where  $K = \text{poly}(1/\varepsilon)$ , each  $\sigma_i = \pm 1$ , and each random variable  $A_i$  is a concatenation of  $O\left(\frac{\log(1/\varepsilon)}{\log n}\right)$  truncations of independent samples from  $G$ . From here, we could immediately obtain an  $\varepsilon$ -WPRG by taking  $G$  to be Nisan’s generator [19], but such a WPRG would have seed length  $\Omega(\log(1/\varepsilon) \cdot \log n)$  due to the cost of sampling  $A_i$  via independent seeds to Nisan’s generator. To get a better seed length, we would like to use *correlated* seeds to Nisan’s generator.

The approach of Cohen et al. and Pyne and Vadhan [10, 22] is to use the Impagliazzo-Nisan-Wigderson (INW) PRG [15] to generate a pseudorandom sequence of seeds to Nisan’s generator. Because the INW generator is non-optimal, this approach leads to the seed length  $O(\log^2 n + \log(1/\varepsilon) \log \log_n(1/\varepsilon))$ .

Our approach is based on a simple observation. The proof of Equation (3) does not actually require that  $G$  fool *all* width- $n$  length- $n$  ROBPs. Indeed, Equation (3) holds under the weaker assumption that  $G$  fools all subprograms of *the specific ROBP*  $f$  that we are analyzing.

To exploit this observation, we apply a trick that uses an “averaging sampler”  $\text{Samp}$ . We start with a PRG  $G_0$  for width- $n$  length- $n$  ROBPs with moderate error  $1/\text{poly}(n)$  and seed length  $O(\log^2 n)$ , such as Nisan’s generator [19]. Our WPRG selects a string  $x$  of length  $O(\log^2 n + \log(1/\varepsilon))$  uniformly at random. The sampler condition implies that for any ROBP  $f$ , with high probability over  $x$ , the PRG  $G(y) \stackrel{\text{def}}{=} G_0(\text{Samp}(x, y))$  fools all subprograms of  $f$  with error  $1/\text{poly}(n)$  and optimal seed length  $O(\log n)$ . Our WPRG now applies Equation (3) to  $G$  rather than  $G_0$ . Because  $G$  has such a short seed length, sampling  $A_i$  only costs us  $O(\log(1/\varepsilon))$  truly random bits now, which we can afford. (Similar tricks have been used previously in space-bounded derandomization [20, 3, 14].)

<sup>3</sup> In the older literature, the notation “ $\mathbf{BPSPACE}(S)$ ” refers to a different model where the algorithm is not required to always halt. The class that we study in this paper is sometimes denoted “ $\mathbf{BP}_{\text{H}}\text{SPACE}(S)$ ” in older papers.

In general, our reduction converts any PRG for width- $w$  length- $n$  ROBPs with error  $1/\text{poly}(wn)$  and seed length  $r$  into a WPRG for width- $w$  length- $n$  ROBPs with any desired error  $\varepsilon$  and seed length  $O(r + \log(wn/\varepsilon))$ . Our reduction is incomparable with the prior reduction by Cohen, Doron, Renard, Sberlo, and Ta-Shma and Pyne and Vadhan [10, 22], because we get a better seed length, but we require the initial PRG to have error  $1/\text{poly}(wn)$ , whereas the prior reduction merely requires the initial PRG to have error  $1/\text{poly}(n)$ . (This is shown by Cohen et al. [10], who give a slightly tighter analysis compared to Pyne and Vadhan [22].)

We also take this opportunity to give a slightly different perspective on the proof of Equation (3), the basis of both our reduction and the earlier reduction [10, 22]. The original proof of Equation (3) is based on “preconditioned Richardson iteration,” a method for improving the accuracy of an approximate matrix inverse [1, 10, 22]. Cohen et al. pointed out that the proof has a resemblance to the notion of *local consistency errors* introduced by Cheng and Hoza [9]. We show how Equation (3) can be understood in terms of local consistency without bringing any matrices into the picture. As we explain in Appendix B, this is not a substantially different proof, but rather a different way of thinking about the same proof. We hope that this alternative perspective might yield new insights in the future.

### 1.6.2 Overview of our Improved Derandomization

The proof of Theorem 1.6 (simulating randomized space  $S$  in deterministic space  $o(S^{3/2})$ ) builds on Saks and Zhou’s algorithm [23]. To derandomize space- $(\log w)$  algorithms, Saks and Zhou rely heavily on Nisan’s PRG for width- $w$  length- $n$  ROBPs. Crucially, Saks and Zhou set  $n$  to be *much smaller* than  $w$ . To fool such programs with error  $\varepsilon$ , Nisan’s PRG has seed length  $O(\log(wn/\varepsilon) \log n)$ , so by choosing  $n = 2^{O(\sqrt{\log w})}$  and  $\varepsilon = 1/\text{poly}(w)$ , the seed length of Nisan’s PRG is only  $O(\log^{3/2} w)$ . The crux of Saks and Zhou’s work [23] is a clever method of reusing a seed of this PRG many times to derandomize a  $(\log w)$ -space algorithm even though it might use up to  $w$  random bits.

Saks and Zhou’s work therefore provides extra motivation for studying width- $w$  length- $n$  ROBPs when  $n \ll w$ . These programs correspond to algorithms that only use a small amount of randomness. In this “low-randomness” regime, PRGs have long been known that are slightly better than Nisan’s PRG. Most famously, Nisan and Zuckerman designed a PRG for the case  $n = \text{polylog } w$  with error  $2^{-\log^{0.99} w}$  and optimal seed length  $O(\log w)$  [21]. Later, Armoni designed a PRG that interpolates between Nisan’s PRG [19] and the Nisan-Zuckerman PRG [21], suitable for the regime  $\text{polylog } w \ll n \ll w$  [3]. Using extractors that were not available to Armoni at the time of his work [3], Armoni’s PRG can be implemented [17] to have seed length

$$O\left(\frac{\log(wn/\varepsilon) \log n}{\max\{1, \log \log w - \log \log(n/\varepsilon)\}}\right).$$

For  $n \ll w$  and  $\varepsilon = 1/\text{poly}(n)$ , this is better than Nisan’s PRG by a factor of  $\Theta(\log \log w)$ .

Furthermore, although Saks and Zhou [23] relied on the specific structure of Nisan’s PRG [19], Armoni showed how to modify the Saks-Zhou algorithm to use any generic PRG for ROBPs [3]. It is therefore natural to try to improve the Saks-Zhou theorem by replacing Nisan’s PRG with Armoni’s, and indeed, it has been suggested that Theorem 1.6 follows already from Armoni’s work.<sup>4</sup>

<sup>4</sup> I have heard a speaker make this claim during an oral presentation, but the speaker clarified that they

However, it seems that Theorem 1.6 does *not* follow directly from Armoni’s work. The trouble is the error parameter. For the Saks-Zhou method to work, it seems to be necessary that the PRG has error  $1/\text{poly}(w)$  rather than  $1/\text{poly}(n)$ . When  $\varepsilon = 1/\text{poly}(w)$ , Armoni’s PRG is no better than Nisan’s PRG, so we get no improvement. Armoni himself understood this issue and did not claim to beat the Saks-Zhou bound in the general case. Instead, he showed how to use his PRG to get an improved derandomization of *low-randomness* algorithms [3].

Today, however, we have new tools for fooling ROBPs with low error. In particular, we can use the recent error reduction procedure due to Cohen et al. and Pyne and Vadhan [10, 22]. Cohen et al. show how to convert a PRG for width- $w$  length- $n$  ROBPs with error  $1/\text{poly}(n)$  and seed length  $r$  into a WPRG for width- $w$  length- $n$  ROBPs with any desired error  $\varepsilon$  and seed length  $r + \tilde{O}(\log(w/\varepsilon))$  [10]. Applying this reduction to Armoni’s PRG with  $n = 2^{\sqrt{\log w \cdot \log \log w}}$  (slightly larger than the choice in Saks and Zhou’s original work [23]), we obtain a WPRG for width- $w$  length- $n$  ROBPs with error  $1/\text{poly}(w)$  and seed length

$$O\left(\frac{\log^{3/2} w}{\sqrt{\log \log w}}\right) + \tilde{O}(\log w) = O\left(\frac{\log^{3/2} w}{\sqrt{\log \log w}}\right).$$

Meanwhile, Chattopadhyay and Liao showed [8] that WPRGs can be used in place of PRGs in Saks and Zhou’s algorithm, provided the WPRG is  $\text{poly}(w)$ -bounded. The WPRG from Cohen et al.’s reduction [10] is indeed  $\text{poly}(1/\varepsilon)$ -bounded, completing the proof of Theorem 1.6. The more detailed proof is in Appendix A.

## 1.7 WPRGs vs. HSGs

We remark that the proof of Theorem 1.6 sheds light on the relative strengths of HSGs and WPRGs. Cheng and Hoza recently showed that optimal HSGs would imply  $\mathbf{L} = \mathbf{BPL}$  [9], which might cause one to question whether WPRGs have value above and beyond the value of HSGs. Chattopadhyay and Liao addressed this concern by showing that WPRGs could hypothetically be used in the Saks-Zhou algorithm to prove a new and improved derandomization of space-bounded computation [8], whereas it is still not known how to use HSGs in the Saks-Zhou algorithm. Theorem 1.6 makes the hypothetical possibility envisioned by Chattopadhyay and Liao a reality<sup>5</sup> and thereby demonstrates the strength of the WPRG approach to derandomization.

## 2 Preliminaries

### 2.1 Pseudodistributions

For most of our analysis, we will work with *pseudodistributions* rather than the WPRG formalism. For our purposes, a pseudodistribution is a generalization of a probability distribution in which probabilities are replaced with “pseudoprobabilities,” which are arbitrary real numbers that do not necessarily sum to one.

---

were not familiar with a careful proof and were merely communicating what someone else had said. I am also aware of an instance in which this claim was made in typeset lecture notes, but the claim was removed after a revision.

<sup>5</sup> To be clear, we only achieve derandomization in space  $O(S^{3/2}/\sqrt{\log S})$ , whereas Chattopadhyay and Liao proposed a route toward the much better bound  $O(S^{4/3})$  [8], developing an earlier proposal by Braverman, Cohen, and Garg [6].

► **Definition 2.1** (Pseudodistribution). A pseudodistribution over  $\{0, 1\}^n$  is a formal real linear combination of  $n$ -bit strings,<sup>6</sup> i.e., a sum of the form

$$A = \sum_{i=1}^R a_i \cdot x^{(i)},$$

where  $a_i \in \mathbb{R}$  and  $x^{(i)} \in \{0, 1\}^n$ . A probability distribution over  $\{0, 1\}^n$  is the special case that  $a_i \geq 0$  and  $\sum_{i=1}^R a_i = 1$ . We define  $U_n$  to be the uniform distribution over  $\{0, 1\}^n$ , i.e.,  $U_n = \sum_{x \in \{0, 1\}^n} 2^{-n} \cdot x$ . We often identify a function  $f$  on  $\{0, 1\}^n$  with the induced probability distribution  $f(U_n)$ . We define the pseudoexpectation of a function  $f: \{0, 1\}^n \rightarrow \mathbb{R}$  under the pseudodistribution  $A$  by

$$\tilde{\mathbb{E}}[f(A)] = \sum_{i=1}^R a_i \cdot f(x^{(i)}).$$

We say that  $A$  fools  $f$  with error  $\varepsilon$  if  $|\mathbb{E}[f] - \tilde{\mathbb{E}}[f(A)]| \leq \varepsilon$ .

► **Definition 2.2** (Operations on Pseudodistributions). Linear combinations of pseudodistributions over  $\{0, 1\}^n$  are defined in the natural way. The tensor product of two pseudodistributions is given by

$$\left( \sum_{i=1}^R a_i \cdot x^{(i)} \right) \otimes \left( \sum_{j=1}^{R'} b_j \cdot y^{(j)} \right) = \sum_{i=1}^R \sum_{j=1}^{R'} a_i b_j \cdot (x^{(i)} \circ y^{(j)}),$$

where  $\circ$  denotes concatenation. Thus if  $A$  is a pseudodistribution over  $\{0, 1\}^n$  and  $B$  is a pseudodistribution over  $\{0, 1\}^{n'}$ , then  $A \otimes B$  is a pseudodistribution over  $\{0, 1\}^{n+n'}$ .

The following facts are easy to verify.

► **Proposition 2.3.** Let  $A$  and  $B$  be pseudodistributions over  $\{0, 1\}^n$ , let  $c \in \mathbb{R}$ , and let  $f: \{0, 1\}^n \rightarrow \mathbb{R}$ . Then  $\tilde{\mathbb{E}}[f(A + cB)] = \tilde{\mathbb{E}}[f(A)] + c \cdot \tilde{\mathbb{E}}[f(B)]$ .

► **Proposition 2.4.** For  $b \in \{0, 1\}$ , let  $n_b \in \mathbb{N}$ , let  $A_b$  be a pseudodistribution over  $\{0, 1\}^{n_b}$ , and let  $f_b: \{0, 1\}^{n_b} \rightarrow \mathbb{R}$ . Let  $f(x, y) = f_0(x) \cdot f_1(y)$ . Then

$$\tilde{\mathbb{E}}[f(A_0 \otimes A_1)] = \tilde{\mathbb{E}}[f_0(A_0)] \cdot \tilde{\mathbb{E}}[f_1(A_1)].$$

## 2.2 Weighted PRGs

As discussed in Section 1, a WPRG is a pair  $(G, \rho)$ , where  $G: \{0, 1\}^r \rightarrow \{0, 1\}^n$  and  $\rho: \{0, 1\}^r \rightarrow \mathbb{R}$ . Each WPRG has a corresponding pseudodistribution, just as a PRG has a corresponding distribution.

► **Definition 2.5** (Pseudodistribution Sampled by a WPRG). If  $(G, \rho)$  is a WPRG with seed length  $r$ , the pseudodistribution sampled by  $(G, \rho)$  is  $A = \sum_{x \in \{0, 1\}^r} 2^{-r} \cdot \rho(x) \cdot G(x)$ . Note that  $(G, \rho)$  is an  $\varepsilon$ -WPRG for  $f$  if and only if  $A$  fools  $f$  with error  $\varepsilon$ .

<sup>6</sup> Equivalently,  $A$  is a vector in the  $n$ -fold tensor product space  $\mathbb{R}^2 \otimes \dots \otimes \mathbb{R}^2 \cong \mathbb{R}^{2^n}$ . The reader might find it helpful to make an analogy with quantum computing; recall that a pure state of an  $n$ -qubit system is a vector in the  $n$ -fold tensor product space  $\mathbb{C}^2 \otimes \dots \otimes \mathbb{C}^2 \cong \mathbb{C}^{2^n}$ . We could even have used ket notation for pseudodistributions:  $A = \sum_{i=1}^R a_i \cdot |x^{(i)}\rangle$ .

WPRGs can be combined in the same ways as pseudodistributions. Consideration of these operations will help us verify the seed length, boundedness, and efficiency of our WPRG.

► **Definition 2.6** (Operations on WPRGs). *Suppose we have two WPRGs  $(G_0, \rho_0)$  and  $(G_1, \rho_1)$ , where  $G_b: \{0, 1\}^{r_b} \rightarrow \{0, 1\}^{n_b}$  and  $\rho_b: \{0, 1\}^{r_b} \rightarrow \mathbb{R}$ . We define the tensor product  $(G_0, \rho_0) \otimes (G_1, \rho_1)$  to be a WPRG  $(G, \rho)$  with seed length  $r_0 + r_1$  given by*

$$G(x, y) = G_0(x) \circ G_1(y) \qquad \rho(x, y) = \rho_0(x) \cdot \rho_1(y).$$

If  $n_0 = n_1$ , we define the sum  $(G_0, \rho_0) + (G_1, \rho_1)$  to be a WPRG  $(G, \rho)$  with seed length  $r + 1$  given by

$$G(x, b) = G_b(x) \qquad \rho(x, b) = 2 \cdot \rho_b(x).$$

(There is a factor of 2 because in the definition of WPRGs, we look at an expectation over seeds rather than a sum.) For a WPRG  $(G, \rho)$  and a real number  $c$ , we define  $c \cdot (G, \rho) = (G, \rho')$ , where  $\rho'(x) = c \cdot \rho(x)$ . Under these definitions, if  $(G_b, \rho_b)$  samples from the pseudodistribution  $A_b$  over  $\{0, 1\}^{n_b}$ , then  $(G_0, \rho_0) \otimes (G_1, \rho_1)$  samples from  $A_0 \otimes A_1$ , and if  $n_0 = n_1$ , then  $(G_0, \rho_0) + c \cdot (G_1, \rho_1)$  samples from  $A_0 + cA_1$ . Furthermore, if  $(G_b, \rho_b)$  is  $K_b$ -bounded, then  $(G_0, \rho_0) \otimes (G_1, \rho_1)$  is  $(K_0K_1)$ -bounded; if  $(G_0, \rho_0)$  and  $(G_1, \rho_1)$  are both  $K$ -bounded, then  $(G_0, \rho_0) + (G_1, \rho_1)$  is  $(2K)$ -bounded; if  $(G, \rho)$  is  $K$ -bounded, then  $c \cdot (G, \rho)$  is  $(cK)$ -bounded.

### 2.3 Applying Pseudodistributions to ROBPs

Let  $f$  be an ROBP with layers  $V_0, \dots, V_n$ . Let  $u \in V_i$  and  $v \in V_j$ . When  $j \geq i$ , we define the *subprogram*  $f_{u \rightarrow v}: \{0, 1\}^{j-i} \rightarrow \{0, 1\}$  to be the length- $(j-i)$  ROBP obtained from  $f$  by setting  $u$  to be the start vertex and  $v$  to be the accept vertex. For convenience, we extend  $f_{u \rightarrow v}$  to a function  $f_{u \rightarrow v}: \{0, 1\}^{\geq j-i} \rightarrow \{0, 1\}$  that ignores all but the first  $j-i$  bits of its input.

If  $A$  is a pseudodistribution over  $\{0, 1\}^d$  with  $i + d \geq j$ , we define  $A[u \rightarrow v]$  to be the pseudoprobability of reaching  $v$  from  $u$  using  $A$ , i.e.,  $A[u \rightarrow v] = \mathbb{E}[f_{u \rightarrow v}(A)]$ . We extend the definition by defining  $A[u \rightarrow v] = 0$  when  $i > j$ .

### 2.4 Local Consistency

As mentioned in Section 1.6.1, we will present a WPRG analysis based on the notion of *local consistency* introduced by Cheng and Hoza [9]. The idea behind local consistency is that we measure the quality of a pseudodistribution by using it to estimate  $\mathbb{E}[f_{u \rightarrow v}]$  in two different ways and comparing the results.

► **Definition 2.7** (Local Consistency Error). *Let  $f$  be an ROBP with layers  $V_0, \dots, V_n$ . Let  $u \in V_i$  and  $v \in V_j$  with  $i < j$ , and let  $A$  be a pseudodistribution over  $\{0, 1\}^d$  with  $i + d \geq j$ . The local consistency error  $\text{LCErr}_{u \rightarrow v}(A)$  is defined by*

$$\text{LCErr}_{u \rightarrow v}(A) = \left( \sum_{t \in V_{j-1}} A[u \rightarrow t] \cdot U_1[t \rightarrow v] \right) - A[u \rightarrow v].$$

We extend the definition by setting  $\text{LCErr}_{u \rightarrow v}(A) = 0$  when  $j \leq i$ . We say that  $A$  is  $\alpha$ -locally consistent with respect to  $f$  if for every  $u, v$  we have  $|\text{LCErr}_{u \rightarrow v}(A)| \leq \alpha$ .

## 28:10 Better Pseudodistributions and Derandomization for Space-Bounded Computation

Note that  $U_n$  is 0-locally consistent. As we explain in Appendix B, local consistency is closely connected to approximating the inverse of the random walk Laplacian matrix of  $f$ . Cheng and Hoza's work [9] shows that local consistency and fooling are equivalent, up to some loss in the error parameter [9]. We repeat the argument here for clarity.

► **Lemma 2.8.** *Let  $A$  be a pseudodistribution over  $\{0, 1\}^n$  and let  $f$  be a width- $w$  length- $n$  ROBPP.*

1. *If  $A$  fools every subprogram  $f_{u \rightarrow v}$  of  $f$  with error  $\alpha$ , then  $A$  is  $(2w\alpha)$ -locally consistent with respect to  $f$ .*
2. *If  $A$  is  $\varepsilon$ -locally consistent with respect to  $f$ , then  $A$  fools every subprogram  $f_{u \rightarrow v}$  of  $f$  with error  $wn\varepsilon$ .*

**Proof.** First, suppose  $A$  fools every subprogram  $f_{u \rightarrow v}$  with error  $\alpha$ . Then if  $u \in V_i$  and  $v \in V_j$  with  $i < j$ , we have

$$\begin{aligned} |\text{LCErr}_{u \rightarrow v}(A)| &= \left| A[u \rightarrow v] - \sum_{t \in V_{j-1}} A[u \rightarrow t] \cdot U_1[t \rightarrow v] \right| \\ &\leq |A[u \rightarrow v] - U_n[u \rightarrow v]| + \left| U_n[u \rightarrow v] - \sum_{t \in V_{j-1}} A[u \rightarrow t] \cdot U_1[t \rightarrow v] \right| \\ &\leq \alpha + \sum_{t \in V_{j-1}} |U_n[u \rightarrow t] - A[u \rightarrow t]| \cdot U_1[t \rightarrow v] \\ &\leq (w+1)\alpha \leq 2w\alpha. \end{aligned}$$

Conversely, suppose  $A$  is  $\varepsilon$ -locally consistent with respect to  $f$ . Then for any  $u \in V_i$  and any  $j > i$ ,

$$\begin{aligned} \sum_{v \in V_j} |A[u \rightarrow v] - U_n[u \rightarrow v]| &\leq \sum_{v \in V_j} \left( \left| \sum_{t \in V_{j-1}} A[u \rightarrow t] U_1[t \rightarrow v] - U_n[u \rightarrow v] \right| + \varepsilon \right) \\ &\leq w\varepsilon + \sum_{v \in V_j} \sum_{t \in V_{j-1}} |A[u \rightarrow t] - U_n[u \rightarrow t]| \cdot U_1[t \rightarrow v] \\ &= w\varepsilon + \sum_{t \in V_{j-1}} |A[u \rightarrow t] - U_n[u \rightarrow t]| \cdot \sum_{v \in V_j} U_1[t \rightarrow v] \\ &= w\varepsilon + \sum_{t \in V_{j-1}} |A[u \rightarrow t] - U_n[u \rightarrow t]|. \end{aligned}$$

By induction on  $j - i$ , it follows that

$$\sum_{v \in V_j} |A[u \rightarrow v] - U_n[u \rightarrow v]| \leq wn\varepsilon,$$

and hence  $A$  fools every subprogram with error  $wn\varepsilon$ . ◀

We remark that there is a version of Lemma 2.8 that eliminates both factors of  $w$ . To obtain such bounds, one can consider the *sum* over all  $v \in V_j$  of each type of error  $u \rightarrow v$ . We have no need of this more refined analysis, so we omit the details.

### 3 Amplifying Local Consistency

Let  $G$  be a given pseudodistribution over  $\{0, 1\}^n$ . (Ultimately we will take  $G$  to be a probability distribution, but this stage of the construction makes sense in the more general setting of pseudodistributions.) We will show how to combine multiple samples from  $G$  to *improve its local consistency*. Throughout this section, fix a length- $n$  ROBP  $f$  with layers  $V = V_0 \cup \dots \cup V_n$ , and for convenience, define  $V_i = \emptyset$  when  $i > n$ .

#### 3.1 Construction

For each  $d \leq n$ , define  $G_d$  to be the pseudodistribution obtained by drawing a sample from  $G$  and truncating to the first  $d$  bits. That is, if  $G = \sum_{i=1}^R a_i \cdot x^{(i)}$ , then

$$G_d = \sum_{i=1}^R a_i \cdot x_{1\dots d}^{(i)}. \quad (4)$$

For  $d \in [n]$ , define a pseudodistribution  $\Delta_d$  over  $\{0, 1\}^d$  by

$$\Delta_d = G_{d-1} \otimes U_1 - G_d.$$

The definition of  $\Delta_d$  should remind the reader of local consistency errors. (See Lemma 3.2.) Now we define a “multi-hop” generalization of  $\Delta_d$ . For  $d \in [n]$  and  $m \in [d]$ , define a pseudodistribution  $\Delta_d^{(m)}$  over  $\{0, 1\}^d$  by

$$\Delta_d^{(m)} = \sum_{d_1 + \dots + d_m = d} \Delta_{d_1} \otimes \dots \otimes \Delta_{d_m},$$

where the sum is over all  $m$ -tuples of positive integers  $(d_1, \dots, d_m)$  that sum to  $d$ . Next, for each  $m \geq 1$ , define a pseudodistribution  $T^{(m)}$  over  $\{0, 1\}^n$  by

$$T^{(m)} = \sum_{d=m}^n \Delta_d^{(m)} \otimes G_{n-d},$$

and finally, for each  $m \geq 0$ , define a pseudodistribution  $G^{(m)}$  over  $\{0, 1\}^n$  by

$$G^{(m)} = G + \sum_{i=1}^m T^{(i)} = G + \sum_{i=1}^m \sum_{d=m}^n \Delta_d^{(i)} \otimes G_{n-d}.$$

We will show that as  $m$  gets large,  $G^{(m)}$  becomes increasingly locally consistent.

#### 3.2 Analysis

For  $m \geq 1$ , define a “multi-hop” generalization of local consistency errors by

$$\text{LCErr}_{u \rightarrow v}^{(m)}(G) = \sum_{u=u_0, u_1, \dots, u_m=v} \prod_{j=1}^m \text{LCErr}_{u_{j-1} \rightarrow u_j}(G),$$

where the sum is over all sequences of  $m+1$  vertices starting with  $u$  and ending with  $v$ . Our goal in this section is to prove the following *exact formula* for the local consistency errors of  $G^{(m)}$  in terms of the local consistency errors of  $G$ .

► **Lemma 3.1.** *For any two vertices  $u, v$  and any  $m \geq 0$ , we have  $\text{LCErr}_{u \rightarrow v}(G^{(m)}) = \text{LCErr}_{u \rightarrow v}^{(m+1)}(G)$ .*

Let us briefly pause to marvel at this phenomenon. In most settings, when several imperfect ingredients are combined, we expect that the errors will compound on each other, so the combination has more error than any individual ingredient. We typically consider ourselves lucky if we can prove that the errors compound mildly. The remarkable feature of Lemma 3.1 is that it involves *products* of errors, i.e., the local consistency errors of  $G$  are actually combining *in our favor!*

Toward proving Lemma 3.1, we begin by analyzing  $\Delta_d$ . It is immediate from the definitions that if  $u \in V_i$  and  $v \in V_{i+d}$ , then  $\Delta_d[u \rightarrow v] = \text{LCErr}_{u \rightarrow v}(G)$ . More generally, we have the following formula.

► **Lemma 3.2.** *Let  $d \in [n]$  and  $i, j \leq n$ . Let  $u \in V_i$  and  $v \in V_j$  and let  $A$  be a pseudodistribution over  $\{0, 1\}^{n-d}$ . Then*

$$(\Delta_d \otimes A)[u \rightarrow v] = \sum_{t \in V_{i+d}} \text{LCErr}_{u \rightarrow t}(G) \cdot A[t \rightarrow v]. \quad (5)$$

**Proof.** For the first case, suppose  $i + d \leq j$ . Then for any  $x \in \{0, 1\}^d$  and any  $y \in \{0, 1\}^{n-d}$ , we have  $f_{u \rightarrow v}(x, y) = \sum_{t \in V_{i+d}} f_{u \rightarrow t}(x) \cdot f_{t \rightarrow v}(y)$ . Therefore, for any pseudodistribution  $B$  over  $\{0, 1\}^d$  whatsoever, we have

$$(B \otimes A)[u \rightarrow v] = \sum_{t \in V_{i+d}} B[u \rightarrow t] \cdot A[t \rightarrow v].$$

Since  $\Delta_d[u \rightarrow t] = \text{LCErr}_{u \rightarrow t}(G)$ , we are done in this case.

For the second case, suppose  $i + d > j$ . Then either  $i > j$ , or else the pseudodistributions  $G_{d-1} \otimes U_1 \otimes A$  and  $G_d \otimes A$  agree on their first  $j - i$  bits.<sup>7</sup> Either way,  $(\Delta_d \otimes A)[u \rightarrow v] = 0$ . Meanwhile, for each  $t \in V_{i+d}$ , trivially  $A[t \rightarrow v] = 0$ , so both sides of Equation (5) are zero in this case. ◀

More generally, we have the following relationship between  $\Delta_d^{(m)}$  and  $\text{LCErr}^{(m)}$ .

► **Lemma 3.3.** *Let  $d \in [n]$ ,  $m \in [d]$ , and  $i, j \leq n$  and  $m \geq 0$ . Let  $u \in V_i$  and  $v \in V_j$  and let  $A$  be a pseudodistribution over  $\{0, 1\}^{n-d}$ . Then*

$$(\Delta_d^{(m)} \otimes A)[u \rightarrow v] = \sum_{t \in V_{i+d}} \text{LCErr}_{u \rightarrow t}^{(m)}(G) \cdot A[t \rightarrow v].$$

**Proof.** The base case  $m = 1$  was proven in Lemma 3.2. For the inductive step, note that

$$\Delta_d^{(m+1)} = \sum_{k=m}^{d-1} \Delta_k^{(m)} \otimes \Delta_{d-k},$$

<sup>7</sup> I.e., the induced pseudodistributions on the first  $j - i$  bits (see Equation (4)) are identical.

so

$$\begin{aligned}
& (\Delta_d^{(m+1)} \otimes A)[u \rightarrow v] \\
&= \sum_{k=m}^{d-1} (\Delta_k^{(m)} \otimes \Delta_{d-k} \otimes A)[u \rightarrow v] && \text{(Linearity)} \\
&= \sum_{k=m}^{d-1} \sum_{s \in V_{i+k}} \text{LCErr}_{u \rightarrow s}^{(m)}(G) \cdot (\Delta_{d-k} \otimes A)[s \rightarrow v] && \text{(Induction)} \\
&= \sum_{k=m}^{d-1} \sum_{s \in V_{i+k}} \sum_{t \in V_{i+d}} \text{LCErr}_{u \rightarrow s}^{(m)}(G) \cdot \text{LCErr}_{s \rightarrow t}(G) \cdot A[t \rightarrow v] && \text{(Lemma 3.2)} \\
&= \sum_{t \in V_{i+d}} \text{LCErr}_{u \rightarrow t}^{(m+1)}(G) \cdot A[t \rightarrow v]. \quad \blacktriangleleft
\end{aligned}$$

**Proof of Lemma 3.1.** For any  $u \in V_j$  and  $v \in V_k$ , by Lemma 3.3,

$$T^{(m)}[u \rightarrow v] = \sum_{d=m}^n \sum_{t \in V_{j+d}} \text{LCErr}_{u \rightarrow t}^{(m)}(G) \cdot G[t \rightarrow v] = \sum_{t \in V} \text{LCErr}_{u \rightarrow t}^{(m)}(G) \cdot G[t \rightarrow v].$$

Therefore, if  $u \in V_j$  and  $v \in V_k$  with  $j < k$ , then

$$\begin{aligned}
& \text{LCErr}_{u \rightarrow v}(T^{(m)}) \\
&= \left( \sum_{s \in V_{k-1}} T^{(m)}[u \rightarrow s] \cdot U_1[s \rightarrow v] \right) - T^{(m)}[u \rightarrow v] \\
&= \left( \sum_{s \in V_{k-1}} \sum_{t \in V} \text{LCErr}_{u \rightarrow t}^{(m)}(G) \cdot G[t \rightarrow s] \cdot U_1[s \rightarrow v] \right) - \sum_{t \in V} \text{LCErr}_{u \rightarrow t}^{(m)}(G) \cdot G[t \rightarrow v] \\
&= \sum_{t \in V} \text{LCErr}_{u \rightarrow t}^{(m)}(G) \cdot \underbrace{\left( \left( \sum_{s \in V_{k-1}} G[t \rightarrow s] \cdot U_1[s \rightarrow v] \right) - G[t \rightarrow v] \right)}_{(*)}.
\end{aligned}$$

Quantity  $(*)$  is exactly the local consistency error  $\text{LCErr}_{t \rightarrow v}(G)$ , except in one edge case: when  $t = v$ ,  $\text{LCErr}_{t \rightarrow t}(G) = 0$ , whereas  $(*) = -1$ . Therefore,

$$\begin{aligned}
\text{LCErr}_{u \rightarrow v}(T^{(m)}) &= \left( \sum_{t \in V} \text{LCErr}_{u \rightarrow t}^{(m)}(G) \cdot \text{LCErr}_{t \rightarrow v}(G) \right) - \text{LCErr}_{u \rightarrow v}^{(m)}(G) \\
&= \text{LCErr}_{u \rightarrow v}^{(m+1)}(G) - \text{LCErr}_{u \rightarrow v}^{(m)}(G).
\end{aligned}$$

Thus, we get a telescoping sum:

$$\begin{aligned}
\text{LCErr}_{u \rightarrow v}(G^{(m)}) &= \text{LCErr}_{u \rightarrow v}(G) + \sum_{i=1}^m \text{LCErr}_{u \rightarrow v}(T^{(i)}) \\
&= \text{LCErr}_{u \rightarrow v}(G) + \sum_{i=1}^m \left( \text{LCErr}_{u \rightarrow v}^{(i+1)}(G) - \text{LCErr}_{u \rightarrow v}^{(i)}(G) \right) \\
&= \text{LCErr}_{u \rightarrow v}^{(m+1)}(G).
\end{aligned}$$

(If  $j \geq k$ , then  $\text{LCErr}_{u \rightarrow v}(G^{(m)}) = \text{LCErr}_{u \rightarrow v}^{(m+1)}(G) = 0$ , so the lemma holds trivially in this case.)  $\blacktriangleleft$

The following corollary corresponds to Equation (3).

► **Corollary 3.4.** *If  $G$  fools every subprogram  $f_{u \rightarrow v}$  with error  $\alpha$ , then for every  $m \geq 0$ ,  $G^{(m)}$  fools  $f$  with error  $wn \cdot (2w^2n\alpha)^{m+1}$ .*

**Proof.** For any  $u$  and  $v$ , by Lemma 3.1,

$$\begin{aligned} |\text{LCErr}_{u \rightarrow v}(G^{(m)})| &= |\text{LCErr}_{u \rightarrow v}^{(m+1)}(G)| \\ &\leq \sum_{u=u_0, u_1, \dots, u_{m+1}=v} \prod_{j=1}^{m+1} |\text{LCErr}_{u_{j-1} \rightarrow u_j}(G)| \\ &\leq (wn)^m \cdot (2w\alpha)^{m+1} && \text{(Lemma 2.8)} \\ &\leq (2w^2n\alpha)^{m+1}. \end{aligned}$$

The corollary follows by Lemma 2.8. ◀

We reiterate that Corollary 3.4 follows already from the work of Cohen et al. and Pyne and Vadhan [10, 22], and indeed the proof we have given is not substantially different (see Appendix B). In keeping with our remark after Lemma 2.8, we also remark that there is a version of Corollary 3.4 that eliminates the factors of  $w$  by assuming that for each layer  $j$ , the *sum* of errors  $|G[u \rightarrow v] - U_n[u \rightarrow v]|$  over all  $v \in V_j$  is at most  $\alpha$ . We omit the details.

## 4 Our Improved WPRG for ROBPs

In this section, we will show how to convert a moderate-error PRG for width- $w$  length- $n$  ROBPs into a low-error WPRG for width- $w$  length- $n$  ROBPs. If the given PRG has error  $1/\text{poly}(wn)$  and seed length  $r$ , then for any  $\varepsilon > 0$ , we will obtain a WPRG with error  $\varepsilon$  and seed length  $O(r + \log(wn/\varepsilon))$ .

### 4.1 Construction

Recall the standard notion of an *averaging sampler*, which is essentially equivalent to a seeded randomness extractor [25].

► **Definition 4.1 (Sampler).** *A function  $\text{Samp}: \{0, 1\}^\ell \times \{0, 1\}^q \rightarrow \{0, 1\}^r$  is an  $(\alpha, \gamma)$ -sampler if for every function  $f: \{0, 1\}^r \rightarrow [0, 1]$ ,*

$$\Pr_{x \in \{0, 1\}^\ell} \left[ \left| \mathbb{E}[f] - 2^{-q} \sum_{y \in \{0, 1\}^q} f(\text{Samp}(x, y)) \right| \leq \alpha \right] \geq 1 - \gamma.$$

Let  $\alpha = \frac{1}{4w^3n^2}$  and let  $G: \{0, 1\}^r \rightarrow \{0, 1\}^n$  be a given  $\alpha$ -PRG for width- $w$  length- $n$  ROBPs. Define

$$m = \left\lceil \frac{\log(wn/\varepsilon)}{\log(wn)} \right\rceil \quad \text{and} \quad \gamma = \frac{\varepsilon}{2w^2n^2 \cdot ((8n)^{m+1} + 1)} = \left( \frac{\varepsilon}{wn} \right)^{O(1)},$$

and let  $\text{Samp}: \{0, 1\}^\ell \times \{0, 1\}^q \rightarrow \{0, 1\}^r$  be an  $(\alpha, \gamma)$ -sampler. For each  $x \in \{0, 1\}^\ell$ , let  $G_x$  be the distribution  $G(\text{Samp}(x, U_q))$ , and let  $G_x^{(m)}$  be the corresponding pseudodistribution with amplified local consistency as defined in Section 3.1. Our final pseudodistribution  $G'$  is  $G_x^{(m)}$  for a uniform random  $x$ , i.e.,

$$G' = \sum_{x \in \{0, 1\}^\ell} 2^{-\ell} \cdot G_x^{(m)}.$$

## 4.2 Correctness

▷ Claim 4.2. If  $f$  is a width- $w$  length- $n$  ROBP, then  $G'$  fools  $f$  with error  $\varepsilon$ .

Proof. For each pair of vertices  $u, v$ , since  $G$  is an  $\alpha$ -PRG for width- $w$  ROBPs,  $G$  fools  $f_{u \rightarrow v}$  with error  $\alpha$ . Therefore, by the sampler condition, with probability  $1 - \gamma$  over a uniform random choice of  $x$ ,  $G_x$  fools  $f_{u \rightarrow v}$  with error  $2\alpha$ . Let BAD be the set of  $x$  such that there exist vertices  $u, v$  such that  $G_x$  does *not*  $(2\alpha)$ -fool  $f_{u \rightarrow v}$ . By the union bound,

$$|\text{BAD}| \leq \gamma \cdot w^2 n^2 \cdot 2^\ell = \frac{\varepsilon}{2 \cdot ((8n)^{m+1} + 1)} \cdot 2^\ell.$$

For any  $x$ , unpacking the definitions, we see that  $G_x^{(m)}$  has the form  $\sum_{i=1}^K \pm A_i$ , where

$$K \leq (m+1) \cdot (n+1) \cdot (n+1)^m \cdot 2^m \leq (8n)^{m+1}$$

and each  $A_i$  is a tensor product of probability distributions. Therefore, for  $x \in \text{BAD}$  (indeed for all  $x$ ), we have  $|\tilde{\mathbb{E}}[f(G_x^{(m)})]| \leq (8n)^{m+1}$ . Meanwhile, for  $x \notin \text{BAD}$ , by Corollary 3.4,

$$\left| \tilde{\mathbb{E}}[f(G_x^{(m)})] - \mathbb{E}[f] \right| \leq wn \cdot (4w^2 n \alpha)^{m+1} = wn \cdot \left( \frac{1}{wn} \right)^{m+1} < \frac{\varepsilon}{2}.$$

Therefore, overall,

$$\begin{aligned} \left| \tilde{\mathbb{E}}[f(G')] - \mathbb{E}[f] \right| &= \left| \sum_{x \in \text{BAD}} 2^{-\ell} \cdot (\tilde{\mathbb{E}}[f(G_x^{(m)})] - \mathbb{E}[f]) + \sum_{x \notin \text{BAD}} 2^{-\ell} \cdot (\tilde{\mathbb{E}}[f(G_x^{(m)})] - \mathbb{E}[f]) \right| \\ &\leq \sum_{x \in \text{BAD}} 2^{-\ell} \left( \left| \tilde{\mathbb{E}}[f(G_x^{(m)})] \right| + 1 \right) + \sum_{x \notin \text{BAD}} 2^{-\ell} \cdot \left| \tilde{\mathbb{E}}[f(G_x^{(m)})] - \mathbb{E}[f] \right| \\ &\leq 2^{-\ell} \cdot |\text{BAD}| \cdot ((8n)^{m+1} + 1) + \frac{\varepsilon}{2} \\ &\leq \varepsilon. \end{aligned} \quad \triangleleft$$

## 4.3 Explicitness and Seed Length

We will instantiate **Samp** using the following explicit sampler.

► **Theorem 4.3** ([8, Appendix B]). *For every  $r \in \mathbb{N}$  and every  $\alpha, \gamma > 0$ , there exists an  $(\alpha, \gamma)$ -sampler **Samp**:  $\{0, 1\}^\ell \times \{0, 1\}^q \rightarrow \{0, 1\}^r$  with  $\ell = r + O(\log(1/\gamma) + \log(1/\alpha))$  and  $q = O(\log(1/\alpha) + \log \log(1/\gamma))$ , such that given  $r, \alpha, \gamma, x$ , and  $y$ , the value **Samp**( $x, y$ ) can be computed in space  $O(r + \log(1/\alpha) + \log(1/\gamma))$ .*

**Proof of Theorem 1.5.** Taking **Samp** to be the sampler of Theorem 4.3, we get  $\ell = O(r + \log(1/\gamma)) = O(r + \log(wn/\varepsilon))$  and  $q = O(\log(wn) + \log \log(1/\varepsilon))$ . For a fixed  $x \in \{0, 1\}^\ell$ , as mentioned in the proof of Claim 4.2,  $G_x^{(m)}$  has the form  $\sum_{i=1}^K \pm A_i$ , where

$$K \leq (8n)^{m+1} \leq \text{poly}(n/\varepsilon),$$

and each  $A_i$  is a tensor product of at most  $2m+1$  terms, each of which is either  $(G_x)_d$  for some value of  $d$  or else  $U_1$ . Using the constructions of Definition 2.6, we can sample  $G_x^{(m)}$  by a WPRG with seed length  $O(\log K + mq)$ , and we can sample  $G'$  by a WPRG with seed length

$$\ell + O(\log K + mq) = O\left(r + \log(wn/\varepsilon) \cdot \left(1 + \frac{\log \log(1/\varepsilon)}{\log(wn)}\right)\right) = O(r + \log(wn/\varepsilon)),$$

where the last equality holds without loss of generality, because either  $\varepsilon > 2^{-n}$ , in which case  $\log \log(1/\varepsilon) < \log(wn)$ , or else  $\varepsilon \leq 2^{-n}$ , in which case we can achieve seed length  $O(r + \log(wn/\varepsilon))$  by simply sampling a truly random  $n$ -bit string. Furthermore, as discussed in Definition 2.6, our WPRG is  $(2K)$ -bounded,<sup>8</sup> and we can assume without loss of generality that  $\varepsilon < 1/n$  (since otherwise  $G$  itself would be a suitable WPRG), so our WPRG is indeed  $\text{poly}(1/\varepsilon)$ -bounded.

Finally, pick  $G$  to be Nisan's generator [19]. Then

$$r = O(\log(wn/\alpha) \log n) = O(\log(wn) \log n),$$

so our WPRG has seed length  $O(\log(wn) \log n + \log(1/\varepsilon))$  as claimed. Explicitness is clear. ◀

We remark that because of the specific structure of Nisan's generator [19], the sampler is actually not necessary. Instead, we can let  $x$  be the description of the hash functions in Nisan's generator and let  $y$  be the input to the hash functions.

## 5 Directions for Further Research

As we mentioned in Section 1.4, getting a better WPRG for width- $n$  length- $n$  ROBPs requires beating Nisan's PRG in the standard constant-error regime. However, there are cases where focusing on error dependence might still be fruitful:

- Recall that Nisan and Zuckerman designed a PRG for width- $w$  length- $n$  ROBPs when  $n = \text{polylog } w$  with optimal seed length  $O(\log w)$  [21] but non-optimal error  $2^{-\log^{0.99} w}$ . There are known  $\varepsilon$ -HSGs for this setting with seed length  $O(\log w)$  even when  $\varepsilon = 1/\text{poly}(w)$  [2, 14]; can we match that seed length by a WPRG? The WPRG construction presented in this paper does not seem to work, because if  $G$  has seed length  $o(\log w)$ , then it seems to have too much error for the local consistency amplification procedure  $G^{(m)}$  to work, whereas if  $G$  has seed length  $\Omega(\log w)$ , then we cannot afford to sample multiple independent seeds.
- Currently, the best explicit PRGs for width-3 ROBPs and constant-width regular ROBPs have seed length  $\tilde{O}(\log n \cdot \log(1/\varepsilon))$  [18, 11, 7]. In a similar spirit as Pyne and Vadhan's recent work on permutation ROBPs [22], can we design WPRGs for these models with error  $1/\text{poly}(n)$  and seed length  $o(\log^2 n)$ ?

We also wonder whether there are other applications of recent WPRG constructions. For example, recall that Nisan showed  $\mathbf{BPL} \subseteq \mathbf{DTISP}(\text{poly}(n), \log^2 n)$  [20]. Can we somehow use WPRGs to simulate  $\mathbf{BPL}$  by a deterministic algorithm that simultaneously uses  $\text{poly}(n)$  time and  $o(\log^2 n)$  space?

---

## A Derandomization Beyond Saks-Zhou

In this section, we show that randomized space- $S$  decision algorithms can be simulated deterministically in space  $O(S^{3/2}/\sqrt{\log S})$  (Theorem 1.6). As outlined in Section 1.6.2, the proof does not involve any significant new ideas, but rather amounts to combining several previous works and choosing parameters. For that reason, we will refrain from fully describing the Saks-Zhou method. Instead, we will focus on assisting readers who are already familiar with Saks and Zhou’s work [23] (but who are not necessarily comfortable with WPRGs) in verifying Theorem 1.6. Readers who are not familiar with Saks and Zhou’s work are encouraged to read Chattopadhyay and Liao’s discussion of the Saks-Zhou method in the context of WPRGs [8] or Saks and Zhou’s original paper [23].

Let  $G$  denote Nisan’s PRG [19]. Recall that Saks and Zhou [23] exploited the fact that the seed of Nisan’s PRG can be split into two parts  $(x, y)$ , where  $x = O(\log w \log n)$  and  $y = O(\log w)$ ; for a fixed ROBP  $f$ , if we pick  $x$  at random, then with high probability,  $\mathbb{E}[f] \approx 2^{-r} \cdot \sum_y f(G(x, y))$ . This method of estimating  $\mathbb{E}[f]$  has a key technical feature, which is that each time we read a bit of the input of  $f$ , we only need to be using  $O(\log w)$  bits of work space (not counting the string  $x$ , which we think of as being on a read-only random tape). This feature is beneficial, because in the context of the Saks-Zhou algorithm [23], the program  $f$  is computed recursively, so we would like to use as little space as possible while the recursive computation is taking place. (See the work of Hoza and Umans for further discussion [13].)

Armoni generalized Saks and Zhou’s methods by showing that *any* explicit PRG for ROBPs implies a method of estimating  $\mathbb{E}[f]$  with the same key feature [3]. Later, Chattopadhyay and Liao generalized further by showing that the same holds for any polynomially-bounded explicit WPRG [8]. For clarity, we repeat the argument here (in a slightly different form). It is convenient to generalize the definition of ROBPs to allow a large alphabet.

► **Definition A.1** (ROBP over a large alphabet). *A width- $w$  length- $n$  ROBP over the alphabet  $\Sigma$  is defined as in Definition 1.1, except that each vertex in  $V_{i-1}$  has  $|\Sigma|$  outgoing edges leading to  $V_i$ , labeled with the symbols in  $\Sigma$ . The program computes a function  $f: \Sigma^n \rightarrow \{0, 1\}$  in the natural way.*

► **Lemma A.2** ([8]). *Let  $n = n(w)$ ,  $K = K(w)$ ,  $r = r(w)$ ,  $a = a(w)$ , and  $\varepsilon = \varepsilon(w)$  be functions, each of which can be constructed in space  $O(r)$ . Suppose that for every  $w \in \mathbb{N}$ , there is a  $K$ -bounded  $\varepsilon$ -WPRG  $(G, \rho)$  for width- $w$  length- $n$  ROBPs over the alphabet  $\{0, 1\}^a$  with seed length  $r$  that can be computed in space  $O(r)$ . Then there is an algorithm for estimating the expectation of a given width- $w$  length- $n$  ROBP  $f$  over the alphabet  $\{0, 1\}^a$  with the following properties.*

1. The algorithm uses  $r + O(\log(Kw/\varepsilon))$  random bits from a read-only two-way<sup>9</sup> random tape, and with probability  $1 - \varepsilon/w^2$  it outputs a value that is within  $\pm 2\varepsilon$  of  $\mathbb{E}[f]$ .
2. The algorithm uses  $O(r + a + \log(Kwn/\varepsilon))$  bits of work space. Furthermore, whenever the algorithm reads a bit of the description of  $f$ , it first deletes all but  $O(a + \log(Kwn/\varepsilon))$  bits of its work space.

**Proof.** Let  $\text{Samp}: \{0, 1\}^\ell \times \{0, 1\}^a \rightarrow \{0, 1\}^r$  be the  $(\varepsilon/(2K), \varepsilon/w^2)$ -sampler of Theorem 4.3. To estimate  $\mathbb{E}[f]$ , we pick  $x \in \{0, 1\}^\ell$  uniformly at random, and then we output

$$2^{-q} \cdot \sum_{y \in \{0, 1\}^a} \rho(\text{Samp}(x, y)) \cdot f(G(\text{Samp}(x, y))).$$

To prove that this works, define  $g: \{0, 1\}^r \rightarrow [-K, K]$  by  $g(z) = \rho(z) \cdot f(G(z))$ . The sampler condition implies that with probability  $1 - \varepsilon/w^2$  over the choice of  $x$ , we have

$$\left| \mathbb{E}[g] - 2^{-q} \sum_{y \in \{0, 1\}^a} g(\text{Samp}(x, y)) \right| \leq \varepsilon.$$

Meanwhile, the WPRG condition implies that  $|\mathbb{E}[g] - \mathbb{E}[f]| \leq \varepsilon$ . Thus, with probability  $1 - \varepsilon/w^2$ , our algorithm outputs  $\mathbb{E}[f] \pm 2\varepsilon$ .

Now let us analyze the efficiency of the algorithm. The number of random bits we use is clearly  $\ell = r + O(\log(Kw/\varepsilon))$ . The total space used is  $O(r)$  bits to compute  $G$  and  $\rho$ , plus  $O(r \log(Kw/\varepsilon))$  bits to compute  $\text{Samp}$ , plus  $O(\log(wn))$  bits to keep track of our simulation of  $f$ , plus  $O(q) = O(\log(K/\varepsilon) + \log \log w)$  bits for summing over all  $y$ , which is a total of  $O(r + a + \log(Kwn/\varepsilon))$  bits. Prior to reading a bit of the description of  $f$ , we only need to be storing the  $O(\log(wn))$  bits that keep track of our simulation of  $f$ , plus the  $O(q) = O(\log(K/\varepsilon) + \log \log w)$  bits for summing over all  $y$ , plus a single  $a$ -bit symbol of the string  $G(\text{Samp}(x, y))$  (namely, the single symbol that we are currently feeding into our simulation of  $f$ ), which is a total of  $O(a + \log(wnK/\varepsilon))$  bits. ◀

Having established Lemma A.2, we can now compute the space complexity of the derandomization obtained by plugging any efficient WPRG into the Saks-Zhou framework.

▶ **Theorem A.3** ([23, 8]). *Let  $n = n(w)$ ,  $K = K(w)$ , and  $r = r(w)$  be monotone increasing functions, each of which can be constructed in space  $O(r)$ , with  $n \leq w$ . Define  $\varepsilon = w^{-8}$  and  $a = \lceil 4 \log w \rceil$ . Suppose that for every  $w \in \mathbb{N}$ , there exists a  $K$ -bounded  $\varepsilon$ -WPRG for width- $(w + 1)$  length- $n$  ROBPs over the alphabet  $\{0, 1\}^a$  with seed length  $r$  that can be computed in space  $O(r)$ . Then*

$$\text{BPL} \subseteq \bigcup_{c \in \mathbb{N}} \text{DSPACE} \left( r(N^c) + \frac{\log(N \cdot K(N^c)) \cdot \log N}{\log(n(N^c))} \right),$$

where  $N$  denotes the input length.

**Proof outline.** Suppose we are interested in computing the  $n$ -th power of a given substochastic matrix  $M \in \mathbb{R}^{w \times w}$ , where each entry has  $a$  bits of precision. We can easily construct a width- $(w + 1)$  length- $n$  ROBP  $f$  over the alphabet  $\{0, 1\}^a$  such that for each  $i, j \in [w]$ , if we

<sup>9</sup> I.e., the algorithm is allowed to go back and re-read random bits as many times as it likes, unlike the standard model of randomized space-bounded computation in which the random tape must be read a single time from left to right.

let  $u_i$  be the  $i$ -th vertex in the first layer of  $f$  and we let  $v_j$  be the  $j$ -th vertex in the final layer of  $f$ , then  $\mathbb{E}[f_{u_i \rightarrow v_j}] = (M^n)_{i,j}$ . Using Lemma A.2, we can compute each such value  $\mathbb{E}[f_{u_i \rightarrow v_j}]$  to within  $\pm 2\varepsilon$  with failure probability  $\varepsilon/w^2$ . In this way, we compute a matrix  $P \in \mathbb{R}^{w \times w}$  such that  $\|P - M^n\|_{\max} \leq 2\varepsilon$ . We can reuse the same random bits for each entry of the matrix, so our algorithm uses  $r + O(\log(Kw/\varepsilon))$  random bits from a read-only two-way random tape and succeeds with probability  $1 - \varepsilon$ . Furthermore, this algorithm uses  $O(r + a + \log(Kwn/\varepsilon))$  bits of work space, and whenever it reads a bit of the description of  $M$ , it first deletes all but  $O(a + \log(Kwn/\varepsilon))$  bits of its workspace.

Now, consider some randomized log-space algorithm that we wish to derandomize. There is a constant  $c$  such that the acceptance probability of the **BPL** algorithm on an input of length  $N$  is an entry in  $M^w$ , where  $w = N^c$  and  $M \in \{0, \frac{1}{2}, 1\}^{w \times w}$  is an easily-computable stochastic matrix. We have discussed a randomized algorithm for approximating  $M^n$ . The technique of Saks and Zhou [23] implies [8] an algorithm for computing  $M^w$ . As a reminder, the approach is to repeatedly take approximate  $n$ -th powers, reusing the same random bits each time and randomly rounding each entry of the matrix to  $a$  bits of precision after each iteration to resolve dependency issues. The number of iterations is  $\frac{\log w}{\log n}$ . The algorithm can be implemented to have failure probability  $O(w^3 \cdot (2^a \varepsilon + 2^{-a}))$  and approximation error  $O(w^2 2^{-a})$ , using

$$O\left(r + \log(Kw/\varepsilon) + a \cdot \frac{\log w}{\log n}\right)$$

random bits and

$$O\left(r + (a + \log(Kwn/\varepsilon)) \cdot \frac{\log w}{\log n}\right)$$

bits of space [8, Lemma 43]. By our choices  $\varepsilon = w^{-8}$  and  $a = \lceil 4 \log w \rceil$ , the failure probability is  $O(1/w)$ , the approximation error is  $O(1/w^2)$ , the number of random bits is  $O(r + \log(Kw) + \frac{\log^2 w}{\log n})$ , and the space complexity is  $O(r + \frac{\log(Kw) \log w}{\log n})$ . Trying all possibilities for the random tape completes the proof.  $\blacktriangleleft$

Next, we identify the WPRG family that we will plug into Theorem A.3.

► **Theorem A.4** ([3, 17, 10]). *For every  $w \in \mathbb{N}$ , there exists a  $K$ -bounded  $\varepsilon$ -WPRG for width- $(w + 1)$  length- $n$  ROBPs over the alphabet  $\{0, 1\}^{\lceil 4 \log w \rceil}$  with seed length  $r$  that can be computed in space  $O(r)$ , where*

$$\begin{aligned} n &= \exp\left(\left\lceil \sqrt{\log w \cdot \log \log w} \right\rceil\right), & \varepsilon &= w^{-8}, \\ r &\leq O\left(\frac{\log^{3/2} w}{\sqrt{\log \log w}}\right), & K &\leq \text{poly}(w). \end{aligned}$$

**Proof.** For any  $w, n, a, \alpha$ , Armoni designed an  $\alpha$ -PRG for width- $(w + 1)$  length- $n$  ROBPs over the alphabet  $\{0, 1\}^a$  [3]; with an optimization due to Kane, Nelson, and Woodruff [17], this PRG has seed length

$$r = O\left(a + \frac{\log(wn/\alpha) \log n}{\max\{1, \log \log w - \log \log(n/\alpha)\}}\right)$$

and can be computed in space  $O(r)$ . For  $n = \exp(\lceil \sqrt{\log w \cdot \log \log w} \rceil)$ ,  $\alpha = 1/\text{poly}(n)$ , and  $a = O(\log w)$ , this seed length becomes

$$r = O\left(\frac{\log^{3/2} w}{\sqrt{\log \log w}}\right).$$

Now we apply an error reduction procedure that converts this moderate-error PRG into a low-error WPRG. Specifically, we will use the reduction due to Cohen, Doron, Renard, Sberlo, and Ta-Shma [10]. Given a PRG for width- $w$  length- $n$  ROBPs over the alphabet  $\{0, 1\}^a$  with error  $1/(10n^2)$  and seed length  $r$ , they show [10, Corollary 15] how to construct a WPRG for width- $w$  length- $n$  ROBPs over the alphabet  $\{0, 1\}^a$  with any desired error  $\varepsilon$  and seed length  $r + O(\log(w/\varepsilon) \log \log_n(1/\varepsilon))$ . Furthermore, if the PRG can be computed in space  $O(r)$ , then the WPRG can be computed in space  $O(r + \log \log_n(1/\varepsilon) \cdot (\log \log(w/\varepsilon))^2)$ . Cohen et al. did not explicitly mention it, but by inspection it is easy to see that their WPRG is  $\text{poly}(1/\varepsilon)$ -bounded for the same reason that our main WPRG (Theorem 1.5) is  $\text{poly}(1/\varepsilon)$ -bounded. Since  $\varepsilon = 1/\text{poly}(w)$ , the seed length is  $r + \tilde{O}(\log w) = O(r)$ , the space complexity is  $O(r + \text{poly}(\log \log w)) = O(r)$ , and the WPRG is  $\text{poly}(w)$ -bounded. ◀

► **Corollary A.5.**  $\text{BPL} \subseteq \text{DSPACE}\left(\log^{3/2} N / \sqrt{\log \log N}\right)$ , where  $N$  denotes the input length.

**Proof.** Plugging the WPRG of Theorem A.4 into Theorem A.3, we get a space bound of

$$O\left(\frac{\log^{3/2}(N^c)}{\sqrt{\log \log(N^c)}} + \frac{\log(N \cdot N^{O(c)}) \cdot \log N}{\sqrt{\log(N^c) \cdot \log \log(N^c)}}\right),$$

which simplifies to  $O\left(\log^{3/2} N / \sqrt{\log \log N}\right)$ . ◀

Now we generalize Corollary A.5 to the case of  $\text{BSPACE}(S)$ . When  $S$  is space-constructible, the generalization is a standard padding argument. We now show that  $\text{BSPACE}(S)$  is contained in  $\text{DSPACE}(S^{3/2}/\sqrt{\log S})$  for any  $S(N) \geq \log N$ , whether space-constructible or not.

**Proof of Theorem 1.6.** Observe that the proof of Corollary A.5 extends to promise problems. In particular, for any constants  $0 \leq a < b \leq 1$ , there is a deterministic algorithm  $D_{a,b}$  such that if  $f$  is a width- $w$  length- $w$  ROBP over the binary alphabet, then

$$\mathbb{E}[f] \leq a \implies D_{a,b}(f) = 0,$$

$$\mathbb{E}[f] \geq b \implies D_{a,b}(f) = 1,$$

and  $D_{a,b}(f)$  runs in space  $O\left(\log^{3/2} w / \sqrt{\log \log w}\right)$ .

Let  $A$  be a Turing machine witnessing membership of a language in  $\text{BSPACE}(S)$ . For  $N \in \mathbb{N}$ ,  $y \in \{0, 1\}^N$ , and  $s \in \mathbb{N}$ , there exists a width- $w$  length- $w$  ROBP  $E_{y,s}$ , where  $w = O(N \cdot 2^s)$ , such that  $E_{y,s}(x) = 1$  if and only if the computation  $A(y, x)$  ever touches more than  $s$  cells of the work tape. Furthermore, for the same value of  $w$ , there exists a width- $w$  length- $w$  ROBP  $f_{y,s}$  such that if  $E_{y,s}(x) = 0$ , then  $f_{y,s}(x) = A(y, x) \in \{0, 1\}$ . Given  $y$  and  $s$ , these two ROBPs can be constructed deterministically in space  $O(s + \log N)$ .

On input  $y$ , our deterministic algorithm tries each  $s = 1, 2, 3, \dots$  until it finds the first  $s$  such that  $D_{0,0.01}(E_{y,s}) = 0$ . Then, our deterministic algorithm outputs  $D_{0,4,0.6}(f_{y,s})$ . This works, because if  $D_{0,0.01}(E_{y,s}) = 0$ , then  $\mathbb{E}[E_{y,s}] < 0.01$ , so  $\mathbb{E}[f_{y,s}]$  is within  $\pm 0.01$  of the acceptance probability of  $A(y)$ . Furthermore, our algorithm will find a suitable  $s$  satisfying  $s \leq S(N)$ , because  $\mathbb{E}[E_{y,S(N)}] = 0$ . Therefore, the space complexity of our algorithm is at most  $O(\log^{3/2} w / \sqrt{\log \log w})$ , where  $w = O(N \cdot 2^{S(N)}) = 2^{O(S(N))}$ . This space bound is  $O\left(S(N)^{3/2} / \sqrt{\log S(N)}\right)$  as desired. ◀

## B Local Consistency vs. Approximate Inverse Laplacian

Cohen et al. noted that their WPRG construction is reminiscent of local consistency errors [10]. We now briefly elaborate on the connection, for the sake of readers who are familiar with how prior work used preconditioned Richardson iteration to decrease error in space-bounded derandomization [1, 10, 22].

Prior works [1, 10, 22] looked at the transition probability matrix  $W$  associated with a width- $w$  length- $n$  ROBP  $f$ , considered as a directed graph on  $(n+1) \cdot w$  vertices. This matrix  $W$  is an  $(n+1)w \times (n+1)w$  block matrix of the form

$$W = \begin{bmatrix} 0 & M_1 & 0 & \cdots & 0 \\ 0 & 0 & M_2 & \cdots & 0 \\ \vdots & & \ddots & & \vdots \\ 0 & 0 & 0 & \ddots & M_n \\ 0 & 0 & 0 & \cdots & 0 \end{bmatrix},$$

where  $M_i \in \{0, \frac{1}{2}, 1\}^{w \times w}$  is the transition probability matrix for  $V_{i-1} \times V_i$ . Let  $L = I - W$  (the Laplacian matrix). Then  $L$  is invertible with inverse

$$L^{-1} = \begin{bmatrix} M_{0\dots 0} & M_{0\dots 1} & M_{0\dots 2} & \cdots & M_{0\dots n} \\ 0 & M_{1\dots 1} & M_{1\dots 2} & \cdots & M_{1\dots n} \\ \vdots & & \ddots & & \vdots \\ 0 & 0 & 0 & \ddots & M_{n-1\dots n} \\ 0 & 0 & 0 & \cdots & M_{n\dots n} \end{bmatrix},$$

where  $M_{i\dots j} = M_i \cdot M_{i+1} \cdots M_j$ , i.e.,  $M_{i\dots j}$  is the stochastic matrix containing the probabilities  $U_n[u \rightarrow v]$  for  $u \in V_i$  and  $v \in V_j$ . We are interested in obtaining an approximation  $\widehat{L}^{-1}$  to  $L$ , say

$$\widehat{L}^{-1} = \begin{bmatrix} \widehat{M}_{0\dots 0} & \widehat{M}_{0\dots 1} & \widehat{M}_{0\dots 2} & \cdots & \widehat{M}_{0\dots n} \\ 0 & \widehat{M}_{1\dots 1} & \widehat{M}_{1\dots 2} & \cdots & \widehat{M}_{1\dots n} \\ \vdots & & \ddots & & \vdots \\ 0 & 0 & 0 & \ddots & \widehat{M}_{n-1\dots n} \\ 0 & 0 & 0 & \cdots & \widehat{M}_{n\dots n} \end{bmatrix},$$

where each  $\widehat{M}_{i\dots j}$  is a matrix of estimates for the probabilities  $U_n[u \rightarrow v]$  with  $u \in V_i$  and  $v \in V_j$ . The approach taken by prior work [1, 10, 22] is to use preconditioned Richardson iteration to convert a moderate-error approximation of  $L^{-1}$  into a low-error approximation of  $L^{-1}$ .

The crucial point is that in this analysis, the approximation quality is measured by comparing  $\widehat{L}^{-1}L$  to  $I$  rather than comparing  $L^{-1}$  and  $\widehat{L}^{-1}$  directly. The error matrix  $E \stackrel{\text{def}}{=} I - \widehat{L}^{-1}L$  is given by

$$E = \begin{bmatrix} 0 & E_{0\dots 1} & E_{0\dots 2} & \cdots & E_{0\dots n} \\ 0 & 0 & E_{1\dots 2} & \cdots & E_{1\dots n} \\ \vdots & & \ddots & & \vdots \\ 0 & 0 & 0 & \ddots & E_{n-1\dots n} \\ 0 & 0 & 0 & \cdots & 0 \end{bmatrix},$$

where

$$E_{i\dots j} = \widehat{M_{i\dots j-1}}M_j - \widehat{M_{i\dots j}}.$$

Thus,  $E$  is precisely the matrix of local consistency errors. (This is also plain from one of Pyne and Vadhan's lemmas [22, Lemma 4.6].)

# On the Hardness of Average-Case $k$ -SUM

## Abstract

In this work, we show the first worst-case to average-case reduction for the classical  $k$ -SUM problem. A  $k$ -SUM instance is a collection of  $m$  integers, and the goal of the  $k$ -SUM problem is to find a subset of  $k$  integers that sums to 0. In the average-case version, the  $m$  elements are chosen uniformly at random from some interval  $[-u, u]$ .

We consider the *total* setting where  $m$  is sufficiently large (with respect to  $u$  and  $k$ ), so that we are guaranteed (with high probability) that solutions must exist. In particular,  $m = u^{\Omega(1/k)}$  suffices for totality. Much of the appeal of  $k$ -SUM, in particular connections to problems in computational geometry, extends to the total setting.

The best known algorithm in the average-case total setting is due to Wagner (following the approach of Blum-Kalai-Wasserman), and achieves a running time of  $u^{\Theta(1/\log k)}$  when  $m = u^{\Theta(1/\log k)}$ . This beats the known (conditional) lower bounds for worst-case  $k$ -SUM, raising the natural question of whether it can be improved even further. However, in this work, we show a matching *average-case lower bound*, by showing a reduction from *worst-case lattice problems*, thus introducing a new family of techniques into the field of fine-grained complexity. In particular, we show that any algorithm solving average-case  $k$ -SUM on  $m$  elements in time  $u^{o(1/\log k)}$  will give a super-polynomial improvement in the complexity of algorithms for lattice problems.

## 1 Introduction

The  $k$ -SUM problem is a parameterized version of the classical subset sum problem. Given a collection of  $m$  integers  $a_1, \dots, a_m$ , the  $k$ -SUM problem asks if there is some subset of cardinality  $k$  that sums to zero.<sup>1</sup> This problem (especially for  $k = 3$ , but more generally for

---

<sup>1</sup> This is the homogeneous version of  $k$ -SUM. One could also define the inhomogeneous version where the instance consists also of a target integer  $t$ , and the goal is to produce a subset of  $k$  elements that sums

arbitrary constant  $k$ ) has been influential in computational geometry, where reductions from  $k$ -SUM have been used to show the conditional hardness of a large class of problems [16, 17]. More generally it has been used in computational complexity, where it has formed the basis for several fine-grained hardness results [33, 2, 38, 28]. We refer the reader to the extensive survey of Vassilevska-Williams [37] for an exposition of this line of work. The  $k$ -SUM problem has also been extensively studied in the cryptanalysis community (see, e.g., [36, 12, 10]).

We know two very different algorithms for  $k$ -SUM: a meet-in-the-middle algorithm that achieves run-time  $O(m^{\lceil k/2 \rceil})$  [23], and dynamic programming or FFT-based algorithms that achieve run-time  $\tilde{O}(um)$  [11] where  $u$  is the largest absolute value of the integers  $a_i$  (A sequence of recent works [27, 14, 8, 25] improve the latter to  $\tilde{O}(u+m)$ ). Note that the latter algorithms outperform the former when  $u \ll m^{\lceil k/2 \rceil}$ , in what is sometimes called the *dense regime* of parameters, a point that we will come back to shortly.

In terms of hardness results for  $k$ -SUM, the work of Pătraşcu and Williams [34] shows that an algorithm that solves the problem in time  $m^{o(k)}$  for all  $m$  will give us better algorithms for SAT, in particular refuting the exponential time hypothesis (ETH). The recent work of Abboud, Bringmann, Hermelin and Shabtay [1] shows that a  $u^{1-\varepsilon}$ -time algorithm (for any constant  $\varepsilon > 0$ ) would refute the strong exponential-time hypothesis (SETH). So, we know that the two algorithms described above are essentially optimal, at least in the worst case.

The focus of this work is the natural average-case version of  $k$ -SUM where the problem instance  $a_1, \dots, a_m$  is chosen independently and uniformly at random from an interval  $[-u, u]$ . We call this the *average-case  $k$ -SUM problem*. In this setting, *deciding* whether a  $k$ -SUM solution exists is in many cases trivial. In particular, if  $\binom{m}{k} \ll u$  then a union bound argument shows that the probability of a solution existing approaches 0. We refer to this as the *sparse* regime of the problem. In contrast, if  $\binom{m}{k}$  is sufficiently larger than  $u$ , then a hashing argument guarantees the existence of many solutions, with high probability over the instance. (See Lemma 14.) As already mentioned above, we refer to this as the *dense* regime.

Notwithstanding this triviality, we notice that in the dense regime one could still consider the *search* problem of *finding* a  $k$ -SUM solution. The search problem seems to retain its hardness even in the dense setting and is the focus of our work. Since we consider the search version of the problem, we also refer to the dense regime as the *total* regime, as the associated search problem has a solution with high probability.

The average-case total problem is *not* quite as hard as the worst-case version (at least assuming SETH), since (slight variants of) Wagner’s generalized birthday algorithm [36] and the Blum-Kalai-Wasserman algorithm [12] show how to solve this problem in time  $u^{O(1/\log k)}$  (when  $m = u^{\Omega(1/\log k)}$ ). This contrasts with the  $u^{1-\varepsilon}$  lower bound of [1] in the worst case. (The BKW/Wagner algorithm was originally stated in a slightly different setting, so we restate it in Section 4.) This leaves the question of *how much easier* the average case is compared to the worst case. Given that the lower bounds from the worst-case setting are not a barrier here, it is a-priori unclear what is the best running time in this setting. Can we improve on [12, 36]?

## 1.1 Our Results

In this work we characterize the hardness of average-case  $k$ -SUM in the total regime by presenting a (conditional) lower bound that matches the  $u^{O(1/\log k)}$  upper bound described above, up to the hidden constant in the exponent.

---

to  $t$ . In the worst-case world, the two versions are equivalent.

In more detail, our main result shows that average-case  $k$ -SUM is indeed hard to solve, under the assumption that *worst-case* lattice problems are hard to approximate. We thus introduce a new family of techniques into the study of the hardness of the  $k$ -SUM problem. Concretely, this lower bound shows that a  $u^{o(1/\log k)}$ -time algorithm for average-case  $k$ -SUM (in the dense regime) implies a  $2^{o(n)}$ -time  $n^{1+\varepsilon}$ -approximation algorithm for the shortest independent vectors problem (SIVP) over an  $n$ -dimensional lattice, a lattice problem for which the best known algorithms run in time  $2^{\Omega(n)}$  [4, 3]. E.g., while Wagner’s algorithm runs in time essentially linear in  $m$  when  $m = u^{\Omega(1/\log k)}$ , we show that such behavior for  $m = u^{o(1/\log k)}$  would imply faster algorithms for SIVP. (One can think of our lower bound as ruling out linear-time algorithms for  $m = u^{o(1/\log k)}$ , or more generally ruling out  $u^{o(1/\log k)}$ -time algorithms for any  $m$ . Indeed, notice that the problem only gets easier as  $m$  becomes larger, so that lower bounds against linear-time algorithms for such large choices of  $m$  immediately implies lower bounds against  $u^{o(1/\log k)}$ -time algorithms for any  $m$ . We therefore switch freely between these two perspectives.)

It is widely believed that no faster algorithm can be found for SIVP. In particular, finding a  $2^{o(n)}$ -time algorithm for SIVP, would have major consequences in lattice-based cryptography both in theory and in practice [32, 6, 7].

We also note in the appendix that some of the connections between  $k$ -SUM and geometric problems from [16, 17] carry over to the dense setting as well. This shows an interesting (and not previously known, as far as we could find) connection between approximate short vectors in lattices, and computational geometry.

## 1.2 Our Techniques

The starting point of our reduction is the well known worst-case to average-case reductions in the lattice world, pioneered by Ajtai [5, 31, 19, 18]. These reductions show that the approximate shortest independent vectors (SIVP) problem, a standard problem in the lattice world, is at least as hard in the worst case as a certain problem called short integer solutions (SIS) on the average. The definition of lattices and the approximate shortest vector problem is not crucial for the current discussion, however we note again that the best algorithms on  $n$ -dimensional lattices that compute any poly( $n$ )-approximation to SIVP run in time  $2^{\Omega(n)}$ . (We refer the curious reader to, e.g., [31, 35], Section 2.3, and the references therein for more background on lattices and lattice problems.)

In the (one-dimensional) *average-case* SIS problem with parameters  $m, Q$  and  $\beta$ , one is given random integers  $a_1, \dots, a_m \in \mathbb{Z}_Q$  and the goal is to find a *non-zero* integer linear combination  $\mathbf{x} = (x_1, \dots, x_m) \in \mathbb{Z}^m$  such that  $\sum_{i \in [m]} a_i x_i = 0 \pmod{Q}$  and  $\mathbf{x}$  is short, namely  $\|\mathbf{x}\|_1 \leq \beta$ . Thus, this is exactly the modular subset sum problem (i.e. subset sum over the group  $\mathbb{Z}_Q$ ), except with weights larger than 1. The parameters of the problem live in the dense/total regime where such solutions are guaranteed to exist with high probability. The worst-case to average-case reductions state that an average-case SIS solver for a sufficiently large  $Q$ , namely  $Q = (\beta n)^{\Omega(n)}$ , gives us an  $\tilde{O}(\sqrt{n \log m} \cdot \beta)$ -approximate algorithm for SIVP. (We refer the reader to Theorem 10 for a more precise statement.)

Our main technical contribution is an average-case to average-case reduction from the SIS problem to the  $k$ -SUM problem. We show this by exhibiting a reduction from SIS to modular  $k$ -SUM (i.e.  $k$ -SUM over the group  $\mathbb{Z}_Q$ ), and one from modular  $k$ -SUM to  $k$ -SUM. The latter is easy to see (in the dense regime): indeed, if you have a  $k$ -subset that sums to 0, it also sums to 0 (mod  $Q$ ) for any  $Q$ . Henceforth in this discussion, when we say  $k$ -SUM, we will mean modular  $k$ -SUM.

To reduce from SIS with parameters  $m, Q, \beta$  to  $k$ -SUM on  $m$  numbers over  $\mathbb{Z}_Q$ , we start with a simple, seemingly trivial, idea. SIS and  $k$ -SUM are so similar that perhaps one could simply run the  $k$ -SUM algorithm on the SIS instance. Unfortunately, this fails. For a  $k$ -SUM solution to exist,  $m$  has to be at least roughly  $Q^{1/k} = n^{\Omega(n/k)}$ . But, this could only possibly give us an approximate SIVP algorithm that runs in time  $n^{\Omega(n/k)}$  (where we are most interested in constant  $k$ ), since the reduction from SIVP has to at least write down the  $m$  samples. This is a meaningless outcome since, as we discussed before, there are algorithms for approximate SIVP that run in time  $2^{O(n)}$ .

Fortunately, ideas from the BKW algorithm [12] for subset sum (and the closely related algorithm from [36] for  $k$ -SUM) come to our rescue. We will start with SIS modulo  $Q = q^L$  for some  $q$  and  $L$  that we will choose later. ([18] showed that worst-case to average-case reductions work for any sufficiently large  $Q$ , including  $Q = q^L$ .)

The BKW algorithm iteratively produces subsets that sum to 0 modulo  $q^i$  for  $i = 1, \dots, L$ , finally producing SIS solutions modulo  $Q$ . To begin with, observe that for a  $k$ -subset-sum to exist modulo  $q$ , it suffices that  $m \approx q^{1/k} \ll Q^{1/k}$ , potentially getting us out of the conundrum from before. In particular, we will set  $q \approx 2^{n \log k}$ ,  $L \approx \log n / \log k$ , therefore  $Q = q^L \approx n^n$  as needed. We will also set  $m \approx q^{\varepsilon / \log k} \approx 2^{\varepsilon n}$  for a large enough  $\varepsilon$  so that solutions exist (since  $m^k \gg q$ ). Furthermore, a hypothetical  $k$ -SUM algorithm mod  $q$  that performs better than BKW/Wagner – that is, runs in time  $q^{o(1/\log k)} = 2^{o(n)}$  – is potentially useful to us.

With this ray of optimism, let us assume that we can run the  $k$ -SUM algorithm many times to get several,  $m$  many, subsets  $S_j$  that sum to 0 modulo  $q$ . (We will return to, and remove, this unrealistic assumption soon.) That is,

$$b_j := \sum_{i \in S_j} a_i = 0 \pmod{q}$$

The BKW/Wagner approach would then be to use the  $(b_1, \dots, b_m)$  to generate  $(c_1, \dots, c_m)$  that are 0 (mod  $q^2$ ), and so on. Note that  $c_i$  are a linear combination of  $a_1, \dots, a_m$  with weight  $k^2$ . At the end of the iterations, we will obtain at least one linear combination of  $(a_1, \dots, a_m)$  of weight  $\beta = k^L$  that sums to 0 modulo  $q^L = Q$ , solving SIS. (We also need to make sure that this is a non-zero linear combination, which follows since the coefficients of all intermediate linear combinations are positive.)

This would finish the reduction, except that we need to remove our unrealistic assumption that we can use the  $k$ -SUM oracle to get many  $k$ -subsets of  $(a_1, \dots, a_m)$  that sum to 0. For one, the assumption is unrealistic because if we feed the  $k$ -SUM oracle with the same  $(a_1, \dots, a_m) \pmod{q}$  twice, we will likely get the same  $k$ -SUM solution. On the other hand, using a fresh random instance for every invocation of the  $k$ -SUM oracle will require  $m$  to be too large (essentially returning to the trivial idea above). A natural idea is to observe that each  $k$ -SUM solution touches a very small part of the instance. Therefore, one could hope to first receive a  $k$ -SUM  $a_{i_1} + \dots + a_{i_k}$  from the oracle, and in the next iteration, use as input  $\{a_1, \dots, a_m\} \setminus \{a_{i_1}, \dots, a_{i_k}\}$ , which is nearly as large as the original set. Unfortunately, continuing like this cannot work in general. The distributions of the successive instances that we feed to the oracle will no longer be uniform, and even worse, the oracle itself can choose which elements to remove from our set. A malicious oracle could therefore prevent us from obtaining many  $k$ -SUMs in this way, even if the oracle has high success probability on uniform input. (One can even imagine that the fastest algorithm for  $k$ -SUM would actually yield such a malicious oracle. E.g., if an algorithm has a “preference” for some types of  $k$ -SUMs over others, then running the algorithm repeatedly in this way could eventually deplete the input of such  $k$ -SUMs, causing the algorithm to fail.)

Instead, our key idea is rather simple, namely to resort to (re)randomization. Given an instance  $(a_1, \dots, a_m) \in \mathbb{Z}_q^m$ , we compute many random subset sums to generate  $(a'_1, \dots, a'_m) \in \mathbb{Z}_q^m$ . That is, we choose  $k$ -subsets  $T'_i \subseteq [m]$  and let

$$a'_i = \sum_{j \in T'_i} a_j \pmod{q}$$

Since  $q \gg m^{1/k}$ , the leftover hash lemma [24] tells us that the  $a'_i$  are (statistically close to) uniformly random mod  $q$ . Furthermore, a  $k$ -subset sum of  $(a'_1, \dots, a'_m)$  will give us a  $k^2$ -subset sum of  $(a_1, \dots, a_m)$  that sums to 0 (mod  $q$ ). To obtain a new subset sum of  $(a_1, \dots, a_m)$ , simply run this process again choosing fresh subsets  $T''_i$  to generate  $(a''_1, \dots, a''_m)$ ; and so on. Eventually, this will give us a  $\beta = k^{2L}$  weight solution to SIS, which is a quadratic factor worse than before, but good enough for us. (We are glossing over an important technical detail here, which is how we ensure that the resulting subset sums yield uniformly random independent elements in  $q\mathbb{Z}/q^2\mathbb{Z}$ .)

To finish the analysis of the reduction, observe that it calls the  $k$ -SUM oracle  $\approx mL$  times. Assuming the oracle runs in time  $q^{o(1/\log k)}$ , this gives us a  $2^{o(n)}$ -time algorithm for approximate SIVP. The approximation factor is  $\tilde{O}(\sqrt{n \log m} \cdot \beta) \approx n^3$ . (In the sequel, we achieve  $n^{1+o(1)}$  by a careful choice of parameters.)

Interestingly, our reduction re-imagines the BKW/Wagner *algorithm as a reduction* from the SIS problem to  $k$ -SUM, where the original algorithm is achieved (in retrospect) by plugging in the trivial algorithm for 2-SUM. Of course, the algorithm is much simpler than the reduction (in particular, there is no need for re-randomization) since we don't need to account for "malicious"  $k$ -SUM solvers. Our main technical contribution can therefore be viewed as making the ideas from the BKW/Wagner *algorithm* (ideas which are now ubiquitous in the study of algorithms for subset sum and lattice problems) work as a *reduction* – i.e., with an arbitrary average-case  $k$ -SUM oracle.

### 1.3 Open Problems and Future Directions

Our work introduces the powerful toolkit of lattice problems into the field of average-case fine-grained complexity, and raises several natural directions for further research.

First is the question of whether a result analogous to what we show holds in the sparse/planted regime as well. A possible theorem here would rule out an  $m^{o(k)}$ -time algorithm for  $k$ -SUM, assuming the hardness of lattice problems. To the best of our knowledge, in the sparse/planted regime it is not known whether the average-case problem is easier than the worst-case problem as in the dense regime.

Second is the question of whether we can obtain average-case hardness of  $k$ -SUM for concrete small constants  $k$ , perhaps even  $k = 3$ . Our hardness result is asymptotic in  $k$ .

Third is the question of whether we can show the average-case hardness of natural distributions over *combinatorial and computational-geometric* problems, given their connection to  $k$ -SUM. In this vein, we show a simple reduction to (perhaps not the most natural distribution on) the  $(Q, m, d)$ -plane problem in Appendix A, but we believe much more can be said. More generally, now that we have shown average-case hardness of  $k$ -SUM, it is natural to try to reduce average-case  $k$ -SUM to other natural average-case problems.

### 1.4 Other Related Works

There are now quite a few works that study average-case fine-grained hardness of problems in  $P$ . We mention a few. First, Ball, Rosen, Sabin, and Vasudevan [9] showed a reduction from SAT to an (average-case) variant of the orthogonal vectors problem. They demonstrated that sub-quadratic algorithms for their problem would refute SETH.

There is also a sequence of works on the average-case hardness of counting  $k$ -cliques. The work of Goldreich and Rothblum [20, 21] shows worst-case to average-case *self*-reductions for the problem of counting  $k$ -cliques (and other problems in  $P$ ). Boix-Adserà, Brennan, and Bresler proved the same result for  $G_{n,p}$  [13], and Hirahara and Shimizu recently showed that it is even hard to count the number of  $k$ -cliques with even a small probability of success [22]. In contrast, our reductions go from the worst-case of one problem (SIVP) to the average-case of another ( $k$ -SUM). We find it a fascinating problem to show a worst-case to average-case *self*-reduction for  $k$ -SUM.

Dalirrooyfard, Lincoln, and Vassilevska Williams [15] recently proved fine-grained average-case hardness for many different problems in  $P$  under various complexity-theoretic assumptions. In particular, they show fine-grained average-case hardness of *counting* the number of solutions of a non-standard *factored* variant of  $k$ -SUM under well-studied fine-grained hardness assumptions. In contrast, we show fine-grained average-case hardness of the standard *search*  $k$ -SUM problem under an assumption that is well-studied in the lattice community but perhaps not previously considered in the fine-grained complexity world. So, our conclusion is more natural – both because it works for a search problem rather than a counting problem and because it works with the standard notion of  $k$ -SUM rather than a factored variant – but we rely on a less-standard assumption.

For the lattice expert, we remark that if one unwraps our reduction from SIVP to SIS and then to  $k$ -SUM, we obtain a structure that is superficially similar to [30]. However, in their setting, they do not need to reuse samples and therefore do not need the re-randomization technique, which is the key new idea in this work.

More generally, there are many works that use BKW/Wagner-style techniques together with a specific solver for  $k$ -SUM or subset sum to solve various lattice problems. (See, for example, [29, 30, 26].) In contrast, we show a generic *reduction* from SIVP to average-case  $k$ -SUM that can be instantiated with *any* average-case  $k$ -SUM oracle.

## 1.5 Organization of the Paper

Section 3 describes the modular variant of  $k$ -SUM as well as the standard  $k$ -SUM (over the integers), shows their totality on average, and reductions between them. For completeness, we describe the BKW/Wagner algorithm in Section 4. We remark that while the standard descriptions of the algorithm refer to finite groups, we need one additional trick (namely, Lemma 15) to obtain the algorithm over the integers. Finally, our main result, the worst-case to average-case reduction is described in Section 5. The connection to computational geometry is provided in Appendix A.

## 2 Preliminaries

We write  $\log$  for the logarithm base two and  $\ln$  for the natural logarithm. We write  $\binom{m}{k} := \frac{m!}{(m-k)!k!}$  for the binomial coefficient.

### 2.1 Probability

We make little to no distinction between random variables and their associated distributions.

For two random variables  $X, Y$  over some set  $S$ , we write  $\Delta(X, Y) := \sum_{z \in S} |\Pr[X = z] - \Pr[Y = z]|$  for the statistical distance between  $X$  and  $Y$ . For a finite set  $S$ , we write  $U_S$  for the uniform distribution over  $S$ .

Recall that a set of functions  $\mathcal{H} \subseteq \{h : X \rightarrow Y\}$  is a *universal family of hash functions* from  $X$  to  $Y$  if for any distinct  $x, x' \in X$

$$\Pr_{h \sim \mathcal{H}} [h(x) = h(x')] \leq 1/|Y|.$$

► **Lemma 1** (Leftover hash lemma, [24]). *If  $\mathcal{H}$  is a universal family of hash functions from  $X$  to  $Y$ , then*

$$\Pr[\Delta(h(U_X), U_Y) \geq \beta] \leq \beta,$$

where the probability is over a random choice of  $h \sim \mathcal{H}$  and  $\beta := (|Y|/|X|)^{1/4}$ .

► **Lemma 2.** *For any positive integers  $Q, m$ , let  $\mathcal{H}$  be the family of hash functions from  $\{0, 1\}^m$  to  $\mathbb{Z}_Q$  given by  $h_{\mathbf{a}}(\mathbf{x}) = \langle \mathbf{a}, \mathbf{x} \rangle \bmod Q$  for all  $\mathbf{a} \in \mathbb{Z}_Q^m$ . Then,  $\mathcal{H}$  is a universal family of hash functions.*

**Proof.** Let  $\mathbf{x}, \mathbf{y} \in \{0, 1\}^m$  be distinct vectors, and suppose without loss of generality that  $x_1 = 1$  and  $y_1 = 0$ . We write  $\mathbf{a}' \in \mathbb{Z}_Q^{m-1}$  for the vector obtained by removing the first coordinate from  $\mathbf{a}$  and  $a_1$  for the first coordinate itself. Similarly, we write  $\mathbf{x}', \mathbf{y}' \in \{0, 1\}^{m-1}$  for the vectors  $\mathbf{x}, \mathbf{y}$  with their first coordinate removed. Then,

$$\begin{aligned} \Pr[\langle \mathbf{a}, \mathbf{x} \rangle = \langle \mathbf{a}, \mathbf{y} \rangle \bmod Q] &= \Pr[\langle \mathbf{a}', \mathbf{x}' \rangle + a_1 = \langle \mathbf{a}', \mathbf{y}' \rangle \bmod Q] \\ &= \Pr[a_1 = \langle \mathbf{a}', \mathbf{y}' - \mathbf{x}' \rangle \bmod Q] = 1/Q, \end{aligned}$$

where the probability is over the random choice of  $\mathbf{a} \in \mathbb{Z}_Q^m$ . The last equality follows from the fact that  $a_1 \in \mathbb{Z}_Q$  is uniformly random and independent of  $\mathbf{a}'$ . ◀

► **Corollary 3.** *For any positive integers  $Q, m$  and any subset  $X \subseteq \{0, 1\}^m$ ,*

$$\Pr_{\mathbf{a} \sim \mathbb{Z}_Q^m} [\Delta(\langle \mathbf{a}, U_X \rangle \bmod Q, U_{\mathbb{Z}_Q}) \geq \beta] \leq \beta,$$

where  $\beta := (Q/|X|)^{1/4}$ .

