for other geometric optimization problems including MEB with outliers, polytope distance, one-class and two-class linear SVMs (without or with outliers). Our proposed algorithms also work fine for kernels.

1 Introduction

Many real-world machine learning tasks can be formulated as geometric optimization problems in Euclidean space. We start with a fundamental geometric optimization problem, *Minimum Enclosing Ball (MEB)*, which has attracted a lot of attentions in past years. Given a set P of n points in Euclidean space \mathbb{R}^d , where d could be quite high, the problem of MEB is to find a ball with minimum radius to cover all the points in P [16, 38, 60]. MEB finds several important applications in machine learning [68]. For example, the popular classification model *Support Vector Machine (SVM)* can be formulated as an MEB problem in high dimensional space, if all the mapped points have the same norm by using kernel method, *e.g.*, the popular radial basis function kernel [80]. Hence fast MEB algorithms can be adopted to speed up its training procedure [24, 25, 80]. Recently, MEB has also been used for preserving privacy [37, 69] and quantum cryptography [46].

Usually, we consider the approximate solutions of MEB. If a ball covers all the n points but has a radius larger than the optimal one, we call it a “**radius-approximate solution**”; if a ball has the radius no larger than the optimal one but covers less than n points, we call it a “**covering-approximate solution**” instead (the formal definitions are shown in Section 3). In the era of big data, the dataset could be so large that we cannot even afford linear time algorithms. This motivates us to ask the following questions:

Is it possible to develop approximation algorithms for MEB that run in sublinear time in the input size? And how about other high-dimensional geometric optimization problems arising in machine learning?

It is common to assume that the input data is represented by a $n \times d$ matrix, and thus any algorithm having complexity $o(nd)$ can be considered as a sublinear time algorithm. In practice, data items are usually represented as sparse vectors in \mathbb{R}^d ; thus it can be fast to perform the operations, like distance computing, even though the dimensionality d is high (see the concluding remarks of [25]). Moreover, the number of input points n is often much larger than the dimensionality d in many real-world scenarios. **Therefore, we are interested in designing the algorithms that have complexities sublinear in n (or linear in n but with small factor before it).** Designing sublinear time algorithms has become a promising approach to handle many big data problems, and a detailed discussion on previous works is given in Section 2.

1.1 Our Main Ideas and Results

Our idea for designing sublinear time MEB algorithms is inspired by the recent developments on optimization with respect to stable instances, under the umbrella of *beyond worst-case analysis* [74]. For example, several recent works introduced the notion of stability for problems like clustering and max-cut [8, 10, 15]. In this paper, we give the notion of “stability” for MEB. Roughly speaking, an instance of MEB is stable, if the radius of the resulting ball cannot be significantly reduced by removing a small fraction of the input points (*e.g.*, the radius cannot be reduced by 10% if only 1% of the points are removed). The rationale behind this notion is quite natural: if the given instance is not stable, the small fraction of points causing significant reduction in the radius should be viewed as outliers (or we may need multiple balls to cover the input points as k -center clustering [45, 52]). To the best of our knowledge, this is the first study on MEB from the perspective of stability.

We prove an important implication of the stability assumption: informally speaking, if an instance of MEB is stable, its center should reveal a certain extent of robustness in the space (Section 4). Using this implication, we propose two sampling algorithms for computing $(1 + \epsilon)$ -radius approximate MEB with sublinear time complexities (Section 5); in particular, our second algorithm has the sample size (*i.e.*, the number of sampled points) independent of the number of input points n and dimensionality d (to the best of our knowledge, this is the first algorithm achieving $(1 + \epsilon)$ -radius approximation with such a sublinear complexity).

Moreover, we have an interesting observation: the ideas developed under the stability assumption can even help us to solve the general instance without the stability assumption, if we relax the requirement slightly. We introduce a hybrid approach that can output either a radius-approximate MEB or a covering-approximate MEB, depending upon whether the input instance is sufficiently stable¹ (Section 6). It is worth noting that the simple uniform sampling idea based on VC-dimension [49, 81] can only yield a “bi-criteria” approximation, which has errors on both the radius and the number of covered points (see the discussion on our first sampling algorithm in Section 5.1). Comparing with the sublinear time MEB algorithm proposed by Clarkson *et al.* [25], we reduce the total running time from $\tilde{O}(\epsilon^{-2}n + \epsilon^{-1}d + M)$ to $O(n + h(\epsilon, \delta) \cdot d + M)$, where M is the number of non-zero entries in the input $n \times d$ matrix and $h(\epsilon, \delta)$ is a factor depending on the pre-specified radius error bound ϵ and covering error bound δ . Thus, our improvement is significant if $n \gg d$. The only tradeoff is that we allow a

¹ We do not need to know whether the instance is stable or not, when running our algorithm.

covering approximation for unstable instance (given the lower bound proved by [25], it is quite unlikely to reduce the term $\epsilon^{-2}n$ if we keep restricting the output to be $(1 + \epsilon)$ -radius approximation). Moreover, our algorithm only needs uniform sampling and a single pass over the data; on the other hand, the algorithm of [25] needs $\tilde{O}(\epsilon^{-1})$ passes (the details are shown in Table 1).

■ **Table 1** The existing and our results for computing MEB in high dimensions. In the table, “rad.” and “cov.” stand for “radius approximation” and “covering approximation”, respectively. “ M ” is the number of non-zero entries in the input $n \times d$ matrix. The factor C_1 depends on ϵ and the stability degree of the given instance; the factor C_2 depends on ϵ and δ . The mark “*” means that the method can be extended for MEB with outliers.

Results		Quality	Time	Number of passes
Clarkson <i>et al.</i> [25]		$(1 + \epsilon)$ -rad.	$\tilde{O}(\epsilon^{-2}n + \epsilon^{-1}d + M)$	$\tilde{O}(\epsilon^{-1})$
Core-sets methods* [16, 24, 60, 71]		$(1 + \epsilon)$ -rad.	roughly $O(\epsilon^{-1}nd)$ or $O(\epsilon^{-1}(n + d + M))$ if $M = o(nd)$	$O(\epsilon^{-1})$
Numerical method [76]		$(1 + \epsilon)$ -rad.	$\tilde{O}(\epsilon^{-1/2}nd)$ or $\tilde{O}(\epsilon^{-1/2}(n + d + M))$ if $M = o(nd)$	$O(\epsilon^{-1/2})$
Numerical method [6]		$(1 + \epsilon)$ -rad.	$\tilde{O}(nd + n\sqrt{d}/\sqrt{\epsilon})$	$\tilde{O}(d + \sqrt{d/\epsilon})$
Streaming algorithm [4, 21]		1.22-rad.	$O(nd/\epsilon^5)$	one pass
This paper	stable instance*	$(1 + \epsilon)$ -rad.	$O(C_1 \cdot d)$	uniform sampling
	general instance*	$(1 + \epsilon)$ -rad. or $(1 - \delta)$ -cov.	$O((n + C_2)d)$ or $O(n + C_2 \cdot d + M)$ if $M = o(nd)$	uniform sampling plus a single pass

Our proposed notion of stability can be naturally extended to several other geometric optimization problems arising in machine learning.

MEB with outliers. In practice, we often assume the presence of outliers in given datasets. MEB with outliers is a natural generalization of the MEB problem, where the goal is to find the minimum ball covering at least a certain fraction of input points. The presence of outliers makes the problem not only non-convex but also highly combinatorial in high dimensions. We define the stability for MEB with outliers, and propose the sublinear time approximation algorithms. Our algorithms are the first sublinear time **single-criterion** approximation algorithms for the MEB with outliers problem (comparing with the previous bi-criteria approximations like [18, 31]), to the best of our knowledge.

Polytope distance and SVM. Given a set P of points in \mathbb{R}^d , the *polytope distance* problem is to compute the shortest distance of any point inside the convex hull of P to the origin. Similar to MEB, polytope distance is also a fundamental problem in computational geometry and has many important applications, such as *sparse approximation* [24]. The polytope distance problem is also closely related to SVMs. Actually, training linear SVM is equivalent to solving the polytope distance problem for the Minkowski difference of two differently

labeled training datasets [41]. Though polytope distance is quite different from the MEB problem, they in fact share several common features. For instance, both of them can be solved by the greedy core-set construction method [24]. Following our ideas for MEB, we define the stability for polytope distance, and propose the sublinear time algorithms.

Because the geometric optimization problems studied in this paper are motivated from machine learning applications, we also take into account the **kernels** [78]. Our proposed algorithms only need to conduct the basic operations, like computing the distance and inner product, on the data items. Therefore, they also work fine for kernels.

The rest of the paper is organized as follows. In Section 2, we summarize the previous results that are related to our work. In Section 3, we present the important definitions and briefly introduce the coresets construction method for MEB from [16] (which will be used in our following algorithms design and analysis). In Section 4, we prove the implication of MEB stability. Further, we propose two sublinear time MEB algorithms in Section 5. We also briefly introduce several important extensions in Section 6; due to the space limit, we leave the details to our full paper.

2 Previous Work

The works most related to ours are [7, 25]. Clarkson *et al.* [25] developed an elegant perceptron framework for solving several optimization problems arising in machine learning, such as MEB. Given a set of n points in \mathbb{R}^d represented as an $n \times d$ matrix with M non-zero entries, their framework can compute the MEB in $\tilde{O}(\frac{n}{\epsilon^2} + \frac{d}{\epsilon})$ time². Note that the parameter “ ϵ ” is an additive error (*i.e.*, the resulting radius is $r + \epsilon$ if r is the radius of the optimal MEB) which can be converted into a relative error (*i.e.*, $(1 + \epsilon)r$) in $O(M)$ preprocessing time. Thus, if $M = o(nd)$, the running time is still sublinear in the input size nd (please see Table 1). The framework of [25] also inspires the sublinear time algorithms for training SVMs [51] and approximating Semidefinite Programs [40]. Hayashi and Yoshida [50] presented a sampling-based method for minimizing quadratic functions of which the MEB objective is a special case, but it yields a large additive error $O(\epsilon n^2)$.

Alon *et al.* [7] studied the following property testing problem: given a set of n points in some metric space, determine whether the instance is (k, b) -clusterable, where an instance is called (k, b) -clusterable if it can be covered by k balls with radius (or diameter) $b > 0$. They proposed several sampling algorithms to answer the question “approximately”. Specifically, they distinguish between the case that the instance is (k, b) -clusterable and the case that it is ϵ -far away from (k, b') -clusterable, where $\epsilon \in (0, 1)$ and $b' \geq b$. “ ϵ -far” means that more than ϵn points should be removed so that it becomes (k, b') -clusterable. Note that their method cannot yield a single criterion radius-approximation or covering-approximation algorithm for the MEB problem, since it will introduce unavoidable errors on the radius and the number of covered points due to the relaxation of “ ϵ -far”. But it is possible to convert it into a “**bi-criteria**” approximation, where it allows approximations on both the radius and the number of uncovered outliers (*e.g.*, discard more than the pre-specified number of outliers).

MEB and core-set. A *core-set* is a small set of points that approximates the structure/shape of a much larger point set [1, 35, 72]. The core-set idea has also been used to compute approximate MEB in high dimensional space [18, 57, 60, 71]. Bădoiu and Clarkson [16] showed

² The asymptotic notation $\tilde{O}(f) = O(f \cdot \text{polylog}(\frac{nd}{\epsilon}))$.

that it is possible to find a core-set of size $\lceil 2/\epsilon \rceil$ that yields a $(1 + \epsilon)$ -radius approximate MEB. Several other methods can yield even lower core-set sizes, such as [17, 57]. In fact, the algorithm for computing the core-set of MEB is a *Frank-Wolfe* algorithm [39], which has been systematically studied by Clarkson [24]. Other MEB algorithms that do not rely on core-sets include [6, 38, 76]. Agarwal and Sharathkumar [4] presented a streaming $(\frac{1+\sqrt{3}}{2} + \epsilon)$ -radius approximation algorithm for computing MEB; later, Chan and Pathak [21] proved that the same algorithm actually yields an approximation ratio less than 1.22.

MEB with outliers and bi-criteria approximations. The MEB with outliers problem can be viewed as the case $k = 1$ of the k -center clustering with outliers problem [22]. Bădoiu *et al.* [18] extended their core-set idea to the problems of MEB and k -center clustering with outliers, and achieved linear time bi-criteria approximation algorithms (if k is assumed to be a constant). Huang *et al.* [53] and Ding *et al.* [31, 33] respectively showed that simple uniform sampling approach can yield bi-criteria approximation of k -center clustering with outliers. Several algorithms for the low dimensional MEB with outliers have also been developed [5, 34, 47, 62]. There also exist a number of works on streaming MEB and k -center clustering with outliers [20, 23, 63, 82]. Other related topics include robust optimization [14], robust fitting [3, 48], and optimization with uncertainty [19].

Polytope distance and SVMs. The Gilbert's algorithm [42] is one of the earliest known algorithms for computing polytope distance. Similar to the core-set construction of MEB, the Gilbert's algorithm is also an instance of the Frank-Wolfe algorithm where the upper bound of the number of iterations is independent of the data size and dimensionality [24, 41]. In general, SVM can be formulated as a quadratic programming problem, and a number of efficient techniques have been developed besides the Gilbert's algorithm, such as the soft margin SVM [26, 73], ν -SVM [27, 77], and CVM [80].

Optimizations under stability. Bilu and Linial [15] showed that the Max-Cut problem becomes easier if the given instance is stable with respect to perturbation on edge weights. Ostrovsky *et al.* [70] proposed a separation condition for k -means clustering which refers to the scenario where the clustering cost of k -means is significantly lower than that of $(k - 1)$ -means for a given instance, and demonstrated the effectiveness of the Lloyd heuristic [61] under the separation condition. Balcan *et al.* [10] introduced the concept of approximation-stability for finding the ground-truth of k -median and k -means clustering. Awasthi *et al.* [8] introduced another notion of clustering stability and gave a PTAS for k -median and k -means clustering. More clustering algorithms under stability assumption were studied in [9, 11–13, 59].

Sublinear time algorithms. Besides the aforementioned sublinear MEB algorithm [25], a number of sublinear time algorithms have been studied for the problems like clustering [29, 54, 55, 64, 65] and property testing [44]. More detailed discussion on sublinear time algorithms can be found in the survey papers [28, 75].

3 Definitions and Preliminaries

We describe and analyze our algorithms in the unit-cost RAM model [66]. Suppose the input is represented by an $n \times d$ matrix (*i.e.*, n points in \mathbb{R}^d). As mentioned in [25], it is common to assume that any entry of the matrix can be recovered in constant time.

We let $|A|$ denote the number of points of a given point set A in \mathbb{R}^d , and $\|x - y\|$ denote the Euclidean distance between two points x and y in \mathbb{R}^d . We use $\mathbb{B}(c, r)$ to denote the ball centered at a point c with radius $r > 0$. Below, we give the definitions for MEB and the notion of stability. To keep the structure of our paper more compact, we place other necessary definitions for our extensions to the full paper.

► **Definition 1** (Minimum Enclosing Ball (MEB)). *Given a set P of n points in \mathbb{R}^d , the MEB problem is to find a ball with minimum radius to cover all the points in P . The resulting ball and its radius are denoted by $\mathbf{MEB}(P)$ and $\mathbf{Rad}(P)$, respectively.*

► **Definition 2** (Radius Approximation and Covering Approximation). *Let $0 < \epsilon, \delta < 1$. A ball $\mathbb{B}(c, r)$ is called a $(1 + \epsilon)$ -radius approximation of $\mathbf{MEB}(P)$, if the ball covers all points in P and has radius $r \leq (1 + \epsilon)\mathbf{Rad}(P)$. On the other hand, the ball is called a $(1 - \delta)$ -covering approximation of $\mathbf{MEB}(P)$, if it covers at least $(1 - \delta)n$ points in P and has radius $r \leq \mathbf{Rad}(P)$.*

Both radius approximation and covering approximation are single-criterion approximations. When ϵ (resp., δ) approaches to 0, the $(1 + \epsilon)$ -radius approximation (resp., $(1 - \delta)$ -covering approximation) will approach to $\mathbf{MEB}(P)$. The “covering approximation” seems to be similar to “MEB with outliers”, but actually they are quite different.

► **Definition 3** ((α, β) -stable). *Given a set P of n points in \mathbb{R}^d with two parameters α and β in $(0, 1)$, P is an (α, β) -stable instance if (1) $\mathbf{Rad}(P') > (1 - \alpha)\mathbf{Rad}(P)$ for any $P' \subset P$ with $|P'| > (1 - \beta)n$, and (2) there exists a $P'' \subset P$ with $|P''| = (1 - \beta)n$ having $\mathbf{Rad}(P'') \leq (1 - \alpha)\mathbf{Rad}(P)$.*

The intuition of Definition 3. Actually, β can be viewed as a function of α . For any $\alpha > 0$, there always exists a $\beta \geq \frac{1}{n}$ such that P is an (α, β) -stable instance ($\beta \geq \frac{1}{n}$ because we must remove at least one point). The property of stability indicates that $\mathbf{Rad}(P)$ cannot be significantly reduced unless removing a large enough fraction of points from P . For a fixed α , the larger β is, the more stable P becomes. Actually, our stability assumption is quite reasonable in practice. For example, if the radius can be reduced considerably (say by $\alpha = 10\%$) after removing only a very small fraction (say $\beta = 1\%$) of points, it is natural to view the small fraction of points as outliers. In practice, it is difficult to obtain the exact value of β for a fixed α . However, the value of β only affects the sample sizes in our proposed algorithms in Section 5, and thus only assuming a reasonable lower bound $\beta_0 < \beta$ is already sufficient. To better understand the notion of stability in high dimensions, we consider the following two examples.

Example (i). Suppose that the distribution of P is uniform and dense inside $\mathbf{MEB}(P)$. Let $\alpha \in (0, 1)$ be a fixed number, and we study the corresponding β of P . If we want the radius of the remaining $(1 - \beta)n$ points to be as small as possible, intuitively we should remove the outermost βn points (since P is uniform and dense). Let P'' denote the set of innermost $(1 - \beta)n$ points that has $\mathbf{Rad}(P'') \leq (1 - \alpha)\mathbf{Rad}(P)$. Then we have $\frac{|P''|}{|P|} \approx \frac{\text{Vol}(\mathbf{MEB}(P''))}{\text{Vol}(\mathbf{MEB}(P))} = \frac{(\mathbf{Rad}(P''))^d}{(\mathbf{Rad}(P))^d} \leq (1 - \alpha)^d$, where $\text{Vol}(\cdot)$ is the volume function. That is, $1 - \beta \leq (1 - \alpha)^d$ and thus $\lim_{d \rightarrow \infty} \beta = 1$ when α is fixed; that means P tends to be very stable as d increases.

Example (ii). Consider a regular d -dimensional simplex P containing $d + 1$ points where each pair of points have the pairwise distance equal to 1. It is not hard to obtain $\mathbf{Rad}(P) = \sqrt{\frac{d}{2(1+d)}}$, and we denote it by r_d . If we remove $\beta(d + 1)$ points from P , namely it becomes a regular d' -dimensional simplex with $d' = (1 - \beta)(d + 1) - 1$, the new radius $r_{d'} = \sqrt{\frac{d'}{2(1+d')}}$. To achieve $\frac{r_{d'}}{r_d} \leq 1 - \alpha$ with a fixed α , it is easy to see that $1 - \beta$ should be no larger than $\frac{1}{1+(2\alpha-\alpha^2)d}$ and thus $\lim_{d \rightarrow \infty} \beta = 1$. Similar to example (i), the instance P tends to be very stable as d increases.

3.1 Core-set Construction for MEB [16]

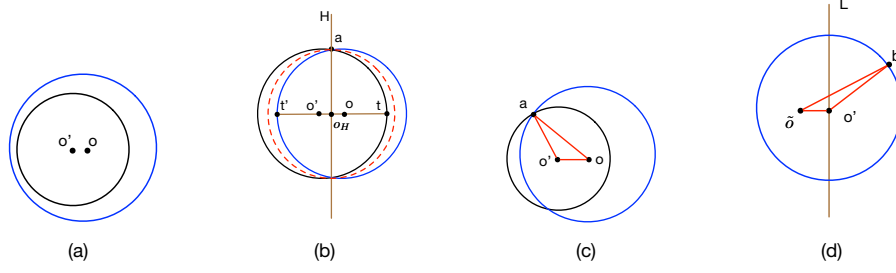

To compute a $(1 + \epsilon)$ -radius approximate MEB, Bădoiu and Clarkson [16] proposed an algorithm yielding an MEB core-set of size $2/\epsilon$ (for convenience, we always assume that $2/\epsilon$ is an integer). We first briefly introduce their main idea, since it will be used in our proposed algorithms (we do not use the MEB algorithm of [24] because it is not quite convenient to analyze under our stability assumption; the other construction algorithms [17, 57], though achieving lower core-set sizes, are more complicated and thus not applicable to our problems).

Given a point set $P \subset \mathbb{R}^d$, the algorithm is a simple iterative procedure. Initially, it selects an arbitrary point from P and places it into an initially empty set T . In each of the following $2/\epsilon$ iterations, the algorithm updates the center of $\mathbf{MEB}(T)$ and adds to T the farthest point from the current center of $\mathbf{MEB}(T)$. Finally, the center of $\mathbf{MEB}(T)$ induces a $(1 + \epsilon)$ -radius approximation for $\mathbf{MEB}(P)$. The selected set of $2/\epsilon$ points (*i.e.*, T) is called the core-set of MEB. However, computing the exact center of $\mathbf{MEB}(T)$ could be expensive; in practice, one may only compute an approximate center of $\mathbf{MEB}(T)$ in each iteration. In the i -th iteration, we let c_i denote the exact center of $\mathbf{MEB}(T)$; also, let r_i be the radius of $\mathbf{MEB}(T)$. Suppose ξ is a given number in $(0, 1)$. Using another algorithm proposed in [16, Section 3], one can compute an approximate center o_i having the distance to c_i less than ξr_i in $O(\frac{1}{\xi^2}|T|d)$ time. Since we only compute o_i rather than c_i in each iteration, we in fact only select the farthest point to o_i (not c_i). In [31], Ding provided a more careful analysis on Bădoiu and Clarkson's method and presented the following theorem.

► **Theorem 4** ([31]). *In the core-set construction algorithm of [16], if one computes an approximate MEB for T in each iteration and the resulting center o_i has the distance to c_i less than ξr_i with $\xi = s \frac{\epsilon}{1+\epsilon}$ for some $s \in (0, 1)$, the final core-set size is bounded by $z = \frac{2}{(1-s)\epsilon}$. Also, the bound could be arbitrarily close to $2/\epsilon$ when s is sufficiently small.*

► **Remark 5.** (i) We can simply set s to be any constant in $(0, 1)$; for instance, if $s = 1/3$, the core-set size will be bounded by $z = 3/\epsilon$. Since $|T| \leq z$ in each iteration, the total running time is $O\left(z(|P|d + \frac{1}{\xi^2}zd)\right) = O\left(\frac{1}{\epsilon}(|P| + \frac{1}{\epsilon^3})d\right)$. (ii) We also want to emphasize a simple observation mentioned in [18, 31] on the above core-set construction procedure, which will be used in our algorithms and analyses later on. The algorithm always selects the farthest point to o_i in each iteration. However, this is actually not necessary. As long as the selected point has distance at least $(1 + \epsilon)\mathbf{Rad}(P)$, the result presented in Theorem 4 is still true. If no such a point exists (*i.e.*, $P \setminus \mathbb{B}(o_i, (1 + \epsilon)\mathbf{Rad}(P)) = \emptyset$), a $(1 + \epsilon)$ -radius approximate MEB (*i.e.*, the ball $\mathbb{B}(o_i, (1 + \epsilon)\mathbf{Rad}(P))$) has been already obtained.

► **Remark 6 (kernels).** If each point $p \in P$ is mapped to $\psi(p)$ in \mathbb{R}^D by some kernel function (*e.g.*, as the CVM [80]), where D could be $+\infty$, we can still run the core-set algorithm of [16, 58], since the algorithm only needs to compute the distances and the center o_i is always a convex combination of T in each iteration; instead of returning an explicit center, the algorithm will output the coefficients of the convex combination for the center. And similarly, our Algorithm 2 presented in Section 5.2 also works fine for kernels.

■ **Figure 1** (a) The case $\text{MEB}(P') \subset \text{MEB}(P)$; (b) an illustration under the assumption $\angle ao'o < \pi/2$ in the proof of Claim 9; (c) the angle $\angle ao'o \geq \pi/2$; (d) an illustration of Lemma 10.

4 Implication of the Stability Property

In this section, we show an important implication of the stability property of Definition 3.

► **Theorem 7.** Assume $\epsilon, \epsilon', \beta_0 \in (0, 1)$. Let P be an (ϵ^2, β) -stable instance of the MEB problem with $\beta > \beta_0$, and o be the center of its MEB. Let \tilde{o} be a given point in \mathbb{R}^d . Assume the number $r \leq (1 + \epsilon'^2)\text{Rad}(P)$. If the ball $\mathbb{B}(\tilde{o}, r)$ covers at least $(1 - \beta_0)n$ points from P , the following holds

$$\|\tilde{o} - o\| < (2\sqrt{2}\epsilon + \sqrt{3}\epsilon')\text{Rad}(P). \quad (1)$$

Theorem 7 indicates that if a ball covers a large enough subset of P and its radius is bounded, its center should be close to the center of $\text{MEB}(P)$. Let $P' = \mathbb{B}(\tilde{o}, r) \cap P$, and assume o' is the center of $\text{MEB}(P')$. To bound the distance between \tilde{o} and o , we bridge them by the point o' (since $\|\tilde{o} - o\| \leq \|\tilde{o} - o'\| + \|o' - o\|$). The following are two key lemmas for proving Theorem 7.

► **Lemma 8.** The distance $\|o' - o\| \leq \sqrt{2}\epsilon\text{Rad}(P)$.

Proof. We consider two cases: $\text{MEB}(P')$ is totally covered by $\text{MEB}(P)$ and otherwise. For the first case (see Figure 1(a)), it is easy to see that

$$\|o' - o\| \leq \text{Rad}(P) - (1 - \epsilon^2)\text{Rad}(P) = \epsilon^2\text{Rad}(P) < \sqrt{2}\epsilon\text{Rad}(P), \quad (2)$$

where the first inequality comes from the fact that $\text{MEB}(P')$ has radius at least $(1 - \epsilon^2)\text{Rad}(P)$ (Definition 3). Thus, we can focus on the second case below.

Let a be any point located on the intersection of the two spheres of $\text{MEB}(P')$ and $\text{MEB}(P)$. Consequently, we have the following claim.

▷ **Claim 9.** The angle $\angle ao'o \geq \pi/2$.

Proof. Suppose that $\angle ao'o < \pi/2$. Note that $\angle ao'o$ is always smaller than $\pi/2$ since $\|o - a\| = \text{Rad}(P) \geq \text{Rad}(P') = \|o' - a\|$. Therefore, o and o' are separated by the hyperplane H that is orthogonal to the segment $\overline{o'o}$ and passes through the point a . See Figure 1(b). Now we show that P' can be covered by a ball smaller than $\text{MEB}(P')$. Let o_H be the point $H \cap \overline{o'o}$, and t (resp., t') be the point collinear with o and o' on the right side of the sphere of $\text{MEB}(P')$ (resp., left side of the sphere of $\text{MEB}(P)$; see Figure 1(b)). Then, we have

$$\begin{aligned} \|t - o_H\| + \|o_H - o'\| &= \|t - o'\| = \|a - o'\| < \|o' - o_H\| + \|o_H - a\| \\ \implies \|t - o_H\| &< \|o_H - a\|. \end{aligned} \quad (3)$$

Similarly, we have $\|t' - o_H\| < \|o_H - a\|$. Consequently, $\mathbf{MEB}(P) \cap \mathbf{MEB}(P')$ is covered by the ball $\mathbb{B}(o_H, \|o_H - a\|)$. Further, because P' is covered by $\mathbf{MEB}(P) \cap \mathbf{MEB}(P')$ and $\|o_H - a\| < \|o' - a\| = \mathbf{Rad}(P')$, P' is covered by the ball $\mathbb{B}(o_H, \|o_H - a\|)$ that is smaller than $\mathbf{MEB}(P')$. This contradicts to the fact that $\mathbf{MEB}(P')$ is the minimum enclosing ball of P' . Thus, the claim $\angle ao'o \geq \pi/2$ is true. \triangleleft

Given Claim 9, we know that $\|o' - o\| \leq \sqrt{(\mathbf{Rad}(P))^2 - (\mathbf{Rad}(P'))^2}$. See Figure 1(c). Moreover, Definition 3 implies that $\mathbf{Rad}(P') \geq (1 - \epsilon^2)\mathbf{Rad}(P)$. Therefore, we have

$$\|o' - o\| \leq \sqrt{(\mathbf{Rad}(P))^2 - ((1 - \epsilon^2)\mathbf{Rad}(P))^2} \leq \sqrt{2\epsilon}\mathbf{Rad}(P). \quad (4)$$

► **Lemma 10.** *The distance $\|\tilde{o} - o'\| < (\sqrt{2}\epsilon + \sqrt{3}\epsilon')\mathbf{Rad}(P)$.*

Proof. Let L be the hyperplane orthogonal to the segment $\overline{\tilde{o}o'}$ and passing through the center o' . Suppose \tilde{o} is located on the left side of L . Then, there exists a point $b \in P'$ located on the right closed semi-sphere of $\mathbf{MEB}(P')$ divided by L (this result was proved in [18, 43] and see Lemma 2.2 in [18]). See Figure 1(d). That is, the angle $\angle bo'\tilde{o} \geq \pi/2$. As a consequence, we have

$$\|\tilde{o} - o'\| \leq \sqrt{\|\tilde{o} - b\|^2 - \|b - o'\|^2}. \quad (5)$$

Moreover, since $\|\tilde{o} - b\| \leq r \leq (1 + \epsilon'^2)\mathbf{Rad}(P)$ and $\|b - o'\| = \mathbf{Rad}(P') \geq (1 - \epsilon^2)\mathbf{Rad}(P)$, (5) implies that $\|\tilde{o} - o'\| \leq \sqrt{(1 + \epsilon'^2)^2 - (1 - \epsilon^2)^2}\mathbf{Rad}(P)$, where this upper bound is equal to

$$\sqrt{2\epsilon'^2 + \epsilon'^4 + 2\epsilon^2 - \epsilon^4}\mathbf{Rad}(P) < \sqrt{3\epsilon'^2 + 2\epsilon^2}\mathbf{Rad}(P) < (\sqrt{2}\epsilon + \sqrt{3}\epsilon')\mathbf{Rad}(P). \quad (6)$$

By triangle inequality, Lemmas 8 and 10, we immediately have

$$\|\tilde{o} - o\| \leq \|\tilde{o} - o'\| + \|o' - o\| < (2\sqrt{2}\epsilon + \sqrt{3}\epsilon')\mathbf{Rad}(P). \quad (7)$$

This completes the proof of Theorem 7.

5 Sublinear Time Algorithms for MEB under Stability Assumption

Suppose $\epsilon \in (0, 1)$. We assume that the given instance P is an (ϵ^2, β) -stable instance where β is larger than a given lower bound β_0 (i.e., $\beta > \beta_0$). Using Theorem 7, we present two different sublinear time sampling algorithms for computing MEB. Following most of the articles on sublinear time algorithms (e.g., [29, 64, 65]), in each sampling step of our algorithms, we always take the sample **independently and uniformly at random**.

5.1 The First Algorithm

The first algorithm is based on the theory of VC dimension and ϵ -nets [49, 81]. Roughly speaking, we compute an approximate MEB of a small random sample (say, $\mathbb{B}(c, r)$), and expand the ball slightly; then we prove that this expanded ball is an approximate MEB of the whole data set (see Figure 2). Our key idea is to show that $\mathbb{B}(c, r)$ covers at least $(1 - \beta_0)n$ points and therefore c is close to the optimal center by Theorem 7. As emphasized

■ **Figure 2** An illustration for the first sampling algorithm. The red points are the samples; we expand $\mathbb{B}(c, r)$ slightly and the larger ball is a radius-approximate MEB of the whole input point set.

in Section 1.1, our result is a single-criterion approximation. If simply applying the uniform sample idea without the stability assumption (as the ideas in [33, 53]), it will result in a bi-criteria approximation where the ball has to cover less than n points for achieving the desired bounded radius.

► **Theorem 11.** *With probability $1 - \eta$, Algorithm 1 returns a λ -radius approximate MEB of P , where*

$$\lambda = \frac{(1 + (2\sqrt{2} + \sqrt{3})\epsilon)(1 + \epsilon^2)}{1 - \epsilon^2} \quad (8)$$

and $\lambda = 1 + O(\epsilon)$ if ϵ is a fixed number in $(0, 1)$.

■ **Algorithm 1 MEB Algorithm I.**

Input: Two parameters $0 < \epsilon, \eta < 1$; an (ϵ^2, β) -stable instance P of MEB problem in \mathbb{R}^d , where β is larger than a known lower bound $\beta_0 > 0$.

- 1: Sample a set S of $\Theta(\frac{1}{\beta_0} \cdot \max\{\log \frac{1}{\eta}, d \log \frac{d}{\beta_0}\})$ points from P uniformly at random.
- 2: Apply any approximate MEB algorithm (such as the core-set based algorithm [16]) to compute a $(1 + \epsilon^2)$ -radius approximate MEB of S , and let the obtained ball be $\mathbb{B}(c, r)$.
- 3: Output the ball $\mathbb{B}(c, \frac{1 + (2\sqrt{2} + \sqrt{3})\epsilon}{1 - \epsilon^2} r)$.

Before proving Theorem 11, we prove the following lemma first.

► **Lemma 12.** *Let S be a set of $\Theta(\frac{1}{\beta_0} \cdot \max\{\log \frac{1}{\eta}, d \log \frac{d}{\beta_0}\})$ points sampled randomly and independently from a given point set $P \subset \mathbb{R}^d$, and B be any ball covering S . Then, with probability $1 - \eta$, $|B \cap P| \geq (1 - \beta_0)|P|$.*

Proof. Consider the range space $\Sigma = (P, \Phi)$ where each range $\phi \in \Phi$ is the complement of a ball in the space. In a range space, a subset $Y \subset P$ is a β_0 -net if for any $\phi \in \Phi$, $\frac{|Y \cap \phi|}{|Y|} \geq \beta_0 \implies Y \cap \phi \neq \emptyset$. Since $|S| = \Theta(\frac{1}{\beta_0} \cdot \max\{\log \frac{1}{\eta}, d \log \frac{d}{\beta_0}\})$, we know that S is a β_0 -net of P with probability $1 - \eta$ [49, 81]. Thus, if $|B \cap P| < (1 - \beta_0)|P|$, i.e., $|P \setminus B| > \beta_0|P|$, we have $S \cap (P \setminus B) \neq \emptyset$. This contradicts to the fact that S is covered by B . Consequently, $|B \cap P| \geq (1 - \beta_0)|P|$. ◀

Proof of Theorem 11. Denote by o the center of $\mathbf{MEB}(P)$. Since $S \subset P$ and $\mathbb{B}(c, r)$ is a $(1 + \epsilon^2)$ -radius approximate MEB of S , we know that $r \leq (1 + \epsilon^2)\mathbf{Rad}(P)$. Moreover, Lemma 12 implies that $|\mathbb{B}(c, r) \cap P| \geq (1 - \beta_0)|P|$ with probability $1 - \eta$. Suppose it is true and let $P' = \mathbb{B}(c, r) \cap P$. Then, we have the distance

$$\|c - o\| \leq (2\sqrt{2} + \sqrt{3})\epsilon \mathbf{Rad}(P) \quad (9)$$

via Theorem 7 (we set $\epsilon' = \epsilon$). For simplicity, we use x to denote $(2\sqrt{2} + \sqrt{3})\epsilon$. The inequality (9) implies that the point set P is covered by the ball $\mathbb{B}(c, (1+x)\mathbf{Rad}(P))$. Note that we cannot directly return $\mathbb{B}(c, (1+x)\mathbf{Rad}(P))$ as the final result, since we do not know the value of $\mathbf{Rad}(P)$. Thus, we have to estimate the radius $(1+x)\mathbf{Rad}(P)$.

Since P' is covered by $\mathbb{B}(c, r)$ and $|P'| \geq (1 - \beta_0)|P|$, r should be at least $(1 - \epsilon^2)\mathbf{Rad}(P)$ due to Definition 3. Hence, we have

$$\frac{1+x}{1-\epsilon^2}r \geq (1+x)\mathbf{Rad}(P). \quad (10)$$

That is, P is covered by the ball $\mathbb{B}(c, \frac{1+x}{1-\epsilon^2}r)$. Moreover, the radius

$$\frac{1+x}{1-\epsilon^2}r \leq \frac{1+x}{1-\epsilon^2}(1+\epsilon^2)\mathbf{Rad}(P). \quad (11)$$

This means that ball $\mathbb{B}(c, \frac{1+x}{1-\epsilon^2}r)$ is a λ -radius approximate MEB of P , where

$$\lambda = (1+\epsilon^2)\frac{1+x}{1-\epsilon^2} = \frac{(1+(2\sqrt{2}+\sqrt{3})\epsilon)(1+\epsilon^2)}{1-\epsilon^2} \quad (12)$$

and $\lambda = 1 + O(\epsilon)$ if ϵ is a fixed number in $(0, 1)$. \blacktriangleleft

Running time of Algorithm 1. For simplicity, we assume $\log \frac{1}{\eta} < d \log \frac{d}{\beta_0}$. If we use the core-set based algorithm [16] to compute $\mathbb{B}(c, r)$ (see Remark 5), the running time of Algorithm 1 is $O(\frac{1}{\epsilon^2}(|S|d + \frac{1}{\epsilon^6}d)) = O(\frac{d^2}{\epsilon^2\beta_0} \log \frac{d}{\beta_0} + \frac{d}{\epsilon^8}) = \tilde{O}(d^2)$ where the hidden factor depends on ϵ and β_0 .

► **Remark 13.** If the dimensionality d is too high, the random projection technique *Johnson-Lindenstrauss (JL) transform* [30] can be used to approximately preserve the radius of enclosing ball [2, 56, 79]. However, it is not very useful for reducing the time complexity of Algorithm 1. If we apply the JL-transform on the sampled $\Theta(\frac{d}{\beta_0} \log \frac{d}{\beta_0})$ points in Step 1, the JL-transform step itself already takes $\Omega(\frac{d^2}{\beta_0} \log \frac{d}{\beta_0})$ time.

5.2 The Second Algorithm

Our first algorithm in Section 5.1 is simple, but has a sample size (*i.e.*, the number of sampled points) depending on the dimensionality d , while **the second algorithm has a sample size independent of both n and d** (it is particularly important when a kernel function is applied, because the new dimension could be very large or even $+\infty$). We briefly overview our idea first.

High level idea of the second algorithm. Recall our Remark 5 (ii). If we know the value of $(1+\epsilon)\mathbf{Rad}(P)$, we can perform almost the same core-set construction procedure described in Theorem 4 to achieve an approximate center of $\mathbf{MEB}(P)$, where the only difference is that we add a point with distance at least $(1+\epsilon)\mathbf{Rad}(P)$ to o_i in each iteration. In this way, we avoid selecting the farthest point to o_i , since this operation will inevitably have a linear time complexity. To implement our strategy in sublinear time, we need to determine the value of $(1+\epsilon)\mathbf{Rad}(P)$ first. We propose Lemma 14 below to estimate the range of $\mathbf{Rad}(P)$, and then perform a binary search on the range to determine the value of $(1+\epsilon)\mathbf{Rad}(P)$ approximately. Based on the stability property, we observe that the core-set construction procedure can serve as an “oracle” to help us to guess the value of $(1+\epsilon)\mathbf{Rad}(P)$ (see Algorithm 3). Let $h > 0$ be a candidate. We add a point with distance at least h to o_i in each iteration. We

prove that the procedure cannot continue for more than z iterations if $h \geq (1 + \epsilon)\mathbf{Rad}(P)$, and will continue more than z iterations with constant probability if $h < (1 - \epsilon)\mathbf{Rad}(P)$, where z is the size of core-set described in Theorem 4. Also, during the core-set construction, we add the points to the core-set via random sampling, rather than a deterministic way. A minor issue here is that we need to replace ϵ by ϵ^2 in Theorem 4, so as to achieve the overall $(1 + O(\epsilon))$ -radius approximation in the following analysis. Below, we introduce Lemma 14 and Theorem 16 first, and then present the main result in Theorem 17.

► **Lemma 14.** *Given a parameter $\eta \in (0, 1)$, one selects an arbitrary point $p_1 \in P$ and takes a sample $Q \subset P$ with $|Q| = \frac{1}{\beta_0} \log \frac{1}{\eta}$ uniformly at random. Let $p_2 = \arg \max_{p \in Q} \|p - p_1\|$. Then, with probability $1 - \eta$,*

$$\mathbf{Rad}(P) \in [\frac{1}{2}\|p_1 - p_2\|, \frac{1}{1 - \epsilon^2}\|p_1 - p_2\|]. \quad (13)$$

Proof. First, the lower bound of $\mathbf{Rad}(P)$ is obvious since $\|p_1 - p_2\|$ is always no larger than $2\mathbf{Rad}(P)$. Then, we consider the upper bound. Let $\mathbb{B}(p_1, l)$ be the ball covering exactly $(1 - \beta_0)n$ points of P , and thus $l \geq (1 - \epsilon^2)\mathbf{Rad}(P)$ according to Definition 3. To complete our proof, we also need the following folklore lemma presented in [32].

► **Lemma 15** ([32]). *Let N be a set of elements, and N' be a subset of N with size $|N'| = \tau |N|$ for some $\tau \in (0, 1)$. Given from N , then with probability*

■ **Figure 3** An illustration of Lemma 14; the red points are the sampled set Q .

In Lemma 15, let N and N' be the point set P and the subset $P \setminus \mathbb{B}(p_1, l)$, respectively. We know that Q contains at least one point from N' according to Lemma 15 (by setting $\tau = \beta_0$). Namely, Q contains at least one point outside $\mathbb{B}(p_1, l)$. Moreover, because $p_2 = \arg \max_{p \in Q} \|p - p_1\|$, we have $\|p_1 - p_2\| \geq l \geq (1 - \epsilon^2)\mathbf{Rad}(P)$, i.e., $\mathbf{Rad}(P) \leq \frac{1}{1 - \epsilon^2}\|p_1 - p_2\|$ (see Figure 3 for an illustration). ◀

Lemma 14 immediately implies the following result.

► **Theorem 16.** *In Lemma 14, the ball $\mathbb{B}(p_1, \frac{2}{1 - \epsilon^2}\|p_1 - p_2\|)$ is a $\frac{4}{1 - \epsilon^2}$ -radius approximate MEB of P , with probability $1 - \eta$.*

Proof. From the upper bound in Lemma 14, we know that $\frac{2}{1 - \epsilon^2}\|p_1 - p_2\| \geq 2\mathbf{Rad}(P)$. Since $\|p_1 - p\| \leq 2\mathbf{Rad}(P)$ for any $p \in P$, the ball $\mathbb{B}(p_1, \frac{2}{1 - \epsilon^2}\|p_1 - p_2\|)$ covers the whole point set P . From the lower bound in Lemma 14, we know that $\frac{2}{1 - \epsilon^2}\|p_1 - p_2\| \leq \frac{4}{1 - \epsilon^2}\mathbf{Rad}(P)$. Therefore, it is a $\frac{4}{1 - \epsilon^2}$ -radius approximate MEB of P . ◀

Since $|Q| = \frac{1}{\beta_0} \log \frac{1}{\eta}$ in Lemma 14, Theorem 16 indicates that we can easily obtain a $\frac{4}{1 - \epsilon^2}$ -radius approximate MEB of P in $O(\frac{1}{\beta_0}(\log \frac{1}{\eta})d)$ time. Below, we present our second sampling algorithm (Algorithm 2) that can achieve a much lower $(1 + O(\epsilon))$ -approximation

ratio. Algorithm 3 serves as a subroutine in Algorithm 2. In Algorithm 3, we simply set $z = \frac{3}{\epsilon^2}$ with $s = 1/3$ as described in Theorem 4 (as mentioned before, we replace ϵ by ϵ^2); we compute o_i having distance less than $s \frac{\epsilon^2}{1+\epsilon^2} \mathbf{Rad}(T)$ to the center of $\mathbf{MEB}(T)$ in Step 2(1).

► **Theorem 17.** *With probability $1 - \eta_0$, Algorithm 2 returns a λ -radius approximate MEB of P , where*

$$\lambda = \frac{(1+x_1)(1+x_2)}{1+\epsilon^2} \quad \text{with} \quad x_1 = O\left(\frac{\epsilon^2}{1-\epsilon^2}\right), x_2 = O\left(\frac{\epsilon}{\sqrt{1-\epsilon^2}}\right), \quad (14)$$

and $\lambda = 1 + O(\epsilon)$ if ϵ is a fixed number in $(0, 1)$. The running time is $\tilde{O}((\frac{1}{\epsilon^2 \beta_0} + \frac{1}{\epsilon^8})d)$, where $\tilde{O}(f) = O(f \cdot \text{polylog}(\frac{1}{\epsilon}, \frac{1}{\eta_0}))$.

■ Algorithm 2 MEB Algorithm II.

Input: Two parameters $0 < \epsilon, \eta_0 < 1$; an (ϵ^2, β) -stable instance P of MEB problem in \mathbb{R}^d , where β is larger than a given lower bound $\beta_0 > 0$. Set the interval $[a, b]$ for $\mathbf{Rad}(P)$ that is obtained by Lemma 14.

- 1: Among the set $\{(1-\epsilon^2)a, (1+\epsilon^2)(1-\epsilon^2)a, \dots, (1+\epsilon^2)^w(1-\epsilon^2)a = (1+\epsilon^2)b\}$ where $w = \lceil \log_{1+\epsilon^2} \frac{2}{(1-\epsilon^2)^2} \rceil + 1 = O(\frac{1}{\epsilon^2})$, perform binary search for the value h by using Algorithm 3 with $z = \frac{3}{\epsilon^2}$ and $\eta = \frac{\eta_0}{2 \log w}$.
- 2: Suppose that Algorithm 3 returns “no” when $h = (1+\epsilon^2)^{i_0}(1-\epsilon^2)a$ and returns “yes” when $h = (1+\epsilon^2)^{i_0+1}(1-\epsilon^2)a$.
- 3: Run Algorithm 3 again with $h = (1+\epsilon^2)^{i_0+2}a$, $z = \frac{3}{\epsilon^2}$, and $\eta = \eta_0/2$; let \tilde{o} be the obtained ball center of T when the loop stops.
- 4: Return the ball $\mathbb{B}(\tilde{o}, r)$, where $r = \frac{1+(2\sqrt{2}+\frac{2\sqrt{6}}{\sqrt{1-\epsilon^2}})\epsilon}{1+\epsilon^2} h$.

■ Algorithm 3 Oracle for testing h .

Input: An instance P , a parameter $\eta \in (0, 1)$, $h > 0$, and a positive integer z .

- 1: Initially, arbitrarily select a point $p \in P$ and let $T = \{p\}$.
- 2: $i = 1$; repeat the following steps:
 - (1) Compute an approximate MEB of T and let the ball center be o_i as described in Theorem 4 (replace ϵ by ϵ^2 and set $s = 1/3$).
 - (2) Sample a set $Q \subset P$ with $|Q| = \frac{1}{\beta_0} \log \frac{z}{\eta}$ uniformly at random.
 - (3) Select the point $q \in Q$ that is farthest to o_i , and add it to T .
 - (4) If $\|q - o_i\| < h$, stop the loop and output “yes”.
 - (5) $i = i + 1$; if $i > z$, stop the loop and output “no”.

Before proving Theorem 17, we provide Lemma 18 first.

► **Lemma 18.** *If $h \geq (1+\epsilon^2)\mathbf{Rad}(P)$, Algorithm 3 returns “yes”; else if $h < (1-\epsilon^2)\mathbf{Rad}(P)$, Algorithm 3 returns “no” with probability at least $1 - \eta$.*

Proof. First, we assume that $h \geq (1+\epsilon^2)\mathbf{Rad}(P)$. Recall the remark following Theorem 4. If we always add a point q with distance at least $h \geq (1+\epsilon^2)\mathbf{Rad}(P)$ to o_i , the loop 2(1)-(5) cannot continue more than z iterations, i.e., Algorithm 3 will return “yes”.

Now, we consider the case $h < (1-\epsilon^2)\mathbf{Rad}(P)$. Similar to the proof of Lemma 14, we consider the ball $\mathbb{B}(o_i, l)$ covering exactly $(1-\beta_0)n$ points of P . According to Definition 3, we know that $l \geq (1-\epsilon^2)\mathbf{Rad}(P) > h$. Also, with probability $1 - \eta/z$, the sample Q contains

38:14 Stability Yields Sublinear Time Algorithms

at least one point outside $\mathbb{B}(o_i, l)$ due to Lemma 15. By taking the union bound, with probability $(1 - \eta/z)^z \geq 1 - \eta$, $\|q - o_i\|$ is always larger than h and eventually Algorithm 3 will return “no”. \blacktriangleleft

Proof of Theorem 17. Since Algorithm 3 returns “no” when $h = (1 + \epsilon^2)^{i_0}(1 - \epsilon^2)a$ and returns “yes” when $h = (1 + \epsilon^2)^{i_0+1}(1 - \epsilon^2)a$, from Lemma 18 we know that

$$(1 + \epsilon^2)^{i_0}(1 - \epsilon^2)a < (1 + \epsilon^2)\mathbf{Rad}(P); \quad (15)$$

$$(1 + \epsilon^2)^{i_0+1}(1 - \epsilon^2)a \geq (1 - \epsilon^2)\mathbf{Rad}(P). \quad (16)$$

The above inequalities together imply that

$$\frac{(1 + \epsilon^2)^3}{1 - \epsilon^2}\mathbf{Rad}(P) > (1 + \epsilon^2)^{i_0+2}a \geq (1 + \epsilon^2)\mathbf{Rad}(P). \quad (17)$$

Thus, when running Algorithm 3 with $h = (1 + \epsilon^2)^{i_0+2}a$ in Step 3, the algorithm returns “yes” (by the right hand-side of (17)). Then, consider the ball $\mathbb{B}(\tilde{o}, h)$. We claim that $|P \setminus \mathbb{B}(\tilde{o}, h)| < \beta_0 n$. Otherwise, the sample Q contains at least one point outside $\mathbb{B}(\tilde{o}, h)$ with probability $1 - \eta/z$ in Step 2(2) of Algorithm 3, *i.e.*, the loop will continue. Thus, it contradicts to the fact that the algorithm returns “yes”. Let $P' = P \cap \mathbb{B}(\tilde{o}, h)$, and then $|P'| \geq (1 - \beta_0)n$. Moreover, the left hand-side of (17) indicates that

$$h = (1 + \epsilon^2)^{i_0+2}a < (1 + \frac{8\epsilon^2}{1 - \epsilon^2})\mathbf{Rad}(P). \quad (18)$$

Now, we can apply Theorem 7, where we set “ ϵ' ” to be “ $\sqrt{\frac{8\epsilon^2}{1 - \epsilon^2}}$ ” in the theorem. Let o be the center of $\mathbf{MEB}(P)$. Consequently, we have

$$\|\tilde{o} - o\| < (2\sqrt{2} + 2\sqrt{6}/\sqrt{1 - \epsilon^2})\epsilon \cdot \mathbf{Rad}(P). \quad (19)$$

For simplicity, we let $x_1 = \frac{8\epsilon^2}{1 - \epsilon^2}$ and $x_2 = (2\sqrt{2} + 2\sqrt{6}/\sqrt{1 - \epsilon^2})\epsilon$. Hence, $h \leq (1 + x_1)\mathbf{Rad}(P)$ and $\|\tilde{o} - o\| \leq x_2\mathbf{Rad}(P)$ in (18) and (19). From (19), we know that $P \subset \mathbb{B}(\tilde{o}, (1 + x_2)\mathbf{Rad}(P))$. From the right hand-side of (17), we know that $(1 + x_2)\mathbf{Rad}(P) \leq \frac{1+x_2}{1+\epsilon^2}h$. Thus, we have $P \subset \mathbb{B}(\tilde{o}, \frac{1+x_2}{1+\epsilon^2}h)$ where $\frac{1+x_2}{1+\epsilon^2}h = \frac{1+(2\sqrt{2} + \frac{2\sqrt{6}}{\sqrt{1-\epsilon^2}})\epsilon}{1+\epsilon^2}h$. Also, the radius

$$\frac{1 + x_2}{1 + \epsilon^2}h \underbrace{\leq}_{\text{by (18)}} \frac{(1 + x_2)(1 + x_1)}{1 + \epsilon^2}\mathbf{Rad}(P) = \lambda \cdot \mathbf{Rad}(P). \quad (20)$$

Thus $\mathbb{B}(\tilde{o}, \frac{1+x_2}{1+\epsilon^2}h)$ is a λ -radius approximate MEB of P , and $\lambda = 1 + O(\epsilon)$ if ϵ is fixed.

Success probability. The success probability of Algorithm 3 is $1 - \eta$. In Algorithm 2, we set $\eta = \frac{\eta_0}{2 \log w}$ in Step 1 and $\eta = \eta_0/2$ in Step 3, respectively. We take the union bound and the success probability of Algorithm 2 is $(1 - \frac{\eta_0}{2 \log w})^{\log w} (1 - \eta_0/2) > 1 - \eta_0$.

Running time. As the subroutine, Algorithm 3 runs in $O(z(\frac{1}{\beta_0}(\log \frac{z}{\eta})d + \frac{1}{\epsilon^6}d))$ time; Algorithm 2 calls the subroutine $O(\log(\frac{1}{\epsilon^2}))$ times. Note that $z = O(\frac{1}{\epsilon^2})$. Thus, the total running time is $\tilde{O}((\frac{1}{\epsilon^2 \beta_0} + \frac{1}{\epsilon^8})d)$. \blacktriangleleft

6 Extensions

We also present two important extensions in this paper (due to the space limit, we place the details to our full paper). We briefly introduce the main ideas and summarize the results below.

We first consider MEB with outliers under the stability assumption and provide a sublinear time constant factor radius approximation. We also consider the general case without the stability assumption. An interesting observation is that the ideas developed for stable instance can even help us to develop a hybrid approach for MEB (without or with outliers) when the stability assumption does not hold. First, we “suppose” the input instance is (α, β) -stable where “ α ” and “ β ” are carefully designed based on the pre-specified radius error bound ϵ and covering error bound δ , and compute a “potential” $(1 + \epsilon)$ -radius approximation (say a ball B_1); then we apply the recently proposed sublinear time bi-criteria MEB with outliers algorithm [31] to compute a “potential” $(1 - \delta)$ -covering approximation (say a ball B_2); finally, we determine the final output based on the ratio of their radii. Specifically, we set a threshold τ that is determined by the given radius error bound ϵ . If the ratio is no larger than τ , we know that B_1 is a “true” $(1 + \epsilon)$ -radius approximation and return it; otherwise, we return B_2 that is a “true” $(1 - \delta)$ -covering approximation. Moreover, for the latter case (*i.e.*, returning a $(1 - \delta)$ -covering approximation), we will show that our proposed algorithm yields a radius not only being strictly smaller than $\mathbf{Rad}(P)$, but also having a gap of $\Theta(\epsilon^2) \cdot \mathbf{Rad}(P)$ to $\mathbf{Rad}(P)$ (*i.e.*, the returned radius is at most $(1 - \Theta(\epsilon^2)) \cdot \mathbf{Rad}(P)$). Our algorithm only needs uniform sampling and a single pass over the input data, where the space complexity in memory is $O(d)$ (the hidden factor depends on ϵ and δ); if the input data matrix is sparse (*i.e.*, $M = o(nd)$), the time complexity is sublinear. Furthermore, we propose the similar results for the polytope distance and SVM problems (for both stable instance and general instance).

7 Future Work

Following our work, several interesting problems deserve to be studied in future. For example, different from radius approximation, the current research on covering approximation of MEB is still inadequate. In particular, can we provide a lower bound for the complexity of computing covering approximate MEB, as the lower bound result for radius approximate MEB proved by [25]? Also, is it possible to extend the stability notion to other geometric optimization problems with more complicated structures (like subspace fitting and clustering [36], and regression problems [67])?

Abstract

In this paper, we investigate the relative power of several conjectures that attracted recently lot of interest. We establish a connection between the Network Coding Conjecture (*NCC*) of Li and Li [25] and several data structure problems such as non-adaptive function inversion of Hellman [19] and the well-studied problem of polynomial evaluation and interpolation. In turn these data structure problems imply super-linear circuit lower bounds for explicit functions such as integer sorting and multi-point polynomial evaluation.

1 Introduction

One of the central problems in theoretical computer science is proving lower bounds in various models of computation such as circuits and data structures. Proving super-linear size lower bounds for circuits even when their depth is restricted is rather elusive. Similarly, proving polynomial lower bounds on query time for certain static data structure problems seems out of reach. To deal with this situation researchers developed various conjectures which if true would imply the sought after lower bounds. In this paper, we investigate the relative power of some of those conjectures. The Network Coding Conjecture (*NCC*) of Li and Li [25] attracted recently lot of attention and it was used to prove various lower bounds such as lower bounds on the size of circuits computing multiplication [3] and the number of IO operations needed for external memory sorting [13].

Another problem that is popular in cryptography is a certain data structure type problem for function inversion [19]. Corrigan-Gibbs and Kogan [9] observed that lower bounds for the function inversion problem imply lower bounds for logarithmic depth circuits. A similar more

general observation was made by Viola [35]. In this paper, we establish a new connection between the function inversion problem and NCC. We show that NCC implies certain weak lower bounds for the inversion data structure problem. That in turn implies the same type of circuit lower bounds as given by Corrigan-Gibbs and Kogan [9]. We show that similar results apply to a host of other data structure problems such as the well-studied polynomial evaluation problem or the Finite Field Fourier transform problem. Corrigan-Gibbs and Kogan [9] gave their circuit lower bound for certain apriori undetermined function. We establish the same circuit lower bounds for sorting integers which is a very explicit function. Similarly, we establish a connection between data structure for polynomial evaluation and circuits for multi-point polynomial evaluation. Our results sharpen and generalize the picture emerging in the literature.

The data structures considered in this paper are static, non-adaptive, and systematic, i.e., a very restricted class of data structures for which lower bounds should perhaps be easier to obtain. Such data structure problems have the following structure: Given the input data described by N bits, create a data structure of size s . Then we receive a single query from a set of permissible queries and we are supposed to answer the query while non-adaptively inspecting at most t locations in the data structure and in the original data. The non-adaptivity means that the inspected locations are chosen only based on the query being answered but not on the content of the inspected memory. We show that when $s \geq \omega(N/\log \log N)$, polynomial lower bounds on t for certain problems would imply super-linear lower bounds on log-depth circuits for computing sorting, multi-point polynomial evaluation, and other problems.

We show that logarithmic lower bounds on t for the data structures can be derived from NCC even in the more generous setting of $s \geq \varepsilon N$ and when inspecting locations in the data structure is for free. This matches the lower bounds of Afshani [3] for certain circuit parameters derived from NCC. One can recover the same type of result they showed from our connection between NCC, data structure lower bounds, and circuit lower bounds. In this regards, NCC seems to be a stronger assumption than that certain functions require large boolean circuits or inefficient data structures. One would hope that for the strongly restricted data structure problems, obtaining the required lower bounds should be within our reach.

Our technique seems applicable to data structure problems that are *involutions* that are inverses of themselves. Although we use a lot of the same technical machinery as the previous papers on NCC our proofs involve new ideas. An interesting aspect of our proofs is that they apply the hypothesized data structure twice in the reductions. This is reminiscent of many quantum algorithms that use Hadamard transform twice in a row.

Organization. The statement of our main results is in Section 4. In the next section, we review the data structure problems we consider. Then we provide a precise definition of Network Coding Conjecture in Section 3. In Section 5 we prove our main result for function inversion. In Section 6 we discuss the connection between data structure and circuit lower bounds for explicit functions. Some of the proofs are left for the full version [12].

2 Data Structure Problems

In this paper, we study lower bounds on *systematic data structures* for various problems – function inversion, polynomial evaluation, and polynomial interpolation. We are given an input $I = \{x_0, \dots, x_{n-1}\}$, where each $x_i \in [n] = \{0, \dots, n-1\}$ or each x_i is an element of

some field \mathbb{F} . First, a data structure algorithm can preprocess I to produce an advice string \mathbf{a}_I of s bits (we refer to the parameter s as *space* of the data structure \mathcal{D}). Then, we are given a query q and the data structure should produce a correct answer (what is a correct answer depends on the problem). To answer a query q , the data structure \mathcal{D} has access to the whole advice string \mathbf{a}_I and can make t probes to the input I , i.e., read at most t elements from I . We refer to the parameter t as the query time of the data structure.

We consider non-uniform data structures as we want to provide connections between data structures and non-uniform circuits. Formally, a non-uniform systematic data structure \mathcal{D}_n for an input $I = \{x_0, \dots, x_{n-1}\}$ is a pair of algorithms $(\mathcal{P}_n, \mathcal{Q}_n)$ with oracle access to I . The algorithm \mathcal{P}_n produces the advice string $\mathbf{a}_I \in \{0, 1\}^s$. The algorithm \mathcal{Q}_n with inputs \mathbf{a}_I and a query q outputs a correct answer to the query q with at most t oracle probes to I . The algorithms \mathcal{P}_n and \mathcal{Q}_n can differ for each $n \in \mathbb{N}$.

2.1 Function Inversion

In the function inversion problem, we are given a function $f : [n] \rightarrow [n]$ and a point $y \in [n]$ and we want to find $x \in [n]$ such that $f(x) = y$. This is a central problem in cryptography as many cryptographic primitives rely on the existence of a function that is hard to invert. To sum up we are interested in the following problem.

Function Inversion

<i>Input:</i>	A function $f : [n] \rightarrow [n]$ as an oracle.
<i>Preprocessing:</i>	Using f , prepare an advice string $\mathbf{a}_f \in \{0, 1\}^s$.
<i>Query:</i>	Point $y \in [n]$.
<i>Answer:</i>	Compute the value $f^{-1}(y)$, with a full access to \mathbf{a}_f and using at most t probes to the oracle for f .

We want to design an efficient data structure, i.e., make s and t as small as possible. There are two trivial solutions. The first one is that the whole function f^{-1} is stored in the advice string \mathbf{a}_f , thus $s = O(n \log n)$ and $t = 0$. The second one is that the whole function f is probed during answering a query $y \in [n]$, thus $t = O(n)$ and $s = 0$. Note that the space s of the data structure is the length of the advice string \mathbf{a}_f in bits but with one oracle-probe x_i the data structure reads the whole $f(x_i)$, thus with n oracle-probes we read the whole description of f , i.e., $n \log n$ bits.

The question is whether we can design a data structure with $s, t \leq o(n)$. Hellman [19] gave the first non-trivial solution and introduced a randomized (adaptive) systematic data structure which inverts a function with a constant probability (over the uniform choice of the function f and the query $y \in [n]$) and $s = O(n^{2/3} \log n)$ and $t = O(n^{2/3} \log n)$. Fiat and Naor [14] improved the result and introduced a data structure that inverts any function at any point, however with a slightly worse trade-off: $s^3 t = O(n^3 \log n)$. Hellman [19] also introduced a more efficient data structure for inverting a permutation – it inverts any permutation at any point and $st = O(n \log n)$. Thus, it seems that inverting a permutation is an easier problem than inverting an arbitrary function.

In this paper, we are interested in lower bounds for the inversion problem. Yao [36] gave a lower bound that any systematic data structure for the inversion problem must have $st \geq \Omega(n \log n)$, however, the lower bound is applicable only if $t \leq O(\sqrt{n})$. Since then, only slight progress was made. De et al. [10] improved the lower bound of Yao [36] to be applicable for the full range of t . Abusalah et al. [1] improved the trade-off, that for any k it must hold that $s^k t \geq \Omega(n^k)$. Seemingly, their result contradicts Hellman's trade-off ($s = t = O(n^{2/3} \log n)$) as it implies $s = t \geq n^{k/k+1}$ for any k . However, for Hellman's attack [19] we need that the function can be efficiently evaluated and the functions introduced by Abusalah et al. [1] cannot be efficiently evaluated. There is also a series of

papers [17, 30, 11, 8] that study how the probability of successful inversion depends on the parameters s and t . However, none of these results yields a better lower bound than $st \geq \Omega(n \log n)$. Hellman's trade-off is still the best-known upper bound trade-off for the inversion problem. Thus, there is still a substantial gap between the lower and upper bounds.

Another caveat of all known data structures for the inversion is that they heavily use adaptivity during answering queries $y \in [n]$. I.e., probes to the oracle depend on the advice string \mathbf{a} and answers to the oracle probes which have been already made. We are interested in non-adaptive data structures. We say a systematic data structure is *non-adaptive* if all oracle probes depend only on the query $y \in [n]$.

As non-adaptive data structures are weaker than adaptive ones, there is a hope that for non-adaptive data structures we could prove stronger lower bounds. Moreover, the non-adaptive data structure corresponds to circuits computation [31, 32, 34, 9]. Thus, we can derive a circuit lower bound from a strong lower bound for a non-adaptive data structure. Non-adaptive data structures were considered by Corrigan-Gibbs and Kogan [9]. They proved that improvement by a polynomial factor of Yao's lower bound [36] for non-adaptive data structures would imply the existence of a function $F : \{0, 1\}^N \rightarrow \{0, 1\}^N$ for $N = n \log n$ that cannot be computed by a linear-size and logarithmic-depth circuit. More formally, they prove that if a function $f : [n] \rightarrow [n]$ cannot be inverted by a non-adaptive data structure of space $O(n \log n / \log \log n)$ and query time $O(n^\varepsilon)$ for some $\varepsilon > 0$ then there exists a function $F : \{0, 1\}^N \rightarrow \{0, 1\}^N$ that cannot be computed by any circuit of size $O(N)$ and depth $O(\log N)$. They interpret $r \in \{0, 1\}^N$ as n numbers in $[n]$, i.e., $r = (r_1, \dots, r_n) \in \{0, 1\}^N$ where each $r_i \in [n]$. The function F is defined as $F(y) = F(y_1, \dots, y_n) = (f^{-1}(y_1), \dots, f^{-1}(y_n))$ where $f^{-1}(y_i) = \min\{x \in [n] \mid f(x) = y_i\}$ and $\min \emptyset = 0$. Informally, if the function f is hard to invert at some points, then it is hard to invert at all points together. Compared to the result of Corrigan-Gibbs and Kogan [9], we provide an explicit function (sorting n -bit integers) which will require large circuits if any of the functions f is hard to invert. A connection similar to Corrigan-Gibbs and Kogan between data structures and circuits was made also by Viola [35].

2.2 Evaluation and Interpolation of Polynomials

In this section, we describe two natural problems connected to polynomials. We consider our problems over a finite field \mathbb{F} to avoid issues with encoding reals.

Polynomial Evaluation over \mathbb{F}

<i>Input:</i>	Coefficients of a polynomial $p \in \mathbb{F}[x]$: $\alpha_0, \dots, \alpha_{n-1} \in \mathbb{F}$ (i.e., $p(x) = \sum_{i \in [n]} \alpha_i x^i$)
<i>Preprocessing:</i>	Using the input, prepare an advice string $\mathbf{a}_p \in \{0, 1\}^s$.
<i>Query:</i>	A number $x \in \mathbb{F}$.
<i>Answer:</i>	Compute the value $p(x)$, with a full access to \mathbf{a}_p and using at most t probes to the coefficients of p .

Polynomial Interpolation over \mathbb{F}

<i>Input:</i>	Point-value pairs of a polynomial $p \in \mathbb{F}[x]$ of degree at most $n - 1$: $(x_0, p(x_0)), \dots, (x_{n-1}, p(x_{n-1})) \in \mathbb{F} \times \mathbb{F}$ where $x_i \neq x_j$ for any two indices $i \neq j$
<i>Preprocessing:</i>	Using the input, prepare an advice string $\mathbf{a}_p \in \{0, 1\}^s$.
<i>Query:</i>	An index $j \in [n]$.
<i>Answer:</i>	Compute j -th coefficient of the polynomial p , i.e., the coefficient of x^j in p , with a full access to \mathbf{a}_p and using at most t probes to the oracle for point-value pairs.

In the paper we often use a version of polynomial interpolation where the points x_0, x_1, \dots, x_{n-1} are fixed in advance and the input consists just of $p(x_0), p(x_1), \dots, p(x_{n-1})$. Since we are interested in lower bounds, this makes our results slightly stronger.

Let $\mathbb{F} = \text{GF}(p^k)$ denote the Galois Field of p^k elements. Let n be a divisor of $p^k - 1$. It is a well-known fact that for any finite field \mathbb{F} its multiplicative group \mathbb{F}^* is cyclic (see e.g. Serre [28]). Thus, there is a primitive n -th root of unity $\sigma \in \mathbb{F}$ (that is an element σ such that $\sigma^n = 1$ and for each $1 \leq j < n$, $\sigma^j \neq 1$). Pollard [27] defines the *Finite Field Fourier transform* (FFFT) (with respect to σ) as a linear function $\text{FFFT}_{n,\sigma}: \mathbb{F}^n \rightarrow \mathbb{F}^n$ which satisfies:

$$\begin{aligned} \text{FFFT}_{n,\sigma}(\alpha_0, \dots, \alpha_{n-1}) &= (\beta_0, \dots, \beta_{n-1}) \text{ where} \\ \beta_i &= \sum_{j \in [n]} \alpha_j \sigma^{ij} \end{aligned} \quad \text{for any } i \in [n]$$

The inversion $\text{FFFT}_{n,\sigma}^{-1}$ is given by:

$$\begin{aligned} \text{FFFT}_{n,\sigma}^{-1}(\beta_0, \dots, \beta_{n-1}) &= (\alpha_0, \dots, \alpha_{n-1}) \text{ where} \\ \alpha_i &= \frac{1}{n} \sum_{j \in [n]} \beta_j \sigma^{-ij} \end{aligned} \quad \text{for any } i \in [n]$$

Here, $\frac{1}{n} = (\sum_{i=1}^n 1)^{-1}$ over \mathbb{F} . In our theorems we always set n to be a divisor of $|\mathbb{F}| - 1 = p^k - 1$ thus n modulo p is non-zero and the inverse exists. Observe, that $\text{FFFT}_{n,\sigma}^{-1} = \frac{1}{n} \text{FFFT}_{n,\sigma^{-1}}$.

FFFT is the finite field analog of Discrete Fourier transform (DFT) which works over complex numbers. The FFT algorithm by Cooley and Tukey [7] can be used for the case of finite fields as well (as observed by Pollard [27]) to get an algorithm using $O(n \log n)$ field operations (addition or multiplication of two numbers). Thus we can compute $\text{FFFT}_{n,\sigma}$ and its inverse in $O(n \log n)$ field operations.

It is easy to see that $\text{FFFT}_{n,\sigma}$ is actually evaluation of a polynomial in multiple special points (specifically in $\sigma^0, \dots, \sigma^{n-1}$). We can also see that it is a special case of interpolation by a polynomial in multiple special points since $\text{FFFT}_{n,\sigma}^{-1} = \frac{1}{n} \text{FFFT}_{n,\sigma^{-1}}$. We provide an NCC-based lower bound for data structures computing the polynomial evaluation. However, we use the data structure only for evaluating a polynomial in powers of a primitive root of unity. Thus, the same proof yields a lower bound for data structures computing the polynomial interpolation.

There is a great interest in data structures for polynomial evaluation in a cell probe model. In this model, some representation of a polynomial $p = \sum_{i \in [n]} \alpha_i x^i \in \mathbb{F}[x]$ is stored in a table \mathcal{T} of s_{cell} cells, each of w bits. Usually, w is set to $O(\log |\mathbb{F}|)$, that we can store an element of \mathbb{F} in a single cell. On a query $x \in \mathbb{F}$ the data structure should output $p(x)$ making at most t_{cell} probes to the table \mathcal{T} . A difference between data structures in the cell probe model and systematic data structures is that a data structure in the cell probe model is charged for any probe to the table \mathcal{T} but a systematic data structure is charged only for probes to the input (the coefficients α_i), reading from the advice string \mathbf{a}_p is for free. Note that, the coefficients α_i of p do not have to be even stored in the table \mathcal{T} . There are again two trivial solutions. The first one is that we store a value $p(x)$ for each $x \in \mathbb{F}$ and on a query $x \in \mathbb{F}$ we probe just one cell. Thus, we would get $t_{\text{cell}} = 1$ and $s_{\text{cell}} = |\mathbb{F}|$ (we assume that we can store an element of \mathbb{F} in a single cell). The second one is that we store the coefficients of p and on a query $x \in \mathbb{F}$ we probe all cells and compute the value $p(x)$. Thus, we would get $t_{\text{cell}} = s_{\text{cell}} = n$.

Let $k = \log |\mathbb{F}|$. Kedlaya and Umans [22] provided a data structure for the polynomial evaluation that uses space $n^{1+\varepsilon} \cdot k^{1+o(1)}$ and query time $\log^{O(1)} n \cdot k^{1+o(1)}$. Note that, $n \cdot k$ is the size of the input and k is the size of the output.

The first lower bound for the cell probe model was given by Miltersen [26]. He proved that for any cell probe data structure for the polynomial evaluation it must hold that $t_{\text{cell}} \geq \Omega(k / \log s_{\text{cell}})$. This was improved by Larsen [23] to $t_{\text{cell}} \geq \Omega(k / \log(s_{\text{cell}} w / nk))$, that gives $t_{\text{cell}} \geq \Omega(k)$ if the data structure uses linear space $s_{\text{cell}} \cdot w = O(n \cdot k)$. However, the size of \mathbb{F} has to be super-linear, i.e., $|\mathbb{F}| \geq n^{1+\Omega(1)}$, and it is not known if the bound holds for smaller fields, e.g., of linear size. Data structures in a bit probe model were studied by Gál and Miltersen [15]. The bit probe model is the same as the cell probe model but each cell contains only a single bit, i.e., $w = 1$. They studied succinct data structures that are data structures such that $s_{\text{cell}} = (n + r) \cdot k$ for $r < o(n)$. Thus, the succinct data structures are related to systematic data structures but still, the succinct data structures are charged for any probe (as any other data structure in the cell probe model). Note that a succinct data structure stores only a few more bits than it is needed due to information-theoretic requirement. Gál and Miltersen [15] showed that for any succinct data structure in the bit probe model it holds that $r \cdot t_{\text{cell}} \geq \Omega(n \cdot k)$. We are not aware of any lower bound for systematic data structures for the polynomial evaluation.

Larsen et al. [24] also gave a log-squared lower bound for dynamic data structures in the cell probe model. Dynamic data structures also support updates of the polynomial p which usually impacts their query time.

There is a great interest in algorithmic questions about the polynomial interpolation such as how fast we can interpolate polynomials [16, 5, 18], how many probes we need to interpolate a polynomial if it is given by oracle [6, 20], how to compute the interpolation in a numerically stable way over infinite fields [29] and many others. However, we are not aware of any results about data structures for the interpolation, i.e., when the interpolation algorithm has an access to some precomputed advice.

3 Network Coding

We prove our conditional lower bounds based on the Network Coding Conjecture. In network coding, we are interested in how much information we can send through a given network. A *network* consists of a graph $G = (V, E)$, positive capacities of edges $c : E \rightarrow \mathbb{R}^+$ and k pairs of vertices $(s_0, t_0), \dots, (s_{k-1}, t_{k-1})$. We say a network $R = (G, c, (s_i, t_i)_{i \in [k]})$ is *undirected* or *directed (acyclic)* if the graph G is undirected or directed (acyclic). We say a network is *uniform* if the capacities of all edges in the network equal to some $q \in \mathbb{R}^+$ and we denote such network as $(G, q, (s_i, t_i)_{i \in [k]})$.

A goal of a coding scheme for directed acyclic network $R = (G, c, (s_i, t_i)_{i \in [k]})$ is that at each target t_i it will be possible to reconstruct an input message w_i which was generated at the source s_i . The coding scheme specifies messages sent from each vertex along the outgoing edges as a function of received messages. Moreover, the lengths of the messages sent along the edges have to respect the edge capacities.

More formally, each source s_i of a network receives an input message w_i sampled (independently of the messages for the other sources) from the uniform distribution \mathbf{W}_i on a set W_i . Without loss of generality we can assume that each source s_i has an in-degree 0 (otherwise we can add a vertex s'_i and an edge (s'_i, s_i) and replace s_i by s'_i). There is an alphabet Σ_e for each edge $e \in E(G)$. For each source s_i and each outgoing edge $e = (s_i, u)$ there is a function $f_{s_i, e} : W_i \rightarrow \Sigma_e$ which specifies the message sent along the edge e as a

function of the received input message $w_i \in W_i$. For each non-source vertex $v \in V, v \neq s_i$ and each outgoing edge $e = (v, u)$ there is a similar function $f_{v,e} : \prod_{e'=(u',v)} \Sigma_{e'} \rightarrow \Sigma_e$ which specifies the message sent along the edge e as a function of the messages sent to v along the edges incoming to v . Finally, each target t_i has a decoding function $d_i : \prod_{e'=(u',t_i)} \Sigma_{e'} \rightarrow W_i$. The coding scheme is executed as follows:

1. Each source s_i receives an input message $w_i \in W_i$. Along each edge $e = (s_i, u)$ a message $f_{s_i,e}(w_i)$ is sent.
2. When a vertex v receives all messages m_1, \dots, m_a along all incoming edges (u', v) it sends along each outgoing edge $e = (v, u)$ a message $f_{v,e}(m_1, \dots, m_a)$. As the graph G is acyclic, this procedure is well-defined and each vertex of non-zero out-degree will eventually send its messages along its outgoing edges.
3. At the end, each target t_i computes a string $\tilde{w}_i = d_i(m'_1, \dots, m'_b)$ where m'_j denotes the received messages along the incoming edges (u', t_i) . We say the encoding scheme is *correct* if $\tilde{w}_i = w_i$ for all $i \in [k]$ and any input messages $w_0, \dots, w_{k-1} \in W_0 \times \dots \times W_{k-1}$.

The coding scheme has to respect the edge capacities, i.e., if \mathbf{M}_e is a random variable that represents a message sent along the edge e , then $H(\mathbf{M}_e) \leq c(e)$, where $H(\cdot)$ denotes the Shannon entropy. A *coding rate* of a network R is the maximum r such that there is a correct coding scheme for input random variables $\mathbf{W}_0, \dots, \mathbf{W}_{k-1}$ where $H(\mathbf{W}_i) = \log |W_i| \geq r$ for all $i \in [k]$. A network coding can be defined also for directed cyclic networks or undirected networks but we will not use it here.

Network coding is related to multicommodity flows. A multicommodity flow for an undirected network $\bar{R} = (\bar{G}, c, (s_i, t_i)_{i \in [k]})$ specifies flows for each commodity i such that they transport as many units of commodity from s_i to t_i as possible. A flow of the commodity i is specified by a function $f^i : V \times V \rightarrow \mathbb{R}^+$ which describes for each pair of vertices (u, v) how many units of the commodity i are sent from u to v . Each function f^i has to satisfy:

1. If u, v are not connected by an edge, then $f^i(u, v) = f^i(v, u) = 0$.
2. For each edge $\{u, v\} \in E(\bar{G})$, it holds that $f^i(u, v) = 0$ or $f^i(v, u) = 0$.
3. For each vertex v that is not the source s_i or the target t_i , it holds that what comes to the vertex v goes out from the vertex v , i.e.,

$$\sum_{u \in V} f^i(u, v) = \sum_{u \in V} f^i(v, u).$$

4. What is sent from the source s_i arrives to the target t_i , i.e.,

$$\sum_{u \in V} f^i(s_i, u) - f^i(u, s_i) = \sum_{u \in V} f^i(u, t_i) - f^i(t_i, u).$$

Moreover, all flows together have to respect the capacities, i.e., for each edge $e = \{u, v\} \in E(\bar{G})$ it must hold that $\sum_{i \in [k]} f^i(u, v) + f^i(v, u) \leq c(e)$. A *flow rate* of a network \bar{R} is the maximum r such that there is a multicommodity flow $F = (f^0, \dots, f^{k-1})$ that for each i transports at least r units of the commodity i from s_i to t_i , i.e., for all i , it holds that $\sum_{u \in V} f^i(u, t_i) - f^i(t_i, u) \geq r$. A multicommodity flow for directed graphs is defined similarly, however, the flows can transport the commodities only in the direction of edges.

Let R be a directed acyclic network of a flow rate r' . It is clear that for a coding rate r of R it holds that $r \geq r'$. As we can send the messages without coding and thus reduce the encoding problem to the flow problem. The opposite inequality does not hold: There is a directed network $R = (G, c, (s_i, t_i)_{i \in [k]})$ such that its coding rate is $\Omega(|V(G)|)$ -times larger than its flow rate as shown by Adler et al. [2]. Thus, the network coding for directed networks provides an advantage over the simple solution given by the maximum flow. However, such a

result is not known for undirected networks. Li and Li [25] conjectured that the network coding does not provide any advantage for undirected networks, thus for any undirected network \bar{R} , the coding rate of \bar{R} equals to the flow rate of \bar{R} . This conjecture is known as *Network Coding Conjecture* (NCC) and we state a weaker version of it below.

For a directed graph $G = (V, E)$ we denote by $\text{un}(G)$ the undirected graph (V, \bar{E}) obtained from G by making each directed edge in E undirected (i.e., replacing each $(u, v) \in E(G)$ by $\{u, v\}$). For a directed acyclic network $R = (G, c, (s_i, t_i)_{i \in [k]})$ we define the undirected network $\text{un}(R) = (\text{un}(G), \bar{c}, (s_i, t_i)_{i \in [k]})$ by keeping the source-target pairs and capacities the same, i.e., $c((u, v)) = \bar{c}(\{u, v\})$.

► **Conjecture 1 (Weaker NCC).** *Let R be a directed acyclic network, r be a coding rate of R and \bar{r} be a flow rate of $\text{un}(R)$. Then, $r = \bar{r}$.*

This conjecture was used to prove a conditional lower bound for sorting algorithms with an external memory [13] and for circuits multiplying two numbers [3].

4 NCC Implies Data Structure Lower Bounds

In this paper, we provide several connections between lower bounds for data structures and other computational models. The first connection is that the Network Coding Conjecture (Conjecture 1) implies lower bounds for data structures for the permutation inversion and the polynomial evaluation and interpolation. Assuming NCC, we show that a query time t of a non-adaptive systematic data structure for any of the above problems satisfies $t \geq \Omega(\log n / \log \log n)$, even if it uses linear space, i.e., the advice string \mathbf{a} has size $\varepsilon n \log n$ for sufficiently small constant $\varepsilon > 0$. Formally, we define $t_{\text{Inv}}(s)$ as a query time of the optimal non-adaptive systematic data structure for the permutation inversion using space at most s . Similarly, we define $t_{\text{Eval}}^{\mathbb{F}}(s)$ and $t_{\text{Interp}}^{\mathbb{F}}(s)$ for the polynomial evaluation and interpolation over \mathbb{F} .

► **Theorem 2.** *Let $\varepsilon > 0$ be a sufficiently small constant. Assuming NCC, it holds that $t_{\text{Inv}}(\varepsilon n \log n) \geq \Omega(\log n / \log \log n)$.*

► **Theorem 3.** *Let \mathbb{F} be a field and n be a divisor of $|\mathbb{F}| - 1$. Let $s = \varepsilon n \log |\mathbb{F}|$ for a sufficiently small constant $\varepsilon > 0$. Then assuming NCC, it holds that $t_{\text{Eval}}^{\mathbb{F}}(s), t_{\text{Interp}}^{\mathbb{F}}(s) \geq \Omega(\log n / \log \log n)$.*

Note that by Theorem 2, assuming NCC, it holds that $s \cdot t \geq \Omega(n \log^2 n / \log \log n)$ for $s = \varepsilon n \log n$ and $t = t_{\text{Inv}}(s)$. The same holds for $t_{\text{Eval}}^{\mathbb{F}}$ and $t_{\text{Interp}}^{\mathbb{F}}$ by Theorem 3. Thus, these conditional lower bounds cross the barrier $\Omega(n \log n)$ for $s \cdot t$ given by the best unconditional lower bounds known for the function inversion [36, 10, 1, 17, 30, 11, 8] and the lower bound for the succinct data structures for the polynomial evaluation by Gál and Miltersen [15]. Note that our lower bound does not contradict Hellman's attack [19] for the permutation inversion, as his data structure is heavily adaptive.

Our lower bound for the data structure for the polynomial evaluation and interpolation is applicable even for linear size field (i.e., linear number of queries). Larsen's lower bound for the data structure for the polynomial evaluation [23] is applicable only for superlinear fields, i.e., $|\mathbb{F}| \geq n^{1+\Omega(1)}$. We give the result for the polynomial evaluation here as it has an analogous proof as the lower bound for the polynomial interpolation and it might illustrate a more general phenomenon that our technique might be applicable to a broader class of functions that contains an involution as a subproblem.

To prove Theorems 2 and 3, we build on the technical machinery of Farhadi et al. [13]. The proof can be divided into two steps:

1. From a data structure for the problem we derive a network R with $O(tn)$ edges such that R admits an encoding scheme that is correct on a large fraction of the inputs. This step is distinct for each problem and the reduction for the function inversion is shown in Section 5, the reduction for the polynomial problems is left to the full version [12]. This step uses new ideas and interestingly, it uses the data structure twice in a sequence.
2. If there is a network R with dn edges that admits an encoding scheme which is correct for a large fraction of inputs, then $d \geq \Omega(\log n / \log \log n)$. This step is common to all the problems. It was implicitly proved by Farhadi et al. [13] and Afshani et al. [3].

5 NCC Implies a Weak Lower Bound for the Function Inversion

In this section, we prove Theorem 2 that assuming NCC, any non-adaptive systematic data structure for the permutation inversion requires query time at least $\Omega(\log n / \log \log n)$ even if it uses linear space. Let \mathcal{D} be a data structure for inverting permutations of a linear space $s = \varepsilon n \log n$, for sufficiently small constant $\varepsilon < 1$, with query time $t = t_{\text{inv}}(s)$. Recall that $t_{\text{inv}}(s)$ is a query time of the optimal non-adaptive systematic data structure for the permutation inversion using space s . From \mathcal{D} we construct a directed acyclic network $R = (G, c, (s_i, t_i)_{i \in [n]})$ and an encoding scheme of a coding rate $\log n$. By Conjecture 1 we get that the flow rate of $\text{un}(R) = (\bar{G}, c, (s_i, t_i)_{i \in [n]})$ is $\log n$ as well. We prove that there are many source-target pairs of distance at least $\Omega(\log_t n)$. Since the number of edges of \bar{G} will be $O(tn)$ and flow rate of $\text{un}(R)$ is $\log n$, we are able to derive a lower bound $t \geq \Omega(\log n / \log \log n)$.

We will design the network based on the *probe graph* of the data structure. By the probe graph of the data structure, we understand a graph with n input vertices corresponding to possible oracle probes and n output vertices corresponding to possible data structure queries. Each query vertex is connected to the vertices of oracle probes executed by the data structure when answering that query. Here, we use the non-adaptivity of the studied data structures as the probe graph does not depend on the stored data but only on the data structure itself. Our construction will utilize two copies of the probe graph connected in a sequence. The network will have input vertices s_0, \dots, s_{n-1} and output vertices u_0, \dots, u_{n-1} where each target t_i is set to $u_{i+b \bmod n}$ for a suitable constant b . The input vertices s_0, \dots, s_{n-1} correspond to the oracle vertices of the first copy of the probe graph. (See Fig. 1 for an illustration.)

We will feed distinct values $x_0, \dots, x_{n-1} \in [n]$ to the input vertices which then send them to the query vertices of the first copy of the probe graph. Values x_0, \dots, x_{n-1} define a permutation $f(i) = x_i$. Each query vertex j of the first copy of the probe graph can determine $f^{-1}(j)$ if it is provided with the advice string \mathbf{a}_f of the data structure corresponding to f . (We will fix the most common advice string \mathbf{a}_f and restrict ourselves to inputs x_0, \dots, x_{n-1} consistent with it.) Each query vertex j can also determine the value of a newly defined function $h(j) = f^{-1}(j) + b$ which it sends along its outgoing edges. The second copy of the data structure serves to invert the function h similarly to inverting f . The oracle vertices of the second copy of the probe graph coincide with the query vertices of the first copy. The query vertices of the second copy of the probe graph are the output vertices u_0, \dots, u_{n-1} . Hence, the query vertex $i + b$ of the second copy will be used to determine $h^{-1}(i + b) = x_i$. Thus, x_i is directed from s_i to $t_i = u_{i+b}$.

The above construction gives a network R with an encoding scheme E that is correct only on a substantial fraction of all possible inputs. Namely on inputs $x_0, \dots, x_{n-1} \in [n]$ which are distinct and consistent with the fixed advices. This forces correlations among messages

received by the sources. However, the Network Coding Conjecture requires independently sampled messages for each source. To overcome this issue we use the technique introduced by Farhadi et al. [13] to augment R so that it admits an encoding scheme for independent messages. We provide technical details next.

Let $R = (G, c, (s_i, t_i)_{i \in [k]})$ be a directed acyclic network. Let each source receive a binary string of length r as its input message, i.e., each $W_i = \{0, 1\}^r$. If we concatenate all input messages w_i we get a string of length $r \cdot k$, thus the set of all possible inputs for an encoding scheme for R corresponds to the set $\mathcal{I} = \{0, 1\}^{rk}$. We say an encoding scheme is correct on an input $\bar{w} = (w_0, \dots, w_{k-1}) \in \mathcal{I}$ if it is possible to reconstruct all messages w_i at appropriate targets. An (ε, r) -encoding scheme is an encoding scheme which is correct on at least $2^{(1-\varepsilon)rk}$ inputs in \mathcal{I} .

We say a directed network $R = (G, c, (s_i, t_i)_{i \in [k]})$ is (δ, d) -long if for at least δk source-target pairs (s_i, t_i) , it holds that distance between s_i and t_i in $\text{un}(G)$ is at least d . Here, we measure the distance in the undirected graph $\text{un}(G)$, even though the network R is directed. The following lemma is implicitly used by Farhadi et al. [13] and Afshani et al. [3].

► **Lemma 4** (Implicitly used in [13, 3]). *Let $R = (G, r, (s_i, t_i)_{i \in [k]})$ be a (δ, d) -long directed acyclic uniform network for $\delta > \frac{5}{6}$ and sufficiently large $r \in \mathbb{R}^+$. Assume there is an (ε, r) -encoding scheme for R for sufficiently small ε . Then assuming NCC, it holds that $\frac{|E(G)|}{k} \geq \delta' \cdot d$, where $\delta' = \frac{\delta-5/6}{10}$.*

Now we are ready to prove a conditional lower bound for the permutation inversion. For the proof we use the following fact which follows from well-known Stirling's formula:

► **Fact 1.** *The number of permutations $[n] \rightarrow [n]$ is at least $2^{n \log n - 2n}$.*

► **Theorem 2.** *Let $\varepsilon > 0$ be a sufficiently small constant. Assuming NCC, it holds that $t_{\text{inv}}(\varepsilon n \log n) \geq \Omega(\log n / \log \log n)$.*

Proof Sketch. Let $\mathcal{D} = \mathcal{D}_n$ be the optimal data structure for the inversion of permutation on $[n]$ using space $\varepsilon n \log n$. We set $t = t_{\text{inv}}(\varepsilon n \log n)$. We will construct a directed acyclic uniform network $R = (G, r, (s_i, t_i)_{i \in [n]})$ where $r = \log n$. Let $\varepsilon' = 2 \cdot \varepsilon + \frac{2}{q} + \frac{2}{\log n}$ for sufficiently large q so that we could apply Lemma 4. The network R will admit an (ε', r) -encoding scheme E . The number of edges of G will be at most $2tn$ and the network R will be $(\frac{9}{10}, d)$ -long for $d = \frac{1}{2} \log_{qt} n$. Thus, by Lemma 4 we get that

$$2t = \frac{2tn}{n} \geq \Omega(\log_{qt} n),$$

from which we can conclude that $t \geq \Omega(\log n / \log \log n)$. Thus, it remains to construct the network R and the scheme E .

First, we construct a graph G' which will yield the graph G by deleting some edges. The graph G' has three layers of n vertices: a source layer A of n sources s_0, \dots, s_{n-1} , a middle layer M of n vertices v_0, \dots, v_{n-1} and a target layer B of n vertices u_0, \dots, u_{n-1} . The targets t_0, \dots, t_{n-1} of R will be assigned to the vertices u_0, \dots, u_{n-1} later.

We add edges according to the data structure \mathcal{D} : Let $Q_j \subseteq [n]$ be the set of oracle probes which \mathcal{D} makes during the computation of $f^{-1}(j)$, i.e., for each $i \in Q_j$, the query j probes the oracle f for $f(i)$. As \mathcal{D} is non-adaptive, the sets Q_j are well-defined. For each $j \in [n]$ and $i \in Q_j$ we add edges (s_i, v_j) and (v_i, u_j) . We set a capacity of all edges to $r = \log n$. This finishes the construction of G' , see Fig. 1 for illustration of the graph G' .

The graph G' has exactly $2tn$ edges. Moreover, the vertices of the middle and the target layer have in-degree at most t as the incoming edges correspond to the oracle probes made by \mathcal{D} . However, some vertices of the source and the middle layer might have large outdegree,

■ **Figure 1** A sketch of the graph G' and encoding scheme E .

which is a problem that might prevent the network R to be $(\frac{9}{10}, d)$ -long. Thus, we need to remove edges adjacent to high-degree vertices. Let $W \subseteq V(G')$ be the set of vertices of out-degree larger than qt . We remove all edges incident to W from G' to obtain the graph G . (For simplicity, we keep the degree 0 vertices in G). Thus, the maximum degree of G is at most qt . Since the graph G' has $2tn$ edges, it holds that $|W| \leq \frac{2}{q} \cdot n$.

Now, we assign the targets of R in such a way that R is $(\frac{9}{10}, d)$ -long. Let C_v be the set of vertices of G which have distance at most d from v in $\text{un}(G)$. Since the maximum degree of G is at most qt and $d = \frac{1}{2} \log_{qt} n$, for each $v \in V(G)$, $|C_v| \leq 2\sqrt{n}$. It follows from an averaging argument that there is an integer b such that there are at least $n - 2\sqrt{n}$ sources s_i with distance at least d from u_{i+b} in $\text{un}(G)$. (Here the addition $i + b$ is modulo n .) We fix one such b and set $t_i = u_{i+b}$. For n large enough, it holds that $n - 2\sqrt{n} \geq \frac{9}{10} \cdot n$. Thus, the network R is $(\frac{9}{10}, d)$ -long.

It remains to construct the (ε', r) -encoding scheme E for R (see Fig. 1 for a sketch of the encoding E). We only sketch the construction here, the full proof is in the full version [12]. At vertices of the middle layer we compute the inversion of f , i.e., at a vertex v_j we compute $f^{-1}(j)$ using the data structure \mathcal{D} . To do that we need to fix the advice string \mathbf{a}_f (of at most $\varepsilon n \log n$ bits) and values on the vertices in W (the high degree vertices).

We define a function $h : [n] \rightarrow [n]$ as $h(j) = f^{-1}(j) + b$. Thus, at each vertex v_j we are able to compute the value $h(j)$. By the analogous strategy, we compute the inverse $h^{-1}(\ell)$ at each vertex u_ℓ (again using the data structure \mathcal{D} , now for the function h). It can be showed that $h^{-1}(i + b) = x_i$, thus we can reconstruct x_i at each vertex $t_i = u_{i+b}$. Overall, we fix at most $(2\varepsilon + \frac{2}{q}) \cdot n \log n$ bits (the advice strings \mathbf{a}_f and \mathbf{a}_h , and the computed values at the vertices in W). Since the scheme E is correct on all inputs encoding a permutation and consistent with the fixing, the scheme E is (ε', r) -encoding scheme for $\varepsilon' = 2\varepsilon + \frac{2}{q} + \frac{2}{\log n}$. ◀

6 Strong Lower Bounds for Data Structures and Lower Bounds for Boolean Circuits

In this section, we study a connection between non-adaptive data structures and boolean circuits. We are interested in circuits with binary AND and OR gates, and unary NOT gates. (See e.g. [21] for background on circuits). Corrigan-Gibbs and Kogan [9] describe a connection between lower bounds for non-adaptive data structures and lower bounds for boolean circuits for a special case when the data structure computes function inversion. They

show that we would get a circuit lower bound if any non-adaptive data structure using $O(N^\varepsilon)$ queries must use at least $\omega(N/\log \log N)$ bits of advice (for some fixed constant $\varepsilon > 0$). They define a *boolean operator* to be a family of functions $(F_N)_{N \in \mathbb{N}}$ for $F_N: \{0, 1\}^N \rightarrow \{0, 1\}^N$ represented by boolean circuits with N input and N output bits and constant fan-in gates. A boolean operator is said to be an *explicit operator* if the decision problem whether the j -th output bit of F_N is equal to one is in the complexity class NP.

► **Theorem 5** (Corrigan-Gibbs and Kogan [9], Theorem 6 (in contraposition)). *If every explicit operator F_N has fan-in-two boolean circuits of size $O(N)$ and depth $O(\log N)$ then, for every $\varepsilon > 0$, there exists a family of strongly non-adaptive black-box algorithms that inverts all functions $f: [n] \rightarrow [n]$ using $O(n \log n / \log \log n)$ bits of advice and $O(n^\varepsilon)$ online probes.*

To prove their theorem Corrigan-Gibbs and Kogan [9] use the common bits model of boolean circuits introduced by Valiant [31, 32, 33]. Valiant proves that for any circuit there is a small cut, called *common bits*, such that each output bit is connected just to few input bits. Corrigan-Gibbs and Kogan [9] use the common bits of the given circuit to create a non-adaptive data structure by setting the advice string to the content of common bits and the queries are to those function values which are still connected to the particular output after removing the common bits. Using Valiant's result directly one can obtain the following corollaries (see the full version [12] for details).

► **Corollary 6.** *Let $\mathcal{S} = \{p^k \mid p \text{ is a prime}, k \in \mathbb{N}, k \neq 0\}$ be the set of all sizes of finite fields. For each $n \in \mathcal{S}$, let $\mathbb{F}_n = GF(n)$ and σ_n be a primitive $(n-1)$ -th root of unity (thus a generator of the multiplicative group \mathbb{F}_n^*). If there is a circuit family computing $FFFT_{n-1, \sigma_n}$ (over \mathbb{F}_n) of size $O(n \log n)$ and depth $O(\log n)$ (where each input and output number is represented by $\log |\mathbb{F}_n|$ bits) then for every $\varepsilon > 0$ there is a family of non-adaptive data structures $\{\mathcal{D}_n\}_{n \in \mathcal{S}}$ where \mathcal{D}_n uses advice of size $O(n \log n / \log \log n)$ and on a query $j \in [n-1]$ outputs the j -th output of $FFFT_{n-1, \sigma_n}$ using $O(n^\varepsilon)$ queries to the input.*

To put the corollary in a counter-positive way: if for some $\varepsilon > 0$, there are no non-adaptive data structures for polynomial interpolation, polynomial evaluation, or FFFT with an advice of size $o(n \log n / \log \log n)$ that use $O(n^\varepsilon)$ queries to the input then there are no linear-size circuits of logarithmic depth for FFFT.

In Theorem 2, resp. Theorem 3, we prove a conditional lower bound for permutation inversion, resp. polynomial evaluation and polynomial interpolation, of the form, that a non-adaptive data structure using $\varepsilon n \log n$ bits must do at least $\Omega(\log n / \log \log n)$ queries. It is not clear if assuming NCC we can get a sufficiently strong lower bound which would rule out non-adaptive data structures with sublinear advice string using $O(n^\varepsilon)$ oracle queries.

► **Corollary 7.** *We say that a circuit $C_n: \{0, 1\}^{n \lceil \log n \rceil} \rightarrow \{0, 1\}^{n \lceil \log n \rceil}$ sorts its input if on an input viewed as n binary strings $x_1, x_2, \dots, x_n \in \{0, 1\}^{\lceil \log n \rceil}$ outputs the strings sorted lexicographically. If there is a circuit family $(C_n)_{n \in \mathbb{N}}$, where $C_n: \{0, 1\}^{n \lceil \log n \rceil} \rightarrow \{0, 1\}^{n \lceil \log n \rceil}$ sorts its inputs, and each circuit C_n is of size $O(n \log n)$ and depth $O(\log n)$ then for every $\varepsilon > 0$, for every permutation $f: [n] \rightarrow [n]$ there is a non-adaptive data structure for inverting f that uses advice of size $O(n \log n / \log \log n)$ and $O(n^\varepsilon)$ queries.*

The works of Farhadi et al. [13] and Asharov et al. [4] connect the NCC conjecture directly to lower bounds for sorting. Their work studies sorting n numbers of $k + w$ bits by their first k bits. Namely Asharov et al. [4] show that NCC implies that constant fan-in constant fan-out circuits must have size $\Omega(nk(w - \log(n) + k))$ whenever $w > \log(n) - k$ and $k \leq \log n$. This is incomparable to our results as we have $w = 0$.

Approximation Schemes for Bounded Distance Problems on Fractionally Treewidth-Fragile Graphs

Zdeněk Dvořák 

Charles University, Prague, Czech Republic

Abhiruk Lahiri 

Ariel University, Israel

Abstract

We give polynomial-time approximation schemes for monotone maximization problems expressible in terms of distances (up to a fixed upper bound) and efficiently solvable on graphs of bounded treewidth. These schemes apply in all fractionally treewidth-fragile graph classes, a property which is true for many natural graph classes with sublinear separators. We also provide quasipolynomial-time approximation schemes for these problems in all classes with sublinear separators.

1 Introduction

In this paper, we consider optimization problems such as:

- **MAXIMUM r -INDEPENDENT SET**, $r \in \mathbb{Z}^+$: Given a graph G , the objective is to find a largest subset $X \subseteq V(G)$ such that distance in G between any two vertices in X is at least r .
- **MAXIMUM WEIGHT INDUCED FOREST**: Given a graph G and an assignment $w : V(G) \rightarrow \mathbb{Z}_0^+$ of non-negative weights to vertices, the objective is to find a subset $X \subseteq V(G)$ such that $G[X]$ does not contain a cycle and subject to that, $w(X) := \sum_{v \in X} w(v)$ is maximized.
- **MAXIMUM (F, r) -MATCHING**, for a fixed connected graph F and $r \in \mathbb{Z}^+$: Given a graph G , the objective is to find a largest subset $X \subseteq V(G)$ such that $G[X]$ can be partitioned into vertex-disjoint copies of F such that distance in G between any two vertices belonging to different copies is at least r .

To be precise, to fall into the scope of our work, the problem must satisfy the following conditions:

- It must be a **maximization problem on certain subsets of vertices** of an input graph, possibly with non-negative weights. That is, the problem specifies which subsets of vertices of the input graph are *admissible*, and the goal is to find an admissible subset of largest size or weight.

- The problem must be **defined in terms of distances between the vertices, up to some fixed bound**. That is, there exists a parameter $r \in \mathbb{Z}^+$ such that for any graphs G and G' , sets $X \subseteq V(G)$ and $X' \subseteq V(G')$, and a bijection $f : X \rightarrow X'$, if $\min(r, d_G(u, v)) = \min(r, d_{G'}(f(u), f(v)))$ holds for all $u, v \in X$, then X is admissible in G if and only if X' is admissible in G' .
- The problem must be **monotone** (i.e., all subsets of an admissible set must be admissible), or at least **near-monotone** (as happens for example for MAXIMUM (F, r) -MATCHING) in the following sense: There exists a parameter $c \in \mathbb{Z}^+$ such that for any admissible set A in a graph G , there exists a system $\{R_v \subseteq A : v \in A\}$ of subsets of A such that
 - each vertex belongs to R_v for at most c vertices $v \in A$,
 - $v \in R_v$ for each $v \in A$, and
 - for every $Z \subseteq A$, the subset $A \setminus \bigcup_{v \in Z} R_v$ is admissible in G .
- The problem must be **tractable in graphs of bounded treewidth**, that is, there must exist a function g and a polynomial p such that given any graph G , its tree decomposition of width t , an assignment w of non-negative weights to the vertices of G , and a set $X_0 \subseteq X$, it is possible to find a maximum-weight admissible subset of X_0 in time $g(t)p(|V(G)|)$.

Let us call such problems $(\leq r)$ -distance determined c -near-monotone (g, p) -tw-tractable. Note that a convenient way to verify these assumptions is to show that the problem is expressible in *solution-restricted Monadic Second-Order Logic (MSOL) with bounded-distance predicates*, i.e., by a MSOL formula with one free variable X such that the quantification is restricted to subsets and elements of X , and using binary predicates d_1, \dots, d_r , where $d_i(u, v)$ is interpreted as testing whether the distance between u and v in the whole graph is at most i . For example, r -INDEPENDENT SET is expressed by the formula $(\forall u, v \in X) u = v \vee \neg d_r(u, v)$. This ensures that the problem is $(\leq r)$ -distance determined, and $(g, O(n))$ -tw-tractable for some function g by Courcelle's meta-algorithmic result [5].

Of course, the problems satisfying the assumptions outlined above are typically hard to solve optimally, even in rather restrictive circumstances. For example, MAXIMUM INDEPENDENT SET is NP-hard even in planar graphs of maximum degree at most 3 and arbitrarily large (fixed) girth [1]. Moreover, it is hard to approximate it within factor of 0.995 in graphs of maximum degree at most three [4]. Hence, to obtain polynomial-time approximation schemes (PTASes), i.e., polynomial-time algorithms for approximating within any fixed precision, a restriction other than just bounding the maximum degree is needed.

A natural restriction that has been considered in this context is the requirement that the graphs have sublinear separators (a set S of vertices of a graph G is a *balanced separator* if every component of $G \setminus S$ has at most $|V(G)|/2$ vertices, and a hereditary class \mathcal{G} of graphs has *sublinear separators* if for some $c < 1$, every graph $G \in \mathcal{G}$ has a balanced separator of size $O(|V(G)|^c)$). This restriction still lets us speak about many interesting graph classes (planar graphs [19] and more generally proper minor-closed classes [2], many geometric graph classes [21], ...). Moreover, the problems discussed above admit PTASes in all classes with sublinear separators or at least in substantial subclasses of these graphs:

- MAXIMUM INDEPENDENT SET has been shown to admit a PTAS in graphs with sublinear separators already in the foundational paper of Lipton and Tarjan [20].
- For any positive integer, MAXIMUM r -INDEPENDENT SET and several other problems are known to admit PTASes in graphs with sublinear separators by a straightforward local search algorithm [16].
- All of the problems mentioned above (and more) are known to admit PTASes in planar graphs by a layering argument of Baker [3]; this approach can be extended to some related graph classes, including all proper minor-closed classes [6, 12].

- The problems also admit PTASes in graph classes that admit thin systems of overlays [11], a technical property satisfied by all proper minor-closed classes and by all hereditary classes with sublinear separators and bounded maximum degree.
- Bidimensionality arguments [7] apply to a wide range of problems in proper minor-closed graph classes.

However, each of the outlined approaches has drawbacks. On one side, the local search approach only applies to specific problems and does not work at all in the weighted setting. On the other side of the spectrum, Baker's approach is quite general as far as the problems go, but there are many hereditary graph classes with sublinear separators to which it does not seem to apply. The approach through thin systems of overlays tries to balance these concerns, but it is rather technical and establishing this property is difficult.

Another option that has been explored is via *fractional treewidth-fragility*. For a function $f: \mathbb{Z}^+ \times \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$ and a polynomial p , a class of graphs \mathcal{G} is *p-efficiently fractionally treewidth-f-fragile* if there exists an algorithm that for every $k \in \mathbb{Z}^+$ and a graph $G \in \mathcal{G}$ returns in time $p(|V(G)|)$ a collection of subsets $X_1, X_2, \dots, X_m \subseteq V(G)$ such that each vertex of G belongs to at most m/k of the subsets, and moreover, for $i = 1, \dots, m$, the algorithm also returns a tree decomposition of $G \setminus X_i$ of width at most $f(k, |V(G)|)$. We say a class is *p-efficiently fractionally treewidth-fragile* if f does not depend on its second argument (the number of vertices of G). This property turns out to hold for basically all known natural graph classes with sublinear separators. In particular, a hereditary class \mathcal{G} of graphs is efficiently fractionally treewidth-fragile if

- \mathcal{G} has sublinear separators and bounded maximum degree [9],
- \mathcal{G} is proper minor-closed [8, 12], or
- \mathcal{G} consists of intersection graphs of convex objects with bounded aspect ratio in a finite-dimensional Euclidean space and the graphs have bounded clique number, as can be seen by a modification of the argument of Erlebach et al. [15]. This includes all graph classes with polynomial growth [18].

In fact, Dvořák conjectured that every hereditary class with sublinear separators is fractionally treewidth-fragile, and gave the following result towards this conjecture.

► **Theorem 1** (Dvořák [10]). *There exists a polynomial p so that the following claim holds. For every hereditary class \mathcal{G} of graphs with sublinear separators, there exists a polynomial q such that \mathcal{G} is p -efficiently fractionally treewidth-f-fragile for the function $f(k, n) = q(k \log n)$.*

Moreover, Dvořák [9] observed that weighted MAXIMUM INDEPENDENT SET admits a PTAS in any efficiently fractionally treewidth-fragile class of graphs. Indeed, the algorithm is quite simple, based on the observation that for the sets X_1, \dots, X_m from the definition of fractional treewidth-fragility, at least one of the graphs $G \setminus X_1, \dots, G \setminus X_m$ (of bounded treewidth) contains an independent set whose weight is within the factor of $1 - 1/k$ from the optimal solution. A problem with this approach is that it does not extend to more general problems; even for the MAXIMUM 2-INDEPENDENT SET problem, the approach fails, since a 2-independent set in $G \setminus X_i$ is not necessarily 2-independent in G . Indeed, this observation served as one of the motivations behind more restrictive (and more technical) concepts employed in [11, 12].

As our main result, we show that this intuition is in fact false: There is a simple way how to extend the approach outlined in the previous paragraph to all bounded distance determined near-monotone tw-tractable problems.

► **Theorem 2.** *For every class \mathcal{G} of graphs with bounded expansion, there exists a function $h : \mathbb{Z}^+ \times \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$ such that the following claim holds. Let c and r be positive integers, $g : \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$ and $f : \mathbb{Z}^+ \times \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$ functions and p and q polynomials. If \mathcal{G} is q -efficiently fractionally treewidth- f -fragile, then for every $(\leq r)$ -distance determined c -near-monotone (g, p) -tw-tractable problem, there exists an algorithm that given a graph $G \in \mathcal{G}$, an assignment of non-negative weights to vertices, and a positive integer k , returns in time $h(r, c)|V(G)| + q(|V(G)|) \cdot p(|V(G)|) \cdot g(f(h(r, c)k, |V(G)|))$ an admissible subset of $V(G)$ whose weight is within the factor of $1 - 1/k$ from the optimal one.*

Note that the assumption that \mathcal{G} has bounded expansion is of little consequence – it is satisfied for any hereditary class with sublinear separators [14] as well as for any fractionally treewidth-fragile class [9]; see Section 2 for more details. The time complexity of the algorithm from Theorem 2 is polynomial if f does not depend on its second argument, and quasipolynomial (exponential in a polylogarithmic function) if f is logarithmic in the second argument and g is single-exponential, i.e., if $g(n) = \exp(n^{O(1)})$. Hence, we obtain the following corollaries.

► **Corollary 3.** *Let c and r be positive integers, $g : \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$ a function and p a polynomial. Every $(\leq r)$ -distance determined c -near-monotone (g, p) -tw-tractable problem admits a PTAS in any efficiently fractionally treewidth-fragile class of graphs.*

We say a problem admits a quasipolynomial-time approximation schemes (QPTAS) if there exist quasipolynomial-time algorithms for approximating the problem within any fixed precision. Combining Theorems 1 and 2, we obtain the following result.

► **Corollary 4.** *Let c and r be positive integers, $g : \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$ a single-exponential function, and p a polynomial. Every $(\leq r)$ -distance determined c -near-monotone (g, p) -tw-tractable problem admits a QPTAS in any hereditary class of graphs with sublinear separators.*

The idea of the algorithm from Theorem 2 is quite simple: We consider the sets X_1, \dots, X_m from the definition of fractional treewidth- f -fragility, extend them to suitable supersets Y_1, \dots, Y_m , and argue that for $i = 1, \dots, m$, any admissible set in $G \setminus X_i$ disjoint from Y_i is also admissible in G , and that for some i , the weight of the heaviest admissible set in $G \setminus X_i$ disjoint from Y_i is within the factor of $1 - 1/k$ from the optimal one. The construction of the sets Y_1, \dots, Y_m is based on the existence of orientations with bounded outdegrees that represent all short paths, a generalization of a result Kowalik and Kurowski [17] that we present in Section 2.

Let us remark one can develop the idea of this paper in further directions. Dvořák proved in [13] (via a substantially more involved argument) that every monotone maximization problem expressible in first-order logic admits a PTAS in any efficiently fractionally treewidth-fragile class of graphs. Note that this class of problems is incomparable with the one considered in this paper (e.g., MAXIMUM INDUCED FOREST is not expressible in first-order logic, while MAXIMUM INDEPENDENT SET consisting of vertices belonging to triangles is expressible in first-order logic but does not fall into the scope of the current paper).

Finally, it is worth mentioning that our results only apply to maximization problems. We were able to extend the previous uses of fractional treewidth-fragility by giving a way to handle dependencies over any bounded distance. However, for the minimization problems, we do not know whether fractional treewidth-fragility is sufficient even for the distance-1 problems. For a simple example, consider the MINIMUM VERTEX COVER problem in fractionally treewidth-fragile graphs, or more generally in hereditary classes with sublinear separators. While the unweighted version can be dealt with by the local search method [16], we do not know whether there exists a PTAS for the weighted version of this problem.

2 Paths and orientations in graphs with bounded expansion

For $r \in \mathbb{Z}_0^+$, a graph H is an r -shallow minor of a graph G if H can be obtained from a subgraph of G by contracting pairwise vertex-disjoint connected subgraphs, each of radius at most r . For a function $f: \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$, a class \mathcal{G} of graphs has *expansion bounded* by f if for all non-negative integers r , all r -shallow minors of graphs from \mathcal{G} have average degree at most $f(r)$. A class has *bounded expansion* if its expansion is bounded by some function f . The theory of graph classes with bounded expansion has been developed in the last 15 years, and the concept has found many algorithmic and structural applications; see [23] for an overview. Crucially for us, this theory includes a number of tools for dealing with short paths. Moreover, as we have pointed out before, all hereditary graph classes with sublinear separators [14] as well as all fractionally treewidth-fragile classes [9] have bounded expansion.

Let \vec{G} be an orientation of a graph G , i.e., uv is an edge of G if and only if the directed graph \vec{G} contains at least one of the directed edges (u, v) and (v, u) ; note that we allow \vec{G} to contain both of them at the same time, and thus for the edge uv to be oriented in both directions. We say that a directed graph \vec{H} with the same vertex set is a *1-step fraternal augmentation* of \vec{G} if $\vec{G} \subseteq \vec{H}$, for all distinct edges $(x, y), (x, z) \in E(\vec{G})$, either (y, z) or (z, y) is an edge of \vec{H} , and for each edge $(y, z) \in E(\vec{H}) \setminus E(\vec{G})$, there exists a vertex $x \in V(\vec{G}) \setminus \{y, z\}$ such that $(x, y), (x, z) \in E(\vec{G})$. That is, to obtain \vec{H} from \vec{G} , for each pair of edges $(x, y), (x, z) \in E(\vec{G})$ we add an edge between y and z in one of the two possible directions (we do not specify the direction, but in practice we would choose directions of the added edges that minimize the maximum outdegree of the resulting directed graph). For an integer $a \geq 0$, we say \vec{F} is an *a-step fraternal augmentation* of \vec{G} if there exists a sequence $\vec{G} = \vec{G}_0, \vec{G}_1, \dots, \vec{G}_a = \vec{F}$ where for $i = 1, \dots, a$, \vec{G}_i is a 1-step fraternal augmentation of \vec{G}_{i-1} . We say \vec{F} is an *a-step fraternal augmentation* of an undirected graph G if \vec{F} is an *a-step fraternal augmentation* of some orientation of G .

A key property of graph classes with bounded expansion is the existence of fraternal augmentations with bounded outdegrees. Let us remark that whenever we speak about an algorithm returning an *a-step fraternal augmentation* \vec{H} or taking one as an input, this implicitly includes outputting or taking as an input the whole sequence of 1-step fraternal augmentations ending in \vec{H} .

► **Lemma 5** (Nešetřil and Ossona de Mendez [22]). *For every class \mathcal{G} with bounded expansion, there exists a function $d: \mathbb{Z}_0^+ \rightarrow \mathbb{Z}^+$ such that for each $G \in \mathcal{G}$ and each non-negative integer a , the graph G has an *a-step fraternal augmentation* of maximum outdegree at most $d(a)$. Moreover, such an augmentation can be found in time $O(d(a)|V(G)|)$.*

As shown already in [22], fraternal augmentations can be used to succinctly represent distances between vertices of the graph. For the purposes of this paper, we need a more explicit representation by an orientation of the original graph without the additional augmentation edges, as we only assume that the original (rather than the augmented) graph is fractionally treewidth-fragile. Let us remark that the existence of such a representation was shown by Kowalik and Kurowski [17] in a more restrictive setting of graph classes closed under topological minors.

By a *walk* in a directed graph \vec{G} , we mean a sequence $W = v_0 v_1 v_2 \dots v_b$ such that for $i = 1, \dots, b$, $(v_{i-1}, v_i) \in E(\vec{G})$ or $(v_i, v_{i-1}) \in E(\vec{G})$; that is, the walk does not have to respect the orientation of the edges. The walk W is *inward directed* if for some $c \in \{0, \dots, b\}$, we have $(v_i, v_{i+1}) \in E(\vec{G})$ for $i = 0, \dots, c-1$ and $(v_i, v_{i-1}) \in E(\vec{G})$ for $i = c+1, \dots, b$. For a positive integer r , an orientation \vec{G} of a graph G *represents* ($\leq r$)-distances if for each $u, v \in V(G)$ and each $b \in \{0, \dots, r\}$, the distance between u and v in G is at most b if and

only if \vec{G} contains an inward-directed walk of length at most b between u and v . Note that given such an orientation with bounded maximum outdegree for a fixed r , we can determine the distance between u and v (up to distance r) by enumerating all (constantly many) walks of length at most r directed away from u and away from v and inspecting their intersections.

Our goal now is to show that graphs from classes with bounded expansion admit orientations with bounded maximum outdegree that represent $(\leq r)$ -distances. Let us define a more general notion used in the proof of this claim, adding to the fraternal augmentations the information about the lengths of the walks in the original graph represented by the added edges. A *directed graph with $(\leq r)$ -length sets* is a pair (\vec{H}, ℓ) , where \vec{H} is a directed graph and ℓ is a function assigning a subset of $\{1, \dots, r\}$ to each *unordered* pair $\{u, v\}$ of vertices of \vec{H} , such that if neither (u, v) nor (v, u) is an edge of \vec{H} , then $\ell(\{u, v\}) = \emptyset$. We say that (\vec{H}, ℓ) is an *orientation* of a graph G if G is the underlying undirected graph of \vec{H} and $\ell(\{u, v\}) = \{1\}$ for each $uv \in E(G)$. We say that (\vec{H}, ℓ) is an $(\leq r)$ -*augmentation* of G if $V(\vec{H}) = V(G)$, for each $uv \in E(G)$ we have $1 \in \ell(\{u, v\})$, and for each $u, v \in V(G)$ and $b \in \ell(\{u, v\})$ there exists a walk of length b from u to v in G . Let (\vec{H}_1, ℓ_1) be another directed graph with $(\leq r)$ -length sets. We say (\vec{H}_1, ℓ_1) is a *1-step fraternal augmentation* of (\vec{H}, ℓ) if \vec{H}_1 is a 1-step fraternal augmentation of \vec{H} and for all distinct $u, v \in V(\vec{H})$ and $b \in \{1, \dots, r\}$, we have $b \in \ell_1(\{u, v\})$ if and only if $b \in \ell(\{u, v\})$ or there exist $x \in V(\vec{H}) \setminus \{u, v\}$, $b_1 \in \ell(\{x, u\})$, and $b_2 \in \ell(\{x, v\})$ such that $(x, u), (x, v) \in E(\vec{H})$ and $b = b_1 + b_2$. Note that a 1-step fraternal augmentation of an $(\leq r)$ -augmentation of a graph G is again an $(\leq r)$ -augmentation of G . The notion of an a -step fraternal augmentation of a graph G is then defined in the natural way, by starting with an orientation of G and performing the 1-step fraternal augmentation operation a times. Let us now restate Lemma 5 in these terms (we just need to maintain the edge length sets, which can be done with $O(a^2)$ overhead per operation).

► **Lemma 6.** *Let \mathcal{G} be a class of graphs with bounded expansion, and let $d : \mathbb{Z}_0^+ \rightarrow \mathbb{Z}^+$ be the function from Lemma 5. For each $G \in \mathcal{G}$ and each non-negative integer a , we can in time $O(a^2 d(a) |V(G)|)$ construct a directed graph with $(\leq a + 1)$ -length sets (\vec{H}, ℓ) of maximum outdegree at most $d(a)$ such that (\vec{H}, ℓ) is an a -step fraternal augmentation of G .*

Let (\vec{H}, ℓ) be an $(\leq r)$ -augmentation of a graph G . For $b \leq r$, a *walk of span b* in (\vec{H}, ℓ) is a tuple $(v_0 v_1 \dots v_t, b_1, \dots, b_t)$, where $v_0 v_1 \dots v_t$ is a walk in \vec{H} , $b_i \in \ell(\{v_{i-1}, v_i\})$ for $i = 1, \dots, t$, and $b = b_1 + \dots + b_t$. Note that if there exists a walk of span b from u to v in (\vec{H}, ℓ) , then there also exists a walk of length b from u to v in G . We say that (\vec{H}, ℓ) *represents $(\leq r)$ -distances* in G if for all vertices $u, v \in V(G)$ at distance $b \leq r$ from one another, (\vec{H}, ℓ) contains an inward-directed walk of span b between u and v . Next, we show that this property always holds for sufficient fraternal augmentations.

► **Lemma 7.** *Let G be a graph and r a positive integer and let (\vec{H}, ℓ) be a directed graph with $(\leq r)$ -length sets. If (\vec{H}, ℓ) is obtained as an $(r - 1)$ -step fraternal augmentation of G , then it represents $(\leq r)$ -distances in G .*

Proof. For $b \leq r$, consider any walk $W = (v_0 v_1 \dots v_t, b_1, \dots, b_t)$ of span b in an $(\leq r)$ -augmentation (\vec{H}_1, ℓ_1) of G , and let (\vec{H}_2, ℓ_2) be a 1-step augmentation of (\vec{H}_1, ℓ_1) . Note that W is also a walk of span b between v_0 and v_t in (\vec{H}_2, ℓ_2) . Suppose that W is not inward-directed in (\vec{H}_1, ℓ_1) , and thus there exists $i \in \{1, \dots, t - 1\}$ such that $(v_i, v_{i-1}), (v_i, v_{i+1}) \in E(\vec{H}_1)$. By the definition of 1-step fraternal augmentation, this implies $b_i + b_{i+1} \in \ell_2(\{v_{i-1}, v_{i+1}\})$, and thus $(v_0 \dots v_{i-1} v_{i+1} \dots v_t, b_1, \dots, b_i + b_{i+1}, \dots, b_t)$ is a walk of span b from v_0 to v_t in (\vec{H}_2, ℓ_2) .

Let $(\vec{G}_0, \ell_0), \dots, (\vec{G}_{r-1}, \ell_{r-1})$ be a sequence of $(\leq r)$ -augmentations of G , where (\vec{G}, ℓ_0) is an orientation of G , $(\vec{G}_{r-1}, \ell_{r-1}) = (\vec{H}, \ell)$, and for $i = 1, \dots, r - 1$, (\vec{G}_i, ℓ_i) is a 1-step fraternal augmentation of $(\vec{G}_{i-1}, \ell_{i-1})$. Let u and v be any vertices at distance $b \leq r$ in G ,

and let P be a shortest path between them. Then P naturally corresponds to a walk P_0 of span b in (\vec{G}_0, ℓ_0) . For $i = 1, \dots, r-1$, if P_{i-1} is inward-directed, then let $P_i = P_{i-1}$, otherwise let P_i be a walk of span b in (\vec{G}_i, ℓ_i) obtained from P_{i-1} as described in the previous paragraph. Since each application of the operation decreases the number of vertices of the walk, we conclude that P_{r-1} is an inward-directed walk of span b between u and v in (\vec{H}, ℓ) . Hence, (\vec{H}, ℓ) represents $(\leq r)$ -distances in G . ◀

Next, let us propagate this property back through the fraternal augmentations by orienting some of the edges in both directions. We say that (\vec{H}, ℓ) is an a -step fraternal supraugmentation of a graph G if there exists an a -step fraternal augmentation (\vec{F}, ℓ) of G such that $V(\vec{F}) = V(\vec{H})$, $E(\vec{F}) \subseteq E(\vec{H})$ and for each $(u, v) \in E(\vec{H}) \setminus E(\vec{F})$, we have $(v, u) \in E(\vec{F})$. We say that (\vec{F}, ℓ) is a support of (\vec{H}, ℓ) .

► **Lemma 8.** *Let G be a graph and r a positive integer and let (\vec{H}, ℓ) be an $(\leq r)$ -augmentation of G of maximum outdegree Δ representing $(\leq r)$ -distances. For $a \geq 1$, suppose that (\vec{H}, ℓ) is an a -step fraternal supraugmentation of G . Then we can in time $O(r^2 \Delta |V(G)|)$ obtain an $(a-1)$ -step fraternal supraugmentation of G representing $(\leq r)$ -distances, of maximum outdegree at most $(r+1)\Delta$.*

Proof. Let (\vec{F}, ℓ) be an a -step fraternal augmentation of G forming a support of (\vec{H}, ℓ) , obtained as a 1-step fraternal augmentation of an $(a-1)$ -step fraternal augmentation (\vec{F}_1, ℓ_1) of G . Let (\vec{H}_1, ℓ_1) be the $(a-1)$ -step fraternal supraugmentation of G obtained from (\vec{F}_1, ℓ_1) as follows:

- For all distinct vertices $y, z \in V(G)$ such that $(y, z), (z, y) \in E(\vec{H})$, $(y, z) \in E(\vec{F}_1)$, and $(z, y) \notin E(\vec{F}_1)$, we add the edge (z, y) .
- For each edge $(y, z) \in E(\vec{H})$ and integer $b \in \ell(\{y, z\}) \setminus \ell_1(\{y, z\})$, we choose a vertex $x \in V(G) \setminus \{y, z\}$ such that $(x, y), (x, z) \in E(\vec{F}_1)$ and $b = b_1 + b_2$ for some $b_1 \in \ell_1(\{x, y\})$ and $b_2 \in \ell_1(\{x, z\})$, and add the edge (y, x) . Note that such a vertex x and integers b_1 and b_2 exist, since b was added to $\ell(\{y, z\})$ when (\vec{F}, ℓ) was obtained from (\vec{F}_1, ℓ_1) as a 1-step fraternal augmentation.

Each edge $(y, x) \in E(\vec{H}_1) \setminus E(\vec{H})$ arises from an edge $(y, z) \in E(\vec{H})$ leaving y and an element $b \in \ell(\{y, z\}) \setminus \ell_1(\{y, z\})$, and each such pair contributes at most one edge leaving y . Hence, the maximum outdegree of \vec{H}_1 is at most $(r+1)\Delta$.

Consider an inwards-directed walk $(v_0 v_1 \dots v_t, b_1, \dots, b_t)$ of span b in \vec{H} , for any $b \leq r$. Then \vec{H} contains an inwards-directed walk of span b from v_0 to v_t obtained by natural edge replacements: For any edge $(y, z) \in E(\vec{H})$ of this walk and $b' \in \ell_i(\{y, z\})$, the construction described above ensures that if $(y, z) \notin E(\vec{H}_1)$ or $b' \notin \ell_1(\{y, z\})$, then there exists $x \in V(G) \setminus \{y, z\}$ such that $(y, x), (x, z) \in E(\vec{H}_1)$ and $b' = b'' + b'''$ for some $b'' \in \ell_1(\{x, y\})$ and $b''' \in \ell_1(\{x, z\})$, and we can replace the edge (y, z) in the walk by the edges (y, x) and (x, z) of $E(\vec{H}_1)$. Since \vec{H} represents $(\leq r)$ -distances in G , this transformation shows that so does \vec{H}_1 . ◀

We are now ready to prove the main result of this section.

► **Lemma 9.** *For any class \mathcal{G} with bounded expansion, there exists a function $d' : \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$ such that for each $G \in \mathcal{G}$ and each positive integer r , the graph G has an orientation with maximum outdegree at most $d'(r)$ that represents $(\leq r)$ -distances in G . Moreover, such an orientation can be found in time $O(r^2 d'(r) |V(G)|)$.*

Proof. Let d be the function from Lemma 5, and let $d'(r) = (r+1)^{r-1} d(r-1)$. By Lemma 6, we obtain an $(r-1)$ -step fraternal augmentation (\vec{H}, ℓ) of G of maximum outdegree at most $d(r-1)$. By Lemma 7, (\vec{H}, ℓ) represents $(\leq r)$ -distances in G . Repeatedly applying Lemma 8,

we obtain a 0-step fraternal supraugmentation (\vec{G}, ℓ_0) of G of maximum outdegree at most $d'(r)$ representing $(\leq r)$ -distances. Clearly, \vec{G} is an orientation of G of maximum outdegree at most $d'(r)$ representing $(\leq r)$ -distances. ◀

3 Approximation schemes

Let us now prove Theorem 2. To this end, let us start with a lemma to be applied to the sets arising from fractional treewidth-fragility.

► **Lemma 10.** *Let \vec{G} be an orientation of a graph G with maximum outdegree Δ . Let A be a set of vertices of G and for a positive integer c , let $\{R_v : v \in A\}$ be a system of subsets of A such that each vertex belongs to at most c of the subsets. For $X \subseteq V(G)$ and a positive integer r , let $D_{\vec{G},r}(X) \subseteq A$ be the union of the sets R_v for all vertices $v \in A$ such that \vec{G} contains a walk from v to X of length at most r directed away from v . For a positive integer k , let X_1, \dots, X_m be a system of subsets of $V(G)$ such that each vertex belongs to at most $\frac{m}{c(\Delta+1)^rk}$ of the subsets. For any assignment w of non-negative weights to vertices of G , there exists $i \in \{1, \dots, m\}$ such that $w(A \setminus D_{\vec{G},r}(X_i)) \geq (1 - 1/k)w(A)$.*

Proof. For a vertex $z \in A$, let $B(z)$ be the set of vertices reachable in \vec{G} from vertices $v \in A$ such that $z \in R_v$ by walks of length at most r directed away from v . Note that $|B(z)| \leq c(\Delta + 1)^r$ and that for each $X \subseteq V(G)$, we have $z \in D_{\vec{G},r}(X)$ if and only if $B(z) \cap X \neq \emptyset$.

Suppose for a contradiction that for each i we have $w(A \setminus D_{\vec{G},r}(X_i)) < (1 - 1/k)w(A)$, and thus $w(D_{\vec{G},r}(X_i)) > w(A)/k$. Then

$$\begin{aligned} \frac{m}{k}w(A) &< \sum_{i=1}^m w(D_{\vec{G},r}(X_i)) = \sum_{i=1}^m \sum_{z \in D_{\vec{G},r}(X_i)} w(z) = \sum_{i=1}^m \sum_{z \in A: B(z) \cap X_i \neq \emptyset} w(z) \\ &\leq \sum_{i=1}^m \sum_{z \in A} w(z) |B(z) \cap X_i| = \sum_{z \in A} w(z) \sum_{i=1}^m |B(z) \cap X_i| \\ &= \sum_{z \in A} w(z) \sum_{x \in B(z)} |\{i \in \{1, \dots, m\} : x \in X_i\}| \leq \sum_{z \in A} w(z) \sum_{x \in B(z)} \frac{m}{c(\Delta + 1)^rk} \\ &= \sum_{z \in A} w(z) |B(z)| \frac{m}{c(\Delta + 1)^rk} \leq \sum_{z \in A} w(z) \frac{m}{k} = \frac{m}{k}w(A), \end{aligned}$$

which is a contradiction. ◀

Next, let us derive a lemma on admissibility for $(\leq r)$ -distance determined problems.

► **Lemma 11.** *For a positive integer r , let \vec{G} be an orientation of a graph G representing $(\leq r)$ -distances. For a set $X \subseteq V(G)$, let $Y_{\vec{G},r}(X)$ be the set of vertices y such that \vec{G} contains a walk from y to X of length at most r directed away from y . For any $(\leq r)$ -distance determined problem, a set $B \subseteq V(G) \setminus Y_{\vec{G},r}(X)$ is admissible in G if and only if it is admissible in $G - X$.*

Proof. Since the problem is $(\leq r)$ -distance determined, it suffices to show that $\min(r, d_G(u, v)) = \min(r, d_{G-X}(u, v))$ holds for all $u, v \in B$. Clearly, $d_G(u, v) \leq d_{G-X}(u, v)$, and thus it suffices to show that if the distance between u and v in G is $b \leq r$, then $G - X$ contains a walk of length b between u and v . Since \vec{G} represents $(\leq r)$ -distances, there exists an inward-directed walk P of length b between u and v in \vec{G} . Since $u, v \notin Y_{\vec{G},r}(X)$, we have $V(P) \cap X = \emptyset$, and thus P is also a walk of length b between u and v in $G - X$. ◀

We are now ready to prove the main result.

Proof of Theorem 2. Let d' be the function from Lemma 9 for the class \mathcal{G} . Let us define $h(r, c) = c(d'(r) + 1)^r$. The algorithm is as follows. Since \mathcal{G} is q -efficiently fractionally treewidth- f -fragile, in time $q(|V(G)|)$ we can find sets $X_1, \dots, X_m \subseteq V(G)$ such that each vertex belongs to at most $\frac{m}{h(r, c)k}$ of them, and for each i , a tree decomposition of $G - X_i$ of width at most $f(h(r, c)k, |V(G)|)$. Clearly, $m \leq q(|V(G)|)$. Next, using Lemma 9, we find an orientation \vec{G} of G that represents $(\leq r)$ -distances. Let $Y_{\vec{G}, r}$ be defined as in the statement of Lemma 11. Since the problem is (g, p) -tw-tractable problem, for each i we can in time $p(|V(G)|) \cdot g(f(h(r, c)k, |V(G)|))$ find a subset A_i of $V(G) \setminus Y_{\vec{G}, r}(X_i)$ admissible in $G - X_i$ of largest weight. By Lemma 11, each of these sets is admissible in G ; the algorithm return the heaviest of the sets A_1, \dots, A_m .

As the returned set is admissible in G , it suffices to argue about its weight. Let A be a heaviest admissible set in G . Let $\{R_v \subseteq A : v \in A\}$ be the system of subsets from the definition of c -near-monotonicity, and let $D_{\vec{G}, r}$ be defined as in the statement of Lemma 10. By the definition of c -near-monotonicity, for each i the set $A \setminus D_{\vec{G}, r}(X_i)$ is admissible in G . Since $v \in R_v$ for each $v \in A$, we have $Y_{\vec{G}, r}(X_i) \cap A \subseteq D_{\vec{G}, r}(X_i)$, and thus $A \setminus D_{\vec{G}, r}(X_i) \subseteq V(G) \setminus Y_{\vec{G}, r}(X_i)$. By Lemma 11, $A \setminus D_{\vec{G}, r}(X_i)$ is also admissible in $G - X_i$, and by the choice of A_i , we have $w(A_i) \geq w(A \setminus D_{\vec{G}, r}(X_i))$. By Lemma 10, we conclude that for at least one i , we have $w(A_i) \geq (1 - 1/k)w(A)$, as required. ◀

Abstract

A multiple knapsack constraint over a set of items is defined by a set of bins of arbitrary capacities, and a weight for each of the items. An assignment for the constraint is an allocation of subsets of items to the bins which adheres to bin capacities. In this paper we present a unified algorithm that yields efficient approximations for a wide class of submodular and modular optimization problems involving multiple knapsack constraints. One notable example is a *polynomial time approximation scheme* for Multiple-Choice Multiple Knapsack, improving upon the best known ratio of 2. Another example is Non-monotone Submodular Multiple Knapsack, for which we obtain a $(0.385 - \epsilon)$ -approximation, matching the best known ratio for a single knapsack constraint. The robustness of our algorithm is achieved by applying a novel *fractional* variant of the classical linear grouping technique, which is of independent interest.

1 Introduction

The Knapsack problem is one of the most studied problems in mathematical programming and combinatorial optimization, with applications ranging from power management and production planning, to blockchain storage allocation and key generation in cryptosystems [31, 26, 38, 41]. In a more general form, knapsack problems require assigning items of various sizes (weights) to a set of bins (knapsacks) of bounded capacities. The bin capacities then constitute the hard constraint for the problem. Formally, a *multiple knapsack constraint* (MKC) over a set of items is defined by a collection of bins of varying capacities and a non-negative weight for each item. A feasible solution for the constraint is an assignment of subsets of items to the bins, such that the total weight of items assigned to each bin does not exceed its capacity. This constraint plays a central role in the classic Multiple Knapsack problem [8, 23, 24]. The input is an MKC and each item also has a profit. The objective is to find a feasible solution for the MKC such that the total profit of assigned items is maximized.

Multiple Knapsack can be viewed as a maximization variant of the Bin Packing problem [25, 13]. In Bin Packing we are given a set of items, each associated with non-negative weight. We need to pack the items into a minimum number of identical (unit-size) bins.

A prominent technique for approximating Bin Packing is *grouping*, which decreases the number of distinct weights in the input instance. Informally, a subset of items is partitioned into groups G_1, \dots, G_τ , and all the items within a group are treated as if they have the *same* weight (e.g., [13, 25]). By properly forming the groups, the increase in the number of bins required for packing the instance can be bounded. Classic grouping techniques require knowledge of the items to be packed, and thus cannot be easily applied in the context of maximization problems, and specifically for a multiple knapsack constraint.

The main technical contribution of this paper is the introduction of *fractional grouping*, a variant of linear grouping which can be applied to multiple knapsack constraints. Fractional Grouping partitions the items into groups using an easy to obtain fractional solution, bypassing the requirement to know the items in the solution.

Fractional Grouping proved to be a robust technique for maximization problems. We use the technique to obtain, among others, a *polynomial-time approximation scheme (PTAS)* for the Multiple-Choice Multiple Knapsack Problem, a $(0.385 - \varepsilon)$ -approximation for non-monotone submodular maximization with a multiple knapsack constraint, and a $(1 - e^{-1} - o(1))$ -approximation for the Monotone Submodular Multiple Knapsack Problem with Uniform Capacities.

1.1 Problem Definition

We first define formally key components of the problem studied in this paper.

A *multiple knapsack constraint* (MKC) over a set I of items, denoted by $\mathcal{K} = (w, B, W)$, is defined by a weight function $w : I \rightarrow \mathbb{R}_{\geq 0}$, a set of bins B and bin capacities given by $W : B \rightarrow \mathbb{R}_{\geq 0}$. An *assignment* for the constraint is a function $A : B \rightarrow 2^I$ which assigns a subset of items to each bin. An assignment A is *feasible* if $\sum_{i \in A(b)} w(i) \leq W(b)$ for all $b \in B$. We say that A is an *assignment of S* if $S = \bigcup_{b \in B} A(b)$.

A set function $f : 2^I \rightarrow \mathbb{R}$ is *submodular* if for any $S \subseteq T \subseteq I$ and $i \in I \setminus T$ it holds that $f(S \cup \{i\}) - f(S) \geq f(T \cup \{i\}) - f(T)$.¹ Submodular functions naturally arise in numerous settings. While many submodular functions, such as coverage [19] and matroid rank function [6], are monotone, i.e., for any $S \subseteq T \subseteq I$, $f(S) \leq f(T)$, this is not always the case (cut functions [18] are a classic example). A special case of submodular functions is *modular* (or, *linear*) functions in which, for any $S \subseteq T \subseteq I$ and $i \in I \setminus T$, we have $f(S \cup \{i\}) - f(S) = f(T \cup \{i\}) - f(T)$.

For a constant $d \in \mathbb{N}$, the problem of *Submodular Maximization with d -Multiple Knapsack Constraints* (d -MKCP) is defined as follows. The input is $\mathcal{T} = (I, (\mathcal{K}_t)_{t=1}^d, \mathcal{I}, f)$, where I is a set of items, \mathcal{K}_t , $1 \leq t \leq d$ are d MKCs over I , $\mathcal{I} \subseteq 2^I$ and $f : 2^I \rightarrow \mathbb{R}_{\geq 0}$ is a non-negative submodular function. \mathcal{I} is an additional constraint which can be one of the following: (i) $\mathcal{I} = 2^I$, i.e., any subset of items can be selected. (ii) \mathcal{I} is the independent set of a matroid,² or (iii) \mathcal{I} is the intersection of independent sets of two matroids, or (iv) \mathcal{I} is a matching.³ A solution for the instance is $S \in \mathcal{I}$ and $(A_t)_{t=1}^d$, where A_t is a feasible assignment of S w.r.t \mathcal{K}_t for $1 \leq t \leq d$. The value of the solution is $f(S)$, and the objective is to find a solution of maximal value.

We assume the function f is given via a value oracle. We further assume that the input indicates the type of constraint that \mathcal{I} represents. Finally, \mathcal{I} is given via a membership oracle, and if \mathcal{I} is a matroid intersection, a membership oracle is given for each matroid.

¹ Alternatively, for every $S, T \subseteq I$: $f(S) + f(T) \geq f(S \cup T) + f(S \cap T)$.

² A formal definition for matroid can be found in [34].

³ \mathcal{I} is a matching if there is a graph $G = (V, I)$, and $S \in \mathcal{I}$ iff S is a matching in G .

■ **Table 1** Results of Theorem 1 for d -MKCP.

Type of Additional Constraint	Modular Maximization	Monotone Submodular Max.	Non-Monotone Sub. Max
No additional constraint	PTAS	$1 - e^{-1} - \varepsilon$	$0.385 - \varepsilon$
Matroid constraint	PTAS	$1 - e^{-1} - \varepsilon$	—
2 matroids or a matching	PTAS	—	—

We refer to the special case in which f is monotone (modular) as monotone (modular) d -MKCP. Also, we use non-monotone d -MKCP when referring to general d -MKCP instances. Similarly, we refer to the special case in which \mathcal{I} is an independent set of a matroid (intersection of independent sets of two matroids or a matching) as d -MKCP with a matroid (matroid intersection or matching) constraint. If $\mathcal{I} = 2^I$ we refer to the problem as d -MKCP with no additional constraint. Thus, for example, in instances of modular 1-MKCP with a matroid constraint the function f is modular and \mathcal{I} is an independent set of a matroid.

Instances of d -MKCP naturally arise in various settings (see a detailed example in the full version of this paper [16]).

1.2 Our Results

Our main results are summarized in the next theorem (see also Table 1).

► **Theorem 1.** *For any fixed $d \in \mathbb{N}_+$ and $\varepsilon > 0$, there is*

1. *A randomized PTAS for modular d -MKCP $((1 - \varepsilon)$ -approximation). The same holds for this problem with a matroid constraint, matroid intersection constraint, or a matching constraint.*
2. *A polynomial-time random $(1 - e^{-1} - \varepsilon)$ -approximation for monotone d -MKCP with a matroid constraint.*
3. *A polynomial-time random $(0.385 - \varepsilon)$ -approximation for non-monotone d -MKCP with no additional constraint.*

All of the results are obtained using a single algorithm (Algorithm 2). The general algorithmic result encapsulates several important special cases. The Multiple-Choice Multiple Knapsack Problem is a variant of the Multiple Knapsack Problem in which the items are partitioned into classes C_1, \dots, C_k , and at most one item can be selected from each class. Formally, Multiple-Choice Multiple Knapsack is the special case of modular 1-MKCP where \mathcal{I} describes a partition matroid.⁴ The problem has natural applications in network optimization [12, 37]. The best known approximation ratio for the problem is 2 due to [12]. This approximation ratio is improved by Theorem 1, as stated in the following.

► **Corollary 2.** *There is a randomized PTAS for the Multiple-Choice Multiple Knapsack Problem.*

While the Multiple Knapsack Problem and the Monotone Submodular Multiple Knapsack Problem are well understood [8, 23, 24, 15, 35], no results were previously known for the Non-Monotone Submodular Multiple Knapsack Problem, the special case of non-monotone 1-MKCP with no additional constraint. A constant approximation ratio for the problem is obtained as a special case of Theorem 1.

⁴ That is, $\mathcal{I} = \{S \subseteq I \mid \forall 1 \leq j \leq k : |S \cap C_j| \leq 1\}$ where C_1, \dots, C_k is a partition of I .

► **Corollary 3.** *For any $\varepsilon > 0$ there is a polynomial time random $(0.385 - \varepsilon)$ -approximation for the Non-Monotone Submodular Multiple Knapsack Problem.*

A PTAS for Multistage Multiple Knapsack, a multistage version of the Multiple Knapsack Problem, can be obtained via a reduction to modular d -MKCP with a matroid constraint.⁵ Here, to obtain a $(1 - O(\varepsilon))$ -approximation for the multistage problem, the reduction solves instances of modular $\Theta(\frac{1}{\varepsilon})$ -MKCP with a matroid constraint (see [14] for details). Beyond the rich set of applications, our ability to derive such a general result is an evidence for the robustness of fractional grouping, the main technical contribution of this paper.

Our result for modular d -MKCP, for $d \geq 2$, generalizes the PTAS for the classic d -dimensional Knapsack problem ($\mathcal{I} = 2^I$ and $|B_t| = 1$ for any $1 \leq t \leq d$). Furthermore, a PTAS is the best we can expect as there is no *efficient PTAS (EPTAS)* already for d -dimensional Knapsack, unless $W[1] = \text{FPT}$ [28]. While there is a well-known PTAS for Multiple Knapsack [8], existing techniques do not readily enable handling additional constraints, such as a matroid constraint.

The approximation ratio obtained for monotone d -MKCP is nearly optimal, as for any $\varepsilon > 0$ there is no $(1 - e^{-1} + \varepsilon)$ -approximation for monotone submodular maximization with a cardinality constraint in the oracle model [32]. The approximation ratio is also tight under $P \neq NP$ due to the special case of coverage functions [19]. Previous works [15, 35] obtained the same approximation ratio for the Monotone Submodular Multiple Knapsack Problem (i.e., monotone 1-MKCP). However, as in the modular case, existing techniques are limited to handling a single MKC (with no other constraints).

In the non-monotone case, the approximation ratio is in fact $(c - \varepsilon)$ for any $\varepsilon > 0$, where $c > 0.385$ is the ratio derived in [4]. This approximation ratio matches the current best known ratio for non-monotone submodular maximization with a single knapsack constraint [4]. A 0.491 hardness of approximation bound for non-monotone d -MKCP follows from [22].

Our technique can be cast also as a variant of *contention resolution scheme* [11]. The scheme can be used to derive approximation algorithms for special cases of d -MKCP which are not considered in Theorem 1. Such a scheme can be found in an earlier version of this paper [17].⁶

The *Monotone Submodular Multiple Knapsack Problem with Uniform Capacities* (USMKP) is the special case of d -MKCP in which $\mathcal{I} = 2^I$, $d = 1$, f is monotone, and furthermore, all the bins in the MKC have the same capacity. That is, $\mathcal{K}_1 = (w, B, W)$ and $W(b_1) = W(b_2)$ for any $b_1, b_2 \in B$. This restricted variant of d -MKCP commonly arises in real-life applications (e.g., in file assignment to several identical storage devices). The best known approximation ratio for USMKP is $(1 - e^{-1} - \varepsilon)$ for any fixed $\varepsilon > 0$ [15, 35]. Another contribution of this paper is an improvement of this ratio.

► **Theorem 4.** *There is a polynomial-time random $(1 - e^{-1} - O((\log |B|)^{-\frac{1}{4}}))$ -approximation for the Monotone Submodular Multiple Knapsack Problem with Uniform Capacities.*

1.3 Related Work

In the classic Multiple Knapsack problem, the goal is to maximize a modular set function subject to a single multiple knapsack constraint. A PTAS for the problem was first presented by Chekuri and Khanna [8]. The authors also ruled out the existence of a *fully polynomial time approximation scheme (FPTAS)*. An EPTAS was later developed by Jansen [23, 24].

⁵ See, e.g., [2] for the Multistage Knapsack model.

⁶ We were unable to obtain tight approximation ratios for the studied problems using this approach.

In the Bin Packing problem, we are given a set I of items, a weight function $w : I \rightarrow \mathbb{R}_{\geq 0}$ and a capacity $W > 0$. The objective is to partition the set I into a minimal number of sets S_1, \dots, S_m (i.e., find a *packing*) such that $\sum_{i \in S_b} w(i) \leq W$ for all $1 \leq b \leq m$. In [25] the authors presented a polynomial-time algorithm which returns a packing using $\text{OPT} + O(\log^2 \text{OPT})$ bins, where OPT is the number of bins in a minimal packing. The result was later improved by Rothvoß [33].

Research work on monotone submodular maximization dates back to the late 1970's. In [32] Nemhauser and Wolsey presented a greedy-based tight $(1 - e^{-1})$ -approximation for maximizing a monotone submodular function subject to a cardinality constraint, along with a matching lower bound in the oracle model. The greedy algorithm of [32] was later generalized to monotone submodular maximization subject to a knapsack constraint [27, 36].

A major breakthrough in the field of submodular optimization resulted from the introduction of algorithms for optimizing the *multilinear extension* of a submodular function ([6, 30, 7, 40, 20, 5]). For $\bar{x} \in [0, 1]^I$, we say that a random set $S \subseteq I$ is distributed by \bar{x} (i.e., $S \sim \bar{x}$) if $\Pr(i \in S) = \bar{x}_i$, and the events $(i \in S)_{i \in I}$ are independent. Given a function $f : 2^I \rightarrow \mathbb{R}_{\geq 0}$, its *multilinear extension* is $F : [0, 1]^I \rightarrow \mathbb{R}_{\geq 0}$ defined as $F(\bar{x}) = \mathbb{E}_{S \sim \bar{x}}[f(S)]$.

The input for the problem of optimizing the multilinear relaxation is an oracle for a submodular function $f : 2^I \rightarrow \mathbb{R}_{\geq 0}$ and a downward closed solvable polytope P .⁷ The objective is to find $\bar{x} \in P$ such that $F(\bar{x})$ is maximized, where F is the multilinear extension of f . The problem admits a random $(1 - e^{-1} - o(1))$ -approximation in the monotone case and a random $(0.385 + \delta)$ -approximation in the non-monotone case (for some small constant $\delta > 0$) due to [7] and [4].

Several techniques were developed for *rounding* a (fractional) solution for the multilinear optimization problem to an integral solution. These include Pipage Rounding [1], Randomized Swap Rounding [9], and Contention Resolution Schemes [11]. These techniques led to the state of art results for many problems (e.g., [29, 7, 1, 9]).

A random $(1 - e^{-1} - \varepsilon)$ -approximation for the Monotone Submodular Multiple Knapsack problem was presented in [15]. The technique in [15] modifies the objective function and its domain. This modification does not preserve submodularity of a non-monotone function and the combinatorial properties of additional constraints. Thus, it does not generalize to d -MKCP.

A deterministic $(1 - e^{-1} - \varepsilon)$ -approximation for Monotone Submodular Multiple Knapsack was later obtained by Sun et al. [35]. Their algorithm relies on a variant of the greedy algorithm of [36] which cannot be extended to the non-monotone case, or easily adapted to handle more than a single MKC.

1.4 Technical Overview

In the following we describe the technical problem solved by fractional grouping and give some insight to the way we solve this problem. For simplicity, we focus on the special case of 1-MKCP, in which the number of bins is large and all bins have unit capacity. Let $(I, (w, B, W), 2^I, f)$ be a 1-MCKP instance where $W(b) = 1$ for all $b \in B$. Also, assume that no two items have the same weight. Let S^* and A^* be an optimal solution for the instance.

⁷ A polytope $P \in [0, 1]^I$ is *downward closed* if for any $\bar{x} \in P$ and $\bar{y} \in [0, 1]^I$ such that $\bar{y} \leq \bar{x}$ (that is, $\bar{y}_i \leq \bar{x}_i$ for every $i \in I$) it holds that $\bar{y} \in P$. A polytope $P \in [0, 1]^I$ is *solvable* if, for any $\bar{\lambda} \in \mathbb{R}^I$, a point $\bar{x} \in P$ such that $\bar{\lambda} \cdot \bar{x} = \max_{\bar{y} \in P} \bar{\lambda} \cdot \bar{y}$ can be computed in polynomial time, where $\bar{\lambda} \cdot \bar{x}$ is the dot product of $\bar{\lambda}$ and \bar{x} .

Fix an arbitrary small $\mu > 0$ such that $\mu^{-2} \in \mathbb{N}$. We say that an item $i \in I$ is *heavy* if $w(i) > \mu$; otherwise, i is *light*. Let $H \subseteq I$ denote the heavy items. We can apply linear grouping [13] to the heavy items in S^* . That is, let $h^* = |S^* \cap H|$ be the number of heavy items in S^* , and partition $S^* \cap H$ to μ^{-2} groups of cardinality $\mu^2 \cdot h^*$, assuming the items are sorted in decreasing order by weights (for simplicity, assume $h^* \geq \mu^{-2}$ and $\mu^2 \cdot h^* \in \mathbb{N}$). Specifically, $S^* \cap H = G_1^* \cup \dots \cup G_{\mu^{-2}}^*$, where $|G_k^*| = \mu^2 \cdot h^*$ for all $1 \leq k \leq \mu^{-2}$ and for any $i_1 \in G_{k_1}^*, i_2 \in G_{k_2}^*$ where $k_1 < k_2$ we have that $w(i_1) > w(i_2)$. Also, for any $1 \leq k \leq \mu^{-2}$ let q_k , the k -th pivot, be the item of highest weight in G_k^* .

We use the pivots to generate a new collection of groups $G_1, \dots, G_{\mu^{-2}}$ where $G_k = \{i \in H \mid w(q_{k+1}) < w(i) \leq w(q_k)\}$ for $1 \leq k < \mu^{-2}$, and $G_{\mu^{-2}} = \{i \in H \mid w(i) \leq w(q_{\mu^{-2}})\}$. Clearly, $G_k^* \subseteq G_k$ for any $1 \leq k \leq \mu^{-2}$. Let $X = \{i \in H \mid w(i) > w(q_1)\}$ be the set of largest items in H .

A standard *shifting* argument can be used to show that any set $S \subseteq I \setminus X$, such that $w(S) \leq |B|$ and $|S \cap G_k| \leq \mu^2 \cdot h^*$ for all $1 \leq k \leq \mu^{-2}$, can be packed into $(1 + 2\mu)|B| + 1$ bins as follows.⁸ The items in $S \cap G_k$ can be packed in place of the items in G_{k-1}^* in A^* , each of the items in $S \cap G_1$ can be packed in a separate bin (observe that $|S \cap G_1| \leq \mu^2 \cdot h^* \leq \mu|B|$ as packing of h^* heavy items requires at least $h^* \cdot \mu$ bins). Finally, First-Fit can be used to pack the light items in S .

Now, assume we know $q_1, \dots, q_{\mu^{-2}}$ and h^* ; thus, the sets $G_1, \dots, G_{\mu^{-2}}$ and X can be constructed. Consider the following optimization problem: find $S \subseteq I \setminus X$ such that $w(S) \leq |B|$, $|S \cap G_k| \leq \mu^2 \cdot h^*$ for all $1 \leq k \leq \mu^{-2}$, and $f(S)$ is maximal. The problem is an instance of non-monotone submodular maximization with a $(1 + \mu^{-2})$ -dimensional knapsack constraint, for which there is a $(0.385 - \epsilon)$ -approximation algorithm [29, 4]. The algorithm can be used to find $S \subseteq I \setminus X$ which satisfies the above constraints and $f(S) \geq (0.385 - \epsilon) \cdot f(S^*)$, as S^* is a feasible solution for the problem. Subsequently, S can be packed into bins using a standard bin packing algorithm. This will lead to a packing of S into roughly $(1 + 2\mu)|B| + O(\log^2 |B|)$ bins. By removing the bins of least value (along with their items), and using the assumption that $|B|$ is sufficiently large, we can obtain a set S' and an assignment of S' into B such that $f(S)$ is arbitrarily close to $0.385 \cdot f(S^*)$.

Indeed, we do not know the values of $q_1, \dots, q_{\mu^{-2}}$ and h^* . This prevents us from using the above approach. However, as in [3], we can overcome this difficulty through exhaustive enumeration. Each of $q_1, \dots, q_{\mu^{-2}}$ and h^* takes one of $|I|$ possible values. Thus, by iterating over all $|I|^{1+\mu^{-2}}$ possible values for $q_1, \dots, q_{\mu^{-2}}$ and h^* , and solving the above problem for each, we can find a solution of value at least $0.385 \cdot f(S^*)$.

While this approach is useful for our restricted class of instances, due to the use of exhaustive enumeration it does not scale to general instances, where bin capacities may be arbitrary. Known techniques ([15]) can be used to reduce the number of unique bin capacities in a general MKC to be logarithmic in $|B|$. As enumeration is required for each unique capacity, this results in $|I|^{\Theta(\log |B|)}$ iterations, which is non-polynomial.

Fractional Grouping overcomes this hurdle by using a polytope $P \subseteq [0, 1]^I$ to represent an MKC. A grouping $G_1^{\bar{y}}, \dots, G_\tau^{\bar{y}}$ with $\tau \leq \mu^{-2} + 1$ is derived from a vector $\bar{y} \in P$. The polytope P bears some similarity to configuration linear programs used in previous works ([24, 21, 3]). While P is not solvable, it satisfies an approximate version of solvability which suffices for our needs.

Fractional grouping satisfies the main properties of the grouping defined for S^* . Each of the groups contains roughly the same number of fractionally selected items. That is, $\sum_{i \in G_k^{\bar{y}}} \bar{y}_i \approx \mu^2 |B|$ for all $1 \leq k \leq \tau$. Furthermore, we show that if \bar{y} is strictly contained in

⁸ For a set $S \subseteq I$ we denote $w(S) = \sum_{i \in S} w(i)$.

P then any subset $S \subseteq I$ satisfying (i) $|S \cap G_k| \leq \mu|B|$ for all $1 \leq k \leq \tau$, and (ii) $w(S \setminus H)$ is sufficiently small, can be packed into strictly less than $|B|$ bins (see the details in Section 2). The existence of a packing for S relies on a shifting argument similar to the one used above. In this case, however, the structure of the polytope P replaces the role of S^* in our discussion.

This suggests the following algorithm. Use the algorithm of [4] to find $\bar{y} \in P$ such that $F(\bar{y}) \geq (0.385 - \varepsilon)f(S^*)$, and sample a random set $R \sim (1 - \delta)^2 \bar{y}$. By the above property, R can be packed into strictly less than $|B|$ bins with high probability, as $\mathbb{E}[|R \cap G_k|] \ll \mu|B|$. Thus, R can be packed into B using a bin packing algorithm. Standard tools (specifically, the FKG inequality as used in [11]) can also be used to show that $\mathbb{E}[f(R)]$ is arbitrarily close to $F(\bar{y})$. Hence, we can obtain an approximation ratio arbitrarily close to $(0.385 - \varepsilon)$ while avoiding enumeration.

This core idea of fractional grouping for bins of uniform capacities can be scaled to obtain Theorem 1. This scaling involves use of existing techniques for submodular optimization ([15, 9, 10, 7, 4]), along with a novel *block association* technique we apply to handle MKCs with arbitrary bin capacities.

Organization

We present the fractional grouping technique in Section 2. Our algorithms for uniform bin capacities and the general case are given in Section 3 and 4, respectively. Due to space constraints, the block association technique and some proofs are omitted. Those appear in the full version [16].

2 Fractional Grouping

Given an MKC (w, B, W) over I , a subset of bins $K \subseteq B$ is a *block* if all the bins in K have the same capacity. Denote by W_K^* the capacities of the bins in block K , then $W_K^* = W(b)$ for any $b \in K$.

We first define a polytope P_K which represents the block $K \subseteq B$ of an MKC (w, B, W) over I . To simplify the presentation, we assume the MKC (w, B, W) and K are fixed throughout this section. W.l.o.g., assume that $I = \{1, 2, \dots, n\}$ and $w(1) \geq w(2) \geq \dots \geq w(n)$. A *K-configuration* is a subset $C \subseteq I$ of items which fits into a single bin of block K , i.e., $w(C) \leq W_K^*$. We use \mathcal{C}_K to denote the set of all K -configurations. Formally, $\mathcal{C}_K = \{C \subseteq I \mid w(C) \leq W_K^*\}$.

► **Definition 5.** *The extended block polytope of K is*

$$P_K^e = \left\{ \bar{y} \in [0, 1]^I, \bar{z} \in [0, 1]^{\mathcal{C}_K} \mid \forall i \in I : \begin{array}{l} \sum_{C \in \mathcal{C}_K} \bar{z}_C \leq |K| \\ \bar{y}_i \leq \sum_{\substack{C \in \mathcal{C}_K \\ i \in C}} \bar{z}_C \end{array} \right\} \quad (1)$$

The first constraint in (1) bounds the number of selected configurations by the number of bins. The second constraint requires that each selected item is (fractionally) covered by a corresponding set of configurations. It is easy to verify that, for any $(\bar{y}, \bar{z}) \in P_K^e$, it holds that $\sum_{i \in I} w(i) \cdot \bar{y}_i \leq |K| \cdot W_K^*$.

► **Definition 6.** *The block polytope of K is*

$$P_K = \{ \bar{y} \in [0, 1]^I \mid \exists \bar{z} \in [0, 1]^{\mathcal{C}_K} : (\bar{y}, \bar{z}) \in P_K^e \}. \quad (2)$$

While P_K^e and P_K are defined using an exponential number of variables (as $\bar{z} \in [0, 1]^{C_K}$ and C_K is exponential), it follows from standard arguments (see, e.g., [21, 25]) that, for any $\bar{c} \in \mathbb{R}^I$, $\max_{\bar{y} \in P_K} \bar{c} \cdot \bar{y}$ can be approximated.

► **Lemma 7.** *There is a fully polynomial-time approximation scheme (FPTAS) for the problem of finding $\bar{y} \in P_K$ such that $\bar{c} \cdot \bar{y}$ is maximized, given an MKC (w, B, W) , a block $K \subseteq B$ and a vector $\bar{c} \in \mathbb{R}^I$, where P_K is the block polytope of K .*

A formal proof for Lemma 7 is given in [16]. We say that $A : K \rightarrow 2^I$ is a *feasible assignment* for K if $w(A(b)) \leq W_K^*$ for any $b \in K$. Also, we use $\mathbb{1}_S = \bar{x} \in \{0, 1\}^I$, where $\bar{x}_i = 1$ if $i \in S$ and $\bar{x}_i = 0$ if $i \in I \setminus S$. The next lemma implies that the definition of P_K^e is sound for the problem.

► **Lemma 8.** *Let A be a feasible assignment for K and $S = \bigcup_{b \in K} A(b)$. Then $\mathbb{1}_S \in P_K$.*

The lemma is easily proved, by setting $\bar{z}_C = 1$ if $A(b) = C$ for some $b \in B$, and $\bar{z}_C = 0$ otherwise. We say an item $i \in I$ is μ -heavy for $\mu > 0$ (w.r.t K) if $W_K^* \geq w(i) > \mu \cdot W_K^*$; $i \in I$ is μ -light if $w(i) \leq \mu W_K^*$. Denote by $H_{K,\mu}$ and $L_{K,\mu}$ the sets of μ -heavy items and μ -light items, respectively.

Given a vector $\bar{y} \in P_K$, we now describe the partition of μ -heavy items into groups G_1, \dots, G_τ , for some $\tau \leq \mu^{-2} + 1$. Starting with $k = 1$ and $G_k = \emptyset$, add items from $H_{K,\mu}$ to the current group G_k until $\sum_{i \in G_k} \bar{y}_i \geq \mu |K|$. Once the constraint is met, mark the index of the last item in G_k as q_k , the μ -pivot of G_k , close G_k and open a new group, G_{k+1} . Each of the groups $G_1, \dots, G_{\tau-1}$ represents a fractional selection of $\approx \mu |K|$ heavy items of \bar{y} . The last group, G_τ , contains the remaining items in $H_{K,\mu}$, for which the μ -pivot is q_{\max} (last item in $H_{K,\mu}$). We now define formally the partition process.

► **Definition 9.** *Let $\bar{y} \in P_K$ and $\mu \in (0, \frac{1}{2}]$. Also, let $q_0 \in \{0, 1, \dots, n\}$ and $q_{\max} \in I$ such that $H_{K,\mu} = \{i \in I \mid q_0 < i \leq q_{\max}\}$. The μ -pivots of \bar{y} , given by q_1, \dots, q_τ , are defined inductively, i.e.,*

$$q_k = \min \left\{ s \in H_{K,\mu} \mid \sum_{i=q_{k-1}+1}^s \bar{y}_i \geq \mu \cdot |K| \right\}.$$

If the set over which the minimum is taken is empty, let $\tau = k$ and $q_\tau = q_{\max}$. The μ -grouping of \bar{y} consists of the sets G_1, \dots, G_τ , where $G_k = \{i \in H_{K,\mu} \mid q_{k-1} < i \leq q_k\}$ for $1 \leq k \leq \tau$.

Note that in the above definition it may be that $q_0 \neq 0$ as there may be items $i \in I$ for which $w(i) > W_K^*$. Given a polytope P and $\delta \in \mathbb{R}$, we use the notation $\delta P = \{\delta \bar{x} \mid \bar{x} \in P\}$. The main properties of fractional grouping are summarized in the next lemma.

► **Lemma 10 (Fractional Grouping).** *For any $\bar{y} \in P_K$ and $0 < \mu < \frac{1}{2}$ there is a polynomial time algorithm which computes a partition G_1, \dots, G_τ of $H_{K,\mu}$ with $\tau \leq \mu^{-2} + 1$ for which the following hold:*

1. $\sum_{i \in G_k} \bar{y}_i \leq \mu \cdot |K| + 1$ for any $1 \leq k \leq \tau$.
2. Let $S \subseteq H_{K,\mu} \cup L_{K,\mu}$ such that $|S \cap G_k| \leq \mu |K|$ for every $1 \leq k \leq \tau$, and $w(S \cap L_{K,\mu}) \leq \sum_{i \in L_{K,\mu}} \bar{y}_i \cdot w(i) + \lambda \cdot W_K^*$ for some $\lambda \geq 0$. Also, assume $\bar{y} \in (1 - \delta)P_K$ for some $\delta \geq 0$. Then S can be packed into $(1 - \delta + 3\mu)|K| + 4 \cdot 4^{\mu^{-2}} + 2\lambda$ bins of capacity W_K^* .

We refer to G_1, \dots, G_τ as the μ -grouping of \bar{y} .

Proof. It follows from Definition 9 that G_1, \dots, G_τ can be computed in polynomial time. Also, $\sum_{i \in G_\tau} \bar{y}_i < \mu \cdot |K|$ and

$$\forall 1 \leq k < \tau : \quad \mu \cdot |K| \leq \sum_{i \in G_k} \bar{y}_i \leq \mu \cdot |K| + 1. \quad (3)$$

Furthermore, $\tau \leq \mu^{-2} + 1$. Thus, it remains to show Property 2 in the lemma.

Define the *type* of a configuration $C \in \mathcal{C}_K$, denoted by $\text{type}(C)$, as the vector $T \in \mathbb{N}^\tau$ with $T_k = |C \cap G_k|$. Let $\mathcal{T} = \{\text{type}(C) \mid C \in \mathcal{C}_K\}$ be the set of all types. Given a type $T \in \mathcal{T}$, consider a set of items $Q \subseteq H_{K,\mu} \setminus G_1$, such that $|Q \cap G_k| \leq T_{k-1}$ for any $2 \leq k \leq \tau$, then $w(Q) \leq W_K^*$. This is true since we assume the items in $H_{K,\mu}$ are sorted in non-increasing order by weights. We use this key property to construct a packing for S .

We note that $\sum_{k=1}^\tau |C \cap G_k| < \mu^{-1}$ for any $C \in \mathcal{C}_K$ (otherwise $w(C) > W_K^*$, as $G_k \subseteq H_{K,\mu}$). It follows that $|\mathcal{T}| \leq 4^{\mu^{-2}}$. Indeed, the number of types is bounded by the number of different non-negative integer τ -tuples whose sum is at most μ^{-1} .

By Definition 5, there exists $\bar{z} \in [0, 1]^{\mathcal{C}_K}$ such that $(\bar{y}, \bar{z}) \in (1 - \delta)P_K^e$. For $T \in \mathcal{T}$, let $\eta(T) = \sum_{C \in \mathcal{C}_K \text{ s.t. } \text{type}(C)=T} \bar{z}_C$. Then, for any $1 \leq k \leq \tau - 1$, we have

$$\mu |K| \leq \sum_{i \in G_k} \bar{y}_i \leq \sum_{i \in G_k} \sum_{C \in \mathcal{C}_K \text{ s.t. } i \in C} \bar{z}_C = \sum_{C \in \mathcal{C}_K} |G_k \cap C| \bar{z}_C = \sum_{T \in \mathcal{T}} T_k \cdot \eta(T) \quad (4)$$

The first inequality follows from (3). The second inequality follows from (1). The two equalities follow by rearranging the terms.

Using \bar{z} (through the values of $\eta(T)$) we define an assignment of $S \cap (G_2 \cup \dots \cup G_\tau)$ to $\eta = \sum_{T \in \mathcal{T}} \lceil \eta(T) \rceil$ bins. We initialize η sets (bins) $A_1, \dots, A_\eta = \emptyset$ and associate a type with each set A_b , such that there are $\lceil \eta(T) \rceil$ sets associated with the type $T \in \mathcal{T}$, using a function R . That is, let $R : \{1, 2, \dots, \eta\} \rightarrow \mathcal{T}$ such that $|R^{-1}(T)| = \lceil \eta(T) \rceil$. We assign the items in $S \cap (G_2 \cup \dots \cup G_\tau)$ to A_1, \dots, A_η while ensuring that $|A_b \cap G_k| \leq R(b)_{k-1}$ for any $1 \leq b \leq \eta$ and $2 \leq k \leq \tau$. In other words, the number of items assigned to A_b from G_k is at most the number of items from G_{k-1} in the configuration type T assigned to bin b by R . The assignment is obtained as follows. For every $2 \leq k \leq \tau$, iterate over the items $i \in S \cap G_k$, find $1 \leq b \leq \eta$ such that $|A_b \cap G_k| < R(b)_{k-1}$ and set $A_b \leftarrow A_b \cup \{i\}$. It follows from (4) and the conditions of the lemma that such b will always be found.

Upon completion of the process, we have that $S \cap (G_2 \cup \dots \cup G_\tau) = A_1 \cup \dots \cup A_\eta$. Furthermore, for every $1 \leq b \leq \eta$, there are $C \in \mathcal{C}_K$ and $T \in \mathcal{T}$ such that $\text{type}(C) = T = R(b)$. Since $A_b \subseteq G_2 \cup \dots \cup G_\tau$, we have

$$w(A_b) = \sum_{k=2}^\tau w(A_b \cap G_k) \leq \sum_{k=2}^\tau T_{k-1} \cdot w(q_{k-1}) = \sum_{k=2}^\tau |C \cap G_{k-1}| \cdot w(q_{k-1}) \leq \sum_{i \in C} w(i) \leq W_K^*.$$

The first inequality holds since $w(q_{k-1}) \geq w(i)$ for every $i \in G_k$, and the second holds since $w(q_{k-1}) \leq w(i)$ for every $i \in G_{k-1}$. By similar arguments, for every $2 \leq k \leq \tau$, we have

$$w(S \cap G_k) \leq |S \cap G_k| \cdot w(q_{k-1}) \leq \mu |K| \cdot w(q_{k-1}) \leq \sum_{i \in G_{k-1}} \bar{y}_i \cdot w(q_{k-1}) \leq \sum_{i \in G_{k-1}} \bar{y}_i \cdot w(i). \quad (5)$$

The third inequality is due to (3). Using (5) and the conditions in the lemma,

$$\begin{aligned} w(S \setminus G_1) &= w(S \cap L_{K,\mu}) + \sum_{k=2}^\tau w(S \cap G_k) \leq \sum_{i \in L_{K,\mu}} \bar{y}_i w(i) + \lambda W_K^* + \sum_{k=1}^{\tau-1} \sum_{i \in G_k} \bar{y}_i w(i) \\ &\leq \sum_{i \in I} \bar{y}_i \cdot w(i) + \lambda W_K^* \leq (1 - \delta) W_K^* \cdot |K| + \lambda W_K^*. \end{aligned} \quad (6)$$

We use First-Fit (see, e.g., Chapter 9 in [39]) to add the items in $S \cap L_{K,\mu}$ to the sets (=bins) A_1, \dots, A_η while maintaining the capacity constraint, $w(A_b) \leq W_K^*$. First-Fit iterates over the items $i \in S \cap L_{K,\mu}$ and searches for a minimal b such that $w(A_b \cup \{i\}) \leq W_K^*$. If such b exists, First-Fit updates $A_b \leftarrow A_b \cup \{i\}$; otherwise, it adds a new bin with i as its content. Let η' be the number of bins by the end of the process. As $w(i) \leq \mu W_K^*$ for $i \in S \cap L_{K,\mu}$, and due to (6), it holds that $\eta' \leq \max\{\eta, (|K|(1-\delta) + \lambda)(1+2\mu) + 1\}$. Finally,

$$\eta = \sum_{T \in \mathcal{T}} \lceil \eta(T) \rceil \leq |\mathcal{T}| + \sum_{T \in \mathcal{T}} \eta(T) \leq 4^{\mu-2} + \sum_{C \in \mathcal{C}_K} \bar{z}_C \leq 4^{\mu-2} + (1-\delta)|K|.$$

Thus, there is a packing of $S \setminus G_1$ into at most $(1-\delta)|K| + 4^{\mu-2} + 1 + 2\mu|K| + 2\lambda$ bins of capacity W_K^* . Since $|S \cap G_1| \leq \mu|K|$, each of the items in $S \cap G_1$ can be packed into a bin of its own. This yields a packing using at most $(1-\delta + 3\mu)|K| + 4 \cdot 4^{\mu-2} + 2\lambda$ bins. ◀

3 Uniform Capacities

In this section we apply fractional grouping (as stated in Lemma 10) to solve the Monotone Submodular Multiple Knapsack Problem with Uniform Capacities (USMKP). An instance of the problem consists of an MKC (w, B, W) over a set I of items, such that $W_B^* = W(b)$ for all $b \in B$, and a submodular function $f : 2^I \rightarrow \mathbb{R}_{\geq 0}$. For simplicity, we associate a solution for the problem with a feasible assignment $A : B \rightarrow 2^I$. Then, the set of assigned items is given by $S = \bigcup_{b \in B} A(b)$.

Our algorithm for USMKP instances applies *Pipage Rounding* [1, 6]. The input for a Pipage Rounding step is a (fractional) solution $\bar{x} \in [0, 1]^I$, and two items $i_1, i_2 \in I$ with costs $c_1, c_2 \geq 0$. The Pipage Rounding step returns a new random solution $\bar{x}' \in [0, 1]^I$ such that $\bar{x}'_i = \bar{x}_i$ for $i \in I \setminus \{i_1, i_2\}$, $\bar{x}'_{i_1} \cdot c_1 + \bar{x}'_{i_2} \cdot c_2 = \bar{x}_{i_1} \cdot c_1 + \bar{x}_{i_2} \cdot c_2$, and either $\bar{x}'_{i_1} \in \{0, 1\}$ or $\bar{x}'_{i_2} \in \{0, 1\}$. Furthermore, for any submodular function $f : 2^I \rightarrow \mathbb{R}_{\geq 0}$ it holds that $\mathbb{E}[F(\bar{x}')] \geq F(\bar{x})$, where F is the multilinear extension of f . Algorithm 1 calls a subroutine $\text{Pipage}(\bar{x}, f, G, \bar{c})$, which can be implemented by an iterative application of Pipage Rounding steps as long as \bar{x} contains two fractional entries, and randomly sampling the last remaining fractional entry. The properties of **Pipage** are summarized in the next result.

► **Lemma 11.** *There is a polynomial time procedure $\text{Pipage}(\bar{x}, f, G, \bar{c})$ for which the following holds. Given $\bar{x} \in [0, 1]^I$, a submodular function $f : 2^I \rightarrow \mathbb{R}_{\geq 0}$, a subset of items $G \subseteq I$ and a cost vector for the items $\bar{c} \in \mathbb{R}_{\geq 0}^G$, the procedure returns a random vector $\bar{x}' \in [0, 1]^I$ such that $\mathbb{E}[F(\bar{x}')] \geq F(\bar{x})$, $\bar{x}'_i \in \{0, 1\}$ for $i \in G$, $\bar{x}'_i = \bar{x}_i$ for all $i \in I \setminus G$, and there is $i^* \in G$ such that $\sum_{i \in G} \bar{x}'_i \cdot c_i \leq c_{i^*} + \sum_{i \in G} \bar{x}_i \cdot c_i$.*

To solve USMKP instances, our algorithm initially finds $\bar{y} \in P_B$, where P_B is the block polytope of B (note that B is a block in this case), for which $F(\bar{y})$ is large (F is the multilinear extension of the value function f). The algorithm chooses a small value for μ and uses G_1, \dots, G_τ , the μ -grouping of $(1-4\mu)\bar{y}$, to guide the rounding process. Pipage rounding is used to convert $(1-4\mu) \cdot \bar{y}$ to $S \subseteq I$ while preserving the number of selected items from each group as $\approx \mu|B|$, and the total weight of items selected from $L_{B,\mu}$ (i.e., μ -light items) as $\approx (1-4\mu) \cdot \sum_{i \in L_{B,\mu}} \bar{y}_i \cdot w(i)$. An approximation algorithm for bin packing is then used to find a packing of S to the bins. Lemma 10 ensures the resulting packing uses at most $|B|$ bins for sufficiently large B . In case the packing requires more than $|B|$ bins we simply assume the algorithm returns an empty solution. We give the pseudocode in Algorithm 1.

► **Lemma 12.** *Algorithm 1 yields a $\left(1 - e^{-1} - O\left((\log |B|)^{-\frac{1}{4}}\right)\right)$ -approximation for USMKP.*

■ **Algorithm 1** Submodular Multiple Knapsack with Uniform Capacities.

Input: An MKC (w, B, W) over I with uniform capacities. A submodular function $f : 2^I \rightarrow \mathbb{R}_{\geq 0}$.

- 1 Find an approximate solution $\bar{y} \in P_B$ for $\max_{\bar{y} \in P_B} F(\bar{y})$, where P_B is the block polytope of B , and F is the multilinear extension of f .
- 2 Choose $\mu = \min \left\{ (\log |B|)^{-\frac{1}{4}}, \frac{1}{2} \right\}$.
- 3 Set $\bar{y}^0 \leftarrow (1 - 4\mu)\bar{y}$. and let G_1, \dots, G_τ be the μ -grouping of \bar{y}^0 .
- 4 **for** $k = 1, 2, \dots, \tau$ **do** $\bar{y}^k \leftarrow \text{Pipage}(\bar{y}^{k-1}, f, G_k, \bar{1})$.
- 5 $\bar{y}' = \text{Pipage}(\bar{y}^\tau, f, L_{B,\mu}, (w(i))_{i \in L_{B,\mu}})$.
- 6 Let $S = \{i \in I \mid \bar{y}'_i = 1\}$.
- 7 Pack the items in S into B using a bin packing algorithm. Return the resulting assignment.

Proof. Let A^* be an optimal solution for the input instance, and $\text{OPT} = f(\bigcup_{b \in B} A^*(b))$ its value. By Lemma 8, $\mathbb{1}_{\bigcup_{b \in B} A^*(b)} \in P_B$. Let $c = 1 - e^{-1}$. By using the algorithm of [7] we have that $F(\bar{y}) \geq \left(c - \frac{1}{|I|}\right) \cdot \text{OPT}$ (\bar{y} is defined in Step 1 of Algorithm 1). The algorithm of [7] is used with the FPTAS of Lemma 7 as an oracle for solving linear optimization problems over P_B . We note that a $\left(c - \frac{1}{|I|}\right)$ -approximate solution can be obtained even when the algorithm is only given an FPTAS (and not an exact solver) for linear optimization problems over the polytope.

Since the multilinear extension has negative second derivatives [7], it follows that $F(\bar{y}^0) \geq (1 - 4\mu) \cdot \left(c - \frac{1}{|I|}\right) \cdot \text{OPT}$. Now, consider the vector \bar{y}' output in Step 5 of the algorithm. By Lemma 11, it follows that $\mathbb{E}[F(\bar{y}')] \geq F(\bar{y}^0) \geq (1 - 4\mu) \cdot \left(c - \frac{1}{|I|}\right) \cdot \text{OPT}$, and $\bar{y}' \in \{0, 1\}^I$ (note that $\bar{y}'_i = \bar{y}_i = 0$ for any i with $w(i) > W_B^*$ due to (1)). Thus, for the set S defined in Step 6 of the algorithm, we have $\mathbb{E}[f(S)] \geq (1 - 4\mu) \cdot \left(c - \frac{1}{|I|}\right) \cdot \text{OPT} \geq \left(c - O\left((\log |B|)^{-\frac{1}{4}}\right)\right) \cdot \text{OPT}$ (observe we may assume w.l.o.g that $|I| \geq |B|$).

To complete the proof, it remains to show that the bin packing algorithm in Step 7 packs all items in S into the bins B . By Lemma 11, for any $1 \leq k \leq \tau$, it holds that $|S \cap G_k| = \sum_{i \in G_k} \bar{y}'_i \leq 1 + \sum_{i \in G_k} \bar{y}_i^0 \leq \mu \cdot |B| + 2$ (the last inequality follows from Lemma 10). Similarly, there is $i^* \in L_{B,\mu}$ such that

$$w(S \cap L_{B,\mu}) = \sum_{i \in L_{B,\mu}} \bar{y}'_i \cdot w(i) \leq w(i^*) + \sum_{i \in L_{B,\mu}} \bar{y}_i^0 \cdot w(i) \leq \mu \cdot W_B^* + \sum_{i \in L_{B,\mu}} \bar{y}_i^0 \cdot w(i).$$

To meet the conditions of Lemma 10, we need to remove (up to) two items from each group, i.e., $S \cap G_k$, for $1 \leq k \leq \tau$. Let $R \subseteq S$ be a minimal subset such that $|(S \setminus R) \cap G_k| \leq \mu|B|$ for all $1 \leq k \leq \tau$. By the above we have that $|R| \leq 2 \cdot \tau \leq 2 \cdot (\mu^{-2} + 1)$. Therefore, $S \setminus R$ satisfies the conditions of Lemma 10. Hence, by taking $\delta = 4\mu$ and $\lambda = \mu$, the items in $S \setminus R$ can be packed into $(1 - \mu)|B| + 4 \cdot 4^{\mu^{-2}} + 2\mu$ bins. By using an additional bin for each item in R , and assuming $|B|$ is large enough, the items in S can be packed into

$$(1 - \mu)|B| + 4 \cdot 4^{\mu^{-2}} + 2\mu + 2 \cdot (\mu^{-2} + 1) \leq |B| - \frac{|B|}{(\log |B|)^{\frac{1}{4}}} + 5 \cdot 4^{\sqrt{\log |B|}} + 3 \leq |B|$$

bins of capacity W_B^* . Recall that the algorithm of [25] returns a packing in at most $\text{OPT} + O(\log^2 \text{OPT})$ bins. Thus, for large enough $|B|$, the number of bins used in Step 7 of

Algorithm 1 is at most

$$|B| - \frac{|B|}{(\log |B|)^{\frac{1}{4}}} + 5 \cdot 4^{\sqrt{\log |B|}} + O(\log^2 |B|) \leq |B|.$$

Finally, we note that Algorithm 1 can be implemented in polynomial time. \blacktriangleleft

4 Approximation Algorithm

In this section we present our algorithm for general instances of d -MKCP, which gives the result in Theorem 1. In designing the algorithm, a key observation is that we can restrict our attention to d -MKCP instances of certain structure, with other crucial properties satisfied by the objective function. For the *structure*, we assume the bins are partitioned into *levels* by capacities, using the following definition of [15].

► **Definition 13.** For any $N \in \mathbb{N}$, a set of bins B and capacities $W : B \rightarrow \mathbb{R}_{\geq 0}$, a partition $(K_j)_{j=0}^\ell$ of B is N -leveled if, for all $0 \leq j \leq \ell$, K_j is a block and $|K_j| = N^{\lfloor \frac{j}{N^2} \rfloor}$. We say that B and W are N -leveled if such a partition exists.

For $N, \xi \in \mathbb{N}$, (N, ξ) -restricted d -MKCP is the special case of d -MKCP in which for any instance $\mathcal{R} = (I, (w_t, B_t, W_t)_{t=1}^d, \mathcal{I}, f)$ it holds that B_t and W_t are N -leveled for all $1 \leq t \leq d$, and $f(\{i\}) - f(\emptyset) \leq \frac{\text{OPT}}{\xi}$ for any $i \in I$, where OPT is the value of an optimal solution for the instance. We assume the input for (N, ξ) -restricted d -MKCP includes the N -leveled partition $(K_j^t)_{j=0}^{\ell_t}$ of B_t for all $1 \leq t \leq d$. Combining standard enumeration with the structuring technique of [15], we derive the next result.

► **Lemma 14.** For any $N, \xi, d \in \mathbb{N}$ and $c \in [0, 1]$, a polynomial time c -approximation for modular/ monotone/ non-monotone (N, ξ) -restricted d -MKCP with a matroid/ matroid intersection/ matching/ no additional constraint implies a polynomial time $c \cdot (1 - \frac{d}{N})$ -approximation for d -MKCP, with the same type of function and same type of additional constraint.

The proof of the lemma is given in [16].

Our algorithm for (N, ξ) -restricted d -MKCP associates a polytope with each instance. To this end, we first generalize the definition of a block polytope (Definition 6) to represent an MKC. We then use it to define a polytope for the whole instance.

► **Definition 15.** For $\gamma > 0$, the extended γ -partition polytope of an MKC (w, B, W) and the partition $(K_j)_{j=0}^\ell$ of B to blocks is

$$P^e = \left\{ (\bar{x}, \bar{y}^0, \dots, \bar{y}^\ell) \left| \begin{array}{ll} \bar{x} \in [0, 1]^I & \\ \sum_{j=0}^\ell \bar{y}^j = \bar{x} & \\ \bar{y}^j \in P_{K_j} & \forall 0 \leq j \leq \ell \\ \bar{y}_i^j = 0 & \forall 0 \leq j \leq \ell, |K_j| = 1, i \in I \setminus L_{K_j, \gamma} \end{array} \right. \right\} \quad (7)$$

where P_{K_j} is the block polytope of K_j , and $L_{K_j, \gamma}$ is the set of γ -light items of K_j . The γ -partition polytope of (w, B, W) and $(K_j)_{j=0}^\ell$ is

$$P = \{ \bar{x} \in [0, 1]^I \mid \exists \bar{y}^0, \dots, \bar{y}^\ell \in [0, 1]^I \text{ s.t. } (\bar{x}, \bar{y}^0, \dots, \bar{y}^\ell) \in P^e \} \quad (8)$$

The last constraint in (7) forbids the assignment of γ -heavy items to blocks of a single bin. This technical requirement is used to show a concentration bound.

Finally, the γ -instance polytope of $(I, (w_t, B_t, W_t)_{t=1}^d, \mathcal{I}, f)$ and a partition $(K_j^t)_{j=0}^{\ell_t}$ of B_t to blocks, for $1 \leq t \leq d$, is $P = P(\mathcal{I}) \cap \left(\bigcap_{t=1}^d P_t\right)$, where $P(\mathcal{I})$ is the convex hull of \mathcal{I} and P_t is the γ -partition polytope of (w_t, B_t, W_t) and $(K_j^t)_{j=0}^{\ell_t}$. In the *instance polytope optimization problem*, we are given a d -MKCP instance \mathcal{R} with a partition of the bins to blocks for each MKC, $\bar{c} \in \mathbb{R}^I$ and $\gamma > 0$. The objective is to find $\bar{x} \in P$ such that $\bar{x} \cdot \bar{c}$ is maximized, where P is the γ -instance polytope of \mathcal{R} . While the problem cannot be solved exactly, it admits an FPTAS.

► **Lemma 16.** *There is an FPTAS for the instance polytope optimization problem.*

The lemma follows from known techniques for approximating an exponential size linear program using an approximate separation oracle for the dual program. The full proof appears in [16].

The next lemma asserts that the γ -instance polytope provides an approximate representation for the instance as a polytope.

► **Lemma 17.** *Given an (N, ξ) -restricted d -MKCP instance \mathcal{R} with objective function f , let $S, (A_t)_{t=1}^d$ be an optimal solution for \mathcal{R} and $\gamma > 0$. Then there is $S' \subseteq S$ such that $\mathbb{1}_{S'} \in P$ and $f(S') \geq \left(1 - \frac{N^2 \cdot d}{\xi \cdot \gamma}\right) f(S)$, where P is the γ -instance polytope of \mathcal{R} .*

Lemma 17 is proved constructively by removing the γ -heavy items assigned to blocks of a single bin in A_t , for $1 \leq t \leq d$. The full proof appears in [16].

Recall that F is the multilinear extension of the objective function f . Our algorithm finds a vector \bar{x} in the instance polytope for which $F(\bar{x})$ approximates the optimum. The fractional solution \bar{x} is then rounded to an integral solution. Initially, a random set $R \in \mathcal{I}$ is sampled, with $\Pr(i \in R) = (1 - \delta)^2 \bar{x}_i$.⁹ The technique by which R is sampled depends on \mathcal{I} . If $\mathcal{I} = 2^I$ then R is sampled according to \bar{x} , i.e., $R \sim (1 - \delta)^2 \bar{x}$ (as defined in Section 1.3). If \mathcal{I} is a matroid constraint, the sampling of [9] is used. Finally, if \mathcal{I} is a matroid intersection, or a matching constraint, then the dependent rounding technique of [10] is used. Each of the distributions admits a Chernoff-like concentration bound. These bounds are central to our proof of correctness. We refer to the above operation as sampling R by \bar{x} , δ and \mathcal{I} .

Given the set R , the algorithm proceeds to a *purging* step. While this step does not affect the content of R if f is monotone, it is critical in the non-monotone case. Given a submodular function $f : 2^I \rightarrow \mathbb{R}$, we define a purging function $\eta_f : 2^I \rightarrow 2^I$ as follows. Fix an arbitrary order over I (which is independent of S), initialize $J = \emptyset$ and iterate over the items in S by their order in I . For an item $i \in S$, if $f(J \cup \{i\}) - f(J) \geq 0$ then $J \leftarrow J \cup \{i\}$; else, continue to the next item. Now, $\eta_f(S) = J$, where J is the set at the end of the process. The purging function was introduced in [11] and is used here similarly in conjunction with the FKG inequality.

While the above sampling and purging steps can be used to select a set of items for the solution, they do not determine how these items are assigned to the bins. We now show that it suffices to associate the selected items with blocks and then use a Bin Packing algorithm for finding their assignment to the bins in the blocks, as in Algorithm 1.

Intuitively, we would like to associate a subset of items I_j^t with a block K_j^t in a way that enables to assign the items in $I_j^t \cap R$ to $|K_j^t|$ bins, for $1 \leq t \leq d$ and $1 \leq j \leq \ell_t$. Consider two cases. If $|K_j^t| > 1$ then we ensure $I_j^t \cap R$ satisfies conditions that allow using Fractional

⁹ Recall that \mathcal{I} is the additional constraint.

Grouping (see Lemma 10). On the other hand, if $|K_j^t| = 1$, it suffices to require that $R \cap I_j^t$ adheres to the capacity constraint of this bin. Such a partition $(I_j^t)_{j=0}^{\ell_t}$ of $\text{supp}(\bar{x})$ can be computed for each of the MKCs. We refer to this partition as the *Block Association* of a point in the γ -partition polytope and μ , on which the partition depends. The formal definition of block association and its properties can be found in [16].

We proceed to analyze our algorithm (see the pseudocode in Algorithm 2).

■ **Algorithm 2** (N, ξ) -restricted d -MKCP.

Input: An (N, ξ) -restricted d -MKCP instance \mathcal{R} defined by

$\left(I, (w_t, B_t, W_t)_{t=1}^d, \mathcal{I}, f \right)$ and $(K_j^t)_{j=0}^{\ell_t}$, the N -leveled partition of B_t for $1 \leq t \leq d$.

Configuration: $\gamma > 0$, $\delta > 0$, $N \in \mathbb{N}$, $\xi \in \mathbb{N}$,

- 1 Optimize $F(\bar{x})$ with $\bar{x} \in P$, where P is the γ -instance polytope of \mathcal{R} , and F is the multilinear extension of f .
 - 2 Let R be a random set sampled by \bar{x} , δ and \mathcal{I} . Define $J = \eta_f(R)$ (η_f is the purging function).
 - 3 Let $\bar{y}^{t,0}, \dots, \bar{y}^{t,\ell_t} \in [0, 1]^I$ such that $(\bar{x}, \bar{y}^{t,0}, \dots, \bar{y}^{t,\ell_t}) \in P_t^e$, where P_t^e is the extended γ -partition polytope of (w_t, B_t, W_t) and the partition $(K_j^t)_{j=0}^{\ell_t}$, for $1 \leq t \leq d$.
 - 4 Find the block association $(I_j^t)_{j=0}^{\ell_t}$ of $(1 - \delta)(\bar{x}, \bar{y}^{t,0}, \dots, \bar{y}^{t,\ell_t})$ and $\mu = \frac{\delta}{4}$ for $1 \leq t \leq d$.
 - 5 Pack the items of $J \cap I_j^t$ into the bins of K_j^t using an algorithm for bin packing if $|K_j^t| > 1$, or simply assign $J \cap I_j^t$ to K_j^t otherwise.
 - 6 Return J and the resulting assignment if the previous step succeeded; otherwise, return an empty set and an empty packing.
-

► **Lemma 18.** *For any $d \in \mathbb{N}$, $\varepsilon > 0$ and $M > 0$, there are parameters $N \in \mathbb{N}$ satisfying $N > M$, $\xi \in \mathbb{N}$, $\gamma > 0$ and $\delta > 0$ such that Algorithm 2 is a randomized $(c - \varepsilon)$ -approximation for (N, ξ) -restricted d -MKCP, where $c = 1$ for modular instances with any type of additional constraint, $c = 1 - e^{-1}$ for monotone instances with a matroid constraint, and $c = 0.385$ for non-monotone instances with no additional constraint.*

A formal proof of the lemma appears in [16]. Theorem 1 follows immediately from Lemmas 18 and 14.

Abstract

Differentially private algorithms protect individuals in data analysis scenarios by ensuring that there is only a weak correlation between the existence of the user in the data and the result of the analysis. Dynamic graph algorithms maintain the solution to a problem (e.g., a matching) on an evolving input, i.e., a graph where nodes or edges are inserted or deleted over time. They output the value of the solution after each update operation, i.e., continuously. We study (event-level and user-level) differentially private algorithms for graph problems under continual observation, i.e., differentially private dynamic graph algorithms. We present event-level private algorithms for partially dynamic counting-based problems such as triangle count that improve the additive error by a polynomial factor (in the length T of the update sequence) on the state of the art, resulting in the first algorithms with additive error polylogarithmic in T .

We also give ε -differentially private and partially dynamic algorithms for minimum spanning tree, minimum cut, densest subgraph, and maximum matching. The additive error of our improved MST algorithm is $O(W \log^{3/2} T / \varepsilon)$, where W is the maximum weight of any edge, which, as we show, is tight up to a $(\sqrt{\log T} / \varepsilon)$ -factor. For the other problems, we present a partially-dynamic algorithm with multiplicative error $(1 + \beta)$ for any constant $\beta > 0$ and additive error $O(W \log(nW) \log(T) / (\varepsilon \beta))$. Finally, we show that the additive error for a broad class of dynamic graph algorithms with user-level privacy must be linear in the value of the output solution's range.

1 Introduction

Differential privacy aims to protect individuals whose data becomes part of an increasing number of data sets and is subject to analysis. A differentially private algorithm guarantees that its output depends only very little on an individual's contribution to the input data. Roughly speaking, an algorithm is ϵ -differentially private if the probability that it outputs O on data set D is at most an e^ϵ -factor of the probability that it outputs O on any adjacent data set D' . Two data sets are *adjacent* if they differ only in the data of a single user. Differential privacy was introduced in the setting of databases [9, 11], where users (entities) are typically represented by rows and data is recorded in columns. An important notion

that allowed for the development of generic techniques and tools (like the Laplace and the exponential mechanism) is the *sensitivity* of a function f : the static sensitivity ρ of f is the maximum $|f(D) - f(D')|$ over all adjacent pairs D, D' . Differential privacy was later generalized to a more challenging setting, where data evolves over time [12, 6]: a differentially private algorithm under *continual observation* must provide the same privacy guarantees as before, but for a sequence (or stream) of data sets instead of just a single data set. Often, this sequence results from updates to the original data set that arrive over time. In this setting, the presence or absence of a single user in one update can affect the algorithm's output on all future data sets, i.e., two adjacent databases can differ on all future outputs and, thus, have infinite sensitivity.

In this paper, we study differentially private graph algorithms under continual observation, i.e., for *dynamic* graph problems. The input is a sequence of graphs that results from node or edge updates, i.e., insertions or deletions. *Partially dynamic* algorithms only allow either insertions or deletions, *fully dynamic* algorithms allow both. After each update, the algorithm has to output a solution for the current input, i.e., the algorithm outputs a sequence of answers that is equally long as the input sequence. For differentially private graph algorithms two notions of *adjacency of graph sequences* exist: node-adjacency and edge-adjacency. Two graph sequences are *edge-adjacent* if they only differ in a single insertion or deletion of an edge. Similarly, two graph sequences are *node-adjacent* if they only differ in an insertion or deletion of a node.¹

We initiate the study of differentially private algorithms for *non-local* partially dynamic graph problems. We consider a problem *non-local* if its (optimum) value cannot be derived from the graph's frequency histogram of constant-size subgraphs and call it *local* otherwise. Non-local problems include the cost of the minimum spanning tree, the weight of the global and s - t minimum cut, and the density of the densest subgraph. We also give improved algorithms for local graph problems and show various lower bounds on the additive error for differentially private dynamic graph algorithms.

Local problems. The only prior work on differentially private dynamic algorithms is an algorithm by Song et al. [29] for various *local* graph problems such as counting high-degree nodes, triangles and other constant-size subgraphs. We present an algorithm for these local problems that improves the additive error by a factor of $\sqrt{T}/\log^{3/2} T$, where T is the length of the update sequence. We also give the first differentially private partially-dynamic algorithm for the value of the minimum spanning tree. Table 1 lists upper and lower bounds for these results, where n is the number of nodes in the graph, W is the maximum edge weight (if applicable), D is the maximum node degree, ϵ is an arbitrarily small positive constant, and δ is the failure probability of the algorithm. We state below our main contributions in more detail. The update time of all our algorithms is linear in $\log T$ plus the time needed to solve the corresponding non-differentially private dynamic graph problem.

► **Theorem 1** (see Section 3). *Let $\epsilon, \delta > 0$. There exist an ϵ -edge-differentially as well as an ϵ -node-differentially private algorithm for partially-dynamic minimum spanning tree, edge count, the number of high-degree nodes, the degree histogram, triangle count and k -star count that with probability at least $1 - \delta$ give an answer with additive error as shown in Table 1.*

¹ Of course, a graph can also be represented by a database, where, e.g., every row corresponds to an edge, but as we present algorithms that solve graph algorithmic problems we use the graph-based terminology through the paper.

■ **Table 1** Additive errors for partially-dynamic ε -differentially private algorithms with failure probability δ . We use D for the maximum degree and W for the maximum edge weight, n for the maximum number of nodes of any graph in the input sequence, and $\Lambda = \log(1/\delta)/\varepsilon$. The upper bounds follow from Corollary 13 and Table 3 on page 11. See Section 5 for results on event-level lower bounds and Section 6 for user-level lower bounds.

Non-local problems. For non-local problems we present an algorithm that, by allowing a small multiplicative error, can obtain differentially private partially dynamic algorithms for a broad class of problems that includes the aforementioned problems. Table 2 lists our results for some common graph problems. The algorithm achieves the following performance.

► **Theorem 2** (see Theorem 16). *Let $\varepsilon, \beta, \delta, r > 0$ and let f be a function with range $[1, r]$ that is monotone on all input sequences and has sensitivity ρ . There exists an ε -differentially private dynamic algorithm with multiplicative error $(1 + \beta)$, additive error $O(\rho \log(r) \log(T) / \log(1 + \delta))$ and failure probability δ that computes f .*

Note that for partially dynamic graph algorithms it holds that $T = O(n^2)$. Thus for local problems the bounds presented in Table 1 are superior to the bounds in Table 2.

Lower bounds. We complement these upper bounds by also giving some lower bounds on the additive error of any differentially private dynamic graph algorithm. For the problems in Table 1 we show lower bounds of $\Omega(W \log T)$, resp. $\Omega(\log T)$. Note that these lower bounds apply to the partially dynamic as well as to the fully dynamic setting.

The above notion of differential privacy is also known as *event-level* differential privacy, where two graph sequences differ in at most one “event”, i.e., one update operation. A more challenging notion is *user-level* differential privacy. Two graph sequences are edge-adjacent *on user-level* if they differ in *any* number of updates for a single edge (as opposed to *one* update for a single edge in the case of the former *event-level* adjacency). Note that requiring

■ **Table 2** Private algorithms with failure probability δ with additional multiplicative error of $(1 + \beta)$ for arbitrary $\beta > 0$. We use $\Lambda = 1/(\varepsilon\delta \log(1 + \beta))$, D for the maximum degree, W for the maximum edge weight and n for the maximum number of nodes of any graph in the input sequence.

Graph function	partially dynamic, event-level	
	edge-adjacency	node-adjacency
minimum cut	$O(W \log(nW) \log(T) \cdot \Lambda)$	$O(DW \log(nW) \log(T) \cdot \Lambda)$
densest subgraph	$O(\log(n) \log(T) \cdot \Lambda)$	$O(\log(n) \log(T) \cdot \Lambda)$
minimum s, t -cut	$O(W \log(nW) \log(T) \cdot \Lambda)$	$O(DW \log(nW) \log(T) \cdot \Lambda)$
maximum matching	$O(W \log(nW) \log(T) \cdot \Lambda)$	$O(W \log(nW) \log(T) \cdot \Lambda)$

user-level edge-differential privacy is a more stringent requirement on the algorithm than event-level edge-differential privacy.² We show strong lower bounds for edge-differentially private algorithms on user-level for a broad class of dynamic graph problems.

► **Theorem 3** (informal, see Theorem 19). *Let f be a function on graphs, and let G_1, G_2 be arbitrary graphs. There exists a $T \geq 1$ so that any ε -edge-differentially private dynamic algorithm on user-level that computes f must have additive error $\Omega(|f(G_1) - f(G_2)|)$ on input sequences of length at least T .*

This theorem leads to the lower bounds for fully dynamic algorithms stated in Table 1.

Technical contribution. Local problems. Our algorithms for local problems (Theorem 1) incorporate a counting scheme by Chan et al. [6] and the *difference sequence technique* by Song et al. [29]. The difference sequence technique addresses the problem that two adjacent graphs might differ on all outputs starting from the point in the update sequence where their inputs differ. More formally, let $f_{\mathcal{G}}(t)$ be the output of the algorithm after operation t in the graph sequence \mathcal{G} . Then the *continuous global sensitivity* $\sum_{t=1}^T |f_{\mathcal{G}}(t) - f_{\mathcal{G}'}(t)|$ might be $\Theta(\rho T)$. Using the “standard” Laplacian mechanism for such a large sensitivity would, thus, lead to an additive error linear in T . The idea of [29] is to use instead the *difference sequence of f* defined as $\Delta f(t) = f(t) - f(t-1)$, as they observed that for various local graph properties the continuous global sensitivity of the difference sequence, i.e., $\sum_{t=1}^T |\Delta f_{\mathcal{G}}(t) - \Delta f_{\mathcal{G}'}(t)|$ can be bounded by a function independent of T . However, their resulting partially-dynamic algorithms still have an additive error linear in \sqrt{T} . We show how to combine the continuous global sensitivity of the difference sequence with the binary counting scheme of Chan et al. [6] to achieve partially-dynamic algorithms with additive error linear in $\log^{3/2} T$.

Furthermore we show that the approach based on the continuous global sensitivity of the difference sequence fails, if the presence or absence of a node or edge can significantly change the target function’s value for all of the subsequent graphs. In particular, we show that for several graph problems like minimum cut and maximum matching changes in the function value between adjacent graph sequences can occur at every time step even for partially dynamic sequences, resulting in a continuous global sensitivity of the difference sequence that is linear in T . This implies that this technique cannot be used to achieve differentially private dynamic algorithms for these problems.

Non-local problems. We leverage the fact that the sparse vector technique [13] provides negative answers to threshold queries with little effect on the additive error to approximate monotone functions f on graphs under continual observation (e.g., the minimum cut value

² Node-adjacency on user-level is defined accordingly but not studied in this paper.

in an incremental graph) with multiplicative error $(1 + \beta)$: If r is the maximum value of f , we choose thresholds $(1 + \beta), \dots, (1 + \beta)^{\log_{1+\beta}(r)}$ for the queries. This results in at most $\log_{1+\beta}(r)$ positive answers, which affect the additive error linearly, while the at most T negative answers affect the additive error only logarithmically instead of linearly.

Lower bounds. Dwork et al. [12] had given a lower bound for counting in binary streams. We reduce this problem to partially dynamic graph problems on the event-level to achieve the event-level lower bounds.

For the user-level lower bounds we assume by contradiction that an ϵ -differentially private dynamic algorithm \mathcal{A} with “small” additive error exists and construct an exponential number of graph sequences that are all user-level “edge-close” to a simple graph sequence \mathcal{G}' . Furthermore any two such graph sequences have at least one position with two very different graphs such that \mathcal{A} (due to its small additive error) must return two different outputs at this position, which leads to two different output sequences if \mathcal{A} answers within its error bound. Let O_i be the set of accurate output sequences of \mathcal{A} on one of the graph sequences G_i . By the previous condition $O_i \cap O_j = \emptyset$ if $i \neq j$. As G_i is “edge-close” to \mathcal{G}' , there is a relatively large probability (depending on the degree of “closeness”) that O_i is output when \mathcal{A} runs on \mathcal{G}' . This holds for all i . However, since $O_i \cap O_j = \emptyset$ if $i \neq j$ and we have constructed exponentially many graph sequences G_i , the sum of these probabilities over all i adds up to a value larger than 1, which gives a contradiction. The proof is based on ideas of a lower bound proof for databases in [12].

All missing proofs can be found in the full version of the paper at <http://arxiv.org/abs/2106.14756>.

Related Work. Differential privacy, developed in [9, 11], is the de facto gold standard of privacy definitions and several lines of research have since been investigated [2, 25, 20, 10, 16, 4]. In particular, differentially private algorithms for the release of various graph statistics such as subgraph counts [19, 3, 7, 21, 32], degree distributions [18, 8, 33], minimum spanning tree [26], spectral properties [31, 1], cut problems [16, 1, 14], and parameter estimation for special classes of graphs [23] have been proposed. Dwork et al. [12] and Chan et al. [6] extended the analysis of differentially private algorithms to the regime of continual observation, i.e., to input that evolves over time. Since many data sets in applications are evolving data sets, this has lead to results for several problems motivated by practice [5, 22, 27, 15, 30]. Only one prior work analyzes evolving graphs: Song et al. [29] study problems in incremental bounded-degree graphs that are functions of local neighborhoods. Our results improve all bounds for undirected graphs initially established in [29] by a factor of $\sqrt{T}/\log^{3/2} T$ in the additive error.

2 Preliminaries

2.1 Graphs and Graph Sequences

We consider undirected graphs $G = (V, E)$, which change dynamically. Graphs may be edge-weighted, in which case $G = (V, E, w)$, where $w : E \rightarrow \mathbb{N}$. The evolution of a graph is described by a *graph sequence* $\mathcal{G} = (G_1, G_2, \dots)$, where $G_t = (V_t, E_t)$ is derived from G_{t-1} by applying updates, i.e., inserting or deleting nodes or edges. We denote by $|\mathcal{G}|$ the length of \mathcal{G} , i.e., the number of graphs in the sequence. At time t we delete a set of nodes ∂V_t^- along with the corresponding edges ∂E_t^- and insert a set of nodes ∂V_t^+ and edges ∂E_t^+ . More formally, $V_t = (V_{t-1} \setminus \partial V_t^-) \cup \partial V_t^+$ and $E_t = (E_{t-1} \setminus \partial E_t^-) \cup \partial E_t^+$, with initial node and edge sets V_0, E_0 , which may be non-empty. If a node v is deleted, then

all incident edges are deleted at the same time, i.e., if $v \in \partial V_t^-$, then $(u, v) \in \partial E_t^-$ for all $(u, v) \in E_{t-1}$. Both endpoints of an edge inserted at time t need to be in the graph at time t , i.e., $\partial E_t^+ \subseteq ((V_{t-1} \setminus \partial V_t^-) \cup \partial V_t^+) \times ((V_{t-1} \setminus \partial V_t^-) \cup \partial V_t^+)$. The tuple $(\partial V_t^+, \partial V_t^-, \partial E_t^+, \partial E_t^-)$ is the *update* at time t . For any graph G and any update u , let $G \oplus u$ be the graph that results from applying u on G .

A graph sequence is *incremental* if $\partial E_t^- = \partial V_t^- = \emptyset$ at all time steps t . A graph sequence is *decremental* if $\partial E_t^+ = \partial V_t^+ = \emptyset$ at all time steps t . Incremental and decremental graph sequences are called *partially dynamic*. Graph sequences that are neither incremental nor decremental are *fully dynamic*.

Our goal is to continually release the value of a *graph function* f which takes a graph as input and outputs a real number. In other words, given a graph sequence $\mathcal{G} = (G_1, G_2, \dots)$ we want to compute the sequence $f(\mathcal{G}) = (f(G_1), f(G_2), \dots)$. We write $f(t)$ for $f(G_t)$. Our algorithms will compute an update to the value of f at each time step, i.e., we compute $\Delta f(t) = f(t) - f(t-1)$. We call the sequence Δf the *difference sequence* of f .

Given a graph function g the *continuous global sensitivity* $\text{GS}(g)$ of g is defined as the maximum value of $\|g(S) - g(S')\|_1$ over all adjacent graph sequences S, S' . We will define adjacency of graph sequences below. In our case, we are often interested in the continuous global sensitivity of the difference sequence of a graph function f , which is given by the maximum value of $\sum_{t=1}^T |\Delta f_{\mathcal{G}}(t) - \Delta f_{\mathcal{G}'}(t)|$, where $\Delta f_{\mathcal{G}}$ and $\Delta f_{\mathcal{G}'}$ are the difference sequences of f corresponding to adjacent graph sequences \mathcal{G} and \mathcal{G}' .

Two graphs are *edge-adjacent* if they differ in one edge. We also define global sensitivity of functions applied to a single graph. Let g be a graph function. Its *static global sensitivity* $\text{GS}_{\text{static}}(g)$ is the maximum value of $|g(G) - g(G')|$ over all edge-adjacent graphs G, G' .

2.2 Differential Privacy

The range of an algorithm \mathcal{A} , $\text{Range}(\mathcal{A})$, is the set of all possible output values of \mathcal{A} . We denote the Laplace distribution with mean μ and scale b by $\text{Lap}(\mu, b)$. If $\mu = 0$, we write $\text{Lap}(b)$.

► **Definition 4** (ε -differential privacy). *A randomized algorithm \mathcal{A} is ε -differentially private if for any two adjacent databases B, B' and any $S \subseteq \text{Range}(\mathcal{A})$ we have $\Pr[\mathcal{A}(B) \in S] \leq e^\varepsilon \cdot \Pr[\mathcal{A}(B') \in S]$. The parameter ε is called the privacy loss of \mathcal{A} .*

To apply Definition 4 to graph sequences we now define adjacency for graph sequences. First, we define edge-adjacency, which is useful if the data to be protected is associated with the edges in the graph sequence. Then, we define node-adjacency, which provides stronger privacy guarantees.

► **Definition 5** (Edge-adjacency). *Let $\mathcal{G}, \mathcal{G}'$ be graph sequences as defined above with associated sequences of updates $(\partial V_t^-), (\partial V_t^+), (\partial E_t^-), (\partial E_t^+)$ and $(\partial V_t^{-'}), (\partial V_t^{+'}), (\partial E_t^{-'}), (\partial E_t^{+'})$. Let $\partial V_t^- = \partial V_t^{-'}$ and $\partial V_t^+ = \partial V_t^{+'}$ for all t . Let the initial node and edge sets for \mathcal{G} and \mathcal{G}' be $V_0 = V_0'$ and $E_0 = E_0'$. Assume w.l.o.g. that $\partial E_t^{-'} \subseteq \partial E_t^-$ and $\partial E_t^{+'} \subseteq \partial E_t^+$ for all t . The graph sequences \mathcal{G} and \mathcal{G}' are adjacent on e^* if $|\mathcal{G}| = |\mathcal{G}'|$, there exists an edge e^* and one of the following statements holds:*

1. $\partial E_t^- = \partial E_t^{-'} \forall t$ and $\exists t^*$ such that $\partial E_{t^*}^+ \setminus \partial E_{t^*}^{+'} = \{e^*\}$ and $\partial E_t^+ = \partial E_t^{+'} \forall t \neq t^*$;
2. $\partial E_t^+ = \partial E_t^{+'} \forall t$ and $\exists t^*$ such that $\partial E_{t^*}^- \setminus \partial E_{t^*}^{-'} = \{e^*\}$ and $\partial E_t^- = \partial E_t^{-'} \forall t \neq t^*$;

Remark. If \mathcal{G} and \mathcal{G}' are edge-adjacent, then for any index i the graphs at index i in the two sequences are edge-adjacent.

Two edge-adjacent graph sequences differ in either the insertion or the deletion of a single edge e^* . There are several special cases that fit into this definition. For example, we may have $\partial V_t^- = \partial V_t^{-'} = \partial V_t^+ = \partial V_t^{+'} = \emptyset$, so only edge updates would be allowed. Similarly, we can use the definition in the incremental setting by assuming $\partial V_t^- = \partial V_t^{-'} = \partial E_t^- = \partial E_t^{-'} = \emptyset$.

The definition of node-adjacency is similar to that of edge-adjacency, but poses additional constraints on the edge update sets.

► **Definition 6 (Node-adjacency).** *Let $\mathcal{G}, \mathcal{G}'$ be graph sequences as defined above with associated sequences of updates $(\partial V_t^-), (\partial V_t^+), (\partial E_t^-), (\partial E_t^+)$ and $(\partial V_t^{-'}), (\partial V_t^{+'}), (\partial E_t^{-'}), (\partial E_t^{+'})$. Assume w.l.o.g. that $\partial V_t^{-'} \subseteq \partial V_t^-$ and $\partial V_t^{+'} \subseteq \partial V_t^+$ for all t . The graph sequences \mathcal{G} and \mathcal{G}' are adjacent on v^* if $|\mathcal{G}| = |\mathcal{G}'|$, there exists a node v^* and one of the following statements holds:*

1. $\partial V_t^- = \partial V_t^{-'} \forall t$ and $\exists t^*$ such that $\partial V_t^+ \setminus \partial V_t^{+'} = \{v^*\}$ and $\partial V_t^+ = \partial V_t^{+'} \forall t \neq t^*$;
 2. $\partial V_t^+ = \partial V_t^{+'} \forall t$ and $\exists t^*$ such that $\partial V_t^- \setminus \partial V_t^{-'} = \{v^*\}$ and $\partial V_t^- = \partial V_t^{-'} \forall t \neq t^*$;
- Additionally, all edges in ∂E_t^+ and ∂E_t^- are incident to at least one node in ∂V_t^+ and ∂V_t^- , respectively. Lastly, we require that $\partial E_t^{+'} (\partial E_t^{-'})$ is the maximal subset of $\partial E_t^+ (\partial E_t^-)$ that does not contain edges incident to v^* .*

We define the following notions of differential privacy based on these definitions of adjacency.

► **Definition 7.** *An algorithm is ε -edge-differentially private (on event-level) if it is ε -differentially private when considering edge-adjacency. An algorithm is ε -node-differentially private (on event-level) if it is ε -differentially private when considering node-adjacency.*

When explicitly stated, we consider a stronger version of ε -differential privacy, which provides adjacency on user-level. While adjacency on event-level only allows two graph sequences to differ in a single update, user-level adjacency allows any number of updates to differ as long as they affect the same edge (for edge-adjacency) or node (for node-adjacency), respectively.

► **Definition 8.** *Let $\mathcal{G} = (G_1, \dots), \mathcal{G}' = (G'_1, \dots)$ be graph sequences. The two sequences are edge-adjacent on user-level if there exists an edge e^* and a sequence of graph sequences $\mathcal{S} = (\mathcal{G}_1, \dots, \mathcal{G}_\ell)$ so that $\mathcal{G}_1 = \mathcal{G}, \mathcal{G}_\ell = \mathcal{G}'$ and, for any $i \in [\ell-1]$, \mathcal{G}_i and \mathcal{G}_{i+1} are edge-adjacent on e^* . An algorithm is ε -edge-differentially private on user-level if it is ε -differentially private when considering edge-adjacency on user-level.*

2.3 Counting Mechanisms

Some of our algorithms for releasing differentially private estimates of functions on graph sequences rely on algorithms for counting in streams.

A *stream* $\sigma = \sigma(1)\sigma(2)\dots$ is a string of items $\sigma(i) \in \{L_1, \dots, L_2\} \subseteq \mathbb{Z}$, where the i -th item is associated with the i -th time step. A *binary stream* has $L_1 = 0$ and $L_2 = 1$. We denote the length of a stream, i.e., the number of time steps in the stream, by $|\sigma|$. Stream σ and σ' are adjacent if $|\sigma| = |\sigma'|$ and if there exists one and only one t^* such that $\sigma(t^*) \neq \sigma'(t^*)$ and $\sigma(t) = \sigma'(t)$ for all $t \neq t^*$.

A *counting mechanism* $\mathcal{A}(\sigma)$ takes a stream σ and outputs a real number for every time step. For all time steps t , \mathcal{A} 's output at time t is independent of all $\sigma(i)$ for $i > t$. At each time t a counting mechanism should estimate the count $c(t) = \sum_{i=1}^t \sigma(i)$.

Following Chan et al. [6] we describe our mechanisms in terms of *p-sums*, which are partial sums of the stream over a time interval. For a p-sum p we denote the beginning and end of the time interval by $\text{start}(p)$ and $\text{end}(p)$, respectively. With this notation the value of p is $\sum_{t=\text{start}(p)}^{\text{end}(p)} \sigma(t)$. To preserve privacy we add noise to p-sums and obtain *noisy p-sums*: given a p-sum p , a noisy p-sum is $\hat{p} = p + \gamma$, where γ is drawn from a Laplace-distribution.

2.4 Sparse Vector Technique

The *sparse vector technique* (SVT) was introduced by Dwork et al. [13] and was subsequently improved [17, 28]. SVT can be used to save privacy budget whenever a sequence of threshold queries f_1, \dots, f_T is evaluated on a database, but only $c \ll T$ queries are expected to exceed the threshold. Here, a threshold query asks whether a function f_i evaluates to a value above some threshold t_i on the input database. Using SVT, only queries that are answered positively reduce the privacy budget. We use the following variant of SVT, which is due to Lyu et al.

► **Lemma 9** ([24]). *Let D be a database, $\epsilon, \rho, c > 0$ and let $(f_1, t_1), \dots$ be a sequence of mappings f_i from input databases to \mathbb{R} and thresholds $t_i \in \mathbb{R}$, which may be generated adaptively one after another so that $\rho \geq \max_i \text{GS}_{\text{static}}(f_i)$. Algorithm 1 is ϵ -private.*

■ **Algorithm 1** SVT algorithm [24].

```

1 Function InitializeSvt( $D, \rho, \epsilon, c$ )
2    $\epsilon_1 \leftarrow \epsilon/2, \zeta \leftarrow \text{Lap}(\rho/\epsilon_1), \epsilon_2 \leftarrow \epsilon - \epsilon_1, \text{count} \leftarrow 0$

3 Mechanisms Based on Continuous Global Sensitivity

Some of our mechanisms for privately estimating graph functions are based on mechanisms for counting in streams. In both settings, we compute the sum of a sequence of numbers and we will show that the mechanisms for counting can be transferred to the graph setting. However, there are differences in the analysis. In counting, the input streams differ at only one time step. This allows us to bound the difference in the true value between adjacent inputs and leads to low error. In the graph setting, the sequence of numbers can vary at many time steps. Here however, we use properties of the counting mechanisms to show that the total difference for this sequence can still be bounded, which results in the same error as in the counting setting.

We first generalize the counting mechanisms by Chan et al. [6] to streams of integers with bounded absolute value, and then transfer them to estimating graph functions.

3.1 Non-Binary Counting

We generalize the counting mechanisms of Chan et al. [6] to streams of numbers in $\{-L, \dots, L\}$, for some constant L . We view these algorithms as releasing noisy p-sums from which the count can be estimated. The generic algorithm is outlined in Algorithm 2 on page 9.

The algorithm releases a vector of noisy p-sums over T time steps, such that at every time step the noisy p-sums needed to estimate the count up to this time are available. Each of the noisy p-sums is computed exactly once. See the proof of Corollary 13 for an example on how to use p-sums.

In order to achieve the desired privacy loss the mechanisms need to meet the following requirements. Let \mathcal{A} be a counting mechanism. We define $\text{Range}(\mathcal{A}) = \mathbb{R}^k$, where k is the total number of p-sums used by \mathcal{A} and every item of the vector output by \mathcal{A} is a p-sum. We assume that the time intervals represented by the p-sums in the output of \mathcal{A} are deterministic and only depend on the length T of the input stream. For example, consider any two streams σ and σ' of length T . The ℓ -th element of $\mathcal{A}(\sigma)$ and $\mathcal{A}(\sigma')$ will be p-sums of the same time interval $[\text{start}(\ell), \text{end}(\ell)]$. We further assume that the p-sums are computed independently from each other in the following way: \mathcal{A} computes the true p-sum and then adds noise from $\text{Lap}(z \cdot \varepsilon^{-1})$, where z is a sensitivity parameter. The next lemma is stated informally in [6].

■ **Algorithm 2** Generic counting mechanism.

- 1 **Input:** privacy loss ε , stream σ of items $\{L_1, \dots, L_2\}$ with $|\sigma| = T$
 - 2 **Output:** vector of noisy p-sums $a \in \mathbb{R}^k$, released over T time steps
 - 3 **Initialization:** Determine which p-sums to compute based on T
 - 4 At each time step $t \in \{1, \dots, T\}$:
 - 5 Compute new p-sums p_i, \dots, p_j for t
 - 6 **For** $\ell = i, \dots, j$:
 - 7 $\hat{p}_\ell = p_\ell + \gamma_\ell, \quad \gamma_\ell \sim \text{Lap}((L_2 - L_1)\varepsilon^{-1})$
 - 8 Release new noisy p-sums $\hat{p}_i, \dots, \hat{p}_j$
-

► **Lemma 10** (Observation 1 from [6]). *Let \mathcal{A} be a counting mechanism as described in Algorithm 2 with $L_1 = 0$ and $L_2 = 1$ that releases k noisy p-sums, such that the count at any time step can be computed as the sum of at most y p-sums and every item is part of at most x p-sums. Then, \mathcal{A} is $(x \cdot \varepsilon)$ -differentially private, and the error is $O(\varepsilon^{-1} \sqrt{y} \log \frac{1}{\delta})$ with probability at least $1 - \delta$ at each time step.*

To extend the counting mechanisms by Chan et al. to non-binary streams of values in $\{-L, \dots, L\}$, we only need to account for the increased sensitivity in the scale of the Laplace distribution. By Lemma 11, we can use the mechanisms of Chan et al. [6] to compute the sum of a stream of numbers in $\{-L, \dots, L\}$, but gain a factor $2L$ in the error.

► **Lemma 11** (Extension of Lemma 10). *Let \mathcal{A} be a mechanism as in Algorithm 2 (see page 9) with $L_1 = -L$ and $L_2 = L$ that releases k noisy p-sums, such that the count at any time step can be computed as the sum of at most y p-sums, and every item is part of at most x p-sums. Furthermore, \mathcal{A} adds noise $\text{Lap}(2L/\varepsilon)$ to every p-sum. Then, \mathcal{A} is $(x \cdot \varepsilon)$ -differentially private, and the error is $O(L\varepsilon^{-1} \sqrt{y} \log \frac{1}{\delta})$ with probability at least $1 - \delta$ at each time step.*

Algorithm 3 Generic graph sequence mechanism.

Input: privacy loss ε , contin. global sensitivity Γ , graph sequence $\mathcal{G} = (G_1, \dots, G_T)$
Output: vector of noisy p-sums $a \in \mathbb{R}^k$, released over T time steps

- 1 **Initialization:** Determine which p-sums to compute based on T
- 2 At each time step $t \in \{1, \dots, T\}$:
 - 3 Compute $f(t)$ and $\Delta f(t) = f(t) - f(t-1)$, $f(0) := 0$
 - 4 Compute new p-sums p_i, \dots, p_j for the sequence Δf
 - 5 **For** $\ell = i, \dots, j$:
 - 6 $\hat{p}_\ell = p_\ell + \gamma_\ell$, $\gamma_\ell \sim \text{Lap}(\Gamma\varepsilon^{-1})$
 - 7 Release new noisy p-sums $\hat{p}_i, \dots, \hat{p}_j$

3.2 Graph Functions via Counting Mechanisms

We adapt the counting mechanisms to continually release graph functions by following the approach by Song et al. [29]. Algorithm 3 outlines the generic algorithm. It is similar to Algorithm 2, with the difference that the stream of numbers to be summed is computed from a graph sequence \mathcal{G} . The algorithm is independent of the notion of adjacency of graph sequences, however the additive error is linear in the continuous global sensitivity of the difference sequence Δf .

In counting binary streams we considered adjacent inputs that differ at exactly one time step. In the graph setting however, the stream of numbers that we sum, i.e., the difference sequence Δf , can differ in multiple time steps between two adjacent graph sequences. We illustrate this with a simple example. Let f be the function that counts the number of edges in a graph and consider two node-adjacent incremental graph sequences $\mathcal{G}, \mathcal{G}'$. \mathcal{G} contains an additional node v^* , that is not present in \mathcal{G}' . Whenever a neighbor is added to v^* in \mathcal{G} , the number of edges in \mathcal{G} increases by more than the number of edges in \mathcal{G}' . Thus, every time a neighbor to v^* is inserted, the difference sequence of f will differ between \mathcal{G} and \mathcal{G}' .

To generalize this, consider two adjacent graph sequences $\mathcal{G}, \mathcal{G}'$ that differ in an update at time t' . Let $\Delta f_{\mathcal{G}}$ and $\Delta f_{\mathcal{G}'}$ be the difference sequences used to compute the graph function f on \mathcal{G} and \mathcal{G}' . As discussed above we may have $\Delta f_{\mathcal{G}}(t) \neq \Delta f_{\mathcal{G}'}(t)$ for all $t \geq t'$. Thus, more than x p-sums can be different, which complicates the proof of the privacy loss. However, we observe that the set P of p-sums with differing values can be partitioned into x sets P_1, \dots, P_x , where the p-sums in each P_i cover disjoint time intervals. By using a bound on the continuous global sensitivity of the difference sequence Δf , this will lead to a privacy loss of $x \cdot \varepsilon$. The following lemma formalizes our result.

► **Lemma 12** (Lemma 11 for graph sequences). *Let f be a graph function whose difference sequence has continuous global sensitivity Γ . Let $0 < \delta < 1$ and $\varepsilon > 0$. Let \mathcal{A} be a mechanism to estimate f as in Algorithm 3 that releases k noisy p-sums and satisfies the following conditions:*

1. *at any time step the value of a graph function f can be estimated as the sum of at most y noisy p-sums,*
2. *\mathcal{A} adds independent noise from $\text{Lap}(\Gamma/\varepsilon)$ to every p-sum,*
3. *the set P of p-sums computed by the algorithm can be partitioned into at most x subsets P_1, \dots, P_x , such that in each partition P_x all p-sums cover disjoint time intervals. That is, for all $P_i \in \{P_1, \dots, P_x\}$ and all $j, k \in P_i$, $j \neq k$, it holds that (1) $\text{start}(j) \neq \text{start}(k)$ and (2) $\text{start}(j) < \text{start}(k) \implies \text{end}(j) < \text{start}(k)$.*

Then, \mathcal{A} is $(x \cdot \varepsilon)$ -differentially private, and the error is $O(\Gamma\varepsilon^{-1}\sqrt{y}\log \frac{1}{\delta})$ with probability at least $1 - \delta$ at each time step.

■ **Table 3** Global sensitivity of difference sequences.

Graph Function f	Continuous Global Sensitivity of Δf			
	Partially Dynamic		Fully Dynamic	
	node-adjacency	edge-adjacency	node-adj.	edge-adj.
edge count ^a	D	1	$\geq T$	2
high-degree nodes ^a	$2D + 1$	4	$\geq T$	$\geq T$
degree histogram ^a	$4D^2 + 2D + 1$	$8D$	$\geq 2T$	$\geq 2T$
triangle count ^a	$\binom{D}{3}$	D	$\geq T$	$\geq T$
k -star count ^a	$D \binom{D-1}{k-1} + \binom{D}{k}$	$2 \cdot \left(\binom{D}{k} - \binom{D-1}{k} \right)$	$\geq T$	$\geq T$
minimum spanning tree	$2DW$	$2W - 2$	$\geq T$	$\geq T$
minimum cut	$\geq T$	$\geq T$	$\geq T$	$\geq T$
maximum matching	$\geq T$	$\geq T$	$\geq T$	$\geq T$

^aBounds for partially dynamic node-adjacency from Song et al. [29]

We can compute the p-sums in Algorithm 3 as in the binary mechanism [6] to release ε -differentially private estimates of graph functions.

► **Corollary 13** (Binary mechanism). *Let f be a graph function whose difference sequence has continuous global sensitivity Γ . Let $0 < \delta < 1$ and $\varepsilon > 0$. For each $T \in \mathbb{N}$ there exists an ε -differentially private algorithm to estimate f on a graph sequence which has error $O(\Gamma \varepsilon^{-1} \cdot \log^{3/2} T \cdot \log \delta^{-1})$ with probability at least $1 - \delta$.*

3.3 Bounds on Continuous Global Sensitivity

Song et al. [29] give bounds on the continuous global sensitivity of the difference sequence for several graph functions in the incremental setting in terms of the maximum degree D . Table 3 summarizes the results on the continuous global sensitivity of difference sequences for a variety of problems in the partially dynamic and fully dynamic setting, both for edge- and node-adjacency. Note that bounds on the continuous global sensitivity of the difference sequence for incremental graph sequences hold equally for decremental graph sequences as for every incremental graph sequence there exists an equivalent decremental graph sequence which deletes nodes and edges in the reverse order.

In the partially dynamic setting, the continuous global sensitivity based approach works well for graph functions that can be expressed as the sum of local functions on the neighborhood of nodes. For non-local problems the approach is less successful. For the weight of a minimum spanning tree the continuous global sensitivity of the difference sequence is independent of the length of the graph sequence. However, for minimum cut and maximum matching this is not the case. In the fully-dynamic setting the approach seems not to be useful. Here, we can show that even for estimating the number of edges the continuous global sensitivity of the difference sequence scales linearly with T under node-adjacency. When considering edge-adjacency we only have low sensitivity for the edge count.

Using Corollary 13 we obtain ε -differentially private mechanisms with additive error that scales with $\log^{3/2} T$, compared to the factor \sqrt{T} in [29]. Note that we recover their algorithm when using the Simple Mechanism II by Chan et al. [6] to sum the difference sequence.

The difference sequence approach can be employed to privately estimate the weight of a minimum spanning tree in partially dynamic graph sequences. If the edge weight is bounded by W , then the continuous global sensitivity of the difference sequence is $O(W)$ and $O(DW)$ under edge-adjacency and node-adjacency, respectively. Using Corollary 13 we obtain the algorithms outlined in Theorems 14 and 15.

► **Theorem 14.** *There exists an ε -edge-differentially private algorithm that outputs the weight of a minimum spanning tree on an incremental graph sequence \mathcal{G} with edge-weights from the set $\{1, \dots, W\}$. At every time step, the algorithm has error $O(W\varepsilon^{-1} \cdot \log^{3/2} T \cdot \log \delta^{-1})$ with probability at least $1 - \delta$, where T is the length of the graph sequence.*

► **Theorem 15.** *There exists an ε -node-differentially private algorithm that outputs the weight of a minimum spanning tree on an incremental graph sequence \mathcal{G} with edge-weights from the set $\{1, \dots, W\}$. At every time step, the algorithm has error $O(DW\varepsilon^{-1} \cdot \log^{3/2} T \cdot \log \delta^{-1})$ with probability at least $1 - \delta$, where T is the length of the graph sequence and D is the maximum degree.*

4 Upper Bound for Monotone Functions

In Section 3.3, we show that privately releasing the difference sequence of a graph sequence does not lead to good error guarantees for partially dynamic problems like minimum cut. Intuitively, the reason is that even for neighboring graph sequences $\mathcal{G}, \mathcal{G}'$, the differences of the difference sequence can be non-zero for all graphs G_i, G'_i . In other words, the difference of objective values for the graphs G_i and G'_i can constantly fluctuate during continual updates. However, the difference of objective values, regardless of fluctuations, is *always small*. We show that, by allowing an arbitrarily small *multiplicative* error, we can leverage this fact for a broad class of partially dynamic problems. In particular, we prove that there exist ε -differentially private algorithms for all dynamic problems that are non-decreasing (or non-increasing) on all valid input sequences. This includes, e.g., minimum cut, maximum matching and densest subgraph on partially dynamic inputs. See Algorithm 4 for the details and Table 2 on page 4 for explicit upper bounds for applications. We state the result for monotonically increasing functions, but it is straightforward to adapt the algorithm to monotonically decreasing functions.

■ **Algorithm 4** Multiplicative error algorithm for monotone functions.

