■ Contents

Preface	
<i>Petra Mutzel, Rasmus Pagh, and Grzegorz Herman</i>	0:xi
Program Committees	
.....	0:xiii
List of External Reviewers	
.....	0:xv

Invited Talks

Network Planning and Routing Problems over Time: Models, Complexity and Algorithms	
<i>Lukas Glomb, Benno Hoch, Frauke Liers, and Florian Rösel</i>	1:1–1:3
A User Friendly Power Tool for Deriving Online Learning Algorithms	
<i>Aaron Roth</i>	2:1–2:1

Regular Papers

Bi-Objective Search with Bi-Directional A*	
<i>Saman Ahmadi, Guido Tack, Daniel Harabor, and Philip Kilby</i>	3:1–3:15
A Unified Approach for All Pairs Approximate Shortest Paths in Weighted Undirected Graphs	
<i>Maor Akav and Liam Roditty</i>	4:1–4:18
The Voronoi Diagram of Rotating Rays With applications to Floodlight Illumination	
<i>Carlos Alegría, Ioannis Mantas, Evanthia Papadopoulou, Marko Savić, Hendrik Schrezenmaier, Carlos Seara, and Martin Suderland</i>	5:1–5:16
Parallel Computation of Combinatorial Symmetries	
<i>Markus Anders and Pascal Schweitzer</i>	6:1–6:18
Graph Connectivity and Single Element Recovery via Linear and OR Queries	
<i>Sepehr Assadi, Deeparnab Chakrabarty, and Sanjeev Khanna</i>	7:1–7:19
Fully Dynamic Set Cover via Hypergraph Maximal Matching: An Optimal Approximation Through a Local Approach	
<i>Sepehr Assadi and Shay Solomon</i>	8:1–8:18
The Randomized Competitive Ratio of Weighted k -Server Is at Least Exponential	
<i>Nikhil Ayyadevara and Ashish Chiplunkar</i>	9:1–9:11
Orienting (Hyper)graphs Under Explorable Stochastic Uncertainty	
<i>Euripidis Bampis, Christoph Dürr, Thomas Erlebach, Murilo Santos de Lima, Nicole Megow, and Jens Schlotter</i>	10:1–10:18
k -Distinct Branchings Admits a Polynomial Kernel	
<i>Jørgen Bang-Jensen, Kristine Vitting Klinkby, and Saket Saurabh</i>	11:1–11:15

29th Annual European Symposium on Algorithms (ESA 2021).

Editors: Petra Mutzel, Rasmus Pagh, and Grzegorz Herman

Leibniz International Proceedings in Informatics

Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Incremental Edge Orientation in Forests <i>Michael A. Bender, Tsvi Kopelowitz, William Kuszmaul, Ely Porat, and Clifford Stein</i>	12:1–12:18
k -Center Clustering with Outliers in the Sliding-Window Model <i>Mark de Berg, Morteza Monemizadeh, and Yu Zhong</i>	13:1–13:13
Incremental SCC Maintenance in Sparse Graphs <i>Aaron Bernstein, Aditi Dudeja, and Seth Pettie</i>	14:1–14:16
Lyndon Words Accelerate Suffix Sorting <i>Nico Bertram, Jonas Ellert, and Johannes Fischer</i>	15:1–15:13
Online Euclidean Spanners <i>Sujoy Bhore and Csaba D. Tóth</i>	16:1–16:19
Distant Representatives for Rectangles in the Plane <i>Therese Biedl, Anna Lubiw, Anurag Murty Naredla, Peter Dominik Ralbovsky, and Graeme Stroud</i>	17:1–17:18
Near-Optimal Deterministic Single-Source Distance Sensitivity Oracles <i>Davide Bilò, Sarel Cohen, Tobias Friedrich, and Martin Schirneck</i>	18:1–18:17
Synchronized Planarity with Applications to Constrained Planarity Problems <i>Thomas Bläsius, Simon D. Fink, and Ignaz Rutter</i>	19:1–19:14
Efficiently Approximating Vertex Cover on Scale-Free Networks with Underlying Hyperbolic Geometry <i>Thomas Bläsius, Tobias Friedrich, and Maximilian Katzmann</i>	20:1–20:15
Efficiently Computing Maximum Flows in Scale-Free Networks <i>Thomas Bläsius, Tobias Friedrich, and Christopher Weyand</i>	21:1–21:14
Asymptotically Optimal Welfare of Posted Pricing for Multiple Items with MHR Distributions <i>Alexander Braun, Matthias Buttkus, and Thomas Kesselheim</i>	22:1–22:16
Covert Computation in Staged Self-Assembly: Verification Is PSPACE-Complete <i>David Caballero, Timothy Gomez, Robert Schweller, and Tim Wylie</i>	23:1–23:18
An Instance-Optimal Algorithm for Bichromatic Rectangular Visibility <i>Jean Cardinal, Justin Dallant, and John Iacono</i>	24:1–24:14
Worst-Case Efficient Dynamic Geometric Independent Set <i>Jean Cardinal, John Iacono, and Grigorios Koumoutsos</i>	25:1–25:15
Balanced Crown Decomposition for Connectivity Constraints <i>Katrin Casel, Tobias Friedrich, Davis Issac, Aikaterini Niklanovits, and Ziena Zeif</i>	26:1–26:15
All-Pairs Shortest Paths for Real-Weighted Undirected Graphs with Small Additive Error <i>Timothy M. Chan</i>	27:1–27:9
Dynamic Colored Orthogonal Range Searching <i>Timothy M. Chan and Zhengcheng Huang</i>	28:1–28:13

ℓ_p -Norm Multiway Cut <i>Karthekeyan Chandrasekaran and Weihang Wang</i>	29:1–29:15
Faster Algorithms for Longest Common Substring <i>Panagiotis Charalampopoulos, Tomasz Kociumaka, Solon P. Pissis, and Jakub Radoszewski</i>	30:1–30:17
Feature Cross Search via Submodular Optimization <i>Lin Chen, Hossein Esfandiari, Gang Fu, Vahab S. Mirrokni, and Qian Yu</i>	31:1–31:16
An FPT Algorithm for the Embeddability of Graphs into Two-Dimensional Simplicial Complexes <i>Éric Colin de Verdière and Thomas Magnard</i>	32:1–32:17
Efficient Sequential and Parallel Algorithms for Multistage Stochastic Integer Programming Using Proximity <i>Jana Cslovjcek, Friedrich Eisenbrand, Michał Pilipczuk, Moritz Venzin, and Robert Weismantel</i>	33:1–33:14
Modular Counting of Subgraphs: Matchings, Matching-Splittable Graphs, and Paths <i>Radu Curticapean, Holger Dell, and Thore Husfeldt</i>	34:1–34:17
Minimum Common String Partition: Exact Algorithms <i>Marek Cygan, Alexander S. Kulikov, Ivan Mihajlin, Maksim Nikolaev, and Grigory Reznikov</i>	35:1–35:16
An Accelerated Newton–Dinkelbach Method and Its Application to Two Variables per Inequality Systems <i>Daniel Dadush, Zhuan Khye Koh, Bento Natura, and László A. Végh</i>	36:1–36:15
Faster 3-Coloring of Small-Diameter Graphs <i>Michał Dębski, Marta Piecyk, and Paweł Rzążewski</i>	37:1–37:15
Stability Yields Sublinear Time Algorithms for Geometric Optimization in Machine Learning <i>Hu Ding</i>	38:1–38:19
Data Structures Lower Bounds and Popular Conjectures <i>Pavel Dvořák, Michal Koucký, Karel Král, and Veronika Slívová</i>	39:1–39:15
Approximation Schemes for Bounded Distance Problems on Fractionally Treewidth-Fragile Graphs <i>Zdeněk Dvořák and Abhiruk Lahiri</i>	40:1–40:10
Modular and Submodular Optimization with Multiple Knapsack Constraints via Fractional Grouping <i>Yaron Fairstein, Ariel Kulik, and Hadas Shachnai</i>	41:1–41:16
Differentially Private Algorithms for Graphs Under Continual Observation <i>Hendrik Fichtenberger, Monika Henzinger, and Wolfgang Ost</i>	42:1–42:16
Experimental Comparison of PC-Trees and PQ-Trees <i>Simon D. Fink, Matthias Pfretzschner, and Ignaz Rutter</i>	43:1–43:13

Boundary-Sensitive Approach for Approximate Nearest-Neighbor Classification <i>Alejandro Flores-Velazco and David M. Mount</i>	44:1–44:15
Compression by Contracting Straight-Line Programs <i>Moses Ganardi</i>	45:1–45:16
Space Efficient Two-Dimensional Orthogonal Colored Range Counting <i>Younan Gao and Meng He</i>	46:1–46:17
Computing the 4-Edge-Connected Components of a Graph in Linear Time <i>Loukas Georgiadis, Giuseppe F. Italiano, and Evangelos Kosinas</i>	47:1–47:17
Deep Multilevel Graph Partitioning <i>Lars Gottesbüren, Tobias Heuer, Peter Sanders, Christian Schulz, and Daniel Seemaier</i>	48:1–48:17
Faster $(1 + \epsilon)$ -Approximation for Unsplittable Flow on a Path via Resource Augmentation and Back <i>Fabrizio Grandoni, Tobias Mömke, and Andreas Wiese</i>	49:1–49:15
Quantum Sub-Gaussian Mean Estimator <i>Yassine Hamoudi</i>	50:1–50:17
Improved Approximation Algorithms for Tverberg Partitions <i>Sariel Har-Peled and Timothy Zhou</i>	51:1–51:15
Near-Linear-Time, Optimal Vertex Cut Sparsifiers in Directed Acyclic Graphs <i>Zhiyang He, Jason Li, and Magnus Wahlström</i>	52:1–52:14
Closing the Gap for Single Resource Constraint Scheduling <i>Klaus Jansen and Malin Rau</i>	53:1–53:15
Certified Approximation Algorithms for the Fermat Point and n -Ellipses <i>Kolja Junginger, Ioannis Mantas, Evanthia Papadopoulou, Martin Suderland, and Chee Yap</i>	54:1–54:19
Parameterized Algorithms for Diverse Multistage Problems <i>Leon Kellerhals, Malte Renken, and Philipp Zschoche</i>	55:1–55:17
Fast and Space-Efficient Construction of AVL Grammars from the LZ77 Parsing <i>Domènec Kempa and Ben Langmead</i>	56:1–56:14
Convex Drawings of Hierarchical Graphs in Linear Time, with Applications to Planar Graph Morphing <i>Boris Klemz</i>	57:1–57:15
QCSP on Reflexive Tournaments <i>Benoît Larose, Petar Marković, Barnaby Martin, Daniël Paulusma, Siani Smith, and Stanislav Žitný</i>	58:1–58:15
Learnable and Instance-Robust Predictions for Online Matching, Flows and Load Balancing <i>Thomas Lavastida, Benjamin Moseley, R. Ravi, and Chenyang Xu</i>	59:1–59:17
Telescoping Filter: A Practical Adaptive Filter <i>David J. Lee, Samuel McCauley, Shikha Singh, and Max Stein</i>	60:1–60:18

Finding an Approximate Mode of a Kernel Density Estimate <i>Jasper C.H. Lee, Jerry Li, Christopher Musco, Jeff M. Phillips, and Wai Ming Tai</i>	61:1–61:19
An Efficient Reduction of a Gammoid to a Partition Matroid <i>Marilena Leichter, Benjamin Moseley, and Kirk Pruhs</i>	62:1–62:13
Efficient Algorithms for Least Square Piecewise Polynomial Regression <i>Daniel Lokshтанov, Subhash Suri, and Jie Xue</i>	63:1–63:15
Bidirectional String Anchors: A New String Sampling Mechanism <i>Grigorios Loukides and Solon P. Pissis</i>	64:1–64:21
The Visibility Center of a Simple Polygon <i>Anna Lubiw and Anurag Murty Naredla</i>	65:1–65:14
Extension of Additive Valuations to General Valuations on the Existence of EFX <i>Ryoga Mahara</i>	66:1–66:15
FPT and FPT-Approximation Algorithms for Unsplittable Flow on Trees <i>Tomás Martínez-Muñoz and Andreas Wiese</i>	67:1–67:15
A Simple Algorithm for Graph Reconstruction <i>Claire Mathieu and Hang Zhou</i>	68:1–68:18
Generalized Max-Flows and Min-Cuts in Simplicial Complexes <i>William Maxwell and Amir Nayyeri</i>	69:1–69:16
Hypersuccinct Trees – New Universal Tree Source Codes for Optimal Compressed Tree Data Structures and Range Minima <i>J. Ian Munro, Patrick K. Nicholson, Louisa Seelbach Benkner, and Sebastian Wild</i>	70:1–70:18
Determining 4-Edge-Connected Components in Linear Time <i>Wojciech Nadara, Mateusz Radecki, Marcin Smulewicz, and Marek Sokółowski</i>	71:1–71:15
Isomorphism Testing Parameterized by Genus and Beyond <i>Daniel Neuen</i>	72:1–72:18
Restricted t -Matchings via Half-Edges <i>Katarzyna Paluch and Mateusz Wasylkiewicz</i>	73:1–73:17
Beating Random Assignment for Approximating Quantum 2-Local Hamiltonian Problems <i>Ojas Parekh and Kevin Thompson</i>	74:1–74:18
Additive Sparsification of CSPs <i>Eden Pelleg and Stanislav Žitný</i>	75:1–75:15
Faster Deterministic Modular Subset Sum <i>Krzysztof Potępa</i>	76:1–76:16
Hardness of Detecting Abelian and Additive Square Factors in Strings <i>Jakub Radoszewski, Wojciech Rytter, Juliusz Straszynski, Tomasz Waleń, and Wiktor Zuba</i>	77:1–77:19

On Approximate Compressions for Connected Minor-Hitting Sets	
<i>M. S. Ramanujan</i>	78:1–78:16
Restricted Adaptivity in Stochastic Scheduling	
<i>Guillaume Sagnol and Daniel Schmidt genannt Waldschmidt</i>	79:1–79:14
A General Framework for Enumerating Equivalence Classes of Solutions	
<i>Yishu Wang, Arnaud Mary, Marie-France Sagot, and Blerina Sinimeri</i>	80:1–80:14
Engineering MultiQueues: Fast Relaxed Concurrent Priority Queues	
<i>Marvin Williams, Peter Sanders, and Roman Dementiev</i>	81:1–81:17
Evidence for Long-Tails in SLS Algorithms	
<i>Florian Wörz and Jan-Hendrik Lorenz</i>	82:1–82:16

Preface

This volume contains the extended abstracts selected for presentation at ESA 2021, the 29th European Symposium on Algorithms. The event was planned by an organizing committee from University of Lisbon, Portugal as part of ALGO 2021. Due to the COVID-19 pandemic, ALGO was organized as an on-line event, rather than as a physical or hybrid event as originally planned, September 6–8, 2021.

The scope of ESA includes original, high-quality, theoretical and applied research on algorithms and data structures. Since 2002, it has had two tracks: the Design and Analysis Track (Track A), intended for papers on the design and mathematical analysis of algorithms, and the Engineering and Applications Track (Track B), for submissions that also address real-world applications, engineering, and experimental analysis of algorithms. Information on past symposia, including locations and proceedings, is maintained at <http://esa-symposium.org>.

In response to the call for papers for ESA 2021, 320 papers were submitted, 274 for Track A and 46 for Track B (these are the counts after track changes and withdrawals). Paper selection was based on originality, technical quality, exposition quality, and relevance. Each paper received at least three reviews. The program committees selected 80 papers for inclusion in the program, 68 from track A and 12 from track B, yielding an acceptance rate of about 1/4 for both tracks.

The presentations of the accepted papers together with two invited talks resulted in a very exciting program. Frauke Liers presented recent work on the complexity of algorithms for network optimization tasks with a timing component, and Aaron Roth about a user-friendly framework for deriving online learning algorithms.

The European Association for Theoretical Computer Science (EATCS) sponsored best paper and best student paper awards. The best paper award for track A was given to Zhiyang He, Jason Li and Magnus Wahlström for the paper *Near-linear-time, Optimal Vertex Cut Sparsifiers in Directed Acyclic Graphs*. For track B, the best paper award was given to Simon D. Fink, Matthias Pfretzschner and Ignaz Rutter for the paper *Experimental Comparison of PC-Trees and PQ-Trees*. A submission was eligible for the best student paper award if all authors were doctoral, master, or bachelor students at the time of submission. The best student paper award for track A was given to Wojciech Nadara, Mateusz Radecki, Marcin Smulewicz and Marek Sokołowski for the paper *Determining 4-edge-connected Components in Linear Time*. For track B, the best student paper award was given to Florian Wörz and Jan-Hendrik Lorenz for the paper *Evidence for Long-Tails in SLS Algorithms*.

We wish to thank all the authors who submitted papers for consideration, the invited speakers, the members of the program committees for their hard work, and the nearly 500 external reviewers who assisted the program committees in the evaluation process. Special thanks go to the organizing committee, who helped us with the organization of the conference.

■ Program Committees

Track A (Design and Analysis) Program Committee

- Akanksha Agrawal, Indian Institute of Technology Madras
- Andrea Lincoln, University of California, Berkeley
- Andrew McGregor, University of Massachusetts, Amherst
- Asaf Levin, Technion - Israel Institute of Technology
- Benjamin Doerr, École Polytechnique
- Chaitanya Swamy, University of Waterloo
- Clément Canonne, University of Sydney
- Debarati Das, University of Copenhagen
- Édouard Bonnet, École normale supérieure de Lyon
- Elias Koutsoupas, University of Oxford
- Eric Price, University of Texas at Austin
- Frances Rosamond, University of Bergen
- Gautam Kamath, University of Waterloo
- Gonzalo Navarro, University of Chile
- Gramoz Goranci, University of Toronto
- Guy Kortsarz, Rutgers University
- Harald Räcke, Technical University Munich
- Huacheng Yu, Princeton University
- Ilan Reuven Cohen, Bar Ilan University
- Ilias Diakonikolas, University of Wisconsin, Madison
- Irina Kostitsyna, Eindhoven University of Technology
- Jakub Łącki, Google Research
- Jason Li, Carnegie Mellon University
- Jeff M. Phillips, University of Utah
- Johannes Fischer, Technical University of Dortmund
- Justin Thaler, Georgetown University
- Laxman Dhulipala, Massachusetts Institute of Technology
- Maarten Löffler, Utrecht University
- Marco Molinaro, Pontifical Catholic University of Rio de Janeiro
- Marvin Künnemann, Max Planck Institute for Informatics
- Melanie Schmidt, University of Cologne
- Michał Pilipczuk, University of Warsaw
- MohammadTaghi HajiAghayi, University of Maryland
- Naveen Garg, Indian Institute of Technology Delhi
- Omri Weinstein, Columbia University and Hebrew University
- Paloma T. Lima, University of Bergen
- Pierre Fraigniaud, Université de Paris and CNRS
- Ran Duan, Tsinghua University
- Rasmus Kyng, ETH Zurich
- Rasmus Pagh (Chair), University of Copenhagen
- Richard Peng, Georgia Institute of Technology and University of Waterloo
- Riko Jacob, IT University of Copenhagen
- Rossano Venturini, University of Pisa

29th Annual European Symposium on Algorithms (ESA 2021).

Editors: Petra Mutzel, Rasmus Pagh, and Grzegorz Herman

Leibniz International Proceedings in Informatics

Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

- Simon Apers, Université libre de Bruxelles and CWI Amsterdam
- Talya Eden, Massachusetts Institute of Technology
- Tobias Christiani, Norwegian University of Science and Technology
- Tobias Friedrich, Hasso Plattner Institute and University of Potsdam
- Yusuke Kobayashi, Kyoto University
- Zachary Friggstad, University of Alberta

Track B (Engineering and Applications) Program Committee

- Petra Berenbrink, University of Hamburg
- Therese Biedl, University of Waterloo
- Gerth Stølting Brodal, Aarhus University
- Sanjeeb Dash, IBM T. J. Watson Research Center
- Kathrin Hanauer, University of Vienna
- Susana Ladra, University of A Coruña
- Leo Liberti, CNRS & Institut Polytechnique de Paris
- Ivana Ljubic, ESSEC Business School of Paris
- Andrea Marino, University of Florence
- Henning Meyerhenke, Humboldt-Universität zu Berlin
- Petra Mutzel (Chair), University of Bonn
- Manuel Penschuck, Goethe University Frankfurt
- Cynthia Phillips, Sandia National Laboratories
- Liam Roditty, Bar-Ilan University
- Daniel Schmidt, University of Bonn
- Nodari Sitchinava, University of Hawaii at Manoa
- Blair D. Sullivan, University of Utah
- Yihan Sun, University of California, Riverside
- Christos Zaroliagis, University of Patras

Abstract

In this invited contribution for ESA 2021, we will study the complexity of and algorithms for network optimization tasks with a timing component. They occur, for example, in planning or routing problems that need to be solved repeatedly over time. Typically, already simplified versions of such problems are NP-hard. In addition, the instances typically are too large to be solved straight-forwardly on a time-expanded graph. After an introduction into the area, we state the problem of determining best possible non-stop trajectories in a network that are not allowed to cross at any point in time. For simplified settings, polynomial-time solution approaches are presented whereas already for restricted settings the problems are shown to be NP-hard. When moving to more complex and more realistic settings as they occur, for example, in determining non-stop disjoint trajectories for a set of aircraft, we present heuristic algorithms that adaptively refine coarse disjoint trajectories in the timing dimension. In order to be able to solve the non-stop disjoint trajectories problem over time, the method is integrated in a rolling-horizon algorithm. We present computational results for realistic settings. Motivated by the fact that rolling-horizon approaches are often applied in practice without knowledge on the quality of the obtained solutions, we study this problem from an abstract point of view. In fact, we more abstractly analyze the solution quality of general rolling-horizon algorithms for optimization tasks that show a timing component. We apply it to different planning problems. We end by pointing out some challenges and possibilities for future research.

1 Summary

In this contribution, we will introduce several network optimization tasks that contain a timing component. Such tasks often occur in planning or routing problems that need to be solved repeatedly over time. Already simplified such network optimization tasks are NP-hard. In addition, realistic instances are typically too large to be solved in an integrated fashion. On the other hand, straight-forward decomposition approaches typically lead to bad solution quality.

We first introduce the class of optimization problems that are considered here. We will then more concretely show complexity results for several settings together with algorithms and computational evaluations. We start by introducing the task of determining best possible non-stop trajectories in a network that are not allowed to cross at any point in time. For simplified settings, polynomial-time solution approaches are presented. Those settings include instances with unit traversal times on the line or grids and meshes, where all commodities have the same destination. For several only slightly more complicated settings the problems are shown to be NP-hard. For example, if time intervals to start the trajectories are given, the problem on the line is hard. On the mesh with arbitrary arc costs the problem is not fixed-parameter tractable in the number of commodities, even if traversal times are unit. More details can be found in [5].

We then move on to more complex and more realistic settings as they occur, for example, in determining non-stop disjoint trajectories for a set of aircraft [4, 7, 8]. We focus on the surroundings of airports where both the planning of conflict-free trajectories as well as the determination of runway schedules are crucial and challenging tasks. In current practice, the resulting continuous and discrete optimization problems are often solved sequentially. In this work, we develop an integrated optimization model for conflict-free multi-aircraft trajectory planning and runway scheduling. We use a space-time discretization and model conflict-free trajectories by an integer linear program that is designed to provide optimal, piecewise-linear reference trajectories and a runway scheduling for multiple aircraft. Even for moderately sized instances, a sufficiently detailed representation of 3D-airspace and time leads to huge models, which cannot be treated by current hard- and software. To overcome this issue, we develop an iterative adaptive-refinement algorithm. Starting from an optimal solution in a coarse discretization, the algorithm re-optimizes trajectories in a neighborhood of the current solution with a higher resolution. The method is integrated into a rolling-horizon approach. The latter repeatedly restricts trajectory determinations within a (sliding) time window. Computational results on realistic instances illustrate the computational efficiency of our approach.

The relevance of the rolling-horizon approach has been demonstrated by applying it to solve a large variety of practical optimization problems, e.g. as in [6] or [1]. Hence it is very interesting to know theoretical properties of the rolling-horizon approach, which have been investigated, e.g. in [2] or [9]. We complement these works in [3]. Hence, we analyze the solution quality of general rolling-horizon algorithms that are applied to multi-period optimization problems with a timing component.

We demonstrate that the solution quality of the standard rolling-horizon procedure can be arbitrarily low considering our general problem setting. We thus adapt the general rolling-horizon procedure such that statements on the quality of solutions obtained from adapted rolling-horizon algorithms can be made.

On the practical side, we present computational results on lot-sizing problems in production planning as well as on tail-assignment problems in aircraft management. The latter assigns available aircraft to specific flights in a best possible way. It can be shown that huge

instances can be solved quickly with an almost negligible loss in solution quality by only a few percent. We end by pointing out some challenges and possibilities for future research.

A User Friendly Power Tool for Deriving Online Learning Algorithms

Aaron Roth ✉

University of Pennsylvania, Philadelphia, PA, USA

Abstract

In this talk, we overview a simple and user friendly framework developed in [4] that can be used to derive online learning algorithms in a number of settings. In the core framework, at every round, an adaptive adversary introduces a new game, consisting of an action space for the learner, an action space for the adversary, and a vector valued objective function that is concave-convex in every coordinate. The learner and the adversary then play in this game. The learner’s goal is to play so as to minimize the maximum coordinate of the cumulative vector-valued loss. The resulting one-shot game is not concave-convex, and so the minimax theorem does not apply. Nevertheless we give a simple algorithm that can compete with the setting in which the adversary must announce their action first, with optimally diminishing regret.

We demonstrate the power of our simple framework by using it to derive optimal bounds and algorithms across a variety of domains. This includes no regret learning: we can recover optimal algorithms and bounds for minimizing external regret, internal regret, adaptive regret, multigroup regret, subsequence regret, and permutation regret in the sleeping experts setting. It also includes (multi)calibration [2] and related notions: we are able to recover recently derived algorithms and bounds for online adversarial multicalibration [1], mean conditioned moment multicalibration [3], and prediction interval multivalidity [1]. Finally we use it to derive a new variant of Blackwell’s Approachability Theorem, which we term “Fast Polytope Approachability”.

Abstract

Bi-objective search is a well-known algorithmic problem, concerned with finding a set of optimal solutions in a two-dimensional domain. This problem has a wide variety of applications such as planning in transport systems or optimal control in energy systems. Recently, bi-objective A*-based search (BOA*) has shown state-of-the-art performance in large networks. This paper develops a bi-directional and parallel variant of BOA*, enriched with several speed-up heuristics. Our experimental results on 1,000 benchmark cases show that our bi-directional A* algorithm for bi-objective search (BOBA*) can optimally solve all of the benchmark cases within the time limit, outperforming the state of the art BOA*, bi-objective Dijkstra and bi-directional bi-objective Dijkstra by an average runtime improvement of a factor of five over all of the benchmark instances.

1 Introduction

Bi-objective search aims at finding a set of non-dominated, Pareto-optimal solutions in a domain with two objectives [2]. It has a wide range of real-world applications, such as planning routes for maritime transportation based on both the fuel consumption and the total risk of the vehicle route [18], or energy efficient paths for electric vehicles with arrival time considerations [13]. When the underlying system is a network, the problem is finding a set of paths between two points that are not dominated by other solution paths.

A comparison of traditional approaches to the bi-objective one-to-all shortest path problem, such as the label correcting algorithm in [15], the label setting approach in [6], and the adaptation of a near shortest path procedure in [1], was presented in [11]. These label-based approaches have been extended in several recent papers. A generalisation of Dijkstra’s algorithm and its bi-directional counterpart (for the one-to-one variant) to the bi-objective problem was presented in [12] by utilising the pruning strategies of [5] to avoid

¹ Corresponding Author

expanding unpromising paths during the search. The results show that the state-of-the-art bi-objective Dijkstra algorithm can outperform the bounded label setting approach in [10] and the depth-first search-based *Pulse* algorithm in [5] on large-size instances.

Another recent work on point-to-point bi-objective search is the Bi-Objective A* search scheme (BOA*) in [17]. BOA* is a standard A* heuristic search that leverages the fast dominance checking procedure of [9] for multi-objective search. In contrast to eager dominance checking approaches, as in [12], BOA* lazily postpones dominance checking for newly generated nodes until their expansion. The experimental results in [17] on a set of large instances show that the efficient dominance checking helps BOA* to perform better than the bi-objective Dijkstra algorithm of [12] and other best-first search approaches such as the label-setting multi-objective search NAMOA* of [8] and its improved version with a dimensionality reduction technique called NAMOA*_{dr} [9].

In this paper, we present Bi-Objective Bi-directional A* (BOBA*), a bi-directional extension of the BOA* algorithm that is easy to parallelise, uses different objective orders and includes several new heuristics to speed up the search. Our experiments on a set of 1,000 large test cases from the literature show that BOBA* can solve all of the cases to optimality, outperforming the state-of-the-art algorithms in both runtime and memory requirement.

2 Background and Notation

For a directed bi-objective graph $G = (S, E)$ with a finite set of states S and a set of edges $E \subseteq S \times S$, the point-to-point bi-objective search problem is to find the set of Pareto-optimal solution paths from $start \in S$ to $goal \in S$ that are not dominated by any solution for both objectives. Every edge $e \in E$ has two non-negative attributes accessed via the cost function $\mathbf{cost} : E \rightarrow \mathbb{R}^+ \times \mathbb{R}^+$. A path is a sequence of states $s_i \in S$ with $i \in \{1, \dots, n\}$. The cost of path $p = \{s_1, s_2, s_3, \dots, s_n\}$ is then defined as the sum of corresponding attributes on all the edges constituting the path as $\mathbf{cost}(p) = \sum_{i=1}^{n-1} \mathbf{cost}(s_i, s_{i+1})$. Following the standard notation in the heuristic search literature, we define our search objects to be *nodes*. A node x is a tuple that contains a state $s(x) \in S$; a value $\mathbf{g}(x)$ which measures the cost of a concrete path from the *start* state to state $s(x)$; a value $\mathbf{f}(x)$ which is an estimate of the cost of a complete path from *start* to *goal* via $s(x)$; and a reference $parent(x)$ which indicates the parent of node x . We perform a systematic search by *expanding* nodes in best-first order. Each expansion operation *generates* a set of successor nodes, each denoted $Succ(s(x))$, which are added into an *Open* list. The *Open* list sorts the nodes according to their \mathbf{f} -values in an ascending order, for the purpose of further expansion.

As with other A*-based algorithms, we compute \mathbf{f} -values using a consistent and admissible heuristic function $\mathbf{h} : S \rightarrow \mathbb{R}^+ \times \mathbb{R}^+$ [7]. In other words, $\mathbf{f}(x) = \mathbf{g}(x) + \mathbf{h}(s)$ where $\mathbf{h}(s)$ is a lower bound on the cost of paths from state s to *goal*. Moreover, in bi-objective search, the cost function has two components which means that every (boldface) cost function is a tuple, eg. $\mathbf{f} = (f_1, f_2)$ or $\mathbf{h} = (h_1, h_2)$ and all operations are considered element-wise.

► **Definition 1.** A heuristic function \mathbf{h} is consistent if we have $\mathbf{h}(s) \leq \mathbf{cost}(s, t) + \mathbf{h}(t)$ for every edge $(s, t) \in E$. It is also admissible iff $\mathbf{h}(s) \leq \mathbf{cost}(p)$ for every $s \in S$ and the optimal path p from state s to the goal state.

► **Definition 2.** For every pair of nodes (x, y) associated with the same state $s(x) = s(y)$, node y is dominated by x if we have $g_1(x) < g_1(y)$ and $g_2(x) \leq g_2(y)$ or if we have $g_1(x) = g_1(y)$ and $g_2(x) < g_2(y)$. Node x weakly dominates y if $g_1(x) \leq g_1(y)$ and $g_2(x) \leq g_2(y)$.

Bi-objective A*. The Bi-Objective A* (BOA*) algorithm [17] first obtains its heuristic function h using two basic one-to-all searches on the reversed graph. BOA* can then establish lower bounds on the cost of complete paths or f -values using the admissible heuristic h . Although either of the two objectives can potentially play the key role in the bi-objective setting, standard BOA* usually chooses the first objective in the (f_1, f_2) order. The search then expands all the promising nodes based on their cost estimates so as to ensure the node with the lexicographically smallest f -value is explored first. The algorithm terminates when there is no node in *Open* while keeping all the non-dominated nodes associated with the *goal* state in the solution set *Sol*. The main steps of the standard BOA* algorithm can be found in Algorithm 2, scripted with normal line numbers (without asterisk *) in black.

► **Theorem 3.** *BOA* computes a set of cost-unique Pareto-optimal solution paths [17].*

BOA* utilises an efficient strategy to check nodes for their dominance, originally employed in [9] for multi-objective search. The idea is simple yet powerful. Let us assume A* explores the graph in the (f_1, f_2) order, that is, nodes are extracted based on their f_1 -value in order (with tie-breaking on f_2 -values). Meanwhile, x and y are two nodes associated with the same state or $s(x) = s(y)$ in the *Open* list where x is going to be expanded first, i.e., we have $f_1(x) \leq f_1(y)$. Since both nodes have used the same heuristic value as $h_1(s(x)) = h_1(s(y))$ to determine their cost estimate f_1 , we can conclude $g_1(x) \leq g_1(y)$. Therefore, the second node will be dominated by the first node if $g_2(x) \leq g_2(y)$ as shown in [9] in detail. BOA* takes advantage of this dimension reduction technique by systematically keeping track of the g_2 -value of the last non-dominated node using $g_2^{min}(s(x))$ via line 11 of Algorithm 2.

BOA* can also prune some of the dominated nodes during the expansion with a similar reasoning via line 28 of Algorithm 2. This is done by comparing the newly generated node of a state and the last expanded node of the state against their secondary costs g_2 . Furthermore, BOA* prunes unpromising nodes based on their cost estimate to the *goal* state, which is known as pruning by bound. Given $g_2^{min}(goal)$ as the upper bound of the secondary cost, partial paths will be pruned if the cost estimate of their complete paths to *goal* on g_2 is greater than that of the last solution already stored in $g_2^{min}(goal)$. Interested readers are referred to the standard BOA* algorithm in [17] for the detailed proof discussion.

Challenges. Lazy dominance checking in BOA* slows down the operations in the *Open* list and consumes more space. In contrast to the costly linear dominance checking approach where new nodes are checked against all of the previously generated nodes associated with a state before their insertion into the *Open* list, BOA* may add a node for which we have an unexpanded dominant node in *Open*. Thus, the search generates more nodes (using extra memory), and the *Open* list will inevitably be longer. Moreover, BOA* is only able to search the graph in one direction and with a specific objective ordering, whereas there can be cases with better performance on the reverse objective ordering as shown in [17]. Our preliminary experiments also reveal that searching backwards (from *goal* to *start*) may lead to significant improvements in the overall runtime. There are also some inefficiencies in BOA* which can be addressed with extra considerations. As an example, for the simple graph in Figure 2, BOA* needs to expand all intermediate states for each individual solution, despite the fact that some of them are not offering any alternative (non-dominated) path to *goal* (eg. s_2).

3 Bi-objective Bi-directional A* Search

Recent improvements in bi-directional heuristic search have introduced new techniques to reduce the number of necessary node expansions, such as Near-Optimal Bi-directional Search in [16] and Dynamic Vertex Cover Bi-directional Search in [14]. Given the single-objective

10 return  $Sol + Sol'$ 

```

nature of the conventional shortest path problem, none of the existing front-to-end or front-to-front algorithms can practically tackle the bi-objective shortest path problem without incorporating necessary modifications. Moreover, those algorithms are not necessarily efficient for the bi-objective search as obtaining the solutions' cost would no longer be possible in $O(1)$ time. In the conventional bi-objective setting where both searches work on the same objective, every state offers a set of non-dominated nodes (partial paths) in each direction, and handling frontier collisions (obtaining all of the complete *start-goal* joined paths of the state) would be an exhaustive process which can outweigh the speed-up achieved by expanding fewer nodes. Our preliminary experiments also confirmed that the conventional front-to-end bi-directional search with an efficient partial paths coupling approach can potentially generate fewer nodes but shows poor performance compared to the unidirectional search scheme BOA*.

We now present our contributions to the problem by explaining our Bi-Objective Bi-directional A* search (BOBA*). BOBA* employs two complementary (enhanced) unidirectional BOA* to search the solution space in both (forward and backward) directions with different objective orders $((f_1, f_2)$ and $(f_2, f_1))$. Therefore, since the algorithm does not perform partial paths coupling, we do not need to handle frontier collisions. In other words, each uni-directional BOA* is allowed to explore the entire graph towards the opposite end for each individual solution. The high level structure of BOBA* is given in Algorithm 1. BOBA* first obtains the preliminary heuristics and then performs two individual searches that explore the graph in both directions concurrently. The output will then be the aggregation of solutions found in each search routine. To avoid searching for the same cost-optimum paths in both directions, BOBA* always chooses different orders for each direction. Figure 1(Left) depicts the way Pareto-optimal solutions are found based on two searches in the two orders. Initial solutions (sol_{init}) at both ends are typically the minimum cost paths already obtained via the heuristic searches for each objective. These cost-optimum paths can also initialise the global upper bounds (ub_1, ub_2) needed by the pruning by bound strategies in BOA*. The upper bounds are updated (always decreasing) during the search every time a valid solution is found, and sol_{last} is the last solution for which we have had $f_1 < ub_1$ and $f_2 < ub_2$.

► **Definition 4.** For every state $s \in S$, $\mathbf{ub}(s)$ is the upper bound on **cost** of complementary paths from state s to goal, eg., $ub_1(s)$ denotes the upper bound on $cost_1$.

► **Definition 5.** A path/node/state x is invalid if its estimated costs $\mathbf{f}(x)$ are not in the search global upper bounds (ub_1, ub_2) , i.e., x is invalid if $f_1(x) \geq ub_1$ or $f_2(x) \geq ub_2$.

■ **Figure 1** Left: Objective orders, bounds and Pareto-optimal solutions. Right: Schematic of states outside or inside of upper bounds. State u is out of bounds for f_1 and will be discarded in f_2 search.

3.1 Preliminary Heuristics

BOBA* requires both lower and upper bounds on the costs of complementary paths for each direction via four individual searches. In each search, we calculate a state's upper bound to be the cost of the optimum path using the non-primary objective. For example, the optimum path to state s for the first objective sets both $h_1(s)$ and $ub_2(s)$ (here $ub_2(s)$ is the cost of the path using the second objective). BOA* traditionally uses two runs of Dijkstra's algorithm to initialise lower bounds. For difficult cases, this initialisation time is usually outweighed by the main search time, but there can be simple cases where the total time of these heuristic searches dominates the main search time, especially in large instances. As a more efficient initialisation approach, we replace Dijkstra's algorithm with cost-bounded A* (or cost-bounded Dijkstra without heuristics), as formally stated in Lemma 6 and shown in lines 2-6 of Algorithm 1.

► **Lemma 6.** *The preliminary A* search on f_1 (or f_2) can terminate before expanding a state with $f_1 > ub_1$ (or $f_2 > ub_2$).*

Proof. Assume that a forward BOA* is intended and, therefore, the corresponding heuristics (via two backward searches) are required. If we start with two simple backward A* searches (one for each objective), each optimum *start-goal* path gives us two bounds as $(h_1(s_{start}), ub_2(s_{start}))$ and $(h_2(s_{start}), ub_1(s_{start}))$. Now, given $h_1(s_{start})$ and $h_2(s_{start})$ as the global lower bounds on f_1 and f_2 -values respectively, we will have $f_1 \geq h_1(s_{start})$ and $f_2 \geq h_2(s_{start})$ for every *start-goal* path. Therefore, any state with a cost estimate of $f_1 > ub_1(s_{start})$ in the A* search on the first objective, and similarly $f_2 > ub_2(s_{start})$ in the search on the second objective, will be dominated by one of the optimum solutions. On the other hand, since A* expands states in an increasing order of f -values, each heuristic search can terminate early with the first out-of-bound state, guaranteeing that all paths via unexplored states are already dominated. ◀

Algorithm 1 shows the parallel computation of all necessary heuristics in BOBA* in two phases. In the first phase (lines 2-3), we can execute our cost-bounded A* using any admissible heuristic for the primary objective (f_1 or f_2) and with tie-breaking on the secondary objective (f_2 or f_1). Note that the upper bounds are unknown prior to the searches in phase one, i.e., we initially have $ub_1 = ub_2 = \infty$, but we can update our global upper bounds as soon as we establish the optimal solution in each search. The initialisation step of BOBA* can be further improved for the heuristic searches in the opposite direction in phase two (lines 5-6). Once the necessary heuristics in one direction have been obtained, the heuristic search

in the opposite direction can use the lower bounds obtained from the first round as more informed heuristics. That is, the second phase of our cost-bounded A* searches are normally executed faster. Moreover, the opposite search in the second round can take advantage of the reduced search space resulting from the first round, delivering better quality heuristics without needing to expand already invalidated (out-of-bound) states. Lemma 8 states this technique more formally.

► **Example 7.** State v in Figure 1 (right) is within the upper bound of both objectives and will be expanded in the opposite direction. However, state u is observed out of bounds for the first objective (but within the bound of the second objective) and will then be discarded if it is going to be expanded in the second round of our heuristic searches. Note that violating at least one objective's upper bound is enough to mark nodes (or states) invalid.

► **Lemma 8.** *In the preliminary A* search on f_1 (or f_2), states with an estimated cost of $f_2 > ub_2$ (or $f_1 > ub_1$) are not part of any solution path.*

Proof. States with $f_2 > ub_2$ are dominated by the optimum path obtained for the first objective. This means that unexplored states with an estimated cost of $f_2 > ub_2$ are all invalid. Therefore, the following search on f_1 can ignore expanding such states knowing that no non-dominated solution can be found via invalid states. The same reasoning is valid for the reverse order. ◀

3.2 Bi-directional Search

BOBA* performs two enhanced BOA* concurrently, one from each direction. Algorithm 2 shows the details of our first enhanced BOA* algorithm used in BOBA* (forward search in the (f_1, f_2) order). Lines scripted in black are from the standard BOA* and the red lines with an asterisk (*) next to line numbers are our proposed enhancements. To be consistent with the BOA* notation, we obtain the latest global upper bounds from g_{min} values, i.e., we have $g_2^{min}(s_{goal}) = ub_2$ and $g_1^{min}(s_{start}) = ub_1$. This is because the forward search on (f_1, f_2) updates $g_2^{min}(s_{goal})$ for every solution, whereas the backward search on (f_2, f_1) simultaneously updates $g_1^{min}(s_{start})$. We also add a pruning criterion to discard nodes violating the primary upper bound $g_1^{min}(s_{start})$ in line 29. To achieve the backward search, we simply reverse the search direction and the objective ordering. For example, instead of $g_2^{min}(s_{goal})$ and $h_1(s(x))$ in Algorithm 2 we will have $g_1^{min}(s_{start})$ and $h'_2(s(x))$ respectively (the backward search establishes its f -values using \mathbf{h}'). Note that each search has an independent *Open* list. Now we describe our contributions to the individual searches of BOBA* followed by their formal presentation in Lemmas 10-12.

Early solution update. This strategy allows the search to update the secondary upper bound and establish a tentative solution before reaching the *goal* state. This is done via line 17 of Algorithm 2 by coupling nodes with their complementary shortest path to *goal*. If the joined path is valid, the corresponding node is then temporarily added to the solution set knowing that solution nodes with a state other than s_{goal} (or $s(x) \neq s_{goal}$) must be joined with their complementary shortest path. This strategy can be further improved by not expanding nodes for which we have a unique non-dominated complementary path. This heuristic is incorporated in line 22 and is formalised in Lemma 10.

Secondary heuristic tuning. Bi-directional search provides our algorithm with a great opportunity to further improve the quality of the preliminary heuristics. Since the main search of BOBA* has more information about non-dominated paths to states and constantly updates upper bounds, there can be more outliers that our preliminary heuristic searches are

■ **Algorithm 2** Enhanced forward Bi-Objective A* (BOA*_{enh}) in (f_1, f_2) objective ordering.

Inputs: A problem instance $(G, \mathbf{cost}, s_{start}, s_{goal})$ and heuristics $(\mathbf{h}, \mathbf{ub}, \mathbf{h}')$
Output: A set of cost-unique Pareto-optimal solutions

```

1  $Open \leftarrow \emptyset, Sol \leftarrow \emptyset$

27     $\mathbf{parent}(y) \leftarrow x$ 
28    if  $g_2(y) \geq g_2^{min}(t)$  or  $f_2(y) \geq g_2^{min}(s_{goal})$  then continue
29*    if  $f_1 \geq g_1^{min}(s_{start})$  then continue
30    Add  $y$  to  $Open$ 
31 return  $Sol$ 

```

not aware of. Therefore, benefiting from the main property of BOA* (finding non-dominated nodes in order), we can tune our findings over the preliminary searches and empower the pruning by bound strategy of the concurrent search in the opposite direction. This tuning is done in $O(1)$ time by updating the secondary heuristics of the reverse direction via line 10 of Algorithm 2. Note that h'_1 denotes the secondary heuristic in the backward search where BOBA* uses f_2 as its primary cost. We discuss the correctness of this technique in Lemma 12.

► **Example 9.** We explain these strategies by just running the forward search of BOBA* for the graph in Figure 2 and iterations in Table 2. In the first iteration, the forward search explores the node associated with the start state s_s . Since the primary (heuristic) cost-optimum path from s_s is initially valid, the search immediately updates its secondary upper bound via the early solution update strategy by setting $g_2^{min}(s_g) = 6$ and adds the node into the Sol set with costs $(4, 6)$. During the s_s expansion, we notice that the extended path for state s_1 is invalid ($f_2(y) \geq g_2^{min}(s_g)$ or $3 + 3 \geq 6$). Therefore, the partial path to s_1 is pruned meaning that s_2 is no longer reachable via its primary cost optimum path. Nodes generated for states s_2 and s_3 , however, are successfully added to $Open$. In the second iteration, the algorithm picks the node associated with s_2 (with higher priority). Now, since this is the first time we see s_2 being expanded, and since future visits will always have higher costs (via s_3 with $g_1 = 5$ for example), we can update the lower bound of reaching

It.	Open list ($s(x)$, $\mathbf{g}(x)$, $\mathbf{f}(x)$)	Sol found	Update $g_2^{min}(s_g)$

■ **Figure 2** Left: An example graph with **cost** on the edges, and with (state, **h**, **ub**) inside the nodes. Right: Status of the *Open* list, new solution (*Sol*) and secondary upper bound $g_2^{min}(s_g)$ in every iteration (It.) for the forward search on the (f_1, f_2) ordering. Symbol \uparrow beside nodes denotes the expanded min-cost node. The second table shows the status of the parent arrays of the states when the search terminates.

s_2 from s_s knowing that all possible shorter paths have already been invalidated. This is done by updating $h'_1(s_2) = 3$. Note that from the preliminary heuristics, we already had $h'_1(s_2) = 2$ (lower bound from s_s to s_2). After this update, the backward search would have better quality secondary lower bounds and can effectively prune more nodes (the backward primary heuristic is h'_2). We skip the backward search for now and continue with our forward expansions. As coupling the node (associated with s_2) with its (complementary) primary cost-optimum path yields a valid complete path, the search updates its secondary upper bound and temporarily adds the node to the *Sol* set with costs (5, 5). The search also skips expanding s_2 as it does not offer any non-dominated path to s_g . In the third iteration, the node associated with state s_3 is picked. This time, s_3 is expanded since coupling does not yield valid path. During the s_3 expansion, the search finds s_g invalid but adds s_2 into *Open*. In the fourth iteration, the node associated with s_2 is the only node in *Open* which reveals the final solution with costs (7, 3), again with the early solution update strategy. This last solution also verifies that the temporary solution found in the second iteration is now a valid non-dominated solution, since the primary cost of the last solution is larger than that of the second solution ($5 < 7$).

Now we formally prove the correctness of the presented techniques as follows.

► **Lemma 10.** *At every iteration, if $g_2(x) + ub_2(s(x)) < g_2^{min}(s_{goal})$, the next solution has a primary cost of $f_1(x)$ and a secondary cost of at most $g_2(x) + ub_2(s(x))$. Node x is also a terminal node if $h_1(s(x)) = ub_1(s(x))$.*

Proof. If the joined path is valid (its secondary cost is within the bounds), expanding nodes on the complementary shortest path will definitely navigate us to s_{goal} with a valid secondary cost as they offer the same f_1 -value. This means we can efficiently update the secondary upper bound earlier assuming that a potential solution path is already established. Therefore, valid joined paths determine the primary cost f_1 of the next solution along with setting a new upper bound for the secondary cost f_2 . Furthermore, given the secondary cost as a tie-breaker in the preliminary heuristic searches, states with $h_1(s(x)) = ub_1(s(x))$ would only offer one complementary path optimum for both objectives. As none of the states on the

complementary path would offer an alternative non-dominated path to s_{goal} , the search can save time by not expanding such terminal nodes. Therefore, nodes with $h_1(s(x)) = ub_1(s(x))$ are terminal nodes if they appear on any solution path. ◀

The early solution update strategy above guarantees that the primary cost f_1 of the next solution is determined by the joined path, but this does not apply to its secondary cost. E.g., we might see two consecutive temporary solutions with the same f_1 -value but different (sequentially) valid secondary costs. Therefore, the search needs to make sure that the previously added solution is not dominated by the next potential solution, and if it is dominated, it must be removed from the non-dominated solution set Sol . We address this matter in $O(1)$ time by checking our last (temporary) solution against new solutions for dominance as shown in lines 13-14 and 19-20 of Algorithm 2. This pruning is formally stated in the following Lemma 11.

► **Lemma 11.** *Given z and x as the last and new temporary solution nodes respectively, node z represents a non-dominated solution if $f_1(z) < f_1(x)$. The temporary solution node z is dominated by x if $f_1(z) = f_1(x)$.*

Proof. Since the secondary cost of the new solution x is already checked to be smaller than that of the last solution z stored in $g_2^{min}(s_{goal})$, we have $f_2(x) < g_2^{min}(s_{goal})$ if $s(x) = s_{goal}$ or $g_2(x) + ub_2(s(x)) < g_2^{min}(s_{goal})$ if $s(x) \neq s_{goal}$. On the other hand, since x is the new potential solution and the search explores nodes in an increasing order of f_1 -values, we must have $f_1(z) \leq f_1(x)$. Therefore, if $f_1(z) < f_1(x)$, we can see that the temporary solution z is now a non-dominated solution. Otherwise, if $f_1(z) = f_1(x)$, the last solution z is dominated by the new solution x because the new solution offers a lower secondary cost. ◀

We now show the correctness of the heuristic tuning approach in BOBA*.

► **Lemma 12.** *The secondary heuristic tuning maintains the correctness of A^* heuristics.*

Proof. BOBA* expands partial paths in the increasing order of f -values. This means the first expanded node of every state is guaranteed to have the minimum valid primary cost g_1 in each search direction, and all of the following valid nodes will have a larger primary cost. Moreover, since BOBA* uses different objective ordering for its searches, updated lower bounds in one direction represent the secondary heuristics of the other direction. Therefore, we can guarantee that the updated secondary heuristic is still admissible as there will not be any min-cost path to states better than what their first expanded node presents. Furthermore, the tuning strategy only updates the secondary heuristics of the opposite search, i.e., $h'_1(s(x))$ in the forward and $h_2(s(x))$ in the backward search. Therefore, the preliminary primary heuristics $h_1(s(x))$ and $h'_2(s(x))$ are unchanged and the A^* searches are correct. ◀

Considering the correctness of the enhancements presented above, we now show the correctness of our BOBA* algorithm.

► **Theorem 13.** *BOBA* returns a set of cost-unique non-dominated solution paths.*

Proof. BOBA* executes two enhanced BOA* searches concurrently, each capable of finding all of the solutions. Therefore, we just need to show the correctness of the stopping criteria. Each (enhanced) BOA* searches the primary objective's domain in the increasing order of f -values and continually shrinks the secondary objective's domain every time a valid solution is found. Furthermore, since BOBA* shares the upper bounds between its searches, each search can terminate with the first node violating the main objective's upper bound (and

consequently other unexplored nodes with larger f -values in *Open*) knowing that the rest of the objective's domain has already been investigated by the concurrent search (see Figure 1). Therefore, the aggregation of the solutions found in each search yields a complete set of cost-unique non-dominated solutions. ◀

4 Practical Considerations

As BOA* enumerates all non-dominated paths, the size of *Open* can grow exponentially over the course of search. Furthermore, the huge number of nodes in difficult cases may result in major memory issues. For instance, for one particular case in our experiments BOA* generates two billion nodes. We now present two techniques to handle search nodes more efficiently.

More efficient *Open* list. To achieve faster operations in our *Open* lists, since the lower and upper bounds on the f -values of the nodes in BOBA* are known prior to its main searches, we replace the conventional heap-based lists with fixed-size bucket lists without tie-breaking [3]. In contrast to other problems where the bucket list is regularly resized and the list is sparsely populated, for the significant number of (cost-bounded) nodes in our problem we expect to see almost all of the buckets filled. Note that the search may also expand dominated nodes if they are not extracted in a lexicographical order (i.e., nodes are sorted based on their primary cost only), but BOBA* can still obtain cost-unique solutions via the dominance checks incorporated in lines 13-14 and 19-20 of Algorithm 2 as formally stated in the following Lemma 14.

► **Lemma 14.** *BOBA* is able to obtain cost-unique solutions even without tie-breaking in its *Open* lists.*

Proof. Let z and x be two solution nodes where $f_1(z) = f_1(x)$ and z is dominated by x . Without any tie-breaking, the search may temporarily add dominated node z to the solution set first. In the next iterations, when x is extracted, the search performs a quick dominance check by comparing the f_1 -value of the new node x against that of the previous solution z and substitutes the dominated solution with the new solution x if $f_1(z) = f_1(x)$, as already shown in the early solution update strategy and Lemma 11 in detail. Therefore, BOBA* computes cost-unique non-dominated solutions even without tie-breaking. ◀

Memory efficient backtracking. Creating nodes is necessary to appropriately navigate the search to valid solution paths. Each new node occupies a constant amount of memory and conventionally contains essential information about paths such as costs and also back-pointers for solution path construction. Considering the difficulty of the problem and the significant number of generated nodes, we suggest a more memory efficient approach for the solution path construction in BOBA*. Since BOBA* only expands nodes once, we propose to recycle the memory used to store heavy processed nodes, while storing their backtracking information in other compact data structures. This technique results in a major reduction in memory use as part of the nodes' information would no longer be required for backtracking. We explain our compact approach using an example from Figure 2. Assume that in the second iteration of the algorithm, we want to store the backtracking information of the node corresponding to s_2 with s_s as the parent state. To this end, we keep two (initially empty) dynamic arrays for each state: one to store the parent state of the node `par_state`, and another to look up the corresponding path index in the parent state `par_path_id`. For our example, since the first

path to s_2 is derived from the first non-dominated path of s_s , we store this sequence in s_2 as `par_state[1]= s_s` and `par_path_id[1]=1`. Similarly, for the second expansion of s_2 with s_3 as the parent in the fourth iteration, we update s_2 arrays, this time with `par_state[2]= s_3` and `par_path_id[2]=1`. Figure 2 also shows the situation of our parent arrays when the forward search terminates. As a further optimisation, we can store the index of incoming edges (which are usually very small integers) instead of parent states. We will investigate the impacts of this compression on memory usage in the following section.

5 Empirical Study and Analysis

We compare our BOBA* with recent algorithms designed for the bi-objective search problem. The selected algorithms are the bi-objective variants of Dijkstra’s algorithm (Dij) and bi-directional Dijkstra (Bi-Dij) from [12], and bi-objective A* (BOA*) from [17]. We use all seven benchmark instances of [12] which include 700 random *start-goal* pairs from the large road networks in the 9th DIMACS challenge [4] with (*distance*, *time*) as objectives. To further challenge the algorithms, we used the competition’s random pair generator to design an additional set of 300 test-cases for the larger networks in the DIMACS instances: E, W and CTR (100 cases each) with up to 15 M nodes and 33 M edges. The details of the instances can be found in [4].

Implementation. We implemented our BOBA* algorithms based on a parallel framework using two cores in C++ and used the C implementations of the Dij, Bi-Dij and BOA* algorithms kindly provided to us by their authors. We also fixed the scalability and tie-breaking issues in the standard BOA* algorithm before running the experiments. All code was compiled with O3 optimisation settings using the GCC7.4 compiler. Our codes are publicly available². We ran the 1,000 experiments on an Intel Xeon E5-2660V3 processor running at 2.6 GHz and with 128 GB of RAM, under the SUSE Linux 12.4 environment and with a one-hour timeout.

BOA* analysis. The search in BOA* can be performed in different directions and objective orders, resulting in four variants. We also consider the virtual best version of the four, called BOA*_{best} (essentially assuming an oracle that could select the best variant). Figure 3 is a cactus plot comparing the performance of all BOA* variants including the virtual best, showing how many instances can be solved in a given time (the plot only shows the longest running 300 instances). Backward BOA* in the (f_1, f_2) order (in green) is the weakest variant, but the other variants perform quite similarly, and it is difficult to declare a clear winner. The performance of the virtual variant BOA*_{best} shows that an ideally-tuned BOA* can be up to two times better than its standard version on average, but is still unable to solve 15 cases to optimality within the time limit (see Table 2).

Memory. We investigate the impact of our compact approach for the solution paths construction in BOBA*. Table 1 compares the memory usage of our proposed compact approach against the conventional backtracking approach on part of the benchmark instances. In order to measure the overall space requirement of the main search, we ignore the memory required for graph construction, shared libraries and heuristics, allocated prior to the search. The results show that BOBA* can solve all of the instances with both approaches within

² <https://bitbucket.org/s-ahmadi>

the time limit, but the compact approach runs slightly faster and is five times more efficient on average in terms of memory. For the most difficult case in the experiments, the required memory of the compact approach can be as low as 21 GB (allocating 15M nodes with recycling) where the conventional approach needs 96 GB (allocating 1B nodes). Note that both approaches nearly expand the same number of nodes to solve the cases to optimality.

BOBA* performance. We compare the performance of our parallel BOBA* algorithm with the state-of-the-art Dij, Bi-Dij and BOA* algorithms from the literature. Table 2 shows the summary of experimental results for the 100 cases of each instance. For unsolved cases, we generously assume a runtime of one hour (the timeout). We also report the average memory usage of the main search of each algorithm over solved cases, ignoring the space allocated for their initialisation phase. The results in Table 2 show that the standard BOA* algorithm runs faster, needs less memory compared to both Dij and Bi-Dij algorithms and solves more instances. However, our new BOBA* outperforms BOA* in all of the instances, showing an (arithmetic) average speed up of 16 over all of the individual cases. For the average runtime of all instances, BOBA* is around five times faster than BOA*. We also compare the algorithms' performance over the solved instances for both CPU time and memory usage in Figure 4. As shown for both metrics, BOBA* delivers superior performance to its competitors by solving all of the instances to optimality within the time limit and with a maximum memory usage of 21 GB, compared to the nearly full (128 GB) memory usage of other algorithms in difficult instances. BOBA* also shows a massive speed up in the easy cases due to its efficient initialisation phase. It can solve 282 cases before BOA* solves its easiest case. Moreover, the figure shows that BOBA* completes the task eight times more efficiently in terms of memory than BOA* on average. Note that because of the difficulties in reporting the memory usage, we allow 1 MB tolerance in our experiments.

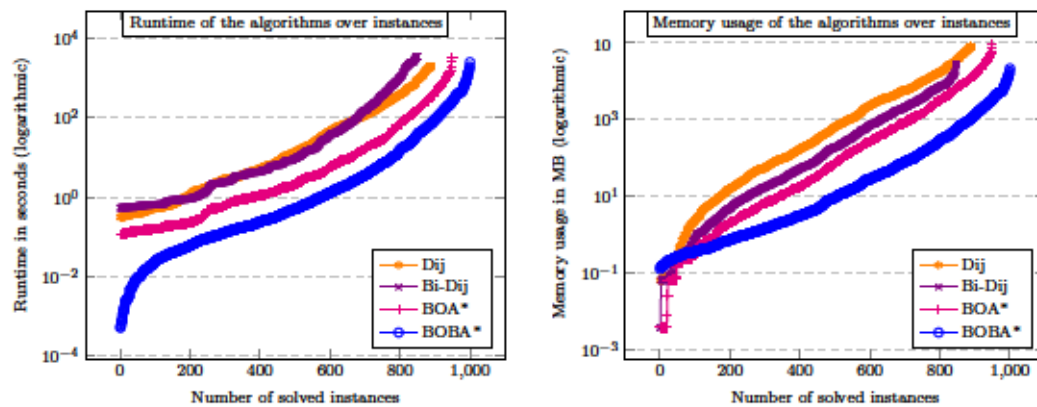

Multi-threading. We investigate the impact of multi-threading in BOBA* by running the (unmodified) algorithm on a single core instead of two cores, allowing decisions on scheduling of the threads to be made by the operating system. We compare single-core BOBA*_{1c} with the virtual best variant BOA*_{best} and our BOBA* with two cores in Table 2. The results show a slowdown of around 1.8 compared to parallel BOBA*, but it still outperforms

BOA*_{best}, solving more instances and showing an (arithmetic) average speed-up of six over all of the individual cases. Note that this virtual best version BOA*_{best} does not exist, and the results are based on the best timings obtained via four individual runs of the standard BOA* algorithm.

Enhanced BOA*. To measure the contributions of our improvements to the uni-directional bi-objective search, we analyse the performance of the enhanced variant BOA*_{enh} with the speed-up techniques above. This variant is obtained by switching off the backward search of BOBA*. Based on the results given in Table 2, BOA*_{enh} outperforms BOA*_{best} in almost all of the cases and shows a comparable performance to BOBA*_{1c}, solving a few more cases in the CTR map and using less memory on average. Comparing the maximum runtime over instances, we can see that BOBA*_{1c} is faster than BOA*_{enh} in half of the instances (maps NY, BAY, COL, FLA and CAL). Nonetheless, given the results in Table 2, BOBA* is still superior to BOA*_{enh} showing a speed-up factor of 1.5 on average.

■ **Figure 4** Cactus plots of algorithms' performance. Left: Runtime. Right: Search memory usage.

Bucket vs. heap. We found BOBA* with the bucket-based *Open* list around 1.8 times faster than BOBA* with heap for the same set of instances on average. Nonetheless, BOBA* with heap is still 2.2 times faster than standard heap-based BOA* (average over instances).

6 Conclusion

This paper introduced BOBA*, a bi-directional version of the state-of-the-art BOA* algorithm for bi-objective search. Our new algorithm explores the graph from both (forward and backward) directions in different objective orders in parallel. We enrich BOBA* with more efficient approaches for both the initial heuristic procedure and the solution path construction. We also present several speed up strategies to enhance BOBA*'s searches in various scenarios. Our experiments show that BOBA* outperforms the state-of-the-art algorithms in both runtime and memory use, solving all of the 1,000 benchmark cases to optimality in one hour timeout. Furthermore, compared to BOA*, BOBA* is five times faster and needs eight times less memory on average. Additional experiments reveal that the single-core version of BOBA* is around 1.8 times slower than the parallel version but still superior to the virtual best variant of BOA* and shows a comparable performance to BOA* enhanced with the speed-up strategies of this study.

A Unified Approach for All Pairs Approximate Shortest Paths in Weighted Undirected Graphs

Maor Akav ✉

Liam Roditty ✉

Bar-Ilan University, Ramat Gan, Israel

Abstract

Let $G = (V, E)$ be a weighted undirected graph with n vertices and m edges, and let $d_G(u, v)$ be the length of the shortest path between u and v in G . In this paper we present a unified approach for obtaining algorithms for all pairs approximate shortest paths in weighted undirected graphs. For every integer $k \geq 2$ we show that there is an $\tilde{O}(n^2 + kn^{2-3/k}m^{2/k})$ expected running time algorithm that computes a matrix M such that for every $u, v \in V$:

$$d_G(u, v) \leq M[u, v] \leq (2 + \frac{k-2}{k})d_G(u, v).$$

Previous algorithms obtained only specific approximation factors. Baswana and Kavitha [FOCS 2006, SICOMP 2010] presented a 2-approximation algorithm with expected running time of $\tilde{O}(n^2 + m\sqrt{n})$ and a $7/3$ -approximation algorithm with expected running time of $\tilde{O}(n^2 + m^{2/3}n)$. Their results improved upon the results of Cohen and Zwick [SODA 1997, JoA 2001] for graphs with $m = o(n^2)$. Kavitha [FSTTCS 2007, Algorithmica 2012] presented a $5/2$ -approximation algorithm with expected running time of $\tilde{O}(n^{9/4})$.

For $k = 2$ and $k = 3$ our result gives the algorithms of Baswana and Kavitha. For $k = 4$, we get a $5/2$ -approximation algorithm with $\tilde{O}(n^{5/4}m^{1/2})$ expected running time. This improves upon the running time of $\tilde{O}(n^{9/4})$ due to Kavitha, when $m = o(n^2)$.

Our unified approach reveals that all previous algorithms are a part of a family of algorithms that exhibit a smooth tradeoff between approximation of 2 and 3, and are not sporadic unrelated results. Moreover, our new algorithm uses, among other ideas, the celebrated approximate distance oracles of Thorup and Zwick [STOC 2001, JACM 2005] in a non standard way, which we believe is of independent interest, due to their extensive usage in a variety of applications.

1 Introduction

Computing All Pairs of Shortest Paths (APSP) is one of the most fundamental problems in Computer Science. The fastest known algorithms for APSP in weighted graphs run in $\min\{\tilde{O}(mn), n^3 / \exp(\sqrt{\log n})\}$ [27, 19, 20].

In unweighted undirected graphs the fastest known APSP algorithms run in $\tilde{O}(\min\{mn, n^\omega\})$ time¹ [21], where $\omega < 2.373$ is the exponent of square matrix multiplication [28, 17, 24], n is the number of vertices and m is the number of edges. For an extension of this result to undirected graphs with integral weights see [22] and to directed graphs see [30]. Fast Matrix Multiplication (FMM) algorithms hide large constants and are thus far from being practical. A fundamental research question is whether one can obtain fast “combinatorial” algorithms, that can be implemented.

¹ \tilde{O} notation hides polylogarithmic factors

Aingworth, Chekuri, Indyk and Motwani [1] initiated the research on efficient APSP algorithms in unweighted undirected graphs, that settle for an approximated solution and do not use FMM. An all pairs approximate shortest paths (APASP) algorithm has (α, β) -approximation if every distance X is estimated by the algorithm to be at least X and at most $\alpha X + \beta$, where α is the multiplicative approximation and β is the additive approximation. Aingworth et al. [1] presented a $(1, 2)$ -approximation that runs in $\tilde{O}(n^{2.5})$.

Dor, Halperin and Zwick [10] improved and generalized the results of [1]. For every even $k > 2$, they presented a generalized scheme with $\tilde{O}(\min\{n^{2-\frac{2}{k+2}}m^{\frac{2}{k+2}}, n^{2+\frac{2}{3k-2}}\})$ running time and an additive approximation of k . For $k = 2$, the running time is $\tilde{O}(\min\{n^{\frac{3}{2}}m^{\frac{1}{2}}, n^{\frac{7}{3}}\})$ and the additive approximation is 2. They also obtained an algorithm with $\tilde{O}(n^2)$ running time and $(3, 0)$ -approximation. Berman and Kasiviswanathan [6] improved this result and obtained an algorithm with the same running time of $\tilde{O}(n^2)$ and $(2, 1)$ -approximation. The question of obtaining efficient APASP algorithms for *unweighted* undirected graphs was considered by many subsequent works [11, 5, 3, 23, 16, 2].

Cohen and Zwick [9] extended the results of Dor et al. [10] to *weighted* undirected graphs. They obtained an $\tilde{O}(n^2)$ time algorithm with a $(3, 0)$ -approximation, an $\tilde{O}(n^{\frac{3}{2}}m^{\frac{1}{2}})$ time algorithm with a $(2, 0)$ -approximation and also $\tilde{O}(n^{\frac{7}{3}})$ time algorithm with $(7/3, 0)$ -approximation. Their analysis of the $(3, 0)$ -approximation algorithm allowed them to obtain a general scheme with a running time of $\tilde{O}(n^{2-1/k}m^{1/k})$ that for every pair $u, v \in V$ computes an additive approximation of $2 \sum_{i=1}^{k-1} w_i$, where w_i is the i th heaviest edge on the shortest path between u and v . (For a similar result see also [12].) This is still a $(3, 0)$ -approximation in the worst case.

Baswana and Kavitha [4] presented several algorithms that perform better than the algorithms of Cohen and Zwick when $m = o(n^2)$. They presented a $(2, 0)$ -approximation algorithm with expected running time of $\tilde{O}(n^2 + m\sqrt{n})$ and a $(7/3, 0)$ -approximation algorithm with expected running time of $\tilde{O}(n^2 + m^{2/3}n)$. Notice that both algorithms have the same running times as those of Cohen and Zwick when $m = \Theta(n^2)$. Kavitha [15] presented a $(5/2, 0)$ -approximation algorithm with expected running time of $\tilde{O}(n^{9/4})$. Baswana and Kavitha [4] presented also a $(2, W)$ -approximation algorithm, where W is the largest edge weight, with expected running time of $\tilde{O}(\min\{n^2, m\sqrt{n}\})$. This is still a $(3, 0)$ -approximation in the worst case. A deterministic algorithm with the same bounds was presented by Berman and Kasiviswanathan [6].

It stems from all the previous results mentioned above that for $m = \Theta(n^2)$ there is a $(2 + (k - 2)/k, 0)$ -approximation algorithm with an expected running time of $\tilde{O}(n^{2+1/k})$, for every $k \in \{2, 3, 4\}$. For $k \in \{2, 3\}$, there is a $(2 + (k - 2)/k, 0)$ -approximation algorithm with expected running time of $\tilde{O}(n^2 + n^{2-\frac{2}{k}}m^{\frac{2}{k}})$. Therefore, in light of the existing results and the lack of progress in improving them for more than 15 years, a natural research question that arises is, whether there is a general scheme of algorithms with $(2 + (k - 2)/k, 0)$ -approximation and $\tilde{O}(n^{2+1/k})$ running time, for every $k > 4$ or even more generally, is there a general scheme of algorithms with $(2 + (k - 2)/k, 0)$ -approximation that work better for sparse graphs and have a running time of $\tilde{O}(n^2 + n^{2-\frac{3}{k}}m^{\frac{2}{k}})$, for every $k > 3$. Obtaining the latter scheme requires first to improve the $(5/2, 0)$ -approximation algorithm with expected running time of $\tilde{O}(n^{9/4})$ of Kavitha [15]. In this paper we answer the more general question positively and prove:

► **Theorem 1.** *For every integer $k \geq 2$, there is an APASP algorithm with expected running time of $\tilde{O}(n^2 + m^{\frac{2}{k}}n^{2-\frac{3}{k}})$ and multiplicative approximation of $2 + \frac{k-2}{k}$.*

For $k = 2, 3$ we get the results of Baswana and Kavitha [4]. For $k = 4$, we improve upon the result of Kavitha [15] and get a $(5/2, 0)$ -approximation algorithm with $\tilde{O}(n^2 + n^{\frac{5}{4}}m^{\frac{1}{2}})$ expected running time, which is better than $\tilde{O}(n^{9/4})$ when $m = o(n^2)$.

The main contribution of Theorem 1 is in unifying all previous algorithms into one general systematic scheme which reveals for the previous known algorithms with 2, $7/3$ and $5/2$ approximation, that rather than being accidental ad-hoc results, they are part of a family of algorithms that exhibits a smooth tradeoff between time and approximation.

Another aspect of Theorem 1 is that the current state of the art in conditional lower bounds only rules out the existence of a $(2 - \varepsilon)$ -approximation algorithm whose running time is better than the running time of FMM. No conditional lower bounds are currently known for approximation factors in the range between 2 and 3. Our result shed a light on this range from the upper bound perspective.

From the technical perspective our result is obtained by a combination of several observations with one important key ingredient that might be useful for generalizing also other algorithms that are based on distance computation. Very roughly speaking, the algorithms for $k = 2, 3$ of [4] and for $k = 4$ of [15] are obtained by using a case analysis in which one of the cases uses the following approach. For every $u, v \in V$ there is some edge $(a, b) \in E$ on a shortest path between u and v that is used to get an estimation to the distance between u and v based on approximate distance queries between u and b and v and a . We develop a generalization of this idea which is based on the query procedure of the *approximate distance oracles* (ADO) of Thorup and Zwick [26]. However, this key ingredient in its own is not enough to obtain Theorem 1. A tighter analysis of the algorithm of [4] for the case that $k = 2$ and a careful combination of it with our generalization technique is required.

The ADO of Thorup and Zwick [26] plays a pivotal role in many results related to approximating distances. Formally, Thorup and Zwick showed that for any integer $k \geq 1$ it is possible to preprocess a weighted undirected graph in $O(kmn^{1/k})$ expected time and to create ADO of size $O(kn^{1+1/k})$. For every $u, v \in V$ a query returns in $O(k)$ time a $(2k - 1, 0)$ -approximation. Many of the subsequent works on ADO were focused on improving the preprocessing time. (For more details see for example [4, 29, 23].) Baswana and Kavitha [4] showed that for $k > 2$ it is possible to compute ADO in $\tilde{O}(\min\{n^2, kmn^{1/k}\})$ expected running time. Other aspects of ADO were considered as well. For more details see for example [18, 29, 7, 8, 13, 14].

The rest of this paper is organized as follows. In the next section we present notations and review previous works. In Section 3 we present the main ingredients needed for obtaining the generalization. In Section 4 we present a couple of additional ingredients whose combination with the generalization presented in Section 3 yields the proof of Theorem 1.

2 Preliminaries

Let $G = (V, E)$ be a weighted undirected graph with $n = |V|$ vertices and $m = |E|$ edges. Let $\mathbf{w} : E \rightarrow \mathbb{R}^+$ be a weight function on the edges of G . For a vertex $u \in V$, let $N(u)$ be the set of neighbours of u including u itself. Let E_u be the set of incident edges of u . Let $E_u(i)$ be the i lightest edges² that are incident to u and let $N(u, i) = \{v \mid (u, v) \in E_u(i)\}$. Let $E(i) = \cup_{u \in V} E_u(i)$. Let $u, v \in V$ and let $d_G(u, v)$ be the distance between u and v in G , that is, the length of the shortest path between u and v . Let $S \subseteq V$. Let $p_S(u) = \arg \min_{w \in S} d_G(u, w)$ and let $d_G(u, S) = d_G(u, p_S(u))$. If $S = \emptyset$ then $d_G(u, S) = \infty$. Notice that $p_S(s) = s$ for every $s \in S$. Let $E_S(u) = \{(u, v) \in E_u \mid \mathbf{w}(u, v) < d_G(u, S)\}$ and let $E_S = \cup_{u \in V} E_S(u)$. Notice that in the degenerate case that $S = \emptyset$ we have $E_S = E$, since $d_G(u, S) = \infty$.

² Ties are broken arbitrarily. If i is not integral we take the $\lceil i \rceil$ lightest edges.

Several variants of the next two Lemmas were used in many of the previous papers [10, 9, 26]. For our needs we use the formulation of Baswana and Kavitha [4]:

► **Lemma 2** ([4]). *Given a weighted undirected graph $G = (V, E)$ and a set $S \subseteq V$ the following holds:*

1. *If $d_G(u, v) < d_G(u, S)$ then all the edges on a shortest path between u and v are in $G(V, E_S)$ and $d_{G(V, E_S)}(u, v) = d_G(u, v)$.*
2. *$d_{G(V, E_S \cup E_{p_S(u)})}(u, p_S(u)) = d_G(u, p_S(u))$.*

► **Lemma 3** ([4]). *If $v \in V$ is added to S with probability p then $\mathbb{E}[|E_S|]$ is $O(n/p)$.*

For every $u \in V$, the *ball* of u with respect to S is $B_S(u) = \{w \mid d_G(u, w) < d_G(u, S)\}$. An example to a ball is presented in The next definition of *overlapping* balls is used implicitly in many of the previous research on ADO and APASP. This definition was stated explicitly by Kavitha [15].

► **Definition 4** ([15]). *Balls $B_S(u)$ and $B_S(v)$ overlap if $d_G(u, S) + d_G(v, S) > d_G(u, v)$.*

The next Corollary from [15] is crucial for our new algorithms.

► **Corollary 5** ([15]). *If $P(u, v)$ is a shortest path and $B_S(u)$ and $B_S(v)$ overlap then $P(u, v)$ can be divided into a portion $P(u, a)$ in $B_S(u)$, a portion $P(v, b)$ in $B_S(v)$, and an edge (a, b) ³.*

Let $S_0 \subseteq V$, $S_{i+1} \subseteq S_i$, where $i \in [0, k]$ and $k \geq 1$. The set S_{i+1} is constructed by picking every vertex of S_i independently at random with probability $p \cdot c \log n$, for some constant c . We denote these $k + 1$ vertex sets with \mathcal{S}_k^p and call them a *regular* hierarchy if $S_0 = V$ and $S_k = \emptyset$. Later we also define *augmented* and *mixed* hierarchies. We will usually refer to vertices in S_i , for $i > 0$, as pivots. For every $u \in V$ let $p_i(u) = p_{S_i}(u)$.

Thorup and Zwick [26] introduced approximate distance oracles (ADO). Given $k \geq 1$, an ADO of size $\tilde{O}(n^{1+1/k})$ can be constructed in $\tilde{O}(mn^{1/k})$ time. A query between any $u, v \in V$ returns in $O(k)$ time a $(2k - 1)$ -multiplicative approximation of the distance. At the core of the ADO is the definition of a *bunch* $B_i(u)$ for every vertex $u \in V$ and $i \in [0, k - 1]$. For a given $i \in [0, k - 1]$ and $u \in V$ a bunch $B_i(u)$ is defined as follows: $B_i(u) = \{w \in S_i \setminus S_{i+1} \mid d_G(u, w) < d_G(u, p_{i+1}(u))\}$. Notice that if we translate the definition of bunches to the terminology of balls then for every $u \in V$ and $i \in [0, k - 1]$, $B_i(u) = S_i \cap B_{S_{i+1}}(u)$. In particular, for $i = 0$ we have that the bunch $B_0(u)$ is simply the ball $B_{S_1}(u)$. Thorup and Zwick [26] proved the following Lemma on the size of the bunches.

► **Lemma 6** ([26]). *Let $p = qc \log n$, where c is a large constant and $q \in (0, 1/(c \log n))$. For every $i \in [0, k - 2]$ the size of $B_i(u)$ is $O(q^{-1} \log n)$ with high probability. The size of $B_{k-1}(u)$ is $O(n(q \log n)^{k-1})$, whp.*

The different bound on $|B_{k-1}(u)|$ is not really relevant for the ADO of Thorup and Zwick, as they set $q = n^{-1/k}$ and both bounds coincide at the same value. In our case, however, it raises a non trivial obstacle on the way to obtain efficient algorithms for sparse graphs. We will elaborate more on this issue later on.

The ADO is composed of an hierarchy \mathcal{S}_k^p , where $p = n^{-1/k} c \log n$, and $S_k = \emptyset$. For every $u \in V$ and $i \in [0, k]$, $p_i(u)$ and $B_i(u)$ are computed and saved in the data structure. Thorup and Zwick defined also *clusters* $C_i(w) = \{u \mid w \in B_i(u)\}$, for every $w \in S_i \setminus S_{i+1}$. The query algorithm is presented in Algorithm 1.

³ Notice that in the degenerate case of a path of two edges either $u = a$ or $b = v$

Algorithm 1 $\text{DIST}(u, v)$.

```

 $i \leftarrow 0$ ;
while  $p_i(u) \notin B_i(v)$  do
     $i \leftarrow i + 1$ ;
    swap  $u$  and  $v$ ;
end
return  $d(u, p_i(u)) + d(v, p_i(u))$ ;

```

Algorithm 2 $\text{DIST}(u, v, r)$.

```

 $i \leftarrow r$ ;
while  $p_i(u) \notin B_i(v)$  do
     $i \leftarrow i + 1$ ;
    swap  $u$  and  $v$ ;
end
return  $d(u, p_i(u)) + d(v, p_i(u))$ ;

```

For the purpose of our new algorithms we generalize the query of Thorup and Zwick's ADO (see Algorithm 2) by adding an additional input value r . The search is for the first $i \geq r$, for which $p_i(u) \in B_i(v)$, alternating between u and v after each iteration. Let $f(u, v, r)$ be the value of i when $\text{DIST}(u, v, r)$ ends.

► **Lemma 7.** *Let $u, v \in V$, $r \in [0, k-1]$ and $f = f(u, v, r)$. If $f-r$ is even then $d_G(u, p_f(u)) \leq d_G(u, p_r(u)) + (f-r)d_G(u, v)$. If $f-r$ is odd then $d_G(v, p_f(v)) \leq d_G(u, p_r(u)) + (f-r)d_G(u, v)$.*

Proof. Consider every $i \in [r, f-1]$. If $i-r$ is even then $p_i(u) \notin B_i(v)$ and from bunch definition together with the triangle inequality we get $d_G(v, p_{i+1}(v)) \leq d_G(v, p_i(u)) \leq d_G(u, v) + d_G(u, p_i(u))$. Similarly, if $i-r$ is odd then $p_i(v) \notin B_i(u)$ and $d_G(u, p_{i+1}(u)) \leq d_G(u, p_i(v)) \leq d_G(u, v) + d_G(v, p_i(v))$. This implies that for even $i-r$ we have $d_G(v, p_{i+1}(v)) \leq (i+1-r) \cdot d_G(u, v) + d_G(u, p_r(u))$ and for odd $i-r$ we have $d_G(u, p_{i+1}(u)) \leq (i+1-r) \cdot d_G(u, v) + d_G(u, p_r(u))$.

Thus, if $f-r$ is even we have $d_G(u, p_f(u)) \leq (f-r) \cdot d_G(u, v) + d_G(u, p_r(u))$ and if $f-r$ is odd we have $d_G(v, p_f(v)) \leq (f-r) \cdot d_G(u, v) + d_G(u, p_r(u))$.

As before we consider two subcases. The first is that r is even and the second is that r is odd.

In case that r is even then we let $f = f(u, v, r)$. ◀

3 A generalized scheme for APASP algorithms

3.1 Improving the pivots data

Baswana and Kavitha [4] presented a simple algorithm that given an hierarchy \mathcal{S}_k^p computes the distance between every pair of vertices $(s, v) \in S_i \times V$ in the graph $(V, E_{S_{i+1}} \cup E_s)$, where $i \in [0, k-1]$, in expected running time of $\tilde{O}(n^{2+1/k})$.

In our new PIVOT-DIST algorithm we compute the bunches of every $u \in V$ with respect to hierarchy \mathcal{S}_k^p . We also change the way distances are computed for the pairs $(s, v) \in S_i \times V$ in the graph $(V, E_{S_{i+1}} \cup E_s)$ by using more edges and in particular edges which are not necessarily in E .

We define a new graph $G_{i+1}(s) = (V, H_{i+1}(s))$, for every $i \in [0, k-1]$ and $s \in S_i$ and run Dijkstra's algorithm for s in $G_{i+1}(s)$. The graph $G_{i+1}(s)$ is constructed as follows. The edge set $H_{i+1}(s)$ is initialized with $E_{S_{i+1}}$. The first change is that we add to $H_{i+1}(s)$ the set of edges $E(1/(p^{i+1}))$.

The second change is that for every $s \in S_i$ the set $H(s)$ contains an edge between s and every $u \in V$. The weight of every $(s, v) \in H(s) \setminus E_s$ is initially set to ∞ . Every $(s, v) \in H(s) \cap E_s$ already has a weight. Next, we ensure in a loop that the weight of $(s, v) \in H(s)$ is at most $\min\{\mathbf{w}(s, v), \min_{u \in C_i(s) \cap N(v)} \{d_G(s, u) + \mathbf{w}(u, v)\}, \min_{u \in N(v) \wedge p_i(u)=s} \{d_G(s, u) + \mathbf{w}(u, v)\}\}$ and add $H(s)$ to $H_{i+1}(s)$.

As mentioned above we perform these computations using algorithm PIVOT-DIST. The additional data computed by PIVOT-DIST for the pairs $(s, v) \in S_i \times V$ enables us later on to perform more queries when computing the approximate distance between pairs $u, v \in V$.

■ **Algorithm 3** PIVOT-DIST(\mathcal{S}_k^p).

```

 $M[i, j] \leftarrow \infty$ , for every  $(i, j) \in [n] \times [n]$ ;
for  $i \leftarrow 0$  to  $k - 1$  do
    // Phase 1: Adding shortcut edges
    foreach  $s \in S_i \setminus S_{i+1}$  do
         $H(s) \leftarrow \{(s, v) \mid v \in V\}$ ;
        foreach  $e \in H(s) \setminus E_s$  do  $w(e) \leftarrow \infty$ ;
    end
    // Phase 2: Computing  $d_G(u, S_i)$ ,  $p_i(u)$ ,  $B_i(u)$  and updating edge weights.
    foreach  $u \in V$  do
        compute  $d_G(u, S_i)$ ,  $p_i(u)$  and  $B_i(u)$ ;
         $M[p_i(u), u] \leftarrow d_G(u, S_i)$ ,  $M[u, p_i(u)] \leftarrow d_G(u, S_i)$ ;
         $w(p_i(u), u) = d_G(u, S_i)$ ;
        (1) foreach  $(u, v) \in E_u$  do
             $w(p_i(u), v) \leftarrow \min\{w(p_i(u), v), d_G(p_i(u), u) + w(u, v)\}$ ;
            foreach  $s \in B_i(u)$  do  $M[s, u] \leftarrow d_G(u, s)$ ,  $M[u, s] \leftarrow d_G(u, s)$ ;
            (2) foreach  $(u, v) \in E_u$  do
                foreach  $s \in B_i(u)$  do  $w(s, v) \leftarrow \min\{w(s, v), d_G(s, u) + w(u, v)\}$ ;
            end
        end
    end
    // Phase 3: Computing shortest paths for the vertices of  $S_i$ 
    foreach  $s \in S_i$  do
         $G_{i+1}(s) = (V, E_{S_{i+1}} \cup E(1/(p^{i+1})) \cup H(s))$ ;
        run Dijkstra's algorithm from  $s$  in  $G_{i+1}(s)$ ;
        foreach  $u \in V$  do
             $M[s, u] \leftarrow \min\{M[s, u], d_{G_{i+1}(s)}(s, u)\}$ ,
             $M[u, s] \leftarrow \min\{M[u, s], d_{G_{i+1}(s)}(s, u)\}$ 
        end
    end
end
return  $M$ ;

```

A pseudocode of PIVOT-DIST(\mathcal{S}_k^p) for computing distance information for $(s, v) \in S_i \times V$, for every $i \in [0, k - 1]$, $s \in S_i$ and $v \in V$, is presented in Algorithm 3. A matrix M of size $n \times n$ is initialized with ∞ in every entry. We iterate on i from 0 to $k - 1$. For every i we have three phases. In the first phase we iterate on the set S_i . For every $s \in S_i \setminus S_{i+1}$ the set $H(s)$ is initialized with edges between s and every $v \in V$. For every $(s, v) \in H(s) \setminus E_s$ we set $w(s, v)$ to ∞ . In the second phase for every $u \in V$ we compute $p_i(u)$, $d_G(u, S_i)$ and $B_i(u)$. We then set $M[p_i(u), u] = d_G(u, S_i)$ and $w(p_i(u), u) = d_G(u, S_i)$. Notice that here we update the weight of edges in $H(s)$, some might be in the original graph and some might not. In line (1) we scan the edges of u and for each $(u, v) \in E_u$ we set $w(p_i(u), v) = \min\{w(p_i(u), v), d_G(p_i(u), u) + w(u, v)\}$. We set $M[s, u] = d_G(u, s)$, for every

$s \in B_i(u)$. Notice that by this we ensure that we have for every $u \in V$ the distance between u and every vertex in its bunches, according to the bunch definition of Thorup and Zwick's ADO. In line (2) we scan the edges of u and the vertices of $B_i(u)$ and for every $(u, v) \in E_u$ and $s \in B_i(u)$ we set $\mathbf{w}(s, v) = \min\{\mathbf{w}(s, v), d_G(s, u) + \mathbf{w}(u, v)\}$.

In the third phase we iterate on the vertices of S_i . We compute the distance from every $s \in S_i$ to every vertex in V in the graph $G_{i+1}(s)$ by running Dijkstra's algorithm from s and update M accordingly. The matrix M is returned as the output. Next, we analyze the running time of Algorithm 3.

► **Lemma 8.** *PIVOT-DIST(S_k^p) runs in $\tilde{O}(n^2 + (k-1)n^2p^{-1} + mnp^{k-1})$ expected time.*

Proof. Initializing M takes $O(n^2)$ time. In the first phase of the loop on i we scan $S_i \setminus S_{i+1}$ and for every $s \in S_i \setminus S_{i+1}$ we add an edge between s and every vertex of V to the set $H(s)$. We then update the weight. This costs $O(|S_i \setminus S_{i+1}|n)$. The total cost of the first phase for every $i \in [0, k-1]$ is $O(n^2)$.

In the second phase we compute $p_i(u)$, $d_G(u, S_i)$ and $B_i(u)$ for every $u \in V$. It is easy to compute $p_i(u)$ and $d_G(u, S_i)$, for every $u \in V$, in $\tilde{O}(m)$ time by connecting a dummy vertex only to the vertices of S_i and running Dijkstra's algorithm from the dummy vertex.

Thorup and Zwick [26] showed that computing $B_i(u)$ for every $u \in V$ takes $\tilde{O}(\sum_{u \in V} |B_i(u)| \cdot |N(u)|)$ time (Section 4.3 in [26]). For $i \in [0, k-2]$ this results in a running time of $\tilde{O}(m \cdot p^{-1})$, since from Lemma 6 we have $B_i(u) = \tilde{O}(1/p)$. The cost of computing $B_{k-1}(u)$, for every $u \in V$, is $\tilde{O}(m \cdot np^{k-1})$, since from Lemma 6 we have $B_{k-1}(u) = \tilde{O}(np^{k-1})$.

For every i , the cost of line (1) is $\tilde{O}(\sum_{u \in V} |N(u)|) = \tilde{O}(m)$ and the cost of line (2) is $\tilde{O}(\sum_{u \in V} |B_i(u)| \cdot |N(u)|)$. Thus, the total cost of the second phase is $\tilde{O}(km \cdot p^{-1} + m \cdot np^{k-1})$.

In the third phase we run Dijkstra's algorithm from every $s \in S_i$ in $G_{i+1}(s)$. The set of edges of $G_{i+1}(s)$ is $E_{S_{i+1}} \cup E(1/(p^{i+1})) \cup H(s)$. The set $H(s)$ is of size $O(n)$. The set $E(1/(p^{i+1}))$ is of size $O(n/(p^{i+1}))$.

Consider now the set $E_{S_{i+1}}$, for $i < k-1$. The probability of a vertex to be in S_{i+1} is $\tilde{O}(p^{i+1})$. Applying Lemma 3 we get that the expected size of the set $E_{S_{i+1}}$ is $O(n/(p^{i+1}))$.

We get that the cost of the third phase for every integer $i \in [0, k-2]$ is $\tilde{O}(|S_i| \cdot n/p^{i+1})$. Since the expected size of S_i is $\tilde{O}(np^i)$ we get a bound of $\tilde{O}(\sum_{i=0}^{k-2} (n \cdot p^i \cdot n/p^{i+1})) = \tilde{O}(n^2 + (k-1)n^2p^{-1})$.

When $i = k-1$ we cannot apply Lemma 3 to bound the size of E_{S_k} since $S_k = \emptyset$, thus, we bound the cost of running Dijkstra's algorithm from every $s \in S_{k-1}$ in $G_k(s)$ with $\tilde{O}(|S_{k-1}|m) = \tilde{O}(n \cdot p^{k-1}m)$. We get a running time of $O(n^2 + (k-1)n^2p^{-1} + mnp^{k-1})$. ◀

In the next Lemma we summarize several properties of the matrix M returned by PIVOT-DIST. These properties are ensured by phase 2.

► **Lemma 9.** *Let $i \in [0, k-1]$, let $s \in S_i$ and let $u \in V$.*

1. *If $s \in \{p_i(u)\} \cup B_i(u)$ then $M[s, u] = d_G(s, u)$*
2. *If $s \in \{p_i(u)\} \cup B_i(u)$ and $(u, v) \in E$ then $M[s, v] \leq d_G(s, u) + \mathbf{w}(u, v)$*

Proof. The proof easily follows from the execution of phase 2. ◀

We finish this section with a Lemma that summarizes several additional properties that follow from the structure of the graph $G_{i+1}(s)$, where $s \in S_i$ and $i \in [0, k-1]$. These properties are ensured by phase 3 of PIVOT-DIST.

► **Lemma 10.** *Let $u, v \in V$ and let $P(u, v)$ be a shortest path between u and v with at least two edges. Let $s \in S_i$ and let $p_i(u) = s$, where $i \in [0, k-1]$.*

1. *If $P(u, v)$ is in $G_{i+1}(s)$ then $M[s, v] \leq d_G(s, u) + d_G(u, v)$.*
2. *If $P(u, v)$ is not in $G_{i+1}(s)$ then $i \leq k-2$.*
3. *If $P(u, v)$ is not in $G_{i+1}(s)$ and $B_{S_{i+1}}(u)$ and $B_{S_{i+1}}(v)$ overlap, where $(a, b) \in P(u, v)$ is the edge that connects them, then $(a, b) \notin E_a(1/p^{i+1}) \cup E_b(1/p^{i+1}) \cup E_{S_{i+1}}$.*

Proof.

1. The claim follows since $P(u, v)$ is in $G_{i+1}(p_i(u))$, $(p_i(u), u) \in H(p_i(u))$ and $\mathbf{w}(p_i(u), u) = d_G(p_i(u), u)$.
2. Assume towards a contradiction that $i = k-1$. The graph $G_k(p_{k-1}(u))$ contains the edges E_{S_k} and since $S_k = \emptyset$ we have $E_{S_k} = E$. Thus, $G_k(p_{k-1}(u))$ contains E and in particular, $P(u, v)$ is $G_k(p_{k-1}(u))$, a contradiction.
3. Since $d_G(u, a) < d_G(u, p_{i+1}(u))$ and $d_G(v, b) < d_G(v, p_{i+1}(v))$ it follows from Lemma 2 that $P(u, a)$ and $P(v, b)$ are in $E_{S_{i+1}}$ and thus in $G_{i+1}(p_i(u))$. Since $P(u, v)$ is not in $G_{i+1}(p_i(u))$ it must be that $(a, b) \notin E_a(1/p^{i+1}) \cup E_b(1/p^{i+1}) \cup E_{S_{i+1}}$. ◀

3.2 A general scheme

We turn now to describe our new and general scheme for APASP algorithm. We denote this algorithm with APASP. Our new algorithm is obtained by using $\text{PIVOT-DIST}(\mathcal{S}_k^p)$ to obtain better estimations in several important cases. These better estimations are then combined with a procedure similar to the query of Thorup and Zwick distance oracles. The main challenge is in the analysis of the approximation factor.

The algorithm gets as an input a weighted undirected graph G and an hierarchy \mathcal{S}_k^p . The algorithm returns a matrix M of approximate distances.

The algorithm works as follows. We start by initializing the matrix M . For every $(i, j) \in E$ we set $M[i, j]$ to $\mathbf{w}(i, j)$ and for every $(i, j) \notin E$ we set $M[i, j]$ to ∞ . Next, we run $\text{PIVOT-DIST}(\mathcal{S}_k^p)$ and update matrix M with the result. Finally, we scan for every $u, v \in V$ the vertices $p_i(u)$, for every $i \in [0, k-1]$ and the vertices in $B_i(u)$, for every $i \in [0, k-2]$. We update $M[u, v]$ if we find a vertex w such that $M[u, w] + M[v, w] < M[u, v]$. Notice that we are not scanning the vertices of $B_{k-1}(u)$ deliberately. This caveat is because the size of $B_{k-1}(u)$ is $\tilde{O}(np^{k-1})$, for every $u \in V$, thus scanning these bunches is prohibited if we like to obtain an algorithm with an efficient running time in sparse graphs. A careful case analysis of odd and even values of k allows us to avoid scanning $B_{k-1}(u)$ without affecting the approximation factor. A pseudocode of APASP is presented in Algorithm 4.

We now analyze the approximation of the algorithm.

► **Lemma 11.** *The output M of $\text{APASP}(G, \mathcal{S}_k^p)$ satisfies $d_G(u, v) \leq M[u, v] \leq 2d_G(u, v) + \frac{k-2}{k} \cdot d_G(u, v)$.*

Proof. Let $u, v \in V$. Let $P(u, v)$ be a shortest path between u and v . If $P(u, v)$ has a single edge then $M[u, v] = \mathbf{w}(u, v)$ since we set $M[u, v]$ to $\mathbf{w}(u, v)$ in APASP. Thus, we can assume that $P(u, v)$ has at least 2 edges. Let $i \in [0, k-1]$ be the largest index such that $d_G(u, S_i) + d_G(v, S_i) \leq d_G(u, v)$. Such an index must exist since $S_0 = V$ which implies that $d_G(u, S_0) + d_G(v, S_0) = 0 \leq d_G(u, v)$.

⁴ If $P(u, v)$ has two edges then the claim hold since either $v = b$ or $u = a$.

Algorithm 4 APASP(G, \mathcal{S}_k^p).

```

foreach  $(i, j) \in [n] \times [n]$  do  $M[i, j] \leftarrow \infty$ ;
foreach  $(i, j) \in E$  do  $M[i, j] \leftarrow \mathbf{w}(i, j)$ ;
 $M \leftarrow \min\{M, \text{PIVOT-DIST}(\mathcal{S}_k^p)\}$ ;
foreach  $u \in V$  do
  for  $i \leftarrow 0$  to  $k - 1$  do
    foreach  $v \in V$  do
      (1)  $M[u, v] \leftarrow \min\{M[u, v], M[p_i(u), u] + M[p_i(u), v], M[v, u]\}$ ;
      if  $i \leq k - 2$  then
        (2) foreach  $w \in B_i(u)$  do
           $M[u, v] \leftarrow \min\{M[u, v], M[w, u] + M[w, v], M[v, u]\}$ 
        end
      end
    end
  end
end
return  $M$ ;

```

Assume, wlog, that $d_G(u, S_i) \leq d_G(v, S_i)$. If $P(u, v)$ is in $G_{i+1}(p_i(u))$ it follows from Lemma 9(i) and from Lemma 10(i) that after updating M with the result of PIVOT-DIST $M[p_i(u), u] = d_G(p_i(u), u)$ and $M[p_i(u), v] \leq d_G(p_i(u), u) + d_G(u, v)$. In line (1) of APASP we update $M[u, v]$ if needed, therefore, it is guaranteed that $M[u, v] \leq 2d_G(p_i(u), u) + d_G(u, v) \leq 2d_G(u, v)$.

Consider now the case that $P(u, v)$ is not in $G_{i+1}(p_i(u))$. From Lemma 10(ii) it follows that $i < k - 1$. Since i is the largest index for which we have $d_G(u, S_i) + d_G(v, S_i) \leq d_G(u, v)$ it follows that $d_G(u, S_{i+1}) + d_G(v, S_{i+1}) > d_G(u, v)$, which implies that $B_{S_{i+1}}(u)$ and $B_{S_{i+1}}(v)$ overlap. Let $(a, b) \in P(u, v)$ be the edge that connects $B_{S_{i+1}}(u)$ and $B_{S_{i+1}}(v)$. From Lemma 10(iii) it follows that $(a, b) \notin E_a(1/p^{i+1})$ and $(a, b) \notin E_b(1/p^{i+1})$. Therefore, for the rest of the proof we can assume that $P(u, v)$ has at least 2 edges, $i < k - 1$, $P(u, a)$ is in $G(V, E_{S_{i+1}})$, $P(v, b)$ is in $G(V, E_{S_{i+1}})$ and $(a, b) \notin E_a(1/p^{i+1}) \cup E_b(1/p^{i+1}) \cup E_{S_{i+1}}$.

Next, we will prove two different bounds on $M[u, v]$.

▷ **Claim 12.** $M[u, v] \leq \min\{3d_G(u, v) - 2d_G(b, v), 3d_G(u, v) - 2d_G(a, u)\}$.

Proof. Let $j > i + 1$ be the smallest index for which $(a, b) \in E(1/p^j)$. If $j \geq k$ we set j to k . Assume that $(a, b) \in E_a(1/p^j)$ and $(a, b) \in E_b(1/p^{j'})$, where $j' \geq j$. If $j = k$ we set j' to k . By definition, the sets $N(a, 1/p^{j-1})$ and $N(b, 1/p^{j-1})$ are of size $1/p^{j-1}$. Since vertices of V are in S_{j-1} with probability at least $p^{j-1}c \log n$, it follows that, whp, S_{j-1} contains at least one vertex from $N(a, 1/p^{j-1})$ and $N(b, 1/p^{j-1})$.

Let $x \in N(a, 1/p^{j-1}) \cap S_{j-1}$ and let $y \in N(b, 1/p^{j-1}) \cap S_{j-1}$. Since $(a, x) \in E_a(1/p^{j-1})$ and $(a, b) \notin E_a(1/p^{j-1})$ we have $\mathbf{w}(a, x) \leq \mathbf{w}(a, b)$. Similarly, since $(b, y) \in E_b(1/p^{j-1})$ and $(a, b) \notin E_b(1/p^{j-1})$ we have $\mathbf{w}(b, y) \leq \mathbf{w}(a, b)$. Thus, we get that $d_G(u, p_{j-1}(u)) \leq d_G(u, a) + \mathbf{w}(a, b) \leq d_G(u, b)$ and $d_G(v, p_{j-1}(v)) \leq d_G(v, b) + \mathbf{w}(a, b) \leq d_G(v, a)$.

Now since $(a, b) \in E_a(1/p^j)$ it follows that the path $P(u, v)$ is in $G_j(p_{j-1}(u))$ and $G_j(p_{j-1}(v))$, when $j < k$. When $j = k$ we have $E_{S_k} = E$ and $P(u, v)$ is in $G_k(p_{k-1}(u))$. It follows from Lemma 10(i) that $M[p_{j-1}(u), v] \leq d_G(p_{j-1}(u), u) + d_G(u, v)$ and $M[p_{j-1}(v), u] \leq d_G(p_{j-1}(v), v) + d_G(u, v)$.

Thus, after line (1) of APASP is executed for the pair u, v and for the pair v, u we have $M[u, v] = M[v, u] \leq \min\{2d_G(u, p_{j-1}(u)) + d_G(u, v), 2d_G(v, p_{j-1}(v)) + d_G(u, v)\}$. We get:

$$\begin{aligned} M[v, u] = M[u, v] &\leq \min\{2d_G(u, p_{j-1}(u)) + d_G(u, v), 2d_G(v, p_{j-1}(v)) + d_G(u, v)\} \\ &\leq \min\{d_G(u, v) + 2d_G(u, b), d_G(u, v) + 2d_G(v, a)\} \\ &= \min\{3d_G(u, v) - 2d_G(b, v), 3d_G(u, v) - 2d_G(a, u)\}, \end{aligned}$$

since $d_G(u, p_{j-1}(u)) \leq d_G(u, b)$ and $d_G(v, p_{j-1}(v)) \leq d_G(v, a)$ and since $d_G(u, b) = d_G(u, v) - d_G(b, v)$ and $d_G(v, a) = d_G(u, v) - d_G(a, u)$. \triangleleft

We now turn to prove a second bound on $M[u, v]$.

\triangleright **Claim 13.** $M[u, v]$ is bounded either by (i) $2 \cdot (k-1)d_G(u, a) + d_G(u, v)$ or by (ii) $2 \cdot (k-1)d_G(v, b) + d_G(u, v)$

Proof. We consider the pair of vertices u and a and the pair of vertices v and b .

Let r be the largest index such that $a \notin B_{S_r}(u)$ and $u \notin B_{S_r}(a)$. Let r' be the largest index such that $b \notin B_{S_{r'}}(v)$ and $v \notin B_{S_{r'}}(b)$. Since $S_0 = V$ it follows that $B_{S_0}(x) = \{x\}$, for every $x \in V$. Thus, we have $a \notin B_{S_0}(u)$ and $u \notin B_{S_0}(a)$ and also $b \notin B_{S_0}(v)$ and $v \notin B_{S_0}(b)$.

We assume that $r \geq r'$ and show that $M[u, v] \leq 2 \cdot (k-1)d_G(u, a) + d_G(u, v)$. If $r' \geq r$ then a symmetric proof shows that $M[u, v] \leq 2 \cdot (k-1)d_G(v, b) + d_G(u, v)$. In the degenerate case that $P(u, v)$ has only two edges and $b = v$ we set $r' = r$. The proof below works for this case as well and hence $M[u, v] \leq 2 \cdot (k-1)d_G(u, a) + d_G(u, v)$. If $a = u$ a symmetric proof shows that $M[u, v] \leq 2 \cdot (k-1)d_G(v, b) + d_G(u, v)$.

Recall that we are in the case that $d_G(u, a) < d_G(u, p_{i+1}(u))$ and $d_G(v, b) < d_G(v, p_{i+1}(v))$, thus we have $a \in B_{S_{i+1}}(u)$ and $b \in B_{S_{i+1}}(v)$. This implies that $r \leq i < k-1$ and $r' \leq i < k-1$, since $i < k-1$.

From the definition of r it follows that either $a \in B_{S_{r+1}}(u)$ or $u \in B_{S_{r+1}}(a)$. If $a \in B_{S_{r+1}}(u)$ then $d_G(u, a) < d_G(u, p_{r+1}(u))$ and it follows from Lemma 2 that $P(u, a) \in E_{S_{r+1}}$. Similarly, if $u \in B_{S_{r+1}}(a)$ then $d_G(u, a) < d_G(a, p_{r+1}(a))$ and it follows from Lemma 2 that $P(u, a) \in E_{S_{r+1}}$. From symmetrical arguments we get that $P(v, b) \in E_{S_{r'+1}}$. Since $E_{S_j} \subseteq E_{S_{j+1}}$, for every $j \in [0, k-1]$, we have and $P(u, a) \cup P(v, b) \subseteq E_{S_{q+1}}$, for every $q \geq r$.

Next, we distinguish between odd and even values of k . Assume first that k is odd. This implies that $k-1$ is even. We now consider two subcases. The first is that r is even and the second is that r is odd. In case that r is even then we let $f = f(u, a, r)$.

From Lemma 7 it follows that if $f-r$ is even then we have $d_G(u, p_f(u)) \leq d_G(u, p_r(u)) + (f-r)d_G(u, a)$ and if $f-r$ is odd then $d_G(a, p_f(a)) \leq d_G(u, p_r(u)) + (f-r)d_G(u, a)$.

We proceed by considering these two scenarios.

1. **Even $f-r$.** In this case $d_G(u, p_f(u)) \leq d_G(u, p_r(u)) + (f-r)d_G(u, a)$ and $p_f(u) \in B_f(a)$. It follows from Lemma 9(ii) that after Phase 2 of PIVOT-DIST $M[p_f(u), b] \leq d_G(p_f(u), a) + \mathbf{w}(a, b)$. When executing in Phase 3 of PIVOT-DIST Dijkstra's algorithm from $p_f(u)$ in $G_{f+1}(p_f(u))$ with edge set $E_{S_{f+1}} \cup E(1/(p^{f+1})) \cup H(p_f(u))$ the weight of the edge $(p_f(u), b) \in H(p_f(u))$ is $M[p_f(u), b] \leq d_G(p_f(u), a) + \mathbf{w}(a, b)$ and $P(v, b) \subseteq E_{S_{f+1}}$. Thus, we get that $M[p_f(u), v] \leq d_G(p_f(u), a) + d_G(a, v) \leq d_G(p_f(u), u) + d_G(u, v)$. In line (1) of APASP we update $M[u, v]$ so that it is at most $M[p_f(u), u] + M[p_f(u), v]$. From Lemma 9(i) it follows that $M[p_f(u), u] = d_G(p_f(u), u)$ and since $M[p_f(u), v] \leq d_G(p_f(u), u) + d_G(u, v)$ we get that $M[u, v] \leq 2 \cdot d_G(p_f(u), u) + d_G(u, v)$. (See
Combining this with the fact that $d_G(u, p_f(u)) \leq d_G(u, p_r(u)) + (f-r)d_G(u, a)$ we get that for even $f-r$ we have $M[u, v] \leq 2 \cdot (d_G(u, p_r(u)) + (f-r)d_G(u, a)) + d_G(u, v)$. Recall also that $f \leq k-1$. In the degenerate case of $r = 0$ we have $p_0(u) = u$ and $M[u, v] \leq 2 \cdot (k-1)d_G(u, a) + d_G(u, v)$.

For the case that $r \geq 1$ since $a \notin B_{S_r}(u)$ we have $d_G(u, p_r(u)) \leq d_G(u, a)$. Using this we get $M[u, v] \leq 2 \cdot ((f - r + 1)d_G(u, a)) + d_G(u, v) \leq 2 \cdot (k - 1)d_G(u, a) + d_G(u, v)$.

2. **Odd $f - r$.** In this case $d_G(a, p_f(a)) \leq d_G(u, p_r(u)) + (f - r)d_G(u, a)$ and $p_f(a) \in B_f(u)$. It follows from Lemma 9(ii) that after Phase 2 of PIVOT-DIST $M[p_f(a), b] \leq d_G(p_f(a), a) + \mathbf{w}(a, b)$. When executing in Phase 3 of PIVOT-DIST Dijkstra's algorithm from $p_f(a)$ in $G_{f+1}(p_f(a))$ with edge set $E_{S_{f+1}} \cup E(1/(p^{f+1})) \cup H(p_f(a))$ the weight of the edge $(p_f(a), b) \in H(p_f(a))$ is $M[p_f(a), b] \leq d_G(p_f(a), a) + \mathbf{w}(a, b)$ and $P(v, b) \subseteq E_{S_{f+1}}$. Thus, we get that $M[p_f(a), v] \leq d_G(p_f(a), a) + d_G(a, v)$.

Consider the execution of line (2) in APASP for vertices v, u and a and the index f . Notice that this line is only executed for indices $i \leq k - 2$. In our case we have $p_f(a) \in B_f(u)$ and since r is even and $f - r$ is odd, f must be odd. Since $k - 1$ is even we have $f \leq k - 2$. Thus line (2) is executed and we update $M[u, v]$ so that it is at most $M[p_f(a), u] + M[p_f(a), v]$. Since $p_f(a) \in B_f(u)$ it follows from Lemma 9(i) that $M[p_f(a), u] = d_G(p_f(a), u) \leq d_G(u, a) + d_G(p_f(a), a)$ and since $M[p_f(a), v] \leq d_G(p_f(a), a) + d_G(a, v)$ we get that $M[u, v] \leq 2 \cdot d_G(p_f(a), a) + d_G(u, v)$.

Combining this with the fact that $d_G(a, p_f(a)) \leq d_G(u, p_r(u)) + (f - r)d_G(u, a)$ we get that for odd $f - r$ we have $M[u, v] \leq 2 \cdot (d_G(u, p_r(u)) + (f - r)d_G(u, a)) + d_G(u, v)$. Recall also that $f \leq k - 1$.

In the degenerate case of $r = 0$ we have $p_0(u) = u$ and $M[u, v] \leq 2 \cdot (k - 1)d_G(u, a) + d_G(u, v)$.

For the case that $r \geq 1$ since $a \notin B_{S_r}(u)$ we have $d_G(u, p_r(u)) \leq d_G(u, a)$. Using this we get $M[u, v] \leq 2 \cdot ((f - r + 1)d_G(u, a)) + d_G(u, v) \leq 2 \cdot (k - 1)d_G(u, a) + d_G(u, v)$.

Consider now the second case in which r is odd and let $f = f(a, u, r)$.

1. **Odd $f - r$.** In this case $d_G(u, p_f(u)) \leq d_G(a, p_r(a)) + (f - r)d_G(u, a)$ and $p_f(u) \in B_f(a)$. The proof is identical to the proof for even r , $f = f(u, a, r)$ and even $f - r$.
2. **Even $f - r$.** In this case $d_G(a, p_f(a)) \leq d_G(a, p_r(a)) + (f - r)d_G(u, a)$ and $p_f(a) \in B_f(u)$. The proof is identical to the proof for even r , $f = f(u, a, r)$ and odd $f - r$.

Assume now that k is even. This implies that $k - 1$ is odd.

1. **Odd $f - r$.** In this case $d_G(u, p_f(u)) \leq d_G(a, p_r(a)) + (f - r)d_G(u, a)$ and $p_f(u) \in B_f(a)$. The proof is identical to the proof for even r , $f = f(u, a, r)$ and even $f - r$.
2. **Even $f - r$.** In this case $d_G(a, p_f(a)) \leq d_G(a, p_r(a)) + (f - r)d_G(u, a)$ and $p_f(a) \in B_f(u)$. The proof is identical to the proof for even r , $f = f(u, a, r)$ and odd $f - r$.

Consider now the second case in which r is odd and let $f = f(u, a, r)$.

1. **Even $f - r$.** In this case $d_G(u, p_f(u)) \leq d_G(u, p_r(u)) + (f - r)d_G(u, a)$ and $p_f(u) \in B_f(a)$. The proof is identical to the proof for even r , $f = f(u, a, r)$ even $f - r$.
2. **Odd $f - r$.** In this case $d_G(a, p_f(a)) \leq d_G(u, p_r(u)) + (f - r)d_G(u, a)$ and $p_f(a) \in B_f(u)$. The proof is identical to the proof for even r , $f = f(u, a, r)$ and odd $f - r$. \triangleleft

We now combine the two bounds to complete the proof. From Claim 13 it follows that either $M[u, v] \leq 2 \cdot (k - 1)d_G(u, a) + d_G(u, v)$ or $M[u, v] \leq 2 \cdot (k - 1)d_G(v, b) + d_G(u, v)$. Assume that $M[u, v] \leq 2 \cdot (k - 1)d_G(u, a) + d_G(u, v)$. From Claim 12 it follows that $M[u, v] \leq \min\{3d_G(u, v) - 2d_G(b, v), 3d_G(u, v) - 2d_G(a, u)\}$. Thus, $M[u, v] \leq \min\{2 \cdot (k - 1)d_G(u, a) + d_G(u, v), 3d_G(u, v) - 2d_G(a, u)\}$. Let $X = 2 \cdot (k - 1)d_G(u, a) + d_G(u, v)$ and let $Y = 3d_G(u, v) - 2d_G(a, u)$. When $d_G(u, a) = d_G(u, v)/k$, we have $X = Y = 2d_G(u, v) + \frac{k-2}{k} \cdot d_G(u, v)$. When $d_G(u, a) < d_G(u, v)/k$ we have $X < 2d_G(u, v) + \frac{k-2}{k} \cdot d_G(u, v)$. When $d_G(u, a) > d_G(u, v)/k$ we have $Y < 2d_G(u, v) + \frac{k-2}{k} \cdot d_G(u, v)$. Since $M[u, v] \leq \min\{X, Y\}$ we get that $M[u, v] \leq 2d_G(u, v) + \frac{k-2}{k} \cdot d_G(u, v)$.

Consider the degenerate case in which $P(u, v)$ has only two edges, and assume that $b = v$. From Claim 13 it follows that $M[u, v] \leq 2 \cdot (k-1)d_G(u, a) + d_G(u, v)$. From Claim 12 it follows that $M[u, v] \leq 3d_G(u, v) - 2d_G(a, u)$. Thus, from the same arguments as above, $M[u, v] \leq 2d_G(u, v) + \frac{k-2}{k} \cdot d_G(u, v)$. \blacktriangleleft

We now turn to analyze the running time of the algorithm.

► **Lemma 14.** *The expected running time of $\text{APASP}(G, \mathcal{S}_k^p)$ is $\tilde{O}(n^2 + (k-1)n^2p^{-1} + mnp^{k-1})$*

Proof. Initializing M takes $O(n^2)$ time. From Lemma 8 it follows that the call to PIVOT-DIST takes $\tilde{O}(n^2 + (k-1)n^2p^{-1} + mnp^{k-1})$ time. Finally, for every $u \in V$, $i \in [0, k-2]$ and $v \in V$ we do $|B_i(u)| + 1$ read operations to matrix M . This takes $\tilde{O}(n^2 + k(n^2p^{-1}))$ time, since $|B_i(u)| = \tilde{O}(p^{-1})$, for $i \in [0, k-2]$. \blacktriangleleft

We can now prove:

The approach presented so far powerful enough on its own to obtain the following non trivial generalization, which already improves the general scheme presented by Cohen and Zwick [9].

► **Theorem 15.** *For every integer $k \geq 2$, there is an APASP algorithm with expected running time of $\tilde{O}(kn^{2-1/k}m^{1/k})$ and multiplicative approximation of $2 + \frac{k-2}{k}$.*

Proof. We run APASP with the hierarchy \mathcal{S}_k^p . From Lemma 14 it follows that the running time is $\tilde{O}(n^2 + (k-1)n^2p^{-1} + mnp^{k-1})$. Setting $n^2p^{-1} = mnp^{k-1}$ we get $p = \left(\frac{n^2}{mn}\right)^{1/k}$. Thus, the running time is $\tilde{O}(kn^{2-1/k}m^{1/k})$. From Lemma 11 it follows that the multiplicative approximation is $2 + \frac{k-2}{k}$. \blacktriangleleft

4 A faster scheme

In this section we first present augmented hierarchies. This is basically the first part of the 2-approximation algorithm of Baswana and Kavitha [4]. We provide a tighter analysis that relaxes the requirements for getting a 2-approximation. We then present the idea of mixed hierarchies, a combination of a regular hierarchy with the last set of the augmented hierarchy. This allows us to connect our algorithm from Section 3, that worked with a base set V , to the first part of the 2-approximation algorithm, by forcing the second set of a mixed hierarchy to be the last set of the augmented hierarchy. We end by proving Theorem 1.

4.1 Augmented hierarchy with $\hat{S}_k \neq \emptyset$

Thorup and Zwick [25] showed that if a set $S \subseteq V$ is constructed by a careful recursive sampling procedure then the maximum size of every cluster is bounded as well. They proved:

► **Lemma 16** ([25]). *Given a parameter p , we can compute a set S of size $\tilde{O}(np)$ in $\tilde{O}(mp^{-1})$ expected time such that, $|C_S(w)| = O(1/p)$ for every vertex $w \in V \setminus S$, and $|B_S(v)| = O(1/p)$ for every $v \in V$.*

Following Baswana and Kavitha [4] we will extend the vertex hierarchy to an *augmented hierarchy*, denoted with $\hat{\mathcal{S}}_k^p$. Let \mathcal{S}_k^p be a regular hierarchy with $S_0 = V$ and $S_k = \emptyset$. Let S be a set computed using Lemma 16 with parameter p^k . In $\hat{\mathcal{S}}_k^p$ we have $\hat{S}_i = S_i \cup S$, for every $i \in [0, k]$. In particular, we have $\hat{S}_k = S$. We also set $\hat{S}_{k+1} = \emptyset$. We refer to S as the augmenting set of the hierarchy.

The pivots data that we compute for an augmented hierarchy \hat{S}_k^p is computed using algorithm AUG-PIVOT-DIST. Algorithm AUG-PIVOT-DIST differs from PIVOT-DIST by an additional special phase that is added between the first phase and the second phase and by avoiding the explicit computation of bunches in phase 2. The special phase is devoted for the set \hat{S}_k . For every $u \in V$, we compute $B_{\hat{S}_k}(u)$ and $C_{\hat{S}_k}(u)$. For every $a \in B_{\hat{S}_k}(u) \cup C_{\hat{S}_k}(u)$ and $i \in [0, k]$ we scan the edges of a and update the weight of the edge between $p_i(u)$ and every $b \in N(a)$ so that it will be at most $d_G(p_i(u), u) + d_G(u, a) + \mathbf{w}(a, b)$.

Next, we analyze the running time of AUG-PIVOT-DIST.

► **Lemma 17.** *If S is computed using Lemma 16 with parameter p^k then the expected running time of Algorithm AUG-PIVOT-DIST(\hat{S}_k^p) is $\tilde{O}(n^2 + (k-1)n^2p^{-1} + kmp^{-k})$*

Proof. Phase 1 remains unchanged, therefore, its cost remains $\tilde{O}(n^2)$ as in Lemma 8.

In the special phase we compute for every $u \in V$ the ball $B_S(u)$ in $\tilde{O}(\sum_{u \in V} \deg(u)|B_S(u)|)$ time as was shown by Baswana and Kavitha [4]. Since $|B_S(u)| = O(p^{-k})$ this part takes $\tilde{O}(mp^{-k})$ time. Since clusters are simply the inverse of balls we can compute them at the same cost. For every $a \in B_{\hat{S}_k}(u) \cup C_{\hat{S}_k}(u)$ and for every $i \in [0, k-1]$ we scan the edges of a and update for every $b \in N(a)$ the value of $\mathbf{w}(p_i(u), b)$, if needed. The total cost of this is $O(k \sum_{a \in V} |C_{\hat{S}_k}(a) \cup B_{\hat{S}_k}(a)| \deg(a)) = O(kmp^{-k})$. In phase 2 we do not compute bunches as before and thus the cost is only $\tilde{O}(m)$ for the computation of $p_i(u)$ and $d_G(u, S_i)$. In phase 3 we no longer have to split the analysis of the case that $i = k-1$ from the analysis of the general case. This is due to the fact that $\hat{S}_k \neq \emptyset$. Since a vertex is in \hat{S}_k with probability less than p^k we can apply Lemma 3 and get that the expected size of E_{S_k} is $O(n/(p^k))$. Therefore, phase 3 takes $\tilde{O}(n^2 + (k-1)n^2p^{-1})$ time. ◀

We use AUG-PIVOT-DIST for computing APASP in an algorithm denoted with AUG-APASP. The running time analysis of AUG-APASP stems from Lemma 17 and Lemma 14.

► **Corollary 18.** *AUG-APASP(G, \hat{S}_k^p) has $\tilde{O}(n^2 + kn^2p^{-1} + kmp^{-k})$ expected running time.*

In order to analyse the approximation produced by AUG-APASP we introduce the following definition which allows us to relax the condition required for proving a 2 approximation.

► **Definition 19.** *Let $u, v \in V$ and let $S \subseteq V$. We say that u and v are covered by balls $B_S(u)$ and $B_S(v)$ if there is a shortest path P between u and v such that $P \subseteq B_S(u) \cup B_S(v)$.*

The next Lemma follows easily from the above definition.

► **Lemma 20.** *If $B_S(u)$ and $B_S(v)$ do not cover $u, v \in V$ then $d_G(u, S) + d_G(v, S) \leq d_G(u, v)$*

Proof. As u and v are not covered by $B_S(u)$ and $B_S(v)$ every shortest path $P(u, v)$ has a vertex $w \notin B_S(u) \cup B_S(v)$. Thus, $d_G(u, S) \leq d_G(u, w)$ and $d_G(v, S) \leq d_G(v, w)$. Since $w \in P(u, v)$ we get $d_G(u, v) = d_G(u, w) + d_G(v, w)$ and $d_G(u, S) + d_G(v, S) \leq d_G(u, v)$. ◀

We are now ready to bound the approximation produced by AUG-APASP.

► **Lemma 21.** *Let \hat{S}_k^p be an augmented hierarchy with $\hat{S}_0 = V$ and $\hat{S}_k = S$. If $B_{\hat{S}_k}(u)$ and $B_{\hat{S}_k}(v)$ do not cover $u, v \in V$ then AUG-APASP(G, \hat{S}_k^p) returns a matrix M that satisfies: $d_G(u, v) \leq M[u, v] \leq 2d_G(u, v)$.*

Proof. Let $u, v \in V$. Let $i \in [0, k]$ be the smallest index such that $B_{\hat{S}_i}(u)$ and $B_{\hat{S}_i}(v)$ cover u and v . Such an index must exist since u and v are covered by $B_{\hat{S}_k}(u)$ and $B_{\hat{S}_k}(v)$. Since $B_{\hat{S}_0}(v) = \{v\}$ and $B_{\hat{S}_0}(u) = \{u\}$ and since we can assume that any shortest path between u

and v is of at least two edges we have that u and v are not covered by $B_{\hat{S}_0}(v)$ and $B_{\hat{S}_0}(u)$. Thus, $i > 0$. From Lemma 20 it follows that $d_G(u, \hat{S}_{i-1}) + d_G(v, \hat{S}_{i-1}) \leq d_G(u, v)$. Assume, wlog, that $d_G(u, \hat{S}_{i-1}) \leq d_G(v, \hat{S}_{i-1})$. Let $P(u, v)$ be a shortest path between u and v such that $P(u, v) \subseteq B_{\hat{S}_i}(u) \cup B_{\hat{S}_i}(v)$.

We can partition $P(u, v)$ into three portions. A portion $P(u, a)$ between u and a in $B_{\hat{S}_i}(u)$, a portion $P(b, v)$ between v and b in $B_{\hat{S}_i}(v)$, and an edge (a, b) . Since $d_G(u, a) < d_G(u, p_i(u))$ it follows from Lemma 2 that $P(u, a)$ is in $G(V, E_{\hat{S}_i})$ and $d_{(V, E(\hat{S}_i))}(u, a) = d_G(u, a)$. Similarly, $P(v, b)$ is in $G(V, E_{\hat{S}_i})$ and $d_{(V, E(\hat{S}_i))}(v, b) = d_G(v, b)$.

Now $B_{\hat{S}_i}(u) \subseteq B_{\hat{S}_k}(u)$. This implies that $a \in B_{\hat{S}_k}(u)$ and $\mathbf{w}(p_{i-1}(u), b)$ was updated in the special phase of AUG-PIVOT-DIST such that $\mathbf{w}(p_{i-1}(u), b) \leq d_G(p_{i-1}(u), u) + d_G(u, a) + \mathbf{w}(a, b)$. After running Dijkstra's algorithm in phase 3 of AUG-PIVOT-DIST for $p_{i-1}(u)$ in $G_i(p_{i-1}(u))$ we have $M[p_{i-1}(u), v] \leq d_G(p_{i-1}(u), u) + d_G(u, v)$. Thus, after updating the M with the result of AUG-PIVOT-DIST we have $M[p_{i-1}(u), v] \leq d_G(p_{i-1}(u), u) + d_G(u, v)$ and $M[p_{i-1}(u), u] = d_G(p_{i-1}(u), u)$. In line (1) of AUG-APASP we update $M[u, v]$ if needed, therefore, it is guaranteed that $M[u, v] \leq 2d_G(p_{i-1}(u), u) + d_G(u, v) \leq 2d_G(u, v)$. \blacktriangleleft

4.2 A mixed hierarchy

Let S be the augmenting set of an augmented hierarchy. We define a *mixed hierarchy* as follows: $\bar{S}_0 = V$, $\bar{S}_1 = S$. For $i \in [2, k-1]$ the set \bar{S}_i is constructed by picking every vertex of \bar{S}_{i-1} independently at random with probability $p \cdot c \log n$, for some constant c . The set \bar{S}_k is empty. We denote a mixed hierarchy with $\bar{S}_k^{p,q}$, where q is the parameter used to create S by Lemma 16.

We update PIVOT-DIST to handle a mixed hierarchy. We add a special phase as in AUG-PIVOT-DIST for the set \bar{S}_1 . Since $|\bar{S}_0| = n$ and $|E_{\bar{S}_1}| = O(nq^{-1})$ we do not execute phase 3 for the vertices of $\bar{S}_0 = V$ to avoid an additional cost of $\tilde{O}(n^2q^{-1})$ time. In phase 3 the set $E(1/(p^{i+1}))$ is changed to $E(1/(qp^i))$, so that it reflects the size of \bar{S}_1 . The updated algorithm is called MIX-PIVOT-DIST.

Next, we analyze the running time of MIX-PIVOT-DIST.

► **Lemma 22.** *MIX-PIVOT-DIST($\bar{S}_k^{p,q}$) has an expected running time of $\tilde{O}(n^2 + (k-2)n^2p^{-1} + mq^{-1} + mnqp^{k-2})$.*

Proof. The analysis of the first phase remains as in Lemma 8, and therefore it is $O(n^2)$. The special phase costs $\tilde{O}(mq^{-1})$ as in Lemma 17. In the second phase we compute $p_i(u)$, $d_G(u, \bar{S}_i)$ and $B_i(u)$ for every $u \in V$. It takes $\tilde{O}(m)$ time to compute $p_i(u)$ and $d_G(u, \bar{S}_i)$, for every $u \in V$. Computing $B_i(u)$ for every $u \in V$, where $i \in [2, k-2]$ costs $\tilde{O}(m \cdot p^{-1})$. Computing $B_1(u)$ for every $u \in V$ costs $\tilde{O}(m \cdot q^{-1})$ since q is the parameter used for \bar{S}_1 . Computing $B_{k-1}(u)$, for every $u \in V$, costs $\tilde{O}(m \cdot nqp^{k-2})$, since from Lemma 6 we have $B_{k-1}(u) = \tilde{O}(nqp^{k-2})$.

Line (1) costs $\tilde{O}(\sum_{u \in V} |N(u)|) = \tilde{O}(m)$ and line (2) costs $\tilde{O}(\sum_{u \in V} |B_i(u)| \cdot |N(u)|) = \tilde{O}(m \cdot (p^{-1} + q^{-1}))$.

In the third phase we run Dijkstra's algorithm from every $s \in \bar{S}_i$ in $G_{i+1}(s)$, as before. The set of edges of $G_{i+1}(s)$ is $E_{\bar{S}_{i+1}} \cup E(1/(qp^i)) \cup H(s)$. The set $H(s)$ is of size $O(n)$. The set $E(1/(qp^i))$ is of size $O(n/(qp^i))$. Consider now the set $E_{\bar{S}_{i+1}}$, for $0 < i < k-1$. The probability of a vertex to be in \bar{S}_{i+1} is $\tilde{O}(qp^i)$. Applying Lemma 3 we get that the expected size of the set $E_{\bar{S}_{i+1}}$ is $O(n/(qp^i))$. We get that the cost of the third phase for every $i \in [1, k-2]$ is $\tilde{O}(|\bar{S}_i| \cdot n/(qp^i))$. Since the expected size of \bar{S}_i is $\tilde{O}(nqp^{i-1})$ we get a bound of $\tilde{O}(\sum_{i=1}^{k-2} (n \cdot qp^{i-1} \cdot n/(qp^i)) = \tilde{O}(n^2 + (k-2)n^2p^{-1})$.

When $i = k - 1$ we cannot apply Lemma 3 to bound the size of $E_{\bar{S}_k}$ since $\bar{S}_k = \emptyset$, thus, we bound the cost of running Dijkstra's algorithm from every $s \in \bar{S}_{k-1}$ in $G_k(s)$ with $\tilde{O}(|\bar{S}_{k-1}|m) = \tilde{O}(n \cdot qp^{k-2}m)$. We get a running time of $O(n^2 + (k-2)n^2p^{-1} + mnqp^{k-2})$. ◀

MIX-APASP is algorithm APASP in which MIX-PIVOT-DIST is called instead of PIVOT-DIST. We do not execute Line (2) of APASP when $i = 0$, from the same reason we have not executed phase 3 for the vertices of $\bar{S}_0 = V$ in MIX-PIVOT-DIST. The analysis of the running time of MIX-APASP is relatively straightforward and stems from Lemma 22 and Lemma 14.

► **Corollary 23.** *MIX-APASP($G, \hat{S}_k^{p,q}$) runs in $\tilde{O}(n^2 + kn^2p^{-1} + mq^{-1} + mnqp^{k-2})$ expected time.*

We prove a variant of Lemma 11 for MIX-APASP ($G, \bar{S}_k^{p,q}$). The difference with respect to Lemma 11 is that the Lemma is proved only for vertices $u, v \in V$ that are not covered by $B_{\bar{S}_1}(u)$ and $B_{\bar{S}_1}(v)$. This change is required since we are not computing shortest paths for the vertices of \bar{S}_0 in phase 3 of MIX-PIVOT-DIST.

► **Lemma 24.** *MIX-APASP($G, \bar{S}_k^{p,q}$) returns a matrix M that satisfies: $d_G(u, v) \leq M[u, v] \leq 2d_G(u, v) + \frac{k-2}{k} \cdot d_G(u, v)$, for every $u, v \in V$ that are not covered by $B_{\bar{S}_1}(u)$ and $B_{\bar{S}_1}(v)$.*

Proof. Let $u, v \in V$. Let $P(u, v)$ be a shortest path between u and v . Let $i \in [0, k-1]$ be the largest index such that $d_G(u, \bar{S}_i) + d_G(v, \bar{S}_i) \leq d_G(u, v)$. Such an index must exist since $\bar{S}_0 = V$, which implies that $d_G(u, \bar{S}_0) + d_G(v, \bar{S}_0) = 0 \leq d_G(u, v)$. Since u and v are not covered by $B_{\bar{S}_1}(u)$ and $B_{\bar{S}_1}(v)$, it follows from Lemma 20 that $d_G(u, \bar{S}_1) + d_G(v, \bar{S}_1) \leq d_G(u, v)$, as well and $i \geq 1$. This implies that the analysis of the case that $P(u, v)$ is in $G_{i+1}(p_i(u))$ remains the same and is not affected by the fact that in MIX-PIVOT-DIST no data is computed in phase 3 for the set \bar{S}_0 .

The analysis of the case that the path $P(u, v)$ is not in $G_{i+1}(p_i(u))$ is not using the third phase data of \bar{S}_0 and remains the same. Thus, for the rest of the proof we can assume that $0 < i < k-1$, $P(u, a)$ is in $G(V, E_{\bar{S}_{i+1}})$, $P(v, b)$ is in $G(V, E_{\bar{S}_{i+1}})$ and $(a, b) \notin E_a(1/qp^i) \cup E_b(1/qp^i) \cup E_{\bar{S}_{i+1}}$.

The proof of Claim 12 remains the same since we only use data for pivots from \bar{S}_{j-1} , where $j > i+1$ and $i > 0$. Thus, not computing data for \bar{S}_0 in phase 3 of MIX-PIVOT-DIST has no affect.

The proof of Claim 13 remains also the same from the following reason. Recall that we focus on the pair of vertices u and a and the pair of vertices v and b . In the proof we use r which is defined to be the largest index such that $a \notin B_{\bar{S}_r}(u)$ and $u \notin B_{\bar{S}_r}(a)$ and r' which is defined to be the largest index such that $b \notin B_{\bar{S}_{r'}}(v)$ and $v \notin B_{\bar{S}_{r'}}(b)$. Recall also that since $\bar{S}_0 = V$ we have $B_{\bar{S}_0}(x) = \{x\}$, for every $x \in V$ and thus $a \notin B_{\bar{S}_0}(u)$ and $u \notin B_{\bar{S}_0}(a)$ and similarly $b \notin B_{\bar{S}_0}(v)$ and $v \notin B_{\bar{S}_0}(b)$.

From the definition of r it follows that either $a \in B_{\bar{S}_{r+1}}(u)$ or $u \in B_{\bar{S}_{r+1}}(a)$. If $a \in B_{\bar{S}_{r+1}}(u)$ then $d_G(u, a) < d_G(u, \bar{S}_{r+1})$ and it follows from Lemma 2 that $P(u, a) \in E_{\bar{S}_{r+1}}$. Similarly, if $u \in B_{\bar{S}_{r+1}}(a)$ then $d_G(u, a) < d_G(a, \bar{S}_{r+1})$ and it follows from Lemma 2 that $P(u, a) \in E_{\bar{S}_{r+1}}$.

From symmetrical arguments we get that $P(v, b) \in E_{\bar{S}_{r'+1}}$. Since $E_{\bar{S}_j} \subseteq E_{\bar{S}_{j+1}}$, for every $j \in [0, k-1]$, we have and $P(u, a) \subseteq E_{\bar{S}_{q+1}}$, and $P(v, b) \subseteq E_{\bar{S}_{q'+1}}$ for every $q \geq r$ and $q' \geq r'$, respectively.

Because we do not compute in the third phase data for the set \bar{S}_0 we deal separately with the special case that $r = r' = 0$. In such a case we have $a \in B_{\bar{S}_1}(u)$ or $u \in B_{\bar{S}_1}(a)$ and also $b \in B_{\bar{S}_1}(v)$ or $v \in B_{\bar{S}_1}(b)$ ⁵. Now since u and v are not covered by $B_{\bar{S}_1}(u)$ and $B_{\bar{S}_1}(v)$ it must

⁵ If there are only two edges of the path the same proof holds with $b = v$

Algorithm 5 MAIN-APASP(G, k').

create a set S with prob. $n^{-\beta}$ using Lemma 16;
 create an augmented hierarchy $\hat{S}_{\log n}^{n^{-\beta/\log n}}$ with S as the augmenting set;
 create a mixed hierarchy $\bar{\mathcal{H}}_{k'}^{n^{-\gamma/(k'-2)}, n^{-\beta}}$ with $\bar{H}_1 = S$;
 $M_1 \leftarrow \text{AUG-APASP}(G, \hat{S}_{\log n}^{n^{-\beta/\log n}})$;
 $M_2 \leftarrow \text{MIX-APASP}(G, \bar{\mathcal{H}}_{k'}^{n^{-\gamma/(k'-2)}, n^{-\beta}})$;
 $M \leftarrow \min\{M_1, M_2\}$;
 return M ;

be that either $a \notin B_{\bar{S}_1}(u)$ or $b \notin B_{\bar{S}_1}(v)$. Assume, wlog, that $a \notin B_{\bar{S}_1}(u)$. From the definition of r it must be that $u \in B_{\bar{S}_1}(a)$, as otherwise $r > 0$. Because $u \in B_{\bar{S}_1}(a)$ we update $\mathbf{w}(p_1(u), b)$ in the special phase of MIX-PIVOT-DIST so that it is at most $d_G(p_1(u), u) + d_G(u, a) + \mathbf{w}(a, b)$.

Since $r' = 0$ we have that $P(v, b) \in E_{\bar{S}_2}$. Thus, at the third phase of MIX-PIVOT-DIST we update $M[p_1(u), v]$, due to the bound of $\mathbf{w}(p_1(u), b)$, so that it is at most $d_G(p_1(u), u) + d_G(u, v)$. Now in line (1) of MIX-APSP $M[u, v]$ is updated so that it is at most $2d_G(p_1(u), u) + d_G(u, v)$. Since $a \notin B_{\bar{S}_1}(u)$ we have $d_G(p_1(u), u) \leq d_G(u, a)$ and we get that $M[u, v] \leq 2d_G(u, a) + d_G(u, v)$. This is exactly bound (i) in Claim 13 for $k = 2$ and thus holds for every $k \geq 2$. Thus, we can assume that $r > 0$ and not computing data for \bar{S}_0 in phase 3 of MIX-PIVOT-DIST has no affect on the proof of Claim 13 since $f \geq r$. \blacktriangleleft

4.3 Combining augmented hierarchies and mixed hierarchies

We now describe our main APASP algorithm MAIN-APASP. The input is a weighted undirected graph G and an integer k' . We use two hierarchies. An augmented hierarchy \hat{S}_k^p , $k = \log n$ levels, set \hat{S}_0 is V and the probability p is $\tilde{O}(n^{-\beta/\log n})$. The hierarchy is augmented with a set S computed by Lemma 16 with parameter $n^{-\beta}$. Notice that $|\hat{S}_{\log n}| = \tilde{O}(n^{1-\beta})$, and for every $v \in V$ we have $|B_{\hat{S}_{\log n}}(v)| = |C_{\hat{S}_{\log n}}(v)| = O(n^\beta)$. The second hierarchy is a mix hierarchy $\bar{\mathcal{H}}_{k'}^{p,q}$ with k' levels, $\bar{H}_1 = \hat{S}_{\log n}$ and $\bar{H}_{k'} = \emptyset$. Since $\hat{S}_{\log n}$ is formed using Lemma 16 with parameter $n^{-\beta}$ we have $q = n^{-\beta}$. The probability p is $\tilde{O}(n^{-\gamma/(k'-2)})$.

Next, we run $\text{AUG-APASP}(G, \hat{S}_{\log n}^{n^{-\beta/\log n}})$. Then we run $\text{MIX-APASP}(G, \bar{\mathcal{H}}_{k'}^{n^{-\gamma/(k'-2)}, n^{-\beta}})$. MAIN-APASP is presented in Algorithm 5. We now turn to analyse the running time.

► **Lemma 25.** MAIN-APASP(G, k') runs in of $\tilde{O}(n^2 + m^{\frac{2}{k'}} n^{2-\frac{3}{k'}})$ expected time.

Proof. It follows from Lemma 16 that S can be computed in $\tilde{O}(mn^\beta)$ expected running time. It follows from Corollary 18 that the expected running time of $\text{AUG-APASP}(G, \hat{S}_{\log n}^{n^{-\beta/\log n}})$ is $\tilde{O}(n^2 + n^2 \cdot n^{\beta/\log n} \log n + mn^\beta \log n) = \tilde{O}(n^2 + mn^\beta)$. It follows from Corollary 23 that the expected running time of $\text{MIX-APASP}(G, \bar{\mathcal{H}}_{k'}^{n^{-\gamma/(k'-2)}, n^{-\beta}})$ is $\tilde{O}(n^2 + (k' - 2)n^2 n^{\gamma/(k'-2)} + mn^{1-\beta-\gamma})$. We first express n^β as a function of n^γ using the equation $n^2 n^{\gamma/(k'-2)} = mn^{1-\beta-\gamma}$ which balances the two main terms in the running time of MIX-APASP.

$$n^2 n^{\gamma/(k'-2)} = mn^{1-\beta-\gamma} \longrightarrow n^\beta = \frac{mn^{1-\gamma}}{n^2 n^{\gamma/(k'-2)}} \longrightarrow n^\beta = \frac{m}{n^{1+\gamma(1+1/(k'-2))}}$$

Next, we substitute n^β as a function of n^γ in the running time of AUG-APASP.

$$\tilde{O}(n^2 + mn^\beta) \xrightarrow{n^\beta = \frac{m}{n^{1+\gamma(1+1/(k'-2))}}} \tilde{O}(n^2 + \frac{m^2}{n^{1+\gamma(1+1/(k'-2))}})$$

We now compute the value of n^γ using the equation $n^{2+\gamma/(k'-2)} = \frac{m^2}{n^{1+\gamma(1+1/(k'-2))}}$ which balances the two main terms in the running times of MIX-APASP and AUG-APASP.

$$n^{\gamma(1+2/(k'-2))} = \frac{m^2}{n^3} \longrightarrow n^\gamma = \left(\frac{m^2}{n^3}\right)^{\frac{k'-2}{k'}}$$

To obtain the running time of APASP we substitute n^γ in $n^{2+\gamma/(k'-2)}$:

$$n^{2+\gamma/(k'-2)} \xrightarrow{n^\gamma = \left(\frac{m^2}{n^3}\right)^{\frac{k'-2}{k'}}} n^2 \left(\frac{m^2}{n^3}\right)^{\frac{1}{k'}} = n^{2-\frac{3}{k'}} m^{\frac{2}{k'}}$$

Thus, we get that the running time of APASP is $\tilde{O}(n^2 + m^{\frac{2}{k'}} n^{2-\frac{3}{k'}})$. ◀

We now bound the approximation of MAIN-APASP.

► **Lemma 26.** *Algorithm MAIN-APASP(G, k') returns a matrix M that satisfies: $d_G(u, v) \leq M[u, v] \leq 2d_G(u, v) + \frac{k'-2}{k'} \cdot d_G(u, v)$, where $k' \geq 2$.*

Proof. Let $u, v \in V$. Recall that $\bar{H}_1 = \hat{S}_{\log n}$. If u and v are covered by $B_{\bar{H}_1}(u)$ and $B_{\bar{H}_1}(v)$ then it follows from Lemma 21 that Algorithm AUG-APASP returns a matrix M_1 that satisfies: $d_G(u, v) \leq M_1[u, v] \leq 2d_G(u, v)$. If u and v are not covered by $B_{\bar{H}_1}(u)$ and $B_{\bar{H}_1}(v)$ then it follows from Lemma 24 that Algorithm MIX-APASP returns a matrix M that satisfies:

$$d_G(u, v) \leq M_2[u, v] \leq 2d_G(u, v) + \frac{k'-2}{k'} \cdot d_G(u, v).$$

Since $M = \min\{M_1, M_2\}$ the claim follows. ◀

Proof of Theorem 1

Proof. The proof follows from Lemma 25 and Lemma 26. ◀

Abstract

We introduce the *Voronoi Diagram of Rotating Rays*, a Voronoi structure where the input sites are rays, and the distance function is the counterclockwise angular distance between a point and a ray-site. This novel Voronoi diagram is motivated by illumination and coverage problems, where a domain has to be covered by floodlights (wedges) of uniform angle, and the goal is to find the minimum angle necessary to cover the domain. We study the diagram in the plane, and we present structural properties, combinatorial complexity bounds, and a construction algorithm. If the rays are induced by a convex polygon, we show how to construct the ray Voronoi diagram within this polygon in linear time. Using this information, we can find in optimal linear time the *Brocard angle*, the minimum angle required to illuminate a convex polygon with floodlights of uniform angle. This last algorithm improves upon previous results, settling an interesting open problem.

■ **Figure 1** (a) An α -floodlight aligned with a ray r , having apex $p(r)$. The angle α is the angular distance from a point x to r . (b) The Rotating Rays Voronoi diagram of four rays in the plane. Each region is represented by a different color, and all points in a region are first illuminated by the ray of the respective color.

1 Introduction

In this work, we study the *Voronoi diagram of rotating rays* in the plane, which is defined by a set of n rays in \mathbb{R}^2 , under an angular distance function. Given a point x and a ray r in the plane, the *angular distance* from x to r is the smallest angle α such that, if we counterclockwise rotate r around its apex by α , it reaches (*illuminates*) x ; see Figure 1. We define this diagram and use it to solve related floodlight illumination problems.

Motivation. Illumination problems are well known *art gallery* type of problems, where a given domain has to be covered by so-called *floodlights*, which are light sources that illuminate a cone from their apex. The distance measure we study in this work is motivated by the following illumination problem. An α -floodlight is a floodlight with aperture α . Given a simple polygon P , an α -floodlight facing the interior of P is placed on each vertex v , in such a way that one of its rays contains the successor of v in the counterclockwise order of the vertices of P ; see Figure 2(a). The *Brocard Illumination problem* [1] asks for the *Brocard angle*, the smallest value of α for which the set of α -floodlights covers the interior of P .

When P is a convex polygon, the Brocard angle α^* can be revealed by constructing the Voronoi diagram of the rays placed at the vertices of P . In particular, α^* is realized at a vertex of the diagram with the maximum angular distance; see Figure 2(b). A rather natural extension is to follow a similar approach, not only in polygonal, but also in different domains. In addition to polygons, traditional domains to illuminate by floodlights include the entire plane, a region in the plane, or a single curve; see e.g., [6, 10, 25, 27]. Constructing the respective Voronoi diagram restricted to each domain yields the minimum angle needed by the floodlights to illuminate this domain. Hence, there is an interest in studying such Voronoi diagrams and in designing efficient construction algorithms for different domains.

Related work. In the Brocard illumination problem, a polygon P is called a *Brocard polygon*, if the Brocard angle is realized at a point, which is illuminated by all the floodlights, and is also equidistant to all the rays containing the sides of P [4]. The characterization of Brocard polygons has a long history, yet, only harmonic polygons (which include triangles and regular polygons) are known to be Brocard [7]. Nevertheless, we can detect if a convex polygon with n vertices is Brocard in $O(n)$ time, and compute the Brocard angle in such case in $O(1)$

■ **Figure 2** A polygon P . (a) Illumination by α -floodlights aligned with each edge of P . (b) The Voronoi diagram of the edge-aligned rays confined into P . Highlighted are the rays that realize the Brocard angle α^* , along with the point at which α^* is realized.

time. Algorithms for the computation of the Brocard angle of arbitrary simple polygons were recently presented by Alegría et al. [1]. The authors gave an $O(n^3 \log^2 n)$ time algorithm and complemented this with an $O(n \log n)$ -time algorithm for convex polygons¹.

Since their introduction [6], floodlight illumination problems have been studied a lot, see e.g., [22, 28]. The case when the floodlights are of uniform angle has also been explored by several authors, see e.g., [8, 13, 16, 23, 27]. From a different viewpoint, rotating α -floodlights can also be used to model devices with limited sensing range, like surveillance cameras or directional antennae; see [3, 9, 20, 21]. In this context, the minimum angle is interpreted as the minimum range needed by a set of devices to cover a domain. The Rotating Rays Voronoi Diagram is novel with respect to both the input sites and the distance function. A somewhat related diagram was defined in [11] to model dominance regions in the analysis of soccer matches [26].

Our contribution. We introduce the *Rotating Rays Voronoi Diagram* and prove a series of results, paving the way for future work on similar problems. Our interest in this diagram stems from its application to floodlight illumination in different domains.

- In Section 3, we consider the diagram in the plane. We identify structural properties which we complement with complexity results: an $\Omega(n^2)$ worst case lower bound and an $O(n^{2+\epsilon})$ upper bound. As a by-product we get an $O(n^{2+\epsilon})$ -time construction algorithm. This algorithm allows us to find, within the same time, the minimum angle needed to illuminate the plane with a given set of ray-aligned floodlights.
- Motivated by the Brocard illumination problem, in Section 4, we restrict our domain to a convex polygonal region bounded by the input set of sites. We study the Voronoi diagram in such domain and describe a construction algorithm that works in deterministic $\Theta(n)$ time. As our main contribution, we show how to use the resulting diagram to find the Brocard angle of a convex polygon in optimal linear time.
- Finally, in Section 5, we consider the case where the domain of interest is a curve, and we show how to construct the diagram along various types of curves.

¹ The $O(n)$ time analysis of the algorithm for convex polygons stated in [1] is not correct.

■ **Figure 3** The bisector of two rays r and s , consisting of r (red ray), s (blue ray) and an arc of $C_b(r, s)$ (black curve), in different configurations. (a) Non-intersecting with $I \notin r \cup s$. (b) Non-intersecting with $I \in r$. (c) Intersecting. (d) “Tangent” with $p(r) \in s$. (e) “Tangent” with $p(r) \in l(s) \setminus s$. (f) Sharing their apex. (g) Parallel. (h) Anti-parallel with $l(r) \neq l(s)$. (i) Anti-parallel with $l(r) = l(s)$.

2 Preliminaries

Let S be a set of n rays in \mathbb{R}^2 . Given a ray r , we denote its apex by $p(r)$, its supporting line by $l(r)$, and its direction in the unit circle by $\hat{d}(r)$. We define the distance function as follows.

► **Definition 1.** Given a ray r and a point $x \in \mathbb{R}^2$, the oriented angular distance from x to r , denoted by $d_{\angle}(x, r)$, is the minimum counterclockwise angle α from r to a ray with apex $p(r)$ passing through x ; see Figure 1(a). Further, we define $d_{\angle}(p(r), r) = 0$.

It is easy to see that the oriented angular distance is not a metric. Moreover, observe that $d_{\angle}(x, r) \in [0, 2\pi)$, and there is a discontinuity at 2π . Using this distance function, we define the bisector of two rays and the Voronoi diagram of a set of rays.

► **Definition 2.** Given two rays r and s , the dominance region of r over s , denoted by $dr(r, s)$, is the set of points with smaller angular distance to r than to s , i.e., $dr(r, s) := \{x \in \mathbb{R}^2 \mid d_{\angle}(x, r) < d_{\angle}(x, s)\}$. The angular bisector of r and s , denoted by $b_{\angle}(r, s)$, is the curve delimiting $dr(r, s)$ and $dr(s, r)$; see Figure 3.

Note that, due to the discontinuity of the distance function, our definition of a bisector is slightly different from standard, which is the locus of points equidistant from two sites.

Given two rays r and s , let $I = l(r) \cap l(s)$. The bisector $b_{\angle}(r, s)$ is the union of the two rays r and s , and a circular arc a that connects $p(r)$ to $p(s)$; see Figure 3. The arc a belongs to the bisecting circle $C_b(r, s)$, which we define as follows:

- If I , $p(r)$, and $p(s)$ are three distinct points, then $C_b(r, s)$ is the circle through I , $p(r)$, and $p(s)$. The arc a contains I , if and only if I lies either on none or on both of r and s ; see Figure 3(a), Figure 3(b) and Figure 3(c).

- If $I = p(r)$ and $I \neq p(s)$, then $C_b(r, s)$ is the circle tangent to $l(r)$ passing through $p(r)$ and $p(s)$. Both a and r lie on the same side of $l(s)$, if and only if $p(r)$ lies on s . We analogously define $C_b(r, s)$ if $I = p(s)$ and $I \neq p(r)$; see Figure 3(d) and Figure 3(e).
- If $p(r) = p(s)$, then both $C_b(r, s)$ and a degenerate to a single point; see Figure 3(f).
- If $l(r)$ and $l(s)$ are parallel, then $C_b(r, s)$ degenerates to the line through $p(r)$ and $p(s)$. If $\hat{d}(r) = -\hat{d}(s)$, then a is a line segment. If instead $\hat{d}(r) = \hat{d}(s)$, then a consists of two half-lines; see Figure 3(g), Figure 3(h) and Figure 3(i).

Observe that the oriented angular distance is monotone along the circular arc a . Further, the angular bisector is connected, unless its defining rays are parallel. For the sake of simplicity, unless otherwise stated, we assume that no two rays in \mathcal{S} have parallel supporting lines, and that the apex of any ray does not lie on any other ray.

► **Definition 3.** *The Rotating Rays Voronoi Diagram (RVD) of a set of rays \mathcal{S} is the subdivision of \mathbb{R}^2 into Voronoi regions defined as follows:*

$$vreg(r) := \{x \in \mathbb{R}^2 \mid \forall s \in \mathcal{S} \setminus \{r\} : d_{\angle}(x, r) < d_{\angle}(x, s)\}.$$

The graph structure of the diagram is $RVD(\mathcal{S}) := (\mathbb{R}^2 \setminus \bigcup_{r \in \mathcal{S}} vreg(r)) \cup \mathcal{S}$.

The Voronoi region $vreg(r)$ can be equivalently defined as the intersection of all the dominance regions of r , i.e., $vreg(r) = \bigcap_{s \in \mathcal{S} \setminus \{r\}} dr(r, s)$. A Voronoi region may be disconnected; each connected component of a Voronoi region is called a *face*.

The diagram $RVD(\mathcal{S})$ has different types of edges and vertices. An edge can be a line segment, a half-line, or a circular arc. A vertex can be the apex of a ray, the intersection point of two rays, the intersection point of three circular arcs, or the intersection point of a ray and a circular arc. Further, $RVD(\mathcal{S})$ is a planar graph with bounded maximum degree; thus, to bound its complexity, it suffices to bound any of its edges, vertices, or faces.

3 RVD in the Plane

In this section we study the diagram $RVD(\mathcal{S})$ in the plane. We first look at some properties and combinatorial complexity bounds. Then we consider the problem of illuminating the plane with a set of floodlights aligned with \mathcal{S} .

3.1 Properties, complexity, and an algorithm

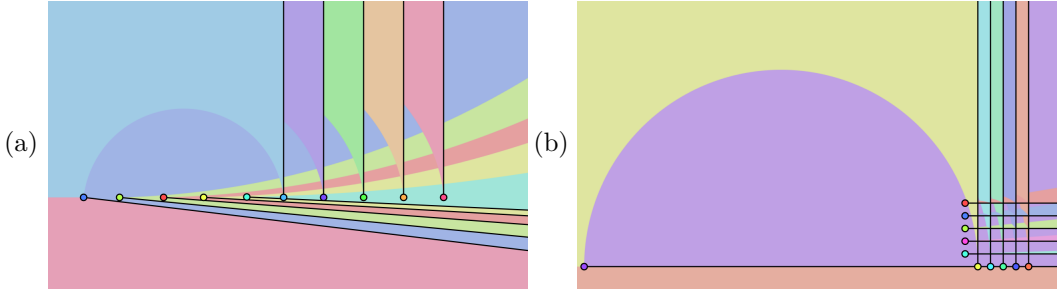

The diagram $RVD(\mathcal{S})$ satisfies the following two simple structural properties.

► **Lemma 4.** *$RVD(\mathcal{S})$ has exactly n unbounded faces, one for each ray in \mathcal{S} .*

Proof. Let r be an arbitrary ray of \mathcal{S} . To examine the unbounded portion of $vreg(r)$, consider the intersection of $RVD(\mathcal{S})$ with a circle Γ of sufficiently large radius, enclosing the vertices of $RVD(\mathcal{S})$ and the bisecting circles of all the bisectors of \mathcal{S} .

For $s \in \mathcal{S} \setminus \{r\}$, the intersection $dr(r, s) \cap \Gamma$ is a circular arc of Γ going counterclockwise from $r \cap \Gamma$ to $s \cap \Gamma$. The region $vreg(r)$ is the intersection of all the dominance regions of r , thus, $vreg(r) \cap \Gamma$ is the intersection of $n - 1$ circular arcs, all starting from r . Hence, $vreg(r) \cap \Gamma$ is a single arc starting from r and ending at the first ray on the counterclockwise ordering along Γ . So, for any ray r , the region $vreg(r)$ has exactly one unbounded face. ◀

► **Lemma 5.** *$RVD(\mathcal{S})$ is connected.*

■ **Figure 4** (a) A set of pairwise non-intersecting rays with $\text{RVD}(\mathcal{S})$ having $\Theta(n^2)$ complexity. (b) A diagram with a Voronoi region (purple ray - leftmost apex) having $\Theta(n^2)$ complexity.

Proof. Assume that $\text{RVD}(\mathcal{S})$ is not connected, hence, it has at least two connected components. Then some region $\text{vreg}(r)$ disconnects $\text{RVD}(\mathcal{S})$ by either having an unbounded face with two occurrences at infinity, or by enclosing a component creating conceptually an *island*.

The first case is excluded by the proof of Lemma 4. For the second case, consider the disconnected component of $\text{RVD}(\mathcal{S})$ surrounded by $\text{vreg}(r)$. This component consists of at least one face of a region $\text{vreg}(s)$ for some $s \in \mathcal{S}$. Then, in $\text{RVD}(\{r, s\})$, there is an island inside $\text{vreg}(r)$. Thus, $b_{\angle}(r, s)$ has a bounded connected component, in contradiction to the fact that each bisector is a single unbounded curve. ◀

We now study the combinatorial complexity of $\text{RVD}(\mathcal{S})$. An $\Omega(n^2)$ lower bound is easily achieved by a set \mathcal{S} of n pairwise intersecting rays. In such case, $\text{RVD}(\mathcal{S})$ has $\binom{n}{2} = \Theta(n^2)$ vertices (one per intersection of rays) and thus $\Omega(n^2)$ complexity. Next, we show that this bound also holds for pairwise non-intersecting rays.

► **Theorem 6.** *The worst case combinatorial complexity of $\text{RVD}(\mathcal{S})$ has an $\Omega(n^2)$ lower bound, even if the rays are pairwise non-intersecting.*

Proof. We give the following construction illustrated in Figure 4(a), where the Voronoi regions of the $n/2 - 1$ rays with the leftmost apices have $n/2 + 1$ faces each. We set $n = 2m$ and let $p(r_i) = (i, 0)$, $i = 1, \dots, 2m$, with rays r_{m+1}, \dots, r_{2m} pointing vertically upwards. For $i = 1, \dots, m$, let the direction of r_i be $\hat{d}(r_i) = (\sin \alpha_i, \cos \alpha_i)$ with $\alpha_1 \in (3\pi/2, 2\pi)$ and $\alpha_i = \alpha_{i-1} + \epsilon_i$ where $\epsilon_i > 0$ for $i = 2, \dots, m$. We choose ϵ_i one by one, in the increasing order of i , so that both r_i and r_{i+1} have a face between any two consecutive upward shooting rays. This is always possible since we can choose ϵ_i small enough so that, at any x -coordinate $x < 2m$, the circular arc of $b_{\angle}(r_i, r_{i+1})$ is arbitrarily close to the x -axis and, thus, it is below the circular arc of $b_{\angle}(r_{i-1}, r_i)$. ◀

► **Theorem 7.** *A Voronoi region of $\text{RVD}(\mathcal{S})$ has $\Theta(n^2)$ complexity in the worst case.*

Proof. We first argue that the complexity of a region is $O(n^2)$. A vertex v of $\text{RVD}(\mathcal{S})$ can be defined by a triplet of rays $r, s, t \in \mathcal{S}$. The bisectors $b_{\angle}(r, s)$ and $b_{\angle}(r, t)$ intersect $O(1)$ times, hence, $\text{RVD}(\{r, s, t\})$ has $O(1)$ vertices. Now consider a ray r and its region $\text{vreg}(r)$. All but at most $O(n)$ vertices on the boundary of $\text{vreg}(r)$ are defined by r and a pair of sites. There are $\Theta(n^2)$ pairs, each inducing $O(1)$ vertices on $\text{vreg}(r)$, so $\text{vreg}(r)$ has $O(n^2)$ vertices.

We now give a construction of $n = 2m + 1$ rays, where a single region has $\Theta(n^2)$ complexity; refer to the construction of Figure 4(b). We first create a grid structure. For $i = 1, \dots, m$, let r_i be a ray with $p(r_i) = (i, 0)$ shooting vertically upward, and let s_i be a ray with $p(s_i) = (0, i)$ shooting horizontally to the right. For all $(i, j) \in \{1, \dots, m - 1\}^2$,

let $R(i, j)$ be the square $[i, i + 1) \times [j, j + 1)$. Each square $R(i, j)$ is made up of two faces of $\text{RVD}(\{r_1, \dots, r_m, s_1, \dots, s_m\})$, one belonging to $\text{vreg}(r_i)$ and one belonging to $\text{vreg}(s_j)$. Now let $\alpha(i, j) := \max\{\min\{d_{\angle}(x, r_i), d_{\angle}(x, s_j)\} \mid x \in R(i, j)\}$ and let $\alpha_{\min} := \min\{\alpha(i, j) \mid (i, j) \in \{1, \dots, m-1\}^2\}$. It is easy to see that $\alpha_{\min} < \arctan 1/(m-1)$.

We now introduce another ray t , so that $\max\{d_{\angle}(x, t) \mid x \in [1, n-1]^2\} < \alpha_{\min}$. This can be achieved if $p(t) = (-n^2, 0)$ and t is shooting horizontally to the right. This means that in each $R(i, j)$, for $(i, j) \in \{1, \dots, n-1\}^2$, t will visit some point before any of the rays r_i or s_j , implying that $\text{vreg}(t)$ has $\Theta(n^2)$ faces. ◀

We now show how the angular distance function can be adapted in order to apply the general upper bounds of Sharir [24]. As a by-product we also obtain an algorithm for $\text{RVD}(\mathcal{S})$.

► **Theorem 8.** *$\text{RVD}(\mathcal{S})$ has $O(n^{2+\epsilon})$ combinatorial complexity, for any $\epsilon > 0$. Further, $\text{RVD}(\mathcal{S})$ can be constructed in $O(n^{2+\epsilon})$ time.*

Proof. Each site r induces a function $d_{\angle}^r(x) = d_{\angle}(x, r)$ which maps a point $x = (x_1, x_2) \in \mathbb{R}^2$ to its angular distance from r . The RVD can be seen as the projection of the lower envelope of the graphs of these distance functions in 3-space to the plane. For algebraic distance functions, Sharir [24] gives complexity bounds for this lower envelope accompanied with algorithmic results. The angular distance functions though are not algebraic. Our strategy is to find algebraic functions d_{alg}^r that are equivalent to the functions d_{\angle}^r for the computation of the lower envelope, i.e., they fulfill the following property for all $r, s \in \mathcal{S}$ and $x \in \mathbb{R}^2$:

$$d_{\angle}^r(x) < d_{\angle}^s(x) \Leftrightarrow d_{\text{alg}}^r(x) < d_{\text{alg}}^s(x).$$

Without loss of generality, assume that $p(r)$ lies on the origin and r is facing to the right, that is, in the positive x_1 -direction of the coordinate system. Let $x \in \mathbb{R}^2$ and $\alpha := d_{\angle}^r(x)$. Then we want to set $d_{\text{alg}}^r(x) := 1 - \cos(\alpha)$ if $0 \leq \alpha \leq \pi$, and $d_{\text{alg}}^r(x) := 3 + \cos(\alpha)$ if $\pi < \alpha < 2\pi$. The function $x \mapsto \cos(\alpha)$ is indeed algebraic since it is obtained by first scaling x to unit length and then mapping it to its first coordinate. Then we have

$$d_{\text{alg}}^r(x) = \begin{cases} 0 & \text{if } x_1 = x_2 = 0, \\ 1 - \frac{x_1}{\sqrt{x_1^2 + x_2^2}} & \text{if } x_1 \neq 0, x_2 \geq 0, \\ 3 + \frac{x_1}{\sqrt{x_1^2 + x_2^2}} & \text{otherwise.} \end{cases}$$

Since d_{alg}^r consists of three patches, which are all algebraic and have simple domain boundaries, applying [24] to these functions yields the claimed results. ◀

3.2 Minimum angle needed to illuminate the plane

Given a set \mathcal{S} of n rays in \mathbb{R}^2 , the Brocard Illumination problem can be naturally extended to the plane as follows. An α -floodlight f is *aligned with* a ray r , if f is equal to r when $\alpha = 0$. Let f_r denote a floodlight aligned with the ray $r \in \mathcal{S}$. The goal is to find the minimum angle α^* for which the set of α^* -floodlights $\{f_r \mid r \in \mathcal{S}\}$ illuminates the entire plane.

The angle α^* is realized at a point x^* that has the maximum angular distance to its nearest ray, that is, $\alpha^* = \max_{x \in \mathbb{R}^2} \min_{r \in \mathcal{S}} d_{\angle}(x, r)$. Hence, the point x^* necessarily lies on $\text{RVD}(\mathcal{S})$. Since the distance along a circular edge is monotone, it follows that x^* cannot lie on such an edge. Thus, x^* is either a vertex of $\text{RVD}(\mathcal{S})$ or a point at infinity on a ray of \mathcal{S} . We can find x^* , and hence α^* , by first constructing $\text{RVD}(\mathcal{S})$ in $O(n^{2+\epsilon})$ time, and then traversing the diagram in linear time in its size. We obtain the following result.

► **Theorem 9.** *Given a set of rays \mathcal{S} and an α -floodlight aligned with each ray, the minimum angle α^* needed to illuminate \mathbb{R}^2 can be found in $O(n^{2+\epsilon})$ time, for any $\epsilon > 0$.*

Next, we give tight bounds on the value of α^* .

► **Proposition 10.** *Given a set of rays \mathcal{S} and an α -floodlight aligned with each ray, the angle α^* is greater or equal to $2\pi/n$. Further, α^* can take any value in the interval $[2\pi/n, 2\pi)$.*

Proof. For the lower bound, consider that in order to illuminate the entire plane, all the points at infinity should also be illuminated. To illuminate these points, the sum of the angles of all rays, should be at least 2π . Hence, in the best case, each point at infinity is seen by exactly one ray, and the $2\pi/n$ lower bound follows. Next, we give a construction realizing this bound.

Let \mathcal{S} be a set of rays having their apices on $(0,0)$, with the property that any two consecutive rays have an angular difference of $2\pi/n$. The last points to be illuminated will be all the points on the right side of each ray r_i . These points are illuminated simultaneously by r_{i-1} when α reaches $2\pi/n$. Further, this construction can be easily adapted to attain any value in $(2\pi/n, 2\pi)$, by expanding a wedge bounded by two consecutive rays to the desired angle and shrinking all the other wedges analogously. ◀

4 RVD of a convex polygon: Brocard illumination

We now turn our attention to the Brocard illumination problem. We are given a convex polygon P with n vertices, and we want to find the Brocard angle α^* of P . By computing an RVD restricted to P , we show how to compute α^* in optimal $\Theta(n)$ time.

Let \mathcal{S}_P be the set of n rays such that each ray has a vertex $v \in P$ as apex, and passes through the successor vertex of v in a counterclockwise traversal of P ; see Figure 5(a). Let $\text{PRVD}(\mathcal{S}_P)$ be the diagram $\text{RVD}(\mathcal{S}_P)$ restricted to the interior of P . We first describe an algorithm to construct $\text{PRVD}(\mathcal{S}_P)$ and then show to use this diagram to obtain α^* . Note that we do not construct the complete $\text{RVD}(\mathcal{S}_P)$, which may have $\Theta(n^2)$ complexity, but only $\text{PRVD}(\mathcal{S}_P)$, which has $\Theta(n)$ size.

4.1 Algorithm to compute RVD of a convex polygon

The general strategy is to split the problem into four subproblems. Each subproblem will satisfy a set of conditions that allows us to use the existing $\Theta(n)$ time algorithms, which are based on *abstract Voronoi diagrams* [17, 19]. We then complete our construction by merging the resulting diagrams.

■ **Figure 5** (a) A convex polygon P and the corresponding set of rays \mathcal{S}_P . (b) The partitioning of \mathcal{S}_P into the four subsets $\mathcal{S}_N, \mathcal{S}_W, \mathcal{S}_S$ and \mathcal{S}_E , depending on the direction of the rays.

■ **Figure 6** (a) The diagram $\text{RVD}(\mathcal{S}_S)$; some Voronoi regions are disconnected. (b) The diagram $\text{RVD}(\mathcal{S}_S^r)$, after a clockwise rotation of $\pi/2$; all Voronoi regions are connected.

More specifically, we first partition \mathcal{S}_P into four sets $\mathcal{S}_N, \mathcal{S}_W, \mathcal{S}_S$ and \mathcal{S}_E depending whether a ray points north, west, south or east respectively; see Figure 5(b). In this way, rays in a subset are consecutive and the direction of any two rays have a difference of at most $\pi/2$. For each set \mathcal{S}_d , $d \in \{N, W, S, E\}$, we obtain a set \mathcal{S}_d^r in which every ray of \mathcal{S}_d is rotated clockwise by an angle of $\pi/2$; see Figure 6. Then, we construct each diagram $\text{RVD}(\mathcal{S}_d^r)$ independently. Finally, we merge the four diagrams to obtain $\text{PRVD}(\mathcal{S}_P)$; see Figure 8.

4.2 The four diagrams of \mathcal{S}_d^r

To construct the diagram of each subset \mathcal{S}_d^r in $\Theta(|\mathcal{S}_d^r|)$ time, we make use of the *abstract Voronoi diagrams* framework [17, 18]. To fall under this framework, the system of angular bisectors must satisfy the following three *axioms*:

- **(A1)** The bisector $b_{\angle}(r, s)$, $\forall r, s \in \mathcal{S}$, is an unbounded Jordan curve.
- **(A2)** The region $\text{vreg}(r)$ in $\text{RVD}(\mathcal{S}')$, $\forall \mathcal{S}' \subseteq \mathcal{S}$ and $\forall r \in \mathcal{S}'$, is non-empty and connected.
- **(A3)** The closure of the union of all regions in $\text{RVD}(\mathcal{S}')$, $\forall \mathcal{S}' \subseteq \mathcal{S}$, covers \mathbb{R}^2 .

► **Lemma 11.** *The system of bisectors of \mathcal{S}_d^r satisfies the axioms (A1)-(A3).*

Proof sketch. **(A1):** Consider a pair of rays $r, s \in \mathcal{S}_d^r$. Let ℓ be the line through $p(r)$ and $p(s)$. Let $x \neq p(r)$ and $y \neq p(s)$ denote respectively, two points lying on r and s . Observe that the angles $\angle(p(s), p(r), x)$, $\angle(x, p(r), p(s))$, $\angle(y, p(s), p(r))$, and $\angle(p(r), p(s), y)$ are all greater than or equal to $\frac{\pi}{2}$, where $\angle(x, y, z)$ denotes the counterclockwise angle at point y , between the rays with apex y passing through x and z , respectively. Hence, r and s are non-intersecting regardless of whether both are contained on ℓ , or lie on the same side of ℓ . The bisector of two non-intersecting rays is an unbounded Jordan curve.

(A2): A Voronoi region $\text{vreg}(r)$ is obviously non-empty as it contains the ray r . Regarding the region connectivity, we claim that no ray of \mathcal{S}_d^r cuts twice a bisecting circle induced by the rays of \mathcal{S}_d^r . From the analysis of Section 2, this implies that every region of $\text{RVD}(\mathcal{S}_d^r)$ is connected, since it consists of a single unbounded face. Consider three rays $r, s, t \in \mathcal{S}_d$. The angle $-\alpha$ required to rotate r around $p(r)$ such that $l(r)$ is either tangent to or not intersecting $C_b(s, t)$ is strictly greater than $-\frac{\pi}{2}$. After rotating r by $-\frac{\pi}{2} \in [-\alpha, -(\alpha + \pi)]$, we obtain a ray in \mathcal{S}_d^r that does not intersect twice $C_b(r, s)$; see Figure 6(b). Our claim follows since \mathcal{S}_d and \mathcal{S}_d^r induce the same set of bisecting circles.

(A3): The diagram $\text{RVD}(\mathcal{S}_d^r)$ is defined by distance functions, one for each site in \mathcal{S}_d^r , whose domain is the entire plane. Thus, it follows that any point in the plane belongs to the closure of a region of $\text{RVD}(\mathcal{S}_d^r)$. ◀

■ **Figure 7** (a) $\text{RVD}(\mathcal{S}_P)$ of a polygon with five vertices. (b) A subset of three rays rotated by $-\pi/2$. The teal region has two faces; for it to be connected, the rays should be rotated by an angle greater than $-\pi/2$. (c) A subset of three rays rotated by $-\pi/2$. The red region has two faces; for it to be connected, the rays should be rotated by an angle smaller than $-\pi/2$.

Since each Voronoi region is connected, and it has exactly one unbounded face, as shown in Lemma 4, it follows that $\text{RVD}(\mathcal{S}_d^r)$ is a tree of complexity $\Theta(\mathcal{S}_d^r)$.

It is worth to note that the original set \mathcal{S}_P need not satisfy axioms (A1)-(A3), thus, $\text{RVD}(\mathcal{S}_P)$ need not fall under the framework of abstract Voronoi diagrams, and hence, the partition into the four subsets and the rotation.

The intuition behind the rotation of the rays comes from the fact that only circular parts of bisectors appear in $\text{PRVD}(\mathcal{S}_P)$, and that the bisecting circles remain the same under a uniform rotation. The partitioning of \mathcal{S}_P into the specific four sets is justified by the following remark.

► **Remark 12.** There are sets of rays \mathcal{S}_P for which there exists no unique angle to rotate the rays in \mathcal{S}_P , so that (A2) is satisfied. Refer to Figure 7.

$\text{RVD}(\mathcal{S}_d^r)$ can be constructed in $O(n \log n)$ time [17]. We can construct $\text{RVD}(\mathcal{S}_d^r)$ in $O(n)$ time by showing that the system of bisectors of \mathcal{S}_d^r falls under the *Hamiltonian abstract Voronoi diagram* framework of Klein and Lingas [19]. In addition to satisfying (A1)-(A3), the *cyclic version* of [19] requires the following axiom to be satisfied:

- **(A4)** There exists a Jordan curve \mathcal{H} of constant complexity such that, \mathcal{H} visits the region $\text{vreg}(r)$ in $\text{RVD}(\mathcal{S}')$, $\forall \mathcal{S}' \subseteq \mathcal{S}$ and $\forall r \in \mathcal{S}'$, exactly once.

If a Voronoi diagram satisfies axioms (A1)-(A4) and the ordering of the regions of $\text{RVD}(\mathcal{S}')$ along \mathcal{H} is given, then $\text{RVD}(\mathcal{S})$ can be computed in $\Theta(n)$ -time [19]. Hence, it suffices to find a curve \mathcal{H} satisfying these properties. We show this in the following.

► **Lemma 13.** $\text{RVD}(\mathcal{S}_d^r)$ can be constructed in deterministic $\Theta(|\mathcal{S}_d|)$ time.

Proof. We show that \mathcal{S}_d^r satisfies axiom (A4) of the Hamiltonian abstract Voronoi diagram framework [19]. The linear time algorithm is then a direct corollary of the existing results [19].

Let Γ be a circle of sufficient large radius enclosing all bisecting circles. Γ is obviously a Jordan curve of constant complexity. For any $\mathcal{S}' \subseteq \mathcal{S}_d^r$, the diagram $\text{RVD}(\mathcal{S}')$ is a tree, and by definition, Γ does not intersect any bisecting circle, hence, Γ visits each region of $\text{RVD}(\mathcal{S}')$ exactly once, with a change on the visited region happening when Γ intersects a ray. Γ is a Hamiltonian curve \mathcal{H} satisfying axiom (A4).

The ordering of the unbounded faces of $\text{RVD}(\mathcal{S}_d^r)$ corresponds to the ordering of the respective vertices along the polygon P , and this is maintained for any $\mathcal{S}' \subset \mathcal{S}_d^r$. The ordering of the vertices of P is given, so this concludes the proof. ◀

4.3 Merging the four diagrams

We now merge all the diagrams to obtain $\text{PRVD}(\mathcal{S}_P)$. Our merging procedure consists of two steps; see Figure 8. In an initial step we merge $\text{RVD}(\mathcal{S}_W^r)$ with $\text{RVD}(\mathcal{S}_S^r)$ to obtain $\text{RVD}(\mathcal{S}_W^r \cup \mathcal{S}_S^r)$, and analogously we obtain $\text{RVD}(\mathcal{S}_E^r \cup \mathcal{S}_N^r)$. Then, in a final step we merge the diagrams $\text{RVD}(\mathcal{S}_W^r \cup \mathcal{S}_S^r)$ and $\text{RVD}(\mathcal{S}_E^r \cup \mathcal{S}_N^r)$, restricted to the interior of P , to obtain $\text{PRVD}(\mathcal{S}_P)$. We show the following statement.

► **Lemma 14.** *Given $\text{RVD}(\mathcal{S}_d)$, for all $d \in \{N, W, S, E\}$, $\text{PRVD}(\mathcal{S}_P)$ can be constructed in $\Theta(n)$ time.*

We now describe the two merging steps and sketch the arguments of the proof. Refer also to Figure 8 and Figure 9. Note that, although the four Voronoi diagrams $\text{RVD}(\mathcal{S}_d)$ to be merged fall under the abstract Voronoi framework, this is not the case for the resulting diagrams. This requires special care in the merging process.

Initial step. We describe how to merge $\text{RVD}(\mathcal{S}_W^r)$ with $\text{RVD}(\mathcal{S}_S^r)$. Let w_1, \dots, w_k be the rays in \mathcal{S}_W^r and let s_1, \dots, s_l be the rays in \mathcal{S}_S^r , as they appear ordered on P . We need to construct the *merge curve*, which consists of the rays s_1, w_1 and the set of circular edges of $\text{RVD}(\mathcal{S}_W^r \cup \mathcal{S}_S^r)$ equidistant to sites $w \in \mathcal{S}_W^r$ and $s \in \mathcal{S}_S^r$, which we denote by E_C . We describe each procedure separately.

- **Tracing s_1 :** The ray s_1 lies entirely in $\text{vreg}(w_k)$. To see this, consider the set \mathcal{S}_W (before rotation) and continuously clockwise rotate all rays by an angle of $\pi/2$. During this process, w_k does not intersect any of the rays in \mathcal{S}_W , hence, $s_1 \in \text{vreg}(w_k)$. Thus, s_1 does not intersect $\text{RVD}(\mathcal{S}_W^r)$ and it can be trivially traced in $O(1)$ time.
- **Tracing E_C :** We start from the point $p(s_1)$, using the bisector $b_{\angle}(s_1, w_k)$ and we trace a chain of circular edges until we reach the ray w_1 . In order to identify at each step the next bisector to proceed, we adapt standard tracing techniques for Voronoi diagrams, see e.g., [2]. More specifically, while going from s_1 to w_1 , the curve E_C visits the regions of the sites s_1, \dots, s_l in exactly that order (some sites might possibly not appear at all). The same holds for the sites w_1, \dots, w_k but in reverse order. Hence, to trace E_C we can go over the two lists of regions in the aforementioned order.
- **Structure of E_C :** To see that the chain ends up at w_1 , consider the distance of any point on the chain to the nearest ray. The distance when the chain starts, at $p(s_1)$, is exactly $\pi/2$, and it is monotonically increasing. Moreover, consider the polygonal chain P^* consisting of the line segments $\overline{p(w_1)p(w_2)}, \overline{p(w_2)p(w_3)}, \dots, \overline{p(w_k)p(s_1)}, \overline{p(s_1)p(s_2)}, \dots, \overline{p(s_{l-1})p(s_l)}$ and the ray s_l . The distance of any point on P^* to its nearest ray, is exactly $\pi/2$. Hence, since the distance along the chain of circular edges is increasing, the chain may only end up at w_1 (but not necessarily at its apex, see e.g., Figure 9(a)).

We now need to show that the chain, which we traced, is the complete set E_C , i.e., there are no other connected components to identify. Additionally, we have to show that E_C does not induce any bounded faces in $\text{RVD}(\mathcal{S}_W^r \cup \mathcal{S}_S^r)$. To prove both statements we define an auxiliary Voronoi diagram, where in contrast to Definition 2, we define the bisector between two rays r and s , to be the entire circle $C_b(r, s)$.

We use this auxiliary diagram due to the simplicity of its bisectors. Since only the circular arcs of the bisectors appear inside P , some properties of the auxiliary Voronoi diagram also hold for $\text{RVD}(\mathcal{S}_W^r \cup \mathcal{S}_S^r)$. More specifically, each region in the auxiliary diagram is connected and the union of all the regions covers P . In addition, the auxiliary Voronoi diagram implies that $\text{RVD}(\mathcal{S}_W^r \cup \mathcal{S}_S^r)$ has $\Theta(|\mathcal{S}_W^r| + |\mathcal{S}_S^r|)$ size, hence, E_C has $O(n)$ size. The curve E_C has $O(n)$ size, and there is no backtracking while traversing the two lists of regions (to identify the edges), hence, E_C can be constructed in time $O(n)$.

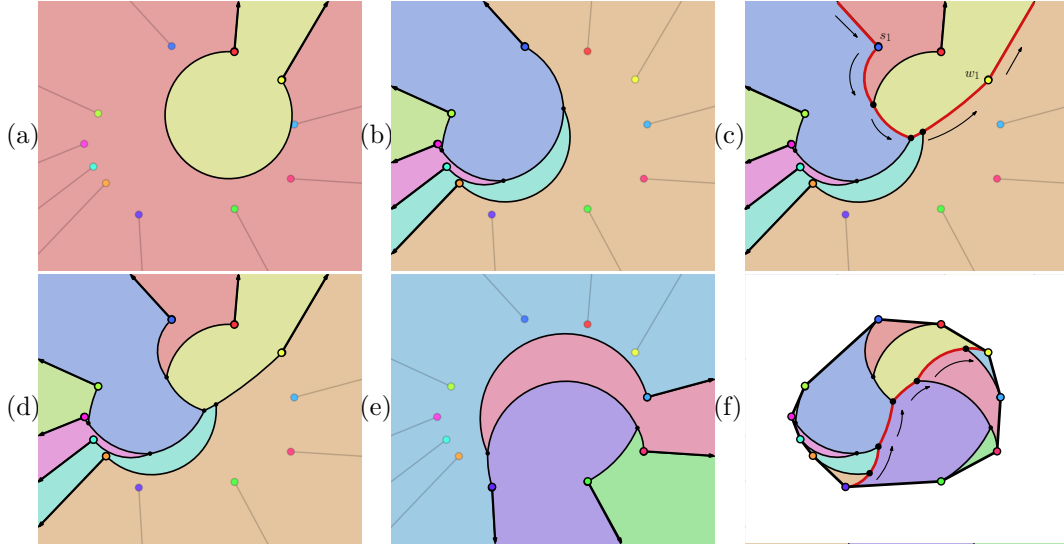

Figure 8 Merging diagrams (a) $\text{RVD}(\mathcal{S}_W^r)$ and (b) $\text{RVD}(\mathcal{S}_S^r)$ into (c) $\text{RVD}(\mathcal{S}_W^r \cup \mathcal{S}_S^r)$. Merging diagrams (d) $\text{RVD}(\mathcal{S}_W^r \cup \mathcal{S}_S^r)$ and (e) $\text{RVD}(\mathcal{S}_E^r \cup \mathcal{S}_N^r)$ into (f) $\text{PRVD}(\mathcal{S}_P)$. The highlighted red edges correspond to the merge curve. The arrows schematize tracing.

Figure 9 Two special cases of merging two diagrams $\text{RVD}(\mathcal{S}_W^r)$ and $\text{RVD}(\mathcal{S}_S^r)$. (a) The sequence of circular edges does not end at $p(w_1)$. (b) Ray w_1 intersects $\text{RVD}(\mathcal{S}_S^r)$.

- **Tracing w_1 :** In contrast to s_1 , the ray w_1 may intersect many circular edges of $\text{RVD}(\mathcal{S}_S^r)$, each inducing a vertex; see e.g., Figure 9(b). To identify such vertices, we can intersect w_1 (starting from the point on w_1 where E_C ended) with $\text{RVD}(\mathcal{S}_S^r)$. This can be easily done in $O(\mathcal{S}_S^r)$ time, as $\text{RVD}(\mathcal{S}_S^r)$ is a tree.

All steps described can be done in $O(n)$ time, concluding the initial merging step.

Final step. We now merge $\text{RVD}(\mathcal{S}_W^r \cup \mathcal{S}_S^r)$ and $\text{RVD}(\mathcal{S}_E^r \cup \mathcal{S}_N^r)$ restricted to P . The merge curve, as it lies inside P , consists only of E_C , the set of circular edges equidistant to sites $r \in \mathcal{S}_S^r \cup \mathcal{S}_W^r$ and $t \in \mathcal{S}_E^r \cup \mathcal{S}_N^r$. Using the same properties as in the initial step, it follows that E_C consists of a single chain, it does not create bounded faces in $\text{PRVD}(\mathcal{S}_P)$, and tracing may not go outside P . Overall, E_C can be identified in $O(n)$ time, and a simple truncation of the merged diagram inside P , yields $\text{PRVD}(\mathcal{S}_P)$ in $\Theta(n)$ time, concluding the proof.

We can summarize the main result of this section as follows.

► **Theorem 15.** *Given a convex polygon P , we can construct $\text{PRVD}(\mathcal{S}_P)$ in $\Theta(n)$ time.*

4.4 Minimum angle needed to illuminate P - Brocard angle

We now turn back to the problem of computing the Brocard angle α^* of a convex polygon P . As in the respective problem in \mathbb{R}^2 , the angle α^* is realized at a point x^* on $\text{PRVD}(\mathcal{S}_P)$. Since the distance along the edges of $\text{PRVD}(\mathcal{S}_P)$ is monotone, x^* cannot lie on an edge. Further, since $\text{PRVD}(\mathcal{S}_P)$ is confined to P by definition, x^* lies actually on a vertex of $\text{PRVD}(\mathcal{S}_P)$. A special case occurs when α^* is realized by two anti-parallel rays (edges), and the circular arc of their bisector degenerates to a line segment ℓ , as in Figure 3(h). In this case, any point on ℓ is at distance α^* from the rays, but since the endpoints of ℓ are also at distance α^* , the Brocard angle is still realized at a vertex of $\text{PRVD}(\mathcal{S}_P)$.

Therefore, to find α^* we can construct $\text{PRVD}(\mathcal{S}_P)$ and then traverse it to find the vertex of maximum distance. Both steps can be done in $\Theta(n)$ time, so we obtain the following.

► **Theorem 16.** *Given a convex polygon the Brocard angle α^* can be found in $\Theta(n)$ time.*

Following, we give tight bounds on the Brocard angle.

► **Proposition 17.** *Given a convex polygon P , the Brocard angle α^* is less or equal to $\pi/2 - \pi/n$. Further, α^* can take any value in the interval $(0, \pi/2 - \pi/n]$.*

Proof. A $\pi/2 - \pi/n$ upper bound on the Brocard angle is given in [5, 12]. Such an angle is realized by regular polygons. The last illuminated point is the center of the regular polygon, which is simultaneously illuminated by all the floodlights at an angle of $\pi/2 - \pi/n$.

To prove the lower bound, consider a polygon with a bounding box of width w and height h . The aspect ratio $\frac{h}{w}$ can be arbitrarily close to zero, hence α^* is also arbitrarily close to zero. Further, we can smoothly transform any such polygon to a regular polygon, while preserving convexity. Thus, it is possible to get any Brocard angle in the range $(0, \pi/2 - \pi/n]$. ◀

As a final note, observe that the three floodlights, which realize α^* , suffice to illuminate P ; see the dashed segments in Figure 2(a). Consider the k -floodlight illumination problem [28], which asks for the minimum angle α_k , under which a convex polygon is illuminated by k floodlights, $k \geq 3$, where the sum of their apertures is α_k . The Brocard illumination gives an $\alpha_3 = 3\alpha^*$ solution to the problem. By Proposition 17, it follows that $\alpha_3 \leq 3\pi/2 - 3\pi/n$. Hence, for $n \leq 6$, the Brocard angle improves the current $a_3 = \pi$ solution given in [28].

5 RVD on curves

Floodlight illumination problems have also been considered restricted to curves. In this section, we are given a set \mathcal{S} of n rays in \mathbb{R}^2 , a set of α -floodlights each aligned with a ray, and a curve \mathcal{C} , and we want to find the minimum value of α such that \mathcal{C} is completely illuminated

■ **Figure 10** A set \mathcal{S} of 3 rays and the line $\mathcal{C} : x_2 = 0$. (a) $\text{RVD}(\mathcal{S})$ in \mathbb{R}^2 and its intersection with \mathcal{C} . (b) $\text{RVD}(\mathcal{S})$ along \mathcal{C} as the lower envelope (highlighted) of distance functions. The angle α^* is illustrated; the last illuminated point is $(-\infty, 0)$ (first illuminated by the blue ray).

by the set of α -floodlights. We show how these problems can be solved by viewing $\text{RVD}(\mathcal{S})$ as the lower envelope of distance functions in 2-space; see Figure 10. We give the proof for the case when \mathcal{C} is a line and then discuss how this approach can be extended to other curves.

► **Theorem 18.** *Given a line \mathcal{C} , $\text{RVD}(\mathcal{S})$ along \mathcal{C} has complexity $O(n2^{\alpha(n)})$ and it can be constructed in $O(n\alpha(n) \log n)$ time.*

Proof. Without loss of generality, let \mathcal{C} be the horizontal line $x_2 = 0$. Each site $r \in \mathcal{S}$ induces a distance function which maps a point $x = (x_1, 0) \in \mathcal{C}$ to $d_{\angle}(x, r)$; see Figure 10(b). If r intersects \mathcal{C} at point $(i, 0)$, then there is a point of discontinuity, and the distance function is split into two partially defined functions, one with the domain up to i and one with the domain starting at i . $\text{RVD}(\mathcal{S})$ along \mathcal{C} is the lower envelope of these distance functions. The lower envelope of n partially defined functions, where each pair of functions intersects at most s times, has $O(\lambda_{s+2}(n))$ complexity [14] and it can be constructed in $O(\lambda_{s+1}(n) \log n)$ time [15], where $\lambda_s(n)$ is the length of the longest (n, s) Davenport-Schinzel sequence.

In our case, a pair of functions intersects at most twice, as \mathcal{C} may intersect twice the bisecting circle of the two respective rays, so $s = 2$. Further, we have at most $2n$ partially defined functions. Thus, $\text{RVD}(\mathcal{S})$ along \mathcal{C} has complexity $O(n2^{\alpha(n)})$ and it can be constructed in $O(n\alpha(n) \log n)$ time, where $\alpha(n)$ is the inverse Ackermann function. ◀

Observe that, the minimum angle α^* needed to illuminate the line \mathcal{C} is realized either at an intersection point between $\text{RVD}(\mathcal{S})$ and \mathcal{C} , or at a point of \mathcal{C} at infinity; see for example the point $(-\infty, 0)$ in Figure 10. Hence, after constructing $\text{RVD}(\mathcal{S})$ along \mathcal{C} , the angle α^* is revealed by a simple traversal of $\text{RVD}(\mathcal{S})$ in time linear in its size.

The aforementioned approach can be generalized to arbitrary curves in a straightforward way. Let \mathcal{C} be a closed curve enclosing the apices of all the rays of \mathcal{S} . Note that, if \mathcal{C} is a circle, then the same results as Theorem 18 can be derived, since \mathcal{C} intersects a bisecting circle at most twice; hence, $s = 2$. On the other hand, if \mathcal{C} is an m -sided convex polygon, then \mathcal{C} intersects a bisecting circle at most $2m$ times, hence $s = 2m$; see Figure 11(b). If \mathcal{C} is an arbitrary simple polygon, then there might be portions of \mathcal{C} not visible by a ray; thus, an additional parameter k should be introduced, to represent the number of partially defined functions corresponding to each ray.

■ **Figure 11** Illustration of the parameters s and k related to curve illumination. The boundary of the polygon P is the curve to be illuminated. (a) The distance function of the ray r is split into 5 partial functions, i.e., $k = 5$. Splits are induced by visibility constraints due to P itself (breakpoint 3-4), by visibility constraints due to other curves (breakpoint 2-3), or by the discontinuity of the distance function at the ray (breakpoint 1-2). (b) The circular arc of the bisector of the two rays r and s intersects the boundary of P at 6 points, i.e., $s = 6$.

Finally, the approach generalizes to cases where the apices of the rays are not enclosed by some curve; see Figure 11(a). As before, the complexity of $\text{RVD}(\mathcal{S})$ restricted to a curve, will be affected by a parameter s , representing the number of times a curve intersects a bisecting circle, and a parameter k , representing the number of partially defined functions in which a distance function has to be split due to visibility constraints.

6 Concluding remarks

Using the Rotating Rays Voronoi Diagram, we showed how to find the Brocard angle of a convex polygon in optimal linear time, settling an interesting open problem. We exhibited that our method is more general: given any domain D and a set of rays \mathcal{S} , we can find the minimum angle that is required to illuminate D using floodlights aligned with \mathcal{S} , by constructing $\text{RVD}(\mathcal{S})$ restricted to D .

There are many interesting questions to investigate. Regarding the Brocard angle of polygons, we would like to see how our approach could extend to other classes of polygons. We expect to have some difficulties due to the visibility constraints, but we believe that our algorithm could be adapted to work as well. Regarding $\text{RVD}(\mathcal{S})$ in \mathbb{R}^2 , we would like to settle whether the worst case combinatorial complexity is $\Theta(n^2)$. Further, if the current $O(n^{2+\epsilon})$ bound is not tight, we believe that it is possible to design $o(n^{2+\epsilon})$ -time algorithms.

Parallel Computation of Combinatorial Symmetries

Markus Anders

TU Darmstadt, Germany

Pascal Schweitzer

TU Darmstadt, Germany

Abstract

In practice symmetries of combinatorial structures are computed by transforming the structure into an annotated graph whose automorphisms correspond exactly to the desired symmetries. An automorphism solver is then employed to compute the automorphism group of the constructed graph. Such solvers have been developed for over 50 years, and highly efficient sequential, single core tools are available. However no competitive parallel tools are available for the task.

We introduce a new parallel randomized algorithm that is based on a modification of the individualization-refinement paradigm used by sequential solvers. The use of randomization crucially enables parallelization.

We report extensive benchmark results that show that our solver is competitive to state-of-the-art solvers on a single thread, while scaling remarkably well with the use of more threads. This results in order-of-magnitude improvements on many graph classes over state-of-the-art solvers. In fact, our tool is the first parallel graph automorphism tool that outperforms current sequential tools.

1 Introduction

Exploitation of symmetry has a dramatic impact on the efficiency of algorithms in various fields. This includes the fields of computer vision and computer graphics [15], automated reasoning [10], machine learning [22] and in particular convolutional neural networks [7], mathematical programming [14], chemical databases [20], SAT-solving [12], constraint programming [8], software verification [5], model checking [9, 18] and so on.

Before symmetries of a structure can be exploited, one first has to have algorithmic means to find the symmetries. For this, the structure is usually transformed into an annotated graph whose automorphisms correspond to the symmetries of the original structure. Then tools are employed that compute the graph's automorphism group.

The current state-of-the-art implementations of solvers computing automorphism groups are BLISS [11], NAUTY and TRACES [17], CONAUTO [16] as well as SAUCY [6]. All of the mentioned algorithms follow the individualization-refinement (IR) framework.

These tools have become increasingly powerful through a multitude of techniques. Initially, each mentioned tool provided insightful new pruning ideas or new implementation tricks. However, many of these very diverse ideas from all the tools have transcended into all of the other tools by now. This lead to a second generation comprised of improved versions of the tools. The most recent and currently fastest solver is TRACES which excels at pruning the search space of difficult graphs. The tool has been meticulously engineered by Piperno over the past decade ever improving its performance. The tool is fastest on most graph classes, and on the few where it is not, it still performs competitively with the best of all the solvers.

Recently the requirements of the application domains for the tools have changed. One major change stems from the different architecture of modern hardware. In fact, all of the aforementioned tools are sequential, single-threaded applications: spreading the work load across multiple cores would align with the contemporary hardware trend of steadily increasing core counts. While there are some theoretical results, research on practical parallel isomorphism algorithms is quite limited. In his thesis, Tener [23] describes approaches to parallel isomorphism testing. However, he has subsequently not pursued this further in the last decade, and the described algorithm is based on algorithms of the first generation. The study [4] only performs comparisons against slow sequential algorithms. Overall, parallel graph isomorphism testing has not witnessed any of the ideas that characterize the second generation of algorithms. Generally, fast isomorphism and automorphism algorithms have been persistently resistant to parallelization attempts in theory and practice.

The goal of this paper is to stimulate a third generation of isomorphism solvers by harnessing the power of a modern CPU for the computation of graph automorphisms. Parallelizing existing libraries is not a straightforward task, since the practical algorithms are based on the IR technique, which is a priori sequential.

Contribution. We introduce DEJAVU, a novel randomized algorithm solving the automorphism group problem based on the IR paradigm. The tool is (1) on a single thread competitive with currently fastest solvers available (sometimes even outperforming them), and (2) on 8 threads outperforms the currently fastest solvers on most graph classes. Using the de facto standard benchmark suite, we report extensive experimental results corroborating these two claims. The results also demonstrate the scalability of the tool as the number of threads is varied from 1 to 8.

Underlying ideas and techniques. The quintessence of our new algorithm, by which we achieve parallelizability, is to replace inherently sequential traversal strategies with randomized traversal: DEJAVU mainly performs repeated random root-to-leaf walks in the search tree (stemming from the IR-framework) in conjunction with a probabilistic abort criterion. The main motivation is that computing multiple random root-to-leaf walks can be parallelized. To allow for an even split of the work load, various subroutines, most notably the so-called sifting algorithm which is used for the probabilistic abort criterion, also have to be parallelized efficiently. However, to create a truly efficient tool, the algorithm has to be combined with further heuristics tailored to the new parallel, probabilistic setting.

Randomization. Our tool DEJAVU is a randomized tool which, in principle, means that the output is not always correct. The idea of exploiting randomization originated from isomorphism testing algorithms [3, 13] which however neither compute automorphisms nor have any form of parallelization whatsoever. For these randomized approaches (including DEJAVU), the user can set an error probability (e.g. 1%) and the tool guarantees that for each

input the probability of error is at most this number. However, crucially our approach only has a 1-sided error. This means while some automorphisms may be missed when queried for the automorphism group of a graph, the solver guarantees that the output consists entirely of automorphisms of the graph. For applications exploiting symmetry this is the *right kind of error*. This way, they may sometimes fail to exploit symmetries that were missed but this only slows down the running time. It does not lead to incorrect results for the application.

2 Preliminaries

2.1 Individualization-Refinement

Following [17] closely, we introduce IR algorithms. The summary is focused on the results necessary to describe automorphism computations and what is needed for our algorithms.

Colored Graphs. An undirected, finite graph $G = (V, E)$ consists of a set of vertices $V \subseteq \mathbb{N}$ and a set of edges $E \subseteq V^2$, where E is symmetric. We always assume $V = \{1, \dots, n\}$.

A coloring $\pi: V \rightarrow \{1, \dots, k\}$ is a surjective map, mapping vertices of a graph to *cells* $1, \dots, k$. We call $\pi^{-1}(i) \subseteq V$ with $i \in \{1, \dots, k\}$ the *i-th cell* of π , which is non-empty since π is surjective. With $|\pi| = k$ we denote the number of cells in a coloring. If $|\pi| = n$ holds, we call π *discrete*. Note that a discrete coloring also characterizes a permutation of V .

A colored graph (G, π) consists of a graph and a coloring. The symmetric group on $\{1, \dots, n\}$ is denoted $\text{Sym}(n)$. With $\text{Aut}(G)$ we denote the automorphism group of a graph. An element $\varphi \in \text{Aut}(G)$ is a permutation of vertices which maps the graph to itself, i.e., a bijective map $\varphi: V \rightarrow V$ where $G^\varphi := (\varphi(V), \varphi(E)) = (V, E) = G$ holds. For colored graphs we additionally require that the coloring is preserved, i.e., a vertex of a cell c must be mapped to a vertex of cell c . We thus define the colored automorphism group $\text{Aut}(G, \pi)$ as those permutations φ with $(G, \pi)^\varphi = (G^\varphi, \pi^\varphi) = (G, \pi)$. Note that in all of these definitions actual equality, e.g., equality of adjacency matrices and not isomorphism, is required. In the following, we only consider uncolored input graphs for the sake of simplicity. Let us remark, however, that we could use exactly the same machinery for colored graphs (see [17]).

Refinement. In the following, we want to *individualize* vertices and *refine* colorings. Individualizing vertices in a coloring is a process that artificially forces the vertex into its own singleton cell. We use $\nu \in V^*$ to denote a sequence of vertices. In particular, we can record in such a sequence which vertices have been individualized.

A *refinement* is a function $\text{Ref}: G \times V^* \rightarrow \Pi$. Here Π is the set of colorings of V , i.e., the set of ordered partitions of V . Given a graph G and sequence of vertices ν , it must satisfy the following properties: first, it is invariant under isomorphism, i.e., $\text{Ref}(G^\varphi, \nu^\varphi) = \text{Ref}(G, \nu)^\varphi$ holds for all $\varphi \in \text{Sym}(n)$. Secondly, it respects vertices in ν as being individualized, i.e., $\{v\}$ is a singleton cell in $\text{Ref}(G, \nu)$ for all $v \in \nu$.

Cell Selector. If refinement classifies all vertices into different cells, determining automorphisms and isomorphisms for a graph is easy, after all, cells have to be preserved. Otherwise, individualization is used to artificially single out a vertex inside a non-singleton class. The task of a *cell selector* is to isomorphism invariantly pick a non-singleton cell of the coloring. In the IR paradigm, all vertices of the selected cell will then be individualized one after the other using some form of backtracking. After the individualization, refinement is applied again and the process continues recursively. Formally, a cell selector is a function $\text{Sel}: G \times \Pi \rightarrow 2^V$ into the power set of V satisfying the following properties:

- It is invariant under isomorphism, that is $\text{Sel}(G^\varphi, \pi^\varphi) = \text{Sel}(G, \pi)^\varphi$ holds for $\varphi \in \text{Sym}(n)$.
- If π is discrete then $\text{Sel}(G, \pi) = \emptyset$.
- If π is not discrete then $|\text{Sel}(G, \pi)| > 1$ and $\text{Sel}(G, \pi)$ is a cell of π .

Search Tree. With the functions Ref and Sel at hand, we are now ready to define the *search tree*. For a graph G we use $T_{(\text{Ref}, \text{Sel})}(G)$ to denote the search tree of G with respect to refinement operator Ref and cell selector Sel. The search tree is constructed as follows: each node of the search tree corresponds to a sequence of vertices of G .

- The root of $T_{(\text{Ref}, \text{Sel})}(G)$ is the empty sequence ϵ .
- If ν is a node in $T_{(\text{Ref}, \text{Sel})}(G)$ and $C = \text{Sel}(G, \text{Ref}(G, \nu))$, then its children are $\{\nu.v \mid v \in C\}$, i.e., all extensions of ν by one vertex v of C .

With $T_{(\text{Ref}, \text{Sel})}(G, \nu)$ we denote the subtree of $T_{(\text{Ref}, \text{Sel})}(G)$ rooted in ν . We omit indices Sel and Ref if they are apparent from context. Note that the leaves of a search tree correspond to discrete colorings of the graph, and therefore to permutations of V .

We recite the following crucial facts on isomorphism invariance of the search tree as given in [17], which follows from the isomorphism invariance of Sel and Ref:

► **Lemma 1.** *For a graph G and $\varphi \in \text{Sym}(n)$ we have $T(G)^\varphi = T(G^\varphi)$.*

► **Corollary 2.** *If ν is a node of $T(G)$ and $\varphi \in \text{Aut}(G)$, then ν^φ is a node of $T(G)$ and $T(G, \nu)^\varphi = T(G, \nu^\varphi)$.*

We have yet to mention how the search tree is used to find automorphisms of a graph:

► **Lemma 3.** *If ν and ν' are leaves of $T(G)$, then there exists an automorphism $\varphi \in \text{Aut}(G)$ such that $\nu = \varphi(\nu')$ if and only if $\text{Ref}(G, \nu')^{-1} \cdot \text{Ref}(G, \nu)$ is an automorphism of G .*

We also say that ν' is an *occurrence* of ν if there is some automorphism $\varphi \in \text{Aut}(G)$ for which $\varphi(\nu') = \nu$.

Pruning. In the overall algorithm, we fix a single leaf τ and then search for automorphisms by comparing other leaves to it. We call this fixed leaf τ the *target leaf*. Corollary 2 and Lemma 3 show that this suffices to derive all automorphisms from the search tree.

Unfortunately, however, the search tree itself can be exponentially large in the input [19]. Therefore, we want to prune it as much as possible.

Towards this goal, we define a *node invariant* $\text{Inv}: G \times V^* \rightarrow I$, which is a function mapping nodes of the tree to a totally ordered set I . We require some further properties:

- The invariant must be isomorphism invariant, i.e., we require $\text{Inv}(G, \nu_1) = \text{Inv}(G^\varphi, \nu_1^\varphi)$ for all $\varphi \in \text{Sym}(n)$.
- If $|\nu_1| = |\nu_2|$ and $\text{Inv}(G, \nu_1) < \text{Inv}(G, \nu_2)$, then for all leaves $\nu'_1 \in T(G, \nu_1)$ and $\nu'_2 \in T(G, \nu_2)$ we require $\text{Inv}(G, \nu'_1) < \text{Inv}(G, \nu'_2)$.

It follows that even if we remove all nodes of the tree whose invariant deviates from the corresponding node invariant on the same level on the path to the target leaf, we can still retrieve the entire automorphism group. This operation is called *pruning using invariants*. Formally, we define $\text{Prune}_{\text{Inv}}(\tau', \nu')$ to denote the operation that removes the subtree of node ν' if $\text{Inv}(G, \tau') \neq \text{Inv}(G, \nu')$, where $|\tau'| = |\nu'|$ holds and τ' is the prefix of length $|\nu'|$ of τ .

We now describe *pruning using automorphisms*. Assume we already have $\varphi \neq \text{id}$ of $\text{Aut}(G)$ available. For nodes ν where ν^φ is not a prefix of the target leaf, we define $\text{Prune}_{\text{Aut}}(\nu, \nu^\varphi)$ to denote the operation which removes the subtree rooted at ν^φ from the search tree. Applying $\text{Prune}_{\text{Aut}}$ can only cut away parts of the search tree which are generated by the already available automorphisms anyway [17].

■ **Algorithm 1** Sifting.

```

1 function Sift( $S, T, B, \varphi$ )
    Input : generators  $S$ , transversal table  $T$ , base points  $B$ , element  $\varphi$ 
    Output : whether  $S, B$  and  $T$  remained unchanged
2 for ( $i = 1; i \leq |B|; i = i + 1$ )
3      $b_i := \varphi(B_i);$ 
4      $t := (T_i)_{b_i};$ 
5     if  $t = \perp$  then break;
6      $\varphi := \varphi \cdot t^{-1};$ 
7 if  $\varphi \neq \text{id}$  then
8      $S := S \cup \{\varphi\};$ 
9      $b_i := \varphi(B_i);$ 
10     $(T_i)_{b_i} := \varphi;$ 
11    return false;
12 return true;

```

2.2 Schreier-Sims Fundamentals

The procedure to aggregate automorphisms of DEJAVU works on similar principles as the random Schreier-Sims algorithm, which provides us with a data structure to dynamically manage permutation groups. To be more precise, our algorithm needs a way to determine whether a newly found automorphism φ is in the group generated by the automorphisms that were found previously. The procedure we use for this is called *sifting*. We give a brief description following the lines of [21].

All groups we consider are permutation groups $\Gamma \leq \text{Sym}(\Omega)$. For the domain we always set $\Omega = \{1, \dots, n\}$. By $\langle S \rangle$ we denote the group generated by the elements of S , i.e., all elements that can be written as a product of elements of S . If $\langle S \rangle = \Gamma$ holds, we call S a *generating set* of Γ .

We need the notion of a *pointwise stabilizer* of a permutation group $\Gamma \subseteq \text{Sym}(\Omega)$. Let $\beta \in \Omega$ be a point, then $\Gamma_{(\beta)} := \{\varphi \in \Gamma \mid \varphi(\beta) = \beta\}$. For a sequence of points $(\beta_1, \dots, \beta_m) \in \Omega^m$ we just recursively take the pointwise stabilizer of all elements:

$$\Gamma_{(\beta_1, \dots, \beta_m)} := \begin{cases} \Gamma & \text{if } m = 0 \\ (\Gamma_{(\beta_1, \dots, \beta_{m-1})})_{(\beta_m)} & \text{otherwise.} \end{cases}$$

We call a sequence of points $B = (\beta_1, \dots, \beta_m) \in \Omega^m$ a *base* relative to $\Gamma \leq \text{Sym}(\Omega)$ if $\Gamma_B = \{\text{id}\}$. For a generating set $\langle S \rangle = \Gamma$ and a base $(\beta_1, \dots, \beta_m)$ we define $S_i = S \cap \Gamma_{(\beta_1, \dots, \beta_i)}$. We call S *strong* relative to Γ and $(\beta_1, \dots, \beta_m)$ if $\langle S_i \rangle = \Gamma_{(\beta_1, \dots, \beta_i)}$ holds for all $i \in \{0, \dots, m\}$.

Given a subgroup $\Delta \leq \Gamma$, a *transversal* of Δ in Γ is a subset $T \subseteq \Gamma$ that satisfies $|T \cap gH| = 1$ for every coset $g\Delta$ of Δ in Γ . We construct a *transversal table* for a given base B and generating set S , which contains a transversal for each subgroup $\langle S_i \rangle$ in $\langle S_{i-1} \rangle$. We refer with T_i to the transversal of S_i . Careful inspection of the definition reveals that each $\langle S_i \rangle$ fixes the i -th base point of B , i.e., for all $\varphi \in \langle S_i \rangle$ it is true that $\varphi(\beta_i) = \beta_i$. If we want to know the cosets of S_i in $\langle S_{i-1} \rangle$, we need to find the possible images of β_i in $\langle S_{i-1} \rangle$. Elements of $\langle S_{i-1} \rangle$ under which β_i has the same image are in the same coset of $\langle S_i \rangle$. Thus, we can differentiate transversal elements T_i according to the image of β_i under them. We denote by $(T_i)_b$ the element in T_i mapping $\beta_i \mapsto b$ if it exists. We set $(T_i)_b = \perp$ if such an element does not exist. The cosets correspond to the orbit of β_i in S_{i-1} . Given an element

$\varphi \in S_{i-1}$, we need to determine to where φ maps β_i in order to find the coset in which it is contained. The representative of the coset is that element t in the transversal T_i which also maps β_i to $\varphi(\beta_i)$. By forming the product $\varphi \cdot t^{-1} \in S_i$ we obtain an element that fixes β_i .

Algorithm 1 describes a *sifting* procedure, which can be used to test membership in a given permutation group whenever a strong generating set S and corresponding base B are available. Otherwise, if S is not strong or B not complete, the sifting procedure computes a non-trivial permutation. In the version of the algorithm described here, this permutation is added to the generating set to ensure that now the sifted element is covered. Possibly one needs to extend the base for this purpose. If an element *sifts successfully*, i.e., the procedure returns *true*, we know that it is contained in $\langle S \rangle$. On the other hand, if the sifting is unsuccessful then the element was not in the group or the generating set was not strong and has been extended towards ensuring it to become strong.

The algorithm repeatedly multiplies transversal elements to the initial element. The operations preserve the property of whether the initially given element is in the group. Each operation modifies the element so that it is contained the next respective pointwise stabilizer.

We refer to base, transversal table and generating set together as a *Schreier structure*. As elements are sifted, such a structure captures the progress made towards constructing the group. A crucial result we exploit is the following, related to Lemma 4.3.1 in [21]:

► **Lemma 4.** *Let Γ be a group, B a base, S a set of permutations in Γ and φ a uniformly distributed element in Γ . If $\langle S \rangle \neq \Gamma$, the probability that φ does not successfully sift through the Schreier structure defined by B and S is at least $\frac{1}{2}$.*

The previous results are also the foundation for the random Schreier-Sims method, which is used by all competitive solvers to detect possibilities to apply the pruning function $\text{Prune}_{\text{Aut}}$.

Let us also record that the individualized vertices in a leaf of the search tree (defined in Section 2.1) actually form a base of the respective automorphism group [17].

3 Parallel Computation of Automorphisms

We first describe how to turn random walks on IR trees into a correct, probabilistic algorithm. Then, we discuss how to parallelize sifting as required by the algorithm. Lastly, we augment the algorithm using breadth-first traversal into the underlying procedure of DEJAVU .

The motivation is that the three fundamental methods mentioned above parallelize efficiently as long as the IR tree is sufficiently large.

3.1 Random Walks and Automorphisms

The first step of our algorithm is to compute a random walk to one of the leaves, the target leaf. The goal is then to find another occurrence target leaf through random walks, whereby automorphisms are found. A key observation is that by choosing uniform, random walks through the tree – which we describe in Algorithm 2 – we also get a uniform distribution of elements in the automorphism group. The algorithm applies the refinement to the input graph and then repeatedly chooses a uniform random vertex of the target cell chosen by the cell selector for individualization. Starting from the initial coloring, it then keeps individualizing and refining until the coloring becomes discrete. It returns the coloring and the sequence of individualized vertices.

Recall that we refer to a leaf τ' as an *occurrence* of τ if τ' can be mapped to τ using an element $\varphi \in \text{Aut}(G)$ (i.e., $\varphi(\tau') = \tau$). In this situation we call φ the *corresponding automorphism* with regard to τ' . Note that there is a unique occurrence of τ for every $\varphi \in \text{Aut}(G)$:

► **Lemma 5.** *A leaf τ can be mapped to exactly $|\text{Aut}(G)|$ leaves in $T(G)$ using elements of the automorphism group $\text{Aut}(G)$.*

Proof. Note that τ is a base of $\text{Aut}(G)$. Now consider an element $\varphi \in \text{Aut}(G)$. Clearly, τ^φ also corresponds to a leaf in the tree (Lemma 2) and τ^φ is a base as well. Now consider a different element $\varphi' \in \text{Aut}(G)$, i.e., $\varphi' \neq \varphi$. Clearly, $\tau^\varphi \neq \tau^{\varphi'}$ holds since τ is a base. ◀

► **Lemma 6.** *As a random variable, the output of Algorithm 2, which is a leaf in the search tree, is uniformly distributed within each equivalence class of leaves.*

Proof. There is a unique occurrence of τ for every automorphism (Lemma 5). Hence, it suffices to argue that the probability of finding each occurrence of τ through a random walk in the tree is equal. Assume that we are in a node ν of the search tree and let ν_1, \dots, ν_k be the children of ν . Let ν'_1, \dots, ν'_k be the children that correspond to the subtrees of ν that do contain an occurrence of τ . Since we are sampling an element uniformly from ν_1, \dots, ν_k in Algorithm 2, each of these subtrees has the same probability of being chosen. Therefore, it suffices to argue that the chance of finding an occurrence of τ in each of ν'_1, \dots, ν'_k is equal. Since they all contain an occurrence of τ , they can all be mapped to each other using the corresponding automorphisms. But this immediately implies that all of these subtrees must be isomorphic (Lemma 1), showing the claim. ◀

The following lemma immediately follows.

► **Lemma 7.** *Let τ be a fixed leaf. Consider the distribution of outputs of Algorithm 2 under the condition that an occurrence of τ is computed. For such a given output τ' consider the automorphism φ with $\varphi(l) = l'$ corresponding τ' . Then φ is uniformly distributed in $\text{Aut}(G)$.*

So, Algorithm 2 provides us with a method to uniformly sample random automorphisms. We now need a method to collect these automorphisms and determine when we have found enough of them to generate the entire automorphism group.

Description of Algorithm 3. The algorithm repeatedly samples automorphisms from the automorphism group through random walks (using Algorithm 2). Then, it uses a probabilistic test based on Lemma 4 and Lemma 7 to determine termination. When a certain number $d = \lceil -\log_2(\frac{\varepsilon}{2}) \rceil$ of *consecutively* sampled automorphisms turn out to be already covered by the previously found automorphisms (i.e., they sift successfully) the algorithm terminates. The initial value of d is linked to the guaranteed bound on the error probability ε that can be chosen by the user. To guarantee that the error bound is kept, when some but not d consecutively found automorphisms were discovered, the value of d is incremented.

Finishing the execution therefore hinges on seeing already explored leaves as well as already generated automorphisms again. Note that the correctness of the algorithm depends on the fact that we are probing automorphisms uniformly from the group. In Section 3.3, we introduce further techniques to prune the search tree. When we do so, we always make sure to do this in a manner that still enables us to probe uniformly after the pruning. Ensuring this suffices to retain a correct behavior of the algorithm.

We now argue correctness for Algorithm 3.

► **Lemma 8.** *Given a graph G and probability ε , Algorithm 3 produces a generating set for the automorphism group of G with probability at least $1 - \varepsilon$.*

Proof. First, observe that the discovered permutations are certified before being added to the group, which immediately ensures that all elements of the computed group are actual automorphisms. The algorithm can therefore only fail by not adding enough elements to the group.

■ **Algorithm 2** Random Walk of the Search Tree.