► **Corollary 4.** *Let  $\mathbf{a} := (a_1, \dots, a_M) \in \mathbb{Z}_Q^M$  be sampled uniformly at random, and let  $S_1, \dots, S_{M'} \subset [M]$  be sampled independently and uniformly at random with  $|S_i| = t$ . Let  $c_i := \sum_{j \in S_i} a_j \bmod Q$ . Then,  $(\mathbf{a}, \mathbf{c}) := (a_1, \dots, a_M, c_1, \dots, c_{M'})$  is within statistical distance  $\delta$  of a uniformly random element in  $\mathbb{Z}_Q^{M+M'}$ , where*

$$\delta := (M' + 1) \cdot Q^{1/4} \cdot \binom{M}{t}^{-1/4} \leq (M' + 1) \cdot \left(\frac{Qt^t}{M^t}\right)^{1/4}.$$

**Proof.** Let  $X_t := \{\mathbf{x} \in \{0, 1\}^M : \|\mathbf{x}\|_1 = t\}$ , and notice that  $|X_t| = \binom{M}{t}$ . Call  $\mathbf{a}$  good if  $\Delta(\langle \mathbf{a}, U_{X_t} \rangle \bmod Q, U_{\mathbb{Z}_Q}) \leq \beta := Q^{1/4}/|X_t|^{1/4}$ . From Corollary 3, we see that  $\mathbf{a}$  is good except with probability at most  $\beta$ .

Finally, notice that the  $c_i$  are distributed exactly as independent samples from  $\langle \mathbf{a}, U_{X_t} \rangle$ . Therefore, if  $\mathbf{a}$  is good, each of the  $c_i$  is within statistical distance  $\beta$  of an independent uniform sample. The result then follows from the union bound. ◀

## 2.2 Hitting probabilities

► **Definition 5.** For  $\mathbf{a} := (a_1, \dots, a_M) \in \mathbb{Z}_Q^M$ ,  $\mathbf{c} := (c_1, \dots, c_{M'}) \in \mathbb{Z}_Q^{M'}$ ,  $I \subset [M]$ ,  $J \subset [M']$ , and a positive integer  $t$ , the  $t$ -hitting probability of  $\mathbf{a}$ ,  $\mathbf{c}$ ,  $I$ , and  $J$  is defined as follows. For each  $j \in J$ , sample a uniformly random  $S_j \in \binom{[M]}{t}$  with  $\sum_{i \in S_j} a_i = c_j$ . (If no such  $S_j$  exists, then we define the hitting probability to be 1.) The hitting probability is then

$$p_{\mathbf{a}, \mathbf{c}, I, J, t} := \Pr[\exists j, j' \in J \text{ such that } S_j \cap I \neq \emptyset \text{ or } S_{j'} \cap I \neq \emptyset].$$

► **Lemma 6.** For any positive integers  $Q, M, t$  and  $0 < \varepsilon < 1$ ,

$$\Pr_{\mathbf{a} \sim \mathbb{Z}_Q^M, \mathbf{c} \sim \mathbb{Z}_Q} \left[ p_{\mathbf{a}, \mathbf{c}, t} \geq \frac{1 + \varepsilon}{1 - \varepsilon} \cdot \frac{t}{M} \right] \leq \frac{4Q^{1/4}}{\varepsilon \cdot \binom{M-1}{t-1}^{1/4}}.$$

where

$$p_{\mathbf{a}, \mathbf{c}, t} := p_{\mathbf{a}, \mathbf{c}, \{1\}, \{1\}, t}.$$

**Proof.** We have

$$p_{\mathbf{a}, \mathbf{c}, t} = \Pr_{\mathbf{x} \sim X_t} [x_1 = 1 \mid \langle \mathbf{a}, \mathbf{x} \rangle = c \bmod Q],$$

where  $X_t := \{\mathbf{x} \in \{0, 1\}^M : \|\mathbf{x}\|_1 = t\}$ . Therefore,

$$\begin{aligned} p_{\mathbf{a}, \mathbf{c}, t} &= \Pr_{\mathbf{x} \sim X_t} [x_1 = 1] \cdot \Pr_{\mathbf{x} \sim X_t} [\langle \mathbf{a}, \mathbf{x} \rangle = c \bmod Q \mid x_1 = 1] / \Pr_{\mathbf{x} \sim X_t} [\langle \mathbf{a}, \mathbf{x} \rangle = c \bmod Q] \\ &= \frac{t}{M} \cdot \Pr_{\mathbf{x}' \sim X'_{t-1}} [\langle \mathbf{a}_{-1}, \mathbf{x}' \rangle = c - a_1 \bmod Q] / \Pr_{\mathbf{x} \sim X_t} [\langle \mathbf{a}, \mathbf{x} \rangle = c \bmod Q], \end{aligned}$$

where  $\mathbf{a}_{-1}$  is  $\mathbf{a}$  with its first coordinate removed and  $X'_{t-1} := \{\mathbf{x} \in \{0, 1\}^{M-1} : \|\mathbf{x}\|_1 = t-1\}$ .

So, let

$$p_{\mathbf{a}, \mathbf{c}} := \Pr_{\mathbf{x} \sim X_t} [\langle \mathbf{a}, \mathbf{x} \rangle = c \bmod Q],$$

and

$$p'_{\mathbf{a}, \mathbf{c}} := \Pr_{\mathbf{x}' \in X'_{t-1}} [\langle \mathbf{a}_{-1}, \mathbf{x}' \rangle = c - a_1 \bmod Q].$$

As in the proof of Corollary 4, we see that

$$\sum_{c \in \mathbb{Z}_Q} |p_{\mathbf{a}, \mathbf{c}} - 1/Q| = \Delta(\langle \mathbf{a}, U_{X_t} \rangle \bmod Q, U_{\mathbb{Z}_Q}) \leq Q^{1/4} / \binom{M}{t}^{1/4} \quad (1)$$

except with probability at most  $Q^{1/4} / \binom{M}{t}^{1/4}$  over  $\mathbf{a}$ . Similarly,

$$\sum_{c \in \mathbb{Z}_Q} |p'_{\mathbf{a}, \mathbf{c}} - 1/Q| = \Delta(\langle \mathbf{a}_{-1}, U_{X'_{t-1}} \rangle \bmod Q, U_{\mathbb{Z}_Q}) \leq Q^{1/4} / \binom{M-1}{t-1}^{1/4} \quad (2)$$

except with probability at most  $Q^{1/4} / \binom{M-1}{t-1}^{1/4}$  over  $\mathbf{a}$ .

So, suppose that  $\mathbf{a}$  satisfies Eq. (1) and Eq. (2). Then, by Markov's inequality,

$$\Pr_{c \in \mathbb{Z}_Q} [p_{\mathbf{a}, \mathbf{c}} \geq (1 - \varepsilon)/Q] \leq \frac{Q^{1/4}}{\varepsilon \cdot \binom{M}{t}^{1/4}}$$

for any  $0 < \varepsilon < 1$ , and similarly,

$$\Pr_{c \in \mathbb{Z}_Q} [p'_{\mathbf{a},c} \leq (1+r)/Q] \leq \frac{Q^{1/4}}{\varepsilon \cdot \binom{M-1}{t-1}^{1/4}}.$$

Therefore, for such  $\mathbf{a}$ ,

$$\Pr[p_{\mathbf{a},c,t} \geq (1+\varepsilon)t/((1-\varepsilon)M)] \leq \frac{2Q^{1/4}}{\varepsilon \cdot \binom{M-1}{t-1}^{1/4}}.$$

The result then follows by union bound.  $\blacktriangleleft$

By repeated applications of union bound, we derive the following corollary.

► **Corollary 7.** *For any positive integers  $Q, M, M', t, v, v'$  and  $0 < \varepsilon < 1$ , let  $\mathbf{a} \sim \mathbb{Z}_Q^M$  and  $\mathbf{c} \sim \mathbb{Z}_Q^{M'}$  be sampled uniformly at random. Then,*

$$p_{\mathbf{a},\mathbf{c},I,J,t} \leq (v + tv') \cdot v' \cdot \frac{1+\varepsilon}{1-\varepsilon} \cdot \frac{t}{M}$$

for all  $I \in \binom{[M]}{\leq v}$ ,  $J \in \binom{[M']}{\leq v'}$  except with probability at most

$$4MM' \frac{Q^{1/4}}{\varepsilon \cdot \binom{M-1}{t-1}^{1/4}}.$$

**Proof.** Let  $\eta := \max_{i,j} p_{\mathbf{a},\mathbf{c},\{i\},\{j\},t}$ . By union bound, for any set  $I$ , we have

$$p_{\mathbf{a},\mathbf{c},I,\{j\},t} \leq \sum_{i \in I} p_{\mathbf{a},\mathbf{c},\{i\},\{j\},t} \leq |I| \cdot \eta.$$

Fix some set  $J$ . Let  $S_j$  be as in the definition of the hitting probability, and let  $I_{-j} := I \cup \bigcup_{j' \in J \setminus \{j\}} S_{j'}$ . Notice that  $|I_{-j}| \leq |I| + t|J|$ . Then,

$$p_{\mathbf{a},\mathbf{c},I,J,t} \leq \sum_{j \in J} p_{\mathbf{a},\mathbf{c},I_{-j},\{j\},t} \leq (|I| + t|J|) \cdot |J| \cdot \eta.$$

Finally, by union bound and Lemma 6, we have

$$\eta \leq \frac{1+\varepsilon}{1-\varepsilon} \cdot \frac{r}{M}$$

except with probability at most

$$4MM' \frac{Q^{1/4}}{\varepsilon \cdot \binom{M-1}{t-1}^{1/4}}.$$

The result follows.  $\blacktriangleleft$

### 2.3 Lattices and Lattice Problems

► **Definition 8** (Shortest Independent Vectors Problem). *For an approximation factor  $\gamma := \gamma(n) \geq 1$ ,  $\gamma$ -SIVP is the search problem defined as follows. Given a lattice  $\mathcal{L} \subset \mathbb{R}^n$ , output  $n$  linearly independent lattice vectors which all have length at most  $\gamma(n)$  times the minimum possible,  $\lambda_n(\mathcal{L})$ .*

► **Definition 9** (Short Integer Solutions). For integers  $m, Q, \beta$ , the (average-case) short integer solutions problem  $\text{SIS}(m, Q, \beta)$  is defined by  $m$  integers  $a_1, \dots, a_m$  drawn uniformly at random and independently from  $\mathbb{Z}_Q$ , and the goal is to come up with a non-zero vector  $\mathbf{x} = (x_1, \dots, x_m)$  where

$$\sum_{i \in [m]} x_i a_i = 0 \pmod{Q} \quad \text{and} \quad \|\mathbf{x}\|_1 := \sum_{i=1}^m |x_i| \leq \alpha$$

Following the seminal work of Ajtai [5], there have been several works that show how to solve the *worst-case*  $\gamma$ -SIVP problem given an algorithm for the *average-case* SIS problem. We will use the most recent one due to Gama et al. [18] (specialized to the case of cyclic groups for simplicity).

► **Theorem 10** (Worst-Case to Average-Case Reduction for SIS [31, 18]). Let  $n, Q, \beta \in \mathbb{N}$  where  $Q = (\beta n)^{\Omega(n)}$ . If there is an algorithm for the average-case SIS problem  $\text{SIS}(m, Q, \beta)$  over  $\mathbb{Z}_Q$  that runs in time  $T$ , then there is an  $(m + T) \cdot \text{poly}(n)$ -time algorithm for worst-case  $\tilde{O}(\sqrt{n \log m} \cdot \beta)$ -SIVP on any  $n$ -dimensional lattice  $L$ .

### 3 Variants of Average-case $k$ -SUM: Totality and Reductions

We define two variants of average-case  $k$ -SUM, one over the integers (which is the standard version of  $k$ -SUM) and one over the finite group  $\mathbb{Z}_Q$  of integers modulo  $Q$ . We show that the hardness of the two problems is tied together, which will allow us to use the modular version for our results down the line.

► **Definition 11** (Average-case  $k$ -SUM). For positive integers  $m, k \geq 2$  and  $u \geq 1$ , the average-case  $k$ -SUM( $u, m$ ) problem is the search problem defined as follows. The input is  $a_1, \dots, a_m \in [-u, u]$  chosen uniformly and independently at random, and the goal is to find  $k$  distinct indices  $i_1, \dots, i_k$  such that  $a_{i_1}, \dots, a_{i_k}$  with  $a_{i_1} + \dots + a_{i_k} = 0$ .

We define the modular version of the problem where the instance consists of numbers chosen at random from the finite additive group  $\mathbb{Z}_Q$  of numbers modulo  $Q$ . This will appear as an intermediate problem in our algorithm in Section 4 and our worst-case to average-case reduction in Section 5.

► **Definition 12** (Average-case Modular  $k$ -SUM). For integers  $m, k \geq 2$  and integer modulus  $Q \geq 2$ , the average-case  $k$ -SUM( $\mathbb{Z}_Q, m$ ) problem is the search problem defined as follows. The input is  $a_1, \dots, a_m \sim \mathbb{Z}_Q$  chosen uniformly and independently at random, and the goal is to find  $k$  distinct indices  $i_1, \dots, i_k$  such that  $a_{i_1}, \dots, a_{i_k}$  with  $a_{i_1} + \dots + a_{i_k} = 0 \pmod{Q}$ .

We highlight the distinction in our notation for the two problems. The former (non-modular version) is denoted  $k$ -SUM( $u, m$ ) (the first parameter is the bound  $u$  on the absolute value of the elements), whereas the latter is denoted  $k$ -SUM( $\mathbb{Z}_Q, m$ ) (the first parameter indicates the group on which the problem is defined). The second parameter always refers to the number of elements in the instance.

We now show that the modular problem is total when  $\binom{m}{k} \gtrsim Q$  and is unlikely to have a solution when  $\binom{m}{k} \lesssim Q$ .

► **Lemma 13.** If  $a_1, \dots, a_m \sim \mathbb{Z}_Q$  are sampled uniformly at random, and  $E_k$  is the event that there exist distinct indices  $i_1, \dots, i_k$  with  $a_{i_1} + \dots + a_{i_k} = 0 \pmod{Q}$ , then

$$1 - Q / \binom{m}{k} \leq \Pr[E_k] \leq \binom{m}{k} / Q.$$

**Proof.** Notice that for fixed indices  $i_1, \dots, i_k$ , the probability that  $a_{i_1} + \dots + a_{i_k} = 0$  is exactly  $1/Q$ . The upper bound then follows from a union bound over all  $\binom{m}{k}$   $k$ -tuples of indices. Furthermore, notice that  $i_1, \dots, i_k$  and  $j_1, \dots, j_k$ , the event that  $a_{i_1} + \dots + a_{i_k} = 0 \pmod{Q}$  is independent of the event that  $a_{j_1} + \dots + a_{j_k} = 0 \pmod{Q}$  as long as  $\{i_1, \dots, i_k\} \neq \{j_1, \dots, j_k\}$ . The lower bound then follows from Chebyshev's inequality.  $\blacktriangleleft$

► **Lemma 14.** *If  $a_1, \dots, a_m \sim [-u, u]$  are sampled uniformly at random, and  $E_k$  is the event that there exist distinct indices  $i_1, \dots, i_k$  with  $a_{i_1} + \dots + a_{i_k} = 0$ , then*

$$1 - e^{-\alpha} \leq \Pr[E_k] \leq \binom{m}{k} / (2u + 1),$$

where

$$\alpha := \frac{1}{4k + 2} \cdot \left\lfloor \frac{m}{k(20u + 10)^{1/k}} \right\rfloor \approx m / (k^2 u^{1/k}).$$

**Proof.** The upper bound follows immediately from the upper bound in Lemma 13 together with the observation that elements that sum to zero over the integers must sum to zero modulo  $Q := 2u + 1$  as well.

Let  $m' := k(10Q)^{1/k}$ . Let  $E'_k$  be the event that there exist distinct indices  $i_1, \dots, i_k \leq m'$  with  $a_{i_1} + \dots + a_{i_k} = 0$ . Notice that

$$\Pr[E_k] \geq 1 - (1 - \Pr[E'_k])^{\lfloor m/m' \rfloor} \geq 1 - \exp(-\lfloor m/m' \rfloor \Pr[E'_k]).$$

So, it suffices to show that

$$\Pr[E'_k] \geq \frac{1 - Q / \binom{m'}{k}}{2k + 1} \geq \frac{1}{4k + 2}.$$

By Lemma 13, we know that with probability at least  $1 - Q / \binom{m'}{k}$ , there exists a  $k$ -SUM that sums to zero modulo  $Q$  in the first  $m'$  elements. I.e.,  $a_{i_1} + \dots + a_{i_k} = \ell Q$  for some  $\ell \in \{-k, -k + 1, \dots, k - 1, k\}$  and  $i_1, \dots, i_k \leq m'$ . We wish to argue that  $\ell = 0$  is at least as likely as  $\ell = i$  for any  $i$ .

Let  $p(k', s) := \Pr[a_1 + \dots + a_{k'} = s]$  for integers  $k', s$ . Notice that for  $s \geq 0$ , we have

$$\begin{aligned} p(k' + 1, s) - p(k' + 1, s + 1) &= (p(k', -(s + u)) - p(k', s + u + 1)) / (2u + 1) \\ &= (p(k', s + u) - p(k', s + u + 1)) / (2u + 1). \end{aligned}$$

It then follows from a simple induction argument that  $p(k, s + 1) \leq p(k, s)$ . In particular,  $p(k, \ell Q) \leq p(k, 0)$  for any  $\ell$ . Therefore, letting  $E'_{k,Q}$  be the event that the first  $m'$  elements contain a  $k$ -SUM modulo  $Q$ , we have

$$\begin{aligned} \Pr[E'_k] &\geq \Pr[E'_{k,Q}] \cdot \Pr[a_{i_1} + \dots + a_{i_k} = 0 \mid a_{i_1} + \dots + a_{i_k} = 0 \pmod{Q}] \\ &\geq \frac{\Pr[E'_{k,Q}]}{2k + 1}. \end{aligned}$$

Finally, by Lemma 13, we have

$$\Pr[E'_{k,Q}] \geq 1 - Q / \binom{m'}{k} \geq 1/2,$$

as needed.  $\blacktriangleleft$

### 3.1 From $k$ -SUM to Modular $k$ -SUM and Back

We first show that an algorithm for the modular  $k$ -SUM problem gives us an algorithm for the  $k$ -SUM problem. A consequence of this is that when we describe the algorithm for  $k$ -SUM in Section 4, we will focus on the modular variant.

► **Lemma 15.** *Let  $u$  be a positive integer and let  $Q = 2u + 1$ . If there is an algorithm for the  $k$ -SUM( $\mathbb{Z}_Q, m$ ) that runs in time  $T$  and succeeds with probability  $p$ , then there is an algorithm for  $2k$ -SUM( $u, 2m$ ) that runs in time  $O(T)$  and succeeds with probability at least  $p^2/k$ .*

**Proof.** Let  $\mathcal{A}$  be the purported algorithm for  $k$ -SUM( $\mathbb{Z}_Q, m$ ). The algorithm for  $2k$ -SUM( $u, 2m$ ) receives  $2m$  integers  $a_1, \dots, a_{2m}$  in the range  $[-u, u]$  and works as follows. We use the natural embedding to associate elements in  $\mathbb{Z}_Q$  with elements in  $[-u, u]$ , so we may think of  $a_1, \dots, a_{2m}$  also as elements in  $\mathbb{Z}_Q$  (simply by considering their coset modulo  $Q$ ).

- Run  $\mathcal{A}$  on  $a_1, \dots, a_m$  to obtain a  $k$ -subset  $S_1$ . If  $\mathcal{A}$  does not succeed, then fail.
- Run  $\mathcal{A}$  on  $-a_{m+1}, \dots, -a_{2m}$  to obtain a  $k$ -subset  $S_2$ . If  $\mathcal{A}$  does not succeed, then fail.
- If  $\sum_{i \in S_1} a_i = -\sum_{i \in S_2} a_i$ , output  $S_1 \cup S_2$  as the  $2k$ -subset. Fail otherwise.

It is clear that the run-time is  $O(T)$  and that if the algorithm does not fail then it indeed outputs a valid  $2k$ -sum. It suffices to bound the probability that the algorithm succeeds.

Since the first two steps run  $\mathcal{A}$  on independent and identically distributed input, we can deduce that the probability that both succeed is  $p^2$ , and in the case that both succeed, their output satisfies

$$\sum_{i \in S_1} a_i = \alpha_1 Q \quad \text{and} \quad \sum_{i \in S_2} a_i = \alpha_2 Q$$

for some integers  $\alpha_1, \alpha_2 \in (-k/2, k/2)$ , which are independent and identically distributed random variables. The probability that  $\alpha_1 = \alpha_2$  is therefore at least  $1/k$ , since the collision probability of a random variable is bounded by the inverse of its support size. If this happens then,  $\sum_{i \in S_1} a_i = \sum_{i \in S_2} a_i$  and the algorithm succeeds. Thus, we conclude that our algorithm succeeds with probability at least  $p^2/k$ . ◀

Finally, we show a proof in the other direction. Namely, that an algorithm for the  $k$ -SUM problem gives us an algorithm for the modular  $k$ -SUM problem. We will use this when we describe the worst-case to average-case reduction in Section 5.

► **Lemma 16.** *For  $m \geq k \cdot u^{2/k}$ , if there is an algorithm for  $k$ -SUM( $u, m$ ) that runs in time  $T$  and succeeds with probability  $p$ , then there is an algorithm for  $k$ -SUM( $\mathbb{Z}_{2u+1}, m$ ) that runs in time  $T$  and succeeds with probability  $p$ .*

**Proof.** Let  $\mathcal{A}$  be the purported algorithm for  $k$ -SUM( $u, m$ ). The algorithm for  $k$ -SUM( $\mathbb{Z}_{2u+1}, m$ ) receives  $m$  integers  $a_1, \dots, a_m \in \mathbb{Z}_{2u+1}$  and works as follows.

As before, identify  $\mathbb{Z}_{2u+1}$  with the interval  $[-u, u]$  and run  $\mathcal{A}$  on  $a_1, \dots, a_m$ . We can then simply output the resulting  $k$ -subset  $S$ . In particular, if  $\sum_{i \in S} a_i = 0$ , then we of course have  $\sum_{i \in S} a_i = 0 \pmod{2u+1}$ .

Clearly, the success probability of the resulting algorithm is at least  $p$ , since the input to  $\mathcal{A}$  is distributed uniformly. ◀

#### 4 The $u^{O(1/\log k)}$ -time Algorithm for Average-case $k$ -SUM

In this section, we describe a variant of the Blum-Kalai-Wasserman algorithm [12] for the average-case  $k$ -SUM problem that runs in time  $u^{O(1/\log k)}$ .

► **Theorem 17.** *There is a  $\tilde{O}(2^\ell q^2)$ -time algorithm that solves average-case  $2^\ell$ -SUM( $\mathbb{Z}_{q^\ell}, m$ ) for  $m = \tilde{\Theta}(2^\ell q^2)$ .*

**Proof.** On input  $a_1, \dots, a_m \in \mathbb{Z}_{q^\ell}$  with  $m := 1000\ell^2 q^2 2^\ell \log q = \tilde{\Theta}(2^\ell q^2)$ , the algorithm behaves as follows. Let  $L_1 := (a_1, \dots, a_m)$ . For  $i = 1, \dots, \ell$ , the algorithm groups the elements in  $L_i$  according to their value modulo  $q^i$ . It then greedily groups them into  $m_{i+1}$  disjoint points  $(a, b)$  with  $a + b = 0 \pmod{q^i}$ . It sets  $L_{i+1}$  to be the list of sums of these pairs (and records the indices of the  $2^i$  input elements that sum to  $a + b$ ). If at any point the algorithm fails to find such pairs, it simply fails; otherwise, the algorithm outputs the elements  $a_{i_1}, \dots, a_{i_{2^\ell}}$  satisfying  $\sum a_{i_j} = 0 \pmod{q^\ell}$  found in the last step.

The running time of the algorithm is clearly  $\text{poly}(\ell, \log q, \log m)m$  as claimed. To prove correctness, we need to show that at each step the algorithm is likely to succeed in populating the list  $L_{i+1}$  with at least  $m_i := (\ell^2 - i^2)/\ell^2 \cdot m/2^{i-1}$  elements, since clearly the algorithm outputs a valid  $2^\ell$ -SUM in this case.

Suppose that the algorithm succeeds up to the point where it populates  $L_i$ . Let  $L_i = (b_1, \dots, b_{m_i})$ , and  $b'_i := (b_i/q^{i-1}) \pmod{q}$ , where the division by  $q^{i-1}$  is possible because  $b_i = 0 \pmod{q^{i-1}}$  by assumption. Notice that the  $b'_i$  are independent and uniformly random. For  $j \in \mathbb{Z}_q$ , let  $c_j := |\{i : b'_i = j \pmod{q}\}|$ . Notice that the algorithm successfully populates  $L_{i+1}$  if and only if

$$\sum_{j \in \mathbb{Z}_q} \min\{c_j, c_{-j}\}/2 \geq m_{i+1}.$$

By the Chernoff-Hoeffding bound, we have that

$$\Pr [c_j < m_i/q - 10\sqrt{m_i \log m_i}] \leq 1/m_i^2$$

It follows that

$$\sum_j \min\{c_j, c_{-j}\}/2 \geq q \min\{c_j\}/2 \geq m_i/2 - 5q\sqrt{m_i \log m_i} \geq m_{i+1}$$

except with probability at most  $1/m_i$ . By union bound, we see that the algorithm succeeds in populating every list except with probability at most  $\sum 1/m_i \ll 1/10$ , as needed. ◀

Combining this with Lemma 15 (the reduction from  $k$ -SUM to modular  $k$ -SUM), we obtain the following corollary.

► **Corollary 18.** *For  $u = (q^\ell - 1)/2$  for odd  $q$  and  $k = 2^{\ell+1}$ , there is a  $u^{O(1/\log k)}$ -time algorithm for  $k$ -SUM( $u, m$ ) for  $m = u^{\Theta(1/\log k)}$ .*

#### 5 From Worst-case Lattice Problems to Average-case $k$ -SUM

In this section, we describe our main result, namely a worst-case to average-case reduction for  $k$ -SUM. We state the theorem below.

► **Theorem 19.** *Let  $k, m, u, n$  be positive integers, and  $0 < \varepsilon < \varepsilon'$  where*

$$u = k^{2(1+\varepsilon')cn/\varepsilon'} \text{ and } m = u^{\varepsilon/(2 \log k)}$$

*for some universal constant  $c > 0$ . If there is an algorithm for average-case  $k$ -SUM( $u, m$ ) that runs in time  $T_{\text{kSUM}} = T_{\text{kSUM}}(k, u, m)$ , then there is an algorithm for the worst-case  $n^{1+\varepsilon'}$ -approximate shortest independent vectors problem (SIVP) that runs in time  $2^{O(\varepsilon n/\varepsilon' + \log n)} \cdot T_{\text{kSUM}}$ .*

When we say that a  $k$ -SUM algorithm succeeds, we mean that it outputs a  $k$ -subset of the input that sums to 0 with probability  $1 - \delta$  for some tiny  $\delta$ . This can be achieved starting from an algorithm that succeeds with (some small) probability  $p$  by repeating, at the expense of a multiplicative factor of  $1/p \cdot \log(1/\delta)$  in the run-time. We ignore such issues for this exposition, and assume that the algorithm outputs a  $k$ -sum with probability  $1 - \delta$  for a tiny  $\delta$ .

Before we proceed to the proof, a few remarks on the parameters of Theorem 19 are in order. First, note that the parameter settings imply that  $m^k \gg u$ , therefore putting us in the total regime of parameters for  $k$ -SUM. Secondly, setting  $\varepsilon' = 100$  (say), we get the following consequence: if there is a  $k$ -SUM algorithm that, on input  $m = u^{\varepsilon/(2 \log k)}$  numbers, runs in time roughly  $m$ , then we have an  $n^{101}$ -approximate SIVP algorithm that runs in time  $\approx 2^{\varepsilon cn}$ . Now,  $\varepsilon$  is the “knob” that one can turn to make the SIVP algorithm run faster, assuming a correspondingly fast  $k$ -SUM algorithm that works with a correspondingly smaller instance.

**Proof.** The theorem follows from the following observations:

- First, by Theorem 10, there is a reduction from  $\tilde{O}(\sqrt{n \log m'} \cdot \beta)$ -approximate SIVP to SIS( $m', Q, \beta$ ), where we take  $m' := \lceil k^{10cn/(k\varepsilon')} n^{10} \rceil$ . The reduction produces SIS instances over  $\mathbb{Z}_Q$  where  $Q \geq (\beta n)^{cn}$  for some constant  $c$ , and works as long as the SIS algorithm produces solutions of  $\ell_1$  norm at most  $\beta$ . If the SIS algorithm runs in time  $T_{\text{SIS}} = T_{\text{SIS}}(m', Q, \beta)$ , the SIVP algorithm runs in time  $(m' + T_{\text{SIS}}) \cdot \text{poly}(n)$ . We take  $\beta := n^{\varepsilon'}$ .
- Second, as our main technical contribution, we show in Lemma 20 how to reduce SIS to  $k$ -SUM. Note that Theorem 10 gives us the freedom to pick  $Q$ , as long as it is sufficiently large. We will set  $Q = q^r$  where  $r = \lfloor \varepsilon' \log n / (2 \log k) \rfloor$  for a prime  $q \approx u \approx (\beta n)^{cn/r} \approx k^{2(1+\varepsilon')cn/\varepsilon'}$ .

Now, Lemma 20 (with  $k = t$ ) shows a reduction from SIS( $m', Q, \beta$ ) to  $2k$ -SUM( $\mathbb{Z}_q, m$ ) (provided that  $m' \gg q^{1/k} k^{4r/k} m^{4/k}$ , which holds in this case). The reduction produces a SIS solution with  $\ell_1$  norm bounded by  $k^{2r} \leq \beta$ .

The running time of the resulting algorithm is

$$rm'(m \cdot \text{poly}(k, \log q) + 10T_{\text{kSUM}}) \approx 2^{O(\varepsilon n/\varepsilon' + \log n)} \cdot T_{\text{kSUM}} .$$

- Finally, by Lemma 16, we know that modular  $2k$ -SUM over  $\mathbb{Z}_q$  can be reduced to  $k$ -SUM over the integers in the interval  $[-u, u]$  for  $u \approx q$  with essentially no overhead.

This finishes the proof. ◀

The following lemma shows our main reduction from SIS to  $k$ -SUM. In particular, taking  $k = t$ ,  $m' \gg (m^4 q)^{1/k} \cdot (10k)^{4r}$  (so that  $\delta$  is small), and  $m \gg q^{1/k}$  (so that  $k$ -SUM( $\mathbb{Z}_q, m$ ) is total) gives a roughly  $rm m'$ -time reduction from SIS over  $\mathbb{Z}_{q^r}$  to  $k$ -SUM over  $\mathbb{Z}_q$  with high success probability.

► **Lemma 20.** *Let  $m, m', k, r, t$  be positive integers and  $q > (tk)^r$  a prime, and let  $Q = q^r$ . If there is an algorithm that solves (average-case)  $k$ -SUM( $\mathbb{Z}_q, m$ ) in time  $T$  with success probability  $p$ , then there is an algorithm that solves SIS( $m', Q, \beta$ ) in time  $r \cdot m'(m \cdot \text{poly}(k, t, \log q) + 10T)/p$  with success probability at least  $1 - \delta$  and produces a solution with  $\ell_1$  norm  $\beta \leq (tk)^r$ , where*

$$\delta := \frac{100rm(m')^2}{p} \cdot \frac{q^{1/4}}{(m'/(10tk)^{2r+1})^{t/4}}.$$

**Proof.** At a high level, the idea is to run a variant of the Blum-Kalai-Wasserman [12] algorithm where in each iteration, we call a  $k$ -SUM oracle. In particular, on input  $a_1, \dots, a_{m'}$ , the algorithm operates as follows.

- In the beginning of the  $i^{\text{th}}$  iteration, the algorithm starts with a sequence of

$$m_i := \lceil m' / (10t^2k^2)^{i-1} \rceil$$

numbers  $a_{i,1}, \dots, a_{i,m_i}$ . The invariant is that  $a_{i,j} = 0 \pmod{q^{i-1}}$  for all  $j$ . It then generates disjoint  $S_{i,1}, \dots, S_{i,m_{i+1}} \subseteq [m_i]$  such that  $|S_{i,\ell}| \leq kt$  and  $\sum_{j \in S_{i,\ell}} a_{i,j} = 0 \pmod{q^i}$ , in a way that we will describe below.

As the base case, for  $i = 1$ ,  $a_{1,j} = a_j$ , the input itself, and the invariant is vacuous.

- In the  $i^{\text{th}}$  iteration, we apply the re-randomization lemma (Corollary 4), computing subsets of  $t$  randomly chosen elements from  $a_{i,1}, \dots, a_{i,m_i}$ , to generate  $m_i^* := 10m \lceil m_{i+1}/p \rceil$  numbers  $c_{i,1}, \dots, c_{i,m_i^*}$ .
- Let  $d_{i,j} = c_{i,j}/q^{i-1} \pmod{q} \in \mathbb{Z}_q$ . Note that this is well-defined because each  $c_{i,j} = 0 \pmod{q^{i-1}}$ .
- Divide the  $d_{i,j}$  into  $10 \lceil m_{i+1}/p \rceil$  disjoint blocks of  $m$  elements each, set  $\ell = 1$ . For each block, feed the block to the  $k$ -SUM algorithm to obtain  $d_{i,j_1}, \dots, d_{i,j_k}$ . This yields corresponding subsets  $S_1^*, \dots, S_k^* \in \binom{[m_i]}{t}$  such that  $\sum_{j \in S_x^*} a_{i,j}/q^{i-1} = d_{i,j_x} \pmod{q}$ . If  $d_{i,j_1} + \dots + d_{i,j_k} = 0 \pmod{q}$  and the sets  $S_1^*, \dots, S_k^*, S_{i,1}, \dots, S_{i,\ell-1}$  are pairwise disjoint, then set  $S_{i,\ell} := \bigcup S_x^*$  and increment  $\ell$ .
- If  $\ell \leq m_{i+1}$ , the algorithm fails. Otherwise, take  $a_{i+1,\ell} := \sum_{j \in S_{i,\ell}} a_{i,j}$  for  $\ell = 1, \dots, m_{i+1}$ .
- At the end of the  $r^{\text{th}}$  iteration we obtain a  $(kt)^r$ -subset of the  $a_1, \dots, a_{m'}$  that sums to 0  $\pmod{Q}$ .

We now analyze the correctness, run-time and the quality of output of this reduction.

The reduction calls the  $k$ -SUM oracle  $\sum m_i^*/m \leq 20rm'/p$  times. The rest of the operations take  $rm m' \text{poly}(k, t, \log q)/p$  time for a total of  $r \cdot m'(m \text{poly}(k, t, \log q) + 10T)/p$  time, as claimed. Furthermore, the  $\ell_1$  norm of the solution is  $\beta \leq (tk)^r$ , as claimed.

Finally, we show that the algorithm succeeds with the claimed probability. Since the sets  $S_{i,\ell}$  are disjoint and do not depend on  $a_{i,j} - (a_{i,j} \pmod{q^i})$ , it follows from a simple induction argument that at each step the  $a_{i,j}$  are uniformly random and independent elements from  $q^{i-1}\mathbb{Z}/q^r\mathbb{Z}$ . Therefore, by Corollary 4, the statistical distance of the collection of all  $d_{i,j}$  (for a given  $i$ ) from uniformly random variables that are independent of the  $a_{i,j}$  is  $\delta_i \leq (m_i^* + 1) \cdot (\frac{qt}{m_i^*})^{1/4}$ . In total, the statistical distance of all samples from uniform is then at most  $\sum \delta_i < \delta/3$  for our choice of parameters. So, up to statistical distance  $\delta/3$ , we can treat the  $d_{i,j}$  as uniformly random and independent elements.

It remains to show that, assuming that the  $d_{i,j}$  are uniformly random and independent, then we will find *disjoint* sets  $S_{i,1}, \dots, S_{i,m_{i+1}}$  with  $\sum_{j \in S_{i,\ell}} d_{i,j} = 0 \pmod{q}$  at each step except with probability at most  $2\delta/3$ . Let  $\mathbf{b}_i := (a_{i,1}/q^{i-1} \pmod{q}, \dots, a_{i,m_i}/q^{i-1} \pmod{q})$ . By Corollary 7, we have

$$p_{\mathbf{b}_i, \mathbf{d}_i, I, J, t} \leq 10t^2k^2m_{i+1}/m_i \leq 1/2$$

for all  $I \in \binom{[m_i]}{\leq v}$  and  $J \in \binom{[m_i^*]}{\leq v}$  except with probability at most  $10m_i m_i^* q^{1/4} / \binom{m_i-1}{t-1}^{1/4} < \delta/3$  for  $v := tkm_{i+1} \geq |T|$ ,  $v' := k$ , and  $\varepsilon := 1/2$ .

So, suppose this holds. Notice that  $\Pr[d_{i,j_1} + \dots + d_{i,j_k} = 0 \pmod{q}] = p$  by definition. And, conditioned on  $d_{i,j_1}, \dots, d_{i,j_k}$ , the  $S_x^*$  are independent and uniformly random subject to the constraint that  $\sum_{j \in S_x^*} a_{i,j} / q^{i-1} = d_{i,j_x} \pmod{q}$ . Therefore, the probability that  $S_1^*, \dots, S_k^*$ ,  $I := S_{i,1} \cup \dots \cup S_{i,\ell-1}$  are pairwise disjoint in this case is exactly

$$pb_{i,d_i,I,J,t} \leq 1/2,$$

where  $J := \{j_1, \dots, j_k\}$ . So, each time we call the oracle, we increment  $\ell$  with probability at least  $p/2$ . It follows from the Chernoff-Hoeffding bound that we increment  $\ell$  at least  $m_{i+1}$  times except with probability at most  $e^{-m_{i+1}/100} \ll \delta/3$ .

Putting everything together, we see that the algorithm fails with probability at most  $\delta$ , as claimed.  $\blacktriangleleft$

## A Total $k$ -SUM and Computational Geometry

Here, we show that one of the main results in [16, 17] can be extended meaningfully to our setting, i.e., to the case of search  $k$ -sum over  $\mathbb{Z}_Q$  with  $\binom{m}{k} \gg Q$ . (In [16, 17], Gajentaan and Overmars only considered decisional 3-SUM.) Specifically, we will reduce the following problem to  $k$ -SUM in this regime.

► **Definition 21.** For  $d \geq 1$  and  $Q, m \geq 2$  with  $Q$  prime, the  $(Q, m, d)$ -Plane problem is the following search problem. The input is  $\mathbf{a}_1, \dots, \mathbf{a}_m \in \mathbb{Z}_Q^{d+1}$ . The goal is to find distinct  $\mathbf{a}_{i_1}, \dots, \mathbf{a}_{i_{d+2}}$  that lie in a  $d$ -dimensional affine hyperplane over the field  $\mathbb{Z}_Q$ . (In other words,  $\mathbf{a}_{i_{d+1}} - \mathbf{a}_{i_{d+2}}$  can be written as a linear combination of  $\mathbf{a}_{i_1} - \mathbf{a}_{i_{d+2}}, \dots, \mathbf{a}_{i_d} - \mathbf{a}_{i_{d+2}}$  over  $\mathbb{Z}_Q$ .)

► **Lemma 22.** For  $d \geq 1$  and  $Q, m \geq 2$  with  $Q$  prime, there is a reduction from  $(d+2)$ -SUM( $\mathbb{Z}_Q, m$ ) to  $(Q, m, d)$ -Plane.

**Proof.** Let  $f_d : \mathbb{Z}_Q \rightarrow \mathbb{Z}_Q^{d+1}$  be the map  $f_d(a) := (a, a^2, a^3, \dots, a^d, a^{d+2})$ . E.g.,  $f_1(a) = (a, a^3)$ ,  $f_2(a) = (a, a^2, a^4)$ , etc. On input  $a_1, \dots, a_m \in \mathbb{Z}_Q$ , the reduction simply calls its  $(Q, m, d)$ -Plane oracle on  $f_d(a_1), \dots, f_d(a_m) \in \mathbb{F}_Q^{d+1}$ , receiving as output distinct indices  $i_1, \dots, i_{d+2}$  such that  $f_d(a_{i_1}), \dots, f_d(a_{i_{d+2}})$  lie in a  $d$ -dimensional affine hyperplane (assuming that such indices exist). The reduction simply outputs these indices, i.e., it claims that  $a_{i_1} + \dots + a_{i_{d+2}} = 0 \pmod{Q}$ .

Notice that  $d+2$  points  $\mathbf{b}_1, \dots, \mathbf{b}_{d+2} \in \mathbb{Z}_Q^{d+1}$  lie in a  $d$ -dimensional affine hyperplane if and only if the matrix  $(\mathbf{b}_1 - \mathbf{b}_{d+2}, \mathbf{b}_2 - \mathbf{b}_{d+2}, \dots, \mathbf{b}_{d+1} - \mathbf{b}_{d+2}) \in \mathbb{Z}_Q^{(d+1) \times (d+1)}$  has determinant zero. (Here, we have used the fact that  $\mathbb{Z}_Q$  is a field.) So, we consider the matrix

$$\mathbf{M} := \mathbf{M}(b_1, \dots, b_{d+2}) := \begin{pmatrix} b_1 - b_{d+2} & b_2 - b_{d+2} & \cdots & b_{d+1} - b_{d+2} \\ b_1^2 - b_{d+2}^2 & b_2^2 - b_{d+2}^2 & \cdots & b_{d+1}^2 - b_{d+2}^2 \\ \vdots & \vdots & \ddots & \vdots \\ b_1^d - b_{d+2}^d & b_2^d - b_{d+2}^d & \cdots & b_{d+1}^d - b_{d+2}^d \\ b_1^{d+2} - b_{d+2}^{d+2} & b_2^{d+2} - b_{d+2}^{d+2} & \cdots & b_{d+1}^{d+2} - b_{d+2}^{d+2} \end{pmatrix} \in \mathbb{F}_Q^{(d+1) \times (d+1)}.$$

We claim that

$$\det(\mathbf{M}) = (-1)^d (b_1 + \dots + b_{d+2}) \cdot \prod_{i < j} (b_j - b_i),$$

The result then follows, since this is zero if and only if  $b_i = b_j$  for some  $i \neq j$  or  $b_1 + \dots + b_{d+2} = 0$ . Since by definition the  $(Q, m, d)$ -Plane oracle only outputs distinct vectors on a hyperplane, this means that its output must correspond to distinct elements with  $a_{i_1} + \dots + a_{i_{d+2}} = 0 \pmod{Q}$ .

To prove that the determinant has the appropriate form, we first notice that without loss of generality we may take  $b_{d+2} = 0$ . Next, we define

$$\mathbf{M}' := \mathbf{M}'(b_1, \dots, b_{d+1}) := \begin{pmatrix} b_1 & b_2 & \cdots & b_{d+1} \\ b_1^2 & b_2^2 & \cdots & b_{d+1}^2 \\ \vdots & \vdots & \ddots & \vdots \\ b_1^d & b_2^d & \cdots & b_{d+1}^d \\ b_1^{d+1} & b_2^{d+1} & \cdots & b_{d+1}^{d+1} \end{pmatrix} \in \mathbb{F}_Q^{(d+1) \times (d+1)}$$

This is just a Vandermonde matrix with columns scaled up by  $b_i$ . So, its determinant is a scaling of the Vandermonde determinant,

$$\det(\mathbf{M}') = b_1 \cdots b_{d+1} \cdot \prod_{i < j} (b_j - b_i).$$

Finally, we recall Cramer's rule, which in particular tells us that

$$\det(\mathbf{M}) = p_{d+1} \det(\mathbf{M}')$$

for the unique  $\mathbf{p} := (p_1, \dots, p_{d+1}) \in \mathbb{Z}_Q^{d+1}$  satisfying  $\mathbf{p}^T \mathbf{M}' = (b_1^{d+2}, \dots, b_{d+1}^{d+2})$ . I.e., the coordinates of  $\mathbf{p}$  form the polynomial  $p(x) := p_1 + p_2x + \dots + p_{d+1}x^d$  such that  $p(b_i) = b_i^{d+1}$ . The result follows by noting that  $p_i = (-1)^{i-1} \sum_{S \in \binom{[d+2-i]}{d+2-i}} \prod_{j \in S} b_j$ . In particular,  $p_{d+1} = (-1)^d (b_1 + \dots + b_{d+1})$ , as needed.  $\blacktriangleleft$

# Improved Hitting Set for Orbit of ROABPs

Vishwas Bhargava

Sumanta Ghosh  

Department of Computer Science, IIT Bombay, India

---

## Abstract

The orbit of an  $n$ -variate polynomial  $f(\mathbf{x})$  over a field  $\mathbb{F}$  is the set  $\{f(A\mathbf{x}+\mathbf{b}) \mid A \in \text{GL}(n, \mathbb{F}) \text{ and } \mathbf{b} \in \mathbb{F}^n\}$ , and the orbit of a polynomial class is the union of orbits of all the polynomials in it. In this paper, we give improved constructions of hitting-sets for the orbit of read-once oblivious algebraic branching programs (ROABPs) and a related model. Over fields with characteristic zero or greater than  $d$ , we construct a hitting set of size  $(ndw)^{O(w^2 \log n \cdot \min\{w^2, d \log w\})}$  for the orbit of ROABPs in unknown variable order where  $d$  is the individual degree and  $w$  is the width of ROABPs. We also give a hitting set of size  $(ndw)^{O(\min\{w^2, d \log w\})}$  for the orbit of polynomials computed by  $w$ -width ROABPs in any variable order. Our hitting sets improve upon the results of Saha and Thankey [43] who gave an  $(ndw)^{O(d \log w)}$  size hitting set for the orbit of commutative ROABPs (a subclass of *any-order* ROABPs) and  $(nw)^{O(w^6 \log n)}$  size hitting set for the orbit of multilinear ROABPs. Designing better hitting sets in large individual degree regime, for instance  $d > n$ , was asked as an open problem by [43] and this work solves it in small width setting.

We prove some new rank concentration results by establishing *low-cone concentration* for the polynomials over vector spaces, and they strengthen some previously known *low-support* based rank concentrations shown in [17]. These new low-cone concentration results are crucial in our hitting set construction, and may be of independent interest. To the best of our knowledge, this is the first time when low-cone rank concentration has been used for designing hitting sets.

## 1 Introduction

Polynomial identity testing (PIT) problem is a fundamental problem in the area of algebraic circuit complexity. PIT is the problem of deciding whether a given multivariate polynomial is identically zero, where the input is given as an algebraic formula, circuit or other computational models like algebraic branching program. One way of testing zeroness of a polynomial is to check whether the coefficients of all the monomials are zero. However, the polynomial computed by a circuit or a branching program may have, in the worst-case, an exponential number of monomials compared to its size. Hence, by computing the explicit polynomial from the input, we cannot solve PIT problem in polynomial time. However, evaluating the polynomial at a point can be done in polynomial time of the input size. This helps us to

get a polynomial time randomized algorithm for PIT by evaluating the input circuit at a random point, since any nonzero polynomial evaluated at a random point gives a nonzero value with high probability [10, 57, 49]. However, finding a deterministic polynomial time algorithm for PIT is a long-standing open question in algebraic complexity theory.

PIT captures several problems in algebra and combinatorics. For example, parallel algorithms for perfect matching [55, 35, 14, 54], primality testing [2], multivariate polynomial factorization [31], and many other problems [50, 11, 22]. PIT also has strong connection to circuit lower bounds [25, 26, 13, 7, 21]. See [45, 53, 48] for surveys on PIT.

PIT problem is studied in two different settings: 1) *whitebox*, where we are allowed to access the internal structure of the circuit, and 2) *blackbox*, where only evaluation of the circuit at points is allowed. Deterministic blackbox PIT for an  $n$ -variate circuit class is equivalent to efficiently finding a set of points  $\mathcal{H} \subseteq \mathbb{F}^n$ , called a *hitting-set*, such that for any nonzero  $P$  in that circuit class, the set  $\mathcal{H}$  contains a point at which  $P \neq 0$ <sup>1</sup>. In this work, we only focus on the blackbox model.

Despite a lot of effort, little progress has been made on the PIT problem in general. However, efficient deterministic PIT algorithms are known for many special circuit models. For example, blackbox PIT for depth-2 circuits (or sparse polynomials) [6, 30, 34], PIT algorithms for depth-3 circuits with bounded top fan-in [12, 29, 28, 27, 46, 47, 48], depth-3 diagonal circuits [44, 17, 16] and various other subclasses of depth-3 circuits [42, 1, 9], PIT for the subclasses of depth-4 circuits [3, 5, 15, 32, 40] and certain types of symbolic determinants [14, 54, 24].

The focus of this work is on the model of *read-once oblivious algebraic branching programs (ROABPs)*. An ROABP is a product of matrices

$$f = \mathbf{a}^T \cdot M_1(x_{\pi(1)})M_2(x_{\pi(2)}) \cdots M_n(x_{\pi(n)}) \cdot \mathbf{c},$$

where  $\mathbf{a}, \mathbf{c} \in \mathbb{F}^{w \times 1}$  and for some permutation  $\pi$  on  $[n]$  for each  $i \in [n]$ ,  $M_i(x_{\pi(i)}) \in \mathbb{F}^{w \times w}[x_{\pi(i)}]$  can be viewed as a polynomial over the matrix algebra. The permutation  $\pi$  is called the variable order of the ROABP. One reason to be interested in ROABP is that derandomizing blackbox PIT for ROABP can be viewed as an algebraic analogue of the RL vs. L question. Besides that, the ROABP model is surprisingly rich and powerful. It captures several other interesting circuit classes such as sparse polynomials or depth-two circuits, depth-three powering circuits (symmetric tensors), set-multilinear depth-three circuits (tensors), and semi-diagonal depth-3 circuits [19]. Some notable polynomials such as the iterated matrix multiplication polynomial, the elementary and the power symmetric polynomials, and the sum-product polynomials can be computed by linear size ROABPs. Hitting sets for ROABPs have also led to the derandomization of an interesting case of the Noether Normalization Lemma [38, 18], and to hitting sets for non-commutative algebraic branching programs [19].

PIT question for ROABPs and its variants has been widely studied. There are three parameters associated with an ROABP: the number of variables  $n$ , the size of the matrices  $w$  called *width* and the individual degree  $d$  which is the maximum possible degree of any variable. First, [41] gave a polynomial time whitebox PIT algorithm for this model. [19] first gave  $(ndw)^{O(\log n)}$  size hitting set for ROABPs when the variable order is known. Later, [17] gave an  $(ndw)^{O(d \log w \cdot \log n)}$  size hitting set for ROABPs with unknown variable order, and subsequently, [1] gave an improved hitting set of size  $(ndw)^{O(\log n)}$  for this model. For zero or large characteristic fields, [22] gave an  $ndw^{\log n}$  size hitting sets for the known order ROABPs

---

<sup>1</sup> When  $\mathbb{F}$  is a finite field, we are allowed to go some suitable extension  $\mathbb{K}$  of  $\mathbb{F}$  and pick points from  $\mathbb{K}^n$ .

and the size becomes polynomially large when the width is constant. Better hitting set is known for a special class of ROABPs, called *any-order* ROABP. A polynomial  $f$  is computable by a  $w$ -width *any-order* ROABP, if for every permutation  $\pi$  on  $[n]$ ,  $f$  is computable by a  $w$ -width ROABP. The notion of *any-order* ROABP subsumes the notion of commutative ROABP. An ROABP is called commutative ROABP if the polynomial computed by it remains unchanged under any permutation of the matrices involved in the product. [17] gave two different constructions of hitting sets of size  $(ndw)^{O(\log w)}$  and  $d^{O(\log w)} \cdot (nw)^{O(\log \log w)}$  for *any-order* ROABPs<sup>2</sup>. Later, [22] gives an improved hitting set of size  $(ndw)^{O(\log \log w)}$  for this model. Recently, [20] gives improved hitting sets for both ROABPs and *any-order* ROABPs. Compared to the previous constructions, the size of hitting sets in [20] have finer dependence on the parameters of ROABPs. However, the construction of polynomial size hitting sets for ROABPs and its variants is still open.

In this work, we study the PIT question for the orbit of ROABPs. The *orbit* of an  $n$ -variate polynomial  $f(\mathbf{x})$  over a field  $\mathbb{F}$ , denoted by  $\text{orbit}(f)$ , is the set of polynomials obtained by applying invertible affine transformations on the variables of  $f$ , that is,  $\text{orbit}(f) = \{f(A\mathbf{x} + \mathbf{b}) \mid A \in \text{GL}(n, \mathbb{F}), \text{ and } \mathbf{b} \in \mathbb{F}^n\}$ . The orbit of a polynomial class  $\mathcal{C}$ , denoted by  $\text{orbit}(\mathcal{C})$ , is the union of the orbits of the polynomials in the class. Apart from being a natural question to study the sturdiness of the known techniques (and improving them), designing hitting sets for the orbits of polynomial families and circuit classes is interesting for the following reasons:

- As observed by [43], the affine projections of “simple” polynomials have great expressive power. The set of affine projections of an  $n$ -variate polynomial  $f(\mathbf{x})$  over a field  $\mathbb{F}$  is  $\text{aproj}(f) := \{f(A\mathbf{x} + \mathbf{b}) \mid A \in \mathbb{F}^{n \times n} \text{ and } \mathbf{b} \in \mathbb{F}^n\}$ . Formally, they show that if the characteristic of  $\mathbb{F}$  is zero, the set of affine projections of an  $n$ -variate polynomial  $f(\mathbf{x})$  over a field  $\mathbb{F}$  lies inside the Zariski closure of the orbit of  $f$  (denoted by  $\overline{\text{orbit}(f)}$ ), that is  $\text{aproj}(f) \subseteq \overline{\text{orbit}(f)}$ . This observation has some interesting implications. For instance, using the above observation one can show that, the entire class of depth-3 circuits  $\Sigma\Pi\Sigma$  with top fan-in  $s$  and degree  $d$  is contained in  $\text{aproj}(\text{SP}_{s,d})$ , where  $\text{SP}_{s,d} := \sum_{i \in [s]} \prod_{j \in [d]} x_{i,j}$  is a very structured  $s$ -sparse polynomial. The orbit closure of ROABPs is also very powerful, in fact they are as powerful as general ABPs. This can be seen by observing, the iterated matrix multiplication polynomial  $\text{IMM}_{w,d}$  is computable by a linear-size ROABP, yet every polynomial computable by a size- $s$  general algebraic branching program is in  $\text{aproj}(\text{IMM}_{s,s})$ . For more polynomial families whose orbit closures contain interesting circuit classes, see [36].
- For an  $n$ -variate polynomial  $f$  over a field  $\mathbb{F}$ , let  $\mathbb{V}(f)$  denotes the variety (that is, zero locus) of  $f$ . Hitting set construction for an  $n$ -variate polynomial class  $\mathcal{C}$  is the problem of picking a set of points  $\mathcal{H}$  such that for each polynomial  $f \in \mathcal{C}$ ,  $\mathcal{H}$  is not entirely contained in  $\mathbb{V}(f)$ . On the other hand, Constructing hitting sets for the orbits of a polynomial class  $\mathcal{C}$  is the task of finding a small set of points  $\mathcal{H}$  such that for every  $f \in \mathcal{C}$ ,  $\mathcal{H}$  is not entirely contained in the set  $\{A\mathbf{a} + \mathbf{b} \mid \mathbf{a} \in \mathbb{V}(f), A \in \text{GL}(n, \mathbb{F}) \text{ and } \mathbf{b} \in \mathbb{F}^n\}$ . This ensures that  $\mathcal{H}$  will be independent to the choice of coordinate system, making it mathematically and geometrically robust.

For a more detailed discussion on the reasons for studying hitting set of orbits, see [43].

Hitting set construction for orbits of circuit classes is very recent, somewhat simultaneously Medini and Shpilka [36] and Saha and Thankey [43] started exploring PIT for the orbit of various polynomial classes. Medini and Shpilka [36] gave a quasi-polynomial size hitting

<sup>2</sup> In [17], *any-order* ROABPs are referred by “commutative ROABPs”.

set for the orbits of sparse polynomials ( $\sum \prod$  circuits) and read-once formulas (ROFs). Saha and Thankey [43] gave hitting sets for the orbits of ROABPs and constant-read (more generally, constant-occur) formulas. Concretely, [43] gave an  $(ndw)^{d \log w}$  size hitting set for the orbit of  $n$ -variate individual degree  $d$  width  $w$  commutative ROABPs. They also gave an  $(nw)^{O(w^6 \log n)}$  size hitting set for the orbit of  $n$ -variate multilinear polynomials computed by width  $w$  ROABPs. Building on this, they also gave quasi-polynomial size hitting set for constant-depth constant-occur formulas whose leaves are labeled by  $s$ -sparse polynomials with constant individual degree. In this work, we design hitting sets for the orbit of ROABPs and *any-order* ROABPs. Our results significantly improve the dependence on individual degree in the size of hitting sets in comparison to [43], from exponential to polynomial.

## 1.1 Our Results

First, we define the models studied in this paper. Algebraic branching programs (ABPs) were defined by Nisan in [39]. In this paper, we study a variant of ABPs known as read-once oblivious ABPs (ROABPs). While Nisan defined ABPs using directed graphs, we use a more conventional definition using product of matrices. Let  $f(x_1, \dots, x_n)$  be an  $n$ -variate individual degree  $d$  polynomial over a field  $\mathbb{F}$ . Let  $\pi$  be a permutation on  $[n]$ . We say  $f$  is computed by a width  $w$  ROABP with variable order  $\pi$ , if  $f$  can be written as

$$f = \mathbf{a}^T \cdot M_1(x_{\pi(1)})M_2(x_{\pi(2)}) \cdots M_n(x_{\pi(n)}) \cdot \mathbf{c},$$

where  $\mathbf{a}, \mathbf{c} \in \mathbb{F}^{w \times 1}$  and for all  $i \in [n]$ ,  $M_i(x_{\pi(i)}) \in \mathbb{F}^{w \times w}[x_{\pi(i)}]$  can be viewed as a polynomial in  $x_{\pi(i)}$  over the matrix algebra with degree at most  $d$ . We say  $f$  is computable by a  $w$ -width *any order* ROABP, if for every permutation  $\pi$  on  $[n]$ ,  $f$  is computable by a width  $w$  ROABP. We say  $f$  is computed by a width  $w$  *commutative* ROABP, if all  $M_i(x_{\pi(i)})$ 's are polynomials over a commutative sub-algebra of the matrix algebra. For example, consider the coefficients of each  $M_i$  are diagonal matrices. One can observe that the set of polynomials computed by  $w$ -width commutative ROABPs are also computable by  $w$ -width *any-order* ROABPs. However, the converse direction is unknown to us. All PIT algorithms for ROABPs are designed by analyzing the coefficient space of  $M_1(x_{\pi(1)})M_2(x_{\pi(2)}) \cdots M_n(x_{\pi(n)})$ .

In this paper, we design hitting sets for the orbits of ROABPs and *any-order* ROABPs. Let  $f(\mathbf{x})$  be an  $n$ -variate polynomial over a field  $\mathbb{F}$ . The orbit of  $f$ , denoted by  $\text{orbit}(f)$ , is the set  $\{f(A\mathbf{x} + \mathbf{b}) \mid A \in \text{GL}(n, \mathbb{F}) \text{ and } \mathbf{b} \in \mathbb{F}^n\}$ . For a polynomial class  $\mathcal{C}$ , the orbit of  $\mathcal{C}$ , denoted by  $\text{orbit}(\mathcal{C})$ , is the union of orbits of all the polynomials in  $\mathcal{C}$ . Now, we describe our result for the orbit of *any-order* ROABPs.

► **Theorem 1.** *Let  $\mathbb{F}$  be a field of characteristic zero or greater than  $d$ . Let  $\mathcal{C}$  be the set of  $n$ -variate polynomials over  $\mathbb{F}$  with individual degree at most  $d$  and computable by a width  $w$  *any-order* ROABP. Then, there exists a hitting set for  $\text{orbit}(\mathcal{C})$  computable in time  $(ndw)^{O(\ell)}$  where  $\ell = \min\{w^2, 2d \log w\}$ .*

### Comparison with previous works

As far as we know, this is the first result addressing the orbit of *any-order* ROABPs, and it subsumes the commutative ROABP result of Saha and Thankey [43]. They gave an  $(ndw)^{O(d \log w)}$  size hitting set for the orbit of commutative ROABPs. In fact, our result strengthens [43] in “low width” setting. Concretely, if the individual degree is  $\text{poly}(\log n)$ , [43] gives quasi-polynomial time PIT for the orbit of commutative ROABPs. However, when  $d \geq n$ , their algorithm does not give any non-trivial PIT for the orbit of commutative

ROABPs. On the other hand, our result gives quasi-polynomial time PIT for the orbit of *any-order* ROABPs when  $\min\{d, w\} = \text{poly}(\log n)$ . Also, for constant width *any-order* ROABPs with unbounded individual degree, our result gives a polynomial time PIT for its orbit. However, [43] gives polynomial time PIT for the orbit commutative ROABPs when both  $d$  and  $w$  are constants. Thus, our result has much better dependence on the individual degree in comparison with [43].

Now, we describe our result regarding the orbit of ROABPs.

► **Theorem 2.** *Let  $\mathbb{F}$  be a field of characteristic zero or greater than  $d$ . Let  $\mathcal{C}$  be the set of  $n$ -variate polynomials over  $\mathbb{F}$  with individual degree at most  $d$  and computable by a width  $w$  ROABP. Then there exists a hitting set for  $\text{orbit}(\mathcal{C})$  computable in time  $(ndw)^{O(\ell)}$  where  $\ell = (w^2 \log n) \cdot \min\{w^2, 2d \log w\}$ .*

### Comparison with previous works

Saha and Thankey [43] gave an  $(nw)^{O(w^6 \log n)}$  time PIT for the orbit of multilinear polynomials computed by ROABPs. Therefore, our result can be seen as the first one which gives PIT for the orbit of ROABPs with unbounded individual degree. Irrespective of the value of the individual degree, our result gives a quasi-polynomial time PIT for the orbit of ROABPs when the width  $w = \text{poly}(\log n)$ . Also, the time complexity of our algorithm has better dependence on the width of ROABPs in comparison with [43].

### Remark

Our results in this paper continue to hold even if we consider a more generalized definition for the orbit of an  $n$ -variate polynomial  $f(\mathbf{x})$ , that is  $\text{orbit}(f) = \{f(A\mathbf{y} + \mathbf{b}) \mid m \geq n, A \in \mathbb{F}^{n \times m} \text{ with rank } n \text{ and } \mathbf{b} \in \mathbb{F}^n\}$  where  $\mathbf{y} = (y_1, \dots, y_m)$ . However, we work with the conventional definition of the orbit of polynomials for the simplicity of exposition, and because the proofs of the results with the generalized definition of orbit is almost the same as the proofs given in this paper.

## 1.2 Proof techniques

First, we briefly sketch the abstract framework followed by the proofs of our results. Let  $\mathcal{C}$  be a set of  $n$ -variate polynomials in  $\mathbf{y} = (y_1, \dots, y_n)$  with individual degree at most  $d$ . Then  $\text{orbit}(\mathcal{C})$  is the set of  $n$ -variate polynomials in  $\mathbf{x} = (x_1, \dots, x_n)$  is defined as follows: for all  $f(\mathbf{x}) \in \text{orbit}(\mathcal{C})$  there exists a polynomial  $h(\mathbf{y}) \in \mathcal{C}$ , an invertible linear transformation  $L(\mathbf{x}) = (\ell_1, \dots, \ell_n)$  from  $\mathbb{F}^n$  to  $\mathbb{F}^n$  and a point  $\mathbf{b} \in \mathbb{F}^n$  such that

$$f(\mathbf{x}) = h(L(\mathbf{x}) + \mathbf{b}).$$

In this paper, we design hitting sets for the orbits of ROABPs and *any-order* ROABPs. Hitting sets for ROABPs are constructed by designing a “smartly” chosen shift  $\mathbf{g}(\mathbf{t})$  (a low variate polynomial map) such that when we shift any polynomial  $h(\mathbf{y})$  computable by a small size ROABP, then there exists a “low-support” monomial (with nonzero coefficient) in  $h(\mathbf{x} + \mathbf{g})$ . Note that, it is straightforward to construct hitting sets when such a low-support monomial (with nonzero coefficient) exists. However, this approach does not *directly* work for a polynomial  $f(\mathbf{x}) = h(L(\mathbf{x}) + \mathbf{b})$  in the orbit of ROABPs as shifting  $f$  has a slightly different effect. Note,

$$f(\mathbf{x} + \mathbf{g}) = h(L(\mathbf{x} + \mathbf{g}) + \mathbf{b}) = h(L(\mathbf{x}) + L \circ \mathbf{g} + \mathbf{b}).$$

That is, the shift gets composed with the affine transformation  $L(\mathbf{x}) + \mathbf{b}$ . The main idea in our construction is to choose a shift such that the transformed shift (for *any* affine transformation) is also “smart”. That is, for any invertible linear transformation  $L(\mathbf{x})$  and  $\mathbf{b} \in \mathbb{F}^n$ , there exists a “low-support” monomial (with nonzero coefficient) in  $f(\mathbf{x} + \mathbf{g}) = h(L(\mathbf{x}) + L \circ \mathbf{g} + \mathbf{b})$ .

Let  $\mathbf{g}(\mathbf{t}) = (g_1, \dots, g_n)$  be a polynomial map from  $\mathbb{F}^m$  to  $\mathbb{F}^n$  and  $h'(\mathbf{y}) = h(\mathbf{y} + L \circ \mathbf{g} + \mathbf{b})$ . Note that,  $f'(\mathbf{x}) := f(\mathbf{x} + \mathbf{g}) = h'(L(\mathbf{x}))$ . Our abstract format to design hitting sets for the orbits of ROABPs and *any-order* ROABPs has the following two steps.

**Step 1:** First we find some suitable low degree polynomial map  $\mathbf{g}$  in few variables (compare to  $n$ ) such that for *all* invertible linear transformation  $L(\mathbf{x})$  and  $\mathbf{b} \in \mathbb{F}^n$ , after shifting  $h(\mathbf{y}) \in \mathcal{C}$  by  $L \circ \mathbf{g} + \mathbf{b}$ , the new polynomial  $h'(\mathbf{y}) = h(\mathbf{y} + L \circ \mathbf{g} + \mathbf{b})$  has the following property: for some small positive integer  $k$ ,  $\text{hom}_{\leq k}(h'(\mathbf{y}))$  is a nonzero polynomial in  $\mathbf{y}$  over the field  $\mathbb{F}(\mathbf{t})$ , where  $\text{hom}_{\leq k}(\cdot)$  denotes the degree up to  $k$  part of the input polynomial. This step, more specifically the construction of  $\mathbf{g}(\mathbf{t})$ , heavily relies on the structure of  $\mathcal{C}$ .

**Step 2:** Since  $L(\mathbf{x})$  is an invertible linear transformation, all  $\ell_i$ 's are algebraically independent. Also,  $\text{hom}_{\leq k}(f') = \text{hom}_{\leq k}(h')(L(\mathbf{x}))$ . Therefore,  $\text{hom}_{\leq k}(f')$  is a nonzero polynomial in  $\mathbf{x}$  over the field  $\mathbb{F}(\mathbf{t})$ . This implies that there exists a monomial  $\mathbf{x}^{\mathbf{e}} = \prod_{i=1}^n x_i^{e_i}$  such that the support of  $\mathbf{e}$  is at most  $k$  and the coefficient of  $\mathbf{x}^{\mathbf{e}}$  in  $f'$  is a nonzero polynomial in  $\mathbf{t}$ . There are well known constructions of hitting sets for polynomials like  $f'(\mathbf{x})$ . For example, combining Lemma 23 and Observation 17 we get a hitting set for  $f'$  of size around  $(nd)^{O(m+k)}$ . Thus, we design a hitting set for orbit( $\mathcal{C}$ ). This step is independent of the polynomial class  $\mathcal{C}$ .

For instance, assume that  $\mathcal{C}$  is the set of  $n$ -variate polynomials with individual degree and sparsity are at most  $d$  and  $s$ , respectively. Then, from [15], after shifting any polynomial  $h(\mathbf{y}) \in \mathcal{C}$  by an  $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_n)$  with all  $\alpha_i$ 's are nonzero the following holds: there exists a monomial  $\mathbf{y}^{\mathbf{e}}$  such that the support of  $\mathbf{e}$  is at most  $\log s$  and its coefficient in  $h(\mathbf{y} + \boldsymbol{\alpha})$  is nonzero. Let  $\mathbf{g}(t)$  be the polynomial map from  $\mathbb{F}$  to  $\mathbb{F}^n$  defined as  $(t, t^2, \dots, t^n)$  and  $\mathbf{b} = (b_1, \dots, b_n)$ . Then, each  $\ell_i(\mathbf{g}) + b_i$  is a nonzero polynomial. Therefore, there exists a monomial  $\mathbf{y}^{\mathbf{e}}$  of support-size at most  $\log s$  such that its coefficient in  $h'(\mathbf{y})$  is a nonzero polynomial in  $t$ . Since the individual degree is at most  $d$ , the degree of  $\mathbf{y}^{\mathbf{e}}$  is at most  $\leq d \log s$ . Now from the step 2, there exists a monomial in  $\mathbf{x}$  of support-size at most  $d \log s$  such that its coefficient in  $f'$  is a nonzero polynomial in  $t$ . Thus, we have a hitting set for orbit( $\mathcal{C}$ ) of size  $(nd)^{O(d \log s)}$ . This gives a different (and much simpler) hitting set construction than [43, Theorem 7] for the orbit of sparse polynomials with low individual degree.

### Stronger rank concentration results

We describe some stronger rank concentration results, which will be very useful in designing our hitting sets for the orbits of ROABPs and *any-order* ROABPs. Let  $G(\mathbf{x})$  be an  $n$ -variate polynomial over the vector space  $\mathbb{F}^k$ . The *coefficient space* of  $G$  is the vector space spanned by the coefficients (from  $\mathbb{F}^k$ ) in  $G$ . In general, the coefficient space of  $G$  can be spanned by the coefficients of any arbitrary set of monomials. In rank concentration, our goal is to construct a polynomial map  $\mathbf{g}(\mathbf{t})$  such that after shifting  $G(\mathbf{x})$  by  $\mathbf{g}(\mathbf{t})$ , the coefficient space of the new polynomial  $G'(\mathbf{x}) = G(\mathbf{x} + \mathbf{g})$  is spanned the coefficients of a “small” set of monomials  $S$ . For example,

1. if  $S$  is the set of monomials whose support-size is  $\leq \ell$ , we say  $G'$  has  $\ell$ -support concentration. The support-size of a monomial is the number of variables appearing in it.

2. if  $S$  is the set of monomials whose cone-size is  $\leq \ell$ , we say  $G'$  has  $\ell$ -cone concentration. The cone-size of a monomial is the number of monomials dividing it.
3. if  $S$  is the set of monomials which is closed under sub-monomials, we say  $G'$  has a cone-closed basis.

The notion of rank-concentration was introduced in [4]. Subsequently, many PIT results are obtained based on “low-support” rank concentration [4, 17, 23, 22, 43]. Later, [16] introduced the notion of cone concentration and cone-closed basis. Among the three notions of rank concentrations, cone-closed basis is stronger than the other two, then comes cone concentration and after that support concentration. More specifically, cone-closed basis of  $G'$  implies that it has also  $k$ -cone concentration, and  $k$ -concentration for  $G'$  implies it has also  $\log k$ -support concentration. For more details about the relation between these three notions of rank concentrations see Lemma 26. The notion of cone concentration is important for designing our improved hitting sets over [43]. Although the notion of cone concentration was first introduced in [16] and they showed some low-cone concentration result, we are not aware of any “non-trivial” application of them in designing PIT algorithms. Therefore, to the best of our knowledge, this is the first time when the notion of cone concentration is used in designing PIT algorithms.

In this work, we strengthen some of the rank concentration results shown in [17, 16]. [17] showed that if  $G(\mathbf{x})$  is shifted by  $\mathbf{t} = (t_1, \dots, t_n)$ , the new polynomial  $G(\mathbf{x} + \mathbf{t})$  has  $\log k$ -support concentration over the field  $\mathbb{F}(\mathbf{t})$ . Moreover, they showed that if  $G$  is shifted by a  $n$ -wise independent monomial map  $\mathbf{g}'(\mathbf{s}, \mathbf{t})$ , then the new shifted polynomial has  $\log k$ -support concentration. A polynomial map  $\mathbf{g}'(\mathbf{s}, \mathbf{t})$  from  $\mathbb{F}^m \times \mathbb{F}^{m'}$  to  $\mathbb{F}^n$  is called  $\ell$ -wise independent monomial map if for every  $S \subseteq [n]$  of size  $\leq \ell$  there exists an  $\boldsymbol{\alpha} \in \mathbb{F}^m$  such that polynomials  $\{\mathbf{g}'(\boldsymbol{\alpha}, \mathbf{t})^e\}_{\text{supp}(\mathbf{e}) \subseteq S}$  are distinct monomials in  $\mathbf{t}$ . Later, [16] showed that  $G(\mathbf{x} + \mathbf{t})$  has a cone-closed basis. Their result can also be extended to show that  $G(\mathbf{x} + \mathbf{g}')$  has a cone-closed basis when  $\mathbf{g}'$  is an  $n$ -wise independent monomial map. However, when we take composition of  $\mathbf{g}'$  with an invertible affine transformation, that is  $\mathbf{b} + L \circ \mathbf{g}'$  where  $\mathbf{b} \in \mathbb{F}^n$  and  $L(\mathbf{x})$  is an invertible linear transformation from  $\mathbb{F}^n$  to  $\mathbb{F}^n$ , the  $n$ -wise independence property of  $\mathbf{g}'$  breaks down. Therefore, the previous rank concentration results are not helpful in designing hitting sets for the orbits of circuit classes. We strengthen the rank concentration results of [17, 16] in the following way: After shifting  $G$  by a polynomial map  $\mathbf{g}' = (g_1, \dots, g_n)$  such that all  $g_i$ 's are *algebraically independent*, the new polynomial has a cone-closed basis, hence  $k$ -cone concentration. Observe that the  $n$ -wise independence property implies the algebraic independence property needed in our hypothesis. Therefore, our hypothesis is weaker than the hypothesis used in [17, 16]. Also, algebraic independence property of  $\mathbf{g}'$  preserves even after composing it with invertible affine transformations. For details see Lemma 4. This rank concentration result will be helpful in designing the hitting sets for the orbit of *any-order* ROABPs.

We show one more rank concentration result which will help in designing PIT algorithms for the orbit of ROABPs. Assume that the coefficients of the monomials of total degree up to  $D$  spans the coefficient space of  $G$ . Let  $\mathbf{g}'(\mathbf{s}, \mathbf{t})$  be a *total degree  $D$  independent monomial map* from  $\mathbb{F}^m \times \mathbb{F}^{m'}$  to  $\mathbb{F}^n$ , that is, there exists an  $\boldsymbol{\alpha} \in \mathbb{F}^m$  such that the polynomials  $\{\mathbf{g}'(\boldsymbol{\alpha}, \mathbf{t})^e\}_{|\mathbf{e}|_1 \leq D}$  are distinct monomials in  $\mathbf{t}$ . Then [17] showed that if  $G(\mathbf{x})$  is shifted by  $u\mathbf{g}'$ , then the new shifted polynomial has  $\log k$ -support concentration over the field  $\mathbb{F}(u, \mathbf{s}, \mathbf{t})$ . Our rank concentration result differs from [17] in the following ways:

1. Our hypothesis is slightly stronger than [17]. Instead of total degree  $D$  independent monomial map, we assume that  $\mathbf{g}'(\mathbf{s}, \mathbf{t})$  is a total degree  $Dk$  independent monomial map.

2. On the other hand, we strengthen the conclusion as follows: for every invertible linear transformation  $L(\mathbf{x})$  from  $\mathbb{F}^n$  to  $\mathbb{F}^n$ , if we shift  $G$  by  $uL \circ \mathbf{g}'$ , then the new shifted polynomial has a cone-closed basis over the field  $\mathbb{F}(u, \mathbf{s}, \mathbf{t})$ .

For details see Lemma 5.

### Proof idea of Theorem 1

Suppose that  $\mathcal{C}$  is the set of all  $n$ -variate polynomials in  $\mathbf{y}$  with individual degree at most  $d$  and computed by width  $w$  *any-order* ROABPs. Let  $f(\mathbf{x})$  be an  $n$ -variate polynomial in  $\text{orbit}(\mathcal{C})$ . Then there exists a polynomial  $h(\mathbf{y}) \in \mathcal{C}$ , an invertible linear transformation  $L(\mathbf{x})$  and a point  $\mathbf{b} \in \mathbb{F}^n$  such that

$$f(\mathbf{x}) = h(L(\mathbf{x}) + \mathbf{b}).$$

Since  $h(\mathbf{y}) \in \mathcal{C}$ , there exists a polynomial  $G(\mathbf{y}) \in \mathbb{F}[\mathbf{y}]^{w \times w}$  with individual degree at most  $d$  and computed by a width  $w$  *any-order* ROABP such that

$$h(\mathbf{y}) = \mathbf{a}^T \cdot G(\mathbf{y}) \cdot \mathbf{c},$$

where  $\mathbf{a}, \mathbf{c} \in \mathbb{F}^w$ .

Now we will describe the first step of aforementioned abstract format. First, we show how to achieve  $w^2$ -cone concentration in  $G(\mathbf{y})$ . Let  $\mathbf{g}(\mathbf{t}) = (g_1, \dots, g_n)$  be a polynomial map from  $\mathbb{F}^m$  to  $\mathbb{F}^n$  such that for any  $S \subseteq [n]$  of size  $k := \lceil 2 \log w + 1 \rceil$ , the set of polynomials  $\{g_i \mid i \in S\}$  are algebraically independent. Then, in Lemma 6, we prove that  $G(\mathbf{y} + \mathbf{g})$  has  $w^2$ -cone concentration over the field  $F(\mathbf{t})$ . It strengthens the rank-concentration result for *any-order* ROABPs shown in [17, Theorem 4.1]. They showed that if we shift  $G$  by a  $k$ -wise independent monomial map, then the new polynomial has  $2 \log w$ -support concentration. Next, in Lemma 7, we show that for any invertible linear transformation  $L(\mathbf{x})$  and  $\mathbf{b} \in \mathbb{F}^n$ , the polynomial map defined as the composition of  $L(\mathbf{x}) + \mathbf{b}$  and Shpilka-Volkovich generator  $\mathcal{G}_{n,k}^{SV}$  (see Definition 21, or [51]), that is  $L \circ \mathcal{G}_{n,k}^{SV} + \mathbf{b}$ , satisfies the property required for achieving  $w^2$ -cone concentration in  $G(\mathbf{y})$ . Therefore,  $G(\mathbf{y} + L \circ \mathcal{G}_{n,k}^{SV} + \mathbf{b})$  has  $w^2$ -cone concentration. This implies that there exists a monomial  $\mathbf{y}^e$  of cone-size  $\leq w^2$  such that the coefficient of  $\mathbf{y}^e$  in  $h'(\mathbf{y}) = h(\mathbf{y} + L \circ \mathcal{G}_{n,k}^{SV} + \mathbf{b})$  is nonzero. For any monomial of cone-size  $\leq w^2$ , its degree is less than  $w^2$  and the support set is of size at most  $2 \log w$ . Since the individual degree is at most  $d$ , the degree of  $\mathbf{y}^e$  is at most  $\ell$  where  $\ell := \min\{w^2, d \log w\}$ . Therefore,  $\text{hom}_{\leq \ell}(h')$  is nonzero. Now we apply the step two of the abstract format, which is independent of  $\mathcal{C}$ , and get our desired hitting set for  $\text{orbit}(\mathcal{C})$ .

### Proof idea of Theorem 2

Suppose that  $\mathcal{C}$  is the set of all  $n$ -variate polynomials in  $\mathbf{y}$  with individual degree at most  $d$  and computed by width  $w$  ROABPs. Let  $f(\mathbf{x})$  be an  $n$ -variate polynomial in  $\text{orbit}(\mathcal{C})$ . Then there exists a polynomial  $h(\mathbf{y}) \in \mathcal{C}$ , an invertible linear transformation  $L(\mathbf{x})$  and  $\mathbf{b} \in \mathbb{F}^n$  such that

$$f(\mathbf{x}) = h(L(\mathbf{x}) + \mathbf{b}).$$

Since  $h(\mathbf{y}) \in \mathcal{C}$ , there exists a polynomial  $G(\mathbf{y}) \in \mathbb{F}[\mathbf{y}]^{w \times w}$  and a permutation  $\pi$  on  $[n]$  such that

$$h(\mathbf{y}) = \mathbf{a}^T \cdot G(\mathbf{y}) \cdot \mathbf{c} \text{ and } G(\mathbf{y}) = \prod_{i=1}^n M_i(x_{\pi(i)})$$

where  $\mathbf{a}, \mathbf{c} \in \mathbb{F}^w$  and for all  $i \in [n]$ ,  $M_i(x_{\pi(i)})$  is a polynomial in  $\mathbb{F}[x_{\pi(i)}]^{w \times w}$ .

Now like *any-order* ROABPs, we want to achieve  $w^2$ -cone concentration in  $G(\mathbf{y})$ . However, our approach here will be different from *any-order* ROABPs. Here, we strengthen the “merge-and-reduce” approach of [17] in the following ways:

1. In [17], the polynomial maps  $\mathbf{h}_j$  (for  $j = 0, 1, \dots, \lceil \log n \rceil$ ) were inductively constructed such that after shifting  $G$  by  $\mathbf{h}_j$ , in the new polynomial  $G(\mathbf{x} + \mathbf{h}_j)$ , the product of any  $2^j$  consecutive matrices have  $2 \log w$ -support concentration. We strengthen this result by showing  $w^2$ -cone concentration at each inductive step.
2. At each induction step, since we are dealing with polynomials in orbit (of ROABPs), we not only need to construct a polynomial map which helps to achieve  $w^2$ -cone concentration, but its composition with any invertible affine transformation also helps to achieve the same property.

In [17],  $\mathbf{h}_j$  was constructed as follows:  $\mathbf{h}_0 = \mathbf{0}$  and for all  $j \in [\lceil \log n \rceil]$ ,  $\mathbf{h}_j = \mathbf{h}_{j-1} + u_j \mathbf{g}(\mathbf{s}_j, \mathbf{t}_j)$  where  $\mathbf{g}(\mathbf{s}_j, \mathbf{t}_j)$  is a total degree  $4d \log w$  independent monomial map from  $\mathbb{F}^m \times \mathbb{F}^{m'}$  to  $\mathbb{F}^n$ . They showed that the product of any  $2^j$  consecutive matrices in  $G(\mathbf{y} + \mathbf{h}_j)$  has  $2 \log w$ -support concentration over the field  $\mathbb{F}((u_k, \mathbf{s}_k, \mathbf{t}_k)_{k \in [j]})$ .

Our definition of  $\mathbf{h}_j$  is very close to the definition used in [17]. For  $j = 0$ ,  $\mathbf{h}_j = (t, t^2, \dots, t^n)$  and for all  $j \in [\lceil \log n \rceil]$ ,  $\mathbf{h}_j = \mathbf{h}_{j-1} + u_j \mathbf{g}(\mathbf{s}_j, \mathbf{t}_j)$  where  $\mathbf{g}(\mathbf{s}_j, \mathbf{t}_j)$  is a total degree  $D$  independent monomial map from  $\mathbb{F}^m \times \mathbb{F}^{m'}$  to  $\mathbb{F}^n$  where  $D = 2w^2 \cdot \min\{w^2, 2d \log w\}$ . We show that for every invertible linear transformation  $L(\mathbf{x})$  from  $\mathbb{F}^n$  to  $\mathbb{F}^n$  and  $\mathbf{b} \in \mathbb{F}^n$ , the product of any  $2^j$  consecutive matrices in  $G(\mathbf{y} + L \circ \mathbf{h}_j + \mathbf{b})$  has a cone-closed basis, hence has  $w^2$ -cone concentration, over the field  $\mathbb{F}(t, (u_k, \mathbf{s}_k, \mathbf{t}_k)_{k \in [j]})$ . Our rank concentration results play an important role in proving this property of  $\mathbf{h}_j$ . For more details see Lemma 9 and 10. There are many known constructions of total degree  $D$  independent monomial map with  $m = m' = O(D)$ . For example see Lemma 20. After constructing a polynomial map which gives  $w^2$ -cone concentration in  $G(\mathbf{y})$ , the rest of the proof will be similar to what we did for the *any-order* ROABP case.

## Notations

By  $\mathbb{N}$  we denote the set of natural numbers. For any positive integer  $n$ ,  $[n]$  denotes the set  $\{1, 2, \dots, n\}$ . For a variable tuple  $\mathbf{x} = (x_1, \dots, x_n)$  and a tuple  $\mathbf{e} = (e_1, \dots, e_n) \in \mathbb{N}^n$ ,  $\mathbf{x}^{\mathbf{e}}$  denotes the monomial  $\prod_{i=1}^n x_i^{e_i}$ . The *degree*, or *total degree*, of  $\mathbf{x}^{\mathbf{e}}$  is  $|\mathbf{e}|_1 = \sum_{i=1}^n e_i$  and the *individual degree* of  $\mathbf{x}^{\mathbf{e}}$  is  $|\mathbf{e}|_\infty = \max_{i \in [n]} e_i$ . The *support* of  $\mathbf{x}^{\mathbf{e}}$  is the subset  $S$  of  $[n]$  such that  $i \in S$  if and only if  $e_i > 0$ , and the *support-size* denotes the cardinality of  $S$ . The *cone* of  $\mathbf{x}^{\mathbf{e}}$  is the set of monomials which divide it and the *cone-size* is the cardinality of that set, that is  $\prod_{i=1}^n (e_i + 1)$ . A monomial  $\mathbf{x}^{\mathbf{f}}$  is called a *sub-monomial* of  $\mathbf{x}^{\mathbf{e}}$ , if  $\mathbf{x}^{\mathbf{e}}$  divides  $\mathbf{x}^{\mathbf{f}}$ , that is  $e_i \leq f_i$  for all  $i \in [n]$ . A set of monomials  $B$  is called *cone-closed* if for every monomial in  $B$  all its sub-monomials are also in  $B$ . For a polynomial  $f$  in  $\mathbf{x}$  and a monomial  $\mathbf{x}^{\mathbf{e}}$ ,  $\text{coef}_f(\mathbf{x}^{\mathbf{e}})$  denotes the coefficient of  $\mathbf{x}^{\mathbf{e}}$  in  $f$ .

## 2 Achieving Cone-closed basis by shift

In this section, we show our rank concentration results for polynomials over the vector space  $\mathbb{F}^k$ . By  $M_{n,d}$ , we denote the set of  $n$ -variate monomials with individual degree at most  $d$ . We also use  $M_{n,d}$  to denote the exponent vectors for those monomials since there is one-to-one correspondence between monomials and their exponent vectors. For any  $\mathbf{a}, \mathbf{b} \in \mathbb{N}^n$  with  $\mathbf{a} = (a_1, \dots, a_n)$  and  $\mathbf{b} = (b_1, \dots, b_n)$ ,  $\binom{\mathbf{a}}{\mathbf{b}}$  denotes  $\prod_{i=1}^n \binom{a_i}{b_i}$ .

### 30:10 Improved Hitting Set for Orbit of ROABPs

Let  $G(\mathbf{x})$  be an  $n$ -variate polynomial over  $\mathbb{F}^k$  with individual degree at most  $d$ . After shifting  $G(\mathbf{x})$  by  $\mathbf{z}$ , the coefficients of the shifted polynomial  $G'(\mathbf{x}) = G(\mathbf{x} + \mathbf{z})$  can be written as follows: for all  $\mathbf{e} \in M_{n,d}$ ,

$$\text{coef}_{\mathbf{x}^{\mathbf{e}}}(G') = \sum_{\mathbf{f} \in M_{n,d}} \binom{\mathbf{f}}{\mathbf{e}} \text{coef}_{\mathbf{x}^{\mathbf{f}}}(G) \mathbf{z}^{\mathbf{f}-\mathbf{e}}.$$

The above equation can be written in matrix form as follows:

$$F'(\mathbf{z}) = W^{-1}(\mathbf{z})TW(\mathbf{z})F, \quad (1)$$

where

- $F$  and  $F'(\mathbf{z})$  are the matrices with entries from  $\mathbb{F}$  and  $\mathbb{F}[\mathbf{z}]$ , respectively. The rows of both the matrices are indexed by the elements of  $M_{n,d}$ , and for any monomial  $\mathbf{e} \in M_{n,d}$ , the rows indexed by  $\mathbf{e}$  in  $F$  and  $F'$  are  $\text{coef}_{\mathbf{x}^{\mathbf{e}}}(G)$  and  $\text{coef}_{\mathbf{x}^{\mathbf{e}}}(G')$ , respectively.
- $W(\mathbf{z})$  be the diagonal matrix whose rows and columns are indexed by the elements of  $M_{n,d}$  and for all  $\mathbf{e} \in M_{n,d}$ ,  $W(\mathbf{z})_{\mathbf{e},\mathbf{e}} = \mathbf{z}^{\mathbf{e}}$ .
- $T$  is a square matrix such that the rows and columns are indexed by  $M_{n,d}$  and for all  $\mathbf{e}, \mathbf{f} \in M_{n,d}$ ,  $T_{\mathbf{e},\mathbf{f}} = \binom{\mathbf{f}}{\mathbf{e}}$ . In the literature,  $T$  is known as *transfer matrix*.