```

1 Function Initialize( $D, \rho, \epsilon, r, \beta$ )
2    $k_0 \leftarrow 0$ 
3   InitializeSvt ( $D, \rho, \epsilon, \log_{1+\beta}(r)$ )           // see Algorithm 1
4 Function Process( $f_i$ )
5    $k_i \leftarrow k_{i-1}$ 
6   while ProcessSvtQuery( $f_i, (1 + \beta)^{k_i} = \top$ ) do           // see Algorithm 1
7      $k_i \leftarrow k_i + 1$ 
8   return  $(1 + \beta)^{k_i}$ 

```

► **Theorem 16.** *Let $r > 0$ and let f be any monotonically increasing function on dynamic inputs (e.g., graphs) with range $[1, r]$ and static global sensitivity $\rho := \text{GS}_{\text{static}}(f)$. Let $\beta \in (0, 1), \delta > 0$ and let $\alpha = 16 \log_{1+\beta}(r) \rho \cdot \ln(2T/\delta)/\epsilon$. There exists an ε -differentially private algorithm for computing f with multiplicative error $(1 + \beta)$, additive error α and failure probability δ .*

5 Lower Bounds for Event-Level Privacy

We can show lower bounds for the error of edge- and node-differentially private algorithms in the partially dynamic setting. We derive the bounds by reducing differentially private counting in binary streams to these problems and apply a lower bound of Dwork et al. [12], which we restate here.

► **Theorem 17** (Lower bound for counting in binary streams [12]). *Any differentially private event-level algorithm for counting over T rounds must have error $\Omega(\log T)$ (even with $\varepsilon = 1$).*

We obtain a lower bound of $\Omega(W \log T)$ for minimum cut, maximum weighted matching and minimum spanning tree. The same approach yields a lower bound of $\Omega(\log T)$ for the subgraph-counting problems, counting the number of high-degree nodes and the degree histogram. See Table 1 on page 3. Note that any lower bound for the incremental setting can be transferred to the decremental setting, using the same reductions but proceeding in reverse.

6 Lower Bound for User-Level Privacy

We show that for several fundamental problems on dynamic graphs like minimum spanning tree and minimum cut, a differentially private algorithm with edge-adjacency on user-level must have an additive error that is linear in the maximum function value. Technically, we define the *spread* of a graph function as the maximum difference of the function's value on any two graphs. Then, we show that any algorithm must have an error that is linear in the graph function's spread. We write this section in terms of edge-adjacency but the corresponding result for node-adjacency carries over.

► **Definition 18.** *Let G_1 and G_2 be a pair of graphs. We define $\tau(G_1, G_2)$ to be an update sequence u_1, \dots, u_ℓ of minimum length that transforms G_1 into G_2 . We denote the graph sequence that results from applying $\tau(G_1, G_2)$ to G_1 by $T(G_1, G_2)$.*

Let $s, \ell : \mathbb{N} \rightarrow \{2i \mid i \in \mathbb{N}\}$ be functions. A graph function f has spread $(s(n), \ell(n))$ on inputs of size n if, for every n , there exist two graphs G_1, G_2 of size n so that $|f(G_1) - f(G_2)| \geq s(n)$ and $|\tau(G_1, G_2)| = \ell(n)$.

See Table 1 on page 3 for the resulting lower bounds.

► **Theorem 19.** *Let $\epsilon, \delta > 0$ and let f be a graph function with spread (s, ℓ) that spares an edge e . For streams of length T on graphs of size n , where $T > \log(e^{4\epsilon\ell}/(1 - \delta)) \in O(\epsilon\ell + \log(1/(1 - \delta)))$, every ϵ -differentially private dynamic algorithm with user-level edge-adjacency that computes f with probability at least $1 - \delta$ must have error $\Omega(s(n))$.*

► **Fact 20.** *Minimum spanning tree has spread $(\Theta(nW), \Theta(n))$. Minimum cut has spread $(\Theta(nW), \Theta(n^2))$. Maximal matching has spread $(\Theta(n), \Theta(n))$. Maximum cardinality matching has spread $(\Theta(n), \Theta(n))$. Maximum weight matching has spread $(\Theta(nW), \Theta(n))$.*

Abstract

PQ-trees and PC-trees are data structures that represent sets of linear and circular orders, respectively, subject to constraints that specific subsets of elements have to be consecutive. While equivalent to each other, PC-trees are conceptually much simpler than PQ-trees; updating a PC-tree so that a set of elements becomes consecutive requires only a single operation, whereas PQ-trees use an update procedure that is described in terms of nine transformation templates that have to be recursively matched and applied.

Despite these theoretical advantages, to date no practical PC-tree implementation is available. This might be due to the original description by Hsu and McConnell [14] in some places only sketching the details of the implementation. In this paper, we describe two alternative implementations of PC-trees. For the first one, we follow the approach by Hsu and McConnell, filling in the necessary details and also proposing improvements on the original algorithm. For the second one, we use a different technique for efficiently representing the tree using a Union-Find data structure. In an extensive experimental evaluation we compare our implementations to a variety of other implementations of PQ-trees that are available on the web as part of academic and other software libraries. Our results show that both PC-tree implementations beat their closest fully correct competitor, the PQ-tree implementation from the OGDF library [6, 15], by a factor of 2 to 4, showing that PC-trees are not only conceptually simpler but also fast in practice. Moreover, we find the Union-Find-based implementation, while having a slightly worse asymptotic runtime, to be twice as fast as the one based on the description by Hsu and McConnell.

1 Introduction

PQ-trees represent linear orders of a ground set subject to constraints that require specific subsets of elements to be consecutive. Similarly, PC-trees do the same for circular orders subject to consecutivity constraints. PQ-trees were developed by Booth and Lueker [3] to

solve the consecutive ones problem, which asks whether the columns of a Boolean matrix can be permuted such that the 1s in each row are consecutive. PC-trees are a more recent generalization introduced by Shih and Hsu [16] to solve the circular consecutive ones problem, where the 1s in each row only have to be circularly consecutive.

Though PQ-trees represent linear orders and PC-trees represent circular orders, Haeupler and Tarjan [10] show that in fact PC-trees and PQ-trees are equivalent, i.e., one can use one of them to implement the other without affecting the asymptotic running time. The main difference between PQ-trees and PC-trees lies in the update procedure. The update procedure takes as input a PQ-tree (a PC-tree) T and a subset U of its leaves and produces a new PQ-tree (PC-tree) T' that represents exactly the linear orders (circular orders) represented by T where the leaves in U appear consecutively. The update procedure for PC-trees consists only of a single operation that is applied independently of the structure of the tree. In contrast, the update of the PQ-tree is described in terms of a set of nine template transformations that have to be recursively matched and applied.

PQ-trees have numerous applications, e.g., in planarity testing [3, 16], recognition of interval graphs [3] and genome sequencing [1]. Nevertheless, PC-trees have been adopted more widely, e.g., for constrained planarity testing problems [2, 5] due to their simpler update procedure. Despite their wide applications and frequent use in theoretical algorithms, few PQ-tree implementations and even fewer PC-tree implementations are available. Table 1 shows an overview of all PC/PQ-tree implementations that we are aware of, though not all of them are working.

In this paper we describe the first correct and generic implementations of PC-trees. Section 2 contains an overview of the update procedure for applying a new restriction to a PC-tree. In Section 3, we describe the main challenge when implementing PC-trees and how our two implementations take different approaches at solving it. In Section 4, we present an extensive experimental evaluation, where we compare the performance of our implementations with the implementations of PC-trees and PQ-trees from Table 1. Our experiments show that, concerning running time, PC-trees following Hsu and McConnell's original approach beat their closest competitor, the PQ-tree implementation from the OGDF library [6] by roughly a factor 2. Our second implementation using Union-Find is another 50% faster than this first one, thus beating the OGDF implementation by a factor of up to 4.

2 The PC-tree

A *PC-tree* T is a tree without degree-2 vertices whose inner nodes are partitioned into *P-nodes* and *C-nodes*. Edges incident to C-nodes have a circular order that is fixed up to reversal, whereas edges incident to P-nodes can be reordered arbitrarily. Traversing the tree according to fixed orders around the inner nodes determines a circular ordering of the leaves L of the tree. Any circular permutation of L that can be obtained from T after arbitrarily reordering the edges around P-nodes and reversing orders around C-nodes is a *valid permutation* of L . In this way a PC-tree represents a set of circular permutations of L .

When applying a *restriction* $R \subseteq L$ to T , we seek a new tree that represents exactly the valid permutations of L where the leaves in R appear consecutively. We call a restriction *impossible* if there is no valid permutation of L where the leaves in R are consecutive. Thus, restriction R is possible if and only if the edges incident to P-nodes can be rearranged and orders of edges incident to C-nodes can be reversed in such a way that all leaves in R are consecutive. Updating a PC-tree to enforce the new restriction can thus be done by identifying and adapting the nodes that decide about the consecutivity of the elements of R and then changing the tree to ensure that this consecutivity can no longer be broken.

■ **Figure 1** (a) Two equivalent PC-Trees with their nodes colored according to the restriction $\{4, 8, 10, 11, 12, 15\}$. C-nodes are represented by big double circles and the P-nodes are represented by small circles. The white nodes represent empty nodes, the black nodes represent full nodes and the gray nodes represent partial nodes. The thick edges represent the terminal path with terminal nodes t_1 and t_2 . As the restriction is possible, all full leaves of the tree on the left can be made consecutive, as shown on the right. Furthermore all nodes that must be modified lie on a path. (b) Updated PC-tree with new central C-node c .

Let a leaf $x \in L$ be *full* if $x \in R$ and *empty* otherwise. We call an edge *terminal* if the two subtrees separated by the edge both contain at least one empty and at least one full leaf. Exactly the endpoints of all terminal edges need to be “synchronized” to ensure that all full leaves are consecutive. Hsu and McConnell [14, 13] show that R is possible if and only if the terminal edges form a path and all nodes of this path can be flipped so that all full leaves are on one side and all empty leaves are on the other. This path is called the *terminal path*, the two nodes at the ends of the terminal path are the *terminal nodes*. Observe that each node in T that is adjacent to two subtrees of which one only contains full leaves and the other contains only empty leaves is contained in the terminal path. Figure 1a illustrates the terminal path.

When updating T in order to apply the restriction, every node on the terminal path is split into two nodes, one of which holds all edges to neighbors of the original node whose subtree has only full leaves, the other holds all edges to empty neighbors, while terminal edges are deleted. A new central C-node c is created that is adjacent to all the split nodes in such a way that it preserves the order of the neighbors around the terminal path. Contracting all edges to the split C-nodes incident to c and contracting all nodes with degree two results in the updated tree that represents the new restriction [14, 13]. Figure 1 shows an example of this update, while Figure 2 details changes made to the terminal path.

It remains to efficiently find the terminal edges, and thus the subtrees with mixed full and empty leaves. To do so, Hsu and McConnell first choose an arbitrary node of the tree as root. They also assign labels to the inner nodes of the tree, marking an inner node (and conceptually the subtree below it) *partial* if at least one of its neighbors (i.e. children or parent) is full, *full* if all its neighbors except one (which usually is the parent) are full, and *empty* otherwise. Then, an edge is terminal if and only if it lies on a path between two partial nodes [14, 13]. Assigning the labels and subsequently finding the terminal edges can be done by two bottom-up traversals of the tree. We summarize these steps in the following, more fine-granular description of Hsu and McConnell’s algorithm for updating the PC-tree [13, Algorithm 32.2]:

■ **Figure 2** Left: The terminal path with all full subtrees shown in black on top and all empty subtrees shown in white on the bottom. Middle: The updated PC-tree, where all terminal edges were deleted, all nodes on the terminal were split in a full and empty half and all new nodes were connected to a new C-node c . Right: The PC-Tree after contracting all new C-nodes and all degree-2 P-nodes into c .

Algorithm for Applying Restrictions. To add a new restriction R to a PC-tree T :

1. Label all partial and full nodes by searching the tree bottom-up from all full leaves.
2. Find the terminal path by walking the tree upwards from all partial nodes in parallel.
3. Perform flips of C-nodes and modify the cyclic order of edges incident to P-nodes so that all full leaves lie on one side of the path.
4. Split each node on the path into two nodes, one incident to all edges to full leaves and one incident to all edges to empty leaves.
5. Delete the edges of the path and replace them with a new C-node c , adjacent to all split nodes, whose cyclic order preserves the order of the nodes on this path.
6. Contract all edges from c to adjacent C-nodes, and contract any node that has only two neighbors.

3 Our Implementations

The main challenge posed to the data structure for representing the PC-tree is that, in step 6, it needs to be able to merge arbitrarily large C-nodes in constant time for the overall algorithm to run in linear time. This means that, whenever C-nodes are merged, updating the pointer to a persistent C-node object on every incident edge would be too expensive. Hsu and McConnell (see [13, Definition 32.1]) solve this problem by using C-nodes that, instead of having a permanent node object, are only represented by the doubly-linked list of their incident half-edges, which we call *arcs*. This complicates various details of the implementation, like finding the parent pointer of a C-node, which are only superficially covered in the initial work of Hsu and McConnell [14]. These issues are in part remedied by the so called *block-spanning pointers* introduced in the later published book chapter [13], which are related to the pointer borrowing strategy introduced by Booth and Lueker [3]. These block-spanning pointers link the first and last arc of a consecutive block of full arcs (i.e. the arcs to full neighbors) around a C-node and can be accompanied by temporary C-node objects. Whenever a neighbor of a C-node becomes full, either a new block is created for the corresponding arc of the C-node, an adjacent block grows by one arc, or the two blocks that now became adjacent are merged.

Using this data structure, Hsu and McConnell show that the addition of a single new restriction R takes $O(p + |R|)$ time, where p is the length of the terminal path, and that applying restrictions R_1, \dots, R_k takes $\Theta(|L| + \sum_{i=1}^k |R_i|)$ time [14, 13]. Especially for steps 1 and 2, they only sketch the details of the implementation, making it hard to directly put

it into practice. In the full version, we fill in the necessary details for these steps and also refine their runtime analysis, showing that step 1 can be done in $O(|R|)$ time and step 2 can be done in $O(p)$ time. Using the original procedures by Hsu and McConnell, steps 3 and 4 can be done in $O(|R|)$ time and steps 5 and 6 can be done in $O(p)$ time.

For our first implementation, which we call HsuPC, we directly implemented these steps in C++, using the data structure without permanent C-node objects as described by Hsu and McConnell. During the evaluation, we realized that traversals of the tree are expensive. This is plausible, as they involve a lot of pointer-dereferencing to memory segments that are not necessarily close-by, leading to cache misses. To avoid additional traversals for clean-up purposes, we store information that is valid only during the update procedure with a timestamp. Furthermore, we found that keeping separate objects for arcs and nodes and the steps needed to work around the missing C-node objects pose a non-negligible overhead.

To remove this overhead, we created a second version of our implementation, which we call UFPC, using a Union-Find tree for representing C-node objects: Every C-node is represented by an entry in the Union-Find tree and every incident child edge stores a reference to this entry. Whenever two C-nodes are merged, we apply `union` to both entries and only keep the object of the entry that survives. This leads to every lookup of a parent C-node object taking amortized $O(\alpha(|L|))$ time, where α is the inverse Ackermann function. Although this makes the overall runtime super-linear, the experimental evaluation following in the next section shows that this actually improves the performance in practice. As a second change, the UFPC no longer requires separate arc and node objects, allowing us to use a doubly-linked tree consisting entirely of nodes that store pointers to their parent node, left and right sibling node, and first and last child node. Edges are represented implicitly by the child node whose parent is the other end of the edge. Note that of the five stored pointers, a lookup in the Union-Find data structure is only needed for resolving the parent of a node.

Our algorithmic improvements and differences of both implementations are described in more detail in the full version. We use the Union-Find data structure from the OGDF [6] and plan to merge our UFPC implementation into the OGDF. Furthermore, both implementations should also be usable stand-alone with a custom Union-Find implementation. The source code for both implementations, our evaluation harness and all test data are available on GitHub (see Table 1).

4 Evaluation

In this section, we experimentally evaluate our PC-tree implementations by comparing the running time for applying a restriction with that of various PQ- and PC-tree implementations that are publicly available. In the following we describe our method for generating test cases, our experimental setup and report our results.

4.1 Test Data Generation

To generate PQ-trees and restrictions on them, we make use of the planarity test by Booth and Lueker [3], one of the initial applications of PQ-trees. This test incrementally processes vertices one by one according to an *st*-ordering. Running the planarity test on a graph with n vertices applies $n - 1$ restrictions to PQ-trees of various sizes. Since not all implementations provide the additional modification operations necessary to implement the planarity test, we rather export, for each step of the planarity test, the current PQ-tree and the restriction that is applied to it as one instance of our test set. We note that the use of *st*-orderings ensures that the instances do not require the ability of the PC-tree to represent circular permutations, making them good test cases for comparing PC-trees and PQ-trees.

43:6 Experimental Comparison of PC-Trees and PQ-Trees

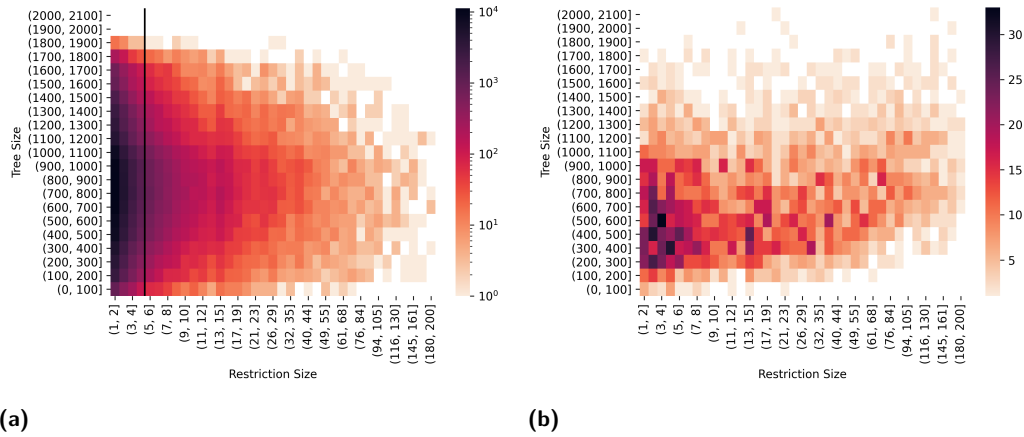

Figure 3 Distribution of tree and restriction size for the data sets **(a) SER-POS** and **(b) SER-IMP**. Please note the different color scales. The **SER-POS** instances that are left of the black line are too small and filtered out.

In this way, we create one test set **SER-POS** consisting of only PQ-trees with possible restrictions by exporting the instances from running the planarity test on a randomly generated biconnected planar graph for each vertex count n from 1000 to 20,000 in steps of 1000 and each edge count $m \in \{2n, 3n - 6\}$. To avoid clutter, to remedy the tendency of the planarity test to produce restrictions with very few leaves, and to avoid bias from trivial optimizations such as filtering trivial restrictions with $|R| \in \{1, |L| - 1, |L|\}$, which is present in some of the implementations, we filter test instances where $|R|$ lies outside the interval $[5, |L| - 2]$. Altogether, this test set contains 199,831 instances, whose distribution with regards to tree and restriction size is shown in Figure 3a.

To guard against overly permissive implementations, we also create a small test set **SER-IMP** of impossible restrictions. It is generated in the same way, by adding randomly chosen edges to the graphs from above until they become non-planar. In this case the planarity test fails with an impossible restriction at some point; we include these 3,800 impossible restrictions in the set, see Figure 3b.

As most of the available implementations have no simple means to store and load a PQ-/PC-tree, we serialize each test instance as a set of restrictions that create the tree, together with the additional new restriction. When running a test case, we then first apply all the restrictions to reobtain the tree, and then measure the time to apply the new restriction from the test case. The prefix **SER-** in the name of both sets emphasizes this serialization.

To be able to conduct a more detailed comparison of the most promising implementations, we also generate a third test set with much larger instances. As deserializing a PC- or PQ-tree is very time-consuming, we directly use the respective implementations in the planarity test by Booth and Lueker [3], thus calling the set **DIR-PLAN**. We generated 10 random planar graphs with n vertices and m edges for each n ranging from 100,000 to 1,000,000 in steps of 100,000 and each $m \in \{2n, 3n - 6\}$, yielding 200 graphs in total. The planarity test then yields one possible restriction per node. As we only want to test big restrictions, we filter out restrictions with less than 25 full leaves, resulting in **DIR-PLAN** containing 564,300 instances.

Table 1 Implementations considered for the evaluation. Implementations that are entirely unusable as they are incomplete or crash/produce incorrect results on almost all inputs (marked with $-$) and those where no stand-alone PC-/PQ-tree implementation could be extracted (marked with n.a.) could not be evaluated. Correct implementations are marked with \checkmark and implementations that are functional, but do not always produce correct results are marked with \times . These two categories are included in our experimental evaluation. The last column shows how many of 203,630 restrictions in the sets SER-POS and SER-IMP failed.

¹ PQR-Trees are a variant of PQ-Trees that can also represent impossible restrictions, replacing any node that would make a restriction impossible by an R-node (again allowing arbitrary permutation). To make the implementations comparable, we abort early whenever an impossible restriction is detected and an R-node would be generated.

4.2 Experimental Setup

Table 1 gives an overview of all implementations we are aware of, although not all implementations could be considered for the evaluation.

The three existing implementations of PC-trees we found are incomplete and unusable (Luk&Zhou) or tightly intertwined with a planarity test in such a way that we were not able to extract a generic implementation of PC-trees (Hsu, Noma). We further exclude two PQ-tree implementations as they either crash or produce incorrect results on almost all inputs (GTea) or have an excessively poor running time (TryAlgo). Among the remaining PQ-tree implementations only three correctly handle all our test cases (OGDF, Gregable, SageMath). Several other implementations have smaller correctness issues: After applying a fix to prevent segmentation faults in a large number of cases for BiVoC, the remaining implementations crash (BiVoC, GraphSet, Zanetti) and/or produce incorrect results (Reisle, JGraphEd, Zanetti) on a small fraction of our tests; compare the last column of Table 1. We nevertheless include them in our evaluation.

We changed the data structure responsible for mapping the input to the leaves of the tree for BiVoC and Gregable from `std::map` to `std::vector` to make them competitive. Moreover, BiVoC, Gregable and GraphSet use a rather expensive cleanup step that has to be executed after each update operation. As this could probably largely be avoided by the use of timestamps, we do not include the cleanup time in their reported running times. For SageMath the initial implementation turned out to be quadratic, which we improved to linear by removing unnecessary recursion. As Zanetti turned out to be a close competitor to our implementation in terms of running time, we converted the original Java implementation to C++ to allow a fair comparison. This decreased the runtime by one third while still producing the exact same results. All other non-C++ implementations were much slower or had other issues, making a direct comparison of their running times within the same language environment as our implementations unnecessary. Further details on the implementations can be found in the full version.

Each experiment was run on a single core of a Intel Xeon E5-2690v2 CPU (3.00 GHz, 10 Cores) with 64 GiB of RAM, running Linux Kernel version 4.19. Implementations in C++ were compiled with GCC 8.3.0 and optimization `-O3 -march=native -mtune=native`. Java implementations were executed on OpenJDK 64-Bit Server VM 11.0.9.1 and Python implementations were run with CPython 3.7.3. For the Java implementations we ran each experiment several times, only measuring the last one to remove startup-effects and to facilitate optimization by the JIT compiler. We used OGDF version 2020.02 (Catalpa) to generate the test graphs.

4.3 Results

Our experiments turn out that SageMath, even with the improvements mentioned above, is on average 30 to 100 times slower than all other implementations.² For the sake of readability, we scale our plots to focus on the other implementations. As the main application of PC-/PQ-trees is applying possible restrictions, we first evaluate on the dataset SER-POS. Figure 4 shows the runtime for individual restrictions based on the size of the restriction (i.e. the number of full leaves) and the overall size of the tree. Figure 4a clearly shows that for all implementations the runtime is linear in the size of the restriction. Figure 4b suggests that

² Part of this might be due to the overhead of running the code with CPython. As the following analysis shows, SageMath also has other issues, allowing us to safely exclude it.

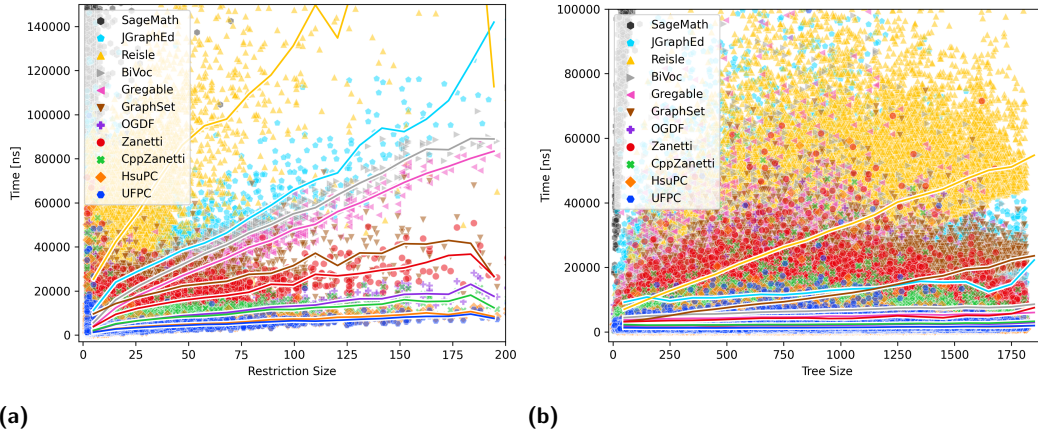

Figure 4 Runtime for SER-POS restrictions depending on (a) restriction size and (b) tree size.

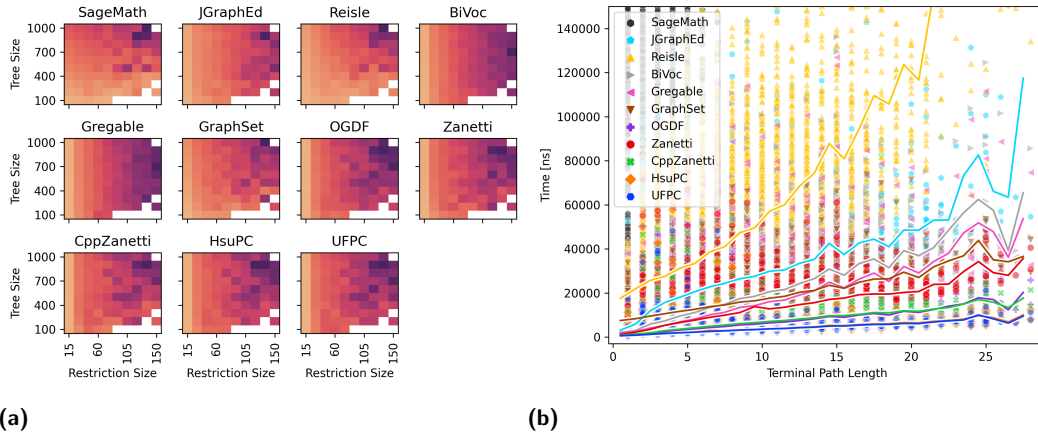

Figure 5 (a) A heatmap showing the average runtime of SER-POS restrictions, depending on both the size of the restriction and the size of the tree. The color scale is based on the maximum runtime of each respective implementation. (b) Runtime for SER-POS restrictions depending on the terminal path length.

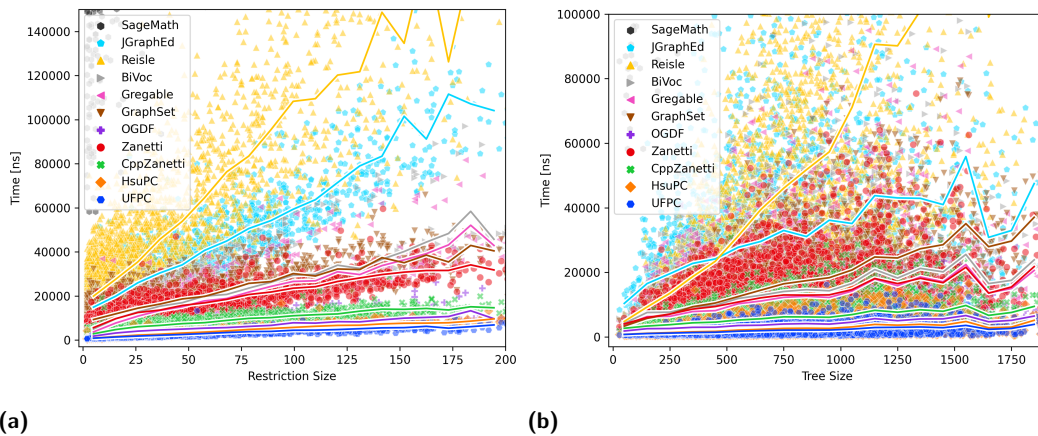

Figure 6 Runtime for SER-IMP restrictions depending on (a) restriction size and (b) tree size for all implementations.

the runtime of Reisle and GraphSet does not solely depend on the restriction size, but also on the size of the tree. To verify this, we created for each implementation a heatmap that indicates the average runtime depending on both the tree size and the restriction size, shown in Figure 5a. The diagonal pattern shown by SageMath, Reisle, and GraphSet confirms the dependency on the tree size. All other implementations exhibit vertical stripes, which shows that their runtime does not depend on the tree size. Finally, Figure 5b shows the runtime compared to the terminal path length. As expected, all implementations show a linear dependency on the terminal path length, with comparable results to Figure 4a.

Figure 6 shows the performance on the dataset **SER-IMP**. The performance is comparable with that on **SER-POS**. Noteworthy is that Zanetti performs quite a bit worse, which is due to its implementation not being able to detect failure during a labeling step. It always performs updates until a so-called R-node would be generated. Altogether, the data from **SER-POS** and **SER-IMP** shows that the implementations GraphSet, OGDF, Zanetti, HsuPC and UFPC are clearly superior to the others. In the following, we conduct a more detailed comparison of these implementations by integrating them into a planarity test and running them on much larger instances, i.e., the data set **DIR-PLAN**. In addition to an update method, this requires a method for replacing the now-consecutive leaves by a P-node with a given number of child leaves. Adding the necessary functionality would be a major effort for most of the implementations, which is why we only adapted the most efficient implementations to run this set. We also exclude GraphSet from this experiment; the fact that it scales linearly with the tree size causes the planarity test to run in quadratic time. Figure 7 again shows the runtime of individual restrictions depending on the restriction size. Curiously, Zanetti produces incorrect results for nearly all graphs with $m = 2n$ in Figure 7a. As the initial tests already showed, the implementation has multiple flaws; one major issue is already described in an issue on GitHub and another independent error is described in the full version. Both plots show that HsuPC is more than twice as fast as OGDF and that UFPC is again close to two times faster than HsuPC. Zanetti's runtime is roughly the same as that of HsuPC, while converting its Java code to C++ brings the runtime down close to that of UFPC.

As OGDF is the slowest, we use it as baseline to calculate the speedup of the other implementations. Figure 8a shows that the runtime improvement for all three implementations is the smallest for small restrictions, quickly increasing to the final values of roughly 0.4 times the runtime of OGDF for HsuPC and 0.25 for both CppZanetti and UFPC. Figure 8b shows the speedup depending on the length of the terminal path. For very short terminal paths (which are common in our datasets), both implementations are again close; but already for slightly longer terminal paths UFPC quickly speeds up to being roughly 20% faster than CppZanetti. This might be because creating the central node in step 5 is more complicated for UFPC, as the data structure without edge objects does not allow arbitrarily adding and removing edges (which is easier for HsuPC) and allowing circular restrictions forces UFPC to also pay attention to various special cases (which are not necessary for PQ-trees).

5 Conclusion

In this paper we have presented the first fully generic and correct implementations of PC-trees. One implementation follows the original description of Hsu and McConnell [14, 13], which contains several subtle mistakes in the description of the labeling and the computation of the terminal path. This may be the reason why no fully generic implementation has been available so far. A corrected version that also includes several small simplifications is described in the full version of this paper.

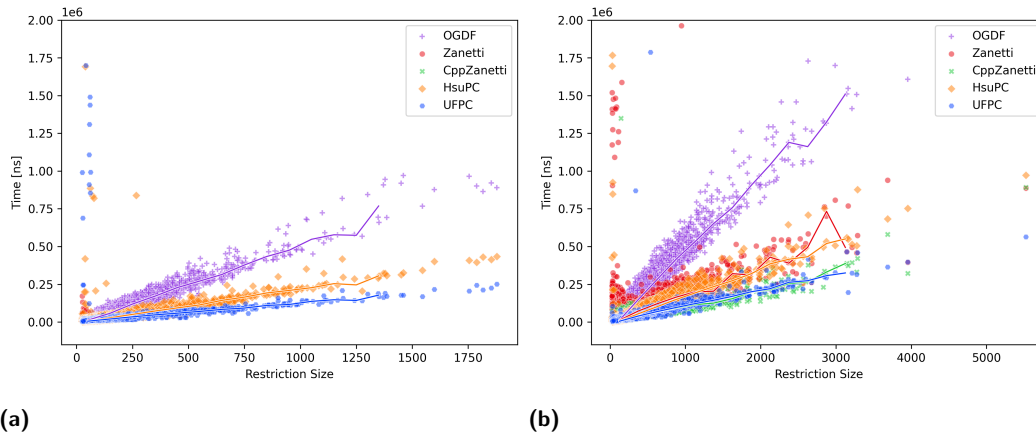

Figure 7 Runtime of individual restrictions of DIR-PLAN with OGDF, Zanetti and our implementations for graphs of size (a) $m = 2n$ and (b) $m = 3n - 6$.

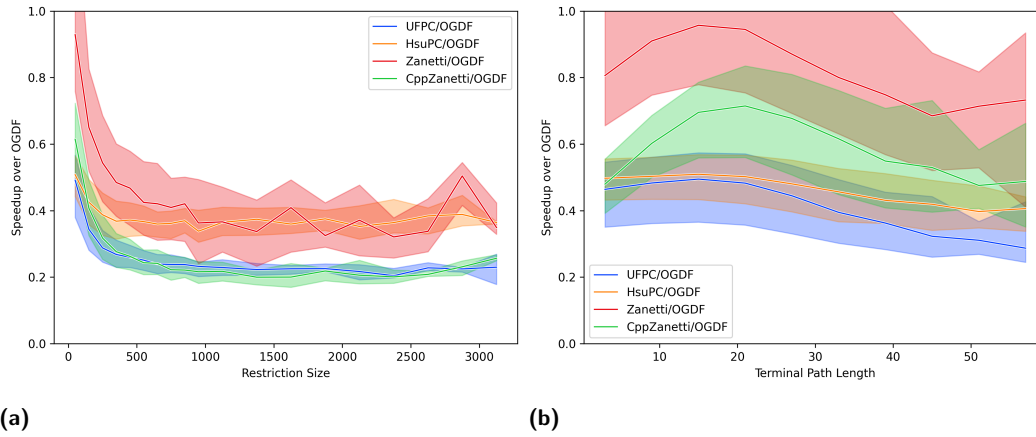

Figure 8 Median performance increase depending on (a) the size of the restriction and (b) the terminal path length, with OGDF as baseline. The shaded areas show the interquartile range.

Furthermore, we provided a second, alternative implementation, using Union-Find to replace many of the complications of Hsu and McConnell's original approach. Technically, this increases the runtime to $O((|R| + p) \cdot \alpha(|L|))$, where α is the inverse Ackerman function. In contrast, our evaluations show that the Union-Find-based approach is even faster in practice, despite the worse asymptotic runtime.

Our experimental evaluation with a variety of other implementations reveals that surprisingly few of them seem to be fully correct. Only three other implementation have correctly handled all our test cases. The fastest of them is the PQ-tree implementation of OGDF, which our Union-Find-based PC-tree implementation beats by roughly a factor of 4. Interestingly, the Java implementation of PQR-trees by Zanetti achieves a similar speedup once ported to C++. However, Zanetti's Java implementation is far from correct and it is hard to say whether it is possible to fix it without compromising its performance.

Altogether, our results show that PC-trees are not only conceptually simpler than PQ-trees but also perform well in practice, especially when combined with Union-Find. To put the speedup of factor 4 into context, we compared the OGDF implementations of the

planarity test by Booth and Lueker and the one by Boyer and Myrvold on our graph instances. The Boyer and Myrvold implementation was roughly 40% faster than the one based on Booth and Lueker's algorithm. Replacing the PQ-trees, which are the core part of the latter, by an implementation that is 4 time faster, might make this planarity test run faster than the one by Boyer and Myrvold. We leave a detailed evaluation, also taking into account the embedding generation, which our PC-tree based planarity test not yet provides, for future work.

Abstract

The problem of *nearest-neighbor classification* is a fundamental technique in machine-learning. Given a training set P of n labeled points in \mathbb{R}^d , and an approximation parameter $0 < \varepsilon \leq \frac{1}{2}$, any unlabeled query point should be classified with the class of any of its ε -approximate nearest-neighbors in P . Answering these queries efficiently has been the focus of extensive research, proposing techniques that are mainly tailored towards resolving the more general problem of ε -approximate nearest-neighbor search. While the latest can only hope to provide query time and space complexities dependent on n , the problem of nearest-neighbor classification accepts other parameters more suitable to its analysis. Such is the number k_ε of ε -border points, which describes the complexity of boundaries between sets of points of different classes.

This paper presents a new data structure called Chromatic AVD. This is the first approach for ε -approximate nearest-neighbor classification whose space and query time complexities are only dependent on ε , k_ε and d , while being independent on both n and Δ , the spread of P .

1 Introduction

Non-parametric classification is a fundamental technique in machine-learning. In this context, we are given a *training set* P consisting of n points in a metric space $(\mathcal{X}, \mathbf{d})$, with domain \mathcal{X} and distance function $\mathbf{d} : \mathcal{X}^2 \rightarrow \mathbb{R}^+$. Additionally, the training set is partitioned into a finite set of *classes* C by associating each point $p \in P$ with a *label* $l(p)$, which indicates the class to which it belongs. Given an *unlabeled* query point $q \in \mathcal{X}$, the goal of a *classifier* is to predict q 's label using the training set P .

The *nearest-neighbor rule* is among the best-known classification techniques [15]. It assigns a query point the label of its closest point in P according to the defined metric. This technique exhibits good classification accuracy both experimentally and theoretically [12, 13, 34], but it is often criticized due to its high space and time complexities. Despite the advent of more sophisticated techniques (*e.g.*, support-vector machines [11] and deep neural networks [32]), nearest-neighbor classification is still widely used in practice [9, 22, 26], proving its value in constructing resilient defense strategies against adversarial [27] and poisoning [29] attacks, as well as in achieving interpretable machine-learning models [28, 33].

As mentioned, the criticism towards nearest-neighbor classification lingers on the bases of exceedingly high query times and space requirements. The standard approach to answering these queries, even approximately, involves storing the entire training set P or at least a

sufficiently large part of it. This implies that the time spent to answer such queries depends to a large degree on the size and dimensionality of the training set of points stored, limiting the use of nearest-neighbor classification on large-scale applications.

In this paper we explore efficient methods for approximate nearest-neighbor classification. We are given the training set P and an approximation parameter $0 < \varepsilon \leq \frac{1}{2}$. The objective is to construct a data structure so that given any query point q , it is possible to efficiently classify q according to any valid ε -approximate nearest-neighbor in P . Throughout, we take the domain \mathcal{X} to be d -dimensional Euclidean space \mathbb{R}^d , the distance function d to be the L_2 norm, and we assume that the dimension d is a fixed constant, independent of n and ε .

1.1 Related Work

In the standard ε -approximate nearest-neighbor searching (ε -ANN), the objective is to compute a point whose distance from the query point is within a factor of $1 + \varepsilon$ of the true nearest neighbor. This problem, referred to as “standard ANN” throughout, has been widely studied. In *chromatic ε -ANN search* the objective is to return just the class (or more visually, the “color”) of any such point [6, 18]. We refer to this as ε -classification.

Clearly, chromatic ANN queries can be reduced to standard ANN queries. Hence, most of the efficiency improvements in nearest-neighbor classification have arisen from improvements to the standard ANN problem. While standard ANN has been well studied in high-dimensional spaces (see, e.g., [1]), in constant-dimensional Euclidean space, the most efficient data structures involve variants of the *Approximate Voronoi Diagram* (or AVD) (see [3–5, 23]). Arya *et al.* [6] proposed a data structure specifically tailored for ε -classification. Unfortunately, this work was based on older technology, and its results are not competitive when compared to the most recent advances on standard ANN search via AVDs.

All previous results have query and space complexities that depend on n , the total size of the training set P . In many cases, a much smaller portion of the training set may suffice to correctly ε -classify queries. Think of the boundaries between adjacent Voronoi cells of points of different classes (see Figure 1a). The points that define these boundaries are known as *border points*. Throughout, let k denote the number of such border points in P (clearly, $k \leq n$, and hopefully, $k \ll n$). Furthermore, the notion of border points can be generalized to the context of ε -classification (see Section 2 for a formal definition). Thus, denote k_ε as the number of ε -border points, where $k \leq k_\varepsilon \leq n$. Ideally, we would like the query and space complexities of answering chromatic ε -ANN queries to depend on k_ε instead of n .

In order to achieve this goal, previous research has focused on reducing the training set P by selecting a subset $R \subseteq P$. Once R is computed, it is assumed that this subset will be used to build a standard AVD for ε -classification. Research in this area is vast, but there are two broad approaches, depending on the type and size of the computed subsets, and the classification guarantees provided.

Heuristics: Most of the work has focused on proposing heuristics to compute smaller training sets $R \subseteq P$. These are often known as *condensation algorithms*, and the literature on these is extensive (see [25, 35] for comprehensive surveys, and [2, 7, 8, 21, 24, 30] for some of the proposed algorithms). The most recent condensation algorithms [16, 17, 20] show that it is possible to compute subsets of P of size $\mathcal{O}(k)$ in $\mathcal{O}(n^2)$ time. However, when AVDs are built from these subsets, the resulting data structures are likely to introduce classification errors [19], especially for query points that should be easily ε -classified. Thus, while often used in practice, these approaches do not guarantee that chromatic ε -ANN queries are answered correctly.

Coresets: Recent results propose a technique to compute a coreset for ε -classification [19].

A coreset R guarantees that every query point will be correctly classified when assigning the class of the point of R returned by the AVD. That is, for any query $q \in \mathbb{R}^d$, the point of R returned by the AVD belongs to the same class as one of q 's ε -approximate nearest-neighbors in P . Unfortunately, the size of the computed coreset can be as large as $\mathcal{O}((k \log \Delta)/\varepsilon^{d-1})$, where Δ is the spread¹ of P .

1.2 Contributions

From the previous section, we have seen that existing approaches for ε -classification achieve only one of the following goals:

- The size of the resulting data structure is dependent only on ε , k_ε (the number of ε -border points) and d , while being independent from n and Δ .
- It guarantees correct ε -classification for any query point.

The main result of this paper is an approach that achieves both goals. We propose a new data structure built specifically to answer chromatic ε -ANN queries over the training set P , which we call a *Chromatic AVD*. Given any query point $q \in \mathbb{R}^d$, this data structure returns the class to be assigned to q , which matches the class of at least one of q 's ε -approximate nearest-neighbors in P . More generally, our data structure returns a set of classes such that there is an ε -approximate nearest-neighbor of q from each of these classes.

Therefore, the Chromatic AVD can be used to correctly ε -classify any query point. The main result of this work is summarized in the following theorem, expressed in the form of a space-time tradeoff based on a parameter γ .

► **Theorem 1.** *Given a training set P of n labeled points in \mathbb{R}^d , an error parameter $0 < \varepsilon \leq \frac{1}{2}$, and a separation parameter $2 \leq \gamma \leq \frac{1}{\varepsilon}$. Let k_ε be the number of ε -border points of P . There exists a data structure for ε -classification, called *Chromatic AVD*, with:*

$$\text{Query time: } \mathcal{O}\left(\log(k_\varepsilon \gamma) + \frac{1}{(\varepsilon \gamma)^{\frac{d-1}{2}}}\right) \quad \text{Space: } \mathcal{O}\left(k_\varepsilon \gamma^d \log \frac{1}{\varepsilon}\right).$$

Which can be constructed in time $\tilde{\mathcal{O}}\left(\left(n + k_\varepsilon / (\varepsilon \gamma)^{\frac{3}{2}(d-1)}\right) \gamma^d \log \frac{1}{\varepsilon}\right)$.

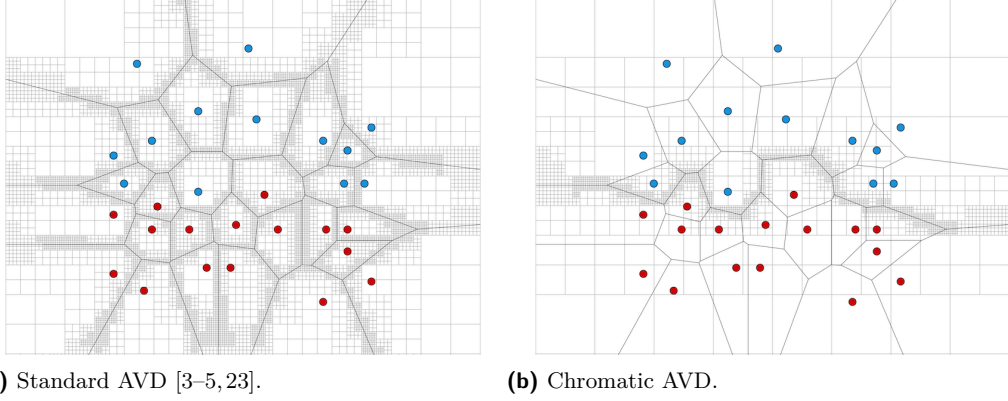

By setting γ to either of its extreme values, we obtain the following query times and space complexities.

► **Corollary 2.** *The separation parameter γ describes the tradeoffs between the query time and space complexity of the Chromatic AVD. This yields the following results:*

$$\begin{aligned} \text{If } \gamma = 2 & \longrightarrow \text{Query time: } \mathcal{O}\left(\log k_\varepsilon + \frac{1}{\varepsilon^{\frac{d-1}{2}}}\right) & \text{Space: } \mathcal{O}\left(k_\varepsilon \log \frac{1}{\varepsilon}\right). \\ \text{If } \gamma = \frac{1}{\varepsilon} & \longrightarrow \text{Query time: } \mathcal{O}\left(\log \frac{k_\varepsilon}{\varepsilon}\right) & \text{Space: } \mathcal{O}\left(\frac{k_\varepsilon}{\varepsilon^d}\right). \end{aligned}$$

The approach towards constructing this data structure is hybrid, combining a quadtree-induced partitioning of space (leveraging similar techniques to the ones used for standard AVDs), with the construction of coresets for only some cells of this partition. All other cells can be discarded, and a new quadtree can be built with only the remaining cells. The final size of the tree is bounded in terms of k_ε . This technique allows us to maintain coresets in the most critical regions of space, and thus, avoiding the dependency on the spread of P .

¹ The *spread* of a point set is defined to be the ratio between the largest and smallest pairwise distances.

■ **Figure 1** Examples of the space partitioning achieved by any standard AVD, compared to the Chromatic AVD data structure proposed in this paper. Our approach subdivides the space around the boundaries defined by the ε -border points, while ignoring other boundaries.

2 Preliminary Ideas and Intuition

Preliminaries. First, we need to introduce some preliminary definitions and notations that are relevant to the results presented in the remaining of the paper. Given any point $q \in \mathbb{R}^d$, denote its nearest-neighbor as $\text{nn}(q)$, and the distance between them by $d_{\text{nn}}(q) = d(q, \text{nn}(q))$.

Additionally, let's introduce a few concepts and related properties that will prove useful in the construction of the Chromatic AVD. These are Well-Separated Pair Decompositions [10] (WSPDs), Quadtrees [14, 31], and Approximate Voronoi Diagrams [3-5, 23] (AVDs).

Well-Separated Pair Decompositions: Given the point set P , and a separation factor $\sigma > 2$, we say that two sets $X, Y \subseteq P$ are *well separated* if they can be enclosed within two disjoint balls of radius r , such that the distance between the centers of these balls is at least σr . We say that X and Y form a *dumbbell*, where both sets are the *heads* of this dumbbell. Consider the line segment that connects the centers of both balls, and let z and ℓ be the center and length of this line segment, respectively (*i.e.*, the center and the length of the dumbbell). The following properties hold when $\sigma > 4$, for $x \in X$ and $y \in Y$:

$$d(x, z) < \ell \quad \ell < 2d(x, y) \quad \ell > d(x, y)/2.$$

Furthermore, a well-separated pair decomposition of P is defined as a set $\mathcal{D} = \{(X_i, Y_i)\}_i$ where every X_i and Y_i are well separated, and for every two distinct points $p_1, p_2 \in P$ there exists a unique pair $\mathcal{P} = (X, Y) \in \mathcal{D}$ such that $p_1 \in X$ and $p_2 \in Y$, or vice-versa. It is known how to construct a WSPD of P with $\mathcal{O}(\sigma^d n)$ pairs in $\mathcal{O}(n \log n + \sigma^d n)$ time.

Quadrees: These are tree data structures that provide a hierarchical partition of space. Each node in this tree consists of a d -dimensional hypercube, where non-leaf nodes partition its corresponding hypercube into 2^d equal parts. The root of this tree corresponds to the $[0, 1]^d$ hypercube. We will use a variant of this structure called a *balanced box-decomposition tree* (BBD tree) [6]. Such data structure satisfies the following properties:

1. Given a point set P , such a tree can be built in $\mathcal{O}(n \log n)$ time, having space $\mathcal{O}(n)$ such that each leaf node contains at most one point of P .
2. Given a collection \mathcal{U} of n quadtree boxes in $[0, 1]^d$, such a tree can be built in $\mathcal{O}(n \log n)$ time, having $\mathcal{O}(n)$ nodes such that the subdivision induced by its leaf cells is a refinement of the subdivision induced by the Quadtree boxes in \mathcal{U} .
3. Given the trees from 1 or 2, it is possible to determine the leaf cell containing any arbitrary query point q in $\mathcal{O}(\log n)$ time.

Approximate Voronoi Diagram: Generally, AVDs are quadtree-based data structures that can be used to efficiently answer ANN queries. The partitioning of space induced by this data structure is often generated from a WSPD of P . Additionally, every leaf cell w of this quadtree has an associated set of ε -representatives R_w that has the following property: for any query point $q \in w$, at least one point in R_w is one of q 's ε -approximate nearest-neighbors in P .

New Ideas and Intuitions. Consider the space partitioning induced by a standard AVD, as previously described. By construction, any leaf cell w of this partition has an associated set of ε -representatives R_w . Evidently, for the purposes of ε -classification, the most important information related to this leaf cell comes from the classes of the points in R_w , and not necessarily the points themselves.

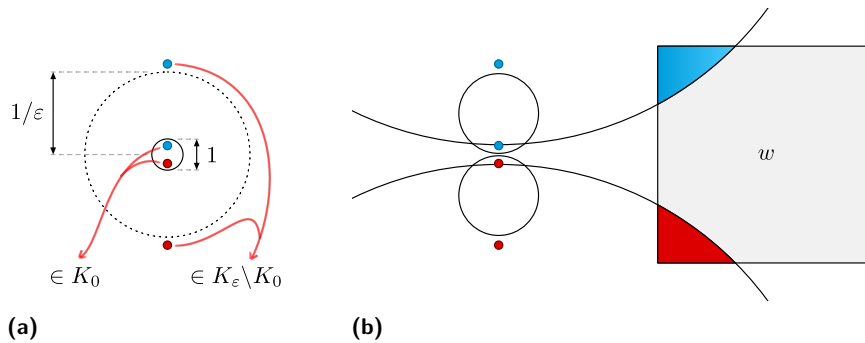

This leads to an initial approach to simplify an AVD. We distinguish between two types of leaf cells, based on the points inside their corresponding ε -representative sets. Any leaf cell w is said to be:

- **Resolved:** If every point in R_w belongs to the same class.
- **Ambiguous:** Otherwise, if at least two points in R_w belong to different classes.

Clearly, there is no need to store the set of ε -representatives of any resolved leaf cell, as instead, we can simply mark the leaf cell w as *resolved with the class* that is shared by all the points in R_w . This effectively reduces the space needed for such cells to be constant.

Furthermore, it seems that the bulk of the “work” needed to decide the class of a given query point can be carried out by the ambiguous leaf cells, along with some groupings of resolved leaf cells. The data structure presented in this paper, called Chromatic AVD, builds upon this hypothesis.

Additionally, we formally define the set of ε -border points of the training set P . This set, denoted as K_ε , contains any point $p \in P$ for which there exist some $q \in \mathbb{R}^d$ and $\bar{p} \in P$, such that p and \bar{p} are ε -approximate nearest-neighbors of q , and both belong to different classes. Denote $k_\varepsilon = |K_\varepsilon|$ as the number of ε -border points of the training set P . Note that $K_\varepsilon \subseteq K_{\varepsilon'}$ if and only if $\varepsilon \leq \varepsilon'$. Additionally, note that K_0 defines the set of (exact) border points of P , where $k = k_0$.

■ **Figure 2** Intuition to think that K_ε (and not K_0) is needed to ε -classify some query points.

This generalization of the definition of border points seems better suited to analyze the problem of ε -classification, as illustrated in Figure 2. Figure 2b shows the ε -approximate bisectors between the two closest and two farthest points (the first two belong to K_0 , while the others belong to K_ε but not K_0). A hypothetical leaf cell w is sufficiently separated from the only two exact border points, but intersects the ε -approximate bisectors between the

two farthest points. This implies that inside the cell w lie query points that *can only* be ε -classified with one class, and others with the other class, forcing this cell to be ambiguous. This suggests that K_0 is insufficient to account for the necessary complexity of ε -classification.

3 Chromatic AVD Construction

In this section, we describe our method for constructing the proposed Chromatic AVD. The following overview outlines the necessary steps followed to construct this data structure.

- *The Build step* (Section 3.1): Consists of building an initial quadtree-based subdivision of space, designed specifically to achieve the properties described in Lemma 3.
- *The Reduce step* (Section 3.2): Seeks to identify the leaf cells of the initial subdivision that are relevant for ε -classification, as well as those that can be ignored or simplified. This process consists of the following substeps.
 - Computing the sets of ε -representatives for every leaf cell of the initial quadtree.
 - Based on these sets, marking the leaf cells as either ambiguous or resolved.
 - Selecting those leaf cells which are relevant for ε -classification.
 - Building a new quadtree-based subdivision using the previously selected leaf cells.

3.1 The Build Step

We begin by constructing the tree T_{init} using similar methods as the ones used to construct a standard AVD. Thus, the first step is to compute a well-separated pair decomposition \mathcal{D} of P using a constant separation factor of $\sigma > 4$. While the standard construction would use all pairs in this decomposition, for the purpose of the Chromatic AVD, we filter \mathcal{D} to only keep bichromatic pairs. Denote $\mathcal{D}' \subseteq \mathcal{D}$ to be the set of bichromatic pairs in \mathcal{D} , where a pair $\mathcal{P} \in \mathcal{D}$ is said to be bichromatic if and only if the dumbbell heads separate points of different classes. Note that \mathcal{D}' can be computed similarly to \mathcal{D} , using a simple modification of the well-known algorithm for computing WSPDs [10] (the details are left to the reader).

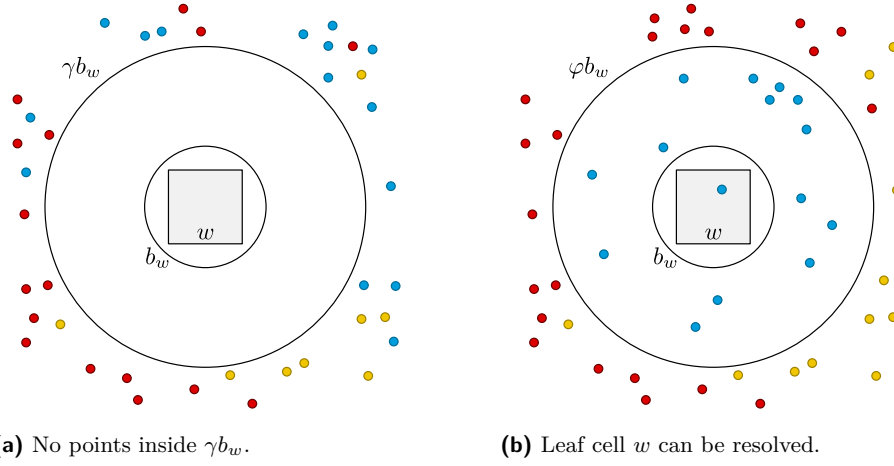

Next, we compute an initial set of quadtree boxes $\mathcal{U}(\mathcal{P})$ for every pair in \mathcal{D}' as follows. This construction depends on two constants c_1 and c_2 whose assignment will be described later in this section. For $0 \leq i \leq \lceil \log(c_1 1/\varepsilon) \rceil$, we define $b_i(\mathcal{P})$ as the ball centered at z of radius $r_i = 2^i \ell$. Thus, this set of balls involves radius values ranging from ℓ to $\Theta(\ell/\varepsilon)$. For each such ball $b_i(\mathcal{P})$, let $\mathcal{U}_i(\mathcal{P})$ be the set of quadtree boxes of size $r_i/(c_2 \gamma)$ that overlap the ball. Let $\mathcal{U}(\mathcal{P})$ denote the union of all these boxes over all the $\mathcal{O}(\log 1/\varepsilon)$ values of i .

After performing this process on every pair of the filtered decomposition \mathcal{D}' , take the union of all these boxes denoted as $\mathcal{U} = \bigcup_{\mathcal{P} \in \mathcal{D}'} \mathcal{U}(\mathcal{P})$. Finally, build the tree T_{init} from the set of quadtree boxes \mathcal{U} , leveraging property 2 of quadtrees described in Section 2. Additionally, for each class i in the training set, build an auxiliary tree T_{aux}^i from the point set P_i (i.e., the points of P of that are labeled with class i), using property 1 of quadtrees. These auxiliary trees will be used together with T_{init} in order to build our final tree T , the Chromatic AVD.

While the standard AVD construction satisfies that all resulting leaf cells of the tree have certain separation properties from the points of set P , the same is not true for tree T_{init} . However, the following result describes a relaxed notion of the separation properties, now based on the classes of the points, which are achieved by T_{init} .

► **Lemma 3** (Chromatic Separation Properties). *Given two separation parameters $\gamma > 2$ and $\varphi > 3$, every leaf cell w of the tree T_{init} satisfies at least one of the following separation properties, where b_w is the minimum enclosing ball of w :*

- (i) $P \cap \gamma b_w$ is empty (see Figure 3a), and hence b_w is concentrically γ -separated from P .
- (ii) The cell w can be resolved with the classes present inside $P \cap \varphi b_w$ (see Figure 3b).

■ **Figure 3** Basic separation properties achieved by during the construction of the Chromatic AVD.

Proof. Let w be any leaf cell of T_{init} , with center c_w and side length s_w , where its (minimum) enclosing ball b_w has radius $r_w = \sqrt{d}/2 s_w$ and shares the center c_w . Additionally, let $x_i \in P_i$ be a 1-approximate nearest-neighbor of c_w among the points of P of class i . In other words, for each class of points we use the auxiliary trees T_{aux}^i to compute a 1-approximate nearest-neighbor of c_w . A few cases unfold from here:

The first case is rather simple. If $4\gamma\varphi b_w \cap \{x_i\}_i = \emptyset$, knowing that the points x_i are 1-approximate nearest-neighbors of c_w , this implies that the ball $2\gamma\varphi b_w$ is empty (*i.e.*, we know that $2\gamma\varphi b_w \cap P = \emptyset$). Clearly, this means the first separation property holds for w .

Consider the case when $|4\gamma\varphi b_w \cap \{x_i\}_i| = 1$, and let i be the class of the point that lies inside $4\gamma\varphi b_w$. Following similar arguments to the previous case, this implies that only points of class i could potentially lie inside of $2\gamma\varphi b_w$. Then, check if x_i lies inside the smaller ball expansion $2\gamma b_w$. If not, we know that γb_w is empty (*i.e.*, $\gamma b_w \cap P = \emptyset$), making the first separation property hold for w . Otherwise, we know that $2\gamma b_w$ contains at least one point (*i.e.*, x_i), and additionally we know that $2\gamma b_w$ is φ -separated from points of all other classes but i (as $2\gamma\varphi b_w$ only contains points of class i). Given that $\varphi > 3$, the nearest neighbor of every query point inside $2\gamma b_w$ has class i . Therefore, w can be resolved with class i (namely, $C_w = \{i\}$), satisfying the second separation property.

Lastly, it is possible that $|4\gamma\varphi b_w \cap \{x_i\}_i| \geq 2$. However, it is possible to show that if this is the case, it immediately implies that every point inside $4\gamma\varphi b_w$ actually lies inside of some ball b'_w which is β -separated from w (see Figure 5a), where $\beta = 1/\varepsilon$. The details of this part of the proof are omitted, and left in the Appendix A, as the arguments are similar to the ones described in [5]. However, proving this provides insights into how to set constants c_1 and c_2 , where $c_1 \geq 3(1 + \varepsilon)$ and $c_2 \geq 20\varphi\sqrt{d}$.

Finally, if $|4\gamma\varphi b_w \cap \{x_i\}_i| \geq 2$, we know all points inside $4\gamma\varphi b_w$ are β -separated from w . We can now proceed similarly to the previous case, by checking if one of the computed 1-approximate nearest-neighbors lies inside the ball $2\gamma b_w$. If $2\gamma b_w \cap \{x_i\}_i = \emptyset$ we know that γb_w is empty (*i.e.*, $\gamma b_w \cap P = \emptyset$), making the first separation property hold for w . Otherwise, note that b'_w is completely contained inside $2\gamma(1 + \varepsilon)b_w$. Given that $\varphi > 3$, it is possible to show that for any query point in w , all points in b'_w are valid ε -approximate nearest neighbors. This implies that we can resolve w with the class of any of the points inside of b'_w , thus satisfying the second separation property. In particular, we mark w as resolved with every class present in the inner cluster b'_w , namely, $C_w = \{l(p) \mid \forall p \in b'_w \cap P\} = \{i \mid x_i \in 4\gamma\varphi b_w\}$. ◀

3.2 The Reduce Step

From the initial partitioning as described in Lemma 3, every leaf cell w of T_{init} is either concentrically γ -separated from P (i.e., $\gamma b_w \cap P = \emptyset$), or it is already marked as resolved. For every leaf cell w in the first case, we will compute a set of ε -representatives by leveraging the *concentric ball lemma* (see Lemma 5.1 in [5]). It states that there exists a set R_w of ε -representatives for w of size $\mathcal{O}(1/(\varepsilon\gamma)^{\frac{d-1}{2}})$, and provides a way to compute such set.

Instead of directly applying this result, we use it to compute a set of $\varepsilon/3$ -representatives for any leaf cell w that is yet unresolved. Essentially, this leads to the same asymptotic upper-bound on the size of R_w , meaning that $|R_w| = \mathcal{O}(1/(\varepsilon\gamma)^{\frac{d-1}{2}})$. Once R_w is computed, we can proceed to mark w as either resolved or ambiguous as follows.

Procedure to Mark Leaf Cells. For every leaf cell w , this procedure marks w as either resolved or ambiguous, following a few defined cases that unfold from the contents of the set R_w of points selected as representatives for w . Let $r_w^- = \varepsilon(1-\gamma)r_w/3$.

1. If all the points in R_w belong to the same class.

For every point $p \in R_w$ and class $i \in C$, compute a 1-approximate nearest-neighbor of p among the points of P_i , denoted as the point $x_{p,i}$. If $d(p, x_{p,i}) < r_w^-$, then add $x_{p,i}$ to R_w . It is easy to show that $x_{p,i}$ would also be an ε -representative for w . Repeat this for every point originally in R_w , and every class in the training set.

 - a. If any point $x_{p,i}$ was added to R_w , proceed with *Case 2*.
 - b. Otherwise, mark w as resolved with the class of the points in R_w . Namely, let i be the class of every point in R_w , then $C_w = \{i\}$.
2. If R_w contains points of more than one class.

Before proceeding, we will do some basic pruning of the set R_w . For every class i , compute a *net* among the points of R_w of class i , using a radius of r_w^- to compute the net, and replace the points of class i in R_w with the computed net. It is easy to see that the remaining points of R_w are a set of ε -representatives of w , and that every two points in R_w of the same class are at distance at least r_w^- .

 - a. If the diameter of R_w is less than r_w^- , it is easy to prove that all the points in R_w are ε -representatives of any point inside b_w . Therefore, w can be labeled as resolved with the class of all of the points in R_w . That is, $C_w = \{l(p) \mid \forall p \in R_w\}$.
 - b. If the diameter is greater than or equal to r_w^- , w is marked as ambiguous.

Let \mathcal{A} and \mathcal{R} be the sets of ambiguous and resolved leaf cells of T_{init} , respectively. We will use some of these cells to build the Chromatic AVD, while ignoring the remaining cells.

Consider the set of resolved leaf cells \mathcal{R} , we partition this set into two subsets \mathcal{R}_b and \mathcal{R}_i (named *boundary* and *interior* resolved leaf cells, respectively). We say a resolved leaf cell w_1 belongs to \mathcal{R}_b , if and only if there exists another resolved leaf cell w_2 adjacent to w_1 , such that $C_{w_2} \setminus C_{w_1} \neq \emptyset$. Every other resolved leaf cell belongs to \mathcal{R}_i (i.e., $\mathcal{R}_i = \mathcal{R} \setminus \mathcal{R}_b$). Note that both sets \mathcal{R}_b and \mathcal{R}_i can be identified by a simple traversal over the leaf cells of T_{init} , using linear time in the size of the tree².

Finally, we build a new tree T from the set of ambiguous and boundary resolved leaf cells $\mathcal{A} \cup \mathcal{R}_b$. By well-known construction methods of quadrees, as described in Section 2, the leaf cells of T either belong to $\mathcal{A} \cup \mathcal{R}_b$, or are “Steiner” leaf cells added during the construction of T that cover the remainder of the space that is uncovered by $\mathcal{A} \cup \mathcal{R}_b$.

² Two leaf cells are adjacent if and only if a vertex of one of the cells “touches” the other cell. This implies that the number of adjacency relations (i.e., edges in the implicit graph where the leaf cells are the nodes) is $\mathcal{O}(2^d m)$, where m is the number of leaf cells of the tree T_{init} .

► **Lemma 4.** *For any leaf cell w in the tree T such that $w \notin \mathcal{A} \cup \mathcal{R}_b$, w must cover a space that is also covered by a collection of leaf cells of T_{init} , all of which are resolved with the same set of classes C_w .*

Proof. This becomes apparent from the construction of T . In the new tree T , consider any leaf cell w of T that is not part of $\mathcal{A} \cup \mathcal{R}_b$ (i.e., a “Steiner” leaf cell added during the construction of the tree). Now, recall that the leaf cells of both T and T_{init} are a partitioning of (the same) space, which means that we can define $\mathcal{W}_w = \{w' \in T_{\text{init}} \mid w \cap w' \neq \emptyset\}$ as the collection of leaf cells of T_{init} that cover the same space covered by w .

Now, for any fixed w of T , it is easy to see that any two leaf cells $w_1, w_2 \in \mathcal{W}_w$ must be resolved with the same set of classes. Otherwise, at least one of these two would be part of the set \mathcal{R}_b , which would be a contradiction to the fact that w is a “Steiner” leaf cell of T . Therefore, any query inside w can be answered with the classes $C_w = C_{w_1} = C_{w_2}$, and this can be determined during preprocessing by a single query on T_{init} (e.g., finding the leaf cell of T_{init} that contains the center c_w of w is sufficient to know the contents of C_w). ◀

This implies that after building tree T , and with some extra preprocessing to resolve the “Steiner” leaf cells of the tree, we can use the resulting data structure to correctly answer chromatic ε -approximate nearest-neighbor queries over the training set P . In other words, T can be used to answer ε -classification queries over P . We call this data structure T the Chromatic AVD.

► **Lemma 5.** *The construction of T takes $\tilde{O}(n\gamma^d \log \frac{1}{\varepsilon})$ time.*

Proof. Let’s analyze the total time needed to build our Chromatic AVD, namely the tree T , by analyzing the time required to perform each step of the construction.

- Building T_{init} has essentially the same complexity of building any standard AVD [3–5, 23]. This means that constructing T_{init} takes $\mathcal{O}(m \log m)$ time, where $m = n\gamma^d \log \frac{1}{\varepsilon}$. Note that during the construction, while computing the set of ε -representatives of each leaf cell, each leaf cell can already be marked as either ambiguous or resolved.
- Building the auxiliary trees T_{aux}^i for every class i , takes $\mathcal{O}(n \log n)$ time, as the number of classes of P is considered to be a constant. Recall that because these trees are only used to for 1-ANN queries, they only need to be standard Quadrees, and not AVDs.
- Identifying the set \mathcal{R}_b requires a traversal over the leaf-level partitioning of the space, which is linear in terms of the number of cells. Therefore, this step requires $\mathcal{O}(m)$ time.
- Once the sets of ambiguous and boundary resolved leaf cells are identified, namely, the sets \mathcal{A} and \mathcal{R}_b , the final tree T can be built. Roughly, this step takes $\mathcal{O}(m \log m)$ time.
- Finally, we must resolve the “Steiner” leaf cells of T , which can be done by a single query over T_{init} , each taking $\mathcal{O}(\log m)$ time. Thus, this step takes $\mathcal{O}(m \log m)$ total time.

All together, the total construction time is dominated by the first step. Therefore, the time required to construct T is $\mathcal{O}(m \log m) = \tilde{O}(m) = \tilde{O}(n\gamma^d \log \frac{1}{\varepsilon})$. ◀

4 Tree-size Analysis

4.1 Initial Size Bounds

Define the set of important leaf cells \mathcal{I} of the tree T_{init} as those leaf cells w for which there exists two ε -border points inside $\rho\gamma b_w$ for some constant ρ , such that the distance between these points is lower-bounded by $\Omega(\varepsilon\gamma r_w)$. Formally, we define this set as $\mathcal{I} = \{w \in T_{\text{init}} \mid \exists p_1, p_2 \in \rho\gamma b_w \cap K_\varepsilon, d(p_1, p_2) = \Omega(\varepsilon\gamma r_w)\}$.

► **Lemma 6.** *The number of important leaf cells of T_{init} is $|\mathcal{I}| = \mathcal{O}(k_\varepsilon \gamma^d \log \frac{1}{\varepsilon})$.*

Proof. This proof follows from a charging argument on the set K_ε of ε -border points of P . More specifically, consider a well-separated pair decomposition \mathcal{D}'' of K_ε with constant separation factor of $\sigma > 4$, the charging scheme assigns every important leaf cell $w \in \mathcal{I}$ to a pair of \mathcal{D}'' . Recall that \mathcal{D}'' can generally be considered to have $\mathcal{O}(k_\varepsilon)$ pairs, where $k_\varepsilon = |K_\varepsilon|$. It is important to note that both K_ε and \mathcal{D}'' need not be computed.

Given that $w \in \mathcal{I}$, we know there exist two points $p_1, p_2 \in \rho\gamma b_w \cap K_\varepsilon$. Let $\mathcal{P} \in \mathcal{D}''$ be the pair of \mathcal{D}'' that contains both p_1 and p_2 , each in one of its dumbbell heads. We then charge w to the pair \mathcal{P} . Denote z and ℓ to be the center and length of \mathcal{P} , respectively, we know the following. First, note that the distance from c_w (the center of w) to z is $d(c_w, z) \leq \rho\gamma r_w + \ell$. Additionally, we know that $\ell \geq d(p_1, p_2)/2 = \Omega(\varepsilon\gamma r_w)$ by the properties of WSPDs described in Section 2. Therefore, this implies that the ratio $d(c_w, z)/\ell = \mathcal{O}(1/\varepsilon)$.

Finally, fix some pair $\mathcal{P} \in \mathcal{D}''$ with center z and length ℓ , and consider all important leaf cells according to their distance to z . For any value of $i \in [0, 1, \dots, \mathcal{O}(\log 1/\varepsilon)]$, consider all leaf cells that can charge \mathcal{P} whose distance to z is between $2^i \ell$ and $2^{i+1} \ell$. From our previous analysis, $r_w \geq d(c_w, z)/\rho\gamma \geq 2^i \ell/\rho\gamma$. By a simple packing argument, the number of such leaf cells is at most $\mathcal{O}(\gamma^d)$. Thus, a total of $\mathcal{O}(\gamma^d \log 1/\varepsilon)$ cells can charge \mathcal{P} . Note that no leaf cell whose distance to z is $\Omega(\ell/\varepsilon)$ can charge \mathcal{P} , as it would contradict the fact that both p_1 and p_2 are separated by a distance of $\Omega(\varepsilon\gamma r_w)$. Finally, the proof follows by knowing that there are at most $\mathcal{O}(k_\varepsilon)$ pairs in \mathcal{D}'' . ◀

► **Lemma 7.** *Every ambiguous leaf cell of T_{init} is important, namely $\mathcal{A} \subseteq \mathcal{I}$.*

Proof. Consider any ambiguous leaf cell $w \in \mathcal{A}$ of the tree T_{init} . Knowing that w is ambiguous implies that there must exist some point $q \in \frac{\gamma}{2}b_w$ for which two of the ε -representatives of w are valid ε -approximate nearest neighbors for q , both points belong to different classes, and the distance between them is $\Omega(\varepsilon\gamma r_w)$. Formally, denote these points as $p_1, p_2 \in P$ such that $l(p_1) \neq l(p_2)$, $d(p_1, p_2) \geq \varepsilon(1-\gamma)r_w/4$, and $d(q, p_1), d(q, p_2) \leq (1+\varepsilon)d_{\text{nn}}(q)$.

We will see now how to bound the distance from c_w to any of these points as a constant factor of r_w (recall that $r_w = \sqrt{d}/2 s_w$). From the proof of Lemma 6.3 in [5], we know that the ball $c_3\gamma b_w \cap P \neq \emptyset$, for some constant $c_3 \geq 1 + 2c_2/\sqrt{d}$. In other words, $d_{\text{nn}}(c_w) \leq c_3\gamma r_w$. From this, we can say that $d_{\text{nn}}(q) \leq (\frac{1}{2} + c_3)\gamma r_w$. Applying the triangle inequality yields that $d(c_w, p_1) \leq d(c_w, q) + d(q, p_1) \leq (\frac{1}{2} + (1+\varepsilon)(\frac{1}{2} + c_3))\gamma r_w$. Similarly, we can achieve the same bound for $d(c_w, p_2)$.

Therefore, both $p_1, p_2 \in \rho\gamma b_w$ for sufficiently large constant ρ (i.e., $\rho \geq \varepsilon(\frac{1}{2} + c_3) + c_3 + 1$). Knowing also that $d(p_1, p_2) = \Omega(r_w^-) = \Omega(\varepsilon\gamma r_w)$ yields that the leaf cell $w \in \mathcal{I}$. ◀

► **Lemma 8.** *Every boundary resolved leaf cell of T_{init} is important, namely $\mathcal{R}_b \subseteq \mathcal{I}$.*

Proof. Let $w_1 \in \mathcal{R}_b$ be any boundary resolved leaf cell of the tree T_{init} , we know there exists another leaf cell $w_2 \in \mathcal{R}_b$ adjacent to w_1 , such that there exists some class $i \in C_{w_2} \setminus C_{w_1}$. Let b_{w_1} and b_{w_2} be the corresponding bounding balls of w_1 and w_2 . By definition, any point q on the boundary shared by w_1 and w_2 has at least one ε -representative from each cell, namely some points $p_1 \in R_{w_1}$ and $p_2 \in R_{w_2}$, where $l(p_1) \neq i$ and $l(p_2) = i$. Additionally, by similar arguments to the ones described in Lemma 7, we know that both $p_1, p_2 \in \rho\gamma b_w$ for sufficiently large constant ρ .

Now, we proceed to prove that $d(p_1, p_2) \geq r_w^-/2$. First, note that if w_1 was resolved by the initial marking of leaf cells as described in Lemma 3, then p_2 must lie outside of γb_w . In such cases, clearly $d(p_1, p_2) \geq r_w^-/2$. The remaining possibility is that w_1 was resolved after computing the set of representatives. From the described procedure, in Case 1, we know

that if $d(p_1, p_2) < r_w^-/2$, the point $x_{p_1, i}$ (which is a 1-approximate nearest-neighbor of p_1 among points in P_i) would hold that $d(p_1, x_{p_1, i}) < r_w^-$. Hence, $x_{p_1, i}$ should have been added to the set of representatives of w_1 , contradicting the assumption that w_1 is resolved, or that C_{w_1} does not contain i . All together, we have that $d(p_1, p_2) = \Omega(r_w^-) = \Omega(\varepsilon \gamma r_w)$. From the definition of the set of important leaf cells, $w \in \mathcal{I}$. \blacktriangleleft

Lemmas 7 and 8 imply that all the leaf cells used to build T belong to the set of important leaf cells (i.e., $\mathcal{A} \cup \mathcal{R}_b \subseteq \mathcal{I}$), whose size is upper-bounded by Lemma 6. All together, and leveraging construction methods of quadrees (see Section 2), the size of T is proportional to the total number of leaf cells used to build it, which we now know is $\mathcal{O}(k_\varepsilon \gamma^d \log \frac{1}{\varepsilon})$. However, we also need to account for the set of ε -representatives stored for each ambiguous leaf cell, leading to a worst-case upper-bound of $\mathcal{O}(k_\varepsilon \gamma^d \log \frac{1}{\varepsilon} \cdot 1/(\varepsilon \gamma)^{\frac{d-1}{2}})$ total space to store T .

4.2 Spatial Amortization

The previous result can be improved by applying a technique called *spatial amortization*, described by Arya *et al.* [5]. That is, we can remove the extra $\mathcal{O}(1/(\varepsilon \gamma)^{\frac{d-1}{2}})$ factor from the analysis of the space requirements for T .

This will be twofold process, as in order to successfully apply spatial amortization to the analysis of the data structure, we first need to further reduce the set of ε -representatives of every ambiguous leaf cell in the tree. Actually, the new set will no longer be a set of ε -representatives, but it will just be a *weak* ε -coreset for query points inside of each leaf cell.

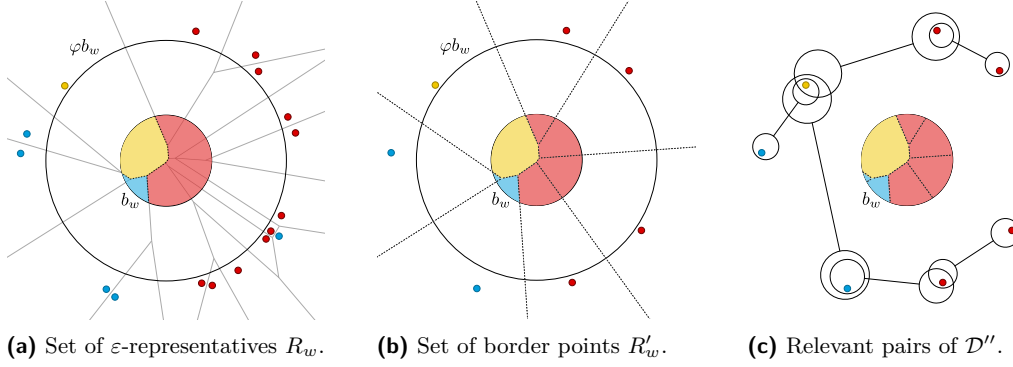

► **Lemma 9.** *The total space required to store the ambiguous leaf cells of T is $\mathcal{O}(k_\varepsilon \gamma^d \log \frac{1}{\varepsilon})$.*

Consider any ambiguous leaf cell w of T , and in particular, consider the set R_w of ε -representatives of w . By construction, R_w has the property that every point $q \in b_w$ has at least one ε -approximate nearest-neighbor in the set R_w . However, note that the opposite is not necessarily true, as not every $p \in R_w$ is an ε -approximate nearest-neighbor of some point in b_w . Even worst, while the fact the w is ambiguous indicates that at least two points in R_w belong to K_ε , the remaining points of R_w might not, which in turn prevents the application of a spatial amortization analysis. Overall, this suggests some of the points of R_w might not be necessary to distinguish between the classes that change the classification of points inside b_w (see Figure 4a).

This can be resolved as follows. Suppose we have access to the Voronoi diagram of the set of points R_w , and consider the boundaries between adjacent cells of this diagram. Any boundary that separates two points of R_w of different classes, and that intersects b_w , is relevant to the classification any query point inside b_w . Formally, we define the set $R'_w \subseteq R_w$ of border points of R_w as (see Figure 4b):

$$R'_w = \{p \in R_w \mid \exists q \in b_w, p' \in R_w \text{ such that } l(p) \neq l(p') \wedge d(q, p) = d(q, p')\}$$

This new set R'_w has some useful properties. Note that for any query point $q \in b_w$, its (exact) nearest-neighbor in R'_w belongs to the same class as its (exact) nearest-neighbor in R_w , which itself is an ε -approximate nearest-neighbor of q among the points of P . In other words, R'_w is an ε -coreset for any query point in b_w . This implies that we can replace the set of ε -representatives of w with the set R'_w . Moreover, this means that by the definition of ε -border points, $R'_w \subseteq K_\varepsilon$. Note that we don't need to compute the Voronoi diagram of R_w , but instead just part of the 1-skeleton. While not immediately evident, the set R'_w can be computed in time $\mathcal{O}(|R_w|^3)$, by fixing every two pairs of R_w , and checking whether there exists a point $q \in b_w$ with the desired properties. The later step can be solved using Linear Programming via the lifting transform into a parabola in $d + 1$ Euclidean space.

■ **Figure 4** The set R_w of ε -representatives of w can be reduced to the set R'_w . This latter set is a subset of K_ε , and can be charged to a proportional number of relevant pairs of \mathcal{D}'' .

Now, let's proceed with the charging argument over the pairs of the same WSPD \mathcal{D}'' used in Lemma 6. Instead of only charging w to a single pair (as described in Lemma 7), we charge every point stored in R'_w to a pair of \mathcal{D}'' . Thus, consider the following procedure to find a sufficient number of pairs to charge all the points in R'_w , which is derived from a similar procedure proposed in [5]. See Figure 4c for an illustrative example.

1. Compute a net of R'_w using radius r_w^- , and denote this subset R''_w . Given that all the points of R'_w that belong to the same class are already separated by a distance of at least r_w^- , we know that $|R''_w| = \Theta(|R'_w|)$, hiding constants³ that depend exponentially on d .
2. Find the two points of $p_1, p_2 \in R''_w$ with smallest pairwise distance, and consider the pair of $\mathcal{P} \in \mathcal{D}''$ that contains both points p_1 and p_2 , each in one of its dumbbell heads. Note that by having computed a net in the previous step, $d(p_1, p_2) \geq r_w^-$.
3. Delete one of the two points from R''_w (without loss of generality, delete p_1).
4. Charge every point of R'_w that is covered by p_1 (i.e., whose distance to p_1 is $\leq r_w^-$) to the pair \mathcal{P} . By the arguments described in step 1 on the size of R''_w , we know that \mathcal{P} receives a charge from $\mathcal{O}(1)$ points of R'_w .
5. Repeat steps 2-4 with the remaining points of R''_w until the set is empty.

Evidently, the number of pairs found (and charged) equals $|R''_w| - 1$. All together, we have that the total space required to store all the ambiguous leaf cells is proportional to the sum of charges to every pair of \mathcal{D}'' . Using the same arguments as Lemma 6, this implies that the total storage is $\mathcal{O}(k_\varepsilon \gamma^d \log \frac{1}{\varepsilon})$. This completes the proof of Theorem 1.

A Proof Details

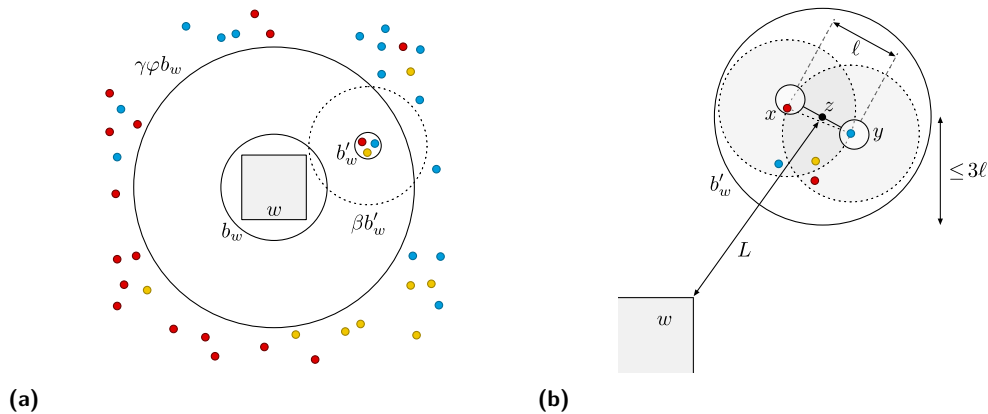

Figure 5 It is possible that points of ≥ 2 classes lie inside of $\gamma\varphi b_w$. However, this case can be reduced to the two separation properties illustrated in Figure 3.

To finish the proof of Lemma 3, we shall proof the assumption that if $|4\gamma\varphi b_w \cap \{x_i\}_i| \geq 2$, then every point inside $4\gamma\varphi b_w$ lies inside the ball b'_w which is β -separated from w .

Proof. Let $x, y \in 4\gamma\varphi b_w$ be the two points of different classes inside the ball $4\gamma\varphi b_w$ with largest pairwise distance. Thus, it is easy to show that all the points inside $4\gamma\varphi b_w$ lie inside the two balls centered at x and y with radii equal to $d(x, y)$, as shown in Figure 5b. By definition of the (bichromatic) well-separated pair decomposition \mathcal{D}' , there exists a pair $\mathcal{P} \in \mathcal{D}'$ that contains x and y each in one of its dumbbells, with length ℓ and center z . Now, we define the ball b'_w with center at z and radius $r'_w = \max(d(z, x), d(z, y)) + d(x, y)$. By definition of \mathcal{P} , we know that $d(z, x), d(z, y) \leq \ell$ and $d(x, y) \leq 2\ell$, thus making $r'_w \leq 3\ell$. Let L be the distance from w to z , we distinguish two cases based on the relationship between L and ℓ :

- $L > c_1\beta\ell$. Consider the distance that separates the ball b'_w from the cell w .

$$d(w, b'_w) = L - r'_w > c_1\beta\ell - r'_w \geq (c_1\beta/3 - 1)r'_w$$

Since $\beta = 1/\varepsilon$, for all sufficiently large constants $c_1 \geq 3(1 + \varepsilon)$, the distance $d(w, b'_w)$ exceeds $\beta r'_w$ which implies that b'_w is concentrically β -separated from w .

- $L \leq c_1\beta\ell$. We will show that this case cannot occur, since otherwise the dumbbell \mathcal{P} would have caused w to be split, contradicting the assumption that it is a leaf cell of T_{init} . Since x, y , and w are all contained in the ball $4\gamma\varphi b_w$ whose center lies within w , we have both that $d(x, w) \leq 4\gamma\varphi r_w$, and $\ell < 2d(x, y) \leq 2(8\gamma\varphi r_w) = 16\gamma\varphi r_w$. Thus, by the triangle inequality, we have:

$$L \leq d(x, y) + d(x, w) < \ell + 4\gamma\varphi r_w < 16\gamma\varphi r_w + 4\gamma\varphi r_w = 20\gamma\varphi r_w$$

Because $L \leq c_1\beta\ell$, it follows from our construction that there is at least one ball $b_i(\mathcal{P})$ (with $0 \leq i \leq \lceil \log c_1\beta \rceil$) that overlaps w . Let b denote the smallest such ball, and let r denote its radius. By the construction, we have that $r \leq \max(\ell, 2L)$. Since our construction generates all quadtree boxes of size $r/(c_2\gamma)$ that overlap b , it follows that $s_w \leq r/(c_2\gamma)$. Thus, we have:

$$r_w = s_w \frac{\sqrt{d}}{2} \leq \frac{r\sqrt{d}}{2c_2\gamma} \leq \frac{\max(\ell, 2L)\sqrt{d}}{2c_2\gamma} < \frac{20\gamma\varphi r_w \sqrt{d}}{c_2\gamma} = \frac{20\varphi r_w \sqrt{d}}{c_2}$$

Choosing $c_2 \geq 20\varphi\sqrt{d}$ yields the desired contradiction.

This completes the proof of Lemma 3. ◀

Compression by Contracting Straight-Line Programs

Moses Ganardi 

Max Planck Institute for Software Systems (MPI-SWS), Kaiserslautern, Germany

Abstract

In grammar-based compression a string is represented by a context-free grammar, also called a *straight-line program (SLP)*, that generates only that string. We refine a recent balancing result stating that one can transform an SLP of size g in linear time into an equivalent SLP of size $\mathcal{O}(g)$ so that the height of the unique derivation tree is $\mathcal{O}(\log N)$ where N is the length of the represented string (FOCS 2019). We introduce a new class of balanced SLPs, called *contracting* SLPs, where for every rule $A \rightarrow \beta_1 \dots \beta_k$ the string length of every variable β_i on the right-hand side is smaller by a constant factor than the string length of A . In particular, the derivation tree of a contracting SLP has the property that every subtree has logarithmic height in its leaf size. We show that a given SLP of size g can be transformed in linear time into an equivalent contracting SLP of size $\mathcal{O}(g)$ with rules of constant length. This result is complemented by a lower bound, proving that converting SLPs into so called α -balanced SLPs or AVL-grammars can incur an increase by a factor of $\Omega(\log N)$.

We present an application to the navigation problem in compressed unranked trees, represented by *forest straight-line programs (FSLPs)*. A linear space data structure by Reh and Sieber (2020) supports navigation steps such as going to the parent, left/right sibling, or to the first/last child in constant time. We extend their solution by the operation of moving to the i -th child in time $\mathcal{O}(\log d)$ where d is the degree of the current node.

Contracting SLPs are also applied to the finger search problem over SLP-compressed strings where one wants to access positions near to a pre-specified *finger* position, ideally in $\mathcal{O}(\log d)$ time where d is the distance between the accessed position and the finger. We give a linear space solution for the dynamic variant where one can set the finger in $\mathcal{O}(\log N)$ time, and then access symbols or move the finger in time $\mathcal{O}(\log d + \log^{(t)} N)$ for any constant t where $\log^{(t)} N$ is the t -fold logarithm of N . This improves a previous solution by Bille, Christiansen, Cording, and Gørtz (2018) with access/move time $\mathcal{O}(\log d + \log \log N)$.

1 Introduction

In grammar-based compression a long string is represented by a context-free grammar, also called a *straight-line program (SLP)*, that generates only that string. Straight-line programs can achieve exponential compression, e.g. a string of length 2^n can be produced by the grammar with the rules $A_n \rightarrow A_{n-1}A_{n-1}, \dots, A_0 \rightarrow a$. While it is NP-hard to compute a smallest SLP for a given string [5] there are efficient grammar-based compressors of both practical and theoretical interest such as the LZ78/LZW-algorithms [25, 24], SEQUITUR [19], and RE-PAIR [16]. There is a close connection between grammar-based compression and the LZ77 algorithm, which parses a string into z phrases (without self-references): On the one

hand z is always a lower bound on the size of the smallest SLP for the string [5]. On the other hand one can always construct an SLP of size $\mathcal{O}(z \log N)$ where N is the string length [5, 22] (see also [13] for LZ77 with self-referential phrases). Furthermore, the hierarchical structure of straight-line programs makes them amenable to algorithms that work directly on the compressed representation, without decompressing the string first. We refer to [17] for a survey on the broad literature on algorithms on grammar-compressed data.

Balanced grammars. For some algorithmic applications it is useful if the SLP at hand satisfies certain balancedness conditions. In the following we always denote by N the length of the represented string. A recent result states that one can transform an SLP of size g in linear time into an equivalent SLP of size $\mathcal{O}(g)$ so that the height of the unique derivation tree is $\mathcal{O}(\log N)$ [10]. This yields a clean $\mathcal{O}(g)$ space data structure which supports random access to any position i in the string in time $\mathcal{O}(\log N)$, by descending in the derivation tree from the root to the i -th leaf. The original solution for the random access problem by Bille, Landau, Raman, Sadakane, Satti, and Weimann relied on a sophisticated weighted ancestor data structure [3]. Its advantage over the balancing approach from [10] is that it supports random access to the string defined by any given variable A in time $\mathcal{O}(\log |A|)$.

Although the derivation tree of an SLP may have logarithmic height its subtrees may still be very unbalanced. Arguably, the strongest balancedness notions are α -balanced SLPs [5] and AVL-grammars [22]. An SLP in Chomsky normal form is α -balanced if for every rule $A \rightarrow BC$ the ratios $|B|/|A|$ and $|C|/|A|$ lie between α and $1 - \alpha$. An *AVL-grammar* is an SLP in Chomsky normal form whose derivation tree is an AVL-tree, i.e. for every rule $A \rightarrow BC$ the subtree heights below B and C differ at most by one. In fact, the aforementioned transformations from LZ77 into SLPs produce an α -balanced SLP, with $\alpha \leq 1 - \frac{1}{2}\sqrt{2}$ [5], and an AVL-grammar [22]. Using the same proof techniques one can also transform an SLP of size g into an α -balanced SLP or an AVL-grammar of size $\mathcal{O}(g \log N)$ [5, 22].

Let us list a few algorithmic results on α -balanced SLPs and AVL-grammars. The *compressed pattern matching problem* can be solved in linear time if the text is given by an α -balanced SLP and the pattern is given explicitly [13]. Gagie, Gawrychowski, Kärkkäinen, Nekrich, and Puglisi [7] presented a solution for the *bookmarking problem* in α -balanced SLPs or AVL-grammars of size g . Given b positions in the string, called bookmarks, we can decompress any substring of length ℓ that covers a bookmark in time $\mathcal{O}(\ell)$ and space $\mathcal{O}(g + b \log^* N)$. Based on this bookmarking data structure they present *self-indexes* for LZ77 and SLPs [7, 8], which support extracting substrings and finding all occurrences of a given pattern. Abboud, Backurs, Bringmann, and Künnemann studied the Hamming distance problem and the subsequence problem on SLP-compressed strings [1]. As a first step their algorithms convert the input SLPs into AVL-grammars, and solve both problems in time $\tilde{\mathcal{O}}(g^{1.410} \cdot N^{0.593})$, improving on the decompress-and-solve $\mathcal{O}(N)$ time algorithms.

Main results. The starting point of this paper is the observation that the size increase by a $\mathcal{O}(\log N)$ factor in the transformation from SLPs to α -balanced SLPs or AVL-grammars is unavoidable (Theorem 4). This lower bound holds whenever in the derivation tree any path from a variable A to a leaf has length $\Theta(\log |A|)$. This motivates the search for balancedness notions of SLPs that can be established without increasing the size by more than a constant factor and that provide good algorithmic properties. We introduce a new class of balanced SLPs, called *contracting straight-line programs*, in which every variable β_i occurring on the right-hand side of a rule $A \rightarrow \beta_1 \dots \beta_k$ satisfies $|\beta_i| \leq |A|/2$. The derivation tree of an contracting SLP has the property that every subtree has logarithmic height in its leaf size,

i.e. in the number of descendant leaves. We explicitly admit rules with right-hand sides of length greater than two, however, the length will always be bounded by a constant in this paper. We say that an SLP \mathcal{G} defines a string s if some variable in \mathcal{G} derives s (and s only). The main theorem of this paper refines the balancing theorem from [10] as follows:

► **Theorem 1.** *Given an SLP \mathcal{G} of size g , one can compute in linear time a contracting SLP of size $\mathcal{O}(g)$ with constant-length right-hand sides which defines all strings that \mathcal{G} defines.*

As an immediate corollary we obtain a simple $\mathcal{O}(g)$ size data structure supporting access to the i -th symbol of a variable A in time $\mathcal{O}(\log |A|)$ instead of $\mathcal{O}(\log N)$. This is useful whenever multiple strings s_1, \dots, s_m are compressed using a single SLP since we can support random access to any string s_i in time $\mathcal{O}(\log |s_i|)$. We present an example application to unranked trees represented by *forest straight-line programs (FSLPs)*. FSLPs are a natural generalization of SLPs that can compress trees both horizontally and vertically, and share the good algorithmic applicability of their string counterparts [11]. Reh and Sieber presented a linear space data structure on FSLP-compressed trees that allows to perform various navigation steps in constant time [21]. We extend their data structure by the operation of moving to the i -th child in time $\mathcal{O}(\log d)$ where d is the degree of the current node.

► **Theorem 2.** *Given an FSLP \mathcal{G} of size g , one can compute an data structure in $\mathcal{O}(g)$ time and space supporting the following operations in constant time: Move to the root of the first/last tree of a given variable, move to the first/last child, to the left/right sibling or to the parent of the current node, return the symbol of the current node. One can also move to the i -th child of the current node in time $\mathcal{O}(\log d)$ where d is the degree of the current node.*

A second application concerns the *finger search problem* on grammar-compressed strings. A finger search data structure supports fast updates and searches to elements that have small rank distance from the *fingers*, which are pointers to elements in the data structure. The survey [4] provides a good overview on dynamic finger search trees. In the setting of finger search on a string s , Bille, Christiansen, Cording, and Gørtz [2] considered three operations: `access(i)` returns symbol $s[i]$, `setfinger(i)` sets the finger at position i of s , and `movefinger(i)` moves the finger to position i in s . Given an SLP of size g for a string of length N , they presented an $\mathcal{O}(g)$ size data structure which supports `setfinger(i)` in $\mathcal{O}(\log N)$ time, and `access(i)` and `movefinger(i)` in $\mathcal{O}(\log d + \log \log N)$ time where d is the distance from the current finger position [2]. If we assume that the SLP is α -balanced or an AVL-grammar, there is a linear space solution supporting `access(i)` and `movefinger(i)` in $\mathcal{O}(\log d)$ time (Theorem 17). For general SLPs we present a finger search structure with improved time bounds:

► **Theorem 3.** *Let $t \geq 1$. Given an SLP of size g for a string of length N , one can support `setfinger(i)` in $\mathcal{O}(\log N)$ time, and `access(i)` and `movefinger(i)` in $\mathcal{O}(\log d + \log^{(t)} N)$ time, where d is the distance between i and the current finger position, after $\mathcal{O}(tg)$ preprocessing time and space.*

Here $\log^{(t)} N$ is the t -fold logarithm of N , i.e. $\log^{(0)} N = N$ and $\log^{(t+1)} N = \log \log^{(t)} N$. Choosing any constant t we obtain a linear space solution for dynamic finger search, supporting `access(i)` and `movefinger(i)` in $\mathcal{O}(\log d + \log^{(t)} N)$ time. Alternatively, we obtain a clean $\mathcal{O}(\log d)$ time solution if we admit a $\mathcal{O}(g \log^* N)$ space data structure. Theorem 3 also works for multiple fingers where every finger uses additional $\mathcal{O}(\log N)$ space.

Let us remark that Theorem 1 holds in the *pointer machine model* [23], whereas for Theorem 2 and Theorem 3 we assume the *word RAM model* with the standard arithmetic and bitwise operations on w -bit words, where $w \geq \log N$. The assumption on the word length is standard in the area of grammar-based compression, see [3, 2].

Overview of the proofs. The proof of Theorem 1 follows the ideas from [3] and [10]. The obstacle for $\mathcal{O}(\log N)$ time random access or $\mathcal{O}(\log N)$ height are occurrences of *heavy* variables on right-hand sides of rules $A \rightarrow \beta_1 \dots \beta_k$, i.e. variables β_i whose length exceeds $|A|/2$. These occurrences can be summarized in the *heavy forest*, which is a subgraph of the directed acyclic graph associated with the SLP. The random access problem can be reduced to *weighted ancestor queries* (see Section 5) on every heavy tree whose edges are weighted by the lengths of the variables that branch off from the heavy tree. Using a “biased” weighted ancestor data structure one can descend in the derivation tree in $\mathcal{O}(\log N)$ time, spending amortized constant time on each heavy tree [3]. Our main contribution is a solution of the weighted ancestor problem in the form of an SLP: Given a tree T of size n where the edges are labeled by weighted symbols, we construct a contracting SLP of size $\mathcal{O}(n)$ defining all prefixes in T , i.e. labels of paths from the root to some node. The special case of defining all prefixes of a weighted string by a weight-balanced SLP of linear size (i.e. T is a path) was solved in [10]; however, the constructed SLP only satisfies a weaker balancedness condition.

To solve finger search efficiently, Bille, Christiansen, Cording, and Gørtz first consider the *fringe access problem* [2]: Given a variable A and a position $1 \leq i \leq |A|$, access symbol $A[i]$, ideally in time $\mathcal{O}(\log d)$ where $d = \min\{i, |A| - i + 1\}$. For this purpose the SLP is partitioned into *leftmost* and *rightmost trees*, which produce strings of length N , $N^{1/2}$, $N^{1/4}$, $N^{1/8}$, etc. The leftmost/rightmost trees can be traversed in $\mathcal{O}(\log \log N)$ time using a $\mathcal{O}(\log \log N)$ time weighted ancestor data structure by Farach-Colton and Muthukrishnan [6]. Applying this approach to contracting SLPs one can solve fringe access in time $\mathcal{O}(\log d + \log \log |A|)$ since the trees have $\mathcal{O}(\log N)$ height, for which one can answer weighted ancestor queries in constant time using a predecessor data structure by Pătraşcu-Thorup [20]. Using additional weighted ancestor structures, we can reduce the term $\log \log |A|$ to $\log^{(t)} N$.

2 Straight-line programs

A *context-free grammar* $\mathcal{G} = (\mathcal{V}, \Sigma, \mathcal{R}, S)$ consists of a finite set \mathcal{V} of *variables*, an alphabet Σ of *terminal symbols*, where $\mathcal{V} \cap \Sigma = \emptyset$, a finite set \mathcal{R} of *rules* $A \rightarrow u$ where $A \in \mathcal{V}$ and $u \in (\mathcal{V} \cup \Sigma)^*$ is a *right-hand side*, and a *start variable* $S \in \mathcal{V}$. The set of *symbols* is $\mathcal{V} \cup \Sigma$. We call \mathcal{G} a *straight-line program (SLP)* if every variable occurs exactly once on the left-hand side of a rule and there exists a linear order $<$ on \mathcal{V} such that $A < B$ whenever B occurs on the right-hand side of a rule $A \rightarrow u$. This ensures that every variable A derives a unique string $\llbracket A \rrbracket \in \Sigma^*$. We also write $|A|$ for $|\llbracket A \rrbracket|$. A string $s \in \Sigma^*$ is *defined* by \mathcal{G} if $\llbracket A \rrbracket = s$ for some $A \in \mathcal{V}$. The *size* of \mathcal{G} is the total length of all right-hand sides in \mathcal{G} . We denote by $\text{height}(A)$ the height of the derivation tree rooted in A . The height of \mathcal{G} is $\text{height}(S)$. We define the directed acyclic graph $\text{dag}(\mathcal{G}) = (\mathcal{V} \cup \Sigma, E)$ where E is a multiset of edges, containing for every rule $A \rightarrow \beta_1 \dots \beta_k$ in \mathcal{R} the edges $(A, \beta_1), \dots, (A, \beta_k)$. An SLP \mathcal{G} can be transformed in linear time into an SLP \mathcal{G}' in *Chomsky normal form* which defines all strings that \mathcal{G} defines, i.e. each rule is of the form $A \rightarrow BC$ or $A \rightarrow a$ where $A, B, C \in \mathcal{V}$ and $a \in \Sigma$.

An SLP is α -*balanced*, for some constant $0 < \alpha \leq 1/2$, if it is in Chomsky normal form and for all rules $A \rightarrow BC$ both $|B|/|A|$ and $|C|/|A|$ lie between α and $1 - \alpha$. An *AVL-grammar* is an SLP in Chomsky normal form where for all rules $A \rightarrow BC$ we have $|\text{height}(B) - \text{height}(C)| \leq 1$. An SLP in Chomsky normal form is (α, β) -*path balanced*, for some constants $0 < \alpha \leq \beta$, if for every variable A the length of every root-to-leaf path in the derivation tree is between $\alpha \log |A|$ and $\beta \log |A|$. Observe that every α -balanced SLP is $(1/\log(\alpha^{-1}), 1/\log((1 - \alpha)^{-1}))$ -path balanced and AVL-grammars are $(0.5, 2)$ -path balanced. The latter follows from the fact that the height decreases at most by 2 when going from an

AVL-tree to an immediate subtree. There are algorithms that compute for given a string w an α -balanced SLP [5] and an AVL-grammar [22] of size $\mathcal{O}(g \log N)$ where g is the size of a smallest SLP for w . We show that these bounds are optimal even for path balanced SLPs: There are strings for which the smallest path balanced SLPs have size $\Omega(g \log N)$.

► **Theorem 4.** *There exists a family of strings $(s_n)_{n \geq 1}$ over $\{a, b\}$ such that $|s_n| = \Omega(2^n)$, s_n has an SLP of size $\mathcal{O}(n)$ and every (α, β) -path balanced SLP has size $\Omega(n^2)$.*

Proof. First we use an unbounded alphabet. Let $s_n = b_1 a^{2^n} b_2 a^{2^n} \dots b_{n-1} a^{2^n} b_n$, which has an SLP of size $\mathcal{O}(n)$ with the rules $S \rightarrow b_1 A_n b_2 A_n \dots b_n$, $A_0 \rightarrow a$ and $A_i \rightarrow A_{i-1} A_{i-1}$ for all $1 \leq i \leq n$. Consider an (α, β) -path balanced SLP \mathcal{G} for s_n . We will show that $\text{dag}(\mathcal{G})$ has $\Omega(n^2)$ edges. Let $1 \leq i \leq n$ and consider the unique path in $\text{dag}(\mathcal{G})$ from the starting variable to b_i . Let π_i be the suffix path starting in the lowest node A_i such that $\llbracket A_i \rrbracket$ contains some symbol b_j with $i \neq j$. Therefore $|A_i| \geq 2^n$. Since \mathcal{G} is (α, β) -path balanced π_i has length $\geq \alpha n$. Since all paths π_i are edge-disjoint it follows that \mathcal{G} has size $\Omega(n^2)$.

For a binary alphabet define the separator $T_i = b a^{2^{i-2}} b a^{2^{i-1}} b$ for $1 \leq i \leq n$ and define $s_n = T_1 a^{2^n} T_2 \dots T_{n-1} a^{2^n} T_n$ of length $\Omega(2^n)$. The string s_n also has an SLP of size $\mathcal{O}(n)$. Consider an (α, β) -path balanced SLP \mathcal{G} for s_n . Let $1 \leq i \leq n$ and consider the unique path ρ_i in $\text{dag}(\mathcal{G})$ from the starting variable to the symbol b in the middle of the separator $T_i = b a^{2^{i-2}} b a^{2^{i-1}} b$. Let B_i be the lowest node on ρ_i such that $\llbracket B_i \rrbracket$ contains either $b a^{2^{i-2}} b$ or $b a^{2^{i-1}} b$. Since the successor of B_i on ρ_i produces a string strictly shorter than $|T_i| \leq 4n$, the suffix path of ρ_i starting in B_i has length at most $1 + \beta \log(4n) = \mathcal{O}(\log n)$. Let A_i be the lowest ancestor of B_i on ρ_i such that $\llbracket A_i \rrbracket$ contains a symbol from a separator T_j for $i \neq j$. Therefore $|A_i| \geq 2^n$ and hence the suffix path of ρ_i starting in A_i has length at least $\alpha \log(2^n) = \alpha n = \Omega(n)$. Thus, the path π_i from A_i to B_i has length $\Omega(n) - \mathcal{O}(\log n) = \Omega(n)$. All paths π_i are edge-disjoint since for any edge (X, Y) in π_i , $\llbracket Y \rrbracket$ is of the form $a^\ell b a^{2^{i-2}} b a^r$ or $a^\ell b a^{2^{i-1}} b a^r$. This implies that \mathcal{G} has size $\Omega(n^2)$. ◀

We define contracting SLPs over a weighted alphabet, i.e. an alphabet Γ equipped with a function $\|\cdot\|: \Gamma \rightarrow \mathbb{N} \setminus \{0\}$, which is extended additively to Γ^* . The standard weight function is the length function $|\cdot|$. A symbol β occurring in a weighted string s is *heavy in s* if $\|\beta\| > \|s\|/2$; otherwise it is *light in s* . Consider an SLP $\mathcal{G} = (\mathcal{V}, \Sigma, \mathcal{R}, S)$ over a weighted alphabet Σ . We define $\|A\| = \|\llbracket A \rrbracket\|$ for $A \in \mathcal{V}$. A symbol $\beta \in \mathcal{V} \cup \Sigma$ is a *heavy child* of $A \in \mathcal{V}$ if β is heavy on the right-hand side of the rule $A \rightarrow u$. We also call β a *heavy symbol*. A rule $A \rightarrow u$ is *contracting* if u contains no heavy variables, i.e. every variable B occurring in u satisfies $\|B\| \leq \|A\|/2$. Let us emphasize that heavy *terminal* symbols from Σ are permitted in contracting rules. If all rules in \mathcal{G} are contracting we call \mathcal{G} contracting. If B occurs heavily in a rule $A \rightarrow u B v$ and the rule $B \rightarrow x$ is contracting we can *expand* the occurrence of B and obtain a contracting rule $A \rightarrow u x v$.

3 Transformation into contracting SLPs

A *labeled tree* $T = (V, E, \gamma)$ is a rooted tree where each edge $e \in E$ is labeled by a string $\gamma(e)$ over a weighted alphabet Γ . A *prefix* in T is the labeling of a path starting from the root. The first step towards proving Theorem 1 is a reduction to the following problem: Given a labeled tree T , construct a contracting SLP over Γ of size $\mathcal{O}(|T|)$, defining all prefixes in T .

Decomposition into heavy trees. Consider an SLP $\mathcal{G} = (\mathcal{V}, \Sigma, \mathcal{R}, S)$. If a rule $A \rightarrow \beta_1 \dots \beta_k$ contains a unique heavy symbol β_i then $\beta_1 \dots \beta_{i-1}$ is the *light prefix* of A and $\beta_{i+1} \dots \beta_k$ is the *light suffix* of A . The *heavy forest* $H = (\mathcal{V} \cup \Sigma, E_H)$ contains all edges (A, β) where

■ **Figure 1** An excerpt from the dag representation of an SLP. The variables S, T, U, V form a heavy tree with root U . The value of S can be split into the prefix ACD , the root U of the heavy tree, and the suffix B . Observe that the left labeling of the path from U to S is DCA , which is the reverse of the prefix ACD .

$\beta \in \mathcal{V} \cup \Sigma$ is a heavy child of $A \in \mathcal{V}$, which is a subgraph of $\text{dag}(\mathcal{G})$. Notice that the edges in H point towards the roots, i.e. if $(\alpha, \beta) \in E$ then α is a child of β in H . We define two labeling functions: The *left label* $\lambda(e)$ of an edge $e = (A, \beta)$ is the *reversed* light prefix of A and the *right label* $\rho(e)$ of e is the light suffix of A . The connected components of (H, λ) and (H, ρ) are called the *left labeled* and *right labeled heavy trees*, which can be computed in linear time from \mathcal{G} . If β is the root of a heavy tree containing a variable A we can factorize $\llbracket A \rrbracket$ into the reversed left labeling from A to its root β in H , the value of β , and the right labeling of the path from β to A . In that way one can redefine every variable using SLPs which define all prefixes in the left labeled and the right labeled heavy trees.

► **Proposition 5.** *Given an SLP \mathcal{G} and contracting SLPs \mathcal{H}_L and \mathcal{H}_R defining all prefixes of all left labeled and right labeled heavy trees of \mathcal{G} . Let g be the total number of variables in the SLPs and r be the maximal length of a right-hand side. One can compute in linear time a contracting SLP \mathcal{G}' which defines all strings that \mathcal{G} defines, has $\mathcal{O}(g)$ variables and right-hand sides of length $\mathcal{O}(r)$.*

The goal of this section is to prove the following result.

► **Theorem 6.** *Given a labeled tree T with n edges and labels of length $\leq \ell$, one can compute in linear time a contracting SLP with $\mathcal{O}(n)$ variables and right-hand sides of length $\mathcal{O}(\ell)$ defining all prefixes in T .*

Together with Proposition 5 it implies Theorem 1. We can always assume that every edge in T is labeled by a single symbol: Edges labeled by ε can clearly be contracted. Edge labels u of length > 1 are replaced by a new symbol X_u of weight $\|u\|$, which can be replaced by u again in the constructed SLP. We will also assume that all symbols in T are distinct.

Prefixes of weighted strings. We start with the case where the tree is a path, i.e. we need to define all prefixes of a weighted string s using $\mathcal{O}(|s|)$ contracting rules. The following theorem refines [10, Lemma III.1] where only the path length from a prefix variable S_i to a symbol a_j in the derivation tree was bounded by $\mathcal{O}(1 + \log \frac{\|S_i\|}{\|a_j\|})$.

► **Theorem 7.** *Given a weighted string s of length n one can compute in linear time a contracting SLP with $\mathcal{O}(n)$ variables with right-hand sides of length at most 10 that defines all nonempty prefixes of s .*

Let us illustrate the difficulty of defining all prefixes with contracting rules. Consider the weighted string $s = a_1 \dots a_n$ where symbol a_i has weight 2^{n-i} . Since in every factor $a_i \dots a_j$ the left-most symbol a_i is heavy, every rule for $a_i \dots a_j$ must split off the first symbol. If for

■ **Figure 2** The derivation tree D of a base SLP and the modified tree D_0 containing all symbols which are not a left-most child in D .

every prefix we would only repeatedly split off the first symbol we would create $\Omega(n^2)$ many variables. This shows that there is no better solution with right-hand sides of length ≤ 2 . However, using longer rules we can simultaneously reduce both the weight (in a contracting fashion) and the length.

First we recursively construct a contracting “base” SLP $\mathcal{B} = (\mathcal{V}, \Sigma, \mathcal{R}, S)$ for the weighted string $s = a_1 \dots a_n$. It will have the additional property of being *left-heavy*, i.e. for every rule $A \rightarrow \beta_1 \dots \beta_k$ and all $2 \leq i \leq k$ with $\beta_i \in \mathcal{V}$ we have $\|\beta_1 \dots \beta_{i-1}\| \geq \|\beta_i\|$. Let us emphasize that the condition does not apply when β_i is a terminal symbol. The case $n = 1$ is clear. If $n > 1$ we factorize $s = ua_iv$ such that $u, v \in \Sigma^*$ have weight at most $\|s\|/2$. Next factorize $v = v_1v_2$ such that $|v_1|$ and $|v_2|$ differ at most by one. We add the rule $S \rightarrow Ua_iV_1V_2$ to the SLP, possibly omitting variables if some of the strings u, v_1, v_2 are empty. Finally, we recursively define the variables U, V_1 and V_2 . The SLP \mathcal{B} is clearly contracting, has at most n variables, since every variable can be identified with the unique symbol $a \in \Sigma$ on its right-hand side, and its right-hand sides have length at most 4. Notice that the rule $S \rightarrow Ua_iV_1V_2$ is left-heavy since $\|ua_i\| > \|s\|/2 \geq \|v_1\| + \|v_2\|$.

► **Lemma 8.** *The base SLP \mathcal{B} can be computed in linear time from s .*

Consider the derivation tree D of \mathcal{B} whose node set is $\mathcal{S} = \mathcal{V} \cup \Sigma$. Let \preceq_D and \prec_D be the ancestor and the proper ancestor relation on \mathcal{S} . For all $\alpha \preceq_D \beta$ we define $\text{left}(\alpha, \beta) = u$ where $\alpha \Rightarrow_{\mathcal{B}}^* u\beta v$ is the unique derivation with $u, v \in \Sigma^*$. In the derivation tree $\text{left}(\alpha, \beta)$ is the string that branches off to the left on the path from α to β . Notice that every proper nonempty prefix of s can be written as $\text{left}(S, a_i) = a_1 \dots a_{i-1}$. For $\alpha \in \mathcal{S} \setminus \{S\}$ occurring in the unique rule $\alpha' \rightarrow u\alpha v$ we define the *left sibling string* $\text{lsib}(\alpha) = u$. It satisfies $\text{lsib}(\alpha) \Rightarrow_{\mathcal{B}}^* \text{left}(\alpha', \alpha)$. Notice that we can have $\text{left}(\alpha, \beta) = \text{left}(\alpha', \beta')$ for different pairs $(\alpha, \beta), (\alpha', \beta')$. For a unique description we define the set of nodes $\mathcal{S}_0 \subseteq \mathcal{S}$ which are not a left-most child in D , i.e. symbols α such that $\alpha = S$ or $\text{lsib}(\alpha) \neq \varepsilon$. In particular S belongs to \mathcal{S}_0 . Observe that $\text{left}(\alpha, \beta) = \text{left}(\alpha', \beta')$ where α' and β' are the lowest ancestors of α and β , respectively, that belong to \mathcal{S}_0 . In particular, every proper nonempty prefix of s is of the form $\text{left}(\alpha, \beta)$ for some $\alpha, \beta \in \mathcal{S}_0$. Let D_0 be the unique unordered tree with node set \mathcal{S}_0 whose ancestor relation is the ancestor relation of D restricted to \mathcal{S}_0 . Figure 2 shows an example of a tree D with the modified tree D_0 .

We will introduce variables $L_{\alpha, \beta}$ for the strings $\text{left}(\alpha, \beta)$. The variable $L_{\alpha, \beta}$ can be defined using $L_{\alpha', \beta'}$ where α' is a child of α in D_0 and β' is the parent of β in D_0 . To achieve the $\mathcal{O}(n)$ bound we will restrict to variables $L_{\alpha, \beta}$ that are used in the derivation of a prefix variable, namely $\mathcal{L} = \{L_{\alpha, \beta} \mid \alpha, \beta \in \mathcal{S}_0, \alpha \prec \beta, \text{level}(\alpha) \leq \text{height}(\beta)\}$. Here $\text{level}(\alpha)$ refers to distance from α to the root in D_0 , and $\text{height}(\beta)$ is the height of the subtree of D_0 below β .

► **Lemma 9.** *We can compute in linear time a contracting SLP $\mathcal{G} = (\mathcal{V} \cup \mathcal{L}, \Sigma, \mathcal{R} \cup \mathcal{Q}, S)$ with right-hand sides of constant length such that $\llbracket L_{\alpha, \beta} \rrbracket = \text{left}(\alpha, \beta)$ for all $L_{\alpha, \beta} \in \mathcal{L}$.*

We have seen that \mathcal{G} defines all nonempty prefixes (S derives s and every proper nonempty prefix is defined by some variable L_{S, a_i}). To finish the proof of Theorem 7 remains to show that \mathcal{G} has $\mathcal{O}(n)$ variables. The SLP \mathcal{G} consists of n variables from the base SLP \mathcal{B} and the variables in \mathcal{L} . A variable $L_{\alpha, \beta} \in \mathcal{L}$ is determined by β and the level of α , which is an integer between 0 and the height of β in D_0 . Hence it suffices to show that $\sum_{\beta \in S_0} \text{height}(\beta)$ is $\mathcal{O}(n)$. This follows from the fact that every node in D_0 has logarithmic height in its leaf size.

Prefixes in trees. For Theorem 6 we will construct an SLP \mathcal{G} for the prefixes in T , which will not be contracting in general. Still, its heavy forest is a disjoint union of *caterpillar trees*, i.e. trees where every node has at most one child which is not a leaf. Put differently, every heavy tree of \mathcal{G} consists of a central path $\alpha_1, \dots, \alpha_m$ such that every α_i occurs at most once heavily in a rule $A \rightarrow u$ where A is heavy, namely $A = \alpha_{i-1}$. We first extend Theorem 7 to caterpillar trees and then apply Proposition 5 to \mathcal{G} , concluding the proof of Theorem 6.

► **Proposition 10.** *Given a labeled caterpillar tree T with n edges and labels of length $\leq \ell$, one can compute a contracting SLP \mathcal{G} defining all nonempty prefixes in T such that \mathcal{G} has $\mathcal{O}(n)$ variables and right-hand sides of length $\mathcal{O}(\ell)$.*

► **Proposition 11.** *Given a labeled tree T with n edges we can compute an SLP \mathcal{G} defining all nonempty prefixes in T such that*

- (a) \mathcal{G} has $4n$ variables and right-hand sides of length ≤ 6 ,
- (b) the subgraph of $\text{dag}(\mathcal{G})$ induced by the set of heavy symbols is a disjoint union of paths.

Proof sketch. We proceed by induction on n . Let us assume a tree $T = (V, E, \omega)$ with $n \geq 2$ edges. We partition E into maximal *unary paths* $\pi = (v_0, \dots, v_k)$, where $k \geq 1$, and v_1, \dots, v_{k-1} have degree one. For every such a path π we create an SLP \mathcal{G}_π with the rules $P_{v_0, v_1} \rightarrow \omega(v_0, v_1)$ and $P_{v_0, v_i} \rightarrow P_{v_0, v_{i-1}} \omega(v_{i-1}, v_i)$ for $2 \leq i \leq k$. We contract every such a maximal unary path into a single edge (v_0, v_k) labeled by the variable P_{v_0, v_k} and remove all leaves. This new tree T' has at most $n/2$ many edges. Let $V' \subseteq V$ be the node set of T' .

For $v \in V'$ let $d(v)$ be the weight of the path from the root to v in T' and define $\text{rk}(v) = \inf\{k \in \mathbb{Z} \mid d(v) \leq 2^k\}$. Let \hat{v} be the highest ancestor of v in T' with $\text{rk}(v) = \text{rk}(\hat{v})$, called the *peak node* of v . We partition T' into subtrees consisting of nodes with the same peak node, and apply the construction recursively on each part. Let \mathcal{G}' be the union of all obtained SLPs with at most $4 \cdot n/2 \leq 2n$ variables. For every node $v \in V'$ which is not a peak node \mathcal{G}' contains a variable $B_{\hat{v}, v}$ where $\llbracket B_{\hat{v}, v} \rrbracket$ is the path labeling from \hat{v} to v in T' .

Let \mathcal{G} be the union of \mathcal{G}' and all SLPs \mathcal{G}_π , which has at most $n + 2n = 3n$ variables. For every $x \in V$ which is not the root of T we add a variable A_x such that $\llbracket A_x \rrbracket$ is the labeling of the path from the root to x in T . This yields $4n$ variables, as claimed. Let v be the lowest ancestor of x in T contained in V' . If v is the root then we add the rule

$$A_x \rightarrow P_{v, x}. \quad (1)$$

Now assume that v is not the root and hence \hat{v} is also not the root, since the children of the root are peak nodes. Let u be the parent of \hat{v} in T' . If u is the root of T' we add the rule

$$A_x \rightarrow P_{u, \hat{v}} B_{\hat{v}, v} P_{v, x}. \quad (2)$$

Otherwise, u and \hat{u} are not the root. Let s be the parent node of \hat{u} in T' and add the rule

$$A_x \rightarrow A_s P_{s,\hat{u}} B_{\hat{u},u} P_{u,\hat{v}} B_{\hat{v},v} P_{v,x}. \quad (3)$$

One can prove correctness by induction on $\text{rk}(v)$. It remains to prove property (b) of the statement. One can observe that the A - and B -variables are light in the rules (2) and (3). Consider a maximal unary path $\pi = (v_0, \dots, v_k)$. The variable P_{v_0, v_i} for $1 \leq i \leq k-1$ only occurs in the rule of $P_{v_0, v_{i-1}}$. The variable P_{v_0, v_k} can occur on the right-hand sides of (1), (2) and (3), but the corresponding left-hand side A_x is not heavy. By induction hypothesis P_{v_0, v_k} is the heavy child of at most one heavy variable in \mathcal{G}' . This concludes the proof. \blacktriangleleft

4 Navigation in FSLP-compressed trees

As a simple application we extend the navigation data structure on FSLP-compressed trees [21] by the operation which moves to the i -th child in time $\mathcal{O}(\log d)$ where d is the degree of the current node. This is established by applying Theorem 1 to the substructure of the FSLP that compresses forests horizontally.

SLP navigation. The navigation data structure on FSLPs is based on a navigation data structure on (string) SLPs from [18], which extends the data structure from [12] from one-way to two-way navigation. The data structure represents a position $1 \leq i \leq |A|$ in a variable A by a data structure $\sigma(A, i)$, that we will call *pointer*, which is a compact representation of the path in the derivation tree from A to the leaf corresponding to position i .

► **Theorem 12** ([18]). *A given SLP \mathcal{S} can be preprocessed in $\mathcal{O}(|\mathcal{S}|)$ time and space so that the following operations are supported in constant time:*

- *Given a variable A , compute $\sigma(A, 1)$ or $\sigma(A, |A|)$.*
- *Given $\sigma(A, i)$, compute $\sigma(A, i-1)$ or $\sigma(A, i+1)$, or return \perp if the position is invalid.*
- *Given $\sigma(A, i)$, return the symbol at position i in A .*

Furthermore, a single pointer $\sigma(A, i)$ uses $\mathcal{O}(\text{height}(A))$ space and can be computed in time $\mathcal{O}(\text{height}(A))$ for a given pair (A, i) .

Forest straight-line programs. In this section we use the natural term representation for forests. Let Σ be an alphabet of node labels. The set of *forests* is defined inductively as follows: The concatenation of $n \geq 0$ forests is a forest (this includes the empty forest ε), and, if $a \in \Sigma$ and t is a forest, then $a(t)$ is a forest. A *context* is a forest over $\Sigma \cup \{x\}$ where x occurs exactly once and this occurrence is at a leaf node. If f is a context and g is a forest or a context then $f\langle g \rangle$ is obtained by replacing the unique occurrence of x in f by g . A *forest straight-line program (FSLP)* $\mathcal{G} = (\mathcal{V}_0, \mathcal{V}_1, \Sigma, \mathcal{R}, S)$ consists of finite sets of forest variables \mathcal{V}_0 and context variables \mathcal{V}_1 , the alphabet Σ , a finite set of rules \mathcal{R} , and a start variable $S \in \mathcal{V}_0$. The rules contain arbitrary applications of horizontal concatenation and substitutions of forest and context variables. We restrict ourselves to rules in a certain *normal form*, which can be established in linear time with a constant factor size increase [11]. The normal form assumes a partition $\mathcal{V}_0 = \mathcal{V}_0^\top \cup \mathcal{V}_0^\perp$ where \mathcal{V}_0^\top -variables produce trees whereas \mathcal{V}_0^\perp -variables

■ **Figure 3** An example FSLP with the variables $\mathcal{V}_0^\perp = \{A, C, D\}$, $\mathcal{V}_0^\top = \{B, E\}$ and $\mathcal{V}_1 = \{X, Y\}$. The tree defined by A is displayed on the right.

produce forests with arbitrarily many trees. The rules in \mathcal{R} have one of the following forms:

$A \rightarrow \varepsilon$	where $A \in \mathcal{V}_0^\top$,
$A \rightarrow BC$	where $A \in \mathcal{V}_0^\top$ and $B, C \in \mathcal{V}_0$,
$A \rightarrow a(B)$	where $A \in \mathcal{V}_0^\perp$, $a \in \Sigma$, and $B \in \mathcal{V}_0$,
$A \rightarrow X\langle B \rangle$	where $A, B \in \mathcal{V}_0^\perp$ and $X \in \mathcal{V}_1$,
$X \rightarrow Y\langle Z \rangle$	where $X, Y, Z \in \mathcal{V}_1$
$X \rightarrow a(LxR)$	where $X \in \mathcal{V}_1$, $a \in \Sigma$, and $L, R \in \mathcal{V}_0$,

Every variable $A \in \mathcal{V}_0$ derives a forest $\llbracket A \rrbracket$ and every variable $X \in \mathcal{V}_1$ derives a context $\llbracket X \rrbracket$, see [11] for formal definitions. An example FSLP for a tree is shown in Figure 3.

The normal form allows us to define two string SLPs (without start variables) that capture the horizontal and the vertical compression in \mathcal{G} . The *rib SLP* $\mathcal{G}_\square = (\mathcal{V}_0, \Sigma_\square, \mathcal{R}_\square)$ over the alphabet $\Sigma_\square = \{\underline{A} \mid A \in \mathcal{V}_0^\perp\}$ contains all rules of the form $A \rightarrow \varepsilon$ or $A \rightarrow BC$ from \mathcal{R} where $A \in \mathcal{V}_0^\top$, and the rule $A \rightarrow \underline{A}$ for all $A \in \mathcal{V}_0^\perp$. We write $\llbracket A \rrbracket_\square = \underline{A}_1 \dots \underline{A}_n$ for the string derived by A in \mathcal{G}_\square , which satisfies $\llbracket A \rrbracket = \llbracket A_1 \rrbracket \dots \llbracket A_n \rrbracket$. In the example of Figure 3 we have $\llbracket B \rrbracket_\square = \underline{C} \underline{C}$. The *spine SLP* $\mathcal{G}_\sqcap = (\mathcal{V}_0^\perp \cup \mathcal{V}_1, \Sigma_\sqcap, \mathcal{R}_\sqcap)$ is defined over the alphabet

$$\Sigma_\sqcap = \{a(B) \mid (A \rightarrow a(B)) \in \mathcal{R}\} \cup \{a(LxR) \mid (X \rightarrow a(LxR)) \in \mathcal{R}\}.$$

The set \mathcal{R}_\sqcap contains all rules $A \rightarrow a(B)$ and $X \rightarrow a(LxR)$ from \mathcal{R} . It also contains the rule $A \rightarrow X$ for all $(A \rightarrow X\langle B \rangle) \in \mathcal{R}$ where $A \in \mathcal{V}_0^\perp$, and $X \rightarrow YZ$ for all $(X \rightarrow Y\langle Z \rangle) \in \mathcal{R}$. We write $\llbracket V \rrbracket_\sqcap$ for the string derived by V in \mathcal{G}_\sqcap . If $X \in \mathcal{V}_1$ and $\llbracket X \rrbracket_\sqcap = a_1(L_1xR_1) \dots a_n(L_nxR_n)$ then $\llbracket X \rrbracket$ is the vertical composition of all contexts $a_i(\llbracket L_i \rrbracket_\sqcap x \llbracket R_i \rrbracket_\sqcap)$. In the example of Figure 3 we have $\llbracket C \rrbracket_\sqcap = b\langle Dx D \rangle b\langle Dx D \rangle$.

FSLP navigation. Now we define the data structure from [21]. It represents a node v in a tree produced by a variable $A \in \mathcal{V}_0$ by a pointer $\tau(A, v)$, which is basically a sequence of navigation pointers in the SLPs \mathcal{G}_\square and \mathcal{G}_\sqcap describing the path from the root of $\llbracket A \rrbracket$ to v . Intuitively, the pointer $\tau(A, v)$ can be described as follows. First we select the subtree of $\llbracket A \rrbracket$ which contains v , by navigating in \mathcal{G}_\square to a symbol \underline{B}_0 where $B_0 \in \mathcal{V}_0^\perp$. The tree $\llbracket B_0 \rrbracket$ is defined by a sequence of insertion rules $B_0 \rightarrow X_1\langle B_1 \rangle$, $B_1 \rightarrow X_2\langle B_2 \rangle$, \dots , $B_{k-1} \rightarrow X_k\langle B_k \rangle$, where possibly $k = 0$, and a final rule $B_k \rightarrow a(C)$. We navigate in \mathcal{G}_\sqcap in the variable B_0 from left to right. The string $\llbracket B_0 \rrbracket_\sqcap$ specifies the contexts $a_j(L_jxR_j)$ which together form the context $\llbracket X_1 \rrbracket$. If we encounter a context $a_j(L_jxR_j)$ which contains v , there are two cases. If v is the a_j -labeled root then we are done. If v is contained in either L_j or R_j then we record the direction (L or R) and continue recursively from the variable L_j or R_j . If v is not contained in the context X_1 then we reach the end of $\llbracket B_0 \rrbracket_\sqcap$, and continue searching from B_1 ,

etc. If v is contained in B_k then it is either its root or it is contained in C . In the former case, we are done; in the latter case we record the direction \mathbf{M} and continue recursively from C .

To define $\tau(A, v)$ formally, let us write $\sigma_{\sqsubseteq}(A, i)$ and $\sigma_{\sqsupset}(A, i)$ for the pointers to the i -th position of a variable $A \in \mathcal{V}_0$ in $\mathcal{G}_{\sqsubseteq}$ and \mathcal{G}_{\sqsupset} , respectively. We represent every node v in every variable $A \in \mathcal{V}_0$ by a *horizontal pointer* $\tau_{\sqsubseteq}(A, v)$. Furthermore, we represent every node v in every variable $A \in \mathcal{V}_0^{\perp}$, deriving a tree, by a *vertical pointer* $\tau_{\sqsupset}(A, v)$. The pointers are defined recursively as follows:

1. Let $A \in \mathcal{V}_0$. If $\llbracket A \rrbracket_{\sqsubseteq} = \underline{A_1} \dots \underline{A_n}$ and v is contained in $\llbracket A_i \rrbracket$ then set $\tau_{\sqsubseteq}(A, v) := \sigma_{\sqsubseteq}(A, i) \tau_{\sqsubseteq}(A_i, v)$.
2. Let $A \in \mathcal{V}_0^{\perp}$ with a rule $A \rightarrow a(B)$. If v is the root of $\llbracket A \rrbracket$ set $\tau_{\sqsupset}(A, v) := \sigma_{\sqsupset}(A, 1)$, and otherwise $\tau_{\sqsupset}(A, v) := \sigma_{\sqsupset}(A, 1) \mathbf{M} \tau_{\sqsupset}(B, v)$.
3. Let $A \in \mathcal{V}_0^{\perp}$ with a rule $A \rightarrow X \langle B \rangle$ and $\llbracket A \rrbracket_{\sqsupset} = \llbracket X \rrbracket_{\sqsupset} = a_1(L_1 x R_1) \dots a_n(L_n x R_n)$. If v is contained in $f_i = a_i(\llbracket L_i \rrbracket x \llbracket R_i \rrbracket)$ set $\tau_{\sqsupset}(A, v)$ to be $\sigma_{\sqsupset}(A, i)$, $\sigma_{\sqsupset}(A, i) \mathbf{L} \tau_{\sqsupset}(L_i, v)$ or $\sigma_{\sqsupset}(A, i) \mathbf{R} \tau_{\sqsupset}(R_i, v)$, depending whether v is the root of f_i or is contained in $\llbracket L_i \rrbracket$ or $\llbracket R_i \rrbracket$. If v is contained in $\llbracket B \rrbracket$ set $\tau_{\sqsupset}(A, v) := \sigma_{\sqsupset}(A, n) \tau_{\sqsupset}(B, v)$.

For the navigation we only use the horizontal pointers and write $\tau(A, v)$ instead of $\tau_{\sqsubseteq}(A, v)$.

► **Theorem 13** ([21]). *A given FSLP \mathcal{G} can be preprocessed in $\mathcal{O}(|\mathcal{G}|)$ time and space so that the following operations are supported in constant time:*

- *Given a variable A , compute $\tau(A, v)$ where v is the root of the first/last tree in $\llbracket A \rrbracket$.*
- *Given $\tau(A, v)$, compute $\tau(A, v')$ where v' is the parent, first/last child or left/right sibling of v , or return \perp if it does not exist.*
- *Given $\tau(A, v)$, return the symbol of node v .*

Navigation to a child. We extend Theorem 13 by the operation which, given a pointer $\tau(S, v)$ and a number $1 \leq j \leq d$, where v has degree d , moves the pointer to the j -th child of v in $\mathcal{O}(\log d)$ time. To this end we apply Theorem 1 to $\mathcal{G}_{\sqsubseteq}$ so that every variable $A \in \mathcal{V}_0$ in the rib SLP has height $\mathcal{O}(\log |\llbracket A \rrbracket_{\sqsubseteq}|)$, by adding only $\mathcal{O}(g)$ new variables. In particular, we can compute a pointer $\sigma_{\sqsubseteq}(A, i)$ in $\mathcal{O}(\log |\llbracket A \rrbracket_{\sqsubseteq}|)$ time by Theorem 12. Furthermore, we compute the length $|\llbracket A \rrbracket_{\sqsubseteq}|$ for all $A \in \mathcal{V}_0$ in linear time.

Suppose we are given a pointer $\tau(S, v)$ to a node v with degree d for some variable $S \in \mathcal{V}_0$. We show how to compute $\tau(S, v_j)$ where v_j is the j -th child of v in $\mathcal{O}(\log d)$ time.

1. In the first case the last pointer in $\tau(S, v)$ is $\sigma_{\sqsubseteq}(A, 1)$ where the rule of $A \in \mathcal{V}_0^{\perp}$ is of the form $A \rightarrow a(B)$. Here B derives the forest below the a -node and we need to move to the root of the j -th tree in the forest. We compute the pointer $\sigma_{\sqsubseteq}(B, j)$ in $\mathcal{O}(\log |\llbracket B \rrbracket_{\sqsubseteq}|) \leq \mathcal{O}(\log d)$ time. Then we query the symbol $\underline{B_j}$ at pointer $\sigma_{\sqsubseteq}(B, j)$ and compute the pointer $\sigma_{\sqsupset}(B_j, 1)$ in constant time. Then we obtain $\tau(S, v_j) = \tau(S, v) \mathbf{M} \sigma_{\sqsubseteq}(B, j) \sigma_{\sqsupset}(B_j, 1)$.
2. In the second case the last pointer in $\tau(S, v)$ is $\sigma_{\sqsupset}(A, i)$ where the rule of $A \in \mathcal{V}_0^{\perp}$ is of the form $A \rightarrow X \langle B \rangle$. We query the symbol $a_i(L_i x R_i)$ at pointer $\sigma_{\sqsupset}(A, i)$. The j -th child v_j is either in L_i , R_i or at the position of the parameter x . If $j = |\llbracket L_i \rrbracket_{\sqsubseteq}| + 1$ we replace $\sigma_{\sqsupset}(A, i)$ by $\sigma_{\sqsupset}(A, i + 1)$ in constant time. If this is not successful then v_j is the root of B and we have $\tau(S, v_j) = \tau(S, v) \sigma_{\sqsupset}(B, 1)$, which can be computed in constant time. If $j \leq |\llbracket L_i \rrbracket_{\sqsubseteq}|$ we compute $\sigma_{\sqsubseteq}(L_i, j)$ in $\mathcal{O}(\log |\llbracket L_i \rrbracket_{\sqsubseteq}|) \leq \mathcal{O}(\log d)$ time. We query the symbol $\underline{B_j}$ at $\sigma_{\sqsubseteq}(L_i, j)$ and compute $\sigma_{\sqsupset}(B_j, 1)$ in constant time. Then we have $\tau(S, v_j) = \tau(S, v) \mathbf{L} \sigma_{\sqsubseteq}(L_i, j) \sigma_{\sqsupset}(B_j, 1)$. If $j \geq |\llbracket L_i \rrbracket_{\sqsubseteq}| + 2$ we proceed similarly using $\sigma_{\sqsubseteq}(R_i, j - |\llbracket L_i \rrbracket_{\sqsubseteq}| - 1)$.

Remarks. In its original form the SLP navigation data structure from [18] is non-persistent, i.e. the operations modify the given pointer. However, it is not hard to adapt the structure so that an operation returns a fresh pointer, by representing paths in the derivation tree using

linked lists that share common prefixes. In a similar fashion, Theorem 2 can be adapted so that a pointer is not modified by a navigation step.

Finally, let us comment on the space consumption of a single pointer in Theorem 2. A single pointer $\tau(A, v)$ consists of a sequence of pointers in \mathcal{G}_{\square} and \mathcal{G}_{\sqcap} that almost describes a path in the derivation tree of A in \mathcal{G} . The sequence may contain pointers $\sigma_{\square}(A, n)$ that point to the lowest node above the parameter of a context $\llbracket X \rrbracket$. However, in the representation of [18] such a pointer $\sigma_{\square}(A, n)$ only uses $\mathcal{O}(1)$ space, since it is a rightmost path in the derivation tree of A in \mathcal{G}_{\square} . Therefore $\tau(A, v)$ uses $\mathcal{O}(\text{height}(A))$ space where $\text{height}(A)$ is the height of the derivation tree of A in \mathcal{G} . By [10, Theorem VII.3] we can indeed assume that the FSLP \mathcal{G} has $\mathcal{O}(\log N)$ height while retaining the size bound of $\mathcal{O}(|\mathcal{G}|)$. We also need the fact that the transformation into the normal form increases the height only by a constant factor. However, since the application of Theorem 1 to the rib SLP may possibly increase the total height of the FSLP \mathcal{G} by more than a constant factor, it is unclear whether Theorem 2 can be achieved with $\mathcal{O}(\log N)$ sized pointers.

5 Finger search in SLP-compressed strings

In this section we present our solution (Theorem 3) for the finger search problem using contracting SLPs. Our finger data structure is an *accelerated path*, which compactly represents the path from root to the finger in the derivation tree using precomputed forests on the dag of the SLP. To move the finger we ascend to some variable on the path, branch off from the path, and descend in a subtree while computing the new accelerated path. We can maintain the accelerated path in a dynamic predecessor structure with constant update and query time, thanks to the $\mathcal{O}(\log N)$ height of the SLP. We follow the approach of [2] and present an improved $\mathcal{O}(tg)$ space solution for the *fringe access problem*: Given a variable A and a position $1 \leq i \leq |A|$, we can access the i -th symbol of $\llbracket A \rrbracket$ in time $\mathcal{O}(\log d + \log^{(t)} N)$ where $d = \min\{i, |A| - i + 1\}$ is the distance from the fringe of A , and t is any parameter.

Data structures. Recall that we assume the word RAM model with word size $w \geq \log N$ where N is the string length. Since all occurring sets and trees have size $n \leq N$ we have $w \geq \log n$ in the following. We use a dynamic predecessor data structure by Pătraşcu-Thorup, which represents a dynamic set S of $n = w^{\mathcal{O}(1)}$ many w -bit integers in space $\mathcal{O}(n)$, supporting the following updates and queries in constant time [20]: $\text{insert}(S, x) = S \cup \{x\}$, $\text{delete}(S, x) = S \setminus \{x\}$, $\text{pred}(S, x) = \max\{y \in S \mid y < x\}$, $\text{succ}(S, x) = \min\{y \in S \mid y > x\}$, $\text{rank}(S, x) = |\{y \in S \mid y < x\}|$, and $\text{select}(S, i) = x$ with $\text{rank}(S, x) = i$, if any. By enlarging the word size to $2w$ we can identify a number $x \cdot 2^w + y$, where x, y are w -bit numbers, with the key-value pair (x, y) , allowing us to store key-value pairs in the data structure sorted by their keys. We remark that all standard operations on a $2w$ -bit word RAM can be simulated by a constant number of w -bit operations. This dynamic predecessor structure is used to maintain the accelerated path to the finger. We extend the data structure by the operation $\text{split}(S, x) = \{y \in S \mid y \leq x\}$ for $\mathcal{O}(w)$ -sized sets.

► **Theorem 14** ([20]). *There is a data structure representing a dynamic set S of at most $n = \mathcal{O}(w)$ many w -bit numbers in space $\mathcal{O}(n)$ supporting the operations $\text{insert}(S, x)$, $\text{split}(S, x)$ and $\text{pred}(S, x)$ in constant time.*

A *weighted tree* T is a rooted tree where each node v carries a nonnegative integer $d(v)$, called the *weighted depth*, satisfying $d(u) \leq d(v)$ for all nodes v with parent u . Given a node v and a number $p \in \mathbb{N}$, the *weighted ancestor query* (v, p) asks to return the highest ancestor

u of v with $d(u) > p$. Given a node v and $p \in \mathbb{N}$, we can also compute the highest ancestor u of v where the *weighted distance* $d(u, v) = d(v) - d(u)$ is less than p , by the weighted ancestor query $(v, d(v) - p)$. In our application the edges have nonnegative weights and the weighted depth of a node is computed as the sum of all edge weights on the path from the root.

Kopelowitz and Lewenstein [15] showed that weighted ancestor queries on a tree of size n can be answered in time $\mathcal{O}(\text{pred}(n) + \log^* n)$ where $\text{pred}(n)$ is the query time of a predecessor data structure. It was claimed in [14] that the $\log^* n$ -term can be eliminated without giving an explicit proof. We refer to [9, Proposition 17] for a proof in the setting where $n \leq w$ using the predecessor structure from [20]. Furthermore, we can also support constant time weighted ancestor queries if the tree height is $\mathcal{O}(w)$.

► **Proposition 15.** *A weighted tree T with n nodes and height $h = \mathcal{O}(w)$ can be preprocessed in $\mathcal{O}(n)$ space and time so that weighted ancestor queries can be answered in constant time.*

The fringe access problem. Consider an SLP \mathcal{G} with the variable set \mathcal{V} containing g variables for a string of length N . Using Theorem 1 we assume that \mathcal{G} is in Chomsky normal form and that every variable A has height $\mathcal{O}(\log |A|)$. We precompute in linear time the length of all variables in \mathcal{G} . To simplify notation we assume that the variables B and C in all rules $A \rightarrow BC$ are distinct, which can be established by doubling the number of variables. We assign to each edge e in $\text{dag}(\mathcal{G})$ a *left weight* $\lambda(e)$ and a *right weight* $\rho(e)$: For every rule $A \rightarrow BC$ in \mathcal{G} , the edge $e = (A, B)$ has left weight $\lambda(e) = 0$ and right weight $\rho(e) = |C|$, whereas the edge $e = (A, C)$ has left weight $\rho(e) = |B|$ and right weight $\lambda(e) = 0$.

Let \mathcal{F} be a finite set of subforests of $\text{dag}(\mathcal{G})$ with node set \mathcal{V} whose edges point towards the roots (as for example in the heavy forest). The forests will be computed later in Proposition 16. For every forest $F \in \mathcal{F}$ we define two edge-weighted versions F_L and F_R where the edges inherit the left weights and the right weights from $\text{dag}(\mathcal{G})$, respectively, yielding $2|\mathcal{F}|$ many weighted forests. Let $\lambda_F(A)$ and $\rho_F(A)$ be the weighted depths of A in F_L and F_R , respectively. In $\mathcal{O}(|\mathcal{F}| \cdot g)$ time we compute for all $A \in \mathcal{V}_0$ the weighted depths $\lambda_F(A)$ and $\rho_F(A)$ and the root $\text{root}_F(A)$ of the subtree of F containing A . We write $\lambda_F(A, B)$ and $\rho_F(A, B)$ for the weighted distances between A and B in F_L and F_R , respectively. We preprocess all $2|\mathcal{F}|$ weighted forests in time and space $\mathcal{O}(|\mathcal{F}| \cdot g)$ to support weighted ancestor queries in constant time according to Proposition 15. This is possible because the height of the forests is $\mathcal{O}(\log N) = \mathcal{O}(w)$.

We denote by $\langle A, i \rangle$ the state in which we aim to compute a compact representation of the path from A to the i -th leaf in the derivation tree of A . Starting from state $\langle A, i \rangle$ we can take short steps and long steps. A *short step* considers the rule of A : If it is a terminal rule $A \rightarrow a$ we have found the symbol a . If it is a binary rule $A \rightarrow BC$ we compare i with $|B|$: If $i \leq |B|$ then the short step leads to $\langle B, i \rangle$, and otherwise to $\langle C, i - |B| \rangle$. A *left long step in* $F \in \mathcal{F}$ is possible if $i \leq \lambda_F(A) + |\text{root}_F(A)|$. Put differently, the path from A to $A[i]$ branches off to the left on the path from A to $\text{root}_F(A)$, or continues below $\text{root}_F(A)$. We determine the highest ancestor X of A in F_L with $\lambda_F(A, X) < i$ and move to $\langle X, i - \lambda_F(A, X) \rangle$. Using the weighted ancestor data structure on F the variable X can be determined in constant time. Symmetrically, a *right long step in* F is possible if $|A| - i + 1 \leq \rho_F(A) + |\text{root}_F(A)|$. Put differently, the path from A to $A[i]$ branches off to the right on the path from A to $\text{root}_F(A)$, or continues below $\text{root}_F(A)$. After finding the highest ancestor X of A in F_R with $\rho_F(A, X) < |A| - i + 1$ we move to $\langle X, |A| - i + 1 - \rho_F(A, X) \rangle$.

If we take a long step in a forest F then a subsequent short step moves us from one subtree in F to a different subtree, by maximality of the answer from the weighted ancestor query. A sequence of short and long steps is summarized in an *accelerated path* (e_1, \dots, e_m) of

short and long edges. A *short edge* is an edge (A, B) in $\text{dag}(\mathcal{G})$ whereas a *long edge* is a triple (A, F, B) such that $F \in \mathcal{F}$ contains a (unique) path from A to B . In the triple (A, F, B) we store only an identifier of F instead of the forest itself. The left weight and the right weight of a long edge $e = (A, F, B)$ are $\lambda(e) = \lambda_F(A, B)$ and $\rho(e) = \rho_F(A, B)$, respectively.

► **Proposition 16.** *Let $t \geq 1$. One can compute and preprocess in $\mathcal{O}(tg)$ time a set of forests \mathcal{F} with $|\mathcal{F}| = \mathcal{O}(t)$ so that given a variable A and a position $1 \leq i \leq |A|$, one can compute an accelerated path from A to $A[i]$ in time $\mathcal{O}(\log d + \log^{(t+1)} N)$ where $d = \min\{i, |A| - i + 1\}$.*

Proof sketch. First let us assume that $i \leq |A|/2$. To this end we construct forests $\mathcal{F} = \{F_0, \dots, F_{t-1}\}$ in $\mathcal{O}(tg)$ time so that an accelerated path from A to $A[i]$ can be computed in time $\mathcal{O}(\log i + \log^{(t+1)} N)$. For all $F \in \mathcal{F}$ we construct two constant time weighted ancestor data structures (for F_L and F_R), and compute $\lambda_F(A)$, $\rho_F(A)$ and $\text{root}_F(A)$ for all $A \in \mathcal{V}$.

The simple algorithm which only uses short steps takes time $\mathcal{O}(\log |A|)$. We first improve the running time to $\mathcal{O}(\log i + \log \log |A|)$. Let $\text{rk}(A) = \min\{k \in \mathbb{N} : |A| \leq 2^{2^k}\}$, which is at most $1 + \log \log |A|$. The forest F_0 contains for every rule $A \rightarrow BC$ in \mathcal{G} either the edge (A, B) , if $\text{rk}(A) = \text{rk}(B)$, or the edge (A, C) if $\text{rk}(A) = \text{rk}(C) > \text{rk}(B)$. If $\text{rk}(A)$ is strictly greater than both $\text{rk}(B)$ and $\text{rk}(C)$ then no edge is added for the rule $A \rightarrow BC$. To query $A[i]$ where $\text{rk}(A) = k$ we make a case distinction. If $i \leq \lambda_{F_0}(A) + |\text{root}_{F_0}(A)|$ we take a left long step in F_0 to some state $\langle X, j \rangle$ with $\text{rk}(X) < k$ and $j \leq i$, and repeat the procedure from there. Otherwise $i > |\text{root}_{F_0}(A)| > 2^{2^{k-1}} \geq \sqrt{|A|}$ and we query $A[i]$ using short steps in time $\mathcal{O}(\log |A|) \leq \mathcal{O}(\log i)$. Since the rank is reduced in the former case this procedure takes time $\mathcal{O}(\log i + k) \leq \mathcal{O}(\log i + \log \log |A|)$.

We can replace $\log \log |A|$ by $\log^{(t+1)} N$ by adding forests F_1, \dots, F_{t-1} to \mathcal{F} : The forest F_k where $1 \leq k \leq t-1$ contains for every rule $A \rightarrow BC$ in \mathcal{G} either the edge (A, B) , if $|B| > \log^{(k)} N$, or the edge (A, C) , if $|B| \leq \log^{(k)} N$ and $|C| > \log^{(k)} N$. To query $A[i]$ we compute the maximal $k \in [0, t-1]$ such that $i \leq \log^{(k)} N$. We will compute the accelerated path in time $\mathcal{O}(\log i + \log^{(k+2)} N) \leq \mathcal{O}(\log i + \log^{(t+1)} N)$. If $|A| \leq \log^{(k)} N$ we can query $A[i]$ in time $\mathcal{O}(\log i + \log \log |A|) \leq \mathcal{O}(\log i + \log^{(k+2)} N)$. If $i \leq \log^{(k)} N < |\text{root}_{F_k}(A)|$ we can take a left long step in F_k and then a short step to some state $\langle X, j \rangle$ where $|X| \leq \log^{(k)} N$ and $j \leq i$. We can query $X[j]$ in time $\mathcal{O}(\log j + \log \log |X|) \leq \mathcal{O}(\log i + \log^{(k+2)} N)$.

Finally, for every forest $F \in \mathcal{F}$ we include a mirrored right-skewed version of F , which then supports access to symbol $A[i]$ in time $\mathcal{O}(\log(|A| - i + 1) + \log^{(t+1)} N)$. ◀

Solving the finger search problem. We are ready to prove Theorem 3. We maintain an accelerated path $\pi = (e_1, \dots, e_m)$ from the start variable S to the current finger position f with its left weights and right weights as follows. Let $\ell_j = \sum_{k=1}^j \lambda(e_k)$ and $r_j = \sum_{k=1}^j \rho(e_k)$ be the prefix sums of the weights. Observe that $f = \ell_m + 1$. We store a stack $\gamma = ((e_1, \ell_1, r_1), (e_2, \ell_2, r_2), \dots, (e_m, \ell_m, r_m))$, implemented as an array. Given $i \in [1, m]$, one can pop all elements at positions $i+1, \dots, m$ in constant time. We store the set of distinct prefix sums $L = \{\ell_j \mid 0 \leq j \leq m\}$ in a dynamic predecessor data structures from Theorem 14 where a prefix sum ℓ is stored together with the maximal index j such that $\ell = \ell_j$. Similarly $R = \{r_j \mid 0 \leq j \leq m\}$ is stored in a predecessor data structure.

For $\text{setfinger}(f)$ we compute an arbitrary accelerated path from S to $S[f]$, say only using only short steps, and set up the list γ and the predecessor data structures for L and R in time $\mathcal{O}(\log N)$. For $\text{movefinger}(i)$ we can assume that $f - i = d > 0$ since the data structures are left-right symmetric. By a predecessor query on L we can find the unique index j with $\ell_j < i \leq \ell_{j+1}$. Then we restrict γ to its prefix of length j , and perform $\text{split}(L, \ell_j)$ and $\text{split}(R, r_j)$, all in constant time. Using fringe access we can compute an accelerated path

π' from A to $S[i] = A[i']$ where $i' = i - \ell_j$: If e_{j+1} is a short edge we take a short step and then use Proposition 16 for the remaining path. If e_{j+1} is a left or right long edge in a forest $F \in \mathcal{F}$ we take a *left* long step, followed by a short step, and then use Proposition 16 for the remaining path. Finally, we update the stack γ and the prefix sums in L and R in time $\mathcal{O}(|\pi'|)$. This concludes the proof of Theorem 3.

We leave it as an open question whether there exists a linear space finger search data structure, supporting $\text{access}(i)$ and $\text{movefinger}(i)$ in $\mathcal{O}(\log d)$ time. For path balanced SLPs such a solution does exist.

► **Theorem 17.** *Given an (α, β) -path balanced SLP of size g for a string of length N , one can support $\text{setfinger}(i)$ in $\mathcal{O}(\log N)$ time, and $\text{access}(i)$ and $\text{movefinger}(i)$ in $\mathcal{O}(\log d)$ time, where d is the distance between i and the current finger position, after $\mathcal{O}(g)$ preprocessing time and space.*

Abstract

In the two-dimensional orthogonal colored range counting problem, we preprocess a set, P , of n colored points on the plane, such that given an orthogonal query rectangle, the number of distinct colors of the points contained in this rectangle can be computed efficiently. For this problem, we design three new solutions, and the bounds of each can be expressed in some form of time-space tradeoff. By setting appropriate parameter values for these solutions, we can achieve new specific results with (the space costs are in words and ϵ is an arbitrary constant in $(0, 1)$):

- $O(n \lg^3 n)$ space and $O(\sqrt{n} \lg^{5/2} n \lg \lg n)$ query time;
- $O(n \lg^2 n)$ space and $O(\sqrt{n} \lg^{4+\epsilon} n)$ query time;
- $O(n \frac{\lg^2 n}{\lg \lg n})$ space and $O(\sqrt{n} \lg^{5+\epsilon} n)$ query time;
- $O(n \lg n)$ space and $O(n^{1/2+\epsilon})$ query time.

A known conditional lower bound to this problem based on Boolean matrix multiplication gives some evidence on the difficulty of achieving near-linear space solutions with query time better than \sqrt{n} by more than a polylogarithmic factor using purely combinatorial approaches. Thus the time and space bounds in all these results are efficient. Previously, among solutions with similar query times, the most space-efficient solution uses $O(n \lg^4 n)$ space to answer queries in $O(\sqrt{n} \lg^8 n)$ time (SIAM. J. Comp. 2008). Thus the new results listed above all achieve improvements in space efficiency, while all but the last result achieve speed-up in query time as well.

1 Introduction

In computational geometry, there have been extensive studies on problems over points associated with information represented as colors [13, 14, 20, 19, 21, 11, 23, 10, 12, 5, 3, 16, 24]. Among them, the *2D orthogonal range counting* query problem is one of the most fundamental. In this problem, we preprocess a set, P , of n points on the plane, each colored in one of C different colors, such that given an orthogonal query rectangle, the number of distinct colors of the points contained in this rectangle can be computed efficiently.

This problem is important in both theory and practice. Theoretically, it has connections to matrix multiplication: The ability to answer m colored range counting queries offline over n points on the plane in $o(\min\{n, m\}^{\omega/2})$ time, where ω is the best current exponent of the running time of matrix multiplication, would yield a faster algorithm for Boolean matrix multiplication [19]. In practice, the records in database systems and many other applications are often associated with categorical information which can be modeled as colors. The Structured Programming Language (SQL) thus provides keywords such as `DISTINCT`

and GROUP BY to compute information about the distinct categories of the records within a query range, which can be modeled using colored range query problems, and these queries have also been used in database query optimization [6].

One challenge in solving the 2D orthogonal range counting problem is that the queries are not easily decomposable: if we partition the query range into two or more subranges, we cannot simply obtain the number of distinct colors in the query range by adding up the number of distinct colors in each subrange. Furthermore, the conditional lower bound based on matrix multiplication as described above gives theoretical evidence on the hardness of this problem. Indeed, if polylogarithmic query times are desired, the solution with the best space efficiency [22] uses $O(n^2 \lg n / \lg \lg n)$ words of space to answer queries in $O((\lg n / \lg \lg n)^2)$ time. There is a big gap between the complexities of this solution to those of the optimal solution to *2D orthogonal range counting* for which we do not have color information and are only interested in computing the number of points in a 2D orthogonal query range. The latter can be solved in merely linear space and $O(\lg n / \lg \lg n)$ query time [17].

Applications that process a significant amount of data would typically require structures whose space costs are much lower than quadratic. As the running time of the best known combinatorial algorithm of multiplying two $n \times n$ Boolean matrices is $\Theta(n^3 / \text{polylog}(n))$ [1, 2, 26], the conditional lower bound of 2D orthogonal colored range counting implies that no solution can simultaneously have preprocessing time better than $\Omega(n^{3/2})$ and query time better than $\Omega(\sqrt{n})$, by purely combinatorial methods¹ with current knowledge, save for polylogarithmic speed-ups. To match this query time within polylogarithmic factors, the most space-efficient solution uses $O(n \lg^4 n)$ words of space to answer queries in $O(\sqrt{n} \lg^8 n)$ time [19]. Despite this breakthrough, the exponents in the polylogarithmic factors in the time and space bounds leave much room for potential improvements. Hence, in this paper, we aim at decreasing these polylogarithmic factors in both space and time costs, to design solutions that are more desirable for applications that manage large data sets.

Previous Work. Gupta et al. [13] showed how to reduce the orthogonal colored range searching problem in 1D to orthogonal range searching over uncolored points in 2D, thus achieving a linear-space solution with $O(\lg n / \lg \lg n)$ query time. Later, the query time was improved to $O(\lg C / \lg \lg n)$ by Nekrich [23], where C is the number of colors.

To solve 2D colored orthogonal range counting, Gupta et al. [13] used persistent data structures to extend their 1D solution to 2D and designed a data structure of $O(n^2 \lg^2 n)$ words that supports queries in $O(\lg^2 n)$ time. Kaplan et al. [19] achieved the same bounds by decomposing the input points into disjoint boxes in 3D and reduced the problem to 3D stabbing counting queries. Recently, Munro et al. [22] showed that 3D 3-sided colored range counting can be answered in $O((\lg n / \lg \lg n)^2)$ time using a data structure of $O(n(\lg n / \lg \lg n))$ words of space, which implies a solution to 2D 3-sided colored range counting with the same time and space bound. For each distinct x -coordinate x_i of the points in the point set, if we use the strategy in [13, 19] to build a data structure supporting 2D 3-sided queries upon the points whose x -coordinates are greater than or equal to x_i , then this set of data structures constructed can be used to answer a 4-sided query. This yields a solution to the 2D orthogonal colored range counting problem with $O(n^2 \lg n / \lg \lg n)$ words of space and $O((\lg n / \lg \lg n)^2)$ query time. Kaplan et al. [19] further showed how to achieve time-space tradeoffs by designing a solution with $O(X \lg^7 n)$ query time that uses $O((\frac{n}{X})^2 \lg^6 n + n \lg^4 n)$

¹ When algebraic approaches are allowed, $\omega \approx 2.3727$ [25], implying that the preprocessing time and the query time cannot be simultaneously less than $\Omega(n^{1.18635})$ and $\Omega(n^{0.18635})$, respectively.

words of space. Setting $X = \sqrt{n} \lg n$ minimizes space usage, achieving an $O(n \lg^4 n)$ -word solution with $O(\sqrt{n} \lg^8 n)$ query time. When only linear space is allowed, Grossi and Vind [11] showed how to answer a query in $O(n / \text{polylog}(n))$ time. Though not explicitly stated anywhere, by combining an approach that Kaplan et al. [19] presented for dimensions of 3 or higher (which also works for 2D) and a linear space solution to 2D orthogonal range emptiness [4], the query time can be improved to $O(n^{3/4} \lg^\epsilon n)$ for any constant ϵ using a linear space structure. Finally, Kaplan et al. also considered the offline version of this problem and showed that n 2D orthogonal colored range counting queries can be answered in $O(n^{1.408})$ time.

Researchers have also studied approximate colored range counting problem. In 1D, El-Zein et al. [10] designed a succinct data structure to answer a $(1 + \epsilon)$ -approximate colored counting query in constant time. In 2D, Rahul [24] provided a reduction from $(1 + \epsilon)$ -approximate orthogonal colored range counting to 2D colored orthogonal range reporting which reports the number of distinct colors in a 2D orthogonal query range. Based on this, they gave an $O(n \lg n)$ -word data structure with $O(\lg n)$ query time.

The orthogonal colored range counting problem has also been studied in higher dimensions [21, 19, 24, 16]. Furthermore, He and Kazi [16] generalized it to categorical path counting by replacing the first dimension with tree topology. One of their solutions to a path query problem generalized from 2D orthogonal colored range counting also uses linear space and provides $O(n^{3/4} \lg^\epsilon n)$ query time. We end this brief survey by commenting that, after a long series of work [18, 13, 19, 23, 11, 12], Chan and Nekrich [5] solved the related 2D orthogonal range reporting problem in $O(n \lg^{3/4+\epsilon} n)$ words of space and $O(\lg \lg n + k)$ query time for points in rank space, where k is output size. This almost matches the bounds of the optimal solution to (uncolored) 2D orthogonal range reporting over points in rank space, which uses $O(n \lg^\epsilon n)$ words to answer queries in $O(\lg \lg n + k)$ time.

Our Results. Under the word RAM model, we present three results, all in the form of time-space tradeoffs, for two-dimensional orthogonal colored range counting. Specifically, for an integer parameter $X \in [1, n]$, we propose solutions (all space costs are in words):

- with $O((\frac{n}{X})^2 \lg^4 n + n \lg^3 n)$ space and $O(\lg^4 n + X \lg^2 n \lg \lg n)$ query time; setting $X = \sqrt{n} \lg n$ achieves $O(n \lg^3 n)$ space and $O(\sqrt{n} \lg^{5/2} \lg \lg n)$ query time;
- with $O((\frac{n}{X})^2 \lg^4 n + n \lg^2 n)$ space and $O(\lg^6 n + X \lg^{3+\epsilon} n)$ query time for any constant $\epsilon \in (0, 1)$; setting $X = \sqrt{n} \lg n$ achieves $O(n \lg^2 n)$ space and $O(\sqrt{n} \lg^{4+\epsilon})$ query time;
- with $O((\frac{n}{X})^2 \lg^2 n \cdot \log_\lambda^2 n + n \lg n \cdot \log_\lambda n)$ space and $O(\lambda^2 \cdot \lg^6 n \cdot \log_\lambda^2 n + X \cdot \lg^{3+\epsilon} n \cdot \lambda \log_\lambda n)$ query time for an integer parameter $\lambda \in [2, n]$; setting $X = \sqrt{n \lg n \log_\lambda n}$ and $\lambda = \lg^\epsilon n$ achieves $O(n \frac{\lg^2 n}{\lg \lg n})$ space and $O(\sqrt{n} \lg^{5+\epsilon'})$ query time for any $\epsilon' > 2\epsilon$, while setting $X = \sqrt{n \lg n}$ and $\lambda = n^{\epsilon/5}$ achieves $O(n \lg n)$ space and $O(n^{1/2+\epsilon})$ query time.

When presenting each result, we also showed the bounds of the most space-efficient tradeoff that can be achieved by setting appropriate parameter values. The conditional lower bound based on Boolean matrix multiplication which we discussed before gives some evidence on the difficulty of achieving query time better than \sqrt{n} by more than a polylogarithmic factor using combinatorial approaches without increasing these space costs polynomially.

When comparing to previous results, note that only the time-space tradeoff presented by Kaplan et al. [19] could possibly achieve near-linear space and $O(\sqrt{n} \text{polylog}(n))$ query time. More specifically, their solution uses $O((\frac{n}{X})^2 \lg^6 n + n \lg^4 n)$ words of space to achieve $O(X \lg^7 n)$ query time. The most space-efficient tradeoff that could be obtained from it is an $O(n \lg^4 n)$ -word structure with $O(\sqrt{n} \lg^8 n)$ query time. Thus we indeed achieve the goal of improving the polylogarithmic terms in both their time and space costs significantly.

■ **Table 1** Bounds of 2D orthogonal colored range counting structures. The results in the form of time-space tradeoffs are listed in the top portion, in which X and λ are integer parameters in $[1, n]$ and $[2, n]$, respectively. The bottom portion presents results with specific bounds, among which marked with a \dagger are those obtained from the top portion by setting appropriate parameters values.

[19, 4]	RAM	$O(n^{3/4} \lg^\epsilon n)$	$O(n)$

It is worthwhile to mention that the result of Kaplan et al. can work under the pointer machine (PM) model. Thus, for an absolutely fair comparison, we show how our first result can be adapted to the same model of computation to achieve $O((\frac{n}{X})^2 \lg^4 n + n \lg^3 n)$ space and $O(\lg^5 n + X \lg^3 n)$ query time. Thus under PM, we have an $O(n \lg^3 n)$ -word structure with $O(\sqrt{n} \lg^{7/2} \lg n)$ query time. This is still a significant improvement over previous similar results. In the rest of the paper, however, we assume the word RAM model of computation unless otherwise specified, since most of our results are designed under it. See Table 1 for a comparison of our results to all previous results.

To achieve these results, we use the standard technique of decomposing a 4-sided query range to two 3-sided subranges with a range tree. Then the answer can be obtained by adding up the numbers of distinct colors assigned to points in each subrange and then subtracting the number of distinct colors that exist in both. We still use an approach of Kaplan et al. to reduce 2D 3-sided colored range counting to 3D stabbing queries over a set of boxes. What is new is our scheme of achieving time-space tradeoffs when computing the number of colors that exist in both subranges. Based on a parameter, we selectively precompute the sizes of the intersections between pairs of colors sets, each of which corresponds to a prefix of a certain box list somewhere in the stabbing query structures. Compared to the scheme of Kaplan et al. for the same purpose, ours gives more flexibility in the design of the 3D stabbing query structures that could work with the scheme. This extra flexibility further allows us to use and design different stabbing query structures to achieve new results.

2 Preliminaries

In this section, we introduce some notation and previous results used in our paper.

Notation. Throughout this paper, we assume points are in general positions unless otherwise specified. In three-dimensional space, we call a box B *canonical* if it is defined in the form of $[x_1, +\infty) \times [y_1, y_2) \times [z_1, z_2)$, where $x_1, y_1, z_1 \in \mathbb{R}$ and $y_2, z_2 \in \mathbb{R} \cup \{+\infty\}$. We use $B.x_1$ to refer to the lower bound of the x -range of B , $B.y_1$ and $B.y_2$ to respectively refer to the lower and upper bounds of the y -range of B , and so on. Let $(p.x, p.y, p.z)$ denote the coordinates of a point p . We say a point $q \in \mathbb{R}^3$ *dominates* another point $p \in \mathbb{R}^3$, if $q.x \geq p.x$, $q.y \geq p.y$ and $q.z \geq p.z$ hold simultaneously.

2D Orthogonal Colored Range Emptiness. An *orthogonal range emptiness* query determines whether an axis-aligned query rectangle contains at least one point in the point set P . Observe that a solution to this query problem directly leads to a solution to the colored version of this problem called *orthogonal colored range emptiness*, in which each point in P is colored in one of C different colors, and given a color c and an axis-aligned rectangle, the query asks whether the query range contains at least one point colored in c . The reduction works as follows: For each color $1 \leq c \leq C$, let P_c denote the subset of P containing all points colored in c . If we construct an orthogonal range emptiness structure over P_c for each color c , then we can answer an orthogonal colored range emptiness query by querying the structure constructed over the points with the query color. The following lemma thus directly follows from the work of Chan et al. [4] on range emptiness:

► **Lemma 1** ([4]). *Given n colored points in 2-dimensional rank space, there is a data structure of $nf(n)$ words that answers 2D orthogonal colored range emptiness queries in $g(n)$ time, where*

- a) $f(n) = O(1)$ and $g(n) = O(\lg^\epsilon n)$ for any constant $\epsilon > 0$; or
- b) $f(n) = O(\lg \lg n)$ and $g(n) = O(\lg \lg n)$.

Orthogonal Stabbing Queries over 3D Canonical Boxes. In the *3D stabbing counting* problem, we preprocess a set of 3D boxes, such that, given a query point q , we can compute the number of boxes containing q efficiently, while in the *3D stabbing reporting* query problem, we report these boxes. In both our solution and the solution of Kaplan et al. [19], we use data structures for this problem in a special case in which each box is a canonical box.

Here we introduce the data structure of Kaplan et al. [19] that solves the stabbing query problems over a set of n canonical boxes in 3D, as our first solution to the colored range counting problem augments this data structure and uses it as a component. Their data structure consists of two layers of segment trees. The structure at the top layer is a segment tree constructed over the z -coordinates of the boxes. More precisely, we project each box onto the z -axis to obtain an interval, and the segment tree is constructed over all these intervals. A box is assigned to a node in this tree if its corresponding interval on the z -axis is *associated* with this node. (Recall that as a segment tree, the leaves correspond to the elementary intervals induced by the endpoints of the intervals projected by each box onto the z -axis; and each internal node v of the tree corresponds to an interval $I_z(v)$ that are the union of elementary intervals of the leaves in the subtree rooted at v . A box is assigned to a node v in this tree if its corresponding interval on the z -axis covers the interval $I_z(v)$ but does not cover the interval $I_z(u)$, where u is the parent node of v .) For each node v in the top-layer segment tree, we further construct a segment tree over the projections of the

boxes assigned to v on the y -axis, and the segment trees constructed for all the nodes of the top-layer tree form the bottom-layer structure. Finally, for each node, v' , of a segment tree at the bottom layer, we construct a list, $sList(v')$, of the boxes assigned to v' , sorted by their x_1 -coordinates, i.e. the left endpoints of their projections on the x -axis; recall that the right endpoint is always $+\infty$ by the definition of canonical boxes. The lists of boxes associated with the nodes in the same bottom-level segment tree are linked together in a fractional cascading [8] data structure to facilitate the search among x_1 -coordinates of the boxes in each list.

With these data structures, the query algorithm first performs a search in the top-layer segment tree to locate the $O(\lg n)$ nodes whose associated intervals (which are projections of boxes on the z -axis) contain the z -coordinate of the query point q . For each of these nodes, we then query the bottom-layer segment tree constructed for it to find the boxes whose projections on the yz -plane contain $(q.y, q.z)$. The searches with this layer of structures end at $O(\lg^2 n)$ nodes of the bottom-layer trees, whose $sList$'s are disjoint. Finally, a binary search at the $sList$ of each of these nodes, sped up by fractional cascading, gives us the answer. Thus:

► **Lemma 2** ([19]). *Given a set of n canonical boxes in three dimension, the above data structure occupies $O(n \lg^2 n)$ words and answers stabbing counting queries in $O(\lg^2 n)$ time and stabbing reporting queries in $O(\lg^2 n + k)$ time, where k denotes the number of boxes reported. Furthermore, the output of the reporting query is the union of $O(\lg^2 n)$ disjoint subsets, each containing the boxes stored in a nonempty prefix of a bottom-layer sorted list. The preprocessing time is $O(n \lg^2 n)$.*

Reducing 2D 3-Sided Colored Range Counting to 3D Orthogonal Stabbing Counting over Canonical Boxes. A key technique used in both the solutions of Kaplan et al. [19] and our solutions is a reduction from 2D 3-sided colored range counting queries, in which each query range is of the form $[a, b] \times [c, +\infty)$ for some $a, b, c \in \mathbb{R}$, to 3D orthogonal stabbing queries over canonical boxes². The reduction is performed in two steps. First we reduce the 2D 3-sided colored range counting query problem to the 3D dominance colored range counting problem, in which we preprocess a set, P , of colored points in \mathbb{R}^3 , such that given a query point q in \mathbb{R}^3 , one can report the number of distinct colors in $P \cap (-\infty, q.x] \times (-\infty, q.y] \times (-\infty, q.z]$ efficiently. This reduction works as follows: For each point, $p = (p.x, p.y)$, we create a point, $p' = (-p.x, p.x, -p.y)$, in \mathbb{R}^3 , and assign it with the color of p . Then a 2D 3-sided colored range counting query over the original points in which the query range is $[a, b] \times [c, +\infty)$ can be answered by performing a 3D dominance colored range query over the created points, using $(-\infty, -a] \times (-\infty, b] \times (-\infty, -c]$ as the query range.

To further reduce the 3D dominance colored range counting problem to 3D orthogonal stabbing counting over canonical boxes, we need some additional notation: Given a point p in 3D, let Q_p^+ denote region $[p.x, +\infty) \times [p.y, +\infty) \times [p.z, +\infty)$. Furthermore, given a point set A , let $U(A)$ denote the region of $\cup_{p \in A} Q_p^+$. Then the following lemma is crucial:

► **Lemma 3** ([19]). *Given a set, A , of n points in three-dimensional space, a set of $O(n)$ pairwise disjoint 3D canonical boxes can be computed in $O(n \lg^2 n)$ time such that the union of these boxes is the region $U(A)$.*

² Later we sometimes deal with query ranges of the form $[a, b] \times (\infty, d]$ for some $a, b, d \in \mathbb{R}$, and a similar reduction also works.

Originally Kaplan et al. [19, Theorem 2.1] proved the above lemma for d -dimensional space where $d \geq 1$; for a general d , the number of boxes required to cover $U(A)$ is $O(n^{\lfloor d/2 \rfloor})$.

With this lemma, the reduction works as follows. Let P denote the input colored point set of the 3D dominance colored range counting problem, and let C denote the number of colors. Then, for each color $1 \leq c \leq C$, we apply Lemma 3 to partition $U(P_c)$, where P_c is the set of all the points in P that are colored c , into a set, B_c , of $O(|U(P_c)|)$ disjoint 3D canonical boxes. We then construct a 3D stabbing counting structure over $B = \cup_{c=1}^C B_c$. Note that this data structure is constructed over $O(|P|)$ canonical boxes, as $\sum_{c=1}^C |B_c| = \sum_{c=1}^C O(|P_c|) = O(|P|)$. To answer a 3D dominance colored range counting query over P , for which the query range is the region dominated by a point q , observe that, if q dominates at least one point in P_c , then it must be located with $U(P_c)$. Then, since $U(P_c)$ is partitioned into the boxes in B_c , we conclude that q dominates at least one point in P_c iff q is contained in a box in B_c . Furthermore, since the boxes in B_c are pairwise disjoint, q is either contained in exactly one box in B_c or outside $U(P_c)$. Hence, the number of distinct colors in the region dominated by q is equal to the number of boxes in B that contains q , which can be computed by performing a stabbing counting query in B using q as the query point.

3 A New Framework of Achieving Time-Space Tradeoffs

We present three new solutions to 2D orthogonal colored range counting in this section and Section 4. They follow the same framework, of which we give an overview in Section 3.1. One key component of this framework is a novel scheme of computing the sizes of the intersections between the color sets assigned to different subsets of points that lie within the query range; Section 3.2 describes this scheme and shows how to combine it with Lemma 2 to immediately achieve a new time-space tradeoff for 2D orthogonal colored range counting.

3.1 Overview of the Data Structure Framework

Let P denote a set of n points on the plane, each assigned a color identified by an integer in $[1, C]$. To support orthogonal colored range counting over P , we construct a binary range tree T over the y -coordinates of the points in P such that each leaf of T stores a point of P , and, from left to right, the points stored in the leaves are increasingly sorted by y -coordinate. For each internal node v of T , we construct the following data structures:

- A list $P(v)$ containing the points stored at the leaf descendants of v , sorted by x -coordinate;
- A list $P_y(v)$ containing the sorted list of y -coordinates of the points in $P(v)$;
- 2D 3-sided colored range counting structures, $S(v_l)$ and, $S(v_r)$, constructed over $P(v_l)$ and $P(v_r)$ respectively, where v_l and v_r are respectively the left and right children of v ($S(v_l)$ requires query ranges to open at the top while $S(v_r)$ requires them to open at the bottom; the exact data structures used will be selected later for different tradeoffs);
- 2D orthogonal colored range emptiness query structures, $E(v_l)$, and, $E(v_r)$, constructed over $\hat{P}(v_l)$ and $\hat{P}(v_r)$, respectively (using Lemma 1), where $\hat{P}(v_l)$ and $\hat{P}(v_r)$ are the point set in rank space converted from $P(v_l)$ and $P(v_r)$.

Let $Q = [a, b] \times [c, d]$ be the query rectangle. Given an internal node v , let $C_Q(v)$ denote the set of distinct colors assigned to points in $P(v) \cap Q$. The query algorithm first locates the lowest common ancestor u of the c -th and d -th leaves of T . As all the points from P that are in the query range Q must be in $P(u)$, $|C_Q(u)|$ is the answer to the query. To compute $|C_Q(u)|$, let u_l and u_r denote the left and right children of u , respectively. By the exclusion-inclusion principle, we know that $|C_Q(u)| = |C_Q(u_l)| + |C_Q(u_r)| - |C_Q(u_l) \cap C_Q(u_r)|$.

Among the terms on the right hand side of this equation, $|C_Q(u_l)|$ and $|C_Q(u_r)|$ can be computed by performing 2D 3-sided colored range counting queries over $S(v_l)$ and $S(v_r)$, using $[a, b] \times [c, +\infty)$ and $[a, b] \times (-\infty, d]$ as query ranges, respectively. What remains is to compute $|C_Q(u_l) \cap C_Q(u_r)|$.

This idea of decomposing a 4-sided query range into two 3-sided query ranges has been used before for both 2D orthogonal colored range reporting [12] and counting [19]. Furthermore, to support 2D 3-sided colored range counting, we apply the reduction of Kaplan et al. [19] (summarized in Section 2 of our paper) to reduce it to the 3D stabbing query problems over canonical boxes. Thus, the techniques summarized so far have been used in previous work (without the construction of range emptiness structures). What is new is our scheme of achieving time-space tradeoffs when computing $|C_Q(u_l) \cap C_Q(u_r)|$; it gives us more *flexibility* in the design of 3D stabbing query structures, thus allowing us to achieve new results.

Here we describe the conditions that a 3D stabbing query structure must meet so that we can combine it with our scheme of computing $|C_Q(u_l) \cap C_Q(u_r)|$, while deferring the details of the latter to Section 3.2. The stabbing query structure consists of multiple layers of trees of some kind. The top-layer tree is constructed over the entire set of canonical boxes, and each of its nodes is assigned a subset of boxes. The second layer consists of a set of trees, each constructed over the boxes assigned to a node in the top-layer tree, and so on. Thus each bottom-layer tree node is also assigned a list of boxes in a certain order (e.g., the *sList* in the data structure for Lemma 2). The query algorithm locates a set S of bottom-layer tree nodes. For each node $v \in S$, there exists a nonempty prefix of the box list assigned to v , such that such prefixes over all the nodes in S form a partition of the set of boxes containing the query point q . Furthermore, the size of each such prefix can be computed efficiently, and each box in such a prefix can also be reported efficiently.

Clearly Lemma 2 satisfies these conditions and can be used in our framework. On the contrary, even though Kaplan et al. proved this lemma and used it successfully in their $O(n^2 \lg^2 n)$ space solution, they can not directly use it with their scheme of achieving time-space tradeoffs. Instead, they expand this structure with a third layer which is a segment tree constructed over x -coordinates of the boxes, increasing both time and space costs. Recall that in their scheme the set of boxes containing the query point are also decomposed into a fixed number of subsets. The reason Kaplan et al. cannot directly apply Lemma 2 is that their scheme requires each of the decomposed subsets to be equal to the entire set of boxes stored in a bottom-layer tree node, while our scheme allows each subset to be part of such a box set. Hence, this extra flexibility allows us to use Lemma 2 and alternative 3D stabbing query structures to be designed later (in Section 4) in our framework.

3.2 Computing Intersections between Color Sets

We now introduce our new scheme of computing $|C_Q(u_l) \cap C_Q(u_r)|$, and combine it with the stabbing query structure from Lemma 2 to achieve a new time-space tradeoff for 2D orthogonal colored range counting. Since our scheme works with some other stabbing query structures, we describe it assuming a stabbing query structure satisfying the conditions described in Section 3.1 is used. To understand this scheme more easily, it may be advisable for readers to think about how it applies to the stabbing query structure of Lemma 2.

Recall that, the problems of computing $|C_Q(u_l)|$ and $|C_Q(u_r)|$ have each been reduced to a 3D stabbing query. Furthermore, for each stabbing query, all reported boxes are distributed into a number of disjoint sets; the boxes in each such set form a nonempty prefix of the box list assigned to a node of the bottom-layer tree (henceforth we call each such box list a *bottom list* for convenience). Then, for the stabbing query performed to compute $|C_Q(u_l)|$, we

define D_Q to be a set in which each element is a such a disjoint set, and all these disjoint sets (whose union form the set of reported boxes) are elements of D_Q . U_Q is defined in a similar way for $|C_Q(u_r)|$. Thus, if we use the data structure for Lemma 2 to answer these stabbing queries, both $|D_Q|$ and $|U_Q|$ will be upper bounded by $O(\lg^2 n)$. As shown in Section 2, when reducing 2D 3-sided colored counting to 3D stabbing queries over canonical boxes, we guarantee that, each canonical box is part of the region $U(P_c)$ for each color c ; we call this color the color of this canonical box, and explicitly store with each box its color. Furthermore, for each color $1 \leq c \leq C$, at most one canonical box colored in c contains the query point, which implies that each box in $\cup_{s \in D_Q} s$ (resp. $\cup_{t \in U_Q} t$) has a distinct color. For each set $s \in D_Q$ and $t \in U_Q$, let $C(s)$ and $C(t)$ denote the set of colors associated with the boxes in s and t , respectively. Then we have $|C_Q(u_l)| = \sum_{s \in D_Q} |C(s)|$, $|C_Q(u_r)| = \sum_{t \in U_Q} |C(t)|$, and $|C_Q(u_l) \cap C_Q(u_r)| = \sum_{s \in D_Q, t \in U_Q} |C(s) \cap C(t)|$.

It now remains to show how to compute $\sum_{s \in D_Q, t \in U_Q} |C(s) \cap C(t)|$, for which more preprocessing is required. For each node v in the binary range tree T , we construct a matrix $M(v)$ as follows: Let $X \in [1, n]$ be a parameter to be chosen later. If the length, m , of a bottom list in the stabbing query structure $S(v_l)$ or $S(v_r)$ is greater than X , we divide the list into $\lceil m/X \rceil$ blocks, such that each block, with the possible exception of the last block, is of length X . If $m \leq X$, then the entire list is a single block. If a block is of length X , we call it a *full block*. Let $b_l(v)$ and $b_r(v)$ denote the total numbers of full blocks over all bottom lists in $S(v_l)$ and $S(v_r)$, respectively. Then $M(v)$ is a $b_l(v) \times b_r(v)$ matrix, in which each row (or column) corresponds to a nonempty prefix of a bottom list in $S(v_l)$ (or $S(v_r)$) that ends with the last entry of a full block, and each entry $M[i, j]$ stores the number of colors that exist in both the set of colors assigned to the boxes in the prefix corresponding to row i and the set of colors assigned to the boxes in the prefix corresponding to column j . To bound the size of $M(v)$, we define the *duplication factor*, $\delta(n)$, of a stabbing query structure that satisfies the conditions in Section 3.1 to be the maximum number of bottom lists that any canonical box can be contained in. For example, the duplication factor of the structure for Lemma 2 is $O(\lg^2 n)$. (To see this, observe that in a segment tree constructed over n intervals, each interval may be stored in $O(\lg n)$ tree nodes. Since segment trees are used in both layers of the data structure for Lemma 2, each box can be stored in $O(\lg^2 n)$ different bottom lists.) Since each full block contains X boxes, the numbers of full blocks in the bottom lists of $S(v_l)$ and $S(v_r)$ are at most $\delta(n)|P(v_l)|/X$ and $\delta(n)|P(v_r)|/X$, respectively. Therefore, $M(v)$ occupies $O(\delta(n)^2 |P(v_l)| |P(v_r)| / X^2) = O((\delta(n) |P(v)| / X)^2)$ words.

With these matrices, the computation of $\sum_{s \in D_Q, t \in U_Q} |C(s) \cap C(t)|$ can proceed as follows. Since each set $s \in D_Q$ (resp. $t \in U_Q$) occupies a prefix of a bottom list, s (resp. t) can be split into two parts: s_h (resp. t_h) which is the (possibly empty) prefix of s (resp. t) that consists of all the full blocks entirely contained in s (resp. t), and s_l (resp. t_l) which contains the remaining entries of s (resp. t). Thus we have $C(s_h) \cup C(s_l) = C(s)$ and $C(t_h) \cup C(t_l) = C(t)$. Since no two boxes in s have the same color and the same applies to the boxes in t , $C(s_h) \cap C(s_l) = C(t_h) \cap C(t_l) = \emptyset$ also holds. Thus, we have

$$\begin{aligned} \sum_{s \in D_Q, t \in U_Q} |C(s) \cap C(t)| &= \sum_{s \in D_Q, t \in U_Q} (|C(s_h) \cap C(t_h)| + |C(s_h) \cap C(t_l)| + |C(s_l) \cap C(t)|) \\ &= \sum_{s \in D_Q, t \in U_Q} |C(s_h) \cap C(t_h)| + \sum_{s \in D_Q, t \in U_Q} |C(s_h) \cap C(t_l)| + |(\cup_{s \in D_Q} C(s_l)) \cap \cup_{t \in U_Q} C(t)| \end{aligned} \quad (1)$$

For the first term in the last line of Equation 1, we can retrieve $|C(s_h) \cap C(t_h)|$ from the matrix $M(v)$ for each possible pair of s_h and t_h and sum them up. Therefore, the first term can be computed in $O(|D_Q| \cdot |U_Q|)$ time. For the third term, observe that, $\cup_{t \in U_Q} C(t) = C_Q(u_r)$.

Therefore, the third term can be computed by performing, for each color $c \in \cup_{s \in D_Q} C(s_l)$, a 2D orthogonal colored range emptiness query over $P(u_r)$ with c as the query color and Q as the query range. Note that the range emptiness query data structure $E(v_r)$ defined in Section 3.1 is built upon the points $\hat{P}(v_r)$ in rank space. We need to reduce Q into rank space with respect to $\hat{P}(v_r)$ before performing colored range emptiness queries. Since all these queries share the same query range, we need only convert Q into rank space once. This can be done by performing binary searches in $P(v)$ and $P_y(v)$ in $O(\lg n)$ time. As $|\cup_{s \in D_Q} C(s_l)| = |\cup_{s \in D_Q} s_l| = O(|D_Q| \cdot X)$, it requires $O(X|D_Q| \cdot (g(n) + \tau(n)) + \lg n)$ time to compute these colors and then answer all these queries, where $g(n)$ denotes the query time of each range emptiness query in Lemma 1 and $\tau(n)$ denotes the query time of reporting a box and its color in the query range.

Finally, to compute the second term in the last line of Equation 1, observe that,

$$\sum_{s \in D_Q, t \in U_Q} |C(s_h) \cap C(t_l)| = |(\cup_{s \in D_Q} C(s)) \cap (\cup_{t \in U_Q} C(t_l))| - |(\cup_{s \in D_Q} C(s_l)) \cap (\cup_{t \in U_Q} C(t_l))| \quad (2)$$

The first term of the right hand side of Equation 2 can be computed in $O(X|U_Q| \cdot (g(n) + \tau(n)) + \lg n)$ time, again by performing range emptiness queries, but this time we use $E(v_l)$. The second term can be computed by retrieving and sorting the colors in $\cup_{s \in D_Q} C(s_l)$ and those in $\cup_{t \in U_Q} C(t_l)$, and then scanning both sorted lists to compute their intersection. Since $|\cup_{s \in D_Q} C(s_l)|$ (resp. $|\cup_{t \in U_Q} C(t_l)|$) are bounded by $O(X|D_Q|)$ (resp. $O(X|U_Q|)$), the two sets of colors can be retrieved in $O(X|D_Q|\tau(n))$ and $O(X|U_Q|\tau(n))$ time and then sorted using Han's sorting algorithm [15] in $O(X|D_Q|\lg \lg n)$ and $O(X|U_Q|\lg \lg n)$ time. Thus the second term in the last line of Equation 1 can be computed in $O(X(|U_Q| + |D_Q|)(\lg \lg n + \tau(n)))$ time. Overall, computing $|C_Q(u_l) \cap C_Q(u_r)|$ requires $O(|D_Q| \cdot |U_Q| + X(|U_Q| + |D_Q|)(\lg \lg n + g(n) + \tau(n)) + \lg n)$ time. Lemma 4 summarizes the complexities of our framework.

► **Lemma 4.** *Suppose that the 3D stabbing query structure of $S(v_l)$ (or $S(v_r)$) for each node $v \in T$ has duplication factor $\delta(n)$, occupies $O(|P(v)|h(n))$ words, and, given a query point q , it can compute $\phi(n)$ disjoint sets of boxes whose union is the set of boxes containing q in $O(\phi(n))$ time. Furthermore, each subset is a nonempty prefix of a bottom list, and after this prefix is located, its length can be computed in $O(1)$ time and each box in it can be reported in $O(\tau(n))$ time. Let $f(n)$ and $g(n)$ be the functions set in Lemma 1 to implement $E(v_l)$ and $E(v_r)$. Then the structures in our framework occupy $O((n\delta(n)/X)^2 + n \lg n(f(n) + h(n)))$ words and answer a 2D orthogonal colored range counting query in $O(\phi^2(n) + X\phi(n)(\lg \lg n + g(n) + \tau(n)) + \lg n)$ time, where X is an integer parameter in $[1, n]$.*

Proof. Each node v of T stores a pair of lists, $P(v)$ and $P_y(v)$, of points, the colored range emptiness query structures $E(v_l)$ and $E(v_r)$, the stabbing query data structures $S(v_l)$ and $S(v_r)$, and the matrix $M(v)$. Among them, both $P(v)$ and $P_y(v)$ use $|P(v)|$ words of space. $E(v_l)$ and $E(v_r)$ use $O(|P(v)|f(n))$ words of space by Lemma 1. $S(v_l)$ and $S(v_r)$ use $O(|P(v)|h(n))$ words of space. The matrix $M(v)$ uses $O((\delta(n)|P(v)|/X)^2)$ words of space. Summing the space costs over all internal nodes of the range tree T , the overall space cost is at most $\sum_{v \in T} O((\delta(n)|P(v)|/X)^2 + |P(v)|(f(n) + h(n)))$. To simplify this expression, first observe that $\sum_{v \in T} |P(v)| = O(n \lg n)$. Furthermore, we can calculate $\sum_{v \in T} |P(v)|^2$ as follows: At the i -th level of T , there are 2^i nodes, and each node stores a point list of length $n/2^i$. Therefore, the sum of the squares of the lengths of the point lists at the i th level is $n^2/2^i$. Summing up over all levels, we have $\sum_{v \in T} |P(v)|^2 = O(n^2)$. Therefore, the overall space cost simplifies to $O((n\delta(n)/X)^2 + n \lg n(f(n) + h(n)))$.

Given a query range, we use $O(\phi(n))$ time to compute $|C_Q(u_l)|$ and $|C_Q(u_r)|$. As shown before, computing $|C_Q(u_l) \cap C_Q(u_r)|$ can be reduced to computing $\sum_{s \in D_Q, t \in U_Q} |C(s) \cap C(t)|$, which requires $O(|D_Q| \cdot |U_Q| + X(|U_Q| + |D_Q|)(\lg \lg n + g(n) + \tau(n)) + \lg n)$ time. Since both $|D_Q|$ and $|U_Q|$ are upper bounded by $\phi(n)$, the overall query time is $O(\phi^2(n) + X\phi(n)(\lg \lg n + g(n) + \tau(n)) + \lg n)$. \blacktriangleleft

We can now achieve a new time-space tradeoff by using the stabbing queries data structure from Lemma 2 in our framework. To combine Lemmas 2 and 4, observe that $h(n) = O(\lg^2 n)$, $\phi(n) = O(\lg^2 n)$ and $\tau(n) = O(1)$. As discussed before, $\delta(n) = O(\lg^2 n)$. We use part b) of Lemma 1 to implement $E(v_l)$ and $E(v_r)$, so $f(n) = O(\lg \lg n)$ and $g(n) = O(\lg \lg n)$. Hence:

► **Theorem 5.** *Given n colored points on the plane, there is a data structure of $O((\frac{n}{X})^2 \lg^4 n + n \lg^3 n)$ words of space that answers colored orthogonal range counting queries in $O(\lg^4 n + X \lg^2 n \lg \lg n)$ time, where X is an integer parameter in $[1, n]$. In particular, setting $X = \sqrt{n \lg n}$ yields an $O(n \lg^3 n)$ -word structure with $O(\sqrt{n} \lg^{5/2} n \cdot \lg \lg n)$ query time.*

Unlike our result in Theorem 5, the solution of Kaplan et al. [19] with $O((\frac{n}{X})^2 \lg^6 n + n \lg^4 n)$ words of space and $O(X \lg^7 n)$ query time works under the pointer machine model. Nevertheless, with some modifications, our solution can also be made to work under this same model. First, Lemma 1 requires the word RAM model, we can replace it by the optimal solution to the 2D orthogonal range emptiness query problem by Chazelle [7] with $O(n \lg n / \lg \lg n)$ words of space and $O(\lg n)$ query time. Thus, $g(n) = O(\lg n)$, but the overall space cost of the data structure remains unchanged. Second, when computing $|(\cup_{s \in D_Q} C(s_l)) \cap (\cup_{t \in U_Q} C(t_l))|$, we cannot use Han's sorting algorithm [15] which requires the word RAM. Instead, using mergesort, we can compute this value in $O(X(|U_Q| + |D_Q|) \cdot \lg n)$ time. Finally, to simulate a matrix $M(v)$, we can use lists indexed by binary search trees, so that we can retrieve each entry in $O(\lg n)$ time. Thus, we achieve the following result:

► **Corollary 6.** *Under the arithmetic pointer machine model, given n colored points on the plane, there is a data structure of $O((\frac{n}{X})^2 \lg^4 n + n \lg^3 n)$ words of space that answers colored orthogonal range counting queries in $O(\lg^5 n + X \lg^3 n)$ time, where X is an integer parameter in $[1, n]$. In particular, setting $X = \sqrt{n \lg n}$ yields an $O(n \lg^3 n)$ -word structure with $O(\sqrt{n} \lg^{7/2} n)$ query time.*

4 Two More Solutions with Better Space Efficiency

As the space cost in Theorem 5 is at least $\Omega(n \lg^3 n)$, we now design two more solutions with potentially better space efficiency for 2D orthogonal colored range counting.

4.1 Achieving $O(n \lg^2 n)$ Space

We design an alternative solution for 3D stabbing queries over canonical boxes whose space cost is a logarithmic factor less of that in Lemma 2 asymptotically, and it also satisfies the conditions described in Section 3.1 and can thus be applied in our framework. This leads to another time-space tradeoff for 2D orthogonal colored range counting, whose space cost can be as little as $O(n \lg^2 n)$ by choosing the right parameter value.

This new 3D stabbing query solution requires us to design a data structure supporting 2D dominance counting and reporting, by augmenting a binary range tree constructed over the y -coordinates of the input points. Each internal node v of T is conceptually associated with a list, $P(v)$, of points that are leaf descendants of v , sorted by x -coordinate, but we do not store $P(v)$ explicitly. Lemma 7 presents this data structure. Even though better solutions exist for these problems [17, 4], Lemma 7 gives us additional range tree functionalities that are required for our next two solutions to colored range counting.

► **Lemma 7.** *Consider a binary range tree T constructed over a set, P , of n points on the plane as described above. T can be augmented using $O(n)$ additional words such that, given a query range Q which is the region dominated by a point q , a set, S , of $O(\lg n)$ nodes of T can be located in $O(\lg n)$ time that satisfies the following conditions: For each node $v \in S$, there exists a nonempty prefix $L(v)$ of $P(v)$ such that the point set $P \cap Q$ can be partitioned into $|S|$ disjoint subsets, each consisting of the points in such a prefix. Furthermore, the individual sizes of all these subsets can be computed in $O(\lg n)$ time in total, and each point in such a subset can be reported in $O(\lg^\epsilon n)$ additional time for any positive constant ϵ .*

Proof. For simplicity, we assume that point coordinates are in rank space. Then each leaf of the range tree T represents an integer range $[p.y, p.y]$ if p is stored at this leaf. The range represented by an internal node of T is the union of the ranges represented by its children.

At each internal node v of T , we store a bit vector, $\mathcal{B}(v)$, such that if the point $P(v)[i]$ is a leaf descendant of the left child of v , then $\mathcal{B}(v)[i]$ is set to 0; otherwise $\mathcal{B}(v)[i]$ is set to 1. We construct a data structure of $O(|\mathcal{B}(v)|)$ bits of space upon $\mathcal{B}(v)$ to support the computation of $\text{rank}(v, k)$, which is $\sum_{i \leq k} \mathcal{B}(v)[i]$, for any k in constant time [9]. These bit vectors over all internal nodes v of T use $\sum_v O(|\mathcal{B}(v)|) = O(n \lg n)$ bits, which is $O(n)$ words of space.

Given a query range $Q = [1, q.x] \times [1, q.y]$, we find the path, π , from the root node of T to the $q.y$ -th leaf. For each node u in π , if it is the right child of its parent, we add its left sibling, v , into a set S' . We also add the $q.y$ -th leaf into S' . Then the ranges represented by the nodes in S' form a partition of the query y -range $[1, q.y]$, so $P \cap Q \subseteq \cup_{v \in S'} P(v)$. Furthermore, for each node $v \in S'$, we add it into S if $|P(v) \cap Q| > 0$. To compute $|P(v) \cap Q|$, observe that, since the y -coordinates of points in $P(v)$ are within the query y -range, and these points are increasingly sorted by their x -coordinates, $|P(v) \cap Q|$ is equal to the index, i , of the rightmost point of $P(v)$ whose x -coordinate is no more than $q.x$. Furthermore, if $|P(v) \cap Q| > 0$, then $L(v) = P(v)[1..i]$. Thus the following observation is crucial: Let s and t be two nodes of T , where s is the parent of t , let j be the number of points in $P(s)$ whose x -coordinates are no more than $q.x$. Then, if t is the left child of s , the number of points in $P(t)$ whose x -coordinates are no more than $q.x$ is $|P(s)| - \text{rank}(s, j)$. Otherwise, it is $\text{rank}(s, j)$. We know that at the root node r , the number of points in $P(r)$ whose x -coordinates are no more than $q.x$ is simply $q.x$. Then, during the top down traversal of π , we can make use of this observation and perform up to two **rank** operations at each level, so that for any node $u \in \pi \cup S'$, we can compute the index of the rightmost point of $P(u)$ whose x -coordinate is no more than $q.x$. This way we can compute S and for each $v \in S$, compute $|L(v)|$. The total running time is $O(\lg n)$. To report the coordinates of each point in $L(v)$ for any $v \in S$, we augment T with the *ball inheritance* data structure [4], which can use $O(n)$ additional words of space to support each query in $O(\lg^\epsilon n)$ time. The details are deferred to the full version of the paper. ◀

Next we present the new stabbing query data structure. This time we construct data structures consisting of three layers of trees to answer stabbing queries over a given set of n canonical boxes in three-dimensional space, but a different tree structure is adopted in each layer. At the top-layer we construct a segment tree over the z -coordinates of the boxes. More precisely, we project each box onto the z -axis to obtain an interval, and the segment tree is constructed over all these intervals. A box is assigned to a node in this tree if its corresponding interval on the z -axis is associated with this node. For each node v in the top-layer segment tree, we further construct an interval tree over the projections of the boxes assigned to v on the y -axis, and the interval trees constructed for all the nodes of the top-layer tree form the middle-layer structure. For each node v' of an interval tree, we use

the set $B(v')$, of boxes assigned to it to define the two point sets, $S_{lower}(v')$ and $S_{upper}(v')$, on the plane as follows: We project all the boxes in $B(v')$ onto the xy -plane and get a set of right-open rectangles. Then, $S_{lower}(v')$ is the set of the lower left vertices of these rectangles (henceforth called *lower points*), i.e., $\{(B.x_1, B.y_1) | B \in B(v')\}$, and $S_{upper}(v')$ is the set of the upper left vertices (henceforth called *upper points*), i.e., $\{(B.x_1, B.y_2) | B \in B(v')\}$. We then use Lemma 7 to build a pair of binary range trees, $T_{lower}(v')$ and $T_{upper}(v')$, over $S_{lower}(v')$ and $S_{upper}(v')$, respectively. The range trees constructed for all these interval tree nodes form the bottom-layer structure.

Recall that, each node v'' of a binary range tree in the bottom layer is conceptually associated with a list, $P(v'')$, of lower or upper points, which are the points stored in the leaf descendants of v'' , sorted by x -coordinate. Each point of $P(v'')$ represents a box. Since there is a one-to-one correspondence between a point in $P(v'')$ and the box it represents, we may abuse notation and use $P(v'')$ to refer to the list of boxes that these points represent when the context is clear. Hence $P(v'')$ is the bottom list when the data structure is used in our framework. Lemma 8 summarizes the solution.

► **Lemma 8.** *Given a set of n canonical boxes in three dimension, the data structure above occupies $O(n \lg n)$ words and answers stabbing counting queries in $O(\lg^3 n)$ time and stabbing reporting queries in $O(\lg^3 n + k \cdot \lg^\epsilon n)$ time, where k denotes the number of boxes reported. Furthermore, the set of reported boxes is the union of $O(\lg^3 n)$ different disjoint sets, each of which is a nonempty prefix of some bottom list in the data structure.*

Proof. The top-layer segment tree occupies $O(n \lg n)$ words, while both interval trees and binary ranges trees from Lemma 7 are linear-space data structures. Therefore, the overall space cost is $O(n \lg n)$ words.

To show how to answer a query, let q be the query point. Our query algorithm first searches for $q.z$ in the top-layer segment tree. This locates $O(\lg n)$ nodes of the top-layer tree. Each node v located in this phase stores a list, $B(v)$, of boxes whose z -ranges contain $q.z$. It now suffices to show how to count and report the boxes in each list $B(v)$ whose projections on the xy -plane contain $(q.x, q.y)$. To do this, we use the interval tree in the middle layer that is constructed over $B(v)$. In an interval tree, each node v' stores the median, denoted by $m(v')$, of the endpoints of the intervals associated with its descendants (including itself), and it also stores a set, $I(v')$, of the intervals that contain $m(v')$. In our case, each interval in $I(v')$ is the y -range of a canonical box in $B(v)$, its left endpoint corresponds to the y -coordinate of a point in $S_{lower}(v')$, and its right endpoint corresponds to the y -coordinate of a point in $S_{upper}(v')$. The next phase of our algorithm then starts from the root, r , of this interval tree. If $q.y \leq m(r)$, then an interval in $I(v')$ contains $q.y$ iff its left endpoint is less than or equal to $q.y$. This means, among the points in $S_{lower}(v')$, those lie in $(-\infty, q.x] \times (-\infty, q.y]$ correspond to the boxes whose projections on the xy -plane contain $(q.x, q.y)$. Since the z -range of these boxes already contains $q.z$, they contain q in the three-dimensional space. Hence, by performing a dominance query over $T_{lower}(v')$ using $(-\infty, q.x] \times (-\infty, q.y]$ as the query range, we can compute these boxes. Then, since the nodes in the right subtree r store intervals whose left endpoints are greater than $m(r)$ which is at least $q.y$, none of these intervals can possibly contain $q.y$. Thus, we descend to the left child of r afterwards and repeat this process. If $q.y > m(r)$ instead, then we perform a dominance query over $T_{upper}(v')$ using $[-\infty, q.x] \times (q.y, +\infty)$ as the query range to compute the boxes associated with r that contain q , descend to the right child of r , and repeat.

To analyze the running time, observe that this algorithm locates $O(\lg n)$ nodes in the top-layer segment tree, and for each of these nodes, it further locates $O(\lg n)$ nodes in the middle-layer interval trees. Hence, we perform a 2D dominance counting and reporting query using Lemma 7 for each of these $O(\lg^2 n)$ interval tree nodes, and the proof completes. ◀

In an interval tree, each interval is stored in exactly one node, while in a segment tree or a binary range tree, each interval or point can be associated with $O(\lg n)$ nodes. Therefore, this data structure has duplication factor $\delta = O(\lg^2 n)$. If we combine Lemmas 2 and 4, we also have $h(n) = O(\lg n)$, $\phi(n) = O(\lg^3 n)$ and $\tau(n) = O(\lg^\epsilon n)$. We again use part b) of Lemma 1 to implement $E(v_l)$ and $E(v_r)$, so $f(n) = O(\lg \lg n)$ and $g(n) = O(\lg \lg n)$. Hence:

► **Theorem 9.** *Given n colored points on the plane, there is a data structure of $O((\frac{n}{X})^2 \lg^4 n + n \lg^2 n)$ words of space that answers colored orthogonal range counting queries in $O(\lg^6 n + X \lg^{3+\epsilon} n)$ time, where X is an integer parameter in $[1, n]$ and ϵ is an arbitrary positive constant. In particular, setting $X = \sqrt{n} \lg n$ yields an $O(n \lg^2 n)$ -word structure with $O(\sqrt{n} \lg^{4+\epsilon} n)$ query time.*

4.2 Achieving $O(n \lg n)$ Space

We further improve the space cost of the data structure for 3D stabbing queries over canonical boxes. The new solution also satisfies the conditions described in Section 3.1 and can thus be applied in our framework. This leads to our third time-space tradeoff for 2D orthogonal colored range counting, whose space cost can be as little as $O(n \lg n)$ by choosing the right parameter value.

Our solution will use a space-efficient data structure for 3D orthogonal range searching. Using a range tree with node degree $\lambda \in [2, n]$, we can transform a 2D linear space data structure shown in Lemma 7 into a three-dimensional data structure that uses $O(n \log_\lambda n)$ words. Therefore, we can solve 3D dominance range searching as shown in Lemma 10, whose proof is deferred to the full version of the paper.

► **Lemma 10.** *Given n points in three dimension, there is a data structure of $O(n \log_\lambda n)$ words of space that answers 3D dominance counting queries in $O(\lambda \lg n \cdot \log_\lambda n)$ time and 3D dominance reporting queries in $O(\lambda \lg n \cdot \log_\lambda n + k \lg^\epsilon n)$ time, where k is the number of reported points and λ is an integer parameter in $[2, n]$.*

Next, we design a new data structure for stabbing queries over 3D canonical boxes. It again contains trees of three layers, with interval trees in the top- and middle- layers plus the data structures for 3D dominance range searching from Lemma 10 in the bottom layer. More precisely, the structure at the top layer is an interval tree, T_1 , constructed over the z -coordinates of the boxes. That is, we project each box onto the z -axis to obtain an interval, and the interval tree is constructed over all these intervals. A box is assigned to a node in this tree if its corresponding interval on the z -axis is associated with this node. For each node v in the top-layer interval tree, we further construct an interval tree, $T_2(v)$, over the projections of the boxes assigned to v on the y -axis, and the interval trees constructed for all the nodes of the top-layer tree form the middle-layer structure. For each node v' of an interval tree in the middle-layer, we use the set $B(v')$, of boxes assigned to it to define the four point sets, $S_{ll}(v')$, $S_{lr}(v')$, $S_{ul}(v')$, and $S_{ur}(v')$ in 3D such that $S_{ll}(v') = \{(B.x_1, B.y_1, B.z_1) | B \in B(v')\}$, $S_{lr}(v') = \{(B.x_1, B.y_1, B.z_2) | B \in B(v')\}$, $S_{ul}(v') = \{(B.x_1, B.y_2, B.z_1) | B \in B(v')\}$, and $S_{ur}(v') = \{(B.x_1, B.y_2, B.z_2) | B \in B(v')\}$. We then use Lemma 10 to build a set of 3D dominance range searching structures, $T_{ll}(v')$, $T_{lr}(v')$, $T_{ul}(v')$ and $T_{ur}(v')$, over $S_{ll}(v')$, $S_{lr}(v')$, $S_{ul}(v')$, and $S_{ur}(v')$, respectively. The 3D dominance range searching structures constructed for the nodes of all interval trees in the middle-layer form the bottom-layer structure.

As shown in the previous section, we need to identify the bottom lists from the data structures described above, which would be used in our framework. Without loss of generality, we take the 3D dominance range searching structure, $T_{ll}(v')$, built in the bottom-layer as

an example. Observe that $T_{ll}(v')$ is a λ -ary range tree, of which each internal node, v'' , stores a binary range tree data structure $T_b(v'')$ implemented by Lemma 7 for 2D dominance range searching. Recall that, each node \hat{v} of a binary range tree $T_b(v'')$ is conceptually associated with a list, $P(\hat{v})$, of points from the set $S_{ll}(v')$, which are the points stored in the leaf descendants of \hat{v} , sorted by x -coordinate. Each point of $P(\hat{v})$ represents a box. Since there is a one-to-one correspondence between a point in $P(\hat{v})$ and the box it represents, we may abuse notation and use $P(\hat{v})$ to refer to the list of boxes that these points represent when the context is clear. Hence $P(\hat{v})$ is the bottom list when the data structure is used in our framework. The following lemma summarizes this solution:

► **Lemma 11.** *Given a set of n canonical boxes in three dimension, the data structure described above occupies $O(n \log_\lambda n)$ words of space and answers stabbing counting queries in $O(\lg^2 n \cdot \lambda \lg n \cdot \log_\lambda n)$ time and stabbing reporting queries in $O(\lg^2 n \cdot \lambda \lg n \cdot \log_\lambda n + k \cdot \lg^\epsilon n)$ time, where k denotes the number of boxes reported and λ is an integer parameter in $[2, n]$. Furthermore, the set of reported boxes is the union of $O(\lg^2 n \cdot \lambda \lg n \cdot \log_\lambda n)$ different disjoint sets, each of which is a nonempty prefix of some bottom list in the data structure.*

Proof. The top- and middle- layer interval trees are linear-space data structure, while the 3D dominance range searching structures from Lemma 10 occupy $O(n \log_\lambda n)$ words of space in total. Therefore, the overall space cost is $O(n \log_\lambda n)$ words.

To show how to answer a query, let $q = (q.x, q.y, q.z)$ be the query point. In an interval tree T_1 (resp. $T_2(v)$), each node v (resp. v') stores the median, denoted by $m_z(v)$ (resp. $m_y(v')$), of the endpoints of the intervals associated with its descendants (including itself), and it also stores a set, $I_z(v)$ (resp. $I_y(v')$), of the intervals that contain $m_z(v)$ (resp. $m_y(v')$). In our case, each interval in $I_z(v)$ (resp. $I_y(v')$) is the z -range (resp. y -range) of a canonical box in $B(v)$ (resp. $B(v')$). The query algorithm starts from the root, r , of T_1 . If $q.z \leq m_z(r)$, then an interval in $I_z(r)$ contains $q.z$ iff its left endpoint is less than or equal to $q.z$. Then we visit the interval tree $T_2(r)$ in the middle-layer that is constructed upon the y -ranges of the boxes in $B(r)$. The next phase of our algorithm then starts from the root, r' , of $T_2(r)$. If $q.y \leq m_y(r')$, then an interval in $I_y(r')$ contains $q.y$ iff its lower endpoint is less than or equal to $q.y$. This means, among the points in $S_{ll}(v')$, those lie in $(-\infty, q.x] \times (-\infty, q.y] \times (-\infty, q.z]$ correspond to the boxes containing $(q.x, q.y, q.z)$. Hence, by performing a dominance query over $T_{ll}(v')$ using $(-\infty, q.x] \times (-\infty, q.y] \times (-\infty, q.z]$ as the query range, we can compute these boxes. Then, since the nodes in the right subtree r' store intervals whose lower endpoints are greater than $m_y(r')$ which is at least $q.y$, none of these intervals can possibly contain $q.y$. Thus, we descend to the left child of r' afterwards and repeat this process. Otherwise if $q.y > m_y(r')$ instead, then we perform a dominance query over $T_{ul}(v')$ using $(-\infty, q.x] \times (q.y, +\infty) \times (-\infty, q.z]$ as the query range to compute the boxes associated with r' that contain q , descend to the right child of r' , and repeat this process until reaching the leaf level of $T_2(r)$. Once $T_2(r)$ has been traversed, we return the root node r of T_1 . Since the nodes in the right subtree r store intervals whose left endpoints are greater than $m_z(r)$ which is at least $q.z$, none of these intervals can possibly contain $q.z$. Thus, we descend to the left child of r afterwards and repeat this process. Otherwise, if $q.z > m_z(r)$ instead, then we perform a dominance query over either $T_{lr}(v')$ using $(-\infty, q.x] \times (-\infty, q.y] \times (q.z, +\infty)$ as the query range or $T_{ur}(v')$ using $[-\infty, q.x] \times (q.y, +\infty) \times (q.z, +\infty)$ as the query range to compute the boxes associated with v' that contain q , where v' is a node of $T_2(r')$ that we visit, descend to the right child of r , and repeat the process. In summary, let v denote a node on the traversed path of T_1 and given node v , let v' denote a node on the traversed path of $T_2(v)$. By comparing $q.z$ against $m_z(v)$ and $q.y$ against $m_y(v')$, we can decide which

3D dominance range searching data structure to be used in the bottom-layer. It includes the following four different cases:

- when $q.z \leq m_z(v)$ and $q.y \leq m_y(v')$, we search $T_{ll}(v')$ for the points of $S_{ll}(v')$ in the query range $(-\infty, q.x] \times (-\infty, q.y] \times (-\infty, q.z]$;
- when $q.z \leq m_z(v)$ and $q.y > m_y(v')$, we search $T_{ul}(v')$ for the points of $S_{ul}(v')$ in the query range $(-\infty, q.x] \times (q.y, +\infty) \times (-\infty, q.z]$;
- when $q.z > m_z(v)$ and $q.y \leq m_y(v')$, we search $T_{lr}(v')$ for the points of $S_{lr}(v')$ in the query range $(-\infty, q.x] \times (-\infty, q.y] \times (q.z, +\infty)$;
- when $q.z > m_z(v)$ and $q.y > m_y(v')$, we search $T_{ur}(v')$ for the points of $S_{ur}(v')$ in the query range $(-\infty, q.x] \times (q.y, +\infty) \times (q.z, +\infty)$.

To analyze the running time, observe that this algorithm locates $O(\lg n)$ nodes in the top-layer interval tree, and for each of these nodes, it further locates $O(\lg n)$ nodes in the middle-layer interval trees. Hence, we perform a 3D dominance counting and reporting query using Lemma 10 for each of these $O(\lg^2 n)$ interval tree nodes, and the proof completes. ◀

In an interval tree, each interval is stored in exactly one node, while in a 3D dominance range searching structure from Lemma 10, each point can be associated with $O(\lg n \cdot \log_\lambda n)$ nodes. Therefore, this data structure has duplication factor $\delta(n) = O(\lg n \cdot \log_\lambda n)$. If we combine Lemmas 11 and 4, we have $h(n) = O(\log_\lambda n)$, $\phi(n) = O(\lg^2 n \cdot \lambda \lg n \cdot \log_\lambda n)$ and $\tau(n) = O(\lg^\epsilon n)$. We use part a) of Lemma 1 to implement $E(v_l)$ and $E(v_r)$, so $f(n) = O(1)$ and $g(n) = O(\lg^\epsilon n)$. Hence:

► **Theorem 12.** *Given n colored points on the plane, there is a data structure of $O((\frac{n}{X})^2 \lg^2 n \cdot \log_\lambda^2 n + n \lg n \cdot \log_\lambda n)$ words of space that answers colored orthogonal range counting queries in $O(\lambda^2 \cdot \lg^6 n \cdot \log_\lambda^2 n + X \cdot \lg^{3+\epsilon} n \cdot \lambda \log_\lambda n)$ time, where X is an integer parameter in $[1, n]$, λ is an integer parameter in $[2, n]$, and ϵ is any constant in $(0, 1)$. Setting $X = \sqrt{n \lg n \log_\lambda n}$ and $\lambda = \lg^\epsilon n$ yields an $O(n \frac{\lg^2 n}{\lg \lg n})$ -word structure with $O(\sqrt{n} \lg^{5+\epsilon'} n)$ query time for any constant $\epsilon' > 2\epsilon$. Alternatively, setting $X = \sqrt{n \lg n}$ and $\lambda = n^{\epsilon/5}$ yields an $O(n \lg n)$ -word structure with $O(n^{1/2+\epsilon})$ query time.*

Abstract

We present the first linear-time algorithm that computes the 4-edge-connected components of an undirected graph. Hence, we also obtain the first linear-time algorithm for testing 4-edge connectivity. Our results are based on a linear-time algorithm that computes the 3-edge cuts of a 3-edge-connected graph G , and a linear-time procedure that, given the collection of all 3-edge cuts, partitions the vertices of G into the 4-edge-connected components.

1 Introduction

Let $G = (V, E)$ be a connected undirected graph with m edges and n vertices. An (*edge*) *cut* of G is a set of edges $S \subseteq E$ such that $G \setminus S$ is not connected. We say that S is a k -*cut* if its cardinality is $|S| = k$. Also, we refer to the 1-cuts as the *bridges* of G . A cut S is *minimal* if no proper subset of S is a cut of G . The *edge connectivity* of G , denoted by $\lambda(G)$, is the minimum cardinality of an edge cut of G . A graph is k -*edge-connected* if $\lambda(G) \geq k$.

A cut S separates two vertices u and v , if u and v lie in different connected components of $G \setminus S$. Vertices u and v are k -edge-connected, denoted by $u \stackrel{G}{\equiv}_k v$, if there is no $(k-1)$ -cut that separates them. By Menger’s theorem [16], u and v are k -edge-connected if and only if there are k -edge-disjoint paths between u and v . A k -*edge-connected component* of G is a maximal set $C \subseteq V$ such that there is no $(k-1)$ -edge cut in G that disconnects any two vertices $u, v \in C$ (i.e., u and v are in the same connected component of $G \setminus S$ for any $(k-1)$ -edge cut S). We can define, analogously, the *vertex cuts* and the k -*vertex-connected components* of G .

Computing and testing the edge connectivity of a graph, as well as its k -edge-connected components, is a classical subject in graph theory, as it is an important notion in several application areas (see, e.g., [19]), that has been extensively studied since the 1970’s. It is known how to compute the $(k-1)$ -edge cuts, $(k-1)$ -vertex cuts, k -edge-connected components

and k -vertex-connected components of a graph in linear time for $k \in \{2, 3\}$ [5, 10, 18, 21, 25]. The case $k = 4$ has also received significant attention [2, 3, 11, 12]. Unfortunately, none of the previous algorithms achieved linear running time. In particular, Kanevsky and Ramachandran [11] showed how to test whether a graph is 4-vertex-connected in $O(n^2)$ time. Furthermore, Kanevsky et al. [12] gave an $O(m + n\alpha(m, n))$ -time algorithm to compute the 4-vertex-connected components of a 3-vertex-connected graph, where α is a functional inverse of Ackermann's function [23]. Using the reduction of Galil and Italiano [5] from edge connectivity to vertex connectivity, the same bounds can be obtained for 4-edge connectivity. Specifically, one can test whether a graph is 4-edge-connected in $O(n^2)$ time, and one can compute the 4-edge-connected components of a 3-edge-connected graph in $O(m + n\alpha(m, n))$ time. Dinitz and Westbrook [3] presented an $O(m + n \log n)$ -time algorithm to compute the 4-edge-connected components of a general graph G (i.e., when G is not necessarily 3-edge-connected). Nagamochi and Watanabe [20] gave an $O(m + k^2 n^2)$ -time algorithm to compute the k -edge-connected components of a graph G , for any integer k . We also note that the edge connectivity of a simple undirected graph can be computed in $O(m \text{polylog} n)$ time, randomized [8, 13] or deterministic [9, 15]. The best current bound is $O(m \log^2 n \log \log^2 n)$, achieved by Henzinger et al. [9] which provided an improved version of the algorithm of Kawarabayashi and Thorup [15].

Our results and techniques. In this paper we present the first linear-time algorithm that computes the 4-edge-connected components of a general graph G , thus resolving a problem that remained open for more than 20 years. Hence, this also implies the first linear-time algorithm for testing 4-edge connectivity. We base our results on the following ideas. First, we extend the framework of Georgiadis and Kosinas [7] for computing 2-edge cuts (as well as mixed cuts consisting of a single vertex and a single edge) of G . Similar to known linear-time algorithms for computing 3-vertex-connected and 3-edge-connected components [10, 25], Georgiadis and Kosinas [7] define various concepts with respect to a depth-first search (DFS) spanning tree of G . We extend this framework by introducing new key parameters that can be computed efficiently and provide characterizations of the various types of 3-edge cuts that may appear in a 3-edge-connected graph. We deal with the general case by dividing G into auxiliary graphs H_1, \dots, H_ℓ , such that each H_i is 3-edge-connected and corresponds to a different 3-edge-connected component of G . Also, for any two vertices x and y , we have $x \stackrel{G}{\equiv}_4 y$ if and only if x and y are both in the same auxiliary graph H_i and $x \stackrel{H_i}{\equiv}_4 y$. Furthermore, this reduction allows us to compute in linear time the number of *minimal 3-edge cuts* in a general graph G . Next, in order to compute the 4-edge-connected components in each auxiliary graph H_i , we utilize the fact that a minimum cut of a graph G separates G into two connected components. Hence, we can define the set V_C of the vertices in the connected component of $G \setminus C$ that does not contain a specified root vertex r . We refer to the number of vertices in V_C as the r -size of the cut C . Then, we apply a recursive algorithm that successively splits H_i into smaller graphs according to its 3-cuts. When no more splits are possible, the connected components of the final split graph correspond to the 4-edge-connected components of G . We show that we can implement this procedure in linear time by processing the cuts in non-decreasing order with respect to their r -size.

Due to the space constraints we omit several technical details and proofs. They can be found in the full version of the paper which is available at [6].

2 Concepts defined on a DFS-tree structure

Let $G = (V, E)$ be a connected undirected graph, which may have multiple edges. For a set of vertices $S \subseteq V$, the induced subgraph of S , denoted by $G[S]$, is the subgraph of G with vertex set S and edge set $\{e \in E \mid \text{both ends of } e \text{ lie in } S\}$. Let T be the spanning tree of G provided by a depth-first search (DFS) of G [21], with start vertex r . The edges in T are called tree-edges; the edges in $E \setminus T$ are called back-edges, as their endpoints have ancestor-descendant relation in T . A vertex u is an ancestor of a vertex v (v is a descendant of u) if the tree path from r to v contains u . Thus, we consider a vertex to be an ancestor (and, consequently, a descendant) of itself. We let $p(v)$ denote the parent of a vertex v in T . If u is a descendant of v in T , we denote the set of vertices of the simple tree path from u to v as $T[u, v]$. The expressions $T[u, v)$ and $T(u, v]$ have the obvious meaning (i.e., the vertex on the side of the parenthesis is excluded). From now on, we identify vertices with their preorder number (assigned during the DFS). Thus, v being an ancestor of u in T implies that $v \leq u$. Let $T(v)$ denote the set of descendants of v , and let $ND(v)$ denote the number of descendants of v (i.e. $ND(v) = |T(v)|$). With all $ND(v)$ computed, we can check in constant time whether a vertex u is a descendant of v , since $u \in T(v)$ if and only if $v \leq u$ and $u < v + ND(v)$ [22].

Whenever (x, y) denotes a back-edge, we shall assume that x is a descendant of y . We let $B(v)$ denote the set of back-edges (x, y) , where x is a descendant of v and y is a proper ancestor of v . Thus, if we remove the tree-edge $(v, p(v))$, $T(v)$ remains connected to the rest of the graph through the back-edges in $B(v)$. This implies that G is 2-edge-connected if and only if $|B(v)| > 0$, for every $v \neq r$. Furthermore, G is 3-edge-connected only if $|B(v)| > 1$, for every $v \neq r$. We let $b_count(v)$ denote the number of elements of $B(v)$ (i.e. $b_count(v) = |B(v)|$). $low(v)$ denotes the lowest y such that there exists a back-edge $(x, y) \in B(v)$. Similarly, $high(v)$ is the highest y such that there exists a back-edge $(x, y) \in B(v)$.

We let $M(v)$ denote the nearest common ancestor of all x for which there exists a back-edge $(x, y) \in B(v)$. Note that $M(v)$ is a descendant of v . Let m be a vertex and v_1, \dots, v_k be all the vertices with $M(v_1) = \dots = M(v_k) = m$, sorted in decreasing order. (Observe that v_{i+1} is an ancestor of v_i , for every $i \in \{1, \dots, k-1\}$, since m is a common descendant of all v_1, \dots, v_k .) Then we have $M^{-1}(m) = \{v_1, \dots, v_k\}$, and we define $nextM(v_i) := v_{i+1}$, for every $i \in \{1, \dots, k-1\}$, and $lastM(v_i) := v_k$, for every $i \in \{1, \dots, k\}$. Thus, for every vertex v , $nextM(v)$ is the successor of v in the decreasingly sorted list $M^{-1}(M(v))$, and $lastM(v)$ is the lowest element in $M^{-1}(M(v))$.

The following two facts have been proved in [7].

► **Fact 1.** All $ND(v)$, $b_count(v)$, $M(v)$, $low(v)$ and $high(v)$ can be computed in total linear-time, for all vertices v .

► **Fact 2.** $B(u) = B(v) \Leftrightarrow M(u) = M(v)$, and $high(u) = high(v) \Leftrightarrow M(u) = M(v)$ and $b_count(u) = b_count(v)$.

Furthermore, [7] implies the following characterization of a 3-edge-connected graph.

► **Fact 3.** G is 3-edge-connected if and only if $|B(v)| > 1$, for every $v \neq r$, and $B(v) \neq B(u)$, for every pair of vertices u and v , $u \neq v$.

Now let us provide some extensions of those concepts that will be needed for our purposes. Assume that G is 3-edge-connected, and let $v \neq r$ be a vertex of G . By Fact 3, $b_count(v) > 1$, and therefore there are at least two back-edges in $B(v)$. Thus, there is at least one back-edge $(x, y) \in B(v)$ such that $y = low(v)$. We let $low1(v)$ denote y , and $low1D(v)$ denote x . In other

words, $low1(v)$ is the *low* point of v , and $low1D(v)$ is a descendant of v which is connected with a back-edge to its *low* point. (Notice, however, that $low1D(v)$ is not uniquely determined.) Similarly, we let $highD(v)$ denote a descendant of v which is connected with a back-edge to the *high* point of v . Then we define $low2(v) := \min\{y' \mid \exists(x', y') \in B(v) \setminus \{(low1D(v), low1(v))\}\}$, and we let $low2D(v)$ denote a descendant of v which is connected with a back-edge to $low2(v)$. Thus, if $v \neq r$, we have that $(low1D(v), low(v))$ and $(low2D(v), low2(v))$ are two distinct back-edges in $B(v)$. It is easy to compute all $low1(v)$, $low1D(v)$, $low2(v)$ and $low2D(v)$ during the DFS. It is also easy to extend the algorithm for the computation of *high* points in order to compute all $highD(v)$. (We refer to [6] for the details.)

We let $l(v)$ denote the lowest y for which there exists a back-edge (v, y) , or v if no such back-edge exists. Thus, $low(v) \leq l(v)$. Now let c_1, \dots, c_k be the children of v sorted in non-decreasing order w.r.t. their *low* point. Then we call c_1 the *low1* child of v , and c_2 the *low2* child of v . (Of course, the *low1* and *low2* children of v are not uniquely determined after a DFS on G , since we may have $low(c_1) = low(c_2)$.) We let $\tilde{M}(v)$ denote the nearest common ancestor of all x for which there exists a back-edge $(x, y) \in B(v)$ with x a proper descendant of $M(v)$. Formally, $\tilde{M}(v) := nca\{x \mid \exists(x, y) \in B(v) \text{ and } x \neq M(v)\}$. If the set $\{x \mid \exists(x, y) \in B(v) \text{ and } x \neq M(v)\}$ is empty, we leave $\tilde{M}(v)$ undefined. We also define $M_{low1}(v)$ as the nearest common ancestor of all x for which there exists a back-edge $(x, y) \in B(v)$ with x being a descendant of the *low1* child of $M(v)$, and also define $M_{low2}(v)$ as the nearest common ancestor of all x for which there exists a back-edge $(x, y) \in B(v)$ with x a descendant of the *low2* child of $M(v)$. Formally, $M_{low1}(v) := nca\{x \mid \exists(x, y) \in B(v) \text{ and } x \text{ is a descendant of the } low1 \text{ child of } M(v)\}$ and $M_{low2}(v) := nca\{x \mid \exists(x, y) \in B(v) \text{ and } x \text{ is a descendant of the } low2 \text{ child of } M(v)\}$. If the set in the formal definition of $M_{low1}(v)$ (resp. $M_{low2}(v)$) is empty, we leave $M_{low1}(v)$ (resp. $M_{low2}(v)$) undefined.

The following list summarizes the concepts that we use on a DFS-tree; they are defined for all $v \neq r$. (For an illustration, see Figure 1.)

- $B(v) := \{(x, y) \mid x \text{ is a descendant of } v \text{ and } y \text{ is a proper ancestor of } v\}$.
- $l(v) := \min(\{y \mid \exists(v, y) \in B(v)\} \cup \{v\})$.
- $low(v) := \min\{y \mid \exists(x, y) \in B(v)\}$.
- $low1(v) := low(v)$.
- $low1D(v) := \text{a vertex } x \text{ such that } (x, low1(v)) \in B(v)$.
- $low2(v) := \min\{y' \mid \exists(x', y') \in B(v) \setminus \{(low1D(v), low1(v))\}\}$.
- $low2D(v) := \text{a vertex } x \text{ such that } (x, low2(v)) \in B(v)$.
- $high(v) := \max\{y \mid \exists(x, y) \in B(v)\}$.
- $highD(v) := \text{a vertex } x \text{ such that } (x, high(v)) \in B(v)$.
- $M(v) := nca\{x \mid \exists(x, y) \in B(v)\}$.
- $\tilde{M}(v) := nca\{x \mid \exists(x, y) \in B(v) \text{ and } x \text{ is a proper descendant of } M(v)\}$.
- $M_{low1}(v) := nca\{x \mid \exists(x, y) \in B(v) \text{ and } x \text{ is a descendant of the } low1 \text{ child of } M(v)\}$.
- $M_{low2}(v) := nca\{x \mid \exists(x, y) \in B(v) \text{ and } x \text{ is a descendant of the } low2 \text{ child of } M(v)\}$.

In Section 2.1 of the full paper [6], we show how to compute all these concepts in linear time.

■ **Figure 1** An illustration of some concepts defined on a DFS-tree. The red arrows correspond to the back-edges in $B(v)$. Dashed lines correspond to tree-paths.

3 Computing the 3-cuts of a 3-edge-connected graph

In this section we present a linear-time algorithm that computes all the 3-edge-cuts of a 3-edge-connected graph $G = (V, E)$. It is well-known that the number of the 3-edge-cuts of G is $O(n)$ [19] (e.g., it follows from the definition of the cactus graph [1, 14]), but we provide an independent proof of this fact. Then, in Section 4.1, we show how to extend this algorithm so that it can also count the number of minimal 3-edge-cuts of a general graph. Note that there can be $O(n^3)$ such cuts [2].

Our method is to classify the 3-cuts on the DFS-tree T in a way that allows us to compute them efficiently. If $\{e_1, e_2, e_3\}$ is a 3-cut, we can initially distinguish three cases w.l.o.g.: either e_1 is a tree-edge and both e_2 and e_3 are back-edges, or e_1 and e_2 are two tree-edges and e_3 is a back-edge, or e_1, e_2 and e_3 is a triplet of tree-edges. Then, we divide those cases in subcases based on the concepts we have introduced in the previous section. Figure 2 gives a general overview of the cases we will handle in some detail in the following sections.

3.1 One tree-edge and two back-edges

The following lemma characterizes all 3-cuts consisting of a tree-edge and two back-edges.

► **Lemma 4.** *Let $\{(u, p(u)), e, e'\}$ be a 3-cut such that e and e' are back-edges. Then $B(u) = \{e, e'\}$. Conversely, if for a vertex $u \neq r$ we have $B(u) = \{e, e'\}$ where e and e' are back-edges, then $\{(u, p(u)), e, e'\}$ is a 3-cut.*

Thus, to compute all the 3-cuts of this type, we have to find all $u \neq r$ with $b_count(u) = 2$. For every such u , there are two back-edges e_1, e_2 such that $B(u) = \{e_1, e_2\}$, and so, w.l.o.g., we have $e_1 = (low1D(u), low1(u))$ and $e_2 = (low2D(u), low2(u))$. Then we mark $\{(u, p(u)), e_1, e_2\}$ as a 3-cut.

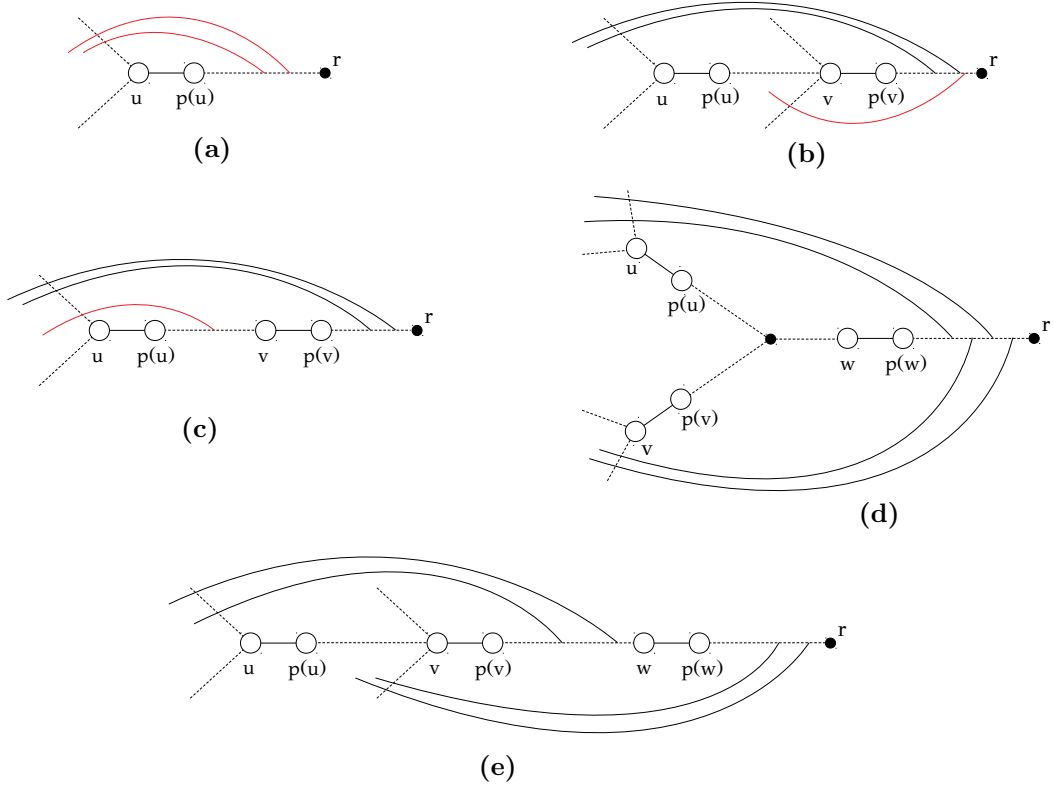

Figure 2 The types of 3-cuts with respect to a DFS-tree. (a) One tree-edge $(u, p(u))$ and two back-edges. (b) Two tree-edges $(u, p(u))$ and $(v, p(v))$, where u is a descendant of v , and one back-edge in $B(v) \setminus B(u)$. (c) Two tree-edges $(u, p(u))$ and $(v, p(v))$, where u is a descendant of v , and one back-edge in $B(u) \setminus B(v)$. (d) Three tree-edges $(u, p(u))$, $(v, p(v))$ and $(w, p(w))$, where w is an ancestor of u and v , but u and v are not related as ancestor and descendant. (e) Three tree-edges $(u, p(u))$, $(v, p(v))$ and $(w, p(w))$, where u is a descendant of v and v is a descendant of w .

3.2 Two tree-edges and one back-edge

In the case of 3-cuts consisting of two tree-edges and a back-edge, we have the following.

► Lemma 5. *Let $\{(u, p(u)), (v, p(v)), e\}$ be a 3-cut such that e is a back-edge. Then u and v are related as ancestor and descendant.*

► Proposition 6. *Let $\{(u, p(u)), (v, p(v)), e\}$ be a 3-cut, where e is a back-edge. Then, either (1) $B(v) = B(u) \sqcup \{e\}$ or (2) $B(u) = B(v) \sqcup \{e\}$. Conversely, if there exists a back-edge e such that (1) or (2) is true, then $\{(u, p(u)), (v, p(v)), e\}$ is a 3-cut.*

We let $V(u)$, for a $u \neq r$, be the set of all v that are ancestors of u such that $B(v) = B(u) \sqcup \{e\}$, for a back-edge e . We also let $U(v)$, for a $v \neq r$, be the set of all u that are descendants of v such that $B(u) = B(v) \sqcup \{e\}$, for a back-edge e . Then, for every 3-cut $\{(u, p(u)), (v, p(v)), e\}$, where e is a back-edge, Proposition 6 implies that either $u \in V(u)$ or $v \in U(v)$.

The following two lemmata imply that the number of 3-cuts consisting of two tree-edges and a back-edge is $O(n)$.

► Lemma 7. *Let v, v' be two distinct vertices. Then $V(u) \cap V(u') = \emptyset$.*

► Lemma 8. *Let u, u' be two distinct vertices. Then $U(v) \cap U(v') = \emptyset$.*

Now, every $v \in V(u)$ has either $\tilde{M}(v) = M(u)$, or $M_{low1}(v) = M(u)$, or $M_{low2}(v) = M(u)$, and u is the lowest vertex which is greater than v such that $\tilde{M}(v) = M(u)$, or $M_{low1}(v) = M(u)$, or $M_{low2}(v) = M(u)$, respectively. This suggests a method to compute, for every vertex v , the unique u (if it exists) such that $v \in V(u)$. We process all vertices v , and for every v that we process we have to find the lowest element u of $M^{-1}(x)$ which is greater than v , for every $x \in \{\tilde{M}(v), M_{low1}(v), M_{low2}(v)\}$, and check whether $v \in V(u)$. To perform this efficiently, we have the lists $M^{-1}(x)$, for every vertex x , sorted in decreasing order, and we process the vertices in a bottom-up fashion. Then, for every v that we process, and every $x \in \{\tilde{M}(v), M_{low1}(v), M_{low2}(v)\}$, we search for the lowest u in $M^{-1}(x)$ which is greater than v , by traversing the list $M^{-1}(x)$ starting from the last element of $M^{-1}(x)$ that we considered, which is being stored in a variable `currentVertex[x]`. This is to avoid traversing $M^{-1}(x)$ from the beginning each time we process a vertex v . We can check in constant time whether $v \in V(u)$ thanks to the following lemma.

► **Lemma 9.** *Let v be an ancestor of u such that either $\tilde{M}(v) = M(u)$, or $M_{low1}(v) = M(u)$, or $M_{low2}(v) = M(u)$, and let $m = \tilde{M}(v)$, or $m = M_{low1}(v)$, or $m = M_{low2}(v)$, depending on whether $\tilde{M}(v) = M(u)$, or $M_{low1}(v) = M(u)$, or $M_{low2}(v) = M(u)$, respectively. Then, $v \in V(u)$ if and only if u is the lowest element in $M^{-1}(m)$ which is greater than v and such that $high(u) < v$ and $b_count(v) = b_count(u) + 1$.*

Finally, for a $v \in V(u)$, we can immediately identify the back-edge (x, y) with $B(v) = B(u) \sqcup \{(x, y)\}$, since we have $x = \tilde{M}(v)$ and $y = l(\tilde{M}(v))$, or $x = M_{low1}(v)$ and $y = l(M_{low1}(v))$, or $x = M_{low2}(v)$ and $y = l(M_{low2}(v))$, depending on whether $\tilde{M}(v) = M(u)$, or $M_{low1}(v) = M(u)$, or $M_{low2}(v) = M(u)$, respectively. Algorithm 1 shows how we can compute all 3-cuts of the form $\{(u, p(u)), (v, p(v)), e\}$, with $B(v) = B(u) \sqcup \{e\}$.

We can use a similar method to compute the 3-cuts of the form $\{(u, p(u)), (v, p(v)), e\}$, with $B(u) = B(v) \sqcup \{e\}$.

3.3 Three tree-edges

The case of 3-cuts consisting of three tree-edges is more involved and is subdivided into several subcases. The following is generally true for all such 3-cuts.

► **Lemma 10.** *Let $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ be a 3-cut, and assume, without loss of generality, that $w < \min\{v, u\}$. Then w is an ancestor of both u and v .*

First we treat the case that u and v are not related as ancestor and descendant. We have the following characterizations of the 3-cuts of this type.

► **Proposition 11.** *Let u and v be two vertices which are not related as ancestor and descendant, and let w be an ancestor of both u and v . Then $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ is a 3-cut if and only if $B(w) = B(u) \sqcup B(v)$.*

► **Lemma 12.** *Let u and v be two vertices which are not related as ancestor and descendant, and let w be an ancestor of both u and v . Then $B(w) = B(u) \sqcup B(v)$ if and only if: $M_{low1}(w) = M(u)$ and $M_{low2}(w) = M(v)$ (or $M_{low1}(w) = M(v)$ and $M_{low2}(w) = M(u)$), and $high(u) < w$, $high(v) < w$, and $b_count(w) = b_count(u) + b_count(v)$.*

Then, as an implication of the following lemma, we see that the pair $\{u, v\}$ with the property that u and v are descendants of w , but are not related as ancestor and descendant, and $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ is a 3-cut, is uniquely determined by w (and thus the number of those 3-cuts is $O(n)$).

■ **Algorithm 1** Find all 3-cuts $\{(u, p(u)), (v, p(v)), e)\}$, where u is a descendant of v and $B(v) = B(u) \sqcup \{e\}$, for a back-edge e .

```

1 initialize an array currentVertex with  $n$  entries
  //  $m = \tilde{M}(v)$ 
2 foreach vertex  $x$  do currentVertex $[x] \leftarrow x$ 
3 for  $v \leftarrow n$  to  $v = 1$  do
4    $m \leftarrow \tilde{M}(v)$ 
5   if  $m = \emptyset$  then continue
    // find the lowest  $u \in M^{-1}(m)$  which is greater than  $v$ 
6    $u \leftarrow \text{currentVertex}[m]$ ,  $\text{prev} \leftarrow u$ 
7   while  $\text{nextM}(u) \neq \emptyset$  and  $\text{nextM}(u) > v$  do  $\text{prev} \leftarrow u$ ,  $u \leftarrow \text{nextM}(u)$ 
8   currentVertex $[m] \leftarrow \text{prev}$ 
    // check the condition in Lemma 9
9   if  $\text{high}(u) < v$  and  $b\_count(v) = b\_count(u) + 1$  then
10    | mark the triplet  $\{(u, p(u)), (v, p(v)), (M(v), l(M(v)))\}$ 
11  end
12 end
  //  $m = M_{low1}(v)$ 
13 foreach vertex  $x$  do currentVertex $[x] \leftarrow x$ 
14 for  $v \leftarrow n$  to  $v = 1$  do
15    $m \leftarrow M_{low1}(v)$ 
16   if  $m = \emptyset$  or  $l(M(v)) < v$  then continue
    // find the lowest  $u \in M^{-1}(m)$  which is greater than  $v$ 
17    $u \leftarrow \text{currentVertex}[m]$ ,  $\text{prev} \leftarrow u$ 
18   while  $\text{nextM}(u) \neq \emptyset$  and  $\text{nextM}(u) > v$  do  $\text{prev} \leftarrow u$ ,  $u \leftarrow \text{nextM}(u)$ 
19   currentVertex $[m] \leftarrow \text{prev}$ 
    // check the condition in Lemma 9
20   if  $\text{high}(u) < v$  and  $b\_count(v) = b\_count(u) + 1$  then
21    | mark the triplet  $\{(u, p(u)), (v, p(v)), (M_{low2}(v), l(M_{low2}(v)))\}$ 
22  end
23 end
  //  $m = M_{low2}(v)$ 
24 foreach vertex  $x$  do currentVertex $[x] \leftarrow x$ 
25 for  $v \leftarrow n$  to  $v = 1$  do
26    $m \leftarrow M_{low2}(v)$ 
27   if  $m = \emptyset$  or  $l(M(v)) < v$  then continue
    // find the lowest  $u \in M^{-1}(m)$  which is greater than  $v$ 
28    $u \leftarrow \text{currentVertex}[m]$ ,  $\text{prev} \leftarrow u$ 
29   while  $\text{nextM}(u) \neq \emptyset$  and  $\text{nextM}(u) > v$  do  $\text{prev} \leftarrow u$ ,  $u \leftarrow \text{nextM}(u)$ 
30   currentVertex $[m] \leftarrow \text{prev}$ 
    // check the condition in Lemma 9
31   if  $\text{high}(u) < v$  and  $b\_count(v) = b\_count(u) + 1$  then
32    | mark the triplet  $\{(u, p(u)), (v, p(v)), (M_{low1}(v), l(M_{low1}(v)))\}$ 
33  end
34 end

```

► **Lemma 13.** *Let $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ be a 3-cut such that u and v are not related as ancestor and descendant and let w is an ancestor of both u and v . By Proposition 11 and Lemma 12, we may assume w.l.o.g. that $M_{low1}(w) = M(u)$ and $M_{low2}(w) = M(v)$, and let $m_1 = M_{low1}(w)$ and $m_2 = M_{low2}(w)$. Then u is the lowest vertex in $M^{-1}(m_1)$ which is greater than w , and v is the lowest vertex in $M^{-1}(m_2)$ which is greater than w .*

This suggests a method to compute those u, v (if they exist) for a particular w . We simply have to find the lowest u in $M^{-1}(M_{low1}(w))$ which is greater than w , and the lowest v in $M^{-1}(M_{low2}(w))$ which is greater than w , and, if they exist, check whether $high(u) < w$, $high(v) < w$, and $b_count(w) = b_count(u) + b_count(v)$. To perform this search efficiently, we have the lists $M^{-1}(x)$, for every vertex x , sorted in decreasing order, we process the vertices w in a bottom-up fashion, and we keep stored in a variable *currentVertex*[x] the most recent element of $M^{-1}(x)$ that we considered. Algorithm 2 is an implementation of this procedure, for computing all 3-cuts of this type.

■ **Algorithm 2** Find all 3-cuts $\{(u, p(u)), (v, p(v)), (w, p(w))\}$, where w is an ancestor of u and v , and u, v are not related as ancestor and descendant.

```

1 initialize an array currentVertex with  $n$  entries
2 foreach vertex  $x$  do currentVertex[ $x$ ]  $\leftarrow x$ 
3 for  $w \leftarrow n$  to  $w = 1$  do
4    $m_1 \leftarrow M_{low1}(w)$ ,  $m_2 \leftarrow M_{low2}(w)$ 
5   if  $m_1 = \emptyset$  or  $m_2 = \emptyset$  then continue
6   // find the lowest  $u$  in  $M^{-1}(m_1)$  which is greater than  $w$ 
7    $u \leftarrow \text{currentVertex}[m_1]$ 
8   while  $\text{nextM}(u) \neq \emptyset$  and  $\text{nextM}(u) > w$  do  $u \leftarrow \text{nextM}(u)$ 
9   currentVertex[ $m_1$ ]  $\leftarrow u$ 
10  // find the lowest  $v$  in  $M^{-1}(m_2)$  which is greater than  $w$ 
11   $v \leftarrow \text{currentVertex}[m_2]$ 
12  while  $\text{nextM}(v) \neq \emptyset$  and  $\text{nextM}(v) > w$  do  $v \leftarrow \text{nextM}(v)$ 
13  currentVertex[ $m_2$ ]  $\leftarrow v$ 
14  // check the condition in Lemma 12
15  if  $b\_count(w) = b\_count(u) + b\_count(v)$  and  $high(u) < w$  and  $high(v) < w$ 
16    then
17      | mark the triplet  $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ 
18    end
19 end

```

Now we treat the case that u and v are related as ancestor and descendant, and assume w.l.o.g. that u is a descendant of v . We have the following characterization of those 3-cuts.

► **Proposition 14.** *Let u, v, w be three vertices such that u is a descendant of v and v is a descendant of w . Then $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ is a 3-cut if and only if $B(v) = B(u) \sqcup B(w)$.*

This implies that $M(v)$ is an ancestor of $M(w)$, and we distinguish two cases, depending on whether $M(v)$ is a proper ancestor of $M(w)$. In the first case we have the following.

► **Lemma 15.** *Let u be a descendant of v and v a descendant of w , and $M(v) \neq M(w)$. Then, $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ is a 3-cut if and only if: $M(w) = M_{low1}(v)$ and w is the greatest vertex with $M(w) = M_{low1}(v)$ which is lower than v , $M(u) = M_{low2}(v)$ and u*

47:10 Computing the 4-Edge-Connected Components of a Graph in Linear Time

is the lowest vertex with $M(u) = M_{low2}(v)$, $high(u) < v$ and $b_count(v) = b_count(u) + b_count(w)$.

This shows that the number of such 3-cuts is $O(n)$, and it immediately suggests an algorithm to compute them efficiently (i.e. we work as in Algorithm 2).

Now, if $M(v) = M(w)$, we distinguish two cases, depending on whether $w = nextM(v)$ or $w < nextM(v)$. In any case, there is a unique u which is a descendant of v such that $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ is a 3-cut, since by Proposition 14 we have $B(u) = B(v) \setminus B(w)$, and we have assumed that the graph is 3-edge-connected (and so the result follows from Fact 3). The next lemma shows that u satisfies $high(u) = high(v)$ and $nextM(u) = \emptyset$.

► **Lemma 16.** *Let u, v, w be three vertices such that u is a descendant of v , v is a descendant of w , and $M(v) = M(w)$. Then, $B(v) = B(u) \sqcup B(w)$ only if $high(u) = high(v)$ and $nextM(u) = \emptyset$.*

Thus, for every vertex h , we seek in the decreasingly sorted list $high^{-1}(h)$ pairs of vertices $\{u, v\}$ that have the potential to provide a 3-cut of the form $\{(u, p(u)), (v, p(v)), (w, p(w))\}$, where u is a descendant of v , v is a descendant of w , and $M(v) = M(w)$. In the case $w = nextM(v)$ we have the following:

► **Proposition 17.** *Let $h = high(v)$ and $w = nextM(v)$, and suppose that the list $high^{-1}(h)$ is sorted in decreasing order. Then, u is a descendant of v such that $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ is a 3-cut if and only if u is a predecessor of v in $high^{-1}(h)$, $nextM(u) = \emptyset$, $low(u) \geq w$, $b_count(u) = b_count(v) - b_count(w)$, and all elements of $high^{-1}(h)$ between u and v are ancestors of u .*

Thus we traverse the decreasingly sorted list $high^{-1}(h)$ from its first element, and we keep consecutive entries that are related as ancestor and descendant in a stack. When we meet a $v \in high^{-1}(h)$ that has $nextM(v) \neq \emptyset$, we simply check whether there is an entry u in the stack that satisfies $nextM(u) = \emptyset$, $low(u) \geq nextM(v)$ and $b_count(u) = b_count(v) - b_count(nextM(v))$, whence we immediately infer that $\{(u, p(u)), (v, p(v)), (nextM(v), p(nextM(v)))\}$ is a 3-cut. This procedure is shown in Algorithm 3.

The case $w < nextM(v)$ is more complicated, since for a particular $v \in high^{-1}(h)$ there may be many pairs $\{u, w\}$ such that u is a descendant of v and w is a proper ancestor of $nextM(v)$ with $M(w) = M(v)$, and $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ is a 3-cut. Thus, we keep in a stack $stackU[v]$, for every $v \in high^{-1}(h)$, a set of $u \in high^{-1}(h)$ with the potential to provide such a 3-cut. In particular, let $\tilde{U}(v)$, for a vertex v , denote the set of all descendants u of v with the property that there exists a w with $M(w) = M(v)$ and $w < nextM(v)$, such that $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ is a 3-cut. Then the stacks $stackU[v]$ are filled with Algorithm 4, and satisfy the following:

► **Lemma 18.** *For every vertex v we have $\tilde{U}(v) \subseteq stackU(v)$, and for every $v' \neq v$ we have $stackU(v) \cap stackU(v') = \emptyset$. Furthermore, if u' is a successor of u in $stackU(v)$, then u' is an ancestor of u .*

This implies that the number of 3-cuts of the form $\{(u, p(u)), (v, p(v)), (w, p(w))\}$, where u is a descendant of v and w is a proper ancestor of $nextM(v)$ with $M(w) = M(v)$, is $O(n)$. The next lemma provides a criterion to determine whether a $u \in stackU(v)$ is in $\tilde{U}(v)$, and a way to compute the vertex w with $M(w) = M(v)$ and $w < nextM(v)$, such that $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ is a 3-cut.

■ **Algorithm 3** Find all 3-cuts $\{(u, p(u)), (v, p(v)), (w, p(w))\}$, where u is a descendant of v and $w = \text{nextM}(v)$.

```

1 initialize an array  $A$  with  $m$  entries (where  $m$  is the number of edges of the graph)
2 initialize a stack  $S$ 
3 sort the elements of every list  $\text{high}^{-1}(h)$ , for every vertex  $h$ , in decreasing order
4 foreach vertex  $h$  do
5    $u \leftarrow$  first element of  $\text{high}^{-1}(h)$ 
6   while  $u \neq \emptyset$  do
7      $z \leftarrow$  next element of  $\text{high}^{-1}(h)$ 
8     if  $z = \emptyset$  then break
9     if  $z$  is not an ancestor of  $u$  then
10      while  $S$  is not empty do
11         $u' \leftarrow S.\text{pop}()$ 
12         $A[b\_count(u')] \leftarrow \emptyset$ 
13      end
14    end
15    if  $\text{nextM}(z) = \emptyset$  then
16       $S.\text{push}(z)$ 
17       $A[b\_count(z)] \leftarrow z$ 
18    end
19    else if  $\text{nextM}(z) \neq \emptyset$  then
20       $v \leftarrow z, w \leftarrow \text{nextM}(v)$ 
21      if  $A[b\_count(v) - b\_count(w)] \neq \emptyset$  then
22         $u \leftarrow A[b\_count(v) - b\_count(w)]$ 
23        if  $\text{low}(u) \geq w$  then
24          mark the triplet  $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ 
25        end
26      end
27    end
28     $u \leftarrow z$ 
29  end
30 end

```

► **Lemma 19.** Let u be a vertex in $\text{stackU}[v]$ and w a proper ancestor of v such that $M(w) = M(v)$. Then, if $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ is a 3-cut, we have that $b_count(v) = b_count(u) + b_count(w)$ and w is the greatest element of $M^{-1}(M(v))$ such that $w \leq \text{low}(u)$. Conversely, if $b_count(v) = b_count(u) + b_count(w)$ and $w \leq \text{low}(u)$, then $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ is a 3-cut.

Thus, for every $u \in \text{stackU}[v]$, we have to find the greatest $w \in M^{-1}(M(v))$ such that $w \leq \text{low}(u)$ and $b_count(v) = b_count(u) + b_count(w)$. To do this efficiently, we take advantage of the fact that the stack $\text{stackU}[v]$ has been filled in such a way, that the successor of every $u \in \text{stackU}[v]$ is an ancestor of u , and of the fact that $\text{low}(u') \leq \text{low}(u)$, for every ancestor u' of u . Then we have the lists $M^{-1}(x)$, for every vertex x , sorted in decreasing order, and we process the vertices v from lowest to highest. For every $u \in \text{stackU}[v]$, we traverse the list $M^{-1}(M(v))$ in order to find the greatest $w \in M^{-1}(M(v))$ that has $w \leq \text{low}(u)$.

■ **Algorithm 4** Fill all stacks $stackU[v]$, for all vertices v .

```

1 initialize a stack  $S$ 
2 sort the elements of every list  $high^{-1}(h)$ , for every vertex  $h$ , in decreasing order
3 foreach vertex  $v$  do initialize a stack  $stackU[v]$ 
4 foreach vertex  $h$  do
5    $u \leftarrow$  first element of  $high^{-1}(h)$ 
6   while  $u \neq \emptyset$  do
7      $z \leftarrow$  next element of  $high^{-1}(h)$ 
8     if  $z = \emptyset$  then break
9     if  $z$  is not an ancestor of  $u$  then
10      | pop out all elements from  $S$ 
11    end
12    if  $nextM(z) = \emptyset$  then
13      |  $S.push(z)$ 
14    end
15    else if  $nextM(z) \neq \emptyset$  then
16      | while  $low(S.top()) < lastM(z)$  do  $S.pop()$ 
17      | while  $low(S.top()) < nextM(z)$  do
18      |    $u \leftarrow S.pop()$ 
19      |    $stackU[v].push(u)$ 
20      | end
21    end
22     $u \leftarrow z$ 
23  end
24 end

```

Using a path-compression method, we can bypass segments of $M^{-1}(M(v))$ that we have already visited. This procedure is shown in Algorithm 5. A detailed proof of correctness and linear complexity is given in the full version of this paper [6].

■ **Algorithm 5** Find all 3-cuts $\{(u, p(u)), (v, p(v)), (w, p(w))\}$, where u is a descendant of v , v is a descendant of w with $M(v) = M(w)$, and $w \neq nextM(v)$.

```

1 initialize an array  $lowestW$  with  $n$  entries
2 foreach vertex  $v$  do  $lowestW[v] \leftarrow nextM(v)$ 
3 for  $v \leftarrow 1$  to  $v \leftarrow n$  do
4   while  $stackU[v].top() \neq \emptyset$  do
5      $u \leftarrow stackU[v].pop()$ 
6      $w \leftarrow lowestW[v]$ 
7     while  $w > low(u)$  do  $w \leftarrow lowestW[w]$ 
8      $lowestW[v] \leftarrow w$ 
9     if  $b\_count(v) = b\_count(u) + b\_count(w)$  then
10      | mark the triplet  $\{(u, p(u)), (v, p(v)), (w, p(w))\}$ 
11    end
12  end
13 end

```

4 Computing the 4-edge-connected components in linear time

Now we consider how to compute the 4-edge-connected components of an undirected graph G in linear time. First, we reduce this problem to the computation of the 4-edge-connected components of a collection of auxiliary 3-edge-connected graphs.

4.1 Reduction to the 3-edge-connected case

Given a (general) undirected graph G , we execute the following steps:

1. Compute the connected components of G .
2. For each connected component, we compute the 2-edge-connected components which are subgraphs of G .
3. For each 2-edge-connected component, we compute its 3-edge-connected components C_1, \dots, C_ℓ .
4. For each 3-edge-connected component C_i , we compute a 3-edge-connected auxiliary graph H_i , such that for any two vertices x and y , we have $x \stackrel{G}{\equiv}_4 y$ if and only if x and y are both in the same auxiliary graph H_i and $x \stackrel{H_i}{\equiv}_4 y$.
5. Finally, we compute the 4-edge-connected components of each H_i .

Steps 1–3 take overall linear time [21, 25]. We describe step 5 in the next section, so it remains to give the details of step 4. Let H be a 2-edge-connected component (subgraph) of G . We can construct a compact representation of the 2-cuts of H , which allows us to compute its 3-edge-connected components C_1, \dots, C_ℓ in linear time [7, 25]. Now, since the collection $\{C_1, \dots, C_\ell\}$ constitutes a partition of the vertex set of H , we can form the quotient graph Q of H by shrinking each C_i into a single node. Graph Q has the structure of a tree of cycles [2]; in other words, Q is connected and every edge of Q belongs to a unique cycle. Let (C_i, C_j) and (C_i, C_k) be two edges of Q which belong to the same cycle. Then (C_i, C_j) and (C_i, C_k) correspond to two edges (x, y) and (x', y') of G , with $x, x' \in C_i$. If $x \neq x'$, we add a virtual edge (x, x') to $G[C_i]$. (The idea is to attach (x, x') to $G[C_i]$ as a substitute for the cycle of Q which contains (C_i, C_j) and (C_i, C_k) .) Now let \bar{C}_i be the graph $G[C_i]$ plus all those virtual edges. Then \bar{C}_i is 3-edge-connected and its 4-edge-connected components are precisely those of G that are contained in C_i [2]. Thus we can compute the 4-edge-connected components of G by computing the 4-edge-connected components of the graphs $\bar{C}_1, \dots, \bar{C}_\ell$ (which can easily be constructed in total linear time). Since every \bar{C}_i is 3-edge-connected, we can apply Algorithm 6 of the following section to compute its 4-edge-connected components in linear time. Finally, we define the multiplicity $m(e)$ of an edge $e \in \bar{C}_i$ as follows: if e is virtual, $m(e)$ is the number of edges of the cycle of Q which corresponds to e ; otherwise, $m(e)$ is 1. Then, the number of minimal 3-cuts of H is given by the sum of all $m(e_1) \cdot m(e_2) \cdot m(e_3)$, for every 3-cut $\{e_1, e_2, e_3\}$ of \bar{C}_i , for every $i \in \{1, \dots, \ell\}$ [2]. Since the 3-cuts of every \bar{C}_i can be computed in linear time, the minimal 3-cuts of H can also be computed within the same time bound.

4.2 Computing the 4-edge-connected components of a 3-edge-connected graph

Now we describe how to compute the 4-edge-connected components of a 3-edge-connected graph G in linear time. Let r be a distinguished vertex of G , and let C be a minimum cut of G . By removing C from G , G becomes disconnected into two connected components. We let V_C denote the connected component of $G \setminus C$ that does not contain r , and we refer to the number of vertices of V_C as the r -size of the cut C . (Of course, these notions are relative to r .)

■ **Figure 3** $C = \{(x_1, y_1), (x_2, y_2), (x_3, y_3)\}$ is a 3-cut of G , with $\{x_1, x_2, x_3\}$ and $\{y_1, y_2, y_3\}$ lying in different connected components of $G \setminus C$. The split operation of G at C consists of the removal of the edges of C from G , and the introduction of two new nodes x, y , and six virtual edges $(x_1, y), (x_2, y), (x_3, y), (x, y_1), (x, y_2), (x, y_3)$. Now, the split graph is made of two connected components, G_1 and G_2 . Every 3-cut $C' \neq C$ of G (or more precisely: a 3-cut that corresponds to C') lies entirely within G_1 or G_2 . Conversely, every 3-cut of either G_1 or G_2 corresponds to a 3-cut of G . Thus, every 4-edge-connected component of G lies entirely within G_1 or G_2 .

Let $G = (V, E)$ be a 3-edge-connected graph, and let \mathcal{C} be the collection of the 3-cuts of G . If the collection \mathcal{C} is empty, then G is 4-edge-connected, and V is the only 4-edge-connected component of G . Otherwise, let $C \in \mathcal{C}$ be a 3-cut of G . By removing C from G , G is separated into two connected components, and every 4-edge-connected component of G lies entirely within a connected component of $G \setminus C$. This observation suggests a recursive algorithm for computing the 4-edge-connected components of G , by successively splitting G into smaller graphs according to its 3-cuts. Thus, we start with a 3-cut C of G , and we perform the splitting operation shown in Figure 3. Then we take another 3-cut C' of G and we perform the same splitting operation on the part which contains (the corresponding 3-cut of) C' . We repeat this process until we have considered every 3-cut of G . When no more splits are possible, the connected components of the final split graph correspond (by ignoring the newly introduced vertices) to the 4-edge-connected components of G .

To implement this procedure in linear time, we must take care of two things. First, whenever we consider a 3-cut C of G , we have to be able to know which ends of the edges of C belong to the same connected component of $G \setminus C$. And second, since an edge e of a 3-cut of the original graph may correspond to two virtual edges of the split graph, we have to be able to know which is the virtual edge that corresponds to e . We tackle both these problems by locating the 3-cuts of G on a DFS-tree T of G rooted at r , and by processing them in increasing order with respect to their r -size. By locating a 3-cut $C \in \mathcal{C}$ on T we can answer in $O(1)$ time which ends of the edges of C belong to the same connected component of $G \setminus C$. And then, by processing the 3-cuts of G in increasing order with respect to their size, we ensure that (the 3-cut that corresponds to) a 3-cut $C \in \mathcal{C}$ that we process lies in the split part of G that contains r .

Now, due to the analysis of the preceding sections, we can distinguish the following types of 3-cuts on a DFS-tree T (see also Figure 2):

- (I) $\{(v, p(v)), (x_1, y_1), (x_2, y_2)\}$, where (x_1, y_1) and (x_2, y_2) are back-edges.
- (IIa) $\{(u, p(u)), (v, p(v)), (x, y)\}$, where u is a descendant of v and $(x, y) \in B(v)$.
- (IIb) $\{(u, p(u)), (v, p(v)), (x, y)\}$, where u is a descendant of v and $(x, y) \in B(u)$.
- (III) $\{(u, p(u)), (v, p(v)), (w, p(w))\}$, where w is an ancestor of both u and v , but u, v are not related as ancestor and descendant.
- (IV) $\{(u, p(u)), (v, p(v)), (w, p(w))\}$, where u is a descendant of v and v is a descendant of w .

Let r be the root of T . Then, for every 3-cut $C \in \mathcal{C}$, V_C is either $T(v)$, or $T(v) \setminus T(u)$, or $T(w) \setminus (T(u) \cup T(v))$, or $T(u) \cup (T(w) \setminus T(v))$, depending on whether C is of type (I), (II), (III), or (IV), respectively. Thus we can immediately calculate the size of C and the ends of its edges that lie in V_C . In particular, the size of C is either $ND(v)$, or $ND(v) - ND(u)$, or $ND(w) - ND(u) - ND(v)$, or $ND(u) + ND(w) - ND(v)$, depending on whether it is of type (I), (II), (III), or (IV), respectively; V_C contains either $\{v, x_1, x_2\}$, or $\{p(u), v, x\}$, or $\{p(u), v, y\}$, or $\{p(u), p(v), w\}$, or $\{u, p(v), w\}$, depending on whether C is of type (I), (IIa), (IIb), (III), or (IV), respectively.

Algorithm 6 shows how we can compute the 4-edge-connected components of G in linear time, by repeatedly splitting G into smaller graphs according to its 3-cuts. When we process a 3-cut C of G , we have to find the edges of the split graph that correspond to those of C , in order to delete them and replace them with (new) virtual edges. That is why we use the symbol v' , for a vertex $v \in V$, to denote a vertex that corresponds to v in the split graph. (Initially, we set $v' \leftarrow v$.) Now, if (x, y) is an edge of C with $x \in V_C$, the edge of the split graph corresponding to (x, y) is (x', y') . Then we add two new vertices v_C and \tilde{v}_C to G , and the virtual edges (x', \tilde{v}_C) and (v_C, y') . Finally, we let x correspond to v_C , and so we set $x' \leftarrow v_C$. This is sufficient, since we process the 3-cuts of G in increasing order with respect to their size, and so the next time we meet the edge (x, y) in a 3-cut, we can be certain that it corresponds to (v_C, y') .

■ **Algorithm 6** Compute the 4-edge-connected components of a 3-edge-connected graph $G = (V, E)$.

```

1 Find the collection  $\mathcal{C}$  of the 3-cuts of  $G$ 
2 Locate and classify the 3-cuts of  $G$  on a DFS-tree of  $G$  rooted at  $r$ 
3 For every  $C \in \mathcal{C}$ , calculate  $size(C)$  (relative to  $r$ )
4 Sort  $\mathcal{C}$  in increasing order w.r.t. the  $size$  of its elements
5 foreach  $v \in V$  do Set  $v' \leftarrow v$ 
6 foreach  $C = \{(x_1, y_1), (x_2, y_2), (x_3, y_3)\} \in \mathcal{C}$  do
7   Find the ends of the edges of  $C$  that lie in  $V_C$  // Let those ends be  $x_1, x_2$ 
   and  $x_3$ 
8   Remove the edges  $(x'_1, y'_1), (x'_2, y'_2), (x'_3, y'_3)$  from  $G$ 
9   Introduce two new vertices  $v_C$  and  $\tilde{v}_C$  to  $G$ 
10  Add the edges  $(x'_1, \tilde{v}_C), (x'_2, \tilde{v}_C), (x'_3, \tilde{v}_C), (v_C, y'_1), (v_C, y'_2), (v_C, y'_3)$  to  $G$ 
11  Set  $x'_1 \leftarrow v_C, x'_2 \leftarrow v_C, x'_3 \leftarrow v_C$ 
12 end
13 Output the connected components of  $G$ , ignoring the newly introduced vertices

```

Final Remarks

Independently from our work, Nadara et al. [17] also presented a linear-time algorithm for computing the 4-edge-connected components of a graph. Both our algorithm and the algorithm of [17] require the use of the static tree disjoint-set-union data structure of Gabow and Tarjan [4] to achieve linear running time. Also, similar to our algorithm, the main part in the algorithm of Nadara et al. is the computation of the 3-edge cuts of a 3-edge-connected graph G . Both algorithms operate on a depth-first search tree of G , with start vertex r , and distinguish 3 types of cuts $C = \{e_1, e_2, e_3\}$, depending on the number of tree edges in C . These cases are handled in a different manner in [17]. In particular, Nadara et al. [17] show

that the case where C consists of three tree edges can be reduced, in linear time, to the other two cases. We note that by applying this idea in our framework, we are able to avoid the use of *high* points. (We achieve this by modifying the algorithm that identifies 3-edge cuts consisting of two tree edges, described in Section 3.2.) This way, we obtain a linear-time algorithm that does not require the Gabow-Tarjan disjoint-set-union data structure, and thus is implementable in the pointer machine computation model [24].

Abstract

Partitioning a graph into blocks of “roughly equal” weight while cutting only few edges is a fundamental problem in computer science with a wide range of applications. In particular, the problem is a building block in applications that require parallel processing. While the amount of available cores in parallel architectures has significantly increased in recent years, state-of-the-art graph partitioning algorithms do not work well if the input needs to be partitioned into a large number of blocks. Often currently available algorithms compute highly imbalanced solutions, solutions of low quality, or have excessive running time for this case. This is due to the fact that most high-quality general-purpose graph partitioners are *multilevel algorithms* which perform graph coarsening to build a hierarchy of graphs, initial partitioning to compute an initial solution, and local improvement to improve the solution throughout the hierarchy. However, for large number of blocks, the smallest graph in the hierarchy that is used for initial partitioning still has to be large.

In this work, we substantially mitigate these problems by introducing *deep multilevel graph partitioning* and a shared-memory implementation thereof. Our scheme continues the multilevel approach deep into initial partitioning – integrating it into a framework where recursive bipartitioning and direct k -way partitioning are combined such that they can operate with high performance and quality. Our integrated approach is stronger, more flexible, arguably more elegant, and reduces bottlenecks for parallelization compared to existing multilevel approaches. For example, for large number of blocks our algorithm is on average at least an order of magnitude faster than competing algorithms while computing partitions with comparable solution quality. At the same time, our algorithm consistently produces balanced solutions. Moreover, for small number of blocks, our algorithms are the fastest among competing systems with comparable quality.

1 Introduction

Graphs are a universal abstraction for modelling relations between objects. Thus they are used throughout computer science and have applications with an ever growing volume and variety of the considered graphs. One frequently needed basic operation is *balanced graph partitioning* – cutting a graph into k pieces of “roughly equal” weight while cutting only few edges. Balanced graph partitioning is NP-hard and even NP-hard to approximate [5] and thus usually solved using heuristics. In particular, *multilevel graph partitioning (MGP)* is used in most high-quality general-purpose systems: During *coarsening*, build a hierarchy of graphs where each graph is a coarse approximation of the previous one. When the coarse graph is “small”, run a possibly expensive *initial partitioning* method on it. This is useful because a feasible partition at the coarsest level is a feasible partition of the original input with the same cut value. The partition is successively *uncoarsened* to each finer level and *locally improved*. This is often both faster and higher quality than applying comparable improvement algorithms only on the finest level since MGPs have a more global view on the coarse levels and can move entire groups of nodes in constant time.

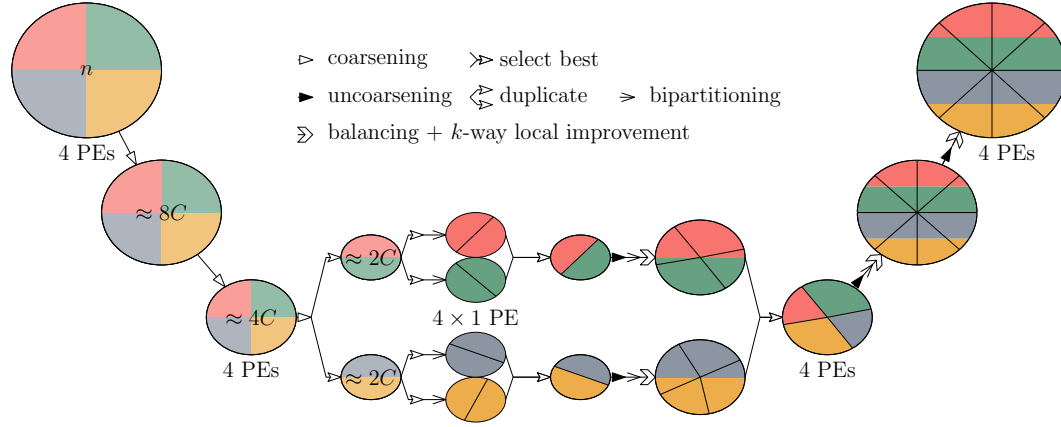

A prominent application (out of many) is distributing workload across parallel machines with little communication. With growing numbers of processors in parallel machines, we are interested in large values of k – in the order of millions. However, existing research has mostly focused on small values, typically $2 \leq k \leq 256$. Unsurprisingly, these systems perform poorly for large k . If *direct k -way partitioning* is used, the coarsest graph still has to be large when initial partitioning is called. *Recursive bipartitioning* performs $\log(k)$ cycles of (un)coarsening and is either restricted to very small imbalances or unlikely to return a feasible solution. Further, both exhibit parallelization bottlenecks on coarse levels.

We mitigate these problems by introducing *deep MGP*, an approach that continues the multilevel scheme deep into initial partitioning and integrates aspects of direct k -way and recursive bipartitioning. Deep MGP can be instantiated with concrete (parallel) building blocks for (un)coarsening, k -way local improvement, and bipartitioning of small graphs. We also include *balancing* as an explicit component. Figure 1 summarizes the approach. Deep MGP performs only one cycle of (un)coarsening. Bipartitioning is done during uncoarsening so that it is always applied to graphs with about C nodes (input parameter) until the desired number of k blocks is reached. To exploit all the available parallelism, the invariant is maintained that parallel tasks performed by x processing elements (*PEs*) work on graphs with at least xC nodes. Maintaining this invariant during coarsening allows multiple diversified attempts with little overhead invested.

Under certain simplifying assumptions, deep MGP for k -partitioning an n -node graph with bounded degree can be done in time $\mathcal{O}((n/p) \max(1, \log(kC/n)) + \log^2 n)$, i.e., with linear work and polylogarithmic span unless k is very large; see Section 4.

After introducing notation and basic concepts in Section 2 and discussing related work in Section 3, Section 4 introduces deep MGP as a generic method. In Section 5 we describe the simple and fast **KaMinPar** partitioner which uses deep MGP to achieve scalability to both large k and a considerable number of parallel cores while guaranteeing balanced solutions.

In Section 6 we report on extensive experiments which indicate that **KaMinPar** has a very favorable quality-performance tradeoff and very good scaling behavior. For traditional values of k , it is faster than previous algorithms that can achieve comparable or better quality. For large k , previous algorithms mostly find infeasible solutions and exhibit excessive running times, whereas **KaMinPar** consistently finds feasible solutions with comparable quality and is an order of magnitude faster. Section 7 summarizes the results and outlines possible future directions.

■ **Figure 1** Partitioning a graph with n nodes into 8 blocks using 4 PEs. Duplicate while coarsening to maintain load $\geq C$ on each PE. Successively bipartition during uncoarsening. Colors indicate work performed by each PE.

2 Preliminaries

Notation and Definitions. Let $G = (V, E, c, \omega)$ be an undirected graph with node weights $c : V \rightarrow \mathbb{N}_{>0}$, edge weights $\omega : E \rightarrow \mathbb{N}_{>0}$, $n := |V|$, and $m := |E|$. We extend c and ω to sets, i.e., $c(V') := \sum_{v \in V'} c(v)$ and $\omega(E') := \sum_{e \in E'} \omega(e)$. $N(v) := \{u \mid \{u, v\} \in E\}$ denotes the neighbors of v and $E(v) := \{e \mid v \in e\}$ denotes the edges incident to v . For some $V' \subseteq V$, $G[V']$ denotes the subgraph of G induced by V' . We are looking for *blocks* of nodes $\Pi := \{V_1, \dots, V_k\}$ that partition V , i.e., $V_1 \cup \dots \cup V_k = V$ and $V_i \cap V_j = \emptyset$ for $i \neq j$. The *balance constraint* demands that $\forall i \in \{1..k\} : c(V_i) \leq L_{\max, k} := \max\{(1 + \varepsilon) \frac{c(V)}{k}, \frac{c(V)}{k} + \max_v c(v)\}$ for some imbalance parameter ε .¹ The objective is to minimize $\text{cut}(\Pi) := \sum_{i < j} \omega(E_{ij})$ (weight of all cut edges), where $E_{ij} := \{\{u, v\} \in E \mid u \in V_i, v \in V_j\}$. We call a node $v \in V_i$ that has a neighbor $w \in V_j$, $i \neq j$ a *boundary node*. A *clustering* $\mathcal{C} := \{C_1, \dots, C_l\}$ is also a partition of V , where the number of blocks l is not given in advance (there is also no balance constraint).

Multilevel Graph Partitioning. Many high-quality graph partitioners employ the multilevel paradigm, which consists of three phases: During the *coarsening phase*, the algorithms build a hierarchy of successively smaller graphs where each graph is a coarse approximation of the previous one. Coarse graphs are built by either computing node clusters or matchings and afterwards *contracting* them. A clustering $\mathcal{C} = \{C_1, \dots, C_l\}$ is contracted by collapsing each cluster C_i into a single node c_i with weight $c(c_i) = \sum_{v \in C_i} c(v)$. There is an edge $e = (c_i, c_j)$ in the contracted graph with weight $\omega(e) = \sum_{(u, v) \in E_{ij}} \omega(u, v)$ where E_{ij} are the edges that connect cluster C_i and C_j in the original graph, if $|E_{ij}| > 0$. Once the number of nodes of a coarse graph falls below a certain threshold or the coarsening algorithm converges, *initial partitioning* computes a partition of the coarsest graph. Finally, *refinement* subsequently undoes the contractions performed during coarsening. In each uncontraction, the partition is first projected to the finer graph and then improved using *local improvement* algorithms.

¹ Traditionally, $L_k := (1 + \varepsilon) \lceil \frac{c(V)}{k} \rceil$ is used as balance constraint. However, finding a balanced partition with L_k is NP-complete, which, as we will see in Section 4, is not case for $L_{\max, k}$.

Generally, there are two ways to partition a graph into k blocks using the multilevel paradigm, namely *direct k -way* partitioning and *recursive bipartitioning*. The former coarsens the graph until $\Omega(k)$ nodes are left – usually kC nodes where C is an input parameter – and then computes a k -way partition of the coarsest graph. The latter first computes a bipartition $\Pi = \{V_1, V_2\}$ and then recurses on the induced subgraphs $G[V_1]$ and $G[V_2]$ by partitioning V_1 into $\lceil \frac{k}{2} \rceil$ and V_2 into $\lfloor \frac{k}{2} \rfloor$ blocks. Note that many multilevel graph partitioners based on the direct k -way partitioning scheme use recursive bipartitioning to compute an initial partition of the coarsest graph [25, 37, 28, 3, 19].

Size-Constrained Label Propagation. Based on the *label propagation clustering* algorithm by Raghavan et al. [36], Meyerhenke et al. [34] introduced the *size-constrained label propagation* algorithm as a coarsening and refinement algorithm. The algorithm is parameterized by a maximum cluster size U . In the coarsening resp. refinement phase, each node is initially assigned to its own cluster resp. to its corresponding block of the partition. The algorithm then works in rounds. In each round, the nodes are visited in some order and a node u is moved to the cluster resp. block K that contains the most neighbors of u without violating the size constraint, i.e., $c(K) + c(u) \leq U$. The algorithm terminates once no more nodes were moved during a round or a maximum number of rounds has been exceeded.

Maintaining the Balance Constraint. Finding a balanced partition of a weighted graph with $L_k := (1 + \varepsilon) \lceil \frac{c(V)}{k} \rceil$ as balance constraint is NP-complete as it can be reduced to the problem of scheduling jobs on identical parallel machines [17]. Therefore, many partitioners incorporate techniques that prevent the formation of heavy nodes during the coarsening process by penalizing the contraction of nodes with large weights [9] or enforcing a strict upper bound for node weights [21]. This makes it easier for initial partitioning to find a feasible initial solution. However, as we will see in Section 4, if we replace L_k with $L_{\max, k}$ the problem of finding a balanced partition becomes solvable in polynomial time. In the recursive bipartitioning setting, using the input imbalance parameter ε for each bipartition can produce blocks in the final k -way partition that would violate the balance constraint. Therefore, KaHyPar [20, 38] ensures that a k -way partition obtained via recursive bipartitioning is balanced by adapting the imbalance ratio for each bipartition individually. Let $G[V']$ be the subgraph of the current bipartition that should be partitioned recursively into $k' \leq k$ blocks. Then, $\varepsilon' := \left((1 + \varepsilon) \frac{c(V)}{k} \cdot \frac{k'}{c(V')} \right)^{\frac{1}{\lceil \log_2(k') \rceil}} - 1$ is the imbalance ratio used for the bipartition of $G[V']$. If each bipartition is ε' -balanced, then the final k -way partition is ε -balanced.

3 Related Work

There has been a huge amount of research on graph partitioning so that we refer the reader to overview papers [39, 7, 43, 8, 40] for most of the general material. Here, we give a brief overview of techniques used in parallel multilevel graph partitioners and issues closely related to our main contributions.

Most modern high-quality graph partitioners are based on the multilevel paradigm. Well-known software packages based on this approach include KaHiP [37] and Metis [24] (sequential graph partitioners), Mt-KaHiP [4] and Mt-Metis [28, 30] (shared-memory graph partitioners), Jostle [43], PT-Scotch [11], ParHiP [35] and ParMetis [23] (distributed graph partitioners).

The matching [11, 13, 28, 23, 43] and clustering algorithms [4, 10, 19] used by different sequential partitioners in the coarsening phase are well-suited for parallelization, sometimes with only minor quality losses [10, 33]. The coarsening phase proceeds until a fixed number of nodes remains, usually kC , where C is a tuning parameter.

In the initial partitioning phase, parallel partitioners either call sequential multilevel algorithms with different random seeds [4, 11, 13, 22] or use parallel recursive bipartitioning [19, 28, 23, 30]. In the former case, the graph is copied to each PE and the best partition obtained from all independent runs is projected back to the coarsest graph. In the latter case, parallelism is achieved by either splitting the thread pool into two evenly-sized groups and assigning each to one of the two recursive calls [23, 28] or dynamically assign the threads to the recursive calls with a task scheduler [19]. To obtain an initial bipartition of the coarsest graph, often portfolio approaches composed of different bipartitioning algorithms are used [37, 38, 19, 9].

Most parallel partitioners use the label propagation heuristic to improve the solution quality during the refinement phase [4, 28, 19, 35, 43, 13]. More advanced techniques are based on parallel variants of the FM local search [15] that are widely used in sequential partitioners. PT-Scotch [11], KaPPa [22] and Jostle [43] use sequential 2-way FM refinement on two adjacent blocks of the partition. Mt-KaHiP [4] and Mt-KaHyPar [19] implement a parallel k -way FM algorithm based on the *localized multi-try* FM of the sequential graph partitioner KaHiP [37]. Mt-Metis [30] uses greedy refinement (FM with only positive gain moves), and hill-scanning, a simplification of localized FM where small groups of vertices, whose individual gains are negative, are moved if their combined gain is positive.

In the parallel setting, nodes can change their block concurrently which requires synchronization to ensure that the balance constraint is not violated [28]. Existing systems either explicitly communicate their local changes and reject moves that would violate the balance constraint [28, 23, 13] or use atomic *compare-and-swap* instructions to maintain block weights [19, 4].

Limitations of Existing Systems for Large k . The coarsening phase of MGP usually stops when kC nodes are left. For large k , this breaks the assumption that the coarsest graph is small. Thus, really expensive initial partitioners are infeasible at this level. Many MGPs therefore use multilevel recursive bipartitioning for the coarsest graph [25, 37, 28, 3, 19]. This results in a sequential running time of $\mathcal{O}(T \log k)$ where T is the running time of the bipartitioning algorithm. When this is used within a parallel algorithm, initial partitioning can become a major bottleneck [4].

Furthermore, a feasible solution for the k -way graph partitioning problem must satisfy the balance constraint that usually depends on the average block weight $\frac{c(V)}{k}$. Thus, increasing the number of blocks leads to a tighter balance constraint and drastically reduces the space of feasible solutions. Therefore, a partitioner handling larger values of k has to employ techniques to ensure that the balance constraint is not violated.

4 Generic Deep MGP

In this section, we present our first major contribution – a new partitioning scheme that we call *Deep Multilevel Graph Partitioning*. Deep MGP continues coarsening deep into the initial partitioning phase. Roughly speaking, it starts by coarsening the input graph until $2C$ nodes are left – for some input parameter C . Then, the coarsest graph is bipartitioned into two blocks. During uncoarsening, it maintains the key invariant that the partition of a coarse graph with n' nodes has $k' = \min\{k, \text{ceil}_2(\frac{n'}{C})\}$ blocks, where $\text{ceil}_2(x)$ is x rounded up to the next power of two. This value is chosen such that each invocation of flat bipartitioning works on a graph with roughly $2C$ nodes. Thus, the graph is divided into $\min\{k, \text{ceil}_2(\frac{n}{C})\}$ blocks after unrolling the graph hierarchy. If $k > \text{ceil}_2(\frac{n}{C})$, blocks are further subdivided until k blocks are obtained.

Algorithm 1 partition.

Input: $G = (V, E)$, $k, \varepsilon > 0$, const. C
Output: k' -way partition Π of G

```

1 if  $|V(G)| > 2C$  and coarsening has not
   converged then // recursion
2    $G_c := \text{coarsen}(G)$ 
3    $\Pi_c := \text{partition}(G_c, k, \varepsilon, C)$ 
4    $\Pi := \text{project}(G, \Pi_c)$ 
5 else // base case
6    $\Pi := \{V\}$ 
7  $k' := \begin{cases} k, & |V| = n \\ \text{ceil}_2(|V|/C), & \text{else} \end{cases}$ 
8  $k' := \max\{\min\{k, k'\}, 2\}$ 
9 while  $|\Pi| < k'$  do // obtain  $k'$  blocks
10   $\Pi := \text{bipartitionBlocks}(G, \Pi, k)$ 
11  $\Pi := \text{refine}(G, \text{balance}(G, \Pi))$ 
12 return  $\Pi$ 

```

Algorithm 2 bipartitionBlocks.

Input: G , k' -way partition Π , k , const. R
Output: $2k'$ -way partition Π'