```

1 function RandomWalk( $G$ )
  Input : graph  $G$ 
  Output : a random leaf of the search tree and the individualized vertices
2   $base := ()$ ;
3   $col := \text{Ref}(G, [v \mapsto 1], base)$ ;
4   $cell := \text{Sel}(G, col)$ ;
5  while  $cell \neq \emptyset$  do
6     $v := \text{RandomElement}(cell)$ ;
7     $base := base.v$ ; // append  $v$  to  $base$ 
8     $col := \text{Ref}(G, col, base)$ ;
9     $cell := \text{Sel}(G, col)$ ;
10 return ( $col, base$ );

```

■ **Algorithm 3** Parallel Randomized Automorphisms.

```

1 function Automorphisms( $G, \epsilon$ )
  Input : graph  $G$  and probability  $\epsilon$ 
  Output : a subset of  $\text{Aut}(G)$  that generates  $\text{Aut}(G)$  with probability at least  $1 - \epsilon$ 
2   $c := 0, d := \lceil -\log_2(\frac{\epsilon}{2}) \rceil, S := \emptyset$ ;
3   $(\tau, B) := \text{RandomWalk}(G)$ ;
4  initialize trivial transversal table  $T$  relative to  $B$ ;
5  while  $c \leq d$  do in parallel
6    // run multiple instances of the body of the loop in parallel
7     $(l', \_) := \text{RandomWalk}(G)$ ;
8     $\varphi := l' \cdot \tau^{-1}$ ;
9    if  $\varphi(G) = G$  then
10     if  $\neg \text{Sift}(S, T, B, \varphi)$  then  $c := c + 1$ ;
11     else
12       if  $c > 0$  then  $d := d + 1$ ;
13        $c := 0$ ;
14 return  $S$ ;

```

Choosing random walks through the tree produces a uniform distribution of occurrences of the leaf τ , which gives us a uniform distribution of elements in $\text{Aut}(G)$ (Lemma 7). This in turn enables us to use Lemma 4 to argue correctness as follows.

We terminate the algorithm after we sifted uniform elements of G successfully into the Schreier structure d times in a row. As long as sifting fails and we add elements to the Schreier structure, we know that no error occurs and that we are not done. We view the computation as a sequence of *tests* against the hypothesis that we are missing automorphisms. We define the beginning of a test to be right after sifting succeeds once (i.e., at the moment when c is set to 1 in an execution of Line 10). The probability that the test fails (i.e., that we do not abort the test early and instead increment c for d times in a row) is bounded by $(\frac{1}{2})^d$ (Lemma 4). In order to ensure a total error bound of ϵ for the algorithm, we require the sum of the probabilities of the tests to fail is at most ϵ . For this it suffices to have that the i -th test fails with probability at most $\frac{\epsilon}{2^i}$. The probability that the entire computation fails is then surely at most ϵ since $\sum_{i=1}^{\infty} \frac{\epsilon}{2^i} \leq \epsilon$.

In order to satisfy this bound of $\frac{\varepsilon}{2^i}$, we increment d after each successful test. Initially, for the first test, we set $d_1 = \lceil -\log_2(\frac{\varepsilon}{2}) \rceil$ which ensures that $(\frac{1}{2})^d \leq \frac{\varepsilon}{2}$. Note the value d_i for variable d used during the i -th test is then $d_i = d_1 + i - 1$, so $(\frac{1}{2})^{d_i} < \frac{\varepsilon}{2^i}$, as desired. ◀

We should clarify that while the algorithm is based on some of the same principles as the isomorphism test of [3], that isomorphism test neither has to consider uniformity of automorphism sampling (Lemma 7), nor employ repeated testing, nor requires any form of sifting.

Through the use of the randomized approach, a simple opportunity for parallelization arises by running the body of the while-loop in Line 6 on multiple threads. In particular, only two components have to be synchronized: the state of the abort criterion c and d , as well as the Schreier structure S and T which is manipulated by the sifting procedure. While the former is trivial, parallelization of the sifting procedure is discussed in the following section.

There is a slight technical issue we should address when running Algorithm 3 in parallel. If, say, the elements that are already generated by S can be computed more quickly than those that are not, using many threads would create a bias towards finding the former type of element first, leading to an incrementation of c with a probability larger than $1/2$. This would break the error bound. However, there is a simple way to fix the issue: whenever c exceeds d , it suffices to additionally ensure all threads finish their current iteration.

3.2 Sifting in Parallel

For the abort criterion of the algorithm, we check whether an automorphism is contained in the group generated by the automorphisms found so far (see Line 10 of Algorithm 3). To check this, we sift it into a Schreier structure using a base of the automorphism group.

As it turns out, sifting elements is sometimes expensive: using a conventional, sequential implementation of the sifting procedure to determine the abort criterion of our algorithm does not scale with more threads. In practice, sifting would often become the bottleneck.

For the random abort criterion we observe the following when sifting elements.

1. The base is never changed or extended.
 2. Changes in the transversal tables T are always local to one level in the Schreier structure.
 3. In practice, if sifting is expensive, many elements are sifted. The computationally expensive part is then mostly multiplication of elements (Line 6 of Algorithms 1 and 4).
- We should stress that in particular, (1) and (2) are generally *not true* when sifting is employed by previous IR algorithms, and are indeed specific to the way it is used by Algorithm 3.

Crucially, these three observations enable a rather simple modification to the algorithm: we can sift elements into a Schreier structure concurrently, as long as we synchronize changes to transversal tables when changing a level. We add a lock for every level and one global lock for the generating set to enable parallel sifting on a fixed base (see Algorithm 4). We should remark that the locking mechanism could be made more granular to further improve scaling. However, due to observation (3), we never deemed this necessary in practice.

3.3 Uniform Pruning

While Algorithm 3 is able to solve the problem on its own and parallelizes whenever enough random walks are required, it never actually prunes the search tree. This means that if it is discovered during random probing that a certain path does not lead to an occurrence of the target leaf, there is no mechanism to prevent making the same bad choices again.

■ **Algorithm 4** Thread-safe Sifting.

```

1 function Sift( $S, T, B, \varphi$ )
  Input : generators  $S$ , transversal table  $T$ , base  $B$ , element  $\varphi$ 
  Output : whether  $S$  and  $T$  remained unchanged
2 for (  $i = 1$ ;  $i \leq |B|$ ;  $i = i + 1$  )
3    $b_i := \varphi(B_i)$ ;
4    $t := (T_i)_{b_i}$ ;
5   if  $t = \perp$  then break;
6    $\varphi := \varphi \cdot t^{-1}$ ;

```

To rectify this, we want to intersperse the random walks of the tree with breadth-first search. Fortunately, probing after breadth-first traversal of an entire level has been performed naturally results in a uniform distribution of leaves again. Indeed, upon completion of an entire level of breadth-first traversal, probing can also be characterized as starting a random walk at a uniformly random node of that level. We probe from a level k by choosing uniformly at random a node ν' with $|\nu'| = k$ of the search tree that satisfies $\text{Inv}(\nu') = \text{Inv}(\nu)$. Here ν is the prefix of length k of the vertex sequence corresponding to the target leaf. Due to Lemma 1, the trees rooted in prefixes that contain some occurrence of the target leaf are isomorphic. Therefore they yield the same probability for finding an occurrence of the target leaf within them. The process therefore samples automorphisms with a uniform distribution. Hence, breadth-first traversal can safely be combined with Algorithm 3.

When using the breadth-first traversal, we still want to be able to use the automorphism pruning rule $\text{Prune}_{\text{Aut}}$. However, this can break uniformity. Assume for example ν and ν' are both children of μ' . Assume further they each correspond to a “bad choice” on this level of the search tree in the sense that neither of them contains an occurrence of the target leaf. During the algorithm we would not yet know whether these choices are bad, but suppose we find an automorphism mapping one to the other. By contracting them to a single node, we reduce the number of children without a target leaf and thus increase the chance of finding an occurrence of the target leaf in μ' .

Our solution to this problem is that whenever we use $\text{Prune}_{\text{Aut}}$, we artificially restore uniformity. We do so by introducing *weights* to nodes of the tree, which essentially denote the number of paths represented by a node of the tree. When combining elements of the same level, their weights (represented paths) are combined as well. Later on, when probing for leaves, we take weights into account when sampling random elements. Considering the example again, when we contract the bad choices ν and ν' to a single node, and both have weight 1 to begin with, the remaining node gets weight 2. The remaining node is then chosen with the same probability as both of the initial nodes together – hence, keeping the same probability of finding the target leaf in μ .

Since the probability of finding automorphisms is supposed to remain constant, one might wonder why this kind of pruning should be applied at all. The reason is that the work for the breadth-first traversal is reduced: we need to compute less nodes when advancing the breadth-first level, since symmetric nodes are contracted. On later levels, we may be able to throw away nodes (uniformly, since we are performing breadth-first traversal) and thus actually increase the probability of finding target leaves.

We now formalize the notion of weights. We describe this using the following construction: we start by defining internal weights \bar{w} and external weights w for all nodes. The internal weights and external weights of all nodes are initially set to 1, i.e., $w(\nu) := \bar{w}(\nu) := 1$ for all ν . The internal weights are then manipulated by the algorithm. Whenever internal weights are modified, the following formula calculates the corresponding external weights:

$$w(\nu) := \begin{cases} 1 & \text{if } \nu = \epsilon \\ \bar{w}(\nu) \cdot w(\nu_1, \dots, \nu_{k-1}) & \text{if } \nu = \nu_1, \dots, \nu_k \end{cases}$$

We now modify $\text{Prune}_{\text{Aut}}$ into $\text{Prune}'_{\text{Aut}}$ by making it update the internal weights in addition to pruning: assume we already have φ of $\text{Aut}(G)$ available. For all nodes ν where ν^φ is not a prefix of the target leaf, $\text{Prune}'_{\text{Aut}}(\nu, \nu^\varphi)$ removes ν^φ from the search tree and updates $\bar{w}(\nu) = \bar{w}'(\nu) + \bar{w}'(\nu^\varphi)$, where \bar{w}' are the previous internal weights.

Additionally, we want to formalize the notion that the tree rooted in ν^φ is now *represented* by the tree rooted in ν . We do this by introducing an equivalence relation \sim , which we update every time $\text{Prune}_{\text{Aut}}$ is executed. Initially, every node represents itself, hence $[\nu]_\sim = \{\nu\}$ holds. Note that trivially $|\llbracket \nu \rrbracket_\sim| = w(\nu) = 1$ is satisfied initially. We update the relation whenever $\text{Prune}'_{\text{Aut}}(\nu, \nu^\varphi)$ is executed. The old relation \sim' is then replaced by \sim , which we define in the following. We do so using three states of the search tree: first, the *unpruned tree* $T(G, \nu)$, which is the initial tree where no pruning rule has been applied. Secondly, there is the *pruned tree before* the operation $\text{Prune}'_{\text{Aut}}$ was executed, i.e., $T(G, \nu)'$ with the relation \sim' . Lastly, there is the *pruned tree after* the operation $\text{Prune}'_{\text{Aut}}$ has taken place, for which we want to define the relation \sim . The goal is then to argue inductively that the size of the equivalence class is equal to the external weight of the representative in the pruned trees.

We stipulate that ν^φ , as well as all nodes currently represented by ν^φ , are now represented by ν . Formally, we unify the equivalence classes of the root nodes in question, i.e., we set $[\nu]_\sim := [\nu]_{\sim'} \cup [\nu^\varphi]_{\sim'}$.

We extend this definition recursively for all nodes of the tree rooted in ν , i.e., all elements of the unpruned tree rooted in ν^φ need to be represented by some element of $\nu' \in T(G, \nu)'$. The tree rooted at ν^φ may also represent other trees, which need to be considered. We let $[\nu^\varphi]_{\sim'} = \{\nu^{\varphi_1}, \dots, \nu^{\varphi_k}\}$, where clearly $\varphi_i \in \langle S \rangle$ for $i \in \{1, \dots, k\}$ holds. Since all of these trees may have been pruned differently through applications of $\text{Prune}'_{\text{Aut}}$, we refer back to nodes of the unpruned tree $T(G)$. For every node ν' in the pruned tree $T(G, \nu)'$, we find all of the nodes of the unpruned tree that are now represented by it, i.e., $[\nu']_\sim := [\nu']_{\sim'} \cup \{\nu''^{\varphi_i} \mid \nu'' \in [\nu']_{\sim'}, i \in \{1, \dots, k\} \mid \nu'' \in T(G, \nu)\}$. Note that this is well-defined in terms of equivalence relations, since all φ_i define bijections between nodes of $T(G, \nu)$ and $T(G, \nu^{\varphi_i})$ (Lemma 2). All other nodes of the pruned tree keep their equivalence classes of \sim' , which is correct since their weight is unaltered as well.

We now argue that the external weight of a remaining node represents the size of its respective equivalence class:

► **Lemma 9.** *Let A be a sequence of applications of $\text{Prune}'_{\text{Aut}}$ to a search tree $T(G)$. Assume that applying A results in $T(G)'$ with external weight function w' and \sim' is the corresponding equivalence relation (as described previously). Then, it holds that $|\llbracket \nu \rrbracket_\sim| = w'(\nu)$.*

Proof. We argue the claim by induction over the sequence A . Initially, the claim is true since all weights are 1 and every node represents itself in \sim .

Let us now argue that when applying some $\text{Prune}'_{\text{Aut}}(\nu, \nu^\varphi)$, the invariant remains valid. For the root node this is easy to see: by induction $|\nu]_{\sim}| = w'(\nu)$ and $|\nu^\varphi]_{\sim}| = w'(\nu^\varphi)$ hold, which in turn shows $|\nu]_{\sim}| = |\nu]_{\sim} \cup [\nu^\varphi]_{\sim}| = w'(\nu) + w'(\nu^\varphi) = w(\nu)$. The third equality holds since $\varphi \neq \text{id}$ is required by definition. We now show this for all $\nu' \in T(G, \nu)'$ by induction. Let $\nu' = \nu'_1, \dots, \nu'_k$ and $\mu = \nu'_1, \dots, \nu'_{k-1}$. We know that $w(\mu) = |\mu]_{\sim}|$ holds, i.e., the statement is true for the parent of ν' .

It can be easily seen that set of the elements $\mu' \in T(G, \nu)$ with $\mu' \in [\mu]_{\sim}$, i.e., elements represented by μ in the subtree of ν , has not been altered. Hence, we can rewrite $w(\mu) = |\mu]_{\sim}| = |\{\mu' \in [\mu]_{\sim} \mid \mu' \in T(G, \nu)\}| \cdot w(\nu)$. The internal weight \bar{w} of ν' is only changed whenever $\text{Prune}'_{\text{Aut}}$ is directly applied on ν' . This means that in the unpruned tree, ν' represents $\bar{w}(\nu')$ many elements in $T(G, \mu)$. We can conclude $|\nu']_{\sim}| = |\{\nu'' \in [\nu']_{\sim} \mid \nu'' \in T(G, \nu)\}| \cdot w(\nu) = \bar{w}(\nu') \cdot |\{\mu' \in [\mu]_{\sim} \mid \mu' \in T(G, \nu)\}| \cdot w(\nu) = \bar{w}(\nu') \cdot w(\mu)$, which proves our claim. \blacktriangleleft

Since we weigh each equivalence class of nodes with its size in the pruned tree, it does not matter up to \sim whether we perform random walks on the pruned search tree or the unpruned tree. The distributions of equivalence classes are indistinguishable. Let us now argue why this suffices for the correctness of our algorithm. By looking carefully at the previous discussion, we can observe that all elements of an equivalence class can be mapped to each other through elements of $\langle S \rangle$. This implies that given a leaf ν , all elements represented by ν are generated by S if and only if ν is generated by S . In terms of Lemma 4, the automorphism derived from a leaf sampled uniformly at random from ν therefore has the same chance of sifting through the structure as one of ν^φ . Therefore, by using a modified version of Lemma 4 as the abort criterion, we can consider sampled weighted nodes of the pruned tree instead of proper uniform random nodes of the unpruned tree:

► **Lemma 10.** *Let G be a graph, B a base, S a set of permutations, $T(G)'$ the search tree resulting from repeated application of $\text{Prune}'_{\text{Aut}}$ with elements of S and $\tau \in T(G)'$ the target leaf. Furthermore, let ν be a leaf drawn from $T(G)'$ with weight $w(\nu)$ where $\nu^{-1} \cdot \tau = \varphi \in \text{Aut}(G)$. If $\langle S \rangle \neq \text{Aut}(G)$ holds, then the probability that φ does not sift through the Schreier structure defined by B and S is at least $\frac{1}{2}$.*

Proof. Since ν is an occurrence of the target leaf, we can require $\nu^\varphi = \tau$. From the previous discussion, we know that external weights of remaining leaves determine the amount of leaves in the unpruned tree represented by them (Lemma 9) and that no other remaining leaves represent them. It therefore suffices to argue that the derivable automorphisms of leaves of $T(G)$ represented by ν all have the same chance of being generated by $\langle S \rangle$. Since leaves are represented by ν if they were pruned using $\text{Prune}'_{\text{Aut}}$ – which by assumption can only use elements of S – all of them can be derived by applying some $\varphi' \in \langle S \rangle$ to ν : hence, $\varphi \in \langle S \rangle \iff \varphi \cdot \varphi' \in \langle S \rangle$. \blacktriangleleft

The actual solver will – in addition to finding a generating set in the first place – still need to fill the Schreier structure sufficiently. This can however only require more elements and thus increases the chance of elements not sifting successfully. Hence, it even decreases error probabilities.

■ **Figure 1** Potential search tree traversed when using trace deviation sets. Orange indicates base nodes and gray indicates pruned nodes. Children of pruned nodes are of course eventually pruned as well.

4 Implementation and Heuristics

We use the tools of the previous section to construct the parallel graph automorphism solver DEJAVU. We start by describing the high-level structure of DEJAVU. It consists of 4 modes of operation, between which it continuously switches. The solver decides how to switch between the modes using heuristics, which are based on a cost estimation.

The solver begins by trying to sample a good cell selector (in parallel). Then, *base-aligned* automorphism search is performed (Section 4.2), followed by breadth-first search (Section 4.1), followed by *level* automorphism search (see Section 4.2). At any point, depending on the cost estimation, the solver can decide to go to a preceding mode again.

The tool is written in C++. Threads of the C++ standard library are used for parallelization. It contains some modified code of the NAUTY / TRACES distribution (available at [2]), namely specialized versions of the Schreier-Sims implementation. The source code is available at [1].

The refinement of DEJAVU is a highly-engineered version of color refinement [17], following the implementation of TRACES closely. We also exploit the blueprint technique as described in [3], extending the technique to also cache cell selector choices for subsequent branches.

Next, we provide further details on practical and conceptual aspects of the solver.

4.1 Breadth-first Traversal and Trace Deviation Sets

The work of the breadth-first traversal is shared between threads through lock-free queues. A master thread adds all of the elements which have to be computed to a queue. Threads then dequeue a chunk of work, compute the elements, and report their results back to the master thread through another queue. In order to minimize overhead, large chunks of work are enqueued and dequeued from the queue rather than single elements. Furthermore, DEJAVU uses automorphism pruning when performing breadth-first search as described in Section 3.3 while filling up the queue (not enqueueing multiple elements known to be isomorphic).

During breadth-first traversal, we make use of a *trace* invariant, as introduced by TRACES and described in [17]. Furthermore, we introduce the *trace deviation set* technique. The approach is related to the special automorphism algorithm of TRACES [17] as well as the trace deviation trees used in [3].

During breadth-first traversal, we also keep a *trace deviation set*. The idea of this pruning technique is related to the special automorphism algorithm of TRACES (see [17]) and the trace deviation tree technique of [3]. We present the idea in the following.

To describe the technique, we first define a new node invariant, which we call the *deviation value* $\text{Dev}_{\text{Inv}}: V^* \rightarrow \mathbb{N}^2 \cup \{\perp\}$. Consider a fixed trace $\text{Inv}(\tau)$, which for our purposes will be the trace invariant of the target leaf τ . The deviation value $\text{Dev}_{\text{Inv}}(\nu)$ for a node ν is then defined as a tuple of the first position and the corresponding value in the trace $\text{Inv}(\nu)$ that is different from $\text{Inv}(\tau)$. If there are no differences, we set the deviation value to \perp denoting “no deviation”. Since the deviation value is a function of the invariant computed up until an isomorphism-invariant point, it is also naturally invariant under isomorphism.

Consider a node μ in the search tree. The crucial observation is that in our algorithm, we can also use the set of deviation values of its children as an invariant for μ itself. Assume ν_1, \dots, ν_k are children of μ and none of the subtrees rooted in the children has been pruned through $\text{Prune}_{\text{Inv}}$. Then, $D(\mu) := \{\text{Dev}_{\text{Inv}}(\nu_1), \dots, \text{Dev}_{\text{Inv}}(\nu_k)\}$, the trace deviation set of μ , can be used as an invariant for μ : we claim that for any other node μ' with children ν'_1, \dots, ν'_k , it must hold that $D(\mu) = \{\text{Dev}_{\text{Inv}}(\nu_1), \dots, \text{Dev}_{\text{Inv}}(\nu_k)\} = \{\text{Dev}_{\text{Inv}}(\nu'_1), \dots, \text{Dev}_{\text{Inv}}(\nu'_k)\} = D(\mu')$ whenever μ and μ' are isomorphic. If no pruning has taken place, this is easy to see since the branches are isomorphic by assumption, immediately implying that branches must contain the same invariant values. But if $\text{Prune}'_{\text{Aut}}$ is applied, no invariant values can be removed either: since pruned nodes are isomorphic to remaining nodes, they, again immediately by definition, must contain the same invariant values.

When advancing in a breadth-first manner, the aforementioned requirements are guaranteed to be satisfied: no $\text{Prune}_{\text{Inv}}$ has taken place on the level that is currently being pruned. Furthermore, while computing the level, the set of deviation values is automatically calculated anyway: whenever we observe that a node ν below μ deviates from the desired invariant $\text{Inv}(\nu)$ and should be pruned using $\text{Prune}_{\text{Inv}}$, we already have enough information to derive $\text{Dev}_{\text{Inv}}(\nu)$.

These observations are specifically exploited as follows: first, all children of the base node τ' (which belongs to the path on the way to the target leaf τ) are computed. If nodes deviate from the trace, their deviation values are recorded into a set, i.e., we calculate the trace deviation set $D(\tau')$. The idea is that if a node is (supposedly) isomorphic to the base node τ' , then, for its (supposedly) isomorphic children, it must deviate from the trace in the same manner at the same position. Hence, for all other parent nodes μ , we also keep track of $D(\mu)$ when calculating their children. Whenever we discover a new element of $D(\mu)$, we check whether the set equivalence $D(\tau') = D(\mu)$ can still be satisfied. If not, μ can be pruned immediately, without the necessity to calculate all its children.

For example, assume that we calculated deviation values $\{d_1, d_2\}$ for the base node (illustrated in Figure 1). From the previous discussion, it follows that we can immediately prune all nodes that produce a value other than $\{d_1, d_2\}$. We can also prune nodes that do not produce all of the deviation values. If for example a value $d_3 \notin \{d_1, d_2\}$ is encountered, the parent node can immediately be removed from the tree.

A crucial point is that pruning through trace deviation sets has negligible cost: children of the base node always have to be computed, and the trace deviation does not necessitate more calculation than is done for that particular node anyway. We are still able to fully use the early-out capabilities of the trace invariant. In the parallel implementation, only the initial recording of deviation values of base nodes has to be synchronized. In the implementation we do however, depending on a heuristic, use a slight variation: to make deviation values more distinct, it is sometimes beneficial to not use the early-out immediately. Instead, for a fixed constant k , color refinement is continued past the deviation for k more cells, accumulating more information for the deviation value. The trade-off is as follows: if k becomes larger, the early-out in color refinement is taken later, but deviation values become more distinct. In practice, this trades per-node cost for the number of nodes in the search tree. However, in our experiments we observed that even for very small k (we use $k = 5$), node reduction can be substantial – while not increasing per-node cost by a significant amount.

4.2 Automorphism Sampling

A central aspect when sampling automorphisms is whether we can guarantee that the resulting automorphisms are distributed uniformly in the group or not. If the distribution is uniform, they count towards the probabilistic abort criterion of the solver. The solver

■ **Figure 2** Level search (left) and base-aligned search (right). Squiggly lines indicate where random walks originate, orange indicates base nodes and gray nodes are pruned by breadth-first traversal.

uses two approaches, namely *base-aligned search* (generally non-uniform) and *level search* (uniform).

Level search is essentially sampling as described in Section 3 (see Figure 2, left). Walks are initiated from the remaining nodes of the search tree at the current breadth-first level, and when drawing the initial node, weights are accounted for to make the resulting distribution of automorphisms uniform. Crucially, in this mode, DEJAVU usually stores additional target leaves, which is proven to result in an exponential speedup in the worst-case [3].

Base-aligned search is designed to find as many automorphisms as possible with minimal effort. This typically entails giving up on uniformity. Base-aligned search initiates random walks from a base point of a given strategy (see Figure 2, right). Whenever finding automorphisms from a certain base point is deemed hard, search is advanced to the next base point. As a side effect, this handles inherently easy graphs efficiently: whenever color refinement already determines the orbit partition, base-aligned search finds all automorphisms and is even able to terminate search deterministically.

5 Practical Performance

We provide benchmark results corroborating that DEJAVU performs competitively on a large variety of graphs while scaling with the use of more threads.

5.1 Benchmarks

All benchmarks were run on an Intel Core i7 9700K (8 cores) processor with 16GB of RAM and Ubuntu 19.04. All graphs were randomly permuted, but every solver was given the same permuted version of a graph. All runtimes are measured without parsing the input.

The benchmarks include most sets from [2], which is the de facto standard when it comes to symmetry computation. We extended two of the sets to larger instance sizes. The respective graphs can be found in [1]. We should point out that for random trees and pipe graphs TRACES benefits from specialized code that is not implemented in DEJAVU.

The (user-definable) error bound for DEJAVU was set to 1%. A 1% error bound means that with at most that probability at least 1 generator of the generating set is missing. It can be proven however that the probability of missing at least 2 generators then only has a probability of at most $\frac{1}{2}\%$, missing at least 3 only at most $\frac{1}{2^2}\%$ and so forth (the argument for this is similar to the proof of Lemma 8 involving the index of the subgroup found). Hence, even if errors occur, it is highly likely only a small part of the generating set is missing.

Actual error probabilities are even lower. Due to the one-sided nature of the error, on asymmetric graphs DEJAVU can not err (e.g. most random regular graphs, random graphs, multipedes, `latin-sw`). Secondly, on many graph families DEJAVU can invoke a deterministic criterion for termination (e.g. for most of `rantree`, `hypercubes`, `dac`, `lattice`, complete graphs, `tran`). This means for the majority of the benchmarks errors can not be observed.

■ **Figure 3** Relative runtimes of benchmark sets for TRACES and DEJAVU (using the respective number of threads). For sets marked with *, we capped the runtime of TRACES at 2.

The benchmarks corroborate that through the use of parallelism, we are able to achieve significant speedup over state-of-the-art tools in a domain that so far has been exclusively dominated by sequential solvers (see Figure 3). Specifically, we do so on the particular, representative benchmark suite state-of-the-art solvers are tuned to solve.

Overall benchmarks show that DEJAVU with a single thread performs competitively with TRACES (on 12 benchmark sets DEJAVU is faster, while TRACES is faster on the other 10 sets). Using 8 threads, DEJAVU outperforms TRACES on most sets (on 17 out of 22 sets). Additionally, on *lattice*, DEJAVU performs better than TRACES for larger instances.

5.2 Scaling

We want to discuss in detail how DEJAVU scales with the use of more threads. In Figure 3, scaling is illustrated. To lessen the bonus of sampling cell selectors (see Section 4) gained when adding threads, we provide the 1 and 2 thread variants with the best cell selector for each set. (Otherwise, scaling would be even better, but the comparison would not be fair.) The diagram shows the summed up runtimes for a graph class relative to the runtime of a single thread, i.e., the single thread variant has a runtime of 1. This might overrepresent larger instances in the data, but of course larger instances are exactly those of biggest interest.

The diagram shows that for most sets of the benchmark suite, on our hardware, DEJAVU scales remarkably with the use of more threads. Overall we achieved our goal of designing a competitive tool that on most graph classes can efficiently exploit parallelism, in our experiments sometimes even approaching what is theoretically possible on 8 cores.

6 Conclusion and Future Work

We presented the new randomized, parallel algorithm DEJAVU that computes automorphism groups and can be used to compute symmetries of combinatorial objects. Benchmarks show that DEJAVU is competitive with state-of-the-art solvers, and parallelizes to 8 cores remarkably well on a wide variety of instances. In order to show further scaling in the same generic manner, we believe developing more large-scale, meaningful benchmark sets is required. For harder instances, preliminary testing shows that the use of more cores significantly improves the runtimes even further.

In future work, we intend to improve DEJAVU by adding dedicated subroutines to handle low degree vertices and gadget graph constructions. On very simple graphs, color refinement is the bottleneck which seems to necessitate an efficient parallel implementation for color refinement.

Abstract

We study the problem of finding a spanning forest in an undirected, n -vertex multi-graph under two basic query models. One are **Linear** queries which are linear measurements on the incidence vector induced by the edges; the other are the weaker **OR** queries which only reveal whether a given subset of plausible edges is empty or not. At the heart of our study lies a fundamental problem which we call the *single element recovery* problem: given a non-negative vector $x \in \mathbb{R}_{\geq 0}^N$, the objective is to return a single element $x_j > 0$ from the support. Queries can be made in rounds, and our goals is to understand the trade-offs between the query complexity and the rounds of adaptivity needed to solve these problems, for both deterministic and randomized algorithms. These questions have connections and ramifications to multiple areas such as sketching, streaming, graph reconstruction, and compressed sensing. Our main results are as follows:

- For the single element recovery problem, it is easy to obtain a deterministic, r -round algorithm which makes $(N^{1/r} - 1)$ -queries per-round. We prove that this is tight: any r -round *deterministic* algorithm must make $\geq (N^{1/r} - 1)$ **Linear** queries in some round. In contrast, a 1-round $O(\text{polylog}(N))$ -query *randomized* algorithm is known to exist.
- We design a *deterministic* $O(r)$ -round, $\tilde{O}(n^{1+1/r})$ -OR query algorithm for graph connectivity. We complement this with an $\tilde{\Omega}(n^{1+1/r})$ -lower bound for any r -round deterministic algorithm in the OR-model.
- We design a *randomized*, 2-round algorithm for the graph connectivity problem which makes $\tilde{O}(n)$ -OR queries. In contrast, we prove that any 1-round algorithm (possibly randomized) requires $\tilde{\Omega}(n^2)$ -OR queries. A *randomized*, 1-round algorithm making $\tilde{O}(n)$ -Linear queries is already known.

All our algorithms, in fact, work with more natural graph query models which are *special* cases of the above, and have been extensively studied in the literature. These are **Cross** queries (cut-queries) and **BIS** (bipartite independent set) queries.

1 Introduction

Many modern applications compel algorithm designers to rethink random access to input data, and revisit basic questions in a *query access model* where the input is accessed only via answers to certain kinds of queries. There are many reasons for this ranging from data volume (only snapshots of the data can be accessed) to data ownership (access is restricted via certain APIs).

In this paper, we study algorithms accessing an unknown, undirected multi-graph G on n vertices in the following two basic query models. Think of the graph as an unknown non-negative $\binom{n}{2}$ dimension vector x_G with $\text{supp}(x_G)$ denoting the positive coordinates. With this view, answers to these queries below can be interpreted as *measurements* on this vector.

- **Linear Queries (Linear):** Given any non-negative¹ $\binom{n}{2}$ dimension vector a_G , what is $a_G \cdot x_G$?
- **OR Queries (OR):** Given any subset S of the $\binom{n}{2}$ dimensions, is $\text{supp}(x_G) \cap S$ empty? Reverting back to the combinatorial nature of graphs, it is perhaps more natural to think of different kinds of queries, and indeed the following two have been extensively studied. These are however special² cases, respectively, of the queries above.
- **Cross-additive Queries (Cross):** Given two disjoint subsets A, B of V , $\text{Cross}(A, B)$ returns the number of edges, including multiplicity, that have one endpoint in A and the other in B .
- **Bipartite Independent Set Queries (BIS):** Given two disjoint subsets A, B of V , $\text{BIS}(A, B)$ returns whether or not there is an edge that has one endpoint in A and the other in B .

The above query models (and similar variants such as additive queries [30], cut-queries [49], edge-detection queries [6, 9]) have a rich literature [1, 4, 9, 16, 17, 30, 41, 44, 49]. Most previous works, however, have focused on either *graph reconstruction* [15–17, 41], or on *parameter estimation* (e.g., estimating the number of edges [9] or triangles [11]). In this work, however, our goal is to understand the power and limitations of these queries to reveal **structural properties** of the underlying graph. In particular, we study the following basic property.

► **Problem 1 (Graph connectivity).** *Given query access to an undirected multigraph on the vertex set $V = \{1, \dots, n\}$, return a spanning forest.*

It is not too hard to implement the *classic* BFS or DFS traversals to obtain an $\tilde{O}(n)$ -query deterministic algorithm for the above problem in either query model. However, such algorithms are *adaptive*, that is, the queries depend on the answers obtained so far. A much more modern algorithm of Ahn, Guha, and McGregor [2] gives³ an $\tilde{O}(n)$ -Linear query *non-adaptive* but *randomized* algorithm for the problem. This raises the following questions that motivate us

What is the rounds-of-adaptivity versus query-complexity trade-off for deterministic algorithms for Problem 1? Can randomization also help in the OR and BIS models?

It turns out that understanding the complexity of Problem 1 is closely related to understanding an even more basic problem which we discuss below.

¹ Non-negativity is for convenience. A general linear query can be broken into two non-negative queries.

² The Cross (and BIS queries) correspond to $\{0, 1\}$ vectors a_G (and subsets) corresponding to cuts. Indeed, our algorithms work with the weaker queries while our lower bounds will be for the stronger queries. It should also be clear that the Linear (and respectively Cross) queries are at least as strong as OR (resp. BIS) queries.

³ Using results in [51], one can also obtain a $\tilde{O}(n)$ -query deterministic algorithm in the Cross-query model.

Single Element Recovery

Consider a non-negative real-valued vector $x \in \mathbb{R}_{\geq 0}^N$ and suppose we have access to x only via **Linear** or **OR** queries where the dimension is now N . We define the following problem which we call the *single-element recovery* problem (following the standard “support-recovery” problem in compressed sensing).

► **Problem 2** (Single-element recovery). *Given a non-negative real-valued vector $x \in \mathbb{R}_{\geq 0}^N$, accessed via either **Linear**-queries or **OR**-queries, output any arbitrary element⁴ from the support $\text{supp}(x)$.*

To see how the above problem relates to Problem 1, consider the vector of possible edges incident to a single vertex. A spanning forest must find an edge incident to this vertex. This corresponds to solving Problem 2 on this vector. The problem is also interesting in its own right, with connections to *combinatorial group testing* [23, 24, 43], *compressed sensing* [19, 22, 33], and *coin-weighing problems*. [12, 30, 40, 50]. While most of these works have focused on recovering the full support, we ask the simpler question of just recovering a single element.

If one allows *randomization*, then one can use ℓ_0 -samplers [34] to solve the above problem using $O(\log^2 N \log(\frac{1}{\delta}))$ **Linear** queries⁵, *non-adaptively*. In fact, ℓ_0 -samplers return a random element in $\text{supp}(x)$. The parameter δ is the error probability. There have been numerous applications of these (see the table in Figure 1 of [37], for instance), and indeed many applications (including the AGM [2] algorithm alluded to above) need only an arbitrary element in the support. This is precisely what is asked in Problem 2. Furthermore, the upper bound for randomized algorithms is nearly tight [34, 37], and therefore, for randomized algorithms, our understanding is pretty much complete. But what can be said about *deterministically* finding a single support element⁶? This is an important question for it relates to deterministic analogs to the various applications stated above.

It is not too hard to make a couple of observations. One, any *non-adaptive* deterministic algorithm for Problem 2 using **Linear**-queries can in fact be recursively used to completely recover the whole vector. This implies an $\tilde{\Omega}(N)$ information theoretic lower bound. Two, if one allows more rounds, then one can indeed do better using a binary-search style idea. More precisely, in each round the algorithm partitions the search space into $N^{1/r}$ parts and using $N^{1/r}$ queries finds a non-zero part. In this way in r rounds, one can get algorithm making $N^{1/r}$ -queries per round. This leads to the following fundamental question which we answer in our paper.

What is the rounds-of-adaptivity versus query-complexity trade-off for deterministic algorithms for Problem 2?

1.1 Motivation and Perspective

Why should we care about the questions above?

- We think that algorithmic question of computation on graphs via queries is as natural and important as the reconstruction question. Indeed, our study was inspired by trying to understand the power of *cut*-queries to check whether a graph was connected or not; this

⁴ In the case of **OR**-queries, we can only return the j with $x_j > 0$

⁵ A similar result holds with **OR** queries as well. See Section 3

⁶ A “deterministic ℓ_0 sampler”, if you allow us the abuse of notation.

is an (extremely) special case of submodular function minimization. More recently, this type of “property-testing via queries” question on graphs has been asked for matchings by Nisan [44], and more generally for matrix properties by [51] and [46]. Single element recovery is also as natural as whole-vector recovery. Indeed, one can imagine a scenario where recovering a big⁷ subset of the support (diseased blood samples, say) faster and with fewer queries may be more beneficial than reconstructing the whole vector.

- The **Linear** query model is closely connected to *linear sketches* that have found plenty of applications in dynamic streaming; see, e.g. [29, 35, 39]. The single element recovery problem also has connections to the *universal relation* \mathbf{UR}^C problem in communication complexity, which was studied in [37, 42]. Understanding these questions, therefore, have ramifications to other areas. As a concrete example, one consequence of our results is a deterministic, $O(r)$ -pass dynamic streaming algorithm for graph connectivity in $\tilde{O}(n^{1+1/r})$ space. This was not known before.
- We believe the question of the trade-off between rounds versus query complexity is natural and important, especially in today’s world of massively parallel computing. Such trade-offs are closely related to similar questions in communication complexity, number of passes in streaming algorithms, etc. It is worthwhile building up an arsenal of tools to attack such questions. Indeed, one main contribution of this paper is to show how LP-duality can be used as one such tool.
- Why do we focus on deterministic algorithms? Mainly because, as mentioned above, our understanding of the complexity of randomized algorithms for the problems above is near complete. However, in some applications one may require exponentially low error, or has to deal with an “adversary” (say, the one giving updates to a streaming algorithm) that is not oblivious to the algorithm’s randomness; see, e.g. [10]. This further motivates the study of deterministic algorithms in this context. Furthermore, we need to design lower-bounding techniques which only work against deterministic algorithms, and this is of technical interest.

1.2 Our Results

Our first result is a tight lower bound for the question on single element recovery. The binary-search style algorithm mentioned above is the best one can do.

► **Result 1.** *For the single element recovery with **Linear**-query access, any r -round, deterministic algorithm must make $\geq N^{1/r} - 1$ queries in some round.*

We should remind the reader that the above lower bound is for vectors whose domain is non-negative rationals. In particular, it does not hold for Boolean vectors⁸. Moving to the continuous domain allows one to use tools from geometry, in particular duality theory and Caratheodory’s theorem, to prove the tight lower bound.

As mentioned above, **Linear** queries are stronger than **OR** queries, and thus the above lower bound holds for **OR** queries as well. The proof for **OR** queries, however, is combinatorial, arguably simpler, and more importantly can be generalized to prove the following lower bound for Problem 1 as well.

⁷ As we show later in Lemma 16, algorithmically we can get results when the “single” in single element recovery can be larger.

⁸ Indeed, for Boolean vector with **Linear** queries one can recover the whole vector if the query vector has exponentially large coefficients. Even when the coefficients are small ($\{0, 1\}$ even), the vector can be recovered with $O(n/\log n)$ -queries which is information theoretically optimal.

► **Result 2.** *Any r -round deterministic algorithm for finding a spanning forest, must make $\tilde{\Omega}(n^{1+\frac{1}{r}})$ -OR queries.*

As we explain below, the above smooth trade-off between rounds and query complexity is optimal, even when we allow the weaker BIS-queries. Algorithmically, we have the following result. We mention that such a result was not known even using Linear or Cross queries. A similar lower bound as in Result 2 with Cross-queries is left open.

► **Result 3.** *For any positive integer r , there exists an $O(r)$ -round deterministic algorithm which makes $\tilde{O}(n^{1+\frac{1}{r}})$ -BIS queries per round, and returns a spanning forest of the graph.*

It is worth remarking that our algorithm with Linear queries (which is implied by the weaker BIS queries) above also implies an $O(r)$ -pass $\tilde{O}(n^{1+1/r})$ -space *deterministic* algorithm for maintaining a spanning forest in *dynamic* graph streams. As the edge updates arise, one simply updates the answers to the various queries made in each round. This result was not known before.

Finally, we show that for Problem 1, randomization is helpful in decreasing the number of rounds. More precisely, we consider Monte-Carlo algorithms.

► **Result 4.** *There exists a 2-round randomized algorithm for graph connectivity which makes $\tilde{O}(n)$ -OR queries per round. There exists a 4-round randomized algorithm for graph connectivity which makes $\tilde{O}(n)$ -BIS queries per round. Any non-adaptive, randomized algorithm for graph connectivity must make $\tilde{\Omega}(n^2)$ -OR queries.*

Table 1 summarizes our contributions.

■ **Table 1** Summary of the state-of-the-art and our results for graph connectivity and single-element recovery problems. In each cell, we write the number of rounds followed by the query complexity per round. All lower bounds are with respect to the stronger model (Linear and OR). For upper bounds, if there is a discrepancy between the stronger and weaker models, we show this using a | as partition. Bold results are ours. The remaining results are folklore unless a reference is explicitly cited. The ? indicates the main open question of our paper.

		Linear Cross		OR BIS	
		Upper Bound	Lower Bound	Upper Bound	Lower Bound
Single Element Recovery	Det	$r, N^{1/r} - 1$	$r, N^{1/r} - 1$	$r, N^{1/r} - 1$	$r, N^{1/r} - 1$
	Rand	$r = 1, O(\log^2 N)$	$r = 1, \Omega(\log^2 N)$ [34]	$r = 1, O(\log^2 N)$	$r = 1, \Omega(\log^2 N)$
Graph Connectivity	Det	$O(r), n^{1+1/r}$?	$O(r), n^{1+1/r}$	$r, \tilde{\Omega}(n^{1+1/r})$
	Rand	$r = 1, \tilde{O}(n)$ [2] $\tilde{O}(n)$ [2, 51]	$r, \Omega(n/\log n)$	$r = 2 4, \tilde{O}(n)$	$r = 1, \tilde{\Omega}(n^2)$

1.3 Technical Overview

In this section we give a technical overview of our results. These highlight the main underlying ideas and will assist in reading the detailed proofs which appear in the subsequent sections.

Overview of Result 1. It is relatively easy to prove an r -round lower bound for single element recovery in the OR-query model via an adversary argument (see [7]). At a high level, OR-queries only mildly interact with each other and can be easily fooled. Linear queries, on the other hand, strongly interact with each other. To illustrate: if we know $x(A)$ and $x(B)$ for $B \subseteq A$, then we immediately know $x(A \setminus B)$. This is untrue for OR-queries – if x has a non-zero entry in both A and B , nothing can be inferred about its entries in $A \setminus B$. Indeed, this power manifests itself in the non-adaptive, randomized algorithm using Cross-queries; it is important that we can use subtraction. This makes proving lower bounds against Linear-queries distinctly harder.

In our proof of Result 1, we use duality theory. To highlight our idea, for simplicity, let's consider a warmup *non-adaptive* problem. The algorithm has to ask $\ll \sqrt{N}$ queries, and on obtaining the response, needs to return a subset $S \subseteq [N]$ of size $\ll \sqrt{N}$ with the guarantee that $\text{supp}(x) \cap S$ is not empty. Note that if this were possible, then there would be a simple 2-round $o(\sqrt{N})$ -algorithm – simply query the individual coordinates of S in the second round. This is what we want to disprove. Therefore, given the first round's $\ll \sqrt{N}$ queries, we need to show there exists responses such that *no matter* which set S of $\ll \sqrt{N}$ size is picked, there exists a feasible $x \in \mathbb{R}_{\geq 0}^N$ which sets all entries in S to 0. Note this is a $\exists \forall \exists$ -statement. How does one go ahead establishing this?

We first observe that for a fixed response \mathbf{a} and a fixed set S , whether or not a feasible $x \in \mathbb{R}_{\geq 0}^N$ exists is asking whether a system of linear inequalities has a feasible solution. Farkas Lemma, or taking the dual, tells us exactly when this is the case. The nice thing about the dual formulation is that the “response” \mathbf{a} becomes a “variable” in the dual program, as it should be since we are trying to find it. To say it another way, taking the dual allows us to assert conditions that the response vector \mathbf{a} must satisfy, and the goal becomes to hunt for such a vector. How does one do that? Well, the conditions are once again linear inequalities, and we again use duality. In particular, we use Farkas Lemma again to obtain conditions certifying the *non-existence* of such an \mathbf{a} . The final step is showing that the existence of this certificate is impossible. This step uses another tool from geometry – Carathéodory's theorem. Basically, it shows that if a certificate exists, then a *sparse* certificate must exist. And then a simple counting argument shows the impossibility of sparse certificates. This, of course, is an extremely high-level view and for just the warmup problem. In Section 2 we give details of this warmup, and also details of how one proves the general r -round lower bound building on it.

The interested reader may be wondering about the two instantiations of duality (isn't the dual of the dual the primal?). We point out that duality can be thought of as transforming a \exists statement into a \forall statement: feasibility is a \exists statement, Farkas implies infeasibility is a different \exists statement, and negating we get the original feasibility as a \forall statement. Since we were trying to assert a $\exists \forall \exists$ -statement, the two instantiations of duality hit the two different \exists .

Overview of Result 2. At a high level, the lower bound for Problem 1, the spanning forest problem, boils down to a “direct sum” version of Problem 2, the single element recovery problem. Imagine the graph is an $n \times n$ bipartite graph. Therefore, finding a spanning forest requires us finding an edge incident to *each* of the n vertices on one side. This is precisely solving n -independent versions of Problem 2 in parallel. However, note that a single query can “hit” different instances at once. The question is, as all direct-sum questions are, does this make the problem n -times harder? We do not know the answer for Linear queries and leave this as the main open question of our work. However, we can show that the simpler,

combinatorial proof of Result 1 against OR-queries does have a direct-sum version, and gives an almost tight lower bound for Problem 1. This is possible because OR-queries, as mentioned in the previous paragraph, have only mild interaction between them. We show that this interaction cannot help by more than a $\text{poly}(r)$ -factor. Our proof is an adversary argument, and a similar argument was used recently by Nisan [44] to show that matchings cannot be approximated well by deterministic algorithms with OR-queries. Details of this are given in [7].

Overview of Result 3. In Section 3, we show some simple, folklore, and known results for single element recovery. We build on these algorithms to obtain our algorithms for Problem 1. With every vertex one associates an unknown vector which is an indicator of its neighborhood. If one applies the r -round binary-search algorithm for the single element recovery problem on each such vector, then in r -rounds with $O(n^{1+1/r})$ -BIS queries, for every vertex one can obtain a single edge incident on it. This alone however doesn't immediately help: perhaps, we only detect $n/2$ edges and get $n/2$ disconnected clusters. Recursively proceeding only gives an $O(r \log n)$ -round algorithm. And we would like no dependence on n .

To make progress, we actually give a more sophisticated algorithm for single element recovery than binary search, which gives more and may be of independent interest. In particular, we describe an algorithm (Lemma 16) for single element recovery which in $O(r)$ rounds, and making $N^{1/r}$ -queries per round, can in fact return as many as $N^{1/4r}$ elements in the support. Once we have this, then for graph connectivity we observe that in $O(r)$ rounds, we get polynomially many edges incident on each vertex. Thus as rounds go on, the number of effective vertices decreases, which allows us to query more aggressively. Altogether, we get an $O(r)$ -round algorithm making only $\tilde{O}(n^{1+1/r})$ -BIS queries. The details of this are described in Section 4.

Overview of Result 4. In the overview of the deterministic algorithm, we had to be a bit conservative in that even after every vertex found k edges (k being 1 or $n^{O(1/r)}$) incident on it, we pessimistically assumed that after this step the resulting graph still has $\Theta(n/k)$ disconnected clusters, and we haven't learned *anything* about the edges across these clusters. In particular, we allow for the situation that the cross-cluster edges can be dense. With randomization, however, we get to sample k *random* edges incident on a vertex. This is where we use the recent result of Holm *et al.* [31] which shows that if the k incident edges are random, then, as long as $k = \Omega(\log n)$, the number of *inter-component* edges between the connected components induced by the sampled edges, is $O(n/k)$. That is the cross-cluster edges are sparse. Therefore, in a single round with $\tilde{O}(n)$ -randomized BIS queries, we can obtain a disconnected random subgraph, but one such that, whp, there exist at most $\tilde{O}(n)$ edges across the disconnected components.

Given the above fact, the algorithm is almost immediate. After round 1, we are in a sparse graph (where nodes now correspond to subsets of already connected vertices). If we were allowed general OR-queries, then a single round with $\tilde{O}(n)$ -OR queries suffices to learn this sparse graph, which in turn, gives us a spanning forest in the original graph. This follows from algorithms for single element recovery when the vector is promised to be sparse (discussed in Section 3). Unfortunately, these queries may not be BIS-queries; recall that BIS-queries are restricted to ask about edges across two subsets. Nevertheless, we can show how to implement the above idea using 2-extra rounds with only BIS-queries, giving a 4-round algorithm. Details can be found in [7].

To complement the above, we also prove that even with randomization, one cannot get non-adaptive (1-round) $o(n^2/\log^2 n)$ -query algorithms with OR-queries. Indeed, the family of examples is formed by two cliques (dense graphs) which could have a single edge, or not, that connects them. A single collection of $o(n^2/\log^2 n)$ -OR queries cannot distinguish between these two families. Details can be found in [7].

1.4 Related Works

Our work falls in the broad class of algorithm design in the *query access model*, where one has limited access to the input. Over the years there has been a significant amount of work relevant to this paper including in graph reconstruction [1, 3, 4, 6, 12, 14, 15, 17, 30, 41, 47], parameter estimation [9, 11, 21, 48], minimum cuts [8, 49] sketching and streaming [2, 5, 8, 27, 28, 34, 36, 37, 42, 51], combinatorial group testing, compressed sensing, and coin weighing [12, 19, 22–25, 50]. It is impossible to do complete justice, but in the full version [7] we give a more detailed discussion of some of these works and how they fit in with our paper.

2 Lower Bound for Single Element Recovery

The following is the formal statement of the r -round lower bound for single element recovery.

► **Theorem 1.** *Any r -round deterministic algorithm for Single Element Recovery must make $\geq (N^{1/r} - 1)$ -Linear queries in some round.*

In fact, we prove (see Corollary 9) that if k_1, \dots, k_r are r positive integers such that $\prod_{i=1}^r (k_i + 1) < N$, then no r -round algorithm making $\leq k_i$ queries in round i can be successful for the Single Element Recovery problem. This implies Theorem 1. To begin with, we give a proof for essentially the $r = 2$ case, which was the warm-up question we discussed in Section 1.3. More precisely, we prove that if $(k + 1)s < N$ then no one-round algorithm making $\leq k$ queries can return a subset S of size $\leq s$ with $x_j > 0$ for some $j \in S$. That is, a subset which traps an element in $\text{supp}(x)$. This essentially implies the $r = 2$ case with $k_1 = k$ and $k_2 = s - 1$. This proof contains the core ideas behind the more general statement, which follows via an inductive application of the same idea. The complete proof of Theorem 1 can be found in Section 2.1. For now, we focus on proving the following statement.

► **Theorem 2.** *If $(k + 1)s < N$, then there cannot exist a 1-round deterministic algorithm making k -Linear queries for the trapping problem with parameter s .*

Note that if s divides N , then $k = \frac{N}{s} - 1$ queries suffice and so the above theorem is tight.

Proof. Since x is a non-zero, non-negative vector, by scaling, we assume that $x([N]) = 1$. We let \mathbf{A} denote the $k \times N$ matrix corresponding to the k queries arranged as row vectors. We use $\mathbf{a} \in \mathbb{R}_{\geq 0}^k$ to denote the answers we will give to fool any algorithm. To find this, fix any subset S with $|S| \leq s$, and consider the following system of inequalities parametrized by the answer vector \mathbf{a} . The only inequalities are the non-negativity constraints. Below, and throughout, $[N] := \{1, 2, \dots, N\}$.

$$\mathcal{P}(\mathbf{a}; S) = \{x \in \mathbb{R}_{\geq 0}^N : x([N]) = 1 \quad \mathbf{A} \cdot x = \mathbf{a} \quad x(S) = 0\} \quad (\text{P})$$

Note that if $\mathcal{P}(\mathbf{a}; S)$ has a feasible solution, then given the answers \mathbf{a} to its queries, the algorithms *cannot* return the subset S . This is because there is a non-negative x consistent with these answers with S disjoint from its support. In other words, S is *safe* for the lower

bound w.r.t. \mathbf{a} . Therefore, if there exists an answer vector \mathbf{a} such that *every* subset $S \subseteq [N]$ with $|S| \leq s$ is safe with respect to \mathbf{a} , that is $\mathcal{P}(\mathbf{a}; S)$ is feasible, then we would have proved our lower bound. We use duality and geometry to prove the existence of this vector (if $(k+1)s < N$).

The first step is to understand when for a *fixed* set S , the system $\mathcal{P}(\mathbf{a}; S)$ is infeasible. This is answered by Farkas Lemma. In particular, consider the following system⁹ of inequalities where the variables are the Lagrange multipliers corresponding to the equalities in (P). We note that the variables are *free*, since $\mathcal{P}(\mathbf{a}; S)$ has only equalities in the constraints. For convenience, we have eliminated the variable corresponding to the subset S and have moved it to the right hand side. Below, and throughout, for any subset $S \subseteq [N]$, we use $\mathbf{1}_S$ to denote the N -dimensional 0,1-vector which has 1 in the coordinates $i \in S$.

$$\mathcal{C}_S := \left\{ (y^{(0)}, \mathbf{y}) \in \mathbb{R} \times \mathbb{R}^k : y^{(0)} \cdot \mathbf{1}_{[N]} + \mathbf{y} \cdot \mathbf{A} \leq \mathbf{1}_S \right\}$$

Farkas Lemma asserts that $\mathcal{P}(\mathbf{a}; S)$ is *infeasible* if and only if there exists $(y^{(0)}, \mathbf{y}) \in \mathcal{C}_S$ such that $y^{(0)} \cdot \mathbf{1} + \mathbf{y} \cdot \mathbf{a} > 0$. Contrapositively, we get that $\mathcal{P}(\mathbf{a}; S)$ is feasible, that is S is safe with respect to \mathbf{a} , iff $y^{(0)} + \mathbf{y} \cdot \mathbf{a} \leq 0$ for *all* $\mathbf{y} \in \mathcal{C}_S$. Since we want an answer \mathbf{a} such that *all* subsets S with $|S| \leq s$ are safe, we conclude that such an answer exists if and only if the following system of linear inequalities has a feasible solution.

$$\mathcal{Q} := \left\{ \mathbf{a} \in \mathbb{R}_{\geq 0}^k : \mathbf{y} \cdot \mathbf{a} \leq -y^{(0)}, \quad \forall S \subseteq [N], |S| \leq s, \quad \forall (y^{(0)}, \mathbf{y}) \in \mathcal{C}_S \right\} \quad (\text{D})$$

In summary, to prove the lower bound, it suffices to show that \mathcal{Q} has a feasible solution, and this solution will correspond to the answers to the queries. Suppose, for the sake of contradiction, \mathcal{Q} is *infeasible*. Then, again by Farkas Lemma (but on a different system of inequalities), there exists multipliers $\lambda_t > 0$ corresponding to constraints $(S_t \text{ s.t. } |S_t| \leq s, (y_t^{(0)}, \mathbf{y}_t) \in \mathcal{C}_{S_t})$ for some $t = 1 \dots T$ such that (P1) $\sum_{t=1}^T \lambda_t \mathbf{y}_t \geq \mathbf{0}_k$ where $\mathbf{0}_k$ is the k -dimensional all zero (row) vector, and (P2) $\sum_{t=1}^T \lambda_t y_t^{(0)} > 0$. Note that this time λ_t 's are non-negative since \mathcal{Q} has inequalities in the constraints.

We can focus on the λ_t 's which are *positive* and discard the rest. The next key observation is to *upper bound* the size T of the support. Note that the conditions (P1) and (P2) can be equivalently stated as asserting that the $(k+1)$ -dimensional *cone* spanned by the vectors $(y_t^{(0)}, \mathbf{y}_t)$ contains a non-negative point with first coordinate positive. Caratheodory's theorem (for cones) asserts that any such point can be expressed as a conic combination of at most $(k+1)$ vectors. Therefore, we can assume that $T \leq k+1$.

Now we are almost done. Since $(y_t^{(0)}, \mathbf{y}_t) \in \mathcal{C}_{S_t}$, we have $y_t^{(0)} \cdot \mathbf{1}_{[N]} + \mathbf{y}_t \cdot \mathbf{A} \leq \mathbf{1}_{S_t}$. Taking λ_t combinations and adding, we get (since all $\lambda_t > 0$) that

$$\left(\sum_{t=1}^T \lambda_t y_t^{(0)} \right) \cdot \mathbf{1}_{[N]} + \left(\sum_{t=1}^T \lambda_t \mathbf{y}_t \right) \cdot \mathbf{A} \leq \sum_{t=1}^T \lambda_t \mathbf{1}_{S_t}$$

Since every $|S_t| \leq s$, the support of the right hand side vector is $\leq sT \leq s(k+1)$. The support of the left hand side vector is $= N$. This is because the second summation is a non-negative vector by (P1), and the first has full support. This contradicts $(k+1)s < N$. Hence, \mathcal{Q} has a feasible solution, which in turn means there exists answers \mathbf{a} which foils \mathbf{A} . This proves Theorem 2. \blacktriangleleft

⁹ Here \mathbf{y} and $\mathbf{1}_S$ are *row vectors*. In the general proof, there will be multiple \mathbf{y} 's indexed with super-scripts. All of them are row-vectors.

2.1 The General r -round Lower Bound

We begin by formally defining what an r -round deterministic algorithm is, and what it means for such an algorithm to successfully solve Single Element Recovery.

► **Definition 3** (r -round deterministic algorithm.). An r -round deterministic algorithm \mathcal{A} proceeds by making a collection of linear queries $\mathbf{A}^{(1)} \in \mathbb{R}_{\geq 0}^{k_1 \times N}$ and obtains the answer $\mathbf{a}^{(1)} = \mathbf{A}^{(1)} \cdot x$. This is the first round of the algorithm. For $1 < i \leq r$, in the i th round the algorithm makes a collection of linear queries $\mathbf{A}^{(i)} \in \mathbb{R}_{\geq 0}^{k_i \times N}$. This matrix depends on the history $(\mathbf{A}^{(1)}, \mathbf{a}^{(1)}), \dots, (\mathbf{A}^{(i-1)}, \mathbf{a}^{(i-1)})$. Upon making this query it obtains the answer $\mathbf{a}^{(i)} = \mathbf{A}^{(i)} \cdot x$. We call $\Pi_r := ((\mathbf{A}^{(1)}, \mathbf{a}^{(1)}), \dots, (\mathbf{A}^{(r)}, \mathbf{a}^{(r)}))$ the r -round **transcript** of the algorithm. The output of the deterministic algorithm \mathcal{A} only depends on Π_r .

A vector $y \in \mathbb{R}_{\geq 0}^N$ is said to be **consistent** with respect to a transcript Π_r if $\mathbf{A}^{(i)} \cdot y = \mathbf{a}^{(i)}$ for all $1 \leq i \leq r$. A transcript $\Pi_r = ((\mathbf{A}^{(1)}, \mathbf{a}^{(1)}), \dots, (\mathbf{A}^{(r)}, \mathbf{a}^{(r)}))$ is **feasible** for the algorithm if there is some vector y consistent with respect to it, and if the algorithm indeed queries $\mathbf{A}^{(i)}$ given the $(i-1)$ -round transcript $((\mathbf{A}^{(1)}, \mathbf{a}^{(1)}), \dots, (\mathbf{A}^{(i-1)}, \mathbf{a}^{(i-1)}))$.

► **Definition 4.** An r -round deterministic algorithm \mathcal{A} is said to successfully solve Single Element Recovery if for all non-zero $x \in \mathbb{R}_{\geq 0}^N$, upon completion of r -rounds the algorithm \mathcal{A} returns a coordinate $j \in [N]$ with $x_j > 0$. In particular, if the algorithm returns a coordinate j given a feasible transcript Π_r , then every x that is consistent with Π_r must have $x_j > 0$.

For technical reasons, we add a 0th-round for any r -round algorithm. In this round, the query “matrix” $\mathbf{A}^{(0)}$ is the single N -dimensional row with all ones. That is, we ask for the sum of x_j for all $j \in [N]$. We assume that the answer $\mathbf{a}^{(0)}$ is the scalar 1 to capture the fact that the vector x is non-zero.

Next we define the notion of safe subsets with respect to a transcript generated till round i . A safe subset of coordinates are those for which there is a consistent vector x whose support is disjoint from the subset, that is, $x_j = 0$ for all $j \in S$, or equivalently $x(S) = 0$ since $x \geq 0$.

► **Definition 5.** Given an i -round transcript $\Pi_i = ((\mathbf{A}^{(0)}, \mathbf{a}^{(0)}), \dots, (\mathbf{A}^{(i)}, \mathbf{a}^{(i)}))$, a subset $S \subseteq [N]$ is **safe** w.r.t. Π_i if the following system of linear inequalities

$$\mathcal{P}(\mathbf{a}^{(\leq i)}; S) := \left\{ x \in \mathbb{R}^N : \begin{cases} \mathbf{A}^{(j)} \cdot x = \mathbf{a}^{(j)} & \forall 0 \leq j \leq i \\ x(S) = 0 \\ x \geq 0 \end{cases} \right\} \quad (\text{Primal})$$

has a feasible solution.

► **Claim 6.** If Π_r is a feasible r -round transcript of an algorithm \mathcal{A} such that all singletons are safe w.r.t Π_r , then the algorithm \mathcal{A} cannot be successful in solving Single Element Recovery.

Proof. Given Π_r , the algorithm \mathcal{A} must return some coordinate $j \in [N]$. However $\{j\}$ is safe. That is, there is a feasible solution x to $\mathcal{P}(\mathbf{a}^{(\leq r)}, \{j\})$. Indeed, if x were the input vector, the algorithm would return a coordinate not in the support. \triangleleft

► **Definition 7** (Transcript Creation Procedure). Given an r -round algorithm \mathcal{A} , the transcript creation procedure is the following iterative process. In round i , given the transcript $\Pi_{i-1} := ((\mathbf{A}^{(0)}, \mathbf{a}^{(0)}), \dots, (\mathbf{A}^{(i-1)}, \mathbf{a}^{(i-1)}))$ upon which the algorithm \mathcal{A} queries $\mathbf{A}^{(i)}$, and the transcript creation procedure produces an answer $\mathbf{a}^{(i)}$ such that $\Pi_i = \Pi_{i-1} \circ (\mathbf{A}^{(i)}, \mathbf{a}^{(i)})$ is feasible.

Our main theorem, which implies Theorem 1, is the following.

► **Theorem 8** (Transcript Creation Theorem). *Let k_1, \dots, k_r and s_0, s_1, \dots, s_r be positive integers such that $s_0 \leq n - 1$ and $(k_i + 1)s_i \leq s_{i-1}$ for all $i \geq 1$. Then given any r -round algorithm \mathcal{A} making $\leq k_i$ queries in round i , there is a transcript creation procedure to create an r -round transcript such that for all $0 \leq i \leq r$, any subset $S \subseteq [N]$ with $|S| \leq s_i$ is safe with respect to Π_i .*

► **Corollary 9.** *Let k_1, \dots, k_r be any r positive integers with $\prod_{i=1}^r (k_i + 1) < n$. No r -round algorithm \mathcal{A} which makes $\leq k_i$ queries in round i can be successful for the Single Element Recovery problem. In particular, this implies Theorem 1.*

Proof. Set $s_r = 1$, $s_{r-1} = (k_r + 1)$, and in general, $s_i = (k_r + 1)(k_{r-1} + 1) \cdots (k_{i+1} + 1)$. Note that the conditions of Theorem 8 are satisfied. Therefore given any algorithm \mathcal{A} making $\leq k_i$ queries in round i , we can create a r -round transcript such that all singleton sets are safe with respect to Π_r . Claim 6 implies \mathcal{A} cannot be successful. ◀

2.1.1 Proof of the Transcript Creation Theorem

We start with writing the dual representation of safe sets. Fix a subset $S \subseteq [N]$ and a transcript Π_i . By Farkas lemma we know that the system $\mathcal{P}(\mathbf{a}^{(\leq i)}; S)$ is infeasible only if there exists a infeasibility certificate

$$\left(\mathbf{y}^{(0)}, \mathbf{y}^{(1)}, \dots, \mathbf{y}^{(i)} \right) \in \mathbb{R} \times \mathbb{R}^{k_1} \times \dots \times \mathbb{R}^{k_i} : \sum_{j=0}^i \mathbf{y}^{(j)} \cdot \mathbf{A}^{(j)} \leq \mathbf{1}_S \quad \text{and} \quad \sum_{j=0}^i \mathbf{y}^{(j)} \cdot \mathbf{a}^{(j)} > 0$$

Here $\mathbf{1}_S$ is the n -dimensional indicator vector of the subset S , that is, it has 1 in the coordinates $j \in S$ and 0 otherwise. Taking negations, we get that the system $\mathcal{P}(\mathbf{a}^{(\leq i)}; S)$ is *feasible*, that is $S \subseteq [N]$ is safe w.r.t Π_{i-1} , if and only if the following condition holds

$$S \text{ is safe w.r.t. } \Pi_i \text{ iff } \mathbf{y}^{(\leq i)} \cdot \mathbf{a}^{(\leq i)} := \sum_{j=0}^i \mathbf{y}^{(j)} \cdot \mathbf{a}^{(j)} \leq 0 \quad \text{for all } \mathbf{y}^{(\leq i)} \in \mathcal{C}_S^{(i)} \quad (\text{Dual})$$

where,

$$\mathcal{C}_S^{(i)} := \left\{ \mathbf{y}^{(\leq i)} := (\mathbf{y}^{(0)}, \mathbf{y}^{(1)}, \dots, \mathbf{y}^{(i)}) \in \mathbb{R} \times \mathbb{R}^{k_1} \times \dots \times \mathbb{R}^{k_i} : \sum_{j=0}^i \mathbf{y}^{(j)} \cdot \mathbf{A}^{(j)} \leq \mathbf{1}_S \right\}$$

We are now ready to prove Theorem 8 via induction on i . The above representation is the dual definition of safe sets, and this definition is what is easy to induct with.

Base Case: $i = 0$. We need to show that any subset $S \subseteq [N]$ of size $|S| \leq s_0 = N - 1$ is safe with respect to the transcript $(\mathbf{A}^{(0)}, \mathbf{a}^{(0)})$. To remind the reader, $\mathbf{A}^{(0)}$ is just the all ones vector and $\mathbf{a}^{(0)}$ is just the scalar 1. Using (Dual), we need to show for any subset $S \subseteq [N]$ with $|S| \leq N - 1$, we must have

$$\mathbf{y}^{(0)} \cdot \mathbf{a}^{(0)} \leq 0 \quad \text{for all } \mathbf{y}^{(0)} \in \mathbb{R} \text{ such that } \mathbf{y}^{(0)} \cdot \mathbf{A}^{(0)} \leq \mathbf{1}_S$$

However, $\mathbf{y}^{(0)} \cdot \mathbf{A}^{(0)}$ is the n -dimensional vector which is $\mathbf{y}^{(0)}$ on all coordinates. Since $|S| \leq n - 1$, there is some coordinate $j \notin S$ such that $\mathbf{1}_S[j] = 0$. Thus, $\mathbf{y}^{(0)} \leq 0$ implying $\mathbf{y}^{(0)} \cdot \mathbf{a}^{(0)} \leq 0$. The base case holds.

Inductive Case: $i \geq 1$. Assume the conclusion of the theorem holds for all $0 \leq j \leq i-1$. That is, there is a procedure which has created a transcript $\Pi_{i-1} = ((\mathbf{A}^{(0)}, \mathbf{a}^{(0)}), \dots, (\mathbf{A}^{(i-1)}, \mathbf{a}^{(i-1)}))$ such that every subset $S \subseteq [N]$ with $|S| \leq s_{i-1}$ is safe w.r.t Π_{i-1} . Using (Dual), we can rewrite this as the following statement

$$\forall S \subseteq [N], |S| \leq s_{i-1}, \quad \text{for all } \mathbf{y}^{(\leq i-1)} \in \mathcal{C}_S^{(i-1)} \quad \text{we have} \quad \mathbf{y}^{(\leq i-1)} \cdot \mathbf{a}^{(\leq i-1)} \leq 0. \quad (\text{IH})$$

Given Π_{i-1} , the algorithm \mathcal{A} now queries $\mathbf{A}^{(i)}$ in round i . Our goal is to find answers $\mathbf{a}^{(i)} \in \mathbb{R}_{\geq 0}^{k_i}$ such that any subset $S \subseteq [N]$ with $|S| \leq s_i$ is safe w.r.t $\Pi_i = \Pi_{i-1} \circ (\mathbf{A}^{(i)}, \mathbf{a}^{(i)})$. Again referring to (Dual), we need to find $\mathbf{a}^{(i)} \in \mathbb{R}_{\geq 0}^{k_i}$ satisfying the following system of linear inequalities.

$$\mathcal{Q}^{(i)} := \left\{ \mathbf{a}^{(i)} \in \mathbb{R}_{\geq 0}^{k_i} : \mathbf{y}^{(i)} \cdot \mathbf{a}^{(i)} \leq -(\mathbf{y}^{(\leq i-1)} \cdot \mathbf{a}^{(\leq i-1)}), \quad \forall S \subseteq [N], |S| \leq s_i, \quad \forall \mathbf{y}^{(\leq i)} \in \mathcal{C}_S^{(i)} \right\}$$

Although it may appear that the above system has infinitely many constraints, it suffices to write the constraints for extreme points for the polyhedra $\mathcal{C}_S^{(i)}$'s. To complete the proof, we need to show that $\mathcal{Q}^{(i)}$ is non-empty; if so, we can select any $\mathbf{a}^{(i)} \in \mathcal{Q}^{(i)}$ for completing the transcript creation procedure, and proving the theorem by induction. The next lemma does precisely that; this completes the proof of the theorem. ◀ Theorem 8

► **Lemma 10.** *The system of inequalities $\mathcal{Q}^{(i)}$ has a feasible solution.*

Proof. For the sake of contradiction, suppose not. Applying Farkas lemma (again), we get the following certificate of infeasibility. There exists the tuples $(\lambda_t > 0, S_t \subseteq [N])$ with $|S_t| \leq s_i$, $\mathbf{y}_t^{(\leq i)} \in \mathcal{C}_{S_t}^{(i)}$ for $1 \leq t \leq k_i + 1$ such that

(P1): $\sum_{t=1}^{k_i+1} \lambda_t \mathbf{y}_t^{(i)} \geq \mathbf{0}_{k_i}$, and

(P2): $\sum_{t=1}^{k_i+1} \lambda_t (\mathbf{y}_t^{(\leq i-1)} \cdot \mathbf{a}^{(\leq i-1)}) > 0$.

Since $\mathbf{y}_t^{(\leq i)} \in \mathcal{C}_{S_t}^{(i)}$, we get $\sum_{j=0}^i \mathbf{y}_t^{(j)} \cdot \mathbf{A}^{(j)} \leq \mathbf{1}_{S_t}$ for all $1 \leq t \leq k_i$. Taking the positive λ_t -combinations of these inequalities, we get

$$\sum_{t=1}^{k_i+1} \lambda_t \cdot \left(\sum_{j=0}^i \mathbf{y}_t^{(j)} \cdot \mathbf{A}^{(j)} \right) \leq \sum_{t=1}^{k_i+1} \lambda_t \mathbf{1}_{S_t} \quad (\text{P3})$$

Now, define $\mathbf{w}^{(j)} := \sum_{t=1}^{k_i+1} \lambda_t \mathbf{y}_t^{(j)}$ for $0 \leq j \leq i$. (P1) above implies (Q1): $\mathbf{w}^{(i)} \geq \mathbf{0}_{k_i}$, and (P2) implies (Q2): $\mathbf{w}^{(\leq i-1)} \cdot \mathbf{a}^{(\leq i-1)} > 0$. And finally, (P3) translates to

$$\underbrace{\sum_{j=0}^{i-1} \mathbf{w}^{(j)} \cdot \mathbf{A}^{(j)}}_{\text{Call this } \mathbf{u}_1} + \underbrace{\mathbf{w}^{(i)} \cdot \mathbf{A}^{(i)}}_{\text{Call this } \mathbf{u}_2} \leq \underbrace{\sum_{t=1}^{k_i+1} \lambda_t \mathbf{1}_{S_t}}_{\text{Call this } \mathbf{v}} \quad (\text{Q3})$$

Now we are ready to see the contradiction. First observe that the vector \mathbf{v} has at most $(k_i + 1)s_i$ positive entries since it is the sum of $k_i + 1$ vectors each of support $\leq s_i$. Since $\mathbf{w}^{(i)}$ and $\mathbf{A}^{(i)}$ are both non-negative, \mathbf{u}_2 is a non-negative vector. This implies that \mathbf{u}_1 must have $\leq (k_i + 1)s_i$ positive entries. From the conditions of the theorem, we get $(k_i + 1)s_i \leq s_{i-1}$. Thus, \mathbf{u}_1 has $\leq s_{i-1}$ positive entries. This in turn implies there exists a scalar θ such that $\theta \mathbf{u}_1 \leq \mathbf{1}_S$ for some subset $S \subseteq [N]$ with $|S| \leq s_{i-1}$. That is,

$$\sum_{j=0}^{i-1} (\theta \mathbf{w}^{(j)}) \cdot \mathbf{A}^{(j)} \leq \mathbf{1}_S \quad \Rightarrow \quad \theta \mathbf{w}^{(\leq i-1)} \in \mathcal{C}_S^{(i-1)}$$

The induction hypothesis (IH) implies $\theta \mathbf{w}^{(\leq i-1)} \cdot \mathbf{a}^{(\leq i-1)} \leq 0$. This contradicts (Q2). This completes the proof of the lemma. ◀

3 Algorithms Warmup: Algorithms for Single Element Recovery

In this section, we state some simple and/or well known algorithms for single element recovery which we use these as subroutines for our algorithms for graph connectivity as well.

► **Lemma 11.** *Let $x \in \mathbb{R}_{\geq 0}^N$ be a non-zero, non-negative vector, and let r be a positive integer. There exists an r -round deterministic algorithm $\text{BinarySearch}_r(x)$ which makes $(N^{1/r} - 1)$ -OR queries per round, and returns a coordinate j with $x_j > 0$. If Linear queries are allowed, then one can recover x_j as well.*

Proof. (Sketch) Divide $[N]$ into $N^{1/r}$ blocks each of size $N^{1-1/r}$, and run OR query on each block but the last, taking $N^{1/r} - 1$ queries in all. If one of them evaluates to 1, recurse on that for the next $r - 1$ rounds. Otherwise, recurse on the last block. ◀

Next, we state a standard result from the combinatorial group testing and coin-weighing literature [19, 25, 32, 38, 45] which says that if the support of x is known to be small, then there exist efficient *one-round* deterministic algorithms to recover the complete vector.

► **Lemma 12.** [32, 45] *Let $x \in \mathbb{R}_{\geq 0}^N$ be a non-zero vector, and let d be any positive integer. There exists a 1-round (non-adaptive) deterministic algorithm $\text{BndSuppRec}(x, d)$ which makes $O(d^2 \log N)$ -OR queries and (a) either asserts $\text{supp}(x) > d$, or (b) recovers the full support of x . With Linear queries, the number of queries reduces to $O(d \log N)$.*

Proof. (Sketch) We give a very high level sketch only for the sake of completeness. For the case of $d = 1$, take the $O(\lceil \log N \rceil \times N)$ matrix A where column i is the number i represented in binary. Then Ax (the “OR product”) points to the unique element in the support. To see the *existence* of a deterministic procedure for larger d , one can proceed by the probabilistic method. If one samples each coordinate with probability $1/d$, then with constant probability the vector restricted to this sample has precisely support 1 for which the above “ $d = 1$ ” algorithm can be used to recover it. Repeating this $O(d \log N)$ times leads to error probability which swamps the union bound over $\leq N^d$ possible sets, implying the existence of a deterministic scheme. Finally, another $O(d)$ arises since we need to recover all the $\leq d$ coordinates. All this can be made explicit by using ideas from error correcting codes; we point the interested reader to [32, 45] for the details. ◀

Next we move to randomized algorithms. Here ideas from F_0 -estimation [5, 27] and ℓ_0 -sampling [18, 28, 34] give the following algorithms.

► **Lemma 13.** *Let $x \in \mathbb{R}_{\geq 0}^N$ be a non-zero vector. There exists a 1-round (non-adaptive) randomized algorithm $\text{RandSuppSamp}(x)$ which makes $O(\log^2 N \log(\frac{1}{\delta}))$ -OR queries and returns a random $j \in \text{supp}(x)$ with probability $\geq 1 - \delta$.*

Proof. (Sketch) Suppose we knew the support $\text{supp}(x) = d$. Then, we sample each $j \in [N]$ with probability $1/d$ to get a subset $R \subseteq [N]$. With constant probability $\text{supp}(x \cap R) = 1$ and, conditioned on that, it contains a random $j \in \text{supp}(x)$. Therefore, running the algorithm $\text{BndSuppRec}(x \cap R, 1)$ asserted in Lemma 12, we can find a random $j \in \text{supp}(x)$ with constant probability. Repeating this $O(\log(1/\delta))$ times gives the desired error probability. Since we don’t know $\text{supp}(x)$, we run for various powers of 2 in 1 to N . ◀

► **Lemma 14.** (Theorem 7 in [13], also in [20, 26]) *Let $x \in \mathbb{R}_{\geq 0}^N$ be a non-zero vector. There exists a 1-round (non-adaptive) randomized algorithm $\text{SuppEst}(x)$ which makes $O(\log N \cdot \log(1/\delta))$ -OR-queries and returns an estimate \tilde{s} of the support which satisfies $\frac{\text{supp}(x)}{3} \leq \tilde{s} \leq 3\text{supp}(x)$ with probability $\geq 1 - \delta$.*

4 Deterministic Algorithm for Graph Connectivity

In this section, we prove the following theorem which formalizes Result 3.

► **Theorem 15.** *Let r be any fixed positive integer. There exists an $35r$ -round deterministic algorithm $\text{DetGraphConn}(G)$ which makes at most $O(n^{1+\frac{1}{r}} \log n)$ -BIS-queries per round on an undirected multigraph G , and returns a spanning forest of G .*

We start by establishing some simple subroutines which we need. We will refer to some algorithmic paradigms defined in Section 3.

4.1 Simple Subroutines

We begin by strengthening the simple algorithm BinarySearch asserted in Lemma 11. While in r -rounds with $O(N^{1/r})$ -OR queries $\text{BinarySearch}_r(x)$ recovers a single element in the support, one can in fact get many more elements from the support. This result may be of independent interest.

► **Lemma 16.** *Let $x \in \mathbb{R}_+^N$ be a non-zero, non-negative vector, and let r be a positive integer, and let $c < r$. There exists a $\lceil 2r/c \rceil$ -round deterministic algorithm $\text{DetFindMany}_{r,c}(x)$ which makes $O(N^{c/r} \log N)$ -OR queries per round, and returns $\min(N^{c/4r}, \text{supp}(x))$ distinct coordinates from $\text{supp}(x)$.*

Proof. In the first round, we partition the range $[N]$ into $N^{c/2r}$ blocks of size $N^{1-c/2r}$ each. Let these blocks be B_1, \dots, B_k with $k = N^{c/2r}$. For each $i \in [k]$, we run the algorithm $\text{BndSuppRec}(x \cap B_i, N^{c/4r})$ asserted in Lemma 12. The total number of queries used here is $O(N^{c/2r} \cdot (N^{c/4r})^2 \log N) = O(N^{c/r} \log N)$.

At the end of this round, either we recover $\text{supp}(x \cap B_i)$ for each block, and thus recover $\text{supp}(x)$, and we are done. Or, there is at least one block of size $N^{1-c/2r}$ which is guaranteed to contain $\geq N^{c/4r}$ elements in its support. We call this the heavy block of round 1. Next, we now proceed to recover $N^{c/4r}$ elements from this heavy block of round 1.

In the second round, we partition the indices of this heavy block again into $N^{c/2r}$ blocks of size $N^{1-2c/2r}$ each, and run BndSuppRec again on this block with $d = N^{c/4r}$. Once again, either we recover the entire support of the heavy block (which is guaranteed to contain at least $N^{c/4r}$ elements) and we are done. Or find a block of size $N^{1-2c/2r}$ that contains at least $N^{c/4r}$ elements in its support—this is the heavy block of round 2—and we now proceed to recover $N^{c/4r}$ elements in the heavy block of round 2.

We continue in this manner, and after $\lceil 2r/c \rceil - 1$ rounds, either we have already recovered at least $N^{c/4r}$ elements in the support of x , or have identified a heavy block of size $N^{1-(\lceil \frac{2r}{c} \rceil - 1) \cdot \frac{c}{2r}} = N^{c/2r}$ that contains at least $N^{c/4r}$ elements in the support of x . In the final round, we can simply probe each entry completing the proof. ◀

► **Remark 17.** The trade-off between the number of queries and number of elements recovered is not tightly established for the purpose of what we need in the graph connectivity algorithm. For instance, using the same idea as above, in 2 rounds one can actually recover $\min(N^{1/4}, \text{supp}(x))$ coordinates making $O(N^{3/4})$ -queries per round.

Next, we give an algorithm to find edges between two disjoint sets of vertices using BIS-queries.

► **Lemma 18.** *Let A and B be two disjoint sets of vertices with at least one edge between them. There exists a $2r$ -round deterministic algorithm $\text{DetFindEdge}_r(A, B)$ which makes $O(|A|^{1/r} + |B|^{1/r})$ -BIS queries per round, and returns an edge (a, b) with $a \in A$ and $b \in B$.*

Proof. Consider the $|B|$ dimensional vector x where x_b indicates the number of edges from a vertex $b \in B$ to vertices in A . We can simulate an OR-query in this vector using a BIS-query in the graph – for any subset $S \subseteq B$, $\text{OR}(S)$ on x has the same answer as $\text{BIS}(A, S)$. Therefore, using Lemma 11, in r -rounds and $|B|^{1/r}$ -BIS-queries, we can find a coordinate $b^* \in B$ with $x_{b^*} > 0$. That is, there is an edge between b^* and some vertex in A .

We can find one such vertex $a \in A$ to which b^* has an edge, again as above. We define the $|A|$ -dimensional vector y where y_a indicates the number of edges from b^* to a . Once again, the OR-query on y can be simulated using a BIS query on the graph – for any subset $S \subseteq A$, $\text{OR}(S)$ on y is the same as $\text{BIS}(S, \{b^*\})$. ◀

4.2 The Connectivity Algorithm

Now we give the $O(r)$ -round deterministic algorithm to find a spanning forest. First, we need the following simple claim.

▷ **Claim 19.** Let $G(V, E)$ be an arbitrary connected multigraph graph on n vertices, and let D be an arbitrary integer in $\{0, 1, \dots, (n-1)\}$. Let V_L denote all vertices in V which has at most D neighbors in G , and let $V_H = V \setminus V_L$. Let $E' \subseteq E$ be an arbitrary set of edges that satisfies the following property: for each vertex $u \in V_L$, the set E' contains all edges incident on u , and for every each vertex $v \in V_H$, the set E' contains D arbitrary edges incident on v . Then the graph $G' = (V, E')$ contains at most $\lfloor n/D \rfloor$ connected components.

Proof. Suppose G' has $K \geq \frac{n}{D}$ connected components. Thus, there must exist some component C with $\leq D$ vertices. Firstly, that C must have some vertex $v \in V_H$. If not, then since vertices in V_L have all their edges in G also in G' , this component would be disconnected in G which contradicts G 's connectedness. Secondly, observe that this leads to a contradiction: v has at least D neighbors in G' , and since there are at most $D-1$ other vertices in C , one of v 's neighbor in G' must lie outside C . This contradicts that C is a connected component. ◀

We are now ready to describe the algorithm $\text{DetGraphConn}(G)$. For simplicity, assume G is connected and our goal is to find a spanning *tree*. Subsequently, we explain how to modify the algorithm to find a spanning forest of a general graph. The algorithm proceeds in $O(\log r)$ phases starting with phase 0. The input to phase i is a partition $\Pi_i = (S_1, \dots, S_p)$ of the vertices. Each S_j in Π_i is guaranteed to be a connected in the graph G . Π_0 is the trivial partition of n singletons. Given Π_i , we define the graph $G_i = (\Pi_i, \mathcal{E}_i)$ where \mathcal{E}_i is the collection of *pseudo-edges* between components: we have a pseudo-edge $(S_a, S_b) \in \mathcal{E}_i$ if and only if there exists some edge in G between a vertex $u \in S_a$ and a vertex $v \in S_b$. Thus, G_0 is indeed the original graph. Note that by our assumption that G is connected, all the G_i 's are connected. We will be collecting pseudo-edges which will imply the connected components; we initialize this set \mathcal{F} to empty set. We will maintain the following invariant for a phase: $|\Pi_i| \leq n^{1-\frac{4^i-1}{r}}$; this is certainly true for $i = 0$. Next, we describe a phase i .

1. For each $S \in \Pi_i$, we construct a vector x indexed by all sets in $\Pi_i \setminus S$ where x_T indicates whether there is a pseudo-edge (S, T) in G_i . Next, we run the algorithm $\text{DetFindMany}_{r,c}(x)$ asserted in Lemma 16 to either find all pseudo-edges incident on S , or at least $n^{4^i/4r}$ of them. To do so, we set c such that $N^{c/4r} = n^{4^i/4r}$, where N is the dimension of x . That is, $N = |\Pi_i| - 1$. Indeed, we should set $c = \theta \cdot 4^i$ where $N^\theta = n$. Note, $\theta \geq 1$. Also note that the OR-queries on x can be simulated using BIS-queries on the original graph G . This is because we are looking at edges between S and a union of a subset of parts in $\Pi_i \setminus S$.

The number of rounds is $\lceil \frac{2r}{c} \rceil \leq \lceil \frac{2r}{4^i} \rceil$. The number of BIS-queries per round is $O(N^{c/r} \log N) = O(n^{4^i/r} \log n)$ per subset $S \in \Pi_i$. And thus, the total number of queries made is $N \cdot O(n^{4^i/r} \log n) \leq |\Pi_i| \cdot O(n^{4^i/r} \log n) \leq n^{1-\frac{4^i-1}{r}} \cdot O(n^{4^i/r} \log n) = O(n^{1+1/r} \cdot \log n)$.

2. Let $\mathcal{E}'_i \subseteq \mathcal{E}_i$ be the pseudo-edges obtained from the previous step. Let \mathcal{F}'_i be an arbitrary spanning forest of \mathcal{E}'_i . We add all these edges to the collection \mathcal{F} . Note, \mathcal{F}'_i is a collection of $\leq |\Pi_i|$ pseudo-edges.
3. Applying Claim 19 to the graph G_i , adding the pseudo edges in \mathcal{E}'_i reduces the number of connected components to at most $|\Pi_i|/n^{\frac{4^i}{4r}}$. We now repeat the above two steps 11 more times *sequentially*, and each time the number of connected components multiplicatively drops by $n^{\frac{4^i}{4r}}$. Thus, after the 12 sub-phases we end up with the partition Π_{i+1} of connected components, with $|\Pi_{i+1}| \leq |\Pi_i|/n^{\frac{12 \cdot 4^i}{4r}} \leq n^{1-\frac{4^i-1}{r}} \cdot n^{-\frac{12 \cdot 4^i}{4r}} = n^{1-\frac{4^{i+1}-1}{r}}$, as desired. The second inequality follows from the invariant before phase $(i+1)$ started.

To summarize, Phase i performs $O(\frac{r}{4^i})$ -rounds and makes $O(n^{1+1/r} \log n)$ -BIS queries per round. We run phase 0 to $L = O(\log r)$, till we get $|\Pi_L| \leq \sqrt{n}$. After that we run a clean up phase.

4. *Clean-up Phase.* Once $|\Pi_L| = O(\sqrt{n})$, for each pair (S, T) in $\Pi_L \times \Pi_L$, we make a single BIS-query to detect if the pseudo-edge $(S, T) \in \mathcal{E}_L$. The total number of queries is $O(n)$. We add an arbitrary spanning tree of \mathcal{E}_L to the set \mathcal{F} . At this point, \mathcal{F} lets us know the structure of connectivity via pseudo-edges. The next step is to recover the actual graph edges.
5. *Tree Building Phase.* Note that the total number of pseudo-edges in \mathcal{F} is $< n - 1$. For each $(S, T) \in \mathcal{F}$, we now desire to find an edge (s, t) in the graph where $s \in S$ and $t \in T$. Note that once we do this, we have the spanning tree the graph. This can be done in $2r$ more rounds using the algorithm $\text{DetFindEdge}_r(S, T)$ using $O(|S|^{1/r} + |T|^{1/r})$ -BIS queries per round. Therefore, the total number of queries per round of this phase is $O(n) \cdot O(n^{1/r}) = O(n^{1+1/r})$.

The number of rounds is $\sum_{i=1}^{O(\log r)} \frac{24r}{4^i} + 1 + 2r \leq 35r$.

This ends the description of the algorithm when G is connected. If G had more than one connected component, then one can recognize the connected components as the algorithm progresses. More precisely, if the algorithm is processing the partition $\Pi_i = (S_1, \dots, S_p)$ and find that S_i has no edges coming out of it, then by the invariant that S_i is connected, the algorithm can discard this component and proceed on the remaining graph as if it were connected. The analysis becomes better as the effective number of vertices decrease but the number of available queries don't. This completes the proof of Theorem 15.

Fully Dynamic Set Cover via Hypergraph Maximal Matching: An Optimal Approximation Through a Local Approach

Sepehr Assadi 

Rutgers University, New Brunswick, NJ, USA

Shay Solomon 

Tel Aviv University, Israel

Abstract

In the (fully) dynamic set cover problem, we have a collection of m sets from a universe of size n that undergo element insertions and deletions; the goal is to maintain an approximate set cover of the universe after each update. We give an $O(f^2)$ update time algorithm for this problem that achieves an f -approximation, where f is the maximum number of sets that an element belongs to; under the unique games conjecture, this approximation is best possible for any fixed f . This is the first algorithm for dynamic set cover with approximation ratio that *exactly* matches f (as opposed to *almost* f in prior work), as well as the first one with runtime *independent of* n, m (for any approximation factor of $o(f^3)$).

Prior to our work, the state-of-the-art algorithms for this problem were $O(f^2)$ update time algorithms of Gupta et al. [STOC'17] and Bhattacharya et al. [IPCO'17] with $O(f^3)$ approximation, and the recent algorithm of Bhattacharya et al. [FOCS'19] with $O(f \cdot \log n / \varepsilon^2)$ update time and $(1 + \varepsilon) \cdot f$ approximation, improving the $O(f^2 \cdot \log n / \varepsilon^5)$ bound of Abboud et al. [STOC'19].

The key technical ingredient of our work is an algorithm for maintaining a *maximal* matching in a dynamic hypergraph of rank r – where each hyperedge has at most r vertices – that undergoes hyperedge insertions and deletions in $O(r^2)$ amortized update time; our algorithm is randomized, and the bound on the update time holds in expectation and with high probability. This result generalizes the maximal matching algorithm of Solomon [FOCS'16] with constant update time in ordinary graphs to hypergraphs, and is of independent merit; the previous state-of-the-art algorithms for set cover do not translate to (integral) matchings for hypergraphs, let alone a maximal one. Our quantitative result for the set cover problem is translated directly from this qualitative result for maximal matching using standard reductions.

An important advantage of our approach over the previous ones for approximation $(1 + \varepsilon) \cdot f$ (by Abboud et al. [STOC'19] and Bhattacharya et al. [FOCS'19]) is that it is inherently *local* and can thus be distributed efficiently to achieve low amortized round and message complexities.

1 Introduction

In the set cover problem, we are given a family $\mathcal{S} = (S_1, \dots, S_m)$ of m sets on a universe $[n]$. The goal is to find a minimum-size subfamily of sets $\mathcal{F} \subseteq \mathcal{S}$ such that \mathcal{F} covers all the elements of $[n]$. Throughout the paper, we use f to denote the maximum frequency of any element $i \in [n]$ inside the sets in \mathcal{S} (by frequency of element i , we mean the number of sets in \mathcal{S} that contain i).

The set cover problem is one of the most fundamental and well-studied NP-hard problems, with two classic approximation algorithms, both with runtime $O(fn)$: greedy $\ln n$ -approximation and primal-dual f -approximation. One cannot achieve approximation $(1 - \varepsilon) \ln n$ unless $P = NP$ [26, 17] or approximation $f - \varepsilon$ for any fixed f under the unique games conjecture [20].

In recent years there is a growing body of work on this problem in the dynamic setting, where one would like to efficiently maintain a set cover for a universe that is subject to element insertions and deletions. The holy grail is to coincide with the bounds of the static setting: approximation factor of either $\ln n$ or f with (amortized) update time $O(f)$ (as a static runtime of $\Theta(fn)$ means that we spend $\Theta(f)$ time per each element of the universe on average). Indeed, in any dynamic model where element updates are explicit, update time $\Omega(f)$ is inevitable. Even in stronger models where updates are supported implicitly in constant time, recent SETH-based conditional lower bounds imply that update time $O(f^{1-\varepsilon})$ requires polynomial approximation factor [1].

The dynamic set cover problem was first studied by Gupta et al. [18] who gave an $O(\log n)$ -approximation with update time $O(f \log n)$ based on a greedy algorithm. The rest of the known algorithms are primal-dual-based and their approximation factor depends only on f . The state-of-the-art algorithms are: (1) An $O(f^3)$ -approximation with $O(f^2)$ update time, by Gupta et al. [18] and independently by Bhattacharya et al. [9], and (2) A $(1 + \varepsilon) \cdot f$ -approximation with update time $O(f \cdot \log n / \varepsilon^2)$ by Bhattacharya et al. [11], improving the $O(f^2 \cdot \log n / \varepsilon^5)$ bound of Abboud et al. [1] as well as an earlier result by Bhattacharya et al. [10]. Interestingly, the state-of-the-art algorithms for this problem are all *deterministic* (the algorithm of [1] is randomized however).

Our Result

In this work we demonstrate the power of randomization for the dynamic set cover problem by achieving the best possible approximation of f with runtime independent of both m, n :

► **Theorem (Informal).** *There is an algorithm for the dynamic set cover problem that achieves an exact f -approximation in $O(f^2)$ expected (and with high probability) amortized update time.*

This gives the first algorithm for dynamic set cover with approximation ratio that *exactly* matches f (as opposed to *almost* f in prior work), as well as the first one with runtime *independent of n, m* (for any approximation factor of $o(f^3)$). The bound $O(f^2)$ on the update time of our algorithm holds with high probability and in expectation. As in [1] and in the great majority of randomized dynamic graph algorithms, we assume an oblivious adversary. We shall remark that even for the much simpler problem of dynamic vertex cover (corresponding to $f = 2$ case), no algorithm is known against an adaptive adversary that achieves an exact 2-approximation in time independent of other input parameters (although $(2 + \varepsilon)$ -approximation algorithms have been known for some time now [13, 9, 6, 8]).

Maximal Hypergraph Matching

The key technical ingredient of our work is an algorithm for maintaining a *maximal* matching in a dynamic hypergraph of rank r – where each hyperedge has at most r vertices – that undergoes hyperedge insertions and deletions in $O(r^2)$ amortized update time. This result generalizes the maximal matching algorithm of Solomon [25] with constant update time for ordinary graphs, and is of independent merit; the previous state-of-the-art algorithms for set cover do not translate to (integral) matchings for hypergraphs, let alone a maximal one (however the algorithm of [1] translates to an integral (non-maximal) matching). The result for set cover follows immediately from this: taking all the matched vertices in a maximal hypergraph matching of rank f yields an f -approximate hypergraph vertex cover, or equivalently, an f -approximate set cover; (see Section 2 for details of this standard reduction).

We stress that there is an inherent difference between a maximal matching (yielding exactly f -approximation) and an almost-maximal matching (yielding $(1 + \varepsilon) \cdot f$ -approximation), wherein an ε -fraction of the potentially matched vertices may be unmatched; this is true in general but particularly important in the dynamic setting. Despite extensive work on dynamic algorithms for matching and vertex cover in ordinary graphs ($f = 2$), the state-of-the-art deterministic algorithm (or even randomized against adaptive adversary) for 2-approximate matching and vertex cover (via a maximal matching) has update time $O(\sqrt{|E|})$ [21], while $(2 + \varepsilon)$ -approximate matching and vertex cover can be maintained deterministically in poly-log update time [6, 7]; for approximate vertex cover and *fractional* matching, the update time can be further reduced to $O(1/\varepsilon^2)$ [13]. Therefore, it is only natural that our algorithm, which achieves an integral maximal hypergraph matching, is randomized and assumes an oblivious adversary.

Distributed networks

There is a growing body of work on distributed networks that change dynamically (cf. [22, 24, 15, 3, 19, 14, 2]). A distributed network can be modeled as an undirected (hyper)graph $G(V, E)$, where each vertex $v \in V$ is identified with a unique processor and the edge set E corresponds to direct communication links between the processors. In a static distributed setting all processors wake up simultaneously, and computation proceeds in fault-free synchronous rounds during which every processor exchanges messages of size $O(\log n)$ with its neighbors. We consider the standard *CONGEST* model (cf. [23]), which captures the essence of spatial locality and congestion. For hypergraphs, the messages should be of size $O(\log m)$, where m is the number of edges in the graph.

We focus on the standard setting in dynamic graph algorithms – dynamically changing networks that undergo edge updates (both insertions and deletions, a single edge update per step), which initially contain no edges. But in a *distributed* network we are subject to the following *local* constraint: After each edge update, only the affected vertices – the endpoints of the updated edge – are woken up; this is referred to in previous work as the (*CONGEST*) *local wakeup model*. Those affected vertices initiate an update procedure, which also involves waking up the vertices in the network (beyond the affected ones) that are required to participate in the update procedure, to adjust all outputs to agree on a valid global solution – in our case a maximal hypergraph matching; the output of each vertex is the set of its incident edges that belong to the matching. We make a standard assumption that the edge updates occur in large enough time gaps, and hence the network is always “stable” before the next change occurs (see, e.g., [22, 15, 3]). In this setting, the goal is to optimize (1) the number of communication rounds, and (2) the number of messages, needed for repairing the solution per edge update, over a worst-case sequence of edge updates.

Our dynamic maximal hypergraph matching algorithm can be naturally adapted to *distributed networks*. Note that following an edge update, $O(1)$ communication rounds trivially suffice for updating a maximal hypergraph matching. However, the number of messages sent per update via this naive algorithm may be a factor of r^2 greater than the maximum degree in the hypergraph, which could be $\Omega(\binom{n}{r-1})$, where n is the number of vertices and r is the rank. An important objective is to design a dynamic distributed algorithm that achieves, in addition to low round complexity, a low *message complexity*. The inclusion-maximality of our maintained matching enforces our algorithm to work persistently so there is never any “slack”; that is, the algorithm makes sure that every edge that can be added to the matching is added to it, which stands in contrast to “lazy” approximate-maximal matching (or approximate set cover) algorithms, which may wait to accumulate an ε -factor additive slack in size or weight, and only then run an update procedure. However, such a lazy update procedure is inherently non-local, where, following an edge update e , the required changes to the maintained graph structure may involve edges and vertices that are arbitrarily far from e ; indeed, this is the case with the previous algorithms that achieve approximation factor close to f [11, 1]; moreover, the “lazy” feature of these algorithms must rely on a centralized agent that orchestrates the update algorithm with the use of global data structures, and this is, in fact, the key behind the efficiency of these algorithms [11, 1]. Our algorithm, on the other hand, does not employ any global update procedure or global data structures, and as such it is inherently *local* and can be easily distributed, so that the average number of messages sent per update is $O(r^2)$, matching the sequential update time. The number of rounds is clearly upper bounded by the number of messages. Refer to Section 9 in the full version [4] for more details.

Recent related work

Independently and concurrently to our work, Bhattacharya, Henzinger, Nanongkai, and Wu [arXiv’20, SODA’21] obtained an algorithm for dynamic set cover with $O(f^2/\varepsilon^3)$ amortized update time and $O(f \cdot \log^2 n/\varepsilon^3)$ worst case update time and $(1 + \varepsilon) \cdot f$ approximation. While closely related, their results and ours are incomparable. Our algorithm can achieve a better approximation ratio of *exactly* f as opposed to $(1 + \varepsilon)f$ (which is the first dynamic algorithm with this guarantee) but is randomized, while their result is deterministic and can work for weighted set cover (with extra $\log C$ -dependence on the update time where C is the maximum weight of any set). Also, as mentioned, our algorithm is inherently local and can be distributed efficiently, whereas the algorithm of Bhattacharya et al., as the previous aforementioned algorithms, is non-local. In terms of techniques, the two works are disjoint.

1.1 Technical overview

At a high level, all the previous state-of-the-art algorithms [18, 9, 11] (as well as the independent work of [12]) follow a deterministic primal-dual approach by maintaining a fractional packing solution as a dual certificate. The main advantage of this approach over ours, of course, is in being deterministic, and its drawbacks are that (1) the approximation factor is almost f rather than exactly f , (2) it does not give rise to an *integral* matching in the context of hypergraphs, and (3) it is non-local.

Our algorithm generalizes and strengthens the maximal matching algorithm by Solomon [25], which, in turn, builds on and refines the pioneering approach of Baswana et al. [5]. For conciseness, we shall sometimes refer only to [25] in the following (to avoid explaining the differences between [25] and [5]); of course, by that we do not mean to take any credit of [5], on which [25] relies.

Maximal matching algorithm of [5, 25]. Consider a deletion of a matched edge (u, v) from the graph (for $r = 2$), which is the only nontrivial update. Focusing on u , if u has an unmatched neighbor, we need to match u . To avoid a naive scan of the neighbors of u (requiring $O(n)$ time), the key idea is to match u with a randomly sampled (possibly matched) neighbor w . Under the oblivious adversarial model, the expected number of edges incident on u deleted from the graph before the deletion of edge (u, w) is roughly half the “sample space” size of u , i.e., the number of neighbors of u from which we sampled w , which can be viewed as “time token” (or potential value) that is expected to arrive in the future.

To benefit from these tokens, [5, 25] introduces a *leveling scheme* where the *levels* of vertices are exponentially smaller estimates of these potential values: Unmatched vertices have level -1 and matched vertices are assigned the levels of their matched edge, which is roughly the logarithm of the sample space size. This defines a dynamic hierarchical partition of *vertices* into $O(\log n)$ levels.

A key ingredient in the algorithm of [5, 25] is the *sampling rule*: A random mate w is chosen for a vertex u among its neighbors of strictly lower level. Intuitively, if w ’s level is lower than u ’s, then w ’s potential value is much smaller than u ’s, and the newly created matched edge (u, w) provides enough potential value to cover the cost of deleting the old matched edge on w (if any).

Difficulties of going from ordinary graphs to hypergraphs. The main difficulty of extending the prior work in [5, 25] to hypergraphs of rank $r > 2$ has to do with the “vertex-centric” approach taken by these works [5, 25]. For instance, even at the definition level, it is already unclear how to generalize the sampling rule of the algorithm for hypergraphs, even for $r = 3$, since the hyperedges incident on u may consist of endpoints of various levels, some smaller than that of u , some higher. Ideally we would want to sample the matched hyperedge among those where *all* endpoints have lower level than that of u , but it is a-priori unclear how to maintain this hyperedge set efficiently. In particular, to perform the sampling rule efficiently, the strategy of [25] is to dynamically orient each edge towards the lower level endpoint, and a central obstacle is to efficiently cope with edges where both endpoints are at the same level. For hypergraphs, naturally, these obstacles become more intricate considering there are r different endpoints now.

There are also other hurdles that need to be carefully dealt with, such as the following. Say a matched hyperedge $e = (u_1, \dots, u_r)$ gets deleted from the hypergraph. When $r = 2$, any edge incident on u_1 is different than any edge incident on u_2 , hence informally the update algorithm can handle u_1 and u_2 *independently* of each other. When $r > 2$ (even for $r = 3$), different endpoints of e may share (many) hyperedges in common. Therefore, when choosing random matched hyperedges for the newly unmatched endpoints of e , we need to (i) be careful not to create conflicting matched hyperedges, but at the same time (ii) keep the sample spaces of endpoints sufficiently large so that the potential values can cover the runtime of the update procedure; balancing between these two contradictory requirements is a key challenge in our algorithm.

An $O(r^3)$ update time algorithm. We manage to cope with these and other hurdles by instead switching to a “hyperedge-centric” view of the algorithm. Informally speaking, this means that instead of letting vertices derive the potential values and levels, we assign these values to the hyperedges and use those to define the corresponding level for remaining vertices. Under this new view of the algorithm, we can indeed generalize the approach of [25] to obtain an $O(r^4)$ -update time algorithm for rank r hypergraphs. Considering the intricacies in [25], already achieving this $O(r^4)$ time bound turned out to be considerably challenging.

Improving the update time to $O(r^3)$ is based on the following insight. In this hyperedge-centric view, a level- ℓ matched hyperedge e is sampled to the matching from a sample space $S(e)$ of size roughly α^ℓ , where $\alpha = \Theta(r)$. We refer to the hyperedges in $S(e)$ as the *core hyperedges* of e . All the core hyperedges of e are then also assigned a level ℓ . Let us focus on an $e' = (u_1, \dots, u_r) \in S(e)$. Subsequently, u_1 may initiate the creation of a new matched hyperedge at level $\ell' > \ell$, at which stage we randomly sample a new matched hyperedge, denoted by e_1 , among all its incident hyperedges of level lower than ℓ' , so $e' \in S(e_1)$, i.e., hyperedge e' is now a core hyperedge of e_1 as well. Perhaps later u_2 may initiate the creation of a new matched hyperedge e_2 at level $\ell'' > \ell'$, and then hyperedge e' will become a core hyperedge of e_2 , and so on and so forth. Thus any hyperedge may serve as a core hyperedge of up to r matched hyperedges at any point in time.

To shave a factor of r from the runtime, we need to make sure that each hyperedge serves as a core hyperedge of a *single* matched hyperedge. This is achieved by “freezing” (or *temporarily* deleting) all core hyperedges of a newly created matched hyperedge e ; in the sequel (see Section 3.2) we shall refer to these hyperedges as *temporarily deleted hyperedges* (due to e) rather than “core hyperedges”, and they will comprise the set $\mathcal{D}(e)$. Then, whenever the matched hyperedge gets deleted from the matching, we need to “unfreeze” these core hyperedges and update all their *ignored* data structures – our analysis shows that this can be carried out efficiently.

Since this algorithm already requires an entirely new view of the previous approaches for ordinary graphs and several nontrivial ideas, we present it as a standalone result in Section 3.

An $O(r^2)$ update time algorithm. The main step is to improve the update time from $O(r^3)$ to $O(r^2)$. We next provide a couple of technical highlights behind this improvement.

In our algorithm, the potential values of level- ℓ matched hyperedges are in the range $[\alpha^\ell, \alpha^{\ell+1})$, for $\alpha = O(r)$, hence they may differ by a factor of $O(r)$. Consider the moment a level- ℓ matched hyperedge $e = (u_1, \dots, u_r)$ gets deleted by the adversary; the leveling scheme allows us to assume we have an $O(\alpha^{\ell+2})$ “potential time” for handling this hyperedge. To get an update time of $O(r^2)$, we need to handle each of the endpoints $u_i \in e$ within time $O(\alpha^{\ell+1})$ time or instead “contribute” to the potential by creating a new matched hyperedge. If u_i has more than $\alpha^{\ell+1}$ incident hyperedges of level at most ℓ , we can sample a random hyperedge among them to be added to the matching, thereby creating a level- $(\ell+1)$ matched hyperedge; we discuss some issues related to the creation of matched edges later. But if u_i has slightly less than $\alpha^{\ell+1}$ incident edges, this sample space size suffices only for creating a level- ℓ matched edge, but it is crucial that the sample space of a level- ℓ matched edge would consist only of edges where all endpoints have level strictly lower than ℓ . Even checking whether this is the case is too costly, since iterating over all endpoints of all such edges takes time (slightly less than) $O(\alpha^{\ell+2})$, and if we are in the same scenario for each u_i this gives rise to a runtime of $O(\alpha^{\ell+3})$, and thus to an amortized update time of $O(r^3)$. Even if we could check this for free, if most of the edges have endpoints of level ℓ , we need to find those endpoints, and to pass the “ownership” of the edges to those endpoints. To cope with these issues, we maintain a data structure for each hyperedge e that keeps track of all its endpoints of highest level and in $O(1)$ time returns an arbitrary such endpoint or reports that none exists. Of course, now the challenge becomes maintaining these data structures for the edges with $O(r^2)$ update time.

Consider the moment that a level- ℓ matched edge e is created. At this stage, another crucial invariant tells us to “raise” all endpoints of edge e to level ℓ , and then to update the ownership set of each endpoint according to its up-to-date level. One challenging case is when

each endpoint u_i of e now owns slightly less than $\alpha^{\ell+1}$ new edges. This sample space size does not suffice for creating a level- $(\ell + 1)$ matched edge yet it is too costly to update each of the endpoints of these edges about the up-to-date level of u_i ; summing over all endpoints of e , this again gives rise to update time of $O(r^3)$. However, if we are equipped with the aforementioned data structure, we can efficiently focus on the edges where all endpoints have level lower than ℓ , and can thus create a level- ℓ matched edge. This is not enough, however, since we are merely replacing one level- ℓ matched edge by another, and this process could repeat over and over. Our goal would be to replace one level- ℓ matched edge by *at least two others*, so as to provide enough increase in “potential” to cover for this runtime. Since the total number of edges incident on e in this case is slightly less than $\alpha^{\ell+2}$, the intuition is that we should be able to easily achieve here a fan-out of 2, and therefore a valid charging argument. Alas, there is one significant caveat when working with hypergraphs, which we already mentioned above – dependencies. It is possible that the first level- ℓ matched edge that we randomly sampled for u_1 intersects all the edges incident on e , which will result in fan-out 1. To overcome this final obstacle, we take our hyperedge-centric view to the next level by employing a new sampling method different than [5, 25] altogether. In particular, in this case, our sample space is not necessarily restricted to hyperedges incident on a single vertex, but could be an arbitrary hyperedge set as a function of the deleted hyperedge; however, importantly, to achieve a *local* sampling method, we will make sure that the entire sample space is incident to the endpoints of a single edge. This new sampling method (see Procedure `insert-hyperedge` in Section 5 of the full version [4]) entails a few technical complications primarily to ensure that we still get enough “potential” from the adversary, but it ultimately enables us to achieve the desired update time bound of $O(r^2)$.

The role of randomness in our algorithm. Our algorithm relies crucially on randomization and on the oblivious adversary assumption, and the probabilistic analysis employed in this work is highly nontrivial; in particular, the usage of randomization for reducing the update time bound from $O(r^3)$ to $O(r^2)$ relies on several new insights. We note that if the entire update sequence is known in advance and is stored in a data structure that allows for fast access, which is sometimes referred to as the “(dynamic) offline setting” (cf. [16]) – then a straightforward variant of our algorithm works *deterministically* with $O(r^2)$ amortized update time. Specifically, whenever a matched edge is randomly sampled by our algorithm (which is always done uniformly) from a carefully chosen sample space of edges – in the offline setting, instead of randomly sampling the matched edge, one can choose the matched edge *deterministically* to be the one that will be deleted last among all edges in the sample space. It is not difficult to verify that this simple tweak translates our probabilistic $O(r^2)$ amortized update time bound into a deterministic $O(r^2)$ time bound, while avoiding the entire probabilistic analysis. The probabilistic ingredients of the analysis are omitted due to space constraints; they appear in Sections 7 and 8 of the full version [4].

2 Preliminaries and Organization

Hypergraph Notation. For a hypergraph $G = (V, E)$, V denotes the set of vertices and E denotes the set of hyperedges. We use $v \in e$ to mean that v is one of the vertices incident on hyperedge e . Rank r of a hypergraph is the maximum number of vertices incident on any edge, i.e., $r := \max \{|e| \mid e \in E\}$. A matching M in G is a collection of vertex-disjoint hyperedges of M . A matching M is called *maximal* if no other edge of G can be added to M without violating its matching constraint. A vertex cover U in G is a collection of vertices so that every hyperedge in E has at least one endpoint in U . We use the next standard fact.

► **Fact 1.** *Let G be any hypergraph with rank r . Suppose M is a maximal matching in G and U denotes all vertices incident on M . Then U is an r -approximate vertex cover of G .*

Hypergraph Formulation of Set Cover. Consider a family $\mathcal{S} = \{S_1, \dots, S_m\}$ of sets over a universe $[n]$. We can represent \mathcal{S} by a hypergraph G on m vertices corresponding to sets of \mathcal{S} and n hyperedges corresponding to elements of $[n]$: Any element $i \in [n]$ is now a hyperedge between vertices corresponding to sets in \mathcal{S} that contain i . It is easy to see that there is a one-to-one correspondence between set covers of \mathcal{S} and vertex covers of G and that the rank r of G is the same as the maximum frequency parameter f in the set cover instance. With this transformation, by Fact 1, obtaining an f -approximation to this instance of set cover reduces to obtaining a maximal matching of G . This is the direction we take in this paper for designing fully dynamic algorithms for set cover by designing a fully dynamic algorithm for hypergraph maximal matching.

Organization. Due to space constraints, in this extended abstract we focus on the $O(r^3)$ update time algorithm and its analysis, where we provide only part of the analysis. The $O(r^2)$ update time algorithm and its analysis are inherently more involved and are entirely omitted. All the missing details appear in the full version [4].

3 An $O(r^3)$ -Update Time Algorithm

Throughout, we use M to denote the maximal matching of the underlying hypergraph $G = (V, E)$ maintained by the algorithm. We use the following parameters in our algorithm:

$$\alpha := (4 \cdot r), \quad L := \lceil \log_\alpha |N| \rceil \quad (1)$$

where N approximates the dynamic number of edges $|E|$ plus the fixed number of vertices $|V|$ from above, so that $\log_\alpha |N| = \Theta(\log_\alpha (|V| + |E|))$. Every $\Omega(N)$ steps we update the value of N , and as a result rebuild all the data structures; this adds a runtime of $O(|V| + |E|) = O(N)$ every $\Omega(N)$ update steps, hence a negligible overhead to the amortized cost of the algorithm. We may henceforth ignore this technical subtlety and treat N as a fixed value in what follows.

3.1 A Leveling Scheme and Hyperedge Ownerships

We use a leveling scheme for the input hypergraph that partitions hyperedges and vertices. This is done by assigning a *level* $\ell(e)$ to each hyperedge $e \in E$ and a *level* $\ell(v)$ to each vertex $v \in V$.

► **Invariant 2.** *Our leveling scheme satisfies the following properties:*

1. *For any hyperedge $e \in E$, $0 \leq \ell(e) \leq L$ and for any vertex $v \in V$, $-1 \leq \ell(v) \leq L$; moreover, $\ell(v) = -1$ iff v is **unmatched** by M .*
2. *For any **matched** hyperedge $e \in M$ and any incident vertex $v \in e$, $\ell(v) = \ell(e)$.*
3. *For any **unmatched** hyperedge $e \notin M$, $\ell(e) = \max_{v \in e} \ell(v)$.*

Our leveling scheme needs only to specify $\ell(e)$ for each $e \in M$; the rest are fixed deterministically by Invariant 2. Moreover, this invariant ensures that the matching M obtained by the algorithm is maximal as all unmatched vertices are at level -1 while the level of any hyperedge is at least 0 and at the same time equal to the maximum level of any of its incident vertices. Based on the leveling scheme, we assign each hyperedge e to exactly one of its incident vertices $v \in e$ with $\ell(v) = \ell(e)$ to *own* (the ties between multiple vertices at the same level are broken by the algorithm). We use $\mathcal{O}(v)$ to denote the set of edges owned by v . This definition, combined with Invariant 2, implies the following invariant.

► **Invariant 3.** (i) For any vertex $v \in V$, any owned hyperedge $e \in \mathcal{O}(v)$, and any other incident vertex $u \in e$, $\ell(u) \leq \ell(v)$. (ii) For any vertex $v \in V$, any incident hyperedge $e \in v$ has $\ell(e) \geq \ell(v)$.

3.2 Temporarily Deleted Hyperedges

To obtain the desired update time of $O(r^3)$, we would need to allow some hyperedges of the hypergraph to be considered *temporarily deleted* and no longer participate in any of the other data structures; moreover, whenever we no longer consider them deleted, we simply treat them as a hyperedge insertion to our hypergraph and handle them similarly (which will take $O(r)$ time per each hyperedge exactly as in the previous algorithm). The role of these deleted hyperedges becomes apparent only in the probabilistic analysis that is omitted due to space constraints; see Section 7 in the full version [4] for this analysis. However, it is the goal of the algorithm itself (rather than the analysis) to cope efficiently with the required deletions. We shall note that these deletions constitute one of several differences of our algorithm with that of [25]. The next invariant allows us to maintain the maximality of our matching.

► **Invariant 4.** Any *temporarily deleted* hyperedge is incident on some **matched** hyperedge.

To maintain Invariant 4, each matched hyperedge $e \in M$ is *responsible* for a set of deleted edges denoted by $\mathcal{D}(e)$ and stored in a linked-list data structure. This set will be *finalized* at the time e joins the matching M and will remain unchanged throughout the algorithm until e is removed from M ; at that point, we simply bring back all hyperedges in $\mathcal{D}(e)$ to the graph as new hyperedge insertions. Invariant 4 is crucial for the correctness of our algorithm.

We note that besides this data structure $\mathcal{D}(e)$, these deleted hyperedges *do not appear* in any other data structure of the algorithm and do not (necessarily) satisfy any of the invariants in the algorithm – they are simply treated as if they do not belong to the hypergraph. Invariant 4 ensures that even though we are ignoring temporarily deleted hyperedges in the algorithm, the resulting maximal matching on the hypergraph of undeleted hyperedges is still a maximal matching for the entire hypergraph. As such, throughout the rest of the paper, with a slight abuse of notation, whenever we talk about hyperedges of G , we refer to the hyperedges that are not temporarily deleted (unless explicitly stated otherwise).

3.3 Data Structures

We maintain the following information for each vertex $v \in V$ (again, to emphasize, we ignore the temporarily deleted hyperedges in all the following data structures):

- $\ell(v)$: the level of v in the leveling scheme;
- $M(v)$: the hyperedge in M incident on v (if v is unmatched $M(v) = \perp$);
- $\mathcal{O}(v)$: the set of hyperedges e owned by v – we define $o_v := |\mathcal{O}(v)|$;
- $\mathcal{N}(v)$: the set of hyperedges e incident on v ;
- $\mathcal{A}(v, \ell)$ for any integer $\ell \geq \ell(v)$: the set of hyperedges $e \in \mathcal{N}(v)$ that are *not* owned by v and have level $\ell(e) = \ell$ – we define $a_{v, \ell} := |\mathcal{A}(v, \ell)|$.

We also maintain the following information for each hyperedge $e \in E$:

- $\ell(e)$: the level of e in the leveling scheme;
- $O(e)$: the single vertex $v \in e$ that owns e , i.e., $e \in \mathcal{O}(v)$;
- $M(e)$: a Boolean variable to indicate whether or not e is matched.

We also maintain back-and-forth pointers between these different data structures that refer to the same hyperedge or vertex in a straightforward way.

8:10 Fully Dynamic Set Cover via Hypergraph Maximal Matching

Next, we introduce the main procedures used for updating these data structures. In these procedures, if there is room for confusion, we use superscript $^{\text{old}}$ to denote a parameter or data structure $*$ before the update and $^{\text{new}}$ to denote the value of $*$ after the update.

Procedure $\text{set-owner}(e, v)$. Given a hyperedge e and vertex $v \in e$ where $\ell(v) = \max_{u \in e} \ell(u)$, sets owner of e to be v , i.e., $O(e) = v$.

To implement $\text{set-owner}(e, v)$, we first set $O^{\text{new}}(e) = v$ and $\ell^{\text{new}}(e) = \ell(v)$, add e to $\mathcal{O}(v)$, and remove e from $\mathcal{O}(O^{\text{old}}(e))$. If $\ell^{\text{new}}(e) = \ell^{\text{old}}(e)$, there is nothing else to do. Otherwise, for any $w \neq v \in e$, we remove e from $\mathcal{A}(w, \ell^{\text{old}}(e))$ and instead insert e in $\mathcal{A}(w, \ell^{\text{new}}(e))$.

▷ **Claim 5 (straightforward proof).** $\text{set-owner}(e, v)$ takes $O(r)$ time.

Procedure $\text{set-level}(v, \ell)$. Given a vertex $v \in V$ and integer $\ell \in \{-1, 0, \dots, L\}$, updates the level of v to ℓ , i.e., sets $\ell(v) = \ell$.

The implementation of $\text{set-level}(v, \ell)$ is as follows. First, we determine the ownership of all hyperedges $e \in \mathcal{O}^{\text{old}}(v)$ that were previously owned by v . We go over each hyperedge $e \in \mathcal{O}^{\text{old}}(v)$ one by one, find $u := \arg \max_{w \in e} \ell(w)$ (where we use $\ell^{\text{new}}(v) = \ell$ for the computations here), and use the procedure $\text{set-owner}(e, u)$ to update the owner of e to u .

If $\ell^{\text{old}}(v) > \ell$, nothing is left to do as no new hyperedge needs to be owned by v now that level of v has decreased (Invariant 3). If $\ell^{\text{old}}(v) < \ell$, we should make v the new owner of all hyperedges $e \in \mathcal{N}(v)$ with level between $\ell^{\text{old}}(v)$ to $\ell - 1$. This is done by traversing the lists maintained in $\mathcal{A}(v, \ell^{\text{old}}(v)), \dots, \mathcal{A}(v, \ell - 1)$, and running $\text{set-owner}(e, v)$ for each edge e in these lists.

Remark. It will be the responsibility of the procedure calling set-level to make sure that the invariants (and particularly Invariant 2) continue to hold.

▷ **Claim 6.** $\text{set-level}(v, \ell)$ takes $O(r \cdot (o_v^{\text{old}} + o_v^{\text{new}}) + \ell + 1)$ time.

Proof. The algorithm iterates over all hyperedges in $\mathcal{O}^{\text{old}}(v)$ and use set-owner that takes $O(r)$ time by Claim 5 for each one. When $\ell^{\text{old}}(v) > \ell$, this is all that is done by the algorithm and the bound on runtime follows. Otherwise, the algorithm also needs to iterate over the lists $\mathcal{A}(v, \ell^{\text{old}}(v)), \dots, \mathcal{A}(v, \ell - 1)$ one by one which takes $O(\ell)$ time and run set-owner for each of them that takes $O(r \cdot o_v^{\text{new}})$ time in total. This gives the bound on runtime. ◁

3.4 The Update Algorithm

There are multiple cases to handle by the update algorithm depending on whether the updated hyperedge is an insertion or deletion, and whether or not it belongs to the maximal matching M . But the only interesting case is when a hyperedge in M is deleted and that is where we start with.

3.4.1 Case 1: a hyperedge $e \in M$ is deleted

There are two things we should take care of upon deletion of a hyperedge e from M ; bringing back the temporarily deleted hyperedges in $\mathcal{D}(e)$ to maintain Invariant 4, and more importantly, updating the matching M to ensure its maximality. All the interesting part of the algorithm happen in the second step, but before we get to that, let us quickly mention how the first part is done.

Maintaining Invariant 4

Throughout the course of handling a single hyperedge update, we may need to delete multiple hyperedges e_1, e_2, \dots from M , starting from the originally deleted hyperedge by the adversary. Each of these hyperedge $e_i \in M$ that are now removed from M is responsible for temporarily deleted hyperedges $\mathcal{D}(e_i)$.

We will maintain a queue of all hyperedges in $\mathcal{D}(e_1), \mathcal{D}(e_2), \dots$ during the course of this update. At the *very end* of the update, once all other changes are finalized, we will insert the hyperedges in this queue one by one to the hypergraph as if they were inserted by the adversary (using the procedure of Section 3.4.3). This allows us to maintain Invariant 4.

We note that throughout the update we may also temporarily delete some new hyperedges. We'll show that in that case, all these hyperedges are also incident on some matched hyperedge which is responsible for them and thus Invariant 4 holds for these hyperedges as well.

Maintaining maximality of M

Let us now begin the main part of the update algorithm. Suppose $e = (v_1, \dots, v_r)$ is deleted from M . This makes the vertices v_1, \dots, v_r *temporarily* free. We will handle each of these vertices using the procedure **handle-free** which is the key ingredient of the update algorithm (we will simply run **handle-free**(v_1), \dots , **handle-free**(v_r)).

Procedure handle-free(v). Handles a given vertex $v \in V$ which is *unmatched* currently in the algorithm (its matched hyperedge may have been deleted via an update or by the algorithm in this time step, or v may simply be unmatched at this point of the algorithm)^a.

^a To simplify the exposition, we may some time call **handle-free**(v) for a vertex v that is now matched again (while handling other vertices). In that case, this procedure simply aborts.

The execution of Procedure **handle-free**(v) depends on the number of owned hyperedges of v , i.e., o_v (both procedures used within this one are described below): (i) if $o_v < \alpha^{\ell(v)+1}$, we will run **deterministic-settle**(v); and otherwise (ii) if $o_v \geq \alpha^{\ell(v)+1}$, we run **random-settle**(v) instead. We now describe each procedure.

Procedure deterministic-settle(v). Handles a given vertex $v \in V$ with $o_v < \alpha^{\ell(v)+1}$.

In **deterministic-settle**(v), we iterate over all hyperedges $e \in \mathcal{O}(v)$ owned by v and check whether all endpoints of e are now unmatched; if so, we add e to M , and run **set-level**($v, 0$) and **set-owner**(e, v). Moreover, for any vertex $u \neq v \in e$, we further run **set-level**($u, 0$) so all vertices incident on e are now at level 0. If no such hyperedge is found, we run **set-level**($v, -1$).

▷ **Claim 7.** **deterministic-settle**(v) takes $O(r \cdot o_v^{\text{old}}) = O(r \cdot \alpha^{\ell^{\text{old}}(v)+1})$ time and maintains Invariants 2 and 3 for vertex v and hyperedges incident on v .

Proof. Checking if there is any hyperedge that can be added to M takes $O(r \cdot o_v^{\text{old}})$ time. Moreover, running **set-level**($v, 0$) or **set-level**($v, -1$) take $O(r \cdot o_v^{\text{old}})$ time by Claim 6 as $o_v^{\text{new}} \leq o_v^{\text{old}}$ considering level of v has not increased. If the algorithm finds a hyperedge e to add to M , we run **set-level**($u, 0$) for $u \neq v \in e$ as well which takes $O(1)$ time for each u by Claim 6 as $\ell^{\text{old}}(u) = -1$ (u was unmatched and by Invariant 2) and thus $o_u^{\text{old}} = o_u^{\text{new}} = 0$. As there are at most $r - 1$ choices for u , this step takes $O(r) = O(r \cdot \alpha^{\ell^{\text{old}}(v)+1})$ time (we are not being tight here). We also need to run **set-owner**(e, v) in this case which takes another $O(r)$ time by Claim 5. Since **deterministic-settle**(v) is only called when $o_v^{\text{old}} < \alpha^{\ell^{\text{old}}(v)+1}$, the desired time bound follows.

8:12 Fully Dynamic Set Cover via Hypergraph Maximal Matching

As for maintaining Invariant 2, consider the hyperedge e chosen by the algorithm to be added to M . We set the level of all vertices incident on e to be 0 and making v the owner of e , hence satisfying Invariant 2. On the other hand, if we cannot find such a hyperedge e incident on v , we know that all hyperedges incident on v are already at level at least 0 by Invariant 2 (even after removing v) and hence setting $\ell^{\text{new}}(v) = -1$ keeps Invariant 2. Invariant 3 also holds by maintaining Invariant 2 and the fact that we choose correct owners in the algorithm. \triangleleft

Before defining **random-settle**, we need the following definition. For any vertex $v \in V$ and integer $\ell > \ell(v)$, we define:

■ $\tilde{o}_{v,\ell}$: the number of edges v will own *assuming* we increase its level from $\ell(v)$ to ℓ .

The following claim is a straightforward corollary of procedure **set-level**.

▷ **Claim 8.** For any $v \in V$ and $\ell > \ell(v)$, $\tilde{o}_{v,\ell} = \left(\sum_{\ell'=\ell(v)}^{\ell-1} a_{v,\ell'} \right) + o_v$. In particular, $\tilde{o}_{v,\ell}$ can be obtained from $\tilde{o}_{v,\ell-1}$ in $O(1)$ time.

We can now describe **random-settle** (this is the main procedure of our update algorithm).

Procedure random-settle(v). Handles a given vertex $v \in V$ with $o_v \geq \alpha^{\ell(v)+1}$.

In **random-settle**(v), we first compute the level $\ell^{\text{new}}(v)$ as *minimum* $\ell > \ell(v)$ with $\tilde{o}_{v,\ell} < \alpha^{\ell+1}$ and run **set-level**($v, \ell^{\text{new}}(v)$). Then, we sample a hyperedge e uniformly at random from $\mathcal{O}^{\text{new}}(v)$. The next step of the algorithm now depends on this particular hyperedge e .

- **Case (a):** for all $u \in e$, $\tilde{o}_{u,\ell^{\text{new}}(v)} < \alpha^{\ell^{\text{new}}(v)+1}$. In this case, we add the hyperedge e to M and run **set-level**($u, \ell^{\text{new}}(v)$) for all $u \in e$ to maintain Invariant 2. This potentially can make M not a matching since some matched hyperedges e_1, \dots, e_k for $k < r$ incident on e might be in M . We will thus delete these hyperedges from M one by one and *recursively* run the procedure of Section 3.4.1 for each one, treating it *as if* this hyperedge was deleted by the adversary (although we do *not* remove the hyperedge from the hypergraph).
- **Case (b):** there exists $u \in e$, s.t. $\tilde{o}_{u,\ell^{\text{new}}(v)} \geq \alpha^{\ell^{\text{new}}(v)+1}$. We run **deterministic-settle**(v) to handle v and “switch” the focus to u instead. We then call **set-level**($u, \ell^{\text{new}}(v)$). If u is matched in M , say by hyperedge e_u , we remove e_u from M , and then *recursively* run the procedure of Section 3.4.1 for hyperedge e_u – we only note that when processing e_u , we start by running **handle-free**(u) first before all other vertices incident on e_u ; this is only done for making the analysis more clear and is not needed. If u is *not* matched in M , we will simply run **handle-free**(u).

▷ **Claim 9.** The first step of **random-settle**(v) before either case (changing level of v and picking hyperedge e) takes $O(r \cdot \alpha^{\ell^{\text{new}}(v)+1})$ time. Additionally, case (a) takes $O(r^2 \cdot \alpha^{\ell^{\text{new}}(v)+1})$ time and case (b) takes $O(r \cdot o_u^{\text{new}})$ time ignoring the recursive calls. Finally, **random-settle**(v) maintains Invariants 2 and 3.

Proof. Finding $\ell^{\text{new}}(v)$ takes $O(\ell^{\text{new}}(v))$ time by Claim 8 and **set-level**($v, \ell^{\text{new}}(v)$) takes $O(r \cdot o_v^{\text{new}} + \ell^{\text{new}}(v)) = O(r \cdot \alpha^{\ell^{\text{new}}(v)+1})$ time by Claim 6 as level of v is increased (and so is number of its owned edges) and since $o_v^{\text{new}} < \alpha^{\ell^{\text{new}}(v)+1}$ by design. This proves the first part.

The second part for case (a) also follows because for any $u \in e$, **set-level**($u, \ell^{\text{new}}(v)$) takes $O(r \cdot o_u^{\text{new}} + \ell^{\text{new}}(u)) = O(r \cdot \tilde{o}_{u,\ell^{\text{new}}(v)} + \ell^{\text{new}}(v))$ by Claim 6 as level of u is increased. This is $O(r \cdot \alpha^{\ell^{\text{new}}(v)+1})$ by the condition $\tilde{o}_{u,\ell^{\text{new}}(v)} < \alpha^{\ell^{\text{new}}(v)+1}$ in case (a). Multiplying this with at most r vertices $u \in e$ gives the desired bound.

The second part for case (b) holds because v has $o_v \leq \alpha^{\ell^{\text{new}}(v)+1}$ by the definition of $\ell^{\text{new}}(v)$ and thus **deterministic-settle**(v) takes $O(r \cdot \alpha^{\ell^{\text{new}}(v)+1})$ time by Claim 7. Moreover, running **set-level**($u, \ell^{\text{new}}(v)$) takes $O(r \cdot o_u^{\text{new}})$ by Claim 6 which is at least $O(r \cdot \alpha^{\ell^{\text{new}}(v)+1})$ by the lower bound on $\tilde{o}_{u, \ell^{\text{new}}(v)}$ in this case.

Finally, Invariants 2 and 3 also hold as explained in the description of the procedure. \triangleleft

The following observation plays a key rule in the recursive analysis of our algorithm.

► **Observation 10.** *In **random-settle**(v): (i) the hyperedge e is sampled uniformly at random from at least $\alpha^{\ell^{\text{new}}(v)}$ edges. Moreover, (ii) any hyperedge e_1, \dots, e_k or e_u deleted from M during this procedure is at level at most $\ell^{\text{new}}(v) - 1$.*

Part (i) of the observation follows from the definition of $\ell^{\text{new}}(v)$. For part (ii), note that any deleted edge e' in the process is incident on e with $\ell^{\text{old}}(e) = \ell^{\text{old}}(v) < \ell^{\text{new}}(v)$. Let u be any vertex incident on both e' and e . Firstly, $\ell(u) \leq \ell^{\text{old}}(v)$ as e was owned by v and not u , and secondly $\ell(e') = \ell(u)$ as e' is a matched hyperedge (see Invariant 2); thus $\ell(e') \leq \ell(e) < \ell^{\text{new}}(v)$ as well.

Temporarily deleting new hyperedges

An astute reader may have noticed that we have not yet temporarily deleted any hyperedge in the update algorithm. The only place that this will be done is in case (a) of **random-settle**. In this case, when we decide to insert e to M , we will temporarily delete all other hyperedges in $\mathcal{O}^{\text{new}}(v)$ from which e was sampled from, and make e responsible for them by adding them to $\mathcal{D}(e)$. The deletions of these hyperedges is done by the procedure of Section 3.4.2 (as they do not belong to M). As the cost of each such hyperedge deletion is $O(r)$ and their total number is $O(\alpha^{\ell^{\text{new}}(v)+1})$, this does not change the asymptotic bounds of Claim 9. Finally, since these edges are incident on e which now belongs to M , Invariant 4 will be maintained by this process. The following observation is now immediate.

► **Observation 11.** *Any hyperedge $e \in M$ is responsible for $O(\alpha^{\ell(e)+1})$ hyperedges in $\mathcal{D}(e)$.*

3.4.2 Case 2: a hyperedge $e \notin M$ is deleted

We only need to remove e from the corresponding data structures which can be done in $O(r)$ time for the (at most) r endpoints of e .

3.4.3 Case 3: a hyperedge e is inserted

We need to find $v = \arg \max_{u \in e} \ell(u)$ and run **set-owner**(e, v) which takes $O(r)$ time. Moreover, if all vertices incident on e are unmatched, we should additionally add e to M and run **set-level**($u, 0$) for all $u \in e$ which takes $O(r)$ time per vertex by Claim 6.

This concludes the description of our algorithm for update time $O(r^3)$.

4 Part of the Analysis of the $O(r^3)$ -Update Time Algorithm

A key definition in analysis is the notion of an *epoch* borrowed from the prior work in [5, 25].

► **Definition 12 (Epoch).** *For any time t and any hyperedge e in the matching M at time t , **epoch** of e and t , denoted by $\text{epoch}(e, t)$, is the pair $(e, \{t'\})$ where $\{t'\}$ denotes the maximal continuous time period containing t during which e was always present in M (not even deleted temporarily during one step and inserted back at the same time step).*

We further define level of $\text{epoch}(e, t)$ as the level $\ell(e)$ of e during the time period of the epoch; we note that our update algorithm never changes level of a hyperedge in M without removing it from M first and thus level of an epoch is well-defined.

The update algorithm in Section 3.4 takes $O(r)$ time deterministically for any update step that does *not* change the matching M . However, an update at a time step t that changes M may force the algorithm a large computation time and hence we use amortization to charge the cost of processing such an update at time t to the epochs that are created and removed at time t . In particular, for any time step t , define:

- $\text{epochs}_{\text{create}}(t)$: the set of all $\text{epoch}(e, t)$ that are *created* at time t ; respectively, $\text{epochs}_{\text{term}}(t)$ is defined for epochs *terminated* at time t ;
- $C_{\text{create}}(\text{epoch}(e, t))$: the computation cost at time t for *creation* of $\text{epoch}(e, t)$; respectively, $C_{\text{term}}(\text{epoch}(e, t))$ is defined for the cost of *termination* of $\text{epoch}(e, t)$.

Then, the total cost of update at time t is:

$$C(t) = O(r) + \sum_{\substack{\text{epoch}(e, t) \in \\ \text{epochs}_{\text{create}}(t)}} C_{\text{create}}(\text{epoch}(e, t)) + \sum_{\substack{\text{epoch}(e, t) \in \\ \text{epochs}_{\text{term}}(t)}} C_{\text{term}}(\text{epoch}(e, t)). \quad (2)$$

► **Lemma 13.** *The total computation cost $C(t)$ of an update at time t in Equation (2) can be charged to the epochs in the RHS so that any level- ℓ epoch is charged with $O(\alpha^{\ell+3})$ units of cost.*

Proof. We prove this lemma in a sequence of claims. In the following, whenever we say “some computation cost can be charged to $C_{\text{create}}(\text{epoch}(e, t))$ or $C_{\text{term}}(\text{epoch}(e, t))$ ” we mean that the cost of computation is $O(\alpha^{\ell+3})$ and there is a level- ℓ epoch $\text{epoch}(e, t)$ at time t that is either created or terminated, respectively, and that this cost is charged to $C_{\text{create}}(\text{epoch}(e, t))$ or $C_{\text{term}}(\text{epoch}(e, t))$. We emphasize that each epoch during this process is only charged a *constant* number of times. This then immediately satisfies the bounds in Lemma 13.

▷ **Claim 14.** Cost of a hyperedge-insertion update e at time t can be charged to $C_{\text{create}}(\text{epoch}(e, t))$.

Proof. As in Section 3.4.3, this update takes $O(r)$ time and creates a level-0 $\text{epoch}(e, t)$. ◁

From now on, we consider the main case of a hyperedge-deletion update e from M at time t using the procedure in Section 3.4.1. In this case, we remove e from M which results in $\text{epoch}(e, t)$ to be terminated (and hence $\text{epoch}(e, t) \in \text{epochs}_{\text{term}}(t)$ in RHS of $C(t)$ in Equation (2)). This step is then followed by running **handle-free**(v) for all $v \in e$. Recall that **handle-free**(v) can be handled either by **deterministic-settle**(v) or **random-settle**(v) (depending on value of o_v).

▷ **Claim 15.** Let e be a hyperedge in M deleted at time t (either by the adversary or the algorithm in a recursive call). Cost of **handle-free**(v) for all $v \in e$ that are handled by **deterministic-settle**(v) can be charged to $C_{\text{term}}(\text{epoch}(e, t))$.

Proof. By Claim 7, for each $v \in e$ that is handled by **deterministic-settle**(v), the runtime of **handle-free**(v) is $O(r \cdot \alpha^{\ell(e)+1})$. As there are at most r such vertices, their total cost is $O(r^2 \cdot \alpha^{\ell(e)+1}) = O(\alpha^{\ell(e)+3})$ by the choice of α in Equation (1). Hence the total cost of all these vertices that are charged to $C_{\text{term}}(\text{epoch}(e, t))$ is $O(\alpha^{\ell(e)+3})$. ◁

We now switch to analyzing **random-settle**(v) for a fixed $v \in e$. The easier part, when we can process **random-settle**(v) by case (a), is handled via the next claim.

▷ **Claim 16.** Cost of case (a) of **random-settle**(v) at time t ignoring the recursive calls can be charged to $C_{create}(\text{epoch}(e_v, t))$, where e_v is the hyperedge inserted to M in this case.

Proof. In case (a) of **random-settle**(v), we create a new edge e_v in M at level $\ell(e_v) = \ell^{\text{new}}(v)$. By Claim 9, ignoring the recursive calls, this case takes $O(r^2 \cdot \alpha^{\ell(e_v)+1}) = O(\alpha^{\ell(e_v)+3})$ time. We can thus charge the cost of **random-settle**(v) to $C_{create}(\text{epoch}(e_v, t))$. ◁

We now analyze case (b) of **random-settle**(v). In this case, instead of handling v , we in fact recursively handle the vertex u (with $\tilde{o}_{u, \ell^{\text{new}}(v)} \geq \alpha^{\ell^{\text{new}}(v)+1}$) using **handle-free**(u) and only after that will come back to take care of v if needed. Moreover, since we first set level of u to $\ell^{\text{new}}(v)$, we will have $o_u^{\text{new}} \geq \alpha^{\ell^{\text{new}}(u)+1}$. This means **handle-free**(u) will be handled using **random-settle**(u) recursively. It is again possible that **random-settle**(u) hits case (b) and so on and so forth. However, note that when going from v to u , we obtain that $\ell^{\text{new}}(v) < \ell^{\text{new}}(u)$ by Observation 10 (here $\ell^{\text{new}}(u)$ refers to $\ell(u) = \ell^{\text{new}}(v)$ at the beginning of **random-settle**(u)) and hence whenever case (b) happens, the vertex we move on to will have a strictly larger level. As such, this chain of recursive calls to **random-settle** will terminate eventually in some case (a) of **random-settle**.

We'll denote the vertices in the chain of calls to **random-settle** in case (b) for v by $(v =)w_0, w_1, w_2, \dots, w_k$ for some $k \leq L$ (number of levels); in particular, w_1 is the vertex u in case (b) of **random-settle**(v), w_2 is the vertex u in case (b) of **random-settle**(w_1), etc.

The computation cost of **random-settle**(v) in case (b) then involves two parts: (i) pre-processing before calling each **random-settle**(w_i) (which is bounded in Claim 9), (ii) calling **random-settle**(w_i) itself, and (iii) removing hyperedges e_{w_i} from M (for each one that exist) and recursively handling them using the procedure of Section 3.4.1.

Among these costs, the cost of handling e_{w_i} for $i \in [k]$ is handled separately by recursion (charged either to the termination of $\text{epoch}(e_{w_i}, t)$ or creation of new epochs). We thus need to handle the costs in parts (i) and (ii) in the following claim, whose proof is omitted.

▷ **Claim 17.** Cost of case (b) of **random-settle**(v) at time t with chain of vertices w_0, w_1, \dots, w_k ignoring the recursive calls (i.e., part (iii) of costs above) can be charged to $C_{create}(\text{epoch}(e^*, t))$, where e^* is the hyperedge inserted to M in case (a) of **random-settle**(w_k). (Note that by definition, **random-settle**(w_k) finishes in case (a).)

Finally, we also have to handle the cost associated with maintaining Invariant 4, namely, “bringing back” temporarily deleted hyperedges at the very end of the update step (the cost of temporarily deleting new hyperedges is accounted for in Claim 9 already).

▷ **Claim 18.** Cost of inserting back the temporarily deleted hyperedges in $\mathcal{D}(e)$ for any hyperedge $e \in M$ can be charged to $C_{term}(\text{epoch}(e, t))$.

Proof. Any hyperedge $e \in M$ is responsible for $O(\alpha^{\ell(e)+1})$ hyperedges in $\mathcal{D}(e)$ by Observation 11. As bringing back these hyperedges requires $O(r \cdot \alpha^{\ell(e)+1})$ time in total, this charge can be charged to the termination of $\text{epoch}(e, t)$. ◁

We thus showed that any cost in $C(t)$ can be charged by a factor of $O(\alpha^{\ell+3})$ to some level- ℓ epoch in RHS of Equation (2) without charging any epoch more than a constant number of times, thus finalizing the proof of Lemma 13. ◀

In Lemma 13, we charge at most $O(\alpha^{\ell+3})$ to the creation and/or termination of a level- ℓ epoch. It can be shown that, without loss of generality, we may assume that every epoch created will also be terminated, hence we can re-distribute the charges to creation of each level- ℓ epoch to the termination of the same epoch. We now have an equivalent charging

scheme in which *only termination* of each level- ℓ epoch is charged with $O(\alpha^{\ell+3})$ computation time (and not the creations). Recall that an epoch is terminated when the corresponding hyperedge e is deleted from the maximal matching M . There are two types of hyperedge deletions from M in the algorithm: those that are the result of the adversary deleting a hyperedge from the graph, and those that are the result of the update algorithm to remove a matched hyperedge in favor of another (so the original hyperedge is still part of the hypergraph). Based on this, we differentiate between epochs as follows:

- **Natural epoch:** Ending with the adversary deleting the hyperedge e from G .
 - **Induced epoch:** Ending with the update algorithm removing the hyperedge e from M .
- With the following lemma, we are going to re-distribute the charge assigned to all induced epochs between the natural epochs. This then will allow us to focus solely on natural epochs.

► **Lemma 19** (proof omitted). *The total cost charged to all induced epochs can be charged to natural epochs so that any level- ℓ natural epoch is charged with the costs of at most $r - 1$ induced epochs at lower levels.*

Next, we move from natural and induced epochs to the corresponding notions in *levels*: A level ℓ is called an **induced level** (resp., **natural level**) if the number of induced level- ℓ epochs is greater than (resp., at most) the number of natural level- ℓ epochs. We will charge the computation costs incurred by any induced level to the computation costs at higher levels, so that in the end, the entire cost of the algorithm will be charged to natural levels. Specifically, in any induced level ℓ , we define a one-to-one mapping from the natural to the induced epochs. For each induced epoch, at most one natural epoch (at the same level) is mapped to it; any natural epoch that is mapped to an induced epoch is called *semi-natural*. For any induced level ℓ , all natural ℓ -level epochs are semi-natural by definition. For any natural level, all natural epochs terminated at that level remain as before; these epochs are called *fully-natural*. By Lemma 19, for any epoch, at most $r - 1$ induced epochs at lower levels are charged to it. We define the **recursive cost** of an epoch as the sum of its actual cost and the recursive costs of the at most $r - 1$ induced epochs charged to it as well as the (at most) $r - 1$ semi-natural epochs mapped to them; the recursive cost of a level-0 epoch is defined as its actual cost. We are now ready to state the following lemma (proof omitted).

► **Lemma 20.** *For any $\ell \geq 0$, the recursive cost of any level- ℓ epoch is bounded by $O(\alpha^{\ell+3})$.*

The sum of recursive costs over all fully-natural epochs is equal to the sum of actual costs over all epochs (fully-natural, semi-natural and induced) that have been *terminated* throughout the update sequence, which also bounds the total runtime of the algorithm.

For the omitted proofs in the above statements, we refer the reader to Section 4 in the full version [4]. The final step of the analysis is to use the randomization in the algorithm (and obliviousness of the adversary) to prove a probabilistic upper bound on the amortized cost of the algorithm; this part is handled in detail in Section 7 of the full version [4].

This allows us to conclude the following theorem.

► **Theorem 21.** *For any integer $r > 1$, starting from an empty rank- r hypergraph on a fixed set of vertices, a maximal matching can be maintained over any sequence of t hyperedge insertions and deletions in $O(t \cdot r^3)$ time in expectation and with high probability.*

Abstract

The weighted k -server problem is a natural generalization of the k -server problem in which the cost incurred in moving a server is the distance traveled times the weight of the server. Even after almost three decades since the seminal work of Fiat and Ricklin (1994), the competitive ratio of this problem remains poorly understood even on the simplest class of metric spaces – the uniform metric spaces. In particular, in the case of randomized algorithms against the oblivious adversary, neither a better upper bound than the doubly exponential deterministic upper bound, nor a better lower bound than the logarithmic lower bound of unweighted k -server, is known. In this paper, we make significant progress towards understanding the randomized competitive ratio of weighted k -server on uniform metrics. We cut down the triply exponential gap between the upper and lower bound to a singly exponential gap by proving that the competitive ratio is at least exponential in k , substantially improving on the previously known lower bound of about $\ln k$.

1 Introduction

The k -server problem of Manasse, McGeoch, and Sleator [12] is one of the cleanest, simple-looking, and yet profound problems in online computation, and has been actively studied for over three decades. The k -server problem concerns deciding movements of k mobile servers on an underlying metric space to serve a sequence of online requests. Each request is issued at some point of the metric space, and to serve such a request, a server must move to the requested point (unless a server is already present there). The cost incurred in the movement of a server is equal to the distance through which the server moves, and the goal is to minimize the total cost.

Since an online algorithm is required to take its decisions only based on the past inputs, it cannot output the optimal solution, in general. An online algorithm for a minimization problem is said to be c -competitive if, on any instance, it produces a solution whose (expected) cost is at most c times the cost of the optimum solution. The competitive ratio of an algorithm is the minimum (technically, the infimum of all) c such that the algorithm is c -competitive. The deterministic (resp. randomized) competitive ratio of an online minimization problem is the minimum (technically, the infimum of all) c for which a c -competitive deterministic (resp. randomized) algorithm exists. Note that, unless otherwise specified, we assume that in case of randomized algorithms, the adversarial input is *oblivious*, that is, constructed with the knowledge of the algorithm but not the random choices the algorithm makes.

In their seminal work, Manasse, McGeoch, and Sleator [12] proved that the deterministic competitive ratio of the k -server problem is at least k on every metric with more than k points. They conjectured that the deterministic competitive ratio is, in fact, equal to k on any metric. This conjecture is popularly called the deterministic k -server conjecture and it remains unresolved to date. The deterministic algorithm with the best known competitive ratio of $2k - 1$ is due to Koutsoupias and Papadimitriou [10]. Surprisingly, no better algorithm is known even using randomization. The randomized k -server conjecture states that a randomized algorithm with competitive ratio $O(\log k)$ exists on all metrics, and this remains unresolved after some recent progress [5, 11]. The k -server problem on uniform metric spaces is particularly interesting because it is equivalent to the paging problem. In this case, several deterministic algorithms including Least-Recently-Used (LRU) and First-In-First-Out (FIFO) are known to be k -competitive. The randomized competitive ratio is known to be exactly $H(k) = \sum_{i=1}^k 1/i \approx \ln k$, where the lower bound is due to Fiat et al. [8] and the upper bound is due to [13, 1].

The weighted k -server problem is a natural generalization of the k -server problem where the objective is to minimize the weighted sum of the movements of servers. Specifically, the k servers have weights $\beta_1 \leq \dots \leq \beta_k$, and the cost of moving the i 'th server is β_i times the distance through which it moves. It is easy to see that a c -competitive k -server algorithm has competitive ratio at most $c\beta_k/\beta_1$ for the weighted k -server problem, and therefore, the challenge is to design an algorithm with competitive ratio independent of the servers' weights. Surprisingly, this innocuous-looking introduction of weights into the k -server problem makes it incredibly difficult, and a competitive algorithm is known only for $k \leq 2$ [14] (of which, the $k = 1$ case is trivial).

1.1 Weighted k -Server on Uniform Metrics

Owing to the difficulty of the weighted k -server problem on general metrics, the problem becomes particularly interesting on uniform metrics. The weighted k -server problem on uniform metric spaces models the paging problem where the cost of page replacement is determined by the location where the replacement takes place. Note that this problem is different from weighted caching [15], where the cost of page replacement is determined by the pages that get swapped in and out.

The seminal paper of Fiat and Ricklin [9] gave a deterministic algorithm for weighted k -server on uniform metrics whose competitive ratio is doubly exponential in k : about $3^{4^k/3}$ specifically, but can be improved to $2^{2^{k+2}} = 16^{2^k}$ due to the result of Bansal et al. [3] for a more general problem. The fact that the deterministic competitive ratio is indeed doubly exponential in k was established only recently by Bansal et al. [2], who proved a lower bound of $2^{2^{k-4}}$, improving the previously known lower bound of $(k+1)!/2$ due to Fiat and Ricklin [9].

The only known algorithm for the weighted k -server problem on uniform metrics which makes non-trivial use of randomness is by Chiplunkar and Vishwanathan [6]. This algorithm also achieves a doubly exponential competitive ratio of about c^{2^k} for $c \approx 1.59792$. It is, in fact, a *randomized memoryless algorithm* generalizing the algorithm by Chrobak and Sgall [7] for $k = 2$, and it achieves the competitive ratio against a stronger form of adversary called *adaptive online adversary*¹. Chiplunkar and Vishwanathan also proved

¹ An adaptive online adversary can see the movements of the algorithm's servers even though the algorithm is randomized. However, the adversary must also serve its requests in an online manner. The algorithm's

that no randomized memoryless algorithm can achieve a better competitive ratio against adaptive online adversaries. However, even when an algorithm is allowed to use both memory and randomness, and the adversary is oblivious, no better upper bound is known. More embarrassingly, for randomized algorithms, no better lower bound than the logarithmic lower bound of (unweighted) k -server on uniform metrics is known, thus, leaving a triply exponential gap between the upper and lower bounds.

In this paper, we cut down the triply exponential gap between the best known bounds on the randomized competitive ratio of weighted k -server on uniform metrics by a doubly exponential improvement in the lower bound. We prove,

► **Theorem 1.** *The competitive ratio of any randomized algorithm for weighted k -server on uniform metrics is at least exponential in k , even when the algorithm is allowed to use memory and the adversary is oblivious.*

Due to our result, we now have only a singly exponential gap between the best known upper and lower bounds on the randomized competitive ratio of weighted k -server on uniform metrics.

1.2 Comparison with the Deterministic Lower Bound

Our proof of the randomized lower bound for weighted k -server is inspired by the proof of the deterministic lower bound by Bansal et al. [2]. Both proofs give adversaries which run recursively defined strategies relying crucially on a certain set-system \mathcal{Q} . However, our proof differs in the following aspects.

1. The adversary in the deterministic lower bound proof is able to carefully pick from \mathcal{Q} a set of points that does not contain points covered by the algorithm's heavier servers, and run its strategy on that set. In contrast, our adversary is oblivious and is unable to see the positions of the algorithm's servers. Therefore, it merely picks a random set from \mathcal{Q} and hopes that none of the points in that set is covered by the algorithm's heavier servers.
2. The strategy of Bansal et al. to defeat deterministic algorithms ensures that whenever an adversary's server other than the heaviest moves, it is accompanied by an eventual movement of a heavier server of the algorithm. Therefore, assuming that the weights of the servers are well-separated, their task reduces to proving that the heaviest server of the algorithm moves a large number of times as compared to the heaviest server of the adversary. On the other hand, we are unable to charge the movement of an adversary's server to the movement of an algorithm's heavier server. Consequently, we need to carefully track the contributions of all k servers towards the algorithm's and the adversary's costs.

2 Preliminaries

Let the weights of the k servers be $1, \beta, \beta^2, \dots, \beta^{k-1}$ for some large integer β which we will fix later. Define the sequence n_0, n_1, \dots inductively as follows. $n_0 = 1$, and for $\ell > 0$,

$$n_\ell = \left(\left\lceil \frac{n_{\ell-1}}{2} \right\rceil + 1 \right) \cdot \left(\left\lfloor \frac{n_{\ell-1}}{2} \right\rfloor + 1 \right).$$

cost is compared with the cost of the adversary's online solution to determine the competitive ratio.

Observe that n_k grows doubly exponentially with respect to k . Since $n_\ell \geq n_{\ell-1}^2/4$, it is easy to prove using induction that $n_\ell \geq 4 \cdot (64^{1/32})^{2^\ell}$ for all $\ell \geq 5$. Let H denote the harmonic function, that is, $H(n) = \sum_{i=1}^n 1/i$. It is known that $H(n) \geq \ln n$. We will establish Theorem 1 by proving the following bound.

► **Theorem 2.** *The randomized competitive ratio of weighted k -server on uniform metric spaces is at least $H(n_{k-1}) = \Omega(2^k)$.*

We use the following version of Yao's principle to prove the above bound.

► **Proposition 3 (Yao's principle).** *Suppose there exists a probability distribution \mathcal{D} on the instances of an online minimization problem such that for every deterministic online algorithm A , we have,*

$$\mathbb{E}_{I \sim \mathcal{D}}[A(I)] > \alpha \cdot \mathbb{E}_{I \sim \mathcal{D}}[OPT(I)],$$

where $A(I)$ is the cost of the algorithm's solution and $OPT(I)$ is the cost of an optimal solution to instance I . Then the problem does not have an α -competitive randomized online algorithm.

Thus, in order to prove Theorem 2, our task is exhibit a distribution on instances of weighted k -server on a uniform metric space such that the expected cost of any deterministic online algorithm is greater than $H(n_{k-1})$ times the expectation of the optimum cost. To construct our distribution on instances, we use a combinatorial result with a constructive proof given by Bansal et al. [2]. We reproduce its proof in Appendix A for completeness. The result is as follows.

► **Lemma 4.** *Let $\ell \in \mathbb{N}$ and let P be a set of n_ℓ points. There exists a set-system $\mathcal{Q}_\ell \subseteq 2^P$ satisfying the following properties.*

1. \mathcal{Q}_ℓ contains $\lceil n_{\ell-1}/2 \rceil + 1$ sets, each of size $n_{\ell-1}$.
2. For every $p \in P$, there exists a set in \mathcal{Q}_ℓ not containing p .
3. For every $p \in P$, there exists a $q \in P$ such that every set in \mathcal{Q}_ℓ contains at least one of p and q .

3 Adversarial Strategy and Analysis

Consider the uniform metric space on a set S of $n_{k-1} + 1$ points. Our adversarial input distribution is generated by the procedure **adversary** which uses a recursive procedure **strategy**, an oblivious version of its counterpart in Bansal et al. [2]. These procedures are defined as follows.

■ **Procedure 1** **adversary.**

repeat *infinitely many times*

- ┌ Pick a point p uniformly at random from S (with replacement);
 - └ Call **strategy**($k - 1, S \setminus \{p\}$);
-

■ **Procedure 2** $\text{strategy}(\ell, P)$ (Promise: $|P| = n_\ell$).