In the following lemma, we recall a property of transfer matrix from [16].

► **Lemma 3** (Lemma 17 [16]). *Let  $\mathbb{F}$  be a field of characteristic 0 or greater than  $d$ . Then, for every  $B \subseteq M_{n,d}$ , there exists a cone-closed set  $A \subseteq M_{n,d}$  with  $|A| = |B|$  such that  $T_{A,B}$  is full rank over  $\mathbb{F}$ .*

Next, we show our first rank concentration result. Informally, we prove that if  $G(\mathbf{x})$  is shifted by algebraically independent polynomials, the new polynomial has a cone-closed basis.

► **Lemma 4.** *Let  $\mathbb{F}$  be a field of characteristic 0 or greater than  $d$ . Let  $G(\mathbf{x}) \in \mathbb{F}^k[\mathbf{x}]$  be an  $n$ -variate polynomial with individual degree at most  $d$ . Let  $\mathbf{g}(\mathbf{z}) = (g_1, \dots, g_n)$  be a polynomial map from  $\mathbb{F}^n$  to  $\mathbb{F}^n$  such that all  $g_i$ 's are algebraically independent. Then  $G(\mathbf{x} + \mathbf{g})$  has a cone-closed basis over  $\mathbb{F}(\mathbf{z})$ .*

**Proof.** First we show that  $G'(\mathbf{x}) = G(\mathbf{x} + \mathbf{z})$  has a cone-closed basis over  $\mathbb{F}(\mathbf{z})$ . This part of our proof closely follows the proof outline of [16, Theorem 2]. From Equation 1, we know that the shifted polynomial  $G(\mathbf{x} + \mathbf{z})$  yields the following matrix equation:

$$F'(\mathbf{z}) = W(\mathbf{z})^{-1}TW(\mathbf{z})F.$$

Let  $k'$  be the rank of the matrix  $F$ . Then we divide our proof in two cases:

**Case 1 ( $k' < k$ ).** We reduce this case to the other one where  $k' = k$ . Since the rank of  $F$  is  $k'$ , there exists a  $S \subseteq [k]$  of size  $k'$  such that  $F_{M,S}$  is full rank where  $M = M_{n,d}$ . Let  $G_S(\mathbf{x})$  and  $G'_S(\mathbf{x})$  be the projections of  $G(\mathbf{x})$  and  $G'(\mathbf{x})$  on the coordinates indexed by  $S$ . Then  $G'_S(\mathbf{x}) = G_S(\mathbf{x} + \mathbf{z})$ . One can observe that for any set of monomials  $A$ , if their coefficients in  $G_S(\mathbf{x})$  forms a basis for its coefficient space, then their coefficients in  $G(\mathbf{x})$  also forms a basis for the coefficients space of  $G(\mathbf{x})$ . Similarly, this is also true between  $G'_S(\mathbf{x})$  and  $G'(\mathbf{x})$ . Now from the case 2,  $G'_S(\mathbf{x})$  has a cone-closed basis over  $\mathbb{F}(\mathbf{z})$ , that is, there exists a cone-closed set of monomials  $A$  such that their coefficients in  $G'_S(\mathbf{x})$  forms a basis for its coefficient space. This implies that  $G'(\mathbf{x})$  also has a cone-closed basis over  $\mathbb{F}(\mathbf{z})$ .

**Case 2 ( $k' = k$ ).** The rows of  $F$  are indexed by the monomials in  $M_{n,d}$ . Fix a monomial ordering  $\prec$  on the monomials in  $\mathbf{z}$ . For example, assume  $\prec$  is the lexicographic monomial ordering. Then, from Lemma 13, we have a unique subset  $B$  of  $M_{n,d}$  with the following properties:  $\text{rank}(F_{B,[k]}) = k$ , and for every other subset  $C$  of  $M_{n,d}$  with  $\text{rank}(F_{C,[k]}) = k$ ,

$$\prod_{\mathbf{e} \in B} \mathbf{z}^{\mathbf{e}} \prec \prod_{\mathbf{e}' \in C} \mathbf{z}^{\mathbf{e}'}$$

Using Lemma 3, we have a cone-closed subset  $A$  of  $M_{n,d}$  such that  $T_{A,B}$  has full rank. Now

$$\det(F'(\mathbf{z})_{A,[k]}) = \det(W(\mathbf{z})_{A,A})^{-1} \cdot \det((TW(\mathbf{z})F)_{A,[k]}). \tag{2}$$

Applying Lemma 14, we get that

$$\det((TW(\mathbf{z})F)_{A,[k]}) = \sum_{C \in \binom{M_{n,d}}{k}} \det(T_{A,C}) \det(F_{C,[k]}) \prod_{\mathbf{e} \in C} \mathbf{z}^{\mathbf{e}}. \tag{3}$$

For every  $C \in \binom{M_{n,d}}{k} \setminus \{B\}$  such that  $F_{C,[k]}$  is a full rank matrix, the following holds:  $\prod_{\mathbf{e} \in B} \mathbf{z}^{\mathbf{e}} \prec \prod_{\mathbf{e}' \in C} \mathbf{z}^{\mathbf{e}'}$ . Therefore, the coefficient of  $\prod_{\mathbf{e} \in B} \mathbf{z}^{\mathbf{e}}$  in the above polynomial does not get cancelled by other monomials. Also, the coefficient of  $\prod_{\mathbf{e} \in B} \mathbf{z}^{\mathbf{e}}$ ,  $\det(T_{A,B}) \det(F_{B,[k]}) \neq 0$ . Therefore, the polynomial  $\det((TW(\mathbf{z})F)_{A,[k]})$  is a nonzero polynomial in  $\mathbf{z}$ . Also,  $\det(W(\mathbf{z})_{A,A})^{-1}$  is a nonzero element in  $\mathbb{F}(\mathbf{z})$  since  $\det(W(\mathbf{z})_{A,A})$  is a nonzero polynomial in  $\mathbf{z}$ . Therefore,  $\det(F'(\mathbf{z})_{A,[k]})$  is nonzero in  $\mathbb{F}(\mathbf{z})$ . This implies that  $G'(\mathbf{x}) = G(\mathbf{x} + \mathbf{z})$  has a cone-closed basis over  $\mathbb{F}(\mathbf{z})$ .

Now we show that  $G(\mathbf{x} + \mathbf{g})$  has a cone-closed basis over  $\mathbb{F}(\mathbf{z})$ . In Equation 2, since both  $\det(W(\mathbf{z})_{A,A})$  and  $\det((TW(\mathbf{z})F)_{A,[k]})$  are nonzero polynomials in  $\mathbf{z}$ . Therefore, after evaluating them on any  $n$  algebraically independent polynomials, they will remain nonzero. Thus,  $\det(F'(\mathbf{g})_{A,[k]})$  remains nonzero. This implies that for the polynomial  $G(\mathbf{x} + \mathbf{g})$ , the coefficients of the monomials in  $A$  form a cone-closed basis (over  $\mathbb{F}(\mathbf{z})$ ) for its coefficient space. ◀

The above lemma combined Lemma 26 implies that the polynomial  $G(\mathbf{x} + \mathbf{g})$  also has  $k$ -cone concentration over  $\mathbb{F}(\mathbf{t})$ . Here, we would like to mention that although the above rank concentration result is described in terms of cone-closed basis, to design our hitting sets, proving  $k$ -cone concentration property of  $G(\mathbf{x} + \mathbf{g})$  is sufficient. The similar thing is also true for our next rank concentration result.

► **Lemma 5.** *Let  $\mathbb{F}$  be a field of characteristic zero or greater than  $d$ . Let  $G(\mathbf{x})$  be an  $n$ -variate individual degree  $\leq d$  polynomial over  $\mathbb{F}^k$  such that the coefficients of all the monomials of total degree up to  $D$  spans the coefficient space of  $G$ . For some  $N \geq n$ , let  $L(\mathbf{y}) = (\ell_1, \dots, \ell_n)$  be a linear transformation from  $\mathbb{F}^N$  to  $\mathbb{F}^n$  such that all  $\ell_i$ 's are linearly independent. Let  $\mathbf{g}(\mathbf{s}, \mathbf{t})$  be a total degree  $Dk$  independent monomial map from  $\mathbb{F}^m \times \mathbb{F}^{m'}$  to  $\mathbb{F}^N$ . Then  $G(\mathbf{x} + \mathbf{g}')$ , where  $\mathbf{g}' = uL \circ \mathbf{g}$ , has a cone-closed basis over  $F(u, \mathbf{s}, \mathbf{t})$ .*

For proof of the above lemma see Section B.

### 3 Hitting set for orbit of any-order ROABPs

In this section, we describe our hitting set for the orbit of any-order ROABPs. As mentioned earlier, the notion of low-cone concentration plays an important role is designing our hitting sets. We begin by showing that for  $w$ -width  $n$ -variate any-order ROABPs,  $w^2$ -cone concentration can be established by showing  $w^2$ -cone concentration for every  $\Omega(\log w)$ -size subset of variables.

### 30:12 Improved Hitting Set for Orbit of ROABPs

► **Lemma 6.** *Let  $\mathbb{F}$  be a field of characteristic 0 or greater than  $d$ . Let  $G(\mathbf{x}) \in \mathbb{F}[\mathbf{x}]^{w \times w}$  be an  $n$ -variate polynomial over  $\mathbb{F}$  with individual degree at most  $d$  and computed by a  $w$ -width any-order ROABP. Let  $\ell = \lfloor 2 \log w \rfloor + 1$ . Let  $\mathbf{g}(\mathbf{t}) = (g_1, \dots, g_n)$  be a polynomial map such that for all  $S \subseteq [n]$  of size  $\ell$ , the polynomials  $\{g_i \mid i \in S\}$  are algebraically independent. Then  $G(\mathbf{x} + \mathbf{g})$  has  $w^2$ -cone concentration over  $\mathbb{F}(\mathbf{t})$ .*

For proof of the above lemma see the full version. Our next lemma, using Shpilka-Volkovich generator (Definition 21), gives the construction of a polynomial map which satisfies the condition of the above lemma.

► **Lemma 7.** *Let  $L(\mathbf{x}) = (\ell_1, \dots, \ell_n)$  be an invertible linear transformation from  $\mathbb{F}^n$  to  $\mathbb{F}^n$ . Let  $\mathbf{b}$  be a point in  $\mathbb{F}^n$ . For some  $k \leq n$ , let  $\mathbf{g}(\mathbf{s}, \mathbf{t}) = (g_1, \dots, g_n)$  be the polynomial map from  $\mathbb{F}^k \times \mathbb{F}^k$  to  $\mathbb{F}^n$ , defined as  $\mathbf{g} = L \circ \mathcal{G}_{n,k}^{SV} + \mathbf{b}$ . Then for all  $S \subseteq [n]$  of size  $k$ , the polynomials  $\{g_i \mid i \in S\}$  are algebraically independent.*

For proof of the above lemma the full version. Combining the above two lemmas, we get the following.

► **Corollary 8.** *Let  $\mathbb{F}$  be a field of characteristic 0 or greater than  $d$ . Let  $G(\mathbf{x}) \in \mathbb{F}[\mathbf{x}]^{w \times w}$  be an  $n$ -variate polynomial with individual degree at most  $d$  and computed by a width  $w$  any-order ROABP. Let  $L(\mathbf{x})$  be an invertible linear transformation from  $\mathbb{F}^n$  to  $\mathbb{F}^n$  and  $\mathbf{b}$  be a point in  $\mathbb{F}^n$ . Let  $k = \lfloor 2 \log w \rfloor + 1$  and  $\mathbf{g} = L \circ \mathcal{G}_{n,k}^{SV} + \mathbf{b}$ . Then  $G(\mathbf{x} + \mathbf{g})$  has  $w^2$ -cone concentration over  $\mathbb{F}(\mathbf{s}, \mathbf{t})$ .*

**Proof.** Let  $\mathbf{g}(\mathbf{s}, \mathbf{t}) = (g_1, \dots, g_n)$ . From Lemma 7, for every subset  $S \subseteq [n]$  of size  $k$ , the polynomials  $\{g_i \mid i \in S\}$  are algebraically independent. Therefore, using Lemma 6, we get that  $G(\mathbf{x} + \mathbf{g})$  has  $w^2$ -cone concentration over  $\mathbb{F}(\mathbf{s}, \mathbf{t})$ . ◀

Now we describe the construction of our hitting set for the orbit of any-order ROABPs.

**Proof of Theorem 1.** Let  $f(\mathbf{x})$  be an  $n$ -variate individual degree  $\leq d$  polynomial which is in the orbit of width  $w$  any-order ROABPs. Then, there exists an  $n$ -variate individual degree  $\leq d$  polynomial  $G(\mathbf{y}) \in \mathbb{F}^{w \times w}[\mathbf{y}]$  computed by a width  $w$  any-order ROABP, an invertible linear transformation  $L(\mathbf{x})$  from  $\mathbb{F}^n$  to  $\mathbb{F}^n$  and a point  $\mathbf{b} \in \mathbb{F}^n$  such that

$$f(\mathbf{x}) = \mathbf{a}^T \cdot G(L\mathbf{x} + \mathbf{b}) \cdot \mathbf{c},$$

where  $\mathbf{a}, \mathbf{c} \in \mathbb{F}^n$ . Let  $\mathbf{g}(\mathbf{s}, \mathbf{t}) = L \circ \mathcal{G}_{n,k}^{SV} + \mathbf{b}$  where  $k = \lfloor 2 \log w \rfloor + 1$ , and let

$$h(\mathbf{y}) = \mathbf{a}^T \cdot G(\mathbf{y} + \mathbf{g}) \cdot \mathbf{c}.$$

This implies that

$$f'(\mathbf{x}) = f(\mathbf{x} + \mathcal{G}_{n,k}^{SV}) = h(L(\mathbf{x})). \quad (4)$$

From Corollary 8,  $G(\mathbf{y} + \mathbf{g})$  has  $w^2$ -cone concentration over  $\mathbb{F}(\mathbf{s}, \mathbf{t})$ . This implies that there exists a monomial  $\mathbf{y}^e$  in  $h$  with cone-size  $\leq w^2$  such that  $\text{coef}_{\mathbf{y}^e}(h)$  is nonzero. For a monomial of cone-size  $\leq w^2$ , its total degree is less than  $w^2$  and the support-size is  $\leq \log w^2$ . Since the individual degree of each variable in  $G(\mathbf{y})$  is at most  $d$ , Therefore, the degree of  $\mathbf{y}^e$  is  $\leq \ell$  where  $\ell = \min\{w^2, 2d \log w\}$ . Hence,  $\text{hom}_{\leq \ell}(h(\mathbf{y}))$  is a nonzero polynomial in  $\mathbf{y}$ . Since

$$\text{hom}_{\leq \ell}(h(L(\mathbf{x}))) = (\text{hom}_{\leq \ell}(h))(L(\mathbf{x})),$$

from Lemma 24,  $\text{hom}_{\leq \ell}(h(L(\mathbf{x})))$  is a nonzero polynomial. Therefore, from Equation 4,  $\text{hom}_{\leq \ell}(f'(\mathbf{x}))$  is a nonzero polynomial over  $\mathbb{F}(\mathbf{s}, \mathbf{t})$ . This implies that there exists a monomial  $\mathbf{x}^e$  of support-size  $\leq \ell$  such that its coefficient in  $f'$  is nonzero. Thus, from Lemma 23,  $f'(\mathcal{G}_{n,\ell}^{SV}) = f'(\mathcal{G}_{n,k+\ell}^{SV})$  is a  $k + \ell$ -variate nonzero polynomial over  $\mathbb{F}$ . The total degree of  $f$  is at most  $nd$ , and from Observation 22, the individual degree of each coordinate of  $\mathcal{G}_{n,k+\ell}^{SV}$  is at most  $n$ . Also,  $\mathcal{G}_{n,k+\ell}^{SV}$  is  $\text{poly}(ndw)$ -explicit. Thus, from Observation 17,  $f$  has a hitting set computable in time  $(ndw)^{O(\ell)}$ . ◀

#### 4 Hitting Set for orbit of ROABPs

Here, we discuss the construction of our hitting set for the orbit of ROABPs. Towards that, first we need to construct some polynomial map which helps us in achieving low-cone concentration for ROABPs. At this step, we also have to be more careful as we are dealing with the orbit of ROABPs. Lemma 10 describes inductive construction of a polynomial map, by taking sum of logarithmically many variable disjoint copies of total degree  $D$  independent monomial maps (Definition 19) for some small  $D$ , such that the following holds: by shifting its composition with any invertible affine transformation we can achieve low-cone concentration for ROABPs. We begin by showing how to achieve cone-closed basis for the product of two polynomials in a disjoint set of variables, with the property that each polynomial also has a cone-closed basis.

► **Lemma 9.** *Let  $\mathbf{y}$  and  $\mathbf{z}$  be two disjoint sets of variables. Let  $G(\mathbf{y}) \in \mathbb{F}[\mathbf{y}]^{w \times w}$  and  $H(\mathbf{z}) \in \mathbb{F}[\mathbf{z}]^{w \times w}$  be two  $n$ -variate individual degree  $\leq d$  polynomials such that both have cone-closed bases. Let  $L(\mathbf{x}) = (\ell_1, \dots, \ell_{|\mathbf{y}|+|\mathbf{z}|})$  be a linear transformation from  $\mathbb{F}^{|\mathbf{x}|}$  to  $\mathbb{F}^{|\mathbf{y}|} \times \mathbb{F}^{|\mathbf{z}|}$  such that all  $\ell_i$ s are linearly independent. Let  $D = 2w^2 \cdot \min\{w^2, 2d \log w\}$ ,  $\mathbf{g}(\mathbf{s}, \mathbf{t})$  be a total degree  $D$  independent monomial map from  $\mathbb{F}^{|\mathbf{s}|} \times \mathbb{F}^{|\mathbf{t}|}$  to  $\mathbb{F}^{|\mathbf{x}|}$ , and  $\mathbf{g}' = uL \circ \mathbf{g}$ . Then  $G(\mathbf{y} + \mathbf{g}'|_{\mathbf{y}})H(\mathbf{z} + \mathbf{g}'|_{\mathbf{z}})$  has a cone-closed basis over  $F(u, \mathbf{s}, \mathbf{t})$ , where  $\mathbf{g}'|_{\mathbf{y}}$  and  $\mathbf{g}'|_{\mathbf{z}}$  are the restrictions of  $\mathbf{g}'$  over  $\mathbf{y}$  and  $\mathbf{z}$ , respectively.*

For proof of the above lemma see the full version. Applying the above lemma repeatedly, the next one gives the construction of a polynomial map which helps us to achieve low-cone concentration for ROABPs.

► **Lemma 10.** *Let  $n \geq 0$ ,  $N = 2^n$  and  $d, w \geq 1$ . Let  $D = 2w^2 \cdot \min\{w^2, 2d \log w\}$ . Let  $\mathbf{g}(\mathbf{s}, \mathbf{t})$  be a total degree  $D$  independent monomial map from  $\mathbb{F}^m \times \mathbb{F}^{m'}$  to  $\mathbb{F}^N$ . Let  $\mathbf{t}_0 = (t, t^2, \dots, t^N)$ . Let*

$$\mathcal{G}_{n,d,w} = \mathbf{t}_0 + \sum_{i=1}^n u_i \mathbf{g}(\mathbf{s}_i, \mathbf{t}_i),$$

where all  $\mathbf{s}_i$ 's and  $\mathbf{t}_i$ 's are disjoint set of variables.

Let  $\pi$  be permutation on  $[N]$ . Let  $F(\mathbf{x}) = \prod_{i=1}^N M_i(x_{\pi(i)})$  such that each  $M_i(x_{\pi(i)})$  is a polynomial in  $\mathbb{F}^{w \times w}[x_{\pi(i)}]$  with individual degree at most  $d$ . Then for every invertible linear transformation  $L(\mathbf{x})$  from  $\mathbb{F}^N$  to  $\mathbb{F}^N$  and  $\mathbf{b} \in \mathbb{F}^N$ ,  $F(\mathbf{x} + \mathbf{b} + L \circ \mathcal{G}_{n,d,w})$  has a cone-closed basis over the field  $\mathbb{F}(t, (u_i, \mathbf{s}_i, \mathbf{t}_i)_{i \in [n]})$ .

**Proof.** Let  $L(\mathbf{x}) = (\ell_1, \dots, \ell_N)$ . Let  $\mathbf{h}_0 = \mathbf{b} + L(\mathbf{t}_0)$ , and for all  $k \in [n]$ ,

$$\mathbf{h}_k = \mathbf{h}_{k-1} + u_k L \circ \mathbf{g}(\mathbf{t}_k, \mathbf{s}_k).$$

Then  $\mathbf{h}_n = \mathbf{b} + L \circ \mathcal{G}_{n,d,w}$ . For all  $1 \leq i \leq j \leq N$ , let

$$F_{i,j}[\mathbf{x}] = \prod_{r=i}^j M_r(x_{\pi(r)}).$$

### 30:14 Improved Hitting Set for Orbit of ROABPs

Using induction, we show that for all  $k \in \{0, 1, \dots, n\}$  and  $i, j \in [n]$  with  $j - i + 1 = 2^k$ ,  $F_{ij}[\mathbf{x} + \mathbf{h}_k]$  has a cone-closed basis over  $\mathbb{F}(t, (u_i, \mathbf{s}_i, \mathbf{t}_i)_{i \in [k]})$ .

**For  $k = 0$ .** Let  $\mathbf{b} = (b_1, \dots, b_N)$ . We need to show that for all  $i \in [N]$ ,  $M_i(x_{\pi(i)} + \ell_{\pi(i)}(\mathbf{t}_0) + b_{\pi(i)})$  has a cone-closed basis over  $\mathbb{F}(t)$ . Since  $L(\mathbf{x})$  is an invertible linear transformation, each  $\ell_i$  is a nonzero linear polynomial over  $\mathbf{x}$ . Therefore,  $\ell_i(\mathbf{t}_0)$  is a non-constant polynomial in  $t$ . Hence, using Lemma 3, for all  $i \in [N]$ ,  $M_i(x_{\pi(i)} + \ell_{\pi(i)}(\mathbf{t}_0) + b_{\pi(i)})$  has a cone-closed basis over  $\mathbb{F}(t)$ .

**For  $k > 0$ .** Let  $i, j \in [N]$  such that  $j - i + 1 = 2^k$ . Let  $\mathbf{y}$  and  $\mathbf{z}$  be a partition of the variables  $(x_{\pi(i)}, \dots, x_{\pi(j)})$  into two equal halves such that they respect the permutation  $\pi$ . Then  $F_{ij}[\mathbf{x}]$  can be written as  $G(\mathbf{y})H(\mathbf{z})$  where  $G(\mathbf{y}) \in \mathbb{F}[\mathbf{y}]^{w \times w}$  and  $H(\mathbf{z}) \in \mathbb{F}[\mathbf{z}]^{w \times w}$ . From the induction hypothesis, we know that both

$$G'(\mathbf{y}) = G(\mathbf{y} + \mathbf{h}_{k-1}|\mathbf{y}) \text{ and } H'(\mathbf{z}) = H(\mathbf{z} + \mathbf{h}_{k-1}|\mathbf{z})$$

have cone-closed bases over  $\mathbb{F}(t, (u_i, \mathbf{s}_i, \mathbf{t}_i)_{i \in [k-1]})$ . Let  $F'_{ij}(\mathbf{x}) = G'(\mathbf{y})H'(\mathbf{z})$ . Then, using Lemma 9,

$$F_{ij}(\mathbf{x} + \mathbf{h}_k) = F'_{ij}(\mathbf{x} + u_k L \circ \mathbf{g}(\mathbf{s}_k, \mathbf{t}_k))$$

has a cone-closed basis over  $\mathbb{F}(t, (u_i, \mathbf{s}_i, \mathbf{t}_i)_{i \in [k]})$ . This completes our proof.  $\blacktriangleleft$

From Lemma 20, using Klivans-Spielman generator (Lemma 18), we can construct a total degree  $D$  independent monomial map. Therefore, Klivans-Spielman generator combined with the above lemma we get the following corollary.

**► Corollary 11.** *Let  $n \geq 0$ ,  $N = 2^n$  and  $d, w \geq 1$ . Let  $D = 2w^2 \cdot \min\{w^2, 2d \log w\}$ . Let*

$$\mathcal{G}'_{n,d,w} = \mathbf{t}_0 + \sum_{i=1}^n u_i \mathcal{G}_{N,d,ND}^{KS}(\mathbf{s}_i, \mathbf{t}_i). \quad (5)$$

*Let  $\pi$  be permutation on  $[N]$ . Let  $F(\mathbf{x}) = \prod_{i=1}^N M_i(x_{\pi(i)})$  such that each  $M_i(x_{\pi(i)})$  is a polynomial in  $\mathbb{F}[x_{\pi(i)}]^{w \times w}$  with individual degree at most  $d$ . Then,*

1. *for every invertible linear transformation  $L(\mathbf{x})$  from  $\mathbb{F}^N$  to  $\mathbb{F}^N$  and  $\mathbf{b} \in \mathbb{F}^N$ , the polynomial  $F(\mathbf{x} + \mathbf{b} + L \circ \mathcal{G}'_{n,d,w})$  has a cone-closed basis over the field  $\mathbb{F}(t, (u_i, \mathbf{s}_i, \mathbf{t}_i)_{i \in [n]})$ .*
2.  *$\mathbf{b} + \mathcal{G}'_{n,d,w}$  is a polynomial map from  $\mathbb{F} \times (\mathbb{F} \times \mathbb{F}^m \times \mathbb{F}^m)^n$  to  $\mathbb{F}^N$  where  $m = O(D)$ .*
3.  *$\mathcal{G}'_{n,d,w}$  is poly( $dND$ )-explicit polynomial map and its each coordinate is a polynomial of individual degree at most poly( $dN$ ).*

**Proof.** From Lemma 20,  $\mathcal{G}_{N,d,ND}^{KS}(\mathbf{s}, \mathbf{t})$  is a poly( $NDd$ )-explicit total degree  $D$  independent monomial map from  $\mathbb{F}^m \times \mathbb{F}^m$  to  $\mathbb{F}^N$ , where  $m = O(D)$ . Also, each coordinate of  $\mathcal{G}_{N,d,ND}^{KS}$  is a polynomial of individual degree at most poly( $dN$ ). Now this combined with Lemma 10 prove the above corollary.  $\blacktriangleleft$

Now we describe the construction of hitting set for orbit of ROABPs.

**Proof of Theorem 2.** Let  $f(\mathbf{x})$  be an  $n$ -variate individual degree  $\leq d$  polynomial which is in the orbit of width  $w$  ROABPs. Then, there exists an  $n$ -variate individual degree  $\leq d$  polynomial  $G(\mathbf{y}) \in \mathbb{F}[\mathbf{y}]^{w \times w}$  computed by a  $w$ -width ROABP, an invertible linear transformation  $L(\mathbf{x})$  from  $\mathbb{F}^n$  to  $\mathbb{F}^n$  and  $\mathbf{b} \in \mathbb{F}^n$  such that

$$f(\mathbf{x}) = \mathbf{a}^T \cdot G(L(\mathbf{x}) + \mathbf{b}) \cdot \mathbf{c},$$

where  $\mathbf{a}, \mathbf{c} \in \mathbb{F}^n$ . Let  $D = 2w^2 \cdot \min\{w^2, d \log w^2\}$ . Let  $\mathcal{G}'_{\lceil \log n \rceil, d, w}$  be defined as Equation 5 in Corollary 11, that is

$$\mathcal{G}'_{\lceil \log n \rceil, d, w} = \mathbf{t}_0 + \sum_{i=1}^{\lceil \log n \rceil} u_i \mathcal{G}_{n, d, n^D}^{KS}(\mathbf{s}_i, \mathbf{t}_i),$$

where  $\mathbf{t}_0 = (t, t^2, \dots, t^n)$ . Then,  $\mathcal{G}'_{\lceil \log n \rceil, d, w}$  is a polynomial map from  $\mathbb{F} \times (\mathbb{F} \times \mathbb{F}^m \times F^m)^{\lceil \log n \rceil}$  to  $\mathbb{F}^n$  where  $m = O(D)$ . This implies that the number of variables used in  $\mathcal{G}'_{\lceil \log n \rceil, d, w}$  is  $O(D \log n)$ . Let

$$g(\mathbf{y}) = \mathbf{a}^T \cdot G(\mathbf{y} + \mathbf{b} + L \circ \mathcal{G}'_{\lceil \log n \rceil, d, w}) \cdot \mathbf{c}.$$

Then

$$f'(\mathbf{x}) = f(\mathbf{x} + \mathcal{G}'_{\lceil \log n \rceil, d, w}) = g(L(\mathbf{x})). \quad (6)$$

From Corollary 11,

$$G'(\mathbf{y}) = G(\mathbf{y} + \mathbf{b} + L \circ \mathcal{G}'_{\lceil \log n \rceil, d, w})$$

has a cone-closed basis over  $\mathbb{F}(t, (u_i, \mathbf{s}_i, \mathbf{t}_i)_{i \in [\lceil \log n \rceil]})$ . Therefore, from Lemma 26,  $G'(\mathbf{y})$  has also  $w^2$ -cone concentration. This implies that  $g(\mathbf{y})$  has a monomial of nonzero coefficient and its cone-size is at most  $w^2$ . For every monomial of cone-size at most  $w^2$ , its degree is also at most  $w^2$  and its support-size is at most  $2 \log w$ . Therefore, for every monomial of cone-size  $\leq w^2$  and individual degree  $\leq d$ , its degree is at most  $k = \min\{w^2, 2d \log w\}$ . Therefore,  $\text{hom}_{\leq k}(g(\mathbf{y}))$  is a nonzero polynomial in  $\mathbf{y}$  over  $\mathbb{F}(t, (u_i, \mathbf{s}_i, \mathbf{t}_i)_{i \in [\lceil \log n \rceil]})$ . Since

$$\text{hom}_{\leq k}(g(L(\mathbf{x}))) = (\text{hom}_{\leq k}(g))(L(\mathbf{x})),$$

from Lemma 24,  $\text{hom}_{\leq k}(g(L(\mathbf{x})))$  is also nonzero polynomial. Therefore, from Equation 6,  $\text{hom}_{\leq k}(f'(\mathbf{x}))$  is also a nonzero polynomial. This implies that there exists a monomial  $\mathbf{x}^e$  of support-size at most  $k$  such that  $\text{coef}_{\mathbf{x}^e}(f')$  is nonzero. Thus, from Lemma 23,

$$f'(\mathcal{G}_{n, k}^{SV}) = f(\mathcal{G}_{n, k}^{SV} + \mathcal{G}'_{\lceil \log n \rceil, d, w})$$

is a nonzero polynomial. Let  $\mathcal{G} = \mathcal{G}_{n, k}^{SV} + \mathcal{G}'_{\lceil \log n \rceil, d, w}$ . Then,  $\mathcal{G}$  is a polynomial map in  $O(kw^2 \log n)$  many variables and the individual degree of each coordinate is at most  $\text{poly}(ndw)$ . Since both  $\mathcal{G}_{n, k}^{SV}$  and  $\mathcal{G}'_{\lceil \log n \rceil, d, w}$  both are  $\text{poly}(ndw)$ -explicit,  $\mathcal{G}$  is also  $\text{poly}(ndw)$ -explicit. Thus, applying Observation 17, we have a hitting set for  $f$  computable in time  $(ndw)^{O(\ell)}$  where  $\ell = (w^2 \log n) \cdot \min\{w^2, d \log w^2\}$ . ◀

## 5 Conclusion

In this paper, we studied the hitting set problem for the orbits of ROABPs and *any-order* ROABPs. We have designed improved hitting sets for these two polynomial classes. In low-width but high-individual-degree setting, our hitting sets are more efficient than the previous ones given by Saha and Thankey. On the technical front, we have shown some stronger rank concentration results by establishing low-cone concentration for polynomials over vector spaces. These new rank concentration results have played a significant role in designing our hitting sets. However, our hitting sets for the orbits of ROABPs and *any-order* ROABPs are yet to match the time complexity of hitting sets known for ROABPs and its variants. Therefore, it is an interesting open question to close this gap.

## A Preliminaries

We start with the following observation.

► **Observation 12.** *For a monomial of cone-size at most  $k$ , its degree is less than  $k$  and the support-size is at most  $\log k$ .*

A *monomial ordering* is a total ordering on the set of all monomials in  $\mathbf{x}$  with following properties:

1. for all  $\mathbf{a} \in \mathbb{N}^n \setminus \{\mathbf{0} = (0, \dots, 0)\}$ ,  $\mathbf{1} \prec \mathbf{x}^{\mathbf{a}}$ .
2. for all  $\mathbf{a}, \mathbf{b}, \mathbf{c} \in \mathbb{N}^n$ , if  $\mathbf{x}^{\mathbf{a}} \prec \mathbf{x}^{\mathbf{b}}$  then  $\mathbf{x}^{\mathbf{a}+\mathbf{c}} \prec \mathbf{x}^{\mathbf{b}+\mathbf{c}}$ .

For more on monomial ordering, see [8, Chapter 2].

Suppose that  $M$  is a matrix whose rows and columns are indexed by  $A$  and  $B$ , respectively. Then for every  $S \subseteq A$  and  $T \subseteq B$ ,  $M_{S,T}$  denotes the submatrix of  $M$  with rows and columns indexed by  $S$  and  $T$ , respectively. The next lemma is a well known phenomenon in matroid theory which, informally, says that given distinct weights to the elements of a matroid there exists a unique minimum weight base. Here, we describe it in a language which is suitable for our context.

► **Lemma 13.** *Let  $k$  be a positive integer and  $M_{n,d}$  be the set of all  $n$ -variate monomials in  $\mathbf{x}$  with individual degree  $\leq d$ . Let  $M$  be a matrix over  $\mathbb{F}$  of rank  $r$  such that its rows are indexed by  $[k]$  and the columns are indexed by  $M_{n,d}$ . Let  $\prec$  be a monomial ordering on the set of monomials in  $\mathbf{x}$ . Then there exists a unique subset  $B \subseteq M_{n,d}$  of size  $r$  such that  $\text{rank}(M_{[k],B}) = r$  and for every other subset  $B' \subseteq M_{n,d}$  with  $\text{rank}(M_{[k],B'}) = r$ ,  $\prod_{\mathbf{e} \in B} \mathbf{x}^{\mathbf{e}} \prec \prod_{\mathbf{e}' \in B'} \mathbf{x}^{\mathbf{e}'}$ .*

Here we give a very brief sketch of the proof. Using the monomial ordering  $\prec$ , greedily choose  $r$  linearly independent columns of  $M$  as follows: at each step pick the least  $\prec$ -indexed column of  $M$  such that it increases the rank of the chosen vectors, and denote that set by  $B = \{m_1, \dots, m_r\}$  with  $m_1 \prec \dots \prec m_r$ . Let  $B'$  be another subset of  $M_{n,d}$  with  $r$  linearly independent columns of  $M$ , and  $B' = \{m'_1, \dots, m'_r\}$  with  $m'_1 \prec \dots \prec m'_r$ . Then one can show that  $B \preceq B'$  point-wise, that is  $m_i \preceq m'_i$  for all  $i \in [r]$ , and there exists an  $i_0 \in [r]$  such that  $m_{i_0} \prec m'_{i_0}$ . This implies that  $\prod_{i \in [r]} m_i \prec \prod_{i \in [r]} m'_i$ . For more details one can see [17, Lemma 5.2 and 5.3].

Next, we give an expression for the product of a “fat” matrix with a “tall” matrix. It is known as Cauchy-Binet formula. It will be useful to prove the rank concentration results in Section 2.

## 30:20 Improved Hitting Set for Orbit of ROABPs

► **Lemma 14** (Cauchy-Binet formula, [56]). *Let  $n \geq m$  be two positive integers. Let  $M$  and  $N$  two  $m \times n$  and  $n \times m$  matrices, respectively, over  $\mathbb{F}$ . Then*

$$\det(AB) = \sum_{S \in \binom{[n]}{m}} \det(M_{[m],S}) \cdot \det(M_{S,[m]}).$$

### A.1 Hitting sets

► **Definition 15.** *Let  $\mathcal{C}$  be a set of  $n$ -variate polynomials over a field  $\mathbb{F}$ . A set of points  $\mathcal{H} \subseteq \mathbb{F}^n$  is called a hitting set for  $\mathcal{C}$  if for every polynomial  $f \in \mathcal{C}$ ,  $f$  is nonzero if and only if there exists a point  $\alpha \in \mathcal{H}$  such that  $f(\alpha) \neq 0$ .*

We say a hitting set  $\mathcal{H}$  is *computable in time  $T$*  if there exists an algorithm which computes all the points in the set  $\mathcal{H}$  in time  $T$ . When  $\mathbb{F}$  is a finite field, we are allowed to pick points from  $\mathbb{K}^n$  where  $\mathbb{K}$  is a polynomially large extension of  $\mathbb{F}$ . In PIT literature, a common method of designing hitting sets is via hitting set generator.

► **Definition 16.** *Let  $\mathcal{C}$  be a set of  $n$ -variate polynomial class over a field  $\mathbb{F}$ . A polynomial map  $\mathbf{g}(\mathbf{t})$  from  $\mathbb{F}^m$  to  $\mathbb{F}^n$  is called hitting set generator for  $\mathcal{C}$  if for every  $f \in \mathcal{C}$ ,  $f$  is nonzero if and only if  $f(\mathbf{g}) \neq 0$ .*

*Furthermore,  $\mathbf{g}(\mathbf{t})$  is called  $t(m, n)$ -explicit if there exists an  $n$ -output circuit which computes  $\mathbf{g}(\mathbf{t})$  and the circuit is computable in  $t(m, n)$  time.*

Hitting set generators immediately give us hitting sets.

► **Observation 17.** *Let  $\mathcal{C}$  be an  $n$ -variate polynomial class over a field  $\mathbb{F}$  such that the degree of each polynomial is at most  $d$ . Let  $\mathbf{g}(\mathbf{t}) : \mathbb{F}^m \leftarrow \mathbb{F}^n$  be a hitting set generator for  $\mathcal{C}$  such that the individual degree of each coordinate of  $\mathbf{g}$  is at most  $r$ . Let  $S$  be a subset of  $\mathbb{F}$  of size  $dr + 1$ . Then  $\mathcal{H} := \mathbf{g}(S^m)$  is a hitting set for  $\mathcal{C}$ . Moreover, if  $\mathbf{g}(\mathbf{t})$  is  $t$ -explicit then the hitting set  $\mathcal{H}$  is computable in  $\text{poly}(t(dr)^m)$  time.*

**Proof.** Since  $\mathbf{g}$  is a hitting set generator for  $\mathcal{C}$  and each coordinate of  $\mathbf{g}$  is a  $m$ -variate polynomial, for every nonzero  $f \in \mathcal{C}$ ,  $f(\mathbf{g})$  is a nonzero  $m$ -variate polynomial. Also, the individual degree of  $f(\mathbf{g})$  is at most  $dr$ . Thus, there exists a point  $\alpha \in S^m$  such that  $f(\mathbf{g}(\alpha)) \neq 0$ . Therefore,  $\mathcal{H}$  is a hitting set for  $\mathcal{C}$ . Since  $\mathbf{g}$  is  $t$ -explicit, each point in  $\mathcal{H}$  is computable in time  $\text{poly}(t)$ . Therefore,  $\mathcal{H}$  is computable in time  $\text{poly}(t(dr)^m)$ . ◀

### A.2 Some useful polynomial maps

Suppose that  $\mathbf{g}(\mathbf{t}) = (g_1, \dots, g_n)$  be a polynomial map from  $\mathbb{F}^m$  to  $\mathbb{F}^n$ . Then, we say  $\mathbf{g}$  is a  $t(m, n)$ -explicit polynomial map if there exists an  $n$ -output circuit  $C$  which computes the polynomials  $(g_1, \dots, g_n)$  and the circuit  $C$  is computable in time  $t(m, n)$ . Let  $\mathbf{g}(\mathbf{y})$  be a polynomial map from  $\mathbb{F}^m$  to  $\mathbb{F}^n$  and  $\mathbf{h}(\mathbf{x}) = (h_1, \dots, h_k)$  be a polynomial map from  $\mathbb{F}^n$  to  $\mathbb{F}^k$ . Then  $\mathbf{h} \circ \mathbf{g}$  denotes the composition of  $\mathbf{g}$  with  $\mathbf{h}$ , that is  $\mathbf{h}(\mathbf{g}) = (h_1(\mathbf{g}), \dots, h_k(\mathbf{g}))$ . A polynomial map  $L(\mathbf{x}) = (\ell_1, \dots, \ell_n)$  from  $\mathbb{F}^n$  to  $\mathbb{F}^n$  is called an *invertible linear transformation* if each  $\ell_i$  is a linear polynomial of form  $\ell_{i1}x_1 + \dots + \ell_{in}x_n$  and all  $\ell_i$ 's are linearly independent. An *invertible affine transformation* is a polynomial map of form  $L(\mathbf{x}) + \mathbf{b}$  where  $L(\mathbf{x})$  is an invertible linear transformation and  $\mathbf{b} \in \mathbb{F}^n$ . Next, we describe some well known polynomial maps and their properties which are frequently used in designing PIT algorithms, and they also will be useful for us. First, we describe the generator for sparse polynomial due to Klivans and Spielman [30].

► **Lemma 18** (Klivans-Spielman generator [30]). *Let  $n, d, s, m$  be positive integers such that  $m = \Theta(\log_{nd} s)$ . Let  $\mathbb{F}$  be a field of size  $\geq \text{poly}(nd)$ . Then there exists a  $\text{poly}(nd)$ -explicit polynomial map  $\mathcal{G}_{n,d,s}^{KS}(\mathbf{s}, \mathbf{t})$  from  $\mathbb{F}^m \times \mathbb{F}^m$  to  $\mathbb{F}^n$  such that*

1. *for all  $i \in [n]$ ,  $(\mathcal{G}_{n,d,s}^{KS})_i$  is a polynomial of individual degree  $\leq \text{poly}(nd)$ .*
2. *for every subset  $S$  of at most  $s$  monomials in  $n$ -variables with individual degree at most  $d$ , there exists an  $\boldsymbol{\alpha} \in \mathbb{F}^m$  such that the polynomials  $\{(\mathcal{G}_{n,d,s}^{KS}(\boldsymbol{\alpha}, \mathbf{t}))^e\}_{e \in S}$  are nonzero, distinct monomials in  $\mathbf{t}$ .*

The above generator is a slight variation of the construction given in [30], but it can be constructed from their techniques. For a proof-sketch see [17, Theorem 2.3]. Next, we define total degree  $D$  independent monomial map from [17].

► **Definition 19.** *For some positive integers  $n$  and  $D$ , a polynomial map  $\mathbf{g}(\mathbf{s}, \mathbf{t})$  from  $\mathbb{F}^m \times \mathbb{F}^{m'}$  to  $\mathbb{F}^n$  is called total degree  $D$  independent monomial map if there exists an  $\boldsymbol{\alpha} \in \mathbb{F}^m$  such that the polynomials  $\{\mathbf{g}(\boldsymbol{\alpha}, \mathbf{t})^e\}_{|e|_1 \leq D}$  are nonzero, distinct monomials in  $\mathbf{t}$ .*

In the following lemma, we describe a construction of total degree  $D$  independent monomial map using Klivans-Spielman generator.

► **Lemma 20.** *Let  $n, d, D$  be positive integers. Let  $|\mathbb{F}| \geq \text{poly}(nd)$ . Then,  $\mathcal{G}_{n,d,n^D}^{KS}$  is a  $\text{poly}(ndD)$ -explicit total degree  $D$  independent monomial map from  $\mathbb{F}^m \times \mathbb{F}^m$  to  $\mathbb{F}^n$  where  $m = O(D)$ .*

For proof see [17, Lemma 6.4]. Next, we describe a polynomial map introduced by Shpilka and Volkovich [51]. It is a widely used tool in PIT and other related results [51, 17, 52, 37, 33, 36, 43], and also crucial for proving our results.

► **Definition 21** (Shpilka-Volkovich generator [51]). *Fix a positive integer  $n$  and a set of  $n$  distinct elements  $\mathcal{A} = \{\alpha_1, \dots, \alpha_n\} \subseteq \mathbb{F}$ . Let  $L_i(t)$  be the  $i$ th Lagrange interpolation polynomial for the set  $\mathcal{A}$ . That is,  $L_i(t)$  is a univariate polynomial of degree  $n - 1$  such that  $L_i(\alpha_j) = \delta_{ij}$ . Let  $\mathbf{s} = (s_1, \dots, s_k)$  and  $\mathbf{t} = (t_1, \dots, t_k)$ . Then  $\mathcal{G}_{n,k}^{SV}(\mathbf{s}, \mathbf{t})$  is the polynomial map from  $\mathbb{F}^k \times \mathbb{F}^k$  to  $\mathbb{F}^n$  defined as follows: for all  $i \in [n]$*

$$(\mathcal{G}_{n,k}^{SV})_i = \sum_{j=1}^k L_i(s_j) t_j.$$

The above definition gives the following properties of Shpilka-Volkovich generator.

► **Observation 22.** *Fix a set of  $k$  distinct elements  $S = \{i_1, \dots, i_k\} \subseteq [n]$ . Let  $\boldsymbol{\alpha} = (\alpha_{i_1}, \dots, \alpha_{i_k})$ . Then, for all  $j \in [k]$ ,  $(\mathcal{G}_{n,k}^{SV}(\boldsymbol{\alpha}, \mathbf{t}))_{i_j} = t_j$ , and the other coordinates of  $\mathcal{G}_{n,k}^{SV}(\boldsymbol{\alpha}, \mathbf{t})$  are zero. Furthermore, for all  $i \in [n]$ , the degree of the polynomial  $(\mathcal{G}_{n,k}^{SV})_i$  is at most  $n$ .*

Using Shpilka-Volkovich generator, the following lemma describes a nonzeroness preserving variable reduction for polynomials having a “low-support” monomial with nonzero coefficient.

► **Lemma 23.** *Let  $f(\mathbf{x})$  be an  $n$ -variate polynomial over  $\mathbb{F}$  such that there exists a monomial  $\mathbf{x}^e$  with nonzero coefficient in  $f$  and the support-size of  $\mathbf{e}$  is at most  $\ell$ . Then  $f \circ \mathcal{G}_{n,\ell}^{SV} \neq 0$ .*

**Proof.** Let  $\{x_{i_1}, \dots, x_{i_\ell}\}$  be the support set of the monomial  $\mathbf{x}^e$ . Then, from Observation 22, there exists an  $\boldsymbol{\alpha} \in \mathbb{F}^\alpha$  such that for all  $j \in [\ell]$ ,  $(\mathcal{G}_{n,\ell}^{SV}(\boldsymbol{\alpha}, \mathbf{t}))_{i_j} = t_j$  and the other coordinates of  $\mathcal{G}_{n,\ell}^{SV}(\boldsymbol{\alpha}, \mathbf{t})$  are zero. This implies that  $f(\mathcal{G}_{n,\ell}^{SV}(\boldsymbol{\alpha}, \mathbf{t})) \neq 0$ , and therefore  $f \circ \mathcal{G}_{n,\ell}^{SV} \neq 0$ . ◀

### A.3 Algebraic independence

Suppose that  $\mathcal{A} = \{g_1, \dots, g_k\}$  is a set of  $n$ -variate polynomials over a field  $\mathbb{F}$ . We say that the set of polynomials  $\mathcal{A}$  are *algebraically dependent* over  $\mathbb{F}$  if there exists a nonzero  $k$ -variate polynomial  $A(z_1, \dots, z_k)$  over  $\mathbb{F}$  such that  $A(g_1, \dots, g_k) = 0$ . Otherwise, they are called *algebraically independent* (over  $\mathbb{F}$ ). In the following lemma, we describe a well known criteria regarding algebraic independence of a set of linear polynomials.

► **Lemma 24.** *Let  $m \geq n$  be two positive integers. Let  $L(\mathbf{x}) = (\ell_1, \dots, \ell_n)$  be a linear transformation from  $\mathbb{F}^m$  to  $\mathbb{F}^n$  such that all  $\ell_i$ 's are linearly independent. Then, all  $\ell_i$ 's are also algebraically independent.*

**Proof.** For the sake of contradiction, assume that all  $\ell_i$ 's are not algebraically independent. Then there exists a nonzero polynomial  $A(z_1, \dots, z_n)$  such that  $A(L(\mathbf{x})) = A(\ell_1, \dots, \ell_n) = 0$ . Let  $\mathbf{x} = (x_1, \dots, x_m)$  and  $A'(\mathbf{x}) = A(L(\mathbf{x}))$ . Since all  $\ell_i$ 's are linearly independent, there exists a tuple of linear polynomials  $U(\mathbf{x}) = (u_1, \dots, u_m)$  and a subset  $\{i_1, \dots, i_n\}$  of  $[m]$  such that for all  $j \in [n]$ ,

$$\ell_j(U(\mathbf{x})) = x_{i_j}.$$

This implies that  $A'(U(\mathbf{x})) = A(x_{i_1}, \dots, x_{i_n}) = 0$  which is a contradiction. Therefore, all  $\ell_i$ 's are algebraically independent. ◀

### A.4 Various notions of rank concentration

We define various notions of rank concentration and show the relation between them. Suppose that  $G(\mathbf{x})$  be an  $n$ -variate polynomial over the vector space  $\mathbb{F}^k$ . The *coefficient space* of  $G$  is the vector space spanned by the coefficient vectors of  $G$ .

► **Definition 25** (Rank Concentration). *We say that  $G$  has*

1.  $\ell$ -support concentration if there exists a set of monomials  $B$  such that the support-size of each monomial in  $B$  is at most  $\ell$  and their coefficients form a basis for the coefficient space of  $G$ .
2.  $\ell$ -cone concentration if there exists a set of monomials  $B$  such that the cone-size of each monomial in  $B$  is at most  $\ell$  and their coefficients form a basis for the coefficient space of  $G$ .
3. a cone-closed basis if there is a cone-closed set of monomials  $B$  whose coefficients in  $G$  form a basis of the coefficient space of  $G$ .

In the next lemma, we show that cone-closed basis notion subsumes the other two notions of rank concentration.

► **Lemma 26.** *Let  $G(\mathbf{x})$  be a polynomial in  $\mathbb{F}[\mathbf{x}]^k$ . Suppose that  $G(\mathbf{x})$  has a cone-closed basis. Then,  $G(\mathbf{x})$  has  $k$ -cone concentration and  $\log k$ -support concentration.*

**Proof.** Let  $B$  be a cone-closed set of monomials whose coefficients in  $G$  form a basis for the coefficient space of  $G$ . Since the cardinality of  $B$  is at most  $k$  and it is closed under submonomials, the cone-size of each monomial  $B$  is at most  $k$ . Therefore,  $G$  has  $k$ -cone concentration.

Let  $m \in B$  and  $S$  be the support set of  $m$ . Let  $m'$  be the monomial defined as  $m' = \prod_{i \in S} x_i$ . Since  $B$  is cone-closed, every sub-monomial  $m'$  is also in  $B$ . Thus the cardinality of  $S$  can be at most  $\log k$ . Therefore,  $G$  has  $\log k$ -support concentration. ◀

## B Proof of Lemma 5

**Proof of Lemma 5.** First we study the shifted polynomial  $G'(\mathbf{x}) = G(\mathbf{x} + u\mathbf{z})$ . To do so, we revisit the proof of our Lemma 4. There we considered the lexicographic monomial ordering over the monomials in  $\mathbf{z}$ . Here we consider the *deg-lex* monomial ordering, that is, first order the monomials from lower degree to higher degree and then within each degree arrange them in lexicographic order. Like Equation 1, the matrix equation for the shifted polynomial  $G'(\mathbf{x})$  will be

$$F'(u\mathbf{z}) = W^{-1}(u\mathbf{z})TW(u\mathbf{z})F, \quad (7)$$

that is scaling of each variable in Equation 1 by  $u$ . Applying Lemma 13, let  $B$  be the unique subset of  $M_{n,d}$  such that the rows of  $F$  indexed by  $B$  form the least basis for the row-space of  $F$  with respect to the deg-lex monomial ordering. From the hypothesis of the lemma, there exists a subset  $C \subseteq M_{n,d}$  such that the rows in  $F$  indexed by  $C$  forms a basis for the row-space of  $F$  (same as the coefficient space of  $G$ ) and  $\deg(C) = \sum_{\mathbf{e} \in C} |\mathbf{e}|_1 \leq Dk$ . Therefore,  $\deg(B)$  is also  $\leq Dk$  since the rows indexed by  $B$  forms the least basis (with respect to deg-lex monomial ordering) for the row-space of  $F$ . As promised by Lemma 3, let  $A$  be a cone-closed subset of  $M_{n,d}$  such that  $T_{A,B}$  is full rank. Now we see how Equation 2 and 3 in the proof of Lemma 4 change here. Like Equation 2, we get

$$\det(F'(u\mathbf{z})_{A,[k]}) = \det(W(u\mathbf{z})_{A,A})^{-1} \cdot \det((TW(u\mathbf{z})F)_{A,[k]}) \quad (8)$$

and Equation 3 changes as follows:

$$\det((TW(u\mathbf{z})F)_{A,[k]}) = \sum_i \left( \sum_{C \in \binom{M_{n,d}}{k} : \deg(C)=i} \det(T_{A,C}) \det(F_{C,[k]}) \prod_{\mathbf{e} \in C} \mathbf{z}^{\mathbf{e}} \right) u^i. \quad (9)$$

Since  $B$  is the least basis (with respect to deg-lex monomial ordering), the coefficient of  $u^{\deg(B)}$  is a nonzero degree  $\deg(B)$  homogeneous polynomial in  $\mathbf{z}$ . Thus,  $\det(F'(u\mathbf{z})_{A,[k]})$  is a nonzero-polynomial in  $(u, \mathbf{z})$ . This implies the coefficients of the monomials in  $A$  is a cone-close basis for  $G(\mathbf{x} + u\mathbf{z})$ . For  $G(\mathbf{x} + uL)$ , the polynomial  $\det((TW(uL)F)_{A,[k]})$  looks like the following:

$$\det((TW(uL)F)_{A,[k]}) = \sum_i \left( \sum_{C \in \binom{M_{n,d}}{k} : \deg(C)=i} \det(T_{A,C}) \det(F_{A,C}) \prod_{\mathbf{e} \in C} L^{\mathbf{e}} \right) u^i.$$

Since all  $\ell_i$ 's are linearly independent, from Lemma 24, they are also algebraically independent. Therefore, the coefficient of  $u^{\deg(B)}$  in  $\det((TW(uL)F)_{A,[k]})$  is also a nonzero degree  $\deg(B)$  homogeneous polynomial in  $\mathbf{y}$ . Also,  $\deg(B) \leq Dk$ . Therefore, after substituting  $\mathbf{z}$  by  $L \circ \mathbf{g}$  in Equation 9, we get  $\det((TW(\mathbf{g}')F)_{A,[k]})$  which is a nonzero polynomial in  $(u, \mathbf{s}, \mathbf{t})$ . Since  $\det(W(\mathbf{g}'))$  is also a nonzero polynomial in  $(u, \mathbf{s}, \mathbf{t})$ ,  $\det(F'(\mathbf{g}')_{A,[k]})$  is nonzero in  $\mathbb{F}(u, \mathbf{s}, \mathbf{t})$ . This implies that  $G(\mathbf{x} + \mathbf{g}')$  has a cone-closed basis over  $\mathbb{F}(u, \mathbf{s}, \mathbf{t})$ .  $\blacktriangleleft$

# A New Notion of Commutativity for the Algorithmic Lovász Local Lemma

## Abstract

The Lovász Local Lemma (LLL) is a powerful tool in probabilistic combinatorics which can be used to establish the *existence* of objects that satisfy certain properties. The breakthrough paper of Moser & Tardos and follow-up works revealed that the LLL has intimate connections with a class of stochastic local search algorithms for finding such desirable objects. In particular, it can be seen as a sufficient condition for this type of algorithms to converge fast.

Besides conditions for convergence, many other natural questions can be asked about algorithms; for instance, “are they parallelizable?”, “how many solutions can they output?”, “what is the expected “weight” of a solution?”. These questions and more have been answered for a class of LLL-inspired algorithms called commutative. In this paper we introduce a new, very natural and more general notion of commutativity (essentially matrix commutativity) which allows us to show a number of new refined properties of LLL-inspired local search algorithms with significantly simpler proofs.

## 1 Introduction

The Lovász Local Lemma (LLL) is a powerful tool in probabilistic combinatorics which can be used to establish the *existence* of objects that satisfy certain properties [9]. At a high level, it states that given a collection of bad events in a probability space  $\mu$ , if each bad-event is not too likely and, further, is independent of most other bad events, then the probability of avoiding all of them is strictly positive.

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

In its simplest, “symmetric” form, it states that if each bad-event has probability at most  $p$  and is dependent with at most  $d$  others, where  $epd \leq 1$ , then with positive probability no bad-events become true. In particular, a configuration avoiding all the bad-events exists. Although the LLL applies to general probability spaces, most constructions in combinatorics use a simpler setting we refer to as the *variable version LLL*. Here, the probability space  $\mu$  is a cartesian product with  $n$  independent variables, and each bad-event is determined by a subset of the variables. Two bad-events may conflict if they depend on a common variable.

For example, consider a CNF formula with  $n$  variables where each clause has  $k$  literals and each variable appears in at most  $L$  clauses. For each clause  $c$  we can define the bad event  $B_c$  that  $c$  is violated in a chosen assignment of the variables. For a uniformly random variable assignment, each bad-event has probability  $p = 2^{-k}$  and affects at most  $d \leq kL$  others. So when  $L \leq \frac{2^k}{ek}$ , the formula is satisfiable; crucially, this criterion does not depend on the number of variables  $n$ .

A generalization known as the Lopsided LLL (LLLL) allows bad-events to be *positively* correlated with others; this is as good as independence for the purposes of the LLL. Some notable probability spaces satisfying the LLLL include the uniform distribution on permutations and the variable setting, where two bad-events  $B, B'$  are dependent only if they *disagree* on the value of a common variable.

In a seminal work, Moser & Tardos [25] presented a simple local search algorithm to make the variable-version LLLL constructive. This algorithm can be described as follows:

■ **Algorithm 1** The Moser-Tardos (MT) resampling algorithm.

- 
- 1: Draw the state  $\sigma$  from distribution  $\mu$
  - 2: **while** some bad-event is true on  $\sigma$  **do**
  - 3:     Select, arbitrarily, a bad-event  $B$  true on  $\sigma$
  - 4:     Resample, according to distribution  $\mu$ , all variables in  $\sigma$  affecting  $B$
- 

Moser & Tardos showed that if the symmetric LLL criterion (or more general asymmetric criterion) is satisfied, then this algorithm quickly converges. Following this work, a large effort has been devoted to making different variants of the LLL constructive. This research has taken many directions, including further analysis of Algorithm 1 and its connection to different LLL criteria [6, 22, 26].

One line of research has been to use variants of Algorithm 1 for general probability spaces beyond the variable LLL. These include applications of the LLL to permutations and matchings of the clique [1, 2, 17, 21, 19] as well as settings not directly connected to the LLL itself [3, 7, 18]. At a high level of generality, we summarize this in the following framework. There is a discrete state space  $\Omega$ , with a collection  $\mathcal{F}$  of subsets (which we call *flaws*) of  $\Omega$ . There is also some problem-specific randomized procedure called the *resampling oracle*  $\mathfrak{R}_f$  for each flaw  $f$ ; it takes some random action to attempt to “fix” that flaw, resulting in a new state  $\sigma' \leftarrow \mathfrak{R}_f(\sigma)$ . With these ingredients, we define the general local search algorithm as follows:

■ **Algorithm 2** The general local search algorithm.

- 
- 1: Draw the state  $\sigma$  from some distribution  $\mu$
  - 2: **while** some flaw holds on  $\sigma$  **do**
  - 3:     Select a flaw  $f$  of  $\sigma$ , according to some rule  $S$ .
  - 4:     Update  $\sigma \leftarrow \mathfrak{R}_f(\sigma)$ .
-

We refer to Algorithm 2 throughout as the *Search Algorithm*. The most important question about its behavior is whether it converges to a flawless object. But, there are other important questions to ask; for instance, “is it parallelizable?”, “how many solutions can it output?”, “what is the expected “weight” of a solution?”. These questions and more have been answered for the Moser-Tardos algorithm in a long series of papers [6, 8, 11, 12, 15, 16, 22, 25]. As a prominent example, the result of Haeupler, Saha and Srinivasan [12], as well as follow-up work of Harris and Srinivasan [14, 16], allows one to argue about the dynamics of Algorithm 1, resulting in several new applications such as estimating the entropy of the output distribution, partially avoiding bad events and dealing with super-polynomially many bad events.

There is one important difference between Algorithm 1 and Algorithm 2: the choice of which flaw to resample, if multiple flaws are simultaneously true. The flaw selection rule  $S$  in the Search Algorithm should select a flaw  $f \ni \sigma$  at each time  $t$ ; it may depend on the prior states and may be randomized. The original MT algorithm allows nearly complete freedom for this. For general resampling oracles,  $S$  is much more constrained; only a few relatively rigid rules are known to guarantee convergence, such as selecting the flaw of least index [19]. However, in [23], Kolmogorov identified a general property called *commutativity* that allows a free choice for  $S$ . This free choice, seemingly a minor detail, turns out to play a key role in extending the additional properties of the MT algorithm to the general Search Algorithm. For instance, it leads to parallel algorithms [23] and to bounds on the output distribution [20].

At a high level, our goal is to provide a more conceptual, algebraic explanation for the commutativity properties of resampling oracles and their role in the Search Algorithm. We do this by introducing a notion of commutativity, essentially matrix commutativity, that is both more general and simpler than the definition in [23]. Most of our results had already been shown, in slightly weaker forms, in prior works [23, 20, 14]. However, the proofs were computationally heavy and narrowly targeted to certain probability spaces, with numerous technical side conditions and restrictions.

Before we provide formal definitions, let us give some intuition. For each flaw  $f$ , consider an  $|\Omega| \times |\Omega|$  transition matrix  $A_f$ . Each row of  $A_f$  describes the probability distribution obtained by resampling  $f$  at a given state  $\sigma$ . We call the resampling oracle *commutative* if the transition matrices commute for any pair of flaws which are “independent” (in the LLL sense). We show a number of results for such oracles:

1. We obtain bounds on the distribution of the state at the termination of the Search Algorithm. These bounds are comparable to the *LLL-distribution*, i.e., the distribution induced by conditioning on avoiding all bad events. Similar results, albeit with a number of additional technical restrictions, had been shown in [20] for the original definition of commutativity.
2. For some probability spaces, stronger and specialized distributional bounds are available, beyond the “generic” LLL bounds [14]. Previously, these had been shown with ad-hoc arguments specialized to each probability space. Our construction recovers most of these results automatically.
3. We develop a generic parallel implementation of the Search Algorithm. This extends results of [23, 15], with simpler and more general proofs.
4. In many settings, flaws are formed from smaller “atomic” events [15]. We show that, if the atomic events satisfy the generalized commutativity definition, then so do the larger “composed” events. This natural property did not seem to hold for the original commutativity definition of [23].

## 1.1 Example application: latin transversals

As a motivating example, let us examine a classic combinatorial problem of latin transversals. Consider an  $n \times n$  array  $C$ , wherein each entry of  $C$  has a color. A latin transversal of  $C$  is a permutation  $\pi$  over  $\{1, \dots, n\}$  such that all the colors  $C(i, \pi i)$  are distinct for  $i = 1, \dots, n$ .

The “lopsided” variant of the LLL was first developed by Erdős & Spencer [10] for this problem. The underlying probability space is the uniform distribution on permutations. For each pair of cells  $(x_1, y_1), (x_2, y_2)$  of the same color, there is a corresponding flaw defined by  $\pi x_1 = y_1 \wedge \pi x_2 = y_2$ . They showed that if each color appears at most  $\Delta = \frac{n}{4e}$  times, then the LLL criteria are satisfied and a transversal exists. The cluster-expansion criterion [5] tightens this to  $\Delta = \frac{27n}{256}$ , which is the strongest bound currently known.

This construction has been a motivating example for much of the research on the algorithmic LLL, particularly for “exotic” probability spaces (beyond the variable setting). In particular, [17] showed that the Search Algorithm generates a latin transversal  $\pi$  under the same conditions as the existential LLLL. One of the main applications in this paper is to show that  $\pi$  has nice distributional properties. In particular, we show the following:

► **Theorem 1.** *If each color appears at most  $\frac{27}{256}n$  times in the array, then the Search Algorithm generates a latin transversal  $\pi$  where, for every pair  $(x, y)$ , we have  $0.53/n \leq \Pr(\pi x = y) \leq 1.36/n$ .*

The upper bound improves quantitatively over a similar bound of [14]; to the best of our knowledge, no non-trivial lower bound of any kind could previously be shown. Intriguingly, such bounds are not known to hold for the LLL-distribution itself.

To better situate Theorem 1, note that Alon, Spencer, & Tetali [4] showed that there is a (minuscule) universal constant  $\beta > 0$  with the following property. If each color appears at most  $\Delta = \beta n$  times in the array and  $n$  is a power of two, then the array can be *partitioned* into  $n$  independent transversals. In this case, if we randomly select one transversal from this list, we would have  $\Pr(\pi x = y) = 1/n$ . Theorem 1 can be regarded as a simplified *fractional* analogue of their result, i.e. we fractionally decompose the given array into  $O(n)$  transversals, such that  $\Pr(\pi x = y) = \Theta(1/n)$  for all pairs  $x, y$ . Furthermore, we achieve this guarantee automatically, merely by running the Search Algorithm.

## 1.2 Overview of our approach

Although it will require significant definitions and technical development to state our results formally, let us try to provide a high-level summary here. As a starting point, consider the MT algorithm. Moser & Tardos [25] used a construction referred to as a *witness tree* for the analysis: for each resampling of a bad-event  $B$  at a given time, there is a corresponding witness tree which records an “explanation” of why  $B$  was true at that time. More properly, it provides a history of all the prior resamplings which affected the variables involved in  $B$ .

The main technical lemma governing the behavior of the MT algorithm is the “Witness Tree Lemma,” which states that the probability of producing a given witness tree is at most the product of the probabilities of the corresponding events. The bounds on the algorithm runtime, as well as parallel algorithms and distributional properties, then follow from a union bound over witness trees.

Versions of this Witness Tree Lemma have been shown for some variants of the MT algorithm [13, 18] Iliopoulos [20] further showed that it held for general spaces which satisfy the commutativity property; this, in turn, leads to the nice algorithmic properties such as parallel algorithms.

Our main technical innovation is to generalize the Witness Tree Lemma. Instead of keeping track of a *scalar* product of probabilities in a witness tree, we instead consider a *matrix product*. We bound the probability of a given witness tree (or, more properly, a slight generalization known as the witness DAG) in terms of the products of the transition matrices of the corresponding flaws. Commutativity can thus be rephrased and simplified in terms of *matrix commutativity* for the transition matrices.

At the end, we obtain the scalar form of the Witness Tree Lemma by projecting everything to a one-dimensional space. For this, we take advantage of some methods of [3] for viewing the evolution of the Search Algorithm in terms of spectral bounds.

## 2 Background and Basic Definitions

Throughout the paper we consider implementations of the Search Algorithm. For each flaw  $f$ , state  $\sigma \in f$ , and state  $\sigma' \in \Omega$ , we define  $A_f[\sigma, \sigma']$  to be the probability that applying the resampling oracle  $\mathfrak{R}_f$  to  $\sigma$  yields state  $\sigma'$ , i.e.  $A_f[\sigma, \sigma'] = \Pr(\mathfrak{R}_f(\sigma) = \sigma')$ . For  $\sigma \notin f$ , we define  $A_f[\sigma, \sigma'] = 0$ . We sometimes write  $\sigma \xrightarrow{f} \sigma'$  to denote that the algorithm resamples flaw  $f$  at  $\sigma$  and moves to  $\sigma'$ . Observe that, for any vector  $\theta$  over  $\Omega$ , there holds  $\|\theta^\top A_f\|_1 = \sum_{\sigma \in f} \theta[\sigma] \leq \|\theta^\top\|_1$ . Thus, the matrix  $A_f$  is substochastic.

We define a *trajectory*  $T$  to be a finite or countably infinite sequence of the states and flaws of the form  $(\sigma_0, f_1, \sigma_1, f_2, \dots)$ , and  $\text{len}(T)$  is its *length* (possibly  $\text{len}(T) = \infty$ ). We define the *shift* of  $T$  to be  $(\sigma_1, f_2, \sigma_2, f_3, \dots)$ . We define  $\hat{T}$  to be the sequence states and flaws resampled during the Search Algorithm, i.e.  $\sigma_i$  is the state at time  $i$  and flaw  $f_i \in \sigma_i$  is the flaw resampled.

For our purposes, we use an *undirected* notion of dependence. Formally, we suppose that we have fixed some symmetric relation  $\sim$  on  $\mathcal{F}$ , with the property that  $f \sim f$  for all  $f$  and for every distinct pair of flaws  $f \not\sim g$ , we are guaranteed that resampling flaw  $f$  cannot introduce  $g$  or vice-versa, i.e.  $\mathfrak{R}_f$  never maps a state  $\Omega - g$  into  $g$  and likewise  $\mathfrak{R}_g$  never maps a state from  $\Omega - f$  into  $f$ . We define  $\bar{\Gamma}(f)$  to be the set of flaws  $g$  with  $f \sim g$ , and we also define  $\Gamma(f) = \bar{\Gamma}(f) \setminus \{f\}$ .

We say that a set  $I \subseteq \mathcal{F}$  is *stable* if  $f \not\sim g$  for all distinct pairs  $f, g \in I$ .

For an arbitrary event  $E \subseteq \Omega$ , we define  $e_E$  to be the indicator vector for  $E$ , i.e.  $e_E[\sigma] = 1$  if  $\sigma \in E$  and  $e_E[\sigma] = 0$  otherwise. For a state  $\sigma \in \Omega$ , we write  $e_\sigma$  as shorthand for  $e_{\{\sigma\}}$ , i.e. the basis vector which has a 1 in position  $\sigma$  and zero elsewhere.

For vectors or matrices  $u, v$  we write  $u \preceq v$  if  $u[i] \leq v[i]$  for all entries  $i$ . We write  $u \propto v$  if there is some scalar value  $c$  with  $u = cv$ .

**Regenerating oracles.** The Moser-Tardos algorithm and extensions to other probability spaces can be viewed in terms of *regenerating oracles* [19], i.e. each resampling action  $\mathfrak{R}_f$  should convert the distribution of  $\mu$  conditioned on  $f$  into the unconditional distribution  $\mu$ . We provide more detail later in Section 4, but, we can summarize this crisply with our matrix notation: the resampling oracle  $\mathfrak{R}$  is regenerating if  $\mu$  is a left-eigenvector of each matrix  $A_f$ , with associated eigenvalue  $\mu(f)$ , i.e.

$$\forall f \quad \mu^\top A_f = \mu(f) \cdot \mu^\top \tag{1}$$

### 2.1 The new commutativity definition

The original definition of commutativity given by Kolmogorov [23] required that for every  $f \approx g \in \mathcal{F}$ , there is an injective mapping from state transitions  $\sigma_1 \xrightarrow{f} \sigma_2 \xrightarrow{g} \sigma_3$  to state transitions  $\sigma_1 \xrightarrow{g} \sigma'_2 \xrightarrow{f} \sigma_3$ , so that  $A_f[\sigma_1, \sigma_2]A_g[\sigma_2, \sigma_3] = A_g[\sigma_1, \sigma'_2]A_f[\sigma'_2, \sigma_3]$ .

This definition is cumbersome, as well as lacking important symmetry and invariance properties. As one of the major contributions of this paper, we introduce a more natural notion of algorithmic commutativity that is also more general than the notion of [23].

► **Definition 2** (Transition matrix commutativity). *We say that the resampling oracle is transition matrix commutative with respect to dependence relation  $\sim$  if  $A_f A_g = A_g A_f$ , for every  $f, g \in \mathcal{F}$  such that  $f \approx g$ .*

► **Observation 3.** *If the resampling oracle is commutative in the sense of [23], then it is transition matrix commutative.*

**Proof.** Consider  $f \not\approx g$  and states  $\sigma, \sigma'$ . By symmetry, we need to show that  $A_f A_g[\sigma, \sigma'] \leq A_g A_f[\sigma, \sigma']$ . Since  $f \not\approx g$ , we can see that both the LHS and RHS are zero unless  $\sigma \in f \cap g$ .

Let  $V$  denote the set of states  $\sigma''$  with  $A_f[\sigma, \sigma''] A_g[\sigma'', \sigma'] > 0$ . By definition, there is an injective function  $F : V \rightarrow \Omega$  such that  $A_f[\sigma, \sigma''] A_g[\sigma'', \sigma'] = A_g[\sigma, F(\sigma'')] A_f[F(\sigma''), \sigma']$ . Therefore, we have  $(A_f A_g)[\sigma, \sigma'] = \sum_{\sigma'' \in V} A_f[\sigma, \sigma''] A_g[\sigma'', \sigma'] = \sum_{\sigma'' \in V} A_g[\sigma, F(\sigma'')] A_f[F(\sigma''), \sigma']$ .

Since  $F$  is injective, each term  $A_g[\sigma, \tau] A_f[\tau, \sigma']$  is counted at most once in this sum with  $\tau = F(\sigma'')$ . So  $(A_f A_g)[\sigma, \sigma'] \leq \sum_{\tau \in f} A_g[\sigma, \tau] A_f[\tau, \sigma'] = (A_g A_f)[\sigma, \sigma']$ . ◀

For brevity, we say *commutative* to mean transition matrix commutative throughout this paper; by contrast, we refer to the previous notion as *commutative in the sense of [23]*.

When this definition applies, we define  $A_I$  to be the matrix  $\prod_{f \in I} A_f$  for a stable set  $I$ ; note that this product is well-defined (without specifying ordering of  $I$ ) since the matrices  $A_f$  all commute.

**For the remainder of this paper, we assume that the resampling oracle  $\mathfrak{R}$  is transition-matrix commutative unless explicitly stated otherwise.**

### 3 Witness DAGs and matrix bounds

In this section, we study *witness DAGs*, a key graph structure developed in [11] for analyzing the evolution of commutative resampling oracles. The main result of this section is Lemma 5, which is a generalization of the Witness Tree Lemma described in the introduction. Notably, while our result is more general, its proof is significantly simpler. At a high level, the role of a witness DAG is to give an “explanation” of why a certain flaw appeared during the execution of the algorithm. To bound the probability that flaw  $f$  appears during the algorithm execution, we simply add up the probabilities of all the witness DAGs that explain it.

Formally, we define a *witness DAG* (abbreviated *wdag*) to be a directed acyclic graph  $G$ , where each vertex  $v \in G$  has a label  $L(v)$  from  $\mathcal{F}$ , and such that for all pairs of vertices  $v, w \in G$ , there is an edge between  $v$  and  $w$  (in either direction) if and only if  $L(v) \sim L(w)$ . For a wdag  $G$  with sink nodes  $v_1, \dots, v_k$ , note that  $L(v_1), \dots, L(v_k)$  are all distinct and  $\{L(v_1), \dots, L(v_k)\}$  is a stable set which we denote by  $\text{sink}(G)$ . We say that a flaw  $f$  is *unrelated* to a wdag  $G$  if there is no node  $v \in G$  with  $L(v) \sim f$ .

We define  $\mathfrak{H}$  to be the collection of all wdaGs, and we define  $\mathfrak{H}(I)$  to be the collection of all such wdaGs with  $\text{sink}(H) = I$ . With some abuse of notation, we also write  $\mathfrak{H}(f)$  as shorthand for  $\mathfrak{H}(\{f\})$ .

There is a key connection between wdaGs and the transition matrices. For any wdag  $H$ , we define an associated  $|\Omega| \times |\Omega|$  matrix  $A_H$  inductively as follows. If  $H = \emptyset$ , then  $A_H$  is the identity matrix on  $\Omega$ . Otherwise, we choose an arbitrary source node  $v$  of  $H$  and set  $A_H = A_{L(v)} A_{H-v}$ .

► **Proposition 4.** *The definition of  $A_H$  does not depend on the chosen source node  $v$ . Furthermore, there is an enumeration of the nodes of  $H$  as  $v_1, \dots, v_t$  such that  $A_H = A_{L(v_1)} \cdots A_{L(v_t)}$ .*

**Proof.** Let us show the first property by induction on  $|H|$ . When  $|H| = 0$  this is vacuously true. For induction case, suppose  $H$  has two source nodes  $v_1, v_2$ . We need to show that we get the same value by recursing on  $v_1$  or  $v_2$ , i.e.  $A_{L(v_1)}A_{H-v_1} = A_{L(v_2)}A_{H-v_2}$ .

We can apply the induction hypothesis to  $H - v_1$  and  $H - v_2$ , noting that  $v_2$  is a source node of  $H - v_1$  and  $v_1$  is a source node of  $H - v_2$ . We get  $A_{H-v_1} = A_{L(v_2)}A_{H-v_1-v_2}$ ,  $A_{H-v_2} = A_{L(v_1)}A_{H-v_1-v_2}$ . Thus, in order to show  $A_{L(v_1)}A_{H-v_1} = A_{L(v_2)}A_{H-v_2}$ , it suffices to show that  $A_{L(v_1)}A_{L(v_2)} = A_{L(v_2)}A_{L(v_1)}$ . Since  $v_1, v_2$  are both source nodes, we have  $L(v_1) \not\sim L(v_2)$ . Thus, this follows from commutativity.

For the second property, we have  $A_H = A_{L(v_1)}A_{H-v_1}$  for a source node  $v$ . Recursively peeling away vertices gives  $A_H = A_{L(v_1)}A_{L(v_2)} \cdots A_{L(v_t)}$ . ◀

As a warm-up, we first show how to use wdags to bound the number of resamplings performed in commutative algorithms. This will allow us to show bounds on the expected runtime of the Search Algorithm as well as allowing parallel implementations. The main point here is to demonstrate how the new commutativity definition helps with the crucial task of bounding the probability of appearance of a given wdag.

As in the original proof of Moser & Tardos [25], we will estimate the expected number of times each flaw  $f \in F$  is resampled. Consider an execution of the Search Algorithm with trajectory  $T$ . For each time  $t \leq \text{len}(T)$ , we generate a corresponding wdag  $G_t^T$  which provides the history of the  $t^{\text{th}}$  resampling. Initially, we set  $G_t^T$  to consist of a singleton node labeled  $f_t$ . Then, for  $s = t - 1, \dots, 1$ , there are two cases:

1. if wdag  $G_t^T$  has any node with label  $g$  where  $g \sim f_s$ , then we add a vertex labeled  $f_s$ , with a sink node to all nodes  $w$  such that  $L(w) \sim f_s$ ;
2. Otherwise, if  $G_t^T$  is unrelated to  $f_s$ , then we do not modify  $G_t$ .

We define  $G_{[s,t]}^T$  to be the partial wdag formed only by considering times  $t, \dots, s$ ; then  $G_t^T = G_{[1,t]}^T$  and  $G_{[t,t]}^T$  is a singleton node labeled  $f_t$  and  $G_{[s,t]}^T$  is formed by copying  $G_{[s+1,t]}^T$  and adding, or not, a node labeled  $f_s$ . We say that a wdag  $H$  appears if  $H$  is isomorphic to  $G_t$  for any value  $t$ ; with a slight abuse of notation, we write this as  $G_t = H$ .

To calculate the expected running time of the Search Algorithm, we sum the wdag appearance probabilities. One of the main ingredients in the original proof of Moser & Tardos is that any wdag  $G$  appears with probability at most  $\prod_{v \in G} \mu(L(v))$ , i.e., the product of probabilities of the flaws that label its vertices. Their proof depends on properties of the variable setting and does not extend to other probability spaces.

Our key message is that commutativity allows us to bound the probability of a wdag appearing by considering the product of transition matrices for flaws that label its vertices. Specifically, we show the following. (Recall that  $\mu$  denotes the initial state distribution.)

► **Lemma 5.** *For any wdag  $H$ , the probability that  $H$  appears is at most  $\mu^\top A_H \vec{1}$ .*

**Proof.** We first show that if the Search Algorithm runs for at most  $t_{\max}$  steps starting with state  $\sigma$ , where  $t_{\max}$  is an arbitrary integer, then  $H$  appears with probability at most  $e_\sigma^\top A_H \vec{1}$ . We prove this claim by induction on  $t_{\max}$ . If  $t_{\max} = 0$ , or  $\sigma$  is flawless, the claim can be easily seen to hold vacuously.

So suppose that  $t_{\max} \geq 1$  and  $S$  selects a flaw  $g$  to resample in  $\sigma$ , and define  $\mathcal{E}_H$  to be the event that  $H$  appears when running the search algorithm  $\mathcal{A}$ . By conditioning on the random seed used by the flaw choice strategy  $S$  (if any), we may assume that the search strategy  $S$  is deterministic.

We can now view the evolution of  $\mathcal{A}$  as a two-part process: we first resample  $g$ , reaching state  $\sigma'$  with probability  $A_g[\sigma, \sigma']$ . We then execute a new search algorithm  $\mathcal{A}'$  starting at state  $\sigma'$ , wherein the flaw selection rule  $S'$  on history  $(\sigma', \sigma_2, \dots, \sigma_t)$  is the same as the choice of  $S$  on history  $(\sigma, \sigma', \sigma_2, \dots, \sigma_t)$ . Let us denote by  $G'_s$  the wdags produced for this new search algorithm  $\mathcal{A}'$ .

Suppose that  $H$  appears, so that  $G_s = H$  for some value  $s \leq t_{\max}$ . In this case, we claim that one of the two conditions must hold: (i)  $H$  has a unique source node  $v$  labeled  $g$  and  $G'_{s-1} = H - v$ ; or (ii)  $g$  is unrelated to  $H$  and  $G'_{s-1} = H$ . For, suppose that  $H$  has another node  $w$  with  $L(w) \sim L(v)$ ; in this case, when forming the wdag  $G_s$ , the rule would be to add a new node labeled  $g$ , which is perforce a source node.

In case (i), then in order for event  $\mathcal{E}_H$  to occur on the original search algorithm  $\mathcal{A}$ , we must also have  $\mathcal{E}_{H-v}$  hold on  $\mathcal{A}'$  within  $t-1$  timesteps. By induction hypothesis, this has probability at most  $e_{\sigma'}^\top A_{H-v} \vec{1}$  for a fixed  $\sigma'$ . Summing over  $\sigma'$  gives a total probability of  $\sum_{\sigma'} A_g[\sigma, \sigma'] e_{\sigma'}^\top A_{H-v} \vec{1} = e_\sigma^\top A_g A_{H-v} \vec{1} = e_\sigma^\top A_H \vec{1}$  as required.

In case (ii), then in order for event  $\mathcal{E}_H$  to occur for  $\mathcal{A}$ , we must also have  $\mathcal{E}_H$  occur for  $\mathcal{A}'$  within  $t-1$  timesteps. By induction hypothesis, this has probability at most  $e_{\sigma'}^\top A_H \vec{1}$  for a fixed  $\sigma'$ . Summing over  $\sigma'$  gives a total probability of  $\sum_{\sigma'} A_g[\sigma, \sigma'] e_{\sigma'}^\top A_H \vec{1} = e_\sigma^\top A_g A_H \vec{1}$ . Since  $A_g$  commutes with  $A_H$ , this is at most  $e_\sigma^\top A_H A_g \vec{1}$ . Since  $A_g$  is substochastic, this in turn is at most  $e_\sigma^\top A_H \vec{1}$ , which completes the induction.

By countable additivity, we can compute the probability that  $H$  ever appears from starting state  $\sigma$ , as  $\Pr(\bigvee_{t=1}^{\infty} G_t^{\hat{T}} = H) = \lim_{t_{\max} \rightarrow \infty} \Pr(\bigvee_{t=1}^{t_{\max}} G_t^{\hat{T}} = H) \leq \lim_{t_{\max} \rightarrow \infty} e_\sigma^\top A_H \vec{1} = e_\sigma^\top A_H \vec{1}$ .

Finally, integrating over  $\tau$ , gives  $\sum_{\tau} \mu[\tau] e_\tau^\top A_H \vec{1} = \mu^\top A_H \vec{1}$ .  $\blacktriangleleft$

This can be used to show a generalization of the key Witness Tree Lemma of Moser & Tardos:

► **Corollary 6.** *Suppose the resampling oracle is regenerating. Then, for a given wdag  $H$ , the probability that  $H$  appears is at most  $\prod_{v \in H} \mu(L(v))$ .*

**Proof.** Let  $f_1, \dots, f_t$  be the labels of the vertices in  $H$ , ordered from source nodes to sink nodes. We can write  $A_H = A_{f_1} \cdots A_{f_t}$ . Since  $\mu$  is a left-eigenvector of every transition matrix (see Eq. (1)), we have  $\mu^\top A_H \vec{1} = \mu^\top A_{f_1} \cdots A_{f_t} \vec{1} = \mu(f_1) \cdots \mu(f_t) \mu^\top \vec{1} = \mu(f_1) \cdots \mu(f_t)$ .  $\blacktriangleleft$

As we have already discussed, this gives the following important corollary:

► **Corollary 7.** *The expected number of steps of the Search Algorithm is at most  $\sum_{\substack{f \in \mathcal{F} \\ H \in \mathfrak{H}(f)}} \mu^\top A_H \vec{1}$ .*

For example, if the resampling oracle is regenerating, then, the expected number of steps of the algorithm is at most  $\sum_{f \in \mathcal{F}} \sum_{H \in \mathfrak{H}(f)} \prod_{v \in H} \mu(L(v))$ , i.e. the usual Witness Tree Lemma.

We emphasize that we are not aware of any direct proof of Corollary 6; it seems necessary to first show the matrix bound of Lemma 5, and then project down to scalars. As we show in Appendix A, under some natural conditions the matrix commutativity property is necessary to obtain Lemma 5.

#### 4 Estimating weights of wdags

The statement of Lemma 5 in terms of matrix products is very general and powerful, but difficult for calculations. To use it effectively, we need to bound the sums of the form

$$\sum_{H \in \mathfrak{H}} \mu^\top A_H \vec{1}$$

There are two, quite distinct, issues that arise in this calculation. First, for a given fixed wdag  $H$ , we need to estimate  $\mu^\top A_H \vec{1}$ ; second, we need to bound the sum of these quantities over  $H$ . The second issue is well-studied and is at the heart of the probabilistic and algorithmic conditions for the LLL. The first issue is not as familiar. Following [3], we can bound the matrix product by using a heuristic based on spectral bounds of the matrices  $A_f$ . Let us define a quantity called the *charge*  $\gamma_f$  for each flaw  $f$  as follows.

$$\gamma_f = \max_{\tau \in \Omega} \sum_{\sigma \in f} \frac{\mu(\sigma)}{\mu(\tau)} A_f[\sigma, \tau] \quad (2)$$

The following result of [21] illustrates the connection between this measure and the Lopsided Lovász Local Lemma (LLLL):

► **Theorem 8** ([21]). *For each set  $S \subseteq \mathcal{F} - \Gamma(f)$ , there holds  $\mu(f \mid \bigcap_{g \in S} \bar{g}) \leq \gamma_f$ .*

Moreover, as shown in [2], the charge  $\gamma_f$  captures the compatibility between resampling oracle for  $f$  and the measure  $\mu$ . A resampling oracle  $\mathfrak{R}$  with  $\gamma_f = \mu(f)$  for all  $f$ , is called a *regenerating oracle* [19], as it perfectly removes the conditional of the resampled flaw. (This is equivalent to satisfying Eq. (1).)

For a wdag  $H$ , let us define the scalar value  $w(H) = \prod_{v \in H} \gamma_{L(v)}$ . We get the following estimate for  $\mu^\top A_H \vec{1}$  in terms of  $w(H)$ :

► **Theorem 9.** *For any event  $E \subseteq \Omega$  we have  $\mu^\top A_H e_E \leq \mu(E) \cdot w(H)$ . In particular, with  $E = \Omega$ , we have  $\mu^\top A_H \vec{1} \leq w(H)$ .*

**Proof.** From definition of  $\gamma_f$ , it can be observed that  $\mu^\top A_f \preceq \gamma_f \mu^\top$  for any  $f$ . In particular,  $\mu^\top A_f \cdot \theta \leq \gamma_f \theta$  for any vector  $\theta$ . Now, by Proposition 4, we can write  $A_H = A_{f_1} \dots A_{f_t}$  where  $f_1, \dots, f_t$  are the labels of the nodes of  $H$ . We thus have:

$$\mu^\top A_H e_E = \mu^\top A_{f_1} \dots A_{f_t} e_E \leq \mu^\top \gamma_{f_1} A_{f_2} \dots A_{f_t} \leq \dots \leq \gamma_{f_1} \dots \gamma_{f_t} \mu^\top e_E = w(H) \mu(E) \blacktriangleleft$$

In light of Theorem 9, we define for any stable set  $I$  the key quantity  $\Psi(I) = \sum_{H \in \mathfrak{H}(I)} w(H)$ . We also define  $\Psi(f) = \Psi(\{f\})$  for brevity.