```

1  $\Pi' := \emptyset$ 
2 foreach  $V_i \in \Pi$  do
3    $\varepsilon' := \left( (1 + \varepsilon)^{\frac{c(V)}{|\Pi|c(V_i)}} \right)^{1/\log_2(k/|\Pi|)} - 1$ 
4    $G_i := G[V_i]$ 
5   // compute  $R$  bipartitions of  $V_i$ 
6    $\Pi_1, \dots, \Pi_R := \text{bipartition}(G_i, \varepsilon', R)$ 
7   // select lowest (feasible) edge cut
8    $\Pi' := \Pi' \cup \text{lowest}(G_i, \Pi_1, \dots, \Pi_R)$ 

```

This approach combines the merits of direct k -way partitioning and recursive bipartitioning: similar to direct k -way partitioning, deep MGP coarsens and uncoarsens the graph only once, and enables the use of k -way local improvement algorithms throughout the graph hierarchy. Moreover, it enforces that (possibly expensive) bipartitioning algorithms are only applied to small graphs. Thereby, it eliminates the initial partitioning bottleneck for large values of k or parallel graph partitioning.

In the remainder of this section, we give a detailed description of deep MGP. We simplify this description by restricting k to powers of two, but lift this restriction in a subsequent paragraph. Finally, we describe how to parallelize it and analyze its running time.

Deep Multilevel Graph Partitioning. Deep MGP starts by coarsening the input graph $G_1 = (V_1, E_1)$, building a hierarchy of successively coarse representations G_1, \dots, G_ℓ of G_1 . This is achieved by clustering each graph G_i and contracting all clusters to build G_{i+1} . Coarsening stops once the coarsest graph G_ℓ has at most $2C$ nodes, or the process converged. In Algorithm 1, this process is implemented in Lines 2–3.

From here, we start a sequence of the following operations: use recursive initial bipartition to subdivide the current graph into more blocks, possibly rebalance the partition and improve it using a k -way local improvement algorithm, project the partition onto the previous graph $G_{\ell-1}$ and repeat the process on that graph. During these operations, we maintain the following key invariants:

(P) A coarse graph G_i is partitioned into $k_i := \text{ceil}_2(|V_i|/C)$ blocks (bounded by 2 and k).

(B) A k_i -way partition of G_i fulfills the balance constraint.

An idealized coarsening algorithm produces a graph hierarchy where the number of nodes is halved between two levels and the coarsest graph has $2C$ nodes. In this case, it is sufficient to bipartition the coarsest graph G_ℓ once to fulfill invariant (P). To restore the invariant after uncoarsening (doubling the number of nodes in the current graph), each block of the current partition has to be bipartitioned once.

In the more general case, where coarsening can shrink the number of nodes of a graph by a larger factor than 2, we use recursive initial bipartitioning to maintain (P). More precisely, whenever the partition Π_i of graph G_i violates invariant (P), we recursively bipartition each

block of Π_i until we have k_i blocks in total. In Algorithm 1, this process is implemented in Lines 7–10. Initial bipartitioning is implemented in Algorithm 2.

Uncoarsening and initial bipartitioning can cause violations of invariant (B) (see below). If this is the case, we run a balancing algorithm afterwards. The resulting partition – which satisfies invariants (P) and (B) – is then improved using a k -way local improvement algorithm (Algorithm 1, Line 11).

If $k > \text{ceil}_2(|V_1|/C)$, the partition computed by the process described above has less than k blocks. In this case, we perform an additional round of recursive initial bipartitioning to obtain k blocks, and run balancing and k -way local improvement once more on the final partition.

Parallelization. We parallelize the partitioning method described above using parallel coarsening, local improvement and balancing algorithms. On very coarse levels, we maintain the invariant that parallel tasks performed by p PEs work on graphs with at least pC nodes. This is achieved by running initial partitioning on more and more copies of the coarsened graph, as illustrated by Figure 1. We diversify this search by using randomized coarsening, initial bipartitioning and local improvement algorithms. More precisely, we follow the algorithm described above until the coarsest graph G_C has pC nodes left. To uphold the invariant that tasks performed by p PEs work on graphs with at least pC nodes, we obtain two copies G_C^r and G_C^ℓ of G_C , and split PEs into two groups (conceptually) with $p' = \frac{p}{2}$ PEs each. If $p' > 1$, we continue by coarsening G_C^r with PEs of the first group and G_C^ℓ with PEs of the second group, until each graph has $p'C$ nodes left. We proceed in this fashion recursively, until we have obtained p graphs with $2C$ nodes each after $\log_2(p)$ recursion levels.

Each of these graphs is then bipartitioned using a single PE. Let G_C^r and G_C^ℓ with respective bipartitions Π_C^r and Π_C^ℓ be two such graphs that are copies of G_C on the previous recursion level. We use the better bipartition of Π_C^r and Π_C^ℓ (i.e., if only one of these partitions is feasible, we use that one, otherwise the one with the lower edge cut) as partition Π_C of G_C . We proceed on G_C as before, i.e., bipartition each block of Π_C if applicable, and apply the balancing and local improvement algorithm. This process is repeated for all $\log_2(p)$ recursion levels.

Handling General k . The simplified description of deep MGP only considers the case where k is a power of two. For the general case, we associate each block B with a final block count f_B – the number of blocks B is subdivided into in the final partition. Initially, $f_V = k$. To bipartition B into two blocks B_0 and B_1 , we set $f_{B_0} = \lfloor \frac{f_B}{2} \rfloor$ and $f_{B_1} = \lceil \frac{f_B}{2} \rceil$, and divide the weight of B in a f_{B_0} to f_{B_1} ratio between B_0 and B_1 . Thus, once we have computed a $k' := \text{floor}_2(k)$ -way partition, there are $k - k'$ heavy blocks with $f_B = 2$ and $2k' - k$ light blocks with $f_B = 1$. During the next and final initial partitioning step, we obtain a k -way partition by only bipartitioning heavy blocks.

Maintaining the Balance Constraint. Since MGP implementations usually employ coarsening algorithms that do not guarantee strictly uniform node weights, maintaining the balance constrain used in other partitioning systems, $L_k := (1 + \varepsilon) \lceil \frac{c(V)}{k} \rceil$, becomes an NP-complete problem [17] on coarse levels. To mitigate this problem, we use $L_{\max,k} := \max\{(1 + \varepsilon) \frac{c(V)}{k}, \frac{c(V)}{k} + \max_v c(v)\}$ as balance constraint instead. This ensures that a feasible partition always exists, and that it can be found with simple greedy algorithms. Both claims are based on the fact that the average block weight of a partition is $\frac{c(V)}{k}$ and thus, there always exists a block V_i with $c(V_i) \leq \frac{c(V)}{k}$. In the multilevel setting, projecting a partition

to a finer graph can violate the balance constraint due to the change in $\max_v c(v)$. However, the overload per block is bounded by $\max_v c(v)$, which implies that a balancing algorithm only needs to move a small number of nodes out of a block to restore the balance constraint.

Running Time. Next, we analyze the running time of parallel (deep) MGP using highly idealized assumption. We do not claim that the results hold for our implementation but use this simplified analysis to give a quantitative expression to the qualitative reasoning that deep MGP is scalable if its components are scalable. The analysis also allows us to compare the asymptotic performance of different approaches to parallel MGP without having to discuss which particular implementations of the basic operations can or cannot avoid certain difficult cases. We assume: (1) k is a power of two and we have unit node/edge weights, (2) $n > Cp \log p$, (3) coarsening a graph halves the number of nodes, (4) (un)coarsening or balancing a graph with n nodes takes time $\mathcal{O}(n/p + \log n)$, (5) sequential bipartitioning takes linear time. We effectively ignore edges here. This implies the assumption that nodes have bounded degree and that the degrees remain bounded when the graph is shrunk.

► **Theorem 1.** *Under the assumptions made above, deep MGP requires time*

$$\mathcal{O}\left(\frac{n}{p} \max\left(1, \log \frac{kC}{n}\right) + \log^2 n\right).$$

Proof. By (3), MGP goes through $\log(n/C)$ levels so that the overhead terms “ $\log n$ ” in (4) sum to $\mathcal{O}(\log^2 n)$ – we ignore these overhead from now on. While $> pC$ nodes are left, the graph shrinks geometrically with the levels so that the total remaining cost for (un)coarsening and balancing from (4) is linear – $\mathcal{O}(n/p)$.

When $\leq pC$ nodes are left, replication and selection of the best partition keeps the number of nodes at each level at $\Theta(pC)$. There are $\log p$ such levels incurring total cost $\mathcal{O}(C \log p)$ for (un)coarsening and balancing. By (2) this cost is bounded by $\mathcal{O}(n/p)$.

For the cost of bipartitioning we consider three cases:

Case (a) $k \leq p$: Each PE performs $\log k$ bipartitions with total cost $C \log k$. By (2) this is bounded by $\mathcal{O}(n/p)$.

Case (b) $p < k \leq n/C$: Each PE performs $\log p + k/p$ bipartitions with total cost $C(k/p + \log p)$. Once more, by (2) this is bounded by $\mathcal{O}(n/p)$.

Case (c) $k > n/C$: In this case, deep MGP first performs an n/C -way partitioning into blocks of size about C . By the above analysis, this takes time $\mathcal{O}(n/p + \log^2 n)$. Then the remaining blocks are partitioned into $k/(n/C) = kC/n$ blocks using recursive bipartitioning in time $\mathcal{O}(C \log(kC/n))$. Summing over all blocks assigned to a PE we get additional cost $n \log(kC/n)/p$. ◀

5 Implementation

In this section we describe the different components in our shared-memory parallel implementation of deep MGP called KaMinPar. Recall that the components are coarsening, bipartitioning on small graphs, and uncoarsening with k -way balancing and refinement.

5.1 Coarsening by Size-Constrained Label Propagation

We use size-constrained label propagation [34] to compute a clustering for contraction, where the weight of the heaviest cluster is restricted by a fixed upper bound U . We set $U := \varepsilon \frac{c(V)}{k'}$, where $k' = \min\{k, |V|/C\}$ is the number of blocks we obtain on the finest level (before

further bipartitioning if necessary) and ε is the imbalance from the problem formulation. This choice implies that $\frac{c(V)}{k'} + \max_v c(v) \stackrel{\max_v c(v) \leq U}{\leq} (1 + \varepsilon) \lceil \frac{c(V)}{k'} \rceil = L_{k'}$ on every level, and hence $L_{\max, k}$ simplifies to the traditional balance constraint L_k on unweighted inputs. If the current number of nodes is $\leq \frac{k'}{2}C$, we adapt k' to $\frac{k'}{2}$ and U accordingly. We perform 5 rounds of label propagation, but terminate early if no nodes were moved. To further improve the running time, we only move a node, if one of its neighbors changed its cluster in the previous round.

Parallelization. We parallelize the algorithm by iterating over all nodes in parallel. When moving a node to another cluster, we use atomic fetch-and-add operations to update the respective cluster weights. Note that we do not strictly enforce the weight limit. The limit could be violated if multiple PEs move a node to the same cluster at the same time. However, this is unproblematic in practice since the weight limit violations are usually small.

Iteration Order and Cache Locality. Solution quality of label propagation is improved when nodes are visited in increasing degree order [34, 4]. Since this is not cache efficient and lacks diversification by randomization, we sort the nodes of the graph into exponentially spaced degree buckets, i.e., bucket i contains all nodes with degree $2^i \leq d < 2^{i+1}$, and rearrange the graph such that nodes are sorted by their bucket number. For node traversal, we split buckets into small chunks and randomize node traversal on a inter-chunk and intra-chunk level. This is analogous to the randomization in Metis' matching algorithm [24].

Two-hop Clustering. We observed that size-constrained label propagation is unable to shrink some irregular graph instances sufficiently. We solve this by implementing a technique similar to the two-hop matching algorithm of Metis [31]. During label propagation, if node u cannot be moved into any neighboring cluster due to the size constraint, we store the highest rated neighboring cluster as u 's *favoured cluster*. If the graph is shrunk by less than 50% after termination, we merge singleton clusters that share the same favored cluster until the graph shrunk by 50%.

5.2 Initial Bipartitioning

We perform multilevel bipartitioning to compute an initial bipartition of a subgraph $G_{V'}$ (with $|V'| \approx 2C$). On this size, the used algorithms are sequential. For coarsening, we use label propagation and set the maximum cluster weight to the same value used in KaHiP [37]. The maximum block weight for bipartitioning is set to $L_2 := (1 + \varepsilon') \lceil \frac{c(V')}{2} \rceil$, where ε' is the adaptive imbalance as defined in Section 2. We coarsen until no further contractions are possible. For refinement, we use 2-way FM [15]. We use a pool of simple algorithms to bipartition the coarsest graph, namely random bipartitioning, breadth-first searches and greedy graph growing [24]. We repeat each algorithm several times with different random seeds and select the bipartition with the lowest edge cut. Moreover, we use the adaptive algorithm selection technique of Mt-KaHyPar [18].

5.3 Uncoarsening

After bipartitioning the blocks of a $\frac{k}{2}$ -way partition, we use a k -way balancing algorithm to restore the balance constraint (if violated). Afterwards, we run a local improvement algorithm based on size-constrained label propagation to improve it.

Balancing. In contrast to Section 4, our implementation prevents balance constraint violations by changes in $\max_v c(v)$ due to our choice of the maximum cluster weight during coarsening. However, balance violations can occur during initial bipartitioning, in particular due to our multilevel bipartitioning approach.

For each overloaded block B , we store just enough nodes of B in a priority queue P_B ordered by *relative gains*, to remove the excess weight $o(B) := c(B) - L_{\max,k}$. The *relative gain* of a node v is $d \cdot c(v)$ if $d \geq 0$ and $d/c(v)$ if $d < 0$, where d is the largest reduction in edgecut when moving v to a block that would not become overloaded. We initialize the priority queues by iterating over the nodes in G . If a node is in an overloaded block and $c(P_B) < o(B)$, we insert it. Otherwise, we only insert it if its relative gain is higher than the lowest relative gain of any element in P_B and remove its lowest element if $c(P_B) > o(B) + \max_v c(V)$ after the insertion.

Once the priority queues are initialized, we empty each overloaded block B individually by repeatedly removing the node v with the largest relative gain from P_B . If its relative gain changed since insertion, or its designated target block can no longer take v without becoming overloaded, we re-insert v (if v is still a border node). Otherwise, we move v to its target block or a random block that can take v without becoming overloaded. Subsequently, we try to insert all neighbors from its former block. To reduce the running time, we only try to insert each node once.

We parallelize the algorithm as follows. During initialization, we iterate over all nodes in parallel and maintain one thread-local priority queue for each overloaded block. Afterwards, we iterate over all blocks in parallel, merge the respective thread-local priority queues and perform node movements as described above.

Local Improvement. We use the same parallelization of size-constrained label propagation as described in Section 5.1, but strictly enforce the maximum cluster weight (set to the maximum block weight) using an atomic compare-and-swap instruction. We run at most 5 rounds of size-constrained label propagation (same value as used in Mt-KaHyPar [19]), but terminate early if no node was moved during a round.

6 Experimental Evaluation

We implemented the proposed algorithm KaMinPar in C++ and compiled it using g++-10.2 with flags `-O3 -march=native`. We use Intel’s TBB [1] as parallelization library.

Setup. We perform our experiments on two different machines. Machine A is equipped with an AMD EPYC 7702 64-Core processor clocked at 2 GHz and 1 TB main memory. This machine is only used for our scalability experiment. All other experiments are run on Machine B, which is a node of a cluster equipped with Intel Xeon Gold 6230 processors (2 sockets with 20 cores each) clocked at 2.1 GHz and 96 GB or 192 GB main memory.

We compare our algorithm with Mt-Metis 0.7.2 [30], Mt-KaHiP 1.0 [4], PuLP 0.11 [41], Metis 5.1.0 [31] and the `fsocial` preset of KaHiP 3.10 [37]. We chose this preset because it is one of the fastest configurations that computes good quality. While other presets of KaHiP achieve better partition quality, they are also much slower. We do not include ParMetis [23] and Pt-Scotch [11] in our comparison since they are slower than Mt-Metis and produce partitions with comparable solution quality [29]. Moreover, we exclude ParHiP [35] since it is outperformed by Mt-KaHiP [2]. In the following, we add a suffix to the name of each parallel partitioner to indicate the number of threads used, e.g., KaMinPar 64 for 64 threads.

Instances. We evaluate our algorithm on a benchmark set composed of 197 graphs (referred to as set A), including 129 graphs from the 10th DIMACS Implementation Challenge [6], 25 randomly generated graphs [16, 26], 25 large social networks [27, 32], and 18 graphs from various application domains [12, 44, 42]. Scalability and experiments with larger values of k are performed on a subset of set A that contains 21 graphs (referred to as set B). This benchmark set includes the 18 largest graphs (by number of nodes)² and 3 randomly chosen small graphs of set A such that a partition with 2^{20} blocks only contains a few nodes per block. Basic properties of benchmark instances are shown in Appendix A, Figure 6.

Methodology. We consider a combination of a graph and number of blocks k as an *instance*. For each instance, we usually perform several runs with different random seeds and aggregate running times and edge cuts using the arithmetic mean over all seeds. To further aggregate over multiple instances, we use the harmonic mean for relative speedups, and the geometric mean for absolute running times and edge cuts. Runs with imbalanced partitions are not excluded from aggregated running times and for instances that exceeded the time limit, we use the time limit in the aggregates. We consider an instance as infeasible, if all runs failed or computed an imbalanced partition and mark them with **X** in the plots.

To compare the solution quality of different algorithms, we use *performance profiles* [14]. Let \mathcal{A} be the set of all algorithms we want to compare, \mathcal{I} the set of instances, and $q_A(I)$ the quality of algorithm $A \in \mathcal{A}$ on instance $I \in \mathcal{I}$. For each algorithm A , we plot the fraction of instances $\frac{|\mathcal{I}_A(\tau)|}{|\mathcal{I}|}$ (y -axis) where $\mathcal{I}_A(\tau) := \{I \in \mathcal{I} \mid q_A(I) \leq \tau \cdot \min_{A' \in \mathcal{A}} q_{A'}(I)\}$ and τ is on the x -axis. Achieving higher fractions at lower τ -values is considered better. For $\tau = 1$, the y -value indicates the percentage of instances for which an algorithm performs best. Since performance profiles relate the quality of an algorithm to the best solution, the ranking induced by $\tau = 1$ does not permit full ranking of all algorithms, if more than two algorithms are included.

Running Time and Solution Quality for Small k . In Figure 2, Figure 3 and Table 1, we compare the quality and running time of KaMinPar with different sequential and parallel partitioners for $k \in \{2, 4, 8, 16, 32, 64\}$, $\varepsilon = 0.03$ and 5 repetitions per instance on set A and machine B. These are commonly used values to evaluate graph partitioning systems. We execute each parallel partitioner using 10 threads to simulate the performance on commodity machines.

KaMinPar 10 is the overall fastest algorithm on average and also an order of magnitude faster than the sequential partitioners Metis and KaHIP-fsocial on large graphs ($m \geq 10^8$), while producing partitions with comparable solution quality (see Figure 3 (left)). KaMinPar 10 (0.39 s geometric mean running time) is moderately faster than Mt-Metis 10 (0.48 s) and more than a factor of 2 resp. 3 faster than PuLP 10 (1.11 s) and Mt-KaHIP 10 (1.33 s). The differences in running time, as shown in Figure 2 (right), are more pronounced on larger instances, e.g., KaMinPar 10 (9.36 s) is more than factor of 3 resp. 5 faster than Mt-Metis 10 (30.36 s) resp. Mt-KaHIP 10 (55.76 s) on instances with more than 10^8 edges. Figure 2 (left) shows that Mt-KaHIP 10 computes the partition with lowest edge cut on a majority of the instances ($\approx 60\%$), while the partitions produced by PuLP 10 are more than a factor of 2 worse than the best achieved edge cuts on more than 55% of the instances. These results are expected, since Mt-KaHIP is the only partitioner that implements a parallel direct k -way FM algorithm and PuLP is the only non-multilevel system in our evaluation.

² excluding **er-fact1.5-scale26**, since Mt-KaHiP and Mt-Metis are unable to compute a partition on this graph even for small k , and **kmer_V2a** to avoid over-representation of k -mer graphs

■ **Table 1** Geometric mean running time and solution quality for different algorithms on benchmark set A and $k \in \{2, 4, 8, 16, 32, 64\}$. Running time only includes instances for which all algorithms produced a result. The number of included instances is shown in the last row. Solution quality is relative to KaMinPar (lower is better) and only includes instances for which the respective algorithm computed a balanced partition. Thus, solution quality cannot be compared between different competitors.

Algorithm	T	$T[m \geq 10^6]$	$T[m \geq 10^8]$	rel. cut	# infeasible
KaMinPar 10	0.39 s	0.85 s	9.36 s	1.00	0
Mt-Metis 10	0.48 s	1.49 s	30.36 s	1.00	349
Mt-KaHiP 10	1.33 s	3.84 s	55.76 s	0.94	6
PuLP 10	1.11 s	5.70 s	95.93 s	2.39	72
Metis	1.00 s	4.15 s	97.44 s	1.05	2
KaHiP-fsocial	2.93 s	11.05 s	200.67 s	1.03	8
# instances	1,150	832	196		

■ **Figure 2** Performance profile and running time plot (shows time per edge with a right-aligned rolling geometric mean over 50 instances) comparing the performance of KaMinPar with different partitioners for $k \in \{2, 4, 8, 16, 32, 64\}$ on set A.

We also ran KaMinPar, Mt-Metis and Mt-KaHiP on all 64 cores of machine A. Here, we partitioned each graph of the reduced benchmark set B into $k \in \{2, 4, 8, 16, 32, 64\}$ blocks allowing a maximum imbalance of $\varepsilon = 0.03$. In this setup, KaMinPar 64 is 5 resp. 4.4 times faster than Mt-KaHiP 64 resp. Mt-Metis 64, whereas on the same instances on 10 cores of machine B, it is 5.7 resp. 3.1 times faster. Thus, we can see that the running time of KaMinPar scales slightly worse to 64 cores than Mt-KaHiP, but slightly better than Mt-Metis for smaller values of k . In Figure 3 (right), we compare the solution quality of each algorithm on the reduced benchmark set B. We can see that the differences of the partitioners in terms of solution quality are more pronounced on this set than on set A (compare with Figure 2). However, this is due to the benchmark set, since each partitioner produced partitions with comparable quality if we compare them individually with 10 and 64 threads. Overall, we can conclude that KaMinPar offers a compelling trade-off between running time and quality compared to established shared-memory and sequential GP systems.

Running Time and Solution Quality for Large k . In Table 2, we present the results of our experiment with different parallel partitioners (each using 10 threads) for larger values of $k \in \{2^{11}, 2^{14}, 2^{17}, 2^{20}\}$, $\varepsilon = 0.03$ and 3 repetitions per instance with a time limit of one

■ **Table 2** Results of our experiment for large values of k with different parallel partitioners on set B. The last two columns show the geometric mean running time and edge cuts relative to KaMinPar of all instances that do not crash (timeout instances are additionally excluded in edge cut comparison).

Algorithm	# timeout	# crash	# imbalanced	# feasible	rel. time	rel. cut
KaMinPar 10	0	0	0	84	1.00	1.00
Mt-Metis-K 10	19	10	51	4	11.91	0.99
Mt-Metis-RB 10	0	25	55	4	5.61	1.03
Mt-KaHiP 10	31	7	11	35	38.64	1.00
PuLP 10	76	0	0	8	73.52	1.25

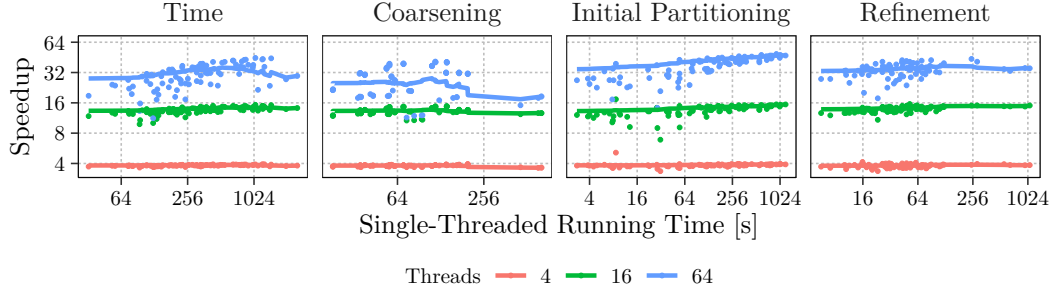

■ **Figure 3** Left: performance profile of KaMinPar, Metis and KaHiP-fsocial on benchmark set A with $k \in \{2, 4, 8, 16, 32, 64\}$ and $\varepsilon = 0.03$. Right: performance profile of KaMinPar, Mt-KaHiP and Mt-Metis on 64 cores of machine A, reduced benchmark set B with $k \in \{2, 4, 8, 16, 32, 64\}$ and $\varepsilon = 0.03$. Note that the change in relative solution quality is due to the reduced benchmark set.

hour on set B and machine B (192 Gb main memory). Note that the time limit is 10 times larger than the longest running time of KaMinPar for an instance. We additionally included the recursive bipartitioning version of Mt-Metis (referred to as Mt-Metis-RB) to evaluate the performance of recursive bipartitioning on large k . In the following, we consider a run of an algorithm for an instance as *feasible*, if the algorithm terminates in the given time limit and the produced partition satisfies the balance constraint $L_k := (1 + \varepsilon) \lceil \frac{c(V)}{k} \rceil$.

Out of the 84 evaluated instances (21 graphs times 4 values of k), Mt-Metis-RB 10, Mt-Metis-K 10, PuLP 10 and Mt-KaHiP 10 were only able to produce on 4, 4, 8 resp. 35 instances a feasible solution. Mt-Metis-RB 10 and Mt-Metis-K 10 primarily failed to produce solutions that satisfy the balance constraint (55 resp. 51 instances). Figure 4 (right) shows that Mt-Metis-K 10 generally produces larger balance violations (median resp. maximum imbalance is 1.14 resp. 15.56) than Mt-Metis-RB 10 (median 1.05 and maximum 1.15). Mt-KaHiP 10 and PuLP 10 were mostly unable to compute a partition in the given time limit (31 resp. 76 instances). KaMinPar 10 produced a feasible solution on all instances. The fastest competitor is Mt-Metis-RB 10, which is more than 5 times slower than KaMinPar 10 on average. All other partitioners are an order of magnitude slower. If we include all imbalanced partitions and individually compare the partitioners on those instances with respect to solution quality, we can see that all perform comparable (except for PuLP 10). However, a fair comparison is difficult due to the large number of infeasible solutions. We can conclude that KaMinPar is currently the only partitioner considered in our evaluation that can reliably compute feasible partitions for larger values of k in a reasonable amount of time.

■ **Figure 4** Left: imbalance of infeasible partitions computed by Mt-KaHiP 10, Mt-Metis 10, PuLP 10, Metis and KaHiP-fsocial on benchmark set A with $k \in \{2, 4, 8, 16, 32, 64\}$ and $\varepsilon = 0.03$. Right: imbalance of infeasible partitions computed by Mt-Metis-K 10, Mt-Metis-RB 10 and Mt-KaHiP 10 on benchmark set B with $k \in \{2^{11}, 2^{14}, 2^{17}, 2^{20}\}$ and $\varepsilon = 0.03$.

■ **Figure 5** Self-relative speedups for the different components of KaMinPar on set B.

Scalability of KaMinPar. In Figure 5, we show the scalability of KaMinPar for $k \in \{2^{11}, 2^{14}, 2^{17}, 2^{20}\}$, $\varepsilon = 0.03$ and three repetitions per instance on set B using $p \in \{1, 4, 16, 64\}$ cores of machine A. In the plot, we represent the speedup of each instance as a point and the cumulative harmonic mean speedup over all instances with a single-threaded running time $\geq x$ seconds with a line. Note that initial partitioning includes all calls to our initial bipartitioning algorithms on graphs with more than $2pC$ nodes.

The overall harmonic mean speedup of KaMinPar is 3.8 for $p = 4$, 13.3 for $p = 16$ and 27.9 for $p = 64$. The harmonic mean speedups of coarsening, initial partitioning and refinement are 25.0, 34.5 and 33.1 for $p = 64$. We note that our refinement component achieves slightly better speedups than our coarsening component, although both are based on the size-constrained label propagation algorithm. This effect is most pronounced on instances with larger node degrees. During coarsening, each thread aggregates ratings to neighboring clusters in a local hash map (with only 2^{15} entries) for nodes with small degree and in a local vector of size n for high degree nodes ($\geq 2^{15}/3$). During refinement, each thread uses a local vector of size k for this. Instances with larger node degrees more often uses the local vector of size n to aggregate ratings during coarsening, which can limit scalability due to cache effects. Note that KaMinPar performs no expensive arithmetic operations. Hence, perfect speedups are not possible due to limited memory bandwidth.

7 Conclusion and Future Work

We presented a new graph partitioning scheme that successfully combines the merits of classical direct k -way partitioning and recursive bipartitioning. Similar to direct k -way partitioning, deep MGP coarsens and uncoarsens the graph only once, and allows the use of k -way local improvement algorithms. Yet, it does not suffer scalability problems if k is large and has a better asymptotic running time than recursive bipartitioning. Our experimental evaluation shows that our shared-memory parallel implementation of deep MGP runs efficiently on up to 64 PEs, while achieving comparable results to established graph partitioners if k is small. Furthermore, our evaluation showed that KaMinPar is an order of magnitude faster than other graph partitioners based on direct k -way partitioning if k is large, while consistently producing balanced solutions. In the future, we would like to explore graph partitioning for very large values of k , e.g., $k \in \Theta(n)$.

Abstract

Unsplittable flow on a path (UFP) is an important and well-studied problem. We are given a path with capacities on its edges, and a set of tasks where for each task we are given a demand, a subpath, and a weight. The goal is to select the set of tasks of maximum total weight whose total demands do not exceed the capacity on any edge. UFP admits an $(1 + \epsilon)$ -approximation with a running time of $n^{O_\epsilon(\text{poly}(\log n))}$, i.e., a QPTAS [Bansal et al., STOC 2006; Batra et al., SODA 2015] and it is considered an important open problem to construct a PTAS. To this end, in a series of papers polynomial time approximation algorithms have been developed, which culminated in a $(5/3 + \epsilon)$ -approximation [Grandoni et al., STOC 2018] and very recently an approximation ratio of $(1 + \frac{1}{e+1} + \epsilon) < 1.269$ [Grandoni et al., 2020]. In this paper, we address the search for a PTAS from a different angle: we present a faster $(1 + \epsilon)$ -approximation with a running time of only $n^{O_\epsilon(\log \log n)}$. We first give such a result in the relaxed setting of resource augmentation and then transform it to an algorithm *without* resource augmentation. For this, we present a framework which transforms algorithms for (a slight generalization of) UFP under resource augmentation in a black-box manner into algorithms for UFP *without* resource augmentation, with only negligible loss.

1 Introduction

The unsplittable flow on a path problem (UFP) is a natural packing problem which has received a lot of attention, e.g., [3, 17, 15, 6, 7, 4, 8, 9]. We are given a path $G = (V, E)$ with a capacity $u(e) \in \mathbb{N}_0$ for each edge $e \in E$ and a set of tasks T . For each task $i \in T$ we are given a sub-path $P(i)$ of E , a demand $d(i) \in \mathbb{N}_0$, and a weight (or profit) $w(i) \in \mathbb{N}_0$. For any set of tasks $T' \subseteq T$, we define $d(T') := \sum_{i \in T'} d(i)$ and $w(T') := \sum_{i \in T'} w(i)$ and for each $e \in E$ we define $T_e \subseteq T$ to be the set of all tasks $i \in T$ using e , i.e., such that $e \in P(i)$. Similarly we sometimes say that i is contained, contains, or intersects a subpath P if $P(i)$ does. The goal is to select a set of tasks $T' \subseteq T$ of maximum total weight $w(T')$ such that T' obeys the edge capacities, i.e., $d(T' \cap T_e) \leq u(e)$ for each edge $e \in E$. We denote by n the size of the input, and hence in particular $|T| \leq n$ and $|E| \leq n$.

UFP is a generalization of KNAPSACK (i.e., if $|E| = 1$) and it is motivated by various applications. For example, the path G can represent a network with a chain of communication links in which we seek to select the most profitable set of possible transmissions that obey the given edge capacities. Also, the edges in E can correspond to discrete time slots, each task models a job that we might want to execute, and the edge capacities model the available amount of a resource shared by the jobs like energy or machines. Also, there is a connection between UFP and general caching, i.e., where pages can have different (possible non-unit) sizes and different costs for being evicted [12].

There is a $(1 + \epsilon)$ -approximation algorithm known for UFP with running time of $n^{O_\epsilon(\log n)}$ [7], i.e., a QPTAS (improving an earlier QPTAS in [5]), and it has been a long-standing open problem to construct a PTAS. Towards this goal, polynomial time approximation algorithms for UFP have been developed and the best known approximation ratio has been gradually improved from $O(\log n)$ [6] to $7 + \epsilon$ [8], $2 + \epsilon$ [3], and $5/3 + \epsilon$ [17], while the currently best known ratio is $1 + \frac{1}{1+\epsilon} + \epsilon < 1.269$ [15].

1.1 Our Contribution

In this paper, we contribute to the search for a PTAS for UFP from a different angle: we improve the *running time* of the known QPTAS for UFP [7] and present a $(1 + \epsilon)$ -approximation with a running time of only $n^{O_\epsilon(\log \log n)}$. Hence, our result is in the same spirit as similar improvements for the Maximum Independent Set of Rectangles problem in [13] and precedence constrained scheduling for unit-size jobs in [18].

We first present our result for the case of resource augmentation, i.e., when we allow ourselves to increase the edge capacities by a factor of $1 + \delta$ for some constant $\delta > 0$ while the compared optimal solution OPT does not have this privilege. Let u_{\min} and u_{\max} denote the minimum and maximum edge capacities, respectively. In that setting, it is easy to show that we can assume that the edge capacities are in a constant range, namely $u_{\max} = O_{\epsilon, \delta}(u_{\min})$. We classify each task $i \in T$ to be *small* or *large*, depending on whether i uses a relatively small or a relatively large fraction of the available capacity on the edges of $P(i)$. Since we have a constant range of edge capacities, one can show easily that each edge e can be used by only a constant number of large tasks in OPT .

The high level strategy in the known QPTASs [5, 7] is to take the middle edge e^* , guess the large tasks using e^* , split the small tasks using e^* into $O(\log n)$ or $(\log n)^{O(1)}$ groups, and guess an *under-estimating capacity profile* for each group with $O_\epsilon(1)$ uniform steps. In more detail, in the latter step one guesses for each edge $e \in E$ approximately how much capacity from $u(e)$ is used in OPT by the tasks crossing e^* in each group. For each group one argues that one loses only a factor of $1 + \epsilon$ in the profit by underestimating the true capacity. Then one recurses on the subpaths of E on the left of e^* and on the right of e^* which yields a recursion depth of $O(\log n)$.

Instead, when we consider the small tasks using e^* , we use only *one over-estimating* profile with *non-uniform* step size for *all* tasks together with only $O_{\epsilon, \delta}(\log \log n)$ steps. Each step is a power of $1 + \delta$ in $[\frac{\delta}{\log n} u_{\min}, u_{\max}]$. This yields $O_{\epsilon, \delta}(\log \log n)$ steps since the profile is monotone on the left and on the right of e^* and $u_{\max} = O_{\epsilon, \delta}(u_{\min})$. Also, our justification for the error is very different. On some edges e the error is at most $\frac{\delta}{\log n} u_{\min}$ which accumulates to at most $O(\delta)u_{\min} \leq O(\delta)u(e)$ during the recursion. On the other edges e the error is at most a δ -fraction of the total demand used on e by tasks crossing e^* ; over the recursion this can add up to at most $\delta u(e)$ since in OPT edge e is used by tasks with a total demand of at most $u(e)$.

When we recurse we employ another novelty: we consider the tasks crossing at least one of *two* specially defined edges e_1^*, e_2^* , and recurse in *three* subpaths induced by them: e_1^* is like before the middle edge of current subpath. The other edge e_2^* is chosen such that half of previously guessed steps are on the left and the other half on the right (like in the QPTAS in [7]). This ensures that *at the same time* the recursion depth is $O(\log n)$ and each recursive call is described by a subpath of E and only $O_{\epsilon, \delta}(\log \log n)$ steps from previously guessed profiles. Thus, we can embed this recursion into a dynamic program (DP) with DP-table of size $n^{O_{\epsilon, \delta}(\log \log n)}$.

Then, we present a new framework using which one can transform algorithms for UFP under resource augmentation (like ours) in a black-box manner into algorithms for UFP *without* resource augmentation, while losing only a factor of $1 + \epsilon$ in the approximation ratio. To this end, we define a slight generalization of UFP that we denote by *Bonus-UFP*. The key difference to UFP is that in addition to profit from normal tasks, one receives a bonus for subpaths which do not completely contain the path of any selected task. Also, its instances are required to have a simpler structure than general UFP instances, yielding similar properties as obtained via resource augmentation. For example, on each edge one is allowed to select only a constant number of large tasks (independently of the actual edge capacities!), so they can be easily guessed in time $n^{O_{\epsilon}(1)}$ for each edge. Also, the capacity allocated for small tasks in *OPT* is intuitively in a constant range (similarly as above) and the notion of resource augmentation is defined such that this capacity for the small tasks is increased by a factor $1 + \delta$.

Our framework directly transforms any algorithm for Bonus-UFP under resource augmentation to an algorithm for UFP *without* resource augmentation, while increasing the approximation ratio only by a factor $1 + \epsilon$. The transformation uses the slack-lemma [16] which was employed in previous algorithms for UFP [16, 15, 17] in order to gain free capacity on the edges within quite complicated dynamic programs. With our framework one does not need to apply the slack-lemma and construct this technical machinery “by hand” anymore, but it is sufficient to design an algorithm for Bonus-UFP under resource augmentation and then the framework does the transformation automatically.

► **Theorem 1** (informal). *Given an α -approximation algorithm for Bonus-UFP under resource augmentation with a running time of $T(n)$, we can construct a $(1 + \epsilon)\alpha$ -approximation algorithm for UFP (without resource augmentation) with a running time of $T(n)n^{O_{\epsilon}(1)}$.*

We hope that this facilitates future research on UFP for (eventually) finding a PTAS. In particular, we believe that if one constructs an algorithms for UFP under resource augmentation then it is very likely that it can be adjusted to an algorithm for Bonus-UFP under resource augmentation. For example, we demonstrate that this can be easily done with our algorithm for UFP under resource augmentation above, which yields the following theorem.

► **Theorem 2.** *For any $\epsilon > 0$ there is a $(1 + \epsilon)$ -approximation algorithm for UFP with a running time of $n^{O_{\epsilon}(\log \log n)}$.*

1.2 Other related work

There are some special cases of UFP for which PTASs are known, for example when there are $O(1)$ edges such that each input task uses one of them [16], each input task can be selected an unbounded number of times [16], or when the profit of each task is proportional to its demand [7]. Also, there is an FPT- $(1 + \epsilon)$ -algorithm known for the unweighted case of UFP where the fixed parameter is the cardinality of the optimal solution [19].

Variations of UFP have been studied like bagUFP where the input tasks are partitioned into bags, and we are allowed to select at most one task from each bag [14]. Also, since the natural LP-formulation of UFP suffers from an integrality gap of $\Omega(n)$ [9], stronger LP-formulations have been investigated [10, 2]. Furthermore, unsplittable flow has been studied on trees, where the best known results are a $O(\log^2 n)$ -approximation [10]. This was generalized to a $O(k \cdot \log n)$ -approximation [1] for submodular objectives where k denotes the pathwidth of the given tree (bounded by $O(\log n)$).

2 Faster approximation scheme for UFP with resource augmentation

We first provide a $(1+\epsilon)$ -approximation algorithm for UFP with a running time of $n^{O_{\epsilon,\delta}(\log \log n)}$ for the simplified setting of δ -resource augmentation where we permit the algorithm to compute a solution S where for each edge $e \in E$ we have that $\sum_{i \in S \cap T_e} d(i) \leq (1 + \delta)u(e)$ and we require the optimal solution OPT to respect the original capacities $u(\cdot)$, i.e., $\sum_{i \in \text{OPT} \cap T_e} d(i) \leq u(e)$ for each $e \in E$. For a UFP instance with a path $G = (V, E)$ and edge capacities $u(\cdot)$, we define $u_{\min} := \min_{e \in E} u(e)$ and $u_{\max} := \max_{e \in E} u(e)$. First, we use the resource augmentation to reduce the general case to the setting of a constant range of (polynomially bounded) edge capacities where $u_{\max} \leq u_{\min}/\delta^{(2/\epsilon)}$.

► **Lemma 3.** *Assume that for any constants $\epsilon > 0$, $\delta > 0$, there is an α -approximation algorithm under δ -resource augmentation for UFP with a running time of $T(n)$ for instances such that $u_{\min} = n/\delta$ and $u_{\max} \leq u_{\min}/\delta^{2/\epsilon}$. Then there is an $(\alpha+\epsilon)$ -approximation algorithm for UFP under 4δ -resource augmentation with a running time of $T(n)(n \log u_{\max})^{O_{\epsilon,\delta}(1)}$.*

Due to Lemma 3, in the following we assume that we are given an instance of UFP such that $n/\delta \leq u(e) \leq n/(\eta\delta)$ for each $e \in E$ and some $\epsilon, \delta > 0$, with $\eta := \delta^{2/\epsilon}$, and that we are in the setting of δ -resource augmentation. By contracting edges suitably we can assume w.l.o.g. that each edge $e \in E$ is the first or the last edge of the path $P(i)$ of some input task $i \in T$.

2.1 Recursive Algorithm

We describe our algorithm first as a recursive algorithm and then embed it into a dynamic program which will have a running time of $n^{O_{\epsilon,\delta}(\log \log n)}$.

Let $e^* \in E$ be an edge in the middle of E , i.e., such that at most $\lfloor |E|/2 \rfloor$ edges are on the left of e^* and at most $\lfloor |E|/2 \rfloor$ edges are on the right of e^* . We would like to guess the tasks in $\text{OPT} \cap T_{e^*}$. Since there are too many possibilities for this, we first guess approximately how much capacity the tasks in $\text{OPT} \cap T_{e^*}$ use on each edge $e \in E$. For any set of tasks $S \subseteq T$, we define $u_S(e) := \sum_{i \in S \cap T_e} d(i)$ for each $e \in E$. Observe that $u_{T_{e^*} \cap \text{OPT}}$ is non-decreasing on the left of e^* and non-increasing on the right of e^* , since all tasks in $T_{e^*} \cap \text{OPT}$ use e^* . We will guess an *over-estimating* profile $\text{mp}_{T_{e^*} \cap \text{OPT}}: E \rightarrow \mathbb{N}$ of $u_{T_{e^*} \cap \text{OPT}}(e)$ defined below, with the properties that

- for each edge e it holds that $\text{mp}_{T_{e^*} \cap \text{OPT}}(e) \geq u_{T_{e^*} \cap \text{OPT}}(e)$,
- $\text{mp}_{T_{e^*} \cap \text{OPT}}$ is a step-function with only $O_{\epsilon,\delta}(\log \log n)$ steps (i.e., E can be partitioned into $O_{\epsilon,\delta}(\log \log n)$ subpaths and $\text{mp}_{T_{e^*} \cap \text{OPT}}$ is constant on each subpath), and
- $\text{mp}_{T_{e^*} \cap \text{OPT}}(e)$ and $u_{T_{e^*} \cap \text{OPT}}(e)$ do not differ too much on each edge $e \in E$.

Formally, let $D := \log n$; our overall algorithm will intuitively be a recursion with D levels. For any set of tasks $S \subseteq T$ we define the *minimal profile* $\text{mp}_S: E \rightarrow \mathbb{N}$ of S as follows. Let $\theta := \lfloor u_{\min} \cdot \delta/D \rfloor$. If for an edge $e \in E$ it holds that $d(S \cap T_e) = 0$ then we define

■ **Figure 1** Overestimating profile $\text{mp}(u_{T_{e^*} \cap \text{OPT}})$ (the red line). The edge e' halves the number of steps and e'' the length of the path on the left-hand side of e^* .

$\text{mp}_S(e) := 0$. Otherwise, we define $\text{mp}_S(e) := \lfloor \theta(1 + \delta)^{k_e} \rfloor$ where k_e is the smallest integers such that $\theta(1 + \delta)^{k_e} \geq d(S \cap T_e)$ (see Figure 1). It turns out that $\text{mp}_S(\cdot)$ is a step-function with only $O_{\delta, \epsilon}(\log \log n)$ steps, assuming that there is an edge \bar{e} that is used by all tasks in S (like the edge e^* above).

► **Lemma 4.** *There is a value $\Gamma = O_{\delta, \epsilon}(\log D) = O_{\delta, \epsilon}(\log \log n)$ such that for every edge $\bar{e} \in E$ and every set $S \subseteq T_{\bar{e}}$ with $d(S \cap T_e) \leq u(e)$ for each $e \in E$, we have that $\text{mp}_S(\cdot)$ is a step-function with at most Γ steps.*

Proof. Recall that by Lemma 3 $u_{\min} = n/\delta$ and $u_{\max} \leq n/(\delta\eta)$. We therefore search for an upper bound on the smallest value k such that $\lfloor \theta(1 + \delta)^k \rfloor \geq n/(\delta\eta)$. We have that

$$\begin{aligned} k &\in O(\log_{1+\delta}\left(\frac{n}{\delta\eta\theta}\right)) = O\left(\log_{1+\delta}\left(\frac{nD}{\eta\delta^2 u_{\min}}\right)\right) \\ &= O\left(\log_{1+\delta}\left(\frac{D}{\eta\delta^2}\right)\right) = O_{\delta, \epsilon}(\log D) = O_{\delta, \epsilon}(\log \log n). \end{aligned}$$

The second claim follows due to monotonicity of the profile formed by the tasks $\text{OPT}_S \cap T_e$. ◀

For any set S , the profile $\text{mp}_S(\cdot)$ overestimates the true demand of the tasks S on each edge e . Therefore, we define the error of this estimation by $\text{err}(\text{mp}_S, e) := \text{mp}_S(e) - u_S(e)$ for each edge $e \in E$. Intuitively, in our algorithm we will guess profiles mp_S in each of the $D = \log n$ recursion levels, such that at the end each edge e is in the support of at most $2D$ of these profiles. A key insight is the following lemma which implies that for each edge e , the sum of the errors of these $2D$ profiles is bounded by the extra space of $\delta u(e)$ due to the resource augmentation. Intuitively, if $\text{mp}_S(e) = \theta$ on some edge e , then the error is at most $\theta = u_{\min} \cdot \delta/D$ and for $2D$ profiles the errors of this type can accumulate to at most $2D \cdot \theta \leq 2\delta u_{\min} \leq 2\delta u(e)$. On the other hand, if $\text{mp}_S(e) > \theta$ then the error is at most $\delta \cdot d(S \cap T_e)$, and this can accumulate to at most $\delta \cdot u(e)$ for all profiles together if these profiles correspond to disjoint sets of tasks $S_1, S_2, \dots, S_{D'}$ that use at most $u(e)$ units of capacity on e altogether, for any D' .

► **Lemma 5.** *Let $S_1, S_2, \dots, S_{D'} \subseteq T$ be disjoint sets of tasks with $D' \in O(D)$. If $\sum_j d(S_j \cap T_e) \leq u(e)$ for an edge e , then $\sum_{j=1}^{D'} \text{err}(\text{mp}_{S_j \cap T_e}, e) \leq O(\delta) \cdot u(e)$.*

Proof. For each index j and edge e such that $\text{mp}_{S_j \cap T_e}(e) = \lfloor \theta(1+\delta)^{k_j} \rfloor$ for some k_j , the error $\text{err}(\text{mp}_{S_j \cap T_e}, e)$ is bounded from above by $\lfloor \theta \rfloor$ if $k_j = 0$ and by $\lfloor \theta \cdot (1+\delta)^{k_j} \rfloor - \lceil \theta \cdot (1+\delta)^{k_j-1} \rceil \leq \theta(1+\delta)^{k_j-1} \cdot \delta \leq \delta d(S_j)$ if $k_j > 0$. (Observe that the rounding is valid because the demands are integers.) Thus $\text{err}(\text{mp}_{S_j \cap T_e}, e) \leq \max\{\theta, \delta d(S_j)\}$. Summing up over all errors we obtain

$$\sum_{j=1}^{D'} \text{err}(\text{mp}_{S_j \cap T_e}, e) \leq D' \cdot \theta + \sum_j \delta d(S_j \cap T_e) \leq \frac{D' u_{\min} \delta}{D} + \delta u(e) \in O(\delta)u(e). \quad \blacktriangleleft$$

As mentioned above, we guess $\text{mp}_{T_{e^*} \cap \text{OPT}}$, which can be done in time $n^{O_{\delta, \epsilon}(\log \log n)}$ due to Lemma 4. Then, we compute the essentially most profitable set of tasks $T' \subseteq T_{e^*}$ that fits into $\text{mp}_{T_{e^*} \cap \text{OPT}}$, i.e., such that $d(T' \cap T_e) \leq \text{mp}_{T_{e^*} \cap \text{OPT}}(e)$ on each edge $e \in E$. This can be done using a PTAS in [16] for *rooted* UFP instances in which all input tasks share a common edge (like the edge e^* in our case).

► **Theorem 6 ([16]).** *There is a PTAS for instances of UFP in which there is an edge that is used by every input task (rooted UFP). The same holds if there exist $O(1)$ edges such that each task uses at least one of them.*

We recurse on the subpaths on the left and on the right of e^* . Let us consider the left subpath, i.e., let E_L denote the path from the left-most edge of E up to e^* , not including e^* . (The recursion to the right is analogous.) We subdivide E_L into three parts determined by two edges e', e'' in E_L (or two parts if these edges coincide). We choose the first edge $e' \in E_L$ on the left of e^* such that the number of steps in the profile $\bar{u} := \text{mp}_{\text{OPT} \cap T_{e^*}}$ within E_L is halved (a similar trick was used in [7]). Formally, let $\Gamma = O_{\delta, \epsilon}(\log \log n)$ such that $\text{mp}_{\text{OPT} \cap T_{e^*}}$ is a step-function with Γ steps. We choose e' such that $\text{mp}_{\text{OPT} \cap T_{e^*}}$ restricted to the subpath of E_L on the left of e' is a step-function with at most $\lceil \Gamma/2 \rceil$ steps, and the same is true for $\text{mp}_{\text{OPT} \cap T_{e^*}}$ restricted to the subpath of E_L on the right of e' . The second edge e'' lies in the middle of E_L such that on the left of e'' there are at most $\lfloor |E_L|/2 \rfloor$ edges of E_L and the same is true on the right of e'' . We may assume without loss of generality that e' lies on the left of e'' .

We guess the profiles $\bar{u}' := \text{mp}_{(\text{OPT} \cap T_{e'}) \setminus T_{e^*}}$ and $\bar{u}'' := \text{mp}_{(\text{OPT} \cap T_{e''}) \setminus (T_{e^*} \cup T_{e'})}$ and apply Theorem 6 to compute essentially the most profitable subset of tasks that fit into \bar{u}' (and \bar{u}''), among the input tasks $i \in T_{e'}$ with $P(i) \subseteq E_L$ (among the input tasks $i \in T_{e''} \setminus T_{e'}$ with $P(i) \subseteq E_L$). Then we recurse on each of the up to three components of $E_L \setminus \{e', e''\}$, where the parameter is the respective subpath and the profile $\bar{u} + \bar{u}' + \bar{u}''$ restricted to that subpath. Due to the choice of e'' , the depth of our recursion is bounded by $D = \log n$. In particular, at the end each edge e is in the support of at most $O(D)$ guessed profiles. By Lemma 5, the total error of these profiles is at most $O(\delta)u(e)$ which is compensated by the resource augmentation. Due to the choice of e' , one can show that in each recursive call the profile of the parameter is a step function with only $4\Gamma = O_{\delta, \epsilon}(\log \log n)$ steps: each recursive call “inherits” only half of the steps that were given to its parent subproblem, and additionally up to 2Γ new steps due to the guessed profiles in the parent subproblem. This allows us to embed this recursion into a dynamic program (DP) with only $n^{O_{\delta, \epsilon}(\log \log n)}$ DP-cells as follows, and hence we obtain an overall running time of $n^{O_{\delta, \epsilon}(\log \log n)}$.

2.2 Dynamic program

We define the mentioned DP formally. In our DP table, we have a cell (P, \hat{u}) for each subpath $P \subseteq E$ and each function $\hat{u} : P \rightarrow \mathbb{N}_0$ such that $0 \leq \hat{u}(f) \leq n/(\delta\eta)$ for each edge $f \in P$ and \hat{u} is a step-function with at most 4Γ steps, i.e., one can partition P into 4Γ subpaths such that \hat{u} is constant on each one of them. The intuitive meaning of \hat{u} is that for each edge $e \in P$,

$\hat{u}(e)$ units of capacity have already been assigned to some tasks. The goal is to compute a set of tasks with maximum total weight and with $P(i) \subseteq P$ for each selected task i , such that on each edge $e \in P$ the selected tasks use a total capacity of at most $u(e) - \hat{u}(e)$.

► **Lemma 7.** *There are at most $n^{O_{\delta,\epsilon}(\log \log n)}$ many different DP cells.*

Proof. There are $O(n^2)$ possible choices for P . To determine the number of possible profiles \hat{u} , recall that \hat{u} has at most $4\Gamma = O_{\delta,\epsilon}(\log \log n)$ many steps. There are $\binom{O(n)}{O_{\delta,\epsilon}(\log \log n)} \in n^{O_{\delta,\epsilon}(\log \log n)}$ possibilities to partition P into at most $O_{\delta,\epsilon}(\log \log n)$ subpaths. For each subpath, there are at most $n/(\delta\eta)$ possibilities for the value of \hat{u} on this subpath, i.e., $(n/(\delta\eta))^{O_{\delta}(\log \log n)}$ possible combinations overall. Recall that $\eta = \delta^{2/\epsilon}$. Multiplying these two numbers gives the total number of profiles. ◀

Given a DP cell $\text{DP}(P, \hat{u})$. We identify two edges $e', e'' \in P$ similarly as above, i.e., we select $e' \in P$ such that if we restrict \hat{u} to the edges of P on the left of e' or on the right of e' , then \hat{u} is a step-function with at most 2Γ steps. Also, we select e'' such that at most $\lfloor |P|/2 \rfloor$ edges of P lie on the left of e'' , and at most $\lfloor |P|/2 \rfloor$ edges of P lie on the right of e'' . Let P_1, P_2, P_3 denote the subpaths of P induced by e' and e'' , i.e., the components of $P \setminus \{e', e''\}$.

Let \mathcal{T} be the set of all pairs (\hat{u}', \hat{u}'') such that $\hat{u}' : P \rightarrow \mathbb{N}_0$ and $\hat{u}'' : P \rightarrow \mathbb{N}_0$ are step-functions with at most Γ steps each, and on each edge $f \in P$ they use at most $(1 + \delta)u(f)$ units of capacity, i.e., $\hat{u}(f) + \hat{u}'(f) + \hat{u}''(f) \leq (1 + \delta)u(f)$. We apply the algorithm due to Theorem 6 to the instance whose input tasks contain all tasks in $i \in T_{e'}$ with $P(i) \subseteq P$ and with edge capacities given by \hat{u}' . Similarly, we apply this algorithm to the instance whose input tasks contain all tasks in $i \in T_{e''} \setminus T_{e'}$ with $P(i) \subseteq P$ and with edge capacities given by \hat{u}'' . Denote by $\text{alg}(\hat{u}')$ and $\text{alg}(\hat{u}'')$ the respective solutions. With the pair (\hat{u}', \hat{u}'') we associate the solution given by $\text{alg}(\hat{u}') \cup \text{alg}(\hat{u}'')$ and the solutions stored in the cells $\text{DP}(P_j, (\hat{u} + \hat{u}' + \hat{u}'')|_{P_j})$ for $j \in \{1, 2, 3\}$. We store in $\text{DP}(P, \hat{u})$ the weight of the most profitable solution for all pairs $(\hat{u}', \hat{u}'') \in \mathcal{T}$, i.e.,

$$\text{DP}(P, \hat{u}) := \max_{t=(\hat{u}', \hat{u}'') \in \mathcal{T}} ((\text{alg}(\hat{u}')) + w(\text{alg}(\hat{u}'')) + \sum_{j=1}^3 \text{DP}(P_j, (\hat{u} + \hat{u}' + \hat{u}'')|_{P_j})).$$

Observe that $(\hat{u} + \hat{u}' + \hat{u}'')|_{P_j}$ has at most 4Γ steps as required for valid DP cells: the profile \hat{u} restricted to P_j has at most 2Γ steps due to the halving and both \hat{u}' and \hat{u}'' introduce at most Γ new steps each.

At the end we output $\text{DP}(E, u_0)$ where u_0 is the profile with $u_0(e) = 0$ for all $e \in E$. By standard memoization we can also output the solution associated with $\text{DP}(E, u_0)$.

We need to show that the DP computes a near-optimal solution. It is clear that we output a feasible solution since in the computation for each cell, the set \mathcal{T} contains only pairs (\hat{u}', \hat{u}'') such that $\hat{u}(f) + \hat{u}'(f) + \hat{u}''(f) \leq (1 + \delta)u(f)$ for each edge $f \in P$. Intuitively, Lemma 5 allows us to argue that in each step we can guess for \hat{u}' and \hat{u}'' the profiles $\text{mp}_{\text{OPT}' \cap T_{e'}}$ and $\text{mp}_{(\text{OPT}' \cap T_{e''}) \setminus T_{e'}}$, respectively, where OPT' denotes the tasks $i \in \text{OPT}$ with $P(i) \subseteq P$, without violating the capacities of the edges.

► **Lemma 8.** *The dynamic program computes a solution ALG which is feasible with $O(\delta)$ -resource augmentation and $w(\text{ALG}) \geq (1 - \epsilon)w(\text{OPT})$.*

Proof. Consider a DP-cell (P, \hat{u}) for which the DP defined the edges e', e'' when calculating its solution. Consider the profiles $\text{mp}_{\text{OPT} \cap \{i \in T_{e'} \mid P(i) \subseteq P\}}$ and $\text{mp}_{\text{OPT} \cap \{i \in T_{e''} \setminus T_{e'} \mid P(i) \subseteq P\}}$. Observe that all tasks $\{i \in \text{OPT} \cap (T_{e'} \cup T_{e''}) \mid P(i) \subseteq P\}$ fit into the combined profile and all remaining tasks from OPT within P will be considered in subproblems. If the two profiles are a feasible choice, then the DP obtains a profit of at least $(1 - \epsilon)w(\{i \in \text{OPT} \cap (T_{e'} \cup T_{e''}) \mid P(i) \subseteq P\})$

from the tasks in $T_{e'} \cup T_{e''}$ when choosing these profiles. Therefore, it suffices to prove the claim that if in each recursive call up to some recursion level ℓ the DP chooses exactly these profiles, then in each subsequent recursive call of level $\ell + 1$ the corresponding profiles will be a feasible choice again. Inductively, we can conclude then that the DP obtains a profit of at least $(1 - \epsilon)\text{opt}$.

To prove the mentioned claim, intuitively, due to the halving of the paths, the recursion depth is bounded from above by $O(\log n)$ and therefore the total error does not exceed the available amount of resource augmentation. Formally, we inductively maintain the invariant that for a DP cell (P, \hat{u}) , if the profile \hat{u} is composed of $2k$ profiles (from previous DP cells), then the length of P is bounded from above by $2n/2^k$. Recall that we assumed that $|E| \leq O(n)$. For each edge, we therefore have that at most $O(\log n)$ profiles overlap and by Lemma 5, the total error of is at most $O(\delta)u(e)$ for each edge e , i.e., $O(\delta)$ -resource augmentation is sufficient. \blacktriangleleft

Together with Lemma 3 we conclude that we obtain a $(1 + \epsilon)$ -approximation algorithm for UFP with δ -resource augmentation.

3 Bonus-UFP

In this section we define formally the Bonus-UFP problem (BUFP) and formalize how an algorithm with resource augmentation for Bonus-UFP yields an algorithm for (ordinary) UFP *without* resource augmentation.

3.1 Problem definition

Like in (ordinary) UFP, in the Bonus-UFP problem we are given as input a path $G = (V, E)$ and a set of tasks T where each task $i \in T$ has a demand $d(i) \in \mathbb{N}$, a sub-path $P(i)$ of E , and a weight $w(i) \in \mathbb{N}_0$. The profit of a computed solution with task set $T' \subseteq T$ stems as usual from $w(T')$ and, additionally, from some *bonus profit* that we obtain from subpaths $E' \subseteq E$ (i.e., E' forms the edges of the respective subpath) such that no task $i \in T'$ satisfies that $P(i) \subseteq E'$ (but it might be that $P(i) \cap E' \neq \emptyset$). The amount of bonus of such a subpath E' depends on the tasks $i \in T'$ with $P(i) \cap E' \neq \emptyset$. The reader may imagine that we get more bonus from E' if fewer tasks from T' intersect E' . In particular, the computed solution consists of T' and of the subpaths E' from which the respective bonus profit is collected. Additionally, the input tasks are divided into large and small tasks, and on any edge we are allowed to select only $O(1)$ large tasks (in particular, for each edge e the large tasks in $OPT \cap T_e$ can be guessed easily in time $n^{O(1)}$). Also, for technical reasons, the selected small tasks are allowed to use at most $2b$ units of capacity of each edge $e \in E$ for some given value b (see Figure 2).

Formally, in the input we are given a constant $\tau \in \mathbb{N}$ and values $\mu \in (0, 1)$, $b > 0$ which partition the tasks T into a set of *large tasks* $T_L = \{i \in T : d(i) > \mu b\}$ and *small tasks* $T_S = \{i \in T : d(i) \leq \mu b\}$. For each pair of a subpath $E' \subseteq E$ and a set $L'_{int} \subseteq T_L$ such that

- the path of each task $i \in L'_{int}$ uses the leftmost or the rightmost edge of E' and
- $|L'_{int} \cap T_e| \leq \tau$ for each edge $e \in E'$

we are given a possible *bonus* $bn(E', L'_{int}) \geq 0$. As described above, we obtain the bonus $bn(E', L'_{int})$ if no selected task (large or small) is contained in E' and the tasks in L'_{int} are exactly the selected large tasks that use some edge of E' (the amount of bonus does not depend on the selected small tasks i with $P(i) \cap E' \neq \emptyset$). A feasible solution to an instance of BUFP consists of a set of tasks $R \subseteq T_L \cup T_S$ and a collection of node-disjoint subpaths E_1, \dots, E_q of G such that the following holds:

■ **Figure 2** A Bonus-UFP instance with two bonus intervals E' and E'' . The hatched task within E'' is not allowed. The bonus depends on the intervals and the tasks depicted in dark gray – the large tasks that intersect with an interval.

1. R is a feasible UFP solution, i.e., for every $e \in E$ it holds that $d(R \cap T_e) \leq u(e)$,
 2. the small tasks in R use at most a capacity of $2b$ on each edge $e \in E$, i.e., $d(R \cap T_S \cap T_e) \leq 2b$,
 3. each edge $e \in E$ is used by at most τ tasks in $R \cap T_L$, i.e., $|R \cap T_L \cap T_e| \leq \tau$, and
 4. for no $i \in R$ the path $P(i)$ is contained in any E_j (but possibly $P(i) \cap E_j \neq \emptyset$).
- The profit of the solution is $w(R)$ plus the bonus for each subpath E_j , where the latter depends on the large tasks in R that use E_j , i.e., the total profit is $w(R) + \sum_{j=1}^q bn(E_j, L_{int,j})$ where $L_{int,j} = \{i \in R \cap T_L \mid P(i) \cap E_j \neq \emptyset\}$.

We say that a solution to the above problem is feasible *under δ -resource augmentation* if we relax the first two conditions to

- 1.' for every $e \in E$ it holds that $d(R \cap T_e) \leq u(e) + \delta b$,
- 2.' for every $e \in E$ it holds that $d(R \cap T_S \cap T_e) \leq 2b + \delta b$.

So intuitively this increases the capacity for the small tasks by at least a factor $1 + O(\delta)$. Also, note that Property 3 ensures that each edge e is used by at most $\tau = O(1)$ large tasks, and hence we can guess the large tasks for each edge in time $n^{O(\tau)} = n^{O(1)}$.

For non-negative values $\alpha, \beta, \gamma \leq 1$ we say that a tri-criteria (α, β, γ) -*approximation algorithm for BUFP with δ -resource augmentation* is an algorithm that computes a solution that is feasible under δ -resource augmentation of profit at least $\alpha \text{opt}_S + \beta \text{opt}_L + \gamma \text{opt}_B$, assuming that there exists an (optimal) solution R^* with bonuses $\{bn(E_j^*, L_{int,j}^*)\}_j$ such that $\text{opt}_S = w(R^* \cap T_S)$, $\text{opt}_L = w(R^* \cap T_L)$, and $\text{opt}_B = \sum_{j=1}^q bn(E_j^*, L_{int,j}^*)$. Then our main result states that if $\gamma = 1$ we can translate such an algorithm to an algorithm for normal UFP whose approximation ratio is $1/\min\{\alpha, \beta\}$. We will prove the following theorem in Section 3.2.

► **Theorem 9** (Black-box reduction). *Assume that there is a $(\alpha, \beta, 1)$ -approximation algorithm for BUFP with δ -resource augmentation with a running time of $T_{\tau, \delta}(n, u_{\max})$. Then there is a $\frac{1+\epsilon}{\min\{\alpha, \beta\}}$ -approximation algorithm for UFP (without resource augmentation) with a running time of $T_{O_\epsilon(1), O_\epsilon(1)}(n, u_{\max}) \cdot (n \cdot \log u_{\max})^{O_\epsilon(1)}$.*

3.2 Black-box reduction

In this section we explain the key ideas for the black-box reduction due to Theorem 9 (omitting details due to space constraints). We start with a lemma indicating that there are near-optimal solutions in which each edge has a certain amount of slack. This slack is a

constant fraction of the capacity used by small tasks according to a suitable definition of small and large tasks. To avoid confusion, we refer to large and small tasks as in definition of BUFP as bonus-large and bonus-small, respectively.

In the lemma, we assign a level $\ell(e)$ to each edge e . We say that a task i is of level ℓ if $P(i)$ includes an edge e with $\ell(e) = \ell$ and no edge e' with $\ell(e') < \ell$; let $T^{(\ell)} \subseteq T$ denote all tasks of level ℓ . Intuitively, each edge e of level ℓ has an amount of slack $\varepsilon^4 a(\ell)$ for some value $a(\ell)$ corresponding to level ℓ . We define small and large tasks such that on each edge e of level ℓ , the small tasks of level ℓ use a total capacity of at most $2b(\ell)$ with $b(\ell) = O_\epsilon(a(\ell))$ and each edge e of level ℓ is used by at most $\tau = O_\epsilon(1)$ large tasks i with $d(i) = \Omega(a(\ell))$. Formally, for an offset $h' \in \{0, \dots, 1/\epsilon - 1\}$ and a value $h = \Theta(\frac{1}{\epsilon} \ln \frac{7}{\epsilon^2})$ defined in the next lemma, we set $a(\ell) := (1 + \varepsilon)^{h' + \ell h \cdot (1 + \frac{1}{\epsilon}) - \frac{h}{\epsilon}}$ and $b(\ell) = a(\ell) \cdot (1 + \varepsilon)^{\frac{h}{\epsilon}}$. Let opt denote the weight of the optimal solution to the given instance.

► **Lemma 10 (Slack Lemma).** *Let $\epsilon > 0$. There are two constants $\mu_1, \mu_2 \in (0, \varepsilon^4)$ with $\mu_1 < \mu_2 / (1 + \varepsilon)^{1/\varepsilon^3}$, values $h = \Theta(\frac{1}{\epsilon} \ln \frac{7}{\epsilon^2})$ and $\tau = O_\epsilon(1)$, an offset h' contained in a set of size $O_\epsilon(1)$ that can be computed in polynomial time, a near-optimal solution OPT with $w(\text{OPT}) \geq (1 - O(\epsilon))\text{opt}$, and a level $\ell(e)$ for each edge $e \in E$ with the following properties. We define*

- $T_L := \{i \in T : d(i) \geq \mu_2 \cdot a(\ell(e)) \text{ for some edge } e \in P(i)\}$ (large tasks)
- $T_S := \{i \in T : d(i) < \mu_1 \cdot b(\ell(e)) \text{ for every edge } e \in P(i)\}$ (small tasks)
- $\text{OPT}_L = \text{OPT} \cap T_L$ and $\text{OPT}_S^{(\ell)} := \text{OPT} \cap T_S \cap T^{(\ell)}$ for each ℓ .

Then, for each edge e of level $\ell(e) = \ell$, it holds that:

- $d(T_e \cap \text{OPT}_L) + d(T_e \cap \text{OPT}_S^{(\ell)}) \leq u(e) - \varepsilon^4 a(\ell)$,
- $d(T_e \cap \text{OPT}_S^{(\ell)}) \leq 2b(\ell)$,
- e is used by at most τ tasks $i \in \text{OPT}_L \cap T^{(\ell)}$ with $d(i) \geq \mu_2 \cdot a(\ell)$.

Our goal is to define an algorithm BB that solves UFP given an oracle OR for BUFP with δ -resource augmentation. We will use the notation $G^B, T^B, T_S^B, T_L^B, u^B, \tau^B$ for the input path, input tasks, edge capacities, and threshold τ of the constructed instances of BUFP, while we use G, T, u to denote the corresponding values of the given instance of UFP.

Intuitively, BB solves a subproblem of BUFP for each maximally long path G^B in which each edge is of level at least ℓ for some given value $\ell \in \{0, \dots, \ell_{\max}\}$ (where ℓ_{\max} denotes the maximum level due to Lemma 10), and the bonus subpaths E_j selected in an optimal solution will correspond to maximal subpaths of G^B consisting of edges of level at least $\ell + 1$. With this interpretation, the amount of received bonus on such a subpath E_j is calculated via subproblems of BUFP defined on this subpath E_j , level $\ell + 1$, and any possible set of $O_\epsilon(1)$ selected large tasks of level ℓ that use at least one edge of E_j but which are not contained in E_j . The parameters of the calls to OR for this a subproblem (i.e., path G^B and level ℓ) will be intuitively as follows. We set $b = b(\ell)$, $\mu = \mu_1$, and $a = a(\ell)$. We place in T^B the tasks in T contained in G^B whose demand is at most $\mu_1 b(\ell)$ or at least $\mu_2 a(\ell)$. This yields that $T_L^B = \{i \in T^B | d(i) \geq \mu_2 a(\ell)\}$ and $T_S^B = \{i \in T^B | d(i) \leq \mu_1 b(\ell)\}$ according to the definition of BUFP. We remark that either $\mu_2 a(\ell) > \mu_1 b(\ell)$ or $\mu_1 b(\ell) < 1$ (in which case $T_L^B = \emptyset$); hence T_L^B and T_S^B are distinct. This way we will enforce that $T_L^B \subseteq T_L$ and $T_S^B \subseteq T_S$ for the sets T_L, T_S due to Lemma 10. We will set τ^B to be the respective value τ due to Lemma 10.

Note that in this recursive call there are $O_\epsilon(1)$ (previously selected) large tasks that use some but possibly not all edges of E_j . However, in the definition of Bonus-UFP, we have a global upper bound of τ^B for the number of allowed large tasks using an edge. To this end, we guess some further large tasks whose paths are contained in E_j , profiles for some of the

small tasks, and a partition of E_j into $O_\epsilon(1)$ subpaths, such that we split this problem into subproblems in which each edge can be used by the same number $\tau^B \leq \tau$ of large tasks, so that we can call OR on the resulting subproblem. We denote by opt_S and opt_L the profit due to small and large tasks, resp., in the solution OPT from Lemma 10.

► **Theorem 11.** *Given a $T_{\tau,\delta}(n, u_{\max})$ time $(\alpha, \beta, 1)$ -approximation algorithm OR for BUFP with δ -resource augmentation, for every given constant $\delta > 0$. Then, for every constant $\epsilon > 0$, there exists a $T_{O_\epsilon(1), O_\epsilon(1)}(n, u_{\max}) \cdot (n \log u_{\max})^{O_\epsilon(1)}$ time algorithm BB for UFP that computes a solution of profit at least $(1 - \epsilon)\alpha \text{opt}_S + (1 - \epsilon)\beta \text{opt}_L$.*

Theorem 9 then follows from Lemma 10 and Theorem 11, where we set $\alpha = 1 - \epsilon$ and $\beta = 1$.

The reader might wonder why we proved the above theorem for general α and β . The reason is that it turns out that tasks $i \in OPT_S = OPT \cap T_S$ from Lemma 10 satisfy $d(i) \leq \epsilon^2 u(e)$ for each $e \in P(i)$. Therefore, we can use LP-rounding techniques as in [11] to compute an alternative UFP solution with profit at least $(1 - O(\epsilon))\text{opt}_S$. Hence any algorithm for BUFP as in Theorem 11 implies a $(\frac{1+\beta-\alpha}{\beta} + O(\epsilon))$ -approximation for UFP. Recent work showed how to obtain (α, β) -approximation algorithms for UFP in the above sense with $\beta = 1$ and α equal to $\frac{1}{3}$ [17]. This result becomes substantially easier to prove with resource augmentation in the BUFP setting. So we hope that Theorem 11 as stated can be a handy tool for future work along the same line.

4 Algorithm for Bonus-UFP under resource augmentation

We describe now how to adjust our algorithm for ordinary UFP with resource augmentation from Section 2 to an algorithm for Bonus-UFP with resource augmentation. Intuitively, there are two extra issues than one needs to address. First, the edges e' and e'' that partition the considered subpath P might happen to fall within the interval of some bonus. This has to be taken into account in the definition of the subproblems which are solved recursively. Second, we need to keep track of the large tasks that use each edge so that the threshold τ is not exceeded. Therefore it is convenient to *guess* them explicitly, and use the over-estimated profiles for the small tasks only.

► **Theorem 12.** *There is a $(1 - \epsilon, 1, 1)$ -approximation algorithm for Bonus-UFP with δ -resource augmentation with a running time of $n^{O_{\epsilon,\delta}(\log \log n)}$.*

Theorems 9 and 12 together yield Theorem 2. It remains a challenging open problem to construct a PTAS for (Bonus-)UFP. One key bottleneck in our approach is that already in the first iteration we need to guess a profile with up to $\Omega(\log \log n)$ many steps, and it is not clear how to do this in polynomial time.

In the remaining section, we prove Theorem 12. Again, we start with normalizing the instance. Since we have an additive resource augmentation of δb , we can use half of it in order to ensure $u_{\min} \geq \delta b/2$. Thus $2b \leq 4u_{\min}/\delta$, i.e., $u_{OPT_S}(e)$ together with half of the resource augmentation has a constant capacity profile. Furthermore, analogous to Lemma 3, we can assume that each task $i \in T$ has an integer demand $d(i) \in \mathbb{N}$ and $b \in O_\delta(n)$. Unlike before, we do not lose a profit of $\epsilon w(\text{OPT}_L)$.

► **Lemma 13.** *For arbitrary $\delta > 0$, suppose there is an (α, β, γ) -approximation algorithm for BUFP instances I with $(1 + \delta)$ resource augmentation such that $u_{\min} = \delta b$, $b \in O_\delta(n)$, and $d(i) \in \mathbb{N}$ for all $i \in T$. Then there is an $((1 - \epsilon)\alpha, \beta, \gamma)$ -approximation algorithm for BUFP with $(1 + 4\delta)$ resource augmentation.*

49:12 Faster $(1 + \epsilon)$ -Approximation for Unsplittable Flow on a Path

Due to Lemma 13, in the following we assume that we are given an instance of BUFP with $(1 + \delta)$ resource augmentation such that $u_{\min} = \delta b$, $2b = n/\eta$ for some $\eta \in O_\delta(1)$, and $d(i) \in \mathbb{N}$ for all $i \in T$.

We adapt the strategy used for UFP with resource augmentation and we use the same notation. Again we overestimate profiles based on the value $\theta := \lfloor u_{\min} \cdot \delta / D \rfloor$, now with $u_{\min} = \delta b$ and $D = \log n$. Lemma 4 is still valid for BUFP, if we restrict the set S to small tasks.

► **Lemma 14.** *There is a value $\Gamma = O_{\delta,\epsilon}(\log D) = O_{\delta,\epsilon}(\log \log n)$ such that for every edge $\bar{e} \in E$ and every set $S \subseteq T_S \cap T_{\bar{e}}$ with $d(S \cap T_e) \leq 2b$ for each $e \in E$, we have that $mp_S(\cdot)$ is a step-function with at most Γ steps.*

Proof. Since the demand $d(S)$ is bounded from above by $2b$, it is sufficient to consider the profile that for each edge $e \in E$ has the capacity $\min\{2b, u(e)\}$. With the modification, we can apply Lemma 4. ◀

Furthermore, Lemma 5 does not change for BUFP, if we restrict it to small tasks, i.e., $S_j \subseteq T_S$ for all j .

For ease of notation, we assume that for each edge f and each set $L \subseteq T_L \cap T_e$ with $d(L) \leq u(f)$, the BUFP instance to be solved has is a (dummy) bonus interval $(\{f\}, L)$. If the bonus interval is not part of the original instance, it has zero bonus, i.e., $bn(\{f\}, L) = 0$. By duplicating edges, we can assume without loss of generality that there is no task i with $P(i) = f$.

4.1 Dynamic program for BUFP

In our DP table, we have a cell (P, \hat{u}, L) for each subpath $P \subseteq E$, each function $\hat{u} : P \rightarrow \mathbb{N}_0$, and each set of large tasks $L \subseteq T_L$ with the following properties. We require $0 \leq \hat{u}(f) \leq n/\eta$ for each edge $f \in P$ and \hat{u} is a step-function with at most 8Γ steps, i.e., one can partition P into 8Γ subpaths such that \hat{u} is constant on each of them. A set L is valid, if each task in L uses the leftmost or the rightmost edge of P . Note that $|L| \leq 2\tau$ since there can only be at most τ large tasks crossing each of the two boundaries of P .

The intuitive meaning of \hat{u} and L is that for each edge $e \in P$, $\hat{u}(e)$ units of capacity have already been assigned to some small tasks and the tasks L have already been selected. For a set of tasks T' , we define $u_{T'} : E \rightarrow \mathbb{N}_0$ to be the profile with $u_{T'}(e) = d(T' \cap T_e)$ for each $e \in E$. The goal is to compute a set of tasks with maximum total weight and with $P(i) \subseteq P$ for each selected task i , such that on each edge $e \in P$ the selected tasks use a total capacity of at most $u(e) - \hat{u}(e) - u_L(e)$.

► **Lemma 15.** *There are at most $n^{O_{\delta,\epsilon,\tau}(\log \log n)}$ many different DP cells.*

Proof. There are $O(n^2)$ possible choices for P . To determine the number of possible profiles \hat{u} , recall that \hat{u} has at most $8\Gamma = O_{\delta,\epsilon}(\log \log n)$ many steps and L has a size of at most 2τ .

There are $\binom{O(n)}{O_{\delta,\epsilon,\tau}(\log \log n)} \in n^{O_{\delta,\epsilon,\tau}(\log \log n)}$ possibilities to partition P into at most $O_{\delta,\epsilon,\tau}(\log \log n)$ subpaths. For each subpath, there are at most n/η possibilities for the value of \hat{u} on this subpath and $\binom{n}{2\tau} \leq n^{2\tau}$ possibilities for selecting L , i.e., $(n/\eta)^{O_{\delta,\epsilon}(\log \log n)} \cdot n^{2\tau}$ possible combinations overall. Multiplying these two numbers gives the total number of profiles. ◀

Suppose that we are given a DP cell $DP(P, \hat{u}, L)$. We identify two edges $e', e'' \in P$. We select $e' \in P$ such that if we restrict \hat{u} to the edges of P on the left of e' or on the right of e' , then \hat{u} is a step-function with at most 4Γ steps. Also, we select e'' such that at most

$\lfloor |P|/2 \rfloor$ edges of P lie on the left of e'' , and at most $\lfloor |P|/2 \rfloor$ edges of P lie on the right of e'' . Let P_1, P_2, P_3 denote the subpaths of P induced by $E_{j'}$ and $E_{j''}$, i.e., the components of $P \setminus (E_{j'} \cup E_{j''})$.

Let \mathcal{T} be the set of all tuples $(p_1, p_2, \hat{u}', \hat{u}'')$ with $p_1 := (E_{j'}, L_{\text{int},j'})$ and $p_2 := (E_{j''}, L_{\text{int},j''})$ specified as follows. The pair $(E_{j'}, L_{\text{int},j'})$ is a bonus interval with $e' \in E_{j'}$ and $(E_{j''}, L_{\text{int},j''})$ is a bonus interval with $e'' \in E_{j''}$ such that $E_{j'} \cap E_{j''} = \emptyset$ or $p_1 = p_2$. A task i which overlaps with both $E_{j'}$ and $E_{j''}$ (i.e., $P(i) \cap E_{j'} \neq \emptyset$ and $P(i) \cap E_{j''} \neq \emptyset$) is either in both $L_{\text{int},j'}$ and $L_{\text{int},j''}$ or in none.

Each of the remaining two entries of the tuple $\hat{u}' : P \rightarrow \mathbb{N}_0$ and $\hat{u}'' : P \rightarrow \mathbb{N}_0$ is composed of two step-functions with at most Γ steps each, and on each edge $f \in P$, $\hat{u}'(f) + \hat{u}''(f) \leq (2 + \delta)b$. Furthermore, the capacity of all step-functions use at most $u(f) + \delta b$ units of capacity, i.e., $\hat{u}(f) + \hat{u}'(f) + \hat{u}''(f) + u_L(f) + u_{L_{\text{int},j'}}(f) + u_{L_{\text{int},j''}}(f) \leq u(f) + \delta b$. Let $e'_\ell, e'_r, e''_\ell, e''_r$ be the left-most and right-most edge of $E_{j'}$ and $E_{j''}$, respectively. We apply the algorithm due to Theorem 6 to the instance whose input tasks contain all tasks in $i \in T_{e'_\ell} \cup T_{e'_r}$ with $P(i) \subseteq P$ and $P(i) \not\subseteq E_{j'}$, with edge capacities given by \hat{u}' . Similarly, we apply this algorithm to the instance whose input tasks contain all tasks in $i \in T_{e''_\ell} \cup T_{e''_r} \setminus (T_{e'_\ell} \cup T_{e'_r})$ with $P(i) \subseteq P$ and $P(i) \not\subseteq E_{j''}$, with edge capacities given by \hat{u}'' . Denote by $\text{alg}(\hat{u}')$ and $\text{alg}(\hat{u}'')$ the respective solutions. With the tuple $(p_1, p_2, \hat{u}', \hat{u}'')$ we associate the solution given by $\text{alg}(\hat{u}') \cup \text{alg}(\hat{u}'')$, the bonuses $\text{bn}(p_1), \text{bn}(p_2)$, the profit from large tasks $w(L_{\text{int},j'} \cup L_{\text{int},j''} \setminus L)$, and the solutions stored in the cells $\text{DP}(P_j, (\hat{u} + \hat{u}' + \hat{u}'')|_{P_j}, L')$ for $j \in \{1, 2, 3\}$ and L' the tasks from $L \cup L_{\text{int},j'} \cup L_{\text{int},j''}$ crossing P_j . We store in $\text{DP}(P, \hat{u}, L)$ the weight of the most profitable solution for all tuples $(p_1, p_2, \hat{u}', \hat{u}'') \in \mathcal{T}$, i.e.,

$$\begin{aligned} \text{DP}(P, \hat{u}, L) := & \max_{t=(p_1, p_2, \hat{u}'_S, \hat{u}''_S) \in \mathcal{T}} (w(\text{alg}(\hat{u}')) + w(\text{alg}(\hat{u}''))) \\ & + \sum_{p \in \{p_1, p_2\}} \text{bn}(p) + w(L_{\text{int},j'} \cup L_{\text{int},j''} \setminus L) + \sum_{j=1}^3 \text{DP}(P_j, (\hat{u} + \hat{u}' + \hat{u}'')|_{P_j}), \end{aligned}$$

where \hat{u}' and \hat{u}'' are derived from t as described before. Observe that if $p_1 = p_2$, we collect only one bonus. We have to ensure that $\hat{u}^{(j)} := (\hat{u} + \hat{u}' + \hat{u}'')|_{P_j}$ is a valid profile. Due to the halving, restricted to P_j the profile \hat{u} has at most 4τ steps and each of the other two profiles has at most 2Γ steps from small tasks, which results in 8Γ steps in total. Independently, we always have a total number of at most 4τ steps from large tasks

At the end we output $\text{DP}(E, u_0)$ where u_0 is the profile with $u_0(e) = 0$ for all $e \in E$. By standard memoization we can also output the solution associated with $\text{DP}(E, u_0)$.

We need to show that the DP computes a near-optimal solution. It is clear that we always output a feasible solution since in the computation for each cell, the set \mathcal{T} contains only tuples $(\hat{u}'_S, \hat{u}''_S, p_1, p_2)$ such that $\hat{u}(f) + \hat{u}'(f) + \hat{u}''(f) + u_L(f) + u_{L_{\text{int},j'}}(f) + u_{L_{\text{int},j''}}(f) \leq u(f) + \delta b$ for each edge $f \in P$. Intuitively, Lemma 5 allows us to argue that in each step we can guess for \hat{u}' and \hat{u}'' , the pairs p_1 and p_2 , the profiles $\text{mp}_{\text{OPT}' \cap T_{e'}}$ and $\text{mp}_{(\text{OPT}' \cap T_{e''}) \setminus T_{e'}}$, respectively, where OPT' denotes the tasks $i \in \text{OPT}$ with $P(i) \subseteq P$, without violating the capacities of the edges. Let OPT_B be the set of bonus pairs of an optimal solution and $w(\text{OPT}_B)$ the sum of bonuses.

► **Lemma 16.** *The dynamic program computes a solution ALG which is feasible with $O(\delta)$ -resource augmentation and $w(\text{ALG}) \geq (1 - \epsilon)w(\text{OPT}_S) + w(\text{OPT}_L) + w(\text{OPT}_B)$.*

Proof. Initially, the DP chooses the middle edge e (i.e., $e = e' = e''$) and a bonus interval containing e . One of the choices is the bonus pair $p = (E_j, L_{\text{int},j})$ such that $p \in \text{OPT}_B$ and $e \in E_j$. Since OPT is feasible, it has no tasks contained in E_j . Let e_ℓ and e_r be the left-most and right-most edge of E_j . Then one of the options for the profile is to choose

$$\hat{u} := \text{mp}_{\text{OPT} \cap T_{e_\ell}} + \text{mp}_{\text{OPT} \cap T_{e_r}}.$$

All tasks $\text{OPT} \cap (T_{e_\ell} \cup T_{e_r})$ fit into the profile \hat{u} . Since the DP approximates the profit from these tasks, the value of the DP cell without the values from the subproblems is at least $(1 - \epsilon)w(\text{OPT}_S \cap T_e) + w(\text{OPT}_L \cap (T_{e_\ell} \cup T_{e_r})) + \text{bn}(p)$. The instance is split into the left hand side of E_j and the right hand side of E_j . Let (P, \hat{u}, L) be a sub-problem reached (recursively) by the described choice of profile. Each edge e' chosen subsequently within P has the property that the DP can choose the bonus pair $p_1 := (E_{j'}, L_{\text{int},j'})$ (where as before we assume that e'_ℓ and e'_r are the leftmost and rightmost edges of $E_{j'}$, respectively) from OPT_B containing e' and a feasible choice of \hat{u}' is $\text{mp}_{\text{OPT}_S \cap \{i \in T_{e'_\ell} \cup T_{e'_r} \mid P(i) \subseteq P\}}$. Each edge e'' chosen subsequently within P has the property that the DP can choose the bonus pair $p_2 := (E_{j''}, L_{\text{int},j''})$ (where as before we assume that e''_ℓ and e''_r are the leftmost and rightmost edges of $E_{j''}$, respectively) from OPT_B containing e'' and a feasible choice of \hat{u}' is $\text{mp}_{\text{OPT}_S \cap \{i \in T_{e'_\ell} \cup T_{e'_r} \setminus (T_{e''_\ell} \cup T_{e''_r}) \mid P(i) \subseteq P\}}$. Observe that all tasks $\{i \in \text{OPT}_S \cap (T_{e'_\ell} \cup T_{e'_r} \cup T_{e''_\ell} \cup T_{e''_r}) \mid P(i) \subseteq P\}$ fit into the combined profiles, we select all tasks specified in p_1 and p_2 , and all remaining tasks from OPT within P will be available in sub-problems. The DP collects a profit of at least $(1 - \epsilon)w(\{i \in \text{OPT}_S \cap (T_{e'_\ell} \cup T_{e'_r} \cup T_{e''_\ell} \cup T_{e''_r}) \mid P(i) \subseteq P\}) + w(\{i \in \text{OPT}_L \cap (T_{e'_\ell} \cup T_{e'_r} \cup T_{e''_\ell} \cup T_{e''_r}) \setminus L \mid P(i) \subseteq P\}) + \text{bn}(p_1) + \text{bn}(p_2)$. We inductively conclude that if all choices as described above are feasible, the DP obtains a profit of at least $(1 - \epsilon)w(\text{OPT}_S) + w(\text{OPT}_L) + w(\text{OPT}_B)$.

To show feasibility, we have to argue that none of the described choices exceeds the overall capacity of $u(f) + \delta b$ for an edge $f \in E$. The argument is analogous to the proof of Lemma 8. \blacktriangleleft

Together with Lemma 13 we conclude that we obtain a $(1 - \epsilon, 1, 1)$ -approximation algorithm for BUFP with δ -resource augmentation.

Quantum Sub-Gaussian Mean Estimator

Yassine Hamoudi 

Université de Paris, IRIF, CNRS, F-75013 Paris, France

Abstract

We present a new quantum algorithm for estimating the mean of a real-valued random variable obtained as the output of a quantum computation. Our estimator achieves a nearly-optimal quadratic speedup over the number of classical i.i.d. samples needed to estimate the mean of a heavy-tailed distribution with a sub-Gaussian error rate. This result subsumes (up to logarithmic factors) earlier works on the mean estimation problem that were not optimal for heavy-tailed distributions [9, 8], or that require prior information on the variance [23, 32, 22]. As an application, we obtain new quantum algorithms for the (ϵ, δ) -approximation problem with an optimal dependence on the coefficient of variation of the input random variable.

1 Introduction

The problem of estimating the mean μ of a real-valued random variable X given *i.i.d.* samples from it is one of the most basic tasks in statistics and in the Monte Carlo method. The properties of the various classical *mean estimators* are well understood. The standard non-asymptotic criterion used to assess the quality of an estimator is formulated as the following *high probability deviation bound*: upon performing n random experiments that return n samples from X , and given a failure probability $\delta \in (0, 1)$, what is the smallest error $\epsilon(n, \delta, X)$ such that the output $\tilde{\mu}$ of the estimator satisfies $|\tilde{\mu} - \mu| > \epsilon(n, \delta, X)$ with probability at most δ ? Under the standard assumption that the unknown random variable X has a finite variance σ^2 , the best possible performances are obtained by the so-called *sub-Gaussian estimators* [30] that achieve the following deviation bound

$$\Pr \left[|\tilde{\mu} - \mu| > L \sqrt{\frac{\sigma^2 \log(1/\delta)}{n}} \right] \leq \delta \quad (1)$$

for some constant L . The term “sub-Gaussian” reflects that these estimators have a Gaussian tail even for non-Gaussian distributions. The most well-known sub-Gaussian estimator is arguably the *median-of-means* [35, 27, 2], which consists of partitioning the n samples into roughly $\log(1/\delta)$ groups of equal size, computing the empirical mean over each group, and returning the median of the obtained means.

The process of generating a random sample from X is generalized in the quantum model by assuming the existence of a unitary operator U where $U|0\rangle$ coherently encodes the distribution of X . A *quantum experiment* is then defined as one application of this operator or its inverse. The celebrated quantum amplitude estimation algorithm [9] provides a way to estimate the mean of any *Bernoulli* random variable by performing fewer experiments

than with any classical estimator. Yet, for general distributions, the existing quantum mean estimators either require additional information on the variance [23, 32, 22] or are less performant than the classical sub-Gaussian estimators when the distribution is heavy tailed [9, 38, 8, 32]. These results leave open the existence of a general quantum speedup for the mean estimation problem. We address this question by introducing the concept of *quantum sub-Gaussian estimators*, defined through the following deviation bound

$$\Pr\left[|\tilde{\mu} - \mu| > L \frac{\sigma \log(1/\delta)}{n}\right] \leq \delta \quad (2)$$

for some constant L . We give the first construction of a quantum estimator that achieves this bound up to a logarithmic factor in n . Additionally, we prove that it is impossible to go below that deviation level. This result provides a clear equivalent of the concept of sub-Gaussian estimator in the quantum setting.

A second important family of mean estimators addresses the (ϵ, δ) -approximation problem, where given a fixed relative error $\epsilon \in (0, 1)$ and a failure probability $\delta \in (0, 1)$ the goal is to output a mean estimate $\tilde{\mu}$ such that

$$\Pr[|\tilde{\mu} - \mu| > \epsilon|\mu|] \leq \delta. \quad (3)$$

The aforementioned sub-Gaussian estimators do not quite answer this question since the number of experiments they require (respectively $n = \Omega((\frac{\sigma}{\epsilon\mu})^2 \log(1/\delta))$ and $n = \tilde{\Omega}(\frac{\sigma}{\epsilon|\mu|} \log(1/\delta))$) depends on the *unknown* quantities σ and μ . Sometimes a good upper bound is known on the *coefficient of variation* $|\sigma/\mu|$ and can be used to parametrize a sub-Gaussian estimator. Otherwise, the standard approach is based on *sequential analysis* techniques, where the number of experiments is chosen adaptively depending on the results of previous computations. Given a random variable distributed in $[0, 1]$, the optimal classical estimators perform $\Theta((\frac{\sigma}{\epsilon\mu})^2 + \frac{1}{\epsilon\mu}) \log(1/\delta)$ random experiments *in expectation* [17] for computing an (ϵ, δ) -approximation of μ . We construct a quantum estimator that reduces this number to $\tilde{\Theta}((\frac{\sigma}{\epsilon\mu} + \frac{1}{\sqrt{\epsilon\mu}}) \log(1/\delta))$ and we prove that it is optimal.

1.1 Related work

There is an extensive literature on classical sub-Gaussian estimators and we refer the reader to [30, 15, 12, 18, 28] for an overview of the main results and recent improvements. We point out that the *empirical mean* estimator is not sub-Gaussian, although it is optimal for Gaussian random variables [37, 15]. The non-asymptotic performances of the empirical mean estimator are captured by several standard concentration bounds such as the Chebyshev, Chernoff and Bernstein inequalities.

There is a series of quantum mean estimators [21, 1, 8] that get close to the bound $\Pr\left[|\tilde{\mu} - \mu| > L \frac{\log(1/\delta)}{n}\right] \leq \delta$ for any random variable distributed in $[0, 1]$ and some constant L . Similar results hold for numerical integration problems [1, 36, 23, 39, 24]. The amplitude estimation algorithm [9, 38] leads to a sharper bound of $\Pr\left[|\tilde{\mu} - \mu| > L\left(\frac{\sqrt{\mu(1-\mu)} \log(1/\delta)}{n} + \frac{\log(1/\delta)^2}{n^2}\right)\right] \leq \delta$ (see Proposition 12) when X is distributed in $[0, 1]$. Nevertheless, the quantity $\mu(1-\mu)$ is always larger than or equal to the variance σ^2 . The question of improving the dependence on σ^2 was considered in [23, 32, 22]. The estimators of [23, 32] require to know an upper bound Σ on the standard deviation σ , whereas [22] needs an upper bound Δ on the coefficient of variation σ/μ (for non-negative random variables). The performances of these estimators are captured (up to logarithmic factors) by the deviation bound given in Equation (2) with σ replaced by Σ and $\mu\Delta$ respectively.

The (ϵ, δ) -approximation problem has been addressed by several classical works such as [17, 31, 20, 26]. In the quantum setting, there is a variant [9, Theorem 15] of the amplitude estimation algorithm that performs $O(\log(1/\delta)/(\epsilon\sqrt{\mu}))$ experiments in expectation to compute an (ϵ, δ) -approximate of the mean of a random variable distributed in $[0, 1]$ (see Theorem 7 and Proposition 15). However, the complexity of this estimator does not scale with σ . Given an upper bound Δ on σ/μ , the estimator of [22] can be used to compute an (ϵ, δ) -approximate with roughly $\tilde{O}(\Delta \log(1/\delta)/\epsilon)$ quantum experiments if the random variable is non-negative.

We note that the related problem of estimating the mean with *additive* error ϵ , that is $\Pr[|\tilde{\mu} - \mu| > \epsilon] \leq \delta$, has also been considered by several authors. The optimal number of experiments is $\Theta(\log(1/\delta)/\epsilon^2)$ classically [14] and $\Theta(1/\epsilon)$ quantumly [34] (with failure probability $\delta = 1/3$). These bounds do not depend on unknown parameters (as opposed to the relative error case), thus sequential analysis techniques are unnecessary here. Montanaro [32] also described an estimator that performs $\tilde{O}(\Sigma \log(1/\delta)/\epsilon)$ quantum experiments given an upper bound Σ on the standard deviation σ .

1.2 Contributions and organization

We first formally define the input model in Section 2.1. We introduce the concept of “q-random variable” (Definition 3) to describe a random variable that corresponds to the output of a quantum computation. We measure the complexity of an algorithm by counting the number of *quantum experiments* (Definition 4) it performs with respect to a q-random variable. We also introduce some needed tools in Section 2.2. Next, we construct a quantum algorithm for estimating the quantiles of a q-random variable in Section 3, and we use it in Section 4 to design the following quantum sub-Gaussian estimator.

Theorem 13 (Restated). *There exists a quantum algorithm with the following properties. Let X be a q-random variable with mean μ and variance σ^2 , and set as input a time parameter n and a real $\delta \in (0, 1)$ such that $n \geq \log(1/\delta)$. Then, the algorithm outputs a mean estimate $\tilde{\mu}$ such that $\Pr\left[|\tilde{\mu} - \mu| > \frac{\sigma \log(1/\delta)}{n}\right] \leq \delta$ and it performs $O(n \log^{3/2}(n) \log \log(n))$ quantum experiments.*

Then we turn our attention to the (ϵ, δ) -approximation problem in Section 5. In case we have an upper bound Δ on the coefficient of variation $|\sigma/\mu|$, we directly use our sub-Gaussian estimator to obtain an algorithm that performs $\tilde{O}(\frac{\Delta}{\epsilon} \log(1/\delta))$ quantum experiments (Corollary 14). Next, we consider the more subtle parameter-free setting where there is no prior information about the input random variable, except that it is distributed in $[0, 1]$. In this case, the number of experiments is chosen *adaptively*, and the bound we get is stated in expectation.

Theorem 16 (Restated). *There exists a quantum algorithm with the following properties. Let X be a q-random variable distributed in $[0, 1]$ with mean μ and variance σ^2 , and set as input two reals $\epsilon, \delta \in (0, 1)$. Then, the algorithm outputs a mean estimate $\tilde{\mu}$ such that $\Pr[|\tilde{\mu} - \mu| > \epsilon\mu] \leq \delta$, and it performs $\tilde{O}\left(\left(\frac{\sigma}{\epsilon\mu} + \frac{1}{\sqrt{\epsilon\mu}}\right) \log(1/\delta)\right)$ quantum experiments in expectation.*

Finally, we prove several lower bounds in Section 6 that match the complexity of the above estimators. We also consider the weaker input model where one is given copies of a quantum state encoding the distribution of X . We prove that no quantum speedup is achievable in this setting (Theorem 22).

1.3 Proof overview

Sub-Gaussian estimator. Our approach (Theorem 13) combines several ideas used in previous classical and quantum mean estimators. In this section, we simplify the exposition by assuming that the random variable X is non-negative and by replacing the variance σ^2 with the second moment $\mathbb{E}[X^2]$. We also take the failure probability δ to be a small constant. Our starting point is a variant of the *truncated mean estimators* [6, 12, 30]. Truncation is a process that consists of replacing the samples larger than some threshold value with a smaller number. This has the effect of reducing the tail of the distribution, but also of changing its expectation. Here we study the effect of replacing the values larger than some threshold b with 0, which corresponds to the new random variable $Y = X \mathbb{1}_{X \leq b}$. We consider the following classical sub-Gaussian estimator that we were not able to find in the literature: set $b = \sqrt{n\mathbb{E}[X^2]}$ and compute the empirical mean of n samples from Y . By a simple calculation, one can prove that the expectation of the removed part is at most $\mathbb{E}[X - Y] \leq \mathbb{E}[X^2]/b = \sqrt{\mathbb{E}[X^2]}/n$. Moreover, using Bernstein's inequality and the boundedness of Y , the error between the output estimate and $\mathbb{E}[Y]$ is on the order of $\sqrt{\mathbb{E}[X^2]}/n$. These two facts together imply that the overall error for estimating $\mathbb{E}[X]$ is indeed of a sub-Gaussian type. This approach can be carried out in the quantum model by performing the truncation in superposition. This is similar to what is done in previous quantum mean estimators [23, 32, 22]. In order to obtain a quantum speedup, one must balance the truncation level differently by taking $b = n\sqrt{\mathbb{E}[X^2]}$. Then, by a clever use of amplitude estimation discovered by Heinrich [23], the expectation of Y can be estimated with an error on the order of $\sqrt{\mathbb{E}[X^2]}/n$. The main drawback of this estimator is that it requires the knowledge of $\mathbb{E}[X^2]$ to perform the truncation. In previous work [23, 32, 22], the authors made further assumptions on the variance to be able to approximate b . Here, we overcome this issue by choosing the truncation level b differently. Borrowing ideas from classical estimators [30], we define b as the quantile value that satisfies $\Pr[X \geq b] = 1/n^2$. This quantile is always smaller than the previous threshold value $n\sqrt{\mathbb{E}[X^2]}$. Moreover, it can be shown that the removed part $\mathbb{E}[X - Y]$ is still on the order of $\sqrt{\mathbb{E}[X^2]}/n$. We give a new quantum algorithm for approximating this quantile with roughly n quantum experiments (Theorem 11), whereas it would require n^2 random experiments classically. Our quantile estimation algorithm builds upon the quantum minimum finding algorithm of Dürr and Høyer [19, 3] and the k th-smallest element finding algorithm of Nayak and Wu [34]. Importantly, it does not require any knowledge about $\mathbb{E}[X^2]$.

(ϵ, δ) -Approximation without side information. We follow an approach similar to that of a classical estimator described in [17]. Our algorithm (Theorem 16) uses the quantum sub-Gaussian estimator and the quantum *sequential Bernoulli estimator* described in Proposition 15. The latter estimator can estimate the mean μ of a random variable X distributed in $[0, 1]$ with constant relative error by performing $O(1/\sqrt{\mu})$ quantum experiments in expectation. The first step of the (ϵ, δ) -approximation algorithm is to compute a rough estimate $\hat{\mu}$ of μ with the sequential Bernoulli estimator. Then, the variance σ^2 of X is estimated by using again the sequential Bernoulli estimator on the random variable $(X - X')/2$ (where X' is an independent copy of X). The latter estimation is stopped if it uses more than $O(1/\sqrt{\epsilon\hat{\mu}})$ quantum experiments. We show that if $\sigma^2 \geq \Omega(\epsilon\mu)$ then the computation is not stopped and the resulting estimate $\tilde{\sigma}^2$ is close to σ^2 with high probability. Otherwise, it is stopped with high probability and we set $\tilde{\sigma} = 0$. Finally, the quantum sub-Gaussian estimator is used with the parameter $n \approx \max\left(\frac{\tilde{\sigma}}{\epsilon\mu}, \frac{1}{\sqrt{\epsilon\mu}}\right)$ to obtain a refined estimate $\tilde{\mu}$ of μ . The choice of the first

(resp. second) term in the maximum value implies that $|\tilde{\mu} - \mu| \leq \epsilon\mu$ with high probability when the variance σ^2 is larger (resp. smaller) than $\epsilon\mu$. In order to upper bound the expected number of experiments performed by this estimator, we show in Proposition 15 that the estimates $\hat{\mu}$ and $\hat{\sigma}$ obtained with the sequential Bernoulli estimator satisfy the expectation bounds $\mathbb{E}[1/\hat{\mu}] \leq 1/\mu$, $\mathbb{E}[\hat{\sigma}] \leq \sigma$ and $\mathbb{E}[1/\sqrt{\hat{\mu}}] \leq 1/\sqrt{\mu}$.

Lower bounds. We sketch the proof of optimality of the quantum sub-Gaussian estimator (Theorem 18). The lower bound is proved in the stronger quantum query model, which allows us to extend it to all the other models mentioned in Section 2.1. Our approach is inspired by the truncation level chosen in the algorithm. Given σ and n , we consider the two distributions p_0 and p_1 that output respectively $\frac{n\sigma}{\sqrt{1-1/n^2}}$ and $\frac{-n\sigma}{\sqrt{1-1/n^2}}$ with probability $1/n^2$, and 0 otherwise. The two distributions have variance σ^2 and the distance between their means is larger than $\frac{2\sigma}{n}$. Thus, any estimator that satisfies the bound $\Pr[|\tilde{\mu} - \mu| > \frac{\sigma}{n}] \leq \frac{1}{3}$ can distinguish between p_0 and p_1 with constant success probability. However, we show by a reduction to Quantum Search that it requires at least $\Omega(n)$ quantum experiments to distinguish between two distributions that differ with probability at most $1/n^2$.

2 Preliminaries

2.1 Model of input

The input to the mean estimation problem is represented by a real-valued random variable X defined on some probability space. A classical estimator accesses this input by obtaining n *i.i.d* samples of X . In this section, we describe the access model for quantum estimators and we compare it to previous models suggested in the literature. We only consider finite probability spaces for finite encoding reasons. First, we recall the definition of a random variable, and we define a classical model of access called a *random experiment*.

► **Definition 1** (RANDOM VARIABLE). A finite random variable is a function $X : \Omega \rightarrow E$ for some probability space (Ω, p) , where Ω is a finite sample set, $p : \Omega \rightarrow [0, 1]$ is a probability mass function and $E \subset \mathbb{R}$ is the support of X . As is customary, we will often omit to mention (Ω, p) when referring to the random variable X .

► **Definition 2** (RANDOM EXPERIMENT). Given a random variable X on a probability space (Ω, p) , we define a random experiment as the process of drawing a sample $\omega \in \Omega$ according to p and observing the value of $X(\omega)$.

We now introduce the concept of “q-random variable” to represent a quantum process that outputs a real number.

► **Definition 3** (Q-RANDOM VARIABLE). A q-variable is a triple (\mathcal{H}, U, M) where \mathcal{H} is a finite-dimensional Hilbert space, U is a unitary transformation on \mathcal{H} , and $M = \{M_x\}_{x \in E}$ is a projective measurement on \mathcal{H} indexed by a finite set $E \subset \mathbb{R}$. Given a random variable X on a probability space (Ω, p) , we say that a q-variable (\mathcal{H}, U, M) generates X when,

1. \mathcal{H} is a finite-dimensional Hilbert space with some basis $\{|\omega\rangle\}_{\omega \in \Omega}$ indexed by Ω .
 2. U is a unitary transformation on \mathcal{H} such that $U|0\rangle = \sum_{\omega \in \Omega} \sqrt{p(\omega)}|\omega\rangle$.
 3. $M = \{M_x\}_x$ is the projective measurement on \mathcal{H} defined by $M_x = \sum_{\omega: X(\omega)=x} |\omega\rangle\langle\omega|$.
- A random variable X is a q-random variable if it is generated by some q-variable (\mathcal{H}, U, M) .

We stress that the sample space Ω may not be known explicitly, and we do not assume that it is easy to perform a measurement in the $\{|\omega\rangle\}_{\omega \in \Omega}$ basis for instance. Often, we are given a unitary U such that $U|0\rangle = \sum_{x \in E} \sqrt{p(x)}|\psi_x\rangle|x\rangle$ for some unknown garbage unit

state $|\psi_x\rangle$, together with the measurement $M = \{I \otimes |x\rangle\langle x|\}_{x \in E}$. In this case, we can consider the q-random variable X defined on the probability space (Ω, p) where $\Omega = \{|\psi_x\rangle|x\rangle\}_{x \in E}$ and $X(|\psi_x\rangle|x\rangle) = x$.

We further assume that there exist two quantum oracles, defined below, for obtaining information on the function $X : \Omega \rightarrow E$. These two oracles can be efficiently implemented if we have access to a quantum evaluation oracle $|\omega\rangle|0\rangle \mapsto |\omega\rangle|X(\omega)\rangle$ for instance. The rotation oracle (Assumption 2) has been extensively used in previous quantum mean estimators [38, 8, 32, 22]. The comparison oracle (Assumption 1) is needed in our work to implement the quantile estimation algorithm.

► **Assumption 1** (COMPARISON ORACLE). Given a q-random variable X on a probability space (Ω, p) , and any two values $a, b \in \mathbb{R} \cup \{-\infty, +\infty\}$ such that $a < b$, there is a unitary operator $C_{a,b}$ acting on $\mathcal{H} \otimes \mathbb{C}^2$ such that for all $\omega \in \Omega$,

$$C_{a,b}(|\omega\rangle|0\rangle) = \begin{cases} |\omega\rangle|1\rangle & \text{when } a < X(\omega) \leq b, \\ |\omega\rangle|0\rangle & \text{otherwise.} \end{cases}$$

► **Assumption 2** (ROTATION ORACLE). Given a q-random variable X on a probability space (Ω, p) , and any two values $a, b \in \mathbb{R} \cup \{-\infty, +\infty\}$ such that $a < b$, there is a unitary operator $R_{a,b}$ acting on $\mathcal{H} \otimes \mathbb{C}^2$ such that for all $\omega \in \Omega$,

$$R_{a,b}(|\omega\rangle|0\rangle) = \begin{cases} |\omega\rangle \left(\sqrt{1 - \left| \frac{X(\omega)}{b} \right|} |0\rangle + \sqrt{\left| \frac{X(\omega)}{b} \right|} |1\rangle \right) & \text{when } a < X(\omega) \leq b, \\ |\omega\rangle|0\rangle & \text{otherwise.} \end{cases}$$

We now define the measure of complexity used to count the number of accesses to a q-random variable, which are referred to as *quantum experiments*.

► **Definition 4** (QUANTUM EXPERIMENT). Let X be a q-random variable that satisfies Assumptions 1 and 2. Let (\mathcal{H}, U, M) be a q-variable that generates X . We define a quantum experiment as the process of applying any of the unitaries U , $C_{a,b}$, $R_{a,b}$ (for any values of $a < b$), their inverses or their controlled versions, or performing a measurement according to M .

Note that a random experiment (Definition 2) can be simulated with two quantum experiments by computing the state $U|0\rangle$ and measuring it according to M . We briefly mention two other possible input models. First, some authors [21, 34, 23, 10, 16, 8, 29] consider the stronger query model where p is the uniform distribution and a quantum evaluation oracle is provided for the function $\omega \mapsto X(\omega)$. A second model tackles the problem of *learning from quantum states* [11, 5, 4], where the input consists of several copies of $\sum_{x \in E} \sqrt{\Pr[X = x]}|x\rangle$ (we do not have access to a unitary preparing that state). We show in Theorem 22 that no quantum speedup is achievable for our problem in the latter setting.

2.2 Tools

We will use a variant of the amplitude amplification algorithm that does not need a time parameter n as input. We call it the “sequential amplitude amplification” algorithm in reference to *sequential analysis*. The original version of this algorithm was analysed in Theorem 3 of [7, 9], with a bound on the expected complexity $\mathbb{E}[T]$. We propose a slightly different version that allows us to bound $\mathbb{E}[T^2]$ and $\mathbb{E}[1/T]$ (note that $\mathbb{E}[T] \leq \sqrt{\mathbb{E}[T^2]}$). The algorithm and its analysis are deferred to the extended version of this paper.

► **Theorem 5** (SEQUENTIAL AMPLITUDE AMPLIFICATION). *Let U be a unitary quantum algorithm and let Π be a projection operator. Define the number $p \in [0, 1]$ and the two unit states $|\psi_0\rangle, |\psi_1\rangle$ such that $U|0\rangle = \sqrt{1-p}|\psi_0\rangle + \sqrt{p}|\psi_1\rangle$ and $\Pi U|0\rangle = \sqrt{p}|\psi_1\rangle$. If $p > 0$ then the sequential amplitude amplification algorithm $\text{Seq-AAmp}(U, \Pi)$ outputs the state $|\psi_1\rangle$ with probability 1. Moreover, if we let T denote the number of applications of U , U^\dagger and $I - 2\Pi$ used by the algorithm, then $\mathbb{E}[T^2] \leq O(1/p)$ and $\mathbb{E}[1/T] \leq O(\sqrt{p})$.*

The next result is a generalization of Quantum Counting that corresponds to Theorems 11 and 12 in [9].

► **Theorem 6** (AMPLITUDE ESTIMATION, [9]). *Let U be a unitary quantum algorithm and let Π be a projection operator. Define the number $p \in [0, 1]$ such that $p = \|\Pi U|0\rangle\|^2$. Then, for any integer $n \geq 0$, the amplitude estimation algorithm $\text{AEst}(U, \Pi, n)$ outputs an amplitude estimate \tilde{p} such that, $\Pr\left[|\tilde{p} - p| \leq \frac{2\pi\sqrt{p(1-p)}}{n} + \frac{\pi^2}{n^2}\right] \geq 8/\pi^2$. The algorithm uses n applications of U , U^\dagger , $I - 2\Pi$ and $O(\log^2(n))$ 2-qubit quantum gates.*

We will also use a sequential version of the amplitude estimation algorithm that does not need a time parameter n as input. This result was first obtained by [9, Theorem 15]. We describe a variant with additional properties that is based on the sequential amplitude amplification algorithm.

► **Theorem 7** (SEQUENTIAL AMPLITUDE ESTIMATION). *There exists an algorithm, called the sequential amplitude estimation algorithm Seq-AEst , with the following properties. Let U be a unitary quantum algorithm and let Π be a projection operator. Define the number $p \in [0, 1]$ such that $p = \|\Pi U|0\rangle\|^2$. Then, the algorithm $\text{Seq-AEst}(U, \Pi)$ outputs an amplitude estimate \tilde{p} and uses a number T of applications of U , U^\dagger , $I - 2\Pi$ such that,*

1. *There is a universal constant $c \in (0, 1)$ such that $\Pr[|\tilde{p} - p| \leq cp] \geq 7/8$.*
2. *There is a universal constant c' such that $\mathbb{E}[T^2] = \mathbb{E}[1/\tilde{p}] \leq c'/p$.*
3. *There is a universal constant c'' such that $\mathbb{E}[1/T] = \mathbb{E}[\sqrt{\tilde{p}}] \leq c''\sqrt{p}$.*

Proof. The algorithm $\text{Seq-AEst}(U, \Pi)$ consists of recording the number T of applications of U , U^\dagger , $I - 2\Pi$ used by the sequential amplitude amplification algorithm $\text{Seq-AAmp}(U, \Pi)$ (Theorem 5), and choosing the estimate $\tilde{p} = 1/T^2$. The results follow immediately from Theorem 5 and Markov's inequality. ◀

3 Quantile estimation

In this section, we present a quantum algorithm for estimating the quantiles of a finite random variable X . This is a key ingredient for the sub-Gaussian estimator of Section 4. For the convenience of reading, we define a quantile in the following non-standard way (the cumulative distribution function is replaced with its complement).

► **Definition 8** (QUANTILE). *Given a discrete random variable X and a real $p \in [0, 1]$, the quantile of order p is the number $Q(p) = \sup\{x \in \mathbb{R} : \Pr[X \geq x] \geq p\}$.*

Our result is inspired by the minimum finding algorithm of Dürr and Høyer [19] and its generalization in [3]. The problem of estimating the quantiles of a set of numbers under the uniform distribution was studied before by Nayak and Wu [34, 33]. We differ from that work by allowing arbitrary distributions, and by not using the amplitude estimation algorithm. On the other hand, we restrict ourselves to finding a constant factor estimate, whereas [34, 33] can achieve any wanted accuracy.

The idea behind our algorithm is rather simple: if we compute a sequence of values $-\infty = y_0 \leq y_1 \leq y_2 \leq y_3 \leq \dots$ where each y_{j+1} is sampled from the distribution of X conditioned on $y_{j+1} \geq y_j$, then when $j \simeq \log(1/p)$ the value of y_j should be close to the quantile $Q(p)$. The complexity of sampling each y_j is on the order of $1/\Pr[X \geq y_j]$ classically, but it can be done quadratically faster in the quantum setting. We analyze a slightly different algorithm, where the sequence of samples is strictly increasing and instead of stopping after roughly $\log(1/p)$ iterations we count the number of experiments performed by the algorithm and stop when it reaches a value close to $1/\sqrt{p}$. This requires showing that the times T_j spent on sampling y_j is neither too large nor too small with high probability, which is proved in the next lemma.

► **Lemma 9.** *There is a quantum algorithm such that, given a q -random variable X and a value $x \in \mathbb{R} \cup \{-\infty, +\infty\}$, it outputs a sample y from the probability distribution of X conditioned on $y > x$. If we let T denote the number of quantum experiments performed by this algorithm, then there exist two universal constants $c_0 < c_1$ such that $\mathbb{E}[T] \leq c_1/\sqrt{\Pr[X > x]}$ and $\Pr[T < c_0/\sqrt{\Pr[X > x]}] \leq 1/10$.*

Proof. Let (\mathcal{H}, U, M) be a q -variable generating X . We use the comparison oracle $C_{x,+\infty}$ from Assumption 1 to construct the unitary $V = C_{x,+\infty}(U \otimes I)$ acting on $\mathcal{H} \otimes \mathbb{C}^2$. By definition of $C_{x,+\infty}$ and U (Section 2.1), we have that $V|0\rangle = \sum_{\omega \in \Omega: X(\omega) \leq x} \sqrt{p(\omega)}|\omega\rangle|0\rangle + \sum_{\omega \in \Omega: X(\omega) > x} \sqrt{p(\omega)}|\omega\rangle|1\rangle = \sqrt{1 - \Pr[X > x]}|\phi_0\rangle|0\rangle + \sqrt{\Pr[X > x]}|\phi_1\rangle|1\rangle$ for some unit states $|\phi_0\rangle, |\phi_1\rangle$ where $|\phi_1\rangle = \frac{1}{\sqrt{\Pr[X > x]}} \sum_{\omega: X(\omega) > x} \sqrt{p(\omega)}|\omega\rangle$. The algorithm for sampling y conditioned on $y > x$ consists of two steps. First, we use the sequential amplitude amplification algorithm **Seq-AAmp**($V, I \otimes |1\rangle\langle 1|$) from Theorem 5 on V to obtain the state $|\phi_1\rangle$. Next, we measure $|\phi_1\rangle$ according to M . The claimed properties follow directly from Theorem 5. ◀

We use the next formula for the probability that a value x occurs in the sequence $(y_j)_j$ defined before. This lemma is adapted from [19, Lemma 1].

► **Lemma 10** (Lemma 47 in [3]). *Let X be a discrete random variable. Consider the increasing sequence of random variables Y_0, Y_1, Y_2, \dots where Y_0 is a fixed value and Y_{j+1} for $j \geq 0$ is a sample drawn from X conditioned on $Y_{j+1} > Y_j$. Then, for any $x, y \in \mathbb{R}$,*

$$\Pr[x \in \{Y_1, Y_2, \dots\} \mid Y_0 = y] = \begin{cases} \Pr[X = x \mid X \geq x] & \text{when } x > y, \\ 0 & \text{otherwise.} \end{cases}$$

The quantile estimation algorithm is described in Algorithm 1 and the analysis is detailed in the extended version of this paper.

■ **Algorithm 1** Quantile estimation algorithm, $\text{Quantile}(X, p, \delta)$.

-
1. Repeat the following steps for $i = 1, 2, \dots, \lceil 6 \log(1/\delta) \rceil$.
 - a. Set $y_0 = -\infty$ and initialize a counter $C = 0$ that is incremented each time a quantum experiment is performed.
 - b. Set $j = 1$. Repeat the following process and interrupt it when $C = c'/\sqrt{p}$ (where c' is a constant chosen in the proof of Theorem 11): sample an element y_{j+1} from X conditioned on $y_{j+1} > y_j$ by using the algorithm of Lemma 9, set $j \leftarrow j + 1$.
 - c. Set $\tilde{Q}^{(i)} = y_j$.
 2. Output $\tilde{Q} = \text{median}(\tilde{Q}^{(1)}, \dots, \tilde{Q}^{(\lceil 6 \log(1/\delta) \rceil)})$.
-

► **Theorem 11** (QUANTILE ESTIMATION). *Let X be a q -random variable. Given two reals $p, \delta \in (0, 1)$, the approximate quantile \tilde{Q} produced by the quantile estimation algorithm $\text{Quantile}(X, p, \delta)$ (Algorithm 1) satisfies $Q(p) \leq \tilde{Q} \leq Q(cp)$ with probability at least $1 - \delta$, where $c < 1$ is a universal constant. The algorithm performs $O\left(\frac{\log(1/\delta)}{\sqrt{p}}\right)$ quantum experiments.*

4 Sub-Gaussian estimator

In this section, we present the main quantum algorithm for estimating the mean of a random variable with a near-quadratic speedup over the classical sub-Gaussian estimators. Our result uses the following *Bernoulli estimator*, which is a well-known adaptation of the amplitude estimation algorithm to the mean estimation problem [9, 38, 32]. The Bernoulli estimator allows us to estimate the mean of the truncated random variable $X \mathbb{1}_{a < X \leq b}$ for any a, b .

► **Proposition 12** (BERNOULLI ESTIMATOR). *There exists a quantum algorithm, called the Bernoulli estimator, with the following properties. Let X be a q -random variable and set as input a time parameter $n \geq 0$, two range values $0 \leq a < b$, and a real $\delta \in (0, 1)$ such that $n \geq \log(1/\delta)$. Then, the Bernoulli estimator $\text{BernEst}(X, n, a, b, \delta)$ outputs a mean estimate $\tilde{\mu}_{a,b}$ of $\mu_{a,b} = \mathbb{E}[X \mathbb{1}_{a < X \leq b}]$ such that $|\tilde{\mu}_{a,b} - \mu_{a,b}| \leq \frac{\sqrt{b\mu_{a,b} \log(1/\delta)}}{n} + \frac{b \log(1/\delta)^2}{n^2}$. It performs $O(n)$ quantum experiments.*

Proof. Let (\mathcal{H}, U, M) be a q -variable generating X . Using the rotation oracle $R_{a,b}$ from Assumption 2, we define the unitary algorithm $V = R_{a,b}(U \otimes I)$ acting on $\mathcal{H} \otimes \mathbb{C}^2$. In order to simplify notations, let us first assume that the random variable X is only distributed in the interval (a, b) . Then, we have $\mu = \mu_{a,b}$ and by definition of $R_{a,b}$ and U (Section 2.1) the operator V satisfies that $V|0\rangle = \sum_{\omega \in \Omega} \sqrt{p(\omega)} |\omega\rangle \left(\sqrt{1 - \frac{X(\omega)}{b}} |0\rangle + \sqrt{\frac{X(\omega)}{b}} |1\rangle \right) = \sqrt{1 - \frac{\mu}{b}} \left(\sum_{\omega \in \Omega} \sqrt{\frac{p(\omega)(b-X(\omega))}{b-\mu}} |\omega\rangle \right) |0\rangle + \sqrt{\frac{\mu}{b}} \left(\sum_{\omega \in \Omega} \sqrt{\frac{p(\omega)X(\omega)}{\mu}} |\omega\rangle \right) |1\rangle$. Thus, there exist some unit states $|\psi_0\rangle, |\psi_1\rangle$ such that $V|0\rangle = \sqrt{1 - \frac{\mu}{b}} |\psi_0\rangle + \sqrt{\frac{\mu}{b}} |\psi_1\rangle$ and $(I \otimes |1\rangle\langle 1|)V|0\rangle = \sqrt{\frac{\mu}{b}} |\psi_1\rangle$. If X takes values outside the interval (a, b) then the same result holds with $\mu_{a,b}$ in place of μ and a different definition of $|\psi_0\rangle, |\psi_1\rangle$.

Consider the output \tilde{v} of the amplitude estimation algorithm $\text{AEst}(V, \Pi, \lceil \frac{2\pi n}{\log(1/\delta)} \rceil)$ (Theorem 6) where $\Pi = I \otimes |1\rangle\langle 1|$. Then, the estimate $b\tilde{v}$ satisfies the statement of the proposition with probability $8/\pi^2$ by Theorem 6. The Bernoulli estimator consists of running $\lceil 6 \log(1/\delta) \rceil$ copies of $\text{AEst}(V, \Pi, \lceil \frac{2\pi n}{\log(1/\delta)} \rceil)$ and outputting the median of the results. The success probability is at least $1 - \delta$ by the Chernoff bound. ◀

The Bernoulli estimator can estimate the mean of a non-negative q -random variable X by setting $a = 0$ and $b = \max X$. However, its performance is worse than that of the classical sub-Gaussian estimators when the maximum of X is large compared to its variance. Our quantum sub-Gaussian estimator (Algorithm 2) uses the Bernoulli estimator in a more subtle way, and in combination with the quantile estimation algorithm.

► **Theorem 13** (SUB-GAUSSIAN ESTIMATOR). *Let X be a q -random variable with mean μ and variance σ^2 . Given a time parameter n and a real $\delta \in (0, 1)$ such that $n \geq \log(1/\delta)$, the sub-Gaussian estimator $\text{SubGaussEst}(X, n, \delta)$ (Algorithm 2) outputs a mean estimate $\tilde{\mu}$ such that, $\Pr\left[|\tilde{\mu} - \mu| \leq \frac{\sigma \log(1/\delta)}{n}\right] \geq 1 - \delta$. The algorithm performs $O(n \log^{3/2}(n) \log \log(n))$ quantum experiments.*

■ **Algorithm 2** Sub-Gaussian estimator, $\text{SubGaussEst}(X, n, \delta)$.

1. Set $k = \log n$ and $m = dn\sqrt{\log n} \frac{\log(9k/\delta)}{\log(1/\delta)}$, where $d > 1$ is a constant chosen in the proof of Theorem 13 (if k is not an integer, round n to the next power of two).
2. Compute the median η of $\lceil 30 \log(2/\delta) \rceil$ classical samples from X and define the non-negative random variables

$$Y^+ = (X - \eta) \mathbb{1}_{X \geq \eta} \quad \text{and} \quad Y^- = -(X - \eta) \mathbb{1}_{X \leq \eta}.$$

3. Compute an estimate $\tilde{\mu}_{Y^+}$ of $\mathbb{E}[Y^+]$ and an estimate $\tilde{\mu}_{Y^-}$ of $\mathbb{E}[Y^-]$ by executing the following steps with $Y := Y_+$ and $Y := Y_-$ respectively:
 - a. Compute an estimate \tilde{Q} of the quantile of order $p = \left(\frac{\log(1/\delta)}{6n}\right)^2$ of Y with failure probability $\delta/8$ by using the quantile estimation algorithm $\text{Quantile}(Y, p, \delta/8)$.
 - b. Define $a_{-1} = 0$ and $a_\ell = \frac{2^\ell}{n} \tilde{Q}$ for $\ell \geq 0$. Compute an estimate $\tilde{\mu}_\ell$ of $\mathbb{E}[Y \mathbb{1}_{a_{\ell-1} < Y \leq a_\ell}]$ with failure probability $\delta/(9k)$ for each $0 \leq \ell \leq k$, by using the Bernoulli estimator $\text{BernEst}(Y, m, a_{\ell-1}, a_\ell, \delta/(9k))$ with m quantum experiments.
 - c. Set $\tilde{\mu}_Y = \sum_{\ell=0}^k \tilde{\mu}_\ell$.
4. Output $\tilde{\mu} = \eta + \tilde{\mu}_{Y^+} - \tilde{\mu}_{Y^-}$.

Proof. First, by standard concentration inequalities, the median η computed at step 2 satisfies $|\eta - \mu| \leq 2\sigma$ with probability at least $1 - \delta/2$. Moreover, if $|\eta - \mu| \leq 2\sigma$ then $\sqrt{\mathbb{E}[(X - \eta)^2]} = \sqrt{\mathbb{E}[(X - \mu + \mu - \eta)^2]} \leq \sqrt{\mathbb{E}[(X - \mu)^2]} + |\mu - \eta| \leq 3\sigma$, by using the triangle inequality. Below we prove that for any non-negative random variable Y the estimate $\tilde{\mu}_Y$ of $\mu_Y = \mathbb{E}[Y]$ computed at step 3 satisfies

$$|\tilde{\mu}_Y - \mu_Y| \leq \frac{\sqrt{\mathbb{E}[Y^2]} \log(1/\delta)}{5n} \quad (4)$$

with probability at least $1 - \delta/4$. Using the fact that $X = \eta + Y_+ - Y_-$ and $(X - \eta)^2 = Y_+^2 + Y_-^2$, we can conclude that

$$|\tilde{\mu} - \mu| \leq \frac{\left(\sqrt{\mathbb{E}[Y_+^2]} + \sqrt{\mathbb{E}[Y_-^2]}\right) \log(1/\delta)}{5n} \leq \frac{\sqrt{2\mathbb{E}[(X - \eta)^2]} \log(1/\delta)}{5n} \leq \frac{\sigma \log(1/\delta)}{n}$$

with probability at least $1 - \delta$. The algorithm performs $O(\log(1/\delta)) \leq O(n)$ classical experiments during step 2, $O(\log(1/\delta)/\sqrt{p}) \leq O(n)$ quantum experiments during step 3.a, and $O(km) \leq O(n \log^{3/2}(n) \log \log(n))$ quantum experiments during step 3.b.

We now turn to the proof of Equation (4). We make the assumption that all the subroutines used in step 3 are successful, which is the case with probability at least $(1 - \delta/8)(1 - \delta/(9k))^{k+1} \geq 1 - \delta/4$. First, according to Theorem 11, we have $Q(p) \leq \tilde{Q} \leq Q(cp)$ for some universal constant c . It implies that $cp \leq \Pr[Y \geq Q(cp)] \leq \Pr[Y \geq \tilde{Q}] \leq \mathbb{E}[Y^2]/\tilde{Q}^2$, where the first two inequalities are by definition of the quantile function Q , and the last inequality is a standard fact. Consequently, by our choice of p ,

$$\tilde{Q} \leq \frac{6n\sqrt{\mathbb{E}[Y^2]}}{\sqrt{c} \log(1/\delta)}. \quad (5)$$

Next, we upper bound the expectation of the part of Y that is above the largest threshold $a_k = \tilde{Q}$ considered in step 3.b. By Cauchy-Schwarz' inequality, we have $\mathbb{E}[Y \mathbb{1}_{Y > \tilde{Q}}] \leq$

$\sqrt{\mathbb{E}[Y^2] \Pr[Y > \tilde{Q}]}$. Moreover, by definition of Q , $\Pr[Y > \tilde{Q}] \leq \Pr[Y > Q(p)] \leq p$. Thus,

$$\mathbb{E}[Y \mathbb{1}_{Y > \tilde{Q}}] \leq \frac{\sqrt{\mathbb{E}[Y^2] \log(1/\delta)}}{6n}. \quad (6)$$

The expectation of Y is decomposed into the sum $\mu_Y = \sum_{\ell=0}^k \mu_\ell + \mathbb{E}[Y \mathbb{1}_{Y > a_k}]$, where $\mu_\ell = \mathbb{E}[Y \mathbb{1}_{a_{\ell-1} < Y \leq a_\ell}]$ is estimated at step 3.b. We have $|\tilde{\mu}_\ell - \mu_\ell| \leq \frac{\sqrt{a_\ell \mu_\ell} \log(1/\delta)}{dn \sqrt{\log n}} + \frac{a_\ell \log(1/\delta)^2}{d^2 n^2 \log n}$ for all $0 \leq \ell \leq k$ according to Proposition 12. Thus, by the triangle inequality,

$$\begin{aligned} |\tilde{\mu}_Y - \mu_Y| &\leq \sum_{\ell=0}^k |\tilde{\mu}_\ell - \mu_\ell| + \mathbb{E}[Y \mathbb{1}_{Y > a_k}] \\ &\leq \sum_{\ell=0}^k \frac{\sqrt{a_\ell \mu_\ell} \log(1/\delta)}{dn \sqrt{\log n}} + \sum_{\ell=0}^k \frac{a_\ell \log(1/\delta)^2}{d^2 n^2 \log n} + \mathbb{E}[Y \mathbb{1}_{Y > a_k}] \\ &\leq \frac{\tilde{Q} \log(1/\delta)}{dn^2 \sqrt{\log n}} + \sum_{\ell=1}^k \frac{\sqrt{2\mathbb{E}[Y^2 \mathbb{1}_{a_{\ell-1} < Y \leq a_\ell}] \log(1/\delta)}}{dn \sqrt{\log n}} + \frac{2\tilde{Q} \log(1/\delta)^2}{d^2 n^2 \log n} + \mathbb{E}[Y \mathbb{1}_{Y > a_k}] \\ &\leq \frac{\sqrt{2k} \sqrt{\sum_{\ell=1}^k \mathbb{E}[Y^2 \mathbb{1}_{a_{\ell-1} < Y \leq a_\ell}] \log(1/\delta)}}{dn \sqrt{\log n}} + \frac{3\tilde{Q} \log(1/\delta)^2}{dn^2 \sqrt{\log n}} + \mathbb{E}[Y \mathbb{1}_{Y > a_k}] \\ &\leq \frac{\sqrt{2k} \sqrt{\mathbb{E}[Y^2] \log(1/\delta)}}{dn \sqrt{\log n}} + \frac{3\tilde{Q} \log(1/\delta)^2}{dn^2 \sqrt{\log n}} + \mathbb{E}[Y \mathbb{1}_{Y > a_k}] \\ &\leq \frac{\sqrt{2} \sqrt{\mathbb{E}[Y^2] \log(1/\delta)}}{dn} + \frac{18 \sqrt{\mathbb{E}[Y^2] \log(1/\delta)}}{\sqrt{cdn} \sqrt{\log n}} + \frac{\sqrt{\mathbb{E}[Y^2] \log(1/\delta)}}{6n} \\ &\leq \frac{\sqrt{\mathbb{E}[Y^2] \log(1/\delta)}}{5n} \end{aligned}$$

where the third step uses $a_0 \mu_0 \leq a_0^2 = (\tilde{Q}/n)^2$ and $a_\ell \mu_\ell \leq (a_\ell/a_{\ell-1}) \mathbb{E}[Y^2 \mathbb{1}_{a_{\ell-1} < Y \leq a_\ell}] \leq 2\mathbb{E}[Y^2 \mathbb{1}_{a_{\ell-1} < Y \leq a_\ell}]$ when $\ell \geq 1$, the fourth step uses the Cauchy-Schwarz inequality, the sixth step uses Equations (5) and (6), and in the last step we choose $d = 600/\sqrt{c}$. ◀

5 (ϵ, δ) -Estimators

We study the (ϵ, δ) -approximation problem under two different scenarios. First, we consider the case where we know an upper bound Δ on the coefficient of variation $|\sigma/\mu|$. As a direct consequence of Theorem 13 we obtain the following estimator that subsumes a similar result shown in [22] for non-negative random variables.

► **Corollary 14** (Relative estimator). *There exists a quantum algorithm with the following properties. Let X be a q -random variable with mean μ and variance σ^2 , and set as input a value $\Delta \geq |\sigma/\mu|$ and two reals $\epsilon, \delta \in (0, 1)$. Then, the algorithm outputs a mean estimate $\tilde{\mu}$ such that $\Pr[|\tilde{\mu} - \mu| > \epsilon|\mu|] \leq \delta$ and it performs $\tilde{O}(\frac{\Delta}{\epsilon} \log(1/\delta))$ quantum experiments.*

Proof. The algorithm runs the sub-Gaussian estimator $\text{SubGaussEst}(X, \frac{\Delta}{\epsilon} \log(1/\delta), \delta)$. ◀

Next, we construct a parameter-free estimator that performs $\tilde{O}((\frac{\sigma}{\epsilon\mu} + \frac{1}{\sqrt{\epsilon\mu}}) \log(1/\delta))$ quantum experiments in expectation for any random variable distributed in $[0, 1]$. We follow an approach similar to the classical \mathcal{AA} algorithm described in [17]. We first give a sequential estimator that approximates the mean with constant relative error and that performs $O(1/\sqrt{\mu})$ quantum experiments in expectation. We use the term “sequential” in reference to sequential analysis techniques. The classical counterpart of this estimator is the Stopping Rule Algorithm in [17].

► **Proposition 15** (SEQUENTIAL BERNOULLI ESTIMATOR). *There is an algorithm, called the sequential Bernoulli estimator, with the following properties. Let X be a q -random variable distributed in $[0, 1]$ with mean μ . Then, the sequential Bernoulli estimator $\text{Seq-BernEst}(X)$ outputs an estimate $\tilde{\mu}$ and performs a number T of quantum experiments such that,*

1. *There is a universal constant $c \in (0, 1)$ such that $\Pr[|\tilde{\mu} - \mu| \leq c\mu] \geq 7/8$.*
2. *There is a universal constant c' such that $\mathbb{E}[T^2] = \mathbb{E}[1/\tilde{\mu}] \leq c'/\mu$.*
3. *There is a universal constant c'' such that $\mathbb{E}[\sqrt{\tilde{\mu}}] \leq c''\sqrt{\mu}$.*

Proof. The algorithm is identical to the one of Proposition 12 with $a = 0$ and $b = 1$, except that the amplitude estimation algorithm is replaced with the sequential amplitude estimation algorithm (Theorem 7). The algorithm inherits the properties proved in Theorem 7. ◀

The expected number of experiments performed by the sequential Bernoulli estimator is $\mathbb{E}[T] \leq \sqrt{\mathbb{E}[T^2]} \leq 1/\sqrt{\mu}$. The output $\tilde{\mu}$ of the sequential Bernoulli estimator can be used in the Bernoulli estimator (Proposition 12) with parameter $n = 8 \log(1/\delta)/(\epsilon\sqrt{\tilde{\mu}})$ to solve the (ϵ, δ) -approximation problem. However, the expected number of experiments performed with this approach is $O(\log(1/\delta)/(\epsilon\sqrt{\mu}))$. We propose a better algorithm with an improved dependence on ϵ . The algorithm uses the sequential Bernoulli estimator and the sub-Gaussian estimator.

■ **Algorithm 3** Sequential (ϵ, δ) -estimator.

1. For $i = 1, \dots, 32 \log(1/\delta)$:
 - a. Compute an estimate $\tilde{\mu}_X$ of $\mu = \mathbb{E}[X]$ by using the sequential Bernoulli estimator $\text{Seq-BernEst}(X)$ (Proposition 15).
 - b. Let Y denote the random variable $(X - X')^2/2$ where X' is independent from X and identically distributed. Compute an estimate $\tilde{\mu}_Y$ of $\mu_Y = \mathbb{E}[Y]$ by using the sequential Bernoulli estimator $\text{Seq-BernEst}(Y)$ (Proposition 15). Stop the computation if it performs more than $\frac{c_1}{\sqrt{\epsilon\mu_X}}$ quantum experiments (where c_1 is a constant chosen in the proof of Theorem 16) and set $\tilde{\mu}_Y = 0$.
 - c. Compute a second estimate $\tilde{\mu}_X^{(i)}$ of μ by using the sub-Gaussian estimator $\text{SubGaussEst}(X, n, 15/16)$ (Theorem 13) with $n = c_2 \max\left(\frac{\sqrt{\tilde{\mu}_Y}}{\epsilon\mu_X}, \frac{1}{\sqrt{\epsilon\mu_X}}\right)$ (where c_2 is a constant chosen in the proof of Theorem 16).
2. Output $\tilde{\mu} = \text{median}\left(\tilde{\mu}_X^{(1)}, \dots, \tilde{\mu}_X^{(32 \log(1/\delta))}\right)$.

► **Theorem 16** (SEQUENTIAL RELATIVE ESTIMATOR). *Let X be a q -random variable distributed in $[0, 1]$ with mean μ and variance σ^2 . Given two reals $\epsilon, \delta \in (0, 1)$ the estimate $\tilde{\mu}$ output by the sequential relative estimator (Algorithm 3) satisfies $\Pr[|\tilde{\mu} - \mu| > \epsilon\mu] \leq \delta$. The algorithm performs $\tilde{O}\left(\left(\frac{\sigma}{\epsilon\mu} + \frac{1}{\sqrt{\epsilon\mu}}\right) \log(1/\delta)\right)$ quantum experiments in expectation.*

Proof. We prove that, for a fixed value of i , the estimate $\tilde{\mu}_X^{(i)}$ computed at step 1.c satisfies $\Pr[|\tilde{\mu}_X^{(i)} - \mu| \leq \epsilon\mu] \geq 5/8$ and the number of experiments performed during its computation is $\tilde{O}\left(\left(\frac{\sigma}{\epsilon\mu} + \frac{1}{\sqrt{\epsilon\mu}}\right)\right)$ in expectation. The theorem follows by the Chernoff bound and the linearity of expectation.

Let c, c', c'' denote the constants mentioned in Proposition 15, and set $c_1 = 16c'\sqrt{1+c}$ and $c_2 = 4(1+c)/\sqrt{1-c}$. We assume that $|\tilde{\mu}_X - \mu| \leq c\mu$ at step 1.a, which is the case with probability at least $7/8$ by Proposition 15. The analysis of steps 1.b and 1.c is split into two cases to show that $\Pr[|\tilde{\mu}_X^{(i)} - \mu| \leq \epsilon\mu] \geq 5/8$. First, if $\sigma \leq \sqrt{\epsilon\mu}$, then we can

ignore step 1.b and consider the second term in the max at step 1.c. By Theorem 13, the estimate $\tilde{\mu}_X^{(i)}$ satisfies $|\tilde{\mu}_X^{(i)} - \mu| \leq \frac{4\sigma}{c_2/\sqrt{\epsilon\mu_X}} \leq \frac{4\sqrt{1+c}}{c_2}\epsilon\mu \leq \epsilon\mu$ with probability 15/16.

Secondly, if $\sigma \geq \sqrt{\epsilon\mu}$, then by Proposition 15 and the fact that $\mu_Y = \sigma^2$, the estimate $\tilde{\mu}_Y$ computed at step 1.b satisfies $|\tilde{\mu}_Y - \sigma^2| \leq c\sigma^2$ with probability 7/8 if we remove the stopping condition. Since we assumed that $\tilde{\mu}_X \leq (1+c)\mu$, the computation is interrupted if it performs more than $\frac{c_1}{\sqrt{\epsilon\mu_X}} \geq \frac{c_1}{\sqrt{(1+c)\mu_Y}} = \frac{16c'}{\sqrt{\mu_Y}}$ experiments. However, by Proposition 15 and Markov's inequality, the number of experiments performed by the sequential Bernoulli estimator at step 1.b is at most $16c'/\sqrt{\mu_Y}$ with probability at least 15/16. Consequently, we can assume that $\tilde{\mu}_Y \geq (1-c)\sigma^2$ with success probability at least $7/8 \cdot 15/16$. In this case, by considering the first term in the max at step 1.c, the estimate $\tilde{\mu}_X^{(i)}$ satisfies $|\tilde{\mu}_X^{(i)} - \mu| \leq \frac{4\sigma}{c_2\sqrt{\mu_Y/(\epsilon\mu_X)}} \leq \frac{4(1+c)}{c_2\sqrt{1-c}}\epsilon\mu \leq \epsilon\mu$ with probability 15/16. The overall success probability is at least $(7/8)^2(15/16)^2 \geq 5/8$.

We now analyse the expected number of quantum experiments performed during the computation of $\tilde{\mu}_X^{(i)}$. Step 1.a performs $O(1/\sqrt{\mu})$ experiments in expectation by Proposition 15. Step 1.b is stopped after $O(1/(\sqrt{\epsilon\mu}))$ experiments in expectation since $\mathbb{E}[1/\sqrt{\tilde{\mu}_X}] \leq O(1/\sqrt{\mu})$ by Proposition 15. Step 1.c performs $\tilde{O}\left(\max\left(\frac{\sqrt{\mu_Y}}{\epsilon\mu_X}, \frac{1}{\sqrt{\epsilon\mu_X}}\right)\right)$ experiments by Theorem 13. The estimates $\tilde{\mu}_Y$ and $\tilde{\mu}_X$ are independent if we ignore the stopping condition at step 1.b, in which case $\mathbb{E}\left[\frac{\sqrt{\mu_Y}}{\mu_X}\right] = \mathbb{E}\left[\frac{1}{\mu_X}\right]\mathbb{E}[\sqrt{\mu_Y}] \leq O\left(\frac{\sigma}{\mu}\right)$ by Proposition 15. The stopping condition can only decrease this quantity. Thus, step 1.c performs $\tilde{O}\left(\max\left(\frac{\sigma}{\epsilon\mu}, \frac{1}{\sqrt{\epsilon\mu}}\right)\right)$ experiments in expectation. \blacktriangleleft

6 Lower bounds

We prove several lower bounds for the mean estimation problem under different scenarios. In Section 6.1, we study the number of experiments that must be performed to estimate the mean with a sub-Gaussian error rate. In Section 6.2, we study the number of experiments needed to solve the (ϵ, δ) -approximation problem. Finally, in Section 6.3, we consider the mean estimation problem in the state-based model, where the input consists of several copies of a quantum state encoding a distribution.

6.1 Sub-Gaussian estimation

We show that the quantum sub-Gaussian estimator described in Theorem 13 is optimal up to a polylogarithmic factor. We make use of the following lower bound for Quantum Search in the small-error regime.

► **Proposition 17** (Theorem 4 in [13]). *Let $N > 0$, $1 \leq K \leq 0.9N$ and $\delta \geq 2^{-N}$. Let $T(N, K, \delta)$ be the minimum number of quantum queries any algorithm must use to decide with failure probability at most δ whether a function $f : [N] \rightarrow \{0, 1\}$ has 0 or K preimages of 1. Then, $T(N, K, \delta) \geq \Omega(\sqrt{N/K} \log(1/\delta))$.*

We construct two particular probability distributions that allow us to reduce the Quantum Search problem to the sub-Gaussian mean estimation problem.

► **Theorem 18.** *Let $n > 1$ and $\delta \in (0, 1)$ such that $n \geq 2 \log(1/\delta)$. Fix $\sigma > 0$ and consider the family \mathcal{P}_σ of all q -random variables with variance σ^2 . Let $T(n, \sigma, \delta)$ be the minimum number of quantum experiments any algorithm must perform to compute with failure probability at most δ a mean estimate $\tilde{\mu}$ such that $|\tilde{\mu} - \mu| \leq \frac{\sigma \log(1/\delta)}{n}$ for any $X \in \mathcal{P}_\sigma$ with mean μ . Then, $T(n, \sigma, \delta) \geq \Omega(n)$.*

Proof. Let $m = \frac{n}{\log(1/\delta)}$ and $b = \frac{m}{\sqrt{1-1/m^2}}\sigma$. We define the probability distribution p_0 with support $\{0, b\}$ that takes value b with probability $\frac{1}{m^2}$. Similarly, we define the probability distribution p_1 with support $\{0, -b\}$ that takes value $-b$ with probability $\frac{1}{m^2}$. The variance of each distribution is equal to σ^2 . Moreover, the means μ_0 and μ_1 of the two distributions satisfy that,

$$\mu_0 - \mu_1 > 2 \frac{\sigma \log(1/\delta)}{n}. \quad (7)$$

Let N, K be two integers such that $N \geq \log(1/\delta)$ and $K/N = 1/m^2$ (assuming m is rational). Let F_0 be the family of all functions $f : [N] \rightarrow \{0, 1\}$ with exactly K preimages of 1. Similarly, let F_1 be the family of all functions $f : [N] \rightarrow \{-1, 0\}$ with exactly K preimages of -1 . By using Proposition 17, it is easy to see that any algorithm that can distinguish between $f \in F_0$ and $f \in F_1$ with success probability $1 - \delta$ must use at least $\Omega(\sqrt{N/K} \log(1/\delta)) = \Omega(m \log(1/\delta)) = \Omega(n)$ quantum queries to f . We associate with each function $f \in F_0 \cup F_1$ the q-variable $(\mathcal{H}, U, M)_f$ where $\mathcal{H} = \mathbb{C}^{N+2}$, $U|0\rangle = \frac{1}{\sqrt{N}} \sum_{x \in [N]} |x\rangle |f(x)\rangle$, and $M = \{I \otimes |0\rangle\langle 0|, I \otimes |-1\rangle\langle -1|, I \otimes |1\rangle\langle 1|\}$. The random variable X generated by $(\mathcal{H}, U, M)_f$ is distributed according to p_0 if $f \in F_0$, and according to p_1 if $f \in F_1$. Moreover, one quantum experiment with respect to X can be simulated with one quantum query to f . Consequently, any algorithm that can distinguish between a random variable distributed according to p_0 or p_1 with success probability $1 - \delta$ must perform at least $\Omega(n)$ quantum experiments. On the other hand, by Equation (7), if an algorithm can estimate the mean with an error rate smaller than $\frac{\sigma \log(1/\delta)}{n}$ then it can distinguish between $f \in F_0$ and $f \in F_1$. Thus, $T(n, \sigma, \delta) \geq \Omega(n)$. ◀

6.2 (ϵ, δ) -Estimation

We consider the (ϵ, δ) -estimation problem in the parameter-free setting, when the coefficient of variation is unknown. We make use of the next lower bound for Quantum Counting.

► **Proposition 19** (Theorem 4.2.6 in [33]). *Let $N > 0$, $1 < K \leq N$ and $\epsilon \in (\frac{1}{4K}, 1)$. Consider the set of all quantum algorithms such that, given a query oracle to any function $f : [N] \rightarrow \{0, 1\}$, they return an estimate \tilde{C} of the number C of preimages of 1 in f such that $|\tilde{C} - C| \leq \epsilon C$ with probability at least $2/3$. Let $T_K(N, \epsilon)$ be the minimum number of quantum queries any such algorithm must use when the oracle has exactly K preimages of 1. Then, $T_K(N, \epsilon) \geq \Omega\left(\frac{\sqrt{K(N-K)}}{\epsilon K+1} + \sqrt{\frac{N}{\epsilon K+1}}\right)$.*

We obtain by a simple reduction to the above problem that the result described in Theorem 16 is nearly optimal.

► **Proposition 20.** *Let $\epsilon \in (0, 1)$. Let $\mathcal{P}_{\mathcal{B}}$ denote the family of all q-random variables that follow a Bernoulli distribution. Consider any algorithm that takes as input $X \in \mathcal{P}_{\mathcal{B}}$ and that outputs a mean estimate $\tilde{\mu}$ such that $|\tilde{\mu} - \mathbb{E}[X]| \leq \epsilon \mathbb{E}[X]$ with probability at least $2/3$. Then, for any $\mu \in (0, 1)$, there exists $X \in \mathcal{P}_{\mathcal{B}}$ with mean μ such that the algorithm performs at least $\Omega\left(\frac{\sigma}{\epsilon\mu} + \frac{1}{\sqrt{\epsilon\mu}}\right)$ quantum experiments on input X , where $\sigma^2 = \text{Var}[X]$.*

Proof. Given $\epsilon \in (0, 1)$ and $\mu \in (0, 1)$, we choose two integers K and N such that $K > 1/(4\epsilon)$ and $K/N = \mu$ (assuming μ is rational). Similarly to the proof of Theorem 18, we associate with each function $f : [N] \rightarrow \{0, 1\}$ the q-variable $(\mathcal{H}, U, M)_f$ where $\mathcal{H} = \mathbb{C}^{N+2}$, $U|0\rangle = \frac{1}{\sqrt{N}} \sum_{x \in [N]} |x\rangle |f(x)\rangle$, and $M = \{I \otimes |0\rangle\langle 0|, I \otimes |1\rangle\langle 1|\}$. If an algorithm can estimate the mean

of any Bernoulli random variable with error ϵ and success probability $2/3$, then it can be used to count the number of preimages of 1 in f with the same accuracy. Thus, by Proposition 19, it must perform at least $\Omega\left(\frac{\sqrt{K(N-K)}}{\epsilon K+1} + \sqrt{\frac{N}{\epsilon K+1}}\right) = \Omega\left(\frac{\sqrt{\mu(1-\mu)}}{\epsilon\mu+1/N} + \frac{1}{\sqrt{\epsilon\mu+1/N}}\right) = \Omega\left(\frac{\sigma}{\epsilon\mu} + \frac{1}{\sqrt{\epsilon\mu}}\right)$ quantum experiments on a q -random variable with mean μ and variance $\sigma^2 = \mu(1-\mu)$. ◀

6.3 State-based estimation

We consider the *state-based* model where the input consists of several copies of a quantum state $|p\rangle = \sum_{x \in E} \sqrt{p(x)}|x\rangle$ encoding a distribution p over E . This model is weaker than the one described before, since it does not provide access to a unitary algorithm preparing $|p\rangle$. We prove that no quantum speedup is achievable in this setting. Our result uses the next lower bound on the number of copies needed to distinguish two states.

► **Lemma 21.** *Let $\delta \in (0, 1)$ and consider two probability distributions p_0 and p_1 with the same finite support $E \subset \mathbb{R}$. Define the states $|\phi_0\rangle = \sum_{x \in E} \sqrt{p_0(x)}|x\rangle$ and $|\phi_1\rangle = \sum_{x \in E} \sqrt{p_1(x)}|x\rangle$. Then, the smallest integer T such that there is an algorithm that can distinguish $|\phi_0\rangle^{\otimes T}$ from $|\phi_1\rangle^{\otimes T}$ with success probability at least $1 - \delta$ satisfies $T \geq \frac{\ln(1/(4\delta))}{D(p_0\|p_1)}$, where $D(p_0\|p_1) = \sum_{x \in E} p_0(x) \ln\left(\frac{p_0(x)}{p_1(x)}\right)$ is the KL-divergence from p_0 to p_1 .*

Proof. According to Helstrom's bound [25] the best success probability to distinguish between two states $|\phi\rangle$ and $|\phi'\rangle$ is $\frac{1}{2}(1 + \sqrt{1 - |\langle\phi|\phi'\rangle|^2})$. Thus, the smallest number T needed to distinguish $|\phi_0\rangle^{\otimes T}$ from $|\phi_1\rangle^{\otimes T}$ must satisfy $\frac{1}{2}(1 + \sqrt{1 - \langle\phi_0|\phi_1\rangle^{2T}}) \geq 1 - \delta$. It implies that $T \geq \frac{-\ln(1 - (1 - 2\delta)^2)}{-2 \ln(\langle\phi_0|\phi_1\rangle)} \geq \frac{\ln(1/(4\delta))}{-2 \ln\left(\sum_x p_0(x) \sqrt{\frac{p_1(x)}{p_0(x)}}\right)} \geq \frac{\ln(1/(4\delta))}{\sum_x p_0(x) \ln\left(\frac{p_0(x)}{p_1(x)}\right)} = \frac{\ln(1/(4\delta))}{D(p_0\|p_1)}$ where the second inequality uses the concavity of the logarithm function. ◀

We use the above lemma to show that no quantum mean estimator can perform better than the classical sub-Gaussian estimators in the state-based input model.

► **Theorem 22.** *Let $n > 1$ and $\delta \in (0, 1)$ such that $n \geq 2 \log(1/\delta)$. Fix $\sigma > 0$ and consider the family \mathcal{P}_σ of all distributions with finite support whose variance lies in the interval $[\sigma^2, 4\sigma^2]$. For any $p \in \mathcal{P}_\sigma$ with support $E \subset \mathbb{R}$, define the state $|p\rangle = \sum_{x \in E} \sqrt{p(x)}|x\rangle$. Let $T(n, \sigma, \delta)$ be the smallest integer such that there exists an algorithm that receives the state $|p\rangle^{\otimes T(n, \sigma, \delta)}$ for any $p \in \mathcal{P}_\sigma$, and that outputs an estimate $\tilde{\mu}$ of the mean μ of p such that $\Pr\left[|\tilde{\mu} - \mu| > \sqrt{\frac{\sigma^2 \log(1/\delta)}{n}}\right] \leq \delta$. Then, $T(n, \sigma, \delta) \geq \Omega(n)$.*

Proof. Let $m = \frac{n}{\log(1/\delta)}$, $b = \frac{m}{\sqrt{m-1}}\sigma$ and $\alpha = 2 \ln\left(1 + \sqrt{1 - \frac{1}{m}}\right)$. We define the two distributions p_0 and p_1 with support $E = \{0, b\}$ such that $p_0(b) = \frac{e^\alpha}{m}$ and $p_1(b) = \frac{1}{m}$. Let μ_0 and σ_0^2 (resp. μ_1 and σ_1^2) denote the expectation and the variance of p_0 (resp. p_1). Observe that $p_0, p_1 \in \mathcal{P}_\sigma$ since $\sigma_0 \in [\sigma, 2\sigma]$ and $\sigma_1 = \sigma$. Moreover, $\mu_0 - \mu_1 = \sigma \frac{e^\alpha - 1}{\sqrt{m-1}} = \sigma(e^{\alpha/2} + 1) \frac{e^{\alpha/2} - 1}{\sqrt{m-1}} > 2\sqrt{\frac{\sigma^2 \log(1/\delta)}{n}}$. Thus, we can distinguish $|p_0\rangle^{\otimes T(n, \sigma, \delta)}$ from $|p_1\rangle^{\otimes T(n, \sigma, \delta)}$ with failure probability δ by using any optimal algorithm that satisfies the error bound stated in the theorem. Since the KL-divergence from p_0 to p_1 is $D(p_0\|p_1) \leq p_0(b) \ln\left(\frac{p_0(b)}{p_1(b)}\right) = \frac{\alpha e^\alpha}{m^2} \leq \frac{6}{m}$, we must have $T(n, \sigma, \delta) \geq \Omega\left(\frac{\log(1/\delta)}{D(p_1\|p_0)}\right) = \Omega(n)$ by Lemma 21. ◀

Improved Approximation Algorithms for Tverberg Partitions

Sariel Har-Peled

Department of Computer Science, University of Illinois, Urbana, IL, USA

Abstract

Tverberg's theorem states that a set of n points in \mathbb{R}^d can be partitioned into $\lceil n/(d+1) \rceil$ sets whose convex hulls all intersect. A point in the intersection (aka Tverberg point) is a centerpoint, or high-dimensional median, of the input point set. While randomized algorithms exist to find centerpoints with some failure probability, a partition for a Tverberg point provides a certificate of its correctness.

Unfortunately, known algorithms for computing exact Tverberg points take $n^{O(d^2)}$ time. We provide several new approximation algorithms for this problem, which improve running time or approximation quality over previous work. In particular, we provide the first strongly polynomial (in both n and d) approximation algorithm for finding a Tverberg point.

1 Introduction

Given a set P of n points in the plane and a query point q , classification problems ask whether q belongs to the same class as P . Some algorithms use the convex hull $\mathcal{CH}(P)$ as a decision boundary for classifying q . However, in realistic datasets, P may be noisy and contain outliers, and even one faraway point can dramatically enlarge the hull of P . Thus, we would like to measure how deeply q lies within P in way that is more robust against noise.

In this paper, we investigate the notion of Tverberg depth. However, there are many related measures of depth in the literature, including:

1. **Tukey depth.** The Tukey depth of q is the minimum number of points that must be removed before q becomes a vertex of the convex hull. Computing the depth is equivalent to computing the closed halfspace that contains q and the smallest number of points of P , and this takes $O(n \log n)$ time in the plane [7].
2. **Centerpoint.** In \mathbb{R}^d , a point with Tukey depth $n\alpha$ is an α -centerpoint. There is always a $1/(d+1)$ -centerpoint, known simply as the centerpoint, which can be computed exactly in $O(n^{d-1})$ time [19, 7]. It can be approximated using the centerpoint of a sample [11], but getting a polynomial-time (in both n and d) approximation algorithm proved challenging. Clarkson *et al.* [11] provided an algorithm that computes a $1/4d^2$ -centerpoint in roughly

- $O(d^9)$ time. Miller and Sheehy [23] derandomized it to find a (roughly) $1/2d^2$ -centerpoint in $n^{O(\log d)}$ time. More recently, Har-Peled and Mitchell [16] improved the running time to compute a (roughly) $1/d^2$ -centerpoint in (roughly) $O(d^7)$ time.
3. **Onion depth.** Imagine peeling away the vertices of the current convex hull and removing them from P . The onion depth is the number of layers which must be removed before the point q is exposed. The convex layers of points in the plane can be computed in $O(n \log n)$ time by an algorithm of Chazelle [8]. The structure of convex layers is well-understood for random points [12] and grid points [13].
 4. **Uncertainty.** Another model considers uncertainty about the locations of the points. Suppose that each point of P has a certain probability of existing, or alternatively, its location is given via a distribution. The depth of query point q is the probability that q is in the convex hull once P has been sampled. Under certain assumptions, this probability can be computed exactly in $O(n \log n)$ time [2]. Unfortunately, the computed value might be very close to zero or one, and therefore tricky to interpret.
 5. **Simplicial depth.** The simplicial depth of q is the number of simplices induced by P containing it. This number can be approximated quickly after some preprocessing [1]. However, it can be quite large for a point which is intuitively shallow.

Tverberg depth

Given a set P of n points in \mathbb{R}^d , a **Tverberg partition** is a partition of P into k disjoint sets P_1, \dots, P_k such that $\bigcap_i \mathcal{CH}(P_i)$ is not empty. A point in this intersection is a **Tverberg point**. Tverberg's theorem states that P has a Tverberg partition into $\lceil n/(d+1) \rceil$ sets. In particular, the *Tverberg depth* (*T-depth*) of a point q is the maximum size k of a Tverberg partition such that $q \in \bigcap_{i=1}^k \mathcal{CH}(P_i)$.

By definition, points of T-depth $n/(d+1)$ are centerpoints for P . In the plane, Reay [25] showed that if a point has Tukey depth $k \leq |P|/3$, then the T-depth of q is k . This property is already false in three dimensions [4]. The two-dimensional case was handled by Birch [5], who proved that any set of n points in the plane can be partitioned into $n/3$ triples whose induced triangles have a common intersection point.

Computing a Tverberg point

For work on computing approximate Tverberg points, see [23, 24, 26, 9] and the references therein. Currently, no polynomial-time (in both n and d) approximation algorithm is known for computing Tverberg points. This search problem is believed to be quite hard, see [22].

Algorithms for computing an *exact* Tverberg point of T-depth $n/(d+1)$ implement the construction implied by the original proof. The runtime of such an algorithm is $d^{O(d^2)} n^{d(d+1)+1}$, see the full version [17]. As previously mentioned, the exception is in two dimensions, where the algorithm of Birch [5] runs in $O(n \log n)$ time. But even in three dimensions, we are unaware of an algorithm faster than $O(n^{13})$.

Convex combinations and Carathéodory's theorem

The challenge in finding a Tverberg point is that we have few subroutines at our disposal with runtimes polynomial in d . Consider the most basic task – given a set P of n points and a query point q , decide if q lies inside $\mathcal{CH}(P)$, and if so, compute the convex combination of q in term of the points of P . This problem can be reduced to linear programming. Currently, the fastest strongly polynomial LP algorithms run in super-polynomial time $2^{O(\sqrt{d \log d})} + O(d^2 n)$

[10, 21], where d is the number of variables and n is the number of constraints. However, any given convex combination of P representing q can be sparsified in polynomial time into a convex combination using only $d + 1$ points of P . Lemma 22 describes this algorithmic version of Carathéodory's theorem.

Radon partitions in polynomial time

Finding points of T-depth 2 is relatively easy. Any set of $d + 2$ points in \mathbb{R}^d can be partitioned into two disjoint sets whose convex hulls intersect, and a point in the intersection is a *Radon point*. Radon points can be computed in $O(d^3)$ time by solving a linear system with $d + 2$ variables. Almost all the algorithms for finding Tverberg points mentioned above amplify the algorithm for finding Radon points.

Our results

The known and new results are summarized in Table 1.1. In Section 2, we review preliminary information and known results, which include the following.

1. **An exact algorithm.** The proof of Tverberg's theorem is constructive and leads to an algorithm with running time $O(n^{d(d+1)})$. It seems that the algorithm has not been described and analyzed explicitly in the literature. For the sake of completeness, we provide this analysis in the full version [17].
2. **In two dimensions.** Given a set P of n points in the plane and a query point q of Tukey depth k , Birch's theorem [5] implies that q can be covered by $\min(k, \lfloor n/3 \rfloor)$ vertex-disjoint triangles of P . One can compute k and this triangle cover in $O(n + k \log k)$ time, and use them to compute a Tverberg point of depth $\lfloor n/3 \rfloor$ in $O(n \log n)$ time.

In Section 3, we provide improved algorithms for computing Tverberg points and partitions.

1. **Projections in low dimensions.** We use projections to find improved approximation algorithms in dimensions 3 to 7, see Table 1.2. For example, in three dimensions, one can compute a point with T-depth $n/6$ in $O(n \log n)$ time.
2. **An improved quasi-polynomial algorithm.** We modify the algorithm of Miller and Sheehy to use a buffer of free points. Coupled with the algorithm of Mulzer and Werner [24], this idea yields an algorithm that computes a point of T-depth $\geq (1 - \delta)n/2(d + 1)^2$ in $d^{O(\log(d/\delta))}n$ time. This improves the approximation quality of the algorithm of [24] by a factor of $2(d + 1)$, while keeping (essentially) the same running time.
3. **A strongly polynomial algorithm.** In Section 3.3, we present the first strongly polynomial approximation algorithm for Tverberg points, with the following caveats:
 - a. the algorithm is randomized, and might fail,
 - b. one version returns a Tverberg partition, but not a point that lies in its intersection,
 - c. the other (inferior) version returns a Tverberg point and a partition realizing it, but not the convex combination of the Tverberg point for each set in the partition.

Specifically, one can compute a partition of P into $n/O(d^2 \log d)$ sets, such that the intersection of their convex hulls is nonempty (with probability close to one), but without finding a point in the intersection. Alternatively, one can also compute a Tverberg point, but the number of sets in the partition decreases to $n/O(d^3 \log d)$.

■ **Table 1.1** The known and improved results for Tverberg partition. The notation \mathcal{O}_w hides terms with polylogarithmic dependency on size of the numbers, see Remark 21. The parameter δ can be freely chosen.

Depth	Running time	Ref / Comment
$n/(d+1)$	$d^{O(d^2)} n^{d(d+1)+1}$	Tverberg theorem
$d = 2 : n/3$	$O(n \log n)$	[5]: Theorem 8
$\frac{n}{2(d+1)^2}$	$n^{O(\log d)}$	Miller and Sheehy [23]
$\frac{n}{4(d+1)^3}$	$d^{O(\log d)} n$	Mulzer and Werner [24]
$\frac{n}{2d(d+1)^2}$	$\mathcal{O}_w(n^4)$	Rolnick and Soberón [26]
$\frac{(1-\delta)n}{d(d+1)}$	$(d/\delta)^{O(d)} + \mathcal{O}_w(n^4)$	Rolnick and Soberón [26]

New results

$\frac{(1-\delta)n}{2(d+1)^2}$	$d^{O(\log(d/\delta))} n$	Theorem 18
$\frac{n}{O(d^2 \log d)}$	$O(dn)$	Lemma 19: Only partition
$\frac{n}{O(d^3 \log d)}$	$O(dn + d^7 \log^6 d)$	Lemma 20: Partition + point, but no convex combination
$\frac{n}{O(d^2 \log d)}$	$\mathcal{O}_w(n^{5/2} + nd^3)$	Lemma 24: Weakly polynomial
$\frac{(1-\delta)n}{2(d+1)^2}$	$d^{O(\log \log(d/\delta))} \mathcal{O}_w(n^{5/2})$	Theorem 25: Weakly quasi polynomial
$\frac{(1-\delta)n}{d(d+1)}$	$O(c + c'n + d^2 n \log^2 n)$ $c = d^{O(d)} / \delta^{2(d-1)}$ $c' = 2^{O(\sqrt{d \log d})}$	Lemma 26: Useful for low dimensions

■ **Table 1.2** The best approximation ratios for Tverberg depth in low dimensions, with nearly linear-time algorithms, as implied by Lemma 16. Note that the new algorithm is no longer an improvement in dimension 8. We are unaware of any better approximation algorithms (except for running the exact algorithm for Tverberg's point, which requires $n^{O(d^2)}$ time).

Dim	T. Depth	New depth	Known	Ref	Comment
3	$n/4$	$n/6$	$n/8$	[24]	
4	$n/5$	$n/9$	$n/16$		
5	$n/6$	$n/18$	$n/32$		
6	$n/7$	$n/27$	$(1-\delta)n/42$	[26]	Original paper describes a weakly polynomial algorithm. The improved algorithm is described in Lemma 26.
7	$n/8$	$n/54$	$(1-\delta)n/56$		
8	$n/9$	$n/81$	$(1-\delta)n/72$		

4. **A weakly polynomial algorithm.** Revisiting an idea of Rolnick and Soberón [26], we use algorithms for solving LPs. The resulting running time is either weakly polynomial (depending logarithmically on the relative sizes of the numbers in the input) or super-polynomial, depending on the LP solver. In particular, the randomized, strongly polynomial algorithms described above can be converted into constructive algorithms that compute the convex combination of the Tverberg point over each set in its partition. Having computed approximate Tverberg points of T-depth $\geq n/O(d^2 \log d)$, we can feed them into the buffered version of Miller and Sheehy's algorithm to compute Tverberg points of depth $\geq (1 - \delta)n/2(d + 1)^2$. This takes $d^{O(\log \log(d/\delta))} \mathcal{O}_w(n^{5/2})$ time, where \mathcal{O}_w hides polylogarithmic terms in the size of the numbers involved, see Remark 21.
5. **Faster approximation in low dimensions.** One can compute (or approximate) a centerpoint, then repeatedly extract simplices covering it until the centerpoint is exposed. This leads to an $O_d(n^2)$ approximation algorithm [26]. Since O_d hides constants that depend badly on d , this method is most useful in low dimensions. By random sampling, we can speed up this algorithm to $O_d(n \log^2 n)$ time.

2 Background, preliminaries and known results

► **Definition 1.** A *Tverberg partition* (or a *log*) of a set $P \subseteq \mathbb{R}^d$, for a point q , is a set $\ell = \{P_1, \dots, P_k\}$ of vertex-disjoint subsets of P , each containing at most $d + 1$ points, such that $q \in \mathcal{CH}(P_i)$, for all i . The **rank** of ℓ is $k = |\ell|$. The maximum rank of any log of q is its **Tverberg depth** (**T-depth**).

A set P_j in a log is a **batch**. For every batch $P_j = \{p_1, \dots, p_{d+1}\}$ in the log, we store the convex coefficients $\alpha_1, \dots, \alpha_{d+1} \geq 0$ such that $\sum_i \alpha_i p_i = q$ and $\sum_i \alpha_i = 1$. A pair (q, ℓ) of a point and its log is a **site**.

Tverberg's theorem states that, for any set of n points in \mathbb{R}^d , there is a point in \mathbb{R}^d with Tverberg depth $\lceil n/(d + 1) \rceil$. For simplicity, we assume the input is in general position.

2.1 An exact algorithm

The constructive proof of Tverberg and Vrećica [28] implies an algorithm for computing exact Tverberg points – see [17] for details.

► **Lemma 2.** Let P be a set of n points in \mathbb{R}^d . In $d^{O(d^2)} n^{d(d+1)+1}$ time, one can compute a point q and a partition of P into disjoint sets P_1, \dots, P_r such that $q \in \bigcap_i \mathcal{CH}(P_i)$, where $r = \lceil n/(d + 1) \rceil$.

2.2 In two dimensions

We first review Tukey depth, which is closely related to Tverberg depth in two dimensions.

► **Definition 3.** The **Tukey depth** of a point q in a set $P \subseteq \mathbb{R}^d$, denoted by $d_{\text{TK}}(q)$, is the minimum number of points contained in any closed halfspace containing q .

The following result is implicit in the proof of Theorem 5.2 in [6]. Chan solves the decision version of the Tukey depth problem, while we need to compute it explicitly, resulting in a more involved algorithm. For the sake of completeness, we provide the details in Appendix A.

► **Lemma 4** (Proof in Appendix A). Given a set P of n points in the plane and a query point q , such that $P \cup \{q\}$ is in general position, one can compute, in $O(n + k \log k)$ time, the Tukey depth k of q in P . The algorithm also computes the halfplane realizing this depth.

For shallow points in the plane, the Tukey and Tverberg depths are equivalent, and we can compute the associated Tverberg partition.

► **Lemma 5** (Proof in Appendix B). *Let P be a set of n points in the plane, let q be a query point such that $P \cup \{q\}$ is in general position, and suppose that $k = d_{TK}(q) \leq n/3$. Then one can compute a log for q of rank k in $O(n + k \log k)$ time.*

The Tukey depth of a point can be as large as $\lfloor n/2 \rfloor$. Indeed, consider the vertices of a regular n -gon (for odd n), the polygon center has depth $\lfloor n/2 \rfloor$.

► **Lemma 6**. *Let P be a set of n points in the plane, and let q be a query point such that $P \cup \{q\}$ is in general position, and q has Tukey depth larger than $n/3$. Then, one can compute a log for q of this rank in $O(n \log n)$ time.*

Proof. Let $N = \lfloor n/3 \rfloor$. Assume q that is the origin, and sort the points of P in counter-clockwise order, where p_i is the i th point in this order, for $i = 1, \dots, n$. For $i = 1, \dots, N$, let $\Delta_i = \Delta_{p_i p_{N+i} p_{2N+i}}$. We claim that $\angle p_i q p_{N+i} \leq \pi$. Otherwise, there is a halfspace containing fewer than N points induced by the line passing through p_i and q . Similarly, $\angle p_{N+i} q p_{2N+i} \leq \pi$ and $\angle p_{2N+i} q p_i \leq \pi$, so that q lies inside Δ_i , as desired. ◀

► **Theorem 7**. *Let P be a set of n points in the plane, let q be a query point such that $P \cup \{q\}$ is in general position, and suppose that $k = d_{TK}(q)$ is the Tukey depth of q in P . Then one can compute the Tukey depth k of q , along with a log of rank $\tau = \min(\lfloor n/3 \rfloor, k)$, in $O(n + k \log k)$ time.*

Proof. Compute the Tukey depth of q in $O(n + k \log k)$ time, using the algorithm of Lemma 4. If $k \leq n/3$, then compute the log using the algorithm of Lemma 5, and otherwise using the algorithm of Lemma 6. ◀

The above implies the following theorem of Birch, which predates Tverberg's theorem.

► **Theorem 8** ([5]). *Let P be a set of $n = 3k$ points in the plane. Then there exists a partition of P into k vertex-disjoint triangles, such that their intersection is not empty. The partition can be computed in $O(n \log n)$ time.*

Proof. A centerpoint of P can be computed in $O(n \log n)$ time [7]. Such a centerpoint has Tukey depth at least k , so the algorithm of Lemma 6 partitions P into k triangles. ◀

► **Remark 9.** (A) Note that Tverberg's theorem in the plane is slightly stronger – it states that any point set with $3k - 2$ points has Tverberg depth k . In such a decomposition, some of the sets may be pairs of points or singletons.

(B) In the colored version of Tverberg's theorem in the plane, one is given $3n$ points partitioned into three classes of equal size. Agarwal *et al.* [3] showed how to compute a decomposition into n triangles covering a query point, where every triangle contains a vertex of each color (if such a decomposition exists). This problem is significantly more difficult, and their running time is a prohibitive $O(n^{11})$.

2.3 Miller and Sheehy's algorithm

Here, we review Miller and Sheehy's [23] approximation algorithm for computing a Tverberg point before describing our improvement.

Radon partitions

Radon's theorem states that a set P of $d+2$ points in \mathbb{R}^d can be partitioned into two disjoint subsets P_1, P_2 such that $\mathcal{CH}(P_1) \cap \mathcal{CH}(P_2) \neq \emptyset$. This partition can be computed via solving a linear system in $d+2$ variables in $O(d^3)$ time. A point in this intersection (which is an immediate byproduct of computing the partition) is a **Radon point**.

Let p be a point in \mathbb{R}^d . It is a **convex combination** of points $\{p_1, \dots, p_m\}$ if there are $\alpha_1, \dots, \alpha_m \in [0, 1]$ such that $p = \sum_{i=1}^m \alpha_i p_i$ and $\sum_i \alpha_i = 1$.

► **Lemma 10** ([23, 17]: Sparsifying conv. combination). *Let p be a point in \mathbb{R}^d , and let $P = \{p_1, \dots, p_m\} \subseteq \mathbb{R}^d$ be a point set. Furthermore, assume that we are given p as a convex combination of points of P . Then, one can compute a convex combination representation of p that uses at most $d+1$ points of P . This takes $O(md^3)$ time.*

► **Lemma 11** ([23, 17]). *Given $d+2$ sites $(p_1, \ell_1), \dots, (p_{d+2}, \ell_{d+2})$ of rank r in \mathbb{R}^d , where the logs ℓ_i are disjoint, one can compute a site (p, ℓ) of rank $2r$ in $O(rd^5)$ time.*

A recycling algorithm for computing a Tverberg point

The algorithm of Miller and Sheehy maintains a collection of sites. Initially, it converts each input point $p \in P$ into a site $(p, \{p\})$ of rank one. The algorithm then merges $d+2$ sites of rank r into a site of rank $2r$, using Lemma 11. Before the merge, the input logs use $r(d+2)(d+1)$ points in total. After the merge, the new log uses only $2(d+1)r$ points. The algorithm recycles the remaining $(d+2)(d+1)r - 2(d+1)r = d(d+1)r$ points by reinserting them into the collection as singleton sites of rank one. When no merges are available, the algorithm outputs the maximum-rank site as the approximate Tverberg point.

Analysis

For our purposes, we need a slightly different way of analyzing the above algorithm of Miller and Sheehy [23], so we provide the analysis in detail.

Let 2^h be the rank of the output site. The number of points in all the logs is n . Since a site of rank 2^i has at most $(d+1)2^i$ points of P in its log, and there are at most $d+1$ sites of each rank, n is at most $\sum_{i=0}^h (d+1)2^{2^i}$. As such,

$$n \leq \sum_{i=0}^h (d+1)2^{2^i} = (d+1)^2(2^{h+1} - 1) \iff \frac{n}{(d+1)^2} + 1 \leq 2^{h+1} \implies 2^h \geq \left\lceil \frac{n}{2(d+1)^2} \right\rceil. \quad (2.1)$$

Every site in the collection is associated with a history tree that describes how it was computed. Thus, the algorithm execution generates (conceptually) a forest of such history trees, which is the **history** of the computation.

► **Lemma 12.** *Let 2^h be the maximum rank of a site computed by the algorithm. The total number of sites in the history that are of rank (exactly) 2^{h-i} is at most $(d+2)^{i+1} - 1$.*

Proof. There are at most $T(0) = d+1$ nodes of rank 2^{h-0} in the history, and each has $d+2$ children of rank 2^{h-1} . In addition, there might be $d+1$ trees in the history whose roots have rank 2^{h-1} . Thus, $T(1) = d+1 + (d+2)T(0)$. By induction, there are at most

$$T(i) = d+1 + (d+2)T(i-1) = (d+2)^{i+1} - 1$$

nodes in the history of rank 2^{h-i} . ◀

► **Lemma 13.** *Let 2^h be the maximum rank of a site computed by the algorithm. The total amount of work spent (directly) by the algorithm (throughout its execution) at nodes of rank $\geq 2^{h-i}$ is $O(d^{4+i}n)$. In particular, the overall running time of the algorithm is $O(d^4n^{1+\log_2 d})$.*

Proof. There are at most $(d+2)^{i+1}$ nodes of rank 2^{h-i} in the history. The rank of such a node is $r_i = O(\frac{n}{2^{i+1}(d+1)^2})$, and the amount of work spent in computing the node is $O(r_i d^6) = O(d^4n/2^i)$. As such, the total work in the top i ranks of the history is proportional to $L_i = \sum_{j=0}^i (d+2)^j \cdot d^4n/2^j = O(d^{4+i}n)$.

Since $h \leq \log_2 n$, the overall running time is $O(L_h) = O(d^{4+\log_2 n}n) = O(d^4n^{1+\log_2 d})$. ◀

3 Improved Tverberg approximation algorithms

3.1 Projections in low dimensions

► **Lemma 14.** *Let P be a set of n points in three dimensions. One can compute a Tverberg point of P of depth $n/6$ (and the log realizing it) in $O(n \log n)$ time.*

Proof. Project the points of P to two dimensions, and compute a Tverberg point p and a partition for it of size $n/3$. Lifting from the plane back to the original space, the point p lifts to a vertical line ℓ , and every triangle lifts to a triangle which intersects ℓ . Pick a point q on this line which is the median of the intersections. Now, pair every triangle intersecting ℓ above q with a triangle intersecting ℓ below it. This partitions P into $n/6$ sets, each of size 6, such that the convex hull of each sets contains q . Within each set, compute at most 4 points whose convex hull contains q . These points yield the desired log for q of rank $n/6$. ◀

► **Remark 15.** Lemma 14 seems innocent enough, but to the best of our knowledge, it is the best one can do in near-linear time in 3D. The only better approximation algorithm we are aware of is the one suggested by Tverberg's theorem. It yields a point of Tverberg depth $n/4$, but its running time is probably at least $O(n^{13})$ (see Lemma 2).

As observed by Mulzer and Werner [24], one can repeat this projection mechanism. Since Mulzer and Werner [24] bottom their recursion at dimension 1, their algorithm computes a point of Tverberg depth $n/2^d$ (in three dimensions, depth $n/8$). Applying this projection idea but bottoming at two dimensions, as above, yields a point of Tverberg depth $n/(3 \cdot 2^{d-2})$.

► **Lemma 16.** *Let P be a set of n points in four dimensions. One can compute a Tverberg point of P of depth $n/9$ (and the log realizing it) in $O(n \log n)$ time.*

More generally, for d even, and a set P of n points in \mathbb{R}^d , one can compute a point of depth $n/3^{d/2}$ in $d^{O(1)}n \log n$ time. For d odd, we get a point of depth $n/(2 \cdot 3^{(d-1)/2})$.

Proof. As mentioned above, the basic idea is due to Mulzer and Werner. Project the four-dimensional point set onto the plane spanned by the first two coordinates (i.e. “eliminate” the last two coordinates), and compute a $n/3$ centerpoint using Theorem 8. Translate the space so that this centerpoint lies at the origin. Now, consider each triangle in the original four-dimensional space. Each triangle intersects the two-dimensional subspace formed by the first two coordinates. Pick an intersection point from each lifted triangle. On this set of $n/3$ points, living in this two dimensional subspace, apply again the algorithm of Theorem 8 to compute a Tverberg point of depth $(n/3)/3 = n/9$. The resulting centerpoint p is now contained in $n/9$ triangles, where every vertex is contained in an original triangle of points. That is, p has depth $n/9$, where each group consists of 9 points in four dimensions. Now, sparsify each group into 5 points whose convex hull contains p .

The second part of the claim follows from applying the above argument repeatedly. ◀

3.2 An improved quasi-polynomial algorithm

The algorithm of Miller and Sheehy is expensive at the bottom of the recursion tree, so we replace the bottom with a faster algorithm. We use a result of Mulzer and Werner [24]:

► **Theorem 17** ([24]). *Given a set P of n points in \mathbb{R}^d , one can compute a site of rank $\geq n/4(d+1)^3$ (together with its log) in $d^{O(\log d)}n$ time.*

Let $\delta \in (0, 1)$ be a small constant. We modify the algorithm of Miller and Sheehy by keeping all the singleton sites of rank one in a buffer of *free* points. Initially, all points are in the buffer. Whenever the buffer contains at least δn points, we use the algorithm of Theorem 17 to compute a site of rank $\rho \geq \delta n/8(d+1)^3$, where ρ is a power of two. (If the computed rank is too large, we throw away entries from the log until the rank reaches a power of two.) We insert this site into the collection of sites maintained by the algorithm. As in Miller and Sheehy's algorithm, we repeatedly merge $d+2$ sites of the same rank to get a site of double the rank. In the process, the points thrown out from the log are recycled into the buffer. Whenever the buffer size exceeds δn , we compute a new site of rank ρ . This process stops when no sites can be merged and the number of free points is less than δn .

► **Theorem 18.** *Given a set P of n points in \mathbb{R}^d , and a parameter $\delta \in (0, 1)$, one can compute a site of rank at least $\frac{(1-\delta)n}{2(d+1)^2}$ (together with its log) in $d^{O(\log(d/\delta))}n$ time.*

Proof. When the algorithm above stops, there are at least $(1-\delta)n$ points in its logs. Arguing as in Eq. (2.1), the output site has rank

$$2^h \geq \frac{(1-\delta)n}{2(d+1)^2}.$$

We now consider runtime. The algorithm maintains only nodes of rank $\rho \geq 2^{h-H}$, where

$$H = \left\lceil \log_2 \frac{2^h}{\rho} \right\rceil \leq \left\lceil \log_2 \frac{n/2(d+1)^2}{\delta n/8(d+1)^3} \right\rceil = 1 + \log_2 \frac{4(d+1)}{\delta} = O(\log(d/\delta)).$$

The total work spent on merging nodes with these ranks is equivalent to the work in Miller and Sheehy's algorithm for such nodes. By Lemma 13, the total work performed is $O(d^{4+H}n)$.

As for the work associated with the buffer, observe that Theorem 17 is invoked $(d+2)^{H+1}$ times (this is the number of nodes in the history of rank 2^{h-H}). Each invocation takes $d^{O(\log d)}n$ time, so the total running time of the algorithm is

$$d^{O(H)}n + (d+1)^{H+1}d^{O(\log d)}n = d^{O(\log(d/\delta))}n. \quad \blacktriangleleft$$

3.3 A strongly polynomial algorithm

► **Lemma 19.** *Let P be a set of n points in \mathbb{R}^d . For $N = \Theta(d^2 \log d)$, consider a random coloring of P by $k = \lfloor n/N \rfloor$ colors, and let $\{P_1, \dots, P_k\}$ be the resulting partition of P . With probability $\geq 1 - k/d^{O(d)}$, this partition is a Tverberg partition of P .*

Proof. Let $\varepsilon = 1/(d+1)$. The VC dimension of halfspaces in \mathbb{R}^d is $d+1$ by Radon's theorem. By the ε -net theorem [18, 15], a sample from P of size

$$N = \left\lceil \frac{8(d+1)}{\varepsilon} \log(16(d+1)) \right\rceil = \Theta(d^2 \log d)$$

is an ε -net with probability $\geq 1 - 4(16(d+1))^{-2(d+1)}$. Then P_1, \dots, P_k are all ε -nets with the probability stated in the lemma.

Now, consider the centerpoint q of P . We claim that $q \in \mathcal{CH}(P_i)$, for all i . Indeed, assume otherwise, so that there is a separating hyperplane between q and some P_i . Then the halfspace induced by this hyperplane that contains q also contains at least εn points of P , because q is a centerpoint of P . But this contradicts that P_i is an ε -net for halfspaces. ◀

► **Lemma 20.** *Let P be a set of n points in \mathbb{R}^d . For $N = O(d^3 \log d)$, consider a random coloring of P by $k = \lfloor n/N \rfloor = \Omega(\frac{n}{d^3 \log d})$ colors, and let $\{P_1, \dots, P_k\}$ be the resulting partition of P . One can compute, in $O(d^7 \log^6 d)$ time, a Tverberg point that lies in $\bigcap_i \mathcal{CH}(P_i)$. This algorithm succeeds with probability $\geq 1 - k/d^{O(d)}$.*

Proof. Compute a $1/(2d^2)$ -centerpoint q for P using the algorithm of Har-Peled and Jones [16], and repeat the argument of Lemma 19 with $\varepsilon = 1/(2d^2)$. With the desired probability, $q \in \mathcal{CH}(P_i)$ for all i . ◀

3.4 A weakly polynomial algorithm

Let $T_{LP}(n, m)$ be the time to solve an LP with n variables and m constraints. Using interior point methods, one can solve such LPs in weakly polynomial time. The fastest known method runs in $\mathcal{O}_w(mn + n^3)$ [29] or $\mathcal{O}_w(mn^{3/2})$ [20], where \mathcal{O}_w hides polylogarithmic terms that depends on n, m , and the width of the input numbers.

► **Remark 21.** The *error* of the LP solver, see [29], for a prescribed parameter ε , is the distance of the computed solution from an optimal one. Specifically, let R be the maximum absolute value of any number in the given instance. In $O((nm + n^3) \log^{O(1)} n \log(n/\varepsilon))$ time, the LP solver can find an assignment to the variables which is \mathcal{E} close to complying with the LP constraints, where $\mathcal{E} \leq \varepsilon n m R$ [29]. That is, the LP solver can get arbitrarily close to a true solution. This is sufficient to compute an exact solution in polynomial time if the input is made out of integer numbers with polynomially bounded values, as the running time then depends on the number of bits used to encode the input. We use $\mathcal{O}_w(\cdot)$ to denote such **weakly polynomial** running time.

► **Lemma 22** (Carathéodory via LP). *Given a set P of n points in \mathbb{R}^d and query point q , one can decide if $q \in \mathcal{CH}(P)$, and if so, output a convex combination of $d + 1$ points of P that is equal to q . The running time of this algorithm is $O(T_{LP}(n, n + d) + nd^3) = \mathcal{O}_w(nd + nd^3)$.*

Alternatively, one can compute such a point in $2^{O(\sqrt{d \log d})} + O(d^2 n)$ time.

Proof. We write the natural LP for representing q as a point in the interior of $\mathcal{CH}(P)$. This LP has n variables (one for each point), and $n + 2d + 2$ constraints (all variables are positive, the points sum to q , and the coefficients sum to 1), where an equality constraint counts as two constraints. If the LP computes a solution, then we can sparsify it using Lemma 10.

The alternative algorithm writes an LP to find a hyperplane separating q from P . First, it tries to find a hyperplane which is vertically below P and above q . This LP has d variables, and it can be solved in $O(2^{\sqrt{d \log d}} + d^2 n)$ time [27, 10, 21]. If there is no such separating hyperplane, then the algorithm provides d points whose convex hull lies below q and tries again. This time, it computes a separating hyperplane below q and above P . Again, if no such separating hyperplane exists, then the algorithm returns d points whose convex hull lies above q . The union of the computed point sets above and below q contains at most $2d$ points. Now, write the natural LP with $2d$ variables as above, and solve it using linear-time LP solvers in low dimensions. This gives the desired representation. ◀

► **Remark 23.** Rolnick and Soberón [26] achieved a result similar to that of Lemma 22, but they used binary search to find the $d + 1$ coefficients in the minimal representation. Thus their running time is $O(T_{LP}(n, n + d)d \log n)$.

Using Lemma 19, we get the following.

► **Lemma 24.** *Let P be a set of n points in \mathbb{R}^d . For $N = O(d^2 \log d)$, one can compute a site q of rank $k = n/O(d^2 \log d)$ in $\mathcal{O}_w(n^{5/2} + nd^3)$ time. The algorithm succeeds with probability $\geq 1 - k/d^{O(d)}$.*

Proof. We compute a Tverberg partition using Lemma 19. Next we write an LP for computing an intersection point q that lies in the interior of the $k = n/O(d^2 \log d)$ sets. This LP has $O(n + d)$ constraints and n variables, and it can be solved in $\mathcal{O}_w(n^{5/2})$ time [20]. We then sparsify the representations over each of the k sets. This requires $O(d^2 \log d \cdot d^3)$ time per set and hence $O(nd^3)$ time overall. The result is a site q with a log of rank k , as desired. ◀

► **Theorem 25.** *Given a set P of n points in \mathbb{R}^d , and a parameter $\delta \in (0, 1)$, one can compute a site of rank at least $\frac{(1-\delta)n}{2(d+1)^2}$ (together with its log) in $d^{O(\log \log(d/\delta))} \mathcal{O}_w(n^{5/2})$ time.*

Proof. We modify the algorithm of Theorem 18 to use Lemma 24 to compute a Tverberg point on the points in the buffer. Since the gap between the top rank of the recursion tree and rank computed by Lemma 24 is $O(\log(d/\delta))$, it follows that the algorithm uses only the top $O(\log \log(d/\delta))$ levels of the recursion tree, and the result follows. ◀

3.5 Faster approximation in low dimensions

► **Lemma 26.** *Let P be a set of n points in \mathbb{R}^d , and let $\delta \in (0, 1)$ be some parameter. One can compute a Tverberg point of depth $\geq (1 - \delta)n/d(d + 1)$, together with its log, in $O(d^{O(d)}/\delta^{2(d-1)} + 2^{O(\sqrt{d \log d})}n + d^2 n \log^2 n)$ time. The algorithm succeeds with probability close to one.*

Proof. Let $\varepsilon = 1/2(d + 1)$, and let R be a random sample from P of size

$$m = O(d\varepsilon^{-1}\delta^{-2} \log \varepsilon^{-1}) = O(d^2\delta^{-2} \log d).$$

This sample is a (ε, δ) -relative approximation for P with probability close to one [14]. Compute a centerpoint c for the sample using “brute force” in $O(m^{d-1})$ time [7]. Now, repeatedly use the algorithmic version of Carathéodory’s theorem (Lemma 22) to extract a simplex that contains c . One can repeat this process $\lfloor n/d(d + 1) \rfloor$ times before getting stuck, since every simplex contains at most d points in any halfspace passing through c . Naively, the running time of this algorithm is $2^{O(\sqrt{d \log d})}n^2$.

However, one can do better. The number of simplices extracted by the above algorithm is $L = \lfloor n/d(d + 1) \rfloor$. For $i = 1, \dots, L$, let $b_i = \lfloor n/(d + 1) \rfloor - d(i - 1)$ be a lower bound on the Tukey depth of c at the beginning of the i th iteration of the above extraction algorithm. At this moment, the point set has $n_i = n - (d + 1)(i - 1) \geq n/2$ points. Hence the relative Tukey depth of c is $\varepsilon_{L-i} = b_{L-i}/n_{L-i}$. In particular, an ε_i -net R_i for halfspaces has size $r_i = O(\frac{d}{\varepsilon_i} \log \frac{1}{\varepsilon_i})$. If r_i is larger than the number of remaining points, then the sample consists of the remaining points of P . The convex hull of such a sample contains c with probability close to one, so one can apply Lemma 22 to R_i to get a simplex that contains P (if the sample fails, then the algorithm resamples). The algorithm adds the simplex to the output log, removes its vertices from P , and repeats.

Since the algorithm invokes Lemma 22 $O(n/d^2)$ times, the running time is bounded by $2^{O(\sqrt{d \log d})} n/d^2 + O(d^2 \sum_i r_i)$. Since $n_{L-i} \geq n/2$ and $b_{L-i} \geq i \cdot d$, we have that $\varepsilon_{L-i} \geq (id/(n/2)) = 2id/n$. Therefore,

$$\sum_i r_i = O(n) + \sum_{i=1}^{L-1} r_{L-i} = O(n) + \sum_{i=1}^{L-1} O\left(\frac{dn}{2id} \log \frac{n}{id}\right) = O(n \log^2 n). \quad \blacktriangleleft$$

A Tukey depth in two dimensions

Restatement of Lemma 4. *Given a set P of n points in the plane and a query point q , such that $P \cup \{q\}$ is in general position, one can compute, in $O(n + k \log k)$ time, the Tukey depth k of q in P . The algorithm also computes the halfplane realizing this depth.*

Proof. In the dual, q^* is a line, and the task is to find a point on this line which minimizes the number of lines of P^* (i.e., set of lines dual to the points of P) strictly below it. More precisely, one has to also solve the upward version, and return the minimum of the two solutions. Handling the downward version first, every point $p \in P$ has a dual line p^* . The portion of q^* that lies above p^* is a closed ray on q^* . As such, we have a set of rays on the line (which can be interpreted as the x -axis), and the task is to find a point on the line contained in the minimum number of rays. (This is known as linear programming with violations in one dimension.)

Let R_{\Rightarrow} (resp. L_{\Leftarrow}) be the set of points that corresponds to heads of rays pointing to the right (resp. to the left) by P^* on q^* . Let R_i be the set of $\lfloor n/2^i \rfloor$ rightmost points of R_{\Rightarrow} , for $i = 0, \dots, h = \lceil \log_2 n \rceil$. Using median selection, each set R_i can be computed from R_{i-1} in $|R_{i-1}|$ time. As such, all these sets can be computed in $\sum_i O(n/2^i) = O(n)$ time. The sets L_0, L_1, \dots, L_h are computed in a similar fashion. For all i , we also compute the rightmost point r_{i-1} of $R_{i-1} \setminus R_i$ (which is the rightmost point in $R \setminus R_i$). Similarly, ℓ_i is the leftmost point of $L_{i-1} \setminus L_i$, for $i = 1, \dots, h$. Let r_0 (resp. ℓ_0) be the rightmost (resp. leftmost) point of R_0 (resp. L_0).

Now, compute the maximum j such that r_j is to the left of ℓ_j . Observe that $(R \setminus R_j) \cup (L \setminus L_j)$ form a set of rays that their intersection is non-empty (i.e., feasible). Similarly, the set of rays $(R \setminus R_{j+1}) \cup (L \setminus L_{j+1})$ is not feasible, and any set of feasible rays must be created by removing at least $|R_{j+1}| = |L_{j+1}| = \lfloor n/2^{j+1} \rfloor$ rays from $R_{\Rightarrow} \cup L_{\Leftarrow}$. Hence, in linear time, we have computed a 4-approximation to the minimum number of rays that must be removed for feasibility. In particular, if S is a set of rays such that $(R_{\Rightarrow} \cup L_{\Leftarrow}) \setminus S$ is feasible, then $(R_{j-1} \cup L_{j-1}) \setminus S$ is also feasible. Namely, if the minimum size of such a removeable set S is k , then we have computed a set of $O(k)$ rays, such that it suffices to solve the problem on this smaller set.

In the second stage, we solve the problem on $R_{j-1} \cup L_{j-1}$. We first sort the points, and then for each point in this set, we compute how many rays must be removed before it lies in the intersection of the remaining rays. Given a location p on the line, we need to remove all the rays of R_{j-1} (resp. L_{j-1}) whose heads lie to the right (resp. left) of p . This can be done in $O(k \log k)$ time by sweeping from left to right and keeping track of the rays that need to be removed.

As such, we can solve the LP with violations on the line in $O(n + k \log k)$ time, where k is the minimum number of violated constraints. A 4-approximation to k can be computed in $O(n)$ time.

Now we return to the Tukey depth problem. First we compute a 4-approximation, denoted by \tilde{k}_{\downarrow} , for the minimum number of lines crossed by a vertical ray shot down from a point on q^* . Similarly, we compute \tilde{k}_{\uparrow} . If $4\tilde{k}_{\downarrow} < \tilde{k}_{\uparrow}$, then we compute k_{\downarrow} exactly and return the point on q^* that realizes it. (In the primal, this corresponds to a closed halfspace containing q along with exactly k_{\downarrow} points of P .) Similarly, if $\tilde{k}_{\downarrow} > 4\tilde{k}_{\uparrow}$, then we compute k_{\uparrow} exactly, and return it as the desired solution. In the remaining case, we compute both quantities and return the minimum of the two. ◀

B Tverberg partitions in two dimensions

Restatement of Lemma 5. *Let P be a set of n points in the plane, let q be a query point such that $P \cup \{q\}$ is in general position, and suppose that $k = d_{TK}(q) \leq n/3$. Then one can compute a log for q of rank k in $O(n + k \log k)$ time.*

Proof. Using the algorithm of Lemma 4, compute the Tukey depth of q and the closed halfplane h^+ realizing it, where q lies on the line h bounding h^+ . This takes $O(n + k \log k)$ time. By translation and rotation, we can assume that q is the origin and h is the x -axis. Let $P^+ = P \cap h^+$ be the k points realizing the Tukey depth of q , and let $P^- = P \setminus P^+$ be the set of points below the x -axis, so that $|P^-| = n - k \geq 2k$.

Consider the counterclockwise order of the points of P^- starting from the negative side of the x -axis. Let T be the set containing the first and last k points in this order, computed in $O(n)$ time by performing median selection twice. Let $T = \{t_1, \dots, t_{2k}\}$ be the points of T sorted in counterclockwise order. Similarly, let $P^+ = \{p_1, \dots, p_k\}$ be the points of P^+ sorted in counterclockwise order starting from the positive side of the x -axis, see Figure B.1.

Let $\Delta_i = \Delta_{p_i t_i t_{k+i}}$, for $i = 1, \dots, k$. We claim that $q \in \Delta_i$ for all i . To this end, let ℓ_i be the line passing through the origin and p_i , and let ℓ_i^+ denote the halfspace it induces to the left of the vector $\overrightarrow{qp_i}$. Then ℓ_i^+ must contain t_i , as otherwise, $|P \cap \ell_i^+| < k$, contradicting the Tukey depth of q . Namely, the segment $p_i t_i$ intersects the negative side of the x -axis. A symmetric argument, applied to the complement halfplane, implies that the segment $t_{k+i} p_i$ intersects the positive side of the x -axis. Then the origin q is contained in Δ_i , as claimed.

Computing these triangles, we have found a log for q of rank k in $O(n + k \log k)$ time. ◀

Abstract

Let G be a graph and $S, T \subseteq V(G)$ be (possibly overlapping) sets of terminals, $|S| = |T| = k$. We are interested in computing a *vertex sparsifier* for terminal cuts in G , i.e., a graph H on a smallest possible number of vertices, where $S \cup T \subseteq V(H)$ and such that for every $A \subseteq S$ and $B \subseteq T$ the size of a minimum (A, B) -vertex cut is the same in G as in H . We assume that our graphs are unweighted and that terminals may be part of the min-cut. In previous work, Kratsch and Wahlström (FOCS 2012/JACM 2020) used connections to matroid theory to show that a vertex sparsifier H with $O(k^3)$ vertices can be computed in randomized polynomial time, even for arbitrary digraphs G . However, since then, no improvements on the size $O(k^3)$ have been shown.

In this paper, we draw inspiration from the renowned *Bollobás's Two-Families Theorem* in extremal combinatorics and introduce the use of total orderings into Kratsch and Wahlström's methods. This new perspective allows us to construct a sparsifier H of $\Theta(k^2)$ vertices for the case that G is a DAG. We also show how to compute H in time near-linear in the size of G , improving on the previous $O(n^{\omega+1})$. Furthermore, H recovers the *closest* min-cut in G for every partition (A, B) , which was not previously known. Finally, we show that a sparsifier of size $\Omega(k^2)$ is required, both for DAGs and for undirected edge cuts.

1 Introduction

Let $G = (V, E)$ be an unweighted, directed graph, and let $S, T \subseteq V$ be sets of terminals, not necessarily disjoint. In the vertex sparsifier problem, our goal is to construct a smaller graph H , called a *vertex sparsifier*, that preserves the cut structure of S, T in G . More precisely, H includes all vertices in S, T , and for all subsets $A \subseteq S$ and $B \subseteq T$, the size of the minimum vertex cut separating A and B is the same in G and H . Here, we allow the min-cut to contain vertices from A and B ; for other notions of cut sparsifiers from the literature, see related work, below.

A result of Kratsch and Wahlström proved the first bound on the size of a vertex sparsifier that is polynomial in the number of terminals. When S, T have size k , the vertex sparsifier has $O(k^3)$ vertices. Kratsch and Wahlström's main insight is to phrase the problem in terms of constructing representative families on a certain matroid, after which they can appeal to the rich theory on representative families [19, 16]. Their result, also known as the

cut-covering lemma in the areas of fixed-parameter tractability and kernelization, has led to many new algorithmic developments [13, 12, 9, 10]. Nevertheless, despite the recent surge in applications of the cut-covering lemma, the original bound of $O(k^3)$ has yet to be improved.

In this paper, we introduce the ordered version of the representative family method, and use it to give a sparsifier on $O(k^2)$ vertices in directed acyclic graphs. This matches lower bounds of $\Omega(k^2)$, which we present in Section 4. Furthermore, unlike Kratsch and Wahlström’s result, our new algorithm runs in near-linear time in the size of the graph, and preserves all *closest* min-cuts between subsets of the terminals. In fact, the latter is an important ingredient in the improved running time; see discussion below. We expect that covering closest min-cuts may lead to further applications in the theory of kernelization. The central method we use is the following theorem.

► **Theorem 1.** *Suppose \mathcal{F} is a family of subsets of \mathbb{F}^d for some field \mathbb{F} and for all $B \in \mathcal{F}$, $|B| = s$. Let*

$$\mathcal{A} = \{A \subseteq \mathbb{F}^d \mid |A| \leq r \text{ and } \exists B \in \mathcal{F} \text{ s.t. } A \uplus B \text{ is linearly independent}\}.$$

Fix any ordering σ of \mathcal{F} , namely $\mathcal{F} = \{B_1, B_2, \dots, B_n\}$, and suppose $d \geq r + s$. Then there exists $\mathcal{B} \subseteq \mathcal{F}$, $\mathcal{B} = \{B_{i_1}, B_{i_2}, \dots, B_{i_m}\}$ where $i_1 < i_2 < \dots < i_m$, such that

- (a) *For all $A \in \mathcal{A}$, there exists $B_{i_k} \in \mathcal{B}$ where $A \uplus B_{i_k}$ is independent and for all $j \in [n]$, $j > i_k$, $A \uplus B_j$ is dependent. Note that B_j is not necessarily in \mathcal{B} . Here \uplus denotes disjoint union, which particularly implies that if A and B are not disjoint, then $A \uplus B$ is a multi-set and therefore dependent.*
- (b) *$m \leq \binom{d}{s}$, and we can find \mathcal{B} algorithmically using $O(\binom{d}{s}ns^\omega + \binom{d}{s}^{\omega-1}n)$ field operations over \mathbb{F} (in particular, in a number of operations linear in $|\mathcal{F}|$).*

The condition that $A \uplus B_j$ is required to be dependent only for $j > i_k$, as opposed to $A \uplus B_j$ being dependent for every $j \neq i_k$, recalls the *skew* version of Bollobás’s two-families theorem, proven by Frankl [8].

Technically, this version is equivalent to the weighted version of the representative family method shown by Fomin et al. [6]. In that version, every element $X \in \mathcal{F}$ has a weight $w(X)$, and condition a is replaced by the condition that $w(B_{i_k})$ is maximal among all sets B_j such that $A \uplus B_j$ is independent. Indeed, given σ we can simply use $w(B_j) = j$, and conversely any input where all the weights are distinct enforces a corresponding total ordering on the elements¹. However, the difference in focus between weights and an ordering is significant, as a total element ordering can carry semantic meaning that is obscured when implemented using weights.

Applying Theorem 1 to vertex cut sparsifiers, we obtain the main result of this paper.

► **Theorem 2.** *Given a directed acyclic graph $G = (V, E)$ with terminal sets S, T of size k , we can find a vertex cut sparsifier of G of size $\Theta(k^2)$ algorithmically in time $\tilde{O}((m+n)k^{O(1)})$.*

Our proof initially follows that of Kratsch and Wahlström [13]. Like Kratsch and Wahlström, we compute a “cut-covering set”, i.e., a set $Z \subseteq V(G)$ such that for every $A \subseteq S$ and $B \subseteq T$ there is an (A, B) -min cut C with $C \subseteq Z$. However, Kratsch and Wahlström’s result is based around *essential vertices*, i.e., vertices $v \in V(G)$ that must be included in any

¹ In the first version of this paper, we presented a proof of Theorem 1 that runs in polynomial time. It was later pointed out to us that this theorem is equivalent to Theorem 3.7 in [6], which runs in near-linear time. We thereby refer the readers to the proof in [6], as our proof shares similar underlying ideas with theirs.

cut-covering set. Using the unordered version of Theorem 1 (see Lemma 1.1 of [11]), they compute a set X of $O(k^3)$ vertices which is guaranteed to include all essential vertices in G . They then eliminate one vertex not in X , recompute the representative family, and repeat until exhaustion. This gives a superlinear running time and a final bound of $|Z| = O(k^3)$. This iterative process for computing Z was required because the initial set X could not be guaranteed to contain *all* vertices of any (A, B) -min cut C , unless that min-cut happens to be unique (i.e., consist only of essential vertices).

We use Theorem 1 to improve over this in two ways. By using the additional power of an ordering, we reduce the bound from $|Z| = O(k^3)$ to $|Z| = O(k^2)$ when G is a DAG. Furthermore, instead of covering some arbitrary min-cut for every pair (A, B) , we observe that our construction guarantees that Z contains the unique *closest* (A, B) -min cut to A , i.e., that mincut C for which the set of vertices reachable from A is minimized. This is an interesting consequence that was not previously known, but additionally, it allows us to significantly improve the running time required to compute a cut-covering set. Since the output of Theorem 1 contains all vertices of the closest (A, B) -min cut C for every (A, B) , we can compute a cut-covering set Z with a single application of Theorem 1, eliminating the iterative nature of [13] and improving the running time of the procedure.

Finally, to achieve a linear running time, one more obstacle must be overcome. In order to apply Theorem 1, we need to compute a representation for the matroids underlying the result, known as *gammoids*, in time linear in $n + m$. The usual method for representing gammoids goes via the class of *transversal matroids*, however, this requires taking the inverse of an $n \times n$ matrix. Luckily, we observe that an older construction of Mason [17] can be used to represent gammoids more efficiently over DAGs; see Lemma 10. This allows us to compute Z in time linear in $n + m$, and computing the final sparsifier H is then a simple task.

We also show that there are graphs G with k terminals such that any cut sparsifier H requires $\Omega(k^2)$ vertices, both when H is a directed vertex cut sparsifier for a DAG G , and when H is an undirected edge cut sparsifier for an undirected graph G .

Related work. Several different notions of cut sparsifiers have been considered, as well as vertex sparsifiers for other problems. Vertex cut sparsifiers were first introduced by Moitra [18] in the setting of approximation algorithms; see also [15, 2, 4]. Recently, they have found applications in fast graph algorithms, especially in the dynamic setting [5, 1, 3]. Compared to our setting, many of these results replicate min-cuts only approximately, rather than exactly, and most apply only to undirected edge cuts. On the other hand, in the general case (e.g., when working with edge cuts or when terminals are not deletable), there is an important distinction between parameterizing by the *number of terminals* and the *total terminal capacity*. Our setting, with deletable terminals, corresponds to parameterizing edge cuts by the total capacity of the terminal set. Previous results for this setting include Kratsch and Wahlström [13] discussed above and Chuzhoy [4], as well as recent results on terminal multicut sparsification [20]. By contrast, parameterizing by the number of terminals in a setting where terminals have unbounded capacity makes for a much harder sparsification task, and this is the setting that has been most commonly considered in approximation algorithms. Indeed, it is known that any exact cut sparsifier for k terminals with unbounded capacity needs to have at least exponential size in k , and possibly double-exponential [14].

2 Preliminaries

Throughout the paper, all graphs are directed and unweighted. We begin with standard terminology on cuts and cut sparsifiers.

► **Definition 3** (Vertex Cut). *Given a directed unweighted graph $G = (V, E)$ with sets $X, Y \subseteq V$, a set $C \subseteq V$ is a vertex cut of (X, Y) if after removing C from G , there does not exist a path from a vertex in X to a vertex in Y . We denote the size of a minimum vertex cut between X, Y in G as $\text{mincut}_G(X, Y)$.*

► **Definition 4** (Vertex Cut Sparsifier). *Consider a directed unweighted graph $G = (V, E)$ with sets $S, T \subseteq V$. A directed unweighted graph $H = (V', F)$ is a vertex cut sparsifier of G if*

- (a) $S, T \subseteq V'$.
- (b) For all $X \subseteq S, Y \subseteq T$, $\text{mincut}_G(X, Y) = \text{mincut}_H(X, Y)$.

The problem we consider in this paper is the minimum size of a vertex sparsifier.

► **Problem 5** (Minimum Vertex Cut Sparsifier). *Given a directed unweighted graph $G = (V, E)$ with terminal sets $S, T \subseteq V$, what is the minimum number of vertices in a vertex cut sparsifier of G ?*

Kratsch and Wahlström [13] obtained a bound for this problem of $O(k^3)$ vertices, where $|S| = |T| = k$. Their application was in the fixed-parameter tractability setting, specifically in constructing kernels for cut-based problems. Our proof utilizes similar matroid-theoretic techniques as in their work. We introduce these techniques next.

► **Definition 6** (Matroid). *Given a finite ground set E , a set system $M = (E, I)$ where $I \subseteq \mathcal{P}(E)$ is called a matroid if*

- (a) $\emptyset \in I$.
- (b) For $X, Y \subseteq E$, if $Y \in I$ and $X \subseteq Y$, then $X \in I$.
- (c) If $X, Y \in I$ and $|X| < |Y|$, then there exists $y \in Y \setminus X$ such that $X \cup \{y\} \in I$.

Central to our proof is the use of gammoids and their representations.

► **Definition 7** (Gammoid). *Given a graph $G = (V, E)$ and a subset of vertices S (which we refer to as the “source vertices”), the gammoid on S is the matroid $M = (V, I)$ where I contains all subsets $T \subseteq V$ such that there exist $|T|$ vertex-disjoint paths from S to T in G .*

► **Definition 8** (Matroid disjoint union). *Given two matroids on disjoint ground sets, their matroid disjoint union is the matroid whose ground set is the union of their ground sets, and a set is independent if the corresponding part in each matroid is independent.*

► **Definition 9** (Representable matroid). *Given a field F , a matroid $M = (E, I)$ is representable over F if there exists a matrix A over the field F and a bijective mapping from E to the columns of A , such that a set $S \subseteq E$ is independent if and only if its corresponding set of columns of A are linearly independent.*

In particular, it is well known in matroid theory that gammoids are representable in randomized polynomial time; see Marx [16]. However, to control the running time, we revisit an older representation by Mason [17], and note that it leads to a representation in near-linear time in $|V| + |E|$ on DAGs. (Proofs of results marked ★ are deferred to the full version of this paper.)

► **Lemma 10** (★ Construction of Gammoid Representation on DAGs). *Given a directed acyclic graph $G = (V, E)$, a set $S \subseteq V$, and $\varepsilon > 0$, with $|V| = n$, $|E| = m$ and $|S| = k$, a representation of the gammoid on S of dimension k over a finite field with entries of bit length $\ell = O(k \log n + \log(1/\varepsilon))$ can be constructed in randomized time $\tilde{O}((n+m)k\ell)$ with one-sided error at most ε , where \tilde{O} hides factors logarithmic in ℓ .*

We also note that the disjoint union of two representable matroids is representable. Given these definitions, we now present the main arguments of this paper.

3 Vertex Cut Sparsifier for DAGs

In this section, we prove our main result, Theorem 2. We first borrow the following key concepts from Kratsch and Wahlström [13].

► **Definition 11** (Essential Vertex). *A vertex $v \in V \setminus (S \cup T)$ is called essential if there exist $X \subseteq S, Y \subseteq T$ such that v belongs to every minimum vertex cut between X, Y .*

► **Definition 12** (Neighborhood Closure). *For a digraph $G = (V, E)$ and a vertex $v \in G$, the neighborhood closure operation is defined by removing v from G and adding an edge from every in-neighbor of v to every out-neighbor of v . The new graph is denoted by $\text{cl}_v(G)$.*

► **Definition 13** (Closest Set). *For sets of vertices $X, A \subseteq V$, A is closest to X if A is the unique min-cut between X and A .*

We introduce the following definitions to simplify our discussions.

► **Definition 14**. *For sets $X \subseteq S, Y \subseteq T$, let C be a vertex cut for X, Y . Let G' be the subgraph formed by the union of all paths from X to Y . The left-hand side of C , denoted $L(C)$, is the set of vertices that are still reachable from X in G' after C is removed. Similarly, the right-hand side of C , denoted $R(C)$, is the set of vertices that can still reach Y in G' after C is removed.*

► **Definition 15** (Saturation). *Let C be a vertex cut for $X \subseteq S, Y \subseteq T$. For a vertex $v \in C$, we say that (C, v) is saturated by X if there exist $|C| + 1$ paths from X to C that are vertex disjoint except for two paths that both ends at v . Similarly, (C, v) is saturated by Y if there exist $|C| + 1$ paths from C to Y that are vertex disjoint except for two paths that both start at v .*

The following three lemmas follow from [13, Section 5.1]. Their proofs, as presented in [13] and Chapter 11.6 of [7], are included in the Appendix for completeness.

► **Lemma 16** (Essential Vertex Lemma). *Let v be an essential vertex with respect to $X \subseteq S, Y \subseteq T$. Let C be any minimum vertex cut between X, Y . Then (C, v) is saturated by both X and Y .*

► **Lemma 17** (Closure Lemma). *If $v \in V \setminus (S \cup T)$ is not an essential vertex, then $\text{cl}_v(G)$ is a vertex cut sparsifier of G .*

► **Lemma 18** (Closest Cut Lemma). *Let C be a vertex cut for $X \subseteq S, Y \subseteq T$ that is closest to X (resp. Y), then for all vertices $v \in C$, (C, v) is saturated by X (resp. Y).*

Using the saturation properties of essential vertices (as in Lemma 16), Kratsch and Wahlström presented a construction of matroids which, combined with the unordered version of Theorem 1, computes a set of vertices P of size $O(k^3)$ that contains all the essential vertices.

They then apply Lemma 17 iteratively to any one vertex not in P and repeat the process. The repetition is required since Lemma 17 may change the essential vertices of the graph.

In our proof, instead of marking only essential vertices we consider all vertices on closest min-cuts. These have weaker saturation properties than essential vertices (as in Lemma 18), but these weaker properties suffice thanks to the ordering imposed in Theorem 1. This ordering, when applied to the topological ordering of a DAG, allows us to mark all vertices of closest min-cuts in a single application of Theorem 1, which eliminates the iterative nature of the previous result. This intuition will be made clear in the following discussion.

We now present our construction, which results in Theorem 2.

► **Theorem 19.** *For a directed acyclic graph $G = (V, E)$ with terminal sets S and T , let $k = |S \cup T|$. Then there exists a set of vertices P of size $O(k^2)$ such that for each pair of $X \subseteq S, Y \subseteq T$, the min- (X, Y) cut that is closest to Y is contained in P . This set can be found in time $\tilde{O}(nk^{2\omega-1} + mk^2)$, and a sparsifier on P can then be constructed in the same asymptotic running time.*

Proof. Let $G_R = (V, E_R)$ be the graph G with the direction of all edges reversed. We make the following modification to our graphs G, G_R . For each vertex $v \in V \setminus (S \cup T)$, add a vertex v' into V and for each directed edge $(u, v) \in E$, add (u, v') into E . We refer to v' as the sink-only copy of v . Denote this new directed graph $G' = (V', E')$, we add sink-only copies of vertices to G_R and obtain $G'_R = (V', E'_R)$. Note that G', G'_R are both acyclic. Enumerate V in a reverse topological ordering, namely $V = (v_1, v_2, \dots, v_n)$ where v_i cannot reach any v_j for $j > i$.

Let $M_1 = (E_1, I_1)$ be the gammoid constructed on the graph G and the set of terminals S in G , and let $M_2 = (E_2, I_2)$ be the gammoid constructed on the graph G'_R and the set of terminals T in G'_R . To distinguish between vertices of E_1 and E_2 , we label vertices in E_1 as v_1, \dots, v_n , and elements in E_2 as $\bar{v}_1, \dots, \bar{v}_n, \bar{v}'_1, \dots, \bar{v}'_n$. Note that E_1 does not contain sink-only copies. For any set of vertices $U \subseteq V$, denote the respective sets in E_1 and E_2 as U_1 and U_2 . Let M be the disjoint union of matroids M_1 and M_2 , so M is representable and it has rank $O(k)$.

Observe that for any $X \subseteq S, Y \subseteq T$, the min-cuts between X and Y in G are the same as in G' because the vertex copies v' we added to G have no outgoing edges. Therefore, G and G' have the same set of closest cuts. We now consider the following constructions. For a min-cut C between X, Y that is closest to Y , and a vertex $v \in C$, define

$$A_{(C,v)} = [(S_1 \setminus X_1) \cup (C_1 \setminus \{v\})] \cup [(T_2 \setminus Y_2) \cup C_2].$$

Let $\tilde{\mathcal{A}}$ consist of $A_{(C,v)}$ for all such cut-vertex pairs. Define

$$\mathcal{F} = \{B_v = \{v, v'\} \mid v \in V\}.$$

We pause for a moment to explain the ideas behind these definitions. First of all, note that the algorithm in Theorem 1 only takes as input a family \mathcal{F} . Intuitively, one should think of the sets in \mathcal{F} as answers to potential queries, and the sets in \mathcal{A} (defined in Theorem 1) as all queries answered by \mathcal{F} . As we will show, the family of queries $\tilde{\mathcal{A}}$ we defined is a subset of \mathcal{A} . If we can further show that for each v in a closest min-cut C , B_v is the unique answer that the algorithm will find for query $A_{(C,v)}$, then we know that the output of the algorithm must contain all vertices of all closest min-cuts, because all queries in $\mathcal{A} \supseteq \tilde{\mathcal{A}}$ must be answered.

More specifically, for each query $A_{(C,v)}$, Theorem 1 promises to find the answer B_u to $A_{(C,v)}$ (which means $A_{(C,v)} \uplus B_u$ is independent in M) that is the last answer according to the reverse topological ordering on \mathcal{F} . This means for all $w > u$, $A_{(C,v)} \uplus B_w$ is dependent

in M . Since our goal is for Theorem 1 to output a set containing all vertices on all closest min-cuts, we want to show that B_v is the last answer in the ordering to $A_{(C,v)}$. This is precisely captured in the following claim.

▷ **Claim 20.** For each $A = A_{(C,v)}$, B_v is the unique set in \mathcal{F} such that

- $A \uplus B_v$ is independent in M , and
- for all $u > v$ in the reverse topological ordering of V , $A \uplus B_u$ is dependent in M .

Proof. We first show that $A \uplus B_v$ is independent. Since M is a disjoint union matroid, we need to show that $(A \cap E_1) \uplus \{v\} = (S_1 \setminus X_1) \cup C_1$ is independent in M_1 and $(A \cap E_2) \uplus \{\bar{v}'\} = (T_2 \setminus Y_2) \cup C_2 \cup \{\bar{v}'\}$ is independent in M_2 .

Since both M_1 and M_2 are gammoids, we need to show existence of vertex disjoint paths from S_1 to $(S_1 \setminus X_1) \cup C_1$. First note that singleton paths can cover all vertices in $S_1 \setminus X_1$. Since C_1 is a min-cut between X_1 and Y_1 , by duality there exist vertex disjoint paths from X_1 to C_1 . Therefore $(S_1 \setminus X_1) \cup C_1$ is independent in M_1 . Similarly, singleton paths can cover all vertices in $T_2 \setminus Y_2$. It suffices for us to show the existence of vertex disjoint paths from Y_2 to $C_2 \cup \{\bar{v}'\}$.

By Lemma 18, there exist $|C_2| + 1$ paths from Y_2 to C_2 that are vertex disjoint except for two paths that both ends at \bar{v} . Therefore, we can redirect one of these two paths to end at \bar{v}' , and we obtain $|C_2| + 1$ vertex disjoint paths from Y_2 to $C_2 \cup \{\bar{v}'\}$. This proves independence.

Now fix $u > v$ in the reverse topological ordering, so that there does not exist a path from v to u . We want to show that either $(A \cap E_1) \uplus \{u\}$ is dependent in M_1 , or $(A \cap E_2) \uplus \{\bar{u}'\}$ is dependent in M_2 . Consider four possible cases:

- u is not on any path from X to Y . Assume for the sake of contradiction that both $(A \cap E_1) \uplus \{u\}$ and $(A \cap E_2) \uplus \{\bar{u}'\}$ are independent. Then there must exist a path from X to u and a path from u to Y , which forms a path from X to Y through u (since G is acyclic), contradiction.
- $u \in L(C)$ (see Definition 14). Then any path from u to Y (or from Y to u in G_R) must intersect with C , which means there does not exist vertex disjoint paths from Y to $C \cup \{u\}$ in G_R . Therefore $(A \cap E_2) \uplus \{\bar{u}'\}$ is dependent.
- $u \in R(C)$. Then any path from X to u must intersect C . Assume for the sake of contradiction that $(A \cap E_1) \uplus \{u\}$ is independent, then there exist vertex disjoint paths from X to $C \setminus \{v\} \cup \{u\}$, which means there is a path from X to u that goes through v . However, since $u > v$ in the topological ordering, there does not exist paths from v to u . This is a contradiction, so $(A \cap E_1) \uplus \{u\}$ is dependent.
- $u \in C$. Then $u \in (A \cap E_1)$, which implies $(A \cap E_1) \uplus \{u\}$ contains two copies of u . Therefore it is dependent.

This completes the proof. ◁

We now apply Theorem 1 on \mathcal{F} with a reverse topological ordering, and we note that the family $\tilde{\mathcal{A}}$ we defined in this proof is a subfamily of \mathcal{A} defined in Theorem 1. Let P be the collection of vertices that Theorem 1 finds. Then by the above claim, for each pair of $X \subseteq S, Y \subseteq T$ and their min-cut C closest to Y , all vertices in C must be in P . Note that this also implies that all essential vertices are in P .

To construct the final sparsifier H on P , for each vertex $u \in P$, we run a depth-first search starting at u on the graph G_u , defined to be G minus the out-edges of vertices in $P \setminus \{u\}$. For each vertex $v \in P \setminus \{u\}$ that is reachable from u in G_u , we add an edge (u, v) to H . Note that this procedure returns the same graph H as the one that sequentially applies Lemma 17 on all vertices not in P , but achieves a shorter runtime of $O(k^2m)$. To see the

equivalence, observe that in both cases, there is an edge (u, v) in the final sparsifier if and only if there is a path from u to v in G whose internal vertices are disjoint from P . We conclude that the output graph H is a valid sparsifier.

For the final running time, note that computing the gammoids takes time $\tilde{O}((m+n)k^2)$ by Lemma 10 with $\varepsilon = 1/n^{O(1)}$, and computing the representative sets takes time $\tilde{O}(nk^{2\omega-1})$ by taking $d = k$ and $s = 2$ in Theorem 1. \blacktriangleleft

We make a few remarks regarding this proof. Intuitively, the gammoid M_2 and its respective query $A_{(C,v)} \cap E_2 = (T_2 \setminus Y_2) \cup C_2$ is used to filter out all vertices on the left-hand side of C , because no vertex in $L(C)$ can reach T without crossing C . The gammoid M_1 and its query $A_{(C,v)} \cap E_1 = (S_1 \setminus X_1) \cup (C_1 \setminus \{v\})$, however, is different, because the query itself allows terminals in X to reach the right-hand side of C through v . If we do not impose a reverse topological ordering on the vertices and use the unordered version of Theorem 1 (Lemma 1.1 in [11]), our proof will fail – there may exist $u \in R(C)$ reachable from v such that $A_{(C,v)} \uplus B_u$ is independent, and the algorithm may not find B_v as the answer. By imposing the reverse topological ordering, we demand the algorithm to find the answer last in the ordering, thereby ensuring the algorithm discovering B_v .

This is the critical difference between our proof and Kratsch and Wahlström’s proof. In Kratsch and Wahlström’s paper, they presented a construction with three matroids – one gammoid on G' and S_1 (note that our first gammoid is constructed on G and S_1), one gammoid on G'_R and T_2 , and one uniform matroid of rank k on V . They then utilized the property that essential vertices can be saturated from both sides (see Lemma 16) and constructed queries similar to our definition of $A_{(C,v)}$. Their first (resp. second) gammoid serves to filter out $R(C)$ (resp. $L(C)$), and they use the uniform matroid to filter out vertices $u \neq v \in C$. We managed to merge their first gammoid and uniform matroid with an asymmetrical construction, thereby proving a stronger bound.

We finally remark that in our proof, we never explicitly compute the queries $A_{(C,v)}$. As mentioned previously, the algorithm in Theorem 1 only takes as input the family \mathcal{F} , and we are simply showing that given our construction of \mathcal{F} , $\tilde{\mathcal{A}}$ is a subset of queries answered. If one can show that another meaningful set of queries are answered by the same \mathcal{F} , then they can derive more properties of the output set of the algorithm (while the output set itself remains unchanged).

We now present tight lower bound constructions in the following section.

4 Lower Bound Constructions

In this section we present two constructions graphs for which any vertex cut sparsifier requires $\Omega(k^2)$ vertices. The first construction is presented by Kratsch and Wahlström [13] (construction found in arXiv preprint only); note that the graph is a DAG.

► **Lemma 21 (★).** *Let S and T be two vertex sets of size $2k$. Enumerate them as*

$$S = \{v_1, v'_1, v_2, v'_2, \dots, v_k, v'_k\}, \quad T = \{u_1, u'_1, u_2, u'_2, \dots, u_k, u'_k\}.$$

For each $i, j \in [k]$, create a vertex $w_{i,j}$ and add edges from v_i, v'_i to $w_{i,j}$, and from $w_{i,j}$ to u_j, u'_j . Any vertex cut sparsifier for the resulting graph requires $\Omega(k^2)$ vertices.

Next, we show the same bound holds also for *edge cut* sparsifiers, when both G and its sparsifier H are undirected. For simplicity, we also restrict ourselves to just one terminal set T .

■ **Figure 1** The lower bound construction for $k = 6$.

■ **Figure 2** The set T_i for $i = 2$.

► **Definition 22** ((Undirected) Edge Cut Sparsifier). *Consider an unweighted, undirected graph $G = (V, E)$ with terminal set $T \subseteq V$. An unweighted, undirected graph $H = (V', F)$ is an edge cut sparsifier of G if*

- (a) $T \subseteq V'$.
- (b) For all disjoint $X, Y \subseteq T$, $\text{emincut}_G(X, Y) = \text{emincut}_H(X, Y)$.

Consider the k -by- k grid with leaf terminals attached in Figure 1: begin with a k -by- k grid of non-terminals, and add the following leaf (degree-1) terminals:

1. one leaf terminal adjacent to each vertex on the top row, called the *top* terminals,
 2. one leaf terminal adjacent to each vertex on the bottom row, called the *bottom* terminals,
 3. one leaf terminal adjacent to each vertex on the left column, called the *left* terminals, and
 4. one leaf terminal adjacent to each vertex on the right column, called the *right* terminals.
- Note that non-terminals on the corner of the grid have two terminals attached. This concludes the construction of the terminal set T . We now show that any edge cut sparsifier of G , even with directed edges allowed, has at least k^2 vertices. Since G has $O(k)$ terminals, this proves the quadratic lower bound.

► **Lemma 23.** *Any (undirected) edge cut sparsifier of G has $\Omega(k^2)$ vertices.*

For the rest of this section, we prove Lemma 23. For an undirected graph G and a subset of vertices S , we define $\partial_G S$ as the set of edges with exactly one endpoint in S .

Consider a directed sparsifier H with vertex set $V' \supseteq T$. For $0 \leq i \leq k$, let $T_i \subseteq T$ be following set of terminals: all of the left terminals, plus the first i top and bottom terminals, counting from the left (see Figure 2). Let $C_i \subseteq V'$ be T_i 's side of the mincut between $T_i, T \setminus T_i$

in the sparsifier H , which must have $|\partial C_i| = |\partial(V' \setminus C_i)| = k$, since $\text{emincut}_G(T_i, T \setminus T_i)$ is k and H is a sparsifier of G . Similarly, let $T'_i \subseteq T$ be all the top terminals, plus the first i left and right terminals, counting from the top, and let $R_i \subseteq V'$ be T'_i 's side of the mincut between $T'_i, T \setminus T'_i$ in H , so that $|\partial R_i| = |\partial(V' \setminus R_i)| = k$.

▷ **Claim 24.** Without loss of generality, we may assume that $C_0 \subseteq C_1 \subseteq \dots \subseteq C_k$ and $R_0 \subseteq R_1 \subseteq \dots \subseteq R_k$.

Proof. We only prove the statement for C_i ; the one for R_i follows by symmetry of G . Suppose for contradiction that $C_i \setminus C_{i+1} \neq \emptyset$. By submodularity,

$$|\partial C_i| + |\partial C_{i+1}| \geq |\partial(C_i \cap C_{i+1})| + |\partial(C_i \cup C_{i+1})|.$$

Since $C_i \cap C_{i+1}$ is a $(T_i, T \setminus T_i)$ -cut in H and $C_i \cup C_{i+1}$ is a $(T_{i+1}, T \setminus T_{i+1})$ -cut in H , their cut values $\partial(C_i \cap C_{i+1})$ and $\partial(C_i \cup C_{i+1})$ are at least k . Therefore,

$$k + k = |\partial C_i| + |\partial C_{i+1}| \geq |\partial(C_i \cap C_{i+1})| + |\partial(C_i \cup C_{i+1})| \geq k + k,$$

so the inequality must be an equality. It follows that we can replace C_i with $C_i \cap C_{i+1}$, which is still a $(T_i, T \setminus T_{i+1})$ -cut in H , and we can also replace C_{i+1} with $C_i \cup C_{i+1}$. While there exists an i such that $C_i \setminus C_{i+1} \neq \emptyset$, we perform the replacement; this can only happen a finite number of times, since the quantity $\sum_{i=0}^k |C_i|^2$ increases by at least 1 each time and has an upper limit. ◁

For each $1 \leq i, j < k$, define $S_{i,j} \subseteq V'$ as $S_{i,j} = (C_{i+1} \setminus C_i) \cap (R_{j+1} \setminus R_j)$; see Figure 3a. Our goal is to prove that $S_{i,j} \neq \emptyset$ for all i, j ; since the sets are disjoint over all $1 \leq i, j \leq k$, this implies the k^2 bound.

▷ **Claim 25.** There are no edges between $S_{i,j}$ and $S_{i',j'}$ for $i \neq i'$ and $j \neq j'$.

Proof. First, consider some $1 \leq i, i', j, j' \leq k$ where $i < i'$ and $j < j'$ (see Figure 3a). By submodularity on the sets C_{i+1} and $R_{j'+1}$,

$$|\partial C_{i+1}| + |\partial R_{j'+1}| \geq |\partial(C_{i+1} \cap R_{j'+1})| + |\partial(C_{i+1} \cup R_{j'+1})|.$$

Since $\partial(C_{i+1} \cap R_{j'+1})$ is a $(T_{i+1} \cap T'_{j'+1}, T \setminus (T_{i+1} \cap T'_{j'+1}))$ -cut, its value is at least

$$\text{emincut}_G(T_{i+1} \cap T'_{j'+1}, T \setminus (T_{i+1} \cap T'_{j'+1})) = (i+1) + (j'+1).$$

Similarly, $|\partial(C_{i+1} \cup R_{j'+1})| \geq k - (i+1) + k - (j'+1)$. It follows that

$$\begin{aligned} k + k &= |\partial C_{i+1}| + |\partial R_{j'+1}| \geq |\partial(C_{i+1} \cap R_{j'+1})| + |\partial(C_{i+1} \cup R_{j'+1})| \\ &\geq (i+1) + (j'+1) + k - (i+1) + k - (j'+1) \\ &= k + k, \end{aligned}$$

so the inequality must be an equality. It follows that there are no edges between $C_{i+1} \setminus R_{j'+1}$ and $R_{j'+1} \setminus C_{i+1}$, since those edges would make the submodularity inequality strict. In particular, there are no edges between $S_{i,j}$ and $S_{i',j'}$.

Finally, the $i < i'$ and $j < j'$ assumptions can be removed essentially by symmetry, replacing C_{i+1} by $V' \setminus C_{i+1}$ or $R_{j'+1}$ by $V' \setminus R_{j'+1}$ (or both). ◁

(a) The setting for the proof of Claim 25.

(b) The definitions of X and Y , and the different types of edges that are allowed by Claim 25 and leave or enter the sets R_{j+1} , R_{j+2} , C_i , C_{i+1} . The long edges marked in red make the inequality $|\partial_H X| + |\partial_H Y| \leq |\partial_H R_{j+1}| + |\partial_H R_{j+2}| + |\partial_H C_i| + |\partial_H C_{i+1}|$ strict.(c) The cut and flow that establishes that $\text{emincut}_G(X \cap T, T \setminus X) = 2k$. The flow is drawn in red and dark blue.(d) The definitions of X' and Y' . The red edge makes the submodularity inequality strict.■ **Figure 3** Figures for Lemma 23.

▷ **Claim 26.** There are no edges between $S_{i,j}$ and $S_{i,j'}$ for $|j - j'| \geq 2$. Similarly, there are no edges between $S_{i,j}$ and $S_{i',j}$ for $|i - i'| \geq 2$.

Proof. We first prove the inequality for $S_{i,j}$ and $S_{i,j'}$ for $j' \geq j + 2$. As shown in Figure 3b, define $X = (R_{j+1} \cap C_{i+1}) \cup ((V \setminus R_{j+2}) \cap (V \setminus C_i))$ and $Y = (R_{j+2} \cap C_i) \cup ((V' \setminus R_{j+1}) \cap (V' \setminus C_{i+1}))$. We now claim the inequality

$$|\partial_H X| + |\partial_H Y| \leq |\partial_H R_{j+1}| + |\partial_H R_{j+2}| + |\partial_H C_i| + |\partial_H C_{i+1}| \quad (1)$$

by examining each type of edge in Figure 3b and its contribution to both sides of the inequality:

1. Each edge between $C_i \cap R_{j+1}$ and $(C_{i+1} \setminus C_i) \cap R_{j+1}$ contributes 1 to $|\partial_H Y|$ and 1 to $|\partial_H C_i|$.
2. Each edge between $C_{i+1} \cap R_{j+1}$ and $(V \setminus C_{i+1}) \cap R_{j+1}$ contributes 1 to $|\partial_H X|$ and 1 to $|\partial_H C_{i+1}|$.

3. Each edge between $C_i \cap R_{j+1}$ and $(V \setminus C_{i+1}) \cap R_{j+1}$ contributes 1 to $|\partial_H X|$ and $|\partial_H Y|$ and 1 to $|\partial_H C_i|$ and $|\partial_H C_{i+1}|$.
4. Each edge between $C_i \cap R_{j+1}$ and $C_i \cap (R_{j+2} \setminus R_{j+1})$ contributes 1 to $|\partial_H X|$ and 1 to $|\partial_H R_{j+1}|$.
5. Each edge between $C_i \cap R_{j+2}$ and $C_i \cap (V \setminus R_{j+2})$ contributes 1 to $|\partial_H Y|$ and 1 to $|\partial_H R_{j+1}|$.
6. Each edge between $C_i \cap R_{j+1}$ and $C_i \cap (V \setminus R_{j+2})$ contributes 1 to $|\partial_H X|$ and $|\partial_H Y|$ and 1 to $|\partial_H R_{j+1}|$ and $|\partial_H R_{j+2}|$.
7. Each edge between $C_i \cap (V \setminus R_{j+2})$ and $(C_{i+1} \setminus C_i) \cap (V \setminus R_{j+2})$ contributes 1 to $|\partial_H X|$ and 1 to $|\partial_H C_i|$.
8. Each edge between $C_{i+1} \cap (V \setminus R_{j+2})$ and $(V \setminus C_{i+1}) \cap (V \setminus R_{j+2})$ contributes 1 to $|\partial_H Y|$ and 1 to $|\partial_H C_{i+1}|$.
9. Each edge between $C_i \cap (V \setminus R_{j+2})$ and $(V \setminus C_{i+1}) \cap (V \setminus R_{j+2})$ contributes 1 to $|\partial_H X|$ and $|\partial_H Y|$ and 1 to $|\partial_H C_i|$ and $|\partial_H C_{i+1}|$.
10. Each edge between $(V \setminus C_{i+1}) \cap R_{j+1}$ and $(V \setminus C_{i+1}) \cap (R_{j+2} \setminus R_{j+1})$ contributes 1 to $|\partial_H Y|$ and 1 to $|\partial_H R_{j+1}|$.
11. Each edge between $(V \setminus C_{i+1}) \cap R_{j+2}$ and $(V \setminus C_{i+1}) \cap (V \setminus R_{j+2})$ contributes 1 to $|\partial_H X|$ and 1 to $|\partial_H R_{j+1}|$.
12. Each edge between $(V \setminus C_{i+1}) \cap R_{j+1}$ and $(V \setminus C_{i+1}) \cap (V \setminus R_{j+2})$ contributes 1 to $|\partial_H X|$ and $|\partial_H Y|$ and 1 to $|\partial_H R_{j+1}|$ and $|\partial_H R_{j+2}|$.
13. Each edge between $C_i \cap (R_{j+2} \setminus R_{j+1})$ and $(C_{i+1} \setminus C_i) \cap (R_{j+2} \setminus R_{j+1})$ contributes 1 to $|\partial_H Y|$ and 1 to $|\partial_H C_i|$.
14. Each edge between $(C_{i+1} \setminus C_i) \cap (R_{j+2} \setminus R_{j+1})$ and $(V \setminus C_{i+1}) \cap (R_{j+2} \setminus R_{j+1})$ contributes 1 to $|\partial_H Y|$ and 1 to $|\partial_H C_{i+1}|$.
15. Each edge between $C_i \cap (R_{j+2} \setminus R_{j+1})$ and $(V \setminus C_{i+1}) \cap (R_{j+2} \setminus R_{j+1})$ contributes 1 to $|\partial_H C_i|$ and 1 to $|\partial_H C_{i+1}|$.
16. Each edge between $(C_{i+1} \setminus C_i) \cap R_{j+1}$ and $(C_{i+1} \setminus C_i) \cap (R_{j+2} \setminus R_{j+1})$ contributes 1 to $|\partial_H X|$ and 1 to $|\partial_H R_{j+1}|$.
17. Each edge between $(C_{i+1} \setminus C_i) \cap (R_{j+2} \setminus R_{j+1})$ and $(C_{i+1} \setminus C_i) \cap (V \setminus R_{j+2})$ contributes 1 to $|\partial_H X|$ and 1 to $|\partial_H R_{j+2}|$.
18. Each edge between $(C_{i+1} \setminus C_i) \cap R_{j+1}$ and $(C_{i+1} \setminus C_i) \cap (V \setminus R_{j+2})$ contributes 1 to $|\partial_H R_{j+1}|$ and 1 to $|\partial_H R_{j+2}|$.

All of the above types of edges contribute the same to both sides of (1) except those of type 15 and 18, namely those indicated by long red edges in Figure 3b. We call such edges *red*. Then, the inequality (1) is strict if and only if red edges are present.

Since all edges between $S_{i,j}$ and $S_{i',j'}$ are red, it suffices to show that (1) is actually an equality, which would exclude all red edges and hence all edges between $S_{i,j}$ and $S_{i',j'}$ as well. Observe that $\text{emincut}_G(X \cap T, T \setminus X) = 2k$, as seen in Figure 3c, which shows a cut and a flow both of value $2k$. Similarly, $\text{emincut}_G(Y \cap T, T \setminus Y) = 2k$. Since H is a sparsifier of G , we must have

$$\begin{aligned} 2k + 2k &= |\partial_H X| + |\partial_H Y| \leq |\partial_H R_{j+1}| + |\partial_H R_{j+2}| + |\partial_H C_i| + |\partial_H C_{i+1}| \\ &= k + k + k + k. \end{aligned}$$

In other words, the inequality is tight, as desired.

The case for $S_{i,j}$ and $S_{i',j'}$ for $i' \geq i+2$ is similar. Note that edges between $S_{i,j}$ and $S_{i',j'}$ correspond to the red horizontal edges in Figure 3b (for different values of i, j), which we have already shown do not exist. \triangleleft

▷ Claim 27. For each $1 \leq i, j \leq k$, we have $S_{i,j} \neq \emptyset$.

Proof. Suppose for contradiction that $S_{i,j} = \emptyset$ for some $1 \leq i, j \leq k$. As shown in Figure 3d, define the sets $X' = C_i \cup (C_{i+1} \cap R_j)$ and $Y' = C_i \cup (C_{i+1} \setminus R_{j+1})$. We have $X' \cap Y' = C_i$, and since $S_{i,j} = \emptyset$ by assumption, we also have $X' \cup Y' = C_{i+1}$. By submodularity,

$$|\partial_H X'| + |\partial_H Y'| \geq |\partial_H(X' \cap Y')| + |\partial_H(X' \cup Y')| = |\partial_H C_i| + |\partial_H C_{i+1}|.$$

Moreover, the inequality is tight because the only types of edges that can make the inequality strict (marked red in Figure 3d) are prohibited by Claim 26. Since H is a sparsifier of G ,

$$\text{emincut}_G(X' \cap T, T \setminus X') + \text{emincut}_G(Y' \cap T, T \setminus Y') \leq |\partial_H X'| + |\partial_H Y'| = |\partial_H C_i| + |\partial_H C_{i+1}| = 2k.$$

However, it is not hard to see that $\text{emincut}_G(X' \cap T, T \setminus X') = \text{emincut}_G(Y' \cap T, T \setminus Y') = k+1$, a contradiction. ◁

5 Conclusions

We showed that every unweighted, directed acyclic graph G with k terminals admits a vertex cut sparsifier H with $O(k^2)$ vertices, assuming that the terminals are deletable. This improves the previous result by Kratsch and Wahlström of $O(k^3)$ vertices, for general directed graphs [13]. Furthermore, the sparsifier can be computed in near-linear time in the size of G , specifically in time $O((m+n)k^{O(1)})$ plus $O((m+n)k^{O(1)})$ field operations over a finite field with entries of bitlength $O(k \log n)$, where $n = |V(G)|$ and $m = |E(G)|$. This improves over previous work [13], whose time complexity was not explicitly given but is at least $O(n^{\omega+1})$ due to the repeated construction of a representation of a gammoid.

Furthermore, we showed that $\Omega(k^2)$ vertices in a sparsifier may be required, both for vertex cuts in DAGs and for the seemingly simpler setting of undirected edge cuts. However, we leave it open whether such a bound applies to the mixed setting, where we want to preserve undirected edge cuts in the input graph G but allow the sparsifier to be a directed graph.

More importantly, we leave open the question of whether vertex cut sparsifiers of $O(k^2)$ vertices exist for general directed graphs. We conjecture that $O(k^2)$ is the correct bound for general directed graphs, but we were not able to find a proof.

Closing the Gap for Single Resource Constraint Scheduling

Klaus Jansen 

Universität Kiel, Germany

Malin Rau 

Universität Hamburg, Germany

Abstract

In the problem called single resource constraint scheduling, we are given m identical machines and a set of jobs, each needing one machine to be processed as well as a share of a limited renewable resource R . A schedule of these jobs is feasible if, at each point in the schedule, the number of machines and resources required by jobs processed at this time is not exceeded. It is NP-hard to approximate this problem with a ratio better than $3/2$. On the other hand, the best algorithm so far has an absolute approximation ratio of $2 + \varepsilon$. In this paper, we present an algorithm with absolute approximation ratio $(3/2 + \varepsilon)$, which closes the gap between inapproximability and best algorithm with exception of a negligible small ε .

1 Introduction

In the single resource constraint scheduling problem, we are given m identical machines, a discrete renewable resource with a fixed size $R \in \mathbb{N}$ and a set of n jobs \mathcal{J} . Each job has a processing time $p(j) \in \mathbb{Q}$. We define the total processing time of a set of jobs $\mathcal{J}' \subseteq \mathcal{J}$ as $p(\mathcal{J}') := \sum_{j \in \mathcal{J}'} p(j)$. To be scheduled, each job $j \in \mathcal{J}$ needs one of the machines as well as a fix amount $r(j) \in \mathbb{N}$ of the resource which it will allocate during the complete processing time $p(j)$ and which it deallocates as soon as it has finished its processing. Neither machine nor any part of the resource can be allocated by two different jobs at the same time. We define the area of a job as $\text{area}(j) := r(j) \cdot p(j)$ and the area of a set of jobs $\mathcal{J}' \subseteq \mathcal{J}$ as $\text{area}(\mathcal{J}') := \sum_{j \in \mathcal{J}'} r(j) \cdot p(j)$.

A schedule $\sigma : \mathcal{J} \rightarrow \mathbb{N}$ maps each job $j \in \mathcal{J}$ to a starting point $\sigma(j) \in \mathbb{Q}$. We say a schedule is feasible if

$$\forall t \in \mathbb{Q} : \sum_{j: t \in [\sigma(j), \sigma(j) + p(j))} r(j) \leq R \text{ and} \quad (\text{resource condition})$$

$$\forall t \in \mathbb{Q} : \sum_{j: t \in [\sigma(j), \sigma(j) + p(j))} 1 \leq m. \quad (\text{machine condition})$$

Given a schedule σ where these two conditions hold, we can generate an assignment of resources and machines to the jobs such that each machine and each resource part is allocated by at most one job at a time, see [27]. The objective is to find a feasible schedule, which minimizes the total length of the schedule called makespan, i.e., we have to minimize $\max_{j \in \mathcal{J}} \sigma(j) + p(j)$.

This problem arises naturally, e.g., in parallel computing, where jobs that are scheduled in parallel share common memory or in production logistics where different jobs need a different number of people working on it. From a theoretical perspective this problem is a sensible generalization of problems like scheduling on identical machines, parallel task scheduling and bin packing with cardinality constraint.

The algorithm with the best absolute ratio so far is a $(2 + \varepsilon)$ -approximation by Niemeier and Wiese [31]. In this paper, we close this gap between approximation and lower bound by presenting an algorithm with approximation ratio $(3/2 + \varepsilon)$.

► **Theorem 1.** *There is an algorithm for single resource constraint scheduling with approximation ratio $(3/2 + \varepsilon)$ and running time $\mathcal{O}(n \log(1/\varepsilon)) + \mathcal{O}(n)(m \log(R)/\varepsilon)^{\mathcal{O}_\varepsilon(1)}$, where \mathcal{O}_ε dismisses all factors solely dependent on $1/\varepsilon$.*

As a by-product of this algorithm, we also present an algorithm, which has an approximation guarantee of $(1 + \varepsilon)\text{OPT} + p_{\max}$. Note that we can scale each instance such that $p_{\max} = 1$ and hence we can see p_{\max} as a constant independent of the instance. Algorithms with an approximation guarantee of the form $(1 + \varepsilon)\text{OPT} + c$ for some constant c are called asymptotic polynomial time approximation schemes (APTAS). Note that this algorithm is a $(2 + \varepsilon)$ -approximation as well, but improves this ratio, in the case that p_{\max} is strictly smaller than OPT and for $p_{\max} < \text{OPT}/2$ improves the approximation ratio of the algorithm from Theorem 1.

► **Theorem 2.** *There is an APTAS for single resource constraint scheduling with an additive term p_{\max} and running time $\mathcal{O}(n \log(1/\varepsilon + n)) + \mathcal{O}(n)(m \log(R)/\varepsilon)^{\mathcal{O}_\varepsilon(1)}$.*

In the schedule generated by this APTAS, almost all jobs are completed before $(1 + \mathcal{O}(\varepsilon))\text{OPT}$, except for a small set \mathcal{J}' of jobs that all start simultaneously at $(1 + \mathcal{O}(\varepsilon))\text{OPT}$, after the processing of all other jobs is finished. The processing of this set \mathcal{J}' causes the additive term p_{\max} .

Methodology and Organization of this Paper

In Section 2, we will present the main results to generate the APTAS from Theorem 2. The general structure of the algorithm can be summarized as follows. First, we simplify the instance by rounding the processing time of the jobs and partitioning them into large, medium, and small corresponding to their processing time. Afterward, we use some linear programming approaches to find a placement of these jobs inside the optimal packing. The few jobs that are placed fractionally with this linear program will be placed on top of the packing contributing to the set \mathcal{J}' which was mentioned before.

As usual for this kind of algorithms for packing and scheduling problems, we divide the jobs into large, medium and small jobs. While for the placement of medium and small jobs, we use techniques already known, see e.g. [21], we used a new technique to place the large jobs. For the following $(3/2 + \varepsilon)$ approximation, it is important to guarantee that only $\mathcal{O}_\varepsilon(1)$, i.e. constant in $1/\varepsilon$, large jobs are not placed inside the optimal scheduling area. To find such a schedule, we divide the schedule into $\mathcal{O}_\varepsilon(1)$ time slots and guess the machine requirement and a rounded resource requirement of large jobs during this slot. Afterward, the large jobs are placed inside this profile using a linear program, which schedules only $\mathcal{O}_\varepsilon(1)$ of these jobs fractionally. We have to remove these $\mathcal{O}_\varepsilon(1)$ fractionally scheduled jobs, as well as only one extra job per time slot due to the rounded guess, and assign them to the set \mathcal{J}' .

Afterward, in Section 3, we present the $(3/2 + \varepsilon)$ -approximation and prove Theorem 1. Instead of placing the fractional jobs on top of the packing, we stretch the packing by $(1/2 + \mathcal{O}(\varepsilon))\text{OPT}$, and place the fractional scheduled large jobs inside a gap in this stretched

schedule. This stretching allows us to define a common finishing point of (almost) all the jobs, which have a processing time larger than $\text{OPT}/2$ and, thus, we avoid scheduling them fractionally with the linear program. While the general idea of creating such a gap was used before, e.g., in [19], the novelty of this approach is to search for this gap at multiple points in time while considering two and not only one constraint. This obstacle of considering two instead of one constraint while searching for a gap requires a more careful analysis of the shifted schedule, as was needed in other gap constructions.

Related Work

The problem resource constraint scheduling is one of the classical problems in scheduling. It was first studied in 1975 by Garey and Graham [10]. Given m identical machines and capacities R_1, \dots, R_s of s distinct resources such that each job requires a share of each of them, they proved that the greedy list algorithm produces a schedule of length at most $(s + 2 - (2s + 1)/m)\text{OPT}$. This corresponds to an approximation ratio of $(3 - 3/m)$ for the case of $s = 1$ i.e., the problem studied in this paper. In the same year Garey and Johnson [11] showed that this general scheduling problem is NP-complete even if just one resource is given, i.e., $s = 1$. Lately, Niemeier and Wiese [31] presented a $(2 + \varepsilon)$ -approximation for single resource constraint scheduling, and this is the best known ratio so far.

Note that the problem single resource constraint scheduling contains multiple problems as subproblems. When all the processing times are equal to one, this problem corresponds to bin packing with cardinality constraint. Hence there is no algorithm with an approximation guarantee better than $3/2$ for this problem unless $P = NP$. For bin packing with cardinality constraint Epstein and Levin [8] presented an AFPTAS. This AFPTAS was improved and extended to work for single resource constraint scheduling by Jansen et al. [21]. It has an additive term of $\mathcal{O}(p_{\max} \log(1/\varepsilon)/\varepsilon)$.

On the other hand, if the number of machines m is larger than n , the constraint that only m jobs can be processed at the same time is no longer a restriction. The resulting problem is known as the parallel task scheduling problem. This problem is strongly NP-complete for $R \geq 4$ [17] and there exists a pseudo polynomial algorithm for $R \leq 3$ [7]. Furthermore, for R constant and $R \in n^{\mathcal{O}(1)}$ there exists polynomial time approximation schemes by Jansen and Porkolab [22] as well as Jansen and Thöle [26] respectively. For an arbitrary large R there exists no algorithm with approximation ratio smaller than $3/2$ unless $P = NP$. The best algorithm for this scenario is a $(3/2 + \varepsilon)$ approximation by Jansen [19].

Finally, if each job requires at most R/m from the resource, the used resources are no longer a restriction. The corresponding problem is known as the NP-hard problem makespan scheduling on identical machines. For this problem several algorithms are known, see, e.g., [13, 18, 2, 20].

An interesting extension of the considered problem is the consideration of resource dependent processing times. In this scenario, instead of a fixed resource requirement for the jobs, each jobs processing time depends on the amount of allocated resources. The first result for this extension was achieved by Grigoriev et al. [14]. They studied a variant where the processing time of a job depends on the machine it is processed on as well as the number of assigned resources and described a 3.75-approximation. For the case of identical machines this result was improved by Kellerer [28] to a $(3.5 + \varepsilon)$ -approximation. Finally, Jansen et al [21] presented an AFPTAS for this problem with additive term $\mathcal{O}(\pi_{\max} \log(1/\varepsilon)/\varepsilon)$, where π_{\max} is the largest occurring processing time considering all possible resource assignments.

Closely related to single resource constraint scheduling is the strip packing problem. Here we are given a set of rectangular items that have to be placed overlapping free into a strip with bounded width and infinite height. We can interpret single resource constraint

scheduling as a Strip Packing problem by setting the jobs processing time to the height of a rectangular item and the resource requirement to its width. The difference to strip packing is now, that when placing an item, we are allowed to slice it vertically as long as the lower border of all slices are placed at the same *vertical level*. Furthermore, we have an single resource constraint scheduling carnality condition that allows only m items to intersect each horizontal line through the strip. The strip packing problem has been widely studied [3, 4, 5, 6, 12, 16, 25, 29, 32, 33, 34, 35]. The algorithm with approximation ratio $(5/3 + \varepsilon)$, which is the smallest so far, was presented by Harren, Jansen, Prädel, and van Stee [15]. On the other hand, using a reduction from the partition problem, we know that there is no polynomial-time algorithm with an approximation ratio smaller than $3/2$. Closing this gap between the best approximation ratio and lower bound represents an open question. Strip packing has also been studied with respect to asymptotic approximation ratio [3, 6, 12, 29]. The best algorithms in this respect are an *AFPTAS* with additive term $\mathcal{O}(1/\varepsilon \log(1/\varepsilon))h_{\max}$ [35, 5] and an APTAS with additive term h_{\max} [25], where h_{\max} is the tallest height in the set of given items. Finally, this problem has been studied with respect to pseudo-polynomial processing time [36, 26, 30, 9, 23, 1], where the width of the strip is allowed to occur polynomial in the running time of the algorithm. There is no pseudo-polynomial algorithm with an approximation ratio smaller than $5/4$ [17] and a ratio of $(5/4 + \varepsilon)$ is achieved by the algorithm in [24].

2 APTAS with additive term p_{\max}

In this section, we present an asymptotic PTAS for the single resource constraint scheduling problem which has an approximation guarantee of $(1 + \varepsilon)\text{OPT} + p_{\max}$ and a running time of $\mathcal{O}(n \log(n)) + (m \log(R))^{\mathcal{O}_\varepsilon(1)}$, i.e., we prove Theorem 2 in this section. Due to space limitations the proofs of this section can be found in the appendix.

Simplifying the input instance. In the first step of the algorithm, we simplify the given instance such that it has a simple structure and a reduced set of processing times. Consider the lower bound on the optimal makespan $T := \min\{p_{\max}, \text{area}(\mathcal{J})/R, p(\mathcal{J})/m\}$. By the analysis of the greedy list schedule, as described in [31], we know that the optimal schedule has a size of at most $\frac{1}{m}p(\mathcal{J}) + \frac{2}{R}\text{area}(\mathcal{J}) + p_{\max} \leq 4T$, giving us appropriate bounds for a dynamic search framework.

In the next step, we will create a gap between jobs with a large processing time and jobs with a small processing time, by removing a set of medium sized jobs. We want to schedule this set of medium sized jobs in the beginning or end of the schedule using the greedy list schedule. However this schedule of the medium sized items should add at most $\mathcal{O}(\varepsilon)\text{OPT}$ to the makespan. The schedule generated by the greedy list schedule algorithm has a makespan of at most $\frac{1}{m}p(\mathcal{J}) + \frac{2}{R}\text{area}(\mathcal{J}) + p_{\max} \leq 4\text{OPT}$. Hence, we choose the set of medium jobs \mathcal{J}_M such that $p_{\max}(\mathcal{J}_M) \leq \varepsilon\text{OPT}$, i.e. the maximal processing time appearing in the set of medium jobs is bounded by εOPT . On the other hand, the total area and the total processing time of the medium jobs should be small enough.

► **Lemma 3.** *Consider the sequence $\gamma_0 = \varepsilon$, $\gamma_{i+1} = \gamma_i \varepsilon^4$. There exists an $i \in \{1, \dots, 1/\varepsilon\}$ such that*

$$\frac{1}{m}p(\mathcal{J}_{\gamma_i}) + \frac{2}{R}\text{area}(\mathcal{J}_{\gamma_i}) \leq \varepsilon \left(\frac{1}{m}p(\mathcal{J}) + \frac{2}{R}\text{area}(\mathcal{J}) \right), \quad (1)$$

where $\mathcal{J}_{\gamma_i} := \{j \in \mathcal{J} \mid p(j) \in [\gamma_i T, \gamma_{i-1} T)\}$ and we can find this i in $\mathcal{O}(n + 1/\varepsilon)$.

Let $i \in \{1, \dots, 1/\varepsilon\}$ be the smallest value such that \mathcal{J}_{γ_i} has the property from Lemma 3 and define $\mu := \gamma_i$ and $\delta := \gamma_{i-1}$. Note that $\gamma_i = \varepsilon^{1+4i}$ and hence $\delta \geq \varepsilon^{4/\varepsilon+1}$. Using these values for δ and μ , we partition the set of jobs into large $\mathcal{J}_L := \{j \in \mathcal{J} | p(j) \geq \delta T\}$, small $\mathcal{J}_S := \{j \in \mathcal{J} | p(j) < \mu T\}$ and medium $\mathcal{J}_M := \{j \in \mathcal{J} | \mu T \leq p(j) < \delta T\}$.

► **Lemma 4.** *The medium jobs can be scheduled in $\mathcal{O}(n \log(n))$ operations with makespan $\mathcal{O}(\varepsilon)T$*

The final simplification step is to round the processing times of the large jobs using the rounding in Lemma 5 to multiples of $\varepsilon\delta T$.

► **Lemma 5** (See [23]). *Let $\delta \geq \varepsilon^k$ for some value $k \in \mathbb{N}$. At loss of a factor $(1 + 2\varepsilon)$ in the approximation ratio, we can round the processing time of each job j with processing time $\varepsilon^{l-1}T \geq p(j) \geq \varepsilon^l T$ for some $l \in \mathbb{N} \leq k$ such that it has a processing time $k_j \varepsilon^{l+1}T$ for a value $k_j \in \{1/\varepsilon, \dots, 1/\varepsilon^2 - 1\}$. Furthermore, the jobs can be started at a multiple of $\varepsilon^{l+1}T$.*

In this step, we reduce the number of different processing times of large jobs to $\mathcal{O}(\log_\varepsilon(\delta)/\varepsilon^2) = \mathcal{O}(1/\varepsilon^3)$. However, we lengthen the schedule at most by the factor $(1 + 2\varepsilon)$. Furthermore, this rounding reduces the starting times of these jobs to at most $\mathcal{O}(1/(\varepsilon\delta))$ possibilities since all the large jobs start and end at multiples of $\varepsilon\delta T$ and the optimal makespan of the rounded instance is bounded by $(1 + 2\varepsilon) \cdot 4T$.

Scheduling Large Jobs. In this section, we describe how to schedule the large jobs when given the size of the makespan $T' := l\varepsilon T$ of the rounded schedule. For a given set \mathcal{S} of start and endpoints of long jobs, we define a layer l_i as the processing time between two consecutive starting times $s_i, s_{i+1} \in \mathcal{S}$. Notice that, during the processing of a layer in a rounded optimal schedule, the resource requirement and number of machines used by large jobs stays unchanged since the large jobs only start and end at the starting points in \mathcal{S} .

► **Lemma 6.** *Let $\gamma \in (0, 1]$ and $T' = l\varepsilon T \geq \text{OPT}$ for some $l \in \mathbb{N}$, and $\bar{\mathcal{J}}$ be a set of jobs for which an optimal schedule exists such that all jobs in $\bar{\mathcal{J}}$ have their starting and endpoints in \mathcal{S} . There exists an algorithm that finds in $\mathcal{O}((m \log(R))^{\mathcal{O}_\varepsilon(1)|\mathcal{S}|/\gamma})$ operations $\mathcal{O}((m \log(R))^{\mathcal{O}_\varepsilon(1)/\gamma})$ schedules with the following properties*

1. *In each of the schedules, all large jobs are scheduled except for a set $\mathcal{J}' \subseteq \bar{\mathcal{J}}$ of at most $|\mathcal{J}'| \in 3|\mathcal{S}|$ jobs and a total resource requirement of at most $R(\mathcal{J}') \leq \gamma R$.*
2. *In at least one of the schedules, in each layer given by \mathcal{S} , the total number of machines and resources not used by jobs in $\bar{\mathcal{J}}$ is as large as in a rounded optimal schedule.*

In the APTAS we will use the algorithm from Lemma 6 with $\bar{\mathcal{J}} := \mathcal{J}_L$ and $\mathcal{S}' := \mathcal{S}$.

Scheduling Small Jobs. We will schedule small jobs inside the layers using the residual free resources and machines given by the guess for the large jobs. We define $m_s^{(S)}$ as the number of machines in layer s not used by jobs with processing times larger than δT and analogously define $R_s^{(S)}$ as the number of resources not used by jobs with processing times larger than δT during the processing of this layer in an optimal schedule.

► **Lemma 7.** *Define for each layer $s \in \mathcal{S}$ a box with processing time $(1 + \varepsilon)\varepsilon\delta T$, $m_s^{(S)}$ machines and $R_s^{(S)}$ resources, where the values $m_s^{(S)}$ and $R_s^{(S)}$ are at least as large as in a rounded optimal schedule. There exists an algorithm with time complexity $\mathcal{O}(n) \cdot \mathcal{O}_{\varepsilon, |\mathcal{S}|}(1)$, that places the jobs inside the boxes and an additional horizontal box with m machines, R resources, and processing time $\mathcal{O}(\varepsilon)T$.*

This algorithm uses the same techniques as the AFPTAS designed by Jansen et al. [21]. For the sake of completeness the ideas can be found in the appendix.

The AFPTAS. We can summarize the algorithm as follows. We define $T := \min\{p_{\max}, \text{area}(\mathcal{J})/R, p(\mathcal{J})/m\}$ and simplify the instance as described above. Then via a binary search framework, we try values $T' \in [T, 4T]$ as optimal makespan. For each of the considered values T' , we use the algorithm from Lemma 6 to generate several schedules for the large jobs each with makespan at most T' . If we cannot find a feasible schedule, the value T' was too small. Otherwise, we use the algorithm from Lemma 7 to schedule the small jobs inside each of the generated schedules for the large jobs. If T' was large enough, we can place the small jobs inside the layers, by increasing the schedule by a factor of at most $\mathcal{O}(\varepsilon)$. If the small jobs do not fit in one of the schedules for large jobs, the chosen T' was too small. If we have found a schedule for the small jobs, we try the next smaller value for T' in binary search fashion. In the final step, we use greedy list schedule to schedule the medium jobs and place the set \mathcal{J}' of non scheduled large jobs at the top.

3 A $(3/2 + \varepsilon)$ -Approximation

We aim to find a schedule with makespan $(3/2 + \mathcal{O}(\varepsilon))T'$, where T' is the assumed optimal makespan given by a binary search framework. Consider Lemma 6. If one of the jobs in \mathcal{J}' has a processing time larger than $T'/2 + \mathcal{O}(\varepsilon)T$, we exceed the aspired approximation ratio of $(3/2 + \mathcal{O}(\varepsilon))T$, when placing the set \mathcal{J}' on top of the schedule. We call this set of critical jobs huge jobs, i.e., $\mathcal{J}_H := \{j \in \mathcal{J} | p(j) > T'/2\}$, and redefine the set of large jobs as $\mathcal{J}_L := \{j \in \mathcal{J} | \delta T \leq p(j) \leq T'/2\}$ respectively.

Notice that the processing of all huge jobs has to intersect the time $T'/2$ in each schedule with makespan at most T' and each machine can contain at most one of these jobs. If we could guess the starting positions of these huge jobs, and schedule only the large jobs with the algorithm from Lemma 6, the discarded jobs \mathcal{J}' would have a processing time of at most $T'/2$ and could be placed on top of the schedule, resulting in a schedule of makespan at most $(3/2 + \mathcal{O}(\varepsilon))T'$. Sadly this guessing step is not possible in polynomial time since there are up to m of these jobs and iterating all combinations of their starting position needs $\Omega((1/\varepsilon\delta)^m)$ operations. Our idea is to let almost all the huge jobs end at a common point in time, e.g. T' , and thus avoid the guessing step. To solve the violation of the resource or machine condition, we shift up all the jobs which start after $\lceil T'/2 \rceil_{\varepsilon\delta T}$ by $\lceil T'/2 \rceil_{\varepsilon\delta T}$ such that they now start after T' , where we denote by $\lceil T'/2 \rceil_{\varepsilon\delta T}$ the integer multiple of $\varepsilon\delta T$ that is the first which has a size of at least $T'/2$.

While this shift fixes the start positions of the huge jobs, the large jobs are again placed with the techniques described in Section 2. Since Lemma 6 states that each of the generated schedules may not schedule a subset \mathcal{J}' of the large jobs, we need to find a gap in the shifted schedule where we can place them. In the following, we will consider optimal schedules and the possibilities to rearrange the jobs. Depending on this arrangement, we can find a gap of processing time $\lceil T'/2 \rceil_{\varepsilon\delta T}$ for the fractional scheduled large jobs.

Let us assume that we have to schedule $k := |\mathcal{J}'| \in \mathcal{O}_\varepsilon(1) \leq m/4$ jobs with total resource requirement at most $\gamma R \leq R/(3|\mathcal{S}|)$. We consider an optimal schedule, after applying the simplification steps and the corresponding transformed optimal schedule, where each large job starts at a multiple of $\varepsilon\delta T$ and each huge job starts at a multiple of $\varepsilon^2 T$. Furthermore, we will assume that there are more than $4k = \mathcal{O}_\varepsilon(1)$ huge jobs. Otherwise, we can guess their starting positions in $\mathcal{O}((1/\varepsilon\delta)^{4k})$ and place the fractional scheduled large jobs on top of the schedule.

In the following, we will prove that by extending it by $\lceil T'/2 \rceil_{\varepsilon\delta T}$, we can transform the rounded optimal schedule $\text{OPT}_{\text{rounded}}$ such that all the huge jobs, except for $\mathcal{O}(k)$ of them, end at a common point in time and we can place k further narrow large jobs without violating the machine or the resource constraint.

■ **Figure 1** In this and the following figures we present the processing time on the y-axis, while the resource requirements of jobs can be found on the x-axis. While the machines are not visually represented in these figures, the machine condition has to apply for each horizontal cut through the schedule. **On the left:** A rounded optimal schedule. The hatched rectangles are the jobs that start after $T'/2$ and intersect τ , the dark gray area corresponds to large jobs, which start before $T'/2$ and end after τ and the dark gray rectangles on the left are huge jobs. **On the right:** The corresponding shifted schedule.

► **Lemma 8.** Let $k := |\mathcal{J}'| \leq m/4$ and $\gamma \leq 1/(3|\mathcal{S}|)$. Furthermore, let a rounded optimal schedule $\text{OPT}_{\text{rounded}}$ with makespan at most T' and at most $|\mathcal{S}|$ starting positions for large jobs be given.

Without removing any job from the schedule, we can find a transformed schedule $\text{OPT}_{\text{shift}}$ with makespan at most $T' + \lceil T'/2 \rceil_{\epsilon\delta T}$, with the following properties:

1. We can guess the end positions of all huge jobs in polynomial time.
2. There is a gap of processing time $\lceil T'/2 \rceil_{\epsilon\delta T}$ with k empty machines and γR free resources where we can schedule the jobs in \mathcal{J}' .
3. There is an injection which maps each layer s in $\text{OPT}_{\text{rounded}}$ with $m_{s,S}$ machines and $R_{s,S}$ resources not used by huge and large jobs to a layer in $\text{OPT}_{\text{shift}}$ where there are at least as many machines and resources not used by these jobs.

Proof. We will prove this lemma by a careful analysis of the structure of the schedule $\text{OPT}_{\text{rounded}}$. First, however, we introduce some notations. Let $s \in \mathcal{S}$, with $s > T'/2$ be any starting point of large jobs. We say a job $j \in \mathcal{J}$ intersects s or is intersected by s if $\sigma(j) < s < \sigma(j) + p(j)$. We will differentiate sets of jobs that start before $T'/2$ and those that start at or after $T'/2$ by adding the attribute pre to sets of jobs that contain only jobs starting before $T'/2$, and the attribute post to those that contain only jobs that start at or after $T'/2$. Furthermore, we will identify the sets of jobs that intersect certain points of time. We will add the attribute s_{\geq} to denote a set of jobs that is processed at least until the point in time $s \in \mathcal{S}$, i.e., we denote by $\mathcal{J}_{s_{\geq}, \text{pre}} := \{j \in \mathcal{J} | p(j) \geq \delta T, \sigma(j) < T'/2, \sigma(j) + p(j) \geq s\}$ the set of large and huge jobs starting before $T'/2$ and ending at or after s . On the other hand, if we are only interested in the jobs that intersect the time s , we add the attribute $s_{>}$ to the set and mean $\mathcal{J}_{s_{>}, \text{pre}} := \{j \in \mathcal{J} | p(j) \geq \delta T, \sigma(j) < T'/2, \sigma(j) + p(j) > s\}$. Finally, we will indicate if the set contains only huge or only large jobs, by adding the attribute H or L .

Let $\tau \in \{s | s \in \mathcal{S}, T'/2 \leq s \leq T'\}$ be the smallest value such that there are at most $m - k$ jobs (huge or large) that start before $T'/2$ and intersect τ , i.e., end after τ . We partition the set of large jobs intersected by τ into two sets. Let $\mathcal{J}_{L, \tau, >, \text{pre}} := \{j \in \mathcal{J}_L | \sigma(j) < T'/2, \sigma(j) + p(j) > \tau\}$ be the set of large jobs which start before $T'/2$ and end at or after τ . Further let $\mathcal{J}_{L, \tau, >, \text{post}} := \{j \in \mathcal{J}_L | T'/2 \leq \sigma(j) < \tau, \sigma(j) + p(j) > \tau\}$ be the set of large jobs, which are started at or after $T'/2$ but before τ and end after τ , see Figure 1.

Note that by the choice of τ in each point between τ and $T'/2$ in the schedule there are more than $m - k$ machines used by $\mathcal{J}_{\tau, \geq, \text{pre}}$. As a result there are at most $k - 1$ machines used by jobs starting after $T'/2$ at each point between $T'/2$ and τ , implying $|\mathcal{J}_{L, \tau, >, \text{post}}| < k$.

We now construct a shifted schedule. Starting times in this schedule will be denoted by σ' . We shift each job $j \in \mathcal{J}$ with $\sigma(j) \geq T'/2$ and $\sigma(j) + p_j \geq \tau$ exactly $\lceil T'/2 \rceil_{\varepsilon \delta T}$ upwards, i.e., we define $\sigma'(j) := \sigma(j) + \lceil T'/2 \rceil_{\varepsilon \delta T}$ for these jobs. Furthermore, each huge job $j \in \mathcal{J}_H$ intersecting τ is shifted upwards such that it ends at T' , i.e., we define $\sigma'(j) := T' - p_j$ for these jobs j , see Figure 1. Note that there are at most k huge jobs ending strictly before τ . If the total number of huge jobs ending before or at τ is larger than k , we choose arbitrarily from the set of jobs ending at τ and shift them until there are exactly k huge jobs ending before or at τ .

▷ **Claim 9.** After this shift there are at least k machines at each point between τ and $\tau + \lceil T'/2 \rceil_{\varepsilon \delta T}$ that are not used by any other job.

Proof. Up to T' , there are k free machines, because there is no new job starting between τ and T' since we shifted all of them up such that they start after $\lceil T'/2 \rceil_{\varepsilon \delta T}$. On the other hand, only jobs from the set $\mathcal{J}_{L, \tau, >, \text{post}}$ are processed between T' and $\tau + \lceil T'/2 \rceil_{\varepsilon \delta T}$. Since $|\mathcal{J}_{L, \tau, >, \text{post}}| < k$ and $m - k \geq k$ this leaves k free machines which proves the claim. ◁

The idea is to place the gap at τ since there are enough free machines. However, it can happen that at a point between τ and $\tau + \lceil T'/2 \rceil_{\varepsilon \delta T}$ there is not enough free resource for the gap. In the following, we carefully analyze where we can place the k jobs, dependent on the structure of the optimal schedule $\text{OPT}_{\text{rounded}}$

Case 1: $r(\mathcal{J}_{\tau, \geq, \text{pre}}) \leq R - \gamma R$. In this case there are at least γR free resources at each point in the shifted schedule between τ and T' since there are no jobs starting between these points of time. To place the k fractional scheduled jobs, we have to generate a gap of processing time $\lceil T'/2 \rceil_{\varepsilon \delta T}$. In this gap there have to be k unused machines and γR unused resources. For the time between τ and T' , we have this guarantee, while for the time between T' and $\tau + \lceil T'/2 \rceil_{\varepsilon \delta T}$, we have k free machines, but might have less than γR free resource. The only jobs overlapping in this time window are the jobs from the set $\mathcal{J}_{L, \tau, >, \text{post}}$, see Figure 1. If these jobs have a small resource requirement, we have found our gap, see Case 1.1. and, otherwise, we have to look more careful at the schedule.

Case 1.1: $r(\mathcal{J}_{L, \tau, >, \text{post}}) \leq R - \gamma R$. In this case, the required gap is positioned between τ and $\tau + \lceil T'/2 \rceil_{\varepsilon \delta T}$, see Figure 2. In this shifted optimal schedule there are at most k huge jobs ending before τ . In the algorithm, we will guess τ dependent on a given solution for the large jobs and guess these k huge jobs and their start points in $\mathcal{O}(m^k S^k)$, which is polynomial in the input size, see Section 3 for an overview.

Case 1.2: $r(\mathcal{J}_{L, \tau, >, \text{post}}) > R - \gamma R$. In this case, there is a point $t \in [\tau, T']$ such that after this point there are less than γR free resources. Therefore, we need another position to place the fractionally scheduled jobs. We partition the set $\mathcal{J}_{L, \tau, >, \text{post}}$ into at most $|\mathcal{S}|/2$ sets $\mathcal{J}_{L, \tau, >, \text{post}}^\iota$ by their original finishing points $\iota \in \mathcal{S}_{>\tau}$, i.e., each job in $\mathcal{J}_{L, \tau, >, \text{post}}^\iota$ finishes at ι in the non shifted rounded optimal schedule.

▷ **Claim 10.** One of the sets $\mathcal{J}_{L, \tau, >, \text{post}}^\iota$, $\iota \in \mathcal{S}_{>\tau}$, has a resource requirement of at least γR .

■ **Figure 2** Examples for the two Cases 1.1. and 1.2. In Case 1.1 the gap is positioned between τ and $\tau + \lceil T'/2 \rceil_{\epsilon \delta T}$. In Case 1.2 the jobs in the set $\mathcal{J}_{L,\tau,>,\text{post}}^\iota$ are shifted back down. At each point between ι and $\iota + \lceil T'/2 \rceil_{\epsilon \delta T}$ there are at least γR unused resources.

Proof. The jobs in $\mathcal{J}_{L,\tau,>,\text{post}}$ use more than $R - \gamma R$ resource in total. Since $\gamma \leq 1/(3|\mathcal{S}|) \leq 1/(|\mathcal{S}|/2 - 1)$, it holds that

$$\frac{R - \gamma R}{|\mathcal{S}|/2} \geq \frac{(1 - 1/(|\mathcal{S}|/2 - 1))R}{|\mathcal{S}|/2} = R/(|\mathcal{S}|/2 - 1) \geq \gamma R.$$

Hence, by the pigeon principle, one of the sets, say $\mathcal{J}_{L,\tau,>,\text{post}}^\iota$, must have a resource requirement of at least γR . \triangleleft

Let $\mathcal{J}_{L,\tau,>,\text{post}}^\iota$ be this set. To generate a gap, we shift down all jobs in $\mathcal{J}_{L,\tau,>,\text{post}}^\iota$ back to their primary start position, see Figure 2.

▷ **Claim 11.** As a result of this shift, there are at least γR free resources at each point between ι and $\iota + \lceil T'/2 \rceil_{\epsilon \delta T}$.

Proof. At each point between ι and T' there were γR unused resources before. Each job which starts between T' and $\tau + \lceil T'/2 \rceil_{\epsilon \delta T}$ is an element of $\mathcal{J}_{L,\tau,>,\text{post}}$ and was therefore scheduled in parallel to the jobs in $\mathcal{J}_{L,\tau,>,\text{post}}^\iota$. Therefore, at each point between T' and $\tau + \lceil T'/2 \rceil_{\epsilon \delta T}$ at least γR resources are unused. From $\tau + \lceil T'/2 \rceil_{\epsilon \delta T}$ to $\iota + \lceil T'/2 \rceil_{\epsilon \delta T}$ the jobs $\mathcal{J}_{L,\tau,>,\text{post}}^\iota$ were scheduled, so there are at least γR free resources. \triangleleft

We now have to differentiate if there are at least k machines unused between $\tau + \lceil T'/2 \rceil_{\epsilon \delta T}$ and $\iota + \lceil T'/2 \rceil_{\epsilon \delta T}$, see Figure 2. Let $\rho \in \{s | \tau \leq s \leq T, s \in \mathcal{S}\}$ be the first point in the schedule where at most k jobs from $\mathcal{J}_{\tau,\geq,\text{pre}}$ are scheduled in the given optimal schedule (not the shifted one), i.e., ρ is the first point in time where $|\mathcal{J}_{\rho,\geq,\text{pre}}| \leq k$. Note that as a consequence $|\mathcal{J}_{\rho,\geq,\text{pre}}| \geq k$ since otherwise there would have been a point in time before ρ , where at most k machines are used by jobs starting before $T'/2$. We know that between T' and $\rho + \lceil T'/2 \rceil_{\epsilon \delta T}$ there always will be k machines unused since before the first shift they were blocked by jobs in $\mathcal{J}_{\tau,\geq,\text{pre}}$.

Case 1.2.1: $\rho \geq \iota$. In this case, at each point between ι and $\iota + \lceil T'/2 \rceil_{\epsilon \delta T}$ there are k machines unused. Between ι and T' there are k free machines by the choice of τ and between T' and $\rho + \lceil T'/2 \rceil_{\epsilon \delta T}$ there are k free machines by the choice of ρ . Therefore, there is a gap between ι and $\iota + \lceil T'/2 \rceil_{\epsilon \delta T}$, see Figure 3. Similar as in Case 1.1. the total number of guesses needed to place the huge jobs is bounded by $m_\epsilon^\mathcal{O}(1)$, although we have to add the guess for ρ .

■ **Figure 3** Examples for the shifted schedule and the position of the gap in the Cases 1.2.1 and 1.2.2.

Case 1.2.2: $\rho < \iota$. Let $\mathcal{J}_{H,\rho} := \{j \in \mathcal{J}_H | s_j + p_j > \rho\}$ be the set of huge jobs, which are still scheduled after ρ . It holds that $|\mathcal{J}_{H,\rho}| \leq k$. As a consequence, it is possible to guess their starting positions in polynomial time. Therefore, the algorithm will schedule each job in $\mathcal{J}_{H,\rho}$ as in the original simplified schedule $\text{OPT}_{\text{rounded}}$. The other huge jobs, which end between τ and ρ , are scheduled such that they end at ρ , i.e., we define $\sigma'(j) := \rho - p(j)$ for each of these huge jobs j . Next, we shift the all the jobs j with starting time $\sigma'(j) \geq \rho + [T'/2]_{\epsilon\delta T}$ downwards such that they start as they had started before the first shift. As a result between T' and $T' + [T'/2]_{\epsilon\delta T}$, there are just jobs left which overlap the time from $\tau + [T'/2]_{\epsilon\delta T}$ to $\rho + [T'/2]_{\epsilon\delta T}$, see Figure 3. By the choice of ρ and τ at each point between $\tau + [T'/2]_{\epsilon\delta T}$ and $\rho + [T'/2]_{\epsilon\delta T}$ there are at most $m - k$ jobs which use at most $R - \gamma R$ resource since the job i was scheduled there before. Since each job between T' and $T' + [T'/2]_{\epsilon\delta T}$ overlaps this area there are at least k free machines and γR free resources in this area. Hence, we position the gap at T' . In the algorithm, we will guess τ and ρ dependent on a given fractional solution for the large jobs and guess the at most k jobs ending before τ and the k jobs ending after ρ in $\mathcal{O}(m^{2k-1})$. For each of these jobs, we have to guess its starting time out of at most $|\mathcal{S}|/2$ possibilities.

Case 2: $r(\mathcal{J}_{\tau,\geq,\text{pre}}) > R - \gamma R$. In this case, the gap has to start strictly after τ since at τ there is not enough free resource. Let $\mathcal{J}_{L,T'/2}$ be the set of large jobs intersecting the point in time $T'/2$. Remember that $\mathcal{J}_{\tau,\geq,\text{pre}}$ contains huge and large jobs. Since $r(\mathcal{J}_{\tau,\geq,\text{pre}}) > R - \gamma R$ at least one of these sets of jobs (huge or large) has to contribute a large resource requirement to $r(\mathcal{J}_{\tau,\geq,\text{pre}})$. In the following, we will find the gap, depending on which of both sets contributes a suitable large resource requirement.

Case 2.1: $r(\mathcal{J}_{L,T'/2}) \geq 2\gamma R$. Let $\tau' \in \{s \in \mathcal{S} | \tau \leq s \leq T'\}$ be the first point in time where $r(\mathcal{J}_{L,T'/2}) - r(\mathcal{J}_{L,\tau',>,\text{pre}}) \geq \gamma R$. Note that $\tau \leq \tau'$ since, otherwise, there would be γR free resources at τ .

▷ **Claim 12.** By this choice at each point between τ' and $\tau' + [T'/2]_{\epsilon\delta T}$ there are at least γR free resources.

Between τ' and T' there are γR free resources since jobs from $\mathcal{J}_{L,T'/2}$ with a resource requirement of at least γR end before τ' . On the other hand, before the shift there was at least γR resource blocked by jobs from $\mathcal{J}_{L,T'/2}$ between $T'/2$ and τ' and hence after the shift there is at least γR free resource at any time between T' and $\tau' + [T'/2]_{\epsilon\delta T}$. Moreover, as in Case 1.2, let $\rho \in \{s | \tau \leq s \leq T', s \in \mathcal{S}\}$ be the first point in the schedule where $|\mathcal{J}_{\rho,>,\text{pre}}| \leq k$, i.e., where at most k jobs are scheduled that start before $T'/2$.

■ **Figure 4** Examples for the shifted schedules and the position of the gap in Cases 2.1.1 and Case 2.1.2.

▷ **Claim 13.** By this choice at each point between τ and $\rho + \lceil T'/2 \rceil_{\epsilon\delta T}$ there are at least k unused machines.

From τ to T' there are k unused machines, by the choice of τ . On the other hand, at each point in time between T' and $\rho + \lceil T'/2 \rceil_{\epsilon\delta T}$ there where k machines blocked by jobs from that started before $T'/2$ and these machines are now unused.

Similar as in Cases 1.2.1 and 1.2.2, we will find the gap dependent of the relation between τ' and ρ .

Case 2.1.1: $\rho \geq \tau'$. In this case between τ' and $\tau' + \lceil T'/2 \rceil_{\epsilon\delta T}$ there are at least k unused machines. Therefore, we have a gap between these two points, which is large enough, see Figure 4. In the algorithm, we have to guess the k huge jobs, which end before τ and their start point, as well as the points τ , τ' and ρ . All the guesses for this case can be iterated in polynomial time.

Case 2.1.1: $\rho < \tau'$. In this case, we act like in Case 1.2.2 and shift all huge jobs, but the at most k jobs ending after ρ , downwards such that they end at ρ , see Figure 4. Furthermore, we shift all jobs starting after $\rho + \lceil T'/2 \rceil_{\epsilon\delta T}$ back downwards such that they again start at their primary start position. Now after T' there are just jobs having their start or end position between $\tau + \lceil T'/2 \rceil_{\epsilon\delta T}$ and $\rho + \lceil T'/2 \rceil_{\epsilon\delta T}$. At each point between these two points there are at least k unused machines and γR unused resource with the same arguments as in Case 1.2.2. Hence, we have a gap with the right properties between T' and $T' + \lceil T'/2 \rceil_{\epsilon\delta T}$. All the guesses for this case can be iterated in polynomial time.

Case 2.2: $r(\mathcal{J}_{L, T'/2}) < 2\gamma R$. Since we have $r(\mathcal{J}_{\tau, \geq, \text{pre}}) > R - \gamma R$ (by Case 2.) and it holds that $(\mathcal{J}_H \cap \mathcal{J}_{\tau, \geq, \text{pre}}) \cup (\mathcal{J}_{L, T'/2} \cap \mathcal{J}_{\tau, \geq, \text{pre}}) = \mathcal{J}_{\tau, \geq, \text{pre}}$ we get that $r(\mathcal{J}_H \cap \mathcal{J}_{\tau, \geq, \text{pre}}) \geq R - 3\gamma R$. Similar as before, let $\rho \in \{s | \tau \leq s \leq T, s \in S\}$ be the first point in the schedule where less than k jobs are scheduled that start before $T'/2$. By the same argument as in Case 2.1, we know that at every point between τ and $\rho + \lceil T'/2 \rceil_{\epsilon\delta T}$ there are at least k unused machines in the shifted schedule.

Case 2.2.1: $r(\mathcal{J}_{\rho, \geq, \text{pre}}) \geq \gamma R$. In this case, we can construct a schedule in the same way as in case 1.2.2 or 2.1.2 by shifting down the jobs that start after $\rho + \lceil T'/2 \rceil_{\epsilon\delta T}$ and positioning the gap at T' , see Figure 5. This is possible because the jobs that are scheduled

■ **Figure 5** The shifted schedule and the position of the gap in Cases 2.2.1 and 2.2.2. Note that in Case 2.2.2 the gap is not displayed continuously. However, by swapping the used resource, we can make it continuous. We only need the fact that at each point in time there are enough free resources and machines.

between $\tau + \lceil T'/2 \rceil_{\varepsilon\delta T}$ and $\rho + \lceil T'/2 \rceil_{\varepsilon\delta T}$ can use at most $R - \gamma R$ resources in this case since $r(\mathcal{J}_{\rho, \geq, \text{pre}}) \geq \gamma R$ and hence at least γR resources are blocked by the jobs in $\mathcal{J}_{\rho, \geq, \text{pre}}$. All the guesses for this case can be iterated in polynomial time.

Case 2.2.2: $r(\mathcal{J}_{\rho, \geq, \text{pre}}) < \gamma R$. Let $\rho' \in \{i\delta^2 | \tau/\delta^2 \leq i \leq \rho/\delta^2, i \in \mathbb{N}\}$ be the smallest value, where $r(\mathcal{J}_{\rho', \geq, \text{pre}}) \leq \gamma R$. Remember, we had $r(\mathcal{J}_H \cap \mathcal{J}_{\tau, \geq, \text{pre}}) \geq R - 3\gamma R$ so huge jobs with summed resource requirement of at least $R - 4\gamma R$ are finished till ρ' . We partition the huge jobs that finish between τ and ρ by their processing time. Since each job has a processing time of at least $\lceil T'/2 \rceil_{\varepsilon\delta T}$, we get at most $\mathcal{O}(1/\varepsilon\delta) \leq |\mathcal{S}|/2$ sets. As seen in Section 2, we have to discard at most $k \leq 3|\mathcal{S}|$ large jobs, which have to be placed later on.

▷ **Claim 14.** There exists a set in the partition, which uses at least $3\gamma R$ resource total.

Proof. Since $\gamma \leq 1/(2|\mathcal{S}|) \leq 1/(3|\mathcal{S}|/2 + 4)$ it holds that

$$\frac{R - 4\gamma R}{|\mathcal{S}|/2} \geq \frac{(1 - 4/(3|\mathcal{S}|/2 + 4))R}{|\mathcal{S}|/2} = 3R/(3|\mathcal{S}|/2 + 4) \geq 3\gamma R.$$

Therefore, by the pigeon principle, there must be one set in the partition, which has summed resource requirement of at least $3\gamma R$. ◁

We sort the jobs in this partition by non increasing order of resource requirement. We greedily take jobs from this set, till they have a summed resource requirement of at least γR and schedule them such that they end before ρ' . If there was a job with more than γR resource requirement, it had to be finished before ρ' since the resource requirement of huge jobs finishing after ρ' is smaller than γR and we only chose it. Otherwise, the greedily chosen jobs have summed resource requirement of at least $2\gamma R$. Since the considered set has a summed resource requirement of at least $3\gamma R$, jobs of this set with summed resource requirement at least $2\gamma R$ end before ρ' . Therefore, we do not violate any constraint by shifting down these jobs such that they end at ρ' , see Figure 5.

Concerning property three, note that since we only use the free area (machines and resources) to schedule the k large jobs inside the gap, there is a layer s' in the shifted schedule, for each layer $s \in \mathcal{S}$ that has at least as many machines and resources not used by large and huge jobs as the layer s . ◀

Algorithm Summary. Given a value $T' := i\varepsilon'T$, we determine the set \mathcal{S} and call the algorithm from Lemma 6 with $\gamma = 1/(3|\mathcal{S}| + 4)$ to generate the set of schedules for the large jobs. One of these schedules uses in each layer at most as many machines and resources for large jobs, as the rounded optimal schedule, or the value T' is too small. Furthermore, the set of not scheduled large jobs \mathcal{J}' has a total machine requirement of at most $3|\mathcal{S}|$, a total resource requirement of at most γR , and each job has a processing time of at most $T'/2$.

For each of these schedules, the algorithm iterates all values for τ and ρ and all possibilities for the at most $2k$ huge jobs ending before or after these values and their starting positions. Then, we identify the case and the other variables dependent on the guesses and the solution schedule for the large jobs. By this we generate a new set of schedules, for which it will try to place the small jobs. We refer to the full version for more details.

To bound the total number of guesses that we add by this procedure, note that we have to guess τ , ρ and ρ' from at most $\mathcal{O}(|\mathcal{S}|)$ possibilities. Further, we for each of these guesses, the algorithm guesses at most $2k$ huge jobs and their starting positions. The total number of these guesses is bounded by $(m/\varepsilon^2)^{\mathcal{O}(k)}$, since the huge jobs start at multiples of $\varepsilon^2 T$. Therefore, the total number of guesses for the large jobs is bounded by $(m/\varepsilon^2)^{\mathcal{O}(k)} \cdot \mathcal{O}(|\mathcal{S}|^3)$. Since $k \leq 3|\mathcal{S}|$, this guess for the huge jobs lengthens the running time by a factor of at most $(m/\varepsilon)^{1/\varepsilon^{\mathcal{O}(1/\varepsilon^2)}}$. This concludes the proof of Theorem 1.

Abstract

Given a set A of n points in \mathbb{R}^d with weight function $w : A \rightarrow \mathbb{R}_{>0}$, the Fermat distance function is $\varphi(\mathbf{x}) := \sum_{\mathbf{a} \in A} w(\mathbf{a}) \|\mathbf{x} - \mathbf{a}\|$. A classic problem in facility location dating back to 1643, is to find the *Fermat point* \mathbf{x}^* , the point that minimizes the function φ . We consider the problem of computing a point $\tilde{\mathbf{x}}^*$ that is an ε -approximation of \mathbf{x}^* in the sense that $\|\tilde{\mathbf{x}}^* - \mathbf{x}^*\| < \varepsilon$. The algorithmic literature has so far used a different notion based on ε -approximation of the value $\varphi(\mathbf{x}^*)$. We devise a certified subdivision algorithm for computing $\tilde{\mathbf{x}}^*$, enhanced by Newton operator techniques. We also revisit the classic Weiszfeld-Kuhn iteration scheme for \mathbf{x}^* , turning it into an ε -approximate Fermat point algorithm. Our second problem is the certified construction of ε -isotopic approximations of n -ellipses. These are the level sets $\varphi^{-1}(r)$ for $r > \varphi(\mathbf{x}^*)$ and $d = 2$. Finally, all our planar ($d = 2$) algorithms are implemented in order to experimentally evaluate them, using both synthetic as well as real world datasets. These experiments show the practicality of our techniques.

1 Introduction

A classic problem in Facility Location, see e.g., [21, 43], is the placement of a facility to serve a given set of demand points or customers so that the total transportation costs are minimized. The total cost at any point is interpreted as the sum of the distances to the demand points. The point that minimizes this sum is called the *Fermat Point*; see Figure 1. This is an old geometric problem that has inspired scientists over the last three centuries.

A *weighted foci set* is a non-empty finite set of (demand) points $A = \{\mathbf{a}_1, \dots, \mathbf{a}_n\}$ in \mathbb{R}^d associated with a positive weight function $w : A \rightarrow \mathbb{R}_{>0}$. Each $\mathbf{a} \in A$ is called a *focus* with weight $w(\mathbf{a})$. Let $W := \sum_{\mathbf{a} \in A} w(\mathbf{a})$. The *Fermat distance function* of A is given by

$$\varphi(\mathbf{x}) := \sum_{\mathbf{a} \in A} w(\mathbf{a}) \|\mathbf{x} - \mathbf{a}\|,$$

■ **Figure 1** The Fermat point of the 28 EU-capitals (pre-Brexit), highlighted with (x), along with three 28-ellipses of different radii. (a) The foci (capitals) are unweighted. (b) Each focus has the weight of the country's population. The source of the map is <https://www.consilium.europa.eu>.

where $\|\cdot\|$ is the Euclidean norm in \mathbb{R}^d . The global minimum value of φ is called the *Fermat radius* of A , denoted by $r^* = r^*(A)$. Any point $\mathbf{x} \in \mathbb{R}^d$ that achieves this minimum, $\varphi(\mathbf{x}) = r^*$, is called a *Fermat point*, denoted by $\mathbf{x}^* = \mathbf{x}^*(A)$. The Fermat point is not unique if and only if A is collinear and n is even. We can check if A is collinear in $O(n)$ time, and in that case, the median, which is a Fermat point, can be found in $O(n \log n)$ time. So henceforth, we assume that A is not collinear. In that case φ is a strictly convex function [35, 37], and \mathbf{x}^* is unique.

We also consider the closely related problem of computing n -ellipses of A . For any $r > r^*(A)$, the level set of the Fermat distance function is $\varphi^{-1}(r) := \{\mathbf{x} \in \mathbb{R}^d : \varphi(\mathbf{x}) = r\}$. If $n = 1$, the level set is a sphere; and if $n = 2$ and $d = 2$, it is the classic ellipse. When A has n points, we call $\varphi^{-1}(r)$ an n -ellipsoid, or an n -ellipse if $d = 2$; hence the term *foci set*. From an application perspective, an n -ellipse of radius r can be viewed as a curve that bounds the candidate area for facility location [46], such that the total transportation cost to the demand points is at most r , as in Figure 1.

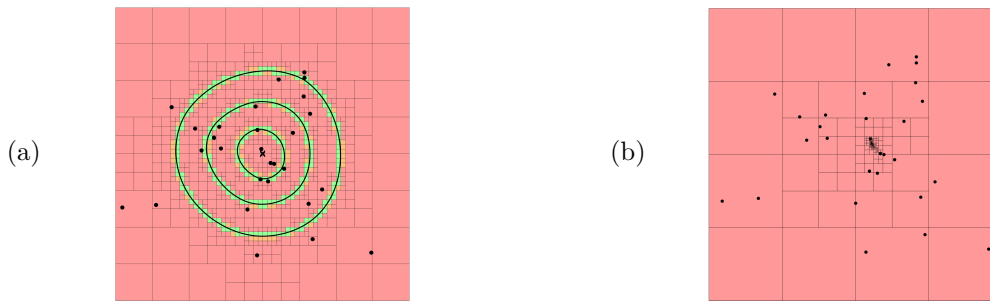

The question of approximating the Fermat point is of great interest as its coordinates are roots of polynomials of degree exponential in n [3]. For any $\varepsilon > 0$, an ε -approximation $\tilde{\mathbf{x}}^*$ to the Fermat point \mathbf{x}^* can be interpreted in 3 ways:

- (A) **Approximate Fermat Point:** $\|\tilde{\mathbf{x}}^* - \mathbf{x}^*\| \leq \varepsilon$;
- (B) **Absolute Approximate Fermat Radius:** $\varphi(\tilde{\mathbf{x}}^*) \leq \varphi(\mathbf{x}^*) + \varepsilon$;
- (C) **Relative Approximate Fermat Radius:** $\varphi(\tilde{\mathbf{x}}^*) \leq (1 + \varepsilon)\varphi(\mathbf{x}^*)$.

Thus, we have three ε -approximation problems: (A), (B) and (C). Essentially (B) and (C) are approximations of the Fermat radius, while (A) is a direct approximation of the Fermat point. In this paper we consider approximations in the sense of (A); to the best of our knowledge, only approximations in the sense of (B) and (C), have been considered before, see e.g., [8, 16]. Below, we show that (B) and (C) are easily *reduced* to (A) while the converse reductions are non-obvious (reductions in the sense of complexity theory).

In this work we introduce certified algorithms for approximating the Fermat point and n -ellipses, combining a subdivision approach with interval methods (cf. [33, 48]). The approach can be formalized in the framework of *soft predicates* [56]. Our certified algorithms are fairly easy to implement, and are shown to have good performance experimentally.

Related Work. The problem we study has a long history, with numerous extensions and variations. Out of the 15 names found in the literature, see [23], we call it *the Fermat point problem*. Other common names are the *Fermat-Weber problem* and the *Geometric median*.

■ **Figure 2** The resulting box subdivision of Figure 1(a) for (a) the n -ellipses and (b) the Fermat point.

problem. Apart from the Facility Location application introduced by Weber [57], the problem is motivated by applications in diverse fields such as statistics and data mining where it is known as the *1-Median problem*, and is an instance of the k -median clustering technique [27].

For $d = 2, n = 3$, the problem was first stated by P. Fermat (1607 - 1665) and was solved by E. Torricelli (1608 - 1647) and Krarup and Vajda [30] using a geometric construction. For $n = 4$, solutions were given by Fagnano [20] and Cieslik [14]. The first general method, for arbitrary n , is an iterative scheme proposed by Weiszfeld [58] in 1937. It was later corrected and improved by Kuhn [32] and Ostresh [43]; see Beck and Sabach [4] for a review. The method is essentially a gradient descent iterative algorithm. It behaves quite well in practice and has only linear convergence, with guaranteed convergence from any starting point.

A plethora of approximation algorithms for the Fermat point, in the senses of (B) and (C), can be found in the literature using various methods. There are algorithms based on semidefinite programming [45], interior point methods [16, 60], sampling [2, 16], geometric data structures [8] and coresets [26], among others [13, 22]. Moreover, special configurations of foci have been considered [7, 15], a continuous version of the problem [21], and also a generalized Fermat point of planar convex objects [1, 12, 18].

The literature on n -ellipses is smaller but equally old: Nagy [38] proved that n -ellipses are convex curves, calling them *egg curves*, and dating them back to Tschirnhaus in 1695 [55, p. 183]. Further, he characterized the singular points of the n -ellipses as being either foci or the Fermat point. Another early work is by Sturm in 1884 [53]. Sekino [51] showed that the Fermat distance function φ is C^∞ on $\mathbb{R}^2 \setminus A$. So, the n -ellipse is a piecewise smooth curve, as it may pass through several foci. Nie et al. [42] showed that the polynomial equation defining the n -ellipses has algebraic degree exponential in n .

Our Contributions. In this paper, we design, implement and experimentally evaluate algorithms for approximating the Fermat point of a given set of foci in \mathbb{R}^d . We also compute an ε -approximate n -ellipse; a problem not considered in computational literature before. These are the first certified algorithms [36, 54] for these problems. Our contributions are summarized as follows:

- We design two certified algorithm for the approximate Fermat point: one based on subdivision, the other based on Weiszfeld iteration [58].
- Our notion of ε -approximate Fermat point appears to be new; in contrast, several recent works focus on ε -approximation of the Fermat radius. The approximate Fermat radius can be reduced to approximate Fermat point; the converse reduction is unclear.
- Based on the *PV construction* [47, 33], we design an algorithm to compute a regular isotopic ε -approximation of an n -ellipse. We also augment the algorithm to compute simultaneous contour plots of the distance function φ , resulting in a useful visualization tool (see Figure 1).

- We implement and experimentally evaluate the performance of all our algorithms on different datasets in the plane, as a function of n and ε . Various details of the interval primitives and proofs can be found in the full arXiv version.

2 Preliminaries

Vector variables are written in bold font: thus $\mathbf{0}$ is the origin of \mathbb{R}^d and $\mathbf{x} = (x_1, \dots, x_d)$. For a differentiable function $f : \mathbb{R}^d \rightarrow \mathbb{R}$, let $\partial_i f$ denote partial differentiation with respect to x_i . The *gradient* $\nabla f : \mathbb{R}^d \rightarrow \mathbb{R}^d$ of f is given by the vector $\nabla f(\mathbf{x}) = (f_1(\mathbf{x}), \dots, f_d(\mathbf{x}))^T$ where $f_i = \partial_i f$. In general, the operator ∇ is partial, i.e., $\nabla f(\mathbf{x}_0)$ might not be defined at a point \mathbf{x}_0 . A point \mathbf{x}_0 is a *critical point* of f if $\nabla f(\mathbf{x}) = \mathbf{0}$ or $\nabla f(\mathbf{x})$ is undefined.

We consider analytic properties of a scalar function $f : \mathbb{R}^d \rightarrow \mathbb{R}$, mainly from the viewpoint of convex analysis [35, 39]. In our case, f is the Fermat distance function for some weighted set A . From an abstract perspective, the Fermat point problem (resp., n -ellipsoid problem) amounts to computing the critical points of the gradient of f (resp., computing the level sets of f). The Fermat point is the only critical point of ∇f in $\mathbb{R}^d \setminus A$, assuming A is non-collinear.

Most of the basic properties regarding the Fermat point are well-known and may be found in our references such as [32, 35, 39, 43, 58]. To emphasize the foci set A , we explicitly write φ_A instead of φ . A focus $\mathbf{a} \in A$ is the Fermat point of A if and only if $\|\nabla \varphi_{A \setminus \mathbf{a}}(\mathbf{a})\| \leq w(\mathbf{a})$. Testing if the Fermat point \mathbf{x}^* is in A can be done in $O(n^2 d)$ time. If \mathbf{x}^* is not one of the foci, then $\nabla f(\mathbf{x}^*) = \mathbf{0}$, and the problem can be reduced to general finding real zeros of a square system of polynomial equations (e.g., [59]). However, the thrust of this paper is to develop direct methods that exploit the special properties of the Fermat problem.

We formally define the two main problems which we consider:

- APPROXIMATE FERMAT POINT: Given a weighted point set A in \mathbb{R}^d and $\varepsilon > 0$, compute a point $\tilde{\mathbf{x}}^*$ within ε distance to the Fermat point \mathbf{x}^* of A .
- APPROXIMATE ISOTOPIC n -ELLIPSES: Given $\varepsilon > 0$, a weighted point set A in \mathbb{R}^2 of size n and a radius $r > r^*(A)$, compute a closed polygonal curve E that is ε -isotopic to $\varphi^{-1}(r)$, i.e., there exists an ambient isotopy¹ $\gamma : \mathbb{R}^2 \times [0, 1] \rightarrow \mathbb{R}^2$ with $\gamma(E, 1) = \varphi^{-1}(r)$ and for any point $\mathbf{a} \in \varphi^{-1}(r)$, the parametric curve $\gamma(\mathbf{a}, \cdot)$ has at most length ε . This implies a bound of ε on the Hausdorff distance between E and $\varphi^{-1}(r)$.

Approximation notions. We compare the three different notions of ε -approximation for the Fermat point. We reduce the approximation problem of notion (C) to (B), and (B) to (A). An ε -approximation $\tilde{\mathbf{x}}^*$ of \mathbf{x}^* in the sense $\|\tilde{\mathbf{x}}^* - \mathbf{x}^*\| \leq \varepsilon$ is also a $(W\varepsilon)$ -approximation in the sense $\varphi(\tilde{\mathbf{x}}^*) \leq \varphi(\mathbf{x}^*) + W\varepsilon$, which follows directly from the triangle inequality

$$\varphi(\tilde{\mathbf{x}}^*) = \sum_{\mathbf{a} \in A} w(\mathbf{a}) \|\tilde{\mathbf{x}}^* - \mathbf{a}\| \leq \sum_{\mathbf{a} \in A} w(\mathbf{a}) (\|\tilde{\mathbf{x}}^* - \mathbf{x}^*\| + \|\mathbf{x}^* - \mathbf{a}\|) = W\varepsilon + \varphi(\mathbf{x}^*).$$

An ε -approximation $\tilde{\mathbf{x}}^*$ of \mathbf{x}^* in the sense $\varphi(\tilde{\mathbf{x}}^*) \leq \varphi(\mathbf{x}^*) + \varepsilon$ is also a $\frac{2\varepsilon}{\varphi(g)}$ -approximation in the sense $\varphi(\tilde{\mathbf{x}}^*) \leq (1 + \frac{2\varepsilon}{\varphi(g)})\varphi(\mathbf{x}^*)$. The center of gravity g is a 2-approximation of the Fermat radius r^* (see [16]), i.e. $\varphi(\mathbf{x}^*) \geq \frac{1}{2}\varphi(g)$. Hence

$$\varphi(\tilde{\mathbf{x}}^*) \leq \varphi(\mathbf{x}^*) + \varepsilon = \left(1 + \frac{\varepsilon}{\varphi(\mathbf{x}^*)}\right) \varphi(\mathbf{x}^*) \leq \left(1 + \frac{2\varepsilon}{\varphi(g)}\right) \varphi(\mathbf{x}^*)$$

¹ That is, a continuous map $\gamma : \mathbb{R}^2 \times [0, 1] \rightarrow \mathbb{R}^2$ such that $\gamma_0 = \gamma(\cdot, 0)$ is the identity map, and, for all $t \in [0, 1]$, $\gamma_t = \gamma(\cdot, t)$ is a homeomorphism on \mathbb{R}^2 .

On the other hand, it is not clear how to derive an ε -approximation of type (A) if an approximation algorithm for type (B) and (C) is at hand, as the following 2 examples show.

Example 1: For any $\varepsilon > 0$ choose $c \leq \frac{\varepsilon}{2\sqrt{2}-2}$ and consider the weighted foci $\mathbf{a}_1 = (1, 0)$, $\mathbf{a}_2 = (0, 1)$, $\mathbf{a}_3 = (-1, 0)$, $\mathbf{a}_4 = (0, -1)$ with $w(\mathbf{a}_1) = w(\mathbf{a}_3) = 1$ and $w(\mathbf{a}_2) = w(\mathbf{a}_4) = c$ for which the Fermat point is $\mathbf{x}^* = (0, 0)$ for symmetry reasons, see Figure 3(a). Point $p = (1, 0)$ is an ε -approximation of \mathbf{x}^* in the sense (B) and (C), but it has a distance of 1 to \mathbf{x}^* .

Example 2: For any $\varepsilon > 0$ we choose $h > 0$ small enough such that: $2\sqrt{4+h^2} + 2h \leq 4\sqrt{1+h^2} + \varepsilon$. Consider the foci $\mathbf{a}_1 = (0, -h)$, $\mathbf{a}_2 = (0, h)$, $\mathbf{a}_3 = (2, -h)$, $\mathbf{a}_4 = (2, h)$ with unit weights. The Fermat point is $\mathbf{x}^* = (1, 0)$ for symmetry reasons, see Figure 3(b). Point $p = (2, 0)$ is an ε -approximation of \mathbf{x}^* in the sense (B) and (C), but it has a distance of 1 to \mathbf{x}^* .

■ **Figure 3** (a) Example that a *good* approximation of the Fermat point in sense (B) does not imply a *good* approximation in sense (A). (b) Analogous example for sense (C).

Subdivision Paradigm. The subdivision algorithms presented in this paper take as input an initial box $B_0 \subset \mathbb{R}^d$ and recursively split it. We organize the boxes in a *generalized quadtree* data structure [50]. A box can be specified by d intervals as $B = I_1 \times I_2 \times \dots \times I_d$. Let m_B denote the *center* of B , r_B the *radius* of B (distance between m_B and a corner), and $\omega(B)$ the *width* of B (the maximum length of its defining intervals). The term $c \cdot B$ denotes the box with center m_B and radius $c \cdot r_B$. The function SPLIT_1 takes a box B and returns 2^d congruent subboxes (*children*), one for each orthant. We use SPLIT_2 to indicate that we do two successive levels of SPLIT_1 operations (i.e., $1 + 2^d$ SPLIT_1 operations, resulting in $(2^d)^2 = 4^d$ leaves).

Soft Predicates. Let $\square \mathbb{R}^d$ denote the set of closed d -dimensional boxes (i.e., Cartesian products of intervals) in \mathbb{R}^d . Let P be a logical *predicate* on boxes, i.e., $P : \square \mathbb{R}^d \rightarrow \{\text{true}, \text{false}\}$. For example, the *Fermat point predicate* is given by $P_{\text{fp}}(B) = \text{true}$ if and only if $\mathbf{x}^* \in B$. Logical predicates are hard to implement, and thus, we may focus on *tests*, which are viewed as one-sided predicates. Formally, a test T looks like a predicate: $T : \square \mathbb{R}^d \rightarrow \{\text{success}, \text{failure}\}$ and it is always associated to some predicate P : call T a *test for predicate P* if $T(B) = \text{success}$ implies $P(B) = \text{true}$. However, we conclude nothing if $T(B) = \text{failure}$. Denote this relation by “ $T \Rightarrow P$ ”.

Soft predicates [56] are an intermediate concept between a test and a predicate. Typically, they arise from a partial scalar function $f : \mathbb{R}^d \rightarrow \mathbb{R} \cup \{\uparrow\}$ where $f(\mathbf{x}) = \uparrow$ means $f(\mathbf{x})$ is not defined. We then define a partial *geometric predicate* P_f on boxes B as follows:

$$P_f(B) = \begin{cases} \uparrow & \text{if } \uparrow \in f(B), \\ +1 & \text{if } f(B) > 0, \\ -1 & \text{if } f(B) < 0, \\ 0 & \text{else.} \end{cases}$$

We can now derive various logical predicates P from P_f , by identifying the values in the set $\{-1, 0, +1, \uparrow\}$ with **true** or **false**. For instance, we call P an *exclusion predicate* if we associate the 0- and \uparrow -value with **false** and the other values with **true**. For the *inclusion* predicate, we associate the 0-value with **true**, others with **false**. For example, a test for the Fermat point predicate P_{fp} is an inclusion predicate based on the partial function $f(\mathbf{x}) = \sum_i (\partial_i f(\mathbf{x}))^2$; the function is partial because $f(\mathbf{x}) = \uparrow$ when \mathbf{x} is a focus point. Although our box predicates $P(B)$ are defined for full-dimensional boxes B , we can extend them to any point \mathbf{x} as follows: $P(\mathbf{x})$ has the logical value associated with the $\text{sign}(f(\mathbf{x})) \in \{\uparrow, +1, -1, 0\}$.

► **Definition 1.** Let T be a test for a predicate P . We call T a *soft predicate* (or *soft version of P*) if it is convergent in this sense: if $(B_i : i = 0, 1, \dots)$ is a monotone sequence of boxes $B_{i+1} \subseteq B_i$ that converges to a point \mathbf{a} , then $P(\mathbf{a}) \equiv T(B_i)$ for i large enough.

Here, “ $P(\mathbf{a}) \equiv T(B_i)$ ” means $P(\mathbf{a}) = \text{true}$ if and only if $T(B_i) = \text{success}$. A soft version of $P(B)$ is usually denoted $\Box P(B)$. We note that soft versions of exclusion predicates are generally easier to construct than inclusion predicates. The former can be achieved by numerical approximation, while the latter requires some deeper principle such as the Brouwer fixed point theorem [9].

Interval arithmetic. We construct soft predicates using functions of the form $F : \Box\mathbb{R}^d \rightarrow \Box(\mathbb{R} \cup \{-\infty, \infty\})$ that approximate the scalar function $f : D \rightarrow \mathbb{R}$ with $D \subset \mathbb{R}^d$.

► **Definition 2.** Call F a *soft version of f* if it is

- i) conservative, i.e., for all $B \in \Box\mathbb{R}^d$, $F(B)$ contains $f(B) := \{f(p) : p \in B \cap D\}$, and
- ii) convergent, i.e., if for monotone sequence $(B_i : i \geq 0)$ that converges to a point $\mathbf{a} \in D$, $\lim_{i \rightarrow \infty} \omega(F(B_i)) = 0$ holds.

We shall denote F by $\Box f$ when F is a soft version of f . There are many ways to achieve $\Box f$. For example, if f has an arithmetic expression E , we can simply evaluate E using interval arithmetic. More sophisticated methods may be needed for performance. The next lemma shows how $\Box f$ leads to soft exclusion predicates based on f .

► **Lemma 3.** If P is an exclusion predicate based on f , then the test $\Box P(B) : 0 \notin \Box f(B)$ is a soft version of P .

Below, we need a multivariate generalization, to the case where $\mathbf{f} : \mathbb{R}^d \rightarrow \mathbb{R}^m$, and the exclusion predicate $P(B)$ is $\mathbf{0} \notin \mathbf{f}(B)$. If $\Box \mathbf{f} : \Box\mathbb{R}^d \rightarrow \Box\mathbb{R}^m$ is a soft version of \mathbf{f} , then a soft version of $P(B)$ is the given by the test $T(B) : \mathbf{0} \notin \Box \mathbf{f}(B)$. If $\mathbf{f} = (f_1, \dots, f_m)$, then this reduces to $0 \notin \Box f_i(B)$ for some $i = 1, \dots, m$.

3 Approximate Fermat points

We now present three approximation algorithms for the Fermat point \mathbf{x}^* . For simplicity, we assume in our algorithms that the Fermat point is not a focus, i.e. $\mathbf{x}^* \notin A$. This assumption can be easily checked in $O(n^2d)$ preprocessing time, or with a more elegant approach, in $O(nd)$ time during the execution of our subdivision algorithms.

■ **Figure 4** Different steps during the the execution of Algorithm 1. The dark red boxes cannot contain the Fermat point, whereas the light green boxes may contain it.

3.1 Using the Subdivision Paradigm

The subdivision paradigm requires an initial box B_0 to start subdividing. If B_0 is not given, it is easy to find a box that contains \mathbf{x}^* , since \mathbf{x}^* lies in the convex hull of A [32]. We use a function INITIAL-BOX(A) which, in $O(nd)$ time, computes an axis-aligned bounding box with corners having the minimum and maximum x, y coordinates.

We define an exclusion and inclusion predicate based on the gradient function $\nabla\varphi$.

► **Definition 4.** *Given a box B , the gradient exclusion predicate $C_0^\nabla(B)$ is defined by the condition $\mathbf{0} \notin \nabla\varphi(B)$. The gradient inclusion predicate $C_1^\nabla(B)$ is just the complement of $C_0^\nabla(B)$, that is $\mathbf{0} \in \nabla\varphi(B)$.*

Under our assumptions that $\mathbf{x}^* \notin A$, we have that $C_1^\nabla(B)$ holds if and only if $\mathbf{x}^* \in B$. We obtain a soft version of the exclusion predicate $C_0^\nabla(B)$ by replacing $\nabla\varphi$ in its definition with any soft version $\square\nabla\varphi$, see Lemma 3. But it is not so easy to get a soft version of $C_1^\nabla(B)$; we shall return to this when we treat the Newton operator below.

In Algorithm 1, using the exclusion predicate we discard boxes that are guaranteed not to contain \mathbf{x}^* (red in Figure 4) and we split boxes that might contain \mathbf{x}^* (green in Figure 4). While subdividing, we test whether we can already approximate \mathbf{x}^* well enough by putting a bounding box around all the boxes that are not excluded yet, using the following predicate.

► **Definition 5.** *Given a set of boxes Q that contains the Fermat point, the stopping predicate $C^\varepsilon(Q)$ returns true, if and only if the minimum axis-aligned bounding box containing all boxes in Q has a radius at most ε .*

If C^ε returns true, then we can stop. Since the radius of the minimum bounding box is at most ε , the center of the box is an ε -approximate Fermat point $\tilde{\mathbf{x}}^*$.

■ **Algorithm 1** Subdivision for the approximate Fermat point (SUB).

Input : Foci set A , constant $\varepsilon > 0$

Output: Point $\tilde{\mathbf{x}}^*$

```

1  $B_0 \leftarrow \text{INITIAL-BOX}(A); \quad Q \leftarrow \text{QUEUE}(); \quad Q.\text{PUSH}(B_0);$ 
2 while not  $C^\varepsilon(Q)$  do
3    $B \leftarrow Q.\text{POP}();$ 
4   if not  $\square C_0^\nabla(B)$  then
5      $Q.\text{PUSH}(\text{SPLIT}_1(B));$ 
6 return  $\tilde{\mathbf{x}}^* \leftarrow \text{Center of the bounding box of } Q;$ 

```

Regarding the runtime of Algorithm 1, evaluating $\nabla\varphi$ and its soft version takes linear time in n . The subdivision approach induces an exponential dependency on d , as splitting a box creates 2^d many children. Further, a SPLIT_1 operation decreases the boxwidth by a factor of 2, therefore, Algorithm 1 cannot converge faster than linear in ε .

3.2 Enhancing the Subdivision Paradigm

In this section, we augment Algorithm 1 with a speed up based on a *Newton operator*, which will ensure eventual quadratic convergence.

The Newton operator. Newton-type algorithms have been considered in the past, usually independently of other methods, and thus suffer from lack of global convergence. Moreover, from a numerical viewpoint, such methods face the *precision-control problem*. Our algorithm integrates subdivision with the Newton operator (an old idea that goes back to Dekker [17] in the 1960's), thus ensuring global convergence.

We want to find the Fermat point, i.e., the root of $\mathbf{f} = \nabla\varphi$. Newton-type operators are well-studied in the interval literature, and they have the form $N = N_{\mathbf{f}} : \square\mathbb{R}^d \rightarrow \square\mathbb{R}^d$. There are three well-known versions of $N_{\mathbf{f}}$: the simplest version, from Moore [36] and Nickel [40], is

$$N(B) = m_B - J_{\mathbf{f}}^{-1}(B) \cdot \mathbf{f}(m_B),$$

where $J_{\mathbf{f}}$ is the Jacobian matrix of \mathbf{f} . Since $\mathbf{f} = \nabla\varphi$, this matrix is actually the Hessian of φ . The second version by Krawczyk [31, 52] is:

$$N(B) = m_B - K \cdot \mathbf{f}(m_B) + (I - K \cdot \mathbf{f}(B)) \cdot (B - m_B),$$

where K is any non-singular $d \times d$ matrix, usually chosen to be an approximation of $J_{\mathbf{f}}^{-1}(m_B)$. The third version, from Hansen and Sengupta [24, 25], can be viewed as a sophisticated implementation of the Moore-Nickel operator using an iteration reminiscent of the Gauss-Seidel algorithm, combined with preconditioning. Later we report on our implementation of the first two Newton operators. In general, the Newton operator $N(B)$ does not return a box even if B is a box; so we define $\square N(B)$ to be a box that contains $N(B)$. For simplicity, we assume that $\square N(B)$ is the smallest box containing $N(B)$ with the same aspect ratio as B .

The following three properties of Newton box operators are consequences of Brouwer's Fixed Point Theorem [9, 41, 52, 59]:

1. (Inclusion Property) If $N(B) \subseteq B$ then $\mathbf{x}^* \in N(B)$.
2. (Exclusion Property) If $N(B) \cap B = \emptyset$ then $\mathbf{x}^* \notin B$.
3. (Narrowing Operator) If $\mathbf{x}^* \in B$ then $\mathbf{x}^* \in N(B)$.

Based on these properties, we can define two tests and an operator:

► **Definition 6.** *Newton tests for gradient exclusion/inclusion predicates (below we explain why we use $2B$ instead of B):*

- **Newton exclusion test:**
 $T_0^N(B) = \text{success}$ iff $N(2B) \cap B = \emptyset$. Thus $T_0^N(B) \Rightarrow C_0^{\nabla}(B)$.
- **Newton inclusion test:**
 $T_1^N(B) = \text{success}$ iff $N(2B) \subseteq 2B$. Thus $T_1^N(B) \Rightarrow C_1^{\nabla}(2B)$.
- **Newton narrowing operator:**
 $N_{\cap}(B)$ returns $B \cap N(2B)$.

Note that the Newton tests $T_0^N(B)$ and $T_1^N(B)$ are defined using the exact Newton operator $N(B)$. If we replace it by a soft version $\Box N(B)$ in these definitions, they remain as inclusion/exclusion tests for $C_1^\nabla(B)$ and $C_0^\nabla(B)$; we denote them by $\Box C_1^\nabla(B)$ and $\Box C_0^\nabla(B)$.

To compute $\Box N(B)$, we use standard interval arithmetic to evaluate the Newton operators. We already noted that if $N(B) \subseteq B$, then $\mathbf{x}^* \in N(B)$. But if \mathbf{x}^* is on the boundary of B , then $\Box N(B) \subseteq B$ might not hold, and this issue persists even after splitting B . We circumvent this problem by using $2B$ instead of B in the definition of $T_1^N(B)$.

We enhance Algorithm 1 by the soft inclusion predicate $\Box T_1^N(B)$, as sketched in Algorithm 2. If $\Box T_1^N(B)$ succeeds, we conclude that \mathbf{x}^* is contained in $\Box N(2B)$. In that case, we can discard all other boxes and initialize a new queue Q on $\Box N(2B)$. In subsequent calls to $\Box T_1^N(B')$ for $B' \in Q$, we conclude that $\mathbf{x}^* \in 2B'$. But to ensure that $w(2B') < w(B)$ (to avoid an infinite loop), we initialize the queue Q with the 4^d boxes of $\text{SPLIT}_2(\Box N(2B))$.

■ **Algorithm 2** Enhanced subdivision for the approximate Fermat point (*ESUB*).

As in Algorithm 1 but replace line 5 with the following:

5.1	if $\Box T_1^N(B)$ then	
5.2	$Q \leftarrow \text{QUEUE}();$	// initialize a new queue
5.3	$Q.\text{PUSH}(\text{SPLIT}_2(\Box N(2B)));$	// 2 SPLIT operations
5.4	else	
5.5	$Q.\text{PUSH}(\text{SPLIT}_1(B));$	

With respect to the runtime of Algorithm 2, we observe that once the soft Newton inclusion predicate succeeds, then it will also do so for an initial box of the new queue. This, essentially, divides the algorithm into two phases. The first phase can be basically seen as Algorithm 1. In the second phase, the Newton test guarantees quadratic convergence in ε . Getting into the second phase depends on the configuration of the foci set but not on ε , hence, our approach is of particular interest for small values of ε .

The termination of both subdivision algorithms follows from the soft gradient exclusion predicate being convergent. The algorithms terminate once the predicate $C^\varepsilon(Q)$ succeeds, yielding an ε -approximate Fermat point, so we summarize as follows.

► **Theorem 7.** *Both Algorithms 1 and 2 terminate and return an ε -approximate Fermat point.*

3.3 Certifying the Weiszfeld method

Weiszfeld's iterative method [32, 43, 58] describes a sequence \mathbf{p}_i ($i = 0, 1, \dots$) of points that converges to the Fermat point \mathbf{x}^* , starting from any initial \mathbf{p}_0 . The recurrence relation is $\mathbf{p}_{i+1} = T(\mathbf{p}_i)$, where $T(\mathbf{x})$ is defined by

$$T(\mathbf{x}) = \frac{\sum_{\mathbf{a} \in A, \mathbf{a} \neq \mathbf{x}} w(\mathbf{a}) \frac{\mathbf{a}}{\|\mathbf{x} - \mathbf{a}\|}}{\sum_{\mathbf{a} \in A, \mathbf{a} \neq \mathbf{x}} w(\mathbf{a}) \frac{1}{\|\mathbf{x} - \mathbf{a}\|}}.$$

Note that when \mathbf{x} is a focus, then $T(\mathbf{x})$ depends just on all other foci.

This simple iterative method is widely used, and although it converges, it does not solve our ε -approximation problem as we do not know when to stop. To see that this is a real issue, consider the example in Figure 5.

We augment the Weiszfeld iteration by adding Newton tests during the computation, turning it into an ε -approximation algorithm. While at the i -th iteration, we define a small box B with point \mathbf{p}_i as center, and map it to the box $\Box N(B)$ using the Newton operator; see Figure 6. If $\Box N(B) \subseteq B$, then the Fermat point \mathbf{x}^* lies in $\Box N(B)$. On the contrary, if $\Box N(B) \not\subseteq B$ we move on to the next point \mathbf{p}_{i+1} and adjust the box size as follows.

■ **Figure 5** An example with 500 foci, showing that Weiszfeld's scheme does not solve the ε -approximation problem. The scheme stopped when $\|p_{i-1} - p_i\| \leq 1/10$, after 207 steps (blue points). The distance $\|x^* - p_{207}\|$ can be arbitrarily big ($\|x^* - p_{207}\| > 15$ in this case).

If $\frac{B}{10} \cap \square N(\frac{B}{10}) = \emptyset$, then the box $\frac{B}{10}$ does not contain x^* and we therefore expand B by a factor of 10. If $\frac{B}{10} \cap \square N(\frac{B}{10}) \neq \emptyset$, then there might be a focus in box $\frac{B}{10}$, which hinders $\square N(B) \subseteq B$ to succeed. In that case we shrink B by a factor of 10. If a focus is not in $\frac{B}{10}$, shrinking B does not effect the algorithm negatively, as B can expand again.

Using these tests we augment the point sequence scheme, sketched in Algorithm 3, with the property that if the Newton test evaluates to true, then we are guaranteed an ε -approximation of x^* . As a starting point, we choose the *center of mass* p_0 of A , i.e., $p_0 = \frac{1}{W} \sum_{a \in A} w(a) a$.

With respect to the runtime, the point sequence $T(x)$ converges linearly in ε towards x^* [29] but in order for Algorithm 3 to terminate the test $\square N(B) \subseteq B$ must succeed. Similar to other Newton operators, $\square N(B) \subseteq B$ succeeds for boxes in a neighborhood surrounding x^* . This neighborhood depends only on the configuration of A but not on ε . Further, evaluating $T(x)$ and $\square N(B)$ can be done in $O(nd^2)$ time. We conclude as follows.

► **Theorem 8.** *Algorithm 3 terminates and returns an ε -approximate Fermat point.*

■ **Algorithm 3** Certified Weiszfeld for the approximate Fermat point (CW).

Input: Foci set A , constant $\varepsilon > 0$	Output: Point \tilde{x}^*
1 $p \leftarrow p_0$; $l \leftarrow \varepsilon$;	
2 while $TRUE$ do	
3 $B \leftarrow \text{Box } B(m_B = p, \omega(B) = l)$;	
4 if $\square N(B) \subseteq B$ then	// Figure 6(a)
5 return $\tilde{x}^* \leftarrow p$;	
6 else if $\square N(\frac{B}{10}) \cap \frac{B}{10} = \emptyset$ then	// Figure 6(b)
7 $l \leftarrow \min\{10 \cdot l, \varepsilon\}$;	
8 else	// Figure 6(c)
9 $l \leftarrow \frac{1}{10} \cdot l$;	
10 $p \leftarrow T(p)$;

4 Approximating n -ellipses

In this section, we describe an algorithm to construct approximate n -ellipses, based on the subdivision paradigm. Throughout this work we maintain the subdivision *smooth*, i.e., the width of any two adjacent boxes, which are leaves of the quadtree, may differ at most by a factor of 2. Maintaining smoothness is easy to implement and has amortized $O(1)$ cost per operation [6]. Without maintaining smoothness, the amortized cost can be $\Omega(\log n)$ [6].

The Plantinga and Vegter (PV) construction [47, 33, 34] approximates the zero set of a function $F : \mathbb{R}^d \rightarrow \mathbb{R}$ where $d \in \{2, 3\}$. Assuming that $S = F^{-1}(0)$ is regular, i.e., the gradient ∇F is non-zero at every point of S , this approximation is isotopic to S . Our goal is to use this construction to approximate the n -ellipse defined by $F(p) := \varphi(p) - r$ with $r > r^*$. For simplicity, we assume all boxes are square; for the construction to succeed, we only need an aspect ratio $\leq \sqrt{2}$ (see [33]). We use the notation $\langle \cdot, \cdot \rangle$ for the scalar product. The following are the key predicates and tests in the PV construction of the n -ellipse $F^{-1}(0)$.

► **Definition 9.** Fix $F(p) = \varphi(p) - r$. Let B be a square box.

1. The fundamental box predicate is the inclusion predicate $C_1^F(B) : 0 \in F(B)$, and its complement, the exclusion predicate $C_0^F(B) : 0 \notin F(B)$.
2. The (corner) inclusion test $T_{\text{cor}}(B) = \text{success}$ iff F , when evaluated at the corners of B , admits both negative and positive values. Clearly, $T_{\text{cor}}(B)$ is a test for $C_1^F(B)$. (There is a standard PV trick whereby any 0-value can be arbitrarily made positive.)
3. The normal variation predicate $C_{\text{nv}}(B)$ is defined by the condition $\langle \nabla F(B), \nabla F(B) \rangle > 0$.

We obtain the soft versions $\Box C_0^F(B)$ and $\Box C_{\text{nv}}(B)$ by the usual device of replacing $F(B)$ in the definition of the predicates by a soft version $\Box F(B)$. But for the inclusion predicate $C_1^F(B)$ we have no soft version. Instead, the corner test $T_{\text{cor}}(B)$ is a test for $C_1^F(B)$. To supplement the corner test, we need the normal variation predicate $C_{\text{nv}}(B)$. This predicate is equivalent to the condition that the angle between the gradient of any two points in B is at most 90° . It implies that the n -ellipse is monotone in either x - or y -direction within the box. In Figure 7, boxes are: **red** if they pass the $\Box C_0^F(B)$ test, **green** if they pass both $\Box C_{\text{nv}}$ and T_{cor} , **orange** if they pass only $\Box C_{\text{nv}}$, and **gray** otherwise. Note that orange boxes may, or may not, contain parts of the approximate n -ellipse.

An n -ellipse is not regular if it passes through some focus [51]; in that case a direct PV construction is not possible. We develop a variation, sketched in Algorithm 4, where we simultaneously subdivide boxes and construct pieces of the n -ellipse *on the fly*, instead of doing that in the end. Further, boxes in which the n -ellipse may not be regular are treated differently. During the subdivision part of the algorithm, we classify boxes in three categories:

1. Boxes which satisfy $\Box C_0^F(B)$ (**red**): These do not contain any piece of the n -ellipse, so they do not need to be further considered and are discarded.
2. Boxes which satisfy $\Box C_{\text{nv}}$ and have width smaller than $\varepsilon/2$ (**green** or **orange**): We immediately draw edges in each of these boxes, in contrast to the normal PV construction. Note that at a later stage of the algorithm it might happen that we split one of B 's neighboring boxes. In that case we need to take into account the sign of F at the new vertex on B 's boundary. If necessary, the edges in box B then need to be updated.
3. The remaining boxes (**gray**): Such boxes occur near foci and need more careful attention, as we cannot apply the standard PV construction. Instead, given a set of gray boxes we first distinguish them in connected components, using a DFS algorithm. Then, for each connected component of gray boxes K_i , we check if a set of conditions is satisfied:

■ **Figure 7** (a) A 3-ellipse passing through two foci. Components of gray boxes (temporarily) surround the foci. (b) If a gray component satisfies (B1) - (B3) the two ingoing edges are connected with an edge (shown dashed).

(B1) K_i contains exactly one focus.

(B2) There are exactly two PV-edges leading to K_i .

(B3) The distance between any two corners of the boxes in K_i is at most $\varepsilon/2$.

If K_i satisfies all (B1) - (B3), then we connect the 2 PV-edges leading to K_i by a line segment and discard boxes of K_i , see Figure 7(b). Otherwise, the children of the boxes of K_i are put back in Q for further classification.

■ **Algorithm 4** Approximating an n -ellipse.

Input: Foci set A , radius r , constant ε , box B_0	Output: Curve E
--	--------------------------