```

if  $\ell = 0$  (and therefore,  $|P| = n_0 = 1$ ) then
  Request the unique point in  $P$ ;
else
  Construct the set-system  $\mathcal{Q}_\ell \subseteq 2^P$  using Lemma 4;
  repeat  $(\beta - 1) \cdot (\lceil n_{\ell-1}/2 \rceil + 1)$  times
    Pick a set  $P'$  uniformly at random from  $\mathcal{Q}_\ell$  (with replacement);
    Call  $\text{strategy}(\ell - 1, P')$ ;

```

Procedure **strategy** gets as input a non-negative number ℓ and a set P of n_ℓ points. In the base case where $\ell = 0$, the procedure issues a request to the unique point in P . In the inductive case where $\ell > 0$, the procedure constructs the set-system \mathcal{Q}_ℓ with properties stated in Lemma 4 on the set P . Then it repeatedly gives recursive calls, passing $\ell - 1$ in place of ℓ , on sets chosen uniformly at random from \mathcal{Q}_ℓ . Recall that these sets have size $n_{\ell-1}$, as required. Procedure **adversary** takes a uniform metric space on $n_{k-1} + 1$ points. It repeatedly picks a point p uniformly at random and calls the procedure **strategy** on the set of points other than p .

For analysis, fix an arbitrary deterministic online algorithm and the initial positions of its servers. We first consider requests given by one execution of procedure $\text{strategy}(\ell, P)$, and bound the number of movements of the algorithm's servers to serve those requests.

► **Lemma 5.** *For every $\ell \in \{0, \dots, k-1\}$ the following holds. Let ρ_0 be an arbitrary sequence of requests and L be the set of positions of the algorithm's heaviest $k - \ell$ servers after serving ρ_0 . Let P be an arbitrary set of n_ℓ points disjoint from L . Suppose ρ_0 is followed by a random sequence ρ of requests given by a $\text{strategy}(\ell, P)$ call. For $i = 1, \dots, k$, let the random variable X_i denote the number of movements of the algorithm's i 'th lightest server while the algorithm serves ρ . Then we have,*

$$\sum_{i=1}^k \beta^{\min(i-1, \ell)} \cdot \mathbb{E}[X_i] \geq (\beta - 1)^\ell.$$

We defer the proof of this lemma to Appendix B. On a high level, the proof goes as follows. If the algorithm moves one of its heaviest $k - \ell$ servers while it serves ρ , then it pays a lot already. If not, it must serve ρ using its lightest ℓ servers only. In this case, each recursive call given by the $\text{strategy}(\ell, P)$ call is, with sufficient probability, on a set P' not containing the location of the algorithm's ℓ 'th lightest server. This enables us to use induction hypothesis to bound the algorithm's cost in each recursive call.

Intuitively, Lemma 5 gives a lower bound of $(\beta - 1)^\ell$ on the expected cost incurred by the algorithm in serving requests given by a $\text{strategy}(\ell, P)$ call, but with the following caveat: movements of the heaviest $k - \ell - 1$ servers are charged at a discounted rate of β^ℓ . However, when ℓ is instantiated to $k - 1$ in particular, no discount remains applicable. Thus, $(\beta - 1)^{k-1}$ becomes a lower bound on the expected actual cost of the algorithm in serving requests given by a $\text{strategy}(k - 1, P)$ call. With this observation, we immediately get the following bound on the expected cost of the algorithm in serving requests given by each **strategy** call made by the procedure **adversary**.

► **Corollary 6** (to Lemma 5). *The expected cost of the algorithm in serving requests given by each **strategy** call made by **adversary** is at least $(\beta - 1)^{k-1} / (n_{k-1} + 1)$.*

Proof. Consider any $\text{strategy}(k-1, S \setminus \{p\})$ call, where p is a uniformly random point in S . Let r be the location of the algorithm's heaviest server at the time the call is made. Then $\Pr[r \notin S \setminus \{p\}] = \Pr[p = r] = 1/|S| = 1/(n_{k-1} + 1)$. Lemma 5 implies that conditioned on $r \notin S \setminus \{p\}$, the expected cost of the algorithm in serving requests given by the $\text{strategy}(k-1, S \setminus \{p\})$ call is at least $(\beta - 1)^{k-1}$. Thus, the claim follows. \blacktriangleleft

Let us now turn our attention towards the adversary's cost. We will show how the adversary, having the ability to see the future requests, can ensure that whenever $\text{strategy}(\ell, P)$ is called, it has at least one server other than its ℓ lightest servers occupying a point in P already. On the contrary, recall that in Lemma 5, we relied on the algorithm not having any of its servers except the ℓ lightest ones occupying points in P at the time $\text{strategy}(\ell, P)$ is called. Intuitively, the adversary is able to obtain advantage over the algorithm by having one server other than the ℓ lightest ones in P whereas the algorithm has none.

► **Lemma 7.** *Define the sequence c_0, c_1, \dots inductively as follows: $c_0 = 0$, and for $\ell > 0$,*

$$c_\ell = \beta^{\ell-1} + \beta \cdot (\lceil n_{\ell-1}/2 \rceil + 1) \cdot c_{\ell-1}.$$

Suppose that the adversary has at least one server other than its ℓ lightest servers occupying some point in P at the time $\text{strategy}(\ell, P)$ is called. Then the adversary is able to serve all requests given in this call with cost at most c_ℓ by moving only its ℓ lightest servers.

Proof. We prove the claim by induction on ℓ . For the base case, suppose $\ell = 0$. Then $|P| = 1$ and by assumption, the adversary has at least one server at the unique point in P . Therefore, the adversary can serve the unique request given by $\text{strategy}(0, P)$ with cost $c_0 = 0$, without moving any server.

For the inductive case, suppose $\ell > 0$. We have assumed that the adversary has at least one server other than its lightest ℓ servers occupying some point p in P . By the third property of the set-system \mathcal{Q}_ℓ from Lemma 4, there exists a point $q \in P$ such that each set in \mathcal{Q}_ℓ contains at least one of p and q . The adversary moves its ℓ 'th lightest server to such a point q and keeps it there until the end of the $\text{strategy}(\ell, P)$ call. Due to this movement, the adversary incurs cost $\beta^{\ell-1}$, the first term in the definition of c_ℓ . As a result, both p and q become occupied by the adversary's servers other than the $\ell - 1$ lightest ones. We now show how the requests in all recursive calls made by $\text{strategy}(\ell, P)$ can be served by moving the $\ell - 1$ lightest servers only.

Consider any of the recursive calls made by $\text{strategy}(\ell, P)$. The set $P' \in \mathcal{Q}_\ell$ on which this call is made contains at least one of p and q . Both p and q were occupied by the adversary's servers other than the $\ell - 1$ lightest ones before $\text{strategy}(\ell, P)$ made its first recursive call. All the previous recursive calls were served by moving only the $\ell - 1$ lightest servers. Thus, at the time the current recursive call $\text{strategy}(\ell - 1, P')$ is made, points p and q are still occupied by the adversary's servers other than the $\ell - 1$ lightest ones. Therefore, at least one of these servers occupies a point in P' . By induction hypothesis, the adversary can serve all requests in the current recursive call $\text{strategy}(\ell - 1, P')$ with cost at most $c_{\ell-1}$ by moving only the $\ell - 1$ lightest servers. Since the number of such recursive calls is $(\beta - 1) \cdot (\lceil n_{\ell-1}/2 \rceil + 1) \leq \beta \cdot (\lceil n_{\ell-1}/2 \rceil + 1)$, the adversary serves all requests made in these calls with cost at most $\beta \cdot (\lceil n_{\ell-1}/2 \rceil + 1) \cdot c_{\ell-1}$, the second term in the expression for c_ℓ . \blacktriangleleft

We now use Corollary 6 and Lemma 7 to prove Theorem 2.

► **Theorem 2.** *The randomized competitive ratio of weighted k -server on uniform metric spaces is at least $H(n_{k-1}) = \Omega(2^k)$.*

Proof. We track the costs incurred by the algorithm and the adversary per $\text{strategy}(k-1, P)$ call made by the procedure **adversary**, and show that the former is at least $H(n_{k-1})$ times the latter.

Here is how the adversary serves the requests. Let q denote the position of the adversary's heaviest server at the time a $\text{strategy}(k-1, P)$ call is made. If $P = S \setminus \{q\}$, that is, the random point sampled from S turns out to be q , then the adversary finds the point q' which is sampled farthest in future by the procedure **adversary**, and moves its heaviest server there. These are the only movements of the adversary's heaviest server. By the standard coupon-collector argument, the expected number of samples from the current sample of q to q' is $(n_{k-1} + 1)H(n_{k-1})$, because $|S| = n_{k-1} + 1$ and we have already sampled q . Thus, in the long run, the cost of the adversary resulting from moving its heaviest server, per strategy call made by the procedure **adversary**, is $\beta^{k-1}/((n_{k-1} + 1)H(n_{k-1}))$.

By moving its heaviest server as described above, the adversary ensures the following. Before the adversary starts serving requests given by a $\text{strategy}(k-1, S \setminus \{p\})$ call, its heaviest server is located at some point different from p , and therefore, in $S \setminus \{p\}$. By Lemma 7, the adversary is able to serve requests given by each $\text{strategy}(k-1, S \setminus \{p\})$ with cost at most c_{k-1} without moving its heaviest server. In other words, the contribution of the adversary's servers other than the heaviest towards its cost per strategy call is at most c_{k-1} .

Thus, the adversary's cost per strategy call made by the procedure **adversary** is at most $\beta^{k-1}/((n_{k-1} + 1) \cdot H(n_{k-1})) + c_{k-1}$, which, by unrolling the recurrence in the statement of Lemma 7, is given by

$$\frac{\beta^{k-1}}{(n_{k-1} + 1) \cdot H(n_{k-1})} + c_{k-1} = \frac{\beta^{k-1}}{(n_{k-1} + 1) \cdot H(n_{k-1})} + \beta^{k-2} \cdot \sum_{i=1}^{k-1} \prod_{j=i}^{k-2} \left(\left\lceil \frac{n_j}{2} \right\rceil + 1 \right).$$

Let ε be an arbitrarily small positive number. By choosing

$$\beta = \lceil \varepsilon^{-1} \rceil \cdot (n_{k-1} + 1) \cdot H(n_{k-1}) \cdot \sum_{i=1}^{k-1} \prod_{j=i}^{k-2} \left(\left\lceil \frac{n_j}{2} \right\rceil + 1 \right),$$

the adversary's cost per strategy call is bounded from above by

$$\frac{\beta^{k-1} \cdot (1 + \varepsilon)}{(n_{k-1} + 1) \cdot H(n_{k-1})}.$$

On the other hand, recall from Corollary 6 that the expected cost of the algorithm per strategy call made by the procedure **adversary** is at least

$$\frac{(\beta - 1)^{k-1}}{n_{k-1} + 1} = \frac{\beta^{k-1}}{n_{k-1} + 1} \cdot \left(1 - \frac{1}{\beta}\right)^{k-1} \geq \frac{\beta^{k-1}}{n_{k-1} + 1} \cdot \left(1 - \frac{k-1}{\beta}\right) \geq \frac{\beta^{k-1} \cdot (1 - \varepsilon)}{n_{k-1} + 1},$$

because $\beta \gg k/\varepsilon$. Thus, modulo the $(1 \pm \varepsilon)$ factors, the algorithm's cost per strategy call is at least $H(n_{k-1})$ times the adversary's cost per strategy call. Since ε is arbitrarily small, we use Proposition 3 to conclude that the competitive ratio of any randomized online algorithm for weighted k -server on uniform metrics is at least $H(n_{k-1})$. ◀

4 Concluding Remarks

Given our lower bound on the randomized competitive ratio of weighted k -server on uniform metric spaces, the gap between the known upper and lower bounds has reduced from three orders of exponentiation to one. The natural question that needs to be investigated is to determine the randomized competitive ratio, or at least, prove upper and lower bounds that match in the order of exponentiation.

Our result also sheds light on the randomized competitive ratio of a generalization of the weighted k -server problem on uniform metrics called the generalized k -server problem on weighted uniform metrics. In this problem k servers are restricted to move in k different uniform metric spaces that are scaled copies of one another. A request contains one point from each copy and to serve it, one of the points must be covered by the server moving in its copy. Our lower bound directly applies to the generalized k -server problem on weighted uniform metrics and improves the previously known lower bound² of $\Omega(k/\log^2 k)$ by Bansal et al. [3] to exponential in k . This also proves that the generalized k -server problem on weighted uniform metrics is qualitatively harder than its unweighted counterpart, the generalized k -server problem on uniform metrics, which has randomized competitive ratio $O(k^2 \log k)$ due to Beinkowski, Jeż, and Schmidt [4].

² This bound, in fact, holds for the unweighted counterpart, and to the best of the authors’ knowledge, no better bound for the weighted problem was known.

A Set-system Construction

► **Lemma 4.** *Let $\ell \in \mathbb{N}$ and let P be a set of n_ℓ points. There exists a set-system $\mathcal{Q}_\ell \subseteq 2^P$ satisfying the following properties.*

1. \mathcal{Q}_ℓ contains $\lceil n_{\ell-1}/2 \rceil + 1$ sets, each of size $n_{\ell-1}$.
2. For every $p \in P$, there exists a set in \mathcal{Q}_ℓ not containing p .
3. For every $p \in P$, there exists a $q \in P$ such that every set in \mathcal{Q}_ℓ contains at least one of p and q .

Proof (Bansal et al. [2]). Construct the set-system \mathcal{Q}_ℓ as follows. Recall that

$$|P| = n_\ell = \left(\left\lceil \frac{n_{\ell-1}}{2} \right\rceil + 1 \right) \cdot \left(\left\lfloor \frac{n_{\ell-1}}{2} \right\rfloor + 1 \right).$$

Let M be an arbitrary subset of P having size $\lceil n_{\ell-1}/2 \rceil + 1$, so that

$$|P \setminus M| = \left(\left\lceil \frac{n_{\ell-1}}{2} \right\rceil + 1 \right) \cdot \left\lfloor \frac{n_{\ell-1}}{2} \right\rfloor.$$

Partition $P \setminus M$ into $\lceil n_{\ell-1}/2 \rceil + 1$ sets of size $\lfloor n_{\ell-1}/2 \rfloor$ each, and for each $r \in M$, name a distinct set in the partition P'_r . Next, for each $r \in M$, define $P_r = (M \setminus \{r\}) \cup P'_r$, and let $\mathcal{Q}_\ell = \{P_r \mid r \in M\}$.

We now prove that \mathcal{Q}_ℓ indeed satisfies the required properties. First, the number of sets in \mathcal{Q}_ℓ is equal to $|M| = \lceil n_{\ell-1}/2 \rceil + 1$, and the size of each set $P_r \in \mathcal{Q}_\ell$ is

$$|P_r| = |M| - 1 + |P'_r| = \left\lceil \frac{n_{\ell-1}}{2} \right\rceil + \left\lfloor \frac{n_{\ell-1}}{2} \right\rfloor = n_{\ell-1}.$$

For the second property, observe that a point $p \in M$ is not contained in the corresponding set $P_p \in \mathcal{Q}_\ell$, whereas for a point $p \in P'_r$, the only set in \mathcal{Q}_ℓ that contains p is P_r . For the third property, if $p \in M$, define q to be any other point in M , and if $p \in P'_r$, define $q = r$, and check that the property is indeed satisfied. ◀

B Analysis of the Algorithm's Movements

We present the proof of Lemma 5 here, for which we need the following lemma.

► **Lemma 8.** *Let Z_1 and Z_2 be non-negative random variables and E be an event on a common sample space such that $\mathbb{E}[Z_1 \mid E] \geq b$ and $\mathbb{E}[Z_2 \mid \neg E] \geq b$ for some real number b . Then $\mathbb{E}[Z_1 + Z_2] \geq b$.*

Proof. We have,

$$\mathbb{E}[Z_1 + Z_2] = \mathbb{E}[Z_1 + Z_2 \mid E] \cdot \Pr[E] + \mathbb{E}[Z_1 + Z_2 \mid \neg E] \cdot \Pr[\neg E].$$

Since Z_1 and Z_2 are non-negative, we have,

$$\mathbb{E}[Z_1 + Z_2] \geq \mathbb{E}[Z_1 \mid E] \cdot \Pr[E] + \mathbb{E}[Z_2 \mid \neg E] \cdot \Pr[\neg E] \geq b \cdot \Pr[E] + b \cdot \Pr[\neg E] = b,$$

as required. ◀

► **Lemma 5.** *For every $\ell \in \{0, \dots, k-1\}$ the following holds. Let ρ_0 be an arbitrary sequence of requests and L be the set of positions of the algorithm's heaviest $k-\ell$ servers after serving ρ_0 . Let P be an arbitrary set of n_ℓ points disjoint from L . Suppose ρ_0 is followed by a random sequence ρ of requests given by a $\text{strategy}(\ell, P)$ call. For $i = 1, \dots, k$, let the random*

9:10 The Randomized Competitive Ratio of Weighted k -Server Is at Least Exponential

variable X_i denote the number of movements of the algorithm's i 'th lightest server while the algorithm serves ρ . Then we have,

$$\sum_{i=1}^k \beta^{\min(i-1, \ell)} \cdot \mathbb{E}[X_i] \geq (\beta - 1)^\ell.$$

Proof. We prove the claim by induction on ℓ . For the base case, suppose $\ell = 0$. Then $|P| = 1$, and we are assured that L , the set of points occupied by all the algorithm's servers, is disjoint from P . In other words, none of the algorithm's servers occupies the unique point in P . Therefore, to serve the one request given by $\text{strategy}(0, P)$, the algorithm must move at least one of its servers, and thus,

$$\sum_{i=1}^k \beta^{\min(i-1, \ell)} \cdot \mathbb{E}[X_i] = \sum_{i=1}^k \mathbb{E}[X_i] \geq 1 = (\beta - 1)^\ell,$$

as required.

For the inductive case, suppose $\ell > 0$. We are assured that except for the lightest ℓ servers, none of the servers of the algorithm occupies any point in P at the time the $\text{strategy}(\ell, P)$ call is made. This call makes $m = (\beta - 1) \cdot (\lceil n_{\ell-1}/2 \rceil + 1) = (\beta - 1) \cdot |\mathcal{Q}_\ell|$ recursive calls. For $i = 1, \dots, k$ and $j = 1, \dots, m$, let the random variable Y_i^j denote the number of movements of the algorithm's i 'th lightest server to serve requests from the j 'th recursive call. Thus, for all i , $X_i = \sum_{j=1}^m Y_i^j$.

Consider an arbitrary $j \in \{1, \dots, m\}$. Let E_j denote the event that the random variables $Y_i^{j'}$ are all 0 for all $i > \ell$ and $j' < j$. In words, E_j is the event that none of the algorithm's heaviest $k - \ell$ servers moves during the first $j - 1$ recursive calls. Recall that originally these servers did not occupy any point in P . Therefore, if E_j happens, these servers are guaranteed to be out of the set $P' \subseteq P$ on which the j 'th recursive call is made. Next, let E'_j denote the event that the j 'th recursive call is made on a set P' that does not contain the position of the algorithm's ℓ 'th lightest server after the first $j - 1$ recursive calls. Thus, if both E_j and E'_j happen, then P' is disjoint from the set of positions of the algorithm's $k - \ell + 1$ heaviest servers. We can then apply the induction hypothesis to get,

$$\sum_{i=1}^k \beta^{\min(i-1, \ell-1)} \cdot \mathbb{E}[Y_i^j \mid E_j \wedge E'_j] \geq (\beta - 1)^{\ell-1}. \quad (1)$$

Next, let us understand the behavior of the random variables Y_i^j conditioned on E_j only. We have,

$$\mathbb{E}[Y_i^j \mid E_j] \geq \mathbb{E}[Y_i^j \mid E_j \wedge E'_j] \cdot \Pr[E'_j \mid E_j] \geq \frac{\mathbb{E}[Y_i^j \mid E_j \wedge E'_j]}{|\mathcal{Q}_\ell|}. \quad (2)$$

Here, the first inequality holds because Y_i^j is non-negative. The second inequality holds because, by the second property of the set-system \mathcal{Q}_ℓ given by Lemma 4, for every possible history before the j 'th recursive call, \mathcal{Q}_ℓ contains at least one set which does not contain the position of the algorithm's ℓ 'th lightest server. This implies $\Pr[E'_j \mid E_j] \geq 1/|\mathcal{Q}_\ell|$. From Equation 1 and Equation 2, we get,

$$\sum_{i=1}^k \beta^{\min(i-1, \ell-1)} \cdot \mathbb{E}[Y_i^j \mid E_j] \geq \frac{(\beta - 1)^{\ell-1}}{|\mathcal{Q}_\ell|}. \quad (3)$$

By the non-negativity of the random variables $Y_i^{j'}$ and the definition of E_j , we trivially have,

$$\sum_{i=\ell+1}^k \sum_{j'=1}^m \mathbb{E}[Y_i^{j'} \mid \neg E_j] \geq \sum_{i=\ell+1}^k \sum_{j'=1}^{j-1} \mathbb{E}[Y_i^{j'} \mid \neg E_j] \geq 1,$$

and hence,

$$\frac{(\beta-1)^{\ell-1}}{|\mathcal{Q}_\ell|} \cdot \sum_{i=\ell+1}^k \sum_{j'=1}^m \mathbb{E}[Y_i^{j'} \mid \neg E_j] \geq \frac{(\beta-1)^{\ell-1}}{|\mathcal{Q}_\ell|}. \quad (4)$$

From Equation 3 and Equation 4, using Lemma 8, we get,

$$\sum_{i=1}^k \beta^{\min(i-1, \ell-1)} \cdot \mathbb{E}[Y_i^j] + \frac{(\beta-1)^{\ell-1}}{|\mathcal{Q}_\ell|} \cdot \sum_{i=\ell+1}^k \sum_{j'=1}^m \mathbb{E}[Y_i^{j'}] \geq \frac{(\beta-1)^{\ell-1}}{|\mathcal{Q}_\ell|}.$$

The above inequality holds for all $j \in \{1, \dots, m\}$. Summing up over all j and recalling $X_i = \sum_{j=1}^m Y_i^j$, we get,

$$\sum_{i=1}^k \beta^{\min(i-1, \ell-1)} \cdot \mathbb{E}[X_i] + m \cdot \frac{(\beta-1)^{\ell-1}}{|\mathcal{Q}_\ell|} \cdot \sum_{i=\ell+1}^k \mathbb{E}[X_i] \geq m \cdot \frac{(\beta-1)^{\ell-1}}{|\mathcal{Q}_\ell|}.$$

Recall that $m = (\beta-1) \cdot |\mathcal{Q}_\ell|$. Thus,

$$\sum_{i=1}^k \beta^{\min(i-1, \ell-1)} \cdot \mathbb{E}[X_i] + (\beta-1)^\ell \cdot \sum_{i=\ell+1}^k \mathbb{E}[X_i] \geq (\beta-1)^\ell. \quad (5)$$

Finally, note that for $i > \ell$, $\min(i-1, \ell-1) = \ell-1$, and since $\ell \geq 1$, we have $(\beta-1)^\ell \leq \beta^{\ell-1}(\beta-1)$. Therefore, the multiplier of the $\mathbb{E}[X_i]$ term in Equation 5 is bounded as,

$$\beta^{\min(i-1, \ell-1)} + (\beta-1)^\ell \leq \beta^{\ell-1} + \beta^{\ell-1}(\beta-1) = \beta^\ell = \beta^{\min(i-1, \ell)}.$$

On the other hand, for $i \leq \ell$, $\min(i-1, \ell-1) = \min(i-1, \ell)$. Thus, for all $i \in \{1, \dots, k\}$, the multiplier of the $\mathbb{E}[X_i]$ term in Equation 5 is at most $\beta^{\min(i-1, \ell)}$. Since the X_i 's are all non-negative, we get,

$$\sum_{i=1}^k \beta^{\min(i-1, \ell)} \cdot \mathbb{E}[X_i] \geq (\beta-1)^\ell,$$

as required. ◀

Orienting (Hyper)graphs Under Explorable Stochastic Uncertainty

Abstract

Given a hypergraph with uncertain node weights following known probability distributions, we study the problem of querying as few nodes as possible until the identity of a node with minimum weight can be determined for each hyperedge. Querying a node has a cost and reveals the precise weight of the node, drawn from the given probability distribution. Using competitive analysis, we compare the expected query cost of an algorithm with the expected cost of an optimal query set for the given instance. For the general case, we give a polynomial-time $f(\alpha)$ -competitive algorithm, where $f(\alpha) \in [1.618 + \epsilon, 2]$ depends on the approximation ratio α for an underlying vertex cover problem. We also show that no algorithm using a similar approach can be better than 1.5-competitive. Furthermore, we give polynomial-time $4/3$ -competitive algorithms for bipartite graphs with arbitrary query costs and for hypergraphs with a single hyperedge and uniform query costs, with matching lower bounds.

1 Introduction

The research area of explorable uncertainty is concerned with scenarios where parts of the input are initially uncertain, but the precise weight (or value) of an input item can be obtained via a *query*. For example, an uncertain weight may be represented as an interval that is guaranteed to contain the precise weight, but only a query can reveal the precise weight. Adaptive algorithms make queries one by one until they have gathered sufficient information to solve the given problem. The goal is to make as few queries as possible. In most of the previous work on explorable uncertainty, an adversarial model has been studied where an adversary determines the precise weights of the uncertain elements in such a way that the performance of the algorithm, compared to the optimal query set, is as bad as possible. While this model provides worst-case guarantees that hold for every possible instance, it is also very pessimistic because the adversary is free to choose the precise weights arbitrarily. In realistic scenarios, one may often have some information about where in the given interval the precise weight of an uncertain element is likely to lie. This information can be represented as a probability distribution and exploited in order to achieve better performance guarantees.

In this paper, we study the following problem under stochastic uncertainty: Given a family of (not necessarily disjoint) subsets of a set of uncertain elements, determine the element with minimum precise weight in each set, using queries of minimum total cost. Note that we do not necessarily need to obtain the precise minimum weight. We phrase the problem in the language of hypergraphs, where each uncertain element corresponds to a node and each set corresponds to a hyperedge. We call this the *hypergraph orientation* problem, as we can think of orienting each hyperedge towards its minimum-weight vertex. Each node $v \in V$ of a hypergraph $H = (V, E)$ is associated with a known continuous probability distribution¹ d_v over an interval $I_v = (\ell_v, r_v)$ and has query cost c_v . The precise weight of v is drawn independently from d_v and denoted by w_v . We assume that I_v is the minimal interval that contains the support of d_v , i.e., ℓ_v is the largest value satisfying $\mathbb{P}[w_v \leq \ell_v] = 0$ and r_v is the smallest value satisfying $\mathbb{P}[w_v \geq r_v] = 0$. For $S \subseteq V$, we define $c(S) = \sum_{v \in S} c_v$. An algorithm can sequentially make queries to vertices to learn their weights, until it has enough information to identify the minimum-weight vertex of each hyperedge. A query of v reveals its precise weight w_v , which is drawn independently from d_v . If all vertices have the same query cost, we say that the query costs are uniform and assume w.l.o.g. that $c_v = 1$ for all $v \in V$. Otherwise, we speak of arbitrary query costs. The objective of an algorithm is to minimize the expected cost of the queries it makes.

We also consider the special case where we are given a graph $G = (V, E)$ instead of a hypergraph $H = (V, E)$, called the *graph orientation* problem.

As an example consider a multi-national medical company that needs a certain product (say, chemical ingredient, medicine or vaccine) for its operation in each country. The particular products that are available in each country are different due to different approval mechanisms. The task is to find the best product for each country, that is, the best among the approved ones. The quality itself is independent of the country and can be determined by extensive tests in a lab (queries). The set of products available in one country corresponds to a hyperedge, and the problem of identifying the best product in each country is the hypergraph orientation problem.

¹ We assume the distribution is given in such a way that $\mathbb{P}[w_v \in (a, b)]$ can be computed in polynomial time for every $v \in V, a, b \in \mathbb{R}$. For all our algorithms it suffices to be given a probability matrix: rows correspond to vertices v , columns to elementary intervals (t_i, t_{i+1}) , and entries to $\mathbb{P}[w_v \in (t_i, t_{i+1})]$, where $t_1, \dots, t_{2|V|}$ represent the sorted elements of $\{\ell_v, r_v | v \in V\}$.

Our contribution. Our main result (Section 3) is an algorithm for the graph orientation problem with competitive ratio $\frac{1}{2}(\alpha + \sqrt{8 - \alpha(4 - \alpha)})$, assuming we have an α -approximation for the vertex cover problem (which we need to solve on an induced subgraph of the given graph). This factor is always between $\phi \approx 1.618$ (for $\alpha = 1$), and 2 (for $\alpha = 2$). We show that, for the special cases of directing $\mathcal{O}(\log |V|)$ hyperedges and sorting $\mathcal{O}(1)$ sets, the algorithm can be applied with $\alpha = 1$ in polynomial running time. The algorithm has a preprocessing phase in two steps. First, we compute the probability that a vertex is *mandatory*, i.e., that it is part of any feasible solution, and we query all vertices with probability over a certain threshold. The second step uses a LP relaxation of the vertex cover problem to select some further vertices to query. Next, we compute an α -approximation of the vertex cover on a subgraph induced by the preprocessing, and we query the vertices in the given solution. The algorithm finishes with a postprocessing that only queries mandatory intervals. For the analysis, we show two main facts: (1) the expected optimal solution can be bounded by the expected optimal solutions for the subproblems induced by a partition of the vertices; (2) for the subproblem on which we compute a vertex cover, the expected optimal solution can be bounded by applying the König-Egerváry theorem [52] on a particular bipartite graph, in case of uniform costs. When given arbitrary query costs, we show in the full version [6] that we can utilize a technique of *splitting* the vertices in order to obtain a collection of disjoint stars with obvious vertex covers that imply a bound on the expected optimum.

We further show how to generalize the algorithm to hypergraphs. Unfortunately in this case it is $\#P$ -hard to compute the probability of a vertex being mandatory, but we can approximate it by sampling. This yields a randomized algorithm that attains, with high probability, a competitive ratio arbitrarily close to the expression given above for graphs. Here, we need to solve the vertex cover problem on an induced subgraph of an auxiliary graph that contains, for each hyperedge of the given hypergraph, all edges between the node with the leftmost interval and the nodes whose intervals intersect that interval.

We also consider a natural alternative algorithm (Section 4) that starts with a particular vertex cover solution followed by adaptively querying remaining vertices. We prove a competitive ratio of $4/3$ on special cases, namely, for bipartite graphs with arbitrary cost and for a single hyperedge with uniform costs, and complement this by matching lower bounds.

Related work. Graph orientation problems are fundamental in the area of graph theory and combinatorial optimization. In general, graph orientation refers to the task of giving an orientation to edges in an undirected graph such that some given requirement is met. Different types of requirements have been investigated. While Robbins [50] initiated research on connectivity and reachability requirements already in the 1930s, most work is concerned with degree-constraints; cf. overviews given by Schrijver [52, Chap. 61] and Frank [29, Chap. 9].

Our requirement, orienting each edge towards its node with minimum weight, becomes challenging when there is uncertainty in the node weights. While there are different ways of modeling uncertainty in the input data, the model of explorable uncertainty was introduced by Kahan [40]. He considers the task of identifying the minimum element in a set of uncertainty intervals, which is equivalent to orienting a single hyperedge. Unlike in our model, no distributional information is known, and an adversary can choose weights in a worst-case manner from the intervals. Kahan [40] shows that querying the intervals in order of non-decreasing left endpoints requires at most one more query than the optimal query set, thus giving a competitive ratio of 2. Further, he shows that this is best possible in the adversarial model.

Subsequent work addresses finding the k -th smallest value in a set of uncertainty intervals [27,37], caching problems [49], computing a function value [41], and classical combinatorial optimization problems, such as shortest path [26], knapsack [31], scheduling problems [2,3,21], minimum spanning tree and matroids [22,25,28,45,46]. Recent work on sorting elements of a single or multiple non-disjoint sets is particularly relevant as it is a special case of the graph orientation problem [24,38]. For sorting a single set in the adversarial explorable uncertainty model, there is a 2-competitive algorithm and it is best possible, even for arbitrary query costs [38]. The competitive ratio can be improved to 1.5 for uniform query cost by using randomization [38]. Algorithms with limited adaptivity have been proposed in [23].

Although the adversarial model is arguably pessimistic and real-world applications often come with some distributional information, surprisingly little is known on stochastic variants of explorable uncertainty. The only previous work we are aware of is by Chaplick et al. [16], in which they studied stochastic uncertainty for the problem of sorting a given set of uncertain elements, and for the problem of determining the minimum element in a given set of uncertain elements. They showed that the optimal decision tree (i.e., an algorithm that minimizes the expected query cost among all algorithms) for a given instance of the sorting problem can be computed in polynomial time. For the minimum problem, they leave open whether an optimal decision tree can be determined in polynomial time, but give a 1.5-competitive algorithm and an algorithm that guarantees a bound slightly smaller than 1.5 on the expectation of the ratio between the query cost of the algorithm and the optimal query cost. The problem of scheduling with testing [42] is also in the spirit of stochastic explorable uncertainty but less relevant here.

There are many other stochastic problems that take exploration cost into account. Some of the earliest work has studied multi-armed bandits [15,30,54] and Weitzman's Pandora's box problem [55], which are prime examples for analyzing the tradeoff between the cost for exploration and the benefit from exploiting gained information. More recently, query-variants of combinatorial optimization problems received some attention, in general [33,53], and for specific problems such as stochastic knapsack [20,43], orienteering [8,34], matching [5,7,12,13,17], and probing problems [1,35,36]. Typically such work employs a *query-commit* model, meaning that queried elements must be part of the solution, or solution elements are required to be queried. These are quite strong requirements that lead to a different flavor of the cost-benefit tradeoff.

Research involving queries to identify particular graph structures or elements, or queries to verify certain properties, can be found in various flavors. A well-studied problem class is *property testing* [32], and there are many more, see e.g., [4,11,18,44,48,51]. Without describing such problems in detail, we emphasize a fundamental difference to our work. Typically, in these query models, the bounds on the number of queries made by an algorithm are *absolute numbers*, i.e., given as a function of the input size, but independent of the input graph itself and without any comparison to the minimum number of queries needed for the given graph.

2 **Definitions and Preliminary Results**

The hypergraph orientation problem and the graph orientation problem have already been defined in Section 1. In this section we first give additional definitions and discuss how we measure the performance of an algorithm. Then we introduce the concept of mandatory vertices and show how the probability for a vertex to be mandatory can be computed or at least approximated efficiently. We also give a lower bound showing that no algorithm

can achieve competitive ratio better than $\frac{4}{3}$. Next, based on the concept of witness sets, we define the vertex cover instance associated with an instance of our problem and define a class of vertex cover-based algorithms, which includes all the algorithms we propose in this paper. Finally, we characterize the optimal query set for each realization and give lower bounds on the expected optimal query cost, which we will use later in the analysis of our algorithms.

Definitions. To measure the performance of an algorithm, we compare the expected cost of the queries it makes to the expected optimal query cost. Formally, given a realization of the values, we call *feasible query set* a set of vertices to be queried that permits one to identify the minimum-weight vertex in every hyperedge. Note that a query set is feasible if, for each hyperedge, it either queries the node v with minimum weight w_v and all other nodes whose intervals contain w_v , or it does not query the node v with minimum weight but queries all nodes whose intervals overlap I_v , and in addition the precise weights of all those intervals lie to the right of I_v . An *optimal query set* is a feasible query set of minimum query cost. We denote by $\mathbb{E}[\text{OPT}]$ the expected query cost of an optimal query set. Similarly, we denote by $\mathbb{E}[A]$ the expected query cost of the query set queried by an algorithm A . The supremum of $\mathbb{E}[A]/\mathbb{E}[\text{OPT}]$, over all instances of the problem, is called the *competitive ratio* of A . Alternatively, one could compare $\mathbb{E}[A]$ against the cost $\mathbb{E}[A^*]$ of an optimal adaptive algorithm A^* . However, in explorable uncertainty, it is standard to compare against the optimal query set, and, since $\mathbb{E}[\text{OPT}]$ is a lower bound on $\mathbb{E}[A^*]$, all our algorithmic results translate to this alternative setting.

Let $F \in E$ be a hyperedge consisting of vertices v_1, \dots, v_k , indexed in order of non-decreasing left endpoints of the intervals, i.e., $\ell_{v_1} \leq \dots \leq \ell_{v_k}$. We call v_1 the *leftmost* vertex of F . We can assume that $I_{v_1} \cap I_{v_i} \neq \emptyset$ for all $2 \leq i \leq k$, because otherwise the vertex v_i could be removed from the hyperedge F . For the special case of graphs, this means that we assume $I_v \cap I_u \neq \emptyset$ for each $\{u, v\} \in E$, since otherwise we could simply remove the edge.

Mandatory vertices, probability to be mandatory. A vertex v is called *mandatory* if it belongs to every feasible query set for the given realization. For example, if for some edge $\{u, v\}$, vertex u has already been queried and its value w_u belongs to the interval I_v , then v is known to be mandatory. The following lemma was shown in [24] and fully characterizes mandatory vertices.

► **Lemma 2.1.** *A vertex $v \in V$ is mandatory if and only if there is a hyperedge $F \in E$ with $v \in F$ such that either (i) v is a minimum-weight vertex of F and $w_u \in I_v$ for some $u \in F \setminus \{v\}$, or (ii) v is not a minimum-weight vertex of F and $w_u \in I_v$ for the minimum-weight vertex u of F .*

For a hyperedge $F = \{v_1, \dots, v_k\}$, where the vertices are again indexed by non-decreasing left endpoints, it was shown in [16, Section 3] that, if $I_{v_i} \subseteq I_{v_1}$ for some $2 \leq i \leq k$, then v_1 is mandatory for every realization. Thus, every algorithm can iteratively query all such elements in a preprocessing step, without worsening the competitive ratio. In the remainder of the paper, we assume w.l.o.g. that the instance under consideration is already preprocessed.

Similarly, if a hyperedge contains vertices u, v such that v has not been queried yet and is the leftmost vertex, while a query of u has revealed that $w_u \in I_v$, then it follows from Lemma 2.1 that v is mandatory for every realization of the unqueried vertices. The final stage of our algorithms will consist of querying mandatory vertices that are identified by this criterion, until the instance is solved.

We denote by p_v the probability that a vertex v is mandatory. Querying vertices $v \in V$ that have a high probability p_v is a key element of our algorithms. For graphs, p_v is easy to compute as, by Lemma 2.1, v is mandatory iff $w_u \in I_v$ for some neighbor vertex u .

■ **Figure 1** Instance and mandatory probabilities used in the proof of Theorem 2.3.

Hence, $p_v = 1 - \prod_{u:\{u,v\} \in E} \mathbb{P}[w_u \notin I_v]$. For hypergraphs, however, we can show that the computation of p_v is $\#P$ -hard, even if all hyperedges have size 3. Luckily it is not difficult to get a good estimate of the probabilities to be mandatory for hypergraphs using sampling.

► **Lemma 2.2.** *There is a polynomial-time randomized algorithm that, given a hypergraph $H = (V, E)$, a vertex $v \in V$, and parameters $\epsilon, \delta \in (0, 1)$, produces a value y such that $|y - p_v| \geq \epsilon$ with probability at most δ . Its time complexity is $O(|V| \ln(1/\delta)/\epsilon^2)$.*

General lower bound. We have the following lower bound.

► **Theorem 2.3.** *Every algorithm for the graph orientation problem has competitive ratio at least $\frac{4}{3}$, even for uniform query costs and even if no restriction on the running time of the algorithm is imposed.*

Proof. Consider three vertices x, y, z , with $I_x = (0, 2)$ and $I_y = I_z = (1, 3)$, and uniform query costs $c_x = c_y = c_z = 1$. The only edges are $\{x, y\}$ and $\{x, z\}$. The probabilities are such that $\mathbb{P}[w_x \in (1, 2)] = \frac{1}{2}$ and $\mathbb{P}[w_y \in (1, 2)] = \mathbb{P}[w_z \in (1, 2)] = \epsilon$, for some $0 < \epsilon \ll \frac{1}{2}$; see Figure 1. If $w_x \in (0, 1]$, which happens with probability $\frac{1}{2}$, querying x is enough. If $w_x \in (1, 2)$ and $w_y, w_z \in [2, 3]$, which happens with probability $\frac{1}{2}(1 - \epsilon)^2$, querying y and z is enough. Otherwise, all three vertices must be queried. We have

$$\mathbb{E}[\text{OPT}] = \frac{1}{2} \cdot 1 + \frac{1}{2}(1 - \epsilon)^2 \cdot 2 + \frac{1}{2} \left(1 - (1 - \epsilon)^2\right) \cdot 3 = 2 - \frac{(1 - \epsilon)^2}{2},$$

which tends to $\frac{3}{2}$ as ϵ approaches 0. Since y and z are identical and we can assume that an algorithm always queries first a vertex that it knows to be mandatory (if there is one), we only have three possible decision trees to consider:

1. First query x ; if $w_x \in (1, 2)$, then query y and z . The expected query cost is 2.
2. First query y . If $w_y \in (1, 2)$, then query x , and query z if $w_x \in (1, 2)$. If $w_y \in [2, 3]$, then query z , and query x if $w_z \in (1, 2)$. The expected query cost is $1 + \frac{3}{2}\epsilon + (1 - \epsilon)(1 + \epsilon)$, which tends to 2 as ϵ approaches 0.
3. First query y . Whatever happens, query x , then query z if $w_x \in (1, 2)$. The expected query cost is $\frac{5}{2}$, so this is never better than the previous options.

With either choice (even randomized), the competitive ratio tends to at least $\frac{4}{3}$ as $\epsilon \rightarrow 0$. ◀

This lower bound can be adapted for a single hyperedge $\{x, y, z\}$. For arbitrary query costs, it works even for a single edge $\{x, y\}$, by taking $c_x = 1$ and $c_y = 2$.

Witness sets, vertex cover instance, vertex cover-based algorithms. Another key concept of our algorithms is to exploit *witness sets* [14, 25]. A subset $W \subseteq V$ is a *witness set* if $W \cap Q \neq \emptyset$ for all feasible query sets Q . The following lemma was shown in [40].

► **Lemma 2.4.** *Let $F = \{v_1, \dots, v_k\}$ be a hyperedge, and let v_1 be the leftmost vertex of F . Then $\{v_1, v_i\}$ is a witness set for each $2 \leq i \leq k$.*

The lemma implies that one can obtain a 2-competitive algorithm in the adversarial model for the hyperedge orientation problem: For uniform query costs, it suffices to repeatedly query witness sets of size 2 until the instance is solved, by a standard witness set argument [25]. For arbitrary query costs, this approach can be combined with the local ratio technique [9] to obtain the same competitive ratio (in a similar way as done in [38] for the sorting problem). Our goal is to achieve better competitive ratios in the stochastic setting. Motivated by Lemma 2.4, we can now define the *vertex cover instance*.

► **Definition 2.5.** *Given a hypergraph $H = (V, E)$, the vertex cover instance of H is the graph $\bar{G} = (V, \bar{E})$ with $\{v, u\} \in \bar{E}$ if and only if there is a hyperedge $F \in E$ such that $v, u \in F$, v is leftmost in F and $I_v \cap I_u \neq \emptyset$. For the special case of a graph G instead of a hypergraph H , it holds that $\bar{G} = G$.*

Since each edge of the vertex cover instance \bar{G} is a witness set by Lemma 2.4, we can observe that each feasible query set Q is a vertex cover of \bar{G} . Using the vertex cover instance, we can define a class of algorithms for the hypergraph orientation problem as follows: An algorithm is *vertex cover-based* if it implements the following pattern:

1. Non-adaptively query a vertex cover VC of \bar{G} ;
2. Iteratively query mandatory vertices until the minimum-weight vertex of each hyperedge is known: For each hyperedge $F \in E$ for which the minimum weight is still unknown, query the vertices in order of left endpoints until the minimum weight is found.

By definition of the second step, each vertex cover-based algorithm clearly orients each hyperedge. Furthermore, Lemma 2.1 implies that each vertex queried in the last step is indeed mandatory for all realizations that are consistent with the currently known information, i.e., the weights of the previously queried vertices. For graphs, this is easy to see, and for hypergraphs, this can be shown as follows: For a hyperedge F that isn't solved after the first step and has leftmost vertex v initially, the vertex cover VC has queried v or all other vertices of F . In the latter case, v is the only unqueried vertex of F and I_v must contain the precise weight of one of the other vertices, hence v is mandatory. In the former case, the remaining candidates for being the minimum-weight vertex are (1) the vertex with leftmost precise weight among those queried in the first step, and (2) the unqueried vertices whose intervals contain that precise weight. It is then clear that the leftmost vertex is mandatory, and querying it either solves the hyperedge or yields a situation of the same type.

All the algorithms we propose in this paper are vertex cover-based. We have the following lower bounds for vertex cover-based algorithms.

► **Theorem 2.6.** *No vertex cover-based algorithm has competitive ratio better than $\frac{3}{2}$ for the hypergraph orientation problem. This result holds even in the following special cases:*

1. *The graph has only a single hyperedge but the query costs are not uniform.*
2. *The query costs are uniform and the vertex cover instance \bar{G} is bipartite.*
3. *The instance is a non-bipartite graph orientation instance with uniform query costs.*

We remark that the second step of vertex cover-based algorithms must be adaptive: In the full version we show that any algorithm consisting of two non-adaptive stages cannot have competitive ratio $o(\log n)$, even for a single hyperedge with n vertices and uniform query costs.

Bounds on $\mathbb{E}[\text{OPT}]$. Let \mathcal{R} be the set of all possible realizations and let $\text{OPT}(R)$ for $R \in \mathcal{R}$ be the optimal query cost for realization R . As each feasible query set Q must include a vertex cover of \bar{G} , the minimum weight of a vertex cover of \bar{G} (using the query costs as

weights) is a lower bound on the optimal query cost for each realization and, thus, on $\mathbb{E}[\text{OPT}]$. This observation in combination with Lemma 2.1 also gives us a way to identify an optimal query set for a fixed realization, by using the knowledge of the exact vertex weights.

► **Observation 2.7.** *For a fixed realization R of an instance of the hypergraph orientation problem, let M be the set of vertices that are mandatory (cf. Lemma 2.1), and let VC_M be a minimum-weight vertex cover of $\bar{G}[V \setminus M]$. Then $M \cup VC_M$ is an optimal query set for realization R .*

Computing $\text{OPT}(R)$ for a fixed and known realization R is NP-hard [24]. This extends to the hypergraph orientation problem and the computation of $\mathbb{E}[\text{OPT}]$: We can reduce from the problem of computing $\text{OPT}(R)$ by concentrating the probability mass of all intervals onto the weights in realization R . The reduction of [24] in combination with [19] also implies APX-hardness.

To analyze the performance of our algorithms, we compare the expected cost of the algorithms to the expected cost of the optimal solution. By Observation 2.7, $c(M) + c(VC_M)$ is the minimum query cost for a fixed realization R , where $M \subseteq V$ is the set of mandatory elements in the realization and VC_M is a minimum-weight vertex cover for the subgraph $\bar{G}[V \setminus M]$ of the vertex cover instance $\bar{G} = (V, \bar{E})$ induced by $V \setminus M$. Thus, the optimal solution for a fixed realization is completely characterized by the set of mandatory elements in the realization. Using this, we can characterize $\mathbb{E}[\text{OPT}]$ as $\mathbb{E}[\text{OPT}] = \sum_{M \subseteq V} p(M) \cdot c(M) + \sum_{M \subseteq V} p(M) \cdot c(VC_M)$, where $p(M)$ denotes the probability that M is the set of mandatory elements. It follows that $\sum_{M \subseteq V} p(M) \cdot c(M) = \sum_{v \in V} p_v \cdot c(v)$, since both terms describe the expected cost for querying mandatory elements, which leads to the following characterization of $\mathbb{E}[\text{OPT}]$:

$$\mathbb{E}[\text{OPT}] = \sum_{v \in V} p_v \cdot c_v + \sum_{M \subseteq V} p(M) \cdot c(VC_M).$$

A key technique for our analysis is lower bounding $\mathbb{E}[\text{OPT}]$ by partitioning the optimal solution into subproblems and discarding dependencies between elements in different subproblems.

► **Definition 2.8.** *For a realization R and any subset $S \subseteq V$, let $\text{OPT}_S = \min_{Q \in \mathcal{Q}} c(Q \cap S)$, where \mathcal{Q} is the set of all feasible query sets for realization R .*

► **Lemma 2.9.** *Let S_1, \dots, S_k be a partition of V . Then $\mathbb{E}[\text{OPT}] \geq \sum_{i=1}^k \mathbb{E}[\text{OPT}_{S_i}]$.*

Proof. We start the proof by characterizing $\mathbb{E}[\text{OPT}_{S_i}]$ for each $i \in \{1, \dots, k\}$. Let $R \in \mathcal{R}$ be a realization in which M is the set of mandatory elements. Then OPT_{S_i} needs to contain all mandatory elements of S_i , and resolve all remaining dependencies between vertices of S_i , i.e., query a minimum-weight vertex cover $VC_M^{S_i}$ for the subgraph $\bar{G}[S_i \setminus M]$. Thus, it follows

$$\mathbb{E}[\text{OPT}_{S_i}] = \sum_{v \in S_i} p_v \cdot c_v + \sum_{M \subseteq V} p(M) \cdot c(VC_M^{S_i}). \quad (1)$$

By summing Equation (1) over all $i \in \{1, \dots, k\}$, we obtain the lemma:

$$\begin{aligned} \sum_{i=1}^k \mathbb{E}[\text{OPT}_{S_i}] &= \sum_{i=1}^k \left(\sum_{v \in S_i} p_v \cdot c_v + \sum_{M \subseteq V} p(M) \cdot c(VC_M^{S_i}) \right) \\ &= \sum_{v \in V} p_v \cdot c_v + \sum_{M \subseteq V} p(M) \cdot \left(\sum_{i=1}^k c(VC_M^{S_i}) \right) \\ &\leq \sum_{v \in V} p_v \cdot c_v + \sum_{M \subseteq V} p(M) \cdot c(VC_M) = \mathbb{E}[\text{OPT}], \end{aligned}$$

where the second equality follows from S_1, \dots, S_k being a partition. The inequality follows from $\sum_{i=1}^k c(VC_M^{S_i})$ being the cost of a minimum weighted vertex cover for a subgraph of $G[V \setminus M]$, while $c(VC_M)$ is the minimum cost for a vertex cover of the whole graph. ◀

For the case of arbitrary query costs, we will sometimes need to partition V in such a way that a vertex v can be split into fractions that are in different parts of the partition. We view each fraction as a copy of v , and the split is done in such a way that the query costs of all copies of v add up to c_v . Further, the probability distribution for being mandatory in the resulting instance is such that either all copies of v are mandatory or none of them is, and the former happens with probability p_v . (A detailed discussion of this process can be found in the full version.) We refer to the application of this operation to a vertex as a *vertex split* and note that it can be applied repeatedly.

► **Observation 2.10.** *Let OPT' be the optimal solution for an instance that is created by iteratively executing vertex splits. Then, $\mathbb{E}[\text{OPT}'] = \mathbb{E}[\text{OPT}]$. Furthermore, Lemma 2.9 also applies to $\mathbb{E}[\text{OPT}']$ and the modified instance.*

3 A Threshold Algorithm for Orienting Hypergraphs

We present an algorithm for orienting graphs and its generalization to hypergraphs.

3.1 Orienting Graphs

We consider the graph orientation problem. As a subproblem, we solve a vertex cover problem. This problem is NP-hard and 2-approximation algorithms are known [56]. For several special graph classes, there are improved algorithms [39]. Using an α -approximation as a black box, we give a competitive ratio between $\phi \approx 1.618$ ($\alpha = 1$) and 2 ($\alpha = 2$) as a function depending on α .

Algorithm 1 THRESHOLD.

Input: Instance $G = (V, E)$, p_v for each $v \in V$, parameter $d \in [0, 1]$,
and an α -approximation black box for the vertex cover problem

- 1 Let $M = \{v \in V \mid p_v \geq d\}$;
- 2 Solve (LP) for $G[V \setminus M]$ and let x^* be an optimal basic feasible solution;
- 3 Let $V_1 = \{v \in V \mid x_v^* = 1\}$ and similarly $V_{1/2}, V_0$;
- 4 Use the α -approximation black box to approximate a vertex cover VC' for $G[V_{1/2}]$;
- 5 Query $Q = M \cup V_1 \cup VC'$; /* Q is a vertex cover of G */
- 6 Query the mandatory elements of $V \setminus Q$;

10:10 Orienting (Hyper)graphs Under Explorable Stochastic Uncertainty

Algorithm 1 is parameterized by a threshold $d \in [0, 1]$, which is optimized depending on the approximation ratio α of the chosen vertex cover procedure. The algorithm executes a preprocessing of the vertex cover instance by using the following classical LP relaxation, for which each optimal basic feasible solution is half-integral [47]:

$$\begin{aligned} \min \quad & \sum_{v \in V} c_v \cdot x_v \\ \text{s.t.} \quad & x_v + x_u \geq 1 \quad \forall \{u, v\} \in E \\ & x_v \geq 0 \quad \forall v \in V \end{aligned} \tag{LP}$$

► **Theorem 3.1.** *Given an α -approximation with $1 \leq \alpha \leq 2$ for the vertex cover problem (on the induced subgraph $G[V_{1/2}]$, see Line 4), THRESHOLD with parameter d achieves a competitive ratio of $\max\{\frac{1}{d}, \alpha + (2 - \alpha) \cdot d\}$ for the graph orientation problem. Optimizing d yields a competitive ratio of $\frac{1}{2}(\alpha + \sqrt{8 - \alpha(4 - \alpha)})$.*

Proof. Here, we show the result for uniform query costs. The generalization to arbitrary query costs requires an additional technical step involving vertex splitting and is discussed in the full version. Since Q is a vertex cover for G , querying it in Line 5 and resolving all remaining dependencies in Line 6 clearly solves the graph orientation problem. Note that $V \setminus Q$ is an independent set in G , and thus the nodes in $V \setminus Q$ can only be made mandatory by the results of the queries to Q . Hence, it is known after Line 5 which nodes in $V \setminus Q$ are mandatory, and they can be queried in Line 6 in arbitrary order (or in parallel).

We continue by showing the competitive ratio of $\max\{\frac{1}{d}, \alpha + (2 - \alpha) \cdot d\}$. Algebraic transformations show that the optimal choice for the threshold is $d(\alpha) = 2/(\alpha + \sqrt{8 - \alpha(4 - \alpha)})$. The desired competitive ratio for THRESHOLD with $d = d(\alpha)$ follows.

The algorithm queries set Q and all other vertices only if they are mandatory, hence

$$\mathbb{E}[ALG] = |Q| + \sum_{v \in V \setminus Q} p_v = |M| + |V_1| + |VC'| + \sum_{v \in V_0} p_v + \sum_{v \in V_{1/2} \setminus VC'} p_v. \tag{2}$$

The expected optimal cost can be lower bounded by partitioning and Lemma 2.9:

$$\mathbb{E}[\text{OPT}] \geq \mathbb{E}[\text{OPT}_M] + \mathbb{E}[\text{OPT}_{V_1 \cup V_0}] + \mathbb{E}[\text{OPT}_{V_{1/2}}]. \tag{3}$$

In the remainder we compare $\mathbb{E}[ALG]$ with $\mathbb{E}[\text{OPT}]$ component-wise.

We can lower bound $\mathbb{E}[\text{OPT}_M]$ by $\sum_{v \in M} p_v$ using Equation (1). By definition of M , it holds that $\mathbb{E}[\text{OPT}_M] \geq \sum_{v \in M} p_v \geq d \cdot |M|$. Thus,

$$|M| \leq \frac{1}{d} \cdot \mathbb{E}[\text{OPT}_M]. \tag{4}$$

Next, we compare $|V_1| + \sum_{v \in V_0} p_v$ with $\mathbb{E}[\text{OPT}_{V_1 \cup V_0}]$. For this purpose, let $G[V_1 \cup V_0]$ be the subgraph of G induced by $V_1 \cup V_0$, and let $G'[V_1 \cup V_0]$ be the bipartite graph that is created by removing all edges between elements of V_1 from $G[V_1 \cup V_0]$. It follows from similar arguments as in [47, Theorem 2] that V_1 is a minimum vertex cover of $G'[V_1 \cup V_0]$. This allows us to apply the famous König-Egerváry theorem [52]. By the latter there is a matching h mapping each $v \in V_1$ to a distinct $h(v) \in V_0$ with $\{v, h(v)\} \in E$. Denoting $S = \{h(v) \mid v \in V_1\}$, we can infer $\mathbb{E}[\text{OPT}_{V_1 \cup V_0}] \geq \mathbb{E}[\text{OPT}_{V_1 \cup S}] + \mathbb{E}[\text{OPT}_{V_0 \setminus S}]$.

Any feasible solution must query at least one endpoint of all edges of the form $\{v, h(v)\}$. This implies $\mathbb{E}[\text{OPT}_{V_1 \cup S}] \geq |V_1|$. Since additionally $p_{h(v)} \leq d$ for each $h(v) \in S$, we get

$$\sum_{v \in V_1} (1 + p_{h(v)}) \leq (1 + d) \cdot |V_1| \leq (1 + d) \cdot \mathbb{E}[\text{OPT}_{V_1 \cup S}]. \tag{5}$$

By lower bounding $\mathbb{E}[\text{OPT}_{V_0 \setminus S}]$ with $\sum_{v \in V_0 \setminus S} p_v$ and using (5), we get

$$\begin{aligned} |V_1| + \sum_{v \in V_0} p_v &= \sum_{v \in V_1} (1 + p_{h(v)}) + \sum_{v \in V_0 \setminus S} p_v \\ &\leq (1 + d) \cdot \mathbb{E}[\text{OPT}_{V_1 \cup S}] + \mathbb{E}[\text{OPT}_{V_0 \setminus S}] \leq (1 + d) \cdot \mathbb{E}[\text{OPT}_{V_1 \cup V_0}]. \end{aligned} \quad (6)$$

Finally, consider the term $|VC'| + \sum_{v \in V_{1/2} \setminus VC'} p_v$. Let VC^* be a minimum cardinality vertex cover for $G[V_{1/2}]$. Then, it holds $|VC^*| \geq \frac{1}{2} \cdot |V_{1/2}|$. This is, because in the optimal basic feasible solution to the LP relaxation x^* , each vertex in $V_{1/2}$ has a value of $\frac{1}{2}$. A vertex cover with $|VC^*| < \frac{1}{2} \cdot |V_{1/2}|$ would contradict the optimality of x^* . The following part of the analysis crucially relies on $|VC^*| \geq \frac{1}{2} \cdot |V_{1/2}|$, which is the reason why THRESHOLD executes the LP relaxation-based preprocessing before applying the α -approximation.

Now, the expected cost of the algorithm for the subgraph $G[V_{1/2}]$ is $|VC'| + \sum_{v \in I'} p_v \leq |VC'| + d \cdot |I'|$ with $I' = V_{1/2} \setminus VC'$. Since $|VC'| \geq |VC^*| \geq \frac{1}{2} \cdot |V_{1/2}|$, there is a tradeoff between the quality of $|VC'|$ and the additional cost of $d \cdot |I'|$. If $|VC'|$ is close to $\frac{1}{2} \cdot |V_{1/2}|$, then it is close to $|VC^*|$ but, on the other hand, $|I'|$ then is close to $\frac{1}{2} \cdot |V_{1/2}|$, which means that the additional cost $d \cdot |I'|$ is high. Vice versa, if the cost for $|VC'|$ is high because it is larger than $\frac{1}{2} \cdot |V_{1/2}|$, then $|I'|$ is close to zero and the additional cost $d \cdot |I'|$ is low. We exploit this tradeoff and upper bound $\frac{|VC'| + d \cdot |I'|}{|VC^*|}$ in terms of the approximation factor α of the vertex cover approximation. Assume that the approximation factor α is tight, i.e., $|VC'| = \alpha \cdot |VC^*|$. Since $d \leq 1$, this is the worst case for the ratio $\frac{|VC'| + d \cdot |I'|}{|VC^*|}$. (In other words, if the approximation factor was not tight, we could replace α by the approximation factor that is actually achieved and carry out the following calculations with that smaller value of α instead, yielding an even better bound.) Using $|VC'| = \alpha \cdot |VC^*|$ and $|VC^*| \geq \frac{1}{2} \cdot |V_{1/2}|$, we can derive

$$|I'| = |V_{1/2}| - |VC'| = |V_{1/2}| - \alpha \cdot |VC^*| \leq (2 - \alpha) \cdot |VC^*|.$$

For the cost of the algorithm for subgraph $G[V_{1/2}]$ we get

$$|VC'| + d \cdot |I'| \leq \alpha \cdot |VC^*| + d \cdot (2 - \alpha) \cdot |VC^*| = (\alpha + (2 - \alpha) \cdot d) \cdot |VC^*|.$$

Since $|VC^*| \leq \mathbb{E}[\text{OPT}_{V_{1/2}}]$, we get

$$|VC'| + d \cdot |I'| \leq (\alpha + (2 - \alpha) \cdot d) \cdot \mathbb{E}[\text{OPT}_{V_{1/2}}]. \quad (7)$$

Combining Equations (2), (4), (6) and (7), we can upper bound the cost of the algorithm:

$$\begin{aligned} \mathbb{E}[ALG] &= |M| + |V_1| + \sum_{v \in V_0} p_v + |VC'| + \sum_{v \in V_{1/2} \setminus VC'} p_v \\ &\leq \frac{1}{d} \cdot \mathbb{E}[\text{OPT}_M] + (1 + d) \cdot \mathbb{E}[\text{OPT}_{V_1 \cup V_0}] + (\alpha + (2 - \alpha) \cdot d) \cdot \mathbb{E}[\text{OPT}_{V_{1/2}}] \\ &\leq \max \left\{ \frac{1}{d}, (1 + d), (\alpha + (2 - \alpha) \cdot d) \right\} \cdot \mathbb{E}[\text{OPT}], \end{aligned}$$

where the last inequality follows from the lower bound on OPT in (3). Observe that for any $d \in [0, 1]$ and $\alpha \in [1, 2]$, it holds that $(\alpha + (2 - \alpha) \cdot d) \geq (1 + d)$. We conclude with $\mathbb{E}[ALG] \leq \max \left\{ \frac{1}{d}, (\alpha + (2 - \alpha) \cdot d) \right\} \cdot \mathbb{E}[\text{OPT}]$, which implies the theorem. \blacktriangleleft

In the full version of the paper, we show that the analysis of THRESHOLD is tight. To benefit from a better approximation factor than $\alpha = 2$ for solving the minimum vertex cover problem, we would need to know in advance the specialized graph class on which we want to solve this subproblem. In some cases, we can benefit from optimal or approximation algorithms, e.g., using THRESHOLD with the PTAS for planar graphs [10] allows us to achieve a competitive ratio of at most $1.618 + \epsilon$, for any $\epsilon > 0$, if the input graph is planar.

3.2 Orienting Hypergraphs

► **Theorem 3.2.** *Given an α -approximation with $1 \leq \alpha \leq 2$ for the vertex cover problem (on the induced subgraph $\bar{G}[V_{1/2}]$ of the vertex cover instance given by Definition 2.5, cf. Line 4), a modified version of the THRESHOLD algorithm solves the hypergraph orientation problem with arbitrary query costs with competitive ratio $R = \frac{1}{2} \left(\alpha + \sqrt{\alpha^2 + 4(2 - \alpha)(1 + \alpha\epsilon + (2 - \alpha)\epsilon^2)} + (4 - 2\alpha)\epsilon \right)$ with probability at least $1 - \delta$. Its running time is upper bounded by the complexity of the sampling procedure and the vertex cover black box procedure.*

Proof. The modified algorithm works with the vertex cover instance \bar{G} instead of the given hypergraph H , following Definition 2.5. In Line 1, we use $d(\alpha) = 1/R + \epsilon$. In Line 6, we iteratively query mandatory vertices until the instance is solved. In addition, we use a random estimation Y_v of p_v , instead of the precise probability, using the procedure described in Lemma 2.2 with parameters ϵ and δ' such that $1 - \delta = (1 - \delta')^n$. As a result, with probability at least $1 - \delta$ we have that for every vertex v , the estimation Y_v has absolute error at most ϵ . In case of this event we obtain the following bound on the cost (which is optimized for the chosen value of d), namely $\mathbb{E}[\text{ALG}] \leq \max\{\frac{1}{d-\epsilon}, (1+d+\epsilon), (\alpha+(2-\alpha)(d+\epsilon))\} \cdot \mathbb{E}[\text{OPT}]$. ◀

Sorting a set of elements is equivalent to determining, for each pair of elements, which of the two has smaller weight. Hence, the problem of sorting multiple sets of elements with uncertain weights is a special case of the graph orientation problem: For each set to be sorted, the edge set of a complete graph on its elements is added to a graph, and the resulting instance of the graph orientation problem is then equivalent to the given instance of the sorting problem. We can show the following theorem.

► **Theorem 3.3.** *For the special cases of orienting $\mathcal{O}(\log |V|)$ hyperedges and sorting $\mathcal{O}(1)$ sets, THRESHOLD can be applied with $\alpha = 1$ in polynomial running time.*

4 Vertex Cover-Based Algorithms: Improved Results for Special Cases

Consider an arbitrary vertex cover-based algorithm ALG. It queries a vertex cover VC in the first stage, and continues with elements of $V \setminus VC$ if they are mandatory. Thus,

$$\begin{aligned} \mathbb{E}[\text{ALG}] &= c(VC) + \sum_{v \in V \setminus VC} p_v \cdot c_v = \sum_{v \in VC} (p_v \cdot c_v + (1 - p_v) \cdot c_v) + \sum_{v \in V \setminus VC} p_v \cdot c_v \\ &= \sum_{v \in V} p_v \cdot c_v + \sum_{v \in VC} (1 - p_v) \cdot c_v. \end{aligned}$$

Since the first term is independent of VC , ALG is the best possible vertex cover-based algorithm if it minimizes $\sum_{v \in VC} (1 - p_v) \cdot c_v$. We refer to this algorithm as BESTVC.

To implement BESTVC, we need the exact value p_v , for all $v \in V$, and an optimal algorithm for computing a weighted vertex cover. As mentioned in Section 2, the first problem is #P-hard in hypergraphs, but it can be solved exactly in polynomial time for graphs. The weighted vertex cover problem can be solved optimally in polynomial time for bipartite graphs.

In general, BESTVC has competitive ratio at least 1.5 (Theorem 2.6). However, we show in the following that it is $4/3$ -competitive for two special cases. It remains open whether BESTVC still outperforms THRESHOLD if the vertex cover is only approximated with a factor $\alpha > 1$.

4.1 A Best Possible Algorithm for Orienting Bipartite Graphs

► **Theorem 4.1.** *BESTVC is $\frac{4}{3}$ -competitive for the bipartite graph orientation problem.*

Proof. In the full version of the paper, we show that BESTVC is $\frac{4}{3}$ -competitive for the problem of orienting stars if both vertex cover-based algorithms (either querying the leaves or the center first) have the same expected cost. In this proof, we divide the instance into subproblems that fulfill these requirements, and use the result for stars to infer $\frac{4}{3}$ -competitiveness for bipartite graphs.

Let VC be a minimum-weight vertex cover (with weights $c_v \cdot (1 - p_v)$) as computed by BESTVC in the first phase. By the König-Egerváry theorem (e.g., [52]), there is a function $\pi : E \rightarrow \mathbb{R}$ with $\sum_{\{u,v\} \in E} \pi(u,v) \leq c_v \cdot (1 - p_v)$ for each $v \in V$. By duality theory, the constraint is tight for each $v \in VC$, and $\pi(u,v) = 0$ holds if both u and v are in VC . Thus, we can interpret π as a function that distributes the weight of each $v \in VC$ to its neighbors outside of VC .

For each $v \in VC$ and $u \in V \setminus VC$, let $\lambda_{u,v} := \frac{\pi(u,v)}{(1-p_u) \cdot c_u}$ denote the fraction of the weight of u that is used by π to cover the weight of v . Moreover, for $u \in V \setminus VC$, let $\tau_u := 1 - \sum_{\{u,v\} \in E} \lambda_{u,v}$ be the fraction of the weight of u that is not used by π to cover the weight of any $v \in VC$. Then, we can write the expected cost of BESTVC as follows:

$$\mathbb{E}[\text{BESTVC}] = \sum_{v \in VC} \left(c_v + \sum_{u \in V \setminus VC} p_u \cdot \lambda_{u,v} \cdot c_u \right) + \sum_{u \in V \setminus VC} p_u \cdot \tau_u \cdot c_u. \quad (8)$$

Using Observation 2.10, we compare $\mathbb{E}[\text{BESTVC}]$ with the expected optimum $\mathbb{E}[\text{OPT}']$ for an instance $G' = (V', E', c')$ that is created by splitting vertices. We modify the mandatory distribution as in Section 2, which implies $\mathbb{E}[\text{OPT}] = \mathbb{E}[\text{OPT}']$. We add the following copies:

1. For each $v \in VC$, we add a copy v' of v to V' with $c'_{v'} = c_v$.
2. For all $u \in V \setminus VC$ and $v \in VC$ with $\lambda_{u,v} > 0$, we add a copy u'_v of u to V' with $c'_{u'_v} = \lambda_{u,v} \cdot c_u$.
3. For each $u \in V \setminus VC$ with $\tau_u > 0$, we add a copy u' of u to V' with $c'_{u'} = \tau_u \cdot c_u$.

Let p'_v denote the probability of v being mandatory for instance G' . By definition of the vertex split operation, we have $p_v = p'_u$ for each $v \in V$ and each copy $u \in V'$ of v . Further, for each $v \in VC$, define $H'_v = \{u'_v \mid u \in V \text{ with } \lambda_{u,v} > 0\}$. By definition of H'_v and G' , all H'_v are pairwise disjoint. Let $\mathcal{H}' = \bigcup_{v \in VC} (H'_v \cup \{v'\})$; then we can express $\mathbb{E}[\text{BESTVC}]$ as follows:

$$\begin{aligned} \mathbb{E}[\text{BESTVC}] &= \sum_{v \in VC} \left(c_v + \sum_{u \in V \setminus VC} p_u \cdot \lambda_{u,v} \cdot c_u \right) + \sum_{u \in V \setminus VC} p_u \cdot \tau_u \cdot c_u \\ &= \sum_{v \in VC} \left(c'_{v'} + \sum_{u \in H'_v} p'_u \cdot c'_u \right) + \sum_{u \in V' \setminus \mathcal{H}'} p'_u \cdot c'_u. \end{aligned}$$

Similarly, we can lower bound $\mathbb{E}[\text{OPT}']$ using Lemma 2.9:

$$\mathbb{E}[\text{OPT}'] \geq \sum_{v \in VC} \mathbb{E}[\text{OPT}'_{H'_v \cup \{v'\}}] + \sum_{u \in V' \setminus \mathcal{H}'} \mathbb{E}[\text{OPT}'_{\{u\}}] \geq \sum_{v \in VC} \mathbb{E}[\text{OPT}'_{H'_v \cup \{v'\}}] + \sum_{u \in V' \setminus \mathcal{H}'} p'_u \cdot c'_u. \quad (9)$$

Since the term $\sum_{u \in V' \setminus \mathcal{H}'} p'_u \cdot c'_u$ shows up in both inequalities, it remains, for each $v \in VC$, to bound $c'_{v'} + \sum_{u \in H'_v} p'_u \cdot c'_u$ in terms of $\mathbb{E}[\text{OPT}'_{H'_v \cup \{v'\}}]$. By definition of H'_v , we have $(1 - p'_{v'}) \cdot c'_{v'} = \sum_{u \in H'_v} (1 - p'_u) \cdot c'_u$, which implies

$$c'_{v'} + \sum_{u \in H'_v} p'_u \cdot c'_u = p'_{v'} \cdot c'_{v'} + \sum_{u \in H'_v} c'_u. \quad (10)$$

The value $\mathbb{E}[\text{OPT}'_{H'_v \cup \{v'\}}]$ corresponds to the expected optimum for the subproblem which considers the subgraph induced by $H'_v \cup \{v'\}$ (which is a star), uses p'_u as the mandatory probability for each $u \in H'_v \cup \{v'\}$, and uses c'_u as the query cost of each $u \in H'_v \cup \{v'\}$. For this subproblem, $c'_{v'} + \sum_{u \in H'_v} p'_u \cdot c'_u$ corresponds to the expected cost of the vertex cover-based algorithm that queries vertex cover $\{v'\}$ in the first stage. Furthermore, $p'_{v'} \cdot c'_{v'} + \sum_{u \in H'_v} c'_u$ corresponds to the expected cost of the vertex-cover based algorithm that queries vertex cover H'_v in the first stage. In summary, we have a star orientation subproblem for which both vertex cover-based algorithms (querying the leaves or the center first) have the same expected cost (cf. Equation (10)). As a major technical step, we show that BESTVC is $\frac{4}{3}$ -competitive for such subproblems, which implies

$$c'_{v'} + \sum_{u \in H'_v} p'_u \cdot c'_u \leq \frac{4}{3} \cdot \mathbb{E}[\text{OPT}'_{H'_v \cup \{v'\}}].$$

A corresponding lemma is proven in the full version. We remark that the lemma requires $p'_{v'}$ to be independent of each p'_u with $u \in H'_v$; otherwise the subproblem does not correspond to the star orientation problem. As the input graph is bipartite, such independence follows by definition.

Using this inequality and Equation (9), we conclude that BESTVC is $4/3$ -competitive.

$$\begin{aligned} \mathbb{E}[\text{BESTVC}] &= \sum_{v \in VC} \left(c'_{v'} + \sum_{u \in H'_v} p'_u \cdot c'_u \right) + \sum_{u \in V' \setminus \mathcal{H}'} p'_u \cdot c'_u \\ &\leq \frac{4}{3} \cdot \sum_{v \in VC} \mathbb{E}[\text{OPT}'_{H'_v \cup \{v'\}}] + \sum_{u \in V' \setminus \mathcal{H}'} p'_u \cdot c'_u \leq \frac{4}{3} \cdot \mathbb{E}[\text{OPT}'] = \frac{4}{3} \cdot \mathbb{E}[\text{OPT}] \blacktriangleleft \end{aligned}$$

4.2 An Almost Best Possible Algorithm for Orienting a Hyperedge

► **Theorem 4.2.** *BESTVC has a competitive ratio at most $\min\{\frac{4}{3}, \frac{n+1}{n}\}$ for the hypergraph orientation problem on a single hyperedge with $n \geq 2$ vertices and uniform query costs. For a hyperedge with only two vertices, the algorithm is 1.207-competitive.*

Our analysis improves upon a $(n+1)/n$ -competitive algorithm by Chaplick et al. [16] in case that the hyperedge has two or three vertices. Moreover, we show that this is near-optimal: It is not hard to show a matching lower bound for two vertices and, due to Theorem 2.3 and the theorem below, this is the best possible for three vertices, and in general the difference between the upper and lower bounds is less than 4%.

► **Theorem 4.3.** *Any algorithm for orienting a single hyperedge with $n+1 \geq 2$ vertices has competitive ratio at least $n^2/(n^2 - n + 1)$, even for uniform query costs.*

Note that Theorem 4.2 is in contrast to the problem of orienting a hyperedge with arbitrary query costs: In this setting, [16] showed that the algorithm is 1.5-competitive, which matches the corresponding lower bound for vertex cover-based algorithms of Theorem 2.6.

5 Conclusion

In this paper, we present algorithms for the (hyper)graph orientation problem under stochastic explorable uncertainty. It remains open to determine the competitive ratio of BESTVC for the general (hyper)graph orientation problem, and to investigate how the algorithm behaves if it has to rely on an α -approximation to solve the vertex cover subproblem. In

this context, one can consider the resulting algorithm as a standalone algorithm, or as a subroutine for THRESHOLD. Our analysis suggests that, to achieve a competitive ratio better than 1.5, algorithms have to employ more adaptivity; exploiting this possibility remains an open problem. Finally, it would be interesting to characterize the vertex cover instances arising in our THRESHOLD algorithm. In addition to the relevance from a combinatorial point of view, such a characterization may allow an improved α -approximation algorithm for those instances.

Abstract

Unlike the problem of deciding whether a digraph $D = (V, A)$ has ℓ in-branchings (or ℓ out-branchings) is polynomial time solvable, the problem of deciding whether a digraph $D = (V, A)$ has an in-branching B^- and an out-branching B^+ which are arc-disjoint is NP-complete. Motivated by this, a natural optimization question that has been studied in the realm of Parameterized Complexity is called ROOTED k -DISTINCT BRANCHINGS. In this problem, a digraph $D = (V, A)$ with two prescribed vertices s, t are given as input and the question is whether D has an in-branching rooted at t and an out-branching rooted at s such that they differ on at least k arcs. Bang-Jensen et al. [Algorithmica, 2016] showed that the problem is fixed parameter tractable (FPT) on strongly connected digraphs. Gutin et al. [ICALP, 2017; JCSS, 2018] completely resolved this problem by designing an algorithm with running time $2^{\mathcal{O}(k^2 \log^2 k)} n^{\mathcal{O}(1)}$. Here, n denotes the number of vertices of the input digraph. In this paper, answering an open question of Gutin et al., we design a polynomial kernel for ROOTED k -DISTINCT BRANCHINGS. In particular, we obtain the following: Given an instance (D, k, s, t) of ROOTED k -DISTINCT BRANCHINGS, in polynomial time we obtain an equivalent instance (D', k', s, t) of ROOTED k -DISTINCT BRANCHINGS such that $|V(D')| \leq \mathcal{O}(k^2)$ and the treewidth of the underlying undirected graph is at most $\mathcal{O}(k)$. This result immediately yields an FPT algorithm with running time $2^{\mathcal{O}(k \log k)} + n^{\mathcal{O}(1)}$; improving upon the previous running time of Gutin et al. For our algorithms, we prove a structural result about paths avoiding many arcs in a given in-branching or out-branching. This result might turn out to be useful for getting other results for problems concerning in-and out-branchings.

1 Introduction

Let $D = (V, A)$ be a digraph and r be a vertex of D . An *out-branching* (respectively, *in-branching*) in D is a connected spanning subdigraph B_r^+ (respectively, B_r^-) of D in which each vertex $v \neq r$ has precisely one entering (respectively, leaving) arc and r has no entering (respectively, leaving) arc. The vertex r is called the *root* of B_r^+ (respectively, B_r^-). The study of finding a spanning tree in an undirected graph or an out-branching in a digraph satisfying specific properties, such as having at least k leaves, or having at least k internal vertices [1, 4, 7, 10, 11, 13, 14, 18, 19, 22] has been at the forefront of research in parameterized algorithms. This paper aims to study a problem of finding an in-branching and an out-branching, in the given digraph, whose arc sets is disjoint on at least k arcs, in the realm of Kernelization Complexity [21] and Parameterized Complexity [12, 15, 17, 24].

A parameterized problem Π is said to admit a *kernel* if there is a polynomial-time algorithm, called a *kernelization algorithm*, that reduces the input instance of Π down to an equivalent instance of Π whose size is bounded by a function $f(k)$ of k . (Here, two instances

are equivalent if both of them are either yes-instances or no-instances.) Such an algorithm is called an $f(k)$ -kernel for Π . If $f(k)$ is a polynomial function of k , we say that the kernel is a *polynomial kernel*. See [12, 15, 17, 21, 24] for more details.

In studying problems around finding edge-disjoint spanning trees, arc-disjoint in-branchings, or arc-disjoint in-branchings, one of the most important results is due to Edmonds. This classical result states that given a digraph D and a positive integer ℓ , we can test whether D contains ℓ arc-disjoint out-branchings in polynomial time [16]. In contrast to this, Thomassen proved that the problem of deciding whether a digraph contains an out-branching B_s^+ and an in-branching B_t^- which are arc-disjoint is **NP**-complete, even if $s = t$ (the proof is published in [2]). The problem remains **NP**-complete even for 2-regular digraphs [5] but it is polynomial time solvable on tournaments [2], locally semicomplete digraphs [3] and acyclic digraphs [6, 9]. In fact, even deciding whether a digraph D contains an out-branching which is arc-disjoint from some spanning tree in the underlying undirected graph remains **NP**-complete [8].

In this paper, we consider the following parameterized version of the arc-disjoint in- and out-branching problem by using a parameter k to measure how distinct a given pair B_s^+, B_t^- are, where the measure is in terms of the number of arcs that belongs to B_s^+ but not to B_t^- . In particular, we study the following problem.

ROOTED k -DISTINCT BRANCHINGS (R- k -DB)

Parameter: k

Input: A digraph $D = (V, A)$, two fixed vertices $s, t \in V$ and an integer k .

Question: Does there exist an out-branching B_s^+ and an in-branching B_t^- such that $|A(B_s^+) \setminus A(B_t^-)| \geq k$?

Observe that the problem is **NP**-complete since it contains the arc-disjoint in- and out-branching question as to the particular case when k is the number of vertices minus one.

Context of our Study. The problem R- k -DB has a rich history in the realm of Parameterized Complexity. Bang-Jensen and Yeo [7] asked whether the problem would be **FPT** when $s = t$. Answering this question in the affirmative, Bang-Jensen et al. [4] showed that the problem is **FPT** when the input is a strongly connected digraph and asked *whether the problem is FPT on general digraphs*. This was confirmed in affirmative by Gutin et al. [22], who showed that the problem is solvable in time $2^{\mathcal{O}(k^2 \log^2 k)} n^{\mathcal{O}(1)}$ time. A natural follow up question that they ask is: *Does R- k -DB admits a polynomial sized kernel?* This open question is the starting point of our work.

Our Results and Methods. We design a polynomial kernel for R- k -DB.

► **Theorem 1.1.** *R- k -DB admits a polynomial kernel with $\mathcal{O}(k^2)$ vertices.*

A key ingredient in the work of Gutin et al. [22] is out-branchings with many leaves. A vertex v is a leaf in the out-branching B_s^+ if no arc is leaving v in B_s^+ . If the input (D, s, t, k) to the R- k -DB problem is such that D has an out-branching B_s^+ with at least $k + 1$ leaves, then (D, s, t, k) is a “yes”-instance since every in-branching B_t^- will have the property that no arc of B_t^- which leaves a vertex in L will be contained in B_s^+ , where L is the set of leaves of B_s^+ . It was shown in [13, 23] that the problem (parameterized by p) of deciding the existence of an out-branching with at least p leaves is **FPT**. Furthermore, if the input is strongly connected and has no out-branching B_s^+ with at least $k + 1$ leaves, then it has pathwidth

$\mathcal{O}(k \log k)$ and now a result from [4] implies that the ROOTED k -DISTINCT BRANCHINGS problem is FPT for strongly connected digraphs. When the input is not strongly connected, the case is considerably more complicated to handle when following the approach used in [22]. Indeed, the result of Gutin et al. [22] could be viewed as an algorithm that obtains an equivalent instance with treewidth of the underlying graph bounded by $k^{\mathcal{O}(1)}$. Our approach is very different, as we bound the size rather than a structural property.

We use a fundamentally different approach, based on a structural analysis of paths avoiding many arcs of a fixed out-branching, to prove an $\mathcal{O}(k^2)$ -vertex kernel for the R- k -DB problem. In the whole analysis, we work with a fixed out-branching and see how an in-branching can be built that avoids as many arcs of the given out-branching. In a step-by-step procedure, we either obtain reduction rules to reduce our input or at the end, we do get an in-branching and an out-branching that avoids k -arcs of each other. Finally, we argue that the instance on which none of the reduction rules can be applied has at most $\mathcal{O}(k^2)$ vertices.

We further look into our kernel and try to bound the treewidth of the underlying undirected graph. In particular, given an instance (D, k, s, t) of R- k -DB, in polynomial time we obtain an equivalent instance (D', k', s, t) of R- k -DB such that $|V(D')| \leq \mathcal{O}(k^2)$ and the treewidth of the underlying undirected graph is at most $\mathcal{O}(k)$. This result yields the FPT algorithm by a standard dynamic programming approach over graphs of bounded treewidth.

► **Theorem 1.2** (\star).¹ *R- k -DB admits an algorithm with running time $2^{\mathcal{O}(k \log k)} + n^{\mathcal{O}(1)}$.*

The running time obtained in Theorem 1.2 improves upon the running time of Gutin et al. [22]. We conclude by saying that the structural result on so-called *substitute paths of an out-branching* might be of independent interest and could find further applications.

2 Notation and Preliminaries

Given a digraph $D = (V, A)$, we also use $V(D)$ and $A(D)$ to denote the vertex set and the arc set of D , respectively. If it is clear from the context we simply use V and A , respectively. Given a digraph $D = (V, A)$ and an arc $a = (u, v) \in A$ we call u the *tail* of a and v the *head* of a . The vertices u and v are the *endpoints* of a . For a set of arcs $A' \subseteq A$ the *set of heads* denoted $\mathcal{H}(A')$ is the set of heads of the arcs in A' . That is, $\mathcal{H}(A') = \{h \mid (t, h) \in A' \text{ for some } h, t \in V\}$. Similarly, we have the *set of tails* denoted $\mathcal{T}(A')$, which is defined as follows: $\mathcal{T}(A') = \{t \mid (t, h) \in A' \text{ for some } h, t \in V\}$. In a digraph D we will denote a path from u to v as $P_{u,v}$. By $P_{u,v}[x, y]$ we will denote the subpath of $P_{u,v}$ which goes from x to y . We will denote the path $P_{u,v}[x, y] - \{y\}$ as $P_{u,v}[x, y[$ and the path $P_{u,v}[x, y] - \{x\}$ as $P_{u,v}[x, y]$. Given a path $P_{u,v}$ and $P_{v,z}$ we will describe the concatenation of the paths $P_{u,v}$ and $P_{v,z}$ as $P_{u,z} = P_{u,v}P_{v,z}$. For a vertex $u \in V(D)$ and an arc $(u, v) \in A(D)$ we will often use the notation $u \in D$ and $(u, v) \in D$ respectively. For a vertex $v \in V(D)$ we denote the out-neighbors of v as $N^+(v)$ and the in-neighbors as $N^-(v)$. An out-branching with a root $r \in V$ is denoted B_r^+ . For a vertex $u \in V(B_r^+)$ we say that v is *parent* of u if $(v, u) \in A(B_r^+)$. To indicate that v is parent of u we use the notation $v = \mathcal{P}_{B_r^+}(u)$. We denote the directed path from u to v in B_r^+ as $B_r^+[u, v]$ and we say that u is *ancestor* to v in B_r^+ if the path $B_r^+[u, v]$ exists. An in-branching with a root $r \in V$ is denoted B_r^- . For a vertex $u \in V(B_r^-)$ we say that v is *parent* of u if $(u, v) \in A(B_r^-)$. To indicate this we use the notation $v = \mathcal{P}_{B_r^-}(u)$. We denote the directed path from u to v in B_r^- as $B_r^-[u, v]$ and we say that u is *ancestor* to v in B_r^- if the path $B_r^-[u, v]$ exists.

¹ Proofs labeled with \star is not included in this version.

3 Backward Arcs, Crossing Arcs and Substitute-paths

In this section we initiate our structural analysis of substitute paths. Given an out-branching B_r^+ in a digraph $D = (V, A)$, we will work with the arcs in $A(D) \setminus A(B_r^+)$. We therefore divide these arcs into backward and crossing arcs.

► **Definition 1.** *Given an out-branching B_r^+ in a digraph $D = (V, A)$ an arc $(u, v) \in A(D) \setminus A(B_r^+)$ is **backward**, if the path $B_r^+[v, u]$ exists, and **crossing**, if it is not backward.*

In an out-branching B_r^+ the arc $(u, v) \in A$ is backward if and only if v is an ancestor of u . We say that a backward arc (u, v) for B_r^+ **goes over** a vertex p if $p \in B_r^+[v, u]$. It means that a backward arc $(u, v) \in B_r^+$ always goes over u . Figure 1 shows an out-branching B_r^+ together with crossing and backward arcs in B_r^+ .

■ **Figure 1** The figure shows $D = (V, A)$. An out-branching B_r^+ is shown in black, the crossing arcs for B_r^+ are shown in green, and the backwards arcs are shown in blue.

► **Definition 2.** *For an out-branching B_r^+ in a digraph D a backward arc (u, v) is **irrelevant** with respect to B_r^+ if and only if every path from r to u in D contains v . A backward arc which is not irrelevant is **relevant**.*

Definition 2 implies the following.

► **Observation 3.** *An arc a is irrelevant wrt² some out-branching B_r^+ if and only if a is not contained in any out-branching B_r^{*+} , that is, a is irrelevant in any out-branching B_r^{*+} .*

In the rest of this section we consider a fixed out-branching B_r^+ , unless stated otherwise.

► **Lemma 3.1.** *It is possible to find the set of all relevant arcs and the set of all irrelevant arcs for B_r^+ in polynomial time.*

Proof. For any arc $(u, v) \in A(D) \setminus A(B_r^+)$ it can clearly be determined in linear time if the path $B_r^+[v, u]$ exists and, therefore, whether the arc is backward. For every backward arc $(u, v) \in A(D)$ we can also determine in polynomial time if there exists a path $P_{r,u}$ in D which does not contain v , e.g., by determine if a (r, u) -path exists in $D - \{v\}$. ◀

Given the set of relevant arcs wrt B_r^+ in D we can now define the following relation between the relevant arcs and a vertex $u \in V$.

► **Definition 4.** *Let $R(u)$ be the set of those relevant arcs wrt B_r^+ which go over u . The **joint relevant arc set** for u is (recursively) defined as the arc set $J(u) = R(u) \cup \left(\bigcup_{h \in \mathcal{H}(R(u))} J(h) \right)$.*

² We use wrt for an abbreviation of “with respect to”.

Hence for every vertex $u \in B_r^+$ the joint relevant arc set for u is defined recursively as the union of $R(u)$ and the joint relevant arc sets of all the heads of $R(u)$. Figure 2 shows a joint relevant arc set of a vertex v in a out-branching B_r^+ . For notational purpose we let $H(u)$ denote the set $\mathcal{H}(J(u))$.

■ **Figure 2** The Figure shows D . $A(B_r^+)$ is shown in yellow and $J(v)$ is shown in blue.

► **Lemma 3.2.** *For every vertex $u \in V$ such that $\mathcal{H}(u) \neq \emptyset$, it holds that for the last vertex x on $B_r^+[r, u]$ which is also in $\mathcal{H}(u)$ we have $\mathcal{H}(x) = \mathcal{H}(u) - \{x\}$.*

In Figure 2 we have $\mathcal{H}(v) = \{h_1, h_2, h_3, h_4\}$. Lemma 3.2 means that $\mathcal{H}(h_4) = \{h_1, h_2, h_3\}$. The following is the proof for Lemma 3.2.

Proof. Let $u \in V$ be a vertex such that $\mathcal{H}(u) \neq \emptyset$ and let $l = |\mathcal{H}(u)|$. Observe that for every $h \in \mathcal{H}(u)$ it holds that $h \in B_r^+[r, u]$. Now name the vertices in $\mathcal{H}(u)$ as h_1, h_2, \dots, h_l such that h_j comes before h_i on $B_r^+[r, u]$ if $j < i$. Let i be an integer in the range $[1, l-1]$. Since $h_i \in \mathcal{H}(u)$ it holds that there exists a relevant arc (t, h_i) which goes over either u or a head $h_p \in \mathcal{H}(u)$ where $i < p \leq l$. Observe that $h_{i+1} \in B_r^+[h_i, u]$ and $h_{i+1} \in B_r^+[h_i, h_j]$ for $j > i$. Hence (t, h_i) goes over h_{i+1} . Therefore, $h_i \in \mathcal{H}(h_{i+1})$. By induction it means that for $i > 0$ we have $\{h_1, h_2, \dots, h_{i-1}\} \subseteq \mathcal{H}(h_i)$. Now observe that no backward arc with the head h_j for $j \geq i$ can go over h_i as $h_j \in B_r^+[h_i, u]$. Hence $\{h_i, h_{i+1}, \dots, h_l\} \cap \mathcal{H}(h_i) = \emptyset$. As $h_i \in \mathcal{H}(u)$ we have that $J(h_i) \subseteq J(u)$. Hence $\mathcal{H}(h_i) \subseteq \mathcal{H}(u)$. As a result $\mathcal{H}(h_i) = \{h_1, h_2, \dots, h_{i-1}\}$. For $i = l$ we therefore have that $\mathcal{H}(h_l) = \{h_1, h_2, \dots, h_{l-1}\} = \mathcal{H}(u) - \{h_l\}$. ◀

► **Lemma 3.3.** *Let C be the set of crossing arcs wrt. to B_r^+ . Then for every $v \in V$ we have $H(v) \subseteq H(u)$ for some arc $(w, u) \in C$, where it is possible that $v = u$.*

Proof. Assume for contradiction that there exists a vertex $x \in V$ such that $H(x) \not\subseteq H(u)$ for every arc $(v, u) \in C$ where we set $H(u) = \emptyset$ if $C = \emptyset$. Among all such vertices choose x such that $|H(x)|$ is maximized. Recall that for every $h \in H(x)$ we have $h \in B_r^+[r, x]$. Now let h be the last vertex on $B_r^+[r, x]$ which is also in $H(x)$. Observe $h \in H(x)$ and there are no vertices in $B_r^+[h, x] \cap H(x)$. Therefore, there must exist an arc $(t, h) \in R(x)$ which goes over x , and since it is relevant there is a path $P_{r,t}$ in D which does not contain h . As a consequence, there is an arc $(p, q) \in P_{r,t}$ which is either a backward arc or a crossing arc such that its head is in $P_{r,t} \cap B_r^+[h, t]$. Figure 3 shows two possible situations where the arc (p, q) is contained in $P_{r,t}$.

■ **Figure 3** In the top left of the Figure a possible section of B_r^+ is shown in black. In the top right, the path $P_{r,t}$ is shown in blue and the arc (t, h) is shown in gray. The bottom left figure shows another possible section of B_r^+ and the bottom right figure shows the path $P_{r,t}$ in blue and the arc (t, h) in gray.

Observe that since $q \in B_r^+[h, t]$ the arc (t, h) goes over q , implying that $h \in H(q)$ and therefore $\{h\} \cup H(h) \subseteq H(q)$. From Lemma 3.2 we have that $H(h) = H(x) - \{h\}$. Hence $H(x) \subseteq H(q)$. As we have assumed for contradiction that there is no crossing arc (v, u) such that $H(x) \not\subseteq H(u)$ it follows that the arc (p, q) can not be crossing. Hence the arc (p, q) must be backward. Since $(p, q) \in P_{r,t}$ the path $P_{r,t}[r, p]$ does not contain q and, therefore, (p, q) is relevant. Thus $(p, q) \in R(p)$ and $q \in H(p)$. We therefore have that $\{q\} \cup H(q) \subseteq H(p)$. Hence $\{q\} \cup H(x) \subseteq H(p)$. But it means that $|H(x)| < |H(p)|$ which contradicts that x was chosen such that $|H(x)| \geq |H(p)|$. ◀

3.1 Existence of Substitute-path for the Out-branching B_r^+

Now we define a substitute-path for the out-branching B_r^+ in the digraph $D = (V, A)$.

► **Definition 5.** Let u be a vertex in B_r^+ , then a **substitute-path** is a path $S_{r,u}$ from r to u in D such that

$$|J(u) \cap A(S_{r,u})| + |H(u) \setminus V(S_{r,u})| \geq \left\lceil \frac{|H(u)|}{2} \right\rceil. \quad (1)$$

Thus if there exists a substitute-path $S_{r,u}$ to a vertex u in B_r^+ then $S_{r,u}$ either contain at most half of the vertices in $H(u)$ or for each vertex from $H(u)$ it contains more than the half of the vertices in $H(u)$ it also contain an arc from $J(u)$. Let q be the number of vertices from $H(u)$ which are on a substitute-path $S_{r,u}$. It then follows that the number of arcs from $J(u)$ on $S_{r,u}$ is at least $q - \lceil \frac{|H(u)|}{2} \rceil$. Figure 4 shows two substitute-paths in an out-branching.

The following result may be of independent interests. Theorem 3.1 means that every vertex $v \in V$ is reachable from r by a substitute-path.

► **Theorem 3.1.** For the out-branching B_r^+ there exists a substitute-path to every $v \in V$.

■ **Figure 4** To the left, the digraph $D = (V, A)$ is shown. The arcs of the out-branching B_r^+ are shown in yellow, the arcs in $J(v)$ are blue, and the remaining arcs are black. In the middle and to the right, two paths from r to v are shown. One of the paths is green, the other is shown in red. Both paths are substitute-paths to v .

Proof. In this proof we will be modifying paths and, therefore, we will first consider two claims which deals with these modifications.

▷ **Claim 6.** For an arbitrary path $P_{r,v}$ in D the following inequality holds for every vertex $x \in V(P_{r,v})$

$$\begin{aligned} |J(v) \cap A(P_{r,v}[r, x])| + |H(v) \setminus V(P_{r,v}[r, x])| \\ \geq |J(v) \cap A(P_{r,v})| + |H(v) \setminus V(P_{r,v})|. \end{aligned} \quad (2)$$

Proof. As $P_{r,v}[r, x] \subseteq P_{r,v}$ we clearly have that $|J(v) \cap A(P_{r,v}[r, x])| \leq |J(v) \cap A(P_{r,v})|$. Let $j = |J(v) \cap A(P_{r,v})| - |J(v) \cap A(P_{r,v}[r, x])|$. For every arc $(t, h) \in J(v)$ which is also on the path $P_{r,v}$ it follows that $h \in H(v)$ and $h \in V(P_{r,v})$. Thus, the set $H(v) \setminus V(P_{r,v}[r, x])$ contains at least j vertices more than $H(v) \setminus V(P_{r,v})$. That is, $|H(v) \setminus V(P_{r,v}[r, x])| - j \geq |H(v) \setminus V(P_{r,v})|$. From this (2) follows. ◁

▷ **Claim 7.** Given a vertex $v \in B_r^+$, and two paths $P_{r,x}$ and $P_{x,u}$ in D which are disjoint on the vertex set $H(v) - \{x\}$ the following inequality holds for the walk $W = P_{r,x}P_{x,u}$ and for every (r, u) -path $P = P_{r,x}P_{x,u}$ obtained from W by deleting cycles.

$$\begin{aligned} |J(v) \cap A(W)| + |H(v) \setminus V(W)| \\ \leq |J(v) \cap A(P)| + |H(v) \setminus V(P)|. \end{aligned} \quad (3)$$

Proof. If $|J(v) \cap A(W)| > |J(v) \cap A(P)|$ then there must exist one or more cycles in W which contain arcs from $J(v)$. For each such cycle there must exist at least one vertex $z \in (V(P_{r,x}) \cap V(P_{x,u})) - \{x\}$. Since $P_{r,x}$ and $P_{x,u}$ are disjoint on the set $H(v) - \{x\}$ we have that $z \notin H(v)$. It means that for every arc $(t, h) \in J(v)$ contained in W but not in P the head h is not in P either. Therefore, for $j = |J(v) \cap A(W)| - |J(v) \cap A(P)|$ we have $|H(v) \setminus V(P)| - j \geq |H(v) \setminus V(W)|$ and Claim 7 follows. ◁

We are now ready to prove that there exists a substitute-path to every $v \in V$. We will prove this by induction over the cardinality of $H(v) = \mathcal{H}(J(v))$. Clearly, $|H(r)| = 0$ since no backwards arc goes over r . Hence there exists at least one vertex $v \in V$ for which $|H(v)| = 0$.

11:8 k -Distinct Branchings Admits a Polynomial Kernel

For every such vertex the path $B_r^+[r, v]$ is clearly a substitute-path by (1). Thus there exists a substitute-path to every $v \in V$ for which $|H(v)| = 0$. Now assume for some positive integer $i \leq n$ that for every vertex $v \in V$ where $|H(v)| < i$ it holds that there exists a substitute-path to v .

Let $u \in V$ be a vertex for which $|H(u)| = i$. If no such vertex exists in B_r^+ then clearly there exists a substitute-path to every vertex $u \in V$ where $|H(u)| = i$. Hence assume that u exists. Recall that $H(u) \subseteq V(B_r^+[r, u])$. Denote the vertices in $H(u)$ by h_0, h_1, \dots, h_{i-1} such that $B_r^+[r, u] = B_r^+[r, h_0]B_r^+[h_0, h_1] \cdots B_r^+[h_{i-2}, h_{i-1}]B_r^+[h_{i-1}, u]$.

▷ **Claim 8.** $H(h_j) = \{h_0, h_1, \dots, h_{j-1}\}$ for every $j \leq i - 1$.

Proof. From Lemma 3.2 it follows that $H(h_{i-1}) = \{h_0, h_1, \dots, h_{i-2}\}$. Now the claim follows from Lemma 3.2 by induction over $j \leq i - 1$. \triangleleft

Since $h_j \in B_r^+[r, h_{i-1}]$ for $j \leq i - 1$ no backwards arc with head in h_{i-1} can go over h_j . As $h_{i-1} \in H(u)$ this means that there exists a relevant arc which goes over u . Fix such an arc (t, h_{i-1}) .

▷ **Claim 9.** If there exists a path $P_{r,t}$ in D such that

$$|J(u) \cap A(P_{r,t})| + |H(u) \setminus V(P_{r,t})| \geq \lceil \frac{i}{2} \rceil. \quad (4)$$

then there is a substitute-path to u

Proof. Assume that there exists a path $P_{r,t}$ such that $|J(u) \cap A(P_{r,t})| + |H(u) \setminus V(P_{r,t})| \geq \lceil \frac{i}{2} \rceil$. Let x be the first vertex on $P_{r,t}$ which is also on the path $B_r^+[h_{i-1}, t]$. If $x = u$ then the path $P_{r,t}[r, u]$ will be a substitute-path to u as $|J(u) \cap A(P_{r,t})| + |H(u) \setminus V(P_{r,t})| \leq |J(u) \cap A(P_{r,t}[r, u])| + |H(u) \setminus V(P_{r,t}[r, u])|$ by Claim 6. Therefore, we may assume that $x \neq u$. We will consider the two cases: $x \in B_r^+[h_{i-1}, u]$ or $x \in B_r^+[u, t]$. By claim 6 it holds that

$$\begin{aligned} & |J(u) \cap A(P_{r,t}[r, x])| + |H(u) \setminus V(P_{r,t}[r, x])| \\ & \geq |J(u) \cap A(P_{r,t})| + |H(u) \setminus V(P_{r,t})| \geq \lceil \frac{i}{2} \rceil. \end{aligned} \quad (5)$$

If $x \in B_r^+[h_{i-1}, u]$ then for the walk $W'_{r,u} = P_{r,t}[r, x]B_r^+[x, u]$ it clearly holds that $|J(u) \cap A(P_{r,t}[r, x])| + |H(u) \setminus V(P_{r,t}[r, x])| = |J(u) \cap A(W'_{r,u})| + |H(u) \setminus V(W'_{r,u})|$. For the path $P'_{r,u} = P_{r,t}[r, x]B_r^+[x, u]$ we therefore have by Claim 7 that $|J(u) \cap A(P'_{r,u})| + |H(u) \setminus V(P'_{r,u})| \geq |J(u) \cap A(P_{r,t}[r, x])| + |H(u) \setminus V(P_{r,t}[r, x])|$. From (5) it therefore follows that $|J(u) \cap A(P'_{r,u})| + |H(u) \setminus V(P'_{r,u})| \geq \lceil \frac{i}{2} \rceil$. Hence $P'_{r,u}$ is a substitute-path to u . Now consider the second case where $x \in B_r^+[u, t]$. Consider the (x, u) -walk $P''_{x,u} = B_r^+[x, t](t, h_{i-1})B_r^+[h_{i-1}, u]$ and observe that $J(u) \cap A(P''_{x,u}) = (t, h_{i-1})$ and $H(u) \cap V(P''_{x,u}) = h_{i-1}$. It means that $P''_{x,u}$ is disjoint from $H(u) - \{h_{i-1}\}$. As x is the first vertex on $P_{r,t}$ which is on $B_r^+[h_{i-1}, t]$ and $x \in B_r^+[u, t]$ it holds that $h_{i-1} \notin P_{r,t}[r, x]$ and $P_{r,t}[r, x]$ and $P''_{x,u}$ are disjoint except in x . Now consider the $P^*_{r,u} = P_{r,t}[r, x]P''_{x,u}$ and observe that

$$\begin{aligned} & |J(u) \cap A(P^*_{r,u})| + |H(u) \setminus V(P^*_{r,u})| \\ & = |J(v) \cap A(P_{r,t}[r, x])| + 1 + |H(v) \setminus V(P_{r,t}[r, x])| - 1 \\ & = |J(v) \cap A(P_{r,t}[r, x])| + |H(v) \setminus V(P_{r,t}[r, x])| \end{aligned}$$

From (5) it therefore follows that $|J(u) \cap A(P^*_{r,u})| + |H(u) \setminus V(P^*_{r,u})| \geq \lceil \frac{i}{2} \rceil$. Thus $P^*_{r,u}$ is a substitute-path to u . \triangleleft

Now we prove that there always exists a path such that (4) holds. Recall by the definition of a relevant arc, that the relevant arc (t, h_{i-1}) goes over t and there exists a path $P_{r,t}$ in D such that $h_{i-1} \notin P_{r,t}$. If $|H(u) \setminus V(P_{r,t})| = i$ then (4) clearly holds. Hence we may assume that there exists a vertex $h_j \in H(u) \cap V(P_{r,t})$. Now let h_l be the last such vertex on the path $P_{r,t}$, that is, no vertex $h_j \in H(u) - \{h_l\}$ is on the path $P_{r,t}[h_l, t]$. Observe that since $P_{r,t}$ does not contain h_{i-1} we have

$$l \leq i - 2 \quad (6)$$

By Claim 8, $|H(h_j)| = j$ for every $j \leq i - 1$. By the induction assumption it therefore follows that there is a substitute-path S_{r,h_j} to every $h_j \in H(u)$.

▷ **Claim 10.** For every substitute-path to h_l , S_{r,h_l} , either there exists a vertex $h_j \in S_{r,h_l}$ such that $j > l$ or (4) holds.

Proof. Assume that there exists a substitute-path S_{r,h_l} to h_l such that there is no vertex $h_j \in S_{r,h_l}$ for $j > l$. Observe that since S_{r,h_l} is a substitute-path it holds that $|J(h_l) \cap A(S_{r,h_l})| + |H(h_l) \setminus V(S_{r,h_l})| \geq \lceil \frac{l}{2} \rceil$. Now consider the walk $W'_{r,t} = S_{r,h_l} P_{r,t}[h_l, t]$. The path S_{r,h_l} does not contain any heads $h_j \in H(u)$ for $j > l$ and $P_{r,t}[h_l, t]$ does not contain any heads $h_j \in H(u)$ for $j \neq l$. Hence we can deduce that:

$$\begin{aligned} & |J(u) \cap A(W'_{r,t})| + |H(u) \setminus V(W'_{r,t})| \\ & \geq |J(h_l) \cap A(S_{r,h_l})| + |H(h_l) \setminus V(S_{r,h_l})| + |\{h_j | l < j < i\}| \\ & = |J(h_l) \cap A(S_{r,h_l})| + |H(h_l) \setminus V(S_{r,h_l})| + i - l - 1 \\ & \geq \lceil \frac{l}{2} \rceil + i - l - 1 \end{aligned}$$

From this and Claim 7 we have the following inequality for the path $P'_{r,t} = S_{r,h_l} P_{r,t}[h_l, t]$.

$$|J(u) \cap A(P'_{r,t})| + |H(u) \setminus V(P'_{r,t})| \geq \lceil \frac{l}{2} \rceil + i - l - 1 \quad (7)$$

From (6) it follows that $l \leq i - 2$ and since $l \geq 0$ it also holds that $i \geq 2$. These observations together with (7) give us the following inequality.

$$|J(u) \cap A(P'_{r,t})| + |H(u) \setminus V(P'_{r,t})| \geq \lceil \frac{l}{2} \rceil + i - l - 1 \geq \lceil \frac{i}{2} \rceil$$

It means that $P'_{r,t}$ is a path making (4) true. Hence if (4) does not hold we may assume that for every substitute-path S_{r,h_l} to h_l there exists a $j > l$ such that $h_j \in S_{r,h_l}$. ◁

Let S_{r,h_j} be a substitute-path to $h_j \in H(u)$. If there exists a vertex $h_p \in S_{r,h_j}$ such that $p > j$ we will call the first vertex h_p with $p > j$ on the path S_{r,h_j} the **first exceeding head**. Recall that we are proving that a path exists such that (4) holds. Assume for contradiction that no such path exists. Thus by Claim 10 it follows that for every substitute-path S_{r,h_l} to h_l there is a vertex $h_j \in S_{r,h_l}$ for $j > l$, that is, every substitute-path S_{r,h_l} will contain a first exceeding head h_j such that $j > l$. Now let $k \leq l$ be the smallest integer such that for every substitute-path S_{r,h_k} the first exceeding head h_j has $j > l$. Observe that l fulfills this property and therefore k exists. Let S'_{r,h_k} be a substitute-path to h_k and h_j the first exceeding head on this path. Observe that $S'_{r,h_k}[r, h_j]$ is disjoint from the heads $\{h_k, h_{k+1}, \dots, h_{j-1}\}$. Therefore we have:

$$\begin{aligned} & |J(h_j) \cap A(S'_{r,h_k}[r, h_j])| + |H(h_j) \setminus V(S'_{r,h_k}[r, h_j])| \\ & \geq |J(h_k) \cap A(S'_{r,h_k})| + |H(h_k) \setminus V(S'_{r,h_k})| + |\{h_p | k \leq p < j\}| \\ & \geq |J(h_k) \cap A(S'_{r,h_k})| + |H(h_k) \setminus V(S'_{r,h_k})| + j - k \end{aligned} \quad (8)$$

11:10 k -Distinct Branchings Admits a Polynomial Kernel

As S'_{r,h_k} is a substitute-path to h_k and $|H(h_k)| = k$ we have that $|J(h_k) \cap A(S'_{r,h_k})| + |H(h_k) \setminus V(S'_{r,h_k})| \geq \lceil \frac{k}{2} \rceil$. When we combine this with (8) we obtain the following inequality:

$$|J(h_j) \cap A(S'_{r,h_k}[r, h_j])| + |H(h_j) \setminus V(S'_{r,h_k}[r, h_j])| \geq \lceil \frac{k}{2} \rceil + j - k \quad (9)$$

Now consider the (r, t) -path $P^* = S'_{r,h_k}[r, h_j]B_r^+[h_j, t]$. Recall that the path $B_r^+[h_j, t]$ is disjoint from every head h_p for $p < j$ and $S'_{r,h_k}[r, h_j]$. It therefore follow from (9) that.

$$\begin{aligned} & |J(u) \cap A(P^*)| + |H(u) \setminus V(P^*)| \\ & \geq |J(h_j) \cap A(S'_{r,h_k}[r, h_j])| + |H(h_j) \setminus V(S'_{r,h_k}[r, h_j])| \\ & \geq \lceil \frac{k}{2} \rceil + j - k \end{aligned} \quad (10)$$

From (10) and the fact that $l + 1 \leq j$ we obtain the following inequality.

$$|J(u) \cap A(P^*)| + |H(u) \setminus V(P^*)| \geq l + 1 - \lfloor \frac{k}{2} \rfloor \quad (11)$$

From the assumption that (4) does not hold it follows that $|J(u) \cap A(P^*[r, t])| + |H(u) \setminus V(P^*[r, t])| < \lceil \frac{i}{2} \rceil$. Therefore, we have the following observation from (11).

► **Observation 11.** $l + 1 - \lfloor \frac{k}{2} \rfloor < \lceil \frac{i}{2} \rceil$.

Recall that the path $B_r^+[r, h_0]$ is a substitute-path to h_0 and as every substitute-path to h_k has a first exceeding head h_p such that $p > l$ it must hold that $k > 0$. Furthermore, recall that k was chosen as the smallest integer such that the first exceeding head h_p on every substitute-path to h_k had $p > l$. Hence there exist a substitute-path $S^*_{r,h_{k-1}}$ such that either there is no exceeding head or for the first exceeding head h_p it holds that $k - 1 < p \leq l$. If there is no exceeding head let $p = k - 1$ and otherwise let h_p be the first exceeding head. Consider $S^*_{r,h_{k-1}}[r, h_p]$. Observe by Claim 6 and the fact that $S^*_{r,h_{k-1}}$ is a substitute-path that

$$|J(h_{k-1}) \cap A(S^*_{r,h_{k-1}}[r, h_p])| + |H(h_{k-1}) \setminus V(S^*_{r,h_{k-1}}[r, h_p])| \geq \lceil \frac{k-1}{2} \rceil$$

Now consider the (r, t) -walk $W'_{r,t} = S^*_{r,h_{k-1}}[r, h_p]B_r^+[h_p, h_l]P_{r,t}[h_l, t]$. Note that $S^*_{r,h_{k-1}}[r, h_p]$ is disjoint from every head h_q for $q > p$, $B_r^+[h_p, h_l]$ is disjoint from every head h_q for $q < p$ and $q > l$, and furthermore $P_{r,t}[h_l, t]$ is disjoint from $H(u) - \{h_l\}$. Hence:

$$\begin{aligned} & |J(u) \cap A(W')| + |H(u) \setminus V(W')| \\ & = |J(h_{k-1}) \cap A(S^*_{r,h_{k-1}}[r, h_p])| + |H(h_{k-1}) \setminus V([S^*_{r,h_{k-1}}[r, h_p])| + |\{h_q | l < q < i\}| \\ & = |J(h_{k-1}) \cap A(S^*_{r,h_{k-1}}[r, h_p])| + |H(h_{k-1}) \setminus V(S^*_{r,h_{k-1}}[r, h_p])| + i - 1 - l \end{aligned} \quad (12)$$

Consider the (r, t) -path $P' = S^*_{r,h_{k-1}}[r, h_p]B_r^+[h_p, h_l]P_{r,t}[h_l, t]$. Then from (12), claim 7 and the fact that $S^*_{r,h_{k-1}}$ is a substitute-path to h_{k-1} we obtain the following:

$$\begin{aligned} & |J(u) \cap A(P')| + |H(u) \setminus V(P')| \\ & \geq |J(u) \cap A(W')| + |H(u) \setminus V(W')| \\ & \geq \lceil \frac{k-1}{2} \rceil + i - 1 - l \end{aligned} \quad (13)$$

By the assumption that (4) does not hold we have $|J(u) \cap A(P')| + |H(u) \setminus V(P')| < \lceil \frac{i}{2} \rceil$. This combined with (13) gives us:

$$\lceil \frac{i}{2} \rceil > \lceil \frac{k-1}{2} \rceil + i - 1 - l \quad \Leftrightarrow \quad l + 1 - \lceil \frac{k-1}{2} \rceil > \lceil \frac{i}{2} \rceil \quad (14)$$

Combining Observation 11 with (14) and the fact that $\lceil \frac{k-1}{2} \rceil = \lfloor \frac{k}{2} \rfloor$ we obtain the following inequality:

$$\lfloor \frac{i}{2} \rfloor < l + 1 - \lfloor \frac{k}{2} \rfloor < \lceil \frac{i}{2} \rceil \quad (15)$$

Now observe that $l + 1 - \lfloor \frac{k}{2} \rfloor$ is an integer and from (15) we therefore have a contradiction. Hence either the path P^* or the path P' makes (4) true. It means that there exists a path making (4) true. Thus by Claim 9 there exists a substitute-path to u .

Recall that u was an arbitrary fixed vertex $x \in V$ for which $|H(x)| = i$. Thus we can conclude that for every vertex $x \in V$ where $|H(x)| = i$ there exists a substitute path to x . This concludes the induction step over for every vertex $x \in V$ where $|H(x)| = i$. Thus we can conclude that for every vertex $x \in V$ where $|H(x)| = i$ for $i \in [0, |V|]$ there exists a substitute-path. As $|H(x)| \leq n$ for every $x \in V$, the proof is complete. \blacktriangleleft

3.2 Finding Desired Paths in Polynomial Time

We now obtain the following lemma about finding a substitute-path to a vertex $v \in V$.

► **Lemma 3.4** (\star). *There exists a polynomial time algorithm which given an out-branching B_r^+ in $D = (V, A)$ and a vertex $v \in V$ finds a substitute-path to v .*

► **Lemma 3.5** (\star). *For every vertex $u \in V(B_r^+)$ there exists a path $P_{r,u}$ from r to u such that*

$$|R(u) \cap A(P_{r,u})| + |\mathcal{H}(R(u)) \setminus V(P_{r,u})| \geq \left\lceil \frac{|\mathcal{H}(R(u))|}{2} \right\rceil \quad (16)$$

and it can be found in polynomial time

► **Lemma 3.6** (\star). *For every vertex $v \in V(B_r^+)$ let $R_v \in \{J(v), R(v)\}$. If there exists a path $P_{r,v}$ such that*

$$|R_v \cap A(P_{r,v})| + |\mathcal{H}(R_v) \setminus V(P_{r,v})| \geq \left\lceil \frac{|\mathcal{H}(R_v)|}{2} \right\rceil \quad (17)$$

then there exists an out-branching \widehat{B}_r^+ such that $|R_v \cap A(\widehat{B}_r^+)| \geq \left\lceil \frac{|\mathcal{H}(R_v)|}{2} \right\rceil$, and \widehat{B}_r^+ can be found in polynomial time.

4 Backward arcs, Crossing Arcs and Substitute-paths with respect to In-branchings

For in-branchings we have similar definitions and results as we have for out-branchings. Given a digraph $D = (V, A)$ which contains a fixed in-branching B_r^- we can create a corresponding digraph $D' = (V, A')$ and an out-branching B_r^+ by creating an arc (v, u) in A' for each arc $(u, v) \in A$. That is, the direction of the arcs in A are flipped. Observe that the in-branching B_r^- in D will correspond to a fixed out-branching B_r^+ in D' . Due to this one-to-one correspondence all the results given in Section 3 regarding a fixed out-branching will be turned into equivalent statements about a fixed in-branching.

5

A kernel for ROOTED k -DISTINCT BRANCHINGS

In this section we prove the existence of an $\mathcal{O}(k^2)$ -vertex kernel for the problem ROOTED k -DISTINCT BRANCHINGS. The proof of the next lemma will give the desired Theorem 1.1.

► **Lemma 5.1.** *Given an instance $(D = (V, A), k, s, t)$ of R - k -DB; In polynomial time we can either find a kernel (D', k, s', t') such that $|V(D')| < 16k^2 + 5k = \mathcal{O}(k^2)$ or determine the answer to the instance.*

Proof. In linear time it can be determined if an out-branching B_s^+ and an in-branching B_t^- exist. If one of these do not exist then clearly (D, k, s, t) is a no-instance. Hence assume that both exist. At any time during the proof let \mathcal{C}^+ , \mathcal{R}^+ , and \mathcal{I}^+ , respectively, denote the crossing, relevant, and irrelevant arcs wrt.. B_s^+ . Similarly, let \mathcal{C}^- , \mathcal{R}^- , and \mathcal{I}^- , respectively, denote the crossing, relevant, and irrelevant arcs wrt.. B_t^- . Moreover, at all times during the proof let $F = A(D) \setminus (A(B_s^+) \cup A(B_t^-))$ be defined as the **free arcs** and at all times let $E^+ = A(B_s^+) \setminus A(B_t^-)$, $E^- = A(B_t^-) \setminus A(B_s^+)$ denote the **exclusive set**, respectively, for B_s^+ and B_t^- . Note that $|E^+| = |E^-|$. Now we execute the following procedure.

- **Procedure 5.1.** *Change B_s^+ and B_t^- as follows until no longer possible or $|E^+| \geq k$.*
1. *If there exists an arc $(u, v) \in F \cap \mathcal{C}^+$ such that $(\mathcal{P}_{B_s^+}(v), v) \notin E^+$, then remove $(\mathcal{P}_{B_s^+}(v), v)$ from B_s^+ and insert the arc (u, v) into B_s^+ .*
 2. *If there exists an arc $(u, v) \in F \cap \mathcal{C}^-$ such that $(u, \mathcal{P}_{B_t^-}(u)) \notin E^-$, then remove $(u, \mathcal{P}_{B_t^-}(u))$ from B_t^- and insert the arc (u, v) into B_t^- .*

► **Lemma 5.2** (\star) . *Procedure 5.1 can be executed in polynomial time.*

If we have not found a solution when Procedure 5.1 terminates, then we have

$$|E^+| = |E^-| < k. \quad (18)$$

Since $|E^+| < k$ and we can not change B_s^+ further in Procedure 5.1 we have that for every crossing arc $(u, v) \in \mathcal{C}^+$ either $(u, v) \in A(B_t^-)$ or $(\mathcal{P}_{B_s^+}(v), v) \in E^+$. As \mathcal{C}^+ is disjoint from B_s^+ it follows that every arc $(u, v) \in A(B_t^-) \cap \mathcal{C}^+$ is contained in E^- . Hence there are less than k such arcs. For the arcs $(u, v) \in \mathcal{C}^+$ where $(\mathcal{P}_{B_s^+}(v), v) \in E^+$ there is less than k different heads as $|E^+| < k$. Therefore, there must be less than $2k$ different heads for the crossing arcs of B_s^+ , that is, $|\mathcal{H}(\mathcal{C}^+)| < 2k$. Similarly, we have that there are less than $2k$ different tails of \mathcal{C}^- , that is, $|\mathcal{T}(\mathcal{C}^-)| < 2k$.

► **Observation 12.** $|\mathcal{H}(\mathcal{C}^+)| < 2k$ and $|\mathcal{T}(\mathcal{C}^-)| < 2k$

A vertex $v \in V$ is a **Type 1** vertex if it is the tail of an arc $(v, u) \in \mathcal{R}^- \cup \mathcal{C}^-$ and a **Type 2** vertex if it is the head of an arc $(u, v) \in \mathcal{R}^+ \cup \mathcal{C}^+$. Note that a vertex $v \in V$ can be both a Type 1 and a Type 2 vertex. Now we have the following reduction rule.

► **Reduction Rule 5.1.** *As long as there exists an arc $(u, v) \in A(B_s^+) \cap A(B_t^-)$ such that u is not a Type 1 vertex and v is not a Type 2 vertex contract (u, v) into one vertex.*

► **Lemma 5.3** (\star) . *Reduction Rule 5.1 is safe and can be applied in polynomial time.*

Let D_R , B_s^+ and B_t^- be the digraph and branchings that we have obtained after performing Reduction 5.1. We now have the following lemma.

► **Lemma 5.4.** *If $|V(D_R)| \geq 16k^2 + 5k$ then a solution exists.*

Proof. Assume $|V(D_R)| \geq 16k^2 + 5k$. As B_s^+ is an out-branching we have $|A(B_s^+)| = |V(D_R)| - 1$. For every arc $(u, v) \in A(B_s^+)$ it holds that either $(u, v) \notin A(B_t^-)$, u is a Type 1 vertex or v is a Type 2 vertex. By (18) we see that $|A(B_s^+) \setminus A(B_t^-)| < k$. It means that $|A(B_s^+) \cap A(B_t^-)| \geq |V(D_R)| - k \geq 2 \cdot (8k^2 + 2k)$. For every arc $(u, v) \in A(B_s^+) \cap A(B_t^-)$ we have that u is a Type 1 vertex or v is a Type 2 vertex. Hence we can conclude that either there is $8k^2 + 2k$ vertices of Type 1 or $8k^2 + 2k$ vertices of Type 2 (or both). In the following we will only explicitly give the proof that a solution exists if there are at least $8k^2 + 2k$ vertices of Type 2 as the proof for a solution exists if there are at least $8k^2 + 2k$ vertices of Type 1 will follow from the symmetry between $B_s^+, C^+, \mathcal{R}^+, \mathcal{I}^+$ and $B_t^-, C^-, \mathcal{R}^-, \mathcal{I}^-$. Assume therefore that there are at least $8k^2 + 2k$ vertices of Type 2. Recall that it means, there are at least $8k^2 + 2k$ different vertices which are heads of the arcs $\mathcal{R}^+ \cup C^+$. By Observation 12 there are less than $2k$ vertices which are heads of C^+ . Consequently, the number of vertices which are heads of \mathcal{R}^+ must be larger than $8k^2$. Clearly, $|\mathcal{H}(\mathcal{R}^+)| = |\cup_{v \in V} \mathcal{H}(J(v))|$ and we therefore have $8k^2 \leq |\mathcal{H}(\mathcal{R}^+)| = |\cup_{v \in V} \mathcal{H}(J(v))|$. By Lemma 3.3 we have that for every $v \in V$ it holds that $\mathcal{H}(J(v)) \subseteq \mathcal{H}(J(u))$ for some arc $(v, u) \in C^+$. We therefore have that: $|\cup_{(v,u) \in C^+} \mathcal{H}(J(u))| = |\cup_{v \in V} \mathcal{H}(J(v))| \geq 8k^2$. By Observation 12 there are at most $2k$ heads of the arcs in C^+ so there must exist at least one arc $(u, v) \in C^+$ such that $|\mathcal{H}(J(v))| \geq 4k$. Fix (u, v) to be such an arc. By Theorem 3.1 there exist a substitute-path $S[s, v]$ in D such that $|J(v) \cap A(S[s, v])| + |\mathcal{H}(J(v)) \setminus A(S[s, v])| \geq \left\lceil \frac{|\mathcal{H}(J(v))|}{2} \right\rceil$ and therefore by from Lemma 3.6 there exists an out-branching \hat{B}_s^+ such that $|J(v) \cap A(\hat{B}_s^+)| \geq \left\lceil \frac{|\mathcal{H}(J(v))|}{2} \right\rceil \geq 2k$. Observe that B_s^+ is disjoint from $J(v)$ and therefore if $|J(v) \cap A(B_t^-)| \geq k$ then B_s^+ and B_t^- would have been a solution. If $|J(v) \cap A(B_t^-)| < k$ then $|A(\hat{B}_s^+) \setminus A(B_t^-)| \geq k$ and \hat{B}_s^+ and B_t^- is a solution. Hence we conclude that if the number of different heads of R^+ is larger than $4k^2$ a solution exists. \blacktriangleleft

From Lemma 5.4 we can conclude that after applying Reduction Rule 5.1 it either holds that we have a solution or $|V(D_R)| < 16k^2 + 5k$. In the first case we have a solution in the latter we have a kernel of size $\mathcal{O}(k^2)$. It therefore only remains to argue that the solution or the kernel can be found in polynomial time. For an instance $(D = (V, A), k, s, t)$ of R- k -DB it is possible in polynomial time to decide if an out-branching B_s^+ and B_t^- in D exists and find them. By Claim 5.2, and Claim 5.3 we can execute the Procedure 5.1 and afterwards apply Reduction Rule 5.1 in polynomial time. Furthermore, it is polynomial to decide if the resulting digraph has at least $16k^2 + 5k$ vertices and applying Lemma 5.4. Hence in polynomial time we can either find a kernel with a vertex set of size less than $16k^2 + 5k$ or determine the answer to the instance. \blacktriangleleft

6 Conclusion

In this paper, we studied the problem of deciding if a digraph $D = (V, A)$, contains an in- and out-branching rooted at specific vertices s and t , such that the in- and out-branching are distinct on at least k arcs. Before this paper, it was not known if the problem admitted a polynomial kernel, and the best known complexity for solving the problem was $2^{\mathcal{O}(k^2 \log^2 k)} n^{\mathcal{O}(1)}$. We designed a polynomial kernel for the problem with $\mathcal{O}(k^2)$ vertices and found an algorithm with the complexity $2^{\mathcal{O}(k \log k)} + n^{\mathcal{O}(1)}$. To obtain these results, we defined the concept of substitute-paths in out- and in-branchings. This graph-theoretical concept might be useful for obtaining other results on problems regarding in- and out-branchings. It is still open whether there exists a kernel with $\mathcal{O}(k)$ vertices. We believe that using representative set approach

applied for obtaining exact exponential time algorithm for finding a strongly connected subgraph of a given digraph with minimum number of arcs [20], it seem possible to get an algorithm for R-*k*-DB running in time $2^{\mathcal{O}(k)} + n^{\mathcal{O}(1)}$. Making this work seems an interesting direction to pursue.

Abstract

For any forest $G = (V, E)$ it is possible to orient the edges E so that no vertex in V has out-degree greater than 1. This paper considers the incremental edge-orientation problem, in which the edges E arrive over time and the algorithm must maintain a low-out-degree edge orientation at all times. We give an algorithm that maintains a maximum out-degree of 3 while flipping at most $O(\log \log n)$ edge orientations per edge insertion, with high probability in n . The algorithm requires worst-case time $O(\log n \log \log n)$ per insertion, and takes amortized time $O(1)$. The previous state of the art required up to $O(\log n / \log \log n)$ edge flips per insertion.

We then apply our edge-orientation results to the problem of dynamic Cuckoo hashing. The problem of designing simple families \mathcal{H} of hash functions that are compatible with Cuckoo hashing has received extensive attention. These families \mathcal{H} are known to satisfy *static guarantees*, but do not come typically with *dynamic guarantees* for the running time of inserts and deletes. We show how to transform static guarantees (for 1-associativity) into near-state-of-the-art dynamic guarantees (for $O(1)$ -associativity) in a black-box fashion. Rather than relying on the family \mathcal{H} to supply randomness, as in past work, we instead rely on randomness within our table-maintenance algorithm.

1 Introduction

The general problem of maintaining low-out-degree edge orientations of graphs has been widely studied and has found a broad range of applications throughout algorithms (see, e.g., work on sparse graph representations [10], maximal matchings [7–9, 18, 20, 26], dynamic matrix-by-vector multiplication [20], etc.). However, some of the most basic and fundamental versions of the graph-orientation problem have remained unanswered.

This paper considers the problem of incremental edge orientation in forests. Consider a sequence of edges e_1, e_2, \dots, e_{n-1} that arrive over time, collectively forming a tree. As the edges arrive, one must maintain an **orientation** of the edges (i.e., to assign a direction to each edge) so that no vertex ever has out-degree greater than $O(1)$. The orientation can be updated over time, meaning that orientations of old edges can be flipped in order to make room for the newly inserted edges. The goal is achieve out-degree $O(1)$ while flipping as few edges as possible per new edge arrival.

Forests represent the best possible case for edge orientation: it is always possible to construct an orientation with maximum out-degree 1. But, even in this seemingly simple case, no algorithms are known that achieve better than $O(\log / \log \log n)$ edge flips per edge insertion [20]. A central result of this paper is that, by using randomized and intentionally non-greedy edge-flipping one can do substantially better, achieving $O(\log \log n)$ edges flips per insertion.

A warmup: two simple algorithms

As a warmup let us consider two simple algorithms for incremental edge-orientation in forests.

The first algorithm never flips any edges but allows the maximum out-degree of each vertex to be as high as $O(\log n)$. When an edge (u, v) is added to the graph, the algorithm examines the connected components T_u and T_v that are being connected by the edge, and determines which component is larger (say, $|T_v| \geq |T_u|$). The algorithm then orients the edge from u to v , so that it is directed out of the smaller component. Since the new edge is always added to a vertex whose connected component at least doubles in size, the maximum out-degree is $\lceil \log n \rceil$.

The second algorithm guarantees that the out-degree will always be 1, but at the cost of flipping more edges. As before, when (u, v) is added the algorithm orients the edge from u to v . If this increments the out-degree of u to 2, then the algorithm follows the directed path P in T_u starting from u (and such that the edge (u, v) is not part of P) until a vertex r with out-degree 0 is reached. The algorithm then flips the edge orientations on P , which increases the out-degree of r to be 1 and reduces the out-degree of u to be 1. Since every edge that is flipped is always part of a connected component that has just at least doubled in size, the number of times each edge is flipped (in total across all insertions) is at most $\lceil \log n \rceil$ and so the amortized time cost per insertion is $O(\log n)$.¹

These two algorithms sit on opposite sides of a tradeoff curve. In one case, we have maximum out-degree $O(\log n)$ and at most $O(1)$ edges flipped per insertion, and in the other we have maximum out-degree $O(1)$ and at most $O(\log n)$ (amortized) flips per insertion. This raises a natural question: *what is the optimal tradeoff curve between the maximum out-degree and the number of edges flipped per insertion?*

¹ By allowing for a maximum out-degree of 2, the bound of $O(\log n)$ on the number of edges flipped can be improved from being amortized to worst-case. In particular, for any vertex v there is always a (directed) path of length $O(\log n)$ to another vertex with out-degree 1 or less (going through vertices with out-degree 2); by flipping the edges in such a path, we can insert a new edge at the cost of only $O(\log n)$ flips.

Our results

We present an algorithm for incremental edge orientation in forests that satisfies the following guarantees with high probability in n :

- the maximum out-degree never exceeds 3;
- the maximum number of edges flipped per insertion is $O(\log \log n)$;
- the maximum time taken by any insertion is $O(\log n \log \log n)$;
- and the amortized time taken (and thus also the amortized number of edges flipped) per insertion is $O(1)$.

An interesting feature of this result is that the aforementioned tradeoff curve is actually quite different than it first seems: by increasing the maximum out-degree to 3 (instead of 2 or 1), we can decrease the maximum number of edges flipped per insertion all the way to $O(\log \log n)$.

In fact, a similar phenomenon happens on the other side of the tradeoff curve. For any ε , we show that it is possible to achieve a maximum out-degree of $\log^\varepsilon n + 1$ while only flipping $O(\varepsilon^{-1})$ edges per insertion. Notably, this means that, for any positive constant c , one can achieve out-degree $(\log n)^{1/c}$ with $O(1)$ edges flipped per insertion.

A key idea in achieving the guarantees above is to selectively leave vertices with low out-degrees “sprinkled” around the graph, thereby achieving an edge orientation that is amenable to future edges being added. Algorithmically, the main problem that our algorithm solves is that of high-degree vertices clustering in a “hotspot”, which could then force a single edge-insertion to invoke a large number of edge flips.

Related work on edge orientations

The general problem of maintaining low-out-degree orientations of dynamic graphs has served as a fundamental tool for many problems. Brodal and Fagerberg [10] used low-degree edge orientations to represent dynamic sparse graphs – by assigning each vertex only $O(1)$ edges for which it is responsible, one can then deterministically answer adjacency queries in $O(1)$ time. Low-degree edge orientations have also been used to maintain maximal matchings in dynamic graphs [7, 18, 20, 26], and this technique remains the state of the art for graphs with low arboricity. Other applications include dynamic matrix-by-vector multiplication [20], dynamic shortest-path queries in planar graphs [21], and approximate dynamic maximum matchings [8, 9].

The minimum out-degree attainable by any orientation of a graph is determined by the graph’s pseudo-arboricity α . As a result, the algorithmic usefulness of low out-degree orientations is most significant for graphs that have low pseudo-arboricity. This makes forests and pseudoforests (which are forests with one extra edge per component) especially interesting, since they represent the case of $\alpha = 1$ and thus always allow for an orientation with out-degree 1.

Whereas this paper focuses on edge orientation in incremental forests (and thus also incremental pseudoforests), past work has considered a slightly more general problem [7, 10, 18, 20], allowing for edge deletions in addition to edge insertions, and also considering dynamic graphs with pseudo-arboricities $\alpha > 1$. Brodal and Fagerberg gave an algorithm that achieved out-degree $O(\alpha)$ with amortized running time that is guaranteed to be constant competitive with that of any algorithm; they also showed that in the case of $\alpha \in O(1)$, it is possible to achieve constant out-degree with amortized time $O(1)$ per insertion and $O(\log n)$ per deletion [10]. For worst-case guarantees, on the other hand, the only algorithm known to achieve sub-logarithmic bounds for both out-degree and edges flipped per insertion is that of

Kopelowitz et al. [20], which achieves $O(\log n / \log \log n)$ for both, assuming $\alpha \in O(\sqrt{\log n})$. In the case of incremental forests, our results allow for us to improve substantially on this, achieving a worst-case bound of $O(\log \log n)$ edges flipped per insertion (with high probability) while supporting maximum out-degree $O(1)$. An interesting feature of our algorithm is that it is substantially different than any of the past algorithms, suggesting that the fully dynamic graph setting (with $\alpha > 1$) may warrant revisiting.

Our interest in the incremental forest case stems in part from its importance for a specific application: Cuckoo hashing. As we shall now discuss, our results on incremental edge orientation immediately yield a somewhat surprising result on Cuckoo hashing with dynamic guarantees.

1.1 An Application to Cuckoo Hashing: From Static to Dynamic Guarantees via Non-Greedy Eviction

A *s*-**associative Cuckoo hash table** [13, 23, 27, 28] consists of n **bins**, each of which has s **slots**, where s is a constant typically between 1 and 8 [23, 27]. Records are inserted into the table using two hash functions h_1, h_2 , each of which maps records to bins. The invariant that makes Cuckoo hashing special is that, if a record x is in the table, then x must reside in either bin $h_1(x)$ or $h_2(x)$. This invariant ensures that query operations *deterministically* run in time $O(1)$.

When a new record x is inserted into the table, there may not initially be room in either bin $h_1(x)$ or $h_2(x)$. In this case, x **kicks out** some record y_1 in either $h_1(x)$ or $h_2(x)$. This, in turn, forces y_1 to be inserted into the other bin b_2 to which y_1 is hashed. If bin b_2 *also* does not have space, then y_1 kicks out some record y_2 from bin b_2 , and so on. This causes what is known as a **kickout chain**. Formally, a kickout chain takes a sequence of records y_1, y_2, \dots, y_j that reside in bins b_1, b_2, \dots, b_j , respectively, and relocates those records to instead reside in bins b_2, b_3, \dots, b_{j+1} , respectively, where for each record y_i the bins b_i and b_{i+1} are the two bins to which h_1 and h_2 map y_i . The purpose of a kickout chain is to free up a slot in bin b_1 so that the newly inserted record can reside there. Although Cuckoo hashing guarantees constant-time queries, insertion operations can sometimes incur high latency due to long kickout chains.

The problem of designing simple hash-function families for Cuckoo hashing has received extensive attention [1, 4, 5, 11, 14, 15, 25, 27, 30]. Several natural (and widely used) families of hash functions are known *not* to work [11, 14], and it remains open whether there exists $k = o(\log n)$ for which k -independence suffices [24]. This has led researchers to design and analyze *specific families* of simple hash functions that have low independence but that, nonetheless, work well with Cuckoo hashing [1, 4, 5, 15, 25, 27, 30]. Notably, Cuckoo hashing has served as one of the main motivations for the intensive study of tabulation hash functions [1, 12, 29–31].

Work on hash-function families for cuckoo hashing [1, 4, 5, 15, 25, 27, 30] has focused on offering a **static guarantee**: for any set X of $O(n)$ records, there exists (with reasonably high probability) a valid 1-associative hash-table configuration that stores the records X . This guarantee is static in the sense that it does not say anything about the speed with which insertion and deletion operations can be performed.

On the other hand, if the hash functions are fully random, then a strong **dynamic guarantee** is known. Panigrahy [28] showed that, using bins of size two, insertions can be implemented to incur at most $\log \log n + O(1)$ kickouts, and to run in time at most $O(\log n)$, with high probability in n . Moreover, the expected time taken by each insertion is $O(1)$.

The use of bin sizes greater than one is essential here, as it gives the data structure algorithmic flexibility in choosing which record to evict from a bin. Panigrahy [28] uses breadth-first search in order to find the shortest possible kickout chain to a bin with a free slot. The fact that the hash functions h_1 and h_2 are fully random ensures that, with high probability, the search terminates within $O(\log n)$ steps, thereby finding a kickout chain of length $\log \log n + O(1)$.

If a family of hash functions has sufficiently strong randomness properties (e.g., the family of [15]) then one can likely recreate the guarantees of [28] by directly replicating the analysis. For other families of hash functions [1, 4, 5, 15, 25, 27, 30], however, it is unclear what sort of dynamic guarantees are or are not possible.

This raises a natural question: *does there exist a similar dynamic guarantee to that of [28] when the underlying hash functions are not fully random – in particular, if we know only that a hash family \mathcal{H} offers a static guarantee, but we know nothing else about the structure or behavior of hash functions in \mathcal{H} , is it possible to transform the static guarantee into a dynamic guarantee?*

Our results on Cuckoo hashing: a static-to-dynamic transformation

We answer this question in the affirmative by presenting a new algorithm, the Dancing-Kickout Algorithm, for selecting kickout chains during insertions in a Cuckoo hash table. Given any hash family \mathcal{H} that offers a 1-associative static guarantee, we show that the same hash family can be used to offer an $O(1)$ -associative dynamic guarantee. In particular, the Dancing-Kickout Algorithm supports both insertions and deletions with the following promise: as long as the static guarantee for \mathcal{H} has not failed, then with high probability, each insertion/deletion incurs at most $O(\log \log n)$ kickouts, has amortized time (and therefore number of kickouts) $O(1)$, and takes time at most $O(\log n \log \log n)$. We also extend our results to consider families of hash functions \mathcal{H} that offer relaxed static guarantees – that is, our results still apply to families either make assumptions about the input set [25] or require the use of a small auxiliary stash [4, 19].

Unlike prior algorithms, the Dancing-Kickout Algorithm takes a *non-greedy* approach to record-eviction. The algorithm will sometimes continue a kickout chain *past* a bin that has a free slot, in order to avoid “hotspot clusters” of full bins within the hash table. These hotspots are avoided by ensuring that, whenever a bin surrenders its final free slot, the bin is at the end of a reasonably long random walk, and is thus itself a “reasonably” random bin. Intuitively, the random structure that the algorithm instills into the hash table makes it possible for the hash functions from \mathcal{H} to not be fully random.

The problem of low-latency Cuckoo hashing is closely related to the problem of incremental edge orientation. In particular, the static guarantee for a Cuckoo hash table (with bins of size one) means that the edges in a certain graph form a pseudoforest. And the problem of dynamically maintaining a Cuckoo hash table (with bins of size $O(1)$) can be solved by dynamically orienting the pseudoforest in order to maintain constant out-degrees. The Dancing-Kickout algorithm is derived by applying our results for incremental edge orientation along with several additional ideas to handle deletions.

In addition to maintaining n bins, the Dancing-Kickout Algorithm uses an auxiliary data structure of size $O(n)$. The data structure incurs at most $O(1)$ modifications per insertion/deletion. Importantly, the auxiliary data structure is not accessed during queries, which continue to be implemented as in a standard Cuckoo hash table.

Our results come with an interesting lesson regarding the symbiotic relationship between Cuckoo hashing and edge orientation. There has been a great deal of past work on Cuckoo hashing that focuses on parameters such as associativity, number of hash functions, and

choice of hash function. We show that a new dimension that also warrants attention: how to dynamically maintain the table to ensure that a short kickout chain exists for every insertion. Algorithms that greedily optimize *any given operation* (e.g., random walk and BFS) may inadvertently structure the table in a way that compromises the performance of some later operations. In contrast, the non-greedy approach explored in this paper is able to offer strong performance guarantees for all operations, even if the hash functions being used are far from fully random. The results in this paper apply only to 1-associative static guarantees, and are therefore innately limited in the types of dynamic guarantees that they can offer (for example, we cannot hope to support a load factor of better than 0.5). An appealing direction for future work is to design and analyze eviction algorithms that offer strong dynamic guarantees in hash tables with either a large associativity or a large number of hash functions – it would be especially interesting if such guarantees could be used to support a load factor of $1 - q$ for an arbitrarily small positive constant q .

Related work on low-latency hash tables

Several papers have used ideas from Cuckoo hashing as a parts of new data structures that achieve stronger guarantees. Arbritman et al. [2] showed how to achieve a fully constant-time hash table by maintaining a polylogarithmic-size backyard consisting of the elements whose insertions have not yet completed at any given moment. Subsequent work then showed that, by storing almost all elements in a balls-in-bins system and then storing only a few “overflow” elements in a backyard Cuckoo hash table, one can construct a succinct constant-time hash table [3].²

Whereas the focus of these papers [2, 3] is to design new data structures that build on top of Cuckoo hashing, the purpose of our results is to consider *standard* Cuckoo hashing but in the dynamic setting. In particular, our goal is to show that dynamic guarantees for Cuckoo hashing do not have to be restricted to fully random hash-functions; by using the Dancing-Kickout Algorithm for maintaining the Cuckoo hash table, *any* family of hash functions that enjoys static guarantees can also enjoy dynamic guarantees.

2 An Algorithm with High-Probability Worst-Case Guarantees

This section considers the problem of incremental edge orientation in a forest. Let e_1, \dots, e_{n-1} be a sequence of edges between vertices in $V = \{v_1, \dots, v_n\}$ such that the edges form a tree on the vertices.

Our algorithm, which we call the Dancing-Walk Algorithm, guarantees out-degree at most 3 for each vertex, and performs at most $O(\log \log n)$ edge-flips per operation. Each step of the algorithm takes time at most $O(\log n \log \log n)$ to process. The algorithm is randomized, and can sometimes declare failure. The main technical difficulty in analyzing the algorithm is to show that the probability of the algorithm declaring failure is always very small.

We now describe the Dancing-Walk Algorithm. At any given moment, the algorithm allows each vertex v to have up to two **primary** out-going edges, and one **secondary** out-going edge. A key idea in the design of the algorithm is that, once a vertex has two primary out-going edges, the vertex can **volunteer** to take on a secondary out-going edge in order to ensure that a chain of edge flips remains short. But if vertices volunteer too

² It is worth noting, however, that as discussed in [17], the data structure of [3] can be modified to use any constant-time hash table in place of deamortized Cuckoo hashing.

frequently in some part of the graph, then the supply of potential volunteers will dwindle, which would destroy the algorithm's performance. The key is to design the algorithm in a way so that volunteering vertices are able to be useful but are not overused.

Consider the arrival of a new edge e_i . Let v_1 and v_2 be the two vertices that e_i connects, and let T_1 and T_2 be the two trees rooted at v_1 and v_2 , respectively. The algorithm first determines which of T_1 or T_2 is smaller (for this description we will assume $|T_1| \leq |T_2|$). Note that, by maintaining a simple union-find data structure on the nodes, the algorithm can recover the sizes of T_1 and T_2 each in $O(\log n)$ time.

The algorithm then performs a random walk through the (primary) directed edges of T_1 , beginning at v_1 (we call v_1 the **source vertex** of the random walk). Each step of the random walk travels to a new vertex by going down a random outgoing primary edge from the current vertex. If the random walk encounters a vertex u with out-degree less than 2 (note that this vertex u may even be v_1), then the walk terminates at that vertex. Otherwise, the random walk continues for a total of $c \log \log n$ steps, terminating at some vertex u with out-degree either 2 or 3. If the final vertex u has out-degree 2, meaning that the vertex does not yet have a secondary out-going edge, then the vertex u volunteers to take a secondary out-going edge and have its out-degree incremented to 3. If, on the other hand, the final vertex u already has out-degree 3, then the random walk is considered to have **failed**, and the random walk is repeatedly restarted from scratch until it succeeds. The algorithm performs up to $d \log n$ random-walk attempts for some sufficiently large constant d ; if all of these fail, then the algorithm **declares failure**.

Once a successful random walk is performed, all of the edges that the random walk traveled down to get from v_1 to u are flipped. This decrements the degree of v_1 and increments the degree of u . The edge e_i is then oriented to be out-going from v_1 . The result is that every vertex in the graph except for u has unchanged out-degree, and that u has its out-degree incremented by 1.

In the rest of the section, we prove the following theorem:

► **Theorem 1.** *With high probability in n , the Dancing-Walk Algorithm can process all of e_1, \dots, e_{n-1} without declaring failure. If the algorithm does not declare failure, then each step flips $O(\log \log n)$ edges and takes $O(\log n \log \log n)$ time. Additionally, no vertex's out-degree ever exceeds 3.*

For each edge e_t , let B_t be the binary tree in which the random walks are performed during the operation in which e_t is inserted. In particular, for each internal node of B_t , its children are the vertices reachable by primary out-going edges; all of the leaves in B_t are either at depth $c \log \log n$, or are at smaller depth and correspond with a vertex that has out-degree one or zero. Note that the set of nodes that make up B_t is a function of the random decisions made by the algorithm in previous steps, since these decisions determine the orientations of edges. Call the leaves at depth $(c \log \log n)$ in B_t the **potential volunteer leaves**. If every leaf in B_t is a potential volunteer leaf, then B_t can have as many as $(\log n)^c$ such leaves.

The key to proving Theorem 1 is to show with high probability in n , that for each step t , the number of potential volunteer leaves in B_t that have already volunteered in previous steps is at most $(\log n)^c / 2$.

► **Proposition 2.** *Consider a step $t \in \{1, 2, \dots, n-1\}$. With high probability in n , the number of potential volunteer leaves in B_t that have already volunteered in previous steps is at most $(\log n)^c / 2$.*

Assuming the high-probability outcome in Proposition 2, it follows that each random walk performed during the t -th operation has at least a $1/2$ chance of success. In particular, the only way that a random walk can fail is if it terminates at a leaf of depth $c \log \log n$ and that leaf has already volunteered in the past. With high probability in n , one of the first $O(\log n)$ random-walk attempts will succeed, preventing the algorithm from declaring failure.

The intuition behind Proposition 2 stems from two observations:

- **The Load Balancing Property:** Each vertex v is contained in at most $\log n$ trees B_t . This is because, whenever two trees T_1 and T_2 are joined by an edge e_t , the tree B_t is defined to be in the smaller of T_1 or T_2 . In other words, for each step t that a vertex v appears in B_t , the size of the (undirected) tree containing v at least doubles.
- **The Sparsity Property:** During a step t , each potential volunteer leaf in B_t has probability at most $\frac{d \log n}{\log^c n}$ of being selected to volunteer.

Assuming that most steps succeed within the first few random-walk attempts, the two observations combine to imply that most vertices v are never selected to volunteer.

The key technical difficulty comes from the fact that the structure of the tree B_t , as well as the set of vertices that make up the tree, is partially a function of the random decisions made by the algorithm in previous steps. This means that the set of vertices in tree B_t can be partially determined by which vertices have or have not volunteered so far. In this worst case, this might result in B_t consisting entirely of volunteered vertices, despite the fact that the vast majority of vertices in the graph have not volunteered yet.

How much flexibility is there in the structure of B_t ? One constraint on B_t is that it must form a subtree of the undirected graph $G_t = \{e_1, \dots, e_{t-1}\}$. This constraint alone is not very useful. For example, if G_t is a $(\log^{c+1} n)$ -ary tree of depth $c \log \log n$, and if each node in G_t has volunteered previously with probability $1/\log^c n$, then there is a reasonably high probability that every internal node of G_t contains at least two children that have already volunteered. Thus there would exist a binary subtree of G_t consisting entirely of nodes that have already volunteered.

An important property of the Dancing-Walk Algorithm is that the tree B_t cannot, in general, form an arbitrary subtree of G_t . Lemma 3 bounds the number of possibilities for B_t :

► **Lemma 3.** *For a given sequence of edge arrivals e_1, \dots, e_{n-1} , the number of possibilities for tree B_t is at most $(\log n)^{2 \log^c n}$.*

Proof. We will show that, for a given node v in B_t , there are only $\log n$ options for who each of v 's children can be in B_t . In other words, B_t is a binary sub-tree of a $(\log n)$ -ary tree with depth $c \log \log n$. Once this is shown, the lemma can be proven as follows. One can construct all of the possibilities for B_t by beginning with the root node v_1 and iteratively by adding one node at a time from the top down. Whenever a node v is added, and is at depth less than $c \log \log n$, one gets to either decide that the node is a leaf, or to select two children for the node. It follows that for each such node v there are at most $\binom{\log n}{2} + 1 \leq \log^2 n$ options for what v 's set of children looks like. Because B_t can contain at most $\log^c n - 1$ nodes v with depths less than $c \log \log n$, the total number of options for B_t is at most $(\log^2 n)^{\log^c n}$, as stated by the lemma.

It remains to bound the number of viable children for each node v in B_t . To do this, we require a stronger version of the load balancing property. The Strong Load Balancing Property says that, not only is the number of trees B_t that contain v bounded by $\log n$, but the set of $\log n$ trees B_t that can contain v is a function only of the edge sequence (e_1, \dots, e_{n-1}) , and not of the randomness in the algorithm.

- **The Strong Load Balancing Property:** For each vertex v , there is a set $S_v \subseteq [n]$ determined by the edge-sequence (e_1, \dots, e_{n-1}) such that: (1) the set's size satisfies $|S_v| \leq \log n$, and (2) every B_t containing v satisfies $t \in S_v$.

The Strong Load Balancing Property is a consequence of the fact that, whenever a new edge e_t combines two trees T_1 and T_2 , the algorithm focuses only on the smaller of the two trees. It follows that a vertex v can only be contained in tree B_t if the size of the (undirected) tree containing v at least doubles during the t -th step of the algorithm. For each vertex v , there can only be $\log n$ steps t in which the tree size containing v doubles, which implies the Strong Load Balancing Property.

Consider a step t , and suppose that step t orients some edge e to be facing out from some vertex v . Then it must be that the path from edge e_t to vertex v goes through e as its final edge. In other words, for a given step t and a given vertex v , there is only one possible edge e that might be reoriented during step t to be facing out from v . By the Strong Load Balancing Property, it follows that for a given vertex v , there are only $\log n$ possibilities for out-going edges e . This completes the proof of the lemma. ◀

Now that we have a bound on the number of options for B_t , the next challenge is to bound the probability that a given option for B_t has an unacceptably large number of volunteered leaves.

The next lemma proves a concentration bound on the number of volunteered vertices in a given set. Note that the event of volunteering is not independent between vertices. For example, if two vertices v and u are potential volunteer leaves during some step, then only one of v or u can be selected to volunteer during that step.

► **Lemma 4.** *Fix a sequence of edge arrivals e_1, \dots, e_{n-1} , and a set S of vertices. The probability that every vertex in S volunteers by the end of the algorithm is at most, $O\left(n/(\log^{(c-3)}|S|)\right)$.*

Proof. For each step $t \in \{1, 2, \dots, n-1\}$, define F_t to be the number of elements of S that are potential volunteer leaves during step t . Define $p_t = \frac{F_t \cdot d \log n}{\log^c n}$, where $d \log n$ is the number of random-walk attempts that the algorithm is able to perform in each step before declaring failure. By the Sparsity Property, the value p_t is an upper bound for the probability that any of the elements of S volunteer during step t . In other words, at the beginning of step t , before any random-walk attempts are performed, the probability that some element of S volunteers during step t is at most p_t .

Note that the values of p_1, \dots, p_{n-1} are not known at the beginning of the algorithm. Instead, the value of p_t is partially a function of the random decisions made by the algorithm in steps $1, 2, \dots, t-1$. The sum $\sum_t p_t$ is deterministically bounded, however. In particular, since each vertex $s \in S$ can appear as a potential volunteer leaf in at most $\log n$ steps (by the Load Balancing Property), the vertex s can contribute at most $d \log^2 n$ to the sum $\sum_t p_t$. It follows that $\sum_t p_t \leq \frac{|S| d \log^2 n}{\log^c n}$.

Let X_t be the indicator random variable for the event that some vertex in S volunteers during step t . Each X_t occurs with probability at most p_t . The events X_t are not independent, however, since the value of p_t is not known until the end of step $t-1$. Nonetheless, the fact that $\sum_t p_t$ is bounded allows for us to prove a concentration bound on $\sum_t X_t$ using the following version of Azuma's inequality [22].

▷ **Claim 5.** Let $\mu \in [0, n]$, and suppose that Alice is allowed to select a sequence of numbers p_1, p_2, \dots, p_k , $p_i \in [0, 1]$, such that $\sum_i p_i \leq \mu$. Each time Alice selects a number p_i , she wins 1 dollar with probability p_i . Alice is an adaptive adversary in that she can take into account

12:10 Incremental Edge Orientation in Forests

the results of the first i bets when deciding on p_{i+1} . If X is Alice's profit from the game,

$$\Pr \left[X > (1 + \delta)\mu \right] \leq \exp((\delta - \ln(1 + \delta))(1 + \delta)\mu),$$

for all $\delta > 0$.

Applying Claim 5 to $X = \sum_t X_t$, with $\delta = \frac{\log^c n}{d \log^2 n} - 1$ and $\mu = \frac{|S| d \log^2 n}{\log^c n}$ (so that $(\delta + 1)\mu = |S|$), we get that $\Pr[X > |S|]$ is at most

$$\exp \left(|S| - |S| \ln \frac{\log^c n}{d \log^2 n} \right) = O \left(\exp(-|S| \ln \log^{c-3} n) \right) = O \left(\log^{-(c-3)|S|} n \right). \quad \blacktriangleleft$$

Combining Lemmas 3 and 4, we can now prove Proposition 2.

Proof of Proposition 2. Consider a tree B_t . By Lemma 3, the number of options for B_t , depending on the behavior of the algorithm in steps $1, 2, \dots, t-1$, is at most $(\log n)^{2 \log^c n}$. For a given choice of B_t , there are at most $\binom{\log^c n}{\frac{1}{2} \log^c n} \leq 2^{\log^c n}$ ways to choose a subset S consisting of $\frac{\log^c n}{2}$ of the potential volunteer leaves. For each such set of leaves S , Lemma 4 bounds the probability that all of the leaves in S have already volunteered by,

$$O \left(\log^{-(c-3)|S|} n \right) = O \left(\log^{-(\log^c n)(c-3)/2} n \right).$$

Summing this probability over all such subsets S of all possibilities for B_t , the probability that B_t contains $\frac{\log^c n}{2}$ already-volunteered leaves is at most,

$$O \left((\log n)^{2 \log^c n} \cdot 2^{\log^c n} \cdot \log^{-(\log^c n)(c-3)/2} n \right) = O \left(\frac{(2 \log n)^{2 \log^c n}}{\log^{(\log^c n)(c-3)/2} n} \right).$$

For a sufficiently large constant c , this is at most $\frac{1}{n^{\omega(1)}}$. The proposition follows by taking a union bound over all $t \in \{1, 2, \dots, n-1\}$. \blacktriangleleft

We conclude the section with a proof of Theorem 1

Proof of Theorem 1. Consider a step t in which the number of potential volunteer leaves in B_t that have already volunteered is at most $\frac{1}{2} \log^c n$. The only way that a random walk in step t can fail is if it lasts for $c \log \log n$ steps (without hitting a vertex with out-degree 1 or 0) and it finishes at a vertex that has already volunteered. It follows that, out of the $\log^c n$ possibilities for a $(c \log \log n)$ -step random walk, at most half of them can result in failure. Since each random-walk attempt succeeds with probability at least $1/2$, and since the algorithm performs up to $d \log n$ attempts for a large constant d , the probability that the algorithm fails on step t is at most $\frac{1}{n^d} = \frac{1}{\text{poly} n}$.

The above paragraph establishes that, whenever the search tree B_t contains at most $\frac{1}{2} \log^c n$ potential volunteer leaves that have already volunteered, then step t will succeed with high probability in n . It follows by Proposition 2 that every step succeeds with high probability in n .

We complete the theorem by discussing the properties of the algorithm in the event that it does not declare failure. Each step flips at most $O(\log \log n)$ edges and maintains maximum out-degrees of 3. Because each step performs at most $O(\log n)$ random-walk attempts, these attempts take time at most $O(\log n \log \log n)$ in each step. Additionally, a union-find data structure is used in order to allow for the sizes $|T_1|$ and $|T_2|$ of the two trees being combined to be efficiently computed in each step. Because the union-find data structure can be implemented to have worst-case operation time $O(\log n)$, the running time of each edge-insertion remains at most $O(\log n \log \log n)$. \blacktriangleleft

The tradeoff between edges flipped and out-degree

To conclude the section, we consider a modification of the Dancing-Walk Algorithm in which nodes are permitted to have out-degree as large as $k = \log^\varepsilon n + 1$ (instead of 3) for some parameter ε . Rather flipping the edges in a random walk of length $c \log \log n$, the new algorithm instead flips the edges in a random walk of length $c\varepsilon^{-1}$. The length of the random walk is parameterized so that the number of potential volunteers $|D_t|$ is still $\log^c n$, as was the case before. The resulting algorithm yields the following result, which allows for a tradeoff between edges flipped per insertion and maximum out-degree:

► **Theorem 6.** *Consider the Dancing-Walk Algorithm with maximum out-degree $k + 1$. With high probability in n , the algorithm can process all of e_1, \dots, e_{n-1} without declaring failure. If the algorithm does not declare failure, then each step flips $O(\log_k \log n)$ edges and takes $O(\log n \log_k \log n)$ time. Additionally, no vertex's out-degree ever exceeds $k + 1$.*

The proof of Theorem 6 can be found in the extended version of the paper [6].

3 Achieving Constant Amortized Running Time

We now discuss how to modify the Dancing-Walk Algorithm to achieve a total running time of $X = O(n)$. The resulting algorithm, which we call the **Rank-Based Dancing-Walk Algorithm** offers the following guarantee on top of those in Theorem 1:

► **Theorem 7.** *To perform $n - 1$ edge insertions, the total time required by the Rank-Based Dancing-Walk Algorithm is at most $O(n)$ with high probability in n .*

To simplify the discussion in this section, we focus here on the simpler problem of bounding the *expected* total running time $\mathbb{E}[X]$. The full proof of Theorem 7 can be found in the extended version of the paper [6].

Although each random walk is permitted to have length as large as $\Theta(\log \log n)$, one can easily prove that a random walk through a tree of m nodes expects to hit a node with out-degree less than 2 within $O(\log m)$ steps. Recall that, whenever an edge e_t combines two (undirected) trees T_1 and T_2 , the ensuing random walks are performed in the *smaller* of T_1 or T_2 . The expected contribution to the running time X is therefore, $O(\min(\log |T_1|, \log |T_2|))$. That is, even though a given edge-insertion e_t could incur up to $\Theta(\log n)$ random walks each of length $\Theta(\log \log n)$ in the worst case, the expected time spent performing random walks is no more than $O(\min(\log |T_1|, \log |T_2|))$.

Let \mathcal{T} denote the set of pairs (T_1, T_2) that are combined by each of the $n - 1$ edge insertions. A simple amortized analysis shows that

$$\sum_{(T_1, T_2) \in \mathcal{T}} \min(\log |T_1|, \log |T_2|) = O(n). \quad (1)$$

Thus the time spent performing random walks is $O(n)$ in expectation.

In addition to performing random walks, however, the algorithm must also compare $|T_1|$ and $|T_2|$ on each edge insertion. But maintaining a union-find data structure to store the sizes of the trees requires $\Omega(\alpha(n, n))$ amortized time per operation [16], where $\alpha(n, n)$ is the inverse Ackermann function.

Thus, for the algorithm described so far, the maintenance of a union-find data structure prevents an amortized constant running time per operation. We now describe how to modify the algorithm in order to remove this bottleneck.

Replacing size with combination rank

We modify the Dancing-Walk Algorithm so that the algorithm no longer needs to keep track of the size $|T|$ of each tree in the graph. Instead the algorithm keeps track of the **combination rank** $R(T)$ of each tree T – whenever two trees T_1 and T_2 are combined by an edge insertion, the new tree T_3 has combination rank,

$$R(T_3) = \begin{cases} \max(R(T_1), R(T_2)) & \text{if } R(T_1) \neq R(T_2) \\ R(T_1) + 1 & \text{if } R(T_1) = R(T_2). \end{cases}$$

Define the **Rank-Based Dancing-Walk Algorithm** to be the same as the Dancing-Walk Algorithm, except that the source vertex (i.e., the vertex from which the random walk begins) is selected to be in whichever of T_1 or T_2 has smaller combination rank (rather than smaller size).

The advantage of combination rank is that it can be efficiently maintained using a simple tree structure. Using this data structure, the time to merge two trees T_1 and T_2 (running the Dancing-Walk Algorithm with appropriately chosen source vertex) becomes simply $\min(R(T_1), R(T_2))$. This, in turn, can be upperbounded by $O(\min(\log |T_1|, \log |T_2|))$. By (1), the total time spent maintaining combination ranks of trees is $O(n)$.

The other important feature of combination rank is that it preserves the properties of the algorithm that are used to analyze correctness. Importantly, whenever a tree T is used for path augmentation by an edge-insertion e_t , the combination rank of T increases due to that edge insertion. One can further prove that the combination rank never exceeds $O(\log n)$, which allows one to derive the Strong Load Balancing Property and the Preset Children Property.

The disadvantage: longer random walks

The downside of using combination rank to select trees is that *random walks* can now form a running-time bottleneck. Whereas the expected running time of all random walks was previously bounded by (1), we now claim that it is bounded by,

$$\sum_{(T_1, T_2) \in \mathcal{T}} \left(\begin{cases} \log |T_1| & \text{if } R(T_1) \leq R(T_2) \\ \log |T_2| & \text{if } R(T_2) < R(T_1) \end{cases} \right) = O(n). \quad (2)$$

We now justify this claim. The problem is that a tree T can potentially have very small combination rank (e.g., $O(1)$) but very large size (e.g., $\Omega(n)$). As a result, the summation (1) may differ substantially from the summation (2).

Rather than bounding (2) directly, we instead examine the smaller quantity,

$$\sum_{(T_1, T_2) \in \mathcal{T}} \left(\begin{cases} \log |T_1| - R(T_1) & \text{if } R(T_1) \leq R(T_2) \\ \log |T_2| - R(T_2) & \text{if } R(T_2) < R(T_1) \end{cases} \right) = O(n). \quad (3)$$

The difference between (2) and (3) is simply

$$\sum_{(T_1, T_2) \in \mathcal{T}} \min(R(T_1), R(T_2)) = O(n),$$

meaning that an upper bound on (3) immediately implies an upper bound on (2).

The key feature of (3), however, is that it yields to a simple potential-function based analysis. In particular, if we treat each vertex v as initially having $\Theta(1)$ tokens, and we treat each tree combination (T_1, T_2) as incurring a cost given by the summand in (3), then one

can show that every tree T always has at least $\Omega\left(\frac{|T|}{2^{R(T)}}\right)$ tokens, which means that the total number of tokens spent is $O(n)$. This allows us to bound (3) by $O(n)$, which then bounds (2) by $O(n)$, and implies a total expected running time of $\mathbb{E}[X] = O(n)$.

4 Dynamic Cuckoo Hashing

In this section we present the *Dancing-Kickout Algorithm* for maintaining a Cuckoo hash table. For any family of hash functions \mathcal{H} that provides a 1-associative static guarantee, the Dancing-Kickout Algorithm offers a $O(1)$ -associative dynamic guarantee using the same hash-function family \mathcal{H} .

We will state our results so that they also apply to Cuckoo hashing with a stash [4, 19]. A Cuckoo hash table with a **stash** of size s is permitted to store s elements *outside* of the table in a separate list. Having a small stash has been shown by past work to significantly simplify the problem of achieving high-probability static guarantees [4] – our results can be used to make these guarantees dynamic.

Let $h = (h_1, h_2)$ be a pair of hash functions mapping records to $[n]$. A set X of records is ***h-viable*** if it is possible to place the records X into a 1-associative n -bin Cuckoo hash table using hash functions h_1 and h_2 .

Even if a set of records X is not h -viable, it may be that there is a set of s elements Y for which $X \setminus Y$ is h -viable. In this case, we say X is ***h-viable with a stash of size s***.

Past static guarantees [1, 4, 5, 15, 25, 27, 30] for a hash family \mathcal{H} , have taken the following form, where $c \in (0, 1)$, $p(n) \in \text{poly}(n)$, $s \in O(1)$ are parameters: Every set of records X of size cn has probability at least $1 - 1/p(n)$ of being h -viable with a stash of size s , where $h = (h_1, h_2)$ is drawn from \mathcal{H} . In addition to considering guarantees of this type, a fruitful line of work [25] has also placed additional restrictions on the set X of records (namely, that X exhibits high entropy). In this section, we will state our results in such a way so that they are applicable to all of the past variants of static guarantees that we are aware of.

Viability as a graph property

Define the *Cuckoo graph* $G(X, h)$ for a set of records X and for a pair of hash functions $h = (h_1, h_2)$ to be the graph with vertices $[n]$ and with (undirected) edges $\{(h_1(x), h_2(x)) \mid x \in X\}$. The problem of configuring where records should go in the hash table corresponds to an edge-orientation problem in G . In particular, one can think of each record x that resides in a bin $h_i(x)$ as representing an edge $(h_1(x), h_2(x))$ that is oriented to face out of vertex $h_i(x)$. A set of records X is h -viable if and only if the edges in $G(X, h)$ can be oriented so that the maximum out-degree is 1.

Similarly, a set of records X is h -viable with a stash of size s if and only if there are s (or fewer) edges that can be removed from the Cuckoo graph $G(X, h)$ so that the new graph G' can be oriented to have maximum out-degree 1.

Applying static guarantees to dynamic settings

In order to apply static guarantees in a dynamic setting, we define the notion of a sequence of insert/delete operations satisfying a static guarantee.

For $\varepsilon \in (0, 1)$ and for a hash-function pair $h = (h_1, h_2)$, we say that a sequence $\Psi = \langle \psi_1, \psi_2, \dots \rangle$ of insert/delete operations is ***(ε, h)-viable with a stash of size s*** if the following holds: for every subsequence of operations of the form $P_i = \langle \psi_{i\varepsilon n+1}, \psi_{i\varepsilon n+2}, \dots, \psi_{(i+1)\varepsilon n} \rangle$, the set X of records that are present (at any point) during the operations P_i has the property that X is h -viable with a stash of size s .

The dynamic guarantees in this section will assume only that the sequence of operations Ψ is (ε, h) -viable (with a stash of size s) for some known parameter $\varepsilon \in (0, 1)$, and will make no other assumptions about Ψ or the hash-function pair $h = (h_1, h_2)$.

Note that the property of being (ε, h) -viable is a statement about the sets of records X that are present during windows of εn operations. If the table is always filled to capacity cn , for some $c \in (0, 1)$, then the property of being (ε, h) -viable is a statement about sets of $(c + \varepsilon)n$ records. Thus dynamic guarantees for tables on cn records can be derived from static guarantees that apply to tables of $(c + \varepsilon)n$ records. By making ε smaller, one can close the gap between the capacities for the static and dynamic guarantees – but as we shall see, this also increases the constant in the algorithm’s running time.

Our dynamic guarantee

Formally, we say that an *implementation of a k -associative Cuckoo hash table with a stash of size s* is an algorithm that maintains a Cuckoo hash table with n bins, each of size k , and with a stash of size up to s . The implementation is given two hash functions h_1, h_2 , and every record x in the table must either be stored in one of the bins $h_1(x), h_2(x)$ or in the stash. The implementation is permitted to maintain an additional $O(n)$ -space data structure \mathcal{D} for additional bookkeeping, as long as \mathcal{D} is not modified by queries, and as long as each insert/delete incurs at most $O(1)$ writes to \mathcal{D} .

We say that a Cuckoo hash table implementation satisfies *the dynamic guarantee* on a sequence of operations Ψ , if:

- Each insert/delete operation incurs $O(\log \log n)$ kickouts and takes time $O(\log n \log \log n)$.
- The amortized cost of each insert/delete operation is $O(1)$.

The goal of this section will be to describe an implementation of Cuckoo hashing that offers the dynamic guarantee (with high probability) as long as the underlying sequence of operations Ψ is (ε, h) -viable. We call our implementation of Cuckoo hashing the **Dancing-Kickout Algorithm**.

► **Theorem 8.** *Let $\varepsilon \in (0, 1)$ and s be constants (s may be 0). Let $h = (h_1, h_2)$ be a pair of hash functions. Let Ψ be a sequence of $\text{poly}(n)$ insert/delete operations that is (ε, h) -viable with a stash of size s .*

With high probability in n , the Dancing-Kickout Algorithm implements an 8-associative Cuckoo hash table with a stash of size s that satisfies the dynamic guarantee on Ψ .

Proof. We take the approach of starting with a weaker version of the theorem and then working our way towards the full version. Initially we will consider only inserts, but no deletes or stash. Then we will consider only inserts and a stash, but no deletes. Then we will consider all of inserts, deletes, and a stash, but we will make what we call the **full-viability assumption**, which is that the set X of *all* of records inserted and deleted by Ψ is h -viable. Finally, we will show how to remove the full-viability assumption.

We begin by describing the Dancing-Kickout Algorithm in the case where Ψ consists of only insertions (and no deletions). In this case, the algorithm only uses the first 4 slots in each bin. We also begin with the simplifying assumption that the stash size s is 0.

The algorithm thinks of each record x as representing an edge $(h_1(x), h_2(x))$ in the Cuckoo graph G . Since the set of records X being inserted is h -viable, it must be that G can be oriented with out-degree 1. This means that each connected component in G is a pseudotree (i.e., a tree with up to one additional edge added).

In this case, the Dancing-Kickout Algorithm works as follows. Whenever an edge-insertion connects two vertices from different connected components, the Dancing-Kickout Algorithm simply uses the Rank-Based Dancing-Walk Algorithm to maintain an edge-orientation with maximum out-degree 3. On the other hand, when an edge-insertion connects two vertices v, u that are already in the same tree as one another (we call the edge (v, u) a **bad edge**), the Dancing-Kickout Algorithm orients the edge arbitrarily and then disregards that edge in all steps (i.e., the edge cannot be used as part of a random walk). Since G is a pseudoforest, each vertex v is incident to at most one bad edge; it follows that the maximum out-degree in the graph never exceeds 4. This, in turn, means that no bin in the Cuckoo hash table stores more than 4 items.

The analysis of the Rank-Based Dancing-Walk algorithm ensures that the edge-insertions involving good edges satisfy the dynamic guarantee with high probability in n (that is, each operation takes time $O(\log n \log \log n)$, incurs $O(\log \log n)$ edge flips, and takes amortized time $O(1)$). The edge-insertions involving bad edges can be analyzed as follows. Note that the time for the Rank-Based Dancing-Walk Algorithm to identify that an edge $e = (v, u)$ is bad is just the height of the rank tree containing v and u . Since combination ranks never exceed $O(\log n)$, the time to identify a bad edge is never more than $O(\log n)$. Since each rank-tree will have at most one bad edge identified in it (because each connected component contains at most 1 bad edge), the total time spent identifying bad edges is at most the sum of the depths of the rank trees (at the end of all edge insertions); this, in turn, is $O(n)$ since the depth of each rank tree is never more than the number of elements it contains. Thus the operations in which bad edges are inserted do not cause the dynamic guarantee to be broken.

Now we describe what happens if Ψ still consists only of insertions, but a stash of size $s > 0$ is used. In this case, the Dancing-Kickout Algorithm places an edge $e = (v, u)$ in the stash (i.e., the algorithm places the record x for which $h_1(x) = v$ and $h_2(x) = u$ in the stash) if e is a bad edge *and* if both of the vertices v and u are already incident to bad edges. On the other hand, if one of v or u is not already incident to a bad edge, then the edge can be oriented out-going from that vertex (just as was the case without a stash). Call an edge e **super bad** if, when e is inserted, there is already a bad edge in the connected component containing e . Since Ψ is h -viable with a stash of size s , the number of super bad edges is at most s .³ Because the Random-Walk Algorithm only stashes super bad edges, the algorithm is guaranteed to never stash more than s records at a time. The running time of the algorithm on non-super-bad edges is the same as in the case of no stash; on the other hand, the s super bad edges can contribute $s \cdot O(\log n) = O(\log n)$ in total to the running time of the algorithm. Thus, with high probability, the Random-Walk Algorithm still satisfies the dynamic guarantee.

Now we consider what happens if Ψ contains deletes in addition to inserts. To begin, consider the special case where the set X of *all records* that Ψ *ever* inserts (including those that are subsequently deleted) has the property that X is h -viable – we call this the **full-viability assumption**. Under the full-viability assumption, deletes can be implemented with **tombstones**, meaning that when a record is deleted it is simply marked as deleted without actually being removed. In fact, the use of tombstones is not actually necessary. This is because the analysis of the Rank-Based Dancing-Walk Algorithm for edge-orientation

³ To see this formally, note that there must be a set of at most s edges Y such that $X \setminus Y$ is a pseudoforest. That is, without the edges Y there would be *no* super bad edges. On the other hand, one can verify that placing each of the edges from Y back into the sequence of edges $X \setminus Y$ adds at most $|Y|$ super bad edges, since each edge that is placed in can increase the number of super bad edges by at most 1.

continues to work without modification even if edges in the graph disappear arbitrarily over time, as long as all of the edges (*including those that disappear*) form a forest. Thus, in the case where the full-viability assumption holds, we can simply implement deletes by removing the appropriate record from the table, and then we can use the Dancing-Kickout algorithm exactly as described so far. Since the Rank-Based Dancing-Walk Algorithm can handle edges disappearing, it follows that the Dancing-Kickout algorithm still satisfies the dynamic guarantee with high probability.

Finally, we consider what happens if Ψ contains both inserts and deletes, but without making the full-viability assumption. So far, we have only used the first 4 slots of each bin. We now incorporate into the algorithm slots 5, 6, 7, 8, and we modify the algorithm to gradually rebuild the table in phases, where consecutive phases toggle between using only slots 1, 2, 3, 4 or using only slots 5, 6, 7, 8; as we shall see, each phase is designed so that the running-time of its operations can be treated as meeting the full-viability assumption.

In more detail, the algorithm performs gradual rebuilds as follows. The operations Ψ are broken into phases P_1, P_2, \dots each consisting of εn operations. At the beginning of each phase P_i where i is even (resp. i is odd), the hash table uses only the slots 1, 2, 3, 4 (resp. 5, 6, 7, 8) in each bin. During the phase of operations P_i , any new insertions are performed with the Dancing-Kickout Algorithm using slots 5, 6, 7, 8 (resp. 1, 2, 3, 4). Also, during the j -th operation in the phase P_i , the algorithm looks at bin j , takes any records in slots 1, 2, 3, 4 (resp. 5, 6, 7, 8), and reinserts those records into the hash table using slots 5, 6, 7, 8 (resp. 1, 2, 3, 4).⁴ Finally, deletes are implemented simply by removing the appropriate record x , regardless of what slot that record may be in.

During a given phase P_i , the algorithm can be thought of as starting with a new empty Cuckoo hash table (consisting in each bin of either the slots 1, 2, 3, 4 if i is odd or 5, 6, 7, 8 if i is even). Then over the course of P_i , one can think of the algorithm as performing not only the operations in P_i , but also populating the new hash table with any elements that were present at the beginning of the phase P_i (unless those elements are deleted before they have a chance to be re-populated). Let X be the set of all records x that are placed into the new hash table at some point during P_i (this includes both elements that operations in P_i act on, as well as elements that are re-inserted due to the gradual rebuild during the phase). By the (ε, h) -viability of Ψ , we know that X is h -viable. This means that phase P_i can be analyzed as satisfying the full-viability assumption. Thus, with high probability in n , the algorithm does not violate the dynamic guarantee during phase P_i . Since there are $\text{poly}(n)$ phases, it follows that, with high probability in n , the algorithm never violates the dynamic guarantee. ◀

Abstract

The k -center problem for a point set P asks for a collection of k congruent balls (that is, balls of equal radius) that together cover all the points in P and whose radius is minimized. The k -center problem with outliers is defined similarly, except that z of the points in P do need not to be covered, for a given parameter z . We study the k -center problem with outliers in data streams in the sliding-window model. In this model we are given a possibly infinite stream $P = \langle p_1, p_2, p_3, \dots \rangle$ of points and a time window of length W , and we want to maintain a small sketch of the set $P(t)$ of points currently in the window such that using the sketch we can approximately solve the problem on $P(t)$.

We present the first algorithm for the k -center problem with outliers in the sliding-window model. The algorithm works for the case where the points come from a space of bounded doubling dimension and it maintains a set $S(t)$ such that an optimal solution on $S(t)$ gives a $(1 + \varepsilon)$ -approximate solution on $P(t)$. The algorithm uses $O((kz/\varepsilon^d) \log \sigma)$ storage, where d is the doubling dimension of the underlying space and σ is the spread of the points in the stream. Algorithms providing a $(1 + \varepsilon)$ -approximation were not even known in the setting without outliers or in the insertion-only setting with outliers. We also present a lower bound showing that any algorithm that provides a $(1 + \varepsilon)$ -approximation must use $\Omega((kz/\varepsilon) \log \sigma)$ storage.

1 Introduction

Clustering is one of the most important tools to analyze large data sets. A well-known class of clustering algorithms is formed by centroid-based algorithms, which include k -means clustering, k -median clustering and k -center clustering. The latter type of clustering is the topic of our paper. In the k -center problem one is given a set P of points from a metric space and a parameter k , and the goal is to find k congruent balls (that is, balls of equal radius) that together cover the points from P and whose radius is minimized. Note that the special case $k = 1$ corresponds to the minimum-enclosing ball problem. Data sets in practice often contain outliers, leading to the *k -center problem with outliers*. Here we are given, besides P and k , a parameter z that indicates the allowed number of outliers. Thus the radius of the balls in an optimal solution is given by

$\text{OPT}_{k,z}(P) :=$ the smallest radius ρ such that we can cover all points from P ,
except for at most z outliers, by k balls of radius ρ .

In this paper we study the k -center problem with outliers in data streams, where the input is a possibly infinite stream $P = \langle p_1, p_2, \dots \rangle$ of points. The goal is to maintain a solution to the k -center problem as the points arrive over time, without any knowledge of future arrivals and using limited (sub-linear) storage. Since we cannot store all the points in the stream, we cannot expect to maintain an optimal solution. Hence, the two main quality criteria of a streaming algorithm are its approximation ratio and the amount of storage it uses. We will study this problem in the *sliding-window model*. In this model we are given a window length W and we are, at any time t , only interested in the points that arrived in the time window $(t - W, t]$. Working in the sliding-window model is often significantly more difficult than working in the standard (insertion-only) streaming model.

Previous work

Charikar et al. [6] were the first to study the metric k -center problem in data streams. They developed an algorithm in the insertion-only model that computes an 8-approximation for the k -center problem using $\Theta(k)$ space. Later McCutchen and Khuller [13] improved the approximation ratio to $2 + \varepsilon$ at the cost of increasing the storage to $O((k/\varepsilon) \log(1/\varepsilon))$. McCutchen and Khuller also studied the k -center problem with $z \geq 1$ outliers, for which they gave a $(4 + \varepsilon)$ -approximation algorithm that requires $O(kz/\varepsilon)$ space.

The above results are for general metric spaces. In spaces of *bounded doubling dimension*¹ better bounds are possible. Indeed, Ceccarello et al. [3] gave a $(3 + \varepsilon)$ -approximation algorithm for the k -center problem with z outliers, thus improving the approximation ratio $(4 + \varepsilon)$ for general metrics. Their algorithm requires $O((k + z)(1/\varepsilon)^d)$ storage, where d is the doubling dimension of the underlying space (which is assumed to be a fixed constant).

The algorithms mentioned so far are deterministic. Charikar et al. [8] and Ding et al. [10] studied sampling-based streaming algorithms for the Euclidean k -center problem with outliers, showing that if one allows slightly more than z outliers then randomization can reduce the storage requirements. Our focus, however, is on deterministic algorithms.

For the k -center problem in the sliding-window model, the only result we are aware of is due to Cohen-Addad et al. [9]. They deal with the k -center problem in general metric spaces, but without outliers, and they propose a $(6 + \varepsilon)$ -approximation algorithm using $O((k/\varepsilon) \log \sigma)$ storage, and a $(4 + \varepsilon)$ -approximation for the special case $k = 2$. Here σ denotes (an upper bound on) the spread of the points in the stream; in other words, $\sigma := \Delta_{\max}/\Delta_{\min}$, where Δ_{\max} is an upper bound on the maximum distance and Δ_{\min} is a lower bound on the minimum distance between any two distinct points. It is assumed that Δ_{\max} and Δ_{\min} are known to the algorithm. They also prove that any algorithm for the 2-center problem with outliers in general metric spaces that achieves an approximation ratio of less than 4 requires $\Omega(W^{1/3})$ space, where W is the size² of the window. Table 1 gives an overview of the known results on the k -center problem in the insertion-only and the sliding-window model.

While our main interest is in the k -center problem for $k > 1$, our results also apply when $k = 1$. Hence, we also briefly discuss previous results for the 1-center problem.

¹ The *doubling dimension* of a space X is the smallest number d such that any ball B in the space can be covered by 2^d balls of radius $\text{radius}(B)/2$.

² Here the window size W is defined in terms of the number of points in the window, that is, the window consists of the W most recent points. We define the window in a slightly more general manner, by defining W to be the length (that is, duration) of the window. Note that if we assume that the i -th point arrives at time $t = i$, then the two models are the same.

■ **Table 1** Results for the k -center problem with and without outliers in the insertion-only and the sliding-window model. Bounds on the storage are asymptotic. In the papers where the metric space has bounded doubling dimension or is Euclidean, the dimension d is considered a constant.

model	metric space	approx.	storage	outliers	ref.
insertion-only	general	8	k	no	[6]
	general	$2 + \varepsilon$	$(k/\varepsilon) \log(1/\varepsilon)$	no	[13]
	general	$4 + \varepsilon$	kz/ε	yes	[13]
	bounded doubling	$3 + \varepsilon$	$(k + z)/\varepsilon^d$	yes	[3]
sliding window	general	$6 + \varepsilon$	$(k/\varepsilon) \log \sigma$	no	[9]
	bounded doubling	$1 + \varepsilon$	$(kz/\varepsilon^d) \log \sigma$	yes	here

For the 1-center problem in d -dimensional Euclidean space, streaming algorithms that maintain an ε -kernel give a $(1 + \varepsilon)$ -approximation. An example is the algorithm of Zarrabi-Zadeh [14] which maintains an ε -kernel of size $O(1/\varepsilon^{(d-1)/2} \log(1/\varepsilon))$. Moreover, using only $O(d)$ storage one can obtain a 1.22-approximation for the 1-center problem without outliers [2, 4]. For the 1-center problem with outliers, one can obtain a $(1 + \varepsilon)$ -approximation algorithm that uses $z/\varepsilon^{O(d)}$ storage by the technique of Agarwal et al. [1]. Zarrabi-Zadeh and Mukhopadhyay [15] studied the 1-center problem with z outliers in high-dimensional Euclidean spaces, where d is not considered constant, giving a 1.73-approximation algorithm that requires $O(d^3 z)$ storage. Recently, Hatami and Zarrabi-Zadeh [12] extended this result to 2-center problem with z outliers, obtaining a $(1.8 + \varepsilon)$ -approximation using $O(d^3 z^2 + dz^4/\varepsilon)$ storage. None of the 1-center algorithms discussed above works in the sliding-window model.

A problem that is closely related to the 1-center problem is the *diameter problem*, where the goal is to maintain an approximation of the diameter of the points in the stream. This problem has been studied in the sliding-window model by Feigenbaum, Kannan, Zhang [11] and later by Chan and Sadjad [5], who gave a $(1 + \varepsilon)$ -approximation for the diameter problem (without outliers) in the sliding window model, using $O((1/\varepsilon)^{(d+1)/2} \log(\sigma/\varepsilon))$ storage.

Our contribution

We present the first algorithm for the k -center problem with z outliers in the sliding-window model. It works in spaces of bounded doubling dimension and yields a $(1 + \varepsilon)$ -approximation. So far a $(1 + \varepsilon)$ -approximation was not even known for the k -center problem without outliers in the insertion-only model. Our algorithm uses $O((kz/\varepsilon^d) \log \sigma)$ storage,³ where d is the doubling dimension and σ is the spread, as defined above. Thus for the 1-center problem we obtain a solution that uses $O((z/\varepsilon^d) \log \sigma)$ storage. This solution also works for the diameter problem. Note that also for the 1-center problem with outliers (and the diameter problem with outliers) an algorithm for the sliding-window model was not yet known. A useful property of the sketch⁴ maintained by our algorithm for the k -center problem, is that it can also be used for the k' -center problem for any $k' < k$, as well as for the diameter problem. As in the previous papers on the k -center problem (or the diameter problem) in the sliding-window model [5, 9, 11], we assume that Δ_{\max} and Δ_{\min} (upper and lower bounds on the maximum and minimum distance between any two points in the stream) are known to the algorithm.

³ To correctly state the bound for the case $z = 0$ as well, we should actually write $O((k(z + 1)/\varepsilon^d) \log \sigma)$. To keep the bound concise, we will just write $O((kz/\varepsilon^d) \log \sigma)$, however.

⁴ We use the word *sketch* even though we do not study how to compose the sketches for two separate streams into a sketch for the concatenation of the stream, as the term *sketch* seems more appropriate than *data structure*, for example.

As mentioned above, our algorithm provides a $(1 + \varepsilon)$ -approximation. More precisely, it maintains a set $S(t) \subset P(t)$ such that computing an optimal solution for $S(t)$ and then suitably expanding the balls in the solution, gives a $(1 + \varepsilon)$ -approximate solution for $P(t)$. Thus, to obtain a $(1 + \varepsilon)$ -approximate solution for $P(t)$ one needs to compute an optimal (or $(1 + \varepsilon')$ -approximate, for a suitable ε') solution for $S(t)$. Depending on the underlying space this can be slow, and it may be preferable to compute, say, a 2-approximation for $S(t)$, which would then give a $(2 + \varepsilon)$ -approximation for $P(t)$. The various options in Euclidean spaces and general spaces of bounded doubling dimension are discussed in Section 2.3.

Our second contribution is a lower bound for the k -center problem with outliers in the sliding-window model. Our lower bound shows that any algorithm that provides a $(1 + \varepsilon)$ -approximation must use $\Omega((kz/\varepsilon) \log \sigma)$ storage. This matches our upper bound up to the dependency on ε and d . The lower-bound construction uses points in \mathbb{R}^1 , so it shows that our algorithm is optimal in this case. The lower bound model is very general. It allows the algorithm to store points, or weighted points, or balls, or whatever it wants so that it can approximate an optimal solution for $P(t)$ at any time t . The main condition is that each object comes with an expiration time which corresponds to the expiration time of some point in the stream, and that the algorithm can only change its state when an object expires or a new object arrives; see Section 3 for details.

2 The algorithm

Let $P := \langle p_1, p_2, \dots \rangle$ be a possibly infinite stream of points from a metric space X of doubling dimension d and spread σ , where d is considered to be a fixed constant. We denote the arrival time of a point p_i by $t_{\text{arr}}(p_i)$. We say that p_i *expires* at time $t_{\text{exp}}(p_i) := t_{\text{arr}}(p_i) + W$, where W is the given length of the time window. To simplify the exposition, we assume that all arrival times and departure times (that is, times at which a point expires) are distinct. For a time t we define $P(t)$ to be the set⁵ of points currently in the window. In other words, $P(t) := \{p_i : t_{\text{arr}}(p_i) \leq t < t_{\text{exp}}(p_i)\}$. For a point $q \in X$ and a parameter $r \geq 0$, we use $\text{ball}(q, r)$ to denote the ball with center q and radius r .

In the following we show how to maintain a sketch $\Gamma(t)$ of $P(t)$ for the k -center problem with outliers. The idea behind our algorithm is as follows. Consider an optimal solution for $P(t)$ consisting of k balls B_1, \dots, B_k of radius ρ_{opt} . Suppose we cover the points in each ball B_i by a number of smaller balls of radius $\varepsilon \rho_{\text{opt}}$; we will call these *mini-balls*. Since the underlying space has doubling dimension d , we can do this using $O(1/\varepsilon^d)$ mini-balls for each ball B_i . To obtain a $(1 + \varepsilon)$ -approximation, we do not need to know all the points: it suffices to keep $z + 1$ points in each mini-ball, since then we cannot designate all points in the mini-ball as outliers. There are several challenges to overcome to make this idea work. For instance, we do not know ρ_{opt} . Hence, we will develop an algorithm for the decision version of the problem, which we will then apply “in parallel” to different possible values for the optimal radius. But when ρ is much smaller than ρ_{opt} we have another challenge, namely that there can be many outliers (which may need to be stored, because at some later moment in time they may become inliers). Finally, since points arrive and expire, the balls in an optimal solution move over time, which makes it hard to maintain the mini-balls correctly. Below we show how to overcome these challenges.

⁵ We allow the same point from X to occur multiple times in the stream, so $P(t)$ is actually a multi-set. Whenever we refer to “sets” in the remainder of the paper we mean “multi-sets”. The distance Δ_{\min} is defined with respect to distinct points, however.

2.1 A sketch for the decision problem

Recall that for a set Q of points, $\text{OPT}_{k,z}(Q)$ denotes the smallest radius ρ such that we can cover all points from Q , except for at most z outliers, by k balls of radius ρ , and that Δ_{\min} and Δ_{\max} are bounds on the minimum and maximum distance between any two points in the stream. Let ρ be a parameter with $\Delta_{\min} \leq \rho \leq \Delta_{\max}$. We will design a sketch $\Gamma(t)$ and a corresponding decision algorithm `TRYTOCOVER` with the following properties:

- The sketch $\Gamma(t)$ uses $O(kz/\varepsilon^d)$ storage.
- `TRYTOCOVER` either reports a collection \mathcal{C}^* of k balls of radius $\text{OPT}_{k,z}(P(t)) + 2\varepsilon\rho$ that together cover all points in $P(t)$ except for at most z outliers, or it reports `NO`. In latter case we have $\text{OPT}_{k,z}(P(t)) > 2\rho$.

Our sketch $\Gamma(t)$ is a tuple $[\tau(t), \mathcal{B}(t), \mathcal{R}(t), P_{\text{out}}(t)]$, where τ is a *timestamp*, $\mathcal{B}(t)$ is a collection of mini-balls, $\mathcal{R}(t)$ is a collection of so-called *representative sets*, and $P_{\text{out}}(t)$ is a set of outliers. We will maintain the following invariants.

- (Inv-1)** For any time t' with $t \leq t' < \tau(t)$ we are guaranteed that $\text{OPT}_{k,z}(P(t')) > 2\rho$. The idea is that when we find $k + z + 1$ points with pairwise distances greater 2ρ , then we can set τ to the expiration time of the oldest of these points, and we can delete this point (as well as any older points) from the sketch.
- (Inv-2)** Each mini-ball $B \in \mathcal{B}(t)$ has radius $\varepsilon\rho$ and the center of B , denoted by $\text{center}(B)$, is a point from the stream. Note that the center does not need to be a point from $P(t)$. The mini-balls in $\mathcal{B}(t)$ are *well spread* in the sense that no mini-ball contains the center of any other mini-ball. In other words, we have $\text{dist}(\text{center}(B), \text{center}(B')) > \varepsilon\rho$ for any two mini-balls $B, B' \in \mathcal{B}(t)$.
- (Inv-3)** For each mini-ball $B \in \mathcal{B}(t)$ the set $\mathcal{R}(t)$ contains a *representative set* $R(B) \subseteq B \cap P(t)$, and these are the only sets in $\mathcal{R}(t)$. The representative sets $R(B)$ are pairwise disjoint, and each set $R(B)$ contains at most $z + 1$ points. When $|R(B)| = z + 1$, we say that the mini-ball B is *full*.
- (Inv-4)** Define $P_{\text{in}}(t) := \bigcup_{B \in \mathcal{B}(t)} R(B)$ and let $S(t) := P_{\text{in}}(t) \cup P_{\text{out}}(t)$ be the collection of all points in our sketch. For any point $p_i \in P(t) \setminus S(t)$ – these are exactly the points that have not yet expired but that have been discarded by the algorithm – we have (i) $t_{\text{exp}}(p_i) \leq \tau(t)$, and/or (ii) $p_i \in B$ for a mini-ball $B \in \mathcal{B}(t)$ that is full and such that all points in $R(B)$ arrived after p_i .
- (Inv-5)** $|\mathcal{B}(t)| = O(k/\varepsilon^d)$ and $|P_{\text{out}}(t)| \leq z$.

At time $t = 0$, before the arrival of the first point, we have $\tau(t) = 0$ and $\mathcal{B}(t) = \mathcal{R}(t) = P_{\text{out}}(t) = \emptyset$. Since $P(0) = \emptyset$ this trivially satisfies the invariants. Before we prove that we can maintain the sketch upon the arrival and departure of points, we present our decision algorithm `TRYTOCOVER` and prove its correctness.

Algorithm 1 TRYTOCOVER($\Gamma(t)$).

- 1: $S(t) \leftarrow \bigcup_{B \in \mathcal{B}(t)} R(B)$
 - 2: Compute $\text{OPT}_{k,z}(S(t))$ and the corresponding collection $\mathcal{C} := \{C_1, \dots, C_k\}$ of balls.
 - 3: **if** $t < \tau(t)$ or $\text{OPT}_{k,z}(S(t)) > 2\rho$ **then**
 - 4: Report NO
 - 5: **else**
 - 6: Increase the radius of each ball $C_i \in \mathcal{C}$ by $2\varepsilon\rho$.
 - 7: Report the collection $\mathcal{C}^* := \{C_1^*, \dots, C_k^*\}$ of expanded balls.
-

In line 2 we compute an optimal solution on the point set $S(t)$. How this can be done depends on the underlying metric space and will be discussed in Section 2.3. The following lemma establishes the correctness of the algorithm.

► **Lemma 1.** *Algorithm TRYTOCOVER either reports a collection \mathcal{C}^* of k balls of radius $\text{OPT}_{k,z}(P(t)) + 2\varepsilon\rho$ that together cover all points in $P(t)$ except for at most z outliers, or it reports NO. In latter case we have $\text{OPT}_{k,z}(P(t)) > 2\rho$.*

Proof. First suppose the algorithm reports NO. If this happens because $t < \tau(t)$ then $\text{OPT}_{k,z}(P(t)) > 2\rho$ by (Inv-1). Otherwise, this happens because $\text{OPT}_{k,z}(S(t)) > 2\rho$. But then $\text{OPT}_{k,z}(P(t)) > 2\rho$, because (Inv-3) implies that $S(t) \subseteq P(t)$.

Now suppose the algorithm reports a collection $\mathcal{C}^* := \{C_1^*, \dots, C_k^*\}$ of balls. Let \mathcal{C} be the corresponding set of balls before they were expanded. Since \mathcal{C} is an optimal solution for $S(t)$, the balls C_i have radius $\text{OPT}_{k,z}(S(t)) \leq \text{OPT}_{k,z}(P(t))$ and together they cover all points in $S(t)$ except for at most z outliers. Now consider a point $p_i \in P(t) \setminus S(t)$. To finish the proof, we must show that p_i is covered by one of the balls in \mathcal{C}^* . To this end, first observe that $t_{\text{exp}}(p_i) > t$ because $p_i \in P(t)$. Since TRYTOCOVER did not report NO, this implies that $t_{\text{exp}}(p_i) > \tau(t)$. Hence, we can conclude from (Inv-4) that $p_i \in B$ for a mini-ball $B \in \mathcal{B}(t)$ that is full. Thus $R(B)$ contains $z + 1$ points, and since we allow only z outliers this implies that at least one point from $R(B)$ is covered by a ball $C_i \in \mathcal{C}$. Because $\text{diam}(B) = 2\varepsilon\rho$, this implies that p_i must be covered by C_i^* , thus finishing the proof. ◀

Next we show how to update the sketch $\Gamma(t)$.

Handling departures

When a point p_j in one of our representative sets $R(B)$ expires, we simply delete it from $R(B)$, and if $R(B)$ then becomes empty we remove $R(B)$ from $\mathcal{R}(t)$ and B from $\mathcal{B}(t)$. Similarly, if p_j was a point in $P_{\text{out}}(t)$ we remove p_j from $P_{\text{out}}(t)$.

It is trivial to verify that (Inv-1)–(Inv-3) and (Inv-5) still hold for the updated sketch. To see that (Inv-4) holds as well, consider a point $p_i \in P(t) \setminus S(t)$. The only reason for (Inv-4) to be violated, would be when $p_i \in B$ for a mini-ball B that was full before the deletion of p_j but is no longer full after the deletion. However, (Inv-4) states that all points in $R(B)$ arrived after p_i . Since p_i did not yet expire, this means that the point p_j that currently expires cannot be a point from $R(B)$.

Handling arrivals

The arrival of a point p_j at time $t := t_{\text{arr}}(p_j)$ is handled by Algorithm 2. We denote the sketch just before the arrival by $\Gamma(t^-)$, and the updated sketch by $\Gamma(t^+)$.

Algorithm 2 HANDLEARRIVAL($\Gamma(t^-), p_j$).

1. If p_j lies in an existing mini-ball $B \in \mathcal{B}(t^-)$ then add p_j to $R(B)$. If p_j did not lie in an existing mini-ball then add p_j to $P_{\text{out}}(t^-)$.
 2. Let $Q := P_{\text{out}}(t^-) \cup \bigcup_{B \in \mathcal{B}(t^-)} R(B)$ be the set of all points in the current sketch, including the just inserted point. Sort the points in Q by decreasing arrival time, and let $q_1, q_2 \dots$ denote the sorted sequence of points – note that q_1 is the newly inserted point p_j . Let $Q_i := \{q_1, \dots, q_i\}$ denote the set containing the first i points from Q . Find the largest index i^* such that the following holds:
 - The 3-approximation algorithm of Charikar et al. [7] for the k -center clustering algorithm with z outliers, when run on Q_{i^*} , reports a collection \mathcal{B}^* of k balls of radius at most 6ρ . (In fact, any other constant-factor approximation algorithm can be used if we adjust the value 6ρ appropriately. For concreteness, we use the one by Charikar et al.)
 3. If $Q_{i^*} \neq Q$ (and so the point q_{i^*+1} exists) then set $\tau(t^+) := \max(\tau(t^-), t_{\text{exp}}(q_{i^*+1}))$. Remove the points in $Q \setminus Q_{i^*}$ from the representative sets they are in; note that these points all have expiration time at least $\tau(t^+)$.
 4. Let $\mathcal{B}^* := \{B_1, \dots, B_k\}$ be the balls in the solution reported for Q_{i^*} . Note that all points from Q_{i^*} , except for at most z outliers, lie in a ball from \mathcal{B}^* . The new set of mini-balls and outliers is now computed as follows. Increase the radius of the balls in \mathcal{B}^* by $\varepsilon\rho$. Denote the set of expanded balls by $\overline{\mathcal{B}}^*$
 - a. Add each mini-ball $B \in \mathcal{B}(t^-)$ whose center lies inside a ball from $\overline{\mathcal{B}}^*$ to the set $\mathcal{B}(t^+)$ and add their representative sets to $\mathcal{R}(t^+)$.
 - b. Let $Z \subset Q_{i^*}$ be the set of points that are not in a representative set added to $\mathcal{R}(t^+)$ in Step 4a. Let $Z_{\text{in}} \subseteq Z$ be the points that lie inside a ball from $\overline{\mathcal{B}}^*$. Go over the points in Z_{in} one by one, in arbitrary order, and handle each point q as follows: If there is a mini-ball in the current set $\mathcal{B}(t^+)$ that contains q then add q to $R(B)$ for an arbitrary such mini-ball B ; otherwise create a mini-ball B with center q and radius $\varepsilon\rho$, set $R(B) := \{q\}$ and add B to $\mathcal{B}(t^+)$.
 - c. For all mini-balls $B \in \mathcal{B}(t^+)$ such that $|R(B)| > z+1$, remove the oldest $|R(B)| - (z+1)$ points from $R(B)$.
 - d. Set $P_{\text{out}}(t^+) := Z \setminus Z_{\text{in}}$. Note that these are exactly the points from Q_{i^*} that have not been added to a representative set
-

► **Lemma 2.** *After the arrival of point p_j has been handled, the invariants (Inv-1)–(Inv-5) are restored.*

Proof. (Inv-1) If $\tau(t^+) = \tau(t^-)$ then obviously (Inv-1) still holds, so assume that τ is updated by the algorithm in Step 3. Thus the algorithm of Charikar et al. [7] returned a solution of radius more than 6ρ on Q_{i^*+1} . Since the algorithm is a 3-approximation, this means $\text{OPT}_{k,z}(Q_{i^*+1}) > 2\rho$. Because we sorted the points on expiration time, we must have $\text{OPT}_{k,z}(P(t')) > 2\rho$ for all t' with $t \leq t' < t_{\text{exp}}(q_{i^*+1})$. Hence, (Inv-1) still holds.

(Inv-2) By construction, the mini-balls in $\mathcal{B}(t^+)$ have radius $\varepsilon\rho$ and are centered at a point from the stream. The mini-balls from $\mathcal{B}(t^-)$ are well spread by induction, so we only need to prove that any mini-balls created in Step 4b are well spread. This is true because we only create a new mini-ball when its center does not lie inside an existing mini-ball.

(Inv-3) The representative sets $R(B)$ are disjoint by construction, and $|R(B)| \leq z+1$ is guaranteed by Step 4c. Hence (Inv-3) holds.

(Inv-4) Take a point $p_i \in P(t^+) \setminus S(t^+)$ and assume $t_{\text{exp}}(p_i) > \tau(t^+)$. We have two cases.

- The first case is that p_i was discarded due to the arrival of p_j . Then it was either removed in Step 3, which implies $t_{\text{exp}}(p_i) \geq \tau(t^+)$; or it was removed in Step 4c, which implies there is a full mini-ball $B \in \mathcal{B}(t^+)$ such that all points in $R(B)$ are newer than p_i . Hence, (Inv-4) holds for p_i .
- The second case is that p_i was already discarded earlier. We can assume that (Inv-4) holds before the arrival of p_j . If $t_{\text{exp}}(p_i) \leq \tau(t^-)$ then we also have $t_{\text{exp}}(p_i) \leq \tau(t^+)$ and we are done. So assume that $p_i \in B$ for a mini-ball $B \in \mathcal{B}(t^-)$ that was full and such that all points in $R(B)$ arrived after p_i . If $R(B)$ contained a point $p_{i'} \in Q \setminus Q_{i^*}$ then $t_{\text{exp}}(p_i) < t_{\text{exp}}(p_{i'}) \leq \tau(t^+)$, and so (Inv-4) holds. If $R(B)$ only contained points from Q_{i^*} then we have two sub-cases.

The first sub-case is that B is still present in $\mathcal{B}(t^+)$. Then B must still be full, because $R(B)$ only contained points from Q_{i^*} . Hence, (Inv-4) holds.

The second sub-case is that B is not present in $\mathcal{B}(t^+)$. Thus its center must lie outside all balls in $\bar{\mathcal{B}}^*$. But then the points in $R(B)$, which are all in Q_{i^*} , are outside any ball in \mathcal{B}^* . But this is impossible, since $|R(B)| = z + 1$ and \mathcal{B}^* has only z outliers.

(Inv-5) All mini-balls in $\mathcal{B}(t^+)$ have their center inside one of the k balls in $\bar{\mathcal{B}}^*$, which have radius at most 6ρ . Moreover, the mini-balls in $\mathcal{B}(t^+)$ have radius $\varepsilon\rho$ and they are well spread. Since the underlying space has doubling dimension d , this implies that $|\mathcal{B}(t^+)| = O(k/\varepsilon^d)$.

The outlier set $P_{\text{out}}(t^-)$ consists of the points from Q_{i^*} that lie outside the balls in $\bar{\mathcal{B}}^*$. Hence, these points also lie outside the balls in \mathcal{B}^* . Since \mathcal{B}^* is a valid solution to the k -center problem with z outliers, there are at most z such points. Thus $|P_{\text{out}}(t^+)| \leq z$. ◀

2.2 A sketch for the optimization problem

Above we presented a sketch for a decision version of the problem, for given parameters ρ and ε . The sketch uses $O(kz/\varepsilon^d)$ storage. We also gave an algorithm `TRYTOCOVER` that either reports a collection \mathcal{C}^* of k balls of radius $\text{OPT}_{k,z}(P(t)) + 2\varepsilon\rho$ covering all points in $P(t)$ except at most z outliers, or that reports NO. In latter case we know that $\text{OPT}_{k,z}(P(t)) > 2\rho$. To make the parameter ρ and ε explicit, we will from now on denote the sketch by $\Gamma_{\rho,\varepsilon}$.

In the optimization version of the problem we wish to find k congruent balls of minimum radius that together cover all points in $P(t)$ except for at most z outliers. To obtain a $(1 + \varepsilon)$ -approximation for the optimization problem, for a given $\varepsilon > 0$, we maintain a sketch $\Gamma_{\rho_i,\varepsilon/2}$ for every $0 \leq i \leq \lfloor \log \sigma \rfloor$, where $\rho_i := 2^i \cdot \Delta_{\min}$. We can then obtain a $(1 + \varepsilon)$ -approximate solution with the algorithm shown in Algorithm 3.

■ **Algorithm 3** FINDAPPROXIMATECENTERS($\Gamma(t)$).

```

1:  $i \leftarrow 0$ 
2: repeat
3:    $\text{answer} \leftarrow \text{TRYTOCOVER}(\Gamma_{\rho_i,\varepsilon/2})$ ;  $i \leftarrow i + 1$ 
4: until  $\text{answer} \neq \text{NO}$ 
5: if the radii of the balls in  $\text{answer}$  is less than  $\Delta_{\min}$  then
6:   Reduce the radii of the balls to zero
7: Report  $\text{answer}$ 

```

We obtain the following theorem, whose proof can be found in the full version of the paper.

► **Theorem 3.** *The sketch above uses $O((kz/\varepsilon^d) \log \sigma)$ storage and that allows us to report at any time t a collection \mathcal{C}^* of balls of radius at most $(1 + \varepsilon) \cdot \text{OPT}_{k,z}(P(t))$ covering all points from $P(t)$, except at most z outliers.*

Our sketch for the k -center problem can also be used for the k' -center problem for $k' < k$. Moreover, a sketch for the k -center problem for $k \geq 1$ can be used for the diameter problem. Recall that the diameter problem with outliers for the set $P(t)$ asks for the value

$$\text{diam}_z(P(t)) := \min\{\text{diam}(P(t) \setminus Q) : |Q| = z\},$$

that is, $\text{diam}_z(P(t))$ is the smallest diameter one can obtain by deleting z outliers from $P(t)$. We say that an algorithm reports a $(1 + \varepsilon)$ -approximation to $\text{diam}_z(P(t))$ if it reports a value D with $(1 + \varepsilon) \cdot \text{diam}_z(P(t)) \leq D \leq \text{diam}_z(P(t))$. The proof of the following theorem is in the full version of the paper.

► **Theorem 4.** *The sketch for the k -center problem with outliers as presented above can also be used to provide a $(1 + \varepsilon)$ -approximation for the k' -center problem with outliers, for any $1 \leq k' \leq k$. Moreover, it can be used to provide a $(1 + 2\varepsilon)$ -approximation for the diameter problem with outliers.*

Theorem 4 implies that there exists a sketch for the diameter problem with outliers in the sliding-window model that gives a $(1 + \varepsilon)$ -approximation to $\text{diam}_z(P(t))$ using $O((z/\varepsilon^d) \log \sigma)$ storage, namely the sketch for the 1-center problem.

2.3 Time complexity

Above we focused on the storage used by our sketch, and on the approximation ratio it can potentially provide. We now discuss the time complexity.

The algorithm that handles departures trivially runs in $O(1)$ time. The most time-consuming step in the algorithm that handles arrivals is Step 2, where we run the algorithm of Charikar et al. [7] on a set of $O(kz/\varepsilon^d)$ points. This takes $O((kz/\varepsilon^d)^3)$ time. Note that, both for departures and arrivals, we need to execute the respective algorithms for each of the $\log \sigma$ sketches $\Gamma_{\rho_i, \varepsilon/2}$ we maintain.

The time needed for FINDAPPROXIMATECENTERS is more interesting, since it calls TRYTOCOVER, which is supposed to compute an optimal solution for the k -center problem with outliers on a given set $S(t)$ of $O(kz/\varepsilon)$ points. It is routine to check that if TRYTOCOVER would use a c -approximate solution on $S(t)$, instead of an optimal solution, our final result would be a $c(1 + \varepsilon)$ -approximation. In d -dimensional Euclidean space we can solve the k -center problem with outliers in time polynomial in $n := |S(t)|$ (for constant k and d), as follows: first generate all $O(n^{d+1})$ potential centers – there are $O(n^{d+1})$ potential centers because the smallest enclosing ball of a given point set is defined by at most $d + 1$ points – then generate all possible collections of k such centers, and then for each of the $O(n^{(d+1)k})$ such collections find the minimum radius ρ such that we can cover all except for z points. A similar approach is possible for other metrics in \mathbb{R}^d that are sufficiently well-behaved (such as ℓ_p metrics, for instance).

For arbitrary metric spaces the situation is more tricky. The standard assumption, which we also make, is that we can compute the distance between any two given points from the metric space in $O(1)$ time. Still, computing an optimal solution on the set $S(t)$ can be quite slow or perhaps even infeasible. For example, when an optimal center is a point from the metric space that does not occur in the stream, then the algorithm may be unable to retrieve this center. So unless we are in Euclidean space, or some other “well-defined” space, it

seems most natural to define the underlying space as consisting of exactly the points in the stream. Note that this can still be somewhat problematic, as it may require the algorithm to use points that have already expired as centers for the current set $S(t)$. These issues seem unavoidable for any algorithm that maintains a sketch in the sliding-window model. Also note that, using just the points in the current set $P(t)$ as centers, one can always obtain a 2-approximation to the optimal clustering. Invariant (Inv-4) thus implies that by using the set $S(t)$ as potential centers we can obtain a $(2 + \varepsilon)$ approximation. Also note that the optimal k -center clustering with z outliers on $S(t)$, under the restriction that the centers come from $S(t)$, can be trivially computed in $O(|S(t)|^{k+2})$ time.

The following theorem summarizes the performance of our sketch.

► **Theorem 5.** *Consider the k -center problem with z outliers in the sliding-window model, for streams of points from a space with doubling dimension d . Let Δ_{\min} and Δ_{\max} be given (lower and upper) bounds on the minimum and maximum distance between any two points in the stream, and let $\sigma := \Delta_{\max}/\Delta_{\min}$ be (an upper bound on) the spread of the stream. Suppose we have a c -approximation algorithm for the static version of the problem that runs in $T_{k,z}(n)$ time on a set of n points. Then for any $0 < \varepsilon < 1$ we can maintain a sketch with the following properties:*

- *The sketch uses $O((kz/\varepsilon^d) \log \sigma)$ storage.*
- *Departures and arrivals can be handled in $O(\log \sigma)$ and $O((kz/\varepsilon^d)^3 \log \sigma)$ time, respectively.*
- *At any time t , the algorithm can report a valid solution for $P(t)$ of cost at most $(1 + \varepsilon)c \cdot \text{OPT}_{k,z}(P(t))$. The time needed to compute the solution is $T_{k,z}(n)$, where $n := O(kz/\varepsilon^d)$.*

3 A lower bound

Above we presented a sketch of size $O((kz/\varepsilon^d) \log \sigma)$ that provides a $(1 + \varepsilon)$ -approximation for the k -center problem with z outliers in the sliding-window model. In this section we show that this is tight, up to the dependency on d . In particular, we prove that any sketch giving a $(1 + \varepsilon)$ -approximation for the problem in \mathbb{R}^1 must use $\Omega((kz/\varepsilon) \log \sigma)$ storage. In the full paper we show that to obtain any constant approximation ratio, a sketch must use $\Omega(kz)$ storage.

The lower-bound model

Our lower-bound is extremely simple and general. We allow the algorithm to store points, or weighted points, or balls, or whatever it wants so that it can approximate an optimal solution for $P(t)$ at any time t . We only make the following assumptions. Let $S(t)$ be the collection of objects being stored at time t .

- Each object in $S(t)$ is accompanied by an expiration time, which is equal to the expiration time of some point $p_i \in P(t)$.
- Let $p_i \in P(t)$. If no object in $S(t)$ uses $t_{\text{exp}}(p_i)$ as its expiration time, then no object in $S(t')$ with $t' > t$ can use $t_{\text{exp}}(p_i)$ as its expiration time.
- The solution reported by the algorithm is uniquely determined by $S(t)$, and the algorithm only modifies $S(t)$ when a new point arrives or when an object in $S(t)$ expires.
- The algorithm is deterministic and oblivious of future arrivals. In other words, the set $S(t)$ is uniquely determined by the sequence of arrivals up to time t , and the solution reported for $P(t)$ is uniquely determined by $S(t)$.

■ **Figure 1** The lower-bound construction for a $(1 + \varepsilon)$ -approximate sketch. In the example, $s = 3$, $k = 3$, $\varepsilon = 1/2$ and $z = 2$. (i) The initial configuration. (ii) Rotated view of the cluster containing p^* .

The storage used by the algorithm is defined as the number of objects in $S(t)$. The algorithm can decide which objects to keep in $S(t)$ anyway it wants; it may even keep an unbounded amount of extra information in order to make its decisions. The algorithm can also derive a solution for $P(t)$ in any way it wants, as long as the solution is valid and uniquely determined by $S(t)$. Clearly, the sketch from the previous section adheres to the model.

A lower bound for a $(1 + \varepsilon)$ -approximate sketch

Let ALG be a $(1 + \varepsilon')$ -approximation algorithm, for some $0 < \varepsilon' < 1$, where we assume for simplicity that $1/\varepsilon'$ is an integer. The lower-bound instance, which consists of points in \mathbb{R}^1 , is as follows.

Let $\varepsilon := \varepsilon'/8$ and consider the configuration shown in Figure 1(i). The configuration consists of k clusters C_1, \dots, C_k , placed next to each other from left to right. Each cluster C_i consists of s groups, G_1^i, \dots, G_s^i , where $s = \Theta(\log \sigma)$. Each group G_j^i consists of $1/\varepsilon$ subgroups, $G_1^{j,i}, \dots, G_{1/\varepsilon}^{j,i}$. A subgroup $G_{i^{\ell}}^{j,\ell}$ consists of $z+1$ points at distance 2^{j-1} apart; the diameter of a subgroup – that is, the distance between its leftmost and rightmost point – is thus $2^{j-1}z$. Subgroup $G_{i^{\ell}}^{j,\ell}$ is preceded by an empty interval of length $2^{j-1}z$. Hence, the total diameter of the group G_i , including the empty interval preceding its leftmost subgroup, is $2^{i-1}z/\varepsilon$. (The exception is G_1 , for which we do not count the empty interval preceding its leftmost subgroup.) This brings the total diameter of a cluster to

$$L := \sum_{j=1}^s 2^j z/\varepsilon - z/\varepsilon = (2^{s+1} - 3) \cdot z/\varepsilon < 2^{s+1} z/\varepsilon.$$

In between every two consecutive clusters there is an empty interval of length $2L$.

The arrival order of the points in the configuration is as follows. The subgroups within a cluster arrive from right to left, in a round-robin fashion over the clusters: in the first round the subgroups $G_k^{s, \frac{1}{\varepsilon}}, \dots, G_1^{s, \frac{1}{\varepsilon}}$ arrive, in the second round the subgroups $G_k^{s, \frac{1}{\varepsilon}-1}, \dots, G_1^{s, \frac{1}{\varepsilon}-1}$ arrive, and so on. More formally, $G_{i^{\ell}}^{j,\ell}$ arrives before $G_{i'^{\ell'}}^{j',\ell'}$ iff: $j > j'$ or $(j = j' \text{ and } \ell > \ell')$ or $(j = j' \text{ and } \ell = \ell' \text{ and } i > i')$. This finishes the description of the initial part of the instance.

Let t be the time at which the last point in the configuration arrives, let $P(t)$ be the set of all points in the clusters C_1, \dots, C_k , and let $S(t)$ be the set of objects stored by ALG. We will argue that $|S(t)| = \Omega(kzs/\varepsilon)$, otherwise an adversary can continue the instance such that at some time t' in the future the algorithm does not give a $(1 + \varepsilon)$ -approximation.

Consider the points in the subgroups $G_i^{j,\ell}$ with $j > 1$, except for the very first point that arrived. Let T_{exp} be the set of expiration times of these points. Note that $|T_{\text{exp}}| = (k(z+1)(s-1)/\varepsilon) - 1$. Suppose at least one of these expiration times, say the expiration time of point p^* , is not used by any object in $S(t)$. Let $t_{p^*}^-$ and $t_{p^*}^+$ be the times immediately before and after $t_{\text{exp}}(p^*)$, respectively. The conditions of the model imply that the algorithm reports the same solution at times $t_{p^*}^-$ and $t_{p^*}^+$. The adversary will now continue the scenario in such that one of these answers is not sufficiently accurate, as described next.

Let $G_{i^*}^{j^*,\ell^*}$ be the subgroup that p^* belongs to. First, the adversary waits until all points that arrived before p^* have expired. The situation is then as follows: clusters C_i with $i < i^*$ consist of the subgroups up to $G_{j^*,\ell^*}^{(i)}$, while clusters C_i with $i > i^*$ are missing the last of these subgroups. Cluster C_{i^*} has the points up to point p^* (which expires next) in $G_{i^*}^{j^*,\ell^*}$. Before p^* expires, the adversary now adds a new subgroup G_{new} of $z+1$ points to C_{i^*} . The diameter of G_{new} is $z^{j^*-1}z$ and its distance to C_{i^*} is $z^{j^*-1}z$ as well; see Figure 1(ii). (The construction has been rotated by 90 degrees in the figure, to make it fit.) In addition, the adversary adds the points from $G_{j^*,\ell^*}^{(i)}$ that have already expired back.

We now analyze $\text{OPT}_{k,z}(P(t_{p^*}^-))$. Since the distance between any two of the k clusters is larger than the diameter of the clusters, and any cluster still contains at least $z+1$ points – the latter follows because $j^* > 1$ – an optimal solution will use a separate ball for each cluster. The largest cluster is C_{i^*} , because G_{new} was added to it. Since each subgroup in C_{i^*} has $z+1$ points and we can designate only z points as outliers, it is optimal to designate the z rightmost points (topmost in Figure 1(ii)) from $G_{i^*}^{j^*,\ell^*}$ as outliers and cover the remaining points with a ball of diameter $L^* + 3 \cdot 2^{j^*-1}z$, where

$$L^* := \sum_{j=1}^{j^*-1} 2^j z/\varepsilon - z/\varepsilon + 2\ell^* \cdot 2^{j^*-1}z = (2^{j^*} - 3) z/\varepsilon + \ell^* 2^{j^*} z < (2^{j^*+1}) z/\varepsilon,$$

where the last inequality uses that $\ell^* \leq 1/\varepsilon$. Hence, $\text{OPT}_{k,z}(P(t_{p^*}^-)) = (L^* + 3 \cdot 2^{j^*-1}z)/2$.

At time $t_{p^*}^+$ the point p^* expires. Hence, at time $t_{p^*}^+$ the subgroup $G_{i^*}^{j^*,\ell^*}$ has only z points, which can all be designated as outliers. Hence, C_{i^*} minus the outliers can be covered by a ball of diameter $L^* + 2 \cdot 2^{j^*-1}z$ and so $\text{OPT}_{k,z}(P(t_{p^*}^+)) = (L^* + 2 \cdot 2^{j^*-1}z)/2$.

Since the algorithm must report a valid solution at time $t_{p^*}^-$ and it must report the same solution at time $t_{p^*}^+$, the approximation ratio at time $t_{p^*}^+$ is at least

$$\frac{\text{OPT}_{k,z}(P(t_{p^*}^-))}{\text{OPT}_{k,z}(P(t_{p^*}^+))} \geq \frac{L^* + 3 \cdot 2^{j^*-1}z}{L^* + 2 \cdot 2^{j^*-1}z} = 1 + \frac{2^{j^*-1}z}{L^* + 2^{j^*}z} > 1 + \frac{2^{j^*-1}z}{2^{j^*+2}z/\varepsilon} = 1 + \varepsilon/8$$

We conclude that any algorithm that gives a $(1 + \varepsilon')$ -approximation must store at least $k(z+1)(s-1)/(8\varepsilon')$ objects in the worst case.

The spread of the point set used in the construction, including the subgroup G_{new} , is⁶

$$\sigma = kL + (k-1)2L + 2^{j^*}z < 3kL < 3k \cdot 2^{s+1}z/\varepsilon.$$

⁶ In our definition of spread, we are allowed to reuse points, since $\Delta_{\min} = 0$ is defined as the minimum distance between distinct points in the stream. We can also avoid reusing points in our lower-bound scenario, without asymptotically influencing the spread of the points.

If the spread is not too small, namely when $\sigma \geq (3kz/\varepsilon)^2$, we have $s \geq \frac{1}{2} \log \sigma - 1$. We obtain the following theorem.

► **Theorem 6.** *Let ALG be a $(1 + \varepsilon)$ -approximation algorithm for the k -center problem with z outliers in \mathbb{R}^1 , with $z \geq 1$, that works in the model described above. For any spread $\sigma \geq (3kz/\varepsilon)^2$, there is a problem instance of spread σ that requires ALG to store $\Omega((kz \log \sigma)/\varepsilon)$ points.*

Abstract

In the *incremental cycle detection* problem, edges are added to a directed graph (initially empty), and the algorithm has to report the presence of the first cycle, once it is formed. A closely related problem is the *incremental topological sort* problem, where edges are added to an acyclic graph, and the algorithm is required to maintain a valid topological ordering. Since these problems arise naturally in many applications such as scheduling tasks, pointer analysis, and circuit evaluation, they have been studied extensively in the last three decades. Motivated by the fact that in many of these applications, the presence of a cycle is not fatal, we study a generalization of these problems, *incremental maintenance of strongly connected components* (incremental SCC).

Several incremental algorithms in the literature which do cycle detection and topological sort in directed acyclic graphs, such as those by [7] and [16], also generalize to maintain strongly connected components and their topological sort in general directed graphs. The algorithms of [16] and [7] have a total update time of $O(m^{3/2})$ and $O(m \cdot \min\{m^{1/2}, n^{2/3}\})$ respectively, and this is the state of the art for incremental SCC. But the most recent algorithms for incremental cycle detection and topological sort ([8] and [10]), which yield total (randomized) update time $\tilde{O}(\min\{m^{4/3}, n^2\})$, do not extend to incremental SCC. Thus, there is a gap between the best known algorithms for these two closely related problems.

In this paper, we bridge this gap by extending the framework of [10] to general directed graphs. More concretely, we give a Las Vegas algorithm for incremental SCCs with an expected total update time of $\tilde{O}(m^{4/3})$. A key ingredient in the algorithm of [10] is a structural theorem (first introduced in [8]) that bounds the number of “equivalent” vertices. Unfortunately, this theorem only applies to DAGs. We show a natural way to extend this structural theorem to general directed graphs, and along the way we develop a significantly simpler and more intuitive proof of this theorem.

1 Introduction

In dynamic algorithms, our main goal is to maintain a key property of the graph while an adversary makes changes in the graph in the form of edge insertions and deletions. An algorithm is called incremental if it handles only insertions, decremental if it handles only deletions and fully dynamic if it handles both insertions as well as deletions. For a dynamic algorithm we hope to optimize the update time of the algorithm, which is the time taken by the algorithm to adapt to the changes to the input and modify the results. For incremental/decremental algorithms, one typically seeks to minimize the *total* update time over the entire sequence of edge insertions/deletions.

In this paper, we consider the problem of maintaining strongly connected components in the incremental setting (incremental SCC). This is a generalization of the problems of incremental cycle detection and topological sorting in directed acyclic graph, which find application in pointer analysis, deadlock detection [4], circuit evaluation [3] and scheduling tasks. In many of these applications, the presence of a cycle is not fatal, which motivates the general problem of maintaining strongly connected components, as well as the topological order of these components.

The problems of incremental cycle detection and topological sorting were first studied by Katriel and Bodlaender [18], who gave the first non-trivial algorithm for these problems with a total update time of $O(\min\{m^{3/2} \log n, m^{3/2} + n^2 \log n\})$. This bound was improved by Liu and Chao [20] to $O(m^{3/2} + m\sqrt{n} \log n)$. Since then, these problems and incremental SCC have been studied extensively (see for example [1, 2, 6, 16, 7, 13, 21]). Several algorithms that do incremental cycle detection and topological sort maintenance in directed acyclic graphs can be modified to get algorithms for incremental SCC. For example, the algorithm of Haeupler, Kavitha, Mathew, Sen and Tarjan [16] is able to do cycle detection as well as strongly connected component maintenance in $O(m^{3/2})$ total update time. In an important result, Bender, Fineman, Gilbert and Tarjan presented two algorithms for strongly connected components, with total update times of $O(n^2 \log n)$ and $O(m \cdot \min\{m^{1/2}, n^{2/3}\})$, for dense and sparse graphs, respectively (see Table 1).

The two most recent algorithms in this area are limited to cycle detection and topological sort: Bernstein and Chechik [8] gave a Las Vegas algorithm with an expected total update time of $O(m\sqrt{n} \log n)$; Bhattacharya and Kulkarni [10] combined the balanced search approach of [16] with the results of [8] to get an algorithm with a total expected runtime of $\tilde{O}(m^{4/3})$. As a result, there was still a gap between the best known algorithms for cycle detection and topological sort (update time of $\tilde{O}(\min\{m^{4/3}, n^2\})$) and for incremental SCC (update time of $\tilde{O}(\min\{m^{3/2}, n^2\})$). In this paper, we bridge the gap between these closely related problems. More formally, we prove the following result.

► **Theorem 1.** *There exists an incremental algorithm for maintaining strongly connected components in directed graphs with expected total time $\tilde{O}(m^{4/3})$, where m refers to the number of edges in the final graph. The algorithm can also maintain the topological order of these components.*

Summary of Techniques. We obtain our results by extending the technique of [10] to the case of general directed graphs. Both [8] and [10] detect cycles by doing a graph search after the insertion of an edge (u, v) . However, they reduce their search space by only exploring “equivalent” vertices: vertices whose ancestor and descendant sets agree on a random subset S of V . A key ingredient of the analysis is a structural theorem of [8] that bounds the total number of equivalent pairs created by the sequence of insertions. However, their notion of equivalent vertices only applies to acyclic directed graphs. Additionally, the proof of this structural theorem (Lemma 3.2 and 3.5 of [8]) is rather unintuitive.

Our contributions are three-fold. We present a new proof of the structural theorem of [8], which is significantly simpler and more intuitive. We also show a natural generalization of this theorem to general directed graphs. Finally, we show how the framework of [10] can be extended to maintain SCCs in general graphs, rather than just doing cycle detection and topological sort in a DAG.

Related Problems. A closely related problem that has received a lot of attention is maintaining strongly connected components in a *decremental* graph. This problem has been widely studied (see e.g. [22, 19, 11, 9]) and a recent algorithm achieves near-optimal $\tilde{O}(m)$

■ **Table 1** Known Results for Incremental Cycle Detection, Topological Sort and SCC.

Reference	Update Time	Incremental SCC
[18]	$O(\min\{m^{3/2} \log n, m^{3/2} + n^2 \log n\})$	No
[20]	$O(m^{3/2} + m\sqrt{n} \log n)$	No
[2]	$O(n^{2.75})$	No
[6]	$\tilde{O}(n^2)$	No
[16]	$O(m^{3/2})$	Yes
[7]	$O(m \cdot \min\{m^{1/2}, n^{2/3}\}), \tilde{O}(n^2)$	Yes
[8]	$\tilde{O}(m\sqrt{n})$	No
[10]	$\tilde{O}(m^{4/3})$	No

total expected update time [9]. Although the goal in both problems is to maintain SCCs, the incremental and decremental versions have little overlap in terms of techniques. Another related problem is that of maintaining single-source shortest paths in an incremental directed graph. The current state-of-the-art for this problem is $\tilde{O}(n^2)$ in dense graphs [15] and $\tilde{O}(m\sqrt{n} + m^{7/5})$ in sparse ones [12].

2 Preliminaries

We consider the problem of maintaining strongly connected components in directed graphs in the incremental setting. In this setting, we start with an empty graph, and directed edges are added to the graph one at a time. We will let G refer to the current version of the graph, and its vertex and edge sets are denoted as V and E respectively. We use m to denote the total number of edges added to G and n to denote $|V(G)|$.

Consider two vertices $u, v \in V$. We say that the vertex u is an *ancestor* of v , and v is a *descendant* of u if there is a path from u to v in G . We will say that u and v are *related* if one is the ancestor of other. For $u \in V$, we use $A(u)$ and $D(u)$ to denote the current set of ancestors and descendants of u . Consider any $S \subseteq V$, for $u \in V$, we use $A_S(u)$ to denote the set $A(u) \cap S$, and $D_S(u)$ to denote the set $D(u) \cap S$. For any $v \in V$, we will use $C(v)$ to denote the strongly connected component containing v in the current graph G , and $|C(v)|$ will be the number of vertices contained in the component.

We will also use the following result due to Italiano [17] on single-source incremental reachability.

► **Lemma 2** ([17]). *Given $v \in V$, there exists an algorithm that maintains $A(v)$ and $D(v)$ in $O(m)$ total time during the course of insertion of m edges.*

We also use the following simplifying assumption by [8] (proved in the appendix of their paper).

► **Lemma 3** ([8]). *We can assume that every vertex in the current graph $G = (V, E)$ has degree $O(m/n)$.*

Data Structures Used. To maintain the strongly connected components, we use the disjoint set data structure of Tarjan [23]. This data structure stores the partition of the vertex set into disjoint sets. In our case, these disjoint sets will be the strongly connected components. Moreover, the disjoint sets are represented by a *canonical element*, which in this case will be a vertex. Following operations are supported by this data structure.

1. **FIND**(x): Given a vertex x , return the canonical vertex of the component containing x .
2. **LINK**(x, y): This operation joins the components whose canonical vertices are x and y . The newly formed component's canonical vertex is x .

This data structure supports any sequence of **FIND** and **LINK** operations in $O(n \log n)$ total time plus $O(1)$ time per operation. Our search and reordering operations will take $\Omega(n \log n)$ total time, so we can think of the **FIND** and **LINK** operations as being performed in $O(1)$ amortized time per operation.

Additionally, to maintain the topological ordering of the strongly connected component, we use the *ordered list* data structure of [14] and [5], which supports the following operations in $O(1)$ -time.

1. **INSERT-BEFORE**(x, y): This operation inserts the vertex x before the vertex y in the ordered list.
2. **INSERT-AFTER**(x, y): This operation inserts the vertex x after the vertex y in the ordered list.
3. **DELETE**(x): This operation deletes the vertex x from the current ordered list.
4. **ORDER**(x, y): This operation returns whether x appears before y in the ordering or not.

This data structure maintains the topological sort k of the strongly connected components implicitly. We will use some additional data structures for our algorithm, that we will mention when we discuss the algorithm.

3 Similarity

3.1 Previous Work

To bound the running time of their algorithm [8] introduced the notion of *sometime- τ -similar* pairs. We briefly discuss their definition.

► **Definition 4** ([8]). *A pair of vertices u and v are said to be sometime- τ -similar if there is a time t at which u is an ancestor of v , $|A(u) \oplus A(v)| \leq \tau$, and $|D(u) \oplus D(v)| \leq \tau$.*

The total number of *sometime- τ -similar* pairs are $\tilde{O}(n\tau)$. Note that this bound is false if we apply the same definition of similarity to the case of directed graphs with cycles. As an example, consider the case where the entire graph is a cycle. For such a graph, by Definition 4, we have $O(n^2)$ *sometime- τ -similar* pairs. So, a new definition of similarity is needed. Moreover, their proof strategy also uses the final topological ordering of the graph. Such an ordering is not possible in directed graphs with cycles. We overcome this by defining another ordering that (like topological ordering) is consistent with the incremental updates to the graph, but at the same time allows for strongly connected components.

3.2 A New Notion Of Similarity

► **Definition 5.** *Consider $u, v \in V$. Let $C(u)$ and $C(v)$ denote the strongly connected components containing u and v respectively, then u and v are called τ -similar in the current graph G if u and v are related, $|C(u)| \leq \tau$, $|C(v)| \leq \tau$, and $|A(u) \oplus A(v)| \leq \tau$, $|D(u) \oplus D(v)| \leq \tau$. Vertices u and v are called sometime- τ -similar, if they are τ -similar at some point during the course of m edge insertions.*

► **Remark 6.** Consider any $u, v \in V$ with $C(u) = C(v)$. If $|C(u)| \geq \tau + 1$ then u and v are not τ -similar in G . But if $|C(u)| \leq \tau$ then they are τ -similar.

With this remark, we distinguish between two types *sometime- τ -similar* vertices.

► **Definition 7.** We call u and v *related-sometime- τ -similar* if there is a time t when u and v are τ -similar with $C(u) \neq C(v)$. On the other hand if there is a time t when u and v are τ -similar and $C(u) = C(v)$, then we call u and v *equivalent-sometime- τ -similar*. It is possible for u, v to be both *related-sometime- τ -similar* and *equivalent-sometime- τ -similar*.

We show that the total number of *sometime- τ -similar* pairs are bounded.

► **Theorem 8.** The total number of *sometime- τ -similar* pairs are $\tilde{O}(n\tau)$.

Our proof will bound *related-sometime- τ -similar* pairs. It is easy to see that the number of *equivalent-sometime- τ -similar* is $O(n\tau)$.

► **Observation 9.** A vertex v can only be *equivalent-sometime- τ -similar* to the first τ vertices that join the same component as v . Thus, the total number of *equivalent-sometime- τ -similar* pairs is $O(n\tau)$.

To prove Theorem 8 we need the following claim.

▷ **Claim 10.** There exists a fixed total order I on the vertices of G which satisfies the following property:

1. Consider any $u, v \in V$. Let t_1 be the first time u and v become related such that u is an ancestor of v , then $I(u) < I(v)$.

Note that if the final graph G_m is acyclic, then I is satisfied by the topological ordering. We will show that it is possible to obtain an ordering that satisfies the above properties even if the graph has a cycle.

3.3 Existence of A Fixed Total Order

In this subsection, we define an ordering I that satisfies Claim 10.

► **Definition 11.** We define a relation \prec over the vertices of G : $u \prec v$ if and only if at some time t , u is an ancestor of v and $C(u) \neq C(v)$.

We first note that \prec is a strict partial order. We formally state and prove the following claim.

▷ **Claim 12.** The relation \prec on the vertices of G is a strict partial order.

Proof. We need to show that \prec is anti-symmetric and transitive. Anti-symmetry follows from the fact that for each pair of vertices u and v , either $u \not\prec v$ or $v \not\prec u$. Now suppose $u \prec v$ and $v \prec w$. Let t_1 be the time at which u is an ancestor of v and $C(u) \neq C(v)$. Similarly, let t_2 be the time at which v is an ancestor of w and $C(v) \neq C(w)$. Without loss of generality, assume that $t_2 \geq t_1$. Observe that u is an ancestor of w at time t_2 . If $C(u) = C(w)$, then $v \in C(w)$ at time t_2 as well, which is a contradiction. So, at time t_2 , $C(u) \neq C(w)$. This proves our claim. ◁

► **Definition 13.** We define I to be a linear extension of \prec . That is I is a total order consistent with \prec : if $u \prec v$, then $I(u) < I(v)$.

Proof of Claim 10. We claim that I of Definition 13 satisfies Claim 10. Consider any two vertices u and v , and let t_1 be the time at which u and v first become related, with u being an ancestor of v . Therefore at time t_1 , $C(u) \neq C(v)$, which implies that $u \prec v$. Since I is consistent with \prec , we know that $I(u) < I(v)$. ◁

3.4 Bounding the Number of Similar Pairs

In this section we will prove Theorem 8. From Observation 9, we conclude that it is sufficient to show that the number of *related-sometime- τ -similar* pairs are at most $O(n\tau \log n)$. We first introduce some notation. Moving forward we will use I to denote an ordering that satisfies Claim 10. We note that Theorem 8 can be obtained by combining the ordering I satisfying Claim 10 with a modification of the proof of *sometime- τ -similar* pairs in a DAG in Section 3 of [8]. However, even for the simpler case of DAGs, the proof in [8] requires a long case analysis. In this paper we present a different approach to the proof we believe is significantly simpler and more intuitive.

► **Definition 14.** Let u and v be a pair of *related-sometime- τ -similar* vertices. We denote it using an ordered tuple (u, v) if $I(u) < I(v)$.

► **Definition 15.** For a vertex v , we define $A^i(v)$ to be the set of vertices u such that (u, v) is a *related-sometime- τ -similar* pair, and $I(v) - I(u) \in [2^i, 2^{i+1})$. Similarly, we define $D^i(v)$ to be the set of vertices w such that (v, w) is a *related-sometime- τ -similar* pair, and $I(w) - I(v) \in [2^i, 2^{i+1})$.

► **Definition 16.** For a vertex v and a fixed i , we define the graph $G_v^{D,i}$ with the vertex set $D^i(v)$ and the graph $G_v^{A,i}$ with the vertex set $A^i(v)$ as follows.

1. Let $u_1, u_2, \dots, u_\alpha$ be the vertices of $A^i(v)$, where the vertices are ordered according to the increasing order of the time at which they become *related- τ -similar* with v . For $j < k$, we add an edge from u_j to u_k , if u_j is an ancestor of u_k when u_k first becomes τ -similar to v .
2. Let w_1, w_2, \dots, w_β be the vertices of $D^i(v)$, where the vertices are ordered according to the increasing order of time at which they become *related- τ -similar* with v . For $j < k$, we add an edge from w_j to w_k if w_j is a descendant of w_k when w_k first becomes τ -similar to v .

See Figure 1 for an illustration.

► **Claim 17.** Let (u, v) be a *related- τ -similar* pair such that $I(v) - I(u) \in [2^i, 2^{i+1})$. Consider $w \in A^i(v)$ and $z \in D^i(u)$, then $I(w) < I(z)$.

Proof. Suppose $I(z) < I(w)$. Note that $I(u) < I(z)$, and $I(w) < I(v)$. Consequently, $I(u) < I(z) < I(w) < I(v)$. Since $I(z) - I(u) \geq 2^i$, and $I(v) - I(w) \geq 2^i$, this implies that $I(v) - I(u) \geq 2^{i+1}$, which contradicts our assumption that $I(v) - I(u) \in [2^i, 2^{i+1})$. ◁

► **Claim 18.** For a vertex v , consider any $A^i(v) = \{u_1, \dots, u_\alpha\}$, where u_j are ordered in the increasing order of time at which they become *related- τ -similar* to v . Then the number of edges in $G_v^{A,i}$ coming into u_j is at least $j - \tau$. Similarly, let $D^i(v) = \{w_1, \dots, w_\beta\}$, where the vertices are ordered in the increasing order of time at which they become *related- τ -similar* with v . Then the number of edges coming into w_j in $G_v^{D,i}$ is at least $j - \tau$.

Proof. Let t be the time at which (u_j, v) become *related- τ -similar*. By t , for all $i < j$, (u_i, v) are *related- τ -similar*. If the in-degree of u_j is at most $j - \tau - 1$, then this implies that there are at least $\tau + 1$ vertices u_i , $i < j$ such that u_i is not an ancestor of u_j . However, these are all ancestors of v at time t . This implies that $|A(u_j) \oplus A(v)| \geq \tau + 1$, contradicting the fact that u_j and v are *related- τ -similar* at time t . ◁

► **Definition 19.** For a vertex v , consider $w \in A^i(v)$. We call w *bad with respect to v* if the outdegree of w in $G_v^{A,i}$ is at most 2τ . Similarly, we call a vertex $z \in D^i(v)$ *bad with respect to v* if the outdegree of z in $G_v^{D,i}$ is at most 2τ .

■ **Figure 1** We consider a *related- τ -similar* pair (u, v) , where $I(v) - I(u) \in [2^i, 2^{i+1})$. All vertices of $A^i(v)$ appear before the vertices of $D^i(u)$.

▷ **Claim 20.** For any v , the total number of bad vertices in $A^i(v)$ for any i is at most 6τ . Similarly, the total number of bad vertices in $D^i(v)$ for any i is at most 6τ .

Proof. As before, let $A^i(v) = \{u_1, u_2, \dots, u_{\alpha}\}$. Let $B = \{u_{\alpha-4\tau+1}, \dots, u_{\alpha}\}$. Let $A \subset A^i(v) \setminus B$ be the set of vertices outside of B that are bad for v (see Figure 2 for an illustration). We want to prove that $|A| \leq 2\tau$. This will give us the desired bound. Consider any $w \in B$. There are at least $|A| - \tau$ edges from A to w . So, the total number of edges going from A to B is at least $4\tau(|A| - \tau)$. The average outdegree of the vertices in A is at least $\frac{4\tau(|A| - \tau)}{|A|}$. Since the vertices in A are bad, we know that $\frac{4\tau(|A| - \tau)}{|A|} \leq 2\tau$. This implies that $|A| \leq 2\tau$. The proof for $D^i(v)$ is analogous. ◁

► **Lemma 21.** Let (u, v) be a *related-sometime- τ -similar* pair. Then, either u is bad for v or v is bad for u .

Proof. Let $I(v) - I(u) \in [2^i, 2^{i+1})$. As before we consider $A^i(v) = \{u_1, \dots, u_{\alpha}\}$, and let $D^i(u) = \{v_1, \dots, v_{\beta}\}$. Assume that neither u is bad for $A^i(v)$ nor v is bad for $D^i(u)$. This implies that the number of edges going out of u and v in $G_v^{A,i}$ and $G_u^{D,i}$, respectively, are at least $2\tau + 1$. Consider the *related- τ -similar* pairs $(u_1, v), \dots, (u_{\alpha}, v)$ and $(u, v_1), \dots, (u, v_{\beta})$. Note that among these pairs one of (u_{α}, v) or (u, v_{β}) are the last to become *related- τ -similar*. Without loss of generality, assume it is (u, v_{β}) . Since we assume that u is not bad with respect to v , at the point when (u_{α}, v) becomes *related- τ -similar*, u is an ancestor of at least $2\tau + 1$ vertices in u_1, \dots, u_{α} . Note that this claim also holds at the (later) time when (u, v_{β}) become *related-sometime- τ -similar*. We call this set of vertices U . We now consider two different cases:

1. If v_{β} is not an ancestor of at least $\tau + 1$ vertices in U , then this contradicts the fact that (u, v_{β}) is a *related- τ -similar* pair.
2. Suppose v_{β} is an ancestor of at least $\tau + 1$ vertices in U . Consider any $u_j \in U$. Observe from Claim 17 that $I(u_j) < I(v_{\beta})$. Since I satisfies Claim 10, we deduce that if v_{β} is an

■ **Figure 2** The vertices in green are the vertices of $A^i(v) \setminus B$ that are bad for v . Since the vertices in B are τ -similar to v , the total number of edges coming out of A and going into B is at least $4\tau(|A| - \tau)$.

ancestor of u_j , then it lies in the same strongly connected component as u_j . Since this is true for all $u_j \in U$, it follows that $|C(v_\beta)| \geq \tau + 1$, thus contradicting the fact that (u, v_β) is *related- τ -similar* (see Definition 5). ◀

► **Remark 22.** Observe that when we are in the acyclic case, then we don't have to deal with the second case at all, since I corresponds to the topological ordering of the final graph G_m .

Proof of Theorem 8. Consider a *related- τ -similar* pair (u, v) . We charge this pair to u if v is bad for u , and we charge it to v if u is bad for v . From Lemma 21, we know that each pair (u, v) is charged to either u or v . Finally, we observe that for any u , for a fixed i , the total number of bad vertices in $D^i(u)$ or $A^i(u)$ is at most 6τ each. Therefore, the total charge on each vertex is at most $12\tau \log n$ (since i is at most $\log n$). Since the total number of vertices is n , we know that the total charge, and therefore the total number of *related-sometime- τ -similar* pairs is at most $O(n\tau \log n)$. ◀

4 Equivalence

Consider $u, v \in V$, observe that u and v lie in the same strongly connected component iff $A(u) = A(v)$ and $D(u) = D(v)$. However, the sets $A(u)$ and $D(v)$ are expensive to maintain for all vertices. Therefore, Bernstein and Chechik [8] defined a relaxed notion of equivalence between vertices. We define a slightly different version that will be useful for our algorithm.

► **Definition 23.** (*S-equivalence*) Consider S which is created by including every vertex $v \in V$ independently with probability $12 \cdot \log n / \tau$, where τ is a parameter to be defined by the algorithm. Vertices u and v are called *S-equivalent* if they are related, $A_S(u) = A_S(v)$, and $D_S(u) = D_S(v)$. For the analysis of our algorithm, it will be useful to distinguish between two types of *S-equivalence*.

1. Vertices x and y are Type 1 if they satisfy the above-mentioned condition and $|C(x)| \geq \tau+1$ or $|C(y)| \geq \tau+1$.
2. Vertices x and y are Type 2 if they satisfy the above-mentioned condition and $|C(x)| \leq \tau$ and $|C(y)| \leq \tau$.

In [8], the algorithm samples a set S , and maintains a partition $\{V_{i,j}\}$ of V , where $V_{i,j} = \{u \in V \text{ s.t. } |A_S(u)| = i, |D_S(u)| = j\}$. We define an ordering \prec^* on these parts.

► **Definition 24.** We say that $V_{i,j} \prec^* V_{k,l}$ if either $\{i < k\}$, or $\{i = k \text{ and } j > l\}$ (note the slightly unusual ordering, instead of $j < l$, we have $j > l$). For $x \in V$, we use $V(x)$ to denote partition $V_{i,j}$ that contains x .

This partition has the following properties which were proved in [8] for directed acyclic graphs, but extend to general directed graphs as well.

► **Lemma 25.** Let $\{V_{i,j}\}$ be the partition of V maintained by the algorithm determined by the sampled set S , then

1. If x and y are related, with x being an ancestor of y , then either $V(x) \prec^* V(y)$ or $V(x) = V(y)$.
2. Consider a strongly connected component C of the current graph G , then $C \subseteq V_{i,j}$ for some i, j .
3. If x and y are related, and $V(x) = V(y)$, then x and y are S -equivalent.

Proof. We give a short proof of this lemma. If x is an ancestor of y , then $A(x) \subseteq A(y)$, and $D(y) \subseteq D(x)$. In particular, $A_S(x) \subseteq A_S(y)$ and $D_S(y) \subseteq D_S(x)$. This immediately tells us that $|A_S(x)| \leq |A_S(y)|$, and $|D_S(y)| \leq |D_S(x)|$ and the first part of the claim follows. Finally, consider any strongly connected component C , then for any $x, y \in C$, $A(x) = A(y)$, $D(x) = D(y)$. This implies that $A_S(x) = A_S(y)$, $D_S(x) = D_S(y)$ and this proves the second part of the claim. To see the third part, assume without loss of generality that x is an ancestor of y , and $V(x) = V(y)$. Note that $A_S(x) \subseteq A_S(y)$, and since $|A_S(x)| = |A_S(y)|$, we can conclude that $A_S(x) = A_S(y)$. Similarly, we can deduce that $D_S(x) = D_S(y)$, thus proving that x and y are S -equivalent. ◀

Keeping in mind Lemma 25, for a component C , we define $V(C)$ as the partition $V_{i,j}$ containing C . An important component of our algorithm is maintaining a topological sort k of the strongly connected components. This topological sort k will be consistent with the order \prec^* of the partitions. That is, for strongly connected components C and C' with $V(C) \prec^* V(C')$, $k(C) < k(C')$. The existence of such a topological ordering is guaranteed by Lemma 25. We will maintain a topological sort of the components by maintaining an ordered list on the canonical vertices. The components are disjoint and each of them have a unique canonical vertex. So, we will often use $k(\cdot)$ on canonical vertices as well.

The algorithms in [8] and [10] proceed by exploiting the notion of S -equivalence. This notion enables them reduce the space of vertices that need to be explored to detect cycles (from Lemma 25). Finally, they show that with high probability the total number of S -equivalent pairs is bounded, and the runtime of the algorithm is proportional to this number. In order to prove this claim, they show that S -equivalent pairs and sometime- τ -similar pairs are related. We show that our notion of sometime- τ -similarity can be used to bound the number of Type 2 S -equivalent pairs, instead of all S -equivalent pairs. It will be clear as we move forward why this is sufficient.

Recall Definition 23 and Definition 5. We show the following lemma relating *sometime- τ -similar* pairs and *Type 2 S -equivalent* pairs.

► **Lemma 26.** *Suppose $S \subseteq V$ is obtained by including each $x \in V$ independently with probability $\frac{12 \cdot \log n}{\tau}$. Suppose u and v are Type 2 S -equivalent, then with high probability, they are sometime- τ -similar.*

Observe that Theorem 8 and Lemma 26 together imply the following theorem:

► **Theorem 27.** *Let S be sampled by including $v \in V$ independently with probability $\frac{12 \cdot \log n}{\tau}$. Then, the total number of Type 2 S -equivalent pairs is at most $\tilde{O}(n\tau)$ with high probability.*

We now proceed to prove Lemma 26.

Proof of Lemma 26. Note that by the statement of the lemma, u and v are related, $|C(u)| \leq \tau$, $|C(v)| \leq \tau$. We additionally want to show that $|D(u) \oplus D(v)| \leq \tau$ and $|A(u) \oplus A(v)| \leq \tau$. Without loss of generality, assume that $|A(u) \oplus A(v)| \geq \tau + 1$. Then, applying Chernoff bound, we conclude that with probability at least $1 - O(1/n^5)$ there is a vertex $x \in A(u) \oplus A(v)$ that is included in S as well. This implies that u and v are not Type 2 S -equivalent. Taking union bound over all Type 2 S -equivalent pairs, which are at most n^2 in number, we conclude that with probability at least $1 - O(1/n^3)$ any Type 2 S -equivalent pair is also sometime- τ -similar. ◀

5 The Algorithm

When an edge (u, v) is inserted, the algorithm updates the newly formed strongly connected components, if any. Additionally, the algorithm maintains a topological sort k of the strongly connected components. This will be achieved by using canonical vertices as a proxy for the strongly connected components (see Section 2). These canonical vertices will be maintained as an ordered list, and when we are required to reorder the strongly connected components, the corresponding canonical vertices will be reordered. To achieve this, we follow the basic framework of [10]. The algorithm to process the insertion of (u, v) proceeds in the following phases.

1. **Phase 1.** This phase is responsible for maintaining reachability information to and from S (using Lemma 2). Additionally, in this phase, the algorithm uses this reachability information to update the sets $V_{i,j}$ and to handle the case where the new SCC formed by the insertion of (u, v) contains at least one vertex in S . If the algorithm finds such an SCC, it terminates after Phase 1, i.e. it skips Phases 2 and 3.
2. **Phase 2.** This phase is responsible for handling small SCCs. In particular, it detects the case when (u, v) creates a new SCC that does not contain any $s \in S$, as well as the case where (u, v) creates no new SCC. The phase also links together the canonical vertices corresponding to this new SCC (if any).
3. **Phase 3.** This phase updates the topological order of the strongly connected components by reordering canonical vertices. Note that even if (u, v) creates no SCCs, Phase 3 may need to do some reordering to ensure that k remains a valid topological order.

In the main body of the paper, we will describe Phases 2 and 3 and the subroutines used in these phases. The correctness of these subroutines can be found in the full version of the paper. Phase 1 is essentially the same as in the framework of [8], so we postpone the details to the full version of the paper.

5.1 Phase 1: Updating the partition $\{V_{i,j}\}$ and Handling Large SCCs

In this section, we give an overview of Phase 1 and its guarantees. The detailed description is in the full version of the paper. Using Lemma 2, we can maintain reachability to and from every vertex in S in total time $O(m|S|)$ over all edge insertions. This allows us to maintain two additional piece of information. Recall the partition $V_{i,j}$ from Section 4, and note that every $V(x)$ is determined entirely by $A_S(x)$ and $D_S(x)$. Thus, Phase 1 can use the reachability information to/from S to maintain the partition $V_{i,j}$. Phase 1 can also use this reachability information to detect any new SCCs that contain a vertex in S .

We now state these guarantees more formally. The following lemma is essentially identical to the guarantees of [8], but is modified to handle SCCs.

► **Lemma 28** ([8]). *Consider the insertion of edge (u, v) . Phase 1 has the following guarantees:*

1. *At the end of Phase 1, each set $V_{i,j}$ is correct for the new version of the graph (the graph with edge (u, v) inserted). The algorithm also updates the order of the strongly connected components so that they are consistent with \prec^* .*
2. *If the insertion of (u, v) creates a new SCC that contains a vertex in S , then Phase 1 detects the new SCC, links the corresponding canonical vertices, and computes the topological order of the resulting SCCs. The update procedure then terminates and does not continue to Phase 2 or 3.*
3. *If the insertion of (u, v) does not create a new SCC that contains a vertex in S , then Phase 1 does not create any new SCCs. In this case, after the end of Phase 1, the ordering k on the canonical vertices is guaranteed to be a valid topological ordering of the canonical vertices in $G \setminus \{(u, v)\}$. The algorithm then proceeds to Phases 2 and 3.*

5.2 Phase 2: Detecting Small SCCs

The algorithm enters Phase 2 only if the newly inserted edge (u, v) does not create a new SCC that contains a vertex of S ; otherwise the algorithm to process (u, v) terminates after Phase 1. We also remark that if the algorithm enters Phase 2, then with high probability the size of the newly formed strongly connected component (if one exists) is at most τ . This follows from an easy application of Chernoff bound: if the newly formed component has size at least $\tau + 1$, then with high probability, it contains a vertex of S , in which case the algorithm terminates after Phase 1. Taking a union bound over all n^2 edge insertions, we get the following:

► **Observation 29.** *If the algorithm enters Phase 2 while processing an edge (u, v) , then with high probability, the new strongly connected components formed by the addition of (u, v) (if one exists) has size at most τ .*

Additionally, recall that Phase 1 updates the partition set $\{V_{i,j}\}$, so we assume that once we enter Phase 2 this partition already corresponds to the graph G (Lemma 28).

Previous Work. Our Phase 2 will be similar to the cycle detection algorithm of [10], but we need to adapt it to find the newly formed strongly connected component. Previous algorithms for finding SCCs such as the one by [16], proceed by implementing the cycle detection algorithm, but running it only over the canonical vertices. However, our algorithm will do a search over all vertices of the graph. We do this because sizes of the SCCs will be relevant to the runtime of the algorithm, and they weren't relevant in the case of [16].

We now give a brief outline of Phase 2: when an edge (u, v) is added to the graph, then the algorithm first checks if $k(\text{FIND}(u)) < k(\text{FIND}(v))$. If this is the case, then there couldn't have been an existing path from v to u (due to Lemma 28). As a result, a new component

containing u and v could not be formed. So, the algorithm doesn't continue. To detect if a new component is formed and to find all the vertices of this component, the algorithm does alternate steps of forward and backward search. For this purpose, it maintains sets F_a and F_d (to do forward search), B_a and B_d (to do backward search). For the forward search, F_a and F_d are the vertices that are alive (yet to be explored), and dead (already explored). Sets B_a and B_d are similarly defined for the backward search. When we encounter a vertex while exploring in the forward direction, we add it to F_a . When all neighbors of a vertex $v \in F_a$ that are S -equivalent to v been added to $F_a \cup F_d$, we add v to F_d . We add vertices to B_a and B_d similarly. At all times, while exploring vertices in the forward direction, we want to stay as close to v as possible, so we pick out a vertex x with minimum $k(\text{FIND}(x))$ from F_a to explore next. Similarly, while exploring in the backward direction, we want to stay as close to u as possible, so we pick out the vertex y with maximum $k(\text{FIND}(y))$ from B_a to explore next in the backward direction. We refer the reader to Algorithms 1, 2, and 4 for pseudocodes for Phase 2. We give the proof of correctness in the full version of the paper. We briefly outline the proof of runtime.

► **Lemma 30.** *The total runtime of Phase 2 is $O(\sqrt{m^3\tau/n})$.*

Proof Sketch. Suppose we have process edge e_t and let f_t denote the size of F_d after $\text{FINDCOMPONENT}()$ has finished terminated. We observe that $|B_d| = \Theta(f_t)$ as well, since we do a balanced search. From Lemma 3 we conclude that the total update time of the algorithm over m edge insertions is $O(m/n \sum_{t=1}^m f_t)$. The goal is to now bound $\sum_{t=1}^m f_t$. Consider $x \in F_d$ and $y \in B_d$ after $\text{FINDCOMPONENT}()$ has finished processing e_t . We show that (x, y) is a newly formed *related- τ -similar* pair or *equivalent- τ -similar* pair. This implies that $\sum_{t=1}^m f_t^2 = \tilde{O}(n\tau)$ (from Theorem 8). Using Cauchy-Schwarz, we know that $\sum_{t=1}^m f_t = \tilde{O}(\sqrt{mn\tau})$. Thus the total runtime of Phase 2 is $O(\sqrt{m^3\tau/n})$. ◀

5.3 Phase 3: Sorting the Canonical Vertices

We enter this Phase only if there is no vertex of S in the newly created SCC, C_N . After Phase 1 and Phase 2, we know which canonical vertices have combined to give the newly formed strongly connected component. We delete these canonical vertices from the ordered list, and show how to reorder the list so that a topological sort on the canonical vertices is maintained.

To update the topological ordering of the canonical vertices, we follow the framework of [10]. We present it here for completeness, modifying their algorithm slightly to account for the case where a cycle is created.

We will consider two cases, one where a new component is created and one where no new component is created. Suppose no new component is created, and consider the sets F_d and B_d , from the forward and backward searches after we have processed edge (u, v) . Since we do an ordered search, we know that all the vertices of a given component appear in a continuous manner in F_d and B_d . Let $\text{FIND}(v), x_1, \dots, x_f$ be the **canonical** vertices corresponding to the components appearing in F_d , with $k(\text{FIND}(v)) < k(x_1) < \dots < k(x_f)$. Similarly, let $y_1, y_2, \dots, y_b, \text{FIND}(u)$ be the **canonical** vertices corresponding to the components appearing in B_d , with $k(y_1) < k(y_2) < \dots < k(y_b) < k(\text{FIND}(u))$. We use the subroutine $\text{UPDATEFORWARD}()$ and $\text{UPDATEBACKWARD}()$ to update the ordered list (see Algorithm 3). This list only consists of canonical vertices that represent different components.

We now describe how to reorder the vertices. In [10] two cases are considered, the first case corresponds to when the algorithm terminates in conditions: $B_a = \emptyset$ or $\max_{x \in B_a} k(\text{FIND}(x)) < \max_{y \in F_d} k(\text{FIND}(y))$. For this case, we use the subroutine $\text{UPDATEFORWARD}()$. The proof

for the case when the algorithm terminates in conditions $F_a = \emptyset$ or $\min_{x \in F_a} k(\text{FIND}(x)) > \min_{y \in B_d} k(\text{FIND}(y))$ is analogous (we use a subroutine `UPDATEBACKWARD()`) and we omit it here. We postpone the proof of correctness to the full version. We give a proof of the runtime.

► **Lemma 31.** *The total runtime of Phase 3 is $O(\sqrt{mn\tau})$.*

Proof sketch. For each $x \in F_d$ and $y \in B_d$, the algorithm `UPDATEFORWARD()` puts `FIND(x)` and `FIND(y)` in the correct position in the ordered list. This takes time $O(1)$ per vertex in F_d and B_d , giving a total runtime of $O(\sqrt{mn\tau})$. ◀

When a new component C_N is formed. If a new strongly connected component C_N is formed, and it doesn't contain a vertex of S , then the algorithm still needs to reorder some components. Assume without loss of generality that v is the canonical vertex of C_N . We first proceed to delete from the ordered list, all canonical vertices corresponding to the components that combined to form C_N . We define $x_1, x_2, \dots, x_f \in F_d$ and $y_1, y_2, \dots, y_b \in B_d$ as before except we exclude the canonical vertices that combined to form C_N . Finally, if our `FINDCOMPONENT()` terminated in $B_a = \emptyset$ or $\max_{x \in B_a} k(\text{FIND}(x)) \leq \max_{y \in F_d} k(\text{FIND}(y))$, then we execute `UPDATEFORWARD()`, else if `FINDCOMPONENT()` terminated in $F_a = \emptyset$ or $\min_{x \in F_a} k(\text{FIND}(x)) \geq \min_{y \in B_d} k(\text{FIND}(y))$, then we execute `UPDATEBACKWARD()`. The proof of correctness can be found in the full version of the paper and is the same as in the case when there is no new strongly connected component formed.

► **Lemma 32.** *The total update time of our algorithm is $\tilde{O}(m^{4/3})$.*

Proof. The total time taken in Phase 1, 2 and 3 is at most $\tilde{O}(mn/\tau + \sqrt{mn\tau} + \sqrt{m^3\tau/n})$. Substituting $\tau = n/m^{1/3}$, we get the desired bound of $\tilde{O}(m^{4/3})$. ◀

■ **Algorithm 1** `EXPLORE-FORWARD(x)`.

```

1  $F_a = F_a \setminus \{x\}$  and  $F_d = F_d \cup \{x\}$ .

Lyndon Words Accelerate Suffix Sorting

Abstract

Suffix sorting is arguably the most fundamental building block in string algorithmics, like regular sorting in the broader field of algorithms. It is thus not surprising that the literature is full of algorithms for suffix sorting, in particular focusing on their practicality. However, the advances on practical suffix sorting stalled with the emergence of the DivSufSort algorithm more than 10 years ago, which, up to date, has remained the fastest suffix sorter. This article shows how properties of Lyndon words can be exploited algorithmically to accelerate suffix sorting again. Our new algorithm is 6–19% faster than DivSufSort on real-world texts, and up to three times as fast on artificial repetitive texts. It can also be parallelized, where similar speedups can be observed. Thus, we make the first advances in practical suffix sorting after more than a decade of standstill.

1 Introduction & Related Work

Since its introduction [13] in 1990, the suffix array – storing the order of the lexicographically sorted suffixes – has become one of the most important data structures in the field of string processing. Its applications include text indexing, text compression, and in particular the construction of the Burrows–Wheeler transformation.

From a theoretical point of view, the story is almost over: the suffix array can be computed in asymptotically optimal $\mathcal{O}(n)$ time and using only $\mathcal{O}(1)$ additional words of working space [9]¹. However, the fast *practical* construction of the suffix array remains an active topic of research. The efficiency of existing suffix sorters varies immensely [2], and the worst-case time and space bounds do not accurately predict the real world performance. In fact, the practically fastest and also highly memory efficient algorithm DivSufSort is not amongst the linear time algorithms [6], and has remained on the top of the scoreboard ever since its introduction more than a decade ago.