► **Corollary 10.**

1. *Any given wdag  $H$  appears with probability at most  $w(H)$ .*
2. *The expected number of resamplings of any flaw  $f$  is at most  $\Psi(f)$ .*
3. *The expected runtime of the Search Algorithm is at most  $\sum_f \Psi(f)$ .*

We summarize a few well-known bounds on these quantities.

► **Proposition 11.**

1. *(Symmetric criterion) Suppose that  $\gamma_f \leq p$  and  $|\bar{\Gamma}(f)| \leq d$  for parameters  $p, d$  with  $epd \leq 1$ . Then  $\Psi(f) \leq e\gamma_f \leq ep$  for all  $f$ .*
2. *(Asymmetric criterion) Suppose there is some function  $x : \mathcal{F} \rightarrow [0, 1)$  with the property that  $\gamma_f \leq x(f) \prod_{g \in \Gamma(f)} (1 - x(g))$  for all  $f$ . Then  $\Psi(f) \leq \frac{x(f)}{1-x(f)}$  for all  $f$ .*

3. (*Cluster-expansion criterion*) Suppose there is some function  $\eta : \mathcal{F} \rightarrow [0, \infty)$  with the property that  $\eta(f) \geq \gamma_f \cdot \sum_{\substack{I \subseteq \bar{\Gamma}(f) \\ I \text{ stable}}} \prod_{g \in I} \eta(g)$  for all  $f$ . Then  $\Psi(f) \leq \eta(f)$  for all  $f$ .

A related quantity is  $\bar{\Psi}(I) = \sum_{J \subseteq I} \Psi(J)$ . A useful and standard formula (see e.g., [19, Claim 59]) is that for any set  $I$  we have  $\Psi(I) \leq \prod_{f \in I} \Psi(f)$  and  $\bar{\Psi}(I) \leq \prod_{f \in I} (1 + \Psi(f))$ . We also write  $\Psi_{\mathcal{F}}, \bar{\Psi}_{\mathcal{F}}$  to indicate the role of the flaw set  $\mathcal{F}$ , if it is relevant.

As an illustration, consider latin transversals. Here, we have a flaw  $f$  for each pair of cells  $(x_1, y_1), (x_2, y_2)$  of the same color, i.e.  $\pi x_1 = y_1 \wedge \pi x_2 = y_2$ . We denote this by flaw  $[(x_1, y_1), (x_2, y_2)]$ . We define the dependency graph by setting  $f \sim f'$  if and only if  $f$  and  $f'$  are mutually incompatible, i.e.  $f = [(x_1, y_1), (x_2, y_2)], f' = [(x'_1, y'_1), (x'_2, y'_2)]$  where either  $x_1 = x'_1, y_1 \neq y'_1$  or  $x_1 \neq x'_1, y_1 = y'_1$ . We will examine this construction in more detail later in Section 6.

► **Proposition 12.** *Suppose that each color appears at most  $\Delta = \frac{27}{256}n$  times in the array. Then the expected number of steps of the Search Algorithm is  $O(n)$ . Furthermore,  $\Psi(f) \leq \frac{256}{81n^2}$  for each  $f$ .*

**Proof.** We apply the cluster-expansion criterion with  $\eta(f) = \frac{256}{81n^2}$  for each flaw  $f$ . Consider a flaw  $f$  corresponding to cells  $(x_1, y_1), (x_2, y_2)$ , and a stable set  $I$  of neighbors of  $f$ . There can be one or zero elements  $g$  of  $I$  of the form  $[(x_1, y'_1), (x'_2, y'_2)]$ . There are  $n$  choices for  $x_1$ ; given that pair  $(x_1, y'_1)$  is determined, there are at most  $\Delta - 1$  other cells with the same color. Each such  $g$  has  $\eta(g) = \frac{256}{81n^2}$ . Similar arguments apply to elements in  $I$  of the form  $[(x'_1, y_1), (x_2, y'_2)]$  etc. Overall, the sum over stable neighbor sets  $I$  is at most  $(1 + n(\Delta - 1)\frac{256}{81n^2})^4$ .

So we need to show that

$$\frac{256}{81n^2} \geq \frac{1}{n^2} \cdot (1 + n(\Delta - 1)\frac{256}{81n^2})^4$$

and simple calculations show that this holds for  $n \geq 2$ . (The case  $n = 1$  holds trivially).

Also, the total number of flaws is at most  $n^2(\Delta - 1)/2 = O(n^3)$ . Thus, the expected number of steps is at most  $|\mathcal{F}| \cdot \frac{256}{81n^2} \leq O(n)$ . ◀

## 5 Parallel algorithms

Moser & Tardos [25] described a simple parallel version of their resampling algorithm. A variety of parallel resampling algorithms have also been developed for other probability spaces [17, 13]. One main benefit of the commutativity property is that it enables much more general parallel implementations of the Search Algorithm. As a starting point, [23] discussed a generic framework for parallelization which we summarize as follows:

■ **Algorithm 3** Generic parallel resampling framework.

- 
- 1: Draw state  $\sigma$  from distribution  $\mu$
  - 2: **while** some flaw holds on  $\sigma$  **do**
  - 3:     Set  $V \neq \emptyset$  to be the set of flaws currently holding on  $\sigma$
  - 4:     **while**  $V \neq \emptyset$  **do**
  - 5:         Select, arbitrarily, a flaw  $f \in V$ .
  - 6:         Update  $\sigma \leftarrow \mathfrak{R}_\sigma(\sigma)$ .
  - 7:         Remove from  $V$  all flaws  $g$  such (i)  $\sigma \notin g$ ; or (ii)  $f \sim g$
-

Each iteration of the main loop (lines 2 – 7) is called a *round*. We emphasize this is a *sequential* algorithm, which can be viewed as a version of the Search Algorithm with an unusual flaw-selection choice. Most known parallel local search algorithms, including the original parallel algorithm of Moser & Tardos, fall into this framework. One main result of [23] is that, when the resampling oracle is commutative (in the sense of [23]), then the total number of rounds in Algorithm 3 is polylogarithmic with high probability.

Harris [15] further showed a general method for simulating each round in parallel, for resampling oracles which satisfy a property called *obliviousness* (see Section 7 for a formal definition). These two results combine to give an overall RNC search algorithm. We will now extend these results to our commutative resampling oracles, via bounding the weights of certain classes of wdags.

We define  $V_k$  to be the set of flaws  $V$  in round  $k$ , and we define the stable set  $I_k$  to be the set of flaws which are actually resampled at round  $k$  (i.e. a flaw  $f$  selected at some iteration of line 5). Let  $b_k = \sum_{i < k} |I_i|$  be the total number of resamplings made before round  $k$ ; thus  $b_1 = 0$ , and when “serialize” Algorithm 3 and view it as an instance of the Search Algorithm, the resamplings in round  $k$  of Algorithm 3 correspond to the resamplings at iterations  $b_k + 1, \dots, b_{k+1}$  of the Search Algorithm.

► **Proposition 13.** *For all  $f \in V_k$  there exists  $g \in I_{k-1}$  with  $f \sim g$ .*

► **Proposition 14.** *Consider running Algorithm 3 obtaining trajectory  $\hat{T}$ . Then, for each  $t$  in the range  $b_k + 1, \dots, b_k$  the wdag  $G_t^{\hat{T}}$  has depth precisely  $k$ .*

The proof of Propositions 13 and 14 are nearly identical to results for the variable LLLL shown in [15]; we omit them here.

► **Proposition 15.** *For any  $f \in \mathcal{F}$  and index  $k \geq 1$ , we have  $\Pr(f \in V_k) \leq \sum_{\substack{H \in \mathfrak{H}(f) \\ \text{depth}(H)=k}} \mu^\top A_H \vec{1}$ .*

**Proof.** As we have discussed, Algorithm 3 can be viewed as an instantiation of the Search Algorithm with a flaw selection rule  $S$ . For a fixed  $f$ , let us define a new flaw selection rule  $S_f$  as follows: it agrees with  $S$  up to round  $k$ ; it then selects  $f$  to resample at round  $k$  if it is true. The behavior for  $S$  and  $S_f$  is identical up through the first  $b_{k-1}$  resamplings. Furthermore, Algorithm 3 has  $f \in V_k$  if and only if the Search Algorithm selects  $f$  for resampling at iteration  $b_k + 1$ .

Consider the resulting wdag  $G_t^{\hat{T}}$ ; by Proposition 14 it has depth  $k$ . Furthermore, it has a sink node labeled  $f$ . Thus, if  $f \in V_k$ , then there is some  $H \in \mathfrak{H}(f)$  with  $\text{depth}(H) = k$  which appears. To bound the probability of  $f \in V_k$ , we take a union bound over all such  $H$  and apply Lemma 5. ◀

The usual strategy to bound the sum over wdags  $H$  with  $\text{depth}(H) \geq t$  is to use an “inflated” weight function defined as  $w_\epsilon(H) = w(H)(1 + \epsilon)^{|H|}$ , and corresponding sum  $W_\epsilon = \sum_{H \in \mathfrak{H}} w_\epsilon(H)$  for some  $\epsilon > 0$ . Using standard calculations as well as the bounds of Propositions 13, 14, 15, one can show the following results:

► **Proposition 16.** *With probability at least  $1 - \delta$ , Algorithm 3 terminates in  $O(\frac{\log(1/\delta + \epsilon W_\epsilon)}{\epsilon})$  rounds and has  $\sum_k |V_k| \leq O(W_\epsilon/\delta)$ . Furthermore, if the resampling oracle is regenerating and satisfies the computational requirements given in [15] for input length  $n$ , then with probability  $1 - 1/\text{poly}(n)$  the algorithm of [15] terminates in  $O(\frac{\log^4(n + \epsilon W_\epsilon)}{\epsilon})$  time on an EREW PRAM.*

## 31:12 A New Notion of Commutativity for the Algorithmic Lovász Local Lemma

Bounding  $W_\epsilon$  is very similar to bounding  $\sum_H w(H) = W_0$ , except with a small “slack” in the charges. For example, using standard estimates (see [11, 23, 3]) we get the following bounds:

► **Proposition 17.**

1. Suppose that the resampling oracle is regenerating and that the vector of probabilities  $p(1+\epsilon)$  still satisfies the LLLL criterion. Then  $W_{\epsilon/2} \leq O(m/\epsilon)$ . In particular, Algorithm 3 terminates after  $O(\frac{\log(m/\delta)}{\epsilon})$  rounds with probability  $1 - \delta$ .
2. Suppose that  $\gamma_f \leq p$  and  $|\bar{\Gamma}(f)| \leq d$  such that  $\text{epd}(1 + \epsilon) \leq 1$ . Then  $W_{\epsilon/2} \leq O(m/\epsilon)$ . Algorithm 3 terminates after  $O(\frac{\log(m/\delta)}{\epsilon})$  rounds with probability at least  $1 - \delta$ .

## 6 Distributional properties

The most important consequence of commutativity is that it leads to good bounds on the distribution of objects generated by the Search Algorithm. Consider an event  $E$  in  $\Omega$ , and define  $P(E)$  to be the probability that  $E$  holds in the output of the Search Algorithm. Also define  $N(E)$  to be the expected number of times  $t$  such that  $E$  is caused to be true at time  $t$ ; this includes both the original sampling at time  $t = 0$ , or if resampling flaw  $f$  at time  $t$  moved the state from  $\bar{E}$  to  $E$ . Clearly, there holds  $P(E) \leq N(E)$ . We also write  $P_{\mathcal{F}}(E)$  and  $N_{\mathcal{F}}(E)$  to emphasize the dependence on flaw set  $\mathcal{F}$ .

To obtain the tightest bounds on  $N(E)$ , and thereby  $P(E)$ , we will use a more refined construction of wdags. For this we need several definitions.

We say that a stable set  $I \subseteq \mathcal{F}$  is *orderable* for  $E$  if there is an enumeration  $I = \{g_1, \dots, g_r\}$  such that

$$\forall i = 1, \dots, r \quad A_{g_i} A_{g_{i+1}} \dots A_{g_r} e_E \not\subseteq A_{g_{i+1}} \dots A_{g_r} e_E \quad (3)$$

We define  $\mathfrak{D}(E)$  to be the collection of stable sets orderable for  $E$ . Also, we define  $\tilde{\Gamma}(E)$  to be the set of flaws  $f \in \mathcal{F}$  which can cause  $E$  to occur, i.e.  $f$  maps some state  $\sigma' \notin E$  to  $\sigma \in E$ .

► **Observation 18.** If  $I \in \mathfrak{D}(E)$ , then  $I \subseteq \tilde{\Gamma}(E)$ .

With this notation, our main distributional bound will be to show that

$$N(E) \leq \mu(E) \sum_{I \in \mathfrak{D}(E)} \Psi(I)$$

For a flaw  $f$  and wdag  $H$ , we say that  $f$  is *dominated by a wdag  $H$  for  $E$*  if  $A_f A_H \vec{1} \preceq A_H \vec{1}$ . Consider a trajectory  $T = (\sigma_0, f_1, \dots)$ . For each time  $t$  where  $E$  holds (including possibly  $t = 0$ ), we will generate a corresponding wdag  $J_t^T$ , however, the rule for adding nodes is slightly more restrictive. See Algorithm 4 for the precise construction.

■ **Algorithm 4** Forming  $J_t^T$ .

- 
- 1: Initialize  $J_t^T = \emptyset$
  - 2: **for**  $s = t, \dots, 1$  **do**
  - 3:     **if**  $f_s$  is not dominated by  $J_t^T$  or if  $J_t^T$  has a source node labeled  $f_s$  **then**
  - 4:         Add to  $J_t^T$  a node  $v_s$  labeled  $f_s$ , with an edge from  $v_s$  to each  $v_j$  such that  $f_j \sim f_s$
- 

We write  $J_{[s,t]}^T$  for the wdag  $J_t^T$  after iteration  $s$ , so that  $J_{[s,t]}^T$  is derived from  $J_{[s+1,t]}^T$  by adding (or not) a vertex labeled  $f_s$ . We have  $J_t^T = J_{[1,t]}^T$  and  $J_{[t+1,t]}^T = \emptyset$ . Also, if  $E$  is not true at time  $t$ , we define  $J_t^T = \perp$ . We define  $\mathfrak{J}'$  to be the collection of all wdags that can be produced in this process.

► **Proposition 19.** *Consider a wdag  $G \in \mathfrak{S}'$ . If  $J_t^T = G$  for a trajectory  $T$  with  $t \geq 1$  and  $f_1$  resampled at time 1, then the wdag  $G' = J_{t-1}^{T'}$  for the shifted trajectory  $T'$  is uniquely determined according to the following rule:*

- *If  $G$  contains a unique source node  $v$  labeled  $f_1$ , then  $G' = G - v$*
- *Otherwise,  $G' = G$  and  $f_1$  is dominated by  $G_t^T$*

**Proof.** Since  $t \geq 1$ , Algorithm 4 obtains  $J_t^T$  by possibly adding a node  $v_1$  labeled  $f_1$  to  $J_{t-1}^{T'}$ . If Algorithm 4 adds node  $v_1$  to  $G'$ , then  $f_1$  is the label of a source node  $v$  of  $J_t^T = G$ , and  $G' = J_t^T - v$ . If Algorithm 4 does not add such node, then  $J_t^T = G'$ . By the rule for adding nodes, it must be that  $G'$  does not have a source node labeled  $f_1$ , and also  $f_1$  must be dominated by  $J_{t-1}^{T'}$ . Since  $G' = J_t^T$ , these imply that  $f_1$  is dominated by  $J_t^T = G$  as well. ◀

Our main result for this construction will be the following:

► **Lemma 20.** *For any wdag  $H \in \mathfrak{S}'$ , there holds  $\Pr(\bigvee_{t=0}^{\infty} J_t = H) \leq \mu^\top A_H e_E$*

**Proof.** Define  $\mathcal{E}_{H,t_{\max}}$  to be the event that  $J_t^{\hat{T}} = H$  holds for some  $t \leq t_{\max}$  during execution of the Search Algorithm  $\mathcal{A}$ . By a limiting argument, it suffices to show that  $\Pr(\mathcal{E}_{H,t_{\max}}) \leq \mu^\top A_H e_E$  for any integer  $t_{\max} \geq 1$ . We will prove by induction on  $t_{\max}$  that, if we start at any state  $\sigma$ , then  $\Pr(\mathcal{E}_{H,t_{\max}}) \leq e_\sigma^\top A_H e_E$ ; the Lemma then follows by integrating over starting state  $\sigma$ .

If  $t_{\max} = 0$  or  $\sigma$  is flawless, then  $\mathcal{E}_{H,t_{\max}}$  is impossible and the desired bound. So suppose that  $t_{\max} \geq 1$ , and that  $S$  selects a flaw  $g$  to resample in  $\sigma$ . We can now view the evolution of  $\mathcal{A}$  as a two-part process: we first resample  $g$ , reaching state  $\sigma'$  with probability  $A_g[\sigma, \sigma']$ . We then execute a new search algorithm  $\mathcal{A}'$  starting at state  $\sigma'$ , wherein the flaw selection rule  $S'$  on history  $(\sigma', \sigma_2, \dots, \sigma_r)$  is the same as the choice of  $S$  on history  $(\sigma, \sigma', \sigma_2, \dots, \sigma_r)$ .

Suppose now that  $\mathcal{E}_{H,t_{\max}}$  holds for  $\mathcal{A}$ , i.e.  $J_t^{\hat{T}} = H$  for some  $t \leq t_{\max}$ . Note that the actual trajectory  $\hat{T}'$  for  $\mathcal{A}'$  is given by  $\hat{T}'$  which is the shift of  $\hat{T}$ . Thus, by Proposition 19, one of the two conditions must hold: (i) either  $H$  has a unique source node  $v$  labeled  $g$  and  $J_{t-1}^{T'} = H - v$ ; or (ii)  $H$  has no such node and  $J_{t-1}^{T'} = H$  and  $g$  is dominated by  $H$ .

In the first case, there must also hold  $\mathcal{E}_{H-v,t_{\max}-1}$  for  $\mathcal{A}'$ . By induction hypothesis, this has probability at most  $e_{\sigma'}^\top A_H e_E$  conditional on a fixed  $\sigma'$ . Summing over  $\sigma'$ , we get a total probability of  $\sum_{\sigma'} A_g[\sigma, \sigma'] e_{\sigma'}^\top A_H e_E = e_\sigma^\top A_g A_H e_E = e_\sigma^\top A_H e_E$ .

In the second case, there must also hold  $\mathcal{E}_{H,t_{\max}-1}$  for  $\mathcal{A}'$ . By induction hypothesis, this has probability at most  $e_{\sigma'}^\top A_H e_E$  conditional on a fixed  $\sigma'$ . Summing over  $\sigma'$ , we get a total probability of  $\sum_{\sigma'} A_g[\sigma, \sigma'] e_{\sigma'}^\top A_H e_E = e_\sigma^\top A_g A_H e_E$ . Since  $g$  is dominated by  $H$  for  $E$ , this is at most  $e_\sigma^\top A_H e_E$ , again completing the induction. ◀

► **Proposition 21.** *Suppose that event  $E$  is true at times  $s$  and  $t$  with  $s < t$ , but false at some intermediate time. Then  $J_s^T \neq J_t^T$ .*

**Proof.** We prove this by induction on  $s$ . For the base case  $s = 0$ , we have  $J_s^T = \emptyset$ . Suppose for contradiction that  $J_t^T = \emptyset$  as well. Since  $E$  is false at an intermediate time but true at time  $t$ , it must become true due to resampling some  $g$  at time  $t' < t$ . Clearly also  $J_{[t'+1,t]}^T = \emptyset$ . Since  $g$  makes  $E$  be true where it was false, we have  $g \in \tilde{\Gamma}(E)$ . As a result,  $g$  is not dominated for the empty wdag. So the rule for forming  $J_t^T$  would add a node to  $J_{[t',t]}^T$ , contradicting that  $J_t^T = \emptyset$ .

For the induction step, suppose  $s > 0$  and  $J_t^T = J_s^T$ . Let  $T'$  be the shift of  $T$ . By Proposition 19, both  $J_{s-1}^{T'}$  and  $J_{t-1}^{T'}$  are updated in the same manner depending on the flaw  $f_1$ . Thus,  $J_{s-1}^{T'} = J_{t-1}^{T'}$ . But this contradicts the induction hypothesis. ◀

► **Proposition 22.**  $N(E) \leq \sum_{H \in \mathfrak{H}'} \mu^\top A_H e_E$ .

**Proof.** By Proposition 21, for each time  $t$  that  $E$  switches from false to true, the corresponding wdag  $J_t^T$  must be distinct. Thus, the total number of times that  $E$  becomes true is at most  $\sum_{H \in \mathfrak{H}'} [\sum_{t \geq 0} \mathbb{1}_{J_t^T = H}]$ . Now take expectations and apply Lemma 20. ◀

► **Proposition 23.** For a wdag  $H \in \mathfrak{H}'$ , there holds  $\text{sink}(H) \in \mathfrak{D}(E)$ .

**Proof.** Let us fix some value  $t$  where  $E$  holds; for  $s = 1, \dots, t$  let  $H_s = J_{[s,t]}^T$  and  $I_s = \text{sink}(H_s)$ , and so that  $H_1 = H$ . We claim by induction on  $s$  that each wdag  $H_s$  has the stated property. The base case is  $s = t$ ; this holds since  $I_t = \emptyset \in \mathfrak{D}(E)$ .

Now consider some  $s < t$ , where  $H_s$  is formed from  $H_{s+1}$  by possibly adding a new node labeled  $g$ . The induction step is obvious if  $I_s = I_{s+1}$ . Thus, we may assume that  $g$  is unrelated to  $H_{s+1}$  (else it would not form a new sink node.) So the only relevant case is if  $g$  is not dominated by wdag  $G_{[s,t]}^T$ .

By induction hypothesis,  $I_{s+1} \in \mathfrak{D}(E)$ . Then it can be enumerated as  $I_{s+1} = \{g_1, \dots, g_r\}$  to satisfy Eq. (3). Suppose, for contradiction, that  $I_s \notin \mathfrak{D}(E)$ . If we enumerate  $I_s = \{g, g_1, \dots, g_r\}$ , then there would hold  $\theta^\top A_g A_{g_1} \dots A_{g_r} e_E \leq \theta^\top A_{g_1} \dots A_{g_r} e_E$  for all distributions  $\theta$  over the states.

Letting  $V$  denote the sink nodes of  $H_{s+1}$ , we have  $A_{H_{s+1}} = A_{H_{s+1}-V} A_V$ . Then, for any state  $\sigma$ , we have  $e_\sigma^\top A_g A_{H_{s+1}} e_E = e_\sigma^\top A_g A_{H_{s+1}-V} A_V e_E = e_\sigma A_{H_{s+1}-V} A_g A_{g_1} \dots A_{g_r} e_E$ , where in the last inequality we use the facts that  $g$  is unrelated to  $H_{s+1}$  and that  $A_V = A_{g_1} \dots A_{g_r}$ . By our bound with  $\theta = e_\sigma A_{H_{s+1}-V}$ , we see that this is at most  $e_\sigma A_{H_{s+1}-V} A_{g_1} \dots A_{g_r} e_E = e_\sigma A_{H_{s+1}} e_E$ . Hence  $g$  is dominated by  $G_{s+1}$  and we would not add the new node to  $H_s$ , a contradiction. ◀

We now get our desired distributional bounds:

► **Corollary 24.**  $N(E) \leq \mu(E) \sum_{I \in \mathfrak{D}(E)} \Psi(I)$ .

**Proof.** We have shown  $N(E) \leq \sum_{H \in \mathfrak{H}'} \mu^\top A_H e_E$ . Since each  $H \in \mathfrak{H}'$  has  $\text{sink}(H) \in \mathfrak{D}(E)$ , this is at most  $\sum_{I \in \mathfrak{D}(E)} \sum_{H \in \mathfrak{H}(I)} \mu^\top A_H e_E$ . By Theorem 9, this is at most  $\sum_{I \in \mathfrak{D}(E), H \in \mathfrak{H}(I)} w(H) \mu(E) = \mu(E) \sum_{I \in \mathfrak{D}(E)} \Psi(I)$ . ◀

► **Corollary 25.**  $P(E) \leq \mu(E) \sum_{I \in \mathfrak{D}(E)} \Psi_{\mathcal{G}}(I)$  where  $\mathcal{G} = \{f \in \mathcal{F} : f \not\subseteq E\}$ .

**Proof.** Consider the first time that  $E$  becomes true, if any. Then, only flaws in  $\mathcal{G}$  can be resampled up to that point; if some other flaw with  $f \subseteq E$  was resampled, then necessarily  $E$  was true earlier. Up to this time, the behavior of the Search Algorithm is identical to if had restricted to the flaw set  $\mathcal{G}$ . So  $P(E) \leq N_{\mathcal{G}}(E)$ ; by Corollary 24 this is at most  $\sum_{I \in \mathfrak{D}(E)} \Psi_{\mathcal{G}}(I)$ . ◀

Since any set  $I \in \mathfrak{D}(E)$  is also a subset of  $\tilde{\Gamma}(E)$ , we have the following crisp corollary:

► **Corollary 26.**  $P(E) \leq \mu(E) \bar{\Psi}(\tilde{\Gamma}(E))$ .

We note that Iliopoulos [20] had previously shown a bound similar to Corollary 26, but it had three additional technical restrictions: (i) it only worked for commutative resampling oracles in the sense of [23]; (ii) it additionally required the construction of a commutative resampling oracle for the event  $E$  itself; and (iii) if the resampling oracle is not regenerating, it gives a strictly worse bound.

The following result shows how to apply these bounds with common LLL criteria.

► **Proposition 27.** *Under the criteria of Proposition 11, we have the following estimates for  $P(E)$ :*

1. *If the symmetric criterion holds, then  $P(E) \leq \mu(E) \cdot e^{e^{|\tilde{\Gamma}(E)|p}}$ .*
2. *If function  $x$  satisfies the asymmetric criterion, then  $P(E) \leq \mu(E) \cdot \prod_{f \in \tilde{\Gamma}(E)} \frac{1}{1-x(f)}$ .*
3. *If function  $\eta$  satisfies the cluster-expansion criterion, then  $P(E) \leq \mu(E) \cdot \sum_{I \in \mathcal{D}(E)} \prod_{g \in I} \eta(g)$ .*

One weakness of distributional bounds such as Corollary 26 is that the definition of  $\tilde{\Gamma}(E)$  is binary: either flaw  $f$  cannot possibly cause  $E$ , or every occurrence of  $f$  must be tracked to determine if it caused  $E$ . The next results allow us to take account of flaws which can “partially” cause  $E$ .

For flaw  $f$  and event  $E$ , let us define

$$\kappa(f, E) = \max_{\sigma \in f \cap \bar{E}} \frac{e_{\sigma}^{\top} A_f e_E}{e_{\sigma}^{\top} A_f e_{E \cup \bar{f}}}$$

Note that  $\kappa(f, E) = 0$  for  $f \notin \tilde{\Gamma}(E)$ , and  $\kappa(f, E) \leq 1$  always. Thus,  $\kappa(f, E)$  is a weighted measure of the extent to which  $f$  causes  $E$ . Also note that usually  $e_{\sigma}^{\top} A_f e_f$  is small, and the denominator in the definition of  $\kappa(f, E)$  is close to one.

► **Theorem 28.**  $P(E) \leq \mu(E) + \sum_{f \in \mathcal{G}} \kappa(f, E) \cdot \min_{F \supseteq \bar{E}} N_{\mathcal{G}}(F \cap f)$  where  $\mathcal{G} = \{f : f \not\subseteq E\}$ .

**Proof.** See Appendix B. ◀

We remark that to obtain Theorem 28, we needed to bound  $N(F \cap f)$ ; bounds on  $P(F \cap f)$  alone would not have been enough. This explains why we analyzed the more general quantity. By applying Theorem 28 to the event  $\bar{E}$ , we can obtain a *lower bound* on the probability of  $E$ :

► **Corollary 29.**  $P(E) \geq \mu(E) - \sum_{f \in \mathcal{G}} \kappa(f, \bar{E}) \cdot \min_{F \subseteq E} N_{\mathcal{G}}(f - E)$  where  $\mathcal{G} = \{f : f \cap E \neq \emptyset\}$ .

For example, consider the permutation setting, where the probability space  $\Omega$  is the uniform distribution on permutations on  $n$  letters, and each flaw has the form  $g_1 \cap \dots \cap g_k$ , where each  $g_i$  is an atomic event of the form  $\pi x_i = y_i$ . We then get the following distributional result:

► **Theorem 30** ([14]). *In the permutation setting, consider an event  $E = g_1 \cap \dots \cap g_k$  where each  $g_i$  is an atomic event. We have  $N(E) \leq \frac{(n-k)!}{n!} \prod_{i=1}^k \left(1 + \sum_{f \in \mathcal{F}: f \sim g_i} \Psi(f)\right)$ .*

As another example, consider the setting where the underlying probability space  $\Omega$  is the uniform distribution on perfect matchings on the clique  $K_n$ , and each flaw has the form  $g_1 \cap \dots \cap g_k$ , where each  $g_i$  is an atomic event of the form  $\{x_i, y_i\} \subseteq M$ . We then get the following distributional result:

► **Theorem 31.** *In the settings of perfect matchings of the clique, consider an event  $E = g_1 \cap \dots \cap g_k$  where each  $g_i$  is an atomic event. We have  $N(E) \leq \frac{(n-2k-1)!!}{(n-1)!!} \prod_{i=1}^k \left(1 + \sum_{f \in \mathcal{F}: f \sim g_i} \Psi(f)\right)$ .*

The work [14] showed (what is essentially) Theorem 30 using a complicated and ad-hoc analysis based on a variant of witness trees, while Theorem 31 is new. The proofs are deferred to Appendix C.

Using these bounds, we can show the following estimates on individual entries of  $\pi$ :

► **Theorem 32.** *If each color appears at most  $\Delta = \frac{27}{256}n$  times in the array, then the Search Algorithm generates a latin transversal where, for each cell  $x, y$ , there holds*

$$\frac{17}{32n} \leq P(\pi x = y) \leq \frac{173}{128n}$$

**Proof.** Define the event  $E$  that  $\pi x = y$ . For the upper bound, Theorem 28 (with  $F = \Omega$ ) gives  $P(\pi x = y) \leq \mu(E) + \sum_{f \in \mathcal{F}} N_{\mathcal{F}}(f) \kappa(f, E)$ . Now, consider some flaw  $f = [(x_1, y_1), (x_2, y_2)] \in \mathcal{F}$ . The flaw  $f$  must involve cell  $(x, y')$  or  $(x', y)$ , else  $\eta(f, E, \Omega) = 0$ . For a flaw that does so, we can see that there is a probability of at most  $1/(n-1)$  that the resampling causes  $E$ , since there is at most one possible choice that can cause  $\pi x = y$ . Thus  $\eta(f, E, \Omega) \leq \frac{1/(n-1)}{1-1/n(n-1)}$ . By Theorem 30, we have  $N_{\mathcal{F}}(f) \leq \frac{(n-2)!}{n!} (1 + \sum_{f' \in \mathcal{G}: f' \sim f} \Psi(f'))$  where  $g_1, g_2$  are the two atoms in  $f$ . Since  $\Psi(f') \leq \gamma = \frac{256}{81n^2}$ , and there are at most  $2n(\Delta - 1)$  choices for  $f'$ , this is overall at most  $\frac{1}{n(n-1)}(1 + 2n(\Delta - 1)\gamma)$ .

Since either  $x_1 = x$  or  $y_1 = y$ , there are  $2n(\Delta - 1)$  choices for  $f$ . Summing over these, we get

$$P(E) \leq \frac{1}{n} + 2n(\Delta - 1) \cdot \frac{1}{n(n-1)} (1 + 2n(\Delta - 1)\gamma) \cdot \frac{1/(n-1)}{1-1/n(n-1)} \leq \frac{173}{128n}$$

For the lower bound, we use Corollary 29. Letting  $\mathcal{G}$  denote the flaws which do not involve cells  $(x, y')$  for  $y' \neq y$ , or  $(x', y)$  for  $x' \neq x$  and setting  $F = E$ , we have  $P(E) \geq \mu(E) - \sum_{f \in \mathcal{F}} N(E \cap f) \kappa(f, \bar{E})$ . Now, consider some such flaw  $f = [(x_1, y_1), (x_2, y_2)]$ . If  $(x_1, y_2) = (x, y)$ , then in this case,  $f \cap E = f$  and so Theorem 30 implies that  $N_{\mathcal{G}}(f \cap E) \leq \frac{1}{n(n-1)}(1 + (\Delta - 1)\gamma)(1 + 2n(\Delta - 1)\gamma)$ . (We emphasize that, because we are restricting to  $\mathcal{G}$ , there are no neighbors which involve cells  $(x, y')$  etc.) Otherwise, if  $(x, y)$  is distinct from  $(x_1, y_1), (x_2, y_2)$ , then  $f \cap E = [(x_1, y_1), (x_2, y_2), (x, y)]$  and Theorem 30 implies that  $N_{\mathcal{G}}(f \cap E) \leq \frac{1}{n(n-1)(n-2)}(1 + (\Delta - 1)\gamma)(1 + 2n(\Delta - 1)\gamma)^2$ .

There are at most  $(\Delta - 1)$  flaws in the first category, and each trivially has  $\kappa(f, \bar{E}) \leq 1$ . There are at most  $n^2(\Delta - 1)/2$  flaws in the second category; each such flaw  $f$  has  $\kappa(f, \bar{E}) \leq \frac{2/n}{1-1/n(n-1)}$ , since there are two choices for the cell to swap and in each case there is at most one way to get  $\pi x = y$  in a swap.

Putting all terms together, and with some algebraic simplifications, we get  $P(E) \geq \frac{17}{32n}$ . ◀

An analogous result can be shown for perfect matchings of the clique; we omit the proof here.

► **Theorem 33.** *Consider an edge-coloring  $C$  of the clique  $K_n$ , for  $n$  an even integer, such that each color appears on at most  $\Delta = \frac{27}{256}n$  edges. Then the Search Algorithm generates a perfect matching  $M$  such that  $C(e) \neq C(e')$  for all distinct edges  $e, e'$  of  $M$ . Moreover, for each edge  $e$ , the probability there holds  $\frac{17}{32(n-1)} \leq P(e \in M) \leq \frac{173}{128(n-1)}$ .*

## 7 Compositional properties for resampling oracles

The flaws and their resampling oracles are often built out of a collection of simpler, “atomic” events. For example, in the permutation LLL setting, these would be events of the form  $\pi x = y$ . In [15], Harris described a generic construction when the atomic events satisfy an additional property referred to as *obliviousness*. Let us now review this construction, and how it works with commutativity.

Consider a set  $\mathcal{A}$  of events, along with a resampling oracle  $\mathfrak{R}$  and a dependency relation  $\sim$ . It is allowed, but not required, to have  $f \sim f$  for  $f \in \mathcal{A}$ . For the compositional construction, we must define explicitly how the resampling oracle  $\mathfrak{R}_f$  uses the random seed. Specifically, to resample  $\sigma' \leftarrow \mathfrak{R}_f(\sigma)$ , we first draw a random seed  $r$  from some probability space  $R_f$ , and then set  $\sigma' = F(\sigma, r)$  for some *deterministic* function  $F$ . For brevity, we write this as  $\sigma' = r\sigma$ .

We refer to the elements of  $\mathcal{A}$  as *atoms*. These should be thought of as “pre-flaws”, that is, they have the *structural* algebraic properties of a resampling oracle, but do not necessarily satisfy any convergence condition such as the LLLL. We have the following key definition:

► **Definition 34** (Oblivious resampling oracle [15]). *The resampling oracle  $\mathfrak{R}$  is called oblivious if for every pair  $f, g \in \mathcal{A}$  with  $f \not\sim g$  and for each  $r \in R_f$ , one of the following two properties holds:*

- For all  $\sigma \in f \cap g$  we have  $r\sigma \in g$
- For all  $\sigma \in f \cap g$  we have  $r\sigma \notin g$

We assume throughout this section that  $\mathfrak{R}$  is oblivious. For each  $f \in \mathcal{A}$  and  $g_1, \dots, g_s \in \mathcal{A}$  with  $g_i \not\sim f$ , we define  $R_{f;g_1,\dots,g_s}$  to be the set of values  $r \in R_f$  such that  $r\sigma \in g_1 \cap \dots \cap g_t$ . With some abuse of notation, we also use  $R_{f;g_1,\dots,g_s}$  to refer to the probability distribution of drawing  $r$  from  $R_f$ , conditioned on having  $r$  in the set  $R_{f;g_1,\dots,g_s}$ . Note that in light of Definition 34 this is well-defined irrespective of  $\sigma$ .

For a stable set  $C \subseteq \mathcal{A}$ , we define  $\langle C \rangle$  to be the intersection of the events in  $C$ , i.e.,  $\langle C \rangle = \bigcap_{f \in C} f$ . From  $\mathcal{A}$ , one can construct an enlarged set of events  $\overline{\mathcal{A}} = \{\langle C \rangle \mid C \text{ a stable subset of } \mathcal{A}\}$ . We define the relation  $\sim$  on  $\overline{\mathcal{A}}$  by setting  $\langle C \rangle \sim \langle C' \rangle$  iff either (i)  $C = C'$  or (ii) there exist  $f \in C, f' \in C'$  with  $f \sim f'$ . We also define a corresponding resampling oracle  $\mathfrak{R}$  on  $\overline{\mathcal{A}}$  which will satisfy all its required structural properties. The intent is to choose the flaw set  $\mathcal{F}$  to be some arbitrary subset of  $\overline{\mathcal{A}}$ ; as before,  $\overline{\mathcal{A}}$  does not necessarily satisfy any LLLL convergence criterion.

To determine  $\mathfrak{R}$ , consider some  $g = \langle C \rangle$  for a stable set  $C$ , with some arbitrary enumeration  $C = \{f_1, \dots, f_t\}$ . We define  $R_g$  to be the probability distribution on tuples  $r = (r_1, \dots, r_t)$  wherein each  $r_i$  is drawn independently from  $R_{f_i;f_{i+1},\dots,f_t}$ , and we set  $r\sigma = r_t \dots r_1 \sigma$ .

► **Theorem 35** ([15]). *Suppose that  $\mathfrak{R}$  is an oblivious resampling oracle for  $\mathcal{A}$ , which is not necessarily commutative. Then:  $\mathfrak{R}$  with dependency relation  $\sim$  provides an oblivious resampling oracle for  $\overline{\mathcal{A}}$ . If  $\mathfrak{R}$  is regenerating on  $\mathcal{A}$ , then the resampling oracle on  $\overline{\mathcal{A}}$  is also regenerating.*

It would seem reasonable that if  $\mathcal{A}$  is commutative, then  $\overline{\mathcal{A}}$  would be as well. Unfortunately, we do not know how to show this for the commutativity definition of [23]. For our commutativity definition, this is easy to show; in addition,  $\overline{\mathcal{A}}$  will inherit a number of other nice properties. This is a good illustration of how the new definition of commutativity is easier to work with, beyond its advantage of greater generality.

► **Proposition 36.** *Suppose that  $\mathcal{A}$  is oblivious but not necessarily commutative. For a flaw  $g = \langle C \rangle$ , suppose that we have fixed an enumeration  $C = \{f_1, \dots, f_t\}$  to define  $\mathfrak{R}_g$ . Then  $A_g \propto A_{f_1} \dots A_{f_t}$ .*

**Proof.** By definition of  $\mathfrak{R}_g$ , we have  $A_g[\sigma, \sigma'] = \Pr(r_t \dots r_1 \sigma = \sigma')$ , where each  $r_i$  is drawn independently from  $R_{f_i;f_{i+1},\dots,f_t}$ . Let us define  $R'_i = R_{f_i;f_{i+1},\dots,f_t}$  and  $\sigma_i = r_i \dots r_1 \sigma$  for  $i = 0, \dots, t$  (where  $\sigma_0 = \sigma$ ). By enumerating over possible values for  $\sigma_1, \dots, \sigma_t$ , we get  $A_g[\sigma, \sigma'] = \sum_{\substack{\sigma_1, \dots, \sigma_t \\ \sigma_t = \sigma'}} \prod_{i=1}^t \Pr_{r_i \sim R'_i}(r_i \sigma_{i-1} = \sigma_i)$ .

Note that if  $\sigma_i \notin f_j$  for some  $j > i$ , then the term  $\Pr_{r_i \sim R'_i}(r_i \sigma_{i-1} = \sigma_i)$  must be zero, since  $r_i \in R'_i \subseteq R_{f_i; f_j}$ . So we may restrict the sum to terms with  $\sigma_i \in f_{i+1} \cap \dots \cap f_t$  for all  $i = 0, \dots, t$ . For each such term, we have  $\Pr_{r_i \sim R'_i}(r_i \sigma_{i-1} = \sigma_i) = \frac{\Pr_{r_i \sim R_i}(r_i \sigma_{i-1} = \sigma_i)}{\Pr_{r_i \sim R_i}(r_i \in R'_i)} = \frac{A_{f_i}[\sigma_{i-1}, \sigma]}{\Pr_{r_i \sim R_i}(r_i \in R'_i)}$ . So:

$$\begin{aligned} A_g[\sigma, \sigma'] &= \sum_{\substack{\sigma_1, \dots, \sigma_t \\ \sigma_t = \sigma'}} \frac{A_{f_1}[\sigma_0, \sigma_1] \dots A_{f_t}[\sigma_{t-1}, \sigma_t]}{\prod_{i=1}^t \Pr_{r_i \sim R_i}(r_i \in R'_i)} = \frac{\sum_{\sigma_t = \sigma'}^{\sigma_1, \dots, \sigma_t} A_{f_1}[\sigma_0, \sigma_1] \dots A_{f_t}[\sigma_{t-1}, \sigma_t]}{\prod_{i=1}^t \Pr_{r_i \sim R_i}(r_i \in R'_i)} \\ &= (cA_{f_1} \dots A_{f_t})[\sigma, \sigma'] \end{aligned} \quad \blacktriangleleft$$

► **Proposition 37.** *If  $\mathcal{A}$  is commutative, then the transition matrix  $A_g$  for a flaw  $g = \langle C \rangle$  does not depend on the chosen enumeration  $C = \{f_1, \dots, f_t\}$ .*

**Proof.** By Proposition 36, we have  $A_g = cA'_g$  for  $A'_g = A_{f_1} \dots A_{f_t}$ . Since the matrices  $A_{f_i}$  all commute,  $A'_g$  does not depend on the enumeration of  $C$ . Furthermore, the constant  $c$  can be determined from  $A'_g$  by choosing an arbitrary state  $\sigma \in g$  and setting  $c = \frac{1}{\sum_{\sigma'} A'_g[\sigma, \sigma']}$ . ◀

► **Theorem 38.** *If the resampling oracle is commutative on  $\mathcal{A}$ , then it is also commutative on  $\overline{\mathcal{A}}$ .*

**Proof.** Let  $g = \langle C \rangle$  and  $g' = \langle C' \rangle$  for stable sets  $C, C'$  such that  $g \not\sim g'$ . So  $f \not\sim f'$  for all  $f \in C$  and  $f' \in C'$ . By Proposition 36 we have

$$A_g A_{g'} = c_g c_{g'} \left( \prod_{f \in C} A_f \prod_{f' \in C'} A_{f'} \right), \quad A_{g'} A_g = c_{g'} c_g \left( \prod_{f' \in C'} A_{f'} \prod_{f \in C} A_f \right)$$

for scalar constants  $c_g, c_{g'}$ . All these matrices  $A_f, A_{f'}$  commute, so both quantities are equal. ◀

Another useful property for such resampling oracles is *idempotence*. We say that  $\mathcal{A}$  is idempotent if  $A_f^2 \propto A_f$  for all  $f \in \mathcal{A}$ . Most of the known commutative resampling oracles, resampling oracles have this property, including the variable LLLL and the permutation LLL.

► **Proposition 39.** *If the resampling oracle is commutative and idempotent on  $\mathcal{A}$ , then it is also idempotent on  $\overline{\mathcal{A}}$ . Furthermore, for any stable set  $I = \{\langle C_1 \rangle, \dots, \langle C_k \rangle\}$  of  $\overline{\mathcal{A}}$  and stable set  $J = C_1 \cup \dots \cup C_k$  of  $\mathcal{A}$ , there holds  $A_I \propto A_J$ .*

**Proof.** First, let  $f = \langle C \rangle$  for stable set  $C = \{g_1, \dots, g_k\}$ . Proposition 36 gives  $A_f^2 \propto (A_{g_1} \dots A_{g_k})^2$ . Since the matrices  $A_{g_i}$  commute with each other, this gives  $A_f^2 \propto A_{g_1}^2 \dots A_{g_k}^2$ . Since  $\mathcal{A}$  is idempotent, this is proportional to  $A_{g_1} \dots A_{g_k}$ , which again by Proposition 36 is proportional to  $A_f$ .

For the second result, Proposition 36 gives  $A_I \propto \prod_{i=1}^k \prod_{g \in C_i} A_g = \prod_{g \in J} A_g^{n_g}$  where  $n_g \geq 1$  is the number of copies of  $g$  appearing in  $C_1, \dots, C_k$ . Since  $\mathcal{A}$  is idempotent, each term  $A_g^{n_g}$  is proportional to  $A_g$ . Hence we have  $A_I \propto \prod_{g \in J} A_g = A_J$ . ◀

## A Necessity of transition matrix commutativity for Lemma 5

Consider a set of events  $\mathcal{B}^*$  with a dependency relation  $\sim$ . We say that  $\mathcal{B}^*$  is *complete* if for each  $\sigma \in \Omega$  there exists a flaw  $h_\sigma = \{\sigma\} \in \mathcal{B}^*$ , and with  $h_\sigma \sim g$  for all  $g \in \mathcal{B}^*$ . Note that this definition is satisfied if  $\mathcal{B}^*$  is generated by atomic events corresponding to permutations, perfect matchings of hypergraphs, or spanning trees.

We show now that if transition matrix commutativity fails in a complete set of events, even for a single pair of flaws, then some wdags may appear with probability arbitrarily higher than their weight. It can be checked that preconditions of the lemma (and thus its conclusion) apply to some existing resampling oracles, such as the oracle for spanning trees from [19] and the oracle for perfect matchings of complete  $s$ -uniform hypergraphs (for  $s \geq 3$ ) from [15].

► **Theorem 40.** *Suppose that  $\mathcal{B}^*$  is complete, regenerating, and contains a pair  $f, g \in \mathcal{B}^*$  with  $f \approx g$  and  $A_f A_g \neq A_g A_f$ . Then for any  $C > 0$  there exists a set of flaws  $\mathcal{B} \subseteq \mathcal{B}^*$  with  $|\mathcal{B}| = 3$ , wdag  $H$  with a single sink and a flaw resampling strategy  $S$  such that the probability that  $H$  appears in the execution of the algorithm is at least  $C \cdot w(H) = C \cdot \prod_{v \in H} \mu(L(v))$ .*

**Proof.** Consider states  $\sigma, \tau$  with  $A_f A_g[\sigma, \tau] \neq A_g A_f[\sigma, \tau]$ . Denote  $x = A_f A_g e_\tau$  and  $y = A_g A_f e_\tau$ , and assume w.l.o.g. that  $x[\sigma] < y[\sigma]$ . Note that  $\mu^\top A_f A_g = \mu^\top A_g A_f = \gamma_f \gamma_g \cdot \mu^\top$  since the oracles are regenerating, and therefore  $\mu^\top x = \mu^\top y = \gamma_f \gamma_g \cdot \mu[\tau] = \gamma_f \gamma_g \gamma_h$ .

Consider the following strategy  $S$  given a current state  $\sigma_1$ : (i) if  $\sigma_1 \neq \sigma$  then prioritize flaws  $f, g, h$  at steps 1,2,3 respectively; (ii) if  $\sigma_1 = \sigma$  then prioritize flaws  $g, f, h$  at steps 1,2,3 respectively. We say that the run *succeeds* if the sequence of addressed flaws is  $(f, g, h)$  in the first case and  $(g, f, h)$  in the second case. Clearly, the probability of success equals  $e_{\sigma_1}^\top A_f A_g e_\tau = e_{\sigma_1}^\top x$  in the first case and  $e_{\sigma_1}^\top A_g A_f e_\tau = e_{\sigma_1}^\top y$  in the second case. If  $\sigma_1$  is distributed according to  $\mu$  then the probability of success is

$$\begin{aligned} p &= \mu[\sigma] \cdot e_\sigma^\top y + \sum_{\sigma_1 \in \Omega - \{\sigma\}} \mu[\sigma_1] \cdot e_{\sigma_1}^\top x = \mu[\sigma] \cdot (e_\sigma^\top y - e_\sigma^\top x) + \sum_{\sigma_1 \in \Omega} \mu[\sigma_1] \cdot e_{\sigma_1}^\top x \\ &= \mu^\top x + \mu[\sigma] \cdot (y[\sigma] - x[\sigma]) > \gamma_f \gamma_g \gamma_h \end{aligned}$$

Furthermore, if the run succeeds then the last state is distributed according to  $\mu$  (since step 3 resamples  $h$  at state  $\tau$ , and the oracles are regenerating).

Now consider the trajectory which repeats the sequence  $f, g, h$  for  $n$  times, and the corresponding wdag  $H = G_{3n}^T$  which has a single sink node labeled  $h$ . Let  $S^n$  be the strategy  $S$  repeated cyclically. From the previous paragraph, the probability that the run starting with some distribution  $\mu$  produces  $H$  is given by  $c_\mu \cdot p^{n-1}$ , where  $c_\mu$  depends only on the initial distribution. Note that  $w(H) = (\gamma_f \gamma_g \gamma_h)^n$ . Choosing  $n$  sufficiently large now gives the claim. ◀

## B Proof of Theorem 28

First, there is a probability of  $\mu(E)$  that  $E$  is true at time 0. To bound the probability the  $E$  becomes true later, let us say that a pair  $(f, t)$  is *good* if (i)  $E$  is false at time  $t$ ; (ii)  $f$  is resampled at time  $t$ ; and (iii) either this is the first resampling of  $f$ , or if the most recent resampling of  $f$  had occurred at time  $t' < t$ , then  $f$  had been false at some intermediate time between  $t' + 1$  and  $t$ . If  $(f, t)$  is good, we say it is *finalized at time*  $s \geq t$  if (i)  $f$  is resampled at time  $s$ ; (ii)  $E$  has been false at all times prior to  $s$ ; and (iii)  $f$  is true at times  $t, \dots, s$ .

We claim that if  $E$  becomes true, then there is some pair  $(f, t)$  which is good and is finalized at some time  $s \geq t$ . For, suppose that  $E$  first becomes true at time  $s \geq 1$  and that  $f$  is resampled at time  $s$ . Going backward in time, look for the earliest time  $t$  such that the same flaw  $f$  is resampled at time  $t$  and that  $f$  remained true between  $t$  and  $s$  (possibly  $t = s$ ). Then  $(f, t)$  is good and is finalized at time  $s$ .

Now let us fix good pair  $(f, t)$ . For each  $s \geq t$ , let  $\mathcal{E}_s$  be the event that  $(f, t)$  is finalized by some  $s' \geq s$ . We claim that  $\Pr(\mathcal{E}_s) \leq \kappa(f, E)$ ; furthermore, this probability bound holds conditional on the full state of the system at times up to  $s$ .

By a limiting argument, it suffices to show this bound if we restrict to  $s \leq s_{\max}$  for arbitrary integer  $s_{\max}$ . For fixed  $s_{\max}$ , we show it by induction backward on  $s$ . The claim follows immediately from induction if  $f$  is not being resampled at time  $s$  or if  $s = s_{\max}$ . If  $E$  is true at time  $s$ , then  $\mathcal{E}_s$  is impossible (since  $(f, t)$  would have needed to be finalized at some earlier time  $s' < s$ ). Likewise, if there was an intervening time between  $t$  and  $s$  where  $f$  was false, then  $\mathcal{E}_s$  is impossible.

So, suppose we resample  $f$  at time  $s$  while  $E$  is false and  $f$  has remained true for times  $t, \dots, s$ . Let  $\tau \in f \cap \bar{E}$  be the state at time  $s$ . There are three things that can happen when resampling  $f$ :

- $E$  becomes true. This has probability  $e_{\tau}^{\top} A_f e_E$ . In this case, event  $\mathcal{E}_s$  may have occurred.
- $E$  remains false, and  $f$  becomes false. This has probability  $e_{\tau}^{\top} A_f e_{\bar{E} \cap \bar{f}}$ . In this case, event  $\mathcal{E}_s$  is impossible.
- $E$  becomes false, and  $f$  remains true. This has probability  $e_{\tau}^{\top} A_f e_{\bar{E} \cap f}$ . In this case, in order to  $\mathcal{E}_s$  to occur, it must be that  $\mathcal{E}_{s+1}$  holds after resampling  $f$ . By induction hypothesis, this has probability at most  $\kappa(f, E)$ .

Overall, we have  $\Pr(\mathcal{E}_s) \leq e_{\tau}^{\top} A_f e_E \cdot 1 + e_{\tau}^{\top} A_f e_{\bar{E} \cap f} \cdot \kappa(f, E)$ . This is at most  $\kappa(f, E) e_{\tau}^{\top} A_f e_{E \cup \bar{f}} + e_{\tau}^{\top} A_f e_{\bar{E} \cap f} \cdot \kappa(f, E) \leq \kappa(f, E)$ . This concludes the induction.

Now consider any good pair  $(f, t)$ . Because of the claim, we know that the probability that  $(f, t)$  is finalized (by any time  $s \geq t$ ) is at most  $\kappa(f, E)$ , conditional on all other state at time  $t$ . Since this is a necessary condition for  $E$  to become true, the overall probability that  $E$  becomes true is at most  $\mathbf{E}[L_f] \cdot \kappa(f, E)$ , where  $L$  is the number of good pairs  $(f, t)$ . Note that, between any good pairs  $(f, t)$  and  $(f, t')$  for  $t' > t$ , the event  $F \cap f$  is false at least once, where  $F$  is an arbitrary event with  $F \supseteq \bar{E}$ . However, at times  $t$  and  $t'$ , the event  $F \cap f$  is true. Thus,  $F \cap f$  is caused to become true at least  $L_f$  times, and so by Proposition 22, we have  $\mathbf{E}[L_f] \leq N_{\mathcal{G}}(F \cap f)$ .

## C Proof of Theorem 30 and Theorem 31

We begin by considering the setting where  $\Omega$  is the uniform distribution on the permutations  $\pi$  on  $[n]$ . The set  $\mathcal{A}$  is defined as follows: for each pair  $(x, y) \in [n] \times [n]$ , there is atom  $\pi x = y$ , which we denote by  $[x, y]$ . The resampling oracle here, for such an event, is to update the state  $\pi \leftarrow (y z)\pi$ , where  $z$  is uniformly drawn from  $[n]$ . (Here and throughout the section,  $(y z)$  denotes the permutation which swaps  $y$  and  $z$ .) We have  $[x, y] \sim [x', y']$  if exactly one

of the following holds: (i)  $x = x'$  or (ii)  $y = y'$ . Equivalently, this holds iff  $[x, y] \cap [x', y'] = \emptyset$ . See [15] for further details, including a proof that the resampling oracle is commutative and oblivious.

We begin with a basic observation on how atoms of  $\mathcal{A}$  interact with events in  $\bar{\mathcal{A}}$ .

► **Proposition 41.** *Let  $f = [x, y]$  be an atom and let  $E = \langle C \rangle$  where  $C$  is a stable set of  $\mathcal{A}$ . Then  $A_f e_E \propto e_{E'}$ , where  $E' = \langle C' \rangle$  and stable set  $C'$  is obtained from  $C$  as follows:*

- If  $C$  contains exactly two atoms  $f_1, f_2$  which are neighbors of  $f$ , i.e.  $f_1 = [x, y_1]$  and  $f_2 = [x_2, y]$ , then  $C' = C - \{f_1, f_2\} \cup \{[x, y], [x_2, y_1]\}$ .
- If  $C$  contains exactly one atom  $f_1$  which is a neighbor of  $f$ , then  $C' = C - f_1 \cup \{f\}$ .
- Otherwise, if  $C$  contains no neighbors of  $f$ , then  $C' = C \cup \{f\}$ .

**Proof.** Consider state  $\pi$ , and suppose we resample  $f$  to obtain  $\pi' = (y z)\pi$ . If  $\pi \notin f$ , then  $e_\pi^\top A_f e_E = 0 = e_\pi^\top e_{E'}$ . Similarly, for each  $f' \in C$  which is not a neighbor of  $f$ , we must have  $\pi \in f'$  as otherwise  $e_\pi^\top A_f e_E = 0 = e_\pi^\top e_{E'}$ . In these cases, we also automatically have  $\pi' \in f'$  for all such  $f'$ . Thus, we suppose that  $\pi \in f$  and also  $\pi \in f'$  for all  $f' \in C - \Gamma(f)$ . We consider the following cases in turn:

- If  $C$  contains two atoms  $f_1, f_2$ , then we claim that  $\pi' \in E$  precisely when  $z = y_1$  and  $\pi x_2 = y$ . For, in order to have  $\pi' \in f_1$ , we must have  $\pi' x = y_1$ . Since  $\pi x = y$ , this implies that  $(y z)y = y_1$ , i.e.  $z = y_1$ . Thus,  $\pi' = (y y_1)\pi$ . To satisfy  $f_2$ , we must have  $y = \pi' x_2 = (y y_1)\pi x_2$ , i.e.  $\pi x_2 = y$ . In this case, we see that  $e_\pi^\top A_f e_E = 1/n$  for all  $\pi$  and also  $e_\pi^\top e_{E'} = 1$ .
- Suppose that  $C$  contains a neighbor  $f_1 = [x, y_1]$ . In this case, we have  $\pi' \in f_1$  precisely if  $y_1 = z$ . Similarly, suppose that  $C$  contains a neighbor  $f_2 = [x_2, y]$ . In this case, we have  $\pi' \in f_2$  precisely if  $z = \pi x_2$ . Thus, we have  $e_\pi^\top A_f e_E = 1/n$  for all such  $\pi$  and also  $e_\pi^\top e_{E'} = 1$ .
- If  $C$  has no neighbors of  $f$ , then  $\pi'$  is in  $E$  iff  $z \notin \{y_1, \dots, y_k\}$  where  $C = \{[x_1, y_1], \dots, [x_k, y_k]\}$ . Thus  $e_\pi^\top A_f e_E = \frac{n-k}{n}$  and  $e_\pi^\top e_{E'} = 1$  ◀

To understand more complex, multi-atom interactions, let us fix event  $E = \langle C \rangle$  for a stable set  $C$ . For a stable set  $I \subseteq \mathcal{A}$ , we can form an associated bipartite graph  $G_I$ , as follows: the left vertices correspond to  $C$  (we call these  $C$ -nodes), and the right vertices correspond to  $I$  (we call these  $I$ -nodes). It has an edge between  $f$  and  $f'$  iff  $f \sim f'$ . Observe that since  $C$  and  $I$  are stable, the graph  $G_I$  has degree at most two – each node  $[x, y]$  can have one neighbor of the form  $[x', y]$  and another neighbor of the form  $[x, y']$ . So,  $G_I$  decomposes into paths and cycles.

We define  $\tau(I)$  to be the size of a maximum matching in  $G_I$ . We also define the *active conditions* for  $I$ , denoted  $\text{Active}(I) \subseteq \mathcal{A}$ , as follows. First, for each  $f \in I$ , we also place  $f$  into  $\text{Active}(I)$ . Second, consider some maximal path of  $G_I$  starting and ending at  $C$ -nodes (which we call a  $C$ -path). The path can be written (in one of its two orientations) as

$$[x_1, y_1], [x_1, y_2], [x_2, y_2], \dots, [x_k, y_{k-1}], [x_k, y_k].$$

In this case, we also put  $[x_k, y_1]$  into  $\text{Active}(I)$ . (It is possible that  $k = 1$ , in which case  $[x_1, y_1]$  is an isolated  $C$ -node.)

For brevity, we define  $\alpha(I)$  to be the event  $\langle \text{Active}(I) \rangle$  in  $\bar{\mathcal{A}}$ . The active conditions determine the vector  $A_I e_E$ , and also have a number of nice combinatorial properties.

► **Proposition 42.** *Let  $I$  be a stable set of  $\mathcal{A}$ . Then the following properties hold:*

1.  $A_I e_E \propto e_{\alpha(I)}$ .
2.  $|\text{Active}(I)| = |C| + |I| - \tau(I)$ .
3. Any  $f \in I$  with  $\tau(I) = \tau(I - f)$  has  $\text{Active}(I) = \text{Active}(I - f) \cup \{f\}$ .

**Proof.**

1. We show this by induction on  $I$ . The base case  $I = 0$  is clear, since then  $\text{Active}(I) = C$ . For the induction step, consider  $f \in I$ . We have  $A_I e_E = A_f A_{I-f} e_E$ ; by induction hypothesis, this is proportional to  $A_f e_{\langle U \rangle}$  where  $U = \text{Active}(I - f)$ . By Proposition 41, this in turn is proportional to  $e_{\langle U' \rangle}$ , where  $U'$  is formed according to the specific given rules. We thus need to show that  $U' = \text{Active}(I)$ . There are three cases.  
 If  $U$  has no neighbors of  $f$ , then  $U' = U \cup \{f\}$ . Furthermore,  $G_I$  has no changes in its  $C$ -paths compared to  $G_{I-f}$ , so  $\text{Active}(I) = \text{Active}(I - f) \cup \{f\} = U'$ .  
 Next suppose  $U$  has one neighbor  $f' = [x', y']$  of  $f$ . Since  $I$  is a stable set, it must have  $f' \notin I$ , i.e.  $G_{I-f}$  contains a  $C$ -path with endpoints  $x', y'$ . This  $C$ -path now terminates in a degree-one  $I$ -node  $[x, y]$  in  $G_I$ , and hence it is removed from  $G_I$ . So  $\text{Active}(I) = \text{Active}(I - f) - f' \cup \{f\} = U'$ .  
 Finally, If  $U$  has two neighbors  $f_1 = [x, y_1], f_2 = [x_2, y]$ , then again since  $I$  is a stable set these must correspond to  $C$ -paths in  $G_{I-f}$ . Thus, there are two  $C$ -paths with endpoints  $x, y_1$  and  $x_2, y$  respectively. Now in  $G_I$ , there is a new degree-two  $I$ -node  $[x, y]$ . This merges the two  $C$ -paths into a single new  $C$ -path with endpoints  $x_2, y_1$ . Thus again  $\text{Active}(I) = \text{Active}(I - f) - \{f_1, f_2\} \cup \{f, [x_2, y_1]\} = U'$ .
2. Consider some connected component of  $G_I$ ; it is a path or cycle with  $i$  distinct  $I$ -nodes and  $c$  distinct  $C$ -nodes, where  $c \in \{i - 1, i, i + 1\}$ . If  $c = i - 1$ , then it has maximum matching size  $t = i - 1$  else it has maximum matching size  $t = i$ . If  $c = i + 1$ , then it has one additional active condition corresponding to the  $C$ -path on its nodes, and thus has  $a = i + 1$  active conditions; else it has  $a = i$  active conditions. In all cases, it can be checked that  $a = c + i - t$ . The claimed formula is obtained by summing over all components.
3. By part (2), we have  $\tau(I) = \tau(I - f)$  precisely if  $|\text{Active}(I)| = |\text{Active}(I - f)| + 1$ , i.e.  $G_I$  has the same number of  $C$ -paths as  $G_{I-f}$ . We claim in this case that  $G_I$  has the same  $C$ -paths as  $G_{I-f}$  as well, which will show the claim.  
 For, if not, then  $G_I$  would need to gain, and lose, some  $C$ -paths compared to  $G_{I-f}$ . The new  $I$ -node  $[x, y]$  would need to participate in a new  $C$ -path. This can only occur if  $G_{I-f}$  has two  $C$ -paths with endpoints  $[x, y']$  and  $[x', y]$ . But in this case, these two existing  $C$ -paths get destroyed in  $G_I$ , and thus in fact  $G_I$  has strictly fewer  $C$ -paths compared to  $G_{I-f}$ .  $\blacktriangleleft$

► **Proposition 43.** *Let  $I = \{f_1, \dots, f_k\}$  be a stable set in  $\bar{\mathcal{A}}$ , where  $f_i = \langle F_i \rangle$  for each  $i$ . Consider the stable sets  $J' = F_1 \cup \dots \cup F_{k-1}$  and  $J = J' \cup F_k$  of  $\mathcal{A}$ . If  $\tau(J') = \tau(J)$ , then  $f_k$  is dominated by  $I - f_k$  in  $\bar{\mathcal{A}}$ .*

**Proof.** Let  $I' = \{f_1, \dots, f_{k-1}\}$ . It is easily seen that the permutation LLL setting is idempotent. Thus, by Proposition 39, we have  $A_{I'} \propto A_{J'}$ . Combined with Proposition 42(1), this implies that there is some scalar value  $p \geq 0$  such that  $A_{I'} e_E = p e_{\alpha(J')}$ . We want to show that

$$e_{\pi}^{\top} A_I e_E \leq e_{\pi}^{\top} A_{I'} e_E \tag{4}$$

for any state  $\pi$ .

By Proposition 39, we have  $A_I \propto A_J$ . Thus, the LHS of Eq. (4) is zero if  $\pi \notin \alpha(J)$ , in which case the inequality clearly holds. So suppose that  $\pi \in \alpha(J)$ . By Proposition 42(3), we have  $\text{Active}(J') \subseteq \text{Active}(J)$  since  $\tau(J') = \tau(J)$ . In this case, also  $\pi \in \alpha(J')$  so the RHS of Eq. (4) is equal to  $p$ . The LHS can be factored as  $e_{\pi}^{\top} A_I e_E = \sum_{\sigma} A_f[\pi, \sigma] \cdot e_{\sigma}^{\top} A_{I'} e_E = \sum_{\sigma \in \alpha(J')} A_f[\pi, \sigma] p$ . Since matrix  $A_f$  is substochastic, this is at most  $p$ . This establishes the desired inequality.  $\blacktriangleleft$

► **Proposition 44.** *For any  $I \in \mathfrak{D}(E)$ , there is an injective function  $\phi_I : I \rightarrow C$  with  $g \sim \phi_I(g)$  for all  $g \in I$ .*

**Proof.** By definition,  $I$  can be ordered as  $I = \{f_1, \dots, f_k\}$ , where  $f_i = \langle F_i \rangle$  and such that each  $f_i$  is not dominated by  $\{f_1, \dots, f_{i-1}\}$ . Let us define  $J_i = F_1 \cup \dots \cup F_i$  for each  $i$ . By Proposition 43, we must have  $\tau(J_i) > \tau(J_{i-1})$  for each  $i$ . Thus, for each  $i$ , there is some  $g_i \in F_i - J_{i-1}$  and some  $F'_i \subseteq F_i - \{g_i\}$  with  $\tau(J_{i-1} \cup F'_i \cup \{g_i\}) > \tau(J_{i-1} \cup F'_i)$ . It is known (see, e.g. [24, Example 1.4]) that  $\tau$  is a submodular set function. Hence, we have

$$1 = \tau(J_{i-1} \cup F'_i \cup \{g_i\}) - \tau(J_{i-1} \cup F'_i) \leq \tau(\{g_1, \dots, g_{i-1}\} \cup \{g_i\}) - \tau(\{g_1, \dots, g_{i-1}\})$$

since  $\{g_1, \dots, g_{i-1}\} \subseteq J_{i-1}$ .

This implies that  $\tau(\{g_1, \dots, g_k\}) = k$  and  $G_{\{g_1, \dots, g_k\}}$  has a matching  $M$  of size  $k$ . We define the function  $\phi$  by setting  $\phi(f_i) = c_i$  where  $g_i$  is matched to  $c_i$  in  $M$ . ◀

We can now obtain Theorem 30.

**Proof of Theorem 30.** Clearly  $\mu(E) = \frac{(n-k)!}{n!}$ . To enumerate a set  $I \in \mathfrak{D}(E)$ , by Proposition 44, we choose, for each  $g \in C$ , either zero or one preimages  $f = \phi_I^{-1}(g)$  in  $I$ . If we write  $I_g$  for the set of preimages of  $g$ , then  $|I_g| \leq 1$  for all  $g$  and  $I = \bigcup_{g \in C} I_g$ . Overall, this shows that

$$\sum_{I \in \mathfrak{D}(E)} \Psi(I) \leq \sum_{I_{g_1}, \dots, I_{g_k}} \Psi(I_{g_1} \cup \dots \cup I_{g_k}) \leq \sum_{I_{g_1}, \dots, I_{g_k}} \Psi(I_{g_1}) \cdots \Psi(I_{g_k})$$

where the last inequality follows from log-subadditivity of  $\Psi$ . This can be written as  $\prod_{i=1}^k \sum_{I_{g_i}} \Psi(I_{g_i})$ . The case of  $I_{g_i} = \emptyset$  contributes 1, and the case of  $I_{g_i} = \{f\}$  contributes  $\Psi(f)$ . ◀

We next consider the setting where  $\Omega$  is the set of perfect matchings  $M$  on the clique on vertex set  $[n]$ , where  $n$  is an even integer. The set  $\mathcal{A}$  is defined as follows: for each pair  $(x, y) \in [n] \times [n]$  with  $x \neq y$ , there is an atomic event that  $M \supseteq \{x, y\}$ . We denote this event by  $[x, y]$ ; note that  $[x, y] = [y, x]$ , which is different from the permutation setting. The resampling oracle, for such an event with  $x < y$ , is to update the state by drawing  $z$  uniformly from  $[n] - x$  and setting  $M \leftarrow (y z)M$ . Here, we are using the natural left-group action of permutations on matchings, i.e.  $\sigma M = \{\{\sigma x', \sigma y'\} \mid \{x', y'\} \in M\}$ .

We have  $[x, y] \sim [x', y']$  if  $|\{x, y\} \cap \{x', y'\}| = 1$ . Equivalently, this holds iff  $[x, y] \cap [x', y'] = \emptyset$ . See [15] for further details, including a proof that this resampling oracle is commutative and oblivious.

As before, we begin with a basic observation on how atoms of  $\mathcal{A}$  interact with events in  $\overline{\mathcal{A}}$ .

► **Proposition 45.** *Let  $f = [x, y]$  be an atom and let  $E = \langle C \rangle$  where  $C$  is a stable set of  $\mathcal{A}$ . Then  $A_f e_E \propto e_{E'}$ , where  $E' = \langle C' \rangle$  and stable set  $C'$  is obtained from  $C$  as follows:*

- *If  $C$  contains exactly two atoms  $f_1, f_2$  which are neighbors of  $f$ , i.e.  $f_1 = [x, y_1]$  and  $f_2 = [x_2, y]$ , then  $C' = C - \{f_1, f_2\} \cup \{[x, y], [x_2, y_1]\}$ .*
- *If  $C$  contains exactly one atom  $f_1$  which is a neighbor of  $f$ , then  $C' = C - f_1 \cup \{f\}$ .*
- *Otherwise, if  $C$  contains no neighbors of  $f$ , then  $C' = C \cup \{f\}$ .*

**Proof.** Consider state  $M \in f$ , and suppose we resample  $f$  to  $M' = (y z)M$  where  $z$  is drawn from  $[n] - x$ . For each  $f' \in C$  which is not a neighbor of  $f$ , we must have  $M \in f'$  as otherwise  $e_M^\top A_f e_E = 0 = e_M^\top e_{E'}$ . In these cases, we also automatically have  $M' \in f'$  for all such  $f'$ . Thus, we suppose that  $M \in f$  and also  $M \in f'$  for all  $f' \in C - \Gamma(f)$ . We consider the following cases:

- Suppose that  $C$  contains two atoms  $f_1, f_2$ . Then we claim that  $M' \in E$  precisely when  $z = y_1$  and  $\{x_2, y\} \in M$ . First, we have  $\{x, y_1\} \in M'$  with  $M' = (y z)M$  iff  $z = y_1$ . Thus,  $M' = (y y_1)M$ . To satisfy  $f_2$ , we must have  $\{x_2, y_1\} \in M$ . In this case,  $e_M^\top A_f e_E = 1/(n-1)$  and also  $e_M^\top e_{E'} = 1$ .
- Suppose that  $C$  contains a neighbor  $f_1 = [x, y_1]$ . In this case, we have  $M' \in f_1$  precisely if  $y_1 = z$ . Thus, we have  $e_M^\top A_f e_E = 1/(n-1)$  and also  $e_M^\top e_{E'} = 1$ .
- Suppose  $C$  has no neighbors of  $f$ . Let  $C = \{[x_1, x_2], \dots, [x_{2k-1}, x_{2k}]\}$ ; we have  $M \in E'$  precisely if  $z \notin \{x_1, \dots, x_{2k}\}$ . Since  $z \neq x$ , we thus have  $e_M^\top A_f e_E = \frac{n-2k+1}{n-1}$ . We also have  $e_M^\top e_{E'} = 1$ . ◀

To understand multi-atom interactions, let us fix event  $E = \langle C \rangle$  for a stable set  $C$ . For a stable set  $I \subseteq \mathcal{A}$ , we can form an associated bipartite graph  $G_I$ , whose left vertices correspond to  $C$  and whose right vertices correspond to  $I$ . It has an edge between  $f$  and  $f'$  iff  $f \sim f'$ . Observe that since  $C$  and  $I$  are stable, the graph  $G_I$  has degree at most two – each node  $[x, y]$  can have one neighbor of the form  $[x', y]$  and another neighbor of the form  $[x, y']$ . So,  $G_I$  decomposes into paths and cycles.

We define  $\tau(I)$  to be the size of a maximum matching in  $G_I$ . We also define  $\text{Active}(I) \subseteq \mathcal{A}$  as follows. First, for each  $f \in I$ , we also place  $f$  into  $\text{Active}(I)$ . Second, consider some maximal path of  $G_I$  starting and ending at  $C$ -nodes; the path can be written as  $[x_1, x_2], [x_2, x_3], \dots, [x_{k-1}, x_k]$  for even  $k$ . In this case, we also put  $[x_1, x_k]$  into  $\text{Active}(I)$ .

► **Proposition 46.** *Let  $I$  be a stable set of  $\mathcal{A}$ . Then the following properties hold:*

1.  $A_I e_E \propto e_{\alpha(I)}$  where  $\alpha(I) = \langle \text{Active}(I) \rangle$ .
2.  $|\text{Active}(I)| = |C| + |I| - \tau(I)$ .
3. Any  $f \in I$  with  $\tau(I) = \tau(I - f)$  has  $\text{Active}(I) = \text{Active}(I - f) \cup \{f\}$ .

We omit the the proof of Proposition 44, as well as the remainder of the proof of Theorem 31, as they are precisely analogous to the proof of Theorem 30.

# From Coupling to Spectral Independence and Blackbox Comparison with the Down-Up Walk

## Abstract

---

We show that the existence of a “good” coupling w.r.t. Hamming distance for any local Markov chain on a discrete product space implies rapid mixing of the Glauber dynamics in a blackbox fashion. More specifically, we only require the expected distance between successive iterates under the coupling to be summable, as opposed to being one-step contractive in the worst case. Combined with recent local-to-global arguments [16], we establish asymptotically optimal lower bounds on the standard and modified log-Sobolev constants for the Glauber dynamics for sampling from spin systems on bounded-degree graphs when a curvature condition [44] is satisfied. To achieve this, we use Stein’s method for Markov chains [10, 46] to show that a “good” coupling for a local Markov chain yields strong bounds on the spectral independence of the distribution in the sense of [6].

Our primary application is to sampling proper list-colorings on bounded-degree graphs. In particular, combining the coupling for the flip dynamics given by [49, 13] with our techniques, we show optimal  $O(n \log n)$  mixing for the Glauber dynamics for sampling proper list-colorings on any bounded-degree graph with maximum degree  $\Delta$  whenever the size of the color lists are at least  $(\frac{11}{6} - \epsilon) \Delta$ , where  $\epsilon \approx 10^{-5}$  is small constant. While  $O(n^2)$  mixing was already known before, our approach additionally yields Chernoff-type concentration bounds for Hamming Lipschitz functions in this regime, which was not known before. Our approach is markedly different from prior works establishing spectral independence for spin systems using spatial mixing [6, 14, 15, 30], which crucially is still open in this regime for proper list-colorings.

## 1 Introduction

Given a probability distribution  $\mu$  on a collection of subsets of a finite universe  $U$  with a fixed size  $n$ , one would like to generate (approximate) samples from  $\mu$ . This problem is widely encountered in machine learning, statistical physics, and theoretical computer science, and encompasses many problems as special cases, including distributions over bases of matroids, discrete probabilistic graphical models, etc. A popular approach used in practice is to run a Markov chain on  $\text{supp}(\mu)$  whose stationary distribution is  $\mu$ . The main question then becomes how quickly does the distribution of the Markov chain converge to stationarity, i.e. does it mix rapidly?

A particularly natural Markov chain known as the “down-up walk” (or “high-order walk”) originally studied in the high-dimensional expander community [39, 21, 40, 45, 1] has recently received a lot of attention due to applications to sampling from discrete log-concave

distributions [4, 18, 3, 5] and spin systems in statistical physics [1, 6, 14, 15, 30, 2, 16]. For sampling bases of matroids, the down-up walk recovers exactly the bases exchange walk first studied in [29, 43], and for sampling from discrete graphical models, the down-up walk recovers exactly the classical Glauber dynamics. One of the main insights in this area is that to prove rapid mixing of the down-up walk, it suffices to look only at pairwise correlations between elements, albeit for all conditional distributions of  $\mu$  (see Definition 13). One additional advantage behind this approach is that one can prove local-to-global results not just for the spectral gap [40, 1], but also for the rate of entropy decay [18, 34, 16] and even for the rate of decay for arbitrary  $f$ -divergences [2]. This has led to asymptotically optimal mixing times for many problems [18, 5, 16] as well as Chernoff-type concentration bounds for Lipschitz functions.

However, establishing sufficiently strong bounds on pairwise correlations (or, more precisely, pairwise influences; see Definition 13), remains a challenging problem. Prior works typically rely on one of three techniques: Oppenheim’s trickle-down theorem [45, 4], spatial mixing (or correlation decay) [6, 14, 15, 30, 16], or the absence of roots for the multivariate generating polynomial of  $\mu$  in a sufficiently large region of the complex plane [2, 17]. However, there are settings, such as proper list-colorings when the number of colors is less than twice the maximum degree of the graph, where the trickle-down theorem fails, and where spatial mixing and the existence of a nice root-free region are not known.

In this work, we show that the classical technique of (path) coupling can be used to bound these pairwise correlations. In fact, we will show that the existence of a “good” coupling for **any** sufficiently “local” dynamics with stationary distribution  $\mu$  implies spectral independence for  $\mu$  in the sense of [6], and hence, rapid mixing of the down-up walk. Hence, one can view our main result as a blackbox comparison result between any local Markov chain and the down-up walk.

As our main concrete application, we use the variable-length path coupling devised by [13] for the flip dynamics, building off work of Vigoda [49], to show  $O(n \log n)$  mixing of the Glauber dynamics for sampling proper list-colorings on graphs of maximum degree  $\Delta \leq O(1)$  whenever the number of available colors is at least  $(\frac{11}{6} - \epsilon) \Delta$ , where  $\epsilon \approx 10^{-5}$  is a small constant. This mixing time is asymptotically optimal [36]. While  $O(n^2)$  mixing was known earlier [31] (see also [49, 13]) by using a spectral gap comparison argument [19], our approach yields optimal bounds on the rate of entropy decay as well as Chernoff-type concentration inequalities. As mentioned earlier, strong spatial mixing and the existence of sufficiently large root-free regions are not known in this regime for proper list-colorings. Along the way, we make an additional conceptual contribution by answering the natural question of if Dobrushin-type mixing conditions imply spectral independence.

## 1.1 Our Contributions

To state our blackbox comparison result, let us first define the down-up walk for sampling from distributions over homogeneous set systems. We eschew the use of much of the terminology of high-dimensional expanders so as to simplify the exposition. Let  $\mu$  be a distribution over  $\binom{U}{n} = \{S \subseteq U : |S| = n\}$  for a finite set  $U$  and a positive integer  $n \geq 1$ <sup>1</sup>. The down-up walk

---

<sup>1</sup> One can view  $\mu$  as being a distribution over the facets of a “pure simplicial complex” weighted by  $\mu$ . These are a generalization of usual graphs which are studied in geometry, topology, and combinatorics. The notion of spectral independence (Definition 13) was derived from a high-dimensional notion of “expansion” for simplicial complexes known as “local spectral expansion” first discovered by [21, 40, 45].

is described by the following two-step process. If the current state of the chain is  $S^{(t)}$ , then we select the next state  $S^{(t+1)}$  as follows:

1. Select a uniformly random element  $i \in S$ .
2. Sample a set  $S \in \text{supp}(\mu)$  satisfying  $S \supseteq S^{(t)} \setminus \{i\}$  with probability proportional to  $\mu(S)$  and transition to  $S^{(t+1)} = S$ .

As special cases, this class of Markov chains includes the bases exchange walk for matroids [43] and the Glauber dynamics for distributions over discrete product spaces.

We also define our notion of a “good” coupling and locality precisely here.

► **Definition 1 (Amortized Convergent Coupling).** Fix an irreducible transition probability matrix  $P$  which is reversible w.r.t. a distribution  $\pi$  on a finite state space  $\Omega$ . Further endow  $\Omega$  with a metric  $d(\cdot, \cdot)$ . We say a coupling of two faithful copies of the chain  $(X^{(t)})_{t \geq 0}, (Y^{(t)})_{t \geq 0}$  is  **$C$ -amortized convergent w.r.t.  $d(\cdot, \cdot)$**  if the following holds for all  $x, y \in \Omega$ :

$$\sum_{t=0}^{\infty} \mathbb{E}_{X^{(t)}, Y^{(t)}} \left[ d(X^{(t)}, Y^{(t)}) \mid \begin{matrix} X^{(0)}=x \\ Y^{(0)}=y \end{matrix} \right] \leq C \cdot d(x, y).$$

► **Definition 2 (Locality of Dynamics).** Fix an irreducible transition probability matrix  $P$  which is reversible w.r.t. a distribution  $\pi$  on a finite state space  $\Omega$ . Further endow  $\Omega$  with a metric  $d(\cdot, \cdot)$ . For a positive real number  $\ell > 0$ , we say the dynamics  $P$  is  **$\ell$ -local w.r.t.  $d(\cdot, \cdot)$**  if

$$\max_{x, y \in \Omega: P(x, y) > 0} d(x, y) \leq \ell.$$

Throughout the paper, unless stated otherwise, we work with Hamming distance. With these notions in hand, we now state our blackbox comparison result.

► **Theorem 3 (Blackbox Comparison with Down-Up Walk).** Let  $\mu$  be a distribution on  $\binom{U}{n}$ , where  $U$  is a finite universe and  $n \geq 1$  is a positive integer. For each  $A \subseteq U$  with  $|A| \leq n-2$  and  $A \subseteq S$  for some  $S \in \text{supp}(\mu)$ , let  $P_{\mu|A}$  be some Markov chain on  $\text{supp}(\mu \mid A)$  with stationary distribution  $\mu \mid A$ . Assume the family of Markov chains  $\{P_{\mu|A}\}$  satisfy the following:

1. *Locality:* For some  $\ell \geq 0$ ,  $P_{\mu|A}$  is  $\ell$ -local w.r.t. Hamming distance for all  $A$ .
2. *Good Coupling:* For some  $C_{n-k} > 0$ ,  $P_{\mu|A}$  admits a  $C_{n-k}$ -amortized convergent coupling w.r.t. Hamming distance for all  $k$  and  $A$  with  $|A| = k$ .
3. *Bounded Differences Between Chains:* For some  $C'_{n-k} > 0$ , we have the bound

$$\max_{S \in \text{supp}(\mu \mid (A \cup i))} \left\{ \sum_{T \neq S} |P_{\mu|A}(S \rightarrow T) - P_{\mu|(A \cup i)}(S \rightarrow T)| \right\} \leq C'_{n-k},$$

for all  $k, i$  and  $A$  with  $|A| = k$ .

If  $\ell \cdot C_{n-k} \cdot C'_{n-k} \leq O(1)$  for all  $k$ , then the down-up walk has spectral gap at least  $n^{-O(1)}$ . If, in addition,  $\mu$  is the Gibbs distribution of a spin system (see Section 2.1) on a bounded-degree graph, then the spectral gap, standard and modified log-Sobolev constants Equation (4) for the down-up walk are all  $\Omega(1/n)$ .

We refer the reader to Section A and references therein for the importance of lower bounding the spectral gap, standard and modified log-Sobolev constants, and in particular, their relation to mixing and concentration.

► **Remark 4.** While initially it may seem inconvenient to first build an entire family of Markov chains, one for each conditional distribution, this is very natural for many classes of distributions, in particular those which are closed under conditioning. As we will see, in practice, it is easy to obtain bounded differences between chains with  $C'_{n-k} \lesssim \frac{1}{n-k}$  simply via brute force calculation. While  $C_{n-k} \gtrsim n-k$  is often unavoidable, particularly for  $\ell$ -local chains with  $\ell \leq O(1)$ , we will see that in many settings, we have  $C_{n-k} \lesssim n-k$  as well. If additionally our dynamics are  $\ell$ -local with  $\ell \leq O(1)$ , then the above yields a  $n^{-O(1)}$  spectral gap for the down-up walk. It will turn out that our notion of  $\ell$ -locality can also be relaxed; see Remark 10.

Our primary concrete application is to sampling proper list-colorings on graphs via the Glauber dynamics, which may be realized as a down-up walk. In this setting, we compare with another useful Markov chain known as the flip dynamics. The flip dynamics is  $\ell$ -local w.r.t. unweighted Hamming distance with  $\ell \leq 12$ , and was analyzed in [49], who gave a greedy coupling which is one-step contractive whenever the number of available colors is at least  $\frac{11}{6}\Delta$ , implying it is  $C$ -amortized convergent with  $C \leq O(n)$ . [13] tweaked the parameters of the flip dynamics slightly while preserving locality, and further constructed a variable-length coupling which contracts by a constant factor every expected  $O(n)$  steps whenever the number of available colors is at least  $(\frac{11}{6} - \epsilon)\Delta$  for a small constant  $\epsilon \approx 10^{-5}$ . We will show this variable-length coupling is also  $C$ -amortized convergent with  $C \leq O(n)$ , and deduce optimal mixing for list-colorings in this regime.

► **Theorem 5.** *Let  $(G, \mathcal{L})$  be a list-coloring instance where  $G = (V, E)$  is a graph of maximum degree  $\Delta \leq O(1)$  and  $\mathcal{L} = (L(v))_{v \in V}$  is a collection of color lists. Then for some absolute constant  $\epsilon \approx 10^{-5}$ , if  $|L(v)| \geq (\frac{11}{6} - \epsilon)\Delta$  for all  $v \in V$ , then the uniform distribution over proper list-colorings for  $(G, \mathcal{L})$  is  $(\eta_0, \dots, \eta_{n-2})$ -spectrally independent where  $\eta_k \leq O(1)$  for all  $k$ . Furthermore, the spectral gap, standard and modified log-Sobolev constants Equation (4) for the Glauber dynamics are all  $\Omega(1/n)$ , and the mixing time is  $O(n \log n)$ .*

► **Remark 6.** Our running time dependence on  $\Delta$  is roughly  $\Delta^{O(\Delta^c)}$  for a mild constant  $c$ , which is rather poor. The main bottleneck in improving this dependence lies in the local-to-global result of [16], although our spectral independence bound, which depends polynomially on  $\Delta$ , can also be significantly improved.

To prove Theorem 3, we leverage recent local-to-global results [1, 16] (see Theorems 14 and 15 for formal statements), which show that if one has sufficiently strong upper bounds on the total pairwise correlation  $\sum_{j \in U} |\Pr_{S \sim \mu}[j \in S] - \Pr_{S \sim \mu|i}[j \in S]|$ , then one can deduce rapid mixing for the down-up walk [39, 21, 40, 45]. To upper bound these correlations, we considerably generalize a result simultaneously due to [10, 46], which was discovered in the context of bounding the Wasserstein 1-distance between Ising models, or more generally, two measures on the discrete hypercube  $\{-1, +1\}^n$ . More specifically, we extend their results in several different directions:

1. We replace the Glauber dynamics by any local dynamics.
2. We allow the dynamics to admit a coupling which in a sense “contracts on average”, as opposed to a step-wise contraction in the worst-case.

► **Theorem 7.** *Let  $\mu$  be a distribution on  $\binom{U}{n}$ , where  $U$  is some finite universe and  $n \geq 1$  is a positive integer. Fix an arbitrary  $i \in U$ . Let  $P_\mu$  (resp.  $P_{\mu|i}$ ) be the transition kernel of any irreducible Markov chain on  $\text{supp}(\mu)$  (resp.  $\text{supp}(\mu | i)$ ) which is reversible w.r.t.  $\mu$  (resp.  $\text{supp}(\mu | i)$ ). Suppose that  $P_\mu$  is  $\ell$ -local and admits a  $C$ -amortized convergent coupling, both*

w.r.t. the Hamming metric  $d_H(\cdot, \cdot)$ . Then we have the bound

$$\sum_{j \in U} \left| \Pr_{S \sim \mu} [j \in S] - \Pr_{S \sim \mu|i} [j \in S] \right| \leq C \cdot \ell \cdot \max_{S \in \text{supp}(\mu|i)} \left\{ \sum_{T \neq S} |P_\mu(S \rightarrow T) - P_{\mu|i}(S \rightarrow T)| \right\}.$$

## 1.2 Main Technical Result

We now state our main technical result, which provides the most general bound on the difference between marginals of two distributions  $\mu, \nu$ . We immediately use it to deduce Theorem 7.