```

1  $Q \leftarrow \text{QUEUE}(); \quad Q.\text{PUSH}(B_0);$ 
2 while  $Q \neq \emptyset$  do
3    $Q_{\text{new}} \leftarrow \text{QUEUE}();$ 
4   while  $Q \neq \emptyset$  do
5      $B \leftarrow Q.\text{POP}();$ 
6     if not  $\square C_0^F(B)$  then                                     // exclude red
7       if  $\square C_{\text{nw}}(B)$  and  $\omega(B) < \varepsilon/2$  then                 // green or orange
8          $E \cap B \leftarrow \text{ONLINE-PV}(B);$ 
9       else                                                         // gray
10         $Q_{\text{new}}.\text{PUSH}(\text{SPLIT}_4(B));$ 
11    $Q \leftarrow \text{CONNECTED-COMPONENTS-ANALYSIS}(Q_{\text{new}})$ 
12 return  $E;$ 
```

By controlling the size of the boxes containing parts of the output curve, and by the modification the PV construction we prove the following.

► **Theorem 10.** *Algorithm 4 returns an isotopic ε -approximation of the n -ellipse $F^{-1}(0)$.*

Interpolating edges. The PV construction creates edges within a box B , which start and end at midpoints of box edges. One can derive a nicer-looking approximation by using linear interpolation on the box edges by taking into account the value of F at B 's corners.

Contour Plotting. As an application, we can use the above technique in order to produce a topologically correct, ε -approximate and visually nice n -elliptic contour plot. To do so, we first adapt our algorithm in order to simultaneously plot several n -ellipses inside a bounding

Figure 8 Two different 3-elliptic contour plots with 10 contour lines, having the same set of foci. (a) Using radii of *equidistant points*. (b) Using *equidistant radii*.

box, corresponding to the same foci but with different radii. Each n -ellipse is a *contour line*, and we describe how to plot them *visually nice*, i.e., the contour lines are roughly equally distributed in space. See Figure 8 for two different approaches and their visualization effect.

5 Experiments

We implemented our algorithms for \mathbb{R}^2 and conducted a series of experiments. Our current software is written in MATLAB (version R2018b), taking advantage of its graphics ability. The numerical accuracy is therefore IEEE numerical precision. The platform used was MacOS Big Sur v11.2.3, with 2.5 GHz Quad-Core Intel Core i7 and 16 GB 1600MHz DDR3.

Following, we report on our experiments, discussing some notable points one by one. We evaluated our algorithms on both synthetic and real-world datasets. For all algorithms approximating the Fermat point we chose a time limit of 600 seconds. Moreover, for most experiments we executed 10 different instances for completeness. In the illustrated charts, the curves pass through the mean of the 10 running times, and additionally we also marked the minimum and maximum running times. All axes in the charts are of logarithmic scale.

Datasets. We mainly experimented with two different types of synthetic datasets, namely UNIF-1 and UNIF-2. In UNIF-1 the n foci are sampled uniformly from a disk of radius 1. In UNIF-2 again the n foci are sampled uniformly from a disk of radius 1 and then $n/2$ foci are translated by a vector $(10, 10)$, see Figure 9(a) and Figure 9(b). Despite their similarity, the two datasets present strong differences. As we later see, UNIF-2 is significantly more difficult to solve in comparison to UNIF-1, and further UNIF-1 resembles nicely real-world datasets. The foci of UNIF-2 lie almost all on a common line, which implies that there are many points for which the gradient is close to 0. This makes it difficult to find the actual Fermat point, for which the gradient is exactly 0. We experimented with more types of synthetic datasets, such as points in convex position, vertices of a regular n -gon, clusters of points, but we do not report on these results, as they are similar to UNIF-1 or UNIF-2.

Newton operators. Adding a Newton operator to the subdivision process drastically improves the running time. We compared Algorithm 1 with two versions of Algorithm 2, where we once use the Newton operator based on Moore and Nickel and also the operator by Krawczyk. The results for various values of n and ε on both UNIF-1 and UNIF-2 are summarized in Figure 10. Note that Algorithm 2 initially needs to perform simple splitting operations until at some point the Newton test succeeds the first time. After that the algorithm converges quadratically in ε , which explains why the running time of both versions almost do not increase for decreasing ε . Even though the operator by Krawczyk returns a

■ **Figure 9** A box subdivision for $n = 200$ foci: (a) UNIF-1, (b) UNIF-2 and (c) UNIF-2 after PCA.

smaller box $\square N(B)$, i.e. it is more precise, than Moore and Nickel, it performs slower for UNIF-1 as evaluating the operator takes more time. We conclude that using a Newton operator speeds up the computations, and we use the one of by Moore and Nickel in Algorithm 2.

Principal component analysis. Foci sets like UNIF-2 are challenging as all foci are close to a common line. In this case, the subdivision algorithms can be slow because there are many boxes for which the gradient $\nabla\varphi$ is close to 0. Our approach to tackle this problem is to use subdivision with rectangular boxes. In a preprocessing step we do a *principal component analysis* (PCA) of the foci as heuristic. Then, we rotate the coordinate system such that the x -direction is the first principal component. In the box subdivision we use rectangular boxes with long x -width, see Figure 9(c). Observe in the following table, that for well distributed foci sets like UNIF-1, using the PCA adds only a small overhead to the total running time.

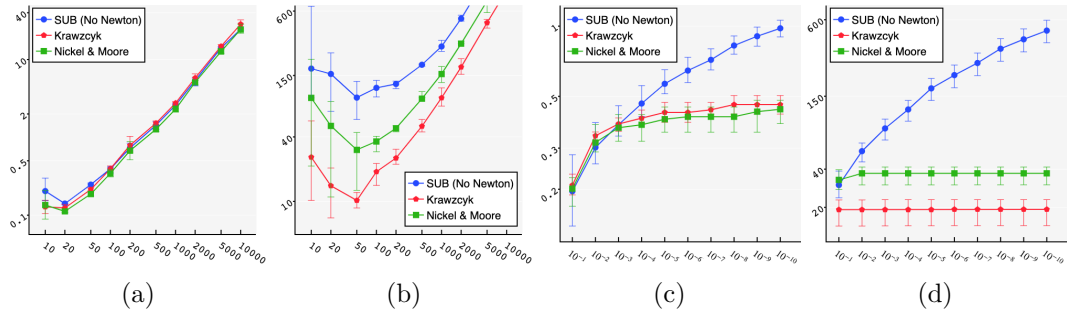

$\varepsilon = 10^{-3}, n =$	10	100	1000	10000
without PCA	0.12	0.31	2.33	23.4
with PCA	0.10	0.30	2.30	23.9

$n = 100, \varepsilon =$	10^{-1}	10^{-3}	10^{-5}	10^{-7}
without PCA	0.20	0.30	0.33	0.34
with PCA	0.18	0.30	0.33	0.35

On the contrary, for sets like UNIF-2, adding the PCA decreases drastically the running time, as shown next. Hence, the PCA preprocessing is a useful addition to Algorithm 2, which we will use also in the following experiments.

$\varepsilon = 10^{-3}, n =$	10	100	1000	10000
without PCA	90.7	48.5	170	timeout
with PCA	0.15	0.40	3.21	32.7

$n = 100, \varepsilon =$	10^{-1}	10^{-3}	10^{-5}	10^{-7}
without PCA	37.1	49.2	49.2	49.5
with PCA	0.36	0.40	0.42	0.43

■ **Figure 10** A comparison of Algorithm 1 (• SUB), Algorithm 2 with the Krawczyk Newton operator (• Krawczyk), and Algorithm 2 with the Nickel and Moore Newton operator (■ Nickel & Moore). (a),(b) Time as a function of n , with $\varepsilon = 10^{-4}$. (c),(d) Time as a function of ε with $n = 100$. (a),(c) UNIF-1 datasets. (b),(d) UNIF-2 datasets.

Real Datasets. Inspired by the applications in facility location we chose to experiment with instances of the well-known *Traveling Salesman Problem Library* [49] or TSPLIB. The foci correspond mostly to location of cities in different areas around the world. It appears that real-world instances show a similar behavior to UNIF-1 datasets; so we infer that UNIF-1 are realistic datasets for the evaluation of different algorithms. In our experiments, to verify that for each TSPLIB dataset we created an additional foci set, where we uniformly sampled the same number of foci in the axis-aligned bounding box. As ε we chose 10^{-6} times the width of the corresponding bounding box. These experiments are illustrated in Figure 12(a), and the similarity of the running time for the two datasets is obvious.

Summary on the Fermat point. We make an overall comparison of Algorithm 1, Algorithm 2 with the PCA, and Algorithm 3, illustrated in Figure 11. The running time of all methods shows a linear dependency on n , but there are big differences regarding the dependency on ε . Overall, Algorithm 3 performs well in all cases, but due to the linear convergence of Weiszfeld's point sequence, it cannot converge faster as ε decreases. In contrast, Algorithm 2 takes more time in the subdivision phase, but once the Newton tests succeeds, the algorithm terminates very quickly. So, it does not exhibit almost any changes in the running time for decreasing ε . This makes it favorable when a high precision approximate solution is required. It is also very fast in UNIF-2 instances and outperforms Algorithm 3. Summarizing, we suggest to use Algorithm 2 in small dimensional spaces and for small ε due to its eventual quadratic convergence in ε . On the other hand, the subdivision methods take exponential time in d , therefore, we suggest to use Algorithm 3 for higher dimensional spaces.

n -ellipses. Finally, we evaluated the runtime of n -ellipses algorithm. In Figure 12(b) we evaluate the dependency on n . In order to keep the length of the curve almost constant we choose the radii $r = \frac{(10\sqrt{2}+2)n}{2}$. The bounding box used is $[-2, 12]^2$. In Figure 12(c) we analyze the dependency on the length of the n -ellipse. The bounding box is fixed and we experimented with different radii such that the lengths of the curve differ by a factor of $3/2$. The runtime shows a linear dependency on n , as expected, and it also shows a linear dependency on the length of curve. This can be justified, as covering an n -ellipse of length l with boxes of width ε takes $O(l/\varepsilon)$ many boxes.

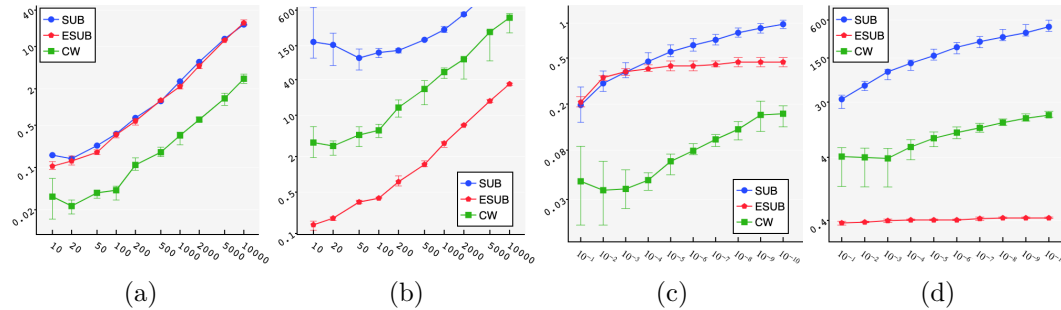

Figure 11 An overall comparison of Algorithm 1 (● SUB), Algorithm 2 with the PCA (◆ ESUB), and Algorithm 3 (■ CW). (a),(b) Time as a function of n , with $\varepsilon = 10^{-4}$. (c),(d) Time as a function of ε with $n = 100$. (a),(c) UNIF-1 datasets. (b),(d) UNIF-2 datasets.

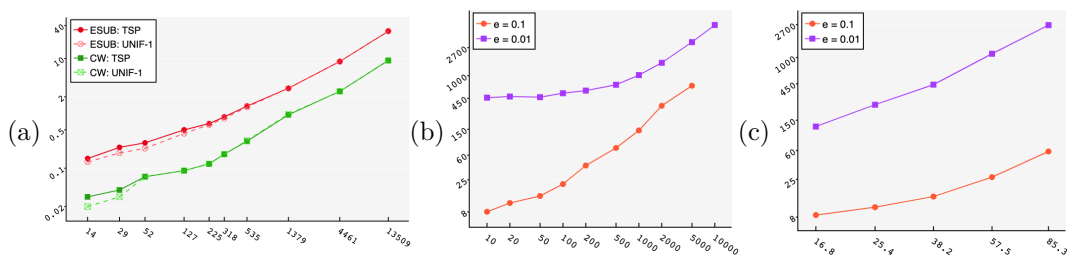

Figure 12 (a) A comparison of TSP data sets (filled shapes) with UNIF-1 (empty shapes, dashed curve) for both Algorithm 2 (● ESUB) and Algorithm 3 (■ CW). Fermat point with time as a function of n . (b),(c) n -ellipse on UNIF-2 with time as a function of (b) n and (c) the length of the n -ellipse. Two ε approximations with $\varepsilon = 0.1$ (●) and $\varepsilon = 0.01$ (■) have been computed.

6 Concluding Remarks

In this work, we mainly focused on finding ε -approximate Fermat points, in a strong sense $\|\tilde{\mathbf{x}}^* - \mathbf{x}^*\| \leq \varepsilon$, which had not been considered before. This approximation can also be used to derive an ε -approximation of the Fermat radius. This was done using a simple-to-implement subdivision approach. All of our algorithms are certified in the sense of interval arithmetic. Moreover, we certified the famous point-sequence algorithm of Weiszfeld [58] to guarantee that it does find an ε -approximate Fermat point. We also designed an algorithm to construct ε -approximate n -ellipses. The simplicity and efficiency of our algorithms were evaluated experimentally for $d = 2$.

There are many directions for further research. One is to derive algorithmic complexity bounds. Our intuition regarding the time complexity of our algorithms was affirmed by the experimental runtime evaluation. Such bounds are rare for iterative numerical algorithms. There has been considerable success in the area of root isolation [10, 11] where the idea of “continuous amortization” should also apply here. Further, we expect the usage of the Hansen-Sengupta Newton operator to result in a speedup.

Regarding the construction of n -ellipses, it would be interesting to design an alternative algorithm based on curve-tracing. This could improve the runtime once a starting point on the n -ellipse is found.

Another direction is related to *Voronoi diagrams*. From one perspective, it is interesting to approximate the Voronoi diagram, where the sites are n -ellipses; so far only 2-ellipses have been studied [19]. From a different perspective, if the sites are sets of foci (each associated with a Fermat distance function) it is interesting to compute their Voronoi diagram, defined as the minimization diagram of the Fermat distance functions. This is a *min-sum* diagram in the context of cluster Voronoi diagrams, see e.g., [28, 44]. We believe that subdivision methods augmented with root boxes, similar to [5], would be applicable to these problems.

Abstract

The world is rarely static – many problems need not only be solved once but repeatedly, under changing conditions. This setting is addressed by the *multistage* view on computational problems. We study the *diverse multistage* variant, where consecutive solutions of large variety are preferable to similar ones, e.g. for reasons of fairness or wear minimization. While some aspects of this model have been tackled before, we introduce a framework allowing us to prove that a number of diverse multistage problems are fixed-parameter tractable by diversity, namely PERFECT MATCHING, s - t PATH, MATROID INDEPENDENT SET, and PLURALITY VOTING. This is achieved by first solving special, colored variants of these problems, which might also be of independent interest.

1 Introduction

In the *multistage* setting, given a sequence of instances of some problem, one asks whether there is a corresponding sequence of solutions such that consecutive solutions relate in some way to each other. Often the aim is to find consecutive solutions that are very *similar* [25, 18, 20, 7, 6, 19]. This is reasonable when changing between distinct solutions incurs some form of cost. In other settings, the opposite goal is more reasonable, that is, consecutive solutions should be very *different*. This is a natural goal when wear minimization, load distribution, or resilience against failures or attacks are of interest. This *diverse multistage* setting is what we want to focus on in this paper. Here, given a sequence of instances of some decision problem, the task is to find a sequence of solutions such that the *diversity*, i.e., the size of the symmetric difference of any two consecutive solutions is *at least* ℓ .

This problem has already received some attention in the literature: Fluschnik et al. [21] studied the problem of finding diverse s - t paths and Bredebeck et al. [11] considered series of committee elections. In a similar setting, but aiming for large symmetric difference between every two (i.e., not just consecutive) solutions, Baste et al. [8] provide a framework for parameterization by treewidth, while the case that all instances are the same is studied for matchings, independent sets of matroids [22, 23], and for Kemeny rank aggregation [3].

We briefly give a formal definition. Assume Π to be some decision problem which asks whether the *family of solutions* $\mathcal{R}(I) \subseteq 2^{\mathcal{B}(I)}$ of an instance I of Π is non-empty, where $\mathcal{B}(I)$ is some *base set* encompassing all possible solutions. For example, for an instance I of VERTEX COVER, the set $\mathcal{B}(I)$ is the set of all vertices and $\mathcal{R}(I)$ is the set of all vertex covers within the size bound. The problem DIVERSE MULTISTAGE Π is now the following.

DIVERSE MULTISTAGE Π

Input: A sequence $(I_i)_{i=1}^\tau$ of instances of Π and an integer $\ell \in \mathbb{N}_0$.

Question: Is there a sequence $(S_i)_{i=1}^\tau$ of solutions $S_i \in \mathcal{R}(I_i)$ such that $|S_i \Delta S_{i+1}| \geq \ell$ for all $i \in [\tau - 1]$?

Our contributions. We present a general framework which allows us to prove fixed-parameter tractability of DIVERSE MULTISTAGE Π parameterized by the diversity ℓ for several problems Π . This includes finding diverse matchings, but also diverse committees (answering an open question by Bredebeck et al. [11]), diverse s - t paths, and diverse independent sets in matroids such as spanning forests. Finally, we show that similar results cannot be expected for finding diverse vertex covers.

Generally, our framework can be applied to DIVERSE MULTISTAGE Π whenever one can solve a 4-colored variant of Π efficiently. Formally, this variant is defined as follows.

4-COLORED EXACT Π

Input: An instance I of Π , a coloring $c: \mathcal{B}(I) \rightarrow [4]$, and $n_i \in \mathbb{N}_0, i \in [4]$.

Output: A solution $S \in \mathcal{R}(I)$ such that $|\{x \in S \mid c(x) = i\}| = n_i$ for all $i \in [4]$ or “no” if no such solution exists.

Our main result reads as follows.

► **Theorem 1.** *For any parameter r of Π , if an instance I of 4-COLORED EXACT Π can be solved in $f(r) \cdot |I|^{O(1)}$ time, then an instance J of DIVERSE MULTISTAGE Π can be solved in $2^{O(\ell)} \cdot f(r_{\max}) \cdot |J|^{O(1)}$ time, where r_{\max} is the maximum of parameter r over all instances of Π in J .¹*

We prove Theorem 1 in Section 3 in a more general form which also allows solving 4-COLORED EXACT Π by a Monte Carlo algorithm. We then apply our framework to the following problems:

Committee Election (Section 4). In DIVERSE MULTISTAGE PLURALITY VOTING, we are given a set A of agents, a set C of candidates, and τ many *voting profiles* $u_i: A \rightarrow C$. The goal is to find a sequence $(C_i)_{i=1}^\tau$ of committees $C_i \subseteq C$ such that each committee C_i is of size at most k and gets at least x votes in the voting profile u_i (i.e., $|u_i^{-1}(C_i)| \geq x$), and $|C_i \Delta C_{i+1}| \geq \ell$ for all $i \in [\tau - 1]$. We show that there is a $2^{O(\ell)} \cdot |J|^{O(1)}$ -time algorithm to solve a DIVERSE MULTISTAGE PLURALITY VOTING instance J . This answers an open question of Bredebeck et al. [11]. In the full version we generalize the algorithm used to solve 4-COLORED EXACT PLURALITY VOTING to matroids.

¹ For example, if the input is a sequence of graphs and r is the treewidth, then r_{\max} is the maximum treewidth over all graphs in the input.

Perfect Matching (Section 5). In the multistage setting, Perfect Matching is among the problems most intensively studied [25, 5, 4, 13, 34]. Given a sequence of graphs $(G_i)_{i=1}^\tau$ and an integer ℓ , DIVERSE MULTISTAGE PERFECT MATCHING asks whether there is a sequence $(M_i)_{i=1}^\tau$ such that each M_i is a perfect matching in G_i , and $|M_i \Delta M_{i+1}| \geq \ell$ for all $i \in [\tau - 1]$. We show that there is a randomized $2^{O(\ell)} \cdot |J|^{O(1)}$ -time algorithm to solve a DIVERSE MULTISTAGE PERFECT MATCHING instance J with constant error probability. This stands in remarkable contrast to the $W[1]$ -hardness of the (non-diverse) MULTISTAGE PERFECT MATCHING, when parameterized by $\ell + \tau$ [34]. To apply our framework, we establish an algebraic algorithm using the Pfaffian of a specific variant of the Tutte matrix to solve s -COLORED EXACT PERFECT MATCHING on an n -vertex graph in $n^{O(s)}$ time with low error probability.

s-t Path (Section 6). Studying s - t PATH in the multistage setting was already suggested in the seminal work of Gupta et al. [25]. In DIVERSE MULTISTAGE s - t PATH one is given a sequence of graphs $(G_i)_{i=1}^\tau$, two distinct vertices s and t , and an integer ℓ , and asks whether there is a sequence $(P_i)_{i=1}^\tau$ such that each P_i is an s - t PATH in G_i , and $|V(P_i) \Delta V(P_{i+1})| \geq \ell$ for all $i \in [\tau - 1]$. Fluschnik et al. [21] provided a comprehensive study of finding s - t paths of bounded length in the multistage setting from the viewpoint of parameterized complexity. Among other results, they showed that DIVERSE MULTISTAGE s - t PATH is NP-hard but fixed-parameter tractable when parameterized by the maximum length of an s - t PATH in the solution. We show that DIVERSE MULTISTAGE s - t PATH parameterized by ℓ is fixed-parameter tractable. At first glance, using our framework seems unpromising since 4-COLORED EXACT s - t PATH can presumably not be solved in polynomial time (it is NP-hard by a straight-forward reduction from HAMILTONIAN PATH). However, we develop a win/win strategy around a generalization of the Erdős-Pósa theorem for long cycles due to Mousset et al. [30] so that we have to solve 4-COLORED EXACT s - t PATH only on graphs on which the treewidth is upper-bounded in the parameter ℓ .

In Section 7, we complement our fixed-parameter tractability results with a $W[1]$ -hardness for DIVERSE MULTISTAGE VERTEX COVER when parameterized by ℓ .

2 Preliminaries

We denote by \mathbb{N} and \mathbb{N}_0 the natural numbers excluding and including zero, respectively. For $n \in \mathbb{N}$, let $[n] := \{1, 2, \dots, n\}$. For two sets A and B , we denote by $A \Delta B := (A \setminus B) \cup (B \setminus A) = (A \cup B) \setminus (A \cap B)$ the *symmetric difference* of A and B , and by $A \uplus B$ the disjoint union of A and B . For a function $c: A \rightarrow B$, let $c(A') := \bigcup_{a \in A'} c(a)$ and $c^{-1}(b) := \{a \in A \mid c(a) = b\}$, where $A' \subseteq A$. We also use the notations c^b and $c^{b, b'}$ as shorthands for $c^{-1}(b)$ and $c^{-1}(b) \cup c^{-1}(b')$, respectively.

A *Monte Carlo algorithm*, or an algorithm with error probability p , is a randomized algorithm that returns a correct answer with probability $1 - p$.

Let Σ be a finite alphabet. A *parameterized problem* L is a subset $L \subseteq \{(x, k) \in \Sigma^* \times \mathbb{N}_0\}$. An instance $(x, k) \in \Sigma^* \times \mathbb{N}_0$ is a *yes-instance* of L if and only if $(x, k) \in L$ (otherwise, it is a *no-instance*). A parameterized problem L is *fixed-parameter tractable* (in FPT) if for every input (x, k) one can decide in $f(k) \cdot |x|^{O(1)}$ time whether $(x, k) \in L$, where f is some computable function only depending on k . If $W[1]$ -hard parameterized problem is not fixed-parameter tractable unless $FPT = W[1]$. We refer to Downey and Fellows [17] and Cygan et al. [14] for more material on parameterized complexity. We use standard notation from graph theory [16]. Throughout this paper, we assume graphs to be simple and undirected.

3 The General Framework

In this section, we introduce a general framework to show (for some decision problem Π) fixed-parameter tractability of DIVERSE MULTISTAGE Π parameterized by ℓ . Recall that, for every instance I of a decision problem Π , we denote by $\mathcal{B}(I)$ the base set encompassing all possible solutions, by $\mathcal{R}(I) \subseteq 2^{\mathcal{B}(I)}$ the family of solutions, and by $|I|$ the input size of I , which is at least $|\mathcal{B}(I)|$. For the remainder of this section we assume that $|\mathcal{B}(I)| \geq 2$ for all instances I of Π . The framework is applicable to DIVERSE MULTISTAGE Π if there is an efficient algorithm for 4-COLORED EXACT Π . Formally, we use the following prerequisite, which is slightly more general than in Theorem 1.

► **Assumption 2.** There are computable functions f, g such that for every $0 \leq p \leq 1$ for which $g(p)$ is defined, there is a Monte-Carlo algorithm \mathcal{A} with error probability p and running time $f(r) \cdot |I|^{O(1)} \cdot g(p)$ that solves an instance I of 4-COLORED EXACT Π , where $r \in \mathbb{N}_0$ is some parameter of I and g is monotone non-increasing.

We allow an error probability in Assumption 2 because for one of our applications (in Section 5), no other polynomial-time algorithm is known. The goal is to prove the following.

► **Theorem 3.** *Let Assumption 2 be true. Then any size- n instance I of DIVERSE MULTISTAGE Π can be solved in $2^{O(\ell)} \cdot f(r_{\max}) \cdot n^{O(1)} \cdot g(p/\tau 2^{O(\ell)} n^{O(1)})$ time by a Monte-Carlo algorithm with error probability p , where r_{\max} is the maximum of parameter r over all instances of Π in I , and $0 \leq p \leq 1$ is an arbitrary probability for which the above expression is defined.²*

Note that, if we have a non-randomized algorithm in Assumption 2 (that is, $g(0)$ is defined and g maps always to one), then Theorem 1 follows directly from Theorem 3.

The underlying strategy of the algorithm for a DIVERSE MULTISTAGE Π -instance J behind Theorem 3 is to compute for each instance I of Π in J a solution family such that the Cartesian product of these families contains a solution for J if and only if J is a *yes*-instance. Once these families are obtained, we can check whether J is a *yes*-instance by dynamic programming. To this end, we compute a small subset of $\mathcal{R}(I)$ satisfying the following definition.

► **Definition 4.** *Let \mathcal{F} be a set family. A subfamily $\hat{\mathcal{F}} \subseteq \mathcal{F}$ is called an ℓ -diverse representative of \mathcal{F} if the following holds: for any pair of sets A, B , if there is an $S \in \mathcal{F}$ with $\min\{|A \Delta S|, |B \Delta S|\} \geq \ell$, then there is an $\hat{S} \in \hat{\mathcal{F}}$ such that $\min\{|A \Delta \hat{S}|, |B \Delta \hat{S}|\} \geq \ell$.*

First of all, we note that ℓ -diverse representatives can be rather small.

► **Lemma 5.** *Let \mathcal{F} be a set family and $S_1, S_2, S_3 \in \mathcal{F}$. If $|S_i \Delta S_j| \geq 2\ell$ for all distinct $i, j \in [3]$, then $\{S_1, S_2, S_3\}$ is an ℓ -diverse representative of \mathcal{F} .*

Proof. Assume for contradiction that there exist sets A and B with $\min\{|A \Delta S_i|, |B \Delta S_i|\} < \ell$ for all i . Without loss of generality, assume that $|A \Delta S_1| < \ell$. Then for $j \in \{2, 3\}$ we have $|A \Delta S_j| \geq |S_1 \Delta S_j| - |S_1 \Delta A| > 2\ell - \ell = \ell$ by the triangle inequality. Therefore, $|B \Delta S_j| < \ell$ for all $j \in \{2, 3\}$. In particular, $|B \Delta S_2| < \ell$. Again, by the triangle inequality $|B \Delta S_3| \geq |S_2 \Delta S_3| - |S_2 \Delta B| > 2\ell - \ell = \ell$, i.e., $\min\{|A \Delta S_3|, |B \Delta S_3|\} \geq \ell$ – a contradiction. ◀

² For example, if we only have an algorithm with non-zero error probability, then $p = 0$ is excluded.

In the following, we measure the distance of two solutions by the size of the symmetric difference. In a nutshell, we compute an ℓ -diverse representative of the family of solutions by first trying to compute three solutions which are far apart from each other (that is, size of symmetric difference at least 2ℓ). If this succeeds, then by Lemma 5 we are done. Otherwise, we distinguish between three cases.

No solution. If there is no solution at all, then trivially \emptyset is an ℓ -diverse representative of the family of solutions.

One solution. If we only find one solution S_1 to the instance of Π , then each other solution is close to S_1 . Hence, for any two sets A, B , if one of them is far away from S_1 , then by the triangle inequality it is also far away from every other solution and can be safely ignored. For those sets which are close to S_1 , we can exploit the upper bound on the symmetric difference by using color-coding [2] and then applying Assumption 2 to compute an ℓ -diverse representative of the family of solutions. This case is handled in Lemma 9.

Two solutions. If we find two diverse solutions S_1 and S_2 such that no other solution is far away from both, then S_1 and S_2 partition the solution space into two parts: the solutions close to S_1 and those close to S_2 . Again, given two sets A, B , if either of them is far away from S_1 and S_2 , then we may ignore it. By including S_1 and S_2 in our family, we may further assume that A is similar to S_1 and B is similar to S_2 . We distinguish two subcases. If the distance between S_1 and S_2 is very large, then A is far away from all solutions in the second part and B is far away from all solutions in the first part. We can thus ignore one of them (say B) and exploit the fact that A, S_1 , and all solutions of interest are close to each other to use color-coding and then apply Assumption 2. In the other subcase where the distance between S_1 and S_2 is bounded, we can utilize that fact similarly. This case is handled in Lemma 10.

Hereafter, the details. Before we dive into the case distinction outlined above, we need to prove two technical lemmata, telling us how to build a diverse representative set that works for all sets obeying some given coloring of the elements of $\mathcal{B}(I)$. These will later work as building blocks in the construction of proper diverse representatives. In the first lemma, only two colors are used, and we are only concerned with one arbitrary set A instead of two.

► **Lemma 6.** *Let Assumption 2 be true. Given an instance I of Π of size n , a coloring $c: \mathcal{B}(I) \rightarrow [2]$, and a solution $M \in \mathcal{R}(I)$, one can compute in $f(r)n^{O(1)}g(pn^{-4})$ time and with error probability at most p a family $\mathcal{F} \subseteq \mathcal{R}(I)$ of size at most n^4 such that for any $S \in \mathcal{R}(I)$ and any $A \subseteq \mathcal{B}(I)$ with $S \setminus A \subseteq c^1$ and $A \setminus S \subseteq c^2$, there is $\hat{S} \in \mathcal{F}$ with $|A\Delta\hat{S}| \geq |A\Delta S|$ and $|M\Delta\hat{S}| = |M\Delta S|$.*

Proof. Let $F'_1 := c^1 \cap M$, $F'_2 := c^2 \cap M$, $F'_3 := c^1 \setminus M$, and $F'_4 := c^2 \setminus M$.

Start with $\mathcal{F} = \emptyset$. Then, for each $m \in [n]$ and each number partition $\sum_{i=1}^4 m_i = m$ with $m_i \geq 0$, use algorithm \mathcal{A} to search in $f(r)n^{O(1)}g(pn^{-4})$ time and with error probability at most pn^{-4} for a set $N \in \mathcal{R}(I)$ such that $|N \cap F'_i| = m_i$ for all $i \in [4]$. If this succeeds, then we add N to \mathcal{F} . Since there are $\binom{n+4}{4} \leq n^4$ possibilities for m_1, \dots, m_4 , the probability of an error occurring is upper-bounded by p . Moreover, the size of \mathcal{F} is upper-bounded by n^4 and hence the time required is bounded by $f(r)n^{O(1)}g(pn^{-4})$.

It remains to be proven that \mathcal{F} has the desired properties. Let $S \in \mathcal{R}(I)$ be arbitrary and set $m_i := |S \cap F'_i|$ for all $i \in [4]$. By construction, \mathcal{F} contains a set $\hat{S} \in \mathcal{R}(I)$ such that $|\hat{S} \cap F'_i| = m_i$. We then have $|\hat{S}\Delta M| = m_3 + m_4 + |M| - m_1 - m_2 = |S\Delta M|$.

Let $A \subseteq \mathcal{B}(I)$ be a set with $S \setminus A \subseteq c^1$ and $A \setminus S \subseteq c^2$. Since $A \setminus S \subseteq c^2$ we have

$$|A \cap S \cap c^1| = |A \cap c^1| \geq |A \cap \hat{S} \cap c^1| \quad (1)$$

and since $S \setminus A \subseteq c^1$, we have that

$$|A \cap S \cap c^2| = |S \cap c^2| = m_2 + m_4 = |\hat{S} \cap c^2| \geq |A \cap \hat{S} \cap c^2|. \quad (2)$$

By adding (1) and (2) we obtain $|A \cap S| \geq |A \cap \hat{S}|$ which in turn implies $|A \Delta S| \leq |A \Delta \hat{S}|$ since $|S| = |\hat{S}|$. \blacktriangleleft

The next lemma extends the approach of Lemma 6 to the case where we have four colors and two arbitrary sets A, B .

► Lemma 7. *Let Assumption 2 be true. Given an instance I of Π of size n and a coloring $c: \mathcal{B}(I) \rightarrow [4]$, one can compute in $f(r)n^{O(1)}g(pn^{-4})$ time and with error probability at most p a family $\mathcal{F} \subseteq \mathcal{R}(I)$ of size at most n^4 such that for any $S \in \mathcal{R}(I)$ and all sets $A, B \subseteq \mathcal{B}(I)$ with $A \setminus (B \cup S) \subseteq c^1$, $B \setminus (A \cup S) \subseteq c^2$, $(A \cap B) \setminus S \subseteq c^3$, and $S \setminus (A \cap B) \subseteq c^4$, there is $\hat{S} \in \mathcal{F}$ with $|C \Delta \hat{S}| \geq |C \Delta S|$ for all $C \in \{A, B\}$.*

Proof. Begin with $\mathcal{F} = \emptyset$. Then, for each $m \in [n]$ and each number partition $\sum_{i=1}^4 m_i = m$ with $m_i \geq 0$, use algorithm \mathcal{A} to search in $f(r)n^{O(1)}g(pn^{-4})$ time and with error probability at most pn^{-4} for an $M \in \mathcal{R}(I)$ such that $|M \cap c^i| = m_i$ for all $i \in [4]$. If this succeeds, then add M to \mathcal{F} . Since there are $\binom{n+4}{4} \leq n^4$ possibilities for m_1, \dots, m_4 , the probability of an error occurring is upper-bounded by p . Moreover, the size of \mathcal{F} is at most n^4 and thus the overall running time is $f(r)n^{O(1)}g(pn^{-4})$.

Now let $S \in \mathcal{R}(I)$ be arbitrary. Set $m_i := |S \cap c^i|$, for all $i \in [4]$. By construction there is $\hat{S} \in \mathcal{F}$ such that $|\hat{S} \cap c^i| = m_i$ for all $i \in [4]$. It remains to be proven that \hat{S} has the desired properties. To this end, let $A, B \subseteq \mathcal{B}(I)$ be two sets as stated in the lemma. By symmetry, it suffices to show that $|A \Delta \hat{S}| \geq |A \Delta S|$.

Since $S \setminus A \subseteq c^4$ we have

$$|S \cap A \cap c^{1,3}| = |S \cap c^{1,3}| = m_1 + m_3 = |\hat{S} \cap c^{1,3}| \geq |\hat{S} \cap A \cap c^{1,3}| \quad (3)$$

and since $A \setminus S \subseteq c^{1,3}$, we have

$$|S \cap A \cap c^{2,4}| = |A \cap c^{2,4}| \geq |\hat{S} \cap A \cap c^{2,4}|. \quad (4)$$

By adding (3) and (4), we obtain $|S \cap A| \geq |\hat{S} \cap A|$ and thus $|S \Delta A| \leq |\hat{S} \Delta A|$ since $|S| = |\hat{S}|$. \blacktriangleleft

We now describe how we generate the colorings required for using Lemmata 6 and 7. Color-coding [2] is well-established in the toolbox of parameterized algorithms. While color-coding was initially described as a randomized technique, we use universal sets [33] to derandomize this technique as shown in the next lemma. Interestingly, without this derandomization the error probability of the color-coding step would later propagate through the dynamic programming method and consequently also depend on the number of instances of Π in the input instance of DIVERSE MULTISTAGE Π . The derandomization works as follows.

► Lemma 8. *For any set A of size n and any $b \leq n$ one can compute in $2^{2b+o(b)} \log n \cdot n$ time a family of functions $\{c_j: A \rightarrow [4] \mid j \in [2^{2b+o(b)} \log n]\}$ such that for any $\bigsqcup_{i=1}^4 B_i \subseteq A$ with $|\bigsqcup_{i=1}^4 B_i| \leq b$ there is a j such that $c_j(B_i) = \{i\}$, for all $i \in [4]$.*

Proof. Let $A := \{a_1, \dots, a_n\}$. By a result of Naor et al. [citeNearOptimalDerandomization], one can compute in $2^{2b} b^{O(\log b)} \cdot \log n \cdot n \subseteq 2^{2b+o(b)} \log n \cdot n$ time a so-called $(2n, 2b)$ -universal set which is a family $\mathcal{U} \subseteq 2^{[2n]}$ such that for every $B' \subseteq A$ with $|B'| = 2b$ the family $\{B' \cap U \mid U \in \mathcal{U}\}$ contains all 2^{2b} subsets of B' . Let $\mathcal{U} := \{U_i\}_{i=1}^{2^{2b+o(b)} \log n}$. We then define

$c_j, j \in [2^{2b+o(b)} \log n]$, by

$$c_j(a_i) := \begin{cases} 1, & \text{if } i, i+n \in U_j, \\ 2, & \text{if } i \in U_j \text{ and } i+n \notin U_j, \\ 3, & \text{if } i \notin U_j \text{ and } i+n \in U_j, \text{ and} \\ 4, & \text{if } i, i+n \notin U_j. \end{cases}$$

Now let $B_1 \uplus B_2 \uplus B_3 \uplus B_4 \subseteq A$ be an arbitrary 4-partition of a subset of A of size at most b . Consider $B' := \{i, i+n \mid a_i \in \bigcup_{q=1}^4 B_q\}$. We assume that B' is of size $2b$, otherwise we add arbitrary elements from $[2n]$. Since $B'' := \{i, i+n \mid a_i \in B_1\} \cup \{i \mid a_i \in B_2\} \cup \{i+n \mid a_i \in B_3\} \subseteq B'$ there is an $U_j \in \mathcal{U}$ such that $B' \cap U_j = B''$. Hence, $c_j(B_i) = \{i\}$, for all $i \in [4]$. ◀

We now show how to generate an ℓ -diverse representative of the family of solutions if there is one solution M^* from which no other solution differs by more than 2ℓ .

► **Lemma 9.** *Let Assumption 2 be true. Given an instance I of Π of size n , and a solution $M^* \in \mathcal{R}(I)$ such that each $M \in \mathcal{R}(I)$ satisfies $|M \Delta M^*| \leq 2\ell$, one can compute in $2^{16\ell+o(\ell)} \log n \cdot f(r) \cdot n^{O(1)} \cdot g(p/2^{16\ell+o(\ell)} \log n \cdot n^4)$ time and with error probability p an ℓ -diverse representative of $\mathcal{R}(I)$ of size at most $2^{16\ell+o(\ell)} \log n \cdot n^4$.*

Proof. For simplicity, let $\mathbb{J} := [2^{16\ell+o(\ell)} \log n]$. Apply Lemma 8 with $b = 8\ell$ to compute in $2^{16\ell+o(\ell)} \log n \cdot n$ time a family of colorings $\{c_j: \mathcal{B}(I) \rightarrow [4] \mid j \in \mathbb{J}\}$. To apply Lemma 8 we assume that $|\mathcal{B}(I)| \geq 8\ell$, otherwise we utilize dummy elements. For each $j \in \mathbb{J}$, apply Lemma 7 to I and c_j to compute a family $\mathcal{F}_j \subseteq \mathcal{R}(I)$ with error probability $p \cdot |\mathbb{J}|^{-1}$. Observe that the probability of an error occurring at any of the $|\mathbb{J}|$ steps is bounded by p . Choose $\mathcal{F} := \{M^*\} \cup \bigcup_{j \in \mathbb{J}} \mathcal{F}_j$. According to Lemma 7 the size of \mathcal{F} is upper-bounded by $|\mathbb{J}| \cdot n^4$ and the time required is bounded by $|\mathbb{J}| \cdot f(r) \cdot n^{O(1)} \cdot g(pn^{-4} \cdot |\mathbb{J}|^{-1})$.

We now show that \mathcal{F} is an ℓ -diverse representative of $\mathcal{R}(I)$. To this end, let $S \in \mathcal{R}(I)$ and let A, B be two arbitrary sets such that $|A \Delta S| \geq \ell$ and $|B \Delta S| \geq \ell$. Since $M^* \in \mathcal{F}$, we may assume by symmetry that, say, $|M^* \Delta A| < \ell$, otherwise we are done. Note that $|M^* \Delta S| \leq 2\ell$ and that $|A \Delta S| \leq |A \Delta M^*| + |M^* \Delta S| < 3\ell$. We say that some coloring c is *good* for A, B, S if the conditions of Lemma 7 are satisfied, i.e. if

$$A \setminus (B \cup S) \subseteq c^1, \quad B \setminus (A \cup S) \subseteq c^2, \quad (A \cap B) \setminus S \subseteq c^3, \quad \text{and} \quad S \setminus (A \cap B) \subseteq c^4.$$

We distinguish between two cases.

Case 1: $|M^* \Delta B| < 3\ell$. Then $|B \Delta S| \leq |B \Delta M^*| + |M^* \Delta S| \leq 5\ell$. According to Lemma 8 there is an $i \in \mathbb{J}$ such that coloring c_i is good for A, B, S , since $|B \Delta S| + |A \Delta S| < 8\ell$. By Lemma 7 and construction of \mathcal{F}_i , there is an $\hat{S} \in \mathcal{F}_i \subseteq \mathcal{F}$ such that $|\hat{S} \Delta A| \geq |S \Delta A| \geq \ell$ and $|\hat{S} \Delta B| \geq |S \Delta B| \geq \ell$.

Case 2: $|M^* \Delta B| \geq 3\ell$. Set $B' := A$. According to Lemma 8 there is an $i \in \mathbb{J}$ such that coloring c_i is good for A, B', S , since $|B' \Delta S| + |A \Delta S| < 6\ell$. Thus, by Lemma 7 and by the construction of \mathcal{F}_i there is an $\hat{S} \in \mathcal{F}_i \subseteq \mathcal{F}$ such that $|\hat{S} \Delta A| \geq |S \Delta A| \geq \ell$. Finally, we observe that $|\hat{S} \Delta B| \geq |M^* \Delta B| - |M^* \Delta \hat{S}| \geq 3\ell - 2\ell \geq \ell$ by the triangle inequality.

This completes the proof. ◀

Next, we show how to generate an ℓ -diverse representative of the family of solutions if there are two solutions such that no other solution differs from both by more than 2ℓ .

► **Lemma 10.** *Let Assumption 2 be true. Let I be an Π -instance of size n , and $M_1, M_2 \in \mathcal{R}(I)$ such that $|M_1 \Delta M_2| \geq 2\ell$ and each $M \in \mathcal{R}(I)$ has $\min\{|M \Delta M_1|, |M \Delta M_2|\} \leq 2\ell$. Then one can compute, in $2^{20\ell+o(\ell)} \log n \cdot f(r) n^{O(1)} g(p/n^{420\ell+o(\ell)} \log n)$ time and with error probability p , an ℓ -diverse representative of $\mathcal{R}(I)$ of size $2^{20\ell+o(\ell)} \log n \cdot n^4$.*

Proof. For simplicity, let $\mathbb{J} := \lceil 2^{20\ell+o(\ell)} \log n \rceil$. Apply Lemma 8 with $b = 10\ell$ to compute in $2^{20\ell+o(\ell)} \log n \cdot n$ time a family of colorings $\{c_j: \mathcal{B}(I) \rightarrow [4] \mid j \in \mathbb{J}\}$. To apply Lemma 8 we assume that $|\mathcal{B}(I)| \geq 10\ell$, otherwise we utilize dummy elements.

For each $j \in \mathbb{J}$, apply Lemma 7 to I and c_j to compute a family $\mathcal{F}_j \subseteq \mathcal{R}(I)$ of size at most n^4 with error probability $p/3 \cdot |\mathbb{J}|^{-1}$. Observe that the probability of an error occurring at any of the $|\mathbb{J}|$ steps is upper-bounded by $p/3$ and the computation of all \mathcal{F}_j takes $|\mathbb{J}|f(r)n^{\mathcal{O}(1)}g(p/3n^4 \cdot |\mathbb{J}|)$ time.

Next, define another family of colorings $\{c'_j: \mathcal{B}(I) \rightarrow [2] \mid j \in \mathbb{J}\}$ by setting $c'_j(x) := \lceil c_j(x)/2 \rceil$. Then, for each $j \in \mathbb{J}$, apply Lemma 6, to I , c'_j and M_1 to compute a family $\mathcal{F}'_j \subseteq \mathcal{R}(I)$, with the same error probability and time bound as before. Repeat with M_2 instead of M_1 to obtain \mathcal{F}''_j .

Set $\mathcal{F} := \{M_1, M_2\} \cup \bigcup_{j \in \mathbb{J}} (\mathcal{F}_j \cup \mathcal{F}'_j \cup \mathcal{F}''_j)$. Then \mathcal{F} has size at most $3|\mathbb{J}|n^4 + 2 \subseteq 2^{20\ell+o(\ell)} \log n \cdot n^4$. Computing \mathcal{F} takes $2^{20\ell+o(\ell)} \log n \cdot f(r)n^{\mathcal{O}(1)}g(p/3n^4 \cdot |\mathbb{J}|)$ time. The probability of an error occurring at any step while computing \mathcal{F} is upper-bounded by p .

We now show that \mathcal{F} is an ℓ -diverse representative of $\mathcal{R}(I)$. To this end, let $S \in \mathcal{R}(I)$ and A, B be two arbitrary sets such that $|A\Delta S| \geq \ell$ and $|B\Delta S| \geq \ell$. We may assume for each $i \in [2]$ that $|M_i\Delta A| < \ell$ or $|M_i\Delta B| < \ell$, otherwise we are done. By symmetry, we may assume $|M_1\Delta A| < \ell$. Then $|M_2\Delta A| \geq |M_2\Delta M_1| - |M_1\Delta A| > \ell$ by the triangle inequality and thus we must have $|M_2\Delta B| < \ell$. By assumption, $\min\{|S\Delta M_1|, |S\Delta M_2|\} \leq 2\ell$, so let without loss of generality $|S\Delta M_1| \leq 2\ell$. Note that $|A\Delta S| \leq |A\Delta M_1| + |M_1\Delta S| < 3\ell$. We distinguish the following two cases.

Case 1: $|M_1\Delta M_2| \leq 4\ell$. Then, $|B\Delta S| \leq |B\Delta M_2| + |M_2\Delta M_1| + |M_1\Delta S| < 7\ell$. We say that some coloring c is *good* for A, B, S if the conditions of Lemma 7 are satisfied, i.e. if $A \setminus (B \cup S) \subseteq c^1$, $B \setminus (A \cup S) \subseteq c^2$, $(A \cap B) \setminus S \subseteq c^3$, and $S \setminus (A \cap B) \subseteq c^4$. According to Lemma 8 there is an $i \in \mathbb{J}$ such that coloring c_i is good for A, B, S , since $|B\Delta S| + |A\Delta S| \leq 10\ell$. By Lemma 7, there is $\hat{S} \in \mathcal{F}_i \subseteq \mathcal{F}$ such that $|\hat{S}\Delta A| \geq |S\Delta A| \geq \ell$ and $|\hat{S}\Delta B| \geq |S\Delta B| \geq \ell$.

Case 2: $|M_1\Delta M_2| > 4\ell$. Since $|S\Delta A| < 3\ell \leq 10\ell$, there is $j \in \mathbb{J}$ such that $S \setminus A \subseteq c_j^1$ and $A \setminus S \subseteq c_j^2$. By Lemma 6 there is $\hat{S} \in \mathcal{F}'_j$ such that $|\hat{S}\Delta M_1| = |S\Delta M_1| \leq 2\ell$ and $|\hat{S}\Delta A| \geq |S\Delta A| \geq \ell$. Finally, observe that by the triangle inequality $|\hat{S}\Delta B| \geq |M_1\Delta M_2| - |M_1\Delta \hat{S}| - |B\Delta M_2| > \ell$.

This completes the proof. \blacktriangleleft

With Lemmata 5, 9, and 10 at hand we can formalize the case distinction outlined in the beginning of the section. This gives us a way to efficiently compute an ℓ -diverse representative in general.

► Lemma 11. *Let Assumption 2 be true. Let I be an instance of Π of size n . One can compute an ℓ -diverse representative of $\mathcal{R}(I)$ of size $2^{20\ell+o(\ell)} \log n \cdot n^4$ in $2^{20\ell+o(\ell)} \log n \cdot f(r)n^{\mathcal{O}(1)}g(p/n^4 \cdot 2^{20\ell+o(\ell)} \log n)$ time with error probability at most p .*

Proof. Our procedure to compute an ℓ -diverse representative of $\mathcal{R}(I)$ works in four steps.

Step 1. We use \mathcal{A} with a monochrome coloring and error probability $p/4n$ to search for some $M_1 \in \mathcal{R}(I)$ in $f(r)n^{\mathcal{O}(1)}g(p/4n)$ time by guessing the size of $|M_1| \leq n$. Observe that the probability of an error occurring in any of the searches is upper-bounded by $p/4$. If we do not succeed, then output the empty set and we are done. Otherwise, we proceed with the next step.

Step 2. For each pair m_1, m_2 with $m_1 + m_2 \leq n$ and $m_2 + |M_1| - m_1 > 2\ell$, try to compute $M_2 \in \mathcal{R}(I)$ with $|M_2 \cap M_1| = m_1$ and $|M_2 \cap (\mathcal{B}(I) \setminus M_1)| = m_2$ in $f(r)n^{O(1)}g(p/4n^2)$ time and with error probability $p/4n^2$ using \mathcal{A} with a 2-coloring where elements in M_1 are assigned one color and elements in $\mathcal{B}(I) \setminus M_1$ are assigned the second color. If no such M_2 is found for any pair m_1, m_2 , then for every $M \in \mathcal{R}(I)$ the symmetric difference $|M \Delta M_1| \leq 2\ell$. In that case we may apply Lemma 9 with error probability $p/2$ and are done. Observe that the probability of an error occurring at any step until here is upper-bounded by p and the overall running time is $2^{16\ell+o(\ell)} \log n \cdot f(r)n^{O(1)}g(p/n^4 \cdot 2^{16\ell+o(\ell)} \log n)$. If we found such an M_2 , then we proceed with the next step.

Step 3. We have $M_1, M_2 \in \mathcal{R}(I)$ with $|M_1 \Delta M_2| \geq 2\ell$. Define the coloring $c: \mathcal{B}(I) \rightarrow [4]$ by

$$c(v) := \begin{cases} i & \text{if } v \in M_i \setminus M_j \text{ for } \{i, j\} = \{1, 2\}, \\ 3 & \text{if } v \in M_1 \cap M_2, \text{ and} \\ 4 & \text{otherwise.} \end{cases}$$

For all m'_1, m'_2, m'_3, m'_4 with $m'_1 + m'_2 + m'_3 + m'_4 \leq n$ and $m'_2 + m'_4 + |M_1| - m'_1 - m'_3 > 2\ell$ and $m'_1 + m'_4 + |M_2| - m'_2 - m'_3 > 2\ell$, search for a solution $M_3 \in \mathcal{R}(I)$ with $|M_3 \cap c^i| = m'_i$, for all $i \in [4]$, using \mathcal{A} with c and error probability $p/4n^4$. For all these combined, we thus have error probability $p/4$ and need $f(r)n^{O(1)}g(p/4n^4)$ time. If no such M_3 is found for any choice of m'_1, m'_2, m'_3, m'_4 , then any $M \in \mathcal{R}(I)$ must have $\min\{|M \Delta M_1|, |M \Delta M_2|\} \leq 2\ell$. In that case we may apply Lemma 10 with error probability $p/4$ and are done. Observe that the probability of an error occurring at any step until here is upper-bounded by p and the overall running time is $2^{20\ell+o(\ell)} \log n \cdot f(r)n^{O(1)}g(p/n^4 \cdot 2^{20\ell+o(\ell)} \log n)$. In case that we found such an M_3 , we proceed with the next step.

Step 4. We have $M_1, M_2, M_3 \in \mathcal{R}(I)$ such that $|M_i \Delta M_j| \geq 2\ell$ for all distinct $i, j \in [3]$. Hence, by Lemma 5, we can output $\{M_1, M_2, M_3\}$. This completes the proof. \blacktriangleleft

Finally, Lemma 11 allows us to formulate a dynamic program for DIVERSE MULTISTAGE II and prove Theorem 3.

Proof of Theorem 3. Let $J := ((I_i)_{i=1}^\tau, \ell)$ be an instance of DIVERSE MULTISTAGE II, where $n := \max_{i \in [\tau]} |I_i|$. For each $i \in [\tau]$ we apply Lemma 11 to obtain an ℓ -diverse representative \mathcal{F}_i of $\mathcal{R}(I_i)$ that has size at most $2^{20\ell+o(\ell)} \log n \cdot n^4$ in $2^{20\ell+o(\ell)} \log n \cdot f(r)n^{O(1)} \cdot g(p/\tau n^4 \cdot 2^{20\ell+o(\ell)} \log n)$ time with error probability p/τ . Observe that the probability of an error occurring at any step is upper-bounded by p . Now we use the following dynamic program to check whether J is a *yes*-instance.

$$\forall i \in \{2, 3, \dots, \tau\}, S \in \mathcal{F}_i: D[i, S] := \begin{cases} \top & \text{if } \exists \widehat{S} \in \mathcal{F}_{i-1}: D[i-1, \widehat{S}] = \top \text{ and } |S \Delta \widehat{S}| \geq \ell, \\ \perp & \text{otherwise,} \end{cases}$$

where $D[1, \widehat{S}] = \top$ if and only if $\widehat{S} \in \mathcal{F}_1$. We report that J is a *yes*-instance if and only there is an $S \in \mathcal{F}_\tau$ such that $D[\tau, S] = \top$. Note that this takes $(2^{20\ell+o(\ell)} \log n \cdot n^4)^2 \tau \subseteq 2^{O(\ell)} n^{O(1)} \tau$ time. Hence our overall running time is $2^{O(\ell)} \cdot f(r_{\max})n^{O(1)} \cdot \tau \cdot g(p/\tau n^4 \cdot 2^{20\ell+o(\ell)} \log n)$, where r_{\max} is the maximum of parameter r over all instances of II in J .

(\Leftarrow): We show by induction over $i \in [\tau]$ that if $D[i, S] = \top$, then there is a sequence $(S_j)_{j \in [i]}$ such that $S_i = S$, $S_j \in \mathcal{R}(I_j)$ for all $j \in [i]$ and $|S_{j-1} \Delta S_j| \geq \ell$ for all $j \in \{2, 3, \dots, i\}$.

By definition of D this is clearly the case for $i = 1$. Now let $1 < i \leq \tau$ and $D[i, S] = \top$. Since $D[i, S] = \top$, $S \in \mathcal{F}_i$ and thus $S \in \mathcal{R}(I_i)$. By definition of D there is an $\widehat{S} \in \mathcal{F}_{i-1}$ with $D[i-1, \widehat{S}] = \top$ and $|S \Delta \widehat{S}| \geq \ell$. By induction hypothesis, there is a sequence $(S_j)_{j \in [i-1]}$ such

that $S_{i-1} = \widehat{S}$, $S_j \in \mathcal{R}(I_j)$ for all $j \in [i-1]$ and $|S_{j-1} \Delta S_j| \geq \ell$ for all $j \in \{2, 3, \dots, i-1\}$. Hence, the sequence $(S_1, \dots, S_{i-1} = \widehat{S}, S)$ completes the induction. Thus, if we report that J is a *yes*-instance, then this is true.

(\Rightarrow): Now let $(S_j)_{j \in [\tau]}$ be a solution for J . To simplify the proof let $S_{\tau+1}$ be a set of ℓ elements that are disjoint from S_τ . We show by induction that for all $i \in [\tau]$ there is a $Z \in \mathcal{F}_i$ such that $D[i, Z] = \top$ and $|Z \Delta S_{i+1}| \geq \ell$.

Let $i = 1$. Then there is a $Z \in \mathcal{F}_1$ such that $|S_2 \Delta Z| \geq \ell$ since \mathcal{F}_1 is an ℓ -diverse representative of $\mathcal{R}(I_1)$. Hence, $D[1, Z] = \top$.

Now let $1 < i \leq \tau$. By induction hypothesis, there is a $Z_{i-1} \in \mathcal{F}_{i-1}$ such that $D[i-1, Z_{i-1}] = \top$ and $|S_i \Delta Z_{i-1}| \geq \ell$. Since $S_i \in \mathcal{R}(I_i)$ and we have $|S_i \Delta Z_{i-1}|, |S_i \Delta S_{i+1}| \geq \ell$ and \mathcal{F}_i is an ℓ -diverse representative of $\mathcal{R}(I_i)$, there is a $Z \in \mathcal{F}_i$ such that $|Z \Delta Z_{i-1}|, |Z \Delta S_{i+1}| \geq \ell$. By definition of D , we also have $D[i, Z] = \top$. This completes the induction step. Thus, there is a $Z \in \mathcal{F}_\tau$ such that $D[\tau, Z] = \top$ and if J is a *yes*-instance, then we report that. \blacktriangleleft

4 Application: Committee Election

Bredereck et al. [11] studied the following problem under the name REVOLUTIONARY MULTISTAGE PLURALITY VOTING.

DIVERSE MULTISTAGE PLURALITY VOTING

Input: A set A of agents, a set C of candidates, a sequence $(u_i)_{i=1}^\tau$ of voting profiles $u_i: A \rightarrow C \cup \{\emptyset\}$, and integers $k, x, \ell \in \mathbb{N}$.

Question: Is there a sequence $(C_1, C_2, \dots, C_\tau)$ such that for all $i \in [\tau]$ it holds that $C_i \subseteq C$, $|C_i| \leq k$, and $|u^{-1}(C_i)| \geq x$, and for all $i \in [\tau-1]$ it holds true that $|C_i \Delta C_{i+1}| \geq \ell$?

In this section, we affirmatively answer the question of Bredereck et al. [11] whether DIVERSE MULTISTAGE PLURALITY VOTING parameterized by ℓ or k is in FPT.³

► **Theorem 12.** *An instance J of DIVERSE MULTISTAGE PLURALITY VOTING can be solved in $2^{\mathcal{O}(\ell)} \cdot |J|^{\mathcal{O}(1)}$ time.*

To prove Theorem 12, we use Theorem 1. In the notation of our framework, we deal with the following problem Π : given an instance $I = (A, C, u, k, x)$ consisting of a set A of agents, a set $C =: \mathcal{B}(I)$ of candidates, a voting profile $u: A \rightarrow C$, and two integers k, x , decide whether $\mathcal{R}(I) := \{S \subseteq C \mid k \geq |S| \text{ and } |u^{-1}(S)| \geq x\}$ is non-empty. Hence, to apply Theorem 1, we consider the following problem.

4-COLORED EXACT PLURALITY VOTING

Input: A set A of agents, a set C of candidates, a voting profile $u: A \rightarrow C \cup \{\emptyset\}$, a coloring $c: C \rightarrow [4]$, and integers $n_i, x, k \in \mathbb{N}, i \in [4]$.

Output: A set $C' \subseteq C$ of at most k candidates so that $|u^{-1}(C')| \geq x$ and $|c^{-1}(i) \cap C'| = n_i$ for all $i \in [4]$ or “no” if no such set exists.

This problem is polynomial-time solvable and hence the following observation together with Theorem 1 proves Theorem 12. In the full version we will generalize this application to independent sets in matroids.

► **Observation 13** (\star^4). 4-COLORED EXACT PLURALITY VOTING is polynomial-time solvable.

³ Note that $\ell \leq 2k$ for all non-trivial instances, so it suffices to prove this for ℓ .

⁴ Proofs of results marked with a star are deferred to the full version.

5 Application: Perfect Matching

In this section, we apply our framework from Section 3 to find a sequence of diverse perfect matchings.

DIVERSE MULTISTAGE PERFECT MATCHING

Input: A sequence $(G_i)_{i=1}^\tau$ of graphs and an integer $\ell \in \mathbb{N}_0$.

Question: Is there a sequence $(M_i)_{i=1}^\tau$ of perfect matchings $M_i \subseteq E(G_i)$ such that $|M_i \Delta M_{i+1}| \geq \ell$ for all $i \in [\tau - 1]$?

There are two closely related variants of this problem which were studied extensively. The first variant is the non-diverse variant, where one seeks to bound the symmetric differences (in some way) from above [5, 4, 13, 25, 34]. Steinhau [34] proved that if the size of the symmetric difference of two consecutive perfect matchings shall be at most ℓ , then this problem variant is NP-hard even if ℓ is constant, and W[1]-hard when parameterized by $\ell + \tau$. The second variant is the non-multistage variant, where one is given a single graph and is asked to compute a set of pairwise diverse perfect matchings [22, 23]. Fomin et al. [22] proved that this variant is NP-hard even if one asks only for two diverse matchings. This directly implies NP-hardness for DIVERSE MULTISTAGE PERFECT MATCHING even when $\tau = 2$.

Our goal is to show fixed-parameter tractability of DIVERSE MULTISTAGE PERFECT MATCHING when parameterized by ℓ . This stands in contrast to the NP-hardness for the non-diverse problem variant with constant ℓ .

► **Theorem 14 (★).** *An instance J of DIVERSE MULTISTAGE PERFECT MATCHING can be solved in $2^{O(\ell)} \cdot |J|^{O(1)}$ time with a constant error probability.*

We will prove Theorem 14 by means of Theorem 3 at the end of this section. To this end we need to consider the following problem.

s -COLORED EXACT PERFECT MATCHING

Input: A graph $G = (V, E)$, a coloring $c: E \rightarrow [s]$, and $k_i \in \mathbb{N}, i \in [s]$.

Output: (if exists) A perfect matching M in G such that $|c^i \cap M| = k_i$, for all $i \in [s]$?

For $s = 2$, this problem is known as EXACT MATCHING, and Mulmuley et al. [32] showed that this special case is solvable by a randomized polynomial-time algorithm. We generalize this result by showing that s -COLORED EXACT PERFECT MATCHING can be solved in polynomial time for any constant s by a randomized algorithm with constant error probability. While we only need this for $s = 4$ in order to prove Theorem 14, we believe that the general case may be of independent interest. We remark that it is open whether EXACT MATCHING can be solved in (deterministic) polynomial time.

► **Lemma 15 (★).** *For every $0 < p < 1$ there is an $(n^{O(s)} \cdot \log 1/p)$ -time algorithm which, given an instance of s -COLORED EXACT PERFECT MATCHING, finds a solution with probability at least $1 - p$ if one exists, and concludes that there is no solution otherwise.*

To determine whether a given s -COLORED EXACT PERFECT MATCHING has a solution we use the following algorithm.

► **Algorithm 16.** Let $0 < p < 1$ and let $I = (G, c, k_1, \dots, k_s)$ be an instance of s -COLORED EXACT PERFECT MATCHING where $G = (V, E)$ has n vertices.

Step 1. Set $\gamma := \lceil n/(2p) \rceil$ and draw $w_{ij} \in [\gamma]$ for all $\{i, j\} \in E$ uniformly at random.

Step 2. Construct an $n \times n$ matrix A' with entries $a_{ij} \in \mathbb{Z}[y_1, \dots, y_s]$, $1 \leq i \leq j \leq n$, where

$$a_{ij} := \begin{cases} 0 & \text{if } \{i, j\} \notin E, \\ w_{ij}y_q & \text{if } \{i, j\} \in c^q \cap E, q \in [s]. \end{cases}$$

Afterwards we compute the skew-symmetric matrix $A := A' - (A')^T$.

Step 3. Compute the polynomial $P := \sqrt{\det(A)} \in \mathbb{Z}[y_1, \dots, z_s]$.

Step 4. If P contains a monomial $b^*y_1^{k_1}y_2^{k_2}\dots y_s^{k_s}$ such that $b^* \neq 0$ then, output *yes*. Otherwise, output *no*. \diamond

Before studying the running time of Algorithm 16, we first focus on its correctness.

► **Lemma 17.** *Let I and p be the input of Algorithm 16. If Algorithm 16 returns *yes*, then there is a solution for I . Conversely, if I is a *yes*-instance, then Algorithm 16 returns *yes* with probability at least $1 - p$.*

Proof. Let \mathcal{P} be the set of all partitions of V into unordered pairs. For $\sigma \in \mathcal{P}$ with $\sigma = \{\{i_1, j_1\}, \{i_2, j_2\}, \dots, \{i_{n/2}, j_{n/2}\}\}$ with $i_k < j_k$ for $k \in [n/2]$ and $i_1 < i_2 < \dots < i_{n/2}$, let

$$\pi_\sigma := \begin{bmatrix} 1 & 2 & 3 & 4 & \dots & n-1 & n \\ i_1 & j_1 & i_2 & j_2 & \dots & i_{n/2} & j_{n/2} \end{bmatrix}$$

be the corresponding permutation. Let $\text{val}(\sigma) := \text{sgn}(\pi_\sigma) \prod_{\{i,j\} \in \sigma} a_{ij}$, where $\text{sgn}(\pi_\sigma) \in \{+1, -1\}$ is the signum of π_σ . The Pfaffian of A (computed by Algorithm 16) is defined as $\text{pf}(A) := \sum_{\sigma \in \mathcal{P}} \text{val}(\sigma)$ [27]. Note that A is skew-symmetric, hence, $\text{pf}(A) = \sqrt{\det(A)} = P$ [31, 27]. As $\text{val}(\sigma) = 0$ whenever σ contains a non-edge, we have $P = \sum_{M \in \mathcal{PM}} \text{val}(M)$, where \mathcal{PM} is the set of perfect matchings in G . Let M be a perfect matching and let $z_q = |c^q \cap M|$, $q \in [s]$. Then $\text{val}(M) = \text{sgn}(\pi_M) \prod_{q \in [s]} \prod_{\{i,j\} \in M \cap c^q} w_{ij}y_q = b \cdot y_1^{z_1}y_2^{z_2}\dots y_s^{z_s}$, where $b \in \mathbb{Z}$. Let $\mathcal{PM}^* \subseteq \mathcal{PM}$ be the family of perfect matchings M^* which have exactly k_i edges of color i , for all $i \in [s]$. Then the coefficient b^* of the monomial $b^*y_1^{k_1}y_2^{k_2}\dots y_s^{k_s}$ of P is $b^* = \sum_{M^* \in \mathcal{PM}^*} \text{sgn}(\pi_{M^*}) \prod_{\{i,j\} \in M^*} w_{ij}$. Hence, if Algorithm 16 returns *yes* (i.e., $b^* \neq 0$), then $\mathcal{PM}^* \neq \emptyset$.

Now conversely assume I to be a *yes*-instance, i.e., $\mathcal{PM}^* \neq \emptyset$. We analyze the probability of the event $b^* = 0$ occurring. Note that b^* can be seen as a polynomial of degree at most $n/2$ over the indeterminates $\{w_{ij} \mid \{i, j\} \in E\}$. As we have drawn the w_{ij} independently and uniformly at random from $[\gamma]$ with $\gamma \geq n/(2p)$, by the DeMillo-Lipton-Schwartz-Zippel lemma the probability that $b^* = 0$ is at most $n/(2\gamma) \leq p$. \blacktriangleleft

Now we show that Algorithm 16 can be executed efficiently.

► **Lemma 18 (★).** *Algorithm 16 runs in $n^{O(s)} \log(1/p)$ time.*

We are now ready to put all parts together and prove Lemma 15. In a nutshell, we use Algorithm 16 to check whether there is a solution. If this is the case, then we try to delete as many edges as possible from the instance until the whole edge set is a solution. Putting Lemma 15 and Theorem 3 together, we can prove the main theorem of this section, see the full version for details.

6 Application: s - t Path

In this section, we apply our framework to the task of finding a sequence of diverse s - t paths. This has obvious applications e.g. in convoy routing [21].

DIVERSE MULTISTAGE s - t PATH

Input: A sequence of graphs $(G_i)_{i=1}^\tau$, two distinct vertices $s, t \in \bigcap_{i=1}^\tau V(G_i)$, and $\ell \in \mathbb{N}_0$.

Question: Is there a sequence $(P_1, P_2, \dots, P_\tau)$ such that P_i is an s - t path in G_i for all $i \in [\tau]$, and $|S_i \Delta S_{i+1}| \geq \ell$ for all $i \in [\tau - 1]$?

Our goal is to show that DIVERSE MULTISTAGE s - t PATH parameterized by ℓ is in FPT.

► **Theorem 19.** DIVERSE MULTISTAGE s - t PATH parameterized by ℓ is in FPT.

We will prove Theorem 19 by means of Theorem 1 at the end of this section. To this end, we need to consider the following problem.

4-COLORED EXACT s - t PATH

Input: A graph G , distinct vertices $s, t \in V(G)$, coloring $c: V(G) \rightarrow [4]$, and $n_i \in \mathbb{N}_0, i \in [4]$.

Output: (if exists) An s - t path P such that $|c^{-1}(i) \cap V(P)| = n_i$ for all $i \in [4]$.

Unfortunately, 4-COLORED EXACT s - t PATH is unlikely to be polynomial-time solvable, as it is NP-hard even if only a single color is used, by a trivial reduction from HAMILTONIAN PATH. However, as we will see in the proof of Theorem 19, by a result of Mousset et al. [30] we can actually reduce 4-COLORED EXACT s - t PATH to the case that all graphs have small treewidth. In this setting, we then employ dynamic programming.

► **Lemma 20 (★).** 4-COLORED EXACT s - t PATH is solvable $k^{\mathcal{O}(k)} \cdot |I|^{\mathcal{O}(1)}$ time, where k is the treewidth of the input graph G .

While some techniques [15, 24, 9] seem applicable to improve the running time of Lemma 20 slightly, for our needs a straight-forward dynamic program on a nice tree decomposition suffices. We are now ready to prove Theorem 19.

Proof of Theorem 19. Let the instance J of DIVERSE MULTISTAGE s - t PATH be given in the form of graphs G_1, \dots, G_τ , two vertices $s, t \in \bigcap_{i=1}^\tau G_i$ and $\ell \in \mathbb{N}$. We may assume that every vertex v of every graph G_i is contained in at least one s - t path in G_i , since otherwise we may delete v . This is equivalent to the assumption that the graph G'_i obtained from adding the edge $\{s, t\}$ to G_i is biconnected.

By a result of Mousset et al. [30], there is a universal constant $\gamma > 0$, such that each G_i with treewidth $\text{tw}(G_i) \geq \gamma\ell$ contains two vertex-disjoint cycles of size at least 4ℓ .

If two such cycles C, C' exist in G_i , then let P_1 be an s - t path containing at least one edge of C . To see that such a path exists, construct a biconnected graph by simply attaching a new degree-two vertex s' to both s and t , create another new vertex t' by subdividing some edge of C , and take two disjoint paths between s' and t' .

Without loss of generality, P_1 enters C and C' at most once each. Construct another s - t path P_2 from P_1 by setting $E(P_2) := E(P_1) \Delta E(C)$. If P_1 contains any edge of C' , then define P_3 by $E(P_3) := E(P_1) \Delta E(C')$. Otherwise, let P_3 be any s - t path containing at least half of the edges of C' (this can be achieved analogously to the construction of P_1 resp. P_2). Observe that P_1, P_2 , and P_3 have pairwise symmetric differences at least 2ℓ . Thus, $\{P_1, P_2, P_3\}$ is an ℓ -diverse representative of all s - t paths in G_i by Lemma 5.

We can then solve the subinstances given by $(G_j)_{j < i}$ and $(G_j)_{j > i}$ separately and pick a suitable path from $\{P_1, P_2, P_3\}$ afterwards.

All subinstances in which every graph G_i has $\text{tw}(G_i) < \gamma\ell$ can be solved by Theorem 1 in combination with Lemma 20 in $2^{\mathcal{O}(\ell)} f(\gamma\ell) |J|^{\mathcal{O}(1)}$ time, where f is given by Lemma 20. ◀

7 Hardness of Vertex Cover

We finally present a problem where our framework from Section 3 is not applicable, unless $\text{FPT} = \text{W}[1]$. The non-diverse variant of the following problem was studied by Fluschnik et al. [20]. Among others, they showed $\text{W}[1]$ -hardness when parametrized by the vertex cover size k or by the maximum number of edges over all instances in the input.

DIVERSE MULTISTAGE VERTEX COVER

Input: A sequence of graphs $(G_i)_{i=1}^\tau$ and $k, \ell \in \mathbb{N}$.

Question: Is there a sequence $(S_1, S_2, \dots, S_\tau)$ such that for all $i \in [\tau]$ the set $S_i \subseteq V(G_i)$ is a vertex cover of size at most k in G_i and $|S_i \Delta S_{i+1}| \geq \ell$ for all $i \in [\tau - 1]$?

The framework from Section 3 is presumably not applicable to DIVERSE MULTISTAGE VERTEX COVER because of the following result.

► **Theorem 21.** DIVERSE MULTISTAGE VERTEX COVER *parameterized by ℓ is $\text{W}[1]$ -hard, even if $\tau = 2$.*

Proof. We reduce from INDEPENDENT SET: Given a graph $G = (V, E)$, and $k \in \mathbb{N}$, is there a vertex set $S \subseteq V$, $|S| \geq k$, such that the vertices in S are pairwise nonadjacent? INDEPENDENT SET is $\text{W}[1]$ -hard with respect to k [17].

Let $I := (G = (V, E), k)$ be an instance of INDEPENDENT SET and let $|V| = n$. Without loss of generality, we assume that $k > 1$. We construct an instance $J := ((G_1, G_2), k', \ell)$ of DIVERSE MULTISTAGE VERTEX COVER as follows. The first graph G_1 is a complete graph on the vertex set $V \cup \{v\}$. The second graph G_2 consists of the vertex set $V \cup \{v\}$ and the edge set $E \cup \{\{u, v\} \mid u \in V\}$, that is, G_2 is a copy of G to which we add a vertex v which is adjacent to every other vertex. Lastly, we set $k' := n$ and $\ell := k + 1$. Clearly, J can be constructed in polynomial time. We now show that I is a *yes*-instance if and only if J is a *yes*-instance.

(\Rightarrow): Let S be an independent set of size at least k in G . Let $S_1 := V$ and $S_2 := \{v\} \cup V \setminus S$. Note that $|S_1 \Delta S_2| \geq k + 1$ and $|S_2| \leq |S_1| = n$, and S_i is a vertex cover in G_i for $i \in [2]$. Thus (S_1, S_2) is a valid solution for our instance of DIVERSE MULTISTAGE VERTEX COVER.

(\Leftarrow): Let (S_1, S_2) be a solution for our instance of DIVERSE MULTISTAGE VERTEX COVER. As G_1 is a complete graph, we have $|S_1| \geq n$. Without loss of generality, we assume that $S_1 = V$. Then $S_1 \Delta S_2 = \{v\} \cup V \setminus S_2$. Note that $v \in S_2$, otherwise S_2 must be equal to V in order to be a vertex cover, and $|S_1 \Delta V| < \ell$. As S_2 is a vertex cover of G_2 , the set $S := (V \cup \{v\}) \setminus S_2$ is an independent set of G_2 . Note that $v \notin S$, hence S is also an independent set of G . Finally, as $S = (S_1 \Delta S_2) \setminus \{v\}$, we have $|S| \geq \ell - 1 = k$, and we are done. ◀

8 Conclusion

We introduced a versatile framework to show fixed-parameter tractability for a variety of diverse multistage problems when parameterized by the diversity ℓ . The only requirement for applying our framework is that a four-colored variant of the base problem can be solved efficiently. We presented four applications of our framework, one of which resolving an open question by Brederick et al. [11]. Two other applications revealed problems which may be of independent interest from a technical and motivational point of view, see Sections 5 and 6.

We believe that our framework can be applied to a broad spectrum of multistage problems. In particular, a broad systematic study of the multistage setting in elections was proposed by Boehmer and Niedermeier et al. [10]. Herein, diversity is a natural goal. From a motivational

point of view, an interesting direction for future research is to combine the diverse multistage setting with time windows, known from other temporal domains [35, 28, 12, 1, 29]. Here, a solution to the i -th instance should be sufficiently different from the δ previous solutions in the sequence; our work covers the case $\delta = 1$. In some multistage scenarios a “global view” [26] on the symmetric differences is desired. In context of this paper this means that two consecutive solutions can have a small symmetric difference as long as the sum of all consecutive symmetric differences is at least ℓ . We believe that our framework (Section 3) can be extended to this setting. To see this, we have to realize that for an ℓ -diverse representative \mathcal{F} of a family of solutions the following holds: For all sets A and B and integers $\ell_a, \ell_b \leq \ell$, if there is an $S \in \mathcal{F}$ such that $|A \Delta S| \geq \ell_a$ and $|B \Delta S| \geq \ell_b$, then there is an $\hat{S} \in \mathcal{F}$ such that $|A \Delta \hat{S}| \geq \ell_a$ and $|B \Delta \hat{S}| \geq \ell_b$. We leave the details for further research. Finally, the presented time and space constraints to compute ℓ -diverse representatives seem to be suboptimal. Hence, improving the time or space constraints could be a fruitful research direction.

Fast and Space-Efficient Construction of AVL Grammars from the LZ77 Parsing

Dominik Kempa 

Department of Computer Science, Johns Hopkins University, Baltimore, MD, USA

Ben Langmead 

Department of Computer Science, Johns Hopkins University, Baltimore, MD, USA

Abstract

Grammar compression is, next to Lempel–Ziv (LZ77) and run-length Burrows–Wheeler transform (RLBWT), one of the most flexible approaches to representing and processing highly compressible strings. The main idea is to represent a text as a context-free grammar whose language is precisely the input string. This is called a straight-line grammar (SLG). An AVL grammar, proposed by Rytter [Theor. Comput. Sci., 2003] is a type of SLG that additionally satisfies the AVL property: the heights of parse trees for children of every nonterminal differ by at most one. In contrast to other SLG constructions, AVL grammars can be constructed from the LZ77 parsing in compressed time: $\mathcal{O}(z \log n)$ where z is the size of the LZ77 parsing and n is the length of the input text. Despite these advantages, AVL grammars are thought to be too large to be practical.

We present a new technique for rapidly constructing a small AVL grammar from an LZ77 or LZ77-like parse. Our algorithm produces grammars that are always at least five times smaller than those produced by the original algorithm, and usually not more than double the size of grammars produced by the practical Re-Pair compressor [Larsson and Moffat, Proc. IEEE, 2000]. Our algorithm also achieves low peak RAM usage. By combining this algorithm with recent advances in approximating the LZ77 parsing, we show that our method has the potential to construct a run-length BWT in about one third of the time and peak RAM required by other approaches. Overall, we show that AVL grammars are surprisingly practical, opening the door to much faster construction of key compressed data structures.

1 Introduction

The increase in the amount of highly compressible data that requires efficient processing in the recent years, particularly in the area of computational genomics [3, 4], has caused a spike of interest in dictionary compression. Its main idea is to reduce the size of the representation of data by finding repetitions in the input and encoding them as references to other occurrences. Among the most popular methods are the Lempel–Ziv (LZ77) compression [32], run-length Burrows–Wheeler transform (RLBWT) [5, 16], and grammar compression [6]. Although in theory, LZ77 and RLBWT are separated by at most a factor of $\mathcal{O}(\log^2 n)$ (where n is the length

of the input text) [15, 20], the gap in practice is usually noticeable (as also confirmed by our experiments). RLBWT is the largest of the three representations in practice, but is also the most versatile, supporting powerful suffix array and suffix tree queries [16]. LZ77, on the other hand, is the smallest, but its functionality includes only the easier longest common extension (LCE), random-access, and pattern matching queries [1, 7, 12, 13, 21]. Grammar compression occupies the middle ground between the two, supporting queries similar to LZ77 [26]. Navarro gives a comprehensive overview of these and related representations [26, 27].

A major practical concern with these representations – RLBWT in particular – is how to construct them efficiently. Past efforts have focused on engineering efficient *general* algorithms for constructing the BWT and LZ77 [10, 18, 2, 17], but these are not applicable to the terabyte-scale datasets routinely found, e.g., in modern genomics [4]. Specialized algorithms for highly repetitive datasets have only been investigated recently. Boucher et al. [4] proposed a method for the efficient construction of RLBWT using the concept of prefix-free parsing. The same problem was approached by Policriti and Prezza, and Ohno et al. [29, 28], using a different approach based on the dynamic representation of RLBWT. These methods represent the state of the art in the practical construction of RLBWT.

A different approach to the construction of RLBWT was recently proposed in [20]. The idea is to first compute the (exact or approximate) LZ77 parsing for the text, and then convert this representation into an RLBWT. Crucially, the LZ77 \rightarrow RLBWT conversion takes only $\mathcal{O}(z \text{ polylog } n)$ time (where z is the size of the LZ77 parsing), i.e., it runs not only in the compressed space but also in *compressed time*.¹ The computational bottleneck is therefore shifted to the easier problem of computing or approximating the LZ77, which is the only step taking $\Omega(n)$ time. Internally, this new pipeline consists of three steps: text \rightarrow (approximate) LZ77 \rightarrow grammar \rightarrow RLBWT, unsurprisingly aligning with the gradual increase in the size and complexity of these representations. Kosolobov et al. [24] recently proposed a fast and space-efficient algorithm to approximate LZ77, called Re-LZ. The second and third steps in the pipeline, from the LZ77 parse to the RLBWT, have not been implemented. The only known algorithm to convert LZ77 into a grammar in compressed time was proposed by Rytter [30], and is based on the special type of grammars called *AVL grammars*, whose distinguishing feature is that all subtrees in the parse tree satisfy the AVL property: the tree-heights for children of every nonterminal do not differ by more than one. The algorithm is rather complex, and until now has been considered impractical.

Our Contribution. Our main contribution is a series of practical improvements to the basic variant of Rytter’s algorithm, and a fast and space-efficient implementation of this improved algorithm. Compared to the basic variant, ours produces a grammar that is always five times smaller, and crucially, the same holds for all intermediate grammars computed during the algorithm’s execution, yielding very low peak RAM usage. The resulting grammar is also no more than twice of the smallest existing grammar compressors such as Re-Pair [25]. We further demonstrate that combining our new improved algorithm with Re-LZ opens up a new path to the construction of RLBWT. Our preliminary experiments indicate that at least a three-fold speedup and the same level of reduction in the RAM usage is possible.

The key algorithmic idea in our variant is to delay the merging of intermediate AVL grammars as much as possible to avoid creating nonterminals that are then unused in the final grammar. We dub this variant *lazy AVL grammars*. We additionally incorporate Karp–Rabin fingerprints [19] to re-write parts of the grammar on-the-fly and further reduce

¹ $\text{polylog } n = \log^c n$ for some constant $c > 0$.

the grammar size. We describe two distinct versions of this technique: greedy and optimal, and demonstrate that both lead to reductions in the grammar size. As a side-result of independent interest, we describe a fast and space-efficient data structure for the dynamic predecessor problem, in which the inserted key is always larger than all other elements currently in the set.

2 Preliminaries

Strings. For any string S , we write $S[i..j]$, where $1 \leq i, j \leq |S|$, to denote a substring of S . If $i > j$, we assume $S[i..j]$ to be the empty string ε . By $[i..j]$ we denote $[i..j-1]$. Throughout the paper, we consider a string (text) $T[1..n]$ of $n \geq 1$ symbols from an integer alphabet $\Sigma = [0..\sigma)$. By $\text{LCE}(i, i')$ we denote the length of the longest common prefix of suffixes $T[i..n]$ and $T[i'..n]$.

Karp–Rabin Fingerprints. Let q be a prime number and let $r \in [0..q)$ be chosen uniformly at random. The *Karp–Rabin fingerprint* of a string S is defined as

$$\Phi(S) = \sum_{i=1}^{|S|} S[i] \cdot r^{|S|-i} \bmod q.$$

Clearly, if $T[i..i+\ell] = T[j..j+\ell]$ then $\Phi(T[i..i+\ell]) = \Phi(T[j..j+\ell])$. On the other hand, if $T[i..i+\ell] \neq T[j..j+\ell]$ then $\Phi(T[i..i+\ell]) \neq \Phi(T[j..j+\ell])$ with probability at least $1 - \ell/q$ [9]. In our algorithm we are comparing only substrings of T of equal length. Thus, the number of different possible substring comparisons is less than n^3 , and hence for any positive constant c , we can set q to be a prime larger than n^{c+4} (but still small enough to fit in $\mathcal{O}(1)$ words) to make the fingerprint function perfect with probability at least $1 - n^{-c}$.

LZ77 Compression. An *LZ77-like factorization* of T is a factorization $T = F_1 \cdots F_f$ into non-empty *phrases* such that every phrase F_j with $|F_j| > 1$ has an earlier occurrence in T , i.e., letting $i = 1 + |F_1 \cdots F_{j-1}|$ and $\ell = |F_j|$, there exists $p \in [1..i)$ satisfying $\text{LCE}(p, i) \geq \ell$. The phrase $F_j = T[i..i+\ell]$ is encoded as a pair (p, ℓ) . If there are multiple choices for p , we choose one arbitrarily. The occurrence $T[p..p+\ell]$ is called the *source* of F_j . If $\ell = 1$, the phrase $F_j = T[i]$ is encoded as a pair $(T[i], 0)$. The LZ77-like parsing, in which we additionally require the phrase to not overlap its source, i.e., $p + \ell \leq i$, is called *non-self-referential*.

The LZ77 factorization [32] (or the LZ77 parsing) of a string T is an LZ77-like factorization constructed by greedily parsing T from left to right into longest possible phrases. More precisely, the j th phrase F_j is the longest substring starting at position $i = 1 + |F_1 \cdots F_{j-1}|$ that has an earlier occurrence in T . If there is no such substring, then $F_j = T[i]$. We denote the number of phrases in the LZ77 parsing by z . For example, the text `bbabaababababaababa` has the LZ77 parsing `b · b · a · ba · aba · bababa · ababa` with $z = 7$ phrases, and is encoded as a sequence $(b, 0), (1, 1), (a, 0), (2, 2), (3, 3), (7, 6), (10, 5)$.

Grammar Compression. A context-free grammar is a tuple $G = (N, \Sigma, R, S)$, where N is a finite set of *nonterminals*, Σ is a finite set of *terminals*, and $R \subseteq N \times (N \cup \Sigma)^*$ is a set of *rules*. We assume $N \cap \Sigma = \emptyset$ and $S \in N$. The nonterminal S is called the *starting symbol*. If $(A, \gamma) \in R$ then we write $A \rightarrow \gamma$. The *language* of G is set $L(G) \subseteq \Sigma^*$ obtained by starting with S and repeatedly replacing nonterminals with their expansions, according to R .

A grammar $G = (N, \Sigma, R, S)$ is called a *straight-line grammar* (SLG) if for any $A \in N$ there is exactly one production with A of the left side, and all nonterminals can be ordered $A_1, \dots, A_{|N|}$ such that $S = A_1$ and if $A_i \rightarrow \gamma$ then $\gamma \in (\Sigma \cup \{A_{i+1}, \dots, A_{|N|}\})^*$, i.e., the

graph of grammar rules is acyclic. The unique γ such that $A \rightarrow \gamma$ is called the *definition* of A and is denoted $\text{rhs}(A)$. In any SLG, for any $u \in (N \cup \Sigma)^*$ there exists exactly one $w \in \Sigma^*$ that can be obtained from u . We call such w the *expansion* of u , and denote it by $\text{exp}(u)$. We define the *parse tree* of $A \in N \cup \Sigma$ as a rooted ordered tree $\mathcal{T}(A)$, where each node v is associated to a symbol $\text{sym}(v) \in N \cup \Sigma$. The root of $\mathcal{T}(A)$ is a node v such that $\text{sym}(v) = A$. If $A \in \Sigma$ then v has no children. If $A \in N$ and $\text{rhs}(A) = B_1 \cdots B_k$, then v has k children and the subtree rooted at the i th child is a copy of $\mathcal{T}(B_i)$. The parse tree $\mathcal{T}(G)$ is defined as $\mathcal{T}(S)$. The *height* of any $A \in N$ is defined as the height of $\mathcal{T}(A)$, and denoted $\text{height}(A)$.

The idea of *grammar compression* is, given a text T , to compute a small SLG G such that $L(G) = \{T\}$. The *size* of the grammar is measured by the total length of all definitions, and denoted $|G| := \sum_{A \in N} |\text{rhs}(A)|$. Clearly, it is easy to encode any G in $\mathcal{O}(|G|)$ space: pick an ordering of nonterminals and write down the definitions of all nonterminals, replacing nonterminal symbols with their numbers in the order.

3 AVL Grammars and the Basic Algorithm

An SLG $G = (N, \Sigma, R, S)$ is said to be in *Chomsky normal form*, if for every $A \in N$, it holds $\text{rhs}(A) \in \Sigma$ or $\text{rhs}(A) = XY$, where $X, Y \in N$. An SLG in Chomsky normal form is called a *straight-line program* (SLP). Rytter [30] defines an *AVL grammar* as an SLP $G = (N, \Sigma, R, S)$ that additionally satisfies the *AVL property*: for every $A \in N$ such that $\text{rhs}(A) = XY$, it holds $|\text{height}(X)| - |\text{height}(Y)| \leq 1$. This condition guarantees that for every $A \in N$ (in particular for $S \in N$), it holds $\text{height}(A) = \mathcal{O}(\log |\text{exp}(A)|)$ [30, Lemma 1].

The main result presented in [30] is an algorithm that given a non-self-referential LZ77-like parsing of a length- n text T consisting of f phrases, computes in $\mathcal{O}(f \log n)$ time an AVL grammar G generating T and satisfying $|G| = \mathcal{O}(f \log n)$. Rytter's construction was extended to allow self-references in [20, Theorem 6.1]. Our implementation of the basic as well as improved Rytter's algorithm works for the self-referential variant, but for simplicity here and in Section 4 we describe the algorithm only for the non-self-referential variant.

The algorithm in [30] works in f steps. It maintains the dynamically changing AVL grammar G such that after the k th step is complete, there exists a nonterminal P_k in G such that $\text{exp}(P_k) = F_1 \cdots F_k$, where $T = F_1 \cdots F_f$ is the input LZ77-like factorization of the input. This implies that at end there exist a nonterminal expanding to T . The algorithm does not delete any nonterminals between steps. At the end, it may perform an optional pruning of the grammar to remove the nonterminals not present in the parse tree $\mathcal{T}(P_f)$. This reduces the grammar size but not the peak memory usage of the algorithm.

The algorithm uses the following three procedures, each of which adds a nonterminal A with a desired expansion $\text{exp}(A)$ to the grammar G , along with a bounded number of extra nonterminals:

1. **AddSymbol(c)**: Given $c \in \Sigma$, add a nonterminal A with $\text{rhs}(A) = c$ to the grammar G .
2. **AddMerged(X, Y)**: Given the identifiers of nonterminals X, Y existing in G , add a nonterminal A to G that satisfies $\text{exp}(A) = \text{exp}(X)\text{exp}(Y)$. The difficulty of this operation is ensuring that the updated G remains an AVL grammar. Simply setting $\text{rhs}(A) = XY$ would violate the AVL condition in most cases. Instead, the algorithm performs the procedure similar to the concatenation of AVL trees [22, p. 474], taking $\mathcal{O}(1 + |\text{height}(X) - \text{height}(Y)|)$ time, and introducing $\mathcal{O}(|\text{height}(X) - \text{height}(Y)|)$ extra nonterminals.
3. **AddSubstring(A, i, j)**: Given the identifier of a nonterminal A existing in G , and two positions satisfying $1 \leq i \leq j \leq |\text{exp}(A)|$, add a nonterminal B to G that satisfies $\text{exp}(B) = \text{exp}(A)[i..j]$. To explain how this is achieved, we define the auxiliary proce-

cedure $\text{Decompose}(A, i, j)$ that given the same parameters as above, returns the sequence B_1, \dots, B_q of nonterminals satisfying $\exp(A)[i..j] = \exp(B_1) \cdots \exp(B_q)$. The nonterminals B_i are found by performing two root-to-leaf traversals in the parse tree $\mathcal{T}(A)$. This takes $\mathcal{O}(1 + \text{height}(A)) = \mathcal{O}(1 + \log |\exp(A)|)$ time and ensures $q = \mathcal{O}(\log |\exp(A)|)$. It is easy to see that given B_1, \dots, B_q , we can now obtain B in $\mathcal{O}(1 + \log^2 |\exp(A)|)$ time using AddMerged . In [30], it was however shown that if we always choose the shortest nonterminal to merge with its neighbor, the total runtime is $\mathcal{O}(1 + \log |\exp(A)|)$ and only $\mathcal{O}(\log |\exp(A)|)$ extra nonterminals are introduced.

Using the above three procedures, the algorithm in [30] works as follows. Suppose we have already processed the leftmost $k - 1$ phrases. The step begins by creating a nonterminal A_k satisfying $\exp(A_k) = F_k$. If $|F_k| = 1$, it uses the procedure $\text{AddSymbol}(F_k)$. Otherwise, A_k is obtained as the output of $\text{AddSubstring}(P_{k-1}, p, p + \ell - 1)$, where $\ell = |F_k|$ and $T[p..p + \ell]$ is the source of phrase F_k . Finally, P_k is obtained as the output of $\text{AddMerged}(P_{k-1}, A_k)$. A single iteration thus takes $\mathcal{O}(1 + \log |F_1 \cdots F_{k-1}|) = \mathcal{O}(\log n)$ time and adds $\mathcal{O}(\log n)$ extra nonterminals, for total of $\mathcal{O}(f \log n)$ nonterminals over all steps.

4 Modified Algorithm

Lazy Merging. We start by observing that the main reason responsible for the large final grammar produced by the algorithm in Section 3 is the requirement that at the end of each step $k \in [1..f]$, there exist a nonterminal P_k satisfying $\exp(P_k) = F_1 \cdots F_k$. We relax this requirement, and instead require only that at the end of step k , there exists a sequence of nonterminals R_1, \dots, R_m such that $\exp(R_1) \cdots \exp(R_m) = F_1 \cdots F_k$. The algorithm explicitly maintains these nonterminals as a sequence of pairs $(\ell_1, R_1), \dots, (\ell_m, R_m)$, where $\ell_j = \sum_{i=1}^j |\exp(R_i)|$. The modified algorithm uses the following new procedures:

1. **MergeEnclosed**(i, j): Given two positions satisfying $1 \leq i \leq j \leq |F_1 \cdots F_{k-1}|$, add to G a nonterminal R satisfying $\exp(R) = \exp(R_x) \cdots \exp(R_y)$, where $x = \min\{t \in [1..m] : \ell_{t-1} \geq i - 1\}$ and $y = \max\{t \in [1..m] : \ell_t \leq j\}$. The positions x and y are found using a binary search. The pairs of the sequence $(\ell_1, R_1), \dots, (\ell_m, R_m)$ at positions between x and y are then removed and replaced with a pair (ℓ_y, R) . In other words, this procedure merges all the nonterminals from the current root sequence whose expansion is entirely inside the given interval $[i..j]$. Merging of R_x, \dots, R_y is performed pairwise, using the AddMerged procedure. Note, however, that there is no dependence between heights of the adjacent nonterminals (in particular, they do not form a bitonic sequence, like in the algorithm in Section 3), and moreover, their number $\hat{m} := y - x + 1$ is not bounded. To minimize the number of newly introduced nonterminals, we thus employ a greedy heuristic, that always chooses the nonterminal with the smallest height among the remaining elements, and merges it with a shorter neighbor. We use a list to keep the pointers between neighbors and a binary heap to maintain heights. The merging thus runs in $\mathcal{O}(\hat{m} \log n)$ time.
2. **DecomposeWithRoots**(i, j): Given two positions satisfying $1 \leq i \leq j \leq |F_1 \cdots F_{k-1}|$, this procedure returns a sequence of nonterminals A_1, \dots, A_q satisfying $(F_1 \cdots F_{k-1})[i..j] = \exp(A_1) \cdots \exp(A_q)$. First, it computes positions x and y , as defined in the description of MergeEnclosed above. It then returns the result of $\text{Decompose}(R_{x-1}, i - \ell_{x-2}, \ell_{x-1} - \ell_{x-2})$, followed by R_x, \dots, R_y , followed by the result of $\text{Decompose}(R_{y+1}, 1, j - \ell_y)$ (appropriately handling the boundary cases, which for clarity we ignore here). In other words, this procedure finds the sequence of nonterminals that uses as many roots from the sequence R_1, \dots, R_m , as possible, and runs the standard Decompose for the boundary roots. Letting $\hat{m} = y - x + 1$, it runs in $\mathcal{O}(\hat{m} + \log n)$ time.

Using the above additional procedures, our algorithm works as follows. Suppose that we have already processed the first $k - 1$ phrases. The step begins by computing the sequence of nonterminals A_1, \dots, A_q satisfying $\exp(A_1) \cdots \exp(A_q) = F_k$. If $|F_k| = 1$, we proceed as in Section 3. Otherwise, we first call `MergeEnclosed`($p, p + \ell - 1$), where $\ell = |F_k|$ and $T[p..p + \ell)$ is the source of F_k . The sequence A_1, \dots, A_q is then obtained as a result of `DecomposeWithRoots`($p, p + \ell - 1$). Finally, A_1, \dots, A_q , is appended to the roots sequence.

The above algorithm runs in $\mathcal{O}(f \log^2 n)$ time. To see this, note that first calling `MergeEnclosed` ensures that the output size of `DecomposeWithRoots` is $\mathcal{O}(\log n)$. Thus, each step appends only $\mathcal{O}(\log n)$ nonterminals to the roots sequence. The total time spend in `MergeEnclosed` is thus bounded by $\mathcal{O}(f \log^2 n)$, dominating the time complexity.

To prove the correctness of the modified algorithm, we need to prove that: (1) every nonterminal in the new algorithm satisfies the AVL property, and (2) after iteration $k \in [1..f]$, the invariant $\exp(R_1) \cdots \exp(R_m) = F_1 \cdots F_k$ holds. To show (1), we note that in the above algorithm, the nonterminals are only created by the `MergeEnclosed` procedure. Internally, this procedure calls `AddMerged`, which guarantees that the newly created nonterminal satisfies the AVL property (see Section 3). To show (2), we first note that, by definition, `MergeEnclosed` does not change $\exp(R_1) \cdots \exp(R_m)$ (although it may change m). The expansion of the roots sequence changes only after appending the sequence of nonterminals A_1, \dots, A_q returned by `DecomposeWithRoots`($p, p + \ell - 1$). Since $T[p..p + \ell)$ is the source of F_k , we thus have $\exp(A_1) \cdots \exp(A_q) = (F_1 \cdots F_{k-1})[p..p + \ell) = T[p..p + \ell) = F_k$.

Utilizing Karp–Rabin Fingerprints. Our second technique is designed to detect the situation in which the algorithm adds a nonterminal A to G , when there already exists some $B \in N$ such that $\exp(A) = \exp(B)$. For any $u \in (N \cup \Sigma)^*$, we define $\Phi(u) = \Phi(\exp(u))$. Let us assume that there are no collisions between fingerprints.² During the algorithm, we maintain a collection of fingerprints $\{\Phi(A) : A \in N'\}$, where $N' \subseteq N$ is some subset of nonterminals. Assume, that given a nonterminal $A \in N$, we can quickly compute $\Phi(A)$, and that given some $x \geq 0$, we can check, if there exists $B \in N'$ such that $\Phi(B) = x$. There are two places in the above algorithm (using lazy merging) where we utilize this to reduce the number of nonterminals:

1. Whenever during the greedy merge in `MergeEnclosed`, we are about to call `AddMerged` for the pair of adjacent nonterminals X and Y , we instead first compute the fingerprint $x = \Phi(XY)$ of their concatenation, and if there already exists $A \in N'$ such that $\Phi(A) = x$, we use A instead, avoiding the call to `AddMerged` and the creation of extra nonterminals.
2. Before appending the nonterminals A_1, \dots, A_q to the roots sequence at the end of the step, we check if there exists an equivalent but shorter sequence $B_1, \dots, B_{q'}$, i.e., such that $\exp(A_1) \cdots \exp(A_q) = \exp(B_1) \cdots \exp(B_{q'})$ and $q' < q$. We utilize that $q = \mathcal{O}(\log n)$, and run a quadratic algorithm (based on dynamic programming) to find the optimal (shortest) equivalent sequence. We then use that equivalent sequence in place of A_1, \dots, A_q .

Observe that the above techniques cannot be applied during `AddMerged`, as the equivalent nonterminal could have a much shorter/taller parse tree, violating the AVL property. Note also that the size and contents of N' do not affect the correctness or the time complexity of the algorithm. To determine the set N' , our implementation uses a parameter $p \in [0..1]$, which is the probability of adding A to N' , whenever a new nonterminal A is created. The value of

² Although such an assumption can be ensured with probability $1 - n^{-c}$ for any constant $c > 0$, it cannot be easily guaranteed. This turns our algorithm into a Monte Carlo randomized algorithm.

p is one of the main parameters controlling the time-space trade-off of the algorithm, as well as the size of the final grammar. To check if there exists $A \in N'$ such that $\Phi(A) = x$, for a given $x \geq 0$, we maintain a hash table that maps the values from the set $\{\Phi(A) : A \in N'\}$ to the corresponding nonterminals (each nonterminal is assigned a unique integer identifier).

5 Implementation Details

Storing Sequences. Our implementation stores many sequences, where the insertion only happens at the end (e.g., the sequence of nonterminals, which are never deleted in the algorithm). A standard approach to this is to use a *dynamic array*, which is a plain array that doubles its capacity, once it gets full. Such implementation achieves an amortized $\mathcal{O}(1)$ insertion time, but suffers from a high peak RAM usage. On all systems we tried, the reallocation call that extends the array is not in-place. Since the peak RAM usage is critical in our implementation, we implemented our own dynamic array that instead of a single allocated block, keeps a larger number of blocks (we use 32). This significantly reduces the peak RAM usage. We found the slowdown in the access-time to be negligible.

Implementation of the Roots Sequence. The roots sequence $(\ell_1, R_1), \dots, (\ell_m, R_m)$ undergoes predecessor queries, deletions (at arbitrary positions), and insertions (only at the end). Rather than using an off-the-shelf dynamic predecessor data structure (such as balanced BST), we exploit as follows the fact that insertions happen only at the end.

All roots are stored as a static sequence that only undergoes insertions at the end (using the space efficient dynamic array implementation described above). Deleted elements are marked as deleted, but remain physically in the array. The predecessor query is implemented using a binary search, with skipping of the elements marked as deleted. To ensure that the predecessor queries are efficient, we keep a counter of accesses to the deleted elements. Once it reaches the current array size, we run the “garbage collector” that scans the whole array left-to-right, and removes all the elements marked as deleted, eliminating all gaps. This way, the predecessor query is still efficient, except the complexity becomes amortized.

Computing $\Phi(A)$ and $|\text{exp}(A)|$ for $A \in N$. During the algorithm, we often need to query the value of $\Phi(A)$ for some nonterminal $A \in N$. In our implementation we utilize 64-bit fingerprints, and hence storing the value $\Phi(A)$ for every nonterminal is expensive. We thus only store $\Phi(A)$ for $A \in N$ satisfying $|\text{exp}(A)| \geq 255$. The number of such elements in N is relatively small. To compute $\Phi(A)$ for any other $A \in N$, we first obtain $\text{exp}(A)$, and then compute $\Phi(A)$ from scratch. This operation is one of the most expensive in our algorithm, and hence whenever possible we avoid doing repeated Φ queries.

As for the values $|\text{exp}(A)|$, we observe that in most cases, it fits in a single byte. Thus, we designate only a single byte, and whenever $|\text{exp}(A)| \geq 255$, we lookup $|\text{exp}(A)|$ in an array ordered by the number of nonterminal, with access implemented using binary search.

6 Experimental Results

Algorithms. We performed experiments using the following algorithms:

- Basic-AVLG, our implementation of the algorithm to convert an LZ-like parsing to an AVL grammar proposed by Rytter [30], and outlined in Section 3. Self-referential phrases are handled as in the full version of [20, Theorem 6.1]. The implementation uses space-efficient dynamic arrays described in Section 5. This implementation is our baseline.

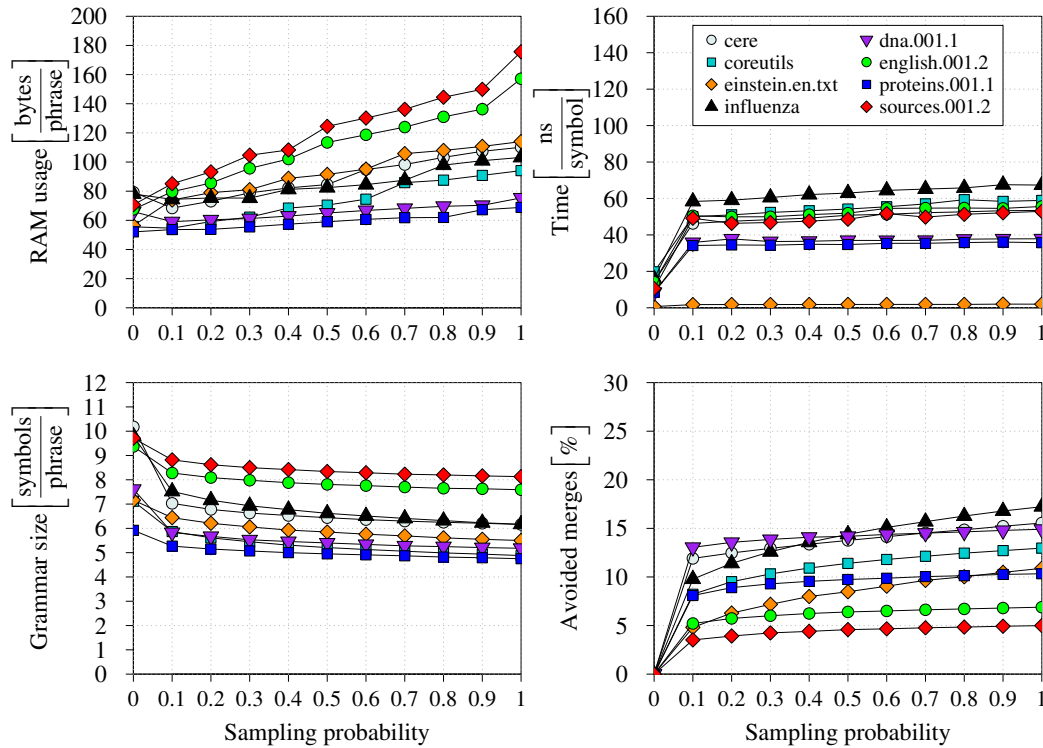

■ **Table 1** Statistics of files used in the experiments, with n denoting text length, σ denoting alphabet size, r denoting the number of runs in the BWT, and z denoting the number of phrases in the LZ77 parsing. For convenience, we also show the average BWT run length n/r and the average LZ77 phrase length n/z . Each of the symbols in the input texts is encoded using a single byte.

- Lazy-AVLG, our implementation of the improved version of Basic-AVLG, utilizing lazy merging and Karp–Rabin fingerprints, as described in Section 4. This is the main contribution of our paper. In some of the experiments below, we consider the algorithm with the different probability p of sampling the Karp–Rabin hash of a nonterminal, but our default value (as discussed below) is $p = 0.125$. Our implementation (including also Basic-AVLG) is available at <https://github.com/dominikkempa/lz77-to-slp>.
- Big-BWT, a semi-external algorithm constructing the RLBWT from the input text in $\Omega(n)$ time, proposed by Boucher et al. [4]. As shown in [4], if the input text is highly compressible, the working space of Big-BWT is sublinear in the text length. We use the implementation from <https://gitlab.com/manzai/Big-BWT>.
- Re-LZ, an external-memory algorithm due to Kosolobov et al. [24] that given a text on disk, constructs its LZ-like parsing in $\Omega(n)$ time [24]. The algorithm is faster than the currently best algorithms to compute the LZ77 parsing. In practice, the ratio f/z between the size f of the resulting parsing and the size z of the LZ77 parsing usually does not exceed 1.5. Its working space is fully tunable and can be specified arbitrarily. We use the implementation from <https://gitlab.com/dvalenzu/ReLZ>.
- Re-Pair, an $\mathcal{O}(n)$ -time algorithm to construct an SLG from the text, proposed by Larsson and Moffat [25]. Although no upper bound is known on its output size, Re-Pair produces grammars that in practice are smaller than any other grammar compression method [25]. Its main drawback is that most implementations need $\Theta(n)$ space [11], and hence are not applicable on massive datasets. The only implementation using $o(n)$ space is [23], but as authors note themselves, it is not practical. There is also work on running Re-Pair on the compressed input [31], but since it already requires the text as a grammar, it is not applicable in our case. In our experiments we therefore use Re-Pair only as a baseline for the achievable grammar size. We note that there exists recent work on optimizing Re-Pair by utilizing maximal repeats [11]. The decrease in the grammar size, however, requires a potentially more expensive nonterminal encoding that includes the length of the expansion. For simplicity, we therefore use the basic version of Re-Pair.

All implementations are in C++ and are largely sequential, allowing for a constant number of additional threads used for asynchronous I/O.

We also considered Online-RLBWT, an algorithm proposed by Ohno et al. [28], that given a text in a right-to-left streaming fashion, construct its run-length compressed BWT (RLBWT) in $\mathcal{O}(n \log r)$ time and using only $\mathcal{O}(r \log n)$ bits of working space (the implementa-

■ **Figure 1** Performance of the Lazy-AVLG algorithm for different values of the parameter p (probability of storing Karp–Rabin fingerprint in the hash table) on the files from Pizza & Chili corpus. The graphs in the top row show the normalized RAM usage (in bytes per phrase of the LZ77 parsing) and the runtime (in ns per symbols of the input text). The bottom row shows the resulting grammar size (the total length of right-hand sides of all productions) divided by z , and the percentage of merges avoided during the greedy merge procedure (in %).

tion is available from: <https://github.com/itomomoti/OnlineRlbwt>). In the preliminary experiment we determined that while using only about a third of the memory of Big-BWT (on the 16 GiB prefix of the kernel testfile), the algorithm was about 10x slower than Big-BWT. We also did not include [14], since in the preliminary experiments we found it to be slower (usually by about 5–10%) than Big-BWT, while using about 1.8x more RAM.

Experimental Platform and Datasets. We performed experiments on a machine equipped with two twelve-core 2.2 GHz Intel Xeon E5-2650v4 CPUs with 30 MiB L3 cache and 512 GiB of RAM. The machine used distributed storage achieving an I/O rate >220 MiB/s (read/write).

The OS was Linux (CentOS 7.7, 64bit) running kernel 3.10.0. All programs were compiled using g++ version 4.8.5 with `-O3 -DNDEBUG -march=native` options. All reported runtimes are wallclock (real) times. The machine had no other significant CPU tasks running. To measure the peak RAM usage of the programs we used the `/usr/bin/time -v` command.

The statistics of testfiles used in our experiments are shown in Table 1. Shorter version of files used in the scalability experiments are prefixes of full files. We used the files from the Pizza & Chili repetitive corpus available at <http://pizzachili.dcc.uchile.cl/repcorpus.html>. We chose a sample of 8 real and pseudo-real files. Since all files are relatively small (less than 512 MiB), we additionally include 2 large repetitive files:

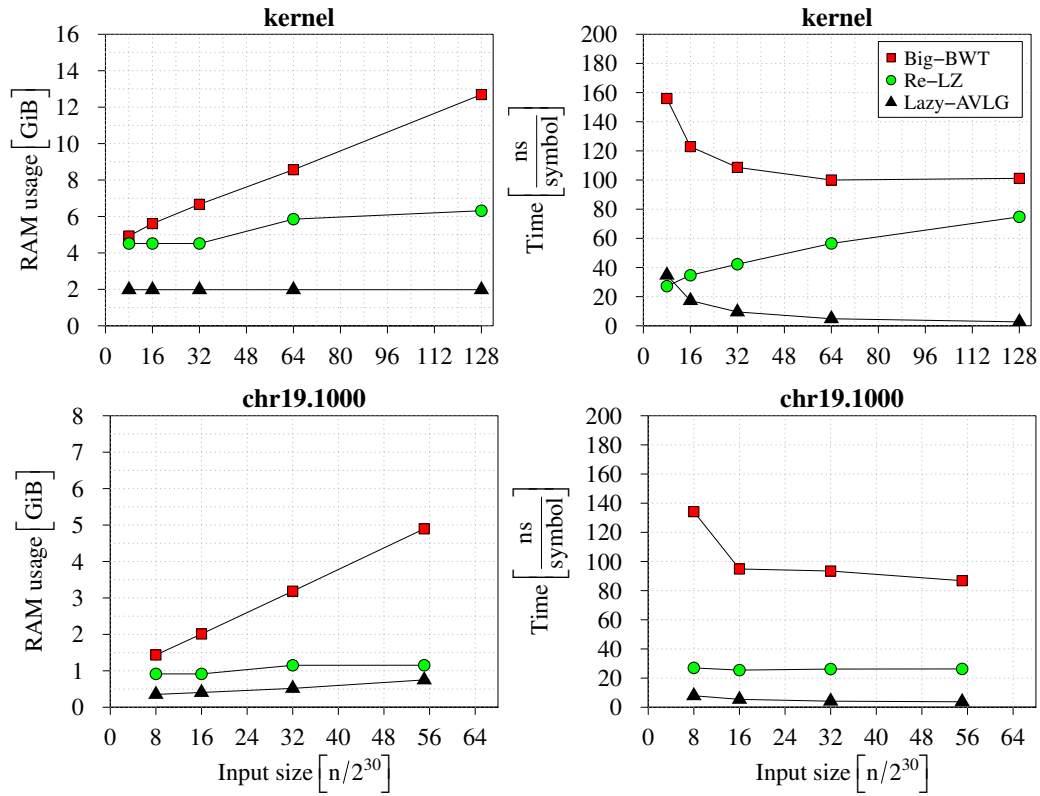

■ **Figure 2** Comparison of the size (measured as the total length of the right hand sides of all nonterminals) of grammars produced by the Basic-AVLG, Lazy-AVLG ($p = 0.125$), and Re-Pair algorithms on the files from the Pizza & Chili corpus. Basic-AVLG (pruned) denotes the size of grammar produced by Basic-AVLG with all nonterminals not reachable from the root removed. All sizes are normalized with respect to the size of the LZ77 parsing (z).

- chr19.1000, a concatenation of 1000 versions of Human chromosome 19. The sequences were obtained from the 1000 Genomes Project [8]. One copy consists of $\sim 58 \times 10^6$ symbols.
- kernel, a concatenation of ~ 10.7 million source files from over 300 versions of the Linux kernel (see <http://www.kernel.org/>).

Karp–Rabin Sampling Rate. The key parameter that controls the runtime, peak RAM usage, and the size of the grammar in our algorithm is the probability p of including the Karp–Rabin fingerprint of a nonterminal in the hash table. In our first experiment, we study the performance of the Lazy-AVLG algorithm for different values of the parameter p . We tested all values $p \in \{0, 0.1, 0.2, \dots, 1\}$ and for each we measured the algorithm’s time and memory usage, and the size of the final grammar. The results are given in Figure 1.

While utilizing the Karp–Rabin fingerprints (i.e., setting $p > 0$) can notably reduce the final grammar size (up to 40% for the *cere* file), it is not worth using values p much larger than 0.1, as it quickly increases the peak RAM usage (e.g., by about 2.3x for the *sources.001.2* testfile) and this increase is not repaid significantly in the further grammar reduction. The bottom right panel in Figure 1 provides some insight into the reason for this. It shows the percentage of cases, where during the greedy merging of nonterminals enclosed by the source of the phrase, the algorithm is able to avoid merging two nonterminals, and instead use the existing nonterminal. Having *some* fingerprints in the hash table turns out to be enough to avoid creating between 4–14% of the new nonterminals, but having more does not lead to a significant difference. We also observe that if a larger grammar is acceptable, disabling the use of Karp–Rabin fingerprints entirely (i.e., setting $p = 0$) can lead to a significant speed-up (the top right panel in Figure 1) and a small saving in the RAM usage (note, that it also makes the algorithm deterministic). We choose to use $p > 0$, however, since in our main application (BWT construction), the final grammar is subject to further processing, and since this processing may dominate the RAM usage, we prefer to keep the grammar as small as possible. Since peak RAM usage is the likely limiting factor for this algorithm – a slower algorithm is still usable, but exhaustion of RAM can prevent it running entirely – we chose $p = 0.125$ as the default value in our implementation (and use in the next two experiments).

■ **Figure 3** Scalability of Big-BWT compared to Re-LZ and Lazy-AVLG. The graphs on the right show the normalized runtime in ns/char. The graphs on the left show the RAM usage in GiB.

Grammar Size. In our second experiment, we compare the size of the grammar produced by Lazy-AVLG to Basic-AVLG and Re-Pair. In the comparison we also include the size of the grammar obtained by running Basic-AVLG and removing all nonterminals not reachable from the root. We have run the experiments on 8/10 testfiles, as running Re-Pair on the large files is prohibitively time consuming. The results are given in Figure 2.

Lazy-AVLG produces grammars that are between 1.59x and 2.64x larger than Re-Pair (1.95x on average). The resulting grammar is always at least 5x smaller than produced by Basic-AVLG, and also always smaller than Basic-AVLG (pruned). Importantly, the RAM usage of our conversion is proportional the size of the final grammar, whereas the algorithm to compute the pruned version of Basic-AVLG must first obtain the initial large grammar, increasing peak RAM usage. This is a major practical concern, as described in the next experiment. In conclusion, Lazy-AVLG compresses only slightly worse than Re-Pair, but its construction requires much less working space.

Application in the Construction of BWT. In our third experiment, we evaluate the potential of the method to construct the RLBWT presented in [20], which works by first computing/approximating the LZ77 parsing of the text in $\Omega(n)$ time, and then converting the resulting compressed representation of T into the RLBWT in $\mathcal{O}(f \text{ polylog } n)$ time (where f denotes the number of factors). We use Re-LZ to implement the first step. As for the second step, we note that the conversion from the (approximate) LZ77 to RLBWT internally consists of two steps: (2a) (approximate) LZ77 \rightarrow grammar, and (2b) grammar \rightarrow RLBWT.

In this experiment, we use Lazy-AVLG to implement step (2a). We have not implemented the step (2b), and leave it as a future work. The results reported here are therefore only a preliminary indication of what is achievable with the approach of [20]. Our baseline for the construction of RLBWT is the Big-BWT algorithm [4].

We evaluated the runtime and peak RAM usage of Big-BWT, Re-LZ, and Lazy-AVLG with $p = 0.125$ (the default value) on successively longer prefixes of the large testfiles (chr19.1000 and kernel). The RAM use of Re-LZ was set to match the RAM use of Big-BWT on the shortest prefix we tried. To allow a comparison with different methods in the future, we evaluated Lazy-AVLG on the LZ77 parsing rather than on the output of Re-LZ. Thus, to obtain the performance of the pipeline Re-LZ + Lazy-AVLG, one should multiply the runtime and RAM usage of Lazy-AVLG by the approximation ratio f/z of Re-LZ. The value f/z did not exceed 1.05 on any of the kernel prefixes, and 1.27 on any of the chr19.1000 prefixes (with the peak reached on the largest prefixes). This puts the RAM use of Lazy-AVLG on the output of Re-LZ still below that of Re-LZ. The results are given in Figure 3.

The runtime of Re-LZ is always below that of Big-BWT. The reduction is by a factor of at least three for all prefixes of chr19.1000, and by at least 25% for all prefixes of kernel. The runtime of Lazy-AVLG stays significantly below that of both other methods. Importantly, this also holds for Lazy-AVLG's peak RAM usage. Given these results, we conclude that the construction of the RLBWT via LZ parsing has the potential to achieve at least a three-fold speedup and reduction in the RAM usage. We also point out that the construction of RLBWT has received much attention in recent years, whereas the practical approximation of LZ77 is a relatively unexplored topic, and hence significant speedup may be possible, e.g., via parallelization. The intuition for this is that, unlike in the case of BWT construction, LZ approximation algorithms need not be exact.

Convex Drawings of Hierarchical Graphs in Linear Time, with Applications to Planar Graph Morphing*

Boris Klemz 

Universität Würzburg, Germany

Abstract

A hierarchical plane st-graph H can be thought of as a combinatorial description of a planar drawing Γ of a 2-connected graph G in which each edge is a y -monotone curve and each face encloses a y -monotone region (that is, a region whose intersection with any horizontal line is a line segment, a point, or empty). A drawing Γ' of H is a drawing of G such that each horizontal line intersects the same left-to-right order of edges and vertices in Γ and Γ' , that is, the underlying hierarchical plane st-graph of both drawings is H . A straight-line planar drawing of a graph is convex if the boundary of each face is realized as a convex polygon.

We study the computation of convex drawings of hierarchical plane st-graphs such that the outer face is realized as a prescribed polygon. Chrobak, Goodrich, and Tamassia [SoCG'96] and, independently, Kleist et al. [CGTA'19] described an idea to solve this problem in $\mathcal{O}(n^{1.1865})$ time, where n is the number of vertices of the graph. Also independently, Hong and Nagamochi [J. Discrete Algorithms'10] described a completely different approach, which can be executed in $\mathcal{O}(n^2)$ time.

In this paper, we present an optimal $\mathcal{O}(n)$ time algorithm to solve the above problem, thereby improving the previous results by Chrobak, Goodrich, and Tamassia, Kleist et al., and by Hong and Nagamochi. Our result has applications in graph morphing. A planar morph is a continuous deformation of a graph drawing that preserves straight-line planarity. We show that our algorithm can be used as a drop-in replacement to speed up a procedure by Alamdari et al. [SICOMP'17] to morph between any two given straight-line planar drawings of the same plane graph. The running time improves from $\mathcal{O}(n^{2.1865})$ to $\mathcal{O}(n^2 \log n)$. To obtain our results, we devise a new strategy for computing so-called archfree paths in hierarchical plane st-graphs, which might be of independent interest.

1 Introduction

A *y-monotone* drawing Γ is a planar drawing of a 2-connected planar graph $G = (V, E)$ where each edge is realized as a *y-monotone* curve and the boundary of each face encloses a *y-monotone* region, that is, a region whose intersection with any horizontal line is a line segment, a point, or empty; for an illustration see Figure 1. Due to the *y-monotone* edges, the drawing Γ uniquely determines for each $v \in V$ (1) the *y*-coordinate $y(v)$ of v , (2) a left-to-right ordering of the edges incident to v that have an endpoint with a *y*-coordinate larger than $y(v)$, and (3) a left-to-right ordering of the edges incident to v that have an endpoint with a *y*-coordinate smaller than $y(v)$. A plane graph is a combinatorial description of a planar drawing of a graph that consists of the graph equipped with the so-called combinatorial embedding of the drawing and a distinguished outer face. Similarly, the underlying *hierarchical plane st-graph* H of Γ is a combinatorial description of the *y-monotone* drawing Γ that consists of G equipped with the above information (Items (1)–(3)) for each vertex. A *drawing* Γ' of H is a *y-monotone* drawing of G whose underlying hierarchical plane st-graph is H . A planar straight-line drawing of a graph is called *convex* if the boundary of each face is realized as a simple convex polygon.

This paper is concerned with the computation of convex drawings of hierarchical plane st-graphs such that the outer face is realized as a prescribed polygon that is, in some sense, compatible with the given graph; for an illustration see Figure 1. A plane graph admits a convex drawing if and only if it is a subdivision of an internally 3-connected graph. Hence, we will assume that our input graphs satisfy this property.

The above problem has applications in graph morphing, as we will discuss next.

Applications. A (*planar*) *morph* is a continuous deformation of a graph drawing that preserves straight-line edges (and planarity) at all times. Graph morphing is motivated by applications in animation and computer graphics [17]. In computational morphing problems, one typically seeks “piece-wise linear” morphs, which are composed of a number of linear morphing steps. In a *linear* morph, each vertex moves along a line segment at constant speed (which depends on the length of the segment) such that it arrives at its final position at the end of the morph. Such a morph is uniquely defined by specifying the initial and the final drawing. Hence, a morph composed of k linear morphs can be efficiently encoded as a sequence of $k + 1$ drawings.

Algorithms to compute convex drawings of hierarchical plane st-graphs such that the outer face is realized as a prescribed polygon serve as a subroutine in several graph morphing algorithms [2, 22, 7, 27, 6]. The key observation is that the linear morph from a *y-monotone* straight-line drawing to a convex drawing of its underlying hierarchical plane st-graph is planar, which is not difficult to prove due to the fact that its vertex trajectories are parallel lines [2]; a linear morph with this property is called *unidirectional*. The restriction to *y-monotone* drawings might seem limiting at first. However, the observation is also useful in a more general context: let Γ be a straight-line planar drawing. Let Γ' be a *y-monotone* augmentation of Γ created by adding a set A of *y-monotone* (but not necessarily straight-line) edges. Finally, let Γ'' be a convex drawing of the underlying hierarchical plane st-graph of Γ' . Then the linear morph from Γ to $\Gamma'' \setminus A$ is also planar [22]. Note that all angles of face boundaries in $\Gamma'' \setminus A$ that were not subdivided by edges of A are convex. In this sense, $\Gamma'' \setminus A$ is a simplified version of Γ , which can be exploited algorithmically. We will illustrate this by discussing an explicit example.

One of the most basic tasks in graph morphing is the computation of a planar morph (composed of linear morphing steps) between two given straight-line planar drawings Γ_1, Γ_2 of the same plane graph G . Alamdari et al. [2] described an algorithm to compute such a morph consisting of a linear number of unidirectional steps. They provide a reduction to show that it suffices to consider the case that Γ_1, Γ_2 , and G are triangulated. For triangulations, the idea is as follows: find a suitable edge $e = \{u, v\}$ shrink it to a point in both drawings, thereby contracting the edge e in G to a new vertex w . Then, recursively compute a morph \mathcal{M} of the reduced graph. Finally, turn the thereby obtained “pseudomorph” of G into an actual morph by placing u and v very close to the position of w in each of the drawings encoding \mathcal{M} . To find an edge e that can be contracted without violating planarity in either drawing, proceed as follows: let u be an internal vertex with $\deg_G(u) \leq 5$. If the polygon defined by the neighbors of u is convex in both Γ_1 and Γ_2 , then u can be contracted towards the same neighbor in both drawings. If this is not the case, the polygon (or some specific angle) can be made convex using the strategy described in the preceding paragraph.

In other types of morphing problems, the task is to compute planar morphs between two given drawings while maintaining additional properties such as convexity [7] or upward-planarity [27], or planar morphs that transform a given drawing in order to achieve a certain property while being in some sense monotonic [1, 22, 11]. Very recently, the problem of morphing graphs was also studied on the torus [9].

We remark that the computation of convex drawings of hierarchical plane st-graphs with a prescribed polygon as the outer face also plays a role when embedding polyhedral graphs in \mathbb{R}^3 with a good vertex resolution [10, 29]. The idea is to first find a convex drawing in the plane where the vertices are placed at, suitably chosen, prescribed small integer y -coordinates. The drawing is then lifted to \mathbb{R}^3 . However, to ensure this strategy can be carried out, the constructed plane drawings are also required to be embeddings with so-called equilibrium stress – the drawings created by the algorithm presented in this paper do not guarantee this property.

Previous algorithms. An idea for constructing convex drawings of hierarchical plane st-graphs with a prescribed polygon as the outer face was described already in 1996 by Chrobak, Goodrich, and Tamassia [10, Section 3] (in the context of realizing polyhedral graphs in \mathbb{R}^3); also see [29, Section 4]. The approach was independently rediscovered by Kleist et al. [22] (in the context of a morphing problem) and is based on using Tutte’s well-known spring theorem [32, 15, 16]. The main idea is to precompute barycenter weights that force the vertices to lie at the prescribed y -coordinates before applying Tutte’s algorithm, which then finds suitable x -coordinates. (Notably, the way in which the barycenter weights are determined in [22] is quite different from the method used in [10] and [29].) Chrobak et al. point out that the approach can be implemented in $\mathcal{O}(n^{\omega/2} + n \log n) \subseteq \mathcal{O}(n^{1.1865})$ time by using the generalized nested dissection method [25, 26, 4], where n is the number of vertices of the graph and $\omega < 2.37286$ [3, 24] denotes the matrix multiplication exponent.

In 2010, Hong and Nagamochi [20] described a completely different approach, based on a recursive combinatorial construction. The runtime of their algorithm is $\mathcal{O}(n^2)$. The idea is to choose a suitable internal vertex y of the given graph G and compute three disjoint (except for y) paths from y to the outer face, see Figure 2a. These paths dissect G into three regions, which are then handled recursively. The outer face of each of the three regions is composed of two of the three paths, which are prescribed to be realized as straight-line segments, and a part of the original prescribed polygon, see Figure 2b. To ensure that the thereby described polygon can be extended to a convex drawing of the entire region, the computed paths need to be *archfree*, meaning that they are not *arched* by an internal face. A path P is arched by

a face f if P contains two distinct vertices a, b that belong to the boundary of f such that the subpath P_{ab} of P between a and b is not a subpath of the boundary of f , see Figure 2c. Indeed, such a path P cannot be realized as a straight-line segment in a convex drawing since in this case the interior of the segment ab has to be disjoint from the realization of f .

■ **Figure 2** (a–b) The idea of Hong and Nagamochi’s [20] construction. (c) The path $P = (x, \dots, y)$ is arched by a face f .

We remark that Chrobak et al.’s result [10] does not appear to be widely known: the morphing papers [2, 7, 27, 6, 22] only refer to the method by Hong and Nagamochi [20]. Moreover, Hong and Nagamochi [20] and Kleist et al. [22] were also unaware of its existence.

Other related work. Pach and Tóth [28] and Eades, Feng, Lin, and Nagamochi [14] studied the problem of finding (not necessarily convex) straight-line drawings of *hierarchical plane graphs*, which can be defined as hierarchical plane *st*-graphs, except that they describe (not necessarily *y*-monotone) planar drawings in which each edge is realized as a *y*-monotone curve. Eades et al. [14] provide a linear-time algorithm for this problem that realizes the outer face as a prescribed polygon.

A graph in which each vertex is equipped with a *y*-coordinate is sometimes called a *level graph*. The central question in the LEVEL PLANARITY [13, 18, 21] problem and its many variants [5, 8, 23] is to decide whether a given level graph admits a *level planar drawing*, that is, a planar drawing in which each vertex is placed at its prescribed *y*-coordinate and each edge is realized as a *y*-monotone curve. By definition, the underlying level graph of each hierarchical plane (st-)graph admits a level planar drawing.

Contribution and organization. In Section 4, we describe an optimal linear-time algorithm for constructing convex drawings of hierarchical plane st-graphs with a prescribed polygon as the outer face (if possible), thereby improving the previous approaches by Chrobak, Goodrich, and Tamassia [10], Kleist et al. [22], and Hong and Nagamochi [20].

► **Theorem 1.** *There exists an algorithm that, given a subdivision $G = (V, E)$ of an internally 3-connected hierarchical plane st-graph and a convex polygon Γ^o that is compatible with G , computes a convex drawing of G with Γ^o as the realization of the outer face in time $\mathcal{O}(n)$ where $n = |V|$.*

We introduce our notation and terminology (including the definitions of compatible polygons and internally 3-connected graphs) and the assumed data structures in Section 2.

To obtain Theorem 1, we follow the idea of the recursive combinatorial construction by Hong and Nagamochi [20]. We observe that the main bottleneck in Hong and Nagamochi’s algorithm is the computation of archfree paths to the boundary: Hong and Nagamochi obtain

such a path by computing an arbitrary y -monotone path P which is then modified to obtain an archfree path P' . In general, not all vertices of P belong to P' . Hence, a given vertex may be involved in the archfree path computation on multiple layers of the recursion. Since the recursion depth can be linear, the overall runtime of their algorithm is quadratic. In Section 3, we describe a new efficient algorithm to obtain archfree paths in a more direct way: the running time of our approach is linear in the sum of the degrees of the internal vertices visited by the computed path. With this tool at hand, the layers of the recursion become, in a sense, disjoint (since archfree paths computed on distinct layers of the recursion are disjoint). This lets us carry out the algorithm corresponding to Theorem 1 in linear time.

► **Theorem 2.** *There exists an algorithm that, given an internally 3-connected hierarchical plane st-graph G and (a pointer to) an internal vertex y of G , computes an archfree directed path P_{yz} from y to some outer vertex z of G such that all vertices of P_{yz} except for z are internal vertices of G in time $\mathcal{O}(\sum_{i \in V(P_{yz}) \setminus \{z\}} \deg_G^+(i))$.*

Alamdari et al. state in [2] that their morphing algorithm, which was already mentioned above, can be executed in time $\mathcal{O}(n^3)$. It uses Hong and Nagamochi's [20] algorithm for constructing convex drawings of hierarchical plane st-graphs as a blackbox with running time $\mathcal{O}(n^2)$. Kleist et al. [22] observed that by replacing the contents of this blackbox with an algorithm based on Tutte's theorem (as described by Chrobak et al. [10]), the running time can be improved to $\mathcal{O}(n^{1+\omega/2} + n^2 \log n) \subseteq \mathcal{O}(n^{2.1865})$. By plugging in Theorem 1 instead, we further improve the running time to $\mathcal{O}(n^2 \log n)$. In fact, if the graph is 2-connected, the running time can be improved to $\mathcal{O}(n^2)$. [2, Theorem 1.1] and [22, Theorem 2] become:

► **Theorem 3.** *There exists an algorithm that, given two straight-line planar drawings of the same n -vertex plane graph G , computes a planar morph between the two drawings that consists of $\mathcal{O}(n)$ unidirectional morphs in time $\mathcal{O}(n^2 \log n)$, and in time $\mathcal{O}(n^2)$ if G is 2-connected.*

Alamdari et al. [2] proved that the number of linear morphing steps to morph between two planar straight-line drawings of a path is bounded by $\Omega(n)$. This bound easily extends to the 2-connected case [22, Theorem 3]. Recall that a linear morph is uniquely defined by the initial and the final drawing. Hence, a natural way to encode a morph composed of k linear morphing steps is to provide a list of $k + 1$ drawings. Since the size of each drawing is $\Omega(n)$, the $\Omega(n)$ bound for the number of morphing steps implies an output complexity of $\Omega(n^2)$ when the morph is assumed to be encoded in this fashion. Hence, in this model, Theorem 3 is near-optimal, and optimal in the 2-connected case. It is an interesting question whether allowing some sort of implicit encoding can lead to better running times.

It seems likely that a similar running time improvement can be obtained for other morphing algorithms (such as the ones stated in [22, 7, 27]), though, we have not analyzed the respective running times in detail yet. We believe that Theorem 3 might be a useful tool for designing morphing algorithms in the future.

2 Terminology, data structures, and preliminary results

All graphs in this paper are simple, that is, we do not allow parallel edges or self-loops. Let $G = (V, E)$ be a graph. We denote by $V(G) = V$ the vertex set and by $E(G) = E$ the edge set of G . Assume that G is planar and let Γ be a planar drawing of G . The boundary of each face f of G can be uniquely described by a counterclockwise sequence of edges, or multiple such sequences if G is disconnected. In the connected case, we use ∂f to denote the boundary of f . If G is 2-connected, then ∂f is a *simple* cycle (otherwise, ∂f can visit vertices

and edges multiple times). The drawing Γ determines a circular ordering of the neighbors of each vertex. The set of these orderings together with the set of face boundaries is called the *combinatorial embedding* of Γ . Two drawings of G may have the same combinatorial embedding, but different outer faces. A *plane* graph is a planar graph equipped with a combinatorial embedding and a distinguished outer face. A plane graph can be efficiently encoded and traversed by means of the well-known *doubly connected edge list* (DCEL) [12].

Let H be a hierarchical plane st-graph. We consider each edge of H to be directed from its lower to its higher endpoint. Note that H has a unique source and sink, which belong to the outer face. Moreover, the boundary of each face of H has a unique source and sink. We refer to this as the *st-property* of H . For a face f of H , we define its *peak*, denoted by $\text{peak}(f)$, to be the y -coordinate of its sink. The *valley* of f , denoted by $\text{valley}(f)$, is the y -coordinate of its source. Let $v \in V(H)$ such that v is not the source or sink of H . There is a natural partition of the faces incident to v : a face with two out-edges of v on its boundary is called an *up-face* of v . Similarly, a face with two in-edges of v on its boundary is called a *down-face* of v . The unique *left-face* of v has the left-most out-edge and the left-most in-edge of v on its boundary. The *right-face* of v is defined analogously. Moreover, we refer to the collection of the left-, right-, and up-faces of v as its *out-faces*, and to the collection of the left-, right-, and down-faces of v as its *in-faces*. The left-to-right ordering of the out-edges (in-edges) of H uniquely determines a left-to-right ordering of the out-faces (in-faces) of H . A hierarchical plane st-graph can be encoded and traversed by means of a slightly augmented DCEL: for each vertex, one simply has to add its y -coordinate and a pointer to its left-most out-edge (except for the sink) and a pointer to its right-most in-edge (except for the source). This augmented DCEL is easily preprocessed in linear time to obtain the peak and valley of each face. Hence, we may assume that each face is equipped with these values. Moreover, we may assume (again via preprocessing in linear time) that the vertices of the outer face are marked, so that it is possible in $\mathcal{O}(1)$ time to test whether a given vertex is external or internal. All hierarchical plane st-graphs in this paper are assumed to be represented by means of this data structure.

We say that an angle is *convex* if it is at most π and *reflex* if it exceeds π . In a *convex* polygon, each internal angle is convex. Recall that a planar straight-line drawing of a graph is called *convex* if the boundary of each face is realized as a simple convex polygon. A *side* of a simple convex polygon is a maximal straight-line segment in its boundary, i.e., a maximal sequence of collinear edges. It is well known that a planar graph admits a convex drawing if and only if it is a subdivision of an *internally 3-connected* graph [31, 30, 20, 19]. There are multiple well-known equivalent definitions of this property. Each of them provides a different perspective on the concept and it will be convenient to refer to all of them. Hence, we define internal 3-connectivity in form of a characterization; a proof of the equivalence of the three properties can be found in [22].

► **Definition 4.** Let G be a plane 2-connected graph and let f_o denote its outer face. Then G is called *internally 3-connected* if and only if the following equivalent statements are satisfied:

- (11) Inserting a new vertex v in f_o and adding edges between v and all vertices of f_o results in a 3-connected graph.
- (12) From each internal vertex w of G there exist three paths to f_o that are pairwise disjoint except for the common vertex w .
- (13) Every separation pair u, v of G is external, meaning that u and v lie on f_o and every connected component of the subgraph of G induced by $V(G) \setminus \{u, v\}$ contains a vertex of f_o .

Let G be a plane graph and Γ° be a convex drawing of the boundary of the outer face of G . Even if G is internally 3-connected, the drawing Γ° cannot necessarily be extended to a convex drawing of G . Recall that a path P of G is *arched* by a face f of G if there exist two distinct vertices $a, b \in V(P) \cap V(\partial f)$ such that the subpath of P between a and b is not a subpath of ∂f , see Figure 2c. Moreover, P is called *archfree* if it is not arched by an internal face of G . The drawing Γ° can be extended to a convex drawing of G if and only if G is a subdivision of an internally 3-connected graph and each side of Γ° corresponds to an archfree path of G [31, 30, 20, 19]. Hong and Nagamochi [20] showed that this characterization carries over to hierarchical graphs: let H be a hierarchical plane st-graph and Λ° be a convex drawing of the restriction of H to the boundary of its outer face. If each side of Λ° corresponds to an archfree path of H , we call Λ° *compatible* with H . The drawing Λ° can be extended to a convex drawing of H if and only if H is a subdivision of an internally 3-connected graph and Λ° is compatible with H [20]. Hong and Nagamochi also proved the following lemma.

► **Lemma 5** ([20, Lemma 1]). *Let G be an internally 3-connected plane graph and let f be an internal face of G . Any subpath P of ∂f with $|E(P)| \leq |E(\partial f)| - 2$ is archfree.*

3 Computing archfree paths efficiently

In this section, we prove Theorem 2, that is, we describe our algorithm for computing archfree paths in internally 3-connected hierarchical plane st-graphs. In fact, we prove the following generalization of Theorem 2, which gives us the freedom to influence the choice of the first edge of the computed path. This aspect will be useful in our algorithm to create convex drawings of hierarchical plane st-graphs.

► **Theorem 6.** *There exists an algorithm that, given an internally 3-connected hierarchical plane st-graph G and (a pointer to) an internal vertex y of G , computes an archfree directed path P_{yz} from y to some outer vertex z of G such that all vertices of P_{yz} except for z are internal vertices of G in time $\mathcal{O}(\sum_{i \in V(P_{yz}) \setminus \{z\}} \deg_G^+(i))$.*

Moreover, the choice of the first edge (y, u) of P_{yz} may be influenced as follows: let F_y be the set of out-faces of y , let $k_y = \max_{g \in F_y} \{\text{peak}(g)\}$, and let $K_y = \{g \in F \mid \text{peak}(g) = k\}$. We may choose (y, u) to be the left-most out-edge of y that is incident to the right-most out-face in K_y ; or the right-most out-edge of y that is incident to the left-most out-face in K_y .

Proof. In the following, we describe the idea of our algorithm; for a full pseudocode version, see Algorithm 1. Suppose we have already computed a directed path P from y to some vertex v such that all vertices of P are internal (initially $v = y$). We will extend P by appending an out-edge e' of v that is incident to an out-face of v with maximum peak, for an illustration see Figure 3. More precisely, let F be the set of out-faces of v , let $k = \max_{g \in F} \{\text{peak}(g)\}$, and, finally, let $K = \{g \in F \mid \text{peak}(g) = k\}$.

(R1) We extend P by appending an out-edge e' of v that is incident to a face $f' \in K$.

At each edge of our path, we store a pointer to the face that was the reason why the edge was chosen, i.e., we *associate* the edge e' with the face f' .

In general, the choice of e' and f' according to Rule (R1) is not unique (see Figure 3), and computing a path while exclusively relying on Rule (R1) does not necessarily lead to an archfree result. We introduce two tiebreaking rules that specialize Rule (R1). Assume for now that $v \neq y$ and let e be the edge of P whose head is v . Let f be the face that is associated with e .

■ **Algorithm 1** The procedure corresponding to Theorem 6.

input : an internally 3-connected hierarchical plane st-graph G
 an internal vertex y of G
 $d \in \{L, R\} \triangleright$ initial associated direction

output : a directed archfree path P_{yz} from y to an outer vertex z of G such that all vertices of P_{yz} except z are internal vertices of G

$v \leftarrow y \triangleright$ The endpoint of our current path P ,
 $P \leftarrow \emptyset \triangleright$ whose list of edges is initially empty.
 $e \leftarrow \text{nil} \triangleright$ The edge that was most recently appended to P
 $f \leftarrow \text{nil} \triangleright$ and the face associated with it.
 $D \leftarrow d \triangleright$ The direction currently associated with P

while true **do**

- \triangleright Let F be the set of out-faces of v
- $k \leftarrow \max_{g \in F} \{\text{peak}(g)\}$
- $K \leftarrow \{g \in F \mid \text{peak}(g) = k\}$
- if** $f \neq \text{nil}$ **and additionally** $\text{peak}(f) = k$ **then**
 - $\mid e \leftarrow$ the unique edge of ∂f with tail v
- else** $\triangleright f = \text{nil}$; or $f \neq \text{nil}$ and additionally $\text{peak}(f) < k$
 - if** $D = L$ **then**
 - $\mid f \leftarrow$ the right-most face in K
 - $\mid e \leftarrow$ the left-most out-edge of v that belongs to ∂f
 - else** $\triangleright D = R$
 - $\mid f \leftarrow$ the left-most face in K
 - $\mid e \leftarrow$ the right-most out-edge of v that belongs to ∂f
- append e to P
- $v \leftarrow \text{head}(e)$
- if** f is to the left of e **then**
 - $\mid D \leftarrow L$
- else** $\triangleright f$ is to the right of e
 - $\mid D \leftarrow R$
- if** v belongs to the outer face of G **then**
 - \mid **return** P

(R2) If $v \neq y$ and $f \in K$, we choose $f' = f$ and e' to be the unique out-edge of v that is incident to f .

In other words, we continue to follow the boundary of a face f until we encounter a vertex v incident to a face with strictly larger peak, see Figure 3a.

It remains to discuss the case where the preconditions of Rule (R2) are not satisfied. We associate a direction $D \in \{L, R\}$ with P , namely, $D = L$ if f is to the left of e , and $D = R$ otherwise. Whenever we switch from f to a new face, we also try to switch the direction associated with our path if possible. That is, if $D = L$, we try to choose f' and e' such that f' is to the right of e' , see Figure 3b. Note that this is impossible if and only if $|K| = 1$ and the unique face $f' \in K$ is the left-face of v , see Figure 3c. Symmetrically, if $D = R$, we try to choose f' and e' such that f' is to the left of e' , which is impossible if and only

Figure 3 The choices of (e', f') made according to Rule (R1) are sometimes unique (c), but in general they are not (a–b). (a) Unique choice of (e', f') according to Rule (R2). (b–c) Unique choice of (e', f') according to Rule (R3). In (c) it is not possible to switch the direction of the path.

if $|K| = 1$ and the unique $f' \in K$ is the right-face of v . In general, this choice of f' and e' is still not unique. Whenever there are multiple options, we choose f' and e' such that if $D = L$ ($D = R$), the face f' is the right-most (left-most) out-face of v such that the above properties are satisfied, see Figure 3b. To streamline the algorithm, the initial path, where $v = y$ (and, hence, f is undefined), is also associated with a direction L or R . This initial direction may be freely chosen. The following rule realizes the strategy discussed in this paragraph:

(R3) If $v = y$ or $f \notin K$, our choice of f' and e' depends on D : if $D = L$ ($D = R$), we choose f' to be the right-most (left-most) face in K and e' to be the left-most (right-most) out-edge of v that belongs to $\partial f'$.

Indeed, whenever we switch to a new face $f' \neq f$, Rule (R3) ensures that the direction associated with the path is switched if possible:

▷ **Claim 7.** If $D = L$ ($D = R$) and f' and e' are chosen according to Rule (R3), then f' is to the right (left) of e' , unless $|K| = 1$ and the unique $f' \in K$ is the left-face (right-face) of v .

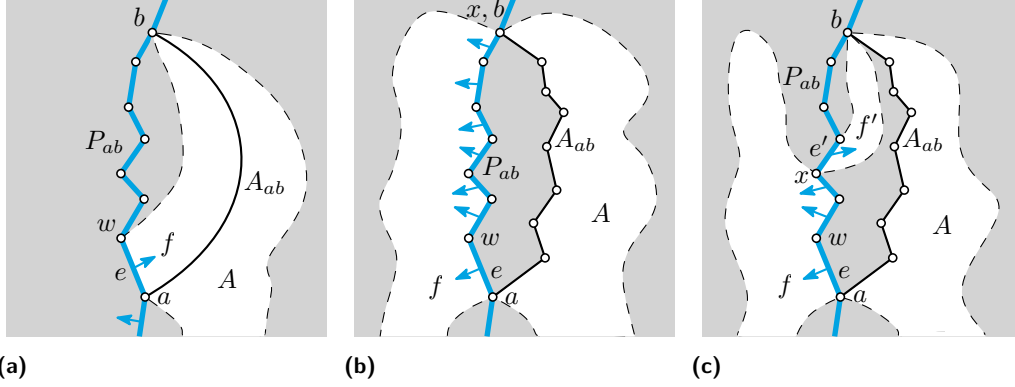

Correctness. Since G has the st-property, Algorithm 1 terminates with a directed path P_{yz} from y to some outer vertex z of G such that all vertices of P except for z are internal vertices of G . Since the initial direction may be freely chosen, Rule (R3) guarantees the choice of the first edge of P_{yz} as described in the statement of the theorem.

It remains to show that P_{yz} is archfree. To the contrary, assume that P_{yz} is arched by a face A . Without loss of generality, we may assume that A is to the right of P_{yz} . This implies the existence of a directed subpath A_{ab} of the left boundary of A that starts at a vertex $a \in V(P_{yz})$, ends at a vertex $b \in V(P_{yz})$ with $b \neq a$, and is interior-disjoint from P_{yz} . Let P_{ab} denote the subpath of P_{yz} that leads from a to b . Let C_{ab} denote the simple cycle formed by P_{ab} and A_{ab} in the underlying undirected graph of G .

In a plane 2-connected graph, every edge belongs to the boundary of at least one internal face. Consequently, Lemma 5 implies that in internally 3-connected graphs every path of length 1 is archfree (since each face is bounded by at least three edges). Since G is internally 3-connected, it follows that $|E(P_{ab})| \geq 2$. Let $e = (a, w)$ denote the unique out-edge of a that belongs to P_{ab} (where $w \neq b$ since $|P_{ab}| \geq 2$). Let f denote the face associated with e . By the definition of A_{ab} , we have $f \neq A$. The face f can be either to the left or the right of e . Accordingly, we distinguish two cases.

Case 1: f is to the right of e . For an illustration see Figure 4a. This implies that f is interior to the cycle C_{ab} . Consequently, we have $\text{peak}(f) \leq \text{peak}(A)$. Moreover, by Rule (R1), we have $\text{peak}(f) = \text{peak}(A)$ since both A and f are out-faces of a . From the fact that f is

interior to the cycle C_{ab} , we can also conclude that a is the (unique) source of f . Therefore, the face f and the edge e were chosen according to Rule (R3) (rather than Rule (R2)). Due to the fact that $\text{peak}(f) = \text{peak}(A)$, Claim 7 implies that the direction associated with the subpath P_{ya} of P_{yz} from y to a is L . Consequently, Rule (R3) implies that f is the right-most out-face of v whose peak is $\text{peak}(f)$ ($= \text{peak}(A)$). We obtain a contradiction to the fact that A is to the right of f . \triangleleft

■ **Figure 4** (a) Case 1 and (b–c) Case 2 in the proof of Theorem 6.

Case 2: f is to the left of e . Let P_{ax} denote the unique maximal subpath of P_{ab} such that all edges of P_{ax} are associated with f .

To the contrary, assume that the endpoint $x \neq a$ of P_{ax} is b ; for an illustration see Figure 4b. It follows that a and b form a separator in G that separates w (and all other vertices in the closed interior of C_{ab} except for a and b) from the outer vertices of G . Consequently, a and b form a nonexternal separation pair; a contradiction to the internal 3-connectivity of G . Therefore, we have $x \neq b$.

Let e' denote the unique out-edge of x that belongs to P_{ab} ; for an illustration see Figure 4c. By Rule (R2), the edge e' is associated with a face f' such that $\text{peak}(f') > \text{peak}(f)$. Therefore, face f' and edge e' were chosen according to Rule (R3). Since f is to the left of e , each edge of P_{ax} has f to its left. Therefore the direction associated with the subpath P_{yx} of P_{yz} from y to x is L . By Rule (R1) applied to a , we have $\text{peak}(f) \geq \text{peak}(A)$. Moreover, we have $\text{peak}(A) > y(x)$ since $x \neq b$. Consequently, $\text{peak}(f) > y(x)$, which implies that f is the left-face of x . Therefore, by Claim 7, the face f' is to the right of e' . This implies that f' is interior to C_{ab} and, consequently, $\text{peak}(f') \leq \text{peak}(A)$. Altogether, we have $\text{peak}(f) < \text{peak}(f') \leq \text{peak}(A) \leq \text{peak}(f)$; a contradiction. \triangleleft

Running time. The claimed running time of $\mathcal{O}(\sum_{i \in V(P_{yz}) \setminus \{z\}} \deg_G^+(i))$ of Algorithm 1 is easy to achieve: the initialization takes $\mathcal{O}(1)$ time. The while loop is executed once for each vertex of P_{yz} that is an internal vertex of G . For each vertex v , the quantity k can be computed in time $\mathcal{O}(\deg_G^+(v))$ by sweeping the linear sequence of out-faces of v once. With a second sweep of the sequence, we can then determine in time $\mathcal{O}(\deg_G^+(v))$ the set K . Actually, it suffices to remember the left-most and the right-most out-face in K . With this information, the remaining lines in the while loop can be executed in time $\mathcal{O}(1)$. \blacktriangleleft

4 Computing convex drawings of hierarchical graphs in linear time

In this section, we describe our $\mathcal{O}(n)$ -time algorithm to create a convex drawing of a hierarchical plane st-graph. We follow the idea of the recursive combinatorial construction by Hong and Nagamochi [20]. As discussed in Section 1, the main improvement comes from using Theorem 6 to compute archfree paths. We also need to make some changes to the low-level details of the original algorithm and apply a more careful (amortized) analysis of its running time. The correctness of our algorithm follows for the most part from the correctness of the algorithm by Hong and Nagamochi.

► **Theorem 1.** *There exists an algorithm that, given a subdivision $G = (V, E)$ of an internally 3-connected hierarchical plane st-graph and a convex polygon Γ° that is compatible with G , computes a convex drawing of G with Γ° as the realization of the outer face in time $\mathcal{O}(n)$ where $n = |V|$.*

Proof sketch. It suffices to prove the claim for the case that G is internally 3-connected. The y -coordinate of each vertex in the desired drawing of G is already fixed. Moreover, the x -coordinates of the vertices of the outer face are also fixed by Γ° . Hence, our goal is to (recursively) compute the x -coordinates of the internal vertices in a convex drawing of G with Γ° as the realization of the outer face.

We assume we are given a cyclic list L that contains the vertices of G corresponding to the vertices of Γ° whose outer angles are reflex in the order in which they appear around Γ° . We refer to L as the *corner list* of Γ° . Initially, we can preprocess G and Γ° to obtain L in $\mathcal{O}(n)$ time. When making recursive calls, we will split L appropriately to create a new corner list for each subproblem in $\mathcal{O}(1)$ time. Given the list L , it is possible in $\mathcal{O}(1)$ time to compute a vertex r that corresponds to a vertex of Γ° whose outer angle is reflex and such that r is not the source or sink of G . Without loss of generality, we assume that r belongs to the right boundary of Γ° . We distinguish two cases regarding the degree of r .

Case 1: $\deg_G(r) = 2$. For an illustration see Figure 5a. Let r_a and r_b denote the in-neighbor and out-neighbor of r , respectively. If $|L| = 3$ and r_a is the source of G and r_b is the sink of G , then G has no internal vertices (otherwise, the internal face incident to r would arch the path corresponding to the side $r_a r_b$ of Γ° thereby contradicting the compatibility of Γ°). Hence, we simply report that the coordinates of all internal vertices are already fixed. This is the base case of our recursion. It can be recognized and dealt with in $\mathcal{O}(1)$ time.

So assume that $|L| \geq 4$ or that r has a neighbor that is not the sink or source of G . Let Γ_1° denote the simple (convex) polygon obtained from Γ° created by replacing the segments rr_a and rr_b with the segment $r_a r_b$. The simplicity of Γ_1° is implied by the above assumption. If $(r_a, r_b) \in E$ we set $G'_1 = G$. Otherwise, we add the edge (r_a, r_b) in the internal face incident to r and call the resulting graph G'_1 . We delete r from G'_1 and call the resulting graph G_1 . Properties (I1)–(I2) of Definition 4 can be used to show that G_1 is internally 3-connected. Moreover, it can be derived by Lemma 5 that Γ_1° is compatible with G_1 . We recursively compute the coordinates of the internal vertices in a convex drawing of G_1 with Γ_1° as the realization of the outer face. These coordinates combined with the coordinates of r correspond to the desired drawing of G . The graph G and its polygon Γ° are easily transformed into G_1 and Γ_1° in $\mathcal{O}(1)$ time, and L can be transformed into a corner list of Γ_1° in $\mathcal{O}(1)$ time. ◀

Case 2: $\deg_G(r) \geq 3$. For illustrations see Figures 5b, 5c, and 6a. Without loss of generality, there is an edge whose head is r and whose tail is an internal vertex of G . Let f_r denote the left-face of r and let P'_r denote the (unique) directed subpath of ∂f_r that connects the source y' of f_r with r . Let y be the first outer vertex of G distinct from r that is

encountered when traversing P'_r from r towards y' – if no such vertex exists, we set $y = y'$. We define P_r to be the subpath of P'_r between y and r . If y and r are nonadjacent, we have $|E(P_r)| \leq |E(\partial f_r)| - 2$ and hence P_r is archfree by Lemma 5. If y and r are adjacent, then $P_r = (y, r)$; otherwise, by the definition of f_r , the edge (y, r) is to the right of P_r , which implies that the vertices r, y form a nonexternal separation pair that separates the internal vertices of P_r from the outer face and, thus, contradicts the internal 3-connectivity of G . Hence, P_r is again archfree by Lemma 5. So in any case P_r is archfree. Moreover, P_r is easily computed in $\mathcal{O}(|E(P_r)|)$ time.

■ **Figure 5** Case 1 and Case 2.1 in the proof of Theorem 1 and [20, Theorem 8]. (b) depicts the case where $y \neq y'$ and $P_r \neq P'_r$, whereas (c) depicts the case where $y = y'$ and $P_r = P'_r$.

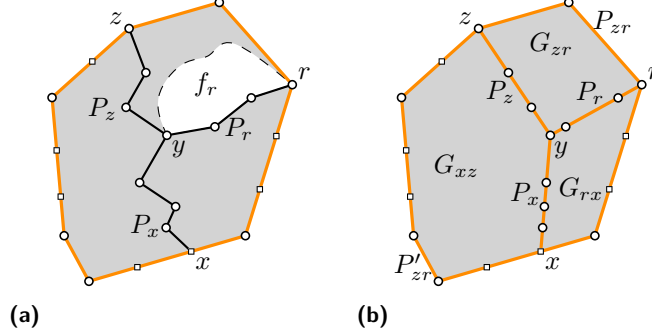

We distinguish two cases depending on whether y is an internal vertex or not.

Case 2.1: y is an outer vertex of G . For illustrations see Figures 5b and 5c. The boundary of the outer face of G contains two interior disjoint paths P_1, P_2 between r and y . Each of these two paths forms a cycle together with P_r . The closed interior of each of these two cycles describes a hierarchical plane st-graph. We denote these two graphs by G_1 and G_2 such that $G_i, i \in \{1, 2\}$ has P_i on its outer face. We define Γ_1^o to be the polygon resulting from replacing the part of Γ^o that corresponds to P_2 with P_r drawn as a straight-line segment, thereby fixing the coordinates of the internal vertices of P_r . The drawing Γ_2^o is defined analogously. Since each side of Γ^o corresponds to an archfree path in G , it follows that r and y do not belong to a common side of Γ^o . Hence, Γ_1^o and Γ_2^o are simple (convex) polygons. Moreover, since P_r is archfree, Γ_1^o is compatible with G_1 and Γ_2^o is compatible with G_2 . By Property (I2) of Definition 4 for G it easily follows that G_1 and G_2 are internally 3-connected. We recursively compute the coordinates of the internal vertices in convex drawings of G_1 and G_2 with outer face Γ_1 and Γ_2 , respectively. Note that these coordinates combined with the coordinates of Γ^o and P_r correspond to the desired drawing of G .

The hierarchical plane st-graphs G_1 and G_2 can be obtained in $\mathcal{O}(|E(P_r)|)$ time by splitting G along P_r . The polygons Γ_1^o and Γ_2^o can be obtained in $\mathcal{O}(|E(P_r)|)$ time by splitting Γ^o and their corner lists can be obtained in $\mathcal{O}(1)$ time by splitting L . \triangleleft

Case 2.2: y is an internal vertex of G . For an illustration see Figure 6a. We compute a directed archfree path P_x from a vertex x on the outer face of G to y by using (a symmetric version of) Theorem 2. The paths P_x and P_r are disjoint except for the common endpoint y . We also compute a directed archfree path P_z from y to a vertex z on the outer face of G by using Theorem 6. To ensure that P_z is disjoint from P_r (except for the common endpoint y), we make use of the ability to influence the choice of the first edge (y, u) of P_z as guaranteed by Theorem 6. Let F_y be the set of out-faces of y , let $k_y = \max_{g \in F_y} \{\text{peak}(g)\}$, and let $K_y = \{g \in F \mid \text{peak}(g) = k\}$. If $K_y = \{f_r\}$, we pick the left-most out-edge of y that is

incident to the right-most out-face in K_y (which is f_r). Since f_r is the left-face of r , this choice guarantees that P_z and P_r are disjoint. Otherwise (if K_y contains at least one face distinct from f_r), we pick the right-most out-edge of y that is incident to the left-most out-face in K_y . Since f_r is the left-face of r , its peak is strictly larger than $y(r)$. Hence, K_y cannot contain any face that is to the right of f_r . Consequently, it contains a face to the left of f_r . Thus, our choice guarantees that P_z is disjoint from P_r since P_r is the left-face of r .

■ **Figure 6** Case 2.2 in the proof of Theorem 1 and [20, Theorem 8].

The boundary of the outer face of G contains two interior disjoint paths from z to r . Let P_{zr} denote the path that does not contain x and let P'_{zr} denote the path that contains x , for an illustration see Figure 6b. The closed interior of the cycle formed by P_{zr} , P_z , and P_r describes a hierarchical plane st-graph G_{zr} , which is easily seen to be internally 3-connected due to Property (I2) of Definition 4. We pick a point p with $y(p) = y(y)$ in the interior of the triangle formed by the vertices r, x, z . Finally, we create a convex polygon Γ^o_{zr} from Γ^o by replacing the part corresponding to P'_{zr} with the straight-line segments pz and pr , which fixes the coordinates of the vertices of P_r and P_z . Since P_r and P_z are archfree in G , it follows that Γ^o_{zr} is compatible with G_{zr} . Analogously, we define two other internally 3-connected hierarchical plane st-graphs G_{rx} and G_{xz} that together with G_{zr} partition the internal faces of G . We also construct two convex polygons Γ^o_{rx} and Γ^o_{xz} that are compatible with G_{rx} and G_{xz} , respectively, that also use the point p as a corner. We recursively compute the internal coordinates of convex drawings of G_{zr} , G_{rx} , and G_{xz} with Γ^o_{zr} , Γ^o_{rx} and Γ^o_{xz} as the realization of the outer face, respectively. Note that these coordinates combined with the coordinates of Γ^o , P_r , P_z , and P_x correspond to the desired drawing of G .

By Theorem 6, the path P_x can be computed in $\mathcal{O}(\sum_{i \in V(P_x) \setminus \{x\}} \deg_G^-(i))$ time and P_z can be computed in $\mathcal{O}(\sum_{i \in V(P_z) \setminus \{z\}} \deg_G^+(i))$ time. By splitting G and Γ^o , we can compute G_{zr} , G_{rx} , and G_{xz} and Γ^o_{zr} , Γ^o_{rx} , and Γ^o_{xz} , respectively, in $\mathcal{O}(|E(P_r)| + |E(P_x)| + |E(P_z)|)$ time. By splitting L , we can compute the corner lists of Γ^o_{zr} , Γ^o_{rx} , and Γ^o_{xz} in $\mathcal{O}(1)$ time. \triangleleft

Running time. The preprocessing (computing L) takes $\mathcal{O}(n)$ time. Case 1 can be dealt with in $\mathcal{O}(1)$ time. The time to take care of Case 2.1 can be expressed as $\mathcal{O}(1) + \mathcal{O}(|E(P_r)|)$. Case 2.2 can be taken care of in time $\mathcal{O}(1) + \mathcal{O}(|E(P_r)| + \sum_{i \in V(P_x) \setminus \{x\}} \deg_G^-(i) + \sum_{i \in V(P_z) \setminus \{z\}} \deg_G^+(i))$. In all three cases, the nonconstant summands only involve internal vertices of G , that is, $|E(P_r)|$ is linear in the number of vertices of P_r that are internal vertices of G , and the expressions $\sum_{i \in V(P_x) \setminus \{x\}} \deg_G^-(i)$ and $\sum_{i \in V(P_z) \setminus \{z\}} \deg_G^+(i)$ only involve the degree of vertices of P_x and P_z , respectively, that are internal to G . The graph G is then split to obtain up to three hierarchical plane st-graphs in which these internal vertices are external. Hence, each vertex of G can contribute to the nonconstant part of the running time of at

most one subproblem in the recursion tree. Therefore, the total sum of these nonconstant parts is bounded by $\sum_{v \in V} \deg_G(v) \subseteq \mathcal{O}(n)$. It remains to find an upper bound on the total number of subproblems. The number of subproblems for which Case 1 arises is bounded by the number of faces of an internal triangulation of G , which is $\mathcal{O}(n)$. Each subproblem for which Case 2 arises splits at least one internal edge, which becomes external in the created subproblems. Hence, each edge is split at most once and so the number of the subproblems for which Case 2 arises is $\mathcal{O}(n)$. Therefore the total running time is $\mathcal{O}(n)$. ◀

Abstract

We give a complexity dichotomy for the Quantified Constraint Satisfaction Problem QCSP(H) when H is a reflexive tournament. It is well-known that reflexive tournaments can be split into a sequence of strongly connected components H_1, \dots, H_n so that there exists an edge from every vertex of H_i to every vertex of H_j if and only if $i < j$. We prove that if H has both its initial and final strongly connected component (possibly equal) of size 1, then QCSP(H) is in NL and otherwise QCSP(H) is NP-hard.

2012 ACM Subject Classification Theory of computation → Problems, reductions and completeness

1 Introduction

The *Quantified Constraint Satisfaction Problem* QCSP(B), for a fixed *template* (structure) B, is a popular generalisation of the *Constraint Satisfaction Problem* CSP(B). In the latter, one asks if a primitive positive sentence (the existential quantification of a conjunction of atoms) φ is true on B, while in the former this sentence may also have universal quantification. Much of the theoretical research into (finite-domain¹) CSPs has been in respect of a complexity classification project [11, 5], recently completed by [4, 22, 24], in which it is shown that all

¹ All structures considered in this article are finite.

such problems are either in P or NP-complete. Various methods, including combinatorial (graph-theoretic), logical and universal-algebraic were brought to bear on this classification project, with many remarkable consequences.

Complexity classifications for QCSPs appear to be harder than for CSPs. Indeed, a classification for QCSPs will give a fortiori a classification for CSPs (if $B \uplus K_1$ is the disjoint union of B with an isolated element, then $\text{QCSP}(B \uplus K_1)$ and $\text{CSP}(B)$ are polynomial-time many-one equivalent). Just as $\text{CSP}(B)$ is always in NP, so $\text{QCSP}(B)$ is always in Pspace. However, no polychotomy has been conjectured for the complexities of $\text{QCSP}(B)$, though, until recently, only the complexities P, NP-complete and Pspace-complete were known. Recent work [25] has shown that this complexity landscape is considerably richer, and that dichotomies of the form P versus NP-hard (using Turing reductions) might be the sensible place to be looking for classifications.

$\text{CSP}(B)$ may equivalently be seen as the *homomorphism* problem which takes as input a structure A and asks if there is a homomorphism from A to B . The *surjective CSP*, $\text{SCSP}(B)$, is a cousin of $\text{CSP}(B)$ in which one requires that this homomorphism from A to B be surjective. From the logical perspective this translates to the stipulation that all elements of B be used as witnesses to the (existential) variables of the primitive positive input φ . The surjective CSP appears in the literature under a variety of names, including *surjective homomorphism* [2], *surjective colouring* [12, 15] and *vertex compaction* [19, 20]. $\text{CSP}(B)$ and $\text{SCSP}(B)$ have various other cousins: see the survey [2] or, in the specific context of reflexive tournaments, [15]. The only one we will dwell on here is the *retraction* problem $\text{CSP}^c(B)$ which can be defined in various ways but, in keeping with the present narrative, we could define logically as allowing atoms of the form $v = b$ in the input sentence φ where b is some element of B (the superscript c indicates that constants are allowed). It has only recently been shown that there exists a B so that $\text{SCSP}(B)$ is in P while $\text{CSP}^c(B)$ is NP-complete [23]. It is still not known whether such an example exists among the (partially reflexive) graphs.

It is well-known that the binary *cousin* relation is not transitive, so let us ask the question as to whether the surjective CSP and QCSP are themselves cousins? The algebraic operations pertaining to the CSP are *polymorphisms* and for QCSP these become *surjective polymorphisms*. On the other hand, a natural use of universal quantification in the QCSP might be to ensure some kind of surjective map (at least under some evaluation of many universally quantified variables). So it is that there may appear to be some relationship between the problems. Yet, there are known irreflexive graphs H for which $\text{QCSP}(H)$ is in NL, while $\text{SCSP}(H)$ is NP-complete (take the 6-cycle [18, 20]). On the other hand, one can find a 3-element B whose relations are preserved by a *semilattice-without-unit* operation such that both $\text{CSP}^c(B)$ and $\text{SCSP}(B)$ are in P but $\text{QCSP}(B)$ is Pspace-complete. We are not aware of examples like this among graphs and it is perfectly possible that for (partially reflexive) graphs H , $\text{SCSP}(H)$ being in P implies that $\text{QCSP}(H)$ is in P.

Tournaments, both irreflexive and reflexive (and sometimes in between), have played a strong role as a testbed for conjectures and a habitat for classifications, for relatives of the CSP both complexity-theoretic [1, 10, 15] and algebraic [14, 21]. Looking at Table 1 one can see the last unresolved case is precisely QCSP on reflexive tournaments. This is the case we address in this paper. For irreflexive tournaments H , $\text{QCSP}(H)$ is in P if and only if $\text{SCSP}(H)$ is in P, but for reflexive tournaments this is not the case. When H is a reflexive tournament, we prove that $\text{QCSP}(H)$ is in NL if H has both initial and final strongly connected components trivial, and is NP-hard otherwise. In contrast to the proof from [10] and like the proof of [15], we will henceforth work largely combinatorially rather than algebraically. Note that we

do not investigate beyond NP-hard, so our dichotomy cannot be compared directly to the trichotomy of [10] for irreflexive tournaments which distinguishes between P, NP-complete and Pspace-complete.

■ **Table 1** Our result in a wider context. The results for irreflexive tournaments were all proved in the more general setting of irreflexive semicomplete digraphs in the papers cited.

	QCSP	CSP	Surjective CSP	Retraction
irreflexive tournaments	trichotomy [10]	dichotomy [1]	dichotomy [1]	dichotomy [1]
reflexive tournaments	this paper	all trivial	dichotomy [15]	dichotomy [14]

In Section 3 we prove the NP-hard cases of our dichotomy. Our proof method follows that from [15], while adapting the ideas of [8] in order to make what was developed for Surjective CSP applicable to QCSP. The QCSP is not naturally a combinatorial problem but can be seen thusly when viewed in a certain way. We indeed closely mirror [15] with [8] in the strongly connected case. For the not strongly connected case, the adaptation from the strongly connected case was straightforward for the Surjective CSP in [15]. However, the straightforward method does not work for the QCSP. Instead, we seek a direct argument that essentially sees us extending the method from [15].

In Section 4 we prove the NL cases of our dichotomy. Here, we use ideas originally developed in (the conference version of) [8] and first used in the wild in [17]. Thus, we do not introduce new proof techniques as such but rather weave our proof through the reasonably intricate synthesis of different known techniques. In Section 5 we state our dichotomy and give some directions for future work. Owing to space restrictions in the original submission, some of our proofs are omitted.

2 Preliminaries

For an integer $k \geq 1$, we write $[k] := \{1, \dots, k\}$. A vertex $u \in V(G)$ in a digraph G is *backwards-adjacent* to another vertex $v \in V$ if $(u, v) \in E$. It is *forwards-adjacent* to another vertex $v \in V$ if $(v, u) \in E$. If a vertex u has a self-loop (u, u) , then u is *reflexive*; otherwise u is *irreflexive*. A digraph G is *reflexive* or *irreflexive* if all its vertices are reflexive or irreflexive, respectively.

The *directed path* on k vertices is the digraph with vertices u_0, \dots, u_{k-1} and edges (u_i, u_{i+1}) for $i = 0, \dots, k-2$. By adding the edge (u_{k-1}, u_0) , we obtain the *directed cycle* on k vertices. A digraph G is *strongly connected* if for all $u, v \in V(G)$ there is a directed path in $E(G)$ from u to v . A *double edge* in a digraph G consists in a pair of distinct vertices $u, v \in V(G)$, so that (u, v) and (v, u) belong to $E(G)$. A digraph G is *semicomplete* if for every two distinct vertices u and v , at least one of (u, v) , (v, u) belongs to $E(G)$. A semicomplete digraph G is a *tournament* if for every two distinct vertices u and v , exactly one of (u, v) , (v, u) belongs to $E(G)$. A reflexive tournament G is *transitive* if for every three vertices u, v, w with $(u, v), (v, w) \in E(G)$, also (u, w) belongs to $E(G)$. A digraph F is a *subgraph* of a digraph G if $V(F) \subseteq V(G)$ and $E(F) \subseteq E(G)$. It is *induced* if $E(F)$ coincides with $E(G)$ restricted to pairs containing only vertices of $V(F)$. A *subtournament* is an induced subgraph of a tournament. It is well known that a reflexive tournament H can be split into a sequence of strongly connected components H_1, \dots, H_n for some integer $n \geq 1$ so that there exists an edge from every vertex of H_i to every vertex of H_j if and only if $i < j$. We will use the notation $H_1 \Rightarrow \dots \Rightarrow H_n$ for H and we refer to H_1 and H_n as the *initial* and *final* components of H , respectively.

A *homomorphism* from a digraph G to a digraph H is a function $f : V(G) \rightarrow V(H)$ such that for all $u, v \in V(G)$ with $(u, v) \in E(G)$ we have $(f(u), f(v)) \in E(H)$. We say that f is *(vertex)-surjective* if for every vertex $x \in V(H)$ there exists a vertex $u \in V(G)$ with $f(u) = x$. A digraph H' is a *homomorphic image* of a digraph H if there is a surjective homomorphism from H to H' that is also *edge-surjective*, that is, for all $(x', y') \in E(H')$ there exists an $(x, y) \in E(H)$ with $x' = h(x)$ and $y' = h(y)$.

The problem H-RETRACTION takes as input a graph G of which H is an induced subgraph and asks whether there is a homomorphism from G to H that is the identity on H . This definition is polynomial-time many-one equivalent to the one we suggested in the introduction (see e.g. [2]). The *quantified constraint satisfaction problem* QCSP(H) takes as input a sentence $\varphi := \forall x_1 \exists y_1 \dots \forall x_n \exists y_n \Phi(x_1, y_1, \dots, x_n, y_n)$, where Φ is a conjunction of positive atomic (binary edge) relations. This is a yes-instance to the problem just in case $H \models \varphi$.

The *canonical query* of G (from [13]) is a primitive positive sentence φ_G that has the property that, for all H , G has a homomorphism to H iff $H \models \varphi_G$. It is built by mapping edges (x, y) from $E(G)$ to atoms $E(x, y)$ is an existentially quantified conjunctive query.

The *direct product* of two digraphs G and H , denoted $G \times H$, is the digraph on vertex set $V(G) \times V(H)$ with edges $((x, y), (x', y'))$ if and only if $(x, x') \in E(G)$ and $(y, y') \in E(H)$. We denote the direct product of k copies of G by G^k . A *k-ary polymorphism* of G is a homomorphism f from G^k to G ; if $k = 1$, then f is also called an *endomorphism*. A *k-ary polymorphism* f is *essentially unary* if there exists a unary operation g and $i \in [k]$ so that $f(x_1, \dots, x_k) = g(x_i)$ for every $(x_1, \dots, x_k) \in G^k$. Let us say that a *k-ary polymorphism* f is *uniformly* z for some $z \in V(G)$ if $f(x_1, \dots, x_k) = z$ for every $(x_1, \dots, x_k) \in V(G^k)$. We need the following two lemmas.

► **Lemma 1.** *Let H be a reflexive tournament and f be a k -ary polymorphism of H . If $f(x, \dots, x) = z$ for every $x \in V(H)$, then f is uniformly z .*

Proof. Consider some tuple (x_1, \dots, x_k) which has m distinct vertices. We proceed by induction on m , where the base case $m = 1$ is given as an assumption. Suppose we have the result for m vertices and let (x_1, \dots, x_k) have $m + 1$ distinct entries. For simplicity (and w.l.o.g.) we will consider this reordered and without duplicates as $(y_1, \dots, y_m, y_{m+1})$. Suppose f maps (x_1, \dots, x_k) to z' . Assume $(y_m, y_{m+1}) \in E(H)$ (the case (y_{m+1}, y_m) is symmetric). Then consider the tuples (y_1, \dots, y_m, y_m) and $(y_1, \dots, y_{m+1}, y_{m+1})$. By the inductive hypothesis, f maps each of these (when reordered and padded appropriately with duplicates) to z . Furthermore, we have co-ordinatewise edges from (y_1, \dots, y_m, y_m) to $(y_1, \dots, y_m, y_{m+1})$ and from $(y_1, \dots, y_m, y_{m+1})$ to $(y_1, \dots, y_{m+1}, y_{m+1})$. Since we deduce by the definition of polymorphism that both $(z, z'), (z', z) \in E(H)$, it follows that $z' = z$. Thus, f maps also $(y_1, \dots, y_m, y_{m+1})$ (when reordered and padded appropriately with duplicates) to z . That is, $f(x_1, \dots, x_k) = z$. ◀

► **Lemma 2.** *Let H be the reflexive tournament $H_1 \Rightarrow \dots \Rightarrow H_i \Rightarrow \dots \Rightarrow H_n$. If f is a k -ary surjective polymorphism of H , then f preserves each of $V(H_1), \dots, V(H_n)$; that is, for every i and every tuple of k vertices $x_1, \dots, x_k \in V(H_i)$, $f(x_1, \dots, x_k) \in V(H_i)$.*

Proof. Suppose f maps some tuple (x_1, \dots, x_m) from $V(H_i)$ to $y \in V(H_\ell)$. Let (x'_1, \dots, x'_m) be any tuple from $V(H_i)$. Since H_i is strongly connected, $f(x'_1, \dots, x'_m) \in V(H_\ell)$. It follows that if $\ell \neq i$, e.g. w.l.o.g. $\ell < i$, then some component $\ell' \geq i$ can not be in the range of f . ◀

The relevance of this lemma is in its sequent corollary, which follows according to Proposition 3.15 of [3].

► **Corollary 3.** *Let H be the reflexive tournament $H_1 \Rightarrow \dots \Rightarrow H_i \Rightarrow \dots \Rightarrow H_n$. Each subset of the domain $V(H_i)$ is definable by a QCSP instance in one free variable.*

An endomorphism e of a digraph G is a *constant map* if there exists a vertex $v \in V(G)$ such that $e(u) = v$ for every $u \in V(G)$, and e is the *identity* if $e(u) = u$ for every $u \in G$. An *automorphism* is a bijective endomorphism whose inverse is a homomorphism. An endomorphism is *trivial* if it is either an automorphism or a constant map; otherwise it is *non-trivial*. A digraph is *endo-trivial* if all of its endomorphisms are trivial. An endomorphism e of a digraph G *fixes* a subset $S \subseteq V(G)$ if $e(S) = S$, that is, $e(x) \in S$ for every $x \in S$, and e *fixes* an induced subgraph F of G if it is the identity on $V(F)$. It *fixes* an induced subgraph F *up to automorphism* if $e(F)$ is an automorphic copy of F . An endomorphism e of G is a *retraction* of G if e is the identity on $e(V(G))$. A digraph is *retract-trivial* if all of its retractions are the identity or constant maps. Note that endo-triviality implies retract-triviality, but the reverse implication is not necessarily true (see [15]). However, on reflexive tournaments both concepts do coincide [15].

We need a series of results from [15]. The third one follows from the well-known fact that every strongly connected tournament has a directed Hamilton cycle [6].

► **Lemma 4** ([15]). *A reflexive tournament is endo-trivial if and only if it is retract-trivial.*

► **Lemma 5** ([15]). *Let H be an endo-trivial reflexive digraph with at least three vertices. Then every polymorphism of H is essentially unary.*

► **Lemma 6** ([15]). *If H is an endo-trivial reflexive tournament, then H contains a directed Hamilton cycle.*

► **Lemma 7** ([15]). *If H is an endo-trivial reflexive tournament, then every homomorphic image of H of size $1 < n < |V(H)|$ has a double edge.*

► **Corollary 8.** *If H is an endo-trivial reflexive digraph on at least three vertices, then $\text{QCSP}(H)$ is NP-hard (in fact it is even Pspace-complete).*

Proof. This follows from Lemma 5 and [3]. ◀

3 The Proof of the NP-Hard Cases of the Dichotomy

We commence with the NP-hard cases of the dichotomy. The simpler NL cases will follow.

3.1 The NP-Hardness Gadget

We introduce the gadget Cyl_m^* from [15] drawn in Figure 1. Take m disjoint copies of the (reflexive) directed m -cycle DC_m^* arranged in a cylindrical fashion so that there is an edge from i in the j th copy to i in the $(j+1)$ th copy (drawn in red), and an edge from i in the $(j+1)$ th copy to $(i+1) \bmod m$ in the j th copy (drawn in green). We consider DC_m^* to have vertices $\{1, \dots, m\}$. Recall that every strongly connected (reflexive) tournament on m vertices has a Hamilton Cycle HC_m . We label the vertices of HC_m as $1, \dots, m$ in order to attach it to the gadget Cyl_m^* .²

The following lemma follows from induction on the copies of DC_m^* , since a reflexive tournament has no double edges.

² The superscripted $*$ indicates that the corresponding graph is reflexive. This notation is inherited from [15]. It is not significant since we could safely assume every graph we work with is reflexive as the template is a reflexive tournament.

■ **Figure 1** The gadget Cyl_m^* in the case $m := 4$ (self-loops are not drawn). We usually visualise the right-hand copy of DC_4^* as the “bottom” copy and then we talk about vertices “above” and “below” according to the red arrows.

► **Lemma 9** ([15]). *In any homomorphism h from Cyl_m^* , with bottom cycle DC_m^* , to a reflexive tournament, if $|h(\text{DC}_m^*)| = 1$, then $|h(\text{Cyl}_m^*)| = 1$.*

We will use another property, denoted (\dagger) , of Cyl_m^* , which is that the retractions from Cyl_m^* to its bottom copy of DC_m^* , once propagated through the intermediate copies, induce on the top copy precisely the set of automorphisms of DC_m^* . That is, the top copy of DC_m^* is mapped isomorphically to the bottom copy, and all such isomorphisms may be realised. The reason is that in such a retraction, the $(j+1)$ th copy may either map under the identity to the j th copy, or rotate one edge of the cycle clockwise, and Cyl_m^* consists of sufficiently many (namely m) copies of DC_m^* . Now let H be a reflexive tournament that contains a subtournament H_0 on m vertices that is endo-trivial. By Lemma 6, we find that H_0 contains at least one directed Hamilton cycle HC_0 . Define $\text{Spill}_m(H[H_0, \text{HC}_0])$ as follows. Begin with H and add a copy of the gadget Cyl_m^* , where the bottom copy of DC_m^* is identified with HC_0 , to build a digraph $F(H_0, \text{HC}_0)$. Now ask, for some $y \in V(H)$ whether there is a retraction r of $F(H_0, \text{HC}_0)$ to H so that some vertex x (not dependent on y) in the top copy of DC_m^* in Cyl_m^* is such that $r(x) = y$. Such vertices y comprise the set $\text{Spill}_m(H[H_0, \text{HC}_0])$.

► **Remark 10.** If x belongs to some copy of DC_m^* that is not the top copy, we can find a vertex x' in the top copy of DC_m^* and a retraction r' from $F(H_0, \text{HC}_0)$ to H with $r'(x') = r(x) = y$, namely by letting r' map the vertices of higher copies of DC_m^* to the image of their corresponding vertex in the copy that contains x . In particular this implies that $\text{Spill}_m(H[H_0, \text{HC}_0])$ contains $V(H_0)$.

We note that the set $\text{Spill}_m(H[H_0, \text{HC}_0])$ is potentially dependent on which Hamilton cycle in H_0 is chosen. We now recall that $\text{Spill}_m(H[H_0, \text{HC}_0]) = V(H)$ if H retracts to H_0 .

► **Lemma 11** ([15]). *If H is a reflexive tournament that retracts to a subtournament H_0 with Hamilton cycle HC_0 , then $\text{Spill}_m(H[H_0, \text{HC}_0]) = V(H)$.*

We now review a variant of a construction from [8]. Let G be a graph containing H where $|V(H)|$ is of size n . Consider all possible functions $\lambda : [n] \rightarrow V(H)$ (let us write $\lambda \in V(H)^{[n]}$ of cardinality N). For some such λ , let $\mathcal{G}(\lambda)$ be the graph G enriched with constants c_1, \dots, c_n where these are interpreted over $V(H)$ according to λ in the natural way (acting on the subscripts). We use calligraphic notation to remind the reader the signature has changed from $\{E\}$ to $\{E, c_1, \dots, c_n\}$ but we will still treat these structures as graphs. If we write $G(\lambda)$ without calligraphic notation we mean we look at only the $\{E\}$ -reduct, that is, we drop the constants. Of course, $G(\lambda)$ will always be G .

■ **Figure 2** Illustrations of direct product with constants.

Let $\mathcal{G} = \bigotimes_{\lambda \in V(H)^{[n]}} \mathcal{G}(\lambda)$. That is, the vertices of \mathcal{G} are N -tuples over $V(G)$ and there is an edge between two such vertices (x_1, \dots, x_N) and (y_1, \dots, y_N) if and only if $(x_1, y_1), \dots, (x_N, y_N) \in E(G)$. Finally, the constants c_i are interpreted as (x_1, \dots, x_N) so that $\lambda_1(c_i) = x_1, \dots, \lambda_N(c_i) = x_N$. An important induced substructure of \mathcal{G} is $\{(x, \dots, x) : x \in V(G)\}$. It is a copy of G called the *diagonal copy* and will play an important role in the sequel. To comprehend better the construction of \mathcal{G} from the sundry $\mathcal{G}(\lambda)$, confer on Figure 2.

The final ingredient of our fundamental construction involves taking some structure \mathcal{G} and making its canonical query with all vertices other than those corresponding to c_1, \dots, c_n becoming existentially quantified variables (as usual in this construction). We then turn the c_1, \dots, c_n to variables y_1, \dots, y_n to make $\varphi_{\mathcal{G}}(y_1, \dots, y_n)$. Let \mathcal{H} come from the given construction in which $G = H$. It is proved in [8] that $H' \models \forall y_1, \dots, y_n \varphi_{\mathcal{H}}(y_1, \dots, y_n)$ if and only if $\text{QCSP}(H) \subseteq \text{QCSP}(H')$ (here we identify $\text{QCSP}(H)$ with the set of sentences that form its yes-instances). By way of a side note, let us consider a k -ary relation R over H with tuples $(x_1^1, \dots, x_k^1), \dots, (x_1^r, \dots, x_k^r)$. For $i \in [r]$, let λ_i map (c_1, \dots, c_k) to (x_1^i, \dots, x_k^i) . Let $\mathcal{H} = \bigotimes_{\lambda \in \{\lambda_1, \dots, \lambda_r\}} \mathcal{H}(\lambda)$. Then $\varphi_{\mathcal{H}}(y_1, \dots, y_n)$ is the closure of R under the polymorphisms of H .

3.2 The strongly connected case: Two Base Cases

Recall that if H is a (reflexive) endo-trivial tournament, then $\text{QCSP}(H)$ is NP-hard due to Lemma 5 combined with the results from [3] (indeed, we may even say Pspace-complete). However H may not be endo-trivial. We will now show how to deal with the case where H is not endo-trivial but retracts to an endo-trivial subtournament. For doing this we use the NP-hardness gadget, but we need to distinguish between two different cases.

► **Lemma 12** (Base Case I.). *Let H be a reflexive tournament that retracts to an endo-trivial subtournament H_0 with Hamilton cycle HC_0 . Assume that H retracts to H'_0 for every isomorphic copy $H'_0 = i(H_0)$ of H_0 in H with $\text{Spill}_m(H[H'_0, i(\text{HC}_0)]) = V(H)$. Then H_0 -RETRACTION can be polynomially reduced to $\text{QCSP}(H)$.*

Proof. Let m be the size of $|V(H_0)|$ and n be the size of $|V(H)|$. Let G be an instance of H_0 -RETRACTION. We build an instance φ of $\text{QCSP}(H)$ in the following fashion. First, take a copy of H together with G and build G' by identifying these on the copy of H_0 that they both possess as an induced subgraph. Now, consider all possible functions $\lambda : [n] \rightarrow V(H)$. For some such λ , let $\mathcal{G}'(\lambda)$ be the graph enriched with constants c_1, \dots, c_n where these are interpreted over some subset of $V(H)$ according to λ in the natural way (acting on the subscripts).

Let $\mathcal{G}' = \bigotimes_{\lambda \in V(H)^{[n]}} \mathcal{G}'(\lambda)$. Let G'^d , H^d and H_0^d be the diagonal copies of G' , H and H_0 in \mathcal{G}' . Let \mathcal{H} be the subgraph of \mathcal{G}' induced by $V(H) \times \dots \times V(H)$. Note that the constants c_1, \dots, c_n live in \mathcal{H} . Now build \mathcal{G}'' from \mathcal{G}' by augmenting a new copy of Cyl_m^* for every vertex $v \in V(\mathcal{H}) \setminus V(H_0^d)$. Vertex v is to be identified with any vertex in the top copy of DC_m^* in Cyl_m^* and the bottom copy of DC_m^* is to be identified with HC_0 in H_0^d according to the identity function. (Thus, in each case, the new vertices are the middle cycles of Cyl_m^* and all but one of the vertices in the top cycle of Cyl_m^* .)

Finally, build φ from the canonical query of \mathcal{G}'' where we additionally turn the constants c_1, \dots, c_n to outermost universal variables. The size of φ is doubly exponential in n (the size of H) but this is constant, so still polynomial in the size of G .

We claim that G retracts to H_0 if and only if $\varphi \in \text{QCSP}(H)$.

First suppose that G retracts to H_0 . Let λ be some assignment of the universal variables of φ to H . To prove $\varphi \in \text{QCSP}(H)$ it suffices to prove that there is a homomorphism from \mathcal{G}'' to H that extends λ . Then for this it suffices to prove that there is a homomorphism h from \mathcal{G}' that extends λ . Let us explain why. Because H retracts to H_0 , we have $\text{Spill}_m(H[H_0, \text{HC}_0]) = V(H)$ due to Lemma 11. Hence, if $h(x) = y$ for two vertices $x \in V(\mathcal{H}) \setminus V(H_0^d)$ and $y \in V(H)$, we can always find a retraction of the graph $F(H_0, \text{HC}_0)$ to H that maps x to y , and we mimic this retraction on the corresponding subgraph in \mathcal{G}'' . The crucial observation is that this can be done independently for each vertex in $V(\mathcal{H}) \setminus V(H_0^d)$, as two vertices of different copies of Cyl_m^* are only adjacent if they both belong to \mathcal{H} .

Henceforth let us consider the homomorphic image of \mathcal{G}' that is $\mathcal{G}'(\lambda)$. To prove $\varphi \in \text{QCSP}(H)$ it suffices to prove that there is a homomorphism from $G'(\lambda)$ to H that extends λ . Note that it will be sufficient to prove that G' retracts to H . Let h be the natural retraction from G' to H that extends the known retraction from G to H_0 . We are done.

Suppose now $\varphi \in \text{QCSP}(H)$. Choose some surjection for λ , the assignment of the universal variables of φ to H . Recall $N = |V(H)^{[n]}|$. The evaluation of the existential variables that witness $\varphi \in \text{QCSP}(H)$ induces a surjective homomorphism s from \mathcal{G}'' to H which contains within it a surjective homomorphism s' from $\mathcal{H} = H^N$ to H . Consider the diagonal copy of $H_0^d \subset H^d \subset G'^d$ in \mathcal{G}' . By abuse of notation we will also consider each of s and s' acting just on the diagonal. If $|s'(H_0^d)| = 1$, by construction of \mathcal{G}'' , we have $|s'(H^d)| = 1$. Indeed, this was the property we noted in Lemma 9. By Lemma 1, this would mean s' is uniformly mapping \mathcal{H} to one vertex, which is impossible as s' is surjective. Now we will work exclusively in the diagonal copy G'^d . As $1 < |s'(H_0^d)| < m$ is not possible either due to Lemma 7, we find that $|s'(H_0^d)| = m$, and indeed s' maps H_0^d to a copy of itself in H which we will call $H'_0 = i(H_0^d)$ for some isomorphism i .

We claim that $\text{Spill}_m(H[H'_0, i(\text{HC}_0^d)]) = V(H)$. In order to see this, consider a vertex $y \in V(H)$. As s' is surjective, there exists a vertex $x \in V(\mathcal{H})$ with $s'(x) = y$. By construction, x belongs to some top copy of DC_m^* in Cyl_m^* in $F(H_0, \text{HC}_0)$. We can extend i^{-1} to an isomorphism from the copy of Cyl_m^* (which has $i(\text{HC}_0^d)$ as its bottom cycle) in the graph $F(H'_0, i(\text{HC}_0^d))$ to the copy of Cyl_m^* (which has HC_0^d as its bottom cycle) in the graph $F(H_0, \text{HC}_0)$. We define a mapping r^* from $F(H'_0, i(\text{HC}_0^d))$ to H by $r^*(u) = s' \circ i^{-1}(u)$ if

■ **Figure 3** An interesting tournament H on six vertices (self-loops are not drawn). This tournament does not retract to the DC_3^* on the left-hand side, yet $\text{Spill}_3(H[DC_3^*, DC_3]) = V(H)$.

u is on the copy of Cyl_m^* in $F(H'_0, i(\text{HC}_0^d))$ and $r^*(u) = u$ otherwise. We observe that $r^*(u) = u$ if $u \in V(H'_0)$ as s' coincides with i on H_0 . As H_0^d separates the other vertices of the copy of Cyl_m^* from $V(H^d) \setminus V(H_0^d)$, in the sense that removing H_0^d would disconnect them, this means that r^* is a retraction from $F(H'_0, i(\text{HC}_0^d))$ to H . We find that r^* maps $i(x)$ to $s' \circ i^{-1}(i(x)) = s'(x) = y$. Moreover, as x is in the top copy of DC_m^* in $F(H_0, \text{HC}_0)$, we conclude that y always belongs to $\text{Spill}_m(H[H'_0, i(\text{HC}_0^d)])$.

As $\text{Spill}_m(H[H'_0, i(\text{HC}_0^d)]) = V(H)$, we find, by assumption of the lemma, that there exists a retraction r from H to H'_0 . Now, recalling that we can view s' acting just on the diagonal copy H^d of H , $i^{-1} \circ r \circ s'$ is the desired retraction of G to H_0 . ◀

We now need to deal with the situation in which we have an isomorphic copy $H'_0 = i(H_0)$ of H_0 in H with $\text{Spill}_m(H[H'_0, i(\text{HC}_0)]) = V(H)$, such that H does not retract to H'_0 (see Figure 3 for an example). We cannot deal with this case in a direct manner and first show another base case. For this we need the following lemma and an extension of endo-triviality that we discuss afterwards.

► **Lemma 13** ([15]). *Let H be a reflexive tournament, containing a subtournament H_0 so that any endomorphism of H that fixes H_0 as a graph is an automorphism. Then any endomorphism of H that maps H_0 to an isomorphic copy $H'_0 = i(H_0)$ of itself is an automorphism of H .*

Let H_0 be an induced subgraph of a digraph H . We say that the pair (H, H_0) is *endo-trivial* if all endomorphisms of H that fix H_0 are automorphisms.

► **Lemma 14** (Base Case II). *Let H be a reflexive tournament with a subtournament H_0 with Hamilton cycle HC_0 so that (H, H_0) and H_0 are endo-trivial and $\text{Spill}_m(H[H_0, \text{HC}_0]) = V(H)$. Then H -RETRACTION can be polynomially reduced to QCSP(H).*

Proof. Let G be an instance of H -RETRACTION. Let m be the size of $|V(H_0)|$ and n be the size of $|V(H)|$. We build an instance φ of QCSP(H) in the following fashion. Consider all possible functions $\lambda : [n] \rightarrow V(H)$. For some such λ , let $\mathcal{G}(\lambda)$ be the graph enriched with constants c_1, \dots, c_n where these are interpreted over some subset of $V(H)$ according to λ in the natural way (acting on the subscripts).

Let $\mathcal{G} = \bigotimes_{\lambda \in V(H)^{[n]}} \mathcal{G}(\lambda)$. Let G^d , H^d and H_0^d be the diagonal copies of G , H and H_0 in \mathcal{G} . Let \mathcal{H} be the subgraph of \mathcal{G} induced by $V(H) \times \dots \times V(H)$. Note that the constants c_1, \dots, c_n live in \mathcal{H} . Now build \mathcal{G}' from \mathcal{G} by augmenting a new copy of Cyl_m^* for every vertex $v \in V(\mathcal{H}) \setminus V(H_0^d)$. Vertex v is to be identified with any vertex in the top copy of DC_m^* in Cyl_m^* and the bottom copy of DC_m^* is to be identified with HC_0 in H_0^d according to the identity function.

Finally, build φ from the canonical query of \mathcal{G}' where we additionally turn the constants c_1, \dots, c_n to outermost universal variables.

First suppose that G retracts to H by r . Let λ be some assignment of the universal variables of φ to H . To prove $\varphi \in \text{QCSP}(H)$ it suffices to prove that there is a homomorphism from \mathcal{G}' to H that extends λ and for this it suffices to prove that there is a homomorphism from \mathcal{G} that extends λ . This is always possible since we have $\text{Spill}_m(H[H_0, \text{HC}_0]) = V(H)$ by assumption.

Henceforth let us consider the homomorphic image of \mathcal{G} that is $\mathcal{G}(\lambda)$. To prove $\varphi \in \text{QCSP}(H)$ it suffices to prove that there is a homomorphism from $G(\lambda)$ to H that extends λ . Note that it will be sufficient to prove that G retracts to H . Well this was our original assumption so we are done.

Suppose now $\varphi \in \text{QCSP}(H)$. Choose some surjection for λ , the assignment of the universal variables of φ to H . Recall $N = |V(H)^{[n]}|$. The evaluation of the existential variables that witness $\varphi \in \text{QCSP}(H)$ induces a surjective homomorphism s from \mathcal{G}' to H which contains within it a surjective homomorphism s' from $\mathcal{H} = H^N$ to H . Consider the diagonal copy of $H_0^d \subset H^d \subset G^d$ in $(G)^N$. By abuse of notation we will also consider each of s and s' acting just on the diagonal. If $|s'(H_0^d)| = 1$, by construction of \mathcal{G}' , we have $|s'(H^d)| = 1$. By Lemma 1, this would mean s' is uniformly mapping \mathcal{H} to one vertex, which is impossible as s' is surjective. Now we will work exclusively on the diagonal copy G^d . As $1 < |s'(H_0^d)| < m$ is not possible either due to Lemma 7, we find that $|s'(H_0^d)| = m$, and indeed s' maps H_0^d to a copy of itself in H which we will call $H'_0 = i(H_0^d)$ for some isomorphism i .

As (H, H_0) is endo-trivial, Lemma 13 tells us that the restriction of s' to H^d is an automorphism of H^d , which we call α . The required retraction from G to H is now given by $\alpha^{-1} \circ s'$. \blacktriangleleft

3.3 The strongly connected case: Generalising the Base Cases

We now generalise the two base cases to more general cases via some recursive procedure. Afterwards we will show how to combine these two cases to complete our proof. We will first need a slightly generalised version of Lemma 13, which nonetheless has virtually the same proof.

► **Lemma 15** ([15]). *Let $H_2 \supset H_1 \supset H_0$ be a sequence of strongly connected reflexive tournaments, each one a subtournament of the one before. Suppose that any endomorphism of H_1 that fixes H_0 is an automorphism. Then any endomorphism h of H_2 that maps H_0 to an isomorphic copy $H'_0 = i(H_0)$ of itself also gives an isomorphic copy of H_1 in $h(H_1)$.*

The following two lemmas generalise Lemmas 12 and 14. The proof of the second is omitted.

► **Lemma 16** (General Case I). *Let $H_0, H_1, \dots, H_k, H_{k+1}$ be reflexive tournaments, the first k of which have Hamilton cycles $\text{HC}_0, \text{HC}_1, \dots, \text{HC}_k$, respectively, so that $H_0 \subseteq H_1 \subseteq \dots \subseteq H_k \subseteq H_{k+1}$. Assume that $H_0, (H_1, H_0), \dots, (H_k, H_{k-1})$ are endo-trivial and that*

$$\begin{aligned} \text{Spill}_{a_0}(H_1[H_0, \text{HC}_0]) &= V(H_1) \\ \text{Spill}_{a_1}(H_2[H_1, \text{HC}_1]) &= V(H_2) \\ \vdots &\quad \quad \quad \vdots \quad \quad \quad \vdots \\ \text{Spill}_{a_{k-1}}(H_k[H_{k-1}, \text{HC}_{k-1}]) &= V(H_k). \end{aligned}$$

Moreover, assume that H_{k+1} retracts to H_k and also to every isomorphic copy $H'_k = i(H_k)$ of H_k in H_{k+1} with $\text{Spill}_{a_k}(H_{k+1}[H'_k, i(\text{HC}_k)]) = V(H_{k+1})$. Then H_k -RETRACTION can be polynomially reduced to $\text{QCSP}(H_{k+1})$.

Proof. Let a_{k+1}, \dots, a_0 be the cardinalities of $|V(H_{k+1})|, \dots, |V(H_0)|$, respectively. Let $n = a_{k+1}$. Let G be an instance of H_k -RETRACTION. We will build an instance φ of $\text{QCSP}(H_{k+1})$ in the following fashion. First, take a copy of H_{k+1} together with G and build G' by identifying these on the copy of H_k that they both possess as an induced subgraph.

Consider all possible functions $\lambda : [n] \rightarrow V(H_{k+1})$. For some such λ , let $\mathcal{G}'(\lambda)$ be the graph enriched with constants c_1, \dots, c_n where these are interpreted over some subset of $V(H_{k+1})$ according to λ in the natural way (acting on the subscripts).

Let $\mathcal{G}' = \bigotimes_{\lambda \in V(H_{k+1})^{[n]}} \mathcal{G}'(\lambda)$. Let G'^d, H_{k+1}^d and H_k^d etc. be the diagonal copies of G'^d, H_{k+1} and H_k in \mathcal{G}' . Let \mathcal{H}_{k+1} be the subgraph of \mathcal{G}' induced by $V(H_{k+1}) \times \dots \times V(H_{k+1})$. Note that the constants c_1, \dots, c_n live in \mathcal{H}_{k+1} . Now build \mathcal{G}'' from \mathcal{G}' by augmenting a new copy of $\text{Cyl}_{a_k}^*$ for every vertex $v \in V(\mathcal{H}_{k+1}) \setminus V(H_k^d)$. Vertex v is to be identified with any vertex in the top copy of DC_{a_k} in $\text{Cyl}_{a_k}^*$ and the bottom copy of DC_{a_k} is to be identified with HC_k in H_k^d according to the identity function.

Then, for each $i \in [k]$, and $v \in V(H_i^d) \setminus V(H_{i-1}^d)$, add a copy of $\text{Cyl}_{a_{i-1}}^*$, where v is identified with any vertex in the top copy of $\text{DC}_{a_{i-1}}$ in $\text{Cyl}_{a_{i-1}}^*$ and the bottom copy of $\text{DC}_{a_{i-1}}^*$ is to be identified with H_{i-1} according to the identity map of $\text{DC}_{a_{i-1}}^*$ to HC_{i-1} .

Finally, build φ from the canonical query of \mathcal{G}'' where we additionally turn the constants c_1, \dots, c_n to outermost universal variables.

First suppose that G retracts to H_k . Let λ be some assignment of the universal variables of φ to H_{k+1} . To prove $\varphi \in \text{QCSP}(H_{k+1})$ it suffices to prove that there is a homomorphism from \mathcal{G}'' to H_{k+1} that extends λ and for this it suffices to prove that there is a homomorphism from \mathcal{G}' that extends λ . Let us explain why. We map the various copies of $\text{Cyl}_{a_{i-1}}^*$ in \mathcal{G}'' in any suitable fashion, which will always exist due to our assumptions and the fact that $\text{Spill}_{a_k}(H_{k+1}[H_k, \text{HC}_k]) = V(H_{k+1})$, which follows from our assumption that H_{k+1} retracts to H_k and Lemma 11.

Henceforth let us consider the homomorphic image of \mathcal{G}' that is $\mathcal{G}'(\lambda)$. To prove $\varphi \in \text{QCSP}(H_{k+1})$ it suffices to prove that there is a homomorphism from $\mathcal{G}'(\lambda)$ to H_{k+1} that extends λ . Note that it will be sufficient to prove that G' retracts to H_{k+1} . Let h be the natural retraction from G' to H_{k+1} that extends the known retraction from G to H_k . We are done.

Suppose now $\varphi \in \text{QCSP}(H_{k+1})$. Choose some surjection for λ , the assignment of the universal variables of φ to H_{k+1} . Let $N = |V(H_{k+1})^{[n]}|$. The evaluation of the existential variables that witness $\varphi \in \text{QCSP}(H_{k+1})$ induces a surjective homomorphism s from \mathcal{G}' to H_{k+1} which contains within it a surjective homomorphism s' from $\mathcal{H} = H_{k+1}^N$ to H_{k+1} . Consider the diagonal copy of $H_0^d \subset \dots \subset H_k^d \subset H_{k+1}^d \subset G'^d$ in \mathcal{G}' . By abuse of notation we will also consider each of s and s' acting just on the diagonal. If $|s'(H_0^d)| = 1$, by construction of \mathcal{G}'' , we could follow the chain of spills to deduce that $|s'(H_{k+1}^d)| = 1$, which is not possible by Lemma 1. Moreover, $1 < |s'(H_0^d)| < |V(H_0^d)|$ is impossible due to Lemma 7. Now we will work exclusively on the diagonal copy G'^d .

Thus, $|s'(H_0^d)| = |V(H_0^d)|$ and indeed s' maps H_0^d to an isomorphic copy of itself in H_{k+1} which we will call $H'_0 = i(H_0^d)$. We now apply Lemma 15 as well as our assumed endotrivialities to derive that s' in fact maps H_k^d by the isomorphism i to a copy of itself in H_{k+1} which we will call H'_k . Since s' is surjective, we can deduce that $\text{Spill}_{a_k}(H_{k+1}[H'_k, i(\text{HC}_k^d)]) = V(H_{k+1})$ in the same way as in the proof of Lemma 12. and so there exists a retraction r from H_{k+1} to H'_k . Now $i^{-1} \circ r \circ s'$ gives the desired retraction of G to H_k . \blacktriangleleft

► **Lemma 17** (General Case II). *Let $H_0, H_1, \dots, H_k, H_{k+1}$ be reflexive tournaments, the first $k+1$ of which have Hamilton cycles $\text{HC}_0, \text{HC}_1, \dots, \text{HC}_k$, respectively, so that $H_0 \subseteq H_1 \subseteq \dots \subseteq H_k \subseteq H_{k+1}$. Suppose that $H_0, (H_1, H_0), \dots, (H_k, H_{k-1}), (H_{k+1}, H_k)$ are endo-trivial*

and that

$$\begin{array}{ll}
\text{Spill}_{a_0}(H_1[H_0, HC_0]) & = V(H_1) \\
\text{Spill}_{a_1}(H_2[H_1, HC_1]) & = V(H_2) \\
\vdots & \vdots \quad \vdots \\
\text{Spill}_{a_{k-1}}(H_k[H_{k-1}, HC_{k-1}]) & = V(H_k) \\
\text{Spill}_{a_k}(H_{k+1}[H_k, HC_k]) & = V(H_{k+1})
\end{array}$$

Then H_{k+1} -RETRACTION can be polynomially reduced to QCSP(H_{k+1}).

► **Corollary 18.** *Let H be a non-trivial strongly connected reflexive tournament. Then QCSP(H) is NP-hard.*

Proof. As H is a strongly connected reflexive tournament, which has more than one vertex by our assumption, H is not transitive. Note that H -RETRACTION is NP-complete (see Section 4.5 in [15], using results from [14, 5, 16]). Thus, if H is endo-trivial, the result follows from Lemma 12 (note that we could also have used Corollary 8).

Suppose H is not endo-trivial. Then, by Lemma 4, H is not retract-trivial either. This means that H has a non-trivial retraction to some subtournament H_0 . We may assume that H_0 is endo-trivial, as otherwise we will repeat the argument until we find a retraction from H to an endo-trivial (and consequently strongly connected) subtournament.

Suppose that H retracts to all isomorphic copies $H'_0 = i(H_0)$ of H_0 within it, except possibly those for which $\text{Spill}_m(H[H'_0, i(HC_0)]) \neq V(H)$. Then the result follows from Lemma 12. So there is a copy $H'_0 = i(H_0)$ to which H does not retract for which $\text{Spill}_m(H[H'_0, i(HC_0)]) = V(H)$. If (H, H'_0) is endo-trivial, the result follows from Lemma 14. Thus we assume (H, H'_0) is not endo-trivial and we deduce the existence of $H'_0 \subset H_1 \subset H$ (H_1 is strictly between H and H'_0) so that (H_1, H'_0) and H'_0 are endo-trivial and H retracts to H_1 . Now we are ready to break out. Either H retracts to all isomorphic copies of $H'_1 = i(H_1)$ in H , except possibly for those so that $\text{Spill}_m(H[H'_1, i(HC_1)]) \neq V(H)$, and we apply Lemma 16, or there exists a copy H'_1 , with $\text{Spill}_m(H[H'_1, i(HC_1)]) = V(H)$, to which it does not retract. If (H, H'_1) is endo-trivial, the result follows from Lemma 17. Otherwise we iterate the method, which will terminate because our structures are getting strictly larger. ◀

3.4 An initial strongly connected component that is non-trivial

This section follows a similar methodology to the previous two sections. However, the proofs are a little more involved and are omitted from this version of the paper.

► **Corollary 19.** *Let H be a reflexive tournament with an initial strongly connected component that is non-trivial. Then QCSP(H) is NP-hard.*

4 The Proof of the NL Cases of the Dichotomy

A particular role in the tractable part of our dichotomy will be played by TT_2^* , the reflexive transitive 2-tournament, which has vertex set $\{0, 1\}$ and edge set $\{(0, 0), (0, 1), (1, 1)\}$.

► **Lemma 20.** *Let $H = H_1 \Rightarrow \dots \Rightarrow H_n$ be a reflexive tournament on $m + 2$ vertices with $V(H_1) = \{s\}$ and $V(H_n) = \{t\}$. Then there exists a surjective homomorphism from $(\text{TT}_2^*)^m$ to H .*

Proof. Build a surjective homomorphism f from $(\text{TT}_2^*)^m$ to H in the following fashion. Let \bar{x}_i be the m -tuple which has 1 in the i th position and 0 in all other positions. For $i \in [m]$, let f map \bar{x}_i to i . Let f map $(0, \dots, 0)$ to s and everything remaining to t .

By construction, f is surjective. To see that f is a homomorphism, let $((y_1, \dots, y_m), (z_1, \dots, z_m)) \in E((\text{TT}_2^*)^m)$, which is the case exactly when $y_i \leq z_i$ for all $i \in [m]$. Let $f(y_1, \dots, y_m) = u$ and $f(z_1, \dots, z_m) = v$. First suppose that y_1, \dots, y_m are all 0. Then $u = s$. As s has an out-edge to every vertex of H , we find that $(u, v) \in E(H)$. Now suppose that y_1, \dots, y_m contains a single 1. If $(y_1, \dots, y_m) = (z_1, \dots, z_m)$, then $u = v$. As H is reflexive, we find that $(u, v) \in E(H)$. If $(y_1, \dots, y_m) \neq (z_1, \dots, z_m)$, then $v = t$. As t has an in-edge from every vertex of H , we find that $(u, v) \in E(H)$. Finally suppose that y_1, \dots, y_m contains more than one 1. Then $u = v = t$. As H is reflexive, we find that $(u, v) \in E(H)$. ◀

We also need the following lemma, which follows from combining some known results.

► **Lemma 21.** *If H is a transitive reflexive tournament then $\text{QCSP}(H)$ is in NL.*

Proof. It is noted in [15] that H has the ternary median operation as a polymorphism. It follows from well-known results (e.g. in [7, 9]) that $\text{QCSP}(H)$ is in NL. ◀

The other tractable cases are more interesting.

We are now ready to prove the main result of this section.

► **Theorem 22.** *Let $H = H_1 \Rightarrow \dots \Rightarrow H_n$ be a reflexive tournament. If $|V(H_1)| = |V(H_n)| = 1$, then $\text{QCSP}(H)$ is in NL.*

Proof. Let $|V(H)| = m + 2$ for some $m \geq 0$. By Lemma 20, there exists a surjective homomorphism from $(\text{TT}_2^*)^m$ to H . There exists also a surjective homomorphism from H to TT_2^* ; we map s to 0 and all other vertices of H to 1. It follows from [8] that $\text{QCSP}(H) = \text{QCSP}(\text{TT}_2^*)$ meaning we may consider the latter problem. We note that TT_2^* is a transitive reflexive tournament. Hence, we may apply Lemma 21. ◀

5 Final result and remarks

We are now in a position to prove our main dichotomy theorem.

► **Theorem 23.** *Let $H = H_1 \Rightarrow \dots \Rightarrow H_n$ be a reflexive tournament. If $|V(H_1)| = |V(H_n)| = 1$, then $\text{QCSP}(H)$ is in NL; otherwise it is NP-hard.*

Proof. The NL case follow from Theorem 22. The NP-hard cases follow from Corollary 18 and Corollary 19, bearing in mind the case with a non-trivial final strongly connected component is dual to the case with a non-trivial initial strongly connected component (map edges (x, y) to (y, x)). ◀

Theorem 23 resolved the open case in Table 1. Recall that the results for the irreflexive tournaments in this table were all proven in a more general setting, namely for irreflexive semicomplete graphs. A natural direction for future research is to determine a complexity dichotomy for QCSP and SCSP for reflexive semicomplete graphs. We leave this as an interesting open direction.

Abstract

We propose a new model for augmenting algorithms with predictions by requiring that they are formally learnable and instance robust. Learnability ensures that predictions can be efficiently constructed from a reasonable amount of past data. Instance robustness ensures that the prediction is robust to modest changes in the problem input, where the measure of the change may be problem specific. Instance robustness insists on a smooth degradation in performance as a function of the change. Ideally, the performance is never worse than worst-case bounds. This also allows predictions to be objectively compared.

We design online algorithms with predictions for a network flow allocation problem and restricted assignment makespan minimization. For both problems, two key properties are established: high quality predictions can be learned from a small sample of prior instances and these predictions are robust to errors that smoothly degrade as the underlying problem instance changes.

1 Introduction

Inspired by advances in machine learning, there is an interest in augmenting algorithms with predictions, especially in online algorithm design [21, 10, 12, 15, 26, 28, 34, 27]. Algorithms augmented with predictions have had empirical success in domains such as look-up tables [26], caching [28], and bloom-filters [31]. These successes and the availability of data to make predictions using machine learning have motivated the development of new analysis models

for going beyond worst-case bounds where an algorithm is supplied with accurate predictions. In these models, an algorithm is given access to a prediction about the problem instance. The algorithm's performance is bounded in terms of the quality of this prediction. Typically the algorithm learns such predictions from a limited amount of past data leading to *error-prone* predictions. The algorithm with accurate predictions should result in better performance than the best worst-case bound. Ideally, the algorithm never performs asymptotically worse than the best worst-case algorithm even if the prediction error is large. In-between, there is a graceful degradation in performance as the prediction error increases. For example, competitive ratio or running time can be parameterized by prediction error. See [32] for a survey.

Learnable and Instance Robust Predictions. The model proposed in this paper has two pillars for augmenting algorithms with predictions. (**Learnability**;) Predictions should be learnable from representative data. (**Instance Robustness**²;) Predictions should be robust to minor changes in the problem instance. As in prior models, determining what to predict remains a key algorithmic challenge.

Suppose there is an unknown distribution \mathcal{D} over instances \mathcal{I} . Building on data driven algorithm design [21] and PAC-learning models, we require that predicted parameters are provably learnable using a small number of sample instances from \mathcal{D} . The sample complexity of this task can be used to compare how difficult different predictions are to construct. Practically, the motivation is that parameters are learned from prior data (e.g. instances of the problem).

In practice, future problem instances may not come from the same distribution used to learn the parameters. Therefore, we also desire predictions that are robust to modest changes in the input. In particular, if the predictions perform well on some instance \mathcal{I} , then the performance on a nearby instance \mathcal{I}' should be bounded as a function of the distance between these instances. This measure of the distance between instances is necessarily problem specific.

We note that learnability is rarely addressed in prior work and our robustness model differs from many prior works by bounding the error by differences in problem instances (instance robustness), rather than by the differences in the predictions themselves (parameter robustness). We present learnable and instance-robust predictions for two concrete online problems.

Online Flow Allocation Problem. We consider a general flow and matching problem. The input is a Directed-Acyclic-Graph (DAG) G . Each node v has an associated capacity C_v . There is a sink node t , such that all nodes in the DAG can reach the sink. Online source nodes arrive that have no incoming edges (and never have any incoming edges in the future) and the other nodes are offline and fixed. We will refer to online nodes I as impressions. When impression i arrives, it is connected to a subset of nodes N_i . At arrival, the algorithm must decide a (fractional) flow from i to t of value at most 1 obeying the node capacities. This flow is fixed the moment the node arrives. The goal is to maximize the total flow that reaches t without exceeding node capacities. Instances are defined by the number of each *type* of impression. The type of an impression is given by the subset of the nodes of G to which it has outgoing arcs. We may consider specific worst-case instances or a distribution over types

² Note that the robustness here is different from the definition of robustness mentioned in previous work, which we refer to as parameter robustness. See Section 2 for a discussion.

in our analysis. This problem captures fractional versions of combinatorial problems such as online matching, unweighted Adwords, and finding a maximum independent set in a laminar matroid or gammoid. We call the problem the Online Flow Allocation Problem.

Restricted Assignment Makespan Minimization. In this problem, there are m machines and n jobs arrive in an online order. When job j arrives it must be immediately and irrevocably assigned to a machine. The job has size p_j and can only be assigned to a subset of machines specific to that job. After j is assigned the next job arrives. A machine's load is the total size of all jobs assigned to it. The goal is to minimize the makespan, or maximum load, of the assignment.

1.1 Overview of Results for Flow Allocation and Restricted Assignment

We first focus on the flow allocation problem and then we give similar results for the makespan minimization problem.

Node Parameters. Our results on learnability and robustness are enabled by showing the existence of node weights which capture interesting combinatorial properties of flows. Inspired by the weights proven in [2] for bipartite matching, we establish that there is a single weight for each node in the DAG that completely describe near optimal flows on a single problem instance. The weights determine an allocation of flow for each impression which is independent of the other impressions. Each node in the DAG routes the flow leaving it proportionally to the weights of its outgoing neighbors. Moreover, the flow is near optimal, giving a $(1 - \epsilon)$ -approximate solution for any constant $\epsilon > 0$ (but requiring time polynomial in $1/\epsilon$ to compute). Given these weights, the flow can be computed in one forward pass for each impression in isolation. Thus they can be used online if given as a prediction. These weights are also efficiently computable offline given the entire problem instance (see Theorem 3).

Instance Robustness. We measure the distance of the two instances as the difference of the number of impressions of each type (see Theorem 5). We show that if the weights are near optimal for one instance, the performance degrades gracefully according to the distance between the two instances. This distance is defined for any two instances irrespective of whether they are generated by specific distributions³.

Learnability. For learnability it is assumed that impressions are drawn from an unknown distribution over types. We show that learning near-optimal weights for this distribution has low sample complexity under two assumptions. First, we assume the unknown distribution is a product distribution. Second, we assume that the optimal solution of the “expected instance” (to be defined later) has at least a constant amount of flow routed through each node. In the 2-layer case, this assumption can be simplified to requiring each node's capacity to be at least a constant (depending on $\frac{1}{\epsilon}$).⁴ The number of samples is polynomial in the size of the DAG without the impressions. Note that in problems such as Adwords, the impressions are usually much larger than the fixed portion of the graph.

We now present our main theorem on the flow allocation problem.

³ We also show that our predictions for the online flow allocation problem have “parameter robustness”, the kind of robustness that has been considered in prior work (Theorem 6).

⁴ This is similar to the lower bound requirement on budgets in the online analysis of the AdWords problem [16].

► **Theorem 1** (Flow Allocation - Informal). *There exist algorithmic parameters for the Online Flow Allocation problem with the following properties:*

- (i) *(Learnability) Learning near-optimal parameters has sample complexity polynomial in $\frac{1}{\epsilon}$ and the size of the graph excluding the impressions. These parameters result in an online algorithm that is a $(1 - \epsilon)$ -approximate solution in expectation as compared to the expected optimal value on the distribution for any constant $\epsilon > 0$. (Theorem 4)*
- (ii) *(Instance Robustness) Using the optimal parameters for an instance on another instance gives a competitive ratio that improves as their distance decreases, where the distance is proportional to the difference of impressions (Theorem 5).*
- (iii) *(Worst-Case Robustness) The competitive ratio of the online algorithm using the parameters is never worse than $\frac{1}{d+1}$, regardless of the distance between the two instances, where d is the diameter of G . (Theorem 5)*

The theorem states that weights are learnable and only a small number of samples are required to construct weights that are near optimal. These predictions break the worst-case $1 - \frac{1}{e}$ bound on the competitive ratio for any randomized algorithm for online fractional matching, a special case. Moreover, the difference in the types of impressions between two instances gives a metric under which we can demonstrate instance robustness. Further the algorithm has worst-case guarantees, i.e. the ratio is never worse than $\frac{1}{d+1}$, which is tight for deterministic integral online algorithms and d -layer graphs (see Theorem 61 in the full version) even though we output fractional allocations.

We now discuss our results for makespan minimization.

► **Theorem 2** (Restricted Assignment - Informal). *There exist algorithmic parameters for the Restricted Assignment Makespan Minimization problem with the following properties:*

- (i) *(Learnability) Learning the near optimal parameters has sample complexity polynomial in m , the number of machines, and $\frac{1}{\epsilon}$. These parameters result in an online algorithm that is a $(1 + \epsilon)$ approximate solution in expectation as compared to the expected optimal value on the distribution for any constant $\epsilon > 0$. (Theorem 8)*
- (ii) *(Instance Robustness) Using the optimal parameters for any instance on a nearby instance gives a competitive ratio for fractional assignment that is proportional to their distance, where the distance is proportional to the relative difference of job sizes of the same type. (Theorem 7)*
- (iii) *(Worst-Case Robustness) The competitive ratio of the algorithm using the parameters is never worse than $O(\log m)$, matching the known $\Omega(\log m)$ lower-bound on any integral online algorithm. (Theorem 7)*

This theorem shows that the predictions of [27] have much stronger properties than what is known and are learnable and instance robust. That paper left open the question if their predictions can be formally learned in any model. Moreover, it was not known if they are instance robust. We remark that this theorem assumes fractional assignments, whereas the original problem (and the lower bound [8]) requires integer assignments. Lattanzi et al. [27] shows that any fractional assignment can be rounded online while losing a $O((\log \log m)^3)$ factor in the makespan.

1.2 Related Work

Algorithms with Predictions. In this paper, we consider augmenting the standard model of online algorithms with erroneous predictions. Several online problems have been studied in this context, including caching [28, 35, 23, 37], page migration [22], metrical task systems [6], ski rental [34, 19, 3], scheduling [34], load balancing [27], online linear optimization [13], speed scaling [38], set cover [39], and bipartite matching and secretary problems [7].

Antoniadis et al. [7] studies online weighted bipartite matching problems with predictions. The main aspect of this work which distinguishes it from ours is that it considers the random order arrival model, rather than adversarial orders.

Mahdian et al. [29] focuses on the design of robust algorithms. Rather than considering online algorithms which use a prediction, they consider two black box online algorithms, one optimistic and the other pessimistic. The goal is to give an online algorithm which never performs much worse than the better of these two algorithms for any given instance. This is shown for problems such as load balancing, facility location, and ad allocation.

The predictions utilized in our algorithm come in the form of vertex weights that guide a proportional allocation scheme. Agrawal et al. [2] first studied proportional allocations for maximum cardinality fractional matching as well as weighted fractional matchings with high entropy. Lattanzi et al. [27] utilize similar predictions based on proportional weights to give algorithms with predictions for online load balancing.

Data-Driven Algorithm Design. This paper considers the learnability of the predictions through the model of data-driven algorithms. In classical algorithm design, the main desire is finding an algorithm that performs well in the worst case against all inputs for some measure of performance, e.g. running time or space usage. Data-driven algorithm design [21, 9, 11, 10, 12, 15], in contrast, wants to find an algorithm that performs well on the instances that the user is typically going to see in practice. This is usually formalized by fixing a class of algorithms and an unknown distribution over instances, capturing the idea that some (possibly worst case) instances are unlikely to be seen in practice. The typical question asked is: how many sample instances are needed to guarantee you have found the best algorithm for your application domain?

Other Related Work. Online matching and related allocation problems have been extensively studied in both the adversarial arrival setting [25, 24, 17, 30] and with stochastic arrivals [16, 18, 20, 33, 1]. A related but different setting to ours is the online algorithms with advice setting [14]. Here the algorithm has access to an oracle which knows the offline input. The oracle is allowed to communicate information to the algorithm about the full input, and the goal is to understand how many bits of information are necessary to achieve a certain competitive ratio. This has also been extended to the case where the advice can be arbitrarily wrong [4]. This can be seen as similar to our model, however the emphasis isn't on tying the competitive ratio to the amount of error in the advice.

2 Algorithms with Learnable and Instance-Robust Predictions

Learnability via Sample Complexity. We consider the following setup inspired by PAC learning and recently considered in data-driven algorithms. Assume a maximization problem and let \mathcal{D} be an unknown distribution over problem instances. Let $\text{ALG}(\mathcal{I}, y)$ be the performance⁵ of an algorithm using parameters y on instance \mathcal{I} . The ideal prediction for this distribution is then $y^* := \arg \max_y \mathbb{E}_{\mathcal{I} \sim \mathcal{D}}[\text{ALG}(\mathcal{I}, y)]$. Since we assume that \mathcal{D} is unknown, we wish to learn from samples. In particular, we wish to use some number s of independent samples to compute a parameter \hat{y} such that $\mathbb{E}_{\mathcal{I} \sim \mathcal{D}}[\text{ALG}(\mathcal{I}, \hat{y})] \geq (1 - \epsilon) \mathbb{E}_{\mathcal{I} \sim \mathcal{D}}[\text{ALG}(\mathcal{I}, y^*)]$

⁵ In general this can be any performance metric, such as running time or solution value. Here we focus on the value of some objective function such as the size of a fractional flow.

with probability $1 - \delta$, for any $\epsilon, \delta \in (0, 1)$. The sample complexity s depends on the problem size as well as $1/\epsilon$ and $1/\delta$. As is standard in learning theory, we require the sample complexity to be polynomial in these parameters⁶.

Inspired by competitive analysis, we also compare to the following stronger benchmark in this paper. For any instance \mathcal{I} , let $\text{OPT}(\mathcal{I})$ be the value of an optimal solution on \mathcal{I} . We give learning algorithms producing predicted parameters \hat{y} such that $\mathbb{E}_{\mathcal{I} \sim \mathcal{D}}[\text{ALG}(\mathcal{I}, \hat{y})] \geq (1 - \epsilon)\mathbb{E}_{\mathcal{I} \sim \mathcal{D}}[\text{OPT}(\mathcal{I})]$ and polynomial sample complexity under the assumptions on \mathcal{D} described earlier. Note that this guarantee implies the first one.

Instance Robustness. Let \mathcal{I} and \mathcal{I}' be two problem instances, and consider running the algorithm on instance \mathcal{I}' with the prediction $y^*(\mathcal{I})$. We bound the performance of the algorithm as a function of the difference between these two instances. In contrast, prior work focuses on differences in the predicted parameters y^* and y' for the same instance \mathcal{I} . Moreover, it is desirable that the algorithm never performs worse than the best worst-case algorithm.

For example, in online flow allocation, we can consider an instance as a vector of types, i.e. \mathcal{I}_i is the number of impressions of type i . Then we can take the difference between the instances as $\gamma = \|\mathcal{I} - \mathcal{I}'\|_1$. Say $y^*(\mathcal{I})$ can be used to give a c -competitive algorithm on instance \mathcal{I} . Let α be the best competitive ratio achievable in the worst-case model. We desire an algorithm that is $\max\{f(c, \gamma), \alpha\}$ -competitive where f is a monotonic function depending on c and γ . We remark that the online model requires \mathcal{I}' to arrive in a worst-case order.

2.1 Putting the Model in Context

Relationship to Prior Predictions Model. The first main difference in this model as compared to prior work is *learnability*. With the notable exception of [3], prior work has introduced predictions without establishing they are learnable. Without this requirement there is no objective metric to detail if a prediction is reasonable or not. To see this shortcoming, imagine simply predicting the optimal solution for the problem instance. This is often not reasonable because the optimal solution is too complex to learn and use as a prediction. We introduce bounded sample complexity for learning predictions in our model to ensure predictions can be provably learned.

Next difference is in how to measure error. The performance of the algorithm is bounded in terms of the error in the prediction in the prior model. For example, say the algorithm is given a predicted vector $\hat{y}(\mathcal{I})$ for problem instance \mathcal{I} and the true vector that should have been predicted is $y^*(\mathcal{I})$. One can define $\eta_{\hat{y}(\mathcal{I})} = \|\hat{y}(\mathcal{I}) - y^*(\mathcal{I})\|_p$ to be the *error* in the parameters for some norm $p \geq 1$. The goal is to give an algorithm that is $f(\eta_{\hat{y}(\mathcal{I})})$ -competitive for an online algorithm where f is some non-decreasing function of $\eta_{\hat{y}(\mathcal{I})}$: the better the function f , the better the algorithm performance. One could also consider run time or approximation ratio similarly. Notice the bound is worst-case for a given error in the prediction. This we call *parameter robustness*.

It is perhaps more natural to define a difference between two problem instances as in our model rather than the difference between two predicted parameters. Indeed, consider predicting optimal dual linear program values. These values can be different for problem instances that are nearly identical. Therefore, accurate parameters will not be sufficient to handle inconsequential changes in the input. Instance robustness allows for more accurate

⁶ For more difficult problems, we can relax the $1 - \epsilon$ requirement to be a weaker factor.

■ **Table 1** Relationship to Prior Work.

Problem	Parameter Robustness	Learnability	Instance Robustness

comparison of two predictions on similar problem instances. More practically, instance closeness is easier to monitor than closeness of the proposed predictions to an unknown optimal prediction for the whole instance.

Learning Algorithm Parameters. Learning algorithmic parameters has distinct advantages over learning an input distribution. In many cases it can be easier to learn a decision rule than it is to learn a distribution. For example, consider the unweighted b -matching problem in bipartite graphs for large b in the online setting. In this problem there is a bipartite graph $G = (I \cup A, E)$ with capacities $b \in \mathbb{Z}_+^A$. The objective is to find a collection of edges such that each node in I is matched at most once and each node $a \in A$ is matched at most b_a times. Nodes on one side of the graph arrive online and must be matched on arrival. Say the nodes are i.i.d. sampled from an unknown discrete distribution over types. A type is defined by the neighbors of the node. Let s be the number of types. Then the sample complexity of learning the distribution is $\Omega(s)$. Notice that s could be superlinear in the number of nodes. In our results, the sample complexity is independent of the number of types in the support of the distribution. The phenomenon that it is sometimes easier to learn good algorithmic parameters rather than the underlying input distribution has been observed in several prior works. See [21, 9, 11, 10, 12, 15] for examples.

Table 1 illustrates how our paper relates to prior work, focusing on the two pillars for augmenting algorithms emphasized in our model.

Paper Organization. In this extended abstract, we give a technical overview of our results. For online flow allocation, both learnability and instance-robustness rely on showing the existence of node predictions which is described in Section 3, followed by learnability and robustness in Sections 4 and 5 respectively. Section 6 considers online load balancing and gives a brief technical overview. All proofs of our results are available in the full version of this paper.

3 Matchings and Flows: Existence of Weights

Consider a directed acyclic graph $G = (\{s, t\} \cup V, E)$, where each vertex $v \in V$ has capacity C_v and is on some $s - t$ path. Our goal is to maximize the flow sent from s to t without violating vertex capacities. Before considering the general version, we examine the 3-layered version. Say a graph is d -layered if the vertices excluding s, t can be partitioned into d ordered sets where all arcs go from one set to the next. Then the 3-layered case is defined as follows. The vertices in V are partitioned into 3 sets I, A , and B . s is connected to all of I and t is connected from all of B , while the remaining edges are only allowed to cross from I to A and from A to B . Let $N_u := \{v \in V \mid (u, v) \in E\}$ be u 's out-neighbors. We have the following result generalizing the prior work of Agrawal et al [2] on 2-layered graphs.

► **Theorem 3.** *Let $G = (\{s, t\} \cup V, E)$ be a 3-layered DAG. For each edge $(u, v) \in E$, let x_{uv} be the proportion of flow through u which is routed along (u, v) . For any $\epsilon \in (0, 1)$, there exist weights $\{\alpha_v\}_{v \in V}$ such that setting $x_{uv} = \frac{\alpha_v}{\sum_{v' \in N_u} \alpha_{v'}}$ yields a $(1 - \epsilon)$ -approximate flow. Moreover, these weights can be obtained in time $O(n^4 \log(n/\epsilon)/\epsilon^2)$.*

We can generalize this theorem to d -layered graphs. In particular, our algorithm for the d -layered case produces weights with additional properties, which we leverage to handle general DAGs. Notice that the number of weights is proportional to the number of nodes in the graph and not the number of edges. We believe it is an interesting combinatorial property that such succinct weights on the nodes can encode a good flow on the asymptotically larger number of edges and is of independent interest.

Technical Overview

Here we give a technical overview. The full proof is omitted in this version.

A Simple Algorithm for Layered Graphs. Prior work [2] showed that there exists a set of weights giving nearly the same guarantees we show, but only for bipartite graphs. The existence of such weights can be generalized to d -layer graphs easily as follows. First find an (optimal) maximum flow f . For each vertex v , let $f(v)$ be the flow going through v . Reset the vertex capacity of v to be $f(v)$. For each pair of adjacent layers find the weights between the two layers independently using the algorithm of [2], treating nodes v on the left hand side as $f(v)$ individual impressions. By the previous result, each layer only loses a negligible portion of the total flow which can be compounded to yield a low loss for these set of weights.

The above reduction does not generalize to general DAGs. One can arrange a DAG into layers, but there are fundamental algorithmic challenges with constructing weights that arise when edges cross layers. One of this paper’s algorithmic contributions is showing how to construct such weights for general DAGs. Moreover, as an intermediate result, we show how to compute the weights directly extending the approach of [2] for multi-layer graphs without first solving a flow problem optimally as in the above reduction.

Finding Weights for Bipartite Graphs. We begin by first simplifying the algorithm of [2] for bipartite graphs. Let $G = (\{s, t\} \cup I \cup A, E)$ be such a graph. In this case, the fraction of flow $u \in I$ sends to $v \in A$ simplifies to $x_{uv} = \frac{\alpha_v}{\sum_{v' \in N_u} \alpha_{v'}}$ where $\{\alpha\}_{v \in I \cup A}$ are the set of weights. Initially all of the weights are 1 for a vertex $a \in A$. Some of the nodes receive more flow than their capacity in this initial proportional allocation according to the weights. We say a node for which the current proportional allocation of flow exceeds its capacity by a $1 + \epsilon$ factor is *overallocated*. In an iteration, the algorithm decreases the weights of these nodes by a $1 + \epsilon$ factor.⁷ After this process continues for a poly-logarithmic number of iterations, we will be able to show the resulting weights result in a near optimal flow.

To prove that the final weights are near optimal, we show that the weights can be directly used to identify a vertex cut whose value matches the proportional flow given by the weights. In particular, we will partition the nodes in A based on their weight values. For a parameter β , we say a node is “above the gap” if its weight is larger than $\beta n/\epsilon$. A node of weight less

⁷ Prior work [2] performed this operation as well as *increasing* the weights of nodes whose allocation was significantly below the capacity. Our simplification to allow only decreases helps with the generalization to more complex graphs and correcting for error in the weights.

than β is below the gap. All others are in the gap. The parameter β is chosen such that the nodes in the gap contribute little to the overall flow and they can essentially be discarded via an averaging argument⁸. Assume this set is empty for simplicity. Let $\mathcal{G}(A)^+$ and $\mathcal{G}(A)^-$ be the sets of vertices in A above and below the gap, respectively.

We now describe a cut. Let $I_0 \subseteq I$ be the impression nodes adjacent to at least one node in $\mathcal{G}(A)^+$. Then the vertex cut is $I_0 \cup \mathcal{G}(A)^-$. Since all paths must either cross I_0 or $\mathcal{G}(A)^-$, this is a valid vertex cut. We now show the cut value is close to the flow achieved by the weights, completing the analysis using the weaker direction of the max-flow min-cut theorem.

First, nodes in I_0 are cut. Due to the way flow is sent based on the weight proportions, for any vertex I_0 , at least a $(1 - \epsilon)$ proportion of its flow will be sent to $\mathcal{G}(A)^+$. Since the nodes in $\mathcal{G}(A)^+$ did not decrease the weights at least once, at some point they were not over-allocated. We claim that because of this, they will never be over-allocated hence and, therefore, nodes in I_0 send nearly all of their flow to the sink successfully. Next nodes in $\mathcal{G}(A)^-$ are cut. These nodes decreased their weights (almost) every iteration because they are at or above their allocation. Thus, for all these nodes we get flow equal to their total capacity. The fraction of this flow through $\mathcal{G}(A)^-$ coming from paths using I_0 is negligible because of the weight proportions so this flow is almost disjoint from that of I_0 . Thus, we have found a proportional flow nearly matching the value of the cut identified.

General Graphs. Now we consider the more general algorithm. To convey intuition, we will only consider directly computing weights for a 3-layered graph $G = (\{s\} \cup I \cup A \cup B \cup \{t\}, E)$ where edges are between adjacent layers. This will highlight several of the new ideas. As before, weights of all nodes are initially one. And as before, a node decreases its weight if it is over-allocated, which we will refer now to as a *self-decrease*. Now though, whenever a node in A decreases its weight it does so by a $(1 + \epsilon')$ factor and those in B decrease at a $(1 + \epsilon)$ factor where $\epsilon' \leq \epsilon$.

A new challenge is that a node b in layer B may be over allocated and it may not be enough for B to reduce its weight. Indeed, B may need some neighbors in A to reduce their allocation. For instance, if $b \in B$ has neighbors in A for which it is the only neighbor, then reducing b 's weight does not change its allocation and the flow needs to be redistributed in the first layer. In this case, the nodes in B will specify that some nodes in A need to decrease their allocation. We call this a *forced decrease*. This set has to be carefully chosen and intuitively only the nodes in A that are the largest weight as compared to $b \in B$ are decreased. We run this procedure for a polylogarithmic number of steps and again we seek to find a cut matching the achieved flow.

We discuss the need for different ϵ and ϵ' . In the bipartite case when a node decreased its weight, that node is guaranteed to receive no more allocation in the next round (it could remain the same though). Intuitively, this is important because in the above proof for bipartite graphs we want that if a node is in $\mathcal{G}(A)^+$, above the gap, if it was ever under-allocated then it never becomes over-allocated in later iterations. Our update ensures this will be the case since self-decreases will continue henceforth to keep the load of such a node below its capacity. Consider setting $\epsilon = \epsilon'$ for illustration. Because of the interaction between layers, a node i in B could receive more allocation even if it decreases its weight in an iteration. This is because the nodes in A and B could change their weights. Nodes in A changing their weight can give up to an extra $(1 + \epsilon)$ allocation (via predecessors of i that are

⁸ This averaging is what necessitates the poly-logarithmic number of weight update iterations in the algorithm

not decreased), and the same for B for a total of $(1 + \epsilon)^2$ extra allocation arriving at i . The node decreasing its weight reduces its allocation by a $(1 + \epsilon)$ factor for a total change of a $(1 + \epsilon)^2 \cdot \frac{1}{(1 + \epsilon)} > 1$ factor. By choosing ϵ and ϵ' to be different, as well as the characterization of which nodes decrease during a forced decrease, we can show any node will not receive less allocation if its weight does not decrease and will not receive more allocation if it performs a decrease. We call these properties “Increasing monotonicity” and “Decreasing monotonicity” in the full version of this paper.

As in the bipartite case, we can find a gap in layers A and B , which gives sets above the gap $\mathcal{G}(A)^+$ and $\mathcal{G}(B)^+$ in A and B , respectively. Let the sets $\mathcal{G}(A)^-$ and $\mathcal{G}(B)^-$ be the nodes below the gap. As before nodes in $\mathcal{G}(A)^-$ (resp., $\mathcal{G}(B)^-$) decreased their weight many more iterations than $\mathcal{G}(A)^+$ (resp., $\mathcal{G}(B)^+$). For simplicity, assume this partitions the nodes of the entire graph, so no nodes are inside either gap. Let $I_0 \subseteq I$ be the nodes adjacent to at least one node in $\mathcal{G}(A)^+$. Let A_0 be nodes in $\mathcal{G}(A)^-$, below the gap, that have an edge to $\mathcal{G}(B)^+$ (the analogue of I_0 in the A -layer). Any flow path that crosses the A layer at $\mathcal{G}(A)^+$, A_0 and $\mathcal{G}(A)^- \setminus A_0$ are blocked by the sets I_0, A_0 and $\mathcal{G}(B)^-$ respectively showing that this set forms a vertex cut.

We show the flow obtained is nearly the value of the vertex cut $I_0 \cup A_0 \cup \mathcal{G}(B)^-$. As before, nodes in I_0 (resp. A_0) send almost all their flow to nodes above the gap in the next layer $\mathcal{G}(A)^+$ (resp. $\mathcal{G}(B)^+$). Like before $\mathcal{G}(A)^+$ and $\mathcal{G}(B)^+$ do not decrease every round, so we can show they are not allocated more than their capacity (see Lemma 11 and Lemma 13 in this paper’s full version). The algorithmic key is that, by choosing the forced decrease carefully, we can show each node in $\mathcal{G}(A)^+$ has a neighbor in $\mathcal{G}(B)^+$. This ensures almost all of $\mathcal{G}(A)^+$ ’s flow reaches the sink because all of these nodes will send essentially all their the flow to $\mathcal{G}(B)^+$ and these nodes are not at capacity. Thus, I_0 can send all its flow to the sink successfully. Similarly, A_0 sends its flow to $\mathcal{G}(B)^+$ and then to the sink. Finally, as before, $\mathcal{G}(B)^-$ (as well as $\mathcal{G}(A)^-$) are sets of nodes near their allocation because they decreased essentially every iteration (see Lemma 12 and Lemma 14 in the full version). Thus, $\mathcal{G}(B)^-$ sends its flow directly to the sink. Moreover, we ensure that only a negligible fraction of this flow is double counted by the definition of the large weight reduction across the gaps (see Lemma 15 in the full version); therefore we have found a flow allocation obtained by the weights whose value nearly matches the value of an identified cut.

This analysis generalizes to layered DAGs where edges do not cross layers. To extend the existence of these weights to general DAGs we reduce the problem to finding weights with additional structural properties on a layered DAG. From the input DAG we make additional copies of nodes that have ancestors in earlier layers and link these copies via a path to the original neighbor. We convert any edge that crosses many layers to one in the layered DAG from its original head node to the copy of its tail node in the next layer. Then we argue that a key functional relation exists between the weights of any original node and its copies in earlier layers. This allows us to transfer the weights computed in the auxiliary layered DAG to the original DAG.

4 Matchings and Flows: Learnability of Predictions

We show that the weights are efficiently learnable. Assuming that each arriving impression is i.i.d. sampled from an unknown distribution, we want to learn a set of weights from a collection of past instances and examine their expected performance on a new instance

from the same distribution⁹. A direct approach might be to learn the unknown distribution from samples and utilize known ideas from stochastic optimization (where knowledge of the distribution is key). A major issue though is that there can be a large number of possible types (potentially exponential in the number of nodes of the DAG). A distribution that is sparse over types is not easy to learn with a small number of samples.

We claim that the weights are efficiently learnable, even if the distribution of types of impressions is not. We show that this task has low sample complexity and admits an efficient learning algorithm. Consequently, if there is an unknown arbitrary distribution that the impressions are drawn from, then only a small number of instances is required to compute the weights. The number of samples is proportional to size of the DAG without the impressions. In most problems such as Adwords, the number of arriving impressions is much larger than the fixed (offline) portion of the graph.

Before stating our results, we introduce two necessary assumptions. The first assumption is that each impression is i.i.d. sampled from an unknown distribution \mathcal{D} . Where no ambiguity will result, we also say an instance is sampled from \mathcal{D} if each impression is an i.i.d sample from \mathcal{D} . The second assumption is related to the expected instance of the distribution \mathcal{D} . The **expected instance** of a distribution is the instance where the number of each type of impressions is exactly the expected value.¹⁰ We assume that in the optimal solution of the expected instance, the load of each node is larger than a constant. Namely, it cannot happen that in the optimal flow, there exist many vertices which obtain very small amount of flow.

► **Theorem 4.** *Under the two assumptions above, for any $\epsilon, \delta \in (0, 1)$, there exists a learning algorithm such that, after observing $O(\frac{n^2}{\epsilon^2} \ln(\frac{n \log n}{\delta}))$ instances, returns weights $\{\hat{\alpha}\}$, satisfying that with probability at least $1 - \delta$, $\mathbb{E}_{I \sim \mathcal{D}}[R(\hat{\alpha}, I)] \geq (1 - \epsilon)\mathbb{E}_{I \sim \mathcal{D}}[R(\alpha^*, I)]$ where $R(\alpha, I)$ is the value of the fractional flow obtained by applying α to instance I and $\alpha^* = \arg \max_{\alpha} \mathbb{E}_{I \sim \mathcal{D}}[R(\alpha, I)]$.*

Technical Overview. Here we overview the analysis. The full proof is omitted in this version. To show that the weights are learnable we utilize a model similar to that of data-driven algorithm design. To illustrate our techniques we focus on the case when the instance is a bipartite graph $G = (I \cup A, E)$ with capacities C_a for each $a \in A$ (also recall that $|A| = n$).

In this setting there is an unknown distribution \mathcal{D} over instances of I of length m . The t 'th entry of I represents the t 'th impression arriving online. Our goal is to find a set of weights that performs well for the distribution \mathcal{D} . In particular let $\alpha^* := \arg \max_{\alpha \in \mathcal{S}} \mathbb{E}_{I \sim \mathcal{D}}[R(\alpha, I)]$ be the *best* set of weights for the distribution. Define $R(\alpha, I)$ to be the value of the matching using weights α on instance I . Here \mathcal{S} is a set of “admissible” weights, and in particular we only consider weights output by a proportional algorithm similar to the algorithm of Agrawal et al. [2]. We are allowed to sample s independent samples I_1, I_2, \dots, I_s from \mathcal{D} and use these samples to compute a set of weights $\hat{\alpha}$. We say that a learning algorithm (ϵ, δ) -learns the weights if with probability at least $1 - \delta$ over the samples from \mathcal{D} , we compute a set of weights $\hat{\alpha}$ satisfying $\mathbb{E}_{I \sim \mathcal{D}}[R(\hat{\alpha}, I)] \geq (1 - \epsilon)\mathbb{E}_{I \sim \mathcal{D}}[R(\alpha^*, I)]$.

This definition is similar to PAC learning [36]. Also note we are aiming for a relative error guarantee rather than an absolute error. The main quantity of interest is then the *sample complexity*, i.e. how large does s need to be as a function of n, m, ϵ , and δ in order to (ϵ, δ) -learn a set of weights? Ideally, s only depends polynomially on $n, m, 1/\epsilon$, and $1/\delta$, and smaller is always better.

⁹ We can also analyze the performance on similar distributions by applying techniques from our instance robustness result

¹⁰ Note this could be a fractional value.

The standard way to understand the sample complexity for this type of problem is via the *pseudo-dimension*. Intuitively, pseudo-dimension is the natural extension of VC-dimension to a class of real valued functions. In our case the class of functions is $\{R(\alpha, \cdot) \mid \alpha \in \mathcal{S}\}$, i.e. we are interested in the class of function mapping each instance I to the value of the fractional matching given by each fixed set of weights α . If the pseudo-dimension of this class of functions is d , then $s \approx \frac{d}{\epsilon^2} \log(1/\delta)$ samples are needed to (ϵ, δ) learn the weights, given that we are able to approximately optimize the empirical *average* performance [5].

The good news for our setting is that the pseudo-dimension of our class of functions is bounded. Each node in the set A can only have one of T different weight values for some parameter T . Then since the number of nodes in A is n , there can only be at most T^n different “admissible” weights. It is well known that the pseudo-dimension of a finite class of k different functions is $\log_2(k)$. Thus the pseudo-dimension of our class of functions is $d = n \log_2(T)$. As long as T isn’t growing too fast as a function of n and m , we get polynomial sample complexity.

Unfortunately, finding weights to optimize the average performance across the s sampled instances is complicated. Note that for a fixed instance I , the value of the matching as a function of the weights, $R(\cdot, I)$, is non-linear in the weights since we are using proportional allocation. Moreover, it is neither convex nor concave in the parameters α so applying a gradient descent approach will not work. Due to this, it is difficult to analyze the learnability via known results on pseudo-dimension.

The main tool we have at our disposal is that for a fixed instance I , we can compute weights α such that $R(\alpha, I) \geq (1 - \epsilon) \text{OPT}(I)$. This motivates the following natural direct approach. Take the s sampled instances I_1, I_2, \dots, I_s and take their union to form a larger “stacked” instance \hat{I} . We then run the aforementioned algorithm on \hat{I} to get weights $\hat{\alpha}$. Intuitively, if s is large enough, then by standard concentration inequalities $\hat{I} \approx s\mathbb{E}[I]$, i.e. the stacked instance approaches s copies of the “expected” instance. Then to complete the analysis, we need to show that $\mathbb{E}[R(\hat{\alpha}, I)] \approx R(\hat{\alpha}, \mathbb{E}[I])$. In general, it is not true that $\mathbb{E}[R(\hat{\alpha}, I)] \approx R(\hat{\alpha}, \mathbb{E}[I])$. Using more careful analysis, we show that when the distribution \mathcal{D} is a product distribution and our two assumptions hold, this is in fact the case.

5 Matching and Flows: Robustness

Instance Robustness. To show the instance robustness, we assume that we can describe the instance directly. Say we have a description of the entire instance denoted by a vector $\hat{I} = (\hat{m}_1, \dots, \hat{m}_i, \dots)$, where \hat{m}_i is the number of impressions of type i . We show that if a set of weights performs well in instance \hat{I} , it can be transferred to a nearby instance I robustly.

► **Theorem 5.** *For any $\epsilon > 0$, if a set of weights $\hat{\alpha}$ returns a $(1 - \epsilon)$ -approximated solution in instance \hat{I} , it yields an online flow allocation on instance I whose value is at least $\max\{(1 - \epsilon)\text{OPT} - 2\gamma, \text{OPT}/(d + 1)\}$. Here OPT is the maximum flow value on instance I , d is the diameter of this graph excluding vertex t , and γ is the difference between two instances, defined by $\|\hat{I} - I\|_1$.*

This theorem can be interpreted as follows. If we sample the instance and compute the weights in it, these weights will work well and break through worst-case bounds when the type proportions are sampled well. Indeed, the weights will perform well in nearby instances with similar type proportions. Moreover, the algorithm never performs worse than a $\frac{1}{d+1}$ factor of optimal. We remark that this is the best competitive ratio a deterministic integral algorithm can achieve because we show a lower bound on such algorithms (see Appendix G.2

in the full version of this paper). This example builds a recursive version of the simple lower bound of $\frac{1}{2}$ on the competitive ratio of deterministic online algorithms for the matching problem.

Recall that the key to showing existence of the weights was to construct a cut whose capacity is nearly the same as the value of the flow given by the weights. To show robustness against nearby instances, we observe how this proof can be extended to nearby cuts. This allows us to argue about the optimal value of the new instance. Standard calculations then let us connect the value of the predicted weights to this optimal value while losing only $O(\gamma)$ in the value of the flow. To ensure the algorithm is never worse than a $\frac{1}{d+1}$ factor of the optimal, we guarantee that the algorithm always returns a maximal allocation.

Parameter Robustness. For the parameter robustness, we show that the performance degrades linearly in the relative error of the weight parameter. Thus, our algorithm has the same robustness guarantees shown in other works as well.

► **Theorem 6.** *Consider a prediction of $\hat{\alpha}_v$ for each vertex $v \in V$. Due to scale invariance, we can assume that the minimum predicted vertex weight $\hat{\alpha}_{\min} = 1$. Define the prediction error $\eta := \max_{v \in V}(\frac{\hat{\alpha}_v}{\alpha_v^*}, \frac{\alpha_v^*}{\hat{\alpha}_v})$, where $\{\alpha_v^*\}_{v \in V}$ are vertex weights that can achieve an $(1 - \epsilon)$ -approximate solution and $\alpha_{\min}^* = 1$ for any fixed $\epsilon > 0$. Employing predictions $\hat{\alpha}$, we can obtain a solution with competitive ratio $\max(\frac{1}{d+1}, \frac{1-\epsilon}{\eta^{2d}})$, where d is the diameter of this graph excluding vertex t .*

When the prediction error η approaches one, the performance smoothly approaches optimal. While the above theorem involves comparing the propagation of the prediction errors in the performance analysis, we also investigate how inaccurate predictions can be adaptively corrected and improved in the 2-layered Adwords case. For that case, we give an improved algorithm that can correct error in the weights, so that the loss is only $O(\log \eta)$. Moreover, we show that the way we adapt is *tight* and the best possible up to constant factors for any algorithm given predicted weights with error η .

The parameter robustness follows almost directly from the definition of the proportional assignment given by the weights. In each layer, the over allocation (potentially above the capacity) can be easily bounded by a η^2 factor, resulting in a loss of at most η^{2d} on a d layer graph. We remark that directly using the weights ensures the algorithm is never worse than a $\frac{1}{d+1}$ factor of the optimal solution. The technical proof, along with the weight-adapting technique for the 2-layered case, is present in Appendix G of this paper's full version.

6 Results on Load Balancing

Next we show results for restricted assignment load balancing problem in our model. In particular, we study the instance robustness and learnability of proportional weights for this problem. The existence of useful weights and parameter robustness for predicting these weights were shown in prior work [2, 27]. As discussed before, we focus on analyzing fractional assignments.

To describe our results we introduce the following notation. Let $[m]$ denote the set of machines and S denote a set of jobs. Each job $j \in S$ has a size p_j and a neighborhood $N(j)$ of feasible machines. Given a set of positive weights $\{w_i\}_{i \in [m]}$ on the machines, we define a fractional assignment for each job j by setting $x_{ij}(w) = \frac{w_i}{\sum_{i' \in N(j)} w_{i'}}$ for each $i \in N(j)$. Let $\text{ALG}(S, w)$ be the fractional makespan on the jobs in S with weights w and similarly let $\text{OPT}(S)$ be the optimal makespan on the jobs in S . Prior work [2, 27] shows that for any set of jobs S and $\epsilon > 0$ there exists weights α such that $\text{ALG}(S, w) \leq (1 + \epsilon)\text{OPT}(S)$.

To describe our instance robustness result we consider an instance of the problem as follows. Consider instances with n jobs. The type of a job is the subset of machines to which it can be assigned. Let S_j be the total size of jobs of type j in instance S . We consider relative changes in the instance and define the difference between instances S and S' as $\eta(S, S') := \max_j \max\{\frac{S_j}{S'_j}, \frac{S'_j}{S_j}\}$. Our instance robustness result is given in the following theorem.

► **Theorem 7.** *For any instance S and $\epsilon > 0$, let w be weights such that $\text{ALG}(S, w) \leq (1 + \epsilon)\text{OPT}(S)$. Then for any instance S' we have $\text{ALG}(S', w) \leq (1 + \epsilon)^2 \eta(S, S')^2 \text{OPT}(S')$.*

Let w be as in the statement of the theorem and w' be weights such that $\text{ALG}(S', w') \leq (1 + \epsilon)\text{OPT}(S')$. Intuitively, we lose the first factor of $\eta(S, S')$ by bounding the performance of w on S' and the second factor by bounding the performance of w' on S .

Next we study learnability. We give the first result showing these weights are learnable in any model. In order to understand the sample complexity of learning the weights we need to consider an appropriate discretization of the space of possible weights. For integer $R > 0$ and $\epsilon > 0$, let $\mathcal{W}(R) = \{\alpha \in \mathbb{R}^m \mid \alpha_i = (1 + \epsilon)^k, i \in [m], k \in \{0, 1, \dots, R\}\}$. Additionally, let p_{\max} be an upper bound on all jobs sizes. The following theorem characterizes the learnability of the weights for restricted assignment load balancing.

► **Theorem 8.** *Let $\epsilon, \delta \in (0, 1)$ be given and set $R = O(\frac{m^2}{\epsilon^2} \log(\frac{m}{\epsilon}))$ and let $\mathcal{D} = \prod_{j=1}^n \mathcal{D}_j$ be a product distribution over n -job restricted assignment instances such that $\mathbb{E}_{S \sim \mathcal{D}}[\text{OPT}(S)] \geq \Omega(\frac{1}{\epsilon^2} \log(\frac{m}{\epsilon}))$. There exists an algorithm which finds weights $w \in \mathcal{W}(R)$ such that $\mathbb{E}_{S \sim \mathcal{D}}[\text{ALG}(S, w)] \leq (1 + \epsilon)\mathbb{E}_{S \sim \mathcal{D}}[\text{OPT}(S)]$ with probability at least $1 - \delta$ when given access to $s = \tilde{O}(\frac{m^3}{\epsilon^2} \log(\frac{1}{\delta}))$ independent samples $S_1, S_2, \dots, S_s \sim \mathcal{D}$.*

Our techniques here are similar to that of the online flow allocation problem in that we use the samples to construct a “stacked” instance then compute a set of near optimal weights on this instance. We then have to show that these weights work well in expectation with high probability. This step necessitates the two assumptions in the theorem statement. First, we need that the expected optimal makespan is reasonably large so that the expected makespan is close to the maximum of the expected loads of the machines. Second, we need that the instance is drawn from a product distribution so that the stacked instance converges in some sense to s copies of the “expected” instance. See the full version of the paper for complete arguments.

Abstract

Filters are small, fast, and approximate set membership data structures. They are often used to filter out expensive accesses to a remote set \mathcal{S} for negative queries (that is, filtering out queries $x \notin \mathcal{S}$). Filters have one-sided errors: on a negative query, a filter may say “present” with a tunable false-positive probability of ε . Correctness is traded for space: filters only use $\log(1/\varepsilon) + O(1)$ bits per element.

The false-positive guarantees of most filters, however, hold only for a single query. In particular, if x is a false positive, a subsequent query to x is a false positive with probability 1, not ε . With this in mind, recent work has introduced the notion of an **adaptive filter**. A filter is adaptive if each query is a false positive with probability ε , regardless of answers to previous queries. This requires “fixing” false positives as they occur.

Adaptive filters not only provide strong false positive guarantees in adversarial environments but also improve query performance on practical workloads by eliminating repeated false positives.

Existing work on adaptive filters falls into two categories. On the one hand, there are practical filters, based on the cuckoo filter, that attempt to fix false positives heuristically without meeting the adaptivity guarantee. On the other hand, the broom filter is a very complex adaptive filter that meets the optimal theoretical bounds.

In this paper, we bridge this gap by designing the **telescoping adaptive filter** (TAF), a practical, provably adaptive filter. We provide theoretical false-positive and space guarantees for our filter, along with empirical results where we compare its performance against state-of-the-art filters. We also implement the broom filter and compare it to the TAF. Our experiments show that theoretical adaptivity can lead to improved false-positive performance on practical inputs, and can be achieved while maintaining throughput that is similar to non-adaptive filters.

1 Introduction

A filter is a compact and probabilistic representation of a set \mathcal{S} from a universe \mathcal{U} . A filter supports insert and query operations on \mathcal{S} . On a query for an element $x \in \mathcal{S}$, a filter returns “present” with probability 1, i.e., a filter guarantees no false negatives. A filter is allowed to have bounded false positives – on a query for an element $x \notin \mathcal{S}$, it may incorrectly return “present” with a small and tunable false-positive probability ε .

Filters are used because they allow us to trade correctness for space. A lossless representation of $\mathcal{S} \subseteq \mathcal{U}$ requires $\Omega(n \log u)$ bits, where $n = |\mathcal{S}|$, $u = |\mathcal{U}|$, and $n \ll u$. Meanwhile, an optimal filter with false-positive probability ε requires only $\Theta(n \log(1/\varepsilon))$ bits [11].

Examples of classic filters are the *Bloom filter* [7], the *cuckoo filter* [18], and the *quotient filter* [6]. Recently, filters have exploded in popularity due to their widespread applicability – many practical variants of these classic filters have been designed to improve upon throughput, space efficiency, or cache efficiency [8, 16, 19, 22, 29, 32].

A filter’s small size allows it to fit in fast memory, higher in the memory hierarchy than a lossless representation of \mathcal{S} would allow. For this reason, filters are frequently used to speed up expensive queries to an external dictionary storing \mathcal{S} .

In particular, when a dictionary for \mathcal{S} is stored remotely (on a disk or across a network), checking a small and fast filter first can avoid expensive remote accesses for a $1 - \varepsilon$ fraction of negative queries. This is the most common use case of the filter, with applications in LSM-based key-value stores [12, 23, 27], databases [13, 15, 17], and distributed systems and networks [9, 31].

False positive guarantees and adaptivity. When a filter is used to speed up queries to a remote set \mathcal{S} , its performance depends on its false-positive guarantees: how often does the filter make a mistake, causing us to access \mathcal{S} unnecessarily?

Many existing filters, such as the Bloom, quotient and cuckoo filters, provide poor false-positive guarantees because they hold only for a single query. Because these filters do not *adapt*, that is, they do not “fix” any false positives, querying a known false positive x repeatedly can drive their false-positive rate to 1, rendering the filter useless.

Ideally, we would like a stronger guarantee: even if a query x has been a false positive in the past, a subsequent query to x is a false positive with probability at most ε . This means that the filter must “fix” each false positive x as it occurs, so that subsequent queries to x are unlikely to be false positives. This notion of adaptivity was formalized by Bender et al. [5]. A filter is **adaptive** if it guarantees a false positive probability of ε for every query, *regardless of answers to previous queries*. Thus, adaptivity provides security advantages against an adversary attempting to degrade performance, e.g., in denial-of-service attacks.

At the same time, fixing previous false positives leads to improved performance. Many practical datasets do, in fact, repeatedly query the same element – on such a dataset, fixing previous false positives means that a filter only incurs one false positive per *unique* query. Past work has shown that simple, easy-to-implement changes to known filters can fix false positives heuristically. Due to repeated queries, these heuristic fixes can lead to reduction of several orders of magnitude in the number of incurred false positives [10, 21, 25].

Recent efforts that tailor filters to query workloads by applying machine learning techniques to optimize performance [14, 24, 30] reinforce the benefits achieved by adaptivity.

Adaptivity vs practicality. The existing work on adaptivity represents a dichotomy between simple filters one would want to implement and use in practice but are not actually adaptive [21, 25], or adaptive filters that are purely theoretical and pose a challenge to implementation [5].

Mitzenmacher et al. [25] provided several variants of the *adaptive cuckoo filter* (ACF) and showed that they incurred significantly fewer false positives (compared to a standard cuckoo filter) on real network trace data. The data structures in [25] use simple heuristics to fix false positives with immense practical gains, leaving open the question of whether such heuristics can achieve worst-case guarantees on adaptivity.

Recently, Kopelowitz et al. [21] proved that this is not true even for a non-adversarial notion of adaptivity. In particular, they defined **support optimality** as the adaptivity guarantee on “predetermined” query workloads: that is, query workloads that are fixed ahead of time and not constructed in response to a filter’s response on previous queries. They showed that the filters in [25] fail to be adaptive even under this weaker notion – repeating $O(1)$ queries n times may cause them to incur $\Omega(n)$ false positives.

Kopelowitz et al. [21] proposed a simple alternative, the *cuckooing ACF*, that achieves support optimality by cuckooing on false positives (essentially reinserting the element). Furthermore, they proved that none of the cuckoo filter variants (including the cuckooing ACF) are adaptive. They showed that a prerequisite to achieving adaptivity is allocating a variable number of bits to each stored element – that is, maintaining variable-length fingerprints. All of the cuckooing filter variants use a bounded number of bits per element.

The only known adaptive filter is the **broom filter** of Bender et al. [5], so-named because it “cleans up” its mistakes. The broom filter achieves adaptivity, while supporting constant-time worst-case query and insert costs, using very little extra space – $O(n)$ extra bits in total. Thus the broom filter implies that, *in theory*, adaptivity is essentially free.

More recently, Bender et al. [4] compared the broom filter [5] to a static filter augmented with a comparably sized top- k cache (a cache that stores the k most frequent requests). They found that the broom filter outperforms the cache-augmented filter on Zipfian distributions due to “serendipitous corrections” – fixing a false positive eliminates future false positives in addition to the false positive that triggered the adapt operation. They noted that their broom filter simulation is “quite slow,” and left open the problem of designing a practical broom filter with performance comparable to that of a quotient filter.

In this paper, we present a practical and efficient filter which also achieves worst-case adaptivity: the **telescoping adaptive filter**. The key contribution of this data structure is a practical method to achieve worst-case adaptivity using variable-length fingerprints.

Telescoping adaptive filter. The telescoping adaptive filter (TAF) combines ideas from the heuristics used in the adaptive cuckoo filter [25], and the theoretical adaptivity of the broom filter [5].

The TAF is built on a rank-and-select quotient filter (RSQF) [29] (a space- and cache-efficient quotient filter [6] variant), and inherits its performance guarantees.

The telescoping adaptive filter is the first adaptive filter that can take advantage of *any* amount of extra space for adaptivity, even a fractional number of bits per element. We prove that if the TAF uses $\left(\frac{1}{\epsilon} + \frac{b}{(1-b)^2}\right)$ extra bits per element in expectation, then it is provably adaptive for any workload consisting of up to $n/(b\sqrt{\epsilon})$ unique queries (Section 4). Empirically, we show that the TAF outperforms this bound: with only 0.875 of a bit extra per element for adaptivity, it is adaptive for larger query workloads. Since the RSQF uses 2.125 metadata bits per element, the total number of bits used by the TAF is $(n/\alpha)(\log_2(1/\epsilon) + 3)$, where α is the load factor.

The TAF stores these extra bits space- and cache-efficiently using a practical implementation of a theoretically-optimal compression scheme: *arithmetic coding* [20,33]. Arithmetic coding is particularly well-suited to the exponentially decaying probability distribution of repeated false positives. While standard arithmetic coding on the unit interval can be slow, we implement an efficient approximate integer variant.

The C code for our implementation can be found at <https://github.com/djslzx/telescoping-filter>.

Our contributions. We summarize our main contributions below.

- We present the first provably-adaptive filter, the telescoping adaptive filter, engineered with space, cache-efficiency and throughput in mind, demonstrating that adaptivity is not just a theoretical concept, and can be achieved in practice.
- As a benchmark for TAF, we also provide a practical implementation of the broom filter [5]. We call our implementation of the broom filter the **extension adaptive filter** (exAF). While both TAF and exAF use the near-optimal $\Theta(n)$ extra bits in total to adapt on $\Theta(n)$ queries, the telescoping adaptive filter is optimized to achieve better constants and eke out the most *adaptivity per bit*. This is confirmed by our experiments which show that given the same space for adaptivity (0.875 bits per element), the TAF outperforms the false-positive performance of the exAF significantly on both practical and adversarial workloads. Meanwhile, our experiments show that the query performance of exAF is factor 2 better than that of the TAF. Thus, we show that there is a trade off between throughput performance and how much adaptivity is gained from each bit.
- We give the first empirical evaluation of how well an adaptive filter can fix positives in practice. We compare the TAF with a broom filter implementation, as well as with previous heuristics. We show that the TAF frequently matches or outperforms other filters, while it is especially effective in fixing false positives on “difficult” datasets, where repeated queries are spaced apart by many other false positives. We also evaluate the throughput of the TAF and the exAF against the vacuum filter [32] and RSQF, showing for the first time that adaptivity can be achieved while retaining good throughput bounds.

2 Preliminaries

In this section, we provide background on filters and adaptivity, and describe our model.

2.1 Background on Filters

We briefly summarize the structure of the filters discussed in this paper. For a more detailed description, we refer the reader to the full version. All logs in the paper are base 2. We assume that ε is an inverse power of 2.

The quotient filter and cuckoo filter are both based on the single-hash function filter [28]. Let the underlying hash function h output $\Theta(\log n)$ bits. To represent a set $\mathcal{S} \subseteq \mathcal{U}$, the filter stores a fingerprint $f(x)$ for each element $x \in \mathcal{S}$. The fingerprint $f(x)$ consists of the first $\log n + \log(1/\varepsilon)$ bits of $h(x)$, where $n = |\mathcal{S}|$ and ε is the false-positive probability.

The first $\log n$ bits of $f(x)$ are called the **quotient** $q(x)$ and are stored implicitly; the remaining $\log(1/\varepsilon)$ bits are called the **remainder** $r(x)$ and are stored explicitly in the data structure. Both filters consist of an array of slots, where each slot can store one remainder.

Quotient filter. The quotient filter (QF) [6] is based on linear probing. To insert $x \in \mathcal{S}$, the remainder $r(x)$ is stored in the slot location determined by the quotient $q(x)$, using linear probing to find the next empty slot. A small number of metadata bits suffice to recover the original slot for each stored element. A query for x checks if the remainder $r(x)$ is stored in the filter – if the remainder is found, it returns “present”; otherwise, it returns “absent.” The rank-and-select quotient filter (RSQF) [29] implements such a scheme using very few metadata bits (only 2.125 bits) per element.

Broom filter. The **broom filter** of Bender et al. [5] is based on the quotient filter. Initially, it stores the same fingerprint $f(x)$ as a quotient filter. The broom filter uses the remaining bits of $h(x)$, called **adaptivity bits**, to extend $f(x)$ in order to adapt on false positives.

On a query y , if there is an element $x \in \mathcal{S}$ such that $f(x)$ is a prefix of $h(y)$, the broom filter returns “present.” If it turns out that $y \notin \mathcal{S}$, the broom filter adapts by extending the fingerprint $f(x)$ until it is no longer a prefix of $h(y)$.¹ Bender et al. show that, with high probability, $O(n)$ total adaptivity bits of space are sufficient for the broom filter to be adaptive on $\Theta(n)$ queries.

Cuckoo filters and adaptivity. The cuckoo filter resembles the quotient filter but uses a cuckoo hash table rather than linear probing. Each element has two fingerprints, and therefore two quotients. The remainder of each $x \in \mathcal{S}$ must always be stored in the slot corresponding to one of x ’s two quotients.

The Cyclic ACF [25], Swapping ACF [25], and Cuckooing ACF [21]² change the function used to generate the remainder on a false positive. To avoid introducing false negatives, a filter using this technique must somehow track which function was used to generate each remainder so that the appropriate remainders can be compared at query time.

The Cyclic ACF stores s extra bits for each slot, denoting which of 2^s different remainders are used. The Swapping ACF, on the other hand, groups slots into constant-sized bins, and has a fixed remainder function for each slot in a bin. A false positive is fixed by moving some $x \in \mathcal{S}$ to a different slot in the bin, then updating its remainder using the function corresponding to the new slot. The Cuckooing ACF works in much the same way, but both the quotient and remainder are changed by “cuckooing” the element to its alternate position in the cuckoo table.

2.2 Model and Adaptivity

All filters that adapt on false positives [5, 21, 25] have access to the original set \mathcal{S} . This is called the *remote representation*, denoted \mathbf{R} . The remote representation does not count towards the space usage of the filter. On a false positive, the filter is allowed to access the set \mathbf{R} to help fix the false positive.

The justification for this model is twofold. (This justification is also discussed in [5, 21, 25].) First, the most common use case of filters is to filter out negative queries to \mathcal{S} – in this case, a positive response to a query accesses \mathbf{R} anyway. Information to help rebuild the filter can be stored alongside the set in this remote database. Second, remote access is necessary to achieve good space bounds: Bender et al. [5] proved that any adaptive filter without remote access to \mathcal{S} requires $\Omega(n \log \log u)$ bits of space.

Our filter can answer queries using only the local state \mathbf{L} . Our filter accesses the remote state \mathbf{R} in order to fix false positives when they occur, updating its local state. This allows our filter to be adaptive while using small (near optimal) space for the local state.

Adaptivity. The **sustained false positive** rate of a filter is the probability with which a query is a false positive, *regardless of the filter’s answers to previous queries*.

¹ These additional bits are stored separately in the broom filter: groups of $\Theta(\log n)$ adaptivity bits, corresponding to $\log n$ consecutive slots in the filter, are stored such that accessing all the adaptivity bits of a particular element (during a query operation) can be done in $O(1)$ time.

² We use the nomenclature of [21] in calling these the Cyclic ACF, Swapping ACF, and Cuckooing ACF.

The sustained false positive rate must hold even if generated by an adversary. We use the definition of Bender et al. [5], which is formally defined by a game between an adversary and the filter, where the adversary’s goal is to maximize the filter’s false positive rate. We summarize this game next; for a formal description of the model see Bender et al. [5].

In the **adaptivity game**, the adversary generates a sequence of queries $Q = x_1, x_2, \dots, x_t$. After each query x_i , both the adversary and filter learn whether x_i is a false positive (that is, $x_i \notin S$ but a query on x_i returns “present”). The filter is then allowed to adapt before query x_{i+1} is made by the adversary. The adversary can use the information about whether queries x_1, \dots, x_i were a false positive or not, to choose the next query x_{i+1} .

At any time t , the adversary may assert that it has discovered a special query \tilde{x}_t that is likely to be a false positive of the filter. The adversary “wins” if \tilde{x}_t is in fact a false positive of the filter at time t , and the filter “wins” if the adversary is wrong and \tilde{x}_t is not a false positive of the filter at time t .

The **sustained false positive** rate of a filter is the maximum probability ε with which the adversary can win the above adaptivity game. A filter is **adaptive** if it can achieve a sustained false positive rate of ε , for any constant $0 < \varepsilon < 1$.

Similar to [5], we assume that the adversary cannot find a never-before-queried element that is a false positive of the filter with probability greater than ε . Many hash functions satisfy this property, e.g., if the adversary is a polynomial-time algorithm then one-way hash functions are sufficient [26]. Cryptographic hash functions satisfy this property in practice, and it is likely that even simple hash functions (like Murmurhash used in this paper) suffice for most applications.

Towards an adaptive implementation. Kopelowitz et al. [21] showed that the Cyclic ACF (with any constant number of hash-selector bits), the Swapping ACF, and the Cuckooing ACF are not adaptive. The key insight behind this proof is that for all three filters, the state of an element – which slot it is stored in, and which fingerprint function is used – can only have $O(1)$ values. Over $o(n)$ queries, an adversary can find queries that collide with an element on all of these states. These queries can never be fixed.

Meanwhile, the broom filter avoids this issue by allowing certain elements to have more than $O(1)$ adaptivity bits – up to $O(\log n)$, in fact. The broom filter stays space-efficient by maintaining $O(1)$ adaptivity bits per element *on average*.

Thus, a crucial step for achieving adaptivity is dynamically changing how much space is used for the adaptivity of each element based on past queries. The telescoping adaptive filter achieves this dynamic space allocation (hence the name “telescoping”) using an arithmetic coding.

3 The Telescoping Adaptive Filter

In this section, we describe the high-level ideas behind the telescoping adaptive filter.

Structure of the telescoping adaptive filter. Like the broom filter, the TAF is based on a quotient filter where the underlying hash function h outputs $\Theta(\log n)$ bits. For any $x \in S$, the first $\log n$ bits of $h(x)$ are the quotient $q(x)$ (stored implicitly), and the next $\log(1/\varepsilon)$ bits are the initial remainder $r_0(x)$, stored in the slot determined by the quotient. We maintain each element’s original slot using the strategy of the rank-and-select quotient filter [29], which stores 2.125 metadata bits per element.

The TAF differs from a broom filter in that, on a false positive, the TAF *changes* its remainder rather than lengthening it, similar to the Cyclic ACF.

For each element in the TAF, we store a **hash-selector value**. If an element x has hash-selector value i , its remainder r_i is the consecutive sequence of $\log(1/\varepsilon)$ bits starting at the $(\log n + i \log(1/\varepsilon))$ th bit of $h(x)$. Initially, the hash-selector values of all elements are 0, and thus the remainder $r(x)$ is the first $\log 1/\varepsilon$ bits immediately following the quotient. When the hash-selector value of an element $x \in S$ is incremented, its remainder “slides over” to the next (non-overlapping) $\log 1/\varepsilon$ bits of the hash $h(x)$, as shown in Figure 1. Thus, the fingerprint of x is $f(x) = q(x) \circ r_i(x)$, where \circ denotes concatenation and i is the hash-selector value of x .

■ **Figure 1** The fingerprint of $x \in S$ is its quotient $q(x)$ followed by its remainder $r_i(x)$, where i is the hash-selector value of x .

On a false positive query $y \notin S$, there must be some $x \in S$ with hash-selector value i , such that $q(x) = q(y)$ and $r_i(x) = r_i(y)$. To resolve this false positive, we increment i . We update the hash-selector value and the stored remainder accordingly.

We describe below how to store hash-selector values using an average 0.875 bits per element. This means that the TAF with load factor α uses $(n/\alpha)(\log(1/\varepsilon) + 3)$ bits of space.

Difference between hash-selector and adaptivity bits. Using hash-selector bits, rather than adaptivity bits (as in the broom filter), has some immediate upsides and downsides.

If fingerprint prefixes $p(x)$ and $p(y)$ collide, they will still collide with probability $1/2$ after each prefix has been lengthened by one bit. But adding a bit also reduces the probability that x will collide with any *future* queries by a factor of $1/2$. Such false positives that are fixed (without being queried) are called **serendipitous false positives** [4].

On the other hand, incrementing the hash-selector value of an element $x \in S$ after it collides with an element $y \notin S$ reduces the probability that y will collide again with x by a factor of $\varepsilon \ll 1/2$. Thus, the TAF is more aggressive about fixing repeated false positives. However, the probability that x collides with future queries that are different from y remains unchanged. Thus, on average the TAF does not fix serendipitous false positives.

Our experiments (Section 6) show that the gain of serendipitous false positive fixes is short-lived; aggressively fixing false positives leads to better false-positive performance.

Storing hash selectors in blocks. The TAF does not have a constant number of bits per slot dedicated solely to storing its hash-selector value. Instead, we group the hash-selector values associated with each $\Theta(\log n)$ contiguous slots (64 slots in our implementation) together in a block. We allocate a constant amount of space for each such block. If we run out of space,

we **rebuild** by setting all hash-selector values in the block to 0. (After a rebuild, we still fix the false positive that caused the rebuild. Therefore, there will often be one non-zero hash-selector value in the block after a rebuild.)

Encoding hash-selector bits. To store the hash selectors effectively, we need a code that satisfies the following requirements: the space of the code should be very close to optimal; the code should be able to use < 1 bits on average per character encoded; and the encode and decode operations should be fast enough to be usable in practice.

In Section 5, we give a new implementation of the arithmetic coding that is tailored to our use case, specifically encoding characters from the distribution given in Corollary 3. Our implementation uses only integers, and all divisions are implemented using bit shifts, leading to a fast and reliable implementation while still retaining good space bounds.

4 Telescoping Adaptive Filter: Analysis

In this section, we analyze the sustained false-positive rate, the hash-selector probabilities, and the space complexity of the telescoping adaptive filter.

We assume the TAF uses a uniform random hash function h such that the hash can be evaluated in $O(1)$ time. In our adaptivity analysis of the TAF (Theorem 1), we first assume that the filter has sufficient space to store all hash-selector values; that is, it does not rebuild. Then, in Theorem 4, we give a bound on the number of unique queries that the TAF can handle (based on its size) without the need to rebuild, thus maintaining adaptivity.

Adaptivity. We first prove that the telescoping adaptive filter is adaptive, i.e., it guarantees a sustained false positive rate of ε .

We say a query x has a **soft collision** with an element $y \in \mathcal{S}$ if their quotients are the same: $q(x) = q(y)$. We say a query x has a **hard collision** with an element $y \in \mathcal{S}$ if both their quotients and remainders are the same: $q(x) = q(y)$ and $r_i(x) = r_i(y)$, where i is the hash-selector value of y at the time x is queried (see Section 3).

► **Theorem 1.** *Consider a telescoping adaptive filter storing a set \mathcal{S} of size n . For any adaptively generated sequence of t queries $Q = x_1, x_2, \dots, x_t$ (possibly interleaved with insertions), where each $x_i \notin \mathcal{S}$, the TAF has a sustained false-positive rate of ε ; that is, $\Pr[x_i \text{ is a false positive}] \leq \varepsilon$ for all $1 \leq i \leq t$.*

Proof. Consider the i -th query $x_i \in Q$. Query x_i is a false positive if there exists an element $y \in \mathcal{S}$ such that there is hard collision between them. Let $h_i(y) = q(y) \circ r_k(y)$ denote the fingerprint of y at time i , where y has the hash-selector value k at time i . Then, x_i and y have a hard collision if and only if $h_i(x_i) = h_i(y)$.

We show that for any y , regardless of answers to previous queries, x_i and y have a hard collision with probability ε/n ; taking a union bound over all elements gives the theorem.

We proceed in cases. First, if x_i is a first-time query, that is, $x_i \notin \{x_1, \dots, x_{i-1}\}$, then the probability that $h_i(x_i) = h_i(y)$ is the probability that both their quotient and remainder match, which occurs with probability $2^{-(\log n + \log 1/\varepsilon)} = \varepsilon/n$.

Next, suppose that x_i is a repeated query, that is, $x_i \in \{x_1, \dots, x_{i-1}\}$. Let $j < i$ be the largest index where $x_i = x_j$ was previously queried. If x_j did not have a soft collision with y , that is, $q(x_j) \neq q(y)$, then x_i cannot have a hard collision with y . Now suppose that $q(x_j) = q(y)$. We have two subcases.

1. y 's hash-selector value has not changed since x_j was queried. Note that, in this case, x_j must not have had a hard collision with y , as that would have caused y 's hash-selector value, and thus its remainder, to be updated. Thus, $h_j(y) = h_i(y) \neq h_j(x_j) = h_i(x_i)$.
2. y 's hash-selector value has been updated since x_j was queried. Such an update could have been caused by a further query to x_j having a hard collision with y , or some other query $x_k \in x_j, x_{j+1}, \dots, x_i$ having a hard collision with y . In either case, the probability that the new remainder matches, i.e., $r_i(y) = r_i(x_i)$, is $2^{-\log 1/\varepsilon} = \varepsilon$.

Therefore, the probability that x_i has a hard collision with y is at most $\varepsilon \cdot \Pr[q(x_j) = q(y)] = \varepsilon/n$. Finally, by a union bound over n possibilities for $y \in \mathcal{S}$, we obtain that $\Pr[x_i \text{ is a false positive}] \leq \varepsilon$ for all $1 \leq i \leq t$, as desired. \blacktriangleleft

Hash-selector probabilities. The telescoping adaptive filter increments the hash-selector value of an element $y \in \mathcal{S}$ whenever a false positive query collides with y . Here we analyze the probability of an element having a given hash-selector value.

► **Lemma 2.** *Consider a sequence $Q = x_1, x_2, \dots, x_t$ of queries (interleaved with inserts), where each $x_i \notin \mathcal{S}$ and Q consists of cn unique queries (with any number of repetitions), where $c < 1/\varepsilon - 1$. Then for any $y \in \mathcal{S}$, if $v(y)$ is the hash-selector value of y after all queries in Q are performed, then:*

$$\Pr[v(y) = k] \begin{cases} = (1 - \frac{\varepsilon}{n})^{cn} & \text{if } k = 0 \\ \leq \varepsilon^k (1 - \varepsilon) \sum_{i=1}^k \binom{cn}{i} \frac{1}{n^i} & \text{if } k > 0 \end{cases}$$

Proof. First, consider the case $k = 0$: the hash-selector value of y stays zero after all the queries are made if and only if none of the queries have a hard collision with y . Since there are cn unique queries, and the probability that each of them has a hard collision with y is ε/n , the probability that none of them collide with y is $(1 - \varepsilon/n)^{cn}$.

Now, consider the case $k \geq 1$. Given that the hash selector value of y is k , we know that there have been exactly k hard collisions between queries and y (where some of these collisions may have been caused by the same query). Suppose there are i unique queries among all queries that have a hard collision with y , where $1 \leq i \leq k$. Let k_j be the number of times a query j collides with y causing an increment in its hash-selector value, where $1 \leq j \leq i$. Thus, $\sum_{j=1}^i k_j = k$.

For a query x_j , the probability that x_j collides with y , the first time x_j is queried, is ε/n . Then, given that x_j has collided with y once, the probability of any subsequent collision with y is ε . (This is because the $\log 1/\varepsilon$ bits of the remainder of y are updated with each collision.) Thus, the probability that x_j collides with y at least k_j times is $\frac{\varepsilon}{n} \cdot \varepsilon^{k_j-1}$.

The probability that a query x_j collides with y at least k_j times, is given by $\prod_{j=1}^i \frac{\varepsilon}{n} \cdot \varepsilon^{k_j-1} = \frac{\varepsilon^k}{n^i}$. There are $\binom{cn}{i}$ ways of choosing i unique queries from cn , for $1 \leq i \leq k$, which gives us

$$\Pr[v(y) \geq k] = \varepsilon^k \sum_{i=1}^k \binom{cn}{i} \frac{1}{n^i} \tag{1}$$

Finally, using Inequality 1, we can upper bound the probability that a hash-selector value is exactly k .

$$\begin{aligned}
\Pr[v(y) = k] &= \Pr[v(y) \geq k] - \Pr[v(y) \geq k+1] \\
&= \varepsilon^k \left[\sum_{i=1}^k \binom{cn}{i} \frac{1}{n^i} - \varepsilon \sum_{i=1}^{k+1} \binom{cn}{i} \frac{1}{n^i} \right] \\
&= \varepsilon^k \cdot (1 - \varepsilon) \left[\sum_{i=1}^k \binom{cn}{i} \frac{1}{n^i} - \frac{\varepsilon}{1 - \varepsilon} \binom{cn}{k+1} \frac{1}{n^{k+1}} \right] \\
&\leq \varepsilon^k (1 - \varepsilon) \sum_{i=1}^k \binom{cn}{i} \frac{1}{n^i} \quad \blacktriangleleft
\end{aligned}$$

We simplify the probabilities in Lemma 2 in Corollary 3. The probability bounds in Corollary 3 closely match the distribution of hash-selector frequencies we observe experimentally.

► **Corollary 3.** *Consider a sequence $Q = x_1, x_2, \dots, x_t$ of queries (interleaved with inserts), where each $x_i \notin \mathcal{S}$ and Q consists of cn unique queries (with any number of repetitions), where $c < 1/\varepsilon - 1$. For any $y \in \mathcal{S}$, if $v(y)$ is the hash-selector value of y after all queries in Q are performed, then:*

$$\Pr[v(y) = 0] < \frac{1}{e^{c\varepsilon}}, \text{ and } \Pr[v(y) = k] < \varepsilon^k \sum_{i=1}^k \frac{c^i}{i!} \text{ for } k \geq 1.$$

Proof. To upper bound $\Pr[v(y) = 0]$, we use the inequality $(1 - 1/x)^x \leq 1/e$ for $x > 1$. To upper bound $\Pr[v(y) = k]$, we upper bound:

$$\binom{cn}{i} \frac{1}{n^i} \leq \frac{cn \cdot (cn-1) \cdots (cn-i)}{i!} \frac{1}{n^i} \leq \frac{c^i n^i}{i! n^i} = \frac{c^i}{i!} \quad \blacktriangleleft$$

Space analysis. Up until now, we have assumed that we always have enough room to store arbitrarily large hash selector values. Next, we give a tradeoff between the space usage of the data structure and the number of unique queries it can support.

We use the hash-selector probabilities derived above to analyze the space overhead of storing hash-selector values. Theorem 4 assumes an optimal arithmetic encoding: storing a hash-selector value k that occurs with probability p_k requires exactly $\log(1/p_k)$ bits. In our implementation we use an approximate version of the arithmetic coding for the sake of performance.

► **Theorem 4.** *For any $\varepsilon < 1/2$ and $b \geq 2$, given a sequence of $n/(b\sqrt{\varepsilon})$ unique queries (with no restriction on the number of repetitions of each), the telescoping adaptive filter maintains a sustained false-positive rate of ε using at most $\left(\frac{1}{e} + \frac{b}{(b-1)^2}\right)$ bits of space in expectation per element.*

Proof. Let $c = 1/(b\sqrt{\varepsilon})$; thus, there are cn unique queries. Consider an arbitrary element $y \in \mathcal{S}$. The expected space used to store the hash-selector value $v(y)$ of y is $\sum_{k=0}^{\infty} p_k \log 1/p_k$, where p_k is the probability that $v(y) = k$.

We separate out the case where $k = 0$, for which p_k is the largest, and upper bound the $p_0 \log 1/p_0$ term below, using the probability derived in Lemma 2.

$$\begin{aligned}
p_0 \log 1/p_0 &= (1 - \varepsilon/n)^{cn} \log \frac{1}{(1 - \varepsilon/n)^{cn}} \leq \frac{1}{e^{c\varepsilon}} \cdot \log(1 + \frac{\varepsilon}{n})^{cn} \\
&= \frac{1}{e^{c\varepsilon}} \cdot cn \log(1 + \frac{\varepsilon}{n}) \leq \frac{1}{e^{c\varepsilon}} \cdot cn \frac{\varepsilon}{n} = \frac{c\varepsilon}{e^{c\varepsilon}} < \frac{1}{e} \quad (2)
\end{aligned}$$

In step (2) above we use the fact that $x/e^x < 1/e$ for all $x > 0$.

We now upper bound the rest of the summation, that is, $\sum_{k=1}^{\infty} p_k \log 1/p_k$ for $k \geq 1$. When upper bounding this summation we will be using upper bounds on p_k – but this is a *lower* bound on $\log 1/p_k$. To deal with this, we observe that the function $x \log 1/x$ is monotonically increasing for $x < 1/e$. Therefore, if we show that the bounds in Corollary 3 never exceed $1/e$, we can substitute both terms in $p_k \log 1/p_k$ in our analysis. We start by showing this upper bound. In the following, we use $b \geq 2$ and $\varepsilon < 1/2$.

$$p_k < \varepsilon^k \sum_{i=1}^k \frac{c^i}{i!} < \varepsilon^k c^k \cdot k < \varepsilon^k \cdot \left(\frac{1}{b\sqrt{\varepsilon}} \right)^k \cdot k = \frac{k}{b^k} \cdot \varepsilon^{k/2} < k \cdot \frac{1}{2^{3k/2}} < \frac{1}{e}.$$

We now upper bound the sum $\sum_{k=1}^{\infty} p_k \log 1/p_k$ by replacing p_k with its upper bound $\varepsilon^k c^k \cdot k$ (this replacement is an upper bound because we showed $\varepsilon^k \sum_{i=1}^k \frac{c^i}{i!} < 1/e$ above).

$$\sum_{k=1}^{\infty} p_k \log 1/p_k \leq \sum_{k=1}^{\infty} k \varepsilon^k c^k \log \frac{1}{\varepsilon^k c^k k} = \sum_{k=1}^{\infty} \frac{k}{b^k} \cdot \left(\varepsilon^{k/2} \cdot \log 1/\varepsilon^k \right) \quad (3)$$

$$< \sum_{k=1}^{\infty} \frac{k}{b^k} = \frac{b}{(b-1)^2}. \quad (4)$$

We simplify step (3) above using the fact that $\sqrt{x} \log 1/x < 1$ for all $x \leq 1$; step (4) is a known identity.

Thus, $\sum_{k=0}^{\infty} p_k \log 1/p_k < 1/e + b/(b-1)^2$, which is the expected number of bits used to store the hash-selector value of y . ◀

Theorem 4 implies that if the TAF is using a certain number of bits per element in expectation to store hash-selector values, then there is a precise bound on the number of unique queries it can handle in any query workload while being provably adaptive. For example, if $\varepsilon = 1/2^8$ and we set $b = 4$ in Theorem 4, then a telescoping adaptive filter that uses $4/9 + 1/e \approx 0.812$ bits per element in expectation can handle $4n$ unique queries without running out of space and having to rebuild. In Section 6, the TAF outperforms this bound, retaining good performance with 0.812 bits per element for $A/S \leq 20$.

5 Implementation

In this section, we describe the implementation of the TAF and our implementation of the broom filter [5], which we call the *extension adaptive filter* (exAF).

Recall that adaptive filters have a local state **L** and a remote representation **R**.

Rank-and-select quotient filter. The local state **L** of both the TAF and exAF is implemented as a rank-and-select quotient filter (RSQF) [29]. The RSQF stores metadata bits – one **occupied** bit and one **runend** bit for each slot. The occupied bit associated with slot i indicates whether any elements with the quotient i have been inserted into the filter. The runend bit associated with slot i tracks whether the remainder placed in slot i is the last remainder in a contiguous run of remainders with the same quotient. These metadata bits are sufficient to find the original slot of an element, but processing them bit-by-bit can be slow. The RSQF cleverly uses *rank* and *select* operations to quickly jump to the original slot [6]. These operations are efficiently implemented using x86 instructions on 64-bit words.

To improve cache efficiency, the RSQF stores remainders (along with their 2 metadata bits) in 64-element *blocks*. In particular, each block stores 64 contiguous remainders and two 64-bit metadata arrays. To search through the blocks efficiently, an **offset** (stored using at

most 8 bits) is stored for each block. The offset of a location i is the distance between i and i 's associated runend. Each block stores the offset of its first slot. In total, the RSQF stores 2.125 metadata bits per element in the filter.

Arithmetic coding on integers. Arithmetic coding can give theoretically optimal compression, but the standard implementation that recursively divides the unit interval relies on floating point operations. These floating point operations are slow in practice, and involve precision issues that can lead to incorrect answers or inefficient representations. In our implementation, we avoid these issues by applying arithmetic coding to a range of integers, $\{0, \dots, 2^k - 1\}$ for the desired code length k , instead of the unit interval. We set $k = 56$, encoding all hash-selector values for a block in a 56-bit word. When multiplying or dividing integral intervals by probabilities in $[0, 1]$, we approximate floating point operations using integer shifts and multiplications.

Remote representation. We implement \mathbf{R} for both filters as an array storing elements in the set \mathcal{S} , along with their associated hashes. We keep \mathbf{R} in sync with \mathbf{L} : if the remainder $r(x)$ is stored in slot s in \mathbf{L} , then x is stored in slot s in \mathbf{R} . This leads to easy lookups: to lookup an element x in \mathbf{R} , we simply check the slot $\mathbf{R}[s]$ where $r(x) = \mathbf{L}[s]$. Insertions that cause remainders to shift in \mathbf{L} are expensive, however, as we need to shift elements in \mathbf{R} as well.

TAF implementation. The local state of TAF is an RSQF where each block of 64 contiguous elements stores the remainders of all elements, all metadata bits (each type stored in a 64-bit word), an 8-bit offset, and a 56-bit arithmetic code storing hash-selector values.

TAF's inserts are similar to the RSQF, which may require shifting remainders. The TAF updates the hash-selector values of all blocks that are touched by the insertion.

Our implementation uses MurmurHash [3] which has a 128-bit output. We partition the output of MurmurHash into the quotient, followed by chunks of size $\log(1/\varepsilon)$, where each chunk corresponds to one remainder. Each time we increment the hash-selector value, we just slide over $\log(1/\varepsilon)$ bits to obtain the new remainder.

On a query x , the TAF goes through each slot s corresponding to quotient $q(x)$ and compares the remainder stored in s to $r_i(y)$, where i is the hash-selector value of s , retrieved by decoding the blocks associated with each s . If they match, the filter returns "present" and checks \mathbf{R} to determine if $x \in \mathcal{S}$. If $x \notin \mathcal{S}$, the filter increments the hash-selector i of x and updates the arithmetic code of the block containing x .

If the 56-bit encoding fails, we **rebuild**: we set all hash-selector bits in the block to 0, and then attempt to fix the false positive again.

exAF implementation. Our implementation of the broom filter, which we call the exAF, maintains its local state as a blocked RSQF, similar to the TAF. The main difference between the two filters is how they adapt. The exAF implements the broom filter's adapt policy of lengthening fingerprints. To do this efficiently, we follow a strategy similar to the TAF. We divide the data structure into blocks of 64 elements, storing all extensions for a single block into an arithmetic code that uses at most 56 bits.

The exAF's insertion algorithm resembles the that of the RSQF and broom filter. However, while the broom filter adapts on inserts to ensure that all stored fingerprints are unique, the exAF does not adapt on inserts, and may have duplicate fingerprints.

During a query operation, the exAF first performs an RQSF query: it finds if there is a stored element whose quotient and remainder bits match, without accessing any extension bit. Only if these match does it decode the block's arithmetic code, allowing it to check extension bits. This makes queries in the exAF faster compared to TAF, which must perform decodes on all queries. If the full fingerprint of a query y collides with an element $x \in \mathcal{S}$, the filter returns “present” and checks \mathbf{R} to determine if $x \in \mathcal{S}$. If $x \notin \mathcal{S}$, the exAF adapts by adding extension bits to $f(x)$ by decoding the block's arithmetic code, updating x 's extension bits, and re-encoding.

As in the TAF, if the 56-bit encoding fails, the exAF rebuilds by setting all adaptivity bits in the block to 0, and then attempts to fix the false positive again.

6 Evaluation

In this section, we empirically evaluate the telescoping adaptive filter and the exAF.

We compare the false-positive performance of these filters to the Cuckooing ACF, the Cyclic ACF (with $s = 1, 2, 3$ hash-selector bits), and the Swapping ACF. The Cyclic ACF and the Cuckooing ACF use 4 random hashes to choose the location of each element, and have bins of size 1. The Swapping ACF uses 2 location hashes and bins of size 4.

We compare the throughput of the TAF and exAF against the vacuum filter [32], our implementation of the RSQF, and a space-inefficient version of the TAF that does not perform arithmetic coding operations.

Experimental setup. We evaluate the filters in terms of the following parameter settings.

- *Load factor.* For the false-positive tests, we use a load factor of .95. We evaluate the throughput on a range of load factors.
- *Fingerprint size.* We set the fingerprint size of each filter so that they all use the same amount of space. We use 8-bit remainders for the TAF. Because the TAF has three extra bits per element for metadata and adaptivity, this corresponds to fingerprints of size 11 for the Swapping and Cuckooing ACF, and size $11 - s$ for a Cyclic ACF with s hash-selector bits.
- *A/S ratio.* The parameter A/S (shorthand for $|A|/|\mathcal{S}|$) is the ratio of the number of unique queries in the query set A and the size of the filter's membership set \mathcal{S} . Depending on the structure of the queries, a higher A/S value may indicate a more difficult workload, as “fixed” false positives are separated by a large number of interspersed queries.

All experiments were run on a workstation with Dual Intel Xeon Gold 6240 18-core 2.6 Ghz processors with 128G memory (DDR4 2666MHz ECC). All experiments were single-threaded.

6.1 False Positive Rate

Firehose benchmark. We measure the false positive rate on data generated by the Firehose benchmark suite [1, 2] which simulates a real-world cybersecurity workload. Firehose has two generators: **power law** and **active set**; we use data from both.

The active set generator generates 64-bit unsigned integers from a continuously evolving “active set” of keys. The probability with which an individual key is sampled varies in time according to a bell-shaped curve to create a “trending effect” as observed in cyberstreams [2]. We generated 10 million queries using the active set generator. We set the value POW_EXP in the active set generator to 0.5 to encourage query repetitions. (Each query is repeated approximately 57 times on average in our final dataset.)

We then generated 50 million queries using the power-law generator, which generates queries using a power-law distribution. This dataset had each query repeated many times; each query was repeated 584 times on average.

■ **Figure 2** False positive rates on the firehose benchmarks. The plot on the left uses the active set generator; the plot on the right uses the power-law generator.

In our tests we vary the size of the stored set S (each uses the same input, so $|A|$ is constant). The results are shown in Figure 2; all data points are the average of 10 experiments. ACF1, ACF2, and ACF3 represent the Cyclic ACF with $s = 1, 2, 3$ respectively.

For the active set generated data, the TAF is the best data structure for moderate A/S . Above $A/S \approx 20$, rebuilds become frequent enough that TAF performance degrades somewhat, after which its performance is similar to that of the Cyclic ACF with $s = 2$ (second to the Swapping ACF). This closely matches the analysis in Section 4.

For the power law data, the TAF is competitive for most A/S values, although again it is best for moderate values.

Notably, in both cases (and particularly for the active set data), the exAF performs substantially worse than the TAF. This shows that given the space amount of extra bits per element on average, the TAF uses them more effectively towards adaptivity than the exAF.

Network Traces. We give experiments on three network trace datasets from the CAIDA 2014 dataset, replicating the experiments of Mitzenmacher et al. [25]. We use three network traces from the CAIDA 2014 dataset, specifically `equinix-chicago.dirA.20140619` (“Chicago A”, Figure 3) `equinixchicago.dirB.20140619-432600` (“Chicago B”, Figure 3), and `equinix-sanjose.dirA.20140320-130400` (“San Jose”, Figure 4).

On network trace datasets, most filters are equally effective at fixing false positives, and their performance is determined mostly by their **baseline false positive rate**, that is, the probability with which a first-time query is a false positive. If s bits are used for adaptivity, that increases the baseline FP rate by 2^s , compared to when those bits are used towards remainders. This gives the Cuckooing ACF an advantage as it uses 0 bits for adapting.

The TAF and exAF perform similarly to the Swapping ACF and ACF1 (Cyclic ACF with $s = 1$) on these datasets.

Adversarial tests. The main advantage of the TAF and exAF is that both are adaptive in theory – even against an adversary. Adversarial inputs are motivated by security concerns, such as denial-of-service attacks, but they may also arise in some situations in practice. For example, it may be that the input stream is performance-dependent, and previous false positives are more likely to be queried again.

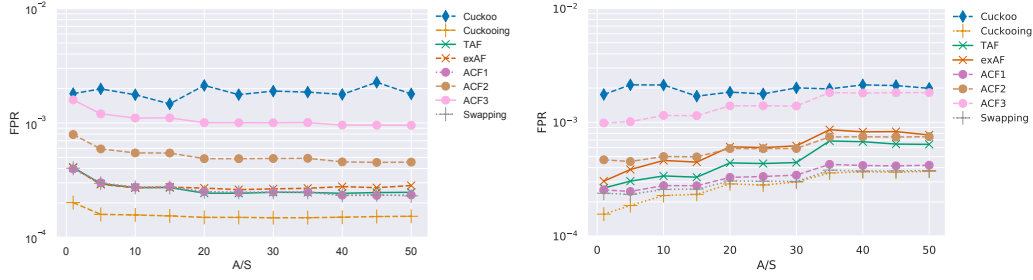

Figure 3 False positive performance of the filters on network trace data. The Chicago A dataset is used on the left, and the Chicago B dataset is on the right.

Figure 4 On the left is the network trace San Jose dataset. On the right is adversarial data, where we vary the size of the initial query set, and plot the proportion of elements in the final set that are false positives.

We test our filter against an “adversarial” stream that probabilistically queries previous false positives. This input is significantly simpler than the lower bounds given in [21] and [5], but shares some of the basic structure.

Our adversarial stream starts with a set of random queries $|Q|$. The queries are performed in a sequence of rounds; each divided into 10 subrounds. In a subround, each element of Q is queried. After a round, any element that was never a false positive in that round is removed from Q . The filter then continues to the next round. The test stops when $|Q|/|\mathcal{S}| = .01$, or a bounded number of rounds is reached.

The x-axis of our plot is $|Q|/|\mathcal{S}|$, and the y-axis is the false positive rate during the final round (after the adversary has whittled Q to only contain likely false positives). We again see that the TAF does very well up until around $|Q|/|\mathcal{S}| \approx 20$. After this point, the adversary is successfully able to force false positives. This agrees closely with the analysis in Section 4.

The Cyclic ACF with $s = 3$ (ACF3) does well on adversarial data even though it is known to not be adaptive. This may be in part because the constants in the lower bound proof [21] are very large (the lower bound uses $1/\epsilon^8 \approx 2^{64}$ queries). However, this adaptivity comes at the cost of a worse baseline FP rate, as this filter struggles on network trace data.

6.2 Throughput

In this section, we compare the throughput of our filters to other similar filters.

For the throughput tests, we introduce several new filters as a point of comparison. The vacuum filter [32] is a cuckoo filter variant designed to be space- and cache-efficient. We compare to the “from scratch” version of their filter [34]. We also compare to our implementation of the RSQF [29]. The RSQF does not adapt, or perform remote accesses.

■ **Figure 5** The throughput for inserts (left) and queries (right) on the active set Firehose data.

Finally, to isolate the cost of the arithmetic coding itself, we compare to our implementation of an **uncompressed telescoping adaptive filter (uTAF)**. The uTAF works exactly as the TAF, except it stores its hash-selector values explicitly, without using an arithmetic coding. This means that the uTAF is very space-inefficient.

For the throughput tests, we evaluated the performance on the active set Firehose data used in Figure 2. Our filters used 2^{24} slots. We varied the load factor to compare performance. All data points shown are the average of 10 runs.

The throughput tests show that the TAF achieves similar performance in inserts to the other filters, though it lags behind in queries at high throughput. The exAF performs significantly better for queries, likely due to skipping decodes as discussed in Section 5.

The uTAF is noticeably faster than the TAF, but is similar in performance to exAF. This highlights the trade-offs between the two ways to achieve adaptivity: the exAF scheme of lengthening remainders has better throughput but worse adaptivity per bit; while the TAF scheme of updating remainders has better adaptivity per bit but worse throughput. Overall, while the query-time decodes of TAF do come at a throughput cost, they stop short of dominating performance.

7 Conclusion

We provide a new provably-adaptive filter, the telescoping adaptive filter, that was engineered with space- and cache-efficiency and throughput in mind. The TAF is unique among adaptive filters in that it only uses a fractional number of extra bits for adaptivity (0.875 bits per element). To benchmark the TAF, we also provide a practical implementation of the broom filter. To effectively compress the adaptivity metadata for both filters, we implement arithmetic coding that is optimized for the probability distributions arising in each filter.

We empirically evaluate the TAF and exAF against other state-of-the-art filters that adapt, on a variety of datasets. Our experiments show that TAF outperforms the exAF significantly on false-positive performance, and frequently matches or outperforms other heuristically adaptive filters. Our throughput tests show that our adaptive filters achieve a comparable throughput to their non-adaptive counterparts.

We believe that our technique to achieve adaptivity through variable-length fingerprints is universal and can be used alongside other filters that stores fingerprints of elements (e.g., a cuckoo or vacuum filter). Thus, there is potential for further improvements by applying our ideas to other filters, taking advantage of many years of filter research.

Abstract

Given points $P = \{p_1, \dots, p_n\}$ subset of \mathbb{R}^d , how do we find a point x which approximately maximizes the function $\frac{1}{n} \sum_{p_i \in P} e^{-\|p_i - x\|^2}$? In other words, how do we find an approximate mode of a Gaussian kernel density estimate (KDE) of P ? Given the power of KDEs in representing probability distributions and other continuous functions, the basic mode finding problem is widely applicable. However, it is poorly understood algorithmically. We provide fast and provably accurate approximation algorithms for mode finding in both the low and high dimensional settings. For low (constant) dimension, our main contribution is a reduction to solving systems of polynomial inequalities. For high dimension, we prove the first dimensionality reduction result for KDE mode finding. The latter result leverages Johnson-Lindenstrauss projection, Kirschbraun's classic extension theorem, and perhaps surprisingly, the mean-shift heuristic for mode finding. For constant approximation factor these algorithms run in $O(n(\log n)^{O(d)})$ and $O(nd + (\log n)^{O(\log^3 n)})$, respectively; these are proven more precisely as a $(1 + \epsilon)$ -approximation guarantee. Furthermore, for the special case of $d = 2$, we give a combinatorial algorithm running in $O(n \log^2 n)$ time. We empirically demonstrate that the random projection approach and the 2-dimensional algorithm improves over the state-of-the-art mode-finding heuristics.

1 Introduction

Given a point set P in \mathbb{R}^d and a kernel $K : \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R}$, the kernel density estimate (KDE) is a function mapping from \mathbb{R}^d to \mathbb{R} and is defined as $\frac{1}{|P|} \sum_{p \in P} K(x, p)$ for any $x \in \mathbb{R}^d$. One common example of kernel K is the Gaussian kernel, $K(x, y) = e^{-\|x - y\|^2}$ for any $x, y \in \mathbb{R}^d$, which is the focus of this paper.

These kernel density estimates are a fundamental tool in statistics [48, 45, 18, 19] and machine learning [44, 23, 36]. For $d = 1$, KDEs with a triangular kernel ($K(x, p) = \max(0, 1 - |x - p|)$) can be seen as the average over all shifts of a fix-width histogram. And

unlike histograms these generalize naturally to a higher dimensions as a stable way to create a continuous function to represent the measure of a finite point set. Indeed, the KDEs constructed on an iid sample from any tame distribution will converge to that distribution in the limit as the sample size grows [48, 45]. Not surprisingly they are also central objects in Bayesian data analysis [27, 21]. Using Gaussian kernels (and other positive definite kernels), KDEs are members of a reproducing kernel Hilbert space [53, 50, 36] where for instance they induce a natural distance between distributions [49, 28]. Their other applications includes outlier detection [56], clustering [43], topological data analysis [40, 14], spatial anomaly detection [2, 24], and statistical hypothesis testing [23].

In this paper, we study how to find an *approximate mode* of a Gaussian KDE. An ϵ -approximate mode of a KDE is a point x' whose KDE value is at least $1 - \epsilon$ times the maximum of the KDE. It is known that Gaussian KDEs can have complex structure of local maximum [20, 26], but other than some heuristic approaches [9, 10, 54, 22] there has been very little prior work [40, 2] (which we discuss shortly) in developing and formally analyzing algorithms to find this maximum. Beyond being a key descriptor (the mode) of one of the most common representations of a continuous distribution, finding the (global) maximum of a KDE has many other specific applications. It is a necessary step to create a simplicial complex to approximate superlevel sets of KDEs [40]; to localize and track objects [13, 46]; to quantify multi-modality of distributions [47]; to finding typical objects, including curves [22].

Problem Definition. For any $x, y \in \mathbb{R}^d$, we define the Gaussian kernel as $K(x, y) = e^{-\|x-y\|^2}$. The Gaussian kernel density estimate (KDE) $\bar{\mathcal{G}}_P(x)$ of a point set P is defined as $\bar{\mathcal{G}}_P(x) = \frac{1}{|P|} \sum_{p \in P} K(p, x)$, for $x \in \mathbb{R}^d$. We will sometimes use the notation $\mathcal{G}_P(x) = |P| \cdot \bar{\mathcal{G}}_P(x)$ to simplify calculations. In line with other works on optimization, we focus on the approximate version of the mode finding problem, defined as follows. Given a point set P of size n where $\max_{x \in \mathbb{R}^d} \bar{\mathcal{G}}_P(x) \geq \rho$ for some parameter ρ below which the maximum is uninteresting, and an error parameter $\epsilon > 0$, the goal is to find an ϵ -approximate mode x' , such that $\bar{\mathcal{G}}_P(x') \geq (1 - \epsilon) \max_{x \in \mathbb{R}^d} \bar{\mathcal{G}}_P(x)$. We assume the lower bound ρ is known to the algorithm; or we can set $\rho = 1/n$ since $\bar{\mathcal{G}}_P(p) \geq 1/n$ for any $p \in P$. In practice, one should expect that $\rho \ll \epsilon$, so we aim for algorithms with far smaller dependence on $1/\rho$ than on $1/\epsilon$.

Known Results. One trivial approach is exhaustive search. It is easy to see that the optimal point x^* cannot be too far away from the input data. More precisely, x^* should be within the radius of $\sqrt{\log \frac{1}{\rho}}$ of a point p for some $p \in P$. Given the above observation, one can construct a grid of width $\frac{1}{\epsilon\rho}$ around each point of input data and evaluate the value of \mathcal{G}_P at each grid point. This approach will allow us to output a solution with additive error at most $\epsilon n \rho$. However, the size of the search space could be as large as $O\left(n\left(\sqrt{\log \frac{1}{\rho}}/\epsilon\rho\right)^d\right)$ which is infeasible in practice. A similar approach is suggested by [40].

Another approach, proposed by [2], is to compute the depth in an arrangement of a set of geometric objects. Namely, it is to find the point that maximizes the number of objects including that point. They consider a set \mathcal{S} of segment in \mathbb{R}^2 and, for any $x \in \mathbb{R}^2$ and $s \in \mathcal{S}$, define $K(x, s) = K(x, y)$ where y is the closest point on s to x . In our setting, we treat the point set P as degenerate (length 0) segments \mathcal{S} . By discretizing the continuous function K into the level set of it, one can view the problem as computing the depth in an arrangement of a collection of level sets. This approach has a running time of $O(\frac{n}{\epsilon^2} \log^3 n)$ (this implicitly sets $\rho = 1/n$). One can generalize their approach to the high dimensional case, but the running time would still be $O(n^{O(d)})$.

Related Work. As mentioned before, computing depth in an arrangement of a set of geometric object is highly related to our problem. Given a collection \mathcal{C} of geometric object in \mathbb{R}^d , one can express the depth as $\sum_{c \in \mathcal{C}} \mathbf{1}_c(x)$ where $\mathbf{1}_c(x)$ is the indicator function of $x \in c$. It is easy to see that KDE is basically the same formula by replacing $\mathbf{1}_c(x)$ with $K(x, p)$. Namely, one can view finding a maximum point of KDE as computing the point of maximum “fractional” depth among kernels. Surprisingly, there are not many non-trivial algorithmic results on computing the depth of high-dimensional geometric objects. In general, whenever \mathcal{C} is a collection of bounded complexity (e.g. VC dimension [52]) objects, the arrangement is always of complexity $O(n^{O(d)})$ and it can be constructed, with the depth encoded, in as much time. A celebrated case is when \mathcal{C} is a collection of axis parallel box, the point of maximum depth can be found in $O(n^{d/2 - o(1)})$ time [12]. For our task we can run such approaches on a sample of size $n_0 = O(\frac{d}{\epsilon^2 \rho} \log \frac{1}{\rho})$ [32, 25], so the runtimes still have a $1/\rho^{O(d)}$ term.

Another line of work [11, 20, 5] attempts to bound the *number* of local maximum of a Gaussian KDE. Perhaps surprisingly, the number is greater than n for dimensions $d \geq 2$, and in fact can be at least $\binom{n}{d} + n$ for $n, d \geq 2$ [5]. It is currently unknown whether the number can be infinite, but the best upper bound *assuming finiteness* is $2^{d + \binom{n}{2}}(5 + 3d)^n$. So even if we could identify all of these, there still would be $\Omega(n^d)$ points to evaluate.

While not as explicit as the dimensionality reduction results we will present, other work based on LSH [6, 7] or related to geometric graphs [41] have shown properties of evaluating KDEs after what can be interpreted as forms of dimensionality reduction. For instance, Quanrud [41] shows that using dimensionality reduction, as well as other approximations and structures, one can evaluate KDEs within $1 \pm \epsilon$ error in roughly $1/\epsilon^2$ time, but also with logarithmic factors depending on, for example, spread parameters for the Gaussian kernel.

Our Approach and Result. We present an approximation scheme that reads the data (to sample it) in $O(nd)$ time, and then its runtime depends only on $1/\epsilon$ and $1/\rho$. At the heart of our algorithm are two techniques: dimensionality reduction and polynomial system solving. We also use standard coresets results for Gaussian kernel density estimates.

For dimensionality reduction (Section 3), we use Johnson-Lindenstrauss matrices to project the point set down to low dimensions, and solve the problem in low dimensions. The crucial issue is, if we solve the mode finding problem in the low dimensional space, it is not immediately clear that the original high dimensional space also has a point that gives a high KDE value. We resolve this with an application of Kirschbraun’s extension theorem [30, 51], which shows the existence of such a high dimensional point. To find the actual point in the high dimensional space, we use one step of the *mean-shift* algorithm [9, 10], which is a known heuristic for the KDE maximum finding problem with provable monotonicity properties. We could alternatively combine a *terminal dimensionality reduction* result [37] with our mean-shift recovery strategy. Doing so would give the same level of dimensionality reduction, at the expense of reduced simplicity and runtime efficiency.

In low dimensions, we consider Taylor series truncations of the Gaussian kernel, and reduce the mode finding problem to solving systems of polynomial inequalities (Section 2). The result of [42] implies that one can find a solution to a system of λ polynomial inequalities with degree D and k variables in time $O((\lambda D)^{O(k)})$. Here, k will essentially be the dimensionality d of the problem, and λ will be a constant as shown in our constructions. We observe that since the optimal point must be close to one of the points in the input, we can consider a sufficiently fine grid in the vicinity of each input point, which totals to $O(n2^{O(d)})$ grid points. For each grid point, we formulate and solve a system of polynomial inequalities based on Taylor expansions, up to $O(\log \frac{1}{\rho})$ terms around that grid point. This gives a running time of $O(n(\log \frac{1}{\rho})^{O(d)})$, where n is the size of the input point set.

Combining the above ideas with standard coresets results (small subsets $Q \subset P$ so $\bar{\mathcal{G}}_Q$ approximates $\bar{\mathcal{G}}_P$) yields approximation schemes for the KDE mode finding problem. We present two such schemes, one with exponential runtime dependence on the dimensionality d which is more suitable for low dimensions, and another with only linear dependence in d (which is necessary for reading the input) and is designed for the high dimensional regime. Guarantees of these approximations are captured by Theorems 1 and 2; we provide algorithmic details and intuition, but proofs are in the appendices.

► **Theorem 1 (Low dimensional regime).** *Given $\epsilon, \rho > 0$ and a point set $P \subset \mathbb{R}^d$ of size n with $\bar{\mathcal{G}}_P(x^*) \geq \rho$, where $x^* = \operatorname{argmax}_{x \in \mathbb{R}^d} \bar{\mathcal{G}}_P(x)$, we can find $x' \in \mathbb{R}^d$ so $\bar{\mathcal{G}}_P(x') \geq (1 - \epsilon)\bar{\mathcal{G}}_P(x^*)$ in $O\left(nd + \frac{d}{\epsilon^2 \rho} \cdot \log \frac{1}{\rho \delta} \cdot \left(\log \frac{d}{\epsilon \rho}\right)^{O(d)}\right)$ time with probability at least $1 - \delta$.*

► **Theorem 2 (High dimensional regime).** *Given $\epsilon, \rho > 0$ and a point set $P \subset \mathbb{R}^d$ of size n with $\bar{\mathcal{G}}_P(x^*) \geq \rho$, where $x^* = \operatorname{argmax}_{x \in \mathbb{R}^d} \bar{\mathcal{G}}_P(x)$, we can find $x' \in \mathbb{R}^d$ so $\bar{\mathcal{G}}_P(x') \geq (1 - \epsilon)\bar{\mathcal{G}}_P(x^*)$ in $O\left(nd + \left(\log \frac{1}{\epsilon \rho}\right)^{O(\frac{1}{\epsilon^2} \log^3 \frac{1}{\epsilon \rho})} \cdot \log \frac{1}{\delta} + \min\{nd \log \frac{1}{\delta}, \frac{d}{\epsilon^2 \rho^2} \log^2 \frac{1}{\delta}\}\right)$ time with probability at least $1 - \delta$.*

One may set the relative error parameter ϵ , and failure probability δ to constants, and observe the mode of $\bar{\mathcal{G}}_P$ must be at least $1/n$ and set $\rho = 1/n$. Then the runtimes become $O(n(\log n)^{O(d)})$ for constant dimensions, and $O(nd + (\log n)^{O(\log^3 n)})$ in high dimensions.

In addition to our result in Theorems 1 and 2, we also consider the special case where $d = 2$. We present a combinatorial algorithm for the 2-dimensional regime which is easier to implement. Here, we borrow the idea from [2] which is to compute the depth. Instead of simply considering the level sets of the Gaussian kernel (which are circles in our setting), we consider a more involved decomposition. One important property of the Gaussian kernel is its multiplicatively separability – namely, the Gaussian kernel can be decomposed into factors, with one factor for each dimension. We now discretize each factor into level sets (which are simply intervals) and then consider their Cartesian products, generating a collection of axis-parallel rectangles. A similar idea was also suggested by [38]. Finally, if we compute the depth of this collection of axis-parallel rectangles, we can find out an approximate mode in time $O(\frac{1}{\epsilon^2 \rho} \log^2 \frac{1}{\rho})$. This approach also works in higher dimensions, but it would yield a slower running time than our general approaches in Theorems 1 and 2. The formal guarantees of this 2-d algorithm are captured in Theorem 3, and proven in the appendices.

► **Theorem 3 (2-dimensional setting).** *Given $\epsilon, \rho > 0$ and a point set $P \subset \mathbb{R}^2$ of size n such that $\bar{\mathcal{G}}_P(x^*) \geq \rho$, where $x^* = \operatorname{argmax}_{x \in \mathbb{R}^d} \bar{\mathcal{G}}_P(x)$, we can find $x' \in \mathbb{R}^2$ so $\bar{\mathcal{G}}_P(x') \geq (1 - \epsilon)\bar{\mathcal{G}}_P(x^*)$ in $O\left(n + \frac{1}{\epsilon^2 \rho} (\log \frac{1}{\rho} + \log \frac{1}{\delta}) \log(\frac{1}{\epsilon \rho} \log \frac{1}{\delta})\right)$ time with probability at least $1 - \delta$.*

There are different extensions of our problem formulation. For example, one can define the weighted KDE of a point set P , $\sum_{p \in P} w_p K(x, p)$, and find its mode. Another common extension is to consider non-spherical Gaussians with different variances. We expect that our technique with some straightforward modifications work for these extensions and will omit the details.

2 KDE Mode Finding via System of Polynomials

In this section we provide algorithms that approximately find the maximum of the Gaussian KDE in \mathbb{R}^d . We first define the following notations. For a point $p \in \mathbb{R}^d$ and $r > 0$, we define $B_p(r)$ as $\{y \in \mathbb{R}^d \mid \|y - p\| \leq r\}$, namely the Euclidean ball around p . For a

point set $P \subset \mathbb{R}^d$ and $r > 0$, we define $B_P(r)$ as $\cup_{p \in P} B_p(r)$, that is the union of Euclidean balls around all the points in P . For a point set $P \subset \mathbb{R}^d$, a point $q \in \mathbb{R}^d$ and $r > 0$, also define $Q_{P,q}(r) = P \cap B_q(r\sqrt{\log \frac{1}{\epsilon\rho}})$. Finally, let $\text{Grid}(\gamma)$ be the infinite grid $\{x = (i_1\gamma, i_2\gamma, \dots, i_d\gamma) \mid i_1, i_2, \dots, i_d \text{ are integers}\}$, parametrized by a cell length $\gamma > 0$.

We first make an observation that the maximum point must be close to one of the data points, captured by Observation 4.

► **Observation 4.** $x^* \in B_P(\sqrt{\log \frac{1}{\rho}})$. Recall that $x^* = \operatorname{argmax}_{x \in \mathbb{R}^d} \mathcal{G}_P(x)$.

Proof. Suppose $x^* \notin B_P(\sqrt{\log \frac{1}{\rho}})$. Then, $\mathcal{G}_P(x^*) = \sum_{p \in P} e^{-\|p-x^*\|^2} < \sum_{p \in P} \rho = n\rho$. However, $\mathcal{G}_P(x^*) \geq n\rho$ by assumption. ◀

The algorithm presented in this section relies crucially on the result of Renegar for solving systems of polynomial inequalities, as stated in the following lemma.

► **Lemma 5** ([42]). *Consider λ polynomial inequalities with maximum degree D and k variables. There is an algorithm either finds a solution that satisfies all λ polynomial inequalities or returns NO SOLUTION in $O((\lambda D)^{O(k)})$ time.*

Before we give details of our algorithm, we present the family of systems of polynomial inequalities we formulate for mode finding. Let $\text{SysPoly}(P, q, r, r', \beta)$ be the following system.

$$\sum_{p \in Q_{P,q}(r')} \prod_{i=1}^d \left(\sum_{j=0}^{s-1} \frac{1}{j!} (-(x_i - p_i)^2)^j \right) \geq \beta \quad \bigwedge \quad \|x - q\|^2 \leq r^2 \log \frac{1}{\epsilon\rho}$$

where $s = (r + r')^2 e^2 \log \frac{d}{\epsilon\rho}$. Intuitively, if a point $x \in \mathbb{R}^d$ satisfies the left inequality of $\text{SysPoly}(P, q, r, r', \beta)$, then the value $\mathcal{G}_P(x)$ is larger than a threshold that is approximately β . It is because the LHS of the left inequality is the sum of the truncated Taylor expansion of the Gaussians centered at p that is around q . On the other hand, the truncated Taylor expansion only gives a good approximation locally. Hence, the right inequality of $\text{SysPoly}(P, q, r, r', \beta)$ ensures that x is around q .

Also, let $\text{SysPoly}(P, q, r, r')$ be the algorithm that performs binary search on β of the above system $\text{SysPoly}(P, q, r, r', \beta)$ and terminates when the search gap is less than $\frac{1}{10} |P| \epsilon\rho$. Note that β lies between 0 and $O(|P|)$ which means we need $O(\log(|P| / \frac{1}{10} |P| \epsilon\rho)) = O(\log \frac{1}{\epsilon\rho})$ iterations in binary search. The total running time of $\text{SysPoly}(P, q, r, r')$ is $O((4s)^{O(d)} \log \frac{1}{\epsilon\rho}) = O(s^{O(d)})$ since $k = d$, $\lambda = 2$ and $D = 2s$ in Lemma 5.

The following lemma captures the approximation error from the Taylor series truncation.

► **Lemma 6.** *Suppose $r + r' > 1$ and $q \in \mathbb{R}^d$ such that $\|x^* - q\| \leq r\sqrt{\log \frac{1}{\epsilon\rho}}$. Then, the output $x^{(q)}$ of $\text{SysPoly}(P, q, r, r')$ satisfies $\mathcal{G}_{Q_{P,q}(r')}(x^{(q)}) \geq \mathcal{G}_{Q_{P,q}(r')}(x^*) - |P| \frac{\epsilon\rho}{2}$.*

In short, it shows that the truncation of the above infinite summation of polynomial terms (wrapped in a sum over all points Q , and the product over d dimensions) induces an error terms $\mathcal{E}(x^{(q)})$ and $\mathcal{E}(x^*)$ at $x^{(q)}$ and x^* , respectively. We can show that the difference between these terms is at most $\epsilon\rho$ for our choice of s , as desired.

61:6 Finding an Approximate Mode of a Kernel Density Estimate

Proof. First, we write $\sum_{p \in Q_q(r')} e^{-\|p - x^{(q)}\|^2}$ into the following form.

$$\begin{aligned} \sum_{p \in Q_q(r')} e^{-\|p - x^{(q)}\|^2} &= \sum_{p \in Q_q(r')} \prod_{i=1}^d \left(\sum_{j=0}^{\infty} \frac{1}{j!} \left(-(x_i^{(q)} - p_i)^2 \right)^j \right) \\ &= \sum_{p \in Q_q(r')} \prod_{i=1}^d \left(\sum_{j=0}^s \frac{1}{j!} \left(-(x_i^{(q)} - p_i)^2 \right)^j \right) + \mathcal{E}(x^{(q)}) \end{aligned}$$

where $\mathcal{E}(x) = \sum_{p \in Q_q(r')} \sum_{j_1, \dots, j_d | \text{one of } j_i \geq s} \frac{1}{j_1! \dots j_d!} \left(-(x_1 - p_1)^2 \right)^{j_1} \dots \left(-(x_d - p_d)^2 \right)^{j_d}$ for any $x \in \mathbb{R}^d$.

Now, we have

$$\begin{aligned} \sum_{p \in Q_q(r')} e^{-\|x^{(q)} - p\|^2} &= \sum_{p \in Q_q(r')} \prod_{i=1}^d \left(\sum_{j=0}^s \frac{1}{j!} \left(-(x_i^{(q)} - p_i)^2 \right)^j \right) + \mathcal{E}(x^{(q)}) \\ &\geq \sum_{p \in Q_q(r')} \prod_{i=1}^d \left(\sum_{j=0}^s \frac{1}{j!} \left(-(x_i^* - p_i)^2 \right)^j \right) - |P| \frac{\epsilon \rho}{10} + \mathcal{E}(x^{(q)}) \\ &\geq \sum_{p \in Q_q(r')} e^{-\|x^* - p\|^2} - |P| \frac{\epsilon \rho}{10} + \mathcal{E}(x^{(q)}) - \mathcal{E}(x^*) \end{aligned}$$

In order to analyze the term $\mathcal{E}(x^{(q)})$ and $\mathcal{E}(x^*)$, we can first analyze the term

$$\left| \sum_{j_1, \dots, j_d | \text{one of } j_i \geq s} \frac{1}{j_1! \dots j_d!} \alpha_1^{j_1} \dots \alpha_d^{j_d} \right|$$

where $\alpha_i = -(y_i - p_i)^2$ where y is $x^{(q)}$ or x^* .

$$\sum_{j_1, \dots, j_d | \text{one of } j_i \geq s} \left(\prod_{i=1}^d \frac{1}{j_i!} \alpha_i^{j_i} \right) = \sum_{i=1}^d \left(\prod_{k=1}^{i-1} \sum_{j=0}^{s-1} \frac{1}{j!} \alpha_k^j \right) \left(\sum_{j=s}^{\infty} \frac{1}{j!} \alpha_i^j \right) \left(\prod_{k=i+1}^d \sum_{j=0}^{\infty} \frac{1}{j!} \alpha_k^j \right)$$

For each $i = 1, 2, \dots, d$, by taking $s = (r + r')^2 e^2 \log \frac{d}{\epsilon \rho}$,

$$\left| \sum_{j=s}^{\infty} \frac{1}{j!} \alpha_i^j \right| \leq \sum_{j=s}^{\infty} \frac{1}{j!} |\alpha_i|^j \leq \max_{\xi \in [-|\alpha_i|, |\alpha_i|]} \frac{e^{\xi}}{s!} |\alpha_i|^s$$

The last inequality is the error approximation of Taylor expansion of exponential function.

Note that $|\alpha_i| = (y_i - p_i)^2 \leq \|y - p\|^2 \leq (\|y - q\| + \|p - q\|)^2 \leq \left(r \sqrt{\log \frac{1}{\epsilon \rho}} + r' \sqrt{\log \frac{1}{\epsilon \rho}} \right)^2 \leq (r + r')^2 \log \frac{1}{\epsilon \rho}$. We have

$$\begin{aligned} \left| \sum_{j=s}^{\infty} \frac{1}{j!} \alpha_i^j \right| &\leq \frac{e^{(r+r')^2 \log \frac{1}{\epsilon \rho}}}{s!} ((r + r')^2 \log \frac{1}{\epsilon \rho})^s \\ &\leq \frac{e^{(r+r')^2 \log \frac{1}{\epsilon \rho}}}{s^s} ((r + r')^2 e \log \frac{1}{\epsilon \rho})^s && \text{by } s! \geq \left(\frac{s}{e}\right)^s \\ &\leq \frac{e^{(r+r')^2 \log \frac{1}{\epsilon \rho}}}{e^s} \leq \left(\frac{\epsilon \rho}{d}\right)^{(r+r')^2 (e^2 - 1)} && \text{recall that } s = (r + r')^2 e^2 \log \frac{d}{\epsilon \rho} \\ &\leq \frac{\epsilon \rho}{20d} && \text{by } r + r' > 1 \text{ and for sufficient small } \epsilon \rho \end{aligned}$$

Now, we can plug this into $\left| \sum_{j_1, \dots, j_d | \text{one of } j_i \geq s} \frac{1}{j_1! \dots j_d!} \alpha_1^{j_1} \dots \alpha_d^{j_d} \right|$.

$$\begin{aligned}
& \left| \sum_{j_1, \dots, j_d | \text{one of } j_i \geq s} \frac{1}{j_1! \dots j_d!} \alpha_1^{j_1} \dots \alpha_d^{j_d} \right| \\
&= \left| \sum_{i=1}^d \left(\prod_{k=1}^{i-1} \sum_{j=0}^{s-1} \frac{1}{j!} \alpha_k^j \right) \left(\sum_{j=s}^{\infty} \frac{1}{j!} \alpha_i^j \right) \left(\prod_{k=i+1}^d \sum_{j=0}^{\infty} \frac{1}{j!} \alpha_k^j \right) \right| \\
&\leq \sum_{i=1}^d \left(\prod_{k=1}^{i-1} \left(1 + \frac{\epsilon \rho}{10d} \right) \right) \left(\frac{\epsilon \rho}{10d} \right) \left(\prod_{k=i+1}^d e^{\alpha_k} \right) \\
&\leq \left(1 + \frac{\epsilon \rho}{20d} \right)^d \frac{\epsilon \rho}{20} \leq e^{\frac{\epsilon \rho}{20}} \frac{\epsilon \rho}{20} \leq \frac{\epsilon \rho}{8} \quad \text{for sufficient small } \epsilon \rho
\end{aligned}$$

That means

$$\begin{aligned}
\sum_{p \in Q_q(r')} e^{-\|x^{(q)} - p\|^2} &\geq \sum_{p \in Q_q(r')} e^{-\|x^* - p\|^2} - |P| \frac{\epsilon \rho}{10} + \mathcal{E}(x^{(q)}) - \mathcal{E}(x^*) \\
&\geq \sum_{p \in Q_q(r')} e^{-\|x^* - p\|^2} - |P| \frac{\epsilon \rho}{10} - |Q_{P,q}(r')| \frac{\epsilon \rho}{8} - |Q_{P,q}(r')| \frac{\epsilon \rho}{8} \\
&= \sum_{p \in Q_q(r')} e^{-\|x^* - p\|^2} - |P| \frac{\epsilon \rho}{2}. \quad \blacktriangleleft
\end{aligned}$$

2.1 Algorithm for Searching Polynomial Systems in Neighborhoods

A first attempt invokes Lemma 6 in a ball $B_p \left(\sqrt{\log \frac{1}{\rho}} \right)$ around each $p \in P$. However, to find out the subset of points that lie inside the ball $B_p \left(\sqrt{\log \frac{1}{\rho}} \right)$ for each $p \in P$, one needs to search linearly over P naively. Therefore, it requires $\Omega(n^2)$ runtime.

Rather, following Algorithm 1, we create a set \mathbf{G}_P of neighborhoods, defined by the subset of $\text{Grid} \left(2\sqrt{\frac{\log \frac{1}{\epsilon \rho}}{d}} \right)$ which is within $4\sqrt{\log \frac{1}{\epsilon \rho}}$ of some point $p \in P$. For each $q \in \mathbf{G}_P$ we define a neighborhood set $Q_{P,q}(4)$, and run the algorithm in Lemma 5. Again we return the output with associated maximum $\mathcal{G}_{Q_{P,q}(4)}(\cdot)$ value, which satisfies Theorem 7.

■ **Algorithm 1** Solving System of Polynomial using an Infinite Grid.

input: a point set $P \subset \mathbb{R}^d$, parameter $\epsilon, \rho > 0$

- 1: **for** each $p \in P$ **do**
- 2: insert p into $Q_{P,q}(4)$ for each $q \in B_p(4\sqrt{\log \frac{1}{\epsilon \rho}}) \cap \text{Grid}(2\sqrt{\frac{\log \frac{1}{\epsilon \rho}}{d}})$
- 3: Let \mathbf{G}_P be the $q \in \text{Grid}(2\sqrt{\frac{\log \frac{1}{\epsilon \rho}}{d}})$ such that $Q_{P,q}(4)$ is non empty
- 4: **for** each $q \in \mathbf{G}_P$ **do**
- 5: Let $x^{(q)}$ be the solution to $\text{SysPoly}(P, q, 2, 4)$ by the algorithm in Lemma 5
- 6: **return** $x' = \text{argmax}_{q \in \mathbf{G}_P} \mathcal{G}_{Q_{P,q}(4)}(x^{(q)})$

► **Theorem 7.** Given $0 < \epsilon, \rho < 1/2$ and a point set $P \subset \mathbb{R}^d$ of size n , let $x^* = \text{argmax}_{x \in \mathbb{R}^d} \bar{\mathcal{G}}_P(x)$. If $\bar{\mathcal{G}}_P(x^*) \geq \rho$, we find $x' \in \mathbb{R}^d$ with $\bar{\mathcal{G}}_P(x') \geq \bar{\mathcal{G}}_P(x^*) - \epsilon \rho$ in time

$$O \left(n \cdot \log n \cdot (2\sqrt{2e\pi})^d + n \cdot \left(\log \frac{d}{\epsilon \rho} \right)^{O(d)} \right).$$

Proof. We need to argue that x^* must be contained in some neighborhood $B_q(2\sqrt{\log \frac{1}{\epsilon\rho}})$ for some $q \in \mathbf{G}_P$, and then apply Lemma 5 with $r = 2$ and $r' = 4$. This follows since, by Lemma 4, $x^* \in B_p(\sqrt{\log \frac{1}{\epsilon\rho}}) \subset B_p(\sqrt{\log \frac{1}{\epsilon\rho}})$ for some $p \in P$. Then let $q \in \mathbf{G}_P$ be the closest grid point to that point p ; the distance $\|p - q\| \leq \sqrt{d}\gamma/2 = \sqrt{\log \frac{1}{\epsilon\rho}}$ with $\gamma = 2\sqrt{\log(1/\epsilon\rho)/d}$. Then by triangle inequality $\|q - x^*\| \leq \|q - p\| + \|p - x^*\| \leq 2\sqrt{\log \frac{1}{\epsilon\rho}}$. Now, we conclude that the output of $\text{SysPoly}(P, p, 2, 4)$ satisfies

$$\begin{aligned} \mathcal{G}_P(x') &\geq \mathcal{G}_{Q_{P,q}(4)}(x') = \mathcal{G}_{Q_{P,q}(4)}(x^{(q)}) \geq \mathcal{G}_{Q_{P,q}(4)}(x^*) - |P| \frac{\epsilon\rho}{2} \\ &= \sum_{p \in P} e^{-\|p - x^*\|^2} - \sum_{p \notin Q_{P,q}(4)} e^{-\|p - x^*\|^2} - |P| \frac{\epsilon\rho}{2} \end{aligned}$$

Note that $\|x^* - p\| \geq \|q - p\| - \|q - x^*\| \geq 4\sqrt{\log \frac{1}{\epsilon\rho}} - 2\sqrt{\log \frac{1}{\epsilon\rho}} = 2\sqrt{\log \frac{1}{\epsilon\rho}}$ since $x^* \in B_q(2\sqrt{\log \frac{1}{\epsilon\rho}})$ and $p \notin B_q(4\sqrt{\log \frac{1}{\epsilon\rho}})$.

$$\mathcal{G}_P(x') \geq \mathcal{G}_P(x^*) - |Q_{P,q}(4)|(\epsilon\rho)^4 - |P| \frac{\epsilon\rho}{2} \geq \mathcal{G}_P(x^*) - |P|\epsilon\rho \quad \text{since } \epsilon, \rho < 1/2$$

We now compute the running time. First, to construct $Q_{P,q}(4)$ (for notation convenience, we use Q_q instead), for each $p \in P$, we enumerate all $q \in B_p(4\sqrt{\log \frac{1}{\epsilon\rho}}) \cap \text{Grid}\left(2\sqrt{\frac{\log \frac{1}{\epsilon\rho}}{d}}\right)$ and insert p into Q_q . Since, by considering the volume of high dimensional sphere, there are $O\left(\frac{\pi^{d/2}}{\Gamma(\frac{d}{2}+1)} \left(4\sqrt{\log \frac{1}{\epsilon\rho}} / 2\sqrt{\frac{\log \frac{1}{\epsilon\rho}}{d}}\right)^d\right) = O((2\sqrt{2e\pi})^d)$ points in $B_p(4\sqrt{\log \frac{1}{\epsilon\rho}}) \cap \text{Grid}\left(2\sqrt{\frac{\log \frac{1}{\epsilon\rho}}{d}}\right)$ for each $p \in P$, we have $\sum_{q \in \mathbf{G}_P} |Q_q| = O(n(2\sqrt{2e\pi})^d)$ and also there are only $O(n(4\sqrt{2e\pi})^d)$ non empty Q_q . Here, Γ is the gamma function and we use the fact of $\Gamma(x+1) \geq (\frac{x}{e})^x$. It is easy to construct a data structure to insert all p into all of the corresponding Q_q in $O(n(2\sqrt{2e\pi})^d \log(n(2\sqrt{2e\pi})^d)) = O(n(2\sqrt{2e\pi})^d(\log n + d))$. Let $s = 36e^2 \log \frac{d}{\epsilon\rho}$. We now can precompute each polynomial $\prod_{i=1}^d \left(\sum_{j=0}^{s-1} \frac{1}{j!} (-(x_i - p_i)^2)^j\right)$ in $O(d(2s)^d)$ time for each $p \in P$ which takes $O(nd(2s)^d)$ total time to compute all of them. For each $q \in \mathbf{G}_P$, it takes $O(|Q_q|(2s)^d)$ to construct the polynomial and $O(s^{O(d)})$ time to solve the system of polynomial as suggested in Lemma 5. Therefore, the total running time is

$$\begin{aligned} &O\left(n(2\sqrt{2e\pi})^d(\log n + d) + nd(2s)^d + \sum_{q \in \mathbf{G}_P} (|Q_q|(2s)^d + s^{O(d)})\right) \\ &= O\left(n \cdot \log n \cdot (2\sqrt{2e\pi})^d + n \cdot \left(\log \frac{d}{\epsilon\rho}\right)^{O(d)}\right). \quad \blacktriangleleft \end{aligned}$$

To achieve our final result for low dimensionality, we pre-process the input P by constructing, under the assumption that $\max_x \bar{\mathcal{G}}_P(x) \geq \rho$, a $(1 - \epsilon/3)$ -approximation coresets from [55] of size $O(\frac{d}{\epsilon^2} \frac{1}{\rho} (\log \frac{1}{\rho} + \log \frac{1}{\delta}))$. Running Algorithm 1 on this coresets yields Theorem 1.

Proof of Theorem 1. Let $x^{**} = \operatorname{argmax}_{x \in \mathbb{R}^d} \bar{\mathcal{G}}_{P_1}(x)$. We first have $\bar{\mathcal{G}}_{P_1}(x^{**}) \geq \bar{\mathcal{G}}_{P_1}(x^*) \geq (1 - \frac{1}{3}\epsilon)\bar{\mathcal{G}}_P(x^*) = \Omega(\rho)$ for small ϵ . By Theorem 7 and reparameterizing ϵ , we have

$$\begin{aligned}
\bar{\mathcal{G}}_P(x') &\geq \bar{\mathcal{G}}_{P_1}(x') - \frac{1}{3}\epsilon M_{x'} && \text{by the construction of } P_1 \\
&\geq \bar{\mathcal{G}}_{P_1}(x^{**}) - \frac{1}{3}\epsilon\rho - \frac{1}{3}\epsilon M_{x'} && \text{since } \bar{\mathcal{G}}_{P_1}(x^{**}) = \Omega(\rho) \text{ and by Theorem 7} \\
&\geq \bar{\mathcal{G}}_{P_0}(x^*) - \frac{1}{3}\epsilon\rho - \frac{1}{3}\epsilon M_{x'} \\
&\geq (1 - \frac{1}{3}\epsilon)\bar{\mathcal{G}}_P(x^*) - \frac{1}{3}\epsilon\rho - \frac{1}{3}\epsilon M_{x'} && \text{by } \bar{\mathcal{G}}_P(x^*) \geq \rho \text{ and construction of } P_1 \\
&\geq (1 - \epsilon)\bar{\mathcal{G}}_P(x^*) && \text{since } M_{x'} \leq \bar{\mathcal{G}}_P(x^*)
\end{aligned}$$

The final running time is $O(nd)$ to read data and construct P_1 plus

$$O\left(n_1 \cdot \log n_1 \cdot (2\sqrt{2e\pi})^d + n_1 \cdot \left(\log \frac{d}{\epsilon\rho}\right)^{O(d)}\right) = O\left(\frac{d}{\epsilon^2\rho} \cdot \log \frac{1}{\rho\delta} \cdot \left(\log \frac{d}{\epsilon\rho}\right)^{O(d)}\right). \blacktriangleleft$$

3 Dimensionality Reduction for KDE Mode Finding

Leveraging Kirschbraun's extension theorem, we prove that compressing $P = \{p_1, \dots, p_n\}$ using a Johnson-Lindenstrauss random projection to $O(\log n \log^2(1/\epsilon\rho)/\epsilon^2)$ dimensions preserves the mode of the KDE with centers in P , to a $(1 - \epsilon)$ factor. Crucially, we then show that it is possible to recover an approximate mode for P from a solution to the low dimensional problem by applying a *single iteration* of the mean-shift algorithm.

In Section 3.1 we combine this result with our low dimensional algorithm from Section 2 and existing coresets results for KDEs (which allow us to eliminate the $\log n$ dependence) to give our final algorithm for high-dimensional mode finding. We first present the dimensionality reduction result in isolation as, like dimensionality reduction strategies for other computational hard problems [15, 35, 8], it could in principle be combined with any other heuristic or approximate mode finding method. For example, we show a practical strategy is to solve the low-dimensional problem using the mean-shift heuristic.

We need one basic definition before outlining our approach in Algorithm 2.

► **Definition 8** ((γ, k, δ) -Johnson-Lindenstrauss Guarantee). *A randomly selected matrix $\Pi \in \mathbb{R}^{m \times d}$ satisfies the (γ, k, δ) -JL Guarantee if, for any k data points $v_1, \dots, v_k \in \mathbb{R}^d$,*

$$\|v_i - v_j\| \leq \|\Pi v_i - \Pi v_j\| \leq (1 + \gamma)\|v_i - v_j\|,$$

for all pairs $i, j \in 1, \dots, k$ simultaneously, with probability $(1 - \delta)$.

Definition 8 is satisfied by many possible constructions. When Π is a properly scaled random Gaussian or sign matrix, it satisfies the (γ, k, δ) -JL guarantee as long as $m = O(\log(k/\delta)/\gamma^2)$ [17, 1]. In this case, Π can be multiplied by a d dimensional vector in $O(md)$ time. For simplicity, we assume such a construction is used in our algorithm. Other constructions, including fast Johnson-Lindenstrauss transforms [3, 4, 31] and sparse random projections [29, 16] satisfy the definition with slightly larger m , but faster multiplication time. Depending on problem parameters, using such constructions may lead to a slightly faster overall runtime.

■ **Algorithm 2** Dimensionality Reduction for KDE mode finding.

input: a set of n points $P \subset \mathbb{R}^d$, parameters $\epsilon, \delta > 0$, ρ such that $\max_x G_P(x) \geq \rho n$
output: a point $x' \in \mathbb{R}^d$ satisfying $G_P(x') \geq (1 - \epsilon) \max_x G_P(x)$ with prob. $1 - \delta$

- 1: Set $\gamma = \frac{\epsilon}{4 \log(4/\epsilon\rho)}$.
- 2: Choose a random matrix $\Pi \in \mathbb{R}^{m \times d}$ satisfying the $(\gamma, n + 1, \delta)$ -JL guarantee (Defn. 8).
- 3: For each $p_i \in P$, compute Πp_i and let ΠP denote the data set $\{\Pi p_1, \dots, \Pi p_n\}$
- 4: Using an algorithm for mode finding in low dimensions (e.g. Algorithm 1) find a point x'' satisfying $\mathcal{G}_{\Pi P}(x'') \geq (1 - \epsilon/2) \max_{x \in \mathbb{R}^m} \mathcal{G}_{\Pi P}(x)$.
- 5: **return** $x' = \frac{\sum_{p \in P} p \cdot e^{-\|x'' - \Pi p\|^2}}{\sum_{p \in P} e^{-\|x'' - \Pi p\|^2}}$

► **Theorem 9.** *With probability $(1 - \delta)$, Algorithm 2 returns an x' satisfying $\mathcal{G}_P(x') \geq (1 - \epsilon) \max_x \mathcal{G}_P(x)$. When implemented with a random Rademacher or Gaussian Π , the algorithm runs in time $O(ndm) + T_{m, (1-\epsilon/2)}$, where $m = O\left(\frac{\log(n/\delta) \log^2(1/\epsilon\rho)}{\epsilon^2}\right)$ and $T_{m, (1-\epsilon)}$ is the time required to compute a $(1 - \epsilon/2)$ approximate mode for an $O(m)$ dimension dataset.*

The runtime claim is immediate, so we focus on proving the correctness of Algorithm 9. The following key lemma is the main structural result, that the mode of our dimensionality reduced problem has approximately the same density as that of the original. Its proof, as we see below, crucially uses Kirschbraun's extension theorem.

► **Lemma 10.** *Suppose Π is a projection satisfying the $(\gamma, n + 1, \delta)$ -JL guarantee, then*

$$(1 - \epsilon/2) \max_{x \in \mathbb{R}^d} \mathcal{G}_P(x) \leq \max_{x \in \mathbb{R}^m} \mathcal{G}_{\Pi P}(x) \leq \max_{x \in \mathbb{R}^d} \mathcal{G}_P(x) \quad (1)$$

Proof. Let $x^* = \operatorname{argmax}_x \mathcal{G}_P(x)$. Since Π was chosen to satisfy the $(\gamma, n + 1, \delta)$ -JL property with $\gamma = \frac{\epsilon}{4 \log(4/\epsilon\rho)}$, we have that, with probability at least $1 - \delta$, for all $y, z \in \{x^*\} \cup P$,

$$\|y - z\|^2 \leq \|\Pi y - \Pi z\|^2 \leq \left(1 + \frac{\epsilon}{4 \log(4/\epsilon\rho)}\right) \|y - z\|^2. \quad (2)$$

The rest of our analysis conditions on this fact being true. We first prove the left side of (1). From (2), we have that $\|\Pi x^* - \Pi p\|^2 \leq (1 + \frac{\epsilon}{4 \log(4/\epsilon\rho)}) \|x^* - p\|^2$ for all $p \in P$. Accordingly,

$$\begin{aligned} \max_{x \in \mathbb{R}^m} \mathcal{G}_{\Pi P}(x) &\geq \mathcal{G}_{\Pi P}(\Pi x^*) = \sum_{p \in P} e^{-\|\Pi x^* - \Pi p\|^2} \geq \sum_{p \in P} e^{-(1 + \frac{\epsilon}{4 \log(4/\epsilon\rho)}) \|x^* - p\|^2} \\ &\geq \sum_{\substack{p \in P \\ \|x^* - p\|^2 < \log(4/\epsilon\rho)}} e^{-\|x^* - p\|^2} e^{-\frac{\epsilon}{4 \log(4/\epsilon\rho)} \|x^* - p\|^2} \geq (1 - \epsilon/4) \sum_{\substack{p \in P \\ \|x^* - p\|^2 < \log(4/\epsilon\rho)}} e^{-\|x^* - p\|^2}. \end{aligned} \quad (3)$$

The last step uses that $e^{-\frac{\epsilon}{4 \log(4/\epsilon\rho)} \|x^* - p\|^2} \geq 1 - \epsilon/4$ when $\|x^* - p\|^2 \leq \log(4/\epsilon\rho)$. Next we have

$$\sum_{\substack{p \in P \\ \|x^* - p\|^2 < \log \frac{4}{\epsilon\rho}}} e^{-\|x^* - p\|^2} \geq \sum_{p \in P} e^{-\|x^* - p\|^2} - \epsilon n \rho = \mathcal{G}_P(x^*) - \epsilon n \rho \geq (1 - \epsilon/4) \mathcal{G}_P(x^*).$$

This statement follows from two facts: 1) If $\|x^* - p\|^2 \geq \log \frac{4}{\epsilon\rho}$ then $e^{-\|x^* - p\|^2} \leq \epsilon\rho/4$ and 2) we assume that $\mathcal{G}_P(x^*) \geq \rho n$. Combining with (3) we conclude that $\mathcal{G}_{\Pi P}(x) \geq (1 - \epsilon/2) \mathcal{G}_P(x^*)$.

We are left to prove the right hand side of (1). To do so, we rely on the classic Kirschbraun extension theorem for Lipschitz functions, which is stated as follows:

► **Theorem 11** (Kirschbraun Theorem [30, 51]). *For any $\mathcal{S} \subset \mathbb{R}^z$, let $f : \mathcal{S} \rightarrow \mathbb{R}^w$ be an L -Lipschitz function: for all $x, y \in \mathcal{S}$, $\|f(x) - f(y)\|_2 \leq L\|x - y\|_2$. Then there always exists some extension $\tilde{f} : \mathbb{R}^z \rightarrow \mathbb{R}^w$ of f to the entirety of \mathbb{R}^z such that:*

1. $\tilde{f}(x) = f(x)$ for all $x \in \mathcal{S}$,
2. \tilde{f} is also L -Lipschitz: for all $x, y \in \mathbb{R}^z$, $\|\tilde{f}(x) - \tilde{f}(y)\|_2 \leq L\|x - y\|_2$.

We will apply this theorem to the function $g : \{\Pi x^*\} \cup \Pi P \rightarrow \{x^*\} \cup P$ with $g(\Pi y) = y$ for any $y \in \{x^*\} \cup P$. By (2), we have that g is 1-Lipschitz. It follows that there is some function $\tilde{g} : \mathbb{R}^m \rightarrow \mathbb{R}^d$ which agrees with g on inputs $\{\Pi x^*\} \cup P$ and satisfies $\|\tilde{g}(s) - \tilde{g}(t)\| \leq \|s - t\|$ for all $s, t \in \mathbb{R}^m$. This fact can be used to establish that, for any $x \in \mathbb{R}^m$, $\mathcal{G}_{\Pi P}(x) \leq \mathcal{G}_P(\tilde{g}(x))$:

$$\mathcal{G}_{\Pi P}(x) = \sum_{p \in P} e^{-\|x - \Pi p\|^2} \leq \sum_{p \in P} e^{-\|\tilde{g}(x) - \tilde{g}(\Pi p)\|^2} = \sum_{p \in P} e^{-\|\tilde{g}(x) - p\|^2} = \mathcal{G}_P(\tilde{g}(x)).$$

It thus follows that $\max_x \mathcal{G}_{\Pi P}(x) \leq \max_x \mathcal{G}_P(x)$, so the right side of (1) is proven. ◀

In proving Lemma 10 we have also proven the following statement.

► **Corollary 12.** *For any $x \in \mathbb{R}^m$, there exists some point $\tilde{g}(x) \in \mathbb{R}^d$ such that, for all $p \in P$, $\|\tilde{g}(x) - p\| \leq \|x - \Pi p\|$.*

We complete the proof of Theorem 9 by showing that, not only does the maximum of $\mathcal{G}_{\Pi P}$ approximate that of \mathcal{G}_P , but an approximate maximizer for $\mathcal{G}_{\Pi P}$ can be used to recover one for \mathcal{G}_P . Algorithm 2 does so on Line 5 by applying a single iteration of the *mean-shift* algorithm, a common heuristic KDE mode finding [9, 10], which repeatedly iterates the equation $x^{(i+1)} = \frac{\sum_{p \in P} p \cdot e^{-\|x^{(i)} - p\|^2}}{\sum_{p \in P} e^{-\|x^{(i)} - p\|^2}}$. While not guaranteed to converge to a point which maximizes \mathcal{G}_P , a useful property of the mean-shift algorithm is that its solution is guaranteed to never decrease in quality on each iteration:

▷ **Claim 13.** Given $y \in \mathbb{R}^d$, let $y' = \frac{\sum_{p \in P} p \cdot e^{-\|y - p\|^2}}{\sum_{p \in P} e^{-\|y - p\|^2}}$, then $\mathcal{G}_P(y') \geq \mathcal{G}_P(y)$.

Proof. We prove this well known fact for completeness. First, observe by rearrangement that $\mathcal{G}_P(y') - \mathcal{G}_P(y) = \sum_{p \in P} \left(e^{-\|y' - p\|^2 + \|y - p\|^2} - 1 \right) e^{-\|y - p\|^2}$. Then, since $e^z \geq 1 + z$ for all z , we have $e^{-\|y' - p\|^2 + \|y - p\|^2} - 1 \geq -\|y' - p\|^2 + \|y - p\|^2 = -(\|y'\|^2 - \|y\|^2 - 2(y' - y)^T p)$.

$$\begin{aligned} \mathcal{G}_P(y') - \mathcal{G}_P(y) &\geq -(\|y'\|^2 - \|y\|^2) \sum_{p \in P} e^{-\|y - p\|^2} + 2(y' - y)^T \sum_{p \in P} p e^{-\|y - p\|^2} \\ &= \mathcal{G}_P(y) (-\|y'\|^2 + \|y\|^2 + 2(y' - y)^T y') = \mathcal{G}_P(y) \|y' - y\|^2 \geq 0. \end{aligned} \quad \blacktriangleleft$$

Proof of Theorem 9. Recall from Corollary 12 that for any x , there is always a $\tilde{g}(x)$ with

$$\|\tilde{g}(x) - p\| \leq \|x - \Pi p\| \tag{4}$$

for all $p \in P$. Suppose this inequality was tight: i.e., suppose that for all $p \in P, x \in \mathbb{R}^m$, $\|\tilde{g}(x) - p\| = \|x - \Pi p\|$. Then letting x'' be as defined in Algorithm 2, we would have that Line 5 sets x' equal to a mean-shift update applied to $\tilde{g}(x'')$. From Claim 13 we would then immediately have that $\mathcal{G}_P(x') \geq \mathcal{G}_P(\tilde{g}(x'')) = \mathcal{G}_{\Pi P}(x'') \geq (1 - \epsilon/2) \max_x \mathcal{G}_{\Pi P}(x) \geq (1 - \epsilon) \max_x \mathcal{G}_P(x)$, which would prove the theorem.

However, since (4) is not tight, we need a more involved argument by lifting to a $d + 1$ -dimensional space. In particular, for each $p \in P$, let $\bar{p} \in \mathbb{R}^{d+1}$ be a vector with its first d entries equal to p and let the final entry be equal to $\sqrt{\|x - \Pi p\|^2 - \|\tilde{g}(x) - p\|^2}$. Additionally,

■ **Algorithm 3** Full algorithm for high dimensional case.

input: a point set $P \in \mathbb{R}^d$, parameter $\epsilon, \rho, \delta > 0$

- 1: Generate $O(\log \frac{1}{\delta})$ random samples $P_0^j \subset P$ of size $n_0 = O(\frac{1}{\epsilon^2 \rho^2})$ (à la Lopaz-Paz et al.)
- 2: **for** $j \leftarrow 1$ to $O(\log \frac{1}{\delta})$ **do**
- 3: Set $\gamma = \frac{\epsilon}{4 \log(4/\epsilon \rho)}$.
- 4: Choose random matrix $\Pi \in \mathbb{R}^{m \times d}$ satisfying $(\gamma, n+1, 1/100)$ -JL guarantee (Defn. 8)
- 5: For each $p_i \in P_0^j$, compute Πp_i and let ΠP_0^j denote the data set $\{\Pi p_1, \dots, \Pi p_n\}$
- 6: Run the algorithm in Phillips and Tai [39] to construct a subset $P_2^j \subset \Pi P_0^j$ of size $n_2 = O(\frac{\sqrt{m}}{\epsilon \rho} \sqrt{\log \frac{1}{\epsilon \rho}}) = O(\frac{1}{\epsilon^2 \rho} \log^2 \frac{1}{\epsilon \rho})$
- 7: Set x'' as the output of Algorithm 1 (Section 2) on P_2^j in dimension m
- 8: Compute new $x' = \frac{\sum_{p \in P_0^j} p \cdot e^{-\|x'' - \Pi p\|^2}}{\sum_{p \in P_0^j} e^{-\|x'' - \Pi p\|^2}}$
- 9: **Return** the best solution from all iterations of Step 8, evaluated on $\bigcup_j P_0^j$

for every point $x \in \mathbb{R}^m$, let $\tilde{g}(x) \in \mathbb{R}^{d+1}$ be a vector with its first d entries equal to $\tilde{g}(x) \in \mathbb{R}^d$ and final entry equal to 0. Clearly, for any $p \in P$,

$$\|\tilde{g}(x) - \tilde{p}\| = \|x - \Pi p\|. \quad (5)$$

For $z \in \mathbb{R}^{d+1}$, let $\bar{\mathcal{G}}_P(z) = \sum_{p \in P} e^{-\|z - \tilde{p}\|^2}$ and let $\tilde{x}' = \frac{\sum_{p \in P} \tilde{p} e^{-\|x'' - \Pi p\|^2}}{\sum_{p \in P} e^{-\|x'' - \Pi p\|^2}}$. It follows from (5) and the argument above that $\bar{\mathcal{G}}_P(\tilde{x}') \geq \bar{\mathcal{G}}_P(\tilde{g}(x')) = \mathcal{G}_{\Pi P}(x'')$. But clearly it also holds that $\mathcal{G}_P(x') \geq \bar{\mathcal{G}}_P(\tilde{x}')$ because, for any $p \in P$, $\|x' - p\| \leq \|\tilde{x}' - \tilde{p}\|$. So we conclude that $\mathcal{G}_P(x') \geq \mathcal{G}_{\Pi P}(x'')$ as desired. Furthermore, recall that x'' is an approximate mode in the projected setting. It satisfies $\mathcal{G}_{\Pi P}(x'') \geq \max_x (1 - \epsilon/2) \mathcal{G}_{\Pi P}(x)$, and from Lemma 10 we have that $\max_x \mathcal{G}_{\Pi P}(x) \geq (1 - \epsilon/2) \max_x \mathcal{G}_P(x)$. Chaining these inequalities gives the desired bound that $\mathcal{G}_P(x') \geq (1 - \epsilon/2)^2 \max_x \mathcal{G}_P(x) \geq (1 - \epsilon) \max_x \mathcal{G}_P(x)$. ◀

3.1 Final Result for High Dimensions

For the high dimensional case, we combine together the techniques of 1) dimensionality reduction, 2) polynomial system solving and 3) coresets by [34] and [39] to obtain an algorithm that is linear in the dimensionality d and exponential only in $\text{poly}(1/\epsilon, \log 1/\rho)$, leading to Theorem 2.

In the regime where ϵ (the relative error) and δ (the probability of failure) are constant, the runtime simplifies to $O\left(\left(n + \frac{1}{\rho^2}\right)d + \left(\log \frac{1}{\rho}\right)^{O(\log^3 \frac{1}{\rho})}\right)$. Note however that if $1/\rho^2 \leq n_0$ dominates n , then we would not have constructed the coresets P_0^j in the first place but used the entire point set instead, and so we can treat the first term as just $O(nd)$. We also recall that $\rho = \bar{\mathcal{G}}_P(x^*) \geq 1/n$, which by substitution gives an upper bound of $O\left(nd + (\log n)^{O(\log^3 n)}\right)$.

Proof of Theorem 2. We first show the approximation guarantee. It suffices to prove that an iteration of the for loop succeeds with constant probability, so we fix a particular j and omit the superscript in P_0 and P_2 . From Lemma 4, $x^* \in B_q\left(\sqrt{\log \frac{1}{\rho}}\right) \subset B_q\left(\sqrt{\log \frac{1}{\epsilon \rho}}\right)$ for some $q \in P_2$. Let x_0^{**} be $\arg \max_{x \in \mathbb{R}^m} \mathcal{G}_{P_2}(x)$. By Lemma 6 with $r = 1$, we have $\bar{\mathcal{G}}_{P_2}(x'') \geq \bar{\mathcal{G}}_{P_2}(x_0^{**}) - \epsilon \rho \geq (1 - \epsilon) \bar{\mathcal{G}}_{P_2}(x_0^{**})$. The coreset result by [39] implies that, both $|\bar{\mathcal{G}}_{\Pi P_0}(x'') - \bar{\mathcal{G}}_{P_2}(x'')| \leq \epsilon \rho$ and $|\bar{\mathcal{G}}_{\Pi P_0}(x^{**}) - \bar{\mathcal{G}}_{P_2}(x^{**})| \leq \epsilon \rho$ which implies $\bar{\mathcal{G}}_{\Pi P_0}(x'') \geq$

$(1 - O(\epsilon))\bar{\mathcal{G}}_{\Pi P_0}(x^{**})$. Now, let x_0^* be $\arg \max_{x \in \mathbb{R}^d} \mathcal{G}_{\Pi P_0}(x)$. By Theorem 9, with constant probability we have $\mathcal{G}_{P_0}(x') \geq (1 - O(\epsilon))\mathcal{G}_{P_0}(x_0^*)$. By [34], a random sample $P_0 \subset P$ of size $n_0 = O(\frac{1}{\epsilon^2 \rho^2})$ is sufficient to have the guarantee of $|\bar{\mathcal{G}}_P(x) - \bar{\mathcal{G}}_{P_0}(x)| \leq \epsilon \rho$ for any $x \in \mathbb{R}^d$. If we combine this inequality and the guarantee of random sampling, we can conclude that $\bar{\mathcal{G}}_P(x') \geq (1 - \epsilon)\bar{\mathcal{G}}_P(x^*)$.

We now analyze the running time. Reading the input and constructing the coresets P_0^j take $O(nd + n_0 \log \frac{1}{\delta})$ time in total. Evaluating all the solutions in Step 9 takes $O(n_0 d \log^2 \frac{1}{\delta})$ time, since there are $O(\log \frac{1}{\delta})$ many candidates evaluated over a coreset of size $O(n_0 \log \frac{1}{\delta})$ in d dimensions. From Theorem 9, the runtime of a single iteration of the loop is $O(n_0 dm) + T_{m, \epsilon/2}$, where $T_{m, \epsilon/2}$ is the runtime of solving the approximate mode finding problem in m dimensions. In our case, $T_{m, \epsilon/2}$ consists of the runtime of the second coreset result as well as Algorithm 1. It takes time $O(n_0 \text{poly}(1/\epsilon \rho))$ to compute the second coreset P_2^j . Then, Theorem 7 implies that Algorithm 1 requires $O(n_2 \log n_2 \cdot (2\sqrt{2e\pi})^m + n_2 \cdot \left(\log \frac{m}{\epsilon \rho}\right)^{O(m)})$.

The single-loop runtime is dominated by the runtime of Algorithm 1. Writing out the runtime of Algorithm 1 gives

$$\begin{aligned} & O \left(n_2 \log n_2 \cdot (2\sqrt{2e\pi})^m + n_2 \cdot \left(\log \frac{m}{\epsilon \rho} \right)^{O(m)} \right) = O \left(n_2 \cdot \left(\log \frac{m}{\epsilon \rho} \right)^{O(m)} \right) \\ & = O \left(\frac{1}{\epsilon^2 \rho} \log^2 \frac{1}{\epsilon \rho} \cdot \left(\log \frac{1}{\epsilon^3 \rho} \log \frac{1}{\epsilon \rho} \log^2 \frac{1}{\epsilon \rho} \right)^{O(\frac{1}{\epsilon^2} \log^3 \frac{1}{\epsilon \rho})} \right) = O \left(\left(\log \frac{1}{\epsilon \rho} \right)^{O(\frac{1}{\epsilon^2} \log^3 \frac{1}{\epsilon \rho})} \right). \end{aligned}$$

Combining with the runtimes for reading the input, coreset construction and evaluating solutions in Step 9, then repeating the loop for $O(\log \frac{1}{\delta})$ times gives the bound in the theorem statement. If $n < n_0 \log \frac{1}{\delta}$, we use the full set P as each P_0^j . \blacktriangleleft

4 KDE mode finding for Two Dimensional Case

In this subsection, we assume that $P \subset \mathbb{R}^2$ and $p = (p_1, p_2)$ for each $p \in P$. We can improve our low-dimensional analysis that used a set of systems of polynomials by about a logarithmic factor using a different approach. This shows how to approximate each Gaussian by a weighted set of rectangles. After sampling by these weights, we can quickly retrieve the point of maximum depth in these rectangles as an approximation of the maximum.

We first define the following notation. We let $s = \frac{\epsilon \rho}{6}$ be a minimal additive error we will allow for the spatial approximation, and then $m = \lceil \frac{1}{s} \rceil$ will be the number of discretizations we will need. A Gaussian has infinite support, but we will only need to consider m such widths defined $r_j = \sqrt{\log \frac{1}{l_j}}$ with $l_j = 1 - \frac{j}{m}$ for $j = 0, 1, \dots, m$.

As a special case we set $r_m = \infty$ (note that this allows $e^{-r_j^2} = l_j$). We can now define a series of axis-parallel rectangles centered at a point $p = (p_1, p_2) \in P$ as $\mathcal{R}_p = \{[p_1 - r_{a_1}, p_1 + r_{a_1}] \times [p_2 - r_{a_2}, p_2 + r_{a_2}] \mid (a_1, a_2) \in \{0, 1, \dots, m-1\}^2\}$. It enumerates all widths r_0, r_1, \dots, r_{m-1} on both directions, so its size is m^2 . Also, let \mathcal{R} be $\cup_{p \in P} \mathcal{R}_p$.

Given any $x \in \mathbb{R}^d$ and any finite collection \mathcal{C} subsets of \mathbb{R}^2 , denote $N(\mathcal{C}, x)$ as the number of $C \in \mathcal{C}$ that $x \in C$, known as the *depth* or *ply* of x . And we can show that the depth, normalized by $1/(nm^2)$, approximates the KDE value $\bar{\mathcal{G}}_P(x)$.

► **Lemma 14.** $\bar{\mathcal{G}}_P(x) \geq \frac{N(\mathcal{R}, x)}{nm^2} \geq \bar{\mathcal{G}}_P(x) - \frac{1}{3}\epsilon \rho$

The main idea is to show that Gaussian kernel can be approximated by a collection of axis-parallel rectangle where m controls precision. Observe that $|\mathcal{R}| = nm^2$. However, $|\mathcal{R}|$ (and therefore m) does not show up in the running time of our algorithm since, we perform the random sampling on \mathcal{R} in the first step of Algorithm 4.

61:14 Finding an Approximate Mode of a Kernel Density Estimate

Proof. For any $p \in P$ and $i \in \{1, 2\}$, let a_i be the integer such that $r_{a_i-1} \leq |p_i - x_i| \leq r_{a_i}$ which implies $e^{-r_{a_i-1}^2} \geq e^{-(p_i - x_i)^2} \geq e^{-r_{a_i}^2} = 1 - \frac{a_i}{m}$. Then, we have

$$e^{-\|p-x\|^2} = e^{-(p_1-x_1)^2-(p_2-x_2)^2} \geq (1 - \frac{a_1}{m})(1 - \frac{a_2}{m}) = \frac{N(\mathcal{R}_p, x)}{m^2}$$

Note that $N(\mathcal{R}, x) = \sum_{i=1}^d N(\mathcal{R}_p, x)$. Now,

$$\mathcal{G}_P(x) = \sum_{p \in P} e^{-\|p-x\|^2} \geq \sum_{p \in P} \frac{N(\mathcal{R}_p, x)}{m^2} = \frac{N(\mathcal{R}, x)}{m^2}$$

On the other hand, let $\Delta_{p,x,i} = e^{-(p_i-x_i)^2} - (1 - \frac{a_i}{m})$ which is larger than 0,

$$\begin{aligned} \frac{N(\mathcal{R}_p, x)}{m^2} &= (1 - \frac{a_1}{m})(1 - \frac{a_2}{m}) = \left(e^{-(p_1-x_1)^2} - \Delta_{p,x,1}\right) \left(e^{-(p_2-x_2)^2} - \Delta_{p,x,2}\right) \\ &= e^{-(p_1-x_1)^2} e^{-(p_2-x_2)^2} - \Delta_{p,x,1} e^{-(p_2-x_2)^2} - \Delta_{p,x,2} e^{-(p_1-x_1)^2} + \Delta_{p,x,1} \Delta_{p,x,2} \\ &\geq e^{-(p_1-x_1)^2} e^{-(p_2-x_2)^2} - \Delta_{p,x,1} e^{-(p_2-x_2)^2} - \Delta_{p,x,2} e^{-(p_1-x_1)^2} \end{aligned}$$

Recall that $e^{-r_{a_i-1}^2} \geq e^{-(p_i-x_i)^2} \geq e^{-r_{a_i}^2}$ which implies $\Delta_{p,x,i} \leq e^{-r_{a_i-1}^2} - e^{-r_{a_i}^2} = s$. The above equation becomes

$$\begin{aligned} \frac{N(\mathcal{R}_p, x)}{m^2} &\geq e^{-(p_1-x_1)^2} e^{-(p_2-x_2)^2} - \Delta_{p,x,1} e^{-(p_2-x_2)^2} - \Delta_{p,x,2} e^{-(p_1-x_1)^2} \\ &\geq e^{-\|p-x\|^2} - 2s \end{aligned}$$

Finally, we have

$$\frac{N(\mathcal{R}, x)}{m^2} = \sum_{p \in P} \frac{N(\mathcal{R}_p, x)}{m^2} \geq \sum_{p \in P} (e^{-\|p-x\|^2} - 2s) = \mathcal{G}_P(x) - \frac{1}{3} \epsilon n \rho. \quad \blacktriangleleft$$

Now consider (X, \mathcal{S}) be a range space with VC dimension ν . Given $\epsilon > 0$ and $\alpha > 0$, we call a subset Z of X a relative (α, ϵ) -approximation for (X, \mathcal{S}) if, for any $\tau \in \mathcal{S}$, $\left| \frac{|X \cap \tau|}{|X|} - \frac{|Z \cap \tau|}{|Z|} \right| \leq \epsilon M$ when $M = \max\{\frac{|X \cap \tau|}{|X|}, \alpha\}$. A random sample of size $O(\frac{1}{\epsilon^2 \alpha} (\nu \log \frac{1}{\alpha} + \log \frac{1}{\delta}))$ is an (α, ϵ) -approximation with probability at least $1 - \delta$ [25]. The range space $(\mathbb{R}^2, \mathcal{B})$ where \mathcal{B} is the set of all axis-parallel box in \mathbb{R}^2 has VC dimension 4. Thus its dual range space $(\mathcal{B}, \mathcal{D})$ where $\mathcal{D} = \{B \in \mathcal{B} \mid x \in B\} \mid x \in \mathbb{R}^2\}$, has VC dimension is $O(1)$.

Given a set \mathcal{B}_0 of λ axis-aligned rectangles in \mathbb{R}^2 , [12] finds a maximal depth point, that maximizes $N(\mathcal{B}_0, x)$, in $O(\lambda \log \lambda)$ time. This leads to Algorithm 4 and Theorem 3.

■ Algorithm 4 Computing Depth.

input: a point set $P \subset \mathbb{R}^2$, parameter $\epsilon, \rho, \delta > 0$

- 1: generate a random subset \mathcal{R}_0 of \mathcal{R} of size $O\left(\frac{1}{\epsilon^2 \rho} (\log \frac{1}{\rho} + \log \frac{1}{\delta})\right)$.
- 2: compute $x' \in \mathbb{R}^2$ such that $x' = \arg \max_{x \in \mathbb{R}^d} N(\mathcal{R}_0, x)$ using the algorithm by [12].
- 3: **return** x'

Proof of Theorem 3. First, by Lemma 14, $\frac{N(\mathcal{R}, x^*)}{|\mathcal{R}|} \geq \bar{\mathcal{G}}_P(x^*) - \frac{1}{3} \epsilon \rho = \Omega(\rho)$. Let M be $\max\{\frac{N(\mathcal{R}, x')}{|\mathcal{R}|}, \rho\}$. We also have $M = \max\{\frac{N(\mathcal{R}, x')}{|\mathcal{R}|}, \rho\} \leq \bar{\mathcal{G}}_P(x^*)$. By Lemma 14 and the construction of \mathcal{R}_0 , we have $\bar{\mathcal{G}}_P(x') \geq \frac{N(\mathcal{R}, x')}{|\mathcal{R}|} \geq \frac{N(\mathcal{R}_0, x')}{|\mathcal{R}_0|} - \frac{1}{3} \epsilon M$. Since x' is the optimal solution, the term $\frac{N(\mathcal{R}_0, x')}{|\mathcal{R}_0|}$ is larger than $\frac{N(\mathcal{R}_0, x^*)}{|\mathcal{R}_0|}$.

$$\begin{aligned}
\bar{\mathcal{G}}_P(x') &\geq \frac{N(\mathcal{R}_0, x^*)}{|\mathcal{R}_0|} - \frac{1}{3}\epsilon M \\
&\geq \frac{(1 - \frac{1}{3}\epsilon)N(\mathcal{R}, x^*)}{|\mathcal{R}|} - \frac{1}{3}\epsilon M && \text{by } \frac{N(\mathcal{R}, x^*)}{|\mathcal{R}|} = \Omega(\rho) \text{ and construction of } \mathcal{R}_0 \\
&\geq (1 - \frac{1}{3}\epsilon)(\bar{\mathcal{G}}_P(x^*) - \frac{1}{3}\epsilon\rho) - \frac{1}{3}\epsilon M && \text{by [12]}
\end{aligned}$$

Finally, by the assumption of $\rho \leq M \leq \bar{\mathcal{G}}_P(x^*)$, we have $\bar{\mathcal{G}}_P(x') \geq (1 - \epsilon)\bar{\mathcal{G}}_P(x^*)$.

To see the running time, note that the size of input $\lambda = O\left(\frac{1}{\epsilon^2\rho}(\log \frac{1}{\rho} + \log \frac{1}{\delta})\right)$ in our context and $O(n)$ time to create a sample. Therefore, the total running time is

$$O\left(n + \frac{1}{\epsilon^2\rho}(\log \frac{1}{\rho} + \log \frac{1}{\delta}) \log\left(\frac{1}{\epsilon\rho} \log \frac{1}{\delta}\right)\right). \quad \blacktriangleleft$$

5 Experiments

In this section, we present two sets of experiments, demonstrating the efficacy of 1) our dimensionality reduction approach and 2) our 2D combinatorial algorithm. We did not have a ground truth, so we took the best run of any algorithm as the optimal (OPT), and present the “Error in %” as $(x - \text{OPT})/\text{OPT}$. The experiments were run in Python on Google Colab instances with GPU.

Dimensionality Reduction. The first experiment shows the speedup attained via dimensionality reduction, while sacrificing little in solution quality. As noted in Section 3, dimensionality reduction can be combined with any algorithm for mode finding; we compare the state-of-the-art mean-shift heuristic (described also in Section 3) with applying mean-shift after reducing the dimensionality in the data. We use a subset of the CelebA images [33]: $n = 20,000$ aligned and cropped face 178×218 pixel images of celebrities. We converted each image to greyscale, and treat as $(d = 38804)$ -dimensional vectors.

Given the KDE, we pick 10 random starting points and run mean-shift starting at each of them until the KDE value improves by less than 0.001. Then we return to the original dimensionality by running a single iteration of mean shift, to get a final value. We output the best solution, and report the total time of all restarts. For each target dimension (20–800), we report 500 trials as separate marks in the plot. Each trial with reduced dimensionality uses a single JL matrix across all restarts.

Figure 1 (Left) shows that, even if we reduce from 38804 dimensions down to 20 dimensions, the solution quality loss is only in the order of 0.1%. For reference, the solution quality is roughly 6550. The runtime savings are significant, from roughly 130 seconds in the original 38804 dimensions, to 8-9 seconds in 20 dimensions.

The theory demands a JL matrix with one-sided error; the random Gaussian matrix should be divided by some factor of $1 - \epsilon$. We did not do so because: (1) for very low target dimensions (say, 20), there is no valid $\epsilon \in (0, 1)$; and (2) even when such ϵ exists, this ϵ is large enough that a division by $1 - \epsilon$ introduces significant bias and worsens the solution.

2D Algorithm. Figure 1 (Right) shows the comparison of our 2D combinatorial algorithm and heuristics for mode finding. It shows both the best heuristic from [54] of evaluating random points, and then also the mean-shift iterative improvement on top of these [9, 10].

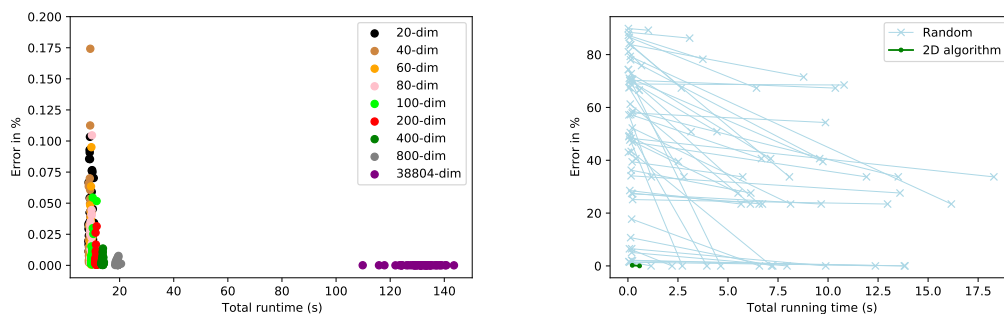

Figure 1 Percentage Error of algorithms as a function of runtime. (Left): Scatterplot for the dimensionality reduction, then mean-shift with 10 restarts. For each target dimension, we show 500 trials. (Right): 2D experiments, our algorithm versus choosing random starting point, then mean-shift. In each segment top point is error before mean-shift, and bottom one is after mean-shift.

We use the entire “Iowa_highway” dataset in [54], which has $n = 1,155,101$ points in \mathbb{R}^2 denoting all waypoints in Iowa from Open Street Maps. It is very multi-modal.

To compare our algorithm, we start with the best heuristic [54] of evaluating the KDE at k data points, and selecting the best. We use k between 1 and 10 random data points, and repeat 5 times for each, and select the lowest error. These are the top blue x s of each segment in the figure. Then for each initial data point, we run mean-shift to improve the error, and report the lowest error (out of each set of k starting points). These are the lower blue x of each segment in the figure. Note that the initial data point sampling heuristic occasionally obtains near-optimal error, but is typically much worse. The blue line segments showing the improvement of mean-shift indicate again it sometimes obtains near-optimal error, but not consistently. It also takes several seconds.

Our algorithm is shown as green dots. The top dot of the green segment is the cost/error of our algorithm, and the lower one is after optimizing with mean shift. We observe that our algorithm is significantly more efficient than the heuristics, taking less than one second, and achieves near-optimality, basically the same error as the best of prior heuristics.

Abstract

Our main contribution is a polynomial-time algorithm to reduce a k -colorable gammoid to a $(2k - 2)$ -colorable partition matroid. It is known that there are gammoids that can not be reduced to any $(2k - 3)$ -colorable partition matroid, so this result is tight. We then discuss how such a reduction can be used to obtain polynomial-time algorithms with better approximation ratios for various natural problems related to coloring and list coloring the intersection of matroids.

1 Introduction

Our main contribution is a polynomial-time algorithm to reduce a k -colorable gammoid to a $(2k - 2)$ -colorable partition matroid. Before elaborating on the statement of this result, we first give the necessary definitions, and the most relevant prior work. After stating the result we then explain some of the algorithmic ramifications.

1.1 Definitions

A set system is a pair $M = (S, \mathcal{I})$ where S is a universe of n elements and $\mathcal{I} \subseteq 2^S$ is a collection of subsets of S . Sets in \mathcal{I} are called **independent** and the rank r is the maximum cardinality of a set in \mathcal{I} . A partition C_1, C_2, \dots, C_k of S into independent sets is a k -coloring of M . The **coloring number** of M is the smallest k such that a k -coloring exists.

If each element $s \in S$ has an associated list A_s of allowable colors, then a list coloring is a coloring C_1, C_2, \dots, C_k such that if an $s \in S$ is in C_i then $i \in A_s$. The **list coloring number** of M is the smallest k that guarantees that if for $s \in S$ it is the case that if $|A_s| \geq k$ then a list coloring exists.

If $R \subseteq S$ then the restriction of M to R , denoted by $M \upharpoonright R$, is a set system where the universe is $S \cap R$ and where a set $I \subseteq S$ is independent if and only if $I \subseteq R$ and $I \in \mathcal{I}$.

A hereditary set system is a set system where if $A \subseteq B \subseteq S$ and $B \in \mathcal{I}$ then $A \in \mathcal{I}$. A matroid is an hereditary set system with the additional properties that $\emptyset \in \mathcal{I}$ and if $A \in \mathcal{I}$, $B \in \mathcal{I}$, and $|A| < |B|$ then there exists an $s \in B \setminus A$ such that $A \cup \{s\} \in \mathcal{I}$. The intersection of matroids $(S, \mathcal{I}_1), \dots, (S, \mathcal{I}_\ell)$ on common universe is a hereditary set system with universe S where a set $I \subseteq S$ is independent if and only if for all $i \in [1, \ell]$ it is the case that $I \in \mathcal{I}_i$.

A **gammoid** is a matroid that has a graphical representation $(D = (V, E), S, Z)$, where $D = (V, E)$ is a directed graph, $S \subseteq V$ is a collection of source vertices and $Z \subseteq V$ is a collection of sink vertices. In the gammoid that is represented by D a set $I \subseteq S$ is in \mathcal{I} if and only if there exists $|I|$ vertex-disjoint paths from the vertices in I to some subcollection of vertices in Z . A **partition matroid** is a type of matroid that can be represented by a partition \mathcal{X} of S . In the partition matroid that is represented by the partition \mathcal{X} a set $Y \subseteq S$ is in \mathcal{I} if and only if $|Y \cap X| \leq 1$ for all $X \in \mathcal{X}$.¹

A matroid N is a reduction (also called weak map) of a matroid M , with the same universe, if and only if every independent set in N is also an independent set in M . If N is a partition matroid, then we say that there exists a **partition reduction** from M to N . [5] defined the following decomposability concept, which generalizes partition reduction.

► **Definition 1.** A matroid $M = (S, \mathcal{I})$ is (b, c) -**decomposable** if S can be partitioned into sets X_1, X_2, \dots, X_ℓ such that:

- For all $i \in [\ell]$, it is the case that $|X_i| \leq c \cdot k$, where k is the coloring number of M .
- For a set $Y = \{v_1, \dots, v_\ell\}$, consisting of one representative element v_i from each X_i , the matroid $M \upharpoonright Y$ is b colorable.

If $b = 1$ then X_1, X_2, \dots, X_ℓ represents a partition matroid. Thus $(1, c)$ -decomposability means there exists a partition reduction where the coloring number increases by at most a factor of c .

1.2 Prior Work

There are two prior, independent, papers in the literature that are directly relevant to our results. [3] showed that any gammoid M admits a $(1, (2 - \frac{2}{k}))$ -decomposition. This proof is constructive, and can be converted into an algorithm. The resulting algorithm is essentially a local search algorithm that selects a neighboring solution in the dual matroid in such a way that an auxiliary potential function always decreases. But there seems to be little hope of getting a better than exponential bound on the time, at least using techniques from [3] as the potential can be exponentially large. Further [3] shows that no better bound is achievable.

[5] gave a polynomial-time algorithm to construct a $(18, 1)$ -decomposition of a gammoid. The reduction was shown by leveraging prior work on unsplittable flows [6]. Both paper [3, 5] also observed that partition reductions are relatively easily obtainable for other common types of combinatorial matroids. In particular transversal matroids are $(1, 1)$ -decomposable [3, 5], graphic matroids are $(1, 2)$ -decomposable [3, 5] and paving matroids are $(1, \lceil \frac{r}{r-1} \rceil)$ -decomposable if they are of rank r [3].

The main algorithmic result from [5] is:

► **Theorem 2 ([5]).** Consider matroids M_1, M_2, \dots, M_ℓ defined over a common universe, where matroid M_i has coloring number k_i . There is a polynomial-time algorithm that, given a (b_i, c_i) -decomposition of each matroid M_i , computes a coloring of the intersection of M_1, M_2, \dots, M_ℓ using at most $\left(\prod_{i \in [k]} b_i\right) \cdot \left(\sum_{i \in [k]} c_i\right) k^*$ colors, where $k^* = \max_{i \in [\ell]} k_i$.

¹ Technically one can generalize this to let there be a separate upper bound for each X_i on the number of elements Y can obtain from X_i , but in this paper we only consider partition matroids where the bound is one.

Combining Theorem 2 with the decompositions in [3, 5] one obtains $O(1)$ -approximation algorithms for problems that can be expressed as coloring problems on the intersection of $O(1)$ common combinatorial matroids. Several natural examples of such problems are given in [5]. [1] showed that for two matroids M_1 and M_2 over a common universe with coloring numbers k_1 and k_2 , the coloring number k of $M_1 \cap M_2$ is at most $2 \max(k_1, k_2)$. The proof in [1] uses topological arguments that do not directly give an algorithm for finding the coloring. The list coloring number of a single matroid equals its coloring number [9]. For the intersection of two matroids [3] observed that a list coloring could be efficiently computed by partitioning each of the matroids. A consequence of the results in [3] is a constructive proof that the list coloring number of $M_1 \cap M_2$ is at most $2 \max(k_1, k_2)$ if M_1 and M_2 are each one of the standard combinatorial matroids. Further a consequence of the results in [5] is an efficient algorithm to compute such a list coloring if M_1 and M_2 are each one of the standard combinatorial matroids besides a gammoid.

For hereditary set systems the coloring number is equal to the set cover number. Set cover has been studied extensively in the field of approximation algorithms. The greedy algorithm has an approximation ratio of $H_n \approx \ln n$ and this is essentially optimal assuming $P \neq NP$ [10, 11].

1.3 Our Main Result and Its Algorithmic Applications

We are now ready to state our main result:

► **Theorem 3.** *A partition reduction from a k -colorable gammoid to a $(2k - 2)$ -colorable partition matroid can be computed in polynomial time given a directed graph D that represents M as input.*

Recall that [3] showed that the $(2k - 2)$ bound is tight.

Combining our main result, Theorem 3, with Theorem 2 from [5] we obtain significantly better approximation guarantees for matroid intersection coloring problems in which one of the matroids is a gammoid. One example is given by the following problem. Initially assume that the input consists of a directed graph D with a designated file server location (a sink) and a collection of clients requesting files from the server at various locations in the networks (the sources). The goal is to as quickly as possible get every client the file that they want from the server, where in each time step one can service any collection of clients for which there exist disjoint paths to the server. This is a matroid coloring problem that can be solved exactly in polynomial-time [4]. Now assume that additionally the input identifies the company to which each client is employed by, and for each company there is a Service Level Agreement (SLA) that upper bounds on how many clients from that company can be serviced in one time unit. Now, the problem becomes a matroid intersection coloring problem, where the intersecting matroids are a gammoid and a partition matroid. Using the $(18, 1)$ -decomposition of a gammoid and Theorem 2 from [5] one obtains a polynomial-time 36-approximation algorithm. However, combining the $(2k - 2)$ -partition reduction of a gammoid from Theorem 3 with Theorem 2 from [5] we now obtain a polynomial-time 3-approximation algorithm.²

Another algorithmic consequence is an efficient algorithm to list coloring the intersection $M_1 \cap M_2$ of a k_1 -colorable matroid M_1 and a k_2 -colorable matroid M_2 if the list of allowable colors for each element has cardinality at least $2 \max(k_1, k_2)$, and each of the matroids is

² This is because Theorem 2 is a $(1, 2)$ -decomposition of a gammoid and a partition matroid is in itself a $(1, 1)$ -decomposition, so Theorem [5] states the approximation is 3.

■ **Figure 1** Example of trees created. Here $k = 3$. Source portals are matched to sink portals along a path not in the trees. All sink portals will have k units of flow entering them and source portals have k units leaving.

either a graphic matroid, paving matroid, transversal matroid, or gammoid. Casting this into the context our running file server example implies that additionally each client has a list of allowable times when the file transfer may be scheduled. Our partition reduction of a gammoid then yields an efficient algorithm to find a feasible schedule as long as the cardinality of allowable times for each client is at least $2 \max(k_1, k_2)$, where k_1 is time required if the network had infinite capacity (so only the SLA constraints come into play), and k_2 is the time required if the SLA allowed infinitely many file transfers (so only the network capacity constraints come into play).

Set cover is a canonical algorithmic problem. So there is considerable interest in discovering examples of natural special types of set cover instances where $o(\log n)$ approximation is possible. For example, several geometrically based types of instances are known, for example covering points in the plane using a discs [7], where a polynomial time approximation scheme is known. Our results provide another example of such a natural special case, namely when the sets come from the intersection of a small number of standard combinatorial matroids.

Theorem 3 and its proof reveal structural properties of gammoids that would seem likely to be of use to address future research on gammoids.

1.4 Overview of Techniques

Given a graphic representation of a gammoid, an optimal coloring can be computed in polynomial-time [4]. By superimposing the source-sink paths for the various color classes one can obtain a flow f from the sources to the sinks that moves at most k units of flow over any vertex. Using standard cycle-canceling techniques [2] one can then convert f to what we call an acyclic flow. A flow f is acyclic if for every undirected cycle C in D at least one edge in C either has flow k or has no flow. Thus by deleting edges that support no flow in f , as they are unnecessary, we are left with a forest \mathcal{T} of edges that have flow in the range $[1, k - 1]$ and a collection of disjoint paths, which we call highways, that have flow k . See Figure 1.

Now each part X in the computed partition \mathcal{X} will be entirely contained in one tree $T \in \mathcal{T}$, and the parts X in a tree $T \in \mathcal{T}$ are computed independently of other trees in \mathcal{T} . There can be four types of vertices in T : (1) sources s that have outflow 1, (2) source portals

\tilde{s} , which are vertices that have a highway directed into them, and which have outflow k in T , (3) sink portals \tilde{z} , which are vertices that have a highway directed out of them, and which have inflow k in T , and (4) normal vertices. Again see Figure 1.

We give a recursive partitioning algorithm for forming the parts X in a tree $T \in \mathcal{T}$. On each recursive step our algorithm first identifies a single part X of at most $2k - 2$ sources and an associated sink portal that are in some sense near each other on the edge of T . The algorithm then removes these sources and sink portal from T , and reconnects disconnected sources back into appropriate places in T . The algorithm then recurses on this new tree T .

Most of the proof that our partitioning algorithm produces a $(1, 2 - \frac{2}{k})$ -decomposition focuses on routing individual trees in \mathcal{T} . So let Y be a collection of sources such that for all $X \in \mathcal{X}$ $|Y \cap X| \leq 1$.

The first key part is proving that as the partitioning algorithm recurses on a tree T , it is always possible to route both the flow coming into T , and the flow emanating within T , out of T , without routing more than k units of flow through any vertex in T . Note that as the algorithm recurses the tree T loses a sink portal (which reduces the capacity of the flow that can leave T by k) and loses up to $2k - 2$ sources (which means there is less flow emanating in T that has to be routed out).

The second key part is to prove that there is a vertex-disjoint routing from the source portals in T and the sources in $T \cap Y$ to the sink portals in T . To accomplish we trace our partitioning algorithm's recursion backwards. So in each step a new collection X of sources and a sink portal is added back into T . We then prove by induction that no matter how the previously considered sources in Y were routed, there is always a feasible way to route the chosen source in $Y \cap X$ to a sink portal in T . Then we finish by observing that unioning the routings constructed within the trees with the highways gives a feasible routing for Y .

2 Preliminaries

This section introduces notation and other necessary definitions. Let $D = (V, E)$ be a directed graph that represents a gammoid. Let $S \subseteq V$ be a set of sources, and $Z \subseteq V$ be the collection of sinks. We may assume without loss of generality that:

- Each vertex $v \in V$ has either out-degree 1 or in-degree 1.
- Each source $s \in S$ has in-degree 0 and out-degree 1.
- Each sink $z \in Z$ has in-degree 1 and out-degree 0 and $|Z| = r$.
- If uv is an edge in E then vu is not an edge in E .

We assume without loss of generality that all color classes have full rank, that is $|S| = rk$. This can be assumed by adding dummy sources to S .

- **Definition 4.** ■ A **feasible flow** in a digraph D from a collection $S' \subset S$ is a collection of paths $\{p^s \mid s \in S'\}$ such that (1) p^s is a simple path from s to some sink, and (2) no vertex or edge in D has more than k such paths passing through it.
- A **feasible routing** in a digraph D from a collection $S' \subset S$ is a collection of paths $\{p^s \mid s \in S'\}$ such that (1) p^s is a simple path from s to some sink, and (2) no vertex or edge in D has more than one such path passing through it.

3 The Partition Reduction Algorithm

This section gives the Partition Reduction Algorithm. First, we define a corresponding flow graph. Using a Cycle-Canceling Algorithm, we decompose the flow graph into a collection of trees. Then we algorithmically create the partitions from the local structure in these trees. The analysis of the algorithm is deferred to the next section.

3.1 Defining the Flow Graph

Given the digraph D we can compute a minimum k such that M is k -colorable in polynomial time using a polynomial-time algorithm for matroid intersection [8]. Further we can compute the collection of resulting color classes $\mathcal{C} = \{C_1, C_2, \dots, C_k\}$. So \mathcal{C} is a partition of the sources S , and for each $C_i \in \mathcal{C}$ there exist r vertex-disjoint paths p_i^1, \dots, p_i^r in the digraph D from the r sources C_i to Z . We create an f where the flow $f(u, v)$ on each edge (u, v) is initialized to the number of paths p_i^j that traverse (u, v) , that is

$$f(u, v) = \sum_{i=1}^k \sum_{j=1}^r \mathbb{1}_{(u,v) \in p_i^j}$$

A flow f is acyclic if for every undirected cycle C in D at least one edge in C either has flow k or has no flow in f . An arbitrary flow can be converted acyclic by finding cycles in a residual network D^r . This is standard [2], but for completeness we define it here.

For every directed edge (u, v) with $f(u, v) < k$ there exists a forward directed edge (u, v) in D^r with capacity $c_r(u, v) := k - f(u, v)$. For every directed edge (u, v) with $f(u, v) > 0$ there exists a backward directed edge (v, u) in D^r with capacity $c_r(v, u) := f(u, v)$. An augmenting cycle in D^r is a simple directed cycle with strictly more than two edges.

Cycle-Canceling Algorithm. While there exists an augmenting cycle C do the following:

- Let $c := \min_{(u,v) \in C} c_r(u, v)$ be the minimum capacity of an edge in C .
- For each forward edge $(u, v) \in C$, increase $f(u, v)$ by c .
- For each backward edge $(u, v) \in C$, decrease $f(u, v)$ by c .

As every iteration increases the number of edges that have flow k in f or that have no flow in f by 1, the Cycle-Canceling Algorithm terminates after at most $|E|$ iterations. The following observations are straight-forward.

► **Observation 5.** *The following properties hold when the Cycle-Canceling Algorithm terminates:*

- f is a feasible flow of kr units of flow from all the sources.
- Every undirected cycle C in D contains at least one edge with flow k in f or one edge with no flow in f .
- The collection of edges in D that has flow strictly between 0 and k in f forms a forest.
- The collection of edges in D with flow k in f are a disjoint union of directed paths, which we will call **highways**.

3.2 Properties of the Acyclic Flows

We now give several definitions and straightforward observations about our acyclic flow f that will be useful in our algorithm design and analysis.

► **Definition 6.**

- A vertex v is a *source portal* if its in-degree in D is 1, and it has k units of flow passing through it in f .
- A vertex v is a *sink portal* if its out-degree in D is 1, and it has k units of flow passing through it in f .
- Let \mathcal{T} be the forest consisting of edges in D that have flow in f strictly between 0 and k .
- For a tree $T \in \mathcal{T}$ and a vertex $v \in T$ define T_v to be the forest that results from deleting the vertex v from T .

► **Observation 7.** *Each sink $z \in Z$ is in a tree $T \in \mathcal{T}$ that consists solely of z .*

Proof. By assumption, the sink z has in-degree 1 in D and all color classes \mathcal{C} have full rank. Hence, k units of flow are entering z through a unique edge. ◀

As our partition reduction algorithm partitions each tree $T \in \mathcal{T}$ independently, it will be notationally more convenient to fix an arbitrary tree $T \in \mathcal{T}$, and make some definitions relative to this fixed T , and make some observations that must hold for any such T . To a large extent these observations are intended to show that the Figure 2 is accurate.

► **Definition 8.**

- Let \tilde{S} be the collection of source portals in tree T .
- Let \tilde{Z} be the collection of sink portals in tree T .
- A *normal vertex* is a vertex that is none of a source, a sink, a source portal, nor a sink portal.

► **Definition 9.**

- A **feasible flow** in T from a collection $S' \subset S$ is a collection of paths, one path p^s for each $s \in S'$ and k paths $p_1^{\tilde{s}}, \dots, p_k^{\tilde{s}}$ for each source portal $\tilde{s} \in \tilde{S}$ such that (1) p^s is a simple path from s to some sink portal, (2) each $p_i^{\tilde{s}}$ is a simple path from \tilde{s} to a sink portal, and (3) no vertex or edge in T has more than k such paths passing through it.
- A **feasible routing** in T from a collection $S' \subset S$ is a collection of paths, one path p^s for each $s \in S'$ and one path $p^{\tilde{s}}$ for each source portal $\tilde{s} \in \tilde{S}$ such that (1) p^s is a simple path from s to some sink portal, (2) $p^{\tilde{s}}$ is a simple path from \tilde{s} to a sink portal, and (3) no vertex or edge in T has more than one such paths passing through it.

This following observation holds for trees in \mathcal{T} initially and gives intuition for the structure of \mathcal{T} . We remark that this observation may not hold throughout the execution of our algorithm for all trees.

► **Observation 10.** *The number of sources in T is an integer multiple of k .*

Proof. This follows from the fact that each source portal $\tilde{s} \in T$ has exactly k units of flow coming into T via \tilde{s} in the flow f and each sink portal $\tilde{z} \in T$ has exactly k units of flow leaving T via \tilde{z} in f . ◀

► **Definition 11.**

- For two vertices $u, v \in T$, let $P(u, v)$ be the unique undirected path from u to v in T .
- The **backbone** B of T is the subgraph of T consisting of the union of all paths in between pairs of sink portals in T , that is $B = \bigcup_{\tilde{y} \in \tilde{Z}} \bigcup_{\tilde{z} \in \tilde{Z}} P(\tilde{y}, \tilde{z})$.
- For the backbone B , let B_v be the induced forest that results from deleting v from B .
- A vertex v in a backbone B is a **branching vertex** if either:
 - v is not a sink portal and the forest B_v contains at least two trees that each contain exactly one sink portal, or
 - v is a sink portal and the forest B_v contains at least one tree that contains exactly one sink portal.
- Let \mathcal{H} be the forest that results from deleting the edges in B from the tree T .
- For two vertices $u, v \in B$, let $S(P(u, v))$ be the sources $s \in S$ such that there exists a tree $H \in \mathcal{H}$ such that $s \in H$ and such that H contains a vertex $w \in P(u, v)$. Intuitively these are the sources in trees in \mathcal{H} hanging off vertices of the path $P(u, v)$.
- Let $S(v)$ denote $S(P(v, v))$.

■ **Figure 2** Backbone of a tree.

► **Observation 12.** *If $\tilde{s} \in \tilde{S}$ is a source portal in T then \tilde{s} is in the backbone B and $\deg_B^+(\tilde{s}) \geq 2$, that is \tilde{s} has out-degree at least 2 in B .*

Proof. By definition \tilde{s} has a unique incoming edge, which is saturated in f , at least one outgoing edge in T that is not saturated in f . Hence, $\deg_B^+(\tilde{s}) \geq 2$. By flow conservation, there has to be at least two directed paths from \tilde{s} to two different sink portals in T . This implies that \tilde{s} is in the backbone B . ◀

► **Observation 13.** *If B contains at least two sink portals, then B contains a branching vertex v .*

Proof. Consider an arbitrary vertex $v \in B$. If v is not a branching vertex, then there must be a subtree $T' \in B_v$ that contains two sink portals. One can then recurse on T' to find a branching vertex. ◀

► **Observation 14.** *If $s \in S$ is a source in T then s is not in the backbone B .*

Proof. As s has out-degree 1 in D , it can not be on any path between sink portals in T . ◀

► **Observation 15.** *For each tree $H \in \mathcal{H}$ it must be the case that all edges in H are directed towards the unique vertex w in H that is also in B .*

Proof. This follows from the fact that $H \setminus \{w\}$ can not contain a sink portal. ◀

► **Observation 16.** *Assume that T has at least two sink portals. Let v be a branching vertex. Let T' be a tree in the forest B_v that contains exactly one sink portal \tilde{z} . Then the following must hold:*

- $T' = P(v, \tilde{z}) \setminus \{v\}$.
- If T' contains a source portal \tilde{s} , then $\deg_B^+(\tilde{s}) = 2$.
- The path T' contains at most one vertex y such that $\deg_B^+(y) = 2$.

Proof. The first statement follows from the definition of B and the fact that T' only contains one sink portal. The second statement follows since every vertex on a path other than its endpoints has degree two. For the last statement assume to reach a contradiction that there were two such y 's, y_1 and y_2 with y_1 being closer to v in B . Then the flow leaving y_1 toward \tilde{z} could not be feasibly routed through y_2 . ◀

3.3 Description of the Partition Reduction Algorithm

Given the collection of trees \mathcal{T} , our Partition Reduction Algorithm returns a partition \mathcal{X} of the sources in S . The algorithm iterates through the trees T in \mathcal{T} and partitions the sources in T based on their locality in T . So let us consider a particular tree $T \in \mathcal{T}$.

The algorithm performs the first listed case below that applies, with the base cases being checked before the other cases. In the non-base cases the tree T will be modified, and the algorithm called tail-recursively on the modified tree. We will show after the algorithm description that the algorithm maintains the invariant that there is a feasible flow on the tree T throughout the recursion.

Base Case A. If T contains no sources then the recursion terminates, and the algorithm moves to the next tree in \mathcal{T} .

Base Case B. Otherwise if T contains at most $2k - 2$ sources and no source portal then these sources are added as a part X in \mathcal{X} . The recursion terminates, and the algorithm then moves to the next tree in \mathcal{T} .

We perform the following recursively on T if neither base case holds. Let v be an arbitrary branching vertex in B . We will show this must exist in Observation 17.

Let \tilde{z}_1 be a sink portal in some tree T_1 in T_v that only contains one sink portal. If v is not a sink portal, let \tilde{z}_2 be a sink portal in some tree T_2 , where $T_1 \neq T_2$, in T_v that only contains one sink portal. If v is a sink portal let $\tilde{z}_2 = v$.

The algorithm's cases are broken up as follows. Case 1 is executed when there is a source portal at v or in T_1 or in T_2 . Case 2 is executed when there is a vertex of out-degree 2 in T_1 or T_2 and there is no source portal. Case 3 is everything else.

Recursive Case 1a. The vertex v is a source portal. In this case T is modified as follows: (1) for each source $s \in T_1$ a directed edge (s, v) is added to T , (2) v is converted into a normal vertex, and (3) all the nonsources in T_1 are deleted from T . The algorithm then recurses on this new T .

Recursive Case 1b. In this case for some $i \in \{1, 2\}$ the path $P(v, \tilde{z}_i) \setminus \{v\}$ contains a source portal. In this case T is modified as follows: (1) for each source $s \in T_i$ a directed edge (s, v) is added to T , and (2) all the nonsources in T_i are deleted from T . The algorithm then recurses on this new T .

Recursive Case 2a. In this case for some $i \in \{1, 2\}$, the path $P(v, \tilde{z}_i) \setminus \{v\}$ contains a vertex y with $\deg_B^+(y) = 2$ and $|S(P(y, \tilde{z}_i))| \leq 2k - 2$. Add the sources in $S(P(y, \tilde{z}_i))$ as a part X to \mathcal{X} . The tree T is then modified as follows: (1) for each source $s \in T_i - X$ a directed edge (s, v) is added to T , and (2) the sources in X and all the nonsources in T_i are deleted from T . The algorithm then recurses on this new T .

Recursive Case 2b. In this case for some $i \in \{1, 2\}$, the path $P(v, \tilde{z}_i) \setminus \{v\}$ contains a vertex y with $\deg_B^+(y) = 2$ and $|S(y)| = k$. In this case the algorithm adds the k sources in $S(y)$ as a part X to \mathcal{X} . The tree T is then modified as follows: (1) for each source $s \in T_i - X$ a directed edge (s, v) is added to T , and (2) the sources in X and all the nonsources in T_i are deleted from T . The algorithm then recurses on this new T .

Recursive Case 2c. In this case for some $i \in \{1, 2\}$, the path $P(v, \tilde{z}_i) \setminus \{v\}$ contains a vertex y with $\deg_B^+(y) = 2$ and $|S(P(y, \tilde{z}_i) \setminus \{y\})| = k$. In this case the algorithm adds the k sources in $S(P(y, \tilde{z}_i) \setminus \{y\})$ as a part X to \mathcal{X} . The tree T is then modified as follows: (1) for each source $s \in T_i - X$ a directed edge (s, v) is added to T , and (2) the sources in X and all the nonsources in T_i are deleted from T . The algorithm then recurses on this new T .

Recursive Case 3a. In this case for some $i \in \{1, 2\}$ T_i contains exactly k sources. Add the sources in T_i as a part X to \mathcal{X} . The tree T is modified by deleting T_i . The algorithm then recurses on this new T .

Recursive Case 3b. The set of sources in $T_1 \cup T_2$ are added as a part X in \mathcal{X} . The tree T is modified by deleting the vertices in T_1 and T_2 . Add a new sink portal \tilde{z} together with a directed edge (v, \tilde{z}) to T . The algorithm then recurses on this new T .

4 Analysis of the Partition Reduction Algorithm

Our goal is to show that the partition matroid, represented by the partition constructed from the trees, indeed corresponds to a feasible partition reduction from the gammoid. The analysis has the following key components.

- Every tree T has a corresponding feasible flow throughout the algorithm.
- Every part X of the partition has size at most $2k - 2$ and all sources are in some part.
- Any collection of sources Y such that $|Y \cap X| \leq 1$ for all $X \in \mathcal{X}$ is in \mathcal{I} and, therefore, can each route a unit of flow to the sink in D .

4.1 The Trees Always Have a Feasible Flow

This section's goal is to show that each tree has a feasible flow as defined in Definition 8 throughout the execution of the algorithm. We will later use this to prove that our partition indeed represents a partition matroid that corresponds to a feasible partition reduction in the following section.

We begin by showing various invariants hold for each tree when a feasible flow exists. In particular, this will show that a branching vertex exists if any of the recursive cases are executed. Moreover, arriving at Cases (3a) and (3b) ensure the existence of T_1 and T_2 . All together this with the fact that each tree has a feasible flow will establish that the algorithm always has a case to execute if \mathcal{T} is non-empty.

This observation shows a branching vertex exists if neither base case holds.

► **Observation 17.** *Fix a tree $T \in \mathcal{T}$ during the execution of the algorithm and say T supports a feasible flow as defined in Definition 8. If neither of the base cases apply then T contains at least two sink portals. Moreover a branching vertex must exist in T in this case.*

Proof. This observation holds because T must contain either more than $2k - 2$ sources or a source portal along with at least one source. In either case, we require two sink portals to support the strictly more than k units of flow from these sources and source portal. A branching vertex must then exist by Observation 13. ◀

► **Observation 18.** *Fix a tree $T \in \mathcal{T}$ during execution of the algorithm and say T supports a feasible flow as defined in Definition 8. Say that T has a branching vertex v with a tree T_i containing exactly one sink \tilde{z}_i . Moreover say that there is no vertex with out-degree 2 in $P(v, \tilde{z}_i)$. It is the case that $P(v, \tilde{z}_i)$ is a directed path from v to \tilde{z}_i .*

Proof. No vertex with out-degree 2 is in $P(v, \tilde{z}_i)$. Thus, $P(v, \tilde{z}_i)$ is either a path from v to \tilde{z}_i or from \tilde{z}_i to v . Sink portals always have out-degree 0 in T , so the observation follows. We note that, sink portals have out-degree 0 in T initially and are never given outgoing edges by the algorithm. ◀

The next observation shows that a branching vertex is not a sink portal when Cases (3a) or (3b) are executed.

► **Observation 19.** *Fix a tree $T \in \mathcal{T}$ during execution of the algorithm and say T supports a feasible flow as defined in Definition 8. Say that T has a branching vertex v and a corresponding tree T_i with exactly one sink \tilde{z}_i . If $P(v, \tilde{z}_i) \setminus \{v\}$ does not contain a vertex of out-degree 2 in B , then v is not a sink portal.*

Proof. Observation 18 implies that $P(v, \tilde{z}_i)$ is a directed path from v to \tilde{z}_i . Sink portals always have out-degree 0 in T , so the observation follows. We note that, sink portals have out-degree 0 in T initially and are never given outgoing edges by the algorithm. ◀

The previous observations guarantee the algorithm always has a case to execute if a feasible flow exists in all trees. The next lemma guarantees the existence of a feasible flow.

► **Lemma 20.** *Fix any tree T during the execution of the algorithm. There must be a feasible flow in T as described in Definition 8.*

4.2 Bounding the Size of the Parts in the Partition

This section shows that every source is in some part X in \mathcal{X} and that every $X \in \mathcal{X}$ has size at most $2k - 2$. Thus we have a valid partition with each part having the desired size.

► **Lemma 21.** *It is the case that $|X| \leq 2k - 2$ for all $X \in \mathcal{X}$. Moreover, every source in S is in some set in \mathcal{X} .*

Proof. It is easy to see that every source in S is in some set in \mathcal{X} . This is because sources are always contained in some tree of \mathcal{T} until they are added to a set placed in \mathcal{X} and the algorithm stops once there is no tree in \mathcal{T} .

Now we show how to bound the size of sets in \mathcal{X} . Cases (1a) and (1b) do not add a set to \mathcal{X} . Cases (2b), (2c) and (3a) add a set to \mathcal{X} of size k by definition. Case (2a) adds a set of size $2k - 2$.

Case (3b) is more interesting. Consider the execution of this case on a tree T with branching vertex v . Let \tilde{z}_1 and \tilde{z}_2 be the corresponding sinks. We know v is not a sink portal by Observation 19 and therefore T_1 and T_2 both exist. By Observation 18, the paths from v to \tilde{z}_1 and \tilde{z}_2 are directed paths from v to \tilde{z}_1 and from v to \tilde{z}_2 . Hence, neither T_1 nor T_2 contains more than k sources. Since case (3a) does not hold, T_1 and T_2 has strictly less than k sources. Thus, there are at most $2k - 2$ sources in the set added to \mathcal{X} . ◀

4.3 Routing Sources within a Tree

In this section, we show that the algorithm is indeed a partition reduction from a k -colorable gammoid to a $(2k - 2)$ -colorable partition matroid. That is, we show that every set Y , that is independent in the partition matroid represented by \mathcal{X} is also independent in the gammoid. More specifically, for any set Y where $|Y \cap X| \leq 1$ for all $X \in \mathcal{X}$ it is the case that $Y \in \mathcal{I}$ or, equivalently, there is a feasible routing in the digraph D from the sources in Y . The key to this will be Lemma 22 which essentially states that there exists a feasible routing in each tree $T \in \mathcal{T}$.

► **Lemma 22.** *Let T be an arbitrary tree in \mathcal{T} . Let \mathcal{X}_T be the parts in \mathcal{X} that are also in T . For a set Y with $|Y \cap X| \leq 1$ for all $X \in \mathcal{X}$, let Y_T be the subset of sources in Y that are also in T . Then there is a feasible routing R in T from Y_T .*

► **Lemma 23.** *Let $Y \subset S$ such that for all $X \in \mathcal{X}$ it is the case that $|X \cap Y| \leq 1$. Then there exists a feasible routing from Y in the digraph D .*

Proof. This follows from Lemma 22 and the fact there is a unique highway into each source portal in each tree and a unique highway leaving each sink portal in every tree. ◀

Abstract

We present approximation and exact algorithms for piecewise regression of univariate and bivariate data using fixed-degree polynomials. Specifically, given a set S of n data points $(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n) \in \mathbb{R}^d \times \mathbb{R}$ where $d \in \{1, 2\}$, the goal is to segment \mathbf{x}_i 's into some (arbitrary) number of disjoint pieces P_1, \dots, P_k , where each piece P_j is associated with a fixed-degree polynomial $f_j : \mathbb{R}^d \rightarrow \mathbb{R}$, to minimize the total loss function $\lambda k + \sum_{i=1}^n (y_i - f(\mathbf{x}_i))^2$, where $\lambda \geq 0$ is a regularization term that penalizes model complexity (number of pieces) and $f : \bigsqcup_{j=1}^k P_j \rightarrow \mathbb{R}$ is the *piecewise polynomial* function defined as $f|_{P_j} = f_j$. The pieces P_1, \dots, P_k are disjoint intervals of \mathbb{R} in the case of univariate data and disjoint axis-aligned rectangles in the case of bivariate data. Our error approximation allows use of any fixed-degree polynomial, not just linear functions.

Our main results are the following. For univariate data, we present a $(1 + \varepsilon)$ -approximation algorithm with time complexity $O(\frac{n}{\varepsilon} \log \frac{1}{\varepsilon})$, assuming that data is presented in sorted order of x_i 's. For bivariate data, we present three results: a sub-exponential exact algorithm with running time $n^{O(\sqrt{n})}$; a polynomial-time constant-approximation algorithm; and a quasi-polynomial time approximation scheme (QPTAS). The bivariate case is believed to be NP-hard in the folklore but we could not find a published record in the literature, so in this paper we also present a hardness proof for completeness.

1 Introduction

Line, or curve, fitting is a classical problem in statistical regression and data analysis, where the goal is to find a simple predictive model that best fits an observed data set. For instance, given a set of two-dimensional points (x_i, y_i) , $i = 1, \dots, n$, the least-square line fitting problem is to find a linear function $f : y = ax + b$ minimizing the cumulative error $\sum_{i=1}^n (y_i - (ax_i + b))^2$. This problem is easily solved in $O(n)$ time because the coefficients of the optimal line have a simple closed form solution in terms of input data. In most cases, however, a single line is a poor fit for the data, and instead the goal is to segment the data into multiple piece, with each piece represented by its own linear function. This problem of poly-line (or piecewise linear) fitting has been studied widely in computational geometry, where the goal is either to minimize the total error *for a given number of pieces* [8, 10], or to minimize the number of pieces for a given upper bound on the error [8], under a variety of error measures. In a related but technically different vein of work on “curve simplification”, the approximation must also form a polygonal chain – that is, the pieces representing neighboring segments must form a continuous curve, and it is conjectured that finding a polygonal chain of k pieces with minimum L_2 error is NP-hard [8]. In our regression setting, such continuity is not required.

These best-fit formulations with a “hard-coded” value for the number of pieces k , however, suffer from the problem of having to specify k , rather than letting the structure in the data dictate the choice. This can be circumvented by running the algorithm for multiple values of k , and then stopping with the smallest number of pieces with an *acceptable* error. A significant issue, however, is the inherent tradeoff between the number of pieces and the error – the larger number of pieces, the smaller the error – which is recognized as the problem of “overfitting” in statistics and machine learning. In order to avoid this overfitting problem, regression typically uses “regularization” and includes a penalty term for the *size* of the representation (model) in the objective, often called the “loss” function. By optimizing the loss function, the algorithm automatically balances the two competing criteria: number of pieces k and approximation error.

In particular, suppose we have a set of data points $(\mathbf{x}_i, y_i) \in \mathbb{R}^d \times \mathbb{R}$, for $i = 1, \dots, n$. We call (\mathbf{x}_i, y_i) univariate data if $d = 1$ and bivariate if $d = 2$. We will consider piecewise approximation of these data points using polynomial functions of any fixed degree g , where linear functions are the special case when the degree is one. Our goal is to segment \mathbf{x}_i ’s into some (arbitrary) number of disjoint pieces P_1, \dots, P_k , each associated with a constant-degree polynomial function f_j , to minimize the total *loss function*

$$\lambda k + \sum_{i=1}^n (y_i - f(\mathbf{x}_i))^2,$$

where $\lambda > 0$ is a pre-specified penalty term for regularizing the model complexity (number of pieces) and $f : \bigsqcup_{j=1}^k P_j \rightarrow \mathbb{R}$ is the *piecewise polynomial* function defined as $f|_{P_j} = f_j$. The pieces P_1, \dots, P_k are disjoint intervals in \mathbb{R} in the case of univariate data and are disjoint axis-aligned rectangles in \mathbb{R}^2 in the case of bivariate data.

Even for piecewise linear approximation of univariate data, the best bound currently known is $\Omega(kn^2)$ [2, 9, 15], and it is an important open problem to either find a sub-quadratic algorithm or prove a $\Omega(n^2)$ lower bound. We make progress on this problem by presenting a linear-time approximation scheme for this problem.

► **Theorem 1.** *There exists a $(1 + \varepsilon)$ -approximation algorithm for univariate piecewise polynomial regression which runs in $O(\frac{n}{\varepsilon} \log \frac{1}{\varepsilon})$ time (excluding the time for pre-sorting).*

For bivariate data, we obtain the following results, including a sub-exponential exact algorithm, a constant-factor approximation in polynomial time, and a quasi-polynomial approximation scheme (QPTAS).

► **Theorem 2.** *There exists an exact algorithm for bivariate piecewise polynomial regression which runs in $n^{O(\sqrt{n})}$ time.*

► **Theorem 3.** *There exists a constant-factor approximation algorithm for bivariate piecewise polynomial regression which runs in polynomial time.*

► **Theorem 4.** *There exists a QPTAS for bivariate piecewise polynomial regression.*

Finally, while the bivariate case (and hence the case of more than two variables) is believed to be NP-hard in the folklore, we could not find a published record in the literature, so we also present a hardness proof for completeness.

► **Theorem 5.** *Bivariate piecewise regression is NP-hard for all fixed degree polynomials, including piecewise constant or piecewise linear functions.*

Related work. Curve fitting and piecewise regression related problems have been studied in computational geometry [6, 8], statistics [16] and machine learning [1, 9] as well as in database theory under the name *histogram approximation* [11, 14]. The main focus of research in computational geometry has been to approximate a curve, or a set of points sampled from a curve, by a fixed-size polygonal chain to minimize some measure of error, such as L_1, L_2, L_∞ error or Hausdorff error. For instance, Goodrich [10] presented an $O(n \log n)$ -time algorithm to compute a polyline (or a connected piecewise linear function) in the plane that minimizes the maximum vertical distance from a set of n points to the polyline, which improves upon the algorithms of [12, 17]. Aronov et al. present an FPTAS for the polyline fitting problem with the min-sum and least-square error measure, and conjecture that finding a polygonal chain of k pieces with minimum L_2 error is NP-hard [8]. Agarwal et al. [6] consider approximation under Hausdorff and Frechet distances.

Unlike these computational geometric models, in statistics, machine learning and database theory, the piecewise approximation is typically *not* required to be “connected”; instead, the goal is to partition the data into a given number k of pieces, each represented by a simple function. Such an optimal histogram (piecewise approximation) can be constructed in $O(kn^2)$ time using dynamic programming, where k is the number of pieces [11, 14]. A similar dynamic programming algorithm can also compute an optimal “regularized” piecewise approximation, where k is the number of pieces in the optimal solution [15]. It is an important open problem to either find a sub-quadratic algorithm or prove a $\Omega(n^2)$ lower bound.

In machine learning, Acharya et al. [2] study a “segmented regression” problem where the goal is to recover a function f , which is promised to be “nice” (say, piecewise linear with k pieces), and the sampled data from f has a small random noise. The quality of recovery is measured by the mean squared error. In this model, they present an algorithm for computing a function with $O(k)$ linear pieces in $O(n \log n)$ time [2]. An extension to multi-dimensional data with similar results is presented in [9]. Our focus is a little different from these results because (1) we do not assume a fixed value of k , and (2) we judge the error of our regression against worst-case input that is not necessarily drawn from a hypothetical k -piece input with small random noise. Thus, these two lines of research are complementary.

Finally, for bivariate data, Agarwal and Suri [7] considered the problem of computing a piecewise linear surface with smallest number of pieces whose vertical distance from data points is at most ε . They showed that the problem is NP-hard and gave a polynomial-time $O(\log n)$ -approximation algorithm.

Organization. Section 2 introduces some basic notations and concepts used throughout the paper. Our linear-time approximation scheme for univariate data (Theorem 1) is presented in Section 3, while our algorithms for bivariate data are presented in Section 4. Finally, in Section 5, we conclude the paper and pose some open questions. Due to limited space, the algorithm of Theorem 2 and the hardness result of Theorem 5 (as well as some proofs and details) are omitted in this version, which will appear in the full paper.

2 Basic notations and concepts

We begin with basic notation and concepts that are used throughout the paper. For an integer $g \geq 0$, we use $\mathbb{R}[x]_g$ and $\mathbb{R}[x, x']_g$ to denote the family of all univariate and bivariate polynomial functions with degree at most g . A univariate (resp., bivariate) *piecewise polynomial function* of degree at most g is a function $f : \bigsqcup_{j=1}^k P_j \rightarrow \mathbb{R}$, where P_1, \dots, P_k are disjoint intervals in \mathbb{R}^1 (disjoint axis-parallel rectangles in \mathbb{R}^2) and $f|_{P_j} = f_j|_{P_j}$ for some

$f_j \in \mathbb{R}[x]_g$ (resp., $f_j \in \mathbb{R}[x, x']_g$), for all $j \in \{1, \dots, k\}$. The intervals (resp., rectangles) P_1, \dots, P_k are the *pieces* of f , and the number k is the *complexity* of f , denoted by $|f|$. The notion of piecewise polynomial functions generalizes to higher dimensions (multi-variables), where the pieces becomes axis-parallel boxes but in this paper we only study univariate and bivariate piecewise polynomial functions.

Let Γ_g^d denote the family of piecewise polynomial functions with d variables and of degree at most g . For a set of n points $S = \{(\mathbf{x}_i, y_i) \in \mathbb{R}^d \times \mathbb{R}\}_{i=1}^n$, we define the *error* of a function $f \in \Gamma_g^d$ for S as

$$\sigma_S(f) = \lambda \cdot |f| + \sum_{i=1}^n (y_i - f(\mathbf{x}_i))^2,$$

where $\lambda > 0$ is a pre-specified (regularizer) parameter. We assume $\sigma_S(f) = \infty$ if the domain of f does not cover all \mathbf{x}_i 's. For a fixed constant g , the *piecewise polynomial regression* problem takes S and λ as the input, and aims to find the function $f^* \in \Gamma_g^d$ that minimizes the error $\sigma_S(f^*)$. By appropriate scaling of the y -values in the input, we can assume without loss of generality that $\lambda = 1$. Therefore, for convenience, we make this assumption throughout the paper.

3 Algorithm for univariate data

The input to the univariate regression problem is a dataset $S = \{(x_i, y_i) \in \mathbb{R} \times \mathbb{R}\}_{i=1}^n$, where $x_1 \leq \dots \leq x_n$, and the goal is to find the function $f^* \in \Gamma_g^1$ minimizing $\sigma_S(f^*)$, for some fixed constant $g \geq 0$, where we assume $\lambda = 1$, as mentioned earlier. This problem can be solved in $O(n^2)$ time with a straightforward dynamic program, and no subquadratic-time (even approximation) algorithm is known. Our main result in this section is a linear-time approximation scheme, which for any $\varepsilon > 0$ computes in $O(\frac{n}{\varepsilon} \log \frac{1}{\varepsilon})$ time a piecewise function $f \in \Gamma_g^1$ whose error is at most $(1 + \varepsilon) \cdot \text{opt}$, assuming that the points in S are pre-sorted by their x -coordinates.

In order to explain the main ideas behind our algorithm, it is helpful to first briefly review the quadratic-time dynamic programming algorithm. That algorithm performs n iterations, where the i th iteration computes an optimal piecewise regression for the subset of points $(x_1, y_1), \dots, (x_i, y_i)$. If the rightmost piece in the optimal solution for this subproblem covers the points $(x_j, y_j), \dots, (x_i, y_i)$, then the solution combines the optimal regression for $(x_1, y_1), \dots, (x_{j-1}, y_{j-1})$ with the best fitting degree g polynomial for $(x_j, y_j), \dots, (x_i, y_i)$. By dynamic programming, the former is already computed in the $(j-1)$ th iteration, and the latter can be computed for all subproblems with an $O(n^2)$ -time preprocessing step. There are $O(i)$ candidates for the rightmost piece, and so the i th iteration takes $O(i)$ time, resulting in an $O(n^2)$ time algorithm.

A natural idea for improving the dynamic program's time complexity is to reduce the number of guesses needed for the rightmost piece in each iteration: ideally, we would like to find the “best” rightmost piece without trying all possibilities. This, however, seems quite difficult if we want the exact optimal solution. Our main idea is to show that this is possible if we only need a $(1 + \varepsilon)$ approximation of the minimum error. Our algorithm builds on three key steps. First, we prove a structural lemma (Lemma 7) showing that there exists an approximate solution f in which the squared error of each piece (essentially) is bounded by $O(1/\varepsilon)$, and therefore contributes between 1 and $1 + O(1/\varepsilon)$ to the final objective $\sigma_S(f)$. The second key idea is to show that, for each $i \in [n]$, there exist a set of $O(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon})$ “candidate” pieces with right endpoint x_i such that a $(1 + \varepsilon)$ -approximate solution can be found using

only these pieces (Lemma 8). Thus, assuming that these candidate pieces and their best fit degree g polynomials are known, we only have to make $O(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon})$ guesses in each iteration, which leads to an $O(\frac{n}{\varepsilon} \log \frac{1}{\varepsilon})$ -time algorithm. The final, and third, step is to compute all the candidate pieces efficiently, which we show can be done using prefix sum and the standard formula for least-square polynomial regression—the details of this part will appear in the full paper.

With this preamble, we are ready to describe our algorithm in detail. For $a, b \in [n]$ satisfying $a \leq b$, we define

$$f[a, b] = \arg \min_{f \in \mathbb{R}[x]_g} \sum_{i=a}^b (y_i - f(x_i))^2 \quad \text{and} \quad \delta[a, b] = \min_{f \in \mathbb{R}[x]_g} \sum_{i=a}^b (y_i - f(x_i))^2.$$

That is, $f[a, b]$ is the best-fit polynomial in $\mathbb{R}[x]_g$ for the set of points $(x_a, y_a), \dots, (x_b, y_b)$ (in terms of square error) and $\delta[a, b]$ is the square error of $f[a, b]$. We have the following simple observation.

► **Lemma 6.** *If $a' \leq a$ and $b' \geq b$, then $\delta[a', b'] \geq \delta[a, b]$. Furthermore, for a sequence of numbers a_0, a_1, \dots, a_r where $a-1 \leq a_0 < \dots < a_r \leq b$, we have $\delta[a, b] \geq \sum_{j=1}^r \delta[a_{j-1}+1, a_j]$.*

Let ε be the approximation factor, which we assume is sufficiently small, say $0 < \varepsilon \leq 1$. Let $\tilde{\varepsilon} > 0$ be such that it satisfies $(1 + \tilde{\varepsilon})^2 = 1 + \varepsilon$. Then, we have $\varepsilon/3 \leq \tilde{\varepsilon} \leq \varepsilon$ since $\varepsilon \leq 1$. For an index $i \in [n]$, we say i is a *left* (resp., *right*) *break point* if $x_{i-1} < x_i$ (resp., $x_{i+1} > x_i$). For a function $f \in \Gamma_g^1$ and a piece P of f , the *cost* of P is defined as $\sum_{x_i \in P} (y_i - f(x_i))^2$. Thus, the total error $\sigma_S(f)$ is simply $|f|$ plus the cost of all the pieces of f .

► **Lemma 7.** *There exists a function $f \in \Gamma_g^1$ such that $\sigma_S(f) \leq (1 + \tilde{\varepsilon}) \cdot \text{opt}$ and each piece of f either has cost at most $2/\tilde{\varepsilon}$ or is a singleton point.*

Proof. Let $f^* \in \Gamma_g^1$ be an optimal solution, and so $\sigma_S(f^*) = \text{opt}$. Consider a piece of f^* , say, $P^* = [x_a, x_b]$ where a is a left break point and b is a right break point and $a, b \in [n]$. Since f^* is optimal, the cost of P^* is $\delta[a, b]$. We replace P^* with $r < \tilde{\varepsilon} \cdot \delta[a, b] + 1$ pieces P_1, \dots, P_r as follows. We say a pair (a', a'') of indices with $a' \leq a''$ is *legal* if $x_{a'} = x_{a''}$ or $\delta[a', a''] \leq 2/\tilde{\varepsilon}$. Starting with $a_0 = a - 1$, we create a sequence a_0, a_1, a_2, \dots of indices, where a_{i+1} is the largest right break point in $\{a_i + 1, \dots, b\}$ such that $(a_i + 1, a_{i+1})$ is legal. The sequence ends at some $a_r = b$, and we claim that $r < \tilde{\varepsilon} \cdot \delta[a, b] + 1$. We first observe that since a_{i+1} is the largest right break point for which $(a_i + 1, a_{i+1})$ is legal, we have $\delta[a_i + 1, a_{i+2}] > 2/\tilde{\varepsilon}$ for all $i \in \{0, 1, \dots, r-2\}$. Now consider the sum $\sum_{i=0}^{\lfloor r/2 \rfloor - 1} \delta[a_{2i} + 1, a_{2(i+1)}]$. Each summand of this sum is greater than $2/\tilde{\varepsilon}$. On the other hand, we have $\delta[a, b] \geq \sum_{i=0}^{\lfloor r/2 \rfloor - 1} \delta[a_{2i} + 1, a_{2(i+1)}]$ by Lemma 6. It directly follows that $\lfloor r/2 \rfloor < \tilde{\varepsilon} \cdot \delta[a, b]/2$ and hence $r < \tilde{\varepsilon} \cdot \delta[a, b] + 1$. We define $P_i = [x_{a_{i-1}+1}, x_{a_i}]$ for $i \in [r]$. We replace P^* of f^* with P_1, \dots, P_r , and call them the *sub-pieces* of P^* . We do this for all pieces of f^* , which gives us our function $f \in \Gamma_g^1$, as follows. First, clearly, the domain of f is contained in the domain of f^* . Next, for each piece $P = [x_a, x_b]$ of f , the function $f|_P$ is simply the polynomial $f[a, b]$ restricted to P , whose cost is $\delta[a, b]$. All that remains is to bound the total error $\sigma_S(f)$. Consider a piece $P^* = [x_a, x_b]$ of f^* and its sub-pieces P_1, \dots, P_r . Let $c(P^*)$ be the total cost of all the sub-pieces P_1, \dots, P_r plus r . By Lemma 6, the total cost of all the sub-pieces P_1, \dots, P_r is at most $\delta[a, b]$, and since $r < \tilde{\varepsilon} \cdot \delta[a, b] + 1$ and $c^*(P^*) = \delta[a, b] + 1$, we get $c(P^*) \leq (1 + \tilde{\varepsilon}) \cdot c^*(P^*)$. This inequality holds for each piece of f^* , and so we get our result that $\sigma_S(f) \leq (1 + \tilde{\varepsilon}) \cdot \sigma_S(f^*)$. ◀

For convenience, we say a function $f \in \Gamma_g^1$ is *S-light* if each piece of f is either a singleton point or of cost at most $2/\tilde{\varepsilon}$. Similarly, for a subset $S' \subseteq S$, we say a function $f \in \Gamma_g^1$ is *S'-light* if each piece of f is either a singleton point or of cost *with respect to* S' (i.e., the sum of only the square error of the points in S') at most $2/\tilde{\varepsilon}$.

For a right break point $b \in [n]$ and an integer $i \geq 0$, let $a_i(b) \in [b]$ be the smallest left break point such that $\delta[a_i(b), b] \leq (1 + \varepsilon)^i - 1$; if such a left break point does not exist, we set $a_i(b)$ to be the largest left break point that is smaller than or equal to b . We define an index set $A(b) = \{a_i(b) : i \geq 0 \text{ and } (1 + \varepsilon)^{i-1} - 1 \leq 2/\varepsilon\}$. We say an interval I is *canonical* if $I = [x_a, x_b]$ for some $a, b \in [n]$ such that b is a right break point and $a \in A(b)$. A function $f \in \Gamma_g^1$ is *canonical* if all pieces of f are canonical intervals. The following lemma shows that we can limit our search to canonical functions.

► **Lemma 8.** *There exists a canonical function $f \in \Gamma_g^1$ such that $\sigma_S(f) \leq (1 + \varepsilon) \cdot \text{opt}$.*

Proof. We claim that for any S -light function $f_0 \in \Gamma_g^1$, there exists a canonical function $f \in \Gamma_g^1$ with $\sigma_S(f) \leq (1 + \varepsilon) \cdot \sigma_S(f_0)$. This claim in combination with Lemma 7 proves the lemma. We prove the claim using induction on the number r of distinct x -coordinates of the points in S , i.e., distinct elements in $\{x_1, \dots, x_n\}$. If $r = 1$, then $x_1 = \dots = x_n$ and the interval $I = [x_1, x_n]$ is a singleton point. Furthermore, in this case, 1 is the unique left break point, hence $1 \in A(n)$ and I is canonical. Therefore, the claim clearly holds. Assume that the claim holds if the number of distinct x -coordinates of the points in S is less than r , and consider the case where the number is r . Let $f_0 \in \Gamma_g^1$ be a S -light function, and we want to show that there exists a canonical function $f \in \Gamma_g^1$ such that $\sigma_S(f) \leq (1 + \varepsilon) \cdot \sigma_S(f_0)$. Consider the rightmost piece P of f_0 . Without loss of generality, we may assume that $P = [x_a, x_n]$ for some left break point $a \in [n]$. Let $c(P)$ be the cost of P . We consider two cases, $c(P) \leq 2/\varepsilon$ and $c(P) > 2/\varepsilon$. If $c(P) \leq 2/\varepsilon$, we define i as the smallest integer such that $(1 + \varepsilon)^i \geq c(P) + 1$. Therefore, $(1 + \varepsilon)^{i-1} \leq c(P) + 1 \leq (1 + \varepsilon)^i$. Since $c(P) \leq 2/\varepsilon$, we have $(1 + \varepsilon)^{i-1} - 1 \leq 2/\varepsilon$ and hence $a_i(n) \in A(n)$. By the definition of $a_i(n)$, we have $a_i(n) \leq a$ and $\delta[a_i(n), n] \leq (1 + \varepsilon)^i - 1$, i.e., $\delta[a_i(n), n] + 1 \leq (1 + \varepsilon)^i$. Since $(1 + \varepsilon)^{i-1} \leq c(P) + 1$, we further deduce that $\delta[a_i(n), n] + 1 \leq (1 + \varepsilon) \cdot (c(P) + 1)$. Now we define $S' = \{(x_1, y_1), \dots, (x_{a-1}, y_{a-1})\} \subseteq S$ and $S'' = \{(x_1, y_1), \dots, (x_{a_i(n)-1}, y_{a_i(n)-1})\} \subseteq S$. Let $f'_0 \in \Gamma_g^1$ be the function obtained by restricting f_0 to the union of the pieces other than P . Then f'_0 is both S' -light and S'' -light. Note that the number of distinct x -coordinates of the points in S'' is strictly less than r , as $a_i(n)$ is a left break point. Therefore, by our induction hypothesis, there exists some canonical function $f'' \in \Gamma_g^1$ with $\sigma_{S''}(f'') \leq (1 + \varepsilon) \cdot \sigma_{S''}(f'_0) \leq (1 + \varepsilon) \cdot \sigma_{S'}(f'_0)$, and we can assume without loss of generality that all pieces of f'' are contained in the range $(-\infty, x_{a_i(n)-1}]$. We define our function f as the “combination” of f'' and $f[a_i(n), n]$. Specifically, the pieces of f consists of all pieces of f'' and the interval $[x_{a_i(n)}, x_n]$. On the piece $[x_{a_i(n)}, x_n]$, f is the same as $f[a_i(n), n]$. On the other pieces, f is the same as f'' . Clearly, $f \in \Gamma_g^1$, and it is canonical because f'' is canonical and $[x_{a_i(n)}, x_n]$ is a canonical interval. Finally, we have

$$\begin{aligned} \sigma_S(f) &= \sigma_{S''}(f'') + \delta[a_i(n), n] + 1 \\ &\leq (1 + \varepsilon) \cdot \sigma_{S'}(f'_0) + (1 + \varepsilon) \cdot (c(P) + 1) \\ &= (1 + \varepsilon) \cdot \sigma_S(f_0). \end{aligned}$$

In the case $c(P) > 2/\varepsilon$, P must be a singleton point as f_0 is S -light. Thus, $x_a = x_n$ and a is the largest left break point smaller than or equal to n , which implies $a_0(n) = a$ and hence P is canonical. By our induction hypothesis, there exists some canonical function $f'' \in \Gamma_g^1$ with $\sigma_{S'}(f'') \leq (1 + \varepsilon) \cdot \sigma_{S'}(f'_0)$, where $S' = \{(x_1, y_1), \dots, (x_{a-1}, y_{a-1})\}$. Without loss of generality, we may assume all pieces of f'' are contained in the range $(-\infty, x_{a-1}]$. Similarly to the above, We define f as the combination of f'' and $f[a, n]$. Since $\sigma_{S'}(f'') \leq (1 + \varepsilon) \cdot \sigma_{S'}(f'_0)$ and the cost of P is at least $\delta[a, n]$, we have $\sigma_S(f) \leq (1 + \varepsilon) \cdot \sigma_S(f_0)$. ◀

We can find a canonical function $f \in \Gamma_g^1$ minimizing $\sigma_S(f)$ using dynamic programming, as shown in Algorithm 1. By Lemma 8, the result is a $(1 + \varepsilon)$ -approximation of the univariate regression problem.

■ **Algorithm 1** APPROXIMATE-REGRESSION-1D(S).