In 2016, Baier introduced the algorithm GSACA [4], which is the first to construct the suffix array in linear time without using recursion. It utilizes properties of so-called *Lyndon words*, which are strings that are lexicographically smaller than all of their proper

suffixes (for example, **artist** is a Lyndon word; **concert** is not a Lyndon word because it is lexicographically larger than its suffix **cert**). Conceptually, the algorithm consists of two phases. Franek et al. showed that the first phase computes (a partially sorted version of) the Lyndon array (a definition follows later), which is then used in the second phase to induce the suffix array [8]. Despite its interesting theoretical properties, GSACA cannot compete with the best suffix sorters in practice.

Our Contributions. We make the first advances on practical suffix sorting since the introduction of DivSufSort more than a decade ago. Our starting point is the GSACA algorithm, but we show how special properties of Lyndon words allow us to use fast integer sorting algorithms for its two phases. As a result, we obtain an efficient algorithm that is also easy to parallelize. Our sequential implementation is around 6–19% faster than DivSufSort on real-world inputs, and up to three times as fast on artificial repetitive inputs. However, it comes at the cost of a larger memory footprint (even though we still use much less space than the original implementation of GSACA). Our parallelization scales well up to at least 16 cores, and on large inputs it is faster than Labeit’s parallel implementation of DivSufSort [12], the currently fastest shared memory suffix sorter.

The rest of the paper is organized as follows: In Section 2 we introduce the definitions and notation that we use throughout the paper. We explain our new version of GSACA in Section 3, and give implementation details and a description of our parallelization in Section 4. We conclude the paper with an experimental evaluation in Section 5.

2 Preliminaries

We write $\lg x$ for $\log_2 x$. For $i, j \in \mathbb{N}$, we use the closed, half-open, and open interval notations $[i, j] = [i, j + 1) = (i - 1, j] = (i - 1, j + 1)$ to represent the set $\{x \mid x \in \mathbb{N} \wedge i \leq x \leq j\}$. Our analysis is performed in the word RAM model [10], where we can perform fundamental operations (logical shifts, basic arithmetic operations etc.) on words of size w bits in constant time. For the input size n of our problems we assume $\lceil \lg n \rceil \leq w$.

A *string* (also called *text*) over the *alphabet* Σ is a finite sequence of *symbols* from the finite and totally ordered set Σ . We say that a string S has length n and write $|S| = n$, if S is a sequence of exactly n symbols. The string of length 0 is called empty string and denoted by ϵ . The i -th symbol of a string S is denoted by $S[i]$, while the *substring* from the i -th to the j -th symbol is denoted by $S[i..j]$. For $i > j$ we define $S[i..j] = \epsilon$. For convenience, we use the interval notations $S[i..j + 1) = S(i - 1..j] = S(i - 1..j + 1) = S[i..j]$. The i -th *suffix* of S is defined as $S_i = S[i..n]$, while the substring $S[1..i]$ is called *prefix* of S . A prefix or suffix of S is called *proper*, if and only if its length is at least 1 and at most $n - 1$. Let S and T be two strings over Σ of lengths n and m , respectively. The concatenation of S and T is denoted by ST . The length of the *longest common prefix* (LCP) between S and T is defined as $\text{LCP}(S, T) = \max\{\ell \mid \ell \in [0, \min(n, m)] \wedge S[1..\ell] = T[1..\ell]\}$. The *longest common extension* (LCE) of indices i and j is the length of the LCP between S_i and S_j , i.e. $\text{LCE}(i, j) = \text{LCP}(S_i, S_j)$. The total order on Σ induces a total order on the set Σ^* of strings over Σ . Let S and T be strings over Σ , and let $\ell = \text{LCP}(S, T)$. We say that S is lexicographically smaller than T and write $S \prec T$, if and only if either $\ell = n < m$ (i.e. S is a prefix of T) or $\ell < \min(n, m) \wedge S[\ell + 1] < T[\ell + 1]$. We write $S \preceq T$ to denote $S \prec T \vee S = T$.

We can simplify the description of our algorithm with a special symbol $\$ \notin \Sigma$ that is smaller than all symbols from Σ . We say that S is *null-terminated*, if $S[n] = \$ \wedge \forall i \in [1, n) : S[i] \neq \$$.

Lexicographical Ordering of Suffixes. The *suffix array* lexicographically orders the suffixes of a string. To save space we only store the starting index of each suffix.

► **Definition 1** (Suffix Array). *Given a string S of length n , its suffix array A is the unique permutation of $[1, n]$ that satisfies $S_{A[1]} \prec S_{A[2]} \prec \dots \prec S_{A[n]}$. The inverse suffix array A^{-1} is the inverse permutation of A , i.e. $\forall i \in [1, n] : A^{-1}[A[i]] = i$.*

Baier's algorithm computes the suffix array by exploiting properties of *Lyndon words*. A Lyndon word is a string that is lexicographically smaller than all of its proper suffixes, i.e. S is a Lyndon word if and only if $\forall i \in [2..n] : S \prec S_i$ [5]. The Lyndon array of S identifies the longest Lyndon word starting at each text position.

► **Definition 2** (Lyndon Array). *Given a string S of length n , its Lyndon array λ is defined by $\forall i \in [1, n] : \lambda[i] = \max\{\ell \mid \ell \in [1, n - i + 1] \wedge S[i..i + \ell) \text{ is a Lyndon word}\}$. We write $w_\lambda(i) = S[i..i + \lambda[i]]$ to denote the longest Lyndon word that starts at index i .*

An important property of the Lyndon array is that it inherently encodes some information about the lexicographical ordering of the suffixes.

► **Lemma 3** ([7, Lemma 15]). *Let S be a string of length n with Lyndon array λ , and let $i \in [1, n]$. It holds $\lambda[i] = \ell$ if and only if*

$$(i + \ell \leq n + 1) \wedge (i + \ell \leq n \implies S_i \succ S_{i+\ell}) \wedge (\forall j \in (i, i + \ell) : S_i \prec S_j).$$

We conclude the preliminaries by showing two relations between Lyndon words and the lexicographical order of suffixes:

► **Lemma 4.** *Let S be a string of length n , let λ be its Lyndon array, and let $i, j \in [1, n]$ be arbitrary indices. If $w_\lambda(i) \prec w_\lambda(j)$, then $S_i \prec S_j$.*

Proof. If $w_\lambda(i) \prec w_\lambda(j)$, then $w_\lambda(j)$ is not a prefix of $w_\lambda(i)$. If also $w_\lambda(i)$ is not a prefix of $w_\lambda(j)$, then the first mismatch between $w_\lambda(i)$ and $w_\lambda(j)$ determines the lexicographical order of S_i and S_j . Thus we only have to consider the case where $w_\lambda(j) = w_\lambda(i)\alpha$ for a non-empty string α . Let $S[i..i + \lambda[j]] = w_\lambda(i)\beta$, then it must hold $\beta \prec \alpha$ and thus also $S_i \prec S_j$. Otherwise, [5, Prop. 1.5] would imply that $w_\lambda(i)\beta$ is a Lyndon word. ◀

► **Lemma 5.** *Let $S_i = \alpha S_j$ (with $j = i + |\alpha|$) be a suffix of a string, where α is a Lyndon word. It holds $S_i \succ S_j \iff w_\lambda(i) = \alpha$. If $S_i \prec S_j$, then $\alpha w_\lambda(j)$ is a Lyndon word.*

Proof. Lemma 3 directly implies $S_i \succ S_j \iff w_\lambda(i) = \alpha$. Assume $S_i \prec S_j$, then Lemma 4 implies $w_\lambda(j) \succeq \alpha$. If $w_\lambda(j) = \alpha$, then due to Lemma 3 it holds $S_j \succ S_{j+|\alpha|}$, which leads to the contradiction $S_i = \alpha S_j \succ \alpha S_{j+|\alpha|} = S_j$. Thus it holds $w_\lambda(j) \succ \alpha$, and [5, Prop. 1.3] implies that $\alpha w_\lambda(j)$ is a Lyndon word. ◀

3 Sequential Algorithm

We start by giving a high level description of Baier's algorithm. For clarity, we write \hat{A} to denote the *not yet computed* suffix array, i.e. an array that serves as preliminary storage during the execution of the algorithm, and ultimately becomes the actual suffix array A . We use the terms suffix and index interchangeably. The algorithm consists of three main steps. For each step, we provide an example in Figure 1a.

Initialization: We sort and group the suffixes by their first symbol. The suffixes of each group are stored in increasing index order in a consecutive interval of \hat{A} , and the order of the intervals is determined by the rank of the starting symbols. In our example, the order of the alphabet is $\$ < a < b < c$. Thus, the leftmost group contains the suffixes that start with $\$$, followed by the group of suffixes that start with a , and so forth.

15:4 Lyndon Words Accelerate Suffix Sorting

(a) Baier's algorithm. Initially, we group the indices by symbol (above the first dotted line). In the first phase, we group the indices by longest Lyndon words (below the first dotted line). In the second phase, we lexicographically sort the suffixes within each group (below the second dotted line).

(b) Data structures during Phase 1. The stack Q contains groups that we may still have to refine (left of the red line). The stack P contains only final groups (right of the red line).

Figure 1 Baier's algorithm and data structures used during Phase 1. The colored boxes represent the group contexts, which are also exactly the longest Lyndon words in (a). (Best viewed in color.)

Phase 1: We refine the groups such that two suffixes S_i and S_j belong to the same group if and only if they share the longest Lyndon word $w_\lambda(i) = w_\lambda(j)$. Again, the indices of each group are stored in increasing order in a consecutive interval of \hat{A} . The order of the groups is determined by the lexicographical order of the Lyndon words. In our example it holds $w_\lambda(3) = \text{abac} \prec \text{abc} = w_\lambda(9)$, and thus the group containing index 3 is stored to the left of the group containing index 9. From Lemma 4 follows that the grouping after Phase 1 is compatible with the suffix array.

Phase 2: We lexicographically sort the suffixes within each group to obtain the suffix array.

Baier uses a special form of induced copying (see e.g. [11, 14]) for Phase 1 and 2, which is elegant but results in a noncompetitive practical performance (see [4, Table 2] and [3, Chapter 6]). In the remainder of this section we explain how to instead use integer sorting for these phases, which allows a more efficient implementation of the algorithm. First, we give a formal definition of the grouping structure.

► **Definition 6** (Suffix Grouping). A suffix grouping consists of an array \hat{A} and a list G_1, \dots, G_m of groups. A group with context $\alpha \in \Sigma^+$ is a triple $\langle \ell, r, |\alpha| \rangle$ with $\ell, r \in [1, n]$ and $\ell < r$, where the following 3 properties hold.

1. The interval $\hat{A}[\ell..r)$ contains exactly the elements of $A[\ell..r)$ in increasing (by text position) order. We write $i \in \langle \ell, r, |\alpha| \rangle$ to denote $\exists x \in [\ell, r) : \hat{A}[x] = i$.
2. All the suffixes share prefix α , i.e. $\forall i \in \langle \ell, r, |\alpha| \rangle : S_i = \alpha S_{i+|\alpha|}$.
3. The context α is a Lyndon word.

The groups G_1, \dots, G_m form a partition of \hat{A} as follows. Let $G_i = \langle \ell_i, r_i, |\alpha_i| \rangle$ be the i -th group, then it holds $\ell_1 = 1$ and $r_m = n + 1$. For $i \in [2, m]$ it holds $\ell_i = r_{i-1}$. We write $G_i < G_j \iff i < j$ to denote that any suffix in G_i is lexicographically smaller than any suffix in G_j , which also means that the context of G_i is lexicographically not larger than the context of G_j . A group $\langle \ell, r, |\alpha| \rangle$ is called *final* if $\forall i \in \langle \ell, r, |\alpha| \rangle : w_\lambda(i) = \alpha$.

As mentioned earlier, the initial suffix grouping partitions the suffixes by their first symbol, which can be implemented as follows. We stably sort the array $\hat{A} = [1, 2, \dots, n]$ in increasing order, using key $S[i]$ for entry i . After that, we determine the group borders with a simple scan over the sorted suffixes. We store the groups on a stack Q , where the bottommost element is the leftmost group, and the topmost element is the rightmost group.

3.1 Phase 1 with Integer Sorting

The goal of Phase 1 is to sort the group contexts lexicographically. To this end, we refine the groups by splitting them into subgroups with possibly longer contexts. The general idea is as follows. For any index i in a group $G_k = \langle \ell, r, |\alpha| \rangle$, let $j = i + |\alpha|$ be the position right after the context. If $S_i \succ S_j$ then $w_\lambda(i) = \alpha$ (Lemma 5), and we place i into a *final* subgroup with unchanged context α . If however $S_i < S_j$, then $\alpha w_\lambda(j)$ is a Lyndon word (Lemma 5), and we place i into a subgroup with context $\alpha w_\lambda(j)$. We repeatedly refine the subgroups in the same way, until all groups are final. At the point in time at which we refine the group $G_k = \langle \ell, r, |\alpha| \rangle$, the data structures used by our Phase 1 algorithm are the following (see Figure 1b for an example):

- A stack Q contains groups G_1, \dots, G_k that form a partition of $\hat{A}[1..r)$. The groups are stored in increasing lexicographical order (the bottommost group G_1 is lex. smallest, the topmost group G_k is lex. largest).
- A stack P contains final groups F_1, \dots, F_h that form a partition of $\hat{A}[r..n]$. The groups are stored in decreasing lexicographical order (the bottommost group F_1 is lex. largest, the topmost group F_h is lex. smallest).
- Together with the array \hat{A} , the groups $G_1, \dots, G_k, F_h, \dots, F_1$ are a suffix grouping according to Definition 6.
- A length- n array **fgrp** maps suffixes to their final groups. If $\exists x \in [1, h] : i \in F_x$, then **fgrp** $[i] = x$. Otherwise, **fgrp** $[i] = \infty$. Note that **fgrp** inherently encodes information about the lexicographical order of suffixes due to $\forall i, j \in [1, n] : \text{fgrp}[i] < \text{fgrp}[j] \implies S_i \succ S_j$.

Now we describe Phase 1 in detail. The description is accompanied by pseudocode in Algorithm 1. The algorithm takes the array \hat{A} and the stack Q from the initialization as input. The stack P is initially empty, and all entries of **fgrp** are set to ∞ (lines 1–2). During the execution of the algorithm, we may mark the groups on the stack Q as *ready* (indicating that the group can easily be refined) or *final* (indicating that no further refinement is necessary). Initially, all groups are unmarked. The refinement is performed in a simple loop. While the stack Q is not empty, we pop the topmost group $G_k = \langle \ell, r, |\alpha| \rangle$ and process it (lines 3–4). Depending on the marking of the group, there are three possible cases:

■ **Algorithm 1** Phase 1 with integer sorting.

Input: Initial suffix grouping represented by array \hat{A} and stack Q (all groups unmarked).

Output: Final suffix grouping represented by array \hat{A} and stack P .

```

1:  $P \leftarrow$  empty stack

33:          $Q.\text{push}(\langle \ell', i, |\alpha| \rangle)$  marked ready
34:          $\ell' \leftarrow i$ 
35:      $Q.\text{push}(\langle \ell', r, |\alpha| \rangle)$  marked ready

```

final
group

ready
group

unmarked
group

The group is marked final. or it is the group containing only the lexicographically smallest suffix $S_n = \$$ (which gets processed last). During an earlier processing step, we have already ensured that $\forall i \in G_k : w_\lambda(i) = \alpha$. We simply push the group onto the final stack P , which now contains $|P| = h + 1$ groups. We update the array **fgrp** accordingly by assigning $\text{fgrp}[i] \leftarrow h + 1$ for each index $i \in G_k$ (lines 5–8).

The group is marked ready. During an earlier processing step, we have already ensured that for each index $i \in G_k$, the index $i + |\alpha|$ is contained in a group that is lexicographically larger than G_k . Since all the lexicographically larger groups are final, it holds $\text{fgrp}[i + |\alpha|] \neq \infty$. Particularly, for any two indices $i, j \in G_k$ it holds $\text{fgrp}[i + |\alpha|] > \text{fgrp}[j + |\alpha|] \implies S_i \prec S_j$ and $\text{fgrp}[i + |\alpha|] < \text{fgrp}[j + |\alpha|] \implies S_i \succ S_j$. We sort the interval $\hat{A}[\ell..r]$ in *decreasing* order, using key $\text{fgrp}[i + |\alpha|]$ for index i (line 10). Indices that share the same key x form a subgroup H_x (we again determine the group borders by scanning; lines 12–13). Let β be the context of the final group F_x , then $\alpha\beta$ becomes the context of subgroup H_x (lines 14–15 and 17–18). We push the subgroups onto the stack Q in lexicographically increasing order. All subgroups are unmarked.

The group is unmarked. We have already seen that ready and final groups are relatively easy to process. In this processing step, we split an unmarked group into at most one final subgroup H_∞ , and possibly multiple ready subgroups H_1, H_2, \dots, H_m (where m is unknown in advance). The lexicographical order of subgroups is $H_\infty \prec H_m \prec \dots \prec H_1$. All subgroups have unchanged context α ; the context extension only takes place when processing the ready subgroups. The subgroup H_∞ will contain exactly the indices $i \in G_k$ with $w_\lambda(i) = \alpha$. Lemma 4 implies that these suffixes are lexicographically smallest amongst the suffixes in G_k . Consider any index $i \in G_k$, and let x be the smallest positive integer such that $i' = i + x \cdot |\alpha| \notin G_k$. It is easy to see that $S_i = \alpha^x S_{i'}$.

- If i' is in one of the lexicographically smaller groups G_1, \dots, G_{k-1} , then $S_i \succ S_{i'}$ and simple properties of the lexicographical order imply $S_i \succ S_{i+|\alpha|} \succ S_{i+2|\alpha|} \succ \dots \succ S_{i+x|\alpha|}$. It follows from Lemma 3 that $w_\lambda(i) = \alpha$, and we place i into subgroup H_∞ . Note that if $x > 1$ and $i \in H_\infty$, then $i + |\alpha| \in H_\infty$.
- If i' is in one of the lexicographically larger groups F_1, \dots, F_h , then $S_i \prec S_{i'}$ and simple properties of the lexicographical order imply $S_i \prec S_{i+|\alpha|} \prec S_{i+2|\alpha|} \prec \dots \prec S_{i+x|\alpha|}$. It follows from Lemma 3 that $\lambda[i] > |\alpha|$, and we place i into subgroup H_x . Note that if $x > 1$ and $i \in H_x$, then $i + |\alpha| \in H_{x-1}$. Thus H_x can be marked ready.

Now we show that in fact $H_m \prec H_{m-1} \prec \dots \prec H_1$. Assume that we place two indices i and j into subgroups H_x and H_y respectively. We have to show that $(x > y \implies S_i \prec S_j)$ and $(x < y \implies S_i \succ S_j)$. If $x > y$, then $S_i = \alpha^y S_{i+y \cdot |\alpha|}$ and $S_j = \alpha^y S_{j+y \cdot |\alpha|}$. Because of $x > y$ it holds $i + y \cdot |\alpha| \in G_k$, while $j + y \cdot |\alpha|$ is in one of the lexicographically larger groups F_1, \dots, F_h . Thus it holds $S_{i+y \cdot |\alpha|} \prec S_{j+y \cdot |\alpha|}$ and therefore also $S_i \prec S_j$. The proof of $x < y \implies S_i \succ S_j$ works analogously.

As seen above, if both i and $i + |\alpha|$ are in G_k , then it holds $i + |\alpha| \in H_\infty \implies i \in H_\infty$ and $i + |\alpha| \in H_{x-1} \implies i \in H_x$. In such cases, we can easily compute i 's subgroup from $(i + |\alpha|)$'s subgroup. We only need an efficient way to check whether $i + |\alpha| \in G_k$ actually holds. Conveniently, $i + |\alpha| \in G_k$ if and only if i and $i + |\alpha|$ are *neighboring* entries in $\hat{A}[\ell..r]$. This is due to the fact that there cannot be a suffix $S_j = \alpha S_{j+|\alpha|}$ with $j \in (i, i + |\alpha|)$ (otherwise α would have a proper prefix that is also a proper suffix, which contradicts the definition of Lyndon words).

Lines 19–35 of Algorithm 1 describe our strategy for unmarked groups in technical detail. First, we compute a key $sg(\hat{A}[i])$ for each $i \in [\ell, r]$ in decreasing order, indicating that we place index $\hat{A}[i]$ into subgroup $H_{sg(\hat{A}[i])}$. If for some index $\hat{A}[i]$ it holds $\hat{A}[i] + |\alpha| \in G_k$,

i.e. if $\hat{A}[i]$ and $\hat{A}[i] + |\alpha|$ are neighbors in $\hat{A}[\ell..r]$, then we compute $\hat{A}[i]$'s subgroup from $(\hat{A}[i] + |\alpha|)$'s subgroup as described above (lines 21–23). Otherwise, we inspect $\text{fgrp}[\hat{A}[i] + |\alpha|]$ to decide whether we place $\hat{A}[i]$ into subgroup H_∞ or subgroup H_1 (lines 24–26). Finally, we rearrange $\hat{A}[\ell..r]$ according to the new subgroups (line 27). We push the subgroups onto stack Q in increasing lexicographical order (once again computing the group borders with a simple scan). If H_∞ exists, then we mark it final (lines 29–30). All other groups are marked ready (lines 31–35).

3.2 Phase 2 with Integer Sorting

In the second phase, we lexicographically sort each final group, and simultaneously compute the inverse suffix array (see Algorithm 2). We proceed similarly to the first phase, using the stack P and the array \hat{A} as input. First, we pop the topmost group of P (which is the lexicographically smallest group containing only the special suffix $S_n = \$$), and assign $A^{-1}[1] = n$ (line 1). Then we sort the remaining groups in a simple loop. While P is not empty, we pop the topmost group $F_h = \langle \ell, r, |\alpha| \rangle$ of the stack (lines 2–3) and lexicographically sort it. At this point in time, we have already sorted the suffixes of all groups that are lexicographically smaller than F_h because P contains the groups in lexicographical order (the topmost group is the lexicographically smallest unsorted group). Therefore, when processing F_h we have $\forall i \in [1, \ell) : A^{-1}[A[i]] = i$.

Since the group is final, it holds $S_{\hat{A}[i]} \succ S_{\hat{A}[i] + |\alpha|}$ for each $i \in [\ell, r)$. Thus $\hat{A}[i] + |\alpha|$ either was in one of the lexicographically smaller groups that we have already sorted, or it holds $\hat{A}[i] + |\alpha| \in F_h$. Ideally, we would simply sort $\hat{A}[\ell..r]$ using key $A^{-1}[\hat{A}[i] + |\alpha|]$ for entry $\hat{A}[i]$. However, if $\hat{A}[i] + |\alpha| \in F_h$, then we have not computed $A^{-1}[\hat{A}[i] + |\alpha|]$ yet. We solve this problem by first rearranging F_h into subgroups $H_1 \prec H_2 \prec \dots \prec H_m$, where subgroup H_x contains the suffixes that have prefix α^x , but not prefix α^{x+1} (the correctness of the lexicographical order of these subgroups can be shown similarly to the order of subgroups for unmarked groups in Phase 1). We assign the indices to the subgroups in decreasing order (line 4). If $\hat{A}[i] + |\alpha| \notin F_h$ (as before, this is the case if and only if $\hat{A}[i]$ and $\hat{A}[i] + |\alpha|$ are not neighbors in $\hat{A}[\ell..r]$), then we place $\hat{A}[i]$ into subgroup H_1 (line 6). Otherwise, we have already placed $\hat{A}[i] + |\alpha|$ into some subgroup H_{x-1} , and we place i into subgroup H_x (line 5). After we have rearranged the indices according to the new grouping (line 7), we finally sort each subgroup using key $A^{-1}[\hat{A}[i] + |\alpha|]$ for entry $\hat{A}[i]$ (lines 8–15). Whenever we sort a group, we also update the inverse suffix array. Since no two indices $\hat{A}[i]$ and $\hat{A}[i] + |\alpha|$ are in the same subgroup, and due to the lexicographical order of subgroups, the required keys are always available once they are needed.

4 Implementation Details

Our C++17 implementation of the algorithm is publicly available on GitHub². In general, it closely follows the description from Section 3. In this section, we discuss the choice of integer sorters as well as other practical optimizations, including the parallelization of the algorithm.

Sequential Implementation. The main computational effort of the algorithm lies in integer sorting, as well as in the computation of the keys prior to sorting. Finding the group borders after sorting only requires simple sequential scans that are cache efficient and very fast in

² <https://github.com/jonas-ellert/gsaca-double-sort>

■ **Algorithm 2** Phase 2 with integer sorting.

Input: Final suffix grouping represented by array \hat{A} and stack P .

Output: Suffix array \hat{A} and inverse suffix array A^{-1} .

```

1:  $P.pop()$ ;  $A^{-1}[1] \leftarrow n$ ;
2: while  $P$  is not empty do
3:    $\langle \ell, r, |\alpha| \rangle \leftarrow P.pop()$ 
4:   for  $i \in [\ell, r]$  in decreasing order do
5:     if  $i < r - 1 \wedge \hat{A}[i + 1] = \hat{A}[i] + |\alpha|$  then  $sg(\hat{A}[i]) \leftarrow sg(\hat{A}[i + 1]) + 1$ 
6:     else  $sg(\hat{A}[i]) \leftarrow 1$ 
7:   Stably sort  $\hat{A}[\ell..r]$  in increasing order, using key  $sg(\hat{A}[i])$  for entry  $\hat{A}[i]$ .
8:    $\ell' \leftarrow \ell$ 
9:   for  $i \in (\ell, r)$  in increasing order do
10:    if  $sg(\hat{A}[i - 1]) \neq sg(\hat{A}[i])$  then
11:      Sort  $\hat{A}[\ell'..i]$  in increasing order, using key  $A^{-1}[\hat{A}[i] + |\alpha|]$  for entry  $\hat{A}[i]$ .
12:      for  $j \in [\ell'..i]$  do  $A^{-1}[\hat{A}[j]] \leftarrow i$ 
13:       $\ell' \leftarrow i$ 
14:   Sort  $\hat{A}[\ell'..r]$  in increasing order, using key  $A^{-1}[\hat{A}[i] + |\alpha|]$  for entry  $\hat{A}[i]$ .
15:   for  $j \in [\ell'..r]$  do  $A^{-1}[\hat{A}[j]] \leftarrow i$ 

```

practice. We use two different sorting algorithms. Whenever the keys are from a small domain, we use a simple counting sort. This applies to the initialization (in practice we assume the byte alphabet $[0, 255]$), the processing of unmarked groups in the first phase, and the computation of subgroups in the second phase (Algorithm 1, line 27 and Algorithm 2, line 7). In both of the latter cases, we simultaneously compute the keys and count their frequencies. When refining ready groups in the first phase (Algorithm 1, line 10), and when performing the final sorting in the second phase (Algorithm 2, lines 11 and 14), we use MSD radix sort. We focus on speed and thus do not use an in-place variant of the sorter. Therefore, apart from the space needed for the suffix array, one auxiliary array (for $fgrp$ and A^{-1}), and the stacks, we need additional space linear in the size of the largest group that we encounter.

We provide three versions DS1, DS3, and DSH of our sequential implementation that differ only in the initialization (where DS stands for *double sort* because we reduced both phases to integer sorting). The first version DS1 corresponds to the description in Section 3, i.e. we sort the suffixes by their first symbol. The second version DS3 directly sorts the suffixes by their first three symbols, resulting in smaller groups after the initialization (potentially resulting in a smaller memory footprint). Finally, the version DSH directly sorts the suffixes using key $w_\lambda(i)$ for suffix S_i . However, if $\lambda[i] > 8$ then we use key $w_\lambda(i)[1..8]$. Thus we immediately place all suffixes with $\lambda[i] < 8$ into their correct final groups, skipping many refinement steps and therefore accelerating Phase 1. The initialization of DSH consists of three steps.

Extract: We use a modification of Duval’s algorithm [5] to compute for each $i \in [1, n]$ the key $x(i) = w_\lambda(i)$, if $\lambda[i] \leq 8$, or $x(i) = w_\lambda(i)[1..8]$ otherwise. We then use a hash table³ to check whether this is the first time we have seen key $x(i)$. If it is, then we add the

³ We use an implementation of Robin Hood hashing by Martin Ankerl, see <https://github.com/martinus/robin-hood-hashing>

tuple $\langle x(i), i \rangle$ to the table. Otherwise, let j be the index where we first discovered key $x(i)$. We store $\hat{A}[i] = j$, indicating that we will place i into the same group as j .

Sort: We use comparison sorting to sort the tuples $\langle x(i), i \rangle$ by their first component.

Rearrange: We group the indices according to the sorted keys, and push the groups onto the stack Q . If a group has context α with $|\alpha| < 8$ then we mark it final.

Parallel Implementation. For our parallel algorithms we implemented the same ideas as described in Section 3 using OpenMP for parallelization. We parallelized the counting sort in the initialization as well as the processing of each suffix group in Phases 1 and 2. Because processing a single suffix group consists mainly of integer sorting and sequential scans we can parallelize them well in practice. We replace the sequential scans with parallel prefix sums. For integer sorting we use `ips4o` [1]. In case we have to sort a range $\hat{A}[\ell..r)$ of elements stably we sort $\hat{A}[\ell..r)$ by their keys, breaking ties by sorting elements with equal keys by their entry $\hat{A}[i]$. Since for small suffix groups the overhead to process the group in parallel is too high compared to the sequential implementation we use a threshold. If the size of a suffix group is at most 1024, we switch to the sequential implementation (we performed a preliminary evaluation to determine a value that performs well in practice).

Unfortunately, we cannot achieve a perfect speedup. We simply cannot process multiple suffix groups in parallel because we heavily rely on processing them in decreasing lexicographical order. For that reason the running time of our parallelization is still linear with respect to the number of processed suffix groups (which is n in the worst case).

Similarly to our sequential implementation, we provide two different parallel versions PDS1 and PDS2. In PDS1 we sort the suffixes in the initialization by their first symbol using a parallel counting sort. In PDS2 we sort the suffixes by their first two symbols using `ips4o`.

5 Experimental Evaluation

We evaluated our algorithms on a number of real and artificial texts taken from the Pizza & Chili text corpus⁴. In Table 1 we give an overview of the used texts. We divide the texts into three different categories. Real texts (PC-Real) include `english`, `dna`, `sources`, `proteins` and `dblp.xml`. They are good examples of texts that occur in real-world applications. Real repetitive texts (PC-Rep-Real) include `cere`, `einstein.en.txt`, `kernel` and `para`. These texts might still occur in real-world applications, but they are rather repetitive and thus highly compressible. And lastly, artificial repetitive texts (PC-Rep-Art) include `fib41`, `rs.13` and `tm29`. These texts were created artificially with the goal of repetitiveness in mind. All the aforementioned texts are sufficiently short to compute the 32-bit suffix array. For our weak scaling experiments we use a collection of larger texts (**Large**) that are summarized at the bottom of Table 1. From each text we use a prefix of up to 16 GiB for our experiments, which means that 32 bits are not sufficient to address the suffixes. Thus, we compute the 64-bit suffix array instead.

5.1 Experimental Setup and Results

We conducted our experiments on a Linux machine with an AMD EPYC 7452 processor (32 cores, 2.35 GHz, L1 32K, L2 512K, L3 16M) and 1 TB of RAM. The code was compiled using GCC 7.5.0. We repeated all of our experiments five times and use the median as the

■ **Table 1** Texts from the Pizza & Chili text corpus and large texts. Apart from the text size n and the alphabet size σ , we provide the number of suffix groups (SGs) and the average size of the suffix groups that we process in Phase 1.

Category	Text	n (MiB)	σ	Count of SGs	Avg. SG Size
PC-Real	english	1,024	237	102,640,785	40.72
	dna	386	16	44,436,473	34.49
	sources	202	230	27,961,111	28.92
	proteins	1,024	27	144,323,711	28.62
	dblp.xml	283	97	16,091,809	71.9
PC-Rep-Real	cere	440	5	10,585,469	174.06
	einstein.en.txt	446	139	409,384	4,568.34
	kernel	247	160	4,027,324	256.15
	para	410	5	12,241,149	139.98
PC-Rep-Art	fib41	256	2	98	10,935,276.92
	rs.13	207	2	197	4,400,958.45
	tm29	256	2	194	5,534,751.23
Large	cc.txt	32,768	243	1,528,252,068	88.53
	dna.txt	32,768	4	2,955,252,973	44.56
	prot.txt	32,768	26	4,308,219,247	30.47

■ **Figure 2** Running time and additional memory usage of the sequential algorithms averaged for each text category, and additionally for the text **dna**. The red line marks the running time of DivSufSort. We do not show the memory usage of DivSufSort because it requires only a very small constant amount of additional working space. (Best viewed in color.)

■ **Figure 3** Throughput and additional memory usage for each parallel algorithm on large texts. The text size scales with the number of used threads (1GiB per thread). (Best viewed in color.)

final result. For the sequential experiments we compare our algorithms DS1, DS3, and DSH with Baier’s original implementation of GSACA [4] and the currently fastest suffix sorter DivSufSort [6]. For the weak scaling experiments we compare our parallel algorithms PDS1 and PDS2 with Labeit’s parallel implementation PDivSufSort of DivSufSort [12], and with our sequential DS1 as a baseline to see how well our parallelization scales.

Sequential Results. For each of the categories PC-Real, PC-Rep-Real and PC-Rep-Art, we averaged the running time and additional memory usage of the texts in each category. Before computing the average, we normalized the running time for each algorithm to show how long the algorithms take for 100 MiB of the input text. The additional memory is normalized as well to show the additional memory usage for each byte in the input text. The results for each category can be seen in Figure 2. Additionally, we provide a separate plot for *dna*, which is one of the most relevant text types in practice.

All of our sequential algorithms are significantly faster than Baier’s original implementation. Our fastest sequential algorithm DSH is around twice as fast as Baier’s algorithm, and is in each category even faster than DivSufSort (over 6% faster on PC-Real, over 19% faster on PC-Rep-Real, and over three times as fast on PC-Rep-Art). On PC-Real and PC-Rep-Real, the additional memory usage of our algorithms is much lower than Baier’s algorithm. Of our new algorithms, DS3 has the lowest memory usage, but the running time is not as good as DS1 and DSH. None of our algorithms comes close to the memory usage of DivSufSort, which only uses a very small amount of constant additional memory.

Weak Scaling Results. Figure 3 shows the results of our weak scaling experiments. We calculate for each text the throughput (text size divided by running time) in MiB/s and the additional memory in bits/n for up to 16 threads. The input size grows proportionally to the number of used threads, such that the input size is p GiB when using p threads. We do not include results for more than 16 threads because otherwise the memory usage exceeds the maximum amount of 500 GB memory that we can address on a single NUMA node, and in some cases even the total memory of 1 TB (which is a limitation of our algorithms).

On `cc.txt` and `prot.txt`, our parallel variants are significantly faster than PDivSufSort for all input sizes. On `dna.txt`, the performance of all algorithms is similar. The memory usage of PDS1 is up to five times as large as PDivSufSort and the memory usage of PDS2 is up to four times as large as PDivSufSort on all input texts. The memory usage of DS1 is on all input texts lower than PDS1. This is due to the fact that the sequential algorithm uses 40-bit types for the additional arrays `fgrp` and A^{-1} . The parallel algorithms however use 64-bit types because the running time gets slower when using 40-bit types in parallel.

Online Euclidean Spanners

Abstract

In this paper, we study the online Euclidean spanners problem for points in \mathbb{R}^d . Given a set S of n points in \mathbb{R}^d , a t -spanner on S is a subgraph of the underlying complete graph $G = (S, \binom{S}{2})$, that preserves the pairwise Euclidean distances between points in S to within a factor of t , that is the *stretch factor*. Suppose we are given a sequence of n points (s_1, s_2, \dots, s_n) in \mathbb{R}^d , where point s_i is presented in step i for $i = 1, \dots, n$. The objective of an online algorithm is to maintain a geometric t -spanner on $S_i = \{s_1, \dots, s_i\}$ for each step i . The algorithm is allowed to *add* new edges to the spanner when a new point is presented, but cannot *remove* any edge from the spanner. The performance of an online algorithm is measured by its competitive ratio, which is the supremum, over all sequences of points, of the ratio between the weight of the spanner constructed by the algorithm and the weight of an optimum spanner. Here the weight of a spanner is the sum of all edge weights.

First, we establish a lower bound of $\Omega(\varepsilon^{-1} \log n / \log \varepsilon^{-1})$ for the competitive ratio of any online $(1 + \varepsilon)$ -spanner algorithm, for a sequence of n points in 1-dimension. We show that this bound is tight, and there is an online algorithm that can maintain a $(1 + \varepsilon)$ -spanner with competitive ratio $O(\varepsilon^{-1} \log n / \log \varepsilon^{-1})$. Next, we design online algorithms for sequences of points in \mathbb{R}^d , for any constant $d \geq 2$, under the L_2 norm. We show that previously known incremental algorithms achieve a competitive ratio $O(\varepsilon^{-(d+1)} \log n)$. However, if the algorithm is allowed to use additional points (Steiner points), then it is possible to substantially improve the competitive ratio in terms of ε . We describe an online Steiner $(1 + \varepsilon)$ -spanner algorithm with competitive ratio $O(\varepsilon^{(1-d)/2} \log n)$. As a counterpart, we show that the dependence on n cannot be eliminated in dimensions $d \geq 2$. In particular, we prove that any online spanner algorithm for a sequence of n points in \mathbb{R}^d under the L_2 norm has competitive ratio $\Omega(f(n))$, where $\lim_{n \rightarrow \infty} f(n) = \infty$. Finally, we provide improved lower bounds under the L_1 norm: $\Omega(\varepsilon^{-2} / \log \varepsilon^{-1})$ in the plane and $\Omega(\varepsilon^{-d})$ in \mathbb{R}^d for $d \geq 3$.

1 Introduction

We study the online Euclidean spanners problem for a set of points in \mathbb{R}^d . Let S be a set of n points in \mathbb{R}^d . A t -spanner for a finite set S of points in \mathbb{R}^d is a subgraph of the underlying complete graph $G = (S, \binom{S}{2})$, that preserves the pairwise Euclidean distances between points in S to within a factor of t , that is the *stretch factor*. The edge weights of G are the Euclidean distances between the vertices. Chew [22, 23] initiated the study of Euclidean spanners in 1986, and showed that for a set of n points in \mathbb{R}^2 , there exists a spanner with $O(n)$ edges and constant stretch factor. Since then a large body of research has been

devoted to Euclidean spanners due to its vast applications across domains, such as, topology control in wireless networks [50], efficient regression in metric spaces [31], approximate distance oracles [36], and many others. Moreover, Rao and Smith [48] showed the relevance of Euclidean spanners in the context of other fundamental geometric NP-hard problems, e.g., Euclidean traveling salesman problem and Euclidean minimum Steiner tree problem. Many different spanner construction approaches have been developed for Euclidean spanners over the years, that each found further applications in geometric optimization, such as spanners based on well-separated pair decomposition (WSPD) [17, 35], skip-lists [4], path-greedy and gap-greedy approaches [3, 5], locality-sensitive orderings [21], and more. We refer to the book by Narasimhan and Smid [47] and the survey of Bose and Smid [16] for a summary of results and techniques on Euclidean spanners up to 2013.

Online Spanners. We are given a sequence of n points (s_1, s_2, \dots, s_n) , where the points are presented one-by-one, i.e., point s_i is revealed at the step i , and $S_i = \{s_1, \dots, s_i\}$ for $i = 1, \dots, n$. The objective of an online algorithm is to maintain a geometric t -spanner G_i for S_i for all i . Importantly, the algorithm is allowed to *add* edges to the spanner when a new point arrives, however is not allowed to *remove* any edge from the spanner.

The performance of an online algorithm ALG is measured by comparing it to the offline optimum OPT using the standard notion of competitive ratio [14, Ch. 1]. The *competitive ratio* of an online t -spanner algorithm ALG is defined as $\sup_{\sigma} \frac{\text{ALG}(\sigma)}{\text{OPT}(\sigma)}$, where the supremum is taken over all input sequences σ , $\text{OPT}(\sigma)$ is the minimum weight of a t -spanner for σ , and $\text{ALG}(\sigma)$ denotes the weight of the t -spanner produced by ALG for this input.

Computing a $(1+\varepsilon)$ -spanner of minimum weight for a set S in Euclidean plane is known to be NP-hard [20]. However, there exists a plethora of constant-factor approximation algorithms for this problem in the offline model; see [3, 25, 26, 48]. Most of these algorithms approximate the parameter *lightness* (the ratio of the spanner weight to the weight of the Euclidean minimum spanning tree $\text{MST}(S)$) of Euclidean spanners, which in turn also approximates the optimum weight of the spanner. We refer to Section 1.1 for a more detailed overview of the parameter lightness.

Minimum spanning trees (MST) on n points in a metric space, which have no guarantee on the stretch factor, have been studied in the online model. It is not difficult to show that a greedy algorithm achieves a competitive ratio $\Theta(\log n)$. The online Steiner tree problem was studied by Imase and Waxman [39], who proved $\Theta(\log n)$ -competitiveness for the problem. Later, Alon and Azar [2] studied minimum Steiner trees for points in the Euclidean plane, and proved a lower bound $\Omega(\log n / \log \log n)$ for the competitive ratio. Their result was the first to analyse the impact of Steiner points on a geometric network problem in the online setting. Several algorithms were proposed over the years for the online Steiner Tree and Steiner forest problems, on graphs in both weighted and unweighted settings; see [1, 6, 10, 37, 46].

Online Steiner Spanners. An important variant of online spanners is when it is allowed to use auxiliary points (Steiner points) which are not part of input sequence of points. It turns out that Steiner points allow for substantial improvements over the bounds on the sparsity and lightness of Euclidean spanners in the offline settings; see [12, 13, 42, 43]. In the geometric setting, an online algorithm is allowed to *add* Steiner points and *subdivide* existing edges with Steiner points at each time step. (This modeling decision has twofold justification: It accurately models physical networks such as roads, canals, or power lines, and from the theoretical perspective, it is hard to tell whether an online algorithm introduced a large number of Steiner points when it created an edge/path in the first place). However, the spanner must achieve the given stretch factor only for the input point pairs.

■ **Figure 1** (a) An optimum $\frac{3}{2}$ -spanner on three points with all edges of unit length. (b) After inserting a fourth point at the center, the weight of the optimum $\frac{3}{2}$ -spanner decreases.

It is easy to see that in this model the online spanners in 1-dimension could attain optimum competitive ratio. However, it is unclear how it extends to higher dimensions as it has been observed in the offline settings that it tends to be more difficult to achieve tight bounds for Steiner spanners than their non-Steiner counterparts.

When the optimal Steiner spanner is lighter than $\text{OPT}(S_i)$ without Steiner points, the adversary may decrease $\text{OPT}(S_i)$ by adding suitable Steiner vertices to S_i ; see Fig. 1. In particular, $\text{OPT}(S_i)$ may or may not increase with i in the model without Steiner points, but $\text{OPT}(S_i)$ monotonically increases in i when Steiner points are allowed.

1.1 Related Work

Dynamic Spanners. In applications, the data (modeled as points in \mathbb{R}^d) changes over time, as new cities emerge, new wireless antennas are built, and users turn their wireless devices on or off. *Dynamic* models aim to maintain a geometric t -spanners for a dynamically changing point set S ; in a restricted *insert-only* model, the input consists of a sequence of point insertions. In the dynamic model, the objective is design algorithms and data structures that minimize the worst-case update time needed to maintain a t -spanner for S over all steps, regardless of its weight, sparsity, or lightness. Notice that dynamic algorithms are allowed to add or delete edges in each step, while online algorithms cannot delete edges. However, if a dynamic (or dynamic insert-only) algorithm always adds edges for a sequence of points insertions, it is also an online algorithm, and one can analyze its competitive ratio.

Arya et al. [4] designed a randomized incremental algorithm for n points in \mathbb{R}^d , where the points are inserted in a random order, and maintains a t -spanner of $O(n)$ size and $O(\log n)$ diameter. Their algorithm can also handle random insertions and deletions in $O(\log^d n \log \log n)$ expected amortized update time. Later, Bose et al. [15] presented an insert-only algorithm to maintain a t -spanner of $O(n)$ size and $O(\log n)$ diameter in \mathbb{R}^d . Fischer and Har-Peled [29] used dynamic compressed quadtrees to maintain a WSPD-based $(1+\varepsilon)$ -spanner for n points in \mathbb{R}^d in expected $O([\log n + \log \varepsilon^{-1}] \varepsilon^{-d} \log n)$ update time. Their algorithm works under the online model, too, however, they have not analyzed the weight of the resulting spanner. Gao et al. [30] used hierarchical clustering for dynamic spanners in \mathbb{R}^d . Their DEFSPANER algorithm is fully dynamic with $O(\log \Delta)$ update time, where Δ is the spread¹ of the set S . They maintain a $(1+\varepsilon)$ -spanner of weight $O(\varepsilon^{-(d+1)} \|MST(S)\| \log \Delta)$, and for a sequence of point insertions, DEFSPANER only adds edges. As $\text{OPT} \geq \|MST(S)\|$, DEFSPANER can serve as an online algorithm with competitive ratio $O(\varepsilon^{-(d+1)} \log \Delta)$.

¹ The *spread* of a finite set S in a metric space is the ratio of the maximum pairwise distance to the minimum pairwise distance of points in S ; and $\log \Delta \geq \Omega(\log n)$ in doubling dimensions.

Gottlieb and Roditty [32] studied dynamic spanners in more general settings. For every set of n points in a metric space of bounded doubling dimension², they constructed a $(1 + \varepsilon)$ -spanner whose maximum degree is $O(1)$ and that can be maintained under insertions and deletions in $O(\log n)$ amortized update time per operation. Later, Roditty [49] designed fully dynamic geometric t -spanners with optimal $O(\log n)$ update time for n points in \mathbb{R}^d . Very recently, Chan et al. [21] introduced *locality sensitive orderings* in \mathbb{R}^d , which has applications in several proximity problems, including spanners. They obtained a fully dynamic data structure for maintaining a $(1 + \varepsilon)$ -spanners in Euclidean space with logarithmic update time and linearly many edges. However, the spanner weight has not been analyzed for any of these constructions. Dynamic spanners have been subject to investigation in abstract graphs, as well. See [8, 9, 11] for some recent progress on dynamic graph spanners.

Lightness and **sparsity** are two natural parameters for Euclidean spanners. For a set S of points in \mathbb{R}^d , the lightness is the ratio of the spanner weight (i.e., the sum of all edge weights) to the weight of the Euclidean minimum spanning tree $MST(S)$. It is known that *greedy-spanner* ([3]) has constant lightness; see [25, 26]. Later, Rao and Smith [48] in their seminal work, showed that the greedy spanner has lightness $\varepsilon^{-O(d)}$ in \mathbb{R}^d for every constant d , and asked what is the best possible constant in the exponent. Then, the *sparsity* of a spanner on S is the ratio of its size to the size of a spanning tree. Classical results [23, 24, 40, 53] show that when the dimension $d \in \mathbb{N}$ and $\varepsilon > 0$ are constant, every set S of n points in d -space admits an $(1 + \varepsilon)$ -spanners with $O(n)$ edges and weight proportional to that of the Euclidean MST of S .

Dependence on $\varepsilon > 0$ for constant dimension d . The dependence of the lightness and sparsity on $\varepsilon > 0$ for constant $d \in \mathbb{N}$ has been studied only recently. Le and Solomon [42] constructed, for every $\varepsilon > 0$ and constant $d \in \mathbb{N}$, a set S of n points in \mathbb{R}^d for which any $(1 + \varepsilon)$ -spanner must have lightness $\Omega(\varepsilon^{-d})$ and sparsity $\Omega(\varepsilon^{-d+1})$, whenever $\varepsilon = \Omega(n^{-1/(d-1)})$. Moreover, they showed that the greedy $(1 + \varepsilon)$ -spanner in \mathbb{R}^d has lightness $O(\varepsilon^{-d} \log \varepsilon^{-1})$. In fact, Le and Solomon [42] noticed that Steiner points can substantially improve the bound on the lightness and sparsity of an $(1 + \varepsilon)$ -spanner. For minimum sparsity, they gave an upper bound of $O(\varepsilon^{(1-d)/2})$ for d -space and a lower bound of $\Omega(\varepsilon^{-1/2} / \log \varepsilon^{-1})$. For minimum lightness, they gave a lower bound of $\Omega(\varepsilon^{-1} / \log \varepsilon^{-1})$, for points in the plane ($d = 2$) [42]. More recently, Bhore and Tóth [13] established a lower bound of $\Omega(\varepsilon^{-d/2})$ for the lightness of Steiner $(1 + \varepsilon)$ -spanners in Euclidean d -space for all $d \geq 2$. Moreover, for points in the plane, they established an upper bound of $O(\varepsilon^{-1})$ [12].

1.2 Our Contributions

We present the main contributions of this paper, and sketch the key technical and conceptual ideas used for establishing these results. (Refer to the technical sections for precise definitions, complete proofs, and additional remarks.)

Points on a line. In Section 2 (Theorem 3), we establish a lower bound $\Omega(\varepsilon^{-1} \log n / \log \varepsilon^{-1})$ for the competitive ratio of any online algorithm for a sequence of points on the real line. Moreover, we show that this bound is tight. We present an online algorithm that maintains a $(1 + \varepsilon)$ -spanner with competitive ratio $O(\varepsilon^{-1} \log n / \log \varepsilon^{-1})$.

² A metric is said to be of a *constant doubling dimension* if a ball with radius r can be covered by at most a constant number of balls of radius $r/2$.

Our online algorithm is a 1-dimensional instantiation of hierarchical clustering, which was used by Roditty [49] for dynamical spanners in doubling metrics. When a new point s_i is “close” to a previous point s_j , we add s_i to the “cluster” of s_j , otherwise we open a new cluster. The key question is to define when s_i is “close” to a previous point. Instead of the closest points on the line, we find the shortest edge pq that contains s_i in the current spanner, and say that s_i is “close” to p (resp., q) if $\|ps_i\| \leq \frac{\varepsilon}{4}\|pq\|$ (resp., $\|qs_i\| \leq \frac{\varepsilon}{4}\|pq\|$). The algorithm (and its analysis), does not explicitly maintain “clusters,” though. It is easy to show, by induction, that ALG maintains a $(1 + \varepsilon)$ -spanner. The main contribution is a tight analysis of the competitive ratio. We partition the edges into *buckets* by weight, where bucket E_ℓ contains edges e of weight $\varepsilon^{-(\ell+1)} < \|e\| \leq \varepsilon^{-\ell}$. The edges of the spanner will form a laminar family (any edges are interior-disjoint or one contains the other); and the edge weight decay by factors of at most $(1 - \frac{\varepsilon}{4})$ along the descending paths in the containment poset. Since $(1 - \frac{\varepsilon}{4})^{4/\varepsilon} < \frac{1}{2}$, we can show that the total weight of edges in a level decreases by a factor of $\frac{1}{2}$ after every $\lceil 5/\varepsilon \rceil$ levels. Thus, the sum of edge weights in a *block* of $\lceil 5/\varepsilon \rceil$ consecutive levels is $O(\varepsilon^{-1}\text{OPT})$. This bound, applied to $O(\log_{\varepsilon^{-1}} n) = O(\log n / \log \varepsilon^{-1})$ buckets, proves the upper bound. The lower bound construction matches the upper bound for each block of levels and for each bucket.

Euclidean d -space without Steiner points. In Section 3, we study the online Euclidean spanners for a sequence of points in \mathbb{R}^d . For constant $d \geq 2$ and parameter $\varepsilon > 0$, we show that the dynamic algorithm by Fischer and Har-Peled achieves, in the online model, competitive ratio $O(\varepsilon^{-(d+1)} \log n)$ for n points in \mathbb{R}^d (Theorem 4 in Section 3.1), matching the competitive ratio of DEFSPANNER by Gao et al. [30, Lemma 3.8].

The new competitive analysis of this algorithm is instrumental for extending the algorithm and its analysis to online Steiner $(1 + \varepsilon)$ -spanners (see below). We briefly describe a key geometric insight. It is well known that for $a, b \in \mathbb{R}^d$, any ab -path of weight at most $(1 + \varepsilon)\|ab\|$ lies in an ellipsoid B_{ab} with foci a and b and great axes $(1 + \varepsilon)\|ab\|$. Summation over *disjoint* ellipsoids gives a lower bound for OPT. Unfortunately, ellipsoids B_{ab} for all pairs $ab \in S$ may heavily overlap. Recently, Bhore and Tóth [13, Lemma 3] proved that any ab -path of weight at most $(1 + \varepsilon)\|ab\|$ must contain edge of total weight at least $\frac{1}{2}\|ab\|$ that are “near-parallel” to ab (technically, they make an angle at most $\varepsilon^{1/2}$ with ab); see Fig. 4(right). By partitioning the edges of the unknown OPT spanner by *both* directions and disjoint ellipsoids, we obtain a bound of $\frac{\text{ALG}}{\text{OPT}} \leq O(\varepsilon^{-(d+1)} \log n)$.

Euclidean d -space with Steiner points. When we are allowed to use Steiner points, we can substantially improve the competitive ratio in terms of ε : We describe an algorithm with competitive ratio $O(\varepsilon^{(1-d)/2} \log n)$ (Theorem 5 in Section 3.2).

The online Steiner algorithm adds a secondary layer to the non-Steiner algorithm: For each edge ab of the non-Steiner spanner G_1 , we maintain a path of weight $(1 + \varepsilon)\|ab\|$ with Steiner points; the stretch factor of the resulting Steiner spanner G_2 is $(1 + \varepsilon)^2 < (1 + 3\varepsilon)$. The key idea is to reduce the weight to maintain *buckets* of edges of G_1 that have roughly the same direction and weight, and are nearby locations; and we construct a common Steiner network N for them. Importantly, we can construct a “backbone” of the network N when the first edge ab in a bucket arrives, and we have $\|N\| \leq O(\varepsilon^{(1-d)/2}\|ab\|)$. When subsequent edges $a'b'$ in the same bucket arrive, then we can add relatively short “connectors” to N so that it also contains an $a'b'$ -path of weight at most $(1 + \varepsilon)\|a'b'\|$. Thus N can easily accommodate new paths in the online model. The key technical tool for constructing Steiner networks N (one for each bucket) is the so-called *shallow-light trees*, introduced by Awerbuch et al. [7] and Khuller et al. [41], and optimized in the geometric setting by Elkin and Solomon [28, 52].

As a counterpart, we show (Theorem 7 in Section 4) that the dependence on n cannot be eliminated in dimensions $d \geq 2$. In particular, we prove that any $(1 + \varepsilon)$ -spanner for a sequence of n points in \mathbb{R}^d , has competitive ratio $\Omega(f(n))$ for some function $f(n)$ with $\lim_{n \rightarrow \infty} f(n) = \infty$. The lower bound construction consists of an adaptive strategy for the adversary in the plane: The adversary recursively maintains a space partition and places points in *rounds* so that the spanner constructed so far is disjoint from most of the ellipses B_{ab} that will contain the ab -paths for pairs of new points a, b . In order to control OPT, the adversary maintains the property that OPT_i is an x -monotone path γ_i after round i . However, this requirement means that any new point must be very close to γ_i , and S will be a set of almost collinear points. The core challenge of the Steiner spanner problem seems to lie in the case of almost collinear points.

Higher dimensions under the L_1 -norm. Finally, in the full version of our paper we provide improved lower bounds for points in \mathbb{R}^d under the L_1 norm (without Steiner points). We show that for every $\varepsilon > 0$, under the L_1 norm, the competitive ratio of any online $(1 + \varepsilon)$ -spanner algorithm $\Omega(\varepsilon^{-2}/\log \varepsilon^{-1})$ in \mathbb{R}^2 and is $\Omega(\varepsilon^{-d})$ in \mathbb{R}^d for $d \geq 3$.

The adversary takes advantage of the non-monotonicity of OPT, mentioned above. In round 1, it presents a point set $S_1 \cup S_2$ for which any $(1 + \varepsilon)$ -spanner (without Steiner points) must contain a complete bipartite graph between S_1 and S_2 ; however the optimal Steiner $(1 + \varepsilon)$ -spanner for $S_1 \cup S_2$ has much smaller weight. Then in round 2, the adversary presents all Steiner points $\hat{S}_1 \cup \hat{S}_2$ of an optimal Steiner $(1 + \varepsilon)$ -spanner for $S_1 \cup S_2$. The key insight is that under the L_1 -norm (and for this particular point set), the optimal Steiner spanner for $S_1 \cup S_2$ already contains Manhattan paths between any two points in $S = (S_1 \cup S_2) \cup (\hat{S}_1 \cup \hat{S}_2)$, and so it remains the optimum solution (without Steiner points) for the point set S .

We were unable to replicate this phenomenon under the L_2 -norm, where the current best lower bound in \mathbb{R}^d , for all $d \geq 1$, derives from the 1-dimensional construction. In particular, it is not sufficient to consider the *Steiner ratio* for $(1 + \varepsilon)$ -spanners, defined as the supremum ratio between the weight of the minimum $(1 + \varepsilon)$ -spanner and the minimum Steiner $(1 + \varepsilon)$ -spanner of a finite point set in \mathbb{R}^d . Under the L_2 -norm, this ratio is $\Theta(\varepsilon^{-1})$ in the plane and $\tilde{\Theta}(\varepsilon^{(1-d)/2})$ in \mathbb{R}^d for $d \geq 3$ [12, 42, 44]. However, an optimal Steiner $(1 + \varepsilon)$ -spanner, need not achieve the desired $1 + \varepsilon$ stretch factor for the Steiner points.

2 Lower and Upper Bounds for Points on a Line

It is easy to analyze the one-dimensional case as the offline optimum network (OPT) for any set of points in a line is a path from the leftmost point to the rightmost point; the stretch factor of this path is always 1. (In contrast, in 2- and higher dimensions, the optimum $(1 + \varepsilon)$ -spanner is highly dependent on the distribution of points, which in turn may change over time in the online model.)

Lower bound. The following adversarial strategy establishes a lower bound $L(n) = \Omega(\varepsilon^{-1})$ for the competitive ratio; refer to Fig. 2 (left). Start with two points $p_0 = 0$ and $q_0 = 1$. For the first two points, ALG must add a direct edge p_0q_0 . Then the adversary successively places points $p_i = i \cdot \frac{\varepsilon}{2}$, for $i = 1, \dots, n$ so that all points remain in the interval $[0, \frac{1}{2}]$. Thus the number of points is $n = 2 + \lfloor \varepsilon^{-1} \rfloor$. In each round, ALG must add the edge p_iq_0 , otherwise any path between p_i and q_0 would have to make a detour via a point in $\{p_0, \dots, p_{i-1}\}$, and so it would be longer than $(1 + \varepsilon)\|p_iq_0\|$. Since $\|p_iq_0\| \geq \frac{1}{2}$, the weight of the network after $n - 2$ iterations is at least $\text{ALG} \geq 1 + \frac{1}{2}(n - 2) \geq 1 + \frac{1}{2}\lfloor \varepsilon^{-1} \rfloor$. Combined with $\text{OPT} = 1$, this yields a lower bound of $\Omega(\varepsilon^{-1})$ for the competitive ratio.

■ **Figure 2** Left: A sequence of n points $(q_0, p_0, p_1, p_2, \dots, p_{n-2})$, for $n = \lceil \varepsilon^{-1} \rceil$, for which any online $(1 + \varepsilon)$ -spanner has weight $\Omega(\varepsilon^{-1} \text{OPT})$. For clarity, the edges are drawn as circular arcs, but the weight of an edge $p_i p_j$ is $\|p_i p_j\| = |p_i - p_j|$. Right: Iteration in each subinterval.

The adversary has placed only $O(\varepsilon^{-1})$ points so far; this is the first stage of the strategy. In subsequent stages, the adversary repeats the same strategy in every subinterval ab of previous stage, as indicated in Fig. 2 (right). After stage $j \geq 1$, we have $\text{ALG} \geq 1 + \frac{j}{2} \lfloor \varepsilon^{-1} \rfloor = \Omega(j \varepsilon^{-1})$ and $\text{OPT} = 1$. The number of points placed in each stage increases by a factor of $\Omega(\varepsilon^{-1})$, hence $j = \Theta(\log_{\varepsilon^{-1}} n) = \Theta(\log n / \log \varepsilon^{-1})$. Overall, the competitive ratio is at least $\text{ALG}/\text{OPT} \geq \Omega(j \varepsilon^{-1}) = \Omega(\varepsilon^{-1} \log n / \log \varepsilon^{-1})$.

Upper bound. For proving a matching upper bound in one-dimension, we use the following online algorithm: For all $i = 1, \dots, n$, we maintain a spanning graph G_i on $S_i = \{s_1, \dots, s_i\}$ and the x -monotone path P_i between the leftmost and the rightmost points in $S_i = \{s_1, \dots, s_i\}$. When point s_i , $i \geq 2$, arrives, we proceed as follows (see Fig. 3). If s_i is left (resp., right) of all previous points, we add an edge from s_i to the closest point in S_{i-1} to both P_{i-1} and G_{i-1} . Otherwise, let ab be the (unique) edge of P_{i-1} that contains s_i , and pq a shortest edge of G_{i-1} that contains s_i . Clearly, we have $P_i = P_{i-1} - ab + as_i + s_i b$. If $\min\{\|ps_i\|, \|s_i q\|\} > \frac{\varepsilon}{4} \|pq\|$, we add both as_i and $s_i b$ to G_i , that is, $G_i = G_{i-1} + as_i + s_i b$. Otherwise, let $G_i = G_{i-1} + as_i$ if $\|ps_i\| \leq \|s_i q\|$, or else $G_i = G_{i-1} + s_i b$.

■ **Figure 3** Left: The graph G_{12} for (s_1, \dots, s_{11}) . Right: $pq = s_1 s_2$ is the shortest edge of G_{11} that contain s_{12} . The algorithm adds edges $as_{12} = s_5 s_{12}$ and $s_{12} b = s_{12} s_7$.

We observe a few properties of G_i that are immediate from the construction: (P1) At the time when edge e is added to G_i , then the interior of e does not contain any vertices. (P2) The edges in G_i form a laminar set of intervals (i.e., any two edges are interior-disjoint, or one contains the other). (P3) If e_1, e_2 are edges in G_i and $e_2 \subset e_1$, then $\|e_2\| \leq (1 - \frac{\varepsilon}{4})\|e_1\|$. We note that properties (P1)–(P3) are inherently 1-dimensional, as the edges are intervals in \mathbb{R} , and they do not seem to generalize to higher dimensions.

► **Lemma 1.** For $i = 1, \dots, n$, the graph G_i is a $(1 + \varepsilon)$ -spanner for S_i .

The standard proof (by induction on n) is available in the full version of the paper.

► **Lemma 2.** For $i = 1, \dots, n$, we have $\|G_i\| \leq O(\varepsilon^{-1} \text{OPT}_i \log i / \log \varepsilon^{-1})$.

Proof. We may assume w.l.o.g. that $i = n$, and let $\text{OPT} = \text{OPT}_n$ for brevity. Let E be the edge set of G_n . The order in which ALG adds edges to E defines a (precedence) poset on E . We partition E by weight as follows: Let $\beta = \varepsilon^{-1}$; and for all $\ell \in \mathbb{Z}$, let E_ℓ be the set of edges $e \in E$ with $\beta^\ell < \|e\| \leq \beta^{\ell+1}$. Since $\|e\| \leq \text{OPT}$ for all $e \in E$, every edge is in E_ℓ for some $\ell \leq \log_\beta \text{OPT}$. Furthermore, for all $\ell \leq \log_\beta (\text{OPT}/n^2)$, the edges $e \in E_\ell$ have weight $\|e\| \leq \text{OPT}/n^2$, and so the total weight of these edges is less than OPT . It remains to consider E_ℓ for $\log_\beta (\text{OPT}/n^2) \leq \ell \leq \log_\beta \text{OPT}$, that is, for $O(\log n / \log \varepsilon^{-1})$ values of ℓ .

Let pq be an edge in E_ℓ that is not contained in any previous edge in E_ℓ . By property (P2), the edges in E_ℓ form a laminar family, and so pq does not overlap with any previous edge in E_ℓ ; and pq contains any subsequent edge that overlaps with it. Let $E_\ell(pq)$ be the set of all edges in E_ℓ that are contained in pq (including pq). We claim that

$$\|E_\ell(pq)\| \leq O(\varepsilon^{-1} \|pq\|). \quad (1)$$

Summation over all edges $pq \in E_\ell$ that are not contained in previous edges in E_ℓ implies $\|E_\ell\| \leq O(\varepsilon^{-1} \text{OPT})$. Summation over all $\ell \in \mathbb{Z}$ then yields

$$\|E\| = \sum_{\ell \in \mathbb{Z}} \|E_\ell\| = \sum_{\ell = \lfloor \log_\beta (\text{OPT}/n^2) \rfloor}^{\lceil \log_\beta \text{OPT} \rceil} \|E_\ell\| + O(\text{OPT}) = O(\varepsilon^{-1} \text{OPT} \log_\beta n).$$

To prove (1), consider the containment poset of $E_\ell(pq)$. In fact, we represent the poset as a rooted binary tree T : The root corresponds to pq , and edges $e_1, e_2 \in E_\ell(pq)$ are in parent-child relation iff $e_2 \subset e_1$, and there is no edge $e' \in E_\ell(pq)$ with $e_2 \subset e' \subset e_1$. Each level of T corresponds to interior-disjoint edges contained in $\|pq\|$, so the sum of weight on each level is at most $\|pq\|$. The total weight of the first $k = \lceil 5\varepsilon^{-1} \rceil$ levels is $O(\varepsilon^{-1} \|pq\|)$.

We claim that the total weight on level $k = \lceil 5\varepsilon^{-1} \rceil$ is at most $\frac{1}{2} \|pq\|$. We distinguish between three types of nodes in the subtree of T between levels 0 and k : A *branching node* has two children, a *single-child node* has one child, and a *leaf* has no children (in particular all nodes in level k are considered leaves in this subtree). The nodes (leaves) at level k correspond to interior-disjoint edges $e \subset pq$ with $\|e\| \geq \varepsilon \|pq\|$ by the definition of $E_\ell(pq)$. Thus there are at most $\lfloor \varepsilon^{-1} \rfloor$ nodes at level k , hence there are less than $\lfloor \varepsilon^{-1} \rfloor$ branching nodes. This implies that for any node e on level k , the descending path from the root pq to e contains at least $k - \lfloor \varepsilon^{-1} \rfloor \geq \lceil 4\varepsilon^{-1} \rceil$ single-child nodes.

For the purpose of bounding the total weight at level k , we can modify T , by incrementally moving all single-child nodes below all branching nodes as follows. While there is an edge uv in T , such that u is a branching node, and its parent v is a single-child node, we suppress u and subdivide the two edges of T below u with new nodes v_1 and v_2 . The weight along the edge uv goes down by a factor of at most $(1 - \frac{\varepsilon}{4})$ by property (P3); we set the weights in the modified tree such that the same decrease occurs along the edges uv_1 and uv_2 . Then each operation maintains property (P3), and the total weight at level k does not change. When the while loop terminates, we obtain a full binary tree with a chain attached to each leaf. As we argued above, each chain has length $\lfloor 4/\varepsilon \rfloor$ or more. The full binary tree does not necessarily decrease the weight. Along each chain of $\lfloor 4/\varepsilon \rfloor$ or more single-child nodes, the weight is cumulatively multiplied by a factor of at most $(1 - \frac{\varepsilon}{4})^{\lfloor 4/\varepsilon \rfloor} < \frac{1}{2}$. Overall, the total weight at level $k = \lceil 5\varepsilon^{-1} \rceil$ is at most $\frac{1}{2} \|pq\|$, as claimed.

By induction, for every integer $j \geq 0$, the total weight at level $jk = j\lceil 5\varepsilon^{-1} \rceil$ is at most $\|pq\|/2^j$. Consequently, the total weight of a *block* of k consecutive levels $\{jk+1, \dots, (j+1)k\}$ is at most $k\|pq\|/2^j$. Overall, $\|E_\ell(pq)\| = \sum_{j \geq 0} k\|pq\|/2^j = O(k\|pq\|) = O(\varepsilon^{-1}\|pq\|)$, which completes the proof of (1). \blacktriangleleft

We can summarize the discussion above in the following theorem.

► **Theorem 3.** *For every $\varepsilon > 0$, the competitive ratio of any online algorithm for $(1 + \varepsilon)$ -spanners for a sequence of points on a line is $\Omega(\varepsilon^{-1} \log n / \log \varepsilon^{-1})$. Moreover, there is an online algorithm that maintains a $(1 + \varepsilon)$ -spanner with competitive ratio $O(\varepsilon^{-1} \log n / \log \varepsilon^{-1})$.*

3 Upper Bounds for Spanners in \mathbb{R}^d under the L_2 Norm

We turn to online $(1 + \varepsilon)$ -spanners in Euclidean d -space for $d \geq 2$. The dynamic algorithm DEFSPANNER by Gao et al. [30], based on hierarchical clustering, achieves $O(\varepsilon^{-(d+1)} \log n)$ competitive ratio in the online model. In Section 3.1, we recover the same bound with a new analysis, where we refine the hierarchical clustering with a partition of the edges into buckets of similar directions, locations, and weights. In Section 3.2, we extend the new analysis to show that the competitive ratio improves to $O(\varepsilon^{(1-d)/2} \log n)$ if we are allowed to use Steiner points. Our spanner algorithm replaces each bucket of “similar” edges with a Steiner network using grids and shallow-light trees, for up to $O(\varepsilon^{(1-d)/2})$ directions.

Preliminaries. *Well-separated pair-decomposition* (for short, WSPD) of a finite point set S in a metric space is a classical tool for constructing $(1 + \varepsilon)$ -spanners [19, 34, 47, 51]. It is a collection of pairs $\{(A_i, B_i) : i \in I\}$ such that for all $i \in I$, we have $A_i, B_i \subset S$ and $\max\{\text{diam}(A_i), \text{diam}(B_i)\} \leq \varepsilon \text{dist}(A_i, B_i)$; and for every point pair $\{s, t\} \subset \binom{S}{2}$, there is a pair (A_i, B_i) such that A_i and B_i each contains precisely one of s and t . It was shown by Callahan and Kosaraju [18] that if a graph $G = (S, E)$ contains an edge between arbitrary points in A_i and B_i , for all $i \in I$, then G is an $(1 + O(\varepsilon))$ -spanner for S ; see also [47, Ch. 9].

Dynamic spanners (including the fully dynamic algorithm by Roditty [49] and DEFSPANNER by Gao et al. [30]) rely on WSPDs and hierarchical clustering. In \mathbb{R}^d , hierarchical clustering can be obtained by classical recursive space partitions such as *quadtrees* [27, Ch. 14]. Dynamic quadtrees and their variants have been studied extensively, due to their broad range of applications; see [38, Ch. 2]. In general, dynamic quadtrees can handle both point insertion and deletion operations. However, in the context of an online algorithm, where the points are only inserted, note that no cell of the quadtree is ever deleted. We analyse the competitive ratio of the dynamic incremental algorithm by Fischer and Har-Peled [29] that maintains an $(1 + \varepsilon)$ -spanner for n points in Euclidean d -space in expected $O([\log n + \log \varepsilon^{-1}] \varepsilon^{-d} \log n)$ update time. However, they have not analyzed the ratio between the *weight* of the resulting $(1 + \varepsilon)$ -spanner and the minimum weight of an $(1 + \varepsilon)$ -spanner.

3.1 Online Algorithm without Steiner Points

Online Algorithm. We briefly review the algorithm in [29] and then analyze the weight. The input is a sequence of points (s_1, s_2, \dots) in \mathbb{R}^d ; the set of the first n points is denoted by $S_n = \{s_i : 1 \leq i \leq n\}$. For every n , we dynamically maintain a quadtree \mathcal{T}_n for S_n . Every node of \mathcal{T}_n corresponds to a cube. The root of \mathcal{T}_n , at level 0, corresponds to a cube Q_0 of side length $a_0 = \Theta(\text{diam}(S_n))$. At every level $\ell \geq 0$, there are at most $2^{d\ell}$ interior-disjoint cubes, each of side length $a_0/2^\ell$. A cube $Q \in \mathcal{T}_n$ is *nonempty* if $Q \cap S_n \neq \emptyset$. For every nonempty cube Q , we select an arbitrary representative $s(Q) \in Q \cap S_n$. At each level ℓ ,

let E_ℓ be the set of all edges $s(Q_1)s(Q_2)$ for pairs of cubes $\{Q_1, Q_2\}$ on level ℓ such that $\frac{c_1 a_0}{\varepsilon 2^\ell} \leq \|s(Q_1)s(Q_2)\| \leq \frac{c_2 a_0}{\varepsilon 2^\ell}$ for some constants $0 < c_1 < c_2$ that depend on d ; see Fig. 4(left). The algorithm maintains the spanner $G = (S_n, E)$ where $E = \bigcup_{\ell \geq 0} E_\ell$. A classical argument by Callahan and Kosaraju [18] (see also [34, 47, 51]) shows that G is a $(1 + \varepsilon)$ -spanner for S_n .

■ **Figure 4** Left: Nonempty squares at level $\ell = 4$ of a quadtree, each with a representative (red dots). Point $s(Q)$ is connected to all other representatives in the annulus between the concentric circles C_1 and C_2 of radii $c_1/(\varepsilon 2^\ell)$ and $c_2/(\varepsilon 2^\ell)$. Right: Ellipse B_{ab} with foci a and b , an ab -path of weight $(1 + \varepsilon)\|ab\|$. The bold edges make an angle at most $\varepsilon^{1/2}$ with ab .

► **Theorem 4.** For every constant $d \geq 2$, parameter $\varepsilon > 0$, and a sequence of $n \in \mathbb{N}$ points in Euclidean d -space, the competitive ratio of the online algorithm above is in $O(\varepsilon^{-(d+1)} \log n)$.

Proof. For the set S_n of the first n points of a sequence in \mathbb{R}^d , let $G = (S_n, E)$ be the $(1 + \varepsilon)$ -spanner produced by the online algorithm, and let $G^* = (S_n, E^*)$ be an $(1 + \varepsilon)$ -spanner of minimum weight. We show that $\|G\|/\|G^*\| = O(\varepsilon^{-(d+1)} \log n)$.

Short edges. Note that the weight of every edge in $E_\ell \subset E$ at level ℓ is $\Theta(\varepsilon^{-1} \text{diam}(S_n)/2^\ell)$, since it connects representatives at $\Theta(\varepsilon^{-1} \text{diam}(S_n)/2^\ell)$ distance apart. In particular, an edge at any level $\ell \geq 2 \log n$ has weight at most $O(\varepsilon^{-1} \text{diam}(S_n)/n^2)$; and the total weight of these edges is $O(\varepsilon^{-1} \text{diam}(S_n)) \leq O(\varepsilon^{-1} \text{OPT})$. It remains to bound the weight of the edges on levels $\ell = 1, \dots, \lfloor 2 \log n \rfloor$. We consider each level separately.

Short edges. For every edge $ab \in E$, let B_{ab} denote the ellipsoid with foci a and b , and great axis of length $(1 + \varepsilon)\|ab\|$. Note that every ab -path of weight at most $(1 + \varepsilon)\|ab\|$ lies in B_{ab} . The set of directions of line segments in \mathbb{R}^d is represented by a hemisphere of \mathbb{S}^{d-1} . The distance between two directions is measured by angles in the range $[0, \pi)$. Recently, Bhore and Tóth [13, Lemma 3] proved that every ab -path of weight at most $(1 + \varepsilon)\|ab\|$ contains edges of total weight at least $\frac{1}{2}\|ab\|$ that make an angle at most $\varepsilon^{1/2}$ with ab (i.e., they are near-parallel to ab); see Fig. 4(right).

Since G^* is a $(1 + \varepsilon)$ -spanner for S_n , it contains an ab -path of weight at most $(1 + \varepsilon)\|ab\|$ for every $ab \in E$. This path lies in the ellipsoid B_{ab} , and contains edges of G^* of weight at least $\frac{1}{2}\|ab\|$ and with direction with at most $\varepsilon^{1/2}$ from ab . We next define suitable *disjoint* sets of ellipsoids, in order to establish a lower bound on $\|G^*\|$.

Edge partition by directions. First, we partition the edge set E_ℓ into subsets based on the *directions* of the edges. We use standard volume argument to construct a *homogeneous* set of directions. Let $H \subset \mathbb{S}^{d-1}$ be the hemisphere of unit vectors in \mathbb{R}^d , then the direction vector of a line segment ab , denoted $\text{dir}(ab)$, is a unique point in H . Consider a maximal packing of H with (spherical) balls of radius $\frac{1}{8}\varepsilon^{1/2}$. Since the spherical volume of H is $\Theta(1)$ and the volume of each ball is $\Theta(\varepsilon^{(d-1)/2})$, the number of balls is $K = \Theta(\varepsilon^{(1-d)/2})$.

By doubling the radii of the spherical balls to $\frac{1}{4}\varepsilon^{1/2}$, we obtain a covering of H with a set of balls $\mathcal{D} = \{D_i : i = 1, \dots, K\}$. For each spherical ball $D_i \in \mathcal{D}$, denote by $2D_i$ the concentric ball of radius $\frac{1}{2}\varepsilon^{1/2}$. By standard packing argument, the ball $2D_i$ intersects only $O(1)$ balls in \mathcal{D} (where $d = O(1)$). We can now define a partition $E_\ell = \bigcup_{i=1}^K E_{\ell,i}$ as follows: let an $ab \in E_\ell$ be in $E_{\ell,i}$ if i is the smallest index such that $\text{dir}(ab) \in D_i$. Now for every $i = 1, \dots, K$, let E_i^* be the set of edges $e^* \in E^*$ such that $\text{dir}(e^*) \in 2D_i$. By construction, every edge $e^* \in E^*$ lies in $O(1)$ sets E_i^* ; consequently $\sum_{i=1}^K \|E_i^*\| = \Theta(\|G^*\|)$. Furthermore, for every edge $ab \in E_{\ell,i}$, all edges in E^* that make an angle at most $\varepsilon^{1/2}$ with ab are in E_i^* .

Disjoint ellipsoids. For every $i = 1, \dots, K$, let $\mathcal{B}_{\ell,i}$ be the set of ellipsoids B_{ab} with $ab \in E_{\ell,i}$. We show that $\mathcal{B}_{\ell,i}$ contains a subset $\mathcal{B}'_{\ell,i}$ of disjoint ellipsoids such that $|\mathcal{B}'_{\ell,i}| \geq \Omega(\varepsilon^{d+1}|\mathcal{B}_{\ell,i}|)$.

We claim that every ellipsoid in $\mathcal{B}_{\ell,i}$ intersects $O(\varepsilon^{-(d+1)})$ other ellipsoids in $\mathcal{B}_{\ell,i}$. We make use of a volume argument. Let $M_\ell = \max\{\|e\| : e \in E_\ell\}$; and note that the side length of every cube at level ℓ of the quadtree is $\Theta(\varepsilon M_\ell)$.

For every ellipsoid $B_{ab} \in \mathcal{B}_{\ell,i}$, the great axis has length $(1 + \varepsilon)\|ab\|$, and the $d - 1$ minor axes each have length $\sqrt{(1 + \varepsilon)^2 - 1^2}\|ab\| < 2\varepsilon^{1/2}\|ab\|$, where $\|ab\| \leq M_\ell$. Hence B_{ab} is contained in a cylinder C_{ab} of height $(1 + \varepsilon)M_\ell$ whose base is a $(d - 1)$ -dimensional ball of diameter $2\varepsilon^{1/2}M_\ell$. Any other ellipsoid in $\mathcal{B}_{\ell,i}$ with great axis parallel to ab is contained in a translate of C_{ab} . If we rotate B_{ab} about its center by an angle at most $\varepsilon^{1/2}$, then its orthogonal projection to the original great axis decreases, and the maximum distance from the original great axis increases by at most $\|ab\| \frac{1+\varepsilon}{2} \sin \varepsilon^{1/2} < M_\ell \varepsilon^{1/2}$. Consequently, every ellipsoid in $\mathcal{B}_{\ell,i}$ is contained in a translated copy of $2C_{ab}$. Hence, every ellipsoid in $\mathcal{B}_{\ell,i}$ that intersects B_{ab} is contained in $3C_{ab}$. Every cube at level ℓ of the quadtree that intersects $3C_{ab}$ is contained in the Minkowski sum of $3C_{ab}$ and such a cube, which is in turn contained in $4C_{ab}$. Note that the volume of the cylinder $4C_{ab}$ is $O(\varepsilon^{(d-1)/2}M_\ell^d)$; while the volume of a cube at level ℓ of the quadtree is $\Theta(\varepsilon^d M_\ell^d)$. Therefore $4C_{ab}$ contains $O(\varepsilon^{(d-1)/2}/\varepsilon^d) = O(\varepsilon^{-(d+1)/2})$ such cubes. Recall that the algorithm maintains one representative from each cube, and the edges $ab \in E_{\ell,i}$ are pairs of representative. Thus $O(\varepsilon^{-(d+1)/2})$ representatives in $4C_{ab}$ can form $O(\varepsilon^{-(d+1)})$ pairs (i.e., edges, hence ellipsoids).

This completes the proof of the claim that every ellipsoid in $\mathcal{B}_{\ell,i}$ intersects $O(\varepsilon^{-(d+1)})$ other ellipsoids in $\mathcal{B}_{\ell,i}$. Hence the *intersection graph* of $\mathcal{B}_{\ell,i}$ is $O(\varepsilon^{-(d+1)})$ -degenerate; and has an independent set $\mathcal{B}'_{\ell,i}$ of size $|\mathcal{B}'_{\ell,i}| \geq \Omega(\varepsilon^{d+1}|\mathcal{B}_{\ell,i}|) = \Omega(\varepsilon^{d+1}|E_{\ell,i}|)$.

Weight analysis. As noted above, all edges in E_ℓ have length $\Theta(M_\ell)$. For every $i = 1, \dots, K$ and for every ellipsoid $B_{ab} \in \mathcal{B}_{\ell,i}$, we have $\|E_i^* \cap B_{ab}\| \geq \frac{1}{2}\|ab\| \Omega(M_\ell)$. Summing over a set of disjoint ellipsoids, we obtain

$$\begin{aligned} \|E_i^*\| &\geq \sum_{B_{ab} \in \mathcal{B}'_{\ell,i}} \|E_i^* \cap B_{ab}\| \geq \sum_{B_{ab} \in \mathcal{B}'_{\ell,i}} \frac{1}{2}\|ab\| \\ &\geq |\mathcal{B}'_{\ell,i}| \cdot \frac{1}{2} \min\{\|ab\| : ab \in E_{\ell,i}\} \\ &\geq \varepsilon^{-(d+1)}|E_{\ell,i}| \cdot \Omega(M_\ell) = \Omega(\varepsilon^{-(d+1)}\|E_{\ell,i}\|). \end{aligned}$$

Summation over all directions $i = 1, \dots, K$ yields

$$\|G^*\| = \Theta \left(\sum_{i=1}^K \|E_i^*\| \right) \geq \Omega \left(\sum_{i=1}^K \varepsilon^{-(d+1)} \|E_{\ell,i}\| \right) = \Omega(\varepsilon^{-(d+1)} \|E_\ell\|).$$

Finally, summation over all $\ell \geq 1$ yields

$$\|E\| = \sum_{\ell \geq 1} \|E_\ell\| \leq \sum_{\ell=1}^{\lfloor 2 \log n \rfloor} \|E_\ell\| + \sum_{\ell > \lfloor 2 \log n \rfloor} \|E_\ell\| \leq \varepsilon^{-(d+1)} \|G^*\| \log n + \varepsilon^{-1} \|G^*\|,$$

as required. \blacktriangleleft

3.2 Online Algorithm with Steiner Points

When Steiner points are allowed, we can substantially improve the competitive ratio in terms of ε . We describe an algorithm with competitive ratio $O(\varepsilon^{(1-d)/2} \log n)$. As a counterpart, we show in Section 4 that the dependence on n is unavoidable in dimensions $d \geq 2$; it remains an open problem whether the dependence on ε is necessary.

► **Theorem 5.** *For every $\varepsilon > 0$, an online algorithm can maintain, for a sequence of $n \in \mathbb{N}$ points in the plane, a Euclidean Steiner $(1 + \varepsilon)$ -spanner of weight $O(\varepsilon^{-1/2} \log n) \cdot \text{OPT}$.*

Proof. Our online algorithm has two *stages*: A_1 and A_2 . Algorithm A_1 is the same as in Section 3.1, it maintains a quadtree \mathcal{T}_n for the point set S_n , and a “primary” $(1 + \varepsilon)$ -spanner G_1 *without* Steiner points. Algorithm A_2 maintains a Steiner $(1 + 3\varepsilon)$ -spanner G_2 as follows: for each edge ab in G_1 , it creates an ab -path of length $(1 + \varepsilon)\|ab\|$ using Steiner points in G_2 . Importantly, algorithm A_2 can bundle together “similar” edges of G_1 , and handle them together using shallow-light trees [52].

In particular, we partition the space of all possible edges of G_1 into *buckets* (edges with similar directions, locations, and weights). For each bucket U , when algorithm A_1 inserts the first edge $ab \in U$ into G_1 , then algorithm A_2 creates a “backbone” Steiner tree $T = T(U)$ of weight $O(\|ab\|)$, which contains an ab -path of length at most $(1 + \varepsilon)\|ab\|$. For any subsequent edge $a'b' \in U$, it suffices to add paths from a' and b' to T , of weight $O(\varepsilon\|ab\|)$, to obtain $a'b'$ -path of length at most $(1 + \varepsilon)\|a'b'\|$. Overall, between any two points $s_i, s_j \in S$, the primary spanner contains a path of weight at most $(1 + \varepsilon)\|s_i s_j\|$, and G_2 contains an Steiner path of weight at most $(1 + \varepsilon)^2\|s_i s_j\| < (1 + 3\varepsilon)\|s_i s_j\|$, as claimed.

It remains to define the buckets U , the backbone $T(U)$ for the first edge in U , and the “connectors” added for each subsequent edge in U . We first describe the algorithm in the plane, where we establish a competitive ratio $O(\varepsilon^{-1/2} \log n)$, and then generalize the construction to higher dimensions.

Buckets. We define buckets for all potential edges in the primary spanner G_1 . We analyze a single level ℓ of the quadtree \mathcal{T} . Without loss of generality, assume that the side length of all quadtree cubes in level ℓ have unit length, hence the weight of every edge in E_ℓ is $\Theta(\varepsilon^{-1})$.

In Section 3.2, we have covered the set $H \subset \mathbb{S}^1$ of directions with a set $\mathcal{D} = \{D_i : i = 1, \dots, K\}$ of balls of diameter $\varepsilon^{1/2}$. For each ball in \mathcal{D} , we define a set of buckets. Let $D \in \mathcal{D}$, and let L be a line such that $\text{dir}(L)$ corresponds to the center of D ; refer to Fig. 5(left). Partition the plane into parallel strips of width $\frac{1}{2}\varepsilon^{1/2}$ by a set of lines parallel to L ; and partition each strip further into rectangles of height $2\varepsilon^{-1}$. By scaling up the rectangles by a factor of 2, we obtain a covering of the square Q_0 with a set \mathcal{R} of $4\varepsilon^{-1} \times \varepsilon^{1/2}$ rectangles such that each point is covered by $O(1)$ rectangles in \mathcal{R} .

For each rectangle $R \in \mathcal{R}$, we create a bucket U comprising all edges $ab \in E_\ell$ such that $ab \subset R$ and $\text{dir}(ab) \in D$ (hence $\angle(\text{dir}(ab), \text{dir}(L)) \leq \varepsilon^{1/2}$). Note that every edge $ab \in E_\ell$ lies in at least one and at most $O(1)$ buckets.

■ **Figure 5** Left: The overlay the the quadtree with a partition of \mathbb{R}^2 into $\frac{1}{2}\varepsilon^{-1/2} \times 2\varepsilon^{-1}$ rectangles aligned with L . Top-Right: A rectangle $R \in \mathcal{R}$, the median $L(U)$, the grid $G(U)$, and the partition of R into $\varepsilon^{-1/2} \times \varepsilon^{-1/2}$ squares. Bottom-Right: A shallow-light tree between a side of an $\frac{1}{2}\varepsilon^{-1/2} \times \frac{1}{2}\varepsilon^{-1/2}$ square and a source $r \in L(U)$.

Backbones and Connectors. Let U be a bucket defined above for a rectangle $R \in \mathcal{R}$. Let $L(U)$ denote the median of the rectangle R parallel to L . When the primary algorithm A_1 inserts the first edge $ab \in U$ into G_1 , then Algorithm A_2 constructs a unit grid graph $G(U)$, formed by a subdivision of R into unit squares; see Fig. 5(top-right). Since R is a $4\varepsilon^{-1} \times \varepsilon^{-1/2}$ rectangle, $\|G(U)\| = O(\varepsilon^{-3/2})$. Furthermore, we partition R into $4\varepsilon^{-1/2}$ squares of side length $\varepsilon^{-1/2}$. For each such square, we insert two shallow-light trees [52] between the two sides of the square orthogonal to L and two points in $L(U)$ at distance ε^{-1} from the square on either side; Fig. 5(bottom-right). The weight of each shallow-light tree is $O(\varepsilon^{-1})$ [52], and so the combined weight of $O(\varepsilon^{-1/2})$ shallow-light trees is $O(\varepsilon^{-3/2})$. The grid $G(U)$ together with the shallow-light trees forms the *backbone* for the bucket U in G_2 .

We add *connector* edges between a (resp., b) and the four corners of unit square of the grid $G(U)$ that contains it. For any subsequent edge $a'b' \in U$ that algorithm A_1 inserts into G_1 , the backbone does not change, we only add connectors between a' (resp., b') and the four corners of the unit square in $G(U)$ that contains it. The weight of the four connectors is $O(1)$ per point. Since $\text{area}(R) = \Theta(\varepsilon^{-3/2})$, then R intersects at most $O(\varepsilon^{-3/2})$ unit squares of the quadtree at level ℓ , and so the total weight of all connectors is $O(\varepsilon^{-3/2})$, as well.

Stretch analysis. Suppose algorithm A_1 inserts an edge cd into G_1 . As noted above, cd lies in $\Theta(1)$ buckets; refer to Fig. 6. Suppose bucket U contains cd ; and in the partition of the rectangle $R = R(U)$, the endpoint c (d) lies squares R_c (R_d) of side length $\varepsilon^{-1/2}$, associated with shallow-light trees rooted at r_c (r_d). Then G_2 contains a cd -path comprised of: (i) connectors from c and d , resp., to the closest point in the grid $G(U)$; (ii) paths in $G(U)$ from the connectors to the boundary of squares R_c and R_d , (iii) paths along the shallow-light trees to the roots $r_c, r_d \in L(U)$, and (iv) the line segment $r_c r_d$ in $G(U)$. The weight of each connector in (i) is at most $2\sqrt{2}$, which is bounded by $O(\varepsilon)\|cd\|$ since $\|cd\| = \Theta(\varepsilon^{-1})$. The edges in (ii) and (iv) are parallel to L , hence they make an angle less than $\varepsilon^{1/2}$ with

cd . Finally, consider the two subpaths in part (iii) in shallow-light trees: The line segment between the two endpoints of each such subpath makes an angle less than $\varepsilon^{1/2}$ with L , hence less than $2\varepsilon^{1/2}$ with cd ; and the weight of a root-to-leaf path in a shallow-light tree is a $(1 + \varepsilon)$ -approximation of the straight-line segment between its endpoints. Overall, the total weight of the cd -path described above is $(1 + O(\varepsilon))\|cd\|$, as required.

■ **Figure 6** A cd -path in the Steiner spanner G_2 .

For every point pair $a, b \in S_n$, the primary graph G_1 contains an ab -path $P = (p_0, \dots, p_m)$ of length $\|P\| \leq (1 + \varepsilon)\|ab\|$, since G_1 is a $(1 + \varepsilon)$ -spanner. We have shown that for every edge $p_{i-1}p_i$ of G_1 , the Steiner spanner G_2 contains a $p_{i-1}p_i$ -path of weight $(1 + O(\varepsilon))\|p_{i-1}p_i\|$. The concatenation of these paths yields an ab -path in G_2 , of weight $\sum_{i=1}^m (1 + O(\varepsilon))\|p_{i-1}p_i\| = (1 + O(\varepsilon))\|P\| = (1 + O(\varepsilon))(1 + \varepsilon)\|ab\| = (1 + O(\varepsilon))\|ab\|$.

Competitive Analysis. Denote by E_ℓ the set of edges of G_2 added at level $\ell = 1, \dots, 2 \log n$, and let b_ℓ be the number of nonempty buckets at level ℓ . We have seen that for each nonempty bucket at level ℓ , E_ℓ contains a subgraph of weight $O(\varepsilon^{-3/2} \text{diam}(S_n)/2^\ell)$; hence $\|E_\ell\| \leq O(b_\ell \cdot \varepsilon^{-3/2} \text{diam}(S_n)/2^\ell)$.

Let $G^* = (S_n, E^*)$ be a Euclidean Steiner $(1 + \varepsilon)$ -spanner for S_n of minimum weight OPT. Consider a nonempty bucket U associated with a line L and a rectangle $R(U)$. Since U is nonempty, there is an edge $ab \in U$ in G_1 . Recall that $ab \in R$ and $\angle(\text{dir}(ab), \text{dir}(L)) \leq \varepsilon^{1/2}$. Since G^* is a $(1 + \varepsilon)$ -spanner, it contains an ab -path P_{ab} of weight at most $(1 + \varepsilon)\|ab\|$. As noted in Section 3.1, P_{ab} lies in the ellipse B_{ab} , and contains edges of weight at least $\frac{1}{2}\|ab\|$ that make an angle at most $\varepsilon^{1/2}$ with ab . All points in the ellipse B_{ab} are at distance less than $\varepsilon^{1/2}$ from the line segment ab . The segment ab lies in the $4\varepsilon^{-1} \times \varepsilon^{1/2}$ rectangle $R(U)$. Thus we have $P_{ab} \subset B_{ab} \subset 2R(U)$, and so $2R(U)$ contains edges of G^* of weight $\frac{1}{2}\|ab\| = \Omega(\varepsilon^{-1} \text{diam}(S_n)/2^\ell)$ whose directions are within $2\varepsilon^{1/2}$ from L ; denote by $E^*(U) \subset E^*$ the set of these edges. By construction, each edge e^* of G^* lies in $E^*(U)$ for only $O(1)$ buckets. Indeed, there are $O(1)$ lines L' with $\angle(\text{dir}(L), \text{dir}(L')) \leq 2\varepsilon^{1/2}$, and for each such direction L' , every point in \mathbb{R}^2 lies in $O(1)$ rectangles $2R(U')$ aligned with L' . We conclude that $\text{OPT} = \|G^*\| = \Omega(b_\ell \cdot \varepsilon^{-1} \text{diam}(S_n)/2^\ell)$. This implies $\|E_\ell\|/\text{OPT} \leq O(\varepsilon^{-1/2})$ for $\ell = 1, \dots, 2 \log n$. Summation over all levels yields

$$\frac{\text{ALG}}{\text{OPT}} = \frac{\sum_{\ell=1}^{\infty} \|E_\ell\|}{\text{OPT}} \leq \sum_{\ell=1}^{2 \log n} O(\varepsilon^{-1/2}) + O(1) = O(\varepsilon^{-1/2} \log n),$$

as claimed. ◀

Generalization to \mathbb{R}^d . Our algorithm and its analysis generalize to Euclidean d -space.

► **Theorem 6.** *For every $\varepsilon > 0$, an online algorithm can maintain, for a sequence of $n \in \mathbb{N}$ points in \mathbb{R}^d , a Euclidean Steiner $(1 + \varepsilon)$ -spanner of weight $O(\varepsilon^{(1-d)/2} \log n) \cdot \text{OPT}$.*

The proof is analogous to that of Theorem 5. The bottleneck of the competitive analysis is the size of the unit grids $G(U)$ which is $\Theta(\varepsilon^{-(d+1)/2})$ in \mathbb{R}^d , and it is contrasted with a path of weight $\Omega(\varepsilon^{-1})$ in OPT. Similarly to Section 3.1, we choose a homogeneous set D of

$\Theta(\varepsilon^{(1-d)/2})$ directions. For each direction $L \in D$, we construct a tiling of \mathbb{R}^d with congruent hyper-rectangles aligned with L of dimensions $\varepsilon^{-1} \times \varepsilon^{-1/2} \times \dots \varepsilon^{-1/2}$. Refer to the full paper for all further details.

4 Lower Bound with Steiner Points

Recall that when Steiner points are allowed, the algorithm may subdivide existing edges with Steiner points. It follows that the in one-dimension, an online algorithm can maintain a Hamiltonian path on S_n , which is the minimum $(1 + \varepsilon)$ spanner for all $\varepsilon \geq 0$. This property carries over to Euclidean Steiner 1-spanners (i.e., the case $\varepsilon = 0$), where we need to maintain the complete straight-line graph on n points. However, we show that for $\varepsilon > 0$ in dimensions $d \geq 2$, the competitive ratio of an online algorithm with Steiner points must depend on n .

► **Theorem 7.** *For every $\varepsilon > 0$, the competitive ratio of any online algorithm that maintains a Euclidean Steiner $(1 + \varepsilon)$ -spanner for a sequence of n points in \mathbb{R}^d is $\Omega(f(n))$ for some function $f(n)$ such that $\lim_{n \rightarrow \infty} f(n) = \infty$.*

Proof. We describe and analyze an adversarial strategy for placing points in the plane in *stages*. In stage 1, the adversary places two points at $s = (0, 0)$ and $t = (1, 0)$, both on the x -axis. In subsequent stages, new points are arranged so that the optimum solution remains an x -monotone path of length at most $1 + \varepsilon$ at all times.

Let us denote by A_i the points placed in stage i . At the end of stage i , adversary constructs the point set A_{i+1} based on the current $(1 + \varepsilon)$ -spanner built by the algorithm ALG, and then placed the points in A_{i+1} in an arbitrary order. The objective is that in each stage, ALG has to add new edges of total weight at least $1/2$. Since $\text{OPT} \leq 1 + \varepsilon$ at all times, and $\text{ALG} \geq \frac{1}{2}(i + 1)$ after i stages, the competitive ratio goes to infinity.

We describe stage 2 in more detail; subsequent stages are similar; see Fig. 7. At the end of stage 1, our point set is $A_1 = \{s = (0, 0), t = (1, 0)\}$, the optimal spanner is a single edge of unit weight, and ALG has constructed a Euclidean Steiner $(1 + \varepsilon)$ -spanner G_1 for A_1 . Let $k_1 = \lceil \|G_1\| \rceil$. The adversary considers $2k_1 + 1$ circular arcs between s and t , each of weight at most $1 + \frac{\varepsilon}{2}$. The arcs define $2k_1$ interior-disjoint bounded regions. Let R_1 be a region that minimizes the weight $\|G_1 \cap R_1\|$, in particular, $\|G_1 \cap R_1\| \leq \frac{1}{2k_1} \|G_1\| \leq \frac{1}{2}$. In the interior of R_1 , let γ_1 be another circular arc between s and t , of weight $\|\gamma_1\| \leq 1 + \frac{\varepsilon}{2}$; and let $A_2 = \{t_1, \dots, t_N\}$ be a set of points along γ_1 , labeled in x -monotone increasing order with the following properties: (1) For every $i = 1, \dots, N - 1$, the ellipse B_i with foci t_i and t_{i+1} , and great axis $(1 + \varepsilon)\|t_i t_{i+1}\|$ lies entirely in R_1 ; and (2) the weight of the x -monotone path (t_1, t_2, \dots, t_N) is at least 1.

■ **Figure 7** Left: For $A_1 = \{s, t\}$, ALG constructs a $(1 + \varepsilon)$ -spanner G_1 (red). Five circular arcs define four regions; region R_1 satisfies $\|G_1 \cap R_1\| \leq \frac{1}{4} \|G_1\|$. In stage 2, the adversary presents points A_2 in R_1 . Middle: The algorithm augments G_1 to G_2 . Right: Region R_2 satisfies $\|G_2 \cap R_2\| \leq \frac{1}{2k_2} \|G_2\|$.

In stage 2, the adversary presents the points in A_2 in an arbitrary order. By the end of stage 2, ALG augments G_1 to a Euclidean Steiner $(1 + \varepsilon)$ -spanner G_2 for $A_1 \cup A_2$. In particular, for every $i = 1, \dots, N - 1$, the graph G_2 contains a $t_i t_{i+1}$ -path of length at most $(1 + \varepsilon)\|t_i t_{i+1}\|$, which lies in the ellipse E_i , hence in the interior of the region R_1 . The part of

the path between the vertical lines passing through t_i and t_{i+1} has weight at least $\|t_i t_{i+1}\|$. Since these parts are disjoint, the total weight all $N-1$ paths is at least $\sum_{i=1}^{N-1} \|t_i t_{i+1}\| \geq 1$. Consequently, $\|G_2 \cap R_1\| \geq 1$. Since we had $\|G_1 \cap R_1\| \leq \frac{1}{2}$, ALG must have added new edges of weight at least $\frac{1}{2}$ in stage 2, as claimed.

In phase $i+1$, in general, let $k_i = \lceil \|G_i\| \rceil$. Label the points in the current point set $S = \bigcup_{j=1}^i A_j$ by s_0, \dots, s_n in x -monotone order, and assume that the x -monotone path spanned by S has weight $\text{OPT} = 1 + (1 - \frac{1}{2^i})\varepsilon$. For all segments $s_j s_{j+1}$, we consider $2k_i + 1$ x -monotone circular arcs such that the total weight of any concatenation of the circular arcs from $s = s_0$ to $t = s_n$ is at most $1 + (1 - \frac{1}{2^{i+1}})\varepsilon$. For each segment $s_j s_{j+1}$, we choose one of $2k_i$ regions that has a minimum-weight intersection with G_i , and let R_i be the union of these regions. Note that $\|G_i \cap R_i\| \leq \frac{1}{2k_i} \|G_i\| \leq \frac{1}{2}$. Let γ_i be an st -path γ_i that connects the points s_0, \dots, s_n via circular arcs in the region R_i , and has weight at most $1 + (1 - \frac{1}{2^{i+1}})\varepsilon$. Now the adversary can choose a finite point set $A_{i+1} = \{t_1, \dots, t_N\}$ along γ_i with properties (1)–(2) above. This completes the description of the adversarial strategy.

Similarly to stage 2, when ALG augments G_i to a Euclidean Steiner $(1 + \varepsilon)$ -spanner G_{i+1} for $\bigcup_{j=1}^{i+1} A_j$, he must add new edges of weight at least $\frac{1}{2}$ in the region R_i . It follows that the competitive ratio for any online algorithm goes to infinity as n goes to infinity. \blacktriangleleft

5 Conclusions

We have studied online spanners for sequences of points in \mathbb{R}^d , in fixed dimensions $d \geq 1$, under L_2 and L_1 norms. We established a tight bound of $\Theta(\varepsilon^{-1} \log n / \log \varepsilon^{-1})$ for the competitive ratio of any online $(1 + \varepsilon)$ -spanner algorithms on a real line (Theorem 3). However it remains an open problem to close the gap between the lower and upper bounds in \mathbb{R}^d , for $d \geq 2$. Under the L_2 norm, previously known algorithms achieve competitive ratio $O(\varepsilon^{-(d+1)} \log n)$ (Theorem 4). The best lower bound we are aware of holds for $d = 1$. It is unclear whether the lower bound can be improved to $\varepsilon^{-\omega(d)} \log n$ for $d \geq 2$.

Next, we have showed that, if an online algorithm is allowed to use Steiner points, it can achieve a substantially better competitive ratio in terms of ε , namely $O(\varepsilon^{(1-d)/2} \log n)$, for a sequence of n points in \mathbb{R}^d and any constant $d \geq 2$, under the L_2 norm (Theorem 6). As a counterpart, we proved that any online spanner algorithm for a sequence of n points in \mathbb{R}^d under L_2 norm has competitive ratio $\Omega(f(n))$, where $\lim_{n \rightarrow \infty} f(n) = \infty$ (Theorem 7). It remains an open problem whether the competitive ratio depends on ε for Euclidean Steiner spanners. Another open problem is whether the factor $\log n$ in the upper bounds can be reduced, e.g., to $\log n / \log \log n$; similar to the work by Alon and Azar [2] who established such a lower bound for Euclidean minimum Steiner trees (EMST) for n points in \mathbb{R}^2 .

We have established a lower bound $\Omega(\varepsilon^{-d})$ for the competitive ratio under the L_1 -norm in \mathbb{R}^d . It is unclear whether it can be improved by a $\log n$ factor in dimensions $d \geq 2$. Designing online algorithms that match these bounds under the L_1 norm is left for future research.

In online spanner algorithms, the decisions are irrevocable, which means that once an edge is added to the spanner by an online algorithm, it can never be deleted. However, if some of the decisions are reversible, better bounds may be possible. This model is commonly known as *online algorithms with recourse* [33, 39, 45]. In 1-dimension, for instance, an optimum spanner is just a monotone path connecting the points in linear order, and any online algorithm that is allowed to remove at least one edge at per iteration can maintain such a path. In higher dimensions, however, it is unclear whether a $O(1)$ -approximation of the minimum-weight $(1 + \varepsilon)$ -spanner can be maintained with $O(\varepsilon^{-d+1})$ recourse.

Abstract

The input to the distant representatives problem is a set of n objects in the plane and the goal is to find a representative point from each object while maximizing the distance between the closest pair of points. When the objects are axis-aligned rectangles, we give polynomial time constant-factor approximation algorithms for the L_1 , L_2 , and L_∞ distance measures. We also prove lower bounds on the approximation factors that can be achieved in polynomial time (unless $P = NP$).

1 Introduction

The *distant representatives problem* was first introduced by Fiala et al. [17]. The name is a play-on-words on the term “distinct representatives” from Philip Hall’s classic work on bipartite matching [21]. The input is a set of geometric objects in a metric space. The goal is to choose one “representative” point in each object such that the points are distant from each other – more precisely, the objective is to maximize the distance between the closest pair of representative points. In the decision version of the problem, we are given a bound δ and the question is whether we can choose one representative point in each object such that the distance between any two points is at least δ .

The distant representatives problem has applications to map labelling and data visualization. To attach a label to each object, we can find representative points that are at least distance δ apart, and label each object with a ball of diameter δ (a square in L_∞) centred at its representative point.

The distant representatives problem is closely related to dispersion and packing problems. When all the objects are copies of a single object, the distant representatives problem becomes the dispersion problem: to choose k points in a region R to maximize the minimum distance between any two chosen points [3]. Equivalently, the problem is to pack k disjoint discs

(in the chosen metric) of diameter δ into an expanded region and maximize δ . The distant representatives problem is also related to problems of “imprecise points” where standard computational geometry problems are solved when each input point is only known to lie within some small region [28].

There is a polynomial time algorithm for the distant representatives problem when the objects are segments on a line [32]. This result comes from the scheduling literature – each representative point is regarded as the centre-point of a unit length job. However, as shown by Fiala et al. [17], the decision version of distant representatives becomes NP-hard in 2D when the objects are unit discs for the L_2 norm or unit squares for the L_∞ norm.

Cabello [5] was the first to consider the optimization version of the distant representatives problem. He gave polynomial time approximation algorithms for the cases in 2D where the objects are squares under the L_∞ norm, or discs under the L_2 norm. The squares/discs may intersect and may have different sizes. His algorithms achieve an approximation factor of 2 in L_∞ and $\frac{8}{3}$ in L_2 , with an improvement to 2.24 if the input discs are disjoint. A main idea in his solution is an “approximate-placement” algorithm that chooses representative points from a fine-enough grid using a matching algorithm; small squares/discs that do not contain grid points are handled separately. Cabello noted that the NP-hardness proof of Fiala et al. [17] can be modified to prove that there is no polynomial time approximation scheme (PTAS) for these problems unless $P=NP$. However, no one has given exact lower bounds on the approximation factors that can be achieved in polynomial time.

Our Results

We consider the distant representatives problem for axis-parallel rectangles in the plane. Rectangles are more versatile than squares or circles in many applications, e.g., for labelling rectangular Euler or Venn diagrams [29].

We give polynomial time approximation algorithms to find representative points for the rectangles such that the distance between any two representative points is at least $1/f$ times the optimum. The approximation factors f are given in Table 1 for the L_1 , L_2 , and L_∞ norms. Since rectangles are not fat objects [8], Cabello’s approach of discretizing the problem by choosing representative points from a grid does not extend. Instead, we introduce a new technique of “imprecise discretization” and choose representative points from 1-dimensional shapes (e.g., $+$ -shapes) arranged in a grid. After that, our plan is similar to Cabello’s. First we solve an approximation version of the decision problem – to find representative points so long as the given distance δ is not too large compared to the optimum δ^* . Then we perform a search to find an approximation to δ^* . Unlike previous algorithms which use the real-RAM model, we use the word-RAM model, and thus must address bit complexity issues.

We accompany these positive results with lower bounds on the approximation factors that can be achieved in polynomial time (assuming $P \neq NP$). The lower bounds are shown in Table 1. They apply even in the special case of horizontal and vertical line segments in the plane. The results are proved via gap-producing reductions from Monotone Rectilinear Planar 3-SAT [10]. These are the first explicit lower bounds on approximation factors for the distant representatives problem for any type of object.

Finally, we consider the even more special case of unit-length horizontal line segments, and the decision version of distant representatives. This is even closer to the tractable case of line segments on a line. However, Roeloffzen in his Master’s thesis [30] proved NP-hardness for the L_2 norm. We give a more careful proof that takes care of bit complexity issues, and we show that the problem is NP-complete in the L_1 and L_∞ norms.

■ **Table 1** Bounds on polynomial time approximation factors for the distant representatives problem for axis-aligned rectangles in the plane. A lower bound of x means that an approximation factor less than x implies $P = NP$. (For other L_p norms, there are some constant factors, but we have not optimized them.)

	L_1	L_2	L_∞
upper bound	5	$\sqrt{34} \approx 5.83$	6
lower bound	1.5	1.4425	1.5

For our algorithms and our hardness results, we must deal with bit complexity issues. For rectangles under the L_1 and L_∞ norms, we show that both the optimum value δ^* and the coordinates of an optimum solution have polynomially-bounded bit complexity. In particular, the decision problems lie in NP. The L_2 norm remains more of a mystery, and the decision problem can only be placed in $\exists\mathbb{R}$ (for an explanation of this class, see [6]).

Background

In one dimension, the decision version of the distant representatives problem for intervals on a line was solved by Barbara Simons [32], as a scheduling problem of placing disjoint unit jobs in given intervals. To transform the decision version of distant representatives to the scheduling problem, scale so $\delta = 1$, then expand each interval by $1/2$ on each side. The midpoints of the unit jobs provide the desired solution. Simons's decision algorithm was speeded up to $O(n \log n)$ by Garey et al. [20]. The optimum δ^* can be found using a binary search – in fact there is a discrete set of $O(n^3)$ possible δ^* values, which provides an $O(n^3 \log n)$ algorithm. (We see how to improve this to $O(n^2 \log n)$ but we are not aware of any published improvement.) There has been recent work on the online version of the problem [9]. The (offline) problem is easier when the intervals are disjoint. More generally, the problem is easier when the ordering of the representative points is specified, or is determined – for example if no interval is contained in another then there is an optimum solution where the ordering of the representative points is the same as the ordering of the interval's left endpoints. This “dispersion problem for ordered intervals” can be solved in linear time [26]. In a companion paper to this one, we improved this to a simpler algorithm using shortest paths in a polygon that solves the harder problem of finding the lexicographic maximum list of distances between successive pairs [4].

Cabello [5] gave polynomial time approximation algorithms for the distant representatives problem for balls in the plane, specifically for squares in L_∞ and for discs in L_2 , with approximation factors of 2 and $\frac{8}{3} = 2.6\bar{6}$, respectively. For disjoint discs in L_2 he improved the approximation factor to 2.24. Dumitrescu and Jiang [14] further improved the approximation factor for disjoint discs to 1.414 ($= 1/.707$) by adding LP-based techniques to Cabello's approach. They also considered the case of unit discs, where they gave an algorithm with approximation factor 2.14 ($= 1/.4674$). For disjoint unit discs they gave a very simple algorithm with approximation factor 1.96 ($= 1/.511$). In a follow-up paper Dumitrescu and Jiang [15] gave bounds on the optimum δ^* for balls and cubes in L_2 depending on the minimum area of the union of subsets of k objects – these results have the flavour of Hall's classic condition for the existence of a set of distinct representatives.

The geometric dispersion problem (when all objects are copies of one object) was studied by Bauer and Fekete [3]. They considered the problem of placing k points in a rectilinear polygon with holes to maximize the min L_∞ distance between any two points or between a point and the boundary of the region. Equivalently, the problem is to pack k as-large-as-possible

identical squares into the region. They gave a polynomial time $3/2$ -approximation algorithm, and proved that $14/13$ is a lower bound on the approximation factor achievable in polynomial time. By contrast, if the goal is to pack as many squares of a given size into a region, the famous shifting-grid strategy of Hochbaum and Maas [23] provides a PTAS. Bauer and Fekete use this PTAS to design an approximate decision algorithm for their problem.

It is NP-hard to decide whether a square can be packed with given (different sized) squares [25] or discs [11]. For algorithmic approaches, see the survey [22]. There is a vast literature on the densest packing of equal discs/squares in a region (e.g. a large circle or square) – see the book [33].

Many geometric packing problems suffer from issues of bit complexity. In particular, there are many packing problems that are not known to lie in NP (e.g., packing discs in a square [11]). This issue is addressed in a recent general approach to geometric approximation [16]. Another direction is to prove that packing problems are complete for the larger class $\exists\mathbb{R}$ (existential theory of the reals) [1].

The distant representatives problem is closely related to problems on imprecise points, where each point is only known to lie within some ε -ball, and the worst-case or best-case representative points, under various measures, are considered. Many geometric problems on points (e.g., convex hulls, spanning trees) have been explored under the model of imprecise points [7, 13, 27, 28].

As mentioned above, the distant representatives problem has application to labelling and visualization, specifically it provides a new approach to the problem of labelling (overlapping) rectangular regions or line segments. Most map labelling research is about labelling point features with rectangular labels of a given size, and the objective is to label as many of the points as possible [18]. There is a small body of literature on labelling line features [12, 36], and even less on labelling regions, except by assuming a finite pre-specified set of label positions [34].

Definitions and Preliminaries

Suppose we are given a set \mathcal{R} of n axis-aligned rectangles in 2D. In the *distant representatives problem*, the goal is to choose a point $p(R) \in R$ for each rectangle R in \mathcal{R} so as to maximize the minimum pairwise distance between points, i.e., we want to maximize $\min_{R, R' \in \mathcal{R}} d_\ell(p(R), p(R'))$, where d_ℓ is the distance-function of our choice. We consider here $\ell = 1, 2, \infty$, i.e., the L_1 -distance, the Euclidean L_2 -distance and the L_∞ -distance. We write δ_ℓ^* for the maximum such distance for $\ell \in \{1, 2, \infty\}$, and omit “ ℓ ” when it is clear from the context.

In the *decision version* of the distant representatives problem, we are given not only the rectangles but also a value δ , and we ask whether there exists a set of representative points that have pairwise distances at least δ .

2 Approximating the decision problem

In this section we give an algorithm that takes as input a set \mathcal{R} of axis-aligned rectangles, and a value δ and finds a set of representative points of distance at least δ apart so long as δ is at most some fraction of the optimum, δ^* , for this instance. Let $n = |\mathcal{R}|$ and suppose that the coordinates of the rectangle corners are even integers in the range $[0, D]$ (which guarantees that the rectangle centres also have integer coordinates).

The idea of the algorithm is to overlay a grid of *blocker-shapes* on top of the rectangles as shown in Figure 1, while ensuring that any two blocker-shapes are distance at least δ apart. The hope is to use a matching algorithm to match every rectangle to a unique intersecting

blocker-shape. Then, if rectangle R is matched to blocker-shape B , we choose any point in $R \cap B$ as the representative point for B , which guarantees distance at least δ between representative points since the blocker-shapes are distance at least δ apart. The flaw in this plan is that there may be *small* rectangles that do not intersect a blocker shape. To remedy this, we represent a small rectangle by its centre point, and we eliminate any nearby blocker-shapes before running the matching algorithm.

For the L_1 and L_∞ norms we assume that δ is given as a rational number with at most t digits in the numerator and denominator. Because we are using the word-RAM model where we cannot compute square roots, we will work with δ^2 for the L_2 norm. Thus, for the L_2 norm, we assume that we are given δ^2 as a rational number with at most t digits in the numerator and denominator. The bit size of the input is $\Theta(n \log D + t)$. Similarly, for L_2 , any output representative point (x, y) will be given as (x^2, y^2) . With these nuances of input and output, we express the main result of this section as follows:

► **Theorem 1.** *There exists an algorithm $\text{PLACEMENT}(\delta)$ that, given input $\ell \in \{1, 2, \infty\}$, rectangles \mathcal{R} , and $\delta > 0$, either finds an assignment of representative points for \mathcal{R} of L_ℓ -distance at least δ , or determines that $\delta > \delta_\ell^*/f_\ell$. Here $f_1 = 5$, $f_2 = \sqrt{34} \approx 5.83$, $f_\infty = 6$.*

The run-time of the algorithm is $O(n^2 \log n)$ in the word RAM model, i.e., assuming we can do basic arithmetic on numbers of size $O(\log D + t)$ in constant time.

To describe our algorithm, we think of overlaying the $D \times D$ bounding box of the rectangles with a grid of horizontal and vertical lines such that the diagonal distance across a square of the grid is δ . This means that grid lines are spaced γ_ℓ apart, where $\gamma_1 = \delta/2$, $\gamma_2 = \delta/\sqrt{2}$, and $\gamma_\infty = \delta$. For L_2 we will work with $\gamma_2^2 = \delta^2/2$ which is rational. Note that the algorithm does not explicitly construct the grid. Number the grid lines from left to right and bottom to top, and identify a grid point by its two indices. Note that the number of indices is D/γ_ℓ , so the size of each index is $O(\log D + t)$. We imagine filling the grid with *blocker-shapes*, where the chosen shape depends on the norm L_ℓ that is used – see Figure 1.

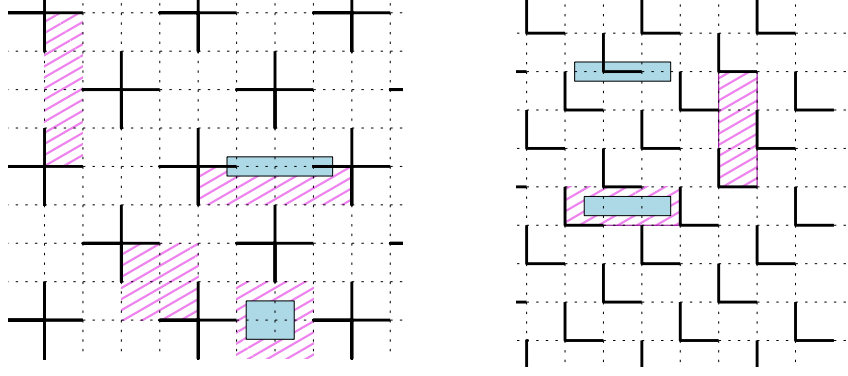

- For $\ell = 1, 2$, we use *+shapes*. Each *+*-shape consists of the four incident grid-segments of one *anchor* grid-point, where (i, j) is the anchor of a *+*-shape iff i is even and $i \equiv j \pmod{4}$.
- For $\ell = \infty$, we use *L-shapes*. Each *L*-shape consists of the two incident grid-segments above and to the right of one *anchor* grid-point, where (i, j) is the anchor of an *L*-shape iff $i \equiv j \pmod{3}$.

Observe that, by our choice of grid size γ_ℓ , any two blocker shapes are distance δ or more apart in the relevant norm.

Algorithm $\text{PLACEMENT}(\delta)$

We now give the rough outline of our algorithm to compute a representative point $p(R)$ for each rectangle R . The details of how to implement each step are given later on. Our algorithm consists of the following steps:

1. Partition the input rectangles into *small* and *big* rectangles. Roughly speaking, a rectangle is *big* if it intersects a blocker-shape, but we give a more precise definition below to deal with intersections on the boundary of the rectangle.
2. For any small rectangle r , let $p(r)$ be the centre of r , i.e., the point where the two diagonals of r intersect each other.
3. If two points $p(r), p(r')$ of two small rectangles r, r' have L_ℓ -distance less than δ , then declare that $\delta^* < f_\ell \delta$, and halt.

■ **Figure 1** Grids and blocker-shapes. We indicate in each a big and a small rectangle (shaded blue) and some cavities (hatched pink). Small rectangles are contained in cavities. (Left) The grid of $+$ -shapes for the L_1 and L_2 norms, with two long cavities and two square cavities. (Right) The grid of L -shapes for the L_∞ -norm with two long cavities.

4. Find all the blocker-shapes that are *owned* by small rectangles, where a blocker-shape B is *owned* by a small rectangle r if $p(r)$ has distance strictly less than δ to some point of B . For L_2 we will enlarge ownership as follows: B is *owned* by r if $d_1(p(r), B) < \sqrt{2}\delta$. To justify that this enlarges ownership, note that $d_1(p, q) \leq \sqrt{2}d_2(p, q)$ so $d_2(p(r), B) < \delta$ implies $d_1(p(r), B) < \sqrt{2}\delta$.
5. Define a bipartite graph H as follows. On one side, H has a vertex for each big rectangle, and on the other side, it has a vertex for each blocker-shape that is not owned by a small rectangle. Add an edge whenever the rectangle intersects the blocker-shape.
6. Construct a subgraph H^- of H as follows. For any big rectangle, if it has degree more than n in H , then arbitrarily delete incident edges until it has degree n . Also delete any blocker-shape that has no incident edges.
7. Compute a maximum matching M in H^- . We say that it *covers all big rectangles* if every big rectangle has an incident matching-edge in M .
8. If M does not cover all big rectangles, then declare that $\delta^* < f_\ell \delta$ and halt.
9. For each big rectangle R let B be the blocker-shape that R is matched to, and let $p(R)$ be an arbitrary point in $B \cap R$. (This exists since (B, R) was an edge.)
10. Return the set $\{p(R)\}$ (for both big and small rectangles R) as an approximate set of distant representatives.

We now define *big* rectangles more precisely. The intuition is that a rectangle is big if it intersects a blocker shape even if δ is decreased by an infinitesimal amount. Note that, as δ decreases, the blocker-shapes change position and size continuously. More formally, a rectangle is *big* with respect to δ if there is some $\varepsilon_0 > 0$ such that for all ε , $0 \leq \varepsilon < \varepsilon_0$, there is a point in the (closed) rectangle and in a blocker-shape (for the blocker-shapes at $\delta - \varepsilon$). The reason for this definition is so the set of big rectangles remains the same if δ is decreased by an infinitesimal amount, a property that becomes relevant when we use the PLACEMENT algorithm to approximately solve the optimization version of distant representatives.

For implementation details and the correctness proof, we need one more definition. A *cavity* is a closed maximal axis-aligned rectangular region with no points of blocker shapes in its interior. We distinguish a *square cavity*, which is a 2×2 block of grid squares (only possible for $+$ -shapes), and a *long cavity* which lies between two consecutive grid lines. For $+$ -shapes a long cavity is a 1×4 or 4×1 block of grid squares, and for L -shapes, a long cavity is a 1×3 or 3×1 block of grid squares. Observe that any small rectangle is contained in a cavity.

Implementation and Runtime. In order to implement the algorithm efficiently we discuss:

- How to test whether a rectangle is big/small.
- How to find the blocker shapes owned by a small rectangle.
- How to construct H^- .
- How to efficiently compute the matching.

We first show how to find which grid square contains a given point. Identify a grid square by the indices of its lower left grid point. Given a point (x, y) in the plane (e.g., a corner of an input rectangle) the vertical grid line just before x has index i where $i\gamma_\ell \leq x < (i+1)\gamma_\ell$ so $i = \lfloor x/\gamma_\ell \rfloor$. For $\ell = 1$, $i = \lfloor 2x/\delta \rfloor$. For $\ell = \infty$, $i = \lfloor x/\delta \rfloor$. For $\ell = 2$, i is the largest natural number such that $i^2 \leq 2x^2/\delta^2$, i.e., i is the integer square root of $\lfloor 2x^2/\delta^2 \rfloor$. The integer square root of a number with $O(\log D + t)$ bits can be found in time $O(\log D + t)$ on a word RAM.

We apply the above procedure $O(n)$ times to find the grid squares of all the rectangles' corners and centres. Using the differences and parities of the indices of the grid squares containing the corners, we can test if a rectangle contains points of blocker shapes in its interior or on its boundary. From this, we can test if a rectangle is big or small in constant time. (Note that our complicated rule is really just testing boundary conditions.)

Each small rectangle r owns a constant number of blocker shapes and these can be found by testing a constant number of grid squares that are near $p(r)$.

Next we show how to construct the bipartite graph H^- and compute a maximum matching. Note that blocker-shapes, which form one vertex set of H^- , are specified using $O(\log D + t)$ bits each, although we do not write that in our run-time bounds. To construct H^- we first build a dictionary for the $O(n)$ blocker-shapes owned by small rectangles. Then for each big rectangle R , enumerate blocker-shapes intersecting R in arbitrary order until we have found n that are not owned by a small rectangle, or until we have found all of them, whichever happens first. The run-time for this step is $O(n^2 \log n)$ which will in fact be the bottleneck in our runtime. The graph H^- has $O(n^2)$ vertices and edges.

To find the maximum matching in H^- , we can use the standard algorithm by Hopcroft and Karp [24] which has run-time $O(\sqrt{\nu}|E|)$, where ν is the size of the maximum matching [31, Theorem 16.5]. We have $\nu \leq n$ and $|E| = O(n^2)$, so the run-time to find the matching is $O(n^{2.5})$. With appropriate further data structures the runtime of computing the matching can be reduced to $O(n\sqrt{n} \log n)$; see the full version. Therefore the runtime becomes $O(n^2 \log n)$.

Correctness

The algorithm outputs either a set of points or a declaration that $\delta_\ell^* < f_\ell \delta$. We first show that the algorithm is correct if it outputs a set of points.

► **Lemma 2.** *If the algorithm returns a point-set, then the L_ℓ -distance between any two points chosen by the algorithm is at least δ .*

Proof. For two small rectangles r, r' , this holds since we test $d_\ell(p(r), p(r'))$ explicitly. For any two big rectangles R, R' , the two assigned points $p(R)$ and $p(R')$ lie on different blocker-shapes, and hence have distance at least δ . For any big rectangle R and small rectangle r , point $p(R)$ lies on a blocker-shape that is not owned by r , so the blocker shape, and hence $p(R)$, has distance at least δ from $p(r)$. ◀

If the algorithm does not output a set of points, then it outputs a declaration that δ is too large compared to the optimum δ^* , viz., $\delta_\ell^* < f_\ell \delta$. This declaration is made either in Step 3 because the points chosen for small rectangles are too close, or in Step 8 because no matching

is found. We must prove correctness in each case, Lemma 3 for Step 3, and Lemma 4 for Step 8. In the remainder of this section we let $p^*(R)$, $R \in \mathcal{R}$ denote an optimum set of distant representatives, i.e., $p^*(R)$ is a point in R and every two such points have L_ℓ -distance at least δ_ℓ^* .

► **Lemma 3.** *If two points $p(r), p(r')$ of two small rectangles r, r' have distance less than δ , then $\delta_\ell^* < f_\ell \delta$.*

Proof. We first show that for any small rectangle r , points $p^*(r)$ and $p(r)$ are close together, specifically, $d_\ell(p^*(r), p(r)) \leq 2.5\gamma_\ell$. Because L_1 -distance dominates L_2 and L_∞ -distances, it suffices to prove that $d_1(p^*(r), p(r)) \leq 2.5\gamma_\ell$. Any small rectangle is contained in a cavity. The L_1 diameter of a cavity (i.e., the maximum distance between any two points in the cavity) is at most $5\gamma_\ell$ – it is $5\gamma_\ell$ for a long cavity with $+$ -shapes; $4\gamma_\ell$ for a square cavity with $+$ -shapes; and $4\gamma_\ell$ for a long cavity with L -shapes. This implies that any point of r is within distance $2.5\gamma_\ell$ from $p(r)$, the centre of rectangle r .

Now consider two small rectangles r and r' with $d_\ell(p(r), p(r')) < \delta$. We will bound the distance between $p^*(r)$ and $p^*(r')$ by applying the triangle inequality:

$$d_\ell(p^*(r), p^*(r')) \leq d_\ell(p^*(r), p(r)) + d_\ell(p(r), p(r')) + d_\ell(p(r'), p^*(r')) < 2.5\gamma_\ell + \delta + 2.5\gamma_\ell = \delta + 5\gamma_\ell.$$

Plugging in the values $\gamma_1 = \delta/2$, $\gamma_2 = \delta/\sqrt{2}$, and $\gamma_\infty = \delta$, we obtain bounds of 3.5δ , $(1 + 5/\sqrt{2})\delta \approx 4.5\delta$, and 6δ , respectively. Since $f_1 = 5$, $f_2 \approx 5.8$, and $f_\infty = 6$, these bounds are at most $f_\ell \delta$ in all three cases. Thus $\delta^* < f_\ell \delta$, as required. ◀

► **Lemma 4.** *If there is no matching M in H^- that covers all big rectangles, then $\delta_\ell^* < f_\ell \delta$.*

Proof. We prove the contrapositive, using the following plan. Take an optimal set of distant representatives, $p^*(R)$, $R \in \mathcal{R}$ with L_ℓ -distance $\delta_\ell^* \geq f_\ell \delta$. For any big rectangle R , we “round” $p^*(R)$ to a point $b(R)$ that is in R and on a blocker-shape $B(R)$. More precisely, we define $b(R)$ to be a point that is in R , on a blocker-shape, and closest (in L_ℓ distance) to $p^*(R)$. In case of ties, choose $b(R)$ so that the smallest rectangle containing $p^*(R)$ and $b(R)$ is minimal (this is only relevant in L_∞). Break further ties arbitrarily. Observe that $b(R)$ exists, since a big rectangle contains blocker-shape points. Define $B(R)$ to be the blocker-shape containing $b(R)$.

By Lemma 5 (stated below) the pairs $R, B(R)$ form a matching in H that covers all big rectangles. We convert this to a matching in H^- by repeatedly applying the following exchange step. If big rectangle R is matched to a blocker shape $B(R)$ that is not in H^- , then R has degree exactly n in H^- . Not all its n neighbours can be used in the current matching since there are at most $n - 1$ big rectangles other than R . So change the matching-edge at R to go to one of the unmatched neighbours in H^- instead. ◀

► **Lemma 5.** *Let R be a big rectangle and let $B = B(R)$. If $\delta^* \geq f_\ell \delta$ then (1) no other big rectangle R' has $B(R') = B$, and (2) no small rectangle owns B .*

The general idea to prove this lemma is to show that either type of collision ($B(R) = B(R')$ or $B(R)$ owned by r) gives points p^* that are “close together”, where close together means in a ball of appropriate radius centred at the anchor of $B(R)$.

Let $C_\ell(B)$ be the open L_ℓ -ball centred at the anchor of B and with diameter $f_\ell \delta$. See Figure 2 and note that the diameter of the ball in the appropriate metric is:

$$f_1 \delta = 5\delta = 10(\delta/2) = 10\gamma_1 \quad f_2 \delta = \sqrt{34}\delta = \sqrt{68}(\delta/\sqrt{2}) = \sqrt{68}\gamma_2 \quad f_\infty \delta = 6\delta = 6\gamma_\infty$$

We need a few claims localizing $p^*(R)$ relative to $b(R)$:

■ **Figure 2** A blocker shape B (heavy black) and $C_\ell(B)$, the L_ℓ -ball of diameter $f_\ell\delta$ centred at B 's anchor (dashed green) which is a diamond for L_1 (left), a circle for L_2 (left), and a square for L_∞ (right). The long cavities that touch B are shaded gray. If a small rectangle r owns B , then $p(r)$ lies in C' (in cyan), and r is contained in the union of the gray and blue-hatched regions.

▷ **Claim 6.** For any big rectangle R , the points $b(R)$ and $p^*(R)$ lie in one long cavity.

Proof. Let T be the rectangle with corners $p^*(R)$ and $b(R)$. By definition of $b(R)$, there are no points of blocker-shapes in or on the boundary of T except $b(R)$. Thus T is contained in a cavity. Furthermore, if T is contained in a square cavity, then we claim that T does not contain the central grid point of the square cavity in its interior (otherwise $b(R)$ could not be the unique point of a blocker shape in T , see Figure 1). Thus T is contained in a long cavity. ◁

▷ **Claim 7.** Let B be a blocker shape. Let R be a big rectangle with $B(R) = B$. Then $p^*(R)$ is contained in the ball $C_\ell(B)$.

Proof. By the previous lemma, $p^*(R)$ lies in a long cavity that contains a point of B . From Figure 2 we see that any long cavity that contains a point of B lies inside the closed ball $C_\ell(B)$. Furthermore, note that if $p^*(R)$ lies on the boundary of the ball, then it lies on a different blocker shape, contrary to $B(R) = B$. Thus $p^*(R)$ is contained in $C_\ell(B)$. ◁

▷ **Claim 8.** Let B be a blocker shape. Let r be a small rectangle that owns B . Then $p^*(r)$ is contained in the ball $C_\ell(B)$.

Proof. Recall that $p(r)$ is the centre of r , and that, by the definition of ownership, for $\ell = 1, \infty$ we have $d_\ell(p(r), B) < \delta$, and for $\ell = 2$ we have $d_1(p(r), B) < \sqrt{2}\delta$. Such points $p(r)$ lie in the open region C' drawn in cyan in Figure 2. Here C' is the Minkowski sum of an open ball with B where we use an L_1 -ball of radius δ for $\ell = 1$, an L_1 -ball of radius $\sqrt{2}\delta$ for $\ell = 2$ and an L_∞ -ball of radius δ for $\ell = \infty$.

We next show that r is contained in the ball $C_\ell(B)$. For $\ell = \infty$, r must lie in a long cavity intersecting C' , i.e. in the open shaded gray region, thus in $C_\infty(B)$.

For $\ell = 1, 2$, r is contained in a cavity that intersects C' . The union of the cavities that intersect C' consists of the gray and blue-hatched region plus the grid square X and its symmetric counterparts. But observe that a small rectangle that contains points of X has a centre outside C' . Therefore r is contained in $C_\ell(B)$. ◁

Proof of Lemma 5. Let R be a big rectangle and let $B = B(R)$. By Claim 7, $p^*(R)$ lies in $C_\ell(B)$. If there is another big rectangle R' with $B(R') = B$, then $p^*(R')$ also lies in $C_\ell(B)$. If there is a small rectangle r that owns B , then by Claim 8, $p^*(r)$ lies in $C_\ell(B)$.

In either case, the distance between $p^*(R)$ and the other p^* point is less than $f_\ell\delta$, since that is the diameter of $C_\ell(B)$. Thus $\delta^* < f_\ell\delta$. ◀

3 Approximating the optimization problem

In this section we use PLACEMENT to design approximation algorithms for the optimization version of the distant representatives problem for rectangles:

► **Theorem 9.** *There is an f_ℓ -approximation algorithm for the distant representatives problem on rectangles in the L_ℓ -norm, $\ell = 1, 2, \infty$ with run time $O(n^2(\log n)^2)$ for L_∞ and run time $O(n^2 \text{polylog}(nD))$ for L_1 and L_2 . Here (as before) $f_1 = 5, f_2 = \sqrt{34} \approx 5.83, f_\infty = 6$.*

One complicating factor is that PLACEMENT is not monotone, i.e., it may happen that PLACEMENT fails for a value δ but succeeds for a larger value δ' . We note that Cabello's algorithm [5] behaves the same way. We deal with L_∞ in Section 3.1 and with L_1 and L_2 in Section 3.2.

We need some upper and lower bounds on δ^* . Note that if the input contains two rectangles that are single identical points, then $\delta^* = 0$. Since this is easily detected, we assume from now on that no two input rectangles are single identical points.

▷ **Claim 10.** We have $1/n \leq \delta^* \leq 2D$.

Proof. The upper bound is obvious. For the lower bound, place a grid of points distance $\frac{1}{n}$ apart. All rectangles with non-zero dimensions will intersect at least $n + 1$ points, and single-point rectangles will hit one point. Since no two single-point rectangles are identical, they can be matched to the sole grid point that overlaps the rectangle. The remaining rectangles can be matched trivially. ◁

Note that a solution with distance at least $\frac{1}{n}$ can be found easily, following the steps above.

3.1 Optimization problem for L_∞

For the L_∞ norm we use the following result about the possible optimum values; a proof is in the full version.

► **Lemma 11.** *In L_∞ , δ_∞^* takes on one of the $O(n^3)$ values of the form $(t - b)/k$ where $k \in \{1, \dots, n\}$ and t, b are rectangle coordinates.*

Let Δ be the set of $O(n^3)$ values from the lemma. We can compute the set Δ in $O(n^3)$ time and sort it in $O(n^3 \log n)$ time. Say $\Delta = \{d_1, d_2, \dots, d_N\}$ in sorted order, and set $c_i := d_i / f_\infty$. Because of non-monotonicity, we cannot efficiently find the maximum c_i for which PLACEMENT succeeds. Instead, we use binary search to find i such that $\text{PLACEMENT}(c_i)$ succeeds but $\text{PLACEMENT}(c_{i+1})$ fails. Therefore $\delta_\infty^* < f_\infty c_{i+1} = d_{i+1}$ which implies that $\delta_\infty^* \leq d_i = f_\infty c_i$ and the representative points found by $\text{PLACEMENT}(c_i)$ provide an f_∞ -approximation.

To initialize the binary search, we first run $\text{PLACEMENT}(c_N)$, and, if it succeeds, return its computed representative points since they provide an f_∞ -approximation of the optimum assignment. Also note that $\text{PLACEMENT}(c_1)$ must succeed – if it fails then $\delta_\infty^* < f_\infty c_1 = d_1$, which contradicts $\delta_\infty^* \in \Delta$. Thus we begin with the interval $[1, N]$ and perform binary search on within this interval to find a value i such that $\text{PLACEMENT}(c_i)$ succeeds but $\text{PLACEMENT}(c_{i+1})$ fails.

We can get away with sorting just the $O(n^2)$ numerators and performing an implicit binary search, to avoid the cost of generating and sorting all of Δ . Let t be the sorted array of $O(n^2)$ numerators, which takes $O(n^2 \log n)$ time to generate and sort. The denominators are just $[n]$, so there is no need to generate and sort it explicitly. Define the implicit *sorted*

matrix a , where $a[r, c] = t[r]/(n - c)$, for $0 \leq r \leq |t| - 1, 0 \leq c \leq n - 1$. Each entry of a can be computed in $O(1)$ time. Since the matrix is sorted, the matrix selection algorithm of Frederickson and Johnson [19] can be used to get an element of Δ at the requested index in $O(n \log n)$ time. Using selection, one can perform the binary search on Δ implicitly. While accessing elements of Δ takes more time, it is still less than the time to call `PLACEMENT` on the element accessed. Each iteration of the binary search is dominated by the runtime of `PLACEMENT`, so the total runtime is $O(n^2(\log n)^2)$. This proves Theorem 9 for L_∞ .

3.2 Optimization problem for L_1 and L_2

In this section we give an approximation algorithm for the optimization version of distant representatives for rectangles in the L_1 and L_2 norms. Define a *critical* value to be a right endpoint

We

► **Len**

success

■ **Figure 3** An illustration of critical values.

Thus our problem reduces to finding a critical value.

► **Lemma 13.** *The `PLACEMENT` algorithm can be modified to detect critical values.*

► **Lemma 14.** *In L_1 any critical value δ is a rational number with numerator and denominator at most $4Dn$. In L_2 for any critical value δ , δ^2 is a rational number with numerator and denominator at most $8D^2n^2$.*

Based on these lemmas, we use continued fractions to find a critical value. We need the following properties of continued fractions.

1. A continued fraction has the form $a_0 + \frac{1}{a_1 + \frac{1}{a_2 + \dots + \frac{1}{a_k}}}$, where the a_i 's are natural numbers.
2. Every positive rational number $\frac{a}{b}$ has a continued fraction representation. Furthermore, the number of terms, k , is $O(\log(\max\{a, b\}))$. This follows from the fact that computing the continued fraction representation of $\frac{a}{b}$ exactly parallels the Euclidean algorithm; see [2, Theorem 4.5.2] or the wikipedia page on the Euclidean algorithm [35]. For the same reason, each a_i is bounded by $\max\{a, b\}$.
3. Suppose we don't know $\frac{a}{b}$ explicitly, but we know some bound G such that $a, b \leq G$, and we have a test of whether a partial continued fraction is greater than, less than, or equal to $\frac{a}{b}$. Then we can find the continued fraction representation of $\frac{a}{b}$ as follows. For $i = 1 \dots \log G$, use binary search on $[2..G]$ to find the best value for a_i . Note that the continued fraction with i terms is increasing in a_i for even i and decreasing for odd i , and we adjust the binary search correspondingly. In each step, we have a lower bound and an upper bound on $\frac{a}{b}$ and the step shrinks the interval. If the test runs in time T , then the time to find the continued fraction for $\frac{a}{b}$ is $O(T(\log G)^2)$, plus the cost of doing arithmetic on continued fractions (with no T factor).

Algorithm for L_1, L_2 . Run the continued fraction algorithm using PLACEMENT (enhanced to detect a critical value) as the test. The only difference from the above description is that we do not have a specific target $\frac{a}{b}$; rather, our interval contains at least one critical value and we search until we find one. At any point we have two values b_l and b_u both represented as continued fractions, where PLACEMENT succeeds at b_l and fails at b_u , so there is at least one critical value between them. We can use the initial interval $[1/n, 2D]$. To justify this, note that if $\text{PLACEMENT}(\frac{1}{n})$ fails, then $f_\ell/n > \delta^*$ by Theorem 1, so we get an f_ℓ -approximation by using the representative points for $\delta = \frac{1}{n}$ (see the remark after Claim 10).

For the runtime, we use the bound $O(T(\log G)^2)$ from point 3 above, plugging in $T = O(n^2 \log n)$ for PLACEMENT and the bounds on G from Lemma 14, to obtain a runtime of $O(n^2 \text{polylog}(nD))$, which proves Theorem 9 for L_1 and L_2 .

The run-time for Theorem 9 can actually be improved to $O(n^2(\log n)^2)$ (i.e., without the dependence on $\log D$) with an approach that is very specific to the problem at hand (and similar to Cabello's approach). The details are complicated for such a relatively small improvement and hence omitted here.

Missing proofs. For space reasons we can here only give the briefest sketch of the proofs of Lemmas 12, 13, and 14; details are in the full version. A crucial ingredient is to study what must have happened if $\text{PLACEMENT}(\delta)$ goes from success to failure (when viewing its outcome as a function that changes over time δ).

► **Observation 15.** *Assume $\text{PLACEMENT}(\delta)$ succeeds but $\text{PLACEMENT}(\delta')$ fails for some $\delta' > \delta$. Then at least one of the following events occurs as we go from δ to δ' :*

1. *the set of small/big rectangles changes,*
2. *the distance between the centres of two small rectangles equals $\hat{\delta}$ for some $\delta \leq \hat{\delta} < \delta'$,*
3. *the set of blocker-shapes owned by a small rectangle increases,*
4. *the set of blocker-shapes intersecting a big rectangle decreases.*

Roughly speaking, Lemma 12 can now be shown by arguing that such events do not happen in a sufficiently small time-interval before PLACEMENT fails (hence the intervals where it fails are open on the left). Lemma 14 holds because there necessarily must have been an event at time δ , and we can analyze the coordinates when events happen. Finally Lemma 13 is achieved by running PLACEMENT at time δ and also symbolically at time $\delta + \varepsilon$.

4 Hardness results

In this section we outline NP-hardness and APX-hardness results for the distant representatives problem. For complete details see the full version of the paper. We first show that, even for the special case of unit horizontal segments, the decision version of the problem is NP-complete for L_1 and L_∞ and NP-hard for L_2 (where bit complexity issues prevent us from placing the problem in NP). This L_2 result was proved previously by Roeloffzen in his Master's thesis [30, Section 2.3] but we add details regarding bit complexity that were missing from his proof.

Next, we enhance our reductions to “gap-producing reductions” to obtain lower bounds on the approximation factors that can be achieved in polynomial time. Since our goal is to compare with our approximation algorithms for rectangles, we consider the more general case of horizontal and vertical segments in the plane (not just unit horizontals). Our main result is that, assuming $P \neq NP$, no polynomial time approximation algorithm achieves a factor better than 1.5 in L_1 and L_∞ and 1.4425 in L_2 .

Our reductions are from the NP-complete problem Monotone Rectilinear Planar 3-SAT [10] in which each clause has either three positive literals or three negative literals, each variable is represented by a thin vertical rectangle at x -coordinate 0, each positive [negative] clause is represented by a thin vertical rectangle at a positive [negative, resp.] x -coordinate, and there is a horizontal line segment joining any variable to any clause that contains it. See Figure 4(a) for an example instance of the problem. For n variables and m clauses, the representation can be on an $O(m) \times O(n + m)$ grid.

4.1 NP-hardness

► **Theorem 16.** *The decision version of the distant representatives problem for unit horizontal segments in the L_1, L_2 or L_∞ norm is NP-hard.*

Lemma 11 implies that the decision problem lies in NP for the L_∞ norm, even for rectangles. In the full version we show the same for L_1 , and we discuss the bit complexity issues that prevent us from placing the decision problem in NP for the L_2 norm.

For our reduction from Monotone Rectilinear Planar 3-SAT we first modify the representation so that each clause rectangle has fixed height and is connected to its three literals via three “wires” – the middle one remains horizontal, the bottom one bends to enter the clause rectangle from the bottom, and the top one bends twice to enter the clause rectangle from the far side. See Figure 4(b). Each wire is directed from the variable to the clause, and represents a literal. The representation is still on an $O(m) \times O(n + m)$ grid.

To complete the reduction to the distant representatives problem we replace the rectangles with variable and clause gadgets constructed from unit horizontal intervals, and also implement the wires using such intervals. The details, which can be found in the full version of the paper, depend on the norm L_ℓ , $\ell = 1, 2, \infty$. We also set a value of δ_ℓ to obtain a decision problem that asks if there is an assignment of a representative point to each interval that is *valid*, i.e., such that no two points are closer than δ_ℓ . We set $\delta_1 = 2$, $\delta_2 = \frac{13}{5}$, and $\delta_\infty = \frac{1}{2}$. An example of the construction for L_1 (with $\delta_1 = 2$) is shown in Figure 4(c).

For the L_2 norm, the bit complexity issue missed in Roeloffzen’s reduction [30, Section 2.3] is that the interval endpoints and their distances must have polynomially-bounded bit complexity. We resolve this by using Pythagorean triples (see Figure 5(a)).

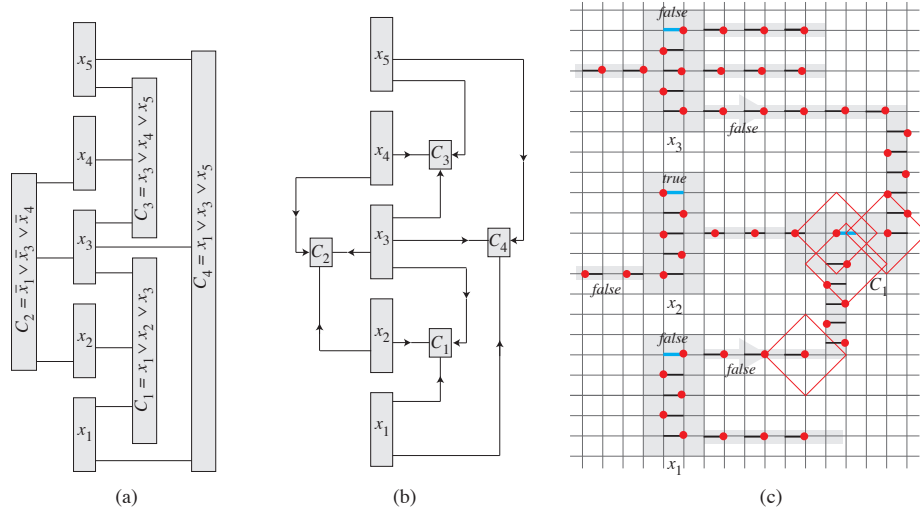

4.2 APX-hardness

In this section, we prove hardness-of-approximation results for the distant representatives problem on horizontal and vertical segments in the plane. Specifically, we prove lower bounds on the approximation factors that can be achieved in polynomial time, assuming $P \neq NP$.

► **Theorem 17.** *For $\ell = 1, 2, \infty$, let g_ℓ be the constant shown in Table 2. Suppose $P \neq NP$. Then, for the L_ℓ norm, there is no polynomial time algorithm with approximation factor less than g_ℓ for the distant representatives problem for horizontal and vertical segments.*

■ **Table 2** Best approximation ratios that can be achieved unless $P=NP$.

	L_1	L_2	L_∞
lower bound	$g_1 = 1.5$	$g_2 = 1.4425$	$g_\infty = 1.5$

■ **Figure 4** (a) An instance of Monotone Rectilinear Planar 3-SAT. (b) The modified representation used for our NP-hardness proofs, with wires from variable to clause gadgets. (c) A detail of our NP-hardness construction for clause $C_1 = x_1 \vee x_2 \vee x_3$ in the L_1 norm showing how the truth-value setting $x_1 = \text{False}$, $x_2 = \text{True}$, $x_3 = \text{False}$, permits representative points (shown as red dots) at distance at least $\delta_1 = 2$.

We prove Theorem 17 using a *gap reduction*. This standard approach is based on the fact that if there were polynomial time approximation algorithms with approximation factors better than g_ℓ then the *gap versions* of the problem (as stated below) would be solvable in polynomial time. Thus, proving that the gap versions are NP-hard implies that there are no polynomial time g_ℓ -approximation algorithms unless $P=NP$.

Recall that δ_ℓ^* is the max over all assignments of representative points, of the min distance between two points.

Gap Distant Representatives Problem.

Input: A set I of horizontal and vertical segments in the plane.

Output:

- YES if $\delta_\ell^*(I) \geq 1$;
- NO if $\delta_\ell^*(I) \leq 1/g_\ell$;
- and it does not matter what the output is for other inputs.

To prove Theorem 17 it therefore suffices to prove:

► **Theorem 18.** *The Gap Distant Representatives problem is NP-hard.*

This is proved via a reduction from Monotone Rectilinear Planar 3-SAT, much like in the previous section. The gadgets are simpler because we can use vertical segments, but we must prove stronger properties. Given an instance Φ of Monotone Rectilinear Planar 3-SAT we construct in polynomial time a set of horizontal and vertical segments I such that:

▷ **Claim 19.** If Φ is satisfiable then $\delta_\ell^*(I) = 1$.

▷ **Claim 20.** If Φ is not satisfiable then $\delta_\ell^*(I) \leq 1/g_\ell$.

Thus a polynomial time algorithm for the Gap Distant Representatives problem yields a polynomial time algorithm for Monotone Rectilinear Planar 3-SAT. We give some of the reduction details, but defer the proofs of the claims to the full version.

Reduction details

We reduce directly from Monotone Rectilinear Planar 3-SAT.

Figure 5 (a) A variable gadget for NP-hardness for L_2 , based on Pythagorean triple 5, 12, 13. To achieve $\delta = 13$ the representative point for the variable interval (in cyan) is forced to the left (true) or the right (false) in which case intervals on the right are also forced. (b) A clause gadget for the APX-hardness reduction, with three horizontal wires attached. For clarity, segments are not drawn all the way to their endpoints. Wires x_1 and x_2 are in the false setting and wire x_3 is in the true setting, which allows the representative point for C_1 to be placed where the x_3 wire meets it, while keeping representative points at least distance 1 apart. (c) The basic splitter gadget for APX-hardness for L_∞ placed on the half grid and showing two wires extending left and two right. The variable segment (in thick cyan) for the variable x_i has its representative point (the large red dot) at the right, which is the false setting. The representative points shown by large red/yellow dots are distance at least 1 apart in L_∞ .

Wire. A wire is a long horizontal segment with 0-length segments at unit distances along it, except at its left and right endpoints. See Figure 5(b). The representative point for a 0-length segment must be the single point in the segment (shown as small red dots in the figure). As before, a wire is directed from the variable gadget to the clause gadget. We distinguish a “false setting” where the wire has its representative point within distance 1 of its forward end (at the clause gadget) and a “true setting” where the wire has its representative point within distance 1 of its tail end (at the variable gadget).

Clause gadget. A clause gadget is a vertical segment. Three wires corresponding to the three literals in the clause meet the vertical segment as shown in Figure 5(b). There are 0-length segments at unit distances along the clause interval except where the three wires meet it.

Variable gadget. A variable segment has length 3, with two 0-length segments placed 1 and 2 units from the endpoints. A representative point in the right half corresponds to a false value for the variable, and a representative point in the left half corresponds to a true value. In order to transmit the variable’s value to all the connecting horizontal wires we build a “splitter” gadget. The basic splitter gadget for L_∞ is shown in Figure 5(c). The same splitter gadget works for the other norms but we can improve the lower bounds using modified splitter gadgets as described in the full version.

5 Conclusions

We gave good approximation algorithms for the distant representatives problem for rectangles in the plane using a new technique of “imprecise discretization” where we limit the choice of representative points not to a discrete set but to a set of one-dimensional “shapes”. This technique may be more widely applicable, and can easily be tailored, for example by using a weighted matching algorithm to prefer representative points near the centres of rectangles.

We also gave the first explicit lower bounds on approximation factors that can be achieved in polynomial time for distant representatives problems.

Besides the obvious questions of improving the approximation factors, the run-times, or the lower bounds, we mention several other avenues for further research.

1. Is the distant representatives problem for rectangles in L_2 hard for existential theory of the reals? Recently, some packing problems have been proved $\exists\mathbb{R}$ -complete [1], but they seem substantially harder.
2. Is there a good [approximation] algorithm for any version of distant representatives for a *lexicographic* objective function. For example, suppose we wish to maximize the smallest distance between points, and, subject to that, maximize the second smallest distance, and so on. Or suppose we ask to lexicographically maximize the sorted vector consisting of the n distances from each chosen point to its nearest neighbour. For the case of *ordered* line segments in 1D there is a linear time algorithm to lexicographically minimize the sorted vector of distances between successive pairs of points [4]. It is an open problem to extend this to unordered line segments.
3. What about weighted versions of distant representatives? Here each rectangle R has a weight $w(R)$, and rather than packing disjoint balls of radius δ we pack disjoint balls of radius $w(R)\delta$ centred at a representative point $p(R)$ in R . Again, there is a solution for ordered line segments in 1D [4].

Abstract

Given a graph with a distinguished source vertex s , the Single Source Replacement Paths (SSRP) problem is to compute and output, for any target vertex t and edge e , the length $d(s, t, e)$ of a shortest path from s to t that avoids a failing edge e . A Single-Source Distance Sensitivity Oracle (Single-Source DSO) is a compact data structure that answers queries of the form (t, e) by returning the distance $d(s, t, e)$. We show how to deterministically compress the output of the SSRP problem on n -vertex, m -edge graphs with integer edge weights in the range $[1, M]$ into a Single-Source DSO that has size $O(M^{1/2}n^{3/2})$ and query time $\tilde{O}(1)$. We prove that the space requirement is optimal (up to the word size). Our techniques can also handle vertex failures within the same bounds.

Chechik and Cohen [SODA 2019] presented a combinatorial, randomized $\tilde{O}(m\sqrt{n} + n^2)$ time SSRP algorithm for undirected and unweighted graphs. We derandomize their algorithm with the same asymptotic running time and apply our compression to obtain a deterministic Single-Source DSO with $\tilde{O}(m\sqrt{n} + n^2)$ preprocessing time, $O(n^{3/2})$ space, and $\tilde{O}(1)$ query time. Our combinatorial Single-Source DSO has near-optimal space, preprocessing and query time for unweighted graphs, improving the preprocessing time by a \sqrt{n} -factor compared to previous results with $o(n^2)$ space.

Grandoni and Vassilevska Williams [FOCS 2012, TALG 2020] gave an algebraic, randomized $\tilde{O}(Mn^\omega)$ time SSRP algorithm for (undirected and directed) graphs with integer edge weights in the range $[1, M]$, where $\omega < 2.373$ is the matrix multiplication exponent. We derandomize it for undirected graphs and apply our compression to obtain an algebraic Single-Source DSO with $\tilde{O}(Mn^\omega)$ preprocessing time, $O(M^{1/2}n^{3/2})$ space, and $\tilde{O}(1)$ query time. This improves the preprocessing time of algebraic Single-Source DSOs by polynomial factors compared to previous $o(n^2)$ -space oracles.

We also present further improvements of our Single-Source DSOs. We show that the query time can be reduced to a constant at the cost of increasing the size of the oracle to $O(M^{1/3}n^{5/3})$ and that all our oracles can be made path-reporting. On sparse graphs with $m = O(\frac{n^{5/4-\varepsilon}}{M^{7/4}})$ edges, for any constant $\varepsilon > 0$, we reduce the preprocessing to randomized $\tilde{O}(M^{7/8}m^{1/2}n^{11/8}) = O(n^{2-\varepsilon/2})$ time. To the best of our knowledge, this is the first truly subquadratic time algorithm for building Single-Source DSOs on sparse graphs.

1 Introduction

One of the basic problems in computer science is the computation of shortest paths and distances in graphs that are subject to a small number of transient failures. We study two central problems of this research area on undirected graphs G with n vertices and m edges, namely, the *Single-Source Replacement Paths* (SSRP) problem and *Single-Source Distance Sensitivity Oracles* (Single-Source DSOs).

The SSRP Problem. In the SSRP problem, we are given a graph G with a fixed source vertex s and are asked to compute, for every vertex t and edge e , the replacement distance $d(s, t, e)$, which is the length of the shortest s - t -path in the graph $G - e$, obtained by dropping the edge e . By first computing any shortest path tree for G rooted at s , one can see that there are only $O(n^2)$ relevant distances $d(s, t, e)$, namely, those for which e is in the tree.

Chechik and Cohen [10] presented an $\tilde{O}(m\sqrt{n} + n^2)$ time¹ combinatorial² SSRP algorithm for unweighted graphs. They also showed that the running time cannot be improved by polynomial factors, assuming that any combinatorial algorithm for Boolean Matrix Multiplication (BMM) on $n \times n$ matrices containing m 1's requires $mn^{1-o(1)}$ time. Gupta et al. [21] simplified the SSRP algorithm and generalized it to multiple sources. For a set of σ sources, they presented a combinatorial algorithm that takes $\tilde{O}(m\sqrt{n\sigma} + \sigma n^2)$ time. Grandoni and Vassilevska Williams [17, 18] gave an algorithm for both directed and undirected graphs with integer edge weights in the range $[1, M]$ that uses fast matrix multiplications and runs in $\tilde{O}(Mn^\omega)$ time, where $\omega < 2.37286$ is the matrix multiplication exponent [2, 25, 35]. We are only concerned with *positive* integer weights, but it is worth noting that SSRP with weights in $[-M, M]$ is strictly harder, modulo a breakthrough in Min-Plus Product computation, with a current best running time of $O(M^{0.8043} n^{2.4957})$ as shown by Gu et al. [20].

All the SSRP algorithms above are randomized, it is an interesting open problem whether they can be derandomized in the same asymptotic running time.

Single-Source DSOs. A Distance Sensitivity Oracle (DSO) is a data structure that answers queries (u, v, e) , for vertices u, v and edge e , by returning the replacement distance $d(u, v, e)$. A Single-Source DSO, with fixed source s , answers queries (t, e) with $d(s, t, e)$.

Of course, any SSRP algorithm gives a Single-Source DSO by just tabulating the whole output in $O(n^2)$ space, the replacement distances can then be queried in constant time. However, the space usage is far from optimal. Parter and Peleg [29] developed a deterministic algorithm that computes an $O(n^{3/2})$ size subgraph of G containing a breadth-first-search tree of $G - e$ for every failing edge e . The subgraph can also be thought of as a Single-Source DSO with $O(n^{3/2})$ space and query time. Bilò et al. [7] presented a Single-Source DSO of the same size with $\tilde{O}(\sqrt{n})$ query time and $\tilde{O}(mn)$ preprocessing time. Gupta and Singh [22] later designed a randomized Single-Source DSO of $\tilde{O}(n^{3/2})$ size, $\tilde{O}(mn)$ preprocessing time,³ but with a better $\tilde{O}(1)$ query time. The results in the latter two works generalize to the case of σ sources in such a way that the time and size scale by $o(\sigma)$ factors.

For the case of $\sigma = n$ sources, that is, general (all-pairs) DSOs, Bernstein and Karger [5, 6] designed an oracle taking $\tilde{O}(n^2)$ space with constant query time, even for directed graphs with real edge weights. The space was subsequently improved to $O(n^2)$ by Duan and Zhang [16],

¹ For a non-negative function $f = f(n)$, we use $\tilde{O}(f)$ to denote $O(f \cdot \text{polylog}(n))$.

² The term “combinatorial algorithm” is not well-defined, and is often interpreted as not using any matrix multiplication. Arguably, combinatorial algorithms can be considered efficient in practice as the constants hidden in the matrix multiplication bounds are rather high.

³ The authors of [22] do not report the preprocessing time, but it can be reconstructed as $\tilde{O}(mn)$.

which is optimal [34]. The combinatorial $\tilde{O}(mn)$ time preprocessing for building the DSOs is conditionally near-optimal as it matches the best known bound (up to polylogarithmic factors) for the simpler problem of finding the All-Pairs Shortest Paths (APSP). The conditional lower bound in [10], stating that there exists no combinatorial algorithm solving the undirected SSRP problem with real edge weights in $O(mn^{1-\varepsilon})$ time for any positive $\varepsilon > 0$, unless there is a combinatorial algorithm for the APSP problem in $O(mn^{1-\varepsilon})$ time, also implies that there exists no *Single-Source* DSO with $\tilde{O}(1)$ query time and $O(mn^{1-\varepsilon})$ preprocessing time for real edge weights. Therefore, the DSOs in [6, 16], are also conditionally near-optimal for the single source case with real edge weights.

Several algebraic all-pairs DSOs with subcubic preprocessing time have been developed in the last decade for graphs with integer edge weights in $[1, M]$ [9, 11, 17, 30, 37]. Very recently, Gu and Ren [19] presented a randomized DSO achieving a $O(Mn^{2.5794})$ preprocessing time with $O(1)$ query time, improving upon the one by Ren [30, 31] with an $\tilde{O}(Mn^{2.6865})$ preprocessing time. Those DSOs can also be used in the single-source case, but the requirement to store the information for all pairs forces them to take $\Omega(n^2)$ space [34]. The algebraic SSRP algorithm in [18], seen as a data structure, has a better preprocessing time than any known (general) DSO but also takes $O(n^2)$ space, which we have seen to be wasteful.

We are not aware of an algebraic Single-Source DSO that simultaneously achieves $o(n^2)$ space and has a better preprocessing time than their all-pairs counterparts. It is interesting whether we can construct space-efficient oracles faster when focusing on a single source.

Additional results on replacement paths and DSOs (for single or multiple failures and directed graphs) can be found in [3, 9, 12, 13, 14, 15, 18, 23, 24, 26, 27, 28, 32, 36]. The most efficient Single-Source DSOs in their respective settings are shown in Table 1 below.

1.1 Our Contribution

We research SSRP algorithms, Single-Source DSO data structures, and the connection between the two. Our first contribution is presented in Section 5. We derandomize the near-optimal combinatorial SSRP algorithm of Chechik and Cohen [10] for undirected, unweighted graphs and the algebraic algorithm of Grandoni and Vassilevska Williams [17, 18] for undirected graphs with integer weights in the range $[1, M]$. (The second algorithm can be found in the full version.) Both deterministic algorithms have the same asymptotic runtime as their randomized counterparts.

► **Theorem 1.** *There is a deterministic, combinatorial SSRP algorithm for undirected, unweighted graphs running in time $\tilde{O}(m\sqrt{n} + n^2)$ and a deterministic, algebraic SSRP algorithm for undirected graphs with integer weights in the range $[1, M]$ running in $\tilde{O}(Mn^\omega)$.*

We present in Section 3 a deterministic reduction from the problem of building a Single-Source DSO to SSRP on undirected graphs with small integer edge weights.

► **Theorem 2.** *Let G be an undirected graph with integer edge weights in the range $[1, M]$ and let s be the source vertex. Suppose we are given access to a shortest path tree T_s of G rooted in s and all values $d(s, t, e)$ for vertices t of G and edges e in T_s . There is a deterministic, combinatorial algorithm that in time $O(n^2)$ builds a Single-Source DSO of size $O(M^{1/2}n^{3/2})$ with $\tilde{O}(1)$ query time. The same statement holds for vertex failures if instead we are given access to the values $d(s, t, v)$ for all vertices t and v of G .*

The algorithm does not require access to the graph G itself. As there can be up to $O(n^2)$ relevant distances $d(s, t, e)$, the running time is linear in the input. If the algorithm additionally has access to G and is given $O(m\sqrt{Mn} + n^2)$ time, the Single-Source DSO also reports the replacement paths $P(s, t, e)$ in time $\tilde{O}(1)$ per edge. The query time of the oracle can be improved to $O(1)$ at the cost of increasing the size of the oracle to $O(M^{1/3}n^{5/3})$.

Plugging the deterministic SSRP algorithms of Theorem 1 into our reduction of Theorem 2, gives the following Single-Source DSOs as corollaries.

► **Theorem 3.** *There is a deterministic, combinatorial Single-Source DSO for undirected, unweighted graphs taking $O(n^{3/2})$ space, with $\tilde{O}(m\sqrt{n} + n^2)$ preprocessing time, and $\tilde{O}(1)$ query time. There is a deterministic, algebraic Single-Source DSO for undirected graphs with integer weights in the range $[1, M]$ taking $O(M^{1/2}n^{3/2})$ space, with $\tilde{O}(Mn^\omega)$ preprocessing time, and $\tilde{O}(1)$ query time.*

When comparing the results with other Single-Source DSO with $o(n^2)$ space, the preprocessing time of our combinatorial solution is better by a factor of \sqrt{n} compared to previous oracles [7, 22]. The preprocessing time of the algebraic part of Theorem 3 improves (ignoring polylogarithmic factors) by a factor of $n^{2.5794-\omega} > n^{0.2}$ over the current best algebraic (all-pairs) DSO [19]. See Table 1 for more details. In fact, we combine the efficient preprocessing of SSRP algorithms (seen as DSOs) with a compression scheme that achieves nearly-optimal space. To the best of our knowledge, Theorem 3 presents the first algebraic Single-Source DSO with $o(n^2)$ space that achieves a better performance than any all-pairs DSO. It is also the first space-efficient Single-Source DSO for graphs with small integer weights.

We further study lower bounds for Single-Source DSOs. Note that given an oracle whose preprocessing time is P and query time is Q , one can solve the SSRP problem in time $P + n^2 \cdot Q$ by building the DSO and running the queries (t, e) for every $t \in V, e \in E(T_s)$. Therefore, if $n^2 \cdot Q = O(P)$, the $mn^{1/2-o(1)} + \Omega(n^2)$ conditional⁴ time-lower bound for the SSRP problem [10], obtained by a reduction from BMM, implies the same lower bound for P . The preprocessing of our combinatorial oracle in Theorem 3 is thus nearly optimal. We further investigate how much a Single-Source DSO can be compressed. In contrast to [10], we obtain an *unconditional* space-lower bound using an argument from information theory.

► **Theorem 4.** *Any Single-Source DSO must take $\Omega(\min\{M^{1/2}n^{3/2}, n^2\})$ bits of space on at least one $O(n)$ -vertex graph with integer edge weights in the range $[1, M]$.*

A small gap remains between Theorems 2 and 4 as the space is bounded at $\Omega(M^{1/2}n^{3/2})$ bits, while the oracle takes this many machine words. Nevertheless, it shows that on dense graphs our Single-Source DSOs in Theorem 3 have near-optimal space.

The Single-Source DSOs presented above all have $\Omega(n^2)$ preprocessing time, which cannot be avoided for graphs with $m = \Omega(n^{3/2})$, assuming the BMM conjecture. SSRP algorithms require $\Omega(n^2)$ time simply to output the solution. It is not clear whether this lower bound also applies to Single-Source DSO on sparse graphs. We partially answer this question negatively by developing a truly subquadratic, randomized Single-Source DSO in Section 6. We use new algorithmic techniques and structural properties of independent interest.

► **Theorem 5.** *There is a randomized Single-Source DSO taking $O(M^{1/2}n^{3/2})$ space that has $\tilde{O}(1)$ query time w.h.p.⁵ The oracle also reports a replacement path in $\tilde{O}(1)$ time per edge w.h.p. On graphs with $m = O(M^{3/4}n^{7/4})$ edges, the preprocessing time is $\tilde{O}(M^{7/8}m^{1/2}n^{11/8})$. If the graph is sparse, meaning $m = O(n^{5/4-\varepsilon}/M^{7/4})$ for any $\varepsilon > 0$, this is $\tilde{O}(n^{2-\varepsilon/2})$.*

1.2 Comparison with Previous Work

Table 1 shows a comparison of the most efficient Distance Sensitivity Oracles in their respective setting, as well as the results presented in this work. We distinguish four dimensions of different problem types.

⁴ The $\Omega(n^2)$ term is unconditional and stems from the size of the output, see [10].

⁵ An event occurs *with high probability* (w.h.p.) if it has probability at least $1 - n^{-c}$ for some $c > 0$.

■ **Table 1** Comparison of results. [†]The preprocessing time is for graphs with $m = O(M^{3/4}n^{7/4})$.

1. Randomized (R) vs. deterministic (D),
2. Combinatorial (C) vs. algebraic (A),
3. Unweighted (U) vs. real weights (W) vs. integer weights in $[1, M]$ (I),
4. All-Pairs (Ap) vs. single-source (Ss).

Our deterministic, combinatorial Single-Source DSO from Theorem 3 has near-optimal space, preprocessing and query time for dense graphs. It improves the preprocessing time of the randomized DSOs by Bernstein and Karger [6], Bilò et al. [7], and Gupta and Singh [22] by a factor of $O(\sqrt{n})$. When viewing the randomized SSRP algorithm of Chechik and Cohen as an oracle, our solution has the same preprocessing time but reduces the space requirement, by an near-optimal factor of $O(n^{1/3})$ while increasing the query time to only $\tilde{O}(1)$.

Our algebraic combinatorial Single-Source DSO from Theorem 3 has near-optimal space and query time for dense graphs, its preprocessing time improves over the randomized, algebraic DSOs of Chechik and Cohen [11], Ren [30, 31], as well as Gu and Ren [19] by a factor of $\tilde{O}(n^{2.5794-\omega})$. It has the same preprocessing time as the SSRP algorithm by Grandoni and Vassilevska Williams [18], but compresses the output to $O(M^{1/2}n^{3/2})$ space.

Our Single-Source DSO from Lemma 10 even achieves constant query time at the expense of larger $O(n^{5/3})$ (respectively, $O(M^{1/3}n^{5/3})$) space. All of our oracles can handle vertex failures and are path-reporting, the query time then corresponds to the time needed per edge of the replacement path. In Theorem 5, we also obtain Single-Source DSO with subquadratic preprocessing time for sparse graphs.

1.3 Techniques

Multi-stage derandomization. To derandomize the SSRP algorithms, we extend the techniques by Alon, Chechik, and Cohen [3] to identify a small set of critical paths we need to hit. In [3], a single set of paths was sufficient, we extend this to a hierarchical multi-stage framework. The set of paths in each stage depends on the hitting set found in the previous ones. For example, a replacement path from s to t avoiding the edge e decomposes into two shortest paths $P(s, q)$ and $P(q, t)$ in the original graph for some unknown vertex q , see [1]. It is straightforward to hit all of the components $P(s, q)$. We then use this hitting set in a more involved way to find sets of vertices that also intersect all of the subpaths $P(q, t)$.

Versatile compression. The key observation of our reduction to SSRP is that any shortest s - t -path can be partitioned into $O(\sqrt{Mn})$ segments such that all edges in a segment have the same replacement distance. Gupta and Singh [22] proved this for unweighted graphs. However, it is not obvious how to generalize their approach to the weighted case. We give a simpler proof in the presence of small integer weights, which immediately transfers also to vertex failures. We further show how to extend this to multiple targets and even reuse it to obtain the subquadratic algorithm on sparse graphs. In [22], a randomized oracle was presented that internally uses the rather complicated data structures of Demetrescu et al. [14]. We instead give a deterministic construction implementable with only a few arrays. Unfortunately, the compression scheme crucially depends on the graph being undirected.

Advanced search for replacement paths. The randomized algorithm building the DSO in subquadratic time for sparse graphs needs to find the $O(\sqrt{Mn})$ segments partitioning the s - t -path. Naively, this takes $O(n)$ time per target vertex t as we need to explore the whole path for potential segment endpoints and do not know the corresponding replacement paths in advance. We use standard random sampling to hit all such replacements paths with only a few vertices and exploit the path's monotonicity properties to develop more advanced search techniques. This reduces the time needed per target to $O(n^{1-\varepsilon})$, after some preprocessing. The analysis uses the fact that entire subpaths can be discarded without exploration.

Open problems. Our compression scheme and the randomized, subquadratic Single-Source DSO on sparse graphs can also handle vertex failures rather than only edge failures. It remains an open question whether one can obtain efficient deterministic SSRP algorithms in the vertex-failure scenario. If an analog of Theorem 1 held for vertex failures, then Theorem 2 would directly transfer the extension also to the DSOs of Theorem 3. Another interesting open question is whether there is a Single-Source DSO with deterministic, truly subquadratic time preprocessing on graphs with $m = O(n^{3/2-\varepsilon})$ edges. Can one obtain better Single-Source DSOs, and prove matching lower bounds, for sparse graphs?

2 Preliminaries

We let $G = (V, E, w)$ denote the undirected, edge-weighted base graph on n vertices and m edges, and tacitly assume $m \geq n$. The weights $w(e)$, $e \in E$, are integers in $[1, M]$ with $M = \text{poly}(n)$. For an undirected, weighted graph H , we denote by $V(H)$ the set of its vertices, and by $E(H)$ edge set of its edges. We write $e \in H$ for $e \in E(H)$ and $v \in H$ for $v \in V(H)$. Let P be a simple path in H . The *length* or *weight* $w(P)$ of P is $\sum_{e \in E(P)} w(e)$. For $u, v \in V(H)$, we denote by $P_H(u, v)$ a shortest path (one of minimum weight) from u to v . If a particular shortest path is intended, this will be made clear from the context. The *distance* of u and v is $d_H(u, v) = w(P_H(u, v))$. We drop the subscript when talking about the base graph G . The restriction on the maximum weight M allows us to store any graph distance in a single machine word on $O(\log n)$ bits. Unless explicitly stated otherwise, we measure space complexity in the number of words.

Let $x, y \in V(P)$ be two vertices on the simple path P . We denote by $P[x..y]$ the subpath of P from x to y . Let $P_1 = (u_1, \dots, u_i)$ and $P_2 = (v_1, \dots, v_j)$ be two paths in H . Their *concatenation* is $P_1 \circ P_2 = (u_1, \dots, u_i, v_1, \dots, v_j)$, provided that $u_i = v_1$ or $\{u_i, v_1\} \in E(H)$.

Fix some *source vertex* $s \in V$ in the base graph G . For any *target vertex* $t \in V$ and edge $e \in E$, we let $P(s, t, e)$ denote a *replacement path* for e , that is, a shortest path from s to t in G that does not use the edge e . Its weight $d(s, t, e) = w(P(s, t, e))$ is the *replacement*

distance. Given a specific shortest path $P(s, t)$ in G and a replacement path $P(s, t, e)$, we can assume w.l.o.g. that the latter is composed of the *common prefix* that it shares with $P(s, t)$, the *detour* part which is edge-disjoint from $P(s, t)$, and the *common suffix* after $P(s, t, e)$ remerges with $P(s, t)$. All statements apply to vertex failures as well.

3 Using SSRP to Build Single-Source DSOs

In this section, we prove Theorem 2. We describe how to deterministically reduce the task of building a Single-Source DSO to computing the replacement distances in the SSRP problem. Recall that we assume we are given a shortest path tree T_s of the base graph G rooted in the source s . This does not lose generality as we could as well compute it in time $O(m)$ via Thorup's algorithm [33]. However, the tree T_s focuses our attention to the $O(n^2)$ *relevant* replacement distances in G . The failure of an edge e can only increase the distance from s to some target t if e lies on the s - t -path $P(s, t)$ in T_s . Given a query (e, t) , we can thus check whether e is relevant for t in $O(1)$ time using a lowest common ancestor (LCA) data structure of size $O(n)$ [4]. If the maximum weight M is larger than n , we are done as we store the relevant replacement distances, original graph distances, and the LCA data structure.

However, for $M \leq n$, there are more space-efficient solutions. Using time $O(n^2)$, that is, linear in the number of relevant distances, we compress the space needed to store them down to $O(M^{1/2} n^{3/2})$ while increasing the query time only to $\tilde{O}(1)$. This scheme also allows several extensions, namely, handling vertex failures, reporting fault-tolerant shortest path trees, or retaining constant query time by using slightly more space. We first give an overview of the reduction. Suppose we have a set of *pivots* $D \subseteq V$ such that any s - t -path $P(s, t)$ in T_s has at least one element of D among its last \sqrt{n} vertices. For a target t , let x be the pivot on $P(s, t)$ that is closest to t . We distinguish three cases depending on the failing edge e .

- **Near case.** The edge e belongs to the near case if it is on the subpath $P(s, t)[x..t]$ from the last pivot to the target. We construct a data structure to quickly identify those edges. It is then enough to store the associated replacement distances explicitly.
- **Far case I.** The edge e belongs to the far case I if it is on the subpath $P(s, t)[s..x]$ and there is a replacement path for e that uses the vertex x . We handle this by storing a linear number of distances for every pivot in D .
- **Far case II.** We are left with edges e on $P(s, t)[s..x]$ for which no replacement path uses x . We show that there are only $O(M^{1/2} n^{3/2})$ many different replacement distances of this kind. We can find the correct distance in $\tilde{O}(1)$. This is the only case with a quadratic running time, space requirements depending on M , and a super-constant query time. We also show how to avoid the latter at the expense of a higher space complexity.

Near case. We first describe how to obtain the set D . We also take D to denote a representing data structure. That is, for all $t \in V$, $D[t]$ shall denote the last pivot on the path $P(s, t)$ in T_s . A deterministic greedy algorithm efficiently computes a small sets D .

► **Lemma 6.** *There exists a set $D \subseteq V$ with $|D| \leq \sqrt{n}$, computable in time $\tilde{O}(n)$, such that every s - t -path in T_s contains a pivot in D among its last \sqrt{n} vertices. In the same time, we can compute a data structure taking $O(n)$ space that returns $D[t]$ in constant time.*

Let $x = D[t]$ be the pivot assigned to t . An edge e belongs to the *near case* with respect to t if it lies on $P(x, t) = P(s, t)[x..t]$. Observe that $P(x, t)$ has less than \sqrt{n} edges. We store $d(s, t, e)$ for the near case in an array with (t, e) as key. With access to the distances, the array can be computed in $O(n^{3/2})$ total time and space. Consider a query (t, e) such that e has already been determined above to be on the path $P(s, t)$. The edge $e = \{u, v\}$ thus belongs to the near case iff $D[u] = D[v] = x$. If so, we look up $d(s, t, e)$ in the array.

Far case I. We say a query (t, e) belongs to the *far case* if e is on the subpath $P(s, x) = P(s, t)[s..x]$. These are the queries not yet handled by the process above. Note that $d(s, t, e) \leq d(s, x, e) + d(x, t)$ holds for all queries in the far case. If a replacement path $P(s, x, e)$ exists, $P(s, x, e) \circ P(s, t)[x..t]$ is some s - t -path that avoids e whose length is the right-hand side; otherwise, we have $d(s, x, e) = \infty$ and $d(s, t, e) \leq d(s, x, e) + d(x, t)$ holds vacuously. We split the far case depending on the existence of certain replacement paths. Recall that we can assume that any replacement path consists of a common pre- and suffix with the original path $P(s, t)$ and a detour that is edge-disjoint from $P(s, t)$. We let (t, e) belong to the *far case I* if e is on $P(s, x)$ and there is a replacement path $P(s, t, e)$ that uses the vertex x . It is readily checked that for a query in the far case this holds iff $d(s, t, e) = d(s, x, e) + d(x, t)$. Otherwise, that is, if no replacement path $P(s, t, e)$ uses x or, equivalently, $d(s, t, e) < d(s, x, e) + d(x, t)$, the query is said to be in the *far case II*.

It takes too much space to store the replacement distances for all edges in the far case, or memorize which edge falls in which subcase. Instead, we build two small data structures and, at query time, compute two (potentially different) distances. We show that always the smaller one is correct, which we return as the final answer. First, for every pivot $x \in D$ and edge $e \in P(s, x)$, we store the replacement distance $d(s, x, e)$. Since $|D| \leq \sqrt{n}$ and $|E(P(s, x))| \leq n$, we can do so in $O(n^{3/2})$ time and space. Given a query (t, e) in the far case, we access the storage corresponding to $D[t] = x$, retrieve $d(s, x, e)$, and add $d(x, t) = d(s, t) - d(s, x)$. This gives the first candidate distance. It may overestimate $d(s, t, e)$, namely, if e belongs to the far case II.

Far case II. This case is more involved than the previous. We make extensive use of what we call break points. Let e_1, \dots, e_k be the edges of $P(s, t)[s..x]$ in the far case II (w.r.t. t) in increasing distance from s . We then have $d(s, t, e_1) \geq \dots \geq d(s, t, e_k)$. This is due to the fact that any replacement path $P(s, t, e_i)$ avoids the whole subpath starting with e_i and ending in x . Its length is thus at least the replacement distance for any $e_j, j \geq i$. Let u_i be vertex of e_i that is closer to s . We say u_i is a *break point* if $d(s, t, e_i) > d(s, t, e_{i+1})$. A break point is the beginning of a segment in which the edges in the far case II have equal replacement distance. We show that there are only $O(\sqrt{Mn})$ break points/replacement distances.

For the analysis, we let the edges choose a *representative* replacement path. They do so one after another in the above order. Edge e_i first checks whether one of its replacement paths has previously been selected by an earlier edge $e_h, h < i$. If so, it takes the same one; otherwise, it chooses a possible replacement path arbitrarily. Let \mathcal{R} denote the set of representatives and let $R \in \mathcal{R}$. We define z_R to be the first vertex on the detour part of R . The vertices $z_R, R \in \mathcal{R}$, are also important for the subquadratic algorithm in Section 6.

► **Lemma 7.** *Edges e_i and e_j that belong to the far case II choose the same representative iff $d(s, t, e_i) = d(s, t, e_j)$. All representatives have different lengths and $|\mathcal{R}|$ equals the number of break points. Let $R, R' \in \mathcal{R}$ be such that R' is the next shorter representative after R . We have $d(s, z_R) < d(s, z_{R'})$ and all edges represented by R lie on the subpath $P(s, t)[z_R..z_{R'}]$. There is exactly one break point on $P(s, t)[z_R..z_{R'}]$, the one corresponding to length $w(R)$.*

Proof. Edges with different replacement distances have disjoint sets of replacement paths to choose from. Now suppose the replacement distances $d(s, t, e_i) = d(s, t, e_j)$ are equal. Without loosing generality, the edge $e_j, j \geq i$, is further away from s and selects its representative after e_i . The representative replacement path R for edge e_i also avoids e_j since it does not remerge with $P(s, t)$ prior to pivot x . As the distances $d(s, t, e_j) = d(s, t, e_i) = w(R)$ are the same, R is in fact a replacement path for e_j and is selected again as representative. The assertions of the different lengths and the total number of representatives easily follow.

Let $R \in \mathcal{R}$ be a representative replacement path. The first vertex z_R of its detour part must be closer to s than all edges it represents as R avoids them. Let e^* be the edge closest to s that belongs to the far case II and is represented by R . The break point u^* starting the segment with replacement distance $w(R)$ is thus the vertex of e^* that is closer to s .

Let now $R' \in \mathcal{R}$ be the next shorter representative after R . If we had $d(s, z_{R'}) \geq d(s, z_R)$, then R' would be a path that avoids e^* and has length $w(R') < w(R) = d(s, t, e^*)$ strictly smaller than the replacement distance, a contradiction. Reusing the same arguments as before, we also get that the break point corresponding to $w(R')$ lies after $z_{R'}$ and that the break point $u^* \in e^*$ cannot lie below $z_{R'}$ (on subpath $P(s, t)[z_{R'}..t]$). In summary, the subpath $P(s, t)[z_R..z_{R'}]$ contains exactly one break point, namely, u^* . ◀

It is left to prove that $|\mathcal{R}| = O(\sqrt{Mn})$. The following lemma is the heart of our compression scheme. It simplifies and thereby generalizes a result by Gupta and Singh [22] for unweighted undirected graphs. The argument we use is versatile enough to not only cover integer-weighted graphs, it extends to vertex failures as well (Lemma 9). A similar idea also allows us to design an oracle with constant query time (Lemma 10) and the subquadratic preprocessing algorithm on sparse graphs (Theorem 5). Unfortunately, the argument crucially depends on the graph being undirected. New techniques are needed to compress the fault-tolerant distance information in directed graphs.

▶ **Lemma 8.** *The number of representatives for edges on $P(s, t)$ is $|\mathcal{R}| \leq 3\sqrt{Mn}$.*

Proof. All representatives are of different length by Lemma 7. Also, they have length at least $d(s, t)$, the weight of the original s - t -path P . Hence, there are only $2\sqrt{Mn}$ many of length at most $d(s, t) + 2\sqrt{Mn}$. We now bound the number of *long* representatives, which are strictly longer than that. Let R be a long representative. Its detour part is longer than $2\sqrt{Mn}$, whence it must span at least $2\sqrt{n/M}$ vertices. Consider the path on the first $\sqrt{n/M}$ vertices of the detour starting in z_R , we call it Stub_R . If Stub_R does not intersect with $\text{Stub}_{R'}$ for any other long $R' \in \mathcal{R}$, $R' \neq R$, there can only be $n/(\sqrt{n/M}) = \sqrt{Mn}$ stubs in total and thus as many long representatives.

To reach a contradiction, assume the stubs of R and R' intersect. Let e be an edge represented by R and $y \in V(\text{Stub}_R) \cap V(\text{Stub}_{R'})$ a vertex on both stubs. W.l.o.g. R' is strictly shorter than R and thus $z_{R'}$ comes behind z_R on the path P and e is on $P[z_R..z_{R'}]$ (Lemma 7). Note that $w(\text{Stub}_R), w(\text{Stub}_{R'}) \leq \sqrt{Mn}$. Therefore, the path $P^* = P[s..z_R] \circ R[z_R..y] \circ R'[y..z_{R'}] \circ P[z_{R'}..t]$ avoids e and has length $w(P^*) \leq d(s, t) + w(R[z_R..y]) + w(R'[y..z_{R'}]) \leq d(s, t) + 2\sqrt{Mn} < w(R)$. This is a contradiction to R being the representative of e . ◀

Observe how the argument in the proof above depends on the fact that we can traverse the segment $R'[z_{R'}..y] \subseteq \text{Stub}_{R'}$ in both directions. When following R' from s to t , we visit $z_{R'}$ prior to y , while for P^* it is the other way around. This is not necessarily true in a directed graph. Indeed, one can construct examples that have a directed path on $\Omega(n)$ edges in which each of them has its own replacement distance.

With access to the replacement distances, all break points can be revealed by a linear scan of the path $P(s, t)$ in time $O(n)$. Let $z_{i_1}, \dots, z_{i_{|\mathcal{R}|}}$ be the break points ordered by increasing distance to the source s and $e_{i_1}, \dots, e_{i_{|\mathcal{R}|}}$ the corresponding edges. For the data structure, we compute an ordered array of the original distances $d(s, z_{i_1}) < \dots < d(s, z_{i_{|\mathcal{R}|}})$ associated with the replacement distances $d(s, t, e_{i_j})$, taking $O(\sqrt{Mn})$ space. Let (e, t) be a query with $e = \{u, v\}$. We compute the index $j = \arg \max_{1 \leq k \leq |\mathcal{R}|} \{d(s, z_{i_k}) \leq d(s, u)\}$, with a binary search on the array in $O(\log n)$ time and retrieve $d(s, t, e_{i_j})$ as the second candidate distance.

The edge e lies on the subpath $P(s, t)[z_{i_j}..z_{i_{j+1}}]$ (respectively, on $P(s, t)[z_{i_{|\mathcal{R}|}}..x]$ if $j = |\mathcal{R}|$). It thus has replacement distance *at most* $d(s, t, e_{i_j})$. If e belongs to the far case II, the second candidate distance is exact and (strictly) smaller than the first one $d(s, x, e) + d(x, t)$; otherwise, the first candidate is smaller (or equal) and correct.

Scaling this solution to all targets $t \in V$ gives a total space requirement of $O(M^{1/2}n^{3/2})$. However, the preprocessing time is $O(n^2)$, dominated by the linear scans for each target.

3.1 Extensions

There are several possible extensions for our Single-Source DSO. While the transfer to vertex failures comes for free, reducing the query time to a constant, making the oracle path-reporting, or returning the whole fault-tolerant shortest path tree incurs additional costs of a higher space requirement or preprocessing time, respectively. We still assume the setting of Theorem 2, i.e., oracle access to the replacement distances for failing edges/vertices.

Vertex failures. The solutions for the near case, and far case I hold verbatim also for vertex failures. A vertex on the path $P(s, t)[s..x]$, except s itself, belongs to the *far case II* iff it satisfies $d(s, t, v) < d(s, t, x) + d(x, t)$. Let \mathcal{R}_V be the sets of representatives, now chosen by the *vertices*. The advantage of the proof of Lemma 8 is that it easily transfers to vertex failures. While the stubs of the detours may no longer be unique, they now intersect at most one other stub and identify *pairs* of representatives.

► **Lemma 9.** *The number of representatives for vertices on $P(s, t)$ is $|\mathcal{R}_V| \leq 5\sqrt{Mn}$.*

Constant query time. If we could query the break point of an edge in the far case II in $O(1)$ time, our Single-Source DSO had a constant overall query time. However, since the break points also depend on the target t , hard-coding them would yield a $O(n^2)$ space solution, which is wasteful for $M = o(n)$. Instead, we improve the analysis in Lemma 8. It hardly made any use of the fact that the pivot x is among the last \sqrt{n} vertices on the s - t -path in T_s and considered only a single target. We now strike a balance between selecting more pivots and grouping targets with the same assigned pivot together.

► **Lemma 10.** *There is an algorithm that, when given oracle access to the replacement distances for failing edges (vertices), preprocesses in $O(n^2)$ time a Single-Source DSO for edge (vertex) failures taking $O(\min\{M^{1/3}n^{5/3}, n^2\})$ space and having constant query time.*

Path-reporting oracles. We can adapt our Single-Source DSOs to also report the replacement paths using the same space. However, to do so it is not enough to have access to the replacement distances as the paths depend on the structure of G . Also, making the oracle path-reporting increases in preprocessing time, which now also depends on m .

► **Lemma 11.** *With access to G , there is a path-reporting Single-Source DSO for edge (vertex) failures with $O(\min\{m\sqrt{Mn}, mn\} + n^2)$ preprocessing time and either $O(\min\{M^{1/2}n^{3/2}, n^2\})$ space and $\tilde{O}(1)$ query time per edge, or $O(\min\{M^{1/3}n^{5/3}, n^2\})$ space and $O(1)$ query time.*

Fault-tolerant shortest path tree oracles. We are going one step further in the direction of fault-tolerant subgraphs, see for example [8, 29]. We enable our oracle to report, for any failing edge or vertex, the whole fault-tolerant single-source shortest path tree. Compared to the path-reporting version, we make sure to return every tree edge only once.

► **Lemma 12.** *With access to G , there is a data structure with $O(\min\{m\sqrt{Mn}, mn\} + n^2)$ preprocessing time, taking $O(\min\{M^{1/2}n^{3/2}, n^2\})$ space that, upon query $e \in E$ (respectively, $v \in V$), returns a shortest path tree for $G - e$ (respectively, $G - v$) rooted in s in time $O(n)$.*

4 Space Lower Bound

We now present an information-theoretic lower bound showing that the space of the Single-Source DSO resulting from our reduction is optimal up to the word size.

► **Theorem 4.** *Any Single-Source DSO must take $\Omega(\min\{M^{1/2}n^{3/2}, n^2\})$ bits of space on at least one $O(n)$ -vertex graph with integer edge weights in the range $[1, M]$.*

Proof. Let $M' = \min\{M, n\}$. We give an incompressibility argument in that we show that one can store any binary $n \times n$ matrix X across $\sqrt{n/M'}$ Single-Source DSOs. Not all of them can use only $o(\sqrt{M'}n^{3/2})$ bits of space as otherwise this would compress X to $o(n^2)$ bits. We create graphs $G_1, G_2, \dots, G_{\sqrt{n/M'}}$. Each of them has $O(n)$ vertices and maximum edge weight M . The graph G_k will be used to store the $\sqrt{M'n}$ rows of X with indices from $(k-1)\sqrt{M'n} + 1$ to $k\sqrt{M'n}$.

We first describe the parts that are common to all of the G_k . Let $A = \{a_1, \dots, a_n\}$ and $B = \{b_1, \dots, b_n\}$ be two sets of n vertices each, we connect a_i and b_j by an edge of weight 1 iff $X[i, j] = 1$. There are no other edges between A and B . We also add a path $P = (v_1, \dots, v_{\sqrt{M'n}})$ all of whose edges have weight 1. The vertex $s = v_{\sqrt{M'n}}$ is the source in each graph. Also, let $\{v_0, v_1\}$ be an edge of weight M , it serves to raise the maximum edge weight to M , if needed. Specifically in G_k and for each $1 \leq i \leq \sqrt{M'n}$, we connect the vertex v_i with $a_{(k-1)\sqrt{M'n}+i}$ by a path $P_{k,i}$ of total weight $2i - 1$. Due to the edge weights, we can make the path $P_{k,i}$ so that it uses at most $2i/M'$ edges and thus so many new vertices. In total, G_k has at most $2n + (\sqrt{M'n} + 1) + \sum_{i=1}^{\sqrt{M'n}} \frac{2i}{M'} = O(n)$ vertices due to $M' \leq n$.

Let e_i denote the edge $\{v_{i-1}, v_i\}$ on P . We claim that $X[(k-1)\sqrt{M'n} + i, j] = 1$ if and only if the replacement distance in G_k is $d_{G_k}(v_{\sqrt{M'n}}, b_j, e_i) = \sqrt{M'n} + i$. We assume $k = 1$, larger k follow in the same fashion. Observe that one has to go through a vertex in $A' = \{a_i, a_{i+1}, \dots, a_{\sqrt{M'n}}\}$ to reach b_j from the source $s = v_{\sqrt{M'n}}$. Conversely, A' is the only part of A that is reachable from s in $G_1 - e_i$ without using any vertex of B .

If there is no replacement path from s to b_j avoiding e_i , we have $d_{G_1}(s, b_j, e_i) = \infty$ and $X[i', j] = 0$ for all $i \leq i' \leq \sqrt{M'n}$, as desired. Let thus $P(s, b_j, e_i)$ be a replacement path and further a_{i^*} its first vertex that is in A (the one closest to the source s). Therefore, $i^* \geq i$ and $P(s, b_j, e_i)$ has the form $(v_{\sqrt{M'n}}, \dots, v_{i^*}) \circ P_{1,i^*} \circ P'$ for some a_{i^*} - b_j -path P' . It holds that $d_{G_1}(v_{\sqrt{M'n}}, b_j, e_i) = (\sqrt{M'n} - i^*) + (2i^* - 1) + w(P') = \sqrt{M'n} + i^* - 1 + w(P') \geq \sqrt{M'n} + i$. Equality holds only if $i^* = i$ and $w(P) = 1$, thus a_i must be a neighbor of b_j and $X[i, j] = 1$ follows; otherwise, the replacement distance is strictly larger. ◀

5 Derandomizing Single-Source Replacement Paths Algorithms

In this section, we derandomize the combinatorial $\tilde{O}(m\sqrt{n} + n^2)$ time algorithm for SSRP of Chechik and Cohen [10] obtaining the same asymptotic running time. In the full version, we also derandomize the algebraic SSRP algorithm of Grandoni and Vassilevska Williams. When combined with the reduction of Section 3, they give deterministic Single-Source DSOs.

Suppose the base graph $G = (V, E)$ is unweighted. It follows from a result by Afek et al. [1, Theorem 1] that for every target $t \in V$, edge $e \in E$, and replacement path $P(s, t, e)$ in $G - e$, there exists a vertex q on $P(s, t, e)$ such that both subpaths $P(s, t, e)[s..q]$ and $P(s, t, e)[q..t]$

are shortest paths in the original graph G . Computing the vertex q directly for each pair (t, e) is too expensive. Instead, the algorithm in [10] employs a random hitting set for the subpaths. The only randomization used in [10] is to sample every vertex independently with probability $O((\log n)/\sqrt{n})$ to create a set $B \subseteq V$ of so-called *pivots*. The set B contains $\tilde{O}(\sqrt{n})$ such pivots w.h.p. The correctness of the algorithm relies on the following important property. With high probability, there exists a vertex $x \in B \cup \{s\}$ before q on $P(s, t, e)$ and a vertex $y \in B \cup \{t\}$ after q such that the subpath of $P(s, t, e)[x..y]$ has length only $\tilde{O}(\sqrt{n})$. Here, we describe how to compute the set B deterministically with the same properties. We defer the proof of correctness of the algorithm to the full version.

We derandomize the vertex selection using an approach similar to the one of Alon, Chechik, and Cohen [3]. Given paths D_1, \dots, D_k , where each contains at least L vertices, the folklore greedy algorithm constructs a hitting set of size $\tilde{O}(n/L)$, by iteratively covering the maximum number of unhit paths, in $\tilde{O}(kL)$ time. The challenge is to quickly compute a suitable set of paths. We construct three systems of path \mathcal{L}_1 , \mathcal{L}_2 , and \mathcal{L}_3 to obtain B .

We prepare some notation. For a rooted tree T , a vertex $v \in V(T)$, and an integer parameter $L \geq 0$, let $\text{Last}_{T,L}(v)$ be the subpath containing the last L edges of the path in the tree T from the root to v , or the whole path if it has length less than L . Let $|\text{Last}_{T,L}(v)|$ denote the number of edges on the path.

- **Paths \mathcal{L}_1 and hitting set B_1 .** Set \mathcal{L}_1 contains the last $\sqrt{n}/2$ edges of every path in T_s , $\mathcal{L}_1 = \{\text{Last}_{T_s, \sqrt{n}/2}(v) \mid v \in V, |\text{Last}_{T_s, \sqrt{n}/2}(v)| = \sqrt{n}/2\}$. As an alternative, we can also use Lemma 6 to compute in $\tilde{O}(n)$ time a deterministic hitting set B_1 for \mathcal{L}_1 of size $2\sqrt{n}$.
- **Paths \mathcal{L}_2 and hitting set B_2 .** We run a breadth-first search from every vertex $x \in B_1$ to compute the shortest paths trees T_x rooted in x , and define the second set to be $\mathcal{L}_2 = \{\text{Last}_{T_x, \sqrt{n}/2}(y) \mid x \in B_1, y \in V, |\text{Last}_{T_x, \sqrt{n}/2}(y)| = \sqrt{n}/2\}$. Greedy selection computes a hitting set B_2 for \mathcal{L}_2 of size $\tilde{O}(\sqrt{n})$ in total time $\tilde{O}(n^2)$.

Before we can define \mathcal{L}_3 , we need additional notation. Let $e = \{u, v\}$ be an edge in T_s such that u is closer to s than v and let $T_{s,v}$ be the subtree of T_s rooted in v . Let further $G_e = (V_e, E_e, w_e)$ be a weighted graph such that V_e contains s and the vertices $x \in V(T_{s,v})$ with $d(s, x) \leq d(s, v) + 4\sqrt{n}$. The edges of G_e that are inside of $T_{s,v}$ are the same as in G , and additionally every shortest path $P(s, x)$ from s to every vertex $x \in V_e$ such that $P(s, x)$ passes only through vertices outside of V_e (except for its first vertex s and its last vertex $x \in V_e$) is replaced with a shortcut edge (s, x) whose weight is equal to the length $d(s, x)$ of the corresponding shortest path $P(s, x)$, preserving the original paths distances (using weights). The SSRP algorithm in [10] computes Dijkstra's algorithm from s in each G_e . We let T_{G_e} denote the resulting shortest path tree.

- **Paths \mathcal{L}_3 and hitting set B_3 .** The third set $\mathcal{L}_3 := \{\text{Last}_{T_{G_e}, \sqrt{n}/2}(x) \mid x \in V, e \in E(T_s), |\text{Last}_{T_{G_e}, \sqrt{n}/2}(x)| = \sqrt{n}/2\}$ contains $O(n^{3/2})$ paths as every vertex $x \in V$ belongs to at most $4\sqrt{n}$ graphs G_e . We thus get a hitting set B_3 of size $\tilde{O}(\sqrt{n})$ in time $\tilde{O}(n^2)$. The deterministic set $B = B_1 \cup B_2 \cup B_3$ can then be used as pivots in the SSRP algorithm.

6 Subquadratic Preprocessing on Sparse Graphs

Finally, we show how to obtain a Single-Source DSO with subquadratic preprocessing at least on sparse graphs. In order to prove Theorem 5, we present an algorithm running in time $\tilde{O}(M^{7/8} m^{1/2} n^{11/8} + \frac{M^{1/8} m^{3/2}}{n^{3/8}})$. If $m = O(M^{3/4} n^{7/4})$, then the dominating term is $\tilde{O}(M^{7/8} m^{1/2} n^{11/8})$. If the graph even satisfies $m = O(n^{5/4-\varepsilon}/M^{7/4})$ for any $\varepsilon > 0$, then

the preprocessing time is $\tilde{O}(n^{2-\varepsilon/2})$. We explain the main part of the randomized algorithm that allows us to design the Single-Source DSO. The algorithm is easily adaptable to deal with vertex failures as well. The proofs and some of the technical details are deferred to the full version due to the lack of space. In the following, we assume that the graph is indeed sparse, that is, $m = O(n^{5/4-\varepsilon}/M^{7/4})$. The next sampling lemma is folklore, see e.g. [18, 32].

► **Lemma 13.** *Let H be a graph with n vertices, $c > 0$ a positive constant, and L such that $L \geq c \ln n$. Define a random set $R \subseteq V$ by sampling each vertex to be in R independently with probability $(c \ln n)/L$. Then, with probability at least $1 - \frac{1}{n^c}$, the size of R is $\tilde{O}(n/L)$. Let further \mathcal{P} be a set of ℓ simple paths in H , each of which spans at least L vertices. Then, with probability at least $1 - \frac{\ell}{n^c}$, we have $V(P) \cap R \neq \emptyset$ for every $P \in \mathcal{P}$.*

We employ random sampling to hit one shortest path on at least $L = \frac{n^{11/8}}{M^{1/8} m^{1/2}}$ edges for every pair of vertices. Any vertex is included in the set R of *random pivots* independently with a probability of $(3 \ln n)/L$. We also include the source s in R to hit all short s - t -paths. By Lemma 13, we have $|R| = \tilde{O}(n/L) = \tilde{O}(\frac{M^{1/8} m^{1/2}}{n^{3/8}})$ w.h.p. Randomization is used here since it takes too long to handle the $O(n^2)$ paths explicitly.

We additionally construct a set D of (possibly different, regular) *pivots* that are used to classify replacement paths into near case, far case I, and far case II similar to Section 3. The set D is computed deterministically using Lemma 6, where we select a pivot every \sqrt{n} levels. For a target vertex $t \neq s$, the *proper pivot* of t shall be that pivot $x \in D$ on the path $P(s, t)$ in T_s that is closest to t but satisfies $d(x, t) \geq 4ML$, or $x = s$ if there is no such pivot. We let $D_1[t]$ denote the proper pivot of t and $D_2[t] = D_1[D_1[t]]$, provided that $D_1[t] \neq s$.

For every random pivot $\chi \in R$ and every edge e on the path $P(s, \chi)$, we compute $d(s, \chi, e)$ in $\tilde{O}(m)$ time per pivot using the algorithm of Malik, Mittal, and Gupta [26]. In the same time bound, we also get the vertex of $P(s, \chi)$ at which $P(s, \chi, e)$ diverges and we assume that $P(s, \chi, e)$ represents the path that diverges from $P(s, \chi)$ at a vertex that is as close as possible to s .⁶ For each pivot $x \in D$ and every e on $P(s, x)$, we also compute $d(s, x, e)$. This takes total time $\tilde{O}(m(|D| + |R|)) = \tilde{O}(mn^{1/2} + \frac{M^{1/8} m^{3/2}}{n^{3/8}}) = \tilde{O}(\frac{m^{1/2} n^{9/8-\varepsilon/2}}{M^{7/8}} + \frac{M^{1/8} m^{3/2}}{n^{3/8}})$ and allows us to answer replacement distance queries in $O(1)$ time if the target is in $D \cup R$.

We are left to handle non-pivot targets. Fix a $t \in V \setminus (D \cup R)$ and let $x_1 = D_1[t]$, and $x_2 = D_2[t]$. We use similar cases as before.

- **Near case.** The edge e is on $P(s, t)[x_2..t] = P(x_2, t)$.
- **Far case I.** The edge e is on $P(s, t)[s..x_2] = P(s, x_2)$ and there is a replacement path $P(s, t, e)$ that passes through x_2 .
- **Far case II.** The edge e is on $P(s, x_2)$ and there is no replacement path $P(s, t, e)$ that passes through x_2 .

In the remainder, we show how to efficiently compute the replacement distances in the far case II as previously this was the only case with quadratic run time. The technical details of the near case are reported in full version. A shortest path tree of G and the replacement distances to targets in D are enough to handle the far case I, see Section 3.

Since in the far case II the pivot x_2 lies on $P(s, t)$, we can assume $P(s, t)$ to have length $d(s, t) \geq d(x_2, t) \geq 4ML$ and at least $4L$ edges. In the following, we use different indexing schemes pointing to objects and distances related to $P(s, t)$, all of them are ordered from the source s to pivot x_2 . First, we denote by R_1, \dots, R_k the k representative replacement paths

⁶ The replacement path $P(s, \chi, e)$ computed in [26] is obtained as the concatenation of a subpath $P(s, u)$ of T_s , an edge $\{u, v\}$ of $G - e$, and a subpath $P(v, \chi)$ in T_χ (the shortest paths tree of G rooted at χ).

for edges in the far case II. We have $k \leq 3\sqrt{Mn}$ by Lemma 8. Let the *distinguished* edge $e_\ell^* \in P(s, t)$ be the one that is closest to s such that R_ℓ represents e_ℓ^* , i.e., R_ℓ is a replacement path in $G - e_\ell^*$ and we fall in far case II. Set $d_\ell = w(R_\ell)$. As no replacement path from s to t for edge e_ℓ^* uses vertex x_2 , we have $d_\ell < d(s, x_2, e_\ell^*) + d(x_2, t)$. The distinguished edges e_1^*, \dots, e_k^* are ordered by increasing distance from s , this implies $d_1 > \dots > d_k$ for their replacement distances, see Section 3. Furthermore, let N be the number of *all* edges (of the far cases I and II) on the path $P(s, x_2) = (e_1, e_2, \dots, e_N)$, seen in order from s to x_2 . This way, we identify $P(s, x_2)$ with the interval $[1, N]$, an index $j \in [1, N]$ stands for the j -th edge e_j on $P(s, x_2)$. With a slight abuse of notation, we also say that $e_j \in [a, b]$ in case $j \in [a, b]$.

We employ the random pivots to efficiently compute all the k pairs (d_ℓ, e_ℓ^*) w.h.p. The key idea is that, for each failing edge e on $P(s, x_2)$, there exists w.h.p. a random pivot $\chi \in R$ such that $d(\chi, t) \leq ML$ and $d(s, t, e) = d(s, \chi, e) + d(\chi, t)$ simultaneously hold. To see this, recall that any replacement path $P(s, t, e)$ has at least $4L$ edges and let y be the vertex such that $P(s, t, e)[y..t]$ consists of the last L of them. We claim that $P(s, t, e)[y..t]$ is in fact a shortest path in G . Assume there were a shorter y - t -path, then it must contain e and have length at least $d(x_2, t) \geq 4ML$, a contradiction. Therefore, *some* shortest y - t -path in G has at least L edges and is thus hit by a random pivot χ w.h.p., which gives the equality. Any reference to high probability refers to this fact. We use it to design a recursive algorithm that finds the pairs (d_ℓ, e_ℓ^*) w.h.p. in time $O(|R|M^{3/4}n^{3/4}) = \tilde{O}(M^{7/8}m^{1/2}n^{3/8})$ per target.

Recall that we view $P(s, x_2)$ as $[1, N]$. When exploring a subinterval $[a, b]$, the algorithm searches for a pair (d_ℓ, e_ℓ^*) with a distinguished edge $e_\ell^* \in [a, b]$. The algorithm knows both an upper bound $\Delta_{[a, b]}$ and a lower bound $\delta_{[a, b]}$ on the admissible values for d_ℓ . More precisely, $\Delta_{[a, b]} + 1$ corresponds w.h.p. to the smallest possible value $d_{\ell'}$ such that $e_{\ell'}^* \in [1, a-1]$ (the lower the index, the higher is $d_{\ell'}$); similarly, $\delta_{[a, b]} - 1$ is the the largest possible value $d_{\ell'}$ for $e_{\ell'}^* \in [b+1, N]$. In the beginning, we set $\Delta_{[1, N]} = \infty$, $\delta_{[1, N]} = 0$ and the algorithm explores the entire interval $[1, N]$. It terminates when there are no more unexplored subintervals.

We now describe the search for d_ℓ with $e_\ell^* \in [a, b]$. We assume $a \leq b$ and $\delta_{[a, b]} \leq \Delta_{[a, b]}$ as otherwise no such pair exists. Set $\mu = \max_{j \in [a, b]} \{d(s, x_2, e_j) + d(x_2, t)\}$. The algorithm keeps searching in the interval only if $\mu > \delta_{[a, b]}$. Indeed, if $\mu \leq \delta_{[a, b]}$, we know for sure that such a pair does not exist as there must be a replacement path (of type far case I) that passes through vertex x_2 . We first compute the largest index $j \in [a, b]$ for which $\mu = d(s, x_2, e_j) + d(x_2, t)$. We do so by employing a range minimum query (RMQ) data structure to support such queries in constant time after an $O(N) = O(n)$ time preprocessing [4]. Observe that the same data structure can be reused for all the target vertices t' for which $D_2[t'] = x_2$. It is enough that it stores the values $d(s, x_2, e)$, instead of $d(s, x_2, e) + d(x_2, t)$. The former distances are independent of the considered target and we already computed them above. We use only $O(|D|)$ RMQ data structures, which we prepare in $O(n|D|) = O(n^{3/2})$ time.

In the following, we assume $\mu > \delta_{[a, b]}$. We select a candidate replacement path for e_j by choosing the shortest one that runs through a random pivot in $O(|R|)$ time via brute-force search in the data we computed above for the targets in R . Ties are broken in favor of the replacement path $P(s, \chi, e_j)$ that diverges from $P(s, x_2)$ at the vertex that is closest to s . Let $\delta = \min_{\chi \in R} \{d(s, \chi, e_j) + d(\chi, t)\}$ be the length of such a replacement path, w.h.p. it is the actual replacement distance $P(s, t, e_j)$. Let further χ_j be the minimizing random pivot, and z_j the vertex of $P(s, x_2)$ at which $P(s, \chi_j, e_j)$ diverges. We check whether $\delta < \mu$ and $\delta \leq \Delta_{[a, b]}$ holds. If either of the two conditions is violated, then there is no need to keep searching in the interval $[a, j]$, as shown in the next lemma. In this case, the algorithm makes a recursive call on the *lower* interval $[j+1, b]$ (the one with smaller replacement distances) by setting $\Delta_{[j+1, b]} = \Delta_{[a, b]}$ and $\delta_{[j+1, b]} = \delta_{[a, b]}$. We say that the search was *unsuccessful*.

► **Lemma 14.** *If $\delta \geq \mu$ or $\delta > \Delta_{[a,b]}$, then, w.h.p. we have $e_\ell^* \notin [a, j]$ for all $\ell \in [k]$.*

Suppose the search is *successful*, that is, $\delta < \mu$ and $\delta \leq \Delta_{[a,b]}$. We then use binary search techniques⁷ to compute in $O(\log n)$ time the smallest index $i \in [a, j]$ for which the edge e_i lies on the subpath $P(s, x_2)[z_j..x_2]$ and $\delta < d(s, x_2, e_i) + d(x_2, t)$ holds. The case $i = j$ is possible. The condition on e_i is such that $P(s, x_j, e_j)$ also avoids e_i , which implies $d(s, t, e_i) \leq \delta < d(s, x_2, e_i) + d(x_2, t)$. The edge e_i must belong to the far case II w.r.t. target t . We show that in fact (δ, e_i) is w.h.p. the sought pair with $e_\ell^* \in [a, j]$ and minimum d_ℓ .

► **Lemma 15.** *Let $\ell \in [k]$ be maximal such that $e_\ell^* \in [a, j]$. Then, w.h.p. $\delta = d_\ell$ and $e_i = e_\ell^*$.*

The algorithm outputs (δ, e_i) and recurses on the lower interval $[j+1, b]$ with new bounds $\Delta_{[j+1,b]} = \delta - 1$ and $\delta_{[j+1,b]} = \delta_{[a,b]}$, as well as on the *upper* interval $[a, i-1]$, with $\Delta_{[a,i-1]} = \Delta_{[a,b]}$ and $\delta_{[a,i-1]} = \delta + 1$. This is justified since the edges in $[i, j]$ that belong to the far case II are w.h.p. precisely the ones represented by the path R_ℓ of length $d_\ell = \delta$.

The time needed for one target t is proportional (up to a log-factor) to the number of random pivots and the overall number of searches. There are $k = O(\sqrt{Mn})$ successful searches by Lemma 8. The following lemma bounds the number of unsuccessful searches.