► **Theorem 8 (Main Technical).** *Let  $\mu, \nu$  be any two distributions on  $2^U$  for a finite set  $U$  with  $\text{supp}(\nu) \subseteq \text{supp}(\mu)$ , where  $U$  is a finite universe and  $n \geq 1$  is a positive integer. Further, let  $P_\mu$  (resp.  $P_\nu$ ) be the transition kernel of any Markov chain on  $\text{supp}(\mu)$  (resp.  $\text{supp}(\nu)$ ) with stationary distribution  $\mu$  (resp.  $\nu$ ). Assume  $P_\mu$  is irreducible and reversible w.r.t.  $\mu$ . Then we may bound both  $\sum_{j \in U} |\Pr_{S \sim \mu}[j \in S] - \Pr_{S \sim \nu}[j \in S]|$  and the 1-Wasserstein distance  $W_1(\mu, \nu)$  (see Definition 11) by the following quantity:*

$$\mathbb{E}_{S \sim \nu} \left[ \sum_{T \neq S} |P_\mu(S \rightarrow T) - P_\nu(S \rightarrow T)| \cdot \sum_{t=0}^{\infty} \mathbb{E}_{X^{(t)}, Y^{(t)}} \left[ d_H(X^{(t)}, Y^{(t)}) \mid \begin{matrix} X^{(0)}=S \\ Y^{(0)}=T \end{matrix} \right] \right],$$

where  $(X^{(t)}, Y^{(t)})_{t=0}^{\infty}$  is a coupling of the Markov chain  $P_\mu$ .

► **Remark 9.** The technical condition  $\text{supp}(\nu) \subseteq \text{supp}(\mu)$  is just for convenience, as it ensures the transition probability  $P_\mu(S \rightarrow T)$  also makes sense when  $S \sim \nu$ . This assumption is certainly satisfied in our application where  $\nu$  is a conditional distribution of  $\mu$ .

**Proof of Theorem 7.** We use Theorem 8 with  $\nu = \mu | i$  to obtain the upper bound

$$\begin{aligned} & \mathbb{E}_{S \sim \mu|i} \left[ \sum_{T \neq S} |P_\mu(S \rightarrow T) - P_{\mu|i}(S \rightarrow T)| \cdot \sum_{t=0}^{\infty} \mathbb{E}_{X^{(t)}, Y^{(t)}} \left[ d_H(X^{(t)}, Y^{(t)}) \mid \begin{matrix} X^{(0)}=S \\ Y^{(0)}=T \end{matrix} \right] \right] \\ & \leq \max_{S \in \text{supp}(\mu|i)} \left\{ \sum_{T \neq S} |P_\mu(S \rightarrow T) - P_{\mu|i}(S \rightarrow T)| \right\} \\ & \quad \cdot \underbrace{\mathbb{E}_{S \sim \mu|i} \left[ \max_{T: P_\mu(S \rightarrow T) > 0} \sum_{t=0}^{\infty} \mathbb{E}_{X^{(t)}, Y^{(t)}} \left[ d_H(X^{(t)}, Y^{(t)}) \mid \begin{matrix} X^{(0)}=S \\ Y^{(0)}=T \end{matrix} \right] \right]}_{(*)}. \end{aligned}$$

It suffices to bound  $(*)$  by  $C \cdot \ell$ . Since  $P_\mu$  admits a  $C$ -amortized convergent coupling, we have that

$$\sum_{t=0}^{\infty} \mathbb{E}_{X^{(t)}, Y^{(t)}} \left[ d_H(X^{(t)}, Y^{(t)}) \mid \begin{matrix} X^{(0)}=S \\ Y^{(0)}=T \end{matrix} \right] \leq C \cdot d_H(S, T).$$

Hence,

$$(*) \leq C \cdot \mathbb{E}_{S \sim \mu|i} \left[ \max_{T: P_\mu(S \rightarrow T) > 0} d_H(S, T) \right] \leq C \cdot \ell. \quad \blacktriangleleft$$

► Remark 10. One can see from the proof that we only needed that

$$\mathbb{E}_{S \sim \mu | i} \left[ \max_{T: P_\mu(S \rightarrow T)} d_H(S, T) \right] \leq \ell,$$

as opposed to the stronger notion of  $\ell$ -locality, where we have  $\max_{S, T: P_\mu(S \rightarrow T)} d_H(S, T) \leq \ell$ . Thus, in some sense, we only need the dynamics to make local moves “on average”. We leave it to future work to exploit this additional flexibility.

### 1.3 Independent Work

The results we obtain here were also independently discovered in [7].

### 1.4 Organization of the Paper

We state preliminaries on spin systems, spectral independence, etc. in Section 2. We then move to the proof of our main technical result (Theorem 8) in Section 3. In Section 4, we apply our techniques to distributions on discrete product spaces. In Section 5, we combine our techniques with couplings constructed in prior works to obtain spectral independence for proper list-colorings.

## 2 Preliminaries

For a positive integer  $n \geq 1$ , we write  $[n] = \{1, \dots, n\}$ . For a distribution  $\mu$  on some finite state space  $\Omega$ , we write  $\text{supp}(\mu) = \{x \in \Omega : \mu(x) > 0\}$  for the support of  $\mu$ . For a matrix  $A$ , we write  $\|A\|_\infty = \max_i \sum_j |A(i, j)|$  for the maximum absolute row sum, and if  $A$  has real eigenvalues, we write  $\lambda_{\max}(A)$  for the largest eigenvalue of  $A$ .

Throughout, we write  $G = (V, E)$  for an undirected graph, and we will write  $\Delta$  for the maximum degree of  $G$ . For a finite universe  $U$  and  $S \subseteq U$ , we write  $\mathbb{I}_S$  for the  $\{0, 1\}$ -indicator function of  $S$ ; for an element  $j \in U$ , we write  $\mathbb{I}_j$  as opposed to  $\mathbb{I}_{\{j\}}$ . If  $\mu$  is a distribution over  $\binom{U}{n}$  and  $S \subseteq U$ , then we write  $\mu | S$  for the conditional distribution of  $\mu$  on  $\binom{U \setminus S}{n - |S|}$ , where  $(\mu | S)(T) \propto \mu(S \cup T)$  whenever  $S \cup T \in \text{supp}(\mu)$ ,  $S \cap T = \emptyset$ , and  $(\mu | S)(T) = 0$  otherwise.

We will measure convergence of our Markov chains using total variation distance, defined as

$$d_{\text{TV}}(\mu, \nu) = \frac{1}{2} \sum_x |\mu(x) - \nu(x)| = \sup_{S \subseteq \Omega} |\mu(S) - \nu(S)|$$

for two distributions  $\mu, \nu$  on a common state space  $\Omega$ . We define the  $\epsilon$ -mixing time of a Markov chain  $P$  on a state space  $\Omega$  with stationary distribution  $\pi$  as

$$t_{\text{mix}}(\epsilon) \stackrel{\text{def}}{=} \max_{x \in \Omega} \min\{t \geq 0 : d_{\text{TV}}(\mathbb{I}_x P^t, \pi) \leq \epsilon\}.$$

The mixing time of the chain is defined as  $t_{\text{mix}}(1/4)$ . For the reader’s convenience, in Section A, we record the relation between mixing, spectral gap, modified and standard log-Sobolev constants. Finally, we also define the 1-Wasserstein distance.

► **Definition 11** (1-Wasserstein Distance). *Given two probability measures  $\mu, \nu$  on a common state space  $\Omega$  endowed with a metric  $d(\cdot, \cdot)$ , we define the 1-Wasserstein distance  $W_1(\mu, \nu)$  w.r.t.  $d(\cdot, \cdot)$  by*

$$W_1(\mu, \nu) = \sup_f |\mathbb{E}_\mu f - \mathbb{E}_\nu f|,$$

where the supremum is over functions  $f : \Omega \rightarrow \mathbb{R}$  which are 1-Lipschitz w.r.t.  $d(\cdot, \cdot)$  (i.e.  $|f(x) - f(y)| \leq d(x, y)$  for all  $x, y \in \Omega$ ).

► **Remark 12.** By Kantorovich duality, one may equivalently define the 1-Wasserstein distance as

$$W_1(\mu, \nu) = \inf_{\gamma} \mathbb{E}_{(x,y) \sim \gamma} [d(x, y)],$$

where the infimum is over all couplings  $\gamma$  of  $\mu, \nu$  on  $\Omega \times \Omega$ .

## 2.1 Spin Systems

Fix an undirected graph  $G = (V, E)$ , and a positive integer  $q \geq 2$ . We view  $[q]$  as a collection of possible “spin assignments” for the vertices of  $G$ . We also fix a symmetric nonnegative matrix  $A \in \mathbb{R}_{\geq 0}^{q \times q}$  of “edge interaction activities” and a positive vector  $h \in \mathbb{R}_{> 0}^q$  of “external fields”. The Gibbs distribution of the spin system on  $G = (V, E)$  with parameters  $A, h$  is the distribution  $\mu = \mu_{G,A,h}$  over configurations  $\sigma : V \rightarrow [q]$  given by

$$\mu(\sigma) \propto \prod_{\{u,v\} \in E} A(\sigma(u), \sigma(v)) \prod_{v \in V} h(\sigma(v)),$$

where the constant of proportionality is the partition function of the system, given by

$$Z_G(A, h) = \sum_{\sigma: V \rightarrow [q]} \prod_{\{u,v\} \in E} A(\sigma(u), \sigma(v)) \prod_{v \in V} h(\sigma(v)).$$

Many classical models in statistical physics as well as distributions over often-studied combinatorial objects on graphs may be found as special cases. Notable examples include the Ising model on cuts, the hardcore gas model on independent sets, the monomer-dimer model on matchings, and the zero-temperature antiferromagnetic Potts model on proper colorings.

We call a configuration  $\sigma : V \rightarrow [q]$  feasible if  $\mu(\sigma) > 0$ . For instance, if  $A$  has all positive entries, then all configurations  $\sigma : V \rightarrow [q]$  are feasible. We call a partial configuration  $\xi : S \rightarrow [q]$ , where  $S \subseteq V$  is a subset of vertices, a boundary condition. For such a boundary condition, we write  $\mu \mid \xi$  for the conditional Gibbs distribution on  $V \setminus S$  given by taking  $\mu$  and conditioning on the event that the sampled  $\sigma \sim \mu$  satisfies  $\sigma(v) = \xi(v)$  for all  $v \in S$ .

## 2.2 Discrete Product Spaces and Homogeneous Set Systems

Fix a collection of finite sets  $(\Omega(v))_{v \in V}$ , where  $V$  is some finite index set with  $|V| = n$ , and consider a measure  $\mu$  on the product space  $\prod_{v \in V} \Omega(v)$ . For instance, if  $\Omega(v) = \{-1, +1\}$  for each  $v \in V$ , then  $\mu$  is just a measure on the discrete hypercube  $\{-1, +1\}^V$ . An important subclass of examples which we will discuss at length include discrete probabilistic graphical models, where the index set  $V$  is the set of vertices of a (hyper)graph, and the measure  $\mu$  designed in such a way that the (hyper)edges represent local interactions between vertices of the model; see Section 2.1 for more details.

As done in [6, 14, 15, 30], we view  $\mu$  as a measure on  $\binom{U}{n}$  where

$$U = \{(v, \omega(v)) : v \in V, \omega(v) \in \Omega(v)\}.$$

Note the usual Hamming distance  $d_H(\cdot, \cdot)$  on  $\binom{U}{n}$  is twice the usual Hamming distance typically associated with a discrete product space.

We will often write a single vertex-assignment pair  $(v, c)$ , where  $v \in V$  and  $c \in \Omega(v)$ , as simply  $vc$ . Here, each configuration  $\sigma \in \prod_{v \in V} \Omega(v)$  corresponds to the set  $\{(v, \sigma(v)) : v \in V\}$ . In this setting, the down-up walk is precisely the **Glauber dynamics** (or **Gibbs sampler**) for sampling from  $\mu$ . For each configuration  $\sigma \in \prod_{v \in V} \Omega(v)$ , we transition to the next configuration by the following process:

1. Select a uniformly random coordinate  $v \in V$ .
2. Resample  $\sigma(v)$  according to  $\mu$  conditioned on  $\sigma_{-v}$ .

Let us make this more concrete. For each  $\sigma \in \prod_{v \in V} \Omega(v)$  and  $v \in V$ , we write  $\sigma_{-v}$  for the partial subconfiguration of  $\sigma$  which only excludes  $\sigma(v)$ . For  $c \in \Omega(v)$ , we also write  $\sigma_{vc}$  for the configuration obtained by flipping the coordinate of  $v$  from  $\sigma(v)$  to  $c$ . We may then write  $\mu^v(\cdot | \sigma_{-v})$  for the marginal distribution of  $\sigma(v)$  under  $\mu$  conditioned on  $\sigma_{-v}$ . The transition kernel of the Glauber dynamics may then be written as

$$P_\mu(\sigma \rightarrow \sigma_{vc}) = \frac{1}{n} \cdot \mu^v(c | \sigma_{-v}).$$

### 2.3 Spectral Independence and The Down-Up Walk

Here, we formalize spectral independence and its connection with rapid mixing of the down-up walk. Throughout the paper, we will assume the following connectivity/nondegeneracy condition. Assuming Theorem 7 holds, we will also give a proof of Theorem 3.

**Assumption:** The down-up walk for  $\mu$  and all of its conditional distributions is connected. In the context of spin systems, this condition is guaranteed by “total connectivity” of the system parameters  $(A, h)$  [16]. For instance, this is satisfied by all “soft-constraint” models (i.e. those with  $A > 0$ ), and many “hard-constraint” models such as the hardcore model and the uniform distribution over proper colorings when  $q \geq \Delta + 2$ .

Let us now formalize spectral independence.

► **Definition 13** (Pairwise Influence and Spectral Independence [6]). *Fix a finite universe  $U$  and a positive integer  $n \geq 1$ . Fix a distribution  $\mu$  on  $\binom{U}{n} = \{S \subseteq U : |S| = n\}$ . We define the **pairwise influence** of an element  $i$  on another element  $j$  by*

$$\mathcal{I}_\mu(i \rightarrow j) \stackrel{\text{def}}{=} \Pr_{S \sim \mu} [j \in S | i \in S] - \Pr_{S \sim \mu} [j \in S].$$

We write  $\mathcal{I}_\mu \in \mathbb{R}^{U \times U}$  defined by  $\mathcal{I}_\mu(i, j) = \mathcal{I}_\mu(i \rightarrow j)$  for the **pairwise influence matrix** of  $\mu$ . We say the distribution  $\mu$  is  **$\eta$ -spectrally independent** if  $\lambda_{\max}(\mathcal{I}_\mu) \leq \eta + 1$ . We say the distribution  $\mu$  is  **$(\eta_0, \dots, \eta_{n-2})$ -spectrally independent** if  $\mu$  is  $\eta_0$ -spectrally independent,  $\mu | i$  is  $\eta_1$ -spectrally independent for all  $i \in U$ , and so on.

Often in practice, and in this paper, instead of bounding  $\lambda_{\max}(\mathcal{I}_\mu)$ , we will bound

$$\|\mathcal{I}_\mu\|_\infty = \max_{i \in U} \sum_{j \in U} |\mathcal{I}_\mu(i \rightarrow j)|,$$

which is sufficient since it is well-known that  $\lambda_{\max}(A) \leq \|A\|_\infty$  for any matrix  $A$  with real eigenvalues. The main usefulness of spectral independence is that it implies rapid mixing of the down-up walk, while only requiring bounds on pairwise correlations. We state the main local-to-global results most relevant to us here. In the most general setting, we may deduce an inverse polynomial spectral gap from sufficiently strong spectral independence [21, 40, 1].

► **Theorem 14** ([1], [6]). *Let  $U$  be a finite universe, and  $n \geq 1$  a positive integer. Let  $\mu$  be a distribution on  $\binom{U}{n}$  which is  $(\eta_0, \dots, \eta_{n-2})$ -spectrally independence. Then the down-up walk on  $\binom{U}{n}$  for sampling from  $\mu$  has spectral gap at least*

$$\frac{1}{n} \prod_{k=0}^{n-2} \left(1 - \frac{\eta_k}{n - k - 1}\right).$$

*In particular, if  $\eta_k \leq O(1)$  for all  $k = 0, \dots, n-2$ , then we have  $n^{O(1)}$ -mixing of the down-up walk.*

Subject to a certain mild technical condition on the marginals of the distribution  $\mu$ , one can transfer spectral independence bounds to “local entropy decay” bounds, and then employ versions of the local-to-global result for entropy decay [34, 16, 2]. In the setting of spin systems, one can further take advantage of the bounded-degree assumption to obtain  $O(n \log n)$  mixing time upper bounds [16], which are asymptotically optimal [36]. We state the current state-of-the-art for spin systems on bounded-degree graphs here, as we will need it in our application to proper list-colorings.

► **Theorem 15** ([16]). *Let  $(A, h)$  be the parameters of a spin system, and let  $G = (V, E)$  be a graph with maximum degree at most  $\Delta \leq O(1)$ . If the Gibbs distribution  $\mu = \mu_{G, A, h}$  is  $(\eta_0, \dots, \eta_{n-2})$ -spectrally independent where  $\eta_k \leq O(1)$  for all  $k$ , then both the standard and modified log-Sobolev constants of the Glauber dynamics (i.e. the down-up walk) for sampling from  $\mu$  are at least  $\Omega(1/n)$ .*

We conclude this section with a proof of Theorem 3.

**Proof of Theorem 3.** By Theorems 14 and 15, it suffices to establish  $(\eta_0, \dots, \eta_{n-2})$ -spectral independence for  $\eta_k \leq O(1)$  for all  $k$ . Fix an arbitrary  $A \subseteq U$  with  $|A| = k \leq n - 2$  and  $A \subseteq S$  for some  $S \in \text{supp}(\mu)$ . With the locality and coupling assumptions, Theorem 7 shows that for each  $i \in U$ , the absolute row sum of  $\mathcal{I}_{\mu|A}$  for row  $i$  is upper bounded by

$$\ell \cdot C_{n-k} \cdot \max_{S \in \text{supp}(\mu|_i)} \left\{ \sum_{T \neq S} |P_\mu(S \rightarrow T) - P_{\mu|_i}(S \rightarrow T)| \right\}.$$

Bounded differences between chains then yields the upper bound  $\lambda_{\max}(\mathcal{I}_{\mu|A}) \leq \|\mathcal{I}_{\mu|A}\|_\infty \leq \ell \cdot C_{n-k} \cdot C'_{n-k}$ , which is  $O(1)$  by assumption. As this holds for all such  $A$ , it follows that  $\eta_k \leq O(1)$ . ◀

### 3 Stein’s Method for Markov Chains

Our goal in this section is to prove Theorem 8. We follow [10, 46], using what is known as **Stein’s method for Markov chains**. Historically, Stein’s method [48] was developed as a method to bound distances between probability measures, with the primary motivation being to prove quantitative central limit theorems. [10, 46] adapted this method to bound the distance between two probability measures  $\mu, \nu$  on the discrete hypercube  $\{-1, +1\}^n$  assuming the Glauber dynamics of either measure admits a contractive coupling. Our main intuition lies in viewing spectral independence (see Definition 13) as a measure of distance between different conditionings of the same distribution. Thus, one can try to apply this method to bound the spectral independence of a distribution. Let us now elucidate this method.

For a fixed function  $f : \Omega \rightarrow \mathbb{R}$ , we will construct an auxiliary function  $h : \Omega \rightarrow \mathbb{R}$  which satisfies the **Poisson equation**

$$h - P_\mu h = f - \mathbb{E}_\mu f.$$

Questions concerning  $\mathbb{E}_\mu f$  may then be studied by looking at  $P_\mu h$ . The following lemma constructs  $h$  more explicitly.

► **Lemma 16** (see Lemma 2.1 [10], Lemma 2.3 [46]). *Fix an irreducible transition probability matrix  $P$  which is reversible w.r.t. a distribution  $\pi$  on a finite state space  $\Omega$ . Let  $(X^{(t)})_{t=0}^\infty$  be the Markov chain generated by  $P$ , and for a fixed function  $f : \Omega \rightarrow \mathbb{R}$ , define  $h : \Omega \rightarrow \mathbb{R}$  by*

$$h(x) = \sum_{t=0}^\infty \mathbb{E} \left[ f(X^{(t)}) - \mathbb{E}_\pi f \mid X^{(0)} = x \right].$$

## 32:10 Coupling to Spectral Independence

Then  $h$  is well-defined as a function, and further satisfies the Poisson equation

$$h - Ph = f - \mathbb{E}_\pi f.$$

With this lemma in hand, we can immediately prove Theorem 8.

**Proof of Theorem 8.** Fix a function  $f : 2^U \rightarrow \mathbb{R}$ , and let  $h$  be the solution to the Poisson equation  $h - P_\mu h = f - \mathbb{E}_\mu f$  given in Lemma 16. Then since  $\nu$  is stationary w.r.t.  $P_\nu$ , we have  $\mathbb{E}_\nu P_\nu h = \mathbb{E}_\nu h$ , so that using the Poisson equation yields

$$\mathbb{E}_\nu(P_\nu - P_\mu)h = \mathbb{E}_\nu h - \mathbb{E}_\nu[h - f + \mathbb{E}_\mu f] = \mathbb{E}_\nu f - \mathbb{E}_\mu f.$$

Hence, by the Triangle Inequality, we have that  $|\mathbb{E}_\mu f - \mathbb{E}_\nu f| \leq \mathbb{E}_\nu |(P_\nu - P_\mu)h|$ .

Now, let us bound  $|(P_\nu - P_\mu)h|$  entrywise. For each  $S \in \text{supp}(\nu)$ , using that  $P_\mu(S \rightarrow S) = 1 - \sum_{T \neq S} P_\mu(S \rightarrow T)$  (and analogously for  $P_\nu$ ),

$$\begin{aligned} & (P_\nu - P_\mu)h(S) \\ &= \sum_T (P_\nu(S \rightarrow T) - P_\mu(S \rightarrow T)) \cdot h(T) \\ &= \sum_{T \neq S} (P_\nu(S \rightarrow T) - P_\mu(S \rightarrow T)) \cdot (h(T) - h(S)) \\ &= \sum_{T \neq S} (P_\nu(S \rightarrow T) - P_\mu(S \rightarrow T)) \cdot \sum_{t=0}^{\infty} \mathbb{E}_{X^{(t)}, Y^{(t)}} \left[ f(Y^{(t)}) - f(X^{(t)}) \mid \begin{matrix} X^{(0)}=S \\ Y^{(0)}=T \end{matrix} \right]. \end{aligned} \tag{Lemma 16}$$

It follows by the Triangle Inequality that

$$\begin{aligned} |(P_\nu - P_\mu)h(S)| &\leq \sum_{T \neq S} |P_\mu(S \rightarrow T) - P_\nu(S \rightarrow T)| \\ &\quad \cdot \sum_{t=0}^{\infty} \mathbb{E}_{X^{(t)}, Y^{(t)}} \left[ \left| f(X^{(t)}) - f(Y^{(t)}) \right| \mid \begin{matrix} X^{(0)}=S \\ Y^{(0)}=T \end{matrix} \right]. \end{aligned} \tag{1}$$

Taking expectations w.r.t.  $\nu$  finally yields a bound on  $|\mathbb{E}_\mu f - \mathbb{E}_\nu f|$ . The bound on the 1-Wasserstein distance follows immediately by taking  $f$  to be an arbitrary function which is 1-Lipschitz the metric  $d_H(\cdot, \cdot)$ . To obtain the bound on the total difference between marginals  $\sum_{j \in U} |\Pr_{S \sim \mu}[j \in S] - \Pr_{S \sim \nu}[j \in S]|$ , we apply the above inequality to  $f = \mathbb{I}_j$  for each  $j \in U$  and sum over all  $j \in U$ , noting that  $d_H(S, T) = \sum_{j \in U} |\mathbb{I}_j(S) - \mathbb{I}_j(T)|$  and  $\mathbb{E}_\mu f = \mathbb{E}_\mu \mathbb{I}_j = \Pr_{S \sim \mu}[j \in S]$  (and analogously for  $\nu$ ). ◀

## 4 Discrete Ricci Curvature on Product Spaces

In this section, we discuss applications of our results to general distributions on discrete product spaces. We show that the existence of a contractive coupling w.r.t. Hamming distance for the Glauber dynamics implies  $O(1)$ -spectral independence. Such a condition is known as a discrete Ricci curvature condition for the dynamics in the sense of [44]. This also shows that the Dobrushin uniqueness condition implies  $O(1)$ -spectral independence. When combined with the local-to-global result of [16], we resolve an unpublished conjecture due Peres and Tetali for spin systems on bounded-degree graphs; see [28] and references therein for recent progress on this conjecture on general graphs. We also give an alternative proof of the  $\Omega(1/n)$  lower bound on the standard and modified log-Sobolev constants of the Glauber dynamics in this setting when a Dobrushin-type condition is satisfied, recovering a result of [42].

Classical work on Dobrushin-type conditions [25, 22, 23, 24, 35, 26] yield relatively simple and direct criteria for rapid mixing of the Glauber dynamics [11, 12]. The main idea here is intuitively similar to that of spectral independence (although the notion of Dobrushin influence here historically precedes spectral independence): so long as some measure of “total influence” is small, then  $\mu$  is close in some sense to a product distribution, for which rapid mixing holds. However, prior to our work, the precise relationship between Dobrushin influence and the notion of pairwise influence used in spectral independence was unclear. This is an additional conceptual contribution of our work.

► **Definition 17** (Discrete Ricci Curvature [44]). *Fix an irreducible transition probability matrix  $P$  which is reversible w.r.t. a distribution  $\pi$  on a finite state space  $\Omega$ . Further, endow  $\Omega$  with a metric  $d(\cdot, \cdot)$ . We define the **discrete Ricci curvature** of the Markov chain  $P$  w.r.t. the metric space  $(\Omega, d)$  by*

$$\alpha = \inf_{x, y \in \Omega: x \neq y} \left\{ 1 - \frac{W_1(P(x \rightarrow \cdot), P(y \rightarrow \cdot))}{d(x, y)} \right\},$$

where  $W_1(\cdot, \cdot)$  is again the 1-Wasserstein distance w.r.t.  $d(\cdot, \cdot)$ . In other words, for every pair  $x, y \in \Omega$ , there is a coupling of the transitions  $P(x \rightarrow \cdot), P(y \rightarrow \cdot)$  such that the expected distance  $d(\cdot, \cdot)$  under the coupling contracts by a  $(1 - \alpha)$ -multiplicative factor. In this case, we will say  $P$  admits a  **$(1 - \alpha)$ -contractive coupling w.r.t.  $d(\cdot, \cdot)$** .

► **Fact 18.** *Suppose  $P$  admits a  $(1 - \alpha)$ -contractive coupling w.r.t.  $d(\cdot, \cdot)$ . Then this coupling is  $C$ -amortized convergent with  $C = \frac{1}{\alpha}$ .*

The following is an immediate application of Theorem 7, and yields a positive resolution to the Peres-Tetali conjecture for spin systems on bounded-degree graphs.

► **Theorem 19** (Curvature Implies Spectral Independence on Product Spaces). *Let  $\mu$  be a measure on a discrete product space  $\Omega = \prod_{v \in V} \Omega(v)$ , where  $V$  is a finite index set and  $\Omega(v)$  is finite for all  $v \in V$ . Endow  $\Omega$  with the Hamming metric  $d_H(\cdot, \cdot)$ , and let  $\alpha$  be the discrete Ricci curvature of the Glauber dynamics w.r.t.  $(\Omega, d_H)$ . Then, the distribution is  $(\eta_0, \dots, \eta_{n-2})$ -spectrally independent where  $\eta_k \leq \frac{4}{\alpha n} - 1$  for all  $k$ . In particular, if  $\alpha \geq \Omega(1/n)$ , then the Glauber dynamics has spectral gap  $n^{-O(1)}$ . If additionally the measure  $\mu$  is the Gibbs distribution of a spin system on a bounded-degree graph, then the spectral gap, standard and modified log-Sobolev constants for the Glauber dynamics are all  $\Omega(1/n)$ .*

Note that since the Glauber dynamics only updates the assignment to a single  $v \in V$  in each step, it must be that  $\alpha \leq O(1/n)$ . Theorem 19 follows almost immediately from Fact 18 and a straightforward calculation involving the entries of the transition matrix of the Glauber dynamics. In the interest of space, we provide the proof in Section B.

## 4.1 Dobrushin Uniqueness and Spectral Independence

We now use Theorem 19 to show that Dobrushin’s uniqueness condition implies spectral independence.

► **Definition 20** (Dobrushin Influence). *Fix a probability measure on a finite product space  $\prod_{v \in V} \Omega(v)$ , where  $V$  is a finite indexing set. For each  $u \in V$ , let  $D_u$  be the collection of pairs  $\tau, \sigma \in \prod_{v \in V} \Omega(v)$  such that  $\tau_{-u} = \sigma_{-u}$  while  $\tau(u) \neq \sigma(u)$ . For distinct  $u, v \in V$ , we may then define the **Dobrushin influence** of  $u$  on  $v$  by*

$$\rho_\mu(u \rightarrow v) = \max_{(\tau, \sigma) \in D_u} d_{TV}(\mu^v(\cdot \mid \tau_{-v}), \mu^v(\cdot \mid \sigma_{-v})).$$

## 32:12 Coupling to Spectral Independence

We write  $\rho_\mu = (\rho_\mu(u \rightarrow v))_{u,v} \in \mathbb{R}^{V \times V}$  for the **Dobrushin influence matrix**. We say the distribution  $\mu$  satisfies the **Dobrushin uniqueness condition** if

$$\|\rho_\mu\|_1 \stackrel{\text{def}}{=} \max_{u \in V} \sum_{v \in V} \rho_\mu(u \rightarrow v) < 1.$$

A straightforward application of the path coupling technique of [11, 12] shows that if  $\|\rho_\mu\|_1 < 1$ , then there is a coupling for the Glauber dynamics which is one-step contractive w.r.t. Hamming distance. We state this well-known implication formally here, and refer to [26] for the proof.

► **Fact 21.** *Let  $\mu$  be a distribution on some finite product space  $\prod_{v \in V} \Omega(v)$ , where  $V$  is a finite index set. If  $\|\rho_\mu\|_1 \leq \gamma < 1$ , then the Glauber dynamics is  $(1 - \alpha)$ -contractive w.r.t. Hamming distance with  $\alpha = \frac{1}{n}(1 - \gamma)$ .*

In particular, combining Theorem 19 and Fact 21 immediately yields spectral independence under the Dobrushin uniqueness condition. Combined with Theorem 15, this additionally recovers a version of a result due to [42], which says that a weaker  $\ell_2$ -version of the Dobrushin uniqueness condition (see also [35, 26]) implies a  $\Omega(1/n)$  log-Sobolev constant for the Glauber dynamics.

► **Corollary 22 (Dobrushin Uniqueness Implies Spectral Independence).** *Let  $\mu$  be a distribution on some finite product space  $\prod_{v \in V} \Omega(v)$ , where  $V$  is a finite index set. If  $\|\rho_\mu\|_1 \leq \gamma < 1$ , then  $\mu$  is  $(\eta_0, \dots, \eta_{n-2})$ -spectrally independent with  $\eta_k \leq \frac{4}{1-\gamma} - 1$  for all  $k$ . If additionally the measure  $\mu$  is the Gibbs distribution of a spin system on a bounded-degree graph, then the spectral gap, standard and modified log-Sobolev constants for the Glauber dynamics are all  $\Omega(1/n)$ .*

## 5 Spectral Independence for Proper List-Colorings

We now specialize to the setting of proper list-colorings of a graph. Formally, we fix a graph  $G = (V, E)$ , a collection of color lists  $(L(v))_{v \in V}$ . We call a configuration  $\sigma \in \prod_{v \in V} L(v)$  a list-coloring of  $G$ . We say a list-coloring  $\sigma$  is proper if  $\sigma(u) \neq \sigma(v)$  whenever  $u \neq v$  are neighbors. Throughout, we will let  $\Delta$  denote the maximum degree of  $G$ , and we assume  $\Delta \leq O(1)$ . We also assume there is a positive integer  $q \geq \Delta + 2$  such that  $L(v) \subseteq [q]$  for all  $v \in V$ .

A well-known result due to [38] using path coupling shows that if  $|L(v)| > 2\Delta$  for all  $v \in V$ , then there is a contractive one-step coupling for the Glauber dynamics which yields  $O(n \log n)$  mixing. As noted in [16], one can adapt the argument of [32] to obtain strong spatial mixing when  $|L(v)| > 2\Delta$ , and use the arguments of [15, 30] to deduce spectral independence in this regime. However, it is still open whether one can obtain strong spatial mixing below the  $2\Delta$  threshold; see [32, 27] for results going below  $2\Delta$  on special classes of graphs.

In the seminal work of Vigoda [49], it was shown that there is a contractive one-step coupling for a different local Markov chain known as the flip dynamics whenever  $|L(v)| \geq \frac{11}{6}\Delta$ . This threshold was further improved to  $|L(v)| \geq (\frac{11}{6} - \epsilon)\Delta$  in a recent breakthrough by [13], this time using a more sophisticated variable-length coupling. Both works further showed that Glauber dynamics mixes in  $O(n^2)$  time in this regime using a spectral gap comparison argument [19].

Our goal is to use these coupling results along with Theorem 7 to obtain spectral independence for the uniform distribution over proper list-colorings in the regime  $|L(v)| \geq$

$(\frac{11}{6} - \epsilon) \Delta$ . Combined with Theorem 15, we improve the previous  $O(n^2)$  mixing time bound to the optimal  $O(n \log n)$ , as well as show Chernoff-type concentration bounds for Lipschitz functions, which were not known before.

### 5.1 The Flip Dynamics

We follow the presentation in [13], which generalizes the flip dynamics analyzed in [49] to list-colorings. Fix a list-coloring  $\sigma$ . We say a path  $u = w_1, \dots, w_\ell = v$  in  $G$  is an alternating path from  $u$  to  $v$  using colors  $\sigma(u), c$  if for all  $i$ , we have  $\sigma_{w_i} \in \{\sigma(u), c\}$  and  $\sigma_{w_i} \neq \sigma_{w_{i+1}}$ . For a fixed list-coloring  $\sigma$ ,  $v \in V$  and color  $c$ , we define the **Kempe component for  $\sigma, v, c$**  by the following subset of vertices.

$$S_\sigma(u, c) = \left\{ v \in V : \exists \text{ alternating path from } u \text{ to } v \text{ using } \sigma(u), c \right\}.$$

Given  $\sigma$  and a Kempe component  $S = S_\sigma(u, c)$ , we define  $\sigma_S$  to be the coloring obtained by “flipping” the color assigned to vertices in  $\{v \in S : \sigma(v) = \sigma(u)\}$  to  $c$ , and the color assigned to vertices in  $\{v \in S : \sigma(v) = c\}$  to  $\sigma(u)$ . Note that  $\sigma_S$  need not be a proper list-coloring; we say a Kempe component  $S = S_\sigma(u, c)$  is **flippable** if the coloring  $\sigma_S$  is a proper list-coloring.

For each  $j \in \mathbb{N}$ , let  $0 \leq p_j \leq 1$  be a tunable parameter to be determined later. We define the flip dynamics with flip parameters  $\{p_j\}_{j \in \mathbb{N}}$  for sampling proper list-colorings as follows: Given the current list-coloring  $\sigma^{(t-1)}$ , we generate the next list-coloring  $\sigma^{(t)}$  by the following two-step process:

1. Select a uniformly random vertex  $v^{(t)} \in V$ , and a uniformly random color  $c^{(t)} \in L(v^{(t)})$ .
2. If the Kempe component  $S = S_{\sigma^{(t-1)}}(v^{(t)}, c^{(t)})$  is flippable, set  $\sigma^{(t)} = \sigma_S^{(t-1)}$  with probability  $\frac{p_j}{j}$  and  $\sigma^{(t)} = \sigma^{(t-1)}$  otherwise, where  $j = |S|$ .

We write  $P_{\mu, \text{flip}}$  for the transition probability matrix of the flip dynamics. It is straightforward to verify that the stationary distribution of the flip dynamics is uniform over proper list-colorings, regardless of the choice of the flip parameters. One can recover the Wang-Swendsen-Kotecký Markov chain by setting  $p_j = j$  for all  $j \in \mathbb{N}$  [50].

[49] showed that with flip parameters

$$p_1 = 1 \quad p_2 = \frac{13}{42} \quad p_3 = \frac{1}{6} \quad p_4 = \frac{2}{21} \quad p_5 = \frac{1}{21} \quad p_6 = \frac{1}{84} \quad p_j = 0, \forall j \geq 7, \tag{2}$$

there is a one-step coupling which is contractive w.r.t. Hamming distance whenever  $|L(v)| \geq \frac{11}{6} \Delta$ . [13] showed using linear programming arguments that this is optimal in the sense that when  $|L(v)| < \frac{11}{6}$ , there is no choice of the flip parameters which has a one-step contractive coupling w.r.t. Hamming distance. They additionally construct an explicit family of hard instances witnessing optimality.

One of the key insights of [13] is that the optimal choice of flip parameters comes out of the solution to a linear program, with the objective value of the program governing the contraction properties of the coupling. By solving this linear program, they show that for the following choice of flip parameters

$$\begin{aligned} \hat{p}_1 = 1 \quad \hat{p}_2 \approx 0.296706 \quad \hat{p}_3 \approx 0.166762 \quad \hat{p}_4 \approx 0.101790 \\ \hat{p}_5 \approx 0.058475 \quad \hat{p}_6 = 0.025989 \quad p_j = 0, \forall j \geq 7, \end{aligned} \tag{3}$$

there is a variable-length coupling such that the Hamming distance contracts by a constant factor every  $O(n)$  steps in expectation. One can thus expect that the coupling is  $C$ -amortized convergent with  $C \leq O(n)$ .

We formalize their main coupling result in the following subsection. For the moment, we state two intermediate lemmas, and show how they imply Theorem 5.

► **Lemma 23.** *Assume the input graph  $G = (V, E)$  has maximum degree  $\Delta \leq O(1)$ . Then, the flip dynamics with parameters given in Equation (3) satisfy the following:*

$$\max_{\tau \in \text{supp}(\mu|_{uc})} \left\{ \sum_{\sigma \neq \tau} |P_{\mu, \text{flip}}(\tau \rightarrow \sigma) - P_{\mu|_{uc}, \text{flip}}(\tau \rightarrow \sigma)| \right\} \leq O(1/n).$$

► **Lemma 24.** *Let  $(G, \mathcal{L})$  be a list-coloring instance, where  $\Delta \leq O(1)$  and  $|L(v)| \geq \lambda^* \Delta$  for all  $v \in V$ , where  $\lambda^* = \frac{11}{6} - \epsilon$  and  $\epsilon \approx 10^{-5}$  is a small constant. Then the flip dynamics with parameters given in Equation (3) admits a  $C$ -amortized convergent coupling w.r.t. Hamming distance where  $C \leq O(n)$ .*

**Proof of Theorem 5.** The flip dynamics is clearly  $O(1)$ -local w.r.t. Hamming distance since only Kempe components of size at most 6 can be flipped.  $(\eta_0, \dots, \eta_{n-2})$ -spectral independence where  $\eta_k \leq O(1)$  for all  $k$  then follows immediately by combining Lemma 23 and Lemma 24 with Theorem 3. The lower bounds on the spectral gap, standard and modified log-Sobolev constants then follow from Theorem 15. ◀

We provide the proof of Lemma 23 in Section B. At this point, all that remains is to prove Lemma 24, which we do using the variable-length path coupling constructed in [13].

## 5.2 Variable-Length Path Coupling: Proof of Lemma 24

To begin, we first define the notion of variable-length coupling following [37, 13].

► **Definition 25 (Path-Generating Set).** *For a finite state space  $\Omega$ , a **path generating set** is a subset  $S \subseteq \binom{\Omega}{2}$  such that the undirected graph  $(\Omega, S)$  is connected. We let  $d_S(\cdot, \cdot)$  denote the induced shortest-path metric on  $\Omega$ , and write  $d(\cdot, \cdot)$  when the path generating set  $S$  is clear from context. We also write  $x \sim y$  whenever  $\{x, y\} \in S$ .*

► **Definition 26 (Variable-Length Path Coupling [37]).** *Fix an irreducible transition probability matrix  $P$  which is reversible w.r.t. a distribution  $\pi$  on a finite state space  $\Omega$ , and let  $d(\cdot, \cdot)$  be a metric on  $\Omega$  induced by a path generating set  $S \subseteq \binom{\Omega}{2}$ . For every pair of starting states  $x^{(0)}, y^{(0)} \in \Omega$  with  $x^{(0)} \sim y^{(0)}$ , we let  $(\bar{x}, \bar{y}, T) = (\bar{x}(x^{(0)}, y^{(0)}), \bar{y}(x^{(0)}, y^{(0)}), T(x^{(0)}, y^{(0)}))$  denote a random variable where  $T$  is a (potentially random) nonnegative integer and  $\bar{x} = (x^{(0)}, x^{(1)}, \dots, x^{(T)})$ ,  $\bar{y} = (y^{(0)}, y^{(1)}, \dots, y^{(T)})$  are length- $T$  sequences of states in  $\Omega$ .*

*For every integer  $t \geq 0$  and every pair of neighboring states  $x^{(0)} \sim y^{(0)}$ , define random variables  $x_t, y_t$  by the following experiment. Sample  $(\bar{x}, \bar{y}, T)$ , and set  $x_t = x^{(t)}, y_t = y^{(t)}$  if  $t \leq T$ , and sample  $x_t \sim P^{t-T}(x^{(T)}, \cdot), y_t \sim P^{t-T}(y^{(T)}, \cdot)$  if  $t > T$ . We say the random variable  $(\bar{x}, \bar{y}, T)$  is a **variable-length path coupling for  $P$**  if  $x_t \sim P^t(x^{(0)}, \cdot), y_t \sim P^t(y^{(0)}, \cdot)$  for every integer  $t \geq 0$  and every pair of neighboring states  $x^{(0)} \sim y^{(0)}$ . In this case, we say that  $\bar{x}, \bar{y}$  are individually **faithful copies**. If  $T = t$  with probability 1 for some nonnegative integer  $t \geq 0$ , we say that  $(\bar{x}, \bar{y}, T)$  is a  **$t$ -step path coupling**.*

► **Remark 27.** In our application to colorings, the random time  $T$  will be a stopping time in the sense that its value only depends on the past, i.e.  $x^{(0)}, y^{(0)}, \dots, x^{(t)}, y^{(t)}$  for  $t \leq T$ .

Given a variable-length path coupling, [37] showed one can construct a full coupling, generalizing the original path coupling theorem of [11, 12]. Furthermore, the contraction properties of the full coupling are inherited from the path coupling. While the original statement in [37] merely states rapid mixing given a variable-length path coupling, its proof implies the following.

► **Theorem 28** (Proof of Corollary 4 from [37]). *Let  $(\bar{x}, \bar{y}, T)$  be a variable-length path coupling w.r.t. a path generating set  $S$  for a reversible Markov chain  $P$  on a state space  $\Omega$  with stationary distribution  $\pi$ . Let*

$$\begin{aligned}\alpha &\stackrel{\text{def}}{=} 1 - \max_{\{x^{(0)}, y^{(0)}\} \in S} \mathbb{E}[d_H(x^{(T)}, y^{(T)})] \\ W &\stackrel{\text{def}}{=} \max_{\{x^{(0)}, y^{(0)}\} \in S, t \leq T} d_H(x^{(t)}, y^{(t)}) \\ \beta &\stackrel{\text{def}}{=} \max_{\{x^{(0)}, y^{(0)}\} \in S} \mathbb{E}[T].\end{aligned}$$

Assume  $0 < \alpha < 1$ . Then there is a full  $M$ -step coupling with  $M = \lceil \frac{2\beta W}{\alpha} \rceil$  such that for all pairs  $x^{(0)}, y^{(0)}$ , which need not be neighbors in  $S$ , we have the inequality

$$\mathbb{E}[d_H(x^{(M)}, y^{(M)}) \mid x^{(0)}, y^{(0)}] \leq \left(1 - \frac{\alpha}{2}\right) \cdot d_H(x^{(0)}, y^{(0)}).$$

Given this, all we need now is a good variable-length path coupling. This is given by the following result due to [13].

► **Theorem 29** ([13]). *Let  $(G, \mathcal{L})$  be a list-coloring instance, where  $G = (V, E)$  is a graph with maximum degree  $\Delta \leq O(1)$ , and  $\mathcal{L} = (L(v))_{v \in V}$  is a collection of color lists. Let the path generating set  $S$  be given by the set of pairs  $\{\tau, \sigma\}$  such that  $\tau, \sigma$  differ on the coloring of exactly one vertex. Assume  $|L(v)| \geq \lambda^* \Delta$  for all  $v \in V$  where  $\lambda^* = \frac{11}{6} - \epsilon$  for an absolute constant  $\epsilon \approx 10^{-5}$ . Then there exists a variable-length path coupling  $(\bar{\tau}, \bar{\sigma}, T)$  for the flip dynamics w.r.t.  $S$  with flip parameters given in Equation (3), where  $T$  is the first time such that the Hamming distance changes, such that  $\alpha = \frac{q - \lambda^* \Delta}{q - \Delta - 2} = \Theta(1)$ ,  $W = 13$  and  $\beta \leq \frac{qn}{q - \Delta - 2} \leq O(n)$*

With these tools in hand, we may now finally prove Lemma 24 and complete the proof of Theorem 5.

**Proof of Lemma 24.** First, note that the path generating set  $S$  generates the Hamming metric  $d_H(\cdot, \cdot)$  on proper list-colorings. Now, given the variable-length path coupling furnished by Theorem 29, we use Theorem 28 to construct an  $M$ -step coupling with  $M = \lceil \frac{2\beta W}{\alpha} \rceil \leq O(n)$  which contracts with rate  $1 - \alpha$  every  $M$  steps, where  $\alpha$  is a constant independent of  $n$ . Under this coupling, for every  $k = 0, \dots, M - 1$  and every positive integer  $j$ , we have that

$$\begin{aligned}&\mathbb{E}_{\tau^{(jM+k)}, \sigma^{(jM+k)}} \left[ d_H(\tau^{(jM+k)}, \sigma^{(jM+k)}) \mid \tau^{(k)}, \sigma^{(k)} \right] \\ &\leq \left(1 - \frac{\alpha}{2}\right) \mathbb{E}_{\tau^{((j-1)M+k)}, \sigma^{((j-1)M+k)}} \left[ d_H(\tau^{((j-1)M+k)}, \sigma^{((j-1)M+k)}) \mid \tau^{(k)}, \sigma^{(k)} \right] \\ &\leq \dots \\ &\leq \left(1 - \frac{\alpha}{2}\right)^j \cdot d_H(\tau^{(k)}, \sigma^{(k)}),\end{aligned}$$

where  $\tau^{(0)} = \tau, \sigma^{(0)} = \sigma$  are arbitrary starting states, which need not be neighbors under  $S$ .

It follows that

$$\begin{aligned}
& \sum_{t=0}^{\infty} \mathbb{E}_{\tau^{(t)}, \sigma^{(t)}} \left[ d_H(\tau^{(t)}, \sigma^{(t)}) \mid \tau^{(0)} = \tau, \sigma^{(0)} = \sigma \right] \\
& \leq \sum_{k=0}^{M-1} \sum_{j=0}^{\infty} \mathbb{E}_{\tau^{(jM+k)}, \sigma^{(jM+k)}} \left[ d_H(\tau^{(jM+k)}, \sigma^{(jM+k)}) \mid \tau^{(k)}, \sigma^{(k)} \right] \\
& \leq \sum_{k=0}^{M-1} \mathbb{E} \left[ d_H(\tau^{(k)}, \sigma^{(k)}) \mid \tau^{(0)}, \sigma^{(0)} \right] \sum_{j=0}^{\infty} \left(1 - \frac{\alpha}{2}\right)^j \\
& = \frac{2}{\alpha} \sum_{k=0}^{M-1} \mathbb{E} \left[ d_H(\tau^{(k)}, \sigma^{(k)}) \mid \tau^{(0)}, \sigma^{(0)} \right] \\
& \leq \frac{2M}{\alpha} d_H(\tau^{(0)}, \sigma^{(0)}) \tag{*} \\
& \leq O(n) \cdot d_H(\tau^{(0)}, \sigma^{(0)}).
\end{aligned}$$

To justify (\*), note that  $T$  is the first time the Hamming distance changes, and that each time the Hamming distance changes, the expected Hamming distance contracts by a factor of  $1 - \alpha$ . ◀

## 6 Future Directions

Two concrete open problems are to bring down the required number of colors from  $(\frac{11}{6} - \epsilon) \Delta$  to  $\Delta + 2$ , and to remove the bounded-degree assumption, both in this work and in [16]. Another interesting question is if spectral independence implies any useful notion of correlation decay, such as strong spatial mixing, or the absence of zeros for partition function in a large region. This is relevant particularly for proper list-colorings, where we showed spectral independence when  $q \geq (\frac{11}{6} - \epsilon) \Delta$ , but correlation decay and absence of zeros are both open in general when number of colors is below  $2\Delta$ .

We also reiterate that one feature of our approach which we haven't exploited is that in order to obtain  $O(1)$ -spectral independence, it suffices for the Markov chain admitting the nice coupling to merely update  $O(1)$ -coordinates in a single move “on average”, as opposed to the worst-case starting state; see Remark 10. We leave it to future work to see if this can be exploited.

---

## A Variance and Entropy Decay

While we primarily use prior results on the spectral gap, and standard and modified log-Sobolev constants as blackboxes, to keep this paper self-contained, we define these constants here, and state their relevance to mixing and concentration. Fix a Markov kernel  $P$  on a finite state space  $\Omega$  which is reversible w.r.t. a distribution  $\pi$ . We may define an inner product using  $\pi$  by  $\langle f, g \rangle_\pi = \mathbb{E}_\pi[fg]$ . This inner product together with the kernel  $P$  induces a positive semidefinite quadratic form known as the Dirichlet form, defined as  $\mathcal{E}_P(f, g) = \langle f, (I - P)g \rangle_\pi$ . The variance of a function  $f : \Omega \rightarrow \mathbb{R}$  is given by  $\text{Var}_\pi(f) = \mathbb{E}_\pi(f^2) - \mathbb{E}_\pi(f)^2$ , while the entropy of a function  $f : \Omega \rightarrow \mathbb{R}_{\geq 0}$  is given by  $\text{Ent}_\pi(f) = \mathbb{E}_\pi(f \log f) - \mathbb{E}_\pi(f) \log \mathbb{E}_\pi(f)$ .

With these notions in hand, we may now define the following constants:

$$\begin{aligned}
 \text{(Spectral Gap)} \quad \lambda(P) &\stackrel{\text{def}}{=} \inf_{f \neq 0} \frac{\mathcal{E}(f, f)}{\text{Var}_\pi(f)} \\
 \text{(Modified Log-Sobolev Constant)} \quad \rho(P) &\stackrel{\text{def}}{=} \inf_{f \geq 0} \frac{\mathcal{E}(f, \log f)}{\text{Ent}_\pi(f)} \\
 \text{(Standard Log-Sobolev Constant)} \quad \kappa(P) &\stackrel{\text{def}}{=} \inf_{f \geq 0} \frac{\mathcal{E}(\sqrt{f}, \sqrt{f})}{\text{Ent}_\pi(f)}. \tag{4}
 \end{aligned}$$

It is known that  $4\kappa(P) \leq \rho(P) \leq 2\lambda(P)$  [8], with lower bounds on  $\kappa(P)$  being the most difficult to establish. For the reader's convenience, we collect some well-known relations between these constants, mixing, and concentration.

► **Proposition 30 (Mixing and Concentration).** *We have the following bounds on the mixing time of a Markov chain with transition probability matrix  $P$  and stationary distribution  $\pi$ .*

$$t_{\text{mix}}(\epsilon) \leq \frac{1}{\lambda(P)} \left( \frac{1}{2} \log \frac{1}{\pi_{\min}} + \log \frac{1}{2\epsilon} \right) \tag{41}$$

$$t_{\text{mix}}(\epsilon) \leq \frac{1}{\rho(P)} \left( \log \log \frac{1}{\pi_{\min}} + \log \frac{1}{2\epsilon^2} \right) \tag{8}$$

$$t_{\text{mix}}(\epsilon) \leq \frac{1}{4\kappa(P)} \left( \log \log \frac{1}{\pi_{\min}} + \log \frac{1}{2\epsilon^2} \right). \tag{20}$$

## 32:20 Coupling to Spectral Independence

Furthermore, for every function  $f : \Omega \rightarrow \mathbb{R}$  which is 1-Lipschitz w.r.t. graph distance under  $P$ , we have the following Chernoff-type concentration inequalities [33, 47, 9].

$$\Pr[f \geq \mathbb{E}_\pi(f) + \epsilon] \leq \exp\left(-\frac{\rho(P)\epsilon^2}{2v(f)}\right)$$

$$\Pr[f \leq \mathbb{E}_\pi(f) - \epsilon] \leq \exp\left(-\frac{\kappa(P)\epsilon^2}{2v(f)}\right),$$

where

$$v(f) \stackrel{\text{def}}{=} \max_{x \in \Omega} \left\{ \sum_{y \in \Omega} P(x \rightarrow y) \cdot (f(x) - f(y))^2 \right\}.$$

### B Missing Proofs

**Proof of Theorem 19.** We show that  $\eta_0 \leq \frac{4}{\alpha n} - 1$ . The bound  $\eta_k \leq \frac{4}{\alpha n} - 1$  follows by the same argument by instead considering the Glauber dynamics for the conditional distributions  $\mu \mid A$  of  $\mu$ . Because the Glauber dynamics only updates at most one coordinate in each step, it is 2-local w.r.t.  $d_H(\cdot, \cdot)$ . By Fact 18, we also have there is a  $C$ -amortized convergent coupling with  $C = \frac{1}{\alpha}$ . It follows from Theorem 7 that

$$\sum_{v \in V} \sum_{c' \in \Omega(v)} \left| \Pr_{\sigma \sim \mu} [\sigma(v) = c' \mid \sigma(u) = c] - \Pr_{\sigma \sim \mu} [\sigma(v) = c'] \right|$$

$$\leq \frac{2}{\alpha} \max_{\sigma \in \text{supp}(\mu \mid uc)} \sum_{\tau \neq \sigma} |P_\mu(\sigma \rightarrow \tau) - P_{\mu \mid uc}(\sigma \rightarrow \tau)|.$$

Now, by the definition of the Glauber dynamics, for each  $\sigma \in \text{supp}(\mu \mid uc)$ , we have

$$\sum_{\tau \neq \sigma} |P_\mu(\sigma \rightarrow \tau) - P_{\mu \mid uc}(\sigma \rightarrow \tau)|$$

$$= \sum_{v \in V} \sum_{c' \in L(v): c' \neq \sigma(v)} \left| \frac{1}{n} \mu^v(c' \mid \sigma_{-v}) - \frac{1}{n-1} \mu_{uc}^v(c' \mid \sigma_{-v}) \right|$$

$$= \sum_{v \in V: v \neq u} \sum_{c' \in L(v): c' \neq \sigma(v)} \left( \frac{1}{n-1} - \frac{1}{n} \right) \mu^v(c' \mid \sigma_{-v}) + \sum_{c' \in L(u): c' \neq c} \frac{1}{n} \mu^v(c' \mid \sigma_{-v})$$

$$\leq \frac{2}{n}.$$

The claim for the spectral gap in the case  $\alpha \geq \Omega(1/n)$  follows by combining with Theorem 14. The final claim for spin systems on bounded-degree graphs follows by combining with Theorem 15.  $\blacktriangleleft$

**Proof of Lemma 23.** The main detail one must be careful of is that the flip dynamics for sampling from  $\mu \mid uc$  always leaves the color for  $u$  fixed to  $c$ . Hence, flipping any Kempe component containing  $u$  leads to potentially different list-colorings under  $P_{\mu, \text{flip}}$  versus  $P_{\mu \mid uc, \text{flip}}$ . However, since we only flip components of  $O(1)$ -size, this isn't an issue for us.

Fix a  $\tau$  with  $\tau(u) = c$ , and let  $B(u, 6)$  denote the set of vertices of shortest path distance at most 6 away from  $u$  in  $G$ . Since we only flip Kempe components of size at most 6, we have that for any  $v \in V \setminus B(u, 6)$  and  $c \in L(u)$ , the flippable Kempe component  $S_\tau(v, c')$

does not contain  $u$ , and hence, flipping it leads to the same list-coloring under  $P_{\mu, \text{flip}}$  and  $P_{\mu|vc, \text{flip}}$ . Hence, we have

$$\begin{aligned}
& \sum_{\sigma \neq \tau} |P_{\mu, \text{flip}}(\tau \rightarrow \sigma) - P_{\mu|uc, \text{flip}}(\tau \rightarrow \sigma)| \\
&= \sum_{v \in V: v \notin B(u, 6)} \sum_{c' \in L(v)} \frac{1}{|L(v)|} \cdot \left( \frac{1}{n} - \frac{1}{n-1} \right) \cdot p_{|S_\tau(v, c')|} \\
&\quad + \sum_{v \in B(u, 6)} \sum_{c' \in [q]} |P_{\mu, \text{flip}}(\tau \rightarrow \sigma) - P_{\mu|uc, \text{flip}}(\tau \rightarrow \sigma)| \\
&\leq \frac{n - |B(u, 6)|}{n(n-1)} + \frac{|B(u, 6)|}{n} \\
&\leq \frac{|B(u, 6)| + 1}{n} \\
&\lesssim \frac{\Delta^6}{n} \\
&\leq O(1/n). \qquad \qquad \qquad \text{(Bounded-degree assumption)}
\end{aligned}$$

◀

► Remark 31. As one can see in the proof from the factor of  $\Delta^6$ , we have made no attempt to optimize constants.

# Singularity of Random Integer Matrices with Large Entries

## Abstract

We study the singularity probability of random integer matrices. Concretely, the probability that a random  $n \times n$  matrix, with integer entries chosen uniformly from  $\{-m, \dots, m\}$ , is singular. This problem has been well studied in two regimes: large  $n$  and constant  $m$ ; or large  $m$  and constant  $n$ . In this paper, we extend previous techniques to handle the regime where both  $n, m$  are large. We show that the probability that such a matrix is singular is  $m^{-cn}$  for some absolute constant  $c > 0$ . We also provide some connections of our result to coding theory.

## 1 Introduction

In this paper we study the probability that a random  $n \times n$  matrix with uniform integer entries in  $\{-m, \dots, m\}$  is singular. Note that the probability that such a matrix is singular is at least  $(2m + 1)^{-n}$ , which is the probability that its first two rows are the same. We show that this bound is tight, up to polynomial factors.

► **Theorem 1** (Singularity of random matrices). *Let  $n, m \geq 1$ . Let  $M$  be an  $n \times n$  random integer matrix with entries chosen uniformly in  $\{-m, \dots, m\}$ . Then for some absolute constant  $c > 0$ ,*

$$\Pr[M \text{ is singular}] \leq m^{-cn}.$$

Note that if instead we chose  $M$  to be a random  $n \times n$  matrix over a finite field  $\mathbb{F}_q$ , then the probability that  $M$  is singular would be about  $1/q$ , independent of how large  $n$  is. This is the main point of difference between random matrices over integers and over finite fields - the singularity probability over integers decreases as the matrix becomes larger, whereas over finite fields it stabilizes.

## 1.1 Connections to coding theory - alphabet size for MDS codes

Our motivation for proving Theorem 1 is a connection to coding theory. More specifically, the question of what alphabet size is needed for Maximum Distance Separable (MDS) codes over the integers.

Coding theory is the study of error correction codes. Codes are widely used in many applications, such as data compression, cryptography, error detection and correction, data transmission and data storage. Algorithms needed to implement codes perform arithmetic operations over an underlying alphabet, and hence their computational complexity is constrained by this alphabet size. Thus, understanding the alphabet size needed to support a given code structure is a central question in coding theory. By far, the most common approach to design codes is to use linear codes over finite fields. Our results in this paper help with investigating the possibility of designing codes over integers. In particular, we study the alphabet size needed to support basic code structures, and focus on the most basic and well-studied family of codes - Maximum Distance Separable (MDS) codes.

An MDS code is a code with the best possible tradeoff between the message length, codeword length and minimal distance. Concretely, an  $(n, k, d)$ -code is a code with message length  $k$ , codeword length  $n$  and minimal distance  $d$ . The Singleton bound [16] gives that  $d \leq n - k + 1$ . MDS codes are codes achieving this bound, namely  $(n, k, d)$ -codes with  $d = n - k + 1$ . If we consider linear codes, then it is well-known that MDS codes are generated by the row span of *MDS matrices*.

► **Definition 2** (MDS matrix). *Let  $n \geq k$ . A  $k \times n$  matrix is called an MDS matrix if any  $k$  columns in it are linearly independent. Equivalently, if any  $k \times k$  minor of it is nonsingular.*

Note that MDS matrices can be defined over finite fields or over the integers. If we define them over a finite field  $\mathbb{F}_q$ , then it is well-known that a linear field size is needed to support MDS matrices. Concretely, if we assume  $n \geq k + 2$ , then it is known that  $q \geq \max(k, n - k + 1)$  (see for example the introduction of [1] for a proof). In particular, this implies that  $q \geq n/2$ . Reed-Solomon codes can be constructed over fields of size  $q \geq n - 1$ , which is tight up to a factor of two. The MDS conjecture of Segre [15] speculates that this is indeed the best possible (except for a few special cases), and Ball [1] proved this over prime finite fields. In summary, over finite fields a linear field size  $q = \Theta(n)$  is both necessary and sufficient.

We show that over the integers, MDS matrices exist over much smaller alphabet sizes.

► **Theorem 3** (MDS matrices over integers). *Let  $n \geq k$ . There exist  $k \times n$  MDS matrices over integers whose entries are in  $\{-m, \dots, m\}$ , where  $m \leq (cn/k)^c$  for some absolute constant  $c > 0$ .*

The typical regime in coding theory is that of linear rate and linear distance; namely, where  $k = \alpha n$  for some constant  $\alpha \in (0, 1)$ . Note that in this regime Theorem 3 shows that MDS codes over the integers exist with a *constant* alphabet size, which is in stark contrast with the case over finite fields. It is easy to see that Theorem 3 is best possible, up to the unspecified constant  $c$ .

Theorem 3 follows directly from Theorem 1.

**Proof of Theorem 3.** Let  $M$  be a random  $k \times n$  matrix with entries chosen uniformly from  $\{-m, \dots, m\}$ . The number of  $k \times k$  minors for  $M$  is  $\binom{n}{k}$ , and the probability that each one is singular is at most  $m^{-ck}$  by Theorem 1. Thus

$$\Pr[M \text{ is not MDS}] \leq \binom{n}{k} m^{-ck} \leq \left(\frac{en}{k}\right)^k m^{-ck} = \left(\frac{en}{km^c}\right)^k.$$

In particular, this probability is at most  $2^{-k}$  (say) whenever  $m \geq (2en/k)^{1/c}$ . ◀

The following claim shows that the bound in Theorem 3 is best possible, up to the value of the unspecified constant  $c$ .

▷ **Claim 4.** Let  $n \geq k \geq 2$ . Let  $M$  be a  $k \times n$  MDS matrix whose entries are in an alphabet  $\Sigma$ . Then  $|\Sigma| \geq \sqrt{n/k}$ .

*Proof.* Let  $P_i = (M_{1,i}, M_{2,i}) \in \Sigma^2$  denote the first two elements in the  $i$ -th column of  $M$ . If  $n > |\Sigma|^2 k$ , then there must be  $k$  distinct columns  $i_1, \dots, i_k \in [n]$  such that  $P_{i_1} = \dots = P_{i_k}$ . But then  $M$  cannot be an MDS matrix, as the  $k \times k$  minor formed by taking these columns has the first two rows being a scalar multiple of each other, and hence cannot be nonsingular. ◁

Note that the proof of Theorem 3 is by choosing the matrix  $M$  randomly, and showing that with high probability it will be an MDS matrix. This is another aspect in which codes over integers seem to be different from codes over finite fields. Constructing MDS matrices over finite fields seems to require algebraic constructions (such as Reed-Solomon codes), unless the field size is exponential in  $n$ ; whereas over the integers, random matrices work well even for very small entries.

## 1.2 Related works on the singularity of random matrices

Most previous works in random matrix theory focused on random matrices whose entries are sampled independently from distributions with bounded tail behaviour. The most studied case is that of random sign matrices, namely with uniform  $\{-1, 1\}$  entries. Komlós [7] proved that the probability that a random  $n \times n$  sign matrix is singular is  $o(1)$  as  $n \rightarrow \infty$ , which already is a nontrivial result. It took nearly 30 years until Kahn, Komlós and Szemerédi [5] improved the bound to  $c^n$  for some constant  $c \in (0, 1)$ . A sequence of works [2, 17, 18] improved the value of the constant  $c$ , and recently Tikhomirov [19] proved that  $c = 1/2 + o(1)$ , which is best possible, as the probability that the first two rows of the matrix are equal is  $2^{-n}$ . For more general distributions, Rudelson and Vershynin [12, 13] proved that if the entries of an  $n \times n$  matrix are sampled from a sub-Gaussian distribution, then the probability it is singular is at most  $c^n$  for some  $c \in (0, 1)$ .

The other regime, of large  $m$  and constant  $n$ , was less explored. The only work we are aware of is by Katznelson [6] which gave a bound of the form  $c_n m^{-n}$  for some constant  $c_n$  depending on  $n$ . While having optimal dependence on  $m$  for constant  $n$ , it has a caveat - it only applies in the regime where  $m$  is much larger than  $n$  (more precisely, for every fixed  $n$ , in the limit of large  $m$ ).

A recent work that did address the regime of both large  $n$  and large  $m$ , but for a different entry distribution, is that of Vempala, Wang and Woodruff [20]. Fix  $\mu \in (0, 1)$ , and let  $\mathcal{D}_\mu$  be a distribution over  $\{-1, 0, 1\}$  with  $\mathcal{D}_\mu(0) = 1 - \mu$ ,  $\mathcal{D}_\mu(1) = \mathcal{D}_\mu(-1) = \mu/2$ . Let  $M$  be a random  $n \times n$  matrix, whose entries are the sum of  $m$  independent copies of  $\mathcal{D}_\mu$ . They show that the probability that  $M$  is singular is at most  $m^{-cn}$  for some constant  $c = c(\mu) > 0$ .

With respect to the connection to coding theory, we note that this result is sufficient to prove Theorem 3. However, we view the entry distribution in Theorem 1 (uniform in  $\{-m, \dots, m\}$ ) as more natural for coding applications. In fact, we conjecture that any entry distribution that doesn't give too much probability to any specific element would do, see Conjecture 5 for the details.

### 1.3 Proof techniques

We prove Theorem 1 following the approach of Rudelson and Vershynin [12, 13], in particular following the lecture notes of Rudelson [11] modified appropriately to handle the case of large  $m$ . On the other hand, Vempala et al. [20] follow the approach of Kahn et al. [5] and Tao and Vu [18]. We briefly discuss the difference between the two approaches below.

At a high level, both approaches aim to study “approximate periodicity” of random vectors. However, they take different routes. The first approach is more direct, using the notion of Lowest Common Denominator (LCD) to define and study approximate periodicity. The second approach is indirect, using Fourier analysis. Fourier analytic techniques seem useful when the underlying entry distribution has well-behaved Fourier tails; for example, this is the case for the distribution considered in [20], where the entries are a sum of  $m$  independent copies of a distribution over  $\{-1, 0, 1\}$ . However, the distribution we consider in this paper, uniform in  $\{-m, \dots, m\}$ , has less well-behaved Fourier tails, and Fourier analytic techniques seem less suited to analyze it.

### 1.4 Directions for further research and applications

#### Singularity of matrices over general distributions

As we discussed above, most works on the singularity of random matrices give a bound on the singularity of  $c^n$  for some absolute constant  $c \in (0, 1)$ . Theorem 1 shows that if the entries are uniformly sampled from  $\{-m, \dots, m\}$ , we can take  $c = 1/\text{poly}(m)$ . We speculate that this is an instance of a much more general phenomena - the singularity probability is determined by the anti-concentration of the underlying entries distribution. Given a distribution  $\mathcal{D}$  over  $\mathbb{R}$ , define its max-probability as  $\|\mathcal{D}\|_\infty = \max_x \mathcal{D}(x)$ . For example, if  $\mathcal{D}$  is the uniform distribution over  $\{-m, \dots, m\}$ , then  $\|\mathcal{D}\|_\infty = 1/(2m + 1)$ .

► **Conjecture 5.** *Let  $\mathcal{D}$  be a distribution over  $\mathbb{R}$  and set  $p = \|\mathcal{D}\|_\infty$ . Let  $M$  be a random  $n \times n$  matrix with independent entries from  $\mathcal{D}$ . Then for some absolute constant  $c > 0$ ,*

$$\Pr[M \text{ is singular}] \leq p^{cn}.$$

One can even speculate a more general conjecture, where each entry comes from a different underlying distribution, as long as they all have bounded max-probability.

#### Applications to coding theory

We view Theorem 3 as a first step towards the study of codes over integers. There are many intriguing questions that arise in coding theory, once we showed that random integer matrices are MDS with high probability.

- **Explicit constructions.** A natural question is to give an explicit construction of MDS matrices over integers with small integer values. Concretely, when  $k = \alpha n$  for some constant  $\alpha \in (0, 1)$ , to give an explicit construction of a  $k \times n$  MDS matrix with a constant alphabet size (namely, independent of  $n$ ).
- **Algorithms.** The next natural question, once there are explicit constructions, is to design efficient decoding algorithms for such codes. In particular, it would be intriguing to see if the smaller alphabet size can be utilized to obtain improved runtime (even by logarithmic factors).

## Paper Outline

We prove Theorem 1 in the remainder of the paper. We start with a high-level overview of our framework in Section 2. We compute some preliminary estimates in Section 3, define and study incompressible vectors in Section 4, define the LCD condition in Section 5, where we also prove some properties of it, and bound the LCD of random vectors in Section 6. We put all the ingredients together and complete the proof in Section 7.

## 2 General approach

We will follow the general approach of Rudelson [11] with several modifications needed to obtain effective bounds for large  $m$ .

### Notation

It will be convenient to scale the entries to be in  $[-1, 1]$ ; we denote by  $\mathcal{D}$  the uniform distribution over  $\{a/m : a \in \{-m, \dots, m\}\}$ . We denote by  $\mathcal{D}^n$  the distribution over  $n$ -dimensional vectors with independent entries from  $\mathcal{D}$ , and by  $\mathcal{D}^{n \times n}$  the distribution over  $n \times n$  matrices with independent entries from  $\mathcal{D}$ . We denote by  $S^{n-1}$  the unit sphere in  $\mathbb{R}^n$ , namely  $S^{n-1} = \{x \in \mathbb{R}^n : \|x\|_2 = 1\}$ . We will use the  $c, c', c_0$ , etc, to denote unspecified positive constants. Note that the same letter (e.g.  $c$ ) can mean different unspecified constants in different lemmas.

### We may assume that $n, m$ are large enough

We will assume throughout the proof that  $n, m$  are large enough; concretely, for any absolute constants  $n_0, m_0$ , we may assume that  $n \geq n_0, m \geq m_0$ , and this would only effect the value of the constant  $c$  in Theorem 1.

To see why, consider first the regime of constant  $m$  and large  $n$ . The distribution  $\mathcal{D}$  is symmetric and bounded in  $[-1, 1]$ . The results of [12] show that in such a case,

$$\Pr[M \text{ is singular}] \leq c^n$$

for some absolute constant  $c \in (0, 1)$ . This proves Theorem 1 for any constant  $m$ .

The other regime is that of constant  $n$  and large  $m$ . While we may appeal to the result of Katznelson [6] in this regime, which gives a sharp bound of  $c_n m^{-n}$ , there is a much simpler argument that gives a bound of the order of  $1/m$  which is good enough to establish Theorem 1 in this regime. As the determinant of an  $n \times n$  matrix is a polynomial of degree  $n$ , the Schwartz-Zippel lemma [14, 21] gives

$$\Pr[M \text{ is singular}] = \Pr[\det(M) = 0] \leq \frac{n}{m}.$$

In particular, for constant  $n$  and large  $m$ , this probability is of the order of  $1/m$ , which is consistent with the claimed bound of Theorem 1 (taking  $c < 1/n$ ).

### General approach

Let  $M \sim \mathcal{D}^{n \times n}$ , and let  $X_1, \dots, X_n$  denote its rows. If  $M$  is singular, then one of the rows belongs to the span of the other rows. By symmetry we have

$$\Pr[M \text{ is singular}] \leq n \cdot \Pr[X_n \in \text{Span}(X_1, \dots, X_{n-1})].$$

### 33:6 Singularity of Random Integer Matrices with Large Entries

Let  $X^*$  be any unit vector orthogonal to  $X_1, \dots, X_{n-1}$  (if there are multiple ones, choose one in some deterministic way). We call it a *random normal vector*. We will shorthand  $X = X_n$ . Observe that  $X, X^*$  are independent. Thus we can bound

$$\Pr[M \text{ is singular}] \leq n \cdot \Pr[\langle X^*, X \rangle = 0].$$

To do so, we will show that unless  $X^*$  belongs to a set of “bad” vectors, then the above probability is at most  $m^{-cn}$ , and that the probability that  $X^*$  is bad is also at most  $m^{-cn}$ .

### 3 Preliminary estimates

We establish some preliminary estimates in this section, which will be needed later in the proof.

#### Maximal eigenvalues of random matrices

The first ingredient is bounding the spectral norm of  $M$ . In fact, we would need this bound for rectangular matrices. Given an  $n \times k$  matrix  $R$  we denote its spectral norm as  $\|R\| = \max\{\|Rx\|_2 : x \in S^{k-1}\}$ . Note that  $\|R\| = \|R^T\|$  since  $\|R\| = \max_{x \in S^{k-1}, y \in S^{n-1}} y^T R x$ .

The following claim is a special case of [11, proposition 4.4], who showed that it holds for any symmetric distribution  $\mathcal{D}$  supported in  $[-1, 1]$ .

▷ **Claim 6.** Let  $R \sim \mathcal{D}^{n \times k}$  for  $n \geq k$ . Then for any  $\lambda > 0$ ,

$$\Pr[\|R\| \geq \lambda\sqrt{n}] \leq 2^{-c\lambda^2 k}.$$

#### Anti-concentration of projections

Next, we need anti-concentration results for projections of  $\mathcal{D}^n$ . To begin with we consider projections of the uniform distribution over the solid cube  $[-1, 1]^n$ .

▷ **Claim 7.** Let  $U \sim [-1, 1]^n$  be uniformly distributed. Then for every  $x \in S^{n-1}$  and  $\varepsilon > 0$ ,

$$\Pr_u [|\langle U, x \rangle| \leq \varepsilon] \leq c\varepsilon.$$

*Proof.* The uniform distribution  $U \sim [-1, 1]^n$  is a log-concave distribution. Let  $S = \langle U, x \rangle$  and note that  $S$  is a projection of  $U$  along the direction  $x$ . The Prékopa–Leindler inequality [8, 10] states that projections of log-concave distributions are log-concave, and so  $S$  is a log-concave distribution. Carbery and Wright [3, Theorem 8] show that the required anti-concentration bound holds for any log-concave distribution. ◁

We extend this anti-concentration to the discrete case using a coupling argument. Here and throughout, we denote by  $\log(\cdot)$  logarithm in base 2.

▷ **Claim 8.** Let  $X \sim \mathcal{D}^n$  and set  $\varepsilon_0 = \frac{\sqrt{\log m}}{m}$ . Then for every  $x \in S^{n-1}$  and  $\varepsilon \geq \varepsilon_0$ ,

$$\Pr[|\langle X, x \rangle| \leq \varepsilon] \leq c\varepsilon.$$

*Proof.* We apply a coupling argument between the uniform distribution in  $[-1, 1]^n$  and  $\mathcal{D}^n$ . Sample  $X \sim \mathcal{D}^n$ ,  $Y \sim [-1, 1]^n$  and set  $Z = X + Y/2m$ . Observe that  $Z$  is uniform in the solid cube  $[-1 - 1/2m, 1 + 1/2m]^n$ . Next, fix  $\varepsilon > 0$  and observe that  $\langle X, x \rangle = \langle Z, x \rangle - \langle Y, x \rangle/2m$ . Thus we can bound

$$\Pr[|\langle X, x \rangle| \leq \varepsilon] \leq \Pr[|\langle Z, x \rangle| \leq 2\varepsilon] + \Pr[|\langle Y, x \rangle| \geq 2\varepsilon m].$$

For the first term, Claim 7 bounds its probability by  $c_1\varepsilon$ . For the second term, the Chernoff bound bounds its probability for  $\varepsilon \geq \varepsilon_0$  by  $1/m$ . As we have  $1/m \leq \varepsilon$ , the claim follows.  $\triangleleft$

### Tensorization lemma

We also need the following “tensorization lemma” [11, Lemma 6.5].

$\triangleright$  **Claim 9.** Let  $Y_1, \dots, Y_n$  be independent real-valued random variables. Assume for some  $K, \varepsilon_0 > 0$  that

$$\Pr[|Y_i| \leq \varepsilon] \leq K\varepsilon \quad \text{for all } \varepsilon \geq \varepsilon_0.$$

Then

$$\Pr\left[\sum_{i=1}^n Y_i^2 \leq \varepsilon^2 n\right] \leq (cK\varepsilon)^n \quad \text{for all } \varepsilon \geq \varepsilon_0.$$

### Nets

A set of unit vectors  $\mathcal{N} \subset S^{n-1}$  is called an  $\varepsilon$ -net, for  $\varepsilon > 0$ , if it satisfies:

$$\forall x \in S^{n-1} \exists y \in \mathcal{N} \|x - y\|_2 \leq \varepsilon.$$

The following claim bounds the size of such a net. For a proof see for example [9, Lemma 2.6].

$\triangleright$  **Claim 10.** For any  $\varepsilon > 0$ , there exists a  $\varepsilon$ -net  $\mathcal{N} \subset S^{n-1}$  of size  $|\mathcal{N}| \leq (3/\varepsilon)^n$ .

### Integer points in ball

We need a bound on the number of integer vectors in a ball of a given radius. Let  $B_n(r) = \{x \in \mathbb{R}^n : \|x\|_2 \leq r\}$  denote the ball of radius  $r$  in  $\mathbb{R}^n$ . The following bound is well known.

$\triangleright$  **Claim 11.** The number of integer vectors in  $B_n(r)$  is at most  $\left(1 + \frac{cr}{\sqrt{n}}\right)^n$ .

## 4 Compressible vectors

The first set of “bad” vectors that we want to rule out are vectors which are close to sparse. A vector  $u \in \mathbb{R}^n$  is  $k$ -sparse if it has at most  $k$  nonzero coordinates.

$\blacktriangleright$  **Definition 12** (Compressible vectors). Let  $\alpha, \beta \in (0, 1)$ . A unit vector  $x \in S^{n-1}$  is called  $(\alpha, \beta)$ -compressible if it can be expressed as  $x = u + v$ , where  $u$  is  $(\alpha n)$ -sparse and  $\|v\|_2 \leq \beta$ . Otherwise, we say that  $x$  is  $(\alpha, \beta)$ -incompressible.

We will later choose  $\alpha, \beta$ , but we note here that  $\alpha$  will be a small enough absolute constant and  $\beta$  a small polynomial in  $1/m$ . Concrete values that work are  $\alpha = 1/50, \beta = 1/\sqrt{m}$ . We will implicitly assume that both  $n, m$  are large enough; concretely, at various places we assume that  $\alpha n \geq 2$ .

The main lemma we prove in this section is the following.

$\blacktriangleright$  **Lemma 13.** Let  $\alpha \in (0, 1/8), \beta \in (\varepsilon_0, 1/2)$  where  $\varepsilon_0 = \frac{\sqrt{\log m}}{m}$ . Then

$$\Pr[X^* \text{ is } (\alpha, \beta)\text{-compressible}] \leq (c\beta)^{n/8}.$$

### 33:8 Singularity of Random Integer Matrices with Large Entries

We need a bound on the smallest singular value of a rectangular matrix.

▷ **Claim 14.** Let  $R \sim \mathcal{D}^{n \times k}$  for  $n \geq k$ . Then for every  $x \in S^{k-1}$  and  $\varepsilon \geq \varepsilon_0$ ,

$$\Pr [\|Rx\|_2 \leq \varepsilon\sqrt{n}] \leq (c\varepsilon)^{n/2}.$$

*Proof.* Assume  $\|Rx\|_2 < \varepsilon\sqrt{n}$ . This implies that  $|(Rx)_i| \leq 2\varepsilon$  for at least  $n/2$  coordinates  $i \in [n]$ . Note that for each fixed  $i$ , the value  $(Rx)_i$  is distributed as  $\langle X, x \rangle$  for some  $X \sim \mathcal{D}^k$ . Applying Claim 8 and the union bound over the choice of the  $n/2$  coordinates gives

$$\Pr [\|Rx\|_2 \leq \varepsilon\sqrt{n}] \leq 2^n (c_1\varepsilon)^{n/2} = (c\varepsilon)^{n/2}. \quad \triangleleft$$

▷ **Claim 15.** Let  $R \sim \mathcal{D}^{n \times k}$  for  $n \geq 8k$ . Then for every  $\varepsilon \geq \varepsilon_0$ ,

$$\Pr \left[ \min_{x \in S^{k-1}} \|Rx\|_2 \leq \varepsilon\sqrt{n} \right] \leq (c\varepsilon)^{n/4}.$$

*Proof.* We may assume that  $\varepsilon \leq 1$  by taking  $c \geq 1$ . Let  $\mathcal{N}$  be an  $(\varepsilon^2)$ -net in  $S^{k-1}$  of size  $|\mathcal{N}| \leq (3/\varepsilon^2)^k$ , as given by Claim 10. Let  $E_1$  denote the event that there exists  $y \in \mathcal{N}$  for which  $\|Ry\|_2 \leq 2\varepsilon\sqrt{n}$ . Applying Claim 14 and a union bound gives

$$\Pr [E_1] \leq (3/\varepsilon^2)^k \cdot (c_1\varepsilon)^{n/2} \leq (c_2\varepsilon)^{n/4},$$

where we used the assumption  $n \geq 8k$ . Let  $E_2$  denote the event that  $\|R\| \geq \lambda\sqrt{n}$  for  $\lambda = \sqrt{\log(1/\varepsilon)}$ . Claim 6 shows that  $\Pr[E_2] \leq (c_3\varepsilon)^n$ . We next show that if  $E_1, E_2$  don't hold then the condition of the claim also doesn't hold, namely that  $\|Rx\|_2 > \varepsilon\sqrt{n}$  for all  $x \in S^{k-1}$ .

Let  $x \in S^{k-1}$  be arbitrary and let  $y \in \mathcal{N}$  be such that  $\|x - y\|_2 \leq \varepsilon^2$ . Then

$$\|Rx\|_2 \geq \|Ry\|_2 - \|R\| \cdot \|x - y\|_2 \geq (2\varepsilon - \varepsilon^2\lambda)\sqrt{n}.$$

It can be verified that for  $\varepsilon \leq 1$  we have  $\varepsilon\lambda \leq 1$ , which implies that  $\|Rx\|_2 \geq \varepsilon\sqrt{n}$ . ◁

We will now use these two claims to prove Lemma 13.

**Proof of Lemma 13.** Let  $M'$  be the  $(n-1) \times n$  matrix with rows  $X_1, \dots, X_{n-1}$ . Assume that there exists an  $(\alpha, \beta)$ -compressible vector  $x \in S^{n-1}$  in the kernel of  $M'$ . By definition,  $x = u + v$  where  $u$  is  $(\alpha n)$ -sparse and  $\|v\|_2 \leq \beta$ . In particular,  $M'(u + v) = 0$  and hence  $\|M'u\|_2 = \|M'v\|_2$ . In addition,  $\|u\|_2 \geq \|x\|_2 - \|v\|_2 \geq 1/2$  since  $x$  is a unit vector and  $\|v\|_2 \leq \beta \leq 1/2$ .

Let  $E$  denote the event that  $\|M'\| \geq \lambda\sqrt{n}$  for  $\lambda = c_1\sqrt{\log(1/\beta)}$ , where we choose  $c_1 \geq 1$  large enough so that by Claim 6,  $\Pr[E] \leq \beta^n$ . Note that as we assume  $\beta \leq 1/2$  we have  $\lambda \geq c_1 \geq 1$ . Assuming that  $E$  doesn't hold, we have

$$\|M'u\|_2 = \|M'v\|_2 \leq \|M'\| \cdot \|v\|_2 \leq \lambda\beta\sqrt{n}.$$

In particular,  $y = u/\|u\|_2$  is an  $(\alpha n)$ -sparse unit vector that satisfies  $\|M'y\|_2 \leq 2\lambda\beta\sqrt{n}$ . We next bound the probability that such a vector exists.

Let  $\varepsilon = 2\lambda\beta$ , and note that  $\varepsilon \geq \varepsilon_0$  since  $\beta \geq \varepsilon_0$  and  $\lambda \geq 1$ . There are  $\binom{n}{\alpha n}$  options for the support of  $y$ . Let  $I = \{i : y_i \neq 0\}$  denote a possible support, set  $k = |I|$  and let  $R$  be an  $(n-1) \times k$  matrix with columns  $(Y_i : i \in I)$ . As  $\alpha < 1/8$  we have  $n-1 \geq 8k$ . Thus we can apply Claim 15 and obtain that

$$\Pr [\neg E \quad \wedge \quad \exists y \in S^{k-1}, \|Ry\|_2 \leq \varepsilon\sqrt{n}] \leq (c_2\varepsilon)^{n/4} = \left( c_3\beta\sqrt{\log(1/\beta)} \right)^{n/4}.$$

Note that for  $\beta \leq 1$  we have  $\beta \log(1/\beta) \leq 1$  and hence the above bound is at most  $(c_4\beta)^{n/8}$ .

To conclude, we union bound over the choices for  $I$ , the number of which is  $\binom{n}{\alpha n} \leq 2^n$ . Thus we can bound the total probability by  $2^n (c_4\beta)^{n/8} = (c_5\beta)^{n/8}$ . ◀

## 5 The LCD condition

In this section we will introduce the notion of the Lowest Common Denominator (LCD) of a vector, which is a variant of the LCD definition in [11]. Informally, the LCD of a vector is a robust notion of “almost periodicity”; concretely, it is the least multiple where most of its entries are close to integers.

Given  $x \in \mathbb{R}^n$  let  $x = [x] + \{x\}$  be its decomposition into integer and fractional parts, where  $[x] \in \mathbb{Z}^n$  and  $\{x\} \in [-1/2, 1/2]^n$ .

► **Definition 16** (Least common denominator (LCD)). *Let  $\alpha, \beta \in (0, 1)$ . Given a unit vector  $x \in S^{n-1}$ , its least common denominator (LCD), denoted  $LCD_{\alpha, \beta}(x)$ , is the infimum of  $D > 0$  such that we can decompose  $\{Dx\} = u + v$ , where  $u$  is  $(\alpha n)$ -sparse and  $\|v\|_2 \leq \beta \min(D, \sqrt{n})$ .*

▷ **Claim 17.** Assume  $x \in S^{n-1}$  is  $(5\alpha, \beta)$ -incompressible. Then  $LCD_{\alpha, \beta}(x) > \sqrt{\alpha n}$ .

*Proof.* Let  $D = LCD_{\alpha, \beta}(x)$  and assume towards a contradiction that  $D \leq \sqrt{\alpha n}$ . Let  $y = Dx$ . As  $\|y\|_2^2 \leq \alpha n$  there are at most  $4\alpha n$  coordinates  $i \in [n]$  where  $|y_i| \geq 1/2$ . In all other coordinates  $\{y_i\} = y_i$ , and hence  $y - \{y\}$  is  $(4\alpha n)$ -sparse. By assumption we can decompose  $\{y\} = u + v$  where  $u$  is  $(\alpha n)$ -sparse and  $\|v\|_2 \leq \beta D$ . This implies that we can decompose  $y = u' + v$  where  $u'$  is  $(5\alpha n)$ -sparse. Thus, we can decompose  $x = y/D$  as  $x = u'' + v''$ , where  $u'' = u'/D$  is  $(5\alpha n)$ -sparse and  $v'' = v/D$  satisfies  $\|v''\|_2 \leq \beta$ . This violates the assumption that  $x$  is  $(5\alpha, \beta)$ -incompressible. ◁

Our main goal in this section is to prove the following lemma, which extends Claim 8 assuming  $x$  has large LCD. To get intuition, we note that the lemma below is useful as long as  $\beta \ll \gamma \ll 1$ . We will later set  $\gamma = \sqrt{\beta}$  to be such a choice. In particular, if we set  $\beta = m^{-1/2}$  then we have  $\gamma = m^{-1/4}$ .

► **Lemma 18.** *Let  $X \sim \mathcal{D}^n$ . Let  $\alpha, \beta, \gamma \in (0, 1/2)$ ,  $x \in S^{n-1}$  be  $(\alpha, \gamma)$ -incompressible and set  $D = LCD_{\alpha, \beta}(x)$ . Then for every  $\varepsilon \geq 1/2\pi m D$ , it holds that*

$$\Pr[|\langle X, x \rangle| \leq \varepsilon] \leq c \left( \frac{\varepsilon}{\gamma} + \frac{1}{(\alpha\beta m)^{\alpha n}} \right).$$

The proof of Lemma 18 relies on Esseen’s lemma [4].