```

1:  $t \leftarrow 0$  and  $\text{opt}_0 \leftarrow 0$ 
2: for  $t$  from 1 to  $n$  do
3:   if  $t$  is a right break point then
4:      $\tilde{a} \leftarrow \arg \min_{a \in A(t)} \{\text{opt}_{a-1} + (\delta[a, t] + 1)\}$ 
5:      $\text{opt}_t \leftarrow \text{opt}_{\tilde{a}-1} + (\delta[\tilde{a}, t] + 1)$ 
6: return  $\text{opt}_n$ 

```

The correctness of Algorithm 1 is clear. To analyze its time complexity, we observe that $|A(b)| = O(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon})$ for all right break points $b \in [n]$. Therefore, assuming that we know all the index sets $A(b)$ and all the $f[a, b]$ and $\delta[a, b]$, where $a \in A(b)$, Algorithm 1 can be directly implemented in $O(\frac{n}{\varepsilon} \log \frac{1}{\varepsilon})$ time. The details of how to compute all $A(b)$ and all $f[a, b], \delta[a, b]$, where $a \in A(b)$, in $O(\frac{n}{\varepsilon} \log \frac{1}{\varepsilon})$ time will appear in the full paper. The following theorem states the main result of this section.

► **Theorem 1.** *There exists a $(1 + \varepsilon)$ -approximation algorithm for univariate piecewise polynomial regression which runs in $O(\frac{n}{\varepsilon} \log \frac{1}{\varepsilon})$ time (excluding the time for pre-sorting).*

4 Algorithms for bivariate data

In this section, we present our algorithms for piecewise polynomial regression for bivariate data. The input of the problem is a dataset $S = \{(x_i, x'_i), y_i\} \in \mathbb{R}^2 \times \mathbb{R}\}_{i=1}^n$, and our goal is to find a function $f^* \in \Gamma_g^2$ that minimizes $\sigma_S(f^*)$ (recall that $\lambda = 1$ by assumption).

We present three algorithms for this problem. The first is a polynomial-time constant-factor approximation. This is the simplest of the three results. The second algorithm computes the exact solution in sub-exponential time $n^{O(\sqrt{n})}$, which makes use of the planar separator theorem (this one will appear in the full paper). The third result is a quasi-polynomial time approximation scheme, and is technically the most sophisticated of the three algorithms.

We begin with a brief overview of the high-level ideas underlying our algorithms. We first observe that a piecewise function corresponds to an orthogonal partition of the plane (induced by the pieces of the function). Therefore, the problem of finding the optimal function $f^* \in \Gamma_g^2$ is (essentially) equivalent to computing an optimal orthogonal partition of the plane (Lemma 9). Our constant-approximation algorithm (Section 4.1) follows easily from the observation that there always exists a *binary* orthogonal partition whose “cost” is a constant factor of the optimal solution (Lemma 11), and we can compute such a partition in polynomial-time using dynamic programming. To obtain our subexponential-time algorithm, we observe that an orthogonal partition of the plane forms a planar graph, and so we can use a divide-and-conquer approach by utilizing balanced separators of this graph. Finally, our QPTAS (Section 4.2) is more complicated. It is also based on a planar separator theorem, together with a cutting lemma (Lemma 13) of [3]. The basic idea is to guess a balanced separator of the planar graph of the cutting and do divide-and-conquer. We then carefully analyze the quality of the solution computed by this divide-and-conquer process (Lemma 15 and Corollary 16), and show it is indeed a $(1 + \varepsilon)$ -approximation.

We begin with introducing some notations and concepts. Let $\Delta > 0$ be a sufficiently small number such that $3\Delta \leq |x_i - x_j|$ for all $i, j \in [n]$ with $x_i \neq x_j$ and $3\Delta \leq |x'_i - x'_j|$ for all $i, j \in [n]$ with $x'_i \neq x'_j$. Define $X = \{x_i - \Delta : i \in [n]\} \cup \{x_i + \Delta : i \in [n]\}$ and $X' = \{x'_i - \Delta : i \in [n]\} \cup \{x'_i + \Delta : i \in [n]\}$. We say a rectangle $[x_-, x_+] \times [x'_-, x'_+]$ is *regular* if $x_-, x_+ \in X \cup \{-\infty, \infty\}$ and $x'_-, x'_+ \in X' \cup \{-\infty, \infty\}$. Let \mathcal{R}_{reg} denote the set of all regular rectangles. The total number of different regular rectangles is $O(n^4)$, i.e., $|\mathcal{R}_{\text{reg}}| = O(n^4)$, because $|X| = O(n)$ and $|X'| = O(n)$. Note that if R is a regular rectangle, then for any $i \in [n]$, the point (x_i, x'_i) is either contained in the interior of R or outside R . We say a regular rectangle R is *nonempty* if $(x_i, x'_i) \in R$ for some $i \in [n]$, and *empty* otherwise. For a nonempty rectangle R , we define

$$\delta_R = 1 + \min_{f \in \mathbb{R}[x, x']_g} \sum_{(x_i, x'_i) \in R} (y_i - f(x_i, x'_i))^2.$$

Note that δ_R can be computed in $n^{O(1)}$ time using the standard approach for least-square polynomial regression. For a set \mathcal{R} of regular rectangles, denote by $\mathcal{R}_\bullet \subseteq \mathcal{R}$ the subset of nonempty rectangles, and define $\sigma_S(\mathcal{R}) = \sum_{R \in \mathcal{R}_\bullet} \delta_R$. A *regular region* refers to a subset of \mathbb{R}^2 that is the union of regular rectangles.

An *orthogonal partition* (OP) Π of a region $K \subseteq \mathbb{R}^2$ is a set of interior-disjoint (axis-parallel) rectangles whose union is K (see Figure 1 for an illustration). An OP Π is *regular* if all rectangles in Π are regular. The following lemma shows that our problem can be reduced to computing a regular OP Π of the plane which minimizes $\sigma_S(\Pi)$.

■ **Figure 1** An orthogonal partition (OP) of the region K .

► **Lemma 9.** *For any $f \in \Gamma_g^2$, there exists a regular OP Π of \mathbb{R}^2 such that $|\Pi| \leq 5|f| + 1$ and $\sigma_S(\Pi) \leq \sigma_S(f)$. Conversely, given a regular OP Π of \mathbb{R}^2 , one can compute in $n^{O(1)}$ time a function $f \in \Gamma_g^2$ such that $\sigma_S(f) = \sigma_S(\Pi)$.*

Using the reduction of Lemma 9, we establish our algorithms for piecewise polynomial regression for bivariate data. Section 4.1 presents a polynomial-time constant-approximation algorithm (Theorem 3), and Section 4.2 presents a QPTAS (Theorem 4).

4.1 A polynomial-time constant-approximation algorithm

In this section, we present a polynomial-time constant-approximation algorithm for the problem. Let Π^* be a regular OP of \mathbb{R}^2 that minimizes $\sigma_S(\Pi^*)$. In order to describe our algorithm, we need to introduce the notion of *binary* OP (and regular binary OP).

► **Definition 10** (binary OP). *Let R be an axis-parallel rectangle. A **binary OP** of R is an OP defined using the following recursive rule:*

- *The trivial partition $\{R\}$ is a binary OP of R .*

■ **Figure 2** A binary OP of the rectangle R .

- If ℓ is a horizontal or vertical line that partitions R into two smaller rectangles R_1 and R_2 , and Π_1 (resp., Π_2) are binary OPs of R_1 (resp., R_2), then $\Pi_1 \cup \Pi_2$ is a binary OP of R .

A binary OP is **regular** if it only consists of regular rectangles.

See Figure 2 for an illustration of binary OP. The basic idea of our approximation algorithm is to, instead of computing an optimal regular OP, compute an optimal *binary* regular OP, i.e., a regular binary OP Π of \mathbb{R}^2 that minimizes $\sigma_S(\Pi)$. This task can be solved in polynomial time by a simple dynamic programming algorithm as follows. Suppose we want to compute an optimal binary regular OP Π of a regular rectangle R . Then Π is either the trivial partition $\{R\}$ of R , or there exists a horizontal or vertical line ℓ separating R into two rectangles R_1 and R_2 , and $\Pi = \Pi_1 \cup \Pi_2$ where Π_1 (resp., Π_2) is a regular binary OPs of R_1 (resp., R_2). In the latter case, the equation of the line ℓ must be $x = \tilde{x}$ for some $\tilde{x} \in X$ or $x' = \tilde{x}'$ for some $\tilde{x}' \in X'$, because Π has to be a regular OP. This implies that R_1 and R_2 are regular rectangles. Furthermore, Π_1 and Π_2 must be optimal regular binary OPs of R_1 and R_2 , respectively, in order to minimize $\sigma_S(\Pi)$. Therefore, if we already know the optimal regular binary OPs of all regular rectangles R' such that $\text{area}(R') < \text{area}(R)$, then an optimal regular binary OPs of R can be computed in $O(n)$ time. The details of our algorithm is shown in Algorithm 2, which computes an optimal regular binary OP of \mathbb{R}^2 . Since $|\mathcal{R}_{\text{reg}}| = O(n^4)$, it is clear that Algorithm 2 runs in polynomial time.

Let Π_{bin} be the optimal regular binary OP of \mathbb{R}^2 computed by Algorithm 2 and Π^* be the regular OP of \mathbb{R}^2 that minimizes $\sigma_S(\Pi^*)$. We shall show that $\sigma_S(\Pi_{\text{bin}}) = O(\sigma_S(\Pi^*))$. To this end, we need the following two lemmas.

► **Lemma 11.** *For any regular OP Π of \mathbb{R}^2 , there exists a regular binary OP Π' of \mathbb{R}^2 such that $|\Pi'| = O(|\Pi_\bullet|)$ and for any $R' \in \Pi'_\bullet$ there exists $R \in \Pi_\bullet$ such that $R' \subseteq R$.*

► **Lemma 12.** *Let Π and Π' be two regular OP of \mathbb{R}^2 . If for any $R' \in \Pi'_\bullet$ there exists $R \in \Pi_\bullet$ such that $R' \subseteq R$, then we have $\sigma_S(\Pi') - \sigma_S(\Pi) \leq |\Pi'_\bullet| - |\Pi_\bullet|$.*

By Lemma 11, there exists a regular binary OP Π' of \mathbb{R}^2 such that $|\Pi'_\bullet| \leq O(|\Pi_\bullet^*|)$ and for any $R' \in \Pi'_\bullet$ there exists $R \in \Pi_\bullet^*$ such that $R' \subseteq R$. Then by Lemma 12, we have $\sigma_S(\Pi')/\sigma_S(\Pi^*) = 1 + (\sigma_S(\Pi') - \sigma_S(\Pi^*))/\sigma_S(\Pi^*) \leq 1 + (|\Pi'_\bullet| - |\Pi_\bullet^*|)/|\Pi_\bullet^*| = |\Pi'_\bullet|/|\Pi_\bullet^*| = O(1)$. Because Π_{bin} is an optimal regular binary OP of \mathbb{R}^2 , we further have $\sigma_S(\Pi_{\text{bin}}) \leq \sigma_S(\Pi') \leq O(\sigma_S(\Pi^*))$. We have $\sigma_S(\Pi^*) \leq \text{opt}$ by the first statement of Lemma 9, and hence $\sigma_S(\Pi_{\text{bin}}) \leq O(\text{opt})$. Using the second statement of Lemma 9, we then compute a function $f \in \Gamma_g^2$ in $O(n \cdot |\Pi_{\text{bin}}|) = O(n^5)$ time such that $\sigma_S(f) = \sigma_S(\Pi_{\text{bin}}) \leq O(\text{opt})$.

► **Theorem 3.** *There exists a constant-factor approximation algorithm for bivariate piecewise polynomial regression which runs in polynomial time.*

Algorithm 2 OPTBINPARTITION(S).

```

1:  $N \leftarrow |\mathcal{R}_{\text{reg}}|$ 
2: sort the rectangles in  $\mathcal{R}_{\text{reg}}$  as  $R_1, \dots, R_N$  such that  $\text{area}(R_1) \leq \dots \leq \text{area}(R_N)$ 
3: for  $i$  from 1 to  $N$  do

12:    if  $\text{opt}[R_i] > \text{opt}[R'_i] + \text{opt}[R''_i]$  then
13:       $\Pi[R_i] \leftarrow \Pi[R'_i] \cup \Pi[R''_i]$  and  $\text{opt}[R_i] \leftarrow \sigma_S(\Pi[R_i])$ 
14: return  $\Pi[\mathbb{R}^2]$ 

```

4.2 A quasi-polynomial-time approximation scheme

In this section, we design a quasi-polynomial-time approximation scheme (QPTAS) for the problem, that is, a $(1 + \varepsilon)$ -approximation algorithm which runs in $n^{\log^{O(1)} n}$ time for any fixed $\varepsilon > 0$. To this end, we borrow an idea from the geometric independent set literature [3, 4, 5, 13], which combines the cutting lemma and the planar separator theorem. We need the following cutting lemma.

► **Lemma 13.** *Given a set \mathcal{R} of interior-disjoint regular rectangles and a number $1 \leq r \leq |\mathcal{R}|$, there exists a regular OP Π of \mathbb{R}^2 with $|\Pi| = O(r)$ such that each rectangle in Π intersects at most $|\mathcal{R}|/r$ rectangles in \mathcal{R} .*

Proof. This lemma follows directly from a result of [3] (Lemma 3.12). The original statement in Lemma 3.12 of [3] only claims the existence of a partition Π of \mathbb{R}^2 satisfying the desired properties. However, by the construction in [3], if \mathcal{R} consists of regular rectangles, then the partition Π is a regular OP. ◀

Using the above cutting lemma and the (weighted) planar separator theorem, we obtain the following corollary.

► **Corollary 14.** *Given a set \mathcal{R} of interior-disjoint regular rectangles in \mathbb{R}^2 and a number $1 \leq r \leq |\mathcal{R}|$, there exists a set Σ of $O(\sqrt{r})$ interior-disjoint regular rectangles such that each rectangle in Σ intersects at most $|\mathcal{R}|/r$ rectangles in \mathcal{R} and for any regular region $K \subseteq \mathbb{R}^2$, the closure of each connected component U of $K \setminus (\bigcup_{R \in \Sigma} R)$ entirely contains at most $\frac{2}{3}|\mathcal{R}|$ rectangles in \mathcal{R} .*

Proof. We shall use the following weighted version of the planar separator theorem. Let $G = (V, E)$ be a planar graph with m vertices where each vertex has a non-negative weight, and W be the total weight of the vertices. The weighted planar separator theorem states that one can partition the vertex set V into three parts V_1, V_2, Σ such that (i) there is no edge between V_1 and V_2 , (ii) $|\Sigma| \leq O(\sqrt{m})$, and (iii) the total weight of the vertices in V_i is at most $\frac{2}{3}W$ for $i \in \{1, 2\}$.

Let Π be the regular partition of \mathbb{R}^2 described in Lemma 13 satisfying that $|\Pi| = O(r)$ and each rectangle in Π intersects at most $|\mathcal{R}|/r$ rectangles in \mathcal{R} . Consider the planar graph G_Π induced by Π . We assign each vertex of G_Π (i.e., each rectangle in Π) a non-negative

weight as follows. For each rectangle $R \in \mathcal{R}$, let $m(R)$ be the number of rectangles in Π that intersects R . The weight of each rectangle $R' \in \Pi$ is the sum of $1/m(R)$ for all $R \in \mathcal{R}$ that intersects R' . Note that the total weight W is equal to $|\mathcal{R}|$ because each rectangle in \mathcal{R} contributes exactly 1 to the total weight. Applying the weighted planar separator theorem to the vertex-weighted graph G_Π , we now partition Π into three parts V_1, V_2, Σ such that (i) there is no edge between V_1 and V_2 in G_Π , (ii) $|\Sigma| \leq O(\sqrt{r})$, and (iii) the total weight of the vertices in V_i is at most $\frac{2}{3}|\mathcal{R}|$ for $i \in \{1, 2\}$. The separator Σ is just the desired set of interior-disjoint regular rectangles described in the corollary. The fact that each rectangle in Σ intersects at most $|\mathcal{R}|/r$ rectangles in \mathcal{R} follows directly from the property of Π . So it suffices to show that for any regular region $K \subseteq \mathbb{R}^2$, (the closure of) each connected component of $K \setminus (\bigcup_{R \in \Sigma} R)$ intersects at most $\frac{2}{3}|\mathcal{R}|$ rectangles in \mathcal{R} . Let U be a connected component of $K \setminus (\bigcup_{R \in \Sigma} R)$. The rectangles in Π that are contained in the closure of U induces a connected subgraph of G_Π , and hence they either all belong to V_1 or all belong to V_2 (because there is no edge between V_1 and V_2 in G_Π). It follows that the total weight of these rectangles is at most $\frac{2}{3}|\mathcal{R}|$, which further implies that the number of rectangles in \mathcal{R} that are (entirely) contained in the closure of U is at most $\frac{2}{3}|\mathcal{R}|$. ◀

With the above corollary in hand, we are ready to describe our QPTAS. Roughly speaking, our algorithm “guesses” the set Σ in Corollary 14 for the optimal regular OP \mathcal{R} (and some parameter r polynomial in $\log n$ and $1/\varepsilon$) and then recursively solve the sub-problem in each rectangle in Σ and in each connected component of the complement of $\bigcup_{R \in \Sigma} R$. The nice properties of Σ described in Corollary 14 can be used to show (with a careful analysis) that the final solution we compute is a $(1 + \varepsilon)$ -approximation of the optimal solution.

Formally, let $r = \omega(1)$ be an integer parameter to be determined later and c be a sufficiently large constant. For a regular region $K \subseteq \mathbb{R}^2$ and an integer m , we denote by $\text{opt}_{K,m}$ as the minimum $\sigma_S(\Pi)$ for a regular OP Π of K with $|\Pi_\bullet| \leq m$. We shall design a procedure $\text{APPXPARTITION}(S, K, m)$, which computes a regular OP Π of the regular region K such that $\sigma_S(\Pi)$ is “not much larger” than $\text{opt}_{K,m}$ (note that we do *not* require $|\Pi_\bullet| \leq m$); what we mean by “not much larger” will be clear shortly.

■ **Algorithm 3** $\text{APPXPARTITION}(S, K, m)$.

```

1:  $\Pi_{\text{opt}} \leftarrow \emptyset$  and  $\text{opt} \leftarrow \infty$ 
2: for all  $\Pi \subseteq \mathcal{R}_{\text{reg}}$  with  $|\Pi| \leq r$  do
3:   if the rectangles in  $\Pi$  are interior-disjoint and contained in  $K$  then
4:     construct an arbitrary regular OP  $\Pi'$  of  $K$  such that  $\Pi \subseteq \Pi'$