► **Lemma 16.** *The number of unsuccessful searches for a single target vertex is $O(M^{3/4}n^{3/4})$.*

The algorithm computes w.h.p. all pairs for one target vertex in time $\tilde{O}(|R|M^{3/4}n^{3/4}) = \tilde{O}(M^{7/8}m^{1/2}n^{3/8})$, scaling this to all targets gives $\tilde{O}(M^{7/8}m^{1/2}n^{11/8})$.

Abstract

We introduce the problem SYNCHRONIZED PLANARITY. Roughly speaking, its input is a loop-free multi-graph together with synchronization constraints that, e.g., match pairs of vertices of equal degree by providing a bijection between their edges. SYNCHRONIZED PLANARITY then asks whether the graph admits a crossing-free embedding into the plane such that the orders of edges around synchronized vertices are consistent. We show, on the one hand, that SYNCHRONIZED PLANARITY can be solved in quadratic time, and, on the other hand, that it serves as a powerful modeling language that lets us easily formulate several constrained planarity problems as instances of SYNCHRONIZED PLANARITY. In particular, this lets us solve CLUSTERED PLANARITY in quadratic time, where the most efficient previously known algorithm has an upper bound of $O(n^8)$.

1 Introduction

A graph is *planar* if it admits an embedding into the plane that has no edge crossings. Planarity is a well-studied concept that facilitates beautiful mathematical structures [20, 9], allows for more efficient algorithms [19], and serves as a cornerstone in the context of network visualization [26]. It is not surprising that various generalizations, extensions, and constrained variants of the PLANARITY problem have been studied [24]. Examples are CLUSTERED PLANARITY, where the embedding has to respect a laminar family of clusters [22, 8]; CONSTRAINED PLANARITY, where the orders of edges incident to vertices are restricted, e.g., by PQ-trees [6]; and SIMULTANEOUS PLANARITY, where two graphs sharing a common subgraph must be embedded such that their embeddings coincide on the shared part [5].

For planar embeddings, there is the important notion of *rotation*. The rotation of a vertex is the counter-clockwise cyclic order of incident edges around it. Many of the above planarity variants come down to the question whether there are embeddings of one or multiple graphs such that the rotations of certain vertices are in sync in a certain way. Inspired by this observation, by the ATOMIC EMBEDDABILITY problem [15], and by the cluster decomposition tree (CD-tree) [8], we introduce a new planarity variant. SYNCHRONIZED PLANARITY has a

loop-free multi-graph together with two types of synchronization constraints as input. Each *Q-constraint* is given as a subset of vertices together with a fixed reference rotation for each of these vertices. The *Q-constraint* is satisfied if and only if either all these vertices have their reference rotation or all these vertices have the reversed reference rotation. Vertices appearing in *Q-constraints* are called *Q-vertices* and all remaining vertices are *P-vertices*.¹ A *P-constraint* between two *P-vertices* u and v defines a bijection between the edges incident to u and v . It is satisfied if and only if u and v have the opposite rotation under this bijection. We require that the *P-constraints* form a matching, that is, no vertex appears in more than one *P-constraint*. The decision problem SYNCHRONIZED PLANARITY now asks whether the given graph can be embedded such that all *Q-* and all *P-constraints* are satisfied.

SYNCHRONIZED PLANARITY serves as a powerful modeling language that lets us express various other planarity variants using simple linear-time reductions. Specifically, we provide such reductions for CLUSTERED PLANARITY, ATOMIC EMBEDDABILITY, PARTIALLY PQ-CONSTRAINED PLANARITY, and SIMULTANEOUS EMBEDDING WITH FIXED EDGES with a connected shared graph (CONNECTED SEFE). Our main contribution is an algorithm that solves SYNCHRONIZED PLANARITY, and thereby all the above problems, in quadratic time.

1.1 Technical Contribution

Our result impacts different planarity variants that have been studied previously. Before discussing them individually in the context of previous publications, we point out a common difficulty that has been a major barrier for all of them, and briefly sketch how we resolve it.

Consider the following constraint on the rotation of a single vertex. Assume its incident edges are grouped and we only allow orders where no two groups alternate, that is, if e_1, e_2 are in one group and e_3, e_4 are in a different group, then the circular subsequence e_1, e_3, e_2, e_4 and its inverse are forbidden. Such restrictions have been called *partition constraints* before [8], and they naturally emerge at cut-vertices where each incident 2-connected component forms a group. A single partition constraint is not an issue by itself, but it becomes difficult to deal with in combination with further restrictions. This is why cut-vertices and disconnected clusters are a major obstacle for SEFE [5] and CLUSTERED PLANARITY [8], respectively.

The same issues appear for SYNCHRONIZED PLANARITY, when we have a cut-vertex v that is involved in *P-constraints*, that is, its rotation has to be synchronized with the rotation of a different vertex u . We deal with these situations as follows, depending on whether u is also a cut-vertex or not. If not, it is rather well understood which embedding choices impact the rotation of u and we can propagate this from u to v .² This breaks the synchronization of u and v down into the synchronization of smaller embedding choices. This is a well-known technique that has been used before [6, 17]. If u is also a cut-vertex, we are forced to actually deal with the embedding choices emerging at cut-vertices. This is done by “encapsulating” the restrictions on the rotations of u and v that are caused by the fact that they are cut-vertices. All additional restrictions coming from embedding choices in the 2-connected components are pushed away by introducing additional *P-constraints*. After this, the cut-vertices u and v have very simple structure, which can be resolved by essentially joining them together. This procedure is formally described in Section 3.2 and illustrated in Figures 2 and 3.

¹ The names are based on PQ-trees, where *Q-* and *P-*nodes have fixed and arbitrary rotation, respectively.

² We can also do this if v is not a cut-vertex.

This solution can be seen as combinatorial perspective on the recent breakthrough result by Fulek and Tóth [15], who resolved the cut-vertex issue by applying an idea coming from Carmesin’s work [10]. While Carmesin works with 2-dimensional simplicial complexes, Fulek and Tóth achieve their result by transferring Carmesin’s idea to the setting of topological graphs on surfaces and combining it with tools from their work on thickenability. Our work transfers the problem and its solution back to an entirely combinatorial treatment of topological graphs in the plane. This further simplification allows us to more clearly highlight the key insight that makes the algorithm tick and at the same time provides access to a wide range of algorithmic tools for speeding up the computations. Due to space constraints, proofs of statements marked with a star are only given in the full version.

1.2 Related Work

CLUSTERED PLANARITY was first considered by Lengauer [22] and later rediscovered by Feng et al. [13]. In both cases, the authors give polynomial-time algorithms for the case that each cluster induces a connected graph. The complexity of the general problem that allows disconnected clusters has been open for 30 years. In that time, many special cases have been shown to be polynomial-time solvable [3, 11, 14, 16] before Fulek and Tóth [15] recently settled CLUSTERED PLANARITY in P. The core ingredient for this is their $O(n^8)$ algorithm for the ATOMIC EMBEDDABILITY problem. It has two graphs G and H as input. Roughly speaking, H describes a 3-dimensional molecule structure with atoms represented by spheres and connections (a.k.a. pipes) represented by cylinders. The other graph G comes with a map to the molecule structure that maps each vertex to an atom such that two neighboring vertices lie on the same atom or on two atoms connected by a pipe. ATOMIC EMBEDDABILITY then asks whether G can be embedded onto the molecule structure such that no edges cross.

ATOMIC EMBEDDABILITY has been introduced as a generalization of the THICKENABILITY problem that appears in computational topology [1]. It can be shown that ATOMIC EMBEDDABILITY and THICKENABILITY are linear-time equivalent [15]. Thus, the above $O(n^8)$ algorithm for ATOMIC EMBEDDABILITY also solves THICKENABILITY and SYNCHRONIZED PLANARITY. In a preprint, Carmesin [10] proves a Kuratowski-style characterization of THICKENABILITY, which he claims yields a quadratic algorithm as a byproduct. While it is believable that the running time of his algorithm is polynomial, a detailed runtime analysis is missing. In light of this, we only compare our algorithm to the $O(n^8)$ -algorithm by Fulek and Tóth. For a detailed comparison of their solution to ATOMIC EMBEDDABILITY and our solution to SYNCHRONIZED PLANARITY, we refer to the full version.

To finally solve CLUSTERED PLANARITY, Fulek and Tóth [15] use the reduction of Cortese and Patrignani [12] to INDEPENDENT FLAT CLUSTERED PLANARITY, which they then reduce further to THICKENABILITY. The last reduction to THICKENABILITY is based on a combinatorial characterization of THICKENABILITY by Neuwirth [23], which basically states that multiple graphs have to be embedded consistently, that is, such that the rotation is synchronized between certain vertex pairs of different graphs. Via the reduction from CONNECTED SEFE to CLUSTERED PLANARITY given by Angelini and Da Lozzo [2], the above result extends to CONNECTED SEFE, which was a major open problem in the context of simultaneous graph representations [7]. We flatten this chain of reductions by giving a simple linear reduction from each of the problems CONNECTED SEFE, CLUSTERED PLANARITY, and ATOMIC EMBEDDABILITY to SYNCHRONIZED PLANARITY, yielding quadratic-time algorithms for all of them. Due to space constraints, the reductions are only given in the full version. Moreover, the problem PARTIALLY PQ-CONSTRAINED PLANARITY, for which we also give a linear reduction to SYNCHRONIZED PLANARITY, has been solved in polynomial time before, but only for biconnected graphs [6] and in the non-partial setting where either all or none of the edges of a vertex are constrained [17].

2 Preliminaries

A *partition* of a base set X is a grouping of its elements into non-empty subsets, the *cells*, so that every element is contained in exactly one cell. We assume a set implementation allowing constant-time insertion and removal of elements, such as doubly-linked lists with pointers stored with the elements. When referring to graphs, we generally mean *loop-free multi-graphs*. A *(multi-)star* consists of a *center vertex* connected by multiple, possibly parallel, edges to its *ray vertices*. A *k-wheel* is a *k-cycle*, where each node is also connected to an additional central node. Furthermore, we assume a graph representation that allows efficient manipulation, such as an adjacency list with doubly-linked lists.

Drawings, Embeddings and Cyclic Orders. A *(topological) drawing* Γ of a graph is a mapping of every vertex v to a point $p_v \in \mathbb{R}^2$ in the plane and a mapping of every edge $\{u, v\}$ to a Jordan arc having p_u and p_v as endpoints. A drawing uniquely defines cyclic orders of edges incident to the same vertex. Drawings with the same cyclic orders are considered equivalent, their equivalence class is called *(combinatorial) embedding*. For an embedding \mathcal{E} , we use $\mathcal{E}(u)$ to denote the cyclic order of the edges incident to u as given by \mathcal{E} , which is also called the *rotation* of u . For a (cyclic) order $\sigma = \langle x_1, \dots, x_k \rangle$ of k elements, we use $\bar{\sigma} = \langle x_k, \dots, x_1 \rangle$ to denote its reversal.

The Synchronized Planarity Problem. An instance is a tuple $I = (G, \mathcal{P}, \mathcal{Q}, \psi)$, where

1. $G = (P \cup Q, E)$ is a (loop-free) multi-graph with P-vertices P and Q-vertices Q ,
2. \mathcal{Q} is a partition of Q ,
3. ψ is a mapping that assigns a rotation to each Q-vertex, and
4. \mathcal{P} is a set of triples (u, v, φ_{uv}) , where u and v are P-vertices of the same degree, φ_{uv} is a bijection between their incident edges, and each P-vertex occurs at most once in \mathcal{P} .

We call the triples $\rho = (u, v, \varphi_{uv})$ in \mathcal{P} *pipes*. Pipes are not directed and we identify (u, v, φ_{uv}) and (v, u, φ_{vu}) with $\varphi_{vu} = \varphi_{uv}^{-1}$. We also define $\deg(\rho) = \deg(u) = \deg(v)$. If two P-vertices are connected by a pipe, we call them *matched*; all other P- and Q-vertices are *unmatched*.

The planar embedding \mathcal{E} of G *satisfies the cell* $X \in \mathcal{Q}$ if it is either $\mathcal{E}(v) = \psi(v)$ for all $v \in X$ or $\mathcal{E}(v) = \bar{\psi(v)}$ for all $v \in X$. We say that the embedding satisfies the *Q-constraints* if it satisfies all cells, that is, vertices in the same cell of the partition \mathcal{Q} are consistently oriented. The embedding \mathcal{E} *satisfies the pipe* $\rho = (u, v, \varphi_{uv})$ if $\varphi_{uv}(\mathcal{E}(u)) = \bar{\mathcal{E}(v)}$, that is, they have opposite rotations under the bijection φ_{uv} . We say that the embedding satisfies the *P-constraints* if it satisfies all pipes. The embedding \mathcal{E} is called *valid* if it satisfies the P-constraints and the Q-constraints. The problem SYNCHRONIZED PLANARITY asks whether a given instance $I = (G, \mathcal{P}, \mathcal{Q}, \psi)$ admits a valid embedding.

PQ-Trees and Embedding Trees. A *PQ-tree* represents a set of circular orders of its leaves by partitioning its inner nodes into two classes: For *Q-nodes* the rotation of incident edges is fixed up to reversal, for *P-nodes*, this order can be chosen arbitrarily. Rooted PQ-trees have initially been studied by Booth and Lueker [9]. There is an equivalence between rooted and unrooted PQ-trees [21], where the latter are also called PC-trees [25]. We thus do not distinguish them and simply use the term PQ-trees. Note that a P-node with three or less neighbors allows the same permutations as a Q-node of the same degree. We thus assume P-nodes to have degree at least 4. We consider a PQ-tree *trivial* if it consists of a single inner P-node (with at least four leaves). Otherwise, it consists of a single Q-node with at least two leaves, or it contains at least two inner nodes, all of which have degree at least 3.

For a vertex of a planar biconnected graph, all rotations induced by planar embeddings can efficiently be represented by a PQ-tree [9]. This PQ-tree is also called the *embedding tree* of the respective node. In the context of SYNCHRONIZED PLANARITY, we assume that the embedding tree of a vertex does not allow rotations that would result in a Q-vertex v having any other rotation than its default ordering $\psi(v)$ or its reverse $\overline{\psi(v)}$. To ensure this, we can subdivide each edge incident to v and connect each pair of two of the new nodes if the edges they subdivide are consecutive in the cyclic order $\psi(v)$ [17]. Note that this generates a k -wheel with center v and that there are exactly two planar rotations of the center of a wheel, which are the reverse of each other. We always generate the embedding trees based on the graph where each Q-vertex in G is temporarily replaced with its respective wheel.

Connected Components. A separating k -set is a set of k vertices whose removal increases the number of connected components. Separating 1-sets are called *cut-vertices*, while separating 2-sets are called *separation pairs*. A connected graph is *biconnected* if it does not have a cut-vertex. A biconnected graph is *triconnected* if it does not have a separation pair. Maximal biconnected subgraphs are called *blocks*. A vertex that is not a cut-vertex and thus resides within an unique block is called *block-vertex*.

Hopcroft and Tarjan [20] define a graph decomposition into triconnected components, also called *SPQR-tree* [4], where the components come in three shapes: *bonds* consist of two *pole* vertices connected by multiple parallel edges, *polygons* consist of a simple cycle, and *rigids*, whose embeddings are unique up to reflection. Each edge of these components is either *real*, representing a single edge of the original graph, or *virtual*, representing a subgraph.

Every planar embedding of a biconnected planar graph can be obtained from an arbitrary planar embedding by flipping its rigids and reordering the parallel edges in its bonds [20]. The decomposition can be computed in linear time [18] and can be used to compute the embedding trees in linear time [6, Section 2.5].

Splits and Joins of Graphs and Embeddings. Let $G = (V, E)$ be a graph. We call a partition $C = (X, Y)$ of V into two disjoint cells a *cut* of G . The edges $E(C)$ that have their endpoints in different cells are called *cut edges*. The *split* of G at $C = (X, Y)$ is the disjoint union of the two graphs obtained by contracting X and Y to a single vertex x and y , respectively (keeping possible multi-edges); see Figure 1. Note that the edges incident to x and y are exactly the cut edges, yielding a natural bijection φ_{xy} between them. Conversely, given two graphs $G_1 = (V_1, E_1), G_2 = (V_2, E_2)$ and vertices $x \in V_1, y \in V_2$ together with a bijection φ_{xy} between their incident edges, their *join* along φ_{xy} is the graph $G = (V, E)$, where $V = V_1 \cup V_2 \setminus \{x, y\}$ and E contains all edges of $E_1 \cup E_2$ that are not incident to x or y , and for each edge $e = ux$ incident to x , E contains an edge uv , where v is the endpoint of $\varphi_{xy}(e)$ distinct from y ; see Figure 1. Observe that split and join are inverse operations.

We say that a planar embedding \mathcal{E} of a graph G *respects* a cut $C = (X, Y)$ if and only if for a topological planar drawing Γ of G with embedding \mathcal{E} there exists a closed curve γ such that (i) γ separates X from Y , (ii) γ crosses each edge in $E(C)$ in exactly one point, and (iii) γ does not cross any edge in $E \setminus E(C)$; see Figure 1. We say that γ *represents* C in Γ .

If \mathcal{E} respects C , a split at C preserves \mathcal{E} as follows. Let G_1 and G_2 be the graphs resulting from splitting G at C and let $x \in V_1$ and $y \in V_2$ such that φ_{xy} identifies their incident edges. Let Γ be a topological planar drawing with embedding \mathcal{E} and let γ be a curve in Γ that represents C in Γ . We obtain planar drawings Γ_1 and Γ_2 of G_1 and G_2 by contracting to a single point the side of γ that contains V_2 and V_1 , respectively. We denote by \mathcal{E}_1 and \mathcal{E}_2 the corresponding combinatorial embeddings of G_1 and G_2 . Note that by construction for

■ **Figure 1** Joining and splitting two graphs at $x \in V_1$ and $y \in V_2$. The bijection φ_{xy} between their incident edges is shown as follows: the two bold edges at the bottom are mapped to each other. The other edges are mapped according to their order following the arrow upwards (i.e. clockwise for x and counter-clockwise for y).

each vertex of $V_1 \setminus \{x\}$ the rotations in \mathcal{E} and \mathcal{E}_1 coincide, and the same holds for vertices of $V_2 \setminus \{y\}$ in \mathcal{E} and \mathcal{E}_2 . Moreover, the rotations $\mathcal{E}_1(x)$ and $\mathcal{E}_2(y)$ are determined by the order in which the edges of $E(C)$ cross γ , and therefore they are oppositely oriented, that is, $\varphi_{xy}(\mathcal{E}_1(x)) = \overline{\mathcal{E}_2(y)}$. We call embeddings \mathcal{E}_1 and \mathcal{E}_2 with this property *compatible with φ_{xy}* .

Conversely, we can join arbitrary embeddings \mathcal{E}_1 of G_1 and \mathcal{E}_2 of G_2 that are compatible with φ_{xy} by assuming that x and y lie on the outer face, removing x and y from the embeddings, and connecting the resulting half-edges according to φ_{xy} . The result is a planar embedding \mathcal{E} where for each vertex $v \in V_i \setminus \{x, y\}$ it is $\mathcal{E}(v) = \mathcal{E}_i(v)$ for $i = 1, 2$.

► **Lemma 1 (*)**. *Let $G = (V, E)$ be a planar graph and let (X, Y) be a cut of G such that X and Y induce connected subgraphs of G . Then every planar embedding of G respects (X, Y) .*

► **Lemma 2 (*)**. *Every planar embedding of a bipartite graph $G = (A \cup B, E)$ respects (A, B) .*

3 The Synchronized Planarity Problem

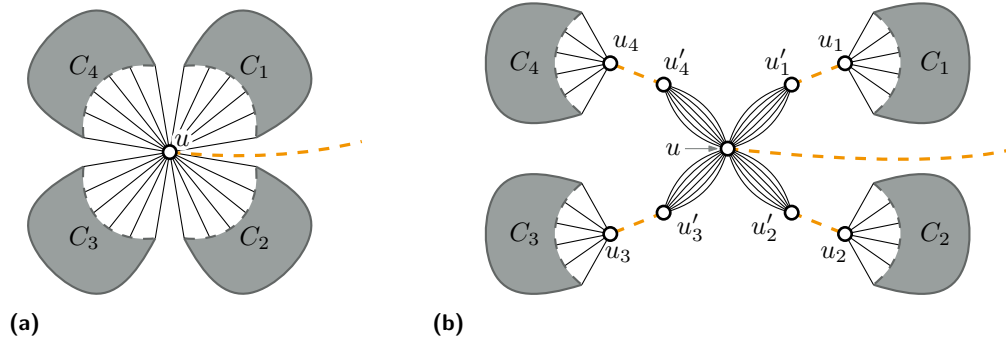

We give an algorithm for solving SYNCHRONIZED PLANARITY for graphs with n vertices and m edges in $O(m^2)$ time. Without loss of generality, we assume that G has no isolated vertices and thus $m \in \Omega(n)$. Furthermore, we assume the input graph G to be planar.

3.1 High-Level Algorithm

Our approach hinges on three main ingredients. The first are the three operations **EncapsulateAndJoin**, **PropagatePQ**, and **SimplifyMatching**, each of which can be applied to pipes that satisfy certain conditions. If an operation is applicable, it produces an equivalent instance I' of SYNCHRONIZED PLANARITY in linear time. Secondly we show that if none of the operations is applicable, then I has no pipes, and we give a simple linear-time algorithm for computing a valid embedding in this case. The third ingredient is a non-negative potential function ϕ for instances of SYNCHRONIZED PLANARITY. We show that it is upper-bounded by $2m$, and that each of the three operations decreases it by at least 1.

Our algorithm is therefore extremely simple; namely, while the instance still has a pipe, apply one of the operations to decrease the potential. Since the potential function is initially bounded by $2m$, at most $2m$ operations are applied, each taking $O(m)$ time. We will show that the resulting instance without pipes has size $O(m^2)$ and can be solved in linear time, thus the total running time is $O(m^2)$.

Conversion of small-degree P-vertices. The main difficulty in SYNCHRONIZED PLANARITY stems from matched P-vertices. However, P-vertices of degree up to 3 behave like Q-vertices in the sense that their rotations are unique up to reversal. Throughout this paper, we

■ **Figure 2** A matched cut-vertex (a) and the result of encapsulating it (b).

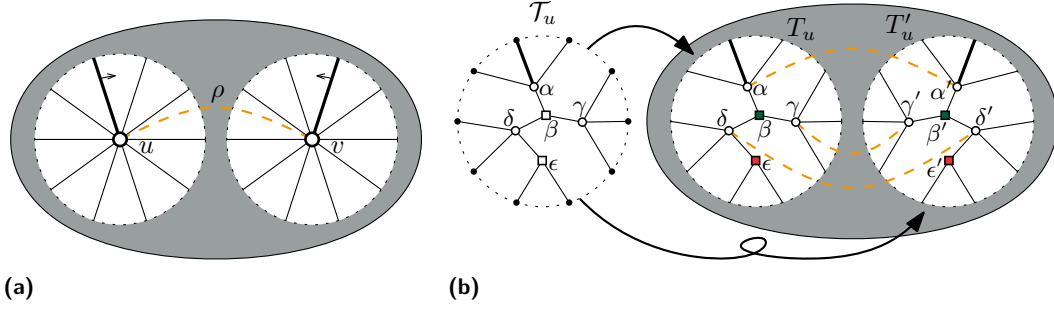

■ **Figure 3** Two (encapsulated) matched cut-vertices (a). Depending on the mapping φ , any bipartite graph can result from joining them. For example, the graph (b) can result, which is isomorphic to the square grid graph shown in (c).

implicitly assume that P-vertices of degree less than 4 are converted into Q-vertices, also converting a pipe of degree less than 4 into a Q-constraint; see the full version for additional details. We therefore assume without loss of generality that P-vertices, and in particular pipes, have degree at least 4.

3.2 The EncapsulateAndJoin Operation

The purpose of the **EncapsulateAndJoin** operation is to communicate embedding restrictions between two matched cut-vertices in two steps: First we encapsulate the cut-vertices into their own independent star components, also disconnecting their incident blocks from each other. In the second step, we join the stars. Figures 2 and 3 show an example.

For an instance $I = (G, \mathcal{P}, \mathcal{Q}, \psi)$ of SYNCHRONIZED PLANARITY, let $\rho = (u, v, \varphi_{uv})$ be a pipe matching two cut-vertices u, v of two (not necessarily distinct) connected components C_u, C_v of G . Operation **EncapsulateAndJoin** (ρ, I) can be applied resulting in an instance $I' = (G', \mathcal{P}', \mathcal{Q}', \psi')$ using the following two steps. We first preprocess both cut-vertices to *encapsulate* them into their own separate star components. Let C_1, \dots, C_k be the connected components of $C_u - u$. We split C_u along the cuts $(V(C_i), V \setminus V(C_i))$ for $i = 1, \dots, k$. We denote the vertices resulting from the split along $(V(C_i), V \setminus V(C_i))$ as u_i and u'_i , where u_i results from contracting $V \setminus V(C_i)$ and u'_i results from contracting $V(C_i)$. Note that, after all splits, u is the center of a star C'_u whose ray vertices are the u'_i . We add the pipes $(u_i, u'_i, \varphi_{u_i u'_i})$ for $i = 1, \dots, k$; see Figure 2. The same procedure is also applied to v , resulting in an intermediate instance I^* . In the second step, we *join* the connected components C'_u and C'_v at u and v along the mapping φ_{uv} of ρ into a component C_{uv} . We also remove the pipe ρ from I^* ; all other parts of the instance remain unchanged. Figure 3 shows a possible result of joining two stars.

■ **Figure 4** A block-vertex u matched with vertex v (a); the bijection φ_{uv} maps the bold edge of u to the bold edge of v , the remaining edges are mapped according to their order, clockwise around u and counter-clockwise around v . The result of applying **PropagatePQ** (u, I) (b). Note that the second inserted tree T'_u is mirrored with respect to T_u . Q-vertices and -nodes are drawn as squares while P-vertices and -nodes are drawn as disks.

► **Lemma 3.** *Applying **EncapsulateAndJoin** to a pipe ρ yields an equivalent instance in $O(\deg(\rho))$ time.*

Proof. By Lemma 1, a valid embedding \mathcal{E} of an instance I respects each of the cuts $(V(C_i), V \setminus V(C_i))$ for $i = 1, \dots, k$, yielding a planar embedding \mathcal{E}^* of I^* . By construction, it is $\mathcal{E}^*(u_i) = \overline{\mathcal{E}^*(u'_i)}$ for $i = 1, \dots, k$, that is, each new pipe $(u_i, u'_i, \varphi_{u_i u'_i})$ is satisfied and \mathcal{E}^* is a valid embedding of I^* . Conversely, if \mathcal{E}^* is a valid embedding of I^* , we can join u_i with u'_i for $i = 1, \dots, k$ to obtain a valid planar embedding \mathcal{E} of I , as the pipe $(u_i, u'_i, \varphi_{u_i u'_i})$ ensures that \mathcal{E}^* is compatible with $\varphi_{u_i u'_i}$. The same applies to C_v .

If \mathcal{E}^* is a valid embedding for I^* , it satisfies the pipe (u, v, φ_{uv}) and we can join the embedding at u and v via φ_{uv} to obtain a planar embedding \mathcal{E}' of G' . Since the rotations of vertices different from u, v are unaffected, \mathcal{E}' is valid for I' . Conversely, assume that \mathcal{E}' is a valid embedding for I' . Note that joining two stars at their centers yields a bipartite graph consisting of the rays of the former stars. Thus C_{uv} is bipartite, and by Lemma 2 every embedding respects the cut of the bipartition. Thus, we can split \mathcal{E}' and obtain a valid embedding of I^* .

As the operation affects exactly the edges incident to u and v and potentially creates a new structure with size proportional to their number, its running time is linear in the degree of the affected pipe. ◀

Observe that this operation replaces a pipe and two cut-vertices by smaller pipes and smaller cut-vertices, respectively. Through multiple applications of **EncapsulateAndJoin** we can thus step by step decrease the degree of cut-vertex-to-cut-vertex pipes, until there are none left in the instance. Note that **EncapsulateAndJoin** can yield an arbitrary bipartite component. If the component is non-planar, we abort and report a no-instance.

3.3 The PropagatePQ Operation

The operation **PropagatePQ** communicates embedding restrictions of a biconnected component across a pipe. These restrictions are represented by the embedding tree of the matched P-vertex of interest. Both endpoints of the pipe are replaced by copies of this tree. To ensure that both copies are embedded in a compatible way, we synchronize their inner nodes using pipes and Q-constraints; see Figure 4.

For an instance $I = (G, \mathcal{P}, \mathcal{Q}, \psi)$ of SYNCHRONIZED PLANARITY, let u be a block-vertex matched by a pipe $\rho = (u, v, \varphi_{uv})$. If the embedding tree \mathcal{T}_u of u is non-trivial (i.e., it not only consists of a single P-node), then the operation **PropagatePQ** (u, I) can be applied, resulting in an instance $I' = (G', \mathcal{P}', \mathcal{Q}', \psi')$ as follows. We turn the PQ-tree \mathcal{T}_u into a tree T_u by interpreting Q-nodes as Q-vertices and P-nodes as P-vertices. To construct G' from G , we replace u with T_u by reconnecting the incident edges of u to the respective leaves of T_u . We also replace v by a second copy T'_u of T_u by reconnecting an edge e incident to v to the leaf of T'_u that corresponds to $\varphi_{vu}(e)$. For a vertex α of T_u we denote the corresponding vertex of T'_u by α' . For an edge $\alpha\beta$ of T_u we define $\varphi_{T_u T'_u}(\alpha\beta) = \alpha'\beta'$. For each Q-vertex α of T_u , we define $\psi'(\alpha)$ according to the rotation of the corresponding Q-node in \mathcal{T}_u . For the Q-vertex α' of T'_u , we define $\psi'(\alpha') = \overline{\varphi_{T_u T'_u}(\psi'(\alpha))}$. For all other Q-vertices of I , ψ' coincides with ψ . We define the partition $\mathcal{Q}' = \mathcal{Q} \cup \{\{\alpha, \alpha'\} \mid \alpha \text{ is a Q-vertex of } T_u\}$. For each P-vertex α of T_u , we define a pipe $\rho_\alpha = (\alpha, \alpha', \varphi_{\alpha\alpha'})$ with $\varphi_{\alpha\alpha'}(e) = \varphi_{T_u T'_u}(e)$ for each edge e incident to α . Finally, we define the matching $\mathcal{P}' = (\mathcal{P} \setminus \{\rho\}) \cup \{\rho_\alpha \mid \alpha \text{ is a P-vertex of } T_u\}$.

► **Lemma 4** (*). *Applying **PropagatePQ** to a block-vertex u with a non-trivial embedding tree yields an equivalent instance. If the embedding tree \mathcal{T}_u is known, operation **PropagatePQ** runs in $O(\deg(u))$ time.*

Note that the tree T'_u inserted instead of v may not be compatible with the rotations of v . In this case, the component becomes non-planar, potentially causing the later generation of an embedding tree to fail. We can then immediately report a no-instance.

Observe that since we assume \mathcal{T}_u to be non-trivial, the degrees of all P-vertices in T_u and T'_u are strictly smaller than the degree of u . Thus, by repeatedly applying **PropagatePQ**, we eventually arrive at an equivalent instance where all matched block-vertices have a trivial embedding tree. Also note that if \mathcal{T}_u consists of a single Q-node, **PropagatePQ** effectively replaces the affected pipe by two Q-vertices in the same partition. The case where \mathcal{T}_u is trivial and thus consists of a single P-node is handled by the next operation.

3.4 The SimplifyMatching Operation

The remaining operation is **SimplifyMatching**, which is used to resolve pipes where one side has no restrictions to be communicated to the other side. This is the case when one of the two matched vertices is a pole of a bond that allows arbitrary rotation. We distinguish three cases: i) bonds where one pole can always mimic the rotation of the other, ii) bonds where the pipe synchronizes one pole with the other (similar to the toroidal instances of Fulek and Tóth [15]), and iii) bonds that link two distinct pipes.

For an instance $I = (G, \mathcal{P}, \mathcal{Q}, \psi)$ of SYNCHRONIZED PLANARITY, let u be a block-vertex of G whose embedding tree is trivial and that is matched by a pipe ρ . Then, its embedding is determined by exactly one triconnected component μ , which is a bond.³ Thus u is the pole of bond μ , and we call the vertex v that is the other pole of μ the *partner* of u . If v is either unmatched or a block-vertex with a trivial embedding tree, the operation **SimplifyMatching** (u, I) can be applied, resulting in an instance $I' = (G', \mathcal{P}', \mathcal{Q}', \psi')$ as follows. Note that, due to the temporary replacement of Q-vertices by wheels when computing the embedding trees, v cannot be a Q-vertex, as that would make the PQ-tree of u contain a Q-node.

- (i) If v is an unmatched P-vertex (Figure 5a), I' is obtained from I by removing ρ .

³ as a second bond would cause another P-node in the embedding tree, a rigid would cause a Q-node and polygons do not affect the embedding trees [6, Section 2.5]

■ **Figure 5** The three cases of the `SimplifyMatching` operation. In Case i (a) and Case ii (b), the pipe ρ is removed. In Case iii (c) the pipes ρ, ρ' are replaced by pipe ρ^* .

- (ii) If ρ matches u with v , it connects the two poles of the bond μ (Figure 5b). Note that the embedding trees of u and v both contain a P-node of the same degree representing μ and the pipe now requires both u and v to have the same degree. Thus, as u has a trivial embedding tree, v also has a trivial embedding tree. The rotation of the vertices is thus exclusively determined by the embedding of the bond and there are bijections δ_u and δ_v between the edges incident to u and v , respectively, and the virtual edges within the bond. We now check that these bijections are compatible with the bijection φ_{uv} given by the pipe. Let $\delta_{vu} = \delta_u^{-1} \circ \delta_v$ be a bijection between the edges incident to v and the edges incident to u , and let $\pi = \varphi_{uv} \circ \delta_{vu}$ be a permutation of the edges incident to v . If all cycles of π have the same length, I' is obtained from I by removing ρ .⁴ Otherwise, I is an invalid instance and we set I' to a trivial no-instance.
- (iii) If v is matched with a P-vertex $v' \neq u$ via pipe $\rho' = (v, v', \varphi_{vv'})$, let u' be the other endpoint of $\rho = (u, u', \varphi_{uu'})$. We remove ρ and ρ' and add the new pipe $\rho^* = (u', v', \varphi_{u'v'})$ with $\varphi_{u'v'} = \varphi_{vv'} \circ \delta_{uv} \circ \varphi_{u'u}$; see Figure 5c.

► **Lemma 5 (*)**. *Applying `SimplifyMatching` to a block-vertex u with a trivial embedding tree yields an equivalent instance in $O(\deg(u))$ time.*

3.5 Reduced and Pipe-Free Instances

With our exposition of the fundamental operations complete, we now study how to solve instances where none of those operations can be applied. We call such instances *reduced*.

► **Lemma 6**. *An instance is reduced if and only if it contains no pipes.*

Proof. Obviously, a pipe-free instance is reduced. Conversely, consider a reduced instance I . Assume, for the sake of contradiction, that I contains a pipe. We now show that this implies that one of the operations is applicable, that is, I is not reduced.

Assume that I contains no matched cut-vertices and thus all matched vertices are block-vertices. If there is a matched P-vertex with a non-trivial embedding tree, `PropagatePQ` can be applied. Otherwise, all matched P-vertices are block-vertices with trivial embedding trees and `SimplifyMatching` can be applied.

Now let u be a matched cut-vertex of maximum degree that is matched to a vertex v by a pipe ρ . If v is also a cut-vertex, we can apply `EncapsulateAndJoin`. If v is a block-vertex with a non-trivial embedding tree, we can apply `PropagatePQ`. Therefore, v must be a block-vertex with a trivial embedding tree. Now we can apply `SimplifyMatching`, unless the partner pole v' of v is a matched cut-vertex. This is however excluded,

⁴ If all cycles of π have the same length, π is *order preserving* and it is $\pi(O) = O$ for any sequence O . See [6, Lemma 2.2] or the proof to the following Lemma 5 in the full version for more details.

since $\deg(u) = \deg(v) < \deg(v')$, contradicting the maximality of $\deg(u)$. The last inequality follows from the fact that $\deg(v) \leq \deg(v')$ already holds in the block of G that contains v and v' , but as v' is a cut-vertex, it has at least one neighbor outside that block. ◀

To solve instances without pipes in linear time, note that a planar embedding of such an instance is valid if and only if it satisfies the Q-constraints. As Q-vertices only have a binary choice for their rotation, it is relatively easy to synchronize them via a 2-SAT formula. Linear-time algorithms follow from, e.g., [6], and can also be obtained from techniques similar to those used by Fulek and Tóth [15] for cubic graphs. For the sake of completeness, we present a self-contained solution in the full version.

► **Lemma 7 (*)**. *An instance of SYNCHRONIZED PLANARITY without pipes can be solved in $O(m)$ time. A valid embedding can be computed in the same time, if it exists.*

3.6 Finding a Reduced Instance

As mentioned above, we exhaustively apply the operations **EncapsulateAndJoin**, **PropagatePQ**, and **SimplifyMatching**. We claim that this algorithm terminates and yields a reduced instance after a polynomial number of steps. The key idea is that the operations always make progress by either reducing the number of pipes, or by splitting pipes into pipes of smaller degree. This suggests that, eventually, we arrive at an instance without pipes. However, there are two caveats. First, the encapsulation in the first step of **EncapsulateAndJoin** creates new pipes and thus has the potential to undo progress. Second, the smaller pipes resulting from splitting a pipe with **PropagatePQ** might cause further growth of the instance, potentially causing a super-polynomial number of steps.

We resolve both issues by using a more fine-grained measure of progress in the form of a potential function. To overcome the first issue, we show that for each application of **EncapsulateAndJoin**, the progress that is undone in the first step is outweighed by the progress made through the following join in the second step. Similarly, for the second issue, we show that the sum of the parts is no bigger than the whole when splitting pipes.

As P-vertices of degree 3 or less are converted to Q-vertices (see Section 3.1), we use $\deg^*(u) = \deg^*(v) = \deg^*(\rho) = \max\{\deg(x) - 3, 0\}$ to denote the number of incident edges that keep a P-vertex u (and also the other endpoint v of its pipe $\rho = (u, v, \varphi_{uv})$) from becoming converted to a Q-vertex. We also partition the set of all pipes \mathcal{P} into the two cells \mathcal{P}_{CC} and $\mathcal{P}_B = \mathcal{P} \setminus \mathcal{P}_{CC}$, where \mathcal{P}_{CC} contains all pipes where both endpoints are cut-vertices. We define the *potential* of an instance I as $\Phi(I) = \sum_{\rho \in \mathcal{P}_B} \deg^*(\rho) + \sum_{\rho \in \mathcal{P}_{CC}} (2\deg^*(\rho) - 1)$. We show that the operations always decrease this potential.

► **Lemma 8 (*)**. *For an instance $I = (G, \mathcal{P}, \mathcal{Q}, \psi)$ of SYNCHRONIZED PLANARITY and an instance $I' = (G', \mathcal{P}', \mathcal{Q}', \psi')$ that results from application of either **EncapsulateAndJoin**, **PropagatePQ** or **SimplifyMatching** to I , the following three properties hold:*

- (i) *The potential reduction $\Delta\Phi = \Phi(I) - \Phi(I')$ is at least 1.*
- (ii) *The number of nodes added to the graph satisfies $\Delta V = |V(G')| - |V(G)| \leq 2 \cdot \Delta\Phi + 12$.*
- (iii) *If the operation replaces a connected component C by one or multiple connected components, then each such component C' satisfies $\Delta E(C) = |E(C')| - |E(C)| \leq 2 \cdot \Delta\Phi$.*

Proof Sketch. We now analyze the effects of **EncapsulateAndJoin** on these three measures. The operations **PropagatePQ** and **SimplifyMatching** are discussed in the full version.

Operation **EncapsulateAndJoin** (ρ, I) in the first step encapsulates both cut-vertices u, v to their own star components. For each block incident to u , this introduces two new vertices that are connected by a new pipe. Let d_1, \dots, d_k be the degrees of the $k \geq 2$ ray vertices of

u after the encapsulation. As one end of the added pipes is a block-vertex, the potential is increased by $\sum_{i=1}^k \max\{d_i - 3, 0\}$. Likewise, the pipes of the k' rays with degrees $d'_1, \dots, d'_{k'}$ around v increase the potential by $\sum_{i=1}^{k'} \max\{d'_i - 3, 0\}$. Using $\deg(\rho) = \sum_{i=1}^k d_i = \sum_{i=1}^{k'} d'_i = D \geq 3$ it is $\deg^*(\rho) = \max\{D - 3, 0\} = D - 3$. In the second step, removing ρ connecting two cut-vertices together with its endpoints reduces the potential by $2\deg^*(\rho) - 1$ and we thus get $\Delta\Phi = 2 \cdot (D - 3) - 1 - \sum_{i=1}^k \max\{d_i - 3, 0\} - \sum_{i=1}^{k'} \max\{d'_i - 3, 0\}$. In the full version, we show that this yields $\Delta\Phi \geq 1$ as claimed by (i). As the encapsulation generates two vertices for each ray and the join removes two vertices, we have $\Delta V = 2k + 2k' - 2$. We also show that claim (ii) holds as $\Delta V \leq 2 \cdot (\Delta\Phi + 6)$. In the first step of **EncapsulateAndJoin**, two new components with $\deg(u) = \deg(v)$ edges each are added, which are then combined in the second step, yielding a new component with $\sum_{i=1}^k d_i$ edges. This is no larger than the components of u or v as required for (iii). ◀

With this lemma, we know that each step decreases the potential by at least 1 without growing the graph too much. As each vertex contributes at most twice its degree, initially $\Phi(I) \leq 2m$. This can then be used to bound the size of instances resulting from applying multiple operations consecutively and finally to bound the time required to find a solution for an instance.

► **Theorem 9 (*)**. *SYNCHRONIZED PLANARITY can be solved in $O(m^2)$ time.*

Proof Sketch. By Lemma 8 the potential function decreases with each applied operation. As initially $\Phi(I) \leq 2m$, a reduced instance I' is reached after $k \leq 2m$ operations. It can be shown that each connected component of I' has $O(m)$ edges, allowing an embedding tree to be computed in $O(m)$ time. Each of the k operations runs in linear time once the PQ-tree it requires is available. In total, it thus takes $O(m^2)$ time to reach a reduced instance. As its size is also in $O(m^2)$, Lemma 7 can be applied to find a solution in $O(m^2)$ time. ◀

4 Conclusion

We have given a quadratic-time algorithm for SYNCHRONIZED PLANARITY, which improves the previous $O(n^8)$ -time algorithm for the linear-time equivalent problem ATOMIC EMBEDDABILITY [15]. Similar to Goldberg and Tarjan's push-relabel algorithm, it relies on few and simple operations that can be applied pretty much in an arbitrary order. This highlights where and how progress is made and thereby clearly exposes key ideas that also underlie the algorithm for ATOMIC EMBEDDABILITY. For a direct comparison of the approaches, we refer to the full version.

The applications of SYNCHRONIZED PLANARITY include solving CLUSTERED PLANARITY, ATOMIC EMBEDDABILITY, CONNECTED SEFE and PARTIALLY PQ-CONSTRAINED PLANARITY in quadratic time, thanks to linear-time reductions to SYNCHRONIZED PLANARITY for all of them described in the full version. This improves over the previously fastest algorithms via the $O(n^8)$ -time algorithm for ATOMIC EMBEDDABILITY. In the case of CONNECTED SEFE the reduction used in [15] includes a quadratic blowup and therefore yields an $O(n^{16})$ -algorithm. Our direct linear-time reduction leads to a quadratic algorithm.

Abstract

Finding a minimum vertex cover in a network is a fundamental NP-complete graph problem. One way to deal with its computational hardness, is to trade the qualitative performance of an algorithm (allowing non-optimal outputs) for an improved running time. For the vertex cover problem, there is a gap between theory and practice when it comes to understanding this tradeoff. On the one hand, it is known that it is NP-hard to approximate a minimum vertex cover within a factor of $\sqrt{2}$. On the other hand, a simple greedy algorithm yields close to optimal approximations in practice.

A promising approach towards understanding this discrepancy is to recognize the differences between theoretical worst-case instances and real-world networks. Following this direction, we close the gap between theory and practice by providing an algorithm that efficiently computes nearly optimal vertex cover approximations on hyperbolic random graphs; a network model that closely resembles real-world networks in terms of degree distribution, clustering, and the small-world property. More precisely, our algorithm computes a $(1 + o(1))$ -approximation, asymptotically almost surely, and has a running time of $\mathcal{O}(m \log(n))$.

The proposed algorithm is an adaption of the successful greedy approach, enhanced with a procedure that improves on parts of the graph where greedy is not optimal. This makes it possible to introduce a parameter that can be used to tune the tradeoff between approximation performance and running time. Our empirical evaluation on real-world networks shows that this allows for improving over the near-optimal results of the greedy approach.

1 Introduction

A *vertex cover* of a graph is a subset of the vertices that leaves the graph edgeless upon deletion. Since the problem of finding a smallest vertex cover is NP-complete [19], there are probably no algorithms that solve it efficiently. Nevertheless, the problem is highly relevant due to its applications in computational biology [1], scheduling [13], and internet security [14]. Therefore, there is an ongoing effort in exploring methods that can be used in practice [2, 3], and while they often work well, they still cannot guarantee efficient running times.

A commonly used approach to overcoming this issue are approximation algorithms. There, the idea is to settle for a near-optimal solution while guaranteeing an efficient running time. For the vertex cover problem, a simple greedy approach computes an approximation in linear time by iteratively adding the vertex with the largest degree to the cover and removing it from the graph. In general graphs, this algorithm, which we call *standard greedy*, cannot guarantee a better approximation ratio than $\log(n)$, i.e., there are graphs where it produces a vertex cover whose size exceeds the one of an optimum by a factor of $\log(n)$. This can be improved to a 2-approximation using a simple linear-time algorithm. The best known polynomial time approximation reduces the factor to $2 - \Theta(\log(n)^{-1/2})$ [18]. However, there is reason to believe that it is NP-hard to approximate an optimal vertex cover within a factor of $2 - \varepsilon$ for all $\varepsilon > 0$ [20] and it is proven that finding a $\sqrt{2}$ -approximation is NP-hard [26].

Therefore, it is very surprising that the standard greedy algorithm not only beats the 2-approximation on autonomous systems graphs like the internet [25], it also performs well on many real-world networks, obtaining approximation ratios that are very close to 1 [11]. So the theoretical bounds do not match what is observed in practice. One approach to explaining this discrepancy is to consider the differences between the examined instances. Theoretical bounds are often obtained by designing worst-case instances. However, real-world networks rarely resemble the worst case. More realistic statements can be obtained by making assumptions about the solution space [4, 9], or by restricting the analysis to networks with properties that are observed in the real world.

Many real networks, like social networks, communication networks, or protein-interaction networks, are considered to be *scale-free*. Such graphs feature a power-law degree distribution (only few vertices have high degree, while many vertices have low degree), high clustering (two vertices are likely to be adjacent if they have a common neighbor), and a small diameter.

Previous efforts to obtain more realistic insights into the approximability of the vertex cover problem have focused on networks that feature only one of these properties, namely a power-law degree distribution [10, 16, 28]. With this approach, guarantees for the approximation factor of the standard greedy algorithm were improved to a constant, compared to $\log(n)$ on general graphs [10]. Moreover, it was shown that it is possible to compute an expected $(2 - \varepsilon)$ -approximation for a constant ε , in polynomial time on such networks [16] and this was later improved to about 1.7 depending on properties of the distribution [28]. However, it was also shown that even on graphs that have a power-law degree distribution, the vertex cover problem remains NP-hard to approximate within some constant factor [10]. This indicates, that focusing on networks that only feature a power-law degree distribution, is not sufficient to explain why vertex cover can be approximated so well in practice.

The goal of this paper is to close this gap between theory and practice, by considering a random graph model that features all of the three mentioned properties of scale-free networks. The *hyperbolic random graph model* was introduced by Krioukov et al. [21] and it was shown that the graphs generated by the model have a power-law degree distribution and high clustering [17], as well as a small diameter [24]. Consequently, they are good representations of many real-world networks [8, 15, 27]. Additionally, the model is conceptually simple, making it accessible to mathematical analysis. Therefore, it has proven to be a useful framework to theoretically explain why algorithms work well in practice [6]. In fact, it has been shown that the vertex cover problem can be solved exactly in polynomial time on hyperbolic random graphs, with high probability [5]. However, we note that the degree of the polynomial is unknown and on large networks even quadratic algorithms are not efficient enough to obtain results in a reasonable amount of time.

In this paper, we link the success of the standard greedy approach to structural properties of hyperbolic random graphs, identify the parts of the graph where it does not behave optimally, and use these insights to derive a new approximation algorithm. On hyperbolic random graphs, this algorithm achieves an approximation ratio of $1 + o(1)$, asymptotically almost surely, and maintains an efficient running time of $\mathcal{O}(m \log(n))$, where n and m denote the number of vertices and edges in the graph, respectively. Since the average degree of hyperbolic random graphs is constant [17], this implies a quasi-linear running time on such networks. Moreover, we introduce a parameter that can be used to tune the tradeoff between approximation quality and running time of the algorithm, facilitating an improvement over the standard greedy approach. While our algorithm depends on the coordinates of the vertices in the hyperbolic plane, we propose an adaption of it that is oblivious to the underlying geometry and compare its approximation performance to the standard greedy algorithm on a selection of real-world networks. On average our algorithm reduces the error of the standard greedy approach to less than 50%. The evaluation of our experiments can be found in the full version of the paper [7].

2 Preliminaries

Let $G = (V, E)$ be an undirected graph. We denote the number of vertices and edges in G with n and m , respectively. The number of vertices in a set $S \subseteq V$ is denoted by $|S|$. The *neighborhood* of a vertex v is defined as $N(v) = \{w \in V \mid \{v, w\} \in E\}$. The size of the neighborhood, called the *degree* of v , is denoted by $\deg(v) = |N(v)|$. For a subset $S \subseteq V$, we use $G[S]$ to denote the *induced subgraph* of G obtained by removing all vertices in $V \setminus S$.

The Hyperbolic Plane. After choosing a designated origin O in the two-dimensional hyperbolic plane, together with a reference ray starting at O , a point p is uniquely identified by its *radius* $r(p)$, denoting the hyperbolic distance to O , and its *angle* (or *angular coordinate*) $\varphi(p)$, denoting the angular distance between the reference ray and the line through p and O . The hyperbolic distance between two points p and q is given by

$$\text{dist}(p, q) = \text{acosh}(\cosh(r(p)) \cosh(r(q)) - \sinh(r(p)) \sinh(r(q)) \cos(\Delta_\varphi(p, q))),$$

where $\cosh(x) = (e^x + e^{-x})/2$, $\sinh(x) = (e^x - e^{-x})/2$ (both growing as $e^x/2 \pm o(1)$), and $\Delta_\varphi(p, q) = \pi - |\pi - |\varphi(p) - \varphi(q)||$ denotes the angular distance between p and q . If not stated otherwise, we assume that computations on angles are performed modulo 2π .

In the hyperbolic plane a disk of radius r has an area of $2\pi(\cosh(r) - 1)$ and circumference $2\pi \sinh(r)$. Thus, the area and the circumference of such a disk grow exponentially with its radius. In contrast, this growth is polynomial in Euclidean space.

Hyperbolic Random Graphs. Hyperbolic random graphs are obtained by distributing n points independently and uniformly at random within a disk of radius R and connecting any two of them if and only if their hyperbolic distance is at most R . See Figure 1 (left) for an example. The disk radius R (which matches the connection threshold) is given by $R = 2 \log(n) + C$, where the constant $C \in \mathbb{R}$ depends on the average degree of the network, as well as the power-law exponent $\beta = 2\alpha + 1$ (for $\alpha \in (1/2, 1)$). The coordinates of the vertices are drawn as follows. For vertex v the angular coordinate, denoted by $\varphi(v)$, is drawn uniformly at random from $[0, 2\pi)$ and the radius of v , denoted by $r(v)$, is sampled according

to the probability density function $\alpha \sinh(\alpha r)/(\cosh(\alpha R) - 1)$ for $r \in [0, R]$. Thus,

$$f(r, \varphi) = \frac{1}{2\pi} \frac{\alpha \sinh(\alpha r)}{\cosh(\alpha R) - 1} = \frac{\alpha}{2\pi} e^{-\alpha(R-r)} (1 + \Theta(e^{-\alpha R} - e^{-2\alpha r})) \quad (1)$$

is their joint distribution function for $r \in [0, R]$. For $r > R$, $f(r, \varphi) = 0$.

We denote areas in the hyperbolic disk with calligraphic capital letters. The set of vertices in an area \mathcal{A} is denoted by $V(\mathcal{A})$. The probability for a given vertex to lie in \mathcal{A} is given by its measure $\mu(\mathcal{A}) = \int_{\mathcal{A}} f(r, \varphi) d\varphi dr$. The hyperbolic distance between two vertices u and v increases with increasing angular distance between them. The maximum angular distance such that they are still connected by an edge is bounded by [17, Lemma 6]

$$\theta(r(u), r(v)) = 2e^{(R-r(u)-r(v))/2} (1 + \Theta(e^{R-r(u)-r(v)})). \quad (2)$$

Hyperbolic Random Graphs with an Expected Number of Vertices. While the positions of the vertices in a hyperbolic random graph are sampled independently of each other, stochastic dependencies are introduced once the positions of some vertices are known. For example, if all vertices lie in an area \mathcal{A} , the probability for a vertex to lie outside of \mathcal{A} is 0. When these dependencies are hard to deal with (which we mention explicitly), we resort to a slightly different hyperbolic random graph model, where the positions are sampled using an inhomogeneous Poisson point process. The result of this process is a *hyperbolic random graph with n vertices in expectation*. There, the number of vertices in disjoint areas are independent random variables. Probabilistic statements for this model can then be translated back to the original hyperbolic random graph model with a small penalty in certainty. A detailed explanation can be found in the full version of the paper [7].

Probabilities. Since we are analyzing a random graph model, our results are of probabilistic nature. To obtain meaningful statements, we show that they hold *with high probability* (with probability $1 - \mathcal{O}(n^{-1})$), or *asymptotically almost surely* (with probability $1 - o(1)$). The following Chernoff bound can be used to show that certain events occur with high probability.

► **Theorem 1** (Chernoff Bound [12, Theorem 1.1]). *Let X_1, \dots, X_n be independent random variables with $X_i \in \{0, 1\}$ and let X be their sum. Then, for $\varepsilon \in (0, 1)$*

$$\Pr[X \geq (1 + \varepsilon)\mathbb{E}[X]] \leq e^{-\varepsilon^2/3 \cdot \mathbb{E}[X]}.$$

Usually, it suffices to show that a random variable does not exceed an upper bound. The following corollary shows that a bound on the expected value suffices to obtain concentration.

► **Corollary 2.** *Let X_1, \dots, X_n be independent random variables with $X_i \in \{0, 1\}$, let X be their sum, and let $f(n)$ be an upper bound on $\mathbb{E}[X]$. Then, for $\varepsilon \in (0, 1)$*

$$\Pr[X \geq (1 + \varepsilon)f(n)] \leq e^{-\varepsilon^2/3 \cdot f(n)}.$$

Moreover, the following lemma can often be used to simplify error terms.

► **Lemma 3** ([22, Lemma 2.3]). *Let $x \in \mathbb{R}$ with $x = \pm o(1)$. Then, $1/(1 + x) = 1 - \Theta(x)$.*

3 An Improved Greedy Algorithm

Previous insights about solving the vertex cover problem on hyperbolic random graphs are based on the fact that the *dominance reduction rule* reduces the graph to a remainder of simple structure [5]. This rule states that a vertex u can be safely added to the vertex cover (and, thus, be removed from the graph) if it *dominates* at least one other vertex, i.e., if there exists a neighbor $v \in N(u)$ such that all neighbors of v are also neighbors of u .

On hyperbolic random graphs, vertices near the center of the disk dominate with high probability [5, Lemma 5]. Therefore, it is not surprising that the standard greedy algorithm that computes a vertex cover by repeatedly taking the vertex with the largest degree achieves good approximation rates on such networks: Since high degree vertices are near the disk center, the algorithm essentially favors vertices that are likely to dominate and can be safely added to the vertex cover anyway.

On the other hand, after (safely) removing high-degree vertices, the remaining vertices all have similar (small) degree, meaning the standard greedy algorithm basically picks the vertices at random. Thus, in order to improve the approximation performance of the algorithm, one has to improve on the parts of the graph that contain the low-degree vertices. Based on this insight, we derive a new greedy algorithm that achieves close to optimal approximation rates efficiently. More formally, we prove the following main theorem.

► **Theorem 4.** *Let G be a hyperbolic random graph on n vertices. Given the radii of the vertices, an approximate vertex cover of G can be computed in time $\mathcal{O}(m \log(n))$, such that the approximation ratio is $(1 + o(1))$ asymptotically almost surely.*

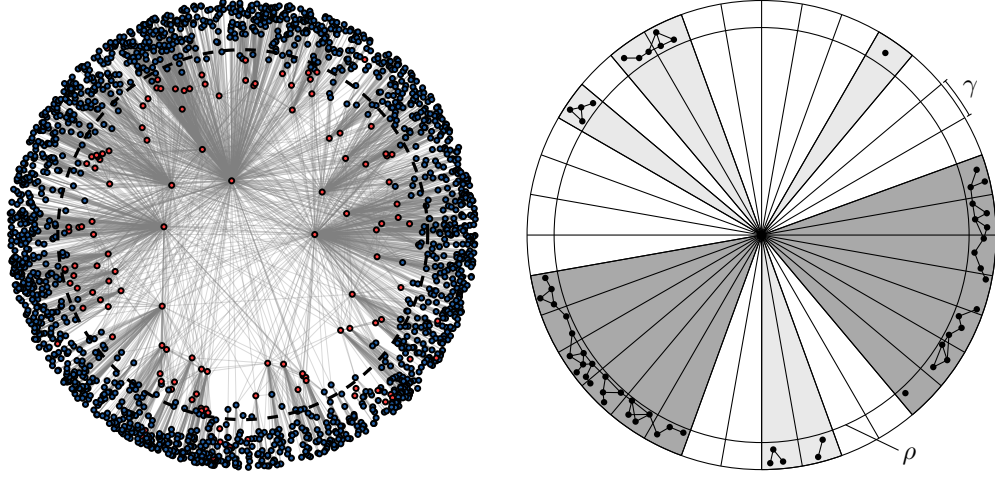

Consider the following greedy algorithm that computes an approximation of a minimum vertex cover on hyperbolic random graphs. We iterate the vertices in order of increasing radius. Each encountered vertex v is added to the cover and removed from the graph. After each step, we then identify the connected components of size at most $\tau \log \log(n)$ in the remainder of the graph, solve them optimally, and remove them from the graph as well. The constant $\tau > 0$ can be used to adjust the tradeoff between quality and running time.

This algorithm determines the order in which the vertices are processed based on their radii, which are not known for real-world networks. However, in hyperbolic random graphs, there is a strong correlation between the radius of a vertex and its degree [17]. Therefore, we can mimic the considered greedy strategy by removing vertices with decreasing degree instead. Then, the above algorithm represents an adaption of the standard greedy algorithm: Instead of greedily adding vertices with decreasing degree until all remaining vertices are isolated, we increase the quality of the approximation by solving small components exactly.

4 Approximation Performance

To analyze the performance of the above algorithm, we utilize structural properties of hyperbolic random graphs. While the power-law degree distribution and high clustering are modelled explicitly using the underlying geometry, other properties of the model, like the logarithmic diameter, emerge as a natural consequence of the first two. Our analysis is based on another emerging property: Hyperbolic random graphs decompose into small components when removing high-degree vertices.

More formally, we proceed as follows. We compute the size of the vertex cover obtained using the above algorithm, by partitioning the vertices of the graph into two sets: V_{Greedy} and V_{Exact} , denoting the vertices that were added greedily and the ones contained in small separated components that were solved exactly, respectively (see Figure 1 (left)). Clearly, we

■ **Figure 1 (Left)** A hyperbolic random graph with 1942 vertices, average degree 7.7, and power-law exponent 2.6. The vertex sets V_{Greedy} and V_{Exact} are shown in red and blue, respectively. The dashed line shows a possible threshold radius ρ . **(Right)** The disk is divided into sectors of equal width γ . Consecutive non-empty sectors form a run (grey). Narrow runs (light grey) consist of few sectors. Wide runs (dark grey) consist of many sectors. Each dark grey sector is a widening sector.

obtain a valid vertex cover for the whole graph, if we take all vertices in V_{Greedy} together with a vertex cover C_{Exact} of $G[V_{\text{Exact}}]$. Then, the approximation ratio is given by the quotient $\delta = (|V_{\text{Greedy}}| + |C_{\text{Exact}}|)/|C_{\text{OPT}}|$, where C_{OPT} denotes an optimal solution. Since all components in $G[V_{\text{Exact}}]$ are solved optimally and since any minimum vertex cover for the whole graph induces a vertex cover on $G[V']$ for any vertex subset $V' \subseteq V$, it holds that $|C_{\text{Exact}}| \leq |C_{\text{OPT}}|$. Consequently, it suffices to show that $|V_{\text{Greedy}}| \in o(|C_{\text{OPT}}|)$ in order to obtain the claimed approximation factor of $1 + o(1)$.

To bound the size of V_{Greedy} , we identify a time during the execution of the algorithm at which only few vertices were added greedily, yet, the majority of the vertices were contained in small separated components (and were, therefore, part of V_{Exact}), and only few vertices remain to be added greedily. Since the algorithm processes the vertices by increasing radius, this point in time can be translated to a threshold radius ρ in the hyperbolic disk (see Figure 1). Therefore, we divide the hyperbolic disk into two regions: an *inner disk* and an *outer band*, containing vertices with radii below and above ρ , respectively. The threshold ρ is chosen such that a hyperbolic random graph decomposes into small components after removing the inner disk. When adding the first vertex from the outer band, greedily, we can assume that the inner disk is empty (since vertices of smaller radii were chosen before or removed as part of a small component). At this point, the majority of the vertices in the outer band were contained in small components, which have been solved exactly. Therefore, we obtain a valid upper bound on $|V_{\text{Greedy}}|$, by counting the total number of vertices in the inner disk and adding the number of vertices in the outer band that are contained in components that are not solved exactly (i.e., components whose size exceeds $\tau \log \log(n)$). In the following, we show that both numbers are sublinear in n with high probability. Together with the fact that an optimal vertex cover on hyperbolic random graphs, asymptotically almost surely, contains $\Omega(n)$ vertices [10], this implies $|V_{\text{Greedy}}| \in o(|C_{\text{OPT}}|)$.

The main contribution of our analysis is the identification of small components in the outer band, which is done by discretizing it into sectors, such that an edge cannot extend beyond an empty sector (see Figure 1 (right)). The foundation of this analysis is the delicate

interplay between the angular width γ of these sectors and the threshold ρ that defines the outer band. Recall that ρ is used to represent the time in the execution of the algorithm at which the graph has been decomposed into small components. For our analysis we assume that all vertices seen before this point (all vertices in the inner disk) were added greedily. Therefore, if we choose ρ too large, we overestimate the actual number of greedily added vertices by too much. As a consequence, we want to choose ρ as small as possible. However, this conflicts our intentions for the choice of γ and its impact on ρ . Recall that the maximum angular distance between two vertices such that they are adjacent increases with decreasing radii (Equation (2)). Thus, in order to avoid edges that extend beyond an angular width of γ , we need to ensure that the radii of the vertices in the outer band are sufficiently large. That is, decreasing γ requires increasing ρ . However, we want to make γ as small as possible, in order to get a finer granularity in the discretization and, with that, a more accurate analysis of the component structure in the outer band. Therefore, γ and ρ need to be chosen such that the inner disk does not become too large, while ensuring that the discretization is granular enough to accurately detect components whose size depends on τ and n . To this end, we adjust the angular width of the sectors using a function $\gamma(n, \tau)$, which is defined as

$$\gamma(n, \tau) = \log(\tau \log^{(2)}(n) / (2 \log^{(3)}(n)^2)),$$

where $\log^{(i)}(n)$ denotes iteratively applying the log-function i times on n (e.g., $\log^{(2)}(n) = \log \log(n)$), and set

$$\rho = R - \log(\pi/2 \cdot e^{C/2} \gamma(n, \tau)),$$

where $R = 2 \log(n) + C$ is the radius of the hyperbolic disk.

In the following, we first show that the number of vertices in the inner disk is sublinear, with high probability, before analyzing the component structure in the outer band. This is mainly done by considering the random variables that denote the numbers of vertices in certain areas of the disk. We give proofs for their expected values throughout the paper. Tight concentration bounds can then be obtained using the previously mentioned Chernoff bound or, when the considered random variables are more involved, the method of (typical) bounded differences. These proofs can be found in the full version of the paper [7].

4.1 The Inner Disk

The inner disk \mathcal{I} contains all vertices whose radius is below the threshold ρ . The number of them that are added to the cover greedily is bounded by the number of all vertices in \mathcal{I} .

► **Lemma 5.** *Let G be a hyperbolic random graph on n vertices with power-law exponent $\beta = 2\alpha + 1$. With high probability, the number of vertices in \mathcal{I} is in $\mathcal{O}(n \cdot \gamma(n, \tau)^{-\alpha})$.*

Proof. We start by computing the expected number of vertices in \mathcal{I} and show concentration afterwards. To this end, we first compute the measure $\mu(\mathcal{I})$. The measure of a disk of radius r that is centered at the origin is given by $e^{-\alpha(R-r)}(1 + o(1))$ [17, Lemma 3.2]. Consequently, the expected number of vertices in \mathcal{I} is

$$\mathbb{E}[|V(\mathcal{I})|] = n\mu(\mathcal{I}) = \mathcal{O}(ne^{-\alpha(R-\rho)}) = \mathcal{O}(ne^{-\alpha \log(\pi/2 \cdot e^{C/2} \gamma(n, \tau))}) = \mathcal{O}(n \cdot \gamma(n, \tau)^{-\alpha}).$$

Since $\gamma(n, \tau) = \mathcal{O}(\log^{(3)}(n))$, this bound on $\mathbb{E}[|V(\mathcal{I})|]$ is $\omega(\log(n))$, and we can apply the Chernoff bound in Corollary 2 to conclude that $|V(\mathcal{I})| = \mathcal{O}(n \cdot \gamma(n, \tau)^{-\alpha})$ holds with probability $1 - \mathcal{O}(n^{-c})$ for any $c > 0$. ◀

Since $\gamma(n, \tau) = \omega(1)$, Lemma 5 shows that, with high probability, the number of vertices that are greedily added to the vertex cover in the inner disk is sublinear. Once the inner disk has been processed and removed, the graph has been decomposed into small components and the ones of size at most $\tau \log \log(n)$ have already been solved exactly. The remaining vertices that are now added greedily belong to large components in the outer band.

4.2 The Outer Band

To identify the vertices in the outer band that are contained in components whose size exceeds $\tau \log \log(n)$, we divide it into sectors of angular width $\gamma = \theta(\rho, \rho) = \pi \cdot \gamma(n, \tau) / n \cdot (1 + o(1))$, where $\theta(\rho, \rho)$ denotes the maximum angular distance between two vertices with radii ρ to be adjacent (see Equation (2)). This division is depicted in Figure 1 (right). The choice of γ (combined with the choice of ρ) has the effect that an edge between two vertices in the outer band cannot extend beyond an empty sector, i.e., a sector that does not contain any vertices, allowing us to use empty sectors as delimiters between components. To this end, we introduce the notion of *runs*, which are maximal sequences of non-empty sectors (grey in Figure 1 (right)). While a run can contain multiple components, the number of vertices in it denotes an upper bound on the combined sizes of the components that it contains.

To show that there are only few vertices in components whose size exceeds $\tau \log \log(n)$, we bound the number of vertices in runs that contain more than $\tau \log \log(n)$ vertices. For a given run this can happen for two reasons. First, it may contain many vertices if its angular interval is too large, i.e., it consists of too many sectors. This is unlikely, since the sectors are chosen sufficiently small, such that the probability for a given one to be empty is high. Second, while the angular width of the run is not too large, it contains too many vertices for its size. However, the vertices of the graph are distributed uniformly at random in the disk, making it unlikely that too many vertices are sampled into such a small area. To formalize this, we introduce a threshold w and distinguish between two types of runs: A *wide* run contains more than w sectors, while a *narrow* run contains at most w sectors. The threshold w is chosen such that the probabilities for a run to be wide and for a narrow run to contain more than $\tau \log \log(n)$ vertices are small. To this end, we set $w = e^{\gamma(n, \tau)} \cdot \log^{(3)}(n)$.

In the following, we first bound the number of vertices in wide runs. Afterwards, we consider narrow runs that contain more than $\tau \log \log(n)$ vertices. Together, this gives an upper bound on the number of vertices that are added greedily in the outer band.

4.2.1 Wide Runs

We refer to a sector that contributes to a wide run as a *widening sector*. In the following, we bound the number of vertices in all wide runs in three steps. First, we determine the expected number of all widening sectors. Second, based on the expected value, we show that the number of widening sectors is small, with high probability. Finally, we make use of the fact that the area of the disk covered by widening sectors is small, to show that the number of vertices sampled into the corresponding area is sublinear, with high probability.

Expected Number of Widening Sectors. Let n' denote the total number of sectors and let $S_1, \dots, S_{n'}$ be the corresponding sequence. For each sector S_k , we define the random variable S_k indicating whether S_k contains any vertices, i.e., $S_k = 0$ if S_k is empty and $S_k = 1$ otherwise. The sectors in the disk are then represented by a circular sequence of indicator random variables $S_1, \dots, S_{n'}$, and we are interested in the random variable W that denotes the sum of all runs of 1s that are longer than w . In order to compute $\mathbb{E}[W]$, we first compute the total number of sectors, as well as the probability for a sector to be empty or non-empty.

► **Lemma 6.** *Let G be a hyperbolic random graph on n vertices. Then, the number of sectors of width $\gamma = \theta(\rho, \rho)$ is $n' = 2n/\gamma(n, \tau) \cdot (1 \pm o(1))$.*

Proof. Since all sectors have equal angular width $\gamma = \theta(\rho, \rho)$, we can use Equation (2) to compute the total number of sectors as $n' = 2\pi/\theta(\rho, \rho) = \pi e^{-R/2+\rho}(1 \pm \Theta(e^{R-2\rho}))^{-1}$. By substituting $\rho = R - \log(\pi/2 \cdot e^{C/2}\gamma(n, \tau))$ and $R = 2\log(n) + C$, we obtain

$$n' = \frac{\pi e^{R/2}}{\pi/2 \cdot e^{C/2}\gamma(n, \tau)} (1 \pm \Theta(e^{-R}\gamma(n, \tau)^2))^{-1} = 2n/\gamma(n, \tau) \cdot (1 \pm \Theta((\gamma(n, \tau)/n)^2))^{-1}.$$

It remains to simplify the error term. Note that $\gamma(n, \tau) = \mathcal{O}(\log^{(3)}(n))$. Consequently, the error term is equivalent to $(1 \pm o(1))^{-1}$. Finally, it holds that $1/(1+x) = 1 - \Theta(x)$ is valid for $x = \pm o(1)$, according to Lemma 3. ◀

► **Lemma 7.** *Let G be a hyperbolic random graph on n vertices and let \mathcal{S} be a sector of angular width $\gamma = \theta(\rho, \rho)$. For sufficiently large n , the probability that \mathcal{S} contains at least one vertex is bounded by*

$$1 - e^{-\gamma(n, \tau)/4} \leq \Pr[V(\mathcal{S}) \neq \emptyset] \leq e^{-\left(e^{-\gamma(n, \tau)}\right)}.$$

We are now ready to bound the expected number of widening sectors, i.e., sectors that are part of wide runs. To this end, we aim to apply the following lemma.

► **Lemma 8** ([23, Proposition 4.3¹]). *Let $S_1, \dots, S_{n'}$ denote a circular sequence of independent indicator random variables, such that $\Pr[S_k = 1] = p$ and $\Pr[S_k = 0] = 1 - p = q$, for all $k \in \{1, \dots, n'\}$. Furthermore, let W denote the sum of the lengths of all success runs of length at least $w \leq n'$. Then, $\mathbb{E}[W] = n'p^w(wq + p)$.*

We note that the indicator random variables $S_1, \dots, S_{n'}$ are *not* independent on hyperbolic random graphs. To overcome this issue, we compute the expected value of W on hyperbolic random graphs with n vertices in expectation (see Section 2) and subsequently derive a probabilistic bound on W for hyperbolic random graphs.

► **Lemma 9.** *Let G be a hyperbolic random graph with n vertices in expectation and let W denote the number of widening sectors. Then,*

$$\mathbb{E}[W] \leq \frac{2^{1/4} \cdot \tau^{3/4} \cdot n}{\gamma(n, \tau) \cdot \log^{(2)}(n)^{1/4} \cdot \log^{(3)}(n)^{1/2}} (1 \pm o(1)).$$

Proof. A widening sector is part of a run of more than $w = e^{\gamma(n, \tau)} \cdot \log^{(3)}(n)$ consecutive non-empty sectors. To compute the expected number of widening sectors, we apply Lemma 8. To this end, we use Lemma 6 to bound the total number of sectors n' and bound the probability $p = \Pr[S_k = 1]$ (i.e., the probability that sector \mathcal{S}_k is not empty) as $p \leq \exp(-(e^{-\gamma(n, \tau)}))$, as

¹ The original statement has been adapted to fit our notation. We use n', w , and W to denote the total number of random variables, the threshold for long runs, and the sum of their lengths, respectively. They were previously denoted by n, k , and S , respectively. In the original statement $s = 0$ indicates that the variables are distributed independently and identically, and c indicates that the sequence is circular.

well as the complementary probability $q = 1 - p \leq e^{-\gamma(n,\tau)/4}$ using Lemma 7. We obtain

$$\begin{aligned}\mathbb{E}[W] &= n' p^{(w+1)} ((w+1)q + p) \\ &\leq \frac{2n}{\gamma(n,\tau)} (1 \pm o(1)) \cdot e^{-((w+1)e^{-\gamma(n,\tau)})} \cdot \left((w+1)e^{-\frac{\gamma(n,\tau)}{4}} + 1 \right) \\ &\leq \frac{2n}{\gamma(n,\tau)} e^{(-e^{\gamma(n,\tau)} \log^{(3)}(n) e^{-\gamma(n,\tau)})} \left((e^{\gamma(n,\tau)} \log^{(3)}(n) + 1) e^{-\frac{\gamma(n,\tau)}{4}} + 1 \right) (1 \pm o(1)) \\ &= \frac{2ne^{3/4 \cdot \gamma(n,\tau)} \log^{(3)}(n)}{\gamma(n,\tau) \cdot \log^{(2)}(n)} \left(1 + \frac{1}{e^{\gamma(n,\tau)} \log^{(3)}(n)} + \frac{1}{e^{3/4 \cdot \gamma(n,\tau)} \log^{(3)}(n)} \right) (1 \pm o(1)).\end{aligned}$$

Since $\gamma(n,\tau) = \omega(1)$, the first error term can be simplified as $(1 + o(1))$. Additionally, we can substitute $\gamma(n,\tau) = \log(\tau \log^{(2)}(n)/(2 \log^{(3)}(n)^2))$ to obtain

$$\mathbb{E}[W] \leq 2^{1/4} \frac{\tau^{3/4} \cdot n \cdot \log^{(3)}(n)}{\gamma(n,\tau) \cdot \log^{(2)}(n)} \cdot \frac{\log^{(2)}(n)^{3/4}}{\log^{(3)}(n)^{3/2}} \cdot (1 \pm o(1)).$$

Further simplification then yields the claim. \blacktriangleleft

Concentration Bound on the Number of Widening Sectors. Lemma 9 bounds the expected number of widening sectors and it remains to show that this bound holds with high probability. To this end, we first determine under which conditions the sum of long success runs in a circular sequence of indicator random variables can be bounded with high probability in general. Afterwards, we show that these conditions are met for our application.

► **Lemma 10.** *Let $S_1, \dots, S_{n'}$ denote a circular sequence of independent indicator random variables and let W denote the sum of the lengths of all success runs of length at least $1 \leq w \leq n'$. If $g(n') = \omega(w\sqrt{n' \log(n')})$ is an upper bound on $\mathbb{E}[W]$, then $W = \mathcal{O}(g(n'))$ holds with probability $1 - \mathcal{O}((n')^{-c})$ for any constant c .*

► **Lemma 11.** *Let G be a hyperbolic random graph on n vertices. Then, with probability $1 - \mathcal{O}(n^{-c})$ for any constant $c > 0$, the number of widening sectors W is bounded by*

$$W = \mathcal{O} \left(\frac{\tau^{3/4} \cdot n}{\gamma(n,\tau) \cdot \log^{(2)}(n)^{1/4} \cdot \log^{(3)}(n)^{1/2}} \right).$$

Number of Vertices in Wide Runs. Let \mathcal{W} denote the area of the disk covered by all widening sectors. By Lemma 11 the total number of widening sectors is small, with high probability. As a consequence, \mathcal{W} is small as well and we can derive that the size of the vertex set $V(\mathcal{W})$ containing all vertices in all widening sectors is sublinear with high probability.

► **Lemma 12.** *Let G be a hyperbolic random graph on n vertices. Then, with high probability, the number of vertices in wide runs is bounded by*

$$|V(\mathcal{W})| = \mathcal{O} \left(\frac{\tau^{3/4} \cdot n}{\log^{(2)}(n)^{1/4} \cdot \log^{(3)}(n)^{1/2}} \right).$$

It remains to bound the number of vertices in large components contained in narrow runs.

4.2.2 Narrow Runs

In the following, we differentiate between *small* and *large* narrow runs, containing at most and more than $\tau \log \log(n)$ vertices, respectively. To obtain an upper bound on the number N of vertices in all large narrow runs, we determine the area \mathcal{N} of the disk that is covered by them. We start by computing the expected number of vertices contained in a single narrow run from which we can derive that the probability for a narrow run to be large is low.

Expected Number of Vertices in Large Narrow Runs.

► **Lemma 13.** *Let G be a hyperbolic random graph on n vertices and let \mathcal{R} be a narrow run. Then, $\mathbb{E}[|V(\mathcal{R})|] \leq 1/2 \cdot e^{\gamma(n,\tau)} \log^{(3)}(n) \gamma(n,\tau) (1 \pm o(1))$.*

Proof. A narrow run consists of at most $w = e^{\gamma(n,\tau)} \log^{(3)}(n)$ sectors. Since the angular coordinates of the vertices are distributed uniformly at random and since we partitioned the disk into n' disjoint sectors of equal width, we can derive an upper bound on the expected number of vertices in \mathcal{R} as $\mathbb{E}[|V(\mathcal{R})|] \leq nw/n'$. As $n' = 2n/\gamma(n,\tau)(1 \pm o(1))$ according to Lemma 6, we have

$$\mathbb{E}[|V(\mathcal{R})|] \leq 1/2 \cdot e^{\gamma(n,\tau)} \log^{(3)}(n) \gamma(n,\tau) (1 \pm o(1))^{-1}.$$

Since $1/(1+x) = 1 - \Theta(x)$ for $x = \pm o(1)$ (Lemma 3), we obtain the claimed bound. ◀

Using this upper bound, we can bound the probability that the number of vertices in a narrow run exceeds the threshold $\tau \log \log(n)$ by a certain amount.

► **Lemma 14.** *Let G be a hyperbolic random graph on n vertices and let \mathcal{R} be a narrow run. For $k > \tau \log \log(n)$ and n large enough, it holds that $\Pr[|V(\mathcal{R})| = k] \leq e^{-k/18}$.*

We are now ready to compute the expected number of vertices in all large narrow runs.

► **Lemma 15.** *Let G be a hyperbolic random graph. Then, the expected number of vertices in all large narrow runs is bounded by*

$$\mathbb{E}[N] = \mathcal{O} \left(\frac{\tau \cdot n \cdot \log^{(2)}(n)}{\gamma(n,\tau) \log(n)^{\tau/18}} \right).$$

Proof. Let n'' denote the total number of narrow runs. We can compute the number of vertices in all large narrow runs, by summing over all narrow runs $\mathcal{R}_1, \dots, \mathcal{R}_{n''}$ and discarding the ones that are not large. That is,

$$N = \sum_{i=1}^{n''} |V(\mathcal{R}_i)| \cdot \mathbb{1}_{|V(\mathcal{R}_i)| > \tau \log^{(2)}(n)}.$$

Consequently, the expected value of N is given by

$$\mathbb{E}[N] = \sum_{i=1}^{n''} \mathbb{E} \left[|V(\mathcal{R}_i)| \cdot \mathbb{1}_{|V(\mathcal{R}_i)| > \tau \log^{(2)}(n)} \right] = \sum_{i=1}^{n''} \sum_{k=\tau \log^{(2)}(n)+1}^n k \cdot \Pr[|V(\mathcal{R}_i)| = k].$$

Lemma 14 gives a valid upper bound on $\Pr[|V(\mathcal{R}_i)| = k]$ for all $i \in \{1, \dots, n''\}$. Furthermore, the number of narrow runs n'' is bounded by the number of sectors n' . Therefore, we obtain

$$\mathbb{E}[N] \leq n' \sum_{k=\tau \log^{(2)}(n)+1}^n k \cdot e^{-k/18}.$$

To get an upper bound, we replace the sum with an integral, which yields

$$\begin{aligned}\mathbb{E}[N] &\leq n' \int_{\tau \log^{(2)}(n)}^n k e^{-\frac{k}{18}} dk \\ &\leq n' \left[18e^{-\tau/18 \log^{(2)}(n)} (\tau \log^{(2)}(n) + 18) - 18e^{-n/18} (n + 18) \right] \\ &\leq 18n' \cdot \frac{\tau \log^{(2)}(n) + 18}{\log(n)^{\tau/18}},\end{aligned}$$

where the last inequality holds since $e^{-n/18}(n+18) \geq 0$. Substituting $n' = 2n/\gamma(n, \tau)(1 \pm o(1))$ (Lemma 6) and more simplification yield the claim. \blacktriangleleft

Concentration Bound on the Number of Vertices in Large Narrow Runs. To show that the actual number of vertices in large narrow runs is not much larger than the expected value, we apply the method of typical bounded differences [29]. (See the full version of the paper for a detailed explanation [7].) To this end, we consider N as a function of the positions of the vertices and bound the effect that changing a single position can have on this function. It is easy to see, that this effect is the largest, when the change splits a wide run \mathcal{R} into two large narrow runs. If \mathcal{R} contained a lot of vertices, the impact on N is large. However, since the vertices are distributed uniformly, it is very unlikely that a run that can be split into two narrow runs contains many vertices.

► **Lemma 16.** *Let G be a hyperbolic random graph. Then, each run of length at most $2w + 1$ contains at most $\mathcal{O}(\log(n))$ vertices with probability $1 - \mathcal{O}(n^{-c})$ for any constant c .*

The method of typical bounded differences now allows us to focus on this case and to milden the impact of the worst case changes as they occur with small probability. Consequently, we can show that the number of vertices in large narrow runs is sublinear with high probability.

► **Lemma 17.** *Let G be a hyperbolic random graph. Then, with high probability, the number of vertices in large narrow runs is bounded by*

$$N = \mathcal{O}\left(\frac{\tau \cdot n \cdot \log^{(2)}(n)}{\gamma(n, \tau) \log(n)^{\tau/18}}\right).$$

4.3 The Complete Disk

In the previous subsections we determined the number of vertices that are greedily added to the vertex cover in the inner disk and outer band, respectively. Before proving our main theorem, we are now ready to prove a slightly stronger version that shows how the parameter τ can be used to obtain a tradeoff between approximation performance and running time.

► **Theorem 18.** *Let G be a hyperbolic random graph on n vertices with power-law exponent $\beta = 2\alpha + 1$ and let $\tau > 0$ be constant. Given the radii of the vertices, an approximate vertex cover of G can be computed in time $\mathcal{O}(m \log(n)^\tau + n \log(n))$, such that the approximation factor is $(1 + \mathcal{O}(\gamma(n, \tau)^{-\alpha}))$ asymptotically almost surely.*

Proof. *Running Time.* We start by sorting the vertices of the graph in order of increasing radius, which can be done in time $\mathcal{O}(n \log(n))$. Afterwards, we iterate them and perform the following steps for each encountered vertex v . We add v to the cover, remove it from the graph, and identify connected components of size at most $\tau \log \log(n)$ that were separated by the removal. The first two steps can be performed in time $\mathcal{O}(1)$ and $\mathcal{O}(\deg(v))$, respectively.

Identifying and solving small components is more involved. Removing v can split the graph into at most $\deg(v)$ components, each containing a neighbor u of v . Such a component can be identified by performing a breadth-first search (BFS) starting at u . Each BFS can be stopped as soon as it encounters more than $\tau \log \log(n)$ vertices. The corresponding subgraph contains at most $(\tau \log \log(n))^2$ edges. Therefore, a single BFS takes time $\mathcal{O}(\log \log(n)^2)$. Whenever a component of size at most $n_c = \tau \log \log(n)$ is found, we compute a minimum vertex cover for it in time $1.1996^{n_c} \cdot n_c^{\mathcal{O}(1)}$ [30]. Since $n_c^{\mathcal{O}(1)} = \mathcal{O}((e/1.1996)^{n_c})$, this running time is bounded by $\mathcal{O}(e^{n_c}) = \mathcal{O}(\log(n)^\tau)$. Consequently, the time required to process each neighbor of v is $\mathcal{O}(\log(n)^\tau)$. Since this is potentially performed for all neighbors of v , the running time of this third step can be bounded by introducing an additional factor of $\deg(v)$. We then obtain the total running time $T(n, m, \tau)$ of the algorithm by summing the running times of all three steps over all vertices, which yields

$$\begin{aligned} T(n, m, \tau) &= \sum_{v \in V} \mathcal{O}(1) + \mathcal{O}(\deg(v)) + \deg(v) \cdot \mathcal{O}(\log(n)^\tau) \\ &= \mathcal{O} \left(\log(n)^\tau \cdot \sum_{v \in V} \deg(v) \right) = \mathcal{O}(m \log(n)^\tau). \end{aligned}$$

Approximation Ratio. As argued before, we obtain a valid vertex cover for the whole graph, if we take all vertices in V_{Greedy} together with a vertex cover C_{Exact} of $G[V_{\text{Exact}}]$. The approximation ratio of the resulting cover is then given by the quotient

$$\delta = \frac{|V_{\text{Greedy}}| + |C_{\text{Exact}}|}{|C_{\text{OPT}}|},$$

where C_{OPT} denotes an optimal solution. Since all components in $G[V_{\text{Exact}}]$ are solved optimally and since any minimum vertex cover for the whole graph induces a vertex cover on $G[V']$ for any vertex subset $V' \subseteq V$, it holds that $|C_{\text{Exact}}| \leq |C_{\text{OPT}}|$. Therefore, the approximation ratio can be bounded by $\delta \leq 1 + |V_{\text{Greedy}}|/|C_{\text{OPT}}|$. To bound the number of vertices in V_{Greedy} , we add the number of vertices in the inner disk \mathcal{I} , as well as the numbers of vertices in the outer band that are contained in the area \mathcal{W} that is covered by wide runs and the area \mathcal{N} that is covered by large narrow runs. That is,

$$\delta \leq 1 + \frac{|V(\mathcal{I})| + |V(\mathcal{W})| + |V(\mathcal{N})|}{|C_{\text{OPT}}|}.$$

Upper bounds on $|V(\mathcal{I})|$, $|V(\mathcal{W})|$, and $|V(\mathcal{N})|$ that hold with high probability are given by Lemmas 5, 12, and 17, respectively. Furthermore, it was previously shown that the size of a minimum vertex cover on a hyperbolic random graph is $|C_{\text{OPT}}| = \Omega(n)$, asymptotically almost surely [10, Theorems 4.10 and 5.8]. We obtain

$$\delta = 1 + \mathcal{O} \left(\frac{1}{\gamma(n, \tau)^\alpha} + \frac{\tau^{3/4}}{\log^{(2)}(n)^{1/4} \cdot \log^{(3)}(n)^{1/2}} + \frac{\tau \cdot \log^{(2)}(n)}{\gamma(n, \tau) \log(n)^{\tau/18}} \right).$$

Since $\gamma(n, \tau) = \mathcal{O}(\log^{(3)}(n))$, the first summand dominates asymptotically. \blacktriangleleft

► Theorem 4. *Let G be a hyperbolic random graph on n vertices. Given the radii of the vertices, an approximate vertex cover of G can be computed in time $\mathcal{O}(m \log(n))$, such that the approximation ratio is $(1 + o(1))$ asymptotically almost surely.*

Proof. By Theorem 18 we can compute an approximate vertex cover in time $\mathcal{O}(n \log(n) + m \log(n)^\tau)$, such that the approximation factor is $1 + \mathcal{O}(\gamma(n, \tau)^{-\alpha})$, asymptotically almost surely. We obtain the claimed bound on the running time by choosing $\tau = 1$. Furthermore, since $\gamma(n, 1) = \omega(1)$ and $\alpha \in (1/2, 1)$, the resulting approximation factor is $(1 + o(1))$. \blacktriangleleft

Abstract

We study the maximum-flow/minimum-cut problem on scale-free networks, i.e., graphs whose degree distribution follows a power-law. We propose a simple algorithm that capitalizes on the fact that often only a small fraction of such a network is relevant for the flow. At its core, our algorithm augments Dinitz’s algorithm with a balanced bidirectional search. Our experiments on a scale-free random network model indicate sublinear run time. On scale-free real-world networks, we outperform the commonly used highest-label Push-Relabel implementation by up to two orders of magnitude. Compared to Dinitz’s original algorithm, our modifications reduce the search space, e.g., by a factor of 275 on an autonomous systems graph.

Beyond these good run times, our algorithm has an additional advantage compared to Push-Relabel. The latter computes a preflow, which makes the extraction of a minimum cut potentially more difficult. This is relevant, for example, for the computation of Gomory-Hu trees. On a social network with 70 000 nodes, our algorithm computes the Gomory-Hu tree in 3 seconds compared to 12 minutes when using Push-Relabel.

1 Introduction

The maximum flow problem is arguably one of the most fundamental graph problems that regularly appears as a subtask in various applications [2, 29, 32]. The go-to general-purpose algorithm for computing flows in practice is the highest-label Push-Relabel algorithm by Cherkassky and Goldberg [11], which is also part of the boost graph library [30]. Beyond that, the BK-algorithm by Boykov and Kolmogorov [8] or its later iteration [17] should be used for instances appearing in computer vision. Our main goal in this paper is to provide a flow algorithm tailored towards *scale-free* networks. Such networks are characterized by their heavy-tailed degree distribution resembling a power-law, i.e., they are sparse with few vertices of comparatively high degree and many vertices of low degree.

At its core, our algorithm is a variant of Dinitz’s algorithm [13], which is an augmenting path algorithm that iteratively increases the flow along collections of shortest paths in the residual network. In each iteration, at least one edge on every shortest path gets saturated, thereby increasing the distance between source and sink in the residual network. To exploit the structure of scale-free networks, we make use of the facts that, firstly, shortest paths tend

to span only a small fraction of such networks, and secondly, a balanced bidirectional breadth first search is able to find the shortest paths very efficiently [7, 6]. Using a bidirectional search to compute shortest paths in Dinitz’s algorithm directly translates this efficiency to the first iteration, as the residual network initially coincides with the flow network. Though the structure of the residual network changes in later iterations, our experiments show that the run time improvements achieved by using a bidirectional search remain high.

Scaling experiments with geometric inhomogeneous random graphs (GIRGs)¹ [9] indicate that the flow computation of our algorithm runs in sublinear time. In comparison, previous algorithms (Push-Relabel, BK, and unidirectional Dinitz) require slightly super-linear time. This is also reflected in the high speedups we achieve on real-world scale-free networks.

With the flow computation itself being so efficient, the total run time for computing the maximum flow for a single source-sink pair in a scale-free network is heavily dominated by loading the graph and building data structures. Thus, our algorithm is particularly relevant when we have to compute multiple flows in the same network. This is, e.g., the case when computing the Gomory-Hu tree [20] of a network. The Gomory-Hu tree is a compact representation of the minimum s - t cuts for all source-sink pairs (s, t) . It can be computed with Gusfield’s algorithm [21] using $n - 1$ flow computations in a network with n vertices. Using our bidirectional flow algorithm as the subroutine for flow computations in Gusfield’s algorithm lets us compute the Gomory-Hu tree of, e.g., the `soc-slashdot` instance with 70k nodes and 360k edges in only 2.6s. In this context, we observe that the Push-Relabel algorithm is also very efficient in computing the flow values by computing a preflow. However, converting this to a flow or extracting a cut from it takes significantly more time.

Contribution. Our findings can be summarized in the following main contributions.

- We provide a simple and efficient flow-algorithm that significantly outperforms previous algorithms on scale-free networks.
- It’s efficiency on non-scale-free instances makes it a potential replacement for the Push-Relabel algorithm for general-purpose flow computations.
- Our algorithm is well suited to compute the Gomory-Hu tree of large instances.
- In contrast to previous observations [11, 12], situations exist where computing a flow with the Push-Relabel algorithm is significantly more expensive than computing a preflow.

Related Work. We briefly discuss only the work most related to our result. For a more extensive overview on the topic of flows, we refer to the survey by Goldberg and Tarjan [19].

Our algorithm is based on Dinitz’s Algorithm [13], which belongs to the family of *augmenting path algorithms* originating from the Ford-Fulkerson algorithm [16]. Augmenting path algorithms use the *residual network* to represent the remaining capacities and iteratively increase the flow by augmenting it with paths from source to sink in the residual network, until no such path exists. At every point in time, a valid flow is known and at the end of execution, non-reachability in the residual network certifies maximality.

From this perspective, the *Push-Relabel algorithm* [18] does the reverse. At every point in time, the sink is not reachable from the source in the residual network, thereby guaranteeing maximality, while the object maintained throughout the algorithm is a so-called *preflow* and the algorithm stops once the preflow is actually a flow. This is achieved using two operations

¹ GIRGs are a generative network model closely related to hyperbolic random graphs [25]. They resemble real-world networks in regards to important properties such as degree distribution, clustering, and distances.

push and *relabel*; hence the name. Different variants of the Push-Relabel algorithm mainly differ with regards to the order in which operations are applied. A strategy performing well in practice is the highest-label strategy [11]. The extensive empirical study by Ahuja et al. [1] on ten different algorithms shows that the highest-label Push-Relabel algorithm indeed performs the best out of the ten. The only small caveat with these experiments is the fact that they are based on artificial networks that are specifically generated to pose difficult instances. Our experiments show that the structure of the instance matters in the sense that it impacts different algorithms differently; potentially yielding different rankings on different types of instances. The so-called pseudoflow algorithm by Hochbaum [23] was later shown to slightly outperform (low single-digit speedups on most instances) the highest-label Push-Relabel algorithm; again based on artificial instances [10].

Boykov and Kolmogorov [8] gave an algorithm tailored specifically towards instances that appear in computer vision; outperforming Push-Relabel on these instances. It was later refined by Goldberg et al. [17]. Most related to our studies is the work by Halim et al. [22] who developed a distributed flow algorithm for MapReduce on huge social networks.

2 Network Flows and Dinitz's Algorithm

Network Flows. A flow network is a directed graph $G = (V, E)$ with source and sink vertices $s, t \in V$, and a capacity function $c : V \times V \rightarrow \mathbb{N}$ with $c(u, v) = 0$ if $(u, v) \notin E$. A *flow* f on G is a function $f : V \times V \rightarrow \mathbb{Z}$ satisfying three constraints: (I) capacity $f(u, v) \leq c(u, v)$ (II) asymmetry $f(u, v) = -f(v, u)$ and (III) conservation $\sum_{v \in V} f(u, v) = 0$ for $u \in V \setminus \{s, t\}$. We call an edge $(u, v) \in E$ *saturated* if $f(u, v) = c(u, v)$. Denote the *value* of a flow f as $\sum_{v \in V} f(s, v)$. The maximum flow problem, *max-flow* for short, is the problem of finding a flow of maximum value.

Given a flow f in G , we define a network G_f called the *residual network*. G_f has the same set of nodes and contains the directed edge (u, v) if $f(u, v) < c(u, v)$. The capacity c' of edges in G_f is given by the residual capacity in the original network, i.e., $c'(u, v) = c(u, v) - f(u, v)$. An s - t path in G_f is called an *augmenting path*.

Dinitz's Algorithm. Let $d_s(v)$ be the distance from s to vertex v in G_f . We define a subgraph of G_f called the *layered network* by restricting the edge set to edges (u, v) of G_f for which $d_s(u) + 1 = d_s(v)$, i.e., edges that increase the distance to the source. We call a flow *blocking* if every s - t path contains at least one edge that is saturated by this flow, i.e., there is no augmenting path.

Dinitz's algorithm (see Algorithm 1) groups augmentations into rounds. It augments a set of edges that constitutes a blocking flow of the layered network in each round. One can find such a set of edges by iteratively augmenting s - t paths in the layered network until source and sink become disconnected. After augmenting a blocking flow, the distance between the terminals in the residual network strictly increases.

Algorithm 1 Dinitz's Algorithm.

```

2   build layered network
3   while  $s$ - $t$  path in layered network do
4     augment flow with  $s$ - $t$  path

```

Asymptotic Running Time. To better understand how our modifications impact the run time, we briefly sketch how Dinitz running time of $O(n^2m)$ is obtained. Since $d_s(t)$ increases each round, the number of rounds is bounded by $n - 1$. Each round consists of two stages: building the layered network and augmenting a blocking flow. The layered network can be constructed in $O(m)$ using a breadth-first search (BFS). Finding the blocking flow is done with a repeated graph traversal, usually using a depth-first search (DFS). The number of found paths is bounded by m , because each found path saturates at least one edge, removing it from the layered network. A single DFS can be done in amortized $O(n)$ time as follows. Edges that are not part of an s - t path in the layered network do not need to be looked at more than once during one round. This is achieved by remembering for each node which edges of the layered network were already found to have no remaining path to the sink. Each subsequent DFS will start where the last one left off. Thus, per round, the depth-first searches have a combined search space of $O(m)$, while each individual search additionally visits the nodes on one s - t path which is $O(n)$.

Practical Performance. In our experiments $d_s(t)$ remains mostly below 10, implying that the number of rounds is significantly lower than $n - 1$. Also, the number of found augmenting paths during one rounds is far below m . In unweighted networks, for example, a DFS saturates all edges of the found path resulting in a bound of $O(m)$ to find a blocking flow. Dinitz's algorithm has a tight upper bound of $O(n^{2/3}m)$ in unweighted networks [14, 24].

3 Improving Dinitz on Scale-Free Networks

We adapt a common Dinitz implementation² to exploit the specific structure of scale-free networks. We achieve a significant speedup by using the fact that a flow and cut respectively often depend only on a small fraction of the network. The following three modifications each tackle a performance bottleneck.

Bidirectional Search. Recently, sublinear running time was shown for balanced bidirectional search in a scale-free network model [6, 7]. We use a bidirectional breadth-first-search to compute the distances that define the layered network during each round of Dinitz's algorithm. A forward search is performed from the source and a backward search from the sink, each time advancing the search that incurs the lower cost to advance one layer. A shortest s - t path is found when a vertex is discovered that was already seen from the other direction. Note that, for our purpose, the bidirectional search has to finish the current layer when such a vertex is discovered, because all shortest paths must be found. Figure 1 visualizes the difference in explored vertices between a normal and a bidirectional BFS. The augmentations with DFS are restricted to the visited part of the layered network, meaning the search space of the BFS plus the next layer.

The distance labeling obtained by the bidirectional BFS requires a change to the DFS. The purpose of the layered network is to contain all edges on shortest s - t paths. The DFS identifies edges (u, v) of the layered network by checking if they increase the distance from the source, i.e., $d_s(u) + 1 = d_s(v)$. However, we no longer obtain the distances from the source for all relevant vertices. For vertices processed by the backward search, distances to the sink $d_t(v)$ are known instead. To resolve the problem, we allow edges that either increase distance from the source or decrease distance to the sink, i.e., $d_s(u) + 1 = d_s(v)$

² <https://cp-algorithms.com/graph/dinic.html>

■ **Figure 1** Search space of a breadth-first search from a source s to a sink t unidirectional (left) and bidirectional (right). The blue area represents the vertices that are explored, i.e., whose outgoing edges were scanned, by the forward search and the green area the backward search. In the gray area are vertices that are seen during exploration of the last layer, but not yet explored. Vertices in the intersection of the upcoming layers of the backward and forward search are marked orange.

or $d_t(u) - 1 = d_t(v)$. This deviates from the definition of the layered network. But since edges on shortest s - t paths must both, increase the distance from the source and decrease the distance to the sink, we do not miss any relevant edges.

Time Stamps. The bidirectional search reduces the search space of the breadth-first search and depth-first search substantially, potentially to sublinear. The initialization, however, still requires linear time. It includes distances from the source and to the sink and one progress counter per node for the augmentations. To avoid the linear initializations, we introduce time stamps to indicate if a vertex was seen during the current round. The initialization of distances and counters is done lazily as vertices are discovered during the BFS.

Skip Next Forward Layer. The DFS proceeds along edges outgoing from the last forward search layer independent from the target vertex being seen only by the forward search (gray in Figure 1) or also by the backward search (orange in Figure 1). However, the former type of vertex cannot be part of a shortest s - t path. By saving the number of explored layers of the forward search we can avoid the exploration of such vertices, thus limiting the DFS to vertices colored blue, green, or orange in Figure 1. With this optimization, the combined search space during augmentation (lines 3,4 in Algorithm 1) is almost limited to the search space of the BFS. The only additional edges that are visited originate from the intersection of the forward and backward search.

4 Experimental Evaluation

In this section, we investigate the performance of our algorithm *DinitzOPT*. First, we compare it to established approaches on real-world networks in Section 4.1. We additionally examine the scaling behavior and how the comparison is affected by problem size, i.e., is there an asymptotic improvement over other algorithms? Then, Section 4.2 evaluates to which extent the different optimizations contribute to better run times and search space. In Section 4.3 we analyze the algorithms in a specific application (Gomory-Hu trees) and compare their usability beyond the speed of the actual flow computation. To this end, we test three different approaches to obtain a cut with the Push-Relabel algorithm.

■ **Figure 2** Runtime comparison of flow computations. The 20 computed flows per instance are divided into *low* and *high* terminal pairs. For *low*, the terminal degree is between 0.75 and 1.25 times the average degree. For *high*, it is between 10 and 100 times the average degree. Pairs are chosen uniformly at random from all vertices with the respective degree.

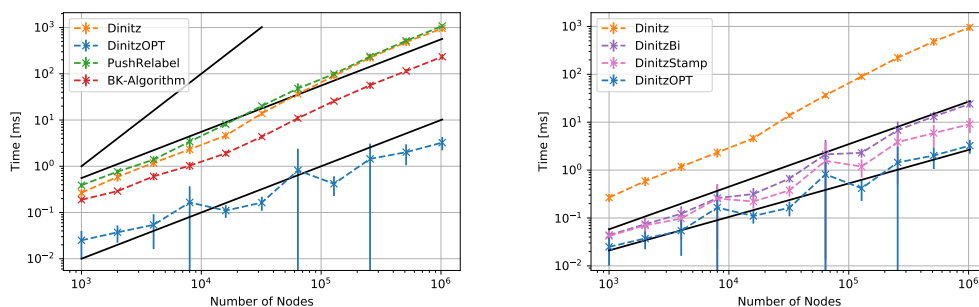

4.1 Runtime Comparison

In this section we compare our new approach to three existing algorithms: Dinitz [13], Push-Relabel [18], and the Boykov-Kolmogorov (BK) algorithm [8]. We modified their respective implementations to support our experiments. This also includes some minor performance-relevant changes listed in the long version of the paper along with further details on the datasets [5]. The experiments include two synthetic and eight real-world networks. All networks are undirected and all but *visualize-us* and *actors* are unweighted. We restrict our experiments in this section to the flow computation only excluding, e.g., loading times and resetting flow values between runs. For Push-Relabel we only measure the computation of the *preflow*, which is sufficient to determine the value of the flow/cut. Figure 2 shows the resulting run times. For this plot, the terminals were chosen uniformly at random from the set of vertices with degree close to the average (*low*) or considerably higher degree (*high*).

One can see that Dinitz and Push-Relabel display comparable times while BK is slightly slower on most large instances. DinitzOPT consistently outperforms the other algorithms by one to three orders of magnitude. The variance is also higher for DinitzOPT with *low* pairs approximately one order of magnitude faster on average than *high* pairs. This is best seen in the *girg100000* instance and suggests that DinitzOPT is able to better exploit easy problem instances. For all other algorithms the effect of the terminal degree on the run time is barely noticeable. Another observation is that all algorithms display drastically lower run times than their respective worst-case bounds would suggest.

The times in our experiments are close to what one might expect from linear algorithms. For example, Dinitz computes a flow on the *as-skitter* instance in one second. Considering the tight $O(mn^{2/3})$ bound in unweighted networks and assuming the throughput per second to be around 10^8 – which is a generous guess for graph algorithms – would result in an estimate of 30 minutes per flow. In contrast to our results, earlier studies found Dinitz to be slower than Push-Relabel and both algorithms clearly super-linear on a series of synthetic instances [1]. However, these synthetic instances exhibit specifically crafted hard structures that are placed between designated source and sink vertices. These instances thus present substantially more challenging flow problems.

Effect of the Terminal Degree. In the following, we discuss the effect of terminal degree and structure of the cut on the run time of Dinitz and DinitzOPT. Note that the terminal degree is an upper bound on the size of the cut in unweighted networks. Moreover, the

(a) Runtime scaling of flow algorithms.

(b) Scaling of Dinitz variants.

■ **Figure 3** (a) The average time per flow over multiple GIRGs and terminal pairs. (b) This plot differs from Figure 3a only in the set of displayed algorithms.

terminal degree in our experiments is based on the average degree, which is assumed to be constant in many real-world networks [3]. Thus, the $O(mC)$ bound for augmenting path based algorithms, with C being the size of the cut, implies not only a linear bound for the eight unweighted networks in our experiments, but would also explain faster *low* pairs. Surprisingly, DinitzOPT exploits low terminal degrees much more than Dinitz. Another explanation for faster *low* pairs is that many cuts are close around one terminal, which is consistent with previous observations about cuts in scale-free networks [27, 31]. Moreover, Dinitz tends to perform well when the source side of the cut is small [28]. Although this does not fully explain why DinitzOPT is more sensitive to the terminal degree, we observe in Section 4.3 that Dinitz slows down massively when the source degree is high, even with low sink degree. Since DinitzOPT always advances the side with smaller volume during bidirectional search it does not matter which terminal has the higher degree.

Scaling. We perform additional experiments to analyze the scaling behavior of the algorithms. Since real networks are scarce and fixed in size, we generate synthetic networks to gradually increase the size while keeping the relevant structural properties fixed. Geometric Inhomogeneous Random Graphs (GIRGs) [9], a generalization of Hyperbolic Random Graphs [25], are a scale-free generative network model that captures many properties of real-world networks. The efficient generator [4] allows us to benchmark our algorithms on differently sized networks with similar structure. Figure 3a and Figure 3b show the results.

We measure the run time over a series of GIRGs with the number of nodes growing exponentially from 1000 to 1 024 000 with 10 iterations each. In each iteration, we sample a new random graph with average degree 10, power-law exponent 2.8, dimension 1, and temperature 0. The run time for each algorithm is then averaged over 10 uniform random pairs of vertices with degree between 10 and 20. Standard deviation is shown as error bars. The lower half of the symmetric error bars seems longer due to the log-axis. We add a quadratic and two linear functions in Figure 3a. Figure 3b shows the functions $n^{0.88}$ and $n^{0.7}$ representing the theoretical upper bound and previously observed typical run times, respectively, for the bidirectional search on hyperbolic random graphs with the chosen power-law exponent [6].

Dinitz, Push-Relabel and BK show a near-linear running time. Compared to the linear functions in Figure 3a, Dinitz and Push-Relabel seem to scale slightly worse than linear, while DinitzOPT scales better than linear. In a construction with super-sink and super-source, a similar scaling was observed for Push-Relabel on the Yahoo Instant Messenger graph [26].

■ **Table 1** Total run times and search space of visited edges for the five intermediate versions of our Dinitz implementation during the computation of 1000 flows in **as-skitter**. Terminals are chosen like *low* pairs in Figure 2. The first seven columns show times in seconds accumulated over all flow computations. BUILD is the construction of the residual network that is reused for all flow computations, RESET means clearing flow on edges between computations, INIT includes initialization of distances and counters per round, BFS and DFS refer to the respective subroutines, FLOW is the summed time during flow computations (sum of BFS, DFS, INIT), and TOTAL is the run time of the whole application including reading the graph from file. The last three columns contain the search space relative to the number of edges in the graph in percent. Search space columns for BFS and DFS are per round, while the FLOW column lists the search space per flow, e.g., Dinitz visits on average 65.66% of all edges per BFS and every edge is visited about 5.58 times on average in one flow computation.

	BUILD	RESET	MaxFlow					Search Space [%]		
			INIT	BFS	DFS	FLOW	TOTAL	BFS	DFS	FLOW
Dinitz	0.50	56.79	14.87	405.46	426.80	847.13	904.85	65.66	63.64	558.04
DinitzBi	0.55	58.15	21.02	2.78	8.94	32.73	91.82	0.26	1.87	8.38
DinitzReset	0.50		20.73	2.47	8.01	31.20	32.06	0.26	1.87	8.38
DinitzStamp	0.55			2.51	10.30	12.81	13.72	0.26	1.87	8.38
DinitzOPT	0.55			2.40	1.06	3.46	4.22	0.26	0.20	2.03

4.2 Optimizations in Detail

Instead of considering all combinations of optimizations, we individually add them in a specific order, such that the next change always tackles a performance bottleneck. In fact, additional benchmarks reveal that the current optimization speeds up the computation more than enabling all other remaining changes together. The four incrementally more optimized versions of the algorithm are: DinitzBi, DinitzReset, DinitzStamp, and DinitzOPT.

Experimental Setup. The experiments and benchmarks in this section consider 1000 uniform random terminal pairs close to the average degree on the **as-skitter** instance. The average distance between source and sink in the initial network is 4.2. The average number of rounds until a maximum flow is found is 4.8, where the last round runs only the BFS to verify that no augmenting path exists. Only counting rounds before the last round, 2.9 units of flow are found on average per round. Out of the 1000 cuts, 882 have value equal to the degree of the smaller terminal. Table 1 shows profiler results and search space for Dinitz and the optimized versions of the algorithm. Figure 4 compares the search space with and without bidirectional search.

Bidirectional Search. Dinitz takes 15 minutes to compute the 1000 flows and the search space per flow is more than five times the number of edges on average. Almost all of that time is spent in BFS or DFS. The bidirectional Dinitz reduces the flow-time from 14 minutes to 30 seconds, an improvement by a factor of 25.

The search space is reduced by factors of 252 for BFS, 34 for DFS, and 67 per flow. It is interesting to note, that the search space of BFS during the last round of each flow changes even more. In this round the BFS will find no s-t path. The bidirectional search visits 39 edges on average, while the normal breadth-first-search visits 44% of the graph. This not only emphasizes that the cuts are close around one terminal, but also shows that the bidirectional search heavily exploits this structure.

The run time does not fully reflect this drastic reduction in search space, because DFS and BFS no longer dominate the flow computation. The initialization time per round increased by 50%, which can be explained by the additional distance label per node to store the

■ **Figure 4** Average number of edges visited per flow computation for the terminal pairs used in Table 1, partitioned as in Figure 1. *Forward/Backward Search* represent the edges explored by the respective search. *Next Forward/Backward Layer* denote the edges that would be explored in the next step of the BFS. Edges in the *Intersection* originate from vertices in both upcoming BFS-layers. The BFS and DFS bars show the edges that are actually visited by the algorithm. The shaded area indicates the edges skipped by our last optimization (from DinitzStamp to DinitzOPT in Table 1) and is excluded in the sum on the right.

distance to the sink (now 3 ints instead of 2). Although the initialization is a simple linear operation in the number of nodes, it takes twice as long as BFS and DFS combined. The real bottleneck, however, is to reset the flow values between computations. RESET takes almost a full minute which is twice as long as computing the flows.

Reset flow between computations. Between flow computations, the residual capacity of all edges has to be reset before another flow can be found. After changing the BFS to a bidirectional search, resetting the flow on all edges between computations dominates the run time. To reduce the time of our benchmarks, and to make the code more efficient in situations where multiple flows are computed in the same network, we address this bottleneck. Instead of explicitly resetting flow values for all edges, we remember the edges that contain flow and reset only those. This change is not mentioned in Section 3 because it does not speed up a single flow computation.

This change reduces the time for RESET to the point that it is no longer detected by the profiler, while other operations are not affected. The total time to compute all 1000 flows is thus three times lower with the flow computation making up for almost all spent time. The slowest part of the flow computation itself is still the initialization with 21 of the 31 seconds.

Time Stamps. The distance labels and counters per node are initialized each round. Using time stamps eliminates the need for initialization while adding a small overhead to DFS. The flow computation gets 2.4 times faster with 13 seconds instead of 31. After introducing the time stamps, the DFS is the new bottleneck and makes up for about 80% of flow time.

Skip Next Forward Layer. This change prevents the DFS from visiting vertices beyond the last layer of the forward search that are not also seen by the backwards search. In Figure 4 the skipped part is shaded. This optimization reduces the average search space for DFS during one round from almost 2% of all edges to just 0.2%. The improvement in search space is reflected by the profiler results. DFS is sped up from 10 seconds to just one second, which is faster than the BFS. The resulting time to compute all 1000 flows is 3.46 seconds, which is only 7 times slower than building the adjacency list in the beginning. In total, the time to compute the flows with the optimized Dinitz is 245 times faster than the unmodified Dinitz.

■ **Figure 5** Runtime comparison of flow computations. The 10 terminal pairs per instance are uniformly chosen out of the $n - 1$ cuts required by Gusfield’s algorithm.

4.3 Gomory-Hu Trees

In the last sections we observed that heterogeneous network structure yields easy flow problems that can be solved significantly faster than the construction of the adjacency list. This performance becomes important in applications that require multiple flows to be found in the same network. Gomory-Hu trees [20] fit this setting and have applications in graph clustering [15]. A Gomory-Hu tree (GH-tree) of a network is a weighted tree on the same set of vertices that preserves minimum cuts, i.e., each minimum cut between any two vertices s and t in the tree is also a minimum s - t cut in the original network. Thus, they compactly represent s - t cuts for all vertex pairs of a graph. For the construction of a GH-tree, we use Gusfield’s algorithm [21] that requires $n - 1$ cut-oracle calls in the original graph.

In this section we evaluate the performance of max-flow algorithms for the construction of Gomory-Hu trees in heterogeneous networks. We will see that the terminal pairs required for Gusfield’s algorithm yield easier flow problems than uniform random pairs. DinitzOPT is able to make use of this easy structure to achieve surprisingly low run times, so is Push-Relabel when only considering the computation of the flow value. However, we find that the need to extract the source side of the cut hinders Push-Relabel to benefit from this performance.

Flow Computation on Gusfield Pairs. Figure 5 shows the same networks and algorithms as in Figure 2 but with terminal pairs sampled out of the $n - 1$ flow computations needed by Gusfield’s algorithm. The run times for all algorithms except the BK-Algorithm have high variance and are spread over up to four orders of magnitude for the larger instances. Although results for different terminal pairs vary greatly, BK seems to be the slowest algorithm followed by Dinitz. DinitzOPT and PR have comparable but significantly lower run times than the other algorithms. For example, 6 out of the 10 *gh* pairs measured for the **soc-slashdot** instance are solved by DinitzOPT and Push-Relabel faster than one microsecond which is the precision of our measurements. This suggests, that these algorithms are more sensitive to the varying difficulty of the flow computations for *gh* pairs. Our speedup over the Push-Relabel algorithm on *gh* pairs is not as pronounced as for the random pairs in Section 4.1. On the **dogster** instance PR is even faster than DinitzOPT.

To further investigate why *gh* pairs are this easy to solve, we analyze a complete run of all pairs needed by Gusfield’s algorithm on the **soc-slashdot** instance. In Gusfield’s algorithm each vertex is the source once, thus the average degree of the source is the average degree of the graph (10.24). In contrast, the average degree of the sink is ca. 1500, which hinders the benefit of bidirectional search. Uni-directional Dinitz slows down by a factor of 15 when computing the flows with switched terminals. The average distance between two vertices

in the original network is 4.16, but interestingly here the average distance from source to sink is 1.78. Out of the 70k flow computations, 56k are trivial cuts around one terminal. Computing a flow for a single s-t pair takes 2.76 rounds on average with the last round only to confirm that the flow is optimal.

DinitzOPT and Push-Relabel are both extremely fast on *gh* pairs. DinitzOPT takes 2.5 seconds to compute all $n = 70k$ required flows, while PR needs 5 seconds. To obtain the 5 seconds for PR we exclusively measured the preflow computation, but PR is not limited by the time to compute the preflow. Actually, the entire computation of the Gomory-Hu tree on the `soc-slashdot` instance takes 12 minutes with Push-Relabel and 2.6 seconds with DinitzOPT. Instead of being caused by the Gusfield logic – which actually makes up less than 3% of the run time when using DinitzOPT as oracle – the bottleneck when using PR as a cut oracle is not the flow computation, but initialization and extracting the cut. The drastic difference in run time is in part due to the optimizations we added to DinitzOPT to reduce time between flow computations, while the Push-Relabel implementation recreates the auxiliary data structures, except the adjacency list, before each flow. However, in the following we will see that a large amount of Push-Relabels run time is actually necessary to extract the cuts for Gusfield’s algorithm.

Computing Cuts with Push-Relabel. In Gusfield’s algorithm we have to iterate over all vertices in the source-side of the cut. For Dinitz algorithm we can obtain a cut by doing a BFS from the source. However, the PR algorithm only computes a preflow. We outline the following three approaches to extract the cut and show that each has major drawbacks.

Convert. Compute a preflow, convert it into a flow, then run BFS from the source.

T-Side. Compute a preflow, run BFS backwards from the sink, then take complement.

Swap. Compute a preflow from sink to source, then run BFS backwards from the source.

The most straightforward way to get a cut from a preflow is to convert it into a flow. Then, as for Dinitz, one partition of a min-cut can be identified by reachability from the source in the residual network. In previous works, the conversion from preflow to flow makes up only a small fraction of the running time [11, 12]. For Gusfield pairs, however, Figure 6 shows that the conversion highly dominates the computation of the preflow. Only about 5 seconds of the 12 minutes of the complete run are spent in preflow computation.

To circumvent the conversion, we use the observation that one can obtain a cut directly from the preflow by finding all sink-reaching vertices in the residual network. Since Gusfield requires the source-side of the cut, the complement of the found set of vertices can be used. Unfortunately, doing the backward search from the sink is even more expensive than the conversion. An explanation for this is the large sink side of the cut. Using this *T-side* approach to identify the cut for DinitzOPT takes 4.5 minutes which is a factor 100 slower than identifying the cut via the source-side for DinitzOPT.

Making use of the fact that the source side of the cut is much smaller than the sink side, the drawbacks of the previous approach can be avoided in undirected networks by computing the preflow from sink to source. A cut can then be extracted by determining the vertices that can reach the original source in the residual network. The drawback of this method is that the preflow computation slows down massively from 5s to 47 minutes.

In conclusion, the *convert* approach is the fastest with just above 12 minutes followed by *T-side* with 18 minutes and *swap* with almost an hour. However, all three methods perform significantly worse than DinitzOPT, not because PR flow computations are slow, but both methods to avoid the four minutes run time of preflow-conversion imply even worse performance cost; either due to a breadth-first search that has to traverse almost the whole graph (*T-side*) or due to significantly slower preflow computations (*Swap*).

Figure 6 Distribution of spent time during Gusfield’s algorithm on the `soc-slashdot` instance with three approaches to use the Push-Relabel algorithm as a min-cut oracle. We split the measurements into initialization, preflow, conversion, and cut identification. The time overhead for measurement, logging, and the logic of Gusfield’s algorithm is included in the numbers on the right but excluded in the bars.

5 Conclusion

We presented a modified version of Dinitz’s algorithm with greatly improved run time and search space on real-world and generated scale-free networks. The scaling behavior appears to be sublinear, which matches previous theoretical and empirical observations about the running time of balanced bidirectional search in scale-free random networks. While these theoretical bounds apply during the first round of our algorithm, it is still unknown whether the analysis can be extended to account for the changes in the residual network. Our experiments, however, indicate that the search space remains small in subsequent rounds.

We observe that the low diameter and heterogeneous degree distribution lead to small and unbalanced cuts that our algorithm finds very efficiently. The flow computations required to compute a Gomory-Hu tree are even easier, making usually insignificant parts of the tested algorithms be a bottleneck. For example, the preflow conversion leads to Push-Relabel being greatly outperformed by our algorithm in this setting.

Abstract

We consider the problem of posting prices for unit-demand buyers if all n buyers have identically distributed valuations drawn from a distribution with monotone hazard rate. We show that even with multiple items asymptotically optimal welfare can be guaranteed.

Our main results apply to the case that either a buyer's value for different items are independent or that they are perfectly correlated. We give mechanisms using dynamic prices that obtain a $1 - \Theta\left(\frac{1}{\log n}\right)$ -fraction of the optimal social welfare in expectation. Furthermore, we devise mechanisms that only use static item prices and are $1 - \Theta\left(\frac{\log \log \log n}{\log n}\right)$ -competitive compared to the optimal social welfare. As we show, both guarantees are asymptotically optimal, even for a single item and exponential distributions.

1 Introduction

Posting prices is a very simple way to de-centralize markets. One assumes that buyers arrive sequentially. Whenever one of them arrives, a mechanism offers a menu of items at suitably defined prices. The buyer then decides to accept any offer, depending on what maximizes her own utility. Such a mechanism is incentive compatible by design, usually easy to explain and can be implemented online. For this reason, there is a large interest in understanding what social welfare and revenue can be guaranteed in comparison to mechanisms that optimize the respective objective.

Let us consider the following setting: There is a set of m heterogeneous items M , each of which we would like to be allocated to one of n buyers. Each buyer i has a private valuation function $v_i: 2^M \rightarrow \mathbb{R}_{\geq 0}$. We assume that valuation functions are unit-demand. That is, $v_i(S) = \max_{j \in S} v_i(\{j\})$, meaning that the value a buyer associates to a set is simply the one of the most valuable item in this set. Let $\text{SW}_{\text{opt}} = \max_{\text{allocations}} (S_1, \dots, S_n) \sum_{i=1}^n v_i(S_i)$ denote the optimal (offline/ex-post) social welfare. Note that this optimal solution is nothing but the maximum-weight matching in a bipartite graph in which all buyers and items correspond to a vertex each and an edge between the vertices of buyer i and item j has weight $v_i(\{j\})$.

To capture the pricing setting, we assume that the functions v_1, \dots, v_n are unknown a priori; all of them are drawn independently from the same, publicly known distribution. For every item, one can either set a static item price or change the prices dynamically over time. Buyers arrive one-by-one and each of them chooses the set of items that maximizes her utility given the current prices among the remaining items. Static prices have the advantage that they are easier to explain and thus give easier mechanisms. However, dynamic prices can yield both higher welfare and revenue because they can be adapted to the remaining supply and the remaining number of buyers to appear.

Coming back to the interpretation of a bipartite matching problem, a posted-prices mechanism corresponds to an online algorithm, where the buyers correspond to online vertices and the items correspond to offline vertices. However, not every online algorithm necessarily corresponds to a posted-prices mechanism: There might not be item prices such that the choices of the algorithm correspond to the ones by a buyer maximizing their utility.

We would like to understand which fraction of the optimal (offline/ex-post) welfare posted-prices mechanisms can guarantee. The case of a single item is well understood via *prophet inequalities* from optimal stopping theory. Let us call a posted-prices mechanism β -competitive (with respect to social welfare) if its expected welfare $\mathbf{E}[\text{SW}_{\text{pp}}]$ is at least $\beta \mathbf{E}[\text{SW}_{\text{opt}}]$. For a static price and a single item, the best such guarantee is $\beta = 1 - \frac{1}{e} \approx 0.63$ [11, 15]; for dynamic pricing and a single item, it is $\beta \approx 0.745$ [1, 11]. There are a number of extensions of these results to multiple items (see Section 1.3 for details), also going beyond unit-demand valuations, many of which are $O(1)$ -competitive.

The competitive ratios of $\beta = 1 - \frac{1}{e} \approx 0.63$ and $\beta \approx 0.745$ are optimal in the sense that there are distributions and choices of n such that no better guarantee can be obtained. Importantly, they are still tight when imposing a lower bound on n . That is, even for large n , there is a distribution such that if all values are drawn from this distribution the respective bound cannot be beaten.

1.1 Distributions with Monotone Hazard Rate

In this paper, we strengthen previous results by restricting the class of distributions to ones with monotone hazard rate. The single-item case is defined as follows. Consider a probability distribution on the reals with probability density function (PDF) f and cumulative distribution function (CDF) F , its hazard rate h is defined by $h(x) = \frac{f(x)}{1-F(x)}$ for x with $F(x) < 1$. It has a *monotone hazard rate* (MHR) – more precisely, increasing hazard rate – if h is a non-decreasing function. It has become a common and well-studied approach to model buyer preferences by MHR distributions. One of the reasons is that many standard distributions exhibit a monotone hazard rate such as, for example, uniform, normal, exponential and logistic distributions. (For a much more extensive list see [25].) Furthermore, the monotone hazard rate of distributions is also preserved under certain operations; for example, order statistics of MHR distributions also have an MHR distribution. Additionally, every MHR distribution is regular in the sense that its virtual value function [8, 24] is increasing.

We generalize results to multiple items and consider two fundamental settings. On the one hand, we consider *independent item valuations*, i.e. $v_{i,j} \sim \mathcal{D}_j$ is an independent draw from a distribution \mathcal{D}_j . In other words, the value of item j is independent of the value of item j' and both values are drawn from (possibly different) MHR distribution as defined above. On the other hand, we assume correlated values for items via the notion of *separable item valuations*, which are common in ad auctions [14, 27]: Each buyer has a type $t_i \geq 0$ and each item has an item-dependent multiplier α_j where now $v_{i,j} = \alpha_j \cdot t_i$. Again, $t_i \sim \mathcal{D}$ and \mathcal{D} is a distribution with monotone hazard rate. We note that this case subsumes and extends the case of k identical items.

As we show, in these cases, asymptotically optimal welfare can be guaranteed. That is, if n grows large, the social welfare when suitably choosing prices is within a $1 - o(1)$ factor of the optimum, where the $o(1)$ term is independent of the distribution as long as its marginals satisfy the MHR property. Stated differently, there is a sequence $(\beta_n)_{n \in \mathbb{N}}$ with $\beta_n \rightarrow 1$ for $n \rightarrow \infty$ such that for every number of buyers n there exists a posted-prices mechanism that takes any distribution with MHR as input and guarantees $\mathbf{E}[\text{SW}_{\text{pp}}] \geq \beta_n \mathbf{E}[\text{SW}_{\text{opt}}]$. As pointed out before, such a result does not hold for arbitrary, non-MHR distributions. Even with a single item, the limit is then upper-bounded by ≈ 0.745 .

A similar effect has already been observed by Giannakopoulos and Zhu [17]. They show that the revenue of static pricing for a single item with MHR distributions asymptotically reaches the optimal revenue. In contrast, our results concern welfare. Still, some of our results also have implications for revenue, either because we bound the revenue or because one could apply the results to virtual values.

1.2 Our Results and Techniques

We design mechanisms for both independent and separable item valuations. The ones using dynamic prices ensure a $\left(1 - O\left(\frac{1}{\log n}\right)\right)$ -fraction of the expected optimal social welfare. The ones using static prices guarantee a $\left(1 - O\left(\frac{\log \log \log n}{\log n}\right)\right)$ -fraction. We also show that these guarantees are best possible, even in the case of only a single item. Note that the bounds are independent of the number of items m , which may also grow in the number of buyers n .

Independent Valuations (Section 3)

The technically most interesting result is the one on dynamic pricing when values are independent across items. The idea is to set prices so that the offline optimum is mimicked. If item j is allocated in the optimal allocation with probability q_j , then we would like it to be sold in every step with an ex-ante probability of $\frac{q_j}{n}$. However, analyzing such a selling process is still difficult because items are incomparable and bounds for MHR distributions cannot be applied directly to draws from multiple distributions, which are not necessarily identical. To bypass this problem, we introduce a reduction that allows us to view item valuations not only as independent but also as identically distributed. To this end, we compare the selling process of our mechanism to a hypothetical setting, in which buyers do not make their decisions based on the actual utility but in quantile space. We observe that the revenue of both is identically distributed and utility is maximized in the former mechanism. As a consequence, the welfare obtained by the quantile allocation rule is a feasible lower bound on the welfare of the sequential posted-prices mechanism. Only afterwards, we can apply a concentration bound due to the MHR restriction.

The idea of our mechanism using static prices is to set prices suitably high in order to bound the revenue of our mechanism with a sufficient fraction of the optimum. While all other bounds apply for any number of items m , this bound unfortunately requires $m \leq \frac{n}{(\log \log n)^2}$. We leave it as an open problem to extend the result for larger number of items.

Separable Valuations (Section 4)

Our way of setting dynamic prices in the case of separable valuations is similar to the approach in independent valuations. This setting is even a little simpler because we can assume without loss of generality that there are as many items as buyers. Our pricing strategy ensures that in each step each item is sold equally likely as well as one item is sold

for sure. In the analysis, we observe that we match a buyer and an item if the quantile of the buyer's value is in a specific range. Now, the MHR property comes into play which allows to bound quantiles of the distribution in a suitable way.

In the static case, to lower-bound the welfare of our mechanism, we compare it to the one of the VCG mechanism [10, 18, 28] which maximizes social welfare. To this end, we split social welfare in revenue and utility and bound each quantity separately. That is, we relate the revenue and the sum of buyer utilities of our posted-pricing mechanism to the ones of the VCG mechanism. For the revenue, we set prices fairly low to ensure that we sell all items with reasonably high probability. Still, these prices are high enough to use the MHR property and derive a suitable lower bound of the prices. The utility comparison is more complicated, we solve this issue by an unusual application of the equality of expected revenue and virtual welfare due to Myerson [24].

Optimality (Section 5)

The achieved bounds on the competitive ratio are optimal for both dynamic as well as static pricing. We show this by considering the single-item case with an exponential distribution, which is a special case of both independent and separable valuations. For dynamic prices, we use the correspondence to a Markov decision process showing that no online algorithm is better than $1 - \Omega\left(\frac{1}{\log n}\right)$ -competitive. Then we also show that the competitive ratio cannot be better than $1 - \Omega\left(\frac{\log \log \log n}{\log n}\right)$ for any choice of a static price by writing out the expected social welfare explicitly.

Subadditive Valuations (Section 6)

We also demonstrate that our techniques are applicable beyond unit-demand settings by giving mechanisms for the more general class of subadditive valuation functions. Our dynamic pricing mechanism is $1 - O\left(\frac{1 + \log m}{\log n}\right)$ -competitive for subadditive buyers. We complement this by a static pricing mechanism which is $1 - O\left(\frac{\log \log \log n}{\log n} + \frac{\log m}{\log n}\right)$ -competitive. Both guarantees can be derived by showing that the revenue of the posted pricing mechanism is at least as high as the respective fraction of the optimal social welfare. As a consequence, these bounds directly imply the competitive ratios for welfare and revenue. For small m , these bounds are again tight by our optimality results. Obtaining tight bounds for large m still remains an open problem.

1.3 Further Related Work

As mentioned already, our setup restricted to a single item is highly related to prophet inequalities. Prophet inequalities have their origin in optimal stopping theory, dating back to the 1970s [22]. Only much later they were considered as a tool to understand the loss by posting prices as opposed to using other mechanisms. In this context, Samuel-Cahn's result [26] then got the interesting interpretation that posting an appropriately chosen static price for an item is $\frac{1}{2}$ -competitive for any buyer distributions; different buyers may even be drawn from different distributions. This guarantee is optimal, even for dynamic pricing.

Improvements for the single-item case are only possible by imposing further assumptions. Most importantly, this concerns the case that all buyer values are drawn from the same distribution. While already discussed by Hill et al. [20], this problem has been solved only very recently by devising an ≈ 0.745 -competitive mechanism that relies on dynamic pricing [1, 11]. By using static pricing, one cannot be better than $1 - \frac{1}{e} \approx 0.63$ -competitive [11, 15].

Better guarantees can also be achieved by assuming that multiple, identical items are for sale. In this case, one can use concentration results. The respective competitive ratios tend to 1 for a growing number of item copies. Hajiaghayi et al. [19] gave the first guarantee for such a setting, Alaei [2] later improved it to tightness.

For identical regular distributions, all of the above results also apply to welfare as well as revenue maximization because the prices can be imposed in the space of the virtual valuation [24]; also see the work by Chawla et al. [9]. Also impossibility results transfer [12].

When it comes to multiple, heterogeneous items, there is a significant difference between welfare and revenue maximization because Myerson's characterization does not apply anymore. For welfare maximization, Feldman et al. [16] show that static item prices still yield a competitive ratio of $\frac{1}{2}$ even for XOS valuations and not necessarily identically distributed buyer valuations. Concerning subadditive valuation functions, Zhang [29] gives a $O(\log m / \log \log m)$ -competitive prophet inequality, Dütting et al. [13] show how to obtain a competitive ratio of $O(\log \log m)$. The only improvement for identically distributed buyers is to $1 - \frac{1}{e}$ for unit-demand buyers based on dynamic pricing [15]. Among others, Chawla et al. [7] considered a combinatorial generalization of such a setting with many item copies (see Lucier's survey [23] on a broader overview of combinatorial generalizations).

For revenue maximization, one usually imposes the additional assumption that items are independent. This makes it possible to also apply prophet inequalities on the sequence of items rather than buyers and thus maximize revenue for unit-demand buyers via posted prices [8, 9]. Cai and Zhao [6] consider more general XOS and subadditive valuations and apply a duality framework instead. They design a posted-prices mechanism with an entry fee that gives an $O(1)$ or $O(\log m)$ approximation to the optimal revenue. In Dütting et al. [13], the approximation of the optimal revenue for subadditive valuations is improved to $O(\log \log m)$.

There are surprisingly few results on pricing and prophet inequalities that derive better guarantees by imposing additional assumptions on the distribution. Babaioff et al. [4] consider the problem of maximizing revenue when selling a single item to one of n buyers drawn i.i.d. from an *unknown* MHR distribution with a bounded support $[1, h]$. If n is large enough compared to h , they get a constant-factor approximation to the optimal revenue using dynamic posted prices. Note that in contrast, in our paper, we assume to know the underlying distributions perfectly. Giannakopoulos and Zhu [17] consider revenue maximization in the single-item setting with valuations drawn independently from the same MHR distribution. They show that by offering the item for the same static price to all bidders one can achieve asymptotically optimal revenue. More precisely, one of their main results is that one gets within a factor of $1 - O\left(\frac{\ln \ln n}{\ln n}\right)$. While they claim this result is “essentially tight”, we show that the best factor is indeed $1 - \Theta\left(\frac{\ln \ln \ln n}{\ln n}\right)$ because it is a special case of our results (see Section 6). It is not clear, how one could apply their result to welfare maximization as the MHR property is not preserved when moving between virtual and actual values. Furthermore, their results do not admit any apparent generalization to multiple items. Jin et al. [21] also consider revenue maximization in the single-item setting with identical and independent MHR values but in a non-asymptotic sense, providing a bound for every n .

2 Preliminaries

We consider a setting of n buyers N and a set M of m items. Every buyer has a valuation function $v_i: 2^M \rightarrow \mathbb{R}_{\geq 0}$ mapping each bundle of items to the buyer's valuation. We assume buyers to be unit-demand, that is $v_i(S) = \max_{j \in S} v_{i,j}$. The functions v_1, \dots, v_n are unknown

a priori but all drawn independently from the same, publicly known distribution \mathcal{D} . Let \mathcal{D}_j be the marginal distribution of $v_{i,j}$, which is the value of a buyer for being allocated item j . We assume that \mathcal{D}_j is a continuous, real, non-negative distribution with monotone hazard rate. That is, let F_j be the cumulative distribution function of \mathcal{D}_j and f_j its probability density function. The distribution's hazard rate is defined as $h_j(x) = f_j(x)/(1 - F_j(x))$ for all x such that $F_j(x) < 1$. We assume a *monotone hazard rate*, which means that h_j is a non-decreasing function. Equivalently, we can require $x \mapsto \log(1 - F_j(x))$ to be a concave function.

We design *posted-prices mechanisms*. That is, the buyers arrive one by one in order $1, \dots, n$. In the i -th step, buyer i arrives and has the choice between all items which have not been allocated so far. Let $M^{(i)}$ denote this set of available items. The mechanism presents the i -th buyer a menu of prices $p_j^{(i)}$ for all items $j \in M^{(i)}$. The buyer then picks the item $j_i \in M^{(i)}$ which maximizes her *utility* $v_{i,j_i} - p_{j_i}^{(i)}$ if positive¹. Buyer i and item j_i are matched immediately and irrevocably. If buyer i has negative utility for all items $j \in M^{(i)}$, then buyer i does not buy any item and remains unmatched. Generally, the prices for buyer i may depend arbitrarily on $M^{(i)}$ and the distribution \mathcal{D} . We call prices *static* if there are p_1, \dots, p_m such that $p_j^{(i)} = p_j$ for all i and all j .

Fix any posted-prices mechanism and let j_i denote the item allocated to buyer i (set $j_i = \perp$ if i remains unmatched in the mechanism). The *expected social welfare* of the mechanism is given by $\mathbf{E}[\sum_{i=1}^n v_{i,j_i}] =: \mathbf{E}[\text{SW}_{\text{pp}}]$. In comparison, let the social welfare maximizing allocation assign item j_i^* to buyer i . Its expected social welfare is therefore given by $\mathbf{E}[\sum_{i=1}^n v_{i,j_i^*}] =: \mathbf{E}[\text{SW}_{\text{opt}}]$.

We call a posted-prices mechanism β -*competitive* if it ensures that the expected social welfare of its allocation is at least a β -fraction of the expected optimal social welfare. That is, for any choice of distribution,

$$\mathbf{E}[\text{SW}_{\text{pp}}] = \mathbf{E}\left[\sum_{i=1}^n v_{i,j_i}\right] \geq \beta \mathbf{E}\left[\sum_{i=1}^n v_{i,j_i^*}\right] = \beta \mathbf{E}[\text{SW}_{\text{opt}}] \quad .$$

3 Asymptotically Tight Bounds for Independent Valuations

In this section, we show how to derive bounds if the buyers' values are independent across items. That is, each $v_{i,j} \sim \mathcal{D}_j$ is drawn independently from a distribution with monotone hazard rate. This is a standard assumption when considering multiple items [8, 9]. As a consequence, the distribution over valuations is a product distribution $v_i = (v_{i,1}, \dots, v_{i,m}) \sim \mathcal{D} = \prod_{j=1}^m \mathcal{D}_j$ for any $i \in N$ and every \mathcal{D}_j satisfies the MHR condition.

3.1 Dynamic prices

We first consider the case of dynamic pricing mechanisms. Without loss of generality, we can assume that $m \geq n$. If we have less items than buyers, i.e. $m < n$, we can add dummy items with value 0 to ensure $m = n$. Matching i to one of these dummy items in the mechanism then corresponds to leaving i unmatched. Observe that technically a point mass on 0 is not a MHR distribution. However, all relevant statements still apply.

¹ We can assume that any buyer is buying at most one item as buyers are unit-demand. Hence, no buyer can increase utility by buying a second (lower valued) item.

Our mechanism is based on a pricing rule which balances the probability of selling a specific item. To this end, let $M^{(i)}$ be the set of remaining items as buyer i arrives. We determine dynamic prices such that one item is allocated for sure in every step. Therefore, always $|M^{(i)}| = m - i + 1$. We can now define $q_j^{(i)}$ to be the probability that item j is allocated in the “remaining” offline optimum on $M^{(i)}$ and $n - i + 1$ buyers if $j \in M^{(i)}$ and 0 else. In other words, if $j \in M^{(i)}$, $q_j^{(i)}$ is the probability that item j is allocated in the offline optimum constrained to buyers $1, \dots, i - 1$ receiving the items from $M \setminus M^{(i)}$. The prices $(p_j^{(i)})_{j \in M^{(i)}}$ are now chosen such that buyer i buys item j with probability $\frac{q_j^{(i)}}{n-i+1}$ and one item is allocated for sure. To see that such prices exist, observe the following: fix any price vector $\mathbf{x} = (x_j)_{j \in M^{(i)}}$ and denote by $r_j^{(i)}(\mathbf{x}) = \Pr[i \text{ buys item } j \text{ at prices } \mathbf{x} \mid M^{(i)}]$. As the random variables $v_{i,j}$ are continuous and independent, the probability that buyer i buys item j at prices \mathbf{x} given the current set of items $M^{(i)}$ is continuous in x_j . Hence, we can consider the mapping $(\phi^{(i)}(\mathbf{x}))_j = \frac{n-i+1}{q_j^{(i)}} \cdot r_j^{(i)}(\mathbf{x}) \cdot x_j$ for any $j \in M^{(i)}$ which is also continuous and hence, by the use of Brouwer’s fixed point theorem² has our desired price vector $(p_j^{(i)})_{j \in M^{(i)}}$ as fixed point. This allows us to state the following theorem.

► **Theorem 1.** *The posted-prices mechanism with dynamic prices and independent item-valuations is $1 - O\left(\frac{1}{\log n}\right)$ -competitive with respect to social welfare.*

Note that in the case $m \leq n$ we will always have $q_j^{(i)} = 1$ for $j \in M^{(i)}$. This significantly simplifies the argument. The proof for the general case can be found in the full version of the paper. Here, we give a sketch with the major steps and key techniques.

In order to bound the social welfare obtained by the posted-prices mechanism, we consider the following *quantile allocation rule*. For any $j \in M^{(i)}$ with $q_j^{(i)} > 0$, compute $R_j^{(i)} := F_j(v_{i,j})^{\frac{1}{q_j^{(i)}}}$ and allocate buyer i the item j which maximizes $R_j^{(i)}$. Observe that by this definition for any i , any j and any $t \in [0, 1]$,

$$\Pr[R_j^{(i)} \leq t] = \Pr[F_j(v_{i,j}) \leq t^{q_j^{(i)}}] = t^{q_j^{(i)}},$$

as $F_j(v_{i,j}) \sim \text{Unif}[0, 1]$. In particular, note that for $q_j^{(i)} = 1$, this is exactly the CDF of a random variable drawn from $\text{Unif}[0, 1]$. Define indicator variables $X_{i,j}$ which are 1 if buyer i is allocated item j in the quantile allocation rule. Then, we can observe the following.

► **Observation 2.** *It holds*

$$\Pr[X_{i,j} = 1 \mid M^{(i)}] = \frac{q_j^{(i)}}{n-i+1}.$$

Note that by this, the probability of allocating item j in step i via the quantile allocation rule is $\frac{q_j^{(i)}}{n-i+1}$, exactly as in the posted-prices mechanism.

Proof. We allocate item j in the quantile allocation rule if $R_j^{(i)} \geq R_{j'}^{(i)}$ for any $j' \in M^{(i)}$. For fixed $M^{(i)}$, also the values of $q_j^{(i)}$ are fixed. Hence, we can use independence of the $v_{i,j}$

² In addition, we can use that prices $\mathbf{x} = (x_j)_{j \in M^{(i)}}$ are always bounded by $0 \leq x_j \leq F_j^{-1}\left(1 - \frac{q_j^{(i)}}{n-i+1}\right)$ to get a convex and compact set of price vectors.

variables to compute:

$$\begin{aligned}
\Pr[X_{i,j} = 1 \mid M^{(i)}] &= \Pr\left[\max_{j' \neq j} R_{j'}^{(i)} \leq R_j^{(i)} \mid M^{(i)}\right] \\
&= \int_0^1 \Pr\left[\max_{j' \neq j} R_{j'}^{(i)} \leq t \mid M^{(i)}\right] q_j^{(i)} t^{q_j^{(i)}-1} dt \\
&= \int_0^1 \prod_{j' \neq j} \Pr[R_{j'}^{(i)} \leq t \mid M^{(i)}] q_j^{(i)} t^{q_j^{(i)}-1} dt \\
&= \int_0^1 \left(\prod_{j' \neq j} t^{q_{j'}^{(i)}}\right) q_j^{(i)} t^{q_j^{(i)}-1} dt \\
&= q_j^{(i)} \int_0^1 t^{(n-i+1)-1} dt = \frac{q_j^{(i)}}{n-i+1},
\end{aligned}$$

where we use that $\sum_{j \in M^{(i)}} q_j^{(i)} = n - i + 1$ for any value of i . \blacktriangleleft

Now, the crucial observation is that the expected contribution of any buyer to the social welfare in the posted-prices mechanism is at least as large as under the quantile allocation rule. To see this, fix buyer i and split buyer i 's contribution to the social welfare into revenue and utility. Concerning revenue, note that in both cases the probability of selling any item j to buyer i is equal to $\frac{q_j^{(i)}}{n-i+1}$ and we allocate one item for sure. So, the expected revenue is identical. Further, since we maximize utility in the posted-prices mechanism, the achieved utility is always at least the utility of the quantile allocation rule. So, overall, we get $\mathbf{E}[\text{SW}_{\text{quantile}}] \leq \mathbf{E}[\text{SW}_{\text{pp}}]$.

Now, we aim to control the distribution of $v_{i,j}$ given that $X_{i,j} = 1$ in order to get access to the value of an agent being allocated an item in the quantile allocation rule. To this end, we use the following lemma.

► **Lemma 3.** *For all i, j and $M^{(i)}$, we have*

$$\Pr[v_{i,j} \leq t \mid X_{i,j} = 1, M^{(i)}] = F_j(t)^{\frac{n-i+1}{q_j^{(i)}}}$$

Proof. Observe that in the vector $(R_j^{(i)})_{j \in M^{(i)}}$, we choose j to maximize $R_j^{(i)}$. Now, for any value $v_{i,j'}$, we consider the following transform ψ_j : For any $j' \in M^{(i)}$, define

$$\psi_j(v_{i,j'}) := F_j^{-1} \left((R_{j'}^{(i)})^{q_j^{(i)}} \right).$$

Observe that for $j' = j$, we get that

$$\psi_j(v_{i,j}) = F_j^{-1} \left((R_j^{(i)})^{q_j^{(i)}} \right) = F_j^{-1} \left(\left(F_j(v_{i,j})^{\frac{1}{q_j^{(i)}}} \right)^{q_j^{(i)}} \right) = F_j^{-1} (F_j(v_{i,j})) = v_{i,j}.$$

Further, we can compute the CDF as

$$\begin{aligned}
\Pr[\psi_j(v_{i,j'}) \leq t] &= \Pr \left[F_j^{-1} \left((R_{j'}^{(i)})^{q_j^{(i)}} \right) \leq t \right] = \Pr \left[R_{j'}^{(i)} \leq F_j(t)^{\frac{1}{q_j^{(i)}}} \right] \\
&= \Pr \left[F_{j'}(v_{i,j'}) \leq F_j(t)^{\frac{q_{j'}^{(i)}}{q_j^{(i)}}} \right] = F_j(t)^{\frac{q_{j'}^{(i)}}{q_j^{(i)}}},
\end{aligned}$$

where in the last step, we used that $F_{j'}(v_{i,j'}) \sim \text{Unif}[0, 1]$. As a consequence,

$$\begin{aligned}
 \Pr[v_{i,j} \leq t \mid X_{i,j} = 1, M^{(i)}] &= \Pr[\psi_j(v_{i,j}) \leq t \mid \psi_j(v_{i,j}) > \psi_j(v_{i,j'}) \text{ for } j \neq j', M^{(i)}] \\
 &= \Pr\left[\max_{j' \in M^{(i)}} (\psi_j(v_{i,j'})) \leq t \mid M^{(i)}\right] \\
 &= \prod_{j' \in M^{(i)}} \Pr[\psi_j(v_{i,j'}) \leq t] = \prod_{j' \in M^{(i)}} F_j(t)^{\frac{q_{j'}^{(i)}}{q_j^{(i)}}} \\
 &= F_j(t)^{\frac{\sum_{j' \in M^{(i)}} q_{j'}^{(i)}}{q_j^{(i)}}} = F_j(t)^{\frac{n-i+1}{q_j^{(i)}}}.
 \end{aligned}$$

For integral values of $\frac{n-i+1}{q_j^{(i)}}$ (in particular $q_j^{(i)} = 1$), observe that this is exactly the CDF of the maximum of $\frac{n-i+1}{q_j^{(i)}}$ independent draws from distribution F_j .

For the remainder of the proof sketch, let us restrict to the case that $m = n$. Observe that in this special case, we have that all $q_j^{(i)} = 1$, so the probability in the quantile allocation rule of allocating any item $j \in M^{(i)}$ in Observation 2 simplifies to $\frac{1}{n-i+1}$. Therefore,

$$\mathbf{E}[v_{i,j} X_{i,j}] = \frac{n-i+1}{n} \cdot \frac{1}{n-i+1} \cdot \mathbf{E}[v_{i,j} \mid X_{i,j} = 1] = \frac{1}{n} \mathbf{E}[v_{i,j} \mid X_{i,j} = 1].$$

Observe that this argument looks rather innocent in the special case of $m = n$, but requires a much more careful treatment in the general variant: The probabilities $q_j^{(i)}$ are random variables themselves depending on the set $M^{(i)}$. Hence, the calculation can not directly be extended and a more sophisticated argument needs to be applied. In addition, by the above considerations on the quantile allocation rule via Lemma 3, we have that $\mathbf{E}[v_{i,j} \mid X_{i,j} = 1] = \mathbf{E}[\max_{i' \in [n-i+1]} v_{i',j}]$ in the special case of $m = n$. Therefore, we can now simply apply Lemma 4 (see below) to get

$$\mathbf{E}[v_{i,j} X_{i,j}] = \frac{1}{n} \mathbf{E}[v_{i,j} \mid X_{i,j} = 1] = \frac{1}{n} \mathbf{E}\left[\max_{i' \in [n-i+1]} v_{i',j}\right] \geq \frac{1}{n} \cdot \frac{H_{n-i+1}}{H_n} \cdot \mathbf{E}\left[\max_{i' \in [n]} v_{i',j}\right]$$

Note that we take the maximum over i.i.d. random variables. As a consequence, we can conclude by basic calculations:

$$\begin{aligned}
 \mathbf{E}[\text{SW}_{\text{pp}}] &\geq \mathbf{E}[\text{SW}_{\text{quantile}}] = \sum_{i=1}^n \sum_{j=1}^n \mathbf{E}[v_{i,j} X_{i,j}] \geq \frac{1}{n} \sum_{i=1}^n \sum_{j=1}^n \frac{H_{n-i+1}}{H_n} \mathbf{E}\left[\max_{i' \in [n]} v_{i',j}\right] \\
 &= \frac{\sum_{i=1}^n H_{n-i+1}}{n H_n} \sum_{j=1}^n \mathbf{E}\left[\max_{i' \in [n]} v_{i',j}\right] = \left(1 - O\left(\frac{1}{\log n}\right)\right) \sum_{j=1}^n \mathbf{E}\left[\max_{i' \in [n]} v_{i',j}\right] \\
 &\geq \left(1 - O\left(\frac{1}{\log n}\right)\right) \mathbf{E}[\text{SW}_{\text{opt}}]
 \end{aligned}$$

Observe that in the general version, comparing to $\sum_{j=1}^n \mathbf{E}[\max_{i' \in [n]} v_{i',j}]$ is a far too strong benchmark. Therefore, we consider an ex-ante relaxation of the offline optimum. As a new technical tool, we introduce in Lemma 5 (see below) an appropriate bound which allows to lower bound the expected maximum of k draws from an MHR distribution by a suitable fraction of $\mathbf{E}[v_{i,j} \mid v_{i,j} \geq F^{-1}(1-q)]$ for any choice of $q \in [0, 1]$. Applying this, we can lower bound the expected contribution of any item j to the quantile welfare by a suitable fraction of its contribution to the offline optimum.

We conclude by giving the lemmas which were used in the proof. First, let us restate a useful lemma from Babaioff et al. [4]. It allows to compare the expectation of the maximum of n and $n' \leq n$ draws from independent and identically distributed random variables, if the distribution has a monotone hazard rate.

► **Lemma 4** (Lemma 5.3 in [4]). *Consider a collection $(X_i)_i$ of independent and identically distributed random variables with a distribution with monotone hazard rate. Then, for any $n' \leq n$, we have*

$$\frac{\mathbf{E} [\max_{i \in [n']} X_i]}{\mathbf{E} [\max_{i \in [n]} X_i]} \geq \frac{H_{n'}}{H_n} \geq \frac{\log n'}{\log n} .$$

In addition, we make use of the following lemma which is used in order to make a suitable comparison to the ex-ante relaxation.

► **Lemma 5.** *Let $z \in [0, 1]$ and $k \in \mathbb{N}$. Further, let \mathcal{D} be a distribution with monotone hazard rate with CDF F , let $X, (Y_i)_i \sim \mathcal{D}$ be independent and identically distributed. For $\alpha \geq \frac{1 + \ln(\frac{1}{z})}{H_k}$, $\alpha \geq 1$, and $\alpha k \leq \frac{1}{z}$, we have $\mathbf{E} [X \mid X \geq F^{-1}(1 - z)] \leq \alpha \mathbf{E} [\max_{i \in [k]} Y_i]$.*

The proof of this lemma can be found in the full version of the paper.

3.2 Static prices

Next, we would like to demonstrate how to use static prices. We consider the case that the number of items m is upper bounded by $\frac{n}{(\log \log n)^2}$. We set the price for item j to

$$p_j = F_j^{-1}(1 - q) , \text{ where } q = \frac{\log \log n}{n} ,$$

which allows us to state the following theorem.

► **Theorem 6.** *The posted-prices mechanism with static prices and independent item-valuations is $1 - O\left(\frac{\log \log \log n}{\log n}\right)$ -competitive with respect to social welfare.*

As before, we defer the proof of this theorem to the full version of the paper and give a quick sketch here: First, observe that we can bound the probability of selling item j to buyer i by the probability of the event that buyer i has only non-negative utility for this item. This implies a bound on the probability of selling item j in our mechanism. Finally, we combine this with a lower bound on the price p_j and hence are able to bound the revenue (and thus the welfare) obtained by our mechanism. Observe that our guarantee only applies if the number of items m is bounded by $\frac{n}{(\log \log n)^2}$. We leave the extension to the general case as an open problem. As a first step, one could try to derive a suitable bound on the utility of agents in order to extend the result.

4 Asymptotically Tight Bounds for Separable Valuations

Let us now come to *separable valuations*, which are common in ad auctions [14, 27]. That is, in order to determine buyer i 's value for item j , let each buyer i have a type $v_i \geq 0$ and let each item have an item-dependent multiplier α_j which can be interpreted as a click through rate in online advertising. Buyer i 's value $v_{i,j}$ for being assigned item j is given by $\alpha_j \cdot v_i$. Without loss of generality, we assume that $\alpha_1 \geq \alpha_2 \geq \dots$ and that $m = n$. The former can be ensured by reordering the items; the latter by adding items with $\alpha_j = 0$ or removing all

items $j \in M$ with $j > n$ respectively. Observe that in the case of $m > n$, items of index larger than n are not matched in either the optimum, nor is it beneficial to match one of these items and leave an item $j \leq n$ unmatched. Note that this correlated setting also contains the single-item scenario as a special case since it can be modeled by $\alpha_1 = 1, \alpha_2 = \dots = 0$. More generally, k identical items can be modeled by $\alpha_1 = \dots = \alpha_k = 1, \alpha_{k+1} = \dots = 0$.

The types $v_1, \dots, v_n \geq 0$ are non-negative, independent and identically distributed random variables with a continuous distribution satisfying the MHR condition. Let j_i denote the item allocated to buyer i and $j_i = m + 1$ if buyer i is not allocated any item where $\alpha_{m+1} = 0$. We can specify the expected social welfare of the matching computed by the mechanism as $\mathbf{E}[\sum_{i=1}^n \alpha_{j_i} v_i] =: \mathbf{E}[\text{SW}_{\text{pp}}]$.

Additionally, the structure of the optimal matching can be stated explicitly. Given any type profile $v = (v_1, \dots, v_n)$, we let $v_{(k)}$ denote the k -th highest order statistics. That is, $v_{(k)}$ is the largest x such that there are at least k entries in v whose value is at least x . Denote its expectation by $\mathbf{E}[v_{(k)}] = \mu_k$. The allocation that maximizes social welfare assigns item 1 to a buyer of type $v_{(1)}$, item 2 to a buyer of type $v_{(2)}$ and so on. Hence, the expected optimal social welfare is given by $\mathbf{E}[\text{SW}_{\text{opt}}] = \mathbf{E}\left[\sum_{j=1}^m \alpha_j v_{(j)}\right] = \sum_{j=1}^m \alpha_j \mu_j$.

4.1 Dynamic prices

First, we focus on posted-prices mechanisms with dynamic prices. Consider step i and buyer i arrives. Let $M^{(i)}$ be the set of remaining items at this time. Our choice of prices ensures that in each step one item is allocated. Therefore, always $|M^{(i)}| = n - i + 1$.

We choose prices $(p_j^{(i)})_{j \in M^{(i)}}$ with the goal that each item is allocated with probability $\frac{1}{n-i+1}$. To this end, let $M^{(i)} = \{\ell_1, \dots, \ell_{n-i+1}\}$ with $\ell_1 < \ell_2 < \dots < \ell_{n-i+1}$ and set

$$p_j^{(i)} = \sum_{k: j \leq \ell_k \leq n-i} (\alpha_{\ell_k} - \alpha_{\ell_{k+1}}) F^{-1}\left(1 - \frac{k}{n-i+1}\right).$$

Given this pricing scheme, we can state the following theorem.

► **Theorem 7.** *The posted-prices mechanism with dynamic prices and separable valuations is $1 - O\left(\frac{1}{\log n}\right)$ -competitive with respect to social welfare.*

The proof can be found in the full version of the paper. First, observe that in principle, buyers will be indifferent between two items j and j' if $\alpha_j = \alpha_{j'}$. As these items are indistinguishable for later buyers anyway and new prices will be defined, we can assume that ties are broken in our favor. That is why we can assume that buyer i will prefer item ℓ_k if and only if $F^{-1}\left(1 - \frac{k}{n-i+1}\right) \leq v_i < F^{-1}\left(1 - \frac{k-1}{n-i+1}\right)$.

Using a suitable lower bound for $F^{-1}\left(1 - \frac{k}{n-i+1}\right)$ via the MHR property, we get a lower bound for the value $v_{i,j}$ if i is matched to j . To this end, we compare quantiles of MHR distributions to the respective order statistics. As stated before, by Section 5, the competitive ratio is optimal.

4.2 Static prices

When restricting to the case of static prices, we define probabilities q_j having the interpretation that a buyer drawn from the distribution has one of items $1, \dots, j$ as their first choice. For technical reasons, we discard items $\hat{m} + 1, \dots, n$ for $\hat{m} = n - n^{5/6}$ by setting $p_j = \infty$ for

these items. For $j \leq \widehat{m}$, we set prices

$$p_j = \sum_{k=j}^n (\alpha'_k - \alpha'_{k+1}) F^{-1}(1 - q_k) \quad , \quad \text{where } q_k = \min \left\{ \frac{k}{n} 2 \log \log n, \frac{k}{n} + \sqrt{\frac{\log n}{n}} \right\} \quad ,$$

where $\alpha'_k = \alpha_k$ for $k \leq \widehat{m}$ and 0 otherwise.

Note the similarity of this price definition to the payments when applying the VCG mechanism. There, the buyer being assigned item j has to pay $\sum_{k=j}^n (\alpha'_k - \alpha'_{k+1}) v_{(k+1)}$.

► **Theorem 8.** *The posted-prices mechanism with static prices and separable valuations is $1 - O\left(\frac{\log \log \log n}{\log n}\right)$ -competitive with respect to social welfare.*

The proof of this theorem can be found in the full version of the paper. The general steps are as follows. We first show that our prices are fairly low, meaning that the probability of selling all items $1, \dots, \widehat{m}$ is reasonably high. Having this, we decompose the social welfare into utility and revenue. The revenue of our mechanism is bounded in terms of the VCG revenue. To this end, we use that our pricing rule is quantile-based and exploit that the quantiles of any MHR distributions are lower-bounded by suitable fractions of expected order statistics. Talking about utility, we use a link to Myerson's theory and virtual values in order to achieve our desired bound. Again, by Section 5, the competitive ratio is asymptotically tight.

5 Asymptotically Upper Bounds on the Competitive Ratios

Our competitive ratios are asymptotically tight. In this section we provide matching upper bounds showing optimality. To this end, we consider the case of selling a single item with static and dynamic prices respectively. In any of the two cases, we can achieve asymptotic upper bounds on the competitive ratio of posted prices mechanisms which match our results from the previous sections. In particular, we prove that these bounds hold for any choice of pricing strategy.

5.1 Dynamic prices

We consider the guarantee of our dynamic-pricing mechanisms first. Even with a single item and types drawn from an exponential distribution, the best competitive ratio is $1 - \Omega\left(\frac{1}{\log n}\right)$. We simplify notation by omitting indices when possible.

► **Proposition 9.** *Let $v_1, \dots, v_n \in \mathbb{R}_{\geq 0}$ be random variables where each v_i is drawn i.i.d. from the exponential distribution with rate 1, i.e., $v_1, \dots, v_n \sim \text{Exp}(1)$. For all dynamic prices, the competitive ratio of the mechanism picking the first v_i with $v_i \geq p^{(i)}$ is upper bounded by $1 - \Omega\left(\frac{1}{\log n}\right)$.*

In order to prove Proposition 9, we use that the expected value of the optimal offline solution (the best value in hindsight) is given by $\mathbf{E} [\max_{i \in [n]} v_i] = H_n$ [3]. Therefore, it suffices to show that the expected value of any dynamic pricing rule is upper bounded by $H_n - c$ for some constant $c > 0$.

To upper-bound the expected social welfare of any dynamic pricing rule, we use the fact that this problem corresponds to a Markov decision process and the optimal dynamic prices are given by³

$$p^{(n)} = 0 \quad \text{and} \quad p^{(i)} = \mathbf{E} [\max\{v_{i+1}, p^{(i+1)}\}] \quad \text{for } i < n \quad .$$

³ To the best of our knowledge, this is a folklore result.

Furthermore, $p^{(0)}$ is exactly the expected social welfare of this mechanism. Therefore, the following lemma with $k = n$ directly proves our claim.

► **Lemma 10.** *Let $v_1, \dots, v_n \in \mathbb{R}_{\geq 0}$ be random variables where each v_i is drawn i.i.d. from the exponential distribution $\text{Exp}(1)$. Moreover, let $p^{(n)} = 0$ and $p^{(i)} = \mathbf{E} [\max\{v_{i+1}, p^{(i+1)}\}]$ for $i < n$. Then, we have $p^{(n-k)} \leq H_k - \frac{1}{8}$ for all $2 \leq k \leq n$.*

The proof via induction over k can be found in the full version of the paper.

5.2 Static prices

For static pricing rules, we show that any mechanism is $1 - \Omega\left(\frac{\log \log \log n}{\log n}\right)$ -competitive. Again, this bound even holds for a single item and the valuations being drawn from an exponential distribution.

► **Proposition 11.** *Let $v_1, \dots, v_n \in \mathbb{R}_{\geq 0}$ be random variables where each v_i is drawn i.i.d. from the exponential distribution with rate 1, i.e., $v_1, \dots, v_n \sim \text{Exp}(1)$. For all static prices $p \in \mathbb{R}_{\geq 0}$ the competitive ratio of the mechanism picking the first v_i with $v_i \geq p$ is upper bounded by $1 - \Omega\left(\frac{\log \log \log n}{\log n}\right)$.*

The proof of Proposition 11 can be found in the full version of the paper. The idea is as follows. The expected welfare obtained by the static-price mechanism using price p is given by $\mathbf{E} [\text{SW}_{\text{pp}}] = \mathbf{E} [v \mid v \geq p] \cdot \Pr [\exists i : v_i \geq p] = (p + 1) \cdot (1 - (1 - e^{-p})^n)$. This has to be compared to the expected value of the optimal offline solution (the best value in hindsight), which is given by $\mathbf{E} [\max_{i \in [n]} v_i] = H_n$ [3].

6 Extensions to Subadditive Buyers and Revenue Considerations

In this section, we illustrate that the same style of mechanisms used for unit-demand buyers in principle is also applicable for subadditive buyers. A valuation function v_i is subadditive if $v_i(S \cup T) \leq v_i(S) + v_i(T)$ for any $S, T \subseteq M$. This generalizes unit-demand functions considered so far in this paper. Instead of being interested in only a single-item, each buyer now has a subadditive valuation function over item bundles and can thus be interested in multiple items.

To generalize the MHR property, we assume that the subadditive valuation functions are drawn from distributions with MHR marginals. That is, $v_i \sim \mathcal{D}$ and we assume that $v_i(\{j\})$ has a marginal distribution with monotone hazard rate. Buyers arrive online and purchase the bundle of items which maximizes the buyer's utility.

We can construct a dynamic-pricing mechanism which is $1 - O\left(\frac{1 + \log m}{\log n}\right)$ -competitive. For a detailed explanation, we refer to the full version of the paper. The general approach is to split the set of buyers in subgroups of size $\lfloor \frac{n}{m} \rfloor$ and sell each item to one of these groups. For the k -th buyer in every group, the price for the item in question is set to $p_j^{(k)} = F_j^{-1}\left(1 - \frac{1}{\lfloor \frac{n}{m} \rfloor - k + 1}\right)$, where F_j^{-1} denotes the quantile function of the marginal distribution of $v_i(\{j\})$. Using techniques similar to the ones in the unit-demand case allows to bound the revenue of the posted-prices mechanism by the desired fraction of the optimal social welfare. Hence, the argument directly implies the respective bounds for welfare and revenue.

In the static pricing environment, our results can be extended to a mechanism which is $1 - O\left(\frac{\log \log \log n}{\log n} + \frac{\log m}{\log n}\right)$ -competitive for subadditive buyers. Details can be found in the full version. As before, let F_j^{-1} be the quantile function of the marginal distribution of

$v_i(\{j\})$. Setting fairly low prices of $p_j = F_j^{-1}(1 - q)$ for $q = \frac{m \log \log n}{n}$ ensures that we sell all items with a suitably high probability. Afterwards, we can apply the same bounds for MHR distributions as in the previous sections in order to bound the revenue of the mechanism with the respective fraction of the optimal social welfare. Again, this directly implies the mentioned competitive ratio for welfare as well as revenue, as the revenue of any individually rational mechanism is upper-bounded by the corresponding social welfare.

Note that the guarantees now depend on the number of items m . To make them meaningful, we need $m = o(n)$. This makes them significantly worse than the ones we obtain for unit-demand functions with a much more careful treatment. However, they are stronger in one aspect, namely that in both cases we bound the revenue of the mechanism in terms of the optimal social welfare. In particular, this means that they are also approximations of the optimal revenue. Interestingly, the optimality results from Section 5 also transfer.

Abstract

Staged self-assembly has proven to be a powerful abstract model of self-assembly by modeling laboratory techniques where several nanoscale systems are allowed to assemble separately and then be mixed at a later stage. A fundamental problem in self-assembly is Unique Assembly Verification (UAV), which asks whether a single final assembly is uniquely constructed. This has previously been shown to be Π_2^P -hard in staged self-assembly with a constant number of stages, but a more precise complexity classification was left open related to the polynomial hierarchy.

Covert Computation was recently introduced as a way to compute a function while hiding the input to that function for self-assembly systems. These Tile Assembly Computers (TACs), in a growth only negative aTAM system, can compute arbitrary circuits, which proves UAV is coNP-hard in that model. Here, we show that the staged assembly model is capable of covert computation using only 3 stages. We then utilize this construction to show UAV with only 3 stages is Π_2^P -hard. We then extend this technique to open problems and prove that general staged UAV is PSPACE-complete. Measuring the complexity of n stage UAV, we show Π_{n-1}^P -hardness. We finish by showing a Π_{n+1}^P algorithm to solve n stage UAV leaving only a constant gap between membership and hardness.

1 Introduction

The *Staged Self-Assembly* model was designed as an extension to the standard hierarchical model of tile self assembly that mimics the abilities of scientists in the lab to control the assembly process by mixing test tubes. The additional features in this model allow for more efficient tile complexity, but increased complexity of certain verification problems.

We use the concept of *Covert Computation*, a requirement of a computational system stipulating that the input and computational history of the computation be hidden in the final output of the system, within the context of Staged Self-assembly, an extension to tile self-assembly that allows for basic operations such as mixing self-assembly batches over a sequence of distinct stages. We use this connection to resolve open questions regarding the complexity of the *Unique Assembly Verification* (UAV) problem within staged self-assembly—the problem of whether a given system uniquely produces a specific assembly. The importance of this work stems from the fundamental nature of the UAV problem, along with the natural and experimentally motivated Staged Self-Assembly model. Further, the novel approach by

which our results are obtained, by way of designing Covert Computation systems in Staged Self-Assembly, may be of independent interest as it shows how to utilize Staged Self-Assembly to implement general purpose computing systems with strong guarantees that might be useful for cryptography or have applications for privacy within biomedical computation.

Staged Self-Assembly. The Staged Self-Assembly model [1, 6, 7, 8, 9, 10, 11, 14, 18] is a generalization of the (2-handed) tile assembly model [4] where particles are modeled by 4-sided Wang tiles which nondeterministically combine based on the affinity of tile edges. Tile self-assembly is a well-studied mathematical abstraction used in the study of self-assembly systems with algorithmically complex behavior, and enjoys experimental success through a DNA implementation [19]. In order to add the basic functionality of what an experimentalist with a set of test tubes could execute [17], the staged model extends tile self-assembly by allowing assembly to occur in multiple separate *bins*, and for the contents of these bins to be either combined or split into a new set of bins after each one of a given sequence of *stages*.

Covert Computation. Tile self-assembly can be used as a model of computation in which tiles attach to an input *seed* structure to grow a final output structure encoding the result of the computation. This basic paradigm is one of most promising avenues for the development of nanoscale molecular computing systems (see [19] for recent experimental work using DNA tiles to implement 6-bit circuits). The authors in [5] recently proposed a new constraint on such computing systems termed *Covert Computation*. A covert computation system computes a function with the additional constraint that the output assembly provides no information about either the original input or the computational history, beyond the actual output of the computed function. This is a particularly daunting self-assembly problem since the output is provided in the form of a self-assembled structure that encodes the exact geometric location of every placed tile. In previous methods of tile self-assembly computation, the entire computational history and original input are easily interpreted from the final output assembly. However, while the output assembly specifies the location of each placed tile, the result of the computation can be a function of not just these tile *locations*, but also of the *order* in which these tiles are placed, which is the technique exploited in [5]. This concept provides a useful technique for proving complexity results, and we use it here to show PSPACE-completeness of verifying unique assembly in staged self-assembly.

Unique Assembly Verification. One well-studied problem in tile self-assembly is the Unique Assembly Verification (UAV) problem which asks if a given system uniquely produces a given assembly. This problem was shown to be solvable in polynomial time in the Abstract Tile Assembly Model [2]. The addition of negative interactions and detachment of tiles makes the UAV problem undecidable [12], while *growth-only* systems with no detachments are coNP-complete [5]. The UAV problem in the 2-Handed Assembly Model was first studied in [4] where coNP membership was shown with coNP-completeness in the third dimension. The problem was also shown to be coNP-complete with a variable temperature [15], but constant temperature UAV in the 2HAM is still open. In the staged assembly model, initial investigation in [16] showed coNP-hardness using four stages and Π_2^P -hardness for seven stages. They also showed membership in PSPACE with a conjecture of PSPACE-completeness.

Our Results. In this paper, we introduce the concept of covert computation in the context of staged self-assembly for the purpose of establishing the complexity of unique assembly verification within the model. First, we show that staged self-assembly is capable of covert

■ **Table 1** Complexities of Unique Assembly Verification in the Staged Assembly Model with respect to the number of stages n . Our results are in bold. *This result uses the temperature as an input parameter/variable for the problem. All other results are true even with a constant temperature.

Stages	Membership		Hardness	
1 (2HAM)	coNP	In [4]	coNP-complete*	In [15]
2	Π_3^P	Thm. 19	coNP-hard*	In [15]
3	Π_4^P	Thm. 19	Π_2^P -hard	Thm. 6
$n > 3$	Π_{n+1}^P	Thm. 19	Π_{n-1}^P -hard	Thm. 12
General	PSPACE	In. [16]	PSPACE-complete	Thm. 10

computation even when limited to three stages. Next, we use this fact to show UAV is PSPACE-complete in staged self-assembly, resolving the open problem from [16]. Along the way, we improve on some results from [16]: we show that UAV is Π_2^P -hard with just three stages, improving on the previous hardness result requiring seven stages. We then generalize this result to show that for n stages, UAV is Π_{n-1}^P -hard, but yields a Π_{n+1}^P algorithm, leaving only a gap of two in levels between membership and hardness for this problem. An overview of our results and known results related to UAV is shown in Table 1.

2 Preliminaries

We first provide definitions for the staged self-assembly model and covert computation.

Tiles. A *tile* is a non-rotatable unit square with each edge labeled with a *glue* from a set Σ . Each pair of glues $g_1, g_2 \in \Sigma$ has a non-negative integer *strength* $\text{str}(g_1, g_2)$.

Configurations, bond graphs, and stability. A *configuration* is a partial function $A : \mathbb{Z}^2 \rightarrow T$ for some set of tiles T , i.e. an arrangement of tiles on a square grid. For a given configuration A , define the *bond graph* G_A to be the weighted grid graph in which each element of $\text{dom}(A)$ is a vertex, and the weight of the edge between a pair of tiles is equal to the strength of the coincident glue pair. A configuration is said to be τ -stable for positive integer τ if every edge cut of G_A has strength at least τ , and is τ -unstable otherwise.

Assemblies. For a configuration A and vector $\vec{u} = \langle u_x, u_y \rangle$ with $u_x, u_y \in \mathbb{Z}^2$, $A + \vec{u}$ denotes the configuration $A \circ f$, where $f(x, y) = (x + u_x, y + u_y)$. For two configurations A and B , B is a *translation* of A , written $B \simeq A$, provided that $B = A + \vec{u}$ for some vector \vec{u} . For a configuration A , the *assembly* of A is the set $\tilde{A} = \{B : B \simeq A\}$. An assembly \tilde{A} is a *subassembly* of an assembly \tilde{B} , denoted $\tilde{A} \subseteq \tilde{B}$, provided that there exists an $A \in \tilde{A}$ and $B \in \tilde{B}$ such that $A \subseteq B$. An assembly is τ -stable provided the configurations it contains are τ -stable. Assemblies \tilde{A} and \tilde{B} are τ -combinable into an assembly \tilde{C} provided there exist $A \in \tilde{A}$, $B \in \tilde{B}$, and $C \in \tilde{C}$ such that $A \cup B = C$, $A \cap B = \emptyset$, and \tilde{C} is τ -stable.

Two-handed assembly and bins. We define the assembly process in terms of bins. A *bin* is an ordered tuple (S, τ) where S is a set of *initial* assemblies and τ is a positive integer parameter called the *temperature*. For a bin (S, τ) , the set of *produced* assemblies $P'_{(S, \tau)}$ is defined recursively as follows:

1. $S \subseteq P'_{(S, \tau)}$.
2. If $A, B \in P'_{(S, \tau)}$ are τ -combinable into C , then $C \in P'_{(S, \tau)}$.

■ **Figure 1** (a) A 2HAM example that uniquely builds a 2×3 rectangle. The top 4 tiles in the tile set all combine with strength-2 glues building the ‘L’ shape. The tile with blue and purple glues needs two tiles to cooperatively bind to the assembly with strength 2. All possible producibles are shown with the terminal assembly highlighted. (b) A simple staged self-assembly example. The system has 3 bins and 3 stages, as shown in the mixgraph. There are three tile types in our system that we assign to bins as desired. From each stage only the terminal assemblies are added to the next stage. The result of this system is the assembly shown in the bin in stage 3.

A produced assembly is *terminal* provided it is not τ -combinable with any other producible assembly, and the set of all terminal assemblies of a bin (S, τ) is denoted $P_{(S, \tau)}$. Intuitively, $P'_{(S, \tau)}$ represents the set of all possible assemblies that can self-assemble from the initial set S , whereas $P_{(S, \tau)}$ represents only the set of supertiles that cannot grow any further. The assemblies in $P_{(S, \tau)}$ are *uniquely produced* iff for each $x \in P'_{(S, \tau)}$ there exists a corresponding $y \in P_{(S, \tau)}$ such that $x \sqsubseteq y$. Thus unique production implies that every producible assembly can be repeatedly combined with others to form an assembly in $P_{(S, \tau)}$.

Staged assembly systems. An r -stage b -bin mix graph $M_{r, b}$ is an acyclic r -partite digraph consisting of rb vertices $m_{i, j}$ for $1 \leq i \leq r$ and $1 \leq j \leq b$, and edges of the form $(m_{i, j}, m_{i+1, j'})$ for some i, j, j' . A *staged assembly system* is a 3-tuple $\langle M_{r, b}, \{T_1, T_2, \dots, T_b\}, \tau \rangle$ where $M_{r, b}$ is an r -stage b -bin mix graph, T_i is a set of tile types, and τ is an integer temperature parameter.

Given a staged assembly system, for each $1 \leq i \leq r$, $1 \leq j \leq b$, we define a corresponding bin $(R_{i, j}, \tau)$ where $R_{i, j}$ is defined as follows:

1. $R_{1, j} = T_j$ (this is a bin in the first stage);
2. For $i \geq 2$, $R_{i, j} = \left(\bigcup_{k: (m_{i-1, k}, m_{i, j}) \in M_{r, b}} P_{(R_{i-1, k}, \tau)} \right)$.

Thus, the j^{th} bin in stage 1 is provided with the initial tile set T_j , and each bin in any subsequent stage receives an initial set of assemblies consisting of the terminally produced assemblies from a subset of the bins in the previous stage as indicated by the edges of the mix graph.¹ The *output* of the staged system is the union of all terminal assemblies from each of the bins in the final stage.² We say this set of output assemblies is *uniquely produced* if each bin in the staged system uniquely produces its respective set of terminal assemblies.

¹ The original staged model [9] only considered $\mathcal{O}(1)$ distinct tile types, and thus for simplicity allowed tiles to be added at any stage. Since our systems may have super-constant tile complexity, we restrict tiles to only be added at the initial stage.

² This is a slight modification of the original staged model [9] in that the final stage may have multiple bins. However, all of our results apply to both variants of the model.

Covert Computation. Tile assembly computers were first defined in [5, 13] with respect to the aTAM. We provide formal definitions of both Tile Assembly Computers and Covert Computation with respect to the Staged Self-Assembly model.

A Staged Tile Assembly Computer (STAC) for a function f consists of a staged self-assembly system, and a format for encoding the input into tiles sets and a format for reading the output from the terminal assembly. The input format is a specification for what set of tiles to add to a specific bin in the first stage. Each bit of the input must be mapped to one of two sets of tiles for the respective bit position: a tile set representing “0”, or tile set representing “1”. The input set for the entire string is the union of all these tile sets. Our staged self assembly system, with the set of tiles needed to build the input seed added in a designated bin, is our final system which performs the computation. The output of the computation is the terminal assembly the system assembles. To interpret what bit-string is represented by the assembly, a second *output* format specifies a pair of sub-assemblies and locations for each bit. An assembly that represents a bitstring is created by the union of each sub-assembly represented by each bit.

For a STAC to *covertly* compute f , the STAC must compute f and produce a unique assembly for each possible output of f . Thus, for all x such that $f(x) = y$, a covert STAC that computes f produces the same output assembly representing output y for each possible input x , making it impossible to determine which input value x was provided to the system.

Input Template. An n -bit input template over tile set T is a sequence of ordered pairs of tile sets over T : $I = (I_{0,0}, I_{0,1}), \dots, (I_{n-1,0}, I_{n-1,1})$. For a given n -bit string $b = b_0, \dots, b_{n-1}$ and n -bit input template I , the input tile set for b with respect to I is the set $I(b) = \bigcup_i I_{i,b_i}$.

Output Template. An n -bit output template over tile set T is a sequence of ordered pairs of configurations over T : $O = (C_{0,0}, C_{0,1}), \dots, (C_{n-1,0}, C_{n-1,1})$. For a given n -bit string $x = x_0, \dots, x_{n-1}$ and n -bit output template O , the *representation* of x with respect to O is $O(x) =$ the assembly of $\bigcup_i C_{i,x_i}$. A template is valid for a temperature parameter $\tau \in \mathbb{Z}^+$ if this union never contains overlaps for any choice of x , and is always τ -stable. An assembly $B \supseteq O(x)$, which contains $O(x)$ as a subassembly, is said to represent x as long as $O(d) \not\subseteq B$ for any $d \neq x$.

Function Computing Problem. A *staged tile assembly computer* (STAC) is an ordered triple $\mathfrak{S} = (\Gamma, I, O)$ where $\Gamma = (M, \{\emptyset, T_2, \dots, T_i\}, \tau)$ is a staged self assembly system, I is an n -bit input template, and O is a k -bit output template. A STAC is said to compute function $f : \mathbb{Z}_2^n \rightarrow \mathbb{Z}_2^k$ if for any $x \in \mathbb{Z}_2^n$ and $y \in \mathbb{Z}_2^k$ such that $f(x) = y$, then the staged self assembly system $\Gamma_{\mathfrak{S},x} = (M, \{I(x), T_2, \dots, T_i\}, \tau)$ uniquely assembles a set of assemblies which all represent y with respect to template O .

Covert Computation. A STAC *covertly* computes a function $f(x) = y$ if 1) it computes f , and 2) for each y , there exists a unique assembly A_y such that for all x , where $f(x) = y$, the system $\Gamma_{\mathfrak{S},x} = (M, \{I(x), T_1, \dots, T_i\}, \tau)$ uniquely produces A_y . In other words, A_y is determined by y , and every x where $f(x) = y$ has the exact same final assembly.

3 Covert Computation in Staged Self-assembly

Here, we demonstrate covert computation in the staged assembly model. This construction creates a logic circuit using a 3-stage temperature-2 system with a number of bins polynomial in the size of the circuit. We consider only circuits made up of functionally universal NAND gates, but these techniques could be used to create any 2-input gate.

Figure 2b shows a basic overview of the mixgraph used for the covert computation implementation. The method requires three stages with a polynomial number of mixing bins.

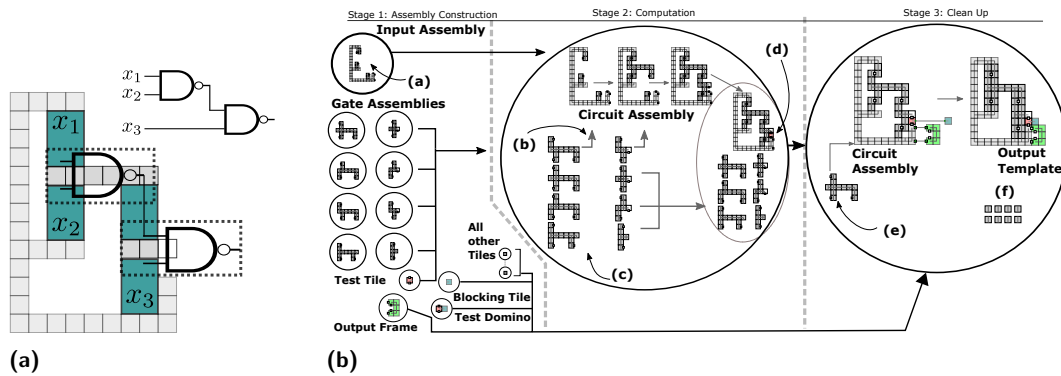

- In the first stage, we assemble the components needed to perform the computation. These include an *Input Assembly*, which encodes the input to the function, *Gate Assemblies*, which act as individual gates and perform the computation via their attachment rules and geometry, and additional assemblies which are used to help “clean up” our circuit and covertly get the output.
- In stage two, the input assembly and gate assemblies are added to a single bin along with a test tile. The gate assemblies will begin to attach to the input assembly creating a *Circuit Assembly*. Once the computation is complete, the test tile can attach to the circuit assembly if and only if the output is true. The circuit assembly is terminal in this bin and will be passed to the final stage.
- The final stage adds additional assemblies to the bin along with most of the tile set as single tiles (not shown in figure). The additional assemblies read the output of the circuit and it grows into one of the output templates. The *Output Frame* searches for the test tile representing the output of the circuit. The single tiles fill in any spaces left in the circuit assembly that would show the computation history, thereby turning the assembly into the output template. This requires a linear number of additional bins in the first and second stage to store these single tiles while mixing takes place in other bins.

For our circuit assembly we implement Planar Logic Circuits with only NAND gates. An example circuit and an assembly showing how the gates are laid out are shown in Figure 2a. Wires are represented by 2×3 blocks of tiles shown in blue in the image. Input and Gate assemblies contain a subset of the tiles in each block we call *arms* which represent the values being passed along the wires. The input assembly is a comb-like structure that is designed so that each input bit reaches the gate it is used at (Figure 3a). For each NAND gate in the circuit we have 4 different assemblies, one for each possible input to the gate. A gate assembly can cooperatively bind to the input assembly if the variable values match. The gate assembly has a third arm that represents the output. This allows the next gate assembly to attach, which continues propagating until the computation is done and the circuit assembly is complete. We now cover the construction in detail by stage.

3.1 First Stage - Assembly Construction

Each bin in the first stage will individually create the assemblies that will come together in the next stage. For an n -input k -gate NAND logic circuit (considering crossovers as three XOR gates [5]), we have an input assembly, $4k$ gate assemblies, and a constant number of other assemblies that will be used in the final stage. Here we will describe the details of the individual assemblies created in addition to the *arms*, which function as wires in our system.

Input. For each bit of the input we have two possible input bit assemblies (Figure 3a). The value of the bit determines which tiles will be added to create that input bit assembly in the first stage. Figure 3a shows the selected assemblies that come together to form the *input assembly* shown in Figure 3b. Each subassembly has a domino which we call an “arm” representing the corresponding bit value. The shape of these assemblies depends on the gates to which they input because the arm of the assembly must reach the location of the gate it inputs to. The last input bit assembly also contains an extra set of tiles that reach the final output gate with a strength-1 glue on its north end and two glues on its east to allow for the test tile and output frame to attach.

■ **Figure 2** (a) Simple 3-input logic circuit using 2 NAND gates, and the high-level abstraction of the circuit assembly showing the input variables and gates highlighted as blocks. Blue blocks are the sections of the assemblies we call *Arms* that function as wires in the systems. (b) (1) Our input assembly and gate assemblies are constructed in separate bins. (2) Gate assemblies attach to the input assembly forming a circuit assembly. (3) Unused gates are terminal in the second stage. (4) This circuit evaluates to true, so the test tile will be able to attach. (5) Gate assemblies in this stage grow into a circuit using single tiles. (6) Single tiles fill in open spots in the circuit assembly to hide the history. The additional assemblies are used to reach the output template.

Arms. We describe assemblies as having input or output *arms* which function as the wires of our circuit. Arms are vertical dominoes that represent bit values, with their location on the assembly representing the bit having a value 0 or 1 (Figure 4a). The output arm being in the left position represents a bit value of 0, with the right position representing 1. The locations of input arms are complementary (right represents 0, left represents 1) to the output arms. These arms have a glue on the second tile on the inner side. An input arm will attach to an output arm to “read” the bit (Figure 4b) if they represent the same wire and the same value. This glue is a strength-1 glue, so the assembly must attach cooperatively elsewhere in the assembly. Another key feature of these arms is the ability to hide the information passed through by adding single tiles in a later stage. The spaces left by the attachment may be filled by single tiles which results in an assembly which looks like Figure 4c where the value passed cannot be read. This feature will be used in the final stage of our system.

Gates. For each gate we create four assemblies with each representing one of the valid input/output combinations of the desired logic gate. Each gate assembly has two input arms and one output arm. We encode the logic gate by placing the output arm in the column representing the output of the gate when input with the bits represented by the input arms (Figure 3c). This assembly has strength-1 glues on each of its arms. The shape of each gate is dependent on the layout of the circuit since the output arm needs to reach to the next gate. In the case a gate has a fan out (outputs to multiple gates) a gate assembly may have multiple output arms which share arm position. We will refer to the final gate of the circuit as the *output gate*. It does not contain an output arm but instead contains a flag tile to represent an output of false, or no flag tile to represent an output of true which can be seen in Figure 3d. The flag tile also contains a strength-1 glue on it’s south edge which allows for the test tile to attach.

3.2 Second Stage - Computation

In the second stage there is a single bin where the circuit assembly is created. In this stage the input assembly and the gate assemblies are mixed together to compute the encoded circuit. The computation starts by attaching gates to the input assembly to begin to build

■ **Figure 3** (a) Possible input bit assemblies for a 3 bit function. Solid lines between tiles indicate a strength 2 glue between the tiles. Small boxes indicate a strength 1 glue. For each bit we select either the left or the right assembly based on the value of the bit and add those tiles to our input bin in the *First Stage*. Lighter tiles are not used. (b) The input assembly that is constructed in the *First Stage*. The last input bit assembly contains an extra column of tiles that reaches to where the output gate will be for cooperative attachment of the test tile. (c) 4 gate assemblies, one for each possible input combination of a NAND gate. Glues are labeled to match the wires of the NAND gate. (d) Output gates. True output gates contain a flag tile (white).

■ **Figure 4** (a) Information being passed along a wire is represented by the position of a domino called an arm. Output arms represent a signal of “1” or “0” by being in the left or right position, respectively. Input arms read bit values and have complimentary arm placement to allow for attachment. (b) Information is passed by attachment. Another assembly may attach if the arms have matching glues (they represent the same wire) and they have complementary arms (represent the same bit value). (c) In the final stage we add additional tiles to hide the information that was passed along a wire.

the circuit assembly. Once both inputs to a gate are present on the circuit assembly, the next gate assembly can cooperatively attach to the circuit assembly since each arm has an attachment strength of 1 as seen in Figure 5a. In this stage we also add the test tile. If the output of the circuit is true, the flag tile can attach as in Figure 5c. If the output is false, the terminal circuit assembly can be seen in Figure 5b. The test assembly is not able to attach to the circuit assembly in this case and will be terminal. We note that at this point it is possible to read the output of the circuit by checking the terminal assemblies, however the computation history can still be read so the covert computation is not complete and we need an additional stage.

3.3 Third Stage - Clean Up

In the third stage we hide the computational history and get the output of the computation. The output template (Full Circuit Assembly) is shown in Figure 5d, which is a circuit assembly with all open spaces in its arm filled in (computation history is hidden) and the additional assemblies attached. The additional assemblies are the Output Frame, which the test tile may attach to, the test domino, which attaches to a circuit assembly but not to the output frame, the blocking tile, which turns a test tile into a test domino, and all single tiles used in the circuit assembly other than the test tile. The difference between the true and false output templates is the inclusion/exclusion of the test tile within the Output Frame.

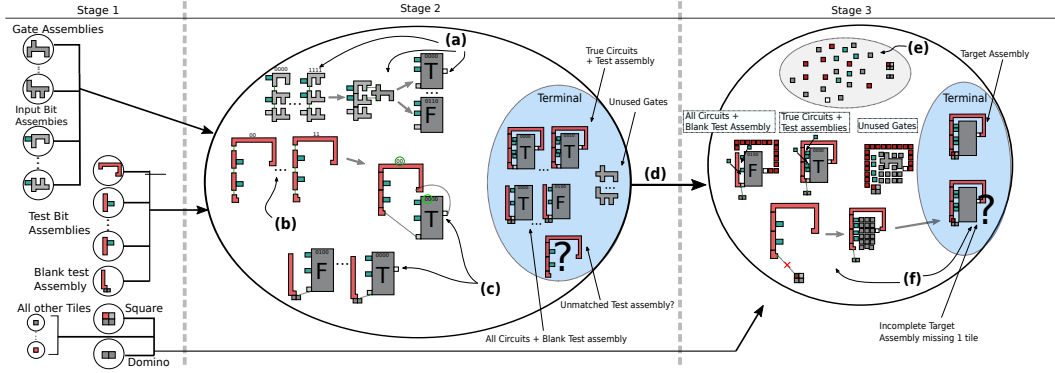

■ **Figure 5** (a) A NAND gate assembly representing input: “10” and output: “1” attaching to the input assembly in the *Second Stage*. (b) False Output Gates which do not contain a flag tile can attach to the circuit if the output is false. This assembly is terminal in the second bin. (c) True Output Gates have an additional flag tile (white) that allows for the test tile (red) to attach cooperatively to the input assembly and the True Output Gate. (d) Single tiles fill in the spaces left by the arms and the output frame attaches forming our target assembly. If there is a flag tile in the output frame the output of this circuit is true. Otherwise, the output is false.

► **Theorem 1.** *For any function f computed by an n -input boolean circuit with k gates, there exists a 3-stage $\mathcal{O}(n^2 + k^2)$ bin, temperature-2 staged tile assembly computer that covertly computes f with an output template size of $\mathcal{O}(n^2 + k^2)$.*

Proof. Given any boolean circuit c , we create gate assemblies for each gate. Given the input to this circuit we create input assemblies that encode the input. In the second stage input assemblies start attaching together to form a circuit assembly. Once two inputs to a gate have attached the gate assembly computing the output of that gate is able to attach. Two gate assemblies cannot attach away from the circuit assembly. There only exist strength-1 glues on the outer edges of a gate assembly, thus a gate can only attach to another assembly with a cooperative bind at each arm. This ensures gates only attach once both inputs are present, and forces the circuit to assemble in the correct order. In the second stage we add in the test tile. This test tile may only attach to a circuit assembly that has a flag tile attached. The flag tile is only present on output gates that evaluate to true so the test tile may attach if and only if the circuit evaluates to true. The test tile is terminal otherwise.

In the final bin we add in single tiles to hide the input to the circuit and the inputs to each gate. As explained above each assembly input to this bin will grow into a full circuit assembly. This full circuit assembly will grow into one of our two output frames. The output frame is a full circuit assembly with the output frame attached. The output frame contains a test tile for false and is empty for true. The terminal assembly of our staged system will have a test tile in the output frame if and only if the circuit evaluated to false which is one of our output frames. If the circuit evaluates to true the test tile will not be present.

This system uses a polynomial number of bins in the first and second stage and a single bin the final stage. The number of bins in the first and second stage are bounded by the size of our tile set since we need individual bins to store each tile so they do not combine before the final stage. The max size of a gate assembly is $\mathcal{O}(\max(n, k))$ since in the worst case a gate needs to stretch across the whole circuit. The same bound applies to input bit assemblies. Therefore the size of the system (the number of tile types + the size of the mix graph) is $\mathcal{O}(n^2 + k^2)$ ◀

■ **Figure 6** A high level overview of the staged system created from an instance of $\forall\text{ESAT}$. (a) An input assembly is created for every possible input to ϕ and is evaluated using the computation technique from Section 3. (b) A test assembly is created for every possible input to X . (c) Test assemblies can attach to a true circuit assembly with the same assignment to X . Blank test assemblies attach to any circuit. (d) Terminal assemblies are passed to the next stage, including unmatched test assemblies if any exist. (e) In this stage we add the domino and square assemblies, as well as every other single tile of the target assembly. (f) Any unmatched test assembly will grow into an incomplete target assembly since it cannot attach to the square assembly. These incomplete target assemblies are terminal, meaning the UAV instance is false.

4 Unique Assembly Verification

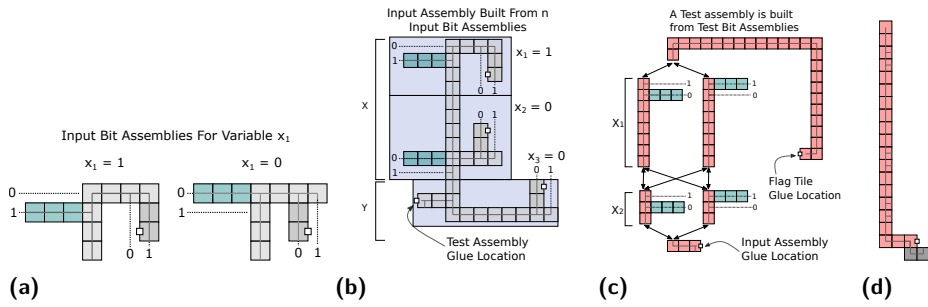

We now utilize covert computation to show that the open problem of Unique Assembly Verification in staged self assembly is PSPACE-complete. We start by showing UAV with 3 stages is Π_2^P -hard. We then show how to extend this construction to show that general staged UAV is PSPACE-complete. With some adjustments the same concept is used to show that when limiting the system to n stages, the problem of UAV is Π_{n-1}^P -hard.

► **Problem 2** (Staged Unique Assembly Verification). *Given a staged system Γ and an assembly A , does Γ uniquely assemble A ?*

4.1 3-stage UAV is Π_2^P -hard

We modify the covert computation construction to provide a reduction from $\forall\text{ESAT}$. Given an instance of $\forall\text{ESAT}$, we create a 3-stage temperature-2 staged system that uniquely produces a target assembly iff the given instance of $\forall\text{ESAT}$ is true. The reduction uses the same high-level idea as [16] and [3]. The process begins with the construction of an assembly for every input to the $\forall\text{ESAT}$ formula. Circuit assemblies build from these inputs and are flagged as true or false, while encoding a partial assignment through their geometry. Separate “test” assemblies are constructed that also encode a partial assignment to the same variables, which attach to true circuit assemblies with matching assignments. The systems uniquely assembles a target assembly if for all test assemblies there exists a compatible true circuit assembly for it to attach to. See Figure 6 for a visual overview of the created system.

► **Problem 3** ($\forall\text{ESAT}$). *Given an n -bit boolean formula $\phi(x_1, x_2 \dots x_n)$ with the inputs divided into two sets X and Y , for every assignment to X , does there exist an assignment to Y such that $\phi(X, Y) = 1$?*

■ **Figure 7** (a) Input bit assemblies for variables in X with geometry on the left reflecting the bit value. (b) An example initial circuit assembly for input $x_1 = 1, x_2 = 0, x_3 = 0$. The geometry on the left side of the assembly represents the assignment of X . (c) Separately built test bit assemblies nondeterministically attach to build one test assembly for every assignment to variables in X . (d) The blank test assembly is composed of the same base but has no protruding arms.

4.1.1 First Stage

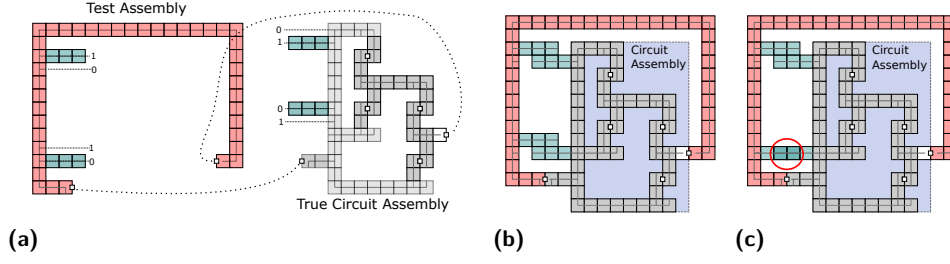

Input and Gate Assemblies. In the first stage an *input bit assembly* for both assignments to every variable x_1, \dots, x_n is built in its own bin ($2n$ bins in total). Input bit assemblies have the same structure as in the covert computation construction, except that input bit assemblies representing bits in X also have a horizontal row of tiles on the left of the frame that reflects the bit value. Figure 7a shows this modification to the input bit assemblies. The bit assemblies representing variable x_n no longer has additional tiles that attach to the test tile used in section 3. The input bit assemblies representing variable $x_{|X|+1}$ have an additional 2 tiles attached, which are used to attach to the test assembly. Gate Assemblies are built in the same way described in Section 3.

Test Assemblies. Similar to the input bit assemblies, two *test bit assemblies* are constructed for every variable in X . A test bit assembly is a column of connected tiles, with a horizontal row of 3 tiles extending to the right, the position of this row represents an assignment “0” or “1”. An example test assembly building from separate test bit assemblies is shown in Figure 7c. A test assembly is composed of $|X|$ test bit assemblies. Test assemblies have additional geometry that allow them to attach to a circuit assembly.

4.1.2 Second Stage

In the second stage the input bit assemblies will attach together nondeterministically to form 2^n unique input assemblies. The “1” and “0” input bit assembly exist for every variable, so the nondeterministic nature of the model allows for the construction of an input assembly for every possible input to the circuit. From this input assembly, computation will begin as described in the covert section. There will exist a circuit assembly for each of the 2^n possible inputs, and each will be flagged as true or false, represented by the existence of a flag tile on the output gate. We call a circuit assembly that contains the flag tile a *true circuit assembly*.

Test Assemblies. Test bit assemblies nondeterministically combine in this stage to create a unique test assembly for every assignment to variables in X , with its assignment encoded in its geometry. A test assembly can cooperatively bind to a true circuit assembly (with the same assignment to X) by having glue strength with the output flag tile and the input assembly (Figure 8b). A test assembly has its assignment encoded in its geometry in a

■ **Figure 8** (a) A test assembly (left) and a true circuit assembly that represent the same assignment to variables in X (In this construction true assemblies contain the flag tile). (b) A test assembly attaching to true circuit assembly with a matching assignment to X . (c) A test assembly that is geometrically blocked from attaching to a true circuit assembly due to having a different assignment to X . The red circled area shows the point of overlap.

complementary fashion to that of a circuit assembly. This ensures that a test assembly is geometrically blocked from attaching to a circuit assembly that encodes a different assignment to X (Figure 8c). If there are no true circuit assemblies with the assignment x to X , the test assembly that represents that assignment of x will be terminal in the second stage. We refer to these as *unmatched* test assemblies.

► **Lemma 4.** *Let t_x be the test assembly representing the assignment x to the variables in X . t_x is unmatched (terminal in the second stage) if and only if for all assignments y to the variables in Y ($\phi(x, y) = 0$).*

Proof. True circuit assemblies are the only assemblies which have the necessary glue types to attach to t_x . The remaining question is whether a true circuit assembly exists which represents a compatible assignment. t_x can attach to any true circuit assembly with a matching assignment to X , regardless of that circuit's assignment to Y . It follows that if there exists an assignment y to Y such that $\phi(x, y) = 1$, then t_x is not terminal. The negation of which is $\forall y(\phi(x, y) = 0)$, then t_x is terminal. ◀

4.1.3 Third Stage

The third stage utilizes a single bin that all assemblies are combined in. Nearly all single tiles of the target assembly are added. Four single tiles are specifically excluded, and instead two subassemblies are added in. This is done carefully to ensure the following property: every assembly except unmatched test assemblies from the second stage will grow to the target assembly. Our target assembly contains a circuit assembly attached to a test assembly with every empty spot filled in. At the point where a test assembly attaches to the circuit assembly, a domino assembly is attached completing the target assembly as seen in Figure 9a.

► **Lemma 5.** *Let A be the set of initial assemblies in the sole bin in the third stage. For all assemblies $a \in A$, a will grow to the target assembly iff a is not an unmatched test assembly.*

Proof. All individual tiles of the target assembly are added into the last stage, with the exception of four withheld tiles: the two tiles where the test assembly and input assembly meet, and the two tiles below that (tiles A, B, C, D in Fig. 9a). Instead of these four tiles, two assemblies are added that we refer to as the square and domino (Fig. 9b). These two assemblies perform the function of allowing every initial assembly besides unmatched test assemblies to grow into the target assembly. True circuit assemblies with test assemblies attached will have their empty spaces filled by single tiles, and the domino assembly will

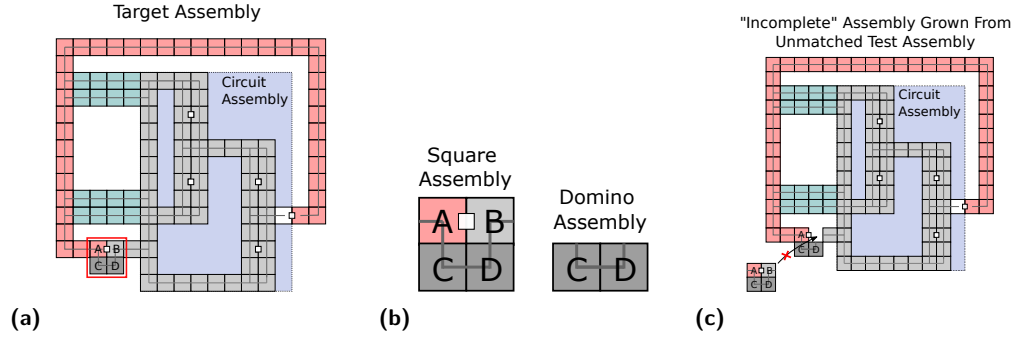

Figure 9 (a) An example target assembly. The area boxed in red shows where the test assembly meets the input assembly (A, B) , and the adjacent domino (C, D) . The four tile types A, B, C, D are not added in individually at the third stage. (b) The two additional assemblies that are added in at the third stage, composed of the same four tile types. (c) The square assembly is geometrically blocked from attaching to an assembly that grew from an unmatched test assembly, as they both contain tile A .

attach. Unused gates will grow to a near-complete circuit, attach to the square assembly, and then continue to grow to the target assembly. True and False Circuit Assemblies with blank test assemblies attached already contain the four withheld tiles, so will grow to the target by attaching to all necessary single tiles. Unmatched test assemblies that did not attach to a true circuit assembly can grow to a near complete target assembly, however, it will never acquire tile B (Fig. 9a), as it could only achieve this by attaching to the square assembly. They both contain tile A , making it geometrically blocked from doing so (Fig. 9c). ◀

► **Theorem 6.** *UAV in the Staged Assembly Model with three stages is Π_2^P -hard with $\tau = 2$.*

Proof. Given an instance of $\forall\text{ESAT}$, the reduction provides an instance of a 3-stage temperature-2 UAV instance which is true if and only if the instance of $\forall\text{ESAT}$ is true.

If the instance of $\forall\text{ESAT}$ is true, then for all assignments x to X , there exists an assignment y to Y with $\phi(x, y) = 1$. By Lemma 4, this implies there will be no unmatched test assemblies. By Lemma 5, every assembly that is not an unmatched test assembly or grown from an unmatched test assembly will grow into the target assembly in the third stage. Thus, the system uniquely produces the target assembly. If the $\forall\text{ESAT}$ instance is false, then there exists an assignment x to X , s.t. for all assignments y to Y , $\phi(x, y) = 0$. By Lemma 4, a test assembly representing assignment x would be unmatched, and by Lemma 5, unable to grow into the target assembly. Thus, this UAV instance is false. ◀

4.2 Staged UAV is PSPACE-hard

In this section, we explain at a high level how the reduction is extended to reduce from TQBF with n quantifiers over n variables to temperature-2 $\mathcal{O}(n)$ -stage UAV, showing that Staged UAV is PSPACE-Hard.

► **Problem 7 (TQBF).** *Given a boolean formula ϕ with n variables x_1, \dots, x_n , is it true that $\forall x_1 \exists x_2 \dots \forall x_n (\phi(x_1, \dots, x_n) = 1)$?*

We utilize the same technique used in section 4.1 which reduced from $\forall\text{ESAT}$, a special case of TQBF limited to only 2 quantifiers, but adapt the technique to work with a QBF with n quantifiers $\forall x_1 \exists x_2 \dots \forall x_n (\phi(x_1, \dots, x_n) = 1)$. In the 3rd stage, instead of adding

■ **Figure 10** An example mix graph for an instance of TQBF with 4 variables. (a) Test bit assemblies combine into T_2 test assemblies. Circuit assemblies evaluate every input. (b) T_2 test assemblies attach to compatible (matching partial assignment) true circuits. Any unmatched T_2 assemblies are passed to the next stage. (c) T_3 test assemblies are added in and attach to compatible T_2 test assemblies. (d) Any unmatched T_3 assemblies are passed to the next stage. (e) T_4 test assemblies are added and attach to compatible T_3 test assemblies. (f) The existence of an unmatched T_4 assembly directly corresponds to the truth of the TQBF instance.

in single tiles to “clean up”, we add in a second set of test assemblies that represent an assignment with one less variable in the next stage and are complementary in their geometry. These new test assemblies then attach to previous test assemblies that were terminal in the previous stage with matching partial assignments. This process computes an additional quantifier. We can then repeat this process of adding in complementary sets of test assemblies for the number of quantifiers required. In the final stage, if a test assembly from the final set couldn’t find a complementary test assembly to attach to, the instance of TQBF is false, and that test assembly is prevented from growing to the target assembly. This allows the truth of instance of staged UAV to correspond to the truth of the QBF. See Figure 10 for a depiction of the mix graph. We now show how in a certain stage the existence of a terminal test assembly relates to the truth of a statement about the boolean formula.

In total the system will have $n + 1$ stages, and $n - 1$ sets of test assemblies will be added (denoted T_2, \dots, T_n). The set T_s will be mixed in at stage s . The first set T_2 represents an assignment to x_1, \dots, x_{n-1} , and each consecutive set represents one less variable than the set before it, i.e., a test assembly $t_s \in T_s$ represents a partial assignment to x_1, \dots, x_{n-s-1} . The sets alternate between type L and R , which correlates to the direction the arms face (Compare T_3 and T_4 in Figure 10). We build all these sets of test assemblies using the same method in the first stage, and pass them along through “helper” bins until they are needed.

► **Lemma 8.** Let $TERM(A, b) \iff (\text{Assembly } A \text{ is terminal in bin } b)$. Let a be the number of variables the test assemblies in T_s represent ($a = n - s + 1$). Let $t_s(x_1, \dots, x_a)$ be the test assembly $t_s \in T_s$ that represents partial assignment x_1, \dots, x_a . In the staged system S_P created from an instance of TQBF P over n variables: $\forall s \in \{1, \dots, n\} (TERM(t_s(x_1, \dots, x_a), b_s) \iff \forall x_{a+1} \exists x_{a+2}, \dots, Qx_n (\phi(x_1, \dots, x_n) = y))$. If s is even, $y = 0$ and $Q = \forall$, and $y = 1$, $Q = \exists$ otherwise.

► **Lemma 9.** In the staged system S_P created from an instance of TQBF P over n variables, in bin b_{n+1} in stage $n + 1$, let A be the set of initial assemblies in b_{n+1} . For all $a \in A$, a will grow to the target assembly if and only if a is not an unmatched test assembly $t_n \in T_n$.

► **Theorem 10.** *Unique Assembly Verification in the Staged Assembly Model is PSPACE-complete with $\tau = 2$.*

Proof. Given an instance of TQBF P over n variables/quantifiers, the reduction provides an instance of $n + 1$ -stage $\tau = 2$ UAV that is true if and only if P is true. If P is true, then in stage $n + 1$, every producible assembly grows into the target assembly. Since n is always even, by Lemma 8, for a bin b_n in stage n , an assembly $t_n \in T_n$ representing an assignment x_1 is terminal in bin b_n if $\forall x_2 \exists x_3, \dots, \forall X_n (\phi(x_1, \dots, x_n) = 0)$. If P is true, then the statement $\forall x_1 \exists x_2 \forall x_3, \dots, \forall X_n (\phi(x_1, \dots, x_n) = 1)$ is true, and therefore no unmatched $t_n \in T_n$ will be passed into b_{n+1} . By Lemma 9, every initial assembly in b_{n+1} that is not some $t_n \in T_n$ grows into the target assembly. Therefore, the target assembly is uniquely assembled if the instance of TQBF is true. If P is false, then there exists an assignment to x_1 such that $\forall x_2 \exists x_3, \dots, \forall X_n (\phi(x_1, \dots, x_n) = 0)$. By Lemma 8, some test assembly $t_n \in T_n$ will be terminal and passed into bin b_{n+1} . By Lemma 9, any $t_n \in T_n$ will not grow into the target assembly. Thus, the instance of staged UAV is false. ◀

4.3 n -Stage Hardness

We now show how the reduction can be used to show hardness for n -stage UAV. We reduce from the boolean satisfiability problem for Π_n^p , which is a quantified boolean formula with n quantifiers (starting with universal) and $n - 1$ alternations. We show an instance of Π_n^p -SAT can be reduced to $n + 1$ -stage $\tau = 3$ UAV.

► **Problem 11** (Π_n^p - SAT). *Given a boolean formula ϕ with variables partitioned into n sets X_1, \dots, X_n , is it true that $\forall X_1 \exists X_2 \dots Q_n X_n (\phi(X_1, \dots, X_n))$.*

► **Theorem 12.** *For all $n > 1$, UAV in the Staged Assembly Model with n stages is Π_{n-1}^p -hard with $\tau = 2$.*

Proof. The system functions nearly identically to the previous reduction. However, if n is odd, the output gate assemblies will now contain the flag tile if they represent a *false* output, rather than true. Each consecutive test assembly added now represents one less *set* of variables, rather than just one less variable.

If n is even, the system acts in the way previously described. If n is odd, then by Lemma 8 any $t_n \in T_n$ representing an assignment to X_1 is terminal if $\forall X_2 \exists X_3 \dots \exists X_n (\phi(X_1, \dots, X_n) = 1)$. However, since we modified the output assemblies to contain the flag tile if they represent a *false* output, they are now terminal if the statement is true for the negation of ϕ . Therefore any t_n representing X_1 is terminal if and only if $\forall X_2 \exists X_3 \dots \exists X_n (\phi(X_1, \dots, X_n) = 0)$. In bin b_{n+1} all assemblies besides any t_n grow to the target assembly in the same way. ◀

4.4 UAV Membership

In this section, we improve on previous work and show that an n -stage UAV problem is in Π_{n+1}^p . We use a similar method as [16], by defining three subproblems that are solved as subroutines of a UAV algorithm. However, these subproblems differ from previous work as we make some assumptions about our input. We first define *bounded* bins and systems, then define the three subproblems, and show their complexity. However, due to space constraints, the proofs have been omitted.