► **Lemma 19** (Esseen’s Lemma). *Let  $Y$  be a real-valued random variable. Let  $\phi_Y(t) = \mathbb{E}[e^{itY}]$  denote the characteristic function of  $Y$ . Then for any  $\varepsilon > 0$ , it holds that*

$$\Pr[|Y| \leq \varepsilon] \leq c\varepsilon \int_{-1/\varepsilon}^{1/\varepsilon} |\phi_Y(t)| dt.$$

Before proving Lemma 18, we need some auxiliary claims. Fix some  $x \in S^{n-1}$ , let  $X \sim \mathcal{D}^n$  and let  $Y = \langle X, x \rangle$ . In order to apply Lemma 19, we need to compute the characteristic function of  $Y$ .

▷ **Claim 20.** Let  $X \sim \mathcal{D}^n$ ,  $x \in S^{n-1}$  and set  $Y = \langle X, x \rangle$ . For  $t \in \mathbb{R}$  it holds that

$$|\phi_Y(t)| = \prod_{k=1}^n F\left(\frac{x_k t}{2\pi m}\right)$$

where  $F : \mathbb{R} \rightarrow \mathbb{R}$  is defined as follows:

$$F(y) = \left| \frac{\sin((2m+1)\pi y)}{(2m+1)\sin(\pi y)} \right|.$$

### 33:10 Singularity of Random Integer Matrices with Large Entries

Proof. We have  $Y = \sum x_i \xi_i$  where  $\xi_1, \dots, \xi_n \sim \mathcal{D}$  are independent. Hence

$$\phi_Y(t) = \prod_{k=1}^n \mathbb{E}[e^{ix_k \xi_k t}].$$

Next we compute

$$\mathbb{E}[e^{ix_k \xi_k t}] = \frac{1}{2m+1} \sum_{\ell=-m}^m e^{ix_k(\ell/m)t} = \frac{1}{2m+1} \cdot \frac{\sin(\frac{2m+1}{2m} x_k t)}{\sin(\frac{1}{2m} x_k t)}.$$

Hence

$$|\mathbb{E}[e^{itx_k \xi_k}]| = F\left(\frac{x_k t}{2\pi m}\right). \quad \triangleleft$$

The next claim proves some basic properties of the function  $F$ .

▷ **Claim 21.** The function  $F$  satisfies the following properties:

1.  $F$  is symmetric:  $F(y) = F(-y)$  for all  $y \in \mathbb{R}$ .
2.  $F$  is invariant to shifts by integers:  $F(y) = F(\{y\})$  for  $y \in \mathbb{R}$ .
3.  $F$  is bounded:  $F(y) \in [0, 1]$  for all  $y \in \mathbb{R}$ .
4.  $F(y) \leq G(my)$  for  $y \in [0, 1/2]$ , where  $G : \mathbb{R}_+ \rightarrow [0, 1]$  is defined as follows:

$$G(y) = \begin{cases} e^{-\eta y^2} & \text{if } y \in [0, 1] \\ \frac{e^{-\eta}}{y} & \text{if } y \geq 1 \end{cases}$$

Here,  $\eta > 0$  is an absolute constant. Note that  $G$  is decreasing.

Proof. The first three claims follow immediately from the definition of  $F$  in Claim 20. In order to prove the last claim, we will prove that  $F(y) \leq \frac{c_1}{my}$  for  $y \in [1/m, 1/2]$  for some  $c_1 \in (0, 1)$ ; and that  $F(y) \leq \exp(-c_2(my)^2)$  for  $y \in [0, 1/m]$  for some  $c_2 > 0$ . The claim then follows by taking  $\eta = \min(\ln(1/c_1), c_2)$ .

First, note that  $F(y) \leq \frac{1}{(2m+1)|\sin(\pi y)|}$ . Using Taylor expansion at 0, we get for  $y \in [0, 1/2]$  that

$$\sin(\pi y) \geq \pi y - \frac{\pi^3 y^3}{6} \geq \frac{\pi y}{2}.$$

In particular,  $F(y) \leq \frac{1}{\pi my}$ , which gives the desired bound for  $c_1 = 1/\pi$ .

Next, note that  $F(y) = \frac{1}{2m+1} |\sin((2m+1)\pi y) \cdot \csc(\pi y)|$ . The Laurent series of  $\csc(x)$  at  $x \neq 0$  is  $\csc(x) = \frac{1}{x} + \frac{x}{6} + \frac{7x^3}{360} + \frac{31x^5}{15120} + \Theta(x^7)$  and the Taylor series for  $\sin(x)$  is  $\sin(x) = x - \frac{x^3}{3!} + \frac{x^5}{5!} + \Theta(x^7)$ . So for  $y \in [0, 1/m]$  we have  $F(y) \leq 1 - c_2(my)^2 \leq \exp(-c_2(my)^2)$ . ◁

We also need the following claim, which shows that incompressible vectors retain a large fraction of their norm when restricted to small coordinates. We use the following notation: given  $x \in \mathbb{R}^n$  and a set of coordinates  $J \subset [n]$ , we denote by  $x|_J \in \mathbb{R}^J$  the restriction of  $x$  to coordinates in  $J$ .

▷ **Claim 22.** Let  $x \in S^{n-1}$  be  $(\alpha, \gamma)$ -incompressible. Let  $J = \left\{i : x_i \leq \frac{1}{\sqrt{\alpha n - 1}}\right\}$ . Then

$$\|x|_J\|_2^2 \geq \|x|_J\|_\infty^2 + \gamma^2.$$

Proof. Let  $J^c = [n] \setminus J$ . Since  $x$  is a unit vector, we have  $|J^c| \leq \alpha n - 1$ . Let  $j \in J$  be such that  $|x_j|$  is maximal and take  $K = J \setminus \{j\}$ . Then  $|K^c| \leq \alpha n$ , and since we assume that  $x$  is  $(\alpha, \gamma)$ -incompressible, we have  $\|x|_K\|_2 \geq \gamma$ . This completes the proof, since

$$\|x|_J\|_2^2 - \|x|_J\|_\infty^2 = \|x|_J\|_2^2 - x_j^2 = \|x|_K\|_2^2 \geq \gamma^2. \quad \triangleleft$$

We would need the following lemma in the computations later on.

► **Lemma 23.** *Let  $\gamma, \delta > 0$ . Let  $x \in \mathbb{R}^n$  be a vector such that  $\|x\|_\infty \leq \delta$  and  $\|x\|_2^2 \geq \|x\|_\infty^2 + \gamma^2$ . Let  $T = \pi m / \delta$ . Then*

$$I = \int_0^T \prod_{i=1}^n F\left(\frac{x_i t}{2\pi m}\right) dt \leq \frac{c}{\gamma}.$$

**Proof.** To simplify the proof, we may assume by Claim 21(1) that  $x_i \geq 0$  for all  $i$ . Reorder the coordinates of  $x$  so that  $x_1 \geq x_2 \geq \dots \geq x_n \geq 0$ . Observe that for  $x_i \in [0, T]$  we have  $\frac{x_i t}{2\pi m} \in [0, 1/2]$  and hence we can apply Claim 21(4) and bound each term by  $F\left(\frac{x_i t}{2\pi m}\right) \leq G\left(\frac{x_i t}{2\pi}\right)$ . Thus

$$I \leq \int_0^T \prod_{i=1}^n G\left(\frac{x_i t}{2\pi}\right) dt = 2\pi \int_0^{T/2\pi} \prod_{i=1}^n G(x_i t) dt \leq 2\pi \int_0^\infty \prod_{i=1}^n G(x_i t) dt.$$

We bound this last integral. Let  $t_i = 1/x_i$  so that  $t_1 \leq t_2 \leq \dots \leq t_n$ . For simplicity of notation set  $t_0 = 0, t_{n+1} = \infty$ . We break the computation of the integral to intervals  $[t_k, t_{k+1})$  for  $k = 0, \dots, n$ , and denote by  $I_k$  the integral in each interval:

$$I_k = \int_{t_k}^{t_{k+1}} \prod_{i=1}^n G(x_i t) dt = \int_{t_k}^{t_{k+1}} \prod_{i=1}^k \frac{e^{-\eta}}{x_i t} \cdot \prod_{i=k+1}^n e^{-\eta t^2 x_i^2} dt = e^{-\eta k} \int_{t_k}^{t_{k+1}} \frac{e^{-\eta t^2 \sum_{i=k+1}^n x_i^2}}{t^k \prod_{i=1}^k x_i} dt.$$

Fix  $k$  and consider first the case that  $\sum_{i=k+1}^n x_i^2 \geq \gamma^2/2$ . In this case, using the fact that  $x_i t \geq 1$  for  $i \in [k]$  and  $t \in [t_k, t_{k+1}]$ , we can bound  $I_k$  by

$$I_k \leq e^{-\eta k} \int_{t_k}^{t_{k+1}} e^{-\eta \gamma^2 t^2 / 2} dt \leq e^{-\eta k} \int_0^\infty e^{-\eta \gamma^2 t^2 / 2} dt \leq \frac{c_1 e^{-\eta k}}{\gamma}.$$

Next, consider the case that  $\sum_{i=k+1}^n x_i^2 < \gamma^2/2$ , which means that  $\sum_{i=1}^k x_i^2 > \|x\|_2^2 - \gamma^2/2 \geq \|x\|_\infty^2 + \gamma^2/2$ . Observe that this is impossible for  $k = 0$  or  $k = 1$ , and hence we may assume  $k \geq 2$ . In this case we bound

$$I_k \leq e^{-\eta k} \int_{t_k}^{t_{k+1}} \frac{1}{t^k \prod_{i=1}^k x_i} dt \leq e^{-\eta k} \int_{t_k}^\infty \frac{1}{t^k \prod_{i=1}^k x_i} dt = \frac{e^{-\eta k} x_k^{k-1}}{(k-1) \prod_{i=1}^k x_i} \leq \frac{e^{-\eta k}}{(k-1)x_1}.$$

By our assumption,  $\sum_{i=1}^k x_i^2 \geq \gamma^2/2$  and hence  $x_1^2 \geq \gamma^2/2k$ . Thus we can bound

$$I_k \leq \frac{e^{-\eta k}}{(k-1)\gamma/\sqrt{2k}} \leq \frac{c_2 e^{-\eta k}}{\gamma}.$$

Overall, we bounded the integral by

$$I \leq 2\pi \sum_{k=0}^n I_k \leq 2\pi \max(c_1, c_2) \sum_{k=0}^n \frac{e^{-\eta k}}{\gamma} \leq \frac{c}{\gamma},$$

where we used the fact that  $c_1, c_2, \eta > 0$  are all absolute constants. ◀

### 33:12 Singularity of Random Integer Matrices with Large Entries

Now we have all the ingredients to complete proof of Lemma 18.

**Proof of Lemma 18.** Let  $Y = \langle X, x \rangle$ . Lemma 19 and Claim 20 give the bound

$$\Pr[|Y| \leq \varepsilon] \leq c_1 \varepsilon I,$$

where  $I$  is the following integral:

$$I = \int_0^{1/\varepsilon} \prod_{i=1}^n F\left(\frac{x_i t}{2\pi m}\right) dt.$$

Let  $T = \pi m \sqrt{\alpha n - 1}$ . We will bound the integral in the regime  $[0, T]$  and  $[T, 1/\varepsilon]$ , and denote the corresponding integrals by  $I_1, I_2$ .

Consider first the integral  $I_1$  in  $[0, T]$ . Let  $\delta = 1/\sqrt{\alpha n - 1}$  and take  $J = \{i : x_i \leq \delta\}$ . Observe that by Claim 21(3), we can bound  $F\left(\frac{x_i t}{2\pi m}\right) \leq 1$  for  $i \notin J$ . Thus

$$I_1 = \int_0^T \prod_{i=1}^n F\left(\frac{x_i t}{2\pi m}\right) dt \leq \int_0^T \prod_{i \in J} F\left(\frac{x_i t}{2\pi m}\right) dt.$$

Next, as we assume that  $x$  is  $(\alpha, \gamma)$ -incompressible, Claim 22 gives that  $\|x|_J\|_2^2 \geq \|x|_J\|_\infty^2 + \gamma^2$ . Applying Lemma 23 to  $x|_J$ , we bound the first integral by

$$I_1 \leq \frac{c_2}{\gamma}.$$

Next, consider the second integral  $I_2$  in  $[T, 1/\varepsilon]$ . We will apply the LCD assumption to uniformly bound the integrand in this range. Given  $t \in [T, 1/\varepsilon]$ , let  $y(t) = \left\{\frac{x_i t}{2\pi m}\right\} \in [-1/2, 1/2]^n$ ,  $\beta(t) = \beta \min(t/\sqrt{n}, 1)$  and  $J(t) = \{i \in [n] : |y(t)_i| \geq \beta(t)\}$ . As  $t \leq 1/\varepsilon \leq 2\pi m D$ , we have that  $\frac{t}{2\pi m} \leq D = \text{LCD}_{\alpha, \beta}(x)$ , and hence  $|J(t)| \geq \alpha n$ . Applying Claim 21, we bound the integrand by

$$\prod_{i=1}^n F\left(\frac{x_i t}{2\pi m}\right) = \prod_{i=1}^n F(y_i) \leq \prod_{i \in J(t)} F(y_i) \leq \prod_{i \in J(t)} G(my_i) \leq \prod_{i \in J(t)} G(m\beta(t)) \leq G(m\beta(t))^{\alpha n}.$$

Following up on this, we have

$$\beta(t) \geq \beta(T) = \beta \frac{\sqrt{\alpha n - 1}}{\sqrt{n}} \geq \beta \sqrt{\alpha/2} \geq \alpha \beta,$$

where we used the assumptions that  $\alpha n \geq 2$  and  $\alpha \leq 1/2$ . We may assume that  $\alpha \beta m \geq 1$ , otherwise the conclusion of the lemma is trivial. In that case we have by Claim 21(4) that

$$G(m\beta(t)) \leq G(\alpha \beta m) \leq \frac{1}{\alpha \beta m}.$$

Thus we can bound the integral  $I_2$  by

$$I_2 = \int_T^{1/\varepsilon} \prod_{i=1}^n F\left(\frac{x_i t}{2\pi m}\right) dt \leq \frac{1/\varepsilon}{(\alpha \beta m)^{\alpha n}}.$$

Overall, we get

$$\Pr[|Y| \leq \varepsilon] \leq c_1 \varepsilon I = c_1 \varepsilon (I_1 + I_2) \leq \frac{c_1 c_2 \varepsilon}{\gamma} + \frac{c_1}{(\alpha \beta m)^{\alpha n}}. \quad \blacktriangleleft$$

## 6 Bounding the LCD

Our main goal in this section is to prove that a random normal vector  $X^*$  has large LCD with high probability. Let  $M'$  denote the  $(n-1) \times n$  matrix with rows  $X_1, \dots, X_{n-1}$ . Let  $D_0 = \sqrt{\alpha n}$  and  $D_1 = \beta(\alpha\beta m)^{\alpha n}$  in this section.

► **Lemma 24.** *Let  $\alpha \in (0, 1/40)$ ,  $\beta \in (0, 1/2)$  and  $D \in (1, D_1)$ . Then*

$$\Pr[\text{LCD}_{\alpha,\beta}(X^*) \leq D] \leq D^2 (1/\alpha c)^n \beta^{cn}$$

for some absolute constant  $c \in (0, 1)$ .

We set  $\gamma = \sqrt{\beta}$  throughout the section. We first condition on a number of bad events not holding. Define:

$$E_1 = [\|M\| \geq \sqrt{n \log(1/\beta)}]$$

$$E_2 = [X^* \text{ is } (5\alpha, \beta)\text{-compressible}]$$

$$E_3 = [X^* \text{ is } (\alpha, \gamma)\text{-compressible}]$$

Applying Claim 6 for  $E_1$ , and Lemma 13 for  $E_2, E_3$ , we get that

$$\Pr[E_1 \text{ or } E_2 \text{ or } E_3] \leq \beta^{cn}.$$

Thus, we will assume in this section that none of  $E_1, E_2, E_3$  hold. Assuming  $\neg E_2$ , Claim 17 yields that  $\text{LCD}_{\alpha,\beta}(X^*) \geq D_0$ . For  $D \geq D_0$  define

$$\mathcal{S}_D = \{x \in S^{n-1} : \text{LCD}_{\alpha,\beta}(x) \in [D, 2D] \text{ and } x \text{ is } (\alpha, \gamma)\text{-incompressible}\}.$$

The following is an analog of Lemma 7.2 in [11].

► **Claim 25.** Let  $D \geq D_0$  and set  $\nu = 6\beta\sqrt{n}/D$ . There exists a  $\nu$ -net  $\mathcal{N}_D \subset \mathcal{S}_D$  of size

$$|\mathcal{N}_D| \leq (D/\beta) \left( \frac{cD}{\sqrt{\alpha n}} \right)^n (1/\beta)^{\alpha n}.$$

Namely, for each  $x \in \mathcal{S}_D$  there exists  $y \in \mathcal{N}_D$  that satisfies  $\|x - y\|_2 \leq \nu$ .

*Proof.* Let  $x \in \mathcal{S}_D$  and shorthand  $D(x) = \text{LCD}_{\alpha,\beta}(x)$ . By definition, we can decompose  $\{D(x)x\} = u + v$  where  $u$  is  $(\alpha n)$ -sparse and  $\|v\|_2 \leq \beta \min(D, \sqrt{n}) \leq \beta\sqrt{n}$ .

Let  $W$  denote the set of  $(\alpha n)$ -sparse vectors  $w \in [-1/2, 1/2]^n$  such that each  $w_i$  is an integer multiple of  $\beta$ . Then  $|W| \leq \binom{n}{\alpha n} (1/\beta)^{\alpha n}$ , and there exists  $w \in W$  such that  $\|u - w\|_\infty \leq \beta$ , which implies  $\|u - w\|_2 \leq \beta\sqrt{n}$ . This implies that

$$\|\{D(x)x\} - w\|_2 \leq 2\beta\sqrt{n}.$$

Next, consider  $[D(x)x] \in \mathbb{Z}^n$ . As  $\lceil |a| \rceil \leq 2|a|$  for all  $a \in \mathbb{Z}$ , we have  $\|[D(x)x]\|_2 \leq 2D(x)\|x\|_2 \leq 4D$ . Let  $Z = \{z \in \mathbb{Z}^n : \|z\|_2 \leq 4D\}$ . Then  $[D(x)x] \in Z$ , and Claim 11 bounds  $|Z| \leq \left(1 + \frac{c_1 D}{\sqrt{n}}\right)^n$ . So there is  $z \in Z$  such that

$$\|D(x)x - z - w\|_2 \leq 2\beta\sqrt{n}.$$

Next, let  $R$  be set of integer multiples of  $\beta$  in the range  $[D, 2D]$ , so that  $|R| \leq D/\beta$  and there exists  $r \in R$  with  $|D(x) - r| \leq \beta$ . As  $\|x\|_2 = 1$  we have

$$\|rx - z - w\|_2 \leq 2\beta\sqrt{n} + \beta \leq 3\beta\sqrt{n}.$$

### 33:14 Singularity of Random Integer Matrices with Large Entries

Finally, define the set

$$Y = \{(z + w)/r : z \in Z, w \in W, r \in R\}.$$

Then there exists  $y \in Y$  such that

$$\|x - y\|_2 \leq 3\beta\sqrt{n}/D = \nu/2.$$

Take a maximal set  $\mathcal{N}_D \subset \mathcal{S}_D$  which is  $\nu$ -separated. That is, for any  $x', x'' \in \mathcal{N}_D$  we have  $\|x' - x''\|_2 > \nu$ . Note that by maximality,  $\mathcal{N}_D$  is a  $\nu$ -net in  $\mathcal{S}_D$ . Next, note that  $|\mathcal{N}_D| \leq |Y|$ , as any point  $x \in \mathcal{N}_D$  must be  $(\nu/2)$ -close to a distinct point in  $Y$ . To conclude, we need to bound  $|Y|$ . We have

$$|Y| \leq |W||Z||R| \leq \binom{n}{\alpha n} (1/\beta)^{\alpha n} \cdot \left(1 + \frac{cD}{\sqrt{n}}\right)^n \cdot (D/\beta).$$

As  $D \geq D_0 = \sqrt{\alpha n}$  we can simplify  $1 + \frac{cD}{\sqrt{n}} \leq \frac{(c+1)D}{\sqrt{\alpha n}}$ . We can trivially bound  $\binom{n}{\alpha n} \leq 2^n$ . Hence

$$|\mathcal{N}_D| \leq |Y| \leq (D/\beta) \left(\frac{2(c+1)D}{\sqrt{\alpha n}}\right)^n (1/\beta)^{\alpha n}. \quad \triangleleft$$

▷ **Claim 26.** For any  $D \in [D_0, D_1]$  we have

$$\Pr[X^* \in \mathcal{S}_D \text{ and } \neg E_1] \leq D^2 (c/\alpha)^n \beta^{n/8}.$$

*Proof.* First, note that we may assume  $\beta \leq \beta_0$  for any absolute constant  $\beta_0 \in (0, 1)$ , by choosing the constant  $c > 0$  large enough to compensate for that (namely, taking  $c \geq 1/\beta_0$ ). In particular, setting  $\beta_0 = 2^{-20}$  works.

If  $X^* \in \mathcal{S}_D$  then there exists  $y \in \mathcal{N}_D$  such that  $\|X^* - y\|_2 \leq \nu$  for  $\nu = 6\beta\sqrt{n}/D$ . By definition of  $X^*$  we have  $M'X^* = 0$ , and as we assume that  $\neg E_1$  hold, we have

$$\|M'y\|_2 \leq \|M'\| \|X^* - y\|_2 \leq \nu\sqrt{n \log(1/\beta)}.$$

Set  $\beta_1 = 6\beta\sqrt{\log(1/\beta)}$ . The assumption  $\beta \leq \beta_0$  implies that  $\beta_1 \leq \beta^{3/4}$ . Set  $\delta = \beta^{3/4}\sqrt{n}/D$ . We will bound the probability that there exists  $y \in \mathcal{N}_D$  such that  $\|M'y\|_2 \leq \delta\sqrt{n}$ .

Fix  $y \in \mathcal{N}_D$ , let  $X \sim \mathcal{D}^n$ , and define  $p(\varepsilon) = \Pr[|\langle X, y \rangle| \leq \varepsilon]$ . As  $y \in \mathcal{N}_D \subset \mathcal{S}_D$  we have that  $y$  is  $(\alpha, \gamma)$ -incompressible, and hence we can apply Lemma 18, which gives

$$p(\varepsilon) \leq c_1 \left( \frac{\varepsilon}{\gamma} + \frac{1}{(\alpha\beta m)^{\alpha n}} \right) \quad \text{for all } \varepsilon \geq 1/2\pi m D.$$

Next, we restrict attention to only  $\varepsilon \geq \delta$ , and note that in this regime the first term is dominant (since  $D \leq D_1$  we have  $\delta \geq \beta^{3/4}\sqrt{n}/D_1 \geq 1/(\alpha\beta m)^{\alpha n}$ ). We can then simplify the bound as

$$p(\varepsilon) \leq \frac{c_2 \varepsilon}{\gamma} \quad \text{for all } \varepsilon \geq \delta.$$

Applying Claim 9, and recalling that we set  $\gamma = \sqrt{\beta}$ , gives

$$\Pr[\|M'y\|_2 \leq \delta\sqrt{n}] \leq \left(\frac{c_3 \delta}{\gamma}\right)^{n-1} = \left(\frac{c_4 \beta^{1/4} \sqrt{n}}{D}\right)^{n-1}.$$

Union bounding over all  $y \in \mathcal{N}_D$ , using Claim 25 to bound its size, gives

$$\begin{aligned} \Pr[\exists y \in \mathcal{N}_D, \|M'y\|_2 \leq \delta\sqrt{n}] &\leq (D/\beta) \left(\frac{cD}{\sqrt{\alpha n}}\right)^n (1/\beta)^{\alpha n} \cdot \left(\frac{c_4\beta^{1/4}\sqrt{n}}{D}\right)^{n-1} \\ &\leq D^2 (c_5/\sqrt{\alpha})^n \beta^{n/4-\alpha n-2}. \end{aligned}$$

Our assumption  $\alpha < 1/40$  and the implicit assumption  $\alpha n \geq 2$  imply that  $\alpha n + 2 \leq n/8$ , which simplifies the above bound to the claimed bound.  $\triangleleft$

We are now in place to prove Lemma 24.

**Proof of Lemma 24.** We may assume that non of  $E_1, E_2, E_3$  hold, as the probability that any of them hold is at most  $\beta^{c_1 n}$  for some absolute constant  $c_1 \in (0, 1)$ . This in particular implies that  $\text{LCD}_{\alpha, \beta}(X^*) \geq D_0$ . Fix  $D \in [D_0, D_1]$ . As  $D \leq D_1$  we can applying Claim 26 to  $D_i = 2^i D_0$  as long as  $D_i \leq D/2$ . Summing the results we get

$$\Pr[\text{LCD}_{\alpha, \beta}(X^*) \leq D \text{ and } \neg E_1, \neg E_2, \neg E_3] \leq (2D)^2 (c_2/\alpha)^n \beta^{n/8}.$$

Thus overall we have

$$\Pr[\text{LCD}_{\alpha, \beta}(X^*) \leq D] \leq \beta^{c_1 n} + (2D)^2 (c_2/\alpha)^n \beta^{n/8}.$$

The lemma follows by taking  $c \in (0, 1)$  small enough.  $\blacktriangleleft$

## 7 Completing the proof

We now prove Theorem 1.

**Proof of Theorem 1.** Fix  $\alpha = 1/50, \beta = 1/\sqrt{m}$  and assume  $m \geq m_0$  for a large enough constant  $m_0$  to be determined soon. Let  $D$  to be determined soon. Lemma 24 gives

$$\Pr[\text{LCD}_{\alpha, \beta}(X^*) \leq D] \leq D^2 (1/\alpha c_1)^n \beta^{c_1 n}.$$

As  $\alpha$  is constant, and using the choice  $\beta = 1/\sqrt{m}$ , we can simplify the bound as follows. For a small enough constant  $c \in (0, 1)$ , setting  $D = m^{cn}$  and  $c_2 = 1/\alpha c_1$ , we have

$$\Pr[\text{LCD}_{\alpha, \beta}(X^*) \leq m^{cn}] \leq m^{2cn} c_2^n m^{-(c_1/2)n} \leq c_2^n m^{-(c_1/2-2c)n} \leq c_2^n m^{-cn}.$$

Assuming  $m \geq m_0$  for a large enough constant  $m_0$ , we can simplify this bound further as

$$\Pr[\text{LCD}_{\alpha, \beta}(X^*) \leq m^{cn}] \leq m^{-(c/2)n}.$$

Next, assume  $D = \text{LCD}_{\alpha, \beta}(X^*) \geq m^{cn}$ . In this case, Lemma 18 for  $\varepsilon = 1/2\pi m D$  gives that

$$\Pr[\langle X^*, X \rangle = 0] \leq \Pr[|\langle X^*, X \rangle| \leq \varepsilon] \leq c_3 \left( \frac{\varepsilon}{\gamma} + \frac{1}{(\alpha\beta m)^{\alpha n}} \right) \leq m^{-c'n}$$

for some  $c' \in (0, 1)$ . Overall we obtain the desired bound.  $\blacktriangleleft$

## Abstract

The graph isomorphism distance between two graphs  $G_u$  and  $G_k$  is the fraction of entries in the adjacency matrix that has to be changed to make  $G_u$  isomorphic to  $G_k$ . We study the problem of estimating, up to a constant additive factor, the graph isomorphism distance between two graphs in the query model. In other words, if  $G_k$  is a known graph and  $G_u$  is an unknown graph whose adjacency matrix has to be accessed by querying the entries, what is the query complexity for testing whether the graph isomorphism distance between  $G_u$  and  $G_k$  is less than  $\gamma_1$  or more than  $\gamma_2$ , where  $\gamma_1$  and  $\gamma_2$  are two constants with  $0 \leq \gamma_1 < \gamma_2 \leq 1$ . It is also called the tolerant property testing of graph isomorphism in the dense graph model. The non-tolerant version (where  $\gamma_1$  is 0) has been studied by Fischer and Matsliah (SICOMP'08).

In this paper, we prove a (interesting) connection between tolerant graph isomorphism testing and tolerant testing of the well studied Earth Mover's Distance (EMD). We prove that deciding tolerant graph isomorphism is equivalent to deciding tolerant EMD testing between multi-sets in the query setting. Moreover, the reductions between tolerant graph isomorphism and tolerant EMD testing (in query setting) can also be extended directly to work in the two party Alice-Bob communication model (where Alice and Bob have one graph each and they want to solve tolerant graph isomorphism problem by communicating bits), and possibly in other sublinear models as well.

Testing tolerant EMD between two probability distributions is equivalent to testing EMD between two multi-sets, where the multiplicity of each element is taken appropriately, and we sample elements from the unknown multi-set **with** replacement. In this paper, our (main) contribution is to introduce the problem of (*tolerant*) EMD testing between multi-sets (over Hamming cube) when we get samples from the unknown multi-set **without** replacement and to show that *this variant of tolerant testing of EMD is as hard as tolerant testing of graph isomorphism between two graphs*. Thus, while testing of equivalence between distributions is at the heart of the non-tolerant testing of graph isomorphism, we are showing that the estimation of the EMD over a Hamming cube (when we are allowed to sample **without** replacement) is at the heart of tolerant graph isomorphism. We believe that the introduction of the problem of testing EMD between multi-sets (when we get samples **without** replacement) opens an entirely new direction in the world of testing properties of distributions.

## 1 Introduction

Graph isomorphism (GI) has been one of the most celebrated problems in computer science. Roughly speaking, the graph isomorphism problem asks whether two graphs are structure-preserving. Namely, given two graphs  $G_u$  and  $G_k$ , graph isomorphism of  $G_u$  and  $G_k$  is a bijection  $\psi : V(G_u) \rightarrow V(G_k)$  such that for all pair of vertices  $u, v \in V(G_u)$ , the edges  $\{u, v\} \in E(G_u)$  if and only if  $\{\psi(u), \psi(v)\} \in E(G_k)$ <sup>1</sup>. One central open problem in complexity theory is whether the graph isomorphism problem can be solved in polynomial time. Recently in a breakthrough result, Babai [5] proved that the graph isomorphism problem could be decided in quasi-polynomial time.

For a central problem like the graph isomorphism, naturally, one would like to understand its (and related problems) computational complexity for various models of computation. While most of the focus has been on the standard time complexity in the RAM model for various classes of graphs (and hyper-graphs), other complexity measures like space complexity, parameterized complexity, and query complexity have also been studied over the past few decades (see the Dagstuhl Report [7] and PhD thesis of Sun [24]).

A natural extension of the GI problem is to estimate the “graph isomorphism distance” between two graphs. In other words, given two graphs  $G_u$  and  $G_k$ , what fraction of edges are necessary to add or delete to make the graphs isomorphic.

► **Definition 1.1.** Let  $G_u = (V_u, E_u)$  and  $G_k = (V_k, E_k)$  be two graphs with  $|V_u| = |V_k| = n$ . Given a bijection  $\phi : V_u \rightarrow V_k$ , the distance between the graphs  $G_u$  and  $G_k$  with respect to the bijection  $\phi$  is

$$d_\phi(G_u, G_k) := |\{(u, v) : \text{Exactly one among } (u, v) \in E_u \text{ or } (\phi(u), \phi(v)) \in E_k \text{ holds}\}|.$$

The GRAPH ISOMORPHISM DISTANCE (or GI-distance in short) between graphs  $G_u$  and  $G_k$  is defined as  $\min_{\phi: V_u \rightarrow V_k} d_\phi(G_u, G_k)/n^2$ , and is denoted by  $\delta_{GI}(G_u, G_k)$  (we will use  $d(G_u, G_k)$  to mean  $n^2 \delta_{GI}(G_u, G_k)$ ).

The problem of computing GI-distance between two graphs is known to be  $\#P$ -hard [18]. The next natural question is:

*What is the complexity for approximating (either by a constant additive or multiplicative factor) the graph isomorphism distance between two graphs?*

In [18], it was also proven that the problem of computing GI-distance between two graphs is APX-hard. So, approximating  $\delta_{GI}(G_u, G_k)$  up to a constant multiplicative factor is NP-hard. In this paper, we study this problem of approximating (up to a constant additive factor) the GI-distance between two graphs in the query model and two party communication complexity model.

### 1.1 Property Testing of Graph Isomorphism

Formally speaking, the main problem is: given two graphs  $G_u$  and  $G_k$  and an approximation parameter  $\zeta \in (0, 1)$ , the goal is to output an estimate  $\alpha$  such that

$$\delta_{GI}(G_u, G_k) - \zeta \leq \alpha \leq \delta_{GI}(G_u, G_k) + \zeta.$$

<sup>1</sup> In a graph  $G$ ,  $V(G)$  and  $E(G)$  denote the sets of vertices and edges in  $G$ , respectively.

In the query model, the problem is equivalent (up to a constant factor) to the tolerant property testing of graph isomorphism in the dense graph model (introduced in the work of Parnas, Ron and Rubinfeld [21]). For  $0 \leq \gamma < 1$ , two graphs  $G_u$  and  $G_k$ , with  $n$  vertices, are called  $\gamma$ -close or  $\gamma$ -far to isomorphic<sup>2</sup> if  $d(G_u, G_k) \leq \gamma n^2$  or  $d(G_u, G_k) \geq \gamma n^2$ , respectively. In  $(\gamma_1, \gamma_2)$ -tolerant GI testing, we are given two graphs  $G_u$  and  $G_k$ , and two parameters  $0 \leq \gamma_1 < \gamma_2 \leq 1$ , with the guarantee that either the graphs are  $\gamma_1$ -close or  $\gamma_2$ -far. One of the graphs (usually denoted as  $G_u$ ) is accessed by querying the entries of its adjacency matrix. In contrast, the other graph (usually denoted as  $G_k$ <sup>3</sup>) is known to the query algorithm, and no cost for accessing the entries of the adjacency matrix of  $G_k$  is incurred. The query complexity is the number of queries (to the adjacency matrix of  $G_u$ ) that are required for testing, (with correctness probability at least  $2/3$ <sup>4</sup>), whether  $G_u$  and  $G_k$  are  $\gamma_1$ -close or  $\gamma_2$ -far. The query algorithm is assumed to have unbounded computational power.

The non-tolerant property testing version of the graph isomorphism problem (that is, when  $\gamma_1 = 0$ ) was first studied by Fischer and Matsliah [13] and subsequently, Babai and Chakraborty [6] studied the non-tolerant property testing version of the hypergraph isomorphism problem. Recently, the non-tolerant testing of GI has been considered in various other models (like Goldreich [15] studied the problem for the *bounded degree graph model* of property testing and Levi and Medina [17] considered the problem in the *distributed* setting). However, the tolerant version of the problem remains elusive and it is surprising that the tolerant version of a fundamental problem like graph isomorphism (in query model) is not addressed in the literature, though the non-tolerant version of GI testing problem has been resolved more than a decade ago in [13] (when one graph is unknown). On a different note, there are also studies of non-tolerant version of graph isomorphism testing in the literature when both the graphs are unknown [13, 19]. We will not discuss much about that case as the main focus of this paper is different.

Before proceeding further, we want to note that there is a simple algorithm with query complexity  $\tilde{O}(n)$  for tolerant testing of graph isomorphism (when one of the graphs is known in advance). Basically, one goes over all possible  $n!$  bijections  $\phi: V_u \rightarrow V_k$  and estimates the distance between  $G_u$  and  $G_k$  with respect to the permutation. The samples may be reused<sup>5</sup>, and hence we have the following observation.

► **Observation 1.2.** Given a known graph  $G_k$  and an unknown graph  $G_u$  and any approximation parameter  $\zeta \in (0, 1)$ , there is a query algorithm that makes  $\tilde{O}(n)$  queries and outputs a number  $\alpha$  such that, with probability at least  $2/3$ , the following holds:

$$\delta_{GI}(G_u, G_k) - \zeta \leq \alpha \leq \delta_{GI}(G_u, G_k) + \zeta.$$

But obtaining a lower bound matching (at least up to a polylog factor) the upper bound of Observation 1.2 is not at all obvious. This paper's main contribution is to show an equivalence between tolerant testing of graph isomorphism and tolerant EMD testing between multi-sets (in the query setting).

<sup>2</sup> As a shorthand, rather than saying  $\gamma$ -close or  $\gamma$ -far to isomorphic, we will just say  $\gamma$ -close or  $\gamma$ -far respectively.

<sup>3</sup>  $G_u$  and  $G_k$  denote the unknown and known graphs, respectively.

<sup>4</sup> The correctness probability can be made any  $1 - \delta$  by incurring a multiplicative factor of  $O(\log \frac{1}{\delta})$  in the query complexity.

<sup>5</sup> If the samples are  $\Theta(\log(n!))$ , then the error probability can be bounded using the union bound.

Like many other property testing problems, the core difficulty in the testing of GI is understanding certain properties of distributions. In the case of the non-tolerant version of GI, it has been shown in [13] that the core problem is testing the variation distance between two distributions. Their upper bound result can be restated as: if there is a property testing algorithm, with query complexity  $q(n)$  for testing equivalence between two distributions, on support size  $n$ <sup>6</sup>, then GI can be tested using  $\tilde{\mathcal{O}}(q(n))$  queries, where the tilde hides a polylogarithmic factor of  $n$  (number of vertices). And since the query complexity for testing identity of distributions (from [8], [20], [1], [26]) is known to be  $\mathcal{O}(\frac{\sqrt{n}}{\epsilon^2})$ , the query complexity for non tolerant GI-testing is  $\tilde{\mathcal{O}}(\sqrt{n})$ .

In the lower bound proof of [13], there is no direct reduction of the graph isomorphism problem to the variation distance problem. But it is important to note that lower bound proofs for both of these problems use the tightness of the *birthday paradox*. So, in some sense, one can say that the heart of the non-tolerant testing of GI is in testing variation distance between two distributions.

## 1.2 Earth Mover's Distance (EMD)

Let  $H = \{0, 1\}^n$  be a Hamming cube of dimension  $n$ , and  $p, q$  be two probability distributions on  $H$ . The *Earth Mover's Distance* between  $p$  and  $q$  is denoted by  $EMD(p, q)$  and defined as the optimum solution to the following linear program:

$$\text{Minimize } \sum_{i,j \in H} f_{ij} d_H(i, j) \quad \text{Subject to } \sum_{j \in H} f_{ij} = p(i) \forall i \in H, \text{ and } \sum_{i \in H} f_{ij} = q(j) \forall j \in H.$$

A standard way to think of sampling from any probability distribution is to consider it as a multi-set of elements with appropriate multiplicities, and samples are drawn **with** replacement from that multi-set. While estimating EMD between two multi-sets, although the most natural way to access the unknown multi-set is sampling **with** replacement, we introduce the problem of tolerant EMD testing over multi-sets with the access of samples **without** replacement.

► **Definition 1.3 (EMD over multi-sets while sampling with and without replacement).** Let  $S_1$  and  $S_2$  denote two multi-sets, over  $n$ -dimensional Hamming cube  $H = \{0, 1\}^n$  such that  $|S_1| = |S_2| = n$ . Consider the two distributions  $p_1$  and  $p_2$  over the Hamming cube  $H$  that are naturally defined by the sets  $S_1$  and  $S_2$  where for all  $x \in H$  probability of  $x$  in  $p_1$  (and  $p_2$ ) is the number of occurrences of  $x$  in  $S_1$  (and  $S_2$ ) divided by  $n$ . We then define the EMD between the multi-sets  $S_1$  and  $S_2$  as

$$EMD(S_1, S_2) \triangleq n \cdot EMD(p_1, p_2).$$

The problem of estimating the EMD over multi-sets while sampling **with** (or **without**) replacement means designing an algorithm, that given any two constants  $\beta_1, \beta_2$  such that  $0 \leq \beta_1 < \beta_2 \leq 1$ , a known multi-set  $S_k$  and access to the unknown multi-set  $S_u$  by sampling **with** (or **without**) replacement, decides whether  $EMD(S_k, S_u) \leq \beta_1 n^2$  or  $EMD(S_k, S_u) \geq \beta_2 n^2$  with probability at least  $2/3$ . Note that estimating the EMD over multi-sets while sampling **with** replacement is exactly same as estimating EMD between the distributions  $p_u$  and  $p_k$  with samples drawn according to  $p_u$ .

---

<sup>6</sup> Testing identity between two distributions means to test if the unknown distribution (from where the samples are drawn) is identical to the known distribution or if the variation distance between them more than  $\epsilon$ .

We will denote by  $\text{QWR}_{\text{EMD}}(n, \beta_1, \beta_2)$  (and  $\text{QWOR}_{\text{EMD}}(n, \beta_1, \beta_2)$ ) the number of samples **with** (or **without**) replacement required to decide the above from the unknown multi-set  $S_u$ . For ease of presentation, we will write  $\text{QWOR}_{\text{EMD}}(n)$  ( $\text{QWR}_{\text{EMD}}(n)$ ) instead of  $\text{QWOR}_{\text{EMD}}(n, \beta_1, \beta_2)$  ( $\text{QWR}_{\text{EMD}}(n, \beta_1, \beta_2)$ ) when the proximity parameters are clear from the context.

Earth Mover's Distance (EMD) is a fundamental metric over the space of distributions supported on a fixed metric space. Estimating EMD between two distributions, up to a multiplicative factor, has been extensively studied in mathematics and computer science. It is closely related to the embedding of the EMD metric into a  $\ell_1$  metric. Even the problem of estimation of EMD between distributions up to an additive factor has been well studied, for reference see [12], [23]. The hardness of estimating EMD between distributions depends heavily on the structure of the domain on which the distributions are supported. In [12], the authors have proved a lower bound of  $\Omega((\Delta/\epsilon)^d)$  on the query complexity for estimating (up to an additive error of  $\epsilon$ ) EMD between two distributions supported on the real cube  $[0, \Delta]^d$ . At the same time, it is not hard to see that if the support has certain structures, estimating EMD may be easy. In this paper, we focus on the estimation of EMD between two distribution when the metric space is the Hamming cube.

As noted earlier, sample access to a probability distribution is precisely the same as uniform sampling from a multi-set **with** replacement. Thus, from the results of Valiant and Valiant [25], it can be shown that the sample complexity for estimating the EMD between two distribution over the Hamming cube of dimension  $n$  is  $\Omega(n/\log n)$ . In other words,  $\text{QWR}_{\text{EMD}}(n) = \Omega(n/\log n)$ , and this is tight ignoring polynomial factor in  $\log n$  (See Theorem B.10 of Appendix B). But what about  $\text{QWOR}_{\text{EMD}}(n)$ ? To the best of our knowledge, the sample complexity measure when the distributions are accessed by sampling a multi-set **without** replacement has never been studied before (for testing/estimating *distances* between distributions/multi-sets). However, it is interesting to note that, sampling **without** replacement model has been considered before in a different context by Raskhodnikova, Ron, Shpilka and Smith [22] for proving a lower bound of distinct elements problem. Also, recently Goldreich [15] considered a similar sampling **without** replacement model while studying the non-tolerant graph isomorphism in the bounded degree model.

Coming back to our context, it can be proven that: if  $\text{QWOR}_{\text{EMD}}(n) = o(\sqrt{n})$ , then  $\text{QWR}_{\text{EMD}}(n) = o(\sqrt{n})$  (See Proposition B.7 of Appendix B). As  $\text{QWR}_{\text{EMD}}(n) = \Omega(\frac{n}{\log n})$ , we have a lower bound of  $\Omega(\sqrt{n})$  on  $\text{QWOR}_{\text{EMD}}(n)$ . To the best of our knowledge, there is no known better lower bound than  $\Omega(\sqrt{n})$  for  $\text{QWOR}_{\text{EMD}}(n)$ , although a lower bound of  $\Omega(\frac{n}{\log n})$  exists for  $\text{QWR}_{\text{EMD}}(n)$  (using observation in [12]). We verified that the proof of [27] also goes through for  $\text{QWOR}_{\text{EMD}}(n)$  as well (See Theorem 1.5). We now present the following conjecture:

► **Conjecture 1.** *There exist two constants  $\beta_1$  and  $\beta_2$  with  $0 < \beta_1 < \beta_2 < 1$  such that in order to decide whether  $\text{EMD}(S_k, S_u) \leq \beta_1 n^2$  or  $\text{EMD}(S_k, S_u) \geq \beta_2 n^2$ , with probability at least  $2/3$ ,  $\Omega\left(\frac{n}{\text{poly}(\log n)}\right)$  samples **without** replacement from the unknown multi-set  $S_u$  are necessary.*

One of our main contributions in this paper is introducing this complexity measure of  $\text{QWOR}_{\text{EMD}}(n)$  as well as the above conjecture. In the rest of the paper, we focus on exploring the connection between  $\text{QWOR}_{\text{EMD}}(n)$  and the query complexity of tolerant GI-testing. For a formal discussion on EMD over Hamming cube, please refer to Appendix B.

### 1.3 Our Results

Our main result of this paper is that we prove estimating GI-distance is as hard as tolerant EMD testing over multi-sets with the access of samples **without** replacement over the unknown multi-set  $S_u$ , ignoring polynomial factors of  $\log n$ .

► **Theorem 1.4 (Main Result).** *Let  $G_k$  and  $G_u$  denote the known and the unknown graphs on  $n$  vertices, respectively, and  $Q_{GI}(G_u, G_k)$  denotes the number of adjacency queries to  $G_u$ , required by the best algorithm that takes two constants  $\gamma_1, \gamma_2$  with  $0 \leq \gamma_1 < \gamma_2 \leq 1$  and decides whether  $d(G_u, G_k) \leq \gamma_1 n^2$  or  $d(G_u, G_k) \geq \gamma_2 n^2$  with probability at least  $2/3$ . Then*

$$Q_{GI}(G_u, G_k) = \tilde{\Theta}(\text{QWoR}_{\text{EMD}}(n))$$

where  $\tilde{\Theta}(\cdot)$  hides polynomial factors in  $\frac{1}{\gamma_2 - \gamma_1}$  and  $\log n$ .

#### 1.3.1 Implication of Theorem 1.4 to Query Complexity of Tolerant GI

It is interesting to note that our lower bound proof is via a *pure reduction* from tolerant graph isomorphism to tolerant testing of *EMD* of multi-sets over the Hamming cube using samples **without** replacement. Thus our reductions also hold for other computational models such as the communication complexity model. Regarding the lower bound on the sample complexity of tolerant EMD testing of multi-sets (in the **with** replacement model), using observation in [12], we note that the tolerant EMD testing is as hard as tolerant testing of variation distance. In [27], they gave a lower bound of  $\Omega(n^{1-o(1)})$  on the sample complexity for tolerant  $\ell_1$  testing. Although the proof of [27] uses samples **with** replacement (when we think of a distribution as a multi-set), it can be verified that the proof also works for samples **without** replacement.

► **Theorem 1.5 (Follows from [27]).** *For any constants  $0 < \alpha < \beta < 1$ , distinguishing between distribution pairs with statistical distance less than  $\alpha$  from those with distance greater than  $\beta$  requires  $n^{1-o(1)}$  samples **without** replacement.*

From Theorem 1.5, a similar lower bound follows for tolerant EMD testing of multi-sets **without** replacement. Thus, from Theorem 1.4, we have the following corollary:

► **Corollary 1.6.** *Let  $G_k$  and  $G_u$  be the known and unknown graphs on  $n$  vertices, respectively. For any constants  $0 < \gamma_1 < \gamma_2 < 1$ , distinguishing between isomorphism distance of  $d(G_u, G_k) \leq \gamma_1 n^2$  with  $d(G_u, G_k) \geq \gamma_2 n^2$  requires  $n^{1-o(1)}$  queries to the adjacency matrix of  $G_u$ . On the other hand, for any constants  $0 < \gamma_1 < \gamma_2 < 1$ , distinguishing between isomorphism distance of  $d(G_u, G_k) \leq \gamma_1 n^2$  with  $d(G_u, G_k) \geq \gamma_2 n^2$  can be done in  $\tilde{O}(n)$  queries.*

The lower bound of [27] was later improved to  $\Omega(\frac{n}{\log n})$  in [25]. However, the arguments of [25] are much more delicate and it is not completely clear to us whether their result of  $\Omega(\frac{n}{\log n})$  can be carried over to the **without** replacement setting, even if we allow a loss of polylogarithmic factor. So, we propose the following conjecture:

► **Conjecture 2.** *Let  $G_k$  and  $G_u$  be the known and unknown graphs on  $n$  vertices, respectively. For any constants  $0 < \gamma_1 < \gamma_2 < 1$ , distinguishing between isomorphism distance of  $d(G_u, G_k) \leq \gamma_1 n^2$  with  $d(G_u, G_k) \geq \gamma_2 n^2$  requires  $\Omega(\frac{n}{\log n})$  queries to the adjacency matrix of  $G_u$ .*

Note that Conjecture 1 and Conjecture 2 are equivalent. Besides, the difference between sampling **with** and **without** replacement is much more subtle. Freedman [14] has shown the difference when we sample elements **with** replacement from a set and that **without** replacement from the same set. However, when the number of samples is  $o(\sqrt{n})$ , the distribution of answers to the queries when samples are drawn **with** replacement is very close (in  $\ell_1$  distance) to the distribution of answers to the queries when samples are drawn **without** replacement. Thus, following Proposition B.7 along with Theorem 1.4, we can get an alternative proof of the following lower bound proved by Fischer and Matsliah [13].

► **Corollary 1.7** (Fischer and Matsliah [13]). *There exists a constant  $\zeta \in (0, 1)$  such that any query algorithm that decides, with probability at least  $2/3$ , if a known graph  $G_k$  and an unknown graph  $G_u$  is isomorphic or  $\gamma$ -far from isomorphic, with  $\gamma \leq \zeta$ , must make  $\Omega(\sqrt{n})$  queries.*

### 1.3.2 Implication of Theorem 1.4 to Communication Complexity of Tolerant GI

One of the central models of computation (particularly in the context of theoretical computer science) is the 2-player communication game introduced by Yao [28] in 1979. Communication complexity is one of the most studied complexity measures and has wide-ranging applications in many different areas of computer science. But surprisingly, as far as we know, the communication complexity problem of GI (where Alice has graph  $G_a$  and Bob has graph  $G_b$ , and they want to decide if  $G_a$  and  $G_b$  are isomorphic) has never been studied. One of the main reasons may be that, in the communication setup, the standard GI problem reduces to the string equality checking problem, and hence GI in the (randomized) communication setup is not that interesting anymore, since the randomized communication complexity, trivially, becomes  $O(1)$  (see the full version for the proof).

But when it comes to tolerant GI testing, the communication version is not at all obvious. So, if Alice and Bob are given two graphs  $G_a$  and  $G_b$  respectively, what is the (randomized) communication complexity for checking if  $d(G_a, G_b) \leq \gamma_1 n^2$  or  $d(G_a, G_b) \geq \gamma_2 n^2$ ? While we don't have a complete answer to this question yet, the following theorem holds from Theorem 1.2:

► **Theorem 1.8** (Informally stated). *If Alice and Bob are given two graphs  $G_a$  and  $G_b$  with  $n$  vertices respectively and the (randomized) communication complexity for checking if the graphs are  $\gamma_1$ -close or  $\gamma_2$ -far is  $c(n, \gamma_1, \gamma_2)$  then the following holds: There exists an absolute constant  $C$  such that if Alice and Bob are given two  $n$ -grained distributions<sup>7</sup> over the  $Cn$ -dimension Hamming cube, then the (randomized) communication complexity of checking if the Earth Mover's Distance between the distributions is at most  $\beta_1 n$  or at least  $\beta_2 n$  is  $\Theta(c(n, \gamma'_1, \gamma'_2))$ , where  $\gamma'_1$  and  $\gamma'_2$  are constants that depend only on  $\beta_1$  and  $\beta_2$ , and  $\tilde{\Theta}(\cdot)$  hides multiplicative factor of  $\text{poly}(\log n)$ .*

Theorem 1.8 says that the communication complexity of solving tolerant graph isomorphism and tolerant EMD testing are essentially the same, ignoring the polylog factor. Note that in the case of the communication setting, the distinction between **with** replacement and **without** replacement is not present. Also, it is important to point out that the lower bounds on tolerant EMD in the sampling model ([27] and [25]) does not give a lower bound

<sup>7</sup> The probability of each element in the sample space is an integer multiple of  $\frac{1}{n}$ .

in the communication setting. Though the tolerant graph isomorphism problem has not been addressed at all in the literature of communication complexity, EMD (for different metric spaces) has been considered in communication, streaming, and sketching models [16, 3, 2, 4]. However, the EMD problem that we have considered in this paper is different from those considered in the literature, and we believe that it will be of independent interest.

We also observe that the deterministic communication complexity of graph isomorphism is  $\Omega(n^2)$  even for the non-tolerant setting.

► **Theorem 1.9.** *Deterministic communication complexity of non-tolerant version of Graph Isomorphism testing (hence the tolerant version) is  $\Theta(n^2)$ .*

The proof of the above theorem is present in the full version of the paper [10].

**Organization of the paper.** In Section 2, we discuss the proof techniques of our main results. We prove the lower bound part (tolerant graph isomorphism is as hard as tolerant EMD testing) and upper bound part (tolerant EMD testing is as hard as tolerant graph isomorphism) of Theorem 1.4 in Sections 3 and 4 respectively. We finally conclude in Section 5. For space constraint, we could not add all possible proofs. Please see [10] for the full version of the paper.

**Notations.** All graphs considered here are undirected, unweighted, and have no self-loops or parallel edges. For a graph  $G(V, E)$ ,  $V(G)$  and  $E(G)$  will denote the vertex set and the edge set of  $G$ , respectively. Since we are considering undirected graphs, we write an edge  $(u, v) \in E(G)$  as  $\{u, v\}$ . The *Hamming distance* between two points  $x$  and  $y$  in a Hamming cube  $\{0, 1\}^k$  will be denoted by  $d_H(x, y)$ .

## 2 Discussion on our proof of Theorem 1.4

### 2.1 Reduction from tolerant EMD testing to tolerant graph isomorphism testing (Lower bound part of Theorem 1.4)

In this reduction, we crucially use the fact that the multi-sets are composed of elements from the Hamming cube. The reduction is based upon an involved gadget construction. In fact, we prove the lower bound for a slightly more powerful query model rather than the standard adjacency matrix query model. The most interesting part of our lower bound proof is that thanks to our reduction, we get to observe the importance of the model of accessing the multi-set **without** replacement in the context of EMD testing.

Now, we discuss the overview of our reduction. Let  $S_k$  and  $S_u$  denote the known and the unknown multi-sets, over a Hamming cube  $\{0, 1\}^d$  (of dimension  $d$ ) with  $d = \Theta(n)$ , having  $n$  elements each. To start with, let us assume that we know both  $S_k$  and  $S_u$ . We will construct two graphs  $G_k$  and  $G_u$  on  $d + n$  vertices as follows:

- The vertex set of  $G_k$  (and  $G_u$ ) are partitioned into two sets  $A_k$  and  $B_k$  (and  $A_u$  and  $B_u$ ) with  $|A_k| = |A_u| = n$  and  $|B_k| = |B_u| = d$ .
- The graph induced by  $A_k$  is a clique, and similarly the graph induced by  $A_u$  is a clique.
- The graphs induced by  $B_k$  and  $B_u$  are copies of a special graph with certain nice properties which enable our reduction to work. The existence of such a graph is proved (in Lemma 3.3) using a probabilistic argument.
- Finally, for the cross edges between  $A_k$  and  $B_k$  (and  $A_u$  and  $B_u$ ), we have: there is an edge between the  $i$ -th vertex of  $A_k$  (or  $A_u$ ) and the  $j$ -th vertex of  $B_k$  (or  $B_u$ ) if and only if the  $j$ -th coordinate of the  $i$ -th element of  $S_k$  (or  $S_u$ ) is 1.
- Finally, a random permutation  $\pi$  is applied to the vertices of  $G_u$ .

The permutation  $\pi$  is not known to the GI-tester. Note that we can construct  $G_k$  explicitly as  $S_k$  is known. However, that is not the same with  $G_u$  as  $S_u$  is unknown. But since we know the permutation  $\pi$ , any query to the adjacency matrix of the graph  $G_u$  can be answered by a single query to one bit of  $S_u$ . But unfortunately we don't have query access to  $S_u$ , and only have sample access to  $S_u$ . To deal with this problem, it is easier to consider a slightly more powerful query. Say, the GI-tester wants to query the  $(i, j)$ -th bit of the graph  $G_u$ . Of course, if both  $i$  and  $j$  are in  $A_u$  or both are in  $B_u$ , we can answer without even sampling from  $S_u$ . But if  $i$  is in  $A_u$  and  $j$  is in  $B_u$ , then what we intend to do is to give the whole neighborhood of  $i$  in  $B_u$  as the answer to the query. This would be like neighbourhood query in a bipartite graph. But the question remains: how do we intend to answer the query by sampling. The key observation here is that since the GI-tester does not know the permutation  $\pi$  that was applied to the vertices in  $G_u$ , to its eye, all the vertices that have not been touched so far look same. So, every time it queries for  $(i, j)$ , where  $i \in A_u$  and  $j \in B_u$ , either of the two cases can happen:

- Either, previously a query of the form  $(i, j_1)$  was asked where  $j_1$  is also in  $B_u$ , but in that case, it must have already got the answer of  $(i, j)$  as we must have given all the neighbors of  $i$  in  $B_u$ . So in that case, we can give back the same answer without sampling.
- Or, previously  $i$  did not participate in any query of the form  $(i, j_1)$  where  $j_1$  is in  $B_u$ . In this case, to the GI-tester's eye,  $i$  is just a new vertex from  $A_u$ . We can then sample **without** replacement from  $S_u$  and whatever sample of the multi-set we have, we can assume that it is the element  $i$  and answer accordingly. Note that this is the exact place where sampling **without** replacement is crucial.

To complete our proof, we need to prove how the GI-distance between  $G_k$  and  $G_u$  is connected to the EMD between  $S_k$  and  $S_u$ . Consider the set  $\Phi$  of all SPECIAL bijections from  $V(G_k)$  to  $V(G_u)$  that maps  $A_k$  into  $A_u$  and  $B_k$  into  $B_u$  such that the  $i$ -th vertex of  $B_k$  is mapped to the  $i$ -th vertex of  $B_u$ . Observe that  $d_\Phi(G_k, G_u) = 2 \cdot \text{EMD}(S_k, S_u)$ , where  $d_\Phi(G_k, G_u) = \min_{\phi \in \Phi} d_\phi(G_k, G_u)$  (See [10], Lemma 3.5 for a formal proof). The factor 2 is because of the way we define  $d_\phi(G_k, G_u)$  (See Definition 1.1). This implies that tolerant isomorphism testing between  $G_k$  and  $G_u$  is at least as hard as tolerant EMD testing between  $S_k$  and  $S_u$  if we restrict the bijection from  $V(G_k)$  to  $V(G_u)$  to be a SPECIAL bijection. The reduction works for all possible bijections, because of the careful choice of the subgraph of  $G_k$  (and  $G_u$ ) induced by  $B_k$  (and  $B_u$ ), thus ensuring  $d(G_k, G_u)$  is close to  $d_\Phi(G_k, G_u)$  (See [10] Lemma 3.6 for a formal proof).

One might compare our proof technique to the lower bound proof of (non-tolerant) testing of GI from [13]. In [13],  $\Omega(\sqrt{n})$  lower bound was proved directly (using Yao's lemma) by constructing two distributions of YES instances and NO instances - the construction of the YES and NO instances were inspired from the tightness of the birthday paradox, which was also the core idea behind the lower bound proof of the equivalence testing of two probability distributions. But, there was no direct reduction from GI testing to equivalence testing of two probability distributions. But in our lower bound proof, we establish a direct reduction to estimating EMD of multi-sets on the Hamming cube with access to samples **without** replacement. This can be of much importance, mainly while considering other models of computation, like in the communication model. From our reduction, we can obtain an alternative proof of  $\Omega(\sqrt{n})$  lower bound for the (non-tolerant) GI testing via the  $\Omega(\sqrt{n})$  lower bound of the equivalence testing of distributions, as pointed out in Corollary 1.7.

## 2.2 Reduction from tolerant graph isomorphism to tolerant EMD testing (Upper bound part of Theorem 1.4)

Given a known graph  $G_k$  and query access to an unknown graph  $G_u$  (both on  $n$  vertices), we present an algorithm for tolerant testing of graph isomorphism between  $G_k$  and  $G_u$  by using a tolerant EMD tester (for distributions over  $H$ ) as a blackbox. Note that this will prove the upper bound part of Theorem 1.4.

**Algorithm for tolerant graph isomorphism using algorithm for tolerant EMD testing as a black box:**

Our testing algorithm is inspired by the algorithm of Fischer and Matsliah [13] for non-tolerant GI testing. But our algorithm significantly differs from that of Fischer-Matsliah in some crucial points. As we explain the high level picture of our algorithm, we will point out some of the crucial differences.

We split our algorithm into three phases. In Phase 1, we first choose a  $\mathcal{O}\left(\frac{1}{\gamma_2 - \gamma_1}\right)$  size collection of random subset of vertices, i.e. *coresets*  $C_u$  from the unknown graph  $G_u$  where each  $C_u \in \mathcal{C}_u$  is of size  $\mathcal{O}(\log n)$ . Thereafter we find all embeddings of  $C_u$  inside the known graph  $G_k$ . Let the embeddings be  $\eta_1, \eta_2, \dots, \eta_J$  where  $C_k^i = \eta_i(C_u)$ . Now each  $C_u$  (as well as each  $C_k^i$ ) defines a label distribution of the vertices of  $G_u$  (as well as  $G_k$ ). Let us denote the set of labels as  $X_{C_u}$  (and  $Y_{C_k^i}$ ). Now we test if the EMD between  $X_{C_u}$  and  $Y_{C_k^i}$  is close or far for each  $i \in [J]$  (See Claim 4.2). We keep only those  $(C_u, \eta_i)$  for Phase 2 such that  $EMD(X_{C_u}, Y_{C_k^i}) \leq (\gamma_1 + \frac{\gamma_2 - \gamma_1}{2000}) n |C_u|$ .

Although Phase 1 of our algorithm is similar to the algorithm of [13], there is a striking difference. Since the authors of [13] were testing the non-tolerant version of graph isomorphism, they were testing the identity of the label distributions of  $X_{C_u}$  and  $Y_{C_k^i}$ . However, since we are solving the tolerant version of the problem, we need to allow some error among the label distributions. We need to pass only those placements of  $C_u$  that under *good bijections* do not produce much error and testing of tolerant EMD fits exactly for this purpose. It is worth noting that Fischer-Matsliah uses an equivalence tester in their algorithm to identify the placements that do not produce “any” error. But, the proof of correctness of the algorithm would not go through even if we use the tolerant testing of the equivalence of distributions. The use of EMD in this phase is crucial for the proof of correctness of our algorithm to hold.

In Phase 2, we choose  $\mathcal{O}\left(\frac{\log^2 n}{(\gamma_2 - \gamma_1)^3}\right)$  many vertices from the unknown graph  $G_u$  randomly and call it  $W$ . We further find the labels of all the vertices of  $W$  under  $C_u$ -labelling by querying the corresponding entries of  $G_u$  for each  $C_u$  that has passed Phase 1. Then we try to match the vertices of  $W$  to the set of all possible labels  $\{l_1, l_2, \dots, l_t\}$  of the vertices of  $G_k$  under  $C_k^i$ -labelling where  $C_k^i = \eta_i(C_u)$ , for those  $\eta_i$  that have passed Phase 1. Ideally, we would like to find a mapping  $\psi : W \rightarrow \{l_1, l_2, \dots, l_t\}$  such that the total distance between the labels of the matched vertices is not too large. If no such  $\psi$  is possible, we reject the current embedding and try some other embedding that has passed Phase 1.

In Phase 3, we construct a random partial bijection  $\hat{\phi} : W \rightarrow V(G_k)$  that maps the vertices of  $W$  to the vertices of  $G_k$  while preserving the labels according to  $\psi$ . We achieve this by mapping each  $w \in W$  to one vertex of  $G_k$  randomly that has same label as determined by  $\psi$ . Finally, we randomly pair the vertices of  $W$  and find the fraction of edge mismatches between the paired up vertices of  $W$  and  $\hat{\phi}(W)$ . If this fraction is at most  $5\gamma_1 + \frac{3}{5}(\gamma_2 - \gamma_1)$ , we accept and say that  $G_u$  and  $G_k$  are  $\gamma_1$ -close. If there is no such embedding of any  $C_u \in \mathcal{C}_u$  that achieves this, we report that  $G_u$  and  $G_k$  are  $\gamma_2$ -far.

The proofs of completeness and soundness follow kind of similar route as Fischer-Matsliah’s proof but the arguments are way more complicated. Many things that were trivial or obvious

in the non-tolerant setting become major hurdles in the tolerant setting, and we overcome them with significantly difficult technical arguments. The proofs are present in the full version of the paper [10].

### 3 Tolerant graph isomorphism is as hard as tolerant EMD testing

In this section, we prove that it is necessary to perform  $\Omega(\text{QWOR}_{\text{EMD}}(n))$  many queries to the adjacency matrix of  $G_u$  to solve  $(\gamma_1, \gamma_2)$ -tolerant GI testing of  $G_k$  and  $G_u$ .

► **Theorem 3.1** (Restatement of the lower bound part of Theorem 1.4). *Let  $G_k$  be the known and  $G_u$  be the unknown graph on  $n$  vertices, where  $n \in \mathbb{N}$  is sufficiently large. There exists a constant  $\epsilon_{\text{ISO}} \in (0, 1)$  such that for any given constants  $\gamma_1, \gamma_2$  with  $0 < \gamma_1 < \gamma_2 < \epsilon_{\text{ISO}}$ , any algorithm that decides whether the graphs are  $\gamma_1$ -close or  $\gamma_2$ -far, requires  $\text{QWOR}_{\text{EMD}}(n)$  adjacency queries to the unknown graph  $G_u$  where  $\text{QWOR}_{\text{EMD}}$  is as defined in Definition 1.3.*

In Section 2.1, we have discussed an overview of our idea to prove the above theorem. To prove Theorem 3.1, we show a reduction from tolerant GI testing to tolerant EMD testing over multi-sets when we have samples **without** replacement from the unknown multi-set.

► **Lemma 3.2.** *Suppose there is a constant  $\epsilon_0 \in (0, \frac{1}{2})$  such that for all constants  $\gamma_1, \gamma_2$  with  $0 < \gamma_1 < \gamma_2 < \epsilon_0$  and any constant  $T \in \mathbb{N}$ , the following holds: There exists a  $(\gamma_1, \gamma_2)$ -tolerant tester for GI that, given a known graph  $G_k$  and an unknown graph  $G_u$  with  $|V(G_u)| = |V(G_k)| = (T+1)n$ , can distinguish whether  $d(G_u, G_k) \leq \gamma_1 T n^2$  or  $d(G_u, G_k) \geq \gamma_2 T n^2$  by performing  $Q$  adjacency queries to  $G_u$ .*

*Then, for any constants  $\beta_1$  and  $\beta_2$  with  $0 < \beta_1 < \beta_2 < \frac{\epsilon_0}{2}$ , the following holds where  $\kappa = \frac{\beta_2 - \beta_1}{8}$  and  $T_\kappa = \lceil \frac{30}{\kappa(2-\kappa)} \rceil$ . There is a tolerant tester for EMD such that, given a known and an unknown multi-set  $S_k$  and  $S_u$  respectively, of the Hamming cube  $\{0, 1\}^{T_\kappa n}$  with  $|S_k| = |S_u| = n$ , can distinguish whether  $\text{EMD}(S_k, S_u) \leq \beta_1 T_\kappa n^2$  or  $\text{EMD}(S_k, S_u) \geq \beta_2 T_\kappa n^2$  with  $Q$  many samples **without** replacement from  $S_u$ .*

► **Remark 1.** Observe that Lemma 3.2 talks about tolerant EMD testing between multi-sets with  $n$  elements over a Hamming cube of dimension  $T_\kappa n$ . But Theorem 3.1 states the lower bound of  $\text{QWOR}_{\text{EMD}}(n)$ , that is, of tolerant *EMD* testing of multi-sets with  $n$  elements over a Hamming cube of dimension  $n$ . However, the query complexity of *EMD* testing increases with the dimension of the Hamming cube (See Proposition B.9). So, we will be done with the proof of Theorem 3.1 by proving Lemma 3.2.

#### 3.1 Tolerant GI to Tolerant EMD testing: Proof of Lemma 3.2

To define the necessary reduction for the proof of Lemma 3.2, we need to show the existence of a graph  $G_p$  satisfying some unique properties.

► **Lemma 3.3.** *Let  $\kappa \in (0, 1)$  and  $s \geq 3$  be given constants. Then for  $C_{\kappa, s} = \lceil \frac{6s}{\kappa(2-\kappa)} \rceil$  and sufficiently large  $n \in \mathbb{N}$ <sup>8</sup>, there exists a graph  $G_p$  with  $C_{\kappa, s} n$  many vertices such that the following conditions hold.*

- (i) *The degree of each vertex in  $G_p$  is at least  $((1-\kappa)C_{\kappa, s} + 1)n - 1$ .*
- (ii) *The cardinality of symmetric difference between the sets of neighbors of any two (distinct) vertices in  $G_p$  is at least  $sn - 2$ .*

<sup>8</sup> The lower bound of  $n$  is a constant that depends on  $\kappa$  and  $s$ .

The proof of Lemma 3.3 uses probabilistic method (See [10] for the proof). Let  $ALG(\gamma_1, \gamma_2, T)$  be the algorithm that takes  $\gamma_1$  and  $\gamma_2$  with  $0 < \gamma_1 < \gamma_2 < \epsilon_0$  as input and decides whether  $d(G_k, G_u) \leq \gamma_1 T n^2$  or  $d(G_k, G_u) \geq \gamma_2 T n^2$ , where  $|V(G_k)| = |V(G_u)| = (T + 1)n$ . Now we show that for any two constants  $\beta_1$  and  $\beta_2$  with  $0 < \beta_1 < \beta_2 < \frac{\epsilon_0}{2}$ ,  $\kappa = \frac{\beta_2 - \beta_1}{8}$  and  $T_\kappa = \lceil \frac{6s}{\kappa(2-\kappa)} \rceil$ , there exists an algorithm  $\mathcal{A}(\beta_1, \beta_2, \kappa, T_\kappa)$  that can test whether two multi-sets  $S_k$  and  $S_u$  over the  $T_\kappa n$ -dimensional Hamming cube have EMD less than  $T_\kappa \beta_1 n^2$  or more than  $T_\kappa \beta_2 n^2$  with  $Q$  many queries to the multi-set  $S_u$ . To be specific, algorithm  $\mathcal{A}(\beta_1, \beta_2, \kappa, T_\kappa)$  for EMD testing will use algorithm  $ALG(\gamma_1, \gamma_2, T)$  for  $(\gamma_1, \gamma_2)$ -tolerant GI such that  $\gamma_1 = 2\beta_1$ ,  $\gamma_2 = 2\beta_2 - 2\kappa$  and  $T = T_\kappa$ . Note that, as  $0 < \beta_1 < \beta_2 < \frac{\epsilon_0}{2}$  and  $\kappa = \frac{\beta_2 - \beta_1}{8}$ ,  $0 < \gamma_1 < \gamma_2 < \epsilon_0$  holds. The details of the reduction, that is, algorithm  $\mathcal{A}$  is described below. Because of space constraint, we are not presenting the proof of correctness of the reduction in this extended abstract. Please refer to our full version [10].

### Description of the reduction

**Input:** A known multi-set  $S_k = \{k_1, \dots, k_n\}$  over  $H_{T_\kappa n} = \{0, 1\}^{T_\kappa n}$  and query access to an unknown multi-set  $S_u = \{u_1, \dots, u_n\}$  over  $H_{T_\kappa n}$ .

**Goal:** To decide whether  $EMD(S_k, S_u) \leq T_\kappa \beta_1 n^2$  or  $EMD(S_k, S_u) \geq T_\kappa \beta_2 n^2$ .

**Construction of  $G_k$  and  $G_u$  from  $S_k$  and  $S_u$ :** Let us first construct the graph  $G_k$  from  $S_k$ .  $G_k$  has  $(T_\kappa + 1)n$  vertices partitioned into two parts  $A_k = \{a_1, \dots, a_n\}$  and  $B_k = \{b_1, \dots, b_{T_\kappa n}\}$ . Now the edges of  $G_k$  are described as follows:

- $G_k[A_k]$  is a clique with  $n$  vertices.
- $G_k[B_k]$  is a copy of the graph  $G_p(V_p, E_p)$  on  $T_\kappa n$  vertices as stated in Lemma 3.3 with parameters  $s = 5$ ,  $\kappa = \frac{\beta_2 - \beta_1}{8}$  and  $T_\kappa = C_{\kappa, 5}$ .
- For the cross edges between the vertices in  $A_k$  and  $B_k$ , we add the edge  $(a_i, b_j)$  to  $E(G_k)$  if and only if the  $j$ -th coordinate of  $k_i$  is 1 for all  $i \in [n]$  and  $j \in [T_\kappa n]$ .

Note that the graph  $G_k$  constructed above is unique for a given multi-set  $S_k$ . The graph  $G_u$  with the vertex sets  $A_u = \{a'_1, \dots, a'_n\}$  and  $B_u = \{b'_1, \dots, b'_{T_\kappa n}\}$  is constructed from the multi-set  $S_u$  in a similar fashion, but at the end, the vertices of  $A_u$  are permuted using a random permutation. So,

- $G_u[A_u]$  is a clique with  $n$  vertices.
- $G_u[B_u]$  is a copy of the graph  $G_p(V_p, E_p)$  on  $T_\kappa n$  vertices as stated in Lemma 3.3, with parameters  $s = 5$ ,  $\kappa = \frac{\beta_2 - \beta_1}{8}$  and  $T_\kappa = C_{\kappa, 5}$ .
- Let us first pick a random permutation  $\pi$  on  $[n]$ . For the cross edges between the vertices in  $A_u$  and  $B_u$ , we add the edge  $(a'_{\pi(i)}, b_j)$  to  $E(G_u)$  if and only if the  $j$ -th coordinate of  $u_i$  is 1 for all  $i \in [n]$  and  $j \in [T_\kappa n]$ .

Note that our final objective is to prove a lower bound on the query complexity for tolerant testing of GI, that is, when we have an adjacency query access to  $G_u$ . We will instead show that the lower bound holds even if we have the following query access, named as  *$A_u$ -neighborhood-query*: the tester can choose a vertex  $a'_i \in A_u$  and in one go obtain the information about the entire neighborhood of  $a'_i$  in  $B_u$ .

Observe that the only part of  $G_u$  that is not known to the tester is the cross edges between  $A_u$  and  $B_u$ . So, in this case, the  $A_u$ -neighborhood query is way more stronger than the standard queries to  $G_u$ , and a lower bound for the  $A_u$ -neighborhood query would imply a lower bound on adjacency query.

### Simulating Queries to $G_u$ by samples drawn from $S_u$ *without* replacement

Following the above discussion, we will only have to show how to simulate  $A_u$ -neighborhood queries using samples drawn from  $S_u$  **without** replacement. So, we can assume that the queries are of the form: *what are the neighbors of  $a'_i$  in  $B_u$ ?* And since in each query the entire neighborhood of  $a'_i$  is obtained, the tester would pick different  $a'_i$  for every query. Note that in  $G_u$ , by construction, the vertices of  $A_u$  were permuted using a random permutation. So, from the point of view of the tester, the  $a'_i$  are just randomly drawn from  $A_u$  minus the set of  $a'_i$  already queried. In other word, the  $a'_i$  are just randomly drawn from  $A_u$  **without** replacement. Now because of the way the edges between  $A_u$  and  $B_u$  are constructed, the neighborhood of a random  $a'_i$  drawn from  $A_u$  **without** replacement is same as obtaining random samples from  $S_u$  **without** replacement. It is also important to note that because of the randomness, the queries made by the tester are actually non-adaptive.

### Description of algorithm $\mathcal{A}$ for testing $EMD(S_k, S_u)$

Run ALG on  $G_k$  and  $G_u$  with parameters  $\gamma_1 = 2\beta_1$  and  $\gamma_2 = 2\beta_2 - 2\kappa$ . If ALG reports  $d(G_k, G_u) \leq T_\kappa \gamma_1 n^2$ , output that  $EMD(S_k, S_u) \leq T_\kappa \beta_1 n^2$ . Similarly, if ALG reports that  $d(G_k, G_u) \geq T_\kappa \gamma_2 n^2$ , then output  $EMD(S_k, S_u) \geq T_\kappa \beta_2 n^2$ .

## 4 Tolerant EMD testing is as hard as tolerant graph isomorphism testing

In this section, we prove the following theorem, that discusses about algorithm for tolerant graph isomorphism testing with a blackbox access to tolerant EMD testing over multi-sets.

► **Theorem 4.1** (Restatement of the upper bound part of Theorem 1.4). *Let  $G_k$  and  $G_u$  be the known and unknown graphs, respectively. There exists an algorithm that takes parameters  $\gamma_1$  and  $\gamma_2$  as input such that  $0 \leq \gamma_1 < \gamma_2 \leq 1$ , performs  $\tilde{\mathcal{O}}(\text{QWoREMD}(n))$  many queries to the adjacency matrix of  $G_u$  for appropriate  $\beta_1$  and  $\beta_2$  depending on  $\gamma_1$  and  $\gamma_2$ , and decides whether  $d(G_u, G_k) \leq \gamma_1 n^2$  or  $d(G_u, G_k) \geq \gamma_2 n^2$ , with probability at least  $2/3$ . Here  $\tilde{\mathcal{O}}(\cdot)$  hides a polynomial factor in  $\frac{1}{\beta_2 - \beta_1}$  and  $\log n$ .*

► **Remark 2.** The theorem stated above works for any  $\gamma_1, \gamma_2$  such that  $0 \leq \gamma_1 < \gamma_2 \leq 1$ . However, for simplicity of representation, we have assumed  $\gamma_2 \geq 11\gamma_1$ .

► **Remark 3.** Note that Theorem 4.1 can also be stated in terms of  $\text{QWR}_{\text{EMD}}(n)$  as  $\text{QWoREMD}(n) \leq \text{QWR}_{\text{EMD}}(n)$  as we can simulate samples **with** replacement when we have query access to samples **without** replacement (See Proposition B.5).

Our algorithm for tolerant GI testing, as stated in Theorem 4.1, uses a special kind of tolerant  $EMD$  tester over multi-sets: we know  $t$  many multi-sets, one multi-set is unknown and two parameters  $\epsilon_1$  and  $\epsilon_2$  are given; the objective is to test tolerant  $EMD$  of each known multi-set with the unknown one. The following theorem gives us the special  $EMD$  tester.

► **Theorem 4.2.** *Let  $H = \{0, 1\}^n$  be a  $n$ -dimensional Hamming cube. Let  $\{S_k^i : i \in [t]\} \cup \{S_u\}$  denote the multi-sets with  $n$  elements from  $H$  where  $\{S_k^i : i \in [t]\}$  denote the set of  $t$  many known multi-sets and  $S_u$  denotes the unknown multi-set. There exists an algorithm ALG-EMD that takes two proximity parameters  $\epsilon_1, \epsilon_2$  with  $0 \leq \epsilon_1 < \epsilon_2 \leq 1$  and a  $\delta \in (0, 1)$  as input and decides whether  $EMD(S_u, S_k^i) \leq \epsilon_1 n^2$  or  $EMD(S_u, S_k^i) \geq \epsilon_2 n^2$ , with probability at least  $1 - \delta$ , for each  $i \in [t]$ . Moreover, ALG-EMD uses  $\text{QWoREMD}(n) \cdot \mathcal{O}(\log \frac{t}{\delta})$  many samples **without** replacement from  $S_u$ .*

The above theorem follows from the definition of  $\text{QWor}_{\text{EMD}}(n)$  (See Definition 1.3) along with union bound and standard argument for amplifying the success probability.

► **Remark 4.** The algorithm of Theorem 4.1, to be discussed in Section 4.1, formulates a tolerant *EMD* instance of multi-sets having  $n$  elements in  $H = \{0, 1\}^d$ , where  $d = \mathcal{O}(\log n / (\gamma_2 - \gamma_1))$ . But ALG-EMD is an algorithm for tolerant *EMD* testing between two multi-sets having  $n$  elements in  $\{0, 1\}^n$ . This is not a problem as the query complexity of *EMD* is an increasing function in dimension (See Proposition B.9 in Appendix B). Moreover, the algorithm in Section 4.1 calls ALG-EMD with parameters  $\epsilon_1 = (\gamma_1 + \frac{\gamma_2 - \gamma_1}{2000})$ ,  $\epsilon_2 = \gamma_2/5$ ,  $t = 2^{\mathcal{O}(\log^2 n / (\gamma_2 - \gamma_1))}$  and  $\delta$  is a suitable constant depending upon  $\gamma_1$  and  $\gamma_2$ , where  $\gamma_1$  and  $\gamma_2$  are parameters as stated in Theorem 4.1. So, each call to ALG-EMD, in our context, makes  $\tilde{\mathcal{O}}(\text{QWor}_{\text{EMD}}(n))$  many queries.

#### 4.1 Algorithm for tolerant graph isomorphism testing

For our algorithm, we need the following definitions of *label* and *embedding*.

► **Definition 4.3.** (*Label of a vertex*) Given a graph  $G$  and  $C \subset V(G) = \{c_1, \dots, c_{|C|}\}$ , the  $C$ -labelling of  $V(G)$  is a function  $\mathcal{L}_C : V(G) \rightarrow \{0, 1\}^{|C|}$  such that the  $i$ -th entry of  $\mathcal{L}_C(v)$  is 1 if and only if  $v$  is a neighbor of  $c_i \in C$ . Also,  $\mathcal{L}_C(v)$  is referred as the label of  $v$  under  $C$ -labelling of  $V(G)$ .

► **Definition 4.4.** (*Embedding of a Vertex Set into another Vertex Set*) Let  $G_u$  and  $G_k$  be two graphs. Consider  $A \subseteq V(G_u)$  and  $B \subseteq V(G_k)$  such that  $|A| \leq |B|$ . An injective mapping  $\eta$  from  $A$  to  $B$  is referred as an *embedding* of  $A$  into  $B$ .

Now we present our query algorithm **TolerantGI**( $G_u, G_k, \gamma_1, \gamma_2$ ) that comprises three phases. The technical overview of the algorithm is already presented in Section 2.2

#### Formal Description of TolerantGI( $G_u, G_k, \gamma_1, \gamma_2$ ):

The three phases of our algorithm are as follows:

##### 4.1.1 Phase 1

The first phase of our algorithm consists of the following three steps.

**Step 1** First we sample a collection  $\mathcal{C}_u$  of  $\mathcal{O}(\log n)$  sized random subsets of  $V(G_u)$  with  $|\mathcal{C}_u| = \mathcal{O}(\frac{1}{\gamma_2 - \gamma_1})$ . We perform **Step 2** and **Step 3** for each  $C_u \in \mathcal{C}_u$ .

**Step 2** We determine all possible embeddings, that is,  $\eta_1, \dots, \eta_J$ , of  $C_u$  into  $V(G_k)$ , where  $J = \binom{n}{\mathcal{O}(\log n)} \leq 2^{\mathcal{O}(\log^2 n)}$ . For each  $i \in [J]$ , let  $C_k^i$  be the set of images of  $C_u$  under the  $i$ -th embedding of  $C_u$  into  $V(G_k)$ , that is,  $C_k^i = \eta_i(C_u)$ . For all  $i \in [J]$ , we construct the multi-set  $Y_{C_k^i}$  that contains  $C_k^i$ -labellings of all the vertices of  $G_k$ .

**Step 3** Now for each vertex  $v \in V(G_u)$ , there is a  $C_u$ -labelling of  $v$ . Let  $X_{C_u}$  be the multi-set of  $C_u$ -labellings of all the vertices in  $V(G_u)$ . However,  $X_{C_u}$  is unknown to the algorithm. We call ALG-EMD (as stated in Theorem 4.2) by setting parameters as described in Remark 4 to decide whether  $\text{EMD}(X_{C_u}, Y_{C_k^i}) \leq (\gamma_1 + \frac{\gamma_2 - \gamma_1}{2000})n|C_u|$  or  $\text{EMD}(X_{C_u}, Y_{C_k^i}) \geq \gamma_2 n|C_u|/5$ , for each  $i \in [J]$ . Let us pair up  $C_u$ 's and their accepted embeddings into  $G_k$  and call the set  $\Gamma$ , that is,

$$\Gamma = \left\{ (C_u, \eta_i) \mid \text{ALG-EMD decides } \text{EMD}(X_{C_u}, Y_{C_k^i}) \leq (\gamma_1 + \frac{\gamma_2 - \gamma_1}{2000})n|C_u| \right\}.$$

### 4.1.2 Phase 2

In the second phase, the algorithm performs the following two steps.

**Step 1** We sample a subset  $W$  of  $\mathcal{O}(\log^2 n / (\gamma_2 - \gamma_1)^3)$  vertices randomly from  $G_u$ .

**Step 2** For each  $(C_u, \eta_i) \in \Gamma$  that has passed **Phase 1**, we perform the following steps:

- (i) We find the  $C_k^i = \eta_i(C_u)$ -labelling of the vertices of  $G_k$ . Let  $l_1, \dots, l_t$  be the labels of the vertices where  $t = 2^{\lfloor C_k^i \rfloor}$  and  $V_j \subseteq V(G_k)$  be the set of vertices with label  $l_j$ .
- (ii) We define a matrix  $M$  of size  $|W| \times 2^{\lfloor C_k^i \rfloor}$  where each row represents the label of a vertex  $w \in W$  and each column represents one of the possible  $C_k^i$ -labelling of  $V(G_k)$ <sup>9</sup>. The  $(i, j)$ -th entry of  $M$  is defined as:  $M_{ij} = d_H(\mathcal{L}_{C_u}(w_i), l_j)$ .
- (iii) We choose a function  $\psi : W \rightarrow \{l_1, \dots, l_t\}$  randomly satisfying

$$\sum_{w \in W} d_H(\mathcal{L}_{C_u}(w), \psi(w)) \leq \frac{2\gamma_2}{5} |C_u| |W| \text{ and } |\{w : \psi(w) = l_j\}| \leq |V_j| \forall j \in [t]. \quad (1)$$

Let  $\Gamma_W$  be the set of tuples such that

$$\Gamma_W = \{(C_u, \eta_i, \psi) : (C_u, \eta_i) \in \Gamma \text{ and } \psi \text{ satisfies Equation (1)}\}.$$

### 4.1.3 Phase 3

The third phase of our algorithm comprises the following four steps.

**Step 1** We randomly pair up the vertices of  $W$ . Let  $\{(a_1, b_1), \dots, (a_p, b_p)\}$  be the pairs of the vertices, where  $p = \mathcal{O}(\log^2 n / (\gamma_2 - \gamma_1)^3)$ . We now determine which  $(a_i, b_i)$  pairs form edges in  $G_u$  by querying the corresponding entries of the adjacency matrix of  $G_u$ .

**Step 2** For each  $(C_u, \eta_i, \psi) \in \Gamma_W$  that has passed **Phase 2**, we perform **Step 3** and **Step 4** as follows.

**Step 3** We choose an embedding  $\hat{\phi} : W \rightarrow V(G_k)$  randomly, satisfying  $\hat{\phi}(w) \in V_j$  if and only if  $\psi(w) = l_j$  and modulo permutation of the vertices in  $V_j$  for all  $j \in [t]$ . In other words, we map each  $w \in W$  to a vertex in  $G_k$  randomly having  $\psi(w) = l_j$  as its  $C_k^i$ -labelling in  $G_k$ .

**Step 4** We find the fraction  $\zeta(C_u, \eta_i, \psi, \hat{\phi}) = |\{(a_i, b_i) : \mathbb{1}_{(a_i, b_i)} = 1\}| / p$ , where  $\mathbb{1}_{(a_i, b_i)} = 1$  if exactly one among  $(a_i, b_i) \in E(G_u)$  and  $(\hat{\phi}(a_i), \hat{\phi}(b_i)) \in E(G_k)$  holds.

If  $\zeta(C_u, \eta_i, \psi, \hat{\phi}) \leq 5\gamma_1 + \frac{3}{5}(\gamma_2 - \gamma_1)$ , then **HALT and REPORT** that  $G_u$  and  $G_k$  are  $\gamma_1$ -close.

While executing **Step 3** and **Step 4** for each tuple in  $\Gamma_W$ , if we did not **HALT**, then we **HALT** now and **REPORT** that  $G_u$  and  $G_k$  are  $\gamma_2$ -far.