14: return  $\Pi_{\text{opt}}$ 

```

Algorithm 3 shows how $\text{APPXPARTITION}(S, K, m)$ works step-by-step, and here we provide an intuitive explanation of the algorithm. Let Π^* be a (unknown) regular OP of K such that $|\Pi^*| \leq m$ and $\sigma_S(\Pi^*) = \text{opt}_{K,m}$. We consider two cases separately: $|\Pi_\bullet^*| \leq r$ and

$|\Pi_\bullet^*| > r$. The for-loop of Line 2-6 handles the case $|\Pi_\bullet^*| \leq r$. We simply guess the (at most) r rectangles in Π_\bullet^* . Note that when we correctly guess Π_\bullet^* , i.e., $\Pi = \Pi_\bullet^*$ in Line 2, any regular OP Π' of K such that $\Pi \subseteq \Pi'$ satisfies $\sigma_S(\Pi') = \sigma_S(\Pi) = \sigma_S(\Pi_\bullet^*) = \sigma_S(\Pi^*)$, because $(x_i, x'_i) \notin K \setminus (\bigcup_{R \in \Pi} R)$ for all $i \in [n]$. Therefore, in the case $|\Pi_\bullet^*| \leq r$, we already have $|\Pi_{\text{opt}}| \leq \text{opt}_{K,m}$ after the for-loop of Line 2-6. The remaining case is $|\Pi_\bullet^*| > r$, which implies $m > r$. This case is handled in the for-loop of Line 8-15. We guess the set Σ described in Corollary 14 with $\mathcal{R} = \Pi_\bullet^*$ (Line 8 of Algorithm 3), which consists of at most $c\sqrt{r}$ interior-disjoint regular rectangles (recall that c is sufficiently large). Let \mathcal{U} be the set of connected components of $K \setminus (\bigcup_{R \in \Sigma} R)$. By Corollary 14, for each $R \in \Sigma$, the regular region $K \cap R$ intersects at most $|\Pi_\bullet^*|/r$ (and hence at most m/r) rectangles in \mathcal{R} , and for each $U \in \mathcal{U}$, the closure of U contains at most $\frac{2}{3}|\Pi_\bullet^*|$ rectangles (and hence at most $\frac{2}{3}m$) in \mathcal{R} . We then recursively call $\text{APPXPARTITION}(S, K \cap R, m/r)$ for all $R \in \Sigma$ and $\text{APPXPARTITION}(S, \text{Closure}(U), \frac{3}{4}m)$ for all $U \in \mathcal{U}$; see Line 11-12 of Algorithm 3. Each recursive call returns us a regular OP of the corresponding sub-region of K ; we set Π to be the union of all the returned regular OPs, which is clearly a regular OP of K (Line 13 of Algorithm 3). Intuitively, $\sigma_S(\Pi)$ should be “not much larger” than $\sigma_S(\Pi^*)$ if our guess for Σ is correct. More precisely, we have the following observation.

► **Lemma 15.** $\sum_{R \in \Sigma} \text{opt}_{K \cap R, m/r} + \sum_{U \in \mathcal{U}} \text{opt}_{\text{Closure}(U), \frac{3}{4}m} \leq (1 + O(1/\sqrt{r})) \cdot \sigma_S(\Pi^*)$.

Proof. We first show that there exists a regular OP Π of K satisfying (i) $|\Pi_\bullet| - |\Pi_\bullet^*| = O(|\Pi_\bullet^*|/\sqrt{r})$, (ii) each rectangle in Π is either contained in some $R \in \Sigma$ or interior-disjoint with all $R \in \Sigma$, (iii) each $R \in \Sigma$ contains at most m/r nonempty rectangles in Π and $\text{Closure}(U)$ contains at most $\frac{3}{4}m$ nonempty rectangles in Π for each $U \in \mathcal{U}$. Consider the regular OP Π^* of K . We further partition each rectangle $R^* \in \Pi^*$ into smaller (regular) rectangles as follows. Let $m(R^*)$ denote the number of rectangles in Σ that intersect (the interior of) R^* . Since the rectangles in Σ are interior-disjoint, the boundaries of these $m(R^*)$ rectangles cut R^* into $m(R^*) + 1$ regions (which are not necessarily rectangles). Now we construct the vertical decomposition the boundaries of these $m(R^*)$ rectangles inside R^* as follows (similarly to what we did in the proof of Lemma 9). For each top (resp., bottom) vertex of the $m(R^*)$ rectangles, if the vertex is contained in the interior of R^* , we shoot an upward (resp., downward) vertical ray from the vertex, which goes upwards (resp., downwards) until hitting the boundary of R^* or the boundary of some other $R \in \Sigma$. See Figure 3 for an illustration. Including one ray cuts R^* into one more piece, and the total number of the rays we shoot is at most $4m(R^*)$. Therefore, the vertical decomposition induces a regular OP of R^* into at most $5m(R^*) + 1$ rectangles. We do this for every rectangle $R^* \in \Pi^*$. After that, we obtain our desired regular OP Π . Next, we verify that Π satisfies

■ **Figure 3** The vertical decomposition inside R^* . The grey rectangles are those in Σ . The rectangle with bolder boundary is R^* .

the three conditions. We have $|\Pi_\bullet| \leq \sum_{R^* \in \Pi_\bullet^*} (5m(R^*) + 1) = \sum_{R^* \in \Pi_\bullet^*} 5m(R^*) + |\Pi_\bullet^*|$ since each rectangle $R^* \in \Pi_\bullet^*$ is partitioned into at most $5m(R^*) + 1$ smaller rectangles in Π (note that the rectangles in $\Pi^* \setminus \Pi_\bullet^*$ do not contribute any nonempty rectangle to Π). Because $|\Sigma| = O(\sqrt{r})$ and each rectangle in Σ intersects at most $|\Pi_\bullet^*|/r = |\Pi_\bullet^*|/r$ rectangles in Π_\bullet^* , we have $\sum_{R^* \in \Pi_\bullet^*} m(R^*) = O(|\Pi_\bullet^*|/\sqrt{r})$. It follows that $|\Pi_\bullet| - |\Pi_\bullet^*| = O(|\Pi_\bullet^*|/\sqrt{r})$, i.e., Π satisfies condition (i). Condition (ii) follows directly from our construction of Π . It suffices to show condition (iii). Let $R \in \Sigma$ be a rectangle. By our construction of Π , inside each $R^* \in \Pi^*$ that intersects (the interior of) R , there is exactly one rectangle in Π that is contained in R . Since R only intersects at most $|\Pi_\bullet^*|/r$ nonempty rectangles in Π^* and $|\Pi_\bullet^*| \leq m$, R contains at most m/r nonempty rectangles in Π . Let $U \in \mathcal{U}$ be a connected component of $K \setminus (\bigcup_{R \in \Sigma} R)$. Denote by $\Pi_\bullet^*(U) \subseteq \Pi_\bullet^*$ be the subset of rectangles that intersect U . Clearly, the number of nonempty rectangles in Π that are contained in $\text{Closure}(U)$ is at most $\sum_{R^* \in \Pi_\bullet^*(U)} (5m(R^*) + 1) = |\Pi_\bullet^*(U)| + O(|\Pi_\bullet^*|/\sqrt{r})$. By Corollary 14, $\text{Closure}(U)$ entirely contains at most $\frac{2}{3}|\Pi_\bullet^*(U)|$ rectangles in $\Pi_\bullet^*(U)$. All the other rectangles in $\Pi_\bullet^*(U)$ are partially contained in $\text{Closure}(U)$. Note that if a rectangle is partially contained in $\text{Closure}(U)$, then it intersects some $R \in \Sigma$. Therefore, the number of rectangles in $\Pi_\bullet^*(U)$ that are partially contained in $\text{Closure}(U)$ is bounded by $O(|\Pi_\bullet^*|/\sqrt{r})$, because $|\Sigma| = O(\sqrt{r})$ and each rectangle in Σ intersects at most $|\Pi_\bullet^*|/r$ rectangles in Π_\bullet^* . It follows that $|\Pi_\bullet^*(U)| = \frac{2}{3}|\Pi_\bullet^*(U)| + O(|\Pi_\bullet^*|/\sqrt{r})$ and the number of rectangles in Π that are contained in $\text{Closure}(U)$ is bounded by $\frac{2}{3}|\Pi_\bullet^*(U)| + O(|\Pi_\bullet^*|/\sqrt{r})$, which is no more than $\frac{3}{4}m$ because $|\Pi_\bullet^*| \leq m$ and we require $r = \omega(1)$.

Now we are ready to prove the lemma. Let Π be the regular OP of K we constructed above. Condition (ii) above guarantees that each rectangle in Π is either contained in some $R \in \Sigma$ or contained in $\text{Closure}(U)$ for some $U \in \mathcal{U}$. For each $R \in \Sigma$, let $\Pi(R) \subseteq \Pi$ denote the subset of rectangles contained in R . Similarly, for each $U \in \mathcal{U}$, let $\Pi(U) \subseteq \Pi$ denote the subset of rectangles contained in $\text{Closure}(U)$. Condition (iii) above guarantees that $|\Pi(R)_\bullet| \leq m/r$ for all $R \in \Sigma$ and $|\Pi(U)_\bullet| \leq \frac{3}{4}m$ for all $U \in \mathcal{U}$. So we have

$$\sigma_S(\Pi) = \sum_{R \in \Sigma} \sigma_S(\Pi(R)) + \sum_{R \in U \in \mathcal{U}} \sigma_S(\Pi(U)) \geq \sum_{R \in \Sigma} \text{opt}_{K \cap R, m/r} + \sum_{U \in \mathcal{U}} \text{opt}_{\text{Closure}(U), \frac{3}{4}m}.$$

On the other hand, we have $\sigma_S(\Pi) - \sigma_S(\Pi^*) \leq |\Pi_\bullet| - |\Pi_\bullet^*| = O(|\Pi_\bullet^*|/\sqrt{r})$ by Lemma 12 and condition (i) above. Because $|\Pi_\bullet^*| \leq \sigma_S(\Pi^*)$, we further have $\sigma_S(\Pi) \leq (1 + O(1/\sqrt{r})) \cdot \sigma_S(\Pi^*)$. Combining the two inequalities above gives us the inequality in the lemma. \blacktriangleleft

► **Corollary 16.** *Let Π_{opt} be the regular OP of K returned by $\text{APPXPARTITION}(S, K, m)$. Then we have $\sigma_S(\Pi_{\text{opt}}) \leq (1 + O(1/\sqrt{r}))^{O(\log m)} \cdot \text{opt}_{K, m}$.*

Proof. As before, let Π^* be a (unknown) regular OP of K such that $|\Pi_\bullet^*| \leq m$ and $\sigma_S(\Pi^*) = \text{opt}_{K, m}$. We prove that $\sigma_S(\Pi_{\text{opt}}) \leq (1 + O(1/\sqrt{r}))^{\log_{3/4} m} \cdot \text{opt}_{K, m}$ by induction on m . In the base case where $m \leq r$, we have $\sigma_S(\Pi_{\text{opt}}) \leq \sigma_S(\Pi^*) = \text{opt}_{K, m}$ after the for-loop of Line 2-6 (as argued before). Now suppose $m > r$. If $|\Pi_\bullet^*| \leq r$, then we still have $\sigma_S(\Pi_{\text{opt}}) \leq \text{opt}_{K, m}$ after the for-loop of Line 2-6 (as argued before). So it suffices to consider the case $|\Pi_\bullet^*| > r$. We show that when we correctly guess the set Σ in Line 8, the regular OP Π of K we construct in Line 13 satisfies $\sigma_S(\Pi) \leq (1 + O(1/\sqrt{r}))^{\log_{3/4} m} \cdot \text{opt}_{K, m}$. Let \mathcal{U} be the set of connected components of $K \setminus (\bigcup_{R \in \Sigma} R)$, as in Line 10. We have $\Pi = (\bigcup_{R \in \Sigma} \Pi_R) \cup (\bigcup_{U \in \mathcal{U}} \Pi_U)$ where $\Pi_R = \text{APPXPARTITION}(S, K \cap R, m/r)$ and $\Pi_U = \text{APPXPARTITION}(S, \text{Closure}(U), \frac{3}{4}m)$.

Recall that $r = \omega(1)$, and hence $m/r \leq \frac{3}{4}m$. By our induction hypothesis and Lemma 15,

$$\begin{aligned}
\sigma_S(\Pi) &= \sum_{R \in \Sigma} \sigma_S(\Pi_R) + \sum_{U \in \mathcal{U}} \sigma_S(\Pi_U) \\
&\leq (1 + O(1/\sqrt{r}))^{\log_{3/4} m - 1} \cdot \left(\sum_{R \in \Sigma} \text{opt}_{K \cap R, m/r} + \sum_{U \in \mathcal{U}} \text{opt}_{\text{Closure}(U), \frac{3}{4}m} \right) \\
&\leq (1 + O(1/\sqrt{r}))^{\log_{3/4} m - 1} \cdot (1 + O(1/\sqrt{r})) \cdot \sigma_S(\Pi^*) \\
&= (1 + O(1/\sqrt{r}))^{\log_{3/4} m} \cdot \sigma_S(\Pi^*),
\end{aligned}$$

which completes the proof. \blacktriangleleft

By Corollary 16, if we set $r = c' \cdot (\log^2 n / \varepsilon^2)$ for a sufficiently large constant c' , then for any regular region K and any $m = O(n)$, the procedure $\text{APPXPARTITION}(S, K, m)$ will return a regular partition Π_{opt} of K such that $\sigma_S(\Pi_{\text{opt}}) \leq (1 + \varepsilon) \cdot \text{opt}_{K, m}$. To solve our problem, we only need to call $\text{APPXPARTITION}(S, \mathbb{R}^2, 5n + 1)$, which will return a regular partition Π_{opt} of \mathbb{R}^2 such that $\sigma_S(\Pi_{\text{opt}}) \leq (1 + \varepsilon) \cdot \text{opt}_{\mathbb{R}^2, 5n+1}$. By the first statement of Lemma 9, we have $\text{opt}_{\mathbb{R}^2, 5n+1} \leq \text{opt}$. Therefore, it suffices to use the second statement of Lemma 9 to compute a function $f \in \Gamma_g^2$ such that $\sigma_S(f) = \sigma_S(\Pi_{\text{opt}}) \leq (1 + \varepsilon) \cdot \text{opt}$.

Time complexity. If $m \leq r$, the procedure $\text{APPXPARTITION}(S, K, m)$ takes $n^{O(r)} = n^{O(\log^2 n / \varepsilon^2)}$ time. In the case $m > r$, there are $n^{O(\sqrt{r})}$ sets Σ to be considered in Line 8. For each Σ , we have $c\sqrt{r}$ recursive calls in Line 11 and $n^{O(1)}$ recursive calls in Line 12, and all the other work in the for-loop of Line 8-15 can be done in $n^{O(1)}$ time. In addition, Line 1-6 takes $n^{O(r)}$ time. Therefore, if we use $T(m)$ to denote the running time of $\text{APPXPARTITION}(S, K, m)$, we have the recurrence

$$T(m) = \begin{cases} n^{O(\sqrt{r})} \cdot T(m/r) + n^{O(\sqrt{r})} \cdot T(\frac{3}{4}m) + n^{O(r)} & \text{if } m > r, \\ n^{O(r)} & \text{if } m \leq r, \end{cases}$$

which solves to $T(m) = n^{O(\sqrt{r} \log m + r)}$. Since our initial call is $\text{APPXPARTITION}(S, \mathbb{R}^2, 5n + 1)$, the total running time of our algorithm is $n^{O(\sqrt{r} \log n + r)} = n^{O(\log^2 n / \varepsilon^2)}$.

► **Theorem 4.** *There exists a QPTAS for bivariate piecewise polynomial regression.*

5 Conclusion and future work

In this paper, we studied the regression problem for univariate and bivariate data using piecewise polynomial functions. The loss of a k -piece polynomial function is measured as the sum of λk and its square error, where $\lambda \geq 0$ is a pre-specified parameter. For univariate data, we gave a $(1 + \varepsilon)$ -approximation algorithm that runs in $O(\frac{n}{\varepsilon} \log \frac{1}{\varepsilon})$ time, assuming the data points are pre-sorted. For bivariate data, we presented three results, a subexponential-time exact algorithm, a polynomial-time constant-approximation algorithm, and a QPTAS. Finally, for completeness, we also proved the problem for bivariate data is NP-hard.

Our work suggests several open problems and future research directions. The complexity of solving the problem exactly for the univariate data remains a challenging open problem. Is there a subquadratic time algorithm, or is there a (conditional or unconditional) near-quadratic lower bound? For bivariate data, does there exist a PTAS, namely, a polynomial-time $(1 + \varepsilon)$ -approximation algorithm for any fixed $\varepsilon > 0$? Finally, designing efficient approximation algorithms for regression problems with more than two variables is an interesting problem.

Bidirectional String Anchors: A New String Sampling Mechanism

Abstract

The minimizers sampling mechanism is a popular mechanism for string sampling introduced independently by Schleimer et al. [SIGMOD 2003] and by Roberts et al. [Bioinf. 2004]. Given two positive integers w and k , it selects the lexicographically smallest length- k substring in every fragment of w consecutive length- k substrings (in every sliding window of length $w + k - 1$). Minimizers samples are approximately uniform, locally consistent, and computable in linear time. Although they do not have good worst-case guarantees on their size, they are often small in practice. They thus have been successfully employed in several string processing applications. Two main disadvantages of minimizers sampling mechanisms are: first, they also do not have good guarantees on the expected size of their samples for every combination of w and k ; and, second, indexes that are constructed over their samples do not have good worst-case guarantees for on-line pattern searches.

To alleviate these disadvantages, we introduce bidirectional string anchors (bd-anchors), a new string sampling mechanism. Given a positive integer ℓ , our mechanism selects the lexicographically smallest rotation in every length- ℓ fragment (in every sliding window of length ℓ). We show that bd-anchors samples are also approximately uniform, locally consistent, and computable in linear time. In addition, our experiments using several datasets demonstrate that the bd-anchors sample sizes decrease proportionally to ℓ ; and that these sizes are competitive to or smaller than the minimizers sample sizes using the analogous sampling parameters. We provide theoretical justification for these results by analyzing the expected size of bd-anchors samples.

We also show that by using any bd-anchors sample, we can construct, in near-linear time, an index which requires linear (extra) space in the size of the sample and answers on-line pattern searches in near-optimal time. We further show, using several datasets, that a simple implementation of our index is consistently faster for on-line pattern searches than an analogous implementation of a minimizers-based index [Grabowski and Raniszewski, *Softw. Pract. Exp.* 2017].

Finally, we highlight the applicability of bd-anchors by developing an efficient and effective heuristic for top- K similarity search under edit distance. We show, using synthetic datasets, that our heuristic is more accurate and more than one order of magnitude faster in top- K similarity searches than the state-of-the-art tool for the same purpose [Zhang and Zhang, KDD 2020].

1 Introduction

The notion of *minimizers*, introduced independently by Schleimer et al. [57] and by Roberts et al. [55], is a mechanism to sample a set of positions over an input string. The goal of this sampling mechanism is, given a string T of length n over an alphabet Σ of size σ , to simultaneously satisfy the following properties:

Property 1 (approximately uniform sampling): Every sufficiently long fragment of T has a representative position sampled by the mechanism.

Property 2 (local consistency): Exact matches between sufficiently long fragments of T are preserved unconditionally by having the same (relative) representative positions sampled by the mechanism.

In most practical scenarios, sampling the smallest number of positions is desirable, as long as Properties 1 and 2 are satisfied. This is because it leads to small data structures or fewer computations. Indeed, the minimizers sampling mechanism satisfies the property of approximately uniform sampling: given two positive integers w and k , it selects at least one length- k substring in every fragment of w consecutive length- k substrings (Property 1). Specifically, this is achieved by selecting the starting positions of the smallest length- k substrings in every $(w + k - 1)$ -long fragment, where smallest is defined by a choice of a total order on the universe of length- k strings. These positions are called the “minimizers”. Thus from similar fragments, similar length- k substrings are sampled (Property 2). In particular, if two strings have a fragment of length $w + k - 1$ in common, then they have at least one minimizer corresponding to the same length- k substring. Let us denote by $\mathcal{M}_{w,k}(T)$ the set of minimizers of string T . The following example illustrates the sampling.

► **Example 1.** The set $\mathcal{M}_{w,k}$ of minimizers for $w = k = 3$ for string $T = \text{aabaaabcbda}$ (using a 1-based index) is $\mathcal{M}_{3,3}(T) = \{1, 4, 5, 6, 7\}$ and for string $Q = \text{abaaa}$ is $\mathcal{M}_{3,3}(Q) = \{3\}$. Indeed Q occurs at position 2 in T ; and Q and $T[2..6]$ have the minimizers 3 and 4, respectively, which both correspond to string aaa of length $k = 3$.

The minimizers sampling mechanism is very versatile, and it has been employed in various ways in many different applications [45, 63, 19, 10, 30, 34, 35, 46, 36]. Since its inception, the minimizers sampling mechanism has undergone numerous theoretical and practical improvements [53, 10, 51, 50, 15, 21, 68, 36, 70] with a particular focus on minimizing the size of the residual sample; see Section 6 for a summary on this line of research. Although minimizers have been extensively and successfully used, especially in bioinformatics, we observe several inherent problems with setting the parameters w and k . In particular, although the notion of length- k substrings (known as *k-mers* or *k-grams*) is a widely-used string processing tool, we argue that, in the context of minimizers, it may be causing many more problems than it solves: it is not clear to us why one should use an extra sampling parameter k to effectively characterize a fragment of length $\ell = w + k - 1$ of T . In what follows, we describe some problems that may arise when setting the parameters w and k .

Indexing: The most widely-used approach is to index the selected minimizers using a hash table. The *key* is the selected length- k substring and the *value* is the list of positions it occurs. If one would like to use length- k' substrings for the minimizers with $\ell = w + k - 1 = w' + k' - 1$, for some $w' \neq w$ and $k' \neq k$, they should compute the new set $\mathcal{M}_{w',k'}(T)$ of minimizers and construct their new index based on $\mathcal{M}_{w',k'}$ from scratch.

Querying: To the best of our knowledge, no index based on minimizers can return in optimal or near-optimal time all occurrences of a pattern Q of length $|Q| \geq \ell = w + k - 1$ in T .

Sample Size: If one would like to minimize the number of selected minimizers, they should consider different total orders on the universe of length- k strings, which may complicate practical implementations, often scaling only up to a small k value, e.g. $k = 16$ [21]. On

the other hand, when k is fixed and w increases, the length- k substrings in a fragment become increasingly decoupled from each other, and that *regardless of the total order* we may choose. Unfortunately, this interplay phenomenon is inherent to minimizers. It is known that $k \geq \log_\sigma(w) + c$, for a fixed constant c , is a *necessary condition* for the existence of minimizers samples with expected size in $\mathcal{O}(n/w)$ [68]; see Section 6.

We propose the notion of bidirectional string anchors (bd-anchors) to alleviate these disadvantages. The bd-anchors is a mechanism that drops the sampling parameter k and its corresponding disadvantages. We only fix a parameter ℓ , which can be viewed as the length $w + k - 1$ of the fragments in the minimizers sampling mechanism. The *bd-anchor* of a string X of length ℓ is the lexicographically smallest rotation (cyclic shift) of X . We unambiguously characterize this rotation by its leftmost starting position in string XX . The set $\mathcal{A}_\ell(T)$ of the order- ℓ bd-anchors of string T is the set of bd-anchors of all length- ℓ fragments of T . It can be readily verified that bd-anchors satisfy Properties 1 and 2.

► **Example 2.** The set $\mathcal{A}_\ell(T)$ of bd-anchors for $\ell = 5$ for string $T = \text{aabaaabcbda}$ (using a 1-based index) is $\mathcal{A}_5(T) = \{4, 5, 6, 11\}$ and for string $Q = \text{abaaa}$, $\mathcal{A}_5(Q) = \{3\}$. Indeed Q occurs at position 2 in T ; and Q and $T[2..6]$ have the bd-anchors 3 and 4, respectively, which both correspond to the rotation **aaaab**.

Let us remark that *string synchronizing* sets, introduced by Kempa and Kociumaka [41], is another string sampling mechanism which may be employed to resolve the disadvantages of minimizers. Yet, it appears to be quite complicated to be efficient in practice. For instance, in [20], the authors used a simplified and specific definition of string synchronizing sets to design a space-efficient data structure for answering longest common extension queries.

We consider the word RAM model of computations with w -bit machine words, where $w = \Omega(\log n)$, for stating our results. We also assume throughout that string T is over alphabet $\Sigma = \{1, 2, \dots, n^{\mathcal{O}(1)}\}$, which captures virtually any real-world scenario. We measure space in terms of w -bit machine words. We make the following three specific contributions:

1. In Section 3 we state that the set $\mathcal{A}_\ell(T)$, for any $\ell > 0$ and any T of length n , can be constructed in $\mathcal{O}(n)$ time; and that the expected size of \mathcal{A}_ℓ for strings of length n , randomly generated by a memoryless source with identical letter probabilities, is in $\mathcal{O}(n/\ell)$, for any integer $\ell > 0$ (proofs are deferred to the full version of our work). The latter is in contrast to minimizers which achieve the expected bound of $\mathcal{O}(n/w)$ only when $k \geq \log_\sigma w + c$, for some constant c [68]. We then show, using five real datasets, that indeed the size of \mathcal{A}_ℓ decreases proportionally to ℓ ; that it is competitive to or smaller than $\mathcal{M}_{w,k}$, when $\ell = w + k - 1$; and that it is *much smaller* than $\mathcal{M}_{w,k}$ for *small* w values, which is practically important, as widely-used aligners that are based on minimizers will require less space and computation time if bd-anchors are used instead.
2. In Section 4 we show an index based on $\mathcal{A}_\ell(T)$, for any string T of length n and any integer $\ell > 0$, which answers on-line pattern searches in near-optimal time. In particular, for any constant $\epsilon > 0$, we show that our index supports the following trade-offs:
 - it occupies $\mathcal{O}(|\mathcal{A}_\ell(T)|)$ extra space and reports all k occurrences of any pattern Q of length $|Q| \geq \ell$ given on-line in $\mathcal{O}(|Q| + (k+1) \log^\epsilon(|\mathcal{A}_\ell(T)|))$ time; or
 - it occupies $\mathcal{O}(|\mathcal{A}_\ell(T)| \log^\epsilon(|\mathcal{A}_\ell(T)|))$ extra space and reports all k occurrences of any pattern Q of length $|Q| \geq \ell$ given on-line in $\mathcal{O}(|Q| + \log \log(|\mathcal{A}_\ell(T)|) + k)$ time.

We also show that our index can be constructed in $\mathcal{O}(n + |\mathcal{A}_\ell(T)| \sqrt{\log(|\mathcal{A}_\ell(T)|)})$ time. We then show, using five real datasets, that a simple implementation of our index is *consistently faster* in on-line pattern searches than an analogous implementation of the minimizers-based index proposed by Grabowski and Raniszewski in [30].

3. In Section 5 we highlight the applicability of bd-anchors by developing an efficient and effective heuristic for top- K similarity search under edit distance. This is a fundamental and extensively studied problem [37, 9, 11, 44, 64, 67, 54, 61, 60, 17, 33, 65, 66] with applications in areas including bioinformatics, databases, data mining, and information retrieval. We show, using synthetic datasets, that our heuristic, which is based on the bd-anchors index, is *more accurate* and *more than one order of magnitude faster* in top- K similarity searches than the state-of-the-art tool proposed by Zhang and Zhang in [66].

In Section 2, we provide some preliminaries; and in Section 6 we discuss works related to minimizers. Let us stress that, although other works may be related to our contributions, we focus on comparing to minimizers because they are extensively used in applications.

2 Preliminaries

We start with some basic definitions and notation following [13]. An *alphabet* Σ is a finite nonempty set of elements called *letters*. A *string* $X = X[1] \dots X[n]$ is a sequence of *length* $|X| = n$ of letters from Σ . The *empty* string, denoted by ε , is the string of length 0. The fragment $X[i..j]$ of X is an *occurrence* of the underlying *substring* $S = X[i] \dots X[j]$. We also say that S occurs at *position* i in X . A *prefix* of X is a fragment of X of the form $X[1..j]$ and a *suffix* of X is a fragment of X of the form $X[i..n]$. The set of all strings over Σ (including ε) is denoted by Σ^* . The set of all length- k strings over Σ is denoted by Σ^k . Given two strings X and Y , the *edit distance* $d_E(X, Y)$ is the minimum number of edit operations (letter insertion, deletion, or substitution) transforming one string into the other.

Let M be a finite nonempty set of strings over Σ of total length m . We define the *trie* of M , denoted by $\text{TR}(M)$, as a deterministic finite automaton that recognizes M . Its set of states (nodes) is the set of prefixes of the elements of M ; the initial state (root node) is ε ; the set of terminal states (leaf nodes) is M ; and edges are of the form $(u, \alpha, u\alpha)$, where u and $u\alpha$ are nodes and $\alpha \in \Sigma$. The size of $\text{TR}(M)$ is thus $\mathcal{O}(m)$. The *compacted trie* of M , denoted by $\text{CT}(M)$, contains the root node, the branching nodes, and the leaf nodes of $\text{TR}(M)$. The term compacted refers to the fact that $\text{CT}(M)$ reduces the number of nodes by replacing each maximal branchless path segment with a single edge, and that it uses a fragment of a string $s \in M$ to represent the label of this edge in $\mathcal{O}(1)$ machine words. The size of $\text{CT}(M)$ is thus $\mathcal{O}(|M|)$. When M is the set of suffixes of a string Y , then $\text{CT}(M)$ is called the *suffix tree* of Y , and we denote it by $\text{ST}(Y)$. The suffix tree of a string of length n over an alphabet $\Sigma = \{1, \dots, n^{\mathcal{O}(1)}\}$ can be constructed in $\mathcal{O}(n)$ time [22].

Let us fix throughout a string $T = T[1..n]$ of length $|T| = n$ over an ordered alphabet Σ . Recall that we make the standard assumption of an integer alphabet $\Sigma = \{1, 2, \dots, n^{\mathcal{O}(1)}\}$.

We start by defining the notion of minimizers of T from [55] (the definition in [57] is slightly different). Given an integer $k > 0$, an integer $w > 0$, and the i th length- $(w + k - 1)$ fragment $F = T[i..i + w + k - 2]$ of T , we define the (w, k) -*minimizers* of F as the positions $j \in [i, i + w)$ where a lexicographically minimal length- k substring of F occurs. The set $\mathcal{M}_{w,k}(T)$ of (w, k) -minimizers of T is defined as the set of (w, k) -minimizers of $T[i..i + w + k - 2]$, for all $i \in [1, n - w - k + 2]$. The *density* of $\mathcal{M}_{w,k}(T)$ is defined as the quantity $|\mathcal{M}_{w,k}(T)|/n$. The following bounds are obtained trivially. The density of any minimizer scheme is at least $1/w$, since at least one (w, k) -minimizer is selected in each fragment, and at most 1, when every (w, k) -minimizer is selected.

If we waive the lexicographic order assumption, the set $\mathcal{M}_{w,k}(T)$ can be computed on-line in $\mathcal{O}(n)$ time, and if we further assume a constant-time computable function that gives us an *arbitrary* rank for each length- k substring in Σ^k in constant amortized time [36]. This can be

implemented, for instance, using a rolling hash function (e.g. Karp-Rabin fingerprints [39]), and the rank (total order) is defined by this function. We also provide here, for completeness, a simple off-line $\mathcal{O}(n)$ -time algorithm that uses a lexicographic order.

► **Theorem 3.** *The set $\mathcal{M}_{w,k}(T)$, for any integers $w, k > 0$ and any string T of length n , can be constructed in $\mathcal{O}(n)$ time.*

Proof. The underlying algorithm has two main steps. In the first step, we construct $\text{ST}(T)$, the suffix tree of T in $\mathcal{O}(n)$ time [22]. Using a depth-first search traversal of $\text{ST}(T)$ we assign at every position of T in $[1, n - k + 1]$ the lexicographic rank of $T[i..i + k - 1]$ among all the length- k strings occurring in T . This process clearly takes $\mathcal{O}(n)$ time as $\text{ST}(T)$ is an ordered structure; it yields an array R of size $n - k + 1$ with lexicographic ranks. In the second step, we apply a folklore algorithm, which computes the minimum elements in a sliding window of size w (cf. [36]) over R . The set of reported indices is $\mathcal{M}_{w,k}(T)$. ◀

3 Bidirectional String Anchors

We introduce the notion of bidirectional string anchors (bd-anchors). Given a string W , a string R is a *rotation* (or cyclic shift or conjugate) of W if and only if there exists a decomposition $W = UV$ such that $R = VU$, for a string U and a nonempty string V . We often characterize R by its starting position $|U| + 1$ in $WW = UVUV$. We use the term rotation interchangeably to refer to string R or to its identifier $(|U| + 1)$.

► **Definition 4** (Bidirectional anchor). *Given a string X of length $\ell > 0$, the bidirectional anchor (bd-anchor) of X is the lexicographically minimal rotation $j \in [1, \ell]$ of X with minimal j . The set of order- ℓ bd-anchors of a string T of length $n > \ell$, for some integer $\ell > 0$, is defined as the set $\mathcal{A}_\ell(T)$ of bd-anchors of $T[i..i + \ell - 1]$, for all $i \in [1, n - \ell + 1]$.*

The *density* of $\mathcal{A}_\ell(T)$ is defined as the quantity $|\mathcal{A}_\ell(T)|/n$. It can be readily verified that the bd-anchors sampling mechanism satisfies Properties 1 (approximately uniform sampling) and 2 (local consistency).

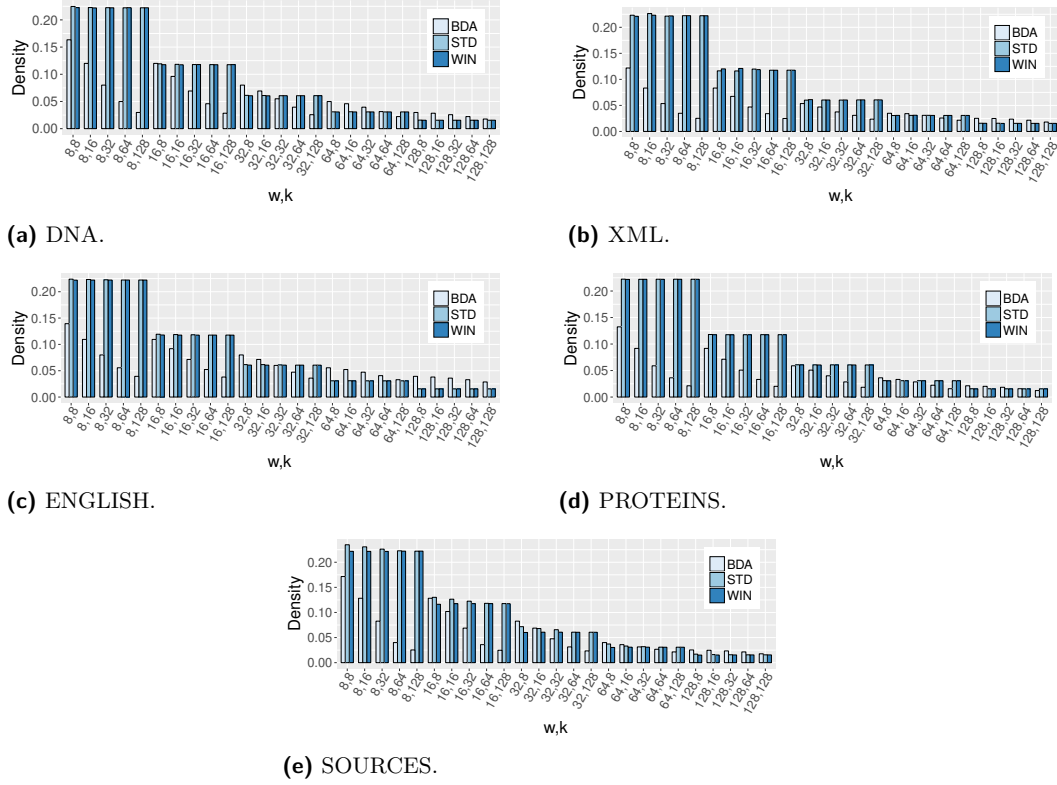

Construction and Size of \mathcal{A}_ℓ . We show that \mathcal{A}_ℓ admits an efficient construction. One can use the linear-time algorithm by Booth [6] to compute the lexicographically minimal rotation for each length- ℓ fragment of T , resulting in an $\mathcal{O}(n\ell)$ -time algorithm, which is reasonably fast for modest ℓ . (Booth's algorithm gives the leftmost minimal rotation by construction.) We can instead design an optimal $\mathcal{O}(n)$ -time algorithm for the construction of \mathcal{A}_ℓ , which is mostly of theoretical interest, via employing some elementary combinatorial observations and the data structure proposed by Kociumaka in [42, Theorem 20].

► **Theorem 5.** *The set $\mathcal{A}_\ell(T)$, for any integer $\ell > 0$ and any string T of length n , can be constructed in $\mathcal{O}(n)$ time.*

We can also show that the expected size of $\mathcal{A}_\ell(T)$ is in $\mathcal{O}(n/\ell)$ via observing that $\mathcal{A}_\ell(T)$ is expected to have many common elements with $\mathcal{M}_{w,k}(T)$, for certain values of w and k .

► **Theorem 6.** *If T is a string of length n , randomly generated by a memoryless source with identical letter probabilities, then, for any integer $\ell > 0$, the expected size of $\mathcal{A}_\ell(T)$ is in $\mathcal{O}(n/\ell)$.*

We defer the proofs of Theorems 5 and 6 to the full version of our work.

■ **Figure 1** Density vs. w, k for $\ell = w + k - 1$ and the datasets of Table 1.

Density Evaluation. We compare the density of bd-anchors, denoted by BDA, to the density of minimizers, for different values of w and k such that $\ell = w + k - 1$. This is a fair comparison because $\ell = w + k - 1$ is the length of the fragments considered by both mechanisms. We implemented bd-anchors, the standard minimizers mechanism from [55], and the minimizers mechanism with robust winnowing from [57], which are referred to as STD and WIN, respectively.

For bd-anchors, we used Booth’s algorithm, which is easy to implement and reasonably fast. For minimizers, we used Karp-Rabin fingerprints [39]. (Note that such “random” minimizers tend to perform *even better* than the ones based on lexicographic total order in terms of density [68].) Throughout, we do not evaluate construction times, as all implementations are reasonably fast, and we make the standard assumption that preprocessing is only required once. We used five string datasets from the popular Pizza & Chili corpus [24] (see Table 1 for the datasets characteristics). All implementations referred to in this paper have been written in C++ and compiled at optimization level -O3. All experiments reported in this paper were conducted using a single core of an AMD Opteron 6386 SE 2.8GHz CPU and 252GB RAM running GNU/Linux.

As can be seen by the results depicted in Figure 1, the density of bd-anchors is either significantly smaller than or competitive to the STD and WIN minimizers density, especially for small w . This is useful because a lower density results in smaller indexes and less computation (see Section 4), and because small w is of practical interest (see Section 5). For instance, the widely-used long-read aligner *Minimap2* [46] stores the selected minimizers of a reference genome in a hash table to find exact matches as anchors for seed-and-extend

■ **Table 1** Datasets characteristics.

Dataset	Length n	Alphabet size $ \Sigma $
DNA	200,000,000	4
XML	200,000,000	95
ENGLISH	200,000,000	224
PROTEINS	200,000,000	27
SOURCES	200,000,000	229

alignment. The parameters w and k are set based on the required sensitivity of the alignment, and thus w and k cannot be too large for high sensitivity. Thus, a lower sampling density reduces the size of the hash table, as well as the computation time, by lowering the average number of selected minimizers to consider when performing an alignment.

There exists a long line of research on improving the density of minimizers in special regimes (see Section 6 for details). We stress that most of these algorithms are designed, implemented, or optimized, *only for the DNA alphabet*. We have tested against two state-of-the-art tools employing such algorithms: Miniception [68] and PASHA [21]. The former did not give better results than STD or WIN for the tested values of w and k ; and the latter does not scale beyond $k = 16$ or with large alphabets. We have thus omitted these results.

We next report the average number (AVG) of bd-anchors of order $\ell \in \{4, 8, 12, 16\}$ over all strings of length $n = 20$ (see Table 2a) and over all strings of length $n = 32$ (see Table 2b), both over a binary alphabet. The results suggest that 2 may be a valid constant in $\mathcal{O}(n/\ell)$. As expected, the analogous AVG values using a ternary alphabet (not reported) were always lower than the corresponding ones with a binary alphabet.

■ **Table 2** Average number of bd-anchors for varying ℓ and: (a) $n = 20$ and (b) $n = 32$.

(a)					(b)				
(n, ℓ)	(20, 4)	(20, 8)	(20, 12)	(20, 16)	(n, ℓ)	(32, 4)	(32, 8)	(32, 12)	(32, 16)
$2n/\ell$	10	5	3.33	2.5	$2n/\ell$	16	8	5.33	4
AVG	8.53	4.37	2.77	1.76	AVG	14.16	7.67	5.26	3.85

4 Indexing Using Bidirectional Anchors

Before presenting our index, let us start with a basic definition that is central to our querying process.

► **Definition 7** ((α, β) -hit). *Given an order- ℓ bd-anchor $j_Q \in \mathcal{A}_\ell(Q)$, for some integer $\ell > 0$, of a query string Q , two integers $\alpha > 0, \beta > 0$, with $\alpha + \beta \geq \ell + 1$, and an order- ℓ bd-anchor $j_T \in \mathcal{A}_\ell(T)$ of a target string T , the ordered pair (j_Q, j_T) is called an (α, β) -hit if and only if $T[j_T - \alpha + 1 .. j_T] = Q[j_Q - \alpha + 1 .. j_Q]$ and $T[j_T .. j_T + \beta - 1] = Q[j_Q .. j_Q + \beta - 1]$.*

Intuitively, the parameters α and β let us choose a fragment of Q that is anchored at j_Q .

We would like to construct a data structure over T , which is based on $\mathcal{A}_\ell(T)$, such that, when we are given an order- ℓ bd-anchor j_Q over Q as an on-line query, together with parameters α and β , we can report all (α, β) -hits efficiently. To this end, we present an efficient data structure, denoted by $\mathcal{I}_\ell(T)$, which is constructed on top of T , and answers (α, β) -hit queries in near-optimal time. We prove the following result.

► **Theorem 8.** *Given a string T of length n and an integer $\ell > 0$, the $\mathcal{I}_\ell(T)$ index can be constructed in $\mathcal{O}(n + |\mathcal{A}_\ell(T)|\sqrt{\log(|\mathcal{A}_\ell(T)|)})$ time. For any constant $\epsilon > 0$, $\mathcal{I}_\ell(T)$:*

- *occupies $\mathcal{O}(|\mathcal{A}_\ell(T)|)$ extra space and reports all k (α, β) -hits in $\mathcal{O}(\alpha + \beta + (k + 1)\log^\epsilon(|\mathcal{A}_\ell(T)|))$ time; or*

- occupies $\mathcal{O}(|\mathcal{A}_\ell(T)| \log^\epsilon(|\mathcal{A}_\ell(T)|))$ extra space and reports all k (α, β) -hits in $\mathcal{O}(\alpha + \beta + \log \log(|\mathcal{A}_\ell(T)|) + k)$ time.

Let us denote by $\overleftarrow{X} = X[|X|] \dots X[1]$ the *reversal* of string X . We now describe our data structure.

Construction of $\mathcal{I}_\ell(T)$. Given $\mathcal{A}_\ell(T)$, we construct two sets $\mathcal{S}_\ell^L(T)$ and $\mathcal{S}_\ell^R(T)$ of strings; conceptually, the reversed suffixes going *left* from j to 1, and the suffixes going *right* from j to n , for all j in $\mathcal{A}_\ell(T)$. In particular, for the bd-anchor j , we construct two strings: $\overleftarrow{T[1..j]} \in \mathcal{S}_\ell^L(T)$ and $T[j..n] \in \mathcal{S}_\ell^R(T)$. Note that, $|\mathcal{S}_\ell^L(T)| = |\mathcal{S}_\ell^R(T)| = |\mathcal{A}_\ell(T)|$, since for every bd-anchor in $\mathcal{A}_\ell(T)$ we have a distinct string in $\mathcal{S}_\ell^L(T)$ and in $\mathcal{S}_\ell^R(T)$.

We construct two *compacted tries* $\mathcal{T}_\ell^L(T)$ and $\mathcal{T}_\ell^R(T)$ over $\mathcal{S}_\ell^L(T)$ and $\mathcal{S}_\ell^R(T)$, respectively, to index all strings. Every string is concatenated with some special letter $\$$ not occurring in T , which is lexicographically minimal, to make $\mathcal{S}_\ell^L(T)$ and $\mathcal{S}_\ell^R(T)$ prefix-free (this is standard for conceptual convenience). The leaf nodes of the compacted tries are *labeled* with the corresponding j : there is a one-to-one correspondence between a leaf node and a bd-anchor j . In $\mathcal{O}(|\mathcal{A}_\ell(T)|)$ time, we also enhance the nodes of the tries with a perfect static dictionary [26] to ensure constant-time retrieval of edges by the first letter of their label. Let $\mathcal{L}_\ell^L(T)$ denote the list of the leaf labels of $\mathcal{T}_\ell^L(T)$ as they are visited using a depth-first search traversal. $\mathcal{L}_\ell^L(T)$ corresponds to the (labels of the) lexicographically sorted list of $\mathcal{S}_\ell^L(T)$ in increasing order. For each node u in $\mathcal{T}_\ell^L(T)$, we also store the corresponding interval $[x_u, y_u]$ over $\mathcal{L}_\ell^L(T)$. Analogously for R , $\mathcal{L}_\ell^R(T)$ denotes the list of the leaf labels of $\mathcal{T}_\ell^R(T)$ as they are visited using a depth-first search traversal and corresponds to the (labels of the) lexicographically sorted list of $\mathcal{S}_\ell^R(T)$ in increasing order. For each node v in $\mathcal{T}_\ell^R(T)$, we also store the corresponding interval $[x_v, y_v]$ over $\mathcal{L}_\ell^R(T)$.

The total size occupied by the tries is $\Theta(|\mathcal{A}_\ell(T)|)$ because they are compacted: we label the edges with intervals over $[1, n]$ from T .

We also construct a 2D range reporting data structure over the following points in set $\mathcal{R}_\ell(T)$:

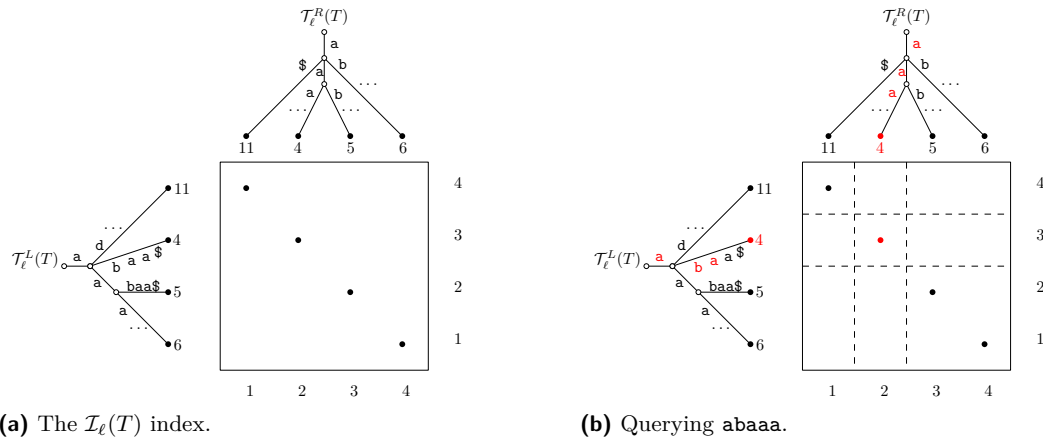

$$(x, y) \in \mathcal{R}_\ell(T) \iff \mathcal{L}_\ell^L(T)[x] = \mathcal{L}_\ell^R(T)[y].$$

Note that $|\mathcal{R}_\ell(T)| = |\mathcal{A}_\ell(T)|$ because the set of leaf labels stored in both tries is precisely the set $\mathcal{A}_\ell(T)$. Let us remark that the idea of employing 2D range reporting for bidirectional pattern searches has been introduced by Amir et al. [2] for text indexing and dictionary matching with one error; see also [47].

This completes the construction of $\mathcal{I}_\ell(T)$. We next explain how we can query $\mathcal{I}_\ell(T)$.

Querying. Given a bd-anchor j_Q over a string Q as an on-line query and parameters $\alpha, \beta > 0$, we spell $\overleftarrow{Q[j_Q - \alpha + 1..j_Q]}$ in $\mathcal{T}_\ell^L(T)$ and $Q[j_Q..j_Q + \beta - 1]$ in $\mathcal{T}_\ell^R(T)$ starting from the root nodes. If any of the two strings is not spelled fully, we return no (α, β) -hits. If both strings are fully spelled, we arrive at node u in $\mathcal{T}_\ell^L(T)$ (resp. v in $\mathcal{T}_\ell^R(T)$), which corresponds to an interval over $\mathcal{L}_\ell^L(T)$ stored in u (resp. $\mathcal{L}_\ell^R(T)$ in v). We obtain the two intervals $[x_u, y_u]$ and $[x_v, y_v]$ forming a rectangle and ask the corresponding 2D range reporting query. It can be readily verified that this query returns all (α, β) -hits.

► **Example 9.** Let $T = \text{aabaaabcbda}$ and $\mathcal{A}_5(T) = \{4, 5, 6, 11\}$. We have the following strings in $\mathcal{S}^L(T)$: $\overleftarrow{T[1..4]} = \text{abaa}$; $\overleftarrow{T[1..5]} = \text{aabaa}$; $\overleftarrow{T[1..6]} = \text{aaabaa}$; and $\overleftarrow{T[1..11]} = \text{adbcbaaabaa}$. We have the following strings in $\mathcal{S}^R(T)$: $T[4..11] = \text{aaabcbda}$; $T[5..11] = \text{aabcbda}$; $T[6..11] = \text{abcbda}$; $T[11..11] = \text{a}$. Inspect Figure 2.

■ **Figure 2** Let $T = \text{aabaaabcbda}$ and $\ell = 5$. Further let $Q = \text{aacabaaaae}$, the bd-anchor $6 \in \mathcal{A}_5(Q)$ of order 5 corresponding to $Q[4..8]$, $\alpha = 3$ and $\beta = 3$. The figure illustrates the $\mathcal{I}_\ell(T)$ index and how we find that $Q[4..8] = T[2..5] = \text{abaaa}$: the fragment $T[2..5]$ is anchored at position 4.

Proof of Theorem 8. We use the $\mathcal{O}(n)$ -time algorithm underlying Theorem 5 to construct $\mathcal{A}_\ell(T)$. We use the $\mathcal{O}(n)$ -time algorithm from [3, 8] to construct the compacted tries from $\mathcal{A}_\ell(T)$. We extract the $|\mathcal{A}_\ell(T)|$ points $(x, y) \in \mathcal{R}_\ell(T)$ using the compacted tries in $\mathcal{O}(|\mathcal{A}_\ell(T)|)$ time. For the first trade-off of the statement, we use the $\mathcal{O}(|\mathcal{A}_\ell(T)|\sqrt{\log(|\mathcal{A}_\ell(T)|)})$ -time algorithm from [5] to construct the 2D range reporting data structure over $\mathcal{R}_\ell(T)$ from [7]. For the second trade-off, we use the $\mathcal{O}(|\mathcal{A}_\ell(T)|\sqrt{\log(|\mathcal{A}_\ell(T)|)})$ -time algorithm from [28] to construct the 2D range reporting data structure over $\mathcal{R}_\ell(T)$ from the same paper. ◀

We obtain the following corollary for the fundamental problem of *text indexing* [62, 48, 22, 38, 23, 31, 32, 4, 12, 52, 41, 27].

► **Corollary 10.** *Given $\mathcal{I}_\ell(T)$ constructed for some integer $\ell > 0$ and some constant $\epsilon > 0$ over string T , we can report all k occurrences of any pattern Q , $|Q| \geq \ell$, in T in time:*

- $\mathcal{O}(|Q| + (k + 1) \log^\epsilon(|\mathcal{A}_\ell(T)|))$ when $\mathcal{I}_\ell(T)$ occupies $\mathcal{O}(|\mathcal{A}_\ell(T)|)$ extra space; or
- $\mathcal{O}(|Q| + \log \log(|\mathcal{A}_\ell(T)|) + k)$ when $\mathcal{I}_\ell(T)$ occupies $\mathcal{O}(|\mathcal{A}_\ell(T)| \log^\epsilon(|\mathcal{A}_\ell(T)|))$ extra space.

Proof. Every occurrence of Q in T is prefixed by string $P = Q[1.. \ell]$. We first compute the bd-anchor of P in $\mathcal{O}(\ell)$ time using Booth's algorithm. Let this bd-anchor be j . We set $\alpha = j$ and $\beta = |Q| - j + 1$. The result follows by applying Theorem 8. ◀

Index Evaluation. Consider a hash table with the following (key, value) pairs: the *key* is the hash value $h(S)$ of a length- k string S ; and the *value* (satellite data) is a list of occurrences of S in T . It should be clear that such a hash table indexing the minimizers of T does not perform well for on-line pattern searches of *arbitrary length* because it would need to verify the remaining prefix and suffix of the pattern using letter comparisons *for all occurrences* of a minimizer in T . We thus opted for comparing our index to the one of [30], which addresses this specific problem by sampling the suffix array [48] with minimizers to reduce the number of letter comparisons during verification.

To ensure a fair comparison, we have implemented the basic index from [30]; we denote it by GR Index. We used Karp-Rabin [39] fingerprints for computing the minimizers of T . We also used the array-based version of the suffix tree that consists of the suffix array (SA) and the longest common prefix (LCP) array [48]; SA was constructed using SDSL [29] and the LCP array using the Kasai et al. [40] algorithm.

We sampled the SA using the minimizers. Given a pattern Q , we searched $Q[j \dots |Q|]$ starting with the minimizer $Q[j \dots j + k - 1]$ using the Manber and Myers [48] algorithm on the sampled SA. For verifying the remaining prefix $Q[1 \dots j - 1]$ of Q , we used letter comparisons, as described in [30]. The space complexity of this implementation is $\mathcal{O}(n)$ and the extra space for the index is $\mathcal{O}(|\mathcal{M}_{w,k}(T)|)$. The query time is not bounded. We have implemented two versions of our index. We used Booth's algorithm for computing the bd-anchors of T . We used SDSL for SA construction and the Kasai et al. algorithm for LCP array construction. We sampled the SA using the bd-anchors thus constructing $\mathcal{L}_\ell^L(T)$ and $\mathcal{L}_\ell^R(T)$. Then, the two versions of our index are:

1. **BDA Index v1:** Let j be the bd-anchor of $Q[1 \dots \ell]$. For $\overleftarrow{Q[1 \dots j]}$ (resp. $Q[j \dots |Q|]$) we used the Manber and Myers algorithm for searching over $\mathcal{L}_\ell^L(T)$ (resp. $\mathcal{L}_\ell^R(T)$). We used range trees [14] implemented in CGAL [59] for 2D range reporting as per the described querying process. The space complexity of this implementation is $\mathcal{O}(n + |\mathcal{A}_\ell(T)| \log(|\mathcal{A}_\ell(T)|))$ and the extra space for the index is $\mathcal{O}(|\mathcal{A}_\ell(T)| \log(|\mathcal{A}_\ell(T)|))$. The query time is $\mathcal{O}(|Q| + \log^2(|\mathcal{A}_\ell(T)|) + k)$, where k is the total number of occurrences of Q in T .
2. **BDA Index v2:** Let j be the bd-anchor of $Q[1 \dots \ell]$. If $|Q| - j + 1 \geq j$ (resp. $|Q| - j + 1 < j$), we search for $Q[j \dots |Q|]$ (resp. $\overleftarrow{Q[1 \dots j]}$) using the Manber and Myers algorithm on $\mathcal{L}_\ell^R(T)$ (resp. $\mathcal{L}_\ell^L(T)$). For verifying the remaining part of the pattern we used letter comparisons. The space complexity of this implementation is $\mathcal{O}(n)$ and the extra space for the index is $\mathcal{O}(|\mathcal{A}_\ell(T)|)$. The query time is not bounded.

For each of the five real datasets of Table 1 and each query string length ℓ , we randomly extracted 500,000 substrings from the text and treated each substring as a query, following [30]. We plot the average query time in Figure 3. As can be seen, BDA Index v2 consistently outperforms GR Index across all datasets and all ℓ values. The better performance of BDA Index v2 is due to two theoretical reasons. First, the verification strategy exploits the fact that the index is *bidirectional* to apply the Manber and Myers algorithm to the largest part of the pattern, which results in fewer letter comparisons. Second, bd-anchors generally have smaller density compared to minimizers; see Figure 4. We also plot the peak memory usage in Figure 5. As can be seen, BDA Index v2 requires a similar amount of memory to GR Index.

BDA Index v1 was slower than GR Index for small ℓ but faster for large ℓ in three out of five datasets used and had by far the highest memory usage. Let us stress that the inefficiency of BDA Index v1 is not due to inefficiency in the query time or space of our algorithm. It is merely because the range tree implementation of CGAL, which is a standard off-the-shelf library, is unfortunately inefficient in terms of both query time and memory usage; see also [58, 25]. As BDA Index v2 was very efficient in all aspects, we defer the investigation of alternative range tree implementations [58] for BDA Index v1 to the full version of our work.

Discussion. The proposed $\mathcal{I}_\ell(T)$ index, which is based on bd-anchors, has the following attributes:

1. **Construction:** $\mathcal{A}_\ell(T)$ is constructed in $\mathcal{O}(n)$ worst-case time and $\mathcal{I}_\ell(T)$ is constructed in $\mathcal{O}(n + |\mathcal{A}_\ell(T)| \sqrt{\log(|\mathcal{A}_\ell(T)|)})$ worst-case time. These time complexities are near-linear in n and do not depend on the alphabet Σ as long as $|\Sigma| = n^{\mathcal{O}(1)}$, which is true for virtually any real scenario.
2. **Index Size:** By Theorem 8, $\mathcal{I}_\ell(T)$ can occupy $\mathcal{O}(|\mathcal{A}_\ell(T)|)$ space. By Theorem 6, the size of $\mathcal{A}_\ell(T)$ is $\mathcal{O}(n/\ell)$ in expectation and so $\mathcal{I}_\ell(T)$ can also be of size $\mathcal{O}(n/\ell)$. In practice this depends on T and on the implementation of the 2D range reporting data structure.
3. **Querying:** The $\mathcal{I}_\ell(T)$ index answers on-line pattern searches in near-optimal time.

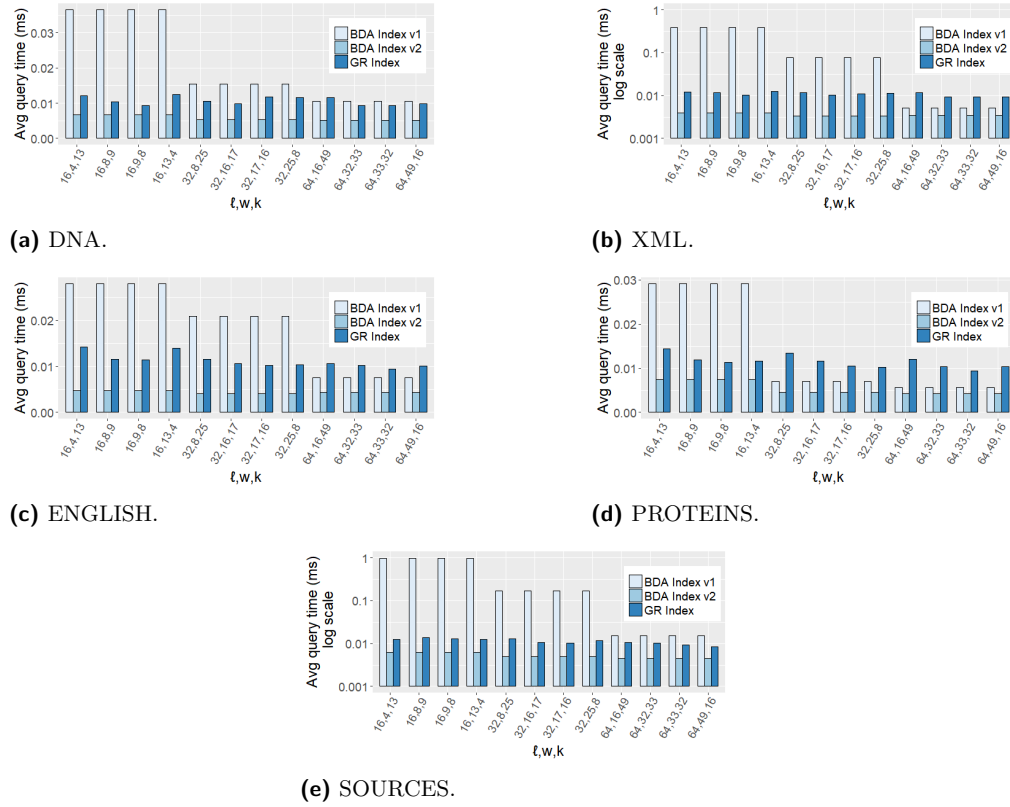

Figure 3 Average query time (ms) vs. w, k for $\ell = w + k - 1$ and the datasets of Table 1.

4. **Flexibility:** Note that one would have to *reconstruct* a (hash-based) index, which indexes the set of (w, k) -minimizers, to increase specificity or sensitivity: increasing k increases the specificity and decreases the sensitivity. Our $\mathcal{I}_\ell(T)$ index, conceptually truncated at string depth k , is essentially an index based on (w, k) -minimizers, which additionally wrap around. We can thus increase *specificity* by considering larger α, β values or increase *sensitivity* by considering smaller α, β values. This effect can be realized *without reconstructing* our $\mathcal{I}_\ell(T)$ index: we just adapt α and β upon querying accordingly.

5 Top- K Similarity Search under Edit Distance

We show how bd-anchors can be applied to speed up similarity search under edit distance. This is a fundamental problem with myriad applications in bioinformatics, databases, data mining, and information retrieval. It has thus been studied extensively in the literature both from a theoretical and a practical point of view [37, 9, 11, 44, 64, 67, 54, 61, 60, 17, 33, 65, 66]. Let \mathcal{D} be a collection of strings called *dictionary*. We focus, in particular, on indexing \mathcal{D} for answering the following type of top- K queries: Given a query string Q and an integer K , return K strings from the dictionary that are closest to Q with respect to edit distance. We follow a typical seed-chain-align approach as used by several bioinformatics applications [1, 16, 45, 46]. The main new ingredients we inject, with respect to this classic approach, is that we use: (1) bd-anchors as seeds; and (2) \mathcal{I}_ℓ to index the dictionary \mathcal{D} , for some integer parameter $\ell > 0$.

Construction. We require an integer parameter $\ell > 0$ defining the order of the bd-anchors. We set $T = S_1 \dots S_{|\mathcal{D}|}$, where $S_i \in \mathcal{D}$, compute the bd-anchors of order ℓ of T , and construct the $\mathcal{I}_\ell(T)$ index (see Section 4) using the bd-anchors.

■ **Figure 4** Density vs. w, k for $\ell = w + k - 1$ and the datasets of Table 1.

Querying. We require two parameters $\tau \geq 0$ and $\delta \geq 0$. The former parameter controls the sensitivity of our filtering step (Step 2 below); and the latter one controls the sensitivity of our verification step (Step 3 below). Both parameters trade accuracy for speed.

1. For each query string Q , we compute the bd-anchors of order ℓ . For every bd-anchor j_Q , we take an arbitrary fragment (e.g. the leftmost) of length ℓ anchored at j_Q as the *seed*. Let this fragment start at position i_Q . This implies a value for α and β , with $\alpha + \beta = \ell + 1$; specifically for $Q[i_Q \dots i_Q + \ell - 1]$ we have $Q[i_Q \dots j_Q] = Q[j_Q - \alpha + 1 \dots j_Q]$ and $Q[j_Q \dots i_Q + \ell - 1] = Q[j_Q \dots j_Q + \beta - 1]$. For every bd-anchor j_Q , we query $\overleftarrow{Q}[j_Q - \alpha + 1 \dots j_Q]$ in $\mathcal{T}_\ell^L(T)$ and $Q[j_Q \dots j_Q + \beta - 1]$ in $\mathcal{T}_\ell^R(T)$ and collect all (α, β) -hits.
2. Let $\tau \geq 0$ be an input parameter and let $L_{Q,S} = (q_1, s_1), \dots, (q_k, s_k)$ be the list of all (α, β) -hits between the queried fragments of string Q and fragments of a string $S \in \mathcal{D}$. If $h < \tau$, we consider string S as not found. The intuition here is that if Q and S are sufficiently close with respect to edit distance, they would have a relatively long $L_{Q,S}$ [16]. If $h \geq \tau$, we sort the elements of $L_{Q,S}$ with respect to their first component. (This comes for free because we process Q from left to right.) We then compute a *longest increasing subsequence* (LIS) in $L_{Q,S}$ with respect to the second component, which *chains* the (α, β) -hits, in $\mathcal{O}(h \log h)$ time [56] per $L_{Q,S}$ list. We use the LIS of $L_{Q,S}$ to *estimate* the *identity score* (total number of matching letters in a fixed alignment) for Q and S , which we denote by $E_{Q,S}$, based on the occurrences of the (α, β) -hits in the LIS.

■ **Figure 5** Peak memory usage (GB) vs. w, k for $\ell = w + k - 1$ and the datasets of Table 1.

- Let $\delta \geq 0$ be an input parameter and let E_K be the K th largest estimated identity score. We extract, as candidates, the ones whose estimated identity score is at least $E_K - \delta$. For every candidate string S , we close the gaps between the occurrences of the (α, β) -hits in the LIS using dynamic programming [43], thus computing an *upper bound* on the edit distance between Q and S (UB score). In particular, closing the gaps consists in summing up the exact edit distance for all pairs of fragments (one from S and one from Q) that lie in between the (α, β) -hits. We return K strings from the list of candidates with the lowest UB score. If $\delta = 0$, we return K strings with the highest $E_{Q,S}$ score.

Index Evaluation. We compared our algorithm, called **BDA Search**, to **Min Search**, the state-of-the-art tool for top- K similarity search under edit distance proposed by Zhang and Zhang in [66]. The main concept used in **Min Search** is the rank of a letter in a string, defined as the size of the neighborhood of the string in which the letter has the minimum hash value. Based on this concept, **Min Search** partitions each string in the dictionary \mathcal{D} into a hierarchy of substrings and then builds an index comprised of a set of hash tables, so that strings having common substrings and thus small edit distance are grouped into the same hash table. To find the top- K closest strings to a query string, **Min Search** partitions the query string based on the ranks of its letters and then traverses the hash tables comprising the index. Thanks to the index and the use of several filtering tricks, **Min Search** is at least one order of magnitude faster with respect to query time than popular alternatives [65, 67, 18].

We implemented two versions of BDA Search: BDA Search v1 which is based on BDA Index v1; and BDA Search v2 which is based on BDA Index v2. For Min Search, we used the C++ implementation from <https://github.com/kedayuge/Search>.

We constructed synthetic datasets, referred to as SYN, in a way that enables us to study the impact of different parameters and efficiently identify the ground truth (top- K closest strings to a query string with respect to edit distance). Specifically, we first generated 50 query strings and then constructed a cluster of K strings around each query string. To generate the query strings, we started from an arbitrary string Q of length $|Q| = 1000$ from a real dataset of protein sequences, used in [66], and generated a string Q' that is at edit distance e from Q , by performing e edit distance operations, each with equal probability. Then, we treated Q' as Q and repeated the process to generate the next query string. To create the clusters, we first added each query string into an initially empty cluster and then added $K - 1$ strings, each at edit distance at most $e' < e$ from the query string. The strings were generated by performing at most e' edit distance operations, each with equal probability. Thus, each cluster contains the top- K closest strings to the query string of the cluster. We used $K \in \{5, 10, 15, 20, 25\}$, $d = \frac{e}{|Q|} \in \{0.1, 0.15, 0.2, 0.25, 0.3\}$, and $d' = \frac{e'}{|Q|} = d - 0.05$. We evaluated query answering accuracy using the F1 score [49], expressed as the harmonic mean of precision and recall¹. For BDA Search, we report results for $\tau = 0$ (full sensitivity during filtering) and $\delta = 0$ (no sensitivity during verification), as it was empirically determined to be a reasonable trade-off between accuracy and speed. For Min Search, we report results using its default parameters from [66].

We plot the F1 scores and average query time in Figures 6 and 7, respectively. All methods achieved almost perfect accuracy, in all tested cases. BDA Search slightly outperformed Min Search (by up to 1.1%), remaining accurate even for large ℓ ; the changes to F1 score for Min Search as ℓ varies are because the underlying method is randomized. However, both versions of BDA Search were *more than one order of magnitude faster* than Min Search on average (over all results of Figure 7), with BDA Search v1 being 2.9 times slower than BDA Search v2 on average, due to the inefficiency of the range tree implementation of CGAL. Furthermore, both versions of BDA Search scaled better with respect to K . For example, the average query time for BDA Search v1 became 2 times larger when K increased from 5 to 25 (on average over ℓ values), while that for Min Search became 5.4 times larger on average. The reason is that verification in Min Search, which increases the accuracy of this method, becomes increasingly expensive as K gets larger. The peak memory usage for these experiments is reported in Figure 8. Although Min Search outperforms BDA Search in terms of memory usage, BDA Search v2 still required a very small amount of memory (less than 1GB). BDA Search v1 required more memory for the reasons mentioned in Section 4.

Discussion. BDA Search outperforms Min Search in accuracy while being more than one order of magnitude faster in query time. These results are very encouraging because the efficiency of BDA Search is entirely due to injecting bd-anchors and not due to any further filtering tricks such as those employed by Min Search. Min Search clearly outperforms BDA Search in memory usage, albeit the memory usage of BDA Search v2 is still quite modest. We defer an experimental evaluation using real datasets to the full version of our work.

¹ Precision is the ratio between the number of returned strings that are among the top- K closest strings to a query string and the number of all returned strings. Recall is the ratio between the number of returned strings that are among the top- K closest strings to a query string and K . Since all tested algorithms return K strings, the F1 score in our experiments is equal to precision and equal to recall.

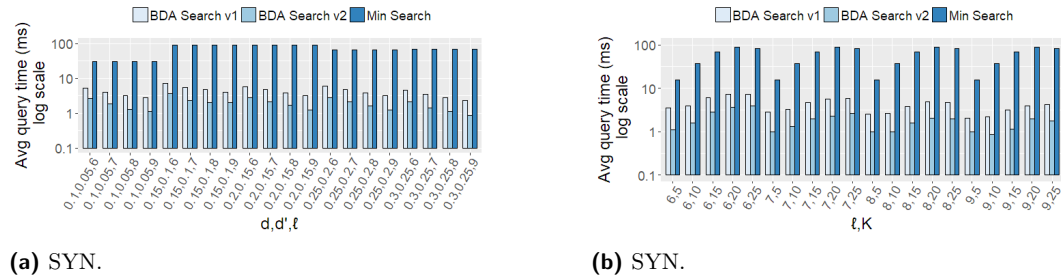

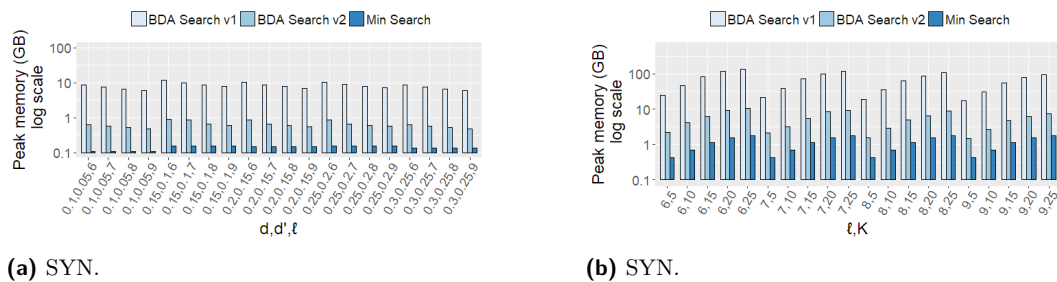

Figure 7 Average query time (ms) vs. (a) d, d', l , for $K = 20$, and (b) l, K , for $d = 0.15$ and $d' = 0.1$.

6 Other Works on Improving Minimizers

Although every sampling mechanism based on minimizers primarily aims at satisfying Properties 1 and 2, different mechanisms employ total orders that lead to substantially different total numbers of selected minimizers. Thus, research on minimizers has focused on determining total orders which lead to the lowest possible density (recall that the density is defined as the number of selected length- k substrings over the length of the input string). In fact, much of the literature focuses on the *average case* [53, 51, 50, 21, 68]; namely, the lowest expected density when the input string is random. In practice, many works use a “random minimizer” where the order is defined by choosing a permutation of all the length- k strings at random (e.g., by using a hash function, such as the Karp-Rabin fingerprints [39], on the length- k strings). Such a randomized mechanism has the benefit of being easy to implement and providing good expected performance in practice.

Minimizers and Universal Hitting Sets. A *universal hitting set* (UHS) is an unavoidable set of length- k strings, i.e., it is a set of length- k strings that “hits” every $(w + k - 1)$ -long fragment of every possible string. The theory of universal hitting sets [53, 50, 41, 69] plays an important role in the current theory for minimizers with low density on average. In particular, if a UHS has small size, it generates minimizers with a provable upper-bound on their density. However, UHSs are less useful in the string-specific case for two reasons [70]: (1) the requirement that a UHS has to hit every $(w + k - 1)$ -long fragment of every possible string is too strong; and (2) UHSs are too large to provide a meaningful upper-bound on the density in the string-specific case. Therefore, since in many practical scenarios the input string is known and does not change frequently, we try to optimize the density for one particular string instead of optimizing the average density over a random input.

■ **Figure 8** Peak memory usage (GB) vs. (a) d, d', ℓ , for $K = 20$, and (b) ℓ, K , for $d = 0.15$ and $d' = 0.1$.

String-Specific Minimizers. In the string-specific case, minimizers sampling mechanisms may employ frequency-based orders [10, 36]. In these orders, length- k strings occurring less frequently in the string compare less than the ones occurring more frequently. The intuition [70] is to obtain a sparse sampling by selecting infrequent length- k strings which should be spread apart in the string. However, there is no theoretical guarantee that a frequency-based order gives low density minimizers (there are many counter-examples). Furthermore, frequency-based orders do not always give minimizers with lower density in practice. For instance, the two-tier classification (very frequent vs. less frequent length- k strings) in the work of [36] outperforms an order that strictly follows frequency of occurrence.

A different approach to constructing string-specific minimizers is to start from a UHS and to remove elements from it, as long as it still hits every $(w + k - 1)$ -long fragment of the input string [15]. Since this approach starts with a UHS that is not related to the string, the improvement in density may not be significant [70]. Additionally, current methods [21] employing this approach are computationally limited to using $k \leq 16$, as the size of the UHS increases exponentially with k . Using such small k values may not be appropriate in some applications.

Other Improvements. When $k \approx w$, minimizers with expected density of $1.67/w + o(1/w)$ on a random string can be constructed using the approach of [68]. Such minimizers have guaranteed expected density less than $2/(w + 1)$ and work for infinitely many w and k . The approach of [68] also does not require the use of expensive heuristics to precompute and store a large set of length- k strings, unlike some methods [53, 15, 21] with low density in practice.

The notion of *polar set*, which can be seen as complementary to that of UHS, was recently introduced in [70]. While a UHS is a set of length- k strings that intersect with every $(w + k - 1)$ -long fragment at least once, a polar set is a set of length- k strings that intersect with any fragment at most once. The construction of a polar set builds upon sets of length- k strings that are sparse in the input string. Thus, the minimizers derived from these polar sets have provably tight bounds on their density. Unfortunately, computing optimal polar sets is NP-hard, as shown in [70]. Thus, the work of [70] also proposed a heuristic for computing feasible “good enough” polar sets. A main disadvantage of this approach is that when each length- k string occurs frequently in the input string, it becomes hard to select many length- k strings without violating the polar set condition.

The Visibility Center of a Simple Polygon

Anurag Murty Naredla ✉

David R. Cheriton School of Computer Science, University of Waterloo, Canada

Abstract

We introduce the *visibility center* of a set of points inside a polygon – a point c_V such that the maximum geodesic distance from c_V to see any point in the set is minimized. For a simple polygon of n vertices and a set of m points inside it, we give an $O((n + m) \log(n + m))$ time algorithm to find the visibility center. We find the visibility center of *all* points in a simple polygon in $O(n \log n)$ time.

Our algorithm reduces the visibility center problem to the problem of finding the geodesic center of a set of half-polygons inside a polygon, which is of independent interest. We give an $O((n + k) \log(n + k))$ time algorithm for this problem, where k is the number of half-polygons.

1 Introduction

Suppose you want to guard a polygon and you have many sensors but only one guard to check on the sensors. The guard must be positioned at a point c_V in the polygon such that when a sensor at any query point u sends an alarm, the guard travels from c_V on a shortest path inside the polygon to *see* point u ; the goal is to minimize the maximum distance the guard must travel. More precisely, we must choose c_V to minimize the maximum, over points u , of the geodesic distance from c_V to a point that sees u . The optimum guard position c_V is called the *visibility center* of the set U of possible query points. See Figure 1. We give an $O((n + m) \log(n + m))$ time algorithm to find the visibility center of a set U of size m in an n -vertex simple polygon. To find the visibility center of *all* points inside a simple polygon, we can restrict our attention to the vertices of the polygon, which yields an $O(n \log n)$ time algorithm.

To the best of our knowledge, the idea of visibility centers is new, though it is a very natural concept that combines two significant branches of computational geometry: visibility problems [12]; and center problems and farthest Voronoi diagrams [5].

There is a long history of finding “center points”, for various definitions of “center”. The most famous of these is Megiddo’s linear time algorithm [20] to find the center of a set of points in the plane (Sylvester’s “smallest circle” problem).

Inside a polygon the relevant distance measure is not the Euclidean distance but rather the shortest path, or *geodesic*, distance. The *geodesic center* of a simple polygon is a point p that minimizes the maximum geodesic distance from p to any point q of the polygon, or equivalently, the maximum geodesic distance from p to any vertex of the polygon. Pollack, Sharir, and Rote [24] gave an $O(n \log n)$ time divide-and-conquer algorithm to find the geodesic center of a polygon. Our algorithm builds on theirs. A more recent algorithm by

■ **Figure 1** (left) Point c_V is the *visibility center* of points $U = \{u_1, \dots, u_6\}$. Starting from c_V , the three points we need to travel (equally) farthest to see are u_1, u_3 and u_5 . The shortest paths (in blue) to see these points must reach the half-polygons bounded by the chords (in red) emanating from the points. (right) Equivalently, c_V is the geodesic center of five half-polygons (each shown as a red boundary chord shaded on one side).

Ahn et al. [1] finds the geodesic center of a polygon in linear time. Another notion of the center of a polygon is the link center, which can be found in $O(n \log n)$ time [10].

Center problems are closely related to farthest Voronoi diagrams, since the center is (modulo degeneracies) a vertex of the corresponding farthest Voronoi diagram. Finding the farthest Voronoi diagram of points in the plane takes $\Theta(n \log n)$ time – thus is it strictly harder to find the farthest Voronoi diagram than to find the center. However, working inside a simple polygon helps for farthest Voronoi diagrams: the farthest geodesic Voronoi diagram of the vertices of a polygon can be found in time $O(n \log \log n)$ [23]. Generalizing the two scenarios (points in the plane, and polygon vertices), yields the problem of finding the farthest Voronoi diagram of m points in a polygon, which was first solved by Aronov et al. [3] with run-time $O((n+m) \log(n+m))$, and improved in a sequence of papers [23, 6, 22], with the current best run-time of $O(n + m \log m)$ [27].

Turning to visibility problems in a polygon, there are algorithms for the “quickest visibility problem” – to find the shortest path from point s to see point q , and to solve the query version where s is fixed and q is a query point [2, 26]. For a simple polygon [2], the preprocessing time and space are $O(n)$ and the query time is $O(\log n)$. We did not find these results useful in our algorithm to find the visibility center c_V , but they are useful afterwards to find the actual shortest path from c_V to see a query point.

A more basic version of our problem is to find, if there is one, a point that sees all points in U . The set of such points is the *kernel* of U . When U is the set of vertices, the kernel can be found in linear time [19]. For a general set U , Ke and O’Rourke [18] gave an $O(n + m \log(n+m))$ time algorithm to compute the kernel, and we use some of their results in our algorithm.

Another problem somewhat similar to ours is the watchman problem [9, 11] – to find a minimum length tour from which a single guard can see the whole polygon. Our first step is similar in flavour to the first step for the watchman problem, namely, to replace the condition of “seeing” everything by a condition of visiting certain “essential chords”.

Our Results

The *distance to visibility* from a point x to point u in P , denoted $d_V(x, u)$ is the minimum distance in P from x to a point y such that y sees u . For a set of points U in P , the *visibility*

radius of x with respect to U is $r_V(x, U) := \max\{d_V(x, u) : u \in U\}$. The *visibility center* c_V of U is a point x that minimizes $r_V(x, U)$. Our main result is:

► **Theorem 1.** *There is an algorithm to find the visibility center of a point set U in a simple n -vertex polygon P with run-time $O((n + m) \log(n + m))$ where m is the size of U .*

The key to our algorithm is to reformulate the visibility center problem in terms of distances to certain *half-polygons* inside the polygon. We illustrate the idea by means of the example in Figure 1 where the visibility center of the 6-element point set U is the *geodesic center* of a set of five half-polygons.

More generally, we will reduce the problem of finding the visibility center to the problem of finding a geodesic center of a linear number of half-polygons. The input to this problem is a set \mathcal{H} of k half-polygons (see Section 2 for precise definitions) and the goal is to find a *geodesic center* c that minimizes the maximum distance from c to a half-polygon. More precisely, the *geodesic radius* from a point x to \mathcal{H} is $r(x, \mathcal{H}) := \max\{d(x, H) : H \in \mathcal{H}\}$, and the *geodesic center* c of \mathcal{H} is a point x that minimizes $r(x, \mathcal{H})$. Our second main result is:

► **Theorem 2.** *There is an algorithm to find the geodesic center of a set \mathcal{H} of half-polygons in a simple n -vertex polygon P with run-time $O((n + k) \log(n + k))$ where k is the size of \mathcal{H} .*

Our algorithm extends the divide-and-conquer approach that Pollack et al. [24] used to compute the geodesic center of the vertices of a simple polygon.

Our main motivation for finding the geodesic center of half-polygons is to find the visibility center, but the geodesic center of half-polygons is of independent interest. Euclidean problems of a similar flavour are to find the center (or the farthest Voronoi diagram) of line segments or convex polygons in the plane [7, 17]. These problems are less well-studied than the case of point sites (e.g., see [4] for remarks on this). The literature for geodesic centers is even more sparse, focusing almost exclusively on geodesic centers of points in a polygon. It is thus interesting that the center of half-polygons inside a polygon can be found efficiently. As a special case, we can find the geodesic center of the edges of a simple polygon in $O(n \log n)$ time.

The reduction from the visibility center problem to the geodesic center of half-polygons is in Section 3. The run time is $O((n + m) \log(n + m))$. The algorithm that proves Theorem 2 is in Section 4. Together these prove Theorem 1.

2 Preliminaries

We add a few more basic definitions to augment the main definitions given above. We work with a simple polygon P of n vertices whose boundary ∂P is directed clockwise. A *chord* of P is a line segment inside P that intersects ∂P only at its two endpoints. Any chord divides P into two *half-polygons*. A half-polygon is specified by its chord (p, q) with the convention that the half-polygon contains the path clockwise from p to q .

The *geodesic distance* $d(x, y)$ (or simply, *distance*) between two points x and y in P is the length of the shortest path $\pi(x, y)$ in P from x to y . For half-polygon H , the *geodesic distance* $d(x, H)$ is the minimum distance from x to a point in H .

Points x and y in P are *visible* (x “sees” y) if the segment xy lies inside P . The *distance to visibility* from x to u , denoted $d_V(x, u)$ is the minimum distance from x to a point y such that y sees u . If x sees u , then this distance is 0, and otherwise it is the distance from x to the half-polygon defined as follows. Let r be the last reflex vertex on the shortest path from x to u . Extend the ray \vec{ur} from r until it hits the polygon boundary ∂P at a point p to

obtain a chord rp (which is an edge of the *visibility polygon* of u). Of the two half-polygons defined by rp , let $H(u, r)$ be the one that contains u . See Figure 1.

► **Observation 3.** $d_V(x, u) = d(x, H(u, r))$.

At their core, our methods depend on convexity properties of the distance functions. A basic result is the following which is proved in the full version of our paper.

▷ **Claim 4.** The set of points x with $r_V(x, U) \leq k$ [or with $r(x, \mathcal{H}) \leq k$] is *geodesically convex*, i.e., if two points x, y lie in the set then so does $\pi(x, y)$.

More detail on convexity properties can be found in the long version of our paper. These convexity properties allow us to prove that the visibility center of a set of points U and the geodesic center of a set of half-polygons \mathcal{H} are unique except in very special cases. We explain this for the geodesic center of half-polygons, but the same argument works for the visibility center (or, alternatively, one can use the reduction from the visibility center to the geodesic center in Section 3). First of all, if the geodesic radius is 0 then any point in the intersection of the half-polygons is a geodesic center. So we assume that the geodesic radius r is positive. Then we have the following (proved in the long version):

▷ **Claim 5.** There is a set $\mathcal{H}' \subseteq \mathcal{H}$ of two or three half-polygons such that the set of geodesic centers of \mathcal{H} is equal to the set of geodesic centers of \mathcal{H}' and furthermore

1. if \mathcal{H}' has size 3 then the geodesic center is unique (see Figure 1)
2. if \mathcal{H}' has size 2 then either the geodesic center is unique or the two half-polygons of \mathcal{H}' have chords that are parallel and the geodesic center consists of a line segment parallel to them and midway between them.

3 Reducing the Visibility Center to the Center of Half-Polygons

In this section we reduce the problem of finding the visibility center of a set of points U in a polygon P to the problem of finding the geodesic center of a linear number of “essential” half-polygons \mathcal{H} , which is solved in Section 4.

By Observation 3 (and see Figure 1) the visibility center of U is the geodesic center of the set of $O(mn)$ half-polygons $H(u, r)$ where $u \in U$, r is a reflex vertex of P that sees u , and $H(u, r)$ is the half-polygon containing u and bounded by the chord that extends \vec{ur} from r until it hits ∂P at a point t . Note that finding t is a ray shooting problem and costs $O(\log n)$ time after an $O(n)$ time preprocessing step [16].

However, this set of half-polygons is too large. We will find a set \mathcal{H} of $O(n)$ “essential” half-polygons that suffice, i.e., such that the visibility center of U is the geodesic center of the half polygons of \mathcal{H} . In fact, we give two possible sets of essential half-polygons, $\mathcal{H}_{\text{reflex}}$ and $\mathcal{H}_{\text{hull}}$, where the latter set can be found more efficiently. The bottleneck is still the algorithm for geodesic center of half-polygons, but it still seems worthwhile to optimize the reduction.

We first observe that any half-polygon that contains another one is redundant. For example, in Figure 1 $H(u_4, r_4)$ is redundant because it contains $H(u_5, r_4)$. At each reflex vertex r of P , there are at most two minimal half-polygons $H(u, r)$. Define $\mathcal{H}_{\text{reflex}}$ to be this set of minimal half-polygons. Note that $\mathcal{H}_{\text{reflex}}$ has size $O(n_r)$ where n_r is the number of reflex vertices of P .

Observe that for the case of finding the visibility center of *all* points of P , $\mathcal{H}_{\text{reflex}}$ consists of the half-polygons $H(v, r)$ where (v, r) is an edge of P , so $\mathcal{H}_{\text{reflex}}$ can be found in time $O(n + n_r \log n)$.

For a point set U , the set $\mathcal{H}_{\text{reflex}}$ was also used by Ke and O'Rourke [18] in their algorithm to compute the kernel of point set U in polygon P . (Recall from the Introduction that the kernel of U is the set of points in P that see all points of U .) They gave a sweep line algorithm ("Algorithm 2") to find $\mathcal{H}_{\text{reflex}}$ in time $O((n+m)\log(n+m))$. To summarize:

► **Proposition 6.** *The geodesic center of $\mathcal{H}_{\text{reflex}}$ is the visibility center of U . Furthermore, $\mathcal{H}_{\text{reflex}}$ can be found in time $O((n+m)\log(n+m))$.*

In the remainder of this section we present a second approach using $\mathcal{H}_{\text{hull}}$ that eliminates the $O(n\log n)$ term. This does not change the runtime to find the visibility center, but it means that improving the algorithm to find the geodesic center of half-polygons will automatically improve the visibility center algorithm. The idea is that $\mathcal{H}_{\text{reflex}}$ is wasteful in that a single point $u \in U$ can give rise to n_r half-polygons. Note that we really only need three half-polygons in an essential set, though the trouble is to find them!

We first eliminate the case where the kernel of U is non-empty (i.e., $r_V = 0$) by running the $O(n+m\log(n+m))$ time kernel-finding algorithm of Ke and O'Rourke [18]. Next we find $\mathcal{H}_{\text{hull}}$ in two steps. First make a subset \mathcal{H}_0 as follows. Construct R , the geodesic convex hull of U in P in time $O(n+m\log(m+n))$ [14, 25]. For each edge (u, r) of R where $u \in U$ and r is a reflex vertex of P , put $H(u, r)$ into \mathcal{H}_0 . Note that \mathcal{H}_0 has size $O(\min\{n_r, m\})$ so ray shooting to find the endpoints of the chords $H(u, r)$ takes time $O(n + \min\{n_r, m\}\log n)$. Unfortunately, as shown in Figure 2, \mathcal{H}_0 can miss an essential half-polygon.

Next, construct a geodesic center c_0 of \mathcal{H}_0 using the algorithm of Section 4. (Note that the geodesic center can be non-unique and in such cases c_0 denotes any one point from the set of geodesic centers.) Then repeat the above step for $U \cup \{c_0\}$, more precisely, construct R' , the geodesic convex hull of $U \cup \{c_0\}$ in P and for each edge (u, r) of R' where $u \in U$ and r is a reflex vertex of P , add $H(u, r)$ to \mathcal{H}_0 . This defines $\mathcal{H}_{\text{hull}}$. Again, $\mathcal{H}_{\text{hull}}$ has size $O(\min\{n_r, m\})$ and ray shooting costs $O(n + \min\{n_r, m\}\log n)$.

■ **Figure 2** The geodesic convex hull of $U = \{u_1, \dots, u_5\}$ is shaded grey. \mathcal{H}_0 consists of the two half-polygons $H(u_2, r_2)$ and $H(u_3, r_3)$ (with solid red chords), but misses $H(u_1, r_1)$, which is essential for the visibility center c_V . The point c_0 denotes a geodesic center of \mathcal{H}_0 .

► **Theorem 7.** *Suppose the kernel of U is empty. Then the geodesic center of $\mathcal{H}_{\text{hull}}$ is the visibility center of U . Furthermore $\mathcal{H}_{\text{hull}}$ can be found in time $O(n+m\log(n+m))$ plus the time to find the geodesic center of $O(\min\{n_r, m\})$ half-polygons.*

Proof. The run-time was analyzed above. Consider the visibility center c_V . By assumption, $r_V > 0$. We consider the half-polygons $H(u, r) \in \mathcal{H}_{\text{reflex}}$ such that $r_V = d(c_V, H(u, r))$.

By Claim 5 either there are three of these half-polygons, H_1 , H_2 and H_3 , that uniquely determine c_V , or there are two, H_1 and H_2 , that determine c_V . Then c_V is the geodesic center of H_i $i = 1, 2, 3$ or $i = 1, 2$ depending on which case we are in. Let $H_i = H(u_i, r_i)$.

If all the H_i 's are in \mathcal{H}_0 , we are done. We will show that at least two are in \mathcal{H}_0 and the third one (if it exists) is “caught” by c_0 . See Figure 2. Let h_i be the chord defining H_i and let \overline{H}_i be the other half-polygon determined by h_i .

▷ **Claim 8.** If U contains a point in \overline{H}_i then (u_i, r_i) is an edge of R so $H_i \in \mathcal{H}_0$.

Proof. Let u be a point in \overline{H}_i . Observe that $\pi(u_i, u)$ contains the segment $u_i r_i$. Thus r_i is a vertex of R . Furthermore $u_i r_i$ is an edge of R . (Note that H_i is extreme at r since we picked it from $\mathcal{H}_{\text{reflex}}$.) Thus H_i is in \mathcal{H}_0 . ◁

▷ **Claim 9.** At least two of the H_i 's lie in \mathcal{H}_0 .

Proof. First observe that if two of the half-polygons are disjoint, say H_i and H_j , then they lie in \mathcal{H}_0 , because $u_i \in H_i$ implies $u_i \in \overline{H}_j$ so by Claim 8, $H_i \in \mathcal{H}_0$, and symmetrically, $H_j \in \mathcal{H}_0$.

We separate the proof into cases depending on the number of H_i 's. If there are two then they must be disjoint otherwise a point in their intersection would be a visibility center with visibility radius $r_V = 0$. Then by the above observation, they are both in \mathcal{H}_0 .

It remains to consider the case of three half-polygons. If two are disjoint, we are done, so suppose each pair H_i, H_j intersects. Then the three chords h_i form a triangle. Furthermore, since $\bigcap \overline{H}_i$ is non-empty (it contains c_V), the inside of the triangle is $\bigcap \overline{H}_i$. Now suppose $H_1 \notin \mathcal{H}_0$. Then by Claim 8, $u_2, u_3 \in H_1$. This implies (see Figure 2) that $u_2 \in \overline{H}_3$ and $u_3 \in \overline{H}_2$, so by Claim 8, H_2 and H_3 are in \mathcal{H}_0 . ◁

We now complete the proof of the theorem. We only need to consider the case of three H_i 's, where one of them, say H_1 , is not in \mathcal{H}_0 . Our goal is to show that c_0 , the geodesic center of \mathcal{H}_0 , lies in \overline{H}_1 and thus H_1 is in $\mathcal{H}_{\text{hull}}$. Let $X = \{x \in P : d(x, H_2) \leq r_V \text{ and } d(x, H_3) \leq r_V\}$. Observe that $c_0 \in X$ (because the radius is non-increasing as we eliminate half-polygons). Now, c_V is the unique point within distance r_V of the half-polygons H_1, H_2 and H_3 . If $c_0 \in H_1$, then c_0 's distance to H_1 would be 0 which contradicts the uniqueness property of c_V . Thus $c_0 \in \overline{H}_1$. By the same reasoning as in Claim 8, this implies that $u_1 r_1$ is an edge of R' , the geodesic convex hull of $U \cup \{c_0\}$. Thus H_1 is in $\mathcal{H}_{\text{hull}}$ by definition of $\mathcal{H}_{\text{hull}}$. ◀

4 The Geodesic Center of Half-Polygons

In this section, we give an algorithm to find the geodesic center of a set \mathcal{H} of k half-polygons inside an n -vertex polygon P . We preprocess by sorting the half-polygons in cyclic order of their first endpoints around ∂P in time $O(k \log k)$. We assume that no half-polygon in \mathcal{H} contains another – any non-minimal half-polygon is irrelevant and can be discarded. Note that the minimal half-polygons can be found in linear time from the sorted order.

We follow the approach that Pollack et al. [24] used to find the geodesic center of the vertices of a polygon. Many steps of their algorithm rely, in turn, on search algorithms of Megiddo's [20].

The main ingredient of the algorithm is a linear time *chord oracle* that, given a chord $K = ab$ of the polygon, finds the *relative geodesic center*, c_K (the optimum center point restricted to points on the chord), and tells us which side of the chord contains the center. We must completely redo the chord oracle in order to handle paths to half-polygons instead of vertices, but the main steps are the same. Our chord oracle runs in time $O(n + k)$. Pollack

et al.'s chord oracle was used as a black box in subsequent faster algorithms [1], so we imagine that our version will be an ingredient in any faster algorithm for the geodesic center of half-polygons.

Using the chord oracle, we again follow the approach of Pollack et al. to find the geodesic center. The total run time is $O((n + k) \log(n + k))$.

We give a road-map for the remainder of this section, listing the main steps, which are the same as those of Pollack et al., and highlighting the parts that we must rework.

§ 4.1 A Linear Time Chord Oracle

1. Test a candidate center point. Given a point x on the chord $K = ab$, is the relative geodesic center c_K to the left or right of x ? Is the geodesic center c to the left or right of chord K ?
2. Find shortest paths from a and from b to all half-polygons. The details of this step are novel, because we need shortest paths to half-polygons rather than vertices.
3. Find a linear number of simple functions defined on K whose upper envelope is the geodesic radius function. We must redo this from the ground up.
4. Find the relative center on K (the point that minimizes the geodesic radius function) using Megiddo's technique.

§ 4.2 Finding the Geodesic Center of Half-Polygons

1. Use the chord oracle to find a region of P that contains the center and such that for any half-polygon $H \in \mathcal{H}$, all geodesic paths from the region to H are combinatorially the same. We give a more modern version of this step using epsilon nets.
2. Solve the resulting Euclidean “intersection radius problem” – to find a smallest disk that contains given disks and intersects given lines. This is new because of the condition about intersecting given lines.

4.1 A Linear Time Chord Oracle

In this section we give a linear time chord oracle. Given a chord $K = ab$ the chord oracle tells us whether the geodesic center of \mathcal{H} lies to the left, to the right, or on the chord K . It does this by first finding the relative geodesic center $c_K = \operatorname{argmin}\{r(x, \mathcal{H}) : x \in K\}$, together with the half-polygons that are farthest from c_K . From this information, we can identify which side of K contains the geodesic center c in the same way as Pollack et al. by testing the vectors of the first segments of the shortest paths from c_K to its furthest half-polygons. This test is described in Subsection 4.1.1.

The chord oracle thus reduces to the problem of finding the relative geodesic center and its farthest half-polygons. The main idea here is to capture the geodesic radius function along the chord (i.e., the function $r(x, \mathcal{H})$ for $x \in K$) as the upper envelope of a linear number of simple functions defined on overlapping subintervals of K . In order to find the simple functions (Section 4.1.3) we first compute shortest paths from a and from b to all the half-polygons (Section 4.1.2). Finally we apply Megiddo's techniques (Section 4.1.4) to find the point c_K on K that minimizes the geodesic radius function.

4.1.1 Testing a Candidate Center Point

Given the relative geodesic center c_K on chord K and the first edges of the paths from c_K to its farthest half-polygons, we can test in constant time whether the geodesic center is equal to c_K or lies to the left or the right of K . We can also test, given a point x on K and the

first edges of the paths to its farthest half-polygons, whether c_K is equal to x or lies to the left or right of x . We illustrate the tests in Figure 3, and defer a more rigorous explanation to the long version of our paper.

■ **Figure 3** Points x_i on chord $K = ab$ with directions of paths to farthest half-polygons in dashed blue and the direction for improvement in dotted red. (a) x_1 is not a relative center. x_2 is a relative center but not the true geodesic center. (b,c) x_3 and x_4 are geodesic centers.

4.1.2 Shortest Paths to Half-Polygons

In this section we give a linear time algorithm to find the shortest path tree from point a on the polygon boundary to all the half-polygons \mathcal{H} . Recall that each half-polygon is specified by an ordered pair of endpoints on ∂P , and the half-polygons are sorted in clockwise cyclic order by their first endpoints. From this, we identify the half-polygons that contain a , and we discard them – their distance from a is 0. Let $H_1, \dots, H_{k'}$ be the remaining half-polygons where H_i is bounded by endpoints $p_i q_i$, and the H_i 's are sorted by p_i , starting at a .

The idea is to first find the shortest path map T_a from a to the set consisting of the polygon vertices and the points p_i and q_i . Recall that the shortest path map is an augmentation of the shortest path tree that partitions the polygon into triangular regions in which the shortest path from a is combinatorially the same (see Figure 4). The shortest path map can be found in linear time [13]. Note that T_a is embedded in the plane (none of its edges cross) and the ordering of its leaves matches their ordering on ∂P . Our algorithm will traverse T_a in depth-first order, and visit the triangular regions along the way.

Our plan is to augment T_a to a shortest path tree \bar{T}_a that includes the shortest paths from a to each half-polygon H_i . Note that \bar{T}_a is again an embedded ordered tree. We can find $\pi(a, H_i)$ by examining the regions of the shortest path map intersected by $p_i q_i$. These lie in the *funnel* between the shortest paths $\pi(a, p_i)$ and $\pi(a, q_i)$. Note that edges of the shortest path map T_a may cross the chord $p_i q_i$. Also, the funnels for different half-polygons may overlap. The key to making the search efficient is the following lemma:

► **Lemma 10.** *The ordering $H_1, H_2, \dots, H_{k'}$ matches the ordering of the paths $\pi(a, H_i)$ in the tree \bar{T}_a .*

Proof. Consider two half-polygons $H_i = p_i q_i$ and $H_j = p_j q_j$, with $i < j$. We prove that $\pi(a, H_i)$ comes before $\pi(a, H_j)$ in \bar{T}_a . If H_i and H_j are disjoint, the result is immediate since the corresponding funnels do not overlap. Otherwise (because neither half-polygon is contained in the other) $p_i q_i$ and $p_j q_j$ must intersect, say at point x . See Figure 4. Let t_i and t_j be the terminal points of the paths $\pi(a, H_i)$ and $\pi(a, H_j)$, respectively. If t_i lies in $p_i x$ and t_j lies in $x q_j$ then the result follows since t_i and t_j lie in order on the boundary of the truncated polygon formed by removing H_i and H_j . So suppose that t_j lies in $p_j x$ (the other case is symmetric). Then $\pi(a, t_j)$ crosses $p_i q_i$ at a point z in $p_i x$. From z to t_j the path $\pi(a, t_j)$ lies inside the cone with apex x bounded by the rays from x through z and from x through t_j . Within that cone, the path only turns left. The angle α_j at t_j is $\geq 90^\circ$ (it may be $> 90^\circ$ if $t_j = p_j$), which implies that the angle α_i at z is $> 90^\circ$. Therefore t_i lies to the left of z , as required. ◀

■ **Figure 4** The shortest path map T_a (thin blue) and the augmentation (dashed red) to include shortest paths to the two half-polygons bounded by chords $p_i q_i$ and $p_j q_j$ (thick red).

Based on the Lemma, the algorithm traverses the regions of the shortest path map T_a in depth first search order, and traverses the half-polygons H_i in order $i = 1, 2, \dots, k'$. It is easy to test if one region contains the shortest path to H_i (either to p_i , or to q_i , or reaching an internal point of $p_i q_i$ at a right angle); if it does, we increment i , and otherwise we proceed to the next region. The total time is $O(n + k)$.

4.1.3 Functions to Capture the Distance to Farthest Half-Polygons

In this section we give a linear time algorithm to find a linear number of simple functions defined on the chord $K = ab$ whose upper envelope is the geodesic radius function $r(x, \mathcal{H})$ for $x \in K$. Specifically, we use the shortest path trees \bar{T}_a and \bar{T}_b constructed in the previous section to build a set of $O(n + k)$ pairs f, I where:

- I is a subinterval of K and f is a function defined on domain I ,
- each function has the form $f(x) = d_2(x, s) + \kappa$ where κ is a constant, d_2 is Euclidean distance, and s is a point or a line,
- for any point $x \in K$ the maximum of $f(x)$ over intervals I containing x is equal to $r(x, \mathcal{H})$.

For intuition, see Figure 5a, which shows several intervals and their associated functions. Note that we deal separately with the two pieces of the polygon on each side of K . There is an obvious set of $O(nk)$ pairs f, I with the above properties, one for each $H \in \mathcal{H}$ and $v \in P$, but we want a set of linear size.

The crucial property is that there are a limited number of farthest half-polygons associated with each vertex, and we can restrict our attention (mostly) to longest paths in the trees \bar{T}_a and \bar{T}_b . In particular, consider a point $x \in K$, a half-polygon H , and the shortest path $\pi(x, H)$. Suppose $\pi(x, H)$ has at least two edges, say $\pi(x, H) = x, u, v, \dots, t$, where t is the terminal point on H . If $\pi(x, H)$ turns left at u , then the part of the path from u to t is part of the tree \bar{T}_a , and symmetrically for right turns and \bar{T}_b . See Figure 5b. Furthermore, if H is a farthest half-polygon from x , then we can show (in the full version) that the part of the path from v to t is the longest path in \bar{T}_a descending from v to any half-polygon. Note that using longest paths from u rather than v is not correct – see Figure 5b.

For any node u in \bar{T}_a let $\ell_a(u)$ be the maximum length of a path in \bar{T}_a descending from u to a node representing a terminal point on some half-polygon. Define $\ell_b(u)$ similarly. We can compute these functions in linear time in leaf-to-root order. In the situation described above, where H is a farthest half-polygon from x and the path $\pi(x, H) = x, u, v, \dots, t$ turns left at u , we have $d(x, H) = |xu| + |uv| + \ell_a(v)$, which is a simple function of the desired form.

The algorithm will output these functions for all pairs u, v where the following conditions hold: u is a vertex visible from a point on the chord ab (equivalently, u has different parents

■ **Figure 5** (a) An illustration of functions and intervals. For x in interval I_1 , $d(x, H_1) = d_2(x, u) + \kappa_1$. For x in I_2 , $d(x, H_1) = d_2(x, v) + \kappa_2$. For x in I_3 , $d(x, H_2) = d_2(x, H_2)$. (b) From point x the farthest half-polygon is H_1 via the path x, u, v, t_1 . This matches the longest path in \bar{T}_a descending from v (which goes to H_1) but does not match the longest path descending from u (which goes to H_2).

in \bar{T}_a and \bar{T}_b); v is a child of u in one of the trees; and x lies in an appropriate interval on ab such that u, v can be the start of a geodesic path from x . We deal separately with shortest paths that go from a point $x \in ab$ to a half-polygon without going through any vertices. Observe that the number of such functions is $O(n + k)$.

We defer further details of the algorithm to the long version of our paper. Besides enhancing the method of Pollack et al. [24] to deal with half-polygons, our aim is to give a clearer and easier-to-verify presentation.

4.1.4 Finding the Relative Geodesic Center on a Chord

The last step of the chord oracle is exactly the same as in Pollack et al. [24]. Given the set of $O(n + k)$ simple convex functions whose upper envelope is the geodesic radius function on chord K (from Section 4.1.3), and given the test of whether the relative center is left/right of a point on K (from Section 4.1.1) we want to find the relative center, c_K , that minimizes the radius function. Pollack et al. use a technique of Megiddo's to do this in $O(n + k)$ time. The idea is to pair up the functions, find the intersection and domain end-points of each pair, and test medians of those in order to eliminate a constant fraction of the functions in each round. Further details are in the long version of this paper. Finally, to find the paths from the relative center c_K to its farthest half-polygons, use the linear time shortest path algorithm (Section 4.1.2) on each side of K .

4.2 Finding the Geodesic Center of Half-Polygons

In this section we show how to use the $O(n + k)$ time chord oracle from Section 4.1 to find the geodesic center of the k half-polygons in $O((n + k) \log(n + k))$ time. The basic structure of the algorithm is the same as that of Pollack et al. [24].

In the first step we use the chord oracle to restrict the search for the geodesic center to a small region where the problem reduces to a Euclidean “intersection radius problem”. In the second step we solve the resulting problem, which involves some new ingredients to handle our case of half-polygons. Each step takes $O((n + k) \log(n + k))$ time.

4.2.1 Finding a Region that Contains the Geodesic Center

Triangulate P in linear time [8]. Run the chord oracle on a chord of the triangulation that splits the polygon into balanced pieces and recurse on the appropriate subpolygon. In $O(\log n)$ iterations, we narrow our search down to one triangle T^* of the triangulation. This step takes $O((n+k)\log n)$ time.

Next, we refine T^* to a region R that contains the center and such that R is *homogeneous*, meaning that for any $H \in \mathcal{H}$ the shortest paths from points in R to H have the same combinatorial structure (the same sequence of polygon vertices along the path).

The idea is to subdivide T^* by $O(n+k)$ lines so that each cell in the resulting line arrangement is homogeneous, and then to find the cell containing the center. Construct the shortest path trees to \mathcal{H} from each of the three corners of triangle $T^* = (a^*, b^*, c^*)$ using the algorithm of Section 4.1.2. For each edge (u, v) of each tree, add the line through uv if it intersects T^* . (In fact, we do not need all these lines. The situation is similar to that shown in Figure 5a, with a^*, b^* in place of a, b . We need the dashed lines shown in the figure. In particular, it suffices to use tree edges (u, v) such that u is visible from an edge of T^* .)

We add three more lines for each half-polygon $H \in \mathcal{H}$, specifically, the chord h that defines H , and the two lines perpendicular to h through the endpoints of h .

The result is a set of $O(n+k)$ lines that we obtain in time $O(n+k)$. It is easy to prove that the resulting line arrangement has homogeneous regions.

All that remains is to find the cell of the arrangement that contains the geodesic center. It is simpler to state the algorithm in terms of ϵ -nets instead of the rather involved description of Megiddo's technique used by Pollack et al. [24]. Informally, to find a homogeneous region, we will look at a range space on ground set L whose ranges consist of the subsets of L that intersect some triangle. Such a range space can be shown to have constant sized ϵ -nets [15]. By using the $O(n+k)$ time chord oracle a constant number of times (on a constant sized ϵ -net) we can restrict the search space to a region that intersects only a fraction of the original lines. Repeating this step for $O(\log(n+k))$ times, we arrive at a region R with the required properties. The details are deferred to the long version due to space constraints. The total runtime for this step is $O((n+k)\log(n+k))$.

4.2.2 Solving an Unconstrained Problem

At this point, we know that the polygonal region R contains a geodesic center of the set \mathcal{H} of half-polygons in P . Furthermore, R is homogeneous. We can pick a point p in R and find the shortest path tree from p to all half-polygons. If $\pi(p, H)$ reaches an internal point of the chord h defining H then $d(x, H) = d_2(x, h)$ for all $x \in R$. And if the first segment of $\pi(x, H)$ reaches a vertex u , then $d(x, H) = d_2(x, u) + \kappa$ for all $x \in R$, where κ is a constant. Our goal is to find the point $x \in R$ that minimizes the maximum over $H \in \mathcal{H}$ of $d(x, H)$. Since this point must lie in the region R (a guarantee we have from the earlier steps), we can completely disregard the underlying polygon P in solving the problem.

In the Euclidean plane, the problem may be reinterpreted in a geometric manner. We wish to find the circle of smallest radius that *contains* $O(n)$ disks and *intersects* $O(k)$ lines. The disk constraints in the new interpretation correspond to half-polygons H where $d(x, H) = d_2(x, u) + \kappa$ – the disk is centered at u with radius κ . The line constraints correspond to half-polygons H where $d(x, H) = d_2(x, h)$.

This is a combination of problems referred to as the spanning circle problem [21] or the intersection radius problem [7] in the literature. We will call it the *intersection radius*

problem for disks and lines, although the name is not entirely accurate. In the long version of this paper we prove:

► **Lemma 11.** *The intersection radius problem for disks and lines can be solved in linear time.*

We outline the method. The problem for disks alone was solved by Megiddo [21] using an ingenious idea. The two-dimensional problem is modified to a problem in three dimensions and the constraints modified in such a way that the bisector between the constraints for two disks becomes a plane in three dimensions. Thereafter, techniques from linear-time algorithms for linear programming are used to prune away disks that do not define the final answer [20]. The prune-and-search technique prunes away a constant fraction of those disks in linear time and repeating the process reduces the number of disks to some constant number, after which a brute force method may be employed.

To extend this to handle our line constraints, we add constraints that ensure that the distances to the lines are less than the radius of the final disk. The bisectors between two lines are an angle bisector pair. These bisectors become vertical planes in the transformed three dimensional version of the problem. We thus have a set of planes in three dimensions that are bisectors between pairs of lines or pairs of disks. Using prune-and-search in two phases per iteration and a few other ideas ([7]), we modify Megiddo's technique for disks to solve our problem in linear time.

5 Conclusions

We introduced the notion of the visibility center of a set of points in a polygon and gave an algorithm with run time $O((n + m) \log(n + m))$ to find the visibility center of m points in an n -vertex polygon. To do this, we gave an algorithm to find the geodesic center of a given set of half-polygons inside a polygon, a problem of independent interest. We conclude with some open questions.

Can the visibility center of a simple polygon be found more efficiently? Note that the geodesic center of the vertices of a simple polygon can be found in linear time [1]. Our current method involves ray tracing and sorting, which are serious barriers. A more reasonable goal is to find the visibility center of m points in a polygon in time $O(n + m \log m)$.

Is there a more efficient algorithm to find the geodesic center of (sorted) half-polygons? In forthcoming work we give a linear time algorithm for the special case of finding the geodesic center of the *edges* of a polygon (this is the case where the half-polygons hug the edges).

How hard is it to find the farthest visibility Voronoi diagram of a polygon? Finally, what about the 2-visibility center of a polygon, where we can deploy two guards instead of one?

Extension of Additive Valuations to General Valuations on the Existence of EFX

Ryoga Mahara

Research Institute for Mathematical Sciences, Kyoto University, Japan

Abstract

Envy-freeness is one of the most widely studied notions in fair division. Since envy-free allocations do not always exist when items are indivisible, several relaxations have been considered. Among them, possibly the most compelling concept is envy-freeness up to any item (EFX). We study the existence of EFX allocations for general valuations. The existence of EFX allocations is a major open problem. For general valuations, it is known that an EFX allocation always exists (i) when $n = 2$ or (ii) when all agents have identical valuations, where n is the number of agents. It is also known that an EFX allocation always exists when one can leave at most $n - 1$ items unallocated.

We develop new techniques and extend some results of additive valuations to general valuations on the existence of EFX allocations. We show that an EFX allocation always exists (i) when all agents have one of two general valuations or (ii) when the number of items is at most $n + 3$. We also show that an EFX allocation always exists when one can leave at most $n - 2$ items unallocated. In addition to the positive results, we construct an instance with $n = 3$ in which an existing approach does not work as it is.

1 Introduction

Fair division of items among competing agents is a fundamental and well-studied problem in Economics and Computer Science. We are given a set M of m items and a set N of n agents with individual preferences. Each agent i has a valuation function $v_i : 2^M \rightarrow \mathbb{R}_{\geq 0}$ for each subset of items. The goal is to distribute items among n agents in a *fair* and *efficient* manner. In this paper, we consider the *indivisible* setting: an item cannot be split among multiple agents. Let an allocation $X = (X_1, X_2, \dots, X_n)$ denote a partition of M into n bundles such that X_i is allocated to agent i . Several concepts of fairness have been considered in the literature, and one of the most well-studied notions of fairness is *envy-freeness*. An allocation X is *envy-free* if for any pair of agents i, j we have $v_i(X_i) \geq v_i(X_j)$, i.e., no agent i envies another agent j ’s bundle. Unfortunately, envy-free allocations do not always exist when items are indivisible. We can easily see this even with two players and a single item having positive value for both of them: one of the agents has to receive the item and the other agent envies her. This motivates the study of relaxations of envy-freeness.

The most compelling relaxations of envy-freeness is *envy-freeness up to any item (EFX)* introduced by Caragiannis et al. [14]. An allocation X is *EFX* if for any pair of agents i, j and for any $g \in X_j$ we have $v_i(X_i) \geq v_i(X_j \setminus \{g\})$, i.e., no agent i envies another agent j after the removal of *any* item in j ’s bundle. EFX is regarded as the best analogue of envy-freeness in discrete fair division: Caragiannis et al. [13] remarked that “*Arguably, EFX is the best fairness analog of envy-freeness for indivisible items.*” However, the existence of

EFX allocations is known only in a few cases. As described in [14], “*Despite significant effort, we were not able to settle the question of whether an EFX allocation always exists (assuming all goods must be allocated), and leave it as an enigmatic open question.*”

For general valuations, i.e., each valuation function v_i is only assumed to be normalized and monotone, Plaut and Roughgarden [31] showed that an EFX allocation always exists (i) when $n = 2$ or (ii) when all agents have identical valuations. Furthermore, it was shown in [31] that exponentially many value queries may be required to identify EFX allocations even in the case where there are only two agents with identical *submodular* valuation functions. It is not known whether EFX allocations always exist even when $n = 3$ for general valuations.

For additive valuations, i.e., each valuation function v_i is normalized, monotone, and *additive*¹, it is known that an EFX allocation always exists when $n = 3$ [16] or all agents have one of two valuations [30]. It is not known whether EFX allocations always exist even when $n = 4$ for additive valuations.

One of relaxations of EFX is *EFX with charity* introduced by Caragiannis et al. [13]. This is a *partial* EFX allocation, where all items need not be allocated to the agents. Thus some items may be left unallocated. On the other hand, an allocation is said to be *complete* if all items are allocated. For general valuations, Chaudhury et al. [18] showed that there exist a partial EFX allocation and a set of unallocated items U such that no agent envies U , and $|U| \leq n - 1$. For additive valuations, Caragiannis et al. [13] showed that there exists a partial EFX allocation where every agent receives at least half the value of her bundle in an optimal *Nash social welfare* allocation². Quite recently, Berger et al. [8] showed that when $n = 4$, there exists an EFX allocation with at most one unallocated item such that no agent envies the unallocated item. Moreover, they extend their results and existing results in [16] and [30] beyond additive valuations to *nice cancelable* valuations which is a class including additive, unit-demand, budget-additive, multiplicative valuations, and so on.

1.1 Our Contributions

We investigate the existence of EFX allocations for general valuations, i.e., the valuation of each agent is not necessarily additive. To prove the existence of EFX, we iteratively construct an EFX allocation from an existing partial EFX allocation to advance with respect to a certain potential function. Chaudhury et al. [16] introduced the *lexicographic potential function* in order to show that they could advance an allocation while keeping EFX. We use not only the lexicographic potential function but also a new potential function, which we call *partition leximin potential function*. When we construct a new EFX allocation, which is better than the previous one with respect to the potential function, some agent may become worse off than in the previous allocation. The problem is that such an agent may become to envy other agents, which results in violating EFX. Our technical contribution is to develop a new technique to avoid such situations (see Section 1.2).

Using this new technique, we obtain some new results on the existence of EFX. Our results are described below, and are summarized in Table 1. Our first result is for the case where each agent has one of two given valuations. The following theorem extends the case when all agent have the identical valuations [31].

► **Theorem 1.** *There exists a complete EFX allocation when each agent has one of two general valuations.*

¹ A valuation function v_i is additive if $v_i(S) = \sum_{g \in S} v_i(\{g\})$ for any $S \subseteq M$.

² This is an allocation that maximizes $\Pi_{i=1}^n v_i(X_i)$.

It is known that there exists an EFX allocation when each agent has one of two additive valuations [30]. Berger et al. [8] extended this result beyond additive valuations to nice cancelable valuations. In [30] and [8], to prove the result they iteratively construct a Pareto dominating (see Section 2.1) EFX allocation from an existing partial EFX allocation. However, such an approach is not likely to work for general valuations. To prove Theorem 1, we introduce a new potential function (*partition leximin potential function*) and show that for any EFX allocation with at least one unallocated item, one can obtain a new EFX allocation that makes progress with respect to the partition leximin potential function. This implies that there exists a complete EFX allocation. More details are discussed in Section 4.

Our second result concerns EFX with charity. As mentioned above, it is known that there exist a partial EFX allocation and a set of unallocated items U such that no agent envies U , and $|U| \leq n - 1$ [18]. The following theorem strengthens the bound on the number of unallocated items from $n - 1$ to $n - 2$.

► **Theorem 2.** *For general valuations, there exists an EFX allocation X with at most $n - 2$ unallocated items. Moreover, no agent envies the set of unallocated items in X .*

Berger et al. [8] showed that for nice cancelable valuations, there exists an EFX allocation X with at most $n - 2$ unallocated items. Theorem 2 extends this results to general valuations. To prove Theorem 2, we show that for any EFX allocation with at least $n - 1$ unallocated items, one can obtain a new EFX allocation that makes progress with respect to the lexicographic potential function. This implies that there exists an EFX allocation with at most $n - 2$ unallocated items.

We also study the case with a small number of items. For additive valuations, Amanatidis et al. [3] showed that when $m \leq n + 2$, there exists an EFX allocation. For general valuations, to the best of our knowledge, non-trivial results are not known. The following theorem extends the existing results in the sense that it not only increases the number of items, but also makes valuation function general instead of additive.

► **Theorem 3.** *For general valuations, there exists a complete EFX allocation when $m \leq n + 3$.*

To prove Theorem 3, we also use the lexicographic potential function.

In addition to the above positive results, we study a limitation of the approach using the lexicographic potential function. We construct an instance with $n = 3$ and $m = 7$ in which there exists an EFX allocation with one unallocated item such that no progress can be made with respect to the lexicographic potential function. This shows that Theorem 2 and Theorem 3 are the best possibilities in a sence.

■ **Table 1** Our positive EFX results, where $|U|$ is the number of unallocated items.

Setting	Prior results	Our results
EFX for one of two valuations	Additive [30], Nice cancelable [8]	General
EFX with charity	General, $ U \leq n - 1$ [18] Nice cancelable, $ U \leq n - 2$ [8]	General, $ U \leq n - 2$
EFX for a small number of items	Additive, $m \leq n + 2$ [3]	General, $m \leq n + 3$

1.2 Our Techniques

We first fix a potential function ϕ for all allocations. For an existing partial EFX allocation, in order to find a new EFX allocation we use the champion graph introduced in [16]. If we have a Pareto improvable cycle (see Definition 7) in the champion graph, then we can

conclude that there exists an EFX allocation Y Pareto dominating X . That is, we have $v_i(Y_i) \geq v_i(X_i)$ for any agent i , and $v_j(Y_j) > v_j(X_j)$ for some agent j . It would imply that $\phi(X) < \phi(Y)$. Otherwise, it may no longer be possible to Pareto dominate X . Thus, we seek an allocation Y such that some agent i is worse off than in X and every agent other than i is not worse off than in X , i.e., $v_i(Y_i) < v_i(X_i)$ and $v_j(Y_j) \geq v_j(X_j)$ for $j \in N \setminus \{i\}$. We choose such an agent i who is less important with respect to ϕ . In order to preserve EFX, we list bundles that can appear in Y . We then allocate to agent i the best of the bundles in such a list, which is a key ingredient in our construction. Since agent i receives the most favorite bundles in Y , agent i does not envy any agent in Y . We can conclude that $\phi(X) < \phi(Y)$ or the structure of the champion graph in Y is better than in X . In the latter case, we will find a Pareto improvable cycle in the champion graph of Y , and obtain a new EFX allocation Y' such that $\phi(X) < \phi(Y')$.

1.3 Related Work

Whereas fair division of divisible resources is a classical topic starting from the 1940's [32], fair division of indivisible items has been actively studied in recent years. One of the most popular relaxations of envy-freeness is *envy-freeness up to one item (EF1)* where no agent envies another agent after the removal of *some* item from the other agent's bundle. While the existence of EFX allocations is open, it is known that there always exists an EF1 allocations for any number of agents, and it can be computed in polynomial time [29]. There are a lot of studies on EF1 and EFX [1, 7–9, 13, 14, 16–18, 30, 31]. Another major concept of fairness is *maximin share (MMS)*, which was introduced by Budish [11]. It was shown in [26] that MMS allocations do not always exist, and there have been several studies on approximate MMS allocations [2, 6, 10, 11, 21, 23, 24, 26]. In addition, study on finding *efficient* fair allocations has attracted attention. *Pareto-optimality* is a major notion of efficiency. Caragiannis et al. [14] showed that any allocation that has maximum Nash social welfare is guaranteed to be Pareto-optimal and EF1. Unfortunately, finding an allocation with the maximum Nash social welfare is APX-hard [27]. There are several studies on approximation algorithms for maximizing Nash social welfare [4, 5, 7, 15, 19–22, 28].

There are many real-world scenarios where items or resources need to be divided fairly, e.g., taxi fare division, rent division, task distribution, and so on. Spliddit (www.spliddit.org) is a fair division website, which offers a fair solution for the division of rent, goods, and credit [25]. This website implements mechanisms for users to log in, define what is to be divided, enter their valuations, and demonstrate fair division. Since its launch in 2014, there have been several thousands of users [14]. For more details on Spliddit, we refer to the reader to [25, 31]. Another fair division application is *Course Allocation* used at the Wharton School at the University of Pennsylvania to fairly allocate courses among students [12, 31].

1.4 Organization

In Section 2, we present the model, denote some basic notions introduced by [16, 18], and prove some useful lemmas. In Section 3, we consider EFX with charity for general valuations, and prove Theorem 2. In Section 4, we consider the setting with only one of two types of general valuations, and prove Theorem 1. In Section 5, we construct an instance with $n = 3$ and $m = 7$ that shows a certain limitations of the approach of the lexicographic potential function. The proofs of other results are given in the full version.

2 Preliminaries

Let $N = \{1, \dots, n\}$ be a set of n agents and M be a set of m items. In this paper, we assume that items are indivisible: an item may not be split among multiple agents. Each agent $i \in N$ has a valuation function $v_i : 2^M \rightarrow \mathbb{R}_{\geq 0}$. We assume that (i) any valuation function v_i is *normalized*: $v_i(\emptyset) = 0$ and (ii) it is *monotone*: $S \subseteq T$ implies $v_i(S) \leq v_i(T)$ for any $S, T \subseteq M$.

To simplify notation, we denote $[k]$ by $\{1, \dots, k\}$, write $v_i(g)$ instead of $v_i(\{g\})$ for $g \in M$, and use $S \setminus g, S \cup g$ instead of $S \setminus \{g\}, S \cup \{g\}$, respectively. We also denote $S <_i T$ instead of $v_i(S) < v_i(T)$. In a similar way, we use the symbols $>_i, \leq_i$, and \geq_i .

For $M' \subseteq M$, an *allocation* $X = (X_1, X_2, \dots, X_n)$ on M' is a partition of M' into n disjoint subsets, where X_i is the *bundle* given to agent i . We say that an allocation $X = (X_1, X_2, \dots, X_n)$ on M' is *complete* if $M' = M$. Otherwise, we say that an allocation X is *partial*.

Given an allocation X , we say that agent i *envies* a set of items S if $X_i <_i S$. We say that agent i *envies* agent j if i envies X_j . We say that agent i *EFX envies* a set of items S if there exists some $h \in S$ such that i envies $S \setminus h$. We say that agent i *EFX envies* agent j if i EFX envies X_j . Note that if i EFX envies j then i envies j , but not vice versa. An allocation X is called *envy-free* if no agent envies another. An allocation X is called *EFX* if no agent EFX envies another.

An instance I is a triple $\langle N, M, \mathcal{V} \rangle$, where $\mathcal{V} = \{v_1, \dots, v_n\}$ is a set of valuation functions. We use an assumption on instances considered in [16].

► **Definition 4.** An instance I is non-degenerate if for any $i \in N$ and $S, T \subseteq M$,

$$S \neq T \Rightarrow v_i(S) \neq v_i(T).$$

We can show that in order to prove the existence of an EFX allocation, we may assume w.l.o.g. that instances are non-degenerate. This assumption was considered for additive valuations in [16], and we can easily extend it for general valuations. More details are given in the full version. In what follows, *we only deal with non-degenerate instances*.

2.1 Overall Approach

All of our results on the existence of EFX can be viewed in a unified framework as follows: we first fix an appropriate potential function ϕ on all allocations. We then show that given any partial EFX allocation X , one can construct a new EFX allocation Y that makes progress with respect to the potential function, i.e., $\phi(X) < \phi(Y)$. Since there are finitely many allocations, there must exist a complete EFX allocation. One of natural potential functions is *social welfare*. Given an allocation X , we denote the *social welfare* of X by $\varphi(X) = \sum_{i \in N} v_i(X_i)$. A typical notion to progress the social welfare is Pareto domination. Given two allocations X, Y , we say that Y *Pareto dominates* X if $Y_i \geq_i X_i$ for all $i \in N$, and $Y_j >_j X_j$ for some agent $j \in N$. Clearly, if Y Pareto dominates X , then $\varphi(Y) > \varphi(X)$. Chaudhury et al. [16] have shown that there does not always exist a Pareto-dominating EFX allocation when $n = 3$ for additive case. To overcome this barrier they introduce a *lexicographic potential function*, which we also use to prove Theorems 2 and 3. In addition, to prove Theorem 1, we use a new potential function. More detail on each potential function is presented in Sections 3 and 4.

2.2 Minimum Preferred Set and Most Envious Agent

Most envious agent is a basic notion, introduced in [18]. Consider an allocation $X = (X_1, X_2, \dots, X_n)$ and a set $S \subseteq M$. For an agent i such that $S >_i X_i$, we define a *minimum preferred set* $P_X(i, S)$ of agent i for S with respect to allocation X as a smallest cardinality subset S' of S such that $S' >_i X_i$. Define $\kappa_X(i, S)$ by

$$\kappa_X(i, S) = \begin{cases} |P_X(i, S)| & \text{if } S >_i X_i, \\ +\infty & \text{otherwise.} \end{cases}$$

Let $\kappa_X(S) = \min_{i \in N} \kappa_X(i, S)$. We define $A_X(S)$ for a set S as the set of agents with the smallest values of $\kappa_X(i, S)$, i.e.,

$$A_X(S) = \{i \in N \mid S >_i X_i \text{ and } \kappa_X(i, S) = \kappa_X(S)\}.$$

We call $A_X(S)$ the set of *most envious agents*. Note that if agent i is a most envious agent for S , it holds that i envies $P_X(i, S)$ and no agent EFX envies $P_X(i, S)$. When it is clear from the context, we abbreviate $P_X(i, S)$ as P .

2.3 Champions and Champion Graph

In order to find a new EFX allocation from the existing partial EFX allocation, Champions and Champion graph are important notions, introduced in [16]. Let X be a partial allocation on $M' \subsetneq M$ and let $g \in M \setminus M'$ be an unallocated item. For agents i and j (possibly $i = j$), we say that i *g-champions* j if i is a most envious agent for $X_j \cup g$. Then, we also call i a *g-champion* of j . When i is a most envious agent for $X_i \cup g$, we call i a *self g-champion*. Note that every agent j has a *g-champion*. Indeed, since instances are non-degenerate, and valuations are monotone, we have $X_j \cup g >_j X_j$. That is, since j envies $X_j \cup g$, there exists at least one most envious agent for $X_j \cup g$.

We say that i *g-decomposes* j if i *g-champions* j , and $\{g\} \subsetneq P \subsetneq X_j \cup g$, where P is a minimum preferred set of i for $X_j \cup g$. When i *g-decomposes* j , we can decompose X_j into $P \setminus g$ and $(X_j \cup g) \setminus P$. If there is no ambiguity, then $T_j = P \setminus g$ and $B_j = (X_j \cup g) \setminus P$ are called *top and bottom half-bundles* of X_j , respectively. The following lemma illustrates a typical situation such that i *g-decomposes* j .

► **Lemma 5.** *If i g-champions j , i does not envy j , and both i and j are not self g-champions, then i g-decomposes j .*

Proof. By the assumption, we have $X_j <_i X_i <_i X_j \cup g$. Let P be a minimum preferred set of i for $X_j \cup g$. If $g \notin P$, then $P \subseteq X_j$, and by the monotonicity, we have $P \leq_i X_j <_i X_i$. This contradicts the definition of P . Thus, $g \in P$. If $P = \{g\}$, then $\kappa_X(i, X_i \cup g) = 1$, and hence it contradicts that i is not a self *g-champion*. Thus, $\{g\} \subsetneq P$. Furthermore if $P = X_j \cup g$, then $\kappa_X(X_j \cup g) = |P|$ and hence it contradicts that j is not a self *g-champion*. Therefore $\{g\} \subsetneq P \subsetneq X_j \cup g$, and thus i *g-decomposes* j . ◀

► **Definition 6.** *The champion graph $M_X = (N, E)$ with respect to allocation X is a labeled directed multi-graph. The vertices correspond to the agents, and E consists of the following two types of edges:*

1. *Envy edges:* $i \rightarrow j$ iff i envies j .
2. *Champion edges:* $i \xrightarrow{g} j$ iff i *g-champions* j , where g is an unallocated item.

Envy graph which consists of only envy edges is introduced in [29]. The original champion graph considered in [16] consists of only champion edges. Our definition of champion graph combines these two notions for convenience. Recently, Berger et al. [8] denote the generalized champion graph that contains more additional edges. For convenience, $i \rightarrow j$ and $i \xrightarrow{g} j$ are sometimes denoted by $i \xrightarrow{\emptyset} j$ and $i \xrightarrow{\{g\}} j$, respectively. Berger et al. [8] denote the notion of Pareto improvable cycle, which is very useful in our argument.

► **Definition 7.** A cycle $C = a_1 \xrightarrow{H_1} a_2 \xrightarrow{H_2} \dots \xrightarrow{H_{k-1}} a_k \xrightarrow{H_k} a_1$ in M_X is called Pareto improvable (PI) if for every $i, j \in [k]$ we have $H_i \cap H_j = \emptyset$, where H_i is an empty set or a singleton of an unallocated item.

The following lemma shows that if we have a Pareto improvable cycle in M_X , then there exists an allocation Y that Pareto dominates X while keeping EFX.

► **Lemma 8** (Berger et al. [8]). Let X be an allocation. If M_X contains a Pareto improvable cycle, then there exists an allocation Y Pareto dominating X such that for any $i, j \in N$, if i does not EFX envy j in X , then neither in Y . In particular, if X is an EFX allocation, then so is Y . Furthermore, every agent i along the cycle satisfies $X_i <_i Y_i$.

► **Corollary 9.** Let X be an EFX allocation. If M_X contains an envy-cycle³, a self g -champion, or a cycle composed of envy edges and at most one champion edge, then there exists an EFX allocation Y that Pareto dominates X .

3 Existence of EFX with at most $n - 2$ unallocated items

In this section, we prove Theorem 2. We use a lexicographic potential function as in [16]. Recall that $N = \{1, \dots, n\}$. For an allocation X , the *lexicographic potential function* $\phi(X)$ is defined as the vector $(v_1(X_1), \dots, v_n(X_n))$. Intuitively, agent 1 is the most important agent and agent n is the least important agent in N .

► **Definition 10.** For two allocations X, Y , We denote $Y \succ_{\text{lex}} X$ if $\phi(Y)$ is lexicographically larger than $\phi(X)$, i.e., for some $k \in N$, we have that $Y_j =_j X_j$ for all $1 \leq j < k$, and $Y_k >_k X_k$.

Note that if Y Pareto dominates X then $Y \succ_{\text{lex}} X$, but not vice versa. The following basic lemma is shown in [8], which we also use.

► **Lemma 11** (Berger et al. [8]). If for every partial EFX allocation X with k unallocated items, there exists an EFX allocation Y such that $Y \succ_{\text{lex}} X$, then there exists an EFX allocation with at most $k - 1$ unallocated items. Moreover, no agent envies the set of $k - 1$ unallocated items.

By Lemma 11, in order to prove Theorem 2, it suffices to show that for every partial EFX allocation X with at least $n - 1$ unallocated items, there exists an EFX allocation Y such that $Y \succ_{\text{lex}} X$. We first prove the following lemma, which is used in the proof of Theorem 2.

³ envy-cycle is a dicycle in M_X composed of only envy edges.

► **Lemma 12.** *Let X be an EFX allocation with at least $n - 1$ unallocated items. Then, there exists an EFX allocation Y Pareto dominating X in the following two cases.*

- (1) *the number of unallocated items is at least n .*
- (2) *there exists at least one envy edge $j \rightarrow i$ in M_X .*

Moreover, in case (2), some agent $l \in N \setminus i$ is strictly better off than in X , i.e., $Y_l >_l X_l$.

Proof. Let $\{g_1, \dots, g_k\}$ denote the set of unallocated items. We first prove the case of (1). It suffices to prove that there exists a PI cycle in M_X by Lemma 8. Let a_1 be an arbitrary agent. Then, some agent a_2 g_1 -champions a_1 . If $a_2 = a_1$, then we have a PI cycle, and we are done. Assume that $a_2 \neq a_1$. Then, some agent a_3 g_2 -champions a_2 . If $a_3 = a_1$ or a_2 , then we have a PI cycle. Indeed, in the first case we have a cycle $a_1 \xrightarrow{g_2} a_2 \xrightarrow{g_1} a_1$, and in the second case we have a self g_2 -champion. We can continue this way to conclude that w.l.o.g. we have a directed path $a_n \xrightarrow{g_{n-1}} a_{n-1} \xrightarrow{g_{n-2}} \dots \xrightarrow{g_1} a_1$ in M_X , where a_1, \dots, a_n are different agents. Now, some agent g_n -champions a_n in M_X . No matter who it is, there exists a PI cycle, and we are done.

We prove the case of (2) in a similar way. Assume w.l.o.g. that some agent a_2 envies a_1 . By a similar argument as above, we can conclude that w.l.o.g. we have a directed path $a_n \xrightarrow{g_{n-1}} a_{n-1} \xrightarrow{g_{n-2}} \dots \xrightarrow{g_3} a_3 \xrightarrow{g_2} a_2 \rightarrow a_1$ in M_X , where a_1, \dots, a_n are different agents. Now, some agent g_1 -champions a_n . No matter who it is, there exists a PI cycle, and we are done. Moreover, in any cases, we have a PI cycle containing some agent in $N \setminus a_1$. Hence, the last statement of lemma holds by Lemma 8. ◀

We are now ready to prove Theorem 2. We fix an arbitrary ordering of the agents.

Proof of Theorem 2. Let X be an EFX allocation with $k \geq n - 1$ unallocated items, and let $\{g_1, \dots, g_k\}$ denote the set of unallocated items. By Lemma 11, it suffices to prove that there exists an EFX allocation Y such that $Y \succ_{\text{lex}} X$. By Lemma 12, when $k \geq n$, or $k = n - 1$ and there exists at least one envy edge in M_X , we are done. Assume that $k = n - 1$ and there exists no envy edge in M_X . Let a_1 be the last agent in the fixed ordering, i.e., a_1 is the least important agent in the lexicographic potential function. By a similar argument in Lemma 12, we conclude that w.l.o.g. we have a directed path $a_n \xrightarrow{g_{n-1}} a_{n-1} \xrightarrow{g_{n-2}} \dots \xrightarrow{g_1} a_1$ in M_X , where a_1, \dots, a_n are different agents. Furthermore, we may assume that there are no self g_i -champions for $1 \leq i \leq n - 1$ since otherwise we have a PI-cycle. Since there are no self-champions, and there exists no envy edge in M_X , a_{i+1} g_i -decomposes a_i for $1 \leq i \leq n - 1$ by Lemma 5. Let T_i and B_i are the top and bottom half-bundles of X_{a_i} decomposed by a_{i+1} for $1 \leq i \leq n - 1$, respectively. Consider $Z = \max_{a_1} \{T_1 \cup g_1, T_2 \cup g_2, \dots, T_{n-1} \cup g_{n-1}, X_{a_2}, \dots, X_{a_n}\}^4$. We discuss in two cases.

Case 1: $Z = T_i \cup g_i$ or X_{a_i} for $2 \leq i \leq n$

We define a new allocation X' as follows:

$$\begin{aligned} X'_{a_1} &= Z, \\ X'_{a_j} &= T_{j-1} \cup g_{j-1} && \text{for } 2 \leq j \leq i, \\ X'_{a_j} &= X_{a_j} && \text{for } i < j \leq n. \end{aligned}$$

We show that X' is EFX and $X' \succ_{\text{lex}} X$. For $1 \leq t \leq i - 1$, since $T_t \cup g_t$ is a minimum preferred set of a_{t+1} and a_{t+1} is a most envious agent for $T_t \cup g_t$, no agent EFX envies

⁴ $\max_{a_1} \{T_1 \cup g_1, T_2 \cup g_2, \dots, T_{n-1} \cup g_{n-1}, X_{a_2}, \dots, X_{a_n}\}$ is a_1 's most favorite bundle out of $T_1 \cup g_1, T_2 \cup g_2, \dots, T_{n-1} \cup g_{n-1}, X_{a_2}, \dots, X_{a_n}$.

$T_t \cup g_t$ in X . Thus, for $2 \leq s \leq n$, since $X'_{a_s} \geq_{a_s} X_{a_s}$, agent a_s does not EFX envy $T_t \cup g_t$ in X' . For $2 \leq s \leq n$, since X is envy-free and the fact that $X'_{a_s} \geq_{a_s} X_{a_s}$, agent a_s does not envy X_{a_u} for $1 \leq u \leq n$ in X' . By the definition of Z , a_1 does not envy any agents in X' . Therefore, X' is EFX. Furthermore, for $2 \leq j \leq i$, each agent a_j is strictly better off than in X , and each agent a_j does not change her bundle for $i < j \leq n$. Thus, we have $X' \succ_{\text{lex}} X$, and we are done.

Case 2: $Z = T_1 \cup g_1$

We define a new allocation X' as follows:

$$\begin{aligned} X'_{a_1} &= Z, \\ X'_{a_i} &= X_{a_i} \quad \text{for } 2 \leq i \leq n. \end{aligned}$$

We show that X' is EFX. Since we change only a_1 's bundle from X , it is enough to check that there is no EFX envy from or to a_1 . By the definition of Z , a_1 does not envy any agent in X' . Since $Z = T_1 \cup g_1$ is a minimum preferred set of a_2 for $X_{a_1} \cup g_1$, and a_2 is a most envious agent for $X_{a_1} \cup g_1$, no agent EFX envies $T_1 \cup g_1$ in X' . Thus X' is EFX. In addition, since $Z = T_1 \cup g_1$ is a minimum preferred set of a_2 , a_2 envies a_1 in X' . By the fact that $B_1 \neq \emptyset$, we now have at least $n - 1$ items in $\{g_2, \dots, g_{n-1}\} \cup B_1$ that are unallocated. Thus by the case of (2) in Lemma 12, there exists an EFX allocation X'' that Pareto dominates X' . Furthermore, there exists some agent a_i ($2 \leq i \leq n$) such that $X''_{a_i} >_{a_i} X'_{a_i} = X_{a_i}$. Since $X''_{a_j} \geq_{a_j} X'_{a_j} = X_{a_j}$ for $2 \leq j \leq n$, we have $X'' \succ_{\text{lex}} X$, and we are done. \blacktriangleleft

4 Existence of EFX with One of Two General Valuations

In this section, we prove Theorem 1. For two general valuation functions v_a and v_b , let N_a (resp. N_b) be the set of agents whose valuation is v_a (resp. v_b). To prove Theorem 1, we introduce a new potential function. For an allocation X , we write $N_a = \{a_0, a_1, \dots, a_s\}$ and $N_b = \{b_0, b_1, \dots, b_t\}$, where $X_{a_0} <_a X_{a_1} <_a \dots <_a X_{a_s}$ and $X_{b_0} <_b X_{b_1} <_b \dots <_b X_{b_t}$. Define the *partition leximin potential function* $\psi(X)$ as the vector $(v_a(X_{a_0}), \dots, v_a(X_{a_s}), v_b(X_{b_0}), \dots, v_b(X_{b_t}))$.

► **Definition 13.** For two allocations X, Y , we denote $Y \succ_{\text{p.lexmin}} X$ if $\psi(Y)$ is lexicographically larger than $\psi(X)$.

That is, we prioritize N_a over N_b , compare agents in N_a by the leximin ordering, and second compare agents in N_b by the leximin ordering. Note that if Y Pareto dominates X , then $Y \succ_{\text{p.lexmin}} X$ but not vice versa. Our goal is to show the following theorem.

► **Theorem 14.** Let X be a partial EFX allocation. Then, there exists an EFX allocation Y such that $Y \succ_{\text{p.lexmin}} X$.

If Theorem 14 holds, then since there are finitely many allocations, there must exist a complete EFX allocation, and thus Theorem 1 holds.

We say that an allocation X is *semi-EFX* if there can be EFX envy only among agents belonging to N_b in X , i.e., no agent belonging to N_a EFX envies any agents, and no agent belonging to N_b EFX envies any agent belonging to N_a in X . The following lemma shows that if we have a semi-EFX allocation, then we can obtain an EFX allocation such that all the agents in N_a and $b_0 \in N_b$ do not change their bundles.

► **Lemma 15.** Let X be a semi-EFX allocation such that $X_{b_0} <_b X_{b_1} <_b \dots <_b X_{b_t}$. Then, there exists an EFX allocation Y such that $Y_{a_i} = X_{a_i}$ for any agent $a_i \in N_a$, and $Y_{b_0} = X_{b_0}$.

■ **Figure 1** The champion graph M_X (the edges are only partially drawn) in the proof of Theorem 14. Every agent other than a_0 and b_0 is envied by some other agents, and a_0 g -decomposes b_0 in M_X .

Proof. If X is EFX, then the lemma obviously holds. Assume that X is not EFX. Then, for some two agents $b_i, b_j \in N_b$, b_i EFX envies b_j in X . Thus, there exists an item $h \in X_{b_j}$ such that $X_{b_i} <_b X_{b_j} \setminus h$. We define a new allocation X' as $X'_{b_j} = X_{b_j} \setminus h$, and $X'_k = X_k$ for any $k \in N \setminus b_j$. Then, X' is also semi-EFX. Indeed, since we only change b_j 's bundle, it suffice to consider EFX envy from or to b_j . Since b_j 's bundle is a subset of X_{b_j} , and valuations are monotone, agents who do not EFX envy b_j in X do not EFX envy b_j either in X' . In addition, since $X_{b_i} = X'_{b_i} <_b X'_{b_j}$, and b_i does not EFX envy any agent belonging to N_a in X , b_j does not EFX envy any agent in N_a either in X' . Therefore X' is also semi-EFX. Furthermore since b_j is not b_0 , we have $X'_{b_0} = X_{b_0}$. If X' is EFX, then we are done. Otherwise, since the number of all items allocated is decreasing, we can continue this way to obtain an EFX allocation Y such that $Y_{a_i} = X_{a_i}$ for any agent $a_i \in N_a$, and $Y_{b_0} = X_{b_0}$. ◀

We are now ready to prove Theorem 14.

Proof of Theorem 14. Let X be a partial EFX allocation and let g be an unallocated item. Define $N_a = \{a_0, a_1, \dots, a_s\}$ and $N_b = \{b_0, b_1, \dots, b_t\}$, where $X_{a_0} <_a X_{a_1} <_a \dots <_a X_{a_s}$ and $X_{b_0} <_b X_{b_1} <_b \dots <_b X_{b_t}$. If there exists a PI cycle in M_X , then we are done by Lemma 8. Assume that there is no PI cycle in M_X . We first show that a_0 g -decomposes b_0 . By the assumption, neither a_0 nor b_0 is a self g -champion. If a_0 envies b_0 , then every agent other than a_0 is envied by some other agents. Some agent g -champions a_0 . No matter who it is, there exists a PI cycle in M_X , and this is a contradiction. Thus, a_0 does not envy b_0 . Now, some agent i g -champions b_0 . If $i \in N_b$, then since $X_{b_0} \leq_b X_i$, we have $\kappa_X(b_0, X_{b_0} \cup g) \leq \kappa_X(i, X_{b_0} \cup g) = \kappa_X(X_{b_0} \cup g)$. This implies that b_0 is a self g -champion, and this is a contradiction. Hence, we have $i \in N_a$. Then, since $X_{a_0} \leq_a X_i$, we have $\kappa_X(a_0, X_{b_0} \cup g) \leq \kappa_X(i, X_{b_0} \cup g) = \kappa_X(X_{b_0} \cup g)$. Hence, a_0 g -champions b_0 . As a result, a_0 g -decomposes b_0 by Lemma 5. Therefore, X_{b_0} is decomposed into top and bottom half-bundles. Let T_{b_0} and B_{b_0} be the top and bottom half-bundles of X_{b_0} . Figure 1 partially illustrates M_X . For $0 \leq i \leq s$, we define $U_{a_i} \subseteq X_{a_i}$ as follows:

$$U_{a_i} = \begin{cases} X_{a_i} & \text{if } b_0 \text{ does not envy } a_i \text{ in } X, \\ \hat{X}_{a_i} & \text{otherwise,} \end{cases}$$

where, \hat{X}_{a_i} is a maximum cardinality proper subset of X_{a_i} maximizing $v_b(\hat{X}_{a_i})$. Note that we have $|\hat{X}_{a_i}| = |X_{a_i}| - 1$. Consider $Z = \max_b \{T_{b_0} \cup g, U_{a_0}, \dots, U_{a_s}\}$. We define a new allocation X' as follows:

$$\begin{aligned}
X'_{a_i} &= \begin{cases} T_{b_0} \cup g & \text{if } Z = U_{a_i} \\ X_{a_i} & \text{otherwise} \end{cases} & \text{for } 0 \leq i \leq s, \\
X'_{b_0} &= Z, \\
X'_{b_j} &= X_{b_j} & \text{for } 1 \leq j \leq t.
\end{aligned}$$

We can easily check that X' is a legal allocation. That is, $X'_{a_0}, \dots, X'_{a_s}, X'_{b_0}, \dots, X'_{b_t}$ is a partition of a subset of M . We show that X' is semi-EFX.

- *Any two agents in N_a do not EFX envy each other:* Note that since $X_{a_0} <_a T_{b_0} \cup g$ and $X_{a_0} <_a X_{a_k}$ for $1 \leq k \leq s$, we have $X_{a_0} \leq_a X'_{a_i}$ for $0 \leq i \leq s$. Let a_i and $a_{i'}$ be two agents in N_a . If $X'_{a_{i'}} = X_{a_{i'}}$, then since $X_{a_0} \leq_a X'_{a_i}$ and by the fact that X is EFX, a_i does not EFX envy $a_{i'}$ in X' . If $X'_{a_{i'}} = T_{b_0} \cup g$, then since $X_{a_0} \leq_a X'_{a_i}$ and a_0 does not EFX envy $T_{b_0} \cup g$ in X , a_i does not EFX envy $a_{i'}$ in X' .
- *Any agent in N_a does not EFX envy any agent in $N_b \setminus b_0$:* Since $X_{a_0} \leq_a X'_{a_i}$ for $0 \leq i \leq s$, X is EFX, and any agent in $N_b \setminus b_0$ does not change her bundle, any agent in N_a does not EFX envy any agent in $N_b \setminus b_0$.
- *Any agent in N_a does not EFX envy b_0 :* If $Z = T_{b_0} \cup g$, then since $X_{a_0} \leq_a X'_{a_i}$ for $0 \leq i \leq s$ and a_0 does not EFX envy $T_{b_0} \cup g$ in X , any agent in N_a does not EFX envy b_0 in X' . If $Z = U_{a_k}$ for some $0 \leq k \leq s$, then since $X_{a_0} \leq_a X'_{a_i}$ for $0 \leq i \leq s$, and a_0 does not EFX envy $U_{a_k} \subseteq X_{a_k}$, any agent in N_a does not EFX envy b_0 in X' .
- *Any agent in $N_b \setminus b_0$ does not EFX envy any agent in N_a :* Let a_i be any agent in N_a and let b_j be any agent in $N_b \setminus b_0$. If $X'_{a_i} = X_{a_i}$, then since $X'_{b_j} = X_{b_j}$ and X is EFX, b_j does not EFX envy a_i . If $X'_{a_i} = T_{b_0} \cup g$, then since b_0 is not a self g -champion in X , we have $T_{b_0} \cup g <_b X_{b_j}$. Thus b_j does not envy a_i in X' .
- *b_0 does not EFX envy any agent in N_a :* Let a_i be any agent in N_a . If $X'_{a_i} = T_{b_0} \cup g$, then since $Z = \max_b \{T_{b_0} \cup g, U_{a_0}, \dots, U_{a_s}\} \geq_b T_{b_0} \cup g$, b_0 does not envy a_i in X' . If $X'_{a_i} = X_{a_i}$, then since $Z = \max_b \{T_{b_0} \cup g, U_{a_0}, \dots, U_{a_s}\} \geq_b U_{a_i}$, for any proper subset S of X_{a_i} , we have $Z \geq_b U_{a_i} \geq_b S$ by the definition of U_{a_i} and \hat{X}_{a_i} . Thus b_0 does not EFX envy a_i in X' .

Therefore X' is semi-EFX. By Lemma 15, there exists an EFX allocation X'' such that $X''_{a_i} = X'_{a_i}$ for $0 \leq i \leq s$, and $X''_{b_0} = X'_{b_0}$. We discuss in the following three cases.

Case 1: $Z = U_{a_0}$

In this case, we have $X''_{a_0} = X'_{a_0} = T_{b_0} \cup g >_a X_{a_0}$ and $X''_{a_k} = X'_{a_k} = X_{a_k}$ for $1 \leq k \leq s$. Thus, we have $X'' \succ_{p.\text{lexmin}} X$, and we are done.

Case 2: $Z = T_{b_0} \cup g$

In this case, since we have $X''_{a_0} = X'_{a_0} = X_{a_0} <_a T_{b_0} \cup g = X'_{b_0} = X''_{b_0}$, a_0 envies b_0 in X'' . Thus, every agent other than a_0 is envied by some other agents in X'' . By the fact that $B_{b_0} \neq \emptyset$, there is an unallocated item $g' \in B_{b_0}$. Then, some agent l g' -champions a_0 (see Figure 2). If $l = a_i \in N_a$, then by following agents in N_a backwards we obtain a PI cycle $a_0 \rightarrow \dots \rightarrow a_{i-1} \rightarrow a_i \xrightarrow{g'} a_0$ in $M_{X''}$. If $l \in N_b$, then by following agents in N_b backwards we also obtain a PI cycle $a_0 \rightarrow b_0 \rightarrow \dots \rightarrow l \xrightarrow{g'} a_0$ in $M_{X''}$. Therefore, in either case, there exists a PI cycle containing a_0 in $M_{X''}$. By Lemma 8, there exists an EFX allocation X''' such that $X'''_{a_0} >_a X''_{a_0} = X'_{a_0} = X_{a_0}$ and $X'''_{a_k} \geq_a X''_{a_k} = X'_{a_k} = X_{a_k}$ for $1 \leq k \leq s$. Therefore, we have $X''' \succ_{p.\text{lexmin}} X$, and we are done.

Case 3: $Z = U_{a_r}$ for some $1 \leq r \leq s$

In this case, if $U_{a_r} = X_{a_r}$, then since we have $X''_{a_0} = X'_{a_0} = X_{a_0} <_a X_{a_r} = X'_{b_0} = X''_{b_0}$, a_0 envies b_0 in X'' . By the fact that $B_{b_0} \neq \emptyset$, there is an unallocated item $g' \in B_{b_0}$. In a similar way to Case 2, the fact that some agent g' -champions a_0 implies that there exists a PI cycle containing a_0 in $M_{X''}$ (see Figure 3). By Lemma 8, there

■ **Figure 2** The champion graph $M_{X''}$ (the edges are only partially drawn) in Case 2. Every agent other than a_0 is envied by some other agents, and some agent g' -champions a_0 in $M_{X''}$.

■ **Figure 3** The champion graph $M_{X''}$ (the edges are only partially drawn) in the case where $U_{a_r} = X_{a_r}$ in Case 3. Every agent other than a_0 is envied by some other agents, and some agent g' -champions a_0 in $M_{X''}$.

■ **Figure 4** The champion graph $M_{X'}$ (the edges are only partially drawn) in the case where $U_{a_r} = \hat{X}_{a_r}$, and some agent in N_a g' -champions a_0 in Case 3.

■ **Figure 5** The champion graph $M_{X'}$ (the edges are only partially drawn) in the case where $U_{a_r} = \hat{X}_{a_r}$, and some agent in N_b g' -champions a_0 in Case 3. b_0 g' -champions a_0 , and a_0 g'' -champions b_0 in $M_{X'}$.

exists an EFX allocation X''' such that $X'''_{a_0} >_a X''_{a_0}$ and $X'''_{a_k} \geq_a X''_{a_k}$ for $1 \leq k \leq s$. Thus, we have $X'''_{a_k} \geq_a X''_{a_k} = X'_{a_k} = X_{a_k} >_a X_{a_0}$ for $1 \leq k \leq s$ with $k \neq r$, and $X'''_{a_r} \geq_a X''_{a_r} = X'_{a_r} = T_{b_0} \cup g >_a X_{a_0}$. That is, $X'''_{a_i} >_a X_{a_0}$ for $0 \leq i \leq s$. Therefore, we have $X''' \succ_{\text{p.lexmin}} X$, and we are done.

If $U_{a_r} = \hat{X}_{a_r}$, then we consider semi-EFX allocation X' , not X'' in this case. some agent l g' -champions a_0 in $M_{X'}$. If $l \in N_a$, then by following agents in N_a backwards we obtain a PI cycle $a_0 \rightarrow \dots \rightarrow l \xrightarrow{g'} a_0$ in $M_{X''}$ (see Figure 4). By Lemma 8, there exists a semi-EFX allocation X''' such that $X'''_{a_0} >_a X'_{a_0}$ and $X'''_{a_k} \geq_a X'_{a_k}$ for $1 \leq k \leq s$. By a similar argument as above, we have $X'''_{a_i} >_a X_{a_0}$ for $0 \leq i \leq s$. By Lemma 15, there exists an EFX allocation X'''' such that $X''''_{a_i} = X'''_{a_i}$ for $0 \leq i \leq s$. Therefore, we have $X''''_{a_i} >_a X_{a_0}$ for $0 \leq i \leq s$, thus we have $X'''' \succ_{\text{p.lexmin}} X$, and we are done.

If $l = b_j \in N_b$, then since $X'_{b_0} \leq_b X'_{b_j}$, we have $\kappa_{X'}(b_0, X'_{a_0} \cup g') \leq \kappa_{X'}(b_j, X'_{a_0} \cup g') = \kappa_{X'}(X'_{a_0} \cup g')$. Thus b_0 g' -champions a_0 in X' . Since $U_{a_r} = \hat{X}_{a_r}$, there exists an unallocated item $g'' \in X_{a_r} \setminus \hat{X}_{a_r}$. Note that we have $X_{a_r} = X'_{b_0} \cup g''$. We claim that a_0 g'' -champions b_0 in X' . Indeed, since any agent $u \in N \setminus \{a_r, b_0\}$ does not change her bundle, and X is EFX, u does not EFX envy $X_{a_r} = X'_{b_0} \cup g''$ in X' . In addition, since $X'_{a_r} = T_{b_0} \cup g >_a X_{a_0}$, and a_0 does not EFX envy X_{a_r} in X , a_r does not EFX envy X_{a_r} in X' . Furthermore, since $X'_{b_0} = U_{a_r} = \hat{X}_{a_r}$ is a maximum cardinality proper subset of X_{a_r} maximizing $v_b(\hat{X}_{a_r})$, b_0 does not EFX envy X_{a_r} in X' . To sum up, for

any proper subset S of $X'_{b_0} \cup g''$, any agent in N does not envy S in X' . Furthermore, since we have $X'_{a_0} = X_{a_0} <_a X_{a_r} = X'_{b_0} \cup g''$, a_0 envies $X'_{b_0} \cup g''$ in X' . Thus, since $\kappa_{X'}(a_0, X'_{b_0} \cup g'') = |X'_{b_0} \cup g''| \leq \kappa_{X'}(w, X'_{b_0} \cup g'')$ for any $w \in N$, a_0 is a most envious agent for $X'_{b_0} \cup g''$. That is, a_0 g'' -champions b_0 in X' (see Figure 5). We now have a PI cycle $a_0 \xrightarrow{g''} b_0 \xrightarrow{g'} a_0$ in $M_{X'}$, and by Lemma 8, we obtain a semi-EFX allocation X''' such that $X'''_{a_0} >_a X'_{a_0}$ and $X'''_{a_k} = X'_{a_k}$ for $1 \leq k \leq s$. By a similar argument as above, we have $X'''_{a_i} >_a X_{a_0}$ for $0 \leq i \leq s$. By Lemma 15, there exists an EFX allocation X'''' such that $X''''_{a_i} = X'''_{a_i}$ for $0 \leq i \leq s$. Therefore, we have $X''''_{a_i} >_a X_{a_0}$ for $0 \leq i \leq s$, thus we have $X'''' \succ_{\text{p.lexmin}} X$, and we are done. \blacktriangleleft

5 Limitations of the Lexicographic Potential Function

In Section 3, in order to prove the existence of EFX, we show that given a partial EFX allocation X , there exists an EFX allocation Y such that $Y \succ_{\text{lex}} X$. Recently, Chaudhury et al. [17] have shown that there does not always exist a lexicographically larger EFX allocation when $n = 4$ for additive valuations. In this section, we show that there does not always exist a lexicographically larger EFX allocation when $n = 3$ for general valuations. Thus, the approach using the lexicographic potential function is not sufficient to show the existence of EFX even when $n = 3$ for general valuations.

The following theorem shows that there exist an instance and a partial EFX allocation X such that no complete EFX allocation Y such that $Y \succ_{\text{lex}} X$.

► Theorem 16. *There exist an instance I with three agents, $\{1, 2, 3\}$ with general valuations, seven items $\{g_i \mid i \in [7]\}$, and a partial EFX allocation X , such that in every complete EFX allocation, the valuation of agent 1 will be strictly worse off than in X .*

Proof. We partially define the conditions of each agent's valuation function. Assume that agent 1 has an additive valuation satisfying the following conditions: $v_1(g_1) = v_1(g_2) > 0, v_1(g_i) = 0$ for $3 \leq i \leq 7$. Agent 2 has a general valuation satisfying following four conditions:

- (1) $\{g_i\} <_2 \{g_1\}$ for $2 \leq i \leq 7$
- (2) $\{g_i, g_j\} <_2 \{g_1\}$ for $2 \leq i < j \leq 7$ and $(i, j) \neq (3, 4), (5, 7)$
- (3) $\{g_4, g_5, g_6\} <_2 \{g_1\} <_2 \{g_3, g_4\} <_2 \{g_5, g_7\}$
- (4) $\{g_5, g_7\} <_2 \{g_1, g_i\}$ for $2 \leq i \leq 7$

Similarly, agent 3 has a general valuation satisfying the following four conditions:

- (1') $\{g_i\} <_3 \{g_1\}$ for $2 \leq i \leq 7$
- (2') $\{g_i, g_j\} <_3 \{g_1\}$ for $2 \leq i < j \leq 7$ and $(i, j) \neq (5, 6), (3, 7)$
- (3') $\{g_3, g_4, g_6\} <_3 \{g_1\} <_3 \{g_5, g_6\} <_3 \{g_3, g_7\}$
- (4') $\{g_3, g_7\} <_3 \{g_1, g_i\}$ for $2 \leq i \leq 7$

Note that all conditions do not violate the monotonicity of valuation functions. We now consider a partial allocation $X = (\{g_1, g_2\}, \{g_3, g_4\}, \{g_5, g_6\})$. We can easily check that X is an EFX allocation. Consider any complete EFX allocation Y . We show that $Y_1 <_1 X_1$. Assume that $X_1 \leq_1 Y_1$. Then, it must be $\{g_1, g_2\} \subseteq Y_1$ by the definition of 1's valuation. If $\{g_1, g_2\} \subsetneq Y_1$, then at least one of agents 2 and 3 has a bundle of size at most 2. If $|Y_2| \leq 2$, then since $Y_2 <_2 \{g_1, g_2\}$ by (2), (3), and (4), agent 2 EFX envies agent 1. This is a contradiction. The similar argument holds when $|Y_3| \leq 2$. Thus, we have $Y_1 = \{g_1, g_2\}$. Therefore, by (1) and (1'), both agent 2 and agent 3 have bundles of size at least 2. This implies that $|Y_2| = 2$ and $|Y_3| = 3$, or $|Y_2| = 3$ and $|Y_3| = 2$.

If $|Y_2| = 2$ and $|Y_3| = 3$, then since agent 2 does not EFX envy agent 1, $Y_2 = \{g_3, g_4\}$ or $\{g_5, g_7\}$ by (2). If $Y_2 = \{g_3, g_4\}$ then $Y_3 = \{g_5, g_6, g_7\}$, and agent 2 EFX envies agent 3 by (3). This is a contradiction. If $Y_2 = \{g_5, g_7\}$ then $Y_3 = \{g_3, g_4, g_6\}$, and agent 3 EFX envies agent 1 by (3'). This is a contradiction. The similar argument holds when $|Y_2| = 3$ and $|Y_3| = 2$. As a result, we conclude that $Y_1 <_1 X_1$, and thus the value of agent 1 will be strictly worse off than in X . ◀

FPT and FPT-Approximation Algorithms for Unsplittable Flow on Trees

Tomás Martínez-Muñoz ✉

Abstract

We study the unsplittable flow on trees (UFT) problem in which we are given a tree with capacities on its edges and a set of tasks, where each task is described by a path and a demand. Our goal is to select a subset of the given tasks of maximum size such that the demands of the selected tasks respect the edge capacities. The problem models throughput maximization in tree networks. The best known approximation ratio for (unweighted) UFT is $O(\log n)$. We study the problem under the angle of FPT and FPT-approximation algorithms. We prove that

- UFT is FPT if the parameters are the cardinality k of the desired solution and the number of different task demands in the input,
- UFT is FPT under $(1 + \delta)$ -resource augmentation of the edge capacities for parameters k and $1/\delta$, and
- UFT admits an FPT-5-approximation algorithm for parameter k .

One key to our results is to compute structured hitting sets of the input edges which partition the given tree into $O(k)$ clean components. This allows us to guess important properties of the optimal solution. Also, in some settings we can compute *core sets* of subsets of tasks out of which at least one task i is contained in the optimal solution. These sets have bounded size, and hence we can guess this task i easily.

A consequence of our results is that the integral multicommodity flow problem on trees is FPT if the parameter is the desired amount of sent flow. Also, even under $(1 + \delta)$ -resource augmentation UFT is APX-hard, and hence our FPT-approximation algorithm for this setting breaks this boundary.

1 Introduction

The unsplittable flow on trees (UFT) problem is a natural problem which models throughput maximization in tree networks. We are given a tree $G = (V, E)$ where each edge e has a capacity $u(e) \in \mathbb{N}$. Also, we are given a set of tasks \mathcal{T} where each task $i \in \mathcal{T}$ is described by a path $P(i) \subseteq E$ and a demand $d(i) \in \mathbb{N}$. Our goal is to select a set of tasks $\mathcal{T}' \subseteq \mathcal{T}$ of maximum cardinality whose combined demands respect the edge capacities, i.e., $\sum_{i \in \mathcal{T}': e \in P(i)} d(i) \leq u(e)$ for each edge e . Hence, one application is that each task models a possible transmission between two nodes in a (tree) network in which the edges have bounded capacities. Note that UFT generalizes the integral multi-commodity flow on trees problem¹

¹ In the integral multi-commodity flow on trees problem we are given a tree G with edge capacities u , and additionally pairs $s_i, t_i \in V$ of source and sink vertices. The goal is to select an integral amount of

which is known to be APX-hard [19]. Also, it generalizes the well-studied unsplittable flow on path (UFP) problem which has several applications, e.g., in caching [14], scheduling [4], and bandwidth allocation [12]. For UFT there is a $O(\log n)$ -approximation algorithm [10] (and $O(\log^2 n)$ -approximation algorithms for the weighted case [10, 18] and for submodular objective functions [1]). In particular, it is open to construct a $O(1)$ -approximation algorithm for UFT.

In order to obtain better approximation ratios for combinatorial optimization problems, one can study them under the angle of FPT-approximation algorithms. In such algorithms, one defines some quantity to be a fixed parameter k which we define to be the size of the desired solution for our case of UFT, and then ensures that the running time is of the form $f(k)n^{O(1)}$ for some computable function f . Furthermore, for UFT we define that an FPT- α -approximation algorithm is an algorithm that either computes a solution of size at least k/α or asserts that there is no solution of size k . In the last years there several such results have been found for different problems. For example, for k -MEDIAN and k -MEANS there are tight FPT-approximation algorithms known with approximation ratios of $1 + 2/e + \epsilon$ and $1 + 8/e + \epsilon$, respectively [15], while the best known polynomial time algorithms for the problems have ratios of 2.611 [8] and 6.357 [3], respectively. For FACILITY LOCATION there is an FPT-approximation algorithm with a ratio of essentially $1.463 + \epsilon$ [15] which matches a known lower bound for (pure) approximation algorithms [21], while the best known upper bound is 1.488 [23]. For the capacitated versions of k -MEDIAN and k -MEANS there are FPT- $(3 + \epsilon)$ - and FPT- $(9 + \epsilon)$ -approximation algorithms known, respectively [16] while the best known polynomial time approximation ratio is only $O(\log k)$ based on an algorithm in [9] (see also [2]). For UFP there is an FPT- $(1 + \epsilon)$ -approximation algorithm [25] while the best known polynomial time approximation ratio is only $5/3 + \epsilon$ [20]. For some W[1]-hard problems, there are even FPT-approximation algorithms known whose approximation ratios beat the best possible ratios of pure approximation algorithms. For example, for the STRONGLY CONNECTED STEINER SUBGRAPH problem, there is an FPT-2-approximation algorithm known when parametrized by the number of terminals [13], but there is a lower bound of $O(\log^{2-\epsilon} n)$ for (pure) approximation algorithms [22]. We refer to the surveys by Marx [24] and Feldmann et al. [17] for more results.

Given that for the mentioned problems FPT-approximation algorithms were found with better ratios than the best known (pure) approximation algorithms, this raises the question whether this is also possible for UFT. In this paper we answer this question in the affirmative and also show that certain special cases of UFT are even FPT.

1.1 Our contribution

Our first result is that UFT admits an *exact* FPT-algorithm if the parameters are k and the number \bar{d} of different task demands in the input. Our first step is to compute a hitting set, i.e., a subset of the edges such that each input task uses at least one of them. Via a routine in [19] we construct a *structured* hitting set of size $O(k)$ or directly a solution of size k (in which case we are done). In particular, our hitting set partitions the tree into $O(k)$ clean components. Then we consider an edge e from the hitting set such that there is no edge from the hitting set underneath e . We consider all input tasks that use e but no other edge from the hitting set, let us denote them by \mathcal{T}' . Using some properties of our hitting set, we show that that in FPT time we can compute a *core set* of size $f(k, \bar{d})$ for \mathcal{T}' (for some

flow to send between each pair (s_i, t_i) , in order to maximize the total amount of sent flow.

function f) which is a set $\mathcal{T}'' \subseteq \mathcal{T}'$ such that we can assume w.l.o.g. that \mathcal{T}'' contains *all* tasks from $\mathcal{T}' \cap \text{OPT}$. Therefore, in some sense, \mathcal{T}'' forms a kernel for \mathcal{T}' (in the sense of being a smaller instance that we reduce our given instance to). This allows us to guess a task in $\mathcal{T}' \cap \text{OPT}$ in time $f(k, \bar{d})$ or we guess that $\mathcal{T}' \cap \text{OPT} = \emptyset$. In either case we make progress: either we find a task in OPT or we can delete one of the $O(k)$ edges of the hitting set. Therefore, our algorithm has only $O(k)$ iterations overall and in each of them there are only $f(k, \bar{d}) + 1$ options for our guesses.

► **Theorem 1.** *There is an FPT-algorithm for UFT for parameters k and \bar{d} with a running time of $k^{O(k \cdot \bar{d}^k)} \cdot O(n^2)$.*

Note that the above mentioned integral multi-commodity flow problem (on trees) can be modeled by UFT instances in which $d(i) = 1$ for each task i and hence $\bar{d} = 1$. Therefore, we obtain an FPT-algorithm for this problem as a by-product. In particular, note that this problem is APX-hard [19] while our algorithm computes an *optimal* solution of size k .

► **Corollary 2.** *There is an FPT-algorithm for integral multi-commodity flow on trees where the parameter k denotes the amount of sent flow.*

Using the algorithm for UFT above we construct an FPT-algorithm for the general case of UFT under $(1 + \delta)$ -resource augmentation: our algorithm either computes a solution of size k that is feasible if we increase the capacity of each edge by a factor $1 + \delta$, or we assert that there is no solution of size k for the original edge capacities. Key for this is to use the available resource augmentation to reduce the given instance to a set of smaller instances in which the input tasks have only $O(\log((k/\delta)^k))$ different demands. On each of these instances we invoke the algorithm from above and combine the obtained solutions. Due to the resource augmentation, we can ensure that this union forms a feasible solution.

► **Theorem 3.** *There is an FPT-algorithm for UFT under $(1 + \delta)$ -resource augmentation with a running time of $k^{(k/\delta)^{O(k)}} n^{O(1)}$.*

Note that our results implies an (exact) FPT-algorithm for UFP (i.e., on paths, rather than trees) under $(1 + \delta)$ -resource augmentation, which was not known before. Also, already UFP is W[1]-hard [25] for parameter k (and hence also UFT), which justifies that we use resource augmentation or the additional parameter \bar{d} . Furthermore, it establishes a distinction in comparison to (pure) approximation algorithms for UFT, since UFT is still APX-hard under resource augmentation, assuming that δ is sufficiently small.

► **Theorem 4** (implied by [19, Section 4]). *UFT is APX-hard under $(1 + \delta)$ -resource augmentation for any $\delta < 1/2$.*

Then we present an FPT-5-approximation algorithm for UFT (i.e., without resource augmentation) where the fixed-parameter is only k (and not also \bar{d}). Recall that the best known polynomial time approximation algorithm for (unweighted) UFT has an approximation ratio of only $O(\log n)$. Intuitively, let $i^* \in \text{OPT}$ be the task of smallest demand in OPT . We guess which edges of our hitting set are used by i^* . Then we select the input task i of smallest demand that uses exactly these edges of the hitting set. By an exchange argument, we show that there are seven task in OPT such that we can replace these seven (unknown) tasks in OPT by our (known) task i and still obtain a feasible solution. For proving this, we again exploit some structural properties of our hitting set. Intuitively, our task i pays for seven tasks in OPT . This yields a 7-approximation algorithm when we iterate this routine (and this argument). In order to improve the approximation ratio to 5, we guess additional properties of i^* such that we can compute a task i' which we can replace by only five tasks from OPT . This yields an FPT-5-approximation algorithm.

► **Theorem 5.** *There is an FPT-5-approximation algorithm for UFT with a running time of $k^{O(k)}n^{O(1)}$.*

1.2 Other related work

For the mentioned integral multi-commodity flow problem on trees there is a 2-approximation algorithm in the unweighted case [19] and a 4-approximation algorithm in the weighted case [11]. Under the no-bottleneck-assumption (NBA), i.e., assuming that $\max_{i \in \mathcal{T}} d(i) \leq \min_{e \in E} u(e)$ there is a 48-approximation algorithm for UFT [11]. For uniform edge capacities and bounded node degrees, there is a 3.542-approximation algorithm for UFT [6]. For UFP there is no better approximation algorithm known under uniform edge capacities (and hence neither for the NBA) than the mentioned $(5/3 + \epsilon)$ -approximation for the general case [20]. However, UFP admits a QPTAS [5, 7], i.e., a $(1 + \epsilon)$ -approximation in time $n^{(\log n)^{O(1)}}$ for any constant $\epsilon > 0$, while for UFT a QPTAS is unlikely to exist since the problem is APX-hard [19].

2 Hitting sets and structuring the tree

In all our algorithms we will use hitting sets as the backbone of our computations. We define that a *hitting set* is a set of edges $E' \subseteq E$ such that each input task uses at least one edge in E' , i.e., $P(i) \cap E' \neq \emptyset$ for each $i \in \mathcal{T}$. In this section, first we show that a result in [19] implies that in time $n^{O(1)}$ we can compute a hitting set of size at most $2k$ or directly find a solution of size k . Then, we use this as a base to compute a more structured hitting set E_{hs} of size $O(k)$. Afterwards, we use E_{hs} to partition the tree G and establish some structural properties that we can assume without loss of generality. Throughout the paper, we denote by n the number of bits in the input.

First, we invoke the mentioned result to compute an initial hitting set E' .

► **Lemma 6** (implicit in [19, Section 5]). *There is an algorithm with a running time of $n^{O(1)}$ that either outputs a set of tasks \mathcal{T}' with $|\mathcal{T}'| = k$ such that $P(i) \cap P(i') = \emptyset$ for all $i, i' \in \mathcal{T}'$ with $i \neq i'$, or it outputs a hitting set E' with $|E'| \leq 2k$.*

If the algorithm returns a set \mathcal{T}' of k tasks with the mentioned properties then we can simply output \mathcal{T}' since it forms a feasible solution. Assume now that the algorithm returns a hitting set E' . We want to add more edges to E' in order to obtain a more structured hitting set. For any two edges e, e' we define $\text{lca}(e, e')$ to be the vertex that is the least common ancestor of the (up to four) vertices incident to e and e' ; also, we denote by $P_{e, e'} \subseteq E$ the (unique) path in G that contains e and e' . Intuitively, a hitting set is *good* if for any two edges $e, e' \in E_{\text{hs}}$ the edges of $P_{e, e'}$ incident to $\text{lca}(e, e')$ are also in the hitting set.

► **Definition 7.** *A hitting set E_{hs} is good if for any two edges $e, e' \in E_{\text{hs}}$ we have that $\delta(\text{lca}(e, e')) \cap P_{e, e'} \subseteq E_{\text{hs}}$.*

We construct a good hitting set E_{hs} based on E' as follows. We take all edges in E' , and for any two edges $e, e' \in E'$ we add the edges in $\delta(\text{lca}(e, e')) \cap P_{e, e'}$, see Figure 1. By some standard tree arguments one can show that then $|E_{\text{hs}}| \leq 6k$. Also, E_{hs} is a good hitting set.

► **Lemma 8.** *Given a hitting set \bar{E}' , in time $n^{O(1)}$ we can construct a good hitting set \bar{E}_{hs} with $|\bar{E}_{\text{hs}}| \leq 3|\bar{E}'|$.*

■ **Figure 1** Assume that the red edges form a hitting set \bar{E}' . Then the union of the red and orange edges forms a good hitting set \bar{E}_{hs} . Given the red edges, the orange edges are selected according to the proof of Lemma 8.

2.1 Backbone and hanging trees

Let E_{hs} denote the good hitting set obtained by applying Lemma 8 to E' . We use E_{hs} in order to partition the edges of G into a backbone of *highway edges* (that will contain E_{hs}) and some subtrees which we will call *hanging trees*. First, we are interested in the edges that lie on some path that connects two edges in E_{hs} (see Figure 2). We say that an edge $e \in E$ is a *highway edge* if there are two edges $e', e'' \in E_{\text{hs}}$ such that $e \in P_{e', e''}$. Let E_{hs}^* denote the set of all highway edges and note that $E_{\text{hs}} \subseteq E_{\text{hs}}^*$. Intuitively, E_{hs}^* forms a backbone of G . Note we cannot bound $|E_{\text{hs}}^*|$ by a function of k only. On the other hand, we observe that $G[E_{\text{hs}}^*]$ is a tree. If an edge $e \in E_{\text{hs}}^*$ is incident to a leaf in $G[E_{\text{hs}}^*]$ then we say that e is a *final edge*. Observe that then $e \in E_{\text{hs}}$ and thus there are at most $6k$ final edges. The final edges will play a special role later.

We say that the edges in $E \setminus E_{\text{hs}}^*$ are *black edges*. Note that they form trees. For each connected component H of $G[E \setminus E_{\text{hs}}^*]$ (i.e., the subgraph of G induced by $E \setminus E_{\text{hs}}^*$), we say that H forms a *hanging tree* and we define its root s to be the vertex of H that is closest to the root of G . In the sequel, we will write H_s for a hanging tree with root s . For a hanging tree H_s we say that its *depth* is the maximum distance of a vertex in H_s to s .

By some easy transformations, we can ensure that the depth of each hanging tree H_s is bounded by a function in k and $\bar{d} := |\{d_i | i \in \mathcal{T}\}|$, i.e., \bar{d} is the number of different task demands in the input. To this end, we note that if there are two edges $e, e' \in H_s$ appearing in this order on the path from s to a leaf of H_s and $u(e) \leq u(e')$, then we can contract e' since any input task T_i using e' also uses e (since $P(i)$ uses at least one edge of E_{hs} and hence $P(i)$ must pass through s). Also, we can assume w.l.o.g. that for each edge e its capacity $u(e)$ is the sum of the demands of at most k input tasks. With these ideas, we can prove the following lemma for which the intuition is that D is bounded by some parameter.

► **Lemma 9.** *In time $O(n^2)$ we can construct an equivalent instance (G', \mathcal{T}') in which the depth of every hanging tree is at most $(\bar{d} + 1)^k + 1$.*

3 Parameterized algorithm for UFT

In this section we present an FPT-algorithm for UFT, assuming that our fixed parameters are k and \bar{d} (recall that \bar{d} is the number of different task demands in the input). In particular, this shows that UFT is FPT if all tasks have unit demands (which is APX-hard).

■ **Figure 2** Partition of E , where E_{hs} are the edges in the good hitting set, E_{hs}^* are the edges in highway paths, and $E \setminus E_{hs}^*$ are the edges in hanging trees.

Our strategy is to identify a subset $\mathcal{T}' \subseteq \mathcal{T}$ of tasks for which we can compute a core set which is intuitively a subset $K \subseteq \mathcal{T}'$ for which we can assume that it contains all tasks in $\mathcal{T}' \cap \text{OPT}$ for some optimal solution OPT . We will ensure that the size of our core set is bounded by a function in k and \bar{d} . Hence, in some sense it is a kernel for the set \mathcal{T}' .

► **Definition 10.** Given a set $\mathcal{T}' \subseteq \mathcal{T}$, we say that a set $K \subseteq \mathcal{T}'$ is a core set for \mathcal{T}' if for every feasible set of tasks $\mathcal{S} \subseteq \mathcal{T}$ there exists a feasible set of tasks \mathcal{S}' such that $|\mathcal{S}'| = |\mathcal{S}|$, $\mathcal{S}' \setminus \mathcal{T}' = \mathcal{S} \setminus \mathcal{T}'$, and $\mathcal{S}' \cap \mathcal{T}' \subseteq K$.

We will ensure that $|K| \leq f(k, \bar{d})$ for our computed core sets K , for some function f . Hence, having computed K , in time $O(f(k, \bar{d}))$ we can guess a task from $\mathcal{T}' \cap \text{OPT}$ or guess that $\mathcal{T}' \cap \text{OPT} = \emptyset$. In our main algorithm, we will compute $O(k)$ core sets for different sets \mathcal{T}' , guess which of their tasks are in OPT , and in this way eventually find a solution of size k in time $(f(k, \bar{d}))^{O(k)} n^{O(1)}$.

First, we prove some basic properties of core sets.

► **Lemma 11.** Let $\mathcal{T}_1, \dots, \mathcal{T}_\ell$ be subsets of \mathcal{T} . If K_1, \dots, K_ℓ are core sets for $\mathcal{T}_1, \dots, \mathcal{T}_\ell$, respectively, then $\bigcup_{i=1}^\ell K_i$ is a core set for $\bigcup_{i=1}^\ell \mathcal{T}_i$.

► **Lemma 12.** Let \mathcal{T}' and \mathcal{T}'' with $\mathcal{T}'' \subseteq \mathcal{T}' \subseteq \mathcal{T}$. If K is a core set for \mathcal{T}'' and \mathcal{T}'' is a core set for \mathcal{T}' then K is also a core set for \mathcal{T}' .

3.1 Constructing core sets

We first present an algorithm \mathcal{A}^{kr} that computes a core set for any set of tasks \mathcal{T}' for which intuitively there are two hanging trees H, H' such that all tasks in \mathcal{T}' start in H and end in H' . Formally, the input of \mathcal{A}^{kr} consists of a path $P = P_{s,t}$ for two nodes s and t that lie in two different hanging trees H, H' , and of a value $d \in \mathbb{N}$ which is the demand of some input task. Let \mathcal{T}' denote the set of all tasks $i \in \mathcal{T}$ such that $P(i)$ contains the path P , $d(i) = d$, and each edge of $P(i) \setminus E_{hs}^*$ lies in H or H' . The algorithm \mathcal{A}^{kr} computes a core set K for \mathcal{T}' . For each node v in some hanging tree H denote by p_v the maximum distance of v to a leaf of H . Recall that by Lemma 9 we can assume that for every $v \in V$ follows that $p_v \leq (\bar{d} + 1)^k + 1$. For any two vertices v, v' denote by $P_{v,v'}$ the (unique) path from v to v' , and for each vertex v denote by $\delta(v)$ the set of edges incident to v .

The algorithm $\mathcal{A}^{\text{kr}}(P, d)$ works as follows:

1. If $p_s = p_t = 0$ then return an arbitrary subset of \mathcal{T}' of size $\min\{k, |\mathcal{T}'|\}$.
2. Otherwise, construct greedily a subset $A \subseteq \mathcal{T}'$ of tasks such that for every pair $i \neq j$ it holds that $P(i) \cap P(j) = P$: keep adding tasks to A until $|A| = 2k$ or if the property would not be fulfilled if we added an additional task $i \in \mathcal{T}' \setminus A$ to A .
3. If $|A| = 2k$ then return A .
4. If $|A| < 2k$ then let \bar{E} be the set of edges in $(\delta(s) \cup \delta(t)) \setminus P$ that are used by tasks in A .
5. For every edge $e_j \in \bar{E}$ compute $K_j = \mathcal{A}^{\text{kr}}(P \cup \{e_j\}, d)$
6. Return $K = \bigcup_{e_j \in \bar{E}} K_j$.

We want to show that $\mathcal{A}^{\text{kr}}(P, d)$ returns a core set for \mathcal{T}' . Observe that $|\bar{E}| \leq O(k)$, the recursion depth is bounded by $O((\bar{d} + 1)^k)$, and hence we output at most $k^{O((\bar{d} + 1)^k)}$ tasks in total. Intuitively, if in a recursive call it holds that $|A| < 2k$ then \bar{E} contains all edges in $(\delta(s) \cup \delta(t)) \setminus P$ that are used by tasks in \mathcal{T}' . Thus, for each task $i \in \mathcal{T}'$ there will be a recursive call $\mathcal{A}^{\text{kr}}(P \cup \{e_j\}, d)$ such that $P(i) \subseteq P \cup \{e_j\}$. On the other hand, if $|A| = 2k$ in some recursive call then A itself is a coresets for this call: if OPT contains a task $i \in \mathcal{T}' \setminus A$ then by the pigeon hole principle there must be another task $i' \in A \setminus \text{OPT}$ such that no task in OPT uses an edge in $P(i') \setminus P$ and hence we can swap i and i' in OPT, using that $d(i) = d(i')$. We formalize this in the following lemma.

► **Lemma 13.** *Let s, t be two nodes in two different hanging trees, let $d \in \mathbb{N}$, and let $\mathcal{T}' = \{i \in \mathcal{T} \mid P_{s,t} \subseteq P(i) \wedge d(i) = d\}$. Then $\mathcal{A}^{\text{kr}}(P_{s,t}, d)$ returns a core set for \mathcal{T}' of size at most $(4k)^{p_s+p_t} \cdot k$ in time $(4k)^{p_s+p_t} \cdot k \cdot O(n)$.*

Proof. Let $\mathcal{T}_{s,t}$ be the set of tasks $i \in \mathcal{T}$ such that $P_{s,t} \subseteq P(i)$. We define the *instance depth* to be $p_s + p_t$, and we give a proof by induction on the instance depth. In the base case $p_s = p_t = 0$. Then in the first step of the algorithm two options can arise:

- $K = \mathcal{T}'$. In this case it follows directly that K is a core set for \mathcal{T}' .
- $K \neq \mathcal{T}'$. Let OPT be a feasible solution of size k . In this case it follows that K has size $2k$, and then we can replace all the tasks in $\text{OPT} \cap \mathcal{T}'$ by tasks of K .

Now consider the case that $p_s + p_t > 0$. Given an edge $e_j \in \bar{E}$, let s_j and t_j be the end nodes of the path $P \cup \{e_j\}$. It follows that $\mathcal{T}' \cap \mathcal{T}_{s_j, t_j}$ is the set of tasks in \mathcal{T}' that uses e_j . Since $|P_{s_j, t_j}| = |P_{s,t}| + 1$, then $p_{s_j} + p_{t_j} = p_s + p_t - 1$, implying by the inductive hypothesis that K_j is a core set of $\mathcal{T}' \cap \mathcal{T}_{s_j, t_j}$. We define $\mathcal{T}'' = \bigcup_{j \in \{1, \dots, |\bar{E}|\}} \mathcal{T}' \cap \mathcal{T}_{s_j, t_j}$. Lemma 11 implies that K is a core set for \mathcal{T}'' . It remains to show that \mathcal{T}'' is a core set for \mathcal{T}' . If $|A| < 2k$ then each task in \mathcal{T}' uses an edge from \bar{E} , which implies that $\mathcal{T}' = \mathcal{T}''$, so we conclude that \mathcal{T}'' is a core set for \mathcal{T}' . Since K is a core set for \mathcal{T}'' and \mathcal{T}'' is a core set for \mathcal{T}' , the Lemma 12 implies that K is a core set of \mathcal{T}' .

Assume now that $|A| = 2k$. Let OPT be a feasible solution of size k , such that among all solutions OPT' of size k with $\text{OPT} \setminus \mathcal{T}' \subseteq \text{OPT}'$, the solution OPT is the solution that maximizes $|\text{OPT}' \cap A|$. Let us assume that there is a task $i \in (\text{OPT} \cap \mathcal{T}') \setminus A$. Each task in OPT shares an edge in $E \setminus P$ with at most two tasks from A . Therefore, there are at most $2(k - 1)$ tasks $i' \in A$ such that $P(i') \setminus P$ contains an edge that is used by some task in OPT. Therefore, there exists a task $i'' \in A$ such that no edge in $P(i'') \setminus P$ is used by any tasks in OPT. Therefore, $\text{OPT} \cup \{i''\} \setminus \{i\}$ is a feasible solution and $|(\text{OPT} \cup \{i''\} \setminus \{i\}) \cap A| > |\text{OPT} \cap A|$ which is a contradiction. Therefore, A is a core set for \mathcal{T}' .

Now we analyse the running time of \mathcal{A}^{kr} . Each of the recursive calls generated by \mathcal{A}^{kr} is associated to a path P_{s_i, t_i} such that $|P_{s_i, t_i}| = |P_{s,t}| + 1$, and therefore $p_{s_i} + p_{t_i} \leq p_s + p_t - 1$. Therefore, the recursion depth is at most $p_s + p_t$. In the recursion tree each node has at most

■ **Figure 3** The sets $A = \{i_1, i_2, i_3, i_4\}$, $\bar{V} = \{v_1, v_2, v_3, v_4\}$, and $\bar{E} = \{e_1, e_2, e_3, e_4\}$ as they are defined in algorithm $\mathcal{A}^{\text{fin}}(P, d)$.

$4k$ childrens. If in a leaf of the recursion tree a core set is returned, this core set contains at most k tasks. We conclude that K is a core set of size at most $(4k)^{p_s+p_t} \cdot k$ which we compute in time $(4k)^{p_s+p_t} \cdot k \cdot O(n)$. ◀

We will use \mathcal{A}^{kr} as a subroutine in a different algorithm \mathcal{A}^{fin} for computing core sets which we describe now. Let e^* be a final edge. Let $H(e^*)$ be the hanging tree underneath e^* , i.e., that is rooted at the vertex incident to e^* that is further away from the root. The input of \mathcal{A}^{fin} consists of a path $P \subseteq H(e^*) \cup \{e^*\}$ and of a value $d \in \mathbb{N}$ which is intuitively the demand of some input task. Let \mathcal{T}' denote the set of all tasks i such that $P \subseteq P(i)$, $P(i) \cap E_{\text{hs}} = \{e^*\}$ and $d(i) = d$. The algorithm \mathcal{A}^{fin} will compute a core set for \mathcal{T}' . In order to present the algorithm, we introduce some definitions. We say that a task $i \in \mathcal{T}'$ *turns* at a node v if v is the endnode of the path $P(i) \cap E_{\text{hs}}^*$ that is closest to the root. For each task i we denote by $v(i)$ the vertex at which i turns. We define that the *level* $\ell(i)$ of a task $i \in \mathcal{T}'$ is the distance between $v(i)$ and e^* , i.e., the number of edges of the path that connects $v(i)$ with the vertex incident to e^* that is closer to the root.

Our algorithm $\mathcal{A}^{\text{fin}}(P, d)$ works as follows (see Figure 3 for an illustration):

1. Initialize $A = \emptyset$. Consider tasks in \mathcal{T}' ordered non-decreasingly by their levels, add each task $i \in \mathcal{T}'$ to A if for each previously added task $i' \in A$ it holds that $P(i) \cap P(i') \subseteq E_{\text{hs}}^* \cup P$. Stop if $|A| = 2k$ or if no more task in \mathcal{T}' can be added to A .
2. Let $\bar{V} = \{v_1, \dots, v_{|\bar{V}|}\}$ be the vertices at which the tasks in A turn, u be the endvertex of P that is in $H(e^*)$, and \bar{E} be the set of edges in $\delta(u) \setminus P$ that are used by tasks in A .
3. For every vertex $v_j \in \bar{V}$ we compute $K_j^{\text{kr}} = \mathcal{A}^{\text{kr}}(P_{v_j, u}, d)$.
4. For every edge $e_j \in \bar{E}$ we define $P_j = P \cup \{e_j\}$ and compute $K_j^{\text{fin}} = \mathcal{A}^{\text{fin}}(P_j, d)$.
5. Return

$$K = \left(\bigcup_{j \in \{1, \dots, |\bar{V}|\}} K_j^{\text{kr}} \right) \cup \left(\bigcup_{j \in \{1, \dots, |\bar{E}|\}} K_j^{\text{fin}} \right).$$

We want to show that $\mathcal{A}^{\text{fin}}(P, d)$ computes a core set with bounded size for \mathcal{T}' . If $|A| = 2k$ we can show by an exchange argument that there is an optimal solution OPT such that each task in $\text{OPT} \cap \mathcal{T}'$ turns at some vertex in V' or use some edge in E' . If $|A| < 2k$ one can show that this is automatically satisfied. In the calls to \mathcal{A}^{kr} we obtain core sets that together contain all tasks in $\text{OPT} \cap \mathcal{T}'$ that turn at some vertex in V' . The recursive calls to \mathcal{A}^{fin} compute core sets that together contain all tasks in $\text{OPT} \cap \mathcal{T}'$ that use some edge in E' . Observe that for \mathcal{A}^{fin} the tasks are ordered, favoring tasks of lower level, since those intuitively use less edges on E_{hs}^* and thus intersect with fewer other tasks on these edges. We define p_{\max} to be the maximum value p_u over all nodes $v \in V$. Since due to Lemma 9 we can assume that $p_v \leq (\bar{d} + 1)^k + 1$ for every $v \in V$, we obtain that $p_{\max} \leq (\bar{d} + 1)^k + 1$.

► **Lemma 14.** *Let e^* be a final edge, let $P \subseteq H(e^*) \cup \{e^*\}$ be a path, and let \mathcal{T}' be the set of all tasks i such that $P \subseteq P(i)$, $P(i) \cap E_{\text{hs}} = \{e^*\}$, and $d(i) = d$. The algorithm $\mathcal{A}^{\text{fin}}(P, d)$ computes a core set for \mathcal{T}' of size at most $(4k)^{2p_{\max}} \cdot k$ in time $(4k)^{2p_{\max}} \cdot k^2 \cdot O(n)$.*

3.2 UFT Algorithm

Now we describe our main FPT-algorithm for UFT which will use $\mathcal{A}^{\text{fin}}(e, d)$ as a subroutine. Recall that there are at most $6k$ edges in E_{hs} . We take an arbitrary final edge $e \in E_{\text{hs}}$. We guess whether there is a task $i \in \text{OPT}$ that uses e but no other edge in E_{hs} , i.e., such that $P(i) \cap E_{\text{hs}} = \{e\}$. If yes, we guess $d(i)$ for which there are only \bar{d} options. Then we call $\mathcal{A}^{\text{fin}}(e, d(i))$ and obtain a core set K of size at most $(4k)^{2p_{\max}} k^2$. Assume w.l.o.g. that OPT is an optimal solution with the property that K contains all tasks in OPT that use e but no other edge in E_{hs} (using that K is a core set). In time $(4k)^{2p_{\max}} k^2$ we guess a task $i \in K \cap \text{OPT}$. We add i to our computed solution and remove i from the set of input tasks \mathcal{T} . We update the edges capacities, taking into account that we selected i , i.e., we update $u(e) := u(e) - d(i)$ for each edge $e \in P(i)$. At this point, we remove from \mathcal{T} each task $i' \in \mathcal{T}$ such that $u(e) < d(i')$ for some edge $e \in P(i)$. We keep on guessing whether there is a task $i \in \text{OPT}$ that uses e but no other edge in E_{hs} , i.e., $P(i) \cap E_{\text{hs}} = \{e\}$. If yes, we repeat the process above. Otherwise, we know that there is no more task $i \in \text{OPT}$ with $P(i) \cap E_{\text{hs}} = \{e\}$. Then we remove e from E_{hs} , we remove from \mathcal{T} all input tasks i with $P(i) \cap E_{\text{hs}} = \{e\}$, and we define E_{hs}^* newly based on the changed set E_{hs} . Then we apply Lemma 9 to the resulting instance.

We repeat the above process with a final edge e' in the (changed) set E_{hs} (note that possibly e' was not a final edge in the original set E_{hs}). We continue until we selected k tasks in total. If all our guesses were correct, then \mathcal{S} forms a feasible solution. Moreover, there are at most $O(k)$ guesses in total with at most $\bar{d} \cdot (4k)^{2p_{\max}} k^2$ possibilities for each guess: if we guess that there is a task $i \in \text{OPT}$ with $P(i) \cap E_{\text{hs}} = \{e\}$ then subsequently we select such a task and this happens at most k times. On the other hand, if we guess that there is no task $i \in \text{OPT}$ with $P(i) \cap E_{\text{hs}} = \{e\}$ then subsequently we remove e from E_{hs} and the initial set E_{hs} has only $O(k)$ edges. For each guess there are at most $\bar{d} \cdot (4k)^{2p_{\max}} k^2$ options. Hence, there are only $(\bar{d} \cdot (4k)^{2p_{\max}} k^2)^{O(k)}$ possibilities for all our guesses overall. Therefore, we obtain a running time of $k^{O(k \cdot \bar{d}^k)} \cdot O(n^2)$ overall, which yields the proof of Theorem 1.

4 Resource augmentation

In this section we present an FPT-algorithm for UFT under $(1 + \delta)$ -resource augmentation. Formally, we present an algorithm with a running time of the form $f(k, \delta)n^{O(1)}$ for some computable function f that outputs a set $\mathcal{S} \subseteq \mathcal{T}$ with $|\mathcal{S}| = k$ that is feasible under $(1 + \delta)$ -resource augmentation, i.e., $\sum_{i: i \in \mathcal{S} \cap \mathcal{T}_e} d(i) \leq (1 + \delta)u(e)$ for each $e \in E$, or outputs that there is no solution of size k (for the original edge capacities).

Our strategy is to split the input tasks \mathcal{T} into groups such that the demands of any two tasks in different groups differ at least by a factor k/δ . Then we can compute a solution for each group separately and their union is a (global) solution under resource augmentation, as the following lemma shows.

► **Lemma 15.** *Consider sets of tasks $\{\mathcal{T}_j\}_{j \in \mathbb{N}}$ with $\mathcal{T}_j \subseteq \mathcal{T}$ for each $j \in \mathbb{N}$ such that for each $j, j' \in \mathbb{N}$ with $j \neq j'$ and any two tasks $T_i \in \mathcal{T}_j$, $T_{i'} \in \mathcal{T}_{j'}$ it holds that $d(i) > \frac{k}{\delta} d(i')$ or $d(i') > \frac{k}{\delta} d(i)$. For each $j \in \mathbb{N}$ let $\mathcal{S}_j \subseteq \mathcal{T}_j$ be a solution with at most k tasks that is feasible under $(1 + \delta')$ -resource augmentation for some $\delta' \geq 0$, and suppose that $\delta < 1/2$. Then $\bigcup_{j \in \mathbb{N}} \mathcal{S}_j$ is feasible under $(1 + 2\delta' + 2\delta)$ -resource augmentation.*

On the other hand, if we can ensure that within each group the task demands differ by at most a factor $(k/\delta)^k$, then we can compute a solution of size k for this group that is feasible under $(1 + \delta)$ -resource augmentation as follows: we first round the task demands to powers of $1 + \delta$ and then invoke our algorithm due to Theorem 1, using that the number of different task demands is only $\log_{1+\delta}((k/\delta)^k)$.

► **Lemma 16.** *Consider a set of tasks $\mathcal{T}' \subseteq \mathcal{T}$ such that for any two tasks $i, i' \in \mathcal{T}'$ it holds that $(\frac{\delta}{k})^k d(i) \leq d(i') \leq (\frac{k}{\delta})^k d(i)$. Then in time $k^{O(k^{k+2} \cdot (\log_{1+\delta}(k/\delta))^{k+1})} \cdot O(n^2)$ we can compute for any $k' \leq k$ a solution $\mathcal{S}' \subseteq \mathcal{T}'$ of size k' that is feasible under $(1 + \delta)$ -resource augmentation, or assert that there is no solution of size k' (for the original edge capacities).*

Now with a shifting argument we can guess sets of tasks $\{\mathcal{T}_j\}_{j \in \mathbb{N}}$ that satisfy the condition of Lemma 15, such that each set \mathcal{T}_j satisfies the condition of Lemma 16, and additionally $\bigcup_{j \in \mathbb{N}} \mathcal{T}_j$ contains a solution of size k . We apply Lemma 16 to each set \mathcal{T}_j to find the largest $k' \leq k$ for which there exists a solution, denote by \mathcal{S}_j the largest solution found, and output the union $\bigcup_{j \in \mathbb{N}} \mathcal{S}_j$ which is feasible under $(1 + 4\delta)$ -resource augmentation due to Lemma 15.

► **Theorem 17.** *There is an FPT-algorithm for UFT under $(1 + \delta)$ -resource augmentation with a running time of $k^{O((k \cdot \log_{1+\delta}(k/\delta))^{k+2})} \cdot O(n^2)$.*

5 FPT-approximation algorithm

In this section we present an FPT-5-approximation algorithm for UFT, i.e., given a parameter k , in time $f(k)n^{O(1)}$ our algorithm either finds a solution of size $k/5$ or asserts that there are no solution of size k . First, we present a simpler FPT-7-approximation algorithm and then explain how to improve it to an FPT-5-approximation.

Again, we invoke Lemmas 6 and 8 to construct a good hitting set E_{hs} (or directly obtain a solution of size k). Since $|E_{\text{hs}}| = O(k)$, we observe that the graph $(V, E \setminus E_{\text{hs}})$ has $K = O(k)$ connected components; we denote them by G_1, \dots, G_K . Since E_{hs} is a hitting set, we obtain the following lemma.

► **Lemma 18.** *For each task $i \in \mathcal{T}$ the two endvertices of $P(i)$ lie in two different components in $\{G_1, \dots, G_K\}$.*

Let $i_1^* \in \text{OPT}$ denote the task with smallest demand in OPT. We guess the two components of the two endvertices of $P(i_1^*)$. We select the input task i_1 with smallest demand whose path has its endvertices in the same two components. It might be that $i_1 \neq i_1^*$; however, we will show that we can find seven tasks $i'_1, \dots, i'_7 \in \text{OPT}$ such that if we replace i'_1, \dots, i'_7 by i_1 then we still obtain a feasible solution. Intuitively, the task i_1 (which we select) pays for the tasks i'_1, \dots, i'_7 (which we lose). We continue iteratively until we picked $\lceil k/7 \rceil$ tasks.

Formally, our algorithm runs in $\lceil k/7 \rceil$ rounds where in each round we select one task i . Let $\text{OPT}_0 = \text{OPT}$. Suppose that after $k' \in \{0, \dots, \lceil k/7 \rceil - 1\}$ rounds we selected tasks $i_1, \dots, i_{k'}$ and defined a solution $\text{OPT}_{k'} \subseteq \text{OPT}$ such that $\text{OPT}_{k'} \cup \{i_1, \dots, i_{k'}\}$ is feasible (note that this is clearly true for $k' = 0$). Let $i_{k'+1}^* \in \text{OPT}_{k'}$ denote a task with smallest demand in $\text{OPT}_{k'}$, i.e., such that $d(i_{k'+1}^*) \leq d(i)$ for each $i \in \text{OPT}_{k'}$. We guess the two components from $\{G_1, \dots, G_K\}$ that contain the two endvertices of $P(i_{k'+1}^*)$. Let $i_{k'+1}$ denote the input task i of smallest demand with the property that $P(i)$ has its endvertices in the same components and $\{i, i_1, \dots, i_{k'}\}$ forms a feasible solution. We select $i_{k'+1}$ and prove in the next lemma that intuitively we can select $i_{k'+1}$ if we are willing to sacrifice at most seven tasks from $\text{OPT}_{k'}$.

► **Lemma 19.** *There exist tasks $i'_1, \dots, i'_7 \in \text{OPT}_{k'}$ such that $\text{OPT}_{k'} \setminus \{i'_1, \dots, i'_7\} \cup \{i_1, \dots, i_{k'}, i_{k'+1}\}$ is feasible.*

Proof. Let G' and G'' denote the two components from $\{G_1, \dots, G_K\}$ that contain the two endvertices of $P(i_{k'+1}^*)$. The idea behind the proof is to identify seven tasks $i'_1, \dots, i'_7 \in \text{OPT}_{k'}$ such that $d(i'_\ell) \geq d(i_{k'+1}^*) \geq d(i_{k'+1})$ for each $\ell \in \{1, \dots, 7\}$ and such that the edges of their paths contain all the edges of $P(i_{k'+1})$ that are used by tasks in $\text{OPT}_{k'}$ (i.e., edges on which selecting $i_{k'+1}$ potentially causes conflicts with other tasks in $\text{OPT}_{k'}$). We will select three tasks for the edges in $P(i_{k'+1}) \cap E(G')$, three for the edges in $P(i_{k'+1}) \cap E(G'')$, and one for the edges in $P(i_{k'+1}) \setminus (E(G') \cup E(G''))$.

Consider the edges in $P(i_{k'+1}) \cap E(G')$. We partition them into $P(i_{k'+1}) \cap E(G') \setminus E_{\text{hs}}^*$ and $P(i_{k'+1}) \cap E(G') \cap E_{\text{hs}}^*$. If an edge $e \in P(i_{k'+1}) \cap E(G') \setminus E_{\text{hs}}^*$ is used by some task $i \in \text{OPT}_{k'}$, then e is also used by the task $i' \in \text{OPT}_{k'}$ that maximizes $|P(i') \cap P(i_{k'+1}) \cap E(G') \setminus E_{\text{hs}}^*|$. Let i'_1 denote this task i' . Regarding the edges in $P(i_{k'+1}) \cap E(G') \cap E_{\text{hs}}^*$, note that they form a path, and let u and v be its end vertices. Let i'_2 denote the task $i \in \text{OPT}_{k'}$ such that $u \in V(P(i))$ and i maximizes $|P(i) \cap E(G') \cap E_{\text{hs}}^*|$. Similarly, let i'_3 denote the task $i \in \text{OPT}_{k'}$ such that $v \in V(P(i))$ and i maximizes $|P(i) \cap E(G') \cap E_{\text{hs}}^*|$. Then, if some task $i \in \text{OPT}_{k'}$ uses an edge $e \in P(i_{k'+1}) \cap E(G') \cap E_{\text{hs}}^*$ then $e \in P(i'_2)$ or $e \in P(i'_3)$ (see Figure 4). In a similar way, we identify three tasks i'_4, i'_5 and i'_6 for $P(i_{k'+1}) \cap E(G'')$.

Finally, all the edges in $P(i_{k'+1}) \setminus (G' \cup G'')$ are used by $i_{k'+1}^*$, and we define $i'_7 := i_{k'+1}^*$. If an edge e is used by some task $i \in \text{OPT}_{k'}$, then $e \in P(i'_\ell)$ for some $\ell \in \{1, \dots, 7\}$. Since $d(i'_\ell) \geq d(i_{k'+1}^*) \geq d(i_{k'+1})$ for each $\ell \in \{1, \dots, 7\}$, the tasks i'_1, \dots, i'_7 satisfy the claim of the lemma. ◀

We remark that the tasks i'_1, \dots, i'_7 might not be pairwise distinct. We define $\text{OPT}_{k'+1} := \text{OPT}_{k'} \setminus \{i'_1, \dots, i'_7\}$ and iterate. Since in each iteration we picked one task and removed at most seven tasks from OPT , one can show easily that at the end we select $\lceil k/7 \rceil$ tasks, assuming that $|\text{OPT}| \geq k$. Our running time is $k^{O(k)} n^{O(1)}$ since in each of the k iterations there are $O(k^2)$ options for our guesses.

► **Theorem 20.** *There is an FPT-7-approximation algorithm for UFT with a running time of $k^{O(k)} n^{O(1)}$.*

5.1 Improvement to an FPT-5-approximation

We improve our approximation factor to 5 by doing additional guesses when we select the task $i_{k'}$ in each round k' . Assume again that at the beginning of round $k' + 1$ we have already selected tasks $i_1, \dots, i_{k'}$, and defined a set $\text{OPT}_{k'} \subseteq \text{OPT}$ such that $\text{OPT}_{k'} \cup \{i_1, \dots, i_{k'}\}$ is feasible. Like before, let $i_{k'+1}^* \in \text{OPT}_{k'}$ denote the task with smallest demand in $\text{OPT}_{k'}$ and we guess the components from G_1, \dots, G_K that contain the endvertices of $P(i_{k'+1}^*)$. Let

■ **Figure 4** The task $i_{k'+1}$ is selected, and Lemma 19 shows that if we remove the tasks i'_1, \dots, i'_7 from $\text{OPT}_{k'}$, we can add the task $i_{k'+1}$ to $\text{OPT}_{k'}$ since each edge on $P(i_{k'+1})$ is used by one of the tasks i'_1, \dots, i'_7 or by no task from $\text{OPT}_{k'}$.

G' and G'' be these components. Like before, let $i_{k'+1}$ denote the input task i of smallest demand with the property that $P(i)$ has its endvertices in G' and G'' and $\{i, i_1, \dots, i_{k'}\}$ forms a feasible solution. We do not select $i_{k'+1}$ yet; instead, we guess some properties of $P(i_{k'+1}^*)$, more precisely, of the part of $P(i_{k'+1}^*)$ within G' and G'' . Since E_{hs} is a good hitting set, it holds that G' (or G'') restricted to E_{hs}^* is a path.

► **Lemma 21.** *Let $\tilde{G} \in \{G_1, \dots, G_K\}$. Then $G[E_{\text{hs}}^* \cap E(\tilde{G})]$ is a path (possibly with zero edges).*

Let $\bar{G}' := G[E_{\text{hs}}^* \cap E(G')]$ and $\bar{G}'' := G[E_{\text{hs}}^* \cap E(G'')]$. Observe that $P(i_{k'+1}^*)$ uses some edges of \bar{G}' and also $P(i_{k'+1})$ uses some edges of \bar{G}' . Note that the respective sets of edges are contained in each other. The same holds for \bar{G}'' . It turns out that for Lemma 19 a particularly bad case is when $P(i_{k'+1})$ uses strictly more edges of both \bar{G}' and \bar{G}'' than $P(i_{k'+1}^*)$, i.e., then we need to remove seven tasks from $\text{OPT}_{k'}$, rather than fewer tasks. Therefore, we guess whether this bad case applies. If yes, instead of $i_{k'+1} =: i_{k'+1}^{(1)}$ we consider a task $i_{k'+1}^{(2)}$ which is the input task i of smallest demand with endvertices in G' and G'' , such that $\{i, i_1, \dots, i_{k'}\}$ forms a feasible solution and $P(i)$ uses strictly less edges than $P(i_{k'+1}^{(1)})$ of both \bar{G}' and \bar{G}'' . Again, we guess whether the bad case applies for $i_{k'+1}^{(2)}$. If yes, we replace $i_{k'+1}^{(2)}$ by some task $i_{k'+1}^{(3)}$ that uses even fewer edges of \bar{G}' and \bar{G}'' and so on. We repeat this for at most $2k$ iterations. Formally, if for some $\ell \in \{1, \dots, 2k\}$ we defined the task $i_{k'+1}^{(\ell)}$ then we guess whether the bad case applies for $i_{k'+1}^{(\ell)}$, i.e., whether $P(i_{k'+1}^{(\ell)})$ uses strictly more edges of both \bar{G}' and \bar{G}'' than $P(i_{k'+1}^*)$. If yes, we define the task $i_{k'+1}^{(\ell+1)}$ to be the input task i of smallest demand with endvertices in G' and G'' , such that $\{i, i_1, \dots, i_{k'}\}$ forms a feasible solution and $P(i)$ uses strictly less edges than $P(i_{k'+1}^{(\ell)})$ of both \bar{G}' and \bar{G}'' . If for some $i_{k'+1}^{(\ell)}$ with $\ell \in \{1, \dots, 2k\}$ the bad case does not apply then intuitively we can show that

for adding $i_{k'+1}^{(\ell)}$ we need to remove only five tasks from OPT, rather than seven. In this case we select $i_k := i_{k'+1}^{(\ell)}$ and define $\text{OPT}_{k'+1} := \text{OPT}_{k'} \setminus \{i'_1, \dots, i'_5\}$ for the tasks i'_1, \dots, i'_5 due to the following lemma, and continue with the next round $k' + 2$.

► **Lemma 22.** *Suppose that for some $\ell \in \{1, \dots, 2k\}$ it holds that $P(i_{k'+1}^{(\ell)})$ does not use strictly more edges of both \bar{G}' and \bar{G}'' than $P(i_{k'+1}^*)$. Then there exist tasks $i'_1, \dots, i'_5 \in \text{OPT}_{k'}$ such that $\text{OPT}_{k'} \setminus \{i'_1, \dots, i'_5\} \cup \{i_1, \dots, i_{k'}, i_{k'+1}^{(\ell)}\}$ is feasible.*

Proof. Assume w.l.o.g. that $P(i_{k'+1}^{(\ell)})$ does not use strictly more edges of \bar{G}'' than $P(i_{k'+1}^*)$. Following the idea behind Lemma 19 we identify five tasks $i'_1, \dots, i'_5 \in \text{OPT}_{k'}$ such that $d(i'_j) \geq d(i_{k'+1}^*) \geq d(i_{k'+1}^{(\ell)})$ for each $j \in \{1, \dots, 5\}$ and such that the edges of their paths (together) contain all the edges of $P(i_{k'+1}^{(\ell)})$ that are used by tasks in $\text{OPT}_{k'}$ (i.e., edges on which selecting $i_{k'+1}^{(\ell)}$ potentially causes conflicts with other tasks in $\text{OPT}_{k'}$). We will select three tasks for the edges in $P(i_{k'+1}^{(\ell)}) \cap E(G')$, one for the edges in $P(i_{k'+1}^{(\ell)}) \cap E(G'') \setminus E(\bar{G}'')$, and one for the edges in $P(i_{k'+1}^{(\ell)}) \setminus (E(G') \cup E(G''))$ and the edges in $P(i_{k'+1}^{(\ell)}) \cap E(\bar{G}'')$.

Consider the edges in $P(i_{k'+1}^{(\ell)}) \cap E(G')$. We partition them into $P(i_{k'+1}^{(\ell)}) \cap E(G') \setminus E(\bar{G}')$ and $P(i_{k'+1}^{(\ell)}) \cap E(\bar{G}')$. If an edge $e \in P(i_{k'+1}^{(\ell)}) \cap E(G') \setminus E(\bar{G}')$ is used by some task $i \in \text{OPT}_{k'}$, then e is also used by the task $i' \in \text{OPT}_{k'}$ that maximizes $|P(i') \cap P(i_{k'+1}^{(\ell)}) \cap E(G') \setminus E(\bar{G}')|$. Let i'_1 denote this task i' . Regarding the edges in $P(i_{k'+1}^{(\ell)}) \cap E(\bar{G}')$, note that they form a path, and let u and v be its end vertices. Let i'_2 denote the task $i \in \text{OPT}_{k'}$ such that $u \in V(P(i))$ and i maximizes $|P(i) \cap E(\bar{G}')|$. Similarly, let i'_3 denote the task $i \in \text{OPT}_{k'}$ such that $v \in V(P(i))$ and i maximizes $|P(i) \cap E(\bar{G}')|$. Then, if some task $i \in \text{OPT}_{k'}$ uses an edge $e \in P(i_{k'+1}^{(\ell)}) \cap E(\bar{G}')$ then $e \in P(i'_2)$ or $e \in P(i'_3)$.

Regarding the edges in $P(i_{k'+1}^{(\ell)}) \cap E(G'') \setminus E(\bar{G}'')$, if an edge $e \in P(i_{k'+1}^{(\ell)}) \cap E(G'') \setminus E(\bar{G}'')$ is used by some task $i \in \text{OPT}_{k'}$, then e is also used by the task $i' \in \text{OPT}_{k'}$ that maximizes $|P(i') \cap P(i_{k'+1}^{(\ell)}) \cap E(G'') \setminus E(\bar{G}'')|$. Let i'_4 denote this task i' . Regarding the edges in $P(i_{k'+1}^{(\ell)}) \cap E(\bar{G}'')$ and the edges in $P(i_{k'+1}^{(\ell)}) \setminus (E(G') \cup E(G''))$, they are all used by $i_{k'+1}^*$, which we now identify as i'_5 .

It follows that if an edge e is used by some task $i \in \text{OPT}_{k'}$, then $e \in P(i'_j)$ for some $j \in \{1, \dots, 5\}$. Since $d(i'_j) \geq d(i_{k'+1}^*) \geq d(i_{k'+1}^{(\ell)})$ for each $j \in \{1, \dots, 5\}$, the tasks i'_1, \dots, i'_5 satisfy the claim of the lemma. ◀

On the other hand, if the bad case applied to each $i_{k'+1}^{(\ell)}$ with $\ell \in \{1, \dots, 2k\}$ then we can show that there must be one task $i_{k'+1}^{(\ell^*)}$ with $\ell^* \in \{1, \dots, 2k\}$ such that the edges of $P(i_{k'+1}^{(\ell^*)}) \setminus E_{\text{hs}}^*$ are not used by any task in OPT. It turns out that this is again a good case. Intuitively, then we do not need to remove any task from OPT in order to make space for $i_{k'+1}^{(\ell^*)}$ on the edges in $P(i_{k'+1}^{(\ell^*)}) \setminus E_{\text{hs}}^*$ and, therefore, it turns out that we need to remove only five tasks from OPT. In this case we guess ℓ^* , select $i_k := i_{k'+1}^{(\ell^*)}$ and define $\text{OPT}_{k'+1} := \text{OPT}_{k'} \setminus \{i'_1, \dots, i'_5\}$ for the tasks i'_1, \dots, i'_5 due to the following lemma, and continue with the next round $k' + 2$.

► **Lemma 23.** *Suppose that for each $\ell \in \{1, \dots, 2k\}$ it holds that $P(i_{k'+1}^{(\ell)})$ uses strictly more edges of \bar{G}' and \bar{G}'' than $P(i_{k'+1}^*)$. Then there is an $\ell^* \in \{1, \dots, 2k\}$ for which there exist tasks $i'_1, \dots, i'_5 \in \text{OPT}_{k'}$ such that $\text{OPT}_{k'} \setminus \{i'_1, \dots, i'_5\} \cup \{i_1, \dots, i_{k'}, i_{k'+1}^{(\ell^*)}\}$ is feasible.*

Proof. Since for each $\ell \in \{1, \dots, 2k\}$ it holds that $P(i_{k'+1}^{(\ell)})$ uses strictly more edges of \bar{G}' and \bar{G}'' than $P(i_{k'+1}^*)$, then there is an $\ell^* \in \{1, \dots, 2k\}$ such that $|P(i_{k'+1}^{(\ell^*)}) \cap E(\bar{G}') \setminus E_{\text{hs}}^*| = |P(i_{k'+1}^{(\ell^*)}) \cap E(\bar{G}'') \setminus E_{\text{hs}}^*| = 0$. Following the idea behind Lemma 19 we identify five tasks

$i'_1, \dots, i'_5 \in \text{OPT}_{k'}$ such that $d(i'_{\ell^*}) \geq d(i'_{k'+1}) \geq d(i_{k'+1})$ for each $j \in \{1, \dots, 5\}$ and such that the edges of their paths contain all the edges of $P(i_{k'+1})$ that are used by tasks in $\text{OPT}_{k'}$ (i.e., edges on which selecting $i_{k'+1}$ potentially causes conflicts with other tasks in $\text{OPT}_{k'}$). Now will select two tasks for the edges in $P(i_{k'+1}^{(\ell^*)}) \cap E(\bar{G}')$, two for the ones in that in $P(i_{k'+1}^{(\ell^*)}) \cap E(\bar{G}'')$ and one for the edges in $P(i_{k'+1}^{(\ell^*)}) \setminus (E(\bar{G}') \cup E(\bar{G}''))$.

Consider the edges in $P(i_{k'+1}^{(\ell^*)}) \cap E(\bar{G}'')$. We partition them into $P(i_{k'+1}^{(\ell^*)}) \cap E(G'') \setminus E(\bar{G}'')$ and $P(i_{k'+1}^{(\ell^*)}) \cap E(\bar{G}'')$. There is no edge $P(i_{k'+1}^{(\ell^*)}) \cap E(G'') \setminus E(\bar{G}'')$ used by some task $i \in \text{OPT}_{k'}$, so we don't need to define a task to cover those edges. Regarding the edges in $P(i_{k'+1}^{(\ell^*)}) \cap E(\bar{G}'')$, we note that they form a path, and let u and v be their end vertices. Let i'_1 denote the task $i \in \text{OPT}_{k'}$ such that $u \in V(P(i))$ and i maximizes $|P(i) \cap E(\bar{G}') \cap E_{\text{hs}}^*|$. Similarly, let i'_2 denote the task $i \in \text{OPT}_{k'}$ such that $v \in V(P(i))$ and i maximizes $|P(i) \cap E(\bar{G}'') \cap E_{\text{hs}}^*|$. Then, if some task $i \in \text{OPT}_{k'}$ uses an edge $e \in P(i_{k'+1}) \cap E(\bar{G}'')$ then $e \in P(i'_1)$ or $e \in P(i'_2)$. In a similar way, we identify two tasks i'_3 and i'_4 for $P(i_{k'+1}^{(\ell^*)}) \cap E(G'')$.

Finally, all the edges in $P(i_{k'+1}^{(\ell^*)}) \setminus (G' \cup G'')$ are used by $i_{k'+1}^*$, and we define $i'_5 := i_{k'+1}^*$. It follows that if an edge e is used by some task $i \in \text{OPT}_{k'}$, then $e \in P(i'_j)$ for some $j \in \{1, \dots, 5\}$. Since $d(i'_j) \geq d(i_{k'+1}^*) \geq d(i_{k'+1})$ for each $j \in \{1, \dots, 5\}$, the tasks i'_1, \dots, i'_5 satisfy the claim of the lemma. \blacktriangleleft

Since in each iteration we picked one task and removed at most five tasks from OPT , one can show easily that at the end we select $\lceil k/5 \rceil$ tasks, assuming that $|\text{OPT}| \geq k$. Our running time is $k^{O(k)} n^{O(1)}$ since in each of the k iterations there are $O(k^2)$ options for our guesses.

► **Theorem 24.** *There is an FPT-5-approximation algorithm for UFT with a running time of $k^{O(k)} n^{O(1)}$.*

A Simple Algorithm for Graph Reconstruction

Abstract

How efficiently can we find an unknown graph using distance queries between its vertices? We assume that the unknown graph is connected, unweighted, and has bounded degree. The goal is to find every edge in the graph. This problem admits a reconstruction algorithm based on multi-phase Voronoi-cell decomposition and using $\tilde{O}(n^{3/2})$ distance queries [27].

In our work, we analyze a simple reconstruction algorithm. We show that, on random Δ -regular graphs, our algorithm uses $\tilde{O}(n)$ distance queries. As by-products, we can reconstruct those graphs using $O(\log^2 n)$ queries to an all-distances oracle or $\tilde{O}(n)$ queries to a betweenness oracle, and we bound the metric dimension of those graphs by $\log^2 n$.

Our reconstruction algorithm has a very simple structure, and is highly parallelizable. On general graphs of bounded degree, our reconstruction algorithm has subquadratic query complexity.

1 Introduction

Discovering the topology of the Internet is a crucial step for building accurate network models and designing efficient algorithms for Internet applications. The topology of Internet networks is typically investigated at the router level, using `traceroute`. It is a common and reasonably accurate assumption that `traceroute` generates paths that are shortest in the network. Unfortunately, sometimes routers block `traceroute` requests due to privacy and security concerns. As a consequence, the inference of the network topology is rather based on the end-to-end delay information on those requests, which is roughly proportional to the shortest-path distances in the network.

In the *graph reconstruction* problem, we are given the vertex set V of a hidden connected, undirected, and unweighted graph and have access to information about the topology of the graph via an oracle, and the goal is to find every edge in E . Henceforth, unless explicitly mentioned, all graphs studied are assumed to be connected. This assumption is standard and shared by almost all references on the subject, e.g., [7, 14, 27, 39, 41]. The efficiency of an algorithm is measured by the *query complexity*, i.e., the number of queries to the oracle. Motivated by `traceroute`, the literature has explored several types of query oracles.

- One type consists of *all-shortest-paths* and *all-distances* queries, when querying a vertex yields either shortest paths from that vertex to all other vertices [7, 41] or distances from that vertex to all other vertices [14]. The latter, of course, is less informative.
- A more refined type of query oracles, suggested in [7, 14], consists of *shortest-path* and *distance* queries, when querying a pair of vertices yields either a shortest path or the distance between them [27, 38, 39]. Again, the latter is less informative.

In this work, we focus on the weakest of those four query oracles, that takes as input a pair of vertices a and b and returns the distance $\delta(a, b)$ between them. Reyzin and Srivastava [38] showed that graph reconstruction requires $\Omega(n^2)$ distance queries on general graphs, so we focus on the bounded degree case. For graphs of bounded degree, Kannan, Mathieu, and Zhou [27] gave a reconstruction algorithm based on multi-phase Voronoi-cell decomposition and using $\tilde{O}(n^{3/2})$ distance queries, and raised an open question of whether $\tilde{O}(n)$ is achievable.¹

We provide a partial answer to that open question by analyzing a simple reconstruction algorithm (Algorithm 1). We show that, on (uniformly) random Δ -regular graphs, where every vertex has the same degree Δ , our reconstruction algorithm uses $\tilde{O}(n)$ distance queries (Theorem 1). As by-products, we can reconstruct those graphs using $O(\log^2 n)$ queries to an all-distances oracle (Corollary 2) or using $\tilde{O}(n)$ queries to a betweenness oracle (Corollary 3), and we bound the metric dimension of those graphs by at most $\log^2 n$ (Corollary 5).

Our analysis exploits the *locally tree-like* property of random Δ -regular graphs, meaning that these graphs contain a small number of short cycles. Our method might be applicable to other locally tree-like graphs, such as Erdős-Rényi random graphs and *scale-free* graphs. In particular, many real world networks, such as Internet networks, social networks, and peer-to-peer networks, are believed to have scale-free properties [6, 25, 34]. We defer the reconstruction of those networks for future work.

Our reconstruction algorithm has a very simple structure, and is highly parallelizable (Corollary 4). On general graphs of bounded degree, the same reconstruction algorithm has subquadratic query complexity (Theorem 6).

1.1 Related Work

The problem of reconstructing a graph using queries that reveal partial information has been extensively studied in different contexts and has many applications.

Reconstruction of Random Graphs

The gist of our paper deals with random graphs. The graph reconstruction problem has already attracted much interest in the setting of random graphs. On Erdős-Rényi random graphs, Erlebach, Hall, and Mihalák [15] studied the approximate network reconstruction using all-shortest-paths queries; Anandkumar, Hassidim, and Kelner [4] used end-to-end measurements between a subset of vertices to approximate the network structure. Experimental results to reconstruct random graphs using shortest-path queries were given in [8, 20].

On random Δ -regular graphs, Achlioptas et al. [2] studied the bias of `traceroute` sampling in the context of the network reconstruction. They showed that the structure revealed by `traceroute` sampling on random Δ -regular graphs admits a power-law degree distribution [2], a common phenomenon as in Erdős-Rényi random graphs [31] and Internet networks [16].

Metric Dimension and Related Problems

Our work yields an upper bound on the *metric dimension* of random Δ -regular graphs. The metric dimension problem was first introduced by Slater [42] and Harary and Melter [21], see also [5, 13, 12, 23, 29, 36, 37, 40]. The metric dimension of a graph is the cardinality of

¹ The notation $\tilde{O}(f(n))$ stands for $O(f(n) \cdot \text{polylog } f(n))$.

a smallest subset S of vertices such that every vertex in the graph has a unique vector of distances to the vertices in S . On regular graphs, the metric dimension problem was studied in special cases [12, 24]. In Erdős-Rényi random graphs, the metric dimension problem was studied by Bollobás, Mitsche, and Prałat [11]. Mitsche and Rué [32] also considered the random forest model.

A related problem is the *identifying code* of a graph [28], which is a smallest subset of vertices such that every vertex of the graph is uniquely determined by its neighbourhood within this subset. The identifying code problem was studied on random Δ -regular graphs [17] and on Erdős-Rényi random graphs [19]. Other related problems received attentions on random graphs as well, such as the *sequential metric dimension* [35] and the *seeded graph matching* [33].

Betweenness Oracle

There exists an oracle that is even weaker than the distance oracle: the *betweenness* oracle [1], which receives three vertices u , v , and w and returns whether w lies on a shortest path between u and v . Our work yields a reconstruction algorithm using $\tilde{O}(n)$ betweenness queries on random Δ -regular graphs. For graphs of bounded degree, Abrahamsen et al. [1] generalized the $\tilde{O}(n^{3/2})$ result in the distance oracle model from [27] to the betweenness oracle model.

Tree Reconstruction and Parallel Setting

Our paper focuses on the distance oracle and bounded degree, and considers the parallel setting. All of those aspects were previously raised in the special case of the *tree reconstruction*. Indeed, motivated by the reconstruction of a phylogenetic tree in evolutionary biology, the tree reconstruction problem using a distance oracle is well-studied [22, 30, 43], in particular assuming bounded degree [22]. Afshar et al. [3] studied the tree reconstruction in the parallel setting, analyzing both the *round complexity* and the *query complexity* in the relative distance query model [26].

1.2 Our Results

Our reconstruction algorithm, called SIMPLE, is given in Algorithm 1. It takes as input the vertex set V of size n and an integer parameter $s \in [1, n]$.

■ **Algorithm 1** SIMPLE (V, s).

-
- 1: $S \leftarrow$ sample of s vertices selected uniformly and independently at random from V
 - 2: **for** $u \in S$ and $v \in V$ **do** QUERY(u, v)
 - 3: $\hat{E} \leftarrow$ set of vertex pairs $\{a, b\} \subseteq V$ such that, for all $u \in S$, $|\delta(u, a) - \delta(u, b)| \leq 1$
 - 4: **for** $\{a, b\} \in \hat{E}$ **do** QUERY(a, b)
 - 5: **return** set of vertex pairs $\{a, b\} \in \hat{E}$ such that $\delta(a, b) = 1$
-

Intuitively, the set \hat{E} constructed in SIMPLE consists of all vertex pairs $\{a, b\} \subseteq V$ that *might* be an edge in E . In order to obtain the edge set E , it suffices to query uniquely the vertex pairs in \hat{E} . We remark that SIMPLE correctly reconstructs the graph for any parameter $s \in [1, n]$, and that choosing an appropriate s only affects the query complexity, see Lemma 9.

1.2.1 Random Regular Graphs

Our first main result shows that SIMPLE (Algorithm 1) uses $\tilde{O}(n)$ distance queries on random Δ -regular graphs for an appropriately chosen s (Theorem 1). The analysis exploits the *locally tree-like* property of random Δ -regular graphs. The proof of Theorem 1 consists of several technical novelties, based on a new concept of *interesting vertices* (Definition 14). See Section 3.

► **Theorem 1.** *Consider a uniformly random Δ -regular graph with $\Delta = O(1)$. Let $s = \log^2 n$. In the distance query model, SIMPLE (Algorithm 1) is a reconstruction algorithm using $\tilde{O}(n)$ queries in expectation.*

We extend SIMPLE and its analysis to reconstruct random Δ -regular graphs in the all-distances query model (Corollary 2), in the betweenness query model (Corollary 3), as well as in the parallel setting (Corollary 4). These extensions are based on the observation that the set \hat{E} constructed in SIMPLE equals the edge set E with high probability (Lemma 17),² see Section 4.

► **Corollary 2.** *Consider a uniformly random Δ -regular graph with $\Delta = O(1)$. In the all-distances query model, there is a reconstruction algorithm using $O(\log^2 n)$ queries in expectation.*

► **Corollary 3.** *Consider a uniformly random Δ -regular graph with $\Delta = O(1)$. In the betweenness query model, there is a reconstruction algorithm using $\tilde{O}(n)$ queries in expectation.*

► **Corollary 4.** *Consider a uniformly random Δ -regular graph with $\Delta = O(1)$. In the parallel setting of the distance query model, there is a reconstruction algorithm using $1 + o(1)$ rounds and $\tilde{O}(n)$ queries in expectation.*

We further extend the analysis of SIMPLE to study the metric dimension of random Δ -regular graphs (Corollary 5), by showing (in Lemma 21) that a random subset of $\log^2 n$ vertices is almost surely a *resolving set* (Definition 20) for those graphs, see Section 5.

► **Corollary 5.** *Consider a uniformly random Δ -regular graph with $\Delta = O(1)$. With probability $1 - o(1)$, the metric dimension of the graph is at most $\log^2 n$.*

With extra work, the parameter $s = \log^2 n$ in Theorem 1 can be reduced to $\log n \cdot (\log \log n)^{2+\epsilon}$, for any $\epsilon > 0$, see the full version of the paper. As a consequence, the query complexity in the all-distances query model (Corollary 2) and the upper bound on the metric dimension (Corollary 5) can both be improved to $O(\log n \cdot (\log \log n)^{2+\epsilon})$.

1.2.2 Bounded-Degree Graphs

On general graphs of bounded degree, SIMPLE (Algorithm 1) has subquadratic query complexity and is highly parallelizable (Theorem 6), see Section 6.

► **Theorem 6.** *Consider a general graph of bounded degree $\Delta = O(\text{polylog } n)$. Let $s = n^{2/3}$. In the distance query model, SIMPLE (Algorithm 1) is a reconstruction algorithm using $\tilde{O}(n^{5/3})$ queries in expectation. In addition, SIMPLE can be parallelized using 2 rounds.*

² This property (i.e., $\hat{E} = E$ with high probability) does not hold on general graphs of bounded degree.

We note that the MULTI-PHASE algorithm³ from [27] also reconstructs graphs of bounded degree in the distance query model. How does SIMPLE compare to MULTI-PHASE? In terms of query complexity, on general graphs of bounded degree, SIMPLE uses $\tilde{O}(n^{5/3})$ queries, so is not as good as MULTI-PHASE using $\tilde{O}(n^{3/2})$ queries; on random Δ -regular graphs, SIMPLE is more efficient than MULTI-PHASE: $\tilde{O}(n)$ versus $\tilde{O}(n^{3/2})$. In terms of round complexity, SIMPLE can be parallelized using 2 rounds on general graphs, and even $1 + o(1)$ rounds on random Δ -regular graphs; while MULTI-PHASE requires up to $3 \log n$ rounds due to a multi-phase selection process for centers.⁴ In terms of structure, SIMPLE is much simpler than MULTI-PHASE, which is based on multi-phase Voronoi-cell decomposition.

► **Remark.** In the worst case, the query complexity of SIMPLE is higher than linear. For example, when the graph is a complete binary tree, SIMPLE would require $\Omega(n\sqrt{n})$ queries (the complexity of SIMPLE is minimized when s is roughly \sqrt{n}). Thus the open question from [27] of whether general graphs of bounded degree can be reconstructed using $\tilde{O}(n)$ distance queries remains open and answering it positively would require further algorithmic ideas.

2 Notations and Preliminary Analysis

Let $G = (V, E)$ be a connected, undirected, and unweighted graph, where V is the set of vertices such that $|V| = n$ and E is the set of edges. We say that $\{a, b\} \subseteq V$ is a *vertex pair* if both a and b belong to V such that $a \neq b$. The *distance* between a vertex pair $\{a, b\} \subseteq V$, denoted by $\delta(a, b)$, is the number of edges on a shortest a -to- b path.

► **Definition 7** (Distinguishing). *For a vertex pair $\{a, b\} \subseteq V$, we say that a vertex $u \in V$ distinguishes a and b , or equivalently that u is a distinguisher of $\{a, b\}$, if $|\delta(u, a) - \delta(u, b)| > 1$. Let $D(a, b) \subseteq V$ denote the set of vertices $u \in V$ distinguishing a and b .*

Let $s \in [1, n]$ be an integer parameter. The set S constructed in SIMPLE consists of s vertices selected uniformly and independently at random from V .

The set \hat{E} constructed in SIMPLE consists of the vertex pairs $\{a, b\} \subseteq V$ such that a and b are not distinguished by any vertex in S , i.e., $D(a, b) \cap S = \emptyset$, or equivalently, $|\delta(u, a) - \delta(u, b)| \leq 1$ for all $u \in S$. For any edge $(a, b) \in E$, it is easy to see that $|\delta(u, a) - \delta(u, b)| \leq 1$ for all $u \in V$, which implies that $\{a, b\} \in \hat{E}$. Hence the following inclusion.

► **Fact 8.** $E \subseteq \hat{E}$.

We show that SIMPLE is correct and we give a preliminary analysis on its query complexity as well as on its round complexity, in Lemma 9.

► **Lemma 9.** *The output of SIMPLE (Algorithm 1) equals the edge set E . The number of distance queries in SIMPLE is $n \cdot s + |\hat{E}|$. In addition, SIMPLE can be parallelized using 2 rounds.*

Proof. The output of SIMPLE consists of the vertex pairs $\{a, b\} \in \hat{E}$ such that $\{a, b\}$ is an edge in E . Since $E \subseteq \hat{E}$ (Fact 8), the output of SIMPLE equals the edge set E .

Observe that the distance queries in SIMPLE are performed in two stages. The number of distance queries in the first stage is $|V| \cdot |S| = n \cdot s$. The number of distance queries in

³ Algorithm 3 in [27].

⁴ The number of rounds in MULTI-PHASE is implicit in the proof of Lemma 2.3 from [27].

the second stage is $|\hat{E}|$. Thus the query complexity of SIMPLE is $n \cdot s + |\hat{E}|$. The distance queries in each of the two stages can be performed in parallel, so SIMPLE can be parallelized using 2 rounds. \blacktriangleleft

From Lemma 9, in order to further study the query complexity of SIMPLE, it suffices to analyze $|\hat{E}|$, which equals $|E| + |\hat{E} \setminus E|$ according to Fact 8. Since $|E| \leq \Delta n$ in a graph of bounded degree Δ , our focus in the subsequent analysis is $|\hat{E} \setminus E|$.

► **Lemma 10.** *Let $s = \omega(\log n)$ be an integer parameter. Let B be the set of vertex pairs $\{a, b\} \subseteq V$ such that $\delta(a, b) \geq 2$ and $|D(a, b)| \leq 3n \cdot (\log n)/s$. We have $\mathbb{E}_S[|\hat{E} \setminus E|] \leq |B| + o(1)$.*

Proof. Denote Z as the set $\hat{E} \setminus E$. Observe that $|Z| \leq |B| + |Z \setminus B|$. Since B is independent of the random set S , we have $\mathbb{E}_S[|Z|] \leq |B| + \mathbb{E}_S[|Z \setminus B|]$. It suffices to show that $\mathbb{E}_S[|Z \setminus B|] = o(1)$.

We claim that for any vertex pair $\{a, b\} \subseteq V$ such that $\{a, b\} \notin B$, the probability that $\{a, b\} \in Z$ is $o(n^{-2})$. To see this, fix a vertex pair $\{a, b\} \notin B$. By definition of B , either $\delta(a, b) = 1$, or $|D(a, b)| > 3n \cdot (\log n)/s$. In the first case, $\{a, b\} \notin Z$ since Z does not contain any edge of E . In the second case, observe that the event $\{a, b\} \in Z$ implies that $\{a, b\} \in \hat{E}$, hence $D(a, b) \cap S = \emptyset$. Therefore,

$$\begin{aligned} & \mathbb{P}_S[\{a, b\} \in Z \mid \{a, b\} \notin B] \\ & \leq \mathbb{P}_S[D(a, b) \cap S = \emptyset \mid \{a, b\} \notin B] \\ & < \left(1 - \frac{3n \cdot (\log n)/s}{n}\right)^s \\ & = o(n^{-2}), \end{aligned}$$

where the second inequality follows since $|D(a, b)| > 3n \cdot (\log n)/s$ and the set S consists of s vertices selected uniformly and independently at random, and the last step follows since $s = \omega(\log n)$.

There are at most $n(n-1)/2$ vertex pairs $\{a, b\} \notin B$. By the linearity of expectation, the expected number of vertex pairs $\{a, b\} \notin B$ such that $\{a, b\} \in Z$ is at most $o(n^{-2}) \cdot n(n-1)/2 = o(1)$, so $\mathbb{E}_S[|Z \setminus B|] = o(1)$. Therefore, $\mathbb{E}_S[|Z|] \leq |B| + \mathbb{E}_S[|Z \setminus B|] = |B| + o(1)$. \blacktriangleleft

3 Reconstruction of Random Regular Graphs (Proof of Theorem 1)

In this section, we analyze SIMPLE (Algorithm 1) on random Δ -regular graphs in the distance query model. We assume that $\Delta \geq 2$ and that Δn is even since otherwise those graphs do not exist.

We bound the expectation of $|\hat{E} \setminus E|$ on random Δ -regular graphs, in Lemma 11.

► **Lemma 11.** *Let G be a uniformly random Δ -regular graph with $\Delta = O(1)$. Let $s = \log^2 n$. Let $S \subseteq V$ be a set of s vertices selected uniformly and independently at random from V . We have $\mathbb{E}_{G,S}[|\hat{E} \setminus E|] = o(1)$.*

Proof of Theorem 1 using Lemma 11. By Lemma 9, SIMPLE is a reconstruction algorithm using $n \cdot s + |\hat{E}| = n \cdot \log^2 n + |\hat{E}|$ distance queries. From Fact 8, $|\hat{E}| = |E| + |\hat{E} \setminus E|$. Since G is Δ -regular, $|E| = \Delta n/2$. By Lemma 11, $\mathbb{E}_{G,S}[|\hat{E} \setminus E|] = o(1)$. Therefore, the expected number of distance queries in SIMPLE is $n \cdot \log^2 n + \Delta n/2 + o(1)$, which is $\tilde{O}(n)$ since $\Delta = O(1)$. \blacktriangleleft

It remains to prove Lemma 11 in the rest of this section.

Configuration Model [9, 44]. We consider a random Δ -regular graph generated according to the *configuration model*. Given a partition of a set of Δn points into n cells v_1, v_2, \dots, v_n of Δ points, a *configuration* is a perfect matching of the points into $\Delta n/2$ pairs. It corresponds to a (not necessarily connected) *multigraph* G' in which the cells are regarded as vertices and the pairs as edges: a pair of points $\{x, y\}$ in the configuration corresponds to an edge (v_i, v_j) of G' where $x \in v_i$ and $y \in v_j$. Since each Δ -regular graph has exactly $(\Delta!)^n$ corresponding configurations, a Δ -regular graph can be generated uniformly at random by rejection sampling: choose a configuration uniformly at random,⁵ and reject the result if the corresponding multigraph G' is not simple or not connected. The configuration model enables us to show properties of a random Δ -regular graph by analyzing a multigraph G' corresponding to a random configuration.

In order to prove Lemma 11, we need the following Structural Lemma.

► **Lemma 12 (Structural Lemma).** *Let $\Delta = O(1)$ be such that $\Delta \geq 3$. Let G' be a multigraph corresponding to a uniformly random configuration. Let $\{v, w\}$ be a vertex pair in G' such that $\delta(v, w) \geq 2$. With probability $1 - o(n^{-2})$, we have $|D(v, w)| > 3n/\log n$.*

We defer the proof of the Structural Lemma for the moment and first show how it implies Lemma 11.⁶

Proof of Lemma 11 using the Structural Lemma (Lemma 12). Let G be a random graph and let S be a random subset of vertices, both defined in the statement of Lemma 11. According to Lemma 10, $\mathbb{E}_{G,S}[\hat{E} \setminus E] \leq \mathbb{E}_G[|B|] + o(1)$. It suffices to prove that $\mathbb{E}_G[|B|] = o(1)$.

First, we consider the case when $\Delta = O(1)$ is such that $\Delta \geq 3$. Our analysis is based on the configuration model. Let G' be a multigraph corresponding to a uniformly random configuration. Let $\mathbb{E}_{G'}[|B|]$ denote the expected size of the set B defined on G' . Since each Δ -regular graph corresponds to the same number of configurations and because the probability spaces of configurations and of Δ -regular graphs, respectively, are uniform, we have $\mathbb{E}_G[|B|] \leq \mathbb{E}_{G'}[|B|]/p$, where p is the probability that G' is both simple and connected. According to [44], when $\Delta \geq 3$, $p \sim e^{(1-\Delta^2)/4}$, which is constant since $\Delta = O(1)$. Thus $\mathbb{E}_G[|B|] = O(\mathbb{E}_{G'}[|B|])$.

In order to bound $\mathbb{E}_{G'}[|B|]$, consider any vertex pair $\{v, w\}$ in G' such that $\delta(v, w) \geq 2$. From Lemma 12, the event $|D(v, w)| \leq 3n/\log n$ occurs with probability $o(n^{-2})$. Equivalently, the event $|D(v, w)| \leq 3n \cdot (\log n)/s$ occurs with probability $o(n^{-2})$, since $s = \log^2 n$. Thus the event $\{v, w\} \in B$ occurs with probability $o(n^{-2})$ according to the definition of B in Lemma 10. There are $n(n-1)/2$ vertex pairs $\{v, w\}$ in G' . By linearity of expectation, $\mathbb{E}_{G'}[|B|]$ is at most $o(n^{-2}) \cdot n(n-1)/2 = o(1)$. Hence $\mathbb{E}_G[|B|] = O(\mathbb{E}_{G'}[|B|]) = o(1)$.

In the special case when $\Delta = 2$, a 2-regular graph G is a ring. Consider any vertex pair $\{v, w\}$ in G such that $\delta(v, w) \geq 2$. It is easy to see that at least $n-4$ vertices u in the ring G are such that $|\delta(u, v) - \delta(u, w)| > 1$, so $|D(v, w)| \geq n-4$ by Definition 7. When n is large enough, $n-4 > 3n/\log n$, so $|D(v, w)| > 3n/\log n$. Equivalently, we have $|D(v, w)| > 3n \cdot (\log n)/s$, since $s = \log^2 n$. Thus $\{v, w\} \notin B$ according to the definition of B in Lemma 10. Therefore, $B = \emptyset$ and $\mathbb{E}_G[|B|] = 0$.

We conclude that $\mathbb{E}_G[|B|] = o(1)$ for any $\Delta = O(1)$. Thus $\mathbb{E}_{G,S}[\hat{E} \setminus E] \leq \mathbb{E}_G[|B|] + o(1) = o(1)$. ◀

⁵ To generate a random configuration, the points in a pair can be chosen sequentially: the first point can be selected using any rule, as long as the second point in that pair is chosen uniformly from the remaining points.

⁶ Note that Lemma 11 is an intermediate step to prove Theorem 1 using Lemma 12. We state Lemma 11 separately since it will be reused in Section 4.

The rest of the section is dedicated to prove the Structural Lemma (Lemma 12).

Let G' be a multigraph corresponding to a uniformly random configuration, and let V be the vertex set of G' . Let $\{v, w\} \subseteq V$ be a vertex pair such that $\delta(v, w) \geq 2$. For a vertex $x \in V$, denote $\ell(x) \in \mathbb{Z}$ as the distance in G' between x and the vertex pair $\{v, w\}$, i.e., $\ell(x) = \min(\delta(x, v), \delta(x, w))$. For any integer $k \geq 0$, denote $U_k \subseteq V$ as the set of vertices $x \in V$ such that $\ell(x) = k$. Denote $U_{\leq k} = \bigcup_{j \leq k} U_j$.

To construct the multigraph G' from a random configuration, we borrow the approach from [10], which proceeds in phases to construct the edges in G' , exploring vertices $x \in V$ in non-decreasing order of $\ell(x)$. We start at the vertices of $U_0 = \{v, w\}$. Initially (i.e., in the 0-th phase), we construct all the edges incident to v or incident to w . Suppose at the beginning of the k -th phase (for $k \in [1, n-1]$), we have constructed all the edges with at least one endpoint belonging to $U_{\leq k-1}$. During the k -th phase, we construct the edges incident to the vertices in U_k one by one, till the degree of all the vertices in U_k reaches Δ . Let G' be the resulting multigraph in the end of the construction.⁷

An edge (a, b) in G' is *indispensable* if it explores either the vertex a or the vertex b for the first time in the edge construction. In the first case, b is the *predecessor* of a ; and in the second case, a is the *predecessor* of b . An edge is *dispensable* if it is not indispensable, in other words, if each of its endpoints either belongs to $\{v, w\}$ or is an endpoint of an edge constructed previously.

► **Fact 13.** *Neither v or w has a predecessor. For any vertex in V , its predecessor, if exists, is unique. If vertex a is the predecessor of vertex b , then $\ell(b) = \ell(a) + 1$.*

We introduce the concept of *interesting vertices*, which is a key idea in the analysis.

► **Definition 14 (Interesting Vertices).** *A vertex $x \in V$ is v -interesting if, for all vertices $z \in V \setminus \{v\}$ with $\delta(v, z) + \delta(z, x) = \delta(v, x)$, the edges incident to z are indispensable. Similarly, a vertex $x \in V$ is w -interesting if, for all vertices $z \in V \setminus \{w\}$ with $\delta(w, z) + \delta(z, x) = \delta(w, x)$, the edges incident to z are indispensable.*

For any finite integer $k \geq 1$, let $I_k(v) \subseteq V$ denote the set of v -interesting vertices $x \in V$ such that $\delta(v, x) = k$, and let $I_k(w) \subseteq V$ denote the set of w -interesting vertices $x \in V$ such that $\delta(w, x) = k$.

We show in Lemma 15 that interesting vertices distinguish the vertex pair $\{v, w\}$, which is a main technical novelty of the section.

► **Lemma 15.** *For any finite integer $k \geq 1$, we have $I_k(v) \cup I_k(w) \subseteq D(v, w)$.*

Proof. Fix a finite integer $k \geq 1$. From the symmetry of v and w , it suffices to prove $I_k(v) \subseteq D(v, w)$.

Let x be any vertex in $I_k(v)$. By definition, x is v -interesting and $\delta(v, x) = k$. Let $a_0 = v, a_1, \dots, a_k = x$ be any shortest v -to- x path. For any vertex a_i with $i \in [1, k]$, the edges incident to a_i are indispensable according to Definition 14.

We claim that, for any $i \in [1, k]$, a_{i-1} is the predecessor of a_i , and in addition, $\ell(a_i) = i$. The proof is by induction. First, consider the case when $i = 1$. The edge (a_0, a_1) is incident to the vertex a_1 , so is indispensable. Thus either a_0 is the predecessor of a_1 , or a_1 is the

⁷ When a multigraph corresponding to a random configuration is not connected, the resulting G' consists of the union of the components of v and of w , respectively, in that multigraph. It is not necessary to extend G' to the entire multigraph. Indeed, any vertex $x \in V$ outside the union of those two components cannot distinguish v and w (i.e., $x \notin D(v, w)$), thus x is irrelevant to $|D(v, w)|$ in the statement of Lemma 12.

■ **Figure 1** a_0, a_1, \dots, a_k is a shortest v -to- x path, and $b_0, b_1, \dots, b_{k'}$ is a shortest w -to- x path. The vertex z represents the branching point of these two paths. Since the vertex x is v -interesting, the highlighted edges are indispensable.

predecessor of a_0 . Since $a_0 (= v)$ has no predecessor (Fact 13), a_1 cannot be the predecessor of a_0 , so a_0 is the predecessor of a_1 . Again using Fact 13, we have $\ell(a_1) = \ell(a_0) + 1$. Since $\ell(a_0) = \ell(v) = 0$, we have $\ell(a_1) = 1$. Next, consider the case when $i \geq 2$, and assume that the claim holds already for $1, \dots, i-1$. The edge (a_{i-1}, a_i) is incident to the vertex a_i , so is indispensable. Thus either a_{i-1} is the predecessor of a_i , or a_i is the predecessor of a_{i-1} . By induction, a_{i-2} is the predecessor of a_{i-1} . Since the predecessor of a_{i-1} is unique (Fact 13), a_i cannot be the predecessor of a_{i-1} , so a_{i-1} is the predecessor of a_i . Again using Fact 13, we have $\ell(a_i) = \ell(a_{i-1}) + 1$. Since $\ell(a_{i-1}) = i-1$ by induction, we have $\ell(a_i) = i$.

In order to show that $x \in D(v, w)$, we prove in the following that $\delta(w, x) \geq k+2$. Indeed, since $\delta(v, x) = k$, the event $\delta(w, x) \geq k+2$ implies that $x \in D(v, w)$ by Definition 7.⁸

Let $b_0 = w, b_1, \dots, b_{k'} = x$ be any shortest w -to- x path, for some integer k' . See Figure 1. Let $i^* \in [0, k]$ be the largest integer such that $a_{k-j} = b_{k'-j}$ for all $j \in [0, i^*]$. Let z denote the vertex a_{k-i^*} , which equals $b_{k'-i^*}$. If $i^* = k$, the v -to- x path a_0, a_1, \dots, a_k is a subpath of the w -to- x path $b_0, b_1, \dots, b_{k'}$. Since $\delta(w, v) \geq 2$, we have $\delta(w, x) = \delta(w, v) + \delta(v, x) \geq 2 + k$, which implies that $x \in D(v, w)$. From now on, it suffices to consider the case when $i^* < k$.

Let y denote the vertex $b_{k'-i^*-1}$. Since y is on a shortest w -to- x path, we have

$$\delta(w, x) = \delta(w, y) + \delta(y, x) = \delta(w, y) + (i^* + 1) \geq \ell(y) + (i^* + 1), \quad (1)$$

where the inequality follows from the definition of $\ell(y)$. It remains to analyze the value of $\ell(y)$.

The edge (z, y) is incident to the vertex $z (= a_{k-i^*})$, so is indispensable. Thus either y is the predecessor of z , or z is the predecessor of y . From the previous claim, a_{k-i^*-1} is the predecessor of z . Since the predecessor of z is unique (Fact 13) and $y \neq a_{k-i^*-1}$ (by definition of i^*), y cannot be the predecessor of z , so z is the predecessor of y . Again by

⁸ When $\delta(w, x)$ is infinite (i.e., w and x are not connected in G'), it is trivial that $x \in D(v, w)$, since $\delta(v, x)$ is finite. Therefore, it suffices to consider the case when $\delta(w, x)$ is finite in the rest of the proof.

68:10 A Simple Algorithm for Graph Reconstruction

Fact 13, $\ell(y) = \ell(z) + 1$. Since $\ell(z) = \ell(a_{k-i^*}) = k - i^*$ by the previous claim, we have $\ell(y) = k - i^* + 1$. We conclude from Equation (1) that

$$\delta(w, x) \geq (k - i^* + 1) + (i^* + 1) = k + 2,$$

which implies that $x \in D(v, w)$.

We proved that $I_k(v) \subseteq D(v, w)$. Similarly, $I_k(w) \subseteq D(v, w)$. Therefore, $I_k(v) \cup I_k(w) \subseteq D(v, w)$. \blacktriangleleft

A lower bound on the number of interesting vertices is given in Lemma 16, which is another technical novelty. The proof is based on the *locally tree-like* property in random Δ -regular graphs. It exploits the concept of interesting vertices in a non-trivial way and extends a 3-level argument from Bollobás [10] in the context of automorphisms of those graphs to an analysis of $\log \log n$ levels. See the full version of the paper for details.

► **Lemma 16.** *Let $\Delta = O(1)$ be such that $\Delta \geq 3$. Let k be any positive integer such that $k \leq \lceil \log_{\Delta-1}(3n/\log n) \rceil + 2$. With probability $1 - o(n^{-2})$, we have $|I_k(v) \cup I_k(w)| > (\Delta - 2 - o(1))(\Delta - 1)^{k-1}$.*

Proof of the Structural Lemma (Lemma 12). We set $k = \lceil \log_{\Delta-1}(3n/\log n) \rceil + 2$. By Lemma 15, $|D(v, w)| \geq |I_k(v) \cup I_k(w)|$. By Lemma 16, with probability $1 - o(n^{-2})$, we have

$$|I_k(v) \cup I_k(w)| > (\Delta - 2 - o(1))(\Delta - 1)^{k-1} \geq (\Delta - 2 - o(1))(\Delta - 1) \cdot (3n/\log n),$$

where the last inequality follows from the definition of k . Since $\Delta \geq 3$, we have $(\Delta - 2 - o(1))(\Delta - 1) > 1$. Thus with probability $1 - o(n^{-2})$, we have $|I_k(v) \cup I_k(w)| > 3n/\log n$, which implies that $|D(v, w)| > 3n/\log n$. \blacktriangleleft

4 Other Reconstruction Models (Proofs of Corollaries 2–4)

In this section, we study the reconstruction of random Δ -regular graphs in the all-distances query model, in the betweenness query model, as well as in the parallel setting.

By extending the analysis from Section 3, we observe that the set \hat{E} constructed in SIMPLE (Algorithm 1) equals the edge set E with high probability, in Lemma 17.

► **Lemma 17.** *Let G be a uniformly random Δ -regular graph with $\Delta = O(1)$. Let $s = \log^2 n$. Let $S \subseteq V$ be a set of s vertices selected uniformly and independently at random from V . With probability $1 - o(1)$, $|\hat{E}| = \Delta n/2$. In addition, the event $|\hat{E}| = \Delta n/2$ implies $\hat{E} = E$.*

Proof. From Lemma 11, $\mathbb{E}_{G,S}[|\hat{E} \setminus E|] = o(1)$. By Markov's inequality, the event that $|\hat{E} \setminus E| \geq 1$ occurs with probability $o(1)$. Thus with probability $1 - o(1)$, we have $\hat{E} \subseteq E$. On the other hand, $E \subseteq \hat{E}$ by Fact 8. Therefore, the event that $\hat{E} = E$ occurs with probability $1 - o(1)$, and this event occurs if and only if $|\hat{E}| = |E|$. The statement follows since $|E| = \Delta n/2$ in a Δ -regular graph. \blacktriangleleft

4.1 A Modified Algorithm

Lemma 17 enables us to design another reconstruction algorithm in the distance query model, called SIMPLE-MODIFIED, which is a modified version of SIMPLE, see Algorithm 2. SIMPLE-MODIFIED repeatedly computes a set \hat{E} as in SIMPLE, until the size of \hat{E} equals $\Delta n/2$. The parameter s is fixed to $\log^2 n$.

Algorithm 2 SIMPLE-MODIFIED (V).