► **Definition 13** (Bounded). *Given a bin $b = (S, \tau)$ in a staged system where S is the set of initial assemblies and τ is the temperature. Let P_b be the set of producible assemblies in bin b . The bin is bounded by an integer $k \in \mathbb{Z}^+$ if for each $a \in P_b$, $|a| \leq k$. A staged system is bounded if all bins are bounded by some k .*

■ **Table 2** Complexity of these problems in 1 stage (2HAM) and in s stages.

Stages	UAV	BPROD	BTERM	BBIN
1	Π_1^p	Σ_0^p	Π_1^p	Π_1^p
s	Π_{s+1}^p	Σ_s^p	Π_s^p	Π_s^p

■ **Algorithm 1** Staged Unique Assembly Verification Membership Algorithm.

Data: Given a staged system Γ with n stages, and an Assembly A .

Result: Does Γ uniquely assemble A and is Γ bounded?

for each stage s' starting with $s' = 1$ **do**

for each bin b in stage s' **do**

if Not $BBIN_{s'}(\Gamma, |A|, b')$ **then** reject;

for each bin b in stage n **do**

if Not $BPROD_n(\Gamma, |A|, b, A)$ **then** reject;

if Not $BTERM_n(\Gamma, |A|, b, A)$ **then** reject;

Nondeterministically select an assembly B with $|B| \leq |A|$;

for each bin b' in stage n **do**

if $BPROD_n(\Gamma, |A|, b', B)$ **then**

if $BTERM_n(\Gamma, |A|, b', B)$ **then** reject;

accept;

► **Problem 14** (Bounded Producibility ($BPROD_s$)). *Given a bounded staged system Γ , an integer k (described in unary), a bin b in stage s bounded by k , and an assembly A , is A producible in b ?*

► **Problem 15** (Bounded Terminal Assembly with producibility promise ($BTERM_s$)). *Given a bounded staged system Γ , an integer k (described in unary), a bin b in stage s bounded by k , and an assembly $A \in P_b$, is A terminal in b ?*

► **Problem 16** (Bounded Bin ($BBIN_s$)). *Given a staged system Γ , a bin b in stage s , an integer k (described in unary), assuming all bins in stages before s are bounded by k , is b bounded by k ?*

► **Lemma 17.** *For a bin b in stage s of a staged self-assembly system,*

■ *the Bounded Producibility problem is in Σ_s^p ,*

■ *the Bounded Terminal Assembly problem with producibility promise is in Π_s^p , and*

■ *the Bounded Bin problem is in Π_s^p*

4.5 UAV_n Membership

We now present a co-nondeterministic algorithm using oracles for the previous problems to solve UAV. For clarity, we use an alternate but equivalent definition of UAV. We provide Algorithm 1 that uses oracles to solve the subproblems presented above.

► **Problem 18** (Staged Unique Assembly Verification). *Given a staged tile-assembly system Γ and an assembly A , is Γ bounded by $|A|$, and for each bin in the last stage, is A the only terminal assembly?*

► **Theorem 19.** *The n -stage Unique Assembly Verification problem in the staged assembly model is in Π_{n+1}^p .*

5 Conclusion

In this paper we answered an open problem from [16] by showing the Unique Assembly Verification problem in the Staged Self-Assembly Model is PSPACE-complete. To show this, we utilized a construction capable of covert computation and extended it to show Π_2^P -hardness of UAV with three stages. We then extended this reduction to show PSPACE-completeness. This reduction is also used to show Π_{s-1}^P -hardness with s stages.

Several important directions for future work remain open. We use three stages to perform covert computation. Is the 2HAM alone capable of covert computation? If not, what is the lower bound on the number of stages needed? If so, can the construction be used to solve the open problem of UAV in that model? This might also mean fewer stages are needed for our results in the staged model. The two known hardness results for 2HAM utilize either one step into the third dimension or a variable temperature. Perhaps stronger results in the staged assembly model can be obtained with one of these variants.

An Instance-Optimal Algorithm for Bichromatic Rectangular Visibility

Abstract

Afshani, Barbay and Chan (2017) introduced the notion of instance-optimal algorithm in the order-oblivious setting. An algorithm A is instance-optimal in the order-oblivious setting for a certain class of algorithms \mathcal{A} if the following hold:

- A takes as input a sequence of objects from some domain;
- for any instance σ and any algorithm $A' \in \mathcal{A}$, the runtime of A on σ is at most a constant factor removed from the runtime of A' on the worst possible permutation of σ .

If we identify permutations of a sequence as representing the same instance, this essentially states that A is optimal on every possible input (and not only in the worst case).

We design instance-optimal algorithms for the problem of reporting, given a bichromatic set of points in the plane S , all pairs consisting of points of different color which span an empty axis-aligned rectangle (or reporting all points which appear in such a pair). This problem has applications for training-set reduction in nearest-neighbour classifiers. It is also related to the problem consisting of finding the decision boundaries of a euclidean nearest-neighbour classifier, for which Bremner et al. (2005) gave an optimal output-sensitive algorithm.

By showing the existence of an instance-optimal algorithm in the order-oblivious setting for this problem we push the methods of Afshani et al. closer to their limits by adapting and extending them to a setting which exhibits highly non-local features. Previous problems for which instance-optimal algorithms were proven to exist were based solely on local relationships between points in a set.

1 Introduction

In the theoretical study of algorithms one often quantifies the performance of an algorithm in terms of the worst case or average running time over a distribution of inputs of a given size. Sometimes, more precise statements can be made about the speed of an algorithm on certain instances by expressing the running time in terms of some parameter depending on the input. One class of such algorithms are the so-called output-sensitive algorithms, where the parameter is the size of the output. In computational geometry, a classical example is

computing the convex hull of a set of n points in the plane in $\mathcal{O}(n \log h)$ time, where h is the size of the convex hull [15, 5]. More recently, Afshani et. al. [1] introduced a specific notion of *instance optimality in the order-oblivious setting* and designed algorithms with this property for different problems on point sets. Roughly speaking, an algorithm is instance optimal in a certain class of algorithms \mathcal{A} if on any input sequence S , its performance on S is at most a constant factor removed from the best performance of any algorithm in \mathcal{A} on S . In the order-oblivious setting, performance is defined as the worst-case runtime over all permutations of the input sequence (the motivation behind this will be made clear below). A common characteristic of most problems solved in [1] is that they are based around local relations between points in S , in the sense that the relation between two points $p, q \in S$ depends solely on their coordinates and not on those of any other point in S . This is important because it allows one to decompose certain queries into independent queries on a partition of S . In this paper we push these methods closer to their limits by adapting and applying them to a problem which does not fit in this framework.

The studied problem. Here we consider the following problem: given a set S of points n in the plane with distinct x and y coordinates, each colored red or blue, report the red/blue pairs of points such that the rectangles they span contain no point of S in their interior. This again has applications to machine learning and more specifically nearest-neighbour classifiers. Indeed, by solving this problem and discarding all points which do not appear in such a pair, we obtain a (possibly much smaller) set of points where for any point y in the plane, the color of its nearest neighbour is the same as in the original set of points for the L_1 distance (as pointed out in [10], where this problem was perhaps first studied). This remains true even when *a priori* unknown (and possibly non-linear) scalings might be applied to the x and y axis after this preprocessing step. In fact, the resulting set of points consists of exactly those necessary for this to hold, so this constitutes an optimal reduction of the training set in that sense. Note that this problem does not fit in the general framework of [1], as whether two point span an empty rectangle depends on the position of all other points.

Related works. Pairs of points spanning empty rectangles and the corresponding graphs have been studied at numerous occasions in the past, under various names. They are called *rectangular influence graphs* in [10], which discusses applications to data clustering and classification. In [9] a similar relation is called *direct dominance*, and a worst-case optimal algorithm to report all pairs of related points is given. This algorithm runs in $\mathcal{O}(n \log n + h)$ time, where h is the size of the output. A straightforward adaptation yields an algorithm with the same running time for the bichromatic problem studied here. In [18] this relation is called *rectangular visibility* and a different algorithm with the same running time is given as well as algorithms for the dynamic query setting. The expected size of a largest independent set in this graph is studied in [7] (where they call such graphs *Delaunay graphs with respect to rectangles*). Generalizations and variations of this type of relation between points have also been widely studied [17, 16, 4, 2, 11, 14, 13, 19, 8]. Another problem of note which is closely related to the one we study here is the following: given a set S of n points in the plane, each colored red or blue, compute the subset of edges of the Voronoï diagram of S which are adjacent to both a site corresponding to a blue point and a site corresponding to a red point. This problem has some relevance to machine learning as we can equivalently state it as finding the boundaries of a nearest-neighbour classifier with two classes in the plane. A third formulation is finding the pairs of red and blue points such that there is an empty disk whose boundary passes through both. In [3], Bremner et. al. show that this problem can

be solved in output-sensitive optimal $\mathcal{O}(n \log h)$ time, where h is the size of the output. It is an interesting open problem to find instance-optimal algorithms for this problem in the order-oblivious setting (or prove that no such algorithm exists).

Paper organization. In Section 2 we motivate and state more precisely the notion of instance-optimality we work with in this paper. In Section 3 we define the problem formally and give an instance lower bound in the order-oblivious model by adapting the adversarial argument of [1]. The key new ingredients are a new definition of safety and a way to deal with the fact that here the adversary cannot necessarily change the expected output of the algorithm by moving a single point inside a so-called non-safe region. In Section 4 we give an algorithm and prove that its runtime matches the lower bound. The main observation which makes this work is that while the algorithms in [1] require the safety queries to be decomposable (which they are not here), we can afford to do some preprocessing to make them behave as if they were decomposable, as long as the amount of work done stays within a constant of the lower bound. In section 5 we mention that when competing against algorithms which can do linear queries, instance-optimality in the order-oblivious setting is impossible. Some details and proofs have been left out of this version and can be found in the full paper [12].

2 Instance optimality in the order-oblivious setting and model of computation

Ideally, we would like to consider a very strong notion of optimality, where an algorithm is optimal if on every instance its runtime is at most a constant factor removed from the algorithm with the smallest runtime on that particular instance. There is an obvious flaw with this definition, as for every instance we can have an algorithm “specialized” for that instance, which simply checks if the input is the one it is specialized for then returns the expected output without any further computation when it is the case (and spends however much time it needs to compute the correct output otherwise). For problems which are not solvable in linear time in the worst-case, this prohibits the existence of such optimal algorithms. One way to get around this issue in some cases and get a meaningful notion of instance-optimality is the following, taken from [1].

► **Definition 1.** *Consider a problem where the input consists of a sequence of n elements from a domain \mathcal{D} . Consider a class \mathcal{A} of algorithms. A correct algorithm refers to an algorithm that outputs a correct answer for every possible sequence of elements in \mathcal{D} . For a set S of n elements in \mathcal{D} , let $T_A(S)$ denote the maximum running time of A on input σ over all $n!$ possible permutations σ of S . Let $\text{OPT}(S)$ denote the minimum of $T_{A'}(S)$ over all correct algorithms $A' \in \mathcal{A}$. If $A \in \mathcal{A}$ is a correct algorithm such that $T_A(S) \leq O(1) \cdot \text{OPT}(S)$ for every set S , then we say A is instance-optimal in the order-oblivious setting.*

By measuring the performance of an algorithm on an instance as the maximum runtime over all permutations of the instance elements, the algorithm can no longer take advantage of the order in which the input elements are presented. In particular, simply checking if the input is a specific sequence is no longer a good strategy. Here, the domain \mathcal{D} consists of all points in the plane, colored red or blue. An instance is a sequence of points, no two sharing the same x or y coordinate. However, we really want to consider this sequence as a set of points, as the order in which the points are presented does not change the instance conceptually. Thus, it makes sense for us to consider a performance metric for which algorithms cannot

take advantage of this order. For the class of algorithms \mathcal{A} , we will consider algorithms in a restricted real RAM model where the input can only be accessed through comparison queries. That is, the algorithms can compare the x or y coordinates of two points but not, for example, evaluate arbitrary arithmetic expressions on these coordinates. We refer to such algorithms as *comparison-based algorithms*. The lower bound works even for a stronger model of computation, comparison-based decision trees (assuming at least a unit cost for every point returned in the output). We could also allow the comparison of the x coordinate of a point with the y coordinate of another without changing any of the results of this paper.

3 Lower-bound for comparison-based algorithms in the order-oblivious setting

Some basic notations and definitions

Throughout this section we consider a set S of n red and blue points in the plane. We assume that S is non-degenerate, in the sense that no two points in S share the same x or y coordinate (in particular, all points are distinct). If p is a point, we will denote its x and y coordinates as $x(p)$ and $y(p)$ respectively and its color as $c(p)$.

► **Definition 2.** A point p dominates $q \neq p$ if $x(p) \geq x(q)$ and $y(p) \geq y(q)$. A point is maximal (resp. minimal) in S if it is dominated by (resp. dominates) no point in S .

► **Definition 3** (Visible and participating points). Let p, q be two points in S . We say that q is visible from p in S (or that p sees q in S) if the axis-aligned box spanned by p and q contains no point of S in its interior. We say that $p \in S$ participates in S if it is visible from a point in S of the opposite color. We will omit the set S when it is clear from context.

The problems we want to solve can thus be restated as follows.

► **Problem 4** (Reporting participating points). Report all points which participate in S .

► **Problem 5** (Reporting red-blue pairs of visible points). Report all red-blue pairs of points (p, q) such that p and q see each other in S .

The following definitions will also be useful for us.

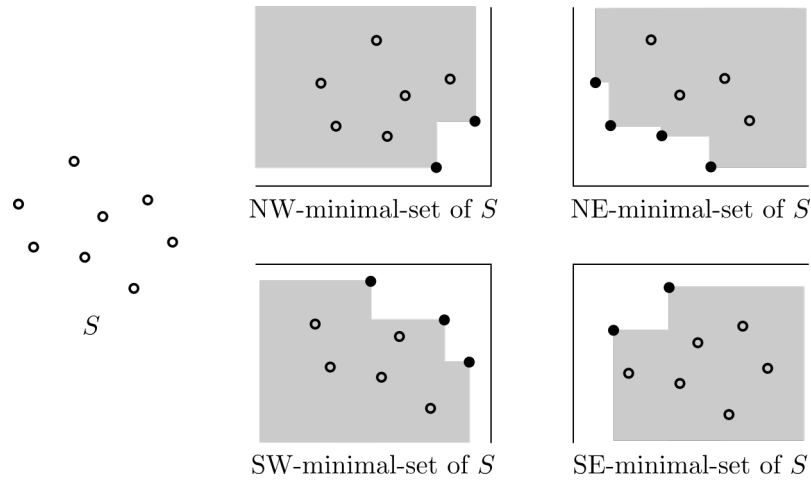

► **Definition 6.** We call the set of minimal points of S the NE-minimal-set of S (for “North-East-minimal set”). The NW-minimal-set, SE-minimal-set and SW-minimal-set of S are defined symmetrically (see Figure 1). In particular, the SE-minimal set of S is the set of maximal points in S .

► **Definition 7.** Let B be an axis-aligned box. We denote the x coordinate of the right boundary (resp. left boundary) of B as $x_{\max}(B)$ (resp. $x_{\min}(B)$). We denote the y coordinate of the top boundary (resp. bottom boundary) of B as $y_{\max}(B)$ (resp. $y_{\min}(B)$).

The cross of B , denoted as $\text{cross}(B)$ is the set of points p in the plane such that $x_{\min}(B) \leq x(p) \leq x_{\max}(B)$ or $y_{\min}(B) \leq y(p) \leq y_{\max}(B)$.

The quadrants of B are the connected components of $\mathbb{R}^2 \setminus \text{cross}(B)$. We call the four components the NE-quadrant, NW-quadrant, SE-quadrant and SW-quadrant, denoted as $\text{NE}(B)$, $\text{NW}(B)$, $\text{SE}(B)$ and $\text{SW}(B)$ respectively (see Figure 2).

All boxes we consider are axis-aligned boxes in the plane. For ease of exposition, we assume that all boxes we consider have no point of S on the boundaries of their four quadrants.

■ **Figure 1** A set of points S and the four minimal-sets of S . No point in the shaded regions can appear on the corresponding minimal-sets.

■ **Figure 2** The four quadrants of an axis-aligned box B . The shaded region corresponds to $\text{cross}(B)$.

■ **Figure 3** A red-safe box B .

Lower Bound

We prove an entropy-like lower bound on the number of comparisons which have to be done to solve the problems of reporting participating points in the order-oblivious setting. The proof and terminology are largely inspired from the lower bound proofs in [1] but some additional arguments, which we underline later, are required. We need a few definitions in order to state our lower bound.

► **Definition 8.** *An axis-aligned box B is red-cross-safe (resp. blue-cross-safe) for S if all points in $S \cap \text{cross}(B)$ are red (resp. blue). It is cross-safe if it is red-cross-safe or blue-cross-safe.*

It is red-safe if it is red-cross-safe and the NE-minimal (resp. NW-minimal, SE-minimal, SW-minimal) set of $S \cap \text{NE}(B)$ (resp. $S \cap \text{NW}(B)$, $S \cap \text{SE}(B)$, $S \cap \text{SW}(B)$) is red (see Figure 3). We define blue-safe boxes similarly. A box is safe if it is red-safe or blue-safe.

A subset $S' \in S$ has one of these properties if it can be enclosed by a box with the property.

Notice that if a subset $S' \in S$ is safe, then no point in S' participates in S . Thus, in an intuitive sense, a partition of non-participating points into safe subsets can be seen as a certificate for the fact that these points do not participate. The minimal entropy of such a partition is then the minimal amount of information required to encode such a certificate.

► **Definition 9.** A partition Π of S is *respectful* if every member $S_k \in \Pi$ is a singleton or a safe subset of S . The entropy of a partition Π is $\mathcal{H}(\Pi) := \sum_{S_k \in \Pi} \frac{|S_k|}{n} \log \frac{n}{|S_k|}$. The structural entropy $\mathcal{H}(S)$ of S is the minimum of $\mathcal{H}(\Pi)$ over all respectful partitions Π of S .

We can now state our lower bound:

► **Theorem 10.** For the problem of reporting participating points in the order-oblivious comparison-based model, $\text{OPT}(S) \in \Omega(n(\mathcal{H}(S) + 1))$. Consequently, for reporting red-blue pairs of visible points, $\text{OPT}(S) \in \Omega(n(\mathcal{H}(S) + 1) + h)$, where h is the size of the output.

The proof is similar to what can be found in [1]. In their case however, if a point can be moved anywhere inside a non-safe box then it can be moved in a way that changes the expected output of the algorithm. In our case, we can do something similar but sometimes need to move multiple points to affect the expected output (but a constant number are enough). We use a simple argument about the maximum number of chips which can be placed on a tree in a constrained way to show that this has no impact on the lower bound. The full proof, which is too long for this version of the paper, can be found in the full paper [12]. From this lower bound one can also deduce that the existence of an instance-optimal algorithm in the order-oblivious setting for reporting participating points implies the existence of such an algorithm for reporting red-blue pairs of visible points (using known results about worst-case optimal algorithms). Thus, we will focus on the former problem from now on.

4 Instance optimal comparison-based algorithm in the order-oblivious setting

In this section we present a comparison-based algorithm for reporting participating points with a runtime matching the lower bound we saw in the previous section (note that worst-case optimal $\mathcal{O}(n \log n + h)$ algorithms are easy to obtain by the method of [9]). Once again, the main algorithm will be very similar to what is done in [1], however their results do not directly apply here. The main difficulty in adapting their algorithm to our case is that the relation we consider here is not decomposable. More precisely, if we know that some point p does or does not participate in S' and S'' , we cannot use this to decide if p participates in $S' \cup S''$. The bulk of the work here will thus be to preprocess the set S in order to make the safety tests decomposable, while keeping our preprocessing time within $\mathcal{O}(n(\mathcal{H}(S) + 1))$.

4.1 The main algorithm

Before we go into detail about how to preprocess the points let us see how, if we can build the right data structure, we can use it to report the participating points in S in $\mathcal{O}(n(\mathcal{H}(S) + 1))$ time. We will need the following definition and observations:

► **Definition 11.** Let S be a set of red and blue points. A subset $S' \subset S$ conforms with S if it contains all points which participate in S .

► **Observation 12.** Let S be a set of red and blue points and let S' be a subset which conforms with S . Then an axis-aligned box is safe for S if and only if it is safe for S' . Moreover, a point participates in S if and only if it participates in S' .

► **Observation 13.** If B is a safe box for S , then any sub-box of B is safe for S .

► **Observation 14.** Let p be a point in S and let B be some axis-aligned box bounding p . If B is safe, then p does not interact in S .

We have the following algorithm and theorem, adapted from [1], where δ is a constant to be chosen later:

■ **Algorithm 1** Reporting participating points.

Input: A point set S of size n

- 1 Set $Q = S$.
- 2 **for** $j = 0, 1, \dots, \lfloor \log(\delta \log n) \rfloor$ **do**
- 3 Partition the points in Q using a kd-tree to get $r_j = 2^{2^j}$ subsets Q_1, \dots, Q_{r_j} of size at most $\lceil |Q|/r_j \rceil$, along with corresponding bounding boxes B_1, \dots, B_{r_j} .
- 4 **for** $i = 0, 1, \dots, r_j$ **do**
- 5 **if** B_i is safe for Q **then**
- 6 Prune all points in Q_i from Q .
- 7 Solve the reporting problem for the remaining set Q directly in $O(|Q| \log |Q|)$ time.

► **Theorem 15.** *Let S be a set of n points in general position. Suppose we have preprocessed S such that for any subset $S' \subset S$ containing all points which participate in S we can test if an axis-aligned box is safe for S' in $O(n^{1-\alpha})$ time, plus the cost of a constant number of range-emptiness queries on S' . Then Algorithm 1 can report all points which participate in S in $O(n(\mathcal{H}(S) + 1))$ time.*

We reiterate the proof for the sake of completeness and to underline how Observation 12 and our additional assumptions on preprocessing factor into it:

Proof. By Observation 12 and Observation 14, we only ever prune points which do not participate in the original set S and we never modify which points participate among those that remain. Thus the algorithm invoked at line 6 will compute the correct output.

By assumption, testing a box for safety in Q can be done in $O(n^{1-\alpha})$ time plus the cost of a constant number of range-emptiness queries on Q . Using a simple and ingenious trick by T. Chan [6], we can perform r orthogonal range emptiness queries on a set of size m in $O(m \log r + r^{O(1)})$ time. Thus, the r_j tests of lines 3 and 4 can be done in $O(|Q| \log r_j + r_j^{O(1)} + r_j n^{1-\alpha})$ time. As $r_j < n^\delta$, by taking δ small enough the $r_j^{O(1)} + r_j n^{1-\alpha}$ term can be made sublinear. As the outer loop of the algorithm is only executed $O(\log(\log n))$ times the total contribution of these terms over the whole algorithm can also be made sublinear and thus negligible. Line 2 can be done in $O(|Q| \log r_j)$ time by the classical recursive algorithm to compute kd-trees.

Now let n_j be the number of points in Q just after iteration j . The runtime of the algorithm is in $O(\sum_j n_j \log r_{j+1})$. This includes the final step at line 6, as for $j = \lfloor \log(\delta \log n) \rfloor$ (i.e. after the last iteration of the outer loop) we have $O(|Q| \log |Q|) \subset O(n_j \log n^{2\delta}) = O(n_j \log r_{j+1})$. Let Π be a respectful partition of S and consider $S_k \in \Pi$. At iteration j all subsets Q_i lying entirely inside the bounding box of S_k are pruned by Observation 13. Since the bounding box of S_k intersects at most $O(\sqrt{r_j})$ cells of the kd-tree, the number of points in S_k remaining after iteration j is $\min\{|S_k|, O(\sqrt{r_j} \cdot n/r_j)\} = \min\{|S_k|, O(n/\sqrt{r_j})\}$. The S_k 's cover the entire point set so by double summation we have:

■ **Figure 4** A cell of red points and the corresponding box B . The relevant points are indicated by arrows. The box point is indicated by a cross.

$$\begin{aligned}
 \sum_j n_j \log r_{j+1} &\leq \sum_j \sum_k \min \left\{ |S_k|, O \left(n / \sqrt{2^{2j}} \right) \right\} \cdot 2^{j+1} \\
 &= \sum_k \sum_j \min \left\{ |S_k|, O \left(n / 2^{2^{j-1}} \right) \right\} \cdot 2^{j+1} \\
 &\in O \left(\sum_k \sum_{j \leq \log(2 \log(n/|S_k|))} |S_k| \cdot 2^j + \sum_{j > \log(2 \log(n/|S_k|))} n \cdot 2^j / 2^{2^{j-1}} \right) \\
 &\in O \left(\sum_k |S_k| (\log(n/|S_k|) + 1) \right) = O(n(\mathcal{H}(S) + 1)). \quad \blacktriangleleft
 \end{aligned}$$

4.2 Cross-safety tree

In order to solve our problem instance-optimally (in the order-oblivious comparison-based model), we want to design a data-structure which allows us to quickly test if a given axis aligned box B is safe for S . To make the presentation clearer, we focus on testing if B is red-cross-safe and the NE-minimal-set of $\text{NE}(B) \cap S$ is red. This can then be repeated symmetrically for $\text{NW}(B)$, $\text{SE}(B)$ and $\text{SW}(B)$ to test if B is red-safe (and similarly for testing if B is blue-safe). We will see how to build and query the following data structure:

► **Definition 16.** A cross-safety tree T_S on S is a recursive partitioning on the plane similar to a kd-tree where we stop subdividing the points once we have reached a cross-safe subset of points. The root of T_S corresponds to S . If S is not cross-safe, we split the points around a vertical line L such that the two open halfplanes defined by L partition S into two sets S_1 and S_2 of size at most $\lceil |S|/2 \rceil$. The children of the root will then correspond to S_1 and S_2 . For every newly created node we repeat the procedure, partitioning the set of points by median x coordinates at even levels of the tree and median y coordinates at odd levels, until the points contained are a cross-safe subset of S .

The cell of a point p , denoted as C_p is the subset of points contained in the same leaf as p . A cell of T_S is red (resp. blue) if the points it contains are red (resp. blue).

The box of a point p , denoted as B_p is the smallest axis-aligned box containing all points in C_p (slightly extended to enforce our assumption of only considering boxes for which there are no points on the boundary of their four quadrants). A box of T_S is red (resp. blue) if the points it contains are red (resp. blue).

The box-point of p is the top-right point of the box of p , and has the same color as p .

A point is relevant if it has the minimum x or y coordinate among all points in its box (or equivalently, in its cell).

(See Figure 4 for an illustration of these definitions.)

Each node u in the tree stores:

- The set of point it contains, which we denote as P_u .

- The smallest axis-aligned bounding box of P_u , which we denote as B_u .
- The red box-points of minimum x and y coordinates among all box-points associated with a red point in P_u .
- The subset of all relevant blue points in the minimal set of P_u , sorted by x -coordinate.

Note that if the points in a minimal set are sorted by x coordinate then they are also sorted (in reverse order) by y coordinate.

4.3 Querying a cross-safety tree

Before we see how to build a cross-safety tree on S efficiently, let us see how we make queries on a node u of T_S . A query consists of a lower range $R_L = [x_L, +\infty] \times [y_L, +\infty]$ and an upper range $R_U = [-\infty, x_U] \times [-\infty, y_U]$ such that $R_L \cap R_U \neq \emptyset$ and neither the boundaries of R_L nor R_U intersect any blue box of T_S . It returns:

- rx_u , the minimum x -coordinate of any red box-points associated with a red point in $P_u \cap R_L$ (set to $+\infty$ if there are no red points in $P_u \cap R_L$).
- ry_u , the minimum y -coordinate of any red box-points associated with a red point in $P_u \cap R_L$ (set to $+\infty$ if there are no red points in $P_u \cap R_L$).
- bx_u , the minimum x -coordinate of any blue points in the minimal set of $P_u \cap R_L \cap R_U$ (set to $+\infty$ if there are no blue points in the minimal set of $P_u \cap R_L \cap R_U$).
- by_u , the minimum y -coordinate of any blue points in the minimal set of $P_u \cap R_L \cap R_U$ (set to $+\infty$ if there are no blue points in the minimal set of $P_u \cap R_L \cap R_U$).

Observe the following:

► **Observation 17.** *If a horizontal or vertical line passes through a red point then it does not intersect any blue-cross-safe box. The same applies when “red” and “blue” are swapped.*

► **Observation 18.** *Let B be a red-cross-safe box. Then all points in B dominate (resp. are dominated by) the same subset of blue points in S . The same applies when “red” and “blue” are swapped.*

We will need a few additional lemmas.

► **Lemma 19.** *The points corresponding to bx_u and by_u are relevant points of T_S .*

Proof. Let $P = P_u \cap R_L \cap R_U$, and suppose there is a blue point on the minimal set of P . Let p be the leftmost point in P which does not dominate any red point in P . Suppose that bx_u is not equal to $x(p)$. The only way this can happen is if p is not on the minimal set of P , meaning that there is a blue point q which is dominated by p (as p does not dominate any red point). In particular, q lies to the left of p . By definition of p , q thus dominates a red point. But if q dominates a red point and p dominates q , then p dominates a red point, which contradicts the definition of p . Thus $bx_u = x(p)$. Moreover, if p does not dominate any red point, then no point in its box dominates a red point, as the box is blue-cross-safe. Because the boundaries of R_L and R_U do not intersect any blue box, the whole box of p is contained in P . Thus, by definition of p , it is the leftmost point in its box and it is relevant. The same reasoning shows that by_u is the y coordinate of a relevant point. ◀

► **Lemma 20.** *If the bounding box B_u of points in P_u lies entirely in R_L , then we can return the necessary information in $O(\log n)$ time.*

Proof. In this case, rx_u and ry_u are already stored in the node, so we can return them in constant time. By Lemma 19, the point giving bx_u is the relevant blue point with minimum x coordinate among all blue points in the minimal set of $P_u \cap R_U$. This is also the relevant blue point with maximum y coordinate among all blue points in the minimal set of $P_u \cap R_U$.

We can do a binary search through the relevant blue points in the minimal set of P_u to find the point p below the line $y = y_U$ with maximum y coordinate. If this point is not in R_U (because $x(p) > x_U$) then no relevant blue point in the minimal set of P_u is in R_U , as all other relevant blue points q in the minimal set of P_u with $y(q) \leq y_U$ will have $x(q) > x(p) > x_U$. In this case we set $bx_u = +\infty$. Otherwise $bx_u = x(p)$.

We can find by_u similarly with a single binary search. \blacktriangleleft

► **Lemma 21.** *If u is not a leaf of T_S and B_u intersects the boundary of R_L , then we can return the necessary information after querying the children of u with the same lower range R_L (but possibly different upper ranges) and a constant amount of additional work.*

Proof. Suppose without loss of generality that the children of u split P_u by a vertical line (the situation for a horizontal line is similar). Let v be the child corresponding to the left half-plane and w the one corresponding to the right half-plane. Let us focus on computing bx_u , as this is the one requiring the most care.

Querying v with the same R_L and R_U returns some values rx_v , ry_v , bx_v and by_v . A blue point p on the minimal set of $P_w \cap R_L \cap R_U$ is a blue point on the minimal set of $P_u \cap R_L \cap R_U$ if and only if $y(p) \leq by_v$ and p does not dominate any red point in $P_v \cap R_U$. By Observation 18 this is equivalent to saying that $y(p) \leq by_v$ and $y(p) \leq ry_v$.

Thus we can compute bx_u by setting $R'_U = [-\infty, x_U] \times [-\infty, \min\{y_U, ry_v\}]$, querying w with R_L and R'_U to get values rx_w , ry_w , bx_w and by_w , then setting $bx_u = \min\{bx_v, bx_w\}$. Notice that by Observation 17, we are allowed to query w with R'_U as its boundary does not intersect any blue box of T_S . It is then easy to see that $rx_u = \min\{rx_v, rx_w\}$, $ry_u = \min\{ry_v, ry_w\}$ and $by_u = \min\{by_v, by_w\}$. \blacktriangleleft

► **Lemma 22.** *If u is a leaf of T_S and B_u intersects the lower boundary or the left boundary of R_L but not both simultaneously, then we can return the necessary information in constant time.*

Proof. In this case, we know that B_u is a red box, as by assumption the boundary of R_L does not intersect any blue box of T_S . Thus B_u contains no blue points and we know $bx_u = by_u = +\infty$. Suppose without loss of generality that B_u intersects the left boundary of R_L . Then the rightmost point of B_u is in R_L , and thus $P_u \cap R_L$ is non-empty. Because all points in P_u have the same box-point $p = (p_x, p_y)$, we have $rx_u = p_x$ and $ry_u = p_y$. \blacktriangleleft

► **Lemma 23.** *If u is a leaf of T_S and B_u intersects both the lower boundary and the left boundary of R_L , then we can return the necessary information after a single orthogonal range-emptiness test.*

Proof. Again, we know that B_u is a red box and all points in P_u have the same box point $p = (p_x, p_y)$. To know if we need to set $rx_u = ry_u = +\infty$ or $rx_u = p_x$ and $ry_u = p_y$, we simply need to test if there is a (necessarily red) point in $B_u \cap R_L$. This requires a single range-emptiness test. \blacktriangleleft

By applying the relevant result among Lemmas 20, 21, 22 and 23 recursively we get:

► **Theorem 24.** *We can query the root of a cross-safety tree T_S in $O(\sqrt{n} \log n)$ time plus the cost of a single range-emptiness test.*

As a corollary, we get:

► **Corollary 25.** *Let B be an axis aligned box. We can query a cross-safety tree T_S to test if B is red-NE-safe for S in $O(\sqrt{n} \log n)$ time plus the cost of a constant number of orthogonal range-emptiness tests on S .*

Proof. With two orthogonal range-emptiness queries on the blue points of S and one on the red points of S we can test if B contains at least one red point and $\text{cross}(B)$ contains only red points (that is, test if B is red-cross-safe for S). If B is not red-cross-safe for S we can immediately return “No”. We assume from now on that it is.

Let R_L be the range corresponding to $\text{NE}(B)$, and let $R_U = [-\infty, +\infty] \times [-\infty, +\infty]$. Because R is red-cross-safe, it is easy to see that the boundary of R_L does not intersect any blue box of T_S (this is also trivially true for R_U). Thus, we can query the root u of T_S with R_L and R_U to get the x coordinate bx_u of the blue point with minimum x coordinate among all blue points on the minimal set of $\text{NE}(B) \cap S$, or $+\infty$ if no such point exists. In particular, this allows us to test if such a point exists. ◀

We also have the following:

► **Lemma 26.** *Let $S' \subset S$ be a subset which conforms with S and let B be an axis-aligned box. If $S' \cap B \neq \emptyset$, then we can replace all orthogonal range-emptiness tests on S with the same tests on S' in the procedure described in Corollary 25 (including the tests done while querying T_S) without affecting the outcome.*

Proof. If there are both red and blue points in $S \cap \text{cross}(B)$, then at least one of these blue points participates in S . Because S' conforms with S , this blue point is also in S' , so S' is not red-cross-safe. The converse is trivially true. Thus, the initial three range-emptiness tests return the same results on S and S' .

Now consider the query done on T_S . If the corner of the lower range R_L does not intersect a red leaf box of T_S , then no range-emptiness test is performed and the claim holds. Now suppose R_L intersects a red leaf box B of T_S . Let S'' be the set of points in S where we remove all points in $S \cap B \cap R_L$ which are not in $S' \cap B \cap R_L$. Notice that by replacing the range-emptiness query on S with one on S' , the procedure behave exactly like querying a cross-safety tree on S'' . Because $S' \subset S'' \subset S$ we know that S'' conforms with S and thus by Observation 12 the claim holds. ◀

Thus, this data-structure fits the prerequisites of Theorem 15, and we can use it to get an algorithm solving the problem in $O(n(\mathcal{H}(S) + 1))$ time after having built it. The only missing ingredient to get an instance-optimal algorithm is building the data-structure within the same asymptotic runtime. We show in the following section that we can indeed do this.

4.4 Construction in $O(n(\mathcal{H}(S) + 1))$ time

Rather than focusing on constructing the cross-safety tree specifically, we start with a bit more general setting.

► **Theorem 27.** *Let S be a set of points. Let C be a property on axis-aligned bounding boxes of the plane such that for boxes $B_2 \subset B_1$, if $C(B_1)$ is true then $C(B_2)$ is true. (Note that C can depend on S).*

A partition Π of S is C -respectful if every set in Π is a singleton or can be enclosed by an axis aligned bounding box B such that $C(B)$ is true.

Let $\mathcal{H}_C(S)$ be the minimum of $\mathcal{H}(\Pi)$ over all C -respectful partitions of S .

If property $C(B)$ can be tested in $O(|S \cap B|)$ time when given access to $S \cap B$, then a kd-tree T_S^C with stopping condition C on the leaves can be built in $O(n(\mathcal{H}_C(S) + 1))$ time.

This remains true if for each node in the tree we do an additional linear amount of work (in the number of points considered at that node).

The proof is similar in spirit to that of Theorem 15, although simpler.

Proof. Consider the classical top-down recursive approach to construct a kd-tree on S (with linear-time median, selection), where we stop subdividing points once we have reached a bounding-box B with property C . Consider any C -respectful partition Π of S . Let $S_k \in \Pi$ and let B_k be a corresponding bounding box with the property C . At the j 'th level of the recursion, we have partitioned the plane into $O(2^j)$ boxes each containing at most $\lceil n/2^j \rceil$ points still to be considered. Any box B of T_S^C which is entirely contained in B_k has property C and can be set as a leaf. In other words the box B does not need to be recursed on and the points in $B \cap S$ are not considered at level j or lower. Because B_k intersects at most $O(\sqrt{2^j})$ boxes of T_S^C at level j , the number of points in S_k to consider at level j is $\min\{|S_k|, O(\sqrt{2^j} \cdot n/2^j)\} = \min\{|S_k|, O(n/\sqrt{2^j})\}$. At each level, the amount of work to be done is linear in the number of points to consider. The S_k 's cover the entire point set so by double summation we get that the runtime is in

$$\begin{aligned} O\left(\sum_j \sum_k \min\{|S_k|, n/\sqrt{2^j}\}\right) &= O\left(\sum_k \sum_j \min\{|S_k|, n/\sqrt{2^j}\}\right) \\ &= O\left(\sum_k \sum_{j \leq 2 \log(n/|S_k|)} |S_k| + \sum_{j > 2 \log(n/|S_k|)} n/\sqrt{2^j}\right) \\ &= O\left(\sum_k |S_k|(\log(n/|S_k|) + 1)\right) \\ &\subset O(n(\mathcal{H}_C(S) + 1)). \quad \blacktriangleleft \end{aligned}$$

Note that the proof generalizes easily to any constant dimension $d > 0$. We can apply this theorem to get the following (omitted proofs can be found in the full paper [12]):

► **Lemma 28.** *A set of points S can be preprocessed in $O(n(\mathcal{H}(S) + 1))$ time so that for any subset $S_k \subset S$, we can test if all points in S_k lie in a common vertical slab containing only points of S of the same color in $O(|S_k|)$ time.*

Which in turn implies:

► **Theorem 29.** *A cross-safety tree on S can be constructed in $O(n(\mathcal{H}(S) + 1))$.*

Finally, putting this together with 26 and Theorem 15 we get the main result.

► **Theorem 30.** *All points participating in S can be reported in $O(n(\mathcal{H}(S) + 1))$ time. In other words, there is an instance-optimal algorithm for this problem in the order-oblivious comparison-based model.*

One thing to note here is that while this guarantees that the algorithm is optimal with respect to any parameter of the instance which does not depend on the order of the input points, it is not immediately obvious that it runs in $O(n \log h)$ time, where h is the number of points to report (we only know that if there is an algorithm in the comparison-based model running within this time bound, then so does ours). The following results shows that the runtime of our algorithm is indeed within this bound.

■ **Figure 5** Type of instance considered in the impossibility proof.

► **Theorem 31.** *Let S be an instance of the Reporting participating points problem and let h be the number of points which participate in S . Then $n(\mathcal{H}(S) + 1) \in O(n \log h)$.*

5 Instance-optimality is impossible with linear queries

In the previous section, we have shown that there is a comparison-based algorithm to report participating points which is instance-optimal in the order-oblivious runtime against all comparison-based algorithm solving the problem. We also show that if we “compete” against algorithms which can do queries of the form $x(p) - x(q) \geq y(p) - y(q)$, then such a result is no longer possible, even if we allow our algorithm to be in a much stronger model of computation, such as algebraic computation trees. The full proof, in which we consider instances of the type illustrated in Figure 5, can be found in the full paper [12]. One caveat of this proof is that it relies on special instances with linear degeneracies (three points can be collinear). It is not clear if instance-optimality is possible when restricted to non-degenerate instances.

Abstract

We consider the problem of maintaining an approximate maximum independent set of geometric objects under insertions and deletions. We present a data structure that maintains a constant-factor approximate maximum independent set for broad classes of fat objects in d dimensions, where d is assumed to be a constant, in sublinear *worst-case* update time. This gives the first results for dynamic independent set in a wide variety of geometric settings, such as disks, fat polygons, and their high-dimensional equivalents. For axis-aligned squares and hypercubes, our result improves upon all (recently announced) previous works. We obtain, in particular, a dynamic $(4 + \epsilon)$ -approximation for squares, with $O(\log^4 n)$ worst-case update time.

Our result is obtained via a two-level approach. First, we develop a dynamic data structure which stores all objects and provides an approximate independent set when queried, with output-sensitive running time. We show that via standard methods such a structure can be used to obtain a dynamic algorithm with *amortized* update time bounds. Then, to obtain worst-case update time algorithms, we develop a generic deamortization scheme that with each insertion/deletion keeps (i) the update time bounded and (ii) the number of changes in the independent set constant. We show that such a scheme is applicable to fat objects by showing an appropriate generalization of a separator theorem.

Interestingly, we show that our deamortization scheme is also necessary in order to obtain worst-case update bounds: If for a class of objects our scheme is not applicable, then no constant-factor approximation with sublinear worst-case update time is possible. We show that such a lower bound applies even for seemingly simple classes of geometric objects including axis-aligned rectangles in the plane.

1 Introduction

Dynamic algorithms for classic NP-hard optimization problems is a quite active research area and major progress has been achieved over the last years (see [1, 9–11, 27]). For such problems, typically improved performance can be achieved when their *geometric* versions are considered, i.e., when the input has a certain geometric structure. As a result, a very recent line of research considers dynamic algorithms for well-known algorithmic problems in the

geometric setting [3, 12, 18, 21, 29]. In this work, we continue this investigation by considering the geometric version of the Maximum Independent Set problem; some of our results improve upon the previous (very recent) work of Henzinger et al. [29] and Bhore et al. [12] and some others provide the first dynamic data structures for various geometric instances.

Static Independent Set

In the maximum independent set problem, we are given a graph $G = (V, E)$ and we aim to produce a subset $I \subseteq V$ of maximum cardinality, such that no two vertices in I are adjacent. This is one of the most well-studied algorithmic problems. It is well-known to be NP-complete and hard to approximate: no polynomial time algorithm can achieve an approximation factor $n^{1-\epsilon}$, for any constant $\epsilon > 0$, unless $P=NP$ [28, 36].

(Static) Geometric Independent Set

In the geometric version of the maximum independent set problem, the graph G is the intersection graph of a set V of geometric objects: each vertex corresponds to an object, and there is an edge between two vertices if and only if the corresponding objects intersect.

Besides the theoretical interest, the study of independent sets of geometric objects such as axis-aligned squares, rectangles or disks has been motivated by applications in various areas such as VLSI design [30], map labeling [4, 35] and data mining [8, 31].

For most classes of geometric objects, the problem remains NP-hard. A notable exception is the case where all objects are intervals on the real line (the well-known *interval scheduling* problem), where the optimal solution can be computed in polynomial time using a folklore greedy algorithm [25]. However, even the simplest 2d-generalization to axis-aligned unit squares is NP-hard [24]. As a result, most of the related work has focused on developing PTASs for certain versions of geometric independent set. This has been achieved for various types of objects such as squares, hypercubes, fat objects and pseudodisks [15, 16, 23, 30].

A substantially harder setting is the when the geometric objects are arbitrary (axis-aligned) rectangles in the plane: Despite the intense interest (see [2, 20]), no PTAS is known. Until very recently the best known approximation factor was $O(\log \log n)$ [13, 14]; in 2021, a $O(1)$ -approximation was claimed [33].

Dynamic Geometric Independent Set

In the dynamic version of geometric independent set, V is a class of geometric objects (for instance squares in the plane) and we maintain a set $S \subseteq V$ of *active* objects. Objects of V may be inserted in S and deleted from S over time and the goal is to maintain a maximum independent set¹ of S , while keeping the time to implement the changes (the *update time*) sublinear on the size of the input.

Previous Work

Most previous work dates from 2020 onwards. The only exception is the work of Gavruskin et al. [26] who considered the very special case of intervals where no interval is fully contained in any other interval. The study of this area was revitalized by a paper of Henzinger,

¹ This problem should not be confused by the related, but very different, *maximal* independent set problem, where the goal is to maintain an inclusionwise maximal independent set subject to updates on the edges (and not the vertices). This problem has been studied in the dynamic setting, with a remarkable recent progress after a sequence of breakthrough results [5–7, 19].

Neumann and Wiese in SoCG'20 [29]. They presented deterministic dynamic algorithms with approximation ratio $(1 + \epsilon)$ for intervals and $(1 + \epsilon) \cdot 2^d$ for d -dimensional hypercubes, under the assumption that all objects are contained in $[0, N]^d$ and each of their edges has at least unit length. Their update time was polylogarithmic in both n and N , but N could be unbounded in n . Furthermore, they showed that no $(1 + \epsilon)$ -approximation scheme with sublinear update time is possible, unless the Exponential Time Hypothesis fails.

Subsequently Bhore et al. [12] obtained the first results for dynamic geometric independent set without any assumption on the input. For intervals, they presented a dynamic $(1 + \epsilon)$ -approximation with logarithmic update time; this was recently simplified and improved by Compton et al. [21]. For squares, [12] presented a randomized algorithm with expected approximation ratio roughly 2^{12} (generalizing to roughly 2^{2d+5} for d -dimensional hypercubes) with amortized update time $O(\log^5 n)$ (generalizing to $O(\log^{2d+1})$ for hypercubes).

Our Results

In this work we obtain the first dynamic algorithms for fat objects (formally defined in Section 2) in fixed dimension d with sublinear worst-case update time. The precise bounds on the approximation ratio and the update time depend on the fatness constant and the running time for worst-case range query structures for each family of objects. However, the results follow from a generic approach, applicable to all those classes of objects.

► **Theorem 1.** *There exists a deterministic data structure for maintaining a $O(1)$ -approximate independent set of a collection of fat objects, with sublinear worst-case update time, that reports $O(1)$ changes in the independent set per update. In particular, it achieves the following approximation ratios and worst-case update times, for any constant $0 < \epsilon \leq 1/4$:*

- $(4 + \epsilon)$ -approximation with $O(\log^4 n)$ update time for axis-aligned squares in the plane.
- $(5 + \epsilon)$ -approximation with $O(n^{3/4})$ update time for disks in the plane.
- $(2^d + \epsilon)$ -approximation with $O(\log^{2d} n)$ update time for d -dimensional hypercubes.
- $O(1)$ -approximation with $O(\log^{2dk} n)$ update time for fat objects which are unions of k (hyper)rectangles
- $O(1)$ -approximation with $O(n^{1 - \frac{1}{d(d+1)}})$ update time for fat simplices in d dimensions.
- $O(1)$ -approximation with $O(n^{1 - \frac{1}{d(d+1)k}})$ update time for fat objects which are unions of k simplices in d dimensions.
- $O(1)$ -approximation with $O(n^{1 - \frac{1}{d+2}})$ update time for balls in d dimensions.

This result gives the first dynamic algorithms with sublinear update time for all the aforementioned classes of objects, apart from d -dimensional hypercubes. Moreover, for hypercubes our result improves upon both of [29] and [12]. In [29] the approximation ratio is the same as ours, but here we achieve this with no extra assumption on the input and our running time $O(\log^{2d} n)$ is faster than the $O(\log^{2d+1} n \cdot \log^{2d+1} N)$, especially since N might be arbitrarily large. Compared to [12], our result is stronger with respect to all three metrics: the approximation factor, the update time, and the worst-case behavior.

In fact, it seems hard to significantly improve our result on any aspect: First, for the approximation factor, as mentioned above, Henzinger, Neumann and Wiese [29] proved that (under the Exponential Time Hypothesis) one cannot maintain a $(1 + \epsilon)$ -approximate maximum independent set of hypercubes in $d \geq 2$ dimensions with update time $n^{O((1/\epsilon)^{1-\delta})}$ for any $\delta > 0$. Moreover, the update time we obtain is essentially the time required for detecting intersections between objects in a range query data structure. Fatness of the objects is a sensible condition for achieving such results: we prove that for (nonfat) rectangles,

ellipses, or arbitrary polygons, no dynamic approximation in sublinear worst-case update time is possible. Finally, we emphasize the remarkable additional property that the number of changes reported per update is always constant.

To obtain the result of Theorem 1 we develop a generic method to obtain dynamic independent set algorithms and show how to apply it for fat objects. Our method uses a combination of several components. The first is a data structure which stores all objects, supports insertions and deletions in sublinear $f(n)$ time and, when queried, returns a β -approximate independent set with output-sensitive running time. The second main component is a generic transformation of such a data structure into a dynamic algorithm with approximation factor $\beta + \epsilon$ and *amortized* update time $O(f(n))$. This is done by periodically updating the solution using the data structure. Then, we apply a generic *deamortization* scheme, involving what we call a *MIX* function, a generic way to switch “smoothly” from one solution to another. We design such a MIX function for fat objects using geometric separators.

2 Overview

Notation

In what follows, V is a class of geometric objects, such as squares in the plane, and we consider a finite set $S \subseteq V$. A subset of S is a *maximum independent set* (MIS) of S if all its objects are pairwise disjoint and it has maximum size over all sets with this property. We use OPT to denote the size of a maximum independent set and let $n = |S|$. We say that I is a β -approximate MIS if its size is at least βOPT (here we adopt the convention that β is a constant $0 < \beta \leq 1$).

The problem we study is to maintain an approximate MIS set I under a sequence of insertions and deletions in S , which we call generically an *update*, starting from an empty set. This can be expressed as implementing a single operation $\Delta = \text{UPDATE}(u)$, where u is the object to be inserted or deleted, and Δ , the *update set*, is the set of objects that change in the approximate MIS I , presented as the symmetric difference from the previous set. In general we will use subscripts to express variables’ states after the indicated update, and unsubscripted versions for the current state. Using the operator \oplus to denote the symmetric difference, we therefore have $S_i := \oplus_{j=1}^i \{u_j\}$ and $I_i := \oplus_{j=1}^i \Delta_j$. We say that UPDATE is a β -approximate MIS algorithm if I_i is always a β -approximate MIS of S_i . We adopt the convention that the update set Δ_i is always returned explicitly and thus the running time of an update u_i is at least the size of the returned update set, $|\Delta_i|$.

We begin with a simple yet crucial observation about MIS.

► **Fact 2.** *The size of a MIS can change by at most one with every update: $|\text{OPT}_i - \text{OPT}_{i-1}| \leq 1$.*

Note that this fact does not hold for the weighted version of the MIS problem. Also note that this does not say that it is possible to have an update algorithm with an update set Δ_i with cardinality always at most 1; this fact bounds how the size of a MIS can change after an update, and not the content. In fact, it is easy to produce examples where $|\Delta_i|$ must be 2, even for intervals (e.g. $u_1 = [1, 4]$, $u_2 = [2, 3]$, $u_3 = [1, 4]$). However, it does leave open the possibility to have an update operation returning constant-size update sets, which is something we will achieve for the classes of geometric objects we consider.

Overview

Our goal is thus to develop a general method for dynamic approximate MIS that has efficient worst-case running times and small update set sizes for various classes of geometric objects. We identify two ingredients that are needed:

β -dynamic independent set query structure (β -DISQS): This is an abstract data type for maintaining a set S of n objects, in which one can insert or delete an object in time $f(n)$, and obtain a β -approximate MIS of the current set S in output-sensitive time $kf(n)$ if the set returned has size k .

MIX algorithm: A MIX algorithm receives two independent sets S_1 and S_2 whose sizes sum to n as input, and smoothly transitions from S_1 to S_2 by adding or removing one element at a time such that at all times the intermediate sets are an independent sets of size at least $\min(|S_1|, |S_2|) - o(n)$. The running time of the MIX algorithm is said to be $\gamma(n)$ if the entire computation takes time $n\gamma(n)$.

The plan of the paper is as follows.

Section 3: Amortized Update Time

In this section, we prove that the first ingredient, the β -DISQS, is sufficient to obtain a $(\beta - \epsilon)$ -approximate dynamic MIS algorithm with $O(f(n))$ amortized update time for any $\epsilon > 0$. This is presented as Theorem 4. We note that this is a bit of a “folklore” algorithm that essentially does nothing more than periodically call QUERY.

Section 4: Worst-case Update time

The second ingredient, MIX, is vital to deamortizing: In Section 4, we show that a DISQS and a MIX together are sufficient to produce a data structure which for any constant $\epsilon > 0$ maintains an approximate MIS of size at least $(\beta - \epsilon) \text{OPT} - o(\text{OPT})$, has a worst-case running time of $O(f(n) + \gamma(n) + \log n)$, and whose UPDATE operation returns a constant-sized update set; this is presented as Theorem 7. We also show in that the non-existence of a MIX function implies the impossibility of an approximate MIS data structure with sublinear update set size, hence sublinear worst-case running time, and that this impossibility holds for rectangles and other classes of nonfat objects (Theorem 8 and Lemma 9).

Given this generic scheme developed, to prove our main result, it remains to show that fat objects have a MIX function and a DISQS. This is the content of Sections 5 and 6.

Section 5: Existence of a MIX function for fat objects

We show in Lemma 13 that for fat objects in any constant dimension a MIX algorithm always exists with $\gamma(n) = O(\log n)$. This is achieved via geometric separators [34].

Section 6: Existence of β -DISQS for fat objects

Last, we show that obtaining a β -DISQS is possible for many types of objects using variants of standard range query results, with the running time $f(n)$ matching what we expect for range queries: polylogarithmic for orthogonal objects of constant complexity, and $O(n^c)$, $c < 1$ for non-orthogonal objects such as disks, triangles or general polyhedra. The result is based on a simple greedy algorithm for the MIS problem on fat objects [22, 32], yielding an approximation factor β that only depends on the fatness constant.

3 Dynamization

► **Definition 3.** A β -dynamic independent set query structure (β -DISQS) is a data structure that maintains a set S whose size is denoted as n and supports the following operations:

- **UPDATE(u):** Insert or remove u , so that S becomes $S \oplus u$.
- **QUERY:** Returns a β -approximate MIS of S

We say that the running time of a DISQS is $f(n)$ if UPDATE takes time $f(n)$ and if QUERY returns a set of size k in time $kf(n)$. We require $f(n)$ to be sublinear.

We now show that a β -DISQS is sufficient to give a approximate MIS data structure with an amortized running time, with a loss of only ϵ in the approximation factor for any $\epsilon > 0$. The intuition is simple, pass through the update operations to the DISQS and periodically replace the approximate MIS seen by the user by querying the DISQS. The only subtlety is to immediately remove any items from the approximate MIS that have been deleted in order to keep the approximate MIS valid. This simple transformation is likely folklore, but we work out the details in the full version of this paper for completeness.

► **Theorem 4.** Given a β -DISQS with sublinear running time $f(n)$ for an independent set problem and a $\epsilon > 0$ there is a fully dynamic data structure to maintain a $(1-\epsilon) \cdot \beta$ -approximate independent set that runs in $O(\frac{1}{\epsilon}f(n) + \log n)$ amortized time per operation.

4 Deamortization

In this section we present our deamortization technique. In particular, we describe a procedure, which we call MIX, which if exists, is used to transform a β -DISQS into a deterministic dynamic algorithm for with worst-case update time guarantees and update set size bounds. We also show that if a MIX does not exist for an independent set problem, then no sublinear worst-case update time guarantees are possible.

MIX function

We now define our main ingredient for deamortization, which essentially says that we can smoothly switch from one solution to another, by adding or removing one item at a time:

► **Definition 5 (MIX function).** Given two solution sets A and B , let $\text{MIX}(A, B, i)$, for $i \in [0, |A| + |B|]$ be a set where:

- $\text{MIX}(A, B, i)$ is always a valid solution
- $\text{MIX}(A, B, 0) = A$
- $\text{MIX}(A, B, |A| + |B|) = B$
- $|\text{MIX}(A, B, i)| \geq \min(|A|, |B|) - \Gamma(|A| + |B|)$, for some $\Gamma(|A| + |B|) = o(|A| + |B|)$.
- $\text{MIX}(A, B, i)$ and $\text{MIX}(A, B, i + 1)$ differ by one item.

Given this purely combinatorial definition, we define a MIX algorithm as follows.

► **Definition 6.** A MIX algorithm with running time $\gamma(n)$ is a data structure such that

1. It is initialized with $A, B, i = 0$ and it has a single operation ADVANCE which advances i and reports the single element in the symmetric difference $\text{MIX}(A, B, i) \oplus \text{MIX}(A, B, i - 1)$.
2. The initialization plus $|A| + |B|$ calls to ADVANCE run in total time $(|A| + |B|) \cdot \gamma(|A| + |B|)$.

The rest of this section is organized as follows. In 4.1 we show that given a β -DISQS and a MIX function for an independent set problem, we can produce a dynamic algorithm with worst-case update time guarantees and approximation ratio arbitrarily close to β . In

4.2, we show the necessity of MIX function; in other words, we show that if there does not exist a MIX function for an independent set problem, then no deterministic algorithms with worst-case update time guarantees exist.

4.1 Dynamic algorithm with worst-Case update time

We now present our main theorem. As we discuss next, the intuition expands upon that for Theorem 4, that in addition to periodically using the β -DISQS to get a new solution, the MIX slowly transitions between the two previous solutions reported by the β -DISQS. Our result is the following.

► **Theorem 7.** *Given a β -DISQS with running time $f(n)$ for an independent set problem, a $\gamma(n)$ -time MIX algorithm with nondecreasing $\Gamma(n) = o(n)$, and an $0 < \epsilon < 1/4$, there is a fully dynamic data structure to maintain an independent set of size at least $(\beta - \epsilon) \text{OPT} - o(\text{OPT})$. The data structure runs in $O_{\epsilon, \beta}(f(n) + \gamma(n) + \log n)$ worst-case time per operation, where n is the current number of objects stored, and reports a $O_\epsilon(1)$ number of changes in the independent set per update.*

High-level description

We saw in the previous section how to obtain an amortized update time algorithm by splitting the update sequence into *rounds* and query the DISQS at the end of each round to recompute an approximate MIS. Let \hat{I}_k be the independent set produced by the DISQS at the end of round k . At a high-level, the main task is to deamortize the computation of \hat{I}_k : we can not afford computing it during one step. Instead, we compute \hat{I}_k gradually during round $k + 1$, making sure that the running time per step is bounded. \hat{I}_k is eventually computed by the end of round $k + 1$. At this point, we would like to have \hat{I}_k (discarding elements deleted during round $k + 1$) as our output independent set; however this can not be done immediately, since \hat{I}_k might be very different from \hat{I}_{k-1} . For that reason, the switch from \hat{I}_{k-1} to \hat{I}_k is done gradually using the MIX function during round $k + 2$. After all, our algorithm uses \hat{I}_k as its independent set at the end of round $k + 2$.

It follows that the independent set reported to the user is a combination of DISQS queries 3 or 2 rounds in the past. We show that by appropriately choosing the lengths of the rounds depending on the sizes of the independent sets, this lag affects the approximation factor by an additive ϵ .

Proof of Theorem 7. We group the updates u_i into rounds, and use r_k to indicate that u_{r_k} is the last update of round k . Let \hat{I}_k be the independent set output by the β -DISQS (if queried) at time r_k , i.e., at the end of k th round. The length of the k th round, $R_k = r_k - r_{k-1}$ is defined to be $R_k := \max\{1, \lfloor \epsilon \cdot |\hat{I}_{k-2}| \rfloor\}$ updates.

For convenience, we define the following functions for any $0 < \epsilon < 1/4$:

$$g(\epsilon) = \frac{1 + \sqrt{1 - 4\epsilon}}{2} \quad h(\epsilon) = \frac{3 - \sqrt{1 - 4\epsilon}}{2} \quad \phi(\epsilon) = \frac{16h^2(\epsilon)}{\epsilon \cdot \beta \cdot g^3(\epsilon)}$$

Note that $g(\epsilon) = 1 - \epsilon - O(\epsilon^2)$ and $h(\epsilon) = 1 + \epsilon + O(\epsilon^2)$. Note also that $g(\epsilon) \in (1/2, 1)$ and in particular $g(\epsilon) \rightarrow 1$ as $\epsilon \rightarrow 0$. Similarly, $h(\epsilon) \in (1, 3/2)$ and $h(\epsilon) \rightarrow 1$ as $\epsilon \rightarrow 0$.

Our Data Structures and Operations

Our overall structure contains a β -DISQS and a MIX algorithm. We also maintain the current active set of objects S_i and our approximate independent set I_i explicitly in a binary search tree; we refer to simply as S and I , each stored according to some total order on the objects². We maintain the invariant that at the beginning of round k , the DISQS stores the set of objects $S_{r_{k-2}}$. Also, our structure stores \hat{I}_{k-3} and \hat{I}_{k-2} .

To execute update operations in round k , the following are performed:

Running MIX slowly: During round k we use MIX to transition from \hat{I}_{k-3} to \hat{I}_{k-2} . This is done by initializing MIX with \hat{I}_{k-3} and \hat{I}_{k-2} and repeatedly running the ADVANCE operation. After each update, we continue running MIX where we left off and continue until either $\phi(\epsilon) \cdot \gamma(|\hat{I}_{k-3}| + |\hat{I}_{k-2}|)$ time has passed or if $\phi(\epsilon)$ calls to ADVANCE have been performed.

Operation archiving: All updates are placed into a queue Q as they arrive. This will ensure that the DISQS will take into account all updates of previous rounds. Moreover, if an update u_i deletes an element v of S , we wish to report it as being deleted. To do so we set a variable $\Delta_i^{\text{DEL}} = \{v\}$, and otherwise $\Delta_i^{\text{DEL}} = \emptyset$.

Interaction with the DISQS: During round k , we want to use the DISQS in order to compute the set \hat{I}_{k-1} . To do that, we first perform to the DISQS all updates of round $k-1$ one by one and remove them from Q . This way, DISQS stores the set $S_{r_{k-1}}$. Then, we perform a query to the DISQS, to get \hat{I}_{k-1} . In each update of the round $\left(1 + \frac{2h(\epsilon)}{\beta\epsilon}\right) f(n)$ time is spent on executing these operations.

Maintaining S : We store S in a binary search tree based on some total ordering of the objects. For each update u_i , we search for u_i in S and remove it if it is there, and add it if it is not, to maintain $S = S_i = S_{i-1} \oplus \{u_i\}$.

Output: After each update, we report the symmetric difference Δ between previous and current independent set to the user. Let Δ_i^{MIX} be the union of the items returned by the ADVANCE operation of the MIX algorithm during the execution of update u_i . We combine Δ_i^{MIX} and Δ_i^{DEL} , and before returning, we remove any items that would result in the insertion into I_i of items that are not in S .

Roadmap

We need to argue about (i) correctness, (ii) running time, (iii) approximation ratio and (iv) *feasibility* of our algorithm, i.e., that during each round the computation of MIX and DISQS have finished before the round ends. Due to space limitations, we provide a brief sketch here and defer the formal proofs to the full version.

Correctness

It is easy to see that the algorithm described above always outputs an independent set to the user: During current round t , the user always sees $\text{MIX}(\hat{I}_{t-3}, \hat{I}_{t-2}, j)$ for some j , with perhaps some items that have been deleted in round $t-1$ or the current round removed. MIX is by definition an independent set at every step as in any subset of it, so the user always sees an independent set.

² Instead of a tree one could use a hash table, which would remove the additive logarithmic term from the update time, at the expense of randomization. However this will not improve our overall result, since functions $\gamma(n)$ and $f(n)$ are at least logarithmic in our application (see sections 5,6); therefore the logarithm can be absorbed while keeping the result deterministic.

Bound on update set size

The update set returned is a subset of $\Delta_i^{\text{MIX}} \cup \Delta_i^{\text{DEL}}$, as insertions of Δ_i^{MIX} might be removed if the items are no longer in S . The size of Δ_i^{MIX} is at most $\phi(\epsilon)$ by construction; the set Δ_i^{DEL} contains at most one element. Therefore,

$$\Delta \leq \phi(\epsilon) + 1 = \frac{16h^2(\epsilon)}{\epsilon \cdot \beta \cdot g^3(\epsilon)} + 1 \leq \frac{16}{\epsilon \cdot \beta} \cdot \frac{(3/2)^2}{(1/2)^3} + 1 = O\left(\frac{1}{\epsilon \cdot \beta}\right) = O_{\epsilon, \beta}(1) \quad (1)$$

Running time

The formal proof is located in the full version. Briefly, MIX takes time $\phi(\epsilon) \cdot \gamma(|\hat{I}_{k-3}| + |\hat{I}_{k-2}|)$. It is easy to show that $|\hat{I}_{k-3}| + |\hat{I}_{k-2}| \leq \frac{2\text{OPT}}{g^3(\epsilon)} \leq 16n$. Using that γ is sublinear, we get that $\phi(\epsilon) \cdot \gamma(|\hat{I}_{k-3}| + |\hat{I}_{k-2}|) = O_{\epsilon}(\gamma(n))$. DISQS works for time $(1 + \frac{2h(\epsilon)}{\beta \cdot \epsilon})f(n) = O_{\epsilon, \beta}(f(n))$. Last, operations for checking if update elements are still in S require time $O(|\Delta_i^{\text{MIX}} \cup \Delta_i^{\text{DEL}}| \cdot \log n) = O_{\epsilon, \beta}(\log n)$, due to (1).

Approximation ratio and feasibility

The proofs of approximation ratio and feasibility are simple but technical, and deferred to the full version. At a high level, the main idea is that the size of each round is carefully chosen such that, combined with Fact 2, the approximation factor β of the DISQS worsens just by an additive ϵ term due to the delayed updates and allows the DISQS and MIX operation to complete during the round. ◀

4.2 Necessity of the MIX function

► **Theorem 8.** *Suppose for any n , there are independent sets A and B of size n such there is no MIX function with $\Gamma(n) \leq (1 - \beta)n$ for all $A' \subseteq A$ and $B' \subseteq B$, where $|A'|, |B'| \geq \beta n$. Then there is no $(\beta + \epsilon)$ -approximate dynamic MIS algorithm that reports at most $o(n)$ changes in the independent set per update, for any $\epsilon > 0$.*

Proof. Let $\delta(n) = o(n)$ and suppose there is a $(\beta - \epsilon)$ -approximate MIS algorithm that reports $\delta(n)$ changes per update in the worst case. Insert A in to the data structure. Then insert B and delete A . This is $|A| + |B|$ update operations. At all times the independent set is at least $(\beta - \epsilon)n$, and there are at most $\delta(n)$ changes per update operation. We could transform this into a MIX function by taking the at most $\delta(n)$ changes from update and report each change one at a time, first deletes and then inserts; thus at each step of the resultant MIX, their independent set is at least $(\beta + \epsilon)n - \delta(n)$ which is at least βn for sufficiently large n . ◀

We can apply this to the case of rectangles in the plane, where we show that with a non-trivial worst-case performance of $o(n)$ changes in the independent set per operation, it is impossible to have an β -approximate MIS for any $\beta > 0$.

► **Lemma 9.** *There is no MIX function for rectangles with $\Gamma(n) < n$. Thus from Theorem 8, for any $\beta > 0$, there is no β -approximate dynamic MIS algorithm that reports at most $o(n)$ changes in the independent set per update.*

Proof. This is equivalent to saying that there are sets of rectangles A and B such that for any MIX function, there is an i such that $\text{MIX}(A, B, i) = \emptyset$. Consider sets of rectangles A and B , each of size n , in the form of a grid such that A are horizontally thin and disjoint, B

are vertically thin and disjoint, and every rectangle of A intersects all rectangles of B . In a MIX function, starting from A , one can not add a single element from B until all elements of A have been removed. ◀

This construction works for any class of objects for such a generalized “hashtag” construction is possible, which includes any class of shapes which are connected and where for any rectangle, there is a shape in the class that has that rectangle as its minimum orthogonal bounding rectangle. This includes natural classes of shapes without fatness constraints, such as triangles, ellipses, polygons, etc.

5 A MIX algorithm for fat objects

Fat objects

There are many possible definitions of fat objects in Euclidean space, we use the following one from [15]. Define the center and size of an object to be the center and side length of one of its minimal enclosing hypercube.

► **Definition 10.** *A collection S of (connected) objects is f -fat, for a constant f , if for any size- r box R , there are f points such that every object that intersects R and has size at least r contains one of the chosen points.*

This implies that any box can only intersect f disjoint objects of size larger than the box. Throughout the whole section, f and the dimension d are considered to be constant.

We will develop and use a variant of the rectangle separator theorem of Smith and Wormald [34]. We first state the classic version, and then prove the variant we need. Our proofs are straightforward adaptations of those in [34].

► **Lemma 11** (Smith and Wormald [34]). *For any set S of disjoint squares objects in the plane, there is a separating rectangle R such that if we partition S into S^{IN} , S^{OUT} and S^{ON} based on whether each object lies entirely inside R , entirely outside R , or intersects R , $|S^{\text{IN}}| \leq \frac{2}{3}|S|$, $|S^{\text{OUT}}| \leq \frac{2}{3}|S|$ and $|S^{\text{ON}}| = O(\sqrt{|S|})$.*

What we need differs from this in that we have two sets of fat objects, in each set the objects are disjoint but intersection is allowed between the two sets, and we want to have the separator intersect with an order-square-root number of objects in each set. However we require the separator to be balanced with respect to the first set only; it is not possible to require balance with respect to both sets. We state the separator theorem here, the proof is in the full version.

► **Lemma 12.** *Let S_1 and S_2 be two sets of disjoint f -fat objects in d -dimensions. Let $n = |S_1| + |S_2|$. We can compute a hypercube s and sets $S_1^{\text{IN}}, S_2^{\text{IN}}, S_1^{\text{OUT}}, S_2^{\text{OUT}}$ with the following properties in time $O(d \cdot n) = O(n)$:*

- *The hypercube s intersects $O(n^{1-\frac{1}{d}})$ objects of $S_1 \cup S_2$.*
- *$S_1^{\text{IN}} \subseteq S_1$, $S_2^{\text{IN}} \subseteq S_2$, $S_1^{\text{OUT}} \subseteq S_1$, $S_2^{\text{OUT}} \subseteq S_2$*
- *All objects in S_1^{IN} and S_2^{IN} lie entirely inside s*
- *All objects in S_1^{OUT} and S_2^{OUT} lie entirely outside s*
- *$|S_1^{\text{IN}}| \leq \frac{4^d-1}{4^d}|S_1|$*
- *$|S_1^{\text{OUT}}| \leq \frac{4^d-1}{4^d}|S_1|$*

► **Lemma 13.** *Fat objects in constant dimension d have a MIX algorithm with running time $\gamma(n) = O(\log n)$: Given independent sets of fat objects S_1 and S_2 , there is a MIX from S_1 to S_2 whose size is always at least $\min(|S_1|, |S_2|) - \Gamma(|S_1| + |S_2|)$, with $\Gamma(n) = O(n^{1-\frac{1}{d}} \log n) = o(n)$. The total running time of initializing the algorithm with S_1 and S_2 and performing all steps of MIX is $O((|S_1| + |S_2|) \cdot \log(|S_1| + |S_2|))$.*

Proof. We compute the separator s from Lemma 12. Let $S_1^{\text{IN}}, S_1^{\text{OUT}}, S_1^s, S_2^{\text{IN}}, S_2^{\text{OUT}}, S_2^s$, denote partition of S_1 and S_2 into parts that are completely inside the separator, completely outside, and those that intersect the separator, respectively.

Main Idea. The main idea is the following: First, we will remove all objects of S_1^s . Then the remaining objects of S_1 would be either completely inside s or completely outside S . We will use recursively the MIX function in both sides to switch from S_1^{IN} to S_2^{IN} and from S_1^{OUT} to S_2^{OUT} respectively. At the end we will add S_2^s .

Applying the recursion carefully. Recall that our goal is twofold: First, minimize the running time of MIX, second, make sure that at each step the size of the current set is at large as possible. Formally, minimize both $\gamma(n)$ and $\Gamma(n)$, which should be definitely sublinear, and as small as possible. Note that towards the second goal, i.e., keeping the set size as high as possible at all times, the sets used to apply the first recursive call of MIX matter: should we start from switching from S_1^{IN} to S_2^{IN} or from S_1^{OUT} to S_2^{OUT} ? We want to make the choice that leads to the largest independent set at the intermediate step when only one of the two recursive calls has been applied.

We denote a and b the sides of separator (IN and OUT) so that $|S_1^a| + |S_2^b| \leq |S_1^b| + |S_2^a|$ holds. As $\min(w + x, y + z) \leq \max(w + z, x + y)$:

$$|S_1^b| + |S_2^a| = \max(|S_1^b| + |S_2^a|, |S_1^a| + |S_2^b|) \geq \min(|S_1^a| + |S_1^b|, |S_2^a| + |S_2^b|). \quad (2)$$

This way, at the intermediate step when we have mixed only one side, the set size will not be smaller than the beginning or the end of the mix operation.

Formal Description. The MIX function then proceeds as follows:

1. Start with S_1 .
2. Remove the elements of S_1^s , one at a time, to give $S_1^a \cup S_1^b$.
3. Recursively MIX S_1^a to S_2^a .
4. Now we have $S_2^a \cup S_1^b$.
5. Recursively MIX S_1^b to S_2^b . At the end of this process we will have $S_2^b \cup S_2^a$.
6. Add the elements of S_2^s , one at a time.
7. We finish with $S_2^a \cup S_2^b \cup S_2^s = S_2$.

The base case is when one of the two sets is empty, and the MIX proceeds in the obvious way by deleting all elements of S_1 if S_2 is empty, or inserting all elements of S_2 if S_1 is empty. In such a case the lemma holds trivially as $\min(|S_1|, |S_2|)$ is zero.

We need to argue that at all times this process generates a set that is an independent set of the claimed size.

Always an independent set. In steps 1-2 we always have a subset of S_1 , which is an independent set, the same holds in steps 6-7 with respect to S_2 . In step 4, $S_2^a \cup S_1^b$ is independent as each of the sets are independent and all of the objects on each set are entirely on opposite sides of the separating rectangle s . Steps 3 and 5 hold by induction, and that the part we are recursively MIXing and the part that is unchanged are entirely on opposite sides of the separating rectangle.

Size bound. Let $\text{MIX}_{\min}(S_1, S_2, n)$ be the smallest size of the independent set during the running of the MIX function from S_1 to S_2 , and where n is an upper bound on $|S_1| + |S_2|$. Then we can directly express MIX_{\min} as a recurrence, taking the minimum of each step of the algorithm:

$$\begin{aligned} \text{MIX}_{\min}(S_1, S_2, n) = \min(&|S_1|, |S_1^a| + |S_1^b|, \text{MIX}_{\min}(|S_1^a|, |S_2^a|, n) + |S_1^b|, |S_2^a| + |S_1^b|, \\ &|S_2^a| + \text{MIX}_{\min}(|S_1^b|, |S_2^b|, n), |S_2^a| + |S_2^b|, |S_2|) \end{aligned}$$

We will prove that

$$\text{MIX}(S_1, S_2, n) \geq \min(|S_1|, |S_2|) - (\log_{\frac{4^d}{4^d-1}} |S_1|) \cdot n^{1-\frac{1}{d}} \quad (3)$$

which implies the claim of this lemma. The details of this inductive proof are given in the full version. It follows exactly the intuition that (i) the only loss in the MIX function is the separators at each level of the recursion, (ii) there are logarithmic levels of the recursion and (iii) the size of the separators in each level are $O(n^{1-1/d})$. Some care must be taken, since the separators are only balanced for one of the two sets.

Running time. The running time is given by the recursion:

$$T(S_1, S_2) = \begin{cases} |S_1| & \text{if } S_2 = \emptyset \\ |S_2| & \text{if } S_1 = \emptyset \\ T(S_1^a, S_2^a) + T(S_1^b, S_2^b) + O(|S_1| + |S_2|) & \text{otherwise} \end{cases}$$

where the additive term in the last case is dominated by the time needed to compute the separator (Lemma 12) which is $O(d \cdot (|S_1| + |S_2|)) = O(|S_1| + |S_2|)$, since d is assumed to be constant.

Recall $|S_1^a|, |S_2^a| \leq \frac{4^d}{4^d-1} |S_1|$, S_1^a and S_1^b are disjoint subsets of S_1 , and S_2^a and S_2^b are disjoint subsets of S_2 . Hence the recursion depth is logarithmic in $|S_1|$ and each item from S_1 and S_2 is passed to at most one of the recursive terms.

Thus the running time is $O((|S_1| + |S_2|) \log |S_1|)$. As the running time is defined to be $(|S_1| + |S_2|) \cdot \gamma(|S_1| + |S_2|)$, we have $\gamma(|S_1| + |S_2|) \leq \log(|S_1| + |S_2|)$.

Remark. We note the effect of the running time of the separator algorithm (Lemma 12) on the running time of the MIX algorithm: If the running time was $O(n^c)$ for some constant c , then the additive term in the recursion would have increase to $O((|S_1| + |S_2|)^c)$, leading to $\gamma(n) = n^{c-1} \cdot \log n$; such a running time would be sublinear only for $c < 2$; here, by achieving $c = 1$, we get the fastest possible running time which implies the polylogarithmic running time for MIX for fat objects. ◀

6 DISQS for fat objects

In this section, we define DISQS for various classes of geometric objects. First observe that for intervals, a 1-DISQS with running time $O(\log n)$ follows from the classic greedy algorithm [25]. By storing the intervals in an augmented binary search tree, one can insert and delete intervals as well as answer queries of the form “What is the interval entirely to the right of x with the leftmost right endpoint?” As intervals are fat, this implies a $(1 - \epsilon)$ approximate MIS algorithm with running time $O(\frac{1}{\epsilon} \log n)$. This is not new, in the past year a complicated structure via local exchanges appeared in [12] and soon after a much simpler method [21] using a local rebuilding was obtained; we obtain this as part of our more general scheme for fat objects.

This involves two ideas. First, we use a simple greedy offline algorithm that computes an constant-approximate MIS for fat objects. Then we combine this algorithm with a range searching data structure to implement the greedy choice.

A greedy offline approximation algorithm

Given a collection of fat objects, we consider the independent set obtained by sorting them by size, from the smallest to the largest, and adding them greedily to the independent set, provided they do not intersect anything added previously. We refer to this algorithm as the *greedy* algorithm. It was considered in particular by Chan and Har-Peled [17], but was known in special cases before [22]. From the definition of f -fat objects, every successive object returned by the algorithm can intersect at most f disjoint objects that are larger. Hence this simple algorithm yields a constant-factor approximation algorithm for fat objects.

► **Lemma 14.** *For f -fat objects in dimension d , the greedy algorithm returns an $1/f$ -approximate MIS.*

We need to implement this greedy method as the query of a DISQS; that is, it should support insertion and deletion of objects, and the running time of the greedy algorithm must be output-sensitive. This can be done with a slight variation of classic range intersection query structures, where we can insert and delete objects, mark or unmark objects that intersect a given query, and return the largest unmarked object. Thus each item returned by the greedy algorithm is reported after a constant number of range intersection query operations.

The DISQS data structures thus have running times that match those of the underlying range intersection query structures when the query ranges are from the same family of objects as the objects stored: $O(\log^{2d} n)$ for hyperrectangles, $\tilde{O}(n^{1-\frac{1}{d+2}})$ for disks and $\tilde{O}(n^{1-\frac{1}{d(d+1)}})$ for simplices, see the full version.

Summary

The range intersection queries (details in the full version) combined with the greedy algorithm (Lemma 14) gives a DISQS whose running time depends on the range intersection queries, and whose approximation ratio is the inverse of the fatness constant. From Lemma 13 fat objects have a MIX algorithm. Given the MIX, DISQS, and constant $\epsilon > 0$, Theorem 7 yields a dynamic MIS structure, with worst-case update time depending on the range intersection queries, approximation ratio within ϵ of that from the fatness, and with only a constant-size update set per operation. Putting all these pieces together yields Theorem 1.

Abstract

We introduce the *balanced crown decomposition* that captures the structure imposed on graphs by their connected induced subgraphs of a given size. Such subgraphs are a popular modeling tool in various application areas, where the non-local nature of the connectivity condition usually results in very challenging algorithmic tasks. The balanced crown decomposition is a combination of a crown decomposition and a balanced partition which makes it applicable to graph editing as well as graph packing and partitioning problems. We illustrate this by deriving improved approximation algorithms and kernelization for a variety of such problems.

In particular, through this structure, we obtain the first constant-factor approximation for the BALANCED CONNECTED PARTITION (BCP) problem, where the task is to partition a vertex-weighted graph into k connected components of approximately equal weight. We derive a 3-approximation for the two most commonly used objectives of maximizing the weight of the lightest component or minimizing the weight of the heaviest component.

1 Introduction

Connected subgraphs are one of the most natural structures to encode aspects of a practical task, modeled as a graph problem. On the one side, such subgraphs represent structures we seek to discover, such as territories for postal delivery and similar districting problems (see e.g. the survey [22]). From another perspective, the structures of interest could be operations that scatter a graph into small connected components; a structure e.g. used to model vulnerability in network security (see e.g. the survey [2]). Partitioning a graph into connected components of a given size is also used as a model for task allocation to robots [43]. From an algorithmic perspective, connectivity is a non-local requirement which makes it particularly challenging. We introduce a graph structure that can be used to design efficient algorithms for a broad class of problems involving connected subgraphs of a given size.

One useful structure to derive information about connected subgraphs is a *connected partition*, defined as follows. Given a graph $G = (V, E)$, a connected partition of G is a partition V_1, \dots, V_k of V such that the graph induced by the vertex set V_i is connected for each $1 \leq i \leq k$, where $k \in \mathbb{N}$ is the size of the partition. Often, we are not interested in just any connected partition but in those that have the additional property of being *balanced*. Informally speaking, a connected partition is considered balanced if the sets V_i have approximately equal cardinality. There are several measures to assess the quality of a *balanced connected partition* (BCP for short), with the two most commonly used objectives being to maximize $\min_{1 \leq i \leq k} |V_i|$ or to minimize $\max_{1 \leq i \leq k} |V_i|$, as first introduced for trees in [30] and [25], respectively. Despite extensive studies on these problems for the past 40 years, see e.g. [7, 30, 32, 35, 37, 38, 39] the best known approximation ratio for the Min-Max objective depends on the number of sets k [11]. For the Max-Min objective not even such a result is known; only for the cases with k restricted to 2 or 3, there exist approximations with ratio $\frac{4}{3}$ [12] and $\frac{5}{3}$ [8], respectively. Deriving an approximation with a ratio independent of k seems to require a new strategy.

Helpful structures for both of the objectives Max-Min and Min-Max, as a sort of compromise, are BCP's such that $\lambda_l \leq |V_i| \leq \lambda_r$ for some fixed bounds λ_l, λ_r . We call this compromise structure $[\lambda_l, \lambda_r]$ -CVP (connected *vertex* partition), and it is one ingredient of *balanced crown decomposition*, the main structural object that we present. In the case that no $[\lambda_l, \lambda_r]$ -CVP exists for a graph, we can learn something about its structure. In particular, our *balanced crown decomposition theorem* (Theorem 7) shows that for any $k, \lambda > 0$, the non-existence of a $[\lambda, 3\lambda - 3]$ -CVP implies the existence of a vertex set $H \subseteq V$ of cardinality at most k that disconnects at least one component of size less than λ from G . Such sets H are in a sense the dual of balanced connected partitions.

Small subsets of vertices that disconnect a graph are usually called *vertex separators*, and they are one of the most powerful tools for designing efficient graph algorithms. In a sense, they are the base requirement of successful divide-and-conquer strategies for graph problems. This generality and their wide applicability has made the study of separators a rich and active research field, see e.g. the book by Rosenberg and Heath [31], or the line of research initialized by the seminal paper of Lipton and Tarjan [27] on separators in planar graphs. Numerous different types of separator structures emerged over the past couple of decades. In the context of connectivity problems, the separator structures of particular interest are crown decompositions; a classical tool to derive kernelizations in the field of parameterized complexity. We refer to chapter 4 of the book on kernelization [18] for more details on crown decompositions and their applications.

Crown decomposition was introduced as a generalization of Hall's Theorem in [13]. More precisely, a *crown decomposition* of a graph $G = (V, E)$ is a partition of V into three sets H (*head*), C (*crown*) and R (*royal body*), such that H separates C from R , C is an independent set in G , and there exists a matching of size $|H|$ among the edges $E \cap (H \times C)$. Notice that the set H is the separator set, and the property of C being an independent set can be seen as H splitting connected components of size 1 from the graph. The condition of the matching from H into C models a trade-off between the size of the separator and the amount of small sets that are separated. Different versions of crown decompositions have been introduced in the literature, adjusting the structure to specific application scenarios.

The structure of particular interest to us is the *q-Weighted Crown Decomposition* introduced by Xiao [40]. Here, the crown C is no longer an independent set, but has the restriction that each connected component in it has size at most q (generalizing the notion of independent set for $q = 1$); and there exist an assignment of connected components of

the crown to the head such that each vertex in the head is assigned at least q vertices. This assignment generalizes the notion of matching in the original crown decomposition. Such a weighted crown decomposition can be derived using the *Expansion Lemma* as stated in [17, Chapter 5.3], and its generalization to the *Weighted Expansion Lemma* as given in slightly different forms in [24] and [40]. The *expansions* derived by these lemmas can be thought of as bipartite analogues of the crown decomposition. Formally, given a bipartite graph $G = (A, B, E)$, a q -(Weighted) Expansion is given by sets $H \subseteq A$ and $C \subseteq B$ such that the neighborhood of C is contained in H and an assignment $f: C \rightarrow H$ such that the number (resp. weight, in the vertex-weighted case) of vertices assigned to each vertex in H is at least q (resp. $q - W + 1$ where W is the largest weight). Both Kumar and Lokshtanov [24] and Xiao [40] use their respective Weighted Expansion Lemma to derive kernels for COMPONENT ORDER CONNECTIVITY, a version of the editing problem that we also consider in a more general form under the name W -WEIGHT SEPARATOR.

To create our new structure *balanced crown decomposition*, we combine balanced connected partitions and crown decompositions to derive a tool that has the advantages of both of the individual structures. Essentially, it is a weighted crown decomposition with the additional property that the body has a balanced connected partition. Also, note that we allow a more generalized version of weighted crown decomposition than Xiao [40], by considering weighted vertices. Formally, we consider *vertex-weighted* graphs $G = (V, E, w)$ with integer-weights $w: V \rightarrow \mathbb{N}$. For simplicity we use $w(V') = \sum_{v \in V'} w(v)$ for the *weight of a subset* $V' \subseteq V$.

We show that balanced crown decompositions have applications for various kinds of problems involving connectivity constraints. Specifically we discuss for the three types editing, packing and partitioning the following problems on input $G = (V, E, w)$ and $k, W \in \mathbb{N}$:

MAX-MIN (MIN-MAX) BCP: Decide if there exists a connected partition V_1, \dots, V_k of V such that $w(V_i) \geq W$ (resp. $w(V_i) \leq W$) for each $i \in [k]$; usually stated as optimization problem to maximize/minimize W .

W -WEIGHT SEPARATOR: Decide if there exists a set $S \subseteq V$ with $|S| \leq k$ whose removal from G yields a graph with each connected component having weight less than W .

W -WEIGHT PACKING: Decide if there exist k pairwise disjoint sets $V_1, \dots, V_k \subseteq V$ with $w(V_i) \geq W$, such that the graph induced by V_i is connected, for each $i \in [k]$.

We remark that the problems W -WEIGHT SEPARATOR and W -WEIGHT PACKING have been studied mostly on the unweighted versions, also known as COMPONENT ORDER CONNECTIVITY and T_r -PACKING, respectively.

For all results of this paper, we consider the RAM model of computation with word size $O(\log(|V| + \max_{v \in V} w(v)))$. All our algorithms are polynomial w.r.t. the encoding of input.

Lastly, we point out that this short version of the paper contains only a summary of how to compute a balanced crown decomposition and its applications. Here we provide descriptions of the algorithms used and proof sketches about the results achieved through this structure. For technical details and complete proofs, we refer to the full version of the paper.

1.1 Our Contribution

Our main contributions can be summarized as follows:

1. **Balanced Crown Decomposition (BCD):** The main contribution of our paper is a new crown decomposition tailored for problems with connectivity constraints. Our novel addition over previous crown decompositions is that we also give a partition of the *body* into connected parts of roughly similar size. More precisely, we divide the graph into

C , H , and R such that C, H, R is a weighted-crown decomposition and also a $[\lambda, 3\lambda]$ -CVP is given for R . Definition 6 gives the formal definition of BCD, and Theorem 7 gives our main result about computing BCD. We believe that apart from the applications used in this paper, BCD will find applications for other problems with connectivity constraints.

2. **Balanced Expansion:** We also give a novel variation of the expansion lemma, which is an important constituent of our algorithm for BCD. Given a bipartite graph $G = (A, B, E)$, we give an expansion with $H \subseteq A, C \subseteq B$, with the addition that the expansion f while being a weighted q -expansion from C to H , now also maps $B \setminus C$ to neighbors in $A \setminus H$ such that only a bounded weight is assigned to each vertex in $A \setminus H$. See Definition 1 for a more formal definition and Theorem 2 for our result on computing balanced expansion. Apart from its usage here to compute BCD, the balanced expansion could be of independent interest, given the significance of the Expansion Lemma in parameterized complexity.
3. **Approximation algorithms for BCP:** Using BCD, we give 3-approximation algorithms for both MAX-MIN and MIN-MAX BCP. These are the first constant approximations for both problems in polynomial time for a general k . Recall that despite numerous efforts in the past 40 years, only a $k/2$ -approximation for MIN-MAX BCP [11], and constant-factor approximations for the particular cases of $k = 2, 3$ for MAX-MIN BCP [12, 8] were known.
4. **Improved Kernels for W-weight separator and packing:** BCD directly gives a $3kW$ -kernel for both of the problems improving over the previous best polynomial time kernels of size $9kW$ [40] and $\mathcal{O}(kW^3)$ [9]. Especially, we get the same improvements for the unweighted versions COMPONENT ORDER CONNECTIVITY and T_r -PACKING.
5. **Faster algorithms for Expansion:** Our algorithm for Balanced Expansion, also gives an alternative flow-based method for computing the standard (weighted) expansion. Our algorithm can compute a (weighted) expansion in $\mathcal{O}(|V||E|)$ surpassing the previous best runtimes of $\mathcal{O}(|V|^{1.5}|E|)$ and $\mathcal{O}(|E||V|^{1.5}W^{2.5})$ [18, Chapter 5.3] (here W is the largest weight) for unweighted and weighted expansion, respectively. In particular, for weighted expansion, our runtime does not depend on the weights and is the first algorithm that runs in time polynomial w.r.t. the length of the input-encoding. The improvement in runtime may turn out to be useful to speed up kernelizations for other problems.

1.2 Related work

Both variants of BCP were first introduced for trees, where MAX-MIN BCP and MIN-MAX BCP are introduced in [30] and [25], respectively. For this restriction to trees, a linear time algorithm was provided for both variants in [19]. For both variants of BCP, a Δ_T -approximation is given in [3] where Δ_T is the maximal degree of an arbitrary spanning tree of the input graph; for MAX-MIN BCP the result holds only when the input is restricted to weights with $\max_{v \in V} w(v) \leq \frac{w(G)}{\Delta_k}$. Also, although not explicitly stated, a $(1 + \ln(k))$ -approximation in $\mathcal{O}(n^k)$ time for MIN-MAX BCP $_k$ follows from the results in [10]. With respect to lower bounds, it is known that there exists no approximation for MAX-MIN BCP with a ratio below $6/5$, unless $P \neq NP$ [7]. For the unweighted case, i.e. $w \equiv 1$, the best known result for MIN-MAX BCP is the $\frac{k}{2}$ -approximation for every $k \geq 3$ given in [11].

Balanced connected partitions are also studied for particular cases of k , denoted BCP $_k$. The restriction BCP $_2$, i.e. balanced connected bipartition, is already **NP**-hard [5]. On the positive side, a $\frac{4}{3}$ -approximation for MAX-MIN BCP $_2$ is given in [12], and in [11] this result is used to derive a $\frac{5}{4}$ -approximation for MIN-MAX BCP $_2$. For tripartition, approximations for MAX-MIN BCP $_3$ and MIN-MAX BCP $_3$ with ratios $\frac{5}{3}$ and $\frac{3}{2}$, respectively, are given in [8].

BCP in unit-weighted k -connected graphs can be seen as a special case of the Győri-Lovász Theorem (independently given by Győri [20] and Lovász [28]). It states that for any k -connected graph $G = (V, E)$ and integers n_1, \dots, n_k with $n_1 + \dots + n_k = |V|$, there exists

a connected partition V_1, \dots, V_k of V with $|V_i| = n_i$ for all $i \in [k]$. Moreover, it is possible to fix vertices v_1, \dots, v_k and request $v_i \in V_i$ for all $i \in [k]$. The Győri-Lovász Theorem is extended to weighted directed graphs in [10] and Győri's original proof is generalized to weighted undirected graphs in [6]. Polynomial algorithms to also compute such connected partitions are only known for the particular cases $k = 2, 3, 4$ [32, 35, 21] and all $k \geq 5$ are still open. A restricted case of BCP where the partitions are allowed to differ only by a size of one, has been studied from the FPT viewpoint [15].

W -WEIGHT SEPARATOR occurs in the literature under different names. The unweighted version is studied under the names p -Size Separator [40] or ℓ -Component Order Connectivity (COC) [14, 24]; where $p, \ell = W - 1$ translate this to our definition of W -WEIGHT SEPARATOR with unit weights. In [14] a weighted version of COC denoted by *Weighted Component Order Connectivity* (w COC) is introduced. This problem differs from our W -WEIGHT SEPARATOR by searching for a set S with $w(S) \leq k$ instead of $|S| \leq k$.

Note that W -WEIGHT SEPARATOR with $W = 2$ and unit weights yields the classical problem VERTEX COVER. This in particular shows that W (alone) is not a suitable parameter from the FPT viewpoint. Further, W -WEIGHT SEPARATOR is $\mathbf{W}[1]$ -hard for parameter k , even when restricted to split graphs [14]. These lower bounds lead to studying parameterization by $W + k$. Stated with $\ell = W - 1$, a kernel of size $9k\ell$ is given in [40]. Also [24] derives a kernel of size $2k\ell$ in time $\mathcal{O}(|V|^\ell)$. Both of these results are for unit weights. An $\mathcal{O}(k\ell(k + \ell)^2)$ weight kernel for the related problem w -COC is given in [14].

For $W = 3$ and unit weights, W -WEIGHT SEPARATOR corresponds to VERTEX COVER P_3 or 3-PATH VERTEX COVER (see e.g. [34] and [4]), first studied by Yannakakis [42] under the name DISSOCIATION NUMBER. The best known kernel for this problem is of size $5k$ and given in [41]. W -WEIGHT PACKING with unit weights is equivalent to T_r -PACKING with $r = W + 1$, where T_r is a tree with at least r edges, as defined in [9]; note that any connected component with at least W vertices has at least $r - 1$ edges, and any tree with $r - 1$ edges has exactly W vertices. The best known kernel for this problem is of size $\mathcal{O}(kW^3)$ by [9].

W -WEIGHT PACKING is also studied for particular values of W . The case $W = 2$ with unit weights is equivalent to the MAXIMUM MATCHING problem; note that a matching of size k can be derived from a solution V_1, \dots, V_k for 2-WEIGHT PACKING by choosing arbitrarily any edge in a set V_i with $|V_i| > 2$. In a similar way, the particular case of $W = 3$ is a problem studied under the names P_2 -PACKING or PACKING 3-VERTEX PATHS (see e.g [36] and [23]). A $5k$ kernel for this problem is given in [26].

2 Balanced Expansion

In this section we introduce a balanced generalization of weighted expansions that we call *balanced expansion*.

Balanced expansion extends the existing weighted expansion structures and is one of the ingredients to derive our main BCD structure in the next section. Like the weighted expansion, it is a structure on bipartite graphs. We write $G = (A \cup B, E, w)$ for bipartite vertex-weighted graphs, where $w: A \cup B \rightarrow \mathbb{N}$ is its weight function. See Figure 1 for an illustration of this structure.

► **Definition 1** (*balanced expansion*). Let $G = (A \cup B, E, w)$ be a bipartite vertex-weighted graph, where $w_{\max}^B = \max_{b \in B} w(b)$. For $q \in \mathbb{N}_0$, a partition $A_1 \cup A_2$ of A and $f: B \rightarrow A$, the tuple (A_1, A_2, f, q) is called a *balanced expansion* if:

1. $w(a) + w(f^{-1}(a)) \begin{cases} \geq q - w_{\max}^B + 1, & a \in A_1 \\ \leq q + w_{\max}^B - 1, & a \in A_2 \end{cases}$
2. $f(b) \in N(b)$
3. $N(f^{-1}(A_1)) \subseteq A_1$

■ **Figure 1** Left: Balanced expansion for $w(b) = 1$ for all $b \in B$, $q = 2$ and assignment f depicted with bold edges. Right: Flow network embedding of the graph on the left.

Our main result of this section is the following theorem.

► **Theorem 2 (balanced expansion).** Consider a vertex-weighted bipartite graph $G = (A \cup B, E, w)$ with no isolates in B , and $q \geq \max_{b \in B} w(b) = w_{\max}^B$. A balanced expansion (A_1, A_2, f, q) for G can be computed in $\mathcal{O}(|V||E|)$ time. Furthermore, if $w(A) + w(B) \geq q|A|$, then $A_1 \neq \emptyset$.

As intermediate structure we use a fractional version of the balanced expansion where we partially assign weights from vertices of B to vertices of A encoded as edge weights.

► **Definition 3 (fractional balanced expansion).** Let $G = (A \cup B, E, w)$ be a bipartite vertex-weighted graph. For $q \in \mathbb{N}_0$, a partition $A_1 \cup A_2$ of A and $g: E \rightarrow \mathbb{N}_0$, the tuple (A_1, A_2, g, q) is called fractional balanced expansion if:

1. $w(a) + \sum_{b \in B} g(ab) \begin{cases} \geq q, & a \in A_1 \\ \leq q, & a \in A_2 \end{cases}$
2. $\forall b \in B: \sum_{a \in A} g(ab) \leq w(b)$ (capacity)
3. $N(B_U \cup B_{A_1}) \subseteq A_1$ (separator)
where $B_a := \{b \in B \mid g(ab) > 0\}$ for $a \in A$, $B_{A'} := \bigcup_{a \in A'} B_a$ for $A' \subseteq A$ and $B_U := \{b \in B \mid \sum_{a \in A} g(ab) < w(b)\}$

We prove a fractional version of our result first in the following lemma.

► **Lemma 4 (fractional balanced expansion).** Given a vertex-weighted bipartite graph $G = (A \cup B, E, w)$ with no isolated vertices in B and $q \in \mathbb{N}_0$, a fractional balanced expansion (A_1, A_2, g, q) can be computed in $\mathcal{O}(|V||E|)$. Also, if $w(A) + w(B) \geq q|A|$, then $A_1 \neq \emptyset$.

Proof Sketch. The main idea is to embed G to a capacitated flow network in a standard way (see Figure 1). We construct a network $H = (A \cup B \cup \{s, t\}, \vec{E}, c)$. To obtain H from G , add source s and sink t , and arcs \vec{E} with a capacity function $c: \vec{E} \rightarrow \mathbb{N}$ defined as follows. For every $b \in B$, add an arc $\vec{s}b$ with capacity $w(b)$ and for every $a \in A$, add an arc $\vec{a}t$ with capacity $q - w(a)$. Moreover, transform every edge $ab \in E$ to an arc $\vec{b}a$ with capacity $w(b)$.

We compute a max flow $f: \vec{E} \rightarrow \mathbb{N}$ and define the saturated vertices $A' \subseteq A$ as $a \in A$ with $f(\vec{a}t) = c(\vec{a}t)$. We now gradually build the sets A_1 and A_2 . The vertices of A' are potential vertices for A_1 while the unsaturated vertices are immediately added to A_2 . We define $F := \sum_{\vec{e} \in \delta^-(t)} f(\vec{e})$ as the flow value, where $\delta^-(v)$ denotes the incoming, and $\delta^+(v)$ the outgoing arcs for $v \in V(G)$. The final selection of A_1 follows by individually increasing the capacity by one for each $\vec{a}t$ for $a \in A'$, and checking whether the flow value increases by computing a new max flow f_a with the increased capacity of $\vec{a}t$. Let F_a be the flow value when the capacity of $\vec{a}t$ is increased by one. If $F_a > F$, then the vertex is added to A_1 , otherwise it is added to A_2 . The intuition behind this selection can be explained as

follows: first observe that each $b \in B$ that has an edge ba_2 to some $a_2 \in A_2$ is saturated, i.e. $\sum_{\vec{e} \in \delta^+(b)} f(\vec{e}) = w(b)$. Otherwise, we could route an additional unit of flow from b to a_2 either in f or in f_{a_2} , giving a contradiction to the fact that $a_2 \in A_2$. Consequently, every unsaturated $b \in B$ is adjacent only to A_1 . The second observation is that there are no $b \in B$ with $f(\vec{ba_1}) > 0$ and $ba_2 \in \vec{E}$ for $a_1 \in A_1$ and $a_2 \in A_2$. If such a b exist, we show that we can route an extra unit of flow from b to a_2 either in f or f_{a_2} . The idea is that we could reroute one unit of flow from $\vec{ba_1}$ to $\vec{ba_2}$ creating a vacuum for one unit of incoming flow in a_1 . Since f_{a_1} routed one unit flow more than f , we could use a similar flow routing as in f_{a_1} to fill this vacuum, thus contradicting the maximality of either f or f_{a_2} . As a result, all vertices added to A_1 have the desired exclusive neighborhood in B encoded by f . Finally, in order to derive g we convert the flow arc values of f to edge weights for g . Note that the required upper bound on the assignment of A_2 follows from the capacities of the arcs from A to t , and the required lower bound on the assignment of A_1 follows from the vertices in A_1 being saturated. Regarding running time, we remark that it is sufficient to find one max-flow f at the beginning and then computing each f_a with only one augmenting flow step. The max-flow f can be computed in $\mathcal{O}(|V||E|)$ time using the algorithm by Orlin [29]. ◀

Proof Sketch of Theorem 2. Once we have the fractional balanced expansion g , our first step is modifying the edge weights g such that the edge-weighted graph $G' := (V, \{ab \in E | g(a, b) > 0\}, g)$ becomes a forest, without changing the sum $\sum_{b \in N(a)} g(a, b)$ for any $a \in A$ and at the same time ensuring that $\sum_{a \in N(b)} g(a, b) \leq w(b)$ for all $b \in B$. This is possible through a standard cycle canceling process. Now consider the trees in this forest. The trees intersecting A_1 are disjoint from the trees intersecting A_2 due to the separation property of the balanced fractional expansion. For a tree T intersecting A_1 , we allocate each $b \in V(T) \cap B$ completely to its parent in T . This way, any $a \in V(T) \cap A_1$ loses at most the assignment from its parent and hence its assignment decreases by at most $w_{\max}^B - 1$ as required. Now consider a tree T intersecting A_2 . If a $b \in V(T) \cap B$ is a leaf of T its assignment has to be non-fractional, so it can be completely assigned to its parent a and deleted from the tree. This way, all leafs can be assumed to be from A_2 . We then allocate each $b \in V(T) \cap B$ to one of its children, and thus to every $a \in V(T) \cap A_2$ at most the assignment from its parent is added, and hence the assignment increases by at most $w_{\max}^B - 1$ as required. ◀

Before moving to BCD, we formally state the aforementioned implication of the results in this section on the runtime of computing (non-balanced) expansions.

► **Lemma 5** (Weighted Expansion Lemma). *Let $G = (A \cup B, E)$ be a bipartite graph without isolated vertices in B , $w: B \rightarrow \{1, \dots, W\}$, and $q \in \mathbb{N}_0$. A q -weighted expansion (f, H, C) in G can be computed in time $\mathcal{O}(|A \cup B||E|)$. Furthermore, if $w(B) \geq q|A|$ then $H \neq \emptyset$.*

3 Balanced Crown Decomposition

In this section we introduce our combination of balanced connected partition and crown decomposition that we call *balanced crown decomposition*, formally defined as follows (see also Figure 2 for an illustration).

► **Definition 6.** A λ -balanced crown decomposition (λ -BCD) of a vertex-weighted graph $G = (V, E, w)$ is a tuple (C, H, \mathfrak{R}, f) , where $\{H, C, R\}$ is a partition of V , the set \mathfrak{R} is a partition of R , and $f: \mathbb{CC}(C) \rightarrow H$ where $\mathbb{CC}(C)$ is the set of connected components of $G[C]$, such that:

1. there are no edges from C to R
 2. $w(Q) < \lambda$ for each $Q \in \mathcal{CC}(C)$
 3. $f(Q) \in N(Q)$ for each $Q \in \mathcal{CC}(C)$
 4. $w(h) + w(f^{-1}(h)) \geq \lambda$ for each $h \in H$
 5. $G[R']$ is connected and $\lambda \leq w(R') \leq 3\lambda - 3$ for each $R' \in \mathfrak{R}$.
- (weighted crown dec.)

Our novel contribution is condition 5, that gives a balanced connected partition of the *body*. Without this condition, the structure is same as the weighted crown decomposition [40]. Observe that if there is a connected component of weight less than λ in G , then there is no λ -balanced crown decomposition for G . In the applications of BCD, such small components in the input are usually removed through some form of preprocessing.

We point out that the ratio 3 between the upper and lower bound in condition 5 of BCD is not arbitrary, but the best possible, since we want to ensure the existence of this structure in case all connected components have weight at least λ . A simple tight example is a triangle with each vertex having a weight of $\lambda - 1$; here, $C = H = \emptyset$ is the only possibility and hence $\mathfrak{R} = \{V\}$ is the only possible partition of $R = V$.

■ **Figure 2** λ -balanced crown decomposition.

The main structural result of the paper is the following.

► **Theorem 7** (Balanced Crown Decomposition Theorem). *Let $G = (V, E, w)$ be a vertex-weighted graph and $\lambda \in \mathbb{N}$, such that each connected component in G has weight at least λ . A λ -balanced crown decomposition (C, H, \mathfrak{R}, f) of G can be computed in $\mathcal{O}(k^2 |V| |E|)$ time, where $k = |H| + |\mathfrak{R}| \leq \min\{w(G)/\lambda, |V|\}$.*

The proof of this result is very technical and we therefore here only give a very high-level overview of the ideas. Observe that the condition $|H| + |\mathfrak{R}| \leq \min\{w(G)/\lambda, |V|\}$ holds, since $\{\{h\} \cup f^{-1}(h) : h \in H\} \cup \mathfrak{R}$ is a partition of the vertices with each part having weight at least λ . This bound is also used to track our progress in our BCD algorithm. We maintain a set H that can be thought of as a *potential head* (not necessarily a separator), a set of connected components of weight smaller than λ (some of them assigned to vertices in H by a partial assignment f) which can be thought of as a *potential crown*, and a remaining *body* that is packed according to condition 5.

To easily talk about condition 5 in the following, we say \mathcal{U} is a *connected packing* in $V' \subseteq V$, if for every $U \in \mathcal{U}$ we have $U \subseteq V'$, U induces a connected subgraph in G and $\bigcup_{U \in \mathcal{U}} U = \emptyset$. We say \mathcal{U} is an $[a, b]$ -*connected packing* of V' if $w(U) \in [a, b]$ for every $U \in \mathcal{U}$ and that \mathcal{U} is *maximal* if the remaining graph does not have a connected component of weight at least a . Recall that we say \mathcal{U} is a CVP or $[a, b]$ -CVP of V' if additionally $\bigcup_{U \in \mathcal{U}} U = V'$ holds, and observe that condition 5 asks for a $[\lambda, 3\lambda - 3]$ -CVP of the body R .

Proof Sketch of Theorem 7. Let $G = (V, E, w)$ be a vertex-weighted graph and $\lambda \in \mathbb{N}$ such that each connected component of G has weight at least λ . We reduce G by deleting all vertices of weight more than λ and all connected components of size smaller than λ that occur after this deletion. Suppose we have a λ -BCD for the reduced graph, then a λ -BCD of G can be built by adding the deleted heavy vertices to the head, the deleted small components to the crown and assigning (by the function f in the definition of λ -BCD) each of these components arbitrarily to a heavy vertex it is adjacent to. Thus, we can assume that every vertex has weight at most λ . See Figure 3 for an illustration of the structures arising below.

We start with a maximal $[\lambda, 2\lambda]$ -connected packing of G which is obtained greedily (slight deviation from the main proof to provide better intuition). Let $\mathfrak{R} = \{R_1, R_2, \dots\}$ be this packing, C be the vertices not in the packing, and let $\mathbb{CC}(C) = \{C_1, C_2, \dots\}$ be the connected components of $G[C]$. Note that by the maximality of the packing, $w(C_i) < \lambda$ for all i . Think of \mathfrak{R} as the current body and C as the current crown, and the head is empty in the beginning. Note that at this point we do not ensure that there are no edges between crown and body. If C is empty then we already have a λ -BCD (with empty crown and head). Also, if we can somehow assign each C_i to some adjacent R_i such that each R_i is assigned weight at most 3λ (including its own weight), then we have also built a λ -BCD (with empty crown and head). Assuming neither of these cases hold, there has to exist an R_i such that its weight plus the weight of the neighborhood in the crown part is at least 3λ ; recall that we assumed that all connected components of G have weight at least λ , so each C_j is connected to at least one component in \mathfrak{R} . We call the subgraph induced by R_i together with all C_j that are connected to it the *effective neighborhood of R_i* , and its weight the *effective weight of R_i* .

In case we have not found a λ -BCD yet, we pick an R_i with effective weight at least 3λ and use the following fact derived from the famous results of Tarjan [33, 16]: for any connected graph of total weight at least 3λ and largest vertex weight at most λ , we can efficiently either find a partition of it into two connected subgraphs of weight at least λ each, or find a cut-vertex that cuts the graph into components each of weight less than λ . If the effective neighborhood is divided into two, we take each of the two parts into the body and remove R_i , thus increasing the body size by one. In the other case, that is, if we find a cut-vertex c , then we add c to the head and the components of $R_i \setminus \{c\}$ (each having weight less than λ) to the crown $\mathbb{CC}(C)$. We assign with a *partial* function $f: \mathbb{CC}(C) \rightarrow H$ some of these components that we just added to $\mathbb{CC}(C)$ to c such that c is assigned a total weight of at least 3λ (including weight of c). The reason for assigning 3λ when we only require λ by the definition of BCD, will become clear in the following. The new components added to the crown could have edges to the old components there and hence can merge with these. If at any point it happens that there is a component of weight at least λ in the crown, then we immediately add it to the body. This could cause some head vertex to loose some of its assignment, but since it had 3λ assigned to it, an assignment of at least λ remains. This is because we ensure that the part we move to the body can have weight at most 2λ , as we move it immediately as the weight is at least λ , and each addition is by steps of less than λ .

We repeat this process of picking an effective neighborhood of an R_i and dividing or cutting it. We point out that when we calculate effective neighborhoods and weights, we do not consider the crown parts that are already assigned by f . This process continues until the effective weights of all sets R_i are less than 3λ . We claim that the reason why we have not arrived at a λ -BCD yet could only be that there are crown parts that do not have edges to the body (we call them *private components*) and *not* assigned by f , while there are also crown parts that have edges to the body (non-private components) and assigned by f . Note that if there are no unassigned private components, we can merge all unassigned crown

parts with some set in the body and create a $[\lambda, 3\lambda]$ -CVP given by the R_i 's and the sets $\{v\} \cup f^{-1}(v)$. Note that since the effective weights were lighter than 3λ , the body parts after the merging are lighter than 3λ . Also, if f does not assign any non-private components, we can assign unassigned private components to arbitrary neighbors in H , and merge unassigned non-private components to body obtaining a λ -BCD.

We modify the assignment f to switch non-private with private components in the best way possible. For this we use the balanced expansion Theorem 2. We build the bipartite graph where the set A are the head vertices, and the set B are the private crown components each contracted into a single vertex. Theorem 2 with expansion parameter 2λ then gives us sets $A' \subseteq A$ and $B' \subseteq B$ and an assignment f' such that $w(\{a'\} \cup f'^{-1}(a')) \geq \lambda$ for all $a' \in A'$ and $w(\{a\} \cup f'^{-1}(a)) \leq 3\lambda$ for all $a \in A \setminus A'$, and the crown components in B' are completely assigned to A' and do not have neighbors in $A \setminus A'$. Note that since B was the set of private components, the components B' do not have neighbors in the body either. Now augment f' by assigning to $A \setminus A'$ also enough non-private components such that they have an assignment of at least 3λ each. This is possible since each vertex in $A \setminus A'$ has an assignment of 3λ by f which did not use any components from B' (as there are no edges from B' to $A \setminus A'$). Note that this augmentation of f' needs to be done carefully since the private components could be assigned by the balanced expansion differently than by f .

By f' all private components are now assigned to the head, but there could still be non-private ones assigned as well. But now, if the effective weight of each R_i is at most 3λ , we can add the unassigned crown parts to sets in \mathfrak{R} , and thus create a λ -BCD: A' with its assignment by f' are head and crown, and \mathfrak{R} plus the sets $\{a\} \cup f'^{-1}(a)$ with $a \in A \setminus A'$ are a $[\lambda, 3\lambda]$ -CVP of the body. Thus, if we are not successful, there exists an R_i with effective weight more than 3λ and we continue by dividing or cutting it. Note that we can proceed with f' replacing f although some head vertices (from what was A' in the balanced expansion) might only have weight λ assigned to them (and not 3λ), because the crown parts assigned to them are private and hence do not interfere with the further process.

To analyse the run time, we estimate how often we divide or cut a set R_i ; note that each such step can be performed in $\mathcal{O}(|V||E|)$. Throughout our algorithm, the value $|H| + |\mathfrak{R}|$ is non-decreasing, and upper bounded by k . Every time we divide some R_i , we increase $|H| + |\mathfrak{R}|$, hence this happens at most k times. Every time we cut some R_i we increase $|H|$ by one. Since $|H|$ is also upper bounded by k , and we are careful not to decrease $|H|$ with the balancing step in-between cut steps, we arrive at a total of at most k^2 divide or cut steps.

One pitfall here is that after applying the balanced expansion one might be tempted to just take A' and its assignment via f' into head and crown respectively, delete it, and start over on the rest of the graph. The problem with this is that we are not guaranteed to find a non-empty set A' (since the private components might not have weight at least $\lambda|A|$). The way we augment f' , we ensure that we retain the preliminary crown, head and body structure, and with this especially the value $|H|$, and can split up another R_i to either increase $|H|$ or $|H| + |\mathfrak{R}|$. Further, the reason why *we cannot use the standard weighted expansion lemma* here is that we would need a lower bound of at least $\lambda|A|$ on the weight of B for this. We cannot ensure that the private components of the crown alone have a weight of at least $\lambda|A|$, since we also used the non-private components for the assignment f .

One detail that we did not mention so far is that it is not possible to assign exactly 3λ to each head vertex. Since the step size we can guarantee is only λ , we might have to assign $(4\lambda - 1)$ in order to get a value of at least 3λ . Recall that we assign a collection of components of weight less than λ . Without further work, this only yields an upper bound of 4λ instead of 3λ for the packing of the body, worsening the quality of our structure (we for

Another technical detail we skipped is that in the assignment f we maintain, the crown parts we map may not be whole sets in $\mathbb{CC}(C)$ (connected components induced by crown vertices). They are connected, but can be subgraphs of some $C_i \in \mathbb{CC}(C)$. We call such subgraphs *sub-components*. Different sub-components of some C_i can be assigned to different heads. Also, for a C_i some of its sub-components can be assigned while others are not. For our structure to converge to a λ -BCD, sub-components have to be classified as private or non-private based on the set $\mathbb{CC}(C)$ they are a part of, so it can happen that a sub-component is non-private but has no edge to the body. Whenever we make the move from crown to body, we therefore have to do a merging of some sub-components such that for each $C_i \in \mathbb{CC}(C)$ either all its sub-components are assigned to the head or none of them are. \blacktriangleleft

4 Applications of Balanced Crown Decomposition

For the problems W -WEIGHT SEPARATOR and W -WEIGHT PACKING we immediately get the following theorems by reducing an instance (G, k, W) by first finding a W -BCD (C, H, \mathfrak{R}, f) of G , and then applying the standard crown reduction rule that removes the head H and crown C from G . We emphasize that the balanced connected partition of the body is crucial to obtain the kernel sizes. These are the first kernels for vertex-weighted graphs, while also improving the state-of-the-art results for the unweighted cases.

► **Theorem 9.** *W-WEIGHT PACKING admits a kernel of weight $3k(W-1)$. Furthermore, such a kernel can be computed in time $\mathcal{O}(k^2|V||E|)$.*

For the optimization variant of the W -WEIGHT PACKING problem, i.e. maximizing the size of packing, the fact that the partition \mathfrak{R} is a solution also gives a 3-approximation; to the best of our knowledge, the first approximation result for the problem.

► **Theorem 10.** *A 3-approximation for the optimization problem of W -WEIGHT PACKING can be computed in $\mathcal{O}(k^{*2}|V||E|)$, where k^* denotes the optimum value.*

To better sketch the ideas for our results for the BCP problems, we denote by I -CVP $_k$ for an interval I , a CVP with k parts where each part has a weight in I . We derive the following result for MAX-MIN BCP, which is the first constant approximation for this problem.

► **Theorem 11.** *A 3-approximation for the MAX-MIN BCP problem can be computed in $\mathcal{O}(\log(X^*)k^2|V||E|)$, where X^* denotes the optimal value.*

Proof. Let (G, k) be an instance of MAX-MIN BCP. For any value X , using BCD, we show how to either obtain an $[X/3, \infty)$ -CVP $_k$, or report that $X > X^*$. Once we have this procedure in hand, a binary search can be used to obtain an $[X^*/3, \infty)$ -CVP $_k$.

We first obtain a λ -BCD (C, H, \mathfrak{R}, f) of G with $\lambda = \lceil X/3 \rceil$. If $|H| + |\mathfrak{R}| \geq k$, we output a $[X/3, \infty)$ -CVP $_k$ given by the body and the assignment to head vertices (if this gives more than k sets, arbitrarily merge some until there are only k). If $|H| + |\mathfrak{R}| < k$, then we report that $X > X^*$. To see that this is correct, assume towards contradiction that $X \leq X^*$, and consider an optimal solution $\mathcal{S}^* = \{S_1^*, \dots, S_k^*\}$. Then in the λ -BCD we computed, we know that $w(R) < X$ for every $R \in \mathfrak{R}$ and $w(C') < X$ for every $C' \in \mathcal{CC}(C)$. Observe that then no $C' \in \mathcal{CC}(C)$ or a subset of it can be a set in \mathcal{S}^* , since $w(S_i^*) \geq X^* \geq X$ for every $S_i^* \in \mathcal{S}^*$. From the separator properties of H and that the fact that each $S_i^* \in \mathcal{S}^*$ is connected, we obtain that any set in \mathcal{S}^* containing vertices from C also has to contain at least one vertex from H . Thus, we can derive that the cardinality of $\mathcal{S}_H^* = \{S_i^* \in \mathcal{S}^* \mid S_i^* \cap (C \cup H) \neq \emptyset\}$ is at most $|H|$. Also, $|\mathcal{S}^* \setminus \mathcal{S}_H^*| \leq w(V(\mathfrak{R}))/X^* \leq w(V(\mathfrak{R}))/X \leq |\mathfrak{R}|$. Thus it follows that $|\mathcal{S}^*| \leq |H| + |\mathfrak{R}| < k$, a contradiction. ◀

The last problem that we consider as application of the balanced crown decomposition is the MIN-MAX BCP problem, where we also provide the first constant approximation result.

► **Theorem 12.** *A 3-approximation for the MIN-MAX BCP problem can be computed in time $\mathcal{O}(\log(X^*)|V||E|(\log \log X^* \log(|V|w_{max}) + k^2))$, where X^* denotes the optimum value and $w_{max} = \max_{v \in V} w(v)$ the maximum weight of a vertex.*

Proof. Achieving this requires several technical steps after having a balanced crown decomposition in hand, including a second use of the balanced expansion. Let (G, k) be an instance of MIN-MAX BCP and let $\mathcal{S}^* = \{S_1^*, \dots, S_k^*\}$ be an optimal solution. Let (C, H, \mathfrak{R}, f) be a λ -BCD of G . Similar to the Max-Min case we try to make a comparison between \mathcal{S}^* and the vertex decomposition C, H and $V(\mathfrak{R})$. The main issue is that, in contrast to the Max-Min case, an optimal solution can (and sometimes has to) build more than $|H|$ sets from the vertices in $H \cup C$. With the connectivity constraints, this means that some components in $G[C]$ are in fact a set in the optimal partition. Hence, when computing an approximate solution from a balanced crown decomposition, we have to also choose some components from $G[C]$ to be sets, while others are combined with some vertex in H . In order to make the decision of where to place the components in $G[C]$, we compute a min-cost flow using the algorithm from [1] on a network that models the options for components in $G[C]$ to either be sets or be combined with some vertex in H . A partial embedding of $\{S_i^* \in \mathcal{S}^* \mid S_i^* \cap (C \cup H) \neq \emptyset\}$ to this cost-flow network allows a comparison with the resulting

partition of $C \cup H$. The balanced weight properties of \mathfrak{R} then yield a comparison with the whole set S^* . With the additional use of a min cost-flow network, our balanced crown structure can be used to estimate the optimal objective value and again enables a binary search for an approximate solution. ◀

All-Pairs Shortest Paths for Real-Weighted Undirected Graphs with Small Additive Error

Timothy M. Chan 

Department of Computer Science, University of Illinois at Urbana-Champaign, IL, USA

Abstract

Given a graph with n vertices and *real* edge weights in $[0, 1]$, we investigate an approximate version of the standard all-pairs shortest paths (APSP) problem where distances are estimated with *additive error* at most ε . Yuster (2012) introduced this natural variant of approximate APSP, and presented an algorithm for directed graphs running in $\tilde{O}(n^{(3+\omega)/2}) \leq O(n^{2.687})$ time for an arbitrarily small constant $\varepsilon > 0$, where ω denotes the matrix multiplication exponent. We give a faster algorithm for *undirected* graphs running in $\tilde{O}(n^{(3+\omega^2)/(\omega+1)}) \leq O(n^{2.559})$ time for any constant $\varepsilon > 0$. If $\omega = 2$, the time bound is $\tilde{O}(n^{7/3})$, matching a previous result for undirected graphs by Dor, Halperin, and Zwick (2000) which only guaranteed additive error at most 2.

1 Introduction

The *all-pairs shortest paths* (APSP) problem is one of the most well-known problems in algorithm design, and plays a central role in the study of fine-grained complexity. Only small (subpolynomial) speedups over the textbook cubic-time algorithms are known for arbitrary real-weighted dense graphs [6, 8, 13, 21], and it has been conjectured that there are no truly subcubic algorithms [20]. If faster running time is desired, one thus turns to *approximation algorithms*.

To this end, Zwick [23] described an $O(n^\omega \log \frac{w_{\max}}{w_{\min}})$ -time algorithm with approximation factor $1 + \varepsilon$ for any constant $\varepsilon > 0$, for any (directed or undirected) graph with positive real edge weights, where n is the number of vertices, w_{\min} and w_{\max} denote the minimum and maximum edge weight, and $\omega < 2.373$ is the matrix multiplication exponent [2, 11]. For every pair of vertices u and v , the algorithm computes a value $\tilde{D}[u, v]$ such that $D[u, v] \leq \tilde{D}[u, v] \leq (1 + \varepsilon)D[u, v]$, where $D[u, v]$ denotes the distance (i.e., the shortest-path weight) from u to v .

While multiplicative approximation is natural, in this paper we are interested in an even stronger form of approximation, where we want small *additive error* bounded by εw_{\max} . More precisely, for every u and v , we seek a value $\tilde{D}[u, v]$ such that $D[u, v] \leq \tilde{D}[u, v] \leq D[u, v] + \varepsilon w_{\max}$. To see how this can yield a much better estimate, imagine the case when the distance $D[u, v]$ is large; a $(1 + \varepsilon)$ -factor approximation may differ from the true value by $\varepsilon D[u, v]$, which could be much bigger than ε times the maximum weight of a single edge.¹

From now on, we assume $w_{\max} = 1$, without loss of generality, by rescaling. In other words, we assume that all edge weights lie in $[0, 1]$ and we tolerate additive error at most ε .

¹ In fact, we can achieve additive error at most $O(\varepsilon w_{\max}[u, v])$, where $w_{\max}[u, v]$ denotes the weight of the longest edge in a shortest path from u to v , by guessing a value $w \in [w_{\max}[u, v]/2, w_{\max}[u, v]]$ and removing all edges of weight exceeding w from the graph; $O(\log \frac{w_{\max}}{w_{\min}})$ guesses of w suffice.

■ **Figure 1** Tradeoffs between additive error and running time for approximate APSP in undirected real-weighted graphs. The blue part indicates the new result using the current matrix multiplication bound $\omega < 2.373$; the red part indicates the new result if $\omega = 2$.

This form of additive approximation was first considered by Yuster [22], who gave an algorithm running in $\tilde{O}(n^{(3+\omega)/2}) \leq O(n^{2.687})$ time² for any constant additive error $\varepsilon > 0$. If $\omega = 2$, the time bound is $\tilde{O}(n^{2.5})$. For arbitrary (dense) directed graphs, this would be difficult to improve, since approximate APSP with additive error at most c for any constant c is at least as hard as exact unweighted APSP, for which the current best algorithm by Zwick [23] has exponent 2.5 when $\omega = 2$ and is conjectured to be near optimal [9]. However, a question remains as to whether an improved result for approximate APSP with additive error ε is possible for *undirected* graphs (for which $\tilde{O}(n^\omega)$ -time algorithms are known for exact unweighted APSP [15, 19]).

For *unweighted undirected* graphs, the seminal work by Aingworth, Chekuri, Indyk, and Motwani [1] described combinatorial algorithms for approximate APSP achieving $O(1)$ additive error without using fast matrix multiplication. Subsequent improvements were described by Dor, Halperin, and Zwick [12]: in particular, for dense graphs, the best results were an $\tilde{O}(n^{7/3})$ -time algorithm with additive error at most 2, and an $\tilde{O}(n^{2+2/(3k-2)})$ -time algorithm with additive error at most k for any even constant $k > 2$. As noted in Dor et al.'s paper, these algorithms for unweighted undirected graphs can actually be extended to weighted undirected graphs with arbitrary real edge weights in $[0, 1]$. However, none of these results achieve additive error below 2. In fact, approximate undirected APSP with additive error strictly below 2 is at least as hard as Boolean matrix multiplication (by considering tripartite graphs with unit edge weights), thus ruling out combinatorial algorithms for arbitrarily small ε .

New result. Our main result is a new algorithm for undirected real-weighted graphs with additive error ε . The algorithm uses fast matrix multiplication and achieves running time $\tilde{O}(n^{(3+\omega^2)/(\omega+1)}) \leq O(n^{2.559})$. This improves Yuster's $O(n^{2.689})$ -time directed-graph algorithm. Furthermore, if $\omega = 2$, our time bound becomes $\tilde{O}(n^{7/3})$, which improves Yuster's $\tilde{O}(n^{2.5})$ bound and also matches Dor, Halperin, and Zwick's time bound for additive error 2 while making the additive error an arbitrarily small constant ε . (See Figure 1.)

Other related work. Other formulations of approximate APSP have been studied in the literature. For example, Bringmann, Künnemann, and Węgrzycki [5] revisited multiplicative approximation, but in a setting where $\frac{w_{\max}}{w_{\min}}$ may be large (Zwick's approximation algorithm [23] works well only when this ratio is bounded). On the other hand, Roditty and

² The \tilde{O} notation hides $\log^{O(1)} n$ factors. Factors dependent on ε are also suppressed, for simplicity, but they will all be polynomial in $1/\varepsilon$.

Shapira [18] gave results (recently improved by Chan, Vassilevska Williams, and Xu [9]) on approximate APSP for unweighted directed APSP that achieved *sublinear* additive error bounded by $D[u, v]^p$ for a given constant $p < 1$; the guarantee is stronger than $1 + \varepsilon$ multiplicative approximation as $D[u, v]$ gets larger, but is not as strong as constant additive error.

In the literature on graph spanners, there have also been many results for unweighted undirected graphs with constant additive errors [1, 4, 10].

Our time bound appears unusual among algorithms in the literature that rely on fast matrix multiplication. Coincidentally, Grandoni et al. [16] gave a matrix-multiplication-based algorithm for an entirely different problem (all-pairs lowest common ancestors in DAGs) with a time bound that is also $\tilde{O}(n^{7/3})$ if $\omega = 2$ (though their exponent got below 2.5 under the current matrix multiplication bound). For our result, $n^{7/3}$ is a natural barrier, since even with additive error 2, the current best algorithm by Dor, Halperin, and Zwick [12] still requires $\tilde{O}(n^{7/3})$ time.

Techniques. To see why the additive approximation problem is challenging for real-weighted graphs, consider the standard idea of rounding edge weights and rescaling to turn them into integers. To guarantee additive error at most a constant ε , since a shortest path may require $\Theta(n)$ edges in the worst case, one would need to round edge weights to multiples of ε/n , and the rescaled integers could then be $\Theta(n)$; unfortunately, APSP (or min-plus product) for integer input of that magnitude still requires near cubic time under the current state of the art.

Yuster’s previous algorithm for directed graphs [22] is based on an approach by Zwick [23] (originally for exact small-edge-weighted APSP), which divides into two cases: paths that use a few edges (i.e., hops) vs. paths that use many edges. For shortest paths with less than L edges, the aforementioned rounding approach reduces the problem to computing min-plus products for small integers bounded by $O(L)$, which reduces to standard matrix multiplication on $\tilde{O}(L)$ -bit numbers. On the other hand, for shortest paths with more than L edges, there exists a small hitting set (also called a “bridging set”) with $\tilde{O}(n/L)$ vertices, and we can run a single-source/single-sink algorithm from/to each such vertex. Finally, the parameter L is chosen (near \sqrt{n} if $\omega = 2$) to balance cost.

To improve the running time, we combine this approach with Aingworth et al.’s approach [1] (which Dor et al.’s algorithm [12] builds upon). Aingworth et al.’s approach divides into two cases differently: vertices with low degree vs. vertices with high degree. Low-degree vertices are less expensive because the number of incident edges is small. On the other hand, for high-degree vertices, there exists a small dominating set, and so these vertices can be covered by a small number of “clusters”; sources in the same cluster are close together, and so distances from one fixed source s give us a good approximation (with $O(1)$ additive error) to distances from other sources in the same cluster (since the graph is undirected). To reduce the additive error from $O(1)$ to $O(\varepsilon)$, we need a number of further ideas. We will use min-plus products at each layer of the BFS tree from s . To make the error sum to $O(\varepsilon)$, we will set the error tolerance at each layer to be proportional to the size of the layer (roughly $\varepsilon n_i/n$ if the i -th layer has size n_i , as we will describe in Section 4). Bounding the total running time requires some care, since the min-plus products are done to matrices of different dimensions at the different layers.

The general plan shares some similarity with an exact combinatorial APSP algorithm by Chan [7] for sparse undirected unweighted graphs, which also modifies Aingworth et al.’s algorithm and simulates BFS to compute distances from multiple sources in a cluster.

However, what makes our algorithm interesting is the combination of Aingworth et al.'s approach with fast matrix multiplication. (A recent algorithm by Chan, Vassilevska Williams, and Xu [9] for a different problem – all-pairs lightest shortest paths for undirected small-weighted graphs – also combines Aingworth et al.'s approach with matrix multiplication, but does not involve approximation nor real weights. Our algorithm here is more elaborate.)

2 Preliminaries

Given two matrices A and B , we let $A \star B$ denote the min-plus product, i.e., $(A \star B)[u, v] = \min_z (A[u, z] + B[z, v])$.

Let $\mathcal{M}(n_1, n_2, n_3)$ denote the time complexity for computing the standard product of an $n_1 \times n_2$ and an $n_2 \times n_3$ matrix.

Let $\mathcal{M}^*(n_1, n_2, n_3 \mid \ell)$ denote the time complexity for computing the min-plus product of an $n_1 \times n_2$ and an $n_2 \times n_3$ matrix, where all the matrix entries are from $\{0, 1, \dots, \ell, \infty\}$. As is well known [3], $\mathcal{M}^*(n_1, n_2, n_3 \mid \ell) \leq \tilde{O}(\ell \cdot \mathcal{M}(n_1, n_2, n_3))$.

3 Small Distances

We begin with a lemma on computing small distances, which will be useful later. Yuster [22] has already observed how to solve the problem for paths with small number of edges, but our lemma is more challenging, since a path with small weight could still have a large number of hops.

► **Lemma 1.** *Given a directed or undirected graph $G = (V, E)$ with n vertices and real edge weights in $[0, 1]$, and given $\beta > \varepsilon$, we can approximate all distances that are at most β , with additive error $O(\varepsilon)$, in $\tilde{O}((\beta/\varepsilon)n^\omega)$ time.*

Proof. We use a form of repeated squaring: loosely speaking, we recursively solve the problem for $\beta/2$ and compute the min-plus product of the resulting matrix with itself. The additive error ε needs to be roughly halved in the recursive call, but luckily the ratio β/ε stays roughly the same.

Let $\delta > 0$ be a parameter to be set later. Let β_{\min} be the smallest edge weight. Assume that $\beta > \varepsilon$. For every $u, v \in V$, we will compute $\tilde{D}^{(\beta, \varepsilon)}[u, v]$, an approximation to $D[u, v]$ with additive error at most ε , provided that $D[u, v] \leq \beta$. (More precisely, if $\tilde{D}^{(\beta, \varepsilon)}[u, v] \neq \infty$, it is a valid approximation; and if $D[u, v] \leq \beta$, then it is guaranteed that $\tilde{D}^{(\beta, \varepsilon)}[u, v] \neq \infty$.)

To compute $\tilde{D}^{(\beta, \varepsilon)}$:

1. First recursively compute $D' = \tilde{D}^{(\beta/2, (1-\delta)\varepsilon/2)}$. Round the entries in D' (upward) to multiples of $\delta\varepsilon/3$.
2. Let $A'[u, v]$ be $w(u, v)$ rounded (upward) to a multiple of $\delta\varepsilon/3$. If $A'[u, v] > \beta$, reset $A'[u, v] = \infty$.
3. Set $\tilde{D}^{(\beta, \varepsilon)} = D' \star A' \star D'$. If $\tilde{D}^{(\beta, \varepsilon)}[u, v] > \beta + \varepsilon$, reset $\tilde{D}^{(\beta, \varepsilon)}[u, v] = \infty$.

Correctness follows since any path with weight at most β can be expressed as $\pi_1 e \pi_2$, where each of π_1 and π_2 is a subpath with weight at most $\beta/2$, and e is a single edge (the “median”). The additive error is bounded by $2(1-\delta)\varepsilon/2 + \delta\varepsilon/3 + \delta\varepsilon/3 + \delta\varepsilon/3 = \varepsilon$.

Since the finite entries of D' and A' after rescaling are integers bounded by $O(\frac{\beta}{\delta\varepsilon})$, these min-plus products take $O(\mathcal{M}^*(n, n, n \mid \frac{\beta}{\delta\varepsilon})) = \tilde{O}(\frac{\beta}{\delta\varepsilon} n^\omega)$ time. The total time satisfies the recurrence

$$T(\beta, \varepsilon) = T(\beta/2, (1-\delta)\varepsilon/2) + \tilde{O}(\frac{\beta}{\delta\varepsilon} n^\omega),$$

which yields $T(\beta, \varepsilon) = \tilde{O}(\frac{\beta}{\delta\varepsilon} (\frac{1}{1-\delta})^{\log(\beta/\beta_{\min})} n^\omega)$.

We may assume that $\beta \leq n$ and $\beta_{\min} \geq \varepsilon/n$, since we can initially round edge weights to multiples of ε/n . We set $\delta = 1/\log(\beta/\beta_{\min}) = \Omega(1/\log(n/\varepsilon))$, so that $(\frac{1}{1-\delta})^{\log(\beta/\beta_{\min})}$ is bounded by a constant. \blacktriangleleft

4 Multiple Sources

Next, we solve the subproblem of approximating shortest paths from multiple sources in a close-knit “cluster” of vertices $S \subseteq V$. (To optimize the final running time, we find it useful to separate out a preprocessing stage that does not depend on S .)

► Lemma 2. *Given an undirected graph $G = (V, E)$ with n vertices and real edge weights in $[0, 1] \cup \{\infty\}$, and a parameter B , we can preprocess in $\tilde{O}((1/\varepsilon)Bn^\omega)$ time, so that: given a subset $S \subseteq V$ of size $O(n/t)$ where every pair of vertices in S have distance at most an integer constant c , we can approximate the distances for all pairs in $S \times V$ with additive error $O(\varepsilon)$, in $\tilde{O}((1/\varepsilon)(n^\omega/B^{\omega-2} + n^\omega/t^{\omega-2}))$ time.*

Proof. Let $\varepsilon' = \varepsilon/\log n$. Fix a vertex $s \in S$. We first compute all distances from s in $O(n^2)$ time by Dijkstra’s algorithm. Let $V_i = \{v \in V : D[s, v] \in [i, i+1)\}$. For any interval I , let $V_I = \bigcup_{i \in I} V_i$. Let $n_i = |V_{[i-2c-3, i+2c+3]}|$; note that $\sum_i n_i = O(n)$.

We describe an algorithm to compute a partial matrix \tilde{D} of approximate distances. For subsets $S_1, S_2 \subseteq V$, let $\tilde{D}(S_1, S_2)$ denote the submatrix of \tilde{D} containing only entries for $(u, v) \in S_1 \times S_2$.

Step 0. For each i , we compute $\tilde{D}(V_{i-1}, V_i)$ by applying Lemma 1 to approximate distances between all $u \in V_{i-1}$ and all $v \in V_i$ that are bounded by $2c+1$, in the subgraph induced by $V_{[i-2c-3, i+2c+3]}$ (which has size $O(n_i)$), with additive error $O(\frac{\varepsilon' n_i}{n})$. (More precisely, for $u \in V_{i-1}$ and $v \in V_i$, if $\tilde{D}[u, v] \neq \infty$, then the computed value $\tilde{D}[u, v]$ is a valid approximation; and if u and v have distance at most $2c+1$ in the induced subgraph, then it is guaranteed that $\tilde{D}[u, v] \neq \infty$.) For all i with $n_i \leq n/B$, the total running time is

$$\begin{aligned} \tilde{O}\left(\sum_i \frac{n}{\varepsilon' n_i} \cdot n_i^\omega\right) &= \tilde{O}\left(\sum_i \frac{n}{\varepsilon'} \cdot n_i^{\omega-1}\right) \\ &\leq \tilde{O}\left(\sum_i \frac{n}{\varepsilon'} \cdot (n/B)^{\omega-2} \cdot n_i\right) \\ &= \tilde{O}\left(\frac{n}{\varepsilon'} \cdot (n/B)^{\omega-2} \cdot n\right) = \tilde{O}((1/\varepsilon')n^\omega/B^{\omega-2}). \end{aligned}$$

In the case when $n_i > n/B$, we apply Lemma 1 instead to the original graph with additive error $O(\varepsilon'/B)$, which is at least as good as $O(\frac{\varepsilon' n_i}{n})$, in $\tilde{O}((1/\varepsilon')Bn^\omega)$ time – note that this can be done just once during preprocessing.

Step 1. For $i = 0, \dots, c$, we compute $\tilde{D}(S, V_i)$ by using Lemma 1 to approximate all distances bounded by $O(c)$, with additive error $O(\varepsilon')$.

For each $i = c+1, \dots, t$, we compute $\tilde{D}(S, V_i)$ by taking the min-plus product $\tilde{D}(S, V_{i-1}) \star \tilde{D}(V_{i-1}, V_i)$, with additive error $O(\frac{\varepsilon' n_i}{n})$. We do the following *filtering* step: for each entry $\tilde{D}[x, y]$ just computed, if $\tilde{D}[x, y] \notin D[s, y] - D[s, x] \pm (2c + O(\varepsilon))$, reset $\tilde{D}[x, y] = \infty$. Because of the filtering step, for all $u \in S$, $z \in V_{i-1}$, and $v \in V_i$, we have $\tilde{D}[u, z] \in i \pm O(c)$ if it is finite, and $\tilde{D}[z, v] \in O(c)$ if it is finite. Thus, in computing $\tilde{D}(S, V_{i-1}) \star \tilde{D}(V_{i-1}, V_i)$, we can

make the matrix entries lie in $O(c)$ by shifting. We can then round entries to multiples of $\frac{n}{\varepsilon' n_i}$. So, the total time to compute the products for all $i = c + 1, \dots, t$ is

$$\begin{aligned}
\tilde{O}\left(\sum_{i=1}^t \mathcal{M}^*(n/t, n_i, n_i \mid \frac{n}{\varepsilon' n_i})\right) &\leq \tilde{O}\left(\sum_{i=1}^t \frac{n}{\varepsilon' n_i} \cdot \mathcal{M}(n/t, n_i, n_i)\right) \\
&\leq \tilde{O}\left(\sum_{i=1}^t \frac{n}{\varepsilon' n_i} \cdot \left(\frac{n}{n_i} n_i^\omega + \left(\frac{n_i}{n/t}\right)^2 (n/t)^\omega\right)\right) \\
&= \tilde{O}\left(\frac{1}{\varepsilon'} \sum_{i=1}^t ((n^2/t) n_i^{\omega-2} + (n^{\omega-1}/t^{\omega-2}) n_i)\right) \\
&\leq \tilde{O}\left(\frac{1}{\varepsilon'} \cdot ((n^2/t) n^{\omega-2} t^{3-\omega} + (n^{\omega-1}/t^{\omega-2}) n)\right) \\
&= \tilde{O}((1/\varepsilon') n^\omega / t^{\omega-2}).
\end{aligned}$$

Step 2. Now, assume that $\tilde{D}(S, V_i)$ has been computed for all $i = 0, \dots, \ell/2$ for a given $\ell \geq 2t$. We will compute $\tilde{D}(S, V_i)$ for all $i = \ell/2 + 1, \dots, \ell$. First pick an $i_0 \leq \ell/2$ with $|V_{i_0}| = O(n/\ell)$. For each $i = i_0 + 1, \dots, \ell$, we compute $\tilde{D}(V_{i_0}, V_i)$ by taking the min-plus product $\tilde{D}(V_{i_0}, V_{i-1}) \star \tilde{D}(V_{i-1}, V_i)$, with additive error $O(\frac{\varepsilon' n_i}{n})$. Do the filtering step as before. Because of the filtering step, for all $u \in V_{i_0}$, $z \in V_{i-1}$, and $v \in V_i$, we have $\tilde{D}[u, z] \in i - i_0 \pm O(c)$ if it is finite, and $\tilde{D}[z, v] \in O(c)$ if it is finite. By a similar analysis, the total time to compute these products for $i = i_0 + 1, \dots, \ell$ is upper-bounded by

$$\tilde{O}\left(\sum_{i=1}^{\ell} \mathcal{M}^*(n/\ell, n_i, n_i \mid \frac{n}{\varepsilon' n_i})\right) \leq \tilde{O}((1/\varepsilon') n^\omega / \ell^{\omega-2}) \leq \tilde{O}((1/\varepsilon') n^\omega / t^{\omega-2}).$$

Finally, we compute $\tilde{D}(S, V_{(\ell/2, \ell]})$ by taking the min-plus product $\tilde{D}(S, V_{i_0})$ and $\tilde{D}(V_{i_0}, V_{(\ell/2, \ell]})$ with additive error $O(\varepsilon')$. Do the filtering step as before. Because of the filtering step, for all $u \in S$, $z \in V_{i_0}$, and $v \in V_{(\ell/2, \ell]}$, we have $\tilde{D}[u, z] \in i_0 \pm O(c)$ if it is finite, and $\tilde{D}[z, v] \in D[s, v] - i_0 \pm O(c)$ if it is finite. We can again make the matrix entries lie in $O(c)$ by shifting. This product takes time

$$\begin{aligned}
\tilde{O}(\mathcal{M}^*(n/t, n/\ell, n \mid 1/\varepsilon')) &\leq \tilde{O}((1/\varepsilon') \mathcal{M}(n/t, n/t, n)) \\
&\leq \tilde{O}((1/\varepsilon') t (n/t)^\omega) = \tilde{O}((1/\varepsilon') n^\omega / t^{\omega-1}).
\end{aligned}$$

We repeat the above for all $\ell \geq 2t$ that are powers of 2.

Correctness. For every $u \in S$ and $v \in V$, we claim that $\tilde{D}[u, v]$ approximates $D[u, v]$ with additive error $O(\varepsilon)$. To see this, let π be the shortest path from u to v . For any subpath of π , say, from x to y , we have $D[x, y] = D[u, y] - D[u, x] \in D[s, y] - D[s, x] \pm 2c$, since $D[s, u] \leq c$ and the graph is undirected (this justifies the filtering step). If $u \in S$ and $v \in V_i$ with $i > c$, then π must pass through a vertex $z \in V_{i-1}$. For every node z' in the subpath from z to v , $D[z, z'] \leq D[u, v] - D[u, z] \leq D[s, v] - D[s, z] + 2c \leq 2c + 2$, and $D[s, z'] \in D[s, z] \pm D[z, z'] \in i \pm (2c + 3)$, so the subpath lies in the subgraph induced by $V_{[i-2c-3, i+2c+3]}$. It follows that the total additive error in Step 1 is $O(\sum_i \frac{\varepsilon' n_i}{n}) = O(\varepsilon')$. The analysis of Step 2 is similar: if $u \in S$ and $v \in V_i$ with $i > \ell/2$, then π must pass through a vertex $u' \in V_{i_0}$, and the subpath from u' to v must pass through a vertex $z \in V_{i-1}$. The overall additive error is bounded by $O(\varepsilon' \log n) = O(\varepsilon)$. ◀

5 Overall Algorithm

Our overall algorithm employs a careful combination of Aingworth et al.'s technique [1] involving low- vs. high-degree vertices, and Zwick's technique [23] involving short vs. long paths, and a judicious choice of several parameters to balance cost.

Let B , L , and t be parameters to be set later. Let V_{high} be the set of all vertices of degree more than n/t , and V_{low} be the set of all vertices of degree at most n/t .

Phase 1. We will first compute an approximation $\tilde{D}[u, v]$ to $D[u, v]$ for all $u \in V_{\text{high}}$ and $v \in V$, as follows:

Let $X \subseteq V$ be a dominating set for V_{high} , such that every vertex in V_{high} is in the (closed) neighborhood of some vertex in X . As noted by Aingworth et al. [1], there exists such a dominating set of size $\tilde{O}(t)$, and it can be found easily by random sampling, or deterministically by a greedy algorithm.

Consequently, we can cover V_{high} by $\tilde{O}(t)$ groups of vertices, such that vertices of each group have distance at most 2 from each other, by taking the neighborhoods of the vertices of X . We may assume that these groups are disjoint (for example, by removing from the i -th group those vertices that appear in the first $i - 1$ groups). Furthermore, we may assume that every group has size $O(n/t)$ (by subdividing the groups, which only increases the number of groups by $O(t)$). For each group S , we apply Lemma 2 (with $c = 2$). The total time of these $\tilde{O}(t)$ invocations of the lemma is $\tilde{O}(t \cdot (1/\varepsilon)n^\omega/B^{\omega-2})$, assuming that $B \leq t$, after $\tilde{O}((1/\varepsilon)Bn^\omega)$ -time preprocessing.

Phase 2. Let $R \subseteq V$ be a subset of vertices that hits all shortest paths with at least L edges. As shown by Zwick [23], there exists such a hitting set of size $\tilde{O}(n/L)$, and it can be found by random sampling, or deterministically. We will next compute an approximation $\hat{D}[u, v]$ to $D[u, v]$ for all $u \in R$ and $v \in V$ as follows:

Fix $u \in R$. Define a graph G_u containing all edges xy with $x \in V_{\text{low}}$ or $y \in V_{\text{low}}$; for each $z \in V_{\text{high}}$, we add an extra edge uz with weight $\tilde{D}[u, z]$, which has been computed in Phase 1. Then the distance from u to v in G_u approximates the distance in G (because if $\langle u_1, \dots, u_k \rangle$ is a shortest path in G with $u_1 = u$, and i is the largest index with $u_i \in V_{\text{high}}$, then $\langle u_1, u_i, \dots, u_k \rangle$ is a path in G_u). We run Dijkstra's algorithm on G_u from the source u . Since G_u has $O(n^2/t)$ edges, this takes $\tilde{O}(n^2/t)$ time per u . The total over all $u \in R$ is $\tilde{O}((n/L) \cdot (n^2/t)) = \tilde{O}(n^3/(tL))$.

Phase 3. We now approximate $D[u, v]$ for all $u, v \in V$ as follows.

For (u, v) with $D[u, v] \leq L$, we use Lemma 1, which takes $\tilde{O}((1/\varepsilon)Ln^\omega)$ time.

For (u, v) with $D[u, v] > L$, recall that we have computed $\hat{D}(V, R)$ from Phase 2. For $u \in V$ and $z \in R$, let $D'[u, z] = \hat{D}[u, z]$ if $\hat{D}[u, z] \leq L + O(\varepsilon)$, and $D'[u, z] = \infty$ otherwise. For $z \in R$ and $v \in V$, let $D''_a[z, v] = (\hat{D}[z, v] + a) \bmod 10L$. Compute the min-plus product $D'(V, R) \star D''_a(R, V)$ with additive error $O(\varepsilon)$ for $a = 0$ and for $a = 5L$. Since the finite entries after rescaling are integers bounded by $O(L/\varepsilon)$, this takes $\tilde{O}(\mathcal{M}^*(n, n/L, n \mid L/\varepsilon)) \leq \tilde{O}((1/\varepsilon)Ln^\omega)$ time. For each (u, v) , we remember which z gives the minimum for the two products, and take the one with the smaller $\hat{D}[u, z] + \hat{D}[z, v]$ among the two.

To justify correctness, consider a pair u, v with $D[u, v] \geq L$. Consider a shortest path π from u to v . There exists a vertex $z^* \in R$ among the first L vertices in π . Thus, $D[u, z^*] \leq L$. Furthermore, among all $z \in R$ with $D[u, z] \leq L + O(\varepsilon)$, we have $D[z, v]$ lying in an interval I of length $2L + O(\varepsilon)$, since the graph is undirected. For either $a = 0$ or $a = 5L$, the shifted interval $I + a$ would be completely contained in $[L, 9L]$ modulo $10L$, and so the minimum of $\hat{D}[u, z] + \hat{D}[z, v]$ would be correctly computed, with additive error $O(\varepsilon) + O(\varepsilon) = O(\varepsilon)$.

Total time. The overall running time (ignoring $\text{poly}(1/\varepsilon)$ factors) is

$$\tilde{O}(Bn^\omega + tn^\omega/B^{\omega-2} + n^3/(tL) + Ln^\omega).$$

Choosing $t = B^{\omega-1}$ and $L = B$ (noting that indeed $B \leq t$) gives $\tilde{O}(Bn^\omega + n^3/B^\omega)$. Finally, choosing $B = n^{(3-\omega)/(\omega+1)}$ gives $\tilde{O}(n^{\omega+(3-\omega)/(\omega+1)}) = O(n^{(3+\omega^2)/(\omega+1)}) = O(n^{2.559})$.

Standard techniques for generating witnesses for matrix products can be applied to recover the approximate shortest paths [14, 23].

► **Theorem 3.** *Given an undirected graph with n vertices and real edge weights in $[0, 1]$, we can solve the approximate APSP problem with additive error $O(\varepsilon)$ in $\tilde{O}(n^{(3+\omega^2)/(\omega+1)}) = O(n^{2.559})$ time, for any constant $\varepsilon > 0$.*

6 Final Remarks

It remains open whether an $\tilde{O}(n^2)$ -time algorithm for undirected real-weighted graphs is possible if $\omega = 2$, even with a large constant additive error.

Under the current bounds on matrix multiplication, could our $O(n^{2.559})$ result be further improved? At the moment, we don't know how to use rectangular matrix multiplication to speed up our algorithm. And we don't know either how to use rectangular matrix multiplication to speed up Yuster's $O(n^{2.687})$ -time algorithm for directed graphs [22] (ideally, to match up with Zwick's unweighted exact APSP algorithm [23], which has running time $O(n^{2.529})$ via the latest bounds on rectangular matrix multiplication [17]).

Dynamic Colored Orthogonal Range Searching

Abstract

In the *colored orthogonal range reporting* problem, we want a data structure for storing n colored points so that given a query axis-aligned rectangle, we can report the distinct colors among the points inside the rectangle. This natural problem has been studied in a series of papers, but most prior work focused on the static case. In this paper, we give a dynamic data structure in the 2D case which can answer queries in $O(\log^{1+o(1)} n + k \log^{1/2+o(1)} n)$ time, where k denotes the output size (the number of distinct colors in the query range), and which can support insertions and deletions in $O(\log^{2+o(1)} n)$ time (amortized) in the standard RAM model. This is the first fully dynamic structure with polylogarithmic update time whose query cost per color reported is *sublogarithmic* (near $\sqrt{\log n}$). We also give an alternative data structure with $O(\log^{1+o(1)} n + k \log^{3/4+o(1)} n)$ query time and $O(\log^{3/2+o(1)} n)$ update time (amortized). We also mention extensions to higher constant dimensions.

1 Introduction

Range searching is one of the most fundamental data structure problems studied in computational geometry. Motivated by applications in databases and information retrieval, many researchers [5, 6, 7, 12, 13, 14, 15, 17, 18, 19, 20, 21, 22, 23, 24, 25, 27, 29, 30, 31, 32, 34] have investigated a natural *colored* variant of range searching (also called “categorical”, or “generalized”, range searching):

Given a set of n points where each point is assigned a color (or “category”), we want to quickly report the distinct colors of the points inside a query range.

The query time should depend on the output size k , i.e., the number of distinct colors in the range (which could be much smaller than the number of points in the range). In this paper, we focus on the basic case of 2D *orthogonal* query ranges, i.e., axis-aligned rectangles.

A long series of work have studied this colored orthogonal range reporting problem, which turns out to be more challenging than the traditional uncolored problem; see Table 1 for a quick summary. Throughout the paper, we assume the standard word RAM model of computation.

All these prior papers addressed primarily static data structures, and surprisingly, not much progress has been made on the equally fundamental *dynamic* problem, where insertions and deletions of points are allowed.

Chan and Nekrich (SODA'20) [7]	$O(n \log^{3/4+\varepsilon} n)$	$O(\log \log U + k)$

Known dynamic colored results. The 1D dynamic colored range reporting problem – in which query ranges are intervals – can be easily reduced to 2D uncolored 3-sided range reporting (e.g., see the survey [16, Section 1.3.1]), and so by “textbook” *range trees* [11, 33], the problem can be solved with $O(\log n + k)$ query time and $O(\log^2 n)$ update time, or by incorporating dynamic fractional cascading [26], $O(\log n \log \log n + k)$ query time and $O(\log n \log \log n)$ update time. By using the current best results of Chan and Tsakalidis [9] on dynamic 2D uncolored range searching, the query time improves to $O(\frac{\log n}{\log \log n} + k)$ and the update time improves to $O(\log^{1/2+\varepsilon} n)$ (amortized) for an arbitrarily small constant $\varepsilon > 0$. (For dynamic 2D uncolored range searching, a lower bound of $\Omega(\frac{\log n}{\log \log n} + k)$ query time is known [2] for data structures with polylogarithmic update time; and $\sqrt{\log n}$ update time has also been recognized as a barrier that would be difficult to break with existing techniques [9].)

Straightforwardly, the dynamic 2D colored range reporting can be reduced dynamic 1D colored range reporting, by using a range tree on the x -coordinates, with a logarithmic-factor increase in both the query and update time. This implies a 2D colored data structure with $O(\frac{\log^2 n}{\log \log n} + k \log n)$ query time and $O(\log^{3/2+\varepsilon} n)$ update time. Notice the extra logarithmic factor in the $O(k \log n)$ term of the query cost: as the query range is decomposed into $O(\log n)$ sub-ranges, the same color may be discovered $O(\log n)$ times with this approach.

Alternatively, it is known (e.g., see [16, Section 3.4]) that a colored range reporting query can be reduced to $O(k \log n)$ number of uncolored range emptiness queries, by using a range tree on the colors. This simple reduction works in the dynamic setting, with update time increased by a logarithmic factor. By Chan and Tsakalidis’s result [9] on dynamic uncolored range emptiness, this implies a different dynamic 2D colored data structure with $O(k \frac{\log^2 n}{\log \log n})$ query time and $O(\log^{3/2+\varepsilon} n)$ update time, which is no better than the above.

Known static methods managed to avoid extra logarithmic factors in the k term (as can be seen in Table 1), but these methods do not adapt well to the dynamic setting. Some results were known in the insertion-only case [17], but it is open whether there exists a fully dynamic data structure with $O(\text{polylog } n + k)$ query time and $O(\text{polylog } n)$ update time for 2D colored orthogonal range reporting.¹

¹ However, it is not difficult to obtain $O(\frac{\log n}{\log \log n} + k)$ query time with $O(n^\varepsilon)$ update time, by modifying the reduction from 2D colored to 1D colored to use a larger fan-out $n^{\varepsilon'}$.

New dynamic colored result. We make progress towards this open problem by presenting a new data structure for dynamic 2D colored orthogonal range reporting with $O(\log n + k \log^{1/2+o(1)} n)$ query time and $O(\text{polylog } n)$ update time. The query cost per reported color is thus sublogarithmic ($\log^{1/2+o(1)} n$).

Interestingly, this improved query time bound is obtained using an approach similar to that in Chan and Pătraşcu’s $O(n\sqrt{\log n})$ -time inversion-counting algorithm [8], or in other known data structures with “fractional-power-of-log” update times [8, 9, 10, 28, 36]. As reinterpreted in Chan and Tsakalidis’ framework [9], the approach roughly involves two parts: (i) the design of *micro-structures* for small input (of size near $2^{\sqrt{\log n}}$), which uses bit packing tricks; and (ii) the design of *macro-structures*, which uses more traditional range trees but with larger fan-out (also near $2^{\sqrt{\log n}}$) to reduce the tree depth. What is novel in our application is that the $\sqrt{\log n}$ factor appears in the k term of the query cost – we will apply bit packing to the query’s output list of colors in the micro-structures. In addition, we follow an idea from Chan and Nekrich’s static data structure for colored range reporting [7]: first solve a “capped” version of the problem, where the number of reported colors k is promised to be upper-bounded by some parameter K_0 , and then extend the solution to general k by building a range tree on the colors. The overall method is conceptually not complicated, as explained in Section 2.

Improving the update time. In its simplest version, our data structure has $O(\log^{3+o(1)} n)$ update time. In Section 3, by combining with the more sophisticated techniques in Chan and Tsakalidis’ work on dynamic uncolored orthogonal range searching [9], we further reduce the update time to $O(\log^{2+o(1)} n)$, while keeping roughly the same query time $O(\log^{1+o(1)} n + k \log^{1/2+o(1)} n)$. These bounds are amortized.

Alternative result. In Section 4, by using a different micro-structure, we also describe an alternative data structure which further lowers the update time to $O(\log^{3/2+o(1)} n)$, although the query time is increased to $O(\log^{1+o(1)} n + k \log^{3/4+o(1)} n)$. Still, compared to the aforementioned prior result with $O(\frac{\log^2 n}{\log \log n} + k \log n)$ query time and $O(\log^{3/2+\varepsilon} n)$ update time, we get a strictly better query time bound while keeping the same update time.

Higher dimensions. Our approach can also be extended to higher dimensions. In Section 5, we show how to answer colored orthogonal range reporting queries in a constant dimension d in $O(\log^{d-1} n + k \log^{d-2+1/d+o(1)} n)$ time, while supporting updates in $O(\text{polylog } n)$ time. The $\log^{d-2+1/d} n$ factor is intriguingly similar to Chan and Pătraşcu’s bound on d -dimensional (uncolored) orthogonal range counting [8].

Computational model. We work with the standard w -bit word RAM model of computation, with $w = \Omega(\log n)$. On occasion, we assume that certain nonstandard word operations take unit time. This assumption may be removed by simulating such operations via table lookup, after an initial preprocessing of the table in $2^{O(w)}$ time, the cost of which is negligible since we will eventually set $w = \delta \log n$ for a sufficiently small constant $\delta > 0$.

2 First Method

In this section, we present our first method for 2D colored orthogonal range reporting, achieving roughly $O(\log n + k\sqrt{\log n})$ query time with polylogarithmic update time.

We begin by solving the case of *3-sided* query ranges, i.e., rectangles that are unbounded on one side, w.l.o.g., from below. The colored 3-sided problem is already challenging (and, in fact, so is 2-sided). The general idea is to build the data structure in two stages. First, in Section 2.1 we design a *micro-structure* to solve the problem for small input size, in which case the colors can be encoded in much fewer bits than $\log n$ and we can apply bit packing tricks. In Sections 2.2–2.3 we then use this micro-structure to build a *macro-structure*, solving the 3-sided problem for large input size. Finally, in Section 2.4, we note how the original 4-sided problem can be reduced to the 3-sided problem, without increasing the query time (though the update time is increased by an extra logarithmic factor).

2.1 3-Sided Micro-Structure

Our micro-structure is obtained by modifying the binary range tree and incorporating bit packing techniques.

► **Lemma 1.** *Given a set of at most s points in $2D$, there is a data structure for colored 3-sided range reporting with*

- *query time $Q_3(s, k) = O(\log s + (k \log k \log^{2+o(1)} s)/w + k)$, and*
- *amortized update time $U_3(s) = O(\log^{1+o(1)} s)$.*

Proof. Since there are at most s points and thus at most s colors, we can map each color to an integer in $\{1, \dots, s\}$. This enables us to pack $w/\log s$ colors into a single word. The mapping can be stored in a “color translation” table of s entries, so that we can translate each mapped color back to its original color in constant time. In an insertion of a point with a new color, we can simply map its color to the next unused integer.

The micro-structure takes the form of a binary range tree. At each node, we divide the plane into two vertical slabs, each with roughly half the number of points, such that each child node stores a recursive data structure for one of the slabs. For each slab σ , we store a list L_σ of all points in σ , sorted by the y -coordinates. In addition, we store a sublist L'_σ that contains the lowest point of each color in L_σ , also sorted by y . Using a colored predecessor search structure [28, Theorem 14], which has $O(\log^2 \log s)$ update time, for any given point, we can find the predecessor in L_σ and L'_σ in $O(\log^2 \log s)$ time, given its predecessor in L_τ of the parent slab τ ; we can also find the predecessor of a specific color in $O(\log^2 \log s)$ time.

When a point p is inserted to L_σ , if p has no predecessor of the same color, we insert it to L'_σ and delete its colored successor (if one exists) from L'_σ . When a point p is deleted from L_σ , if p is in L'_σ , we delete it and insert its colored successor to L'_σ .

By bit packing, we store the list of colors in L_σ in a sequence of words, each containing between $w/(2 \log s)$ and $w/\log s$ colors. During an insertion, when the number of elements in a word exceed $w/\log s$, we split the word into two. During a deletion, when the number of elements in a word drops below $w/(2 \log s)$, we merge the word with its successor in the sequence, and if the number of elements in the merged word exceeds $w/\log s$, we split it. This takes constant time (using standard word operations such as shifts).

We can ensure that the range tree has $O(\log s)$ height, for example, by known weight-balancing techniques [4]. The overall update time is thus $O(\log s \log^2 \log s)$.

For a given 3-sided query range q , if q intersects only one slab, then we recurse in that slab; otherwise, we make a recursive 2-sided query in each slab. Given a 2-sided query range q open to the left, if the vertical side of q intersects the left slab, then we recurse in the left slab; otherwise, we report all distinct colors in the left slab σ by scanning its sublist L'_σ from the bottom and extracting a prefix, and then recurse in the right slab. We can handle 2-sided query ranges open to the right symmetrically.

Each color is reported only once at each level, and therefore is reported $O(\log s)$ times over the recursion. Thus, the combined list of reported colors requires $O(k \log s \cdot \log s)$ bits and can be represented in $O(1 + (k \log^2 s)/w)$ words. We then remove duplicate colors by sorting and performing a linear scan. A bit-packed version of mergesort on m elements takes time $O(\log m)$ times the number of words (using possibly nonstandard word operations). Thus, the cost is $O(\log s + (1 + (k \log^2 s)/w) \cdot \log(k \log s)) = O(\log s + (k \log k \log^{2+o(1)} s)/w)$. Afterwards, we spend $O(k)$ time to translate the output colors. ◀

2.2 3-Sided Capped Macro-Structure

Next, we present our macro-structure for large input. We first solve the K_0 -capped problem. Here, the number of colors in the query range is promised to be smaller than a given fixed value K_0 , i.e., $k \leq K_0$.

► **Lemma 2.** *Fix a value $K_0 \leq 2^{\sqrt{w}}$. Given n points in $2D$, there is a data structure for colored 3-sided K_0 -capped range reporting with*

- *query time $O(\log n + (k \log K_0 \log^{1+o(1)} n)/\sqrt{w} + k) \leq O(\log n + k \log K_0 \log^{1/2+o(1)} n)$;*
- *amortized update time $O(\log^{1+o(1)} n)$.*

Proof. We will still use a variant of the range tree, but with a much larger fan-out s to be set later. At each node, the plane is divided into s vertical slabs, each with about $1/s$ of the points. For each slab σ , among the lowest point of each color, we only take the K_0 lowest ones. We replace the x -coordinates of these points with that of the left side of σ . We then store all sK_0 such points across all slabs in the micro-structure from Lemma 1, with $U_3(sK_0)$ update time and $Q_3(sK_0, k)$ query time. We maintain colored predecessor search structures at each node as before. We can ensure that the range tree has $O(\log_s n)$ height, by known weight-balancing techniques [4].

For a given 3-sided query range q , we identify the child slabs σ_1 and σ_2 containing the two vertices of q , answer a query for the micro-structure for $q - \sigma_1 - \sigma_2$, and then recurse in σ_1 and σ_2 . We make $O(\log_s n)$ queries on the micro-structures along two paths of the tree, so the query time is

$$Q'_3(n, k) = O(Q_3(sK_0, k) \log_s n) = O\left(\log(sK_0) + k \frac{\log k \log^{2+o(1)}(sK_0)}{w} + k\right) \cdot \log_s n.$$

For each update, we make $O(\log_s n)$ updates on the micro-structures along a path of the tree, so the update time is

$$U'_3(n) = O(U_3(sK_0) \log_s n + \log_s n \log^2 \log n) = O((\log^{1+o(1)}(sK_0) + \log^2 \log n) \log_s n).$$

Setting $s = 2^{\sqrt{w}}$ and recalling that $K_0 \leq 2^{\sqrt{w}}$, we obtain $Q'_3(n, k) = O(\log n + (k \log k \log^{1+o(1)} n)/\sqrt{w} + k)$ and $U'_3(n) = O(\log^{1+o(1)} n)$. ◀

Remark. If $k \geq K_0$, the algorithm may or may not succeed in reporting all k distinct colors. It is actually possible to *pre-check* whether the algorithm will succeed, in $O(\log n)$ time (without paying the $O((k \log K_0 \log^{1+o(1)} n)/\sqrt{w} + k)$ cost): In the data structure from Lemma 2, recall that in each slab we store the lowest K_0 points of distinct colors in a micro-structure. We mark the K_0 -th lowest point with a special color. In the micro-structure from Lemma 1, in each L_σ , we maintain the lowest special point. If the query algorithm wants to report a prefix of L'_σ , we check that the lowest special point is not in the query range (otherwise the algorithm would fail). We also check that the K_0 -th lowest point of L'_σ is not in the query range. The cost of pre-checking is $O(\log_s n \cdot \log(sK_0)) = O(\log n)$.

2.3 From Capped to Uncapped

We now remove the assumption $k < K_0$, to obtain a complete solution to the 3-sided problem:

► **Theorem 3.** *Given n points in $2D$, there is a data structure for colored 3-sided range reporting with*

- *query time $O(\log n + (k \log^{1+o(1)} n)/\sqrt{w} + k) \leq O(\log n + k \log^{1/2+o(1)} n)$, and*
- *amortized update time $O(\log^{2+o(1)} n)$.*

Proof. We use a range tree on the colors, as in Chan and Nekrich’s static colored method [7, proof of Theorem 2.3], with fan-out f . At each node we store its point set in the capped data structure from Lemma 2. The color class is partitioned into f color subclasses, each with roughly equal number of colors. Each child of a node corresponds to one of these subclasses. We can ensure that the range tree has $O(\log_f n)$ height, by known weight-balancing techniques [4].

To answer a query, at each node we first pre-check whether the query will succeed, as in the Remark after Lemma 2.² If so, we query the capped structure from Lemma 2 at the node and finish the query. Otherwise, we recurse in all f children.

Whenever we recurse in the children of a node, the node must contain $\geq K_0$ colors in the query range. Thus, the number of recursive calls per level is $O(fk/K_0)$, so the total number of recursive calls is $O((fk/K_0) \log_f n)$, excluding the root. Thus, the total cost of pre-checking is $O((fk/K_0) \log_f n \cdot \log n)$. The total query time spent on capped structures is $O(((fk/K_0) \log_f n + 1) \cdot \log n + (k \log K_0 \log^{1+o(1)} n)/\sqrt{w} + k)$.

For each update, we make $O(\log_f n)$ updates to the capped structures along a path of the tree, so the total update time is $O(\log_f n \cdot \log^{1+o(1)} n)$.

Setting $f = 2$ and $K_0 = \log^2 n$ yields query time $O(\log n + (k \log^{1+o(1)} n)/\sqrt{w} + k)$ and update time $O(\log^{2+o(1)} n)$. ◀

2.4 From 3-Sided to 4-Sided

By building a standard binary range tree where each node stores the 3-sided structure from Theorem 3, we can reduce a 4-sided query to two 3-sided queries. The query time remains the same, and the update time increases by a logarithmic factor. This immediately yields the following result:

► **Corollary 4.** *Given n points in $2D$, there is a data structure for colored 4-sided range reporting with*

- *query time $O(\log n + k \log^{1/2+o(1)} n)$, and*
- *amortized update time $O(\log^{3+o(1)} n)$.*

3 Improving the 4-Sided Update Time

In this section, we apply more advanced techniques to improve the update time for 4-sided queries to $O(\log^{2+o(1)} n)$, which matches our 3-sided update time, avoiding the logarithmic-factor penalty in going from 3-sided to 4-sided.

Chan and Tsakalidis [9] proposed a framework for transforming micro-structures into macro-structures for uncolored range searching. We observe that their transformation works for the capped colored problem as well, with minor modifications. Our improved colored

² Chan and Nekrich [7] originally suggested some nontrivial approximate range counting approach to do the pre-checking, which we have bypassed.

result then follows by combining this transformation with our 3-sided micro-structure from Section 2.1, and with the known transformation of capped to uncapped structures used in Section 2.3.

In more details, Chan and Tsakalidis started with a technique of Mortensen [28, Theorem 1], which they dubbed the *van Emde Boas transformation*, for converting a micro-structure to a data structure for solving the *narrow grid* case, where input points have a small number of distinct x -coordinates. The conversion increases time bounds by only $\log \log$ factors, and is achieved by a recursion similar to van Emde Boas trees [35]. We observe that a similar transformation holds for the capped colored range reporting problem, if the cap K_0 is not too big. The statement below is adapted from Chan and Tsakalidis [9, Lemma 4]. In this section, 3-sided query ranges are unbounded from the left or the right (instead of from below).

► **Lemma 5.** *Fix K_0 . Let X be a set of $O(s)$ values. Given a dynamic data structure for colored j -sided range reporting ($j \in \{3, 4\}$) on s' points in $X \times \mathbb{R}$ with query time $Q_j(s, s', k)$ and update time $U_j(s, s')$ (amortized), there is a data structure for colored j -sided K_0 -capped range reporting on n points in $X \times \mathbb{R}$ with (amortized)*

- query time $Q_j(s, n, k) = O(Q_j(s, (sK_0)^{O(1)}, k) \log \log n)$, and
- update time $U_j(s, n) = O(U_j(s, (sK_0)^{O(1)}) \log^2 \log n)$.

If the given data structure supports updates to X in $U_X(s)$ time and this update procedure depends solely on X (and not the point set), the new data structure can support updates to X in $U_X(s)$ time.

The proof is a straightforward modification of the previous proof [28, 9]. (Basically, whenever in the uncolored solution we refer to the topmost/bottommost point, we now consider the K_0 topmost/bottommost points of distinct colors – this explains why the number of points in the micro-structures goes up from $s^{O(1)}$ to $(sK_0)^{O(1)}$.)

Next, Chan and Tsakalidis [9, Lemma 7] described a way to convert a narrow-grid structure into a data structure for the general case. This transformation, which they dubbed the (first) *range tree transformation*, uses standard range trees with fan-out s . We observe that the same transformation works for the capped colored problem:

► **Lemma 6.** *Fix K_0 . Given a family of data structures $\mathcal{D}_j^{(i)}$ ($i \in \{1, \dots, \log_s n\}$) for dynamic colored j -sided K_0 -capped range reporting ($j \in \{3, 4\}$) on n points in $X \times \mathbb{R}$ ($|X| = O(s)$) with query time $Q_j^{(i)}(s, n, k)$ update time $U_j^{(i)}(s, n)$ (amortized), where updates to X take $U_X(s)$ time, there is a data structure for colored 4-sided K_0 -capped range reporting on n points in the plane with the following query and update time (amortized):*

$$Q'_4(n, k) = O\left(\max_i Q_4^{(i)}(s, n, k) + \max_i Q_3^{(i)}(s, n, k) \log_s n + \log_s n \log^2 \log n\right)$$

$$U'_4(n) = O\left(\sum_{i=1}^{\log_s n} (U_4^{(i)}(s, n) + U_3^{(i)}(s, n)) + \sum_{i=1}^{\log_s n} \frac{U_X^{(i)}(s)}{s^{i-1}} + \log_s n \log^2 \log n\right).$$

The proof of the above requires essentially no change in the previous proof [9].

We are now ready to put together our new improved data structure. We set $K_0 = s$. Our colored 3-sided method in Theorem 3 gives

$$Q_3(s, s^{O(1)}, k) = O(\log s + (k \log^{1+o(1)} s) / \sqrt{w} + k)$$

$$U_3(s, s^{O(1)}) = O(\log^{2+o(1)} s).$$

The known colored 4-sided method mentioned in the introduction gives

$$\begin{aligned} Q_4(s, s^{O(1)}, k) &= O\left(\frac{\log^2 s}{\log \log s} + k \log s\right) \\ U_4(s, s^{O(1)}) &= O(\log^{3/2+\varepsilon} s). \end{aligned}$$

(Actually, a weaker bound of $U_4(s, s^{O(1)}) = O(\log^{2+o(1)} s)$ suffices.) In both of these methods, $U_X(s) = 0$. Applying Lemmas 5–6 (with $Q_4^{(i)} = Q_4$ and $Q_3^{(i)} = Q_3$ for all i) yields

$$\begin{aligned} Q'_4(n, k) &= O\left(\frac{\log^2 s}{\log \log s} + k \log s + (\log s + (k \log^{1+o(1)} s)/\sqrt{w} + k) \log_s n\right) \cdot \log^2 \log n \\ U'_4(n) &= O(\log^{2+o(1)} s \log_s n) \cdot \log^2 \log n. \end{aligned}$$

Setting $s = 2^{\sqrt{\log n}}$ gives

$$\begin{aligned} Q'_4(n, k) &= O(\log^{1+o(1)} n + k \log^{1/2+o(1)} n) \\ U'_4(n) &= O(\log^{3/2+o(1)} n). \end{aligned}$$

All this is for the K_0 -capped problem with $K_0 = s = 2^{\sqrt{\log n}}$. Finally, we solve the general uncapped problem by the color range tree technique in Section 2.3. As in the Remark after Lemma 2, it is possible to pre-check whether the query will succeed, in $O(\log^{1+o(1)} n)$ time (without paying the $O(k \log^{1/2+o(1)} n)$ cost); the modification is straightforward (see the Appendix regarding the van Emde Boas transformation). As in the proof of Theorem 3, by using a range tree on colors with fan-out f , the overall query time is $O(((fk/K_0) \log_f n + 1) \cdot \log^{1+o(1)} n + k \log^{1/2+o(1)} n)$, and the overall update time is $O(\log_f n \log^{3/2+o(1)} n)$.

By setting $f = \sqrt{K_0}$ for example, the query time remains $O(\log^{1+o(1)} n + k \log^{1/2+o(1)} n)$ and the update time becomes $O(\log^{2+o(1)} n)$.

► **Theorem 7.** *Given n points in 2D, there is a data structure for colored 4-sided range reporting with*

- *query time $O(\log^{1+o(1)} n + k \log^{1/2+o(1)} n)$, and*
- *amortized update time $O(\log^{2+o(1)} n)$.*

4 Alternative Method

We now describe an alternative method that has smaller update time $O(\log^{3/2+o(1)} n)$, though the query time is increased to $O(\log^{1+o(1)} n + k \log^{3/4+o(1)} n)$.

The solution uses a different micro-structure, given in the lemma below, which works directly for the general 4-sided case. Its main advantage is that it has *constant* amortized update time when the input size s is sufficiently small (around $2^{\log^{1/4} n}$). It is a colored variant of a micro-structure for uncolored 4-sided queries by Chan and Tsakalidis [9, Lemma 5(ii) and Lemma 6].

► **Lemma 8.** *Fix a parameter $\bar{w} \leq w$ with $\bar{w} = \Omega(\log s)$. Given a set of at most s points in a universe $X \times Y$ with $|X|, |Y| = s^{O(1)}$, and there is a data structure for 4-sided colored range reporting with*

- *amortized query time $O(\log^2 s + (k \log^{3+o(1)} s)/\bar{w} + k)$, and*
- *amortized update time $O(1 + (\log^4 s)/\bar{w})$.*

In addition, it supports:

- *updates to Y in $O(\log^2 \log n)$ time, and*
- *updates to X in $2^{O(\bar{w})}$ time, where the update procedure depends solely on X (and not the point set).*

Proof. Recall that colors can be mapped to $(\log s)$ -bit integers, as noted in the first paragraph of the proof of Lemma 1.

We follow the approach by Chan and Tsakalidis [9, Lemma 5(ii)] and mimic an *external-memory* data structure with block size $B := \delta \bar{w} / \log s$ for a sufficiently small constant δ . A block of B points can be encoded in $O(\delta \bar{w})$ bits and can thus be packed in a single word.

The well-known *buffer tree* of Arge [3] is a 1D external-memory data structure with subconstant ($O(\frac{1}{B} \log_B s)$) amortized update cost. For their 4-sided uncolored micro-structure, Chan and Tsakalidis suggested an analogous *buffered* version of the binary range tree in 2D, which has amortized update cost $O(\frac{1}{B} \log^2 s) = O((\log^3 s)/\bar{w})$. Our solution in the colored setting is similar.

Roughly speaking, in the primary 2D range tree, each node corresponds to a *canonical horizontal slab* and stores a secondary tree, which is a 1D range tree of the points in the corresponding canonical horizontal slab. In a secondary tree, each node corresponds a *canonical rectangle*. In the buffered version, each node of the primary tree and secondary trees holds a buffer of up to B update requests that are yet to be processed.

We will not re-explain all the details of the buffered 2D range tree, but just describe the main changes needed for the colored problem: For each node ν of a secondary tree, we additionally maintain a sorted list L_ν of the distinct colors appearing in the corresponding canonical rectangle, along with the multiplicity of these colors. We also hold a buffer Z_ν of (a possibly large number of) of update requests yet to be processed at ν . Updates in ν are handled lazily, by just appending the requests to the buffer Z_ν . We postpone the work of actually updating L_ν to querying. When a query wants to report the colors in a node ν , we sort Z_ν by color and perform a linear scan to update L_ν . Let ℓ_ν and z_ν be the number of elements in L_ν and Z_ν . The lists L_ν and Z_ν can be packed in $O((\ell_\nu \log s)/w)$ and $O(z_\nu \log s/\bar{w})$ words respectively. By a bit-packed version of mergesort, sorting Z_ν takes time $O((z_\nu \log s)/\bar{w}) \cdot \log s$. Since an update leads to update requests in the buffers Z_ν of $O(\log^2 s)$ nodes ν , we can assign an amortized cost of $O((\log^4 s)/\bar{w})$ per update to cover this sorting cost. Scanning L_ν takes time $O((\ell_\nu \log s)/w)$. Now, ℓ_ν is bounded by the number of colors reported in ν during the previous query that involves ν . Since a query visits $O(\log^2 s)$ nodes, we can assign an amortized cost of $O((k \log^3 s)/w)$ per query with output size k to cover this scanning cost.

In a query, we report the colors in the sorted list L_ν for $O(\log^2 s)$ nodes ν . The combined list of reported colors has $O(k \log^2 s)$ colors and requires $O((k \log^3 s)/\bar{w})$ words. We remove duplicate colors by merging these $O(\log^2 s)$ sorted lists. This multi-way merging can be done in $O(\log \log s)$ rounds, each taking time linear in the number of words. Thus, the cost is $O((k \log^{3+o(1)} s)/\bar{w})$. Afterwards, we spend $O(k)$ time to translate the output colors.

Updates to X and Y can be handled using the same ideas by Chan and Tsakalidis [9, Lemma 6]. ◀

We can now put together the new data structure by combining the new micro-structure with Chan and Tsakalidis' framework [9], via the van Emde Boas transformation and range tree transformation, as we have described in Section 3.

As before, we set $K_0 = s$. For each $j \in \{3, 4\}$ and each $i \in \{1, \dots, \log_s n\}$, we apply Lemma 8 with the choice $\bar{w} = \delta i \log s$ to get

$$\begin{aligned} Q_j^{(i)}(s, s^{O(1)}, k) &= O(\log^2 s + (k \log^{2+o(1)} s)/i + k) \\ U_j^{(i)}(s, s^{O(1)}) &= O(1 + (\log^{3+o(1)} s)/i) \\ U_X^{(i)}(s) &= s^{O(\delta i)}. \end{aligned}$$

28:10 Dynamic Colored Orthogonal Range Searching

Applying Lemmas 5–6 and noting that $\sum_{i=1}^{\log_s n} 1/i = O(\log \log_s n)$ yields

$$\begin{aligned} Q'_4(n, k) &= O\left(\log^2 s \log_s n + k \log^{2+o(1)} s + k \log_s n\right) \cdot \log^3 \log n \\ U'_4(n) &= O(\log_s n + \log^{3+o(1)} s) \cdot \log^3 \log n. \end{aligned}$$

Setting $s = 2^{\log^{1/4} n}$ gives

$$\begin{aligned} Q'_4(n, k) &= O(\log^{5/4+o(1)} n + k \log^{3/4+o(1)} n) \\ U'_4(n) &= O(\log^{3/4+o(1)} n). \end{aligned}$$

All this is for the K_0 -capped problem with $K_0 = s = 2^{\log^{1/4} n}$. Finally, we solve the general uncapped problem by using the color range tree technique in Section 2.3. As before, it is possible to pre-check whether the query will succeed, in $O(\log^{5/4+o(1)} n)$ time (without paying the $O(k \log^{3/4+o(1)} n)$ cost). The overall query time is then $O(((fk/K_0) \log_f n + 1) \cdot \log^{5/4+o(1)} n + k \log^{3/4+o(1)} n)$, and the overall update time is $O(\log_f n \log^{3/4+o(1)} n)$.

By setting $f = \sqrt{K_0}$ for example, the query time remains $O(\log^{5/4+o(1)} n + k \log^{3/4+o(1)} n)$ and the update time becomes $O(\log^{3/2+o(1)} n)$.

The term $O(\log^{5/4+o(1)} n)$ dominates the query time bound only when $k \ll \sqrt{\log n}$, but in this case, we can switch to the method in Section 3, which solves the problem for an even bigger cap $2\sqrt{\log n}$ with a better query time $O(\log^{1+o(1)} n + k \log^{1/2+o(1)} n)$ while keeping update time $O(\log^{3/2+o(1)} n)$.

► **Theorem 9.** *Given n points in 2D, there is a data structure for colored 4-sided range reporting with*

- *amortized query time $O(\log^{1+o(1)} n + k \log^{3/4+o(1)} n)$, and*
- *amortized update time $O(\log^{3/2+o(1)} n)$.*

5 Higher Dimensions

We now point out a generalization of the method in Section 2 to higher dimensions.

First, it is straightforward to generalize the micro-structure from Lemma 1 (here, a $(2d-1)$ -sided range is unbounded along the d -th axis):

► **Lemma 10.** *Given a set of at most s points in a constant dimension d , there is a data structure for colored $(2d-1)$ -sided range reporting with*

- *query time $Q_{2d-1}(s, k) = O(\log^{d-1} s + (k \log k \log^{d+o(1)} s)/w + k)$, and*
- *amortized update time $U_{2d-1}(s) = O(\log^{d-1+o(1)} s)$.*

We generalize the capped macro-structure from Lemma 2:

► **Lemma 11.** *Fix a value $K_0 \leq 2^{w^{1/d}}$. Given n points in a constant dimension d , there is a data structure for colored $(2d-1)$ -sided K_0 -capped range reporting with*

- *query time $O(\log^{d-1} n + k \log K_0 \log^{d-2+1/d+o(1)} n)$;*
- *amortized update time $O(\log^{d-1+o(1)} n)$.*

Proof. For each $j \in \{0, \dots, d-1\}$, define \mathcal{P}_j to be the (capped) subproblem in d dimensions which the first j coordinates of all points come from a set X of $O(s)$ values.

Following the proof of Lemma 2 of using a range tree but along the j -th axis, we can reduce problem \mathcal{P}_j to problem \mathcal{P}_{j+1} at the expense of increasing the query and update time by one $O(\log_s n)$ factor.

We solve problem \mathcal{P}_{d-1} directly: Points lie on $O(s^{d-1})$ vertical lines. For each such vertical lines, among the lowest point of each color, we only take the K_0 lowest points, and store all these $O(s^{d-1}K_0)$ points in the micro-structure from Lemma 10.

Thus, the original problem \mathcal{P}_0 can be solved with query and update time

$$\begin{aligned} Q'_{2d-1}(n, k) &= O(Q_{2d-1}(s^{d-1}K_0, k) \cdot (\log_s n)^{d-1}) \\ &= O\left(\log^{d-1}(sK_0) + k \frac{\log k \log^{d+o(1)}(sK_0)}{w} + k\right) \cdot (\log_s n)^{d-1} \\ U'_{2d-1}(n, K) &= O(U_{2d-1}(s^{d-1}K_0, k) \cdot (\log_s n)^{d-1}) = O(\log^{d-1+o(1)}(sK_0)) \cdot (\log_s n)^{d-1}. \end{aligned}$$

Setting $s = 2^{w^{1/d}}$ and recalling that $K_0 \leq 2^{w^{1/d}}$, we obtain $Q'_{2d-1}(n, k) = O(\log^{d-1} n + (k \log k \log^{d-1+o(1)} n)/w^{1-1/d} + k)$ and $U'_{2d-1}(n) = O(\log^{d-1+o(1)} n)$. ◀

We can solve the general uncapped problem by using the color range tree technique in Section 2.3 (invoking the capped structure with K_0 polylogarithmic). The update time is increased by a logarithmic factor:

► **Theorem 12.** *Given n points in a constant dimension d , there is a data structure for colored $(2d-1)$ -sided range reporting with*

- *query time $O(\log^{d-1} n + k \log^{d-2+1/d+o(1)} n)$, and*
- *amortized update time $O(\log^{d+o(1)} n)$.*

Finally, as in Section 2.4, general $(2d)$ -sided queries can be reduced to $(2d-1)$ -sided queries, with another logarithmic-factor increase in the update time:

► **Corollary 13.** *Given n points in a constant dimension d , there is a data structure for colored $(2d-1)$ -sided range reporting with*

- *query time $O(\log^{d-1} n + k \log^{d-2+1/d+o(1)} n)$, and*
- *amortized update time $O(\log^{d+1+o(1)} n)$.*

6 Final Remarks

All the extra $\log^{o(1)} n$ factors are $(\log \log n)^{O(1)}$. In the 2D query time bound of Corollary 4, the $O(\log n)$ first term is likely improvable slightly to $O(\frac{\log n}{\log \log n})$ (to match known lower bounds), by increasing the fan-out from 2 to $\log^\delta n$ in the proof of Lemma 1.

The main open question is whether $O(\text{polylog } n + k)$ query time is achievable with $O(\text{polylog } n)$ update time in 2D.

In higher dimensions, we have not tried to optimize the number of logarithmic factors in the update time, but the ideas in Section 3 should help. A more intriguing question is whether $O(\text{polylog } n + k \log^{d-2-\delta} n)$ query time is achievable with $O(\text{polylog } n)$ update time. Even for the static problem, we do not know how to get $O(\text{polylog } n + k)$ query time with $O(n \text{ polylog } n)$ space; current techniques only give $O(\text{polylog } n + k \log^{d-3} n)$ query time [7].

Abstract

We introduce and study ℓ_p -NORM-MULTIWAY-CUT: the input here is an undirected graph with non-negative edge weights along with k terminals and the goal is to find a partition of the vertex set into k parts each containing exactly one terminal so as to minimize the ℓ_p -norm of the cut values of the parts. This is a unified generalization of min-sum multiway cut (when $p = 1$) and min-max multiway cut (when $p = \infty$), both of which are well-studied classic problems in the graph partitioning literature. We show that ℓ_p -NORM-MULTIWAY-CUT is NP-hard for constant number of terminals and is NP-hard in planar graphs. On the algorithmic side, we design an $O(\log^2 n)$ -approximation for all $p \geq 1$. We also show an integrality gap of $\Omega(k^{1-1/p})$ for a natural convex program and an $O(k^{1-1/p-\epsilon})$ -inapproximability for any constant $\epsilon > 0$ assuming the small set expansion hypothesis.

1 Introduction

MULTIWAY-CUT is a fundamental problem in combinatorial optimization with both theoretical as well as practical motivations. The input here is an undirected graph $G = (V, E)$ with non-negative edge weights $w : E \rightarrow \mathbb{R}_+$ along with k specified terminals $T = \{t_1, t_2, \dots, t_k\} \subseteq V$. The goal is to find a partition $\mathcal{P} = (P_1, P_2, \dots, P_k)$ of the vertex set with $t_i \in P_i$ for each $i \in [k]$ so as to minimize the sum of the cut values of the parts, i.e., the objective is to minimize $\sum_{i=1}^k w(\delta(P_i))$, where $\delta(P_i)$ denotes the set of edges with exactly one end-vertex in P_i and $w(\delta(P_i)) := \sum_{e \in \delta(P_i)} w(e)$. On the practical side, MULTIWAY-CUT has been used to model file-storage in networks as well as partitioning circuit elements among chips – see [14, 22]. On the theoretical side, MULTIWAY-CUT generalizes the min (s, t) -cut problem which is polynomial-time solvable. In contrast to min (s, t) -cut, MULTIWAY-CUT is NP-hard for $k \geq 3$ terminals [14]. The algorithmic study of MULTIWAY-CUT has led to groundbreaking rounding techniques and integrality gap constructions in the field of approximation algorithms [2, 4–7, 12, 16, 17, 21] and novel graph structural techniques in the field of fixed-parameter algorithms [18]. It is known that MULTIWAY-CUT does not admit a $(1.20016 - \epsilon)$ -approximation for any constant $\epsilon > 0$ assuming the Unique Games Conjecture [4] and the currently best known approximation factor is 1.2965 [21].

Motivated by its connections to partitioning and clustering, Svitkina and Tardos [22] introduced a local part-wise min-max objective for MULTIWAY-CUT – we will denote this problem as MIN-MAX-MULTIWAY-CUT: The input here is the same as MULTIWAY-CUT while the goal is to find a partition $\mathcal{P} = (P_1, P_2, \dots, P_k)$ of the vertex set with $t_i \in P_i$ for each $i \in [k]$ so as to minimize $\max_{i=1}^k w(\delta(P_i))$. We note that MULTIWAY-CUT and MIN-MAX-MULTIWAY-CUT differ only in the objective function – the objective function in MULTIWAY-CUT is to minimize

the sum of the cut values of the parts while the objective function in MIN-MAX-MULTIWAY-CUT is to minimize the max of the cut values of the parts. MIN-MAX-MULTIWAY-CUT can be viewed as a fairness inducing multiway cut as it aims to ensure that no part pays too much in cut value. Svitkina and Tardos showed that MIN-MAX-MULTIWAY-CUT is NP-hard for $k \geq 4$ terminals and also that it admits an $O(\log^3 n)$ -approximation. Bansal, Feige, Krauthgamer, Makarychev, Nagarajan, Naor, and Schwartz subsequently improved the approximation factor to $O(\sqrt{\log n \log k})$ (which is $O(\log n)$) [3].

In this work, we study a unified generalization of MULTIWAY-CUT and MIN-MAX-MULTIWAY-CUT that we term as ℓ_p -NORM-MULTIWAY-CUT: In this problem, the input is the same as MULTIWAY-CUT, i.e., we are given an undirected graph $G = (V, E)$ with non-negative edge weights $w : E \rightarrow \mathbb{R}_+$ along with k specified terminal vertices $T = \{t_1, t_2, \dots, t_k\} \subseteq V$. The goal is to find a partition $\mathcal{P} = (P_1, P_2, \dots, P_k)$ of the vertex set with $t_i \in P_i$ for each $i \in [k]$ so as to minimize the ℓ_p -norm of the cut values of the k parts – formally, we would like to minimize

$$\left(\sum_{i=1}^k \left(\sum_{e \in \delta(P_i)} w(e) \right)^p \right)^{\frac{1}{p}}.$$

Throughout, we will consider $p \geq 1$. We note that ℓ_p -NORM-MULTIWAY-CUT for $p = 1$ corresponds to MULTIWAY-CUT and for $p = \infty$ corresponds to MIN-MAX-MULTIWAY-CUT. We emphasize that ℓ_p -NORM-MULTIWAY-CUT could also be viewed as a multiway cut that aims for a stronger notion of fairness than MULTIWAY-CUT but a weaker notion of fairness than MIN-MAX-MULTIWAY-CUT. For $k = 2$ terminals, ℓ_p -NORM-MULTIWAY-CUT reduces to min (s, t) -cut for all $p \geq 1$ and hence, can be solved in polynomial time.

1.1 Our Results

We begin by remarking that there is a fundamental structural difference between MULTIWAY-CUT and ℓ_p -NORM-MULTIWAY-CUT for $p > 1$ (i.e., between $p = 1$ and $p > 1$). The optimal partition to MULTIWAY-CUT satisfies a nice structural property: assuming that the input graph is connected, every part in an optimal partition for MULTIWAY-CUT will induce a connected subgraph. Consequently, MULTIWAY-CUT is also phrased as the problem of deleting a least weight subset of edges so that the resulting graph contains k connected components with exactly one terminal in each component. However, this nice structural property does not hold for ℓ_p -NORM-MULTIWAY-CUT for $p > 1$ as illustrated by the example in Figure 1. We remark that Svitkina and Tardos made a similar observation suggesting that the nice structural property fails for MIN-MAX-MULTIWAY-CUT, i.e., for $p = \infty$ – in contrast, our example in Figure 1 shows that the nice structural property fails to hold for every $p > 1$.

We now discuss our hardness results for ℓ_p -NORM-MULTIWAY-CUT.

► **Theorem 1.** *We have the following hardness results for ℓ_p -NORM-MULTIWAY-CUT.*

1. ℓ_p -NORM-MULTIWAY-CUT is NP-hard for every $p > 1$ and every $k \geq 4$.
2. ℓ_p -NORM-MULTIWAY-CUT in planar graphs is NP-hard for every $p > 1$.

We note that the case of $p = 1$ and $p = \infty$ are already known to be hard: MULTIWAY-CUT is NP-hard for $k = 3$ terminals and is NP-hard in planar graphs when k is arbitrary (i.e., when k is not a fixed constant) [14]; MIN-MAX-MULTIWAY-CUT is NP-hard for $k = 4$ terminals and is NP-hard in trees when k is arbitrary [22]. Our NP-hardness in planar graphs result also requires k to be arbitrary.

■ **Figure 1** An example where the unique optimum partition for ℓ_p -NORM-MULTIWAY-CUT for $k = 5$ induces a disconnected part for every $p > 1$. The edge weights are as shown with $a := 8^{p/(p-1)}$ and the set of terminals is $\{u_1, v_1, v_2, v_3, v_4\}$. A partition that puts u_2 with one of the terminals in $\{v_1, v_2, v_3, v_4\}$ (and isolates the remaining terminals) has ℓ_p -norm objective value $((3a + 3)^p + 3(3a + 2)^p + 4^p)^{1/p}$ and the partition that puts u_2 with u_1 (and isolates the remaining terminals) has ℓ_p -norm objective value $(4(3a + 2)^p + 8^p)^{1/p}$ – the latter is strictly cheaper by the choice of a .

Given that the problem is NP-hard, we focus on designing approximation algorithms. We show the following result:

► **Theorem 2.** *There exists a polynomial-time $O(\log^{1.5} n \log^{0.5} k)$ -approximation for ℓ_p -NORM-MULTIWAY-CUT for every $p \geq 1$, where n is the number of vertices and k is the number of terminals in the input instance.*

We note that our approximation factor is $O(\log^2 n)$ since $k \leq n$. While it might be tempting to design an approximation algorithm by solving a convex programming relaxation for ℓ_p -NORM-MULTIWAY-CUT and rounding it, we rule out this approach: the natural convex programming relaxation has an integrality gap of $\Omega(k^{1-1/p})$ – see Section 4. Hence, our approach for the approximation algorithm is not based on a convex program but instead based on combinatorial techniques.

For comparison, we state the currently best known approximation factors for $p = 1$ and $p = \infty$: MULTIWAY-CUT admits a 1.2965-approximation via an LP-based algorithm [21] and MIN-MAX-MULTIWAY-CUT admits an $O(\sqrt{\log n \log k})$ -approximation based on a bicriteria approximation for the small-set expansion problem [3].

As a final result, we show that removing the dependence on the number n of vertices in the approximation factor of ℓ_p -NORM-MULTIWAY-CUT is hard assuming the small set expansion hypothesis [20]. In particular, we show that achieving a $(k^{1-1/p-\epsilon})$ -approximation for any constant $\epsilon > 0$ is hard. We note that there is a trivial $O(k^{1-1/p})$ -approximation for ℓ_p -NORM-MULTIWAY-CUT.

1.2 Outline of techniques

We briefly outline the techniques underlying our results.

Hardness results

We show hardness of ℓ_p -NORM-MULTIWAY-CUT for $k = 4$ terminals by a reduction from the graph bisection problem. Our main tool to control the ℓ_p -norm objective in our hardness reduction is the Mean Value Theorem and its consequences. In order to show NP-hardness of ℓ_p -NORM-MULTIWAY-CUT in planar graphs, we reduce from the 3-partition problem. We do a gadget based reduction where the gadget is planar. We note that the number of terminals in this reduction is not a constant and is $\Omega(n)$, where n is the number of vertices. Once again, we rely on the Mean Value Theorem and its consequences to control the ℓ_p -norm objective in the reduction. We mention that the starting problems in our hardness reductions are inspired by the hardness results shown by Svitkina and Tardos for MIN-MAX-MULTIWAY-CUT: they showed that MIN-MAX-MULTIWAY-CUT is NP-hard for $k = 4$ terminals by a reduction from the graph bisection problem and that MIN-MAX-MULTIWAY-CUT is NP-hard in trees by a reduction from the 3-partition problem. We also use these same starting problems, but our reductions are more involved owing to the ℓ_p -norm nature of the objective.

Approximation algorithm

For the purposes of the algorithm, we will assume knowledge of the optimum value, say OPT – such a value can be guessed within a factor of 2 via binary search. Our approximation algorithm proceeds in three steps. We describe these three steps now.

In the first step of the algorithm, we obtain a collection \mathcal{S} of subsets of the vertex set satisfying four properties: (1) each set S in the collection \mathcal{S} has at most one terminal, (2) the ℓ_p -norm of the cut values of the sets in the collection raised to the p th power is small, i.e., $\sum_{S \in \mathcal{S}} w(\delta(S))^p = (\beta^p \log n) \text{OPT}^p$ where $\beta = O(\sqrt{\log n \log k})$, (3) the number of sets in the collection \mathcal{S} is $O(k \log n)$, and (4) the union of the sets in the collection \mathcal{S} is V . We perform this first step via a multiplicative updates method. For this, we use a bicriteria approximation algorithm for the unbalanced terminal cut problem which was given by Bansal et al [3] (see Section 2 for a description of the unbalanced terminal cut problem and the bicriteria approximation).

Although property (2) gives a bound on the ℓ_p -norm of the cut values of the sets in the collection \mathcal{S} relative to the optimum, the collection \mathcal{S} does not correspond to a feasible multiway cut: recall that a feasible multiway cut is a partition $\mathcal{P} = (P_1, \dots, P_k)$ of the vertex set where each P_i contains exactly one terminal. The objective of the next two steps is to refine the collection \mathcal{S} to achieve feasibility without blowing up the ℓ_p -norm of the cut values of the parts.

In the second step of the algorithm, we uncross the sets in the collection \mathcal{S} to obtain a partition \mathcal{Q} without increasing the cut values of the sets. We crucially exploit the posimodularity property of the graph cut function to achieve this: posimodularity implies that for all subsets $A, B \subseteq V$ of vertices, either $w(\delta(A)) \geq w(\delta(A - B))$ or $w(\delta(B)) \geq w(\delta(B - A))$. We iteratively consider all pairs of crossing subsets A, B in the collection \mathcal{S} and replace A with $A - B$ if $w(\delta(A)) \geq w(\delta(A - B))$ or replace B with $B - A$ if $w(\delta(B)) \geq w(\delta(B - A))$. The outcome of this step is a partition \mathcal{Q} of the vertex set V satisfying three properties: (i) each part Q in the partition \mathcal{Q} has at most one terminal, (ii) the ℓ_p -norm of the cut values of the parts in the partition \mathcal{Q} raised to the p th power is still small, i.e., $\sum_{Q \in \mathcal{Q}} w(\delta(Q))^p = (\beta^p \log n) \text{OPT}^p$, and (iii) the number of parts in the partition \mathcal{Q} is $O(k \log n)$.

Once again, we observe that the partition \mathcal{Q} at the end of the second step may not correspond to a feasible multiway cut: we could have more than k parts in \mathcal{Q} with some of the parts having no terminals. We address this issue in the third step by a careful aggregation.

For the third step of the algorithm, let Q_i be the part in \mathcal{Q} that contains terminal t_i – we have k such parts by property (i) – and let R_1, \dots, R_t be the remaining parts in \mathcal{Q} that contain no terminals. We will aggregate the remaining parts of \mathcal{Q} into the k parts Q_1, \dots, Q_k without blowing up the ℓ_p -norm of the cut value of the parts. By property (iii), the number of remaining parts t is $O(k \log n)$. We create k disjoint buckets B_1, \dots, B_k where B_i contains the union of $O(\log n)$ many parts among R_1, \dots, R_t . Finally, we merge B_i with Q_i . This results in a partition $\mathcal{P} = (Q_1 \cup B_1, \dots, Q_k \cup B_k)$ of V with terminal t_i being in the i th part $Q_i \cup B_i$. The key now is to control the blow-up in the p th power of the ℓ_p -norm of the cut values of the parts in \mathcal{P} : we bound this by a $O(\log^{p-1} n)$ -factor relative to the p th power of the ℓ_p -norm of the cut values of the parts in \mathcal{Q} via Jensen's inequality; while using Jensen's inequality, we exploit the fact that each bucket contained $O(\log n)$ many parts. Consequently, using property (ii), the ℓ_p -norm objective value of the cut values of the parts in the partition \mathcal{P} raised to the p th power is still small – we show that $\sum_{P \in \mathcal{P}} w(\delta(P))^p = \beta^p \log^p n \text{OPT}^p$ and hence, we have an approximation factor of $O(\beta \log n)$.

The first step of our algorithm is inspired by the $O(\log n)$ -approximation algorithm for MIN-MAX-MULTIWAY-CUT due to Bansal et al [3] – we modify the multiplicative weights update method and adapt it for ℓ_p -NORM-MULTIWAY-CUT. Our second and third steps differ from that of Bansal et al. We mention that the second and third steps of our algorithm can be adapted to achieve an $O(\beta \log n)$ -approximation factor for ℓ_p -NORM-MULTIWAY-CUT for $p = \infty$, but the resulting approximation factor is only $O(\log^2 n)$ which is weaker than the $O(\log n)$ -factor achieved by Bansal et al. The additional loss of $\log n$ -factor in our algorithm comes from the third step (i.e., the aggregation step). The aggregation step designed in [3] is randomized and saves the $\log n$ -factor in expectation, but it does not generalize to ℓ_p -NORM-MULTIWAY-CUT. As mentioned before, the second step of our algorithm relies on posimodularity. The posimodularity property of the graph cut function has been used in previous works for MIN-MAX-MULTIWAY-CUT in an implicit fashion by a careful and somewhat tedious edge counting argument [3, 22]. We circumvent the edge counting argument here by the clean posimodularity abstraction. Moreover, the posimodularity abstraction makes the counting considerably easier for our more general problem of ℓ_p -NORM-MULTIWAY-CUT.

1.3 Related Work

ℓ_p -NORM-MULTIWAY-CUT can be viewed as a fairness inducing objective in the context of multiway partitioning problems. Recent works have proposed and studied various fairness inducing objectives for graph cuts and partitioning that are different from ℓ_p -NORM-MULTIWAY-CUT. We briefly discuss these works here. All of the works mentioned in this subsection consider a more general problem known as *correlation clustering* – we discuss these works by specializing to cut and partitioning problems since these specializations are the ones related to our work.

Puleo and Milenkovic [19] introduced a local vertex-wise min-max objective for min (s, t) -cut – here, the goal is to partition the vertex set V of the given edge-weighted undirected graph into two parts $(S, V \setminus S)$ each containing exactly one of the terminals in $\{s, t\}$ so as to minimize $\max_{v \in V} w(\delta(v) \cap \delta(S))$. The motivation behind this objective is that the cut should be fair to every vertex in the graph, i.e., no vertex should pay a lot for the edges in the cut. A result of Chvátal [13] implies that this problem is $(2 - \epsilon)$ -inapproximable for every constant $\epsilon > 0$. Charikar, Gupta, and Schwartz [10] gave an $O(\sqrt{n})$ -approximation for this problem. Reducing the approximability vs inapproximability gap for this problem remains an intriguing open problem. Kalhan, Makarychev, and Zhou [15] considered an ℓ_p -norm

version of the objective where the goal is to minimize $(\sum_{v \in V} w(\delta(v) \cap \delta(S))^p)^{1/p}$ and gave an $O(n^{\frac{1}{2} - \frac{1}{2p}} \log^{\frac{1}{2} - \frac{1}{2p}} n)$ -approximation, thus interpolating the best known results for $p = 1$ and $p = \infty$.

Ahmadi, Khuller, and Saha [1] introduced a min-max version of multicut: the input consists of an undirected graph $G = (V, E)$ with edge weights $w : E \rightarrow \mathbb{R}_+$ along with source-sink terminal pairs $(s_1, t_1), \dots, (s_k, t_k)$. The goal is to find a partition $\mathcal{P} = (P_1, \dots, P_r)$ of the vertex set with all source-sink pairs separated by the partition so as to minimize $\max_{i \in [r]} w(\delta(P_i))$. We emphasize that the number of parts here – namely, r – is not constrained by the input and hence, could be arbitrary. Ahmadi, Khuller, and Saha gave an $O(\sqrt{\log n \max\{\log k, \log T\}})$ -approximation for this problem, where T is the number of parts in the optimal solution. Kalhan, Makarychev, and Zhou [15] improved the approximation factor to $2 + \epsilon$.

Organization

We begin with preliminaries in Section 2. We present the complete details of our approximation algorithm and prove Theorem 2 in Section 3. We discuss a convex program and its integrality gap in Section 4. Due to space limitations, the proofs of the rest of the results appear in the complete version of this work [9]. We conclude with a few open problems in Section 5.

2 Preliminaries

We start with notations that will be used throughout. Let $G = (V, E)$ be an undirected graph with edge weight function $w : E \rightarrow \mathbb{R}_+$ and vertex weight function $y : V \rightarrow \mathbb{R}_+$. For every subset $S \subseteq V$, we use $\delta_G(S)$ to denote the set of edges that have exactly one end-vertex in S (we will drop the subscript G when the graph is clear from context), and we write $w(\delta(S)) := \sum_{e \in \delta(S)} w(e)$. Moreover, we will use $y(S)$ to refer to $\sum_{v \in S} y(v)$. We will denote an instance of ℓ_p -NORM-MULTIWAY-CUT by (G, w, T) , where $G = (V, E)$ is the input graph, $w : E \rightarrow \mathbb{R}_+$ is the edge weight function, and $T \subseteq V$ is the set of terminal vertices. We will call a partition $\tilde{\mathcal{P}} = (P_1, \dots, P_r)$ of the vertex set to be a multiway cut if $r = k$ and $t_i \in P_i$ for each $i \in [k]$ and denote the ℓ_p -norm of the cut values of the parts (i.e., $(\sum_{i=1}^k w(\delta(P_i))^p)^{1/p}$) as the ℓ_p -norm objective value of the multiway cut $\tilde{\mathcal{P}}$.

We note that the function $\mu : \mathbb{R} \rightarrow \mathbb{R}$ defined by $\mu(x) := x^p$ is convex for every $p \geq 1$. We will use Jensen's inequality as stated below in our approximation algorithm as well as our hardness reductions.

► **Lemma 3** (Jensen). *Let $\mu : \mathbb{R} \rightarrow \mathbb{R}$ be a convex function. For arbitrary $x_1, \dots, x_t \in \mathbb{R}$, we have*

$$\mu\left(\frac{1}{t} \sum_{i=1}^t x_i\right) \leq \frac{1}{t} \sum_{i=1}^t \mu(x_i).$$

Our algorithm relies on the graph cut function being symmetric and submodular. We recall that the graph cut function $f : 2^V \rightarrow \mathbb{R}_+$ is given by $f(S) := w(\delta(S))$ for all $S \subseteq V$. Let $f : 2^V \rightarrow \mathbb{R}_+$ be a set function. The function f is symmetric if $f(S) = f(V \setminus S)$ for all $S \subseteq V$, submodular if $f(A) + f(B) \geq f(A \cap B) + f(A \cup B)$ for all $A, B \subseteq V$, and posimodular if $f(A) + f(B) \geq f(A - B) + f(B - A)$ for all $A, B \subseteq V$. Symmetric submodular functions are also posimodular (see Proposition 4) – this fact has been used implicitly [3, 22] and explicitly [8, 11] before.

► **Proposition 4.** *Symmetric submodular functions are posimodular.*

Proof. Let $f : 2^V \rightarrow \mathbb{R}$ be a symmetric submodular set function on a set V , and let $A, B \subseteq V$ be two arbitrary subsets. Then, we have

$$\begin{aligned} f(A) + f(B) &= f(V - A) + f(B) \geq f((V - A) \cup B) + f((V - A) \cap B) \\ &= f(V - (A - B)) + f(B - A) = f(A - B) + f(B - A). \end{aligned}$$

In the above, the first and last equations follow by symmetry and the inequality follows by submodularity. ◀

Our algorithm for ℓ_p -NORM-MULTIWAY-CUT relies on an intermediate problem, namely the Unbalanced Terminal Cut problem that we introduce now. In Unbalanced Terminal Cut (UTC), the input (G, w, y, τ, T) consists of an undirected graph $G = (V, E)$, an edge weight function $w : E \rightarrow \mathbb{R}_+$, a vertex weight function $y : V \rightarrow \mathbb{R}_+$, a real value $\tau \in [0, 1]$, and a set $T \subseteq V$ of terminal vertices. The goal is to compute

$$\text{UTC}(G, w, y, \tau, T) := \min \{w(\delta(S)) : S \subseteq V, y(S) \geq \tau \cdot y(V), |S \cap T| \leq 1\}.$$

Bansal et al. gave a bicriteria approximation for UTC that is summarized in the theorem below.

► **Theorem 5.** [3] *There exists an algorithm UTC-BICRIT-ALGO that takes as input (G, w, y, τ, T) consisting of an undirected graph $G = (V, E)$, an edge weight function $w : E \rightarrow \mathbb{R}_+$, a vertex weight function $y : V \rightarrow \mathbb{R}_+$, a number $\tau \in [0, 1]$, and a set $T \subseteq V$ of terminal vertices and runs in polynomial time to return a set $S \subseteq V$ such that*

1. $|S \cap T| \leq 1$,
2. $y(S) = \Omega(\tau)y(V)$, and
3. $w(\delta(S)) \leq \alpha \text{UTC}(G, w, y, \tau, T)$, where $\alpha = O(\sqrt{\log n \log(1/\tau)})$ and $n = |V|$.

3 Approximation Algorithm

Let OPT be the optimal ℓ_p -norm objective value of a multiway cut in the given instance. For the purposes of the algorithm, we will assume knowledge of a value D such that $D \geq \text{OPT}^p$ – such a value can be guessed via binary search.