## 5 Conclusion

In this paper, we proved that the query complexity of tolerant GI testing between a known graph  $G_k$  and an unknown graph  $G_u$  is the same as (up to polylogarithmic factor) tolerant testing of  $EMD$  between a known multi-set  $S_k$  and an unknown multi-set  $S_u$  when we have

<sup>9</sup> Let  $C_u = \{x_1, \dots, x_{\mathcal{O}(\log n / (\gamma_2 - \gamma_1))}\}$ . Note that for each  $w_i \in W$ ,  $\mathcal{L}_{C_u}(w_i) \in \{0, 1\}^{\mathcal{O}(\log n / (\gamma_2 - \gamma_1))}$  such that the  $j$ -th coordinate is 1 if and only if  $w_i$  is a neighbour of  $x_j$ , where  $i \in [\mathcal{O}(\log^2 n / (\gamma_2 - \gamma_1)^3)]$  and  $j \in [\mathcal{O}(\log n / (\gamma_2 - \gamma_1))]$ . Similarly,  $l_j \in \{0, 1\}^{\mathcal{O}(\log n / (\gamma_2 - \gamma_1))}$  such that the  $i$ -th coordinate of  $l_j$  is 1 if and only if  $\eta(x_i)$  is a neighbour of  $v \in V_j$ , where  $j \in [2^{\lfloor C_k^i \rfloor}]$ .

samples **without** replacement from  $S_u$ . In Lemma B.10, we have shown that the sample complexity of testing of  $EMD$  between a known multi-set  $S_k$  and an unknown multi-set  $S_u$  when we have samples **with** replacement from  $S_u$  is  $\Omega(n/\log n)$ . Thus the natural open question is

*What is the query complexity of tolerant  $EMD$  testing when we have samples **without** replacement from the unknown multi-set?*

As mentioned before, it is interesting to note that our lower bound proof is via a *pure reduction* from tolerant graph isomorphism to tolerant testing of  $EMD$  of multi-sets over the Hamming cube using samples **without** replacement. Using our lower bound technique (and Proposition B.7), we can get an alternative proof of Fischer and Matsliah’s lower bound result for testing non-tolerant graph isomorphism [13]. Our upper bound proof is also a pure reduction from tolerant testing of  $EMD$  of multi-sets over the Hamming cube to tolerant graph isomorphism problem. Thus our reductions also hold for other computational models such as the communication complexity model. So, in the communication model (that is, when Alice and Bob have graphs  $G_a$  and  $G_b$  respectively and they want to estimate the GI-distance between them), the amount of bits of communication is same (up to a polylogarithmic factors) to the problem of estimating the  $EMD$  between two distributions over Hamming cube, where Alice and Bob have access to one distribution each. The question we would like to pose is:

*What is the randomized communication complexity of testing tolerant graph isomorphism problem?*

Fischer and Matsliah [13] studied the non-tolerant version of the graph isomorphism problem in two scenarios: (i) one graph is known and the other graph is unknown, (ii) both the graphs are unknown. They resolved the query complexity of (i), whereas Onak and Sun [19] resolved (ii). With this paper, we initiate the study of tolerant graph isomorphism problem in the query and communication world. So, another natural open question to look for is:

*What is the query complexity of tolerant graph isomorphism when both the graphs are unknown?*

## A Preliminaries

All graphs considered here are undirected, unweighted and have no self-loops or parallel edges. For a graph  $G(V, E)$ ,  $V(G)$  and  $E(G)$  will denote the vertex set and the edge set of  $G$ , respectively. Since we are considering undirected graphs, we write an edge  $(u, v) \in E(G)$  as  $\{u, v\}$ . The *Hamming distance* between two points  $x$  and  $y$  in a Hamming cube  $\{0, 1\}^k$  will be denoted by  $d_H(x, y)$ .

### A.1 Notion of distance between two graphs

First let us define the notion of DECIDER of a vertex and then the notion of distance between two graphs, using decider of vertices, that is conceptually same as that of GRAPH ISOMORPHISM DISTANCE defined in Definition 1.1.

► **Definition A.1.** (DECIDER of a vertex) Given two graphs  $G_k$  and  $G_u$  and a bijection  $\phi : V(G_u) \rightarrow V(G_k)$ , DECIDER of a vertex  $x \in V(G_u)$  with respect to  $\phi$  is defined as the set of vertices of  $G_u$  that create the edge difference in  $x$  and  $\phi(x)$ 's neighbourhood in  $G_u$  and  $G_k$ , respectively. Formally,

$$\text{DECIDER}_\phi(x) := \{y \in V(G_u) : \text{one of the edges } \{x, y\} \text{ and } \{\phi(x), \phi(y)\} \text{ is not present}\}$$

► **Definition A.2.** (DISTANCE between two graphs) Let  $G_u$  and  $G_k$  be two graphs and  $\phi : V(G_u) \rightarrow V(G_k)$  be a bijection from the vertex set of  $G_u$  to that of  $G_k$ . The *distance* between  $G_u$  and  $G_k$  under  $\phi$  is defined as the sum of the sizes of the deciders of all the vertices in  $G_u$ , that is,

$$d_\phi(G_u, G_k) := \sum_{x \in V(G_u)} |\text{DECIDER}_\phi(x)|.$$

The *distance* between two graphs  $G_u$  and  $G_k$  is the minimum distance under all possible bijections  $\phi$  from  $V(G_u)$  to  $V(G_k)$ , that is,  $d(G_u, G_k) := \min_{\phi} d_\phi(G_u, G_k)$ .

► **Remark 5.** Recall the definition of  $\delta_{GI}(G_u, G_k)$ , GRAPH ISOMORPHISM DISTANCE between  $G_u$  and  $G_k$ , that is given in Definition 1.1. Observe that  $d(G_u, G_k) = 2 \binom{n}{2} \delta_{GI}(G_u, G_k)$ . Though,  $d(G_u, G_k)$  and  $\delta_{GI}(G_u, G_k)$  represent the same thing, conceptually, we will do our calculations by using  $d(G_u, G_k)$  for simplicity of presentation.

Next we define the concept of closeness between two graphs.

► **Definition A.3.** (CLOSE and FAR) For  $\gamma \in [0, 1)$ , two graphs  $G_u$  and  $G_k$  with  $n$  vertices are  $\gamma$ -close to isomorphic if  $d(G_u, G_k) \leq \gamma n^2$ . Otherwise, we say  $G_u$  and  $G_k$  are  $\gamma$ -far from being isomorphic.<sup>10</sup>

<sup>10</sup>By abuse of notation, we will say  $G_u$  and  $G_k$  are  $\gamma$ -far when  $d(G_u, G_k) \geq \gamma n^2$ .

## A.2 Property Testing of Distribution Properties

Understanding different properties of probability distributions have been an active area of research in property testing (For reference, see [9]). The authors studied these problems assuming random sample access from the unknown distributions. Considering the relation between the distributions and their corresponding representative multi-sets, we can say that all these results hold for multi-sets along with access over sampling **with** replacement.

Although it seems that the change of query model from sample **with** replacement to sample **without** replacement does not make much difference, following the work of Freedman [14], we know that the variation distance between probability distributions when accessed via samples **with** and **without** replacement, becomes arbitrary close to  $1/2$  when the number of samples is  $\Omega(\sqrt{n})$ . Because of this reason, many techniques developed for sampling **with** replacement for various problems no longer work anymore. Most importantly, proving any lower bound better than  $\Omega(\sqrt{n})$  is often nontrivial.

## B Earth Mover's Distance (EMD) over Hamming Cube

In this section, we study some properties of *Earth Mover's distance (EMD)* over probability distributions and multi-sets, which are crucial in the context of both our lower and upper bound. Before proceeding to the discussion on EMD, let us first recall the definition of  $\ell_1$  distance between two distributions.

► **Definition B.1** ( $\ell_1$  distance between two distributions). Let  $p$  and  $q$  be two probability distributions over  $[n]$ . The  $\ell_1$  distance between  $p$  and  $q$  is defined as

$$d_{\ell_1}(p, q) = \sum_{i=1}^n |p(i) - q(i)|$$

► **Definition B.2** (*EMD* between two probability distributions). Let  $H = \{0, 1\}^d$  be a Hamming cube of dimension  $d$ , and  $p, q$  be two probability distributions on  $H$ . The *EMD* between  $p$  and  $q$  is denoted by  $EMD(p, q)$  and defined as the optimum solution to the following linear program:

$$\begin{aligned} & \text{Minimize} && \sum_{x, y \in H} f_{xy} d_H(x, y) \\ & \text{Subject to} && \sum_{y \in H} f_{xy} = p(x) \quad \forall x \in H, \text{ and } \sum_{x \in H} f_{xy} = q(y) \quad \forall y \in H. \end{aligned}$$

Now we define *EMD* between two multi-sets.

► **Definition B.3** (*EMD* between two multi-sets). Let  $S_1, S_2$  be two multi-sets on a Hamming cube  $H = \{0, 1\}^d$  of dimension  $d$  with  $|S_1| = |S_2|$ . The *EMD* between  $S_1$  and  $S_2$  is denoted by  $EMD(S_1, S_2)$  and defined as  $EMD(S_1, S_2) = \min_{\phi: S_1 \rightarrow S_2} \sum_{x \in S_1} d_H(x, \phi(x))$  where  $\phi$  is a bijection from  $S_1$  to  $S_2$ .

Note that an unknown distribution  $p$  is accessed by taking samples from  $p$ . However, a multi-set is accessed as follows:

► **Definition B.4** (Query accesses to multi-sets). A multi-set  $S$  of  $n$  elements is accessed in one of the following ways:

**Sample Access with replacement:** Each element of  $S$  is reported uniformly at random independent of all previous queries.

**Sample Access without replacement:** Let us assume we make  $Q$  queries to  $S$ , where  $Q \leq n$ .

The answer to the first query, say  $s_1$ , is an element from  $S$  chosen uniformly at random.

For any  $2 \leq i \leq Q$ , the answer of the  $i$ -th query is an element chosen uniformly at random from  $S \setminus \{s_1, \dots, s_{i-1}\}$ . Here  $s_j, 1 \leq j \leq Q$ , denotes the answer to the  $j$ -th query.

Although sampling **with** replacement is more natural query model, we need sampling **without** replacement for our lower bound proof. We now note that we can simulate samples **with** replacement when we have samples **without** replacement.

► **Proposition B.5** (Simulating samples **with** replacement from samples **without** replacement). *Given  $Q$  many samples **without** replacement from an unknown multi-set  $S_u$  with  $n$  elements, we can simulate  $Q$  many samples **with** replacement from  $S_u$  where  $Q \leq n$ .*

For a formal proof of the above proposition, see [10]. The following observation connects the *EMD* between two probability distributions with that of between two multi-sets.

► **Observation B.6.** Let  $p, q$  be two  $K$ -grained probability distributions<sup>11</sup> on a  $n$  dimensional Hamming cube  $H = \{0, 1\}^n$ . Then  $p$  and  $q$  induces two multi-sets  $S_1$  and  $S_2$  on  $H$ , respectively, as follows.  $S_1$  ( $S_2$ ) is the multi-set containing  $x \in H$  with multiplicity  $p(x)K$  ( $q(x)K$ ) for each  $x \in H$ . Moreover,  $EMD(p, q) = \frac{EMD(S_1, S_2)}{K}$ .

See [10] for a formal proof.

► **Remark 6.** Note that sample access from a probability distribution is exactly same as uniform sampling from a multi-set **with** replacement.

► **Proposition B.7.** *Let  $\mathcal{D}$  be the set of all multi-sets of size  $n$  over a universe  $[m]$ ; let  $S_k$  and  $S_u$  in  $\mathcal{D}$  denote the known and unknown multi-sets over  $[n]$ ; and  $\text{PROP} : \mathcal{D} \times \mathcal{D} \rightarrow \{0, 1\}$  be a boolean function. Then the following holds:*

*If there exists an algorithm that determines  $\text{PROP}$  by  $Q$  many samples **without** replacement from  $S_u$  with probability at least  $2/3$ , then there exists an algorithm that determines  $\text{PROP}$  by  $\min\{Q, \sqrt{\min\{n, m\}}\}$  many samples **with** replacement from  $S_u$  with probability at least  $2/3 - o(1)$ .*

This follows from the fact that when  $Q = o(\sqrt{n})$  and  $D_{WR}$  ( $D_{WR}$ ) be the probability distribution over all the subsets having  $Q$  elements from  $[n]$  **with** (**without**) replacement, the  $\ell_1$  distance between  $D_{WR}$  and  $D_{WR}$  is  $o(1)$ .

► **Definition B.8** (EMD over multi-sets while sampling **with** and **without** replacement). Let  $S_k$  and  $S_u$  denote the known and the unknown multi-sets, respectively, over  $n$ -dimensional Hamming cube  $H = \{0, 1\}^n$  such that  $|S_u| = |S_k| = n$ . Consider the two distributions  $p_u$  and  $p_k$  over the Hamming cube  $H$  that are naturally defined by the sets  $S_u$  and  $S_k$  where for all  $x \in H$  probability of  $x$  in  $p_u$  (and  $p_k$ ) is the number of occurrences of  $x$  in  $S_u$  (and  $S_k$ ) divided by  $n$ . We then define the EMD between the multi-sets  $S_u$  and  $S_k$  as

$$EMD(S_u, S_k) \triangleq n \cdot EMD(p_u, p_k).$$

The problem of estimating the EMD over multi-sets while sampling **with** (or **without**) replacement means designing an algorithm, that given any two constants  $\beta_1, \beta_2$  such that  $0 \leq \beta_1 < \beta_2 \leq 1$ , and access to the unknown set  $S_u$  by sampling **with** (or **without**)

<sup>11</sup>The probability of each element in the sample space is an integer multiple of  $\frac{1}{K}$ .

replacement decides whether  $EMD(S_k, S_u) \leq \beta_1 n^2$  or  $EMD(S_k, S_u) \geq \beta_2 n^2$  with probability at least  $2/3$ .

Note that estimating the EMD over multi-sets while sampling **with** replacement is exactly same as estimating EMD between the distributions  $p_u$  and  $p_k$  with samples drawn according to  $p_u$ .

Let  $QWR_{EMD}(n, d, \beta_1, \beta_2)$  (and  $QWoR_{EMD}(n, d, \beta_1, \beta_2)$ ) denote the number of samples **with** ( and **without**) replacement required to decide the above from the unknown multi-set  $S_u$ . For ease of presentation, we write  $QWoR_{EMD}(n, d)$  ( $QWR_{EMD}(n, d)$ ) instead of  $QWoR_{EMD}(n, d)$  ( $QWR_{EMD}(n, \beta_1, \beta_2)$ ) when the proximity parameters are clear from the context.

► **Proposition B.9** (Query complexity of EMD increases with number of points as well as dimension). *Let  $n, n_1, n_2, d, d_1, d_2 \in \mathbb{N}$  be such that  $d_1 \leq d_2$  and  $n_1 \leq n_2$ . Then*

- (i)  $QWR_{EMD}(n_1, d) \leq QWR_{EMD}(n_2, d)$ ;
- (ii)  $QWoR_{EMD}(n_1, d) \leq QWoR_{EMD}(n_2, d)$ ;
- (iii)  $QWR_{EMD}(n, d_1) \leq QWR_{EMD}(n, d_2)$ ; and
- (iv)  $QWoR_{EMD}(n, d_1) \leq QWoR_{EMD}(n, d_2)$ .

► **Remark 7.** For  $d = n$  (as considered in Definition 1.3),  $QWoR_{EMD}(n, d)$  (and  $QWR_{EMD}(n, d)$ ) are denoted as  $QWoR_{EMD}(n)$  (and  $QWR_{EMD}(n)$ ).

Now let us state the lower bound of  $QWR_{EMD}(n)$ .

► **Theorem B.10.**  $QWR_{EMD}(n) = \Omega\left(\frac{n}{\log n}\right)$ .

Thus following Proposition B.7, we have

► **Theorem B.11.**  $QWoR_{EMD}(n) = \Omega(\sqrt{n})$ .

Note that an upper bound of  $QWoR_{EMD}(n) = \tilde{O}(n)$  is trivial. In the rest of the section, we focus on proving Theorem B.10 that states the lower bound on  $QWR_{EMD}(n)$ . We also provide an upper bound for  $QWR_{EMD}(n)$  at Lemma B.16 that shows that  $\tilde{O}(n)$  many samples **with** replacement from  $S_u$  to estimate  $QWR_{EMD}(n)$ . Note that by Remark 6, it is enough to show the following lemma that states the lower bound for tolerant EMD testing between two distributions.

► **Lemma B.12.** *Let  $S$  be a subset of a Hamming cube  $H = \{0, 1\}^n$  such that the minimum distance between any pair of points in  $S$  is at least  $\frac{n}{2}$ . Also, let  $p$  and  $q$  be two known and unknown distributions, respectively, supported over a subset of  $S$ . Then there exists a constant  $\epsilon_{EMD}$  such that the following holds. Given two constants  $\beta_1, \beta_2$  with  $0 < \beta_1 < \beta_2 < \epsilon_{EMD}(c)$ ,  $\Omega\left(\frac{n}{\log n}\right)$  samples from the distribution  $q$  are necessary in order to decide whether  $EMD(p, q) \leq \beta_1 n$  or  $EMD(p, q) \geq \beta_2 n$ . More over,  $\epsilon_{EMD} = \frac{1 - \epsilon_{\ell_1}}{4}$ , where  $\epsilon_{\ell_1}$  is the constant that is mentioned in Theorem B.14.*

To prove the above lower bound, let us first consider the following lower bound for tolerant  $\ell_1$  testing between two probability distributions.

► **Theorem B.13** (Valiant and Valiant [25]). *Let  $p$  and  $q$  be two known and unknown probability distributions respectively over  $[n]$ . There is an absolute constant  $\epsilon$  such that in order to decide whether  $\|p - q\|_1 \leq \epsilon$  or  $\|p - q\|_1 \geq 1 - \epsilon$ ,  $\Omega\left(\frac{n}{\log n}\right)$  samples, from the distribution  $q$ , are necessary.*<sup>12</sup>

<sup>12</sup>Note that this is rephrasing of the result proved in [25]. For reference, see Chapter 5 of the survey by Canonne [9].

## 34:22 Graph Isomorphism and EMD

Now, we restate the above result for our purpose.

► **Theorem B.14.** *Let  $p$  and  $q$  be two known and unknown probability distributions, having support size  $n$ , over a Hamming cube  $H = \{0, 1\}^n$ . There is an absolute constant  $\epsilon_{\ell_1}$  such that in order to decide whether  $\|p - q\|_1 \leq \alpha_1$  or  $\|p - q\|_1 \geq \alpha_2$  with  $0 < \alpha_1 < \alpha_2 \leq 1 - \epsilon_{\ell_1}$ ,  $\Omega(\frac{n}{\log n})$  samples, from the distribution  $q$ , are necessary.*

As noted earlier, we will prove Theorem B.10 by using Lemma B.14. However, Theorem B.10 is regarding  $EMD$  between two distributions whereas Lemma B.14 is regarding  $\ell_1$  distance between two distributions. The following observation (from [12]) gives a connection between  $EMD$  between two distributions with the  $\ell_1$  distance between them, which will be required in lower bound proof.

► **Proposition B.15** ([12]). *Let  $(M, D)$  be a finite metric space and  $p$  and  $q$  be two probability distributions on  $M$ . Minimum distance between any two points of  $M$  is  $\Delta_{\min}$  and diameter of  $M$  is  $\Delta_{\max}$ . Then the following condition holds:*

$$\frac{\|p - q\|_1 \Delta_{\min}}{2} \leq EMD(p, q) \leq \frac{\|p - q\|_1 \Delta_{\max}}{2}.$$

Note that the above proposition gives interesting result when  $\frac{\Delta_{\max}}{\Delta_{\min}}$  is bounded by a constant. Note that  $S \subset \{0, 1\}^n$  satisfies  $\frac{\Delta_{\max}}{\Delta_{\min}} \leq 2$ .

**Proof of Lemma B.12.** In  $S \subset H = \{0, 1\}^n$ , the pairwise Hamming distance between any two elements in  $S$  is at least  $\frac{n}{2}$ , to have  $\frac{\Delta_{\max}}{\Delta_{\min}} \leq 2$  in our context. It is well known that  $|S| = \Omega(n)$ . We will show that if there exists an algorithm  $\mathcal{A}$  that decides  $EMD(p, q) \leq \beta_1 n$  or  $EMD(p, q) \geq \beta_2 n$  by using  $t$  samples from  $q$ , then there exists an algorithm  $\mathcal{P}$  that decides whether  $\|p - q\|_1 \leq \alpha_1$  or  $\|p - q\|_1 \geq \alpha_2$  by using  $t$  samples from  $q$ , where  $\alpha_1 = 2\beta_1$  and  $\alpha_2 = 4\beta_2$ . Note that we have  $0 < \beta_1 < \beta_2 < \frac{1 - \epsilon_{\ell_1}}{4}$ . So,  $0 < \alpha_1 < \alpha_2 < 1 - \epsilon_{\ell_1}$ , which satisfies the requirement of Theorem B.14.

### Algorithm $\mathcal{P}$ :

- (1) First run algorithm  $\mathcal{A}$ .
- (2) If the output of algorithm  $\mathcal{A}$  is  $EMD(p, q) \leq \beta_1 n$ , algorithm  $\mathcal{P}$  returns  $\|p - q\|_1 \leq \alpha_1$ .
- (3) If the output of algorithm  $\mathcal{A}$  is  $EMD(p, q) \geq \beta_2 n$ , algorithm  $\mathcal{P}$  returns  $\|p - q\|_1 \geq \alpha_2$ .

To complete the proof, we only need to show that  $\mathcal{P}$  gives desired output with probability at least  $2/3$ . The result then follows from Theorem B.14.

Let us first consider the case  $\|p - q\|_1 \leq \alpha_1$ . Then by Observation B.15, we can say that  $EMD(p, q) \leq \frac{\alpha_1 n}{2} = \beta_1 n$ . Therefore algorithm  $\mathcal{A}$  will output that  $EMD(p, q) \leq \beta_1 n$ . This implies that the algorithm  $\mathcal{P}$  will output  $\|p - q\|_1 \leq \alpha_1$ .

Now, let us consider the case  $\|p - q\|_1 \geq \alpha_2$ . Using the fact that any pair elements in  $S \subset H$  is at least  $\frac{n}{2}$  along with Observation B.15, we get  $EMD(p, q) \geq \frac{\alpha_2 n}{4} = \beta_2 n$ . This implies  $\mathcal{P}$  will output  $\|p - q\|_1 \geq \alpha_2$ . ◀

Till now, we were discussing the proof of Lemma B.12 that states  $QWR_{EMD}(n) = \Omega(\frac{n}{\log n})$ . The lower bound is almost tight, up to a polynomial factor of  $\log n$ . The upper bound is stated in the following observation.

► **Observation B.16.**  $QWR_{EMD}(n) = \tilde{O}(n)$ , where  $\tilde{O}(\cdot)$  hides a polynomial factor in  $\frac{1}{\beta_2 - \beta_1}$  and  $\log n$ .

Instead of proving the above observation, we prove the following lemma that states the upper bound of tolerant EMD testing between two distributions when we know one distribution and have sample access to the unknown distribution. By Remark 6, we will be done with the proof of Observation B.16.

► **Lemma B.17.** *Let  $H = \{0, 1\}^n$  be a  $n$ -dimensional Hamming cube, and let  $p$  and  $q$  denote two known and unknown  $n$ -grained distribution over  $H$ . There exists an algorithm that takes two parameters  $\beta_1, \beta_2$  with  $0 \leq \beta_1 < \beta_2 \leq 1$  and a  $\delta \in (0, 1)$  as input and decides whether  $EMD(p, q) \leq \beta_1 n$  or  $EMD(p, q) \geq \beta_2 n$  with probability at least  $1 - \delta$ . Moreover, the algorithm ALG-EMD queries for  $\tilde{O}(n)$  many samples from  $q$ , where  $\tilde{O}(\cdot)$  hides a polynomial factor in  $\frac{1}{\beta_2 - \beta_1}$  and  $\log n$ .*

**Proof.** Let  $\epsilon$  be a constant less than  $(\beta_2 - \beta_1)$ . We construct a probability distribution  $q'$  such that the  $\ell_1$  distance between  $q$  and  $q'$  will be at most  $\epsilon$ , that is,  $\sum_{i \in [L]} |q(i) - q'(i)| \leq \epsilon$ .

Note that such a  $q'$  can be constructed with probability at least  $1 - \delta$  by querying for  $\tilde{O}(n)$  many samples of  $q$  which follows from [11]. Then, we find  $EMD(p, q')$ . Observe that  $|EMD(p, q) - EMD(p, q')| \leq \frac{\epsilon n}{2}$ . This is because

$$\begin{aligned} |EMD(p, q) - EMD(p, q')| &\leq |EMD(p, q') + EMD(q', q) - EMD(p, q')| \\ &\leq EMD(q, q') \\ &\leq \frac{\epsilon d}{2} \text{ (By Proposition B.15)} \end{aligned}$$

As  $EMD(p, q) \leq \beta_1 n$  or  $EMD(p, q) \geq \beta_2 n$ , by the above observation, we will get either  $EMD(p, q') \leq (\beta_1 + \frac{\epsilon}{2}) n$  or  $EMD(p, q') \geq (\beta_1 + \frac{\epsilon}{2}) n$ , respectively. By our choice of  $\epsilon < \beta_2 - \beta_1$ , we can decide  $EMD(p, q) \leq \beta_1 n$  or  $EMD(p, q) \geq \beta_2 n$  from the value of  $EMD(p, q')$ . ◀

# The Product of Gaussian Matrices Is Close to Gaussian

## Abstract

We study the distribution of the *matrix product*  $G_1 G_2 \cdots G_r$  of  $r$  independent Gaussian matrices of various sizes, where  $G_i$  is  $d_{i-1} \times d_i$ , and we denote  $p = d_0$ ,  $q = d_r$ , and require  $d_i = d_{r-1}$ . Here the entries in each  $G_i$  are standard normal random variables with mean 0 and variance 1. Such products arise in the study of wireless communication, dynamical systems, and quantum transport, among other places. We show that, provided each  $d_i$ ,  $i = 1, \dots, r$ , satisfies  $d_i \geq Cp \cdot q$ , where  $C \geq C_0$  for a constant  $C_0 > 0$  depending on  $r$ , then the matrix product  $G_1 G_2 \cdots G_r$  has variation distance at most  $\delta$  to a  $p \times q$  matrix  $G$  of i.i.d. standard normal random variables with mean 0 and variance  $\prod_{i=1}^{r-1} d_i$ . Here  $\delta \rightarrow 0$  as  $C \rightarrow \infty$ . Moreover, we show a converse for constant  $r$  that if  $d_i < C' \max\{p, q\}^{1/2} \min\{p, q\}^{3/2}$  for some  $i$ , then this total variation distance is at least  $\delta'$ , for an absolute constant  $\delta' > 0$  depending on  $C'$  and  $r$ . This converse is best possible when  $p = \Theta(q)$ .

## 1 Introduction

Random matrices play a central role in many areas of theoretical, applied, and computational mathematics. One particular application is dimensionality reduction, whereby one often chooses a rectangular random matrix  $G \in \mathbb{R}^{m \times n}$ ,  $m \ll n$ , and computes  $G \cdot x$  for a fixed vector  $x \in \mathbb{R}^n$ . Indeed, this is the setting in compressed sensing and sparse recovery [12], randomized numerical linear algebra [18, 20, 36], and sketching algorithms for data streams [25]. Often  $G$  is chosen to be a Gaussian matrix, and in particular, an  $m \times n$  matrix with entries that are i.i.d. normal random variables with mean 0 and variance 1, denoted by  $N(0, 1)$ . Indeed, in compressed sensing, such matrices can be shown to satisfy the Restricted Isometry Property (RIP) [10], while in randomized numerical linear algebra, in certain applications such as support vector machines [29] and non-negative matrix factorization [19], their performance is shown to often outperform that of other sketching matrices.

Our focus in this paper will be on understanding the *product* of two or more Gaussian matrices. Such products arise naturally in different applications. For example, in the over-constrained ridge regression problem  $\min_x \|Ax - b\|_2^2 + \lambda \|x\|_2^2$ , the design matrix  $A \in \mathbb{R}^{n \times d}$ ,

$n \gg d$ , is itself often assumed to be Gaussian (see, e.g., [26]). In this case, the “sketch-and-solve” algorithmic framework for regression [32] would compute  $G \cdot A$  and  $G \cdot b$  for an  $m \times n$  Gaussian matrix  $G$  with  $m \approx sd_\lambda$ , where  $sd_\lambda$  is the so-called statistical dimension [2], and solve for the  $x$  which minimizes  $\|G \cdot Ax - G \cdot b\|_2^2 + \lambda \|x\|_2^2$ . While computing  $G \cdot A$  is slower than computing the corresponding matrix product for other kinds of sketching matrices  $G$ , it often has application-specific [29, 19] as well as statistical benefits [31]. Notice that  $G \cdot A$  is the product of two independent Gaussian matrices, and in particular,  $G$  has a small number of rows while  $A$  has a small number of columns – this is precisely the rectangular case we will study below. Other applications in randomized numerical linear algebra where the product of two Gaussian matrices arises is when one computes the product of a Gaussian sketching matrix and Gaussian noise in a spiked identity covariance model [37].

The product of two or more Gaussian matrices also arises in diverse fields such as multiple-input multiple-output (MIMO) wireless communication channels [24]. Indeed, similar to the above regression problem in which one wants to reconstruct an underlying vector  $x$ , in such settings one observes the vector  $y = G_1 \cdots G_r \cdot x + \eta$ , where  $x$  is the transmitted signal and  $\eta$  is background noise. This setting corresponds to the situation in which there are  $r$  scattering environments separated by major obstacles, and the dimensions of the  $G_i$  correspond to the number of “keyholes” [24]. To determine the mutual information of this channel, one needs to understand the singular values of the matrix  $G_1 \cdots G_r$ . If one can show the distribution of this product is close to that of a Gaussian distribution in total variation distance, then one can use the wide range of results known for the spectrum of a single Gaussian matrix (see, e.g., [35]). Other applications of products of Gaussian matrices include disordered spin chains [11, 3, 15], stability of large complex dynamical systems [22, 21], symplectic maps and Hamiltonian mechanics [11, 4, 28], quantum transport in disordered wires [23, 13], and quantum chromodynamics [27]; we refer the reader to [14, 1] for an overview.

The main question we ask in this work is:

*What is the distribution of the product  $G_1 G_2 \cdots G_r$  of  $r$  independent Gaussian matrices of various sizes, where  $G_i$  is  $d_{i-1} \times d_i$ ?*

Our main interest in the question above will be when  $G_1$  has a small number  $p = d_0$  of rows, and  $G_r$  has a small number  $q = d_r$  of columns. Despite the large body of work on random matrix theory (see, e.g., [34] for a survey), we are not aware of any work which attempts to bound the total variation distance of the entire distribution of  $G_1 G_2 \cdots G_r$  to a Gaussian distribution itself.

## 1.1 Our Results

Formally, we consider the problem of distinguishing the product of normalized Gaussian matrices

$$A_r = \left( \frac{1}{\sqrt{d_1}} G_1 \right) \left( \frac{1}{\sqrt{d_2}} G_2 \right) \cdots \left( \frac{1}{\sqrt{d_{r-1}}} G_{r-1} \right) \left( \frac{1}{\sqrt{d_1}} G_r \right)$$

from a single normalized Gaussian matrix

$$A_1 = \frac{1}{\sqrt{d_1}} G_1.$$

We show that, when  $r$  is a constant, with constant probability we cannot distinguish the distributions of these two random matrices when  $d_i \gg p, q$  for all  $i$ ; and, conversely, with constant probability, we can distinguish these two distributions when the  $d_i$  are not large enough.

► **Theorem 1** (Main theorem). *Suppose that  $d_i \geq \max\{p, q\}$  for all  $i$  and  $d_{r-1} = d_1$ .*

(a) *It holds that*

$$d_{TV}(A_r, A_1) \leq C_1 \sum_{i=1}^{r-1} \sqrt{\frac{pq}{d_i}},$$

where  $d_{TV}(A_r, A_1)$  denotes the total variation distance between  $A_r$  and  $A_1$ , and  $C_1 > 0$  is an absolute constant.

(b) *If  $p, q, d_1, \dots, d_r$  further satisfy that*

$$\sum_{j=1}^{r-1} \frac{1}{d_j} \geq \frac{C_2^r}{\max\{p, q\}^{\frac{1}{2}} \min\{p, q\}^{\frac{3}{2}}},$$

where  $C_2 > 0$  is an absolute constant, then  $d_{TV}(A_r, A_1) \geq 2/3$ .

Part (a) states that  $d_{TV}(A_r, A_1) < 2/3$  when  $d_i \geq C'_1 pq$  for all  $i$  for a constant  $C'_1$  depending on  $r$ . The converse in (b) implies that  $d_{TV}(A_r, A_1) \geq 2/3$  when  $d_i \leq C'_2 \max\{p, q\}^{1/2} \min\{p, q\}^{3/2}$  for some  $i$  for a constant  $C'_2$  depending on  $r$ . When  $p = \Theta(q)$  and  $r$  is a constant, we obtain a dichotomy (up to a constant factor) for the conditions on  $p, q$  and  $d_i$ .

## 1.2 Our Techniques

**Upper Bound.** We start by explaining our main insight as to why the distribution of a product  $G_1 \cdot G_2$  of a  $p \times d$  matrix  $G_1$  of i.i.d.  $N(0, 1)$  random variables and a  $d \times q$  matrix  $G_2$  of i.i.d.  $N(0, 1)$  random variables has low variation distance to the distribution of a  $p \times q$  matrix  $A$  of i.i.d.  $N(0, d)$  random variables. One could try to directly understand the probability density function as was done in the case of Wishart matrices in [7, 30], which corresponds to the setting when  $G_1 = G_2$ . However, there are certain algebraic simplifications in the case of the Wishart distribution that seem much less tractable when manipulating the density function of the product of independent Gaussians [9]. Another approach would be to try to use entropic methods as in [8, 6]. Such arguments try to reveal entries of the product  $G_1 \cdot G_2$  one-by-one, arguing that for most conditionings of previous entries, the new entry still looks like an independent Gaussian. However, the entries are clearly not independent – if  $(G_1 \cdot G_2)_{i,j}$  has large absolute value, then  $(G_1 \cdot G_2)_{i,j'}$  is more likely to be large in absolute value, as it could indicate that the  $i$ -th row of  $G_1$  has large norm. One could try to first condition on the norms of all rows of  $G_1$  and columns of  $G_2$ , but additional issues arise when one looks at submatrices: if  $(G_1 \cdot G_2)_{i,j}, (G_1 \cdot G_2)_{i,j'}$ , and  $(G_1 \cdot G_2)_{i',j}$  are all large, then it could mean the  $i$ -th row of  $G_1$  and the  $i'$ -th row of  $G_1$  are correlated with each other, since they both are correlated with the  $j$ -th column of  $G_2$ . Consequently, since  $(G_1 \cdot G_2)_{i,j'}$  is large, it could make it more likely that  $(G_1 \cdot G_2)_{i',j'}$  has large absolute value. This makes the entropic method difficult to apply in this context.

Our upper bound instead leverages beautiful work of Jiang [16] and Jiang and Ma [17] which bounds the total variation distance between the distribution of an  $r \times \ell$  submatrix of a random  $d \times d$  orthogonal matrix (orthonormal rows and columns) and an  $r \times \ell$  matrix with i.i.d.  $N(0, 1/d)$  entries. Their work shows that if  $r \cdot \ell/d \rightarrow 0$  as  $d \rightarrow \infty$ , then the total variation distance between these two matrix ensembles goes to 0. It is not immediately clear how to apply such results in our context. First of all, which submatrix should we be looking at? Note though, that if  $V^T$  is a  $p \times d$  uniformly random (Haar measure) matrix with orthonormal rows, and  $E$  is a  $d \times q$  uniformly random matrix with orthonormal columns,

## 35:4 The Product of Gaussian Matrices Is Close to Gaussian

then by rotational invariance,  $V^T E$  is identically distributed to a  $p \times q$  submatrix of a  $d \times d$  random orthonormal matrix. Thus, setting  $r = p$  and  $\ell = q$  in the above results, they imply that  $V^T E$  is close in variation distance to a  $p \times q$  matrix  $H$  with i.i.d.  $N(0, 1/d)$  entries. Given  $G_1$  and  $G_2$ , one could then write them in their *singular value decomposition*, obtaining  $G_1 = U\Sigma V^T$  and  $G_2 = E^T F^T$ . Then  $V^T$  and  $E$  are independent and well-known to be uniformly random  $p \times d$  and  $d \times q$  orthonormal matrices, respectively. Thus  $G_1 \cdot G_2$  is close in total variation distance to  $U\Sigma H^T F^T$ . However, this does not immediately help either, as it is not clear what the distribution of this matrix is. Instead, the “right” way to utilize the results above is to (1) observe that  $G_1 \cdot G_2 = U\Sigma V^T G_2$  is identically distributed as  $U\Sigma X$ , where  $X$  is a matrix of i.i.d. normal random variables, given the rotational invariance of the Gaussian distribution. Then (2)  $X$  is itself close to a product  $W^T Z$  where  $W^T$  is a random  $p \times d$  matrix with orthonormal rows, and  $Z$  is a random  $d \times q$  matrix with orthonormal columns, by the above results. Thus,  $G_1 \cdot G_2$  is close to  $U\Sigma W^T Z$ . Then (3)  $U\Sigma W^T$  has the same distribution as  $G_1$ , so  $U\Sigma W^T Z$  is close to  $G'_1 Z$ , where  $G'_1$  and  $G_1$  are identically distributed, and  $G'_1$  is independent of  $Z$ . Finally, (4)  $G'_1 Z$  is identically distributed as a matrix  $A_1$  of standard normal random variables because  $G'_1$  is Gaussian and  $Z$  has orthonormal columns, by rotational invariance of the Gaussian distribution.

We hope that this provides a general method for arguments involving Gaussian matrices - in step (2) we had the quantity  $U\Sigma X$ , where  $X$  was a Gaussian matrix, and then viewed  $X$  as a product of a short-fat random orthonormal matrix  $W^T$  and a tall-thin random orthonormal matrix  $Z$ . Our proof for the product of more than 2 matrices recursively uses similar ideas, and bounds the growth in variation distance as a function of the number  $r$  of matrices involved in the product.

**Lower Bound.** For our lower bound for constant  $r$ , we show that the fourth power of the Schatten 4-norm of a matrix, namely,  $\|X\|_{S_4}^4 = \text{tr}((X^T X)^2)$ , can be used to distinguish a product  $A_r$  of  $r$  Gaussian matrices and a single Gaussian matrix  $A_1$ . We use Chebyshev’s inequality, for which we need to find the expectation and variance of  $\text{tr}((X^T X)^2)$  for  $X = A_r$  and  $X = A_1$ .

Let us consider the expectation first. An idea is to calculate the expectation recursively, that is, for a fixed matrix  $M$  and a Gaussian random matrix  $G$  we express  $\mathbb{E} \text{tr}(((MG)^T(MG))^2)$  in terms of  $\mathbb{E} \text{tr}((M^T M)^2)$ . The real situation turns out to be slightly more complicated. Instead of expressing  $\mathbb{E} \text{tr}(((MG)^T(MG))^2)$  in terms of  $\mathbb{E} \text{tr}((M^T M)^2)$  directly, we decompose  $\mathbb{E} \text{tr}(((MG)^T(MG))^2)$  into the sum of expectations of a few functions in terms of  $M$ , say,

$$\mathbb{E} \text{tr}(((MG)^T(MG))^2) = \mathbb{E} f_1(M) + \mathbb{E} f_2(M) + \dots + \mathbb{E} f_s(M)$$

and build up the recurrence relations for  $\mathbb{E} f_1(MG), \dots, \mathbb{E} f_s(MG)$  in terms of  $\mathbb{E} f_1(M), \mathbb{E} f_2(M), \dots, \mathbb{E} f_s(M)$ . It turns out that the recurrence relations are all linear, i.e.,

$$\mathbb{E} f_i(MG) = \sum_{j=1}^s a_{ij} \mathbb{E} f_j(M), \quad i = 1, \dots, s, \tag{1}$$

whence we can solve for  $\mathbb{E} f_i(A_r)$  and obtaining the desired expectation  $\mathbb{E} \text{tr}((A_r^T A_r)^2)$ .

Now we turn to variance. One could try to apply the same idea of finding recurrence relations for  $\text{Var}(Q) = \mathbb{E}(Q^2) - (\mathbb{E} Q)^2$  (where  $Q = \text{tr}(((MG)^T(MG))^2)$ ), but it quickly becomes intractable for the  $\mathbb{E}(Q^2)$  term as it involves products of eight entries of  $M$ , which all need to be handled carefully as to avoid any loose bounds; note, the subtraction of  $(\mathbb{E} Q)^2$

is critically needed to obtain a small upper bound on  $\text{Var}(Q)$  and thus loose bounds on  $\mathbb{E}(Q^2)$  would not suffice. For a tractable calculation, we keep the product of entries of  $M$  to 4th order throughout, without involving any terms of 8th order. To do so, we invoke the law of total variance,

$$\text{Var}_{M,G}(\text{tr}((MG)^T(MG))^2) = \mathbb{E}_M \left( \text{Var}_G(\text{tr}((G^T M^T M G)^2)) \middle| M \right) + \text{Var}_M \left( \mathbb{E}_G \text{tr}((G^T M^T M G)^2) \middle| M \right). \quad (2)$$

For the first term on the right-hand side, we use Poincaré’s inequality to upper bound it. Poincaré’s inequality for the Gaussian measure states that

$$\text{Var}_{g \sim N(0, I_m)}(f(g)) \leq C \mathbb{E}_{g \sim N(0, I_m)} \|\nabla f(g)\|_2^2$$

for a differentiable function  $f$  on  $\mathbb{R}^m$ . Here we can simply let  $f(X) = \text{tr}((MX)^T(MX))^2$  and calculate  $\mathbb{E} \|\nabla f(G)\|_2^2$ . This is tractable since  $\mathbb{E} \|\nabla f(G)\|_2^2$  involves the products of at most 4 entries of  $M$ , and we can use the recursive idea for the expectation above to express

$$\mathbb{E} \|\nabla f(G)\|_2^2 = \sum_i a_{ij} \mathbb{E} g_i(M)$$

for a few functions  $g_i$ ’s and establish a recurrence relation for each  $g_i$ .

The second term on the right-hand side of (2) can be dealt with by plugging in (1), and turns out to depend on a new quantity  $\text{Var}(\text{tr}^2(M^T M))$ . We again apply the recursive idea and the law of total variance to

$$\text{Var}_{M,G}(\text{tr}^2(G^T M^T M G)) = \mathbb{E}_M \left( \text{Var}_G(\text{tr}^2((G^T M^T M G))) \middle| M \right) + \text{Var}_M \left( \mathbb{E}_G \text{tr}^2(G^T M^T M G) \middle| M \right).$$

Again, the first term on the right-hand side can be handled by Poincaré’s inequality and the second-term turns out to depend on  $\text{Var}(\text{tr}((M^T M)^2))$ , which is crucial. We have now obtained a double recurrence involving inequalities on  $\text{Var}(\text{tr}((M^T M)^2))$  and  $\text{Var}(\text{tr}^2((M^T M)^2))$ , from which we can solve for an upper bound on  $\text{Var}(\text{tr}(A_r^T A_r)^2)$ . This upper bound, however, grows exponentially in  $r$ , which is impossible to improve due to our use of Poincaré’s inequality.

## 2 Preliminaries

**Notation.** For a random variable  $X$  and a probability distribution  $\mathcal{D}$ , we use  $X \sim \mathcal{D}$  to denote that  $X$  is subject to  $\mathcal{D}$ . For two random variables  $X$  and  $Y$  defined on the same sample space, we write  $X \stackrel{d}{=} Y$  if  $X$  and  $Y$  are identically distributed.

We use  $\mathcal{G}_{m,n}$  to denote the distribution of  $m \times n$  Gaussian random matrices of i.i.d. entries  $N(0, 1)$  and  $\mathcal{O}_{m,n}$  to denote the uniform distribution (Haar) of an  $m \times n$  random matrix with orthonormal rows. For a distribution  $\mathcal{D}$  on a linear space and a scaling factor  $\alpha \in \mathbb{R}$ , we use  $\alpha\mathcal{D}$  to denote the distribution of  $\alpha X$ , where  $X \sim \mathcal{D}$ .

For two probability measures  $\mu$  and  $\nu$  on the Borel algebra  $\mathcal{F}$  of  $\mathbb{R}^m$ , the total variation distance between  $\mu$  and  $\nu$  is defined as

$$d_{TV}(\mu, \nu) = \sup_{A \in \mathcal{F}} |\mu(A) - \nu(A)| = \frac{1}{2} \int_{\mathbb{R}^m} \left| \frac{d\mu}{d\nu} - 1 \right| d\nu.$$

If  $\nu$  is absolutely continuous with respect to  $\mu$ , one can define the Kullback-Leibler Divergence between  $\mu$  and  $\nu$  as

$$D_{KL}(\mu \parallel \nu) = \int_{\mathbb{R}^m} \frac{d\mu}{d\nu} \log_2 \frac{d\mu}{d\nu} d\nu.$$

If  $\nu$  is not absolutely continuous with respect to  $\mu$ , we define  $D_{KL}(\mu \parallel \nu) = \infty$ .

## 35:6 The Product of Gaussian Matrices Is Close to Gaussian

When  $\mu$  and  $\nu$  correspond to two random variables  $X$  and  $Y$ , respectively, we also write  $d_{TV}(\mu, \nu)$  and  $D_{\text{KL}}(\mu\|\nu)$  as  $d_{TV}(X, Y)$  and  $D_{\text{KL}}(X\|Y)$ , respectively.

The following is the well-known relation between the Kullback-Leibler divergence and the total variation distance between two probability measures.

► **Lemma 2** (Pinsker's Inequality [5, Theorem 4.19]).  $d_{TV}(\mu, \nu) \leq \sqrt{\frac{1}{2}D_{\text{KL}}(\mu\|\nu)}$ .

The following result, concerning the distance between the submatrix of a properly scaled Gaussian random matrix and a submatrix of a random orthogonal matrix, is due to Jiang and Ma [17].

► **Lemma 3** ([17]). Let  $G \sim \mathcal{G}_{d,d}$  and  $Z \sim \mathcal{O}_{d,d}$ . Suppose that  $p, q \leq d$  and  $\hat{G}$  is the top-left  $p \times q$  block of  $G$  and  $\hat{Z}$  the top-left  $p \times q$  block of  $Z$ . Then

$$d_{\text{KL}}\left(\frac{1}{\sqrt{d}}\hat{G}\left\|\hat{Z}\right.\right) \leq C\frac{pq}{d}, \quad (3)$$

where  $C > 0$  is an absolute constant.

The original paper [17] does not state explicitly the bound in (3) and only states that the Kullback-Leibler divergence tends to 0 as  $d \rightarrow \infty$ . A careful examination of the proof of [17, Theorem 1(i)], by keeping track of the order of the various  $o(1)$  terms, reveals the quantitative bound (3).

**Useful Inequalities.** We list two useful inequalities below.

► **Lemma 4** (Poincaré's inequality for Gaussian measure [5, Theorem 3.20]). Let  $X \sim N(0, I_n)$  be the standard  $n$ -dimensional Gaussian distribution and  $f : \mathbb{R}^n \rightarrow \mathbb{R}$  be any continuously differentiable function. Then

$$\text{Var}(f(X)) \leq \mathbb{E}\left(\|\nabla f(X)\|_2^2\right).$$

► **Lemma 5** (Trace inequality, [33]). Let  $A$  and  $B$  be symmetric, positive semidefinite matrices and  $k$  be a positive integer. Then

$$\text{tr}((AB)^k) \leq \min\left\{\|A\|_{\text{op}}^k \text{tr}(B^k), \|B\|_{\text{op}}^k \text{tr}(A^k)\right\}.$$

### 3 Upper Bound

Let  $r \geq 2$  be an integer. Suppose that  $G_1, \dots, G_r$  are independent Gaussian random matrices, where  $G_i \sim \mathcal{G}_{d_{i-1}, d_i}$  and  $d_0 = p$ ,  $d_r = q$  and  $d_{r-1} = d_1$ . Consider the product of normalized Gaussian matrices

$$A_r = \left(\frac{1}{\sqrt{d_1}}G_1\right) \left(\frac{1}{\sqrt{d_2}}G_2\right) \cdots \left(\frac{1}{\sqrt{d_{r-1}}}G_{r-1}\right) \left(\frac{1}{\sqrt{d_1}}G_r\right)$$

and a single normalized Gaussian random matrix

$$A_1 = \frac{1}{\sqrt{d_1}}G'_1$$

where  $G'_1 \sim \mathcal{G}_{p,q}$ . In this section, we shall show that when  $p, q \ll d_i$  for all  $i$ , we cannot distinguish  $A_r$  from  $A_1$  with constant probability.

For notational convenience, let  $W_i = \frac{1}{\sqrt{d_i}}G_i$  for  $i \leq r$  and  $W_r = \frac{1}{\sqrt{d_1}}G_r$ . Assume that  $pq \leq \beta d_i$  for some constant  $\beta$  for all  $i$ . Our question is to find the total variation distance between the matrix product  $W_1W_2 \cdots W_r$  and the product  $W_1W_r$  of two matrices.

► **Lemma 6.** Let  $p, q, d, d'$  be positive integers satisfying that  $pq \leq \beta d$  and  $pq \leq \beta d'$  for some constant  $\beta < 1$ . Suppose that  $A \in \mathbb{R}^{p \times d}$ ,  $G \sim \frac{1}{\sqrt{d}} \mathcal{G}_{d, d'}$ , and  $L \sim \mathcal{O}_{d', d}$ . Further suppose that  $G$  and  $L$  are independent. Let  $Z \sim \mathcal{O}_{q, d}$  be independent of  $A, G$  and  $L$ . Then

$$d_{TV}(AGL, AZ^T) \leq C \sqrt{\frac{pq}{d}},$$

where  $C > 0$  is an absolute constant.

**Proof.** Let  $A = U\Sigma V^T$  be its singular value decomposition, where  $V$  has dimension  $d \times p$ . Then

$$AGL = U\Sigma(V^T GL) \stackrel{d}{=} U\Sigma X,$$

where  $X$  is a  $p \times q$  random matrix of i.i.d.  $N(0, 1/d)$  entries. Suppose that  $\tilde{Z}$  consists of the top  $p$  rows of  $Z^T$ . Then

$$AZ^T = U\Sigma(V^T Z^T) \stackrel{d}{=} U\Sigma \tilde{Z}.$$

Note that  $X$  and  $Z$  are independent of  $U$  and  $\Sigma$ . It follows from Lemma 3 that

$$d_{\text{KL}}(AGL \| AZ^T) = d_{\text{KL}}(U\Sigma X \| U\Sigma \tilde{Z}) = d_{\text{KL}}(X \| \tilde{Z}) \leq C \frac{pq}{d},$$

where  $C > 0$  is an absolute constant. The result follows from Pinsker's inequality (Lemma 2). ◀

The next theorem follows from the lemma above.

► **Theorem 7.** It holds that

$$d_{TV}(W_1 \cdots W_r, W_1 W_r) \leq C \sum_{i=1}^r \sqrt{\frac{pq}{d_i}},$$

where  $C > 0$  is an absolute constant.

**Proof.** Let  $W_r = U\Sigma V^T$  and  $X_i \sim \mathcal{O}_{q, d_i}$ , independent from each other and from the  $W_i$ 's. Applying the preceding lemma with  $A = W_1 \cdots W_{r-2}$ ,  $G = W_{r-1}$  and  $L = U$ , we have

$$d_{TV}(W_1 \cdots W_{r-2} W_{r-1} W_r, W_1 \cdots W_{r-2} X_{r-1}^T \Sigma V^T) \leq C \sqrt{\frac{pq}{d_{r-1}}},$$

Next, applying the preceding lemma with  $A = W_1 \cdots W_{r-3}$ ,  $G = W_{r-1}$  and  $L = X_r$ , we have

$$d_{TV}(W_1 \cdots W_{r-2} X_r \Sigma V^T, W_1 \cdots W_{r-3} X_{r-2}^T \Sigma V^T) \leq C \sqrt{\frac{pq}{d_{r-2}}},$$

Iterating this procedure, we have in the end that

$$d_{TV}(W_1 W_2 X_3 \Sigma V^T, W_1 X_2 \Sigma V^T) \leq C \sqrt{\frac{pq}{d_2}}.$$

Since  $U, \Sigma$  and  $V$  are independent and  $X_2 \stackrel{d}{=} U$ , it holds that  $X_2 \Sigma V^T \stackrel{d}{=} W_r$ . Therefore,

$$d_{TV}(W_1 \cdots W_r, W_1 W_r) \leq C \sum_{i=2}^{r-1} \sqrt{\frac{pq}{d_i}}. \quad \blacktriangleleft$$

Repeating the same argument for  $W_1 W_r$ , we obtain the following corollary immediately.

► **Corollary 8.** It holds that

$$d_{TV}(A_r, A_1) \leq C \sum_{i=1}^{r-1} \sqrt{\frac{pq}{d_i}},$$

where  $C > 0$  is an absolute constant.

#### 4 Lower Bound

Suppose that  $r$  is a constant. We shall show that one can distinguish the product of  $r$  Gaussian random matrices

$$A_r = \left( \frac{1}{\sqrt{d_1}} G_1 \right) \left( \frac{1}{\sqrt{d_2}} G_2 \right) \cdots \left( \frac{1}{\sqrt{d_{r-1}}} G_{r-1} \right) \left( \frac{1}{\sqrt{d_1}} G_r \right),$$

from one Gaussian random matrix

$$A_1 = \frac{1}{\sqrt{d_1}} G_1'$$

when the intermediate dimensions  $d_1, \dots, d_{r-1}$  are not large enough. Considering  $h(X) = \text{tr}((X^T X)^2)$ , it suffices to show that one can distinguish  $h(A_r)$  and  $h(A_1)$  with a constant probability for constant  $r$ . By Chebyshev's inequality, it suffices to show that

$$\max \left\{ \sqrt{\text{Var}(h(A_1))}, \sqrt{\text{Var}(h(A_r))} \right\} \leq c(\mathbb{E} h(A_r) - \mathbb{E} h(A_1))$$

for a small constant  $c$ . We calculate that:

► **Lemma 9.** *Suppose that  $r$  is a constant,  $d_i \geq \max\{p, q\}$  for all  $i = 1, \dots, r$ . When  $p, q, d_1, \dots, d_r \rightarrow \infty$ ,*

$$\mathbb{E} h(A_r) = \frac{pq(p+q+1)}{d_r^2} + (1+o(1)) \frac{pq(p-1)(q-1)}{d_r^2} \sum_{j=1}^{r-1} \frac{1}{d_j}.$$

► **Lemma 10.** *Suppose that  $r$  is a constant,  $d_i \geq \max\{p, q\}$  for all  $i = 1, \dots, r$ . There exists an absolute constant  $C$  such that, when  $p, q, d_1, \dots, d_r$  are sufficiently large,*

$$\text{Var}(h(A_r)) \leq \frac{C^r(p^3q + pq^3)}{d_1^4}.$$

We conclude with the following theorem, which can be seen as a tight converse to Corollary 8 up to a constant factor on the conditions for  $p, q, d_1, \dots, d_r$ .

► **Theorem 11.** *Suppose that  $r$  is a constant and  $d_i \geq \max\{p, q\}$  for all  $i = 1, \dots, r$ . Further suppose that  $d_1 = d_r$ . When  $p, q, d_1, \dots, d_r$  are sufficiently large and satisfy that*

$$\sum_{j=1}^{r-1} \frac{1}{d_j} \geq \frac{C^r}{\max\{p, q\}^{\frac{1}{2}} \min\{p, q\}^{\frac{3}{2}}},$$

where  $C > 0$  is some absolute constant, with probability at least  $2/3$ , one can distinguish  $A_r$  from  $A_1$ .

#### 4.1 Calculation of the Mean

Suppose that  $A$  is a  $p \times q$  random matrix, and is rotationally invariant under left- and right-multiplication by orthogonal matrices. We define

$$\begin{aligned} S_1(p, q) &= \mathbb{E} A_{11}^4 \quad (\text{diagonal}) \\ S_2(p, q) &= \mathbb{E} A_{21}^4 \quad (\text{off-diagonal}) \\ S_3(p, q) &= \mathbb{E} A_{i1}^2 A_{j1}^2 \quad (i \neq j) \quad (\text{same column}) \end{aligned}$$

$$\begin{aligned} S_4(p, q) &= \mathbb{E} A_{1i}^2 A_{1j}^2 \quad (i \neq j) \quad (\text{same row}) \\ S_5(p, q) &= \mathbb{E} A_{1i}^2 A_{2j}^2 \quad (i \neq j) \\ S_6(p, q) &= \mathbb{E} A_{ik} A_{il} A_{jk} A_{jl} \quad (i \neq j, k \neq l) \quad (\text{rectangle}) \end{aligned}$$

Since  $A$  is left- and right-invariant under rotations, these quantities are well-defined. Then

$$\begin{aligned} \mathbb{E} \operatorname{tr}((A^T A)^2) &= \mathbb{E} \sum_{1 \leq i, j \leq q} (A^T A)_{ij}^2 = \sum_{i=1}^q \mathbb{E} (A^T A)_{ii}^2 + \sum_{1 \leq i, j \leq q, i \neq j} \mathbb{E} (A^T A)_{ij}^2 \\ &= q \mathbb{E} (A^T A)_{11}^2 + q(q-1) \mathbb{E} (A^T A)_{12}^2 \end{aligned}$$

and

$$\begin{aligned} \mathbb{E} (A^T A)_{11}^2 &= \mathbb{E} \left( \sum_{i=1}^p A_{i1}^2 \right)^2 = \sum_{i=1}^p \mathbb{E} A_{i1}^4 + \sum_{1 \leq i, j \leq p, i \neq j} \mathbb{E} A_{i1}^2 A_{j1}^2 \\ &= \mathbb{E} A_{11}^4 + (p-1) \mathbb{E} A_{21}^4 + p(p-1) \mathbb{E} A_{11}^2 A_{21}^2 \\ &=: S_1(p, q) + (p-1) S_2(p, q) + p(p-1) S_3(p, q) \\ \mathbb{E} (A^T A)_{12}^2 &= \mathbb{E} \left( \sum_{i=1}^p A_{i1} A_{i2} \right)^2 = \sum_{i=1}^p \mathbb{E} A_{i1}^2 A_{i2}^2 + \sum_{1 \leq i, j \leq p, i \neq j} \mathbb{E} A_{i1} A_{i2} A_{j1} A_{j2} \\ &= p S_4(p, q) + p(p-1) S_6(p, q). \end{aligned}$$

When  $S_1(p, q) = S_2(p, q)$ , we have

$$\begin{aligned} \mathbb{E} \operatorname{tr}((A^T A)^2) &= q(p S_1(p, q) + p(p-1) S_3(p, q)) + q(q-1)(p S_4(p, q) + p(p-1) S_6(p, q)) \\ &= pq S_1(p, q) + pq(p-1) S_3(p, q) + pq(q-1) S_4(p, q) + p(p-1) q(q-1) S_6(p, q). \end{aligned}$$

When  $A = G$ , we have

$$S_1(p, q) = S_2(p, q) = 3, \quad S_3(p, q) = S_4(p, q) = S_5(p, q) = 1, \quad S_6(p, q) = 0$$

and so

$$\mathbb{E} \operatorname{tr}((A^T A)^2) = 3pq + pq(p-1) + pq(q-1) = pq(p+q+1).$$

Next, consider  $A = BG$ , where  $B$  is a  $p \times d$  random matrix and  $G$  a  $d \times q$  random matrix of i.i.d.  $N(0, 1)$  entries. The following proposition is easy to verify, and its proof is postponed to Appendix A.

► **Proposition 12.** *It holds that  $\mathbb{E} A_{21}^4 = \mathbb{E} A_{11}^4$ .*

Suppose that the associated functions of  $B$  are named  $T_1, T_2, T_3, T_4, T_6, T_5$ . Then we can calculate that (detailed calculations can be found in Appendix B)

$$\begin{aligned} S_1(p, q) &= 3dT_1(p, d) + 3d(d-1)T_4(p, d) \\ S_3(p, q) &= 3dT_3(p, d) + d(d-1)T_5(p, d) + 2d(d-1)T_6(p, d) \\ S_4(p, q) &= dT_1(p, d) + d(d-1)T_4(p, d) \\ S_5(p, q) &= dT_3(p, d) + d(d-1)T_5(p, d) \\ S_6(p, q) &= dT_3(p, d) + d(d-1)T_6(p, d) \end{aligned}$$

It is clear that  $S_1, S_3, S_4, S_5, S_6$  depend only on  $d$  (not on  $p$  and  $q$ ) if  $T_1, T_3, T_4, T_5, T_6$  do so. Furthermore, if  $T_1 = 3T_4$  then we have  $S_1 = 3S_4$  and thus  $S_4 = d(d+2)T_4$ . If  $T_3 = 2T_6 + T_5$  then  $S_3 = d(d+2)T_3$  and  $S_3 = 2S_6 + S_5$ . Hence, if  $T_3 = T_4$  then  $S_3 = S_4$ . We can verify

## 35:10 The Product of Gaussian Matrices Is Close to Gaussian

that all these conditions are satisfied with one Gaussian matrix and we can iterate it to obtain these quantities for the product of  $r$  Gaussian matrices with intermediate dimensions  $d_1, d_2, \dots, d_{r-1}$ . We have that

$$S_3 = S_4 = \prod_{i=1}^{r-1} d_i(d_i + 2), \quad S_1 = 3S_4, \quad S_6 = \sum_{j=1}^{r-1} \left( \prod_{i=1}^{j-1} d_i(d_i + 2) \right) d_j \left( \prod_{i=j+1}^{r-1} d_i(d_i - 1) \right).$$

Therefore, normalizing the  $i$ -th matrix by  $1/\sqrt{d_i}$ , that is,

$$A = \left( \frac{1}{\sqrt{d_1}} G_1 \right) \left( \frac{1}{\sqrt{d_2}} G_2 \right) \cdots \left( \frac{1}{\sqrt{d_{r-1}}} G_{r-1} \right) \left( \frac{1}{\sqrt{d_r}} G_r \right),$$

we have for constant  $r$  that

$$\begin{aligned} \mathbb{E} \operatorname{tr}((A^T A)^2) &= \frac{1}{d_1^2 d_2^2 \cdots d_{r-1}^2 d_r^2} (pq(p+q+1)S_3 + pq(p-1)(q-1)S_6) \\ &\approx \frac{pq(p+q+1)}{d_r^2} + \frac{pq(p-1)(q-1)}{d_r^2} \sum_{j=1}^{r-1} \frac{1}{d_j}. \end{aligned} \quad (4)$$

### 4.2 Calculation of the Variance

Let  $M \in \mathbb{R}^{p \times p}$  be a random symmetric matrix, and let  $G \in \mathbb{R}^{p \times q}$  be a random matrix of i.i.d.  $N(0, 1)$  entries. We want to find the variance of  $\operatorname{tr}((G^T M G)^2)$ . The detailed calculations of some steps can be found in Appendix C.

Our starting point is the law of total variance, which states that

$$\operatorname{Var}(\operatorname{tr}((G^T M G)^2)) = \mathbb{E}_M \left( \operatorname{Var}_G(\operatorname{tr}((G^T M G)^2)) \mid M \right) + \operatorname{Var}_M \left( \mathbb{E}_G \operatorname{tr}((G^T M G)^2) \mid M \right) \quad (5)$$

**Step 1a.** We shall handle each term separately. Consider the first term, which we shall bound using the Poincaré inequality for Gaussian measures. Define  $f(X) = \operatorname{tr}((X^T M X)^2)$ , where  $X \in \mathbb{R}^{p \times q}$ . We shall calculate  $\nabla f$ .

$$f(X) = \|X^T M X\|_F^2 = \sum_{1 \leq i, j \leq q} (X^T M X)_{ij}^2 = \sum_{1 \leq i, j \leq q} \left( \sum_{1 \leq k, l \leq p} M_{kl} X_{ki} X_{lj} \right)^2.$$

Then

$$\frac{\partial f}{\partial X_{rs}} = \sum_{1 \leq i, j \leq q} 2 \left( \sum_{1 \leq u, v \leq p} M_{uv} X_{ui} X_{vj} \right) \left( \sum_{1 \leq k, l \leq p} \frac{\partial}{\partial X_{rs}} (M_{kl} X_{ki} X_{lj}) \right).$$

Note that

$$\frac{\partial}{\partial X_{rs}} (M_{kl} X_{ki} X_{lj}) = \begin{cases} M_{kl} X_{lj}, & (k, i) = (r, s) \text{ and } (l, j) \neq (r, s) \\ M_{kl} X_{ki}, & (k, i) \neq (r, s) \text{ and } (l, j) = (r, s) \\ 2M_{rr} X_{rs}, & (k, i) = (r, s) \text{ and } (l, j) = (r, s) \\ 0, & \text{otherwise.} \end{cases}$$

we have that

$$\frac{\partial f}{\partial X_{rs}} = 4 \left( \sum_{1 \leq u, v \leq p} M_{uv} X_{us} X_{vs} \right) M_{rr} X_{rs} + 2 \sum_{(l, j) \neq (r, s)} \left( \sum_{1 \leq u, v \leq p} M_{uv} X_{us} X_{vj} \right) M_{rl} X_{lj}$$

$$\begin{aligned}
& + 2 \sum_{(k,i) \neq (r,s)} \left( \sum_{1 \leq u,v \leq p} M_{uv} X_{ui} X_{vs} \right) M_{kr} X_{ki} \\
& = 4 \left[ \left( \sum_{1 \leq u,v \leq p} M_{uv} X_{us} X_{vs} \right) M_{rr} X_{rs} + \sum_{(l,j) \neq (r,s)} \left( \sum_{u,v} M_{uv} X_{us} X_{vj} \right) M_{rl} X_{lj} \right] \\
& = 4 \sum_{l,j} \left( \sum_{u,v} M_{uv} X_{us} X_{vj} \right) M_{rl} X_{lj}.
\end{aligned}$$

Next we calculate  $\mathbb{E}(\partial f / \partial X_{rs})^2$  when  $X$  is i.i.d. Gaussian.

$$\left( \frac{1}{4} \frac{\partial f}{\partial X_{rs}} \right)^2 = \sum_{\substack{l,j \\ l',j'}} \sum_{\substack{u,v \\ u',v'}} M_{uv} M_{u'v'} M_{rl} M_{r'l'} \mathbb{E} X_{us} X_{u's} X_{vj} X_{l_j} X_{v'j'} X_{l'j'}$$

We discuss different cases of  $j, j', s$ .

When  $j \neq j' \neq s$ , it must hold that  $u = u', v = l$  and  $v' = l'$  for a possible nonzero contribution, and the total contribution in this case is at most  $q(q-1)B_{r,s}^{(1)}$ , where

$$B_{r,s}^{(1)} = \sum_{1 \leq l, l' \leq p} \sum_u M_{ul} M_{ul'} M_{rl} M_{r'l'} = \sum_u \langle M_{u,\cdot}, M_{r,\cdot} \rangle^2.$$

When  $j = j' \neq s$ , it must hold that  $u = u'$  for a possible nonzero contribution, and the total contribution in this case is at most  $(q-1)B_{r,s}^{(2)}$ , where

$$\begin{aligned}
B_{r,s}^{(2)} & = \sum_{l,l'} \sum_{u,v,v'} M_{uv} M_{u'v'} M_{rl} M_{r'l'} \mathbb{E} X_{us}^2 X_{vj} X_{l_j} X_{v'j} X_{l'j} \\
& = \|M\|_F^2 \|M_{r,\cdot}\|_2^2 + 2 \sum_u \langle M_{u,\cdot}, M_{r,\cdot} \rangle^2.
\end{aligned}$$

When  $j = s \neq j'$ , it must hold that  $v' = l'$  for possible nonzero contribution, and the total contribution in this case is at most  $(q-1)B_{r,s}^{(3)}$ , where

$$\begin{aligned}
B_{r,s}^{(3)} & = \sum_{j' \neq s} \left[ \sum_{l,l'} \sum_{u,v} M_{uv} M_{u'l'} M_{rl} M_{r'l'} \mathbb{E} X_{us} X_{u's} X_{vs} X_{l_s} X_{l'j'}^2 \right] \\
& = \sum_{l,l'} (2 \langle M_{l,\cdot}, M_{l',\cdot} \rangle + \text{tr}(M) M_{ll'}) M_{rl} M_{r'l'}.
\end{aligned}$$

When  $j = j' = s$ , the nonzero contribution is

$$B_{r,s}^{(4)} = \sum_{l,l'} \sum_{\substack{u,v \\ u',v'}} M_{uv} M_{u'v'} M_{rl} M_{r'l'} \mathbb{E} X_{us} X_{u's} X_{vs} X_{l_s} X_{v's} X_{l's}.$$

Since  $u, u', v, v', l, l'$  needs to be paired, the only case which is not covered by  $B_{r,s}^{(1)}$ ,  $B_{r,s}^{(3)}$  and  $B_{r,s}^{(4)}$  is when  $u = v, u' = v'$  and  $l = l'$ , in which case the contribution is at most

$$\sum_l \sum_{u,u'} M_{uu} M_{u'u'} M_{rl}^2 \mathbb{E} X_{us}^2 X_{u's}^2 X_{l_s}^2 \lesssim \text{tr}^2(M) \|M_{r,\cdot}\|_2^2.$$

Hence

$$B_{r,s}^{(4)} \lesssim B_{r,s}^{(1)} + B_{r,s}^{(2)} + B_{r,s}^{(3)} + \text{tr}^2(M) \|M_{r,\cdot}\|_2^2.$$

## 35:12 The Product of Gaussian Matrices Is Close to Gaussian

It follows that

$$\begin{aligned}
\sum_{r,s} B_{r,s}^{(1)} &= q \sum_{u,r} \langle M_{u,\cdot}, M_{r,\cdot} \rangle^2 = q \operatorname{tr}(M^4) \\
\sum_{r,s} B_{r,s}^{(2)} &= q \sum_r \|M\|_F^2 \|M_{r,\cdot}\|_2^2 + 2q \sum_{u,r} \langle M_{u,\cdot}, M_{r,\cdot} \rangle^2 = q \|M\|_F^4 + 2q \operatorname{tr}(M^4) \\
\sum_{r,s} B_{r,s}^{(3)} &= \sum_{r,s} \sum_{l,l'} (2 \langle M_{l,\cdot}, M_{l',\cdot} \rangle + \operatorname{tr}(M) M_{l'l'}) M_{rl} M_{r'l'} \\
&\leq 2q \operatorname{tr}(M^4) + q \operatorname{tr}(M) \|M\|_F \sqrt{\operatorname{tr}(M^4)}
\end{aligned}$$

Note that  $\operatorname{tr}(M^4) \leq \operatorname{tr}^2(M^2) = \|M\|_F^4$ . Hence

$$\begin{aligned}
\frac{1}{16} \mathbb{E} \|\nabla f\|_2^2 &\leq \sum_{r,s} ((q-1)(q-2)B_{rs}^{(1)} + (q-1)B_{rs}^{(2)} + (q-1)B_{rs}^{(3)} + B_{rs}^{(4)}) \\
&\lesssim \sum_{r,s} (q^2 B_{rs}^{(1)} + qB_{rs}^{(2)} + qB_{rs}^{(3)} + \operatorname{tr}^2(M) \|M_{r,\cdot}\|_2^2) \\
&\lesssim q^3 \operatorname{tr}(M^4) + q^2 \|M\|_F^4 + q^2 \operatorname{tr}(M) \|M\|_F \sqrt{\operatorname{tr}(M^4)} + q \operatorname{tr}^2(M) \|M\|_F^2.
\end{aligned}$$

By the Gaussian Poincaré inequality,

$$\begin{aligned}
&\operatorname{Var}_G(\operatorname{tr}((G^T M G)^2) | M) \\
&\lesssim \mathbb{E} \|\nabla f\|_2^2 \\
&\lesssim q^3 \operatorname{tr}(M^4) + q^2 \|M\|_F^4 + q^2 \operatorname{tr}(M) \|M\|_F \sqrt{\operatorname{tr}(M^4)} + q \operatorname{tr}^2(M) \|M\|_F^2.
\end{aligned} \tag{6}$$

For the terms on the right-hand side, we calculate that (using the trace inequality (Lemma 5))

$$\begin{aligned}
\mathbb{E} \operatorname{tr}((G^T M G)^4) &= \mathbb{E} \operatorname{tr}((M G G^T)^4) \leq \mathbb{E} \|G G^T\|_{op}^4 \operatorname{tr}(M^4) = \mathbb{E} \|G\|_{op}^8 \operatorname{tr}(M^4) \\
&\lesssim \max\{p, q\}^4 \operatorname{tr}(M^4), \\
\mathbb{E} \|G^T M G\|_F^4 &\leq \mathbb{E} \|G\|_{op}^8 \|M\|_F^4 \lesssim \max\{p, q\}^4 \|M\|_F^4, \\
\mathbb{E} \operatorname{tr}^2(G^T M G) \|G^T M G\|_F^2 &\leq \mathbb{E} \|G\|_{op}^8 \operatorname{tr}^2(M) \|M\|_F^2 \lesssim \max\{p, q\}^4 \operatorname{tr}^2(M) \|M\|_F^2
\end{aligned}$$

and

$$\begin{aligned}
&\mathbb{E} \operatorname{tr}(G^T M G) \|G^T M G\|_F \sqrt{\operatorname{tr}((G^T M G)^4)} \\
&\leq \mathbb{E} \|G\|_{op}^2 \operatorname{tr}(G) \cdot \|G\|_{op}^2 \|M\|_F^2 \cdot \sqrt{\|G\|_{op}^8 \operatorname{tr}(M^4)} \\
&= \mathbb{E} \|G\|_{op}^8 \operatorname{tr}(M) \|M\|_F \sqrt{\operatorname{tr}(M^4)} \\
&\lesssim \max\{p, q\}^4 \operatorname{tr}(M) \|M\|_F \sqrt{\operatorname{tr}(M^4)}.
\end{aligned}$$

This implies that each term on the right-hand of (6) grows geometrically.

**Step 1b.** Next we deal with the second term in (5). We have

$$\begin{aligned}
\mathbb{E}_G \operatorname{tr}((G^T M G)^2) &= \sum_{i,j} \mathbb{E}_G (G^T M G)_{ij}^2 = \sum_{i,j} \mathbb{E}_G \left( \sum_{k,l} M_{kl} G_{ki} G_{lj} \right)^2 \\
&= \sum_{i,j} \sum_{k,l,k',l'} M_{kl} M_{k'l'} \mathbb{E}_G G_{ki} G_{lj} G_{k'i} G_{l'j}.
\end{aligned}$$

When  $i \neq j$ , for non-zero contribution, it must hold that  $k = l$  and  $k' = l'$  and thus the nonzero contribution is

$$\sum_{i \neq j} \sum_{k,l} M_{kl}^2 = q(q-1) \|M\|_F^2.$$

When  $i = j$ , the contribution is

$$\sum_i \sum_{k,l,k',l'} M_{kl} M_{k'l'} \mathbb{E} G_{ki} G_{li} G_{k'i} G_{l'i} = 2q \|M\|_F^2 + q \operatorname{tr}^2(M). \quad (7)$$

Hence

$$\mathbb{E}_G \operatorname{tr}((G^T M G)^2) = q(q+1) \|M\|_F^2 + q \operatorname{tr}^2(M)$$

and when  $M$  is random,

$$\begin{aligned} & \operatorname{Var}(\mathbb{E} \operatorname{tr}((G^T M G)^2) | M) \\ &= \operatorname{Var}\left(q(q+1) \|M\|_F^2 + q \operatorname{tr}^2(M)\right) \\ &\leq q^2(q+1)^2 \operatorname{Var}(\|M\|_F^2) + q^2 \operatorname{Var}(\operatorname{tr}^2(M)) + 2q^2(q+1) \sqrt{\operatorname{Var}(\|M\|_F^2) \operatorname{Var}(\operatorname{tr}^2(M))}. \end{aligned} \quad (8)$$

**Step 2a.** Note that the  $\operatorname{Var}(\operatorname{tr}^2(M))$  term on the right-hand side of (8). To bound this term, we examine the variance of  $g(G)$ , where  $g(X) = \operatorname{tr}^2(X^T M X)$ . We shall again calculate  $\nabla g$ . Note that

$$\frac{\partial g}{\partial X_{rs}} = 2 \operatorname{tr}(X^T M X) \sum_i \sum_{k,l} M_{kl} \frac{\partial}{\partial X_{rs}} X_{ki} X_{li}$$

and

$$\frac{\partial}{\partial X_{rs}} (X_{ki} X_{li}) = \begin{cases} X_{li}, & (k, i) = (r, s) \text{ and } (l, i) \neq (r, s) \\ X_{ki}, & (k, i) \neq (r, s) \text{ and } (l, i) = (r, s) \\ 2X_{rs}, & (k, i) = (r, s) \text{ and } (l, i) = (r, s) \\ 0, & \text{otherwise.} \end{cases}$$

We have

$$\frac{\partial g}{\partial X_{rs}} = 4 \operatorname{tr}(X^T M X) \sum_l M_{rl} X_{ls} = 4 \sum_{\substack{1 \leq j \leq q \\ 1 \leq l, u, v \leq p}} M_{uv} M_{rl} X_{ls} X_{uj} X_{vj}$$

Next we calculate  $\mathbb{E}(\partial g / \partial X_{rs})^2$  when  $X$  is i.i.d. Gaussian.

$$\left(\frac{1}{4} \frac{\partial g}{\partial X_{rs}}\right)^2 = \sum_{\substack{j,l,u,v \\ j',l',u',v'}} M_{uv} M_{u'v'} M_{rl} M_{r'l'} \mathbb{E} X_{ls} X_{l's} X_{uj} X_{vj} X_{u'j'} X_{v'j'}$$

In order for the expectation in the summand to be non-zero, we must have one of the following cases: (1)  $s \neq j \neq j'$ , (2)  $s = j \neq j'$ , (3)  $s = j' \neq j$ , (4)  $s \neq j = j'$ , (5)  $s = j = j'$ . We calculate the contribution in each case below.

### 35:14 The Product of Gaussian Matrices Is Close to Gaussian

Case 1: it must hold that  $l = l'$ ,  $u = v$  and  $u' = v'$ . The contribution is  $(q-1)(q-2)B_{rs}^{(1)}$ , where

$$B_{rs}^{(1)} = \sum_{l,u,u'} M_{uu} M_{u'u'} M_{rl}^2 = \text{tr}^2(M) \|M_{r,\cdot}\|_2^2.$$

Case 2: it must hold that  $u' = v'$ . The contribution is  $(q-1)B_{rs}^{(2)}$ , where

$$\begin{aligned} B_{rs}^{(2)} &= \sum_{l,l',u,u',v} M_{uv} M_{u'u'} M_{rl} M_{r'l'} \mathbb{E} X_{ls} X_{l's} X_{us} X_{vs} X_{u'j'}^2 \\ &= \text{tr}(M) \left( \text{tr}(M) \|M_{r,\cdot}\|_2^2 + 2 \sum_{l,l'} M_{ll'} M_{rl} M_{r'l'} \right) \end{aligned}$$

Case 3: this gives the same bound as Case 2.

Case 4: it must hold that  $l = l'$ . The contribution is  $(q-1)B_{rs}^{(4)}$ , where

$$B_{rs}^{(4)} = \sum_{l,u,u',v,v'} M_{uv} M_{u'v'} M_{rl}^2 \mathbb{E} X_{uj} X_{vj} X_{u'j} X_{v'j} = 3 \|M_{r,\cdot}\|_2^2 \|M\|_F^2$$

Case 5: the contribution is  $B_{rs}^{(5)}$ , where

$$B_{rs}^{(5)} = \sum_{\substack{l,u,v \\ l',u',v'}} M_{uv} M_{u'v'} M_{rl} M_{r'l'} \mathbb{E} X_{ls} X_{us} X_{vs} X_{l's} X_{u's} X_{v's}.$$

The only uncovered case is  $l = u'$ ,  $l' = v$ ,  $u = v'$  and its symmetries. In such a case the contribution is at most

$$C \sum_{l,u,v} M_{uv} M_{lu} M_{rl} M_{rv} = C \sum_u \langle M_{r,\cdot}, M_{u,\cdot} \rangle^2.$$

Note that

$$\begin{aligned} \sum_{r,s} B_{rs}^{(1)} &= q \text{tr}^2(M) \|M\|_F^2, \\ \sum_{r,s} B_{rs}^{(2)} &= q \text{tr}^2(M) \|M\|_F^2 + 2q \text{tr}(M) \sum_{l,l'} M_{ll'} \langle M_{l,\cdot}, M_{l',\cdot} \rangle \\ &\leq q \text{tr}^2(M) \|M\|_F^2 + 2q \text{tr}(M) \|M\|_F \sqrt{\text{tr}(M^4)}, \\ \sum_{r,s} B_{rs}^{(4)} &= q \|M\|_F^4, \\ \sum_{r,s} B_{rs}^{(5)} &\lesssim \sum_{r,s} B_{rs}^{(1)} + \sum_{r,s} B_{rs}^{(2)} + \text{tr}(M^4). \end{aligned}$$

Therefore,

$$\begin{aligned} \frac{1}{16} \mathbb{E} \|\nabla g\|_2^2 &\leq \sum_{r,s} ((q-1)(q-2)B_{rs}^{(1)} + (q-1)B_{rs}^{(2)} + (q-1)B_{rs}^{(4)} + B_{rs}^{(5)}) \\ &\lesssim q^3 \text{tr}^2(M) \|M\|_F^2 + q^2 \text{tr}(M) \|M\|_F \sqrt{\text{tr}(M^4)} + q^2 \|M\|_F^4 + q \text{tr}(M^4). \end{aligned}$$

By Poincaré's inequality,

$$\begin{aligned} &\text{Var}_G(\text{tr}^2(G^T M G)) \\ &\lesssim \mathbb{E} \|\nabla g\|_2^2 \\ &\lesssim q^3 \text{tr}^2(M) \|M\|_F^2 + q^2 \text{tr}(M) \|M\|_F \sqrt{\text{tr}(M^4)} + q^2 \|M\|_F^4 + q \text{tr}(M^4). \end{aligned} \tag{9}$$

Similar to before, each term on the right-hand side grows geometrically.

**Step 2b.** Next we deal with  $\text{Var}_M(\mathbb{E}_G \text{tr}^2(G^T M G) | M)$ .

$$\mathbb{E} \text{tr}^2(G^T M G) = \mathbb{E} \left( \sum_{i,k,l} M_{kl} G_{ki} G_{li} \right)^2 = \sum_{i,j} \sum_{k,l,k',l'} M_{kl} M_{k'l'} \mathbb{E} G_{ki} G_{li} G_{k'j} G_{l'j}.$$

When  $i \neq j$ , for non-zero contribution, it must hold that  $k = l$  and  $k' = l'$  and thus the nonzero contribution is

$$\sum_{i \neq j} \sum_{k,k'} M_{kk} M_{k'k'} = q(q-1) \text{tr}^2(M).$$

When  $i = j$ , the contribution is (this is exactly the same as (7) in Step 1b.)

$$\sum_i \sum_{k,k',l,l'} M_{kl} M_{k'l'} \mathbb{E} G_{ki} G_{li} G_{k'i} G_{l'i} = 2q \|M\|_F^2 + q \text{tr}^2(M).$$

Hence

$$\mathbb{E} \text{tr}^2(G^T M G) = 2q \|M\|_F^2 + q^2 \text{tr}^2(M)$$

and when  $M$  is random,

$$\begin{aligned} & \text{Var}(\mathbb{E} \text{tr}^2(G^T M G) | M) \\ &= \text{Var}(2q \|M\|_F^2 + q^2 \text{tr}^2(M)) \\ &\leq 4q^2 \text{Var}(\|M\|_F^2) + q^4 \text{Var}(\text{tr}^2(M)) + 2q^3 \sqrt{\text{Var}(\|M\|_F^2) \text{Var}(\text{tr}^2(M))}. \end{aligned} \tag{10}$$

**Step 3.** Let  $U_r$  denote the variance of  $\text{tr}((A_r^T A_r)^2)$  and  $V_r$  the variance of  $\text{tr}^2(A_r^T A_r)$ . Combining (5), (6), (8), (9), (10), we have the following recurrence relations, where  $C_1, C_2, C_3, C_4 > 0$  are absolute constants.

$$\begin{aligned} U_{r+1} &\leq C_1 P_r + 2U_r + \frac{1}{d_r^2} V_r + \frac{3}{d_r} \sqrt{U_r V_r} \\ V_{r+1} &\leq C_2 Q_r + \frac{1}{d_r^2} U_r + V_r + \frac{2}{d_r} \sqrt{U_r V_r} \\ P_{r+1} &\leq C_3 P_r \\ Q_{r+1} &\leq C_4 Q_r \\ U_0 &= V_0 = 0 \end{aligned}$$

In the base case, set  $M = I_p$  (the  $p \times p$  identity matrix in (6)) and note that the second term in (5) vanishes. We see that  $P_1 \lesssim (p^3 q + pq^3)/d_1^4$  after proper normalization. (Alternatively we can calculate this precisely, see Appendix D.) Similarly we have  $Q_1 \lesssim p^3 q^3/d_1^4$ . Note that  $Q_1/d_1^2 \lesssim (p^3 q + pq^3)/d_1^4$ . Now, we can solve that

$$U_{r+1} \leq C^r \frac{p^3 q + pq^3}{d_1^4}$$

for some absolute constant  $C > 0$ .