```

1: repeat
2:    $S \leftarrow$  sample of  $s = \log^2 n$  vertices selected uniformly and independently at random
     from  $V$ 
3:   for  $u \in S$  and  $v \in V$  do QUERY( $u, v$ )
4:    $\hat{E} \leftarrow$  set of vertex pairs  $\{a, b\} \subseteq V$  such that, for all  $u \in S$ ,  $|\delta(u, a) - \delta(u, b)| \leq 1$ 
5: until  $|\hat{E}| = \Delta n/2$ 
6: return  $\hat{E}$ 

```

► **Lemma 18.** *Let G be a uniformly random Δ -regular graph with $\Delta = O(1)$. In the distance query model, SIMPLE-MODIFIED (Algorithm 2) is a reconstruction algorithm, i.e., its output equals the edge set E . The expected number of iterations of the **repeat** loop in SIMPLE-MODIFIED is $1 + o(1)$.*

Proof. Upon termination of the **repeat** loop in SIMPLE-MODIFIED, we have $|\hat{E}| = \Delta n/2$, which implies $\hat{E} = E$ by Lemma 17. Thus the output of SIMPLE-MODIFIED equals the edge set E .

In each iteration of the **repeat** loop, the event that $|\hat{E}| = \Delta n/2$ occurs with probability $1 - o(1)$ by Lemma 17. Thus the expected number of iterations of the **repeat** loop is $1 + o(1)$. ◀

4.2 All-Distances Query Model (Proof of Corollary 2)

By Lemma 18, SIMPLE-MODIFIED is a reconstruction algorithm in the distance query model. We extend SIMPLE-MODIFIED to the all-distances query model.

Observe that in SIMPLE-MODIFIED, the distance queries are performed between each sampled vertex $u \in S$ and all vertices in the graph. This is equivalent to a single query at each sampled vertex $u \in S$ in the all-distances query model. Hence each iteration of the **repeat** loop in SIMPLE-MODIFIED corresponds to $|S| = \log^2 n$ all-distances queries. Again by Lemma 18, the expected number of iterations of the **repeat** loop in SIMPLE-MODIFIED is $1 + o(1)$. Therefore, in the all-distances query model, an algorithm equivalent to SIMPLE-MODIFIED reconstructs the graph using $(1 + o(1)) \cdot \log^2 n = O(\log^2 n)$ all-distances queries in expectation.

4.3 Betweenness Query Model (Proof of Corollary 3)

In the betweenness query model, Abrahamsen et al. [1] showed that $\tilde{O}(\Delta^2 \cdot n)$ betweenness queries suffice to compute the distances from a given vertex to all vertices in the graph (it is implicit in Lemma 16 from [1]), so an all-distances query can be simulated by $\tilde{O}(\Delta^2 \cdot n)$ betweenness queries. As a consequence of Corollary 2, we achieve a reconstruction algorithm using $\tilde{O}(\Delta^2 \cdot n \cdot \log^2 n) = \tilde{O}(n)$ betweenness queries in expectation, since $\Delta = O(1)$.

4.4 Parallel Setting (Proof of Corollary 4)

By Lemma 18, SIMPLE-MODIFIED is a reconstruction algorithm in the distance query model. We analyze SIMPLE-MODIFIED in the parallel setting.

Each iteration of the **repeat** loop consists of $n \cdot \log^2 n$ distance queries, and the distance queries within the same iteration of the **repeat** loop can be performed in parallel. Again by Lemma 18, the expected number of iterations of the **repeat** loop in SIMPLE-MODIFIED is $1 + o(1)$. Thus the expected number of rounds in SIMPLE-MODIFIED is $1 + o(1)$, and the expected number of distance queries in SIMPLE-MODIFIED is $(1 + o(1)) \cdot n \cdot \log^2 n = \tilde{O}(n)$.

5 Metric Dimension (Proof of Corollary 5)

In this section, we study the metric dimension of random Δ -regular graphs. To begin with, we show an elementary structural property of random Δ -regular graphs, in Lemma 19, based on a classical result on those graphs.

► **Lemma 19.** *Let $G = (V, E)$ be a uniformly random Δ -regular graph with $\Delta = O(1)$. With probability $1 - o(1)$, for any edge (a, b) of the graph G , there exists a vertex $c \in V \setminus \{a, b\}$ that is adjacent to b but is not adjacent to a .*

Proof. First, consider the case when $\Delta = 2$. A 2-regular graph is a ring. Let (a, b) be any edge of the graph. The vertex b has two neighbors, the vertex a and another vertex, let it be c . We have $c \in V \setminus \{a, b\}$ and c is not adjacent to a (as soon as $n > 3$). The statement of the lemma follows.

Next, consider the case when $\Delta = O(1)$ is such that $\Delta \geq 3$. Let \mathcal{E} denote the event that, for any edge (a, b) of G , there do not exist two vertices c_1 and c_2 in G , such that all of the 4 edges $(a, c_1), (a, c_2), (b, c_1), (b, c_2)$ belong to G . We show that \mathcal{E} occurs with probability $1 - o(1)$. Indeed, if for some edge (a, b) of G , there exist two vertices c_1 and c_2 such that $(a, c_1), (a, c_2), (b, c_1), (b, c_2)$ are edges of G , then the induced subgraph on $\{a, b, c_1, c_2\}$ consists of at least 5 edges. A classical result on random Δ -regular graphs shows that, for any constant integer k , the probability that there exists an induced subgraph of k vertices with at least $k + 1$ edges is $o(1)$, see, e.g., Lemma 11.12 in [18]. Therefore, \mathcal{E} occurs with probability $1 - o(1)$.

We condition on the occurrence of \mathcal{E} . For any edge (a, b) of G , let $N(a)$ be the set of $\Delta - 1$ neighbors of a that are different from b , and let $N(b)$ be the set of $\Delta - 1$ neighbors of b that are different from a . Since $\Delta \geq 3$, we have $|N(a)| = |N(b)| \geq 2$. The event \mathcal{E} implies that $N(a) \neq N(b)$, so there exists a vertex $c \in N(b) \setminus N(a)$. By definition, c is adjacent to b but is not adjacent to a , and $c \in V \setminus \{a, b\}$. Since \mathcal{E} occurs with probability $1 - o(1)$, we conclude that, with probability $1 - o(1)$, for any edge (a, b) of the graph G , there exists a vertex $c \in V \setminus \{a, b\}$ that is adjacent to b but is not adjacent to a . ◀

► **Definition 20** (e.g., [5, 12]). *A subset of vertices $S \subseteq V$ is a resolving set for a graph $G = (V, E)$ if, for any pair of vertices $\{a, b\} \subseteq V$, there is a vertex $u \in S$ such that $\delta(u, a) \neq \delta(u, b)$. The metric dimension of G is the smallest size of a resolving set for G .*

Based on the analysis of SIMPLE from Lemma 17 and the structural property from Lemma 19, we show that, with high probability, a random subset of $\log^2 n$ vertices is a resolving set for a random Δ -regular graph, in Lemma 21.

► **Lemma 21.** *Let $G = (V, E)$ be a uniformly random Δ -regular graph with $\Delta = O(1)$. Let $S \subseteq V$ be a sample of $s = \log^2 n$ vertices selected uniformly and independently at random from V . With probability $1 - o(1)$, the set S is a resolving set for the graph G .*

Proof. Let \mathcal{E}_1 denote the event that, for any edge (a, b) of the graph G , there exists a vertex $c \in V \setminus \{a, b\}$ that is adjacent to b but is not adjacent to a . By Lemma 19, the event \mathcal{E}_1 occurs with probability $1 - o(1)$. Let \mathcal{E}_2 denote the event $\hat{E} = E$. By Lemma 17, the event \mathcal{E}_2 occurs with probability $1 - o(1)$. Thus with probability $1 - o(1)$, both events \mathcal{E}_1 and \mathcal{E}_2 occur simultaneously. We condition on the occurrences of both events \mathcal{E}_1 and \mathcal{E}_2 in the subsequent analysis.

First, consider any vertex pair $\{a, b\} \subseteq V$ such that $\delta(a, b) \geq 2$. The event \mathcal{E}_2 implies that $\{a, b\} \notin \hat{E}$. By definition, there exists some vertex $u \in S$ such that $|\delta(u, a) - \delta(u, b)| \geq 2$, which implies that $\delta(u, a) \neq \delta(u, b)$.

Next, consider any vertex pair $\{a, b\} \subseteq V$ such that $\delta(a, b) = 1$. The event \mathcal{E}_1 implies that there exists a vertex $c \in V \setminus \{a, b\}$ that is adjacent to b but is not adjacent to a . Since $\delta(a, c) \geq 2$, the event \mathcal{E}_2 implies that $\{a, c\} \notin \hat{E}$. By definition, there exists some vertex $u \in S$ such that $|\delta(u, a) - \delta(u, c)| \geq 2$. Using an elementary inequality of $|x - y| + |y - z| \geq |x - z|$ for any three real numbers x , y , and z , we have

$$\begin{aligned} |\delta(u, a) - \delta(u, b)| &\geq |\delta(u, a) - \delta(u, c)| - |\delta(u, b) - \delta(u, c)| \\ &\geq |\delta(u, a) - \delta(u, c)| - \delta(b, c) && \text{(by the triangle inequality)} \\ &\geq 2 - \delta(b, c) && \text{(by the definition of } u\text{)} \\ &\geq 1 && \text{(since } (b, c) \text{ is an edge in } G\text{).} \end{aligned}$$

Thus $\delta(u, a) \neq \delta(u, b)$.

Therefore, conditioned on the occurrences of both events \mathcal{E}_1 and \mathcal{E}_2 , for any vertex pair $\{a, b\} \subseteq V$, there exists a vertex $u \in S$ such that $\delta(u, a) \neq \delta(u, b)$.

We conclude that, with probability $1 - o(1)$, the set S is a resolving set for G . ◀

From Lemma 21, with probability $1 - o(1)$, the metric dimension of a random Δ -regular graph is at most $\log^2 n$. This completes the proof of Corollary 5.

6 Reconstruction of Bounded-Degree Graphs (Proof of Theorem 6)

In this section, we analyze SIMPLE (Algorithm 1) on general graphs of bounded degree in the distance query model. Recall that a set B of vertex pairs $\{a, b\} \subseteq V$ is defined in Lemma 10. For every vertex $a \in V$, we define the set of vertices $B(a) \subseteq V$ as

$$B(a) = \{b \in V \mid \{a, b\} \in B\}.$$

Intuitively, $B(a)$ consists of the vertices $b \in V$ that has few distinguishers with a . We bound the size of the set $B(a)$ for any vertex a , in Lemma 22.

► **Lemma 22.** *Let G be a general graph of bounded degree Δ . For any vertex $a \in V$, $|B(a)| \leq 9\Delta^3 \cdot n^2 \cdot (\log^2 n)/s^2$.*

We defer the proof of Lemma 22 for the moment and first show how it implies Theorem 6.

Proof of Theorem 6 using Lemma 22. By Lemma 9, SIMPLE is a reconstruction algorithm using $n \cdot s + |\hat{E}|$ distance queries, and in addition, SIMPLE can be parallelized using 2 rounds. It remains to further analyze the query complexity.

From Fact 8, $|\hat{E}| = |E| + |\hat{E} \setminus E|$. Since the graph has bounded degree Δ , $|E| \leq \Delta n$. From Lemma 10, $\mathbb{E}_S[|\hat{E} \setminus E|] \leq |B| + o(1)$. Therefore, the expected number of distance queries in SIMPLE is at most $n \cdot s + \Delta n + |B| + o(1)$. It suffices to analyze $|B|$.

Observe that $|B| \leq \sum_{a \in V} |B(a)|$ by definition of $\{B(a)\}_{a \in V}$. From Lemma 22, $|B(a)| \leq 9\Delta^3 \cdot n^2 \cdot (\log^2 n)/s^2$, for any vertex $a \in V$. Hence $|B| \leq (9\Delta^3 \cdot n^2 \cdot (\log^2 n)/s^2) \cdot n$. Thus the expected number of distance queries in SIMPLE is at most $n \cdot s + \Delta n + (9\Delta^3 \cdot n^2 \cdot (\log^2 n)/s^2) \cdot n + o(1)$, which is $\tilde{O}(n^{5/3})$ since $s = n^{2/3}$ and $\Delta = O(\text{polylog } n)$. ◀

The rest of the section is dedicated to prove Lemma 22.

Let a be any vertex in V . Let T be an (arbitrary) shortest-path tree rooted at a and spanning all vertices in V . For any vertex $b \in V$, let *the shortest a -to- b path* denote the path between a and b in the tree T . To simplify the presentation, we assume that, for any

$b \in B(a)$, $\delta(a, b)$ is even, so that the *midpoint vertex* of the shortest a -to- b path is uniquely defined. We extend our analysis to the general setting in the end of the section.

For any vertex $m \in V$, define the set $B(a, m) \subseteq B(a)$ as

$$B(a, m) = \{b \in B(a) \mid \text{the midpoint vertex of the shortest } a\text{-to-}b \text{ path is } m\}.$$

Define the set $M(a) \subseteq V$ as

$$M(a) = \{m \in V \mid B(a, m) \neq \emptyset\}.$$

In other words, $M(a)$ consists of the vertices $m \in V$ that is the midpoint vertex of the shortest a -to- b path for some $b \in B(a)$. From the construction, we have

$$B(a) = \bigcup_{m \in M(a)} B(a, m). \quad (2)$$

In order to bound the size of $B(a)$, first we bound the size of $B(a, m)$ for any midpoint $m \in M(a)$, in Lemma 23, and then we bound the number of distinct midpoints, in Lemma 24.

► **Lemma 23.** *For any $m \in M(a)$, $|B(a, m)| \leq 3\Delta \cdot n \cdot (\log n)/s$.*

Proof. For any $b \in B(a, m)$, the vertex m is the midpoint vertex of the shortest a -to- b path by definition. From the assumption, $\delta(a, b)$ is even for any $b \in B(a, m)$, so there exists for some positive integer ℓ , such that $\delta(m, a) = \ell$ and $\delta(m, b) = \ell$ for any $b \in B(a, m)$.

For every neighbor m' of m such that $\delta(a, m') = \delta(a, m) + 1$, define a set $Y(m') \subseteq B(a, m)$ that consists of the vertices $b \in B(a, m)$ such that m' is on the shortest a -to- b path. Let \hat{m} be a neighbor of m such that $\delta(a, \hat{m}) = \delta(a, m) + 1$ and that $|Y(\hat{m})|$ is maximized, see Figure 2. Since the graph has bounded degree Δ , we have $|B(a, m)| \leq \Delta \cdot |Y(\hat{m})|$. It suffices to bound $|Y(\hat{m})|$.

The main observation is that any vertex of $Y(\hat{m})$ distinguishes a and any other vertex of $Y(\hat{m})$. To see this, let b_0 be any vertex in $Y(\hat{m})$. By definition, $\delta(a, \hat{m}) = \delta(a, m) + 1 = \ell + 1$. Since \hat{m} is on the shortest a -to- b_0 path, we have $\delta(\hat{m}, b_0) = \delta(a, b_0) - \delta(a, \hat{m}) = \ell - 1$, thus $\delta(\hat{m}, b_0) = \delta(\hat{m}, a) - 2$. For any vertex $b_1 \in Y(\hat{m})$, from the triangle inequalities on δ , we have

$$\delta(b_1, b_0) \leq \delta(b_1, \hat{m}) + \delta(\hat{m}, b_0) = \delta(b_1, \hat{m}) + \delta(\hat{m}, a) - 2 = \delta(b_1, a) - 2.$$

According to Definition 7, the vertex b_1 distinguishes a and b_0 , and equivalently, $b_1 \in D(a, b_0)$. Thus we have $Y(\hat{m}) \subseteq D(a, b_0)$, hence $|Y(\hat{m})| \leq |D(a, b_0)| \leq 3n \cdot (\log n)/s$ using the fact that $b_0 \in Y(\hat{m}) \subseteq B(a)$ and the definition of B in Lemma 10.

We conclude that $|B(a, m)| \leq \Delta \cdot |Y(\hat{m})| \leq 3\Delta \cdot n \cdot (\log n)/s$. ◀

► **Lemma 24.** $|M(a)| \leq 3\Delta \cdot n \cdot (\log n)/s$.

Proof. For each vertex $m \in M(a)$, denote x_m as the second-to-last vertex on the shortest a -to- m path. Denote $X(a) \subseteq V$ as the set of vertices x_m for all $m \in M(a)$. See Figure 3. Since G has bounded degree Δ , we have $|M(a)| \leq \Delta \cdot |X(a)|$. It suffices to bound $|X(a)|$.

Let b^* be a vertex in $B(a)$ such that $\delta(a, b^*)$ is maximized. From the assumption, $\delta(a, b^*)$ is even, so we denote $\delta(a, b^*) = 2\ell$ for some positive integer ℓ .

The main observation is that any vertex of $X(a)$ distinguishes a and b^* . To see this, let x be any vertex in $X(a)$. Let m be any vertex in $M(a)$ such that x is the second-to-last vertex on the shortest a -to- m path.⁹ We have $\delta(a, m) \leq \ell$ and $\delta(a, x) = \delta(a, m) - 1 \leq \ell - 1$. By the

⁹ Such a vertex m exists according to the construction of $X(a)$.

■ **Figure 2** The vertex m is the midpoint of the shortest path between a and any vertex in $B(a, m)$. The vertex \hat{m} is a well-chosen neighbor of m . Consider any vertex $b_0 \in Y(\hat{m})$. We can show that any vertex $b_1 \in Y(\hat{m})$ distinguishes a and b_0 .

triangle inequality on the distances, $\delta(b^*, x) \geq \delta(a, b^*) - \delta(a, x) \geq 2\ell - (\ell - 1) = \ell + 1$. Thus $\delta(b^*, x) - \delta(a, x) \geq 2$. According to Definition 7, the vertex x distinguishes a and b^* , and equivalently, $x \in D(a, b^*)$. Thus $X(a) \subseteq D(a, b^*)$, hence $|X(a)| \leq |D(a, b^*)| \leq 3n \cdot (\log n)/s$ using the fact that $b^* \in B(a)$ and the definition of B in Lemma 10.

We conclude that $|M(a)| \leq \Delta \cdot |X(a)| \leq 3\Delta \cdot n \cdot (\log n)/s$. ◀

■ **Figure 3** Solid circular nodes represent the vertices $m \in M(a)$. Solid curves represent the shortest a -to- m paths. Solid square nodes represent the vertices in $X(a)$. Denote b^* as a vertex in $B(a)$ that is farthest from a . We can show that any vertex $x \in X(a)$ distinguishes a and b^* .

From Equation (2), $|B(a)| \leq \sum_{m \in M(a)} |B(a, m)|$. From Lemma 23, $|B(a, m)| \leq 3\Delta \cdot n \cdot (\log n)/s$ for every $m \in M(a)$. From Lemma 24, $|M(a)| \leq 3\Delta \cdot n \cdot (\log n)/s$. Therefore, $|B(a)| \leq 9\Delta^2 \cdot n^2 \cdot (\log^2 n)/s^2$.

Finally, consider the general setting in which $\delta(a, b)$ is not necessarily even for any $b \in B(a)$. For a vertex m on the shortest a -to- b path, we say that m is the *midpoint vertex* of that path if $\delta(a, m) = \lfloor \delta(a, b)/2 \rfloor$. The definitions of $B(a, m)$ and $M(a)$ remain the same.

Lemma 24 holds in the same way. In Lemma 23, the upper bound of $|B(a, m)|$ is replaced by $3\Delta^2 \cdot n \cdot (\log n)/s$. Indeed, to extend the proof of Lemma 23, instead of considering vertex m' (resp., vertex \hat{m}) that is a neighbor of m , we consider m' (resp., \hat{m}) that is at distance 2 from m . We have $|B(a, m)| \leq \Delta^2 \cdot |Y(\hat{m})|$. The bound $|Y(\hat{m})| \leq 3n \cdot (\log n)/s$ remains the same, so we have $|B(a, m)| \leq 3\Delta^2 \cdot n \cdot (\log n)/s$. Hence $|B(a)| \leq 9\Delta^3 \cdot n^2 \cdot (\log^2 n)/s^2$.

We complete the proof of Lemma 22. Therefore, we obtain Theorem 6.

Abstract

We consider high dimensional variants of the maximum flow and minimum cut problems in the setting of simplicial complexes and provide both algorithmic and hardness results. By viewing flows and cuts topologically in terms of the simplicial (co)boundary operator we can state these problems as linear programs and show that they are dual to one another. Unlike graphs, complexes with integral capacity constraints may have fractional max-flows. We show that computing a maximum integral flow is NP-hard. Moreover, we give a combinatorial definition of a simplicial cut that seems more natural in the context of optimization problems and show that computing such a cut is NP-hard. However, we provide conditions on the simplicial complex for when the cut found by the linear program is a combinatorial cut. For d -dimensional simplicial complexes embedded into \mathbb{R}^{d+1} we provide algorithms operating on the dual graph: computing a maximum flow is dual to computing a shortest path and computing a minimum cut is dual to computing a minimum cost circulation. Finally, we investigate the Ford-Fulkerson algorithm on simplicial complexes, prove its correctness, and provide a heuristic which guarantees it to halt.

1 Introduction

Computing flows and cuts are fundamental algorithmic problems in graphs, which are one dimensional simplicial complexes. In this paper, we explore generalizations of these algorithmic problems in higher dimensional simplicial complexes. In the case of graphs if an edge $e = (u, v)$ is assigned k units of flow we think of the edge as sending k units of flow from u to v . In two dimensions a flow is an assignment of real valued numbers to the triangles of the simplicial complex. A triangle assigned a value k sends k units of flow around its boundary. The difference in interpretation comes from the fact that the boundary of an edge is disconnected while the boundary of a triangle is connected.

Flows and cuts in simplicial complexes have natural algebraic definitions arising from the theory of simplicial (co)homology. A flow is an element of the kernel of the simplicial boundary operator, and a cut is an element of the image of the simplicial coboundary operator. These subspaces serve as generalizations of the cycle and cut spaces of a graph. This generalization has been studied by Duval, Klivans, and Martin in the setting of CW complexes [7]. We formulate the algorithmic problems of computing max-flows and min-cuts algebraically. By forgetting about the underlying graph structure and focusing on the (co)boundary operators, we obtain methods that naturally generalize to high dimensions.

In a graph an st -flow is an assignment of real values to the edges satisfying the conservation of flow constraints: the net flow out of any vertex other than s and t is zero, and, thus, the net flow that leaves s is equal to the net flow that enters t . Therefore, each st -flow can be viewed as a circulation in another graph with an extra edge that connects t to s . Circulations are elements of the cycle space of the graph with coefficients taken over \mathbb{R} . In a d -dimensional simplicial complex \mathcal{K} the d -dimensional cycles are the formal sums (over \mathbb{R}) of d -dimensional simplices whose boundary is zero. Because there are no $(d+1)$ -simplices flows are the elements of the d th homology group $H_d(\mathcal{K}, \mathbb{R})$. The maximum flow problem in a simplicial complex asks to find an optimal element of $H_d(\mathcal{K}, \mathbb{R})$ subject to capacity constraints.

The max-flow min-cut theorem states that in a graph the value of a maximum st -flow is equal to the value of a minimum st -cut. This result is a special case of linear programming duality. By rewriting the linear program in terms of the (co)boundary operator we obtain a similar result for simplicial complexes. The question of whether or not a similar max-flow min-cut theorem holds for simplicial complexes was asked, and left open, in a paper by Latorre [19]. We give a positive answer to this question, but with a caveat. When viewing flows and cuts from a topological point of view their linear programs are dual to one another. However, we also provide a combinatorial definition of a cut which feels more natural for a minimization problem. Topological and combinatorial cuts are equivalent for graphs, but they become different in dimensions $d > 1$. Flows in higher dimension, are dual to topological cuts, but not combinatorial cuts in general. From a computational complexity viewpoint the two notions of cuts are very different. We show that computing a minimum topological cut can be solved via linear programming, but that computing a minimum combinatorial cut is NP-hard.

A closely related problem is the problem of computing a max-flow in a graph which admits an embedding into some topological space. The most well-studied cases are planar graphs and the more general case when the graph embeds into a surface [2, 3, 4, 10, 12, 13, 14, 17, 18, 21, 22]. Max-flows and min-cuts are computationally easier to solve in surface embedded graphs, especially planar graphs. We consider this problem generalized to simplicial complexes. Planar graphs are 1-dimensional complexes embedded in \mathbb{R}^2 , in Section 5 we consider the special case when a d -dimensional simplicial complex admits an embedding into \mathbb{R}^{d+1} . These complexes naturally admit a dual graph which we use to compute maximum flows and minimum cuts (both topological and combinatorial). We show that a maximum flow in a simplicial complex can be found by solving a shortest paths problem in its dual graph. This idea was used by Hassin to solve the maximum flow problem in planar graphs [13]. Further, we show that finding a minimum topological cut can be done by finding a minimum cost circulation in its dual graph. By setting the demand and capacity constraints equal to one in the minimum cost circulation problem we obtain an algorithm computing a minimum combinatorial cut.

Maximum flows in graphs can be computed using the Ford-Fulkerson algorithm. Moreover, the fact that the Ford-Fulkerson algorithm halts serves as a proof that there exists a maximum integral flow when the graph has integral capacity constraints. In dimensions $d > 1$ the maximum flow may be fractional, even with integral capacity constraints. The problem arises due to the existence of torsion in simplicial complexes of dimension $d > 1$. We show that despite the maximum flow being fractional the Ford-Fulkerson algorithm halts on simplicial complexes. However, in order for it to halt a special heuristic on picking the high dimensional analog of an augmenting path must be implemented. Despite the algorithm halting it could we could not prove a polynomial upper bound on the number of iterations it takes.

2 Preliminaries

Given a simplicial complex \mathcal{K} we define $C_d(\mathcal{K}, G)$, $Z_d(\mathcal{K}, G)$, $B_d(\mathcal{K}, G)$, and $H_d(\mathcal{K}, G)$ to be the d -dimensional chain, cycle, boundary, and homology spaces with coefficients over G . In this paper we will consider coefficients over \mathbb{R} and \mathbb{Z} , however when working over \mathbb{R} we will typically drop the G in the notation; for example $C_d(\mathcal{K})$ will refer to the d th chain group over the reals. We will use ∂_d and δ_d to denote the d -dimensional boundary and coboundary operators and we will use \mathcal{K}^d to denote the d -skeleton of \mathcal{K} . We view chains and cochains as both vectors and as functions which are equivalent viewpoints up to duality. For any chain σ by $\text{supp}(\sigma)$ we denote its support which is the set of simplices given a non-zero value on the chain. We call a $(d-1)$ -chain *null-homologous* if it is the boundary of some d -chain.

The fundamental theorem of finitely generated abelian groups gives us the decomposition $H_d(\mathcal{K}, \mathbb{Z}) \cong \mathbb{Z}^k \oplus \mathbb{Z}_{t_1} \oplus \cdots \oplus \mathbb{Z}_{t_n}$ for some $k \in \mathbb{N}$. We call the subgroup $\mathbb{Z}_{t_1} \oplus \cdots \oplus \mathbb{Z}_{t_n}$ the *torsion subgroup* of $H_d(\mathcal{K}, \mathbb{Z})$ and when this subgroup is trivial we call the complex *torsion-free*. We say \mathcal{K} is relatively torsion-free in dimension d if the relative homology groups $H_d(\mathcal{L}, \mathcal{L}_0, \mathbb{Z})$ is torsion-free for all subcomplexes \mathcal{L} and \mathcal{L}_0 of dimensions d and $d-1$, respectively. There exist complexes that are torsion-free but are not relatively torsion-free; see [5] for examples.

Let A be a matrix; we say that A is *totally unimodular* if every square submatrix A' of A has $\det(A') \in \{-1, 0, 1\}$. Totally unimodular matrices are important in combinatorial optimization because linear programs with totally unimodular constraint matrices are guaranteed to have integral solutions [11]. Dey, Hirani, and Krishnamoorthy have provided topological conditions on when a simplicial complex has a totally unimodular boundary matrix [5] stated below. The d th boundary matrix ∂_d of a simplicial complex is totally unimodular if and only if the complex is relative torsion-free in dimension $d-1$.

► **Theorem 1** (Dey et al. [5], Theorem 5.2). *Let \mathcal{K} be a d -dimensional simplicial complex. The boundary matrix $\partial_d: C_d(\mathcal{K}) \rightarrow C_{d-1}(\mathcal{K})$ is totally unimodular if and only if $H_{d-1}(\mathcal{L}, \mathcal{L}_0, \mathbb{Z})$ is torsion-free for all pure subcomplexes $\mathcal{L}_0, \mathcal{L}$ of \mathcal{K} of dimensions $d-1$ and d where $\mathcal{L}_0 \subset \mathcal{L}$.*

Throughout this paper we utilize discrete Hodge theory and recommend the survey by Lim [20] as an introduction to the topic. In particular, we use the Hodge decomposition which can be stated as a result on real valued matrices satisfying $AB = 0$.

► **Theorem 2** (Hodge decomposition [20]). *Let $A \in \mathbb{R}^{m \times n}$ and $B \in \mathbb{R}^{n \times p}$ be matrices satisfying $AB = 0$. We can decompose \mathbb{R}^n into the orthogonal direct sum $\mathbb{R}^n = \text{im}(A^T) \oplus \ker(A^T A + B B^T) \oplus \text{im}(B)$.*

Setting $A = \partial_d$ and $B = \partial_{d+1}$ yields the Hodge decomposition for simplicial complexes. The middle term of the direct sum becomes $\ker(\delta_{d+1}\partial_{d+1} + \partial_d\delta_d)$. The linear operator $\delta_{d+1}\partial_{d+1} + \partial_d\delta_d$ is known as the combinatorial Laplacian of \mathcal{K} which is a generalization of the graph Laplacian. Moreover, it can be shown that $\ker(\delta_{d+1}\partial_{d+1} + \partial_d\delta_d) \cong H_d(\mathcal{K}, \mathbb{R})$. We now state the Hodge decomposition on simplicial complexes as the following isomorphism $C_d(\mathcal{K}, \mathbb{R}) \cong \text{im}(\partial_d) \oplus H_d(\mathcal{K}, \mathbb{R}) \oplus \text{im}(\partial_{d+1})$.

3 Flows and cuts

In this section we give an overview of our generalizations of flows and cuts from graphs to simplicial complexes. Flows and cuts in higher dimensional settings have been studied previously. Duval, Klivans, and Martin have generalized cuts and flows to the setting of

CW complexes [7]. Their definitions are algebraic; defining cuts to be elements of $\text{im}(\delta)$ and flows to be elements of $\ker(\partial)$. Our definitions are closely related, but are motivated by the algorithmic problems of computing max-flows and min-cuts. In Section 3.1 we give definitions of flows and cuts from the perspective of algebraic topology, and in Section 3.2 we give a combinatorial definition of a cut in a simplicial complex. The distinction between the two types of cuts will be important when formulating the minimum cut problem on simplicial complexes.

3.1 Topological flows and cuts

First we briefly recall the definition of an st -flow in a directed graph $G = (V, E)$. An st -flow f is a function $f: E \rightarrow \mathbb{R}$ satisfying the conservation of flow constraint: for all $v \in V \setminus \{s, t\}$ we have $\sum_{(u,v) \in E} f(u, v) = \sum_{(v,u) \in E} f(v, u)$. That is, the amount of flow entering the vertex equals the amount of flow leaving the vertex. The value of f is equal to the amount of flow leaving s (or equivalently, entering t). Alternatively, we may view f as a 1-chain and we have $\partial f = k(t - s)$ where k is the value of f . Note that $t - s$ is a null-homologous 0-cycle. More generally, for any null-homologous $(d - 1)$ -cycle γ we call a d -chain f with $\partial f = k\gamma$ a γ -flow of value k . Note that under our naming convention an “ st -flow” in a graph would be called a $(t - s)$ -flow. However, in the case of graphs we use the traditional naming convention and call a flow from s to t an st -flow.

► **Definition 3** (γ -flow). *Let \mathcal{K} be a d -dimensional simplicial complex and γ be a null-homologous $(d - 1)$ -cycle in \mathcal{K} . A γ -flow is a d -chain f with $\partial f = k\gamma$ where $k \in \mathbb{R}$. We call k the value of the flow f and denote the value of f by $\|f\|$. We say that f is feasible with respect to a capacity function $c: \mathcal{K}^d \rightarrow \mathbb{R}^+$ if $0 \leq f(\sigma) \leq c(\sigma)$ for all $\sigma \in \mathcal{K}^d$.*

Our definition of a γ -flow is very close to the algebraic definition which is element of $\ker(\partial)$. Given a simplicial complex \mathcal{K} and a γ -flow f of value k we convert f into a *circulation*, where a circulation is defined to be an element of $\ker(\partial)$. To convert f into a circulation we add an additional basis element to $C_d(\mathcal{K})$, call it Σ , whose boundary is $\partial \Sigma = -\gamma$. This operation is purely algebraic; we should think of it as operating on the chain complex rather than the underlying topological space. Now we construct the circulation $f' = f + k\Sigma$. We call any circulation built from a γ -flow a γ -circulation. Clearly, $f' \in \ker(\partial)$ in the new chain complex. Moreover, there is a clear bijection between γ -flows and γ -circulations. The value of the circulation is the value of $f'(\Sigma)$, so this bijection preserves the value.

We now shift our focus to the generalization of cuts to a simplicial complex. The algebraic definition, elements of $\text{im}(\delta)$, is natural. The cut space of a graph is commonly defined to be the space spanned by the coboundaries of each vertex. In a simplicial complex \mathcal{K} , removing the support of a d -chain in $\text{im}(\delta)$ increases $\dim H_{d-1}(\mathcal{K})$. In a graph G , removing the support of any 1-chain in $\text{im}(\delta)$ increases $\dim H_0(G)$ which is equivalent to increasing the number of connected components of G .

The above definition implies that a cut is a d -chain in a d -dimensional simplicial complex. However, for our purposes we will define a cut to be a $(d - 1)$ -cochain. To motivate our definition we recall the notion of an st -cut in a graph. An st -cut in a graph is a partition of the vertices into sets S and T such that $s \in S$ and $t \in T$. Define $p: V(G) \rightarrow \{0, 1\}$ such that $p(v) = 1$ if $v \in S$ and $p(v) = 0$ if $v \in T$. The support of the coboundary of p is a set of edges whose removal destroys all st -paths. That is, upon removing the support, the 0-cycle $t - s$ is no longer null-homologous. Moreover, p is a 0-cochain with $p(t - s) = -1$. The sign of $p(t - s)$ will be important when we consider directed cuts. With this in mind we define our notion of a γ -cut.

► **Definition 4** (γ -cut). Let \mathcal{K} be a d -dimensional simplicial complex with weight function $c: \mathcal{K}^d \rightarrow \mathbb{R}^+$ and γ be a null-homologous $(d-1)$ -cycle in \mathcal{K} . A γ -cut is a $(d-1)$ -cochain p such that $p(\gamma) = -1$. Denote the coboundary of p as the formal sum $\delta(p) = \sum \alpha_i \sigma_i$, we define the size of a γ -cut to be $\|p\| = \sum |\alpha_i c(\sigma_i)|$.

Because of the requirement that $p(\gamma) = -1$ we call p a *unit* γ -cut. By relaxing this requirement to $p(\gamma) < 0$ the cochain p still behaves as a γ -cut, but its size can become arbitrarily small by multiplying by some small value $\epsilon > 0$. We justify our definition with the following proposition which shows that removing the support of the coboundary of a γ -cut prevents γ from being null-homologous.

► **Proposition 5.** Let \mathcal{K} be d -dimensional simplicial complex and p be a γ -cut. The cycle γ is not null-homologous in the subcomplex $\mathcal{K} \setminus \text{supp}(\delta(p))$.

3.2 Combinatorial cuts

Alternatively, we can view a γ -cut as a discrete set of d -simplices rather than a d -chain. In the case of graphs a combinatorial st -cut is just a set of edges whose removal disconnects s from t . This distinction will become important when we consider the minimization problem of finding a minimum cost set of d -simplices whose removal prevents γ from being null-homologous.

► **Definition 6** (Combinatorial γ -cut). Let \mathcal{K} be a d -dimensional simplicial complex with weight function $c: \mathcal{K}^d \rightarrow \mathbb{R}^+$ and γ be a null-homologous $(d-1)$ -cycle in \mathcal{K} . A **combinatorial γ -cut** is a set of d -simplices $C \subseteq \mathcal{K}^d$ such that γ is not null-homologous in $\mathcal{K} \setminus \text{supp}(C)$. The size of a combinatorial γ -cut is defined by the sum of the weights of the d -simplices $\|C\| = \sum_{\sigma \in C} c(\sigma)$.

The next proposition shows a relationship between γ -cuts and combinatorial γ -cuts. Removing a combinatorial γ -cut C from \mathcal{K} increases $\dim H_{d-1}(\mathcal{K})$. This is because removing C must decrease the rank of ∂_d and by duality this also decreases the rank of δ_d which increases the dimension of $H^{d-1}(\mathcal{K}) \cong H_{d-1}(\mathcal{K})$. It follows that C must contain the support of some coboundary. Given an additional minimality condition on C we show that C is equal to the support of some coboundary.

► **Proposition 7.** Let C be a combinatorial γ -cut in a d -dimensional simplicial complex \mathcal{K} . Further, assume that C is minimal in the sense that for all $C' \subset C$ we have $\dim H_{d-1}(\mathcal{K} \setminus C') < \dim H_{d-1}(\mathcal{K} \setminus C)$. There exists a $(d-1)$ -cochain p such that $\text{supp}(\delta(p)) = C$.

In graphs the linear program solving the minimum st -cut problem takes as input a directed graph and returns a set of directed edges whose removal destroys all directed st -paths. This is called a directed cut. After removing the directed cut the 0-cycle $t - s$ may still be null-homologous; we can find a 1-chain with boundary $t - s$ using negative coefficients to traverse an edge in the backwards direction. In order to generalize the minimum cut linear program to simplicial complexes we will need to define a directed combinatorial γ -cut, which requires the additional assumption that the d -simplices of \mathcal{K} are oriented.

► **Definition 8** (Directed combinatorial γ -cut). Let \mathcal{K} be an oriented d -dimensional simplicial complex with weight function $c: \mathcal{K}^d \rightarrow \mathbb{R}$ and γ be a null-homologous $(d-1)$ -cycle in \mathcal{K} . A **directed combinatorial γ -cut** is a set of d -simplices $C \subset \mathcal{K}^d$ such that in $\mathcal{K} \setminus \text{supp}(C)$ there exists no d -chain Γ with non-negative coefficients such that $\partial \Gamma = \gamma$. The size of a directed combinatorial γ -cut is defined by the sum of the weights of the d -simplices $\|C\| = \sum_{\sigma \in C} c(\sigma)$.

Given a directed graph consider an st -cut given by the cochain definition. That is, a 0-cochain $p: V(G) \rightarrow \{0, 1\}$ with $p(s) = 1$ and $p(t) = 0$ partitioning V into S and T . The support of $\delta(p)$ consists of two types of edges: edges leaving S and entering T , and edges leaving T and entering S . If $e \in E$ leaves S and enters T we have $(p \circ \partial)(e) = -1$ and if e leaves T and enters S we have $(p \circ \partial)(e) = 1$. To construct a directed st -cut we simply take all of the edges mapped to -1 . The following proposition shows that we can build a directed combinatorial γ -cut from a coboundary just like in the case of directed graphs.

► **Proposition 9.** *Let p be a γ -cut with coboundary $\delta(p) = \sum \alpha_i \sigma_i$. The set of d -simplices $C = \{\sigma_i \mid \alpha_i < 0\}$ is a directed combinatorial γ -cut.*

To conclude the section we will show that computing a minimum combinatorial γ -cut is NP-hard. As we will see in Section 4 minimum topological γ -cuts can be computed with linear programming. Our hardness result holds for both the directed and undirected cases. Our hardness result is a reduction from the well-known NP-hard hitting set problem which we will now define. Given a set S and a collection of subsets $\Sigma = (S_1, \dots, S_n)$ where $S_i \subseteq S$ the hitting set problem asks to find the smallest subset $S' \subseteq S$ such that $S' \cap S_i \neq \emptyset$ for all S_i . We call such a subset S' a *hitting set* for (S, Σ) .

► **Theorem 10.** *Let \mathcal{K} be a d -dimensional simplicial complex and γ be a null-homologous $(d - 1)$ -cycle. Computing a minimum combinatorial γ -cut is NP-hard for $d \geq 2$.*

Proof. Our proof is a reduction from the hitting set problem. First we consider the case when $d = 2$ then we generalize to any $d \geq 2$. Let S be a set and $\Sigma = (S_1, \dots, S_n)$ where each $S_i \subseteq S$. We construct a 2-dimensional simplicial complex \mathcal{K} from S and Σ in the following way. For each $S_i \in \Sigma$ construct a triangulated disk \mathcal{D}_i such that $\partial \mathcal{D}_i = \gamma$. That is, each \mathcal{D}_i shares the common boundary γ . To accomplish this we construct each \mathcal{D}_i by beginning with a single triangle t with $\partial t = \gamma$ and repeatedly adding a new vertex in the center of some triangle with edges connecting it to every vertex in that triangle. By this process we can construct a disk containing any odd number of triangles as each step increments the number of triangles in the disk by two. Moreover, at each step the boundary of the disk is always γ . We construct each disk \mathcal{D}_i such that \mathcal{D}_i consists of one triangle $t_{i,s}$ for each element $s \in S_i$ and potentially one extra triangle t'_i in the case that $|S_i|$ is even. Next, for each $s \in S$ and S_i with $s \in S_i$, we construct the quotient space by identifying each $t_{i,s}$ into a single triangle. A minimum combinatorial γ -cut C must contain at least one triangle from each \mathcal{D}_i and without loss of generality we can assume C does not contain any t'_i . If $t'_i \in C$ then by minimality it is the only triangle in $C \cap \text{supp}(\mathcal{D}_i)$ and we can swap it with any other triangle in \mathcal{D}_i without increasing the size of the cut. By construction C is a hitting set for (S, Σ) since each $C \cap \text{supp}(\mathcal{D}_i) \neq \emptyset$ for all \mathcal{D}_i . The proof generalizes to $d > 2$ by generalizing the subdivision processes. ◀

4 Linear programming

4.1 Max-flow min-cut

A *simplicial flow network* is a tuple (\mathcal{K}, c, γ) where \mathcal{K} is an oriented d -dimensional simplicial complex, c is the *capacity function* which is a non-negative function $c: \mathcal{K}^d \rightarrow \mathbb{R}^+$, and γ is a null-homologous $(d - 1)$ -cycle. In a simplicial flow network we work with real coefficients; that is, we consider the chain groups $C_k(\mathcal{K}, \mathbb{R})$. In order to utilize the Hodge decomposition (Theorem 2) in a convenient way we modify $C_d(\mathcal{K})$ by adding an additional basis element Σ such that $\partial \Sigma = -\gamma$. Moreover, we extend the capacity function such that $c(\Sigma) = \infty$. This

allows us to work with circulations instead of flows while leaving the solution unchanged. The notation n_d will refer to the number of basis elements in $C_d(\mathcal{K}, \mathbb{R})$ which is now one more than the number of d -simplices in the underlying simplicial complex.

The goal of the maximum flow problem is to find a d -chain f obeying the capacity constraints such that $\partial f = k\gamma$ where $k \in \mathbb{R}$ is maximized. Equivalently, we find a d -cycle f which maximizes $f(\Sigma)$. The linear program for the max-flow problem in a simplicial flow network is identical to the familiar linear program for graphs, but expressed in terms of the coboundary operator. In a graph, conservation of flow at a vertex v is the constraint $\delta_1(v) \cdot f = 0$; to formulate the linear program in higher dimensions we simply replace vertices with $(d-1)$ -simplices. The Hodge decomposition states that cycles are orthogonal to coboundaries, so conservation of flow ensures that f is indeed a cycle. We now state the linear program for max-flow in a simplicial flow network.

$$\begin{aligned} & \text{maximize} && f(\Sigma) \\ & \text{subject to} && \delta(\tau) \cdot f = 0 \quad \text{for each } \tau \in \mathcal{K}^{d-1} \\ & && 0 \leq f(\sigma) \leq c(\sigma) \quad \text{for each } \sigma \in \mathcal{K}^d \end{aligned} \tag{LP1}$$

We dualize LP1 to obtain a generalization of the minimum cut problem in directed graphs. To make the dualization more explicit we will write out LP1 in matrix form: maximize $s \cdot f$

subject to $Af \leq b$ and $f \geq 0$, where we have $A = \begin{bmatrix} \partial \\ -\partial \\ I_{n_d} \end{bmatrix}$, $b = \begin{bmatrix} 0_{n_{d-1}} \\ 0_{n_{d-1}} \\ c \end{bmatrix}$, $s = \begin{bmatrix} 0_{n_d-1} \\ 1 \end{bmatrix}$. The

matrix A has dimension $(2n_{d-1} + n_d) \times n_d$. In our notation I_k is the $k \times k$ identity matrix and 0_k is the $k \times 1$ column vector consisting of all zeros. Since the value of the flow is equal to $f(\Sigma)$ the vector s is all zeros except for the final entry which is indexed by Σ and receives an entry equal to one. Further, c is the $n_d \times 1$ capacity vector indexed by the d -simplices such that the entry indexed by σ has value equal to $c(\sigma)$.

We can now state the dual program in matrix form: minimize $y \cdot b$ subject to $y^T A \geq s$ and $y \geq 0$. The vector y is a $(2n_{d-1} + n_d) \times 1$ column vector indexed by both the $(d-1)$ -simplices and the d -simplices. However, only the entries indexed by d -simplices contribute to the objective function since b is zero everywhere outside of the capacity constraints. We will denote the truncated vector consisting of entries indexed by d -simplices by y_d and the entry corresponding to the d -simplex $\sigma \in \mathcal{K}^d$ will be denoted by $y_d(\sigma)$. Similarly we have two truncated vectors y_{d-1}^1 and y_{d-1}^2 corresponding to the entries indexed by the $(d-1)$ -simplices. Moreover, the rows of $y^T A \geq s$ are in the form $(y_{d-1}^1 - y_{d-1}^2)^T \partial + y_d \geq s$. For simplicity we define $y_{d-1} = y_{d-1}^1 - y_{d-1}^2$ and write $y_{d-1}(\tau)$ for the entry indexed by the $(d-1)$ -simplex τ . Putting this together, we state the dual linear program as follows.

$$\begin{aligned} & \text{minimize} && \sum_{\sigma \in \mathcal{K}^d} y_d(\sigma) c(\sigma) \\ & \text{subject to} && y_{d-1} \cdot \partial \sigma + y_d(\sigma) \geq 0 \quad \text{for each } \sigma \in \mathcal{K}^d \\ & && y_{d-1} \cdot \partial \Sigma + y_d(\Sigma) = 1, y_d \geq 0 \end{aligned} \tag{LP2}$$

Note the strict equality in the second constraint does not follow from the duality. However, we can assume a strict equality since if $y_{d-1} \cdot \partial \Sigma + y_d(\Sigma) > 1$ we can multiply $[y_{d-1}, y_d]^T$ by some scalar $\epsilon < 1$ to make the inequality tight. This multiplication only decreases the value of $\sum y_d(\sigma) c(\sigma)$ so it does not change the optimal solution.

In the case of graphs LP2 has dual variables for vertices and edges. Moreover, there exists an integral solution such that each vertex is either assigned a 0 or a 1 since a graph cut is a partition of the vertices. The second inequality requires $y_0(s) = 1$ and $y_0(t) = 0$. To see this, when solving an st -cut on a graph, the basis element Σ is an edge with $\partial\Sigma = s - t$, and $y_1(\Sigma) = 0$ otherwise the solution is infinite. This naturally defines a partition of the vertices: S containing vertices assigned a 1, and T containing vertices assigned a 0. The constraints force an edge to be assigned a 1 if it leaves S and enters T , otherwise it is assigned a 0. This solution can be interpreted as a 0-cochain p with $p(st) = 1$, or in the notation of our definition of a simplicial cut: $p(t - s) = -1$. Further, $y_1(e) = 1$ for every edge e that is negative on $\delta(p)$ and a 0 otherwise, hence y_1 fits our definition of a directed st -cut in a 1-complex. We will show the same result holds in higher dimensions; that is, y_d is a directed γ -cut arising from the $(d - 1)$ -cochain y_{d-1} .

► **Lemma 11.** *Let $y = [y_{d-1}, y_d]^T$ be an optimal solution to LP2. The set $\text{supp}(y_d)$ is a directed combinatorial γ -cut.*

► **Lemma 12.** *Let p be a γ -cut with coboundary $\delta(p) = \sum \alpha_i \sigma_i$ and let $\delta(p)^- = \sum_{\alpha_i < 0} \alpha_i \sigma_i$. The vector $[p, -\delta(p)^-]^T$ is a finite feasible solution to LP2.*

Lemma 11 tells us that a solution to LP2 yields a directed combinatorial γ -cut. Recall, by Proposition 9 every γ -cut p yields a directed combinatorial γ -cut by taking the coboundary $\delta(p) = \sum \alpha_i \sigma_i$ and considering the negative components $\delta(p)^- = \{\sigma_i \mid \alpha_i < 0\}$. By Lemma 12 $\delta(p)^-$ is a feasible solution to LP2; the cost of this solution is $c \cdot \delta(p)^-$. The coefficients α_i need not always equal one; hence in general we have $\|C\| \neq c \cdot \delta(p)^-$. It follows that LP2 need not return a minimum directed combinatorial γ -cut. In Theorem 15 we will give conditions describing when LP2 returns a directed combinatorial γ -cut. To conclude the section we state our main theorem about LP2 whose proof is immediate from Lemmas 11 and 12.

► **Theorem 13.** *Let $y = [y_{d-1}, y_d]^T$ be an optimal solution to LP2. The set $\text{supp}(y_d)$ is a directed combinatorial γ -cut such that $y_d = \delta(y_{d-1})^-$. Moreover, y_d minimizes $c \cdot \delta(p)^-$ where p ranges over all γ -cuts.*

4.2 Integral solutions

In this section we provide an example of a simplicial flow network with integral capacity constraints and fractional maximum flow. By Theorem 1 such a network must contain some relative torsion. This is achieved by the inclusion of a Möbius strip in our simplicial flow network. Our example will be used later in Theorem 14 showing that computing a maximum integral flow in a simplicial flow network is NP-hard.

We will now explicitly describe a simplicial flow network with integral capacities whose maximum flow value is fractional. Let \mathcal{M} be a triangulated Möbius strip with boundary $\partial\mathcal{M} = 2\alpha + \gamma$ such that two vertices in α have been identified making α a simple cycle. This identification makes γ a figure-eight. Now let \mathcal{D} be a triangulated disk oriented such that $\partial\mathcal{D} = -\alpha$. Call the resulting complex \mathcal{MD} . See Figure 1 for an illustration. The capacity function c has $c(t) = 1$ for each triangle $t \in \mathcal{MD}$. Now we solve the max-flow problem on $(\mathcal{MD}, c, \gamma)$. Note that for any flow f we have $f(t_1) = f(t_2)$ for all triangles $t_1, t_2 \in \mathcal{M}$; moreover, for all $t_1, t_2 \in \mathcal{D}$ we also have $f(t_1) = f(t_2)$. The value of any flow f on $(\mathcal{MD}, c, \gamma)$ is equal to its value on \mathcal{M} , and in order to maintain conservation of flow we must have $f(\mathcal{D}) = 2f(\mathcal{M})$. Now, the capacity constraints imply that the maximum flow f has $f(\mathcal{M}) = 1/2$ and $f(\mathcal{D}) = 1$. We have $\partial f = \frac{1}{2}\partial\mathcal{M} + \partial\mathcal{D} = \frac{1}{2}\gamma + \alpha - \alpha$. Hence, $\|f\| = 1/2$.

■ **Figure 1** A triangulated disk \mathcal{D} (left) and Möbius strip \mathcal{M} (right). The Möbius strip has two points on its boundary identified forming the vertex u . In red we have the input cycle (a figure-eight) γ and we set $\alpha = u w v u$. We orient the complex such that $\partial \mathcal{M} = \gamma + 2\alpha$ and $\partial \mathcal{D} = -\alpha$. The capacity on each simplex in both the disk and Möbius strip is one.

Maximum integral flow. Given a simplicial flow network (\mathcal{K}, c, γ) with integral capacities we consider the problem of finding the maximum integral flow. That is, a d -chain $f \in C_d(\mathcal{K}, \mathbb{Z})$ obeying the capacity constraints such that $\partial f = k\gamma$ where $k \in \mathbb{Z}$ is maximized. We show the problem is NP-hard by a reduction from graph 3-coloring. Our reduction is inspired by a MathOverflow post from Sergei Ivanov showing that finding a subcomplex homeomorphic to the 2-sphere is NP-hard [15]. Given a graph G we construct a 2-dimensional simplicial flow network whose maximum flow is integral if and only if G is 3-colorable.

► **Theorem 14.** *Let (\mathcal{K}, c, γ) be a simplicial flow network where \mathcal{K} is a 2-complex and c is integral. Computing a maximum integral flow of (\mathcal{K}, c, γ) is NP-hard.*

Proof. Let $G = (V, E)$ be a graph. We will construct a simplicial flow network (\mathcal{K}, c, γ) such that its maximum flow is integral if and only if G is 3-colorable.

We start our construction with a punctured sphere \mathcal{S} containing $|V| + 1$ boundary components called γ and β_v for each $v \in V$. For each boundary component β_v we construct three disks R_v, B_v, G_v each with boundary $-\beta_v$. These disks represent the three colors in our coloring: red, blue, and green. We refer to these disks as *color disks* and use \mathcal{C}_v to denote an arbitrary color disk associated with v and use $k \in \{r, b, g\}$ to denote an arbitrary color. On each color disk \mathcal{C}_v we add a boundary component for each edge $e = (u, v)$ incident to v . By $\beta_{v,e,k}$ we denote the boundary component corresponding to the vertex v , edge e , and color k . For each edge $e = (u, v)$ and each pair of boundary components β_{u,e,k_u} and β_{v,e,k_v} with $k_u \neq k_v$ we construct a tube with boundary components $-\beta_{u,e,k_u}$ and $-\beta_{v,e,k_v}$ denoted \mathcal{T}_{e,k_u,k_v} . When $k_u = k_v = k$ we construct a tube $\mathcal{T}_{e,k,k}$ and puncture it with a third boundary component α and construct a negatively oriented real projective plane $\mathcal{RP}_{e,k}$ with boundary $\partial \mathcal{RP}_{e,k} = -2\alpha$. We call the resulting complex \mathcal{K} and assign a capacity $c(\sigma) = 1$ for every triangle σ in \mathcal{K} .

We will show that a maximum integral flow f of \mathcal{K} has $\|f\| = 1$ if and only if G is 3-colorable. The following four properties of a maximum integral flow f imply that G is 3-colorable.

- f must assign exactly one unit of flow to each triangle in \mathcal{S} since the value of f is equal to $f(\mathcal{S})$.
- For each vertex $v \in V$ exactly one color disk \mathcal{C}_v is assigned one unit of flow while the other two color disks associated with v are assigned zero units of flow. Otherwise, either conservation of flow is violated or some color disk is assigned a fractional flow value.
- For each edge $e = (u, v) \in E$ exactly one tube \mathcal{T}_{e,k_u,k_v} with $k_u \neq k_v$ must be assigned one unit of flow with all other tubes associated with e assigned zero units of flow. The tube \mathcal{T}_{e,k_u,k_v} assigned one unit of flow is the tube connecting the color disks \mathcal{C}_v and \mathcal{C}_u that are assigned one unit of flow by the previous property.

- f assigns zero flow to every $\mathcal{T}_{e,k,k}$ and $\mathcal{RP}_{e,k}$ since otherwise the triangles in $\mathcal{RP}_{e,k}$ would need to have $1/2$ units of flow assigned to them to maintain conservation of flow.

These four properties imply that the set of color disks $\{\mathcal{C}_v \mid f(\sigma) = 1, \forall \sigma \in \mathcal{C}_v\}$ corresponds to a 3-coloring of G . Conversely, given a 3-coloring of G we assign a flow value of one to each color disk corresponding to the 3-coloring. We extend this assignment to a γ -flow of value one by assigning a flow value of one to \mathcal{S} and the tubes corresponding to the 3-coloring. ◀

Integral cuts. The goal of this section is to show that for simplicial complexes that are relative torsion-free in dimension $d - 1$ there exists optimal solutions to LP2 whose support is a minimum combinatorial γ -cut. Note that by Theorem 1 a simplicial complex that is relative torsion-free in dimension $d - 1$ has a totally unimodular d -dimensional boundary matrix. The total unimodularity is key to our proof. However, we first provide an example of a complex (with relative torsion) whose optimal solution's support does not form a minimum combinatorial γ -cut. Our construction is a slight modification of \mathcal{MD} defined in Section 4.2.

Consider the simplicial complex constructed by taking \mathcal{MD} and glueing a wedge sum of two disks \mathcal{W} along the figure-eight γ . That is, $\partial\mathcal{W} = \gamma$. We give every triangle in the resulting complex a capacity equal to one. A maximum γ -flow has value $3/2$, so the dual program finds a γ -cut of the same value. One potential optimal solution is a $(d - 1)$ -cochain whose coboundary assigns a value of $-1/2$ to two triangles in \mathcal{W} and a value of $-1/2$ to one triangle in \mathcal{D} . The support of this coboundary has weight equal to three, however a minimal combinatorial γ -cut has weight two by taking only one triangle from \mathcal{W} and one from \mathcal{D} . See Figure 2 for an illustration.

■ **Figure 2** The simplicial complex \mathcal{MD} with a wedge sum of two disks \mathcal{W} identified to the figure-eight γ . In red we have a 1-cochain which assigns a value of $-1/2$ to each red edge. The coboundary of the red cochain assigns a value of $-1/2$ to one triangle in \mathcal{D} and a value of $-1/2$ to two triangles in \mathcal{W} . The value of the red cochain coincides with the value of the maximum γ -flow. However, its support is not a minimum combinatorial γ -cut. A minimum combinatorial γ -cut picks one triangle from \mathcal{D} and one triangle from \mathcal{W} .

Now, we show that when \mathcal{K} is relative torsion-free in dimension $d - 1$ LP2 has an optimal solution whose support is a minimum directed combinatorial γ -cut. Specifically, we show that a solution existing on a vertex of the polytope defined by the constraints of LP2 is a cochain y_{d-1} with negative coboundary y_d such that $y_d(\sigma) \in \{0, 1\}$ for all $\sigma \in \mathcal{K}^d$ hence $\sum y_d(\sigma)c(\sigma) = \|\text{supp}(y_d)\|$. That is, the value of a vertex solution to LP2 is equal to the cost of $\text{supp}(y_d)$ as a directed combinatorial γ -cut.

► **Theorem 15.** *Let \mathcal{K} be d -dimensional simplicial complex that is relative torsion-free in dimension $d - 1$ and $[y_{d-1}, y_d]^T$ be an optimal vertex solution to the dual program. The set $\text{supp}(y_d)$ is a minimum directed combinatorial γ -cut.*

Proof. We can write the constraint matrix of LP2 as the $2n_d \times (n_d + n_{d-1})$ block matrix

$$A = \begin{bmatrix} \delta & I_{n_d} \\ 0_{n_d} & I_{n_d} \end{bmatrix}.$$

Since \mathcal{K} is relative torsion-free in dimension $d - 1$ Theorem 1 tells us that ∂_d is totally unimodular; further, we have that $\partial^T = \delta$ is also totally unimodular. Total unimodularity is preserved under the operation of adding a row or column consisting of exactly one component equal to 1 and the remaining components equal to 0, so A is totally unimodular [23, Section 19.4]. We write LP2 as the linear system $Ax \geq b$ where b is a $n_d + n_{d-1}$ dimensional vector with exactly one component equal to 1 and the remaining components equal to 0. Let $y = [y_{d-1}, y_d]^T$ be an optimal vertex solution to LP2. For every $(d - 1)$ -simplex $\tau \in \mathcal{K}^{d-1}$ we either have $y_{d-1}(\tau) \geq 0$ or $y_{d-1}(\tau) \leq 0$. Let $I'_{n_{d-1}}$ be the matrix whose rows correspond to these inequalities. Note that $I'_{n_{d-1}}$ is a diagonal matrix with entries in $\{-1, 1\}$. Now we consider the $(2n_d + n_{d-1}) \times (n_d + n_{d-1})$ dimensional linear system $A'x \geq b'$ where

$$A' = \begin{bmatrix} \delta & I_{n_d} \\ 0 & I_{n_d} \\ I'_{n_{d-1}} & 0 \end{bmatrix}$$

and b' is constructed by appending extra zeros to b . We construct y' from y similarly. Note that A' is totally unimodular and y' is a vertex solution of the system. There exists a vertex v of the polyhedron $P \subseteq \mathbb{R}^{n_d + n_{d-1}}$ corresponding to the linear system such that $A'y' = v \geq b'$ such that $n_{d-1} + n_d$ constraints are linearly independent and tight. Hence, there is an $(n_{d-1} + n_d) \times (n_{d-1} + n_d)$ square submatrix A'' with $A''y' = b''$ where b'' is b' restricted to the tight constraints. We will use Cramer's rule to show that the vertex solution y has components coming from the set $\{-1, 0, 1\}$. Let $A''_{i,b''}$ be the matrix obtained by replacing the i^{th} column of A'' with b'' . By Cramer's rule we compute the i^{th} component of y as $y_i = \frac{\det(A''_{i,b''})}{\det(A'')}$. Since both $A''_{i,b''}$ and A'' are totally unimodular we have $v_i \in \{-1, 0, 1\}$. Further, we know that A'' is non-singular because it corresponds to linearly independent constraints.

By the above argument we know that an optimal solution y to LP2 has all of its components contained in the set $\{-1, 0, 1\}$. The constraint $y_d \geq 0$ means that for all d -simplices σ we have $y_d(\sigma) \in \{0, 1\}$ and $\sum_{\sigma \in \mathcal{K}^d} y_d(\sigma)c(\sigma) = \|\text{supp}(y_d)\|$. Hence, $\text{supp}(y_d)$ is a minimum directed combinatorial γ -cut. ◀

5 Embedded simplicial complexes

In this section we consider a simplicial flow network (\mathcal{K}, c, γ) where \mathcal{K} is a d -dimensional simplicial complex with an embedding into \mathbb{R}^{d+1} . Alexander duality implies that $\mathbb{R}^{d+1} \setminus \mathcal{K}$ consists of $\beta_d + 1$ connected components where $\beta_d = \dim H_d(\mathcal{K})$ is the d th Betti number. We call these connected components *voids*; exactly one void is unbounded and we denote the voids by V_i for $1 \leq i \leq \beta_{d+1}$. Given an embedding into \mathbb{R}^{d+1} , computing the voids of \mathcal{K} can be done in polynomial time [6]. Further, we assume that the d -simplices are consistently oriented with respect to the voids. The embedding guarantees that every d -simplex σ appears on the boundary of at most two voids; by our assumption if σ appears on the boundary of

two voids then it must be oriented positively on one and negatively on the other. We denote the boundary of the void V_i by $\text{Bd}(V_i)$. Every d -simplex contained in the support of some d -cycle is on the boundaries of exactly two voids; it follows that the boundaries of any set of β_d voids is a basis of $H_d(\mathcal{K})$.

In order to state our theorems we need one additional assumption on \mathcal{K} . We assume there exists some void V_i containing two unit γ -flows Γ_1, Γ_2 whose supports partition $\text{Bd}(V_i)$: $\text{supp}(\Gamma_1) \cap \text{supp}(\Gamma_2) = \emptyset$ and $\text{supp}(\Gamma_1) \cup \text{supp}(\Gamma_2) = \text{Bd}(V_i)$. This assumption makes our problem analogous to an st -flow network in a planar graph such that s and t appear on the same face. The existence of two unit γ -flows partitioning the boundary is analogous to the two disjoint st -paths on the boundary of the face. It will be convenient to take the negation of Γ_1 and treat it as a unit $(-\gamma)$ -flow; otherwise the assumption conflicts with the assumed consistent orientation. This is equivalent as it does not change the support of the flow, so for the rest of the section we will take Γ_1 to be a unit $(-\gamma)$ -flow.

From \mathcal{K} we construct its directed dual graph \mathcal{K}^* as follows. Each void becomes a vertex of \mathcal{K}^* . Each d -simplex on the boundary of two voids becomes an edge; since we assumed the d -simplices are consistently oriented we direct the dual edge from the negatively oriented void to the positively oriented void. The remaining d -simplices only appear on one void and become loops in \mathcal{K}^* . For a d -simplex σ on the boundary of voids u and v we denote its corresponding dual edge $\sigma^* = (u^*, v^*)$ and we weight the edges by the capacity function: $c^*(\sigma^*) = c(\sigma)$. Let v_i^* be the vertex dual to the void whose boundary is partitioned by $\text{supp}(\Gamma_1)$ and $\text{supp}(\Gamma_2)$. We split v_i^* into two new vertices denoted s^* and t^* . The edges incident to v_i^* whose dual d -simplices were contained in $\text{supp}(\Gamma_1)$ become incident to s^* , and the edges whose dual d -simplices were contained in $\text{supp}(\Gamma_2)$ become incident to t^* . We add the directed edge (t^*, s^*) and set its capacity to infinity; $c^*((t^*, s^*)) = \infty$. Returning to the analogy of a planar graph with s and t on the same face, splitting v_i^* is analogous to adding an additional edge from t to s which splits their common face into two. However, for our purposes we are only concerned with the algebraic properties of the construction and do not actually need to modify the simplicial complex.

We need to update the chain complex associated with \mathcal{K} to account for the voids and the splitting of v_i^* . We add an additional basis element Σ to $C_d(\mathcal{K})$ such that $\partial \Sigma = \gamma$ and give it infinite capacity; $c(\Sigma) = \infty$. In our construction Σ is dual to the edge (t^*, s^*) . In our planar graph analogy Σ plays the role of an edge from t to s drawn entirely in the outer face; to make this precise we will need to add an additional chain group $C_{d+1}(\mathcal{K})$. We add each void V_j with $j \neq i$ as a basis element of $C_{d+1}(\mathcal{K})$ and define the boundary operator as $\partial_{d+1} V_j = \sum_{\sigma \in \text{Bd}(V_j)} (-1)^{k_\sigma} \sigma$ where $k_\sigma = 0$ if σ is oriented positively on V_j and $k_\sigma = 1$ if σ is oriented negatively on V_j . Next we add additional basis elements S and T whose boundaries are defined by $\partial_{d+1} S = \Gamma_1 + \Sigma$ and $\partial_{d+1} T = \Gamma_2 - \Sigma$. The inclusion of $C_{d+1}(\mathcal{K})$ results in a valid chain complex since by definition the image of ∂_{d+1} under each basis element is a d -cycle. Moreover, in the new complex we have $H_d(\mathcal{K}) \cong 0$ since the boundaries of the voids generate $H_d(\mathcal{K})$.

Given our new chain complex we can extend the dual graph \mathcal{K}^* to a dual complex; this construction is reminiscent of the dual of a polyhedron. We define the dual complex by the isomorphism of chain groups $C_k(\mathcal{K}^*) \cong C_{d-k+1}(\mathcal{K})$. The dual boundary operator $\partial_k^*: C_k(\mathcal{K}^*) \rightarrow C_{k-1}(\mathcal{K}^*)$ is the coboundary operator δ_{d-k+2} , and the dual coboundary operator $\delta_k^*: C_{k-1}(\mathcal{K}^*) \rightarrow C_k(\mathcal{K}^*)$ is the boundary operator ∂_{d-k+2} . The primal boundary operator commutes with the dual coboundary operator, and the primal coboundary operator commutes with the dual boundary operator. We summarize the construction with the following commutative diagram.

$$\begin{array}{ccccccc}
C_{d+1}(\mathcal{K}) & \xleftarrow[\delta_{d+1}]{\partial_{d+1}} & C_d(\mathcal{K}) & \xleftarrow[\delta_d]{\partial_d} & \dots & \xleftarrow[\delta_1]{\partial_1} & C_0(\mathcal{K}) \\
\uparrow \cong & & \uparrow \cong & & & & \uparrow \cong \\
C_0(\mathcal{K}^*) & \xleftarrow[\partial_1^*]{\delta_1^*} & C_1(\mathcal{K}^*) & \xleftarrow[\partial_2^*]{\delta_2^*} & \dots & \xleftarrow[\partial_{d+1}^*]{\delta_{d+1}^*} & C_{d+1}(\mathcal{K}^*)
\end{array}$$

We now have enough structure to state our duality theorems. We show that computing a max-flow for (\mathcal{K}, c, γ) is equivalent to computing a shortest path from s^* to t^* in \mathcal{K}^* and that computing a minimum cost γ -cut p is equivalent to computing a minimum cost unit s^*t^* -flow in \mathcal{K}^* .

Max-flow / shortest path duality. We compute a shortest path from s^* to t^* in \mathcal{K}^* using a well-known shortest paths linear program. Details on the linear program can be found in [9].

$$\begin{array}{ll}
\text{maximize} & \text{dist}(t^*) \\
\text{subject to} & \text{dist}(s^*) = 0 \\
& \text{dist}(v^*) - \text{dist}(u^*) \leq c^*((u^*, v^*)) \quad \forall (u^*, v^*) \in E
\end{array} \tag{LP3}$$

The solution to LP3 is a function $\text{dist}: V(\mathcal{K}^*) \rightarrow \mathbb{R}$ which maps a vertex to its distance from s^* under the weight function c . By duality, dist is a $(d+1)$ -cochain mapping the voids to \mathbb{R} . In the following theorem we will show that dist is equivalent to a γ -flow with value equal to $\text{dist}(t^*)$.

► **Theorem 16.** *Let (\mathcal{K}, c, γ) be a simplicial flow network where \mathcal{K} is a d -dimensional simplicial complex embedded into \mathbb{R}^{d+1} with two unit γ -flows whose supports partition the boundary of some void $\text{Bd}(V_i)$. There is a bijection between γ -flows of (\mathcal{K}, c, γ) and s^*t^* -paths in \mathcal{K}^* such that the value of a γ -flow equals the length of its corresponding s^*t^* -path.*

Min-cut / min cost flow duality. We begin this section by stating the minimum cost flow problem in graphs. The minimum cost flow problem asks to find the cheapest way to send k units of flow from s to t . An instance of the minimum cost flow problem is a tuple (G, w, c, k) where $G = (V, E)$ is a directed graph, $w, c \in C_1(G)$, and $k \in \mathbb{R}$. The 1-chains represent the weight and capacity of each edge, and k is the demand of the network. The goal of the minimum cost flow problem is to find an st -flow satisfying both capacity and demand constraints. The demand constraint can be stated as $\delta(t) \cdot f = k$ and ensures that f sends exactly k units of flow from s to t . We will compute a minimum directed γ -cut in \mathcal{K} by solving the minimum cost flow problem with $k = 1$ in \mathcal{K}^* . We assume there is a weight function $w: \mathcal{K}^d \rightarrow \mathbb{R}^+$ on the d -skeleton of \mathcal{K} , which after dualizing becomes a weight function w^* on the edges of \mathcal{K}^* . In the following theorem the capacity function is not needed, so we will assume each edge in \mathcal{K}^* has infinite capacity.

► **Theorem 17.** *Let \mathcal{K} be a d -dimensional simplicial complex embedded into \mathbb{R}^{d+1} with two unit γ -flows whose supports partition the boundary of some void $\text{Bd}(V_i)$. There is a bijection between γ -cuts p in \mathcal{K} and unit s^*t^* -flows f in \mathcal{K}^* such that $\|p\| = \sum w^*(e)f(e)$.*

► **Corollary 18.** *Let \mathcal{K} be a d -dimensional simplicial complex embedded in \mathbb{R}^{d+1} with two unit γ -flows partitioning some $\text{Bd}(V_i)$. There is a polynomial time algorithm computing a minimum directed combinatorial γ -cut.*

Proof. We solve the minimum cost circulation problem in \mathcal{K}^* setting the demand and every capacity constraint equal to one. The resulting flow is dual to a γ -cut p in \mathcal{K} . Since the minimum cost circulation is integral we have $\|\text{supp}(\delta(p))\| = \|p\|$. That is, the cost of p as a γ -cut equals the cost of $\text{supp}(\delta(p))$ as a combinatorial γ -cut. ◀

6 Ford-Fulkerson algorithm

In this section we show how the Ford-Fulkerson algorithm can be used to compute a max-flow of simplicial flow network (\mathcal{K}, c, γ) . In a simplicial flow network the Ford-Fulkerson algorithm picks out a *augmenting chain* at every iteration which is a high dimensional generalization of an augmenting path. As shown in Section 4.2 a max-flow of a simplicial flow network with integral capacities may not be integral, so it is not immediate that Ford-Fulkerson is guaranteed to halt. To remedy this, our implementation of Ford-Fulkerson contains a heuristic reminiscent of the network simplex algorithm. Our heuristic guarantees that at every iteration of Ford-Fulkerson the flow is a solution on a vertex of the polytope defined by the linear program. Hence, our heuristic makes our implementation of Ford-Fulkerson into a special case of the simplex algorithm. It follows that Ford-Fulkerson does halt on a simplicial flow network, but the running time may be exponential. Our heuristic for picking augmenting chains takes $O(n^{\omega+1})$ time since it requires solving $O(n)$ linear systems, each taking $O(n^\omega)$ time using standard methods [16].

► **Definition 19** (Residual complex). *Let (\mathcal{K}, c, γ) be a simplicial flow network and f be a feasible flow on the network. We define a new simplicial flow network called the **residual complex** to be the tuple $(\mathcal{K}_f, c_f, \gamma)$ constructed in the following way. The d -skeleton of \mathcal{K}_f is the union $\mathcal{K}^d \cup -\mathcal{K}^d$, that is, for each d -simplex σ in \mathcal{K} we add an additional d -simplex $-\sigma$ whose orientation is opposite of σ . $\mathcal{K}_f^{d'} = \mathcal{K}^{d'}$ for dimensions $d' < d$. The **residual capacity function** $c_f: \mathcal{K}_f^d \rightarrow \mathbb{R}$ is given by $c_f(\sigma) = \begin{cases} c(\sigma) - f(\sigma) & \sigma \in \mathcal{K}^d \\ f(\sigma) & -\sigma \in \mathcal{K}^d \end{cases}$.*

► **Definition 20** (Augmenting chain). *Let \mathcal{K}_f be a residual complex for the simplicial flow network (\mathcal{K}, c, γ) . An **augmenting chain** is a d -chain $\Gamma \in C_d(\mathcal{K}_f)$ such that $\Gamma = \sum \alpha_i \sigma_i$ and $\partial \Gamma = \gamma$ with $\alpha_i \geq 0$.*

Note that an augmenting chain need not obey the residual capacity constraint c_f . This is because after finding an augmenting chain the amount of flow sent through the chain will be normalized by the coefficients α_i producing a new chain respecting the capacity constraints. We now state the main theorem of the section.

► **Theorem 21.** *Let (\mathcal{K}, c, γ) be a simplicial flow network. A flow f is a maximum flow if and only if \mathcal{K}_f contains no augmenting chains.*

Augmenting chain heuristic. In this section we provide a heuristic for the Ford-Fulkerson algorithm that is guaranteed to halt on a simplicial flow network. Our example in Section 4.2 shows that a maximum flow may have fractional value, so it's not immediately clear that Ford-Fulkerson halts on all simplicial flow networks. To remedy this our heuristic ensures that at each step the flow corresponds to a vertex of the flow polytope (defined in the next paragraph). As there are a finite number of vertices, and the value of the flow increases at every step, it follows that under this heuristic Ford-Fulkerson must halt. Under our heuristic Ford-Fulkerson becomes a special case of the simplex algorithm. Our heuristic is reminiscent of the network simplex algorithm which maintains a tree at every iteration. See the book by Ahuja, Magnanti, and Orlin for an overview of the network simplex algorithm [1].

We define the *flow polytope* of (\mathcal{K}, c, γ) to be the polytope $P \subset \mathbb{R}^{n_d}$ defined by the constraints of the maximum flow linear program LP1. A *vertex* of the polytope P is any feasible solution to LP1 with at least n_d tight linearly independent constraints. We will ensure that at every step of Ford-Fulkerson our flow f is a vertex of P . To do this we will make sure that the d -simplices corresponding to non-tight constraints of LP1 form an acyclic complex. Some straightforward algebra implies that this condition is enough to make at least n_d constraints tight. Let \mathcal{H}_f be the subcomplex of d -simplices “half-saturated” by f ; that is, $\sigma \in \mathcal{H}_f$ if and only if its capacity constraint is a strict inequality: $0 < f(\sigma) < c(\sigma)$. The half-saturated simplices do not make either of their two corresponding constraints tight, while d -simplices not in \mathcal{H}_f make exactly one of their corresponding constraints tight. We require that \mathcal{H}_f be an acyclic complex at each step of Ford-Fulkerson. In the case of graphs, this just means that \mathcal{H}_f is a forest. For a d -dimensional complex it means that $\dim H_d(\mathcal{H}_f) = 0$. Acyclic complexes have been studied by Duval, Klivans, and Martin who show that they share many properties with forests and trees in graphs [8]. The following lemma shows that if \mathcal{H}_f is acyclic then f is a vertex of the flow polytope.

► **Lemma 22.** *Let f be a feasible flow for the d -dimensional simplicial flow network (\mathcal{K}, c, γ) . If the subcomplex of half-saturated d -simplices \mathcal{H}_f is acyclic then f is a vertex of the flow polytope P .*

At each iteration of Ford-Fulkerson we want to pick an augmenting chain such that the resulting flow leaves \mathcal{H}_f acyclic. It’s not clear how to pick such an augmenting chain. However, no matter what augmenting chain we pick we can always repair the flow in a way that the resulting flow leaves \mathcal{H}_f acyclic. To do so we compute a homology basis of \mathcal{H}_f and update the flow to make $\dim H_d(\mathcal{H}_f) = 0$.

► **Lemma 23.** *Let f be a feasible flow for the d -dimensional simplicial flow network (\mathcal{K}, c, γ) . If the subcomplex of half-saturated d -simplices \mathcal{H}_f is not acyclic then in $O(n^{\omega+1})$ time we can construct a new flow f' such that $\mathcal{H}_{f'}$ is acyclic and $\|f\| = \|f'\|$.*

To wrap up the section, we state our main theorem whose proof is immediate from Lemmas 22 and 23.

► **Theorem 24.** *Given a simplicial flow network (\mathcal{K}, c, γ) we can compute a maximum flow f by using the Ford-Fulkerson algorithm with the following heuristic: at every iteration pick an augmenting chain such that the subcomplex of half-saturated d -simplices \mathcal{H}_f is acyclic.*

Abstract

We present a new universal source code for distributions of unlabeled binary and ordinal trees that achieves optimal compression to within lower order terms for all tree sources covered by existing universal codes. At the same time, it supports answering many navigational queries on the compressed representation in constant time on the word-RAM; this is not known to be possible for any existing tree compression method. The resulting data structures, “hypersuccinct trees”, hence combine the compression achieved by the best known universal codes with the operation support of the best succinct tree data structures.

We apply hypersuccinct trees to obtain a universal compressed data structure for range-minimum queries. It has constant query time and the optimal worst-case space usage of $2n + o(n)$ bits, but the space drops to $1.736n + o(n)$ bits on average for random permutations of n elements, and $2 \lg \binom{n}{r} + o(n)$ for arrays with r increasing runs, respectively. Both results are optimal; the former answers an open problem of Davoodi et al. (2014) and Golin et al. (2016).

Compared to prior work on succinct data structures, we do not have to tailor our data structure to specific applications; hypersuccinct trees automatically adapt to the trees at hand. We show that they simultaneously achieve the optimal space usage to within lower order terms for a wide range of distributions over tree shapes, including: binary search trees (BSTs) generated by insertions in random order / Cartesian trees of random arrays, random fringe-balanced BSTs, binary trees with a given number of binary/unary/leaf nodes, random binary tries generated from memoryless sources, full binary trees, unary paths, as well as uniformly chosen weight-balanced BSTs, AVL trees, and left-leaning red-black trees.

1 Introduction

As space usage and memory access become the bottlenecks in computation, working directly on a compressed representation (“computing over compressed data”) has become a popular field. For text data, substantial progress over the last two decades culminated in compressed text indexing methods that had wide-reaching impact on applications and satisfy strong analytical guarantees. For structured data, the picture is much less developed and clear. In this paper, we develop the analog of entropy-compressed string indices for trees: a data structure that allows one to query a tree stored in compressed form, with optimal query times and space matching the best universal tree codes.

Computing over compressed data became possible by combining techniques from information theory, string compression, and data structures. The central object of study in (classical) information theory is that of a *source* of random strings, whose entropy rate is the fundamental limit for source coding. The ultimate goal in compressing such strings is a *universal code*, which achieves optimal compression (to within lower order terms) for *distributions* of strings from a large class of possible sources *without knowing the used source*.

A classic result in this area is that Lempel-Ziv methods are universal codes for finite-state sources, i.e., sources in which the next symbol’s distribution depends on the previous k emitted symbols (see, e.g., [4, § 13]). The same is true for methods based on the Burrows-Wheeler-transform [6] and for grammar-based compression [30]. The latter two results were only shown around 2000, marking a renewed interest in compression methods.

The year 2000 also saw breakthroughs in compressed text indexing, with the first compressed self-indices that can represent a string and support pattern matching queries using $O(nH_0)$ bits of space [23, 24] and $O(nH_k) + o(n \log |\Sigma|)$ bits of space [8] for H_k the k th order empirical entropy of the string (for $k \geq 0$); many improvements have since been obtained on space and query time; (see [37, 1] for surveys and [15] for lower bounds on redundancy; [35, 36] summarizes more recent trends). For strings, computing over compressed data has mainly been achieved.

In this article, we consider structure instead of strings; focusing on one of the simplest forms of structured data: unlabeled binary and ordinal trees. Unlike for strings, the information theory of structured data is still in its infancy. Random sources of binary trees have (to our knowledge) first been suggested and analyzed in 2009 [31]; a more complete formalization then appeared in [43], together with a first universal tree source code.

For trees, computational results predate information-theoretic developments. *Succinct data structures* date back to 1989 [28] and have their roots in storing trees space-efficiently while supporting fast queries. A succinct data structure is allowed to use $\lg U_n(1 + o(1))$ bits of space to represent one out of U_n possible objects of size n – corresponding to a uniform distribution over these objects. This has become a flourishing field, and several succinct data structures for ordinal or cardinal (including binary) trees supporting many operations are known [34]. Apart from the exceptions discussed below (in particular [29, 5]), these methods do not achieve any compression beyond $\lg U_n$ no matter what the input is.

At the other end of the spectrum, more recent representations for highly repetitive trees [2, 3, 12, 14, 17, 18] can realize exponential space savings over $\lg U_n$ in extreme cases, but recent lower bounds [39] imply that these methods cannot simultaneously achieve constant time² for queries; they are also not known to be succinct when the tree is not highly compressible.

² All running times assume the word-RAM model with word size $w = \Theta(\log n)$.

■ **Table 1** Navigational operations on succinct binary trees. (v denotes a node and i an integer).

<code>parent(v)</code>	the parent of v , same as <code>anc(v, 1)</code>
<code>degree(v)</code>	the number of children of v
<code>left_child(v)</code>	the left child of node v
<code>right_child(v)</code>	the right child of node v
<code>depth(v)</code>	the depth of v , i.e., the number of edges between the root and v
<code>anc(v, i)</code>	the ancestor of node v at depth <code>depth(v) - i</code>
<code>nbdesc(v)</code>	the number of descendants of v
<code>height(v)</code>	the height of the subtree rooted at node v
<code>LCA(v, u)</code>	the lowest common ancestor of nodes u and v
<code>leftmost_leaf(v)</code>	the leftmost leaf descendant of v
<code>rightmost_leaf(v)</code>	the rightmost leaf descendant of v
<code>level_leftmost(ℓ)</code>	the leftmost node on level ℓ
<code>level_rightmost(ℓ)</code>	the rightmost node on level ℓ
<code>level_pred(v)</code>	the node immediately to the left of v on the same level
<code>level_succ(v)</code>	the node immediately to the right of v on the same level
<code>node_rank$_X$(v)</code>	the position of v in the X -order, $X \in \{\text{PRE}, \text{POST}, \text{IN}\}$, i.e., in a preorder, postorder, or inorder traversal of the tree
<code>node_select$_X$(i)</code>	the i th node in the X -order, $X \in \{\text{PRE}, \text{POST}, \text{IN}\}$
<code>leaf_rank(v)</code>	the number of leaves before and including v in preorder
<code>leaf_select(i)</code>	the i th leaf in preorder

In this paper, we fill this gap between succinct trees and dictionary-compressed trees by presenting the first data structure for unlabeled binary trees that answers all queries supported in previous succinct data structures (cf. Table 1) in $O(1)$ time and simultaneously achieves optimal compression over the same tree sources as the best previously known universal tree codes. We also extend the tree-source concepts and our data structure to unlabeled ordinal trees. In contrast to previous succinct trees, we give a single, *universal* data structure, the *hypersuccinct trees*³, that does not need to be adapted to specific classes or distributions of trees.

Our hypersuccinct trees require only a minor modification of existing succinct tree data structures based on tree covering [20, 25, 7], (namely Huffman coding micro-tree types); the contribution of our work is the careful analysis of the information-theoretic properties of the tree-compression method, the “hypersuccinct code”, that underlies these data structures.

As a consequence of our results, we solve an open problem for succinct range-minimum queries (RMQ): Here the task is to construct a data structure from an array $A[1..n]$ of comparable items at preprocessing time that can answer subsequent queries without inspecting A again. The answer to the query $\text{RMQ}(i, j)$, for $1 \leq i \leq j \leq n$, is the index (in A) of the (leftmost) minimum in $A[i..j]$, i.e., $\text{RMQ}(i, j) = \arg \min_{i \leq k \leq j} A[k]$. We give a data structure that answers RMQ in constant time using the optimal expected space of $1.736n + o(n)$ bits when the array is a random permutation, (and $2n + o(n)$ in the worst case); previous work either had suboptimal space [5] or $\Omega(n)$ query time [21]. We obtain the same (optimal) space usage for storing a binary search tree (BST) built from insertions in random order (“random BSTs” hereafter). Finally, we show that the space usage of our RMQ data structure is also bounded by $2 \lg \binom{n}{r} + o(n)$ whenever A has r increasing runs, and that this is again best possible.

³ The name “hypersuccinct trees” is the escalation of the “ultrasuccinct trees” of [29].

Outline. The rest of our article is structured as follows: A comprehensive list of the contributions appears below in Section 2. Section 3 describes our compressed tree encoding. In Section 4, we illustrate the techniques for proving universality of our hypersuccinct code on two well-known types of binary-trees shape distributions – random BSTs and weight-balanced trees – and sketch the extensions necessary for the general results. In Section 5, we present our RMQ data structures. Finally, Section 6 concludes the paper with future directions.

Appendix A contains missing proofs for the RMQ data structures. An extended version of this article is available online (<https://arxiv.org/abs/2104.13457>); it contains formal definitions of tree sources and full proofs for all universality statements.

2 Results

In a binary tree, each node has a left and a right child, either of which can be empty (“null”). For a binary tree t we denote by $|t|$ the number of nodes in t . Unless stated otherwise, $n = |t|$. A binary tree source \mathcal{S} emits a tree t with a certain probability $\mathbb{P}_{\mathcal{S}}[t]$ (potentially $\mathbb{P}_{\mathcal{S}}[t] = 0$); we write $\mathbb{P}[t]$ if \mathcal{S} is clear from the context. $\lg(1/0)$ is taken to mean $+\infty$.

► **Theorem 1** (Hypersuccinct binary trees). *Let t be a binary tree over n nodes. The hypersuccinct representation of t supports all queries from Table 1 in $O(1)$ time and uses $|H(t)| + o(n)$ bits of space, where*

$$|H(t)| \leq \min \left\{ 2n + 1, \min_{\mathcal{S}} \lg \left(\frac{1}{\mathbb{P}_{\mathcal{S}}[t]} \right) + o(n) \right\},$$

and $\mathbb{P}_{\mathcal{S}}[t]$ is the probability that t is emitted by source \mathcal{S} . The minimum is taken over all binary-tree sources \mathcal{S} in the following families (which are explained in Table 4):

- (i) memoryless node-type processes,
- (ii) k th-order node-type processes (for $k = o(\log n)$),
- (iii) monotonic fixed-size sources,
- (iv) worst-case fringe-dominated fixed-size sources,
- (v) monotonic fixed-height sources,
- (vi) worst-case fringe-dominated fixed-height sources,
- (vii) tame uniform subclass sources.

► **Corollary 2** (Hypersuccinct binary trees: Examples & Empirical entropies). *Hypersuccinct trees achieve optimal compression to within lower order terms for all example distributions listed in Table 3. Moreover, for every binary tree t , we have:*

- (i) $|H(t)| \leq H_k^{\text{type}}(t) + o(n)$ with $H_k^{\text{type}}(t)$ the (unnormalized) k th-order empirical entropy of node types (leaf, left-unary, binary, or right-unary) for $k = o(\log n)$.
- (ii) $|H(t)| \leq H_{st}(t) + o(n)$ with $H_{st}(t)$ the “subtree-size entropy”, i.e., the sum of the logarithm of the subtree size of v for all nodes v in t , (a.k.a. the splay-tree potential).

The hypersuccinct code is a *universal code* for the families of binary-tree sources listed in Theorem 1 with bounded maximal pointwise redundancy. We also present a more general class of sources, for which our code achieves $o(n)$ expected redundancy in the appendix; see also Table 4.

To our knowledge, the list in Theorem 1 is a comprehensive account of *all* concrete binary-tree sources for which any universal code is known. Remarkably, in all cases the bounds on redundancies proven for the hypersuccinct code are identical (up to constant factors) to those known for existing universal binary-tree codes. *Our hypersuccinct code thus achieves the same compression as all previous universal codes, but simultaneously supports constant-time queries on the compressed representation with $o(n)$ overhead.*

■ **Table 2** Overview of random tree sources for binary and ordinal trees.

Name	Notation	Intuition	Formal Definition of $\mathbb{P}[t]$
Memoryless Processes	τ	A binary tree is constructed top-down, drawing each node's <i>type</i> (0 = leaf, 1 = left-unary, 2 = binary, 3 = right-unary) i.i.d. according to the distribution $(\tau_0, \tau_1, \tau_2, \tau_3)$.	$\mathbb{P}[t] = \prod_{v \in t} \tau(\text{type}(v))$
Higher-order Processes	$(\tau_z)_z$	A binary tree is constructed top-down, drawing node v 's <i>type</i> according to $\tau_{h_k(v)} : \{0, 1, 2, 3\} \rightarrow [0, 1]$, which depends on the types of the k closest <i>ancestors</i> of v .	$\mathbb{P}[t] = \prod_{v \in t} \tau_{h_k(v)}(\text{type}(v))$
Fixed-size Binary Tree Sources	$\mathcal{S}_{fs}(p)$	A binary tree of size n is constructed top-down, asking source p at each node for its left- and right <i>subtree size</i> .	$\mathbb{P}[t] = \prod_{v \in t} p(t_\ell(v) , t_r(v))$ $t_{\ell/r}(v)$ = left/right subtree of v
Fixed-height Binary Tree Sources	$\mathcal{S}_{fh}(p)$	A binary tree of height h is constructed top-down, asking source p at each node for a left and right subtree <i>height</i> .	$\mathbb{P}[t] = \prod_{v \in t} p(h(t_\ell(v)), h(t_r(v)))$ $h(t)$ = height of t
Uniform Subclass Sources	$\mathcal{U}_{\mathcal{P}}$	A binary tree is drawn uniformly at random from the set $\mathcal{T}_n(\mathcal{P})$ of all binary trees of size n that satisfy property \mathcal{P} .	$\mathbb{P}[t] = \frac{1}{ \mathcal{T}_n(\mathcal{P}) }$
Memoryless Ordinal Tree Sources	d	An ordinal tree is constructed top-down, drawing each node v 's degree $\deg(v)$ according to distribution $d = (d_0, d_1, \dots)$.	$\mathbb{P}[t] = \prod_{v \in t} d_{\deg(v)}$
Fixed-size Ordinal Tree Sources	$\mathcal{S}_{fs}(p)$	An ordinal tree of size n is constructed top-down, asking source p at each node for the number and sizes of the subtrees.	$\mathbb{P}[t] = \prod_{v \in t} p(t_1[v] , \dots, t_{\deg(v)}[v])$

In terms of queries, previous solutions either have suboptimal query times [2, 3, 14], higher space usage [39], or rely on tailoring the representation to a specific subclass of trees [29, 7] to achieve good space and time for precisely these instances, but they fail to generalize to other use cases. Some also do not support all queries. We give a detailed comparison with the state of the art in the extended version of this article.

We focus here on our results for binary trees. In the extended version of this article, we extend the above notions of tree sources (except fixed-height sources) to ordinal trees, which has not been done to our knowledge. Moreover, we extend both our code and data structure to ordinal trees, and show their universality for these sources.

3 From Tree Covering to Hypersuccinct Trees

Our universally compressed tree data structures are based on *tree covering* [20, 25, 7]: A (binary or ordinal) tree t is decomposed into *mini trees*, each of which is further decomposed into *micro trees*; the size of the latter, $B = B(n) = \lg n/8$, is chosen so that we can tabulate all possible shapes of micro trees and the answers to various micro-tree-local queries in one global lookup table (the “Four-Russian Table” technique). For each micro tree, its local shape is stored, e.g., using the balanced-parenthesis (BP) encoding, using a total of exactly $2n$ bits (independent of the tree shape). Using additional data structures occupying only $o(n)$ bits of space, a long list of operations can be supported in constant time (Table 1). The space usage of this representation is optimal to within lower order terms for the worst case, since $\lg C_n \sim 2n$ bits are necessary to distinguish all $C_n = \binom{2n}{n}/(n+1)$ trees of n nodes. (This worst-case bound applies both to ordinal trees and binary trees).

■ **Table 3** An overview over the concrete examples of tree-shape distributions that our hypersuccinct code compresses optimally (up to lower-order terms).

Tree-Shape Distribution	Entropy	Corresponding Source
(Uniformly random) binary trees of size n	$2n$	Memoryless binary, monotonic fixed-size binary
(Uniformly random) full binary trees of size n	n	Memoryless binary
(Uniformly random) unary paths of length n	n	Memoryless binary
(Uniformly random) Motzkin trees of size n	$1.585n$	Memoryless binary
Binary search trees generated by insertions in random order (“random BSTs”)	$1.736n$	Monotonic fixed-size binary
Binomial random trees	$P(\lg n)n^a)$	Average-case fringe-dominated fixed-size binary
Almost paths	— ^{b)}	Monotonic fixed-size binary
Random fringe-balanced binary search trees	— ^{b)}	Average-case fringe-dominated fixed-size binary
(Uniformly random) AVL trees of height h	— ^{b)}	Worst-case fringe-dominated fixed-height binary
(Uniformly random) weight-balanced binary trees of size n	— ^{b)}	Worst-case fringe-dominated fixed-size binary
(Uniformly random) AVL trees of size n	$0.938n$	Uniform-subclass
(Uniformly random) left-leaning red-black trees of size n	$0.879n$	Uniform-subclass
(Uniformly random) full m -ary trees of size n	$\lg(\frac{m}{m-1})n$	Memoryless ordinal
Uniform composition trees	— ^{b)}	Monotonic fixed-size ordinal
Random LRM-trees	$1.736n$	Monotonic fixed-size ordinal

a) Here P is a nonconstant, continuous, periodic function with period 1.

b) No (concise) asymptotic approximation known.

■ **Table 4** Sufficient conditions under which we show universality of our hypersuccinct code H for binary trees. Proofs are given in the extended version of this article (<https://arxiv.org/abs/2104.13457>).

Family of sources	Restriction	Redundancy
Memoryless node-type	—	$O(n \log \log n / \log n)$
k th-order node-type	—	$O((nk + n \log \log n) / \log n)$
Monotonic fixed-size	$p(\ell, r) \geq p(\ell + 1, r)$ and $p(\ell, r) \geq p(\ell, r + 1)$ for all $\ell, r \in \mathbb{N}_0$	$O(n \log \log n / \log n)$
Worst-case fringe-dominated fixed-size	$n_{\geq B}(t) = o(n / \log \log n)$ for all t with $\mathbb{P}[t] > 0$; $n_{\geq B}(t) = \#\text{nodes with subtree size in } \Omega(\log n)$	$O(n_{\geq B}(t) \log \log n + n \log \log n / \log n)$
Weight-balanced fixed-size	$\sum_{\frac{n}{c} \leq \ell \leq n - \frac{n}{c}} p(\ell - 1, n - \ell - 1) = 1$ for constant $c \geq 3$	$O(n \log \log n / \log n)$
Average-case fringe-dominated fixed-size	$\mathbb{E}[n_{\geq B}(T)] = o(n / \log \log n)$ for random T generated by source \mathcal{S}	$O(n_{\geq B}(t) \log \log n + n \log \log n / \log n)^a)$
Monotonic fixed-height	$p(\ell, r) \geq p(\ell + 1, r)$ and $p(\ell, r) \geq p(\ell, r + 1)$ for all $\ell, r \in \mathbb{N}_0$	$O(n \log \log n / \log n)$
Worst-case fringe-dominated fixed-height	$n_{\geq B}(t) = o(n / \log \log n)$ for all t with $\mathbb{P}[t] > 0$	$O(n_{\geq B}(t) \log \log n + n \log \log n / \log n)$
Tame uniform-subclass	class of trees $\mathcal{T}_n(\mathcal{P})$ is hereditary (i.e., closed under taking subtrees), $n_{\geq B}(t) = o(n / \log \log n)$ for $t \in \mathcal{T}_n(\mathcal{P})$, $\lg \mathcal{T}_n(\mathcal{P}) = cn + o(n)$ for constant $c > 0$, heavy-twigged: if v has subtree size $\Omega(\log n)$, v 's subtrees have size $\omega(1)$	$o(n)$

a) Stated redundancy is achieved in expectation for a random tree t generated by the source.

■ **Figure 1** Example binary tree with $n = 70$ nodes and micro trees computed by the Farzan-Munro tree-covering algorithm [7] with parameter $B = 6$. The micro trees are indicated by colors. The algorithm guarantees that each node is part of exactly one micro tree and that each micro tree has at most three edges shared with other micro trees, namely to a parent, a left- and a right-child micro tree.

A core observation is that the dominant space in tree-covering data structures comes from storing the micro-tree types, and these can be further compressed using a different code. This has been used in an ad-hoc manner for specific tree classes [7, 5, 16], but has not been investigated systematically. A natural idea is to use a Huffman code for the micro tree types to simultaneously beat the compression of all these special cases; we dub this as the “Four Russians and One American”⁴ trick. Applying it to the data structures based on the Farzan-Munro tree-covering algorithm [7] yields our hypersuccinct trees.

The main contribution of our present work is the careful analysis of the potential of the Four Russians and One American trick for (binary and ordinal) tree source coding. As an immediate corollary, we obtain a single data structure that achieves optimal compression for all special cases covered in previous work, plus a much wider class of distributions over trees for which no efficient data structure was previously known.

Our analysis builds on previous work on tree compression, specifically DAG compression and tree straight-line programs (TSLPs) [32]. Our core idea is to interpret (parts of the) tree-covering data structures as a *code* for trees, the “hypersuccinct code”: it stores the type, i.e., the local shape, of all micro trees separately from how they interface to form the entire tree. Intuitively, our hypersuccinct code is a restricted version of a grammar-based tree code, where we enforce having nonterminals for certain subtrees;⁵ we strengthen and extend existing universality proofs from general grammar-based tree codes to the restricted hypersuccinct code.

4 Universality for Fixed-Size Sources

In this section, we sketch the proof that our hypersuccinct trees achieve optimal compression for two exemplary tree-shape distributions: random binary search trees and uniform weight-balanced trees (defined below). These examples serve to illustrate the proof techniques and

⁴ It deems us only fair to do D. A. Huffman the same questionable honor of reducing the person to a country of residence that V. L. Arlazarov, E. A. Dinic, M. A. Kronrod, and I. A. Faradžev have experienced ever since their table-lookup technique has become known as the “Four-Russians trick”.

⁵ Differences in technical details make the direct comparison difficult, though: in TSLPs, holes in contexts must be stored (and encoded) alongside the local shapes as they are both part of the right-hand side of productions; in our hypersuccinct code, we separately encode the shapes of micro trees and the positions of portals, potentially gaining a small advantage. Our comment thus remains a motivational hint as to why similar analysis techniques are useful in both cases, but falls short of providing a formal reduction.

to showcase the versatility of the approach. The extension to the general sufficient conditions from Table 4 and full details of computations are spelled out in the extended version of the article.

By *random BSTs*, we mean the distribution of tree shapes obtained by successively inserting n keys in random order into an (initially empty) unbalanced binary search tree (BST). We obtain random BSTs from a fixed-size tree source $\mathcal{S}_{fs}(p_{bst})$ with $p_{bst}(\ell, n-1-\ell) = \frac{1}{n}$ for all $\ell \in \{0, \dots, n-1\}$ and $n \in \mathbb{N}_{\geq 1}$, i.e., making every possible split equally likely. (Any left subtree size ℓ is equally likely in a random BST of a given size n .) Hence, $\mathbb{P}[t] = \prod_{v \in t} 1/|t[v]|$ where $t[v]$ is the subtree rooted at v and $|t[v]|$ its size (in number of nodes).

The second example are the shapes of uniformly random *weight-balanced BSTs* (BB[α]-trees, [38]): A binary tree t is α -weight-balanced if we have for every node v in t that $\min\{|t_\ell[v]|, |t_r[v]|\} + 1 \geq \alpha(|t[v]| + 1)$. Here $t_\ell[v]$ resp. $t_r[v]$ are the left resp. right subtrees of $t[v]$. We denote the set of α -weight-balanced trees of size n by $\mathcal{T}_n(\mathcal{W}_\alpha)$. We obtain random α -weight-balanced trees from another fixed-size source $\mathcal{S}_{fs}(p_{wb})$ with

$$p_{wb}(\ell, n-1-\ell) = \begin{cases} \frac{|\mathcal{T}_\ell(\mathcal{W}_\alpha)| |\mathcal{T}_{n-1-\ell}(\mathcal{W}_\alpha)|}{|\mathcal{T}_n(\mathcal{W}_\alpha)|} & \text{if } \min\{\ell+1, n-\ell\} \geq \alpha(n+1), \\ 0 & \text{otherwise.} \end{cases}$$

It is easy to check that this yields the uniform probability distribution on $\mathcal{T}_n(\mathcal{W}_\alpha)$, i.e., with $\mathbb{P}[t] = 1/|\mathcal{T}_n(\mathcal{W}_\alpha)|$ for $t \in \mathcal{T}_n(\mathcal{W}_\alpha)$ and $\mathbb{P}[t] = 0$ otherwise. We note that computing $|\mathcal{T}_n(\mathcal{W}_\alpha)|$ is a formidable challenge in combinatorics, but we never have to do so; we only require the *existence* of the fixed-size source for weight-balanced BSTs.

The *hypersuccinct code* $H(t)$ is formed by partitioning the nodes of a given binary tree t into $m = \Theta(n/\log n)$ micro trees μ_1, \dots, μ_m , each of which is a connected subtree of at most $\mu = O(\log n)$ nodes; an example is shown in Figure 1. Previous work on tree covering shows how to compute these and how to encode everything but the local shape of the micro trees in $o(n)$ bits of space [7]. (For a mere encoding, $O(n \log \log n / \log n)$ bits suffice.

The dominant part of the hypersuccinct code is the list of *types* of all micro trees, i.e., the (local) shapes of the induced subtrees formed by the set of nodes in the micro trees. Let C be a Huffman code for the string μ_1, \dots, μ_m , where we identify micro trees with their types. For a variety of different tree sources \mathcal{S} , we can prove that $\sum_{i=1}^m |C(\mu_i)|$, the total length of codewords for the micro trees, is upper bounded by $\lg(1/\mathbb{P}[t]) + \text{lower-order terms}$, where $\mathbb{P}[t]$ is the probability that t is emitted by \mathcal{S} ; this is the best possible code length to within lower order terms achievable for that source. We will now show this for our two example distributions.

4.1 Random BSTs

The proof consists of four steps that can be summarized as follows:

<p>Step 1 Construct a source-specific micro-tree encoding $D_S: \{\mu_1, \dots, \mu_m\} \rightarrow \{0, 1\}^*$ Goal: $D_S(\mu_i) \approx \lg(1/\mathbb{P}[\mu_i])$</p>	<p>Step 2 By optimality of Huffman codes: $\sum_{i=1}^m C(\mu_i) \leq \sum_{i=1}^m D_S(\mu_i)$</p>	<p>Step 3 Use properties of \mathcal{S} to show that $\prod_{i=1}^m \mathbb{P}[\mu_i] \gtrsim \mathbb{P}[t]$</p>	<p>Step 4 Conclude $\sum_{i=1}^m C(\mu_i) \approx \lg(1/\mathbb{P}[t])$</p>
---	--	---	---

Steps 2 and 4 do not depend on the source and indeed follow immediately; Steps 1 and 3 are the creative parts. Ignoring proper tracing of error terms, the result then follows as

$$|H(t)| \sim \sum_{i=1}^n |C(\mu_i)| \leq \sum_{i=1}^n |D_{\mathcal{S}}(\mu_i)| \leq \sum_{i=1}^n \lg(1/\mathbb{P}[\mu_i]) \lesssim \lg(1/\mathbb{P}[t]).$$

Let us consider $\mathcal{S}_{fs}(p_{bst})$, the fixed-size source producing (shapes of) random BSTs, and address these steps independently.

Our task in Step 1 is to find a code $D_{\mathcal{S}}$ for the micro-tree types that can occur in t , so that $|D_{\mathcal{S}}(\mu_i)| = \lg(1/\mathbb{P}_{\mathcal{S}}[\mu_i]) + O(\log \log n)$. This code may rely on the decoder to have knowledge of \mathcal{S} . For random BSTs, $D_{\mathcal{S}}(t)$ can be constructed as follows: We initially store n using Elias gamma code⁶ and then, following a depth-first (preorder) traversal of the tree, we encode the size of the left subtree using *arithmetic coding*. Inductively, the size of the currently encoded node is always known, and the source-specific code is allowed to use the probability distributions hardwired into \mathcal{S} without storing them; for random BSTs, we simply encode a number uniformly distributed in $[0..s-1]$ at a node with subtree size s , using exactly $\lg s$ bits. Apart from storing the initial size and the small additive overhead from arithmetic coding, the code length of this “depth-first arithmetic tree code” is best possible: $|D_{\mathcal{S}}(t)| \leq \lg(1/\mathbb{P}[t]) + O(\log |t|)$. This concludes Step 1.

For Step 3, we have to show that the probability for the entire tree t is at most the product of the probabilities for all micro-trees. Recall that μ_1, \dots, μ_m are the micro trees in t . We can write $\mathbb{P}[t]$ as a product over contributions of individual nodes, and can collect factors in $\mathbb{P}[t]$ according to micro trees; this works for any fixed-size source. For random BSTs, we can use the “monotonicity” of node contributions to show

$$\mathbb{P}[t] = \prod_{v \in t} \frac{1}{|t[v]|} = \prod_{i=1}^m \prod_{v \in \mu_i} \frac{1}{|t[v]|} \leq \prod_{i=1}^m \prod_{v \in \mu_i} \frac{1}{|\mu_i[v]|} = \prod_{i=1}^m \mathbb{P}[\mu_i].$$

That completes Step 3, and hence the proof that $|H(t)| \leq \mathbb{P}_{\mathcal{S}_{fs}(p_{bst})}[t] + o(n)$.

4.2 Weight-balanced trees

Let us now consider uniformly random weight-balanced trees, i.e., the source $\mathcal{S} = \mathcal{S}_{fs}(p_{wb})$. We would like to follow the same template as above; however, this is not possible: Step 3 from above is in general not true anymore. The reason is that it is not clear whether the “non-fringe” micro trees, i.e., those that do not contain all descendants of the micro-tree root, have non-zero probability under \mathcal{S} . (A subtree of a tree is called *fringe*, if it consists of a node and all its descendants). Such micro trees will also make Step 1 impossible as they would require a code length of 0. While this issue is inevitable in general (Remark 4), we can under certain conditions circumvent Steps 1 and 3 altogether by directly bounding $\sum_{i=1}^m |D_{\mathcal{S}}(\mu_i)| \leq \mathbb{P}[t] + o(n)$.

As a first observation, note that it suffices to have $|D_{\mathcal{S}}(\mu_i)| = \lg(1/\mathbb{P}_{\mathcal{S}}[\mu_i]) + O(\log \log n)$ for *all but a vanishing fraction* of the micro trees in any tree t ; then we can still hope to show $\sum_{i=1}^m |D_{\mathcal{S}}(\mu_i)| \leq \mathbb{P}[t] + o(n)$ overall. Second, it is known [12] that weight-balanced trees are “*fringe dominated*” in the following sense: Denoting by $n_{\geq B}(t)$ the number of “heavy” nodes, i.e., v in t with $|t[v]| \geq B = \lg n/8$, we have $n_{\geq B}(t) = O(n/B) = o(n)$ for

⁶ Elias gamma code $\gamma : \mathbb{N} \rightarrow \{0,1\}^*$ encodes an integer $n \geq 1$ using $2\lfloor \lg n \rfloor + 1$ bits by prefixing the binary representation of n with that representation’s length encoded in unary.

every weight-balanced tree $t \in \mathcal{T}_n(\mathcal{W}_\alpha)$. Since only a vanishing fraction of nodes are heavy, one might hope that also only a vanishing fraction of micro trees are non-fringe, making the above route succeed. Unfortunately, that is not the case; the non-fringe micro trees can be a constant fraction of all micro trees.

Notwithstanding this issue, a more sophisticated micro-tree code D_S allows us to proceed. D_S encodes any *fringe* micro tree using a depth-first arithmetic code as for random BSTs. Any non-fringe micro tree μ_i , however, is broken up into the subtree of heavy nodes, the “boughs” of μ_i , and (fringe) subtrees $f_{i,j}$ hanging off the boughs. It is a property of the Farzan-Munro algorithm that every micro-tree root is heavy, hence all $f_{i,j}$ are indeed entirely contained within μ_i .

$D_S(\mu_i)$ then first encodes the bough nodes using 2 bits per node (using a BP representation for the boughs subtree) and then appends the depth-first arithmetic code for the $f_{i,j}$ (in left-to-right order). While this does not actually achieve $|D_S(\mu_i)| \approx \lg(1/\mathbb{P}[\mu_i])$ for entire micro trees μ_i , it does so for all the fringe subtrees $f_{i,j}$. Any node not contained in a fringe subtree $f_{i,j}$ must be part of a bough and hence heavy; by the fringe-dominance property, these nodes form a vanishing fraction of all nodes and hence contribute $o(n)$ bits overall. This shows that $|\mathbf{H}(t)| \leq \mathbb{P}_{\mathcal{S}_{fs}(\mathcal{P}_{ub})}[t] + o(n)$.

► **Remark 3 (A simple code whose analysis isn’t).** It is worth pointing out that the source specific code D_S is only a vehicle for the *analysis* of $|\mathbf{H}(t)|$; the complicated encodings D_S do not ever need to be computed when using our codes or data structures.

4.3 Other Sources

For memoryless sources, the analysis follows the four-step template, and is indeed easier than the random BSTs since Step 3 becomes trivial. For higher-order sources, in order to know the node types of the k closest ancestors (in t) of all nodes of depth $\leq k$ in μ_i , we prefix the depth-first arithmetic code by the node types of the k closest ancestors of the root of μ_i . Then the k ancestor types are known inductively for all nodes in a preorder traversal of μ_i .

The tame uniform-subclass sources require the most technical proof, but it is conceptually similar to the weight-balanced trees from above. The source-specific encoding for fringe subtrees is trivial here: we can simply use the rank in an enumeration of all trees of a given size, prefixed by the size of the subtree. Using the tameness conditions, one can show that a similar decomposition into boughs and fringe subtrees yields an optimal code length for almost all nodes. Details are deferred to the extended version of this article.

* * *

Together with the observations from Section 3 this yields Theorem 1. We obtained similar results for ordinal trees; details are deferred to the extended version of this article.

► **Remark 4 (Restrictions are inevitable).** We point out that some restrictions like the ones discussed above cannot possibly be overcome in general. Zhang, Yang, and Kieffer [43] prove that the unrestricted class of fixed-size sources (leaf-centric binary tree sources in their terminology) does not allow a universal code, even when only considering expected redundancy. The same is true for unrestricted fixed-height and uniform-subclass sources. While each is a natural formalism to describe possible binary-tree sources, additional conditions are strictly necessary for any interesting compression statements to be made. Our sufficient conditions are the weakest such restrictions for which any universal source code is known to exist ([43, 13, 40]), even without the requirement of efficient queries.

5 Hypersuccinct Range-Minimum Queries

We now show how hypersuccinct trees imply an optimal-space solution for the range-minimum query (RMQ) problem.⁷ Let $A[1..n]$ store the numbers x_1, \dots, x_n , i.e., x_j is stored at index j for $1 \leq j \leq n$. While duplicates naturally arise in some applications, e.g., in the longest-common extension (LCE) problem, we assume here that x_1, \dots, x_n are n distinct numbers to simplify the presentation. However, our RMQ solution works regardless of which minimum-value index is to be returned so long as the tie breaking rule is deterministic and fixed at construction time.

5.1 Cartesian Trees

The *Cartesian tree* T for x_1, \dots, x_n (resp. for $A[1..n]$) is a binary tree defined recursively as follows: If $n = 0$, it is the empty tree (“null”). Otherwise it consists of a root whose left child is the Cartesian tree for x_1, \dots, x_{j-1} and its right child is the Cartesian tree for x_{j+1}, \dots, x_n where j is the position of the minimum, $j = \arg \min_k A[k]$. A classic observation of Gabow et al. [11] is that range-minimum queries on A are equivalent to lowest-common-ancestor (LCA) queries on T when identifying nodes with their inorder rank:

$$\text{RMQ}_A(i, j) = \text{node_rank}_{\text{IN}}\left(\text{LCA}(\text{node_select}_{\text{IN}}(i), \text{node_select}_{\text{IN}}(j))\right).$$

We can thus reduce an RMQ instance (on an arbitrary input) to an LCA instance on binary trees of the same size; (the number of nodes in T equals the length of the array).

5.2 Random RMQ

We first consider the random permutation model for RMQ: Every (relative) ordering of the elements in $A[1..n]$ is equally likely. Without loss of generality, we identify the n elements with their ranks, i.e., $A[1..n]$ contains a random permutation of $[1..n]$. We refer to this as a random RMQ instance.

We can characterize the distribution of the Cartesian tree associated with such a random RMQ instance: Since the minimum in a random permutation is located at every position $i \in [n]$ with probability $\frac{1}{n}$, the inorder index of the root is uniformly distributed in $[n]$. Apart from renaming, the subarrays $A[1..i-1]$ (resp. $A[i+1..n]$) contain a random permutation of $i-1$ (resp. $n-i$) elements, and these two permutations are independent of each other conditional on their sizes. Cartesian trees of random RMQ instances thus have the same distribution as random BSTs, and in particular shape t arises with probability $\mathbb{P}[t] = \prod_{v \in t} \frac{1}{|t[v]|}$. The former are also known as random increasing binary trees [10, Ex. II.17 & Ex. III.33].

Since the sets of answers to range-minimum queries is in bijection with Cartesian trees, the entropy H_n of the distribution of the shape of the Cartesian tree (and hence random BSTs) gives an information-theoretic lower bound for the space required by any RMQ data structure (in the encoding model studied here). Kieffer, Yang and Szpankowski [31] show⁸

⁷ A technical report containing preliminary results for random RMQ, but including more details on the data structure aspects of our solution, can be found on arXiv [33].

⁸ Hwang and Neininger [26] showed already in 2002 that the quicksort recurrence can be solved explicitly for arbitrary toll functions. H_n satisfies this recurrence with toll function $\lg n$, hence they implicitly proved Equation (1).

that the entropy of random BSTs $H_n = \mathbb{E}_T[\lg(1/\mathbb{P}[T])] = \mathbb{E}_T[\sum_{v \in T} \lg(|T[v]|)]$ is

$$H_n = \lg(n) + 2(n+1) \sum_{i=2}^{n-1} \frac{\lg i}{(i+2)(i+1)} \sim 2n \sum_{i=2}^{\infty} \frac{\lg i}{(i+2)(i+1)} \approx 1.7363771n. \quad (1)$$

With these preparations, we are ready to prove our first result on range-minimum queries.

► **Corollary 5** (Average-case optimal succinct RMQ). *There is a data structure that supports (static) range-minimum queries on an array A of n (distinct) numbers in $O(1)$ worst-case time and which occupies $H_n + o(n) \approx 1.736n + o(n)$ bits of space on average over all possible permutations of the elements in A . The worst case space usage is $2n + o(n)$ bits.*

Proof. We construct a hypersuccinct tree on the Cartesian tree for A . It supports `node_rankIN`, `node_selectIN`, and `LCA` in $O(1)$ time and thus `RMQ` in constant time without access to A . By Corollary 2, the space usage of hypersuccinct trees is at most $\min\{2n, \lg(1/\mathbb{P}[t])\} + o(n)$ for $\mathbb{P}[t] = \prod_{v \in t} \frac{1}{|t[v]|}$. By the above observations, this is the probability to obtain t as the Cartesian trees of a random permutation, so we store t with maximal pointwise redundancy of $o(n)$, hence also $o(n)$ expected redundancy over the entropy $H_n \sim 1.736n$. ◀

5.3 RMQ with Runs

A second example of compressible RMQ instances results from partially sorted arrays. Suppose that $A[1..n]$ can be split into r runs, i.e., maximal contiguous ranges $[j_i, j_{i+1} - 1]$, ($i = 1, \dots, r$ with $j_1 = 1$ and $j_{r+1} = n + 1$), so that $A[j_i] \leq A[j_i + 1] \leq \dots \leq A[j_{i+1} - 1]$.

► **Theorem 6** (Lower bound for RMQ with runs). *Any range-minimum data structure in the encoding model for an array of length n that contains r runs must occupy at least $\lg N_{n,r} \geq 2 \lg \binom{n}{r} - O(\log n)$ bits of space where $N_{n,r} = \frac{1}{n} \binom{n}{r} \binom{n}{r-1}$ are the Narayana numbers.*

The proof follows from a bijection between Cartesian trees on sequences of length n with exactly r runs and mountain-valley diagrams (a.k.a. Dyck paths) of length $2n$ with exactly r “peaks”; the latter is known to be counted by the *Narayana numbers* [27]. Details are given in Appendix A.

► **Corollary 7** (Optimal succinct RMQ with runs). *There is a data structure that supports (static) range-minimum queries on an array A of n numbers that consists of r runs in $O(1)$ worst-case time and which occupies $2 \lg \binom{n}{r} + o(n) \leq 2n + o(n)$ bits of space.*

This follows from the observation that a node’s type in the Cartesian tree, i.e., whether or not its left resp. right child is empty, closely reflects the runs in A : A binary node marks the beginning of a non-singleton run, a leaf node marks the last position in a non-singleton run, a right-unary node (i.e., left child empty, right child nonempty) is a middle node of a run, and a left-unary node corresponds to a singleton run. With $s \in [0..r]$ the number of singleton runs, we can bound the space for a hypersuccinct tree in terms of its empirical node-type entropy by $H_0^{\text{type}}(T) + o(n) = nH\left(\frac{r-s}{n}, \frac{s}{n}, \frac{n-2r+s}{n}, \frac{r-s}{n}\right) + o(n)$, which can be shown to be no more than $2 \lg \binom{n}{r} + o(n)$ for any value of s ; again, details are deferred to Section A.

* * *

We close by pointing out that hypersuccinct trees simultaneously achieve the optimal bounds for RMQ on random permutations and arrays with r runs without taking explicit precautions for either. The same is true for any other shape distributions of Cartesian trees that can be written as one of the sources from Table 4.

6 Conclusion

We presented the first succinct tree data structures with optimally adaptive space usage for a large variety of random tree sources, both for binary trees and for ordinal trees. This is an important step towards the goal of efficient computation over compressed structures, and has immediate applications, e.g., as illustrated above for the range-minimum problem.

A goal for future work is to reduce the redundancy of $o(n)$, which becomes dominant for sources with sublinear entropy. While this has been considered for tree covering in principle [41], many details remain to be thoroughly investigated.

For very compressible trees, the space savings in hypersuccinct trees are no longer competitive. On the other hand, with current methods for random access on dictionary-compressed sequences, constant-time queries are not possible in the regime of mildly compressible strings; the same applies to known approaches to represent trees. An interesting question is whether these opposing approaches can be combined in a way to complement each other's strengths. We leave this direction for future work.

A Range-Minimum Queries With Runs

In this appendix, we give the proofs of the results from Section 5.3.

A.1 Lower Bound

In this section, we proof Theorem 6.

We refer to a run of length one as a singleton run. The types of nodes in the Cartesian tree (whether or not their left and right children exist) directly reflect their role in runs: A binary node is a run head of a non-singleton run, a leaf is the last node of non-singleton run, a right-unary node (i.e., unary node with a right child) is a middle node of run and a left-unary node is a singleton run. The leftmost node, i.e., the node with smallest inorder rank, is the only exception to this rule: if the leftmost run is a singleton run, the leftmost node is a leaf; otherwise it is right-unary.

In any case, a Cartesian tree for an array with r runs that has b binary nodes and u_ℓ left-unary nodes thus satisfies $r = b + u_\ell + 1$: every binary node represents the non-singleton run that begins with it, every left-unary node represents the singleton run at that position, and the leftmost run is counted separately. (Note that we do not double count the latter because the leftmost node is by definition neither binary nor left-unary.) We therefore obtain a lower bound for the number of equivalence classes among length- n arrays with r runs under range-minimum queries by counting binary trees with a given number of nodes n and a given number of nodes of certain types.

That r is the sum of two quantities is inconvenient, hence we instead consider the following sequence of bijections (see Figure 2). First, we map Cartesian trees t of n nodes bijectively to balanced-parenthesis (BP) strings of n pairs of parentheses as follows: The empty tree corresponds to the empty string. For a nonempty tree, we recursively compute the BP strings of the (potentially empty) left resp. right subtrees of the root; let these be denoted by L and R . Then the BP string for the entire tree is obtained as $L(R)$. (This is a variation of the canonical BP representation.)

■ **Figure 2** An example illustrating the bijections: The input array is $A = (2, 3, 4, 1, 6, 5, 7, 9, 10, 8)$, the min-oriented Cartesian tree is shown above with run ends highlighted in red. The BP string for the Cartesian tree is shown above the tree, with tree nodes connected to the corresponding opening parenthesis (note that nodes appear in inorder in the BP string). The mountain-valley (excess, Dyck path) representation of the BP string is on top; run ends correspond to peaks there.

It is easy to check that the resulting sequence is indeed the push/pop sequence of a max-stack [9, 19] where ‘(’ means push and ‘)’ means pop. We map this sequence to a lattice path by replacing ‘(’ by step vector $(1, +1)$ and ‘)’ by $(1, -1)$; the resulting lattice path is a mountain-valley diagram (Dyck paths).

The important property of the above bijections is that they *preserve runs*: A *run end* is an index where the next number is smaller (or nonexistent). In the Cartesian tree, these are the leaves *and* left-unary nodes, in the BP string, these are the occurrences of ‘(’ and in the mountain-valley representations, these are the *peaks*. The latter is known to be counted by the *Narayana numbers*: There are

$$N_{n,r} = \frac{1}{n} \binom{n}{r} \binom{n}{r-1} = \frac{r}{n(n+1-r)} \binom{n}{r}^2 \quad (2)$$

mountain-valley diagrams of length $2n$ with exactly r peaks [27]. This concludes the proof of Theorem 6; the asymptotic approximation for $\lg N_{n,r}$ immediately follows from the above closed form.

A.2 Hypersuccinct RMQ with Runs

In this section, we prove Corollary 7. To this end, we show that using a hypersuccinct tree to represent the Cartesian tree of an array $A[1..n]$ with r increasing runs has a space usage that is bounded by $\lg N_{n,r} + o(n)$ bits. By Theorem 6, this space usage is optimal up to the $o(n)$ term.

As noted in Section A.1, the correspondence between runs and node types in the Cartesian tree can be made more specific by also specifying the number $s \in [r]$ of singleton runs: Singleton runs correspond to the left-unary nodes in the (min-oriented) Cartesian tree t , except possibly for a leftmost singleton run (which corresponds to a leaf). In either case, we will have $u_\ell = s \pm 1$ left-unary nodes and $\ell = r - s \pm 1$ leaves. That implies a number of binary nodes of $b = \ell - 1 \pm 1$; the remaining $u_r = n - b - \ell - u_\ell = n - 2r + s \pm 1$ nodes are right-unary nodes.

By Corollary 2, the hypersuccinct representation of the Cartesian tree t for $A[1..n]$ supports LCA-queries on t in $O(1)$ time and uses

$$|H(t)| + o(n) \leq H_0^{\text{type}}(t) + o(n)$$

bits of space. We show that $H_0^{\text{type}}(t) \leq \lg N_{n,r} + o(n)$. Let

$$p = \left(\frac{b}{n}, \frac{u_\ell}{n}, \frac{u_r}{n}, \frac{\ell}{n} \right)$$

denote the empirical distribution of node types in t , and let $H(p)$ denote the entropy of this distribution. (For probability distribution $d = (d_1, d_2, \dots, d_k)$, its entropy is defined by

$$H(d) = \sum_{i=1}^k d_i \lg \left(\frac{1}{d_i} \right),$$

as usual.)

By definition of the type-entropy H_0^{type} , we find $H_0^{\text{type}}(t) = nH(p)$. By our previous observations, p differs from

$$p' = \left(\frac{r-s}{n}, \frac{s}{n}, \frac{n-2r+s}{n}, \frac{r-s}{n} \right)$$

only by $\|p - p'\|_\infty \leq \frac{2}{n}$. Using [42, Prop. 2.42], we thus find $H(p) \leq H(p') + O(n^{-0.9})$ (this follows from Hölder-continuity of $x \mapsto x \lg x$). It thus remains to show that $nH(p') \leq \lg N_{n,r} + o(n)$. By the grouping property of H , we have

$$nH(p') = n \left(H \left(\frac{r}{n}, \frac{n-r}{n} \right) + \frac{r}{n} H \left(\frac{s}{r}, \frac{r-s}{r} \right) + \frac{n-r}{n} H \left(\frac{r-s}{n-r}, \frac{(n-r)-(r-s)}{n-r} \right) \right).$$

In order to estimate the right-hand side, observe that it follows from [22, Eq. (5.22)] that $\sum_{s=0}^r \binom{r}{s} \binom{n-r}{r-s} = \binom{n}{r}$. Since all summands are positive, we have $\binom{r}{s} \binom{n-r}{r-s} \leq \binom{n}{r}$ and hence

$$\lg \binom{r}{s} + \lg \binom{n-r}{r-s} \leq \lg \binom{n}{r}, \quad \text{for all } s \in [r]. \quad (3)$$

70:18 Hypersuccinct Trees

For a number $q \in [0, 1]$, we set $h(q) = q \lg(1/q) + (1 - q) \lg(1/(1 - q))$. Using the standard inequality

$$\frac{2^{nh(q)}}{n+1} \leq \binom{n}{qn} \leq 2^{nh(q)}, \quad nq \in [0..n], \quad (4)$$

we find

$$\begin{aligned} rh\left(\frac{s}{r}\right) + (n-r)h\left(\frac{r-s}{n-r}\right) &\stackrel{(4)}{\leq} \lg\left(\frac{r}{s}\right) + \lg\left(\frac{n-r}{r-s}\right) + \lg(r+1) + \lg(n-r+1) \\ &\stackrel{(3)}{\leq} \lg\left(\frac{n}{r}\right) + \lg(r+1) + \lg(n-r+1) \\ &\stackrel{(4)}{\leq} nh\left(\frac{r}{n}\right) + \lg(r+1) + \lg(n-r+1). \end{aligned}$$

We thus have

$$\begin{aligned} nH(p') &= n\left(H\left(\frac{r}{n}, \frac{n-r}{n}\right) + \frac{r}{n}H\left(\frac{s}{r}, \frac{r-s}{r}\right) + \frac{n-r}{n}H\left(\frac{r-s}{n-r}, \frac{(n-r)-(r-s)}{n-r}\right)\right) \\ &= n\left(h\left(\frac{r}{n}\right) + \frac{r}{n}h\left(\frac{s}{r}\right) + \frac{n-r}{n}h\left(\frac{r-s}{n-r}\right)\right) \\ &\leq 2nh\left(\frac{r}{n}\right) + O(\log n) \\ &\stackrel{(4)}{\leq} 2\lg\left(\frac{n}{r}\right) + O(\log n) \\ &\stackrel{(2)}{\leq} \lg N_{n,r} + O(\log n). \end{aligned}$$

So in total, we have shown that

$$|\mathbf{H}(t)| \leq \lg N_{n,r} + o(n),$$

which implies Corollary 7.

Determining 4-Edge-Connected Components in Linear Time

Abstract

In this work, we present the first linear time deterministic algorithm computing the 4-edge-connected components of an undirected graph. First, we show an algorithm listing all 3-edge-cuts in a given 3-edge-connected graph, and then we use the output of this algorithm in order to determine the 4-edge-connected components of the graph.

1 Introduction

The connectivity of graphs has always been one of the fundamental concepts of graph theory. The foremost connectivity notions in undirected graphs are the k -edge-connectedness and the k -vertex-connectedness. Namely, a graph G is k -edge-connected for $k \geq 1$ if it is connected, and it remains connected after removing any set of at most $k - 1$ edges. Similarly, G is k -vertex-connected if it contains at least $k + 1$ vertices, and it remains connected after the removal of any set of at most $k - 1$ vertices.

These notions can be generalized to the graphs that are not well-connected. Namely, if H is a maximal k -vertex-connected subgraph of G , we say that H is a k -vertex-connected component of G . The edge-connected variant is, however, defined differently: we say that a pair of vertices u, v of G is k -edge-connected if it is not possible to remove at most $k - 1$ edges from G so that u and v end up in different connected components. This relation of k -edge-connectedness happens to be an equivalence relation; this yields a definition of a k -edge-connected component of G as an equivalence class of the relation. We remark that the notions of k -vertex-connected components and k -edge-connected components coincide for $k = 1$ as both simply describe the connected components of G . However, for $k \geq 2$ these definitions diverge; in particular, for $k \geq 3$ the k -edge-connected components of a graph do not even need to be connected.

There has been a plethora of research into the algorithms deciding the k -vertex- and k -edge-connectedness of graphs, and decomposing the graphs into k -vertex- or k -edge-connected components. However, while classical, elementary, and efficient algorithms exist for $k = 1$ and $k = 2$, these problems become increasingly more difficult for the larger values of k . In fact, even for $k = 4$, there were no known linear time algorithms to any of the considered problems. The following description presents the previous work in this area for $k \in \{1, 2, 3, 4\}$, and exhibits the related work for the larger values of k :

$k = 1$. Here, the notions of k -vertex-connectedness and k -edge-connectedness reduce to that of connectivity and the connected components of a graph. In the static setting, determining the connected components in linear time is trivial. As a consequence, more focus is being laid on dynamic algorithms maintaining the connected components of graphs. In the incremental setting, where the edges can only be added to the dynamic graph, the optimal solution is provided by disjoint-set data structures [38], which solve the problem in the amortized $\mathcal{O}(\alpha(n))$ time per query, where $\alpha(n)$ denotes the inverse of the Ackermann's fast-growing function. The fully dynamic data structures are also considered [44, 7, 9, 18, 19, 20, 40, 27, 22, 25].

$k = 2$. One step further are the notions of 2-vertex-connectivity (biconnectivity) and 2-edge-connectivity. In the static setting, partitioning of a graph into 2-vertex-connected or 2-edge-connected components are classical problems, both solved in linear time by exploiting the properties of the low function [23]. The incremental versions of both problems are again solved optimally in the amortized $\mathcal{O}(\alpha(n))$ time per query [43]. Significant research has been done in the dynamic setting as well [36, 20, 7, 22, 11, 17, 31].

$k = 3$. As a next step, we consider 3-vertex-connectivity (triconnectivity) and 3-edge-connectivity. An optimal, linear time algorithm detecting the 3-vertex-connected components was first given by Hopcroft and Tarjan [24]. The first linear time algorithm for 3-edge-connectivity was discovered much later by Galil and Italiano [12], where they present a linear time reduction from the k -edge-connectivity problem to k -vertex-connectivity for $k \geq 3$, showing that in the static setting, the former problem is the easier of the two. This was later followed by a series of works simplifying the solution for 3-edge-connectivity [41, 35, 34, 42]. The incremental setting [32, 21] and the dynamic setting [11, 7] were also considered.

We also mention that in the case of 3-vertex-connectivity, there exists a structure called SPQR-tree which succinctly captures the structure of 2-vertex-cuts in graphs [4, 21]. Its edge-connectivity analogue also exists, but we defer its introduction to the general setting.

$k = 4$. We move on to the problems of 4-vertex-connectivity and 4-edge-connectivity. A notable result by Kanevsky et al. [26] supports maintaining 4-vertex-connected components in incremental graphs, with an optimal $\mathcal{O}(\alpha(n))$ amortized time per query. Their result also yields the solution for static graphs in $\mathcal{O}(m + n\alpha(n))$ time complexity. By applying the result of Galil and Italiano [12], we derive a static algorithm determining the 4-edge-connected components in the same time complexity. This algorithm is optimal for $m = \Omega(n\alpha(n))$.

Another result by Dinitz and Westbrook [6] supports maintaining the 4-edge-connected components in the incremental setting. Their algorithm processes any sequence of queries in $\mathcal{O}(q + m + n \log n)$ time where q is the number of queries, and m is the total number of inserted edges to the graph.

However, it is striking that the fastest solutions for 4-edge-connectivity and 4-vertex-connectivity for static graphs were derived from the on-line algorithms working in the incremental setting. In particular, no linear time algorithms for $k = 4$ were known before.

$k \geq 5$. As a side note, we also present the current knowledge on the general problems of k -vertex-connectivity and k -edge-connectivity. A series of results [29, 30, 16, 2] show that it is possible to compute the minimum edge cut of a graph (i.e., determine the edge-connectivity of a graph) in near-linear time. The previously mentioned work by Dinitz and Westbrook [6] maintains the k -edge-connected components of an incremental graph which is assumed to already have been initialized with a $(k-1)$ -edge-connected graph. The data structure answers any sequence of on-line queries in $\mathcal{O}(q + m + k^2 n \log(n/k))$ time, where q is the number of queries, and m is the number of edges in the initial graph.

Gomory and Hu [13] proved that for any weighted, undirected graph G there exists a weighted, undirected tree T on the same vertex set such that for any two vertices $s, t \in V(G)$, the value of the minimum s - t edge cut in T is equal to the value of the minimum s - t edge cut in G . Moreover, such a tree can be constructed using $n-1$ invocations of the maximum flow algorithm. In an interesting result by Hariharan et al. [15], the decomposition of any graph into k -edge-connected components is constructed in $\mathcal{O}((m + nk^3) \cdot \text{polylog}(n))$ time, producing a partial Gomory-Hu tree as its result.

Dinitz et al. [5] showed that the set of all minimum edge cuts can be succinctly represented with a *cactus graph*. When the minimum edge cut is odd, this cactus simplifies to a tree (see [8, Corollary 8]). These results imply that if the size of the minimum cut is odd, then the number of minimum cuts is $\mathcal{O}(n)$ and if it is even, then the number of minimum cuts is $\mathcal{O}(n^2)$. The structure of k -vertex-cuts was also investigated [37].

Our results. In this work, we present a linear time, deterministic algorithm partitioning static, undirected graphs into 4-edge-connected components. Even though the area of the dynamic versions of the algorithms for k -edge-connectivity is still thriving, the progress in static variants appears to have plateaued. In particular, both subquadratic algorithms determining the 4-edge-connected components [26, 6] originate from their dynamic incremental equivalents and are almost thirty years old, yet they did not achieve the optimal linear running time. Hence, our work constitutes the first progress in the static setting of 4-edge-connectivity in a long time. As a side result, our algorithm also produces the tree representation of 3-edge-cuts as explained in [8].

Organization of the work. In Section 3 [33], omitted in this abridged version of the work, we show how to reduce the problem of determining 4-edge-connected components to the problem of determining 4-edge-connected components in 3-edge-connected graphs. In Section 4, we show a linear time, randomized Monte Carlo algorithm for listing all 3-edge-cuts in 3-edge-connected graphs. In Section 5, we show how to remove the dependency on the randomness in the algorithm from the previous section, producing a linear time, deterministic algorithm listing all 3-edge-cuts in 3-edge-connected graphs. Then, in Section 6, we construct a tree of 3-edge-cuts in a 3-connected graph, given the list of all its 3-edge-cuts. This tree is then used to determine the 4-edge-connected components of the graph. Finally, in Section 7, we present open problems related to this work.

Section 3 and the proofs of the results marked ★ are deferred to the full version of the work [33] due to the space constraints.

2 Preliminaries

Graphs. In this work, we consider undirected, connected graphs which may contain self-loops and multiple edges connecting pairs of vertices (i.e., multigraphs). The number of vertices of a graph and the number of its edges are usually denoted n and m , respectively.

We use the notions of k -edge-connectedness and k -edge-connected components defined in Section 1. Moreover, we say that a set of k edges of a graph forms a k -edge-cut (or a k -cut for simplicity) if the removal of these edges from the graph disconnects it.

DFS trees. Consider a run of the *depth-first search* algorithm [39] on a connected graph G . A *depth-first search tree* (or a *DFS tree*) is a spanning tree \mathcal{T} of G , rooted at the source of the search r , containing all the edges traversed by the algorithm. After the search is performed, each vertex v is assigned two values: its *preorder* $\text{pre}(v)$ (also called *discovery time* or *arrival time*) and *postorder* $\text{post}(v)$ (also *finishing time* or *departure time*). Their definitions are standard [3]; it can be assumed that the values range from 1 to $2n$ and are pairwise different.

The edges of \mathcal{T} are called *tree edges*, and the remaining edges are called *back edges* or *non-tree edges*. In this setup, every back edge e connects two vertices remaining in ancestor-descendant relationship in \mathcal{T} ; moreover, the graph $\mathcal{T} + e$ contains exactly one cycle, named the *fundamental cycle* of e . For a vertex v of G , we define \mathcal{T}_v to be the subtree of \mathcal{T} rooted at v ; similarly, for a tree edge e whose deeper endpoint is v , we set $\mathcal{T}_e = \mathcal{T}_v$.

When a DFS tree \mathcal{T} of G is fixed, it is common to introduce directions to the edges of the graph: all tree edges of \mathcal{T} are directed away from the root of \mathcal{T} , and all back edges are pointed towards the root of \mathcal{T} . Then, uv is a directed edge (either a tree or a back edge) whose *origin* (or *tail*) is u , and whose *destination* (or *head*) is v .

For our convenience, we introduce the following definition: a back edge $e = pq$ *leaps over* a vertex v if $p \in \mathcal{T}_v$, but $q \notin \mathcal{T}_v$; we analogously define *leaping over* a tree edge f .

Moreover, we define a partial order $\leq_{\mathcal{T}}$ on the vertices of G and the tree edges of \mathcal{T} as follows: $x \leq_{\mathcal{T}} y$ if the simple path in \mathcal{T} connecting the root of \mathcal{T} with y also contains x . Then, $\leq_{\mathcal{T}}$ has one minimal element – the root of \mathcal{T} – and each maximal element is a leaf of \mathcal{T} . When the tree \mathcal{T} is clear from the context, we may write \leq instead of $\leq_{\mathcal{T}}$. We may also use $x < y$ for $x \leq y \wedge x \neq y$. Using the precomputed preorder and postorder values in \mathcal{T} , we can verify if $x \leq_{\mathcal{T}} y$ holds for given $x, y \in V(G) \cup E(\mathcal{T})$ in constant time.

We use the classical low function defined by Hopcroft and Tarjan [23]. However, for our purposes it is more convenient to define it as a function $\text{low} : E(\mathcal{T}) \rightarrow (E \setminus E(\mathcal{T})) \cup \{\perp\}$ such that for a tree edge e , $\text{low}(e)$ is the back edge uv leaping over e minimizing the preorder of its head v , breaking ties arbitrarily; or \perp , if no such edge exists. This function can be computed for all tree edges in time linear with respect to the size of the graph.

Xors. For sets A and B , by $A \oplus B$ we denote their symmetric difference, which is $(A \cup B) \setminus (A \cap B)$, and we call it a *xor* of A and B . Moreover, for a pair of non-negative integers a and b , by $a \oplus b$ we denote their xor, that is, an integer whose binary representation is a bitwise symmetric difference of the binary representations of a and b . The definitions can be easily generalized to the symmetric differences of multiple sets or integers.

4 Simple randomized algorithm

In this section, we will describe a randomized linear time algorithm listing 3-edge-cuts in 3-edge-connected graphs. In particular, the existence of this algorithm will imply that the number of 3-edge-cuts in any 3-edge-connected graph is at most linear. Since the algorithm is significantly simpler than its deterministic variant, and it already contains most of the core ideas of this work, we believe it serves as a good intermediate step in the explanation.

The overview of the algorithm is as follows. First, we will construct a randomized oracle (Lemma 5) that given two edges e, f of the 3-edge-connected graph G , verifies in constant time whether there exists another edge g such that $\{e, f, g\}$ is a 3-edge-cut of G ; and if such

an edge exists, it is returned by the oracle. It will be apparent from the description of the oracle that such an edge – if it exists – is unique. Thanks to Lemma 5, the description of our randomized algorithm will be simplified significantly: now, we only need to identify two out of three edges of each 3-edge-cut of G . Then, the remaining edge of each cut can be easily recovered using a single oracle call.

Next, our algorithm will consider an arbitrary DFS tree \mathcal{T} of G , categorize all 3-edge-cuts by the number $t \in \{0, 1, 2, 3\}$ of tree edges of \mathcal{T} in the cut, and find all 3-edge-cuts separately for each value of t . The case $t = 0$ is trivial: \mathcal{T} is a spanning tree of G , hence each edge cut must contain at least one edge of \mathcal{T} . The cases $t = 1$ and $t = 2$ will proceed by considering all tree edges of \mathcal{T} separately. For each such tree edge e , we will find all 3-edge cuts containing both e and some non-tree edge leaping over e . By performing a case study, we will show that for each e , there is only a constant number of 3-edge-cuts of this form for $t \in \{1, 2\}$; and moreover, each of them can be located by us in constant time after a linear time preprocessing of \mathcal{T} . Finally, the case $t = 3$ will be solved by a recursive call to the algorithm on a properly contracted graph.

We begin the detailed explanation with the description of some auxiliary data structures.

► **Theorem 1** ([10]). *There exists a data structure for the disjoint set union problem which, when initialized with an undirected tree \mathcal{T} (the “union tree”) on n vertices, creates n singleton sets. After the initialization, the data structure accepts the following queries in any order:*

- *find(x): returns the index of the set containing x ,*
- *union(x, y): if x and y are in different sets, then an arbitrary one of them is replaced with their union and the other one with the empty set. This query can only be issued if xy is an edge of \mathcal{T} .*

The data structure executes any sequence of q queries in total $\mathcal{O}(n + q)$ time.

► **Lemma 2** (★). *It is possible to enrich the data structure from Theorem 1, so that after rooting it at an arbitrary vertex, we are able to answer the following query in constant time:*

- *lowest(x): returns the smallest vertex of the set containing x with respect to $\leq_{\mathcal{T}}$.*

Note that each set induces a connected subgraph of \mathcal{T} , so its smallest vertex is well-defined.

► **Theorem 3** (★). *There exists a deterministic algorithm that takes as input:*

- *an undirected, unrooted tree \mathcal{T} with n vertices,*
- *p weighted paths P_1, P_2, \dots, P_p in the tree, where the path P_i has weight $w_i \in \{0, 1, \dots, C\}$,*
- *and a positive integer k ,*

and for each edge e of the tree returns the indices of k paths with the lowest weight containing e , breaking ties arbitrarily; if e is a part of fewer than k paths, all such paths are returned. The time complexity of the algorithm is $\mathcal{O}(nk + p + C)$.

We proceed to the description of our randomized algorithm. Let us choose an arbitrary vertex r of the graph, and perform a depth-first search from r . Let \mathcal{T} be the resulting DFS tree. We are now going to define a *hashing function* $H : E \rightarrow \mathcal{P}(E)$, where $\mathcal{P}(E)$ denotes the powerset of E ; the value $H(e)$ will be called a *hash* of e . If $e \notin \mathcal{T}$, then we define $H(e) = \{e\}$. Otherwise, we take $H(e)$ as the set of non-tree edges leaping over e . Let us note that the set C_e of edges f such that $e \in H(f)$ forms a cycle – the fundamental cycle of e .

► **Lemma 4** (★). *For a connected graph $G = (V, E)$ and a subset A of its edges, the graph $G' := G - A$ is disconnected if and only if there is a nonempty subset $B \subseteq A$ such that *xor* of the hashes of the edges in B is an empty set.*

Since our graph has no 1-edge-cuts or 2-edge-cuts, no created hashes are empty, and no two edges have equal hashes. Hence, removing a set of three edges disconnects a 3-edge-connected graph if and only if xor of the hashes of all of them is the empty set. Moreover, after removing some 3-edge-cut, the graph disconnects into exactly two components, and no removed edge connects vertices within one component.

As storing hashes as sets of edges would be inefficient, we define *compressed hashes*, resembling the notion of sketches introduced by Ahn et al. [1] and Kapron et al. [28]. We express compressed hashes as b -bit numbers where $b = \lceil 3 \log_2(m) \rceil$, i.e., as a function $CH : E \rightarrow \{0, \dots, 2^b - 1\}$. For each non-tree edge e , we draw $CH(e)$ randomly and uniformly from the set of b -bit numbers. For a tree edge e , we define its compressed hash $CH(e)$ as the xor of the compressed hashes of the edges in its hash, i.e., $CH(e) = \bigoplus_{f \in H(e)} CH(f)$. Note that since $b = \mathcal{O}(\log m)$, we can perform arithmetic operations on compressed hashes in constant time. However, this comes at a cost of allowing the collisions of compressed hashes.

For the ease of exposition, in the description of this algorithm we will use hash tables; because of that, the algorithm described in this section will have expected linear instead of worst-case linear running time. Formally, we create a hash table $M : \{0, \dots, 2^b - 1\} \rightarrow E \cup \{\perp\}$, which for any b -bit number x returns an edge whose compressed hash is equal to x ; or \perp if no such edge exists. In the unlikely event that there are multiple edges whose compressed hashes are equal to x , M returns any of them.

We will now categorize 3-edge-cuts based on the number of tree edges they contain, and show how to handle each case. We remark that each 3-edge-cut must intersect \mathcal{T} as it is a spanning tree of G . Therefore, a 3-edge-cut may intersect \mathcal{T} in one edge (Subsection 4.1), two edges (Subsection 4.2), or three edges (Subsection 4.3).

Throughout the case analysis, we will heavily rely on the following fact:

► **Lemma 5.** *Given two edges e and f of some 3-edge-cut in a 3-edge-connected graph, the remaining edge is uniquely identified by its hash: $H(e) \oplus H(f)$.*

Proof. If $\{e, f, g\}$ is a 3-edge-cut, then $H(e) \oplus H(f) \oplus H(g) = \emptyset$, so $H(g) = H(e) \oplus H(f)$. ◀

4.1 One tree edge

Let e be an edge of \mathcal{T} that is the only tree edge of some 3-edge-cut. The two resulting connected components after the removal of such a cut are \mathcal{T}_e and $\mathcal{T} \setminus \mathcal{T}_e$. As e is not a bridge, $\text{low}(e)$ is well-defined and connects \mathcal{T}_e with $\mathcal{T} \setminus \mathcal{T}_e$, so it belongs to the cut as well. By Lemma 5, this uniquely determines the third edge of this cut. Thus, in order to detect all such cuts, we iterate over all tree edges e and for each of them, we look up in M if there exists an edge with compressed hash equal to $CH(e) \oplus CH(\text{low}(e))$. If it exists and if it turns out to be a non-tree edge g , we output the triple $\{e, \text{low}(e), g\}$ as a 3-edge-cut.

4.2 Two tree edges

Let e and f be the edges of \mathcal{T} that form a 3-edge-cut c together with some back edge g . Without loss of generality, we can assume that $e <_{\mathcal{T}} f$, thanks to the following fact:

► **Lemma 6 (★).** *The edges e and f are comparable with respect to $\leq_{\mathcal{T}}$.*

The two connected components of $G \setminus c$ are $L := \mathcal{T}_e \setminus \mathcal{T}_f$ and $R := \mathcal{T} \setminus L$, and the remaining back edge g connects L and R . We distinguish two cases, differing in the location of g (see Figure 2 from the full version of this work): *two tree edges, lower case*, where g connects L with \mathcal{T}_f , and *two tree edges, upper case*, where g connects L with $\mathcal{T} \setminus \mathcal{T}_e$.

Two tree edges, lower case. Let A be the set of back edges between \mathcal{T}_f and $\mathcal{T} \setminus \mathcal{T}_f$. It consists of the edge g , connecting L with \mathcal{T}_f , and of several edges connecting \mathcal{T}_f with $\mathcal{T} \setminus \mathcal{T}_e$. Let B be the set of heads of edges from A (we remind that back edges are directed towards the root r). All elements of B lie on the path from f to the root r , and the head of g is the deepest element of B .

Using this observation, we will use the algorithm from Theorem 3. We initialize an instance of it with the tree \mathcal{T} , $k = 1$, $C = 2n$. Then, for each back edge $e = xy$, we create one input path P_e from x to y of weight $w_e := 2n - \text{pre}(y)$. The algorithm determines, for each tree edge f , the back edge leaping over f with the largest preorder of its head; call this edge $\text{MaxUp}(f)$. This back edge is the only candidate for g , given f .

Hence, we can find all such cuts by firstly initializing the data structure, and then iterating over all tree edges f . For each f , we take $g = \text{MaxUp}(f)$. Knowing f and g , we can look up in M whether there exists an edge whose compressed hash is $CH(f) \oplus CH(g)$ (Lemma 5). If it exists and if it is a tree edge, then we call it e and output the triple $\{e, f, g\}$ as a 3-edge-cut.

Two tree edges, upper case. Let A be the set of non-tree edges between \mathcal{T}_e and $\mathcal{T} \setminus \mathcal{T}_e$. It consists of the back edge g , connecting L with $\mathcal{T} \setminus \mathcal{T}_e$, and of several edges connecting \mathcal{T}_f with $\mathcal{T} \setminus \mathcal{T}_e$. Let B be the set of the tails of the edges from A . Let $v \in L$ be the tail of g . As $v \notin \mathcal{T}_f$, then we either have $\text{pre}(v) < \min_{u \in \mathcal{T}_f} \text{pre}(u)$, or $\text{pre}(v) > \max_{u \in \mathcal{T}_f} \text{pre}(u)$. In the first case, v is the vertex with the smallest preorder which is a tail of some edge leaping over e ; while in the second case v is the analogous vertex with the largest preorder.

Based on this observation, we will again use the algorithm from Theorem 3 again. We initialize one instance of it with the tree \mathcal{T} , $k = 1$, and $C = 2n$. Then for each back edge $e = xy$, we create one input path P_e from x to y of weight $w_e := \text{pre}(x)$. We also initialize another instance of this algorithm in the same way, only that we set $w_e := 2n - \text{pre}(x)$ instead. The first instance determines, for each tree edge e , the back edge $\text{MinDn}(e)$ leaping over e with the smallest preorder of its tail; while the second instance determines the analogous edge $\text{MaxDn}(e)$, with the largest preorder of its tail. By our considerations above, if any desired $\{e, f, g\}$ cut exists, then $g \in \{\text{MinDn}(e), \text{MaxDn}(e)\}$.

Hence, we can find all such cuts by firstly initializing both instances of the data structure. Then, we iterate over all tree edges e , and for each e we check both candidates for g . If our hash table contains an edge whose compressed hash is $CH(e) \oplus CH(g)$ and it is a tree edge, then we call it f and output the triple $\{e, f, g\}$ as a 3-edge-cut.

4.3 Three tree edges

Solving this case in a way similar to the previous cases seems intractable. We consider this subsection, together with the time analysis following it, as one of the key ideas of this work.

In this case, we assume that no non-tree edges belong to the cut. Therefore, we can contract all of them simultaneously and recursively list all 3-edge-cuts in the resulting graph. Since 3-edge-cuts in the contracted graph exactly correspond to the 3-edge-cuts consisting solely of tree edges in the original graph, this reduction is sound. The contraction is performed in $\mathcal{O}(n + m)$ time by identifying the vertices within the connected components of $G - E(\mathcal{T})$. Let G' be the graph after these contractions. Since G is 3-edge-connected, G' is 3-edge connected as well, so the assumption about the input graph being 3-edge-connected is preserved. We do not modify the value of b in the subsequent recursive calls, even though the value of m decreases.

4.4 Time and correctness analysis

We will now compute the expected time complexity of our algorithm. The subroutines from Subsections 4.1 and 4.2 clearly take expected linear time. The only nontrivial part of the analysis is the recursion in Subsection 4.3. Let $T(m)$ denote the maximum expected time our algorithm needs to solve any graph with at most m edges. Since our graph is 3-edge-connected, the degree of each vertex in G is at least 3, so $|E(G)| \geq \frac{3}{2}|V(G)| \geq \frac{3}{2}|E(G')| \Rightarrow |E(G')| \leq \frac{2}{3}|E(G)|$. Therefore, we have that $T(m) \leq \mathcal{O}(m) + T(\frac{2}{3}m)$. The solution to this recurrence is $T(m) = \mathcal{O}(m)$, hence the whole algorithm runs in expected linear time.

We proceed to proving that our algorithm works correctly with sufficiently high probability. The only reason it can output wrong result comes from the compression of hashes – if we used their uncompressed version instead, the algorithm would clearly be correct.

The maximum number of queries to our hash table is linear in terms of n , which follows from a similar argument to the one presented in Subsection 4.4. Hence, there exists some absolute constant c such that the number of queries is bounded by cn . For each query with value q , and for each edge whose hash is not equal to the hash whose compressed version we ask about, there is 2^{-b} probability that compressed version of this hash is equal to q . Hence, the probability that we ever get a false positive is bounded from above by $cnm2^{-b}$. Since $b = \lceil 3\log_2(m) \rceil$ and $n \leq m$, we infer that $cnm2^{-b} \leq \frac{c}{m}$. Therefore, our algorithm works correctly with probability at least $1 - \frac{c}{m}$.

5 Deterministic algorithm

Having established a linear time randomized algorithm producing 3-edge-cuts in 3-edge-connected graphs, we will now determinize it by designing deterministic implementations of the subroutines for each of the cases considered in the randomized algorithm. Three cases need to be derandomized: “one tree edge” (Subsection 4.1), “two tree edges, lower case”, and “two tree edges, upper case” (Subsection 4.2). In the following description, we cannot use compressed hashes anymore: the compression is a random process which inevitably results in false positives. Instead, we will exploit additional properties of 3-edge-cuts in order to produce an efficient deterministic implementation of the algorithm.

Recall that in the description of the randomized implementation of the algorithm, we defined the values $\text{low}(e)$, $\text{MaxUp}(e)$, $\text{MinDn}(e)$, and $\text{MaxDn}(e)$ for any tree edge e . For the deterministic variant of the algorithm, we generalize these notions: we define $\text{low1}(e)$, $\text{low2}(e)$, and $\text{low3}(e)$ as the three back edges leaping over e with the minimal preorders of their targets; in particular, we set $\text{low1}(e) := \text{low}(e)$. We analogously define $\text{MaxUp1}(e)$, $\text{MaxUp2}(e)$, $\text{MinDn1}(e)$, $\text{MinDn2}(e)$, $\text{MaxDn1}(e)$, and $\text{MaxDn2}(e)$. We remark that $\text{low3}(e)$ might not exist if there are fewer than three edges leaping over e ; in this case, we put $\text{low3}(e) := \perp$. However, all the other values must exist – otherwise, at most one edge would leap over e , which would mean that this edge, together with e , would form a 2-edge-cut of G .

It is straightforward to compute all the values defined above in linear time; for instance, the generalizations of MaxUp , MinDn , and MaxDn can be determined by passing $k = 2$ to the algorithm in Theorem 3 instead of $k = 1$. Hence, in the following description, we will assume that all the values above have already been computed.

5.1 One tree edge

Recall that in this case, we are to find all 3-edge-cuts intersecting a fixed depth-first search tree \mathcal{T} in a single edge. This is fairly straightforward: if some 3-edge-cut C contains exactly one tree edge e of \mathcal{T} , then the border of the cut is exactly \mathcal{T}_e ; hence, this cut must include

all back edges leaping over e . Therefore, e belongs to a 3-edge-cut of this kind if and only if $\text{low3}(e) = \perp$, i.e. if there only exist two back edges leaping over e ; in this case, e and these two edges form a 3-edge-cut. Since this check can be easily performed in $\mathcal{O}(n)$ time for all tree edges in \mathcal{T} , the whole subroutine runs in $\mathcal{O}(n + m)$ time complexity.

5.2 Two tree edges, lower case

Recall that this case requires us to find all 3-edge-cuts intersecting a fixed depth-first search tree \mathcal{T} in two edges, say e and f , such that $e < f$ and the remaining back edge g connects \mathcal{T}_f with $\mathcal{T}_e \setminus \mathcal{T}_f$. Hence, g is the only back edge connecting \mathcal{T}_f with $\mathcal{T}_e \setminus \mathcal{T}_f$, no back edges connect $\mathcal{T}_e \setminus \mathcal{T}_f$ with $\mathcal{T} \setminus \mathcal{T}_e$, but there may be multiple back edges connecting \mathcal{T}_f with $\mathcal{T} \setminus \mathcal{T}_e$.

We shall exploit the fact that in a valid 3-edge-cut of this kind, all back edges leaping over e must originate from \mathcal{T}_f . This observation severely limits the set of possible tree edges f . This is formalized by the notion of the *deepest down cut* of e :

► **Definition 7** (deepest down cut). *For a tree edge e in \mathcal{T} , we define the deepest down cut of e , denoted $\text{DeepestDnCut}(e)$, as the deepest tree edge $f \geq e$ for which all back edges leaping over e originate from \mathcal{T}_f .*

► **Lemma 8** (★). *For every tree edge e , $\text{DeepestDnCut}(e)$ is defined correctly and uniquely. Moreover, every 3-edge-cut $\{e, f, g\}$ of the considered kind satisfies $e < f \leq \text{DeepestDnCut}(e)$.*

► **Lemma 9** (★). *For every tree edge e , $\text{DeepestDnCut}(e) = uv$ is the tree edge whose head v is the lowest common ancestor of two vertices: the tails of $\text{MinDn1}(e)$ and $\text{MaxDn1}(e)$.*

Thanks to Lemma 9, we can compute $\text{DeepestDnCut}(e)$ in constant time for each tree edge e as the lowest common ancestor of two vertices can be computed in constant time after linear preprocessing [14].

We now shift our focus to the lower tree edge f . As in Section 4, the only possible candidate g for a back edge of the cut leaping over f is given by $\text{MaxUp1}(f)$. The only problematic part is locating the remaining tree edge e . Previously, we utilized randomness in order to calculate the compressed hash of e given the compressed hashes of f and g . Here, we instead use the following fact:

► **Lemma 10** (★). *If $\{e, f, g\}$ is a 3-edge-cut of the considered kind for some tree edges e and $f > e$, then e is the deepest tree edge satisfying $\text{DeepestDnCut}(e) \geq f$.*

Lemmas 8 and 10 naturally lead to the following idea: given a tree edge e , the set of edges f satisfying $\text{DeepestDnCut}(e) \geq f$ is a path P_e connecting the head of e with the head of $\text{DeepestDnCut}(e)$; we assign this path a weight w_e equal to the depth of e in \mathcal{T} . We then invoke Theorem 3 with the tree \mathcal{T} , the weighted paths $\{P_e \mid e \in E(\mathcal{T})\}$, and $k = 1$. This lets us find, in $\mathcal{O}(n)$ time, for each tree edge $f \in E(\mathcal{T})$, the path P_e of the maximum weight containing f as an edge. This path naturally corresponds to the tree edge e from Lemma 10. This way, for every tree edge f , we have uniquely identified a back edge g and a tree edge e such that the only possible 3-edge-cut containing f as a deeper tree edge is $\{e, f, g\}$.

It only remains to verify that $\{e, f, g\}$ is a 3-edge-cut. Since $\text{DeepestDnCut}(e) \geq f$ guarantees that all back edges leaping over e originate from \mathcal{T}_f , we only need to check that exactly one edge (that is, g) connects \mathcal{T}_f with $\mathcal{T}_e \setminus \mathcal{T}_f$. As $g = \text{MaxUp1}(f)$, it suffices to verify that the edge $\text{MaxUp2}(f)$, which is a back edge leaping over f whose head is the deepest apart from g , also leaps over e (i.e., it does not terminate in \mathcal{T}_e).

It can be easily verified that the implementation of the subroutine is deterministic and runs in linear time with respect to the size of G .

5.3 Two tree edges, upper case

Recall that in this case, we are required to find all 3-edge-cuts intersecting \mathcal{T} in two edges e and f , such that $e < f$ and the remaining back edge g connects $\mathcal{T}_e \setminus \mathcal{T}_f$ with $\mathcal{T} \setminus \mathcal{T}_e$. Similarly to the randomized case, we use the fact that given a tree edge e , the tail of g has either the smallest preorder (i.e., $g = \text{MinDn1}(e)$) or the largest preorder (i.e., $g = \text{MaxDn1}(e)$) among all the back edges leaping over e . Without loss of generality, assume that $g = \text{MinDn1}(e)$; the latter case is analogous.

In a similar vein to previous case, observe that if $\{e, f, g\}$ is a 3-edge-cut for some $f > e$, then all back edges leaping over e other than g must originate from \mathcal{T}_f .

This leads to the following slight generalization of DeepestDnCut (Definition 7):

► **Definition 11.** For a tree edge e in \mathcal{T} , we define the value $\text{DeepestDnCutNoMin}(e)$ as the deepest tree edge $f \geq e$ for which all back edges leaping over e other than $\text{MinDn1}(e)$ originate from \mathcal{T}_f .

The process of computation of $\text{DeepestDnCut}(e)$ asserted by Lemma 9 can be easily modified to match our needs: we take $\text{DeepestDnCutNoMin}(e)$ as the tree edge whose head is the lowest common ancestor of the tails of $\text{MinDn2}(e)$ and $\text{MaxDn1}(e)$. We refer the reader to Figure 4 from the full version of the work for a helpful picture.

Now, fix the shallower tree edge e of the cut. Let $f_0 := \text{DeepestDnCutNoMin}(e)$. Then, if some tree edge $f > e$ belongs to the 3-edge-cut $\{e, f, g\}$, then $f \leq f_0$ (otherwise, there would be multiple edges connecting $\mathcal{T}_e \setminus \mathcal{T}_f$ with $\mathcal{T} \setminus \mathcal{T}_e$). The natural question is then: is $\{e, f_0, g\}$ a 3-edge-cut? The only possible problem is that there may exist back edges connecting \mathcal{T}_{f_0} with $\mathcal{T}_e \setminus \mathcal{T}_{f_0}$. Fortunately, if this is the case, then the back edge $\text{MaxUp1}(f_0)$, dependent only on f_0 , is one of these back edges.

Hence, let $h_0 := \text{MaxUp1}(f_0)$. If h_0 leaps over e , we are done, and $\{e, f_0, g\}$ is an edge cut. Otherwise, the subtree \mathcal{T}_f for the sought 3-edge-cut $\{e, f, g\}$ must contain the head of h_0 (or else h_0 would connect \mathcal{T}_f with $\mathcal{T}_e \setminus \mathcal{T}_f$). Let then $f_1, e \leq f_1 < f_0$ be the deepest tree edge containing the head of h_0 , that is, the edge whose head coincides with the head of h_0 . Then, the edge f of the 3-edge-cut $\{e, f, g\}$ must satisfy $e < f \leq f_1$. We can then repeat this procedure: given f_1 , we compute $h_1 := \text{MaxUp1}(f_1)$, and either h_1 leaps over e and we are done, or we calculate another edge $f_2 < f_1$ supplying a better bound on the depth of f .

Since the graph is finite, this process terminates in $k = \mathcal{O}(n)$ steps, producing the lowest tree edge $f_k \geq e$ such that no back edge connects \mathcal{T}_{f_k} with $\mathcal{T}_e \setminus \mathcal{T}_{f_k}$, and no back edge other than g connects $\mathcal{T}_e \setminus \mathcal{T}_{f_k}$ with $\mathcal{T} \setminus \mathcal{T}_e$. If $f_k = e$, then no 3-edge-cut $\{e, f, g\}$ exists for $f > e$. Otherwise, $\{e, f_k, g\}$ is naturally a correct 3-edge-cut. Since two edges of a 3-edge-cut uniquely identify the third edge (Lemma 5), we conclude that this is the only 3-edge-cut containing e and g . We refer the reader to Figure 5 from the full version of the paper for a helpful picture depicting the iterative process above.

In order to optimize the algorithm, we seek to optimize the iterative process described above. Indeed, for each $e \in E(\mathcal{T})$, the process is very similar: start with some edge $f > e$, and then repeatedly replace f with a higher edge, until a replacement would result in an edge closer to the root than e . We can model this process with a rooted tree \mathcal{U} defined as follows:

- the vertices of \mathcal{U} are the tree edges of \mathcal{T} , and \perp ,
- \perp is the root of \mathcal{U} ,
- for a non-root vertex e of \mathcal{U} , its parent is the tree edge with the same head as $\text{MaxUp1}(e)$.

If the head of $\text{MaxUp1}(e)$ coincides with the root of \mathcal{T} , then the parent of e in \mathcal{U} is \perp . Naturally, \mathcal{U} can be constructed in linear time with respect to the size of \mathcal{T} ; moreover, if an edge p is a parent of another edge q in \mathcal{U} , then $p <_{\mathcal{T}} q$.

Now, the iteration is equivalent to the repeated replacement of f_0 with its parent in \mathcal{U} as long as the parent is greater or equal than e with respect to $<_{\mathcal{T}}$. In other words, the final edge $f' := \text{final}(f_0, e)$ is taken as the shallowest ancestor of f_0 in \mathcal{U} for which $f' \geq_{\mathcal{T}} e$.

This leads to the final idea: we simulate a forest of rooted subtrees of \mathcal{U} using a disjoint set union data structure $F_{\mathcal{U}}$ (Theorem 1). Each subtree additionally keeps its root, which can be retrieved from $F_{\mathcal{U}}$ (Lemma 2). Initially, each subtree of \mathcal{U} contains a single vertex.

After the initialization of $F_{\mathcal{U}}$, we iterate e over the tree edges of \mathcal{T} in the decreasing order of depth in \mathcal{T} . Throughout the process, we maintain the following invariant on $F_{\mathcal{U}}$: an edge $ef \in E(\mathcal{U})$ for $e < f$ has been added to the forest if and only if e has been considered at any previous iteration as the shallower tree edge of the cut. Hence, at the beginning of the iteration for a given edge e , we add to $F_{\mathcal{U}}$ all tree edges of \mathcal{U} originating from e . At this point of time, for every tree edge f such that $f >_{\mathcal{T}} e$, the edge $\text{final}(f, e)$ is given by $F_{\mathcal{U}}.\text{lowest}(f)$. This reduces the entire iterative process described above to a single **lowest** query on $F_{\mathcal{U}}$.

We initialized $F_{\mathcal{U}}$ on a tree with n vertices, and we issued $\mathcal{O}(n)$ queries to it in total. Therefore, the whole subroutine runs in time linear with respect to the size of G .

Summing up, we replaced each randomized subroutine with its deterministic counterpart, preserving the linear guarantee on the runtime of the algorithm. We conclude that there exists a deterministic linear time algorithm listing 3-edge-cuts in 3-edge-connected graphs.

6 Reconstructing the structure of 4-edge-connected components

In this section, we show how to build a structure of 4-edge-connected components of a 3-edge-connected graph G , given the set \mathcal{C} of all 3-edge-cuts in G .

First of all, recall what such a structure looks like.

► **Theorem 12.** [8, Corollary 8] *For a 3-edge-connected graph $G = (V, E)$, there exists a tree $H = (U, F)$ and functions $\phi : \mathcal{C} \rightarrow F$ and $\psi : V \rightarrow U$, such that ϕ is a bijection from 3-edge-cuts of G to the edges of H , and ψ maps (not necessarily surjectively) vertices of G to the vertices of H so that whole 4-edge-connected components are mapped to the same vertex.*

Moreover, if a 3-edge-cut c partitions the vertices of G into two parts V_1 and V_2 , then $\phi(c)$ partitions the vertices of H into U_1 and U_2 such that $\psi^{-1}(U_1) = V_1$ and $\psi^{-1}(U_2) = V_2$.

We refer the reader to Figure 6 in the full version for an illustrative example of a decomposition postulated by Theorem 12.

The tree H is usually unrooted in the literature. However, we are going to root it. Namely, we take a depth-first search tree \mathcal{T} of G , rooted at some vertex r , and we root H at $\psi(r)$. For a vertex $u \in U$, we let H_u denote the subtree of H rooted at u .

► **Definition 13.** *For a 3-edge-cut c , we define $P(c)$ as the set of vertices from the connected component of $G \setminus c$ not containing r .*

We remark that since c is a minimal cut, $G \setminus c$ consists of two connected components, so $P(c)$ is determined uniquely.

► **Lemma 14 (★).** *Let $v, u \in U$, and let $e_1, e_2, \dots, e_k \in F$ be the sequence of edges of H on the path from v and u in H . If v is an ancestor of u , then for each pair of integers i, j such that $1 \leq i < j \leq k$, we have $|P(\phi^{-1}(e_i))| > |P(\phi^{-1}(e_j))|$.*

► **Lemma 15 (★).** *Given a 3-edge-connected graph G and the set of all its 3-edge-cuts \mathcal{C} , the sizes of $P(c)$ for all $c \in \mathcal{C}$ can be computed in linear time with respect to the size of G .*

71:12 Determining 4-Edge-Connected Components in Linear Time

To reconstruct H , we will also use the following structural lemma about cuts sharing the same edge of graph G .

► **Lemma 16 (★).** *For an edge $(u, v) = e \in E$, let $l(e)$ be the set of all 3-edge-cuts containing e . The image $\phi(l(e))$, i.e., the set of all edges of H corresponding to the edge cuts containing e , forms a path in H between $\psi(u)$ and $\psi(v)$.*

We remark an edge case in Lemma 16: if $\psi(u) = \psi(v)$ for some edge $e = (u, v)$, then the image $\phi(l(e))$ is empty. Moreover, since each 3-edge-cut $c \in \mathcal{C}$ contains at least one tree edge of \mathcal{T} , each edge $\phi(c)$ is covered by at least one path $\phi(l(e))$ for $e \in E(\mathcal{T})$. Equivalently, H is a tree, rooted at $\psi(r)$, equal to the union of all paths $\phi(l(e))$ for $e \in E(\mathcal{T})$. This representation of H is the cornerstone of our algorithm reconstructing H from G and \mathcal{C} .

► **Lemma 17.** *There exists a linear time algorithm which, given a graph G and the list \mathcal{C} of all 3-edge-cuts of G , constructs the tree H , along with the mappings ϕ and ψ .*

Sketch of the proof. For each edge $e \in \mathcal{T}$, create a list $l(e)$ of all 3-edge-cuts c containing e , sorted decreasingly by the size of $P(c)$ using radix sort. Let $e_1, \dots, e_{n-1} \in E(\mathcal{T})$ be the sequence of edges visited by a depth-first search of \mathcal{T} and let $e_i = u_i v_i$, where u_i is the vertex of \mathcal{T} closer to the root r . We create H iteratively; initially, H is a single vertex $\psi(r)$. We maintain the following invariant after k iterations of the algorithm: H is a connected tree, rooted at $\psi(r)$, equal to the union of all paths $\phi(l(e_i))$ for $i \in \{1, 2, \dots, k\}$.

It is clear that after $n - 1$ iterations, H will be the required rooted tree. Consider the k -th iteration of the algorithm, $k \in [1, n - 1]$, in which we need to add to H the path $\phi(l(e_k))$, originating from $\psi(u_k)$ and terminating at $\psi(v_k)$. It can be proved that $\psi(u_k)$, together with the vertical path connecting it with the root of H , is already in H . Now, adding the path $\phi(l(e_k))$ to H is rather straightforward: first, starting from $\psi(u_k)$, we go up the tree H along the edges of H corresponding to the edge cuts containing e_k . Then, we proceed down the tree: we iterate the list $l(e_k)$ of cuts, excluding the cuts corresponding to the edges visited in the first part of the traversal. For each such cut, we go down the tree along the edge corresponding to the cut (creating it, if necessary). Each 3-edge-cut c is considered in only a constant number of iterations of the algorithm: an edge of H corresponding to c is traversed by the path $\phi(l(e_k))$ if and only if $e_k \in c$. Therefore, the time complexity of all iterations in total is $\mathcal{O}(m + |\mathcal{C}|) = \mathcal{O}(m + n)$. ◀

This concludes the construction of a tree representing all 3-edge-cuts in G . As a result, each vertex of H , as long as it is not empty, contains a single 4-edge-connected component of G . Hence, this algorithm also computes the decomposition of a 3-edge-connected graph G into 4-edge-connected components in total linear time.

7 Open problems

As a natural open problem whose resolving would complement this result nicely, we suggest investigating if it is possible to extend our result to vertex connectivity or to the higher-order edge connectivity.

Problem 1. Given an undirected graph $G = (V, E)$, is it possible to find all 4-vertex-connected components of G in linear time?

Problem 2. Given an undirected graph $G = (V, E)$, is it possible to find all 5-edge-connected components of G in linear time?

We also remark that our algorithm assumes the word RAM model in which we can perform any arithmetic and bitwise operations on pointers and $\mathcal{O}(\log n)$ -bit words in constant time; this is required by the linear time data structure of Gabow and Tarjan (Theorem 1, [10]). The natural question is whether this assumption can be avoided.

Problem 3. Given an undirected graph $G = (V, E)$, is it possible to find all 4-edge-connected components of G in linear time in the pointer machine model?

Isomorphism Testing Parameterized by Genus and Beyond

Daniel Neuen 

CISPA Helmholtz Center for Information Security,
Saarland Informatics Campus, Saarbrücken, Germany

Abstract

We present an isomorphism test for graphs of Euler genus g running in time $2^{O(g^4 \log g)} n^{O(1)}$. Our algorithm provides the first explicit upper bound on the dependence on g for an fpt isomorphism test parameterized by the Euler genus of the input graphs. The only previous fpt algorithm runs in time $f(g)n$ for some function f (Kawarabayashi 2015). Actually, our algorithm even works when the input graphs only exclude $K_{3,h}$ as a minor. For such graphs, no fpt isomorphism test was known before.

The algorithm builds on an elegant combination of simple group-theoretic, combinatorial, and graph-theoretic approaches. In particular, we introduce (t, k) -WL-bounded graphs which provide a powerful tool to combine group-theoretic techniques with the standard Weisfeiler-Leman algorithm. This concept may be of independent interest.

1 Introduction

Determining the computational complexity of the Graph Isomorphism Problem is a long-standing open question in theoretical computer science (see, e.g., [13]). The problem is easily seen to be contained in NP, but it is neither known to be in PTIME nor known to be NP-complete. In a breakthrough result, Babai [1] recently obtained a quasipolynomial-time algorithm for testing isomorphism of graphs (i.e., an algorithm running in time $n^{O((\log n)^c)}$ where n denotes the number of vertices of the input graphs, and c is a constant), achieving the first improvement over the previous best algorithm running in time $n^{O(\sqrt{n/\log n})}$ [3] in over three decades. However, it remains wide open whether GI can be solved in polynomial time.

In this work, we are concerned with the parameterized complexity of isomorphism testing. While polynomial-time isomorphism tests are known for a large variety of restricted graph classes (see, e.g., [4, 7, 9, 11, 18, 24]), for several important structural parameters such as maximum degree or the Hadwiger number¹, it is still unknown whether isomorphism testing is fixed-parameter tractable (i.e., whether there is an isomorphism algorithm running in time $f(k)n^{O(1)}$ where k denotes the graph parameter in question, n the number of vertices of the

¹ The Hadwiger number of a graph G is the maximum number h such that K_h is a minor of G .

input graphs, and f is some function). On the other hand, there has also been significant progress in recent years. In 2015, Lokshtanov et al. [17] obtained the first fpt isomorphism test parameterized by the tree-width k of the input graph running in time $2^{\mathcal{O}(k^5 \log k)} n^5$. This algorithm was later improved by Grohe et al. [8] to a running time of $2^{\mathcal{O}(k \cdot (\log k)^c)} n^3$ (for some constant c). In the same year, Kawarabayashi [14] obtained the first fpt isomorphism test parameterized by the Euler genus g of the input graph running time $f(g)n$ for some function f . While Kawarabayashi's algorithm achieves optimal dependence on the number of vertices of the input graphs, it is also extremely complicated and it provides no explicit upper bound on the function f . Indeed, the algorithm spans over multiple papers [14, 15, 16] and builds on several deep structural results for graphs of bounded genus.

In this work, we present an alternative isomorphism test for graphs of Euler genus g running in time $2^{\mathcal{O}(g^4 \log g)} n^{\mathcal{O}(1)}$. In contrast to Kawarabayashi's algorithm, our algorithm does not require any deep graph-theoretic insights, but rather builds on an elegant combination of well-established and simple group-theoretic, combinatorial, and graph-theoretic ideas. In particular, this enables us to provide the first explicit upper bound on the dependence on g for an fpt isomorphism test. Actually, the only property our algorithm exploits is that graphs of genus g exclude $K_{3,h}$ as a minor for $h \geq 4g + 3$ [25]. In other words, our main result is an fpt isomorphism test for graphs excluding $K_{3,h}$ as a minor.

► **Theorem 1.** *The Graph Isomorphism Problem for graphs excluding $K_{3,h}$ as a minor can be solved in time $2^{\mathcal{O}(h^4 \log h)} n^{\mathcal{O}(1)}$.*

For this class of graphs, the best existing algorithm runs in time $n^{\mathcal{O}((\log h)^c)}$ for some constant c [21], and no fpt isomorphism test was known prior to this work.

For the algorithm, we combine different approaches to the Graph Isomorphism Problem. On a high-level, our algorithm follows a simple decomposition strategy which decomposes the input graph G into pieces such that the interplay between the pieces is simple. The main idea is to define the pieces in such a way that, after fixing a small number of vertices, the automorphism group of G restricted to a piece $D \subseteq V(G)$ is similar to the automorphism group of a graph of maximum degree 3. This allows us to test isomorphism between the pieces using the group-theoretic graph isomorphism machinery dating back to Luks's polynomial-time isomorphism test for graphs of bounded maximum degree [18].

In order to capture the restrictions on the automorphism group, we introduce the notion of (t, k) -WL-bounded graphs which generalize so-called t -CR-bounded graphs. The class of t -CR-bounded graphs was originally defined by Ponomarenko [23] and was recently rediscovered in [21, 10, 22] in a series of works eventually leading to an algorithm testing isomorphism of graphs excluding K_h as a topological subgraph in time $n^{\mathcal{O}((\log h)^c)}$. Intuitively speaking, a graph G is t -CR-bounded if an initially uniform vertex-coloring χ can be turned into a discrete coloring (i.e., a coloring where every vertex has its own color) by repeatedly (a) applying the standard Color Refinement algorithm, and (b) splitting all color classes of size at most t . We define (t, k) -WL-bounded graphs in the same way, but replace the Color Refinement algorithm by the well-known Weisfeiler-Leman algorithm of dimension k (see, e.g., [5, 12]). Maybe surprisingly, this natural extension of t -CR-bounded has not been considered so far in the literature, and we start by building a polynomial-time isomorphism test for such graphs using the group-theoretic methods developed by Luks [18] as well as a simple extension due to Miller [20]. Actually, it turns out that isomorphism of (t, k) -WL-bounded graphs can even be tested in time $n^{\mathcal{O}(k \cdot (\log t)^c)}$ using recent extensions [21] of Babai's quasipolynomial-time isomorphism test. However, since we only apply these methods for $t = k = 2$, there is no need for our algorithm to rely on such sophisticated subroutines.

Now, as the main structural insight, we prove that each 3-connected graph G that excludes $K_{3,h}$ as a minor admits (after fixing 3 vertices) an isomorphism-invariant rooted tree decomposition (T, β) such that the adhesion width (i.e., the maximal intersection between two bags) is bounded by h . Additionally, each bag $\beta(t)$, $t \in V(T)$, can be equipped with a set $\gamma(t) \subseteq \beta(t)$ of size $|\gamma(t)| \leq h^4$ such that, after fixing all vertices in $\gamma(t)$, G restricted to $\beta(t)$ is $(2, 2)$ -WL-bounded. Given such a decomposition, isomorphisms can be computed by a simple bottom-up dynamic programming strategy along the tree decompositions. For each bag, isomorphism is tested by first individualizing all vertices from $\gamma(t)$ at an additional factor of $|\gamma(t)|! = 2^{\mathcal{O}(h^4 \log h)}$ in the running time. Following the individualization of these vertices, our algorithm can then simply rely on a polynomial-time isomorphism test for $(2, 2)$ -WL-bounded graphs. Here, we incorporate the partial solutions computed in the subtree below the current bag via a simple gadget construction.

To compute the decomposition (T, β) , we also build on the notion of $(2, 2)$ -WL-bounded graphs. Given a set $X \subseteq V(G)$, we define the $(2, 2)$ -closure to be the set $D = \text{cl}_{2,2}^G(X)$ of all vertices appearing in a singleton color class after artificially individualizing all vertices from X , and performing the $(2, 2)$ -WL procedure. As one of the main technical contributions, we can show that the interplay between D and its complement in G is simple (assuming G excludes $K_{3,h}$ as a minor). To be more precise, building on various properties of the 2-dimensional Weisfeiler-Leman algorithm, we show that $|N_G(Z)| < h$ for every connected component Z of $G - D$. This allows us to choose $D = \text{cl}_{2,2}^G(X)$ as the root bag of (T, β) for some carefully chosen set X , and obtain the decomposition (T, β) by recursion.

2 Preliminaries

2.1 Graphs

A *graph* is a pair $G = (V(G), E(G))$ consisting of a *vertex set* $V(G)$ and an *edge set* $E(G)$. All graphs considered in this paper are finite and simple (i.e., they contain no loops or multiple edges). Moreover, unless explicitly stated otherwise, all graphs are undirected. For an undirected graph G and $v, w \in V(G)$, we write vw as a shorthand for $\{v, w\} \in E(G)$. The *neighborhood* of a vertex $v \in V(G)$ is denoted by $N_G(v)$. The *degree* of v , denoted by $\deg_G(v)$, is the number of edges incident with v , i.e., $\deg_G(v) = |N_G(v)|$. For $X \subseteq V(G)$, we define $N_G(X) := (\bigcup_{v \in X} N_G(v)) \setminus X$. If the graph G is clear from context, we usually omit the index and simply write $N(v)$, $\deg(v)$ and $N(X)$. We write $K_{\ell,h}$ to denote the complete bipartite graph on ℓ vertices on the left side and h vertices on the right side. For two sets $A, B \subseteq V(G)$, we denote by $E_G(A, B) := \{vw \in E(G) \mid v \in A, w \in B\}$. Also, $G[A, B]$ denotes the graph with vertex set $A \cup B$ and edge set $E_G(A, B)$. Moreover, $G[A] := G[A, A]$ denotes the induced subgraph on A , and $G - A$ the subgraph induced by the complement of A , that is, the graph $G - A := G[V(G) \setminus A]$. For $F \subseteq E(G)$, we also define $G - F$ to be the graph obtained from G by removing all edges contained in F (the vertex set remains unchanged). A graph H is a *subgraph* of G , denoted by $H \subseteq G$, if $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. A graph H is a *minor* of G if H can be obtained from G by deleting vertices and edges, as well as contracting edges. The graph G *excludes* H *as a minor* if it does not have a minor isomorphic to H .

An *isomorphism* from G to a graph H is a bijection $\varphi: V(G) \rightarrow V(H)$ that respects the edge relation, that is, for all $v, w \in V(G)$, it holds that $vw \in E(G)$ if and only if $\varphi(v)\varphi(w) \in E(H)$. Two graphs G and H are *isomorphic*, written $G \cong H$, if there is an isomorphism from G to H . We write $\varphi: G \cong H$ to denote that φ is an isomorphism

from G to H . Also, $\text{Iso}(G, H)$ denotes the set of all isomorphisms from G to H . The automorphism group of G is $\text{Aut}(G) := \text{Iso}(G, G)$. Observe that, if $\text{Iso}(G, H) \neq \emptyset$, it holds that $\text{Iso}(G, H) = \text{Aut}(G)\varphi := \{\gamma\varphi \mid \gamma \in \text{Aut}(G)\}$ for every isomorphism $\varphi \in \text{Iso}(G, H)$.

A *vertex-colored graph* is a tuple (G, χ_V) where G is a graph and $\chi_V: V(G) \rightarrow C$ is a mapping into some set C of colors, called *vertex-coloring*. Similarly, an *arc-colored graph* is a tuple (G, χ_E) , where G is a graph and $\chi_E: \{(u, v) \mid \{u, v\} \in E(G)\} \rightarrow C$ is a mapping into some color set C , called *arc-coloring*. Observe that colors are assigned to directed edges, i.e., the directed edge (v, w) may obtain a different color than (w, v) . We also consider vertex- and arc-colored graphs (G, χ_V, χ_E) where χ_V is a vertex-coloring and χ_E is an arc-coloring. Typically, C is chosen to be an initial segment $[n] := \{1, \dots, n\}$ of the natural numbers. To be more precise, we generally assume that there is a linear order on the set of all potential colors which, for example, allows us to identify a minimal color appearing in a graph in a unique way. Isomorphisms between vertex- and arc-colored graphs have to respect the colors of the vertices and arcs.

2.2 Weisfeiler-Leman Algorithm

The Weisfeiler-Leman algorithm, originally introduced by Weisfeiler and Leman in its 2-dimensional version [28], forms one of the most fundamental subroutines in the context of isomorphism testing.

Let $\chi_1, \chi_2: V^k \rightarrow C$ be colorings of k -tuples, where C is a finite set of colors. We say χ_1 *refines* χ_2 , denoted $\chi_1 \preceq \chi_2$, if $\chi_1(\bar{v}) = \chi_1(\bar{w})$ implies $\chi_2(\bar{v}) = \chi_2(\bar{w})$ for all $\bar{v}, \bar{w} \in V^k$. The colorings χ_1 and χ_2 are *equivalent*, denoted $\chi_1 \equiv \chi_2$, if $\chi_1 \preceq \chi_2$ and $\chi_2 \preceq \chi_1$.

We describe the *k-dimensional Weisfeiler-Leman algorithm* (k -WL) for all $k \geq 1$. For an input graph G let $\chi_{(0)}^k[G]: (V(G))^k \rightarrow C$ be the coloring where each tuple is colored with the isomorphism type of its underlying ordered subgraph. More precisely, $\chi_{(0)}^k[G](v_1, \dots, v_k) = \chi_{(0)}^k[G](v'_1, \dots, v'_k)$ if and only if, for all $i, j \in [k]$, it holds that $v_i = v_j \Leftrightarrow v'_i = v'_j$ and $v_i v_j \in E(G) \Leftrightarrow v'_i v'_j \in E(G)$. If the graph is equipped with a coloring the initial coloring $\chi_{(0)}^k[G]$ also takes the input coloring into account. More precisely, for a vertex-coloring χ_V , it additionally holds that $\chi_V(v_i) = \chi_V(v'_i)$ for all $i \in [k]$. And for an arc-coloring χ_E , it is the case that $\chi_E(v_i, v_j) = \chi_E(v'_i, v'_j)$ for all $i, j \in [k]$ such that $v_i v_j \in E(G)$.

We then recursively define the coloring $\chi_{(i)}^k[G]$ obtained after i rounds of the algorithm. For $k \geq 2$ and $\bar{v} = (v_1, \dots, v_k) \in (V(G))^k$ let $\chi_{(i+1)}^k[G](\bar{v}) := \left(\chi_{(i)}^k[G](\bar{v}), \mathcal{M}_i(\bar{v}) \right)$ where

$$\mathcal{M}_i(\bar{v}) := \left\{ \left(\chi_{(i)}^k[G](\bar{v}[w/1]), \dots, \chi_{(i)}^k[G](\bar{v}[w/k]) \right) \mid w \in V(G) \right\}$$

and $\bar{v}[w/i] := (v_1, \dots, v_{i-1}, w, v_{i+1}, \dots, v_k)$ is the tuple obtained from \bar{v} by replacing the i -th entry by w (and $\{\dots\}$ denotes a multiset). For $k = 1$ the definition is similar, but we only iterate over neighbors of v , i.e., $\chi_{(i+1)}^1[G](v) := \left(\chi_{(i)}^1[G](v), \mathcal{M}_i(v) \right)$ where

$$\mathcal{M}_i(v) := \left\{ \chi_{(i)}^1[G](w) \mid w \in N_G(v) \right\}.$$

By definition, $\chi_{(i+1)}^k[G] \preceq \chi_{(i)}^k[G]$ for all $i \geq 0$. Hence, there is a minimal i_∞ such that $\chi_{(i_\infty)}^k[G] \equiv \chi_{(i_\infty+1)}^k[G]$ and for this i_∞ the coloring $\chi_{\text{WL}}^k[G] := \chi_{(i_\infty)}^k[G]$ is the *k-stable* coloring of G . The k -dimensional Weisfeiler-Leman algorithm takes as input a (vertex- or arc-)colored graph G and returns (a coloring that is equivalent to) $\chi_{\text{WL}}^k[G]$. This can be implemented in time $\mathcal{O}(n^{k+1} \log n)$ (see [12]).

2.3 Group Theory

We introduce the group-theoretic notions required in this work. We refer to [26, 6] for further background.

Permutation groups. A *permutation group* acting on a set Ω is a subgroup $\Gamma \leq \text{Sym}(\Omega)$ of the symmetric group. The size of the permutation domain Ω is called the *degree* of Γ . If $\Omega = [n]$, then we also write S_n instead of $\text{Sym}(\Omega)$. For $\gamma \in \Gamma$ and $\alpha \in \Omega$ we denote by α^γ the image of α under the permutation γ . For $A \subseteq \Omega$ and $\gamma \in \Gamma$ let $A^\gamma := \{\alpha^\gamma \mid \alpha \in A\}$. The set A is Γ -*invariant* if $A^\gamma = A$ for all $\gamma \in \Gamma$. For a partition \mathcal{P} of Ω let $\mathcal{P}^\gamma := \{A^\gamma \mid A \in \mathcal{P}\}$. Observe that \mathcal{P}^γ is again a partition of Ω . We say \mathcal{P} is Γ -*invariant* if $\mathcal{P}^\gamma = \mathcal{P}$ for all $\gamma \in \Gamma$.

For $A \subseteq \Omega$ and a bijection $\theta: \Omega \rightarrow \Omega'$ we denote by $\theta[A]$ the restriction of θ to the domain A . For a Γ -invariant set $A \subseteq \Omega$, we denote by $\Gamma[A] := \{\gamma[A] \mid \gamma \in \Gamma\}$ the induced action of Γ on A , i.e., the group obtained from Γ by restricting all permutations to A . More generally, for every set Λ of bijections with domain Ω , we denote by $\Lambda[A] := \{\theta[A] \mid \theta \in \Lambda\}$. Similarly, for a partition \mathcal{P} of Ω , we denote by $\theta[\mathcal{P}]: \mathcal{P} \rightarrow \mathcal{P}'$ the mapping defined via $\theta(A) := \{\theta(\alpha) \mid \alpha \in A\}$ for all $A \in \mathcal{P}$. As before, $\Lambda[\mathcal{P}] := \{\theta[\mathcal{P}] \mid \theta \in \Lambda\}$.

Groups with restricted composition factors. We shall be interested in a particular subclass of permutation groups, namely groups with restricted composition factors. Let Γ be a group. A *subnormal series* is a sequence of subgroups $\Gamma = \Gamma_0 \geq \Gamma_1 \geq \dots \geq \Gamma_k = \{\text{id}\}$ such that Γ_i is a normal subgroup of Γ_{i-1} for all $i \in [k]$. The length of the series is k and the groups Γ_{i-1}/Γ_i are the factor groups of the series, $i \in [k]$. A *composition series* is a strictly decreasing subnormal series of maximal length. For every finite group Γ all composition series have the same family (considered as a multiset) of factor groups (cf. [26]). A *composition factor* of a finite group Γ is a factor group of a composition series of Γ .

► **Definition 2.** For $d \geq 2$ let $\widehat{\Gamma}_d$ denote the class of all groups Γ for which every composition factor of Γ is isomorphic to a subgroup of S_d . A group Γ is a $\widehat{\Gamma}_d$ -group if it is contained in the class $\widehat{\Gamma}_d$.

Let us point out the fact that there are two similar classes of groups usually referred by Γ_d in the literature. The first is the class denoted by $\widehat{\Gamma}_d$ here originally introduced by Luks [18], while the second one, for example used in [2], in particular allows composition factors that are simple groups of Lie type of bounded dimension.

Group-Theoretic Tools for Isomorphism Testing. In this work, the central group-theoretic subroutine is an isomorphism test for hypergraphs where the input group is a $\widehat{\Gamma}_d$ -group. Two hypergraphs $\mathcal{H}_1 = (V_1, \mathcal{E}_1)$ and $\mathcal{H}_2 = (V_2, \mathcal{E}_2)$ are isomorphic if there is a bijection $\varphi: V_1 \rightarrow V_2$ such that $E \in \mathcal{E}_1$ if and only if $E^\varphi \in \mathcal{E}_2$ for all $E \in 2^{V_1}$ (where $E^\varphi := \{\varphi(v) \mid v \in E\}$ and 2^{V_1} denotes the power set of V_1). We write $\varphi: \mathcal{H}_1 \cong \mathcal{H}_2$ to denote that φ is an isomorphism from \mathcal{H}_1 to \mathcal{H}_2 . Consistent with previous notation, we denote by $\text{Iso}(\mathcal{H}_1, \mathcal{H}_2)$ the set of isomorphisms from \mathcal{H}_1 to \mathcal{H}_2 . More generally, for $\Gamma \leq \text{Sym}(V_1)$ and a bijection $\theta: V_1 \rightarrow V_2$, we define $\text{Iso}_{\Gamma\theta}(\mathcal{H}_1, \mathcal{H}_2) := \{\varphi \in \Gamma\theta \mid \varphi: \mathcal{H}_1 \cong \mathcal{H}_2\}$. In this work, we define the Hypergraph Isomorphism Problem to take as input two hypergraphs $\mathcal{H}_1 = (V_1, \mathcal{E}_1)$ and $\mathcal{H}_2 = (V_2, \mathcal{E}_2)$, a group $\Gamma \leq \text{Sym}(V_1)$ and a bijection $\theta: V_1 \rightarrow V_2$, and the goal is to compute a representation² of $\text{Iso}_{\Gamma\theta}(\mathcal{H}_1, \mathcal{H}_2)$. The following algorithm forms a crucial subroutine.

² While $\text{Iso}_{\Gamma\theta}(\mathcal{H}_1, \mathcal{H}_2)$ may be exponentially large, it can be represented by a single isomorphism $\varphi \in \text{Iso}_{\Gamma\theta}(\mathcal{H}_1, \mathcal{H}_2)$ and a generating set for $\text{Aut}_\Gamma(\mathcal{H}_1) := \text{Iso}_\Gamma(\mathcal{H}_1, \mathcal{H}_1)$. For general background on how to perform computations on permutation groups, I refer to [27].

► **Theorem 3** (Miller [20]). *Let $\mathcal{H}_1 = (V_1, \mathcal{E}_1)$ and $\mathcal{H}_2 = (V_2, \mathcal{E}_2)$ be two hypergraphs and let $\Gamma \leq \text{Sym}(V_1)$ be a $\widehat{\Gamma}_d$ -group and $\theta: V_1 \rightarrow V_2$ a bijection. Then $\text{Iso}_{\Gamma\theta}(\mathcal{H}_1, \mathcal{H}_2)$ can be computed in time $(n + m)^{\mathcal{O}(d)}$ where $n := |V_1|$ and $m := |\mathcal{E}_1|$.*

► **Theorem 4** (Neuen [21]). *Let $\mathcal{H}_1 = (V_1, \mathcal{E}_1)$ and $\mathcal{H}_2 = (V_2, \mathcal{E}_2)$ be two hypergraphs and let $\Gamma \leq \text{Sym}(V_1)$ be a $\widehat{\Gamma}_d$ -group and $\theta: V_1 \rightarrow V_2$ a bijection. Then $\text{Iso}_{\Gamma\theta}(\mathcal{H}_1, \mathcal{H}_2)$ can be computed in time $(n + m)^{\mathcal{O}((\log d)^c)}$ for some constant c where $n := |V_1|$ and $m := |\mathcal{E}_1|$.*

Observe that both algorithms given by the two theorems tackle the same problem. The second algorithm is asymptotically much faster, but it is also much more complicated and the constant factors in the exponent of the running time are likely to be much higher. Since this paper only applies either theorem for $d = 2$, it seems to be preferable to use the first algorithm. Indeed, the first result is a simple extension of Luks’s well-known isomorphism test for bounded-degree graphs [18], and thus the underlying algorithm is fairly simple. For all these reasons, we mostly build on Theorem 3. However, for future applications of the techniques presented in this work, it might be necessary to build on Theorem 4 to benefit from the improved run time bound. For this reason, we shall provide variants of our results building on Theorem 4 wherever appropriate.

3 Allowing Weisfeiler and Leman to Split Small Color Classes

In this section, we introduce the concept of (t, k) -WL-bounded graphs and provide a polynomial-time isomorphism test for such graphs for all constant values of t and k . The final fpt isomorphism test for graphs excluding $K_{3,h}$ as a minor builds on this subroutine for $t = k = 2$.

The concept of (t, k) -WL-bounded graphs is a natural extension of t -CR-bounded graphs which were already introduced by Ponomarenko in the late 1980’s [23] and which were recently rediscovered in [21, 10, 22]. Intuitively speaking, a graph G is t -CR-bounded, $t \in \mathbb{N}$, if an initially uniform vertex-coloring χ (i.e., all vertices receive the same color) can be turned into the discrete coloring (i.e., each vertex has its own color) by repeatedly

- performing the Color Refinement algorithm (expressed by the letters “CR”), and
- taking a color class $[v]_\chi := \{w \in V(G) \mid \chi(w) = \chi(v)\}$ of size $|[v]_\chi| \leq t$ and assigning each vertex from the class its own color.

A very natural extension of this idea to replace the Color Refinement algorithm by the Weisfeiler-Leman algorithm for some fixed dimension k . This leads us to the notion of (t, k) -WL-bounded graphs (the letters “CR” are replaced by “ k -WL”). In particular, $(t, 1)$ -WL-bounded graphs are exactly the t -CR-bounded graphs. Maybe surprisingly, it seems that this simple extension has not been considered so far in the literature.

► **Definition 5.** *A vertex- and arc-colored graph $G = (V, E, \chi_V, \chi_E)$ is (t, k) -WL-bounded if the sequence $(\chi_i)_{i \geq 0}$ reaches a discrete coloring where $\chi_0 := \chi_V$,*

$$\chi_{2i+1}(v) := \chi_{\text{WL}}^k[V, E, \chi_{2i}, \chi_E](v, \dots, v)$$

and

$$\chi_{2i+2}(v) := \begin{cases} (v, 1) & \text{if } |[v]_{\chi_{2i+1}}| \leq t \\ (\chi_{2i+1}(v), 0) & \text{otherwise} \end{cases}$$

for all $i \geq 0$.

Also, for the minimal $i_\infty \geq 0$ such that $\chi_{i_\infty} \equiv \chi_{i_\infty+1}$, we refer to χ_{i_∞} as the (t, k) -WL-stable coloring of G and denote it by $\chi_{(t,k)\text{-WL}}[G]$.

At this point, the reader may wonder why $(\chi_i)_{i \geq 0}$ is chosen as a sequence of vertex-colorings and not a sequence of colorings of k -tuples of vertices (since k -WL also colors k -tuples of vertices). While such a variant certainly makes sense, it still leads to the same class of graphs. Let G be a graph and let $\chi := \chi_{\text{WL}}^k[G]$. The main insight is that, if there is some color $c \in \text{im}(\chi)$ for which $|\chi^{-1}(c)| \leq t$, then there is also a color $c' \in \text{im}(\chi)$ for which $|\chi^{-1}(c')| \leq t$ and $\chi^{-1}(c') \subseteq \{(v, \dots, v) \mid v \in V(G)\}$. In other words, one can not achieve any additional splitting of color classes by also considering non-diagonal color classes.

We also need to extend several notions related to t -CR-bounded graphs. Let G be a graph and let $X \subseteq V(G)$ be a set of vertices. Let $\chi_V^*: V(G) \rightarrow C$ be the vertex-coloring obtained from individualizing all vertices in the set X , i.e., $\chi_V^*(v) := (v, 1)$ for $v \in X$ and $\chi_V^*(v) := (0, 0)$ for $v \in V(G) \setminus X$. Let $\chi := \chi_{(t,k)\text{-WL}}[G, \chi_V^*]$ denote the (t, k) -WL-stable coloring with respect to the input graph (G, χ_V^*) . We define the (t, k) -closure of the set X (with respect to G) to be the set

$$\text{cl}_{t,k}^G(X) := \{v \in V(G) \mid |[v]_\chi| = 1\}.$$

Observe that $X \subseteq \text{cl}_{t,k}^G(X)$. For $v_1, \dots, v_\ell \in V(G)$ we also use $\text{cl}_{t,k}^G(v_1, \dots, v_\ell)$ as a shorthand for $\text{cl}_{t,k}^G(\{v_1, \dots, v_\ell\})$. If the input graph is equipped with a vertex- or arc-coloring, all definitions are extended in the natural way.

Now, we concern ourselves with designing a polynomial-time isomorphism test for (t, k) -WL-bounded graphs. Actually, we shall prove a slightly stronger result which turns out to be useful later on. The main idea for the algorithm is to build a reduction to the isomorphism problem for $(t, 1)$ -WL-bounded graphs for which such results are already known [23, 21]. Indeed, isomorphism of $(t, 1)$ -WL-bounded graphs can be reduced to the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_t$ -groups. Since one may be interested in using different subroutines for solving the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_t$ -groups (see the discussion at the end of Section 2.3), the main result is stated via an oracle for the Hypergraph Isomorphism Problem on $\widehat{\Gamma}_t$ -groups.

► **Theorem 6.** *Let G_1, G_2 be two vertex- and arc-colored graphs and let $\chi_i := \chi_{(t,k)\text{-WL}}[G_i]$. Also let $\mathcal{P}_i = \{[v]_{\chi_i} \mid v \in V(G_i)\}$ be the partition into color classes of χ_i . Then $\mathcal{P}_1^\varphi = \mathcal{P}_2$ for all $\varphi \in \text{Iso}(G_1, G_2)$.*

Moreover, using oracle access to the Hypergraph Isomorphism Problem for $\widehat{\Gamma}_t$ -groups, in time $n^{\mathcal{O}(k)}$ one can compute a $\widehat{\Gamma}_t$ -group $\Gamma \leq \text{Sym}(\mathcal{P}_1)$ and a bijection $\theta: \mathcal{P}_1 \rightarrow \mathcal{P}_2$ such that

$$\text{Iso}(G_1, G_2)[\mathcal{P}_1] \subseteq \Gamma\theta.$$

In particular, $\text{Aut}(G_1)[\mathcal{P}_1] \in \widehat{\Gamma}_t$.

► **Corollary 7.** *Let G_1, G_2 be two (t, k) -WL-bounded graphs. Then a representation for $\text{Iso}(G_1, G_2)$ can be computed in time $n^{\mathcal{O}(k \cdot (\log t)^c)}$ for some absolute constant c .*

4 Structure Theory and Small Color Classes

Having established the necessary tools, we can now turn to the isomorphism test for graphs excluding $K_{3,h}$ as a minor. We start by giving a high-level overview on the algorithm. The main idea is to build on the isomorphism test for $(2, 2)$ -WL-bounded graphs described in the last section. Let G_1 and G_2 be two (vertex- and arc-colored) graphs that exclude $K_{3,h}$ as a minor. Using well-known reduction techniques building on isomorphism-invariant decompositions into triconnected³ components (see, e.g., [11]), we may assume without loss of generality that G_1 and G_2 are 3-connected.

³ A triconnected component is either 3-connected or a cycle.

The algorithm starts by individualizing three vertices. To be more precise, the algorithm picks three distinct vertices $v_1, v_2, v_3 \in V(G_1)$ and iterates over all choices of potential images $w_1, w_2, w_3 \in V(G_2)$ under some isomorphism between G_1 and G_2 . Let $X_1 := \{v_1, v_2, v_3\}$ and $X_2 := \{w_1, w_2, w_3\}$. Also, let $D_i := \text{cl}_{2,2}^{G_i}(X_i)$ denote the $(2, 2)$ -closure of X_i , $i \in \{1, 2\}$. Observe that D_i is defined in an isomorphism-invariant manner given the initial choice of X_i . Building on Theorems 3 and 6 it can be checked in polynomial time whether G_1 and G_2 are isomorphic restricted to the sets D_1 and D_2 .

Now, the central idea is to follow a decomposition strategy. Let Z_1^i, \dots, Z_ℓ^i denote the vertex sets of the connected components of $G_i - D_i$, and let $S_j^i := N_{G_i}(Z_j^i)$ for $j \in [\ell]$ and $i \in \{1, 2\}$. We recursively compute isomorphisms between all pairs of graphs $G_i[Z_j^i \cup S_j^i]$ for all $j \in [\ell]$ and $i \in \{1, 2\}$. To be able to determine whether all these partial isomorphisms can be combined into a global isomorphism, the crucial insight is that $|S_j^i| < h$ for all $j \in [\ell]$ and $i \in \{1, 2\}$.

► **Lemma 8.** *Let G be a graph that excludes $K_{3,h}$ as a minor. Also let $X \subseteq V(G)$ and define $D := \text{cl}_{2,2}^G(X)$. Let Z be a connected component of $G - D$. Then $|N_G(Z)| < h$.*

Indeed, this lemma forms one of the main technical contributions of the paper. I remark that similar statements are exploited in [10, 21, 22] eventually leading to an isomorphism test running in time $n^{\mathcal{O}((\log h)^c)}$ for all graphs excluding K_h as a topological subgraph. However, all these variants require the (t, k) -closure to be taken for non-constant values of t (i.e., $t = \Omega(h)$). For the design of an fpt-algorithm, this is infeasible since we can only afford to apply Theorem 6 for constant values of t and k (since D_i might be equal to $V(G_i)$).

The lemma above implies that the interplay between D_i and $V(G_i) \setminus D_i$ is simple which allows for a dynamic programming approach. To be more precise, we can recursively list all elements of the set $\text{Iso}((G_i[Z_j^i \cup S_j^i], S_j^i), (G_{i'}[Z_{j'}^{i'} \cup S_{j'}^{i'}], S_{j'}^{i'}))[S_j^i]$ for all $j, j' \in [\ell]$ and $i, i' \in \{1, 2\}$ (i.e., we list all bijections $\sigma: S_j^i \rightarrow S_{j'}^{i'}$ that can be extended to an isomorphism between the corresponding subgraphs). To incorporate this information, we extend the graph $G_i[D_i]$ by simple gadgets obtaining graphs H_i that are $(2, 2)$ -WL-bounded and such that $G_1 \cong G_2$ if and only if $H_1 \cong H_2$. (For technical reasons, the algorithm does not exactly implement this strategy, but closely follows the general idea.)

In order to realize this recursive strategy, it remains to ensure that the algorithm makes progress when performing a recursive call. Actually, this turns out to be a non-trivial task. Indeed, it may happen that $D_i = X_i$, there is only a single component Z_1^i of $G_i - D_i$, and $N_{G_i}(Z_1^i) = D_i$. To circumvent this problem, the idea is to compute an isomorphism-invariant extension $\gamma(X_i) \supseteq X_i$ such that $|\gamma(X_i)| \leq h^4$. Assuming such an extension can be computed, we simply extend the set X_i until the algorithm arrives in a situation where the recursive scheme discussed above makes progress. Observe that this is guaranteed to happen as soon as $|X_i| \geq h$ building on Lemma 8. Also note that we can still artificially individualize all vertices from X_i at a cost of $2^{\mathcal{O}(h^4 \log h)}$ (since any isomorphism can only map vertices from X_1 to vertices from X_2).

To compute the extension, we exploit the fact that G_i is $(h-1, 1)$ -WL-bounded by [21, Corollary 24] (after individualizing 3 vertices). Simply speaking, for every choice of three distinct vertices in X_i , after individualizing these vertices and performing the 1-dimensional Weisfeiler-Leman algorithm, we can identify a color class of size at most $h-1$ to be added to the set X_i . Overall, assuming $|X_i| \leq h$, this gives an extension $\gamma(X_i)$ of size at most $h + h^3(h-1) \leq h^4$.

This completes the description of the general strategy. In the following sections, we provide more detailed arguments. We first provide a sketch on the proof of Lemma 8 in the next section. Afterwards, we compute the entire decompositions of the input graphs in Section 6. Finally, the dynamic programming strategy along the computed decompositions is implemented in Section 7.

5 Finding Disjoint and Connected Subgraphs

In this section, we give some details on the proof of Lemma 8. Let us start by introducing some additional notation for the 2-dimensional Weisfeiler-Leman algorithm.

Let G be a graph and let $\chi := \chi_{\text{WL}}^2[G]$ be the coloring computed by the 2-dimensional Weisfeiler-Leman algorithm. We denote by $C_V = C_V(G, \chi) := \{\chi(v, v) \mid v \in V(G)\}$ the set of *vertex colors* under the coloring χ . Also, for $c \in C_V$, $V_c := \{v \in V(G) \mid \chi(v, v) = c\}$ denotes the set of all vertices of color c . Moreover, we define the graph $G[[\chi]]$ with vertex set $V(G[[\chi]]) := C_V(G, \chi)$ and edges $E(G[[\chi]]) := \{c_1 c_2 \mid \exists v_1 \in V_{c_1}, v_2 \in V_{c_2} : v_1 v_2 \in E(G)\}$.

The next lemma builds the main technical step in the proof of Lemma 8.

► **Lemma 9.** *Let G be a graph and let χ be a 2-stable coloring. Suppose that $G[[\chi]]$ is connected and $|V_c| \geq 3$ for every $c \in C_V$. Then there are vertex-disjoint, connected subgraphs $H_1, H_2, H_3 \subseteq G$ such that $V(H_r) \cap V_c \neq \emptyset$ for all $r \in \{1, 2, 3\}$ and $c \in C_V$.*

Proof Idea. Let F be a spanning tree of $G[[\chi]]$ and fix an arbitrary root node $c_0 \in V(F) = C_V$. On a high-level, the graphs H_1, H_2, H_3 are constructed in a top-to-bottom fashion along the tree F . To start, let us select three arbitrary distinct vertices $v_1, v_2, v_3 \in V_{c_0}$ and add v_r to the graph H_r . Now, let d be a color which is already covered (i.e., $V_d \cap H_r \neq \emptyset$ for all $r \in \{1, 2, 3\}$), and let c be a child of d which is not covered. Consider the graph $G[V_d, V_c]$. Let $v_r \in V_d \cap V(H_r)$ for $r \in \{1, 2, 3\}$. If there are vertices $w_1, w_2, w_3 \in V_c$ such that $v_r w_r \in E(G)$ then we can simply add vertex w_r as well as the edge $v_r w_r$ to H_r in order to cover the color class V_c . Assuming we can always find such vertices, this strategy can be repeated going down the tree F until all color classes are covered.

So suppose that there are no such vertices w_1, w_2, w_3 . By Hall's Marriage Theorem, this means there is a set $V' \subseteq \{v_1, v_2, v_3\}$ such that $|N(V') \cap V_c| < |V'|$. Since χ is 2-stable, we get that $|N(v) \cap V_c| = |N(v') \cap V_c|$ for all $v, v' \in V_d$. Together, this means there is some $\delta \in \{1, 2\}$ such that $|N(v) \cap V_c| = \delta$ for all $v \in V_d$.

First, suppose that $\delta = 1$. Then $G[V_d, V_c]$ is isomorphic to a disjoint union of ℓ stars $K_{1,h}$, for some $\ell \geq 3$ and $h \geq 2$. In this situation, it is possible to contract the connected components of $G[V_d, V_c]$ to single vertices, and proceed by induction. At this point, we crucially exploit that using the 2-dimensional Weisfeiler-Leman algorithm allows us to show that all color classes in the contracted graph still have size at least 3 (such a statement is not true when using the Color Refinement algorithm). By induction, we obtain graphs H'_1, H'_2, H'_3 . To obtain the original graphs, we simply uncontract any contracted vertices contained in H'_1, H'_2, H'_3 .

In the other case, we have $\delta = 2$. Let us partition V_d into *c-twin-classes* where vertices $v, v' \in V_d$ are declared to be *c-twins* if $N(v) \cap V_c = N(v') \cap V_c$. If there are at least 3 twin-classes, then it is again possible to contract the twin-classes to single vertices and proceed by induction. Here, the crucial observation is that the *c-twin-classes* are non-trivial since $|N(V') \cap V_c| < |V'|$ for some set $V' \subseteq \{v_1, v_2, v_3\}$. The critical case occurs if there are exactly 2 twin-classes meaning that $G[V_d, V_c]$ is isomorphic to a disjoint union of 2 copies of $K_{2,h}$, for some $h \geq 3$ (in this case $|V_c| = 4$). Now, the basic idea is to ensure that v_1, v_2, v_3 cover

both connected components (which means there are vertices w_1, w_2, w_3 as above). However, this additional requirement comes with severe additional complications. First, information of this type needs to be propagated up the tree (i.e., vertices in the root color class may already need to be chosen appropriately to avoid problematic situations later on). But much more problematically, each child of c may add a different restriction which all need to be met at the same time. Here, we again crucially rely on the 2-dimensional Weisfeiler-Leman algorithm to show that all requirements can indeed be met at the same time. Unfortunately, this comes at the price that each vertex of V_d has to be contained in one of the graphs H_r , $r \in \{1, 2, 3\}$ (this allows us to choose different triples (v_1, v_2, v_3) for different children of d). To ensure that H_r remains connected, we introduce a second type of restriction that is passed down the tree, and which ensures that all vertices from V_d , which are added to H_r , end up in the same connected component of H_r . By carefully implementing the induction, it can be shown that all these additional requirements can indeed be realized. \blacktriangleleft

Proof of Lemma 8. Let χ be a 2-stable coloring such that $|\chi[v]| = 1$ for all $v \in D$ and $|\chi[w]| \geq 3$ for all $w \in V(G) \setminus D$. Suppose towards a contradiction that $|N_G(Z)| \geq h$, and pick $v_1, \dots, v_h \in N_G(Z)$ to be distinct vertices. Let $C := \{\chi(v, v) \mid v \in Z\}$ be the set of vertex colors appearing in the set Z . Note that $(G[\chi])[C]$ is connected, and $|V_c| \geq 3$ for all $c \in C$. Let $W := \{w \in V(G) \mid \chi(w, w) \in C\}$. Observe that $W \cap D = \emptyset$. By Lemma 9, there are connected, vertex-disjoint subgraphs $H_1, H_2, H_3 \subseteq G[W]$ such that $V(H_r) \cap V_c \neq \emptyset$ for all $r \in \{1, 2, 3\}$ and $c \in C$.

Now let $i \in [h]$. Since $v_i \in N_G(Z)$ there is some vertex $w_i \in Z \subseteq W$ such that $v_i w_i \in E(G)$. Let $c_i := \chi(w_i, w_i)$. Observe that $c_i \in C$. Also, $V_{c_i} \subseteq N_G(v_i)$ since $|\chi[v_i]| = 1$ and χ is 2-stable. This implies that $N_G(v_i) \cap V(H_r) \neq \emptyset$ for all $r \in \{1, 2, 3\}$, because $V(H_r) \cap V_{c_i} \neq \emptyset$. But this results in a minor isomorphic to $K_{3,h}$ with vertices v_1, \dots, v_h on the right side, and vertices $V(H_1), V(H_2), V(H_3)$ on the left side. \blacktriangleleft

Besides Lemma 8, we also require a second tool which is used to define the extension sets $\gamma(X_i)$ which we needed to ensure the recursive algorithm makes progress.

► Lemma 10. *Let G be a graph that excludes $K_{3,h}$ as a minor. Also let $X \subseteq V(G)$ and define $D := \text{cl}_{h-1,1}^G(X)$. Let Z be a connected component of $G - D$. Then $|N_G(Z)| < 3$.*

The lemma essentially follows from [21, Lemma 23]. For the sake of completeness and due to its simplicity, a complete proof is still given below.

Proof. Let χ be a 1-stable coloring such that $|\chi[v]| = 1$ for all $v \in D$ and $|\chi[w]| \geq h$ for all $w \in V(G) \setminus D$. Suppose towards a contradiction that $|N_G(Z)| \geq 3$, and pick $v_1, v_2, v_3 \in N_G(Z)$ to be distinct vertices. Let $C := \{\chi(v) \mid v \in Z\}$, and define H to be the graph with $V(H) := C$ and

$$E(H) := \{c_1 c_2 \mid \exists v_1 \in \chi^{-1}(c_1), v_2 \in \chi^{-1}(c_2): v_1 v_2 \in E(G)\}.$$

Let T be a spanning tree of H . Also, for each $i \in \{1, 2, 3\}$, fix a color $c_i \in C$ such that $N_G(v_i) \cap \chi^{-1}(c_i) \neq \emptyset$. Let T' be the induced subtree obtained from T by repeatedly removing all leaves distinct from c_1, c_2, c_3 . Finally, let T'' be the tree obtained from T' by adding three fresh vertices v_1, v_2, v_3 where v_i is connected to c_i . Observe that v_1, v_2, v_3 are precisely the leaves of T'' . Now, T'' contains a unique node c of degree three (possibly $c = c_i$ for some $i \in \{1, 2, 3\}$). Observe that $|\chi^{-1}(c)| \geq h$. We define C_i to be the set of all internal vertices which appear on the unique path from v_i to c in the tree T'' . Finally, define $U_i := \{v_i\} \cup \bigcup_{c' \in C_i} \chi^{-1}(c')$.

Since χ is 1-stable and $|[v_i]_\chi| = 1$ we get that $G[U_i]$ is connected for all $i \in \{1, 2, 3\}$. Also, $E_G(U_i, \{w\}) \neq \emptyset$ for all $w \in \chi^{-1}(c)$ and $i \in \{1, 2, 3\}$. But this provides a minor isomorphic to $K_{3,h}$ with vertices U_1, U_2, U_3 on the left side and the vertices from $\chi^{-1}(c)$ on the right side. \blacktriangleleft

6 A Decomposition Theorem

Next, we use the insights gained in the last section to prove a decomposition theorem for graphs that exclude $K_{3,h}$ as a minor. In the following, all tree decompositions are rooted, i.e., there is a designated root node and we generally assume all edges to be directed away from the root.

► **Theorem 11.** *Let $h \geq 3$. Let G be a 3-connected graph, and suppose $S \subseteq V(G)$ such that*

(A) $G - E(S, S)$ excludes $K_{3,h}$ as a minor,

(B) $3 \leq |S| \leq h$,

(C) $G - S$ is connected, and

(D) $S = N_G(V(G) \setminus S)$.

Then there is a (rooted) tree decomposition (T, β) of G , a function $\gamma: V(T) \rightarrow 2^{V(G)}$, and a vertex-coloring λ such that

(I) $|V(T)| \leq 2 \cdot |V(G)|$,

(II) *the adhesion width of (T, β) is at most $h - 1$,*

(III) *for every $t \in V(T)$ with children t_1, \dots, t_ℓ , one of the following options holds:*

a. $\beta(t) \cap \beta(t_i) \neq \beta(t) \cap \beta(t_j)$ for all distinct $i, j \in [\ell]$, or

b. $\beta(t) = \beta(t) \cap \beta(t_i)$ for all $i \in [\ell]$,

(IV) $S \subsetneq \gamma(r)$ where r denotes the root of T ,

(V) $|\gamma(t)| \leq h^4$ for every $t \in V(T)$,

(VI) $\beta(t) \cap \beta(s) \subseteq \gamma(t) \subseteq \beta(t)$ for all $t \in V(T) \setminus \{r\}$, where s denotes the parent of t , and

(VII) $\beta(t) \subseteq \text{cl}_{2,2}^{(G,\lambda)}(\gamma(t))$ for all $t \in V(T)$.

Moreover, the decomposition (T, β) , the function γ , and the coloring λ can be computed in polynomial time, and the output is isomorphism-invariant with respect to (G, S, h) .

Proof. We give an inductive construction for the tree decomposition (T, β) as well as the function γ and the coloring λ . We start by arguing how to compute the set $\gamma(r)$.

► **Claim 12.** Let $v_1, v_2, v_3 \in S$ be three distinct vertices, and define $\chi := \chi_{\text{WL}}^1[G, S, v_1, v_2, v_3]$. Then there exists some $v \in V(G) \setminus S$ such that $|[v]_\chi| < h$.

Proof. Let $H := (G - (S \setminus \{v_1, v_2, v_3\})) - E(\{v_1, v_2, v_3\}, \{v_1, v_2, v_3\})$. It is easy to see that $\chi|_{V(H)}$ is 1-stable for the graph H . Observe that $H - \{v_1, v_2, v_3\} = G - S$ is connected. Suppose there is no vertex $v \in V(G) \setminus S$ such that $|[v]_\chi| < h$. Then χ is $(h-1)$ -CR-stable which implies that $\text{cl}_{h-1,1}^G(v_1, v_2, v_3) = \{v_1, v_2, v_3\}$. On the other hand, $Z := V(H) \setminus \{v_1, v_2, v_3\}$ induces a connected component of $H - \{v_1, v_2, v_3\}$, and $N_H(Z) = \{v_1, v_2, v_3\}$ since $S = N_G(V(G) \setminus S)$. But this contradicts Lemma 10. \blacktriangleleft

Let $v_1, v_2, v_3 \in S$ be distinct. We define $\chi[v_1, v_2, v_3] := \chi_{\text{WL}}^1[G, S, v_1, v_2, v_3]$. Also, let $c[v_1, v_2, v_3]$ denote the unique color such that

1. $c[v_1, v_2, v_3] \notin \{\chi[v_1, v_2, v_3](v) \mid v \in S\}$, and
2. $|(\chi[v_1, v_2, v_3])^{-1}(c[v_1, v_2, v_3])| \leq h - 1$

and which is minimal with respect to the linear order on the colors in the image of $\chi[v_1, v_2, v_3]$. Let $\gamma(v_1, v_2, v_3) := (\chi[v_1, v_2, v_3])^{-1}(c[v_1, v_2, v_3])$. Observe that $\gamma(v_1, v_2, v_3)$ is defined in an isomorphism-invariant manner given (G, S, h, v_1, v_2, v_3) . Now, define

$$\gamma(r) := S \cup \bigcup_{v_1, v_2, v_3 \in S \text{ distinct}} \gamma(v_1, v_2, v_3).$$

Clearly, $\gamma(r)$ is defined in an isomorphism-invariant manner given (G, S, h) . Moreover,

$$|\gamma(r)| \leq |S| + |S|^3 \cdot (h - 1) \leq |S|^3 \cdot h \leq h^4.$$

Finally, define $\beta(r) := \text{cl}_{2,2}^G(\gamma(r))$.

Let Z_1, \dots, Z_ℓ be the connected components of $G - \beta(r)$. Also, let $S_i := N_G(Z_i)$ and G_i be the graph obtained from $G[S_i \cup Z_i]$ by turning S_i into a clique, $i \in [\ell]$. We have $|S_i| < h$ by Lemma 8. Also, $|S_i| \geq 3$ and G_i is 3-connected since G is 3-connected. Clearly, $G_i - S_i$ is connected and $S_i = N_{G_i}(V(G_i) \setminus S_i)$. Finally, $G_i - E(S_i, S_i)$ excludes $K_{3,h}$ as a minor because $G - E(S, S)$ excludes $K_{3,h}$ as a minor.

We wish to apply the induction hypothesis to the triples (G_i, S_i, h) . If $|V(G_i)| = |V(G)|$ then $\ell = 1$ and $S \subsetneq S_i$. In this case the algorithm still makes progress since the size of S can be increased at most $h - 3$ times.

By the induction hypothesis, there are tree decompositions (T_i, β_i) of G_i and functions $\gamma_i: V(T_i) \rightarrow 2^{V(G_i)}$ satisfying Properties I - VII. We define (T, β) to be the tree decomposition where T is obtained from the disjoint union of T_1, \dots, T_ℓ by adding a fresh root vertex r which is connected to the root vertices of T_1, \dots, T_ℓ . Also, $\beta(r)$ is defined as above and $\beta(t) := \beta_i(t)$ for all $t \in V(T_i)$ and $i \in [\ell]$. Finally, $\gamma(r)$ is again defined as above, and $\gamma(t) := \gamma_i(t)$ for all $t \in V(T_i)$ and $i \in [\ell]$.

The algorithm clearly runs in polynomial time and the output is isomorphism-invariant (the coloring λ is defined below). We need to verify that Properties I - VII are satisfied. Using the comments above and the induction hypothesis, it is easy to verify that Properties II, IV, V and VI are satisfied.

For Property VII it suffices to ensure that $\text{cl}_{2,2}^{(G_i, \lambda)}(\gamma(t)) \subseteq \text{cl}_{2,2}^{(G, \lambda)}(\gamma(t))$. Towards this end, it suffices to ensure that $\lambda(v) \neq \lambda(w)$ for all $v \in \beta(r)$ and $w \in V(G) \setminus \beta(r)$. To ensure this property holds on all levels of the tree, we can simply define $\lambda(v) := \{\text{dist}_T(r, t) \mid t \in V(T), v \in \beta(t)\}$.

Next, we modify the tree decomposition in order to ensure Property III. Consider a node $t \in V(T)$ with children t_1, \dots, t_ℓ . We say that $t_i \sim t_j$ if $\beta(t) \cap \beta(t_i) = \beta(t) \cap \beta(t_j)$. Let A_1, \dots, A_k be the equivalence classes of the equivalence relation \sim . For every $i \in [k]$ we introduce a fresh node s_i . Now, every $t_j \in A_i$ becomes a child of s_i and s_i becomes a child of t . Finally, we set $\beta(s_i) = \gamma(s_i) := \beta(t) \cap \beta(t_j)$ for some $t_j \in A_i$. Observe that after this modification, Properties II and IV - VII still hold.

Finally, it remains to verify Property I. Before the modification described in the last paragraph, we have that $|V(T)| \leq |V(G)|$. Since the modification process at most doubles the number of nodes in T , the bound follows. \blacktriangleleft

7 An FPT Isomorphism Test for Graphs of Small Genus

Building on the decomposition theorem given in the last section, we can now prove the main result of this paper.

► **Theorem 13.** *Let G_1, G_2 be two (vertex- and arc-colored) graphs that exclude $K_{3,h}$ as a minor. Then one can decide whether G_1 is isomorphic to G_2 in time $2^{\mathcal{O}(h^4 \log h)} n^{\mathcal{O}(1)}$.*

Proof Idea. Suppose $G_i = (V(G_i), E(G_i), \chi_V^i, \chi_E^i)$ for $i \in \{1, 2\}$. Using standard reduction techniques (see, e.g., [11]) we may assume without loss generality that G_1 and G_2 are 3-connected. Pick an arbitrary set $S_1 \subseteq V(G_1)$ such that $|S_1| = 3$ and $G_1 - S_1$ is connected. For every $S_2 \subseteq V(G_2)$ such that $|S_2| = 3$ and $G_2 - S_2$ is connected, the algorithm tests whether there is an isomorphism $\varphi: G_1 \cong G_2$ such that $S_1^\varphi = S_2$. Observe that $S_i = N_{G_i}(V(G_i) \setminus S_i)$ for both $i \in \{1, 2\}$ since G_1 and G_2 are 3-connected. This implies that the triple (G_i, S_i, h) satisfies the requirements of Theorem 11. Let (T_i, β_i) be the tree decomposition, $\gamma_i: V(T_i) \rightarrow 2^{V(G_i)}$ be the function, and λ_i be the vertex-coloring computed by Theorem 11 on input (G_i, S_i, h) .

Now, the basic idea is compute isomorphisms between (G_1, S_1) and (G_2, S_2) using dynamic programming along the tree decompositions. More precisely, we aim at recursively computing the set

$$\Lambda := \text{Iso}((G_1, \lambda_1, S_1), (G_2, \lambda_1, S_2))[S_1]$$

(here, $\text{Iso}((G_1, \lambda_1, S_1), (G_2, \lambda_1, S_2))$ denotes the set of isomorphisms $\varphi: G_1 \cong G_2$ which additionally respect the vertex-colorings λ_i and satisfy $S_1^\varphi = S_2$). Throughout the recursive algorithm, we maintain the property that $|S_i| \leq h$. Also, we may assume without loss of generality that S_i is λ_i -invariant (otherwise, we replace λ_i by λ'_i defined via $\lambda'_i(v) := (1, \lambda_i(v))$ for all $v \in S_i$, and $\lambda'_i(v) := (0, \lambda_i(v))$ for all $v \in V(G_i) \setminus S_i$).

Let r_i denote the root node of T_i . Let ℓ denote the number of children of r_i in the tree T_i (if the number of children is not the same, the algorithm concludes that $\text{Iso}((G_1, \lambda_1, S_1), (G_2, \lambda_1, S_2)) = \emptyset$). Let t_1^i, \dots, t_ℓ^i be the children of r_i in T_i , $i \in \{1, 2\}$. For $i \in \{1, 2\}$ and $j \in [\ell]$ let V_j^i denote the set of vertices appearing in bags below (and including) t_j^i . Also let $S_j^i := \beta_i(r_i) \cap \beta_i(t_j^i)$ be the adhesion set to the j -th child, and define $G_j^i := G_i[V_j^i]$. Finally, let T_j^i denote the subtree of T_i rooted at node t_j^i , and $\beta_j^i := \beta_i|_{V(T_j^i)}$, $\gamma_j^i := \gamma_i|_{V(T_j^i)}$ and $\lambda_j^i := \lambda_i|_{V_j^i}$.

For every $i, i' \in \{1, 2\}$, and every $j, j' \in [\ell]$, the algorithm recursively computes the set

$$\Lambda_{j,j'}^{i,i'} := \text{Iso}((G_j^i, \lambda_j^i, S_j^i), (G_{j'}^{i'}, \lambda_{j'}^{i'}, S_{j'}^{i'}))[S_j^i].$$

We argue how to compute the set Λ . Building on Theorem 11, Item III, we may assume that

(a) $S_j^i \neq S_{j'}^i$ for all distinct $j, j' \in [\ell]$ and $i \in \{1, 2\}$, or

(b) $\beta(r_i) = S_j^i$ for all $j \in [\ell]$ and $i \in \{1, 2\}$

(if r_1 and r_2 do not satisfy the same option, then $\text{Iso}((G_1, \lambda_1, S_1), (G_2, \lambda_1, S_2)) = \emptyset$).

We first cover Option b. In this case $|\beta(r_i)| = |S_j^i| \leq h - 1$ by Theorem 11, Item II. The algorithm iterates over all bijections $\sigma: \beta(r_1) \rightarrow \beta(r_2)$. Now,

$$\sigma \in \text{Iso}((G_1, \lambda_1, S_1), (G_2, \lambda_1, S_2))[\beta(r_1)] \Leftrightarrow \exists \rho \in \text{Sym}([\ell]) \forall j \in [\ell]: \sigma \in \Lambda_{j, \rho(j)}^{1,2}.$$

To test whether σ satisfies the right-hand side condition, the algorithm constructs an auxiliary graph H_σ with vertex set $V(H_\sigma) := \{1, 2\} \times [\ell]$ and edge set

$$E(H_\sigma) := \{(1, j)(2, j') \mid \sigma \in \Lambda_{j,j'}^{1,2}\}.$$

Observe that H_σ is bipartite with bipartition $(\{1\} \times [\ell], \{2\} \times [\ell])$. Now,

$$\sigma \in \text{Iso}((G_1, \lambda_1, S_1), (G_2, \lambda_1, S_2))[\beta(r_1)] \Leftrightarrow H_\sigma \text{ has a perfect matching.}$$

It is well-known that the latter can be checked in polynomial time. This completes the description of the algorithm in case Option b is satisfied.

Next, suppose Option a is satisfied. Here, the central idea is to construct auxiliary vertex- and arc-colored graphs $H_i = (V(H_i), E(H_i), \mu_V^i, \mu_E^i)$ and sets $A_i \subseteq V(H_i)$ such that

1. $\beta_i(r_i) \subseteq A_i$ and $A_i \subseteq \text{cl}_{2,2}^{H_i}(\gamma_i(r_i))$, and
2. $\text{Iso}(H_1, H_2)[S_1] = \text{Iso}(H_1[A_1], H_2[A_2])[S_1] = \Lambda$.

Towards this end, we set

$$V(H_i) := V(G_i) \uplus \{(S_j^i, \gamma) \mid j \in [\ell], \gamma \in \Lambda_{j,j}^{i,i}\}$$

and

$$E(H_i) := E(G_i) \cup \{(S_j^i, \gamma)v \mid j \in [\ell], \gamma \in \Lambda_{j,j}^{i,i}, v \in S_j^i\}.$$

Also, we set

$$A_i := \beta(r_i) \cup \{(S_j^i, \gamma) \mid j \in [\ell], \gamma \in \Lambda_{j,j}^{i,i}\}.$$

The main idea is to use the additional vertices attached to the set S_j^i to encode the isomorphism type of the graph $(G_j^i, \lambda_j^i, S_j^i)$. This information is encoded by the vertex- and arc-coloring building on sets $\Lambda_{j,j}^{i,i'}$ already computed above. Let $\mathcal{S} := \{S_j^i \mid i \in \{1, 2\}, j \in [\ell]\}$, and define $S_j^i \sim S_{j'}^{i'}$ if $\Lambda_{j,j'}^{i,i'} \neq \emptyset$. Observe that \sim is an equivalence relation. Let $\{\mathcal{P}_1, \dots, \mathcal{P}_k\}$ be the partition of \mathcal{S} into the equivalence classes. We set

$$\mu_V^i(v) := (0, \chi_V^i(v), \lambda_i(v))$$

for all $v \in S_i$,

$$\mu_V^i(v) := (1, \chi_V^i(v), \lambda_i(v))$$

for all $v \in \gamma_i(r_i) \setminus S_i$,

$$\mu_V^i(v) := (2, \chi_V^i(v), \lambda_i(v))$$

for all $v \in \beta_i(r_i) \setminus \gamma_i(r_i)$,

$$\mu_V^i(v) := (3, \chi_V^i(v), \lambda_i(v))$$

for all $v \in V(G_i) \setminus \beta_i(r_i)$, and

$$\mu_V^i(S_j^i, \gamma) := (4, q, q)$$

for all $q \in [k]$, $S_j^i \in \mathcal{P}_q$, and $\gamma \in \Lambda_{j,j}^{i,i}$. For every $q \in [k]$ fix some $i(q) \in \{1, 2\}$ and $j(q) \in [\ell]$ such that $S_{j(q)}^{i(q)} \in \mathcal{P}_q$ (i.e., for each equivalence class, the algorithm fixes one representative). Also, for every $q \in [k]$ and $S_j^i \in \mathcal{P}_q$, fix a bijection $\sigma_j^i \in \Lambda_{j(q),j}^{i(q),i}$ such that $\sigma_{j(q)}^{i(q)}$ is the identity mapping. Finally, for $q \in [k]$, fix a numbering $S_{j(q)}^{i(q)} = \{u_1^q, \dots, u_{s(q)}^q\}$.

With this, we are ready to define the arc-coloring μ_E^i . First, we set

$$\mu_E^i(v, w) := (0, \chi_E^i(v, w))$$

for all $vw \in E(G_i)$. Next, consider an edge $(S_j^i, \gamma)v$ where $j \in [\ell]$, $\gamma \in \Lambda_{j,j}^{i,i}$, and $v \in S_j^i$. Suppose $S_j^i \in \mathcal{P}_q$. We set

$$\mu_E^i(v, (S_j^i, \gamma)) = \mu_E^i((S_j^i, \gamma), v) := (1, c)$$

for the unique $c \in [s(q)]$ such that

$$v = (u_c^q)^{\sigma_j^i \gamma}.$$

This completes the description of the graphs H_i and the sets A_i , $i \in \{1, 2\}$. It can be checked that Properties 1 and 2 are satisfied (see the full version for details).

Now, recall that the algorithm aims at computing the set Λ . Building on Property 2, we can simply compute $\text{Iso}(H_1[A_1], H_2[A_2])[S_1]$. Towards this end, the algorithm iterates through all bijections $\tau: \gamma_1(r_1) \rightarrow \gamma_2(r_2)$, and wishes to test whether there is an isomorphism $\varphi \in \text{Iso}(H_1[A_1], H_2[A_2])$ such that $\varphi[\gamma_1(r_1)] = \tau$. Note that, since $\gamma_i(r_i)$ is μ_V^i -invariant, it now suffices to solve this latter problem.

So fix a bijection $\tau: \gamma_1(r_1) \rightarrow \gamma_2(r_2)$ (if $|\gamma_1(r_1)| \neq |\gamma_2(r_2)|$ then the algorithm returns $\Lambda = \emptyset$). Let $\mu_1^*(v) := (1, v)$ for all $v \in \gamma_1(r_1)$, $\mu_1^*(v) := (0, \mu_V^1)$ for all $v \in V(H_1) \setminus \gamma_1(r_1)$, and $\mu_2^*(v) := (1, \tau^{-1}(v))$ for all $v \in \gamma_2(r_2)$ and $\mu_2^*(v) := (0, \mu_V^2)$ for all $v \in V(H_2) \setminus \gamma_2(r_2)$.

Intuitively speaking, μ_1^* and μ_2^* are obtained from μ_V^1 and μ_V^2 by individualizing all vertices from $\gamma_1(r_1)$ and $\gamma_2(r_2)$ according to the bijection τ . Now, we can apply Theorem 6 on input graph $H_1^* = (H_1, \mu_1^*)$ and $H_2^* = (H_2, \mu_2^*)$, and parameters $t = k := 2$.

Building on Property 1, we obtain a $\widehat{\Gamma}_2$ -group $\Gamma \leq \text{Sym}(A_1)$ and a bijection $\theta: A_1 \rightarrow A_2$ such that $\text{Iso}(H_1^*[A_1], H_2^*[A_2]) \subseteq \Gamma\theta$. Now, we can determine whether $H_1^*[A_1] \cong H_2^*[A_2]$ using Theorem 3. Using Property 2, this provides the answer to whether $\tau[S_1] \in \Lambda$ (recall that $S_1 \subseteq \gamma_1(r_1)$ by Theorem 11, Items IV and VI).

Overall, this completes the description of the algorithm. It only remains to analyse its running time. Let n denote the number of vertices of G_1 and G_2 .

The algorithm iterates over at most n^3 choices for the initial set S_2 , and computes the decompositions (T_i, β_i) , the functions γ_i , and the colorings λ_i in polynomial time. For the dynamic programming tables, the algorithm needs to compute $\mathcal{O}(n^2)$ many Λ -sets (using Theorem 11, Item I), each of which contains at most $h! = 2^{\mathcal{O}(h \log h)}$ many elements by Theorem 11, Item II. Hence, it remains to analyse the time required to compute the set Λ given the $\Lambda_{j,j'}^{i,i'}$ -sets. For Option b, this can clearly be done in time $2^{\mathcal{O}(h \log h)} n^{\mathcal{O}(1)}$.

So consider Option a. The graph H_i can clearly be computed in time polynomial in its size. We have that $|V(H_i)| = 2^{\mathcal{O}(h \log h)} n$. Afterwards, the algorithm iterates over $|\gamma_1(r_1)|!$ many bijections τ . By Theorem 11, Item V, we have that $|\gamma_1(r_1)|! = 2^{\mathcal{O}(h^4 \log h)}$. For each bijection, the algorithm then requires polynomial computation time by Theorems 6 and 3. Overall, this proves the bound on the running time. \blacktriangleleft

► **Remark 14.** The algorithm from the last theorem can be extended in two directions. First, if one of the input graphs does not exclude $K_{3,h}$ as a minor, it can be modified to either correctly conclude that G_1 has a minor isomorphic to $K_{3,h}$, or to correctly decide whether G_1 is isomorphic to G_2 . Indeed, the only part of the algorithm that exploits that the input graphs do not have a minor isomorphic to $K_{3,h}$ is the computation of the tree decompositions (T_i, β_i) from Theorem 11. In turn, this theorem only exploits forbidden minors via Lemmas 8 and 10. An algorithm can easily detect if one of the implications of those two statements is violated, in which case it can infer the existence of a minor $K_{3,h}$.

Secondly, using standard reduction techniques (see, e.g., [19]), one can also compute a representation of the set of all isomorphisms $\text{Iso}(G_1, G_2)$ in the same time.

Since every graph of Euler genus g excludes $K_{3,4g+3}$ as a minor [25], we obtain the following corollary.

► **Corollary 15.** *Let G_1, G_2 be two (vertex- and arc-colored) graphs of Euler genus at most g . Then one can decide whether G_1 is isomorphic to G_2 in time $2^{\mathcal{O}(g^4 \log g)} n^{\mathcal{O}(1)}$.*

8 Conclusion

We presented an isomorphism test for graphs excluding $K_{3,h}$ as a minor running in time $2^{\mathcal{O}(h^4 \log h)} n^{\mathcal{O}(1)}$. For this, we provided a polynomial-time isomorphism algorithm for (t, k) -WL-bounded graphs and argued that graphs excluding $K_{3,h}$ as a minor can be decomposed into parts that are $(2, 2)$ -WL-bounded after individualizing a small number of vertices.

Still, several questions remain open. Probably one of the most important questions in the area is whether isomorphism testing for graphs excluding K_h as a minor is fixed-parameter tractable with parameter h . As graphs of bounded genus form an important subclass of graphs excluding K_h as a minor, the techniques developed in this paper might also prove helpful in resolving this question.

As an intermediate step, one can also ask for an isomorphism test for graphs excluding $K_{\ell,h}$ as a minor running in time $f(h, \ell) n^{g(\ell)}$ for some functions f, g . Observe that this paper provides such an algorithm for $\ell = 3$. Indeed, combining ideas from [10, 22] with the approach taken in this paper, it seems the only hurdle towards such an algorithm is a generalization of Lemma 9. Given a connected graph G for which $|V_c| \geq \ell$ for all $c \in C_V(G, \chi_{\text{WL}}^2[G])$, is it always possible to find vertex-disjoint, connected subgraphs $H_1, \dots, H_\ell \subseteq G$ such that $V(H_r) \cap V_c \neq \emptyset$ for all $r \in [\ell]$ and $c \in C_V(G, \chi_{\text{WL}}^2[G])$?

As another intermediate problem, one can also consider the class \mathcal{G}_h of all graphs G for which there is a set $X \subseteq V(G)$ of size $|X| \leq h$ such that $G - X$ is planar. Is isomorphism testing fixed-parameter tractable on \mathcal{G}_h parameterized by h ?

Restricted t -Matchings via Half-Edges

Katarzyna Paluch

Institute of Computer Science, University of Wrocław, Poland

Mateusz Wasylikiewicz

Institute of Computer Science, University of Wrocław, Poland

Abstract

For a bipartite graph G we consider the problem of finding a maximum size/weight square-free 2-matching and its generalization - the problem of finding a maximum size/weight $K_{t,t}$ -free t -matching, where t is an integer greater than two and $K_{t,t}$ denotes a bipartite clique with t vertices on each of the two sides. Since the weighted versions of these problems are \mathcal{NP} -hard in general, we assume that the weights are vertex-induced on any subgraph isomorphic to $K_{t,t}$. We present simple combinatorial algorithms for these problems. Our algorithms are significantly simpler and faster than those previously known. We dispense with the need to shrink squares and, more generally subgraphs isomorphic to $K_{t,t}$, the operation which occurred in all previous algorithms for such t -matchings and instead use so-called *half-edges*. A *half-edge* of edge e is, informally speaking, a half of e containing exactly one of its endpoints.

Additionally, we consider another problem concerning restricted matchings. Given a (not necessarily bipartite) graph $G = (V, E)$, a set of k subsets of edges E_1, E_2, \dots, E_k and k natural numbers r_1, r_2, \dots, r_k , the Restricted Matching Problem asks to find a maximum size matching of G among such ones that for each $1 \leq i \leq k$, M contains at most r_i edges of E_i . This problem is \mathcal{NP} -hard even when G is bipartite. We show that it is solvable in polynomial time if (i) for each i the graph G contains a clique or a bipartite clique on all endpoints of E_i ; in the case of a bipartite clique it is required to contain E_i and (ii) the sets E_1, \dots, E_k are almost vertex-disjoint - the endpoints of any two different sets have at most one vertex in common.

1 Introduction

Given a positive integer t , a subset M of edges of an undirected simple graph G is called a t -matching if every vertex is incident to at most t edges of M . A t -matching of maximum size can be found in polynomial time by a reduction to the classical matching problem. A 2-matching is called *square-free* if it does not contain any cycle of length 4. A C_k -free 2-matching is one without any cycle of length at most k . The C_k -free 2-matching problem consists in finding a C_k -free 2-matching of maximum size. Observe that the C_k -free 2-matching problem for $n/2 \leq k < n$, where n is the number of vertices in the graph, is equivalent to finding a Hamiltonian cycle, and thus \mathcal{NP} -hard. Hartvigsen [13] gave a complicated algorithm for the case of $k = 3$. Papadimitriou [4] showed that this problem is \mathcal{NP} -hard when $k \geq 5$. The complexity of the C_4 -free 2-matching problem is unknown.

When the graph is bipartite the smallest length of a cycle contained in it is at least 4. We refer to cycles of length four as *squares*. Polynomial time algorithms for the C_4 -free 2-matching problem in bipartite graphs were shown by Hartvigsen [14], Pap [30], Babenko [1]

and analyzed by Király [18]. A generalization of a square-free 2-matching in a bipartite graph is a $K_{t,t}$ -free t -matching - a t -matching without any $K_{t,t}$ - a bipartite clique with t vertices on each of the two sides. $K_{t,t}$ -free t -matchings were first considered by Frank [7], who provided a min-max formula for $K_{t,t}$ -free t -matchings based on a result in [8] on crossing bi-supermodular functions. Using this formula, it is possible to compute the size of a maximum $K_{t,t}$ -free t -matching by the ellipsoid method or a combinatorial method by Fleiner [6]. Moreover, one can compute a maximum $K_{t,t}$ -free t -matching through Végh and Benczúr's algorithm [36] for covering pairs of sets and directly using Pap's algorithm [29].

In the weighted version of the $K_{t,t}$ -free t -matching problem, each edge e is associated with a nonnegative weight $w(e)$ and we are interested in finding a $K_{t,t}$ -free t -matching of maximum weight, where the weight of a t -matching M is defined as the sum of weights of edges belonging to M . The weighted square-free 2-matching problem in bipartite graphs was proven to be \mathcal{NP} -hard [12, 19] even if the weight of every edge is either 0 or 1. Bérczi and Kobayashi [2] sharpened the result and showed that the problem is \mathcal{NP} -hard even if the given graph is cubic, bipartite and planar. The weighted $K_{t,t}$ -free t -matching problem in bipartite graphs is solvable in polynomial time when the weights of edges are vertex-induced on every subgraph isomorphic to $K_{t,t}$, which was shown by Makai [24] and Takazawa [33].

Apart from $K_{t,t}$ -free t -matchings, we consider another problem concerning restricted matchings. Given a (not necessarily bipartite) graph $G = (V, E)$, a set of k subsets of edges E_1, E_2, \dots, E_k and k natural numbers r_1, r_2, \dots, r_k , the Restricted Matching Problem asks to find a maximum size classical matching of G among such ones that for each $1 \leq i \leq k$, M contains at most r_i edges of E_i . This problem was first studied in [17] by Itai, Rodeh and Tanimoto for bipartite graphs and shown to be \mathcal{NP} -hard for the general case and solvable in polynomial time for the variant when there is only one set E_1 , i.e., when $k = 1$. The version, in which G is bipartite and each E_i contains two edges (and hence each $r_i = 1$) was proven to be \mathcal{NP} -hard by Garey and Johnson [11]. The problem was also considered in [25] and [31].

Our results We present simple combinatorial algorithms for the weighted and unweighted version of the $K_{t,t}$ -free t -matching problem in bipartite graphs. In the weighted version we assume that the weights of edges are vertex-induced on every subgraph isomorphic to $K_{t,t}$. In these algorithms we successively find and apply a minimum length/weight augmenting path until it is no longer possible. The search for an augmenting path is conducted in a specially modified graph G , called G' . Graph G' is obtained from G by replacing some subgraphs with so-called gadgets that contain *half-edges*. A *half-edge* of edge e is, informally speaking, a half of e containing exactly one of its endpoints. Half-edges have been first introduced in [27]. Each subgraph that is replaced with a gadget in a given step is isomorphic to $K_{t,t}$ and $t^2 - 1$ of its edges belong to the current t -matching M . In previous algorithms for these problems such or similar subgraphs were *shrunk*. One could say that we take an opposite approach and *expand* such subgraphs. However, in our case these expansions do not build on each other and in each step G' is constructed only from the original graph G and a current t -matching M . We give a detailed description of these algorithms for square-free 2-matchings and their analyses and only an outline for the $K_{t,t}$ -free t -matching problem. In addition to being significantly simpler our algorithms are also faster than those known previously. For the unweighted square-free 2-matching problem our algorithm has running time $\mathcal{O}(nm)$, where n denotes the number of vertices in the graph and m the number of edges. Both algorithms by Hartvigsen and Babenko run in $\mathcal{O}(n^3)$ time and the one by Pap in $\mathcal{O}(n^4)$. For the weighted/unweighted version of the $K_{t,t}$ -free t -matching problem we give an algorithm with running time, respectively, $\mathcal{O}(tnm + t^2n^2 \log n)$ and $\mathcal{O}(nm + tn^2 + \sqrt{tnm})$. For the weighted variant the algorithm by Takazawa has runtime $\mathcal{O}(tn^2m + tn^3 \log n)$ for the t -factor

problem (each vertex has to be incident with exactly t edges) and $\mathcal{O}(t^5 n^6 + t^4 n^6 \log n)$ for the t -matching problem because of the costly reduction to the t -factor problem. The algorithm by Makai has polynomial time but it uses the ellipsoid method.

Regarding classical matchings we devise a polynomial time algorithm for the variant of the Restricted Matching Problem when (i) for each i the graph G contains a clique or a bipartite clique on all endpoints of E_i ; in the case of a bipartite clique it is required to contain E_i and (ii) the sets E_1, \dots, E_k are almost vertex-disjoint - the endpoints of any two different sets have at most one vertex in common.

Motivation C_k -free 2-matchings and $K_{t,t}$ -free t -matchings are classical problems of combinatorial optimization. They have applications in traveling salesman problems, problems related to finding a smallest 2-edge-connected spanning subgraph as well as in increasing the vertex-connectivity (see [5, 2, 3, 34] for more details). A good survey of these applications has been given by Takazawa [35].

Related work Some generalizations of the C_k -free 2-matching problem were investigated. Recently, Kobayashi [21] gave a polynomial algorithm for finding a maximum weight 2-matching that does not contain any triangle from a given set of forbidden edge-disjoint triangles. Polynomial algorithms for square-free and/or triangle-free 2-matchings in subcubic graphs were presented in [15, 16, 2, 3, 20, 28, 22]. An algorithm by Paluch and Wasylkiewicz uses a similar approach as the one presented in this paper but requires only one computation of a b -matching. When it comes to the square-free 2-matching problem in general graphs, Nam [26] constructed a complex algorithm for it for graphs, in which all squares are vertex-disjoint.

2 Preliminaries

Let $G = (V, E)$ be an undirected graph with vertex set V and edge set E . We denote the number of vertices of G by n and the number of edges of G by m . We denote a vertex set of G by $V(G)$ and an edge set by $E(G)$. We assume that all graphs are *simple*, i.e., they contain neither loops nor parallel edges. We denote an edge connecting vertices v and u by (v, u) . A *path* of graph G is a sequence $P = (v_0, \dots, v_l)$ for some $l \geq 1$ such that $(v_i, v_{i+1}) \in E$ for every $i \in \{0, 1, \dots, l-1\}$. We refer to l as the *length* of P . A *cycle* of graph G is a sequence $c = (v_0, \dots, v_{l-1})$ for some $l \geq 3$ of pairwise distinct vertices of G such that $(v_i, v_{(i+1) \bmod l}) \in E$ for every $i \in \{0, 1, \dots, l-1\}$. We refer to l as the *length* of c . We will sometimes treat a path or a cycle as an edge set and sometimes as a sequence of edges. For an edge set $F \subseteq E$ and $v \in V$, we denote by $\deg_F(v)$ the number of edges of F incident to v . For any two edge sets $F_1, F_2 \subseteq E$, the symmetric difference $F_1 \oplus F_2$ denotes $(F_1 \setminus F_2) \cup (F_2 \setminus F_1)$.

For a natural number t , we say that an edge set $F \subseteq E$ is a *t -matching* if $\deg_F(v) \leq t$ for every $v \in V$. t -matchings belong to a wider class of b -matchings, where for every vertex v of G , we are given a natural number $b(v)$ and a subset of edges is a *b -matching* if every vertex v is incident to at most $b(v)$ of its edges. A b -matching of G of maximum weight can be computed in polynomial time. We refer to Lovász and Plummer [23] for further background on b -matchings.

Let M be a b -matching. We say that an edge e is *matched* (in M) if $e \in M$ and *unmatched* (in M) otherwise. Additionally, an edge belonging to M will be referred to as a *M -edge* and an edge not belonging to M as a *non- M -edge*. We call a vertex v *deficient (in M)* if $\deg_M(v) < b(v)$. An *M -alternating path* P is any sequence of vertices (v_1, v_2, \dots, v_k) such that edges on P are alternately M -edges and non- M -edges and no edge occurs on P

more than once and $v_1 \neq v_k$. An M -alternating cycle C has the same definition as an M -alternating path except that $v_1 = v_k$ and additionally $(v_{k-1}, v_k) \in M$ iff $(v_1, v_2) \notin M$. Note that an M -alternating path or cycle may go through some vertices more than once but via different edges. An M -alternating path is called M -augmenting if it begins and ends with a non- M -edge and if it begins and ends with a deficient vertex. We say that M is a **maximum** b -matching if there is no b -matching of G with more edges than M . Given a weight function $w : E \rightarrow \mathbb{R}$ we define **weight** of M as $w(M) = \sum_{e \in M} w(e)$. We say that M has **maximum weight** if there is no b -matching of G of weight greater than $w(M)$.

Given a weight function w , the **alternating weight** of an M -alternating path or cycle P is defined as $\tilde{w}(P) = \sum_{e \in P \cap M} w(e) - \sum_{e \in P \setminus M} w(e)$. We say that an M -augmenting path P is **minimum** if it has minimum alternating weight among all M -augmenting paths and cannot be shortened without increasing its alternating weight. An M -alternating cycle is a **negative cycle** if its alternating weight is negative. An **application** of an M -alternating path or cycle P to M is an operation whose result is $M \oplus P$. Note that $w(M \oplus P) = w(M) - \tilde{w}(P)$.

We are interested in computing a b -matching of a graph G where we are given vectors $l, u \in \mathbb{N}^V$ and a weight function $w : E \rightarrow \mathbb{R}$. For a vertex $v \in V$, $[l(v), u(v)]$ is said to be a **capacity interval** of v . An edge set $M \subseteq E$ is said to be an (l, u) -matching if $l(v) \leq \deg_M(v) \leq u(v)$ for every $v \in V$. A maximum weight (l, u) -matching can be computed efficiently.

For a weight function $w : E \rightarrow \mathbb{R}$ and a subgraph H of G , we say that w is **vertex-induced on H** if there exists a function $r : V(H) \rightarrow \mathbb{R}$ such that $w(u, v) = r(u) + r(v)$ for every edge (u, v) of H . We call r a **potential function** of H .

An instance of the square-free 2-matching problem consists of an undirected bipartite graph $G = (V, E)$ and the goal is to find a maximum square-free 2-matching of G . A generalization of a square-free 2-matching in a bipartite graph is a $K_{t,t}$ -free t -matching - a t -matching without any $K_{t,t}$ - a bipartite clique with t vertices on each of the two sides. An instance of the $K_{t,t}$ -free t -matching problem consists of an undirected bipartite graph $G = (V, E)$ and a natural number $t \geq 2$. The aim is to compute a maximum $K_{t,t}$ -free t -matching. We also consider weighted versions of these problems, in which we are additionally given a weight function $w : E \rightarrow \mathbb{R}_{\geq 0}$ that is vertex-induced on each subgraph of G isomorphic to $K_{t,t}$ and the task consists in finding a maximum weight $K_{t,t}$ -free t -matching.

3 Outline of the Algorithm for Square-Free 2-Matchings

The general scheme of the algorithm for each variant of the square-free 2-matching problem is the same - we give it below.

■ **Algorithm 1** Computing a maximum (weight) square-free 2-matching of a bipartite graph G .

-
- 1: Let M be an empty 2-matching of G .
 - 2: Construct an auxiliary bipartite graph $G' = (V', E')$ with $\mathcal{O}(n)$ vertices and $\mathcal{O}(m)$ edges, and its 2-matching M' of size $\mathcal{O}(n)$ by replacing some squares of G with gadgets containing half-edges. (Both gadgets and half-edges are defined later.)
 - 3: Compute a shortest (resp. minimum) M' -augmenting path P of G' . If G' contains no M' -augmenting path (resp. no M' -augmenting path with negative alternating weight), stop the algorithm and return M .
 - 4: Apply P to M' obtaining M'' and extract a square-free 2-matching M_1 of G from M'' such that $|M_1| = |M| + 1$ (resp. $w(M_1) > w(M)$). Set M as M_1 and go to 2.
-

▷ **Claim 3.1.** Algorithm 1 runs in time $O(nm + n^2 \log n)$.

Proof. It will be easy to implement all steps of an Algorithm 1 except 3 in linear time. 3 can be implemented to run in time $O(|E'| + |V'| \log |V'|)$ by Fredman and Tarjan's implementation of Dijkstra's algorithm [9] similarly as in the Hungarian method described by Schrijver [32]. Every step is executed $O(n)$ times since $|M|$ increases by one every time 4 is executed. ◀

Let us also remark that in the unweighted version of the problem Algorithm 1 runs in $O(nm)$ since 3 can be implemented to run in linear time.

4 Maximum square-free 2-matchings in bipartite graphs

In this section we show how to find a maximum square-free 2-matching in a bipartite graph G . When computing a maximum 2-matching N of G , which is not required to be square-free, we can proceed as follows. As long as G contains some N -augmenting path P , apply it to N and repeat. When the goal is to compute a maximum square-free 2-matching of G , this approach is not applicable for two reasons. Firstly, by applying an augmenting path to a square-free 2-matching we may obtain a 2-matching which is not square-free. Secondly, it may happen that a square-free 2-matching M is not maximum but G does not contain any M -augmenting path P such that $M \oplus P$ is square-free. An example of such a 2-matching is shown in Figure 1. Nevertheless, it turns out as we demonstrate below, that we may still use this method if the search for an augmenting path is conducted in an appropriately modified graph G' .

■ **Figure 1** Edges of a square-free 2-matching M are waved. M is not maximum, G contains an M -augmenting path P (with endpoints a_1, b_1) but $M \oplus P$ is not square-free. If we apply both P and an M -alternating cycle C (indicated by red edges), we obtain a larger square-free 2-matching.

First let us check what types of squares of G are in danger of appearing in a 2-matching after the application of a shortest augmenting path. (In fact P does not have to be shortest - it suffices if P has no shortcuts.)

► **Fact 4.1.** *Any shortest M -augmenting path P' has the property that for any vertex v , it contains at most two edges incident to v : at most one matched edge and at most one unmatched one.*

Proof. Otherwise P' would contain an alternating cycle C and hence could be shortened. (This property does not hold in non-bipartite graphs.) ◀

► **Lemma 4.2** (Proposition 2.1. in [33]). *Let M be a square-free 2-matching of G and P any shortest M -augmenting path. If $M \oplus P$ contains a square s , then exactly three edges of s belong to M .*

Proof. Suppose that $M \oplus P$ contains a square $s = (a, b, c, d)$ such that at least two of its edges do not belong to M , one of which is (a, b) . Therefore $(a, b) \in P$ and by the fact above we get that both (b, c) and (a, d) belong to M . Hence, $(c, d) \notin M$. Thus, the edges $(a, b), (c, d)$ belong to P and are connected in P by an odd-length alternating M -path R . R 's endpoints are either a and d or b and c . Also, R begins and ends with an M -edge. This means that P can be shortened by replacing R either with (a, d) or (b, c) - a contradiction. \blacktriangleleft

Suppose that M is a (possibly empty) square-free 2-matching of G . We say that a square s of G is **saturated** (in M) if exactly three edges of s are contained in M . The graph G' in which we are going to search for an augmenting path is obtained from the original graph G by replacing a subset of saturated squares with specially constructed subgraphs called *gadgets*. More details are given below.

One can observe that, since G is bipartite, any edge e of G belongs to at most two different saturated squares.

► **Definition 4.3.** A saturated square s , which has exactly one common edge with some other saturated square is said to be **unproblematic**. Otherwise, s is said to be **problematic**.

Unproblematic squares can be easily got rid of by replacing some edges with other ones as explained in more detail in the proof of Lemma 4.8.

► **Fact 4.4.** If two problematic squares have a common edge, then they share exactly two edges, both of which are in M . Any problematic square is non-edge-disjoint with at most one other problematic square.

Proof. Let s_1 and s_2 be two problematic squares of G with a common edge. Since they are problematic, they have at least two common edges. Note that s_1 and s_2 cannot share more than two edges because otherwise they would share all four vertices. However, two different squares cannot share all vertices because G is simple and bipartite. Let e_1, e_2 be the common edges of s_1 and s_2 . They cannot be vertex-disjoint because then again s_1 and s_2 would have four common vertices. Hence, e_1 and e_2 have a common vertex v .

Next we argue that both e_1 and e_2 must belong to M . Suppose to the contrary that $e_1 \notin M$. This implies that the endpoint v' of e_2 different from v is incident to three edges of M - a contradiction.

To see that s_1 cannot share an edge with a problematic square $s_3 \neq s_2$, observe that in such a case s_3 would have to share with s_1 exactly one of the edges of $\{e_1, e_2\}$ and additionally some edge e_3 . The edge e_3 cannot belong to s_2 because it is incident to a vertex of s_1 not contained in s_2 . Hence, s_3 and s_2 share exactly one edge, which implies that s_2 is not problematic - a contradiction. \blacktriangleleft

If G contains at least one problematic square, we build a graph $G' = (V', E')$ together with its 2-matching M' , in which each problematic square s is replaced with a subgraph, called a **gadget for** s . The precise construction of G' and M' is the following. We start off with $G' = G$. We initialize M' as the set of edges of M which are not part of any problematic square.

Let $s = (a, b, c, d)$ be any problematic square of G such that $(a, b) \notin M$. For each edge (p, q) of s we add two new vertices v_q^p and v_p^q , called **subdivision vertices** (of s), and we replace (p, q) with three new edges: $(p, v_q^p), (v_q^p, v_p^q), (v_p^q, q)$. Each of the edges $(p, v_q^p), (v_p^q, q)$ is called a **half-edge** (of (p, q) and also of s). The edge (v_q^p, v_p^q) is called an **eliminator** (of (p, q)). We remove the eliminator of the edge (a, b) from E' . Additionally, we introduce two new vertices u_s^1 and u_s^2 , called **global vertices**. We connect u_s^1 with every subdivision vertex

connected to a or c . Similarly, we connect u_s^2 with every subdivision vertex connected to b or d . We define vectors $l, u \in \mathbb{N}^{V'}$ as follows. We set a capacity interval of every vertex of the original graph G to $[0, 2]$ and we set a capacity interval of every other vertex of G' to $[1, 1]$, i.e., every vertex of $V' \setminus V$ is matched to exactly one vertex of G' in any (l, u) -matching of G' . For every edge $e \in M$ of s , we add half-edges of e to M' . Additionally, we add (u_s^1, v_b^a) and (u_s^2, v_a^b) to M' . If two problematic squares share two edges, then their gadgets overlap, i.e., we build a gadget for each one of them in the way described above.

The main ideas behind the gadget for a problematic square $s = (a, b, c, d)$ are the following. An (l, u) -matching M' of G' is to represent roughly a square-free 2-matching M of G . If M' contains both half-edges of some edge e , then e is included in M . If M' contains an eliminator of e , then e does not belong to M (is excluded from M). We want to ensure that at least one edge of s does not belong to M . This is done by requiring that the two global vertices u_s^1 and u_s^2 are matched to two subdivision vertices. In this way two half-edges of s are guaranteed not to belong to M' and hence to M .

Additionally, we can observe that for a 2-matching M depicted in Figure 1, there exists one M' -augmenting path in G' comprising all red edges.

■ **Figure 2** A gadget for a problematic square $s = (a, b, c, d)$ such that $(a, b) \notin M$. Weights of the edges for the weighted version are given in red.

It turns out that if G' contains an M' -augmenting path, then we can apply a shortest one to M' , obtaining a larger 2-matching M'' of G' . From M'' we can in turn obtain a square-free 2-matching M_2 of G of size $|M| + 1$. This is achieved by first changing around the half-edges of M'' so that for each edge $e \in E$ belonging to a problematic square we have that either both half-edges of e are contained in M'' or none. Next, if needed, we get rid of unproblematic squares.

► **Lemma 4.5.** *Let P be a shortest M' -augmenting path of G' and let $M'' = M' \oplus P$. Then there exists exactly one 2-matching M_1 of G , denoted as $\text{img}(M'')$, such that:*

1. *for each vertex v of G it holds that $\deg_{M''}(v) = \deg_{M_1}(v)$,*
2. *for each edge $e \in E$ not belonging to any problematic square, we have that $e \in M_1 \Leftrightarrow e \in M''$.*

Proof. We obtain M_1 from M'' as follows. First for each edge $e \in E$ not belonging to any problematic square, we include e into M_1 if and only if $e \in M''$. Next we remove all edges of M'' incident to global vertices and flip the half-edges so that for each edge $e \in E$ belonging to a problematic square we have that either both half-edges of e are contained in M'' or none. To see that the half-edges can indeed be changed around in such a way we use the following observation.

► **Observation 4.6.** *Let $s = (a, b, c, d)$ be a problematic square such that $(a, b) \notin M$. If P goes through any unmatched half-edge of (a, b) , then it does not go through any matched half-edge of s incident to a or b .*

Proof. Assume that P goes through (v_a^b, b) . Then P must also go through the global vertex u_s^2 , which in turn means that P must also go through d . (Otherwise P would contain an alternating cycle going through vertices u_s^2, v_c^b, b, v_a^b .) Suppose now that P also contains the matched half-edge of s incident to b . Then P must also contain (v_c^b, v_b^c) and (v_b^c, c) . (If s shares edges (b, c) and (c, d) with another problematic square s' , then from v_c^b P may go to a global vertex of s' , but then it also has to go to d and the case is as below.) This way we obtain a contradiction, because we could shorten P : instead of going through d and u_s^2, b, c using seven edges P could use three edges $(d, v_c^d), (v_c^d, v_d^c), (v_d^c, c)$ instead.

If, on the other hand, P also contained the matched half-edge incident to a , then it would have to contain also the eliminator of (a, d) and the second half-edge of (a, d) , which would mean that P contains four edges incident to d , using both matched edges incident to it - a contradiction. ◀

This means the following.

1. If P goes through u_s^1 but not u_s^2 , then P also goes through c and thus P contains exactly two half-edges of s : one matched half-edge incident to c and one unmatched half-edge incident to a . As a result M'' contains exactly one matched half-edge incident to c and two matched half-edges incident to a and thus the degrees of vertices a, b, c, d with respect to half-edges of s contained in M'' are equal to, respectively, 2, 1, 1, 2. In this case we set M_1 so that it contains edges $(b, a), (a, d), (d, c)$ but not (b, c) . The case when P goes through u_s^2 but not u_s^1 is symmetrical.
2. If P goes through both u_s^1 and u_s^2 , then P contains exactly four half-edges of s : one matched half-edge incident to c , one matched half-edge incident to d and both half-edges of (a, b) . As a result the degrees of vertices a, b, c, d with respect to half-edges of s contained in M'' are equal to, respectively, 2, 2, 1, 1. In this case we set M_1 to contain edges $(b, a), (a, d), (b, c)$ but not (d, c) .
3. If P goes neither through u_s^1 nor through u_s^2 , then P either does not go through any half-edge of s at all or goes through two matched half-edges of exactly one of the edges $(b, c), (c, d), (a, d)$. As a result M'' has the property that for each edge e of s either both half-edges of e are in M'' or none. In this case we include an edge e of s into M only if its both half-edges are present in M'' .

This finishes the proof. ◀

We have the analogue of Lemma 4.2.

► **Lemma 4.7.** *Let P be any shortest M' -augmenting path in G' . If $M_1 = \text{img}(M' \oplus P)$ contains a square s , then s is unproblematic (in M).*

Proof. Let $s = (a, b, c, d)$ be some square of G that is contained in M_1 . First, we can notice that if each of the unmatched edges of s is also present in G' , then by Lemma 4.2, we know that s can appear in M_1 only if it is saturated and hence only if it is unproblematic (because otherwise s is replaced with a gadget). Second, we observe that s cannot be problematic, because the gadget for s ensures that at least two half-edges of s do not belong to $M' \oplus P$ and hence at least one edge of s does not belong to M_1 .

Suppose then now that s is not saturated and at least one of its unmatched edges, say (a, b) , is not present in G' . It means that there exists a problematic square s' that contains (a, b) . The edge (a, b) appears in M_1 only if at least one of the half-edges of (a, b) is contained

in P . Suppose it is (a, v_b^a) . It means that P contains also some matched (half-)edge e' incident to a . By Observation 4.6 the edge e' cannot be contained in s' . Neither can it be contained in s because then s could not appear in M_1 . This means that the edge (a, d) of s is unmatched. We notice however, that (a, d) cannot belong to M_1 because neither (a, d) can belong to P (as it would mean that P contains four (half-)edges incident to a and thus could be shortened) nor any half-edge of (a, d) can belong to P (if (a, d) belongs to a problematic square s'' then by Observation 4.6, if P contains a half-edge of (a, d) , then it does not contain a matched half-edge incident to a). ◀

► **Lemma 4.8.** *Let P be any shortest M' -augmenting path in G' and $M_1 = \text{img}(M' \oplus P)$. If M_1 is not square-free then it can be transformed into a square-free 2-matching M_2 such that $|M_1| = |M_2|$.*

Proof. We consider every square $s = (a, b, c, d)$ of M_1 . By Lemma 4.7, s is unproblematic. Hence it shares exactly one edge with another unproblematic square s' . Assume that (a, b) is unmatched in M . Observe that (c, d) cannot be a common edge of s and s' because any vertex of G can be incident to at most two edges of M . Neither can (a, b) be a common edge of s and s' , because then P could be shortened and not go through (a, b) at all. Suppose then that (b, c) is a common edge of s and $s' = (b, c, e, f)$. It means that $(c, e) \notin M$ and $(b, f) \in P \cap M$. Since apart from (a, b) none of the edges of s belongs to P , the edge (e, c) cannot belong to P either. Therefore, s' is an M_1 -alternating cycle. We apply s' to M_1 . As a result s does not occur in M_1 any more. Also, this operation does not introduce any new square into M_1 because the edges $(f, b), (b, a), (a, d), (d, c), (c, e)$ form a path of length five and are guaranteed to belong to M_1 ; therefore, none of them can be part of a square. ◀

► **Lemma 4.9.** *If there is no M' -augmenting path in G' , then M is a maximum square-free 2-matching of G .*

Proof. It is a special case of Lemma 5.9. ◀

5 Maximum weight square-free 2-matchings in bipartite graphs

In this section we extend the results from the previous section to the weighted setting. Recall that this problem is \mathcal{NP} -hard for general weights, therefore we assume that the weight function w is vertex-induced on every square. Some proofs are omitted due to space constraints.

► **Lemma 5.1.** *Let s and s' be two problematic squares that have exactly two common edges. Then w is vertex-induced on $s \cup s'$.*

Proof. Let $s = (a, b, c, d)$ and $s' = (a, b, c, e)$. Let r and r' be potential functions of, respectively, s and s' . Observe that $r(a) + r(b) = w(a, b) = r'(a) + r'(b)$ and $r(b) + r(c) = w(b, c) = r'(b) + r'(c)$. Let $\Delta = r(a) - r'(a)$. We increase both $r'(a)$ and $r'(c)$ by Δ and decrease both $r'(b)$ and $r'(e)$ by Δ . Notice that r' is still a valid potential function of s' after this operation. Additionally, now r and r' agree on the common vertices. Therefore, $r \cup r'$ is a potential function of $s \cup s'$. ◀

To the construction of G' from Section 4 we add a weight function $w' : E(G') \rightarrow \mathbb{R}$ defined as follows. The half-edges incident to a, b, c and d get weight $r(a), r(b), r(c)$ and $r(d)$, respectively, where $r(a), \dots, r(d)$ are potentials of s . All the other edges of the gadget get weight 0.

73:10 Restricted t -Matchings via Half-Edges

Define $k : E(G') \rightarrow \{0, 1/2, 1\}$ such that

$$k(e) = \begin{cases} 1 & \text{if } e \in E(G), \\ 1/2 & \text{if } e \text{ is a half-edge,} \\ 0 & \text{otherwise.} \end{cases}$$

For $e \in E(G')$ we say that $k(e)$ is the **size** of e .

► **Definition 5.2.** Consider any (l, u) -matching N of G' . We define the **size** of N as $k(N) = \sum_{e \in N} k(e)$. We say that N is **extreme** if it has maximum weight among all (l, u) -matchings of size $k(N)$ in G' . A matching M of G is said to be **extreme** if it has maximum weight among all matchings of size $|M|$ in G' .

Algorithm 1 for computing a maximum weight square-free 2-matching differs from the variant for computing a maximum (size) 2-matching only in the fact that we compute a minimum M' -augmenting path instead of a shortest M' -augmenting one. Finding a minimum M' -augmenting path requires computing an M' -augmenting path P with minimum alternating weight. To be able to do this, we need to know that there are no negative cycles in G' . We prove the absence of negative cycles in G' as well as the optimality of the 2-matching computed by Algorithm 1 by using linear programming.

The weighted square-free 2-matching problem can be formulated as an integer program as follows. We assign a variable $x(e)$ for each edge $e \in E$. Any such variable can take on only two values: 0 or 1, where setting a variable $x(e)$ to 1 denotes including e in the 2-matching. To ensure that variables $x(e)$ encode a 2-matching we add constraint 2b. Constraint 2c means that for any square s of the graph at most three of its edges can belong to the 2-matching.

Let S denote the set of all squares of G and $x \in \mathbb{R}^{E(G)}$. The weighted square-free 2-matching problem can be formulated as an integer program, whose linear programming relaxation is the following:

$$(P) \quad \text{maximize} \quad \sum_{e \in E(G)} w(e)x(e) \tag{1a}$$

$$\text{subject to} \quad \sum_{e \in \delta(v)} x(e) \leq 2 \quad (\forall v \in V(G)), \tag{1b}$$

$$\sum_{e \in E(s)} x(e) \leq 3 \quad (\forall s \in S), \tag{1c}$$

$$\sum_{e \in E(G)} x(e) = k. \tag{1d}$$

Let x be any feasible solution of (P) and $M = \{e \in E : x(e) = 1\}$. We can check that M is a square-free 2-matching of G . Namely, the first constraint ensures that for any vertex v at most two edges of M are incident to v and the second constraint implies that for any square s of the graph at most three of its edges belong to M . The linear program (P) has been shown to have an integral optimal solution by Makai [24]. For our purposes we need linear programs, which are relaxations of integer programs for, correspondingly, the extreme size k square-free 2-matching problem and the extreme size k (l, u) -matching problem. These linear programs (P_k) and (P'_k) and their duals $(D_k), (D'_k)$ are given below, where $x' \in \mathbb{R}^{E'(G)}$.

$$(P_k) \quad \text{maximize} \quad \sum_{e \in E(G)} w(e)x(e) \quad (2a)$$

$$\text{subject to} \quad \sum_{e \in \delta(v)} x(e) \leq 2 \quad (\forall v \in V(G)), \quad (2b)$$

$$\sum_{e \in E(s)} x(e) \leq 3 \quad (\forall s \in S), \quad (2c)$$

$$\sum_{e \in E(G)} x(e) = k, \quad (2d)$$

$$0 \leq x(e) \leq 1 \quad (\forall e \in E(G)). \quad (2e)$$

$$(D_k) \quad \text{minimize} \quad 2 \sum_{v \in V(G)} p(v) + \sum_{e \in E(G)} q(e) + 3 \sum_{s \in S} \alpha(s) + \beta k \quad (3a)$$

$$\text{subject to} \quad p(u) + p(v) + q(e) + \sum_{s \in S: e \in E(s)} \alpha(s) + \beta \geq w(e) \quad (\forall e = (u, v) \in E(G)), \quad (3b)$$

$$p, q, \alpha \geq 0. \quad (3c)$$

$$(P'_k) \quad \text{maximize} \quad \sum_{e \in E(G)} w'(e)x(e) \quad (4a)$$

$$\text{subject to} \quad \sum_{e \in \delta(v)} x(e) \leq 2 \quad (\forall v \in V(G)), \quad (4b)$$

$$\sum_{e \in \delta(v)} x(e) = 1 \quad (\forall v \in V(G') \setminus V(G)), \quad (4c)$$

$$\sum_{e \in E(G')} k(e)x(e) = k, \quad (4d)$$

$$0 \leq x(e) \leq 1 \quad (\forall e \in E(G')). \quad (4e)$$

$$(D'_k) \quad \text{minimize} \quad 2 \sum_{v \in V(G)} p(v) + \sum_{v \in V(G') \setminus V(G)} p(v) + \sum_{e \in E(G')} q(e) + \beta k \quad (5a)$$

$$\text{subject to} \quad p(u) + p(v) + q(e) + \beta k(e) \geq w'(e) \quad (\forall e = (u, v) \in E(G')), \quad (5b)$$

$$p(v) \geq 0 \quad (\forall v \in V(G)), \quad (5c)$$

$$q \geq 0. \quad (5d)$$

We define the linear program (P') as (P'_k) without the inequality 4d. We denote the dual programs of (P) and (P') , respectively, as (D) and (D') , correspondingly. These dual programs differ from (D_k) and (D'_k) in that they do not contain the variable β .

► **Fact 5.3.** *Consider an optimal integral primal solution x^* of (P_k) and an optimal dual solution $p^*, q^*, \alpha^*, \beta^*$ of (D_k) . Define $M^* = \{e \in E : x^*(e) = 1\}$. From complementarity slackness we have the following:*

73:12 Restricted t -Matchings via Half-Edges

$$e \in M^* \implies p^*(u) + p^*(v) + q^*(e) + \sum_{s \in S: e \in E(s)} \alpha^*(s) + \beta^* = w(e)$$

$$(\forall e = (u, v) \in E(G))$$

$$\begin{aligned} v \text{ is deficient in } M^* &\implies p^*(v) = 0 & (\forall v \in V), \\ e \notin M^* &\implies q^*(e) = 0 & (\forall e \in E), \\ s \text{ is not saturated in } M^* &\implies \alpha^*(s) = 0 & (\forall s \in S). \end{aligned}$$

Similar constraints hold for the other linear programs. We identify a 2-matching with its incidence vector x .

Let us now explain how we use these linear programs. Observe that to show that G' contains no negative cycles, it suffices to demonstrate that M' is extreme in G' , or in other words, that M' is an optimal solution of (P'_k) . Below in Lemma 5.6 we prove that M' is extreme in G' if M is extreme in G . This means that we need to show that for every k , $0 \leq k \leq n$ in iteration k of Algorithm 1, the computed 2-matching M of size k is an optimal solution of (P_k) . Of course, the empty 2-matching is an optimal solution of (P_0) . Assuming that we have an extreme 2-matching of size $k-1$ in M , we build M' and G' and find a minimum M' -augmenting path in G' . Next we show that by applying P to M' we obtain an (l, u) -matching N of size k , which is extreme in G' . This (l, u) -matching N corresponds to a 2-matching M_1 of size k . We prove that the optimality of the solution N of (P'_k) implies the optimality of the solution M_1 of (P_k) .

► **Lemma 5.4.** *Consider any bipartite graph H and $l, u : V(H) \rightarrow \mathbb{N}_{\geq 0}$. Then an (l, u) -matching polytope is defined by the following inequalities:*

$$\begin{aligned} l(v) &\leq x(\delta(v)) \leq u(v) & (\forall v \in V(H)), \\ 0 &\leq x(e) \leq 1 & (\forall e \in E(H)). \end{aligned}$$

Proof. It is known that an incidence matrix of a bipartite graph is totally unimodular, hence incidence matrix A_H of H is totally unimodular. Observe that $P = \{x \in \mathbb{R}^{E(H)} : l \leq A_H x \leq u \wedge 0 \leq x \leq 1\}$, hence P is integral from theory of totally unimodular matrices. ◀

► **Lemma 5.5.** *Linear programs (P'_k) and (P') have integral optimal solutions.*

To compute a minimum M' -augmenting path in G' , we first find an M' -augmenting path P with minimum alternating weight. To be able to do this, we need to know that there are no negative cycles in G' . In the following lemma we prove the absence of negative cycles in G' . Next, if needed, we shorten P .

► **Lemma 5.6.** *Assume that M is an optimal solution to (P_k) . Then M' is an optimal solution to (P'_k) , and thus M' is extreme in G' . Hence, there are no negative cycles in G' .*

► **Lemma 5.7.** *Let M' be an extreme (l, u) -matching in G' and P a minimum M' -augmenting path. Then $N' = M' \oplus P$ is extreme in G' .*

The proof is almost identical to that of Theorem 17.2 in [32].

► **Lemma 5.8.** *Let P be a minimum M' -augmenting path and let $M'' = M' \oplus P$ and $N = \text{img}(M'')$.*

If $M' \oplus P$ is extreme in G' , then N is an optimal solution of (P_k) .

► **Lemma 5.9.** *Assume that M' is a maximum-weight (l, u) -matching of G' . Then M is a maximum-weight square-free 2-matching of G .*

► **Lemma 5.10.** *Let P be a minimum M' -augmenting path and let $M'' = M' \oplus P$ and $M_1 = \text{img}(M'')$. Then $w(M_1) = w'(M') - \tilde{w}'(P)$ and M_1 can contain only unproblematic squares. M_1 can be transformed into a square-free 2-matching M_2 such that $w(M_2) = w(M_1)$.*

Proof. At the beginning we show that $w(M_1) = w'(M'')$. We have that $w'(M'') = w'(M') - \tilde{w}'(P)$. Observe that the flipping of half-edges does not change the weight of M_1 . Hence $w(M_1) = w'(M'')$.

We observe that Fact 4.1 is still valid in the weighted case, because G' contains no negative alternating cycles. The same is true for Observation 4.6 because of Fact 4.1 and the following. We can shorten P going through d and u_s^2, b, c so that it uses three edges $(d, v_c^d), (v_c^d, v_d^c), (v_d^c, c)$ instead, because the weight of each of these two subpaths is the same and equal to $r(c) + r(d)$.

Next we notice that the proof of Lemma 4.7 goes through for the weighted setting as long as Lemma 4.2 is still valid. We now argue that it indeed is. It suffices to prove that if $s = (a, b, c, d)$ is such that $(a, b), (c, d) \in P \setminus M$, $(b, c), (a, d) \in M \setminus P$, then P can be shortened. Suppose that R is a subpath of P that consists of edges strictly between (a, b) and (c, d) and that a and d are its endpoints. (The case that b and c are the endpoints of R is symmetrical.) Let P_R be a path obtained from P by replacing its subpath R by an edge (a, d) . We show that $w'(P_R) \leq w'(P)$, contradicting the choice of P . w is vertex-induced on s , therefore, $w'(P) - w'(P_R) = w'(R) - w'(a, d) = w'(R) + w(a, d) = w'(R) + w(a, b) + w(c, d) - w(b, c) = w'(R) + w'(a, b) + w'(b, c) + w'(c, d) = w'(C)$ where C is an alternating cycle of G consisting of R and three edges of s . Recall that $w'(C) \geq 0$ because M is extreme. ◀

The corollary of Lemmas 4.8, 5.9 and 5.10 is:

► **Theorem 5.11.** *Algorithm 1 computes a maximum (resp. maximum weight) square-free 2-matching of G .*

6 Maximum-weight $K_{t,t}$ -free t -matchings in bipartite graphs

In this section we solve the weighted $K_{t,t}$ -free t -matching problem in bipartite graphs. Since the case of $t = 2$ has already been addressed in the previous section, we assume that $t \geq 3$. Also, similarly as in Section 5, we assume that the weight function w is vertex-induced on every $K_{t,t}$ of G . The general scheme of the algorithm for the weighted $K_{t,t}$ -free t -matching problem is similar to Algorithm 1- we give it below.

■ **Algorithm 2** Computing a maximum weight $K_{t,t}$ -free t -matching of a bipartite graph G .

-
- 1: Let M be an empty t -matching of G .
 - 2: Construct an auxiliary bipartite graph $G' = (V', E')$ with $\mathcal{O}(tn)$ vertices and $\mathcal{O}(m)$ edges, and its t -matching M' of size $\mathcal{O}(tn)$ by replacing some $K_{t,t}$'s of G with gadgets containing half-edges.
 - 3: Compute a minimum M' -augmenting path P of G' . If G' contains no M' -augmenting path with negative alternating weight, stop the algorithm and return M .
 - 4: Apply P to M' obtaining M'' and extract a $K_{t,t}$ -free t -matching M_1 of G from M'' such that $|M_1| = |M| + 1$ and $w(M_1) > w(M)$. Set M as M_1 and go to 2.
-

▷ **Claim 6.1.** Algorithm 2 runs in time $\mathcal{O}(tnm + t^2 n^2 \log n)$.

73:14 Restricted t -Matchings via Half-Edges

Proof. It is possible to implement all steps of an Algorithm 2 except 3 in linear time. Every step is executed $\mathcal{O}(tn)$ times since $|M|$ increases by one every time 4 is executed. \triangleleft

Let us also remark that in the unweighted version of the problem the runtime of Algorithm 2 is $\mathcal{O}(nm + tn^2 + \sqrt{tnm})$ because 3 can be implemented to run in linear time and the algorithm can start not from an empty matching but from a maximum $(t-1)$ -matching, whose computation takes $\mathcal{O}(\sqrt{tnm})$ time. Additionally, we may want to forbid only some subgraphs of G isomorphic to $K_{t,t}$. Then we proceed analogously, but replace only forbidden subgraphs with gadgets.

► **Definition 6.2.** A subgraph H of G isomorphic to $K_{t,t}$ is **saturated** if it contains exactly one non- M -edge.

► **Lemma 6.3.** Any two different saturated $K_{t,t}$'s of G are vertex-disjoint.

Proof. Let H be any saturated $K_{t,t}$ of G . We say that a vertex v of H is **basic** in H if v is an endpoint of the only non- M -edge of H . Otherwise, we say that v is **nonbasic** in H . Let $V_1(G) \cup V_2(G)$ denote the bipartition of $V(G)$. Thus H has exactly two basic vertices: one in $V_1(H)$ and the other in $V_2(H)$.

Let H_1 and H_2 be any two different saturated $K_{t,t}$'s of G with a common vertex $v \in V_1(G_1)$. We first show that it cannot happen that v is nonbasic both in H_1 and H_2 . Suppose to the contrary that v is nonbasic both in H_1 and H_2 . Then all t edges of M incident to v_1 belong both to H_1 and H_2 . Hence, we get that $V_2(H_1) = V_2(H_2)$. Since $t \geq 3$, at least one of the vertices of $V_2(H_1)$ is nonbasic both in H_1 and H_2 , which implies that $V_1(H_1) = V_1(H_2)$, but this contradicts the fact that H_1 and H_2 are different.

Suppose next that v is basic both in H_1 and H_2 . Then v has $t-1$ incident edges of M in H_1 and $t-1$ incident edges of M in H_2 . Since M is a t -matching, at least one of these edges, say (v, v') , belongs both to H_1 and H_2 . This however means that v' is nonbasic both in H_1 and H_2 (because the endpoints of an M -edge cannot be both basic in the same saturated $K_{t,t}$).

Finally, consider the case when v is basic in H_1 and nonbasic in H_2 . It means that at least two M -edges incident to v , say (v, v') and (v, v'') , belong to both H_1 and H_2 . Vertices v', v'' belong to $V_2(H_2)$, none of them is basic in H_1 and at most one is basic in H_2 . Therefore, at least one of them is nonbasic both in H_1 and H_2 - a contradiction. \triangleleft

► **Observation 6.4.** All saturated $K_{t,t}$'s of G can be found in linear time.

Proof. We can use a linear time algorithm by Galil and Italiano [10]. \triangleleft

We replace every saturated $K_{t,t}$ of G with a gadget described below. By Lemma 6.3, all saturated $K_{t,t}$'s of G are vertex-disjoint.

The construction of the gadget for a saturated $K_{t,t}$ is the following. Let H be any $K_{t,t}$ of G , $A_H = \{a_1, a_2, \dots, a_t\}$ be a set of vertices of one side of H and $B_H = \{b_1, b_2, \dots, b_t\}$ - of the other side. Let $r : V(H) \rightarrow \mathbb{R}$ be a potential function of H . Assume that $(a_1, b_1) \notin M$. For every edge (a_i, b_j) of H , we introduce two subdivision vertices, $v_{b_j}^{a_i}$, $v_{a_i}^{b_j}$, two half-edges and one eliminator. We remove an eliminator of (a_1, b_1) . We set the weight of every half-edge incident to $v \in V(H)$ to $r(v)$. Additionally, we add u_s^1 and u_s^2 to G' . We connect u_s^1 to every subdivision vertex adjacent to some vertex of A_H and we connect u_s^2 to every subdivision vertex adjacent to some vertex of B_H . We add all half-edges of this gadget except for $(a_1, v_{b_1}^{a_1})$ and $(b_1, v_{a_1}^{b_1})$ to M' . Additionally, we add $(u_s^1, v_{b_1}^{a_1})$ and $(u_s^2, v_{a_1}^{b_1})$ to M' .

■ **Figure 3** A gadget for a problematic $K_{3,3}$.

7 Restricted matchings

In this section we consider the following variant of the Restricted Matching Problem. We are given (1) a (not necessarily bipartite) graph $G = (V, E)$, (2) a natural number k , (3) a set of k subsets of edges E_1, E_2, \dots, E_k such that for each $1 \leq i \leq k$ (i) the graph G contains a clique or a bipartite clique on all endpoints of E_i ; in the case of a bipartite clique, it contains the whole set E_i and (ii) the sets E_1, \dots, E_k are almost vertex-disjoint - the endpoints of any two different cliques have at most one vertex in common and (4) k natural numbers r_1, r_2, \dots, r_k . The task is to find a maximum size matching M of G among ones that satisfy the condition: for each $1 \leq i \leq k$ it holds that M contains at most r_i edges of E_i . Any matching M of G that satisfies: for each $1 \leq i \leq k$ $|M \cap E_i| \leq r_i$ is called a **restricted matching**.

To solve this problem we construct a graph G' with gadgets for each of the sets E_i . The construction of G' is similar to the one used for square-free 2-matchings. The precise construction of G' is the following. We start off with $G' = G$. For each $1 \leq i \leq k$ we build a subgraph, called a **gadget for E_i** . Let $n_i = |E_i|$. Each edge (p, q) of E_i is replaced with three new edges $(p, v_q^p), (v_q^p, v_p^q), (v_p^q, q)$, two of which are half-edges of (p, q) and the third one the eliminator of (p, q) . If G contains a clique on all endpoints of E_i we introduce one new global vertex u_i and connect it with every subdivision vertex of an edge belonging to E_i . We set the interval of u_i as $[2n_i - 2r_i, 2n_i - 2r_i]$. If G contains a bipartite clique $K_i = (A_i \cup B_i, E_i)$ on all endpoints of E_i we introduce two new global vertices u_i^1 and u_i^2 . We connect u_i^1 with every subdivision vertex of an edge of E_i , which is a neighbour of a vertex of A_i and similarly, we connect u_i^2 with every subdivision vertex of an edge of E_i , which is a neighbour of a vertex of B_i . We set the interval of both u_i^1 and u_i^2 as $[n_i - r_i, n_i - r_i]$. Let $N = \sum_{i=1}^k n_i$, $R = \sum_{i=1}^k r_i$ and $E_R = \bigcup_{i=1}^k E_i$.

An (l, u) -matching M' of G' is to represent roughly a restricted matching M of G . If M' contains both half-edges of some edge $e \in E_R$, then e is included in M . If M' contains an eliminator of e , then e does not belong to M (is excluded from M). The intuition behind the gadget for the set E_i is that the global vertex or vertices in it are required to be matched to $2n_i - 2r_i$ subdivision vertices of edges of E_i . In this way they block $2n_i - 2r_i$ half-edges, which means that at most $2n_i - (2n_i - 2r_i) = 2r_i$ half-edges of edges of E_i can be present in M' . This implies that at most r_i edges of E_i can appear in the matching M .

► **Theorem 7.1.** *Any maximum (l, u) -matching M' of G' yields a maximum restricted matching of G .*

Proof. Any restricted matching M of G corresponds to an (l, u) -matching M_1 of G' such that $|M_1| = |M| + 2N - R$. To construct such M_1 we proceed as follows. We set M_1 to an empty (l, u) -matching. For each $e \in M \cap E_R$, we add both half-edges of e to M_1 . For each edge $e \in M \setminus E_R$, we add e to M_1 . Next for each $1 \leq i \leq k$ there exist at least $n_i - r_i$ edges of E_i that do not belong to M . We choose any such $(n_i - r_i)$ -element subset $F_i \subseteq E_i$ and for each $e \in F_i$ we connect in M_1 the global vertex/the global vertices $u_i/u_i^1, u_i^2$ to the two subdivision vertices of e . For every edge e of $E_i \setminus (M \cup F_i)$ we add the eliminator of e to M_1 . Let us note that the size of any (l, u) -matching N' of G' satisfies: $2|N'| = \sum_{v \in V} \deg_{N'}(v) + \sum_{v \in V' \setminus V} \deg_{N'}(v) = \sum_{v \in V} \deg_{N'}(v) + 4N - 2R$. This means that the thus constructed M_1 has size $|M| + 2N - R$.

Consider now any (l, u) -matching M' of G' . If for every edge $e \in E_r$ it holds that either both half-edges of e are contained in M' or none, then we say that M' is *integral*. Every integral M' yields a restricted matching M of G such that $|M| = |M'| - 2N + R$. We next show that even when M' is not integral, we are able to build a restricted matching M such that $|M| = |M'| - 2N + R$. We only need to say what to do with half-edges, i.e., with those edges of E_r for which M' contains only one of their half-edges. We deal with each set E_i separately. Suppose first that E_i is such that the graph G contains a clique on all endpoints of E_i . Let us notice that the number of edges of E_i with exactly one of its half-edges contained in M' is even. Let F_i denote such edges and V'_i denote those endpoints of edges of F_i that are incident to some half-edge of an edge of F_i . Then $|V'_i|$ is even. We pair vertices of V'_i in an arbitrary way and for two vertices u, u' belonging to one pair we replace two half-edges of M' incident with u and u' with one edge (u, u') of M . The case when G contains a bipartite clique on all endpoints of E_i is analogous. ◀

Beating Random Assignment for Approximating Quantum 2-Local Hamiltonian Problems

Abstract

The quantum k -Local Hamiltonian problem is a natural generalization of classical constraint satisfaction problems (k -CSP) and is complete for QMA, a quantum analog of NP. Although the complexity of k -Local Hamiltonian problems has been well studied, only a handful of approximation results are known. For Max 2-Local Hamiltonian where each term is a rank 3 projector, a natural quantum generalization of classical Max 2-SAT, the best known approximation algorithm was the trivial random assignment, yielding a 0.75-approximation. We present the first approximation algorithm beating this bound, a classical polynomial-time 0.764-approximation. For strictly quadratic instances, which are maximally entangled instances, we provide a 0.801 approximation algorithm, and numerically demonstrate that our algorithm is likely a 0.821-approximation. We conjecture these are the hardest instances to approximate. We also give improved approximations for quantum generalizations of other related classical 2-CSPs. Finally, we exploit quantum connections to a generalization of the Grothendieck problem to obtain a classical constant-factor approximation for the physically relevant special case of strictly quadratic traceless 2-Local Hamiltonians on bipartite interaction graphs, where a inverse logarithmic approximation was the best previously known (for general interaction graphs). Our work employs recently developed techniques for analyzing classical approximations of CSPs and is intended to be accessible to both quantum information scientists and classical computer scientists.

1 Introduction

The design and analysis of approximation algorithms [37, 38] is an extensively studied area in theoretical computer science. In this setting, we are given some (generally NP-hard) optimization problem, and we are tasked with producing a valid (feasible) solution with objective within some provable factor of the optimal objective value. To understand this formally imagine we are given some optimization problem \mathcal{P} , which corresponds to an infinite set of problem instances $\{P_i\}$. Each problem instance corresponds to a triple $P_i = (f_i, \mathcal{T}_i, n_i)$ where $n_i \in \mathbb{N}_+$, $\mathcal{T}_i \subseteq \{0, 1\}^{n_i}$, and $f_i : \mathcal{T}_i \rightarrow \mathbb{R}_+$ is an objective function. This gives rise to an optimization problem of the form: $OPT_i = \max_{s \in \mathcal{T}_i} f_i(s)$.

An approximation algorithm \mathcal{A} acts on an efficient description of an instance to produce some feasible solution to the problem: $\mathcal{A}(f_i, \mathcal{T}_i, n_i) = \bar{s}_i \in \mathcal{T}_i$ in time polynomial in the instance size (polynomial in n_i). It is said that algorithm has approximation factor α for $0 < \alpha \leq 1$ if in the worst-case (over all instances), the solution produced by the algorithm is a factor of α off of the optimal answer:

$$\min_i \frac{f_i(\bar{s}_i)}{OPT_i} \geq \alpha.$$

Since we should not expect to solve NP-hard problems in polynomial time, an interesting question is then the approximability of NP-hard optimization problems, or the study of which approximation factors α are obtainable for different problems. As one might expect, approximability is highly problem sensitive and there are many classes of natural problems with widely varying approximability [15, 17, 23, 37, 38].

2-Local Hamiltonian. In stark contrast, although QMA-hard quantum optimization problems arise naturally through well-known physically motivated problems [5, 35], they have very few known approximation algorithms with provable approximation factors [2, 4, 8, 11, 18, 19, 21, 22, 31]¹. The QMA-hard optimization studied in these works, as well as the problem we will study here, is the *2-Local Hamiltonian problem* [24, 25].

An instance of this problem is specified by a problem size, n , as well as a set of 2-local interactions (i.e., interactions on pairs of qubits), $\{H_{ij}\}_{ij \in E}$. Each $H_{ij} \in \mathbb{C}^{2^n \times 2^n}$ is some *local* Hamiltonian which can be written as the tensor product of $n - 2$ identity terms with some nontrivial operator, $\mathcal{O}_{ij} \in \mathbb{C}^{4 \times 4}$, that acts on at most 2 qubits, i.e. $H_{ij} = \mathcal{O}_{ij} \otimes \mathbb{I}_{[n] \setminus \{i,j\}} \in \mathbb{C}^{2^n \times 2^n}$ (see Section 2.1 for notation). The optimization problem corresponding to a particular instance is to find the smallest or largest eigenvalue, λ_{\min} or λ_{\max} , of $H = \sum_{ij \in E} H_{ij}$.

► **Problem 1** (QLH: Quantum Max 2-Local Hamiltonian). *Given a problem size, n , as well as a classical description of a set of 2-local terms $\{H_{ij} = \mathcal{O}_{ij} \otimes \mathbb{I}_{[n] \setminus \{i,j\}}\}_{ij \in E}$ with $H_{ij} \in \mathbb{C}^{2^n \times 2^n}$ Hermitian, find:*

$$\lambda_{\max}(H) := \max_{|\phi\rangle \in (\mathbb{C}^2)^{\otimes n}} \langle \phi | H | \phi \rangle = \max_{\substack{\rho \in \mathbb{C}^{2^n \times 2^n} \\ \text{Tr}(\rho)=1, \rho \succeq 0}} \text{Tr}[H\rho], \text{ where } H := \sum_{ij \in E} H_{ij}.$$

Ideally, an algorithm solving this problem would also produce a description of or access to a corresponding eigenvector. We will focus on approximating λ_{\max} for special cases of 2-local Hamiltonian. Although exactly computing $\lambda_{\max}(H)$ is equivalent to computing $\lambda_{\min}(-H)$, the approximability of these problems can differ. An approximation algorithm, \mathcal{A} , acts on the description of the local Hamiltonians $\{H_{ij}\}$ to produce a classical description of a valid quantum state, $\bar{\rho}$. Once again we say that the algorithm achieves approximation factor α if:

$$\frac{\text{Tr}\left[\left(\sum_{ij} H_{ij}\right) \bar{\rho}\right]}{\lambda_{\max}\left(\sum_{ij} H_{ij}\right)} \geq \alpha, \text{ for all instances.}$$

¹ Here and throughout this paper we mean a *classical* algorithm which takes as input a classical description of a quantum problem and produces a classical description of a quantum state. An approximation algorithm for a QMA-hard problem can have several natural meanings distinct from this (quantum input, quantum algorithm which produces classical output, etc.).

Generally we assume some property of the Hamiltonian which forces $\lambda_{\max}(H) > 0$ so that this is a sensible definition. A common assumption [18, 21, 24] is that the terms H_{ij} are positive semi-definite (PSD) and nonzero. We note that when all of the terms H_{ij} are taken to be diagonal projectors (in say, the standard computational basis), the corresponding instance of 2-Local Hamiltonian corresponds precisely to an instance of the classical 2-Constraint-Satisfaction problem (2-CSP). In this case, the 4 diagonal entries of \mathcal{O}_{ij} correspond to the $\{0, 1\}$ output values of a Boolean function on variables x_i and x_j corresponding to i and j . See Appendix E in [30] for more details as well as a classical motivation for 2-Local Hamiltonian. In addition Table 1 highlights classical 2-CSP specializations of quantum Max 2-local Hamiltonian problems for which approximation algorithms are known.

The 2-Local Hamiltonian problem is interesting in many different contexts of physics and quantum information [24, 25, 29]. This problem is manifestly interesting to physicists because the 2-local nature of the problem matches the local nature of many physical systems (spin chains, Ising model, etc.). Hence, the study of eigenstates and energies is of utmost importance, and has been since the beginnings of quantum mechanics itself [6]. From a theoretical computer science perspective, the 2-Local Hamiltonian problem is interesting for the same reasons that classical approximation algorithms are interesting. Under standard complexity theoretic assumptions, we should not expect to be able to efficiently solve the problem, so the interesting direction is the study of the approximability of the problem. Can we find rigorous approximation algorithms, and how well can we expect to be able to approximate the answer? Moreover, which classes of instances admit constant-factor approximation algorithms? Akin to the classical PCP Theorem, the potential inapproximability of local Hamiltonian problems to within constant factors is known as the Quantum PCP Conjecture. The resolution of the conjecture would yield insight into properties of quantum mechanics and entanglement (e.g., Section 1.3 in [1]).

1.1 Our Contributions

The QLH problems we consider generalize a variety of classical optimization problems, including Max 2-SAT, Max Cut, general Max 2-CSP, and the Grothendieck problem (see Table 1 for our results). We focus on QLH where each term H_{ij} is a projector and the special case where each projector is strictly quadratic, both of which remain QMA-hard [32]. The strictly quadratic case precludes non-identity 1-local terms (i.e. $\mathcal{O}_i \otimes \mathbb{I}_{[n] \setminus \{i\}}$ with $\mathcal{O}_i \neq \mathbb{I}$) that may be implicit in a 2-local term (see Definition 8). In this case $\mathcal{O}_{ij} = w_{ij}P_{ij}$, where P_{ij} is a 2-qubit projector, and $w_{ij} \geq 0$ is a weight. There are three interesting cases, depending on the rank of P_{ij} . We will obtain approximation factors for each.

► **Problem 2 (QLHP(k): Quantum Max 2-Local Hamiltonian on Projectors).** *Given a problem size, n , as well as a classical description of a set of 2-local terms $\{H_{ij} = w_{ij}P_{ij} \otimes \mathbb{I}_{[n] \setminus \{i,j\}}\}_{i,j \in E}$ with $w_{ij} \geq 0$ and $P_{ij} \in \mathbb{C}^{4 \times 4}$ a 2-qubit projector of rank at least k , find $\lambda_{\max}(\sum_{i,j \in E} H_{ij})$.*

► **Remark 3.** Although Problem 2 is formulated for a single term H_{ij} per pair of qubits i, j , our techniques apply when multiple terms are present per pair. Since any $\mathcal{O}_{ij} \succeq 0$ can be written as a positive combination of rank-1 projectors, the version of QLHP(1) we solve more generally captures instances of QLH where each $H_{ij} \succeq 0$.

► **Theorem 4 (Informal).** *Given an instance of QLHP(k), $\{H_{ij} = w_{ij}P_{ij} \otimes \mathbb{I}_{[n] \setminus \{i,j\}}\}$, where all 2-local projectors P_{ij} are rank $k \in \{1, 2, 3\}$, we give a classical randomized polynomial-time algorithm with approximation ratio $\alpha(k)$, where*

$$\alpha(k) = \begin{cases} 0.387 & \text{if } k = 1 \\ 0.565 & \text{if } k = 2 \\ 0.764 & \text{if } k = 3. \end{cases}$$

► **Theorem 5 (Informal).** *If in addition to the assumptions of Theorem 4, the terms H_{ij} are strictly quadratic, we give a classical randomized polynomial-time algorithm with approximation ratio $\alpha(k)$, where*

$$\alpha(k) = \begin{cases} 0.467 & \text{if } k = 1 \\ 0.639 & \text{if } k = 2 \\ 0.805 & \text{if } k = 3. \end{cases}$$

The decision version of the problem we consider is known as Quantum-SAT and was introduced in 2006 by Bravyi [10], and the approximability of QLHP was first considered in 2011 by Gharibian and Kempe [18], who observed that the maximally mixed state trivially achieves an approximation ratio of $k/4$ for $k \in \{1, 2, 3\}$. The only nontrivial result previously known is a 0.328-approximation for the $k = 1$ case by Hallgren, Lee, and Parekh [21]. In contrast to previous works [19, 21], we are able to directly analyze the expected performance of our algorithm rather than appealing to known but weaker black-boxes.

Significance of our work. We give the first approximation algorithms beating random assignment for QLHP. We show how to move beyond numerical evaluation of approximation ratios for QLH, which is not as critical in the classical case that enjoys only a handful of parameters. This is accomplished by: (1) reducing the number of parameters for analysis of a single term from 18 to 3 (in the strictly quadratic case), and (2) explicitly computing the coefficients of a Hermite decomposition of a multivariate Gaussian expectation. The latter generalizes previous results of Briët, de Oliveira Filho, and Vallentin [13] employed in [19]. We are able to analyze a natural generalization of classical hyperplane rounding that we expect will enable approximation of other QLH problems.

Strictly quadratic instances. We believe the strictly quadratic case is an interesting special case for several reasons. As noted, one of the difficulties in analyzing rounding schemes for QLH is the sheer number of parameters involved. The quadratic case reduces the number of parameters to consider, while still including physically relevant QMA-hard instances such as the Max Heisenberg model that serves as a quantum generalization of Max Cut [19]. Indeed we believe that quadratic instances allow one to glean insights and develop techniques that might otherwise be obscured in more general instances. Some of the first rigorous approximation algorithms for QLH that go beyond product states were recently developed for quantum Max Cut [2, 31]. Moreover, maximally entangled instances are strictly quadratic, and we conjecture these are the hardest cases to approximate.

Numerical results and upper bounds. We conjecture that the true performance of our algorithm for general QLHP, including linear terms, is:

► **Conjecture 6.** (Informal) Our rounding algorithm achieves approximation ratio:

$$\alpha(k) = \begin{cases} 0.498 & \text{if } k = 1 \\ 0.653 & \text{if } k = 2 \\ 0.821 & \text{if } k = 3, \end{cases}$$

and these quantities match the worst-case gap between OPT and our SDP upper bound.

We have indeed confirmed the approximation ratios in Conjecture 6 through numerical experiments. The difficulty in taking these encouraging results as fact is: (1) the increase in complexity for an exhaustive search as the number of parameters grows, and (2) although we do give series expansions for the expected performance of the algorithm, establishing smoothness of the expected performance is more difficult than for classical CSP approximation algorithms. Classical 2-CSP approximation factors are also established numerically; however, the performance is usually a well-behaved function of a single parameter, which makes exhaustive numerical search more plausible. There has been limited work on rigorous analysis of 2-CSP approximation guarantees [36]. We note that for the strictly quadratic case, our approach requires a search over only three parameters, rendering these numerical results more plausible. We also note that the performance of a similar approximation algorithm for quantum Max Cut, a special case of QLPH(1), is a hypergeometric function in one parameter, and the corresponding approximation guarantee is indeed 0.498 [19].

An upper bound on $\alpha(k)$ is given below for an instance of QLPH(k) on 2 qubits, with multiple edges that are each strictly quadratic rank- k projectors. These bounds are fairly close to the values in Conjecture 6.

► **Theorem 7.** There exist an instance of QLH on a single edge e , where $H_e \succeq 0$ is strictly quadratic, is a convex combination of rank- k projectors, and satisfies:

$$\max_{|\phi_1\rangle \in \mathbb{C}^2, |\phi_2\rangle \in \mathbb{C}^2} \langle \phi_1 | \otimes \langle \phi_2 | H_e | \phi_1 \rangle \otimes | \phi_2 \rangle \leq \beta(k) \cdot \lambda_{\max}(H_e),$$

$$\text{where } \beta(k) = \begin{cases} 1/2 & \text{if } k = 1 \\ 2/3 & \text{if } k = 2 \\ 5/6 & \text{if } k = 3. \end{cases}$$

Proof. The Bell states take their usual definition:

$$|\Phi^+\rangle = \frac{|00\rangle + |11\rangle}{\sqrt{2}}, \quad |\Phi^-\rangle = \frac{|00\rangle - |11\rangle}{\sqrt{2}}, \quad |\Psi^+\rangle = \frac{|01\rangle + |10\rangle}{\sqrt{2}}, \quad \text{and } |\Psi^-\rangle = \frac{|01\rangle - |10\rangle}{\sqrt{2}}.$$

We define,

$$H_e(k) = \frac{k-1}{3} \mathbb{I} + \frac{4-k}{3} |\Psi^-\rangle \langle \Psi^-|.$$

Let $\mu(k) = \max_{|\phi_1\rangle \in \mathbb{C}^2, |\phi_2\rangle \in \mathbb{C}^2} \langle \phi_1 | \otimes \langle \phi_2 | H_e(k) | \phi_1 \rangle \otimes | \phi_2 \rangle$. From, e.g., [19], we know that $\mu(1) = 1/2$, while $\lambda_{\max}(H_e(1)) = 1$ since $|\Psi^-\rangle$ is an eigenvector of the rank-1 projector $H_e(1)$. For $k > 1$ we have that

$$\begin{aligned} \mu(k) &= \frac{k-1}{3} + \frac{4-k}{3} \mu(1) = \frac{k+2}{6}, \text{ and} \\ \lambda_{\max}(H_e(k)) &= \frac{k-1}{3} + \frac{4-k}{3} \lambda_{\max}(H_e(1)) = 1, \end{aligned}$$

yielding the desired values of $\beta(k)$. We give explicit descriptions of $H_e(k)$ as convex combinations of rank- k projectors for $k = 2, 3$:

$$\begin{aligned} H_e(2) &= \frac{1}{3}(|\Psi^-\rangle\langle\Psi^-| + |\Phi^+\rangle\langle\Phi^+|) + \frac{1}{3}(|\Psi^-\rangle\langle\Psi^-| + |\Phi^-\rangle\langle\Phi^-|) \\ &\quad + \frac{1}{3}(|\Psi^-\rangle\langle\Psi^-| + |\Psi^+\rangle\langle\Psi^+|), \text{ and} \\ H_e(3) &= \frac{1}{3}(\mathbb{I} - |\Phi^+\rangle\langle\Phi^+|) + \frac{1}{3}(\mathbb{I} - |\Phi^-\rangle\langle\Phi^-|) + \frac{1}{3}(\mathbb{I} - |\Psi^+\rangle\langle\Psi^+|). \end{aligned}$$

1.2 Related Work

In the interest of classical approximations of a 2-Local Hamiltonian instance H , let $OPT := \lambda_{\max}(H)$ and define

$$OPT_{\text{prod}} := \max_{\substack{|\phi_1\rangle, \dots, |\phi_n\rangle \\ \in \mathbb{C}^2}} \langle \phi_1 | \otimes \dots \otimes \langle \phi_n | H | \phi_1 \rangle \otimes \dots \otimes | \phi_n \rangle$$

to be the product state² with the largest objective value or *energy*.

Approximations for QLH generally make assumptions on the form of the terms H_{ij} . One common assumption is on the *geometry* of the interactions in E . Bansal, Bravyi, and Terhal show that 2-Local Hamiltonian on bounded-degree planar graphs admits a polynomial-time approximation scheme³ (PTAS) [4], and Brandão and Harrow generalize this to arbitrary planar graphs [8]. On the other end, for k -Local Hamiltonian on dense graphs, Gharibian and Kempe give a PTAS with respect to OPT_{prod} [18], and Brandão and Harrow extend this result to obtain a PTAS for dense graphs with respect to OPT [8]. Brandão and Harrow also show the existence of product-states with energy nearly that of OPT or give product-state approximations for a variety of graph classes [8].

Bravyi, Gosset, König, and Temme give an $\Omega(\frac{1}{\log n})$ -approximation for traceless⁴ QLH [11]. This case is general enough to capture classical problems with no constant-factor approximations [3]. Harrow and Montanaro give an approximation algorithm for traceless k -Local Hamiltonian with respect to the maximum degree and size of the interaction hypergraph [22]. Note that approximating traceless QLH generalizes all problems considered in this paper, since adding copies of the identity only improves the approximation factor; however there is no reason to expect such analysis could be used to prove constant factor approximations for the classes we study.

A unifying theme among recent approaches (see Table 1 for approximation guarantees) is employing a semi-definite program (SDP) to provide an upper bound on OPT and then using generalization of some classical randomized rounding scheme to produce a product state [11, 19, 21]. Such an approach was first carried out by Brandão and Harrow [8]. Gharibian and Parekh [19] consider a QMA-hard rank-1 QLHP problem that is a generalization of the classical Max Cut problem. Hallgren, Lee, and Parekh [21] study QLHP and give the first approximation beating random assignment for rank-1 QLHP. They also provide

² As is suggested by the expression, a product state is a quantum state which factors according to tensor product of individual quantum states. Such states have no entanglement and are considered “classical” states.

³ This is an approximation algorithm that for a constant $\varepsilon > 0$, allows a $1-\varepsilon$ approximation factor at the expense of a runtime that depends on $1/\varepsilon$.

⁴ A traceless instance is one with $\text{Tr}[H] = 0$. Alternatively, when expressed as a polynomial in the Pauli basis, H is traceless if it has no identity term.

approximations when each term is a product term, $H_{ij} = H_i \otimes H_j$, which is a QMA-hard class of QLH. An approximation result of [8] leverages the quantum Lasserre hierarchy of SDPs. The first level of this hierarchy yields a natural SDP relaxation that is employed by [11] and [19]. Our work adopts the approach of [21] and strengthens the natural SDP relaxation with additional constraints related that enforce positivity of 2-qubit marginals. Both [19] and [21] appeal to approximation results of Briët, de Oliveira Filho, and Vallentin [12, 13] to analyze the expected performance of their rounding algorithms. The rounding scheme of [11] is a generalization of a classical approximation by Charikar and Wirth [14].

Beyond product states. Gharibian and Parekh [19] give a 0.498-approximation for their quantum generalization of Max Cut, where $\frac{1}{2}$ is the best possible approximation by product states (see Theorem 7). Anshu, Gosset, and Morenz [2] demonstrate that it is possible to beat a $\frac{1}{2}$ -approximation for quantum Max Cut by furnishing a classical randomized approximation that outputs a description of a tensor product of 1- and 2-qubit states rather than product states, which are tensor products of 1-qubit states. This result does not rely on an SDP as an upper bound on OPT , instead appealing to well-known monogamy of entanglement bounds for the Heisenberg model. Parekh and Thompson [31] observe that a similar type of approximation is possible using the second level of the quantum Lasserre hierarchy and obtain a slight improvement over the approximation ratio of [2].

Although these results may seem to suggest that the future of approximation algorithms for QLH should look beyond product states, a solid understanding of the approximability of product states is likely necessary for *any* type of general approximation algorithm for QLH. Brandão and Harrow [8] show that for (certain generalizations of) regular graphs, OPT_{prod} approaches OPT as the degree increases. Indeed, trading off product-state approximations with more general quantum states is a key ingredient in both [2] and [31].

2 Semidefinite Relaxation and Rounding Approach

In this section we present a rigorous but high-level overview of our approach, with technical lemmas deferred to later sections. We define the main problems considered and our semidefinite relaxation and rounding algorithm. We conclude by motivating the analysis that will occur in detail in the full version of this paper, [30].

2.1 Preliminaries

Quantum information notation. We adopt some standard notations used in quantum information [28]. The *kets* $|0\rangle := [0, 1]$ and $|1\rangle := [1, 0]$ represent the standard basis vectors for \mathbb{C}^2 , while the *bras* $\langle 0|$ and $\langle 1|$ represent their conjugate transposes. The $d \times d$ identity matrix is denoted by \mathbb{I}_d , and the subscript will be omitted when redundant. We obtain the standard bases for \mathbb{C}^{2^n} as $|b_1 b_2 \dots b_n\rangle := |b_1\rangle |b_2\rangle \dots |b_n\rangle := |b_1\rangle \otimes |b_2\rangle \otimes \dots \otimes |b_n\rangle$, with $b_i \in \{0, 1\}$. The Pauli matrices will have the usual definition:

$$\sigma^0 = \mathbb{I} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad \sigma^1 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad \sigma^2 = \begin{bmatrix} 0 & -i \\ i & 0 \end{bmatrix}, \text{ and } \sigma^3 = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}. \quad (1)$$

We will generally use subscripts to indicate quantum subsystems. If ρ is a density matrix on n qubits, for instance, ρ_{ij} will correspond to the marginal density matrix on qubits i and j , i.e. the partial trace $\rho_{ij} = \text{Tr}_{[n] \setminus \{i, j\}}[\rho]$ (e.g. [28], Section 2.4.3). Similarly, σ_i^j corresponds to Pauli j on qubit i . Subscripts will supercede position in many cases in the paper, for instance $\sigma_i^1 \otimes \sigma_j^2 \otimes \mathbb{I}_{[n] \setminus \{i, j\}}$ is meant as $\mathbb{I} \otimes \mathbb{I} \otimes \dots \otimes \sigma^1 \otimes \dots \otimes \mathbb{I} \otimes \sigma^2 \otimes \dots \otimes \mathbb{I}$ where σ^1 is at

■ **Table 1 Approximation algorithms for Max 2-local Hamiltonian problems.** The number of qubits or Boolean variables is n , and the set of pairwise constraints is E . For readability in the table below, we omit weights $w_{ij} \geq 0$ that may be present in both 2-local Hamiltonian (2-LH) and related classical constraint satisfaction (2-CSP) problems. [30] provides more details on the relationship between 2-LH and 2-CSP, as well as definitions for X_i, Y_i, Z_i . An “N” denotes a numerical result; the classical results are implicitly numerical since they are obtained by numerically finding the worst-case ratio over a range of parameters. The abbreviation “quad.” refers to strictly quadratic instances.

Max 2-LH problem (QMA-hard)	Max 2-CSP specialization (NP-hard)	Classical approx. for 2-CSP	Classical approx. for 2-LH problem (product state)
Traceless $\sum_{ij \in E} H_{ij} \otimes \mathbb{I}_{[n] \setminus \{ij\}}$ H_{ij} has no \mathbb{I} terms	Classical Ising $\max -\sum_{ij \in E} z_i z_j$ $z_i \in \{\pm 1\}$	$\Omega(\frac{1}{\log n})$ [14]	$\Omega(\frac{1}{\log n})^\dagger$ [11]
Bipartite Traceless $\sum_{e \in E} H_{ij} \otimes \mathbb{I}_{[n] \setminus \{ij\}}$ H_{ij} has no \mathbb{I} terms E bipartite	Grothendieck $\max -\sum_{ij \in E} z_i z_j$ $z_i \in \{\pm 1\}$ E bipartite	$0.561 + \varepsilon$ [9]	0.187[†](quad.)
Positive/Rank 1 $\sum_{ij \in E} H_{ij} \otimes \mathbb{I}_{[n] \setminus \{ij\}}$ $\mathbb{I} \succeq H_{ij} \succeq 0$ ($\equiv H_{ij}$ rank 1 projector)	Max 2-CSP ($\equiv 1$ satisfying assignment per clause)	0.874 [27]	0.25 (random) 0.328 [21] 0.387 0.467 (quad.) 0.498 (quad., N) 0.5 (upper bound)

Rank 2 $\sum_{ij \in E} H_{ij} \otimes \mathbb{I}_{[n] \setminus \{ij\}}$ H_{ij} rank 2 projector	Max 2-CSP with 2 satisfying assignments/clause	0.874 [27]	0.5 (random) 0.565 0.639 (quad.) 0.653 (quad., N) 0.667 (upper bound)
2-QSAT $\sum_{ij \in E} H_{ij} \otimes \mathbb{I}_{[n] \setminus \{ij\}}$ H_{ij} rank 3 projector	Max 2-SAT ($\equiv 3$ satisfying assignments/clause)	0.940 [27]	0.75 (random) 0.764 0.805 (quad.) 0.821 (quad., N) 0.834 (upper bound)

* This exceeds the product-state upper bound because it is achieved by a classical approximation algorithm that rounds to a description of a non-product state.

† For any traceless 2-LH problem, we obtain a product-state approximation ratio that is $\frac{1}{3}$ of an approximation ratio for a related classical CSP, using the appropriate classical approximation algorithm as a black box (see Appendix F in the extended version of this article [30]). This also gives another algorithm and proof for the result of [11] in the first row.

the i th position and σ^2 is at the j th position. We encourage readers familiar with classical constraint satisfaction problems to consult Appendix E in [30], which casts such problems as quantum local Hamiltonian problems.

2-local Hamiltonian. Our approximations for QLHP allow multiedges, i.e. distinct edges e and e' on the same pair of qubits i, j . For the sake of exposition, we generally ignore this possibility and conduct our analysis assuming we have a single term H_{ij} for each $ij \in E$. However, when necessary, we will use the notation e_1 and e_2 to refer to the qubits on which an edge e acts. In this context a term H_e is 2-local if it can be written in the form $H_e = \mathcal{O}_e \otimes \mathbb{I}_{[n] \setminus \{e_1, e_2\}}$. Local Hamiltonians have polynomially-sized descriptions which can be given in terms of the local operators \mathcal{O}_e , but for our purposes the details of the description will not be important. We will use $\text{rank}(H_e)$ to mean $\text{rank}(\mathcal{O}_e)$. The actual rank of H_e is $\text{rank}(\mathcal{O}_e)2^{n-2}$, but for ease of exposition we will say that the “rank” of a 2-local term is equal to the rank of its non-trivial part.

The bulk of our work focuses on strictly quadratic instances of QLHP, allowing us to express our main ideas more clearly. The strictly quadratic case precludes non-identity 1-local terms (i.e. $\mathcal{O}_i \otimes \mathbb{I}_{[n] \setminus \{i\}}$ with $\mathcal{O}_i \neq \mathbb{I}$) that may be implicit in a 2-local term.

► **Definition 8 (Strictly Quadratic).** Let H_e be a 2-local term on n qubits. Write $H_e = \mathcal{O}_e \otimes \mathbb{I}_{[n] \setminus \{e_1, e_2\}}$ for some nontrivial operator \mathcal{O}_e . Express \mathcal{O}_e in the Pauli basis as:

$$\mathcal{O}_e = \sum_{k,l=0}^3 \alpha_{k,l} \sigma^k \otimes \sigma^l. \quad (2)$$

We say that H_e is a strictly quadratic if $\alpha_{k,0} = 0$ for all $k \neq 0$, and $\alpha_{0,l} = 0$ for all $l \neq 0$.

Note that the coefficients in Equation (2) may be obtained as $\alpha_{k,l} = \text{Tr}[(\sigma^k \otimes \sigma^l) \mathcal{O}_e] / 4$ and are real since \mathcal{O}_e is Hermitian.

Example. An example of a strictly quadratic instance of QLH is quantum Max Cut [19], where for all $ij \in E$, $\mathcal{O}_{ij} = \frac{1}{4}(\mathbb{I} - \sigma^1 \otimes \sigma^1 - \sigma^2 \otimes \sigma^2 - \sigma^3 \otimes \sigma^3)$. In this case $\mathcal{O}_{ij} = |\Psi^- \rangle \langle \Psi^-|$, with $|\Psi^- \rangle = \frac{1}{\sqrt{2}}(|01\rangle - |10\rangle)$, so that \mathcal{O}_{ij} has rank 1. In general, any maximally entangled pure state on 2 qubits gives rise to a rank-1 strictly quadratic term, since such states must have maximally mixed reduced density matrices.

2.2 Semidefinite Relaxation

We employ a semidefinite programming relaxation for QLH (Problem 1) that is a refinement of the now standard SDP relaxation that has been used in designing approximation algorithms [8, 11, 19]. Our relaxation is related to one used by Hallgren, Lee, and Parekh [21] and may be viewed as a specialization of noncommutative Lasserre hierarchies proposed for quantum information applications [16, 31, 34].

In this section we assume, for the sake of exposition, that there is a single edge ij on any pair of qubits $i, j \in [n]$; however, the relaxation and rounding algorithm may be readily extended to handle general instances of QLH with multiedges. Suppose we have an instance of QLH on n qubits. The first set of variables in our SDPs will be marginal density matrices $\{\rho_{ij}\}$. Since there are n qubits, there are $\binom{n}{2}$ many of these, and each of them is a 4×4 Hermitian matrix. While we cannot impose global consistency, we can force each ρ_{ij} to be a valid density matrix on its own: $\text{Tr}[\rho_{ij}] = 1$ and $\rho_{ij} \succeq 0$ for all $i, j \in [n]$. We could also explicitly force overlapping marginals to be consistent on single qubit density matrices, however this will be implicit through our use of moment matrices.

Moment matrices. Suppose we have a quantum state on n qubits $|\psi\rangle \in \mathbb{C}^{2^n}$. Consider the 1-local Pauli operators, $\mathcal{M} = \{\mathbb{I}\} \cup \{\sigma_i^k \otimes \mathbb{I}_{[n] \setminus \{i\}} \mid k \in [3], i \in [n]\}$. We apply each of the $3n+1$ Pauli operators $\mathcal{O} \in \mathcal{M}$ on $|\psi\rangle$ to obtain columns of a matrix $V = \{\mathcal{O}|\psi\rangle\}_{\mathcal{O} \in \mathcal{M}} \in \mathbb{C}^{2^n \times (3n+1)}$. We call $M := V^\dagger V \in \mathbb{C}^{(3n+1) \times (3n+1)}$ the *moment matrix* of $|\psi\rangle$ with respect to \mathcal{M} ; note that M is Hermitian and $M \succeq 0$ by construction. The notation $M(\mathcal{O}, \mathcal{P})$ refers to the entry of M at the row and column corresponding to $\mathcal{O}, \mathcal{P} \in \mathcal{M}$ respectively. We have $M(\mathcal{O}, \mathcal{P}) = \langle \psi | \mathcal{O} \mathcal{P} | \psi \rangle$, for all $\mathcal{O}, \mathcal{P} \in \mathcal{M}$, so that M captures all the 2-local Pauli statistics of $|\psi\rangle$. In particular the quantity $\langle \psi | H | \psi \rangle$ is a linear function of the entries of M for a 2-local Hamiltonian H . If we let \mathcal{M}_k consist of all the k -local tensor products of Paulis, instead of just the 1-local ones, the corresponding moment matrix M_k , of size $O(n^k)$ by $O(n^k)$, includes all the $2k$ -local Pauli statistics. We may obtain SDP relaxations for QLH problems by constructing a relaxed $M_k \succeq 0$ that satisfies linear constraints of the form $\text{Tr}[AM_k] = b$, that a true moment matrix would satisfy. This corresponds to the k th level of noncommutative Lasserre hierarchies introduced for quantum information [16, 31, 34]. Our approach relaxes \mathcal{M}_1 and adds additional constraints enforcing positivity of 2-local marginals; the relaxation we obtain sits between the $k = 1$ and $k = 2$ levels of the noncommutative Lasserre hierarchy.

SDP Relaxation. We define a (relaxed) moment matrix M , which will track local statistics of the set of marginals $\{\rho_{ij}\}$. Let M be a symmetric, $(3n+1) \times (3n+1)$ real matrix whose rows and columns correspond to operators in \mathcal{M} . Entries of M will correspond to coefficients of the marginal density matrices $\{\rho_{ij}\}$ in the Pauli basis. We use the notation $M(\sigma_i^k, \sigma_j^l)$ to refer to entries of M for $i, j \in [n]$ and $k, l \in [3]$; in addition we have a row and column of M indexed by \mathbb{I} . We set $M(\sigma_i^k, \sigma_j^l) = \text{Tr}[\sigma^k \otimes \sigma^l \rho_{ij}]$ for $(i, k), (j, l)$ in $[n] \times [3]$. In addition we set $M(\mathbb{I}, \mathbb{I}) = 1$, and $M(\sigma_i^k, \mathbb{I}) = \text{Tr}[\sigma^k \otimes \mathbb{I} \rho_{ij}]$ for all $(i, k) \in [n] \times [3]$ and $j \in [n]$. Note that this constraint forces consistent single-qubit marginals since

$$\text{Tr}_u[\rho_{iu}] = \text{Tr}_v[\rho_{iv}] \Leftrightarrow \text{Tr}[\sigma^l \otimes \mathbb{I} \rho_{iu}] = \text{Tr}[\sigma^l \otimes \mathbb{I} \rho_{iv}] \quad \forall l.$$

Since M contains all local information of $\{\rho_{ij}\}$, we can use M to evaluate the objective of our SDP. In this direction, we will define a weight matrix for each edge $H_{ij} = w_{ij} \mathcal{O}_{ij} \otimes \mathbb{I}_{n \setminus \{i, j\}}$, where $\mathcal{O}_{ij} \in \mathbb{C}^{4 \times 4}$, and w_{ij} is a scalar weight. We define the $(3n+1) \times (3n+1)$ matrix C_{ij} , which contains the coefficients of \mathcal{O}_{ij} in the Pauli basis:

$$\begin{aligned} C_{ij}(\sigma_i^k, \sigma_j^l) &= C_{ij}(\sigma_j^l, \sigma_i^k) = \text{Tr}[\sigma^k \otimes \sigma^l \mathcal{O}_{ij}] / 8 \quad \forall k, l \in [3], \\ C_{ij}(\sigma_i^k, \mathbb{I}) &= C_{ij}(\mathbb{I}, \sigma_i^k) = \text{Tr}[\sigma^k \otimes \mathbb{I} \mathcal{O}_{ij}] / 8 \quad \forall k \in [3], \\ C_{ij}(\sigma_j^l, \mathbb{I}) &= C_{ij}(\mathbb{I}, \sigma_j^l) = \text{Tr}[\mathbb{I} \otimes \sigma^l \mathcal{O}_{ij}] / 8 \quad \forall l \in [3], \end{aligned} \tag{3}$$

and all other entries of C_{ij} are 0. To illustrate application of the matrix C_{ij} , suppose \mathcal{O}_{ij} and the marginal density matrix ρ_{ij} have Pauli decompositions:

$$\mathcal{O}_{ij} = \sum_{k, l=0}^3 \alpha_{kl} \sigma^k \otimes \sigma^l \quad \text{and} \quad \rho_{ij} = \frac{1}{4} \sum_{k, l=0}^3 \beta_{kl} \sigma^k \otimes \sigma^l.$$

Since, for $k, l \geq 0$, $(\sigma^k)^2 = \mathbb{I}$ and $\text{Tr}[\sigma^k \sigma^l] = 0$ when $k \neq l$, the value we gain from edge ij , ignoring the weight w_{ij} , is written as:

$$\text{Tr}[\mathcal{O}_{ij} \rho_{ij}] = \alpha_{00} \beta_{00} + \sum_{\substack{k, l: \\ (k \neq 0) \vee (l \neq 0)}} \alpha_{kl} \beta_{kl} = \frac{\text{Tr}[\mathcal{O}_{ij}]}{4} + \text{Tr}[C_{ij} M]. \tag{4}$$

With these facts in hand, we may finally give the main SDP relaxation in this work:

► **Problem 9.** Given an instance of QLH (Problem 1) on n qubits with local terms $\{H_{ij} = w_{ij}\mathcal{O}_{ij} \otimes \mathbb{I}_{[n]\setminus\{i,j\}}\}$, let C_{ij} be defined according to Equation (3) for each $ij \in E$. Solve the following SDP:

$$\max \sum_{ij \in E} w_{ij} \left(\frac{\text{Tr}[\mathcal{O}_{ij}]}{4} + \text{Tr}[C_{ij}M] \right) \quad (5)$$

$$\text{s.t.} \quad M(\mathbb{I}, \mathbb{I}) = 1, \quad (6)$$

$$M(\sigma_i^k, \sigma_i^k) = 1 \quad \forall i \in [n] \text{ and } k \in [3], \quad (7)$$

$$M(\sigma_i^k, \sigma_i^l) = 0 \quad \forall i \in [n] \text{ and } k \neq l \in [3], \quad (8)$$

$$M(\sigma_i^k, \sigma_j^l) = \text{Tr}[\sigma^k \otimes \sigma^l \rho_{ij}] \quad \forall ij \in E \text{ and } k, l \in [3], \quad (9)$$

$$M(\sigma_i^k, \mathbb{I}) = \text{Tr}[\sigma^k \otimes \mathbb{I} \rho_{ij}] \quad \forall ij \in E \text{ and } k \in [3], \quad (10)$$

$$M(\sigma_j^l, \mathbb{I}) = \text{Tr}[\mathbb{I} \otimes \sigma^l \rho_{ij}] \quad \forall ij \in E \text{ and } l \in [3], \quad (11)$$

$$\text{Tr}[\rho_{ij}] = 1 \quad \forall ij \in E, \quad (12)$$

$$\mathcal{H}(\mathbb{C}^{4 \times 4}) \ni \rho_{ij} \succeq 0 \quad \forall ij \in E, \quad (13)$$

$$\mathcal{S}(\mathbb{R}^{(3n+1) \times (3n+1)}) \ni M \succeq 0, \quad (14)$$

where $\mathcal{S}(\cdot)$ and $\mathcal{H}(\cdot)$ refer to the symmetric and Hermitian matrices, respectively.

► **Theorem 10.** The mathematical program of Problem 9 is an efficiently computable semidefinite program that provides an upper bound on $\lambda_{\max}(\sum_{ij \in E} H_{ij})$.

Proof. Constraints (6)–(12) are linear equalities on the entries of PSD matrices M and ρ_{ij} $\forall ij \in E$, hence we do indeed have an SDP. Since there are polynomially many variables of polynomial size, the usual considerations show computational efficiency, i.e. the program can be solved to arbitrary additive precision in polynomial time.

A larger matrix $X \succeq 0$, consisting of M and the ρ_{ij} as its diagonal blocks may be used to put the SDP into a more standard form (e.g. [7], Section 4.6.2). Although the ρ_{ij} are complex, the SDP may be solved as a real SDP by appealing to the standard approach of tracking the real and imaginary parts separately and observing $X \succeq 0$ if and only if

$$\begin{bmatrix} \text{Re}(X) & -\text{Im}(X) \\ \text{Im}(X) & \text{Re}(X) \end{bmatrix} \succeq 0.$$

Let $|\psi\rangle$ be an eigenvector corresponding to $\lambda_{\max}(\sum_{ij \in E} H_{ij})$, and let ρ_{ij}^* , $\forall ij \in E$, be the 2-qubit marginal density matrices of $\rho = |\psi\rangle\langle\psi|$, so that Constraints (12) and (13) are satisfied for the ρ_{ij}^* . In addition consider the moment matrix M for $|\psi\rangle$ with respect to \mathcal{M} , as described above. The matrix M satisfies Constraints (6), (7), (9)–(11), and (14) by the definition of a moment matrix, since

$$\langle\psi| \sigma_i^k \otimes \sigma_j^l \otimes \mathbb{I}_{[n]\setminus\{i,j\}} |\psi\rangle = \text{Tr}[\sigma^k \otimes \sigma^l \rho_{ij}^*], \text{ for } 0 \leq k, l \leq 3. \quad (15)$$

Constraint (8) is the only one that remains. Note that the real part of M , $M^* := \text{Re}(M) \succeq 0$ since $M \succeq 0$. By Equation (15), for any $j \in [n]$ and $k \neq l \in [3]$, $M(\sigma_i^k, \sigma_i^l) = \pm i \text{Tr}[\sigma^m \otimes \mathbb{I} \rho_{ij}^*]$, where $m \in [3] \setminus \{k, l\}$. The quantities in Equation (15) are real since tensor products of Pauli operators are Hermitian. This implies that $M(\sigma_i^k, \sigma_i^l)$ for $k \neq l \in [3]$ is imaginary and more generally that M^* and the ρ_{ij}^* satisfy all the constraints.

Consider the objective value for this solution, $\sum_{ij \in E} w_{ij} (\text{Tr}[\mathcal{O}_{ij}]/4 + \text{Tr}[C_{ij}M^*]) =$

$$\sum_{ij \in E} w_{ij} \text{Tr}[\mathcal{O}_{ij} \rho_{ij}^*] = \text{Tr} \left[\sum_{ij \in E} H_{ij} \rho \right] = \lambda_{\max} \left(\sum_{ij \in E} H_{ij} \right),$$

where the first equality follows from Equation (4). It follows that the optimal solution to Problem 9 has value at least that of the optimal solution of QLH. ◀

2.3 Rounding Approach and Formal Statement of Results

Overview. In classical SDP-based rounding schemes, one typically seeks to randomly “round” unit vectors $\mathbf{v}_i \in \mathbb{R}^d$ to scalars $z_i \in \{\pm 1\}$ so that the expected value of $z_i z_j$ approximates $\mathbf{v}_i \cdot \mathbf{v}_j$. The seminal hyperplane rounding scheme of Goemans and Williamson [20] achieves this by selecting a random unit vector $\mathbf{r} \in \mathbb{R}^d$ and setting $z_i = \mathbf{r} \cdot \mathbf{v}_i / |\mathbf{r} \cdot \mathbf{v}_i|$.

Rounding solutions from SDP relaxations for QLH to product states generalizes this approach. Recall that a product state has the form $|\psi\rangle = |\psi_1\rangle \otimes \dots \otimes |\psi_n\rangle$ where each $|\psi_i\rangle \in \mathbb{C}^2$ is a local state on qubit i . We obtain a density matrix $\rho = |\psi\rangle \langle \psi| = |\psi_1\rangle \langle \psi_1| \otimes \dots \otimes |\psi_n\rangle \langle \psi_n|$, which is a tensor product of single-qubit density matrices $\rho_i := |\psi_i\rangle \langle \psi_i|$. Any such ρ_i may be expressed in the Pauli basis as $\rho_i = \frac{1}{2}(\mathbb{I} + \theta_{i1}\sigma^1 + \theta_{i2}\sigma^2 + \theta_{i3}\sigma^3)$, where $\theta_{ik} = \text{Tr}[\sigma^k \rho_i] \in \mathbb{R}$ and $\sum_{k \in [3]} \theta_{ik}^2 = 1$. In particular, product states with $\theta_{i1} = \theta_{i2} = 0$ and $\theta_{i3}^2 = 1$ correspond precisely to the classical setting (see Appendix E in [30] for an explicit connection between the two). Product states exhibit no entanglement, and we may specify θ_{ik} independently for each qubit i . However, instead of producing a single $z_i^2 = 1$ as in the classical case, we must produce a unit vector $\theta_i = [\theta_{i1}, \theta_{i2}, \theta_{i3}] \in \mathbb{R}^3$ for each $i \in [n]$. Briët, de Oliveira Filho, and Vallentin were the first to consider such generalizations of scalars to unit vectors, in the context of the Grothendieck problem [12, 13], and their analysis has fueled recent approximation algorithms for QLH [19, 21].

The classical Goemans-Williamson rounding scheme obtains the unit vectors \mathbf{v}_i from a Cholesky decomposition of a PSD matrix $V^T V = R \succeq 0$. Taking the \mathbf{v}_i to be columns of V yields $R_{i,j} = \mathbf{v}_i \cdot \mathbf{v}_j$. Recent approximation algorithms [11, 19, 21] for QLH have mimicked this approach, as do we. Let $M^* \succeq 0$ be an optimal solution to Problem 9 (the ρ_{ij}^* are not necessary to describe the rounding algorithm). We find a Cholesky decomposition $V^T V = M^*$, and let $\mathbf{v}_{ik} \in \mathbb{R}^d$ be the column of V associated with σ_i^k for $i \in [n], k \in [3]$; we may assume $d \leq 3n + 1$. In addition we let \mathbf{v}_0 be the column of V corresponding to \mathbb{I} . These are unit vectors as a consequence of Constraints (6) and (7).

We will employ the same rounding algorithm for both the general and strictly quadratic cases. While previous related works [11, 19, 21] have in some cases had to rely on more sophisticated rounding schemes because they have been amenable to analysis, we are able to shed light on what is arguably the most natural generalization of the Goemans-Williamson approach. We draw $\mathbf{r} \sim \mathcal{N}(0, \mathbb{I}_d)$, i.e. a multivariate distribution over d independent and standard Gaussian variables. For each qubit, we obtain the desired vector $\theta_i = [\theta_{i1}, \theta_{i2}, \theta_{i3}]$ as:

$$[\mathbf{v}_{i1} \cdot \mathbf{r}, \mathbf{v}_{i2} \cdot \mathbf{r}, \mathbf{v}_{i3} \cdot \mathbf{r}] / Q_i,$$

where $Q_i := \sqrt{(\mathbf{v}_{i1} \cdot \mathbf{r})^2 + (\mathbf{v}_{i2} \cdot \mathbf{r})^2 + (\mathbf{v}_{i3} \cdot \mathbf{r})^2}$ is a normalization.

The classical Max Cut problem corresponds to a strictly quadratic Hamiltonian (see Appendix E in [30] for justification); however, classical Max 2-SAT and more general Max 2-CSP have 1-local terms (i.e., linear terms in $\{\pm 1\}$ variables). In contrast, strictly quadratic instances of QLHP serve as a quantum generalization of Max 2-SAT and Max 2-CSP that have no 1-local terms. In order to obtain effective classical approximations in the presence of 1-local terms, an additional vector \mathbf{v}_0 is necessary, representing (scalar) identity. Generally, the vector \mathbf{v}_0 is used in conjunction with more sophisticated rounding schemes (e.g. [27]) to obtain positive expectation from the 1-local terms. For the quantum case, relatively simple approaches suffice to get good approximations [21]. Using the vector \mathbf{v}_0 is not necessary for the strictly quadratic case, and including it does not affect its approximation.

Rounding algorithm. The rounding approach described above produces single-qubit density matrices:

$$\rho_i = \frac{1}{2} \left(\mathbb{I} + \frac{\mathbf{v}_{i1} \cdot \mathbf{r}}{Q_i} \sigma^1 + \frac{\mathbf{v}_{i2} \cdot \mathbf{r}}{Q_i} \sigma^2 + \frac{\mathbf{v}_{i3} \cdot \mathbf{r}}{Q_i} \sigma^3 \right).$$

Hence, on any 1-local term, $\mathbb{E}[\text{Tr}[\sigma^k \rho_i]] = \mathbb{E}[\mathbf{v}_{ik} \cdot \mathbf{r}/Q_i] = 0$ since Q_i is an even function and $\mathbf{v}_{ik} \cdot \mathbf{r}$ is an odd function in each entry of \mathbf{r} . Thus, in order to get a nontrivial approximation on 1-local terms, we will use the vector \mathbf{v}_0 to globally flip the sign of the θ_i vectors of all qubits, i.e. $\mathbf{v}_{ik} \cdot \mathbf{r}/Q_i \rightarrow \text{sign}(\mathbf{v}_0 \cdot \mathbf{r})(\mathbf{v}_{ik} \cdot \mathbf{r}/Q_i)$. Since $\text{sign}(\mathbf{v}_0 \cdot \mathbf{r}) \in \{\pm 1\}$, for quadratic objective terms this factor will cancel out, but for 1-local terms we will gain additional objective from the correlation of $\mathbf{v}_0 \cdot \mathbf{r}$ and $\mathbf{v}_{ik} \cdot \mathbf{r}$. Formally, we can state the rounding algorithm, which applies to any instance of QLH, in Algorithm 1.

■ **Algorithm 1** Hyperplane rounding for 2-Local Hamiltonian.

1. Given some instance of Problem 1 formulate and solve the corresponding instance of Problem 9. Let M^* be the optimal moment matrix obtained from Problem 9.
2. Find the Cholesky decomposition of M^* , obtaining Cholesky vectors $\mathbf{v}_0 \in \mathbb{R}^d$ and $\{\mathbf{v}_{ik} \in \mathbb{R}^d\}$ such that $M^*(\sigma_i^k, \sigma_j^l) = \mathbf{v}_{ik} \cdot \mathbf{v}_{jl}$ and $M^*(\mathbb{I}, \sigma_i^k) = \mathbf{v}_0 \cdot \mathbf{v}_{ik}$ for $i, j \in [n]$ and $k, l \in [3]$.
3. Let \mathbf{r} be a random vector with $\mathbf{r} \sim \mathcal{N}(0, \mathbb{I}_d)$.
4. For each qubit i , set $Q_i = \sqrt{(\mathbf{v}_{i1} \cdot \mathbf{r})^2 + (\mathbf{v}_{i2} \cdot \mathbf{r})^2 + (\mathbf{v}_{i3} \cdot \mathbf{r})^2}$, and set $\theta_{ik} = \text{sign}(\mathbf{v}_0 \cdot \mathbf{r})(\mathbf{v}_{ik} \cdot \mathbf{r}/Q_i)$ for $k \in [3]$.
5. Output the (pure) state:

$$\rho = \bigotimes_{i=1}^n \frac{1}{2} (\mathbb{I} + \theta_{i1} \sigma^1 + \theta_{i2} \sigma^2 + \theta_{i3} \sigma^3).$$

We will give the following approximation guarantees for QLHP:

► **Theorem 11.** Fix $k \in \{1, 2, 3\}$. Suppose we are given an instance of QLHP (Problem 2), $\{H_e\}$ where $H_e = w_e P_e \otimes \mathbb{I}_{[n] \setminus \{e_1, e_2\}}$ for $w_e \geq 0$ and P_e a projector of rank at least k , for all $e \in E$. Let M^* be the optimal moment matrix for the corresponding SDP relaxation, Problem 9, and let ρ be the random output of Algorithm 1. Then,

$$\mathbb{E} \left[\text{Tr} \left[\sum_{e \in E} H_e \rho \right] \right] \geq \alpha(k) \left(\sum_{e \in E} w_e \left(\frac{\text{rank}(P_e)}{4} + \text{Tr}[C_e M^*] \right) \right) \geq \alpha(k) \lambda_{\max} \left(\sum_{e \in E} H_e \right),$$

where

$$\alpha(k) = \begin{cases} 2/\pi - 1/4 \approx 0.387 & \text{if } k = 1 \\ 16/(9\pi) \approx 0.565 & \text{if } k = 2 \\ 3/8 + 11/(9\pi) \approx 0.764 & \text{if } k = 3. \end{cases}$$

► **Theorem 12.** If, in addition to the assumptions of Theorem 11, the P_e are strictly quadratic projectors, then the random output of Algorithm 1 satisfies:

$$\mathbb{E} \left[\text{Tr} \left[\sum_{ij \in E} H_{ij} \rho \right] \right] \geq \alpha(k) \lambda_{\max} \left(\sum_{ij \in E} H_{ij} \right),$$

where

$$\alpha(k) = \begin{cases} 22/(15\pi) \approx 0.467 & \text{if } k = 1 \\ 1/3 + 24/(25\pi) \approx 0.639 & \text{if } k = 2 \\ 1/2 + 388/(405\pi) \approx 0.804 & \text{if } k = 3. \end{cases}$$

The above results are rigorous, but non-optimal. The quadratic analysis depends crucially on an expansion of a particular expectation in Hermite polynomials. One can consider a higher order Hermite series to more accurately capture the expectation and achieve a better approximation factor. We have such results, but opt to not include them in the interest of the reader. Higher orders bring increased tedium, and our technique should be clear enough at the end of the paper that an interested reader could do the higher order calculation.

One can ask, why not include a high enough order that the result becomes essentially optimal? The issue is that polynomial expansions often converge slowly in the presence of discontinuities [33]. Indeed, computationally we have determined that to get essentially optimal results one would need to go to high enough order that the polynomial expansion would become intractable. One can determine the optimal approximation factor by using a high order expansion and numerically optimizing or simply by randomly sampling over some “net” of the parameter space. Our observed approximation factors under these approaches are stated in Conjecture 6. Proving an approximation factor as large as the observed performance of our algorithm is the subject of future work.

2.4 Analysis Overview

We present an overview of our analysis for the strictly quadratic case, which will also carry over to the general case with additional bookkeeping and bounding for the 1-local terms. Suppose we are given an instance of QLHP (Problem 2) on which we execute Algorithm 1 to produce a random solution ρ . For $i, j \in [n]$, the 2-qubit marginals of ρ are

$$\rho_{ij} = \frac{1}{4}(\mathbb{I} + \theta_{i1}\sigma^1 + \theta_{i2}\sigma^2 + \theta_{i3}\sigma^3) \otimes (\mathbb{I} + \theta_{j1}\sigma^1 + \theta_{j2}\sigma^2 + \theta_{j3}\sigma^3), \quad (16)$$

and the objective value of ρ is $\sum_{ij \in E} \text{Tr}[H_{ij}\rho] = \sum_{ij \in E} w_{ij} \text{Tr}[P_{ij}\rho_{ij}]$, where $\text{Tr}[P_{ij}\rho_{ij}]$ is the unweighted contribution to the objective value from edge ij . Let M^* and ρ_{ij}^* for $ij \in E$ be the SDP solution obtained by Algorithm 1, and let $\text{SDP}_{ij} := \text{Tr}[P_{ij}\rho_{ij}^*]$ be the unweighted contribution to the SDP objective value from edge ij . The approximation ratio, which we seek to bound from below, is consequently:

$$\alpha = \mathbb{E} \left[\frac{\sum_{ij \in E} w_{ij} \text{Tr}[P_{ij}\rho_{ij}]}{\sum_{ij \in E} w_{ij} \text{SDP}_{ij}} \right] = \frac{\sum_{ij \in E} w_{ij} \mathbb{E}[\text{Tr}[P_{ij}\rho_{ij}]]}{\sum_{ij \in E} w_{ij} \text{SDP}_{ij}}.$$

Observe that $\text{Tr}[P_{ij}\rho_{ij}] \geq 0$ and $\text{SDP}_{ij} \geq 0$ since P_{ij} , ρ_{ij} , and ρ_{ij}^* are all PSD. Since all the terms in the denominator are nonnegative, it follows from an elementary argument that

$$\alpha \geq \frac{\sum_{ij \in E} w_{ij} \mathbb{E}[\text{Tr}[P_{ij}\rho_{ij}]]}{\sum_{ij \in E} w_{ij} \text{SDP}_{ij}} \geq \min_{ij \in E} \frac{\mathbb{E}[\text{Tr}[P_{ij}\rho_{ij}]]}{\text{SDP}_{ij}}.$$

Thus it suffices to bound the approximation ratio for the worst case occurring on a single edge.

Bounding a worst-case edge. We now focus our attention on a single edge $e = 12$ on qubits 1, 2. We collect the vectors \mathbf{v}_{ik} , obtained from a Cholesky decomposition of the SDP solution M^* , into matrices $V_i = [\mathbf{v}_{i1}, \mathbf{v}_{i2}, \mathbf{v}_{i3}] \in \mathbb{R}^{d \times 3}$, for $i = 1, 2$. We define an objective matrix $C \in \mathbb{R}^{3 \times 3}$, containing scaled 2-local Pauli-basis coefficients of P_{12} , in the vein of Equation (3): $C(\sigma_1^k, \sigma_2^l) := \text{Tr}[\sigma^k \otimes \sigma^l P_{12}]$, for $k, l \in [3]$ (note that C is not symmetric). With these definitions in hand, observe that $V_i^T V_i = \mathbb{I}_3$, by the SDP constraints (7) and (8), and that $4\text{Tr}[C_{12}M^*] = \text{Tr}[V_1 C V_2^T]$. The hyperplane rounding produces unit vectors $\theta_i^T = [\theta_{i1}, \theta_{i2}, \theta_{i3}] = \mathbf{r}^T V_i / \|V_i^T \mathbf{r}\|$. In terms of these variables, we have:

$$\begin{aligned} SDP_e &= \text{Tr}[P_{12}\rho_{12}^*] = \frac{1}{4} (\text{rank}(P_{12}) + \text{Tr}[V_1 C V_2^T]), \text{ and} \\ \mathbb{E}[APX_e] &= \mathbb{E}[\text{Tr}[P_{12}\rho_{12}]] = \frac{1}{4} (\text{rank}(P_{12}) + \mathbb{E}[\theta_1^T C \theta_2]) = \\ &= \frac{1}{4} \left(\text{rank}(P_{12}) + \mathbb{E}_{\mathbf{r}} \left[\frac{\mathbf{r}^T V_1 C V_2^T \mathbf{r}}{\|V_1^T \mathbf{r}\| \|V_2^T \mathbf{r}\|} \right] \right), \end{aligned}$$

by Equation (4) and because $\text{Tr}[P_{12}] = \text{rank}(P_{12})$, since P_{12} is a projector. Thus, setting $k = \text{rank}(P_{12})$, the quantity we seek to bound is

$$\alpha \geq \min_{V_1, V_2, C} \frac{k + \mathbb{E}_{\mathbf{r}} \left[\frac{\mathbf{r}^T V_1 C V_2^T \mathbf{r}}{\|V_1^T \mathbf{r}\| \|V_2^T \mathbf{r}\|} \right]}{k + \text{Tr}[V_1 C V_2^T]}.$$

The bulk of our analysis lies in (i) simplifying the above to reduce the number of parameters in the minimization and expectation (Appendix B in [30]), and (ii) deriving analytical bounds on the expectation (Appendix C in [30]).

Simplifying the Gaussian expectation. The first simplification follows from observing that $V_i^T \mathbf{r} \in \mathbb{R}^3$ are multivariate Gaussians for $i = 1, 2$ since they are linear combinations of Gaussians, $\mathbf{r} \sim \mathcal{N}(0, \mathbb{I})$. If we let $\mathbf{z}^T = [z_1, z_2, z_3] = \mathbf{r}^T V_1$ and $(\mathbf{z}')^T = [z'_1, z'_2, z'_3] = \mathbf{r}^T V_2$, then $[\mathbf{z}, \mathbf{z}'] \sim \mathcal{N}(0, \Sigma)$, where

$$\Sigma = \begin{bmatrix} \mathbb{I} & V_1^T V_2 \\ V_2^T V_1 & \mathbb{I} \end{bmatrix} \in \mathbb{R}^{6 \times 6}.$$

The Gaussians z_i are mutually independent as well as the z'_i , and the covariance between \mathbf{z} and \mathbf{z}' is given by $M = V_1^T V_2 \in \mathbb{R}^{3 \times 3}$. Our bound now depends on a constant number of parameters, the 18 entries of C and M :

$$\alpha \geq \min_{M, C} \frac{k + \mathbb{E}_{\mathbf{z}, \mathbf{z}'} \left[\frac{\mathbf{z}^T C \mathbf{z}'}{\|\mathbf{z}\| \|\mathbf{z}'\|} \right]}{k + \text{Tr}[C^T M]}. \quad (17)$$

For classical hyperplane rounding algorithms, C and M simply reduce to scalars, and one may resort to a numerical argument to furnish the desired bound. However, in the case of QLH above, numerical bounds exhibit poor precision or convergence due to the number of parameters. Thus we press on, and our next observation is that only the singular values of M matter for the analysis. The above arguments are detailed in Lemma 15 in [30], which also shows that we may assume:

$$C = \begin{bmatrix} p & 0 & 0 \\ 0 & q & 0 \\ 0 & 0 & r \end{bmatrix} \text{ and } M = \begin{bmatrix} a & 0 & 0 \\ 0 & b & 0 \\ 0 & 0 & c \end{bmatrix}, \quad (18)$$

where a, b, c are the singular values of $V_1^T V_2$. This reduction to 6 parameters puts analysis of α within reach. The special case when $a = b = c$ turns out to be equivalent to the recently studied quantum analog of Max Cut related to the quantum Heisenberg model [2, 19]. For this case, a representation of the expectation,

$$\mathbb{E}_{\mathbf{z}, \mathbf{z}'} \left[\frac{\mathbf{z}^T C \mathbf{z}'}{\|\mathbf{z}\| \|\mathbf{z}'\|} \right] \quad (19)$$

as a hypergeometric function follows from work of Briët, de Oliveira Filho, and Vallentin (the expectation ends up being equivalent to the one in Lemma 2.1 from [13], when $\mathbf{u} \cdot \mathbf{v}$ in the lemma equals $a = b = c$). To the best of our knowledge, no elementary representation is known when a, b, c may be distinct. We appeal to Hermite analysis to express the expectation (19) as a polynomial that we are subsequently able to bound; this is carried out in Lemmas 17-18/Appendix C of [30].

Introducing constraints from positivity. The matrices C and M from (18) are related to the quadratic Pauli-basis coefficients of P_{12} and ρ_{12}^* , respectively. The other ingredient of our analysis of the bound (17) is restricting C and M based on the facts that $P_{12} \succeq 0$ and $\rho_{12}^* \succeq 0$, which is undertaken in Appendix B.1 and Lemma 14 of [30]. This is where the SDP constraint (13) is used. The bound we obtain is

$$\alpha \geq \min_{\substack{[a,b,c] \in \mathcal{S} \\ [p,q,r] \in \mathcal{P}_k}} \frac{k + \mathbb{E}_{\mathbf{z}, \mathbf{z}'} \left[\frac{pz_1 z'_1 + qz_2 z'_2 + rz_3 z'_3}{\sqrt{(z_1^2 + z_2^2 + z_3^2)((z'_1)^2 + (z'_2)^2 + (z'_3)^2)}} \right]}{k + ap + bq + cr}, \quad (20)$$

where \mathcal{S} and \mathcal{P}_k are specific polytopes (\mathcal{S} is a simplex as is \mathcal{P}_k for $k \neq 2$) derived from the positivity of P_{12} and ρ_{12}^* . We further observe in Lemma 34 in [30] that p, q, r may be fixed (e.g., for $k = 3$, we may take $p = q = r = 1$). Finally, Lemmas 17 and 18 in [30] derive the bounds in the main theorems 11 and 12, respectively.

Analysis Highlights. We utilize Hermite polynomials to evaluate the expectation given in Equation (20). As the natural set of polynomials orthogonal under the expectation of Gaussian variables, [26], we obtain an expression for the expectation in terms of a convergent series which we can then truncate and bound to get rigorous results. Obtaining the coefficients in this series requires some additional facts about Hermite polynomials, and some combinatorial identities.

3 Conclusion

In this work we have demonstrated several new approximation algorithms for interesting cases of the Max 2-Local Hamiltonian problem. As is the theme in many works [4, 8, 18], we have given evidence that the geometry of 2-Local interactions can drastically effect approximability for traceless Hamiltonians since we demonstrate the bipartite case has a constant factor approximation algorithm and the unconstrained case is known to have no constant factor algorithm [11]. In addition to this, we have given a novel approximation algorithm and analysis for 2-Local Hamiltonian with local terms that are also projectors. This is especially interesting given the scarcity of approximation algorithms for quantum problems. Indeed, the rank 3 case, has been open for some time [18, 21]. Furthermore, we have provided new techniques for rounding to product states that we believe will have additional applications

in quantum information. Our rounding algorithm is quite natural given the solution of the SDP, and the ability to understand the expectation through Hermite polynomial analysis seems likely to extend to other kinds of Hamiltonians or problems.

Additive Sparsification of CSPs

Eden Pelleg 

Mathematical Institute, University of Oxford, UK

Department of Computer Science, University of Oxford, UK

Abstract

Multiplicative cut sparsifiers, introduced by Benczúr and Karger [STOC'96], have proved extremely influential and found various applications. Precise characterisations were established for sparsifiability of graphs with other 2-variable predicates on Boolean domains by Filtser and Krauthgamer [SIDMA'17] and non-Boolean domains by Butti and Živný [SIDMA'20].

Bansal, Svensson and Trevisan [FOCS'19] introduced a weaker notion of sparsification termed “additive sparsification”, which does not require weights on the edges of the graph. In particular, Bansal et al. designed algorithms for additive sparsifiers for cuts in graphs and hypergraphs.

As our main result, we establish that *all* Boolean Constraint Satisfaction Problems (CSPs) admit an additive sparsifier; that is, for every Boolean predicate $P : \{0, 1\}^k \rightarrow \{0, 1\}$ of a fixed arity k , we show that $\text{CSP}(P)$ admits an additive sparsifier. Under our newly introduced notion of all-but-one sparsification for non-Boolean predicates, we show that $\text{CSP}(P)$ admits an additive sparsifier for *any* predicate $P : D^k \rightarrow \{0, 1\}$ of a fixed arity k on an arbitrary finite domain D .

1 Introduction

Graph sparsification is the problem of, given a graph $G = (V, E)$ with quadratically many (in $|V|$) edges, finding a sparse subgraph $G_\varepsilon = (V, E_\varepsilon \subseteq E)$ such that important properties of G are preserved in G_ε . Sparse in this context usually means with sub-quadratically many edges, though in this work we require (and can achieve) linearly many edges.

One of the most studied properties of preservation is the size of cuts. If $G = (V, E, w)$ is an undirected weighted graph with $w : E \rightarrow \mathbb{R}_{>0}$, given some $S \subseteq V$, the cut of S in G is

$$\text{Cut}_G(S) = \sum_{\substack{\{u,v\} \in E \\ |\{u,v\} \cap S| = 1}} w(\{u,v\}),$$

the sum of weights of all edges connecting S and $S^c = V \setminus S$. In an influential paper, Benczúr and Karger [11] introduced cut sparsification with a multiplicative error. In particular, [11] showed that for any graph $G = (V, E, w)$ and any error parameter $0 < \varepsilon < 1$, there exists a sparse subgraph $G_\varepsilon = (V, E_\varepsilon \subseteq E, w')$ with $O(n(\log n)\varepsilon^{-2})$ edges (and new weights w' on

the edges in E_ε), such that for every $S \subseteq V$ we have

$$\text{Cut}_{G_\varepsilon}(S) \in (1 \pm \varepsilon) \text{Cut}_G(S).$$

This was later improved by Batson, Spielman and Srivastava [10] to a subgraph with $O(n\varepsilon^{-2})$ many edges. Andoni, Chen, Krauthgamer, Qin, Woodruff and Zhang showed that the dependency on ε is optimal [4].

The ideas from cut sparsification paved the way to various generalisations, including streaming [1], sketching [4], cuts in hypergraphs [23, 27], spectral sparsification [33, 32, 34, 21, 31] and the consideration of other predicates besides cuts [20]. In this work, we focus on the latter.

The cut sparsification result in [10] was explored for other Boolean binary predicates by Filtser and Krauthgamer [20], following a suggestion to do so by Kogan and Krauthgamer in [23]. Filtser and Krauthgamer found [20] a necessary and sufficient condition on the predicate for the graph to be sparsifiable (in the sense of [10]). In particular, [20] showed that not all Boolean binary predicates are sparsifiable. Later, Butti and Živný [14] generalised the result from [20] to arbitrary finite domain binary predicates.

We remark that [20, 14] use the terminology of *constraint satisfaction problems* (CSPs) with a fixed predicate P . This is equivalent to a (hyper)graph G with a fixed predicate. Indeed, the vertices of G correspond to the variables of the CSP and the (hyper)edges of G correspond to the constraints of the CSP. If the fixed predicate P is not symmetric, the (hyper)edges of G are directed. We will mostly talk about sparsification of (hyper)graphs with a fixed predicate but this is equivalent to the CSP view.

Recently, while trying to eliminate the requirement for the introduction of new weights for the sparse subgraph, Bansal, Svensson and Trevisan [7] have come up with a new sparsification notion with an additive error term. They have shown (cf. Theorem 3 in Section 2) that under their notion any undirected unweighted hypergraph has a sparse subhypergraph which preserves all cuts up to some additive term.

Motivation

The relatively recent notion of additive sparsification has not yet been explored to the same extent as the notion of multiplicative sparsification has been. We believe that this notion has a lot of potential for applications as the sparsifiers are not weighted, unlike multiplicative sparsifiers. Indeed, the main restriction of multiplicative sparsifiers in applications appears to be the number of distinct weights required in sparsifiers. For some graphs (such as the “barbell graph” – two disjoint cliques joined by a single edge), any nontrivial multiplicative sparsifier requires edges of different weights. In any case, the authors find the notion of additive sparsification interesting in its own right, independently of applications.

The goal of our work is to understand how the notion of additive sparsification developed in [7] for cuts behaves on (hyper)graphs with other predicates (beyond cuts), deriving inspiration from the generalisations of cuts to other predicates in the multiplicative setting established in [20, 14]. In particular, already Boolean binary predicates include interesting predicates such as the *uncut edges* (using the predicate $P(x, y) = 1$ iff $x = y$), *covered edges* (using the predicate $P(x, y) = 1$ iff $x = 1$ or $y = 1$), or *directed cut edges* (using the predicate $P(x, y) = 1$ iff $x = 0$ and $y = 1$). While such graph problems are well-known and extensively studied, it is not clear whether one should expect them to be sparsifiable or not. For instance, as mentioned before, not all (even Boolean binary) predicates are sparsifiable multiplicatively [20]. Are there some predicates that are not additively sparsifiable?

1.1 Contributions

Boolean predicates

Our main result, Theorem 9 in Section 3, shows that *all* hypergraphs with *constant* uniformity k , directed or undirected, admit additive sparsification with respect to all Boolean predicates $P : \{0, 1\}^k \rightarrow \{0, 1\}$; the number of hyperedges of the sparsifier with error $\varepsilon > 0$ is $O(n\varepsilon^{-2} \log \frac{1}{\varepsilon})$, where the $O(\cdot)$ hides a factor that depends on k . This result has three ingredients. First, we observe that the result in [7] also holds true for directed hypergraphs. Second, we use a reduction via the k -partite k -fold covers of hypergraphs to the already solved case of Boolean Cut. Finally, we use linear algebra to prove the correctness of the reduction. While the reduction via the k -partite k -fold cover was used in previous works on multiplicative sparsification [20, 14], the subsequent non-trivial linear-algebraic analysis (Proposition 13) is novel and constitutes our main technical contribution, as well as our result that, unlike in the multiplicative setting, all Boolean predicates can be (additively) sparsified. We also show that our results immediately apply to the more general setting where different hyperedges are associated with different predicates (cf. Remark 10). This corresponds to CSPs with a fixed constraint language (of a finite size) rather than just a single predicate.

Non-Boolean predicates

We introduce a notion of sparsification that generalises the Boolean case to predicates on non-Boolean domains, i.e. a notion capturing predicates of the form $P : D^k \rightarrow \{0, 1\}$, where D is an arbitrary fixed finite set with $|D| \geq 2$. We call this type of sparsification “all-but-one” sparsification since the additive error term includes the maximum volume of $|D| - 1$ (out of $|D|$) parts, where the volume of a subset is the sum of the degrees in the subset. (The precise definition can be found in Section 4.) By building on the techniques used to establish our main result, we show that all hypergraphs (again, directed or undirected) admit additive all-but-one sparsification with respect to all predicates. This is stated as Theorem 20 in Section 4. We also show, in Section 5, that our notion of all-but-one sparsification is, in some sense, optimal.

Comparison to previous work

As mentioned above, our sparsifiability result is obtained by a reduction via the k -partite k -fold cover to the cut case established in [7]. A reduction via the k -partite k -fold cover was also used (for $k = 2$) in previous work on multiplicative sparsification [20, 14]. In particular, the correctness of the reduction for Boolean binary predicates in [20] is done via an ad hoc case analysis for 11 concrete predicates. In the generalisation to binary predicates on arbitrary finite domains in [14], the correctness is proved via a combinatorial property of bipartite graphs without a certain 4-vertex graph¹ as a subgraph and a reduction to cuts with more than two parts.

In our case, we use the same black-box reduction via the k -partite k -fold cover. Thus the reduction itself is pretty straightforward, although the analysis is not. In fact, we find it surprising and unexpected that the k -partite k -fold cover works in the additive setting. Our key contribution is the proof of its correctness. A few simple reductions get us to the most technically involved case, in which k is even and the k -ary predicate satisfies $P(1, \dots, 1) = 0$.

¹ A bipartite graph on four vertices with each part of size two and precisely one edge between the two parts.

Additive sparsifiability of such predicates is established in Proposition 13. Unlike in the multiplicative setting, it is not clear how to do this in a straightforward way similar to [20, 14]. Instead, we associate with a given predicate P a vector v_P in an appropriate vector space, identify special vectors that can be shown additively sparsifiable directly, show that linear combinations preserve sparsifiability, and argue that v_P can be generated by the special vectors. The latter is the most technical part of the proof. While there are several natural ideas how to achieve this in a seemingly simpler way (such as arguing that the special vectors form a basis), we have not managed to produce a simpler or shorter proof.

The result in [7] also works for non-constant k . We emphasise that we deal with constant k , which is standard in the CSP literature in that the predicate (or a set of predicates) is fixed and not part of the input. For constant k , the representation of predicates is irrelevant (cf. Remark 18). Thus we do not keep track of (and have not tried to optimise) the precise dependency of the reduction on the predicate arity k (or the domain size $q = |D|$).

Related work

The already mentioned spectral sparsification [33] is a stronger notion than cut sparsification as it requires that not only cuts but also the Laplacian spectrum of a given graph should be (approximately) preserved [32, 34, 21, 31, 7].

Our focus in this article is on *edge sparsifiers* (of cuts and generalisations via local predicates). There are also vertex sparsifiers, in which one reduces the number of vertices. Vertex sparsifiers have been studied for cut sparsification (between special vertices called terminals) [22, 26, 25, 15] as well as for spectral sparsification [24].

Sparsification in general is about finding a sparse sub(hyper)graph while preserving important properties of interest. In addition to cut sparsifiers, another well studied concept is that of *spanners*. A spanner of a graph is a (sparse) subgraph that approximately preserves distances of shortest paths. Spanners have been studied in great detail both in the multiplicative [5, 28, 3, 17, 6, 9, 30] and additive [2, 18, 12, 8, 35, 16] setting. Emulators are a generalisation of spanners in which the sparse graph is not required to be a subgraph of the original graph. We refer the reader to a nice recent survey of Elkin and Neimain for more details [19]. Some of the proofs are deferred to the full version of this paper [29].

2 Preliminaries

For an integer k , we denote by $[k]$ the set $\{0, 1, \dots, k-1\}$. All graphs and hypergraphs² in this paper are unweighted.

For an assignment $a : V \rightarrow S$ from the set of vertices of a (hyper)graph to some set S containing 0, we denote by $Z_a = \{v \in V : a(v) = 0\}$ the set of vertices mapped to 0.

If $0 \leq i \leq r^k - 1$ is an integer, we denote by $\text{rep}_{r,k}(i)$ the representation of i in base r as a vector in \mathbb{R}^k , where the first coordinate stands for the most significant digit, and the last coordinate for the least significant digit. For the special case $r = 2$, we use the notation $\text{bin}_k(i)$ for the binary representation of i .

We denote by $v[j]$ the j -th coordinate of the vector v , counting from 0.

For an integer $0 \leq i \leq 2^k - 1$, we use $\text{zeros}_k(i) = \{\ell \in [k] : \text{bin}_k(i)[\ell] = 0\}$; for example $\text{zeros}_6(52) = \{2, 4, 5\}$, since $\text{bin}_6(52) = (1, 1, 0, 1, 0, 0)$.

We now define the value of an assignment on a hypergraph with a fixed predicate.

² We use the standard definition of hypergraphs, in which every hyperedge is an ordered tuple of vertices.

► **Definition 1.** Let $G = (V, E)$ be a directed k -uniform hypergraph and let $P : D^k \rightarrow \{0, 1\}$ be a k -ary predicate on a finite set D . Given an assignment $a : V \rightarrow D$ of G , the value of a is defined by $\text{Val}_{G,P}(a) = \sum_{(v_1, \dots, v_k) \in E} P(a(v_1), \dots, a(v_k))$. If G is undirected and P is order invariant,³ we define $\text{Val}_{G,P}(a) = \sum_{\{v_1, \dots, v_k\} \in E} P(a(v_1), \dots, a(v_k))$.⁴

The notion of additive sparsification was first introduced in [7] for cuts in graphs and hypergraphs. In order to define it, we will need the $\text{Cut} : \{0, 1\}^k \rightarrow \{0, 1\}$ predicate defined by $\text{Cut}(b_1, \dots, b_k) = 1 \iff \exists i, j, b_i \neq b_j$. Given a hypergraph $G = (V, E)$ and a set $U \subseteq V$, we denote by $\text{vol}_G(U)$ the *volume* of U , defined as the sum of the degrees in G of all vertices in U .

► **Definition 2.** Let $G = (V, E)$ be an undirected k -uniform hypergraph, and denote $|V| = n$. We say that G admits additive cut sparsification with error ε using $O(f(n, \varepsilon))$ hyperedges if there exists a subhypergraph $G_\varepsilon = (V, E_\varepsilon \subseteq E)$ with $|E_\varepsilon| = O(f(n, \varepsilon))$, called an additive sparsifier of G , such that for every assignment $a : V \rightarrow \{0, 1\}$ we have

$$\left| \frac{|E|}{|E_\varepsilon|} \text{Val}_{G_\varepsilon, \text{Cut}}(a) - \text{Val}_{G, \text{Cut}}(a) \right| \leq \varepsilon(d_G|Z_a| + \text{vol}_G(Z_a)), \quad (1)$$

where d_G is the average degree of G .

Note that (1) can also be written as

$$\frac{|E|}{|E_\varepsilon|} \text{Val}_{G_\varepsilon, \text{Cut}}(a) \in \text{Val}_{G, \text{Cut}}(a) \pm \varepsilon(d_G|Z_a| + \text{vol}_G(Z_a)),$$

which explains the use of the term “additive” for the error.

Bansal, Svensson and Trevisan [7] showed the following sparsification result:

► **Theorem 3** (Additive Cut Sparsification [7, Theorem 1.3]). Let $G = (V, E)$ be an undirected n -vertex k -uniform hypergraph, and $\varepsilon > 0$. Then G admits additive cut sparsification with error ε using $O\left(\frac{n}{k}\varepsilon^{-2} \log\left(\frac{k}{\varepsilon}\right)\right)$ hyperedges.

► **Remark 4.** We call a predicate P *symmetric* if it is order invariant (as in Definition 1). Since Theorem 3 deals with only *undirected* hypergraphs, it is not clear how to generalise it to non-symmetric predicates directly, since the value of such predicates on undirected hypergraphs is not defined. Therefore, our course of action will be first to prove it for the case of directed hypergraphs, and then generalise it to other predicates on directed hypergraphs. In fact, by doing this we also prove the result for undirected hypergraphs with symmetric predicates, since hyperedges can be given arbitrary directions without changing the average degree of G , or the volume in G , or the value of the predicate in any assignment.

► **Remark 5.** Throughout this paper we only discuss the existence of sparsifiers and do not mention the time complexity to find them. However, the (implicit) time complexity results from [7] apply in our more general setting as well since the sparsifiers we find are in fact the same sparsifiers for all predicates, including cuts (cf. Remark 17).

An important tool we use to prove our results is the k -partite k -fold cover of a hypergraph. This construction is a well known one, and has been used for multiplicative sparsification (for $k = 2$) in [20] and [14].

³ $P(b_1, \dots, b_k) = P(b_{\sigma(1)}, \dots, b_{\sigma(k)})$ for all $b_1, \dots, b_k \in D$ and every permutation σ on the set $\{1, \dots, k\}$.

⁴ The terms are well defined since P is order invariant.

► **Definition 6.** Let $G = (V, E)$ be a directed k -uniform hypergraph. The k -partite k -fold cover of G is the hypergraph $\gamma(G) = (V^\gamma, E^\gamma)$ where

$$V^\gamma = \{v^{(0)}, v^{(1)}, \dots, v^{(k-1)} : v \in V\},$$

$$E^\gamma = \{(v_1^{(0)}, v_2^{(1)}, \dots, v_k^{(k-1)}) : (v_1, \dots, v_k) \in E\}.$$

If G is undirected we define the cover in the same way except

$$E^\gamma = \{(v_1^{(0)}, v_2^{(1)}, \dots, v_k^{(k-1)}) : \{v_1, \dots, v_k\} \in E\},$$

so for each hyperedge in G we get $k!$ hyperedges in $\gamma(G)$ in this case.

If $k = 2$ then $\gamma(G)$ corresponds to the well-known *bipartite double cover* of G [13].

3 Sparsification of Boolean Predicates

As mentioned in Section 1, we begin by observing that Theorem 3 also works for directed hypergraphs. The simple proof of this fact can be found in the full version [29]. (We emphasise that we treat k as a constant, cf. Remark 18.)

► **Proposition 7.** Let $G = (V, E)$ be a directed n -vertex k -uniform hypergraph, and $\varepsilon > 0$. Then G admits additive cut sparsification with error ε using $O(n\varepsilon^{-2} \log \frac{1}{\varepsilon})$ hyperedges.

From now on, whenever we say a “hypergraph”, we mean a “directed hypergraph” with n vertices. By Remark 4, the results also apply to undirected hypergraphs (whenever it makes sense, i.e. if the associated predicate is symmetric). We also omit the word additive when discussing sparsification. The following notion of sparsification is a natural generalisation of cut sparsification (Definition 2) to arbitrary predicates.

► **Definition 8.** Let P be a k -ary Boolean predicate and $G = (V, E)$ a k -uniform hypergraph. We say that G admits P -sparsification with error ε using $O(f(n, \varepsilon))$ hyperedges if there exists a subhypergraph $G_\varepsilon = (V, E_\varepsilon \subseteq E)$ with $|E_\varepsilon| = O(f(n, \varepsilon))$, called a P -sparsifier of G , such that for every assignment $a : V \rightarrow \{0, 1\}$ we have

$$\left| \frac{|E|}{|E_\varepsilon|} \text{Val}_{G_\varepsilon, P}(a) - \text{Val}_{G, P}(a) \right| \leq \varepsilon(d_G|Z_a| + \text{vol}_G(Z_a)), \quad (2)$$

where d_G is the average degree of G .

The following theorem is our main result, extending Proposition 7 to *all* k -ary predicates with Boolean domains.

► **Theorem 9 (Main).** For every k -uniform hypergraph G (k is a constant), every k -ary Boolean predicate $P : \{0, 1\}^k \rightarrow \{0, 1\}$, and every $\varepsilon > 0$, G admits P -sparsification with error ε using $O(n\varepsilon^{-2} \log \frac{1}{\varepsilon})$ hyperedges.

Theorem 9 can be informally restated as “every k -uniform hypergraph is sparsifiable with respect to all k -ary Boolean predicates” or “for every Boolean predicate P of constant arity, $\text{CSP}(P)$ is sparsifiable”.

► **Remark 10.** It is possible to consider an even more general case where each hyperedge in G has its own predicate. In this case, we can apply Theorem 9 to each of the hypergraphs obtained by taking only hyperedges corresponding to a specific predicate, and so get a sparsifier for each such predicate. Taking the union of all their hyperedges, we get a new

hypergraph G_ε , which is a sparsifier of the original hypergraph. Indeed, it has $O(n\varepsilon^{-2} \log \frac{1}{\varepsilon})$ hyperedges since it is the union of a constant number of hypergraphs. (The number of predicates $P : \{0,1\}^k \rightarrow \{0,1\}$ is constant, since k is constant.) It also satisfies (2) for any given assignment up to some constant factor, since all the sparsifiers it is composed of do. This constant factor can be eliminated by choosing $\varepsilon_0 = \frac{\varepsilon}{m}$ for an appropriate m that depends only on k .

The main work in the proof of Theorem 9 is for even values of k ; a simple reduction (Proposition 16) then reduces the case of k odd to the even case.

In order to prove Theorem 9 for even k , we use the k -partite k -fold cover of G and apply Proposition 7 to various assignments of it. For a k -ary Boolean predicate $P : \{0,1\}^k \rightarrow \{0,1\}$, we consider the vector $v_P \in \mathbb{R}^{2^k}$, defined by $v_P[i] = P(\text{bin}_k(i))$. For instance, for the Cut predicate on a 3-uniform hypergraph, we have $v_{\text{Cut}} = (0, 1, 1, 1, 1, 1, 1, 0)$.

For a given hypergraph G and an assignment a , we consider the vector $v_{G,a} \in \mathbb{R}^{2^k}$ defined by $v_{G,a}[i] = |\{(v_1, \dots, v_k) \in E : (a(v_1), \dots, a(v_k)) = \text{bin}_k(i)\}|$. In other words, each coordinate of $v_{G,a}$ counts the hyperedges in G whose vertices are assigned some specific set of values by a .

► **Example 11.** Given the graph $G = (V, E)$ in Figure 1 (so $k = 2$) and the assignment $a : V \rightarrow \{0,1\}$ defined as $a(v_1) = a(v_2) = a(v_3) = 0$ and $a(v_4) = a(v_5) = a(v_6) = a(v_7) = 1$, we have $v_{G,a} = (2, 3, 1, 5)$, since there are two edges with assignment $(0,0)$, namely (v_1, v_2) and (v_2, v_3) , three edges with assignment $(0,1)$, namely (v_1, v_4) , (v_2, v_6) , and (v_2, v_7) , etc.

■ **Figure 1** Graph from Example 11.

Under these notations, we get $\text{Val}_{G,P}(a) = \langle v_P, v_{G,a} \rangle$, where $\langle \cdot, \cdot \rangle$ is the standard inner product in \mathbb{R}^{2^k} . We begin by proving the following useful lemma.

► **Lemma 12.** Let $G = (V, E)$ be a k -uniform hypergraph, P_1, \dots, P_m be k -ary Boolean predicates (m is a constant). Suppose that for every $\varepsilon > 0$ and $1 \leq i \leq m$, G admits P_i -sparsification with error ε using $O(n\varepsilon^{-2} \log \frac{1}{\varepsilon})$ hyperedges, and that the same subhypergraph $G_\varepsilon = (V, E_\varepsilon \subseteq E)$ is a P_i -sparsifier for all P_i . Suppose that P is some k -ary Boolean predicate for which we have $v_P = \sum_{i=1}^m \lambda_i v_{P_i}$ for some constants $\lambda_1, \dots, \lambda_m \in \mathbb{R}$. Under these conditions, G admits P -sparsification with error ε using $O(n\varepsilon^{-2} \log \frac{1}{\varepsilon})$ hyperedges.

Proof. Let $\varepsilon > 0$ and denote $\varepsilon_i = \frac{\varepsilon}{m|\lambda_i|}$ (if $\lambda_i = 0$ take $\varepsilon_i = 1$ instead) and $\varepsilon_0 = \min\{\varepsilon_1, \dots, \varepsilon_m\}$. Let $G_{\varepsilon_0} = (V, E_{\varepsilon_0})$ be the common witness subhypergraph for ε_0 promised by the assumption. We know that every P_i satisfies

$$\left| \frac{|E|}{|E_{\varepsilon_0}|} \text{Val}_{G_{\varepsilon_0}, P_i}(a) - \text{Val}_{G, P_i}(a) \right| \leq \varepsilon_0 (d_G(Z_a) + \text{vol}_G(Z_a)) \quad (3)$$

for every assignment $a : V \rightarrow \{0,1\}$. We also have

$$\text{Val}_{G,P}(a) = \langle v_P, v_{G,a} \rangle = \left\langle \sum_{i=1}^m \lambda_i v_{P_i}, v_{G,a} \right\rangle = \sum_{i=1}^m \lambda_i \langle v_{P_i}, v_{G,a} \rangle = \sum_{i=1}^m \lambda_i \text{Val}_{G, P_i}(a),$$

75:8 Additive Sparsification of CSPs

and similarly

$$\text{Val}_{G_{\varepsilon_0}, P}(a) = \sum_{i=1}^m \lambda_i \text{Val}_{G_{\varepsilon_0}, P_i}(a).$$

Therefore, for every assignment a we get

$$\begin{aligned} \left| \frac{|E|}{|E_{\varepsilon_0}|} \text{Val}_{G_{\varepsilon_0}, P}(a) - \text{Val}_{G, P}(a) \right| &= \left| \frac{|E|}{|E_{\varepsilon_0}|} \sum_{i=1}^m \lambda_i \text{Val}_{G_{\varepsilon_0}, P_i}(a) - \sum_{i=1}^m \lambda_i \text{Val}_{G, P_i}(a) \right| \\ &\leq \sum_{i=1}^m |\lambda_i| \left| \frac{|E|}{|E_{\varepsilon_0}|} \text{Val}_{G_{\varepsilon_0}, P_i}(a) - \text{Val}_{G, P_i}(a) \right| \\ &\leq \sum_{i=1}^m |\lambda_i| \varepsilon_0 (d_G |Z_a| + \text{vol}_G(Z_a)) \\ &\leq \varepsilon (d_G |Z_a| + \text{vol}_G(Z_a)), \end{aligned}$$

where the second line is due to the triangle inequality, the third is due to (3) and the fourth is by the definition of ε_0 .

Furthermore, since m and all λ_i are constants,

$$|E_{\varepsilon_0}| = O\left(n \varepsilon_0^{-2} \log \frac{1}{\varepsilon_0}\right) = O\left(n \varepsilon^{-2} \log \frac{1}{\varepsilon}\right),$$

and so G_{ε_0} is a witness for the P -sparsification of G . ◀

The core of the proof of Theorem 9 is in the next proposition, which establishes the result for Boolean predicates on even uniformity hypergraphs, with a small restriction.

► **Proposition 13.** *Let k be an even number and G be a k -uniform hypergraph. Let P be a k -ary Boolean predicate with $P(1, 1, \dots, 1) = 0$. Then for every $\varepsilon > 0$, G admits P -sparsification with error ε using $O(n \varepsilon^{-2} \log \frac{1}{\varepsilon})$ hyperedges.*

Proof. Let $\varepsilon > 0$. We consider $\gamma(G)$, the k -partite k -fold cover of G . Let $\gamma(G)_\varepsilon$ be a subhypergraph of $\gamma(G)$ promised by Proposition 7, and $G_\varepsilon = (V, E_\varepsilon)$ the corresponding subhypergraph of G , i.e. the subhypergraph which satisfies $\gamma(G_\varepsilon) = \gamma(G)_\varepsilon$ (by taking the hyperedges corresponding to the ones of $\gamma(G)_\varepsilon$).

Let $a : V \rightarrow \{0, 1\}$. For every subset $T \subseteq [k]$, we look at the assignment $a_T : V^\gamma \rightarrow \{0, 1\}$ defined by $a_T(v^{(i)}) = 0$ if $i \in T$ and $a(v) = 0$, and $a_T(v^{(i)}) = 1$ otherwise. We therefore have

$$\left| \frac{|E^\gamma|}{|E_\varepsilon^\gamma|} \text{Val}_{\gamma(G)_\varepsilon, \text{Cut}}(a_T) - \text{Val}_{\gamma(G), \text{Cut}}(a_T) \right| \leq \varepsilon (d_{\gamma(G)} |Z_{a_T}| + \text{vol}_{\gamma(G)}(Z_{a_T})). \quad (4)$$

Define the vector $u_T \in \mathbb{R}^{2^k}$ as follows:

$$u_T[j] = \begin{cases} 1 & T \cap \text{zeros}(j) \neq \emptyset, [k] \\ 0 & \text{otherwise} \end{cases}.$$

In other words, the vector u_T is 1 in index j if and only if there exists an index $i \in T$ in which the binary representation of j has a zero, with the exception of $u_{[k]}[0] = 0$. Denote by P_T the predicate corresponding to u_T , that is $P_T(\text{bin}_k(j)) = 1 \iff u_T[j] = 1$. Observe that

$$\text{Val}_{\gamma(G), \text{Cut}}(a_T) = \text{Val}_{G, P_T}(a),$$

■ **Figure 2** An example of a representation of an assignment on $\gamma(G)$. $Z_a^{(i)}$ consists of all vertices in $V^{(i)}$ which are a copy of a vertex $v \in V$ with $a(v) = 0$, and $\bar{Z}_a^{(i)}$ consists of the rest of $V^{(i)}$. Each hyperedge has a unique path from left to right (but a path might belong to multiple hyperedges), choosing one of $Z_a^{(i)}, \bar{Z}_a^{(i)}$ for each i . Each such path is also in 1-1 correspondence with a coordinate in u_T . In this example $T = \{0, 3, k-1\}$ and the shaded sets represent $a_T^{-1}(0)$. By green dotted lines we indicated a path corresponding to a hyperedge counted in $\text{Val}_{\gamma(G), \text{Cut}}(a_T)$, and by red dashed lines we indicated a path which does not. The green dotted path corresponds to a value of 1 in the coordinate of u_T with binary representation $(1, 1, 0, 0, 1, \dots, 0, 1)$, and the red dashed path to a value 0 in the coordinate with binary representation $(1, 0, 1, 1, 0, \dots, 1, 1)$. Note that if $T = [k]$ then any hyperedge corresponding to a path only on $Z_a^{(i)}$ is not counted.

since they both count exactly hyperedges (v_1, \dots, v_k) which have some vertex v_i with $a(v_i) = 0$ with $i \in T$, but if $T = [k]$ then they do not count hyperedges which have $a(v_i) = 0$ for all $i = 1, \dots, k$ (see example in Figure 2). The same is true for any hypergraph, and in particular for G_ε , that is

$$\text{Val}_{\gamma(G_\varepsilon), \text{Cut}}(a_T) = \text{Val}_{G_\varepsilon, P_T}(a).$$

Putting these results in (4), we get

$$\begin{aligned} \left| \frac{|E|}{|E_\varepsilon|} \text{Val}_{G_\varepsilon, P_T}(a) - \text{Val}_{G, P_T}(a) \right| &\leq \varepsilon(d_{\gamma(G)}|Z_{a_T}| + \text{vol}_{\gamma(G)}(Z_{a_T})) \\ &\leq \varepsilon(d_G|Z_a| + \text{vol}_G(Z_a)), \end{aligned}$$

so G admits P_T sparsification with error ε using $O(n\varepsilon^{-2} \log \frac{1}{\varepsilon})$ hyperedges for every $T \subseteq [k]$, and for every ε the sparsification is witnessed by the same subhypergraph G_ε . (Notice that Proposition 7, when applied to $\gamma(G)$ which has kn vertices, gives us a subhypergraph with $O(kn\varepsilon^{-2} \log \frac{1}{\varepsilon})$ hyperedges, and recall that k is a constant.)

Our next goal is to show that the vector v_P is a linear combination of the vectors u_T for all $T \in [k]$. To show that, we show that every vector e_r in the standard basis of \mathbb{R}^{2^k} , with $r \neq 2^k - 1$, is a linear combination of these vectors. This is sufficient since the last coordinate of v_P is 0 by the assumption. First we need to order the various sets T . We order them in the following decreasing lexicographic order $T_0, T_1, \dots, T_{2^k-1}$, where $T_j = \text{zeros}(j)$, so $T_0 = [k], T_1 = [k] \setminus \{k-1\}, T_2 = [k] \setminus \{k-2\}, T_3 = [k] \setminus \{k-1, k-2\}, T_4 = [k] \setminus \{k-3\}$ and so on, until $T_{2^k-1} = \emptyset$.

Let e_r be a vector in the standard basis of \mathbb{R}^{2^k} . We introduce the following coefficients for $0 \leq m \leq 2^k - 1$:

$$\lambda_{r,m} = \frac{1}{2}(-1)^{\text{Ham}(r \oplus m) + (1 - \mathbb{1}_{r \& m})},$$

where $\oplus, \&$ are the Xor and And binary functions respectively,⁵ Ham is the Hamming weight

⁵ The Xor of two integers is defined as the bitwise Boolean Xor of their binary representations, where the

75:10 Additive Sparsification of CSPs

function, and $\mathbf{1}_d$ returns 1 if $d \neq 0$ and 0 if $d = 0$. Denote

$$f_1(m) = \text{Ham}(r \oplus m) \quad , \quad f_2(m) = (1 - \mathbf{1}_{r \& m}).$$

We shall prove that

$$e_r = \sum_{m=0}^{2^k-1} \lambda_{r,m} u_{T_m}. \quad (5)$$

▷ **Claim 14.** The sum of all coefficients is 0; i.e., $\sum_{m=0}^{2^k-1} \lambda_{r,m} = 0$.

Proof. Let $b_1 b_2 \dots b_k$ be the binary representation of r . Since $r < 2^k - 1$, there exists some $1 \leq i \leq k$ for which $b_i = 0$. We can partition the coefficients into pairs, such that $\lambda_{r,m_1}, \lambda_{r,m_2}$ is a pair if and only if m_1, m_2 differ in the i -th coordinate only. This is clearly a partition. For each pair, f_1 gives m_1, m_2 different parity values, and f_2 gives them the same value (since $b_i = 0$), so $\lambda_{r,m_1}, \lambda_{r,m_2}$ have opposite signs, so their sum is zero. This is true for every pair, so the overall sum is zero, and the claim is proved. ◁

We prove (5) coordinate-wise. First we look at the coordinate r . Consider the set W of all vectors u_{T_m} for which the coordinate r is 0. If we show that the sum of the corresponding coefficients of the vectors in W is -1 , using Claim 14 we will deduce the result in this case. We distinguish 2 cases:

Case (I): $r = 0$. By the definition of u_T , in this case the set W contains two vectors, $u_{[k]}$ and u_\emptyset . The corresponding coefficients are $\lambda_{r,0} = -\frac{1}{2}$ and $\lambda_{r,2^k-1} = -\frac{1}{2}$ (since k is even), which sum up to -1 .

Case (II): $r > 0$. As in the proof of Claim 14, let $b_1 b_2 \dots b_k$ be the binary representation of r , and choose a coordinate $1 \leq i \leq k$ for which $b_i = 1$. Partition the vectors in W into pairs where $u_{T_{m_1}}, u_{T_{m_2}}$ is a pair if and only if m_1, m_2 differ in the i -th coordinate only. This is clearly a partition of all vectors, and by the definition of u_T , each such pair is either contained in W or disjoint from W so this is indeed a partition of W . (Note that $u_{T_{m_1}}[r]$ is determined by $T_{m_1} \cap \text{zeros}(r)$ which is in fact $\text{zeros}(m_1) \cap \text{zeros}(r)$, and the same for m_2 . Since m_1, m_2 differ in the i -th coordinate only, and r is not zero in this coordinate, this coordinate contributes nothing to the intersections, and so both these intersections are empty or non-empty together. The intersection never equals $[k]$ since $r > 0$.) For every such pair in W , if it does not contain the negation of $\text{bin}(r)$, then there is some other index $j \neq i$ in which r, m_1, m_2 are all 1. (This is because in all other coordinates m_1, m_2 are equal, and since they are not the negation of r , there is some coordinate $j \neq i$ in which they are equal to the j -th coordinate of r . These coordinates cannot be all 0, since this would imply $u_{T_{m_1}}, u_{T_{m_2}} \notin W$.) This implies that f_2 gives m_1, m_2 the same value, and clearly f_1 gives them different parity values, so $\lambda_{r,m_1} + \lambda_{r,m_2} = 0$. However, for the pair which contains the negation of r (this pair is clearly in W), suppose without loss of generality the negation is m_1 . Then f_2 gives m_1, m_2 the values 1, 0 respectively, and f_1 gives m_1 an even value and m_2 an odd value (since k is even), and so $\lambda_{r,m_1} = \lambda_{r,m_2} = -\frac{1}{2}$, and the overall sum is -1 . This finishes the proof of (5) in the coordinate r .

Now let $r' \neq r$ be some other coordinate, and let $c_1 c_2 \dots c_k$ be its binary representation. First, if $r' = 2^k - 1$ then for all m we have $u_{T_m}[r'] = 0$ by definition, so the linear combination

Boolean Xor of two bits is their sum modulo 2. The And of two integers is defined the same way with the Boolean And function which is defined as $\text{And}(i, j) = 1 \iff i = j = 1$.

of this coordinate is 0. So suppose $r' < 2^k - 1$. As before let W be the set of all vectors u_{T_m} for which the coordinate r' is 0. We show that the sum of the corresponding coefficients is zero, and again deduce the result using Claim 14. Now, there exists some index i for which $b_i \neq c_i$. Again we have two cases:

Case (1): $b_i = 0, c_i = 1$. Partition the vectors in W into pairs where $u_{T_{m_1}}, u_{T_{m_2}}$ is a pair if and only if m_1, m_2 differ in the i -th coordinate only. This is clearly a partition of all the vectors, and by the definition of u_T , each such pair is either contained in W or disjoint from W , so this is indeed a partition of W . For every such pair in W , f_1 gives m_1, m_2 different parity values, and f_2 gives them the same value (since $b_i = 0$), so $\lambda_{r, m_1}, \lambda_{r, m_2}$ have opposite signs, so their sum is zero. This is true for every pair in W , so the overall sum is zero.

Case (2) $b_i = 1, c_i = 0$. Here we consider two sub-cases:

Case (2a): $r' = 0$. The only vectors in W in this case are $u_{[k]}$ and u_\emptyset . The corresponding coefficients are $\lambda_{r, 0} = \frac{1}{2}(-1)^{\text{Ham}(r)+1}$ and $\lambda_{r, 2^k-1} = \frac{1}{2}(-1)^{\text{Ham}(\neg r)}$, where $\neg r$ denotes the negation of the binary representation of r . Since k is even, we know that $r, \neg r$ have the same parity, and so the sum of the two coefficients is 0.

Case (2b): $r' \neq 0$. Choose some j for which $c_j = 1$. Partition the vectors in W into pairs where $u_{T_{m_1}}, u_{T_{m_2}}$ is a pair if and only if m_1, m_2 differ in the j -th coordinate only. The argument for this being a partition of W is similar to the argument in Case (1). For each pair in W , f_1 gives m_1, m_2 a different parity as always, and f_2 gives them the same value, since r, m_1, m_2 are all 1 in the index i (similar argument as before), so the sum of coefficients is 0 for each pair, and so for all coefficients corresponding to vectors in W .

This finishes the proof of (5), and so v_P is a linear combination of the vectors u_T . From the result above and Lemma 12 we deduce that G admits P -sparsification with error ε using $O(n\varepsilon^{-2} \log \frac{1}{\varepsilon})$ hyperedges, as required. ◀

To complete the picture for even k , we reduce to Proposition 13 by a simple “complementarity trick”; the proof can be found in the full version [29].

► **Proposition 15.** *Let k be an even number, and G a k -uniform hypergraph. Let P be a k -ary Boolean predicate. Then for every $\varepsilon > 0$, G admits P -sparsification with error ε using $O(n\varepsilon^{-2} \log \frac{1}{\varepsilon})$ hyperedges.*

The final piece in the jigsaw, proved in the full version [29], shows how to reduce sparsification of k -uniform hypergraphs with k odd to the case of $(k+1)$ -uniform hypergraphs by adding a universal vertex and extending the original predicate by one dimension.

► **Proposition 16.** *Let k be an odd number, and $G = (V, E)$ a k -uniform hypergraph. Let P be a k -ary Boolean predicate. Then for every $\varepsilon > 0$, G admits P -sparsification with error ε using $O(n\varepsilon^{-2} \log \frac{1}{\varepsilon})$ hyperedges.*

Propositions 15 and 16 complete the proof of Theorem 9.

► **Remark 17.** In the proof of Proposition 13 the hypergraph G_ε was chosen independently of the predicate P . Since Propositions 15 and 16 reduce to that case, we have in fact shown that for every $\varepsilon > 0$, Theorem 9 is witnessed by the same subhypergraph G_ε for all different predicates P . This will be important in the proof of Theorem 20.

► **Remark 18.** We note that our main result, Theorem 9, extends Theorem 3 in the regime where k is a constant, which is the main focus of this paper. However, Theorem 3 also works for non-constant k [7]. If k is not a constant, it can be seen from the proof of Lemma 12 that the number of hyperedges of the sparse subhypergraph is multiplied by a factor of $O(m^2)$ (since $O(m)$ is the proportion between ε and ε_0 given that the coefficients λ_i are constant).

In Proposition 13 we have $m = 2^k$, and so for k not constant we get an additional factor of 4^k . Furthermore, in Propositions 7 and 13 we obtain extra factors of k , by considering the k -partite k -fold cover. While the regime with non-constant k is interesting for cuts, for arbitrary predicates one needs to be careful about representation as the natural (explicit) representation of (non-symmetric) predicates requires exponential space in the arity k .

4 Sparsification of Non-Boolean Predicates

We now focus on non-Boolean predicates; i.e., predicates of the form $P : D^k \rightarrow \{0, 1\}$ with $|D| > 2$. Without loss of generality, we assume $D = [q]$ for some $q \geq 2$. The most natural way of generalising Theorem 9 to larger domains appears to be to use the same bound with $Z_a = \{v \in V : a(v) = 0\}$. This, however, cannot give the desired sparsification result (cf. Section 5). Instead we use a different and somewhat weaker kind of generalisation of the Boolean case, and show that all hypergraphs are still sparsifiable with respect to all predicates using this definition.

► **Definition 19.** Let $P : D^k \rightarrow \{0, 1\}$ be a k -ary predicate where $D = [q]$. We say that a k -uniform hypergraph $G = (V, E)$ admits all-but-one P -sparsification with error ε using $O(f(n, \varepsilon))$ hyperedges if there exists a subhypergraph $G_\varepsilon = (V, E_\varepsilon \subseteq E)$ with $|E_\varepsilon| = O(f(n, \varepsilon))$ such that for every assignment $a : V \rightarrow D$ we have

$$\left| \frac{|E|}{|E_\varepsilon|} \text{Val}_{G_\varepsilon, P}(a) - \text{Val}_{G, P}(a) \right| \leq \varepsilon(d_G |M_a| + \text{vol}_G(N_a)), \quad (6)$$

where M_a is the largest set among the sets $\{v \in V : a(v) = i\}$, N_a is the set with the largest volume among the sets $\{v \in V : a(v) = i\}$ for $0 \leq i \leq q-2$, and d_G is the average degree in G .

Observe that the maximum in Definition 19 is over $i = 0, \dots, q-2$ without $i = q-1$, hence the name “all-but-one”. We note that there is nothing special about $q-1$ and any value from $[q]$ could be chosen in Definition 19.

Under Definition 19, Theorem 9 generalises (proof of can be found in the full version [29]).

► **Theorem 20.** For every k -uniform hypergraph $G = (V, E)$, every k -ary predicate $P : D^k \rightarrow \{0, 1\}$ with $D = [q]$ (k, q are constants), and every $\varepsilon > 0$, G admits P all-but-one sparsification with error ε using $O(n\varepsilon^{-2} \log \frac{1}{\varepsilon})$ hyperedges.

Note that in the case of $q = 2$ we have $P : \{0, 1\}^k \rightarrow \{0, 1\}$, and Definition 19 and Theorem 20 coincide with Definition 8 and Theorem 9. This is because when $q = 2$ the definitions of M_a, N_a coincide with the definition of Z_a in the Boolean case.

5 Optimality of All-But-One Sparsification

One might wonder if there is a different, perhaps stronger way to define sparsification for predicates on non-Boolean domains. The following example shows that all-but-one sparsification is optimal.

For a hypergraph $G = (V, E)$ and a fixed assignment $a : V \rightarrow [q]$ denote $S_i = \{v \in V : a(v) = i\}$ (so $S_0 = Z_a$). The definition of all-but-one sparsification lets us take a bound which depends on the sizes and volumes of all the sets S_i except for S_{q-1} . In fact, if we try to take a bound which depends on fewer of these sets, the definition fails to generalise even the most basic case of the Cut predicate. To see this, it is sufficient to consider the graph case,

i.e. $k = 2$. Let us suppose, without loss of generality, that our bound does not depend on S_{q-2}, S_{q-1} . Consider the predicate $\text{Cut} : [q]^2 \rightarrow \{0, 1\}$ defined by $\text{Cut}(x, y) = 1 \iff x \neq y$. A simple (but lengthy) argument in the full version [29] shows that cliques do not have a Cut-sparsifier using such a definition. In fact, the same argument works for any predicate P with $P(q-2, q-1) = P(q-1, q-2) = 1$ and $P(q-2, q-2) = P(q-1, q-1) = 0$. Thus if a definition does not depend on more than just S_{q-2}, S_{q-1} , it specifically does not depend on these two, so the same argument still works. Therefore, no definition with a bound which depends on “less” is possible, under the current assumptions.

Faster Deterministic Modular Subset Sum

Krzysztof Potępa ✉

Jagiellonian University, Kraków, Poland

Abstract

We consider the *Modular Subset Sum* problem: given a multiset X of integers from \mathbb{Z}_m and a target integer t , decide if there exists a subset of X with a sum equal to $t \pmod{m}$. Recent independent works by Cardinal and Iacono (SOSA'21), and Axiotis et al. (SOSA'21) provided simple and near-linear algorithms for this problem. Cardinal and Iacono gave a randomized algorithm that runs in $\mathcal{O}(m \log m)$ time, while Axiotis et al. gave a deterministic algorithm that runs in $\mathcal{O}(m \text{ polylog } m)$ time. Both results work by reduction to a text problem, which is solved using a dynamic strings data structure.

In this work, we develop a simple data structure, designed specifically to handle the text problem that arises in the algorithms for Modular Subset Sum. Our data structure, which we call the *shift-tree*, is a simple variant of a segment tree. We provide both a hashing-based and a deterministic variant of the *shift-trees*.

We then apply our data structure to the Modular Subset Sum problem and obtain two algorithms. The first algorithm is Monte-Carlo randomized and matches the $\mathcal{O}(m \log m)$ runtime of the Las-Vegas algorithm by Cardinal and Iacono. The second algorithm is fully deterministic and runs in $\mathcal{O}(m \log m \cdot \alpha(m))$ time, where α is the inverse Ackermann function.

1 Introduction

The *Subset Sum* is a fundamental problem in computer science. It is defined as follows: given a multiset X of n positive integers and a target integer t , decide if there exists a subset of X , such that the sum of its elements is exactly t . The problem is known to be NP-complete [14], but only in a weak sense: a classic dynamic programming approach of Bellman [5] solves it in pseudo-polynomial $\mathcal{O}(nt)$ time. In recent years, there has been a lot of research towards improving the runtime [16, 17, 7, 12], which culminated in near-linear $\tilde{\mathcal{O}}(n + t)$ algorithms [7, 12].¹

In this work, we focus on the *Modular Subset Sum* problem. The *Modular Subset Sum* is a natural variant of the Subset Sum problem, where all sums are taken modulo m , for some given modulus m . We assume that the input multiset X is provided in a compact form: as a list of $\mathcal{O}(m)$ distinct elements along with their multiplicities. This assumption allows us to omit dependence on the number of elements n in algorithm complexities. Moreover, we focus on algorithms that return all possible subset sums, i.e. a set of all attainable values of t .

The dynamic programming of Bellman [5] can be easily adapted to solve the modular case in $\mathcal{O}(nm)$ time. Let S_i be the set of all attainable subset sums using only the first i elements. Bellman's algorithm iteratively computes the sets S_1, \dots, S_n using formula

¹ By writing $\tilde{\mathcal{O}}(f(n))$, we mean $\mathcal{O}(f(n) \text{ polylog } f(n))$.

$S_i = S_{i-1} \cup (S_{i-1} + x_i)$, where x_i is the i -th input element and $S_{i-1} + x_i = \{a + x_i : a \in S_{i-1}\}$. Most of the currently known improved algorithms simply simulate the consecutive iterations of Bellman's algorithm faster. An early notable exception is the $\tilde{O}(m^{5/4})$ algorithm of Koiliaris and Xu [16], which uses a divide-and-conquer approach based on results from number theory.

Abboud et al. [1] obtained a SETH-based conditional lower bound for the Subset Sum problem, which in particular implies that the Modular Subset Sum cannot be solved in $\mathcal{O}(m^{1-\varepsilon})$ time for any $\varepsilon > 0$. The first randomized algorithm that matched their lower-bound (up to subpolynomial factors) was introduced by Axiotis et al. in [4]. They achieved a running time of $\mathcal{O}(m \log^7 m)$ by simulating Bellman's dynamic programming faster using ideas from linear sketching.

Recently, simple and practical algorithms were provided independently in [9, 3]. Both results work by reducing the problem of computing Bellman's iteration to a text problem, but use different data structures to solve it efficiently. A Las-Vegas randomized $\mathcal{O}(m \log m)$ algorithm by Cardinal and Iacono [9] uses the dynamic strings data structure of Gawrychowski et al. [10]. The authors also introduced a simpler alternative, called *Data Dependent Trees*, with logarithmic bounds per operation. On the other hand, Axiotis et al. [3] obtained a deterministic $\mathcal{O}(m \text{ polylog } m)$ algorithm by employing a deterministic data structure of Mehlhorn et al. [18] instead. More precisely, their algorithm is output-sensitive and works in $\mathcal{O}(|X^*| \text{ polylog } |X^*|)$ time, where X^* is the set of all attainable subset sums. The authors provided also a very simple, randomized $\mathcal{O}(m \log^2 m)$ algorithm that uses only an elementary prefix sum structure.

A very recent result of Bringmann and Nakos [8] provides near-linear algorithms for computing the sumset $A_1 + \dots + A_n$, for $A_1, \dots, A_n \subseteq \mathbb{Z}_m$. This problem generalizes the Modular Subset Sum: the set of all attainable subset sums can be expressed as a sumset $\{0, x_1\} + \dots + \{0, x_n\}$.

1.1 Our contributions

In this work, we develop a simple tree-based data structure, designed specifically to handle the text problem that arises in the algorithms for Modular Subset Sum. Our data structure, which we call a *shift-tree*, maintains a string s under the following operations:

- (i) change a single character of s ;
- (ii) cyclically shift s by k positions;
- (iii) given another string t with its corresponding shift-tree, and an interval $[a; b]$, list all positions in $[a; b]$ where strings s and t differ.

We provide two variants of the data structure: a hashing-based one, and a deterministic one with slightly worse time complexity (by $\alpha(n)$, where α is the inverse Ackermann function). By applying shift-trees to the Modular Subset Sum problem, we obtain the following algorithms:

► **Theorem 1.** *There exists an algorithm that returns all attainable modular subset sums of a multiset of integers from \mathbb{Z}_m with high probability, in time $\mathcal{O}(m \log m)$ and space $\mathcal{O}(m)$.*

► **Theorem 2.** *There exists a deterministic algorithm that returns all attainable modular subset sums of a multiset of integers from \mathbb{Z}_m in time $\mathcal{O}(m \log m \cdot \alpha(m))$ and space $\mathcal{O}(m)$.*

The first variant is Monte-Carlo randomized and matches the runtime of Las-Vegas algorithm by Cardinal and Iacono [9]. The second variant is fully deterministic and improves upon the result of Axiotis et al. [3]. Our algorithms are offline as they process the input elements in specific order to achieve their running times.

Although we provide a detailed analysis only for Monte-Carlo randomized and deterministic shift-trees, it is also possible to obtain a Las-Vegas implementation of the data structure. Such an implementation automatically leads to a Las-Vegas algorithm for Modular Subset Sum that truly matches the runtime obtained in [9]. We outline this approach in Remark 8.

Sketch of the shift-tree data structure

We now explain the high-level idea behind our data structure. The shift-tree is a perfect binary tree built upon some string s . The leaves of the tree store the consecutive letters of string s . Since the tree is perfect, the length of string s is required to be a power of two. The inner nodes correspond to substrings of s formed from underlying leaves and store their hashes. The hashes can be updated in logarithmic time after changing a single character of s .

Consider two shift-trees T_1 and T_2 built for strings s_1 and s_2 respectively, such that $|s_1| = |s_2| = m$. We can find all positions where s_1 and s_2 differ by descending from the roots of both trees simultaneously. We compare hashes in the roots and proceed recursively with the children if the hashes differ. Assuming there is no hash collision, we end up in leaves corresponding to positions where s_1 and s_2 differ. Such a procedure will take $\mathcal{O}(k \log m)$ time, where k is the number of differences.

The tricky operation is the cyclic shift of the maintained string. A naive approach would be to simply rebuild the whole tree in linear time. We improve this by noticing that some parts of the tree can be reused. Assume that the string has length m and we want to shift the string by 2^j . Such operation is equivalent to shifting subtrees of size 2^j by 1, what can be done by changing links to children on the appropriate level of the shift-tree. After such modification, hashes on higher levels still need to be updated, but not the hashes in the moved subtrees. This yields a total time of $\mathcal{O}(m/2^j)$ for a cyclic shift by 2^j , and it can be easily extended to shifts of form $k2^j$. Even though it seems like a subtle improvement, it is enough to obtain a fast algorithm for Modular Subset Sum.

To make the shift-trees deterministic, we replace hashes with *tags*. Tags are identifiers associated with strings, but unlike hashes, they are not unique: one string can be represented by multiple tags. Each time a node is updated it receives a new tag. We propagate the information about tags that represent the same strings lazily while searching for differences. More specifically, if the tags are not known to be equal, the search procedure always recurs. If the recursion was unnecessary, we know about it upon return and we can memorize that the respective tags were equivalent.

Sketch of the algorithm for Modular Subset Sum

Our algorithm follows the ideas of [3, 9]. We simulate Bellman's algorithm faster. We iteratively compute the sets of new attainable subset sums C_i after adding the i -th element. More precisely, $C_i = S_i \setminus S_{i-1} = (S_{i-1} + x_i) \setminus S_{i-1}$. The key idea is to notice that instead of computing C_i , we can compute the symmetric difference $D_i = (S_{i-1} + x_i) \triangle S_{i-1}$, and then reduce it to C_i , because $|D_i| = 2|C_i|$.

Let $s_i \in \{0, 1\}^m$ be the characteristic vector of the set S_i , i.e. $s_i[j] = 1$ iff $j \in S_i$. The problem of finding the set D_{i+1} is then reduced to the problem of finding differences between the string s_i and its cyclic shift. We apply shift-trees to solve this problem efficiently. The shift-tree requires the length of the string to be a power of two, so we assume that $m = 2^k$ for now (we show how to get rid of this assumption in section 5). Consider two shift-trees T_1 and T_2 built for string s_i and its cyclic shift respectively. We simulate the Bellman's algorithm step as follows:

- (i) adjust the cyclic shift of T_2 ;
- (ii) find the set D_i by comparing T_1 and T_2 ;
- (iii) update the trees with new attainable subset sums.

The bottleneck of the algorithm are the adjustments of cyclic shift of T_2 : if elements are processed in arbitrary order, the total complexity of shift operations can be $\mathcal{O}(m^2)$. In section 4, we show that if elements are processed in a bit-reversal order, then the shift operations amortize to $\mathcal{O}(m \log m)$.

1.2 Preliminaries

We introduce the following notation for strings. We use the same notation for other sequences.

► **Definition 3.** Given a string $s = c_0 \dots c_{n-1}$, we refer to c_i as $s[i]$ and to substring $c_i \dots c_j$ as $s[i : j]$.

► **Definition 4.** Given a string s and $k \in \mathbb{Z}$, we denote by s^{+k} and s^{-k} the cyclic shift of s by k positions to the right and left respectively. In other words, for every $i \in \{0, \dots, |s| - 1\}$:

$$s[i] = s^{+k}[(i + k) \bmod |s|] = s^{-k}[(i - k) \bmod |s|]$$

2 Shift-trees

2.1 Overview

We introduce *shift-trees*, a variant of the segment tree data structure. A *shift-tree* T maintains a string s of length $m = 2^n$ over an alphabet Σ and supports the following operations:

- $T.\text{INIT}(s)$: Initialize the data structure with string s .
- $T.\text{SET}(i, x)$: Given an index $i \in \{0, \dots, |s| - 1\}$ and a letter $x \in \Sigma$, change $s[i]$ to x .
- $T.\text{SHIFT}(k)$: Given an offset $k \in \mathbb{Z}$, replace s with s^{+k} , i.e. cyclically shift the string s by k positions to the right.
- $T.\text{DIFF}(Q, a, b)$: Given another shift-tree Q representing a string q such that $|s| = |q|$, list all differences between $s[a : b]$ and $q[a : b]$, i.e. return the list L of all integers x such that $a \leq x \leq b$ and $s[x] \neq q[x]$.

In this section, we describe a hashing-based version of the data structure, which uses $\mathcal{O}(m)$ memory and supports these operations in the following time complexities:

- INIT : $\mathcal{O}(m)$;
- SET : $\mathcal{O}(\log m)$;
- $\text{SHIFT}(k)$: $\mathcal{O}(m/2^j)$, where j is the largest integer such that $2^j \mid k$;
- DIFF : $\mathcal{O}((d + 1) \log m)$, where $d = |L|$ is the number of differences.²

In section 3, we present a variant that is fully deterministic, but achieves a slightly worse time complexity (by $\alpha(m)$, where α is the inverse Ackermann function).

We require an integer alphabet Σ of size $\mathcal{O}(\text{poly}(m))$. We use a standard Rabin-Karp rolling hash function [15]: we choose a sufficiently big prime p and an integer $r \in \mathbb{Z}_p$, where r is chosen uniformly at random. The hash of a string s is defined as $h(s) = \sum_{i=0}^{|s|-1} s[i] \cdot r^i \bmod p$. We assume that $\Sigma \subseteq \mathbb{Z}_p$, so $h(x) = x$ for $x \in \Sigma$. If hashes of two strings of the same length are equal, then the strings are equal with high probability. Moreover, given hashes of some strings s_1 and s_2 , one can compute hash of their concatenation using the following identity: $h(s_1 s_2) = h_1 + h_2 \cdot r^{|s_1|}$. To enable constant-time computation of this formula, we precompute powers of r up to r^m . We use these properties extensively in our data structure.

² By writing $d + 1$ in the complexity, we mean that the runtime of DIFF operation is $\mathcal{O}(\log m)$ if $d = 0$.

(a) $\Delta = 0000_2 = 0$.(b) $\Delta = 0101_2 = 5$.■ **Figure 1** Shift-tree node numbering for different values of Δ .

2.2 Structure

Let s be the string maintained by the data structure and let $|s| = 2^n$. The shift-tree is a perfect binary tree built upon the string s . The leaves of the tree store the consecutive letters of string s , with the leftmost one corresponding to $s[0]$ and the rightmost one corresponding to $s[|s| - 1]$. The inner nodes correspond to substrings of s formed from underlying leaves and store hashes to enable their fast comparison. By $\text{level}(v)$ we denote the distance from the node v to the root node. The root node has level 0 and the leaves have level n . There are 2^k nodes on the k -th level.

We now provide a compact $\mathcal{O}(m)$ memory representation of the data structure that enables us to achieve the desired complexity of SHIFT operation. The only data stored in memory is an array of hashes $H[1 : 2^{n+1} - 1]$ and a single integer $\Delta \in \{0, \dots, 2^n - 1\}$. The values in $H[2^n : 2^{n+1} - 1]$ correspond to the leaves and are letters of the represented string. The value of Δ defines a cyclic shift of leaf indices, i.e. the j -th leftmost leaf of the tree has index $(j - \Delta) \bmod 2^n + 2^n$.

The tree structure is defined implicitly based on the value of Δ as follows. The nodes of the tree are numbered from 1 to $2^{n+1} - 1$. The nodes on the k -th level are numbered from 2^k to $2^{k+1} - 1$. In particular, the root node has index 1 and the leaves have indices from 2^n to $2^{n+1} - 1$. We first introduce the following auxiliary function:

$$\text{skew}(k) = \left\lfloor \frac{\Delta}{2^{n-k}} \right\rfloor \bmod 2$$

Note that floor division by a power of two is equivalent to right bitwise shift, so value of $\text{skew}(k)$ is simply $(n - k)$ -th least significant bit of Δ . Let i be an inner node and let $k = \text{level}(i)$. We define the children of node i as follows:

$$\begin{aligned} \text{left}(i) &= (2i - \text{skew}(k + 1)) \bmod 2^{k+1} + 2^{k+1} \\ \text{right}(i) &= (2i + 1 - \text{skew}(k + 1)) \bmod 2^{k+1} + 2^{k+1} \end{aligned}$$

We also define the parent of node $i \neq 1$ at level k .

$$\text{parent}(i) = \left\lfloor \frac{(i + \text{skew}(k)) \bmod 2^k + 2^k}{2} \right\rfloor$$

The *left*, *right* and *parent* functions can be implemented in constant time. The following lemma and corollary summarize the properties of a tree structure defined as above.

► **Lemma 5.** *The functions left, right and parent define a perfect binary tree, such that the indices of nodes on the k -th level, when ordered from left to right, form a sequence $(2^k, \dots, 2^{k+1} - 1)^{+\lfloor \Delta/2^{n-k} \rfloor}$.*

Proof. We prove the lemma by induction on the level. The condition is satisfied for the 0-th level, which contains only the root node with index 1. Assume now that the condition is satisfied for the k -th level, i.e. the nodes on the k -th level form a sequence $(2^k, \dots, 2^{k+1} - 1)^{+\delta}$, where $\delta = \lfloor \Delta/2^{n-k} \rfloor$. By substituting indices of children in this sequence, we obtain the following sequence for the $(k+1)$ -st level:

$$(\text{left}(2^k), \text{right}(2^k), \dots, \text{left}(2^{k+1} - 1), \text{right}(2^{k+1} - 1))^{+2\delta}$$

The shift is now 2δ , because each element has been replaced by two elements. We want to prove that this is exactly the sequence $(2^{k+1}, \dots, 2^{k+2} - 1)^{+\lfloor \Delta/2^{n-k-1} \rfloor}$. The shift $\lfloor \Delta/2^{n-k-1} \rfloor$ can be rewritten as $2\delta + x$, where $x = \text{skew}(k+1) = \lfloor \Delta/2^{n-k-1} \rfloor \bmod 2$. We now simplify the equation:

$$\begin{aligned} (\text{left}(2^k), \text{right}(2^k), \dots, \text{left}(2^{k+1} - 1), \text{right}(2^{k+1} - 1))^{+2\delta} &\stackrel{?}{=} (2^{k+1}, \dots, 2^{k+2} - 1)^{+2\delta+x} \\ (\text{left}(2^k), \text{right}(2^k), \dots, \text{left}(2^{k+1} - 1), \text{right}(2^{k+1} - 1)) &\stackrel{?}{=} (2^{k+1}, \dots, 2^{k+2} - 1)^{+x} \\ (\text{left}(2^k) - 2^{k+1}, \text{right}(2^k) - 2^{k+1}, \dots, \text{right}(2^{k+1} - 1) - 2^{k+1}) &\stackrel{?}{=} (0, \dots, 2^{k+1} - 1)^{+x} \end{aligned}$$

After substituting the values of *left* and *right*, and simplifying, we obtain the following:

$$((0 - x) \bmod 2^{k+1}, (1 - x) \bmod 2^{k+1}, \dots, (2^{k+1} - 1 - x) \bmod 2^{k+1}) \stackrel{?}{=} (0, \dots, 2^{k+1} - 1)^{+x}$$

The obtained equation trivially satisfies the definition of cyclic shift by x , and all transformations were equivalent. This completes the induction.

We complete the proof by showing that *parent* function is well-defined. Consider an inner node on the k -th level with index $2^k + i$. It is enough to show that it is parent of its children. After substituting and simplifying the formulas, we get the desired result:

$$\begin{aligned} \text{parent}(\text{left}(2^k + i)) &= \left\lfloor \frac{2i + 2^{k+1}}{2} \right\rfloor = 2^k + i \\ \text{parent}(\text{right}(2^k + i)) &= \left\lfloor \frac{2i + 1 + 2^{k+1}}{2} \right\rfloor = 2^k + i \end{aligned} \quad \blacktriangleleft$$

► **Corollary 6.** *The functions *left*, *right* and *parent* define a perfect binary tree such that:*

- (a) *nodes on the k -th level have indices from 2^k to $2^{k+1} - 1$, for each valid k ;*
- (b) *the indices of leaves, when ordered from left to right, form a sequence $(2^n, \dots, 2^{n+1} - 1)^{+\Delta}$;*
- (c) *the structure of subtrees rooted at the k -th level depends only on $\Delta \bmod 2^{n-k}$.*

Proof. The first two properties follow instantly from the lemma 5. For the property (c), notice that the links on these levels depend only on the values $\text{skew}(k+1), \dots, \text{skew}(n)$. These values are exactly the $n - k$ least significant bits of Δ . ◀

2.3 Invariant

Let s be the string maintained by the data structure and let $|s| = 2^n$. We define the string associated with a node i recursively as follows:

$$\text{str}(i) = \begin{cases} s^{-\Delta}[i - 2^n] & \text{for } i \geq 2^n \text{ (i.e. } i \text{ is leaf node)} \\ \text{str}(\text{left}(i)) \text{str}(\text{right}(i)) & \text{for } i < 2^n \text{ (i.e. } i \text{ is inner node)} \end{cases}$$

By corollary 6b, the k -th letter of string s is associated with the k -th leftmost leaf. It follows that $s = \text{str}(1)$, i.e. string associated with the root node is s . We maintain the following invariant:

► **Invariant 7.** For each node i the following holds: $H[i] = h(\text{str}(i))$.

The invariant ensures that each node stores a hash of its associated string. We use this property to implement the DIFF operation in required time complexity.

2.4 Operations

Let s be the string maintained by the data structure and let $|s| = m = 2^n$. We first define an $\text{UPDATE}(i)$ primitive that is used by all operations that modify the data structure. The UPDATE procedure simply recalculates the hash of an inner node i based on hashes of its children. This can be done in constant time using basic modular arithmetic, if appropriate powers of r are precomputed.

■ **Algorithm 1** The UPDATE procedure.

```

1: function  $\text{UPDATE}(i)$ 
2:    $H[i] \leftarrow (H[\text{left}(i)] + H[\text{right}(i)] \cdot r^{|\text{str}(\text{left}(i))|}) \bmod p$ 

```

Init. We initialize Δ with 0 and leaves with the letters of the input string s . Specifically, we set $H[2^n + i] = s[i]$ for each $i \in \{0, \dots, 2^n - 1\}$, because letter $s[i]$ is associated with the node $2^n + i$. We then compute all the hashes by calling an UPDATE on the remaining nodes, beginning at the bottom of the tree. Overall, the INIT operation updates $\mathcal{O}(m)$ nodes and runs in $\mathcal{O}(m)$ time.

Set. Assume that we change $s[i]$ to x . Let $j = (i - \Delta) \bmod 2^n + 2^n$. Notice that, $\text{str}(j) = s^{-\Delta}[j - 2^n] = s[(j + \Delta) \bmod 2^n] = s[i]$. In order to fix the invariant, we set $H[j] = x$ and update hashes of all the ancestors of j . The tree has $\mathcal{O}(\log m)$ levels, so the total runtime of SET operation is $\mathcal{O}(\log m)$.

■ **Algorithm 2** INIT operation.

```

1: function  $\text{INIT}(s)$ 
2:    $\Delta \leftarrow 0$ 
3:   for  $i \leftarrow 0, \dots, 2^n - 1$  do
4:      $H[2^n + i] \leftarrow s[i]$ 
5:   for  $i \leftarrow 2^n - 1, \dots, 1$  do
6:      $\text{UPDATE}(i)$ 

```

■ **Algorithm 3** SET operation.

```

1: function  $\text{SET}(i, x)$ 
2:    $j \leftarrow (i - \Delta) \bmod 2^n + 2^n$ 
3:    $H[j] \leftarrow x$ 
4:   while  $j \neq 1$  do
5:      $j \leftarrow \text{parent}(j)$ 
6:      $\text{UPDATE}(j)$ 

```

Shift. Assume that we apply a right cyclic shift by k positions to s . Let j be the largest integer such that $2^j \mid k$. In order to fix the invariant, we first set Δ to $(\Delta + k) \bmod 2^n$. Notice that the invariant is now satisfied for leaves. Moreover, by corollary 6c the structure of subtrees rooted at level $n - j$ didn't change, so the invariant is also satisfied for levels $n - j, \dots, n$. It remains to update hashes on the remaining $n - j$ levels by calling the UPDATE procedure on their nodes. Overall, $\mathcal{O}(2^{n-j})$ nodes are updated and the SHIFT operation runs in $\mathcal{O}(m/2^j)$ time.³

³ Provided algorithm requires computation of $j = \max\{d \in \mathbb{N} : 2^d \mid k\}$. In practice, it is sufficient to compute 2^j instead of computing j directly. This can be done in constant time using the following bit-hack: $k \& \sim(k-1)$.

■ **Algorithm 4** SHIFT operation.

```

1: function SHIFT( $k$ )
2:   if  $k \bmod 2^n = 0$  then
3:     return
4:    $j \leftarrow \max\{d \in \mathbb{N} : 2^d \mid k\}$ 
5:    $\Delta \leftarrow (\Delta + k) \bmod 2^n$ 
6:   for  $i \leftarrow 2^{n-j} - 1, \dots, 1$  do
7:     UPDATE( $i$ )

```

Diff. Assume we look for differences between the strings maintained by the trees T and Q in interval $[a; b]$. We provide a recursive procedure $\text{FINDDIFFERENCES}(T, Q, a, b, i, j, x, y)$ that returns required set of differences between substrings associated with node i of the tree T and node j of the tree Q . The procedure additionally tracks an interval $[x; y]$ that is associated with both nodes, i.e. $T.\text{str}(i) = T.s[x : y]$ and $Q.\text{str}(j) = Q.s[x : y]$.

The FINDDIFFERENCES procedure works as follows. If $[a; b] \cap [x; y] = \emptyset$ then procedure returns empty set instantly, because we only look for differences in the interval $[a; b]$. If hashes of nodes i and j are equal then the substrings are equal w.h.p., so the procedure returns no differences as well. Otherwise, there is at least one difference between the strings associated with nodes i and j . If the nodes are leaves, then we report the difference. If the nodes are inner nodes, the procedure is invoked recursively on left and right children.

The DIFF operation simply calls FINDDIFFERENCES on roots of the trees T and Q . The procedure will return all the required differences as long as there is no hash collision.

■ **Algorithm 5** The DIFF operation.

```

1: function T.DIFF( $Q, a, b$ )
2:   return FINDDIFFERENCES( $T, Q, a, b, 1, 1, 0, 2^n - 1$ )
3:
4: function FINDDIFFERENCES( $T, Q, a, b, i, j, x, y$ )
5:   if  $[a; b] \cap [x; y] = \emptyset$  or  $T.H[i] = Q.H[j]$  then
6:     return  $\emptyset$ 
7:   if  $x = y$  then ▷ The nodes  $i$  and  $j$  are leaves if they represent an unit interval
8:     return  $\{x\}$ 
9:    $z \leftarrow \frac{x+y+1}{2}$  ▷ The left nodes represent  $[x : z - 1]$  and the right nodes represent  $[z : y]$ 
10:   $A \leftarrow \text{FINDDIFFERENCES}(T, Q, a, b, T.\text{left}(i), Q.\text{left}(j), x, z - 1)$ 
11:   $B \leftarrow \text{FINDDIFFERENCES}(T, Q, a, b, T.\text{right}(i), Q.\text{right}(j), z, y)$ 
12:  return  $A \cup B$ 

```

We now argue the complexity of DIFF operation. Let d be the number of differences that were found. Let s_k be the number of FINDDIFFERENCES calls for which the processed nodes were on the k -th level and the procedure recurred. If the procedure recurred, there existed at least one difference between the strings associated with the nodes. We can divide such calls into two categories:

- (a) there is a difference in $[x; y] \cap [a; b]$ that should be reported;
- (b) there is a difference in $[x; y] \setminus [a; b]$ that should be ignored and $[x; y] \cap [a; b] \neq \emptyset$.

The number of calls that belong to the category (a) is bounded by d , i.e. number of reported differences. There are at most 2 calls that belong to the category (b), because the interval $[x; y]$ must contain a or b . It follows that $s_k \leq d + 2$ and $s_0 + \dots + s_{n-1} \leq (d + 2) \cdot n$. We can charge the calls that didn't recur to their parents, so the total running time of DIFF operation is $\mathcal{O}((d + 1) \log m)$.

In order to complete the analysis, we bound the probability that DIFF operation fails to report all differences. Such situation may occur only if nodes processed by FINDDIFFERENCES have different associated strings, but equal hashes. Let $s_1 \neq s_2$ be strings of length k .

$$\Pr[h(s_1) = h(s_2)] = \Pr\left[\sum_{i=0}^{k-1} (s_1[i] - s_2[i])r^i \equiv 0 \pmod{p}\right] \leq \frac{k}{p}$$

The inequality holds, because the sum on the left side is a non-zero polynomial of degree at most k , evaluated in randomly chosen point r . By application of union bound, we obtain that the probability of failure is at most $m \log m / p$. Assuming operations on hashes of size $\mathcal{O}(\log m)$ are taking constant time, we can choose $p = \Theta(\text{poly}(m))$ and obtain high probability of success.

► **Remark 8.** It is also possible to achieve a Las-Vegas implementation of shift-trees. The key observation is that the hash function doesn't need to be associative, i.e. one can hash "subtrees" instead of substrings. This allows us to replace the hash function with any injective mapping $h(x, y)$ from pairs of hashes into new hashes. Only the UPDATE procedure needs to be adapted to compute the hash $H[i]$ of i -th node as $h(H[\text{left}(i)], H[\text{right}(i)])$.

The missing piece is how to implement the mapping $h(x, y)$. This can be done by simply generating it on demand, and storing the mapping in a hashtable. Some garbage collection mechanism (such as reference counting) is required to maintain linear memory usage. This yields a Las-Vegas implementation of shift-trees, with the same expected runtime bounds.

By replacing hashtable with a BST, one can obtain a deterministic implementation of the data structure. Such modification introduces logarithmic runtime overhead. In the next section, we improve upon this by allowing amortization.

3 Deterministic shift-trees

3.1 Overview

We now provide a deterministic variant of the data structure introduced in previous section. Let $m = 2^n$. Assume that we maintain several shift-trees T_1, \dots, T_r associated with strings $s_1, \dots, s_r \in \Sigma^m$ of the same length, allowing comparisons between those strings. Let $K = |s_1| + \dots + |s_r| = mr$, and let T_i be one of the trees. Then, we can do the shift-tree operations on T_i with the following amortized time complexities:

- INIT: $\mathcal{O}(m \cdot \alpha(K))$;
- SET: $\mathcal{O}(\log m \cdot \alpha(K))$;
- SHIFT(k): $\mathcal{O}(m/2^j \cdot \alpha(K))$, where j is the largest integer such that $2^j \mid k$;
- DIFF: $\mathcal{O}((d+1) \log m \cdot \alpha(K))$, where d is the number of differences.

Moreover, the data structures use $\mathcal{O}(K)$ memory overall. The only constraint that we put on alphabet Σ is the support for equality tests. This contrasts with the randomized variant, where an integer alphabet of polynomial size is required.

3.2 Tags

We replace hashing with the concept of *tags*. Tags are simply identifiers associated with strings. Unlike hashes, they are not unique: one string can be represented by multiple tags. Each inner node of the shift-tree stores a tag instead of a hash. A new tag is created every time a node is updated.

We denote the string associated with a tag t by $\text{str}(t)$. The strings associated with tags are not stored in memory. Instead, we maintain an equivalence relation \mathcal{R} over the set of tags used in all the shift-trees. The relation \mathcal{R} satisfies the following property:

► **Invariant 9.** *For each tag a and tag b such that $a \equiv_{\mathcal{R}} b$, the strings $\text{str}(a)$ and $\text{str}(b)$ are equal.*

Note that the inverse doesn't need to hold. In other words, the relation \mathcal{R} partially captures the equality relation between strings associated with tags. The relation is refined during operations on the shift-trees using the following operations:

- **NEWTAG()**: Create a new tag x with its own singleton equivalence class, and return x .
- **FIND(x)**: Given a tag x , return identifier of its equivalence class.
- **UNION(x, y)**: Given tags x and y , union their equivalence classes (i.e. insert $x \equiv_{\mathcal{R}} y$ and close the relation transitively).
- **DELETETAG(x)**: Given a tag x , remove it from its equivalence class and free its memory.

In order to support these operations efficiently, we represent the equivalence classes of \mathcal{R} using a union-find data structure. A simple extension of standard disjoint-set forest implementation with support for element removal has been proposed by Kaplan et al. in [13].

► **Theorem 10** ([13]). *There exists a data structure that maintains an equivalence relation \mathcal{R} using linear memory under operations **FIND**, **UNION** and **DELETETAG** in amortized $\mathcal{O}(\alpha(n))$ time, and **NEWTAG** in $\mathcal{O}(1)$ time, where n is the number of maintained elements.*

Their approach is based on lazy deletions: elements to be deleted are marked and the union-find trees are rebuilt if the fraction of marked elements is greater than half. More involved approaches with constant time deletions have been known in literature [2, 6], but such improvement doesn't change the amortized time complexity of our data structure.

The idea to use union-find data structure for detecting mismatches has been already proposed by Gawrychowski et al. in [11].

► **Remark.** In general, the **DELETETAG** operation is not only useful for space optimization. If unused tags are not removed, the complexity of operations is dependent on the total number of **NEWTAG** calls, which can be large. This is not an issue if only $\mathcal{O}(\text{poly}(K))$ tags are created in total, because $\mathcal{O}(\alpha(\text{poly}(K))) = \mathcal{O}(\alpha(K))$.

3.3 Operations

We now adapt the **UPDATE** procedure and **DIFF** operation to work with tags. The **INIT**, **SET** and **SHIFT** operations use the **UPDATE** primitive and don't require changes.

Update. We simply create a new tag for the updated node. If the node already contains a tag (i.e. the **UPDATE** is called after initialization), we delete it in order to maintain linear memory usage. The newly created tag is in a singleton equivalence class of \mathcal{R} , so it trivially satisfies the invariant.

■ **Algorithm 6** The **UPDATE** procedure.