Our approximation algorithm to prove Theorem 2 involves three steps. In the first step of the algorithm, we will obtain a collection \mathcal{S} of $O(k \log n)$ sets whose union is the vertex set V such that each set in the collection has at most one terminal, the cut value of each set is not too large relative to D , and the ℓ_p -norm of the cut values of the sets in the collection is within a $\text{polylog}(n)$ factor of D (see Lemma 6). Although the collection \mathcal{S} has low ℓ_p -norm value relative to D , the collection \mathcal{S} may not be a feasible multiway cut. In the second step of the algorithm, we uncross the sets in the collection \mathcal{S} without increasing the ℓ_p -norm of the cut values of the sets in the collection (see Lemma 10). After uncrossing, we obtain a partition, but we could have more than k sets. We address this in our third step, where we aggregate parts to ensure that we obtain exactly k parts (see Lemma 11). We rely on Jensen's inequality to ensure that the aggregation does not blow-up the ℓ_p -norm of the cut values of the sets in the partition.

We begin with the first step of the algorithm in Lemma 6.

► **Lemma 6.** *There exists an algorithm that takes as input an undirected graph $G = (V, E)$, an edge weight function $w : E \rightarrow \mathbb{R}_+$, k distinct terminal vertices $T := \{t_1, \dots, t_k\} \subseteq V$ and a value $D > 0$ such that there exists a partition (P_1^*, \dots, P_k^*) of V with $t_i \in P_i^*$ for all $i \in [k]$ and $\sum_{i=1}^k w(\delta(P_i^*))^p \leq D$, and runs in polynomial time to return a collection of sets $\mathcal{S} \subseteq 2^V$ that satisfies the following:*

29:8 ℓ_p -Norm Multiway Cut

1. $|S \cap T| \leq 1$ and $w(\delta(S)) \leq \beta(2D)^{1/p}$ for every $S \in \mathcal{S}$,
 2. $\sum_{S \in \mathcal{S}} w(\delta(S))^p = \beta^p(\log n)D$, and
 3. $|\mathcal{S}| = O(k \log n)$ and $|\{S \in \mathcal{S} : v \in S\}| \geq \log n$ for each $v \in V$,
- where $\beta = O(\sqrt{\log n \log k})$.

Proof. We will use Algorithm 1 to obtain the desired collection \mathcal{S} . We will show the correctness of Algorithm 1 based on Claims 7, 8 and 9.

■ **Algorithm 1** Multiplicative weights update.

```

Initialize  $t \leftarrow 1$ ,  $\mathcal{S} \leftarrow \emptyset$ ,  $y^1(v) = 1$  for each  $v \in V$ ,  $Y^1 = \sum_{v \in V} y^1(v)$  and
 $\beta = O(\sqrt{\log n \log k})$ 
while  $Y^t > \frac{1}{n}$  do
  for  $i = 1, 2, \dots, \log(2k)$  do
    Execute UTC-BICRIT-ALGO( $G, w, y^t, 2^{-i}, T$ ) to obtain a subset  $S^t(i) \subseteq V$ 
    if  $w(\delta(S^t(i))) \leq \beta(\frac{4D}{2^i})^{1/p}$  then
      Set  $S^t = S^t(i)$  and BREAK
    end if
  end for
   $\mathcal{S} \leftarrow \mathcal{S} \cup \{S^t\}$ .
  for  $v \in V$  do
    Set  $y^{t+1}(v) = \begin{cases} y^t(v)/2 & \text{if } v \in S^t, \\ y^t(v) & \text{if } v \in V \setminus S^t. \end{cases}$ 
  end for
  Set  $Y^{t+1} = \sum_{v \in V} y^{t+1}(v)$ .
  Set  $t \leftarrow t + 1$ .
end while
Return  $\mathcal{S}$ 

```

Our first claim will help in showing that the set S^t added in each iteration of the while loop satisfies certain nice properties.

▷ **Claim 7.** For every iteration t of the while loop of Algorithm 1, there exists $i \in \{1, 2, \dots, \log(2k)\}$ such that the set $S^t(i)$ satisfies the following conditions:

1. $|S^t(i) \cap T| \leq 1$,
2. $y^t(S^t(i)) = \Omega(\frac{Y^t}{2^i})$, and
3. $w(\delta(S^t(i))) \leq \beta(\frac{4D}{2^i})^{1/p}$.

Proof. We have that $\sum_{i=1}^k y^t(P_i^*) = y^t(V)$ and

$$\sum_{i=1}^k w(\delta(P_i^*))^p \leq D.$$

Let L be the subset of indices of parts for which the cut value is relatively low:

$$L := \left\{ j \in [k] : w(\delta(P_j^*))^p \leq \frac{2y^t(P_j^*)}{Y^t} \cdot D \right\}.$$

It follows that

$$\sum_{j \in [k] \setminus L} y^t(P_j^*) < \sum_{j \in [k] \setminus L} \frac{w(\delta(P_j^*))^p Y^t}{2D} \leq \frac{Y^t}{2}$$

and hence,

$$\sum_{j \in L} y^t(P_j^*) = Y^t - \sum_{j \in [k] \setminus L} y^t(P_j^*) > Y^t - \frac{Y^t}{2} = \frac{Y^t}{2}.$$

Since $|L| \leq k$, there exists an index $q \in L$ such that $y^t(P_q^*) > Y^t/(2k)$. Let us fix i_0 to be an integer such that $y^t(P_q^*) \in (Y^t \cdot 2^{-i_0}, Y^t \cdot 2^{-i_0+1}]$. Then, we must have $i_0 \leq \log(2k)$. We note that the set P_q^* satisfies $|P_q^* \cap T| = 1$ and $y^t(P_q^*) > Y^t/(2k) = y^t(V)/(2k)$. This implies P_q^* is feasible to the UTC problem on input $(G, w, y^t, 1/2^{i_0}, T)$. Therefore, according to Theorem 5, the set $S^t(i_0)$ has the following properties: Firstly, $|S^t(i_0) \cap T| \leq 1$. Secondly, $y^t(S^t(i_0)) = \Omega(1/2^{i_0})y^t(V) = \Omega(Y^t/2^{i_0})$. Finally,

$$\begin{aligned} w(\delta(S^t(i_0))) &= O(\sqrt{\log n \log(2k)}) \cdot \text{UTC}\left(G, w, y^t, \frac{1}{2^{i_0}}, T\right) \\ &= O(\sqrt{\log n \log k}) \cdot w(\delta(P_q^*)) \\ &= O(\sqrt{\log n \log k}) \cdot \left(\frac{2y^t(P_q^*)}{Y^t} \cdot D\right)^{\frac{1}{p}} \\ &= O(\sqrt{\log n \log k}) \cdot \left(\frac{2 \cdot Y^t \cdot 2^{-i_0+1}}{Y^t} \cdot D\right)^{\frac{1}{p}} \\ &= O(\sqrt{\log n \log k}) \cdot \left(\frac{4D}{2^{i_0}}\right)^{\frac{1}{p}}. \end{aligned}$$

This completes the proof of Claim 7. \triangleleft

For the rest of the proof, we will use the following notation: In the t 'th iteration of the while loop of Algorithm 1, we will fix $i_t \in \{1, 2, \dots, \log(2k)\}$ to be the integer such that $S^t = S^t(i_t)$. We will use ℓ to denote the total number of iterations of the while loop. For each $v \in V$, We define $N_v := |\{t \in [\ell] : v \in S^t\}|$ to be the number of sets in the collection \mathcal{S} that contain the vertex v .

We observe that for each $v \in V$, we have $y^{\ell+1}(v) = 2^{-N_v}$. Claim 7 and Theorem 5 together imply that the t 'th iteration of the while loop leads to a set S^t being added to the collection \mathcal{S} such that

1. $|S^t \cap T| \leq 1$,
2. $y^t(S^t) = \Omega(\frac{Y^t}{2^{i_t}})$, and
3. $w(\delta(S^t)) \leq \beta(\frac{4D}{2^{i_t}})^{1/p}$.

Our next claim shows that the number of iterations of the while loop executed in Algorithm 1 is small. Moreover, the union of the sets in the collection \mathcal{S} is the vertex set V .

\triangleright **Claim 8.** The number of iterations ℓ of the while loop satisfies $\ell = O(k \log n)$. Moreover, $N_v \geq \log n$ for each $v \in V$.

Proof. Upon termination of Algorithm 1, we must have $Y^{\ell+1} \leq 1/n$. Combining with the earlier observation that $y^{\ell+1}(v) = 2^{-N_v}$ for every $v \in V$, we have that

$$2^{-N_v} = y^{\ell+1}(v) \leq Y^{\ell+1} \leq \frac{1}{n},$$

which implies that $N_v \geq \log n$ for every $v \in V$.

29:10 ℓ_p -Norm Multiway Cut

It remains to show that $\ell = O(k \log n)$. Consider the t th iteration of the while loop for an arbitrary $t \in [\ell]$. By property 2 of the set S^t stated above, we have that $y^t(S^t) \geq cY^t/2^{i_t} \geq cY^t/(2k)$ for some constant $c > 0$. Consequently,

$$Y^{t+1} = Y^t - \frac{y^t(S^t)}{2} \leq Y^t - \frac{cY^t}{4k} = \left(1 - \frac{c}{4k}\right) Y^t.$$

Due to the termination condition of the while loop, we know that $Y^\ell > 1/n$. Hence,

$$\frac{1}{n} < Y^\ell \leq \left(1 - \frac{c}{4k}\right)^{\ell-1} Y^1 = \left(1 - \frac{c}{4k}\right)^{\ell-1} n \leq \exp\left(-\frac{c(\ell-1)}{4k}\right) n.$$

Therefore, $\frac{c(\ell-1)}{4k} = O(\log n)$ which implies that $\ell = O(k \log n)$. This completes the proof of Claim 8. \triangleleft

The next claim bounds the ℓ_p -norm of the cut values of the sets in the collection \mathcal{S} .

\triangleright **Claim 9.** The collection \mathcal{S} returned by Algorithm 1 satisfies $\sum_{S \in \mathcal{S}} w(\delta(S))^p = O(\beta^p \log n) \cdot D$.

Proof. Consider the t th iteration of the while loop for an arbitrary $t \in [\ell]$. By property 3 of the set S^t stated above, we have that $w(\delta(S^t)) \leq \beta(4D/2^{i_t})^{1/p}$ and consequently, $2^{i_t} \leq 4D\beta^p \cdot w(\delta(S^t))^{-p}$. Moreover, by property 2 of the set S^t stated above, we have that $y^t(S^t) \geq cY^t/2^{i_t}$ for some constant $c > 0$. Hence,

$$y^t(S^t) \geq \frac{cY^t}{2^{i_t}} \geq \frac{cY^t \cdot w(\delta(S^t))^p}{\beta^p \cdot 4D}.$$

Therefore,

$$Y^{t+1} = Y^t - \frac{y^t(S^t)}{2} \leq \left(1 - \frac{c \cdot w(\delta(S^t))^p}{\beta^p \cdot 8D}\right) Y^t.$$

Using the fact that $Y^\ell > 1/n$, we observe that

$$\begin{aligned} \frac{1}{n} < Y^\ell &\leq Y^1 \cdot \prod_{t=1}^{\ell-1} \left(1 - \frac{c \cdot w(\delta(S^t))^p}{\beta^p \cdot 8D}\right) = n \cdot \prod_{t=1}^{\ell-1} \left(1 - \frac{c \cdot w(\delta(S^t))^p}{\beta^p \cdot 8D}\right) \\ &\leq n \cdot \prod_{i=1}^{\ell-1} \exp\left(-\frac{c \cdot w(\delta(S^t))^p}{\beta^p \cdot 8D}\right) = n \cdot \exp\left(-\frac{c \cdot \sum_{i=1}^{\ell-1} w(\delta(S^t))^p}{\beta^p \cdot 8D}\right). \end{aligned}$$

This implies that $\frac{c \cdot \sum_{i=1}^{\ell-1} w(\delta(S^t))^p}{\beta^p \cdot 8D} = O(\log n)$, and hence $\sum_{i=1}^{\ell-1} w(\delta(S^t))^p = O(\beta^p \log n) \cdot D$.

In the ℓ 'th iteration of the while loop, we have $w(\delta(S^\ell)) \leq \beta(4D/2^{i_\ell})^{1/p}$ by property 3 of the set S^t stated above and hence $w(\delta(S^\ell))^p \leq \beta^p \cdot 4D/2^{i_\ell} \leq O(\beta^p D)$. Consequently, $\sum_{i=1}^{\ell} w(\delta(S^t))^p = O(\beta^p \log n) \cdot D$. This completes the proof of Claim 9. \triangleleft

We now show correctness of our algorithm to complete the proof of Lemma 6. Firstly, we note that every $S \in \mathcal{S}$ satisfies $|S \cap T| \leq 1$ by property 1 of the set S^t stated above. Moreover, we have $w(\delta(S)) \leq \beta(4D/2^{i_t})^{1/p} \leq \beta(2D)^{1/p}$, which implies conclusion 1 in Lemma 6. Secondly, Conclusion 2 in Lemma 6 is implied by Claim 9. Finally, conclusion 3 of Lemma 6 is implied by Claim 8 because each iteration of the while loop adds exactly one new set to the collection \mathcal{S} .

We now bound the run time of Algorithm 1. Each iteration of the while loop takes polynomial time due to Theorem 5, and the number of iterations of the while loop is $O(k \log n)$. This implies that the total run time of Algorithm 1 is indeed polynomial in the size of the input. \blacktriangleleft

The collection \mathcal{S} that we obtain in Lemma 6 may not be a partition. Our next lemma will uncross the collection \mathcal{S} obtained from Lemma 6 to obtain a partition without increasing the cut values of the sets.

► **Lemma 10.** *There exists an algorithm that takes as input a collection $\mathcal{S} \subseteq 2^V$ of subsets of vertices satisfying the conclusions in Lemma 6 and runs in polynomial time to return a partition $\tilde{\mathcal{Q}}$ of V such that*

1. $|Q \cap T| \leq 1$ for each $Q \in \tilde{\mathcal{Q}}$,
2. $\sum_{Q \in \tilde{\mathcal{Q}}} w(\delta(Q))^p \leq \sum_{S \in \mathcal{S}} w(\delta(S))^p$, and
3. the number of parts in $\tilde{\mathcal{Q}}$ is $O(k \log n)$.

Proof. For convenience, we will define $f : 2^V \rightarrow \mathbb{R}_+$ by $f(S) := w(\delta(S))$ for all $S \subseteq V$. We will use Algorithm 2 to obtain the desired partition $\tilde{\mathcal{Q}}$ of V .

■ **Algorithm 2** Uncrossing.

```

Initialize  $\tilde{\mathcal{Q}} \leftarrow \mathcal{S}$ 
while there exist distinct sets  $A, B \in \tilde{\mathcal{Q}}$  such that  $A \cap B \neq \emptyset$  do
    if  $f(A) \geq f(A - B)$  then
        Set  $A \leftarrow A - B$ 
    else
        Set  $B \leftarrow B - A$ 
    end if
end while
Return  $\tilde{\mathcal{Q}}$ 

```

We now prove the correctness of Algorithm 2. We begin by observing that Algorithm 2 indeed outputs a partition of the vertex set: Firstly, the while loop enforces that the output $\tilde{\mathcal{Q}}$ satisfies $A \cap B = \emptyset$ for all distinct $A, B \in \tilde{\mathcal{Q}}$. Secondly, during each iteration of the while loop, the set $\bigcup_{Q \in \tilde{\mathcal{Q}}} Q$ remains unchanged: In the iteration of the while loop that uncrosses $A, B \in \tilde{\mathcal{Q}}$, let A' and B' denote the updated sets at the end of the while loop, respectively. Then we must have $A' \cup B' = (A - B) \cup B = A \cup B$ or $A' \cup B' = A \cup (B - A) = A \cup B$. In either case, since $A' \cup B' = A \cup B$, the set $\bigcup_{Q \in \tilde{\mathcal{Q}}} Q$ remains unchanged after the update. Therefore, we have $\bigcup_{Q \in \tilde{\mathcal{Q}}} Q = \bigcup_{S \in \mathcal{S}} S$. We recall that $\bigcup_{S \in \mathcal{S}} S = V$ by conclusion 3 of Lemma 6. Hence, $\tilde{\mathcal{Q}}$ is indeed a partition of V .

Furthermore, each set Q in the output $\tilde{\mathcal{Q}}$ is a subset of some set $S \in \mathcal{S}$. This implies $|Q \cap T| \leq |S \cap T| \leq 1$, thus proving the first conclusion.

To prove the second conclusion, we use posimodularity of f as shown in Proposition 4. Namely, for every $A, B \subseteq V$,

$$f(A) + f(B) \geq f(A - B) + f(B - A).$$

Therefore, at least one of the following two hold: either $f(A) \geq f(A - B)$ or $f(B) \geq f(B - A)$. This implies that, by the choice of the algorithm, $\sum_{Q \in \tilde{\mathcal{Q}}} f(Q)^p$ does not increase.

To see the third conclusion, we note that after each iteration of the while loop, the size of $\tilde{\mathcal{Q}}$ is unchanged. Therefore, at the end Algorithm 2, we have $|\tilde{\mathcal{Q}}| = |\mathcal{S}| = O(k \log n)$ by Lemma 6.

Finally, we bound the run time as follows. At initialization, there are $O((k \log n)^2)$ pairs $(A, B) \in \tilde{\mathcal{Q}}^2$ such that $A \cap B \neq \emptyset$. After each iteration of the while loop, the number of such pairs decreases by at least 1. Therefore, the total number of iterations of the while loop is $O((k \log n)^2)$. Hence, Algorithm 2 indeed runs in polynomial time. ◀

The partition $\tilde{\mathcal{Q}}$ that we obtain in Lemma 10 may contain more than k parts and hence, some of the parts may not contain any terminals. Our next lemma will aggregate the parts in $\tilde{\mathcal{Q}}$ from Lemma 10 to obtain a k -partition that contains exactly one terminal in each part while controlling the increase in the ℓ_p -norm of the cut value of the parts.

► **Lemma 11.** *There exists an algorithm that takes as input a partition $\tilde{\mathcal{Q}}$ of V satisfying the conclusions in Lemma 10 and runs in polynomial time to return a partition (P_1, P_2, \dots, P_k) of V such that*

1. $t_i \in P_i$ for each $i \in [k]$, and
2. $\sum_{i=1}^k w(\delta(P_i))^p = O((\beta \log n)^p) \cdot D$.

Proof. We will use Algorithm 3 on input $\tilde{\mathcal{P}}$ to obtain the desired partition.

■ **Algorithm 3** Aggregating.

Let $\mathcal{F} = \{Q \in \tilde{\mathcal{Q}} : Q \cap T = \emptyset\}$.

Let $\mathcal{P}' = \{Q \in \tilde{\mathcal{Q}} : Q \cap T \neq \emptyset\} = \{Q'_1, \dots, Q'_k\}$, where $t_i \in Q'_i$ for each $i \in [k]$.

Partition the sets in \mathcal{F} into k buckets B_1, \dots, B_k such that $|B_i| = O(\log n)$ for each $i \in [k]$ (arbitrarily).

for $i = 1, 2, \dots, k$ **do**

Set $P_i \leftarrow Q'_i \cup (\bigcup_{A \in B_i} A)$

end for

Return (P_1, \dots, P_k) .

The run time of Algorithm 3 is linear in its input size. We now argue the correctness. We note that the third step in Algorithm 3 is possible because $|\mathcal{F}| \leq |\tilde{\mathcal{Q}}| = O(k \log n)$.

Since $|Q \cap T| \leq 1$ for each $Q \in \tilde{\mathcal{Q}}$, the tuple (P_1, \dots, P_k) returned by Algorithm 3 is indeed a partition of V satisfying $t_i \in P_i$ for all $i \in [k]$. We will now bound $\sum_{i=1}^k f(P_i)^p$, where $f : 2^V \rightarrow \mathbb{R}_+$ is given by $f(S) := w(\delta(S))$ for all $S \subseteq V$. We have that

$$\sum_{i=1}^k f(P_i)^p = \sum_{i=1}^k f\left(Q'_i \cup \left(\bigcup_{A \in B_i} A\right)\right)^p \leq \sum_{i=1}^k \left(f(Q'_i) + \sum_{A \in B_i} f(A)\right)^p.$$

Since the number of sets in B_i is $O(\log n)$, we have the following using Jensen's inequality (Lemma 3) for each $i \in [k]$:

$$\begin{aligned} \left(f(Q'_i) + \sum_{A \in B_i} f(A)\right)^p &\leq (|B_i| + 1)^{p-1} \left(f(Q'_i)^p + \sum_{A \in B_i} f(A)^p\right) \\ &= O(\log^{p-1} n) \left(f(Q'_i)^p + \sum_{A \in B_i} f(A)^p\right). \end{aligned}$$

Hence,

$$\begin{aligned} \sum_{i=1}^k f(P_i)^p &= \sum_{i=1}^k O(\log^{p-1} n) \left(f(Q'_i)^p + \sum_{A \in B_i} f(A)^p\right) = O(\log^{p-1} n) \sum_{Q \in \tilde{\mathcal{Q}}} f(Q)^p \\ &= O(\log^{p-1} n) \sum_{S \in \mathcal{S}} f(S)^p = \beta^p O(\log^p n) D. \end{aligned}$$

The last but one equality above is due to conclusion 2 of Lemma 10bbb and the last equality is due to conclusion 2 of Lemma 6. Hence, $\sum_{i=1}^k w(\delta(P_i))^p = \sum_{i=1}^k f(P_i)^p = O((\beta \log n)^p) D$. ◀

Lemmas 6, 10, and 11 together lead to an algorithm that takes as input an undirected graph $G = (V, E)$, an edge weight function $w : E \rightarrow \mathbb{R}_+$, k distinct terminal vertices $T := \{t_1, \dots, t_k\} \subseteq V$, and a value $D > 0$ such that there exists a partition (P_1^*, \dots, P_k^*) of V with $t_i \in P_i^*$ for all $i \in [k]$ such that $\sum_{i=1}^k w(\delta(P_i^*))^p \leq D$, and runs in polynomial time to return a multiway cut $\mathcal{P} = (P_1, \dots, P_k)$ such that

$$\left(\sum_{i=1}^k w(\delta(P_i))^p \right)^{\frac{1}{p}} = (O((\beta \log n)^p D))^{\frac{1}{p}} = O(\beta \log n) D^{\frac{1}{p}} = O(\log^{1.5} n \log^{0.5} k) D^{\frac{1}{p}}.$$

In order to prove Theorem 2, we may use binary search to guess $D \in [\text{OPT}^p, (2\text{OPT})^p]$ and run the above algorithm to obtain a multiway cut $\mathcal{P} = (P_1, \dots, P_k)$ such that

$$\left(\sum_{i=1}^k w(\delta(P_i))^p \right)^{\frac{1}{p}} = O(\log^{1.5} n \log^{0.5} k) D^{\frac{1}{p}} = O(\log^{1.5} n \log^{0.5} k) \text{OPT}.$$

This completes the proof of Theorem 2.

4 Convex program and integrality gap

The following is a natural convex programming relaxation for ℓ_p -NORM-MULTIWAY-CUT on instance (G, w, T) where $T = \{t_1, \dots, t_k\}$ are the terminal vertices (the objective function can be convexified by introducing additional variables and constraints):

$$\begin{aligned} & \text{Minimize} \quad \left(\sum_{i=1}^k \left(\sum_{uv \in E} w(uv) \cdot |x(u, i) - x(v, i)| \right)^p \right)^{1/p} \quad \text{subject to} \\ & \sum_{i=1}^k x(v, i) = 1 \quad \forall v \in V, \\ & x(t_i, i) = 1 \quad \forall i \in [k], \\ & x(v, i) \geq 0 \quad \forall v \in V, \forall i \in [k]. \end{aligned} \tag{1}$$

► **Lemma 12.** *The convex program in (1) has an integrality gap of at least $k^{1-1/p}/2$.*

Proof. Consider the star graph that has k leaves $\{t_1, \dots, t_k\}$ and a center vertex v with all edge weights being 1. Let the terminal vertices be the k leaves. The optimum ℓ_p -norm objective value of a multiway cut is

$$((k-1)^p + k - 1)^{\frac{1}{p}},$$

and it corresponds to the partition $(\{t_1, v\}, \{t_2\}, \{t_3\}, \dots, \{t_k\})$. A feasible solution to the convex program (1) is given by $x(v, i) = 1/k$ for all $i \in [k]$, which yields an objective of

$$\left(k \cdot \left(\frac{k-1}{k} + (k-1) \cdot \frac{1}{k} \right)^p \right)^{\frac{1}{p}} = \frac{2k-2}{k} \cdot k^{\frac{1}{p}}.$$

This results in an integrality gap of at least

$$\frac{((k-1)^p + k - 1)^{\frac{1}{p}}}{\frac{2k-2}{k} \cdot k^{\frac{1}{p}}} \geq \frac{k-1}{\frac{2k-2}{k} \cdot k^{\frac{1}{p}}} = \frac{k^{1-\frac{1}{p}}}{2}. \quad \blacktriangleleft$$

Bansal et al. give an SDP relaxation for MIN-MAX-MULTIWAY-CUT and show that the star graph has an integrality gap of $\Omega(k)$ for this SDP relaxation. This SDP relaxation can be generalized in a natural fashion to ℓ_p -NORM-MULTIWAY-CUT. The star graph still exhibits an integrality gap of $\Omega(k^{1-1/p})$ for the generalized SDP relaxation for ℓ_p -NORM-MULTIWAY-CUT.

5 Conclusion

In this work, we introduced ℓ_p -NORM-MULTIWAY-CUT for $p \geq 1$ as a unified generalization of MULTIWAY-CUT and MIN-MAX-MULTIWAY-CUT. We showed that ℓ_p -NORM-MULTIWAY-CUT is NP-hard for constant number of terminals or in planar graphs for every $p \geq 1$. The natural convex program for ℓ_p -NORM-MULTIWAY-CUT has an integrality gap of $\Omega(k^{1-1/p})$ and the problem is $(k^{1-1/p-\epsilon})$ -inapproximable for any constant $\epsilon > 0$ assuming the small set expansion hypothesis, where k is the number of terminals in the input instance. The inapproximability result suggests that a dependence on n in the approximation factor is unavoidable if we would like to obtain an approximation factor that is better than the trivial $O(k^{1-1/p})$ -factor. On the algorithmic side, we gave an $O(\sqrt{\log^3 n \log k})$ -approximation (i.e., an $O(\log^2 n)$ -approximation), where n is the number of vertices in the input graph. Our results suggest that the approximability behaviour of ℓ_p -NORM-MULTIWAY-CUT exhibits a sharp transition from $p = 1$ to $p > 1$. Our work raises several open questions. We mention a couple of them: (1) Can we achieve an $O(\log n)$ -approximation for ℓ_p -NORM-MULTIWAY-CUT for every $p \geq 1$? We recall that when $p = \infty$, the current best approximation factor is indeed $O(\log n)$ [3]. (2) Is there a polynomial-time algorithm for ℓ_p -NORM-MULTIWAY-CUT for any given p that achieves an approximation factor that smoothly interpolates between the best possible approximation for $p = 1$ and the best possible approximation for $p = \infty$ – e.g., is there an $O(\log^{1-1/p} n)$ -approximation?

Abstract

In the classic longest common substring (LCS) problem, we are given two strings S and T , each of length at most n , over an alphabet of size σ , and we are asked to find a longest string occurring as a fragment of both S and T . Weiner, in his seminal paper that introduced the suffix tree, presented an $\mathcal{O}(n \log \sigma)$ -time algorithm for this problem [SWAT 1973]. For polynomially-bounded integer alphabets, the linear-time construction of suffix trees by Farach yielded an $\mathcal{O}(n)$ -time algorithm for the LCS problem [FOCS 1997]. However, for small alphabets, this is not necessarily optimal for the LCS problem in the word RAM model of computation, in which the strings can be stored in $\mathcal{O}(n \log \sigma / \log n)$ space and read in $\mathcal{O}(n \log \sigma / \log n)$ time. We show that, in this model, we can compute an LCS in time $\mathcal{O}(n \log \sigma / \sqrt{\log n})$, which is sublinear in n if $\sigma = 2^{o(\sqrt{\log n})}$ (in particular, if $\sigma = \mathcal{O}(1)$), using optimal space $\mathcal{O}(n \log \sigma / \log n)$.

We then lift our ideas to the problem of computing a k -mismatch LCS, which has received considerable attention in recent years. In this problem, the aim is to compute a longest substring of S that occurs in T with at most k mismatches. Flouri et al. showed how to compute a 1-mismatch LCS in $\mathcal{O}(n \log n)$ time [IPL 2015]. Thankachan et al. extended this result to computing a k -mismatch LCS in $\mathcal{O}(n \log^k n)$ time for $k = \mathcal{O}(1)$ [J. Comput. Biol. 2016]. We show an $\mathcal{O}(n \log^{k-1/2} n)$ -time algorithm, for any constant integer $k > 0$ and *irrespective* of the alphabet size, using $\mathcal{O}(n)$ space as the previous approaches. We thus notably break through the well-known $n \log^k n$ barrier, which stems from a recursive heavy-path decomposition technique that was first introduced in the seminal paper of Cole et al. [STOC 2004] for string indexing with k errors.

1 Introduction

In the classic longest common substring (LCS) problem, we are given two strings S and T , each of length at most n , over an alphabet of size σ , and we are asked to find a longest string occurring as a fragment of both S and T . The problem was conjectured by Knuth to require $\Omega(n \log n)$ time until Weiner, in his seminal paper introducing the suffix tree [62], showed that the LCS problem can be solved in $\mathcal{O}(n)$ time when σ is constant via constructing the suffix tree of string $S\#T$, for a sentinel letter $\#$. Later, Farach showed that if σ is not constant, the suffix tree can be constructed in linear time in addition to the time required for sorting its letters [33]. This yielded an $\mathcal{O}(n)$ -time algorithm for the LCS problem in the word RAM model for polynomially-bounded integer alphabets. While Farach's algorithm for suffix tree construction is *optimal* for all alphabets (the suffix tree by definition has size $\Theta(n)$), the same does not hold for the LCS problem. We were thus motivated to answer the following basic question:

Can the LCS problem be solved in $o(n)$ time when $\log \sigma = o(\log n)$?

We consider the word RAM model and assume an alphabet $[0, \sigma)$. Any string of length n can then be stored in $\mathcal{O}(n \log \sigma / \log n)$ space and read in $\mathcal{O}(n \log \sigma / \log n)$ time. Note that if $\log \sigma = \Theta(\log n)$, one requires $\Theta(n)$ time to read the input. We answer this basic question positively when $\log \sigma = o(\sqrt{\log n})$:

► **Theorem 1.** *Given two strings S and T , each of length at most n , over an alphabet $[0, \sigma)$, we can solve the LCS problem in $\mathcal{O}(n \log \sigma / \sqrt{\log n})$ time using $\mathcal{O}(n / \log_\sigma n)$ space.*

We also consider the following generalisation of the LCS problem that allows mismatches.

k -MISMATCH LONGEST COMMON SUBSTRING (k -LCS)

Input: Two strings S and T , each of length at most n , over an integer alphabet and an integer $k > 0$.

Output: A pair S', T' of substrings of S and T , respectively, with Hamming distance (i.e., number of mismatches) at most k and maximal length.

Flouri et al. presented an $\mathcal{O}(n \log n)$ -time algorithm for the 1-LCS problem [35]. (Earlier work on this problem includes [6].) This was generalised by Thankachan et al. [59] to an algorithm for the k -LCS problem that works in $\mathcal{O}(n \log^k n)$ time if $k = \mathcal{O}(1)$. Both algorithms use $\mathcal{O}(n)$ space. In [24], Charalampopoulos et al. presented an $\mathcal{O}(n + n \log^{k+1} n / \sqrt{\ell})$ -time algorithm for k -LCS with $k = \mathcal{O}(1)$, where ℓ is the length of a k -LCS. For general k , Flouri et al. presented an $\mathcal{O}(n^2)$ -time algorithm that uses $\mathcal{O}(1)$ additional space [35]. Grabowski [40] presented two algorithms with running times $\mathcal{O}(n((k+1)(\ell_0+1))^k)$ and $\mathcal{O}(n^2 k / \ell_k)$, where ℓ_0 and ℓ_k are, respectively, the length of an LCS of S and T and the length of a k -LCS of S and T . Abboud et al. [1] employed the polynomial method to obtain a $k^{1.5} n^2 / 2^{\Omega(\sqrt{\log n/k})}$ -time randomised algorithm. In [49], Kociumaka et al. showed that, assuming the Strong Exponential Time Hypothesis (SETH) [45, 46], no strongly subquadratic-time solution for k -LCS exists for $k = \Omega(\log n)$. The authors of [49] additionally presented a subquadratic-time 2-approximation algorithm for k -LCS for general k .

Analogously to Weiner's solution to the LCS problem via suffix trees, the algorithm of Thankachan et al. [59] builds upon the ideas of the k -errata tree, which was introduced by Cole et al. [29] in their seminal paper for indexing a string of length n with the aim of answering pattern matching queries with up to k mismatches. For constant k , the size of the k -errata tree is $\mathcal{O}(n \log^k n)$. (Note that computing a k -LCS using the k -errata tree directly is not straightforward as opposed to computing an LCS using the suffix tree.)

We show the following result, breaking through the $n \log^k n$ barrier, for any constant integer $k > 0$ and irrespective of the alphabet size. Recall that, in the word RAM, the letters of S and T can be renumbered in $\mathcal{O}(n \log \log n)$ time [42] so that they belong to $[0, \sigma)$.

► **Theorem 2.** *Given two strings S and T , each of length at most n , over an integer alphabet and a constant integer $k > 0$, the k -LCS problem can be solved in $\mathcal{O}(n \log^{k-1/2} n)$ time using $\mathcal{O}(n)$ space.*

Notably, on the way to proving the above theorem, we improve upon [24] by showing an $\mathcal{O}(n + n \log^{k+1} n / \ell)$ -time algorithm for k -LCS with $k = \mathcal{O}(1)$, where ℓ is the length of a k -LCS. (Our second summand is smaller by a $\sqrt{\ell}$ multiplicative factor compared to [24].)

Our Techniques

At the heart of our approaches lies the following TWO STRING FAMILIES LCP PROBLEM. (Here, the length of the longest common prefix of two strings U and V is denoted by $\text{LCP}(U, V)$; see Preliminaries for a precise definition of compacted tries.)

TWO STRING FAMILIES LCP PROBLEM

Input: Compacted tries $\mathcal{T}(\mathcal{F}_1), \mathcal{T}(\mathcal{F}_2)$ of $\mathcal{F}_1, \mathcal{F}_2 \subseteq \Sigma^*$ and two sets $\mathcal{P}, \mathcal{Q} \subseteq \mathcal{F}_1 \times \mathcal{F}_2$, with $|\mathcal{P}|, |\mathcal{Q}|, |\mathcal{F}_1|, |\mathcal{F}_2| \leq N$.

Output: The value

$$\text{maxPairLCP}(\mathcal{P}, \mathcal{Q}) = \max\{\text{LCP}(P_1, Q_1) + \text{LCP}(P_2, Q_2) : (P_1, P_2) \in \mathcal{P}, (Q_1, Q_2) \in \mathcal{Q}\}.$$

This abstract problem was introduced in [24]. Its solution, shown in the lemma below, is directly based on a technique that was used in [19, 31] and then in [35] to devise an $\mathcal{O}(n \log n)$ -time solution for 1-LCS. In particular, Lemma 3 immediately implies an $\mathcal{O}(n \log n)$ -time algorithm for 1-LCS.

► **Lemma 3** ([24, Lemma 3]). *The TWO STRING FAMILIES LCP PROBLEM can be solved in $\mathcal{O}(N \log N)$ time and $\mathcal{O}(N)$ space.¹*

In the algorithm underlying Lemma 3, for each node v of $\mathcal{T}(\mathcal{F}_1)$ we try to identify a pair of elements, one from \mathcal{P} and one from \mathcal{Q} , whose first components are descendants of v and the LCP of their second components is maximised. The algorithm traverses $\mathcal{T}(\mathcal{F}_1)$ bottom-up and uses mergeable height-balanced trees with $\mathcal{O}(N \log N)$ total merging time to store elements of pairs; see [20].

An $o(N \log N)$ time solution to the TWO STRING FAMILIES LCP PROBLEM is not known and devising such an algorithm seems difficult. The key ingredient of our algorithms is an efficient solution to the following special case of the problem. We say that a family of string pairs \mathcal{P} is an (α, β) -family if each $(U, V) \in \mathcal{P}$ satisfies $|U| \leq \alpha$ and $|V| \leq \beta$.

► **Lemma 4.** *An instance of the TWO STRING FAMILIES LCP PROBLEM in which \mathcal{P} and \mathcal{Q} are (α, β) -families can be solved in time $\mathcal{O}(N(\alpha + \log N)(\log \beta + \sqrt{\log N}) / \log N)$ and space $\mathcal{O}(N + N\alpha / \log N)$.*

The algorithm behind this solution uses a wavelet tree of the first components of $\mathcal{P} \cup \mathcal{Q}$.

¹ The original formulation of [24, Lemma 3] does not include a claim about the space complexity. However, it can be readily verified that the underlying algorithm, described in [31, 35], uses only linear space.

Solution to LCS. For the LCS problem, we design three different algorithms depending on the length of the solution. For short LCS ($\leq \frac{1}{3} \log_\sigma n$), we employ a simple tabulation technique. For long LCS ($\geq \log^4 n$), we employ the technique of Charalampopoulos et al. [24] for computing a long k -LCS, plugging in the sublinear longest common extension (LCE) data structure of Kempa and Kociumaka [47]. Both of these solutions work in $\mathcal{O}(n/\log_\sigma n)$ time.

As for medium-length LCS, let us first consider a case when the strings do not contain highly periodic fragments. In this case, we use the string synchronising sets of Kempa and Kociumaka [47] to select a set of $\mathcal{O}(\frac{n}{\tau})$ anchors over S and T , where $\tau = \Theta(\log_\sigma n)$, such that for any common substring U of S and T of length $\ell \geq 3\tau - 1$, there exist occurrences $S[i^S \dots j^S]$ and $T[i^T \dots j^T]$ of U , for which we have anchors $a^S \in [i^S, j^S]$ and $a^T \in [i^T, j^T]$ with $a^S - i^S = a^T - i^T \leq \tau$. For each anchor a in S , we add a string pair $((S[a - \tau \dots a])^R, S[a \dots a + \beta])$ to \mathcal{P} (and similarly for T and \mathcal{Q}). This lets us apply Lemma 4 with $N = \mathcal{O}(n/\tau)$, $\alpha = \mathcal{O}(\tau)$, and $\beta = \mathcal{O}(\log^4 n)$. In the periodic case, we cannot guarantee that $a^S - i^S = a^T - i^T$ is small, but we can obtain a different set of anchors based on maximal repetitions (runs) that yields multiple instances of the TWO STRING FAMILIES LCP PROBLEM, which have extra structure leading to a linear-time solution.

Solution to k -LCS. In this case we also obtain a set of $\mathcal{O}(n/\ell)$ anchors, where ℓ is the length of k -LCS. If the common substring is far from highly periodic, we use a synchronising set for $\tau = \Theta(\ell)$, and otherwise we generate anchors using a technique of misperiods that was initially introduced for k -mismatch pattern matching [18, 26]. Now the families \mathcal{P}, \mathcal{Q} need to consist not simply of substrings of S and T , but rather of modified substrings generated by an approach that resembles k -errata trees [29]. This requires combining the ideas of Thankachan et al. [59] and Charalampopoulos et al. [24]; this turns out to be technically challenging in order to stay within linear space. We apply Lemma 3 or Lemma 4 depending on the length ℓ , which allows us to break through the $n \log^k n$ barrier for k -LCS.

Other Related Work

A large body of work has been devoted to exploiting bit-parallelism in the word RAM model for string matching [7, 57, 55, 36, 37, 48, 14, 21, 9, 15, 11, 17, 39, 12, 16].

Other results on the LCS problem include the linear-time computation of an LCS of several strings over an integer alphabet [43], trade-offs between the time and the working space for computing an LCS of two strings [13, 50, 56], and the dynamic maintenance of an LCS [2, 3, 25]. Very recently, a strongly sublinear-time quantum algorithm and a lower bound for the quantum setting were shown [38]. The k -LCS problem has also been studied under edit distance and subquadratic-time algorithms for $k = o(\log n)$ are known [58, 4].

The problem of indexing a string of length n over an alphabet $[0, \sigma)$ in sublinear time in the word RAM model, with the aim of answering pattern matching queries, has attracted significant attention. Since by definition the suffix tree occupies $\Theta(n)$ space, alternative indexes have been sought. The state of the art is an index that occupies $\mathcal{O}(n \log \sigma / \log n)$ space and can be constructed in $\mathcal{O}(n \log \sigma / \sqrt{\log n})$ time [47, 53]. Interestingly, the running time of our algorithm (Theorem 1) matches the construction time of this index. Note that, in contrast to suffix trees, such indexes *cannot be used directly* for computing an LCS. Intuitively, these indexes sample suffixes of the string to be indexed, and upon a pattern matching query, they have to treat separately the first $\mathcal{O}(\log_\sigma n)$ letters of the pattern.

As for k -mismatch indexing, for $k = \mathcal{O}(1)$, a k -errata tree occupies $\mathcal{O}(n \log^k n)$ space, can be constructed in $\mathcal{O}(n \log^{k+1} n)$ time, and supports pattern matching queries with at most k mismatches in $\mathcal{O}(m + \log^k n \log \log n + occ)$ time, where m is the length of the pattern and occ

is the number of the reported pattern occurrences. Other trade-offs for this problem, in which the product of space and query time is still $\Omega(n \log^{2k} n)$, were shown in [23, 60], and solutions with $\mathcal{O}(n)$ space but $\Omega(\min\{n, \sigma^k m^{k-1}\})$ -time queries were presented in [22, 27, 44, 61]. More efficient solutions for $k = 1$ are known (see [10] and references therein). Cohen-Addad et al. [28] showed that, under SETH, for $k = \Theta(\log n)$ any indexing data structure that can be constructed in polynomial time cannot have $\mathcal{O}(n^{1-\delta})$ query time, for any $\delta > 0$. They also showed that in the pointer machine model, for $k = o(\log n)$, exponential dependency on k either in the space or in the query time cannot be avoided (for the reporting version of the problem). We hope that our techniques can fuel further progress in k -mismatch indexing.

2 Preliminaries

Strings. Let $T = T[1]T[2] \cdots T[n]$ be a *string* (or *text*) of length $n = |T|$ over an alphabet $\Sigma = [0, \sigma)$. The elements of Σ are called *letters*.

By ε we denote the *empty string*. For two positions i and j of T , we denote by $T[i..j]$ the *fragment* of T that starts at position i and ends at position j (the fragment is empty if $i > j$). A fragment of T is represented using $\mathcal{O}(1)$ space by specifying the indices i and j . We define $T[i..j) = T[i..j-1]$ and $T(i..j] = T[i+1..j]$. The fragment $T[i..j]$ is an *occurrence* of the underlying *substring* $P = T[i] \cdots T[j]$. We say that P occurs at *position* i in T . A *prefix* of T is a fragment of T of the form $T[1..j]$ and a *suffix* of T is a fragment of T of the form $T[i..n]$. We denote the *reverse string* of T by T^R , i.e., $T^R = T[n]T[n-1] \cdots T[1]$. By UV we denote the *concatenation* of two strings U and V , i.e., $UV = U[1]U[2] \cdots U[|U|]V[1]V[2] \cdots V[|V|]$.

A positive integer p is called a *period* of a string T if $T[i] = T[i+p]$ for all $i \in [1, |T| - p]$. We refer to the smallest period as *the period* of the string, and denote it by $\text{per}(T)$. A string T is called *periodic* if $\text{per}(T) \leq |T|/2$ and *aperiodic* otherwise. A *run* in T is a periodic substring that cannot be extended (to the left nor to the right) without an increase of its shortest period. All runs in a string can be computed in linear time [8, 51, 32].

► **Lemma 5** (Periodicity Lemma (weak version) [34]). *If a string S has periods p and q such that $p + q \leq |S|$, then $\gcd(p, q)$ is also a period of S .*

Tries. Let \mathcal{M} be a finite set containing $m > 0$ strings over Σ . The *trie* of \mathcal{M} , denoted by $\mathcal{R}(\mathcal{M})$, contains a node for every distinct prefix of a string in \mathcal{M} ; the root node is ε ; the set of leaf nodes is \mathcal{M} ; and edges are of the form $(u, \alpha, u\alpha)$, where u and $u\alpha$ are nodes and $\alpha \in \Sigma$. The *compacted trie* of \mathcal{M} , denoted by $\mathcal{T}(\mathcal{M})$, contains the root, the branching nodes, and the leaf nodes of $\mathcal{R}(\mathcal{M})$. Each maximal branchless path segment from $\mathcal{R}(\mathcal{M})$ is replaced by a single edge, and a fragment of a string $M \in \mathcal{M}$ is used to represent the label of this edge in $\mathcal{O}(1)$ space. The best known example of a compacted trie is the suffix tree [62]. Throughout our algorithms, \mathcal{M} always consists of a set of substrings or modified substrings with $k = \mathcal{O}(1)$ modifications (see Section 5 for a definition) of a reference string. The value $\text{val}(u)$ of a node u is the concatenation of labels of edges on the path from the root to u , and the *string-depth* of u is the length of $\text{val}(u)$. The size of $\mathcal{T}(\mathcal{M})$ is $\mathcal{O}(m)$. We use the following well-known construction (cf. [30]).

► **Lemma 6.** *Given a sorted list of N strings and the longest common prefixes between pairs of consecutive strings, the compacted trie of the strings can be constructed in $\mathcal{O}(N)$ time.*

Packed strings. We assume the unit-cost word RAM model with word size $w = \Theta(\log n)$ and a standard instruction set including arithmetic operations, bitwise Boolean operations, and shifts. We count the space complexity of our algorithms in machine words used by the

algorithm. The *packed representation* of a string T over alphabet $[0, \sigma)$ is a list obtained by storing $\Theta(\log_\sigma n)$ letters per machine word thus representing T in $\mathcal{O}(|T|/\log_\sigma n)$ machine words. If T is given in the packed representation we simply say that T is a *packed string*.

String synchronising sets. Our solution uses the string synchronising sets introduced by Kempa and Kociumaka [47]. Informally, in the simpler case that T is cube-free, a τ -synchronising set of T is a small set of *synchronising positions* in T such that each length- τ fragment of T contains at least one synchronising position, and the leftmost synchronising positions within two sufficiently long matching fragments of T are consistent.

Formally, for a string T and a positive integer $\tau \leq \frac{1}{2}n$, a set $A \subseteq [1, n - 2\tau + 1]$ is a τ -synchronising set of T if it satisfies the following two conditions:

1. If $T[i..i + 2\tau] = T[j..j + 2\tau]$, then $i \in A$ if and only if $j \in A$.
2. For $i \in [1, n - 3\tau + 2]$, $A \cap [i, i + \tau] = \emptyset$ if and only if $\text{per}(T[i..i + 3\tau - 2]) \leq \frac{1}{3}\tau$.

► **Theorem 7** ([47, Proposition 8.10, Theorem 8.11]). *For a string $T \in [0, \sigma)^n$ with $\sigma = n^{\mathcal{O}(1)}$ and $\tau \leq \frac{1}{2}n$, there exists a τ -synchronising set of size $\mathcal{O}(n/\tau)$ that can be constructed in $\mathcal{O}(n)$ time or, if $\tau \leq \frac{1}{5}\log_\sigma n$, in $\mathcal{O}(n/\tau)$ time if T is given in a packed representation.*

As in [47], for a τ -synchronising set A , let $\text{succ}_A(i) := \min\{j \in A \cup \{n - 2\tau + 2\} : j \geq i\}$.

► **Lemma 8** ([47, Fact 3.2]). *If $p = \text{per}(T[i..i + 3\tau - 2]) \leq \frac{1}{3}\tau$, then $T[i.. \text{succ}_A(i) + 2\tau - 1]$ is the longest prefix of $T[i..|T|]$ with period p .*

► **Lemma 9** ([47, Fact 3.3]). *If a string U with $|U| \geq 3\tau - 1$ and $\text{per}(U) > \frac{1}{3}\tau$ occurs at positions i and j in T , then $\text{succ}_A(i) - i = \text{succ}_A(j) - j \leq |U| - 2\tau$.*

A τ -run R is a run of length at least $3\tau - 1$ with period at most $\frac{1}{3}\tau$. The *Lyndon root* of R is the lexicographically smallest cyclic shift of $R[1.. \text{per}(R)]$. A proof of the following lemma resembles an argument given in [47, Section 6.1.2]; its proof can be found in the full version of this paper.

► **Lemma 10.** *For a positive integer τ , a string $T \in [0, \sigma)^n$ contains $\mathcal{O}(n/\tau)$ τ -runs. Moreover, if $\tau \leq \frac{1}{5}\log_\sigma n$, given a packed representation of T , we can compute all τ -runs in T and group them by their Lyndon roots in $\mathcal{O}(n/\tau)$ time. Within the same complexities, for each τ -run, we can compute the two leftmost occurrences of its Lyndon root.*

► **Theorem 11** ([47, Theorem 4.3]). *Given a packed representation of a string $T \in [0, \sigma)^n$ and a τ -synchronising set A of T of size $\mathcal{O}(n/\tau)$ for $\tau = \mathcal{O}(\log_\sigma n)$, we can compute in $\mathcal{O}(n/\tau)$ time the lexicographic order of all suffixes of T starting at positions in A .*

We often want to preprocess T to be able to answer queries $\text{LCP}(T[i..n], T[j..n])$ [52]. For this case, there exists an optimal data structure that applies synchronising sets.

► **Theorem 12** ([47, Theorem 5.4]). *Given a packed representation of a string $T \in [0, \sigma)^n$, LCP queries on T can be answered in $\mathcal{O}(1)$ time after $\mathcal{O}(n/\log_\sigma n)$ -time preprocessing.*

3 Sublinear-Time LCS

We provide different solutions depending on the length ℓ of an LCS. Lemmas 13, 14, and 17 directly yield Theorem 1.

The proof of the following lemma, for the case where an LCS is short, i.e., of length $\ell \leq \frac{1}{3}\log_\sigma n$, uses tabulation and can be found in the full version of this paper.

► **Lemma 13.** *The LCS problem can be solved in $\mathcal{O}(n/\log_\sigma n)$ time if $\ell \leq \frac{1}{3} \log_\sigma n$.*

The proof of the following lemma, for the case where an LCS is long, i.e., of length $\ell = \Omega(\frac{\log^4 n}{\log^2 \sigma})$, uses difference covers and the $\mathcal{O}(N \log N)$ -time solution to the TWO STRING FAMILIES LCP PROBLEM. This proof closely follows [24] and can be found in the full version of this paper.

► **Lemma 14.** *The LCS problem can be solved in $\mathcal{O}(n/\log_\sigma n)$ time if $\ell = \Omega(\frac{\log^4 n}{\log^2 \sigma})$.*

Solution for medium-length LCS. We now give a solution to the LCS problem for $\ell \in [\frac{1}{3} \log_\sigma n, 2\sqrt{\log n}]$. We first construct three subsets of positions in $S\$T$, where $\$ \notin \Sigma$, of size $\mathcal{O}(n/\log_\sigma n)$ as follows. For $\tau = \lfloor \frac{1}{9} \log_\sigma n \rfloor$, let A_I be a τ -synchronising set of $S\$T$. For each τ -run in $S\$T$, we insert to A_{II} the starting positions of the first two occurrences of the Lyndon root of the τ -run and to A_{III} the last position of the τ -run. The elements of A_{II} and A_{III} store the τ -run they originate from. Finally, we denote $A_j^S = A_j \cap [1, |S|]$ and $A_j^T = \{a - |S| - 1 : a \in A_j, a > |S| + 1\}$ for $j = I, II, III$. The following lemma shows that there exists an LCS of S and T for which $A_I \cup A_{II} \cup A_{III}$ is a set of *anchors* that satisfies certain distance requirements.

► **Lemma 15.** *If an LCS of S and T has length $\ell \geq 3\tau$, then there exist positions $i^S \in [1, |S|]$, $i^T \in [1, |T|]$, a shift $\delta \in [0, \ell)$, and $j \in \{I, II, III\}$ such that $S[i^S \dots i^S + \ell) = T[i^T \dots i^T + \ell)$, $i^S + \delta \in A_j^S$, $i^T + \delta \in A_j^T$, and*

- *if $j = I$, then $\delta \in [0, \tau)$;*
- *if $j = II$, then $S[i^S \dots i^S + \ell)$ is contained in the τ -run from which $i^S + \delta \in A^S$ originates;*
- *if $j = III$, then $\delta \geq 3\tau - 1$ and $S[i^S \dots i^S + \delta]$ is a suffix of the τ -run from which $i^S + \delta \in A^S$ originates.*

Proof. By the assumption, there exist $i^S \in [1, |S|]$ and $i^T \in [1, |T|]$ such that $S[i^S \dots i^S + \ell) = T[i^T \dots i^T + \ell)$. Let us choose any such pair (i^S, i^T) minimising the sum $i^S + i^T$. We have the following cases.

1. If $\text{per}(S[i^S \dots i^S + 3\tau - 2]) > \frac{1}{3}\tau$, then, by the definition of a τ -synchronising set, in this case there exist some elements $a^S \in A_I^S \cap [i^S, i^S + \tau)$ and $a^T \in A_I^T \cap [i^T, i^T + \tau)$. Let us choose the smallest such elements. By Lemma 9, we have $a^S - i^S = a^T - i^T$.
2. Else, $p = \text{per}(S[i^S \dots i^S + 3\tau - 2]) \leq \frac{1}{3}\tau$. We have two subcases.
 - a. If $p = \text{per}(S[i^S \dots i^S + \ell))$, then, by the choice of i^S and i^T there exists a τ -run R_S in S that starts at position in $(i^S - p \dots i^S]$ and a τ -run R_T in T that starts at position in $(i^T - p \dots i^T]$. Moreover, by Lemma 5, both runs have equal Lyndon roots. For each $X \in \{S, T\}$, let us choose a^X as the leftmost starting position of a Lyndon root of R_X that is $\geq i^X$. We have $a^S - i^S = a^T - i^T \in [0, \frac{1}{3}\tau)$. Each position a^X will be the starting position of the first or the second occurrence of the Lyndon root of R_S , so $a^S \in A_{II}^S$ and $a^T \in A_{II}^T$.
 - b. Else, $p \neq \text{per}(S[i^S \dots i^S + \ell))$. We have $d = \min\{b \geq p : S[i^S + b] \neq S[i^S + b - p]\} < \ell$ (and $d \geq 3\tau - 1$). In this case, $a^S = i^S + d - 1$ and $a^T = i^T + d - 1$ are the ending positions of τ -runs with period p in S and T , respectively, so $a^S \in A_{III}^S$ and $a^T \in A_{III}^T$. ◀

Case $j = I$ from the above lemma corresponds to the TWO STRING FAMILIES LCP PROBLEM with \mathcal{P} and \mathcal{Q} being $(\tau, 2\sqrt{\log n})$ -families. Let us introduce a variant of the TWO STRING FAMILIES LCP PROBLEM that intuitively corresponds to the case $j \in \{II, III\}$. A family of string pairs \mathcal{P} is called a *prefix family* if there exists a string Y such that, for each

$(U, V) \in \mathcal{P}$, U is a prefix of Y . We arrive at this special case with first components of \mathcal{P} and \mathcal{Q} being prefixes of some cyclic shift of a power of a (common) Lyndon root of τ -runs. The proof of the following lemma can be found in the full version of this paper.

► **Lemma 16.** *An instance of the TWO STRING FAMILIES LCP PROBLEM in which $\mathcal{P} \cup \mathcal{Q}$ is a prefix family can be solved in $\mathcal{O}(N)$ time.*

We are now ready to state the main result of this subsection.

► **Lemma 17.** *The LCS problem can be solved in $\mathcal{O}(n \log \sigma / \sqrt{\log n})$ time using $\mathcal{O}(n / \log_\sigma n)$ space if $\ell \in [\frac{1}{3} \log_\sigma n, 2^{\sqrt{\log n}}]$.*

Proof. Recall that $\tau = \lfloor \frac{1}{9} \log_\sigma n \rfloor$. The set of anchors $A = A_I \cup A_{II} \cup A_{III}$ consists of a τ -synchronising set and of $\mathcal{O}(1)$ positions per each τ -run in $S\$T$. Hence, $|A| = \mathcal{O}(n/\tau)$ and A can be constructed in $\mathcal{O}(n/\tau)$ time by Theorem 7 and Lemma 10.

We construct sets of pairs of substrings of $X = S\$_1T\$_2S^R\$_3T^R$. First, for $\Delta = \lfloor 2^{\sqrt{\log n}} \rfloor$:

$$\mathcal{P}_I = \{((S[a - \tau \dots a))^R, S[a \dots a + \Delta]) : a \in A_I^S\}.$$

Then, for each group \mathcal{G} of τ -runs in S and T with equal Lyndon root, we construct the following set of string pairs:

$$\mathcal{P}_{II}^{\mathcal{G}} = \{((S[x \dots a))^R, S[a \dots y]) : a \in A_{II}^S \text{ that originates from } \tau\text{-run } S[x \dots y] \in \mathcal{G}\}.$$

We define the *tail* of a τ -run $S[i \dots j]$ with period p and Lyndon root $S[i' \dots i' + p]$ as $(j + 1 - i') \bmod p$ (and same for τ -runs in T). For each group of τ -runs in S and T with equal Lyndon roots, we group the τ -runs belonging to it by their tails. This can be done in $\mathcal{O}(n/\tau)$ time using tabulation, since the tail values are up to $\frac{1}{3}\tau$. For each group \mathcal{G} of τ -runs in S and T with equal Lyndon root and tail, we construct the following set of string pairs:

$$\mathcal{P}_{III}^{\mathcal{G}} = \{((S[x \dots y))^R, S[y \dots |S|]) : S[x \dots y] \in \mathcal{G}\}.$$

Simultaneously, we create sets \mathcal{Q}_I , $\mathcal{Q}_{II}^{\mathcal{G}}$ and $\mathcal{Q}_{III}^{\mathcal{G}}$ defined with T instead of S .

Now, it suffices to output the maximum of $\text{maxPairLCP}(\mathcal{P}_I, \mathcal{Q}_I)$, $\text{maxPairLCP}(\mathcal{P}_{II}^{\mathcal{G}}, \mathcal{Q}_{II}^{\mathcal{G}})$, and $\text{maxPairLCP}(\mathcal{P}_{III}^{\mathcal{G}}, \mathcal{Q}_{III}^{\mathcal{G}})$, where \mathcal{G} ranges over groups of τ -runs. Computing any individual maxPairLCP value can be expressed as an instance of the TWO STRING FAMILIES LCP PROBLEM provided that all the first and second components of families are represented as nodes of compacted tries. We will use Lemma 6 to construct these compacted tries. LCP queries can be answered efficiently due to Theorem 12, so it suffices to be able to sort all the first and second components of each pair of string pair sets lexicographically. Each of the sets \mathcal{P}_I , \mathcal{Q}_I can be ordered by the second components using Theorem 11 since A_I is a τ -synchronising set, and by the first components with easy preprocessing using the fact that the number of possible τ -length strings is $\sigma^\tau = \mathcal{O}(n^{1/9})$. In a set $\mathcal{P}_{II}^{\mathcal{G}}$, both all first and all second components are prefixes of a single string (a power of the common Lyndon root). Hence, they can be sorted simply by comparing their lengths. This sorting is performed simultaneously for all the families $\mathcal{P}_{II}^{\mathcal{G}}$, $\mathcal{Q}_{II}^{\mathcal{G}}$ in $\mathcal{O}(n/\tau)$ time via radix sort. Finally, to sort the second components of the sets $\mathcal{P}_{III}^{\mathcal{G}}$, $\mathcal{Q}_{III}^{\mathcal{G}}$, instead of comparing strings of the form $S[y \dots |S|]$ (and same for T), we can equivalently compare strings $S[y - 2\tau + 1 \dots |S|]$ which are known to start at positions from a τ -synchronising set by Lemma 8. This sorting is done across all groups using radix sort and Theorem 11. The correctness follows by Lemma 15.

Finally, we observe that $(\mathcal{P}_I, \mathcal{Q}_I)$ is a (τ, Δ) -family of size $N = \mathcal{O}(n/\tau)$, and thus $\text{maxPairLCP}(\mathcal{P}_I, \mathcal{Q}_I)$ can be computed in $\mathcal{O}(n \log \sigma / \sqrt{\log n})$ time and $\mathcal{O}(n / \log_\sigma n)$ space using Lemma 4. On the other hand, $(\mathcal{P}_{II}^g, \mathcal{Q}_{II}^g)$ and $(\mathcal{P}_{III}^g, \mathcal{Q}_{III}^g)$ are prefix families of total size $\mathcal{O}(n/\tau)$, so the corresponding instances of the TWO STRING FAMILIES LCP PROBLEM can be solved in $\mathcal{O}(n / \log_\sigma n)$ total time using Lemma 16. \blacktriangleleft

4 Proof of Lemma 4 via Wavelet Trees

Wavelet trees. For an arbitrary alphabet Σ , the *skeleton tree* for Σ is a full binary tree \mathcal{T} together with a bijection between Σ and the leaves of \mathcal{T} . For a node $v \in \mathcal{T}$, let Σ_v denote the subset of Σ that corresponds to the leaves in the subtree of v .

The \mathcal{T} -shaped *wavelet tree* of a string $T \in \Sigma^*$ consists of bit vectors assigned to internal nodes of \mathcal{T} (inspect Figure 1(a)). For an internal node v with children v_L and v_R , let T_v denote the maximal subsequence of T that consists of letters from Σ_v ; the bit vector $B_v[1..|T_v|]$ is defined so that $B_v[i] = 0$ if $T_v[i] \in \Sigma_{v_L}$ and $B_v[i] = 1$ if $T_v[i] \in \Sigma_{v_R}$.

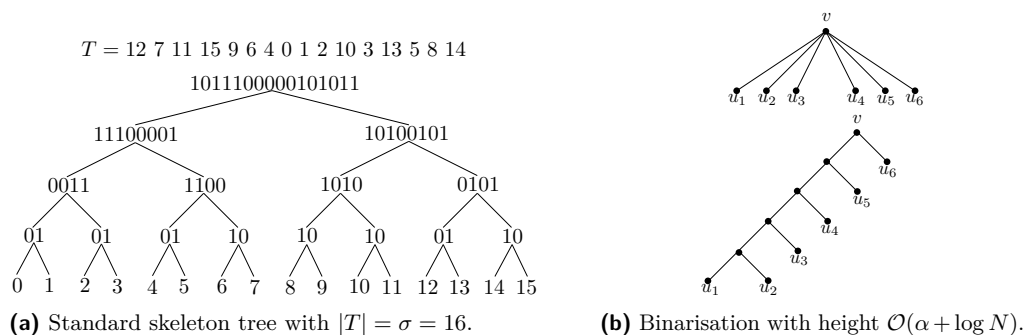

Figure 1 (a) Let v be left child of the root node. Then $\Sigma_v = \{0, 1, \dots, 7\}$, $T_v = 7, 6, 4, 0, 1, 2, 3, 5$ and so $B_v = 11100001$: 7, 6, 4, 5 belong to the right subtree of v and 0, 1, 2, 3 to the left. (b) For each i , let the size of the subtree rooted at u_i be 2^i . The binarisation from [5] leads to height $\mathcal{O}(\alpha + \log N)$, favouring heavier children.

Wavelet trees were introduced in [41], whereas efficient construction algorithms were presented in [54, 5].

► **Theorem 18** (see [54, Theorem 2]). *Given the packed representation of a string $T \in [0, \sigma]^n$ and a skeleton tree \mathcal{T} of height h , the \mathcal{T} -shaped wavelet tree of T takes $\mathcal{O}(nh / \log n + \sigma)$ space and can be constructed in $\mathcal{O}(nh / \sqrt{\log n} + \sigma)$ time.*

Wavelet trees are sometimes constructed for sequences $T \in \mathcal{M}^*$ over an alphabet $\mathcal{M} \subseteq \Sigma^*$ that itself consists of strings (see e.g. [47]). In this case, the skeleton tree \mathcal{T} is often chosen to resemble the compacted trie of \mathcal{M} . Formally, we say that a skeleton tree \mathcal{T} for \mathcal{M} is *prefix-consistent* if each node $v \in \mathcal{T}$ admits a label $\text{val}(v) \in \Sigma^*$ such that:

- if v is a leaf, then $\text{val}(v)$ is the corresponding string in \mathcal{M} ;
- if v is a node with children v_L, v_R , then, for all leaves u_L, u_R in the subtrees of v_L and v_R , respectively, the string $\text{val}(v)$ is the longest common prefix of $\text{val}(u_L)$ and $\text{val}(u_R)$.

Observe that if $\mathcal{M} \subseteq \{0, 1\}^\alpha$ for some integer α , then the compacted trie $\mathcal{T}(\mathcal{M})$ is a prefix-consistent skeleton tree for \mathcal{M} . For larger alphabets, we binarise $\mathcal{T}(\mathcal{M})$ as follows:

► **Lemma 19.** *Given the compacted trie $\mathcal{T}(\mathcal{M})$ of a set $\mathcal{M} \subseteq \Sigma^\alpha$, a prefix-consistent skeleton tree of height $\mathcal{O}(\alpha + \log |\mathcal{M}|)$ can be constructed in $\mathcal{O}(|\mathcal{M}|)$ time, with each node v associated to a node v' of $\mathcal{T}(\mathcal{M})$ such that $\text{val}(v) = \text{val}(v')$.*

Proof. We use [5, Corollary 3.2], where the authors showed that any rooted tree of size m and height h can be binarised in $\mathcal{O}(m)$ time so that the resulting tree is of height $\mathcal{O}(h + \log m)$; see Figure 1(b). For $\mathcal{T}(\mathcal{M})$, we obtain height $\mathcal{O}(\alpha + \log |\mathcal{M}|)$ and time $\mathcal{O}(|\mathcal{M}|)$. \blacktriangleleft

► **Lemma 4.** *An instance of the TWO STRING FAMILIES LCP PROBLEM in which \mathcal{P} and \mathcal{Q} are (α, β) -families can be solved in time $\mathcal{O}(N(\alpha + \log N)(\log \beta + \sqrt{\log N})/\log N)$ and space $\mathcal{O}(N + N\alpha/\log N)$.*

Proof. By traversing $\mathcal{T}(\mathcal{F}_2)$ we can compute in $\mathcal{O}(N)$ time a list \mathcal{R} being a union of sets \mathcal{P} and \mathcal{Q} in which the second components are ordered lexicographically. We also store a bit vector G of length $|\mathcal{R}|$ that determines, for each element of \mathcal{R} , which of the sets \mathcal{P} , \mathcal{Q} it originates from. We construct the wavelet tree of the sequence of strings being the first components of pairs from \mathcal{R} using Theorem 18 and the skeleton tree from Lemma 19. Before the wavelet tree is constructed, we pad each string with a letter $\$ \notin \Sigma$ to make them all of length α ; we will ignore the nodes of the wavelet tree with a path-label containing a $\$$.

For a sublist $\mathcal{X} = (U_1, V_1), \dots, (U_m, V_m)$ of \mathcal{R} , by $\text{LCPs}(\mathcal{X})$ we denote the representation of the list $0, \text{LCP}(V_1, V_2), \dots, \text{LCP}(V_{m-1}, V_m)$ as a packed string over alphabet $[0, \beta]$ in space $\mathcal{O}(N/\log_\beta N)$. Together with each $\text{LCPs}(\mathcal{X})$ we also store the bit vector $G(\mathcal{X})$ of origins of elements of \mathcal{X} without increasing the complexity. The list $\text{LCPs}(\mathcal{R})$ can be computed in $\mathcal{O}(N)$ time when constructing \mathcal{R} . For each node v of the wavelet tree, we wish to compute $\mathcal{L}_v = \text{LCPs}(\mathcal{R}_v)$, where \mathcal{R}_v is the sublist of \mathcal{R} composed of elements whose first component is in the leaf list Σ_v of v . We will construct the lists $\text{LCPs}(\mathcal{R}_v)$ without actually computing \mathcal{R}_v .

Computation of LCPs lists. The lists are computed recursively using the bit vectors from the wavelet tree. Assume we have computed \mathcal{L}_u and wish to compute \mathcal{L}_v for the left child v of u – the computations for the right child are symmetric.

Let $c \in (0, 1)$ be a constant. Let us partition \mathcal{L}_u into blocks of $\lambda = \max(1, \lfloor c \log_\beta N \rfloor)$ LCP values. We will process the blocks in order, constructing \mathcal{L}_v . Each block of \mathcal{L}_u can be represented in a single word and this representation can be extracted from the packed representation of \mathcal{L}_u in $\mathcal{O}(1)$ time. For each block $W = \mathcal{L}_u(a\lambda \dots (a+1)\lambda]$, we retrieve in $\mathcal{O}(1)$ time the corresponding block $D = B_u(a\lambda \dots (a+1)\lambda]$ in the bit vector from the wavelet tree. Further, we store $\mu_a = \min \mathcal{L}_v(p_a \dots a\lambda]$, where $p_a = \max\{i \in [0, a\lambda] : i = 0 \text{ or } B_u[i] = 0\}$. Let us show how, given W , D and μ_a , we can determine μ_{a+1} and the chunk of \mathcal{L}_v that corresponds to $i \in [1, \lambda]$ such that $D[i] = 0$. The calculations are based on the following well-known fact.

► **Fact 20.** *If U_1, U_2, U_3 are strings such that $U_1 \leq U_2 \leq U_3$, then we have $\text{LCP}(U_1, U_3) = \min(\text{LCP}(U_1, U_2), \text{LCP}(U_2, U_3))$.*

For each $i \in [1, \lambda]$ such that $D[i] = 0$, in increasing order, if a previous position j with $D[j] = 0$ exists, then $\min W(i' \dots i]$ should be appended to \mathcal{L}_v , where i' is the predecessor of i satisfying $D[i'] = 0$, and otherwise $\min(\{\mu_a\} \cup W[1 \dots i])$ should. Then, for the last position $i \in [1, \lambda]$ such that $D[i] = 0$, $\mu_{a+1} = \min W(i \dots \lambda]$, and if no such position exists, then $\mu_{a+1} = \min(\{\mu_a\} \cup W[1 \dots \lambda])$.

If $\lambda = 1$, the calculations can be performed in $\mathcal{O}(1)$ time. Otherwise, we make use of preprocessing: for every possible combination of (W, D, μ_a) , i.e., up to $2c \log N + \log \beta < 3c \log N$ bits, precompute the block to be appended to \mathcal{L}_v and μ_{a+1} , i.e., up to $c \log N + \log \beta < 2c \log N$ bits. We can choose $c > 0$ small enough to make the preprocessing $\mathcal{O}(N^{1-\varepsilon})$ for some $\varepsilon > 0$. Thus, the computation takes $\mathcal{O}(|\mathcal{L}_u|/\lambda)$ time. Within this time, we can also populate the bit vector of origins for v .

Application of LCPs lists. For each node u of the wavelet tree, we must extract the maximum LCP between suffixes of different origins, add the string-depth $|\text{val}(u)|$, and compare the result with the stored candidate. The former can be computed in $\mathcal{O}(|\mathcal{L}_u|/\log_\beta N)$ time as follows. Due to Fact 20, the answer will be the LCP between a pair of second components of consecutive elements of \mathcal{R}_u that originate from different sets, i.e. $\max\{\mathcal{L}_u[i] : i \in [2, |\mathcal{R}_u|], G(\mathcal{R}_u)[i-1] \neq G(\mathcal{R}_u)[i]\}$. We can cover all pairs of consecutive elements of \mathcal{L}_u using $\Theta(1 + |\mathcal{L}_u|/\log_\beta N)$ blocks of $\max(2, \lfloor c \log_\beta N \rfloor)$ LCP values. Each such block, augmented with its corresponding bit vector of origins, consists of at most $2c \log N$ bits. We can thus precompute all possible answers in $\mathcal{O}(N^{1-\epsilon})$ time, and then process each node u in $\Theta(1 + |\mathcal{L}_u|/\log_\beta N)$ time.

Time complexity. The wavelet tree can be built in $\mathcal{O}(Nh/\sqrt{\log N})$ time using space $\mathcal{O}(Nh/\log N)$ by Theorem 18, where $h = \mathcal{O}(\alpha + \log N)$. Computing LCPs for children of a single node u takes $\mathcal{O}(1 + |\mathcal{L}_u|/\log_\beta N)$ time; over all nodes, this is $\mathcal{O}(Nh \log \beta / \log N)$. ◀

5 Faster k -LCS

In this section, we outline our $\mathcal{O}(n \log^{k-1/2} n)$ -time algorithm for the k -LCS problem with $k = \mathcal{O}(1)$, that underlies Theorem 2. For simplicity, we focus on computing the length of a k -LCS; an actual pair of strings forming a k -LCS can be recovered easily from our approach. If the length of an LCS of S and T is d , then the length of a k -LCS of S and T is in $[d, (k+1)d + k]$. Below, we show how to compute a k -LCS provided that it belongs to an interval $(\ell/2, \ell]$ for a specified ℓ ; it is sufficient to call this subroutine $\mathcal{O}(\log k) = \mathcal{O}(1)$ times.

Similarly to our solutions for long and medium-length LCS, we first distinguish anchors $A^S \subseteq [1, |S|]$ in S and $A^T \subseteq [1, |T|]$ in T , as summarised in the following lemma.

► **Lemma 21.** *Consider an instance of the k -LCS problem for $k = \mathcal{O}(1)$ and let $\ell \in [1, n]$. In $\mathcal{O}(n)$ time, one can construct sets $A^S \subseteq [1, |S|]$ and $A^T \subseteq [1, |T|]$ of size $\mathcal{O}(\frac{n}{\ell})$ satisfying the following condition: If a k -LCS of S and T has length $\ell' \in (\ell/2, \ell]$, then there exist positions $i^S \in [1, |S|]$, $i^T \in [1, |T|]$ and a shift $\delta \in [0, \ell')$ such that $i^S + \delta \in A^S$, $i^T + \delta \in A^T$, and the Hamming distance between $S[i^S \dots i^S + \ell']$ and $T[i^T \dots i^T + \ell']$ is at most k .*

Proof. As in [26], we say that position a in a string X is a *misperiod* with respect to a substring $X[i \dots j]$ if $X[a] \neq X[b]$, where b is the unique position such that $b \in [i, j]$ and $(j-i) \mid (b-a)$; for example, $j-i$ is a period of X if and only if there are no misperiods with respect to $X[i \dots j]$. We define the set $\text{LeftMisper}_k(X, i, j)$ as the set of k maximal misperiods that are smaller than i and $\text{RightMisper}_k(X, i, j)$ as the set of k minimal misperiods that are not smaller than j . Either set may have fewer than k elements if the corresponding misperiods do not exist. Further, let us define $\text{Misper}_k(X, i, j) = \text{LeftMisper}_k(X, i, j) \cup \text{RightMisper}_k(X, i, j)$ and $\text{Misper}(X, i, j) = \bigcup_{k=0}^{\infty} \text{Misper}_k(X, i, j)$.

Similar to Lemma 15, we construct three subsets of positions in $Y = \#S\$T$, where $\#, \$ \notin \Sigma$. For $\tau = \lfloor \ell/(6(k+1)) \rfloor$, let A_I be a τ -synchronising set of Y . Let $Y[i \dots j]$ be a τ -run with period p and assume that the first occurrence of its Lyndon root is at a position q of Y . Then, for $Y[i \dots j]$, for each $x \in \text{LeftMisper}_{k+1}(Y, i, i+p)$, we insert to A_{II} the two smallest positions in $[x+1, |Y|]$ that are equivalent to $q \pmod{p}$. Moreover, we insert to A_{III} the positions in $\text{Misper}_{k+1}(Y, i, i+p)$. Finally, we denote $A = A_I \cup A_{II} \cup A_{III}$, as well as $A^S = \{a-1 : a \in A \cap [2, |S|+1]\}$ and $A^T = \{a-|S|-2 : a \in A \cap [|S|+3, |Y|]\}$. The proof of the following claim, that can be found in the full version of this paper, resembles that of Lemma 15.

► **Claim 22.** The sets A^S and A^T satisfy the condition stated in Lemma 21.

It remains to show that the sets A^S and A^T can be constructed efficiently. A τ -synchronising set can be computed in $\mathcal{O}(n)$ time by Theorem 7 and all the τ -runs, together with the position of the first occurrence of their Lyndon root, can be computed in $\mathcal{O}(n)$ time [8]. After an $\mathcal{O}(n)$ -time preprocessing, for every τ -run, we can compute the set of the $k+1$ misperiods of its period to either side in $\mathcal{O}(1)$ time; see [26, Claim 18]. \blacktriangleleft

The next step in our solutions to long LCS and medium-length LCS was to construct an instance of the TWO STRING FAMILIES LCP PROBLEM. To adapt this approach, we generalise the notions of LCP and maxPairLCP so that they allow for mismatches. By $\text{LCP}_k(U, V)$, for $k \in \mathbb{Z}_{\geq 0}$, we denote the maximum length ℓ such that $U[1.. \ell]$ and $V[1.. \ell]$ are at Hamming distance at most k .

► **Definition 23.** *Given two sets $\mathcal{U}, \mathcal{V} \subseteq \Sigma^* \times \Sigma^*$ and two integers $k_1, k_2 \in \mathbb{Z}_{\geq 0}$, we define $\text{maxPairLCP}_{k_1, k_2}(\mathcal{U}, \mathcal{V}) = \max\{\text{LCP}_{k_1}(U_1, V_1) + \text{LCP}_{k_2}(U_2, V_2) : (U_1, U_2) \in \mathcal{U}, (V_1, V_2) \in \mathcal{V}\}$.*

Note that $\text{maxPairLCP}(\mathcal{U}, \mathcal{V}) = \text{maxPairLCP}_{0,0}(\mathcal{U}, \mathcal{V})$.

By Lemma 21, if a k -LCS of S and T has length $\ell' \in (\ell/2, \ell]$, then

$$\ell' = \max_{k'=0}^k \text{maxPairLCP}_{k', k-k'}(\mathcal{U}, \mathcal{V}), \text{ for } \mathcal{U} = \{((S[a - \ell \dots a])^R, S[a \dots a + \ell]) : a \in A^S\},$$

$$\mathcal{V} = \{((T[a - \ell \dots a])^R, T[a \dots a + \ell]) : a \in A^T\}.$$

Here, k' bounds the number of mismatches between $S[i^S \dots i^S + \delta)$ and $T[i^T \dots i^T + \delta)$, whereas $k - k'$ bounds the number of mismatches between $S[i^S + \delta \dots i^S + \ell')$ and $T[i^T + \delta \dots i^T + \ell')$. The following theorem, whose full proof can be found in the full version of this paper, is the most technical part of our contribution, and allows for efficiently computing the values $\text{maxPairLCP}_{k', k-k'}(\mathcal{U}, \mathcal{V})$.

► **Theorem 24.** *Consider two (ℓ, ℓ) -families \mathcal{U}, \mathcal{V} of total size N consisting of pairs of substrings of a given length- n text. For any non-negative integers $k_1, k_2 = \mathcal{O}(1)$, the value $\text{maxPairLCP}_{k_1, k_2}(\mathcal{U}, \mathcal{V})$ can be computed:*

- in $\mathcal{O}(n + N \log^{k_1+k_2+1} N)$ time and $\mathcal{O}(n + N)$ space if $\ell > \log^{3/2} N$,
- in $\mathcal{O}(n + N \ell \log^{k_1+k_2-1/2} N)$ time and $\mathcal{O}(n + N \ell / \log N)$ space if $\log N < \ell \leq \log^{3/2} N$,
- in $\mathcal{O}(n + N \ell^{k_1+k_2} \sqrt{\log N})$ time and $\mathcal{O}(n + N)$ space if $\ell \leq \log N$.

Proof Outline. We reduce the computation of $\text{maxPairLCP}_{k_1, k_2}(\mathcal{U}, \mathcal{V})$ into multiple computations of $\text{maxPairLCP}(\mathcal{U}', \mathcal{V}')$ across a family \mathbf{P} of pairs $(\mathcal{U}', \mathcal{V}')$ with $\mathcal{U}', \mathcal{V}' \subseteq \Sigma^* \times \Sigma^*$. Each pair $(U'_1, U'_2) \in \mathcal{U}'$ is associated to a pair $(U_1, U_2) \in \mathcal{U}$, with the string U'_i represented as a pointer to the source U_i and up to k_i substitutions needed to transform U_i to U'_i . Similarly, each pair $(V'_1, V'_2) \in \mathcal{V}'$ consists of *modified strings* with sources $(V_1, V_2) \in \mathcal{V}$. In order to guarantee $\text{maxPairLCP}_{k_1, k_2}(\mathcal{U}, \mathcal{V}) = \max_{(\mathcal{U}', \mathcal{V}') \in \mathbf{P}} \text{maxPairLCP}(\mathcal{U}', \mathcal{V}')$, we require $\text{LCP}(U'_i, V'_i) \leq \text{LCP}_{k_i}(U_i, V_i)$ for every $(U'_1, U'_2) \in \mathcal{U}'$ and $(V'_1, V'_2) \in \mathcal{V}'$ with $(\mathcal{U}', \mathcal{V}') \in \mathbf{P}$ and that, for every $(U_1, U_2) \in \mathcal{U}$ and $(V_1, V_2) \in \mathcal{V}$, there exists $(\mathcal{U}', \mathcal{V}') \in \mathbf{P}$ with $(U'_1, U'_2) \in \mathcal{U}'$ and $(V'_1, V'_2) \in \mathcal{V}'$, with sources (U_1, U_2) and (V_1, V_2) , respectively, such that $\text{LCP}(U'_i, V'_i) = \text{LCP}_{k_i}(U_i, V_i)$. Our construction is based on a technique of [59] which gives an analogous family for two subsets of Σ^* (rather than $\Sigma^* \times \Sigma^*$) and a single threshold: We apply the approach of [59] to $\mathcal{U}_i = \{U_i : (U_1, U_2) \in \mathcal{U}\}$ and $\mathcal{V}_i = \{V_i : (V_1, V_2) \in \mathcal{V}\}$ with threshold k_i , and then combine the two resulting families \mathbf{P}_i to derive \mathbf{P} .

Strengthening the arguments of [59], we show that each string $F_i \in \mathcal{U}_i \cup \mathcal{V}_i$ is the source of $\mathcal{O}(1)$ modified strings $F'_i \in \mathcal{U}'_i \cup \mathcal{V}'_i$ for any single $(\mathcal{U}'_i, \mathcal{V}'_i) \in \mathbf{P}_i$ and $\mathcal{O}(\min(\ell, \log N)^{k_i})$ modified strings across all $(\mathcal{U}'_i, \mathcal{V}'_i) \in \mathbf{P}_i$. This allows bounding the size of individual sets

$(\mathcal{U}', \mathcal{V}') \in \mathbf{P}$ by $\mathcal{O}(N)$ and the overall size by $\mathcal{O}(N \min(\ell, \log N)^{k_1+k_2})$. In order to efficiently build the compacted tries required at the input of the TWO STRING FAMILIES LCP PROBLEM, the modified strings $F'_i \in \mathcal{U}'_i \cup \mathcal{V}'_i$ are sorted lexicographically, and the two derived linear orders (for $i \in \{1, 2\}$) are maintained along with every pair $(\mathcal{U}', \mathcal{V}') \in \mathbf{P}$. Overall, the family \mathbf{P} is constructed in $\mathcal{O}(n + N \min(\ell, \log N)^{k_1+k_2})$ time and $\mathcal{O}(n + N)$ space.

The resulting instances of the TWO STRING FAMILIES LCP PROBLEM are solved using Lemma 3 (if $\ell > \log^{3/2} N$) or Lemma 4 otherwise; note that $\mathcal{U}', \mathcal{V}'$ are (ℓ, ℓ) -families. ◀

Recall that the algorithm of Theorem 24 is called $k + 1 = \mathcal{O}(1)$ times, always with $N = |A^S| + |A^T| = \mathcal{O}(n/\ell)$. Overall, the value $\max_{k'=0}^k \text{maxPairLCP}_{k', k-k'}(\mathcal{U}, \mathcal{V})$ is therefore computed in $\mathcal{O}(n \log^{k-1/2} n)$ time and $\mathcal{O}(n)$ space in each of the following cases:

- in $\mathcal{O}(n + \frac{n}{\ell} \log^{k+1} N) = \mathcal{O}(n \log^{k-1/2} n)$ time and $\mathcal{O}(n + \frac{n}{\ell}) = \mathcal{O}(n)$ space if $\ell > \log^{3/2} N$;
- in $\mathcal{O}(n + \frac{n}{\ell} \ell \log^{k-1/2} N) = \mathcal{O}(n \log^{k-1/2} n)$ time and $\mathcal{O}(n + \frac{n}{\ell} \ell / \log N) = \mathcal{O}(n)$ space if $\log N < \ell \leq \log^{3/2} N$;
- in $\mathcal{O}(n + \frac{n}{\ell} \ell^k \sqrt{\log N}) = \mathcal{O}(n \log^{k-1} n)$ time and $\mathcal{O}(n + \frac{n}{\ell}) = \mathcal{O}(n)$ space if $\ell \leq \log N$.

Accounting for $\mathcal{O}(n)$ time and space to determine the length d of an LCS between S and T , and the $\mathcal{O}(\log k)$ values ℓ that need to be tested so that the intervals $(\ell/2, \ell]$ cover $[d, (k+1)d + k]$, this concludes the proof of Theorem 2.

Moreover, the three cases yield the following complexities: $\mathcal{O}(n + \frac{n}{\ell} \log^{k+1} n)$ if $\ell > \log^{3/2} N$, $\mathcal{O}(n \log^{k-1/2} n) = \mathcal{O}(\frac{n}{\ell} \log^{k+1} n)$ if $\log N < \ell \leq \log^{3/2} N$, and $\mathcal{O}(n \log^{k-1} n) = \mathcal{O}(\frac{n}{\ell} \log^{k+1} n)$ if $\ell \leq \log N$, which gives an $\mathcal{O}(n + \frac{n}{\ell} \log^{k+1} n)$ -time solution for any ℓ , thus improving [24] for $k = \mathcal{O}(1)$.

Abstract

In this paper, we study feature cross search as a fundamental primitive in feature engineering. The importance of feature cross search especially for the linear model has been known for a while, with well-known textbook examples. In this problem, the goal is to select a small subset of features, combine them to form a new feature (called the crossed feature) by considering their Cartesian product, and find feature crosses to learn an *accurate* model. In particular, we study the problem of maximizing a normalized Area Under the Curve (AUC) of the linear model trained on the crossed feature column.

First, we show that it is not possible to provide an $n^{1/\log \log n}$ -approximation algorithm for this problem unless the exponential time hypothesis fails. This result also rules out the possibility of solving this problem in polynomial time unless $P = NP$. On the positive side, by assuming the naïve Bayes assumption, we show that there exists a simple greedy $(1 - 1/e)$ -approximation algorithm for this problem. This result is established by relating the AUC to the total variation of the commutator of two probability measures and showing that the total variation of the commutator is monotone and submodular. To show this, we relate the submodularity of this function to the positive semi-definiteness of a corresponding kernel matrix. Then, we use Bochner's theorem to prove the positive semi-definiteness by showing that its inverse Fourier transform is non-negative everywhere. Our techniques and structural results might be of independent interest.

1 Introduction

Feature engineering is one of the most fundamental problems in machine learning and it is the key to all supervised learning models. In feature engineering, we start with a collection of features (a.k.a., raw attributes) and turn them into a new set of features, with the purpose of improving the accuracy of the learning model. This is often done by some basic operations, such as removing irrelevant and redundant features (studied as feature selection [10, 32, 33, 26, 11, 25, 18]), combining features (a.k.a., feature cross [30, 20]) and bucketing and compressing the vocabulary of the features [2, 7, 28, 1].

Finding an *efficient* set of features to combine (*i.e.*, cross) is one of the main primitives in feature engineering. Let us start with a text book example to show the importance of feature cross for the linear model. Consider a model with two features, language, which can be English or Spanish, and country, which can be Mexico or Scotland. Say if English appears with Scotland, or if Spanish appears with Mexico, the label is 1. Otherwise the label is 0. It is easy to see that in this case there is no linear model using these two features with a nontrivial accuracy (*i.e.*, the best model matches the label with probability $1/2$). By crossing these two features, we get a new feature with four possible values (English, Mexico), (English, Scotland), (Spanish, Mexico), (Spanish, Scotland). Now, a linear model based on this new feature can perfectly match the label. This is a well-known concept in feature engineering.

Unlike feature selection and vocabulary compression, and despite the importance of feature cross search in practice, this problem is not well studied from a theoretical perspective. While some heuristics and exponential-time algorithms have been developed for this problem (*e.g.*, [30, 20]), the complexity of designing approximation algorithms for this problem is not studied. This might be due to the complex behavior of crossing features on the accuracy of the learning models. In this work, we provide a simple formulation of this problem, and initiate a theoretical study.

Let us briefly define the problem as follows and defer the formal definition of the problem to a later section: Given a set of n features, and a number k , compute a set of at most k features out of n features and combine these k features such that the accuracy of the optimum linear model on the combined feature is maximized. To measure the accuracy we use normalized *Area Under the Curve* (AUC). The bound k is to avoid over fitting.² This is a very basic definition for the feature cross search problem and can be considered as a building block in feature engineering. In fact, as we discuss later in the paper, it is still hard to design algorithms for this basic problem.

First, we show that there is no $n^{1/\log \log n}$ -approximation algorithm for feature cross search unless the exponential time hypothesis fails. Our hardness result also implies that there does not exist a polynomial-time algorithm for feature cross search unless $P = NP$. It is easy to extend these hardness results to other notions of accuracy such as probability of matching the label. Obviously, this hardness result holds for any extension of the problem as well.

In fact, often, the real world inputs are not adversarially constructed. Usually, the inputs follow some structural properties that allow simple algorithms to work efficiently. With this intuition in mind, to complement our hardness result, for features under the naïve Bayes assumption [22, 29, 9], we provide a $(1 - 1/e)$ -approximation algorithm that only needs polynomially many function evaluations. We further discuss and justify this assumption in Section 1.1.

In Section 1.1, we define the problem formally and present our results as well as an overview of our techniques. In Section 2, we provide the preliminary definitions and observations that will be used later in the proofs. In Section 3, we present our hardness results. We relate the maximum AUC to the log-likelihood ratio and the total variation of the commutator of two probability distributions in Section 4. Section 5 establishes the monotonicity and submodularity of the maximum AUC as a set function. This section forms the most technical part of the paper. In Section 6 we present other related works. Finally, Section 7 concludes the paper.

² In practice this number is chosen by tracking the accuracy of the model on the validation data. However, this is out of the scope of this paper.

1.1 Problem Statement and Our Contributions

We start with some definitions necessary to present our results, and then, we present our contributions. Assume that the dataset comprises $n = |U|$ categorical feature columns and a binary label column, where U is the set of all feature columns. Let the random variable X_i denote the value of the i -th feature column ($i \in U$) and $C \in \{0, 1\}$ be the value of the binary label. The random variables $X_1, \dots, X_{|U|}, C$ follow a joint distribution \mathcal{D} . Additionally, we assume that the support of the random variable X_i is a finite set $V_i \subseteq \mathbb{N}$. The set V_i is also known as the *vocabulary* of the i -th feature column. If $A \subseteq U$ is a set of feature columns, we write V_A for $\prod_{a \in A} V_a$ and write X_A for $(X_a | a \in A)$, where $(X_a | a \in A)$ is a vector indexed by $a \in A$ (for example, if $A = \{1, 2, 4\}$, the vector X_A is a 3-dimensional vector (X_1, X_2, X_4)).

Suppose that we focus on a set of feature columns and temporarily ignore the remaining feature columns. In other words, we consider the dataset modeled by the distribution of (X_A, C) . Let $\overline{\mathbb{R}} = \mathbb{R} \cup \{-\infty, +\infty\}$ denote the set of extended real numbers. Given a function $\sigma : V_A \rightarrow \overline{\mathbb{R}}$ that assigns a score to each possible value of X_A , and given a threshold τ , we predict a positive label for X_A if $\sigma(X_A) > \tau$ and predict a negative label if $\sigma(X_A) < \tau$. If $\sigma(X_A) = \tau$, we allow for predicting a positive or negative label at random. Let TPR and FPR denote the true and false positive rate of this model given a certain decision rule, respectively. Note that both true and false positive rates lie in $[0, 1]$. If one varies τ from $-\infty$ to ∞ while fixing the score function σ , a curve that consists of the collection of achievable points (FPR, TPR) is produced and the curve resides in the square $[0, 1] \times [0, 1]$. The area under the curve (AUC) [4] is then defined as the area of the region enclosed by this curve, and the two lines FPR = 1 and TPR = 0.

An equivalent definition is that AUC is roughly the probability that a random positive instance has a higher score (in terms of σ) than a negative instance (we say *roughly* because in Definition 1, we have to be careful about tiebreaking, i.e., the second term).

► **Definition 1** (Area under the curve (AUC) [4]). *Given a set of feature columns A and a function $\sigma : V_A \rightarrow \mathbb{R}$, the area under the curve (AUC) of A and σ is*

$$\text{AUC}_\sigma(A) = \Pr[\sigma(X_A^+) > \sigma(X_A^-) | C^+ = 1, C^- = 0] + \frac{1}{2} \Pr[\sigma(X_A^+) = \sigma(X_A^-) | C^+ = 1, C^- = 0],$$

where $(X_A^+, C^+), (X_A^-, C^-) \sim \mathcal{D}$ are i.i.d. and $X_A^\gamma = (X_a^\gamma | a \in A)$ obeys a marginal distribution of \mathcal{D} (γ is either $+$ or $-$).

The maximum AUC is the AUC of the best scoring function. It is a function of the set of feature columns and independent of the scoring function.

► **Definition 2** (Maximum AUC). *Given a set of feature columns A , the maximum AUC is*

$$\text{AUC}^*(A) = \sup_{\sigma: V_A \rightarrow \mathbb{R}} \text{AUC}_\sigma(A).$$

Now we are ready to present our results. We start with Observation 3 which provides a characterization of AUC via the total variation distance.

► **Observation 3** (AUC as total variation distance). *Let P_i^A be the conditional distribution $\Pr[X_A = i]$ on V_A and let $d_{TV}(P, Q)$ denote the total variation distance between two probability measures P and Q . We have*

$$\text{AUC}^*(A) = \frac{1}{2} + \frac{1}{2} d_{TV}(P_1^A \times P_0^A, P_0^A \times P_1^A) = \frac{1}{2} + \frac{1}{2} \sum_{x, y \in V_A} |P_1^A(x)P_0^A(y) - P_0^A(x)P_1^A(y)|,$$

where $P_1^A \times P_0^A$ and $P_0^A \times P_1^A$ denote the product measures.

Recall that if P and Q are two probability measures on a common σ -algebra \mathcal{F} , the *total variation distance* between them is

$$d_{TV}(P, Q) \triangleq \sup_{A \in \mathcal{F}} |P(A) - Q(A)| \in [0, 1].$$

If the sample space Ω (the set of all outcomes) is finite, Scheffé's lemma [27] gives

$$d_{TV}(P, Q) = \frac{1}{2} \|P - Q\|_1 \triangleq \frac{1}{2} \sum_{\omega \in \Omega} |P(\omega) - Q(\omega)|. \quad (1)$$

We present the proof of Observation 3 in Section 4. Observation 3 shows that the maximum AUC is an affine function of the total variation distance between $P_1^A \times P_0^A$ and $P_0^A \times P_1^A$, where P_i^A is the probability measure conditioned on the label. In light of (1), we have $d_{TV}(P_1^A \times P_0^A, P_0^A \times P_1^A) = \frac{1}{2} \|P_1^A \times P_0^A - P_0^A \times P_1^A\|_1$. We call the signed measure $P_1^A \times P_0^A - P_0^A \times P_1^A$ the *commutator* of the two probability measures P_0^A and P_1^A . Our second remark is that since the total variation distance always resides on $[0, 1]$, the range of the maximum AUC is $[1/2, 1]$.

The next theorem is our main hardness result, stating that it is not possible to approximate feature cross search, unless the exponential time hypothesis [12] fails. We consider maximization of $2 \text{AUC}^*(A) - 1$ rather than $\text{AUC}^*(A)$ in (2) because the range of the maximum AUC is $[1/2, 1]$ (as we remark before) and assigning the same score to all feature values in V_A attains an AUC of $1/2$, thereby achieving at least a $1/2$ -approximation. In light of its range, we consider its normalized version $2 \text{AUC}^*(A) - 1$ whose range is $[0, 1]$. We prove this theorem in Section 3. In fact, our hardness result also implies that the feature cross search problem is NP-hard (see Corollary 14).

► **Theorem 4.** *There is no $n^{1/\text{poly}(\log \log n)}$ -approximation algorithm for the following maximization problem unless the exponential time hypothesis [12] fails.*

$$\max_{A \subseteq U, |A|=k} (2 \text{AUC}^*(A) - 1). \quad (2)$$

Although the above hardness result rules out the existence of an algorithm with a good approximation factor in the general case, it is very rare to face such hard examples in practice. We consider the naïve Bayes assumption that all feature columns are conditionally independent given the label. We borrowed this assumption from the widely-used naïve Bayes classifier [22]. For example, under the same assumption, [15] established the submodularity of mutual information and [6] proved that in the sequential information maximization problem, the most informative selection policy behaves near optimally. [29] conducted an empirical study on the public software defect data from NASA with PCA pre-processing. They concluded that this assumption was not harmful. Although relaxing the assumption could produce numerically more favorable results, they were not statistically significantly better than assuming this assumption. In another example [9], based on their analysis on three real-world datasets for natural language processing tasks (MDR, Newsgroup and the ModApte version of the Reuters-21578), they drew a similar conclusion that relaxing the assumption did not improve the performance.

► **Assumption 1 (Naïve Bayes).** Given the label, all feature columns are independent. In other words, it holds for $A \subseteq U$ and $i = 0, 1$ that

$$\Pr[X_A = x_A | C = i] = \prod_{a \in A} \Pr[X_a = x_a | C = i]. \quad (3)$$

Our major algorithmic contribution is to show that under the naïve Bayes assumption the set function AUC^* is monotone submodular, which in turn, implies that a greedy algorithm provides a constant-factor approximation algorithm for this problem.³

► **Theorem 5.** *Under the naïve Bayes assumption, the set function $\text{AUC}^* : 2^U \rightarrow \mathbb{R}$ is monotone submodular.*

This theorem implies the following result in light of the result of [24].

► **Corollary 6.** *Under the naïve Bayes assumption, there exists a $(1 - 1/e)$ -approximation algorithm that only needs polynomially many evaluations of AUC^* for feature cross search.*

To show Theorem 5, we prove Proposition 7. Proving this proposition requires an involved analysis and it may be of independent interest in statistics.

► **Proposition 7** (Proof in Section 5). *Let U be a finite index set. Assume that for every $a \in U$, there are a pair of probability measures P_0^a and P_1^a on a common sample space V_a . For any $A \subseteq U$, define the set function $F : 2^U \rightarrow \mathbb{R}_{\geq 0}$ by*

$$F(A) = d_{TV} \left(\prod_{a \in A} P_1^a \times \prod_{a \in A} P_0^a, \prod_{a \in A} P_0^a \times \prod_{a \in A} P_1^a \right). \quad (4)$$

The set function F is monotone and submodular.

Its proof is presented in Section 5. In fact, the most technical part of this paper is to prove Proposition 7 which claims that the total variation of the commutator of probability measures is monotone submodular. The monotonicity is a consequence of the subadditivity of the absolute value function. Submodularity is the technically harder part and is shown in the following four steps.

First, we introduce the notion of *involution equivalence*. An involution is a map from a set to itself that is equal to its inverse map. Two probability measures P and P' are said to be involution equivalent if there exists an involution f on the sample space Ω such that for every $x \in \Omega$, it holds that $P(x) = P'(f(x))$. Note that if $P(x) = P'(f(x))$ holds for every $x \in \Omega$, we have $P'(x) = P(f(x))$ also holds for every $x \in \Omega$. In fact, it defines a symmetric relation on probability measures on Ω . If P and Q are two probability measures on a common sample space, the product measures $P \times Q$ and $Q \times P$ are involution equivalent and connected by the natural transpose involution f that sends $(x, y) \in \Omega^2$ to $(y, x) \in \Omega^2$.

The second step is in light of a key observation that summing a bivariate function of two involution equivalent probability measures over the common sample space remains invariant under the swapping of the two measures. Based on this key observation, if P and P' are involution equivalent, for every x in their common sample space, we construct the probability measures of two Bernoulli random variables U_x and U'_x such that $U_x(1) = U'_x(0) = \frac{P(x)}{P(x) + P'(x)}$ and $U_x(0) = U'_x(1) = \frac{P'(x)}{P(x) + P'(x)}$. The two Bernoulli probability measures U_x and U'_x are again involution equivalent and connected by the swapping of 0 and 1. To establish submodularity, one has to check an inequality that characterizes the diminishing returns property (see equation (5) in Section 2.2). Another key observation is that after defining the Bernoulli probability measures, the desired inequality can be shown to be a conic combination of the same inequality with *some* (not all) probability measures in the inequality replaced

³ We will review the definition of submodular and monotone set functions in Section 2.2.

by the Bernoulli probability measures U_x and U'_x . To make the above observation work, we have to require that the remaining probability measures unreplaced in the inequality must be either of the form $P \times Q$ or its transpose $Q \times P$. Using this approach, we reduce the problem to the Bernoulli case.

Third, after reducing the problem to the Bernoulli case, performing a series of more involved algebraic manipulations, we re-parametrize the desired inequality that formulates the diminishing returns property and obtain that the inequality is equivalent to the positive semi-definiteness of a quadratic form with respect to a kernel matrix. However, this re-parametrization is valid only for elements of a positive measure with respect to some probability measures in the inequality. As a consequence, prior to the algebraic manipulations and re-parametrization, we have to eliminate those elements of measure zero by showing that their total contribution to the sum is zero. We would like to remark here that the individual terms may not be zero but they are canceled out under the summation.

Finally, to show that the aforementioned kernel matrix is positive semi-definite, we prove that it is induced by a positive definite function. We establish the positive definiteness of the function by showing that its inverse Fourier transform is non-negative everywhere (this is an implication of the Bochner's theorem, see Section 2).

Theorem 5 is a straightforward corollary of Proposition 7.

Proof. Let $P_i^A[\cdot]$ denote $\Pr[X_A|C = i]$, the conditional probability measure on V_A given the labeling being i , where $i = 0, 1$. When $A = \{a\}$ is a singleton, we write P_i^a for $P_i^{\{a\}}$ as a shorthand notation. Under Assumption 1, (3) can be re-written as $P_i^A[x_A] = \prod_{a \in A} P_i^a[x_a]$, or in a more compact way,

$$P_i^A = \bigotimes_{a \in A} P_i^a.$$

By Observation 3, we have

$$\begin{aligned} \text{AUC}^*(A) &= \frac{1}{2} + \frac{1}{2} d_{TV}(P_1^A \times P_0^A, P_0^A \times P_1^A) \\ &= \frac{1}{2} + \frac{1}{2} d_{TV}\left(\bigotimes_{a \in A} P_1^a \times \bigotimes_{a \in A} P_0^a, \bigotimes_{a \in A} P_0^a \times \bigotimes_{a \in A} P_1^a\right) \\ &= \frac{1}{2} + \frac{1}{2} F(A). \end{aligned}$$

Since $F(A)$ is monotone submodular by Proposition 7, so is AUC^* . ◀

2 Preliminaries

Throughout this paper, let Δ_Ω denote the set of all probability measures on a finite set Ω and we always assume that the sample space Ω is finite. The set of extended real numbers is denoted by $\overline{\mathbb{R}}$ and defined as $\mathbb{R} \cup \{-\infty, +\infty\}$.

2.1 Involution Equivalence

We first review the definition of an involution.

► **Definition 8** (Involution). *A map $f : \Omega \rightarrow \Omega$ is said to be an involution if for all $x \in \Omega$, it holds that $f(f(x)) = x$.*

In this paper, we introduce a new notion termed *involution equivalence*, which forms an equivalence relation on Δ_Ω . Intuitively, two probability measures on a common sample space Ω are involution equivalent if they are the same after renaming the elements in Ω via an involution.

► **Definition 9** (Involution equivalence). *Let P, P' be two probability measures on a common sample space Ω . We say that P and P' are involution equivalent if there exists an involution f such that for all $x \in \Omega$, $P(x) = P'(f(x))$. If P and P' are involution equivalent, we denote it by $P \stackrel{f}{\sim} P'$ or $P \sim P'$ with the involution f omitted when it is not of our interest.*

► **Remark 10.** If $P \stackrel{f}{\sim} P'$, we have $P'(x) = P'(f(f(x))) = P(f(x))$.

► **Remark 11** (Transpose involution). If P and P' are two probability measures on a common sample space Ω , the product measure $P \times P'$ is involution equivalent to $P' \times P$ via the natural transpose map \top that sends $(x, y) \in \Omega^2$ to $\top(x, y) = (y, x) \in \Omega^2$. Thus we write $P \times P' \stackrel{\top}{\sim} P' \times P$ and term \top a *transpose involution*.

2.2 Submodular and Monotone Set Functions

Let us recall the definition of submodular and monotone set functions. Submodular set functions are those satisfying that the marginal gain of adding a new element to a set is no smaller than that of adding the same element to its superset. This property is called the *diminishing returns property*, which naturally arises in data summarization [23], influence maximization [34], and natural language processing [19], among others.

► **Definition 12** (Submodular set function, [24, 14]). *A set function $f : 2^U \rightarrow \mathbb{R}_{\geq 0}$ is submodular if for any $A \subseteq U$ and $a, b \in U \setminus A$ such that $a \neq b$, it satisfies*

$$f(A \cup \{a\}) - f(A) \geq f(A \cup \{a, b\}) - f(A \cup \{b\}). \quad (5)$$

The above Equation (5) formulates the diminishing returns property. Its left-hand side is the marginal gain of adding a to a set A while the right-hand side is the marginal gain of adding the same element a to the superset $A \cup \{b\}$.

A monotone set function is a function that assigns a higher function value to a set than all its subsets.

► **Definition 13** (Monotone set function). *A set function $f : 2^U \rightarrow \mathbb{R}$ is monotone if for any $A \subseteq B \subseteq U$, we have $f(A) \leq f(B)$.*

3 Hardness Result

In this section we show the hardness of approximation of the feature cross search problem. We say an algorithm is an α -approximation algorithm for the feature cross search problem if its accuracy (i.e., $2 \text{AUC} - 1$) is at least α times that of the optimum algorithm.

As a byproduct, we show a hardness result for a feature selection problem based on mutual information defined as follows. In the label-based mutual information maximization problem we have a universe of features U and a vector of labels C , and we want to select a subset S of size k from U that maximizes the mutual information $I(S; C)$. In other words we want to solve $\arg\max_{S \subseteq U, |S|=k} I(S; C)$. We say an algorithm is an α -approximation algorithm for the label-based mutual information maximization problem if it reports a set S such that

$$\alpha \leq \frac{I(S; C)}{\max_{S' \subseteq U, |S'|=k} I(S'; C)}.$$

For both problems, we show that an α -approximation algorithm for the problem implies an α -approximation algorithm for the k -densest subgraph problem. In the k -densest subgraph problem we are given a graph $G(V, E)$ and a number k and we want to pick a subset S of size k from V such that the number of edges induced by S is maximized. Recently, [21] shows that there is no [almost polynomial] $n^{-1/\text{poly}(\log \log n)}$ -approximation algorithm for k -densest subgraph that runs in polynomial time unless the exponential time hypothesis fails. The best known algorithm for this problem has approximation factor $n^{-1/4}$ [3].

► **Theorem 4.** *There is no $n^{1/\text{poly}(\log \log n)}$ -approximation algorithm for the following maximization problem unless the exponential time hypothesis [12] fails.*

$$\max_{A \subseteq U, |A|=k} (2 \text{AUC}^*(A) - 1). \quad (2)$$

Proof. We prove this theorem via an approximation preserving reduction from k -densest subgraph. Let $G(V, E)$ be an instance of k -densest subgraph problem. We construct a set of features as follows. There are $n = |V|$ features each corresponding to one vertex of G . For a vertex $v \in V$ we indicate the value of the feature corresponding to v by x_v . There are three possible feature values, 0, 1 and $\#$. The values of the features are determined by the following random process. Select an edge (u, v) uniformly at random from E . The value of the features x_v and x_u are chosen independently and uniformly at random from $\{0, 1\}$. The value of all other features are $\#$. The value of the label is $x_v \oplus x_u$. To show the hardness of approximation of the feature cross search, we show that any solution of accuracy $\phi = 2 \text{AUC} - 1$ corresponds to a subgraph of G with k vertices and ϕm edges and vice versa.

Let H be a subgraph of G with k vertices and ϕm edges. Let S be the set of features corresponding to the vertices in H . We analyze this in two cases.

Case 1. The value of the crossed feature contains zero or one numbers (*i.e.*, all are $\#$, or all but one are $\#$). Note that this case corresponds to a scenario that the pair of features with binary value are not both in S and hence it happens with probability $\frac{m-\phi m}{m} = 1 - \phi$. Moreover, note that in this case the value of the crossed feature is independent of the value of the label (*i.e.*, given the value of the feature the label is 0 or 1 with probability $1/2$).

Case 2. The value of the crossed feature contains two numbers. In this case one can easily predict the correct label with probability 1 (*i.e.*, if the numbers are both 0 or both 1 output 0, otherwise output 1). Moreover, note that this case corresponds to a scenario that the pair of features with binary values are both in S and hence it happen with probability $\frac{\phi m}{m} = \phi$.

Case 1 happens with probability $1 - \phi$ and in this case the label is independent of the value of the crossed feature, and Case 2 happens with probability ϕ , where the label can be predicted with probability 1. Therefore, we have $\text{AUC} = \int_0^1 \phi + (1 - \phi)p dp = \phi + \frac{1-\phi}{2} = \frac{1+\phi}{2}$ which gives us $2 \text{AUC} - 1 = \phi$ as claimed. ◀

In fact, the densest subgraph problem is NP-hard as well, and hence the reduction in the proof of Theorem 4 directly implies the NP-hardness of feature cross search as well.

► **Corollary 14.** *The feature cross search problem is NP-hard.*

Similar proof to that of Theorem 4 implies the hardness of feature selection via label based mutual information maximization.

► **Theorem 15.** *There is no $n^{-1/\text{poly}(\log \log n)}$ -approximation algorithm for feature selection via label based mutual information maximization unless the exponential time hypothesis fails.*

Proof. Similar to Theorem 4 we prove this theorem via an approximation preserving reduction from k -densest subgraph. Consider the hard example provided in the proof of Theorem 4. Here we show that for any arbitrary set of features S if the induced subgraph of the corresponding vertices has ϕm edges, we have $I(S; C) = \phi$. We define a random variable X as follows. X is 0 if none or one of the features in S has a binary value, and X is 1 if two of the features in S have binary values. Note that the value of C is independent of X , and thus we have $I(S; C) = I(S; C|X)$. Hence, we have

$$\begin{aligned} I(S; C) &= I(S; C|X) = \mathbb{E}_X[I(S, C)|X] \\ &= \Pr[X = 0](I(S; C)|X = 0) + \Pr[X = 1](I(S; C)|X = 1). \end{aligned}$$

Note that given $X = 0$, S and C are independent and hence we have $(I(S; C)|X = 0) = 0$. On the other hand if $X = 1$, S uniquely defines C , and hence we have $(I(S; C)|X = 1) = 1$. Therefore we have $I(S; C) = \mathbb{E}_X[I(S, C)|X] = \Pr[X = 1] = \frac{\phi m}{m} = \phi$, as claimed. ◀

4 Reformulating Maximum AUC

Here, we prove Observation 3 and thereby reformulate the maximum AUC as an affine function of the total variation of the commutator of two probability measures. Furthermore, we show that the maximum AUC is achieved by a specific scoring function, *i.e.*, the log-likelihood ratio.

We start with some definitions. We define the log-likelihood ratio of an event E by $\mathcal{L}(E) = \log \frac{P_1[E]}{P_0[E]}$ provided that $P_0[E]P_1[E] \neq 0$, where $P_i[\cdot] = \Pr[\cdot|C = i]$. If $P_0[E] = 0$, the log-likelihood ratio $\mathcal{L}(E)$ is defined to be $+\infty$. If $P_1[E] = 0$, it is defined to be $-\infty$. As a result, the range of the log-likelihood ratio is the set of extended real numbers, denoted by $\overline{\mathbb{R}} = \mathbb{R} \cup \{-\infty, +\infty\}$. Proposition 16 shows that the maximum AUC is achieved by a specific scoring function, *i.e.*, the log-likelihood ratio \mathcal{L} . Here we abuse the notation and define the score $\mathcal{L}(x_A)$ assigned to each $x_A \in V_A$ to be $\mathcal{L}(X_A = x_A)$, where X_A and C are jointly sampled from \mathcal{D} . In other words, if we assign to each value in V_A a score accordingly, then the AUC is maximized.

► **Proposition 16.** *The log-likelihood ratio achieves the maximum AUC among all functions $\sigma : V_A \rightarrow \overline{\mathbb{R}}$*

$$\text{AUC}_{\mathcal{L}}(A) = \max_{\sigma: V_A \rightarrow \overline{\mathbb{R}}} \text{AUC}_{\sigma}(A).$$

The above proposition is a folklore result. However, we provide a proof for completeness, and the proof steps are also used to prove Observation 3.

Proof of Proposition 16 and Observation 3. To prove the above proposition, it suffices to show that for any scoring function σ , its achieved AUC is no greater than that achieved by using the log-likelihood ratio as the scoring function. In other words, we aim to prove that for any $\sigma : V_A \rightarrow \overline{\mathbb{R}}$,

$$\text{AUC}_{\mathcal{L}}(A) \geq \text{AUC}_{\sigma}(A).$$

Recall Definition 1. The AUC given a scoring function σ can be described using i.i.d. random variables $(X_U^+, C^+), (X_U^-, C^-) \sim \mathcal{D}$. We can express this quantity using indicator functions as follows

$$\text{AUC}_{\sigma}(A) = \mathbb{E}[\mathbf{1}\{\sigma(X_A^+) > \sigma(X_A^-)\} + \frac{1}{2}\mathbf{1}\{\sigma(X_A^+) = \sigma(X_A^-)\}|C^+ = 1, C^- = 0].$$

31:10 Feature Cross Search via Submodular Optimization

Note that $\mathbf{1}\{\sigma(X_A^+) > \sigma(X_A^-)\} + \mathbf{1}\{\sigma(X_A^+) = \sigma(X_A^-)\} + \mathbf{1}\{\sigma(X_A^+) < \sigma(X_A^-)\} = 1$, we have

$$\begin{aligned} \text{AUC}_\sigma(A) &= \frac{1}{2} + \mathbb{E} \left[\frac{1}{2} \mathbf{1}\{\sigma(X_A^+) > \sigma(X_A^-)\} - \frac{1}{2} \mathbf{1}\{\sigma(X_A^+) < \sigma(X_A^-)\} | C^+ = 1, C^- = 0 \right] \\ &= \frac{1}{2} + \frac{1}{2} \mathbb{E} [\mathbf{1}\{\sigma(X_A^+) > \sigma(X_A^-)\} - \mathbf{1}\{\sigma(X_A^+) < \sigma(X_A^-)\} | C^+ = 1, C^- = 0] \\ &= \frac{1}{2} + \frac{1}{2} \mathbb{E} [\text{sign}(\sigma(X_A^+) - \sigma(X_A^-)) | C^+ = 1, C^- = 0]. \end{aligned} \quad (6)$$

To maximize the AUC, we focus on the term $\mathbb{E}[\text{sign}(\sigma(X_A^+) - \sigma(X_A^-)) | C^+ = 1, C^- = 0]$. By symmetrizing this quantity, we obtain the following equations.

$$\begin{aligned} &\mathbb{E}[\text{sign}(\sigma(X_A^+) - \sigma(X_A^-)) | C^+ = 1, C^- = 0] \\ &= \frac{1}{2} (\mathbb{E}[\text{sign}(\sigma(X_A^+) - \sigma(X_A^-)) | C^+ = 1, C^- = 0] + \mathbb{E}[\text{sign}(\sigma(X_A^-) - \sigma(X_A^+)) | C^+ = 0, C^- = 1]) \\ &= \frac{1}{2} (\mathbb{E}[\text{sign}(\sigma(X_A^+) - \sigma(X_A^-)) | C^+ = 1, C^- = 0] - \mathbb{E}[\text{sign}(\sigma(X_A^+) - \sigma(X_A^-)) | C^+ = 0, C^- = 1]) \\ &= \frac{1}{2} \sum_{x_A^+, x_A^- \in V_A} (P_1[x_A^+]P_0[x_A^-] \text{sign}(\sigma(x_A^+) - \sigma(x_A^-)) - P_1[x_A^-]P_0[x_A^+] \text{sign}(\sigma(x_A^+) - \sigma(x_A^-))) \\ &= \frac{1}{2} \sum_{x_A^+, x_A^- \in V_A} (P_1[x_A^+]P_0[x_A^-] - P_1[x_A^-]P_0[x_A^+]) \text{sign}(\sigma(x_A^+) - \sigma(x_A^-)). \end{aligned} \quad (7)$$

The above expression can be upper bounded by the total variation distance between $P_1 \times P_0$ and $P_0 \times P_1$.

$$\begin{aligned} \mathbb{E}[\text{sign}(\sigma(X_A^+) - \sigma(X_A^-)) | C^+ = 1, C^- = 0] &\leq \frac{1}{2} \sum_{x_A^+, x_A^- \in V_A} |P_1[x_A^+]P_0[x_A^-] - P_1[x_A^-]P_0[x_A^+]| \\ &= d_{TV}(P_1^A \times P_0^A, P_0^A \times P_1^A). \end{aligned} \quad (8)$$

Note that whenever $P_1[x_A^+]P_0[x_A^-]$ or $P_1[x_A^-]P_0[x_A^+]$ is non-zero, the log-likelihood ratios $\mathcal{L}(x_A^+)$ and $\mathcal{L}(x_A^-)$, as well as $\mathcal{L}(x_A^+) - \mathcal{L}(x_A^-)$, are well defined on \mathbb{R} . Hence, if $P_1[x_A^+]P_0[x_A^-] - P_1[x_A^-]P_0[x_A^+] \neq 0$, one can show that

$$\text{sign}(P_1[x_A^+]P_0[x_A^-] - P_1[x_A^-]P_0[x_A^+]) = \text{sign}(\mathcal{L}(x_A^+) - \mathcal{L}(x_A^-)).$$

Consequently, all equality conditions in (8) can be achieved by using log-likelihood ratio as the scoring function, and we have

$$\begin{aligned} \mathbb{E}[\text{sign}(\sigma(X_A^+) - \sigma(X_A^-)) | C^+ = 1, C^- = 0] &\leq \mathbb{E}[\text{sign}(\mathcal{L}(X_A^+) - \mathcal{L}(X_A^-)) | C^+ = 1, C^- = 0] \\ &= d_{TV}(P_1^A \times P_0^A, P_0^A \times P_1^A). \end{aligned} \quad (9)$$

Combining (6) and (9), we have the following bound that holds true for any σ ,

$$\text{AUC}_\sigma(A) \leq \text{AUC}_\mathcal{L}(A) = \frac{1}{2} + \frac{1}{2} d_{TV}(P_1^A \times P_0^A, P_0^A \times P_1^A), \quad (10)$$

which completes the proof. \blacktriangleleft

According to Proposition 16 and equation (10), Observation 3 directly follows.

5 Total Variation of Commutator of Probability Measures

In this section, we prove Proposition 7, which states that the total variation of commutator of probability measures is a monotone submodular set function.

► **Proposition 7** (Proof in Section 5). *Let U be a finite index set. Assume that for every $a \in U$, there are a pair of probability measures P_0^a and P_1^a on a common sample space V_a . For any $A \subseteq U$, define the set function $F : 2^U \rightarrow \mathbb{R}_{\geq 0}$ by*

$$F(A) = d_{TV} \left(\bigotimes_{a \in A} P_1^a \times \bigotimes_{a \in A} P_0^a, \bigotimes_{a \in A} P_0^a \times \bigotimes_{a \in A} P_1^a \right). \quad (4)$$

The set function F is monotone and submodular.

5.1 Monotonicity Part of Proposition 7

We first show the monotonicity part.

Proof of Proposition 7 (Monotonicity). Let A and B be two subsets of U such that $A \subseteq B$. For any $A \subseteq U$, let $P_i^A = \bigotimes_{a \in A} P_i^a$. Using the above notation, we have $P_i^B = P_i^A \times P_i^{B \setminus A}$. By the definition of F , we have

$$\begin{aligned} F(A) &= d_{TV} (P_1^A \times P_0^A, P_0^A \times P_1^A) \\ &= \frac{1}{2} \sum_{x, y \in V_A} |P_1^A(x)P_0^A(y) - P_0^A(x)P_1^A(y)| \\ &= \frac{1}{2} \sum_{x, y \in V_A} \left| \sum_{z, w \in V_{B \setminus A}} P_1^A(x)P_0^A(y)P_1^{B \setminus A}(z)P_0^{B \setminus A}(w) \right. \\ &\quad \left. - \sum_{z, w \in V_{B \setminus A}} P_0^A(x)P_1^A(y)P_0^{B \setminus A}(z)P_1^{B \setminus A}(w) \right| \\ &\leq \frac{1}{2} \sum_{x, y \in V_A} \sum_{z, w \in V_{B \setminus A}} |P_1^A(x)P_0^A(y)P_1^{B \setminus A}(z)P_0^{B \setminus A}(w) - P_0^A(x)P_1^A(y)P_0^{B \setminus A}(z)P_1^{B \setminus A}(w)| \\ &= d_{TV}(P_1^A \times P_1^{B \setminus A} \times P_0^A \times P_0^{B \setminus A}, P_0^A \times P_0^{B \setminus A} \times P_1^A \times P_1^{B \setminus A}) \\ &= d_{TV}(P_1^B \times P_0^B, P_0^B \times P_1^B) \\ &= F(B). \end{aligned}$$

where the third equality is because

$$\sum_{z, w \in V_{B \setminus A}} P_1^{B \setminus A}(z)P_0^{B \setminus A}(w) = \sum_{z, w \in V_{B \setminus A}} P_0^{B \setminus A}(z)P_1^{B \setminus A}(w) = 1$$

and the inequality is a consequence of the triangle inequality. ◀

5.2 Submodularity Part of Proposition 7

To prove the submodularity part, we need the following lemmas.

► **Lemma 17** (General case, proof in the full version [5]). *Let $R, R' \in \Delta_{\Omega_1}$, $S, S' \in \Delta_{\Omega_2}$, and $P, Q \in \Delta_{\Omega}$, where $\Omega_1, \Omega_2, \Omega$ are finite sets. If $R \stackrel{f}{\sim} R'$ and $S \stackrel{g}{\sim} S'$, it holds that*

$$d_{TV}(R \times S \times P \times Q, R' \times S' \times Q \times P) - d_{TV}(R \times P \times Q, R' \times Q \times P) \\ - d_{TV}(S \times P \times Q, S' \times Q \times P) + d_{TV}(P \times Q, Q \times P) \leq 0.$$

We begin with the Bernoulli case where Ω_1 and Ω_2 in its statement are both $\{0, 1\}$ so that R, R', S, S' are all probability measures of a Bernoulli random variable.

► **Lemma 18** (Bernoulli case, proof in the full version [5]). *Let $R, R', S, S' \in \Delta_{\{0,1\}}$ such that $R \stackrel{f}{\sim} R'$ and $S \stackrel{f}{\sim} S'$, where f is a function on $\{0, 1\}$ such that $f(0) = 1$ and $f(1) = 0$. Let $P, Q \in \Delta_{\Omega}$, where Ω is a finite sample space. The following inequality holds*

$$d_{TV}(R \times S \times P \times Q, R' \times S' \times Q \times P) - d_{TV}(R \times P \times Q, R' \times Q \times P) \\ - d_{TV}(S \times P \times Q, S' \times Q \times P) + d_{TV}(P \times Q, Q \times P) \leq 0. \quad (11)$$

Proof sketch. To prove the Bernoulli case, we first show that under the summation (recall that according to Equation (1), the total variation distance is half of the L^1 distance, and the L^1 distance is the sum of the absolute value of the difference on each singleton), any term that involves an element of measure zero (with respect to P or Q) has no contribution to the expression on the left-hand side. We would like to emphasize that while the term itself may be non-zero, it will be canceled out under the summation. In our second step, we will consider quantities of the form $\sqrt{\frac{P(x)Q(y)}{Q(x)P(y)}}$ in which $Q(x)$ and $P(y)$ must be non-zero for all x and y . As a result, we have to eliminate elements of measure zero in first step by showing that their total contribution is zero.

As the second step, we perform a series of algebraic manipulations and substitutions and finally show that the opposite of left-hand side can be re-written as a quadratic $v^\top M v$, where v is a vector and M is a symmetric square matrix. Recall that the promised inequality claims that the left-hand side is non-positive (thus the opposite of the left-hand side is non-negative). Therefore, we will show it by establishing the positive semi-definiteness of M .

In fact, the matrix M is induced by a positive definite function. The problem of establishing the positive semi-definiteness of M reduces to the problem of proving that the function that induces M is positive definite. In light of the Bochner's theorem (see the full version [5]), we show its positive definiteness by computing its inverse Fourier transform, which turns out to be finite-valued and non-negative everywhere. ◀

The high-level strategy of proving Lemma 17 is to use Observation 19 to reduce the problem to the Bernoulli case (Lemma 18). The proof details can be found in the full version [5].

► **Observation 19.** *Let $P, P' \in \Delta_{\Omega}$ be such that $P \stackrel{f}{\sim} P'$ and $\phi : \mathbb{R}^2 \rightarrow \mathbb{R}$ be a homogeneous bivariate function, i.e., $\phi(\lambda x, \lambda y) = \lambda \phi(x, y)$ holds for any $x, y, \lambda \in \mathbb{R}$. For every element $x \in \Omega$, we define the Bernoulli probability measure U_x on $\{0, 1\}$ such that $U_x(1) = \frac{P(x)}{P(x)+P'(x)}$ and $U'_x(1) = \frac{P'(x)}{P(x)+P'(x)}$. The following equation holds*

$$\sum_{x \in \Omega} \phi(P(x), P'(x)) = \sum_{x \in \Omega} \frac{P(x) + P'(x)}{2} (\phi(U_x(1), U'_x(1)) + \phi(U'_x(1), U_x(1))).$$

Before presenting the proof of Observation 19, we introduce the involutory swapping lemma, which is also used in the proof of Lemma 17. Intuitively, the involutory swapping lemma implies that two involution equivalent probability measures can be swapped inside a summation of a bivariate function.

► **Lemma 20** (Involutory swapping lemma). *Let $P, P' \in \Delta_\Omega$ be such that $P \stackrel{f}{\sim} P'$ and $\phi : \mathbb{R}^2 \rightarrow \mathbb{R}$ be any bivariate function. Then we have*

$$\sum_{x \in \Omega} \phi(P(x), P'(x)) = \sum_{x \in \Omega} \phi(P'(x), P(x)).$$

Proof. Under the assumption of the lemma statement, we have

$$\begin{aligned} & \sum_{x \in \Omega} \phi(P(x), P'(x)) \\ &= \sum_{x \in \Omega} \phi(P'(f(x)), P(f(x))) \\ &= \sum_{x' \in \Omega} \phi(P'(x'), P(x')) \\ &= \sum_{x \in \Omega} \phi(P'(x), P(x)). \end{aligned}$$

The first equality is because for any $x \in \Omega$, we have $P(x) = P'(f(x))$ (by the definition of involution equivalence) and $P(f(x)) = P'(x)$ (Remark 10). The second equality is obtained by setting $x' = f(x)$ (this is because any involution map f is a bijection). The final equality is obtained by renaming x' to x . ◀

Proof of Observation 19. Under the assumption of the observation statement, we have

$$\begin{aligned} \sum_{x \in \Omega} \phi(P(x), P'(x)) &= \frac{1}{2} \sum_{x \in \Omega} \phi(P(x), P'(x)) + \frac{1}{2} \sum_{x \in \Omega} \phi(P(x), P'(x)) \\ &= \frac{1}{2} \sum_{x \in \Omega} \phi(P(x), P'(x)) + \frac{1}{2} \sum_{x \in \Omega} \phi(P'(x), P(x)) \\ &= \sum_{x \in \Omega} \frac{P(x) + P'(x)}{2} (\phi(U_x(1), U'_x(1)) + \phi(U'_x(1), U_x(1))). \end{aligned}$$

We use Lemma 20 in the second term on the second line and the third equality is because ϕ is homogeneous. ◀

We are in a position to show the submodularity part, which follows from Lemma 17.

Proof of Proposition 7 (Submodularity). To show that F is submodular, we need to check its definition that for any $A \subseteq U$ and $a, b \in U \setminus A$ such that $a \neq b$, it holds that

$$F(A \cup \{a\}) + F(A \cup \{b\}) \geq F(A \cup \{a, b\}) + F(A),$$

If we define $P_i^A = \times_{a \in A} P_i^a$, the above definition is equivalent to

$$\begin{aligned} & d_{TV}(P_1^a \times P_0^a \times P_1^A \times P_0^A, P_0^a \times P_1^a \times P_0^A \times P_1^A) \\ &+ d_{TV}(P_1^b \times P_0^b \times P_1^A \times P_0^A, P_0^b \times P_1^b \times P_0^A \times P_1^A) \\ &\geq d_{TV}(P_1^a \times P_0^a \times P_1^b \times P_0^b \times P_1^A \times P_0^A, P_0^a \times P_1^a \times P_0^b \times P_1^b \times P_0^A \times P_1^A) \\ &+ d_{TV}(P_1^A \times P_0^A, P_0^A \times P_1^A). \end{aligned}$$

Re-arranging the terms yields

$$\begin{aligned}
& d_{TV}(P_1^a \times P_0^a \times P_1^b \times P_0^b \times P_1^A \times P_0^A, P_0^a \times P_1^a \times P_0^b \times P_1^b \times P_0^A \times P_1^A) \\
& - d_{TV}(P_1^a \times P_0^a \times P_1^A \times P_0^A, P_0^a \times P_1^a \times P_0^A \times P_1^A) \\
& - d_{TV}(P_1^b \times P_0^b \times P_1^A \times P_0^A, P_0^b \times P_1^b \times P_0^A \times P_1^A) \\
& + d_{TV}(P_1^A \times P_0^A, P_0^A \times P_1^A) \leq 0.
\end{aligned}$$

The above inequality follows from Lemma 17 if we set $P = P_1^A$, $Q = P_0^A$, $R = P_1^a \times P_0^a$, $R' = P_0^a \times P_1^a$, $S = P_1^b \times P_0^b$, and $S' = P_0^b \times P_1^b$. Note that $R \sim R'$ and $S \sim S'$ via the transpose involution (see Remark 11). \blacktriangleleft

6 Other Related Works

As discussed before, our problem falls in the category of feature engineering problems. Perhaps, the most studied problem in feature engineering is feature selection [10, 32, 33, 26, 11, 25, 18, 31]. In this problem, the goal is to select a small subset of the features to obtain a learning model with high accuracy and avoid over-fitting. Here we just mention a couple of feature selection algorithm related to submodular maximization and refer to [10] for an introduction to feature selection and many relevant references. [8] used the notion of weak submodularity to design and analyze feature selection algorithms. [16] used the submodularity of mutual information between the sensors to design a $(1 - 1/e)$ -approximation algorithm for sensor placements, which can be directly used for feature selection. However, as we show in Theorem 15, it is not possible to design such algorithms to maximize the mutual information between the features and the label.

Another related well-studied problem in this domain is vocabulary compression [2, 7, 28, 1]. The goal of vocabulary compression is to improve the learning and serving time, and in some cases to avoid overfitting. Vocabulary compression can be done by simple approaches such as filtering and naive bucketing, or more complex approaches such as mutual information maximization. [1] and [28] used clustering algorithms based on the Jensen-Shannon divergence to compress the vocabulary of features. [7] proposed an iterative algorithm that locally maximizes the mutual information between a feature and the label. Recently, [2] considered this problem for binary labels and presented a quasi-linear-time distributed approximation algorithm to maximize the mutual information between the feature and the label. There are polynomial-time local algorithms for binary labels that maximize the mutual information [17, 13], studied in the context of discrete memoryless channels.

[30] designed an integer programming based algorithm for feature cross search and applied it to learn generalized linear models using rule-based features. They show that this approach obtains better accuracy compared to that of the existing rule ensemble algorithms. [20] proposed a greedy algorithm for feature cross search and show that the greedy algorithm works well on a variety of datasets. Neither of these papers provide any theoretical guarantees for the performance of their algorithm.

7 Conclusion

In this paper, we considered the problem of feature cross search. We formulated it as a problem of maximizing the normalized area under the curve (AUC) of the linear model trained on the crossed feature column. We first established a hardness result that no algorithm can provide $n^{1/\log \log n}$ approximation for this problem unless the exponential time hypothesis

fails. Therefore, no polynomial algorithm can solve this problem unless $P = NP$. In light of its intractable nature, we motivated and assumed the naïve Bayes assumption. We related AUC to the total variation of the commutator of two probability measures. Under the naïve Bayes assumption, we demonstrated that the aforementioned total variation is monotone and submodular with respect to the set of selected feature columns to be crossed. As a result, a greedy algorithm can achieve a $(1 - 1/e)$ -approximation of the problem. Our proof techniques may be of independent interest. Finally, an empirical study showed that the greedy algorithm outperformed the baselines.

Abstract

We consider the embeddability problem of a graph G into a two-dimensional simplicial complex C : Given G and C , decide whether G admits a topological embedding into C . The problem is NP-hard, even in the restricted case where C is homeomorphic to a surface.

It is known that the problem admits an algorithm with running time $f(c)n^{O(c)}$, where n is the size of the graph G and c is the size of the two-dimensional complex C . In other words, that algorithm is polynomial when C is fixed, but the degree of the polynomial depends on C . We prove that the problem is fixed-parameter tractable in the size of the two-dimensional complex, by providing a deterministic $f(c)n^3$ -time algorithm. We also provide a randomized algorithm with expected running time $2^{c^{O(1)}}n^{O(1)}$.

Our approach is to reduce to the case where G has bounded branchwidth via an irrelevant vertex method, and to apply dynamic programming. We do not rely on any component of the existing linear-time algorithms for embedding graphs on a fixed surface; the only elaborated tool that we use is an algorithm to compute grid minors.

1 Introduction

An embedding of a graph G into a host topological space X is a crossing-free topological drawing of G into X . The use and computation of graph embeddings is central in the communities of computational topology, topological graph theory, and graph drawing. A landmark result is the algorithm of Hopcroft and Tarjan [12], which allows to decide whether a given graph is planar (has an embedding into the plane) in linear time. Related results include more planarity testing algorithms [21], algorithms for embedding graphs on surfaces [18, 13] and for computing book embeddings [17], Hanani-Tutte theorems [24], and the theory of crossing numbers and planarization [2].

In this paper, we describe algorithms for deciding the embeddability of graphs into topological spaces that are, in a sense, as general as possible: two-dimensional simplicial complexes (or 2-complexes for brevity), which are made from vertices, edges, and triangles glued together. (We remark that every graph is embeddable in \mathbb{R}^3 , so considering higher-dimensional simplicial complexes is irrelevant.) In a previous article, jointly written with

Mohar [6], we proved that, given a graph G and a 2-complex \mathcal{C} , one can decide whether G embeds into \mathcal{C} in polynomial time for fixed \mathcal{C} ; but the algorithm has running time $f(c) \cdot n^{O(c)}$, where n and c are the respective sizes of G and \mathcal{C} . Using a very different strategy, we describe algorithms for this problem, proving that it is fixed-parameter tractable in the complexity of the input complex:

► **Theorem 1.1.** *One can solve the embeddability problem of graphs into 2-dimensional simplicial complexes in deterministic $f(c)n^3$ time or in expected time $2^{c^{O(1)}}n^{O(1)}$, where c is the number of simplices of the input 2-complex, n is the number of vertices and edges of the input graph, and f is some computable function of c .*

2-complexes are much more general than surfaces, and tools that are suitable for studying embeddability of graphs on surfaces do not generalize. For example, the set of graphs embeddable on a given 2-complex is not closed under minor, which makes many tools for dealing with graphs on surfaces unsuitable for 2-complexes. Moreover, the complexity of some topological problems increase drastically when we consider 2-complexes instead of surfaces, e.g., deciding homeomorphism [20], or deciding the contractibility of curves [8, 16, 10]. Some other topological problems, such as the existence of a drawing a graph with at most k crossings in the plane or in a surface [14], can be recast as deciding whether the graph embeds on a certain 2-complex. For more detailed motivations, see [6, Introduction].

Comparison with previous works on surfaces

Since every surface is homeomorphic to a 2-complex, our problem has been largely considered in the special case where the input 2-complex is (homeomorphic to) a surface. That restricted problem is NP-hard [26], but several algorithms that are fixed-parameter tractable in the genus have been given, which we review now.

Mohar [18] has given an algorithm for this purpose that takes linear time in the input graph, for every fixed surface. This algorithm is very technical and relies on several other articles. The dependence on the genus is not made explicit, but seems to be doubly exponential [13].

Kawarabayashi et al., in an extended abstract [13], have given a simpler linear-time algorithm for this problem, but not all details are presented, which makes the approach hard to check [15, p. 3657, footnote].

General graph minor theory provides an algorithm for the same purpose. The graph minor theorem by Robertson and Seymour [23] implies that, for every fixed surface \mathcal{S} , there is a finite list of graphs $\mathcal{O}_{\mathcal{S}}$ such that a graph G can be embedded on \mathcal{S} if and only if G does not contain any graph in $\mathcal{O}_{\mathcal{S}}$ as a minor. Moreover, there is an algorithm that given any surface \mathcal{S} (specified by its genus and orientability) outputs the list $\mathcal{O}_{\mathcal{S}}$ [1], and there is an algorithm to decide whether a graph M is a minor of another graph G running, for fixed M , in time cubic in the size of G [22][7, Theorem 6.12]. These considerations thus lead to an algorithm to decide embeddability of a graph on a surface that runs, if the input surface is fixed, in cubic time in the size of the input graph.

Finally, in the same vein, Kociumaka and Pilipczuk [15] have studied the following more general problem than the embeddability problem of graphs on surfaces: Given a surface \mathcal{S} , a graph G , and an integer $k \geq 0$, is it possible to remove a set U of at most k vertices from G so that $G - U$ is embeddable on \mathcal{S} ? They provide an algorithm that is fixed-parameter tractable in k and the genus of \mathcal{S} , where the dependence on the genus is unspecified. In particular, as a special case, they decide the embeddability of a graph on a surface; however, they use one of the previous algorithms [18, 13] as a subroutine. The problem that we study, the embeddability of graphs on 2-complexes, is independent from the problem studied by Kociumaka and Pilipczuk, in the sense that there is, a priori, no obvious reduction from one problem to the other. However, we will reuse some ingredients from that paper.

Our algorithms, restricted to the case where we want to embed graphs on surfaces, are not as efficient as the existing algorithms mentioned above. Indeed, the deterministic one runs in cubic time in the size of the input graph (for a fixed complex); the dependence on the size of the complex is not made explicit, because the algorithm uses, as a subroutine, an algorithm to compute grid minors [22]. The second algorithm is randomized, because it uses an algorithmic version of the excluded grid theorem [3] that uses randomness; for every fixed surface, it runs in expected time that is a polynomial of fixed (but large) degree in the size of the input graph. However, our algorithms are independent from the existing algorithms for embedding graphs on surfaces; the only elaborated tool that we use is an algorithm to compute grid minors [3, 22].

Overview and structure of the paper

We use a standard strategy in graph algorithms and parameterized complexity (see, e.g., the book by Cygan et al. [7, Chapter 7]): we show by dynamic programming that the problem can be solved efficiently for graphs of bounded branchwidth, and then, using an irrelevant vertex method, we prove that one can assume without loss of generality that the input graph G has branchwidth bounded by a polynomial in the size of the input 2-complex. In the context of surface-embedded graphs, this paradigm has been used in the extended abstract by Kawarabayashi et al. [13] and in the article by Kociumaka and Pilipczuk [15]; our algorithm takes inspiration from the former, for the idea of the dynamic programming algorithm, and from the latter, for some arguments in the irrelevant vertex method. However, handling 2-complexes requires significantly more effort. More precisely, Theorem 1.1 follows immediately from the following two theorems.

► **Theorem 1.2** (algorithm for bounded branchwidth). *One can solve the embeddability problem of graphs into two-dimensional simplicial complexes in time $(c + w)^{O(c+w)}n$, where c is the number of simplices of the input 2-complex, and where n and w are the number of vertices and edges and the branchwidth of the input graph, respectively.*

► **Theorem 1.3** (algorithm to reduce branchwidth). *Let \mathcal{C} be a 2-complex with c simplices, and G a graph with n vertices and edges. We can correctly report that G is embeddable on \mathcal{C} , or correctly report that G is not embeddable on \mathcal{C} , or compute a subgraph H of G , of branchwidth polynomial in the number of simplices of \mathcal{C} , such that G embeds on \mathcal{C} if and only if H does:*

- *in deterministic time $f(c) \cdot n^3$ for some computable function f ,*
- *or in expected polynomial time.*

We now present the structure of the paper, indicating which techniques are used. We also emphasize which components would be simpler if we were just aiming for an algorithm for embedding graphs on surfaces.

We introduce some standard notions in Section 2.

Then, in Section 3, we show that we can make some simple assumptions on the input, and present data structures for representing 2-complexes and graphs embedded on them. If we restrict ourselves to the case where the input 2-complex is homeomorphic to a surface, we essentially consider combinatorial maps of graphs on surfaces, except that the graphs need not be cellularly embedded. The case of 2-complexes is largely more involved.

In Section 4, we show that if our input graph G has an embedding into our input 2-complex \mathcal{C} , then there exists an embedding of G on \mathcal{C} that is *sparse* with respect to a branch decomposition of G . This means that each subgraph of G induced by the leaves

of any subtree of the branch decomposition can be separated from the rest of G using a graph embedded on \mathcal{C} , called *partitioning graph*, of small complexity. We find that this new structural result, even in the surface case, is interesting and can prove useful in other contexts. If the target space were a surface, we could assume that G is 3-connected and has no loop or multiple edges, which would imply (still with some work) that *any* embedding of G would be sparse, but again the fact that we consider 2-complexes requires additional work.

In Section 5, we present the dynamic programming algorithm, which either determines the existence of an embedding of G on \mathcal{C} , or shows that no sparse embedding of G on \mathcal{C} exists (and thus no embedding at all, by the previous paragraph). The idea is to use bottom-up dynamic programming and to consider all regions of the 2-complex in which the subgraph of G (induced by a subtree of the branch decomposition) can be embedded. The complexity depends exponentially on the branchwidth of G .

The previous arguments, most notably in Section 4, implicitly assumed that, if G has an embedding into \mathcal{C} , it has a *proper and cellular embedding*, in particular, in which the faces are homeomorphic to disks. In Section 6, we show that we can assume this property. Essentially, we build all 2-complexes “smaller” than \mathcal{C} , such that G embeds on \mathcal{C} if and only if it embeds into (at least) one of these 2-complexes, and moreover if it is the case, it has an embedding into (at least) one of these 2-complexes that is proper and cellular. If \mathcal{C} were an orientable surface, we would just consider the surfaces of lower genus; but here a more sophisticated approach is needed.

The above ingredients allow to prove Theorem 1.2 (Section 7).

In Section 8, we show, using an irrelevant vertex method, that we can assume that G has branchwidth polynomial in the size of \mathcal{C} (Theorem 1.3).

2 Preliminaries

2.1 Graphs and branch decompositions

In this paper, graphs may have loops and multiple edges unless noted otherwise. Let G be a graph; as usual, we denote by $V(G)$ and $E(G)$ the sets of vertices and edges of G .

A **(rooted) branch decomposition** of G is a rooted tree \mathcal{B} in which:

- every node has degree either one (it is a **leaf**) or three (it is an **internal node**),
- the root is a leaf,
- each non-root leaf is labelled with an edge of G , and this labelling induces a bijection.

The vertices and edges of \mathcal{B} are called **nodes** and **arcs**, respectively. Each arc α of \mathcal{B} splits the tree \mathcal{B} into two subtrees \mathcal{B}_1 and \mathcal{B}_2 ; if, for $i = 1, 2$, we denote by E_i the set of labels appearing in T_i , we see that α naturally induces a partition (E_1, E_2) of the set of edges of G (if α is the arc incident to the root, then one part of the partition is empty). The **middle set** associated to α is the set of vertices of G which are the endpoints of at least one edge in E_1 and at least one edge in E_2 . The **width** of \mathcal{B} is the maximum size of a middle set associated to an arc of \mathcal{B} . The **branchwidth** of G is the minimum width of its (rooted) branch decompositions.

The usual definition of a branch decomposition is identical, except that the tree is unrooted, and thus the leaves are in bijection with the edges of G . Our definition turns out to be more convenient to use in the dynamic program. The difference is cosmetic, as one can transform one kind of branch decomposition into the other easily while preserving the width.

2.2 Surfaces

We will assume some familiarity with surface topology; see, e.g., [19, 25, 4] for suitable introductions under various viewpoints. We recall some basic definitions and properties. A **surface** (without boundary) \mathcal{S} is a compact, connected Hausdorff topological space in which every point has an open neighborhood homeomorphic to the open disk. Up to homeomorphism, every surface \mathcal{S} is obtained from a sphere by:

- either removing $g/2$ open disks and attaching a handle (a torus with an open disk removed) to each resulting boundary component, where g is an even, nonnegative integer called the (*Euler*) **genus** of \mathcal{S} ; in this case, \mathcal{S} is **orientable**;
- or removing g open disks and attaching a Möbius band to each resulting boundary component, for a positive number g called the (non-orientable) **genus** of \mathcal{S} ; in this case, \mathcal{S} is **non-orientable**.

A **possibly disconnected surface** is a disjoint union of surfaces.

A **surface with boundary** is obtained from a surface (without boundary) by removing a finite set of interiors of disjoint closed disks. The boundary of each disk forms a **boundary component** of \mathcal{S} . The **genus** of \mathcal{S} is defined as the genus of the original surface without boundary. Equivalently, a surface with boundary is a compact, connected Hausdorff topological space in which every point has an open neighborhood homeomorphic to the open disk or the closed half disk $\{(x, y) \in \mathbb{R}^2 \mid y \geq 0, x^2 + y^2 < 1\}$.

2.3 2-complexes

A **2-complex** (or two-dimensional simplicial complex) is an abstract simplicial complex of dimension at most two: a finite set of 0-simplices called **vertices**, 1-simplices called **edges**, and 2-simplices called **triangles**. Each edge is a pair of vertices, and each triangle is a triple of vertices; moreover, each subset of size two in a triangle must be an edge.

Each 2-complex \mathcal{C} corresponds naturally to a topological space, obtained as follows: Start with one point per vertex in \mathcal{C} ; connect them by segments as indicated by the edges in \mathcal{C} ; similarly, for every triangle in \mathcal{C} , create a triangle whose boundary is made of the three edges contained in that triangle. By abuse of language, we identify \mathcal{C} with that topological space.

2.4 Graph embeddings

Each graph has a natural associated topological space (for graphs without loops or multiple edges, this is a specialization of the definition for 2-complexes). An **embedding** Γ of a graph G into a 2-complex \mathcal{C} is an injective continuous map from (the topological space associated to) G to (the topological space associated to) \mathcal{C} . A **face** of Γ is a connected component of the complement of the image of Γ in \mathcal{C} .

3 2-complexes and their data structures

3.1 Some preprocessing

A **3-book** is a topological space obtained from three triangles by considering one side per triangle and identifying these three sides together into a single edge. We say that a 2-complex \mathcal{C} **contains a 3-book** if \mathcal{C} contains three distinct triangles that share a common edge. Because every graph can be embedded into a 3-book [6, Proposition 3.1], we have the following proposition:

■ **Figure 1** On the left: A 2-complex with 5 singular points, numbered from 1 to 5, and 2 isolated edges (one between 3 and 4 and one between 1 and 2) where, at singular points, the cones are in green and the corners in yellow. On the right: the corresponding detached surface.

► **Proposition 3.1.** *To decide the embeddability of a graph G on a 2-complex \mathcal{C} , we can without loss of generality, after a linear-time preprocessing, assume the following properties on the input:*

- \mathcal{C} has no 3-book and no connected component that is reduced to a single vertex;
- G has no connected component reduced to a single vertex, and at most one connected component homeomorphic to a segment.

In the rest of this article, without loss of generality, we implicitly assume that \mathcal{C} and G satisfy the properties stated in Proposition 3.1.

3.2 Structure of 2-complexes without 3-book or isolated vertex

Let \mathcal{C} be a 2-complex without 3-book or isolated vertex, and let p be a vertex of \mathcal{C} . Following [6, Section 2.2], we describe the possible neighborhoods of p in \mathcal{C} . A **cone at p** is a cyclic sequence of triangles t_1, \dots, t_k, t_1 ($k \geq 3$), all incident to p , such that, for each $i = 1, \dots, k$, the triangles t_i and t_{i+1} (where $t_{k+1} = t_1$) share an edge incident with p , and any other pair of triangles have only p in common. A **corner at p** is a sequence of distinct triangles t_1, \dots, t_k , all incident to p , such that, for each $i = 1, \dots, k-1$, the triangles t_i and t_{i+1} share an edge incident with p , any other pair of these triangles have only p in common, and no other triangle in \mathcal{C} shares an edge incident with p and belonging to one of t_1, \dots, t_k . An **isolated segment at p** is an edge incident to p but not incident to any triangle. The cones, corners, and isolated segments at p form the **link components at p** .

The set of edges and triangles incident with a given vertex p of \mathcal{C} are uniquely partitioned into cones, corners, and isolated segments. We say that p is a **regular point** if all the edges and triangles incident to p form a single cone or corner; in that case, p has an open neighborhood homeomorphic to a disk or a closed half-disk. Otherwise, p is a **singular point**. See Figure 1, left, for an illustration.

Detaching a singular point p in \mathcal{C} consists of the following operation: replace p with new vertices, one for each cone, corner, and isolated segment at p . Detaching all singular points of a 2-complex (without 3-book) yields a disjoint union of (1) isolated segments and (2) a surface, possibly disconnected, possibly with boundary, called the **detached surface** (see Figure 1, right). The trace of the singular points on the detached surface are the **marked points**. Conversely, \mathcal{C} can be obtained from a surface (possibly disconnected, possibly with boundary) and a finite set of segments by choosing finitely many subsets of points and identifying the points in each subset together.

The **boundary** of \mathcal{C} is the closure of the set of points of \mathcal{C} that have an open neighborhood homeomorphic to a closed half-plane. Equivalently, it is the union of the edges of \mathcal{C} incident with a single triangle.

3.3 Topological data structure for 2-complexes

Any 2-complex \mathcal{C} without 3-book or isolated vertex is obtained from the detached surface and a set of disjoint segments, by identifying finitely many finite subsets of points. It is thus easy to describe a **topological data structure** for storing 2-complexes, by storing the topology of the detached surface and the segments, and recording additionally the identification of points to obtain the complex. The **size** of \mathcal{C} is the sum of the number of isolated segments, the number of connected components of the detached surface, the total genus of the detached surface, the total number of boundary components of the detached surface, and the total number of marked points of the detached surface (the occurrences of the singular points). This is, up to a constant factor, the size of the topological data structure indicated above, if the genus is stored in unary. Any 2-complex described in the usual combinatorial way can be converted in polynomial time into this representation. Thus, **in the rest of this article, without loss of generality, we implicitly assume that \mathcal{C} is given in the form of the above topological data structure.**

Moreover, given two 2-complexes in the form above, deciding whether they are homeomorphic essentially amounts to testing whether the corresponding data structures are isomorphic, which leads to the following lemma (the running time might be improvable, but this suffices for our purposes):

► **Lemma 3.2.** *Given two 2-complexes \mathcal{C} and \mathcal{C}' , given in the topological representation above, of sizes c and c' respectively, we can decide whether \mathcal{C} and \mathcal{C}' are homeomorphic in time $(c + c')^{O(c+c')}$.*

3.4 Proper and cellular graph embeddings on 2-complexes

Let \mathcal{C} be a 2-complex with size c , G a graph, and Γ an embedding of G on \mathcal{C} . The embedding Γ is **proper** if:

- the image of Γ meets the boundary of \mathcal{C} only on singular points;
- the vertices of Γ cover the singular points of \mathcal{C} .

The embedding Γ is **cellular** if each face of Γ is an open disk plus possibly some part of the boundary of \mathcal{C} . We emphasize that this definition slightly departs from the standard one. Moreover, we will only consider cellular embeddings that are proper.

We will use a data structure to store possibly non-cellular embeddings of graphs on surfaces [5, Section 2.2]. Such a data structure is based on the gem representation of cellular graph embeddings [9, Section 2], but store additional information about the topology of the faces. It is important to remark that this data structure also allows to recover the topology of the underlying surface.

Let Γ be a proper graph embedding of a graph G on a 2-complex \mathcal{C} (under the assumptions of Proposition 3.1). Let \mathcal{S} be the detached surface of \mathcal{C} . Because Γ is proper, it naturally induces an embedding Γ' , of another graph G' , on \mathcal{S} ; some vertices of G located on singular points of \mathcal{C} are duplicated in G' , the vertices of G located in the relative interior of isolated segments are absent from G' , and the edges of G not in G' are edges on the isolated segments of \mathcal{C} . Our data structure, called **combinatorial map**, for storing the graph embedding Γ and the 2-complex \mathcal{C} consists of storing (1) the graph embedding Γ' on \mathcal{S} , as indicated in the previous paragraph, (2) the isolated segments of \mathcal{C} , together with, for each such isolated segment, an ordered list alternating vertices and edges of Γ (or, instead of an edge, a mark indicating the absence of such an edge in the region of the isolated segment between the incident vertices), (3) the identifications of vertices of Γ' that are needed to recover Γ (and thus implicitly \mathcal{C}).

Isomorphisms between combinatorial maps are defined in the obvious way, similar to the concept of isomorphism between topological data structures: Two combinatorial maps are isomorphic if there is an isomorphism between the combinatorial maps restricted to the detached surfaces, isomorphisms between the maps on each isolated segments, and such that incidences are preserved on the singular points. We can easily test isomorphism between two combinatorial maps of size k and k' , respectively, in $(k + k')^{O(k+k')}$ time.

We will need an algorithm to enumerate all proper embeddings of small graphs on a given 2-complex. This is achieved by a brute-force algorithm:

► **Lemma 3.3.** *Let \mathcal{C} be a 2-complex of size c and k an integer. We can enumerate the $(c + k)^{O(c+k)}$ combinatorial maps of graphs with at most k vertices and at most k edges properly embedded on \mathcal{C} in $(c + k)^{O(c+k)}$ time.*

4 Partitioning graphs

Let \mathcal{C} be a 2-complex and G a graph, which satisfy the properties of Proposition 3.1. In this section, we lay the structural foundations of the dynamic programming algorithm, described in the next section (Proposition 5.1). The goal, in this section and the following one, is to obtain an algorithm that takes as input \mathcal{C} and G , and, in time FPT in the size of \mathcal{C} and the branchwidth of G , reports correctly one of the following two statements:

- G has no proper cellular embedding on \mathcal{C} ,
- G has an embedding on \mathcal{C} .

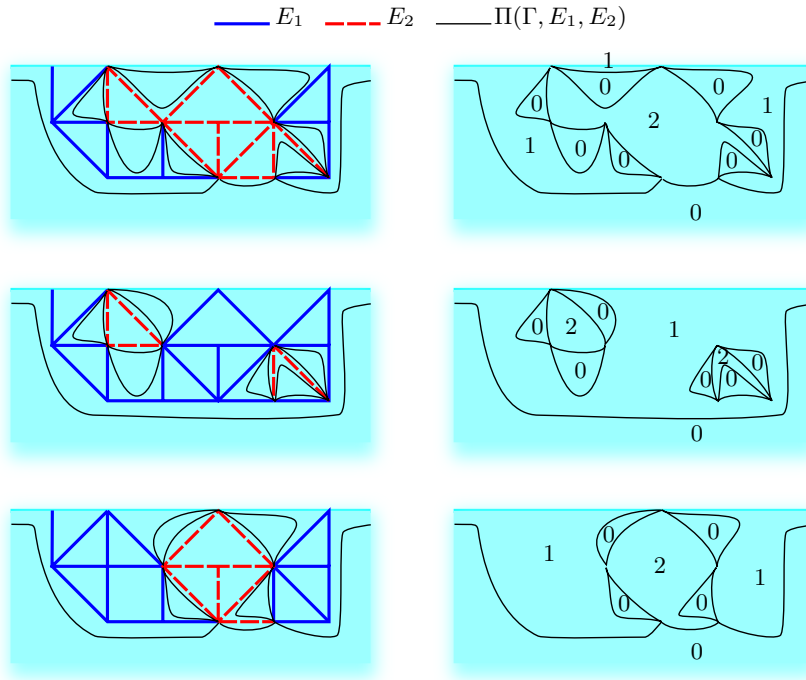

This algorithm uses dynamic programming on a rooted branch decomposition of G . When processing a node of the rooted branch decomposition, it considers embeddings of the subgraph of G induced by the edges in the leaves of the subtree rooted at that node in a region of \mathcal{C} . This region will be delimited by a *partitioning graph* embedded on \mathcal{C} . Our dynamic program will roughly guess the partitioning graph at each node of the rooted branch decomposition. For this purpose, we need that, if G has a proper cellular embedding on \mathcal{C} , it has such an embedding that is *sparse*: at each node of the rooted branch decomposition of G , the partitioning graph corresponding to the embedding of the induced subgraph is small (its size is upper-bounded by a function of the branchwidth of G and of the size of \mathcal{C}). The goal of this section is to prove that this is indeed the case.

Let (E_1, \dots, E_k) be an (ordered) partition of the edge set $E(G)$ of G . (We will only use the cases $k = 2$ or $k = 3$.) The **middle set** of (E_1, \dots, E_k) is the set of vertices of G whose incident edges belong to at least two sets E_i .

Let Γ be a proper cellular embedding of G on \mathcal{C} . Since Γ is cellular, every boundary of \mathcal{C} is incident to at least one vertex of Γ . Let $\hat{\Gamma}$ be obtained from Γ by adding edges as follows: for any pair of vertices u and v of Γ consecutive along a given boundary component of \mathcal{C} , we connect u and v via a new edge that runs along the boundary component. For each (ordered) partition (E_1, \dots, E_k) of the edge set of G , we let \hat{E}_1 be the union of E_1 and of these new edges, and $\hat{E}_i = E_i$ for each $i \neq 1$; thus, $(\hat{E}_1, \dots, \hat{E}_k)$ is a partition of the set of edges of $\hat{\Gamma}$.

The **partitioning graph** $\Pi(\Gamma, E_1, \dots, E_k)$ (or more concisely Π) associated to Γ and (E_1, \dots, E_k) is a graph properly embedded on \mathcal{C} (but possibly non-cellularly), with labels on its faces, defined as follows:

- The vertex set of Π is the union of the singular points of \mathcal{C} and of (the images under Γ of) the middle set of E_1, \dots, E_k .
- The relative interiors of the edges of Π are disjoint from the edges of $\hat{\Gamma}$ and from the isolated segments of \mathcal{C} . Let f be a face of $\hat{\Gamma}$ (which is homeomorphic to an open disk plus possibly some points of the boundary of \mathcal{C}). Let us describe the edges of Π inside f .

■ **Figure 2** Construction of the partitioning graph $\Pi = \Pi(\Gamma, E_1, E_2)$, for three choices of the partition (E_1, E_2) of the same embedding Γ . Only a part of the 2-complex \mathcal{C} is shown, with a boundary at the upper part, and without singular point. Left: The graph embeddings Γ (in thick lines) and Π (in thin lines). Right: The sole graph Π , together with the labelling of its faces.

If, for some $i \in \{1, \dots, k\}$, the boundary of f is comprised only of edges of $\hat{\Gamma}$ that lie in a single set \hat{E}_i , then Π contains no edge inside f . Otherwise, the boundary of f is a succession of edges of $\hat{E}_1, \hat{E}_2, \dots, \hat{E}_k$. The edges of Π inside f run along the boundary of f ; for each $i \in \{1, \dots, k\}$, for each (maximal) group of consecutive edges in \hat{E}_i along the boundary of f , we create an edge of Π that runs along this group, with endpoints the corresponding vertices on the boundary of f (see Figures 2 and 3). These vertices either are in the middle set of (E_1, \dots, E_k) , or lie on the boundary of \mathcal{C} (and thus on singular points of \mathcal{C}).

It follows from the construction that $\hat{\Gamma}$ and Π intersect only at common vertices.

- Each face of Π is labelled by an integer in $\{0, \dots, k\}$ as follows: faces of Π containing edges in \hat{E}_i are labelled i , and the other ones are labelled 0. By construction of the graph Π , each face of Π contains edges from at most one set \hat{E}_i , so this labelling is well defined.

Henceforth, we fix a rooted branch decomposition \mathcal{B} of G , the root of which is denoted by ρ . Every arc α of \mathcal{B} naturally partitions $E(G)$ into two parts E_1 and E_2 , in which E_1 is the part on the same side as ρ ; this (ordered) partition is the **edge partition associated to α** . Recall that Γ is a proper and cellular embedding of G on \mathcal{C} ; we let $\Pi(\Gamma, \alpha)$ be $\Pi(\Gamma, E_1, E_2)$. Similarly, every node ν of \mathcal{B} naturally partitions $E(G)$ into three parts E_1, E_2 , and E_3 , in which E_1 is the part on the same side as ρ ; this partition is the **edge partition associated to ν** ; we let $\Pi(\Gamma, \nu)$ be $\Pi(\Gamma, E_1, E_2, E_3)$.

We say that Γ is **sparse** (with respect to \mathcal{B}) if the following conditions hold, letting c be the size of \mathcal{C} and w the width of \mathcal{B} :

■ **Figure 3** The partitioning graph $\Pi = \Pi(\Gamma, E_1, E_2, E_3)$. Left: The graph embeddings Γ (in thick lines) and Π (in thin lines). Right: The sole graph Π , together with the labelling of its faces.

■ **Figure 4** Left: A vertex with 6 intervals, numbered from 1 to 6. Middle: The cyclic order obtained by applying the first type of simplification operation on intervals 1 and 2. After the simplification, the intervals 1 and 3 are merged into a single one, and similarly for the intervals 2 and 6. Right: The cyclic order obtained by applying the second type of simplification to the configuration on the left, on pairs of intervals $\{1, 2\}$ and $\{4, 5\}$. After the simplification, the intervals 1, 3, and 5 are merged, and similarly for the intervals 2, 6, and 4.

- For each arc α of \mathcal{B} , the graph $\Pi(\Gamma, \alpha)$ has at most $74c + 26w$ edges;
- similarly, for each internal node ν of \mathcal{B} , the graph $\Pi(\Gamma, \nu)$ has at most $3(74c + 26w)$ edges.

The result of this section is the following.

► **Proposition 4.1.** *Let \mathcal{C} be a 2-complex and G a graph, which satisfy the properties of Proposition 3.1. Let \mathcal{B} be a rooted branch decomposition of G . Assume that G has a proper cellular embedding on \mathcal{C} . Then it has a proper cellular embedding Γ on \mathcal{C} that is sparse (with respect to \mathcal{B}).*

4.1 Monogons and bigons

A **monogon** of a graph Π embedded on a 2-complex \mathcal{C} is a face of Π that is an open disk whose boundary is a single edge of Π (a loop). Similarly, a **bigon** of Π is a face of Π that is an open disk whose boundary is the concatenation of two edges of Π (possibly the same edge appearing twice). The following general lemma on graphs embedded on surfaces without monogons or bigons will be used.

► **Lemma 4.2.** *Let \mathcal{S} be a surface of genus g without boundary. Let Π be a graph embedded on \mathcal{S} , not necessarily cellularly. Assume that Π has no monogon or bigon. Then $|E(\Pi)| \leq \max\{0, 3g + 3|V(\Pi)| - 6\}$.*

4.2 Vertex simplifications

The proof of Proposition 4.1 starts with any proper cellular embedding of Γ , and iteratively changes the cyclic ordering of edges around vertices in a specific way. Let (E_1, E_2) be an (ordered) partition of $E(G)$, let v be a vertex of G , and let C be a link component at v (if

the image of v under Γ is a singular point, there may be several such link components). We restrict our attention to the edges of $\hat{\Gamma}$ incident to v and belonging to C , in cyclic order around v . For $i = 1, 2$, an **interval** (at v , relatively to (\hat{E}_1, \hat{E}_2)) is a maximal contiguous subsequence of edges in this cyclic ordering that all belong to \hat{E}_i ; the interval is labelled i . **Simplifying** v (with respect to (E_1, E_2)) means changing the cyclic ordering of the edges of $\hat{\Gamma}$ incident to v in C by one of the two following operations (Figure 4):

1. either exchanging two consecutive intervals in that ordering, in a way that the ordering of the edges in each interval is preserved; this operation is allowed only if v is incident to at least four intervals;
2. or performing the previous operation twice, on two disjoint pairs of consecutive intervals in that ordering; this is allowed only if v is incident to at least six intervals.

We will rely on the following lemma.

► **Lemma 4.3.** *Let Γ be a proper cellular embedding of G on \mathcal{C} , and let (E_1, E_2) be an (ordered) partition of $E(G)$. Let Γ' be another proper cellular embedding of G , obtained from Γ by simplifying one or two vertices with respect to (E_1, E_2) , while keeping the other cyclic orderings unchanged. Then:*

1. $|E(\Pi(\Gamma', E_1, E_2))| < |E(\Pi(\Gamma, E_1, E_2))|$;
2. for each (ordered) partition $(\tilde{E}_1, \tilde{E}_2)$ of $E(G)$ such that $\hat{\tilde{E}}_i \subseteq \hat{E}_j$ for some $i, j \in \{1, 2\}$, we have $|E(\Pi(\Gamma', \tilde{E}_1, \tilde{E}_2))| \leq |E(\Pi(\Gamma, \tilde{E}_1, \tilde{E}_2))|$.

Proof. The proof is based on the following easy but key observations (the second one will be reused later):

- A simplification of v strictly decreases the number of intervals at v ;
- the number of half-edges of $\Pi(\Gamma, E_1, E_2)$ at v in the link component C equals twice the number of intervals associated to (\hat{E}_1, \hat{E}_2) at v in C .

The first point of the lemma immediately follows. For the second point, let us consider, in the cyclic ordering around v in C , a maximal contiguous sequence of edges in $\hat{\tilde{E}}_i$. Since $\hat{\tilde{E}}_i \subseteq \hat{E}_j$, when simplifying with respect to (E_1, E_2) , this sequence is still contiguous in the new embedding Γ' . It follows that the number of intervals associated to $(\hat{\tilde{E}}_1, \hat{\tilde{E}}_2)$ does not increase when replacing Γ with Γ' . ◀

4.3 Rearranging Γ with respect to an edge partition

We can now prove the following lemma:

► **Lemma 4.4.** *Let Γ be a proper cellular embedding of G on \mathcal{C} , and let (E_1, E_2) be an (ordered) partition of $E(G)$. There exists a proper cellular embedding Γ' of G such that:*

- $|E(\Pi(\Gamma', E_1, E_2))| \leq 74c + 26w$, where w is the size of the middle set of (E_1, E_2) ;
- for each (ordered) partition $(\tilde{E}_1, \tilde{E}_2)$ of $E(G)$ such that $\hat{\tilde{E}}_i \subseteq \hat{E}_j$ for some $i, j \in \{1, 2\}$, we have $|E(\Pi(\Gamma', \tilde{E}_1, \tilde{E}_2))| \leq |E(\Pi(\Gamma, \tilde{E}_1, \tilde{E}_2))|$.

Sketch of proof. Let $\Pi := \Pi(\Gamma, E_1, E_2)$. We assume that Π has “many monogons or bigons” and show that there is another cellular embedding Γ' of G such that:

- $|E(\Pi(\Gamma', E_1, E_2))| < |E(\Pi(\Gamma, E_1, E_2))|$;
- for each (ordered) partition $(\tilde{E}_1, \tilde{E}_2)$ of $E(G)$ such that $\hat{\tilde{E}}_i \subseteq \hat{E}_j$ for some $i, j \in \{1, 2\}$, we have $|E(\Pi(\Gamma', \tilde{E}_1, \tilde{E}_2))| \leq |E(\Pi(\Gamma, \tilde{E}_1, \tilde{E}_2))|$.

Intuitively, if Π has many monogons attached to a single vertex, or many bigons glued together, we can change the embedding Γ in a way that leads to vertex simplifications. By repeatedly iterating this argument, and up to replacing Γ with Γ' , this implies that we can assume without loss of generality that Π has “not too many monogons or bigons”. Lemma 4.2 then implies that Π has at most $74c + 26w$ edges, which concludes. ◀

4.4 Proof of Proposition 4.1

Proof of Proposition 4.1. Let \mathcal{B} be a rooted branch decomposition of G , and let Γ be a proper cellular embedding of G on \mathcal{C} . We consider each arc α of the rooted branch decomposition in turn, in an arbitrary order. For each such arc, we modify Γ by applying Lemma 4.4. We first claim that after these iterations, for each arc α of \mathcal{B} , we have $|E(\Pi(\Gamma, \alpha))| \leq 74c + 26w$.

Immediately after applying the above procedure to an arc $\tilde{\alpha}$ of \mathcal{B} , corresponding to the (ordered) partition $(\tilde{E}_1, \tilde{E}_2)$ of $E(G)$, we have $|E(\Pi(\Gamma, \tilde{E}_1, \tilde{E}_2))| \leq 74c + 26w$. We now prove that subsequent applications of Lemma 4.4 to other arcs of the rooted branch decomposition do not increase this number of edges. Indeed, let α be another arc, corresponding to the (ordered) partition (E_1, E_2) of $E(G)$, to which we apply Lemma 4.4. The arc α partitions the nodes of the tree \mathcal{B} into two sets N_1 and N_2 , and similarly $\tilde{\alpha}$ partitions the nodes of the tree \mathcal{B} into two sets \tilde{N}_1 and \tilde{N}_2 . Because \mathcal{B} is a tree, we have $\tilde{N}_i \subseteq N_j$ for some $i, j \in \{1, 2\}$. This implies that $\hat{\tilde{E}}_i \subseteq \hat{E}_j$ for some $i, j \in \{1, 2\}$; so the second item of Lemma 4.4 implies that the number of edges of $\Pi(\Gamma, \tilde{E}_1, \tilde{E}_2)$ does not increase when processing arc α . This proves the claim.

Finally, there remains to prove that, for each internal node ν of \mathcal{B} , the graph $\Pi(\Gamma, \nu)$ has at most $3(74c + 26w)$ edges. This follows relatively easily from the above claim. \blacktriangleleft

5 Dynamic programming algorithm

The result of this section is the following proposition.

► **Proposition 5.1.** *Let \mathcal{C} be a 2-complex and G a graph, which satisfy the properties of Proposition 3.1. Let c be the size of \mathcal{C} and n the number of vertices and edges of G . Let \mathcal{B} be a rooted branch decomposition of G of width w . In $(c + w)^{O(c+w)}n$ time, one can report one of the following statements, which is true:*

- G has no sparse proper cellular embedding into \mathcal{C} ;
- G has an embedding into \mathcal{C} .

(Proposition 4.1 implies that we can remove the adjective “sparse” in the above proposition.)

5.1 Bounding graphs

Let \mathcal{B} be a rooted branch decomposition of G of width w . Recall (see Section 2.1) that the root ρ of \mathcal{B} is a leaf associated to no edge of G . Our algorithm will use dynamic programming in the rooted branch decomposition. For each arc α of \mathcal{B} , let G_α be the subgraph of G induced by the edges of G corresponding to the leaves of the subtree of \mathcal{B} rooted at α . The general idea is that we compute all possible relevant embeddings of G_α in subregions of \mathcal{C} . Such subregions will be delimited by a graph embedded on \mathcal{C} of small complexity. For the dynamic program to work, we also need to keep track of the location of the vertices in the middle set of α . More precisely, a **bounding graph** for G_α is a proper labelled graph embedding Π on \mathcal{C} (but possibly non-cellular), such that:

- some vertices of Π are labelled; these labels are exactly the vertices of the middle set associated with α , and each label appears exactly once;
- each unlabelled vertex of Π is mapped to a singular point of \mathcal{C} ;
- each face of Π is labelled 0, 1, or 2;

- G_α has an embedding Γ_α that **respects** Π : each vertex of Π labelled v is mapped, under Π , to the image of v in Γ_α ; moreover, the relative interior of each edge of Γ_α lies in the interior of a face of Π labelled 2.

A bounding graph for G_α is **sparse** if it has at most $74c + 26w$ edges. Remark that, if Γ is a sparse proper cellular embedding of G on \mathcal{C} (as defined in Section 4), then $\Pi(\Gamma, \alpha)$ is a sparse bounding graph for the restriction of Γ to G_α .

Henceforth, we regard two (labelled) properly embedded graphs as equal if and only if their (labelled) combinatorial maps are isomorphic. A list \mathcal{L}_α of sparse bounding graphs for G_α is **exhaustive** if the following condition holds: If G has a sparse proper cellular embedding on \mathcal{C} , then for each such embedding Γ , the (combinatorial map of the) graph $\Pi(\Gamma, \alpha)$ is in \mathcal{L}_α .

The induction step for the dynamic programming algorithm is the following.

► **Proposition 5.2.** *Let ν be a non-root node of \mathcal{B} and α be the arc of \mathcal{B} incident to ν that is the closest to the root ρ . Assume that, for each arc $\beta \neq \alpha$ of \mathcal{B} incident to ν , we are given an exhaustive list of sparse bounding graphs for G_β . Then we can, in $(c + w)^{O(c+w)}$ time, compute an exhaustive list of $(c + w)^{O(c+w)}$ sparse bounding graphs for G_α .*

Assuming Proposition 5.2, the proof of which is deferred to the next subsection, it is easy to prove Proposition 5.1:

Proof of Proposition 5.1, assuming Proposition 5.2. We apply the algorithm of Proposition 5.2 in a bottom-up manner in the rooted branch decomposition \mathcal{B} . Let α be the arc of \mathcal{B} incident with the root node ρ . We end up with an exhaustive list of sparse bounding graphs for $G_\alpha = G$. By definition of a bounding graph, if this list is non-empty, then G has an embedding on \mathcal{C} . On the other hand, by definition of an exhaustive list, if this list is empty, then G has no sparse proper cellular embedding on \mathcal{C} .

There are $O(n)$ recursive calls, each of which takes $(c + w)^{O(c+w)}$ time. ◀

5.2 The induction step: Proof of Proposition 5.2

Proof of Proposition 5.2. First case. Let us first assume that ν is a (non-root) leaf of \mathcal{B} ; thus, G_α is a single edge uv . Using Lemma 3.3, we compute *all* the labelled combinatorial maps of sparse bounding graphs for G_α . This is clearly an exhaustive list. Indeed, assume that G has a sparse proper cellular embedding Γ on \mathcal{C} ; by sparsity, $\Pi(\Gamma, \alpha)$ has at most $74c + 26w$ edges; thus, one of the labelled combinatorial maps computed will be equal to that of $\Pi(\Gamma, \alpha)$.

Second case. Let us now assume that ν is an internal node of \mathcal{B} . As above, let α be the arc of \mathcal{B} incident to ν that is the closest to the root ρ . Let β and γ be the arcs different from α incident to ν . Let \mathcal{L}_β and \mathcal{L}_γ be exhaustive lists of bounding graphs for G_β and G_γ , respectively. Intuitively, every pair of bounding graphs in \mathcal{L}_β and \mathcal{L}_γ that are compatible, in the sense that the regions labelled 2 in each of these two graphs are disjoint, will lead to a bounding graph in \mathcal{L}_α . This is the motivating idea to our approach. More precisely, we will enumerate labelled combinatorial maps Π , each of which can be “restricted” to two compatible graphs, which are possible bounding graphs for G_β and G_γ . If these two restrictions lie in \mathcal{L}_α and \mathcal{L}_β , this leads to a graph that is added to \mathcal{L}_α .

We first introduce some terminology. Let Π be a graph properly embedded on \mathcal{C} (possibly non-cellularly), with faces labelled 0, 1, 2, or 3, and with labels on some vertices. Let i, j, k be integers such that $\{i, j, k\} = \{1, 2, 3\}$. We will define a graph embedding $\Pi_{i,j}$ obtained

from Π by somehow “merging” faces i and j . First, for an illustration, refer back to Figures 2 and 3: If Π is the graph embedding depicted on the right of Figure 3, then the configurations shown on the right of Figure 2 correspond, from top to bottom, to $\Pi_{2,3}$, $\Pi_{1,3}$, and $(\Pi_{1,2})^-$ (the latter being the graph $\Pi_{1,2}$ in which each face label 3 is replaced by a 2).

Formally, $\Pi_{i,j}$ is defined as follows. First, let us replace all face labels j by i . Now, for each face f of Π that is homeomorphic to a disk and labelled 0, we do the following. The boundary of f is made of edges of Π ; for the sake of the discussion, let us temporarily label each such edge by the label of the face on the other side of f . If all edges on the boundary of f are all labelled i , then we remove all these edges, and f becomes part of a larger face labelled i . Otherwise, for each maximal subsequence e_1, \dots, e_ℓ of edges along the boundary of f that are all labelled i , we remove each of e_1, \dots, e_ℓ , and replace them with an edge inside f from the source of e_1 to the target of e_ℓ . Finally, we remove all isolated vertices that do not coincide with a singular point of \mathcal{C} , and all vertices in the relative interior of an isolated segment that are incident to two faces with the same label.

For any labelled combinatorial map Π , we denote by Π^- the same map where each label 3 on a face is replaced by a 2. The easy but key properties of this construction are the following:

- (i) Assume that $\Pi_{1,3}$ is a bounding graph for G_β and $(\Pi_{1,2})^-$ is a bounding graph for G_γ . Then $\Pi_{2,3}$ is a bounding graph for G_α .
- (ii) The node ν naturally partitions the edge set of G into three parts, which we denote by E_1 (on the side of α), E_2 (on the side of β), and E_3 (on the side of γ). Assume that G has a sparse proper cellular embedding Γ on \mathcal{C} and that $\Pi = \Pi(\Gamma, E_1, E_2, E_3)$. Then:
 - $\Pi(\Gamma, \alpha) = \Pi(\Gamma, E_1, E_2 \cup E_3) = \Pi_{2,3}$;
 - $\Pi(\Gamma, \beta) = \Pi(\Gamma, E_1 \cup E_3, E_2) = \Pi_{1,3}$;
 - $\Pi(\Gamma, \gamma) = \Pi(\Gamma, E_1 \cup E_2, E_3) = (\Pi_{1,2})^-$.

Property (ii) is, again, illustrated by Figures 2 and 3: If (E_1, E_2, E_3) is the edge partition depicted on Figure 3, then the edge partitions depicted on Figure 2, left, are, respectively, $(E_1, E_2 \cup E_3)$, $(E_1 \cup E_3, E_2)$, and $(E_1 \cup E_2, E_3)$. As shown above, the corresponding partitioning graphs are respectively $\Pi_{2,3}$, $\Pi_{1,3}$, and $\Pi_{1,2}^-$.

If Π is the graph embedding depicted on the right of Figure 3, then the configurations shown on the right of Figure 2 correspond, from top to bottom, to $\Pi_{2,3}$, $\Pi_{1,3}$, and $(\Pi_{1,2})^-$ (the latter being the graph $\Pi_{1,2}$ in which each face label 2 is replaced by a 2).

We compute our exhaustive list \mathcal{L}_α of sparse bounding graphs for G_α as follows. Initially, let this list be empty. Using Lemma 3.3, we enumerate all combinatorial maps Π of graphs with at most $c + 3w$ vertices and $3(74c + 26w)$ edges properly embedded on \mathcal{C} (possibly non-cellularly), with faces labelled 0, 1, 2, or 3, and such that the labels appearing on the vertices are exactly the vertices of the middle set of α , β , or γ (and each label appears exactly once). This takes $(c + w)^{O(c+w)}$ time. Whenever $\Pi_{1,3} \in \mathcal{L}_\beta$ and $(\Pi_{1,2})^- \in \mathcal{L}_\gamma$, we add $\Pi_{2,3}$ to \mathcal{L}_α . Finally, we eliminate duplicates by testing pairwise isomorphism between the labelled combinatorial maps in \mathcal{L}_α , and remove the graphs that are not sparse or contain vertices that bear a label not in the middle set of α .

\mathcal{L}_α contains only sparse bounding graphs for G_α , by (i) above. Moreover, let Γ be a sparse proper cellular graph embedding of G on \mathcal{C} . By sparsity, one of the graphs Π enumerated in the previous paragraph is $\Pi(\Gamma, \nu)$. By definition of \mathcal{L}_β and \mathcal{L}_γ , we have that $\Pi(\Gamma, \beta) \in \mathcal{L}_\beta$ and $\Pi(\Gamma, \gamma) \in \mathcal{L}_\gamma$, so by (ii) above, $\Pi(\Gamma, \alpha) \in \mathcal{L}_\alpha$, which implies that \mathcal{L}_α is exhaustive. ◀

6 Reduction to proper cellular embeddings

► **Proposition 6.1.** *Let \mathcal{C} be a 2-complex with at most c simplices, and G a graph with at most n vertices and edges and branchwidth at most w . Assume that G and \mathcal{C} satisfy the properties of Proposition 3.1. In $c^{O(c)} + O(cn)$ time, one can compute a graph G' , and $c^{O(c)}$ 2-complexes \mathcal{C}_i , such that:*

1. *each \mathcal{C}_i and G' satisfy the properties of Proposition 3.1;*
2. *G' has at most $5cn$ vertices and $5cn$ edges, and branchwidth at most w ;*
3. *each \mathcal{C}_i has size at most c ;*
4. *if, for some i , G' embeds into \mathcal{C}_i , then G embeds into \mathcal{C} ;*
5. *if G embeds into \mathcal{C} , then for some i , G' has a proper cellular embedding into \mathcal{C}_i .*

Sketch of proof. Roughly but not exactly, G' is obtained from G by dissolving every degree-two vertex of G and then subdividing edges $\Theta(c)$ times, and the complexes \mathcal{C}_i are all the 2-complexes “smaller” than \mathcal{C} , obtained by detaching the singular points of \mathcal{C} in all possible ways, removing parts of the isolated segments of \mathcal{C} in all possible ways, and simplifying the topology of the detached surface in all possible ways. It is clear that, if G' embeds into one of these complexes, then G embeds into \mathcal{C} . Conversely, if G embeds into \mathcal{C} , then, by the subdivision process above, G' has a proper embedding into \mathcal{C} , and the only problem is that the faces of G' may fail to be disks. However, by modifying \mathcal{C} using the appropriate choice of operations above, these faces are transformed into disks. ◀

7 Algorithm for bounded branchwidth: Proof of Theorem 1.2

Proof of Theorem 1.2. The proof of this theorem follows directly from the previous propositions. After the preprocessing step (Proposition 3.1), combining Propositions 4.1 and 5.1 give an algorithm that takes as input G and \mathcal{C} and reports one of the following true statements: (i) G has no proper cellular embedding on \mathcal{C} ; (ii) G has an embedding on \mathcal{C} . So, we apply this algorithm to the graph G' and each 2-complex \mathcal{C}_i obtained from Proposition 6.1. If for at least one of these instances, the outcome is (ii), then G has an embedding into \mathcal{C} . Otherwise, G has no embedding into \mathcal{C} . ◀

8 Reduction to bounded branchwidth: Proof of Theorem 1.3

Sketch of proof of Theorem 1.3. This is based on an irrelevant method. We assume that G has large branchwidth. An important fact that we will use is that, if G is embeddable on \mathcal{C} , it has genus $O(c)$.

A **wall** of size $k \times k$ is a subgraph of the $(k \times k)$ -grid obtained by removing alternately the vertical edges of even (resp. odd) x -coordinate in each even (resp. odd) line, and then the degree-one vertices.

We first use any algorithm to approximate the treewidth of G , e.g., Fomin et al. [11, Theorem 1.1]: In polynomial time, we either compute a branch decomposition of small width of G , in which case we are done, or correctly report that the treewidth is large. In the latter case, the result by Chekuri and Chuzhoy [3] implies that there is a large grid minor, which we can compute in randomized polynomial time using the same article, or in deterministic $f(k) \cdot n^2$ time, where f is some computable function and k is the size of the grid [22, Algorithm 4.4]. We have thus computed a subdivision of a large wall.

We then partition this wall into $\Omega(c)$ smaller subwalls W_1, \dots, W_m , where $m = \Omega(c)$, each bounded by a cycle γ_i . We then show that we can assume that there are (intuitively) not too many connections, in G , between two different walls W_i, W_j that avoid the cycles γ_i

and γ_j ; otherwise, by computing these connections, we exhibit a subgraph of G of genus $\Omega(c)$, and deduce that G is not embeddable on \mathcal{C} . Finally, we compute a cycle γ of G , such that one connected component of $G - \gamma$ is planar and contains a subdivision of a smaller, but still large, wall.

We then show, borrowing some ingredients to Kociumaka and Pilipczuk [15, Section 5], that the central vertex of this wall is irrelevant, in the sense that its removal does not affect the embeddability or non-embeddability of the graph into \mathcal{C} . Intuitively, v is surrounded by $\Omega(c)$ concentric cycles in the wall; if $G - v$ is embedded in \mathcal{C} , then two concentric cycles must bound an annulus. The planar part inside the inner cycle can be embedded close to the boundary of the annulus that corresponds to this inner cycle.

Iterating the whole procedure, we obtain a graph of branchwidth polynomial in the size of \mathcal{C} . ◀

Abstract

We consider the problem of solving integer programs of the form $\min\{c^T x : Ax = b, x \in \mathbb{Z}_{\geq 0}\}$, where A is a multistage stochastic matrix in the following sense: the primal treedepth of A is bounded by a parameter d , which means that the columns of A can be organized into a rooted forest of depth at most d so that columns not bound by the ancestor/descendant relation do not have non-zero entries in the same row. We give an algorithm that solves this problem in fixed-parameter time $f(d, \|A\|_\infty) \cdot n \log^{O(2^d)} n$, where f is a computable function and n is the number of rows of A . The algorithm works in the strong model, where the running time only measures unit arithmetic operations on the input numbers and does not depend on their bitlength. This is the first fpt algorithm for multistage stochastic integer programming to achieve almost linear running time in the strong sense. For two-stage stochastic integer programs, our algorithm works in time $2^{((r+s)\|A\|_\infty)^{O(r(r+s))}} \cdot n \log^{O(rs)} n$, which improves over previous methods both in terms of the polynomial factor and in terms of the dependence on r and s . In fact, for $r = 1$ the dependence on s is asymptotically almost tight assuming the Exponential Time Hypothesis. Our algorithm can be also parallelized: we give an implementation in the PRAM model that achieves running time $f(d, \|A\|_\infty) \cdot \log^{O(2^d)} n$ using n processors.

The main conceptual ingredient in our algorithms is a new proximity result for multistage stochastic integer programs. We prove that if we consider an integer program P , say with a constraint matrix A , then for every optimum solution to the linear relaxation of P there exists an optimum (integral) solution to P that lies, in the ℓ_∞ -norm, within distance bounded by a function of $\|A\|_\infty$ and the primal treedepth of A . On the way to achieve this result, we prove a generalization and considerable improvement of a structural result of Klein for multistage stochastic integer programs. Once the proximity results are established, this allows us to apply a treedepth-based branching strategy guided by an optimum solution to the linear relaxation.

1 Introduction

We consider *integer linear programming* problems

$$\min\{c^\top x : Ax = b, x \in \mathbb{Z}_{\geq 0}\}, \quad (\spadesuit)$$

that are described by the *constraint matrix* $A \in \mathbb{Z}^{n \times m}$, the *linear objective goal* $c \in \mathbb{Z}^m$ and the *right-hand side* vector $b \in \mathbb{Z}^n$. As in this work we only consider linear objective functions, for brevity we use term *integer programming* instead of *integer linear programming*.

While *integer programming* is NP-hard, there are various natural assumptions on the constraint matrix A for which (\spadesuit) is solvable in polynomial time. Famous examples include *totally unimodular* and *bimodular integer programming* [15, 1], integer programs with a *constant number of variables* [20, 17] or *bipartite matching* and *shortest path* problems, see, e.g. [25]. Another example are *block-structured* integer programs in which the constraint matrix exhibits a (recursive) block structure. For instance, in the case of *N-fold* integer programming [7], the removal of a small number of constraints (rows of A) results in decomposing the instance into a large number of small independent subproblems.

We focus on the case where the removal of a few *columns* of A results in a large number of independent subproblems, i.e., on the case where A is *two-stage* or *multistage stochastic*.

Figure 1 A schematic view of a two-stage stochastic matrix (left panel) and a multistage stochastic matrix (right panel). All non-zero entries are contained in the blocks depicted in grey.

Formally, A is two-stage or (r, s) -*stochastic* (Figure 1, left panel) if after deleting the first r columns the matrix can be decomposed into blocks with at most s columns each. The terminology is borrowed from the field of stochastic integer optimization, a model for discrete optimization under uncertainty. Here, the r “global” variables correspond to a decision made in the first stage, whereas the $\Omega(n)$ blocks involving s variables represent a usually *large* number different *scenarios* that arise in the second stage of stochastic optimization. Two-stage stochastic integer programming has found multiple applications and is a classical topic in optimization, see the survey of Schultz et al. [26] for some examples and algorithms. *Multistage stochastic* integer programming is a generalization of the two-stage variant above obtained by allowing further recursive levels in the block structure (Figure 1, right panel).

The recursive structure in multistage stochastic integer programs can be explained through the notion of the *primal treedepth* of a matrix. The primal treedepth of A , denoted $\text{td}_P(A)$, is the least integer d such that the columns of A can be organized into a rooted forest of depth at most d (called an *elimination forest*) with the following property: for every pair of columns that are not independent – they have non-zero entries in the same row – these columns have to be in the ancestor/descendant relation in the forest. The form presented in Figure 1 can be obtained by ordering the columns as in the top-down depth-first traversal of the elimination forest, and applying a permutation to the rows to form the blocks.

The primal treedepth is a structural parameter that is useful in the design of efficient integer programming solvers. By this, we mean the existence of *fixed-parameter algorithms* for the parameterization by $\text{td}_P(A)$ and $\|A\|_\infty$. For this parameterization, fixed-parameterized tractability can be understood in two ways. *Weak fpt algorithms* have running time of

the form $f(\text{td}_P(A), \|A\|_\infty) \cdot |P|^{\mathcal{O}(1)}$, where f is a computable function and $|P|$ is the total bitlength of the encoding of the input. From *strong fpt algorithms* we require time complexity of the form $f(\text{td}_P(A), \|A\|_\infty) \cdot n^{\mathcal{O}(1)}$, where f is computable and n is the number of rows of the input matrix. Such algorithms work in the model where input numbers occupy single memory cells on which unit-cost arithmetic operations are allowed. Note that thus, the running time is not allowed to depend on the bitlength of the input numbers.

A weak fixed-parameter algorithm for the considered parameterization follows implicitly from the work of Aschenbrenner and Hemmecke [2]. The first to explicitly observe the applicability of primal treedepth to the design of fpt algorithms for integer programming were Ganian and Ordyniak [13], although their algorithm also treats $\|b\|_\infty$ as a parameter besides $\text{td}_P(A)$ and $\|A\|_\infty$. A major development was brought by Koutecký et al. [19], who gave the first strong fpt algorithm, with running time $f(\text{td}_P(A), \|A\|_\infty) \cdot n^3 \log^2 n$. We refer the reader to the joint manuscript of Eisenbrand et al. [10], which comprehensively presents the recent developments in the theory of block-structured integer programming. Corollaries 93 and 96 there discuss the cases of two-stage and multistage stochastic integer programming.

Our contribution. We advance the state-of-the-art of fpt algorithms for two-stage and multistage stochastic integer programming problems by proving the following. Here, n and d respectively denote the number of rows and the primal treedepth of the constraint matrix A .

- A) We give an $f(d, \|A\|_\infty) \cdot n \log^{\mathcal{O}(2^d)} n$ -time algorithm for integer programming (\spadesuit) in the strong sense, where f is a computable function (Theorem 8). This improves upon the currently fastest strong fpt algorithm by Koutecký et al. [19] that is nearly cubic in n .
- B) We provide a $2^{((r+s)\|A\|_\infty)^{\mathcal{O}(r(r+s))}} \cdot n \log^{\mathcal{O}(rs)} n$ -time algorithm for (r, s) -stochastic integer programming, again in the strong sense. This improves upon the currently fastest algorithm that runs in time $2^{(2\|A\|_\infty)^{\mathcal{O}(r^2s+rs^2)}} \cdot n^{\mathcal{O}(1)}$ [10, 18], both in terms of the parametric dependence and in terms of the polynomial factor in the running time.

The algorithmic contributions A and B rely on the following proximity result for integer programs with low primal treedepth. This result can be regarded as the core contribution of this paper, and we believe that it uncovers an important connection between the primal treedepth of A and the solution space of (\spadesuit).

- C) (Proximity) For each optimal solution x^* to the linear relaxation of (\spadesuit) there is an optimal (integral) solution x^\diamond such that $\|x^\diamond - x^*\|_\infty$ is bounded by a computable function of $\text{td}_P(A)$ and $\|A\|_\infty$. (This is proved in Lemma 3.)

This proximity result provides a very simple template for designing fpt algorithms for multistage integer programming. Let us explain it for the case of (r, s) -stochastic IPs. After one has found an optimal fractional solution x^* of the linear relaxation of (\spadesuit), one only has to enumerate the $(2 \cdot f(d, \|A\|_\infty) + 1)^r$ many possible integer assignments for the r stage 1 variables that are within the allowed distance, where $f(d, \|A\|_\infty)$ is the proximity bound provided by Item C. For each of these assignments, the integer program (\spadesuit) decomposes into $\mathcal{O}(n)$ independent sub-problems, each with at most s variables. This results in a $f(r, s, \Delta) \cdot n$ -time algorithm (excluding the time needed for solving the linear relaxation). For multistage-stochastic integer programming, this argument has to be applied recursively.

As for solving the linear relaxation, note that to obtain results A and B we need to be able to solve linear programs with low primal treedepth in near-linear fpt time in the strong sense. This is a non-trivial task. Here we rely on a recent paper, Cslovjeczsek et al. [5] have shown that the dual of the linear programming relaxation of (\spadesuit) can be solved in time $n \log^{\mathcal{O}(2^d)} n$.

By linear programming duality, this provides an algorithm for finding the *optimum value* of the linear relaxation of (\spadesuit) within the required complexity, but for applying the approach presented above, we need to actually compute an optimum fractional solution to (\spadesuit) . While it is likely that the approach of Cslovjcek et al. [5] can be modified so that it outputs such a solution as well, we give a self-contained argument using complementary slackness that applies the results of [5] only as a black-box.

The approach of Cslovjcek et al. [5] is parallelizable, in the sense that the algorithm for solving the linear relaxation of (\spadesuit) can be implemented on a PRAM with n processors so that the running time is $\log^{\mathcal{O}(2^d)} n$, assuming the constraint matrix A is suitably organized on input. As the simple enumeration technique sketched above also can be easily applied in parallel, we obtain the following PRAM counterpart of A and B.

- D) In both cases A and B, we provide algorithms that run in time $f(d, \|A\|_\infty) \cdot \log^{\mathcal{O}(2^d)} n$ and $2^{((r+s)\|A\|_\infty)^{\mathcal{O}(r(r+s))}} \cdot \log^{\mathcal{O}(rs)} n$, respectively, on a PRAM with n processors. For A we assume that the constraint matrix is suitably organized on input.

The proof of Item C relies on a structural lemma of Klein [18], which allows us to bound the ℓ_∞ -norm of the projections of Graver-basis elements to the space of stage 1 variables. In the language of convex geometry, the lemma says the following: if the intersection of integer cones $C_1, \dots, C_m \subseteq \mathbb{Z}^d$ is non-empty, where each generator of each C_i has ℓ_∞ -norm at most Δ , then there is an integer vector $b \in \bigcap_{i=1}^m C_i$ that satisfies $\|b\|_\infty \leq 2^{\mathcal{O}(d\Delta)^d}$. In fact, the original bound of Klein [18] is doubly exponential in d^2 , while we provide a new proof that improves this to a doubly exponential dependence on $d \log d$ only. A direct implication of this is the improvement in the parametric factor reported in B. We also consider some further relaxations of the statement that appear to be important in the proof of Item C.

Related work. The algorithm proposed by Koutecký et al. [19] for multistage stochastic programming relies on *iterative augmentation* using elements of the *Graver basis*, see also [7, 23, 14]. The Graver basis of a matrix A consists of all minimal integer solutions of $Ax = 0$. Here, minimal is w.r.t. the partial order \sqsubseteq of \mathbb{R}^n where $x \sqsubseteq y$ if for each $i \in \{1, \dots, n\}$ we have $|x_i| \leq |y_i|$ and $x_i y_i \geq 0$. Intuitively, a Graver basis element comprises of “single steps” in the lattice of points x satisfying $Ax = 0$. The augmentation framework is to iteratively improve the current solution along directions in the Graver basis. It turns out that in the case of multistage stochastic programs, the ℓ_∞ -norms of the elements of the Graver basis of the constraint matrix A can be bounded by $g(\text{td}_P(A), \|A\|_\infty)$ for some computable function g . This makes the iterative augmentation technique applicable in this setting. It seems that the augmentation framework is however inherently sequential.

Let us note that Koutecký et al. [19] relied on bounds on the function g above due to Aschenbrenner and Hemmecke [2], which only guaranteed computability. Better and explicit bounds on g were later given by Klein [18], see also [10]. Roughly speaking, the proof of Klein [18] shows that $g(d, a)$ is at most d -fold exponential, and it is open whether this bound can be improved to an elementary function.

On a related note, Jansen et al. [16] have very recently given a $2^{2^{\mathcal{O}(s)}} \cdot n^{\mathcal{O}(1)}$ lower bound for $(1, s)$ -stochastic IPs in which all coefficients of the constraint matrix are bounded by a constant in absolute values. This is assuming the Exponential Time Hypothesis. Thus, for $(1, s)$ -stochastic integer programming with bounded coefficients, our result B is almost tight.

While robust and elegant, iterative augmentation requires further arguments to accelerate the convergence to an optimal solution in order to guarantee a good running time. As presented in [10], to overcome this issue one can either involve the bitlength of the input numbers in measuring the complexity, thus resorting to weak fpt algorithms, or reduce this

bitlength using arguments originating in the work of Frank and Tardos [12]. For instance, integer program (\spadesuit) can be solved in time $f(d, \|A\|_\infty) \cdot n^{1+o(1)} \cdot \log^d \|c\|_\infty$, where $d = \text{td}_P(A)$. However, to the best of our knowledge, before this work there was no strong fpt algorithm that would achieve a subquadratic running time dependence on n , even in the setting of two-stage stochastic integer programming.

The setting of N -fold and tree-fold integer programming, which is dual to the setting considered in this work, has received a lot of attention in the literature, see e.g. [3, 5, 7, 10, 14, 24]. Here, we mostly rely on the recent results of Cslovjecsek et al. [5]. They obtained nearly linear-time strong fpt algorithms using an approach quite different from iterative augmentation, which served as a loose inspiration for our work. The key component is a proximity result for integer programs with bounded dual treedepth: they show that if P is an integer program with constraint matrix A , then for every optimal solution x^* to a suitable linear relaxation of P there exists an optimal (integral) solution x^\diamond to P such that $\|x^\diamond - x^*\|_1$ is bounded by a function of $\|A\|_\infty$ and the *dual treedepth* of A (i.e. primal treedepth of A^\top). It follows that if a solution x^* is available, then an optimal integral solution x^\diamond can be found in linear fpt time using dynamic programming, where the bound on $\|x^\diamond - x^*\|$ is used to limit the number of relevant states. This approach requires devising an auxiliary algorithm for solving linear relaxations with bounded dual treedepth in strong fpt time. This is achieved through recursive Laplace dualization using ideas from Norton et al. [22].

Let us stress that our proximity bound provided by Item C requires a different proof using completely different tools than the one obtained for tree-fold integer programs by Cslovjecsek et al. [5]. Note also that our proximity result concerns the standard linear relaxation, whereas the one in [5] holds for the strengthened relaxation, where the blocks are replaced by their integer hulls.

Very recently, Dong et al. [8] proposed a sophisticated interior-point algorithm to approximately solve linear programs whose constraint matrices have primal treewidth t in time $\tilde{O}(nt^2 \cdot \log(1/\varepsilon))$, where ε is an accuracy parameter. Note here that the primal treewidth is bounded by the primal treedepth, so this algorithm in principle could be applied to the linear relaxation of (\spadesuit) . There are two caveats: the algorithm of [8] provides only an approximate solution, and it is unclear whether it can be parallelized. For these reasons we rely on the algorithm of Cslovjecsek et al. [5] through dualization, but exploring the applicability of the work of Dong et al. [8] in our context is an exciting perspective for future work.

Organization. In this paper we focus on presenting the proximity result Item C and deriving algorithmic corollaries. Discussion of solving the linear relaxation as well as full proofs of statements marked with (\heartsuit) , can be found in the full version of this paper, which is available on ArXiv [6].

2 Preliminaries

Model of computation. We assume a real RAM model of computation, where each memory cell stores a real number (of arbitrary bitlength and precision) and arithmetic operations (including rounding) are assumed to be of unit cost. For parallel computation we assume the CRCW PRAM model. As we will be working with sparse matrices, we assume that a matrix is specified on input by a list of its non-zero entries.

(Integer) linear programming. We consider integer programs of the form (\spadesuit) . When replacing the integrality constraint $x \in \mathbb{Z}_{\geq 0}$ by $x \in \mathbb{R}_{\geq 0}$ yields the linear relaxation of (\spadesuit) . We represent a program P as a quadruple $P = (x, A, b, c)$, where x, A, b, c are as in (\spadesuit) . We

denote by $\text{Sol}^{\mathbb{Z}}(P)$ (resp. $\text{Sol}^{\mathbb{R}}(P)$) the set of feasible integral solutions to P (resp. the set of fractional solutions to the linear relaxation to P). Analogously, we denote the set of optimal solutions (with respect to the objective function) by $\text{opt}^{\mathbb{Z}}(P)$ and $\text{opt}^{\mathbb{R}}(P)$ respectively.

Stochastic matrices. We say that a matrix M is *block-decomposable* if there are non-zero block matrices M_1, \dots, M_t such that M can be written as $M = \text{diag}(M_1, \dots, M_t)$. The matrices M, M_1, \dots, M_t need not be square. The *block decomposition* of M is then the unique presentation of M as $M = \text{diag}(M_1, \dots, M_t)$, where the blocks M_1, \dots, M_t are non empty and not block-decomposable.

For nonnegative integers r and s , a matrix A is (r, s) -*stochastic* if the following condition holds: if A' is A with the first r columns removed, then each block in the block decomposition of A' has at most s columns. Equivalently, an (r, s) -stochastic matrix can be written as

$$A = \begin{pmatrix} A_1 & B_1 & & & \\ A_2 & & B_2 & & \\ \vdots & & & \ddots & \\ A_t & & & & B_t \end{pmatrix}, \quad (\diamond)$$

where the blocks A_1, \dots, A_t have r columns and each block B_i has at most s columns. As usual, in (\diamond) and throughout the paper, empty spaces denote blocks filled with zeros. In general, a presentation of matrix A as in (\diamond) is called the *stochastic decomposition* of A . To define the *primal treedepth* $\text{td}_P(A)$ of a matrix A , we first recursively define the *depth* of A :

- if A has no columns, then its depth is 0;
- if A is block-decomposable, then its depth is equal to the maximum among the depths of the blocks in its block decomposition; and
- if A has at least one column and is not block-decomposable, then the depth of A is one larger than the depth of the matrix obtained from A by removing its first column.

The primal treedepth of A is then the smallest integer d , such that the rows and columns of A can be permuted so that the resulting matrix has depth d .

For the remainder of this paper we will assume that matrices of bounded primal treedepth are suitably organized on input. That is, rows and columns are permuted so that the matrix has primal treedepth at most d and is in the block form depicted above. Finding such a permutation can be done in linear fpt time, we discuss this in the full version of the paper.

Graver bases. We collect some basic facts about Graver bases, for a thorough introduction to the theory and its applications we refer to [23, 21]. For an integer matrix A , we write $\ker^{\mathbb{Z}}(A)$ for the set of all integer vectors from $\ker(A)$. The *Graver basis* of A , denoted $\mathcal{G}(A)$, consists of all \sqsubseteq -minimal vectors of $\ker^{\mathbb{Z}}(A)$. We will use the following known bounds on $g_{\infty}(A) := \max_{v \in \mathcal{G}(A)} \|v\|_{\infty}$, the maximum norm of Graver basis elements:

► **Theorem 1** ([9], ∞). *For every integer matrix A with n rows and m columns, we have $g_{\infty}(A) \leq (2n\|A\|_{\infty} + 1)^n$ and $g_{\infty}(A) \leq (2m\|A\|_{\infty} + 1)^m$.*

We will also use the more general bounds for matrices with bounded primal treedepth.

► **Theorem 2** (Lemma 26 of [10]). *There is a computable function $f: \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$ such that for every integer matrix A , $g_{\infty}(A) \leq f(\text{td}_P(A), \|A\|_{\infty})$.*

We note that the proof of Theorem 2 given by Eisenbrand et al. [10] shows that, roughly speaking, $g_{\infty}(A)$ is bounded by a d -fold exponential function of $\|A\|_{\infty}$, where d is the primal treedepth of A .

3 Algorithms

As discussed, our algorithms use two ingredients: proximity results for stochastic integer programs, and algorithms for solving their linear relaxations. In this section we state those ingredients formally and argue how the results claimed in Section 1 follow.

As for proximity, we show that in stochastic integer programs, for every optimal fractional solution there is always an optimal integral solution that is not far, in terms of the ℓ_∞ -norm. Precisely, the following results will be proved in Section 5.

► **Lemma 3.** *There exists a computable function $f: \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$ with the following property. Suppose $P = (x, A, b, c)$ is a linear program in the form (\spadesuit) . Then for every optimal fractional solution $x^\star \in \text{Sol}^{\mathbb{R}}(P)$ there exists an optimal integral solution $x^\diamond \in \text{Sol}^{\mathbb{Z}}(P)$ satisfying*

$$\|x^\diamond - x^\star\|_\infty \leq f(\text{depth}(A), \|A\|_\infty).$$

► **Lemma 4.** *Suppose $P = (x, A, b, c)$ is a linear program in the form (\spadesuit) , where A is (r, s) -stochastic for some positive integers r, s . Then for every optimal fractional solution $x^\star \in \text{Sol}^{\mathbb{R}}(P)$ there exists an optimal integral solution $x^\diamond \in \text{Sol}^{\mathbb{Z}}(P)$ satisfying*

$$\|x^\diamond - x^\star\|_\infty \leq 2^{\mathcal{O}(r(r+s)\|A\|_\infty)^{r(r+s)}}.$$

A (r, s) -stochastic matrix has depth at most $r + s$, so Lemma 4 can be seen as a special case of Lemma 3, but provides an explicit bound. For solving the linear relaxation we obtain:

► **Lemma 5** (\spadesuit). *Suppose we are given a linear program $P = (x, A, b, c)$ in the form (\spadesuit) , where A has n rows. Then, in the PRAM model, one can, using n processors and in time $\log^{\mathcal{O}(2^{\text{depth}(A)})} n$, compute an optimal fractional solution to P .*

► **Lemma 6** (\spadesuit). *Suppose we are given an (r, s) -stochastic linear program $P = (x, A, b, c)$ in the form (\spadesuit) , where A has n rows. Then, in the PRAM model, one can, using n processors and in time $2^{\mathcal{O}(r^2+rs^2)} \cdot \log^{\mathcal{O}(rs)} n$, compute an optimal fractional solution to P .*

Again, Lemma 6 differs from Lemma 5 by considering a more restricted class of matrices (i.e., (r, s) -stochastic), but providing better complexity bounds.

We now combine the tools presented above to show the following theorems.

► **Theorem 7** (\spadesuit). *Suppose we are given an (r, s) -stochastic linear program $P = (x, A, b, c)$ in the form (\spadesuit) , where A has n rows. Then, in the PRAM model, one can, using n processors and in time $2^{((r+s)\|A\|_\infty)^{\mathcal{O}(r(r+s))}} \cdot \log^{\mathcal{O}(rs)} n$, compute an optimal integral solution to P .*

Sketch of proof. Apply Lemma 5 to find an optimal fractional solution x^\star . By Lemma 4, there is an optimal integral solution x^\diamond satisfying $\|x^\diamond - x^\star\|_\infty \leq \rho$, where $\rho \in 2^{\mathcal{O}(r(r+s)\|A\|_\infty)^{r(r+s)}}$. In particular, if x_0^\diamond and x_0^\star are the projections of x^\diamond and x^\star onto the first r coordinates, respectively, then $\|x_0^\diamond - x_0^\star\|_\infty \leq \rho$.

Assume the stochastic decomposition (\diamond) of A . For all $\xi \in \mathbb{Z}_{\geq 0}^r$ satisfying $\|\xi - x_1^\star\|_\infty \leq \rho$ and all $i \in \{1, \dots, t\}$, let us consider the integer program $P_i(\xi)$ defined as:

$$\min\{c_i^\top x_i : B_i x_i = b_i - A_i \xi, x_i \geq 0\},$$

where b_i, c_i, x_i are suitable restrictions of b, c, x to entries corresponding to rows or columns of B_i . It follows that

$$\text{opt}^{\mathbb{Z}}(P) = \min \left\{ c_0^\top \xi + \sum_{i=1}^t \text{opt}^{\mathbb{Z}}(P_i(\xi)) : \xi \geq 0 \text{ is integral and } \|\xi - x_1^\star\|_\infty \leq \rho \right\},$$

where c_0 is the projection of c onto the first r coordinates. Therefore, it suffices to iterate through all integral vectors $\xi \geq 0$ satisfying $\|\xi - x_1^*\| \leq \rho$ one by one – of which there are at most $(2\rho + 1)^r$ many – and for each of them solve all the programs $P_i(\xi)$ in parallel, by assigning to $P_i(\xi)$ as many processors as the number of rows of B_i .

It remains to argue how each of the programs $P_i(\xi)$ is going to be solved efficiently. For this, we may apply the same approach. Namely, we use Lemma 5 to find an optimal fractional solution x_i^* of $P_i(\xi)$, and using Lemma 4 again we can argue that there exists an optimal integral solution x_i° of $P_i(\xi)$ that satisfies $\|x_i^\circ - x_i^*\|_\infty \leq \rho$. Now B_i has at most s columns, so there are only at most $(2\rho + 1)^s$ candidates for an integral vector x_i° satisfying the above, and they can be checked one by one. The overall running time analysis follows easily from the bounds provided by Lemma 4 and Lemma 5; we leave the details to the reader. ◀

The same basic idea, but applied recursively, yields the following.

► **Theorem 8** (\asymp). *There is a computable function $f: \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$ such that the following holds. Suppose we are given a linear program $P = (x, A, b, c)$ in the form (\spadesuit), where A has n rows. Then, in the PRAM model, one can using n processors and in time $f(\text{depth}(A), \|A\|_\infty) \cdot \log^{\mathcal{O}(2^{\text{depth}(A)})} n$ compute an optimal integral solution to P .*

4 A stronger Klein bound

In this section we discuss a stronger variant of a structural result of Klein [18] which we will need for our proximity bounds in the next section.

► **Theorem 9** (Stronger Klein bound, \asymp). *Let $T_1, \dots, T_n \subseteq \mathbb{Z}^d$ be multisets of integer vectors of ℓ_∞ -norm at most Δ such that their respective sums are almost the same in the following sense: there is some $b \in \mathbb{Z}^d$ and a positive integer ϵ such that*

$$\left\| \sum_{v \in T_i} v - b \right\|_\infty < \epsilon \quad \text{for all } i \in \{1, \dots, n\}.$$

There exists a function $f(d, \Delta) \in 2^{\mathcal{O}(d\Delta)^d}$ such that the following holds. Assuming $\|b\|_\infty > \epsilon \cdot f(d, \Delta)$, one can find nonempty submultisets $S_i \subseteq T_i$ for all $i \in \{1, \dots, n\}$, and a vector $b' \in \mathbb{Z}^d$ satisfying $\|b'\|_\infty \leq f(d, \Delta)$, such that

$$\sum_{v \in S_i} v = b' \quad \text{for all } i \in \{1, \dots, n\}.$$

Theorem 9 strengthens the original formulation of Klein [18, Lemma 2] in various aspects. First, the formulation of Klein required all the vectors to be nonnegative. Second, the argument of Klein yields a bound on $f(d, \Delta)$ that is doubly exponential in d^2 , our proof improves this dependence to doubly exponential in $d \log d$. Finally, we allow the sums of the respective multisets to differ by some slack parameter ϵ , while in the original setting of Klein all sums need to be exactly equal. This last aspect will prove essential in the proof of our proximity bound, while the second is primarily used for improving the parametric factor in the running time.

The full proof of Theorem 9 relies on polyhedral techniques and is rather lengthy. However, using only the original formulation due to Klein and the pigeonhole principle, there is a short proof that achieves the third aspect of our improvement, i.e. that we may allow the sums of respective multisets to differ by some slack parameter. As this is central for the next section, we prove only this part and defer the full proof of Theorem 9 to the full version of the paper.

Proof of a simpler variant of Theorem 9. Specifically, we show the following statement:

Let T_1, \dots, T_n be multisets of vectors in $\mathbb{Z}_{\geq 0}^d$ of ℓ_∞ norm at most Δ such that there is some $b \in \mathbb{Z}^d$ and $\epsilon \in \mathbb{N}$ such that

$$\left\| \sum_{v \in T_i} v - b \right\|_\infty < \epsilon \quad \text{for all } i \in \{1, \dots, n\}.$$

Then there is a function $g(d, \Delta)$ such that provided $\|b\|_\infty > \epsilon \cdot g(d, \Delta)$, there exist nonempty submultisets $S_i \subseteq T_i$ for $i \in \{1, \dots, n\}$ and a vector $b' \in \mathbb{Z}_{\geq 0}^d$ satisfying $\|b'\|_\infty \leq g(d, \Delta)$ such that

$$\sum_{v \in S_i} v = b' \quad \text{for all } i \in \{1, \dots, n\}.$$

In fact, one can take $g(d, \Delta) = 2(f(d, \Delta) + 1)^{d+1}$ where $f(d, \Delta)$ is the bound from [18].

To prove this, we first add vectors belonging to $\{0, 1\}^d$ to each multiset T_i so that

$$\sum_{v \in \tilde{T}_i} v = b + \epsilon \cdot \mathbf{1} \quad \text{for all } i \in \{1, \dots, n\},$$

where the \tilde{T}_i are the resulting multisets and $\mathbf{1}$ is the all-ones vector. Clearly, this can be achieved by adding to each multiset T_i at most 2ϵ vectors from $\{0, 1\}^d$.

Assume that $\|b\|_\infty > 2\epsilon \cdot (f(d, \Delta) + 1)^{d+1}$ where $f(d, \Delta)$ is the original bound from [18]. Since the multisets \tilde{T}_i all sum up to $b + \epsilon \cdot \mathbf{1}$ exactly, we can use the original formulation of [18] to infer that there are submultisets $S_i^1 \subseteq \tilde{T}_i$, for all $\{1, \dots, n\}$, and a vector $b_1 \in \mathbb{Z}_{\geq 0}^d$ with $\|b_1\|_\infty \leq f(d, \Delta)$ such that

$$\sum_{v \in S_i^1} v = b_1 \quad \text{for all } i \in \{1, \dots, n\}.$$

Since the multisets $\tilde{T}_i - S_i^1$ sum up to $b + \epsilon \cdot \mathbf{1} - b_1$, we can iteratively find nonempty submultisets $S_i^2 \subseteq \tilde{T}_i - S_i^1, \dots, S_i^k \subseteq \tilde{T}_i - (S_i^1 \cup \dots \cup S_i^k)$ and vectors b_1, \dots, b_k of ℓ_∞ -norm bounded by $f(d, \Delta)$ such that

$$\sum_{v \in S_i^j} v = b_j \quad \text{for all } j \in \{2, \dots, k\} \text{ and } i \in \{1, \dots, n\}.$$

Since we assumed that $\|b\|_\infty > 2\epsilon \cdot (f(d, \Delta) + 1)^{d+1}$, we can continue the above procedure until $k > 2\epsilon \cdot (f(d, \Delta) + 1)^d$. Note that there are at most $(f(d, \Delta) + 1)^d$ integral and nonnegative vectors of ℓ_∞ norm at most $f(d, \Delta)$. Therefore, by pigeonhole principle there exists $b' \in \mathbb{Z}_{\geq 0}^d$ with $\|b'\|_\infty \leq f(d, \Delta)$ and a set of indices J of size $2\epsilon + 1$ such that $\sum_{v \in S_i^j} v = b'$ for all $j \in J$ and $i \in \{1, \dots, n\}$. For each $i \in \{1, \dots, n\}$, one of these multisets $S_i^j \subseteq \tilde{T}_i$ for $j \in J$ does not contain any of the (at most) 2ϵ vectors we have added to T_i to obtain \tilde{T}_i . Thus, for each $i \in \{1, \dots, n\}$ we can find a nonempty submultisets $S_i \subseteq T_i$ satisfying

$$\sum_{v \in S_i} v = b'.$$

Since $\|b'\|_\infty \leq f(d, \Delta) \leq g(d, \Delta)$, this concludes the proof. \blacktriangleleft

5 Proximity

The goal of this section to prove a very general theorem, Theorem 12, that will imply Lemma 3 and Lemma 4, see Corollaries 14 and 15. To facilitate the discussion of proximity, let us introduce the following definition.

► **Definition 10.** Let $P = (x, A, b, c)$ be a linear program in the form (\spadesuit). The proximity of P , denoted $\text{proximity}_\infty(P)$, is the infimum of reals $\rho \geq 0$ satisfying the following: for every fractional solution $x^\star \in \text{Sol}^\mathbb{R}(P)$ and integral solution $x^\square \in \text{Sol}^\mathbb{Z}(P)$, there is an integral solution $x^\diamond \in \text{Sol}^\mathbb{Z}(P)$ such that

$$\|x^\diamond - x^\star\|_\infty \leq \rho \quad \text{and} \quad x^\diamond - x^\star \subseteq x^\square - x^\star.$$

The condition $x^\diamond - x^\star \subseteq x^\square - x^\star$ is equivalent to saying that x^\diamond is contained in the axis parallel box spanned by x^\star and x^\square , see Figure 2.

■ **Figure 2** $x^\diamond - x^\star \subseteq x^\square - x^\star$, x^\diamond is in the rectangle spanned by x^\square and x^\star .

Comparing to earlier work, for instance [4, 11], this notion of proximity is independent of the optimization goal. However, it can also be used to bound the distance of optimal fractional solutions to optimal integral solutions.

► **Lemma 11** (\times). Suppose $P = (x, A, b, c)$ is a linear program in the form (\spadesuit). Then for every optimal fractional solution x^\star to P there is an optimal integral solution x^\diamond to P satisfying

$$\|x^\diamond - x^\star\|_\infty \leq \text{proximity}_\infty(P).$$

Sketch of proof, see Figure 2. Let x^\square any optimal integral solution. By our definition of proximity there is x^\diamond with $\|x^\diamond - x^\star\|_\infty \leq \text{proximity}_\infty(P)$ and $x^\diamond - x^\star \subseteq x^\square - x^\star$. It can be easily checked that if $c^\top x^\square < c^\top x^\diamond$, then $x^\bullet := x^\star + x^\square - x^\diamond$ is feasible and $c^\top x^\bullet < c^\top x^\star$, contradicting the optimality of x^\star . Thus, x^\diamond is an optimal integral solution. ◀

For the remainder of this section we adopt the following notation. Suppose that A has a stochastic decomposition (\diamond). Let x_0, x_1, \dots, x_t be the partition of the vector of variables x so that $x_0 \in \mathbb{R}^r$ corresponds to the columns of matrices A_1, \dots, A_t , while $x_i \in \mathbb{R}^s$ corresponds to the columns of B_i , for each $i \in \{1, \dots, t\}$. Finally, partition b into b_1, \dots, b_t so that b_i corresponds to the rows of A_i and B_i respectively. Thus, $\text{Sol}^\mathbb{R}(P)$ takes the form:

$$\begin{aligned} A_i x_0 + B_i x_i &= b_i & \text{for all } i \in \{1, \dots, t\}, \\ x_i &\geq 0 & \text{for all } i \in \{0, 1, \dots, t\}. \end{aligned}$$

For each $i \in \{1, \dots, t\}$, we define

$$P_i = \left(\begin{pmatrix} x_0 \\ x_i \end{pmatrix}, D_i, b_i, 0 \right) \quad \text{with} \quad D_i := (A_i \ B_i). \quad (1)$$

We observe that

$$\begin{pmatrix} x_0 \\ x_1 \\ \vdots \\ x_t \end{pmatrix} \in \text{Sol}^{\mathbb{R}}(P) \quad \text{if and only if} \quad \begin{pmatrix} x_0 \\ x_i \end{pmatrix} \in \text{Sol}^{\mathbb{R}}(P_i) \quad \text{for all } i \in \{1, \dots, t\}.$$

This decomposition of the constraint matrix is the key to our main technical result.

► **Theorem 12** (Composition Theorem). *Suppose $P = (x, A, b, c)$ is a linear program in the form (\spadesuit) , where A admits a stochastic decomposition (\diamond) . Adopt the notation presented above and let k be the number of columns of each of the matrices A_1, \dots, A_t . Further, let*

$$\gamma := \max_{1 \leq i \leq t} g_{\infty}(D_i) \quad \text{and} \quad \rho := \max_{1 \leq i \leq t} \text{proximity}_{\infty}(P_i).$$

Then

$$\text{proximity}_{\infty}(P) \leq 3k\gamma\rho \cdot f(k, \gamma)$$

where $f(k, \gamma)$ is the bound provided by Theorem 9.

By substituting $f(k, \gamma)$ with the bound of Theorem 9, we get $\text{proximity}_{\infty}(P) \leq \rho \cdot 2^{\mathcal{O}(k\gamma)^k}$. To derive the promised bounds on the proximity we use the following simple lemma.

► **Lemma 13** (\times). *Let $P = (x, A, b, c)$ be a linear program in the form (\spadesuit) where A has m columns. Then*

$$\text{proximity}_{\infty}(P) \leq (m\|A\|_{\infty})^{m+1}.$$

Sketch of proof. Given a feasible fractional solution x^* and an integral vector x^{\square} , we can consider the ILP on m variables defined by constraints $Ax = b$ and $x - x^* \sqsubseteq x^{\square} - x^*$. By the classic theorem of Cook et al. [4], there is an integral solution whose ℓ_{∞} distance from x^* is at most m times the largest sub-determinant. It remains to apply the Hadamard bound. ◀

► **Corollary 14.** *Let $P = (x, A, b, c)$ be a linear program in the form (\spadesuit) , where A is (r, s) -stochastic. Then*

$$\text{proximity}_{\infty}(P) \leq 2^{\mathcal{O}(r(r+s)\|A\|_{\infty})^{r(r+s)}}.$$

Proof. Recalling the definition of P_i in (1) and using that the matrix A is (r, s) -stochastic, we see that the constraint matrix D_i of P_i has at most $r + s$ columns with entries bounded by $\|A\|_{\infty}$. Using Lemma 13 and Theorem 1 respectively, we get

$$g_{\infty}(D_i) \leq (2(r + s)\|A\|_{\infty} + 1)^{r+s} \quad \text{and} \quad \text{proximity}_{\infty}(P_i) \leq ((r + s)\|A\|_{\infty})^{r+s+1}.$$

By Theorem 12 we obtain the claimed bound on $\text{proximity}_{\infty}(A)$. ◀

Applying the same idea recursively yields the following.

► **Corollary 15** (\times). *There is a computable function $h: \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$ such that for every linear program $P = (x, A, b, c)$ in the form (\spadesuit) , we have*

$$\text{proximity}_{\infty}(P) \leq h(\text{td}_P(A), \|A\|_{\infty}).$$

5.1 Proof of Theorem 12

We now use our strengthening of the lemma of Klein [18], Theorem 9, to prove Theorem 12.

Proof of Theorem 12. Consider any $x^* \in \text{Sol}^{\mathbb{R}}(P)$ and $x^\square \in \text{Sol}^{\mathbb{Z}}(P)$. Let $x^\diamond \in \text{Sol}^{\mathbb{Z}}(P)$ be an integral solution such that $x^\diamond - x^* \sqsubseteq x^\square - x^*$ and subject to the condition that $\|x^\diamond - x^*\|_1$ is minimized. Our goal is to show that then $\|x^\diamond - x^*\|_\infty \leq 3k\gamma\rho \cdot f(k, \gamma)$, where $f(\cdot, \cdot)$ is the function given by Theorem 9.

Observe that if there existed a non-zero vector $u \in \ker^{\mathbb{Z}}(A)$ such that $u \sqsubseteq x^* - x^\diamond$, then we would have that $x^\diamond + u \in \text{Sol}^{\mathbb{Z}}(P)$, $(x^\diamond + u) - x^* \sqsubseteq x^\diamond - x^* \sqsubseteq x^\square - x^*$, and the ℓ_1 distance from x^* to $x^\diamond + u$ would be strictly smaller than to x^\diamond . This would contradict the choice of x^\diamond . Therefore, it is sufficient to show the following: if $\|x^\diamond - x^*\|_\infty$ is larger than $3k\gamma\rho \cdot f(k, \gamma)$, then there exists a non-zero vector $u \in \ker^{\mathbb{Z}}(A)$ such that $u \sqsubseteq x^* - x^\diamond$.

To this end, for all $i \in \{1, \dots, t\}$, restrict x^* and x^\diamond to the variables of P_i as follows:

$$\tilde{x}_i^* := \begin{pmatrix} x_0^* \\ x_i^* \end{pmatrix} \in \text{Sol}^{\mathbb{R}}(P_i) \quad \text{and} \quad \tilde{x}_i^\diamond := \begin{pmatrix} x_0^\diamond \\ x_i^\diamond \end{pmatrix} \in \text{Sol}^{\mathbb{Z}}(P_i).$$

By the definition of proximity, for all $i \in \{1, \dots, t\}$ there are integral solutions

$$\tilde{x}_i \in \text{Sol}^{\mathbb{Z}}(P_i) \quad \text{with} \quad \|\tilde{x}_i - \tilde{x}_i^*\|_\infty \leq \text{proximity}_\infty(P_i) \leq \rho \quad \text{and} \quad \tilde{x}_i - \tilde{x}_i^* \sqsubseteq \tilde{x}_i^\diamond - \tilde{x}_i^*.$$

Since \tilde{x}_i and \tilde{x}_i^\diamond are both integral solutions to P_i , we have $\tilde{x}_i - \tilde{x}_i^\diamond \in \ker^{\mathbb{Z}}(A_i \ B_i)$ and we can decompose this vector into a multiset G_i of Graver elements. That is, G_i is a multiset consisting of sign compatible (i.e., belonging to the same orthant) elements of $\mathcal{G}(D_i)$ with $\tilde{x}_i - \tilde{x}_i^\diamond = \sum_{g \in G_i} g$. Note that the first k entries of vectors $\tilde{x}_1, \dots, \tilde{x}_t$ correspond to the same k variables of P , but they may differ for different $i \in \{1, \dots, t\}$. For a vector w , let $\pi(w)$ be the projection onto the first k entries of w .

Let $\pi(G_i)$ be the multiset that includes a copy of $\pi(g)$ for each $g \in G_i$. By the definition of \tilde{x}_i^* and \tilde{x}_i^\diamond , we have $\pi(\tilde{x}_i^*) = \pi(\tilde{x}_j^*)$ and $\pi(\tilde{x}_i^\diamond) = \pi(\tilde{x}_j^\diamond)$ for all $i, j \in \{1, \dots, t\}$. From this, for all $i \in \{1, \dots, t\}$,

$$\left\| \sum_{x \in \pi(G_i)} x - \pi(\tilde{x}_1^* - \tilde{x}_1^\diamond) \right\|_\infty = \left\| \pi(\tilde{x}_i) - \underbrace{\pi(\tilde{x}_1^*)}_{=\pi(\tilde{x}_i^*)} + \underbrace{\pi(\tilde{x}_1^\diamond) - \pi(\tilde{x}_i^\diamond)}_{=0} \right\|_\infty \leq \|\tilde{x}_i - \tilde{x}_i^*\|_\infty \leq \rho.$$

Thus, Theorem 9 is applicable for $d = k$, $\Delta = \gamma$, $\epsilon = \rho$ and $b = \pi(\tilde{x}_1^* - \tilde{x}_1^\diamond)$. Note that for each $i \in \{1, \dots, t\}$ and $g \in G_i$, we have $\|g\|_\infty \leq \gamma$. We now distinguish between two cases:
Case 1: $\|\pi(\tilde{x}_1^* - \tilde{x}_1^\diamond)\|_\infty > \rho \cdot f(k, \gamma)$.

By Theorem 9, there exist nonempty submultisets $S_1 \subseteq \pi(G_1), \dots, S_t \subseteq \pi(G_t)$ such that

$$\sum_{x \in S_i} x = \sum_{x \in S_j} x \quad \text{for all } i, j \in \{1, \dots, t\}.$$

Define a vector u in the following way. For all $i \in \{1, \dots, t\}$, let $\hat{G}_i \subseteq G_i$ be submultisets with $\pi(\hat{G}_i) = S_i$ and set $\tilde{u}_i := \sum_{g \in \hat{G}_i} g \in \ker^{\mathbb{Z}}(D_i)$. Observe that vectors $\pi(\tilde{u}_i)$ are equal for all $i \in \{1, \dots, t\}$. This allows us to define u as the vector obtained by combining all the \tilde{u}_i , so that projecting u to the variables of P_i yields \tilde{u}_i , for each $i \in \{1, \dots, t\}$. Note that since multisets \hat{G}_i are nonempty, u is a non-zero vector. Also $u \in \ker^{\mathbb{Z}}(A)$, since $\tilde{u}_i \in \ker^{\mathbb{Z}}(D_i)$ for all $i \in \{1, \dots, t\}$. Further, we have $u \sqsubseteq x^* - x^\diamond$, because for all $i \in \{1, \dots, t\}$,

$$\tilde{u}_i = \sum_{g \in \hat{G}_i} g \sqsubseteq \tilde{x}_i - \tilde{x}_i^\diamond \sqsubseteq \tilde{x}_i^* - \tilde{x}_i^\diamond.$$

Thus, u contradicts the minimality of $\|x^\diamond - x^\star\|_1$. We move to the second case.

Case 2: $\|\pi(\tilde{x}_1^\star - \tilde{x}_1^\diamond)\|_\infty \leq \rho \cdot f(k, \gamma)$.

Since we have $\|\pi(\tilde{x}_i - \tilde{x}_i^\diamond) - \pi(\tilde{x}_1^\star - \tilde{x}_1^\diamond)\|_\infty \leq \rho$ for all $i \in \{1, \dots, t\}$, we have

$$\|\pi(\tilde{x}_i - \tilde{x}_i^\diamond)\|_\infty \leq \rho \cdot f(k, \gamma) + \rho \leq 2\rho \cdot f(k, \gamma) \quad \text{for all } i \in \{1, \dots, t\}.$$

Suppose for a moment that for some $i \in \{1, \dots, t\}$, there exists an element $g \in G_i$ with $\pi(g) = 0$. Then by putting zeros on all the other coordinates, we can extend g to a vector $u \in \ker^{\mathbb{Z}}(A)$ which satisfies $u \sqsubseteq x^\star - x^\diamond$. As g is non-zero, so is u , hence u satisfies all the requested properties. Hence, from now on we may assume that no multiset G_i contains an element g with $\pi(g) = 0$. It follows that

$$|G_i| = |\pi(G_i)| \leq \left\| \sum_{x \in \pi(G_i)} x \right\|_1 \leq k \left\| \sum_{x \in \pi(G_i)} x \right\|_\infty = k \|\pi(\tilde{x}_i - \tilde{x}_i^\diamond)\|_\infty \leq 2k\rho \cdot f(k, \gamma).$$

Since $\|g\|_\infty \leq \gamma$ for every element $g \in G_i$, we infer that

$$\|\tilde{x}_i - \tilde{x}_i^\diamond\|_\infty \leq \left\| \sum_{g \in G_i} g \right\|_\infty \leq \gamma |G_i| \leq 2k\gamma\rho \cdot f(k, \gamma).$$

By combining this with $\|\tilde{x}_i - \tilde{x}_i^\star\|_\infty \leq \rho$, we get

$$\|\tilde{x}_i^\diamond - \tilde{x}_i^\star\|_\infty \leq \|\tilde{x}_i^\diamond - \tilde{x}_i\|_\infty + \|\tilde{x}_i - \tilde{x}_i^\star\|_\infty \leq 2k\gamma\rho \cdot f(k, \gamma) + \rho \leq 3k\gamma\rho \cdot f(k, \gamma).$$

This implies that $\|x^\diamond - x^\star\| \leq 3k\gamma\rho \cdot f(k, \gamma)$ and concludes the proof. \blacktriangleleft

Abstract

We systematically investigate the complexity of counting subgraph patterns *modulo fixed integers*. For example, it is known that the *parity* of the number of k -matchings can be determined in polynomial time by a simple reduction to the determinant. We generalize this to an $n^{f(t,s)}$ -time algorithm to compute modulo 2^t the number of subgraph occurrences of patterns that are s vertices away from being matchings. This shows that the known polynomial-time cases of subgraph *detection* (Jansen and Marx, SODA 2015) carry over into the setting of *counting modulo 2^t* . Complementing our algorithm, we also give a simple and self-contained proof that counting k -matchings modulo odd integers q is $\text{Mod}_q\text{W}[1]$ -complete and prove that counting k -paths modulo 2 is $\oplus\text{W}[1]$ -complete, answering an open question by Björklund, Dell, and Husfeldt (ICALP 2015).

1 Introduction

The last two decades have seen the development of several complexity dichotomies for pattern counting problems in graphs, including full classifications for counting *subgraphs*, *induced subgraphs*, and *homomorphisms* from fixed computable pattern classes \mathcal{H} . The input to such problems is a *pattern* graph $H \in \mathcal{H}$ and an unrestricted *host* graph G ; the task is to count the relevant occurrences of H in G . Depending on \mathcal{H} , these problems are known to be either polynomial-time solvable or $\#\text{W}[1]$ -hard when parameterized by $|V(H)|$. The latter rules out polynomial-time algorithms under the complexity assumption $\text{FPT} \neq \#\text{W}[1]$.

In this paper, we focus on counting *subgraphs* from any fixed graph class \mathcal{H} . On the positive side, given a pattern graph $H \in \mathcal{H}$ whose smallest vertex-cover has size $\text{vc}(H)$ and an n -vertex host graph G , there are known $O(n^{\text{vc}(H)+1})$ time algorithms [40, 29, 9] to count subgraphs of G that are isomorphic to H : First, find a minimum vertex-cover C of H using exhaustive search. Then, iterate over all possible embeddings f of $H[C]$ into G and count the possible extensions of $G[f(C)]$ to a full copy of H . Complementing this algorithm, an almost matching running time lower bound of $n^{\Omega(\text{vc}(H)/\log \text{vc}(H))}$ under the exponential-time hypothesis (ETH) is also known [8]. Thus, assuming ETH or $\text{FPT} \neq \#\text{W}[1]$, the problem

$\#\text{Sub}(\mathcal{H})$ of counting subgraphs from a fixed class \mathcal{H} is polynomial-time solvable if and only if the vertex-cover numbers (or equivalently, the maximum matching sizes) of the graphs in \mathcal{H} are bounded by a constant. The rightmost column of Figure 1 visualizes this situation.

Turning from counting to the problem $\text{Sub}(\mathcal{H})$ of *detecting* subgraphs from fixed classes \mathcal{H} , the picture is less clear. Evidence points at three strata of complexity: Define the *matching-split number* of H to be the minimum number of vertices whose deletion turns H into a matching, that is, a graph of maximum degree 1. Jansen and Marx [25] show that, if this number is bounded in a graph class \mathcal{H} , then $\text{Sub}(\mathcal{H})$ is polynomial-time solvable. For classes \mathcal{H} of bounded tree-width, it is known [34, 1, 19] that the problem $\text{Sub}(\mathcal{H})$ is fixed-parameter tractable when parameterized by $|V(H)|$. For pattern classes \mathcal{H} of unbounded tree-width, it is conjectured that $\text{Sub}(\mathcal{H})$ is $\text{W}[1]$ -hard – so far, this hardness has only been established for cliques, bicliques [30], grids [6], and less natural graph classes. The leftmost column of Figure 1 visualizes the situation.

We propose to study an intermediate setting between decision and counting, namely, counting subgraph patterns *modulo fixed integers* $q \in \mathbf{N}$. Modular counting has a tradition in classical complexity theory, where the complexity classes Mod_qP for $q \in \mathbf{N}$ capture problems that ask to count accepting paths of polynomially time-bounded non-deterministic Turing machines modulo q . In particular, the class Mod_2P (better known as $\oplus\text{P}$) plays a central role in the proof of Toda’s theorem [38]. Several (partial) classification results for frameworks of modular counting problems are known; this includes homomorphisms to fixed graphs [16, 20, 21, 26, 18], constraint satisfaction problems [15, 22], and Holant problems [11].

Figure 1 summarizes our understanding. If the vertex-cover number is bounded, the polynomial-time algorithms (regions 7 and 8) follow from the algorithm for $\#\text{Sub}(\mathcal{H})$ described above and require no further attention. Our paper is concerned with the remaining regions 1–6.

As argued above, matchings play a central role in decision and counting, so it is natural that they reprise their role in modular subgraph counting: On the positive side, there are known polynomial-time algorithms for counting matchings of a given size modulo fixed powers of two. (For bipartite graphs and counting modulo 2, this essentially follows from the fact that determinant and permanent coincide modulo 2.) On the negative side, if q is not a power of two, counting matchings modulo q is known to be Mod_pP -complete for any odd prime p dividing q . We establish a parameterized analogue of this fact: Let $\text{Mod}_q\text{W}[1]$ be the class of parameterized problems that are fpt-reducible to counting k -cliques modulo q . We show that counting k -matchings (that is, sets of k pairwise disjoint edges) in graphs modulo fixed odd primes $q \in \mathbf{N}$ is $\text{Mod}_q\text{W}[1]$ -hard. In our proof, modular counting allows us to sidestep the algebraic machinery from previous works [9, 7, 8], resulting in a surprisingly simple and self-contained argument.

► **Theorem 1.** *For any integer $q \in \mathbf{N}$ containing an odd prime factor p , counting k -matchings modulo q is $\text{Mod}_p\text{W}[1]$ -hard under Turing fpt-reductions and admits no $n^{o(k/\log k)}$ time algorithm under ETH.*

Known arguments from Ramsey theory (see [10, Section 5]) extend Theorem 1 from matchings to $\#\text{Sub}(\mathcal{H}) \bmod q$ for any hereditary class \mathcal{H} of unbounded vertex-cover number. This suggests that modular subgraph counting may only become tractable when the modulus is a power of two. Indeed, we show that patterns of matching-split number s can be counted modulo $q = 2^t$ in time $n^{O(t4^s)}$. To prove this, we follow the general idea of the bounded vertex-cover number algorithm for $\text{Sub}(\mathcal{H})$ outlined before, and we reduce to counting matchings modulo powers of two. This however requires us to overcome technical complications to avoid unwanted cancellations. Overall, we obtain:

vertex-cover number				7	8	
	decision	counting mod 2^t		counting mod odd q		counting

■ **Figure 1** An overview over known results and our new results. The columns correspond, from left to right, to the problem types $\text{Sub}(\mathcal{H})$, $\#\text{Sub}(\mathcal{H}) \bmod 2^t$, $\#\text{Sub}(\mathcal{H}) \bmod q$ for $q \neq 2^t$, or $\#\text{Sub}(\mathcal{H})$; our results are depicted in the two middle columns. The rows correspond, from bottom to top, to requiring \mathcal{H} to have bounded vertex-cover number, matching-split number, tree-width, or no requirement at all. The complexity along each row is monotone: By Lemma 4, decision is no harder than modular counting, and modular counting trivially is no harder than counting. Our results are depicted in the middle two columns: Regions 1 and 2 are Lemma 5. Region 5 is Theorem 2. Regions 7 and 8 already follow from [40]. The point in region 6 is Theorem 1, and the point in region 3 is Theorem 3. We view the hardness of these points as evidence to conjecture their enclosing regions to be hard, see Conjecture 14.

► **Theorem 2.** *There is an algorithm that, given a graph H of matching-split number $s \in \mathbb{N}$ and an n -vertex graph G , computes the number of H -isomorphic subgraphs of G modulo 2^t in time $n^{O(t4^s)}$.*

We complement this result in two ways: First, we observe that $\oplus\text{Sub}(\mathcal{H})$ is $\oplus\text{W}[1]$ -complete for pattern classes \mathcal{H} of unbounded tree-width; this follows directly from previous hardness proofs for $\#\text{Sub}(\mathcal{H})$. More interestingly, we establish the $\oplus\text{W}[1]$ -completeness of counting k -paths modulo 2 in undirected graphs, thus solving an open problem from [3], where this problem was considered in the context of Hamiltonian cycle detection, following [4].

► **Theorem 3.** *Counting k -paths modulo 2 is $\oplus\text{W}[1]$ -complete.*

This result adds to a rich range of previous work on the k -path problem, and is of interest outside our framework. Bodlaender [5] and Monien [32] showed that *finding* a k -path is fixed-parameter tractable. In contrast, Flum and Grohe [17] showed that *exactly counting* k -paths is $\#\text{W}[1]$ -hard. Nevertheless, Arvind and Raman [2] showed that *approximately counting* k -paths, which corresponds to computing the most significant bit(s) of the number of k -paths, is fixed-parameter tractable. Our Theorem 3 suggests that the *least* significant bit of the number of k -paths is hard to compute. This is surprising, because some of the most influential fpt-algorithms for finding a k -path work over characteristic 2, based on the group algebra framework introduced by Koutis [28].

Let us conclude with a general remark on the techniques used in this paper: Recent works successfully exploited a connection between subgraph counts and (linear combinations of) homomorphism counts to obtain algorithms and hardness results [8, 35, 14, 36, 37]. For

example, the number of k -matchings in a graph G is a linear combination of homomorphism counts from $f(k)$ fixed graphs. Insights on the complexity of counting the homomorphisms occurring in this linear combination then lead to complexity results for counting k -matchings. This connection however does not readily transfer to modular counting, as the relevant linear combinations (which involve rational coefficients) may be *undefined* modulo p . We therefore prove Theorems 1–3 using more combinatorial approaches.

2 Preliminaries

Unless otherwise stated, we consider finite, undirected, simple graphs without self-loops.

Subgraph problems

A *homomorphism* from graph H to graph G is a mapping $\varphi: V(H) \rightarrow V(G)$ such that $\{\varphi(u), \varphi(v)\} \in E(G)$ for each $\{u, v\} \in E(H)$. An *embedding* is an injective homomorphism, and we let $\text{Emb}(H, G)$ denote the set of embeddings from H to G . An *isomorphism* is a bijective homomorphism, and an *automorphism* is an isomorphism from H to itself. The set of all automorphisms of H is called $\text{Aut}(H)$, and forms a group when endowed with function composition \circ .

We let $\text{Sub}(H, G)$ be the set of all H -subgraphs of G , that is, the set of all H' with $V(H') \subseteq V(G)$ and $E(H') \subseteq E(G)$ such that H' is isomorphic to H . This terminology fixes the possible confusion about isomorphic copies of subgraphs: For example, there is exactly one K_k -subgraph in K_k , but there are $k!$ embeddings. The *subgraph problem* Sub is given a pair (H, G) to decide whether G has at least one H -subgraph. The *subgraph counting problem* $\#\text{Sub}$ is given a pair (H, G) to determine the number of H -subgraphs in G .

For a graph class \mathcal{H} , we write $\#\text{Sub}(\mathcal{H})$ for the restricted problem where the input (H, G) is promised to satisfy $H \in \mathcal{H}$. For $q \in \mathbf{Z}_{\geq 2}$, the *modular subgraph counting problem* $\#\text{Sub}(\mathcal{H}) \bmod q$ is the problem to compute the number of H -subgraphs modulo q . In the special case with $q = 2$, we write $\oplus\text{Sub}$.

It will be useful to consider *colorful* subgraph problems, where G is H -colored, that is, there is a given homomorphism $c: V(G) \rightarrow V(H)$. Due to the homomorphism property, we allow edges $\{u, v\} \in E(G)$ only if the corresponding colors satisfy $\{c(u), c(v)\} \in E(H)$. A subgraph H' of an H -colored graph G is *vertex-colorful* if c is bijective on $V(H')$. Let $\text{VertexColorfulSub}(H, G)$ be the set of vertex-colorful subgraphs H' for which c is an isomorphism from H' to H . The corresponding computational problems are defined analogously to the uncolored case; the input consists of a graph G together with an H -coloring c .

Background from complexity theory

A *parameterized counting problem* is a pair (f, κ) of functions $f, \kappa: \{0, 1\}^* \rightarrow \mathbf{N}$ where κ is computable. A *parsimonious fpt-reduction* from a parameterized counting problem (f, κ) to a parameterized counting problem (g, ι) is a function R with the following properties: (i) $f(x) = g(R(x))$ for all $x \in \{0, 1\}^*$, (ii) $\iota(R(x))$ is bounded by a computable function in $\kappa(x)$, and (iii) the reduction is computable in time $h(\kappa(x)) \text{poly}(|x|)$ for some computable function h . A *Turing fpt-reduction* may query the oracle multiple times for instances whose parameter is bounded by a function of the input parameter, and combine the query answers in fpt-time to produce the correct output. Moreover, reductions can also be *randomized*, in which case we require that their error probability is bounded by a small constant.

The *exponential-time hypothesis* (ETH) postulates the existence of some $\varepsilon > 0$ such that no algorithm solves n -variable 3-CNF formulas in time $O(2^{\varepsilon n})$. We write for short that 3-CNF-SAT does not have $2^{o(n)}$ -time algorithms, and we also disallow bounded-error randomized algorithms.

Modular counting

For our purposes, we define the class $\text{Mod}_q\text{W}[1]$ as the class of all parameterized problems (f, κ) with $f: \Sigma^* \rightarrow \{0, \dots, q-1\}$ such that (f, κ) has a parsimonious fpt-reduction to the problem of counting k -cliques modulo q . For $q = 2$, it was shown in [3] that all problems in $\text{W}[1]$ admit randomized fpt-reductions to problems in $\oplus\text{W}[1]$. Another result [39, Lemma 2.1] yields the corresponding generalization for all $q > 2$. We use the following analogous proposition for the vertex-colorful subgraph problem, proven in the full version.

► **Lemma 4.** *For any integer $q \geq 2$, there is a randomized Turing fpt-reduction from the problem VertexColorfulSub to the problem $\#\text{VertexColorfulSub} \bmod q$. On input (H, G) , the reduction only queries instances with the same pattern H .*

Our work relies on the following hardness result for parameterized modular subgraph counting, which follows easily from known results on the colorful subgraph decision problem [13, 31]. See the full version for a proof.

► **Lemma 5.** *Let \mathcal{H} be a graph family of unbounded tree-width and let q be an integer with $q \geq 2$. Then $\#\text{VertexColorfulSub}(\mathcal{H}) \bmod q$ parameterized by $k = |E(H)|$ is $\text{Mod}_q\text{W}[1]$ -hard under parsimonious fpt-reductions. Moreover, if ETH is true, then the problem does not have an algorithm running in time $n^{o(k/\log k)}$, where $n = |V(G)|$.*

3 Hardness of counting k -matchings

In this section, we prove Theorem 1. We first establish $\text{Mod}_q\text{W}[1]$ -hardness of the problem $\#\text{ColMatch} \bmod q$ for odd $q \geq 3$: Given a graph G with an edge-coloring $c: E(G) \rightarrow \mathcal{C}$ for some set of colors \mathcal{C} with $|\mathcal{C}| = k$, this problem asks to count modulo q the edge-colorful matchings in G . These are the matchings that use each color in \mathcal{C} exactly once.

► **Lemma 6.** *For any fixed integer p with odd prime factor q , the problem $\#\text{ColMatch} \bmod p$ is $\text{Mod}_q\text{W}[1]$ -hard under parsimonious fpt-reductions and has no $n^{o(k/\log k)}$ time algorithm under ETH.*

Proof. The class \mathcal{H} of all 3-regular graphs has unbounded tree-width, and hence by Lemma 5, the problem $\#\text{VertexColorfulSub}(\mathcal{H}) \bmod q$ is $\text{Mod}_q\text{W}[1]$ -hard and hard under ETH. We reduce it to $\#\text{ColMatch} \bmod q$, implying the hardness of $\#\text{ColMatch} \bmod p$. Let $H \in \mathcal{H}$ and G be the input for the reduction with $k = |V(H)|$ and H -colored G , and let $\{V_a : a \in V(H)\}$ be the color classes of G , with edge-sets $E_{a,b}(G)$ for $ab \in E(H)$. Using the gadgets from Figure 2, we construct a graph G' :

1. Each vertex $u \in V(G)$ is replaced by three vertices u_1, u_2 , and u_3 . We insert a *consistency gadget* Q_u at these vertices by adding q gadget vertices, connecting u_2 and u_3 to all gadget vertices, and u_1 to the first $(q+1)/2$ gadget vertices. For $S \subseteq \{u_1, u_2, u_3\}$, let m_S count the matchings in Q_u that match precisely S ; it can be checked that

$$m_S \equiv_q \begin{cases} 1 & \text{if } S \text{ is } \emptyset \text{ or } \{u_1, u_2, u_3\}, \\ 0 & \text{if } S \text{ is } \{u_2\}, \{u_3\}, \text{ or } \{u_2, u_3\}. \end{cases} \quad (1)$$

We explicitly ignore the other three cases for S , as they will not be relevant.

(a) The AND-gadget, shown here for $q = 5$. In general, the upper u_i, v_j -path always has 3 edges; both *external vertices* u_i and v_j have $q - 2$ neighboring leaves. If exactly 0 or 1 external vertices are removed, this graph has 0 edges modulo q ; if both vertices are removed, the graph has 1 edge.

(b) The consistency gadget contains q gadget vertices, shown here for $q = 5$. The number of matchings of size 0 and 3 equals 1 modulo q , and if u_1 is deleted, the number of non-empty edge-colorful matchings equals 0 modulo q .

■ **Figure 2** The two gadgets used in the proof of Lemma 6.

2. For $\{a, b\} \in E(H)$, suppose that a is the j th vertex incident to b , and that b is the i th vertex incident to a . For each edge $\{u, v\} \in E_{a,b}(G)$ with $u \in V_a$ and $v \in V_b$, we insert an AND-gadget A_{uv} at $\{u_i, v_j\}$. Then for any set $S \subsetneq \{u_i, v_j\}$, the number of edges in $A_{uv} - S$ is divisible by q , whereas $A_{uv} - \{u_i, v_j\}$ has exactly one edge.
3. The edge-colors of G' are defined as follows: For $u \in V_a$ with $a \in V(H)$, we assign color (CONS, a, i) to all edges of Q_u incident to vertex u_i , for $i \in \{1, 2, 3\}$. For each $ab \in E(H)$, we assign color (AND, ab) to all edges in AND-gadgets between edges in $E_{a,b}(G)$. Overall, we have $k' = 3k + 3k/2$ colors.

Every H -copy F in G induces a set \mathcal{M}_F of colorful matchings in G' . We describe this set in the following, show that $|\mathcal{M}_F| \equiv_q 1$, and that \mathcal{M}_F and $\mathcal{M}_{F'}$ are disjoint for $F \neq F'$.

- For each $v \in V(F)$, match all of $\{v_1, v_2, v_3\}$ within Q_v . For fixed v , the number of possible matchings in Q_v is $m_{\{v_1, v_2, v_3\}} \equiv_q 1$ by (1). Let \mathcal{Q}_F denote the set of all matchings that can be obtained by the previous step. Since matchings can be chosen independently for distinct Q_v , we obtain $|\mathcal{Q}_F| \equiv_q 1^{|V(F)|} \equiv_q 1$.
- Any $M \in \mathcal{Q}_F$ can be extended to several colorful matchings by choosing one edge from each color (AND, ab) for $\{a, b\} \in E(H)$. For each $\{u, v\} \in E(F)$, the AND-gadget A_{uv} has exactly one such edge, while the other AND-gadgets of color (AND, ab) have 0 such edges modulo q . Hence, the number edges of color (AND, ab) that can extend M is 1 modulo q . This implies that the overall number r_M of matchings extending M into a colorful matching is also $r_M \equiv_q 1^{|E(F)|} \equiv_q 1$.

Overall, every H -copy F induces $\sum_{M \in \mathcal{Q}_F} r_M \equiv_q \sum_{M \in \mathcal{M}_F} 1 \equiv_q 1$ colorful matchings, so we indeed have $|\mathcal{M}_F| \equiv_q 1$. We also observe from the construction that $\mathcal{M}_F \cap \mathcal{M}_{F'} = \emptyset$ for distinct H -copies F and F' . In the full version, we use properties of the gadgets to prove that colorful matchings $M \notin \bigcup_F \mathcal{M}_F$ cancel modulo q .

▷ **Claim 7.** The number of colorful matchings M that are not contained in \mathcal{M}_F for any H -copy F is divisible by q .

Overall, we have shown that the number of H -copies in G and the number of colorful matchings in G' agree modulo q . As G' can be computed in polynomial time and the parameter is increased only by a constant factor, the claimed hardness results follow. ◀

To prove Theorem 1, it suffices to give an fpt-reduction from $\#\text{ColMatch mod } q$ to counting k -matchings modulo q . This is achieved by a standard inclusion-exclusion argument that can be found in the full version.

4 Counting matching-splittable subgraphs modulo 2^t

In this section, we prove Theorem 2 by describing an $n^{O(t^4)}$ -time algorithm for counting modulo 2^t the subgraphs of matching-split number s . Our algorithm builds upon known algorithms for the decision and counting versions of subgraph problems; we first review their underlying ideas and sketch our algorithm for Theorem 2.

Counting subgraphs of bounded vertex-cover number

The basic structure of our algorithm is similar to a known $O(n^{s+1})$ time algorithm [40, 29, 9] for counting embeddings from H to G if H has a vertex-cover $S \subseteq V(H)$ of size $s \in \mathbb{N}$. Counting embeddings is sufficient for counting subgraph copies, as we can first compute the number $\#Aut(H)$ of automorphisms on H as $\#Emb(H, H)$, and then use

$$\#Sub(H, G) = \frac{\#Emb(H, G)}{\#Aut(H)}. \quad (2)$$

Given (H, G) with $h = |V(H)|$ and $n = |V(G)|$, the algorithm for computing $\#Emb(H, G)$ first finds a minimum vertex-cover S of H in time $h^{O(s)}$; then $I := V(H) \setminus S$ is an independent set. Then the algorithm enumerates all partial embeddings f from $H[S]$ to G , which takes time at most $n^{O(s)}$. Finally, for each f , it remains to count all functions $g: I \rightarrow V(G)$ that extend f to a full embedding from H to G . We observe that g extends f to a full embedding if and only if every vertex $u \in I$ maps via g to a vertex $v = g(u) \in V(G) \setminus f(S)$ that satisfies the *neighborhood constraint* $N_G(v) \cap f(S) \supseteq f(N_H(u))$. Counting functions g with this property can be achieved (in a not completely obvious way) with dynamic programming; we only need to know the number of vertices $v \in V(G) \setminus f(S)$ that have a specific neighborhood $N_G(v) \cap f(S)$, and for each f , there are at most 2^s different possible such neighborhoods. Overall, in $n^{O(s)}$ time, we can compute the number $\#Emb(H, G)$.

Detecting subgraphs of bounded matching-split number

Jansen and Marx [25] extend the above approach and obtain an $n^{O(s)}$ time algorithm for the *decision* problem $Sub(H, G)$ when H has matching-split number s . In this case, we consider a *splitting set* S of size s instead of a vertex-cover, that is, the graph $M = H - S$ may have isolated edges besides isolated vertices. Now the idea is to not only classify the vertices $v \in V(G) \setminus f(S)$ by their neighborhoods $N_v = N_G(v) \cap f(S)$, but to also classify the edges $\{u, v\} \in E(G - f(S))$ by their neighborhoods $\{N_u, N_v\}$. It then remains to find a matching in $G - f(S)$ that has as many isolated vertices and isolated edges as $H - S$, such that these vertices and edges satisfy the neighborhood constraints in $f(S)$. Jansen and Marx achieve this by reduction to a colored matching problem.

Our algorithm

In our algorithm for Theorem 2, we need to overcome two challenges:

- (a) Since counting embeddings is algorithmically more straight-forward than counting subgraphs, we would like to count embeddings and divide by the number of automorphisms $\#Aut(H)$ as in Equation (2). However, since we are counting modulo 2^t , the number $\#Aut(H) \bmod 2^t$ may be 0, and so the division in Equation (2) is impossible. (In fact, even even numbers $\#Aut(H)$ have no inverse modulo 2^t .)
- (b) When mimicking Jansen and Marx's detection algorithm, we cannot just *count* the relevant matchings in $G - f(S)$, since counting perfect matchings is $\#P$ -hard.

Most of our effort focuses on overcoming (a): In Section 4.1, we show that every graph H of matching-split number s has a splitting set R of size $O(s^2)$ that remains rigid under automorphisms, i.e., any automorphism f of H must satisfy $f(R) = R$. In Section 4.2, we show how to compute $\# \text{Sub}(H, G)$ if such a rigid splitting set R for H is given. Rather than counting H -embeddings and attempting a division by $\# \text{Aut}(H)$, we use the rigidity of R to keep track of the automorphisms of H in a more explicit way.

To overcome (b), we use a determinant-based algorithm [23] to compute the Hafnian over a polynomial ring modulo 2^t . We then reduce our constrained matching counting problem to computing such Hafnians. This part of the algorithm can be found in the full version.

4.1 Rigidizing the splitting set

Let H be a graph with a splitting set S of size s , and let $M = H - S$ be the remaining graph of maximum degree 1; we speak of M as a matching, even though it may contain isolated vertices. An automorphism f of H may map a vertex $v \in S$ in the splitting set to $f(v) \notin S$. We show that if a splitting set of size s exists then there is also a *rigid* splitting set R of size $O(s^2)$, i.e., such that every $f \in \text{Aut}(H)$ satisfies $f(R) = R$. In fact, the following algorithm can find such a set R .

Algorithm Rigidize(H) *Given a graph H of matching-split number s , this algorithm computes a rigid splitting set $R \subseteq V(H)$ of size $O(s^2)$.*

- R1** (Find small splitting set.) Using brute-force, compute a set $S \subseteq V(H)$ of size s such that $H - S$ is a matching.
- R2** (Extend it to neighbors of low-degree vertices.) Let $D \subseteq V(H)$ be the set of all vertices whose degree in H is at most $s + 1$. Set $T := S$. While there is an edge $\{u, v\}$ with $u \in T \cap D$ and $v \in \bar{T}$, add v to T .
- R3** (Refine it.) Set $R := T$. For each component C of $H[T \cap D]$ with at most two vertices, remove $V(C)$ from R .

The following lemma captures useful properties of Rigidize. See the full version for a proof.

► **Lemma 8.** *The algorithm Rigidize runs in time $h^{O(s)}$ where $h = |V(H)|$, and the output set $R \subseteq V(H)$ has the properties that $|R| \leq O(s^2)$, that $H - R$ is a matching, and that every $f \in \text{Aut}(H)$ satisfies $f(R) = R$.*

4.2 Counting subgraphs with rigid splitting sets

We use the rigid splitting set R from Lemma 8 to compute the number of times H occurs as a subgraph modulo a power of two. As a subroutine, we use an algorithm for counting colored matchings modulo a power of two in a setting involving particular “color demands”.

► **Definition 9.** *Let G be a graph, let C be a finite set of colors, and let $c: V(G) \cup E(G) \rightarrow 2^C$ be a function that labels each vertex and edge with a subset of C . For any matching M , let $I(M)$ be the set of its isolated vertices. For a coloring $c_M: I(M) \cup E(M) \rightarrow C$, the colored matching (M, c_M) is permissible if $c_M(t) \in c(t)$ holds for all $t \in I(M) \cup E(M)$.*

Color demands are functions $D_I, D_E: C \rightarrow \mathbb{N}$. The pair (M, c_M) satisfies the demands D_I, D_E if, for each $i \in C$, the graph M contains exactly $D_I(i)$ isolated vertices v with $c_M(v) = i$ and exactly $D_E(i)$ edges with $c_M(e) = i$. Let $\mathcal{M}(G, c, D_I, D_E)$ be the set of all permissible matchings (M, c_M) that satisfy the demand D .

As shown in the full version, we obtain the following algorithm as a corollary to Hirai and Namba’s algorithm [23] for computing the Hafnian over polynomial rings modulo 2^t .

► **Lemma 10.** *Given a graph G , permissible colors $c: V(G) \cup E(G) \rightarrow 2^C$, color demands $D_I, D_E: C \rightarrow \mathbf{N}$, and $t \in \mathbf{N}_{\geq 1}$, there is an algorithm that computes the number $|\mathcal{M}(G, c, D_I, D_E)| \bmod 2^t$ in time $n^{O(t|C|)}$.*

Before we state the main algorithm, we introduce some basic group-theoretic notation. Let R be a splitting set of H that satisfies $f(R) = R$ for all $f \in \text{Aut}(H)$. Let G be a graph and let $S \subseteq V(G)$ be a set with $|S| = |R|$. For an embedding $\sigma \in \text{Emb}(H[R], G[S])$ and an automorphism $\varphi \in \text{Aut}(H)$, we note that the function $\sigma \circ (\varphi|_R)$ is again an embedding in $\text{Emb}(H[R], G[S])$. Indeed, we view this operation as a right-action of the group $\text{Aut}(H)$ on the set $\text{Emb}(H[R], G[S])$. We call two embeddings $\sigma, \sigma' \in \text{Emb}(H[R], G[S])$ *equivalent* if there exists $\varphi \in \text{Aut}(H)$ such that $\sigma' = \sigma \circ (\varphi|_R)$; this clearly defines an equivalence relation. The equivalence class $\sigma \text{Aut}(H)$ is called the *orbit* of σ under $\text{Aut}(H)$. All orbits have the same size. Let E_S be a set of representatives for each orbit, that is, a maximal set of mutually non-equivalent embeddings in $\text{Emb}(H[R], G[S])$.

We are ready to state the modular counting algorithm for s -matching-splittable subgraphs.

Algorithm ModCount(H, G, t) *Given an s -matching-splittable graph H , a host graph G , and an integer $t \geq 2$, this algorithm computes the number $\#\text{Sub}(H, G) \bmod 2^t$.*

- C1** (Compute rigid splitting set.) Call $\text{Rigidize}(H)$ to compute the set R .
- C2** (Reduce to counting colored matchings.) For each $S \subseteq V(G)$ with $|S| = |R|$ (that is, a possible image of R) and each representative embedding $\sigma \in E_S$ from $H[R]$ to $G[S]$, we construct an instance $(G - S, c_\sigma, D_I, D_E)$ of colored matching with demands and use Lemma 10 to obtain the number $|\mathcal{M}(G - S, c_\sigma, D_I, D_E)| \bmod 2^t$:
 - a.** (Set permitted colors.) Let $C = 2^R \cup \binom{2^R}{1} \cup \binom{2^R}{2}$. For each vertex $v \in V(G) \setminus S$, let $N_v \subseteq R$ be the vertices of R that hit $N_G(v) \cap S$ under σ , that is, $N_v = \sigma^{-1}(N_G(v) \cap S)$. Define $c_\sigma(v) = \{N : N \subseteq N_v\}$. Moreover, for each $\{u, v\} \in E(G - S)$, define $c_\sigma(\{u, v\}) = \{\{N, N'\} : N \subseteq N_u, N' \subseteq N_v\}$.
 - b.** (Make demands.) The demands $D_I, D_E: C \rightarrow \mathbf{N}$ depend only on H and R . For each $N \subseteq R$, we let $D_I(N)$ be the number of isolated vertices v in $H - R$ whose neighborhood in H satisfies $N_H(v) \cap R = N$. Moreover, for all $N, N' \subseteq R$, we let $D_E(\{N, N'\})$ be the number of edges $\{u, v\} \in E(H - R)$ with $\{N_H(u) \cap R, N_H(v) \cap R\} = \{N, N'\}$.
- C3** (Sum up.) Output the sum modulo 2^t of all integers returned by the queries in C2.

In the full version, we prove that ModCount satisfies the properties stated in Theorem 2.

5 Hardness of counting paths modulo two

In this section, we prove Theorem 3, that counting k -paths modulo 2 is $\oplus W[1]$ -hard. We first formally introduce this and some intermediate problems.

The *length* of a path is the number of its edges. For a graph G and vertices $s, t \in V(G)$, an s, t -*path* is a simple path from s to t . For a computable, strictly increasing function $f: \mathbf{N} \rightarrow \mathbf{N}$, we define f -Flexible Path to be the problem that is given (G, s, t, k) to decide whether there exists any s, t -path in G whose length ℓ satisfies $k \leq \ell \leq f(k)$. When id denotes the identity function, then Path (also known as k -Path or LONGEST PATH) is defined as id -Flexible Path. We similarly define Directed f -Flexible Path and Directed Path for directed graphs, and we define the counting and parity versions of these problems in the canonical manner.

We start our reduction at the vertex-colorful subgraph problem $\oplus \text{VertexColorfulSub}(\mathcal{H})$ for a class \mathcal{H} of unbounded tree-width, which is $\oplus W[1]$ -hard by Lemma 5. The class we choose consists of connected, almost 4-regular graphs without non-trivial automorphisms;

■ **Figure 3** The construction of the graph G' from the graphs H and G . The homomorphism from G to H is indicated by colors. A colorful H -subgraph H' in G and the canonical path corresponding to H' in G' are highlighted in turquoise. Gadget edges are hinted at as semi-transparent curves. Except for (half of the) gadget edges, all edges are oriented from left to right.

here, we say that a graph is *almost 4-regular* if it can be obtained from a 4-regular graph by deleting one edge. The core part of the reduction is in Lemma 11, where we reduce to counting paths of somewhat flexible length in a directed graph (modulo 2). From there, we reduce to the familiar k -path problem in undirected graphs using standard tricks.

► **Lemma 11.** *For any class \mathcal{H} of connected, almost 4-regular graphs without non-trivial automorphisms, there is a computable, strictly increasing function f such that there is parsimonious polynomial-time fpt-reduction from $\oplus\text{VertexColorfulSub}(\mathcal{H})$ to $\oplus\text{Directed } f\text{-Flexible Path}$.*

Proof. Let $H \in \mathcal{H}$ and G be the undirected graphs that are given as input, where G is given with disjoint color classes V_u for $u \in V(H)$. Let $k = |E(H)|$. Since H is connected and almost 4-regular, it has an Eulerian path $u_0, u_1, \dots, u_{k-1}, u_k$ such that $E(H) = \{\{u_i, u_{i+1}\} : i \in \{0, \dots, k-1\}\}$. Every vertex of H appears exactly twice on the Eulerian path, and u_0 and u_k are the two different degree-3 vertices of H . Our goal is to construct a directed graph G' , such that $\oplus\text{VertexColorfulSub}(H, G) = \oplus\text{Directed } f\text{-Flexible Path}(G')$ holds for a suitable f .

Intuitively, the graph G' “visits” every color class V_{u_i} of G two times according to the Eulerian path in H . Before we give a formal construction, we give an overview; see also Figure 3. Essentially, the graph G' is a sequence of directed bipartite graphs B_0, \dots, B_ℓ whose edges are all directed from left to right. For a bipartite graph B , we write $L(B)$ and $R(B)$ for its left and right part, respectively. We have $R(B_j) = L(B_{j+1})$ for all $j \in \{0, \dots, \ell-1\}$. Each B_j is either a perfect matching M_i or a graph G_i that is a directed copy of $G[V_{u_{i-1}} \cup V_{u_i}]$. (Note that G_i is indeed bipartite, since G is H -colored and H contains no self-loops.) Pictorially, the sequence of bipartite graphs is $M_0 G_1 M_1 \dots M_{k-1} G_k M_k$. We also add some additional *gadget edges* between all M_i and M_j with $i \neq j$ and $u_i = u_j$; note that every M_i is

paired with exactly one M_j in this way, because the Eulerian path visits every vertex exactly twice. The gadget edges are the only edges that may be directed from right to left and that connect non-adjacent layers.

The paths p in G that we wish to count modulo two should correspond to the colourful H -subgraphs of G . The path p is supposed to run from left to right through G' ; intuitively, the edge that the path picks at layer M_i corresponds to the vertex of $V_{u_i} \subseteq V(G)$ that $u_i \in V(H)$ is mapped to in the subgraph embedding, and the edge that the path picks at layer G_i corresponds to the edge of G that $u_{i-1}u_i \in E(H)$ is mapped to in the subgraph embedding. The gadget edges ensure that those paths cancel modulo two that do not consistently select the “same” vertex in V_{u_i} and V_{u_j} when $u_i = u_j$.

We now describe the construction of G' in detail.

1. **Graph edges.** For each $i \in \{1, \dots, k\}$, let G_i be a fresh copy of $G[V_{u_{i-1}} \cup V_{u_i}]$, renamed so that $L(G_i) = \{i\} \times V_{u_{i-1}}$ and $R(G_i) = \{i\} \times V_{u_i}$, and directed from left to right.
2. **Matching edges.** For each $i \in \{0, \dots, k\}$, let M_i be the canonical perfect matching between $L(M_i) = \{i\} \times V_{u_i}$ and $R(M_i) = \{i+1\} \times V_{u_i}$, and directed from left to right. Note that $L(M_i) = R(G_i)$ holds for $i \in \{1, \dots, k\}$ and $R(M_i) = L(G_{i+1})$ holds for $i \in \{0, \dots, k-1\}$.
3. **Gadget edges.** For all $i, j \in \{1, \dots, k\}$ with $i < j$ and $u_i = u_j$, note that $L(M_i) = \{i\} \times V_{u_i}$ and $L(M_j) = \{j\} \times V_{u_i}$. We add the canonical *bidirected* perfect matching between $L(M_i)$ and $L(M_j)$. Similarly, we add the canonical bidirected perfect matching between $R(M_i)$ and $R(M_j)$.
4. **Source/sink.** Let s be a new vertex and add all edges (s, v) for $v \in L(M_0)$. Let t be a new vertex and add all edges (v, t) for $v \in R(M_{k+1})$.
5. **Parameters.** Finally, we set $k' = 2k + 2$ and $f(k') = 6k + 3$ so that we are counting all s, t -paths whose length is between k' and $f(k')$.

This finishes the construction of G' . Note that $G' \setminus \{s, t\}$ is indeed a sequence $B_0 \dots B_\ell$ of bipartite graphs with some additional gadget edges, where $\ell = 2k$. We define the j -th layer of G' as the set $L_j = L(B_j)$ for $j \leq \ell$ and $L_{\ell+1} = R(B_\ell)$. Recall that $L_j = R(B_{j-1})$ holds for $j > 0$.

We describe the *canonical* solutions in the output of the reduction.

To this end, let H' be an H -subgraph of G that is colourful. This means that H is isomorphic to H' and that the “coloring” homomorphism $c: V(G) \rightarrow V(H)$ is bijective on $V(H')$. Moreover, c restricted to $V(H')$ is in fact an isomorphism: It must map non-edges to non-edges because $E(H)$ and $E(H')$ have the same size. Let $\phi: V(H) \rightarrow V(H')$ be the inverse of c restricted to $V(H')$ and note that ϕ is an isomorphism from H to H' . Moreover, because H has non-trivial automorphisms, this isomorphism ϕ is unique for H' .

We define the *canonical s, t -path spt in G' corresponding to H'* : The path p visits exactly one vertex from each layer from left to right; each layer has the form $L_j = \{i\} \times V_u$ for some i and u , and p chooses the vertex $(i, \phi(u)) \in L_j$ in this layer. Note that this determines all vertices of p . We claim that $V(p)$ indeed induces a path on the graph and matching edges.

To show that p is a path, let $j \in \{0, \dots, \ell\}$. We claim that the two vertices in $V(p) \cap V(B_j)$ are adjacent in B_j . If B_j is one of the matching graphs, then $L(B_j) = \{i\} \times V_{u_i}$ and $R(B_j) = \{i+1\} \times V_{u_i}$ for some i . Since the perfect matching is canonical, there is indeed an edge from $(i, \phi(u_i))$ to $(i+1, \phi(u_i))$ in B_j . Otherwise, B_j is one of the graph copies, say $L(B_j) = \{i\} \times V_{u_{i-1}}$ and $R(B_j) = \{i\} \times V_{u_i}$. Recall that $u_{i-1}u_i$ is part of the Eulerian path and thus an edge of H . Since ϕ is a graph homomorphism from H to G respecting the coloring, we have that $\phi(u_{i-1})\phi(u_i)$ is an edge in $G[V_{u_{i-1}} \cup V_{u_i}]$. Since B_j was a copy of this graph by construction, there is an edge from $(i, \phi(u_{i-1}))$ to $(i, \phi(u_i))$. Overall, we get that spt is an s, t -path in G' , and its length is $\ell + 2 = 2k + 2 = k'$; this is the canonical path corresponding to H' .

■ **Figure 4** The left drawing shows the local configuration around the four vertices of G' that represent a vertex $x \in V_u$ from G . These four vertices are contained in two matchings M_i and M_j for $u_i = u_j = u$. Thick edges are contained in M_i or M_j while light edges are gadget edges. Note that (i, x) and (j, x) have only the depicted outgoing edges in the entire graph G' , and $(i+1, x)$ and $(j+1, x)$ have only the depicted incoming edges. The four drawings on the right depict (up to the symmetry of exchanging i and j) all different ways in which paths might not be canonical: Either they illegally use the gadget edges to jump from M_i to M_j as in (J1) or (J2) and continue from there, or they do not consistently visit the corresponding edges in M_i and M_j , which allows them to use the gadget edges to either take (B2) or not take (B1) a short detour from M_i to M_j .

In summary, every vertex-colorful H -subgraph H' in G defines a unique canonical s, t -path in G' , which implies that the number of canonical paths is equal to the number of H -subgraphs. We now characterize canonical paths slightly differently: Let p be any s, t -path in G' that picks exactly one vertex of each layer from left to right with the additional property that it consistently picks the “same” vertex from each color class. That is, whenever p picks (i, x) in layer $\{i\} \times V_u$ and (j, y) in a layer $\{j\} \times V_u$ (with the same V_u), then $x = y$. Such a path p describes a set of $|V(H)|$ vertices and k edges in G that make up a colorful H -subgraph H' of G , which means that every such path is canonical.

Let \mathcal{P} be the set of all s, t -paths whose length r satisfies $k' \leq r \leq f(k')$. The central claim is that the number of non-canonical paths in \mathcal{P} is even. For this, we construct a fixed-point free involution π on non-canonical paths.

First we focus on paths that are *jumpy* (cf. Figure 4): Let $i, j \in \{0, \dots, k\}$ with $i \neq j$ and $u_i = u_j$. By construction, we added gadget edges between M_i and M_j . Recall that vertices have the form

$$(i, x) \in L(M_i), (i+1, x) \in R(M_i), \quad (j, x) \in L(M_j), (j+1, x) \in R(M_j).$$

A path $p \in \mathcal{P}$ is *jumpy* at i, j, x if

- (J1) p uses the edge from (i, x) to (j, x) but not the edge from $(j+1, x)$ to $(i+1, x)$, or
- (J2) p uses the edge from $(i+1, x)$ to $(j+1, x)$ but not the edge from (j, x) to (i, x) .

If p is jumpy (for some choice of i, j, x), we define $\pi(p)$ as follows: First we identify the lexicographically first position i, j, x where p is jumpy. Then we exchange state (J1) with state (J2) at that position. Note that (J1) implies that p uses the M_j -edge from (j, x) to $(j+1, x)$, since (j, x) has no other outgoing edges, and (J2) implies that p uses the M_i -edge from (i, x) to $(i+1, x)$, because $(i+1, x)$ has no other incoming edges; we swap these edges from M_i and M_j too when applying π . Now π is a fixed-point free involution on jumpy paths, and note that $\pi(p)$ has the same length as p .

Since jumpy paths will cancel out when counting modulo two, we can focus on non-canonical paths that are not jumpy. Paths p that are not jumpy have the following property: A gadget edge from (i, x) on the left side of M_i to (j, x) on the left side of M_j is used by p if and only if the corresponding edge from $(j+1, x)$ to $(i+1, x)$ on the right side is used.

Next we consider paths that are *bad* (again, cf. Figure 4): A path $p \in \mathcal{P}$ is bad at i, j, x with $u_i = u_j$ if

- (B1) p uses the M_i -edge from (i, x) to $(i + 1, x)$ but not the M_j -edge from (j, x) to $(j + 1, x)$,
or
- (B2) p does not use the M_i -edge from (i, x) to $(i + 1, x)$ but does use the M_j -edge from (j, x) to $(j + 1, x)$.

We define $\pi(p)$ for a bad path p by finding the first position i, j, x at which p is bad, and switching between these two states. Say, p was in state (B1) at i, j, x as depicted in the figure, then $\pi(p)$ is in state (B2) at i, j, x , and $\pi(p)$ is exactly two edges longer than p .

We claim that all bad paths that are not jumpy pair up in this manner, without having to consider arbitrarily long paths. Indeed, since p is not jumpy, when we look at the vertices that p traverses, we are for the most part traversing the layers in a monotone order, except for potential short two-vertex detours in bad positions as depicted in the figure as (B2). More precisely, for every vertex v on p , if $v \in L_j$ for $j < \ell$, then either the next vertex is in L_{j+1} or the third vertex after it is in L_{j+1} . This means that the path moves to the right by one layer at least once every 3 vertices, and thus paths that are not jumpy have length at most $3\ell + 3 = 6k + 3 = f(k')$, accounting for $\ell + 1$ matching or graph edges and up to 2ℓ gadget edges that p might take in the short detours, and the two edges at the source and sink.

Finally, if an s, t -path is neither jumpy nor bad, then it does not use any gadget edges, and thus is canonical. Since all jumpy or bad paths cancel, the number of s, t -paths of length between k' and $f(k')$ in G' is the number of canonical paths modulo two. ◀

For completeness, we include two simple reductions: First from the flexible-length to the fixed-length problem in directed graphs, then from the directed to undirected problem.

▶ **Lemma 12.** *Let $f : \mathbb{N} \rightarrow \mathbb{N}$ be computable and strictly increasing. There is a parsimonious polynomial-time fpt-reduction from #Directed f -Flexible Paths to #Directed Paths.*

▶ **Lemma 13.** *#Directed Paths admits a parsimonious poly-time fpt-reduction to #Paths.*

With all these prerequisites collected, we can complete the proof.

Proof of Theorem 3. Let \mathcal{H} be the class of all graphs H that are connected, almost 4-regular, and whose automorphism group has size one. We use the probabilistic method to argue that the tree-width of graphs in \mathcal{H} is not bounded. With probability $1 - o(1)$ as $h \rightarrow \infty$, random 4-regular graphs with h vertices are connected [41, Theorem 2.10], they have no nontrivial automorphisms [27], and they are almost Ramanujan [24, Theorem 7.10], that is, their second-largest eigenvalue in absolute value satisfies $\lambda \leq 2\sqrt{3} + o(1) < 3.5$. By a union bound, H has all three properties simultaneously with probability $1 - o(1)$. By Cheeger's inequality [24, Theorem 4.11], we have

$$\min_{S \subseteq V(H), |S| \leq \frac{1}{2}h} \frac{|E(S, \bar{S})|}{|S|} \geq \frac{1}{2}(4 - \lambda) > 0.1,$$

that is, the edge expansion is bounded away from zero, which implies that the tree-width of H is at least linear in h (see, e.g., [12, Exercise 7.34]). Now, if we remove an arbitrary edge e from H , we obtain an almost 4-regular graph that remains connected (since H is Eulerian) and whose tree-width has decreased by at most 1. Moreover, suppose that π is an automorphism of $H - e$. Since π preserves degrees, it has to map the vertex set e to e . But then π is an automorphism of H , too, which implies that π is the trivial automorphism and the automorphism group of $H - e$ has size one as required. Thus, \mathcal{H} contains graphs of arbitrarily large tree-width.

By Lemma 5, $\oplus\text{VertexColorfulSub}(\mathcal{H})$ is $\oplus\text{W}[1]$ -hard under parsimonious fpt-reductions. If there is a parsimonious fpt-reduction from problem $\#A$ to problem $\#B$ then in particular the parity version $\oplus A$ reduces to $\oplus B$. Writing $\oplus A \leq \oplus B$ we can summarize the chain of reductions in Lemmas 11–13 as

$$\oplus\text{VertexColorfulSub}(\mathcal{H}) \leq \oplus\text{Directed } f\text{-Flexible Paths} \leq \oplus\text{Directed Paths} \leq \oplus\text{Paths}.$$

This proves the $\oplus\text{W}[1]$ -hardness of $\oplus\text{Paths}$. The containment follows from the standard fpt-reduction from $\#Paths$ to $\#Clique$, which is parsimonious. Overall, the claim follows. \blacktriangleleft

6 Conclusion

We conducted an initial investigation of modular subgraph counting, leading to the partial classification depicted in Figure 1. To obtain a complete picture, the following conjecture needs to be addressed.

► **Conjecture 14.** *For any computable pattern class \mathcal{H} :*

- *If \mathcal{H} has unbounded matching-split number, then the problem $\oplus\text{Sub}(\mathcal{H})$ is $\oplus\text{W}[1]$ -complete.*
- *If \mathcal{H} has unbounded vertex-cover number, then $\#\text{Sub}(\mathcal{H}) \bmod q$ for fixed $q \in \mathbb{N}$ is $\text{Mod}_p\text{W}[1]$ -complete for any odd divisor p of q .*

An appropriate transfer of the subgraph-homomorphism framework to modular counting is likely to help in settling this conjecture. Partial results towards this have been obtained by Peyerimhoff et al. [33].

Abstract

In the minimum common string partition problem (MCSP), one gets two strings and is asked to find the minimum number of cuts in the first string such that the second string can be obtained by rearranging the resulting pieces. It is a difficult algorithmic problem having applications in computational biology, text processing, and data compression. MCSP has been studied extensively from various algorithmic angles: there are many papers studying approximation, heuristic, and parameterized algorithms. At the same time, almost nothing is known about its exact complexity. In this paper, we present new results in this direction. We improve the known 2^n upper bound (where n is the length of input strings) to ϕ^n where $\phi \approx 1.618...$ is the golden ratio. The algorithm uses Fibonacci numbers to encode subsets as monomials of a certain implicit polynomial and extracts one of its coefficients using the fast Fourier transform. Then, we show that the case of constant size alphabet can be solved in subexponential time $2^{O(n \log \log n / \log n)}$ by a hybrid strategy: enumerate all long pieces and use dynamic programming over histograms of short pieces. Finally, we prove almost matching lower bounds assuming the Exponential Time Hypothesis.

1 Overview

Two strings $s_1, s_2 \in \Sigma^n$ are said to have a common partition of size t if one can cut s_1 into t blocks (by $t-1$ cuts), rearrange them, and get s_2 . This is a string similarity measure having applications in computational biology, text processing, and data compression. The minimum common string partition problem (MCSP) is to find the minimum size of a common partition of two input strings. There are two natural special cases of the problem: in d -MCSP, every symbol appears at most d times in each input string; in MCSP^c, the size of the alphabet Σ is at most c .

1.1 Known results

The problem has been studied extensively from various algorithmic angles.

Computational complexity. Already 2-MCSP is APX-hard, hence MCSP is both NP-hard and APX-hard [8].

Parameterized algorithms. The problem is fixed parameter tractable (FPT) with respect to combinations of various parameters [6, 11, 2, 3]. For example, [2] gives an $O^*(d^{2k})$ algorithm¹ for d -MCSP, whereas [3] gives an FPT algorithm with respect to t only.

Approximation algorithms. The best known approximation ratio for a polynomial-time algorithm is $O(\log n \log^* n)$ [5]. There is also an $O(d)$ -approximation algorithm [15]. The best known approximation ratios for 2-MCSP and 3-MCSP are 1.1037 and 4, respectively [8].

Heuristic algorithms. One natural heuristic approach for MCSP is greedy: cut out a longest common substring and repeat. It is well studied both from practical and theoretical points of view. Its approximation factor is: $O(\log n)$ for many families of inputs [17], between $\Omega(n^{0.46})$ and $O(n^{0.69})$ in the worst case [4, 13]. It can be implemented in linear time [9].

1.2 New results

Much less is known about *the exact* complexity of MCSP. The best known upper bound is $O^*(2^n)$ [7]. This aligns well with what is known for many other permutation problems: say, the shortest common superstring problem, the shortest common supersequence problem, the traveling salesman problem. Whereas many approximation, parameterized, and heuristic algorithms are known for these problems, breaking the 2^n barrier for any of them is a long standing open problem. (For the mentioned problems, n denotes the number of input strings, sequences, or nodes.)

In this paper, we present the following new exact algorithms and lower bounds for MCSP. We start by showing two straightforward $O^*(2^n)$ algorithms: the first one enumerates all possible partitions of both input strings and is perhaps the simplest exact algorithm for the problem; the second one is a straightforward application of the dynamic programming method. Both algorithms use exponential space.

¹ The $O^*(\cdot)$ notation is common in the field of algorithms for NP-hard problems: like $O(\cdot)$ hides constant factors, it suppresses factors that grow polynomially in the input length.

1.2.1 Improving time to ϕ^n : dynamic programming

Then, we show how to improve the dynamic programming algorithm to get the running time $O^*(\phi^n)$ where $\phi \approx 1.618\dots$ is the golden ratio. In short, the improvement is based on the following idea. For two strings to have a common partition, their multisets of symbols should coincide. Then, if one cuts the first string into blocks and maps all blocks of length at least two to the second string (so that the mapped parts do not overlap), all the remaining blocks of length one are mapped automatically.

1.2.2 Improving space to polynomial: FFT and Fibonacci encoding

The improved algorithm still uses exponential space (as it is based on dynamic programming). Again, avoiding exponential space in algorithms for NP-hard problems may be a challenging task. For example, the best known algorithm for the coloring problem has running time $O^*(2^n)$ and uses exponential space [1]; bringing down the space consumption to polynomial is an open problem. Also, for the optimal 2-constraint satisfaction problem (as well as for its special cases: maximum 2-satisfiability and maximum cut), all known better-than- 2^n -time algorithms use exponential space [18, 14]; improving 2^n time while keeping polynomial space is an open problem. For the MCSP problem, we show how to get a polynomial space algorithm with running time $O^*(\phi^n)$.

The approach that we use is inspired by generating functions. Let $c_0, c_1, c_2, \dots = \{c_i\}_{i=0}^\infty$ be an integer sequence of interest, where term c_i is expressed in a complex way through the previous terms, so that it is difficult to directly find a closed form for it. Occasionally, one can solve this problem in three steps.

1. Pack a sequence into a polynomial (or, rather, formal power series):

$$T(x) = c_0 + c_1x + c_2x^2 + \dots = \sum_{i=0}^{\infty} c_i x^i.$$

2. By means of algebraic manipulations, find a closed form expression for $T(x)$.
3. Then, c_i is the coefficient of x_i in Taylor expansion of $T(x)$ that can be found using the value of the i^{th} derivative of T at zero.

What we use can be viewed as a discrete and algorithmic version of this approach. Given strings $s_1, s_2 \in \Sigma^n$, we define a finite sequence $\{c_i\}_{i=0}^N$ with the following property: s_1, s_2 have a common partition of size t iff a particular term c is positive. This term may be expressed through the other terms, but it will take a lot of space, so instead we find it in three steps.

1. Pack a sequence into a polynomial P of finite degree such that the term c is a coefficient of a particular monomial m in P .
2. Describe an efficient way of evaluating P at a given point.
3. Using fast Fourier transform, extract the coefficient of m using values of P at specific points.

The algorithm uses Fibonacci encoding in order to keep the degree of the polynomial low enough.

1.2.3 Subexponential running time for small alphabets: hybrid strategy

Then, we show that for the constant size alphabets, one can even get a subexponential running time: $2^{O(\frac{n \log \log n}{\log n})}$. The main idea is to track short and long blocks differently: we just guess the cut points of all long blocks (this is feasible as there are not too many of them) and we exploit dynamic programming to handle the short ones. By balancing these two cases carefully, one gets a speed up to a subexponential time.

1.2.4 Lower bounds

Finally, we show that substantial improvement of the presented upper bounds is difficult. Namely, we prove that under the Exponential Time Hypothesis (stating that there are no subexponential time algorithms for the satisfiability problem), MCSP cannot be solved in subexponential time (of the form $2^{o(n)}$). This is a simple application of the NP-hardness proof of MCSP. Then, we present a reduction from the general case to the special case of constant size alphabet that gives a lower bound $2^{\Omega(n/\log n)}$ (under ETH) for that special case.

Notation

Throughout the paper, we use the following notation. Let s be a string of length n . We use 1-based indexing and slice notation: $s = s[1]s[2] \cdots s[n]$; for $1 \leq l \leq r \leq n$, $s[l:r] = s[l]s[l+1] \cdots s[r]$. By $[n]$ we denote the set $\{1, \dots, n\}$.

2 2^n time and space: enumerating all partitions

In this section, we present perhaps the most straightforward algorithm. As simple as it is, it has an important feature that many other algorithms lack: it works for any number of input strings. See Algorithm 1. Its running time is $O^*(2^n)$ as the number of different partitions of a string of length n is 2^{n-1} : there are $n-1$ places to make a cut.

■ **Algorithm 1** Enumerating all partitions.

Input: strings s_1, \dots, s_j of length n .
Output: the minimum size of a common partition of s_1, \dots, s_j .

```

1:  $T \leftarrow$  associative array
2: for every partition of  $s_1$  into substrings  $p_1, \dots, p_k$  do
3:    $T[\text{multiset}\{p_1, \dots, p_k\}] \leftarrow j\text{-tuple } (1, 0, \dots, 0)$ 
4: for  $i$  from 2 to  $j$  do
5:   for every partition of  $s_i$  into substrings  $p_1, \dots, p_k$  do
6:     if  $T$  has key  $\text{multiset}\{p_1, \dots, p_k\}$  then
7:        $T[\text{multiset}\{p_1, \dots, p_k\}][i] \leftarrow 1$ 
8:  $t \leftarrow +\infty$ 
9: for every key  $P$  of  $T$  do:
10:  if  $T[P] = (1, \dots, 1)$  then
11:     $t \leftarrow \min(t, |P|)$ 
12: return  $t$ 

```

Hereinafter, we return the size of the optimal partition instead of the partition itself. This is equivalent to the original problem, since there is a polynomial Algorithm 2 for finding the optimal partition given an oracle for minimum size of a common partition. In this algorithm, we first look for the longest prefix p of s_1 that can be matched somewhere in s_2 , such that after replacing it and its match with a new symbol $\#_1$ the size of the optimal partition stay the same. To make sure that the size of the optimal partition does not change, we use the oracle. It is clear that in the optimal partition $\#_1$ is not a prefix of some longer block. After we find p , we replace it and its match with $\#_1$ and start looking for the next longest block in the optimal partition that we replace with a new symbol $\#_2$ and so on. In the end we obtain a partition $\mathcal{P} = \{p_1, p_2, \dots, p_t\}$ such that $s_1 = p_1 \dots p_t$ and p_i is the longest possible block in a common partition of the minimum size t given previous $i-1$ blocks.

■ **Algorithm 2** Constructing the optimal partition.

Input: strings s_1, s_2 of length n , oracle \mathcal{O} for the minimum size of a common partition.
Output: a common partition of s_1, s_2 of the minimum size.

```

1:  $\mathcal{P} \leftarrow \emptyset$ 
2:  $t \leftarrow \mathcal{O}(s_1, s_2)$ 
3: for  $i$  from 1 to  $t$  do
4:    $\#_i \leftarrow$  a symbol that does not occur in  $s_1$  and  $s_2$ 
5:   for all  $j$  from  $n$  down to  $i$ , all  $1 \leq l \leq r \leq n$  do
6:      $s'_1 \leftarrow s_1[1 : i - 1] \#_i s_1[j + 1 : n]$ 
7:      $s'_2 \leftarrow s_2[1 : l - 1] \#_i s_2[r + 1 : n]$ 
8:     if  $s_1[i : j] = s_2[l : r]$  and  $\mathcal{O}(s'_1, s'_2) = t$  then
9:        $\mathcal{P} \leftarrow \mathcal{P} \cup s_1[i : j]$ 
10:     $s_1 \leftarrow s'_1$ 
11:     $s_2 \leftarrow s'_2$ 
12:    break
13: return  $\mathcal{P}$ 

```

3 Improving time to ϕ^n : dynamic programming

Here, we present a dynamic programming solution with roughly the same running time and space as the previous solution. Later, we will be able to improve both time and space of this algorithm. The algorithm works by solving the following subproblem: for $0 \leq k \leq n$, let $C(k)$ be the set of all pairs (S, t) , where $S \subseteq [n]$, $|S| = k$, and $1 \leq t \leq n$, such that one can cut $s_1[1 : k]$ into t blocks and match them to the subsequence of s_2 specified by S . The minimum size of a common partition is then simply the minimum t such that (S, t) is contained in $C(n)$. To compute $C(k)$, we first fix the length i of the last block of $s_1[1 : k]$. Then, this block should be matched somewhere in s_2 , whereas $C(k - i)$ can be used to find the positions where the remaining $t - 1$ blocks should be matched. The formal pseudocode is given in Algorithm 3. The running time and space is $O^*(2^n)$ as the number of different subsets is 2^n whereas all other steps clearly take polynomial time.

■ **Algorithm 3** Dynamic programming.

Input: strings s_1, s_2 of length n .
Output: the minimum size of a common partition of s_1, s_2 .

```

1:  $C(0) \leftarrow \{(\emptyset, 0)\}$ 
2: for  $k$  from 1 to  $n$  do
3:    $C(k) \leftarrow \emptyset$ 
4:   for all  $1 \leq i \leq k$ , all  $1 \leq l \leq n - i + 1$ , all  $(S, t) \in C(k - i)$  do
5:     if  $s_1[k - i + 1 : k] = s_2[l : l + i - 1]$  and  $S \cap \{l, l + 1, \dots, l + i - 1\} = \emptyset$  then
6:        $C(k) \leftarrow C(k) \cup \{(S \cup \{l, l + 1, \dots, l + i - 1\}, t + 1)\}$ 
7: return  $\min\{t : (S, t) \in C(n)\}$ 

```

In the previous algorithm, we considered subsets of s_2 that have a common partition of particular size with the prefix of s_1 . Here, we are going to ignore pieces of size one in every such partition: indeed, if one successfully matched longer pieces, then the pieces of size one will match as well.

With this in mind, one may consider only subsets of s_2 that can be cut into pieces of length at least two and matched to some subset of the prefix of s_1 : the remaining part of the prefix is assumed to be filled with pieces of length one.

In addition to ignoring pieces of length one, we also plug the “holes” of size one in our subsets, since we can plug them only with pieces of size one and may do it immediately. To formalize that, we introduce the function Plug whose pseudocode is given in Algorithm 4. Say that there is a hole at position $i \in [n]$ in a set $S \subseteq [n]$ if $i \notin S$ whereas each of $i - 1$ and $i + 1$ either belong to S or does not belong to $[n]$.

■ **Algorithm 4** The function Plug.

Input: subset $S \subseteq [n]$.
Output: hole-free superset of S of minimum size.

```

1: for  $i$  in  $[n]$  do
2:   if  $S$  has a hole at position  $i$  then
3:      $S \leftarrow S \cup \{i\}$ 
4: return  $S$ 

```

Now we are ready to describe the subproblem of our algorithm. For $0 \leq k \leq n$, let $C(k)$ be the set of all pairs (S, t) , for which there exist a pair (T, β) such that $S = \text{Plug}(T)$, $t = \beta + |S| - |T|$, and one can cut the subsequence of s_2 specified by T into β blocks of size at least two and match them to some subsequence of $s_1[1 : k]$. Thus, t is a number of blocks into which S can be cut so that all the blocks of size at least two match to $s_1[1 : k]$ and blocks of size one (that is, plugged holes in T) match somewhere in s_1 (not necessarily in $s_1[1 : k]$). The minimum size of a common partition is then the minimum value of $t + n - |S|$ such that (S, t) is contained in $C(n)$. Here, $n - |S|$ is the number of ignored but not plugged blocks of size one. Clearly, $C(k) \subseteq C(k')$ for $k < k'$. To compute $C(k)$, we first fix the length $i \neq 1$ of the long block $s_1[k - i + 1 : k]$ and $j \geq 0$ blocks of size one before it that we wish to ignore. Then, this long block should be matched somewhere in s_2 , whereas $C(k - i - j)$ can be used to find the positions where the remaining long blocks should be matched. After we correctly match the long block somewhere in s_2 , we append it to the corresponding S from $C(k - i - j)$, plug the holes and recalculate the number of blocks as the number of blocks in S before appending plus one plus the number of holes plugged after appending. If $i = 0$, then we may skip the choice of j and simply get $C(k - 1)$. The formal pseudocode is given in Algorithm 5.

■ **Algorithm 5** Improved dynamic programming algorithm.

Input: strings s_1, s_2 of length n .
Output: the minimum size of a common partition of s_1, s_2 .

```

1:  $C(0) \leftarrow \{(\emptyset, 0)\}$ 
2: for  $k$  from 1 to  $n$  do
3:    $C(k) \leftarrow C(k - 1)$  (case  $i = 0$ )
4:   for all  $2 \leq i \leq k$ , all  $0 \leq j \leq n - i$ , all  $1 \leq l \leq n - i + 1$ , all  $(S, t) \in C(k - i - j)$  do
5:     if  $s_1[k - i + 1 : k] = s_2[l : l + i - 1]$  and  $S \cap \{l, l + 1, \dots, l + i - 1\} = \emptyset$  then
6:        $S' \leftarrow \text{Plug}(S \cup \{l, l + 1, \dots, l + i - 1\})$ 
7:        $C(k) \leftarrow C(k) \cup \{(S', t + 1 + |S'| - |S|)\}$ 
8: return  $\min\{t + n - |S| : (S, t) \in C(n)\}$ 

```

► **Theorem 1.** Algorithm 5 solves MCSP in time and space $O^*(\phi^n)$.

Proof. Correctness. For every $(S, t) \in C(n)$, the total number of blocks in the corresponding partition is the number of long blocks plus the number of plugged holes ($= t$) plus $|[n] \setminus S|$ blocks of size one we ignore. If the optimal partition contains no pieces longer than one, then we never fulfill the if condition, but nevertheless $C(n)$ will contain $(\emptyset, 0)$ dragged through the whole cycle (thanks to line 3), that corresponds to the partition of size n as required.

Running time. It is sufficient to count all the subsets S we considered. For that, it is convenient to treat every such subset as a sequence $v \in \{0, 1\}^n$ without lonely zeros and ones. Let $f_0(n)$ be the number of such sequences that end up with zero and $f_1(n)$ be the number of such sequences that end up with one. Since every such sequence ending with one ends with at least two ones, we can write the recurrence relation $f_1(n) = \sum_{i=2}^{n-2} f_0(i)$. Similarly, $f_1(n) = f_0(n)$, hence $f_1(n) = \sum_{i=2}^{n-2} f_1(i)$ that, together with the initial conditions $f_1(2) = f_1(3) = 1$, describes the shifted sequence of Fibonacci numbers, thus $f_1(n) = O(\phi^n)$. ◀

4 Improving space to polynomial: FFT and Fibonacci encoding

In this section, we improve the space of the previously considered algorithm to polynomial. The following theorem provides a basic toolkit for this.

► **Theorem 2.** Assume that for two strings $s_1, s_2 \in \Sigma^n$ and a parameter t one can construct a multivariate polynomial (of finite degree) $P(X)$ over a (finite) variable set X and a monomial $m = \prod_{x_i \in X} x_i^{d_i}$, where $d_i \in \mathbb{Z}_{\geq 0}$, with the following three properties:

1. Its coefficients are non negative and less than $W = 2^{\text{poly}(n)}$.
2. For fixed values of variables X , one can compute $P(X)$ in time polynomial in the length of the binary representation of the values.
3. There is a common partition of s_1, s_2 of size t if and only if the coefficient of m in P is non-zero.

Then, MCSP can be solved in time

$$O^* \left(\text{polylog} \left(\prod_{x_i \in X} \deg_{x_i}(P) \right) \prod_{x_i \in X} \deg_{x_i}(P) \right)$$

and space

$$O^* \left(\text{polylog} \left(\prod_{x_i \in X} \deg_{x_i}(P) \right) \right),$$

where $\deg_{x_i}(P)$ is the degree of variable x_i in P , that is, the maximum degree of x_i across the monomials of P with non-zero coefficients.

In the proof, we use the following theorem proved in [10] (Theorem 3.2).

► **Theorem 3.** Let $P(x) = \sum_{i=0}^d p_i x^i$ be a polynomial of degree at most d with non-negative integer coefficients less than W . Given an arithmetic circuit $C(x, p)$ of size $\text{polylog}(d, W)$ which evaluates P modulo a prime $p = d \text{polylog}(d, W)$ at an integer point x , any coefficient of $P(x)$ can be found in time $d \text{polylog}(d, W)$ and space $\text{polylog}(d, W)$.

Here we calculate modulo p just to prevent the numbers we operate from growing exponentially fast.

Proof of Theorem 2. Let $X = \{x_1, \dots, x_q\}$. In order to apply Theorem 3, we need to build a univariate polynomial $Q(x)$ out of $P(x_1, \dots, x_q)$. To do this, we use Kronecker substitution [16]:

$$Q(x) = P\left(x, x^{\deg_{x_1}(P)+1}, x^{(\deg_{x_1}(P)+1)(\deg_{x_2}(P)+1)}, \dots, x^{\prod_{i=1}^{q-1}(\deg_{x_i}(P)+1)}\right).$$

That is, we replace x_i by $x^{\prod_{j=1}^{i-1}(\deg_{x_j}(P)+1)}$. Then, P contains a monomial $m = \prod_{i \in [q]} x_i^{a_i}$ if and only if Q contains a monomial $x^{\sum_{i \in [q]} a_i \cdot \prod_{j=1}^{i-1}(\deg_{x_j}(P)+1)}$.

Since $W = 2^{\text{poly}(n)}$, $\text{polylog}(d, W) = O^*(\text{polylog}(d))$. \blacktriangleleft

As a warm up, we show how to reduce the space complexity of the 2^n dynamic programming Algorithm 3 to polynomial.

► **Theorem 4.** MCSP can be solved in time $O^*(2^n)$ and polynomial space.

Proof. We construct a series of polynomials P_k for $0 \leq k \leq n$ associated with the steps of the dynamic programming algorithm. Each P_k corresponds to $C(k)$ in the mentioned algorithm in the following way: P_k has a monomial $\alpha z^t y^{|S|} \prod_{i \in S} x^{2^{i-1}}$ for some $\alpha > 0$ depending on the monomial if and only if $(S, t) \in C(k)$. The pseudocode for computing P_n is given in Algorithm 6. It is not difficult to see that this is a polynomial time algorithm.

■ **Algorithm 6** Computing P_n .

Input: strings s_1, s_2 of length n , values x, y, z .
Output: value of P_n at the point (x, y, z) .

- 1: $P_0(x, y, z) \leftarrow 1$
- 2: $P_k(x, y, z) \leftarrow 0$ for all $1 \leq k \leq n$
- 3: **for** k **from** 1 **to** n **do**
- 4: **for all** $1 \leq i \leq k$, **all** $1 \leq l \leq n - i + 1$ **do**
- 5: **if** $s_1[k - i + 1 : k] = s_2[l : l + i - 1]$ **then**
- 6: $P_k(x, y, z) \leftarrow P_k(x, y, z) + zy^i x^{2^{l+i-1} - 2^{l-1}} P_{k-i}(x, y, z)$
- 7: **return** $P_n(x, y, z)$

We claim that s_1 and s_2 have a common partition of size t if and only if P_n contains a monomial $z^t y^n x^{2^n - 1}$. One direction is straightforward. Assume that there is a partition of s_1 into pieces $(l_1, r_1), \dots, (l_t, r_t)$, where $l_1 = 1, r_t = n$ and $r_i = l_{i+1} - 1$ for all $i \in [t - 1]$ and it corresponds to a partition of s_2 into pieces $(l'_1, r'_1), \dots, (l'_t, r'_t)$ such that $s_1[l_i : r_i] = s_2[l'_i : r'_i]$ for all $i \in [t]$. Then P_{r_i} has a monomial

$$zy^{r_i - l_i + 1} x^{2^{r'_i} - 2^{l'_i - 1}} P_{r_i - 1}.$$

Then, by induction, P_{r_i} has a monomial

$$z^i y^{\sum_{j=1}^i (r_j - l_j + 1)} x^{\sum_{j=1}^i 2^{r'_j} - 2^{l'_j - 1}}.$$

Hence, $P_n = P_{r_t}$ has a monomial

$$z^t y^{\sum_{j=1}^t (r_j - l_j + 1)} x^{\sum_{j=1}^t 2^{r'_j} - 2^{l'_j - 1}} = z^t y^n x^{2^n - 1}.$$

For the reverse direction, suppose P_n has a monomial $z^t y^n x^{2^n-1}$. It could only be obtained as a product $\prod_{i=1}^t z y^{r_i-l_i+1} x^{2^{r_i}-2^{l_i-1}}$ for some $(l_1, r_1), \dots, (l_t, r_t)$ during the execution of the algorithm. An important invariant of each such terms is that the degree of y is equal to the Hamming weight of the degree of x . (Here, by the Hamming weight of an integer we mean the sum of the bits of its binary representation.)

As $\sum_{i=1}^t (r_i - l_i + 1)$ is equal to the degree of y , it is equal to n . If they are all disjoint, we have a valid partition. Suppose there exist i and j such that (l_i, r_i) and (l_j, r_j) intersect. Consider the product

$$(zy^{r_i-l_i+1}x^{2^{r_i}-2^{l_i-1}})(zy^{r_j-l_j+1}x^{2^{r_j}-2^{l_j-1}}) = z^2 y^{r_i+r_j-l_i-l_j+2} x^{\left(\sum_{t=l_i}^{r_i} 2^{t-1}\right) + \left(\sum_{t=l_j}^{r_j} 2^{t-1}\right)}.$$

Now, let us look at the Hamming weight of the degree of x . As it is the sum of $d = r_i + r_j - l_i - l_j + 2$ powers of 2, it is at most d . But as (l_i, r_i) and (l_j, r_j) intersect, there is at least one carry, so it is actually less than d . Then, when we multiply all the terms, as the Hamming weight of the sum is not more than the sum of Hamming weights, we have that Hamming weight is strictly less than the degree of y , so it is less than n . But the Hamming weight of $2^n - 1$ is equal to n , a contradiction.

Finally, we can solve MCSP by finding the smallest t such that $z^t y^n x^{2^n-1}$ is present in P_n . As we already have a polynomial time algorithm for P_n , its coefficients are not greater than $(n^2)^n = 2^{O(n \log n)}$ and total degree is $O^*(2^n)$, by Theorem 2 there exists an $O^*(2^n)$ time and polynomial space algorithm for MCSP. ◀

We are now going to infuse the previous algorithm with ideas from the improved dynamic programming and introduce a better encoding to get a speed up. In the previous section, we were encoding each segment (l, r) as $2^r - 2^{l-1}$. This is a natural way to represent a subset: this number has ones in its binary representation exactly at positions from l to r . Then we were using a property of the binary representation that the sum of encodings of two intersecting segments has a Hamming weight strictly less than sum of the Hamming weights of the terms. Another way to look at it: for any two intersecting segments $(l_1, r_1), (l_2, r_2)$ there is a collection of nonintersecting segments $(l'_1, r'_1), \dots, (l'_p, r'_p)$ such that:

$$\sum_{i=1}^2 2^{r_i} - 2^{l_i-1} = \sum_{i=1}^p 2^{r'_i} - 2^{l'_i-1}, \text{ but}$$

$$\sum_{i=1}^2 r_i - l_i + 1 > \sum_{i=1}^p r'_i - l'_i + 1$$

Here we can take as (l'_i, r'_i) all the substrings of consecutive 1s in the binary representation of $\sum_{i=1}^2 2^{r_i} - 2^{l_i-1}$.

We are going to do something similar but sacrifice some of this clarity for efficiency. We will encode each segment (l, r) as $F'(r) - F'(l-1)$, where $F'(i)$ is the $(i+1)$ -th Fibonacci number (so $F'(-1) = 0$ and $F'(0) = 1$). Then we will show that this encoding has a similar property as a binary one but only for segments of size greater than one.

► **Theorem 5.** MCSP can be solved in time $O^*(\phi^n)$ and polynomial space.

Proof. Consider a polynomial defined by Algorithm 7.

We call a piece of the partition *long* if it has length greater than one. The meaning of the indices is the following:

- k is the length of the prefix of s_1 that we are currently processing,

■ **Algorithm 7** Computing P_n

Input: strings s_1, s_2 of length n , values x, y, z, w .
Output: value of P_n at the point (x, y, z, w) .

- 1: $P_k \leftarrow 1$ for all $0 \leq k \leq n$
- 2: **for** k **from** 1 **to** n **do**
- 3: **for all** $1 < i \leq j \leq k$, **all** $1 \leq l \leq n - i + 1$, **all** $n - i + 1 \leq q \leq n$ **do**
- 4: **if** $s_1[j - i + 1 : j] = s_2[l : l + i - 1]$ **then**
- 5: $r \leftarrow l + i - 1$
- 6: $P_k \leftarrow P_k + w^{q-r+1} y^{q-l+1} z^{q^2-(l-1)^2} x^{F'(q)-F'(l-1)} P_{j-i}$
- 7: $P_k \leftarrow P_k + w^{q-(r-l)} y^q z^{q^2} x^{F'(q)-1} P_{j-i}$
- 8: **return** P_n

- j is the position of the rightmost symbol of the last long piece in $s_1[1 : k]$,
- i is the length of this long piece $s_1[j - i + 1 : j]$,
- l and r are the endpoints of a potential match of this long piece in s_2 ,
- q is the right endpoint of the block $s_2[r + 1 : q]$ that is cut into pieces of length one.

In short, we consider only long pieces in s_1 and every long piece $s_1[j - i + 1 : j]$ we correspond with a) block $s_2[l : q]$ that consists of $q - r + 1$ pieces: its match $s_2[l : r]$ and the group $s_2[r + 1 : q]$ of pieces of length one after it; b) block $s_2[1 : q]$ that consists of its match and two groups $s_2[1 : l - 1]$ and $s_2[r + 1 : q]$ of pieces of length one.

Now we need to show that s_1 and s_2 have a common partition of size t if and only if P_n contains a monomial $w^t x^{F'(n)-1} y^n z^{n^2}$. The if part is provided by the following lemma:

► **Lemma 6.** *If there is a common partition of s_1 and s_2 of size t , then there is a monomial $w^t x^{F'(n)-1} y^n z^{n^2}$ in P_n .*

Proof. Let $(l_1, r_1), \dots, (l_d, r_d)$ be a set of long pieces in the common partition. Without loss of generality we may assume that all (l_i, r_i) are sorted, that is $\forall i : r_i \leq l_{i+1}$. Each piece (l_i, r_i) for $i > 1$ may contribute a monomial

$$w^{q_i-r_i+1} x^{F'(q_i)-F'(l_i-1)} y^{q_i-(l_i-1)} z^{q_i^2-(l_i-1)^2},$$

where $q_i = l_{i+1} - 1$, $q_d = n$, and (l_1, r_1) may contribute a monomial $w^{q_1-r_1+l_1} x^{F'(q_1)-1} y^{q_1} z^{q_1^2}$, where $q_1 = l_2 - 1$. Here, for $i = 1$ we choose the monomial that takes into account pieces of size one before and after the long block (hence, $q_1 - r_1 + l_1$ in the exponent of w) and for $i > 1$ we choose the monomial that takes into account pieces of size one only after the long block (hence, $q_i - r_i + 1$ in the exponent of w). Thus, the sum of all the exponents of w is equal to the number of pieces in common partition, that is, t .

Multiplying all monomials together, we obtain the following monomial present in P_n :

$$\begin{aligned} & w^{q_1-r_1+l_1} x^{F'(q_1)-1} y^{q_1} z^{q_1^2} \prod_{i=2}^d w^{q_i-r_i+1} x^{F'(q_i)-F'(l_i-1)} y^{q_i-(l_i-1)} z^{q_i^2-(l_i-1)^2} = \\ & = w^t x^{F'(n)-1} y^n z^{n^2}. \end{aligned}$$

Now we are getting to the tricky part. We need to prove that if P_n contains a monomial $w^t x^{F'(n)-1} y^n z^{n^2}$ then s_1 and s_2 have a common partition with k pieces. ◀

For every set $S = \{(l_1, r_1), \dots, (l_d, r_d) \mid (l_i, r_i) \subset [n]\}$ of d intervals let $m(S)$ denote a monomial

$$\begin{aligned} m(S) &:= \prod_{i=1}^d x^{F'(r_i)-F'(l_i-1)} y^{r_i-l_i+1} z^{r_i^2-(l_i-1)^2} = \\ &= x^{\sum_i F'(r_i)-F'(l_i-1)} y^{\sum_i r_i-l_i+1} z^{\sum_i r_i^2-(l_i-1)^2}. \end{aligned}$$

The point of introducing such notation is that polynomial P_n is simply a sum of monomials of the form $w^\alpha m(S)$ for some $S = \{(l_1, r_1), \dots, (l_d, r_d)\}$ where all the intervals are long, so the $m(S)$ part relates to *what* is covered in s_2 and w^α part relates to *how* it is covered (that is, how many blocks).

It is easy to check that if there are no intersecting intervals in S and they cover the whole $[n]$ then $m(S) = x^{F'(n)-1} y^n z^{n^2}$ and we have a common partition of size α . What about intersecting intervals? The following lemma deals with this case:

► **Lemma 7.** *If S contains intersecting intervals and $m(S) = x^{F'(n)-1} y^n z^{n^2}$ then there is a set S' of non-intersecting intervals such that $m(S') = x^{F'(n)-1} y^\alpha z^\beta$ and $(\alpha < n) \vee (\beta < n^2)$.*

Proof. Suppose there are two long intersecting intervals (l_1, r_1) and (l_2, r_2) in S . We can show that there is a set of long non intersecting intervals $(l'_1, r'_1), \dots, (l'_p, r'_p)$ such that:

$$\sum_{j=1}^p (F'(r'_j) - F'(l'_j - 1)) = (F'(r_1) - F'(l_1 - 1)) + (F'(r_2) - F'(l_2 - 1)),$$

and one of the following two statements is true:

- $\sum_{j=1}^p (r'_j - l'_j + 1) < (r_1 - l_1 + 1) + (r_2 - l_2 + 1)$,
- $\sum_{j=1}^p (r'_j - l'_j + 1) = (r_1 - l_1 + 1) + (r_2 - l_2 + 1)$, but $\sum_{j=1}^p (r'^2_j - (l'_j - 1)^2) < (r_1^2 - (l_1 - 1)^2) + (r_2^2 - (l_2 - 1)^2)$.

If we replace (l_1, r_1) and (l_2, r_2) with this intervals we obtain a set S_1 such that $m(S_1) = y^\alpha z^\beta x^{F'(n)}$ and $(\alpha < n) \vee (\beta < n^2)$. We can keep replacing intersecting pairs with non-intersecting intervals preserving the value of \deg_x . It is clear that this process will eventually stop since $\deg_y \geq 0$ and $\deg_z \geq 0$, and thus the resulting set S' is well-defined and consists of non-intersecting intervals.

It remains to present the set $\{(l'_1, r'_1), \dots, (l'_p, r'_p)\}$ for every two intersecting intervals $\{(l_1, r_1), (l_2, r_2)\}$.

Let $T = \{(a_i, b_i), \dots, (a_p, b_p)\}$, such that $\forall i \in [p] : 0 \leq a_i < b_i - 1 \leq n - 1$ or $a_i = b_i$ (the later represents an interval of size 0 and is used only to reduce the number of cases in the analysis). We will use the following notation:

- $f(T) = \sum_{i=1}^{|T|} F'(b_i) - F'(a_i)$,
- $g(T) = \sum_{i=1}^{|T|} b_i - a_i$,
- $h(T) = \sum_{i=1}^{|T|} b_i^2 - a_i^2$.

Let A be a set $\{(a, b), (c, d)\}$ such that $(b \geq d > a \geq c) \vee (b \geq d > c \geq a)$. As there is no difference in analysis (we may replace $(a, b), (c, d)$ with $(a, d), (b, c)$), we consider only the first case. We are going to go through rigorous case analysis to show that we can always construct a set B such that $f(A) = f(B)$ and either $g(A) > g(B)$ or $g(A) = g(B)$ but $h(A) > h(B)$:

1. If $d > a + 2 \vee d = a + 1$ and $a > c + 2 \vee a = c + 1$ then

$$B = \{(c, a - 1), (a + 1, d), (b - 1, b + 1)\},$$

$$g(B) = d - c < b - a + d - c = g(A);$$

2. If $d > a + 2 \vee d = a + 1$ and $a = c + 2$ then

$$B = \{(c - 2, c), (a + 1, d), (b - 1, b + 1)\},$$

$$g(B) = d - a + 3 < b - a + d - c = g(A);$$

3. If $d = a + 2$ then

$$B = \{(c, d - 1), (b - 1, b + 1)\},$$

$$g(B) = d - a + 1 < b - a + d - c = g(A);$$

4. If $a = c$ and $d > a + 3 \vee d = a + 2$ and $b - a > 2$ then

$$B = \{(a - 2, a), (a + 2, d), (b - 1, b + 1)\},$$

$$g(B) = d - a + 2 < b - a + d - c = g(A);$$

5. If $a = c$ and $b - a = 2$ then

$$B = \{(a, b + 1)\},$$

$$g(B) = b - a + 1 < b - a + d - c = g(A);$$

6. If $a = c$ and $d = a + 3$ and $b > a + 3$ then

$$B = \{(a - 2, d - 1), (b - 1, b + 1)\},$$

$$g(B) = d - a + 3 < b - a + d - c = g(A);$$

7. If $a = c$ and $d = b$ and $b = a + 3$

$$B = \{(a - 2, b + 1)\},$$

$$g(B) = d - a + 3 = b - a + d - c = g(A),$$

$$h(B) = (a + 4)^2 - (a - 2)^2 = 12a + 12 < 12a + 18 = 2((a + 3)^2 - a^2) = h(A).$$

In some of the cases, it may turn out that for some interval from B its left endpoint is negative or its right endpoint is greater than n . In fact, the latter case is impossible: if long interval (a, b) covers at least $n + 1$ then $F'(b) - F'(a) > F'(n) - 1$. In the former case we will use the additional manipulations with B :

2. If $c = 0$ then we drop $(-2, 0)$. If $c = 1$ then we replace $(-1, 1)$ with $(0, 2)$;
 4. If $a = 0$ then we drop $(-2, 0)$. If $a = 1$ then we replace $(-1, 1)$ with $(0, 2)$;
 6. If $a = 0$ then we replace $(-2, 2)$ with $(0, 2)$. If $a = 1$ then we replace $(-1, 3)$ with $(2, 4)$;
 7. If $a = 0$ then we replace $(-2, 4)$ with $(0, 4)$. If $a = 1$ then we replace $(-1, 5)$ with $(4, 6)$.

Now to get the desired result we need to apply this case analysis to $\{(l_1 - 1, r_1), (l_2 - 1, r_2)\}$, get a set $B = \{(a'_1, b'_1) \dots (a'_p, b'_p)\}$ and get a collection $(a'_1 + 1, b'_1), \dots, (a'_p + 1, b'_p)$ which would satisfy all the intended properties. ◀

Suppose that there exists a set of intervals S with intersections and $m(S) = x^{F'(n)-1}y^n z^{n^2}$. Let S' be the corresponding set from the statement of the lemma. Since S' contains only non-intersecting intervals, $\deg_x(m(S')) \leq F'(n) - 1$ and equality can be achieved only if this intervals cover the whole $[n]$. If so, then $\deg_y(m(S')) = n = \deg_y(m(S))$ and $\deg_z(m(S')) = n^2 = \deg_z(m(S))$. But at least one of \deg_y and \deg_z decreases while we go from S to S' , which is a contradiction. Thus, the monomial $w^t x^{F'(n)-1} y^n z^{n^2}$ may only correspond to some set without intersections that covers the whole $[n]$ and in turn corresponds to a common partition of size t .

Finally, we can solve MCSP problem by finding the smallest t such that $w^t x^{F'(n)-1} y^n z^{n^2}$ is present in P_n . As we already have a polynomial time algorithm for P_n , its coefficients are not greater than $(2n^3)^n = 2^{O(n \log n)}$ and total degree is $O^*(\phi^n)$, by Theorem 2 there is $O^*(\phi^n)$ time and polynomial space algorithm for MCSP. ◀

5 Subexponential running time for small alphabets: hybrid strategy

For the case of a constant size alphabet, we provide a subexponential time algorithm, that collects information about partitions of s_1 and s_2 separately and then just checks if they have any partition in common. The main idea is to divide all the pieces in a partition into two groups: long ones and short ones. The good thing about long ones is that there are not too many of those due to their length. The good thing about short ones is that there are not too many possible short strings over our alphabet due to its small size. By balancing these two cases, we get the desired running time.

► **Theorem 8.** *MCSP can be solved in time and space $2^{O\left(\frac{n \log |\Sigma| \log \log n}{\log n}\right)}$ when $|\Sigma| = n^{o(1)}$.*

Proof. Let μ be a parameter whose value we will choose later. For every multiset S of strings no longer than μ , we define a *histogram* $\text{hist}_\mu(S) = \{(s, \text{count}(S, s)) \mid s \in \Sigma^*, |s| \leq \mu\}$, where $\text{count}(S, s)$ stands for a number of occurrences of s in S . As before, for both input strings we construct sets of their partitions, but now we treat each partition \mathcal{P} as a pair $(L, \text{hist}_\mu(S))$ of a multiset of long pieces $L = \{s \in \mathcal{P}, |s| > \mu\}$ and a histogram of a multiset of short ones $S = \{s \in \mathcal{P}, |s| \leq \mu\}$.

The construction of all possible partitions goes as follows: we iterate over all possible multisets of long pieces and for each of them we compute all possible histograms of short ones. As the number of long pieces is not greater than n/μ , there are at most $\binom{2n}{2n/\mu}$ ways to choose their ends.

Once we have fixed the long pieces, we want to enumerate all possible ways to cut the rest into small pieces. In order to do this, we use dynamic programming. Let s_1, s_2, \dots, s_k be the multiset of strings after removing all the long pieces. By $R(\{s_1, s_2, \dots, s_k\})$ we define the set of all possible ways to cut these strings into pieces no longer than μ . Then,

$$\begin{aligned} R(\{s_1, s_2, \dots, s_k\}) &= \\ &= \bigcup_{i=1}^{\min\{\mu, |s_k|\}} \{C \cup s_k[|s_k| - i + 1 : |s_k|] \mid C \in R(\{s_1, s_2, \dots, s_k[1 : |s_k| - i]\})\}, \end{aligned}$$

and $R(\{s_1, s_2, \dots, s_k\})$ may be computed in $O^*(n^{|\Sigma|^\mu})$, as $n^{|\Sigma|^\mu}$ is the upper bound on the number of all possible histograms: $\text{count}(S, s) \leq n$ for every $s \in S$ and there are at most $|\Sigma|^{\mu+1}$ distinct s , and it takes polynomial in n and linear in size time to obtain R if all smaller ones are already computed.

Thus, the total time is $O^*\left(\binom{2n}{2n/\mu} \cdot n^{|\Sigma|^\mu}\right)$ and we wish to choose μ so that this time is small as possible. Since $\binom{2n}{2n/\mu} = 2^{O\left(\frac{n}{\mu} \log \mu\right)}$ and $n^{|\Sigma|^\mu} = 2^{O(|\Sigma|^\mu \log n)}$, we may choose $\mu = c \log_2 n / \log_2 |\Sigma|$ with $c < 1$, and then the total time is $2^{O\left(\frac{n \log |\Sigma| \log \log n}{\log n}\right)}$. ◀

6 Lower bounds: reductions to MIS and to binary alphabet

In this section, we prove the ETH based lower bounds: assuming Exponential Time Hypothesis, the best upper bounds for MCSP and MCSP^c are $2^{\Omega(n)}$ and $2^{\Omega(n/\log n)}$, respectively.

► **Lemma 9.** *Assuming ETH, there is no $2^{o(n)}$ time algorithm for MCSP.*

Proof. [8] proves NP-hardness of MCSP by reducing the maximum independent set on degree-3 graphs (3-MIS) to MCSP. The reduction is linear: given a graph with n nodes, it produces an instance of MCSP with strings of length $O(n)$. In turn, [12] shows that there is no $2^{o(n)}$ time algorithm for 3-MIS under ETH. This implies that the same is true for MCSP. ◀

► **Theorem 10.** *Assuming ETH, there is no $2^{o(n/\log n)}$ time algorithm for MCSP on constant size alphabets.*

Proof. We show how to reduce an instance of the general MCSP of length n to an instance of MCSP over binary alphabet that is $4 \log n$ times longer. Since the general MCSP cannot be solved in time $2^{o(n)}$ under ETH, we obtain a lower bound $2^{\Omega(n/\log n)}$ for its constant-size alphabet version.

Consider an instance of MCSP that consists of strings s_1 and s_2 of length n . Since there are at most n distinct symbols in both strings, we can encode each symbol c via binary string $b(c)$ of length $\log_2 n$. For every symbol c we define a *gadget* $\psi(c)$ as a string

$$\psi(c) = 0 \, b(c)[1] \, 0 \, b(c)[2] \, 0 \dots 0 \, b(c)[\log_2 n] \, 0 \, 1 \, 1 \, 0 \, b(c)[1] \, 0 \, b(c)[2] \, 0 \dots 0 \, b(c)[\log_2 n] \, 0.$$

We call the central 1 of a gadget its *pivot*.

We transform $s_1 = s_1[1]s_1[2] \dots s_1[n]$ into a string $s'_1 = \psi(s_1[1])\psi(s_1[2]) \dots \psi(s_1[n])$ and $s_2 = s_2[1]s_2[2] \dots s_2[n]$ into a string $s'_2 = \psi(s_2[1])\psi(s_2[2]) \dots \psi(s_2[n])$. It is clear that (s'_1, s'_2) is an instance of MCSP over binary alphabet of size $n \cdot \lceil 4 \log_2 n + 5 \rceil$. We show that there is a common partition of s_1 and s_2 of size at most t if and only if there is a common partition of s'_1 and s'_2 of size at most t .

Necessity. Given a common partition of s_1 and s_2 , we can transform it into a common partition of s'_1 and s'_2 of the same size simply by replacing each block $b = b[1]b[2] \dots b[b]$ with $\psi(b) = \psi(b[1])\psi(b[2]) \dots \psi(b[b])$.

Sufficiency. Consider a common partition of s'_1 and s'_2 of size t . Call the block of this partition *long* if it contains at least two pivots of some gadgets. Since the pivot and its neighbors are the only consecutive 1's in gadget, if some long block b_1 of s'_1 matched with some long block b_2 of s'_2 then all the pivots of b_1 matched with the corresponding pivots of b_2 . Note that long blocks, along with each pivot, contain information about the corresponding symbols of its gadgets, as this information is duplicated on both sides of the pivot. This means that we can correspond every long block that contains pivots of gadgets $\psi(c[1])\psi(c[2]) \dots \psi(c[c])$ with substring $c[1]c[2] \dots c[c]$ of s_1 and s_2 .

Now we are ready to present a common partition of s_1 and s_2 of size at most t : for every long block in (s'_1, s'_2) we take the corresponding block in (s_1, s_2) and cut the remains into blocks of size one. Clearly, the result is a common partition of s_1 and s_2 : blocks of length at least two do not intersect and are contained in both strings since so do the corresponding long blocks. The remaining blocks of size one match since s_1 and s_2 consists of the same number of each symbol. The size of the constructed partition is equal to the number of blocks in the considered partition of s'_1 and s'_2 that contain at least one pivot and hence is no more than t . ◀

7 Open problems

There are three natural questions left open by the present studies.

1. Close the gap between a lower bound $2^{\Omega(n/\log n)}$ and an upper bound $2^{O(n \log \log n / \log n)}$ for constant size alphabets.
2. Design a moderately exponential time (of the form c^n for $c < 2$) algorithm for the case of more than two input strings.
3. Roughly, it is the “no-holes” property that allows us to improve the 2^n upper bound for MCSP. What are other problems with the same effect?

Abstract

We present an accelerated, or “look-ahead” version of the Newton–Dinkelbach method, a well-known technique for solving fractional and parametric optimization problems. This acceleration halves the Bregman divergence between the current iterate and the optimal solution within every two iterations. Using the Bregman divergence as a potential in conjunction with combinatorial arguments, we obtain strongly polynomial algorithms in three applications domains: (i) For linear fractional combinatorial optimization, we show a convergence bound of $O(m \log m)$ iterations; the previous best bound was $O(m^2 \log m)$ by Wang et al. (2006). (ii) We obtain a strongly polynomial label-correcting algorithm for solving linear feasibility systems with two variables per inequality (2VPI). For a 2VPI system with n variables and m constraints, our algorithm runs in $O(mn)$ iterations. Every iteration takes $O(mn)$ time for general 2VPI systems, and $O(m + n \log n)$ time for the special case of deterministic Markov Decision Processes (DMDPs). This extends and strengthens a previous result by Madani (2002) that showed a weakly polynomial bound for a variant of the Newton–Dinkelbach method for solving DMDPs. (iii) We give a simplified variant of the parametric submodular function minimization result by Goemans et al. (2017).

1 Introduction

Linear fractional optimization problems are well-studied in combinatorial optimization. Given a closed domain $\mathcal{D} \subseteq \mathbb{R}^m$ and $c, d \in \mathbb{R}^m$ such that $d^\top x > 0$ for all $x \in \mathcal{D}$, the problem is

$$\inf c^\top x / d^\top x \quad \text{s.t. } x \in \mathcal{D}. \quad (1)$$

The domain \mathcal{D} could be either a convex set or a discrete set $\mathcal{D} \subseteq \{0, 1\}^m$. Classical examples include finding minimum cost-to-time ratio cycles and minimum ratio spanning trees. One can equivalently formulate (1) as a parametric search problem. Let

$$f(\delta) = \inf\{(c - \delta d)^\top x : x \in \mathcal{D}\}, \quad (2)$$

be a concave and decreasing function. Assuming (1) has a finite optimum δ , it corresponds to the unique root $f(\delta) = 0$.

A natural question is to investigate how the computational complexity of solving the minimum ratio problem (1) may depend on the complexity of the corresponding linear optimization problem $\min c^\top x$ s.t. $x \in \mathcal{D}$. Using the reformulation (2), one can reduce the fractional problem to the linear problem via binary search; however, the number of iterations needed to find an exact solution may depend on the bit complexity of the input. A particularly interesting question is: assuming there exists a strongly polynomial algorithm for linear optimization over a domain \mathcal{D} , can we find a strongly polynomial algorithm for linear fractional optimization over the same domain?

A seminal paper by Megiddo [14] introduced the *parametric search* technique to solve linear fractional combinatorial optimization problems. He showed that if the linear optimization algorithm only uses $p(m)$ comparisons and $q(m)$ additions, then there exists an $O(p(m)(p(m) + q(m)))$ algorithm for the linear fractional optimization problem. This in particular yielded the first strongly polynomial algorithm for the minimum cost-to-time ratio cycle problem. On a very high level, parametric search works by simulating the linear optimization algorithm for the parametric problem (2), with the parameter $\delta \in \mathbb{R}$ being indeterminate.

A natural alternative approach is to solve (2) using a standard root finding algorithm. Radzik [18] showed that for a discrete domain $\mathcal{D} \subseteq \{0, 1\}^m$, the *discrete Newton* method – in this context, also known as *Dinkelbach’s method* [4] – terminates in a strongly polynomial number of iterations. In contrast to parametric search, there are no restrictions on the possible operations in the linear optimization algorithm. In certain settings, such as the maximum ratio cut problem, the discrete Newton method outperforms parametric search; we refer to the comprehensive survey by Radzik [19] for details and comparison of the two methods.

1.1 Our Contributions

We introduce a new, *accelerated variant of Newton’s method for univariate functions*. Let $f : \mathbb{R} \rightarrow \mathbb{R} \cup \{-\infty\}$ be a concave function. Under some mild assumptions on f , our goal is to either find the largest root, or show that no root exists. Let δ^* denote the largest root, or in case $f < 0$, let δ^* denote the largest maximizer of f . For simplicity, we now describe the method for differentiable functions. This will not hold in general: functions of the form (2) will be piecewise linear if \mathcal{D} is finite or polyhedral. The algorithm description in Section 2 uses a form with supergradients (that can be chosen arbitrarily between the left and right derivatives).

The standard Newton method, also used by Radzik, proceeds through iterates $\delta^{(1)} > \delta^{(2)} > \dots > \delta^{(t)}$ such that $f(\delta^{(i)}) \leq 0$, and updates $\delta^{(i+1)} = \delta^{(i)} - f(\delta^{(i)})/f'(\delta^{(i)})$.

Our new variant uses a more aggressive “*look-ahead*” technique. At each iteration, we compute $\delta = \delta^{(i)} - f(\delta^{(i)})/f'(\delta^{(i)})$, and jump ahead to $\delta' = 2\delta - \delta^{(i)}$. In case $f(\delta') \leq 0$ and $f'(\delta') < 0$, we update $\delta^{(i+1)} = \delta'$; otherwise, we continue with the standard iterate δ .

This modification leads to an improved and at the same time simplified analysis based on the *Bregman divergence* $D_f(\delta^*, \delta^{(i)}) = f(\delta^{(i)}) + f'(\delta^{(i)})(\delta^* - \delta^{(i)}) - f(\delta^*)$. We show that this decreases by a factor of two between any two iterations.

A salient feature of the algorithm is that it handles both feasible and infeasible outcomes in a unified framework. In the context of linear fractional optimization, this means that the assumption $d^\top x > 0$ for all $x \in \mathcal{D}$ in (1) can be waived. Instead, $d^\top x > 0$ is now added as a feasibility constraint to (1). This generalization is important when we use the algorithm to solve two variables per inequality systems.

This general result leads to improvements and simplifications of a number of algorithms using the discrete Newton method.

- For *linear fractional combinatorial optimization*, namely the setting (1) with $\mathcal{D} \subseteq \{0, 1\}^m$, we obtain an $O(m \log m)$ bound on the number of iterations, a factor m improvement over the previous best bound $O(m^2 \log m)$ by Wang et al. [25] from 2006. We remark that Radzik's first analysis [18] yielded a bound of $O(m^4 \log^2 m)$ iterations, improved to $O(m^2 \log^2 m)$ in [19].
- Goemans et al. [7] used the discrete Newton method to obtain a strongly polynomial algorithm for parametric submodular function minimization. We give a simple new variant of this result with the same asymptotic running time, using the accelerated algorithm.
- For *two variable per inequality (2VPI)* systems, we obtain a *strongly polynomial label-correcting algorithm*. This will be discussed in more detail next.

1.2 Two Variables Per Inequality Systems

A major open question in the theory of linear programming (LP) is whether there exists a strongly polynomial algorithm for LP. This problem is one of Smale's eighteen mathematical challenges for the twenty-first century [22]. An LP algorithm is *strongly polynomial* if it only uses elementary arithmetic operations ($+$, $-$, \times , $/$) and comparisons, and the number of such operations is polynomially bounded in the number of variables and constraints. Furthermore, the algorithm needs to be in PSPACE, i.e. the numbers occurring in the computations must remain polynomially bounded in the input size.

The notion of a strongly polynomial algorithm was formally introduced by Megiddo [15] in 1983 (using the term “*genuinely polynomial*”), where he gave the first such algorithm for *two variables per inequality (2VPI)* systems. These are feasibility LPs where every inequality contains at most two variables. More formally, let $\mathcal{M}_2(n, m)$ be the set of $n \times m$ matrices with at most two nonzero entries per column. A 2VPI system is of the form $A^\top y \leq c$ for $A \in \mathcal{M}_2(n, m)$ and $c \in \mathbb{R}^m$.

If we further require that every inequality has at most one positive and at most one negative coefficient, it is called a *monotone two variables per inequality (M2VPI)* system. A simple and efficient reduction is known from 2VPI systems with n variables and m inequalities to M2VPI systems with $2n$ variables and $\leq 2m$ inequalities [5, 10].

Connection between 2VPI and parametric optimization. An M2VPI system has a natural graphical interpretation: after normalization, we can assume every constraint is of the form $y_u - \gamma_e y_v \leq c_e$. Such a constraint naturally maps to an arc $e = (u, v)$ with *gain factor* $\gamma_e > 0$ and cost c_e . Based on Shostak's work [21] that characterized feasibility in terms of this graph, Aspvall and Shiloach [2] gave the first weakly polynomial algorithm for M2VPI systems.

We say that a directed cycle C is *flow absorbing* if $\prod_{e \in C} \gamma_e < 1$ and *flow generating* if $\prod_{e \in C} \gamma_e > 1$. Every flow absorbing cycle C implies an upper bound for every variable y_u incident to C ; similarly, flow generating cycles imply lower bounds. The crux of Aspvall and Shiloach's algorithm is to find the tightest upper and lower bounds for each variable y_u .

Finding these bounds corresponds to solving fractional optimization problems of the form (1), where $\mathcal{D} \subseteq \mathbb{R}^m$ describes “generalized flows” around cycles. The paper [2] introduced the *Grapevine* algorithm – a natural modification the Bellman-Ford algorithm – to decide whether the optimum ratio is smaller or larger than a fixed value δ . The optimum value can be found using binary search on the parameter.

Megiddo’s strongly polynomial algorithm [15] replaced the binary search framework in Aspvall and Shiloach’s algorithm by extending the parametric search technique in [14]. Subsequently, Cohen and Megiddo [3] devised faster strongly polynomial algorithms for the problem. The current fastest strongly polynomial algorithm is given by Hochbaum and Naor [11], an efficient Fourier–Motzkin elimination with running time of $O(mn^2 \log m)$.

2VPI via Newton’s method. Since Newton’s method proved to be an efficient and viable alternative to parametric search, a natural question is to see whether it can solve the parametric problems occurring in 2VPI systems. Radzik’s fractional combinatorial optimization results [18, 19] are not directly applicable, since the domain \mathcal{D} in this setting is a polyhedron and not a discrete set.¹ Madani [13] used a variant of the Newton–Dinkelbach method as a tool to analyze the convergence of policy iteration on *deterministic Markov Decision Processes (DMDPs)*, a special class of M2VPI systems (discussed later in more detail). He obtained a weakly polynomial convergence bound; it remained open whether such an algorithm could be strongly polynomial.

Our 2VPI algorithm. We introduce a new type of strongly polynomial 2VPI algorithm by combining the accelerated Newton–Dinkelbach method with a “*variable fixing*” analysis. Variable fixing was first introduced in the seminal work of Tardos [23] on minimum-cost flows, and has been a central idea of strongly polynomial algorithms, see in particular [8, 20] for cycle cancelling minimum-cost flow algorithms, and [16, 24] for maximum generalized flows, a dual to the 2VPI problem.

We show that for every iterate $\delta^{(i)}$, there is a constraint that has been “actively used” at $\delta^{(i)}$ but will not be used ever again after a strongly polynomial number of iterations. The analysis combines the decay in *Bregman divergence* shown in the general accelerated Newton–Dinkelbach analysis with a combinatorial “*subpath monotonicity*” property.

Our overall algorithm can be seen as an extension of Madani’s DMDP algorithm. In particular, we adapt his “unfreezing” idea: the variables y_u are admitted to the system one-by-one, and the accelerated Newton–Dinkelbach method is used to find the best “cycle bound” attainable at the newly admitted y_u in the graph induced by the current variable set. This returns a feasible solution or reports infeasibility within $O(m)$ iterations. As every iteration takes $O(mn)$ time, our overall algorithm terminates in $O(m^2n^2)$ time. For the special setting of deterministic MDPs, the runtime per iteration improves to $O(m + n \log n)$, giving a total runtime of $O(mn(m + n \log n))$.

Even though our running time bound is worse than the state-of-the-art 2VPI algorithm [11], it is of a very different nature from all previous 2VPI algorithms. In fact, our algorithm is a *label-correcting algorithm*, naturally fitting to the family of algorithms used in other combinatorial optimization problems with constraint matrices from $\mathcal{M}_2(n, m)$ such as maximum flow, shortest paths, minimum-cost flow, and generalized flow problems. We next elaborate on this connection.

¹ The problem could be alternatively formulated with $\mathcal{D} \subseteq \{0, 1\}^m$ but with nonlinear functions instead of $c^\top x$ and $d^\top x$.

Label-correcting algorithms. An important special case of M2VPI systems corresponds to the shortest paths problem: given a directed graph $G = (V, E)$ with target node $t \in V$ and arc costs $c \in \mathbb{R}^E$, we associate constraints $y_u - y_v \leq c_e$ for every arc $e = (u, v) \in E$ and $y_t = 0$. If the system is feasible and bounded, the pointwise maximal solution corresponds to the shortest path labels to t ; an infeasible system contains a negative cost cycle. A generic label-correcting algorithm maintains distance labels y that are upper bounds on the shortest path distances to t . The labels are decreased according to violated constraints. Namely, if $y_u - y_v > c_e$, then decreasing y_u to $c_e + y_v$ gives a smaller valid distance label at u . We terminate with the shortest path labels once all constraints are satisfied. The Bellman–Ford algorithm for the shortest paths problem is a particular implementation of the generic label-correcting algorithm; we refer the reader to [1, Chapter 5] for more details.

It is a natural question if label-correcting algorithms can be extended to general M2VPI systems, where constraints are of the form $y_u - \gamma_e y_v \leq c_e$ for a “gain/loss factor” $\gamma_e > 0$ associated with each arc. A fundamental property of M2VPI systems is that, whenever bounded, a unique pointwise maximal solution exists, i.e. a feasible solution y^* such that $y \leq y^*$ for every feasible solution y . A label-correcting algorithm for such a setting can be naturally defined as follows. Let us assume that the problem is bounded. The algorithm should proceed via a decreasing sequence $y^{(0)} \geq y^{(1)} \geq \dots \geq y^{(t)}$ of labels that are all valid upper bounds on any feasible solution y to the system. The algorithm either terminates with the unique pointwise maximal solution $y^{(t)} = y^*$, or finds an infeasibility certificate.

The basic label-correcting operation is the “arc update”, decreasing y_u to $\min\{y_u, c_e + \gamma_e y_v\}$ for some arc $e = (u, v) \in E$. Such updates suffice in the shortest path setting. However, in the general setting arc operations only may not lead to finite termination. Consider a system with only two variables, y_u and y_v , and two constraints, $y_u - y_v \leq 0$, and $y_v - \frac{1}{2}y_u \leq -1$. The alternating sequence of arc updates converges to $(y_u^*, y_v^*) = (-2, -2)$, but does not finitely terminate. In this example, we can “detect” the cycle formed by the two arcs, that implies the bound $y_u - \frac{1}{2}y_u \leq -1$.

Shostak’s [21] result demonstrates that arc updates, together with such “cycle updates” should be sufficient for finite termination. Our M2VPI algorithm amounts to the first strongly polynomial label-correcting algorithm for general M2VPI systems, using arc updates and cycle updates.

Deterministic Markov decision processes. A well-studied special case of M2VPI systems in which $\gamma \leq 1$ is known as *deterministic Markov decision process* (DMDP). A *policy* corresponds to selecting an outgoing arc from every node, and the objective is to find a policy that minimizes the total discounted cost over an infinite time horizon. The pointwise maximal solution of this system corresponds to the optimal values of a policy.

The standard policy iteration, value iteration, and simplex algorithms can be all interpreted as variants of the label-correcting framework.²

Value iteration can be seen as a generalization of the Bellman–Ford algorithm to the DMDP setting. As our previous example shows, value iteration may not be finite. One could still consider as the termination criterion the point where value iteration “reveals” the optimal policy, i.e. updates are only performed using constraints that are tight in the optimal solution. If each discount factor γ_e is at most γ' for some $\gamma' > 0$, then it is well-known that value iteration converges at the rate $1/(1 - \gamma')$. This is in fact true more generally, for nondeterministic MDPs [12]. However, if the discount factors can be arbitrarily close to 1,

² The value sequence may violate monotonicity in certain cases of value iteration.

then Feinberg and Huang [6] showed that value iteration cannot reveal the optimal policy in strongly polynomial time even for DMDPs. Post and Ye [17] proved that simplex with the most negative reduced cost pivoting rule is strongly polynomial for DMDPs; this was later improved by Hansen et al. [9]. These papers heavily rely on the assumption $\gamma \leq 1$, and does not seem to extend to general M2VPI systems.

Madani’s previously mentioned work [13] used a variant of the Newton–Dinkelbach method as a tool to analyze the convergence of policy iteration on deterministic MDPs, and derived a weakly polynomial runtime bound.

Paper organization We start by giving preliminaries and introducing notation below. In Section 2, we present an accelerated Newton’s method for univariate concave functions, and apply it to linear fractional combinatorial optimization and linear fractional programming. Section 3 contains our main application of the method to the 2VPI problem. Our results on parametric submodular function minimization and deterministic MDPs can be found in the full version of the paper. Missing proofs also appear in the full version.

Preliminaries Let \mathbb{R}_+ and \mathbb{R}_{++} be the nonnegative and positive reals respectively, and denote $\bar{\mathbb{R}} := \mathbb{R} \cup \{\pm\infty\}$. Given a proper concave function $f : \mathbb{R} \rightarrow \bar{\mathbb{R}}$, let $\text{dom}(f) := \{x : -\infty < f(x) < \infty\}$ be the effective domain of f . For a point $x_0 \in \text{dom}(f)$, denote the set of supergradients of f at x_0 as $\partial f(x_0) := \{g : f(x) \leq f(x_0) + g(x - x_0) \forall x \in \mathbb{R}\}$. If x_0 is in the interior of $\text{dom}(f)$, then $\partial f(x_0) = [f'_-(x_0), f'_+(x_0)]$, where $f'_-(x_0)$ and $f'_+(x_0)$ are the left and right derivatives. Throughout, we use $\log(x) = \log_2(x)$ to indicate base 2 logarithm. For $x, y \in \mathbb{R}^m$, denote $x \circ y \in \mathbb{R}^m$ as the element-wise product of the two vectors.

2 An Accelerated Newton–Dinkelbach Method

Let $f : \mathbb{R} \rightarrow \bar{\mathbb{R}}$ be a proper concave function such that $f(\delta) \leq 0$ and $\partial f(\delta) \cap \mathbb{R}_{<0} \neq \emptyset$ for some $\delta \in \text{dom}(f)$. Given a suitable starting point, as well as value and supergradient oracles of f , the Newton–Dinkelbach method either computes the largest root of f or declares that it does not have a root. In this paper, we make the mild assumption that f has a root or attains its maximum. Consequently, the point $\delta^* := \max(\{\delta : f(\delta) = 0\} \cup \arg \max f(\delta))$ is well-defined. It is the largest root of f if f has a root. Otherwise, it is the largest maximizer of f . Therefore, the Newton–Dinkelbach method returns δ^* if f has a root, and certifies that $f(\delta^*) < 0$ otherwise.

The algorithm takes as input an initial point $\delta^{(1)} \in \text{dom}(f)$ and a supergradient $g^{(1)} \in \partial f(\delta^{(1)})$ such that $f(\delta^{(1)}) \leq 0$ and $g^{(1)} < 0$. At the start of every iteration $i \geq 1$, it maintains a point $\delta^{(i)} \in \text{dom}(f)$ and a supergradient $g^{(i)} \in \partial f(\delta^{(i)})$ where $f(\delta^{(i)}) \leq 0$. If $f(\delta^{(i)}) = 0$, then it returns $\delta^{(i)}$ as the largest root of f . Otherwise, a new point $\delta := \delta^{(i)} - f(\delta^{(i)})/g^{(i)}$ is generated. Now, there are two scenarios in which the algorithm terminates and reports that f does not have a root: (1) $f(\delta) = -\infty$; (2) $f(\delta) < 0$ and $g \geq 0$ where $g \in \partial f(\delta)$ is the supergradient given by the oracle. If both scenarios do not apply, the next point and supergradient is set to $\delta^{(i+1)} := \delta$ and $g^{(i+1)} := g$ respectively. Then, a new iteration begins.

To accelerate this classical method, we perform an aggressive guess $\delta' := 2\delta - \delta^{(i)} < \delta$ on the next point at the end of every iteration i . We call this procedure *look-ahead*, which is implemented on Lines 7–10 of Algorithm 1. Let $g' \in \partial f(\delta')$ be the supergradient returned by the oracle. If $-\infty < f(\delta') < 0$ and $g' < 0$, then the next point and supergradient are set to $\delta^{(i+1)} := \delta'$ and $g^{(i+1)} := g'$ respectively as $\delta' \geq \delta^*$. In this case, we say that look-ahead is *successful* in iteration i . Otherwise, we proceed as usual by taking $\delta^{(i+1)} := \delta$ and $g^{(i+1)} := g$.

Algorithm 1 LOOK-AHEADNEWTON.

input : Value and supergradient oracles for a proper concave function f , an initial point $\delta^{(1)} \in \text{dom}(f)$ and supergradient $g^{(1)} \in \partial f(\delta^{(1)})$ where $f(\delta^{(1)}) \leq 0$ and $g^{(1)} < 0$.

output : The largest root of f if it exists; report NO ROOT otherwise.

```

1  $i \leftarrow 1$ 
2 while  $f(\delta^{(i)}) < 0$  do
3    $\delta \leftarrow \delta^{(i)} - f(\delta^{(i)})/g^{(i)}$ 
4    $g \in \partial f(\delta)$  /* Empty if  $f(\delta) = -\infty$  */
5   if  $f(\delta) = -\infty$  or ( $f(\delta) < 0$  and  $g \geq 0$ ) then
6     return NO ROOT
7    $\delta' \leftarrow 2\delta - \delta^{(i)}$  /* Look-ahead guess */
8    $g' \in \partial f(\delta')$  /* Empty if  $f(\delta') = -\infty$  */
9   if  $-\infty < f(\delta') < 0$  and  $g' < 0$  then /* Is the guess successful? */
10     $\delta \leftarrow \delta', g \leftarrow g'$ 
11     $\delta^{(i+1)} \leftarrow \delta, g^{(i+1)} \leftarrow g$ 
12     $i \leftarrow i + 1$ 
13 return  $\delta^{(i)}$ 

```

It is easy to see that $\delta^{(i)}$ is monotonically decreasing while $f(\delta^{(i)})$ is monotonically increasing. Furthermore, $g^{(i)}$ is monotonically increasing except in the final iteration where it may remain unchanged (Lemma 2.1). Similarly, we have $g^{(i)} < 0$ except possibly in the final iteration when $f(\delta^{(i)}) = 0$.

► **Lemma 2.1.** *For every iteration $i \geq 2$, we have $\delta^* \leq \delta^{(i)} < \delta^{(i-1)}$, $f(\delta^*) \geq f(\delta^{(i)}) > f(\delta^{(i-1)})$ and $g^{(i)} \geq g^{(i-1)}$, where the last inequality holds at equality if and only if $g^{(i)} = \inf_{g \in \partial f(\delta^{(i)})} g$, $g^{(i-1)} = \sup_{g \in \partial f(\delta^{(i-1)})} g$ and $f(\delta^{(i)}) = 0$. Moreover,*

$$\frac{f(\delta^{(i)})}{f(\delta^{(i-1)})} + \frac{g^{(i)}}{g^{(i-1)}} \leq 1.$$

Our analysis of the Newton–Dinkelbach method utilizes the Bregman divergence associated with f as a potential. Even though the original definition requires f to be differentiable and strictly concave, it can be naturally extended to our setting in the following way.

► **Definition 2.2.** *Given a proper concave function $f : \mathbb{R} \rightarrow \bar{\mathbb{R}}$, the Bregman divergence associated with f is defined as*

$$D_f(\delta', \delta) := \begin{cases} f(\delta) + \sup_{g \in \partial f(\delta)} g(\delta' - \delta) - f(\delta') & \text{if } \delta \neq \delta', \\ 0 & \text{otherwise.} \end{cases}$$

for all $\delta, \delta' \in \text{dom}(f)$ such that $\partial f(\delta) \neq \emptyset$.

Since f is concave, the Bregman divergence is nonnegative. It is again easy to see that $D_f(\delta^*, \delta^{(i)})$ is monotonically decreasing except in the final iteration where it may remain unchanged (Lemma 2.3).

► **Lemma 2.3.** *For every iteration $i \geq 2$, we have $D_f(\delta^*, \delta^{(i)}) \leq D_f(\delta^*, \delta^{(i-1)})$ which holds at equality if and only if $g^{(i-1)} = \inf_{g \in \partial f(\delta^{(i-1)})} g$ and $f(\delta^{(i)}) = 0$.*

If look-ahead is successful, then we have made significant progress. Otherwise, by our choice of δ' , we learn that we are not too far away from δ^* . The next lemma demonstrates the advantage of using the look-ahead Newton–Dinkelbach method. It exploits the proximity to δ^* to produce a geometric decay in the Bregman divergence of $\delta^{(i)}$ and δ^* .

► **Lemma 2.4.** *For every iteration $i > 2$ in Algorithm 1, we have $D_f(\delta^*, \delta^{(i)}) < \frac{1}{2} D_f(\delta^*, \delta^{(i-2)})$.*

In the remaining of this section, we apply the accelerated Newton–Dinkelbach method to linear fractional combinatorial optimization and linear fractional programming. The application to parametric submodular function minimization is in the full version.

2.1 Linear Fractional Combinatorial Optimization

The problem (1) with $\mathcal{D} \subseteq \{0, 1\}^m$ is known as *linear fractional combinatorial optimization*. Radzik [18] showed that the Newton–Dinkelbach method applied to the function $f(\delta)$ as in (2) terminates in a strongly polynomial number of iterations. Recall that $f(\delta) = \min_{x \in \mathcal{D}} (c - \delta d)^\top x$. By the assumption $d^\top x > 0$ for all $x \in \mathcal{D}$, this function is concave, strictly decreasing, finite and piecewise-linear. Hence, it has a unique root. Moreover, $f(\delta) < 0$ and $\partial f(\delta) \cap \mathbb{R}_{<0} \neq \emptyset$ for sufficiently large δ . To implement the value and supergradient oracles, we assume that a linear optimization oracle over \mathcal{D} is available, i.e. it returns an element in $\arg \min_{x \in \mathcal{D}} (c - \delta d)^\top x$ for any $\delta \in \mathbb{R}$.

Our result for the accelerated variant improves the state-of-the-art bound $O(m^2 \log m)$ by Wang et al. [25] on the standard Newton–Dinkelbach method. We will need the following lemma, given by Radzik and credited to Goemans in [19]. It gives a strongly polynomial bound on the length of a geometrically decreasing sequence of sums.

► **Lemma 2.5 ([19]).** *Let $c \in \mathbb{R}_+^m$ and $x^{(1)}, x^{(2)}, \dots, x^{(k)} \in \{-1, 0, 1\}^m$. If $0 < c^\top x^{(i+1)} \leq \frac{1}{2} c^\top x^{(i)}$ for all $i < k$, then $k = O(m \log m)$.*

► **Theorem 2.6.** *Algorithm 1 converges in $O(m \log m)$ iterations for linear fractional combinatorial optimization problems.*

Proof. Observe that Algorithm 1 terminates in a finite number of iterations because f is piecewise linear. Let $\delta^{(1)} > \delta^{(2)} > \dots > \delta^{(k)} = \delta^*$ denote the sequence of iterates at the start of Algorithm 1. Since f is concave, we have $D_f(\delta^*, \delta^{(i)}) \geq 0$ for all $i \in [k]$. For each $i \in [k]$, pick $x^{(i)} \in \arg \min_{x \in \mathcal{D}} (c - \delta^{(i)} d)^\top x$ which maximizes $d^\top x$. This is well-defined because f is finite. Note that $-d^\top x^{(i)} = \min \partial f(\delta^{(i)})$. As $f(\delta^*) = 0$, the Bregman divergence of $\delta^{(i)}$ and δ^* can be written as

$$D_f(\delta^*, \delta^{(i)}) = f(\delta^{(i)}) + \max_{g \in \partial f(\delta^{(i)})} g(\delta^* - \delta^{(i)}) = (c - \delta^{(i)} d)^\top x^{(i)} - d^\top x^{(i)} (\delta^* - \delta^{(i)}) = (c - \delta^* d)^\top x^{(i)}.$$

According to Lemma 2.4, $(c - \delta^* d)^\top x^{(i)} = D_f(\delta^*, \delta^{(i)}) < \frac{1}{2} D_f(\delta^*, \delta^{(i-2)}) = \frac{1}{2} (c - \delta^* d)^\top x^{(i-2)}$ for all $3 \leq i \leq k$. By Lemma 2.3, we also know that $D_f(\delta^*, \delta^{(i)}) > 0$ for all $1 \leq i \leq k-2$. Thus, applying Lemma 2.5 yields $k = O(m \log m)$. ◀

2.2 Linear Fractional Programming

We next consider *linear fractional programming*, an extension of (1) with the assumption that the domain $\mathcal{D} \subseteq \mathbb{R}^m$ is a polyhedron, but removing the condition $d^\top x > 0$ for $x \in \mathcal{D}$. For $c, d \in \mathbb{R}^m$, the problem is

$$\inf c^\top x / d^\top x \quad \text{s.t.} \quad d^\top x > 0, \quad x \in \mathcal{D}. \quad (\text{F})$$

For the problem to be meaningful, we assume that $\mathcal{D} \cap \{x : d^\top x > 0\} \neq \emptyset$. The common form in the literature assumes $d^\top x > 0$ for all $x \in \mathcal{D}$ as in (1); we consider the more general setup for the purpose of solving M2VPI systems in Section 3. It is easy to see that any linear fractional combinatorial optimization problem on a domain $\mathcal{X} \subseteq \{0, 1\}^m$ can be cast as a linear fractional program with the polytope $\mathcal{D} = \text{conv}(\mathcal{X})$ because $c^\top \bar{x} / d^\top \bar{x} \geq \min_{x \in \mathcal{X}} c^\top x / d^\top x$ for all $\bar{x} \in \mathcal{D}$. The next theorem characterizes when (F) is unbounded.

► **Theorem 2.7.** *If $\mathcal{D} \cap \{x : d^\top x > 0\} \neq \emptyset$, then the optimal value of (F) is $-\infty$ if and only if at least one of the following two conditions hold:*

1. *There exists $x \in \mathcal{D}$ such that $c^\top x < 0$ and $d^\top x = 0$;*
2. *There exists $y \in \mathbb{R}^m$ such that $c^\top y < 0$, $d^\top y = 0$ and $x + \lambda y \in \mathcal{D}$ for all $x \in \mathcal{D}, \lambda \geq 0$.*

► **Example 2.8.** Unlike in linear programming, the optimal value may not be attained even if it is finite. Consider the instance given by $\inf(-x_1 + x_2)/(x_1 + x_2)$ subject to $x_1 + x_2 > 0$ and $-x_1 + x_2 = 1$. The numerator is equal to 1 for any feasible solution, while the denominator can be made arbitrarily large. Hence, the optimal value of this program is 0, which is not attained in the feasible region.

We use the Newton–Dinkelbach method for f as in (2), that is, $f(\delta) = \inf_{x \in \mathcal{D}} (c - \delta d)^\top x$. Since $\mathcal{D} \neq \emptyset$, $f(\delta) < \infty$ for all $\delta \in \mathbb{R}$. By the Minkowski–Weyl theorem, there exist finitely many points $P \subseteq \mathcal{D}$ such that $f(\delta) = \min_{x \in P} (c - \delta d)^\top x$ for all $\delta \in \text{dom}(f)$. Hence, f is concave and piecewise linear. Observe that $f(\delta) > -\infty$ if and only if every ray y in the recession cone of \mathcal{D} satisfies $(c - \delta d)^\top y \geq 0$. For f to be proper, we need to assume that Condition 2 in Theorem 2.7 does not hold. Moreover, we require the existence of a point $\delta' \in \text{dom}(f)$ such that $f(\delta') = (c - \delta' d)^\top x' \leq 0$ for some $x' \in \mathcal{D}$ with $d^\top x' > 0$. It follows that f has a root or attains its maximum because $\text{dom}(f)$ is closed. We are ready to characterize the optimal value of (F) using f .

► **Lemma 2.9.** *Assume that there exists $\delta' \in \text{dom}(f)$ such that $f(\delta') = (c - \delta' d)^\top x' \leq 0$ for some $x' \in \mathcal{D}$ with $d^\top x' > 0$. If f has a root, then the optimal value of (F) is equal to the largest root and is attained. Otherwise, the optimal value is $-\infty$.*

3 Monotone Two Variables per Inequality Systems

Recall that an M2VPI system can be represented as a directed multigraph $G = (V, E)$ with arcs costs $c \in \mathbb{R}^m$ and gain factors $\gamma \in \mathbb{R}_{++}^m$. For a u - v walk P in G with $E(P) = (e_1, e_2, \dots, e_k)$, its *cost* and *gain factor* are defined as $c(P) := \sum_{i=1}^k \left(\prod_{j=1}^{i-1} \gamma_{e_j} \right) c_{e_i}$ and $\gamma(P) := \prod_{i=1}^k \gamma_{e_i}$ respectively. If P is a single vertex, then $c(P) := 0$ and $\gamma(P) := 1$. The walk P induces the valid inequality $y_u \leq c(P) + \gamma(P)y_v$, implied by the sequence of arcs/inequalities in $E(P)$. It is also worth considering the dual interpretation. Dual variables on arcs correspond to generalized flows: if 1 unit of flow enter the arc $e = (u, v)$ at u , then γ_e units reach v , at a shipping cost of c_e . Thus, if 1 unit of flow enter a path P , then $\gamma(P)$ units reach the end of the path, incurring a cost of $c(P)$.

Given node labels $y \in \mathbb{R}^n$, the y -cost of a u - v walk P is defined as $c(P) + \gamma(P)y_v$. Note that the y -cost of a walk only depends on the label at the sink. A u - v path is called a *shortest u - v path with respect to y* if it has the smallest y -cost among all u - v walks. A *shortest path from u with respect to y* is a shortest u - v path with respect to y for some node v . Such a path does not always exist, as demonstrated in the full version.

If P is a u - u walk such that its intermediate nodes are distinct, then it is called a *cycle at u* . Given a u - v walk P and a v - w walk Q , we denote PQ as the u - w walk obtained by concatenating P and Q .

► **Definition 3.1.** A cycle C is called flow-generating if $\gamma(C) > 1$, unit-gain if $\gamma(C) = 1$, and flow-absorbing if $\gamma(C) < 1$. We say that a unit-gain cycle C is negative if $c(C) < 0$.

Note that $c(C)$ depends on the starting point u of a cycle C . This ambiguity is resolved by using the term *cycle at u* . For a unit-gain cycle C , it is not hard to see that the starting point does not affect the sign of $c(C)$. Hence, the definition of a negative unit-gain cycle is sound. Observe that a flow-absorbing cycle C induces an upper bound $y_u \leq \frac{c(C)}{1-\gamma(C)}$, while a flow-generating cycle C induces a lower bound $y_u \geq \frac{-c(C)}{\gamma(C)-1}$. Let $\mathcal{C}_u^{abs}(G)$ and $\mathcal{C}_u^{gen}(G)$ denote the set of flow-absorbing cycles and flow-generating cycles at u in G respectively.

► **Definition 3.2.** Given a flow-generating cycle C at u , a flow-absorbing cycle D at v , and a u - v path P , the walk CPD is called a bicycle. We say that the bicycle is negative if $c(P) + \gamma(P)\frac{c(D)}{1-\gamma(D)} < \frac{-c(C)}{\gamma(C)-1}$.

Using these two structures, Shostak characterized the feasibility of M2VPI systems.

► **Theorem 3.3** ([21]). An M2VPI system (G, c, γ) is infeasible if and only if G contains a negative unit-gain cycle or a negative bicycle.

3.1 A Linear Fractional Programming Formulation

Our goal is to compute the pointwise maximal solution $y^{\max} \in \bar{\mathbb{R}}^n$ to an M2VPI system if it is feasible, where $y_u^{\max} := \infty$ if and only if the variable y_u is unbounded from above. It is well known how to convert y^{\max} into a finite feasible solution – we refer to the full version for details. In order to apply Algorithm 1, we first need to reformulate the problem as a linear fractional program. Now, every coordinate y_u^{\max} can be expressed as the following primal-dual pair of linear programs, where $\nabla x_v := \sum_{e \in \delta^+(u)} x_e - \sum_{e \in \delta^-(u)} \gamma_e x_e$ denotes the net flow at a node v .

$$\begin{array}{ll} \min c^\top x & (P_u) \quad \max y_u \quad (D_u) \\ \text{s. t. } \nabla x_u = 1 & \text{s. t. } y_v - \gamma_e y_w \leq c_e \quad \forall e = (v, w) \in E \\ \nabla x_v = 0 \quad \forall v \in V \setminus u & \\ x \geq 0 & \end{array}$$

The primal LP (P_u) is a minimum-cost generalized flow problem with a supply of 1 at node u . It asks for the cheapest way to destroy one unit of flow at u . Observe that it is feasible if and only if u can reach a flow-absorbing cycle in G . If it is feasible, then it is unbounded if and only if there exists a negative unit-gain cycle or a negative bicycle in G . It can be reformulated as the following linear fractional program

$$\inf \frac{c^\top x}{1 - \sum_{e \in \delta^-(u)} \gamma_e x_e} \quad \text{s.t. } 1 - \sum_{e \in \delta^-(u)} \gamma_e x_e > 0, x \in \mathcal{D}. \quad (F_u)$$

with the polyhedron

$$\mathcal{D} := \{x \in \mathbb{R}_+^m : x(\delta^+(u)) = 1, \nabla x_v = 0 \forall v \in V \setminus u\}.$$

Indeed, if x is a feasible solution to (P_u) , then $x/x(\delta^+(u))$ is a feasible solution to (F_u) with the same objective value. This is because $1 - \sum_{e \in \delta^-(u)} \gamma_e x_e / x(\delta^+(u)) = 1/x(\delta^+(u))$. Conversely, if x is a feasible solution to (F_u) , then $x/(1 - \sum_{e \in \delta^-(u)} \gamma_e x_e)$ is a feasible solution to (P_u) with the same objective value. Even though the denominator is an affine function of x , it can be made linear to conform with (F) by working with the polyhedron $\{(x, 1) : x \in \mathcal{D}\}$.

Our goal is to solve (F_u) using Algorithm 1. For a fixed $\delta \in \mathbb{R}$, the value of the parametric function $f(\delta)$ can be written as the following pair of primal and dual LPs respectively

$$\begin{array}{ll}
\min & c^\top x + \delta \sum_{e \in \delta^-(u)} \gamma_e x_e - \delta \\
\text{s. t.} & x \in \mathcal{D} \\
\max & y_u - \delta \\
\text{s. t.} & y_v - \gamma_e \delta \leq c_e \quad \forall e = (v, u) \in \delta^-(u) \\
& y_v - \gamma_e y_w \leq c_e \quad \forall e = (v, w) \notin \delta^-(u).
\end{array}$$

We refer to them as the *primal (resp. dual) LP for $f(\delta)$* , and their corresponding feasible/optimal solution as a *feasible/optimal primal (resp. dual) solution to $f(\delta)$* .

Due to the specific structure of this linear fractional program, a suitable initial point for the Newton–Dinkelbach method can be obtained from any feasible solution to (F_u) . This is a consequence of the unboundedness test given by the following lemma.

► **Lemma 3.4.** *Let x be a feasible solution to (F_u) and $\bar{\delta} := c^\top x / (1 - \sum_{e \in \delta^-(u)} \gamma_e x_e)$. If either $f(\bar{\delta}) = -\infty$ or $f(\bar{\delta}) = c^\top \bar{x} - \bar{\delta}(1 - \sum_{e \in \delta^-(u)} \gamma_e \bar{x}_e) < 0$ for some $\bar{x} \in \mathcal{D}$ with $1 - \sum_{e \in \delta^-(u)} \gamma_e \bar{x}_e \leq 0$, then the optimal value of (F_u) is $-\infty$.*

In order to characterize the finiteness of $f(\delta)$, we introduce the following notion of a negative flow-generating cycle.

► **Definition 3.5.** *For a fixed $\delta \in \mathbb{R}$ and $u \in V$, a flow-generating cycle C is said to be (δ, u) -negative if there exists a path P from a node $v \in V(C)$ to node u such that $c(C) + (\gamma(C) - 1)(c(P) + \gamma(P)\delta) < 0$, where C is treated as a v - v walk in $c(C)$.*

► **Lemma 3.6.** *For any $\delta \in \mathbb{R}$, $f(\delta) = -\infty$ if and only if $\mathcal{D} \neq \emptyset$ and there exists a negative unit-gain cycle, a negative bicycle, or a (δ, u) -negative flow-generating cycle in $G \setminus \delta^+(u)$.*

It turns out that if we have an optimal dual solution y to $f(\delta)$ for some $\delta \in \mathbb{R}$, then we can compute an optimal dual solution to $f(\delta')$ for any $\delta' < \delta$. A suitable subroutine for this task is the so called GRAPEVINE algorithm (Algorithm 2), developed by Aspvall and Shiloach [2].

■ **Algorithm 2** GRAPEVINE.

input : A directed multigraph $G = (V, E)$ with arc costs $c \in \mathbb{R}^m$ and gain factors $\gamma \in \mathbb{R}_{++}^m$, node labels $y \in \mathbb{R}^n$, and a node $u \in V$.
output : Node labels $y \in \mathbb{R}^n$ and a walk P of length at most n starting from u .

```

1 for  $i = 1$  to  $n$  do
2   foreach  $v \in V$  do
3      $y'_v \leftarrow \min(y_v, \min_{vw \in \delta^+(v)} c_{vw} + \gamma_{vw} y_w)$ 
4     if  $y'_v < y_v$  then
5        $\text{pred}(v, i) \leftarrow \arg \min_{vw \in \delta^+(v)} c_{vw} + \gamma_{vw} y_w$  /* Break ties */
6     else
7        $\text{pred}(v, i) \leftarrow \emptyset$ 
8    $y \leftarrow y'$ 
9 Let  $P$  be the walk obtained by tracing from  $\text{pred}(u, n)$ 
10 return  $(y, P)$ 

```

Given initial node labels $y \in \mathbb{R}^n$ and a specified node u , GRAPEVINE runs for n iterations. We say that an arc $e = (v, w)$ is *violated with respect to y* if $y_v > c_e + \gamma_e y_w$. In an iteration $i \in [n]$, the algorithm records the most violated arc with respect to y in $\delta^+(v)$ as $\text{pred}(v, i)$, for each node $v \in V$ (ties are broken arbitrarily). Note that $\text{pred}(v, i) = \emptyset$ if there are

no violated arcs in $\delta^+(v)$. Then, each y_v is decreased by the amount of violation in the corresponding recorded arc. After n iterations, the algorithm traces a walk P from u by following the recorded arcs in reverse chronological order. During the trace, if $\text{pred}(v, i) = \emptyset$ for some $v \in V$ and $i > 1$, then $\text{pred}(v, i - 1)$ is read. Finally, the updated node labels y and the walk P are returned. Clearly, the running time of GRAPEVINE is $O(mn)$.

Given an optimal dual solution $y \in \mathbb{R}^n$ to $f(\delta)$ and $\delta' < \delta$, the dual LP for $f(\delta')$ can be solved using GRAPEVINE as follows. Define the directed graph $G_u := (V \cup \{u'\}, E_u)$ where $E_u := (E \setminus \delta^-(u)) \cup \{vu' : vu \in \delta^-(u)\}$. The graph G_u is obtained from G by splitting u into two nodes u, u' and reassigning the incoming arcs of u to u' . These arcs inherit the same costs and gain factors from their counterparts in G . Let $\bar{y} \in \mathbb{R}^{n+1}$ be node labels in G_u defined by $\bar{y}_{u'} := \delta'$ and $\bar{y}_v := y_v$ for all $v \neq u'$. Then, we run GRAPEVINE on G_u with input node labels \bar{y} and node u . Note that $\bar{y}_{u'}$ remains unchanged throughout the algorithm. The next lemma verifies the correctness of this method.

► **Lemma 3.7.** *Given an optimal dual solution $y \in \mathbb{R}^n$ to $f(\delta)$ and $\delta' < \delta$, define $\bar{y} \in \mathbb{R}^{n+1}$ as $\bar{y}_{u'} := \delta'$ and $\bar{y}_v := y_v$ for all $v \in V$. Let (\bar{z}, P) be the node labels and walk returned by $\text{GRAPEVINE}(G_u, \bar{y}, u)$. If \bar{z}_V is not feasible to the dual LP for $f(\delta')$, then $f(\delta') = -\infty$. Otherwise, \bar{z}_V is a dual optimal solution to $f(\delta')$ and P is a shortest path from u with respect to \bar{y} in G_u .*

If \bar{z}_V is an optimal dual solution to $f(\delta')$, a supergradient in $\partial f(\delta')$ can be inferred from the returned path P . We say that an arc $e = (v, w)$ is *tight with respect to \bar{z}* if $\bar{z}_v = c_e + \gamma_e \bar{z}_w$. By complementary slackness, every optimal primal solution to $f(\delta')$ is supported on the subgraph of G_u induced by tight arcs with respect to \bar{z} . In particular, any u - u' path or any path from u to a flow-absorbing cycle in this subgraph constitutes a basic optimal primal solution to $f(\delta')$. As P is also a path in this subgraph, we have $\gamma(P) - 1 \in \partial f(\delta')$ if P ends at u' . Otherwise, u can reach a flow-absorbing cycle in this subgraph because $\delta' < \delta$. In this case, $-1 \in \partial f(\delta')$.

3.2 A Strongly Polynomial Label-Correcting Algorithm

Using Algorithm 1, we develop a strongly polynomial label-correcting algorithm for solving an M2VPI system (G, c, γ) . The main idea is to start with a subsystem for which (D_u) is trivial, and progressively solve (D_u) for larger and larger subsystems. Throughout the algorithm, we maintain node labels $y \in \mathbb{R}^n$ which form valid upper bounds on each variable. They are initialized to ∞ at every node. We also maintain a subgraph of G , which initially is $G^{(0)} := (V, \emptyset)$.

The algorithm (Algorithm 3) is divided into n phases. At the start of phase $k \in [n]$, a new node $u \in V$ is selected and all of its outgoing arcs in G are added to $G^{(k-1)}$, resulting in a larger subgraph $G^{(k)}$. Since $y_u = \infty$ at this point, we update it to the smallest upper bound implied by its outgoing arcs and the labels of its outneighbours. If y_u is still infinity, then we know that $\delta^+(u) = \emptyset$ or $y_v = \infty$ for all $v \in N^+(u)$. In this case, we find a flow-absorbing cycle at u in $G^{(k)}$ using the multiplicative Bellman–Ford algorithm, by treating the gain factors as arc costs. If there is none, then we proceed to the next phase immediately as y_u is unbounded from above in the subsystem $(G^{(k)}, c, \gamma)$. This is because u cannot reach a flow-absorbing cycle in $G^{(k)}$ by induction. We would like to point out that this does not necessarily imply that the full system (G, c, γ) is feasible (see the full version for details). On the other hand, if Bellman–Ford returns a flow-absorbing cycle, then y_u is set to the upper bound implied by the cycle. Then, we apply Algorithm 1 to solve (D_u) for the subsystem $(G^{(k)}, c, \gamma)$.

■ **Algorithm 3** Label-correcting algorithm for M2VPI systems.

input : An M2VPI system (G, c, γ) .
output : The pointwise maximal solution y^{\max} or the string INFEASIBLE.

```

1 Initialize graph  $G^{(0)} \leftarrow (V, \emptyset)$  and counter  $k \leftarrow 0$ 
2 Initialize node labels  $y \in \bar{\mathbb{R}}^n$  as  $y_v \leftarrow \infty \forall v \in V$ 
3 foreach  $u \in V$  do
4    $k \leftarrow k + 1$ 
5    $G^{(k)} \leftarrow G^{(k-1)} \cup \delta^+(u)$ 
6    $y_u \leftarrow \min_{uv \in \delta^+(u)} c_{uv} + \gamma_{uv} y_v$ 
7   if  $y_u = \infty$  and  $\mathcal{C}_u^{\text{abs}}(G^{(k)}) \neq \emptyset$  then
8      $y_u \leftarrow c(C)/(1 - \gamma(C))$  for any  $C \in \mathcal{C}_u^{\text{abs}}(G^{(k)})$ 
9   if  $y_u < \infty$  then
10    Define node labels  $\bar{y} \in \bar{\mathbb{R}}^{n+1}$  as  $\bar{y}_{u'} \leftarrow y_u$  and  $\bar{y}_v \leftarrow y_v \forall v \in V$ 
11     $(\bar{y}, P) \leftarrow \text{GRAPEVINE}(G_u^{(k)}, \bar{y}, u)$ 
12    if  $\exists$  a violated arc w.r.t.  $\bar{y}$  in  $G_u^{(k)}$  or  $(|E(P)| > 0 \text{ and } \gamma(P) \geq 1)$  then
13      return INFEASIBLE
14     $\bar{y}_{u'} \leftarrow \text{LOOK-AHEAD-NEWTON}(\text{GRAPEVINE}(G_u^{(k)}, \cdot, u), \bar{y}_{u'}, \gamma(P) - 1)$ 
15    if  $\bar{y}_{u'} = \text{NO ROOT}$  then
16      return INFEASIBLE
17     $y \leftarrow \bar{y}_V$ 
18 return  $y$ 

```

The value and supergradient oracle for the parametric function $f(\delta)$ is GRAPEVINE. Let $G_u^{(k)}$ be the modified graph and $\bar{y} \in \bar{\mathbb{R}}^{n+1}$ be the node labels as defined in the previous subsection. In order to provide Algorithm 1 with a suitable initial point and supergradient, we run GRAPEVINE on $G_u^{(k)}$ with input node labels \bar{y} . It updates \bar{y} and returns a walk P from u . If \bar{y}_V is not feasible to the dual LP for $f(\bar{y}_{u'})$ or P is a non-trivial walk with $\gamma(P) \geq 1$, then we declare infeasibility. Otherwise, we run Algorithm 1 with the initial point $\bar{y}_{u'}$ and supergradient $\gamma(P) - 1$. We remark that GRAPEVINE continues to update \bar{y} throughout the execution of Algorithm 1.

► **Theorem 3.8.** *If Algorithm 3 returns $y \in \bar{\mathbb{R}}^n$, then $y = y^{\max}$ if the M2VPI system is feasible. Otherwise, the system is infeasible.*

We would like to point out that Algorithm 3 may return node labels $y \in \bar{\mathbb{R}}^n$ even if the M2VPI system is infeasible. This happens when y contains ∞ entries. It is well-known how to ascertain the system's feasibility status in this case. We refer the reader to the full version for details.

To bound the running time of Algorithm 3, it suffices to bound the running time of Algorithm 1 in every phase. Our strategy is to analyze the sequence of paths whose gain factors determine the right derivative of f at each iterate of Algorithm 1. The next property is crucial in our arc elimination argument.

► **Definition 3.9.** *Let $\mathcal{P} = (P^{(1)}, P^{(2)}, \dots, P^{(\ell)})$ be a sequence of paths from u . We say that \mathcal{P} satisfies subpath monotonicity at u if for every pair $P^{(i)}, P^{(j)}$ where $i < j$ and for every shared node $v \neq u$, we have $\gamma(P_{uv}^{(i)}) \leq \gamma(P_{uv}^{(j)})$.*

► **Lemma 3.10.** *Let $\delta^{(1)} > \delta^{(2)} > \dots > \delta^{(\ell)}$ be a decreasing sequence of iterates. For each $\delta^{(i)} \in \mathbb{R}$, let $P^{(i)}$ be a u - u' path in G_u on which a unit flow is an optimal primal solution to $f(\delta^{(i)})$. Then, the sequence $(P^{(1)}, P^{(2)}, \dots, P^{(\ell)})$ satisfies subpath monotonicity at u .*

Proof. For each $i \in [\ell]$, let $y^{(i)} \in \mathbb{R}^n$ be an optimal dual solution to $f(\delta^{(i)})$. Let $\bar{y}^{(i)} \in \mathbb{R}^{n+1}$ be the node labels in G_u defined by $\bar{y}_{u'}^{(i)} := \delta^{(i)}$ and $\bar{y}_v := y_v$ for all $v \neq u'$. By complementary slackness, every arc in $P^{(i)}$ is tight with respect to $\bar{y}^{(i)}$. Hence, $P^{(i)}$ is a shortest u - u' path in G_u with respect to $\bar{y}^{(i)}$. Now, pick a pair of paths $P^{(i)}$ and $P^{(j)}$ such that $i < j$ and they share a node $v \neq u$. Then, the subpaths $P_{uv}^{(i)}$ and $P_{uv}^{(j)}$ are also shortest u - v paths in G_u with respect to $\bar{y}^{(i)}$ and $\bar{y}^{(j)}$ respectively. Observe that $\bar{y}_v^{(i)} > \bar{y}_v^{(j)}$ because $\bar{y}_{u'}^{(i)} = \delta^{(i)} > \delta^{(j)} = \bar{y}_{u'}^{(j)}$. Define the function $\psi : [\bar{y}_v^{(j)}, \bar{y}_v^{(i)}] \rightarrow \mathbb{R}$ as

$$\psi(x) := \inf \{c(P) + \gamma(P)x : P \text{ is a } u\text{-}v \text{ walk in } G_u\}.$$

Clearly, it is increasing and concave. It is also finite because $\psi(\bar{y}_v^{(i)}) = c(P_{uv}^{(i)}) + \gamma(P_{uv}^{(i)})\bar{y}_v^{(i)}$ and $\psi(\bar{y}_v^{(j)}) = c(P_{uv}^{(j)}) + \gamma(P_{uv}^{(j)})\bar{y}_v^{(j)}$. Subpath monotonicity then follows from the concavity of ψ . ◀

► **Theorem 3.11.** *In each phase k of Algorithm 3, Algorithm 1 terminates in $O(|E(G^{(k)})|)$ iterations.*

The full proof is given in the full version; we highlight some key steps. Let $m_k := |E(G^{(k)})|$. Let $\bar{y} = (\bar{y}^{(1)}, \bar{y}^{(2)}, \dots, \bar{y}^{(\ell)})$ be a sequence of node labels at the start of every iteration of Algorithm 1 in phase k . Let $\mathcal{P} = (P^{(2)}, P^{(3)}, \dots, P^{(\ell)})$ be a sequence of u - u' paths in $G_u^{(k)}$ such that $P^{(i)}$ determines the right derivative $f'_+(\bar{y}_{u'}^{(i)})$ for all $i > 1$. Perturb $\hat{c} := c + \varepsilon \chi_{\delta^{(u)}}$ by a suitably small $\varepsilon \geq 0$ such that the system $(G^{(k)}, \hat{c}, \gamma)$ is feasible. Let $y^* \in \mathbb{R}^n$ be its pointwise maximal solution, and define the reduced cost $c^* \in \mathbb{R}_+^{m_k}$ as $c_{vw}^* := \hat{c}_{vw} + \gamma_{vw}y_{vw}^* - y_v^*$ for all $vw \in E(G^{(k)})$. For every arc $vw \in \cup_{i=1}^{\ell} E(P^{(i)})$, let r_{vw} be the largest gain factor of the u - v subpath of the paths in \mathcal{P} that contain vw . By Lemma 3.10, this is achieved by the last path in \mathcal{P} which contains vw . Order the elements of $r \circ c^*$ as $0 \leq r_1 c_1^* \leq r_2 c_2^* \leq \dots \leq r_{m_k} c_{m_k}^*$, and let $d_i := \sum_{j=1}^i r_j c_j^*$ for every $i \in [m_k]$. The final step is showing that every interval $(d_i, d_{i+1}]$ contains the cost of at most two paths from \mathcal{P} . This can be derived from the Bregman divergence analysis, that yields $c^*(P^{(i)}) \leq \frac{1}{2}c^*(P^{(i-2)})$ for all $3 \leq i \leq \ell$.

The runtime of every iteration of Algorithm 1 is dominated by GRAPEVINE. Thus, we obtain the following result.

► **Corollary 3.12.** *Algorithm 3 solves the feasibility of M2VPI linear systems in $O(m^2 n^2)$ time.*

Abstract

We study the 3-COLORING problem in graphs with small diameter. In 2013, Mertzios and Spirakis showed that for n -vertex diameter-2 graphs this problem can be solved in subexponential time $2^{\mathcal{O}(\sqrt{n \log n})}$. Whether the problem can be solved in polynomial time remains a well-known open question in the area of algorithmic graphs theory.

In this paper we present an algorithm that solves 3-COLORING in n -vertex diameter-2 graphs in time $2^{\mathcal{O}(n^{1/3} \log^2 n)}$. This is the first improvement upon the algorithm of Mertzios and Spirakis in the general case, i.e., without putting any further restrictions on the instance graph.

In addition to standard branchings and reducing the problem to an instance of 2-SAT, the crucial building block of our algorithm is a combinatorial observation about 3-colorable diameter-2 graphs, which is proven using a probabilistic argument.

As a side result, we show that 3-COLORING can be solved in time $2^{\mathcal{O}((n \log n)^{2/3})}$ in n -vertex diameter-3 graphs. We also generalize our algorithms to the problem of finding a list homomorphism from a small-diameter graph to a cycle.

1 Introduction

For many NP-hard graph problems, the instances constructed in hardness reductions are very specific and “unstructured”. Thus a natural direction of research is to study how additional restrictions imposed on the input graphs affect the complexity of the problem. In particular, we would like to understand if the additional knowledge about the structure of the instance makes the problem easier, and what are the “minimal” sets of restrictions that we need to impose in order to make the problem efficiently solvable.

Usually, the main focus in the area is on *hereditary* classes of graphs, i.e., classes that are closed under vertex deletion. Prominent examples are perfect graphs [7, 18], graphs excluding a certain induced subgraph [17] or minor [11], and intersection graphs of geometric objects [19]. Studying these classes has led to a better understanding of the structure of such graphs [8, 9, 20, 29] and a discovery of numerous exciting algorithmic techniques [2, 10, 15, 16, 24]. Let us point out that the property of being hereditary is particularly useful in the construction of recursive algorithms based on branching or the divide & conquer paradigm.

However, there are many natural classes of graphs that are not hereditary, for example graphs with bounded diameter. Such graphs are interesting not only for purely theoretical reasons: for example social networks tend to have small diameter [30].

Observe that for any graph G , a graph G^+ obtained from G by adding a universal vertex has diameter 2. Since the graph G may be arbitrarily complicated, the fact that G^+ has small diameter does not imply that its structure is simple. This observation can be used to show that many classic computational problems are NP-hard for graphs of bounded diameter and they cannot be solved in subexponential time under the ETH. For instance, the size of a maximum independent set in G^+ is equal to the size of a maximum independent set in G , and thus MAX INDEPENDENT SET in diameter-2 graph is NP-hard and cannot be solved in subexponential time, unless the ETH fails.

A similar argument applies to k -COLORING: the graph G^+ is k -colorable if and only if G is $(k - 1)$ -colorable. Thus, for any $k \geq 4$, the k -COLORING problem is NP-hard and admits no subexponential-time algorithm (under the ETH) in diameter-2 graphs. However, the reasoning above breaks down for $k = 3$, as 2-COLORING is polynomial-time solvable.

This peculiar open case was first studied by Mertzios, Spirakis [26] who proved that the problem can be solved in *subexponential time*. The result holds even for the more general LIST 3-COLORING problem, where each vertex v of the instance graph is equipped with a *list* $L(v) \subseteq \{1, 2, 3\}$, and we ask for a proper coloring, in which every vertex gets a color from its list.

► **Theorem 1** (Mertzios, Spirakis [26]). *The LIST 3-COLORING problem on n -vertex graphs with diameter 2 can be solved in time $2^{\mathcal{O}(\sqrt{n \cdot \log n})}$.*

Their algorithm is based on a simple win-win argument. The first ingredient is a well-known fact that every graph with n vertices and minimum degree δ has a dominating set of size $\mathcal{O}\left(\frac{n \log \delta}{\delta}\right)$ [1, Theorem 1.2.2]. On the other hand, in a diameter-2 graph, the neighborhood of each vertex is a dominating set, so there is a dominating set of size δ . Thus, every diameter-2 graph has a dominating set S of size $\mathcal{O}\left(\min(\delta, \frac{n \log \delta}{\delta})\right)$ which is upper-bounded by $\mathcal{O}(\sqrt{n \log n})$.

We exhaustively guess the coloring of vertices in S and update the lists of their neighbors. Note that after this, each uncolored vertex has at least one colored neighbor, and thus each list has at most 2 elements. A classic result by Edwards [12] shows that such a problem can be solved in polynomial time by a reduction to 2-SAT. Summing up, the complexity of the algorithm is bounded by $2^{|S|} \cdot n^{\mathcal{O}(1)} = 2^{\mathcal{O}(\sqrt{n \log n})}$.

Let us point out that the bound \sqrt{n} appears naturally for different parameters of diameter-2 graphs, for example the maximum degree of such a graph is $\Omega(\sqrt{n})$. Based on this, one can also construct different algorithms for LIST 3-COLORING in diameter-2 graphs with running time matching the one of Theorem 1 (see Section 3).

If it comes to 3-COLORING in diameter-3 graphs, Mertzios and Spirakis [26] proved that the problem is NP-hard, but their reduction is quadratic. Thus, under the ETH, the problem cannot be solved in time $2^{o(\sqrt{n})}$. Actually, the authors carefully analyzed how the lower bound depends on the minimum degree of the input graph, and presented three hardness reductions, each for a different range of δ . Furthermore, they showed that the problem can be solved in time $2^{\mathcal{O}(\min(\delta \cdot \Delta, \frac{n \log \delta}{\delta}))}$, where Δ is the maximum degree. The argument again follows from the observation that each diameter-3 graph has a dominating set of size at most $\delta \cdot \Delta$. Let us point out that if $\Delta = \Theta(n)$ and $\delta = \mathcal{O}(1)$, then the running time is exponential in n . In Figure 1 we summarize the results for diameter-3 graphs with given minimum degree.

■ **Figure 1** The complexity of LIST 3-COLORING in n -vertex diameter-3 graphs with minimum degree $\Theta(n^\varepsilon)$ for $\varepsilon \in [0, 1]$. The complexity bound is of the form $2^{\mathcal{O}(n^\beta \cdot \log^{\mathcal{O}(1)} n)}$ for $\beta \in [0, 1]$.

The story stops at diameter 3: a textbook reduction from NAE-SAT to 3-COLORING builds a graph with diameter 4 and number of vertices linear in the size of the formula [27, Theorem 9.8]. This proves that the 3-COLORING problem in diameter-4 graphs is NP-hard and cannot be solved in subexponential time, unless the ETH fails.

Closing the gaps left by Mertzios and Spirakis [26], and in particular determining the complexity of 3-COLORING in diameter-2 graphs, is a notorious open problem in the area of graph algorithms. We know polynomial-time algorithms if some additional restrictions are imposed on the instance [21, 23]. However, to the best of our knowledge, no progress in the general case has been achieved.

Let us also point out that some other problems, including different variants of graph coloring, have also been studied for small-diameter graphs [3, 5, 6, 22].

Our results. As our first result, in Section 3 we show a simple subexponential-time algorithm for the LIST 3-COLORING problem in diameter-3 graphs.

► **Theorem 2.** *The LIST 3-COLORING problem on n -vertex graphs with diameter 3 can be solved in time $2^{\mathcal{O}(n^{2/3} \cdot \log^{2/3} n)}$.*

Note that the running time bound does not depend on the maximum nor the minimum degree of the input graph. In particular, this is the *first* algorithm for LIST 3-COLORING, whose complexity is subexponential for *all* diameter-3 graphs, see Figure 1.

Let us present a high-level overview of the proof. We partition the vertex set of our graph into three sets V_1, V_2, V_3 , where V_i contains the vertices with lists of size i . If the graph contains a vertex $v \in V_2 \cup V_3$ with at least $n^{1/3}$ neighbors in $V_2 \cup V_3$, then we can effectively branch on the color of v . Otherwise, we observe that for any $v \in V_2 \cup V_3$, the set S of vertices at distance at most 2 from v in the graph induced by sets $V_2 \cup V_3$ dominates V_3 , i.e., every vertex from V_3 is in S or has a neighbor in S . Thus, after exhaustively guessing the coloring of S , all lists are reduced to size at most 2 and then we can finish in polynomial time, using the already-mentioned result of Edwards [12].

In Section 4 we prove the following theorem, which is the main result of the paper.

► **Theorem 3.** *The LIST 3-COLORING problem on n -vertex graphs with diameter 2 can be solved in time $2^{\mathcal{O}(n^{1/3} \cdot \log^2 n)}$.*

Again, let us give some intuition about the proof. We partition the vertex set of G into (V_1, V_2, V_3) , as previously. We aim to empty the set V_3 , as then the problem can be solved in polynomial time. We start with applying three branching rules. The first one is similar as in the proof of Theorem 2: if we find a vertex v with many neighbors in V_3 , we can branch on choosing the color of v . The other two branching rules are somewhat technical and their purpose is not immediately clear, so let us not discuss them here.

The main combinatorial insight that is used in our algorithm is as follows. Consider an instance (G, L) , where G is of diameter 2 and none of the previous branching rules can be applied. Suppose that G has a proper 3-coloring φ that respects lists L . Then there is a color $a \in \{1, 2, 3\}$ and sets $S \subseteq V_3 \cap \varphi^{-1}(a)$ and $\tilde{S} \subseteq V_3 \setminus \varphi^{-1}(a)$, each of size $\mathcal{O}(n^{1/3} \log n)$, with the following property:

(★) $S \cup \tilde{S} \cup (N(S) \cap N(\tilde{S}))$ dominates at least $\frac{1}{6}$ -fraction of V_3 ,

where $N(S)$ (resp. $N(\tilde{S})$) denotes the set of vertices with a neighbor in S (resp. \tilde{S}). The existence of the sets S and \tilde{S} is shown using a probabilistic argument.

Now we proceed as follows. We enumerate all pairs of disjoint sets S and \tilde{S} , each of size $\mathcal{O}(n^{1/3} \log n)$. If they satisfy the property (★), we exhaustively guess the color a used for every vertex of S and the coloring of \tilde{S} with colors $\{1, 2, 3\} \setminus \{a\}$. Then we update the lists of the neighbors of colored vertices. Note that the color of every vertex from $N(S) \cap N(\tilde{S})$ is now uniquely determined. Thus, for at least $\frac{1}{6}$ -fraction of vertices $v \in V_3$, they are either already colored or have a colored neighbor and thus their lists are of size at most 2. Thus our instance was significantly simplified and we can proceed recursively.

Finally, in Section 5 we investigate possible extensions of our algorithms to some generalizations of (LIST) 3-COLORING. We observe that our approach can be used to obtain subexponential-time algorithms for the problem of finding a *list homomorphism* from a graph with diameter at most 3 to certain graphs, including in particular all cycles. We refer to Section 5.1 for the definition of the problem and the precise statement of our results; let us just point out that under the ETH the problems considered there cannot be solved in subexponential time in general graphs [13, 14]

We conclude with discussing the possibility of extending our algorithms to weighted coloring problems, with INDEPENDENT ODD CYCLE TRANSVERSAL [4] as a prominent special case.

2 Preliminaries

For an integer n , we denote $[n] := \{1, 2, \dots, n\}$. For a set X , by 2^X we denote the family of all subsets of X . All logarithms in the paper are natural.

Let $G = (V, E)$ be a connected graph. For two vertices u and v , by $\text{dist}_G(u, v)$ we denote the distance from u to v , i.e., the number of edges on a shortest u - v path in G . The *diameter* of G , denoted by $\text{diam}(G)$, is the maximum value of $\text{dist}(u, v)$ over all $u, v \in V$.

For a vertex v , by $N_G(v)$ we denote its *open neighborhood*, i.e., the set of all vertices adjacent to v . The *closed neighborhood* of v is defined as $N_G[v] := N_G(v) \cup \{v\}$. For an integer p , by $N_G^{\leq p}[v]$ we denote the set of vertices at distance at most p from v , and define $N_G^{\leq p}(v) := N_G^{\leq p}[v] \setminus \{v\}$. For a set X of vertices, we define $N_G(X) := \bigcup_{v \in X} N_G(v) \setminus X$ and $N_G[X] := N_G(X) \cup X$. For sets $X, Y \subseteq V$, we say that X *dominates* Y if $Y \subseteq N_G[X]$. By $\deg_G(v)$ we denote the *degree* of a vertex v , i.e., $|N_G(v)|$.

If the graph G is clear from the context, we drop the subscript in the notation above and simply write $\text{dist}(u, v)$, $N(v)$, etc. By $\Delta(G)$ we denote the maximum vertex degree in G .

The following result by Edwards [12] will be an important tool used in all our algorithms.

► **Theorem 4** (Edwards [12]). *Let $G = (V, E)$ be a graph and let $L : V \rightarrow 2^{\mathbb{N}}$ be a list assignment, such that for every $v \in V$ it holds that $|L(v)| \leq 2$. Then in polynomial time we can decide whether G admits a proper vertex coloring that respects lists L .*

Reduction rules. Let (G, L) be an instance of the LIST 3-COLORING problem. It is straightforward to observe that the following reduction rules can be safely applied, as they do not change the set of solutions. Moreover, each of them can be applied in polynomial time.

R1 If there exists a vertex v such that $L(v)$ contains only one color a , then remove a from $L(u)$ for each vertex $u \in N(v)$.

R2 If there exists a vertex v such that $|L(v)| = 0$, then report failure.

R3 If $|L(v)| \leq 2$ for each vertex v , then solve the problem using Theorem 4.

An instance (G, L) for which none of the reduction rules can be applied is called *reduced*. Note that the reduction rules do not remove any vertices from the graph, even if their color is fixed. This is because such an operation might increase the diameter.

Layer structure. Let (G, L) be a reduced instance of LIST 3-COLORING. For $i \in [3]$, let V_i be the set of vertices v of G , such that $|L(v)| = i$. Note that (V_1, V_2, V_3) is a partition of V ; we will call it the *layer structure* of G . Observe that since R1 cannot be applied to (G, L) , it holds that $N(V_1) \subseteq V_2$, i.e., there are no edges between V_1 and V_3 .

We conclude this section with an important observation about layer structures of graphs with diameter at most 3.

► **Proposition 5.** *Let (G, L) be a reduced instance of LIST 3-COLORING, where G has diameter $d \leq 3$, and let (V_1, V_2, V_3) be the layer structure of G . Then, for any $u, v \in V_2 \cup V_3$, at least one of the following holds:*

- a) u and v are at distance at most d in $G[V_2 \cup V_3]$, or
- b) $\{u, v\} \cap V_2 \neq \emptyset$.

Proof. If $V_1 = \emptyset$, then the first outcome follows, since $G = G[V_2 \cup V_3]$. So assume that $V_1 \neq \emptyset$. Consider $u, v \in V_3$ and suppose that they are not at distance at most d in $G[V_2 \cup V_3]$. Since they are at distance at most d in G , all shortest u - v -paths in G must intersect V_1 . However, for any $x \in V_1$, it holds that $\text{dist}(u, x) \geq 2$ and $\text{dist}(v, x) \geq 2$. Thus $\text{dist}(u, v) \geq 4$, contradicting the fact that $\text{diam}(G) \leq 3$. ◀

Observe that Proposition 5 does not generalize to diameter-4 graphs: consider e.g. 5-vertex path P_5 with consecutive vertices v_1, v_2, v_3, v_4, v_5 , where $V_1 = \{v_3\}$. Vertices v_1 and v_5 are in V_3 , they are at distance 4 in P_5 , but not in $P_5[V_2 \cup V_3] = P_5 - \{v_3\}$. For $d = 2$ Proposition 5 can be strengthened by replacing part (b) with $\{u, v\} \subseteq V_2$

Proposition 5 immediately yields the following corollary.

► **Corollary 6.** *Let (G, L) be an instance of the LIST 3-COLORING, where G has diameter $d \in \{2, 3\}$, and let (V_1, V_2, V_3) be the layer structure of G . For every $v \in V_3$, the set $N_{G[V_2 \cup V_3]}^{\leq d-1}[v]$ dominates V_3 .*

3 Coloring diameter-3 graphs

In this section we present a simple proof of Theorem 2. Actually, we will show the following more general result, which yields a $2^{\mathcal{O}(\sqrt{n \log n})}$ -algorithm for diameter-2 graphs; it implies Theorem 1, but the proof is different than the one originally given by Mertzios and Spirakis [26]. This will serve as a warm-up before showing our main result, i.e., Theorem 3.

► **Theorem 7.** *The LIST 3-COLORING problem on n -vertex graphs G can be solved in time:*

1. $2^{\mathcal{O}(n^{1/2} \log^{1/2} n)}$, if $\text{diam}(G) = 2$,
2. $2^{\mathcal{O}(n^{2/3} \log^{2/3} n)}$, if $\text{diam}(G) = 3$.

Proof. Let (G, L) be an instance of LIST 3-COLORING, where G has n vertices and diameter $d \in \{2, 3\}$. Without loss of generality we may assume that it is reduced. Let (V_1, V_2, V_3) be the layer structure of (G, L) and let us define a measure $\mu := 2|V_2| + 3|V_3|$.

First, consider the case that there is a vertex $v \in V_2 \cup V_3$ with at least $(\mu \log \mu)^{1/d}$ neighbors in $V_2 \cup V_3$. Since each vertex of $V_2 \cup V_3$ has one of four possible lists, there is a subset of at least $\frac{(\mu \log \mu)^{1/d}}{4}$ neighbors of v that all have the same list L' . Note that there is $a \in L(v) \cap L'$ since both are subsets of size at least 2 of a set of size 3. We branch on coloring the vertex v with color a or not. In other words, in the first branch we remove from $L(v)$ all elements but a , and in the other one we remove a from $L(v)$. Note that after reducing the obtained instance, at least $\frac{(\mu \log \mu)^{1/d}}{4}$ vertices will lose at least one element from their list in the first branch.

We can bound the number of instances produced by applying this step exhaustively as follows:

$$F(\mu) \leq F\left(\mu - \frac{(\mu \log \mu)^{1/d}}{4}\right) + F(\mu - 1).$$

Solving this inequality, we obtain that $F(\mu) = \mu^{\mathcal{O}\left(\frac{\mu}{(\mu \log \mu)^{1/d}}\right)} = 2^{\mathcal{O}((\mu \log \mu)^{1-1/d})}$.

Now consider the remaining case that $\Delta(G[V_2 \cup V_3]) < (\mu \log \mu)^{1/d}$. Recall that since the reduction rule R3 cannot be applied, it holds that $V_3 \neq \emptyset$. Pick any vertex $v \in V_3$. Define $X := N_{G[V_2 \cup V_3]}^{\leq d-1}[v]$; by Corollary 6, the set X dominates V_3 . Furthermore

$$|X| \leq 1 + \Delta(G[V_2 \cup V_3])^{d-1} = \mathcal{O}((\mu \log \mu)^{(d-1)/d}).$$

We exhaustively guess the coloring of X , which results in at most $3^{|X|} = 2^{\mathcal{O}((\mu \log \mu)^{1-1/d})}$ branches. As X dominates V_3 , after applying the reduction rule R1 to every vertex of X , in each branch there are no vertices with three-element lists. Therefore, the instance obtained in each of the branches is solved in polynomial time using reduction rule R3. The claimed bound follows since $\mu \leq 3n$. ◀

4 Coloring diameter-2 graphs

In this section we prove the main result of the paper, i.e., Theorem 3. Let us recall the following variant of the Chernoff concentration bound.

► **Theorem 8** ([25, Theorem 2.3]). *Let X_1, \dots, X_n be independent random variables with $0 \leq X_i \leq 1$ for each i . Let $X = \sum X_i$ and $\bar{X} = \mathbb{E}[X]$.*

(1) *For any $\varepsilon > 0$,*

$$\Pr(X \geq (1 + \varepsilon)\bar{X}) \leq e^{-\frac{\varepsilon^2 \bar{X}}{2(1 + \varepsilon/3)}}.$$

(2) For any $\varepsilon > 0$,

$$\Pr(X \leq (1 - \varepsilon)\overline{X}) \leq e^{-\frac{\varepsilon^2 \overline{X}}{2}}.$$

It will be more convenient to work with random variables for which we only know bounds on the expected value. For this reason we will use the following corollary of Theorem 8.

► **Corollary 9.** Let X_1, \dots, X_n be independent random variables with $0 \leq X_i \leq 1$ for each i . Let $X = \sum X_i$.

(1) For any $\varepsilon > 0$ and $\hat{X} \geq \mathbb{E}[X]$,

$$\Pr(X \geq (1 + \varepsilon)\hat{X}) \leq e^{-\frac{\varepsilon^2 \hat{X}}{2(1+\varepsilon/3)}}.$$

(2) For any $\varepsilon > 0$ and $\hat{X} \leq \mathbb{E}[X]$,

$$\Pr(X \leq (1 - \varepsilon)\hat{X}) \leq e^{-\frac{\varepsilon^2 \hat{X}}{2}}.$$

Proof. Clearly, if $\hat{X} = \mathbb{E}[X]$, then (1) and (2) follow directly from Theorem 8. So since now assume that this is not the case. In order to prove (1) let us consider a random variable $Y = X + Y_1 + Y_2 + \dots + Y_k$, where $k = \lceil \hat{X} - \mathbb{E}[X] \rceil$ and each Y_i is a constant equal to $\frac{\hat{X} - \mathbb{E}[X]}{k}$. Clearly $\mathbb{E}[Y] = \hat{X}$ and $Y \geq X$, so the statement follows by Theorem 8 (1).

For (2) it is enough to apply Theorem 8 (2) for the random variable $Y = X - \frac{\hat{X}}{\mathbb{E}[X]}$. ◀

We start with a technical lemma that is the crucial ingredient of our algorithm.

► **Lemma 10.** There exists an absolute constant K such that the following is true. Let G be a 3-colorable graph with n vertices such that

- (i) $\Delta(G) \leq n^{2/3}$,
- (ii) for every $v \in V(G)$, the set $N_G^{\leq 2}(v)$ contains at least $n - \frac{1}{36}n^{2/3}$ vertices,
- (iii) for every two vertices $u, v \in V(G)$ there are at most $n^{2/3}$ vertices w such that $N_G(u) \cap N_G(v) \cap N_G(w) \neq \emptyset$.

Let φ be a proper 3-coloring of G , where $a \in [3]$ is the color that appears most frequently. Define $A := \varphi^{-1}(a)$. Then there exist sets $S \subseteq A$ and $\tilde{S} \subseteq V(G) \setminus A$, each of size at most $K \cdot n^{1/3} \log n$, such that $S \cup \tilde{S} \cup (N(S) \cap N(\tilde{S}))$ dominates at least $\frac{n}{6}$ vertices.

Before we prove Lemma 10, let us explain its purpose. Suppose that G is a graph with diameter at most 2 and we are trying to find a 3-coloring of G under the promise that it exists. We start by assigning to each vertex a list of 3 possible colors. Note that if we correctly guess a set S of vertices of the most frequent color a and a set \tilde{S} of vertices together with its coloring using colors $[3] \setminus \{a\}$, then we can deduce the color of each vertex in $N(S) \cap N(\tilde{S})$. Hence, our reduction rules will remove at least one color from the list of each vertex dominated by $S \cup \tilde{S} \cup (N(S) \cap N(\tilde{S}))$. If the sets S and \tilde{S} are as in the lemma, then we have just removed at least $\frac{n}{6}$ colors from all the lists by guessing the coloring of only $\mathcal{O}(n^{1/3} \log n)$ vertices. This is roughly why our algorithm is much faster than an exhaustive search.

The assumptions of the lemma can be read as follows: (i) vertices in G do not have too many neighbors, (ii) G is almost a graph with diameter 2 and (iii) common neighbors of every two vertices u and v do not dominate too many vertices of the graph. As we will see later, those assumptions arise naturally when trying to solve the problem using simple branching rules – if any of them is violated, then searching for a 3-coloring of G becomes easier because of other reasons.

■ **Figure 2** The vertex u threatens w : if $f(x_{uw}) \in \tilde{S}$ and $u \in S$, then w has a neighbor with uniquely determined color.

Proof of Lemma 10. Note that we can assume that $n \geq n_0$, where n_0 is a constant that implicitly follows from the reasoning below. Indeed, otherwise it is sufficient to set $K := n_0$, $S := A$, and $\tilde{S} := V(G) \setminus A$. Thus from now on we assume that n is sufficiently large.

For every two vertices $u, v \in V(G)$ such that $N[u] \cap N[v] \neq \emptyset$, let x_{uv} be a vertex from $N[u] \cap N[v]$. Fix some vertex $v_a \in A$ and a function $f : N^{\leq 2}(v_a) \rightarrow N(v_a)$ defined such that $f(u) \in N[u] \cap N(v_a)$.

We start by selecting \tilde{S} as a subset of neighbors of v_a . For such a set \tilde{S} we say that a vertex $u \in A$ *threatens* a vertex $w \in A$ if

- (1) $N[u] \cap N[w] \neq \emptyset$,
- (2) $x_{uw} \in N^{\leq 2}(v_a)$, and
- (3) $f(x_{uw}) \in \tilde{S}$.

Intuitively, u threatens w if selecting u to S would undoubtedly cause w to be dominated by $S \cup \tilde{S} \cup (N(S) \cap N(\tilde{S}))$, see Figure 2. The following claim gives us a set \tilde{S} such that each vertex of A is threatened by many vertices.

▷ **Claim 11.** There exists a set $\tilde{S} \subseteq N(v_a)$ of order at most $200n^{1/3} \log n$ such that for at least half of vertices $w \in A$ there are at least $8n^{2/3} \log n$ vertices from A that threaten w .

Proof. We select \tilde{S} randomly in such a way that each neighbor of v_a is included in \tilde{S} independently with probability $\tilde{p} = 100n^{-1/3} \log n$. We will show that \tilde{S} satisfies the desired properties with positive probability.

Note that the size of \tilde{S} is a sum of $\deg(v_a)$ independent random boolean variables and the expected value of $|\tilde{S}|$ is $\deg(v_a) \cdot \tilde{p}$. Recall that by the assumption (i) we have $\deg(v_a) \leq n^{2/3}$. Therefore by Corollary 9 (1) applied with $\varepsilon = 1$ we deduce that

$$\Pr(|\tilde{S}| > 200n^{1/3} \log n) \leq e^{-37.5n^{1/3} \log n}.$$

Let $A' \subseteq A$ be the set of those $v \in A$, for which the set $N(N(v) \setminus N^{\leq 2}(v_a))$ contains fewer than half of vertices from A . We will show that $|A'| \geq \frac{1}{2}|A|$. First, let us estimate the number P of ordered pairs of vertices (u, v) such that u and v have a common neighbor outside of $N^{\leq 2}(v_a)$. By (i) each vertex outside of $N^{\leq 2}(v_a)$ can be a common neighbor for at most $n^{4/3}$ pairs of vertices, so (ii) implies that $P \leq \frac{1}{36}n^2$. Note that a vertex from A is not contained in A' only if it is in at least $|A|$ ordered pairs that contribute to P . It follows that A' contains at least $|A| - \frac{2P}{|A|}$ vertices. Since a is the most frequent color used by the 3-coloring φ , we have $|A| \geq \frac{1}{3}n$, and thus $|A'| \geq \frac{1}{2}|A|$, as desired.

Fix a vertex w from A' . Consider a random variable X_w that counts the number of vertices u from A such that u threatens w and $N(u) \cap N(w) \subseteq N^{\leq 2}(v_a)$. Our plan is to use Corollary 9 to show that X_w is at least $8n^{2/3} \log n$ with high probability.

We start by estimating the expected value of X_w . Let U be the set of vertices $u \in A$ such that $N(u) \cap N(w) \subseteq N^{\leq 2}(v_a)$; note that by the definition of U , there is a vertex in $N[u] \cap N[w] \cap N^{\leq 2}(v_a)$, so x_{uw} and $f(x_{uw})$ exist for all vertices $u \in U$. Each vertex $u \in U$

contributes 1 to X_w if and only if $f(x_{uw}) \in \tilde{S}$, i.e., with probability \tilde{p} . Since $w \in A'$, the size of U is at least $\frac{1}{2}|A|$ minus the number of vertices outside of $N^{\leq 2}(w)$, which totals to at least $\frac{n}{6} - \frac{1}{36}n^{2/3}$ by (ii). Therefore, $\mathbb{E}[X_w] \geq 16n^{2/3} \log n$ for large enough n .

Now we express X_w as a sum of a number of independent random variables. Fix an ordering $t_1, t_2, \dots, t_{\deg(v_a)}$ of neighbors of v_a and define U_i as the set of vertices u from U such that $x_{uw} \in N^{\leq 2}(v_a)$ and $f(x_{uw}) = t_i$. For $i = 1, 2, \dots, \deg(v_a)$ let X_i be a random variable that is equal to $|U_i|$ if $t_i \in \tilde{S}$ and 0 otherwise. Clearly $X_w = \sum_i X_i$ and all the variables $X_1, \dots, X_{\deg(v_a)}$ are independent by the independent selection of \tilde{S} .

By (iii), applied for w and t_i , we obtain that $X_i \leq n^{2/3}$ for all i . Therefore we may use Corollary 9 (2) for the sequence of variables $\frac{X_i}{n^{2/3}}$ and $\varepsilon = \frac{1}{2}$ to deduce that

$$\Pr\left(\frac{X_w}{n^{2/3}} \leq 8 \log n\right) \leq e^{-2 \log n},$$

which gives that

$$\Pr(X_w \leq 8n^{2/3} \log n) \leq n^{-2}.$$

By the union bound we obtain that the probability that \tilde{S} has more than $200n^{1/3} \log n$ vertices or that $X_w < 8n^{2/3} \log n$ for any $w \in A'$ is at most $n \cdot n^{-2} + n^{-37.5n^{1/3}}$. Therefore, for large enough n the set \tilde{S} satisfies the required properties with positive probability, so the proof of the claim is complete. \triangleleft

Having selected \tilde{S} , we proceed to selecting S as a subset of A that guarantees the desired domination property.

\triangleright **Claim 12.** There exists a set $S \subseteq A$ of order at most $2n^{1/3}$ such that at least half of the vertices $w \in A$ are dominated by $S \cup \tilde{S} \cup (N(S) \cap N(\tilde{S}))$.

Proof. We randomly select S so that each vertex from A is in S independently with probability $p = n^{-2/3}$. Note that by Corollary 9 (1) the size of S is at most $2n^{1/3}$ with probability at least $1 - e^{-\frac{3}{8}n^{2/3}}$.

Let w be a vertex from A that is threatened by at least $8n^{2/3} \log n$ vertices from A . The probability that w is not dominated by $N(S) \cap N(\tilde{S})$ is at most

$$(1-p)^{8n^{2/3} \log n} \leq e^{-8pn^{2/3} \log n} \leq e^{-8 \log n} \leq n^{-8}.$$

By the union bound it follows that with probability at least $1 - n^{-7}$ all vertices threatened by at least $8n^{2/3} \log n$ vertices from A are dominated by $N(S) \cap N(\tilde{S})$. Claim 11 implies that there are at least $\frac{1}{2}|A|$ such vertices, so the proof is complete. \triangleleft

Setting $K := \max(n_0, 200)$. Now the statement of the lemma follows from Claim 12 by observing that since A is the most frequent color, we have $\frac{1}{2}|A| \geq \frac{1}{6}n$. \blacktriangleleft

Now we are ready to prove Theorem 3.

\blacktriangleright **Theorem 3.** *The LIST 3-COLORING problem on n -vertex graphs with diameter 2 can be solved in time $2^{\mathcal{O}(n^{1/3} \cdot \log^2 n)}$.*

Proof. Let (G, L) be an instance of the LIST 3-COLORING problem. Again, we start by applying reduction rules R1, R2, R3, so we can assume that (G, L) is reduced. Let (V_1, V_2, V_3) be the layer structure of G and set $\mu := |V_3|$.

We use one of the four branching rules to produce a number of instances of the problem, each with fewer vertices with lists of size 3. Those instances are solved recursively and if a success is reported for at least one of them, then the algorithm terminates and reports a success. The following branching rules are applied in the given order – it is essential that B4 is executed only if the rules B1, B2 and B3 cannot be applied.

- B1** If there exists a vertex $v \in V_2 \cup V_3$ such that v has more than $\mu^{2/3}$ neighbors in V_3 , then for every color $a \in L(v)$ solve an instance obtained by replacing $L(v)$ with $\{a\}$ and exhaustively applying the reduction rules.
- B2** If there exists a vertex $v \in V_3$ such that for at least $\frac{1}{36}\mu^{2/3}$ vertices $u \in V_3$ a common neighbor of u and v is in V_2 , then for every color $a \in L(v)$ solve an instance obtained by replacing $L(v)$ with $\{a\}$ and exhaustively applying the reduction rules.
- B3** If there are two vertices $u, v \in V_3$ such that for at least $\mu^{2/3}$ vertices w from V_3 the set $N(u) \cap N(v) \cap N(w)$ is nonempty, then for every two distinct colors a, b construct an instance by setting $L(u) := \{a\}$ and $L(v) := \{b\}$ and one additional instance obtained by replacing vertices u and v with a new vertex z adjacent to $N(u) \cup N(v)$ with $L(z) = [3]$. Apply the reduction rules to each of those instances and solve them recursively.
- B4** Let K be the constant from Lemma 10. For every tuple $(a, S, \tilde{S}, \varphi)$, where
 - $a \in [3]$ is a color,
 - $S \subseteq V_3$ is a set of size at most $K \cdot \mu^{1/3} \log \mu$,
 - $\tilde{S} \subseteq V_3 \setminus S$ is a set of size at most $K \cdot \mu^{1/3} \log \mu$,
 - φ is a coloring of \tilde{S} using colors $[3] \setminus \{a\}$,
 construct an instance by setting $L(v) := \{a\}$ for each $v \in S$ and $L(v) = \{\varphi(v)\}$ for $v \in \tilde{S}$. Apply the reduction rules to each of those instances for which $S \cup \tilde{S} \cup (N(S) \cap N(\tilde{S}))$ dominates at least $\frac{1}{6}\mu$ vertices from V_3 and solve them recursively.

Let us show that the above algorithm is correct. Branching rules B1 and B2 are clearly correct, because if there is a solution to the given instance of the LIST 3-COLORING problem, then it assigns to v one color from $L(v)$. The rule B3 is correct because if there is a solution to the given instance of the problem, then it either assigns two different colors to u and v , or assigns the same color to u and v , hence at least one of the constructed instances will admit a solution. Note that contracting the vertices u and v does not increase the diameter. Now consider the branching rule B4. Recall that it is applied only when rules B1, B2 and B3 are inapplicable, so in this case the graph $G[V_3]$ satisfies the assumptions (i)-(iii) of Lemma 10. Therefore if the original instance has a solution, then by Lemma 10 at least one instance constructed in B4 admits a solution. On the other hand, each instance is obtained by fixing the colors of vertices in $S \cup \tilde{S} \subseteq V_3$, so each such a coloring respects lists L . Furthermore, if this coloring is improper, then the application of reductions rules R1 and R2 will cause the algorithm to reject the instance. Hence, the branching rule B4 is correct.

Let us denote by $F(x)$ the maximum running time of the algorithm on an instance with at most x vertices with lists of size 3. By $p(n)$ we denote the cost of exhaustively applying the reduction rules to an instance with n vertices; note that $p(n)$ is polynomial in n .

Now we will bound the running time of the algorithm on our instance (G, L) with μ vertices with lists of size 3, depending on which branching rule was applied.

Case 1: B1 was applied. Note that this branching produced at most three instances of the problem, each with at most $\mu - \mu^{2/3}$ vertices with lists of size 3. This is because for every vertex $u \in V_3$ that is a neighbor of v the color c was removed from $L(u)$. Therefore, in this

case the running time is at most

$$3F\left(\mu - \mu^{2/3}\right) + 3p(n).$$

Case 2: B2 was applied. For a color x let N_x be the number of vertices $u \in V_3$ such that the list of a common neighbor of v and u in V_2 does not contain x . Let us rename the colors by a, b and c such that $N_a \leq N_b \leq N_c$. Note that if a vertex u contributes to N_c , then after the application of reduction rules b (respectively a) is removed from $L(u)$ in the instance constructed for the color a (respectively b). It follows that the running time of the algorithm in this case is at most

$$F(\mu - 1) + 2F\left(\mu - \frac{1}{108}\mu^{2/3}\right) + 3p(n).$$

Case 3: B3 was applied. Let w be a vertex from V_3 such that the set $N(u) \cap N(v) \cap N(w)$ is nonempty. Note that if we set $L(u)$ to $\{a\}$ and $L(v)$ to $\{b\}$, for $a \neq b$, then after applying the reduction rules common neighbors of u and v will have lists of size 1, hence the size of the list of w will be at most 2. Therefore, in this case the running time is at most

$$F(\mu - 1) + 6F\left(\mu - \mu^{2/3}\right) + 7p(n).$$

Case 4: B4 was applied. Note that in the constructed instances, after applying the reduction rules, all vertices from $S \cup \tilde{S} \cup (N(S) \cap N(\tilde{S}))$ have lists of size 1, so all vertices dominated by $S \cup \tilde{S} \cup (N(S) \cap N(\tilde{S}))$ have lists of size at most 2. Therefore, all instances that are solved recursively have at most $\mu - \frac{1}{6}\mu$ vertices with lists of size 3. The total number of those instances can be upper bounded by

$$3 \cdot \mu^{2K\mu^{1/3} \log \mu} \cdot 2^{K\mu^{1/3} \log \mu} < 2^{K'\mu^{1/3} \log^2 \mu},$$

for some constant K' . Therefore the total running time in this case is at most

$$2^{K'\mu^{1/3} \log^2 \mu} F\left(\frac{5}{6}\mu\right) + 2^{K'\mu^{1/3} \log^2 \mu} p(n)$$

As the considered cases cover all possibilities, we conclude that $F(\mu)$ is bounded by the maximum of the expressions obtained in all four cases. By solving this recurrence we obtain

$$F(\mu) \leq p(n) \cdot 2^{\mathcal{O}(\mu^{1/3} \log^2 \mu)} = 2^{\mathcal{O}(\mu^{1/3} \log^2 \mu)}.$$

Since $\mu \leq n$, the proof is complete. ◀

5 Possible extensions of our results

We conclude the paper with discussing possible extensions of our results.

5.1 Solving List H -Coloring in small-diameter graphs

For a fixed graph H with possible loops, an instance of LIST H -COLORING is a pair (G, L) , where G is a graph and $L : V(G) \rightarrow 2^{V(H)}$ is a list function. We ask whether there exists a *list homomorphism* from (G, L) to H , i.e., a function $\varphi : V(G) \rightarrow V(H)$, such that (i) for

each $uv \in E(G)$ it holds that $\varphi(u)\varphi(v) \in E(H)$, and (ii) for each $v \in V(G)$ it holds that $\varphi(v) \in L(v)$. Clearly LIST K_k -COLORING is equivalent to LIST k -COLORING. This is why we refer to the vertices of H as *colors*.

We observe that the algorithm from Theorem 2 and Theorem 3 can be adapted to LIST H -COLORING if the graph H satisfies certain conditions. First, the algorithm from Theorem 2 can be adapted to solve the LIST H -COLORING problem if

(P1) every vertex of H has at most two neighbors (possibly including itself, if it is a vertex with a loop).

For such graphs H , once we fix a color of some $v \in V(G)$, all its neighbors have lists of size at most 2.

To adapt the algorithm from Theorem 3, in addition to property (P1), we need two more:

(P2) any two distinct vertices of H must have at most one common neighbor,

(P3) H has no loops.

Property (P2) is needed to ensure that as soon as we fix the coloring of the sets S and \tilde{S} selected in Lemma 10, then the color of every vertex in $N(S) \cap N(\tilde{S})$ is uniquely determined. Property (P3) is needed for our selection of the set \tilde{S} : recall that all these vertices are in the neighborhood of some vertex v_a colored a , which is sufficient to ensure that no vertex of \tilde{S} gets the color a .

Let \mathcal{H} be the family of connected graphs that satisfy property (P1). From the complexity dichotomy for LIST H -COLORING by Feder, Hell, and Huang [13,14] it follows that if $H \in \mathcal{H}$, then LIST H -COLORING is polynomial-time solvable if:

- H has at most two vertices,
- $H = C_4$,
- H is a path,
- H is a path with a loop on one endvertex,

and otherwise the problem is NP-complete and does not admit a subexponential-time algorithm under the ETH. So, in other words, there are two families of graphs $H \in \mathcal{H}$ for which the problem is NP-complete (in general graphs):

- all cycles C_k for $k = 3$ or $k \geq 5$, and
- all graphs obtained from a path with $k \geq 3$ vertices by adding loops on both endvertices; let us call such a graph P_k^* .

Let us present one more simple observation about solving LIST H -COLORING in graphs with small diameter. Consider an instance (G, L) of LIST H -COLORING and suppose that H contains two vertices x, y at distance greater than $\text{diam}(G)$. (Here, with a little abuse of notation, we use the convention that if x and y are in different connected components of H , then their distance is infinite.) We note that there is no (list) homomorphism from G to H that uses both x and y . Thus we can reduce the problem to solving an instance (G, L_x) of LIST $(H - x)$ -COLORING and an instance (G, L_y) of LIST $(H - y)$ -COLORING, where lists L_x (resp. L_y) are obtained from L by removing the vertex x (resp., y) from each set.

Combining all observations above, we obtain the following results. We skip the formal proofs, as they are essentially the same as the ones of Theorem 2 and Theorem 3 and bring no new insight.

► **Theorem 13.** *Let $H \in \mathcal{H}$. Consider an instance (G, L) of LIST H -COLORING, where G is of diameter 2. Then (G, L) can be solved*

1. *in polynomial time if $H \notin \{C_3, C_5, P_3^*\}$,*
2. *in time $2^{\mathcal{O}(n^{1/3} \log^2 n)}$ if $H \in \{C_3, C_5\}$,*
3. *in time $2^{\mathcal{O}(n^{1/2} \log^{1/2} n)}$ if $H = P_3^*$.*

► **Theorem 14.** Let $H \in \mathcal{H}$. Consider an instance (G, L) of LIST H -COLORING, where G is of diameter 3. Then (G, L) can be solved

1. in polynomial time if $H \notin \{C_3, C_5, C_6, C_7, P_3^*, P_4^*\}$,
2. in time $2^{\mathcal{O}(n^{2/3} \log^{2/3} n)}$ if $H \in \{C_3, C_5, C_6, C_7, P_3^*, P_4^*\}$.

5.2 Weighted coloring problems

Another possible generalization of LIST 3-COLORING would be to introduce weights: for each pair (v, c) , where $v \in V(G)$ and $c \in \{1, 2, 3\}$, we are given a cost $\mathbf{w}(v, c)$ of coloring v with c , and we ask for a proper coloring minimizing the total cost. A natural special case of this problem is INDEPENDENT ODD CYCLE TRANSVERSAL, where we ask for a minimum-sized independent set which intersects all odd cycles.

Let us point out that the branching phases in our algorithms from Theorem 2 and Theorem 3 can handle this type of modification. However, this is no longer the case for the last phase, when the problem of coloring a graph with all lists of size at most two is reduced to 2-SAT using Theorem 4. It is known that a weighted variant of 2-SAT is NP-complete and admits no subexponential-time algorithm, unless the ETH fails [28]. Thus, in order to extend our algorithmic results to weighted setting, we need to find a way to replace using Theorem 4 with some other strategy of dealing with lists of size 2.