```

1: function UPDATE( $i$ )
2:   if  $H[i] \neq \text{null}$  then
3:     DELETETAG( $H[i]$ )
4:    $H[i] \leftarrow \text{NEWTAG}()$ 

```

Diff. We adapt the `FINDDIFFERENCES` procedure as follows. Assume that we are looking for differences in interval $[a; b]$. Let t_1 and t_2 be tags in compared tree nodes, and $[x; y]$ the interval associated with these nodes. If $t_1 \equiv_{\mathcal{R}} t_2$ then the compared substrings are equal, so we exit instantly. Otherwise, we search for differences recursively in the left and right subtrees. If no differences are found and $[x; y] \subseteq [a; b]$, we know that $\text{str}(t_1) = \text{str}(t_2)$, so we can safely add $t_1 \equiv_{\mathcal{R}} t_2$ to relation \mathcal{R} via `UNION`(t_1, t_2).

■ **Algorithm 7** The `FINDDIFFERENCES` procedure.

```

1: function FINDDIFFERENCES( $T, Q, a, b, i, j, x, y$ )
2:   if  $[a; b] \cap [x; y] = \emptyset$  then                                ▷ Check if we are outside of the search interval
3:     return  $\emptyset$ 
4:   if  $x = y$  then                                                ▷ The nodes  $i$  and  $j$  are leaves if they represent an unit interval
5:     if  $T.H[i] \neq Q.H[j]$  then                                    ▷ The leaves contain letters – compare them directly
6:       return  $\{x\}$ 
7:     else
8:       return  $\emptyset$ 
9:   if  $\text{FIND}(T.H[i]) = \text{FIND}(Q.H[j])$  then                        ▷ The inner nodes contain tags – use  $\mathcal{R}$ .
10:    return  $\emptyset$                                                   ▷  $T.H[i] \equiv_{\mathcal{R}} Q.H[j]$  holds, so the strings are equal
11:   $z \leftarrow \frac{x+y+1}{2}$  ▷ The left nodes represent  $[x; z-1]$  and the right nodes represent  $[z; y]$ 
12:   $A \leftarrow \text{FINDDIFFERENCES}(T, Q, a, b, T.\text{left}(i), Q.\text{left}(j), x, z-1)$ 
13:   $B \leftarrow \text{FINDDIFFERENCES}(T, Q, a, b, T.\text{right}(i), Q.\text{right}(j), z, y)$ 
14:  if  $A \cup B = \emptyset$  and  $[x; y] \subseteq [a; b]$  then
15:    UNION( $T.H[i], Q.H[j]$ )
16:  return  $A \cup B$ 

```

We now briefly address the correctness of the `FINDDIFFERENCES` procedure. Observe that if the condition $[a; b] \cap [x; y] \neq \emptyset$ holds then:

- (i) the invariant 9 guarantees that the procedure will recur if substrings are not equal;
- (ii) the procedure returns a difference for leaves iff their corresponding characters differ.

It follows by an easy induction on the level that the procedure returns all positions in $[a; b]$ where the strings differ and nothing more. Moreover, the procedure doesn't break the invariant when modifying the relation \mathcal{R} : if the condition in line 14 is true, then there are no differences between compared substrings.

3.4 Running time

Let K be the sum of lengths of strings maintained by all shift-trees and let $m = 2^n$ be the length of each string. We first note that the number of elements maintained by relation \mathcal{R} never exceeds the total number of nodes in shift-trees, which is $\mathcal{O}(K)$, so any operation on \mathcal{R} works in amortized $\mathcal{O}(\alpha(K))$ time.

We now argue the amortized running time of the `UPDATE` and `DIFF` operations. Let the actual cost of the i -th operation be a number c_i of operations on the relation \mathcal{R} . Let q_i be the number of equivalence classes of relation \mathcal{R} after i operations. We define potential Φ_i to be $9q_i$. Clearly, $\Phi_i \geq \Phi_0 = 0$. The amortized cost of the i -th operation is $\hat{c}_i = c_i + \Phi_i - \Phi_{i-1}$.

The actual cost of an `UPDATE` operation is $c_i \leq 2$. The operation creates at most one new equivalence class, thus the amortized cost is $\hat{c}_i = c_i + \Phi_i - \Phi_{i-1} \leq 2 + 9 \cdot 1 = 11$. It follows that the amortized time complexity of an `UPDATE` operation is $\mathcal{O}(\alpha(K))$.

To estimate the amortized cost of `DIFF` operation, we consider the `FINDDIFFERENCES` calls that recurred. We say that the call is *wasted* if the compared strings are equal, but comparison of tags reported that they are not. Otherwise, if the compared strings are not

equal and the procedure recurred, we say that the call is *required*. Let w be the number of wasted calls and r be the number of required calls. We can charge the calls that didn't recur to their parents, so the total number of `FINDDIFFERENCES` calls is bounded by $3(r + w)$. Each call does at most three operations on relation \mathcal{R} , so the cost of `DIFF` operation is $c_i \leq 9(r + w)$.

Let d be the number of differences that have been found. We can bound the number of required calls r by $\mathcal{O}((d + 1) \log m)$, the same way as in hashing-based shift-trees. We now focus our attention on the wasted calls. Assume that we are looking for differences in interval $[a; b]$. Let w' be the number of wasted calls such that the interval associated with compared nodes is contained within $[a; b]$. Notice that upon return, each such call unions two different equivalence classes, thus decreasing the potential by 9. It follows that `DIFF` operation reduces the potential in total by $9w'$. On the other hand, the intervals associated with the remaining wasted calls must contain a or b , so there are at most 2 such calls for each tree level. It follows that the number of all wasted calls is bounded by $w' + 2 \log m$. The amortized cost of `DIFF` operation is then:

$$\hat{c}_i \leq 9r + 9w - 9w' \leq 9r + 18 \log m = \mathcal{O}((d + 1) \log m)$$

and the amortized time complexity is $\mathcal{O}((d + 1) \log m \cdot \alpha(K))$.

We complete analysis by providing amortized running time of `INIT`, `SET` and `SHIFT` operations. The `INIT` operation calls `UPDATE` operation $\mathcal{O}(m)$ times, so its amortized running time is $\mathcal{O}(m \cdot \alpha(K))$. By the same argument we obtain the required amortized complexities for `SET` and `SHIFT` operation.

4 Traversing all cyclic shifts

In this section, we consider a problem of going over all the cyclic shifts of the shift-tree efficiently, in some order. This means that we want to consider all shifts $s^{+\sigma(0)}, \dots, s^{+\sigma(|s|-1)}$, for σ being some permutation of $\{0, \dots, |s| - 1\}$. This requires invoking `SHIFT`($\sigma(i) - \sigma(i - 1)$) for $i = 1, 2, \dots, |s| - 1$, assuming the shift-tree initially represents $s^{+\sigma(0)}$. We claim that there exists a permutation σ such that the total complexity of these operations amortizes to $\mathcal{O}(m \log m)$ time. For simplicity, we consider the hashing-based shift-trees; the complexity for deterministic variant is just multiplied by $\alpha(K)$. This technique is crucial for our Modular Subset Sum algorithm and might be used for other problems, where the order of operations doesn't matter.

The time complexity of a single `SHIFT` operation depends heavily on the value of shift. Recall that the running time of `SHIFT`(k) is $\mathcal{O}(m/2^j)$, where j is the largest integer such that $2^j \mid k$, and $m = 2^n$ is the size of the shift-tree. For example, a shift by 1 requires rebuilding the entire tree, while shift by $m/2$ takes constant time. It means that the complexity of going over all the cyclic shifts heavily depends on the permutation σ .

It turns out that a good permutation is a bit-reversal permutation, which we define as follows. We denote the bit-reverse of n -bit number j by $\text{bitrev}_n(j)$, i.e. if $j = \sum_{i=0}^{n-1} c_i 2^i$ then $\text{bitrev}_n(j) = \sum_{i=0}^{n-1} c_i 2^{n-i-1}$. We say that σ is a *bit-reversal permutation* if $\sigma(i) = \text{bitrev}_n(i)$.

► **Lemma 11.** *Let σ be a bit-reversal permutation of length $m = 2^n$ and T a shift-tree of length $\mathcal{O}(m)$. The sequence of operations $T.\text{SHIFT}(\sigma_i - \sigma_{i-1})$ for $i = 1, \dots, m - 1$ takes total time $\mathcal{O}(m \log m)$.*

Proof. Let $\delta_i = \sigma_i - \sigma_{i-1}$ and consider a single $\text{SHIFT}(\delta_i)$ operation. Let j be the largest integer such that $2^j \mid \delta_i$. The complexity of this operation is then $\mathcal{O}(m/2^j) = \mathcal{O}(2^{n-j})$. If $2^j \mid \delta_i$ and $2^{j+1} \nmid \delta_i$ then j is the least significant bit that is different between σ_i and σ_{i-1} . Since σ_i is a bit-reverse of i , it means that $n-j-1$ is the most significant bit that is different between i and $i+1$. Such situation happens only if $i+1$ is of form $k \cdot 2^{n-j-1}$, where k is odd. There are 2^j such numbers in range $[1; 2^n - 1]$. It follows that shifts for a given value of j take overall $\mathcal{O}(2^{n-j} \cdot 2^j) = \mathcal{O}(2^n)$ time. There are $\mathcal{O}(n)$ possible values of j , so the whole sequence of shifts takes $\mathcal{O}(2^n \cdot n) = \mathcal{O}(m \log m)$ time. ◀

5 Modular Subset Sum

In this section, we provide an algorithm for the Modular Subset Sum problem that uses the shift-tree data structure. Let $X = \{x_1, \dots, x_n\}$ be a multiset of integers from \mathbb{Z}_m . Our algorithm computes the set $X^* \subseteq \mathbb{Z}_m$ such that $k \in X^*$ if and only if there exists a subset of X that sums to the value k modulo m . We assume that the input multiset X is provided in a compact form: as a list of $\mathcal{O}(m)$ distinct elements along with their multiplicities.

The algorithm is based on the so-called Bellman's iteration. Consider sets $S_0, \dots, S_n \subseteq \mathbb{Z}_m$ such that $S_0 = \{0\}$ and $S_i = S_{i-1} \cup (S_{i-1} + x_i)$, where $S_{i-1} + x_i = \{a + x_i : a \in S_{i-1}\}$. It is easy to see that the set S_i is a set of all attainable subset sums of $\{x_1, \dots, x_i\}$ and the final result is $X^* = S_n$. In order to compute the set S_i from S_{i-1} , it is sufficient to find the set $C_i = S_i \setminus S_{i-1} = (S_{i-1} + x_i) \setminus S_{i-1}$. If one can compute the set C_i in time $\mathcal{O}(|C_i| \cdot f(m))$, then the set X^* can be computed in total time $\mathcal{O}(m \cdot f(m))$.

The key idea of [4] is to notice that instead of computing $C_i = (S_{i-1} + x_i) \setminus S_{i-1}$, we can compute the symmetric difference $D_i = (S_{i-1} + x_i) \triangle S_{i-1}$. Computing the set D_i doesn't break the time complexity, because its size is only two times larger than C_i . We can now interpret problem of finding the set D_i as a text problem [3, 9]. Let $s_i \in \{0, 1\}^m$ be the characteristic vector of the set S_i , i.e. $s_i[j] = 1$ iff $j \in S_i$. The problem of finding the set D_{i+1} is then reduced to problem of finding differences between the strings s_i and $s_i^{+x_{i+1}}$. The set D_{i+1} is exactly the set of indices, where these strings differ.

We now describe our algorithm. Let S be the set of all subset sums attainable using elements processed so far, and let s be its characteristic vector. Initially, the set S contains only 0. We maintain the characteristic vector s and its cyclic shift using two shift-trees, T_1 and T_2 respectively. The length of a string maintained by a shift-tree is required to be a power of two, but that may not be the case with the string s . We address this issue in the following way. Let L be the smallest power of two such that $L \geq 2m$. We consider the following auxiliary strings:

$$\begin{aligned} s' &= s0^{L-m} \\ s'' &= s0^{L-2m}s \end{aligned}$$

The strings s' and s'' have length L , which is a power of two. Moreover, the string s'' has the following property: the string s^{+d} is a prefix of $(s'')^{+d}$, for any $d \in \{0, \dots, m\}$. This property allows us to find differences between s and s^{+d} by comparing a prefix of s' with a prefix of $(s'')^{+d}$.

The tree T_1 maintains the string s' and the tree T_2 maintains a cyclic shift of the string s'' . Specifically, we traverse all cyclic shifts of T_2 in bit-reversal order, as explained in the previous section. Assume that the current shift of T_2 is x , i.e. the string maintained by T_2 is $(s'')^{+x}$. Let μ be the multiplicity of x in the input multiset X . If $\mu = 0$, then $x \notin X$ and the algorithm proceeds to the next shift. Otherwise, we simulate μ Bellman's iterations for the

element x as follows. The x is contained in the multiset X , so $x \in \{0, \dots, m-1\}$. It implies that we can find the set of differences D between s and s^{+x} by comparing a prefix of s' with a prefix of $(s'')^{+x}$. This is done using DIFF operation on T_1 and T_2 . We then update the set of attainable subset sums S and both shift-trees appropriately. If no differences were found, we skip the rest of iterations for element x .

Every element of X corresponds to some cyclic shift, so all elements will be processed if all the cyclic shifts are considered. The set S is then the set of all attainable subset sums for X . We provide the pseudocode as Algorithm 8. In the pseudocode, we denote the multiplicity of element x in the set X by $\mu_X(x)$.

■ **Algorithm 8** The MODULARSUBSETSUM algorithm.

```

1: function MODULARSUBSETSUM( $X, m$ )
2:    $S = \{0\}$ 
3:    $k \leftarrow \min\{d \in \mathbb{N} : 2^d \geq 2m\}$ 
4:    $L \leftarrow 2^k$ 
5:    $s_0 \leftarrow 10^{m-1}$  ▷ The characteristic vector of  $S_0 = \{0\}$ 
6:   Initialize shift-tree  $T_1$  with  $s_0 0^{L-m}$ 
7:   Initialize shift-tree  $T_2$  with  $s_0 0^{L-2m} s_0$ 
8:   for  $i \leftarrow 1, \dots, L-1$  do
9:      $x \leftarrow \text{bitrev}_k(i)$ 
10:     $T_2.\text{SHIFT}(x - \text{bitrev}_k(i-1))$  ▷ Now  $T_2$  represents the string  $(s'')^{+x}$ 
11:    for  $j \leftarrow 1, \dots, \mu_X(x)$  do
12:       $D \leftarrow T_1.\text{DIFF}(T_2, 0, m-1)$  ▷  $D$  is the set of all differences between  $s$  and  $s^{+x}$ 
13:      if  $D = \emptyset$  then ▷ Skip the rest of iterations for  $x$  if no differences were found
14:        break
15:      for  $d \in D \setminus S$  do
16:         $S \leftarrow S \cup \{d\}$ 
17:         $T_1.\text{SET}(d, 1)$ 
18:         $T_2.\text{SET}((d+x) \bmod L, 1)$ 
19:         $T_2.\text{SET}((d+x-m) \bmod L, 1)$ 
20:  return  $S$ 

```

We now analyse the running time of the algorithm. We assume the hashing-based shift-trees are used; the complexity for deterministic variant is just multiplied by $\alpha(m)$. The initialization of shift-trees takes $\mathcal{O}(m)$ time. The value of $\text{bitrev}_k(i)$ can be computed naively bit by bit in $\mathcal{O}(k) = \mathcal{O}(\log m)$ time, which in total takes $\mathcal{O}(m \log m)$ time. Moreover, the total time of all SHIFT operations amortizes to $\mathcal{O}(m \log m)$ time due to lemma 11. We now focus on the total running time of inner loops.

Consider a single Bellman's iteration. The complexity of a DIFF operation is $\mathcal{O}((|D| + 1) \log m)$. The algorithm adds $|D \setminus S| = |D|/2$ new elements to the set S and updates the shift-trees. Each tree update takes $\mathcal{O}(\log m)$ time. In total, a single Bellman's iteration takes $\mathcal{O}((|D| + 1) \log m)$ time.

The sum of sizes of all the sets of differences is at most $2m$. It means that if there are k Bellman's iterations in total, then their total running time is $\mathcal{O}((m+k) \log m)$. The condition in the line 13 ensures that the total number of executed Bellman's iterations is $\mathcal{O}(m)$ by skipping the iterations if the set is empty. It follows that all the iterations take $\mathcal{O}(m \log m)$ time in total.

We arrive at the total time complexity of $\mathcal{O}(m \log m)$. By replacing hashing-based shift-trees with their deterministic variant, we obtain a deterministic algorithm with running time of $\mathcal{O}(m \log m \cdot \alpha(m))$. We recall the theorems that summarize these results:

► **Theorem 1.** *There exists an algorithm that returns all attainable modular subset sums of a multiset of integers from \mathbb{Z}_m with high probability, in time $\mathcal{O}(m \log m)$ and space $\mathcal{O}(m)$.*

► **Theorem 2.** *There exists a deterministic algorithm that returns all attainable modular subset sums of a multiset of integers from \mathbb{Z}_m in time $\mathcal{O}(m \log m \cdot \alpha(m))$ and space $\mathcal{O}(m)$.*

Abstract

We prove 3SUM-hardness (no strongly subquadratic-time algorithm, assuming the 3SUM conjecture) of several problems related to finding Abelian square and additive square factors in a string. In particular, we conclude conditional optimality of the state-of-the-art algorithms for finding such factors.

Overall, we show 3SUM-hardness of (a) detecting an Abelian square factor of an odd half-length, (b) computing centers of all Abelian square factors, (c) detecting an additive square factor in a length- n string of integers of magnitude $n^{\mathcal{O}(1)}$, and (d) a problem of computing a double 3-term arithmetic progression (i.e., finding indices $i \neq j$ such that $(x_i + x_j)/2 = x_{(i+j)/2}$) in a sequence of integers x_1, \dots, x_n of magnitude $n^{\mathcal{O}(1)}$.

Problem (d) is essentially a convolution version of the AVERAGE problem that was proposed in a manuscript of Erickson. We obtain a conditional lower bound for it with the aid of techniques recently developed by Dudek et al. [STOC 2020]. Problem (d) immediately reduces to problem (c) and is a step in reductions to problems (a) and (b). In conditional lower bounds for problems (a) and (b) we apply an encoding of Amir et al. [ICALP 2014] and extend it using several string gadgets that include arbitrarily long Abelian-square-free strings.

Our reductions also imply conditional lower bounds for detecting Abelian squares in strings over a constant-sized alphabet. We also show a subquadratic upper bound in this case, applying a result of Chan and Lewenstein [STOC 2015].

1 Introduction

Abelian squares. An Abelian square, Ab-square in short (also known as a jumbled square), is a string of the form XY , where Y is a permutation of X ; we say that X and Y are Ab-equivalent. We are interested in factors (i.e., substrings composed of consecutive letters) of a given text string being Ab-squares.

► **Example 1.** The string

0 6 1 0 5 6 5 1 6 1 0 1 1 1 0 6 5 6 5 7 8 6 1 6 5 0 5 1 0 5 6 6 5 0 6 0 3 0 6 5 2

has exactly two Ab-square factors of length 12, shown above (but it has also Ab-squares of other lengths, e.g. 5665, 11, 1111, 011110).

Ab-squares were first studied by Erdős [16], who posed a question on the smallest alphabet size for which there exists an infinite Ab-square-free string, i.e., an infinite string without Ab-square factors. The first example of such a string over a finite alphabet was given by Evdokimov [18]. Later the alphabet size was improved to five by Pleasants [34] and finally an optimal example over a four-letter alphabet was shown by Keränen [27]. Further results on combinatorics of Ab-square-free strings and several examples of their applications in group theory, algorithmic music and cryptography can be found in [26] and references therein. Avoidability of long Ab-squares was also considered [36].

Strings containing Ab-squares were also studied. Motivated by another problem posed by Erdős [16], Entringer et al. [15] showed that every infinite binary string has arbitrarily long Ab-square factors. Fici et al. [19] considered infinite strings containing many distinct Ab-squares. A string of length n may contain $\Theta(n^2)$ Ab-square factors that are distinct as strings, but contains only $\mathcal{O}(n^{11/6})$ Ab-squares which are pairwise Abelian nonequivalent (correspond to different Parikh vectors), see [28]. It is also conjectured that a binary string of length n must have at least $\lfloor n/4 \rfloor$ distinct [20] and nonequivalent [21] Ab-square factors. For more conjectures related to combinatorics of Ab-square factors of strings and circular strings, see [39].

Several algorithms computing Ab-square factors of a string are known. All Ab-squares in a string of length n can be computed in $\mathcal{O}(n^2)$ time [13]. For a string over a constant-sized alphabet, all Ab-square factors of a string can be computed in $\mathcal{O}(n^2/\log^2 n + \text{output})$ time and the longest Ab-square can be computed in $\mathcal{O}(n^2/\log^2 n)$ time [29, 30]. Moreover, for a string of length n that is given by its run-length encoding consisting of r runs, the longest Ab-square that ends at each position can be computed in $\mathcal{O}(|\Sigma|(r^2 + n))$ time [2] or in $\mathcal{O}(rn)$ time [40]; both approaches require $\Omega(n^2)$ time in the worst case.

In [37] a different problem of enumerating strings being Ab-squares was considered.

Additive squares. An additive square is an even-length string over an integer alphabet such that the sums of characters of the halves of this string are the same.

► **Example 2.** The following string has exactly 4 additive squares of length 10, as shown.

1 2 0 3 2 1 2 0 2 3 2 1 0 1 2 3

All of them except for the rightmost one are also Ab-squares. This string does not contain any longer additive square. Altogether this string has 8 additive square factors.

An Ab-square (over an integer alphabet) is an additive square, but not necessarily the other way around. Combinatorially, problems related to additive squares are hard, in particular avoiding additive squares seems more difficult than avoiding Ab-squares. There are infinitely many strings over $\{0, 1, 2, 3\}$ avoiding Ab-squares, but there are only finitely many strings over the same alphabet avoiding additive squares; see [22].

In fact it is unknown if there are infinitely many strings over any finite integer alphabet avoiding additive squares [7, 25, 33]. For additive cubes the property was proved in [9] (see also [32]) however.

Nowadays, combinatorial study of Ab-square and additive square factors often involves computer experiments; see e.g. [9, 19, 36]. In addition to other applications, efficient algorithms detecting such types of squares could provide a significant aid in this research. In case of classic square factors (i.e., factors of the form XX), a linear-time algorithm for computing them is known for a string over a constant [24] and over an integer alphabet [4, 12]. We show that, unfortunately, in many cases the existence of near-linear-time algorithms for detecting Ab-square and additive square factors is unlikely, based on conjectured hardness of the 3SUM problem.

3SUM problem. The problem asks if there are distinct elements $a, b, c \in S$ such that $a + b = c$ for a given set S of n integers; see [35]. It is a general belief that the following conjecture is true for the word-RAM model.

3SUM conjecture. There is no $\mathcal{O}(n^{2-\epsilon})$ time algorithm for the 3SUM problem, for any constant $\epsilon > 0$.

A problem with input of size n is called 3SUM-hard if an $\mathcal{O}(n^{2-\epsilon})$ -time solution to the problem implies an $\mathcal{O}(n^{2-\epsilon'})$ -time solution for 3SUM, for some constants $\epsilon, \epsilon' > 0$.

Our results.

- We show that the problems of computing all centers of Ab-square factors and detecting an odd half-length Ab-square factor, called an *odd Ab-square* (consequently also computing all lengths of Ab-square factors), for a length- n string over an alphabet of size $\omega(1)$, cannot be solved in $\mathcal{O}(n^{2-\epsilon})$ time, for constant $\epsilon > 0$, unless the 3SUM conjecture fails. Weaker conditional lower bounds are also stated in the case of a constant-sized alphabet.
- For constant-sized alphabets, we show strongly sub-quadratic algorithms for these problems based on an involved result of [11] related to jumbled indexing.
- En route we prove that detection of a double 3-term arithmetic progression (see [8]) and additive squares in a length- n sequence of integers of magnitude $n^{\mathcal{O}(1)}$ is 3SUM-hard.

We obtain deterministic conditional lower bounds from a convolution version of 3SUM that is well-known to be 3SUM-hard.

Related work. In the jumbled indexing problem, we are given a text T and are to answer queries for a pattern specified by a Parikh vector which gives, for each letter of the alphabet, the number of occurrences of this letter in the pattern. For each query, we are to check if there is a factor of the text that is Ab-equivalent to the pattern (existence query) or report all such factors (reporting query). Chan and Lewenstein [11] showed a data structure that can be constructed in truly subquadratic expected time and answers existence queries in truly sublinear time for a constant-sized alphabet (deterministic constructions for very small alphabets were also shown). Amir et al. [3] showed under a 3SUM-hardness assumption that jumbled indexing with existence queries requires $\Omega(n^{2-\epsilon})$ preprocessing time or $\Omega(n^{1-\delta})$

queries for any $\epsilon, \delta > 0$ for an alphabet of size $\omega(1)$. They also provided particular constants $\epsilon_\sigma, \delta_\sigma$ for an alphabet of a constant size $\sigma \geq 3$ such that, under a stronger 3SUM-hardness assumption, jumbled indexing requires $\Omega(n^{2-\epsilon_\sigma})$ preprocessing time or $\Omega(n^{1-\delta_\sigma})$ queries. We use the techniques from both results in our algorithm and conditional lower bound for Ab-squares, respectively. The lower bound of Amir et al. was later improved and extended to both existence and reporting variants and any constant $\sigma \geq 2$ by Goldstein et al. [23, Section 7] with the aid of randomization. Moreover, recently an unconditional lower bound for the reporting variant was given in [1].

Our techniques. A subsequence of three distinct positions is a 3-term double arithmetic progression (3dap in short) if it is an arithmetic progression and the elements on these positions also form an arithmetic progression. The problem of finding a 3dap in a sequence is denoted by 3DAP. It is an odd 3dap if the first and the third positions are odd and the middle position is even. The corresponding problem is denoted by ODD-3DAP. First we reduce the convolution problem 3SUM (known to be 3SUM-hard) to the 3DAP problem via ODD-3DAP as an intermediate problem. This uses a divide-and-conquer approach and a partition of sets into sets avoiding *bad* arithmetic progression of length 3.

The 3DAP problem reduces in a simple way to detection of an additive square, showing that the latter problem is 3SUM hard.

Next, the 3DAP problem is encoded as a string. We follow the high-level idea from Amir et al. Instead of checking equality of numbers, we can check equality of their remainders modulo sufficiently many prime numbers. Then, each prime number corresponds to a distinct character. If the numbers are poly n then only $\mathcal{O}(\log n)$ prime numbers are needed. However, there is a certain technical complication, already present in the paper of Amir et al., which needs an introduction of additional gadgets working as *equalizers*. The details, compared with construction of Amir et al., are different, mostly because in the end we want to ask about detection, not indexing.

Then we consider the problem of computing all centers of Ab-squares, this requires new gadgets. We show that computing all centers of Ab-squares is 3SUM-hard, as well as detection of any Ab-square which is *well centred*.

Later we extend this to detection of any odd Ab-square. We use a construction of a string over the alphabet of size 4 with no Ab-square. The input string is “shuffled” with such a string, with some separators added. This forces odd Ab-squares to be *well centered*, in this way we reduce the previously considered problem of detection of any well-centred Ab-square to the detection of any odd Ab-square. Ultimately, this shows that the latter problem is 3SUM-hard.

2 From Conv3SUM to finding double 3-term arithmetic progressions

For integers a, b , by $[a, b]$ we denote the set $\{a, \dots, b\}$. We use the following convolution variant of the 3SUM problem that is 3SUM-hard; see [10, 31, 35] for both randomized and deterministic reductions. As already noted in [3], the range of elements can be made $[-N^2, N^2]$ using a randomized hashing reduction from [5, 35].

CONV3SUM(\bar{x})

Input: A sequence $\bar{x} = [x_1, \dots, x_N] \in [-N^2, N^2]$

Output: Yes if there are $i \neq j$ such that $x_i + x_j = x_{i+j}$; no otherwise.

Let us denote $\text{mid}(a, b) = (a + b)/2$ and define the condition:

$$\Lambda_{\bar{x}}(i, j) = (i \neq j \wedge j - i \text{ is even} \wedge x_{\text{mid}(i, j)} = \text{mid}(x_i, x_j)).$$

We omit the subscript \bar{x} if it is clear from the context. The last part of the condition is equivalent to $x_j - x_{\text{mid}(i, j)} = x_{\text{mid}(i, j)} - x_i$.

Our first goal is to reduce the CONV3SUM problem to the following one with $K = N^{\mathcal{O}(1)}$.

Double 3-Term Arithmetic Progression, 3DAP(\bar{x})

Input: $\bar{x} = [x_1, \dots, x_n]$, each of x_i is in $[0, K]$.

Output: $(\exists i, j) \Lambda(i, j)$.

In Section 2.1 we obtain a reduction of CONV3SUM to an intermediate version of 3DAP with additional constraints on i, j , and in Section 2.2 we show how these constraints can be avoided.

2.1 From Conv3SUM to Odd-3DAP

Let us fix an integer sequence x_1, \dots, x_N . For an arithmetic progression (arithmetic sequence) $\mathcal{I} = i_1, \dots, i_n$, where $1 \leq i_1 < \dots < i_n \leq N$, i.e. $i_2 - i_1 = \dots = i_n - i_{n-1}$, we define the following extended functions.

$$\text{CONV3SUM}(\bar{x}, \mathcal{I}) = (\exists i_a, i_b \in \mathcal{I} : x_{i_a} + x_{i_b} = x_{i_a + i_b}, i_a < i_b)$$

$$\text{ODDCONV3SUM}(\bar{x}, \mathcal{I}) = (\exists i_a, i_b \in \mathcal{I} : x_{i_a} + x_{i_b} = x_{i_a + i_b}, a + b \text{ is odd}).$$

Note that it can happen that $i_a + i_b \notin \mathcal{I}$. For a fixed \bar{x} the input size is $|\mathcal{I}|$.

► **Lemma 3.** *An instance of $\text{CONV3SUM}(\bar{x})$ can be reduced to an alternative of $\mathcal{O}(N)$ instances of $\text{ODDCONV3SUM}(\bar{x}, \mathcal{I})$ of total size $\mathcal{O}(N \log N)$ in $\mathcal{O}(N \log N)$ time.*

Proof. If $\mathcal{I} = i_1, \dots, i_n$, by \mathcal{I}_{odd} and $\mathcal{I}_{\text{even}}$ we denote the subsequences i_1, i_3, \dots and i_2, i_4, \dots , respectively. We proceed recursively as shown in the following function CONV3SUM, with the first call to $\text{CONV3SUM}(\bar{x}, [1, 2, \dots, N])$.

function CONV3SUM(\bar{x}, \mathcal{I})

Comment: \mathcal{I} is an arithmetic progression

if $|\mathcal{I}| \leq 2$ **then return false;**

return ODDCONV3SUM(\bar{x}, \mathcal{I}) \vee CONV3SUM($\bar{x}, \mathcal{I}_{\text{odd}}$) \vee CONV3SUM($\bar{x}, \mathcal{I}_{\text{even}}$);

Correctness. Let $\mathcal{I} = i_1, \dots, i_n$ and assume there are two indices a, b such that $x_{i_a} + x_{i_b} = x_{i_a + i_b}$. If $a + b$ is odd, then ODDCONV3SUM(\bar{x}, \mathcal{I}) returns true. Otherwise both a, b are of the same parity, so $i_a, i_b \in \mathcal{I}_{\text{odd}}$ or $i_a, i_b \in \mathcal{I}_{\text{even}}$. Consequently, the problem is split recursively into subproblems that correspond to \mathcal{I}_{odd} and $\mathcal{I}_{\text{even}}$.

Complexity. Let us observe that one call to CONV3SUM(\bar{x}, \mathcal{I}) creates an instance of ODDCONV3SUM of $\mathcal{O}(|\mathcal{I}|)$ size in $\mathcal{O}(|\mathcal{I}|)$ time (\bar{x} does not change). Let $\#(n)$ and $S(n)$ denote the total number and size of all instances of \mathcal{I} generated by CONV3SUM(\bar{x}, \mathcal{I}), when initially $|\mathcal{I}| = n$. We then have

$$\#(n) = \#(\lfloor n/2 \rfloor) + \#(\lceil n/2 \rceil) + 1 \quad \text{and} \quad S(n) = S(\lfloor n/2 \rfloor) + S(\lceil n/2 \rceil) + \Theta(n),$$

which yields $\#(N) = \mathcal{O}(N)$ and $S(N) = \mathcal{O}(N \log N)$. The reduction takes $\mathcal{O}(S(N))$ time. ◀

77:6 Hardness of Detecting Abelian and Additive Squares

We say that a 3-element arithmetic progression is a *good* progression if the middle element is even and two others are odd and introduce the following problem.

ODD-3DAP(\bar{x})

Input: $\bar{x} = [x_1, \dots, x_n]$, each of x_i is in $[-\mathcal{O}(N^2), \mathcal{O}(N^2)]$.

Output: $(\exists i, j) [\mathbf{A}(i, j) \text{ and } (i, \text{mid}(i, j), j) \text{ is a good progression}]$.

► **Lemma 4.** $\text{ODD CONV 3SUM}(\bar{x}, \mathcal{I})$ is reducible in $\mathcal{O}(|\mathcal{I}|)$ time and space to $\text{ODD-3DAP}(\bar{y})$, where $|\bar{y}| = \mathcal{O}(|\mathcal{I}|)$.

Proof. Let $\mathcal{I} = i_1, \dots, i_n$. Define $\alpha_N = 2N^2 + 1$ and let \bar{y} be a sequence of length $2n - 1$ that is created as follows:

1. put $x_{i_1}, x_{i_2}, \dots, x_{i_n}$ at subsequent odd positions in \bar{y} ;
2. at each even position $2j$, put $x_{i_j + i_{j+1}}$ or, if $i_j + i_{j+1} > N$, put α_N .
3. multiply elements on even positions by 2.

After the first two steps $\text{ODD CONV 3SUM}(\bar{x}, \mathcal{I})$ is equivalent to $(\exists i, j) y_{\text{mid}(i, j)} = y_i + y_j$ for odd i, j and even $\text{mid}(i, j)$; see Figure 1. Then, after the third step, $\text{ODD CONV 3SUM}(\bar{x}, \mathcal{I})$ is equivalent to $\text{ODD-3DAP}(\bar{y})$. ◀

■ **Figure 1** The sequence constructed in Lemma 4 for $\bar{x} = [x_1, x_2, x_3, \dots, x_{11}]$ and $\mathcal{I} = (1, 2, \dots, 11)$ after the first two steps (* denotes α_{11}). Note that the elements connected by arcs all have their sum of indices equal to 7; this is because \mathcal{I} is an arithmetic progression.

2.2 From Odd-3DAP to 3DAP

Our main tool in this subsection is partitioning a set of integers into progression-free sets. A set of integers A is called *progression-free* if it does not contain a non-constant three-element arithmetic progression. We use the following recent result that extends a classical paper of Behrend [6].

► **Theorem 5** ([14]). Any set $A \subseteq [1, n]$ can be partitioned into $n^{o(1)}$ progression-free sets in $n^{1+o(1)}$ time.

► **Lemma 6.** We can construct in $n^{1+o(1)}$ time a family \mathcal{F} of $n^{o(1)}$ subsets of $[1, n]$ satisfying:

- (a) Each good 3-element progression is contained in some $S \in \mathcal{F}$.
- (b) If $S \in \mathcal{F}$, then all 3-element arithmetic progressions in S are good.

Proof. Let us divide the elements from $[1, n]$ into three classes:

$$\text{BLUE} = \{i \leq n : i \text{ is even}\},$$

$$\text{RED} = \{i \leq n : i \bmod 4 = 1\}, \quad \text{GREEN} = \{i \leq n : i \bmod 4 = 3\}.$$

Each element $i \in [1, n]$ has the colour blue, red or green of its corresponding class. Each class forms an arithmetic progression.

A progression is called *multi-chromatic* if its elements are of three distinct colours. Let us observe that a 3-element progression is good if and only if it is multi-chromatic. Indeed, this is because if $i, j \in \text{RED}$ (or GREEN), then $\text{mid}(i, j)$ is odd.

Now instead of good progressions we will deal with multi-chromatic progressions. We treat sets of integers as increasing sequences and for a set $C = \{c_1, \dots, c_m\}$ we denote by C_{odd} and C_{even} the subsets $\{c_1, c_3, \dots\}$ and $\{c_2, c_4, \dots\}$.

For example $\text{BLUE}_{\text{odd}} = \{i \leq n : i \bmod 4 = 2\}$, $\text{RED}_{\text{even}} = \{i \leq n : i \bmod 8 = 5\}$.

Our construction works as follows:

1. Partition the set $[1, n]$ into classes $\text{BLUE}, \text{RED}, \text{GREEN}$.
2. For each class $C \in \{\text{BLUE}, \text{RED}, \text{GREEN}\}$ partition it in $n^{1+o(1)}$ time into a family \mathcal{F}_C of $n^{o(1)}$ progression-free sets with the use of Theorem 5.
3. Refine each partition \mathcal{F}_C , splitting each set $X \in \mathcal{F}_C$ into two sets $X \cap C_{\text{odd}}$, $X \cap C_{\text{even}}$, so that for each set X in the new refined partition \mathcal{F}_C we have $X \subseteq C_{\text{odd}}$ or $X \subseteq C_{\text{even}}$. Each family is still of size $n^{o(1)}$.
4. Return $\mathcal{F} = \{X \cup Y \cup Z : X \in \mathcal{F}_{\text{BLUE}}, Y \in \mathcal{F}_{\text{RED}}, Z \in \mathcal{F}_{\text{GREEN}}\}$.

Proof of point (a). Each multi-chromatic progression is contained in some $S \in \mathcal{F}$ since each element of C is contained in a set from \mathcal{F}_C .

Proof of point (b). The proof is by contradiction. Assume that $S \in \mathcal{F}$ contains a progression which is not multi-chromatic. There are two cases.

Case 1: the progression is monochromatic, hence it appears in a single set $X \in \mathcal{F}_C$. However every X is progression-free (step 2), hence such a progression cannot appear in any $S \in \mathcal{F}$; a contradiction.

Case 2: the progression contains exactly two different colors. Observe that if $i \bmod p = \text{mid}(i, j) \bmod p = r$, then $j \bmod p = r$ (if the middle element of progression belongs to the same class as one of the other elements, then the triple is monochromatic), hence the two-coloured arithmetic progression has to consist of $i, j \in C$ and $\text{mid}(i, j) \notin C$.

Since i, j both belong to C_{odd} or C_{even} (step 3), $\text{mid}(i, j)$ must belong to C (if $i \bmod 2p = j \bmod 2p$, then $i \bmod p = \text{mid}(i, j) \bmod p$). Consequently, the progression cannot contain exactly two colours; a contradiction. \blacktriangleleft

Our next tool is a *deactivation* of a set of elements which indexes are not in a given set E , that is, omitting them in the computation of a solution. For $E \subseteq [1, n]$ the operation $\text{restr}(\bar{x}, E)$ replaces each element x_i on position $i \notin E$ by $5 \max\{MAX, n^2\} + i^2$, where $MAX = \max_{k \geq 1} |x_k|$.

► **Lemma 7.** $3\text{DAP}(\text{restr}(\bar{x}, E)) \iff (\exists i, j) \Lambda_{\bar{x}}(i, j) \wedge i, j, \text{mid}(i, j) \in E$.

Proof. The (\Leftarrow) part is obvious, so it suffices to show (\Rightarrow) . If at least one, but not all, of $i, j, \text{mid}(i, j)$ is not in E , then $\Lambda_{\bar{y}}(i, j)$ cannot hold for $\bar{y} = \text{restr}(\bar{x}, E)$ because $y_{\text{mid}(i, j)}$ and $\text{mid}(y_i, y_j)$ differ by at least $\max\{\max_k \{|x_k|\}, n^2\}$ (for an exhaustive check of all the cases, see the full version). Otherwise, if all the positions $i, j, \text{mid}(i, j)$ are not in E , then $\Lambda_{\bar{y}}(i, j)$ does not hold because $\text{mid}(i^2, j^2) - (\frac{i+j}{2})^2 = (\frac{i-j}{2})^2 > 0$ since $i \neq j$. \blacktriangleleft

An instance \bar{x} is called an **odd-half** instance if $\Lambda(i, j)$ is false for i, j such that $(j - i)/2$ is even (equivalently, for i, j such that i and $\text{mid}(i, j)$ have the same parity). Efficient equivalence

$$\text{ODD-3DAP}(\bar{x}) \iff (\exists S \in \mathcal{F}) 3\text{DAP}(\text{restr}(\bar{x}, S))$$

follows now from Lemmas 6 and 7.

This produces only odd-half instances because only good progressions are left in the construction of Lemma 6. The instances have elements in $[-\mathcal{O}(N^2), \mathcal{O}(N^2)]$. We can increase all the elements by $\mathcal{O}(N^2)$ so that they become non-negative. This implies:

► **Lemma 8.** *An instance of ODD-3DAP can be reduced in $n^{1+o(1)}$ time to $n^{o(1)}$ odd-half instances of 3DAP of total size $n^{1+o(1)}$ and with elements up to $K = \mathcal{O}(N^2)$.*

Finally, we show that the resulting instances can be glued together to a single equivalent one.

► **Theorem 9.** *An instance of CONV3SUM can be reduced in $N^{1+o(1)}$ time to an odd-half instance of 3DAP of size $n = N^{1+o(1)}$ with elements up to $K = N^{3+o(1)}$.*

Proof. With Lemmas 3, 4, and 8 we obtain a reduction from CONV3SUM to $N^{1+o(1)}$ odd-half instances of 3DAP of total size $N^{1+o(1)}$. The instances have elements in $[0, \mathcal{O}(N^2)]$. We will show that these instances can be reduced to a single odd-half instance of 3DAP of size $N^{1+o(1)}$ with elements in the range $[0, N^{3+o(1)}]$ in time $N^{1+o(1)}$. The resulting instance will return true if and only if at least one of the input instances does.

Let $t = N^{1+o(1)}$ be the number of the instances of 3DAP, numbered 1 through t . We use Theorem 5¹ and pick the largest constructed progression-free set $A \subseteq [1, m]$, for some m . By the pigeonhole principle, $|A| \geq m^{1-o(1)}$. We select m that is large enough so that $m^{1-o(1)} \geq t$, so $m = t^{1+o(1)} = N^{1+o(1)}$, and trim the set A to the size t . Let $A = \{a_1, \dots, a_t\}$. For instance i we multiply all its elements by $2m$ and add to each element the value a_i . Finally we concatenate all the instances.

If any of the input instances returns true, then so does the output instance, since multiplication by and addition of the same number to all elements cannot affect the outcome of a single instance. If none of the input instances returns true, then the only possibility for the output instance to return true is to contain a 3-element arithmetic progression with elements from multiple parts corresponding to the input instances. However, this is impossible since, taken modulo $2m$, the progression would form an arithmetic progression in the set A . ◀

► **Corollary 10.** *The general 3DAP problem is also 3SUM-hard.*

► **Remark 11.** Similarly as in CONV3SUM, techniques from [5] can be used to hash down the range in 3DAP to integers of magnitude $\mathcal{O}(N^2)$ (cf. [3]), using randomization.

► **Remark 12.** The AVERAGE problem (introduced by J. Erickson [17]) asks if there are distinct elements $a, b, c \in S$ such that $a + b = 2c$ for a given set S of n integers. It was recently shown to be 3SUM-hard [14]. The 3DAP problem can be viewed as a convolution version of the AVERAGE problem². The ideas based on almost linear hashing used in the reductions from 3SUM to CONV3SUM [35, 10] can be extended with some effort to reduce AVERAGE to 3DAP. We presented a different reduction that additionally directly leads to an instance of 3DAP with an odd-half property, which is essential in our proof of 3SUM-hardness of computing Ab-squares (see the proof of Lemma 19).

¹ Actually, a deterministic version of Behrend's construction from [14] or an earlier construction of Salem and Spencer [38] would suffice here.

2.3 Hardness of detecting additive squares

If the alphabet is a set of integers, then a string W is called an *additive square* if $W = UV$, where $|U| = |V|$ and $\sum_{i=1}^{|U|} U[i] = \sum_{i=1}^{|V|} V[i]$.

► **Theorem 13.** *Finding an additive square in a length- N sequence composed of integers of magnitude $N^{O(1)}$ is 3SUM-hard.*

Proof. We use Theorem 9 to reduce CONV3SUM to an instance of 3DAP of size $n = N^{1+o(1)}$ with elements in the requested range. 3DAP returns true on an instance x_1, \dots, x_n if and only if the sequence $x_2 - x_1, x_3 - x_2, \dots, x_n - x_{n-1}$ contains an additive square. As the reduction works in $N^{1+o(1)}$ total time, the conclusion follows. ◀

3 From arithmetics to Abelian stringology

We use capital letters to denote strings and lower case Greek letters to denote sets of integers. We assume that the positions in a string S are numbered 1 through $|S|$, where $|S|$ denotes the length of S . By $S[i]$ and $S[i..j]$ we denote the i th letter of S and the string $S[i] \cdots S[j]$ called a factor of S . The reverse of string S , i.e. the string $S[|S|] \cdots S[1]$, is denoted as S^R . By ε we denote the empty string. By $\text{Alph}(S)$ we denote the set of distinct letters in S .

We denote Ab-equivalence of U and V by $U \cong V$. For a string U , by $\text{Parikh}(U)$ we denote the Parikh vector of U . Then $U \cong V$ if and only if $\text{Alph}(U) = \text{Alph}(V)$ and $\text{Parikh}(U) = \text{Parikh}(V)$.

We use an encoding of Amir et al. [3] based on the Chinese remainder theorem to connect CONV3SUM-type problems with Abelian stringology.

Let $p_1 < p_2 < \dots < p_k$ be prime numbers. The Chinese remainder theorem states that if one knows the remainders r_1, r_2, \dots, r_k of an integer x , such that $0 \leq x < \prod p_i$, when dividing by p_i 's, then one can uniquely determine x . Assuming that the remainders of an integer x are r_1, r_2, \dots, r_k , we could encode x as a possibly short string $\mathbf{a}_1^{r_1} \mathbf{a}_2^{r_2} \cdots \mathbf{a}_k^{r_k}$ over an alphabet $\{\mathbf{a}_1, \mathbf{a}_2, \dots, \mathbf{a}_k\}$ (the symbols correspond to consecutive prime numbers).

For example for primes 2,3,5 the encoding of 11 would be $\mathbf{a}_1^1 \mathbf{a}_2^2 \mathbf{a}_3^1$ since its remainders modulo 2,3,5 are 1,2,1, respectively. However, we are interested in encodings of subtractions of one number from another one, and it is more complicated.

Let $\bar{x} = [x_1, \dots, x_n]$ be an instance of 3DAP and $r_1^{(i)}, r_2^{(i)}, \dots, r_k^{(i)}$ be remainders of x_i modulo p_1, p_2, \dots, p_k . Like Amir et al. [3], we define for $1 \leq i < n$ and $1 \leq j \leq k$,

$$\text{EXP}_i(j) = r_j^{(i+1)} - r_j^{(i)} + d \text{ where } d = \max_{j=1}^k p_j, \quad \mathbf{S}_i = \mathbf{a}_1^{\text{EXP}_i(1)} \mathbf{a}_2^{\text{EXP}_i(2)} \cdots \mathbf{a}_k^{\text{EXP}_i(k)}.$$

We choose a sequence p_1, \dots, p_k of k distinct primes such that $p_1 \cdots p_k > \max\{x_i\}$. In this way we encode the difference $x_j - x_i$, for $j > i$, by a string $\mathbf{S}_i \mathbf{S}_{i+1} \cdots \mathbf{S}_{j-1}$. An obstacle is the potentially possible inequality $(a \bmod p) - (b \bmod p) \neq (a - b) \bmod p$. However a small correction is sufficient, due to the following observation.

► **Observation 14.** $(a \bmod p) - (b \bmod p) + q = (a - b) \bmod p$, where $q \in \{0, p\}$.

If we apply the encoding to an instance $\bar{x} = x_1, \dots, x_n$ of 3DAP, we obtain a lemma that is analogous to [3, Lemma 1].

► **Lemma 15.** $\Lambda(i, j)$ holds for $i < j$, $j-i$ even, iff for each $t \in [1, k]$, there are $e_t, f_t \in \{0, p_t\}$, such that

$$e_t + \text{EXP}_i(t) + \text{EXP}_{i+1}(t) + \cdots + \text{EXP}_{\text{mid}(i,j)-1}(t) = \\ \text{EXP}_{\text{mid}(i,j)}(t) + \text{EXP}_{\text{mid}(i,j)+1}(t) + \cdots + \text{EXP}_{j-1}(t) + f_t.$$

Let Ψ be a morphism such that $\Psi(i) = \mathbf{a}_i^{p_i}$ for each $i = 1, \dots, k$. We treat a set $U = \{u_1, \dots, u_w\}$ as a string $u_1 \cdots u_w$, where $u_1 < u_2 < \dots < u_w$. If we interpret the vector $(EXP_i(1), EXP_i(2), \dots, EXP_i(k))$ as \mathbf{S}_i , then Lemma 15 directly implies the following fact.

► **Lemma 16.** *Assume $i < j$ and $j - i$ is even. Then*

$$\Lambda(i, j) \iff (\Psi(\alpha) \mathbf{S}_i \mathbf{S}_{i+1} \cdots \mathbf{S}_{mid(i,j)-1} \cong \mathbf{S}_{mid(i,j)} \cdots \mathbf{S}_{j-1} \Psi(\beta))$$

for some disjoint subsets α, β of $[1, k]$.

4 Hardness of computing all centers of Ab-squares

We construct a text T over the alphabet $\{\mathbf{a}_1, \dots, \mathbf{a}_k, \mathbf{b}, \bullet, \star, \#, \$\}$ such that 3DAP has a solution if and only if T contains an Ab-square with one of specified centers, so-called *well-placed* Ab-square.

First we extend each \mathbf{S}_i to have the same length $M \geq \max_{i=1}^{n-1} |\mathbf{S}_i|$, to be defined later. Intuitively, it is needed to control the number of \mathbf{S}_i 's in the strings from Lemma 16. We append $M - |\mathbf{S}_i|$ occurrences of a letter \mathbf{b} to each \mathbf{S}_i . Let \mathbf{S}_i^I denote this modified string.

Lemma 16 immediately implies the following fact.

► **Lemma 17.** *Assume $i < j$ and $j - i$ is even. Then*

$$\Lambda(i, j) \iff (\mathbf{b}^e \Psi(\alpha) \mathbf{S}_i^I \mathbf{S}_{i+1}^I \cdots \mathbf{S}_{mid(i,j)-1}^I \cong \mathbf{S}_{mid(i,j)}^I \cdots \mathbf{S}_{j-1}^I \Psi(\beta) \mathbf{b}^f),$$

for some disjoint subsets α, β of $[1, k]$, where $e + |\Psi(\alpha)| = f + |\Psi(\beta)|$ with $\min(e, f) = 0$.

The parts $\mathbf{b}^e \Psi(\alpha)$, $\Psi(\beta) \mathbf{b}^f$ in the above lemma can be treated as *equalizers*. Let us note that in the above lemma we can assume that $\max(e, f) \leq \max(|\Psi(\alpha)|, |\Psi(\beta)|) \leq kd$.

A pair of disjoint sets α, β that satisfies $\alpha \cup \beta = [1, k]$ will be called a *2-partition* of $[1, k]$. For a 2-partition (α, β) of $[1, k]$, we use the string

$$\Gamma(\alpha, \beta) = \# \alpha \$ \mathbf{b}^{kd} \# \beta \$,$$

called a Γ -string. If $k = 4$, $d = 7$, an example of a Γ -string is $\Gamma(2, 134) = \# 2 \$ \mathbf{b}^{28} \# 134 \$$.

Let $(\pi_1, \pi'_1), (\pi_2, \pi'_2), \dots, (\pi_m, \pi'_m)$ be the sequence of all $m = 4^k$ pairs of Γ -strings. Define

$$U = \pi_m \pi_{m-1} \dots \pi_1, \quad V = \pi'_1 \pi'_2 \dots \pi'_m.$$

We have $\{\pi_1, \dots, \pi_m\} = \{\pi'_1, \dots, \pi'_m\}$, so $U \cong V$.

► **Observation 18.** *For disjoint subsets $\alpha, \beta \subseteq [1, k]$ and integers $0 \leq e, f \leq kd$, there are decompositions $U = U_1 \mathbf{b}^e \# \beta \$ U_2$ and $V = V_1 \# \alpha \$ \mathbf{b}^f V_2$, where $U_2 \cong V_1$.*

Let us recall the morphism Ψ such that $\Psi(i) = \mathbf{a}_i^{p_i}$ for each $i \in [1, k]$. We define additionally $\Psi(c) = c$ for $c \in \{\mathbf{b}, \#, \$\}$ and set

$$\mathbf{B} = \Psi(U), \quad \mathbf{A} = \Psi(V), \quad M = |\mathbf{A}| = |\mathbf{B}|.$$

Let us observe that indeed $\max_{i=1}^{n-1} |\mathbf{S}_i| \leq M$ holds since $|\mathbf{S}_i| \leq kd + \sum_{j=1}^k p_j$ and the length of $\Psi(W)$ for any Γ -string W is $kd + \sum_{j=1}^k p_j + 4$.

We add two new letters \bullet, \star and define the following string (the symbols “ \downarrow ” are not parts of the string, but only show supposed centers of Ab-squares).

$$T = \bullet \mathbf{B} \star \mathbf{S}_1^I \mathbf{A} \bullet \overset{\text{center}}{\downarrow} \star \mathbf{B} \bullet \mathbf{S}_2^I \mathbf{A} \star \overset{\text{center}}{\downarrow} \bullet \mathbf{B} \star \mathbf{S}_3^I \mathbf{A} \bullet \overset{\text{center}}{\downarrow} \star \mathbf{B} \bullet \mathbf{S}_4^I \mathbf{A} \star \dots \quad (1)$$

■ **Figure 2** Internal structure of an Ab-square, shown in a thick box (proportions are symbolic), in $\mathbf{BS}_1^I \mathbf{A} \mathbf{BS}_2^I \mathbf{A}$. Here $x_{mid(1,3)} = mid(x_1, x_3)$ and $\mathbf{b}^e \Psi(\alpha)$, $\Psi(\beta) \mathbf{b}^f$ are equalizers.

An Ab-square is called *well-placed* if its center is between the letters \bullet, \star in any order. Recall that, due to Theorem 9, we can assume that the input to 3DAP guarantees that only odd-half instances could have solutions.

► **Lemma 19.** *Assume \bar{x} is an odd-half instance. Then $3DAP(\bar{x})$ has a solution if and only if T contains a well-placed Ab-square.*

Proof. Let $\bar{x} = [x_1, \dots, x_n]$ be an odd-half instance of 3DAP. We show two implications.

(\Rightarrow) Assume that $\mathbf{A}(i, j)$ holds for \bar{x} . Lemma 17 implies that for strings W, Z such that $W \cong Z$ we have

$$\begin{aligned} \mathbf{b}^e \# \Psi(\alpha) \$ W \star \mathbf{S}_i^I \mathbf{A} \bullet \star \mathbf{B} \bullet \mathbf{S}_{i+1}^I \mathbf{A} \star \dots \bullet \mathbf{B} \star \mathbf{S}_{mid(i,j)-1}^I \mathbf{A} \bullet \cong \\ \star \mathbf{B} \bullet \mathbf{S}_{mid(i,j)}^I \mathbf{A} \star \dots \bullet \mathbf{B} \star \mathbf{S}_{j-2}^I \mathbf{A} \bullet \star \mathbf{B} \bullet \mathbf{S}_{j-1}^I \mathbf{A} \bullet \# \Psi(\beta) \$ \mathbf{b}^f \end{aligned} \quad (2)$$

for some disjoint subsets α, β of $[1, k]$, where $e + |\Psi(\alpha)| = f + |\Psi(\beta)|$ with $\min(e, f) = 0$. Indeed, we use the fact that $\mathbf{A} \cong \mathbf{B}$ and the counts of letters \bullet and \star on both hand sides are equal (because $(j - i)/2$ is odd). By Observation 18, we obtain a well-placed Ab-square in T (or we obtain it after exchanging all letters \bullet with \star).

(\Leftarrow) Assume that T has a well-placed Ab-square factor with center immediately after $\bullet \mathbf{B} \star \mathbf{S}_t^I \mathbf{A} \bullet$ (the case that it is immediately after $\star \mathbf{B} \bullet \mathbf{S}_t^I \mathbf{A} \star$ is symmetric). Let us investigate what can be the position s of the first letter of this Ab-square.

Recall that $|\mathbf{S}_i^I| = |\mathbf{A}| = |\mathbf{B}| = M$ for each $i \in [1, n - 1]$, so T can be seen as composed of blocks of length $M' = M + 1$. We will check which of these blocks can contain s , by checking the counts of each of the letters \bullet, \star in both halves of the Ab-square. The positions of letters \bullet, \star in T repeat with period $6(M + 1)$, so it is sufficient to inspect the first 6 blocks on each side, as the remaining ones will behave periodically; see Figures 3 and 4.

■ **Figure 3** Which position in a block of T can be the starting position of a well-placed Ab-square with the designated center, just counting letters \bullet, \star .

By counting letters \bullet, \star in both halves of the Ab-square, it can be readily verified that s cannot be in any block $\mathbf{A} \bullet$ or $\bullet \mathbf{S}_i^I$; if in any block $\star \mathbf{B}$ or $\star \mathbf{S}_i^I$, it can only be the first position of the block; it cannot be the first position in a block $\bullet \mathbf{B}$; and it can be in any position in a block $\mathbf{A} \star$.

Moreover, s cannot be the first position in a block $\star \mathbf{B}$, since this would imply, by Lemma 17, that $\mathbf{A}(i, j)$ holds for i such that the block $\bullet \mathbf{S}_i^I$ immediately follows the $\star \mathbf{B}$ block and $j = 2t - i$. However, in this case $(j - i)/2$ is even, which is impossible.

If s is the first position of a block $\star S_i^I$, then this implies, again by Lemma 17, that $\Lambda(i, j)$ holds for $j = 2t - i$. In this case $(j - i)/2$ is odd, so this is a valid solution to the corresponding 3DAP instance.

We are left with the case that s belongs to a block $\mathbf{A}\star$ or $\bullet\mathbf{B}$ (and in case of $\bullet\mathbf{B}$ does not coincide with the position of the letter \bullet). Henceforth it suffices to count letters different from \bullet, \star in the halves. Each of the gadgets \mathbf{A}, \mathbf{B} is a concatenation of m Ab-equivalent strings of the form $\# \Psi(\alpha) \$ \mathbf{b}^{kd} \# \Psi(\beta) \$$, where $\Psi(\alpha), \Psi(\beta)$ are composed of letters \mathbf{a}_i only. By counting the letters $\#$ and $\$$ in both halves of the Ab-square, we see that s can only be a position which holds the letter \mathbf{b} or $\#$.

Hence, the Ab-square is necessarily of the form (2), which, by Lemma 17, implies that $\Lambda(i, j)$ holds, where $\star S_i^I$ is the first such block after the position s and $j = 2t - i$. ◀

■ **Figure 4** The global structure of a fragment containing a well-placed Ab-square; there are three types of blocks: $c\mathbf{B}$, cS_i^I , $\mathbf{A}c$, where c is one of \bullet, \star . The blocks of the second type (which can be considered as essential blocks) are in color, each block is of length $M + 1$ (recall that $|\mathbf{A}| = |\mathbf{B}| = |S_i| = M$). The special letters \bullet, \star force each half of a well-placed Ab-square to contain a number of full S_i 's.

► **Theorem 20.** *Computing all positions that are centers of Ab-square factors in a length- n string over an alphabet of size $\omega(1)$ is 3SUM-hard.*

Proof. Due to Theorem 9 we can reduce CONV3SUM in $N^{1+o(1)}$ time to an odd-half instance \bar{x} of 3DAP of size $n = N^{1+o(1)}$ with elements in the range $[0, N^{3+o(1)}]$.

We construct the string T as shown in Eq. 1 for the sequence \bar{x} . Then Lemma 19 implies that 3DAP is a YES-instance if and only if T has a well-placed Ab-square. The string T has length $\mathcal{O}(N^{1+o(1)}M)$. Each of the strings \mathbf{A}, \mathbf{B} has length M and is composed of $m = 4^k$ strings of length $\mathcal{O}(kd)$, i.e., Ψ -images of Γ -strings.

Hence, $M = \mathcal{O}(4^k kd)$. We select k such that $k = \omega(1)$ and simultaneously $k = \mathcal{O}(\log N / \log \log N)$. Then we have $4^k k = N^{o(1)}$ and the k primes are of magnitude $d = \mathcal{O}(N^{(3+o(1))/k}) = N^{o(1)}$ (we can choose k consecutive primes computed using Eratosthenes's sieve).

Overall $|T| = N^{1+o(1)}$ and $|\text{Alph}(T)| \leq k + 5 = \omega(1)$. (One can obtain any alphabet up to $\mathcal{O}(N)$ by appending distinct letters to T .) ◀

With the same argument for a constant-sized alphabet we obtain the following result.

► **Theorem 21.** *All positions that are centers of Ab-square factors in a length- n string over an alphabet of size $5 + k$, for a constant k , cannot be computed in $\mathcal{O}(n^{2 - \frac{6}{3+k} - \varepsilon})$ time, for a constant $\varepsilon > 0$, unless the 3SUM conjecture fails.*

5 Computing centers of Ab-squares for constant-sized alphabets

A set of vectors in $[1, n]^d$ is called *monotone* if its elements can be ordered so that they form a monotone non-decreasing sequence on each coordinate.

► **Definition 22.** For sets \mathcal{A} and \mathcal{B} of vectors we define $\mathcal{A} + \mathcal{B} = \{a + b : a \in \mathcal{A}, b \in \mathcal{B}\}$ and $c \cdot \mathcal{A} = \{ca : a \in \mathcal{A}\}$, and for a string W we define: $P_{l,r}(W) = \{\text{Parikh}(W[l..k]) : l \leq k \leq r\}$. Let us denote by $|A|$ the length of a string corresponding to a Parikh vector A .

In the algorithm we use the following fact shown in [11]. The exact complexities can be found in [11, Theorem 3.1].

► **Fact 1** ([11]). Given three monotone sequences $\mathcal{A}, \mathcal{B}, \mathcal{C}$ in $[1, n]^d$ for a constant d , we can compute $(\mathcal{A} + \mathcal{B}) \cap \mathcal{C}$ in $\mathcal{O}(n^{2-\epsilon})$ expected time for a constant $\epsilon > 0$, or in $\mathcal{O}(n^{2-\epsilon'})$ worst case time for a constant $\epsilon' > 0$ if $d \leq 7$.

■ **Algorithm 1** CENTERS(T).

```

if  $|T| < 2$  return  $\emptyset$ ;
 $m = \lceil n/2 \rceil$ ;
 $\mathcal{A} = P_{0,m-1}(T)$ ;  $\mathcal{B} = P_{m,n}(T)$ ;  $\mathcal{C} = P_{0,n}(T)$ ;
 $\mathcal{M} = \{|C| : 2C \in (\mathcal{A} + \mathcal{B}) \cap 2 \cdot \mathcal{C}\}$ ;
 $T_{\text{left}} = T[1..m-1]$ ;  $T_{\text{right}} = T[m..n]$ ;
return  $\mathcal{M} \cup \text{CENTERS}(T_{\text{left}}) \cup \{k + m : k \in \text{CENTERS}(T_{\text{right}})\}$ 

```

■ **Figure 5** $A \in \mathcal{A}$, $B \in \mathcal{B}$, $C \in \mathcal{C}$ denote Parikh vectors of the corresponding fragments. If $A + B = 2C$, then $D = E$ and $k = |C|$ is a center of an Ab-square.

► **Theorem 23.** For a string of length n over an alphabet of size $d = \mathcal{O}(1)$, we can compute centers of all Ab-squares and centers of all odd Ab-squares in expected time $\mathcal{O}(n^{2-\epsilon})$ or in worst case time $\mathcal{O}(n^{2-\epsilon})$ if $d \leq 7$, for $\epsilon > 0$.

Proof. We use the above algorithm. Correctness of the algorithm is straightforward; see Figure 5. If

$$|A| < |B|, \quad |C| = (|A| + |B|)/2, \quad B = A + D + E, \quad C = A + D$$

then $A + B = 2C \iff 2A + D + E = 2A + 2D$.

Consequently, after cancelling the same parts on both sides, $A + B = 2C \iff E = D$, equivalently if and only if the factor $T[i..j]$ corresponding to DE is an Ab-square centred in $k = |C|$. The figure shows the case when k is in the right half of the strings; the other case is symmetric.

By Fact 1 the cost of the algorithm can be given by a recurrence

$$S(n) = 2 \cdot S\left(\frac{n}{2}\right) + \mathcal{O}(n^{2-\epsilon})$$

which results in $S(n) = \mathcal{O}(n^{2-\epsilon})$ for $\epsilon > 0$.

In case of odd Ab-squares let

$$P_{l,r}^c(W) = \{\text{Parikh}(W[1..k]) : l \leq k \leq r, k \bmod 2 = c\}.$$

In the algorithm the statement $\mathcal{M} = \{|C| : 2C \in (\mathcal{A} + \mathcal{B}) \cap 2 \cdot \mathcal{C}\}$ is executed for both $c \in \{0, 1\}$, with

$$\mathcal{A} = P_{0,m-1}^c(T), \quad \mathcal{B} = P_{m,n}^c(T), \quad \mathcal{C} = P_{0,n}^{1-c}(T).$$

Other parts of the algorithm, as well as its analysis, are essentially the same. \blacktriangleleft

6 Detecting odd Ab-squares

Unfortunately the string T from Lemma 19 has many Ab-squares which are not well-placed. Our approach is to embed the (slightly) modified string T into a string which is a special composition of T and a combination of long quaternary Ab-square-free strings. The resulting string will fix the potential centers in specified locations. We use additional letters: \diamond , \circ and $0, \dots, 6$.

We show first a fact useful in fixing Ab-squares in specified places (Lemma 26). Let P_{t-2} be any Ab-square-free string of length $t-2$ over alphabet $\{3, 4, 5, 6\}$ (it can be constructed using Keränen's construction [27] of quaternary Ab-square-free strings). Let us define

$$U_{2t} = 0 P_{t-2} 1 2 P_{t-2}^R 0.$$

The following lemma is proved in the full version of the paper.

► **Lemma 24.** *The string $(U_{2t})^m$ contains exactly the following Ab-squares:*

- (1) *of length divisible by $4t$; and*
- (2) *with the center between two 0's and of all admissible even lengths other than $(4q+2)t$, for an integer $q \geq 0$.*

For equal-length strings X, Y we define the string

$$\text{shuffle}_{\diamond}(X, Y) = X[1] \diamond Y[1] X[2] \diamond Y[2] X[3] \diamond Y[3] \dots$$

For example, $\text{shuffle}_{\diamond}(\text{abc}, \text{ABC}) = \text{a} \diamond \text{Ab} \diamond \text{Bc} \diamond \text{C}$.

The parity condition for half lengths of Ab-squares in the following observation justifies the usage of the additional letter \diamond in shuffle . Let $U_{[X]}$ be the string resulting from U by removing all letters outside $\text{Alph}(X)$.

► **Observation 25.** *Assume X, Y are equal-length strings composed of disjoint sets of letters distinct from \diamond and W is an Ab-square in $\text{shuffle}_{\diamond}(X, Y)$. Then $W_{[X]}, W_{[Y]}$ are Ab-squares in X, Y , respectively (we say that these Ab-squares are implied by W). Moreover, $|W_{[X]}|/2, |W_{[Y]}|/2, |W|/2$ are of the same parity.*

We say that an even-length factor of a string X is *centred at i* if it has its center between positions i and $i+1$ in X . By $a \mid b$ and $a \nmid b$ we denote that a divides b and a does not divide b . For an illustration of the following lemma, see Figure 6.

► **Lemma 26.** *Let $X = (U_{2t})^{n-1}$, Y be a string of length $|X|$ such that its alphabet is disjoint with $\text{Alph}(X) \cup \{\diamond\}$, $W = \text{shuffle}_{\diamond}(X, Y)$, and let an integer ℓ satisfy $12t \nmid \ell$. Then a length- ℓ factor of W is an Ab-square if and only if it is centred in W at $r \equiv \{0, -1, -2\} \pmod{6t}$, Y contains an Ab-square factor of length $\ell/3$ centred in Y at $\lfloor r/3 \rfloor$, and $6t \nmid \ell$.*

■ **Figure 6** Illustration of Lemma 26. Let $X = (U_6)^2$. The string $Y = (\text{abba})^3$, composed of black letters, contains many Ab-squares. However the string $Z = \text{shuffle}_\diamond(X, Y)$ of length 36, shown above, contains only Ab-squares centred at 16, 17 or 18, as in the figure. The implied Ab-squares in Z are only those which are centred at positions 5 or 6 in Z .

Proof. By the disjointness of sets of letters in X, Y and $\{\diamond\}$, each Ab-square in W has length that is divisible by 3. The following claim is then readily verified (cf. Observation 25).

▷ **Claim 27.** For positive integer ℓ such that $6 \mid \ell$, a length- ℓ factor of W centred at r is an Ab-square if and only if the length- $\ell/3$ factors in X and Y centred at $\lfloor \frac{r+2}{3} \rfloor$ and $\lfloor \frac{r}{3} \rfloor$, respectively, are Ab-squares.

Let integer $\ell > 0$ satisfy $6 \mid \ell$ and $12t \nmid \ell$. We show two implications.

(\Rightarrow) If W contains an Ab-square factor of length ℓ centred at some r , then the implied Ab-square factor of X has length $\ell/3$, where $4t \nmid \ell/3$, so by Lemma 24 it has its center between two 0's, i.e., $2t \mid \lfloor \frac{r+2}{3} \rfloor$. Hence, $r \equiv \{0, -1, -2\} \pmod{6t}$.

Moreover, $2t \nmid \ell/3$ also by Lemma 24. Finally, the implied Ab-square factor of Y indeed has length $\ell/3$ and is centred at $\lfloor r/3 \rfloor$.

(\Leftarrow) Let $r \equiv \{0, -1, -2\} \pmod{6t}$, $6t \nmid \ell$, and assume that Y contains an Ab-square factor of length $\ell/3$ centred at $\lfloor r/3 \rfloor$. We have $2t \mid \lfloor \frac{r+2}{3} \rfloor$ and $2t \nmid \ell/3$, so by Lemma 24 the string X contains an Ab-square factor of length $\ell/3$ centred at $\lfloor \frac{r+2}{3} \rfloor$. Finally, the unary string \diamond^{2tm} , certainly contains an Ab-square factor of length $\ell/3$ centred at $\lfloor \frac{r+1}{3} \rfloor$. By the claim, W contains an Ab-square of length ℓ centred at r that implies the three Ab-squares. ◀

► **Theorem 28.** *Checking if a length- n string over an alphabet of size $\omega(1)$ contains an odd Ab-square is 3SUM-hard. Moreover, for a string over an alphabet of size $14 + k$, for a constant k , the same problem cannot be solved in $\mathcal{O}(n^{2 - \frac{6}{3+k} - \varepsilon})$ time, for a constant $\varepsilon > 0$, unless the 3SUM conjecture fails.*

Proof. We use the technique of fixing Ab-squares from Lemma 26. Moreover, we make the following minor modifications upon the construction of Section 4:

- (1) Each fragment \mathbf{b}^{kd} is extended by one letter to \mathbf{b}^{kd+1} , and
- (2) the letters \bullet, \star are replaced each by two letters $\bullet\circ, \star\circ$, respectively.

Intuitively, (1) allows to extend Ab-squares considered in the proof of Lemma 19 by one letter \mathbf{b} to either side, and (2) makes $|\mathbf{A}| = |\mathbf{B}| = |\mathbf{S}_i^I|$ even which facilitates the usage of Lemma 26 with $Y = T$. It can be verified by inspecting the proof that Lemma 19 still holds after these two changes. We refer to all the notions from Section 4 after these modifications.

It is enough now to show the following claim for $X = (U_{2t})^{n-1}$, where $2t = |T|/(n-1)$. We assume that $n \geq 3$.

▷ **Claim 29.** An odd-half instance of 3DAP is a YES-instance if and only if $W = \text{shuffle}_\diamond(X, T)$ has an odd Ab-square factor.

■ **Figure 7** A schematic structure of a fragment of T after insertion of symbols \circ . There are $3(n-1)$ (underbraced) blocks in T , each of size $M+2$, and $2t = 3M+6$.

Proof. (\Rightarrow) Assume that \bar{x} is an odd-half instance and $3\text{DAP}(\bar{x})$ has a solution.

By Lemma 19, T contains a well-placed Ab-square, that is, an Ab-square centred at a position r' such that $2t \mid r'$. (Recall that $3(M+2) = 2t$.) Moreover, in the proof of that lemma it is shown that in this case there exists a well-placed Ab-square in T that satisfies the following additional requirements: **(1)** it starts within the gadget **B**; **(2)** it starts and ends within a block of **b**'s; **(3)** its maximal prefix and suffix consisting of letters **b** are \mathbf{b}^e and \mathbf{b}^f , where $e, f \leq kd$.

Let ℓ' denote the half length of this Ab-square. By **(2)** and **(3)**, if ℓ' is even, the Ab-square can be extended by one letter \mathbf{b} to either side (because we have extended each block \mathbf{b}^{kd}) so that ℓ' becomes odd. Moreover, by **(1)**, we have $\ell' \bmod (2t) \in [\frac{4}{3}t, 2t)$, in particular, $t \nmid \ell'$. Then Lemma 26 concludes that the factor of W centred at $r = 3r' \equiv 0 \pmod{6t}$ and of length $6\ell'$ such that $6t \nmid 6\ell'$ is an Ab-square. Its half length, $3\ell'$, is odd, as desired.

(\Leftarrow) Assume that W has an Ab-square factor U of length ℓ such that $\ell/2$ is odd. In particular, we have $12t \nmid \ell$, so by Lemma 26 the Ab-square U is centred in W at $r \equiv \{0, -1, -2\} \pmod{6t}$ and T contains an Ab-square factor V of length $\ell/3$ centred in T at $r' = \lfloor r/3 \rfloor$. If $6t \mid r$, then $2t \mid r'$ and V is well-placed.

Otherwise, V cannot be an Ab-square due to the following fact: T does not contain an Ab-square factor of length ℓ not divisible by $4t$ and centred at $r' \equiv -1 \pmod{2t}$. Indeed, similarly as in the proof of Lemma 19, we will show that each even-length factor centred at such r' contains different counts of one of the letters \bullet, \star, \circ in both halves. The positions of letters \bullet, \star, \circ in T repeat with period $6(M+2)$, so it is sufficient to inspect the first 6 blocks on each side, as the remaining ones will behave periodically; see Figures 7 and 8. An exhaustive verification of several cases can be performed by counting distances of letters from $\{\bullet, \star, \circ\}$ in both directions to the center of the factor (for more details see the full version).

■ **Figure 8** A simplified version of Figure 7. Which position in a block can be the starting position of an Ab-square with the center at r' (one position to the left of a *good* center), only counting ●, ★, ○.

Consequently, as in Lemma 19, the corresponding instance of 3DAP is a YES-instance.

△

The complexities in the theorem are obtained as in Theorems 20 and 21.

7 Open problems

The most interesting questions that remain open are as follows:

1. Is checking Ab-square-freeness 3SUM-hard? Our reductions allowed us to show 3SUM-hardness of detecting an odd Ab-square.

2. Can one detect an additive square in a length- n string over a constant-sized alphabet in $\mathcal{O}(n^{2-\varepsilon})$ time, for some $\varepsilon > 0$? We have shown 3SUM-hardness of this problem for an alphabet that is polynomial in n .

On Approximate Compressions for Connected Minor-Hitting Sets

M. S. Ramanujan   

University of Warwick, Coventry, UK

Abstract

In the CONNECTED \mathcal{F} -DELETION problem, \mathcal{F} is a fixed finite family of graphs and the objective is to compute a minimum set of vertices (or a vertex set of size at most k for some given k) such that (a) this set induces a connected subgraph of the given graph and (b) deleting this set results in a graph which excludes every $F \in \mathcal{F}$ as a minor. In the area of kernelization, this problem is well known to exclude a polynomial kernel subject to standard complexity hypotheses even in very special cases such as $\mathcal{F} = \{K_2\}$, i.e., CONNECTED VERTEX COVER.

In this work, we give a $(2 + \epsilon)$ -approximate polynomial compression for the CONNECTED \mathcal{F} -DELETION problem when \mathcal{F} contains at least one planar graph. This is the first approximate polynomial compression result for this generic problem. As a corollary, we obtain the first approximate polynomial compression result for the special case of CONNECTED η -TREEWIDTH DELETION.

1 Introduction

Polynomial-time preprocessing is one of the widely used methods to tackle NP-hardness in practice, and the area of *kernelization* has been extremely successful in laying down a mathematical framework for the design and rigorous analysis of preprocessing algorithms for decision problems. The central notion in this area is that of a *kernelization* (also called a *kernel*), which is a preprocessing algorithm that runs in polynomial time and transforms a “large” instance of a decision problem into a significantly smaller, but equivalent instance. Over the last decade, the area of kernelization has seen the development of a wide range of tools to design preprocessing algorithms and lower bounds techniques. The reader may find an introduction to the field in [24, 25, 3, 7].

An “efficient preprocessing algorithm” in this setting is referred to as a *polynomial kernel* and is simply a kernel whose output has size bounded polynomially in a parameter of the input. The central classification task in the area of kernelization is to identify NP-hard problems and associated parameters for which polynomial kernels exist and one of the main success stories in the area is the development of a rich theory of lower bounds based on complexity theoretic assumptions [1, 5, 2, 18, 4, 9, 21, 6, 20] allowing one to rule out the existence of polynomial kernels completely or lower bound the degree of the polynomial.

One fundamental class of problems for which polynomial kernels have been ruled out in this way is the class of subgraph hitting problems *with connectivity constraints*. It is well-known that placing connectivity constraints on subgraph hitting problems can have a dramatic effect on their amenability to efficient preprocessing. A case in point is the classic VERTEX COVER problem. This problem is known to admit a kernel whose output has $\mathcal{O}(k)$ vertices [3], where the parameter k is the solution size. However, the CONNECTED VERTEX COVER problem is amongst the earliest problems shown to exclude a polynomial kernel [6] and this lower bound immediately rules out the possibility of such a kernel for numerous well-studied generalizations of this problem. Consequently, one cannot hope to design approximation

algorithms for such problems via polynomial kernels in the traditional sense and so, obtaining a finer understanding of the impact of connectivity constraints on the limits of preprocessing is an important objective in furthering the study of preprocessing techniques in general and in the design of approximation algorithms for connectivity constrained subgraph hitting problems.

One of the most frequently investigated subgraph hitting problems in the literature is the \mathcal{F} -DELETION problem which generalizes numerous well-studied NP-complete problems. In this problem, \mathcal{F} is a fixed finite family of graphs and one is given a graph G and an integer k as input. The objective is to determine whether at most k vertices can be deleted from G so that the resulting graph is \mathcal{F} -minor free (does not contain a minor isomorphic to a graph in \mathcal{F}). The optimization version of this problem asks for a minimum set of vertices whose deletion leaves a graph which is \mathcal{F} -minor free. Well-studied special cases of this problem include VERTEX COVER ($\mathcal{F} = \{K_2\}$), FEEDBACK VERTEX SET ($\mathcal{F} = \{K_3\}$), PLANARIZATION ($\mathcal{F} = \{K_{3,3}, K_5\}$) [27], DIAMOND HITTING SET ($\mathcal{F} = \{\theta_3\}$) [14], PATHWIDTH ONE VERTEX DELETION ($\mathcal{F} = \{K_3, T_2\}$) [29], and θ_c -DELETION [22, 15]. A common feature shared by many such well explored special cases of this problem is that \mathcal{F} contains at least one planar graph. Motivated by this, Fomin et al. [17] investigated this restricted variant of the problem (when the family \mathcal{F} contains at least one planar graph) and obtained a polynomial kernel for every such \mathcal{F} . This particular variant of \mathcal{F} -DELETION is known in the literature as the PLANAR \mathcal{F} -DELETION problem.

Motivated by the prevalence of the PLANAR \mathcal{F} -DELETION problem in existing work on subgraph hitting problems, we initiate the study of the PLANAR \mathcal{F} -DELETION problem when there is a connectivity constraint on the solution. This problem, which we call the CONNECTED PLANAR \mathcal{F} -DELETION problem, is formally defined as follows. The input is a graph G , and integer k (the parameter) and the goal is to determine whether there is a set $S \subseteq V(G)$ of size at most k such that $G[S]$ is connected and $G - S$ is \mathcal{F} -minor free? The set S is called a connected \mathcal{F} -deletion set.

As already discussed, CONNECTED PLANAR \mathcal{F} -DELETION displays stark differences to the version without connectivity constraints when considering the approximability as well as amenability to efficient preprocessing even when \mathcal{F} is a very simple family such as $\{K_2\}$. To be specific, since this problem is a clear generalization of CONNECTED VERTEX COVER, it cannot have a $(2 - \varepsilon)$ -approximation in polynomial time for any fixed $\varepsilon > 0$ under UGC [23] and moreover, it is unlikely to have a polynomial kernel [6].

Since using the existing notion of polynomial kernels and associated reduction rules in order to design approximation algorithms for such connectivity constrained problems appears to be difficult, we rely on the recently developed notion of α -approximate kernels which was introduced by Lokshtanov et al. [26] in order to facilitate the rigorous analysis of preprocessing algorithms in conjunction with approximation algorithms.

Informally speaking, an α -approximate kernel is a polynomial-time algorithm that given as input a pair (I, k) where I is the problem instance and k is the parameter, outputs an instance (I', k') of the same problem such that $|I'| + k' \leq g(k)$ for some computable function g and any c -approximate solution for the instance I' can be turned in polynomial time into a $(c \cdot \alpha)$ -approximate solution for the original instance I . When the output is an instance of a different problem (with the remaining conditions holding), one obtains an α -approximate compression.

As earlier, the notion of efficiency in this context is captured by the function g being required to be polynomially bounded, in which case we call this algorithm an α -approximate polynomial kernelization. We refer the reader to Section 2 for a formal definition of all terms related to (approximate) kernelization.

In their work, Lokshtanov et al. considered several problems which are known to exclude polynomial kernels and presented an α -approximate polynomial kernel for these problems for every fixed $\alpha > 1$. This implies that allowing for an arbitrarily small amount of error while preprocessing can drastically improve the extent to which the input instance can be reduced, even when dealing with problems for which polynomial kernels have been ruled out under the existing theory of lower bounds. In particular, they showed that CONNECTED VERTEX COVER admits an α -approximate polynomial kernel for every $\alpha > 1$. Their result provided a promising starting point towards a refined understanding of the role played by connectivity constraints in relation to preprocessing for covering problems on graphs. Subsequently, Eiben et al. [11] extended this result to the CONNECTED \mathcal{H} -HITTING SET problem where \mathcal{H} is a fixed collection of finite subgraphs and the solution is a minimum set of vertices in the given graph G which induce a connected subgraph and hit all copies of graphs in \mathcal{H} which are present in G . Recently, Ramanujan [30] obtained the first α -approximate polynomial kernel (for every $\alpha > 1$) for the CONNECTED FEEDBACK VERTEX SET problem, demonstrating the power of approximate preprocessing for cases where the goal is to hit obstructions of unbounded size while maintaining connectivity of the hitting set.

Our results

A formal definition of α -approximate kernels and compressions can be found in Section 2.

► **Theorem 1.** *For every fixed $0 < \varepsilon < 1$, CONNECTED PLANAR \mathcal{F} -DELETION has a $(2 + \varepsilon)$ -approximate compression of polynomial size.*

As an immediate corollary of Theorem 1, we obtain a factor- $(2 + \varepsilon)$ parameterized approximation algorithm for CONNECTED PLANAR \mathcal{F} -DELETION running in time $2^{\mathcal{O}(k \log k)} n^{\mathcal{O}(1)}$ for every fixed $0 < \varepsilon < 1$. In fact, the proof techniques we use in order to prove Theorem 1 also enable us to obtain a polynomial-time $\text{poly}(\text{OPT})$ approximation for this problem.

► **Theorem 2.** *For every fixed \mathcal{F} containing a planar graph, there is an algorithm that, given a graph G and $k \in \mathbb{N}$, runs in polynomial time and either correctly concludes that G has no connected \mathcal{F} -deletion set of size at most k or returns a connected \mathcal{F} -deletion set of G of size $k^{\mathcal{O}(1)}$.*

Using Theorem 2 and adopting an approach similar to that in [30], we obtain the following.

► **Theorem 3.** *There is a $0 < \delta < 1$ such that CONNECTED PLANAR \mathcal{F} -DELETION can be approximated within a factor $\min\{\text{OPT}^{\mathcal{O}(1)}, n^{1-\delta}\}$ in polynomial time.*

Related work on approximation for connected hitting set problems

Grigoriev and Sitters [19] studied the design of approximation algorithms for the CONNECTED FEEDBACK VERTEX SET problem on planar graphs and obtained a Polynomial Time Approximation Scheme (PTAS), building upon the result of Escoffier et al. [13] for CONNECTED VERTEX COVER. Fiorini et al. [14] studied the DIAMOND HITTING SET problem (where $\mathcal{F} = \{\theta_3\}$) and obtained the first constant-factor approximation.

¹ We note that this problem can be easily seen to be fixed-parameter tractable parameterized by k since the problem is MSO-expressible and the treewidth of yes-instances must be bounded by $\mathcal{O}(k)$, allowing for an invocation of Courcelle's theorem.

2 Preliminaries

For a graph G , we denote by $\mathcal{CC}(G)$ the set of connected components of G . Let G be a graph and $x, y \in V(G)$. Let \mathcal{P} be a set of internally vertex-disjoint x - y paths in G . Then, we call \mathcal{P} an x - y flow. The value of this flow is $|\mathcal{P}|$. Recall that Menger's theorem states that for distinct non-adjacent vertices x and y , the size of the smallest x - y separator is precisely the value of the maximum x - y flow in G . For a set $X \subseteq V(G)$, the graph obtained from G by identifying the vertices in X is the graph G' defined as follows. The vertex set of G' is $(V(G) \setminus X) \cup \{x\}$ where $x \notin V(G)$. For every edge of G which is not incident on X , G' has the same edge. For every edge $(u, v) \in E(G)$ where $u \in X, v \notin X$, we add a new edge (x, v) . Note that we ignore all edges which have both endpoints in X .

Parameterized problems and (approximate) kernels

A parameterized problem Π is a subset of $\Gamma^* \times \mathbb{N}$ for some finite alphabet Γ . An instance of a parameterized problem consists of (x, k) , where k is called the parameter. We assume that k is given in unary and hence $k \leq |x|$. The notion of kernelization is formally defined as follows.

► **Definition 4 (Kernelization).** Let $\Pi \subseteq \Gamma^* \times \mathbb{N}$ be a parameterized problem and g be a computable function. We say that Π admits a kernel of size g if there exists an algorithm referred to as a kernelization (or a kernel) that, given $(x, k) \in \Gamma^* \times \mathbb{N}$, outputs in time polynomial in $|x| + k$, a pair $(x', k') \in \Gamma^* \times \mathbb{N}$ such that (a) $(x, k) \in \Pi$ if and only if $(x', k') \in \Pi$, and (b) $\max\{|x'|, k'\} \leq g(k)$. If $g(k) = k^{\mathcal{O}(1)}$ then we say that Π admits a polynomial kernel.

► **Definition 5 ([26]).** A parameterized optimization (minimization or maximization) problem is a computable function $\Pi : \Sigma^* \times \mathbb{N} \times \Sigma^* \rightarrow \mathbb{R} \cup \{\pm\infty\}$.

The instances of a parameterized optimization problem Π are pairs $(I, k) \in \Sigma^* \times \mathbb{N}$, and a solution to (I, k) is simply a string $s \in \Sigma^*$, such that $|s| \leq |I| + k$. The value of the solution s is $\Pi(I, k, s)$. Since the problems we come across in this paper are minimization problems, we state some of the definitions only in terms of minimization problems when the definition for maximization problems is analogous. For instance, the parameterized optimization version of CONNECTED PLANAR \mathcal{F} -DELETION is defined as follows (using the convention from [26]). This is a minimization problem with the optimization function $\text{CPFD} : \Sigma^* \times \mathbb{N} \times \Sigma^* \rightarrow \mathbb{R} \cup \{\infty\}$ defined as follows.

$$\text{CPFD}(G, k, S) = \begin{cases} \infty & \text{if } S \text{ is not a feasible solution,} \\ \min\{|S|, k + 1\} & \text{otherwise.} \end{cases}$$

► **Definition 6 ([26]).** For a parameterized minimization problem Π , the optimum value of an instance $(I, k) \in \Sigma^* \times \mathbb{N}$ is $\text{OPT}_\Pi(I, k) = \min_{\substack{s \in \Sigma^* \\ |s| \leq |I| + k}} \Pi(I, k, s)$.

We now recall the other relevant definitions from [26] regarding approximate kernels.

► **Definition 7 ([26]).** Let $\alpha \geq 1$ be a real number and Π be a parameterized minimization problem. An α -approximate polynomial-time preprocessing algorithm \mathcal{A} for Π is a pair of polynomial-time algorithms. The first one is called the reduction algorithm, and computes a map $\mathcal{R}_\mathcal{A} : \Sigma^* \times \mathbb{N} \rightarrow \Sigma^* \times \mathbb{N}$. Given as input an instance (I, k) of Π the reduction algorithm outputs another instance $(I', k') = \mathcal{R}_\mathcal{A}(I, k)$.

The second algorithm is called the solution-lifting algorithm. This algorithm takes as input an instance $(I, k) \in \Sigma^* \times \mathbb{N}$ of Π , the output instance (I', k') of the reduction algorithm, and a solution s' to the instance (I', k') . The solution-lifting algorithm works in time polynomial in $|I|, k, |I'|, k'$ and s' , and outputs a solution s to (I, k) such that $\frac{\Pi(I, k, s)}{\text{OPT}_{\Pi}(I, k)} \leq \alpha \cdot \frac{\Pi(I', k', s')}{\text{OPT}_{\Pi'}(I', k')}$.

The size of a polynomial-time preprocessing algorithm \mathcal{A} is a function $\text{size}_{\mathcal{A}} : \mathbb{N} \rightarrow \mathbb{N}$ defined as $\text{size}_{\mathcal{A}}(k) = \sup\{|I'| + k' : (I', k') = \mathcal{R}_{\mathcal{A}}(I, k), I \in \Sigma^*\}$.

► **Definition 8** ([26]). Let $\alpha \geq 1$ be a real number. Let Π and Π' be two parameterized minimization problems. An α -approximate polynomial parameter transformation (α -appt for short) \mathcal{A} from Π to Π' is a pair of polynomial-time algorithms, called reduction algorithm $\mathcal{R}_{\mathcal{A}}$ and solution-lifting algorithm. Given as input an instance (I, k) of Π the reduction algorithm outputs an instance (I', k') of Π' such that $k' = k^{O(1)}$. The solution-lifting algorithm takes as input an instance (I, k) of Π , the output instance $(I', k') = \mathcal{R}_{\mathcal{A}}(I, k)$ of Π' , and a solution s' to the instance I' and outputs a solution s to (I, k) such that

$$\frac{\Pi(I, k, s)}{\text{OPT}_{\Pi}(I, k)} \leq \alpha \cdot \frac{\Pi'(I', k', s')}{\text{OPT}_{\Pi'}(I', k')}.$$

► **Definition 9** ([26], α -approximate compression). Let $\alpha \geq 1$ be a real number. Let Π and Π' be two parameterized minimization problems. An α -approximate compression from Π to Π' is an α -appt \mathcal{A} from Π to Π' such that $\text{size}_{\mathcal{A}}(k) = \sup\{|I'| + k' : (I', k') = \mathcal{R}_{\mathcal{A}}(I, k), I \in \Sigma^*\}$, is upper bounded by a computable function $g : \mathbb{N} \rightarrow \mathbb{N}$, where $\mathcal{R}_{\mathcal{A}}$ is the reduction algorithm in \mathcal{A} . We say that \mathcal{A} is an α -approximate polynomial compression if g is a polynomial function.

Treewidth, t -Boundaried graphs and minors

We now recall standard definitions regarding treewidth and minor models. The notation is based on [17]. Let G be a graph. A *tree decomposition* of G is a pair $(T, \mathcal{X} = \{X_t\}_{t \in V(T)})$ where T is a tree and \mathcal{X} is a collection of subsets of $V(G)$ such that (a) $\forall e = uv \in E(G), \exists t \in V(T) : \{u, v\} \subseteq X_t$ and (b) $\forall v \in V(G), T[\{t \mid v \in X_t\}]$ is a non-empty connected subtree of T . We call the vertices of T *nodes* and the sets in \mathcal{X} *bags* of the tree decomposition (T, \mathcal{X}) . The *width* of (T, \mathcal{X}) is denoted by $\text{width}(T, \mathcal{X})$ is defined as $\max\{|X_t| - 1 \mid t \in V(T)\}$ and the *treewidth* of G is the minimum width over all tree decompositions of G . A t -boundaried graph is a graph G and a set $B \subset V(G)$ of size at most t with each vertex $v \in B$ having a label $\ell_G(v) \in \{1, \dots, t\}$. Each vertex in B has a unique label. We refer to B as the *boundary* of G . We use the notation (G, B) to refer to the t -boundaried graph G with boundary B .

Least Common Ancestor-Closure of Sets in Graphs of Bounded Treewidth

For a graph G with a nice tree decomposition (T, χ) rooted at $r \in V(T)$ and vertex set $X \subseteq V(G)$ the least common ancestor-closure $\text{LCA-closure}(T, \chi, X)$ is defined as follows. We let $M \subseteq V(T)$ denote a minimal set of nodes in T such that for every $x \in X$, there is a bag $u \in M$ such that $x \in \chi(u)$ and moreover, u is the closest such vertex to r . Finally, we define $\text{LCA-closure}(T, \chi, X)$ as the set $\chi(\text{LCA-closure}(M))$, where $\text{LCA-closure}(M)$ denotes the LCA-closure of M in the rooted tree T . We ignore the explicit reference to the root r in the notation $\text{LCA-closure}(T, \chi, X)$ because we will be using an arbitrary vertex as the root when invoking this definition.

The following lemma is a direct consequence of the definition of $\text{LCA-closure}(T, \chi, X)$ and the application of LCA-closure on trees (see, for example, [17]).

► **Lemma 10.** *Let G be a graph with a nice tree decomposition (T, χ) and let $X \subseteq V(G)$. Let X' denote the set $\text{LCA-closure}(T, \chi, X)$. Then, $|X'| \leq 2|X| \cdot \text{width}(T, \chi)$ and for every connected component C of $G - X'$, $|N(C)| \leq 2 \cdot \text{width}(T, \chi)$.*

► **Definition 11.** *Let G be a graph and H be a minor of G with $V(H) = \{h_1, \dots, h_\ell\}$ and suppose that H has no self-loops. A set $\mathcal{P}_H = \{P_1, \dots, P_\ell\}$ of pairwise vertex-disjoint subsets of $V(G)$ is said to be a minor model of H in G if*

- $G[P_i]$ is connected for every $i \in [\ell]$ and
- there is an injective mapping $\phi : E(H) \rightarrow E(G)$ such that for every $e = (i, j) \in E(H)$, $\phi(e)$ is an edge in G with one endpoint in P_i and one in P_j .

Note that if H has parallel edges, then the minor model needs to have a unique edge corresponding to each parallel edge. We say that H is a minimal minor model if there is no strict subgraph of $G[\bigcup_{i \in [\ell]} P_i]$ which also contains H as a minor.

► **Definition 12.** *Let G_1 and G_2 be two graphs, and let t be a fixed positive integer. For $i \in \{1, 2\}$, let f_{G_i} be a function that associates with every vertex of $V(G_i)$ some subset of $[t]$. The image of a vertex $v \in G_i$ under f_{G_i} is called the label of that vertex. We say that G_1 is label-wise isomorphic to G_2 , and denote it by $G_1 \cong_t G_2$, if there is a map $h : V(G_1) \rightarrow V(G_2)$ such that (a) h is one to one and onto; (b) $(u, v) \in E(G_1)$ if and only if $(h(u), h(v)) \in E(G_2)$ and (c) $f_{G_1}(v) = f_{G_2}(h(v))$. We call h a label-preserving isomorphism.*

Notice that the first two conditions of Definition 12 simply indicate that G_1 and G_2 are isomorphic. Now, let G be a t -boundaried graph, that is, G has t distinguished vertices, uniquely labeled from 1 to t . Given a t -boundaried graph G , we define a canonical labeling function $\mu_G : V(G) \rightarrow 2^{[t]}$. The function μ_G maps every distinguished vertex v with label $\ell \in [t]$ to the set $\{\ell\}$, that is $\mu_G(v) = \{\ell\}$, and for all other vertices we have that $\mu_G(v) = \emptyset$.

Next we define a notion of labeled edge contraction. Let H be a graph together with a function $f_H : V(H) \rightarrow 2^{[t]}$ and $(u, v) \in E(H)$. Furthermore, let H' be the graph obtained from H by identifying the vertices u and v into w_{uv} and removing all loops. Then by *labeled edge contraction* of an edge (u, v) of a graph H , we mean obtaining a graph H' with the label function $f_{H'} : V(H') \rightarrow 2^{[t]}$ defined as follows. For $x \in V(H') \cap V(H)$ we have that $f_{H'}(x) = f_H(x)$ and for w_{uv} we define $f_{H'}(w_{uv}) = f_H(u) \cup f_H(v)$. Now we introduce a notion of labeled minors of a t -boundaried graph.

► **Definition 13.** *Let H be a graph together with a function $f : V(H) \rightarrow 2^{[t]}$ and (G, Z) be a t -boundaried graph with canonical labeling function μ_G . A graph H is called a labeled minor of G , if we can obtain a labeled isomorphic copy of H from G by performing edge deletions and labeled edge contractions. The h -folio of a t -boundaried graph (G, Z) is the set $\mathcal{M}_h(G, Z)$ of all labeled minors of G (starting with the canonical labeling on G) on at most h vertices.*

We also need the following well-known result bounding the treewidth of any graph which excludes a fixed planar graph as a minor.

► **Proposition 14 ([17]).** *For every fixed planar graph H , there is a constant λ_H such that any graph G with $\text{tw}(G) \geq \lambda_H$ contains H as a minor.*

Steiner Trees

For a graph G , a set $R \subseteq V(G)$ called *terminals* and a cost function $w : E(G) \rightarrow \mathbb{N} \cup \{0\}$, a *Steiner tree* is a subtree T of G such that $R \subseteq V(T)$, and the *cost* of a tree T is defined as $w(T) = \sum_{e \in E(T)} w(e)$. In the STEINER TREE problem we are given as input the graph G ,

the set R and the cost function $w : E(G) \rightarrow \mathbb{N} \cup \{0\}$. The task is to find an *optimal Steiner tree*, which is a Steiner tree of minimum cost. However, in this paper we will only work with edges of unit or zero cost and we denote by w_1 the function that assigns a cost of 1 to every edge of the graph under consideration. When T is a Steiner tree for the set of terminals R , we say that T is an *R -Steiner tree*. An R -Steiner tree T is said to be *minimal* if there is no $e \in E(T)$ such that $T - e$ also contains an R -Steiner tree. It is well-known that there is an algorithm for STEINER TREE with a single exponential dependence on the number of terminals.

► **Proposition 15** ([8, 28]). *The STEINER TREE problem can be solved in time $2^{O(|R|)} n^{O(1)}$.*

Let R continue to denote the set of terminals. For a $k \in \mathbb{N}$, a *k -component* is a tree with at most k leaves, all of which are in R . A *k -restricted Steiner tree* \mathcal{T} is a collection of k -components, such that the union of these components is a Steiner tree T . The cost of \mathcal{T} is the sum of the costs of all the k -components in \mathcal{T} . It may be the case that multiple k -components which are part of a k -restricted Steiner tree, share edges. As a result, some edges may contribute multiple times to the cost of \mathcal{T} . To keep the presentation simple, if the k -components of a k -restricted Steiner tree are clear from the context, then we also refer to the Steiner tree composed of their union as a k -restricted Steiner tree. Recall that according to its original definition, a k -restricted Steiner tree is a *set* of k -components.

3 Overview of our Algorithms

Fix $0 < \varepsilon < 1$. We identify a partition (A, B, C) of the vertex set of G , where $|B| = k^{O(f(1/\varepsilon))}$ and there are no edges between A and C . In other words, B separates A and C . We then prove that the vertices in C only play the role of “connectors” and removing them from a hypothetical solution S may disconnect $G[S]$, but will still leave a minimal hitting set for all \mathcal{F} -minor models. On the other hand, while the interaction of vertices in A with the solution S could be much more complex, we show that the number of connected components of $G[A]$ is $k^{O(f(1/\varepsilon))}$ and these can be shown to have a well-structured neighborhood in B . Once we have this partition in hand, we focus on each connected component of $G[A]$ separately and from each component we identify a set of $k^{O(f(1/\varepsilon))}$ vertices which, together with B and a $k^{O(f(1/\varepsilon))}$ sized subset of C cover a $(2 + \varepsilon)$ -approximate solution. Finally, the remaining vertices are discarded in an appropriate manner once the relevant information they hold is compiled into a polynomially bounded data structure. This high level approach of identifying “hitters” and “connectors” among the vertices is a natural first step for problems with this flavor [11, 12, 30] and the more involved problem-specific part in each case resides in (a) computing such a partition and (b) setting up a procedure to identify and remove redundant parts of the input, leaving only $k^{O(f(1/\varepsilon))}$ vertices or edges.

Fix $\rho = 2^{O(1/\varepsilon)}$ to be a constant such that $\frac{1}{\lceil \log_2 \rho \rceil} \leq \varepsilon$. Our starting point is a lemma of Fomin et al. [17] showing that there is a polynomial-time algorithm that takes as input the pair (G, k) and either correctly concludes that G has no \mathcal{F} -deletion set (a set of vertices whose deletion leaves an \mathcal{F} -minor free graph) of size at most k or outputs disjoint sets $X, Z \subseteq V(G)$ such that (a) $|X \cup Z| = k^{O(1)}$, (b) X is an \mathcal{F} -deletion set of G , (c) for every connected component C of $G - (X \cup Z)$, $|N(C) \cap Z| \leq 2(\eta + 1)$, and (d) for every $x, y \in X$, either Z intersects every x, y path in $G - (X \setminus \{x, y\})$ or there is an x - y flow of value at least $3k + \eta + 3$ in the graph $G - (X \setminus \{x, y\})$. Let G_τ denote the graph $G - (X \cup Z)$. In the proposed partition (A, B, C) , our intention is to set $B = X \cup Z$.

Given the sets X and Z described above we will compute a subset of vertices covering a $(2 + \varepsilon)$ -approximate connected \mathcal{F} -deletion set (if one of size at most k exists) in two stages. In the first stage, we mark a set of $k^{O(\rho)}$ vertices of G_τ such that for every subset U of $X \cup Z$, if

there is a set T_U of vertices in G_τ using which the vertices in U can be connected, then there is a set of roughly $(1 + \varepsilon)|U|$ *marked* vertices which can do the same connecting task as T_U with respect to the vertices in U . In the second stage, we ignore the connectivity requirement on the subset of the solution in $X \cup Z$ and for each connected component of G_τ , mark $k^{\mathcal{O}(\rho)}$ vertices such that if there is a solution which intersects a component of G_τ then there is a way to select a sufficiently small subset of the *marked* vertices in the component which can be connected to the vertices of the solution in $X \cup Z$ and achieve the same “ \mathcal{F} -minor hitting” behaviour as the original set of vertices.

A major obstacle here is the fact that the number of connected components of G_τ may be unbounded, which might mean that we mark a set of vertices whose size is not bounded by a function of the parameter k at all. It is to overcome this obstacle that we distribute the set $V(G) \setminus B$ among the remaining partitions A and C . In other words, we will be able to partition the components of G_τ into two sets that we call **Type 1** components (corresponding to C) and **Type 2** components (corresponding to A) and then show that the **Type 1** components although unbounded in number, only provide connectivity to a minimal \mathcal{F} -deletion set contained in the solution while, on the other hand, the **Type 2** components are more complex but bounded polynomially (in k) in number. We then argue that there is a way to achieve the objective of our initial marking strategy by marking only a *polynomial* number of vertices of G_τ in total, and these vertices cover a factor- $(2 + \varepsilon)$ approximate solution and moreover, a factor- $\text{OPT}^{\mathcal{O}(1)}$ approximate solution can be recovered by a straightforward examination of the connected components of the subgraph induced by the marked vertices.

To extend this to our approximate compression, we prove the following lemma.

► **Lemma 16.** *There is an algorithm that given G, k, X, Z as described above, runs in time $k^{\mathcal{O}(\rho)} n^{\mathcal{O}(1)}$ and either correctly concludes that G has no connected \mathcal{F} -deletion set of size at most k or returns a set $L \subseteq V(G)$ such that the following statements hold.*

1. $L \supseteq (X \cup Z)$, $|L| = k^{\mathcal{O}(\rho)}$.
2. For every S which is a minimal connected \mathcal{F} -deletion set of G of size at most k , G has a connected \mathcal{F} -deletion set of size at most $(2 + \varepsilon)|S|$ contained in L .
3. For every connected component C of $G - L$, $|N(C) \cap (L \setminus X)| \leq 2(\eta + 1)$.
4. For every \mathcal{F} -deletion set S of G of size at most $3k$ and every $C \in \mathcal{CC}(G - L)$, $|(N(C) \cap X) \setminus S| \leq \eta + 1$.

The above lemma is obtained following the previously discussed marking steps that led to the factor- $\text{OPT}^{\mathcal{O}(1)}$ approximation and can be seen as an “approximate-solution-capturing” variant of the lemma of Fomin et al. [17] in the context of our problem. Once we have this lemma in hand, we define an annotated version of CONNECTED PLANAR \mathcal{F} -DELETION and encode the output of the lemma above as an instance of ANNOTATED CONNECTED PLANAR \mathcal{F} -DELETION whose size is bounded polynomially in k , which completes the compression, giving us Theorem 1.

4 The $(2 + \varepsilon)$ -Approximate Compression for CONNECTED PLANAR \mathcal{F} -DELETION

Recall that we have chosen $\rho = 2^{\mathcal{O}(1/\varepsilon)}$ to be a constant such that $\frac{1}{\lfloor \log_2 \rho \rfloor} \leq \varepsilon$. Throughout this section, we suppress the dependence of the running time and compression size on \mathcal{F} in the $\mathcal{O}(\cdot)$ notation. However, we make the dependencies on ε explicit. Our first aim in this section is to prove Lemma 17, which is then invoked in the proof of Lemma 16. This lemma says that there is a polynomial-time algorithm that identifies a set of $k^{\mathcal{O}(\rho)}$ vertices that cover a $(2 + \varepsilon)$ -approximate solution (if one of size at most k exists).

► **Lemma 17.** *There is an algorithm that, given G and k , runs in time $k^{\mathcal{O}(\rho)} n^{\mathcal{O}(1)}$ and either correctly concludes that G has no connected \mathcal{F} -deletion set of size at most k or returns a set $V^\infty \subseteq V(G)$ such that the following statements hold.*

1. $|V(G) \setminus V^\infty| = k^{\mathcal{O}(\rho)}$.
2. *For every S which is a minimal connected \mathcal{F} -deletion set of G of size at most k , G has a connected \mathcal{F} -deletion set of size at most $(2 + \varepsilon)|S|$ that is disjoint from V^∞ .*

Let η be a constant depending only on \mathcal{F} such that every graph which is \mathcal{F} -minor free has treewidth at most η . By Proposition 14, we know that such a constant exists. Let $h = 10\eta + \max_{F \in \mathcal{F}} |F|$. Note that h is an upper bound on the number of vertices and the number of edges in any graph in \mathcal{F} .

We begin building towards the proof of Lemma 17 by recalling the following lemma from [17] and some associated observations. The numbering of the lemmas in our citations is derived from the full version of [16]. A set $S \subseteq V(G)$ is called an \mathcal{F} -deletion set of G if $G - S$ is an \mathcal{F} -minor free graph.

► **Lemma 18** (Lemma 25, [16]). *There is a randomized polynomial-time algorithm that given (G, k) , either concludes that G has no \mathcal{F} -deletion set of size at most k or outputs disjoint sets $X, Z \subseteq V(G)$ satisfying the following properties.*

1. $|X \cup Z| = k^{\mathcal{O}(1)}$.
2. X is an \mathcal{F} -deletion set of G .
3. *For every connected component C of $G - (X \cup Z)$, $|N(C) \cap Z| \leq 2(\eta + 1)$.*
4. *For every $x, y \in X$, either Z intersects every x - y path in $G - (X \setminus \{x, y\})$ or there is an x - y flow of value at least $3k + \eta + 3$ in the graph $G - (X \setminus \{x, y\})$.*

If G has an \mathcal{F} -DELETION set of size k , then this algorithm outputs the pair (X, Z) with probability $(1 - \frac{1}{2^n})$. Otherwise, the algorithm always correctly concludes that no such set exists.

When the pair $\tau = (X, Z)$ is clear from the context, we use G_τ to refer to the graph $G - (X \cup Z)$.

The randomization in Fomin et al.'s proof of this lemma arises due to the execution of a randomized linear-time constant-factor approximation algorithm for (unconnected) PLANAR \mathcal{F} -DELETION, i.e., the subroutine used to compute the set X . However, this step can be replaced with any deterministic factor- $\text{OPT}^{\mathcal{O}(1)}$ approximation for the same problem with, again, only a constant-factor change in the degree of the polynomial in the first property of the lemma. In particular, we can use the factor- $O(\log^{3/2} \text{OPT})$ approximation from [15] and avoid the randomization.

We now recall the following useful properties of non-solution vertices in the neighborhood of any connected component of G_τ .

► **Proposition 19** (Lemma 26, [16]). *Let P be a set of vertices such that for every distinct $u, v \in P$, there is a u - v flow of value $3k + \eta + 3$, let S be an \mathcal{F} -deletion set of G of size at most $3k$ which is disjoint from P and let (T, χ) be a tree decomposition of $G - S$ of width at most η . Then, for every pair of vertices $u, v \in P$, there is a vertex $x \in V(T)$ such that $u, v \in \chi(x)$ and moreover, there is a vertex $y \in V(T)$ such that $P \subseteq \chi(y)$.*

The above proposition captures the fact that if P is disjoint from S and is a set of vertices with pairwise-high flow, then these vertices must appear together in some bag of the tree decomposition (T, χ) . Indeed, if this were not the case, then a pair of vertices in this set can be separated by deleting a small separator in the graph, contradicting the high flow between them. The next statement follows as a consequence of Proposition 19.

► **Proposition 20** (Lemma 26, [16]). *Let G, k and $\tau = (X, Z)$ be as in Lemma 18. For every \mathcal{F} -deletion set S of G of size at most $3k$ and every connected component C of G_τ , $|N(C) \cap X \setminus S| \leq \eta + 1$.*

Indeed, the fourth property ensured by Lemma 18 guarantees that for every connected component C of G_τ , $N(C) \cap X$ is a set of vertices with a pairwise flow of value at least $3k + \eta + 3$ in G . If it were the case that $|N(C) \cap X \setminus S| > \eta + 1$, then Proposition 19 would imply that some bag of a tree decomposition of $G - S$ of width η contains the set $(N(C) \cap X) \setminus S$, which has size greater than $\eta + 1$, a contradiction.

Proposition 20 guarantees that for every connected component C of G_τ , all but at most $\eta + 1$ vertices in $N(C) \cap X$ must be deleted (equivalently, contained in S). Combining this with the third property ensured by Lemma 18, we may conclude that all but at most $3(\eta + 1)$ vertices in $N(C)$ must be contained in S .

Our marking rules rely on the following result of Du et al. [10] which has found applications in other algorithms for connected deletion problems [11, 30].

► **Proposition 21** ([10]). *For every $p \geq 1$, graph G , $R \subseteq V(G)$, cost function $w : E(G) \rightarrow \mathbb{N} \cup \{0\}$ and R -Steiner tree T , there is a p -restricted R -Steiner tree in G of cost at most $(1 + \frac{1}{\lfloor \log_2 p \rfloor}) \cdot w(T)$.*

4.1 The $\text{OPT}^{\mathcal{O}(1)}$ -approximation for CONNECTED PLANAR \mathcal{F} -DELETION

In what follows, we fix G, k , and $\tau^* = (X, Z)$ as given by Lemma 18.

► **Definition 22.** *For a vertex set C disjoint from X , a set $J \subseteq N(C)$ is called a set compatible with C if $|J \cap X| \leq \eta + 1$. We denote by \mathcal{B}_C the set of all sets compatible with C . For a set C and set J compatible with C , the $|J|$ -boundaried graph $(G[C \cup J], J)$ is denoted by $G_{C,J}$.*

Recall that $\forall C \in \mathcal{CC}(G_{\tau^*})$, $|N(C) \cap Z| \leq 2(\eta + 1)$ (argued using the third property of Lemma 18). Consequently, for every $C \in \mathcal{CC}(G_{\tau^*})$, any set $J \subseteq N(C)$ compatible with C has size at most $3\eta + 3$, which is a constant in our setting. Moreover, due to Proposition 20, we have that for any solution S , the set $N(C) \setminus S$ must be a set compatible with C .

► **Lemma 23.** *There is an algorithm that given G, k , and $\tau^* = (X, Z)$, runs in polynomial time and returns a set $P^\infty \subseteq V(G) \setminus (X \cup Z)$ and a partition of $\mathcal{CC}(G_{\tau^*})$ into sets \mathcal{P} and \mathcal{Q} such that the following statements hold.*

1. $|\mathcal{P}| = k^{\mathcal{O}(1)}$ and $P^\infty \subseteq V(\mathcal{P})$.
2. Every \mathcal{F} -deletion set of $G - V(\mathcal{Q}) - P^\infty$ of size at most $3k$ is an \mathcal{F} -deletion set of G .

► **Definition 24.** *Let $G, k, \tau^* = (X, Z), \mathcal{P}, \mathcal{Q}$ be as in Lemma 23. We call every component in \mathcal{Q} a Type 1 component of G_τ and every component in \mathcal{P} a Type 2 component of G_{τ^*} .*

Lemma 23 implies that the vertices contained in Type 1 components are only required for providing connectivity between those vertices of a minimal \mathcal{F} -deletion set of size at most $3k$ that are contained in $X \cup Z$ and the Type 2 components are bounded polynomially in k . The proof of this lemma closely follows the proof of Fomin et al. (see Lemma 36, [16]) with the following difference: instead of discarding irrelevant vertices, we identify them and use them to define the sets \mathcal{P} and \mathcal{Q} .

We are now ready to state our marking rules. We fix $G, k, \tau^* = (X, Z), P^\infty, \mathcal{P}, \mathcal{Q}$ as given by Lemma 23.

► **Marking Rule 1.** For every $R \subseteq X \cup Z$ of size at most ρ , we compute an optimal R -Steiner tree T_R in G with the unitary cost function (denoted w_1). If $|V(T_R)| \leq (2 + \varepsilon)k$, then we mark the vertices of T_R .

Before we describe our next marking rule, we need the following definition.

► **Definition 25.** For a graph G and vertex $p \in V(G)$, we say that a set $S \subseteq V(G)$ is a p -connected set in G if $p \notin S$ and $G[S \cup \{p\}]$ is connected. For a t -boundaried graph (G, L) , $P \subseteq V(G) \setminus L$, $k \in \mathbb{N}$ and $p \in V(G) \setminus L$, a set $S \subseteq V(G)$ is called a (p, P, k) -representative set for (G, L) if the following holds:

For every p -connected set $S \subseteq V(G) \setminus L$ of size at most k in G , S contains a p -connected set $\tilde{S} \subseteq V(G) \setminus L$ of size at most $|S|$ such that $\mathcal{M}_h(G - p - (S \cup P), L) \supseteq \mathcal{M}_h(G - p - (\tilde{S} \cup P), L)$.

We extend the notion of p -connected sets in a natural way to the additional case when p is not a vertex, but $p = \emptyset$. In this case, S is p -connected if $G[S]$ is connected. The definition of (p, P, k) -representative sets for $p = \emptyset$ is analogous.

The notion of p -connected sets is motivated by the following observation.

► **Observation 26.** Let S be a connected \mathcal{F} -deletion set of G of size at most $3k$ and let $C \in \mathcal{CC}(G_\tau)$. Let $S_C = S \cap C$ and suppose that S_C is non-empty. Let $J = N(C) \setminus S$ and consider the boundaried graph (G_C^J, J) , where G_C^J is defined as the graph obtained from $G[N[C]]$ as follows. If $T_C = N(C) \cap S$ is non-empty, then we identify the vertices in T_C into a single vertex v_J^* to obtain G_C^J . Otherwise, $G_C^J = G[N[C]]$ and set $v_J^* = \emptyset$. Then, S_C is a v_J^* -connected set of size at most $3k$ in the graph G_C^J .

The definition of the (p, P, k) -representative set S (Definition 25) guarantees that for every p -connected set $S \subseteq V(G) \setminus L$ of size at most k in G , there is a p -connected set in S that provides the “same” connectivity as S with respect to p , costs at most $|S|$, and hits every minor model hit by S in $G - p - P$ (and possibly more). The case when $p = \emptyset$ covers the case when the entire solution is contained in a single component of G_{τ^*} .

► **Lemma 27.** Let (G, L) be a t -boundaried graph for some $t \leq 3\eta + 3$, $k \in \mathbb{N}$, $p \in V(G) \setminus L$ and $P \subseteq V(G) \setminus L$. Then, there is a (p, P, k) -representative set for (G, L) of size $\mathcal{O}(k)$. Moreover, if $\text{tw}(G) = \mathcal{O}(\eta)$, then such a set can be computed in polynomial time.

We are now ready to describe our second and final marking rule. Recall that \mathcal{P} , \mathcal{Q} and P^∞ are as given by Lemma 23. Let C be a Type 2 component of $\mathcal{CC}(G_{\tau^*})$. Then, $C \in \mathcal{P}$. Let P_C^∞ denote the set $P^\infty \cap C$.

► **Marking Rule 2.** For each compatible set $J \in \mathcal{B}_C$, we construct a $|J|$ -boundaried graph (G_C^J, J) defined as the graph obtained from $(G[N[C]], J)$ by identifying all vertices of $N(C) \setminus J$ with the resulting vertex denoted by v_J^* . If $J = N(C)$, then we simply define $v_J^* := \emptyset$. We then use Lemma 27 to compute a $(v_J^*, P_C^\infty, 3k)$ -representative set Q_C^J of size $\mathcal{O}(k)$ for (G_C^J, J) and mark the vertices in it.

In the rule above, J is intended to represent the subset of $N(C)$ that is *not* deleted by a hypothetical connected \mathcal{F} -deletion set of size at most $3k$ that intersects $N[C]$. If $N(C) = J$, then any hypothetical connected \mathcal{F} -deletion set that intersects $N[C]$ and has an empty intersection with $N(C)$ must also be contained entirely in C . Consequently, we simulate this case by setting $v_J^* = \emptyset$. Note that (G_C^J, J) is a t -boundaried graph for some $t \leq 3\eta + 3$ because $|J \cap X| \leq \eta + 1$ and $|J \cap Z| \leq 2(\eta + 1)$. Moreover, $\text{tw}(G_C^J) \leq 2\eta + 2$. As the treewidth of $G[C \cup (N(C) \cap Z)]$ is at most η , it follows that adding v_J^* and a subset of X of size at most $\eta + 1$ can increase the treewidth of $G[C \cup (N(C) \cap Z)]$ to at most $2\eta + 2$.

We are now ready to prove Lemma 17.

Proof of Lemma 17. We first invoke Lemma 18 to either correctly conclude that G has no \mathcal{F} -deletion set of size at most k or compute the pair $\tau^* = (X, Z)$. In the former case we return the same. Otherwise, we invoke Lemma 23 to compute the partition $\mathcal{P} \uplus \mathcal{Q}$ of $\mathcal{CC}(G_{\tau^*})$ and the set $P^\infty \subseteq V(\mathcal{P})$. Recall that the components contained in \mathcal{P} are called Type 2 components and those contained in \mathcal{Q} are called Type 1 components. We now execute Marking Rule 1.

For each $C \in \mathcal{CC}(G_{\tau^*})$, let R_C denote the set of marked vertices in the connected component C . Note that the *total* number of vertices marked across all components of G_{τ^*} in this step is at most $3k \cdot |X \cup Z|^\rho = k^{\mathcal{O}(\rho)}$.

Now, for each Type 2 component $C \in \mathcal{CC}(G_{\tau^*})$ we execute Marking Rule 2 with Q_C denoting the subset of its vertices marked in this execution. For every Type 1 component C , $Q_C = \emptyset$. Note that the number of vertices marked in each Type 2 component C in this step is bounded by $\mathcal{O}(k \cdot |\mathcal{B}_C|) = k^{\mathcal{O}(1)}$. Since the number of Type 2 components is bounded by $k^{\mathcal{O}(1)}$, we conclude that Marking Rule 2 marks a total of $k^{\mathcal{O}(1)}$ vertices across all connected components of G_{τ^*} .

We now argue that we have preserved a $(2 + \varepsilon)$ -approximation in the union of the marked set of vertices and $X \cup Z$.

▷ **Claim 28.** If G has a connected \mathcal{F} -deletion set S of size at most k , then it has a connected \mathcal{F} -deletion set of size at most $(2 + \varepsilon)|S|$ contained in $X \cup Z \cup \bigcup_{C \in \mathcal{CC}(G_{\tau^*})} (Q_C \cup R_C)$.

Proof sketch. Let $S'' = S \cap (X \cup Z)$ and $A = S \setminus S''$. Suppose that $G[S'']$ is not connected. Consider the terminal set S'' with a weight function on the edges that assigns 0 to every edge with both endpoints in S'' and assigns 1 to every other edge. Then, we observe that $G[S]$ contains an S'' -Steiner tree with weight at most $|A| + \beta - 1$ where β is the number of connected components in $G[S'']$ and Proposition 21 guarantees that the set of vertices marked by Marking Rule 1 contains a set A'' such that $G[A'' \cup S'']$ is connected, $|A''| + \beta - 1 \leq (1 + \varepsilon)(|A| + \beta - 1)$, implying that $|A'' \cup S''| \leq (1 + \varepsilon)|S|$.

In order to prove the claim, we will show that once we have added A'' to S'' , we can (a) ignore all other vertices of Type 1 components originally contained in S and (b) consider each Type 2 component $C \in \mathcal{CC}(G_{\tau^*})$ independently and replace the set $S \cap C$ with a subset of Q_C of size at most $|S \cap C|$ in such a way that the resulting set is eventually still connected and hits all \mathcal{F} -minor models in G . Observe that if $S'' = \emptyset$, then $A'' = \emptyset$. Moreover, if $G[S'']$ is connected, then we set $A'' = \emptyset$. ◁

Finally, we define V^∞ as follows. $V^\infty = V(G) \setminus (X \cup Z \cup \bigcup_{C \in \mathcal{CC}(G_{\tau^*})} (Q_C \cup R_C))$. ◀

Theorem 2 can now be proved using Lemma 17.

4.2 The approximate compression for CONNECTED PLANAR \mathcal{F} -DELETION

The crux of our approximate compression is the following stronger version of Lemma 18, where we have now also ensured the presence of a $(2 + \varepsilon)$ -approximate solution within a polynomially bounded set L (which plays the role that the set $X \cup Z$ plays in Lemma 18).

► **Lemma 29.** *There is an algorithm that given $G, k, \tau^* = (X, Z)$ from Lemma 18, runs in time $k^{\mathcal{O}(\rho)} n^{\mathcal{O}(1)}$ and either correctly concludes that G has no connected \mathcal{F} -deletion set of size at most k or returns a set $L \subseteq V(G)$ such that the following statements hold.*

1. $L \supseteq (X \cup Z)$, $|L| = k^{\mathcal{O}(\rho)}$.
2. For every S which is a minimal connected \mathcal{F} -deletion set of G of size at most k , G has a connected \mathcal{F} -deletion set of size at most $(2 + \varepsilon)|S|$ contained in L .

3. For every connected component C of $G - L$, $|N(C) \cap (L \setminus X)| \leq 2(\eta + 1)$.
4. For every \mathcal{F} -deletion set S of G of size at most $3k$ and any $C \in \mathcal{CC}(G - L)$, $|(N(C) \cap X) \setminus S| \leq \eta + 1$.

Proof. We invoke Lemma 17 to either conclude that G has no \mathcal{F} -deletion set of size at most k or compute the set V^∞ such that $|V(G) \setminus V^\infty| = k^{\mathcal{O}(\rho)}$ and for every S which is a minimal connected \mathcal{F} -deletion set of G of size at most k , G has a connected \mathcal{F} -deletion set of size at most $(2 + \varepsilon)|S|$ disjoint from V^∞ . In the former case we return the same. Otherwise, let $Y = V(G) \setminus V^\infty$. Although it does not follow from the statement of Lemma 17, an inspection of the definition of V^∞ in the proof shows that $V^\infty \cap (X \cup Z) = \emptyset$ and so we may assume without loss of generality that $Y \supseteq X \cup Z$.

Consider the graph $G - X$ which is known to be \mathcal{F} -minor free and hence has treewidth at most η . Let (T, χ) be an arbitrary tree decomposition of $G - X$ of minimum width and suppose that it is arbitrarily rooted. We now define L to be the set $X \cup \text{LCA-closure}(T, \chi, Y \setminus X)$. The fact that $L \supseteq X \cup Z$ and $|L| = k^{\mathcal{O}(\rho)}$ follows from the fact that $X \cup Z \subseteq Y \subseteq L$, $|Y| = k^{\mathcal{O}(\rho)}$, and Lemma 10. Moreover, Lemma 10 also implies that the third statement holds. Similarly, the second statement follows from the fact that for every S which is a minimal connected \mathcal{F} -deletion set of G of size at most k , G has a connected \mathcal{F} -deletion set of size at most $(2 + \varepsilon)|S|$ contained in Y which is contained in L .

For the final statement, we know from Lemma 18 that for every $x, y \in X$, either $Z \subseteq Y \subseteq L$ intersects every x, y path in $G - (X \setminus \{x, y\})$ or there is an x - y flow of value at least $3k + \eta + 3$ in the graph $G - (X \setminus \{x, y\})$. Consequently, we can invoke Proposition 20 with the pair $(X, L \setminus X)$ instead of (X, Z) to conclude that for every \mathcal{F} -deletion set S of G of size at most $3k$ and any $C \in \mathcal{CC}(G - L)$, $|(N(C) \cap X) \setminus S| \leq \eta + 1$. This completes the proof of the lemma. \blacktriangleleft

Before proceeding to the description of the compression (Theorem 1), we need to define an annotated version of our problem. Recall that $h \geq \max\{10\eta, \max_{F \in \mathcal{F}} |F|\}$. In the ANNOTATED CONNECTED \mathcal{F} -DELETION problem, the input is a graph G , integer k , and a set $\mathcal{R} = \{(P_i, Q_i, \mathcal{T}_i)\}_{i \in [\ell]}$ where $\forall i \in [\ell]$, $P_i \cap Q_i = \emptyset$, $P_i \cup Q_i \subseteq V(G)$, $|Q_i| \leq 3(\eta + 1)$, and \mathcal{T}_i is a set of $|Q_i|$ -labeled graphs of size at most h . The goal is to decide whether there is a set $S \subseteq V(G)$ of size at most k such that $G[S]$ is connected and G_S has no minor isomorphic to a graph in \mathcal{F} , where G_S is defined as the graph obtained from G by going over all $i \in [\ell]$ and gluing a graph (H_i, Q_i) on to (G, Q_i) using the canonical labeling, whenever $P_i \subseteq S$ and $Q_i \cap S = \emptyset$, and where $\mathcal{M}_h(H_i, Q_i) = \mathcal{T}_i$.

A set S (not necessarily of size at most k) satisfying the properties above is said to be a feasible solution. Following the convention from [26], the parameterized optimization version of ANNOTATED CONNECTED \mathcal{F} -DELETION is defined to be a minimization problem with the optimization function $ACFD : \Sigma^* \times \mathbb{N} \times \Sigma^* \rightarrow \mathbb{R} \cup \{\infty\}$ defined as follows.

$$ACFD(G, \mathcal{R}, k, S) = \begin{cases} \infty & \text{if } S \text{ is not a feasible solution,} \\ \min\{|S|, k + 1\} & \text{otherwise.} \end{cases}$$

We next describe a compression algorithm that takes as input an instance of CONNECTED \mathcal{F} -DELETION and outputs an instance of ANNOTATED CONNECTED \mathcal{F} -DELETION with size bounded polynomially in k and in which a $(2 + \varepsilon)$ -approximate solution for the original instance is preserved.

► **Lemma 30.** *There is an algorithm that given G, k , runs in time $k^{\mathcal{O}(\rho)} n^{\mathcal{O}(1)}$ and either correctly concludes that G has no connected \mathcal{F} -deletion set of size at most k or returns an instance $\Gamma = (\tilde{G}, \tilde{k}, \tilde{\mathcal{R}} = \{(\tilde{P}_i, \tilde{Q}_i, \tilde{\mathcal{T}}_i)\}_{i \in [\ell]})$ of ANNOTATED CONNECTED \mathcal{F} -DELETION such that the following statements hold.*

1. $|V(\tilde{G})| = k^{\mathcal{O}(\rho)}$, $\ell = k^{\mathcal{O}(\rho)}$.
2. If G has a connected \mathcal{F} -deletion set S of size at most k , then Γ has a feasible solution of size at most $(2 + \varepsilon)|S|$.
3. Every feasible solution of Γ is a connected \mathcal{F} -deletion set of G .

Proof sketch. We begin by executing Lemma 18 and then Lemma 29 to either conclude that G has no connected \mathcal{F} -deletion set of size at most k or compute $\tau = (X, Z)$ and the set $L \supseteq X \cup Z$. We set $\tilde{G} = G[L]$ and $\tilde{k} = (2 + \varepsilon)k$. Recall that $|L| = k^{\mathcal{O}(\rho)}$.

If the number of connected components of $G - L$ is not already bounded by $k^{\mathcal{O}(\rho)}$, then we use the arguments from Lemma 23 (with L used in place of $X \cup Z$) to partition them into \mathcal{P} and \mathcal{Q} and compute the set $P^\infty \subseteq V(\mathcal{P})$ such that every \mathcal{F} -deletion set of size at most $3k$ for $G - V(\mathcal{Q}) - P^\infty$ is an \mathcal{F} -deletion set of G and $|\mathcal{P}| = k^{\mathcal{O}(\rho)}$. Observe that because we are now using L in place of $X \cup Z$, the size of the set $|\mathcal{P}|$ is now bounded by $k^{\mathcal{O}(\rho)}$ (because $|L| = k^{\mathcal{O}(\rho)}$) as opposed to $k^{\mathcal{O}(1)}$ where the degree of the polynomial only depends on \mathcal{F} .

We now define $\tilde{\mathcal{R}}$ as follows. Let $\hat{G} = G - V(\mathcal{Q}) - P^\infty$. For every $C \in \mathcal{CC}(\hat{G})$ and compatible set $J \in \mathcal{B}_C$ in the graph \hat{G} , we add to $\tilde{\mathcal{R}}$ the tuple $(N(C) \setminus J, J, \mathcal{M}_h(\hat{G}_C^J, J))$. This completes the definition of $\tilde{\mathcal{R}}$ and consequently, the definition of Γ . We now show that the three properties specified in the lemma hold.

Since we have $k^{\mathcal{O}(\rho)}$ connected components in $\mathcal{CC}(\hat{G})$ and each connected component has $k^{\mathcal{O}(1)}$ compatible sets, we conclude that $\ell = k^{\mathcal{O}(\rho)}$. It remains to prove the second and third statements of the lemma. For the second statement, Lemma 29 guarantees that if G has a connected \mathcal{F} -deletion set S of size at most k then it has a connected \mathcal{F} -deletion set S' of size at most $(2 + \varepsilon)|S|$ which is contained in L . We claim that S' is also a feasible solution for the constructed instance of ANNOTATED CONNECTED \mathcal{F} -DELETION. If this were not the case then there is an \mathcal{F} -minor model in the graph $\tilde{G}_{S'}$ as defined in the definition of the problem. However, the definition of the tuples in $\tilde{\mathcal{P}}$ implies that every \mathcal{F} -minor model present in $\tilde{G}_{S'}$ is also present in $G - S'$, a contradiction to S' being a connected \mathcal{F} -deletion set of G . Therefore, we conclude that the second statement holds.

For the third statement, let S be a feasible solution for the constructed instance of ANNOTATED CONNECTED \mathcal{F} -DELETION and suppose that it is not a connected \mathcal{F} -deletion set of G . Then, there is an \mathcal{F} -minor model in $G - S$. In fact, due to Lemma 23 and the definition of the sets P^∞ and \mathcal{Q} , we conclude that there is an \mathcal{F} -minor model in $G - V(\mathcal{Q}) - P^\infty - S = \hat{G} - S$ because otherwise S must be an \mathcal{F} -deletion set of G as well.

However, for every \mathcal{F} -minor model in $\hat{G} - S$, one can invoke “cut and paste” arguments similar to those used in the proof of Lemma 23 to construct an alternate minor model in \tilde{G}_S for the same graph in \mathcal{F} , a contradiction to our choice of S as a feasible solution of Γ . This completes the proof of the lemma. \blacktriangleleft

Theorem 1 now follows from Lemma 30. The reduction algorithm uses the algorithm of this lemma and the solution-lifting algorithm simply returns the approximate solution computed for the instance of ANNOTATED CONNECTED \mathcal{F} -DELETION.

5 Conclusion and Open Problems

Our result on the approximate compressibility of the connectivity constrained variant of PLANAR \mathcal{F} -DELETION demonstrates that preprocessing lower bounds can be side-stepped even for very general versions of problems such as Vertex Cover and Feedback Vertex Set as long as one allows a small loss in accuracy. While a step forward in our understanding of preprocessing under connectivity constraints, our work leaves some natural questions for follow-up work.

1. Is there a $(1 + \varepsilon)$ -approximate kernel for this problem (for every $0 < \varepsilon < 1$)?
2. What is the best approximation factor one can achieve for this problem in polynomial time?
3. Is there a fixed-parameter algorithm for CONNECTED PLANAR \mathcal{F} -DELETION with a single-exponential dependence on k ? To the best of our knowledge, such an algorithm is not known in the literature even when $\mathcal{F} = \{\theta_c\}$ for $c \geq 3$. Here, θ_c is the graph on 2 vertices with c parallel edges between them.

Restricted Adaptivity in Stochastic Scheduling

Abstract

We consider the stochastic scheduling problem of minimizing the expected makespan on m parallel identical machines. While the (adaptive) list scheduling policy achieves an approximation ratio of 2, any (non-adaptive) fixed assignment policy has performance guarantee $\Omega\left(\frac{\log m}{\log \log m}\right)$. Although the performance of the latter class of policies are worse, there are applications in which non-adaptive policies are desired. In this work, we introduce the two classes of δ -delay and τ -shift policies whose degree of adaptivity can be controlled by a parameter. We present a policy – belonging to both classes – which is an $\mathcal{O}(\log \log m)$ -approximation for reasonably bounded parameters. In other words, an exponential improvement on the performance of any fixed assignment policy can be achieved when allowing a small degree of adaptivity. Moreover, we provide a matching lower bound for any δ -delay and τ -shift policy when both parameters, respectively, are in the order of the expected makespan of an optimal non-anticipatory policy.

1 Introduction

Load balancing problems are one of the most fundamental problems in the field of scheduling, with applications in various sectors such as manufacturing, construction, communication or operating systems. The common challenge is the search for an efficient allocation of scarce resources to a number of tasks. While many variants of the problem are already hard to solve, in addition one may have to face uncertainty regarding the duration of the tasks; one way to model this is to use stochastic information learned from the available data.

In contrast to the solution concept of a schedule in deterministic problems, we are concerned with *non-anticipatory policies* in stochastic scheduling problems. Such a policy has the ability to *react* to the information observed so far. While this adaptivity can be very powerful, there are situations where assigning resources to jobs prior to their execution is a highly desired feature, e.g. for the scheduling of healthcare services. This is especially true for the daily planning of elective surgery units in hospitals, where a sequence of patients is typically set in advance for each operating room. In this work, we present and analyze semi-adaptive policies, which allow one to control the level of adaptivity of the policy.

■ **Figure 1** Snippets of the execution of a δ -delay policy: Realizations of jobs observed up to time t (left) and up to some time $> t + \delta$ (right) are depicted by rectangles in dark grey; the running job non-completed by the time of each snippet is indicated by squared dots in dark grey; jobs that did not start yet are depicted in light grey with the corresponding machine assignment.

The problem considered in this paper is the stochastic counterpart of the problem of minimizing the makespan on parallel identical machines, denoted by $P \parallel \mathbb{E}[C_{\max}]$ using the three field notation due to Graham, Lawler, Lenstra and Rinnooy Kan [13]. The input consists of a set of n jobs \mathcal{J} and a set of m parallel identical machines \mathcal{M} . Each job $j \in \mathcal{J}$ is associated with a non-negative random variable P_j representing the processing time of the job. The processing times are assumed to be (mutually) independent and to have finite expectation. In this work, it is sufficient to only know the expected processing times.

Roughly speaking, a non-anticipatory policy may, at any point in time t , decide to start a job on an idle machine or to wait until a later decision time. However, it may not anticipate any future information of the realizations, i.e., it may only make decisions based on the information observed up to time t . For further details we refer to the work by Möhring, Radermacher and Weiss [26]. The task is to find a non-anticipatory policy minimizing the expected makespan $\mathbb{E}[C_{\max}] := \mathbb{E}[\max_{j \in \mathcal{J}} C_j]$, where C_j denotes the (random) completion time of job j under the considered policy. An optimal policy is denoted by OPT. By slight abuse of notation we use Π for both the policy and the expected makespan of the policy.

An alternative way of understanding non-anticipatory policies is that they maintain a queue of jobs for every machine. At any point in time t it may start the first job in the queue of a machine if it is idle or it may change the queues arbitrarily, using only the information observed up to time t . In this work we consider a policy to be adaptive if it has the ability to react to the observations by changing the queues arbitrarily. The important class of non-idling non-adaptive policies is called the class of fixed assignment policies. Such a policy assigns all jobs to the machines beforehand, in form of ordered lists, and each machine processes the corresponding jobs as early as possible in this order.

While the class of (fully adaptive) non-anticipatory policies and the class of (non-adaptive) fixed assignment policies can be considered as two extremes, the purpose of this paper is to introduce two classes of policies bridging the gap between them continuously.

► **Definition 1.1** (δ -delay and τ -shift policies). *A δ -delay policy for $\delta > 0$ is a non-anticipatory policy which starts with a fixed assignment of all jobs to the machines and which may, at any point in time t , reassign not-started jobs to other machines with a delay of δ : the reassigned jobs are not allowed to start before time $t + \delta$.*

A τ -shift policy for $\tau > 0$ is a non-anticipatory policy which starts with a fixed assignment of all jobs to the machines and which may reassign jobs to other machines, but only at times that are an integer multiple of τ .

Snippets of the execution of a δ -delay policy and a τ -shift policy can be found in Figure 1 and Figure 2, respectively. Observe that we recover the class of fixed assignment policies by letting δ or τ go to ∞ , and the class of non-anticipatory in the limit when δ or τ goes to 0.

Related Work. Minimizing the makespan on parallel identical machines is a fundamental deterministic scheduling problem which dates back to the 60s. Graham [11] showed that the list scheduling algorithm computes a solution which is within a factor of $(2 - \frac{1}{m})$ away from

■ **Figure 2** Snippets of the execution of a τ -shift policy: Realizations of jobs observed up to time 2τ (left) and some time $> 2\tau$ (right) are depicted by rectangles in dark grey; the running job non-completed by the time of each snippet is indicated by squared dots in dark grey; jobs that did not start yet are depicted in light grey with the corresponding machine assignment.

an optimal solution. When the jobs are arranged in LPT-order, i.e., in non-increasing order of their processing times, he showed that list scheduling gives a $(\frac{4}{3} - \frac{1}{3m})$ -approximation [12]. While $Pm||C_{\max}$, where the number of machines m is constant, and $P||C_{\max}$ are (weakly) and strongly NP-complete [9], respectively, Sahni [32] and Hochbaum and Shmoys [18] obtained a FPTAS and a PTAS, respectively. In subsequent work [3, 5, 17, 21, 22] the running time of the PTAS was improved. More general machine environments were also considered in the literature [19, 24].

The stochastic counterpart $P||E[C_{\max}]$ where the processing times of the jobs are random and the objective is to minimize the expected makespan has also attracted attention. One can easily see that the list scheduling algorithm by Graham [11] also yields a 2-approximation compared to an optimal non-anticipatory policy for the stochastic problem, as its analysis can be carried over to any realization. While list scheduling can be considered as a very adaptive policy, some applications require rather restricted policies, e.g. when scheduling operating rooms at a hospital [7, 36]. A class of non-adaptive policies analyzed in the literature is comprised of fixed assignment policies, in which jobs must be assigned to the machines beforehand. Although more applicable, it is well known that the performance guarantee of an optimal fixed assignment is at least of the order $\Omega\left(\frac{\log m}{\log \log m}\right)$ with respect to an optimal non-anticipatory policy; see [14]. Much work was done in designing fixed assignment policies that are within a constant factor of an optimal fixed assignment policy. Kleinberg, Rabani and Tardos [23] obtain a constant factor approximation for this problem for general probability distributions. When the processing times are exponentially and Poisson distributed, PTASes were found [10, 6]. For the more general problem of makespan minimization on unrelated machines, Gupta, Kumar, Nagarajan and Shen [14] obtained a constant factor approximation. Closely related to the makespan objective, Molinaro [28] obtained a constant factor approximation for the ℓ_p -norm objective. In contrast to the literature for minimizing the makespan where approximative results were compared to an optimal fixed assignment policy, much work on the min-sum objective was done for designing approximative policies compared to an optimal non-anticipatory policy [27, 25, 34, 35, 15]. When minimizing the sum of weighted completion times, Skutella, Sviridenko and Uetz [35] showed that the performance ratio of an optimal fixed assignment policy compared to an optimal non-anticipatory policy can be as large as $\Omega(\Delta)$, where Δ is an upper bound on the squared coefficient of variation of the random variables. Lastly, Sagnol, Schmidt genannt Waldschmidt and Tesch [31] considered the extensible bin packing objective, for which they showed that the fixed assignment policy induced by the LEPT order has a tight approximation ratio of $1 + e^{-1}$ with respect to an optimal non-anticipatory policy.

Closely related to the reassignment of jobs in δ -delay and τ -shift policies, various non-preemptive scheduling problems with migration were considered in offline and online settings. Aggarwal, Motwani and Zhu [1] examined the offline problem where one must perform budgeted migration to improve a given schedule. For online makespan minimization on

parallel machines, different variants on limited migration, e.g. bounds on the processing volume [33] or bounds on the number of jobs [2], were studied. Another related online problem was considered by Englert, Ozmen and Westermann [8] where a reordering buffer can be used to defer the assignment of a limited number of jobs.

One source of motivation for this research is the aforementioned application to surgery scheduling. In this domain, a central problem is the allocation of patients to operating rooms. Although additional resource constraints exist, the core of the problem can be modeled as the allocation of jobs with stochastic durations to parallel machines [7]. In this field, committing to a fixed assignment policy is common practice in order to simplify staff management and reduce the stress level in the operating theatre [4, 29, 36]. Another obstacle to the introduction of sophisticated adaptive policies is the reluctance of computer-assisted scheduling systems among practitioners [20]. That being said, it is clear that resource reallocations do occasionally occur in operating rooms to deal with unforeseen events, hence, giving a reason to study some kind of semi-adaptive model. The proposed model of δ -delay is an attempt to take into account the organizational overhead associated with rescheduling decisions; the model of τ -shift policy by the fact that rescheduling decisions cannot be made at any point in time, but must be agreed upon in short meetings between the OR manager and the medical team. Moreover, we point out that the class of τ -shift policies encompasses the popular class of *proactive-reactive policies* used for the more general resource constrained project scheduling problem [16], in which a baseline schedule can be reoptimized after a set of predetermined decision points (these approaches typically consider a penalty in the objective function to account for deviations between the initial baseline schedule and the reoptimized ones).

Our Contribution. We introduce and analyze two new classes of policies (δ -delay and τ -shift policies) that interpolate between the two extremes of non-adaptive and adaptive policies. For the stochastic problem of minimizing the expected makespan on m parallel identical machines, we analyze the policy $\text{LEPT}_{\delta,\alpha}$, which belongs to the intersection of both classes. This policy can in fact be seen as a generalization of the list policy LEPT , which waits for predefined periods of time before reassigning the non-yet started jobs, taking the delay of δ into account. While an optimal fixed assignment policy has performance guarantee of at least $\Omega\left(\frac{\log m}{\log \log m}\right)$ compared to an optimal non-anticipatory policy, we show that $\text{LEPT}_{\delta,\alpha}$ is an $\mathcal{O}(\log \log m)$ -approximation for some constant $\alpha > 0$ and all $\delta = \mathcal{O}(1) \cdot \text{OPT}$. Therefore, we exponentially improve the performance of non-adaptive policies by allowing a small amount of adaptivity. Moreover, we provide a matching lower bound for δ -delay policies as well as for τ -shift policies if δ or τ are in $\Theta(\text{OPT})$. This shows that there is no δ -delay or τ -shift policy beating the approximation ratio of $\text{LEPT}_{\delta,\alpha}$ by more than a constant factor.

Organization. Section 2 is devoted for the upper bound on the performance guarantee of $\text{LEPT}_{\delta,\alpha}$. A lower bound on optimal δ -delay policies as well as τ -shift policies is given in Section 3. At the end, we conclude and give possible future research directions. Useful results from probability theory and detailed proofs can be found in the appendix of the full version of this paper [30].

2 Upper Bound

In this section, we show that there exists $\alpha > 1$ such that the policy $\text{LEPT}_{\delta,\alpha}$ (see Definition 2.5) has a performance guarantee doubly logarithmic in m if $\delta = \mathcal{O}(1) \cdot \text{OPT}$.

► **Theorem 2.1.** *There exists $\alpha > 1$ such that $\text{LEPT}_{\delta,\alpha}$ is an $\mathcal{O}(\log \log m)$ -approximation for $\delta = \kappa \cdot \text{OPT}$ for any constant $\kappa > 0$.*

In the following, we show Theorem 2.1 for $\alpha = 33$. We note that we did not optimize the constants appearing in our calculation as our lower bound shows that $\log \log(m)$ is the correct order. Notice that it suffices to show the performance guarantee for m large enough as for $m = \mathcal{O}(1)$ the trivial policy assigning all jobs to a single machine is a constant factor approximation. To prove the main theorem, we proceed as follows: First, we define and discuss properties of the fixed assignment policy FLEPT as it lies at the heart of our policy called $\text{LEPT}_{\delta,\alpha}$. After we give the formal definition of $\text{LEPT}_{\delta,\alpha}$, we derive lower bounds on OPT needed to show its performance guarantee. The remaining part is devoted to show Theorem 2.1. The main idea of the proof is that the policy works over a sequence of reassignment periods; at the beginning of each period, there is a constant fraction of available machines with high probability. This can be used to show the following squaring effect: if the remaining volume of non-started jobs is $\epsilon \cdot m \cdot \text{OPT}$ in a period, it will be at most $\epsilon^2 \cdot m \cdot \text{OPT}$ in the next period, with high probability.

Recall that the List Scheduling algorithm due to Graham [11] with respect to a list of all jobs schedules the next job in the list on the next idle machine. Let us define the fixed assignment policy induced by list scheduling in LEPT order.

► **Definition 2.2** (The fixed assignment policy FLEPT). *Let all jobs be arranged in non-increasing order of their expected processing times. FLEPT is the fixed assignment policy that assigns the jobs in this order to the same machines as List Scheduling would yield for the deterministic instance in which the processing times are replaced by their expected value.*

As shown by Sagnol, Schmidt genannt Waldschmidt and Tesch [31], FLEPT admits bounds on the expected load of any machine captured in the next lemma.

► **Lemma 2.3** ([31]: Section 3, Lemma 3). *Given an assignment of jobs to machines induced by FLEPT, let ℓ_i denote the expected load of machine i , i.e., the sum of expected processing times of the jobs assigned to i . Moreover, let n_i denote the number of jobs assigned to i and let $\ell := \min_{i \in \mathcal{M}} \ell_i$. Then, for all $i \in \mathcal{M}$ we have $\ell \leq \ell_i \leq \frac{n_i}{n_i - 1} \ell$, where $\frac{n_i}{n_i - 1} = \frac{1}{0} := +\infty$ whenever $n_i = 1$.*

We immediately obtain by Lemma 2.3 the following structure on FLEPT.

► **Corollary 2.4.** *Given an assignment of jobs to machines induced by FLEPT, we can partition the set of machines into two types of machines: Either there is only a single job assigned to a machine or the expected load of a machine is bounded by 2ℓ . Moreover, ℓ can be bounded from above by the averaged expected load. In particular, if x denotes the total (remaining) expected load and m' is a lower bound on the total number of machines m , then $2\ell \leq 2 \cdot \frac{x}{m'}$.*

Corollary 2.4 will play a central role in showing Theorem 2.1 as FLEPT constitutes an essential part of $\text{LEPT}_{\delta,\alpha}$, which we define now.

► **Definition 2.5** (Policy $\text{LEPT}_{\delta,\alpha}$). *Let $\delta, \alpha > 0$, $k^* := \lfloor \log_2(\frac{2}{3}(\log_2(m)) + 1) \rfloor + 2$ and let $T := 2 \cdot \max\{\frac{1}{m} \sum_{j \in \mathcal{J}} \mathbb{E}[P_j], \max_j \mathbb{E}[P_j]\}$. Moreover, let $\tau_k := k(\delta + \alpha T)$ for $k \in [k^* + 1]$. At the beginning the jobs are assigned according to FLEPT. For $k = 1, \dots, k^* + 1$, $\text{LEPT}_{\delta,\alpha}$ reassigns the jobs that have not started yet before τ_k to the machines that have processed all jobs assigned at previous iterations $0, \dots, k - 1$ by time τ_1, \dots, τ_k , respectively, according to FLEPT. The reassigned jobs may start at time $\tau_k + \delta$ at the earliest.*

We note that in practice it makes sense to use all available machines at each iteration instead of the machines that were available in each previous iteration. Although our policy is limited, we show that in its execution a constant fraction of machines is available in each iteration with high probability. It also simplifies our analysis and matches the bound shown in the next section. Furthermore, observe that $\text{LEPT}_{\delta,\alpha}$ is both a δ -delay policy and a $(\delta + \alpha T)$ -shift policy. Next, let us introduce some quantities which will turn out to be helpful to analyze $\text{LEPT}_{\delta,\alpha}$.

► **Definition 2.6.** Let Ξ_k denote the random variable describing the total expected processing time of the remaining jobs which have not been started at time $< \tau_k$ divided by Tm . Moreover, let A_k denote the random variable describing the fraction of machines which are available at each time τ_1, \dots, τ_k , i.e., the machines have completed all jobs assigned in each iteration $0, \dots, k-1$.

■ **Figure 3** Snippet of $\text{LEPT}_{\delta,\alpha}$: Realizations of jobs observed up to time τ_k are depicted by rectangles in dark grey; the running jobs non-completed by the time of the snippet are indicated by squared dots in dark grey; the expected processing times of the jobs that did not start yet are depicted in light gray. The remaining expected processing time of the twelve light gray jobs is $\Xi_k Tm$. These jobs are reassigned in an FLEPT fashion to the $A_k m$ machines at the bottom at time τ_k , and the first job of each newly formed queue will start at time $\tau_k + \delta$.

A snippet of $\text{LEPT}_{\delta,\alpha}$ together with the introduced notation is illustrated in Figure 3.

Observe that the randomness of Ξ_k occurs only in the set of remaining jobs. We begin with some simple observations.

► **Observation 2.7.** For any k , we have $\Xi_k \leq \Xi_{k-1} \leq 1$ and $A_k \leq A_{k-1} \leq 1$ almost surely.

Next, we want to discuss lower bounds on the expected makespan of an optimal non-anticipatory policy. The first one justifies the use of T in the definition of $\text{LEPT}_{\delta,\alpha}$.

► **Lemma 2.8.** Let $T := 2 \cdot \max\{\frac{1}{m} \sum_{j \in \mathcal{J}} \mathbb{E}[P_j], \max_j \mathbb{E}[P_j]\}$ and ℓ be defined as in Lemma 2.3. Then, we have $2\ell \leq T \leq 2 \cdot \text{OPT}$.

Proof. By Corollary 2.4 we immediately obtain the first inequality as ℓ is a lower bound on the averaged load $\frac{1}{m} \sum_{j \in \mathcal{J}} \mathbb{E}[P_j]$. Clearly, for each realization \mathbf{p} the makespan is bounded from below by $\frac{1}{m} \sum_{j \in \mathcal{J}} p_j$. Hence, taking expectations we obtain $\text{OPT} \geq \frac{1}{m} \sum_{j \in \mathcal{J}} \mathbb{E}[P_j]$. Lastly, in any non-anticipatory policy obviously all jobs must be scheduled non-preemptively. Therefore, $\max_j \mathbb{E}[P_j]$ is another lower bound on OPT . ◀

We obtain another lower bound when only at most m jobs have to be scheduled.

► **Lemma 2.9.** *We have $\mathbb{E}[\max_{j \in \mathcal{J}} P_j] \leq \text{OPT}$.*

Proof. For any realization \mathbf{p} , a lower bound on the optimal makespan for \mathbf{p} is $\max_{j \in \mathcal{J}} p_j$. Taking expectations yields the statement. ◀

We have now set all necessary definitions and lower bounds on the cost of an optimal non-anticipatory policy to devote the remaining part of this section to prove Theorem 2.1. We first derive an upper bound on $\text{LEPT}_{\delta, \alpha}$ in terms of Ξ_{k^*+1} .

► **Lemma 2.10.** *We have that $\text{LEPT}_{\delta, \alpha} \leq \tau_{k^*+1} + \delta + \text{OPT} + \mathbb{E}[\Xi_{k^*+1}] \cdot Tm$.*

Proof. Let $C(\mathbf{p})$ denote the first point in time in realization \mathbf{p} in which all jobs that started before τ_{k^*+1} are completed. We consider an auxiliary policy Π which is identical to $\text{LEPT}_{\delta, \alpha}$ up to time τ_{k^*+1} and starts processing the remaining jobs at time $\max\{\tau_{k^*+1} + \delta, C(\mathbf{p})\}$ on an arbitrary single machine. Clearly, $\text{LEPT}_{\delta, \alpha} \leq \Pi$ since $\text{LEPT}_{\delta, \alpha}$ starts the remaining jobs at time $\tau_{k^*+1} + \delta$, hence, not later than Π and uses at least as many machines as Π . For any realization \mathbf{p} and the starting time of the remaining jobs $S(\mathbf{p})$ we have

$$S(\mathbf{p}) = \tau_{k^*+1} + \max\{\delta, C(\mathbf{p}) - \tau_{k^*+1}\} \leq \tau_{k^*+1} + \max\{\delta, \max_{j \in \mathcal{J}} p_j\} \leq \tau_{k^*+1} + \delta + \max_{j \in \mathcal{J}} p_j.$$

Hence, by Lemma 2.9 the expected starting time is at most $\tau_{k^*+1} + \delta + \text{OPT}$. By definition of Ξ_{k^*+1} the expected remaining load is exactly $\mathbb{E}[\Xi_{k^*+1}] \cdot Tm$. ◀

Due to the derived upper bound it only remains to bound $\mathbb{E}[\Xi_{k^*+1}]$. The next central lemma provides an upper bound on the probability that this quantity is large.

► **Lemma 2.11.** *There exists $\alpha > 1$ such that we have $\mathbb{P}(\Xi_{k^*+1} > \frac{1}{m}) = o(\frac{1}{m})$.*

Let us assume for a moment that Lemma 2.11 is true. We then can prove the main theorem.

Proof of Theorem 2.1. By Lemmas 2.10 and 2.11 and by the law of total expectation we obtain

$$\begin{aligned} \text{LEPT}_{\delta, \alpha} &\leq \tau_{k^*+1} + \delta + \text{OPT} + \mathbb{E}[\Xi_{k^*+1}] \cdot Tm \\ &= \tau_{k^*+1} + \delta + \text{OPT} + \underbrace{\mathbb{P}\left(\Xi_{k^*+1} \leq \frac{1}{m}\right)}_{\leq 1} \cdot \underbrace{\mathbb{E}\left[\Xi_{k^*+1} \mid \Xi_{k^*+1} \leq \frac{1}{m}\right]}_{\leq T} \cdot Tm \\ &\quad + \underbrace{\mathbb{E}\left[\Xi_{k^*+1} \mid \Xi_{k^*+1} > \frac{1}{m}\right]}_{\leq 1} \cdot \underbrace{\mathbb{P}\left(\Xi_{k^*+1} > \frac{1}{m}\right)}_{=o(1)} \cdot m \cdot T \\ &\leq (\alpha T + \delta) \cdot \mathcal{O}(\log \log(m)) + \delta + \text{OPT} + T + o(1) \cdot T \\ &= \mathcal{O}(\log \log(m)) \cdot \text{OPT}, \end{aligned}$$

where the last step follows by Lemma 2.8 and the choice of δ and α . ◀

Let us return to the proof of Lemma 2.11. The high level idea is to use induction to show that in each iteration there is a constant fraction of available machines with high probability and hence, the remaining expected load after k^* iterations is small with high probability. The first lemma provides a stochastic dominance relation of Ξ_k and A_k to binomially distributed random variables in order to simplify calculations.

79:8 Restricted Adaptivity in Stochastic Scheduling

► **Lemma 2.12.** For all $u, \xi \in (0, 1)$, for all $a \in [\frac{1}{2}, 1]$ and for any iteration k we have,

$$\mathbb{P}(\Xi_{k+1} \leq u | \Xi_k \leq \xi, A_k \geq a) \geq \mathbb{P}\left(\frac{2\xi}{am}Y \leq u\right), \text{ where } Y \sim \text{Bin}\left(m, \frac{2\xi}{a\alpha}\right) \quad (1)$$

and

$$\mathbb{P}(A_{k+1} \geq u | \Xi_{k-1} \leq \xi, A_k \geq a) \geq \mathbb{P}\left(\frac{1}{m}Z \geq u\right), \text{ where } Z \sim \text{Bin}\left(\lceil am \rceil, 1 - \frac{2\xi}{a\alpha}\right). \quad (2)$$

Proof sketch. For (2) the key idea is that in each iteration k a machine is available with probability at least $\left(1 - \frac{2\xi}{a\alpha}\right)$ using Corollary 2.4 and Markov's inequality. To show (1) we additionally bound the (normalized) remaining expected load by $\frac{2\xi}{am}$ using Corollary 2.4. ◀

Using Lemma 2.12 we inductively prove probability bounds on Ξ_k and A_k without conditioning on the random variables of the previous iterations. The next lemma handles the base case of the induction stated in Lemma 2.14.

► **Lemma 2.13** (Base case of induction). Let $\gamma_1 = 1$ and $\beta_2 = \frac{3}{4}$. Then, there exists $\epsilon = e^{-\Theta(m^{\frac{1}{3}})}$ such that

$$\mathbb{P}(\Xi_1 \leq \gamma_1) \geq 1 - \epsilon, \quad (3)$$

$$\mathbb{P}(A_2 \geq \beta_2) \geq 1 - 3\epsilon. \quad (4)$$

Proof sketch. The first statement (3) is clear, as $\Xi_1 \leq 1$ almost surely. For the second statement, we first show that A_1 is large with high probability using Corollary 2.4 and the Chernoff bound. This bound can be used together with Lemma 2.12 and the Chernoff bound to show (4). ◀

We use the above statement as the base case of an induction to show the next lemma.

► **Lemma 2.14.** Let $\gamma_1 = 1$, $\gamma_{k+1} = \frac{1}{2}\gamma_k^2$ ($\forall k \geq 1$), $\beta_k = \frac{3}{4} - \frac{2}{\alpha} \sum_{h=1}^{k-2} \gamma_h$ ($\forall k \geq 2$) and let $k^* := \lfloor \log_2\left(\frac{2}{3}(\log_2(m)) + 1\right) \rfloor + 2$. Then, there exists $\psi = \Theta\left(\frac{1}{\log \log(m)}\right)$ and $\epsilon = e^{-\Theta(m^{\frac{1}{3}})}$ such that

$$\mathbb{P}(\Xi_k \leq \gamma_k) \geq 1 - (2^k - 1)\epsilon, \quad \forall k = 1, \dots, k^* \quad (5)$$

$$\mathbb{P}(A_k \geq \beta_k - (k - 2)\psi) \geq 1 - (2^k - 1)\epsilon, \quad \forall k = 2, \dots, k^*. \quad (6)$$

Proof sketch. The doubly exponential decrease of γ_k and the choice of α implies that $\beta_k > \beta_\infty > \frac{5}{8}$. Additionally, the choice of ψ yields $\beta_\infty - (k - 2)\psi \geq \frac{1}{2}$. Thus, we can assume that at each iteration with high probability half of the machines are available. For the induction step we make use of Lemma 2.12, the Chernoff bound and the union bound. ◀

By Lemmas 2.12–2.14 we can now show the probability bound on the remaining expected load at iteration $(k^* + 1)$.

Proof of Lemma 2.11. Let $u = \frac{1}{m}$, $\xi = m^{-\frac{2}{3}}$ and $a = \frac{1}{2}$. Lemma 2.12 (1) implies

$$\mathbb{P}(\Xi_{k^*+1} \leq u | \Xi_{k^*} \leq \xi, A_{k^*} \geq a) \geq \mathbb{P}\left(Y \leq \frac{1}{4}m^{\frac{2}{3}}\right),$$

where $Y \sim \text{Bin}\left(m, \frac{4}{\alpha}m^{-\frac{2}{3}}\right)$. As $\mathbb{E}[Y] = \frac{4}{\alpha}m^{\frac{1}{3}}$ we obtain by applying the Chernoff bound for $\zeta = \frac{\alpha}{16}m^{\frac{1}{3}} - 1 > 0$

$$\mathbb{P}\left(Y \leq \frac{1}{4}m^{\frac{2}{3}}\right) = \mathbb{P}(Y \leq (1 + \zeta) \cdot \mathbb{E}[Y]) \geq \exp\left(-\frac{\mathbb{E}[Y] \cdot \zeta^2}{2 + \zeta}\right) = 1 - \exp(-\Theta(m^{\frac{2}{3}})) \geq 1 - \epsilon,$$

for m large enough. This yields

$$\begin{aligned} \mathbb{P}(\Xi_{k^*+1} \leq u) &\geq \mathbb{P}(\Xi_{k^*+1} \leq u \mid \Xi_{k^*} \leq \xi, A_{k^*} \geq a) \cdot \mathbb{P}(\Xi_{k^*} \leq \xi, A_{k^*} \geq a) \\ &\geq (1 - \epsilon) \cdot (1 - (2^{k^*} - 1)\epsilon - (2^{k^*} - 1)\epsilon) \\ &\geq 1 - (1 + 2 \cdot (2^{k^*} - 1))\epsilon \\ &= 1 - (2^{k^*+1} - 1)\epsilon, \end{aligned}$$

where we used the law of total probability in the first inequality and for the second step we used the union bound and Lemma 2.14. Therefore, as $2^{k^*+1} = \Theta(\log(m))$, we have $\mathbb{P}(\Xi_{k^*+1} > \frac{1}{m}) \cdot m \rightarrow 0$ as $m \rightarrow \infty$. \blacktriangleleft

3 Lower Bound

Throughout this section, we consider an instance I_N with $n = Nm$ jobs over m machines. Each job has processing time $P_j \sim \text{Bernoulli}(\frac{1}{N})$, i.e. $P_j = 1$ with probability $\frac{1}{N}$, and $P_j = 0$ otherwise. The main result of this section is a $\Omega(\delta \log \log(m))$ lower bound on the performance of any δ -delay policy for large values of N . This matches the upper bound obtained in the previous section. Note that the hidden constant in the Ω notation does not depend on the value of $\delta > 0$. For $\delta = \Theta(\text{OPT})$, this implies that no δ -delay policy can improve on the $\log \log m$ performance guarantee of $\text{LEPT}_{\delta, \alpha}$ by more than some constant factor. At the end of the section we show that an analogous result holds for τ -shift policies as well.

► **Theorem 3.1.** *Let $\delta \leq 1$. For instance I_N let $\text{OPT}_{\delta}^{\text{DELAY}}$ and OPT denote the value of an optimal δ -delay policy and of an optimal non-anticipatory policy, respectively. Then, for $N = \Omega(\sqrt{m})$ we have*

$$\frac{\text{OPT}_{\delta}^{\text{DELAY}}}{\text{OPT}} = \Omega(\delta \cdot \log \log(m)).$$

The proof is split into two main lemmas. The first one relates the expected makespan of an optimal δ -delay policy to the expected makespan of an optimal 1-delay policy.

► **Lemma 3.2.** *Assume $\frac{1}{\delta} \in \mathbb{N}$. Then, we have $\text{OPT}_{\delta}^{\text{DELAY}} \geq \delta \cdot \text{OPT}_1$.*

The second lemma shows that OPT_1 grows doubly logarithmically with m .

► **Lemma 3.3.** *For $N = \Omega(\sqrt{m})$ it holds $\text{OPT}_1 = \Omega(\log \log(m))$.*

Let us assume for now that the above lemmas hold. Then, we simply need to show that $\text{OPT} = O(1)$ to prove the theorem.

Proof of Theorem 3.1. On the one hand, Lemma 3.2 and Lemma 3.3 imply $\text{OPT}_{\delta}^{\text{DELAY}} = \Omega(\delta \cdot \log \log(m))$. On the other hand, we can use the List Scheduling policy (*LS*) due to Graham [11] to obtain an upper bound on the value of an optimal non-anticipatory policy.

Whenever a machine becomes idle, LS schedules any non-scheduled job on it. For any fixed realization $\mathbf{p} = (p_j)_{j \in [Nm]}$ we obtain for its makespan $C_{\max}^{LS}(\mathbf{p}) = \left\lceil \frac{1}{m} \sum_{j \in [Nm]} p_j \right\rceil \leq 1 + \frac{1}{m} \sum_{j \in [Nm]} p_j$. As a result, taking expectations on both sides yields

$$\text{OPT} \leq \mathbb{E}[C_{\max}^{LS}] \leq 1 + \frac{1}{m} \sum_{j \in [Nm]} \mathbb{E}[P_j] = 1 + \frac{1}{m} \cdot Nm \cdot \frac{1}{N} = 2,$$

concluding the proof of the theorem. \blacktriangleleft

To prove the lemmas, we first make an observation on the structure of optimal δ -delay policies. When we execute a set of Bernoulli jobs on a machine, we immediately observe whether one of the jobs was a long job (i.e., $p_j = 1$), and also the number of vanishing jobs (i.e., $p_j = 0$) that have already been executed. This indicates that optimal δ -delay policies do not insert deliberate idle time in the schedule (since waiting does not provide any information on running jobs), and for the case $\frac{1}{\delta} \in \mathbb{N}$, they may only take reassignment decisions at times of the form $k\delta$ for $k \in \mathbb{N}$. We call policies with this property *δ -active*.

Proof of Lemma 3.2. The starting time of each job in $\text{OPT}_{\delta}^{\text{DELAY}}$ is an integer multiple of δ , because $1/\delta \in \mathbb{N}$ and $\text{OPT}_{\delta}^{\text{DELAY}}$ is δ -active. Let $J_{ki}(\mathbf{p})$ denote the set of jobs started on machine i at time $k\delta$ by $\text{OPT}_{\delta}^{\text{DELAY}}$, for a realization $\mathbf{p} \in \{0, 1\}^n$ of the processing times. $J_{ki}(\mathbf{p})$ may contain many vanishing jobs executed at time $t = k\delta$, and at most one long job executed during the time interval $[k\delta, k\delta + 1)$. It is easy to construct a 1-delay policy (call it Π_1) that executes the same set of jobs $J_{ki}(\mathbf{p})$ during the interval $[k, k + 1)$ on machine i , by taking at time $k - 1$ the same reassignment decisions as $\text{OPT}_{\delta}^{\text{DELAY}}$ takes at time $(k - 1)\delta$, and by waiting until time $t = k$ to execute the reassigned jobs. In both schedules, the makespan is caused by the same long job (if there is at least one long job). Its starting time is $\text{OPT}_{\delta}^{\text{DELAY}}(\mathbf{p}) - 1$ in the optimal δ -delay policy and $\frac{1}{\delta}(\text{OPT}_{\delta}^{\text{DELAY}}(\mathbf{p}) - 1)$ in the policy Π_1 . Hence the policy Π_1 has makespan $\Pi_1(\mathbf{p}) = \frac{1}{\delta} \cdot (\text{OPT}_{\delta}^{\text{DELAY}}(\mathbf{p}) - 1) + 1$ for any realization $\mathbf{p} \neq \mathbf{0}$, and $\Pi_1(\mathbf{p}) = \text{OPT}_{\delta}^{\text{DELAY}}(\mathbf{p}) = 0$ if $\mathbf{p} = \mathbf{0}$. Taking expectations yields

$$\text{OPT}_1 \leq \mathbb{E}[\Pi_1(\mathbf{p})] = \frac{1}{\delta} \cdot \text{OPT}_{\delta}^{\text{DELAY}} + \mathbb{P}(\mathbf{p} \neq \mathbf{0}) \cdot \left(1 - \frac{1}{\delta}\right) \leq \frac{1}{\delta} \cdot \text{OPT}_{\delta}^{\text{DELAY}},$$

where we have used the fact that $\delta \leq 1$. This implies $\text{OPT}_{\delta}^{\text{DELAY}} \geq \delta \cdot \text{OPT}_1$. \blacktriangleleft

This lemma allows us to work with 1-delay policies, which are easier to handle: At all times $t \in \mathbb{N}$, a 1-active policy observes the set of jobs non-started yet at time $t - 1 + \epsilon$ (for an infinitesimal small $\epsilon > 0$) and reassigns them to *any* machine, on which they will start at time t at the earliest: we call it an *iteration*.

We denote by R_t the random variable describing the number of remaining jobs at time $t \in \mathbb{N}_0$, before OPT_1 runs the jobs, and by $\Lambda_t = \frac{R_t}{Nm}$ the fraction of remaining jobs at time t . For the initial state we have $\Lambda_0 = 1$ (a.s.). Not surprisingly, the optimal policy balances the remaining jobs as evenly as possible on the m machines.

► **Proposition 3.4.** *In iteration t , OPT_1 assigns the remaining $\Lambda_t Nm$ jobs by balancing the load as evenly as possible, i.e., each machine receives $\lceil \Lambda_t N \rceil$ or $\lfloor \Lambda_t N \rfloor$ jobs.*

Proof sketch. Consider a realization of the jobs started before time $t - 1$ for some $t \in \mathbb{N}$, and in which r jobs remain at time $t - 1$. A 1-active policy must reassign the r jobs to the m machines. By moving jobs between two machines, one can show that the balancing policy, which assigns $\lfloor \frac{r}{m} \rfloor$ or $\lceil \frac{r}{m} \rceil$ jobs to each machine, minimizes the (random) number

of remaining jobs at time t for the order of stochastic dominance, in the class of 1-active policies. Then, the optimality of the balancing policy follows from the fact that the expected cost-to-go from iteration t , $r \mapsto \mathbb{E}[\text{OPT}_1 - t | R_t = r]$ is monotone decreasing with respect to the number of remaining jobs. ◀

For notational convenience let $\lfloor \Lambda_t N \rfloor_i$ denote the number of jobs assigned to machine i by OPT_1 . By independence of the processing times, the number of jobs that must be drawn before picking a long job is geometrically distributed with parameter $\frac{1}{N}$. Consequently, we obtain the following observation.

► **Observation 3.5.** *For $i \in [m]$ let $G_i \sim \text{Geom}(\frac{1}{N})$ be i.i.d. random variables. Then, we have*

$$\Lambda_{t+1} \stackrel{d}{=} \frac{1}{Nm} \sum_{i=1}^m (\lfloor \Lambda_t N \rfloor_i - G_i)_+.$$

We can now prove that OPT_1 is of order $\Omega(\log \log(m))$. To do this, we first need a lemma showing that Λ_t converges quadratically to 0.

► **Lemma 3.6.** *For $N = \Omega(\sqrt{m})$ and $t \in \{1, \dots, \lfloor \log_2(\frac{1}{4} \log_{2e}(m)) \rfloor\}$ we have*

$$\mathbb{P}(\Lambda_t \geq (2e)^{1-2^t}) \geq (1 - e^{-2\sqrt{m}})^t.$$

A rigorous proof of this lemma is proved in the appendix of the full version [30]. For now, we just explain the intuition behind the quadratic convergence of Λ_t to 0 in expectation, by taking a (hand-wavy look) at the conditional expectation $\mathbb{E}[\Lambda_{t+1} | \Lambda_t = \lambda]$ for large values of N . Using that $\frac{\lfloor \lambda N \rfloor}{N} \rightarrow \lambda$ and the well-known fact that $\frac{G_i}{N}$ converges in distribution to an exponential random variable $X \sim \text{Exp}(1)$, we see that when $N \rightarrow \infty$, $\mathbb{E}[\Lambda_{t+1} | \Lambda_t = \lambda]$ should approach $\mathbb{E}[(\lambda - X)_+] = \int_{x=0}^{\lambda} (\lambda - x)e^{-x} dx = \lambda + e^{-\lambda} - 1$. Then, the quadratic convergence of Λ_t is suggested by the inequalities $\frac{\lambda^2}{e} \leq \lambda + e^{-\lambda} - 1 \leq \frac{\lambda^2}{2}$, which hold for all $\lambda \in [0, 1]$.

With this lemma, we obtain a short proof for Lemma 3.3.

Proof of Lemma 3.3. By Lemma 3.6 we obtain for $t = \Omega(\log \log(m))$ and $N = \Omega(\sqrt{m})$

$$\text{OPT}_1 \geq \mathbb{P}(C_{\max} \geq t) \cdot t \geq \mathbb{P}(\Lambda_t \geq (2e)^{1-2^t}) \cdot t \geq \underbrace{\left(1 - e^{-2\sqrt{m}}\right)^t}_{\xrightarrow{m \rightarrow \infty} 1} \cdot t = \Omega(\log \log(m)). \quad \blacktriangleleft$$

A similar result can be shown for τ -shift policies, for the same instance I_N .

► **Theorem 3.7.** *Let $\tau \leq 1$, such that $\frac{1}{\tau} \in \mathbb{N}$. For instance I_N let $\text{OPT}_\tau^{\text{SHIFT}}$ and OPT denote the value of an optimal τ -shift policy and of an optimal non-anticipatory policy, respectively. Then, for $N = \Omega(\sqrt{m})$ we have*

$$\frac{\text{OPT}_\tau^{\text{SHIFT}}}{\text{OPT}} = \Omega(\tau \cdot \log \log(m)).$$

Proof. Similarly as for the case of δ -delay policies, for $1/\tau \in \mathbb{N}$ it is clear that an optimal τ -shift policy for instance I_N must be τ -active. Therefore, the optimal τ -active policy coincides with both the optimal τ -shift and the optimal τ -delay policy. This shows that $\text{OPT}_\tau^{\text{SHIFT}} = \text{OPT}_\tau^{\text{DELAY}}$, and the result follows from Theorem 3.1. ◀

4 Conclusion

We considered the stochastic optimization problem of minimizing the expected makespan on parallel identical machines. While any list scheduling policy is a constant factor approximation, the performance guarantee of all fixed assignment policies is at least $\Omega\left(\frac{\log m}{\log \log m}\right)$. We introduced two classes of policies to establish a happy medium between the two extremes of adaptive and non-adaptive policies. The policy $\text{LEPT}_{\delta, \alpha}$, which is both a δ -delay and a τ -shift policy, was shown to have performance guarantee of $\mathcal{O}(\log \log m)$ if δ and τ are in the scale of the instance. Moreover, we provided a matching lower bound for $\delta, \tau = \Theta(\text{OPT})$. Therefore, $\text{LEPT}_{\delta, \alpha}$ improves upon the performance of an optimal fixed assignment policy using a small amount of adaptivity. Moreover, there exists no δ -delay or τ -shift policy beating its performance guarantee by more than a constant.

For the case of $\delta, \tau = \mathcal{O}\left(\frac{1}{\log \log m}\right)$, Theorem 3.1 gives a constant lower bound, while Theorem 2.1 only gives a doubly logarithmic upper bound. An open question is whether a constant approximation guarantee is possible in this case.

A possible future line of research is the analysis of δ -delay and τ -shift policies for stochastic scheduling problems with other numerous objectives, different machine environments as well as various job characteristics. Moreover, it would be interesting to design other non-anticipatory policies whose adaptivity can be controlled.

Abstract

When a problem has more than one solution, it is often important, depending on the underlying context, to enumerate (i.e., to list) them all. Even when the enumeration can be done in polynomial delay, that is, spending no more than polynomial time to go from one solution to the next, this can be costly as the number of solutions themselves may be huge, including sometimes exponential. Furthermore, depending on the application, many of these solutions can be considered equivalent. The problem of an efficient enumeration of the equivalence classes or of one representative per class (without generating all the solutions), although identified as a need in many areas, has been addressed only for very few specific cases. In this paper, we provide a general framework that solves this problem in polynomial delay for a wide variety of contexts, including optimization ones that can be addressed by dynamic programming algorithms, and for certain types of equivalence relations between solutions.

1 Introduction

Enumerating the solutions of an optimization problem solved by a dynamic programming algorithm (DP-algorithm) is a classical and well-known question. However, many enumeration problems have a huge number of solutions in practice, which might be an issue. From a computational point of view, since the number of solutions is a lower bound on the time complexity of any enumeration algorithm, it might make the algorithm impractical on real instances. Furthermore, even if the number of solutions is reasonable enough to be enumerated, the purpose of some applications is to give the output of the algorithm to a human specialist (this is necessary, for example, when some of the constraints of the problem are subjective and cannot be modeled).

Indeed, one of the advantages of an enumeration algorithm compared to an optimization one which in general outputs only one optimal solution, is to be able to understand the space of solutions. While this is important in many cases, no human can understand an output composed of billions of solutions.

The approach generally used to address this consists of enumerating all solutions, and then applying some type of clustering (grouping) algorithm to the set of optimal solutions. The final output presented to the user would then be some “representative description” of the clusters (groups) themselves. However, since the number of solutions is a lower bound for the total execution time of any enumeration algorithm, the first step of such a strategy becomes impossible when the number of solutions is too big. A natural question is then whether it would be possible to enumerate directly what we just called a “representative description” of the clusters of solutions. This could be for instance an element per cluster. Sometimes a cluster can also be seen as a set of characteristics that the solutions within the cluster share. In such a case, the representative description of a cluster could then be such a set of characteristics. A particularly convenient situation is however when the clusters correspond to equivalence classes of an equivalence relation over the set of solutions that we could establish *a priori*. The output could be in this case the quotient space of the equivalence relation. Notice that the enumeration of equivalence classes of solutions is a combinatorial problem that could be solved exactly given a well-defined equivalence relation, and unlike data analysis methods such as incremental clustering, it does not require the definition of a similarity or dissimilarity measure between solutions which, depending on the mathematical nature of the solutions (numerical values, graphs, functions on graphs, etc.), can be difficult to define or costly to compute.

The problem this paper addresses is how to perform the task of enumerating equivalence classes of solutions with polynomial delay for a wide variety of problems (including optimization problems solved by dynamic programming algorithms), for certain types of equivalence relations between solutions.

The problem of enumerating equivalence classes, and particularly the generation of representative solutions is a challenge in the context of enumeration algorithms. It has been identified as a need in different areas, such as Genome Rearrangements [10], Artificial Intelligence [1] or Pattern Matching [7, 26]. It was listed as an important open problem in a recent Dagstuhl workshop on “Algorithmic Enumeration: Output-sensitive, Input-Sensitive, Parameterized, Approximative” (see, e.g., Sections 4.2 and 4.10 in [15]). To the best of our knowledge, this challenge has been addressed only for some few specific problems in the literature (e.g., [2, 10, 24, 25]).

To enumerate equivalence classes, we go through an intermediate problem, namely the enumeration of colored subtrees in acyclic decomposable AND/OR graphs (ad-AND/OR graph). The paper is organized as follows: Section 2 provides an algorithm to enumerate with polynomial delay colored subtrees in ad-AND/OR graphs; Section 3 details how this algorithm applies to the enumeration of equivalence classes in DP-problems. In that direction, we present some examples from well-known optimization problems in the literature. Finally, in Section 4 we conclude with some open problems.

2 Enumeration of colored subtrees in an ad-AND/OR graph

2.1 AND/OR graphs and solution subtrees

An *AND/OR graph* (see, for example [23, 27]) is a well-known structure in the field of Logic and Artificial Intelligence (AI) that represents problem solving and problem decomposition. In this paper, we consider a particular flavor of AND/OR graphs known as *explicit AND/OR graphs for trees* [12].

This is a directed acyclic graph (DAG) G which explicitly represents an *AND/OR state space* for solving a certain problem by decomposing it into subproblems. The set of nodes (or states) $S := V(G)$ contains OR and AND nodes (the OR nodes represent alternative ways for solving the problem while the AND nodes represent problem decomposition into subproblems, all of which need to be solved). There is a set of goal nodes $S_g \subseteq S$ and a set of start nodes $S_0 \subseteq S$ representing respectively the terminal states and the initial states. The children (out-neighbors) of an OR node are AND nodes, and the children of an AND node are OR nodes or goal nodes. We say that a node is an OR^+ node when it is either an OR node or a goal node. Furthermore, the AND/OR graphs that we consider must have the property of being *decomposable* (they can model a problem for which every decomposition yields disjoint subproblems that can be solved independently): for any AND node, the sets of nodes that are reachable from each one of its child nodes are pairwise disjoint. The example graph in Figure 1 is decomposable.

■ **Figure 1** An acyclic decomposable AND/OR graph with four start nodes. Squares are OR^+ nodes (OR nodes or goal nodes); crossed circles are AND nodes. One solution subtree of size 8 is shown in bold.

Formally, in this paper, any graph that satisfies the properties in Definition 1 will be called an ad-AND/OR graph. Notice that this definition corresponds only to a particular case of the general AND/OR graphs in the AI literature; the latter may be neither acyclic nor decomposable.

► **Definition 1** (ad-AND/OR graph). *A directed graph G is an acyclic decomposable AND/OR graph, henceforth denoted by ad-AND/OR graph, if it satisfies the following:*

- G is a DAG.
- G is bipartite: its node set $V(G)$ can be partitioned into $(\mathcal{A}, \mathcal{O})$ so that all arcs of G are between these two sets. Nodes in \mathcal{A} are called AND nodes; nodes in \mathcal{O} are called OR^+ nodes.
- Every AND node has in-degree at least one and out-degree at least one. The set of nodes with out-degree zero is then a subset of \mathcal{O} and is called the set of goal nodes; the remaining OR^+ nodes are simply the OR nodes. The subset of OR nodes of in-degree zero is the set of start nodes.
- G is decomposable: for any AND node, the sets of nodes that are reachable from each one of its child nodes are pairwise disjoint.

► **Definition 2** (solution subtree). *A solution subtree T of an ad-AND/OR graph G is a subgraph of G which: (1) contains exactly one start node; (2) for any OR node in T it contains one of its child nodes in G , and for any AND node in T it contains all its children in G .*

It is immediate to see that a solution subtree is indeed a subtree of G : it is a rooted tree, the root of which is a start node. If we would drop the requirement of G being decomposable, the object defined in Definition 2 would not be guaranteed to be a tree. One solution subtree of the example graph in Figure 1 is shown in bold.

The set of all solution subtrees of G is denoted by $\mathbb{T}(G)$. Given an ad-AND/OR graph G , counting the number of its solution subtrees and enumerating all solution subtrees can be solved by folklore approaches based on depth-first search (DFS).

Before going further, we recall that the motivation of this paper is concerned with solutions of dynamic programming problems. The correspondence between the solutions of DP-style recurrence equations and the solution subtrees of general AND/OR graphs has been formally proven in [16]. In the case where the underlying graph is acyclic, the recurrence equations can be solved efficiently by DP-algorithms. While we will now concentrate on the solution subtrees of an ad-AND/OR graph and on the equivalence classes of solution subtrees, we will demonstrate in Section 3 how to apply our algorithms to analyze equivalence classes of solutions of a very general class of problems solvable by DP. It is important to point out that solution subtrees of general AND/OR graphs are equivalent to various other well-known formalisms, e.g., acceptance trees of a nondeterministic tree automata, languages of regular tree grammars, complete subcircuits of tropical circuits. The reader who is more familiar with those may also find this paper interesting even outside of a dynamic programming context.

2.2 Equivalence classes

Let G be an ad-AND/OR graph. Let C be an **ordered** set of colors. We will consider equivalence relations on the set of solution subtrees of G which are based on a local comparison of the colors of the OR^+ nodes. Intuitively, two OR^+ nodes having the same color represent two alternative ways of solving the problem that can be considered equivalent.

► **Definition 3** (e-coloring). *An ad-AND/OR graph G is e-colored if its OR^+ nodes are colored in such a way that for any AND node all its children have distinct colors.*

Notations. If s is a OR^+ node of G , we denote by $c(s)$ its color. If s is an AND node, we denote by $\tilde{C}(s)$ the tuple of colors of the children of s sorted in increasing order of the colors. If $T_1 \in \mathbb{T}(G)$ is a solution subtree of G , we use the notation $\pi(T_1)$ for the result of contracting the AND nodes in T_1 : for each OR node s of T , contract the only child node of s in T (i.e., remove the child and connect s to each one of its “grandchildren”).

► **Definition 4** (equivalence class). *A node-colored rooted tree T is an equivalence class of solution subtrees of an e-colored ad-AND/OR graph G (or shortly an equivalence class of G) if there exists a solution subtree T_1 of G such that $\pi(T_1)$ is equal to T . Such a T_1 is said to be a solution subtree belonging to the class T .*

More notations. We denote by $\mathbb{C}(G)$ the set of equivalence classes of G . The notation π can be seen as a function $\pi: \mathbb{T}(G) \rightarrow \mathbb{C}(G)$. We denote by $\pi^{-1}(T) := \{T_1 \in \mathbb{T}(G) \mid \pi(T_1) = T\}$ the subset of solution subtrees of G belonging to the class T . The notations $c(s)$ and $\tilde{C}(s)$ are naturally extended to the case where s is a node in an equivalence class T . The root node of a rooted tree T is denoted by $r(T)$. The set of the children of a node s is denoted by $Ch(s)$.

An example of an e-colored ad-AND/OR graph with five equivalence classes is given in Figure 2.

■ **Figure 2** An e-colored ad-AND/OR graph and its five equivalence classes. The colors of the OR^+ nodes are written inside the squares.

2.3 Enumerating equivalence classes

Given an e-colored ad-AND/OR graph G , we propose a polynomial delay algorithm to enumerate all equivalence classes of G . Given a total ordering c_1, \dots, c_m of the colors of G , we define a total ordering \prec over $\mathbb{C}(G)$, the set of equivalence classes of G . If T and T' have their roots colored differently, we say that T is smaller than T' , denoted by $T \prec T'$, if the root color of T precedes the one of T' . If T and T' have the same root color, let (T_1, \dots, T_k) (resp. (T'_1, \dots, T'_k)) be the child subtrees of $r(T)$ (resp. $r(T')$) sorted recursively with respect to \prec . We then say that T is smaller than T' if the tuple (T_1, \dots, T_k) is lexicographically smaller than (T'_1, \dots, T'_k) , i.e., if $T_i \prec T'_i$ with i being the smallest index such that $T_i \neq T'_i$. We also assume that \emptyset is smaller than any tree, and therefore a single node tree colored with color c comes before any other tree whose root is colored with c in \prec .

2.3.1 Definitions and notations

Recall that given an AND-node x , $\tilde{C}(x)$ is the tuple of colors of the children of x sorted in increasing order. Given an OR-node o , we denote by $\mathcal{T}(o)$ the set of color tuples of its children, i.e., $\mathcal{T}(o) := \{\tilde{C}(x) : x \in \text{Ch}(o)\}$. In other words, a color tuple (c_1, \dots, c_j) belongs to $\mathcal{T}(o)$ if o has an AND-child node whose children are colored with (c_1, \dots, c_j) . If we consider an equivalence class T of $\mathbb{C}(G/\{o\})$ rooted at o , the tuples of $\mathcal{T}(o)$ are precisely the possible colorings of the children of $r(T)$. Indeed, if the AND-child node $x \in \text{Ch}(o)$ is chosen in a solution subtree, then $\tilde{C}(x)$ will be the colors of the children of o in that solution. Notice that several AND-children nodes of o may have the same color tuple.

We extend this definition to a set \mathcal{O} of OR^+ nodes with $\mathcal{T}(\mathcal{O}) = \bigcup_{o \in \mathcal{O}} \mathcal{T}(o)$. In the same way, $t = (c_1, \dots, c_j)$ is a color tuple of $\mathcal{T}(\mathcal{O})$ if and only if there exists an equivalence class T of $\mathbb{C}(G/\mathcal{O})$ such that the children of $r(T)$ are colored with (c_1, \dots, c_j) . Given a set \mathcal{O} of OR^+ nodes, we denote by $t_1, \dots, t_{|\mathcal{T}(\mathcal{O})|}$ the different color tuples of $\mathcal{T}(\mathcal{O})$ ordered lexicographically, and we denote by $\text{Ch}^\ell(\mathcal{O})$ the set of AND-nodes in $\text{Ch}(\mathcal{O})$ whose color tuple is t_ℓ , i.e., $\text{Ch}^\ell(\mathcal{O}) = \{x \in \text{Ch}(\mathcal{O}) : \tilde{C}(x) = t_\ell\}$. The sets $\text{Ch}^1(\mathcal{O}), \dots, \text{Ch}^{|\mathcal{T}(\mathcal{O})|}(\mathcal{O})$ form a partition of $\text{Ch}(\mathcal{O})$, each part corresponding to a color tuple $t_i \in \mathcal{T}(\mathcal{O})$.

Finally, given a color tuple $t_\ell := (c_1, \dots, c_j) \in \mathcal{T}(\mathcal{O})$, for each $i \leq j$, by Definition 3, each node of $\text{Ch}^\ell(\mathcal{O})$ has exactly one child with color c_i . We denote by C_i^ℓ the set of children of $\text{Ch}^\ell(\mathcal{O})$ colored with c_i , i.e., $C_i^\ell = \{o \in \text{Ch}(x) : x \in \text{Ch}^\ell(\mathcal{O}), c(o) = c_i\}$ (it is a set of “grandchildren” of \mathcal{O}).

■ **Algorithm 1** Next solution.

```

1 Input: A set  $\mathcal{O}$  of  $\text{OR}^+$  nodes having all the same color  $c$  and an equivalence class  $T$ 
   of  $G/\mathcal{O}$ 
2 Output: The equivalence class  $T'$  of  $G/\mathcal{O}$  that follows  $T$  w.r.t the  $\prec$  ordering.
3 Function  $\text{Next}(T, \mathcal{O})$ :
4   if  $T = \emptyset$  and  $\mathcal{O}$  contains terminal nodes then
5     | Return A tree with a single root node colored with  $c$ 
6   end
7    $r \leftarrow 0$ 
8   if  $T = \emptyset$  or  $T$  is a single node tree then
9     |  $r \leftarrow r + 1$ 
10    | if  $r > |\mathcal{T}(\mathcal{O})|$  then
11      | | Return  $\perp$ 
12    | end
13    | Let  $(c_1, \dots, c_j)$  be the color tuple of  $t_r \in \mathcal{T}(\mathcal{O})$  and let  $T_1, \dots, T_j \leftarrow \emptyset$ 
14    |  $\mathcal{O}_1 \leftarrow C_1^r$ 
15    |  $\ell \leftarrow 1$ 
16  else
17    | Let  $r$  be such that  $t_r \in \mathcal{T}(\mathcal{O})$  is the root color tuple  $\tilde{C}(r(T))$ 
18    | Let  $(T_1, \dots, T_j)$  be the child subtrees of  $r(T)$ , the roots of which are colored
      | respectively with  $(c_1, \dots, c_j) := t_r$ 
19    | For all  $i \leq j$ , let  $\mathcal{O}_i \subseteq C_i^r$  be the set of nodes in  $C_i^r$  compatible with
      |  $(T_1, \dots, T_{i-1})$ 
20    | Let  $\ell$  be the largest index  $i \leq j$  such that  $\text{Next}(T_i, \mathcal{O}_i) \neq \perp$  if such index
      | exists. Otherwise,  $T \leftarrow \emptyset$  and go to line 8
21  end
22   $T_\ell \leftarrow \text{Next}(T_\ell, \mathcal{O}_\ell)$ 
23  for  $\ell < i \leq j$  do
24    | Let  $\mathcal{O}_i \subseteq C_i^r$  be the set of nodes in  $C_i^r$  compatible with  $(T_1, \dots, T_{i-1})$ 
25    |  $T_i \leftarrow \text{Next}(\emptyset, \mathcal{O}_i)$ 
26  end
27  Return A tree with root color  $c$  and root child subtrees  $(T_1, \dots, T_j)$ 

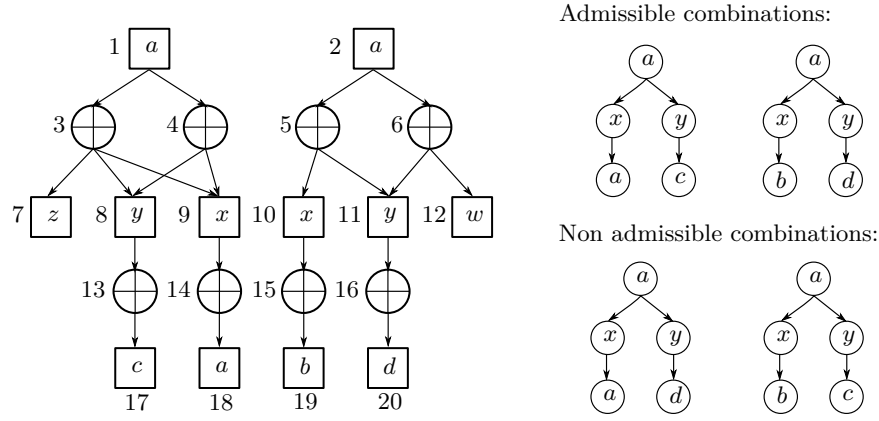

```

In the left panel of Figure 3, an example graph is shown where each node is labeled by an integer. The colors are, in increasing order, w , x , y , and z . For $\mathcal{O} = \{1, 2\}$, the set $\mathcal{T}(\mathcal{O})$ contains the three tuples $t_1 = (w, y)$, $t_2 = (x, y)$, and $t_3 = (x, y, z)$. We have $Ch^1(\mathcal{O}) = \{6\}$, $Ch^2(\mathcal{O}) = \{4, 5\}$, and $Ch^3(\mathcal{O}) = \{3\}$. The sets C_i^ℓ are $C_1^1 = \{12\}$, $C_2^1 = \{11\}$, $C_1^2 = \{9, 10\}$, $C_2^2 = \{8, 11\}$, $C_1^3 = \{9\}$, $C_2^3 = \{8\}$, and $C_3^3 = \{7\}$.

2.3.2 Algorithm description

Notice that by definition of \prec , given a set of OR^+ nodes \mathcal{O} , all having the same color c , and a color tuple $t_\ell \in \mathcal{T}(\mathcal{O})$, all equivalence classes T of G/\mathcal{O} such that $\tilde{C}(r(T)) = t_\ell$ are consecutive with respect to \prec .

The algorithm outputs the equivalence classes in ascending order with respect to \prec . Given an equivalence class T of G/\mathcal{O} for a set of OR^+ nodes \mathcal{O} of color c , it will output the equivalence class T' of G/\mathcal{O} that succeeds T w.r.t. \prec if it exists or output the symbol \perp if T is the last solution.

■ **Figure 3** Left panel: An e-colored ad-AND/OR graph. Right panel: For $\mathcal{O} = \{1, 2\}$, there are four combinations between $\mathbb{C}(G/C_1^2)$ and $\mathbb{C}(G/C_2^2)$; only two of them are admissible.

Assume that the children of $r(T)$ are colored with the *root color tuple* $(c_1, \dots, c_j) =: t_r \in \mathcal{T}(\mathcal{O})$ and let (T_1, \dots, T_j) be the child subtrees of T , the roots of which are colored with the tuple t_r . Notice that for all $i \leq j$, T_i is an equivalence class of G/C_i^r . The algorithm will output the next equivalence class T' such that $\tilde{C}(r(T')) = t_r$ if there remains one (same color tuple at the root), or it will output the first solution such that $\tilde{C}(r(T')) = t_{r+1} \in \mathcal{T}(\mathcal{O})$ otherwise (the next color tuple at the root).

To find the next solution corresponding to the root color tuple t_r , the algorithm will replace recursively T_j by its successor T'_j w.r.t. \prec if there exists one. We obtain the solution T' whose subtrees are $(T_1, \dots, T_{j-1}, T'_j)$ which is by definition the successor of T in \prec whenever T'_j is the successor of T_j . If T_j has no successor (that is, if it is the last one), we replace if possible T_{j-1} by its successor T'_{j-1} and we replace T_j by the smallest admissible solution (i.e., the successor of \emptyset). In general, we select at each step the greatest index ℓ such that T_ℓ has a successor w.r.t. \prec , we replace it by its successor T'_ℓ and we take the smallest admissible solution for every $\ell < i \leq j$.

Without further care, the above described procedure would output solutions whose child subtrees (T_1, \dots, T_j) of the root correspond to the elements of the Cartesian product of $\mathbb{C}(G/C_i^r)$, $i \leq j$. However, while it is true that if T is a solution, its child subtree T_i is an equivalence class of G/C_i^r for all $i \leq j$, the converse is not true. Indeed, not all elements of $\mathbb{C}(G/C_1^r) \times \dots \times \mathbb{C}(G/C_j^r)$ lead to an admissible solution (an example is given in the right panel of Figure 3). In order to find an admissible solution, we should guarantee that the choice of a given T_i is *compatible* with the previous choices (T_1, \dots, T_{i-1}) . This is done by selecting the subset of OR^+ nodes $\mathcal{O}_i \subseteq C_i^r$ that are compatible with (T_1, \dots, T_{i-1}) (see Definition 5 below). An admissible choice of T_i will then be any equivalence class of G/\mathcal{O}_i . The two key properties are that the set \mathcal{O}_i can be easily computed, and that it is never empty, i.e., there is always a choice for T_i that is compatible with the previous choices of (T_1, \dots, T_{i-1}) (there is at least one choice that corresponds to the current solution). Notice that if the latter were not true, the algorithm would not have a polynomial delay complexity since we may spend exponential time without reaching a final solution. With this property, we are guaranteed that we can always extend a partial tuple (T_1, \dots, T_i) until we reach a complete tuple (T_1, \dots, T_j) that will form a solution.

Compatible nodes

Given a set of OR^+ nodes \mathcal{O} all colored with the same color c and a tree T of $\mathbb{C}(G/\mathcal{O})$, we denote by $r(\pi^{-1}(T)) := \{r(S) : S \in \pi^{-1}(T)\}$ the subset of OR^+ nodes of \mathcal{O} , each one of which is the root of a solution subtree of class T . The following definition formalizes the notion of compatible nodes mentioned previously.

► **Definition 5.** Let \mathcal{O} be a set of OR^+ nodes of color c , $t_r = (c_1, \dots, c_j) \in \mathcal{T}(\mathcal{O})$, and let T_1, \dots, T_k , with $k < j$, be respectively equivalence classes of $\mathbb{C}(G/C_i^r)$ for all $i \leq k$. We say that a node $o \in C_{k+1}^r$ is compatible with (T_1, \dots, T_k) if there exists an AND-node $x \in Ch^r(\mathcal{O})$ such that o is a child of x and such that $r(\pi^{-1}(T_i))$ contains a child of x for all $i \leq k$.

2.3.3 Analysis

► **Proposition 6.** Let T be an equivalence class of G/\mathcal{O} for a set \mathcal{O} of OR^+ nodes of G , all colored with the same color c . Then, the function *Next* of Algorithm 1 is such that:

1. *Next* (\emptyset, \mathcal{O}) returns the smallest equivalence class of G/\mathcal{O} w.r.t. \prec .
2. *Next* (T, \mathcal{O}) returns the equivalence class of G/\mathcal{O} that follows T w.r.t. \prec .
3. if T is the last equivalence class of G/\mathcal{O} , *Next* (T, \mathcal{O}) returns \perp .

Due to space constraints, some proofs are omitted and can be found in the full version of this paper [36].

► **Theorem 7.** Given an e -colored ad-AND/OR graph G , the set $\mathbb{C}(G)$ can be enumerated with delay $O(n \cdot s)$ where n is the number of nodes of G and s is the maximum size of a solution.

Proof. To enumerate $\mathbb{C}(G)$, we first split the start nodes of G into sets S_0, \dots, S_k according to their colors. For each set S_i , starting with $T = \emptyset$, we repeatedly assign *Next* (T, S_i) to T and output it until $T = \perp$. By Proposition 6, this guarantees that we output every solution of $\mathbb{C}(G/S_i)$ exactly once. Since any solution of $\mathbb{C}(G)$ belongs to $\mathbb{C}(G/S_i)$ for a given $i \leq k$, every solution of $\mathbb{C}(G)$ will be outputted exactly once.

For the complexity, notice that at most one recursive call is performed by the node of the next solution. More precisely, if *Next* $(T, \mathcal{O}) = T'$, there will be exactly one recursive call per node in T' that is not in T , and thus at most s recursive calls will be performed.

In each recursive call, both the set $\mathcal{T}(\mathcal{O})$ and the partition $\{C_i^r\}_{i \leq j}$ of grandchildren of \mathcal{O} can be computed in $O(n)$ time. It remains to show that the sets of compatible nodes \mathcal{O}_i , $i \leq j$, can be computed in $O(n)$ time in total which will conclude the proof. To do this, we should be able to compute the sets $r(\pi^{-1}(T_i))$ for all $i \leq j$. If *Next* $(T, \mathcal{O}) = T'$, the easiest way is to return the set $r(\pi^{-1}(T'))$ together with T' when the call *Next* (T, \mathcal{O}) returns. This could be done by observing that if $T \in \mathbb{C}(G/\mathcal{O})$ where \mathcal{O} is a set of goal nodes all having the same color c , then $r(\pi^{-1}(T)) = \mathcal{O}$, and if T has child subtrees T_1, \dots, T_j then $r(\pi^{-1}(T))$ is the set of nodes of \mathcal{O} that has at least an AND-child x such that the children of x contain exactly one node in $r(\pi^{-1}(T_i))$ for each $i \leq j$, which can be found in $O(n)$ time. Thus only $O(n)$ time is necessary at each recursive call to return $r(\pi^{-1}(T'))$ in addition to T' . ◀

3 Application to dynamic programming

3.1 A formalism for tree-sequential dynamic programming

Since its introduction by Karp and Held [21], *monotone sequential decision processes* (mSDP) have been the classical model for problems solvable by dynamic programming (DP). This formalism is based on finite-state automata. The solutions of DP-problems are thus equivalent

to languages of regular expressions, or to paths in directed graphs. It is known that Bellman's *principle of optimality* [5] also applies to problems for which the solutions are not sequential but *tree-like* [9]. Various generalizations have been proposed to characterize broader classes of problems solvable by DP or DP-like techniques [11, 19]. In this paper, we consider a framework which is the immediate generalization of the mSDP model, i.e., generalizing finite automata (regular expressions, paths in DAGs) to finite tree automata (regular tree grammars, solution trees of general AND/OR graphs). Further generalizations exist (from trees to graphs of treewidth > 1); the collection of these methods is known as *Non-serial dynamic programming* [6].

In this model, a tree-sequential problem can be specified by a finite (bottom-up) tree automaton $A = (Q, \Sigma, \delta, q_0, Q_F)$, where Q is a finite set of states, Σ is a ranked alphabet, δ is a set of transition rules of the form (q_1, \dots, q_n, a, q) where $q_1, \dots, q_n, q \in Q$ and $a \in \Sigma$, $q_0 \in Q$ is the initial state, $Q_F \subseteq Q$ is a set of final states. The problem specification also includes a cost function. The set $L(A)$ of trees accepted by the tree automaton A defines the set of feasible solutions. The minimization problem seeks to minimize the cost function over the set $L(A)$ of feasible solutions.

We will consider the simple case of a positive additive cost function that always equals zero in the initial state. An additive cost function can be defined via an incremental cost function $I: Q^* \times \Sigma \rightarrow \mathbb{R}$, where Q^* consists of tuples of states in Q of the form (q_1, \dots, q_n) . $I(q_1, \dots, q_n, a)$ can be viewed as the cost of attaching n child subtrees to a new root of symbol a . While it might seem restrictive to require an additive structure on the cost function, this simple case does cover many important problems admitting a DP-algorithm, for instance, Travelling Salesman [4, 18], Knapsack [22], or Levenshtein distance [34].

In this case, the answer of the minimization problem can be shown to be equal to $\min_{q \in Q_F} D(q)$, where $D: Q \rightarrow \mathbb{R}_{\geq 0}$ is defined by the following recurrence equations:

$$\begin{aligned} D(q_0) &= 0, \\ \text{for } q \neq q_0, \quad D(q) &= \min_{(q_1, \dots, q_n, a, q) \in \delta} \sum_{1 \leq i \leq n} D(q_i) + I(q_1, \dots, q_n, a). \end{aligned} \quad (1)$$

A *dynamic programming algorithm* for the minimization problem corresponds to an algorithm that computes D ; the function D is commonly called a *dynamic programming table* (a DP-tabled, also called a DP-array, or a DP-matrix). Needless to say, such an algorithm does not exist in general for given arbitrary tree automata and cost functions [20].

Using an algebraic approach, Gnesi and Montanari [16] have shown that solving the functional Equation (1) corresponds to finding the solution subtrees of a general AND/OR graph. An important special case in which DP-algorithms exist is when the underlying AND/OR graph is acyclic.

When a fixed tree is given as an input to the problem, the underlying AND/OR graph is acyclic and decomposable (that is, it is an ad-AND/OR graph). Such problems are hence naturally solvable by DP-algorithms. These algorithms are known in folklore under the name *Dynamic programming on a tree*. Many graph-theoretical problems (e.g., maximum matching, longest path) can be solved optimally on trees by DP-algorithms. Numerous real-world applications also rely on DP-algorithms on trees; examples can be found, for instance, in Data Science [30], Computer Vision [14, 33], and Computational Biology [3, 13].

Explicit construction of the ad-AND/OR graph for DP on a fixed tree

Due to its usefulness for the examples that we will develop next, in the case of DP on a fixed tree, an explicit construction of the ad-AND/OR graph from Equation (1) is described below. The construction is done in two steps. In the first step, we build a graph in which every node

retains an additional attribute, its *value*, and every OR^+ node is labeled by a state $q \in Q$. In the second step, we *prune* the graph by removing nodes that do not yield optimal values.

1. For each $(q_0, a, q) \in \delta$, create a goal node of value 0 labeled by q . Then, for each $q \neq q_0$ in post-order,
 - i. For each $(q_1, \dots, q_n, a, q) \in \delta$, create an AND node, connect it to the n OR^+ nodes labeled by q_1, \dots, q_n . Its value is equal to the sum of the values of its children, plus $I(q_1, \dots, q_n, a)$.
 - ii. Create a single OR node, connect it to every AND node created in the previous step. Its label is q , and its value is the minimum of the values of its children.
2. For each $q \in Q_F$, remove the OR node labeled by q unless its value is equal to $\min_{q \in Q_F} G(q)$. For each OR node s , remove the arc to its AND-child node s_i if the value of s_i is not equal to the value of s . Finally, remove recursively all AND nodes without incoming arcs.

3.2 Examples

3.2.1 Optimal tree coloring problem

Description

A prototypical problem that fits into the framework of DP on a tree is **OPTIMAL TREE COLORING**, that is, finding an optimal node-coloring of the input tree. Many problems of practical interest reduce to **OPTIMAL TREE COLORING**; three concrete examples are given later in this section.

If T is the input (rooted, ordered) tree and C is the set of colors, such a problem seeks a coloring $\phi: V(T) \rightarrow C$ that minimizes the cost function. There can be many constraints on the coloring function: some nodes of T may be forced to have a certain color, the possible colors of a node may depend on the colors of its descendants. In our tree-sequential dynamic programming formalism, a tree automaton and a cost function are given as part of the input. The tree automaton defines the set $L(A)$ of feasible coloring functions satisfying all those constraints. A state q can be interpreted as a colored subtree of T with a particular root color; the unique initial state is an empty coloring and transitions into a colored leaf of T ; a final state corresponds to a fully colored T with a particular root color. A commonly used form of cost functions considers the (possibly weighted) sum over the edges of the tree of the cost of putting two colors on each end of an edge, that is, an incremental cost function I of the form $I(q_1, \dots, q_n, a, p) = \sum_{1 \leq i \leq n} p(a_i, a)$ where a_i is the color of the root of the subtree in state q_i and $p: C^2 \rightarrow \mathbb{R}_{\geq 0}$ is a function that gives the cost of putting two colors at each end of an edge.

Equivalence relations on the set of solutions

A possible strategy to define equivalence classes on the solution space of the **OPTIMAL TREE COLORING** problem is to consider some colors to be locally equivalent on a node. In practical applications (see the next section), the space of colors can be quite large. Even though the precise colors of each node are necessary for correctly computing the cost function, when the solutions are analyzed by a human expert, it can be desirable to omit the colors and just look at whether the color of a node belongs to some group of colors. Therefore, this kind of equivalence relations is natural in many situations. Our Definition 4 of equivalence classes of an e-colored ad-AND/OR graph deals exactly with equivalence relations of this type.

Let e be a function that maps a color c to its “color group” $e(c)$. Two solutions of the OPTIMAL TREE COLORING problem $\phi_1, \phi_2: V(T) \rightarrow C$ are said to be *equivalent* if $\forall u \in V(T)$, $e(\phi_1(u)) = e(\phi_2(u))$. Let G be the ad-AND/OR graph associated with this instance. For each OR^+ node s of G labeled with the state q , where q is interpreted as a colored subtree of T with a particular root color c , color the node s with $e(c)$. Then G is e -colored and $\mathbb{C}(G)$ corresponds to the set of equivalence classes of the solutions of the instance. Notice that the constraint we had on the e -coloring of an ad-AND/OR graph is naturally satisfied by any meaningful function e because in a DP setting we only consider ordered trees: the i -th and j -th children of a node of T cannot be in the same color group unless $i = j$.

Concrete examples of tree coloring problems

Example 1. The first example is related to the alignment of gene sequences on a phylogenetic tree [31]. The input is a tree T , a set Σ of letters (DNA alphabet or protein alphabet), a function that labels each leaf node of T with a letter, and a distance function $d: \Sigma^2 \rightarrow \mathbb{R}_{\geq 0}$ between two letters. The goal is to extend the leaf labeling to a full labeling $\phi: V(T) \rightarrow \Sigma$ such that the sum of the distances over the edges of T is minimized. Defining equivalence relations of the solutions based on a grouping of the letters is uncontrived in this problem: for the DNA or protein alphabet, the letters can be subdivided into structurally similar groups.

Example 2. The FREQUENCY ASSIGNMENT problems are a family of problems that naturally arise in telecommunication networks, and that have been extensively studied in graph theory as a generalization of graph coloring known as the T-coloring problem [17, 29, 32]. In the variant called the list T-coloring, the input is a graph G representing the interference between radio stations, a set C of colors, a function S that gives for each vertex $v \in V(G)$ a set $S(v) \subseteq C$ of colors (possible frequencies for a station), and a set $T \subseteq C^2$ of forbidden pairs of colors (interfering frequencies). The goal is to find a coloring $\phi: V(G) \rightarrow C$ such that a $\forall v \in V(G)$, $\phi(v) \in S(v)$, and $\forall (u, v) \in E(G)$, $(\phi(u), \phi(v)) \notin T$. While this problem is hard in general, it can be solved by DP when the underlying graph is a tree. In this case, we can enumerate colorings of the input trees without any forbidden pair of colors on the edges. Defining equivalence relations by grouping some of the colors together (similar frequencies) can be a practical way of reducing the size of the output.

Example 3. The TREE RECONCILIATION problem is the main method for analyzing the co-evolution of two sets of species, the hosts and their parasites [28]. The input are two phylogenetic trees H, P (of the hosts and of the parasites, respectively), together with a mapping $\phi_0: \text{Leaves}(P) \rightarrow \text{Leaves}(H)$ that reflects the present-day parasite infections. What needs to be enumerated are then all past associations, that is, all mappings of the non-leaf nodes of the parasite tree to the nodes of the host tree that optimize a function which overall represents the sum of the number of different possible “events” weighted by the inverse of their estimated probability. The number of optimal solutions is often huge and, by applying our Algorithm 1, the enumeration of biologically inspired equivalence classes have allowed a significant reduction (in some cases from 10^{42} to only 96 classes) of the size of the output while still preserving the important biological information (see [35]).

3.2.2 Dynamic programming on tree decomposition of a graph

Many graph problems can be solved in polynomial time with a dynamic programming algorithm when the input graph has bounded treewidth (see for example [8]). The underlying idea is that, given a tree decomposition of a graph, the dynamic programming algorithm

traverses the nodes (bags) of the decomposition and consecutively solves the respective sub-problems. For vertex subset optimization problems, given a bag X , a dynamic programming algorithm generally computes for each $Z \subseteq X$ the optimal solution of the sub-problem whose intersection with X is Z . In this context, we could define two solutions to be equivalent if they intersect each bag of the decomposition in an “equivalent” way. The equivalence relation on the solutions is then defined by an equivalence relation over the subsets of each bag, and two solutions S_1 and S_2 are equivalent if for all bags X of the decomposition, $S_1 \cap X$ is equivalent to $S_2 \cap X$.

One of the simplest examples is to consider that all the nonempty subsets of vertices of a bag are equivalent. Thus, what we are interested in is whether a solution “hits” a bag (i.e., whether it has a nonempty intersection with the vertices in the bag). Consequently, two solutions would be considered equivalent if they hit the same bags.

We can also consider two subsets of a bag to be equivalent if they have the same size. In this case, two solutions would be equivalent if each bag contains the same number of vertices in the two solutions.

We believe that considering solutions in the way they are distributed along the tree decomposition of a graph could give a good overview of the diversity of the solution space.

4 Conclusion and perspectives

In this paper, we provide a general framework for the enumeration of equivalence classes of solutions in polynomial delay for a wide variety of contexts. This work opens a door to different research directions.

It would be interesting to ask whether we can efficiently enumerate groups of solutions that result from classical clustering procedures, or one representative per group. Moreover, in this paper we heavily rely on the decomposability property of the structure of the solution space. It remains open whether the problem of enumerating equivalence classes is hard without this restriction.

Engineering MultiQueues: Fast Relaxed Concurrent Priority Queues

Abstract

Priority queues with parallel access are an attractive data structure for applications like prioritized online scheduling, discrete event simulation, or greedy algorithms. However, a classical priority queue constitutes a severe bottleneck in this context, leading to very small throughput. Hence, there has been significant interest in concurrent priority queues with relaxed semantics. We investigate the complementary quality criteria *rank error* (how close are deleted elements to the global minimum) and *delay* (for each element x , how many elements with lower priority are deleted before x). In this paper, we introduce *MultiQueues* as a natural approach to relaxed priority queues based on multiple sequential priority queues. Their naturally high theoretical scalability is further enhanced by using three orthogonal ways of batching operations on the sequential queues. Experiments indicate that MultiQueues present a very good performance–quality tradeoff and considerably outperform competing approaches in at least one of these aspects.

We employ a seemingly paradoxical technique of “wait-free locking” that might be of more general interest to convert sequential data structures to relaxed concurrent data structures.

1 Introduction

Priority queues (PQs) are a fundamental data structure for many applications. They manage a set of elements and support operations for efficiently inserting elements and deleting the smallest element (*deleteMin*). Whenever we have to dynamically reorder operations performed by an algorithm, PQs can turn out to be useful. Examples include job scheduling, graph algorithms for shortest paths and minimum spanning trees, discrete event simulation, best first branch-and-bound, and other best first heuristics.

On modern parallel hardware, we often have the situation that p parallel threads want to access the PQ concurrently both to insert and to delete elements. This is problematic for several reasons. First of all, even the semantics of a parallel PQ is unclear. The classical notion of serializability is not only expensive to achieve but also not very useful from an application point of view. For example, in a branch-and-bound application, a serializable parallel PQ could arbitrarily postpone insertion and corresponding deletion of a search tree node on the path leading to the eventual solution. This makes the application arbitrarily slower than the sequential one. The *ideal* semantics of a concurrent PQ (CPQ) would be that any element for which an insertion has started becomes visible instantaneously for deletion from any other thread. This is unattainable for fundamental physical reasons but can serve as a basis for defining the quality of relaxed priority queues (RPQs). In Section 2 we use this approach to define the complementary notions of the *rank error* of deleted elements and the *delay* of elements that are overtaken by larger elements. After discussing related work in Section 3, Section 4 describes the main contribution of this paper: MultiQueues are a simple approach to CPQs based on $c \cdot p$ sequential PQs (SPQs) for some constant $c > 1$. Insertions go to a random SPQ so that each of them contains a representative sample of the globally available elements. Deleted elements are the smaller of the minima of *two* randomly chosen SPQs. By choosing two rather than one queue, fluctuations in the distribution of queue elements are stabilized. Consistency is maintained by locking queues that are changed. See Figure 1 for an example. Since there are more queues than threads, no thread ever has to wait for a lock. Thus, we achieve a lock-free (and even wait-free) algorithm despite using locks which is an interesting feature of MultiQueues.

Although MultiQueues scale better than competitors both in theory and practice, they have the practical problem that they lack cache locality – in each operation, a thread accesses several cache lines from randomly chosen SPQs which are rarely reused but usually cause cache invalidation costs later. We therefore introduce three orthogonal measures for improving locality: (1) Insertion and deletion *buffers* ensure that most operations access only a small number of cache lines. (2) We use sequential queues that allow *bulk access* in a more cache-efficient way than using several single-element operations. (3) Threads optionally *stick* to the same set of queues for several consecutive operations. In the analysis (Section 4.5), we show that MultiQueue operations are almost as fast as their sequential counterparts – scaling linearly with the number of threads. We are also able to analyze rank error and delay

Figure 1 A MultiQueue with 8 sequential queues and 4 threads. Thread T2 currently locks PQ7 to insert an element. T4 inspected PQ3 and PQ8 and now locks PQ8 to remove its smallest element.

under moderately simplifying assumptions – it is linear in expectation and $O(p \log p)$ with high probability. Section 5 summarizes an extensive experimental evaluation of MultiQueues including a comparison with alternative approaches. Section 6 concludes the paper.

2 Preliminaries

A priority queue pq represents a set of elements. We use $n = |pq|$ for the size of the queue. Classical priority queues support the operations *insert* for inserting an element and *deleteMin* for obtaining and removing the smallest element. The most frequently used SPQ is the binary heap [29].

A *relaxed CPQ* does not require the *deleteMin* operation to return the minimum element. The *rank* of an element of a set M is its position in a sorted representation of M . A natural quality criterion for the *deleteMin* operation is the *rank error* of the returned element, i.e., the number of elements in the CPQ at the time of deletion that are smaller than the returned element. Over the entire use of the CPQ, one can look at the mean rank, the largest observed rank, or, more generally, the distribution of observed ranks. A complementary measure that has previously been largely neglected is the *delay* of a queue element x . The delay of x is the number of elements with lower priority than x that are deleted before x . This measure is important because it can be closely tied to the performance of applications. For example, consider a CPQ used in an optimization problem where the currently best queue element leads to the ultimate solution. If the CPQ from now on always remove the second best element, it has excellent rank error but will never find the solution because the best element is infinitely delayed.

It is difficult for a CPQ to consistently and efficiently maintain its exact *size*. A straightforward way to approximate the size can for example be implemented similarly to concurrent hash tables [16]. While knowing the size is not of direct importance for most applications, many of them need some kind of *termination detection*. Sequential algorithms would often terminate after they found the queue to be *empty*. Even the check for emptiness is difficult in concurrent settings since there is no way to know whether some other thread has concurrently called an insertion operation (or is about to do so). Hence, we view termination detection as a problem that has to be solved by the application. We adopt the semantics of most RPQs we are aware of that the *deleteMin* operation is allowed to fail – implying that the queue could not find any remaining elements without being able to prove that the queue is actually empty. A failed *deleteMin* has the current size of the queue as its rank error, i.e., as if ∞ was removed from the queue.

An algorithm is *wait-free* if it is guaranteed to make progress in a bounded number of steps [13]. Since we discuss randomized algorithms, we use this term also if the bound is probabilistic, i.e., if the expected number of steps is bounded.

3 Related Work

There has been considerable work on bulk parallel priority queues (BPQs) in the 1990s [8, 18, 23]. BPQs differ from CPQs in that they assume synchronized batched operation but they are still relevant as a source of ideas for asynchronous implementations. Indeed, Sanders [23] already discusses how these data structures could be made asynchronous in principle: Queue server threads periodically and collectively extract the globally smallest elements from the queue moving them into a buffer that can be accessed asynchronously. Note that within this buffer, priorities can be ignored since all buffered elements have a low

rank. Similarly, an insertion buffer keeps recently inserted elements. Moreover, the best theoretical results on BPQs give us an idea of how well RPQs should scale asymptotically. For example, Sanders' BPQ [23] removes the p smallest elements of the BPQ in time $O(\log n)$. This indicates that the worst-case rank error and delay close to *linear* in the number of threads should be achievable.

Sanders' BPQ [23] is based on the very simple idea to maintain a local SPQ on each thread and to send inserted elements to random threads. This idea is older, stemming from Karp and Zhang [14]. This approach could actually be used as an RPQ. Elements are inserted into the SPQ of a randomly chosen thread. Each thread deletes elements from its local SPQ. It is shown that this approach leads to only a constant factor more work compared to a sequential algorithm for a globally synchronized branch-and-bound application where producing and consuming elements takes constant time. Unfortunately, for a general asynchronous RPQ, the Karp-Zhang-queue [14] has limitations since slow threads could "sit" on small elements, while fast threads would busily process elements with high rank – in the worst case, the rank error could grow arbitrarily large. Our MultiQueue builds on the Karp-Zhang-queue [14], adapting it to a shared memory setting, decoupling the number of queues from the number of threads, and, most importantly, using a more robust protocol for *deleteMin*.

Many previous CPQs are based on the SkipList data structure [17]. At its bottom, the SkipList is a sorted linked list of elements. Search is accelerated by additional layers of linked lists. Each list in level i is a random sample of the list in level $i - 1$. Many previous CPQs delete the exact smallest element [26, 27, 15, 6]. This works well if there are not too many concurrent *deleteMin* operations competing for deleting the same elements. However, this inevitably results in heavy contention if very high throughput is required. The SprayList [3] reduces contention for *deleteMin* by removing not the global minimum but an element among the $O(p \log^3 p)$ smallest elements. However, for worst case inputs, insertions can still cause heavy contention. This is a fundamental problem of any data structure that attempts to maintain a single globally sorted sequence. Wimmer et al. [31] describe a RPQ for task scheduling based on a hybrid between local and global linked lists and local SPQs. Measurements in Alistarh et al. [3] indicate that this data structure does not scale as well as SprayLists – probably due to a frequently accessed central linked list. Henzinger et al. [12] give a formal specification of RPQs and mention a SkipList based implementation without giving details. Interestingly, for a relaxed FIFO-queue, the same group proposes a MultiQueue-like structure [11].

The *contention avoiding priority queue (CAPQ)* [21, 22] is based on a centralized skip-list S but switches to thread-local insertion and deletion buffers when it detects contention on S . To maintain some global view, operations will still occasionally use S . This combines high accuracy in uncontended situations with high throughput under contention. However, the quality penalty for switching to local buffers is fairly high. Assuming the centralized queue is accessed every $m \in \Theta(p)$ steps (which seems necessary to avoid contention) the paper shows that a rank error in $O(p^2)$ is guaranteed for every m -th step. Nothing can be guaranteed for the remaining fraction of $1 - 1/m$ operations.¹

For large SPQs, cache-efficient data structures are useful. Unfortunately, the best of these (e.g., [24]) are not useful for CPQs since they are only efficient in an amortized sense and locking an SPQ for an extended period of time could lead to large rank errors and delays.

¹ Such a guarantee could also be achieved with a simplistic version of MultiQueues where each thread inserts and deletes from a fixed queue except that every p steps a thread scans all queues for the globally smallest element.

4 MultiQueues

We first describe the basic MultiQueue in Section 4.1 and then refine it to improve cache locality in Sections 4.2–4.4. In Section 4.5 we provide a simplified theoretical analysis of the run time and quality of the MultiQueue. Section 4.6 discusses implementation details.

4.1 Basic MultiQueue

The basic MultiQueue data structure is an array Q of $c \cdot p$ SPQs where c is a tuning parameter and p is the number of parallel threads. Figure 1 gives an example with $c = 2$. Access to each local queue is protected by a lock flag. The *insert* operation locks a random unlocked queue $Q[i]$ and inserts the element into $Q[i]$. Figure 2 gives pseudocode. Note that this operation is wait-free since we never wait for a locked queue. Since at most p queues can be locked at any time, for $c > 1$ we will have a constant success probability. Hence, the expected time for acquiring a queue is constant. Together with the time for insertion we get expected insertion time $O(\log n)$.

An analogous implementation of *deleteMin* would lock a random unlocked queue and return its minimal element. However, the quality of this approach leaves a lot to be desired. In particular, it deteriorates not only with p but also with the queue size. One can show that the rank error grows proportional to \sqrt{n} due to random fluctuations in the number of operations addressing the individual queues. Therefore we invest slightly more effort into the *deleteMin* operation by looking at *two* random queues and deleting from the one with the smaller minimum. Figure 2 gives pseudocode for the *insert* and *deleteMin* operations. Our intuition why considering two choices may be useful stems from previous work on randomized load balancing, where it is known that placing a ball on the least loaded of two randomly chosen machines gives a maximum load that is very close to the average load independent of the number of allocated balls [4].

Even when the queue is small, cache efficiency is a major issue for MultiQueues since accessing a queue $Q[i]$ from a thread j will move the cache lines accessed by the operation into the cache of thread j . But most likely, some random other thread j' will next need that data causing not only cache misses for j' but also invalidation traffic for j .

Procedure *insert*(e)

```

repeat
   $i := \text{uniformRandom}(1..cp)$ 
  try to lock  $Q[i]$ 
until lock was successful
 $Q[i].\text{insertToSPQ}(e)$ 
unlock  $Q[i]$ 

```

Procedure *deleteMin*

```

repeat
   $i := \text{uniformRandom}(1..cp)$ 
   $j := \text{uniformRandom}(1..cp)$ 
  if  $Q[i].\text{min} > Q[j].\text{min}$  then swap  $i, j$ 
  try to lock  $Q[i]$ 
until lock was successful
 $e := Q[i].\text{deleteMinFromSPQ}$ ; unlock  $Q[i]$ 
return  $e$ 

```

■ **Figure 2** Pseudocode for basic MultiQueue *insert* and *deleteMin*. This code assumes that an empty SPQ returns ∞ as the minimum element. A return value of ∞ from *deleteMin* then indicates that no element could be found (which does not guarantee that all SPQs are empty). A practical implementation might make additional efforts to find elements when encountering empty SPQs.

Procedure insertToSPQ(e) if $D = \emptyset \vee e < \max D$ then if $ D < b$ then $D := D \cup \{e\}$; return $(e, D) := (\max D, (D \setminus \{\max D\}) \cup \{e\})$ if $ I = b$ then flush I to M $I := I \cup \{e\}$	Procedure deleteFromSPQ if $D = \emptyset$ then return ∞ // fail $e := D.deleteMin$ if $D = \emptyset$ then refill D from $M \cup I$ return e
---	--

■ **Figure 3** Pseudocode for inserting and deleting elements from an already locked sequential queue represented by the main queue M , an insertion buffer I and a deletion buffer D .

4.2 Buffering

To reduce the average number of cache lines accessed, we represent each SPQ by the main queue M , an *insertion buffer* I and a *deletion buffer* D that is organized as a sorted ring-buffer. Each buffer has a fixed capacity b . We maintain the invariant that (unless the SPQ is empty) D contains the smallest elements of $M \cup D \cup I$. This implies that **min** of the SPQ is always the first element of D .

To maintain this invariant, **inserting** an element e into an SPQ first checks whether D is empty or contains a larger element. If so, e is inserted into D . If D was not full, this finishes the insertion. Otherwise, e becomes the largest element in D . If I is full, it is flushed into the main queue. Finally, e is inserted into I . See Figure 3 for high-level pseudocode.

DeleteMin is straightforward. When D is not empty, its smallest element is removed and returned. If this empties D , it is refilled from $M \cup I$. A simple way to do this is to first flush I into M and then extract the smallest b elements from M into D . Alternatively, we can first refill D from M only and then scan through I to swap elements smaller than $\max D$ with the largest elements from D in a fashion analogous to what is done in *insertSPQ*. This has the advantage that all interactions between the buffers and M is in the form of batches of predictable size. This will be exploited in Section 4.3.

Buffering implies that the operations most often only access the buffers themselves and the lock (accessing and modifying the buffers requires the SPQ to be locked). More specifically, an insertion “usually” reads the largest element from D and then operates on I (assuming that inserted elements rarely go to D). *deleteMin* “usually” only accesses D . When buffers are flushed or refilled, a single thread performs a batch of operations on a single queue and thus can exploit whatever locality the main queue supports. In binary heaps for example, insertions exhibit high locality. Deletions at least exhibit some locality near the root, at the variable specifying the size of the queue, and at the rightmost end of the bottom layer of the tree.

4.3 Batching

To fully exploit that MultiQueues with buffering access the main queues in a bulk fashion we can use SPQs that directly support batch operations. In our prototype, we considered *merging binary heaps*. These are structured like binary heaps but each node contains k sorted elements. The heap invariant remains that nodes contain elements that are no smaller than the elements in the parent node. Insertion and deletion are also analogous to ordinary binary heaps except that compare-and-swap operations are generalized to merge-and-split.

On the one hand, merging binary heaps yield higher cache locality for bulk operations than binary heaps since all elements in each tree node can be stored consecutively and fewer nodes have to be accessed. On the other hand, they come with additional algorithmic complexity and higher worst-case access time. They are also not easily combined with a -ary heaps that are a simpler alternative to achieve somewhat higher locality than in binary heaps.

4.4 Stickiness

As a third measure to improve cache locality we introduce the concept of *stickiness*. The stickiness parameter s controls for how many consecutive operations a thread t reuses a particular local queue for its *insert* and *deleteMin* operations. After the stickiness period of one local queue ends for t or if locking the queue fails, t randomly chooses another queue to stick to. The intuition behind this protocol is that for large enough s and $c \geq 3$, the system converges to a state where threads use disjoint queues most of the time. Stickiness provides a simple mechanism to trade-off increased cache efficiency at the cost of potentially higher rank errors and increased delay.

4.5 Analysis

In this section we analyze the theoretical performance of the MultiQueue under simplifying assumptions.

4.5.1 Running Time

We analyze the asymptotic running time of the operations *insert* and *deleteMin* of the MultiQueue in a realistic asynchronous model of shared memory computing where k threads contending to write the same machine word need time $O(k)$ to perform those operations (e.g., the aCRQW model [25, Section 2.4.1]).

► **Theorem 1.** *With $c > 1$, the expected execution time of the operations *insert* and *deleteMin* is $O(1)$ plus the time for the sequential queue access.*

Proof. Whenever a thread attempts to lock a queue q , there are at most $p - 1$ locked queues. Hence the success probability is at least

$$s := 1 - \frac{p-1}{cp} \geq 1 - \frac{1}{c} \in \Omega(1).$$

Hence the expected number of attempts is

$$\sum_{i=1}^{\infty} i s (1-s)^{i-1} = \frac{1}{s} \leq \frac{1}{1-\frac{1}{c}} = \frac{c}{c-1} \in O(1).$$

The stickiness does not affect the expected number of attempts since it only dictates the first queue to attempt to lock but not subsequent attempts in case of failure. The buffers have constant size, so all operations on them are in $O(1)$. The bulk-inserting of the insertion buffer into the queue and refilling the deletion buffer amortize to the same asymptotic cost as accessing a sequential queue for each element individually. ◀

Note that the above analysis even holds when threads are blocked: In the worst case, each thread holds a lock. The overhead for another thread to avoid these locks is already accounted for in the above proof. Hence all other threads are guaranteed to make progress (in a probabilistic sense). Thus MultiQueues are probabilistically wait-free.

Using different sequential queues, we get the following bounds for the comparison based model and for integer keys:

► **Corollary 2.** *MultiQueues with binary heaps need constant average insertion time and expected time $O(\log n)$ per operation for worst case operations sequences. For integer keys in the range $0..U$, using van Emde Boas search trees [28, 7] as local queues, time $O(\log \log U)$ per operation is sufficient.*

4.5.2 Quality

Quality analysis is still a partially open problem. However, we will explain how *rank errors* and *delays* can be estimated under simplified but intuitive assumptions in the absence of stickiness.

Let us assume that all m current elements have been allocated uniformly at random to the local queues. This assumption holds if there have been no *deleteMin* operations so far and no locking attempt during *insert* failed. It is an open question whether lock contention and *deleteMin* operations invalidate this assumption in practice. Furthermore, let us assume that we choose the queues to look at for deletion randomly and no queue is currently locked.

Rank Errors

With these assumptions, the probability to delete an element e of rank i is

$$P(\text{rank} = i) = \left(1 - \frac{2}{cp}\right)^{i-1} \frac{2}{cp}$$

The first factor expresses that the $i - 1$ elements with smaller ranks are not present at the two chosen queues. The second factor is the probability that the element with rank i is *present*. Therefore, the expected rank error in the described situation is

$$\sum_{i=1}^m iP(\text{rank} = i) \leq \sum_{i \geq 1} i \left(1 - \frac{2}{cp}\right)^{i-1} \frac{2}{cp} = \frac{c}{2}p \in O(p). \quad (1)$$

The cumulative probability that the rank of e is larger than k is

$$P(\text{rank} > k) = \left(1 - \frac{2}{cp}\right)^k, \quad (2)$$

as none of the elements with a rank smaller than k must be present on the two chosen queues. $P(\text{rank} > k)$ drops to p^{-a} for $k = \frac{ca}{2}p \ln p$, i.e., with probability polynomially large in p , we have a rank error in $O(p \log p)$.

We can also give qualitative arguments on how the performed operations change the distribution of the elements. Insertions are random and hence move the system towards a random distribution of elements. Deletions tend to remove more elements from queues with small keys than from queues with large keys, thus stabilizing the system. Alistarh et al. [2, 1] confirm our conjecture for a slightly simplified process and also show that it suffices to only “sometimes” look at more than one key. On the other hand, they show that the rank error grows in an unbounded fashion if always only a single queue is considered for deletion.

Delay

The delay of an element e with rank i is equal to the number of deletions of elements with rank higher than i . Let D denote the event that a particular *deleteMin* operation delays or removes element e . Let R denote the event that e is removed. We now compute the conditional probability that e is deleted given that it is delayed or deleted by the *deleteMin* operation. By the definition of conditional probability, we have $P(R | D) = \frac{P(R \cap D)}{P(D)}$.

With $P(R \cap D) = P(\text{rank} = i) = \left(1 - \frac{2}{cp}\right)^{i-1} \frac{2}{cp}$ and $P(D) = P(\text{rank} \geq i) = \left(1 - \frac{2}{cp}\right)^{i-1}$, we get $P(R | D) = \frac{2}{cp}$. Since $P(R | D)$ is constant, the delay follows a geometric distribution with an expected value of $\frac{cp}{2}$ and values in $O(p \log p)$ with high probability.

4.6 Implementation Details

Figure 4 The array containing the lock, the buffers as well the pointer to the SPQ in each entry. The padding blocks (grey) prevent false sharing of neighboring entries.

We first give a detailed description and reasoning of the data structures used in our implementation of the MultiQueue as described above. We then show implementations of the *insert* and *deleteMin* operations.

At its core, a MultiQueue is an array Q with one entry for each local queue. Each entry contains a lock, the insertion and deletion buffers, and a pointer to the main queue itself. Moreover, the key of the minimum element in the deletion buffer is redundantly stored next to the lock. Comparing the minima of two local queues thus only involves atomic access to this key and does not access the deletion buffer, which would require locking. Note that this technique allows for slight inaccuracies, as the minimum in the deletion buffer could be different from the explicitly stored minimum key if another thread deletes the minimum from the deletion buffer during comparison. However, consistency is not impacted by this. The entries are padded and aligned to *cache lines* to prevent false sharing of neighboring entries. On systems with nonuniform memory access (NUMA) the padding is extended to *virtual memory pages* that are distributed round-robin over the NUMA-nodes. This balances memory traffic over the nodes. See Figure 4 for an illustration. Additionally, each thread stores local data such as stickiness counters. False sharing between these data structures is also avoided.

The insertion buffer is implemented as a fixed array of size b , preceded by a size counter. The deletion buffer must support efficient removal of the first element, lookup of the last element, and insertions at arbitrary positions. We chose a ring buffer that stores its size and the index of the first element upfront as the underlying data structure. Ring buffers support random lookup and removing the first element in constant time, while inserts at arbitrary positions take at most $b/2$ element moves. We implement both 8-ary heaps and k -merging binary heaps as SPQs, where k is a tuning parameter. 8-ary heaps provide the same theoretical guarantees as binary heaps but better cache locality. To achieve stable worst-case access times, our implementation allocates enough memory so that array resizes by the local queues are unlikely. Having stable worst-case access times is relevant for MultiQueues since an operation that exceptionally takes very long would lock a queue for a long time. If this queue also contains elements of low rank, their delay as well as the rank error of elements deleted in the meantime could become large. On machines with NUMA, the memory for each SPQ is allocated on the same NUMA node.

While our MultiQueue implementation can handle arbitrary element types, the implementation is designed and optimized with elements of small size in mind.

5 Experiments

We first compare our theoretical analysis of rank errors and delays with experimental results. We then perform parameter tuning and examine different implementation variants of the MultiQueue. Afterward, we compare the MultiQueue with other concurrent priority queues in

terms of quality, throughput, and scalability. For these experiments, each thread repeatedly either deletes an element from the queue or inserts a new one. This benchmark provides good insights on the maximum throughput and quality of the queues under high contention.

Queue elements are key-value pairs consisting of two 32-bit unsigned integers, where the key determines the element's priority. The queue is filled with n_0 elements prior to the measurement. Unless otherwise noted, $n_0 = 10^6$, the inserted elements are uniformly distributed in $[0, \dots, 2^{32} - 1]$, and the rank errors and delays are measured over the course of 10^7 *deleteMin* operations. To conclude this chapter, we perform a parallel single-source shortest-path (SSSP) benchmark to shed light on the performance under more realistic settings.

Experiments were conducted on two machines: Machine *A* utilizes an AMD EPYC™ 7702P 64-core processor. Each core runs at 2.0 GHz and supports two hardware threads. The system runs on Ubuntu 20.04 with Linux kernel version 5.4.0. Machine *B* is a dual socket system with an Intel® Xeon® Platinum 8368 Processor with 2.4 GHz on each socket, yielding 2×38 cores and 152 available hardware threads. The system runs on SUSE Linux Enterprise Server 15 with Linux kernel version 5.3.18. The experiments in Section 5.2 were performed on machine *A*, for the comparison experiments in Section 5.3 we additionally used machine *B*. The implementation is written in C++17 and compiled with GCC 10.2.0 with optimization level `-O3`. We use pthreads for thread management and synchronization. Each thread is pinned to a hardware thread.

5.1 Measuring Rank Error and Delay of Relaxed PQs

Measuring the rank errors and delays in real-time imposes the practical problem that we need to know which elements are in the queue at the time of each *deleteMin* operation. We approach this problem as follows. Each thread logs its operations into a preallocated local vector. The log entries get timestamps obtained using a low-overhead high-resolution clock (we currently use the Posix `CLOCK_REALTIME`). For the evaluation, we merge these logs to one global sequence S of operations (sorted by time-stamp). S is then sequentially replayed using an augmented B+ tree (based on a `tlx::btree_map` from the `tlx` library [5]) whose leaves are the current queue elements (sorted by key). By augmenting nodes with their size, this allows determining ranks of deleted elements (and thus rank errors) in logarithmic time (e.g., [25, Section 7.5]). We further augment the interior nodes with delay counters d_v and maintain the invariant that the delay of a leaf e is the sum of the delay counters on the root- e path. When inserting an element, we can establish the invariant by setting d_e to $-\sum_v d_v$ for v on the root- e path. When performing balancing operations on the tree, we can maintain the invariant by pushing the delay counters of the manipulated nodes downward to unchanged subtrees.

5.2 MultiQueue Parameter Tuning

The baseline MultiQueue uses 8-ary heaps as SDQs and does not use stickiness or buffers. As seen in Figure 5, the measured rank errors follow the predicted distribution closely independent of the number of threads and values for c . However, we cannot quite match the prediction in practice.² We now inspect the impact of various parameter configurations for

² The discrepancy is not due to locking since it persists when threads wait for a long time after each operation. Other sources could be noise in time measurements or inaccuracies due to our random data distribution assumption.

■ **Figure 5** The rank error distribution compared to the distribution from the theoretical analysis for $p = 8$ and $p = 64$, respectively.

■ **Figure 6** The impact of different buffer sizes to the throughput. The left plot is for $c = 2$, the right one for $c = 4$. The suffix “ht” denotes active hyper-threading.

the MultiQueue on its performance. In particular, we optimize the buffer sizes and explore different values for c and the stickiness. The throughputs are reported for a running time of 3 s and averaged over 5 runs.

Buffer Size. As Figure 6 shows, buffering increases the throughput of the MultiQueue considerably. However, the buffer size has to be chosen carefully, as too large buffers hamper the performance. This is due to the overhead of inserting elements into the deletion buffer. The difference of buffer sizes 4, 8, and 16 is negligible until hyper-threading is active, where a buffer size of 4 gains most. However, the larger the buffers, the less frequent we have to access the SPQ to perform bulk operations. Accessing the SPQ likely generates cache misses, which are especially expensive with NUMA if the SPQ is located on another NUMA node. We therefore use a buffer size of $b = 16$ for further experiments. We have observed no significant differences in rank errors and delays with or without buffering.

■ **Table 1** The throughput, average rank error and delay for $p = 64$. The number in parentheses indicates the expected rank error according to the theoretical analysis.

c	s	Throughput (MOps/s)	Avg. rank error	Avg. delay
2	1	125.9	(64) 103.1	103.1
	4	215.5	413.2	412.5
	8	271.6	900.2	896.0
	16	322.5	1853.8	1827.6
	64	411.9	7443.5	7183.2

	8	542.0	6415.2	6338.3
	16	529.3	12814.4	12547.8
	64	603.3	50854.5	47695.3

Stickiness and Number of Queues. Table 1 shows measurements that suggest that rank errors and delays are not just linear in the number of queues cp but also in the stickiness s . While rank errors and delays of MultiQueues are always very similar, this is not generally true. We use the configurations $(c, s) \in \{(4, 1), (4, 4), (8, 8), (16, 8)\}$ for further benchmarks, as they provide interesting trade-offs between throughput and quality.

k -Merging Heap. Our experiments with k -binary merging heaps instead of 8-ary heaps for the SPQs indicated that merging heaps can improve the throughput for high values of s compared to 8-ary heaps. However, the impact is moderate (see Figure 7) in most cases and we stick to 8-ary heaps. Our experiments further showed that using merging heaps has no impact on the quality of the priority queue.

5.3 Comparison with Other Approaches

We compare the MultiQueue to the following state-of-the-art concurrent priority queues.

Linden [15] is a priority queue based on skip lists by Lindén and Jonsson. It only returns suboptimal elements in case of contention on the list head.

Spraylist [3] relaxes skip lists by deleting elements close to the list head to reduce contention.

k -LSM [30] combines thread-local priority queues with a relaxed shared priority queue component. We use the variants with $k = 256$ (**klsm256**) and $k = 1024$ (**klsm1024**).

CAPQ [21] dynamically detects contention to switch from using a shared skip list based priority queue to thread-local buffers.

■ **Figure 7** Throughput comparison using 8-ary heaps and k -merging heaps with $k = 16$. The numbers in parentheses are (c, s) -pairs. The suffix “ht” denotes active hyper-threading.

■ **Figure 8** Comparison of rank error and delay distribution for different priority queues for 10^6 *deleteMin* operations, $p = 64$.

We used the implementation found in the Github repository of the k -LSM³ for all of the above priority queues.

Figure 8 shows the rank error distributions and delays for 64 threads. Unsurprisingly, the Linden queue yields by far the best quality. The k -LSM achieves low rank error but high delay. For the Spraylist it is the other way around as it has high rank error but low delay. Multiqueues have similar delays and rank errors. With small values for c and s they are more accurate than all the competitors except for the Linden queue. The CAPQ exhibits quality comparable to the MultiQueue with the rather loose setting $c = s = 4$.

As seen in Figure 9, the CAPQ is among the fastest priority priority queues for up to 32 threads. Beyond that, it accesses the centralized queue so often that contention deteriorates performance. This could probably be remedied with different settings of the tuning parameters but only with a commensurate effect on even higher rank errors and delays. The very loose MultiQueue with $c = s = 8$ exhibits very good scalability. Even the higher-quality variants can take advantage of all hardware threads and eventually outperform the CAPQ. The k -LSM scales up to around 16 threads while Linden and Spraylist scale

³ <https://github.com/klmpq/klsm>

■ **Figure 9** Throughput comparison between the MultiQueue and other implementations. On the left is machine A, and on the right machine B.

■ **Figure 10** The SSSP benchmark on the *USA* graph running on machine A.

very poorly even on very few threads. The authors of the k -LSM show that the scalability of the k -LSM can be improved by selecting higher values for k such as 4096 at the cost of lower quality [10]. Machines A and B have similar performance with B having a slight advantage when all threads are used but suffering from the switch from one to two sockets. Unfortunately, the Spraylist crashed in our setup on both machines with higher thread count, so we had to exclude it from the SSSP benchmark below.

The parallel SSSP benchmark uses Dijkstra's algorithm to calculate the shortest paths from one node to all other nodes in a weighted graph. Dijkstra's algorithm has to be adapted to be used in a parallel setting with relaxed priority queues. Sagonas and Winblad use a similar benchmark for the CAPQ and describe the algorithm in greater detail [21]. The algorithm terminates as soon as the queue is empty. To detect when the queue is empty, they use the property of the CAPQ and k -LSM that if *deleteMin* fails for all threads some time after the last insertion happened, the queue must be empty. This does not hold for MultiQueues, thus we cannot rely solely on *deleteMin* to guarantee correct termination. Instead, we use a dedicated emptiness detection routine, where a thread checks c designated local queues for emptiness if it thinks that the queue is empty. The MultiQueue is empty if all threads have successfully completed this emptiness check some time after the last insertion has happened. For $c > 2$ the emptiness check is slightly more expensive than a *deleteMin* operation, but it is only executed after multiple failed *deleteMins*, so the added overhead is minuscule. We report the time to solve the SSSP problem for different thread counts as

■ **Figure 11** The SSSP benchmark on a random hyperbolic graph with 2^{20} nodes, an average degree of 16 and $\gamma = 2.3$ running on machine A.

well as the number of nodes that were extracted from the queue and then relaxed. We used real road networks and artificial random hyperbolic graphs (rhg) as benchmark instances. The road network *USA*⁴ has about 24m nodes and 58m edges. The road network *GER*⁵ has about 20m nodes and 42m edges. The weights on these graphs represent the travel time. We used a modified version of the KaGen framework [9] to generate random hyperbolic graphs with 2^{20} and 2^{22} nodes and the geometric distances as edge weights. Figure 10 and 11 give results for the *USA* road network and the rhg with 2^{20} nodes on machine A, respectively.

On the road map graphs, all the relaxed PQs considerably outperform the Linden queue. However, none of them scales particularly well beyond 16 threads with the MultiQueue variants performing best. Despite having considerably better rank errors than the CAPQ, the klsm1024 leads the algorithm to processes many more nodes on the *USA* graph. The k -LSM variants have very high delays, which indicates that the delay is a distinctive metric to measure the quality of relaxed priority queues. Rhgs paint a different picture: While only the CAPQ leads to nodes being processed more than once, both k -LSM variants are noticeably slower than both the CAPQ and MultiQueues. MultiQueues lead to very low overhead considering the extracted nodes in all our benchmarks and are very competitive at the same time. Especially in algorithms where processing the individual elements is expensive, this could be a decisive factor.

6 Conclusions and Future Work

MultiQueues are a simple and efficient approach to relaxed concurrent priority queues. They allow a transparent trade-off between throughput and quality and considerably outperform previous approaches in at least one of these aspects. An important open problem is to complete the theoretical analysis to encompass stickiness. We believe that further practical improvements could be possible by better avoiding conflicting queue accesses of the sticky variant even when few queues are used. It would also be interesting to make MultiQueues contention aware to achieve higher quality and more graceful degradation than the simple binary switch between local and global access used in the CAPQ [21].

A conceptual contribution of our paper is in introducing the quality measure of *delay* as a complement to *rank error*. We give evidence that this is important for the actual performance of applications such as shortest path search and explain how to measure it efficiently. We are

⁴ <http://users.diag.uniroma1.it/challenge9/download.shtml>

⁵ <https://i11www.itk.kit.edu/resources/roadgraphs.php>

currently having a closer look at using CPQs for branch-and-bound where it seems that the parallel performance of the applications is provably tied to the delays incurred by the CPQ. Beyond priority queues, it would be interesting to see whether our approach to “wait-free” locking can be used for other applications, e.g., for FIFOs.

Evidence for Long-Tails in SLS Algorithms

Abstract

Stochastic local search (SLS) is a successful paradigm for solving the satisfiability problem of propositional logic. A recent development in this area involves solving not the original instance, but a modified, yet logically equivalent one [23]. Empirically, this technique was found to be promising as it improves the performance of state-of-the-art SLS solvers.

Currently, there is only a shallow understanding of how this modification technique affects the runtimes of SLS solvers. Thus, we model this modification process and conduct an empirical analysis of the hardness of logically equivalent formulas. Our results are twofold. First, if the modification process is treated as a random process, a lognormal distribution perfectly characterizes the hardness; implying that the hardness is long-tailed. This means that the modification technique can be further improved by implementing an additional restart mechanism. Thus, as a second contribution, we theoretically prove that all algorithms exhibiting this long-tail property can be further improved by restarts. Consequently, all SAT solvers employing this modification technique can be enhanced.

1 Introduction

Although algorithms for solving the NP-complete satisfiability problem, so-called SAT solvers, are nowadays remarkably successful in solving large instances, randomized versions of these solvers often show a high variation in the runtime required to solve a fixed instance over repeated runs [16]. In the past, research on randomized algorithms often focused on studying the unsteady behavior of statistical measures like the mean, variance, or higher moments of the runtime over repeated runs of the respective algorithm. In particular, these measures are unable to capture the long-tailed behavior of difficult instances. In a different line of work [13, 15, 32], the focus has shifted to studying the runtime distributions of search algorithms, which helps to understand these methods better and draw meaningful conclusions for the design of new algorithms.

Recently, the hybrid solver **GapSAT** [23] was introduced, combining a stochastic local search (SLS) solver with a conflict-driven clause learning (CDCL) solver. In the analysis conducted, it was empirically shown that adding new clauses is beneficial to the mean runtime (in flips) of the SLS solver **probsAT** [3] underlying the hybrid model. The authors also demonstrated that although adding new clauses can improve the mean runtime, there exist instances where adding clauses can harm the performance of SLS. This behavior is worth studying to help eliminate the risk of increasing the runtime of such procedures.

For this reason, we study the runtime (or more precisely, hardness) distribution of the procedure **Alfa**, introduced in this work, that models the addition of a set of logically equivalent clauses L to a formula F and the subsequent solving of this amended formula $F^{(1)} := F \cup L$ by an SLS solver. Our empirical evaluations show that this distribution is long-tailed. We want to stress the fact that studies on the runtime distribution of algorithms are quite sparse even though knowledge of the runtime distribution of an algorithm is extremely valuable: (1) Intuitively speaking, if the distribution is long-tailed, one knows there is a risk of ending in the tail and experiencing very long runs; simultaneously, the knowledge that the time the algorithm used thus far is in the tail of the distribution can be exploited to restart the procedure (and create a new logically equivalent instance $F^{(2)}$). We will prove this statement in a rigorous manner for all long-tailed algorithms. (2) Given the distribution of an algorithm's sequential runtime, it was shown how to predict and quantify the algorithm's expected speedup due to parallelization [1]. (3) If the distribution of hardness is known, experiments with few instances can lead to parameter estimations of the underlying distribution [13]. (4) Knowledge of the distribution can help compare competing algorithms: one can test if the difference in the means of algorithm runtimes is significant if the distributions are known [13].

1.1 Our Contributions

Our contributions consist of an empirical as well as theoretical part, specified below.

Statistical Runtime/Hardness Distribution Analysis. By conducting a plethora of experiments (total CPU time 80 years) and using several statistical tools for the analysis of empirical distributions, we conjecture that **Alfa** equipped with SLS solvers based on Schönning's Random Walk Algorithm [36], **SRWA** for short, follows a long-tailed distribution (Conjecture 8). The evidence obtained further suggests that this distribution is, in fact, lognormal (Conjecture 6). We measure the goodness-of-fit of our results over the whole domain using the χ^2 -statistic.

Restarts Are Useful For Long-Tailed Algorithms. Lorenz [22] has analyzed the lognormal and the generalized Pareto distribution for the usefulness of restarts and their optimal restart times. Given that our Strong Conjecture 6 holds, this result implies that restarts are useful for **Alfa**. We will also show that this is the case if only the Weak Conjecture 8 holds: We theoretically prove that restarts are useful for the class of algorithms exhibiting a long-tailed distribution.

1.2 Related Work and Differentiation

In [13], the authors presented empirical evidence for the fact that the distribution of the effort (more precisely, the number of consistency checks) required for backtracking algorithms to solve constraint satisfaction problems randomly generated at the 50 % satisfiable point

can be approximated by the Weibull distribution (in the satisfiable case) and the lognormal distribution (in the unsatisfiable case). These results were later extended to a wider region around the 50 % satisfiable point [32]. It should be emphasized that this study created all instances using the same generation model. This resulted in the creation of similar yet logically non-equivalent formulas. We, however, will firstly use different models to rule out any influence of the generation model and secondly generate logically equivalent modifications of a base instance (see Algorithm 1). This approach lends itself to the analysis of existing SLS solvers [23]. The major advantage is that the conducted work is not lost in the case of a restart: only the logically equivalent instance could be changed while keeping the current assignment.

In [16], the cost profiles of combinatorial search procedures were studied. The authors showed that they are often characterized by the Pareto-Lévy distribution and empirically demonstrated how rapid randomized restarts can eliminate this tail behavior. We will theoretically prove the effectiveness of restarts for the larger class of long-tailed distributions.

The paper [1] studied the solvers **Sparrow** and **CCASAT** and found that for randomly generated instances the lognormal distribution is a good fit for the runtime distributions. For this, the Kolmogorov-Smirnov statistic $\sup_{t \in \mathbb{R}} |\hat{F}_n(t) - F(t)|$ was used. Although the KS-test is very versatile, this comes with the disadvantage that its statistical power is rather low. Clearly, the KS statistic is also nearly useless in the tails of a distribution: A high relative deviation of the empirical from the theoretical cumulative distribution function in either tail results in a very small absolute deviation. It should also be remarked that the paper studies only few formulas in just two domains, 10 randomly generated and 9 crafted. Our work will address both shortcomings in this paper: The χ^2 -test gives equal importance to the goodness-of-fit over the entire support; and various instance domain models (both theoretical and applied) are considered in this paper.

► **Remark.** Unfortunately, the term heavy- or long-tailed distribution is not used consistently in the literature. We will follow [12] and use the notion given in Definition 7.

2 Preliminaries

We assume familiarity with terminologies such as Boolean variable, literal, clause, CNF formula, the SAT problem, and assignment flips in SLS solvers and refer the reader to e.g. [37]. We furthermore trust that the reader has basic knowledge of the proof system Resolution [8, 33]. *Stochastic local search* (SLS) solvers operate on complete assignments for a formula F . These solvers are started with a randomly generated complete initial assignment α_0 . If α_0 satisfies F , a solution is found. Otherwise, the SLS solver tries to find a solution by performing a random walk over the set of complete assignments for the underlying formula. A formula F *logically implies* a clause C if every complete truth assignment which satisfies F also satisfies C , for which we write $F \models C$. If L is a set of clauses we write $F \models L$ if $F \models C$ for all $C \in L$.

► **Definition 1.** Let X be a random variable for the runtime of an SLS algorithm \mathcal{A} on some input. For $t > 0$, the algorithm \mathcal{A}_t is obtained by restarting \mathcal{A} after time t if no solution was found. Restarts are useful if there is a $t > 0$ such that

$$\mathbb{E}[X_t] < \mathbb{E}[X],$$

where X_t models the runtime of \mathcal{A}_t .

► **Definition 2** ([19]). Let X be a real-valued random variable.

■ Its cumulative distribution function (cdf) is the function $F: \mathbb{R} \rightarrow [0, 1]$ with

$$F(t) := \Pr[X \leq t].$$

- Its quantile function $Q: (0, 1) \rightarrow \mathbb{R}$ is given by $Q(p) := \inf\{t \in \mathbb{R} \mid F(t) \geq p\}$.
- A non-negative, integrable function f such that $F(t) = \int_{-\infty}^t f(u) du$ is called probability density function (pdf) of X .

► **Definition 3** ([40]). An absolutely continuous, positive random variable X is (three-parameter) lognormally distributed with parameters $\sigma^2 > 0$, $\gamma > 0$, and $\mu \in \mathbb{R}$, if $\log(X - \gamma)$ is normally distributed with mean μ and variance σ^2 . In the following, we refer to σ as the shape, μ as the scale, and γ as the location parameter.

► **Definition 4.** Let X_1, \dots, X_n be independent, identically distributed real-valued random variables with realizations x_i of X_i . Then the empirical cumulative distribution function (ecdf) of the sample (x_1, \dots, x_n) is defined as

$$\hat{F}_n(t) := \frac{1}{n} \sum_{i=1}^n \mathbb{1}_{\{x_i \leq t\}}, \quad t \in \mathbb{R},$$

where $\mathbb{1}_A$ is the indicator of event A .

3 Design of the Adjusted Logical Formula Algorithm Alfa

Our SLS solver **Alfa** (Adjusted logical formula algorithm) receives a satisfiable formula F as input. The algorithm then proceeds by adding to F a set L of logically generated clauses. It finally calls an SLS solver to solve the clause set $F \cup L$.

■ **Algorithm 1** Alfa acts as a base algorithm that can use different SLS algorithms.

Input: Boolean formula F , **Promise:** $F \in \text{SAT}$

Generate **randomly** a set L of clauses such that $F \models L$

Call $\text{SLS}(F \cup L)$ for some SLS solver SLS

Definition 5 is used in Algorithm 2 as a natural way to sample a set L of logically equivalent clauses with respect to a base instance F .

■ **Algorithm 2** Generation of the random set L with resolution.

Input: Boolean formula F , integer w , probability $p \in (0, 1]$, Boolean *shuffle*

foreach $R \in \text{Res}_w^*(F) \setminus F$ **do**

 | **with probability** p **do** $L := L \cup \{R\}$

if *shuffle* **then return** $\text{Shuffle}(L)$ **else return** L ;

► **Definition 5.** Let F be a clause set, and w be a positive integer. We define the operator

$$\text{Res}_w(F) := F \cup \{R \mid R \text{ is a resolvent of two clauses in } F \text{ and } |R| \leq w\}.$$

Also, we inductively define $\text{Res}_w^0(F) := F$ and

$$\text{Res}_w^{n+1}(F) := \text{Res}_w(\text{Res}_w^n(F)), \text{ for } n \geq 0.$$

Finally, we set

$$\text{Res}_w^*(F) := \bigcup_{n \geq 0} \text{Res}_w^n(F).$$

4 Empirical Evaluation

4.1 Experimental Setup, Instance Types, and Solvers Used

Hoos and Stützle [18] introduced the concept of *runtime distribution* to characterize the cdf of Las Vegas algorithms, where the runtime can vary from one execution to another, even with the same input. To obtain enough data for a fitting of such a distribution, for each base instance F we created 5000 modified instances $F^{(1)}, \dots, F^{(5000)}$ by generating resolvent sets $L^{(1)}, \dots, L^{(5000)}$ each by using Algorithm 2 with $w = 4$ and a value of p such that the expected number of resolvents being added was $\frac{1}{10}|F|$. Note that we also conducted a series of experiments to rule out the influence of p on our results. Each of these modified instances was solved 100 times, each time using a different seed. For $i = 1, \dots, 5000$ and $j = 1, \dots, 100$ we thus obtained the values $\text{flips}_S(F^{(i)}, s_j)$ indicating how many flips were used to solve the modified instance $F^{(i)}$ with solver S when using the seed s_j . Next, we calculated the mean number of flips $\text{mean}_S(F^{(i)}) := \frac{1}{100} \sum_{j=1}^{100} \text{flips}_S(F^{(i)}, s_j)$ required to solve $F^{(i)}$ with solver S whose hardness distribution we are going to analyze.

All experiments were performed on bwUniCluster 2.0 and three local servers. Sputnik [39] was used to distribute the computation and to parallelize the trials. Due to the heterogeneity of the computer setup, measured runtimes are not directly comparable to each other. Consequently, we instead measured the number of variable flips performed by the SLS solver. This is a hardware-independent performance measure with the benefit that it can also be analyzed theoretically. To give an indication of how flips relate to wall-clock time, one million flips take about one second of computing time on one of our servers. To give an idea of the computational effort involved, obtaining the data for the ecdf of a 100 variable base instance with SRWA took an average of 17,193,517 seconds (≈ 199 days) when unparallelized. This clearly prohibited examining instances having a number of variables currently being routinely solved by the state-of-the-art SLS algorithms. For the experiments the following instance types were used:

1. **Hidden Solution:** We implemented the CDC algorithm [5, 6] in [24] to generate instances with a hidden solution. For this, at the beginning, a complete assignment α is specified to ensure the generated formula's satisfiability. Then, repeatedly a randomly generated clause C is added to the formula with a weighted probability p_i depending on the number i of correct literals in C with respect to α . We included this type of instances because SLS solvers struggle to solve such instances. Experiments like these might be beneficial to find theoretical reasons for this behavior.
2. **Hidden Solution With Different Chances:** We also created sets of formulas with different underlying p_i values to rule out the influence of these.
3. **Uniform Random:** To generate uniform, random k -SAT instances with n variables and m clauses, each clause is generated by sampling k literals uniformly and independently. Using Gableske's `kcnfgen` [14], we generated formulas with $n \in \{50, 60, 70, 80, 90\}$ variables and a clause-to-variable ratio r close to the *satisfiability threshold* [29] of $r \approx 4.267$. We checked each instance with `Glucose3` [2, 11] for satisfiability until we had 5 formulas of each size.
4. **Factoring:** These formulas encode the factoring problem in the interval $\{128, \dots, 256\}$ and were generated with [10].
5. **Coloring:** These formulas assert that a graph is colorable with 3 colors. We generated these formulas, using [21], over random graphs with n vertices and $m = 2.254n$ edges in expectation, which is slightly below the *non-colorability threshold* [20]. We obtained 32 satisfiable instances in 150 variables.

Our experiments investigated leading SLS solvers where the dominating component is based on the random walk procedure proposed in [36]. In this paper, Schöning’s Random Walk Algorithm **SRWA** was introduced, which is one of the solvers we used. The **probsAT** solver family [3] is based on this approach. One of these solvers won the random track of the SAT competition 2013 [4]. Another advancement of **SRWA** was implemented as **YALSAT** [7], which won the random track of the SAT competition 2017 [17]. These performances and similarities were reasons for choosing **SRWA**, **probsAT**, and **YALSAT** as SLS solvers for this paper. The connection to **GapSAT** [23] is another case in point.

We excluded the solvers **DCCAlm** [25] and **CSCCSat** [28] (combining **FrwCB** [26] and **DCCASat** [27]) as all of these depend on heuristics (like **CC**, **BM**, **CSDvars**, **NVDvars**, **SDvars**) that ultimately reduce the probabilistic nature when choosing the next variable to flip.

For **SRWA** we conducted most of our experiments: All instance types were tested, including different change values for the generation of the hidden solution. For **probsAT**, 55 hidden solution instances with $n \in \{50, 100, 150, 200, 300, 800\}$ were used. Since **YALSAT** can be regarded as a **probsAT** derivate, we tested **YALSAT** with 10 hidden solution instances with 300 variables each.

4.2 Experimental Results and Statistical Evaluation

The goal of this section is to explore the scenarios described above in more detail. We are particularly interested in how the hardness of an instance changes when logically equivalent clauses are added in the manner described above. To characterize this effect as accurately as possible, studying the ecdf is the most suitable method for this purpose. In turn, the ecdf can be described using well-known distribution types such as e.g., the normal distribution. In the following, we shall demonstrate that the three-parameter lognormal distribution, in particular, provides an exceptionally accurate description of the runtime behavior, and this is true for all considered problem domains and all solvers. The results are so compelling that we ultimately conjecture that the runtimes of **Alfa**-type algorithms all follow a lognormal distribution, regardless of the considered problem domain.

To illustrate this point, we first demonstrate our approach using two base instances. The first one is a factorization instance that was solved by **SRWA**. The second instance has a hidden solution and was solved by **probsAT**. For later reference, we refer to the first instance as *A* and to the second instance as *B*. As described above, we obtain 5000 samples for each base instance. Using these data points, we estimate the lognormal distribution’s three parameters by applying the maximum likelihood method (see [42]). After that, one can visually evaluate the suitability of the fitted lognormal distribution for describing the data. A useful method of visualizing the suitability is to plot the ecdf and the fitted cdf on the same graph.

Such a comparison is illustrated in Figure 1 for the two instances *A* and *B*. In both cases, no difference between the empirical data of the ecdf and the fitted distribution can be detected visually. In other words, the absolute error between the predicted probabilities from the fitted cdf versus the empirical probabilities from the ecdf is minuscule. Even though these are only two examples, it should be noted that these two instances are representative of the behavior of the investigated algorithms. Hardly any deviation could be observed in this plot type for all instances and all algorithms. All data is published under [42].

For the analysis, however, one should not confine oneself to this plot type. Although absolute errors can be observed easily, relative errors are more difficult to detect. Such a relative error may have a significant impact when used for decisions such as restarts. To illustrate this point, suppose that the true probability of a run of length ℓ is 0.0001. In contrast, the probability estimated based on a fit is 0.001. As can be seen, the absolute error

■ **Figure 1** The ecdf and fitted cdf of the hardness distribution of instance *A* (left) and *B* (right).

of 0.0009 is small, whereas the relative error of 10 is large. If one were to perform restarts after ℓ steps, the actual expected runtime would be ten times greater than the estimated expected runtime. Thus, the erroneous estimate of that probability would have translated into an unfavorable runtime. This example should illustrate the importance of checking the tails of a distribution for errors as well.

The left tail, i. e., the probabilities for very small values, can be checked visually by plotting the ecdf and fitted cdf with both axes logarithmically scaled. Thereby, the probabilities for extreme events (in this case, especially easy instances) can be measured accurately.

■ **Figure 2** Logarithmically scaled ecdf and fitted cdf of instances *A* (left) and *B* (right).

The two instances *A* and *B* are being examined in this manner in Figure 2. As can be observed, the lognormal fit accurately predicts the probabilities associated with very short runs. For the other instances, lognormal distributions were mostly also able to accurately describe the probabilities for short runs. However, the behavior of the ecdf and the fitted lognormal distribution differed very slightly in a few instances.

Lastly, the probabilities for particularly hard instances should also be checked. Any mistakes in this area could lead to underestimating the likelihood of encountering an exceptionally hard instance. For analyses of this type, the survival function S is a useful tool; if F is the cdf, $S(x) := 1 - F(x)$. Therefore, the survival function's value $S(x)$ represents the probability that an instance is (on average) harder than x in our case. If we plot the empirical survival function, i. e., $\hat{S}_n(x) := 1 - \hat{F}_n(x)$, and the fitted survival function together on a graph with logarithmically scaled axes, we can easily detect errors in the right tail.

■ **Figure 3** Logarithmically scaled empirical survival function and fitted survival function of instances *A* (left) and *B* (right).

Figure 3 illustrates this type of plot for the instances *A* and *B*. Here, there is a discernible deviation between *A* and *B*. While for *A*, the lognormal fit provides an accurate description of the probabilities for long runs, in the case of *B*, the empirical survival function seems to approach 0 somewhat slower than the lognormal estimate. In the vast majority of cases, these extreme value probabilities are accurately reflected by the lognormal fit. In most other cases, the empirical survival function approaches 0 more slowly than the lognormal fit. Thus, in these cases, the likelihood of encountering an exceptionally hard instance is underestimated.

So far, we discussed the behavior of lognormal fits based on this visual inspection. Altogether, we concluded that lognormal distributions seem to be well suited for describing the data. Next, we shall concretize this through a statistical test. To be more precise, we apply the χ^2 -test as a goodness-of-fit test for each base instance. For each such instance, the fitted lognormal distribution used the 5000 data points, and afterwards, the χ^2 -test statistic is computed. Subsequently, the probability that such a value of the test statistic occurs under the assumption of the so-called null hypothesis is determined. We will refer to this probability as the *p*-value. In our case, the null hypothesis is the assumption that the data follow a lognormal distribution. If the fit is poor, then a small *p*-value will occur. If *p* is sufficiently small, the null hypothesis is rejected. We reject the null hypothesis if $p < 0.05$.

Two more remarks are due on this matter. First, from a high *p*-value, one cannot prove that the assumption that the data are lognormally distributed is correct. However, we use a sufficiently high *p*-value as a heuristic whether this assumption is reasonable.

Secondly, there is an obstacle that complicates statistical analysis by this method. As described, each of the 5000 data points is obtained by first sampling 100 runtimes of the corresponding instance and then calculating the mean. This means that we do not work with the actual expected values but only estimates. In other words, this implies that our data is noisy. The greater the variance in the respective instance, the greater the corresponding noise. If one were to apply the χ^2 -test to this noisy data, some cases would be incorrectly rejected, especially if the variance is large. To overcome this limitation, we additionally use a bootstrap-test, which is based on Cheng [9]. This test is presented in Algorithm 3.

Briefly summarized, this test simulates how our data points were generated, assuming the null hypothesis. For this purpose, particular attention should be paid to how the test sample is rendered noisy. Owing to the central limit theorem, it is reasonable to assume that the initial data's sample mean originates from a normal distribution around the true expected value. We use this assumption in the bootstrap-test using a noise signal drawn from a normal distribution with expected value 0. The variance of this normal distribution is determined from the initial data and divided by 100 (cf. central limit theorem).

■ **Algorithm 3** Bootstrap-test for noisy data.

Input: (noisy) random sample $\mathbf{y} = (y_1, y_2, \dots, y_n)$, integer N , significance $\alpha \in (0, 1)$

$\hat{\theta} \leftarrow \text{MLE}(\mathbf{y}, F)$, lognormal maximum likelihood estimation, F is the lognormal cdf

$X^2 \leftarrow \text{ChiSquare}(\mathbf{y}, \hat{\theta})$, Chi-squared goodness of fit test statistic

for $j = 1$ **to** N **do**

$\mathbf{y}' \leftarrow (y'_1, \dots, y'_n)$, where all y'_i are i.i.d. samples from the fitted lognormal distribution with parameters $\hat{\theta}$

$\mathbf{y}' \leftarrow \mathbf{y}' + \text{noise}$, where noise is sampled from an n -dimensional normal distribution

$\hat{\theta}' \leftarrow \text{MLE}(\mathbf{y}', F)$

$X_j^2 \leftarrow \text{ChiSquare}(\mathbf{y}', \hat{\theta}')$

Let $X_{(1)}^2 \leq X_{(2)}^2 \leq \dots \leq X_{(N)}^2$ be the sorted test statistics.

if $X_{(\lfloor (1-\alpha) \cdot N \rfloor)}^2 < X^2$ **then** reject **else** accept;

If there is a large difference between the respective p -values of the χ^2 - and bootstrap-tests, this suggests that the variance in the initial data is too high and that the number of samples used to calculate the sample mean should be increased. However, this case has only occurred twice, and we explicitly indicate it later. In all other cases, the p -values of the χ^2 - and the bootstrap-tests were similar. To illustrate this point, let us consider the p -values of the two instances A and B . The excellent representation of the runtime behavior over the entire support on instance A is also reflected in the two p -values. Using the χ^2 -test, one obtains a p -value of approximately 0.783, and using the bootstrap-test, one obtains a p -value of 0.76. Since these two p -values are both above 0.05, we conclude that the assumption that lognormal distributions describe the runtimes is reasonable.

In contrast, for instance B , we observed that while a lognormal distribution accurately describes the main part of the distribution, the probabilities for extremely long runs are inadequately represented. This observation is again reflected in the respective p -values. The χ^2 -test yields a p -value of ≈ 0.008 , and the bootstrap-test yields a p -value of 0.013. Since both p -values are below 0.05, the assumption that these data originate from a lognormal distribution is rejected.

Overall, this example is intended to demonstrate that these two statistical tests can show an inadequate fit, even if the problems only arise for extreme values. Second, it should demonstrate that the p -values of the two tests are generally similar; if the p -values differ significantly, then more samples should be used to calculate the sample mean.

We now proceed by considering the adequacy of lognormal distributions for describing SRWA runtimes. The results of the statistical analysis are reported in Table 1 and can be found in [42].

■ **Table 1** Statistical goodness-of-fit results for Alfa+SRWA runtimes over various problem domains. The *rejected* row contains the number of instances where the lognormal distribution is not a good fit according to the χ^2 -test at a significance level of 0.05. To put these results into perspective, the second row contains the total number of instances of each domain. Out of a total of 230 instances, 5 got rejected.

	hidden	different chances	uniform	factoring	coloring	total
rejected	0	2	1	2	0	5
# of instances	20	120	25	33	32	230

The first line in the table represents for how many instances the statistical tests rejected the lognormal distribution hypothesis. The second line indicates how many instances have been checked in total. It should be noted that the same number of instances was rejected by the χ^2 -test as was by the bootstrap-test. Thus, there is no need to distinguish between the tests here. It should also be mentioned that in statistical tests, there is always a possibility that a hypothesis will be rejected even though the null hypothesis holds (type 1 error). At a significance level of 0.05, this probability is at the most 5%. Accordingly, the total of 5 rejected instances may be attributed to so-called type 1 errors. This statement is also supported by the fact that no exceptionally low p -value was observed, i. e., no p -value that is unusual for a total of 230 samples.

For **probSAT**, on the other hand, the situation appears to be different. The results are summarized in Table 2 and [42]. The columns refer to the number of variables in the

■ **Table 2** Goodness-of-fit results for **Alfa+probSAT** over various hidden solution instance sizes. The *rejected* row contains the number of instances where the lognormal distribution is not a good fit according to the χ^2 -test at a significance level of 0.05. To put these results into perspective, the second row contains the total number of instances of each instance size.

number of variables	50	100	150	200	300	800	total
rejected	2	2	1	0	2	0	7
# of instances	10	10	10	10	10	5	55

corresponding SAT instances. The number of rejected instances is again identical regardless of whether the χ^2 - or bootstrap-test is applied. As can be seen, the lognormal distribution hypothesis was rejected for 7 of the 55 instances. This number can no longer be accounted for by type 1 errors at a significance level of 0.05. However, one can observe that the majority of rejected instances occur for a small number of variables. If one were to consider only the instances from 150 variables onwards, then the remaining rejected instances may be attributed to type 1 errors. This raises the suspicion that there may be a limiting process, i. e., that the lognormal distribution hypothesis is only valid for $n \rightarrow \infty$.

Lastly, a difference between the two static tests emerges for **YALSAT**. According to the χ^2 -test, 2 of the total 10 instances are rejected. However, using the bootstrap-test, the lognormal distribution hypothesis is not rejected for any instance. Therefore, one cannot rule out the possibility that lognormal distributions are the natural model to describe the instances, but more experiments are required to make a more precise statement.

In summary, the presumption that lognormal distributions are the appropriate choice for describing runtimes has been reinforced for **SRWA**. For **probSAT**, this appears plausible at least above a certain instance size. Likewise, the choice of lognormal distributions also seems reasonable for **YALSAT**. These observations lead us to the following conjecture.

► **Conjecture 6** (Strong Conjecture). *The runtime of **Alfa** with $SLS \in \{\text{SRWA}, \text{probSAT}, \text{YalSAT}\}$ follows a lognormal distribution.*

If this statement is true, then it would be intriguing in that one can infer how modifying the base instance affects the hardness of instances. This effect is likely to be the result of generating models for lognormal distributions. Just as the normal distribution is a natural model for the sum of i. i. d. random variables, the lognormal distribution is a natural model for the multiplication of i. i. d. random variables. Thus, one can hypothesize that each added clause exerts a small multiplicative effect on the instance's hardness.

Simultaneously, the three parameters of the lognormal distribution also provide insight into how the hardness of the instance changes. For example, the location parameter γ implies an inherent problem hardness that cannot be decreased regardless of the added clauses'

choice. At the same time, γ also serves as a numerical description for the value of this intrinsic hardness. Using Bayesian statistics, it is possible to infer the parameters while the solver is running. These estimated parameters can, for example, be used to schedule restarts. This would lead to a scenario similar to that discussed in [34].

Conjecture 6 is a strong statement. However, a small deviation of the probabilities, for example, at the left tail, would render the strong conjecture invalid from a strict mathematical point of view. Particularly, visual analyses revealed that the left tail's behavior, i. e., for extremely short runs, is occasionally not accurately reflected by lognormal distributions. Conversely, the right tail, i. e., the probabilities for particularly long runs, are usually either correctly represented by lognormal distributions or, occasionally, the corresponding probability approaches 0 even more slowly. We, therefore, rephrase our conjecture in a weakened form. Our observations fit a class of distributions known as long-tail distributions defined purely in terms of their behavior at the right tail.

► **Definition 7** ([12]). *A positive, real-valued random variable X is long-tailed, if and only if*

$$\forall x \in \mathbb{R}^+ : \Pr[X > x] > 0 \quad \text{and} \quad \forall y \in \mathbb{R}^+ : \lim_{x \rightarrow \infty} \frac{\Pr[X > x + y]}{\Pr[X > x]} = 1.$$

► **Conjecture 8** (Weak Conjecture). *The runtime of **Alfa** with $SLS \in \{SRWA, probSAT, YaSAT\}$ follows a long-tailed distribution.*

It should be noted that lognormal distributions have the long-tail property [12, 30]. That is, if the Strong Conjecture holds, the Weak Conjecture is implied. The reverse is, however, not true. In the next section, we show an important consequence in case the Weak Conjecture holds.

5 Restarts Are Useful For Long-Tailed Distributions

If the Strong Conjecture holds, i. e., if the runtimes are lognormally distributed, then restarts are useful [22]. This section extends this result and mathematically proves that restarts are useful even if only the Weak Conjecture holds. This will be achieved by showing that restarts are useful for long-tailed distributions.

A condition for the usefulness of restarts, as defined in Definition 1, was proven in [22]. We will show the result using this theorem that is restated below.

► **Theorem 9** ([22]). *Let X be a positive, real-valued random variable having quantile function Q , then restarts are useful if and only if there is a quantile $p \in (0, 1)$ such that*

$$R(p, X) := (1 - p) \cdot \frac{Q(p)}{E[X]} + \frac{\int_0^p Q(u) du}{E[X]} < p.$$

Even if the quantile function and the expected value are unknown, $R(p, X)$ can be characterized for large values of p .

► **Lemma 10.** *Consider a positive, real-valued random variable X with pdf f and quantile function Q such that $E[X] < \infty$. Also, assume that the limit $\lim_{t \rightarrow \infty} t^2 \cdot f(t)$ exists. Then,*

$$\lim_{p \rightarrow 1} R(p, X) = \lim_{p \rightarrow 1} \left((1 - p) \cdot \frac{Q(p)}{E[X]} + \frac{\int_0^p Q(u) du}{E[X]} \right) = 1.$$

Proof. In the following, let F and f be the cdf and pdf of X , respectively. We start by specifying the derivative of Q with respect to p as a preliminary consideration. From $F = Q^{-1}$ and the application of the inverse function theorem [35] it follows:

$$Q'(p) := \frac{d}{dp} Q(p) = \frac{1}{f(Q(p))}. \quad (1)$$

As the first step in our proof, we consider the limiting value of the second summand of $R(p, X)$. This value can be determined by integration by substitution with $x = Q(u)$ followed by applying the change of variable method with $p = F(t)$:

$$\lim_{p \rightarrow 1} \frac{\int_0^p Q(u) du}{E[X]} = \lim_{p \rightarrow 1} \frac{\int_0^{Q(p)} x \cdot f(x) dx}{E[X]} = \lim_{t \rightarrow \infty} \frac{\int_0^t x \cdot f(x) dx}{E[X]} = 1.$$

The last equality holds because the numerator matches the definition of the expected value.

Next, we examine the limit of $(1-p)Q(p)/E[X]$. Since $\lim_{p \rightarrow 1}(1-p) = 0$, the limit of $(1-p) \cdot Q(p)/E[X]$ needs to be examined more closely. For this purpose, L'Hospital's rule is applied twice as well as the change of variable method with $p = F(t)$ is used in the following:

$$\lim_{p \rightarrow 1} (1-p) \cdot Q(p) = \lim_{p \rightarrow 1} Q(p)^2 \cdot f(Q(p)) = \lim_{t \rightarrow \infty} t^2 \cdot f(t).$$

It is well-known that if $\liminf_{t \rightarrow \infty} t^2 \cdot f(t) > 0$ were to hold, then the expected value $E[X]$ would be infinite (this statement is, for example, implicitly given in [12]). This would contradict the premise of the lemma; therefore, $\liminf_{t \rightarrow \infty} t^2 \cdot f(t) = 0$. Moreover, since, by assumption, $\lim_{t \rightarrow \infty} t^2 \cdot f(t)$ exists, we may conclude that

$$\lim_{t \rightarrow \infty} t^2 \cdot f(t) = \limsup_{t \rightarrow \infty} t^2 \cdot f(t) = \liminf_{t \rightarrow \infty} t^2 \cdot f(t) = 0. \quad \blacktriangleleft$$

A frequently used tool for the description of distributions is the hazard rate function.

► **Definition 11** ([31]). *Let X be a positive, real-valued random variable having cdf F and pdf f . The hazard rate function $r: \mathbb{R}^+ \rightarrow \mathbb{R}^+$ of X is given by*

$$r(t) := \frac{f(t)}{1 - F(t)}.$$

In particular, there is an interesting relationship between the long-tail property and the hazard rate function's behavior.

► **Lemma 12** ([30]). *Let X be a positive, real-valued random variable with hazard rate function r such that the limit $\lim_{t \rightarrow \infty} r(t)$ exists. Then, the following three statements are equivalent:*

1. X is long-tailed.
2. $\lim_{x \rightarrow \infty} \int_x^{x+y} r(t) dt = 0, \quad \forall y > 0.$
3. $\lim_{t \rightarrow \infty} r(t) = 0.$

Proof. The full length-version of this paper [41] contains a proof of this lemma since the manuscript [30] was still unpublished at the time of writing. ◀

With the help of these preliminary considerations, we are now ready to show that restarts are useful for long-tailed distributions.

► **Theorem 13.** *Consider a positive, long-tailed random variable X with continuous pdf f and hazard rate function r . Also assume that either $E[X] = \infty$ holds or the limits $\lim_{t \rightarrow \infty} r(t)$ and $\lim_{t \rightarrow \infty} t^2 \cdot f(t)$ both exist. In both cases, restarts are useful for X .*

Proof. Let F be the cdf and Q the quantile function of X . We begin with the case $E[X] = \infty$. According to Theorem 9, restarts are useful if and only if

$$(1-p) \cdot \frac{Q(p)}{E[X]} + \frac{1}{E[X]} \cdot \int_0^p Q(u) du < p$$

for some $p \in (0, 1)$. However, if the expected value $E[X]$ is infinite, then the left side of this inequality is zero and the inequality is obviously satisfied. Hence, the statement follows.

Secondly, we assume that $E[X] < \infty$ and that both $\lim_{t \rightarrow \infty} r(t)$ and $\lim_{t \rightarrow \infty} t^2 \cdot f(t)$ exist. Equation (1) can now be used to calculate the following derivative:

$$\frac{d}{dp} (R(p, X) - p) = \frac{d}{dp} \left((1-p) \cdot \frac{Q(p)}{E[X]} + \frac{\int_0^p Q(u) du}{E[X]} - p \right) = \frac{1-p}{E[X] \cdot f(Q(p))} - 1.$$

Consider the limit of this expression for $p \rightarrow 1$. Once again, the change of variable method is applied with $p = F(t)$, resulting in:

$$\lim_{p \rightarrow 1} \frac{1-p}{E[X] \cdot f(Q(p))} - 1 = \lim_{t \rightarrow \infty} \frac{1-F(t)}{E[X] \cdot f(t)} - 1 = \lim_{t \rightarrow \infty} \frac{1}{E[X] \cdot r(t)} - 1.$$

By assumption, X has a long-tail distribution and the limit of $\lim_{t \rightarrow \infty} r(t)$ exists. For this reason, $\lim_{t \rightarrow \infty} r(t) = 0$ follows as a result of Lemma 12. Furthermore, since $E[X] < \infty$ holds, we may conclude that

$$\lim_{p \rightarrow 1} \frac{1-p}{E[X] \cdot f(Q(p))} - 1 = \lim_{t \rightarrow \infty} \frac{1}{E[X] \cdot r(t)} - 1 = \infty. \quad (2)$$

The condition from Theorem 9 can be rephrased in such a way that restarts are useful if and only if $R(p, X) - p < 0$. According to Lemma 10, the left-hand side of this inequality approaches 0 for $p \rightarrow 1$. However, as has been shown in Equation (2), the derivative of $R(p, X) - p$ approaches infinity for $p \rightarrow 1$. These two observations imply that there is a $p \in (0, 1)$ satisfying $R(p, X) - p < 0$. Consequently, restarts are useful for X . ◀

It should be noted that the conditions of this theorem are not restrictive since all naturally occurring long-tail distributions satisfy these conditions (see also [30]).

► **Conjecture 14** (Corollary of the Weak Conjecture). *Restart are useful for Alfa with $SLS \in \{SRWA, probSAT, YaLSAT\}$.*

If Conjecture 8 is true, then this statement follows immediately by Theorem 13.

6 Conclusion

We have provided compelling evidence that the runtime of **Alfa** follows a long-tailed or lognormal distribution. According to [38], the usefulness of restarts is a necessary, however not a sufficient, condition to obtain super-linear speedups by parallelization. Since we have shown that the necessary condition is (presumably) satisfied, this immediately raises the question of whether super-linear speedups are obtained by parallelizing **Alfa**-type algorithms.

We additionally want to pose the question whether some of the Conjectures 6 or 8 can be theoretically proven. A first line of attack would be to analyze the special case of an solver like **SRWA** whose runtime was already theoretically analyzed.

The technique of analyzing the runtime distribution of **Alfa** could be further developed to help better understand the behavior of CDCL solvers. These kind of solvers heavily employ the technique of adding new clauses and deleting some clauses. This can be thought of as solving a new logically equivalent formula of the base instance.

Preliminary results on the solvers excluded for heuristic reasons seem to suggest that the **Alfa**-method forces the runtime of the base solver to exhibit a multimodal behavior. Thus, the lognormal distribution is not a good fit in this case. However, an initial visual inspection of the data indicates an even heavier tail.