## A Proof of Proposition 12

**Proof.** We have

$$\begin{aligned} \mathbb{E} A_{11}^4 &= \mathbb{E} \left( \sum_i B_{1i} G_{i1} \right)^4 = \sum_{i,j,k,l} \mathbb{E} B_{1i} B_{1j} B_{1k} B_{1l} \mathbb{E} G_{i1} G_{j1} G_{k1} G_{l1} \\ &= 3 \sum_i \mathbb{E} B_{1i}^4 + 3 \sum_{i \neq j} \mathbb{E} B_{1i}^2 B_{1j}^2 \end{aligned}$$

and

$$\begin{aligned} \mathbb{E} A_{21}^4 &= \mathbb{E} \left( \sum_i B_{2i} G_{i1} \right)^4 = \sum_{i,j,k,l} \mathbb{E} B_{2i} B_{2j} B_{2k} B_{2l} \mathbb{E} G_{i1} G_{j1} G_{k1} G_{l1} \\ &= 3 \sum_i \mathbb{E} B_{2i}^4 + 3 \sum_{i \neq j} \mathbb{E} B_{2i}^2 B_{2j}^2 = \mathbb{E} A_{11}^4. \end{aligned} \quad \blacktriangleleft$$

**B** Omitted Calculations in Section 4.1

$$S_1(p, q) = 3 \sum_i \mathbb{E} B_{1i}^4 + 3 \sum_{i \neq j} \mathbb{E} B_{1i}^2 B_{1j}^2 = 3dT_1(p, d) + 3d(d-1)T_4(p, d)$$

$$\begin{aligned} S_3(p, q) &= \mathbb{E} A_{11}^2 A_{21}^2 = \mathbb{E} \left( \sum_i B_{1i} G_{i1} \right)^2 \left( \sum_k B_{2k} G_{k1} \right)^2 \\ &= \sum_{i,j,k,l} \mathbb{E} B_{1i} B_{1j} B_{2k} B_{2l} \mathbb{E} G_{i1} G_{j1} G_{k1} G_{l1} \\ &= 3 \sum_i \mathbb{E} B_{1i}^2 B_{2i}^2 + \sum_{i \neq j} \mathbb{E} B_{1i}^2 B_{2j}^2 + 2 \sum_{i \neq j} \mathbb{E} B_{1i} B_{2i} B_{1j} B_{2j} \\ &= 3dT_3(p, d) + d(d-1)T_5(p, d) + 2d(d-1)T_6(p, d) \end{aligned}$$

$$\begin{aligned} S_4(p, q) &= \mathbb{E} A_{11}^2 A_{12}^2 = \mathbb{E} \left( \sum_i B_{1i} G_{i1} \right)^2 \left( \sum_k B_{1k} G_{k2} \right)^2 \\ &= \sum_{i,j,k,l} \mathbb{E} B_{1i} B_{1j} B_{1k} B_{1l} \mathbb{E} G_{i1} G_{j1} G_{k2} G_{l2} \\ &= \sum_i \mathbb{E} B_{1i}^4 + \sum_{i \neq j} \mathbb{E} B_{1i}^2 B_{1j}^2 = dT_1(p, d) + d(d-1)T_4(p, d). \end{aligned}$$

$$\begin{aligned} S_5(p, q) &= \mathbb{E} A_{11}^2 A_{22}^2 = \mathbb{E} \left( \sum_i B_{1i} G_{i1} \right)^2 \left( \sum_k B_{2k} G_{k2} \right)^2 \\ &= \sum_{i,j,k,l} \mathbb{E} B_{1i} B_{1j} B_{2k} B_{2l} \mathbb{E} G_{i1} G_{j1} G_{k2} G_{l2} \\ &= \sum_{i,j} \mathbb{E} B_{1i}^2 B_{2j}^2 = dT_3(p, d) + d(d-1)T_5(p, d) \end{aligned}$$

$$\begin{aligned} S_6(p, q) &= \mathbb{E} A_{11} A_{12} A_{21} A_{22} = \sum_{i,j,k,l} \mathbb{E} B_{1i} B_{1j} B_{2k} B_{2l} \mathbb{E} G_{i1} G_{j2} G_{k1} G_{l2} \\ &= \sum_i \mathbb{E} B_{1i}^2 B_{2i}^2 + \sum_{i \neq j} \mathbb{E} B_{1i} B_{1j} B_{2i} B_{2j} \\ &= dT_3(p, d) + d(d-1)T_6(p, d) \end{aligned}$$

## C

 Omitted Calculations in Section 4.2

In Step 1a.

$$\begin{aligned}
B_{r,s}^{(2)} &= \sum_{l,l'} \sum_{u,v,v'} M_{uv} M_{uv'} M_{rl} M_{r'l'} \mathbb{E} X_{us}^2 X_{vj} X_{lj} X_{v'j} X_{l'j} \\
&= \underbrace{\sum_{l \neq l'} \sum_u M_{ul} M_{ul'} M_{rl} M_{r'l'}}_{v=l \neq v'=l'} + \underbrace{\sum_l \sum_{\substack{u \\ v \neq l}} M_{uv}^2 M_{rl}^2}_{v=v' \neq l=l'} + \underbrace{\sum_{l \neq l'} \sum_u M_{ul'} M_{ul} M_{rl} M_{r'l'}}_{v=l' \neq l=v'} \\
&\quad + 3 \underbrace{\sum_{l,u} M_{ul}^2 M_{rl}^2}_{v=v'=l=l'} \\
&= \left( \sum_{u,v} M_{uv}^2 \right) \left( \sum_l M_{rl}^2 \right) + 2 \sum_{l,l',u} M_{ul'} M_{ul} M_{rl} M_{r'l'} \\
&= \|M\|_F^2 \|M_{r,\cdot}\|_2^2 + 2 \sum_u \langle M_{u,\cdot}, M_{r,\cdot} \rangle^2. \\
\\
B_{r,s}^{(3)} &= \sum_{j' \neq s} \left[ \sum_{l,l'} \sum_{u,v} M_{uv} M_{u'l'} M_{rl} M_{r'l'} \mathbb{E} X_{us} X_{u's} X_{vs} X_{l's} X_{l'j'}^2 \right] \\
&= \underbrace{\sum_{l,l'} \sum_{u \neq l} M_{ul} M_{ul'} M_{rl} M_{r'l'}}_{u=u' \neq v=l} + \underbrace{\sum_{l,l'} \sum_{u \neq l} M_{uu} M_{ll'} M_{rl} M_{r'l'}}_{u=v \neq u'=l} + \underbrace{\sum_{l,l'} \sum_v M_{lv} M_{v'l'} M_{rl} M_{r'l'}}_{u=l \neq u'=v} \\
&\quad + 3 \underbrace{\sum_{l,l'} M_{ll} M_{ll'} M_{rl} M_{r'l'}}_{u=u'=v=l} \\
&= \sum_{l,l'} \sum_u (2M_{ul} M_{ul'} + M_{uu} M_{ll'}) M_{rl} M_{r'l'} \\
&= \sum_{l,l'} (2\langle M_{l,\cdot}, M_{l',\cdot} \rangle + \text{tr}(M) M_{ll'}) M_{rl} M_{r'l'}. \\
\\
\sum_{r,s} B_{r,s}^{(3)} &= \sum_{r,s} \sum_{l,l'} (2\langle M_{l,\cdot}, M_{l',\cdot} \rangle + \text{tr}(M) M_{ll'}) M_{rl} M_{r'l'} \\
&= q \sum_{l,l'} (2\langle M_{l,\cdot}, M_{l',\cdot} \rangle + \text{tr}(M) M_{ll'}) \sum_r M_{rl} M_{r'l'} \\
&= q \sum_{l,l'} (2\langle M_{l,\cdot}, M_{l',\cdot} \rangle + \text{tr}(M) M_{ll'}) \langle M_{l,\cdot}, M_{l',\cdot} \rangle \\
&= q \sum_{l,l'} 2\langle M_{l,\cdot}, M_{l',\cdot} \rangle^2 + q \text{tr}(M) \sum_{l,l'} M_{ll'} \langle M_{l,\cdot}, M_{l',\cdot} \rangle \\
&\leq 2q \text{tr}(M^4) + q \text{tr}(M) \left( \sum_{l,l'} M_{ll'}^2 \right)^{\frac{1}{2}} \left( \sum_{l,l'} \langle M_{l,\cdot}, M_{l',\cdot} \rangle^2 \right)^{\frac{1}{2}} \\
&\leq 2q \text{tr}(M^4) + q \text{tr}(M) \|M\|_F \sqrt{\text{tr}(M^4)}
\end{aligned}$$

In Step 1b.

$$\begin{aligned}
 & \sum_i \sum_{\substack{k,l \\ k',l'}} M_{kl} M_{k'l'} \mathbb{E} G_{ki} G_{li} G_{k'i} G_{l'i} \\
 &= \sum_i \left( \underbrace{\sum_{k \neq l} M_{kl}^2}_{k=k' \neq l=l'} + \underbrace{\sum_{k \neq l} M_{kl}^2}_{k=l' \neq k'=l} + \underbrace{\sum_{k \neq l} M_{kk} M_{k'l'}}_{k=l \neq k'=l'} + 3 \underbrace{\sum_k M_{kk}^2}_{k=k'=l=l'} \right) \\
 &= \sum_i \left( \sum_{k,l} M_{kl}^2 + \sum_{k,l} M_{kl}^2 + \sum_{k,l} M_{kk} M_{k'l'} \right) \\
 &= \sum_i (2 \|M\|_F^2 + \text{tr}^2(M)) \\
 &= 2q \|M\|_F^2 + q \text{tr}^2(M).
 \end{aligned}$$

In Step 2a.

$$\begin{aligned}
 B_{rs}^{(2)} &= \sum_{l,l',u,u',v} M_{uv} M_{u'u'} M_{rl} M_{r'l'} \mathbb{E} X_{ls} X_{l's} X_{us} X_{v's} X_{u'j'}^2 \\
 &= \underbrace{\sum_{\substack{l \neq u \\ u'}} M_{uu} M_{u'u'} M_{rl}^2}_{l=l' \neq u=v} + \underbrace{\sum_{\substack{l \neq l' \\ u'}} M_{ll'} M_{u'u'} M_{rl} M_{r'l'}}_{l=u \neq l'=v} + \underbrace{\sum_{\substack{l \neq l' \\ u'}} M_{ll'} M_{u'u'} M_{rl} M_{r'l'}}_{l=v \neq l'=u} \\
 &\quad + 3 \underbrace{\sum_{l,u'} M_{ll} M_{u'u'} M_{rl}^2}_{l=u=l'=v} \\
 &= \text{tr}(M) \left( \sum_{l,u} M_{uu} M_{rl}^2 + 2 \sum_{l,l'} M_{ll'} M_{rl} M_{r'l'} \right) \\
 &= \text{tr}(M) \left( \text{tr}(M) \|M_{r,\cdot}\|_2^2 + 2 \sum_{l,l'} M_{ll'} M_{rl} M_{r'l'} \right)
 \end{aligned}$$

$$\begin{aligned}

 &= \left( \sum_l M_{rl}^2 \right) \left( \underbrace{\sum_{u,v} M_{uv}^2}_{u=u' \neq v=v'} + \underbrace{\sum_{u,v} M_{uv}^2}_{u=v' \neq u=v} + \underbrace{\sum_{u,v} M_{uv}^2}_{u=v \neq u'=v'} + 3 \underbrace{\sum_u M_{uu}^2}_{u=v=u'=v'} \right) \\
 &= 3 \left( \sum_l M_{rl}^2 \right) \sum_{u,v} M_{u,v}^2 \\
 &= 3 \|M_{r,\cdot}\|_2^2 \|M\|_F^2
 \end{aligned}$$

### D Exact Variance when $r = 2$

Suppose that  $A$  is rotationally invariant under both left- and right-multiplication of an orthogonal matrix. Define

$$\begin{aligned}
U_1(p, q) &= \text{Var}((A^T A)_{ii}^2) \\
U_2(p, q) &= \text{Var}((A^T A)_{ij}^2) \quad i \neq j \\
U_3(p, q) &= \text{cov}((A^T A)_{ii}^2, (A^T A)_{ik}^2) \quad i \neq k \quad (\text{same row, one entry on diagonal}) \\
U_4(p, q) &= \text{cov}((A^T A)_{ij}^2, (A^T A)_{ik}^2) \quad j \neq k \quad (\text{same row, both entries off-diagonal}) \\
U_5(p, q) &= \text{cov}((A^T A)_{ii}^2, (A^T A)_{jj}^2) \quad i \neq j \quad (\text{diff. rows and cols, both entries on diagonal}) \\
U_6(p, q) &= \text{cov}((A^T A)_{ii}^2, (A^T A)_{jk}^2) \quad i \neq j \neq k \quad (\text{diff. rows and cols, one entry on diagonal}) \\
U_7(p, q) &= \text{cov}((A^T A)_{ij}^2, (A^T A)_{kl}^2) \quad i \neq j \neq k \neq l \quad (\text{diff. rows and cols, nonsymmetric around diag.})
\end{aligned}$$

It is clear that they are well-defined.

$$\begin{aligned}
& \text{Var}(\text{tr}((A^T A)^2)) \\
&= \text{Var}\left(\sum_{i,j} (A^T A)_{ij}^2\right) \\
&= \sum_{i,j,k,l} \text{cov}((A^T A)_{ij}^2, (A^T A)_{kl}^2) \\
&= \sum_{i,j} \text{Var}((A^T A)_{ij}^2) + 2 \sum_i \sum_{j \neq l} \text{cov}((A^T A)_{ij}^2, (A^T A)_{il}^2) + \sum_{\substack{i \neq k \\ j \neq l}} \text{cov}(\mathbb{E}(A^T A)_{ij}^2, (A^T A)_{kl}^2) \\
&= q \text{Var}((A^T A)_{11}^2) + q(q-1) \text{Var}(\mathbb{E}(A^T A)_{12}^2) \\
&\quad + 2 [2q(q-1) \text{cov}((A^T A)_{11}^2, (A^T A)_{12}^2) + q(q-1)(q-2) \text{cov}((A^T A)_{12}^2, (A^T A)_{13}^2)] \\
&\quad + q(q-1) \text{cov}(\mathbb{E}(A^T A)_{11}^2, (A^T A)_{22}^2) + q(q-1) \text{cov}(\mathbb{E}(A^T A)_{12}^2, (A^T A)_{21}^2) \\
&\quad + 2q(q-1)(q-2) \text{cov}((A^T A)_{11}^2, (A^T A)_{23}^2) \\
&\quad + 2q(q-1)(q-2) \text{cov}((A^T A)_{12}^2, (A^T A)_{31}^2) \\
&\quad + q(q-1)(q-2)(q-3) \mathbb{E}(A^T A)_{12}^2 (A^T A)_{34}^2 \\
&= qU_1(p, q) + q(q-1)U_2(p, q) + 2q(q-1)(2U_3(p, q) + (q-2)U_4(p, q)) \\
&\quad + q(q-1)(U_5(p, q) + U_2(p, q)) + 2q(q-1)(q-2)(U_6(p, q) + U_4(p, q)) \\
&\quad + q(q-1)(q-2)(q-3)U_7(p, q) \\
&= qU_1(p, q) + q(q-1)(2U_2(p, q) + 4U_3(p, q) + U_5(p, q)) \\
&\quad + 2q(q-1)(q-2)(2U_4(p, q) + U_6(p, q)) + q(q-1)(q-2)(q-3)U_7(p, q).
\end{aligned}$$

Let us calculate  $U_1, \dots, U_7$  for a  $p \times q$  Gaussian random matrix  $G$ .

$$\begin{aligned}
U_1(p, q) &= \mathbb{E}(G^T G)_{11}^4 - (\mathbb{E}(G^T G)_{11}^2)^2 = \mathbb{E} \|G_1\|_2^8 - (\mathbb{E} \|G_1\|_2^4)^2 \\
&= p(p+2)(p+4)(p+6) - (p(p+2))^2 \\
&= 8p(p+2)(p+3) \\
U_2(p, q) &= \mathbb{E}(G^T G)_{12}^4 - (\mathbb{E}(G^T G)_{12}^2)^2 = \mathbb{E} \left( \sum_r G_{r1} G_{r2} \right)^4 - (\mathbb{E} \langle G_1, G_2 \rangle)^2 \\
&= \sum_{r,s,t,u} \mathbb{E} G_{r1} G_{s1} G_{t1} G_{u1} G_{r2} G_{s2} G_{t2} G_{u2} - p^2 \\
&= 3 \sum_{r \neq t} \mathbb{E} G_{r1}^2 G_{t1}^2 G_{r2}^2 G_{t2}^2 + \sum_r G_{r1}^4 G_{r2}^4 - p^2 \\
&= 3p(p-1) + 9p - p^2 = 2p(p+3).
\end{aligned}$$

**35:22 The Product of Gaussian Matrices Is Close to Gaussian**

$$\begin{aligned}
U_3(p, q) &= \mathbb{E}(G^T G)_{11}^2 (G^T G)_{12}^2 - \mathbb{E}(G^T G)_{11}^2 \mathbb{E}(G^T G)_{12}^2 \\
&= \mathbb{E}(G_1^T G_1)^2 G_1^T G_2 G_2^T G_1 - \mathbb{E} \|G_1\|_2^4 \mathbb{E} \langle G_1, G_2 \rangle^2 \\
&= \mathbb{E}(G_1^T G_1)^2 G_1^T (\mathbb{E} G_2 G_2^T) G_1 - p(p+2) \cdot p \\
&= \mathbb{E}(G_1^T G_1)^3 - p^2(p+2) \\
&= \mathbb{E} \|G_1\|_2^6 - p^2(p+2) = p(p+2)(p+4) - p^2(p+2) = 4p(p+2) \\
U_4(p, q) &= \mathbb{E}(G^T G)_{12}^2 (G^T G)_{13}^2 - \mathbb{E}(G^T G)_{12}^2 \mathbb{E}(G^T G)_{13}^2 \\
&= \mathbb{E} G_1^T G_2 G_2^T G_1 G_1^T G_3 G_3^T G_1 - p^2 \\
&= \mathbb{E} G_1^T \mathbb{E}(G_2 G_2^T) G_1 G_1^T \mathbb{E}(G_3 G_3^T) G_1 - p^2 \\
&= \mathbb{E}(G_1^T G_1)^2 - p^2 = \mathbb{E} \|G_1\|_2^4 - p^2 = p(p+2) - p^2 = 2p \\
U_5(p, q) &= \mathbb{E}(G^T G)_{11}^2 (G^T G)_{22}^2 - \mathbb{E}(G^T G)_{11}^2 \mathbb{E}(G^T G)_{22}^2 \\
&= \mathbb{E} \|G_1\|_2^4 \|G_2\|_2^4 - \mathbb{E} \|G_1\|_2^4 \mathbb{E} \|G_2\|_2^4 = 0 \\
U_6(p, q) &= \mathbb{E}(G^T G)_{11}^2 (G^T G)_{23}^2 - \mathbb{E}(G^T G)_{11}^2 \mathbb{E}(G^T G)_{23}^2 \\
&= \mathbb{E} \|G_1\|_2^4 \langle G_2, G_3 \rangle^2 - \mathbb{E} \|G_1\|_2^4 \mathbb{E} \langle G_2, G_3 \rangle^2 = 0 \\
U_7(p, q) &= \mathbb{E}(G^T G)_{12}^2 (G^T G)_{34}^2 - \mathbb{E}(G^T G)_{12}^2 \mathbb{E}(G^T G)_{34}^2 \\
&= \mathbb{E} \langle G_1, G_2 \rangle^2 \langle G_3, G_4 \rangle^2 - \mathbb{E} \langle G_1, G_2 \rangle^2 \mathbb{E} \langle G_3, G_4 \rangle^2 = 0
\end{aligned}$$

Therefore

$$\begin{aligned}
\text{Var}(\text{tr}((G^T G)^2)) &= qU_1 + q(q-1)(2U_2 + 4U_3 + U_5) + 2q(q-1)(q-2)(2U_4 + U_6) \\
&\quad + q(q-1)(q-2)(q-3)U_7 \\
&= qU_1 + q(q-1)(2U_2 + 4U_3) + 4q(q-1)(q-2)U_4 \\
&= 4pq(5 + 5p + 5q + 2p^2 + 5pq + 2q^2).
\end{aligned}$$

When  $r = 2$ , recalling that  $\mathbb{E}(A_2 - A_1) = (1 + o(1))p^2q^2/d^3$  (see (4)), we have that

$$\frac{\sqrt{\text{Var}(\text{tr}((\frac{1}{\sqrt{d}}G^T \cdot \frac{1}{\sqrt{d}}G)^2))}}{p^2q^2/d^3} \leq \frac{6d}{\max\{p, q\}^{\frac{1}{2}} \min\{p, q\}^{\frac{3}{2}}}.$$

If the right-hand side above is at most a small constant  $c$ , we can distinguish  $A_2$  from  $A_1$  with probability at least a constant.

# Fast Mixing via Polymers for Random Graphs with Unbounded Degree

## Abstract

The polymer model framework is a classical tool from statistical mechanics that has recently been used to obtain approximation algorithms for spin systems on classes of bounded-degree graphs; examples include the ferromagnetic Potts model on expanders and on the grid. One of the key ingredients in the analysis of polymer models is controlling the growth rate of the number of polymers, which has been typically achieved so far by invoking the bounded-degree assumption. Nevertheless, this assumption is often restrictive and obstructs the applicability of the method to more general graphs. For example, sparse random graphs typically have bounded average degree and good expansion properties, but they include vertices with unbounded degree, and therefore are excluded from the current polymer-model framework.

We develop a less restrictive framework for polymer models that relaxes the standard bounded-degree assumption, by reworking the relevant polymer models from the edge perspective. The edge perspective allows us to bound the growth rate of the number of polymers in terms of the total degree of polymers, which in turn can be related more easily to the expansion properties of the underlying graph. To apply our methods, we consider random graphs with unbounded degrees from a fixed degree sequence (with minimum degree at least 3) and obtain approximation algorithms for the ferromagnetic Potts model, which is a standard benchmark for polymer models. Our techniques also extend to more general spin systems.

## 1 Introduction

The polymer model framework [21, 14] is a classical tool from statistical mechanics which has recently been used to obtain efficient approximation algorithms for analysing spin systems (such as the Potts model) in parameter regimes where standard algorithmic approaches are provably inefficient/inaccurate on general graphs. These algorithms apply to certain classes of graphs that typically have sufficiently strong expansion properties relative to their local growth rates. Typically, the local growth rate is restricted by a bounded-degree assumption. Examples of such classes include bounded-degree expanders [20, 22, 7, 5, 6, 2, 10, 15] and the  $d$ -dimensional grid [16, 4, 20, 17]. The purpose of this work is to expand the current framework for applying polymer models by relaxing the bounded-degree assumption and using alternative methods to capture the growth of the graph.

To briefly review the current framework, we use as a running example the  $q$ -state ferromagnetic Potts model with parameter  $\beta > 0$ . For a graph  $G = (V_G, E_G)$ , the set  $\Omega_{G,q}$  of configurations of the model is the set of all (not necessarily proper)  $q$ -colourings  $\sigma$  of  $V_G$  using the set of colours  $[q] = \{1, \dots, q\}$  where  $q \geq 3$ . The weight of a colouring  $\sigma$  is  $w(\sigma) = e^{\beta m_G(\sigma)}$  where  $m_G(\sigma)$  is the number of monochromatic edges under  $\sigma$ . The so-called partition function  $Z = Z_{G,q,\beta}$  is the aggregate weight of all  $\sigma$  and the Gibbs distribution  $\mu = \mu_{G,q,\beta}$  is the probability distribution on the set of all  $\sigma$ , in which each  $\sigma$  has mass proportional to its weight, i.e.,  $\mu(\sigma) = w(\sigma)/Z$ . We will study the computational problems of approximating the partition function and approximately sampling from the Gibbs distribution. In general, these problems are computationally hard ( $\#$ BIS-hard) when the parameter  $\beta$  is sufficiently large [13, 12].

The recent works [16, 20] introduced a framework based on polymer models that bypasses the worst-case hardness, on classes of bounded-degree graphs with expansion properties. The rough intuition for the Potts model is that, for large  $\beta$ , due to the expansion properties, the colourings with non-negligible weight are close to the so-called ground-states of the model, i.e., the  $q$  configurations in which all vertices get the same colour. Polymer models capture the deviation of configurations from these ground states. Given a ground state with colour  $r$ , a polymer is a connected set of vertices, none of which is coloured with  $r$ , and a polymer configuration (with respect to the ground state  $r$ ) corresponds to the set of all polymers (see Example 4 for more details). The Potts model can then be decomposed into  $q$  polymer models, each of which can be studied using relatively streamlined algorithmic methods (based on interpolation [1] and Markov chains). This framework has already found multiple algorithmic applications in far more general settings [16, 4, 17, 20, 19, 22, 7, 9, 5, 6, 10, 15].

Despite these advances, the current applications of polymer models rely crucially on the fact that the maximum degree of the underlying graph is bounded. This fact is used to control the number of polymers of a given size (which is crucially needed for the algorithmic analysis). As a result of this limitation, applications to several other interesting classes of graphs are ruled out, excluding for example sparse random graphs, which have bounded average degree and good expansion properties, but include vertices with unbounded degree.

## 1.1 Main Results

In this paper, we propose a framework for polymer models that overcomes the bounded-degree limitations of previous algorithms, by revisiting the Markov chain approach of [7]. We introduce a new condition which requires that the weight of each polymer decays exponentially in its total degree (the sum of the degrees of the vertices in the polymer) instead of decaying exponentially in the polymer's size. This new condition allows us to prove rapid mixing for a Markov chain which is an adapted edge-version of the so-called polymer dynamics of [7]. Crucially, the fact that the new condition is formulated in terms of the total degree of a polymer allows us to relax the assumption that the instance has bounded degree.

As an application of our method, we consider the  $q$ -state ferromagnetic Potts model on sparse random graphs of unbounded degree with a given degree sequence, as detailed below.

► **Definition 1.** *Let  $d$  be a positive real number and  $n$  be a positive integer. We define  $\mathcal{D}_{n,d}$  to be the set of all degree sequences  $\{x_1, x_2, \dots, x_n\}$  that satisfy*

1. *For all  $i \in [n]$ ,  $3 \leq x_i \leq n^\rho$  where  $\rho = \frac{1}{50}$ , and*
2.  *$\sum_{i \in [n]} x_i^2 \leq dn$ .*

*We write  $G \sim \mathcal{G}(n, \vec{x})$  to indicate that  $G$  is a graph chosen uniformly at random from the set of all simple  $n$ -vertex graphs with degree sequence  $\vec{x}$ .  $G$  satisfies a property with high probability (whp) if the probability that  $G$  satisfies the property is  $1 - o(1)$ , as a function of  $n$  (uniformly over  $\vec{x}$ ).*

Note that  $\mathcal{D}_{n,d}$  is empty unless  $d \geq 9$ . The assumption that all degrees are greater than or equal to 3 (rather than 2) guarantees that the random graph  $G$  is connected and has good expansion properties. The degree lower bound also means that our results do not apply to Erdős-Rényi random graphs. The upper bound on the degrees is mild and can in fact be relaxed somewhat further (but in general cannot be made to be linear in  $n$  due to the sparsity assumption in Item 2).

We give an efficient algorithm for approximately sampling<sup>1</sup> from and approximating the partition function<sup>2</sup> of the ferromagnetic Potts model on random graphs with a given degree sequence for all sufficiently large  $\beta$ .

► **Theorem 2.** *Let  $d$  be a real number and  $q \geq 3$  be an integer. For the ferromagnetic Potts model, there is  $\beta_0$  such that for all  $\beta \geq \beta_0$  there is a poly-time approximate sampling algorithm for  $\mu_{G,q,\beta}$  and an FPRAS for  $Z_{G,q,\beta}$  that work with high probability on random graphs  $G \sim \mathcal{G}(n, \vec{x})$  for any degree sequence  $\vec{x} \in \mathcal{D}_{n,d}$ .*

► **Remark 3.** Note that  $\beta_0$  depends on  $d$  and  $q$ , and our arguments later (see Remark 17) show that  $\beta_0 = Cd \log d \log q$  for some  $C > 0$  (independent of  $d$  or  $q$ ). If the desired accuracy  $\varepsilon$  is at least  $e^{-n}$  then the running time of the sampling algorithm is  $O(n \log \frac{n}{\varepsilon} \log \frac{1}{\varepsilon})$  and the running time of the FPRAS is  $O(n^2 (\log \frac{n}{\varepsilon})^3)$ .

We further remark that the bounded-degree assumption has also been relaxed in [17] for the ferromagnetic Potts model on lattice graphs; the approach therein however is tailored to a certain flow representation of the Potts model, which is used as a basis for the corresponding polymer models and therefore does not extend to general spin systems. Our approach applies to general polymer models as detailed in the next section and our focus on the ferromagnetic Potts model is mainly to illustrate the method without further technical overhead; the approach for example can be adapted to general spin systems on bipartite random graphs with a given degree sequence (analogously to [10]).

## 2 Polymers

The main technique that we use to prove Theorem 2 is to refine the polymer framework by introducing a new polymer sampling condition which requires that the weight of each polymer decays exponentially in its total degree. In order to state the new condition we first give some relevant definitions.

Let  $G = (V_G, E_G)$  be a graph – we refer to  $G$  as the “host graph” of the polymer model. Let  $[q] = \{1, \dots, q\}$  be a set of spins and  $g = \{g_v\}_{v \in V_G}$  specify a set of ground-state spins for the vertices, i.e.,  $g_v \subseteq [q]$  for each  $v \in V_G$ . A polymer is a pair  $\gamma = (V_\gamma, \sigma_\gamma)$  consisting of a connected set of vertices  $V_\gamma$  and an assignment  $\sigma_\gamma: V_\gamma \rightarrow [q]$  such that  $\sigma_\gamma(v) \in [q] \setminus g_v$ . Let  $\mathcal{P}_G$  be the set of all polymers. A polymer model for the host graph  $G$  is specified by a subset of allowed polymers  $\mathcal{C}_G \subseteq \mathcal{P}_G$ , and a weight function  $w_G: \mathcal{C}_G \rightarrow \mathbb{R}_{\geq 0}$ . For polymers  $\gamma, \gamma' \in \mathcal{P}_G$ , we write  $\gamma \sim \gamma'$  to denote that  $\gamma, \gamma'$  are compatible, i.e., that

<sup>1</sup> A polynomial-time approximate sampling algorithm for  $\mu_{G,q,\beta}$  is an algorithm that, given an accuracy parameter  $\varepsilon > 0$  and a graph  $G = (V_G, E_G)$  as input, outputs a sample from a probability distribution that is within total variation distance  $\varepsilon$  of  $\mu_{G,q,\beta}$ , in time  $\text{poly}(|V_G|, 1/\varepsilon)$ .

<sup>2</sup> Given an accuracy parameter  $\varepsilon > 0$ , we say that  $\hat{Z}$  is an  $\varepsilon$ -approximation to the quantity  $Z$  if  $e^{-\varepsilon} Z \leq \hat{Z} \leq e^\varepsilon Z$ . A fully polynomial randomised approximation scheme (FPRAS) for  $Z_{G,q,\beta}$  is a randomised algorithm that, given an accuracy parameter  $\varepsilon > 0$  and a graph  $G = (V_G, E_G)$  as input, outputs a random variable that is an  $\varepsilon$ -approximation to  $Z_{G,q,\beta}$  with probability at least  $3/4$ , in time  $\text{poly}(|V_G|, 1/\varepsilon)$ .

for every  $u \in \gamma$  and  $u' \in \gamma$  the graph distance in  $G$  between  $u$  and  $u'$  is at least 2. We define  $\Omega_G = \{\Gamma \subseteq \mathcal{C}_G \mid \forall \gamma, \gamma' \in \Gamma, \gamma \sim \gamma'\}$  to be the set of all sets of mutually compatible polymers of  $\mathcal{C}_G$ ; elements of  $\Omega_G$  are called polymer configurations. We define the partition function as  $Z_G = \sum_{\Gamma \in \Omega_G} \prod_{\gamma \in \Gamma} w_G(\gamma)$ , and the Gibbs distribution on  $\Gamma \in \Omega_G$  as  $\mu_G(\Gamma) = \prod_{\gamma \in \Gamma} w_G(\gamma) / Z_G$ . We use  $(\mathcal{C}_G, w_G)$  to denote the polymer model.

► **Example 4** (The polymer model  $(\mathcal{C}_{G,q}^r, w_{G,\beta})$ , [20]). Consider the  $q$ -state ferromagnetic Potts model with parameter  $\beta$ , and let  $r \in [q]$  be a colour. Let  $G$  be a graph and set  $g_v = \{r\}$  for every  $v \in V_G$ . The weight of a polymer  $\gamma = (V_\gamma, \sigma_\gamma)$  is defined as  $w_{G,\beta}(\gamma) = e^{-\beta B_\gamma}$ , where  $B_\gamma$  denotes the number of edges from  $V_\gamma$  to  $V_G \setminus V_\gamma$  plus the number of edges of  $G$  with both endpoints in  $V_\gamma$  that are bichromatic under  $\sigma_\gamma$ . We let  $\mathcal{P}_{G,q}^r$  denote the set of all polymers and the set of allowed polymers  $\mathcal{C}_{G,q}^r$  to be the set of polymers  $\gamma \in \mathcal{P}_{G,q}^r$  such that  $|V_\gamma| < |V_G|/2$ . Note that a polymer configuration  $\Gamma$  consisting of the polymers  $\gamma_1, \dots, \gamma_k$  corresponds to a colouring  $\sigma$ , where a vertex  $v$  takes the colour  $\sigma_{\gamma_i}(v)$  if  $v \in V_{\gamma_i}$  for some  $i \in [k]$ , and the colour  $r$  otherwise; moreover,  $e^{\beta|E_G|} \prod_{i \in [k]} w_G(\gamma_i) = w_G(\sigma)$ .

Polymer models have been used to approximate the partition function of spin systems on bounded-degree host graphs. There are several existing algorithmic frameworks which can be used to sample from these resulting polymer models. One such deterministic algorithm uses the polynomial interpolation method of Barvinok [1] combined with the cluster expansion to approximate the partition function of the polymer model (see [16] for more details). Typical running times for these deterministic algorithms are of the form  $n^{O(\log(\Delta))}$ , where  $\Delta$  is the maximum degree of the host graph, though for polymer models these have been improved to give a running time of  $n^{1+o_\Delta(1)}$ , see [20]. Another approach, described in Section 4 of the full version [11], uses a Markov chain called the polymer dynamics to sample from  $\mu_G$  (see also [7] for more details). The running times of algorithms obtained using the Markov chain approach are usually faster and of the form  $O(n \log n)$ . Both of these approaches work for roughly the same range of parameters, and the essential condition required is that the weight of each polymer decays exponentially in the number of vertices it contains. To obtain our results, we give a simple generic way to modify this condition, as detailed below.

For a vertex  $v \in V_G$  we write  $\deg_G(v)$  to denote the degree of  $v$  in  $G$ , and for a vertex subset  $S \subseteq V_G$  we write  $\deg_G(S)$  to denote  $\sum_{v \in S} \deg_G(v)$ .

► **Definition 5.** Let  $q \geq 2$  be an integer,  $\mathcal{G}$  be a class of graphs, and  $\mathcal{F}_\mathcal{G} = \{(\mathcal{C}_G, w_G) \mid G \in \mathcal{G}\}$  be a family of  $q$ -spin polymer models. We say that  $\mathcal{F}_\mathcal{G}$  satisfies the polymer sampling condition with constant  $\tau \geq 3 \log(8e^3(q-1))$  if  $w_G(\gamma) \leq e^{-\tau \deg_G(V_\gamma)}$  for all  $G \in \mathcal{G}$  and all  $\gamma \in \mathcal{C}_G$ .<sup>3</sup>

Using Definition 5, we will show (Lemma 8, below) that if a “computationally feasible” family of polymer models on a class of graphs  $\mathcal{G}$  satisfies this new condition, then there is an efficient algorithm which, given a graph  $G \in \mathcal{G}$ , approximately samples from the Gibbs distribution of the polymer model corresponding to  $G$ .

The new polymer sampling condition in Definition 5 is analogous to the original one in [7] except that the original condition requires the weight of a polymer to decay exponentially in its size, and in particular that the constant  $\tau$  is sufficiently big relative to the maximum degree of  $G$ . The new condition relaxes this, allowing us to choose the constant  $\tau$  in Definition 5 so that it does not depend on the maximum degree of the host graph, which is how we overcome the limitations of previous work. Technically, the improvement comes from the fact that previous work relies on bounding the number of connected vertex subsets of a given size

<sup>3</sup> Unless we specify otherwise, the base of all logarithms in this paper is assumed to be  $e$ .

(with bounds that depend on the maximum degree of the graph), but here we are able to instead rely on the following lemma which bounds the number of connected vertex subsets with a given total degree and this enables us to avoid restricting the maximum degree of the graph. The new condition, which replaces the notion of “size” with total degree, fits well with the original abstract polymer model framework of [21], where the notion of the “size” of a polymer is an abstract function.

► **Lemma 6.** *Let  $G = (V_G, E_G)$  be a graph,  $v \in V_G$ , and  $\ell \geq 1$  be an integer. The number of connected vertex subsets  $S \subseteq V_G$  such that  $v \in S$  and  $\deg_G(S) = \ell$  is at most  $(2e)^{2\ell-1}$ .*

In addition to the bound on the number of connected vertex subsets in Lemma 6, we will use the fact that these connected vertex subsets can be enumerated in time exponential in the total degree  $\ell$  (see Lemma 21 of the full version). Although the bound in Lemma 6 is exponential in  $\ell$ , this will be mitigated by the fact that the new polymer sampling condition ensures that the weight of each polymer is exponentially small in its total degree. The new polymer sampling condition therefore allows us to prove that the following condition holds – this condition is analogous to the polymer mixing condition of [7], except that we consider edges instead of vertices. For a polymer  $\gamma \in \mathcal{P}_G$ , let  $E_\gamma$  denote the set of edges of  $G$  with at least one endpoint in  $V_\gamma$ .

► **Definition 7.** *Let  $q \geq 2$  be an integer,  $\mathcal{G}$  be a class of graphs, and  $\mathcal{F}_\mathcal{G} = \{(\mathcal{C}_G, w_G) \mid G \in \mathcal{G}\}$  be a family of  $q$ -spin polymer models. We say that  $\mathcal{F}_\mathcal{G}$  satisfies the polymer mixing condition with constant  $\theta \in (0, 1)$  if  $\sum_{\gamma' \sim \gamma} |E_{\gamma'}| \cdot w_G(\gamma') \leq \theta |E_\gamma|$  for all  $G \in \mathcal{G}$  and all  $\gamma \in \mathcal{C}_G$ .*

In contrast to the conditions in [7], the two new conditions consider edges since we modify the polymer dynamics algorithm to sample edges instead of vertices. Subject to these new conditions, the techniques of [7] can be adapted to show that the modified polymer dynamics mixes rapidly, therefore giving the efficient algorithm for sampling from the Gibbs distribution of a polymer model. We give the details of the modified dynamics in Section 4 of the full version [11].

Finally, in order to use the modified polymer dynamics as an efficient algorithm for computing an approximate sample from  $\mu_G$ , we will need a mild computational condition for polymers. More precisely, we say that a family of polymer models  $\{(\mathcal{C}_G, w_G) \mid G \in \mathcal{G}\}$  is *computationally feasible* if for all  $G \in \mathcal{G}$  and all  $\gamma \in \mathcal{P}_G$ , it is possible to decide whether  $\gamma \in \mathcal{C}_G$  and to compute  $w_G(\gamma)$ , if it is, in  $O(e^{\deg_G(V_\gamma)})$  time. Computational feasibility serves exactly the same purpose as it did in Definition 3 of [7], which requires that the same operations are able to be carried out in time depending on  $|V_\gamma|$  (instead of  $\deg_G(V_\gamma)$  that we use here).

In Section 4 of the full version [11], we prove the following lemma which gives an efficient algorithm for sampling<sup>4</sup> from the Gibbs distribution of a polymer model and for approximating its partition function. In order to prove the lemma, we extend the polymer dynamics algorithm of [7] to the unbounded degree setting. The proof of the lemma uses the fact (see Lemma 18 of the full version) that the polymer sampling condition implies the polymer mixing condition.

<sup>4</sup> Given an accuracy parameter  $\varepsilon > 0$ , we say that a random variable  $X$  is an  $\varepsilon$ -sample from the probability distribution  $\mu$  if the total variation distance between the distribution of  $X$  and  $\mu$  is at most  $\varepsilon$ .

► **Lemma 8.** *Let  $q \geq 2$  be an integer,  $\mathcal{G}$  be a class of graphs, and  $\mathcal{F}_{\mathcal{G}}$  be a family of computationally feasible  $q$ -spin polymer models satisfying the polymer sampling condition.*

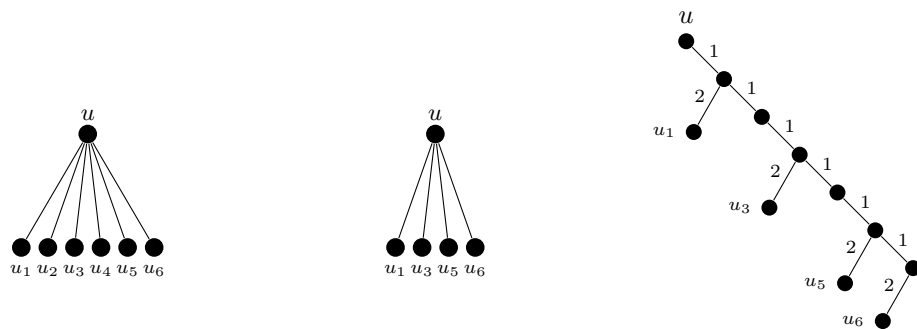

*There are randomised algorithms which, given as input a graph  $G \in \mathcal{G}$  with  $m$  edges and an accuracy parameter  $\varepsilon > 0$ , output an  $\varepsilon$ -sample from  $\mu_G$  in  $O(m \log \frac{m}{\varepsilon} \log \frac{1}{\varepsilon})$  time, and an  $\varepsilon$ -approximation to  $Z_G$ , with probability at least  $3/4$ , in  $O(m^2 \log(\frac{m}{\varepsilon})^3)$  time.*

We next give the proof of Lemma 6 which is one of the key technical ingredients allowing us to relax the bounded-degree restriction and to remove the dependence of the constant  $\tau$  in Definition 5 on the maximum degree of the host graph, as noted earlier.

**Proof of Lemma 6.** Let  $N(G, v, \ell)$  be the set of subtrees  $T = (V_T, E_T)$  of  $G$  such that  $v \in V_T$ ,  $\deg_G(V_T) = \ell$ . We will show that  $|N(G, v, \ell)| \leq (2e)^{2\ell-1}$ , which gives us the desired result for the following reason. Let  $S \subseteq V_G$  be a connected vertex subset such that  $v \in S$  and  $\deg_G(S) = \ell$ . Since  $S$  is connected, it has at least one spanning tree  $T = (V_T = S, E_T)$  such that  $v \in V_T$  and  $\deg_G(V_T) = \ell$ . Since  $S$  is the unique connected vertex subset that  $T$  spans, this gives us an injective map from the set of all connected vertex subsets containing  $v$  with total degree  $\ell$ , to  $N(G, v, \ell)$ .

We now give an injective map from  $N(G, v, \ell)$  to  $T^*(2\ell, 3)$  – the set of subtrees of size  $2\ell$  that contain the root, of the infinite rooted 3-regular tree. By a result of Bollobás [3, p. 129], we know that  $|T^*(2\ell, 3)|$  is at most  $(2e)^{2\ell-1}$ . Let  $T = (V_T, E_T)$  be a subtree from  $N(G, v, \ell)$ . We will map  $T$  to a rooted subtree  $T' = (V_{T'}, E_{T'})$  from  $T^*(2\ell, 3)$ . For each vertex of  $V_G$ , fix an ordering of its neighbours. In the infinite rooted 3-regular tree, label the edges incident to the root with  $\{1, 2, 3\}$ , and for each other vertex label the edges connecting it to its two children with  $\{1, 2\}$ . As we construct  $T'$ , we will label its edges so that it is clear which subtree from  $T^*(2\ell, 3)$  we are constructing, we will also label some of its vertices. We construct  $T'$  as follows (see Figure 1 for an example of the following construction).

1. Add the root to  $V_{T'}$  and label it  $v$ .
2. While there is a labelled vertex of  $T'$  (call its label  $u$ ) such that  $u$  has a child  $w$  in  $T$  but no vertex of  $T'$  is labelled  $w$ , then we do the following. First, we create a path  $P$  of length  $\deg_G(u)$  where each edge is labelled 1. We then connect the vertex of  $T'$  labelled  $u$  to  $P$  via an edge labelled 1. Finally, for  $1 \leq i \leq \deg_G(u)$ , we connect a vertex labelled  $w$  to the  $i^{\text{th}}$  vertex of  $P$  via an edge labelled 2, if  $w$  is the  $i^{\text{th}}$  neighbour of  $u$  in  $G$  and  $w$  is a child of  $u$  in  $T$ .

(a) Neighbourhood of  $u$  in  $G$ .      (b) Neighbourhood of  $u$  in  $T$ .      (c) Neighbourhood of  $u$  in  $T'$ .

■ **Figure 1** Constructing  $T'$ .

Each  $T \in N(G, v, \ell)$  maps to a different  $T' \in T^*(2\ell, 3)$ . When constructing  $T'$ , we used edge labels from  $\{1, 2, 3\}$ , therefore the maximum degree of  $T'$  is 3. For each  $v \in V_T$ , we added at most  $2 \deg_G(v)$  vertices to  $T'$ , therefore the size of  $T'$  is at most  $2 \deg_G(V_T) = 2\ell$ . ◀

### 3 Application to unbounded-degree graphs

Let  $\alpha > 0$  be a real number. We say that a graph  $G$  is an  $\alpha$ -total-degree expander if, for all connected vertex subsets  $S \subseteq V_G$  with  $|S| \leq |V_G|/2$ , we have  $e_G(S, S^c) \geq \alpha \deg_G(S)$ , where  $e_G(S, S^c)$  denotes the number of edges with one endpoint in  $S$  and the other in  $S^c := V_G \setminus S$ . Let  $\mathcal{G}_\alpha$  denote the set of all  $\alpha$ -total-degree expanders. Note, every connected  $G \in \mathcal{G}_\alpha$  is also an  $\alpha$ -expander (i.e.,  $e_G(S, S^c) \geq \alpha|S|$ ).

When  $\beta$  is sufficiently large, the polymer model from Example 4 satisfies the polymer sampling condition (Definition 5) with constant  $\tau = \alpha\beta$ . To see this, consider  $\gamma \in \mathcal{C}_{G,q}^r$  and observe that since  $B_\gamma \geq e_G(V_\gamma, V_\gamma^c)$  and  $|V_\gamma| < |V_G|/2$ , it follows that

$$w_{G,\beta}(\gamma) \leq \exp\{-\alpha\beta \deg_G(V_\gamma)\} = e^{-\tau \deg_G(V_\gamma)}, \tag{1}$$

where  $\tau \geq 3 \log(8e^3(q-1))$  if  $\beta \geq \frac{3}{\alpha} \log(8e^3(q-1))$ .

We may therefore apply Lemma 8 in order to efficiently sample from the ferromagnetic Potts model and to estimate  $Z_G$  for  $G \in \mathcal{G}_\alpha$ , provided that  $\beta$  is sufficiently large. The proof of the following theorem is in Section 5 of the full version [11].

► **Theorem 9.** *Let  $\alpha > 0$  be a real number. Let  $q \geq 3$  be an integer and  $\beta \geq \frac{3}{\alpha} \log(8e^3(q-1))$  be a real. For the Potts model on  $G \in \mathcal{G}_\alpha$ , there is a poly-time approximate sampling algorithm for  $\mu_{G,q,\beta}$  and an FPRAS for  $Z_{G,q,\beta}$ .*

*In fact, for  $n = |V_G|$  and  $m = |E_G|$ , if the desired accuracy  $\varepsilon$  satisfies  $\varepsilon \geq e^{-n}$  then the running time of the sampler is  $O(m \log \frac{m}{\varepsilon} \log \frac{1}{\varepsilon})$  and the running time of the FPRAS is  $O(m^2 (\log \frac{m}{\varepsilon})^3)$ .*

#### 3.1 Expansion of random graphs with specified degree sequences

Let  $d$  be a real number. In this section, we will show that a graph  $G \sim \mathcal{G}(n, \vec{x})$  for a degree sequence  $\vec{x} \in \mathcal{D}_{n,d}$  is whp an  $\alpha$ -total-degree-expander for some constant  $\alpha > 0$ , i.e., that  $G \in \mathcal{G}_\alpha$ .

To work with  $G \sim \mathcal{G}(n, \vec{x})$ , we consider the standard configuration model, where a random multigraph  $H = (V_H, E_H)$  with the given degree sequence  $\vec{x}$  is sampled by the following process. For each  $i \in [n]$ , we attach  $x_i$  half-edges to the vertex  $i$ . We then sample a uniformly random perfect matching on the half-edges to give  $E_H$ . This uniformly random perfect matching can be sampled by performing the following until no half-edges remain: choose any remaining half-edge, choose another remaining half-edge uniformly at random, then pair these two half-edges and remove them from the set of remaining half-edges. We write  $H \sim \text{CM}(n, \vec{x})$ . Note, for two vertices  $i, j \in V_H$  such that  $i \neq j$ , the probability that a half edge attached to  $i$  and a half edge attached to  $j$  are paired is

$$p_{\{i,j\}} = \frac{x_i x_j}{2m - 1}, \text{ where } m = \frac{1}{2} \sum_{k=1}^n x_k, \tag{2}$$

and similarly the probability that two half-edges of  $i$  are connected is  $p_{\{i,i\}} = \frac{x_i(x_i-1)}{2m(2m-1)}$ .

We first prove results about  $\text{CM}(n, \vec{x})$ , since asymptotic properties of  $\text{CM}(n, \vec{x})$  can easily be transferred back to  $\mathcal{G}(n, \vec{x})$  using the following straightforward consequence of [18, Theorem 1.1]. A proof is included in the full version [11] for completeness.

► **Lemma 10.** *Let  $d$  be a positive real number. For every positive integer  $n$ , let  $\mathcal{E}_n$  be a set of  $n$ -vertex multigraphs. If, for some  $\vec{x} \in \mathcal{D}_{n,d}$ ,  $G \sim \mathcal{G}(n, \vec{x})$  and  $H \sim \text{CM}(n, \vec{x})$  then the following is true. If  $H \in \mathcal{E}_n$  with high probability, then  $G \in \mathcal{E}_n$  with high probability.*

For a (multi)graph  $H = (V_H, E_H)$  we define the tree-excess to be  $t_H = |E_H| - (|V_H| - 1)$ ; that is, the number of edges more than a tree that  $H$  has. First, we show that multigraphs drawn from the configuration model have locally bounded tree excess.

► **Lemma 11.** *Let  $d$  be a positive real number. The following is true with high probability when  $H = (V_H, E_H)$  is drawn from  $\text{CM}(n, \vec{x})$  uniformly over all degree sequences  $\vec{x} \in \mathcal{D}_{n,d}$ . For all connected vertex sets  $S \subseteq V_H$  with  $|S| \leq (\log n)^2$  and  $\deg_H(S) \geq 36$ , we have that  $t_{H[S]} \leq \frac{1}{6} \deg_H(S)$ .*

**Proof.** For positive integers  $k$  and  $\ell$ , and a non-negative integer  $t$ , let the random variable  $X_{k,\ell,t}$  denote the number of connected vertex subsets  $S \subseteq V_H$  such that  $|S| = k$ ,  $\deg_H(S) = \ell$ , and  $t_{H[S]} = t$ . To prove the lemma, we will show that whp

$$\sum_{k \leq \lfloor (\log n)^2 \rfloor} \sum_{\ell \geq 36} \sum_{t \geq \lfloor \ell/6 \rfloor + 1} X_{k,\ell,t} = 0.$$

In fact, we can further restrict the range of summation. From the lower bound in Item 1 of Definition 1, we have that  $x_i \geq 3$  for all  $i$ , and therefore  $\ell \geq 3k$ . Item 2 shows that  $\sum_i x_i \leq dn$ , and therefore  $\ell \leq dn$  and  $t \leq \ell/2 \leq dn/2$ . So, consider any integer  $\ell$  in the range  $36 \leq \ell \leq dn$ , any integer  $k$  in the range  $1 \leq k \leq \min\{(\log n)^2, \ell/3\}$ , and any integer  $t > \ell/6$ . There are at most  $\binom{n}{k}$  vertex subsets  $S \subseteq V_H$  with  $|S| = k$  and  $\deg_G(S) = \ell$ . Let  $j = k - 1 + t$  be the number of edges with both endpoints in  $S$ . Given such a set  $S$ , there are at most  $\binom{\ell}{2j}$  possibilities for the set of half-edges in these  $j$  edges. On a given set of  $2j$  half-edges, there are  $(2j - 1)!! = \frac{(2j)!}{2^j j!}$  perfect matchings. Using the upper bound on the degrees from Item 1 of Definition 1, the probability that a set of  $j$  edges is present in  $H$  is at most

$$\frac{n^{2\rho}}{2m-1} \frac{n^{2\rho}}{2m-3} \cdots \frac{n^{2\rho}}{2m-2j+1} \leq \left( \frac{n^{2\rho}}{2m-2j} \right)^j \leq \left( \frac{n^{2\rho}}{n} \right)^j,$$

where the final inequality follows from the fact that  $k \leq (\log n)^2$  and therefore that  $2m - 2j \geq \deg_G(S^c) \geq 3|S^c| = 3(n - k) > n$  (as long as  $n$  is sufficiently big). We also have that

$$\binom{\ell}{2j} \cdot \frac{(2j)!}{2^j j!} < \frac{\ell!}{(\ell - 2j)! j!} < \frac{\ell^{2j} e^j}{j^j} \leq \left( \frac{e\ell^2}{t} \right)^j.$$

Putting everything together, it follows that

$$\mathbb{E}[X_{k,\ell,t}] \leq \binom{n}{k} \left( \frac{e\ell^2}{t} \right)^{k-1+t} \left( \frac{n^{2\rho}}{n} \right)^{k-1+t} < \left( \frac{e^2 \ell^2}{t} \right)^{k-1+t} \frac{n^{2\rho(k-1+t)}}{n^{t-1}}.$$

Furthermore, since  $t > \ell/6$ ,  $k < 2t$ , and (by the upper bound in Item 1 of Definition 1)  $\ell \leq kn^\rho \leq n^{2\rho}$ , we have that

$$\mathbb{E}[X_{k,\ell,t}] < \frac{(6e^2 n^{4\rho})^{3t-1}}{n^{t-1}}. \quad (3)$$

Let

$$X = \sum_{\ell=36}^{dn} \sum_{k=1}^{\lfloor \min\{(\log n)^2, \ell/3\} \rfloor} \sum_{t=\lfloor \ell/6 \rfloor + 1}^{\lfloor dn/2 \rfloor} X_{k,\ell,t}.$$

Since  $t > \ell/6 \geq 6$ , it follows that  $t \geq 7$ . For big enough  $n$ , (3) shows that  $\mathbb{E}[X_{k,\ell,t}] \leq n^{13\rho t}/n^{t-1}$ . Since  $\rho \leq 2/91$  and  $t \geq 7$ ,  $1 - 13\rho \geq 5/7 \geq 5/t$  so  $13\rho t \leq t - 5$  and  $\mathbb{E}[X_{k,\ell,t}]$  is at most  $n^{-4}$ . Taking a union bound over all permissible values for  $\ell$ ,  $k$ , and  $t$ , we find that  $\mathbb{E}[X] = o(1)$ . Applying Markov's inequality, we have that  $\Pr(X > 0) = \Pr(X \geq 1) \leq \mathbb{E}[X] = o(1)$ , and the result follows.  $\blacktriangleleft$

To obtain the expansion bounds in Lemmas 13 and 14, we require the following result from [8, Proposition 4.5]. Although this result is stated in [8] in terms of the random graph model, it is first proved for the configuration model, so this is how we state it. Also, Fountoulakis and Reed require that the vector  $\vec{x}$  be in  $\mathcal{D}_{n,d}$  but this is only important for lifting their result to the random graph model, so it is not relevant for us.

► **Lemma 12.** (Fountoulakis, Reed) *Let  $H = (V_H, E_H)$  be drawn from  $\text{CM}(n, \vec{x})$  for some length- $n$  degree sequence  $\vec{x}$ . For any set  $S \subseteq V_H$  we have  $\Pr(e_H(S, S^c) = 0) \leq \binom{m}{\deg_H(S)/2}^{-1}$ , where  $m = \frac{1}{2} \sum_i x_i$ .*

Note that Fountoulakis and Reed's lemma was stated for  $S$  such that  $\deg_H(S)$  is even, but if  $\deg_H(S)$  is odd, it is not possible to have  $e_H(S, S^c) = 0$ . Next, we show that in a multigraph  $H$  drawn from the configuration model, small vertex subsets satisfy certain expansion properties.

► **Lemma 13.** *Let  $d$  be a positive real number. The following is true with high probability when  $H = (V_H, E_H)$  is drawn from  $\text{CM}(n, \vec{x})$  uniformly over all degree sequences  $\vec{x} \in \mathcal{D}_{n,d}$ . For all connected vertex sets  $S \subseteq V_H$  with  $|S| \leq (\log n)^2$ , we have that  $e_H(S, S^c) \geq |S|/4$ .*

**Proof.** For positive integers  $k$  and  $\ell$ , and a non-negative integer  $j$ , let the random variable  $X_{k,j,\ell}$  denote the number of connected vertex subsets  $S \subseteq V_H$  with  $|S| = k$ ,  $e_H(S, S^c) = j$ , and  $\deg_H(S) = \ell$ . By Item 1 of Definition 1, we need only consider  $\ell$  satisfying  $3k \leq \ell \leq kn^\rho$ . Let

$$X = \sum_{k=1}^{\lfloor (\log n)^2 \rfloor} \sum_{j=0}^{\lfloor k/4 \rfloor} \sum_{\ell=3k}^{\lfloor kn^\rho \rfloor} X_{k,j,\ell}.$$

To prove the lemma we will show that  $X = 0$ , whp. Consider any integer  $k$  in the range  $1 \leq k \leq (\log n)^2$ , any integer  $j$  in the range  $0 \leq j < k/4$ , and any integer  $\ell$  in the range  $3k \leq \ell \leq kn^\rho$ . There are at most  $\binom{n}{k}$  candidates for vertex sets  $S$  with  $|S| = k$  and  $\deg_H(S) = \ell$ . There are then at most  $\binom{\ell}{j}$  choices for the  $j$  half-edges emanating from vertices of  $S$  that will be matched with half-edges emanating from vertices of  $S^c$ , once  $H$  is drawn. Applying Lemma 12 to the degree sequence derived from  $\vec{x}$  by removing the  $j$  half-edges (and their partners), the probability that the remaining  $\ell - j$  half-edges are matched amongst themselves is at most

$$\left( \frac{m'}{(\ell - j)/2} \right)^{-1} \leq \left( \frac{(\ell - j)}{2m'} \right)^{\frac{(\ell - j)}{2}} \leq \left( \frac{kn^\rho}{n} \right)^{\frac{11k}{8}},$$

where  $2m' = (\sum_{i=1}^n x_i) - 2j$  and the last inequality follows (for big enough  $n$ ) since  $11k/4 \leq$

## 36:10 Fast Mixing via Polymers for Random Graphs with Unbounded Degree

$\ell - j \leq kn^\rho$  and  $2m' \geq 3n - 2j > n$ . We therefore have that

$$\begin{aligned} \mathbb{E}[X] &\leq \sum_{k=1}^{\lfloor (\log n)^2 \rfloor} \sum_{j=0}^{\lfloor k/4 \rfloor} \sum_{\ell=3k}^{\lfloor kn^\rho \rfloor} \binom{n}{k} \binom{\ell}{j} \left( \frac{kn^\rho}{n} \right)^{\frac{11k}{8}} \\ &\leq \sum_{k=1}^{\lfloor (\log n)^2 \rfloor} \sum_{j=0}^{\lfloor k/4 \rfloor} \sum_{\ell=3k}^{\lfloor kn^\rho \rfloor} \left( \frac{ne}{k} \right)^k \left( \frac{e\ell}{j} \right)^j \left( \frac{kn^\rho}{n} \right)^{\frac{11k}{8}} \\ &\leq \sum_{k=1}^{\lfloor (\log n)^2 \rfloor} \left( \frac{(\log n)^{O(1)} n^{\rho(2+11/8)}}{n^{3/8}} \right)^k. \end{aligned}$$

This is  $o(1)$  since  $\rho < 1/9$ . Applying Markov's inequality, we have that  $\Pr(X > 0) = \Pr(X \geq 1) = o(1)$ , and the result follows.  $\blacktriangleleft$

The next lemma handles the expansion of sets  $S$  with relative big size.

**► Lemma 14.** *Let  $d$  be a positive real number. There is a positive real number  $\alpha$  (depending on  $d$ ) such that the following is true with high probability when  $H = (V_H, E_H)$  is drawn from  $\text{CM}(n, \vec{x})$  uniformly over all degree sequences  $\vec{x} \in \mathcal{D}_{n,d}$ . For all connected vertex sets  $S \subseteq V_H$  with  $(\log n)^2 \leq |S| \leq n/2$ , we have that  $e_H(S, S^c) \geq \alpha \deg_H(S)$ .*

**Proof.** We will give the proof for vertex sets  $S \subseteq V_H$  with  $(\log n)^2 \leq |S| \leq n/2$  and  $\deg_H(S) > \max\{100d|S|, n/2\}$ , the cases where  $\deg_H(S) \leq \max\{100d|S|, n/2\}$  follow by arguments that are close to those in [8], and are given in the full version [11].

Let  $C = 10^4 d$ . By the Cauchy-Schwarz inequality, we have that  $|S| \sum_{i \in S} x_i^2 \geq (\deg_H(S))^2 \geq 10^4 d^2 |S|^2$ , so using Item 2 of Definition 1 which ensures that  $\sum_{i \in S} x_i^2 \leq dn$ , we find that  $|S| \leq n/C$ .

Let  $f = (eC)^{1/C}$ . The number of sets  $S$  satisfying  $|S| \leq n/C$  is at most  $n \binom{n}{n/C} \leq n f^n$  since there are at most  $n$  possibilities for  $|S|$  to consider, and for each of them  $\binom{n}{|S|} \leq \binom{n}{n/C}$ .

Fix any set  $S \subseteq V_H$  with  $|S| \leq n/C$  and consider the random construction of  $H$ , starting from half-edges in  $S^c$  (and choosing their mates in the pairing). Let

$$j = \left\lfloor \frac{\deg_H(S^c)}{2} \right\rfloor \geq \left\lfloor \frac{3|S^c|}{2} \right\rfloor \geq \left\lfloor \frac{3n(1 - \frac{1}{C})}{2} \right\rfloor \geq \frac{3n(1 - \frac{2}{C})}{2},$$

where the first inequality uses the fact that each  $x_i$  is at least 3 (from Item 1 of Definition 1) and the final inequality uses the fact that  $n$  is sufficiently large.

Note that the process initiates a pairing from at least  $j$  half-edges in  $S^c$ . For each  $i \in [j]$ , let  $Y_i$  be the indicator random variable for the event that the  $i$ 'th half-edge from which pairing is initiated connects to an endpoint in  $S$  (conditioned on the pairings of the first  $i - 1$  half-edges initiated from  $S^c$ ).

Let  $\varepsilon = 3(1 - 2/C)/(8d) \leq 1/2$ . Recall from Item 2 in Definition 1 that  $\sum_{i=1}^n x_i \leq dn$ . For any  $t \in [j]$  satisfying  $\sum_{i=1}^{t-1} Y_i < \varepsilon n/2$  we have

$$\Pr(Y_t = 1) \geq \frac{\deg_H(S) - \varepsilon n/2}{dn} > \frac{1 - \varepsilon}{2d} \geq \frac{1}{4d}.$$

Now let  $X_1, \dots, X_j$  be i.i.d. Bernoulli random variables which are 1 with probability  $1/(4d)$ . We can couple the evolution of these variables so that, for any  $t \in [j]$  satisfying  $\sum_{i=1}^{t-1} Y_i < \varepsilon n/2$ , we have  $\sum_{i=1}^t Y_i \geq \sum_{i=1}^t X_i$ . We conclude that  $\Pr(\sum_{i=1}^j Y_i < \varepsilon n/2) \leq \Pr(\sum_{i=1}^j X_i < \varepsilon n/2)$ .

To conclude we will show that  $nf^n \Pr(\sum_{i=1}^j X_i < \varepsilon n/2) = o(1)$ , implying that we can take  $\alpha = \varepsilon/(2d)$  since  $\varepsilon n/2 = \alpha dn \geq \alpha \deg_H(S)$ .

Let  $X = \sum_{i=1}^j X_i$  and  $\delta = 1/2$ . Note that  $\mathbb{E}[X] = j/(4d)$  and that

$$\frac{(1-\delta)j}{4d} \geq \frac{(1-\delta)3n(1-\frac{2}{C})}{8d} = \frac{\varepsilon n}{2}.$$

By a Chernoff bound,  $\Pr(X \leq \varepsilon n/2) \leq \Pr(X \leq (1-\delta)j/(4d)) \leq \exp(-j\delta^2/(8d))$ .

To conclude that  $nf^n \exp(-j\delta^2/(8d)) = o(1)$  we observe that  $f < \exp(3(1-2/C)\delta^2/(16d))$ . Taking  $\alpha = \varepsilon/(2d)$ , we conclude the proof. ◀

We can now prove the following result, which establishes the desired expansion properties of the multigraphs generated by the configuration model.

► **Lemma 15.** *Let  $d$  be a positive real number. There is a positive real number  $\alpha$  (depending on  $d$ ) such that the following is true with high probability when  $H = (V_H, E_H)$  is drawn from  $\text{CM}(n, \vec{x})$  uniformly over all degree sequences  $\vec{x} \in \mathcal{D}_{n,d}$ . For all connected vertex sets  $S \subseteq V_H$  with  $|S| \leq n/2$ , we have that  $e_H(S, S^c) \geq \alpha \deg_H(S)$ .*

**Proof.** We consider three cases.

**Case 1.** Consider all connected subsets  $S \subseteq V_H$  with  $(\log n)^2 \leq |S| \leq n/2$ . By Lemma 14 there is a positive real number  $\alpha'$  such that, whp, every such subset  $S$  has  $e_H(S, S^c) \geq \alpha' \deg_H(S)$ .

**Case 2.** Consider all connected subsets  $S \subseteq V_H$  with  $|S| \leq (\log n)^2$  and  $\deg_H(S) \geq 36$ .

- Consider first those subsets  $S$  with  $|S| \leq \frac{1}{6} \deg_H(S)$ . We have that

$$e_H(S, S^c) = \deg_H(S) - 2(t_{H[S]} + |S| - 1) \geq \frac{2}{3} \deg_H(S) - 2|S| \geq \frac{1}{3} \deg_H(S),$$

by Lemma 11 and our assumption on the size of  $S$ .

- Now consider those subsets  $S$  with  $|S| > \frac{1}{6} \deg_H(S)$ , then by Lemma 13, we have that  $e_H(S, S^c) \geq |S|/4 \geq \deg_H(S)/24$ .

**Case 3.** Finally, consider connected subsets  $S \subseteq V_H$  with  $|S| \leq (\log n)^2$  and  $\deg_H(S) < 36$ .

By Lemma 13, we have that  $e_H(S, S^c) \geq |S|/4 \geq 1/4 = 36/144 > \deg_H(S)/144$ .

The result follows from the three cases by taking  $\alpha = \min\{1/144, \alpha'\} = \alpha'$ . ◀

Using the definition of  $\mathcal{G}_\alpha$  and Lemma 10, we have the following corollary of Lemma 15.

► **Corollary 16.** *Let  $d$  be a real number. There is a positive real number  $\alpha$  (depending on  $d$ ) such that the following holds. With high probability, when  $G \sim \mathcal{G}(n, \vec{x})$  for some  $\vec{x} \in \mathcal{D}_{n,d}$ , it holds that  $G \in \mathcal{G}_\alpha$ .*

Combining Corollary 16 with Theorem 9 implies our main theorem.

► **Theorem 2.** *Let  $d$  be a real number and  $q \geq 3$  be an integer. For the ferromagnetic Potts model, there is  $\beta_0$  such that for all  $\beta \geq \beta_0$  there is a poly-time approximate sampling algorithm for  $\mu_{G,q,\beta}$  and an FPRAS for  $Z_{G,q,\beta}$  that work with high probability on random graphs  $G \sim \mathcal{G}(n, \vec{x})$  for any degree sequence  $\vec{x} \in \mathcal{D}_{n,d}$ .*

**Proof.** Let  $d$  be a real number and let  $q \geq 2$  be an integer. Let  $\alpha$  be the positive real number from Corollary 16. Let  $\beta_0 = \frac{3}{\alpha} \log(8e^3(q-1))$ .

Consider  $\vec{x} \in \mathcal{D}_{n,d}$  and let  $G$  be drawn from  $\mathcal{G}(n, \vec{x})$ . By Corollary 16,  $G \in \mathcal{G}_\alpha$  whp. The result then follows by using the algorithms from Theorem 9. ◀

► Remark 17. The bounds on  $\beta$  in Remark 3 follow from the choice of  $\beta_0$  in the proof of Theorem 2 and from the fact that  $\alpha = O(\frac{1}{d \log d})$  which follows from the proofs of Lemmas 14 and 15. The running time bounds in Remark 3 come from those in Theorem 9 using the fact that  $|E_G| = O(n)$  which follows from Item 2 of Definition 1.

## Abstract

We study the problem of deterministically approximating the number of satisfying assignments of a polynomial threshold function (PTF) over Boolean space. We present and analyze a scheme for transforming such algorithms for PTFs over *Gaussian space* into algorithms for the more challenging and more standard setting of Boolean space. Applying this transformation to existing algorithms for Gaussian space leads to new algorithms for Boolean space that improve on prior state-of-the-art results due to Meka and Zuckerman [19] and Kane [13]. Our approach is based on a bias-preserving derandomization of Meka and Zuckerman’s regularity lemma for polynomials [19] using the [23] pseudorandom generator for PTFs.

## 1 Introduction

Unconditional derandomization has emerged as a major topic of inquiry in complexity theory over the past several decades. One important strand in this study is the development of deterministic algorithms that can perform *approximate counting* for various function classes: given the description of a function  $f \in \mathcal{C}$  and an accuracy parameter  $\epsilon > 0$ , deterministically output an estimate of the acceptance probability of  $f$  (i.e.  $\Pr_{\mathbf{x} \leftarrow \{-1,1\}^n} [f(\mathbf{x}) = 1]$ ) that is additively accurate to within  $\pm\epsilon$ . This problem is trivially easy to solve with a randomized algorithm, but is much more challenging if a deterministic algorithm is required. Indeed, recall that the P vs. BPP problem is essentially equivalent to solving the deterministic approximate counting problem for  $\mathcal{C}$  being the class of all polynomial-size circuits (and  $\epsilon = 0.1$ ).

In this work we focus on the class of *low-degree polynomial threshold functions*, an important class of functions that has been the subject of intensive study in unconditional derandomization in recent years [5, 12, 11, 13, 16, 19, 14, 3, 4, 15, 9, 10, 17, 23, 22].

## 1.1 Background: Deterministic approximate counting algorithms for PTFs

A *degree- $d$  polynomial threshold function* (PTF) is a function  $f(x) = \text{sign}(p(x))$  where  $p(x_1, \dots, x_n)$  is a polynomial of degree at most  $d$  and  $\text{sign} : \mathbb{R} \rightarrow \{-1, 1\}$  outputs 1 iff its argument is nonnegative. Deterministic approximate counting algorithms for PTFs have been well studied in a number of different works, and the following table summarizes the runtimes of the fastest known algorithms prior to this work:

■ **Table 1** Prior work on deterministic approximate counting algorithms for degree- $d$  PTFs. In the runtime of [13],  $O_d(\cdot)$  hides an Ackermann-type dependence on  $d$ , and likewise, in the runtime of [4],  $O_{d,\epsilon}(\cdot)$  hides an Ackermann-type dependence on  $d$  and  $1/\epsilon$ . With the exception of [4], all these algorithms are based on the construction of pseudorandom generators for PTFs.

Reference	Runtime
[19]	$n^{(d/\epsilon)^{O(d)}}$
[13]	$n^{O_d(\text{poly}(1/\epsilon))}$
[4]	$O_{d,\epsilon}(1) \cdot n^{O(d)}$
[17]	$\text{poly}(n) \cdot \exp(2^{\tilde{O}(\sqrt{\log(1/\epsilon)})})$ for $d = 2$
[23]	$\exp(2^{\sqrt{d \log n}}) \cdot \text{quasipoly}(1/\epsilon)$

### 1.1.1 Algorithms for PTFs over Gaussian space

A fruitful theme that has emerged in the study of PTFs concerns the relationship between PTFs in the standard setting of *Boolean space* – PTFs over  $\{-1, 1\}^n$  endowed with the uniform distribution – and PTFs in the setting of *Gaussian space*: PTFs over  $\mathbb{R}^n$  endowed with the Gaussian measure  $N(0, 1)^n$ .

The Gaussian setting enjoys numerous useful features that are not afforded by the Boolean setting, most of them owing to the continuous nature of  $\mathbb{R}^n$  and the rotational invariance of the Gaussian measure. In fact, the problem of approximate counting of degree- $d$  PTFs over Gaussian space (i.e. approximating  $\Pr_{\mathbf{g} \leftarrow N(0,1)^n}[f(\mathbf{g}) = 1]$  where  $f$  is a degree- $d$  PTF) can be seen to be a *special case* of the same problem over Boolean space, in the sense that an algorithm for the latter setting can be used to obtain an algorithm with a comparable runtime for the former setting. (This is a consequence of the invariance principle [20].) For this reason, many works have focused on the special case of designing deterministic approximate counting algorithms for PTFs over Gaussian space. There are by now a number of results in this setting for which no counterparts are yet known for the more challenging Boolean setting:

**Contrasting the state of the art over Boolean and Gaussian space.** Comparing Tables 1 and 2, we note that the runtime of [12] is strictly better than those of [19]’s and [13]’s algorithms for the Boolean setting; the runtime of [14] is strictly better than that of [13]; the runtime of [3] is strictly better than that of [17]; and the runtime of [22] remains subexponential for  $d = 2^{\tilde{\Omega}(\sqrt{\log n})}$ , whereas all algorithms for the Boolean setting trivialize once  $d = \Omega(\log n)$ .

■ **Table 2** Current best deterministic approximate counting algorithms for degree- $d$  PTFs over Gaussian space. With the exception of [3], all these algorithms are based on the construction of pseudorandom generators for PTFs over Gaussian space.

[12]	$n^{2^{O(d)} \cdot \text{poly}(1/\epsilon)}$
[14]	$n^{O_{d,\kappa}(1/\epsilon)^\kappa}$ for all $\kappa > 0$
[3]	$\text{poly}(n, 1/\epsilon)$ for $d = 2$
[22]	$n^{(d/\epsilon)^{O(\log d)}}$

## 1.2 This work: Upgrading algorithms for Gaussian space into ones for Boolean space

In this work we establish a new connection between the derandomization of PTFs over Boolean and Gaussian space. We leverage this connection to transform existing deterministic approximate counting algorithms for the Gaussian setting (i.e. those summarized in Table 2) into new state-of-the-art deterministic algorithms for approximate counting of PTFs for the more challenging Boolean setting, improving upon those summarized in Table 1.

The runtimes of our new algorithms improve upon the prior state of the art for a broad range of parameters. For  $d = \Theta(1)$ , we obtain a strict improvement for all  $\epsilon$  satisfying  $2^{-\Theta(\sqrt{\log n})} \leq \epsilon \leq o_n(1)$ . For  $d = \omega_n(1)$ , we obtain a strict improvement for all  $\epsilon$  satisfying  $d \log(d/\epsilon) \leq \Theta(\log n)$ . We now give precise statements of the runtimes of our new algorithms, and provide example parameter settings that highlight the main qualitative advantages of these new runtimes.

## 1.3 Our results: New deterministic approximate counting algorithms for PTFs over Boolean space

First, by instantiating our framework with [12]’s algorithm for the Gaussian setting, we obtain the following algorithm for the Boolean setting:

► **Theorem 1.** *There is a deterministic algorithm for  $\epsilon$ -approximate counting  $n$ -variable degree- $d$  PTFs over Boolean space that runs in time*

$$\exp\left(2^{O(d\sqrt{\log(d/\epsilon)})}\right) \cdot n^{2^{O(d)} \cdot \text{poly}(1/\epsilon)}.$$

This runtime is a strict improvement of [19]’s runtime and very nearly matches the  $n^{2^{O(d)} \cdot \text{poly}(1/\epsilon)}$  running time of the [12] algorithm for Gaussian space. For any  $\epsilon = \Theta(1/\text{polylog}(n))$ , our runtime remains  $n^{\text{polylog}(n)}$  for  $d$  as large as  $\tilde{\Omega}(\log \log n)$ , whereas the runtimes of all previous algorithms for the Boolean setting exceed  $n^{\text{polylog}(n)}$  once  $d$  is even a slightly superconstant function of  $n$ .

Next, by instantiating our framework with [14]’s algorithm for the Gaussian setting, we obtain the following algorithm for the Boolean setting:

► **Theorem 2.** *For all  $\kappa > 0$ , there is a deterministic algorithm for  $\epsilon$ -approximate counting  $n$ -variable degree- $d$  PTFs over Boolean space that runs in time*

$$n^{O_{d,\kappa}(1/\epsilon)^\kappa}.$$

This runtime is a strict improvement of [13]’s runtime and matches that of [14]’s algorithm for the Gaussian setting. For arbitrarily large constants  $c, d \in \mathbb{N}$  and  $\epsilon = 1/(\log n)^c$ , our runtime is barely superpolynomial,  $n^{O((\log n)^\kappa)}$  for any arbitrarily small constant  $\kappa > 0$ , whereas all previous algorithms for the Boolean setting run in time at least  $n^{(\log n)^{\Omega(c)}}$  or  $n^{(\log n)^{\Omega(d)}}$ .

■ **Table 3** Our new algorithms for deterministic approximate counting of degree- $d$  PTFs over Boolean space. The runtime of Theorem 1 is a strict improvement of [19]’s; the runtime of Theorem 2 is a strict improvement of [13]’s, and matches that of [14]’s algorithm for Gaussian space.

	Runtime	Follows by instantiating our framework with:
Theorem 1	$\exp\left(2^{O(d\sqrt{\log(d/\epsilon)})}\right) \cdot n^{2^{O(d)} \cdot \text{poly}(1/\epsilon)}$	[12]’s Gaussian PRG
Theorem 2	$n^{O_{d,\kappa}(1/\epsilon)^\kappa}$	[14]’s Gaussian PRG

Finally, we remark that:

- Our framework can also be instantiated with [3]’s algorithm for degree-2 PTFs in the Gaussian setting to recover [17]’s PRG-based algorithm for degree-2 PTFs in the Boolean setting (and in fact, we are able to improve it slightly by eliminating the  $\text{polylog}(1/\epsilon)$  factor suppressed by the  $\tilde{O}(\cdot)$  in its runtime);
- Our framework can also be instantiated with [22]’s algorithm for degree- $d$  PTFs in the Gaussian setting, yielding a deterministic algorithm for degree- $d$  PTFs over Boolean space that runs in time  $\exp\left(2^{O(d\sqrt{\log(d/\epsilon)})}\right) \cdot n^{(d/\epsilon)^{O(\log d)}}$ . Like Theorem 1, this runtime is a strict improvement of [19]’s runtime.

### 1.4 Our approach: Derandomizing Meka and Zuckerman’s regularity lemma

Our main new tool is a *derandomization of the [19] regularity lemma*. To explain what this means, we begin by recalling the basics of the original [19] regularity lemma.

A multivariate polynomial  $p$  is said to be *regular* if, intuitively, no variable has high influence (we give precise definitions in Section 2). Let us recall the original [19] regularity lemma: given any degree- $d$  polynomial over  $\{-1, 1\}^n$ , it gives an efficient (deterministic) algorithm which builds a not-too-large decision tree such that at almost every leaf  $\rho$ , the resulting polynomial  $p_\rho$  ( $p$  restricted according the partial assignment corresponding to that leaf) is such that either (i)  $p_\rho$  is regular, or (ii)  $\text{sign}(p_\rho)$  is close to either the constant  $+1$  function or the constant  $-1$  function.<sup>1</sup>

<sup>1</sup> We note that a similar regularity lemma was given in simultaneous work of [6] (see also [18]); that work employed a slightly different technical definition of what it means for a polynomial to be “regular”, and it gave a similar algorithm to build a decision tree with similar properties for that related notion. However, in the current work for technical reasons it is essential that we use the [19] notion of regularity; we explain this in more detail in Remark 22 in Appendix B.2.

The [19] regularity lemma is useful for derandomization because it lets one reduce the general Boolean case to the “regular” Boolean case, which can be easier because sophisticated mathematical tools like central limit theorems and invariance principles can be brought to bear on regular polynomials over  $\{-1, 1\}^n$  to relate them to the corresponding polynomials over the Gaussian domain. Indeed, the [19] regularity lemma and related results play an important role in a number of PRG and approximate counting results for polynomial threshold functions, including the works of [19, 13, 4] mentioned above. However there is often a substantial algorithmic cost associated with the use of a regularity lemma, because building the decision tree (or equivalently, exploring all of its leaves) can be relatively expensive.

**Our derandomization of the regularity lemma.** The above-described standard strategy of building and visiting all of the leaves of a decision tree corresponds to using true uniform randomness to choose a path through the decision tree. The intuition behind our derandomized version of the regularity lemma is as follows: by choosing a path through the decision tree according to a suitable *pseudorandom* distribution, it is possible, from an algorithmic perspective, to “build and visit only a tiny fraction of the leaves of the decision tree.” This can be much more efficient than visiting all leaves.

Intuitively, the leaves that our derandomized regularity lemma constructs are determined by the output of a PRG for degree- $d$  PTFs over  $m$  variables where  $m$  is the depth of the decision tree.<sup>2</sup> As our analysis shows, for the purpose of deterministic approximate counting for the original PTF  $\text{sign}(p)$ , it suffices to do deterministic approximate counting on just the PTFs  $\text{sign}(p_\rho)$  for these (relatively few) leaves  $\rho$ .

More precisely, we prove a general result, Theorem 15, which encapsulates the above approach. It outputs a collection of restrictions (which can be thought of as a very small subset of the leaves of the decision tree that the original regularity lemma constructs) with the following property: given an accurate estimate of the fraction of assignments satisfying  $\text{sign}(p_\rho)$  for each restriction  $\rho$  in the collection, combining these estimates in the obvious way gives an accurate estimate of the overall fraction of inputs in  $\{-1, 1\}^n$  that satisfy the original PTF  $\text{sign}(p)$ . Moreover (and crucially), each restriction  $\rho$  in the collection is such that either the restricted polynomial  $p_\rho$  is highly regular, or else  $\text{sign}(p_\rho)$  is a close-to-constant function.

For the purpose of deterministic approximate counting, restrictions where  $\text{sign}(p_\rho)$  is a close-to-constant function are easy to handle, and thanks to the invariance principle, at restrictions where  $p_\rho$  is regular we can do Gaussian deterministic approximate counting and the resulting estimate of  $\Pr_{\mathbf{g} \leftarrow N(0,1)^n}[\text{sign}(p_\rho(\mathbf{g})) = 1]$  will be an accurate estimate of  $\Pr_{\mathbf{x} \leftarrow \{-1,1\}^n}[\text{sign}(p_\rho(\mathbf{x}))]$  for the Boolean problem. Thus, the overall running time of the deterministic approximate counting algorithm we obtain from the regularity lemma is essentially the running time of (i) “fooling Boolean PTFs over few variables” (to build the tree) times the running time of (ii) “Gaussian deterministic approximate counting” (to handle the regular leaves).

### 1.4.1 Applying the derandomized regularity lemma

To obtain an efficient deterministic approximate counting algorithm from this approach, in part (i) above it is okay to use a PRG with a relatively poor dependence on the number of variables, since the number of variables is quite small. Such a generator is provided for us by

<sup>2</sup> This is actually an oversimplification: the regularity lemma works in a sequence of “atomic stages” to build a tree, and our approach actually works by derandomizing each atomic stage separately. The cost of a single atomic stage provides the dominant contribution to the overall cost, though, so the intuition is correct.

the [23] PRG (or rather a slight variant of it which we need for technical reasons); we can afford this generator's poor dependence on the number of variables, and using it lets us take advantage of its better dependence on the other parameters (it is clear from Table 1 that [23] has a better dependence on both  $d$  and  $\epsilon$  than any of the other algorithms in that table).

By applying our derandomized regularity lemma with (essentially) the [23] PRG for part (i) and the Gaussian result of [12] for part (ii), we obtain Theorem 1. By using instead [14]'s algorithm for the Gaussian setting for part (ii), we obtain Theorem 2.

## 2 Preliminaries

We start by establishing some basic notation. We write  $[n]$  to denote  $\{1, 2, \dots, n\}$  and  $[k, \ell]$  to denote  $\{k, k+1, \dots, \ell\}$ . We use bold font to denote random variables. We write  $\mathbf{E}[\mathbf{X}]$  and  $\mathbf{Var}[\mathbf{X}]$  to denote expectation and variance of a random variable  $\mathbf{X}$  and write  $\mathbf{E}_{\mathbf{X} \leftarrow \mathcal{D}}[\mathbf{X}]$ ,  $\mathbf{Var}_{\mathbf{X} \leftarrow \mathcal{D}}[\mathbf{X}]$ , and the like to indicate that the random variable  $\mathbf{X}$  has distribution  $\mathcal{D}$ . If  $S$  is a finite set then " $\mathbf{X} \leftarrow S$ " means that  $\mathbf{X}$  is distributed uniformly over  $S$ ; if no distribution is specified for a random variable taking values in  $\{-1, 1\}^n$  then the implied distribution is uniform over  $\{-1, 1\}^n$ . For  $x \in \{-1, 1\}^n$  and  $A \subseteq [n]$  we write  $x_A$  to denote  $(x_i)_{i \in A}$ .

For a function  $f : \{-1, 1\}^n \rightarrow \mathbb{R}$  and  $q \geq 1$ , we denote by  $\|f\|_q$  its  $\ell_q$  norm with respect to the uniform distribution, i.e.,  $\|f\|_q \stackrel{\text{def}}{=} \mathbf{E}[|p(\mathbf{x})|^q]^{1/q} = \mathbf{E}_{\mathbf{x} \leftarrow \{-1, 1\}^n}[|p(\mathbf{x})|^q]^{1/q}$ . We write  $\|f\|_{q, \mathcal{D}}$  to denote its  $\ell_q$  norm with respect to the distribution  $\mathcal{D}$ , i.e.  $\|f\|_{q, \mathcal{D}} \stackrel{\text{def}}{=} \mathbf{E}_{\mathbf{x} \leftarrow \mathcal{D}}[|p(\mathbf{x})|^q]^{1/q}$ .

For Boolean-valued functions  $f, g : \{-1, 1\}^n \rightarrow \{-1, 1\}$  the distance between  $f$  and  $g$ , denoted  $\text{dist}(f, g)$ , is  $\Pr[f(\mathbf{x}) \neq g(\mathbf{x})]$ .

### 2.1 Fourier analysis of Boolean functions

**Fourier Analysis over  $\{-1, 1\}^n$  and Influences.** We consider functions  $f : \{-1, 1\}^n \rightarrow \mathbb{R}$ , and we think of the inputs  $x$  to  $f$  as being distributed according to the uniform probability distribution. The set of such functions forms a  $2^n$ -dimensional real inner product space with inner product given by  $\langle f, g \rangle = \mathbf{E}[f(\mathbf{x})g(\mathbf{x})]$ . The set of functions  $(\chi_S)_{S \subseteq [n]}$  defined by  $\chi_S(x) = \prod_{i \in S} x_i$  forms a complete orthonormal basis for this space. Given a function  $f : \{-1, 1\}^n \rightarrow \mathbb{R}$  we define its *Fourier coefficients* by  $\hat{f}(S) \stackrel{\text{def}}{=} \mathbf{E}[f(\mathbf{x})\chi_S(\mathbf{x})]$ , and we have that  $f(x) = \sum_S \hat{f}(S)\chi_S(x)$ . We refer to the maximum  $|S|$  over all nonzero  $\hat{f}(S)$  as the *Fourier degree* of  $f$ .

As a consequence of orthonormality we have *Plancherel's identity*  $\langle f, g \rangle = \sum_S \hat{f}(S)\hat{g}(S)$ , which has as a special case *Parseval's identity*,  $\mathbf{E}[f(\mathbf{x})^2] = \sum_S \hat{f}(S)^2$ . From this it follows that for every  $f : \{-1, 1\}^n \rightarrow \{-1, 1\}$  we have  $\sum_S \hat{f}(S)^2 = 1$ . We recall the well-known fact that the total influence  $\text{Inf}(f)$  of any Boolean function equals  $\sum_S \hat{f}(S)^2 |S|$ . Note that, in this setting, the expectation and the variance can be expressed in terms of the Fourier coefficients of  $f$  by  $\mathbf{E}[f] = \hat{f}(\emptyset)$  and  $\mathbf{Var}[f] = \sum_{\emptyset \neq S \subseteq [n]} \hat{f}(S)^2$ .

Let  $f : \{-1, 1\}^n \rightarrow \mathbb{R}$  and  $f(x) = \sum_S \hat{f}(S)\chi_S(x)$  be its Fourier expansion. The *influence* of variable  $i$  on  $f$  is  $\text{Inf}_i(f) \stackrel{\text{def}}{=} \sum_{S \ni i} \hat{f}(S)^2$ , and the *total influence* of  $f$  is  $\text{Inf}(f) = \sum_{i=1}^n \text{Inf}_i(f)$ .

**Bounded independence and bounded uniformity distributions.** A distribution  $\mathcal{D}$  on  $\{-1, 1\}^n$  is said to be *k-wise independent* if any collection of  $k$  distinct coordinates  $i_1, \dots, i_k$  are such that  $\mathbf{x}_{i_1}, \dots, \mathbf{x}_{i_k}$  are independent when  $\mathbf{x} \leftarrow \mathcal{D}$ . If each  $\mathbf{x}_i$  additionally is uniform

over  $\{-1, 1\}$ , then the distribution  $\mathcal{D}$  is said to be *k-wise uniform*. We note that if  $\mathcal{D}$  is a *k-wise uniform* distribution over  $\{-1, 1\}^n$ , then for any degree-*k* polynomial  $p$ , it holds by linearity of expectation that

$$\mathbf{E}_{z \leftarrow \mathcal{D}} [p(z)] = \mathbf{E}_{x \leftarrow \{-1, 1\}^n} [p(x)], \tag{1}$$

and hence if  $\mathcal{D}$  is  $(qk)$ -wise uniform for even  $q$ , it holds that

$$\|p\|_q = \|p\|_{q, \mathcal{D}}. \tag{2}$$

**Useful probability bounds.** We first recall the (2,4)-Hypercontractivity theorem of [2, 7]:

► **Theorem 3** ((2,4)-Hypercontractivity, special case of Theorem 9.21 of [21] / Lemma 4.3 of [8]). *Let  $p : \{-1, 1\}^n \rightarrow \mathbb{R}$  be a degree- $d$  multilinear polynomial. Then*

$$\|p\|_4 \leq 3^{d/2} \cdot \|p\|_2.$$

For our purposes we will need a *derandomized* version of Theorem 3, where the expectations are with respect to a suitable pseudorandom distribution. As an immediate consequence of Equation (2), we obtain the following corollary of Theorem 3:

► **Corollary 4** ((2,4)-Hypercontractivity for bounded-uniformity distributions). *Let  $p : \{-1, 1\}^n \rightarrow \mathbb{R}$  be a degree- $d$  multilinear polynomial. If  $\mathcal{D}$  is a  $4d$ -wise uniform distribution over  $\{-1, 1\}^n$ , then*

$$\|p\|_{4, \mathcal{D}} \leq 3^{d/2} \cdot \|p\|_{2, \mathcal{D}}.$$

We will need the following fact, which is a consequence of (2, 4)-hypercontractivity and states that a low-degree polynomial must exceed its expectation with nonnegligible probability:

► **Fact 5** (Lemma 5.4 of [8]). *Let  $p : \{-1, 1\}^n \rightarrow \mathbb{R}$  be a degree- $d$  multilinear polynomial normalized so that  $\mathbf{Var}[p] = 1$ . Then there is an absolute constant  $C > 0$  such that*

$$\Pr_{x \leftarrow \{-1, 1\}^n} [p(x) \geq \mathbf{E}[p] + 2^{-Cd}] \geq 2^{-O(d)}.$$

We will also need a derandomized version of Fact 5:

► **Fact 6** (Fact 5 for bounded-uniformity distributions). *Let  $p : \{-1, 1\}^n \rightarrow \mathbb{R}$  be a degree- $d$  multilinear polynomial normalized so that  $\mathbf{Var}[p] = 1$ . If  $\mathcal{D}$  is a  $4d$ -wise uniform distribution over  $\{-1, 1\}^n$ , then there is an absolute constant  $C > 0$  such that*

$$\Pr_{x \leftarrow \{-1, 1\}^n} [p(x) \geq \mathbf{E}[p] + 2^{-Cd}] \geq 2^{-O(d)}.$$

For the sake of completeness, we include the short proof of Fact 6 in Appendix A.

**Invariance.** We recall the invariance principle of Mossel, O’Donnell and Oleszkiewicz, specifically Theorem 3.19 under hypothesis **H4** in [20]:

► **Theorem 7** ([20]). *Let  $p(x) = \sum_{S \subseteq [n], |S| \leq d} \widehat{p}(S) \chi_S(x)$  be a degree- $d$  multilinear polynomial with  $\mathbf{Var}[p] = 1$ . Suppose each coordinate  $i \in [n]$  has  $\text{Inf}_i(p) \leq \tau$ . Then,*

$$\sup_{t \in \mathbb{R}} \left| \Pr_{x \leftarrow \{-1, 1\}^n} [p(x) \leq t] - \Pr_{g \leftarrow N(0, 1)^n} [p(g) \leq t] \right| \leq O(d\tau^{1/(8d)}).$$

## 2.2 PTFs, regularity, and the critical index

► **Definition 8** (Regularity). *We say that a degree- $d$  polynomial  $p$  is  $\tau$ -regular if*

$$\sqrt{\sum_{j=i}^n \text{Inf}_j(p)^2} \leq \tau \sum_{j=1}^n \text{Inf}_j(p).$$

► **Definition 9** ( $\tau$ -critical index). *Let  $p$  be a degree- $d$  polynomial, and assume (without loss of generality) that the variables of  $p$  are ordered so that  $\text{Inf}_1(p) \geq \text{Inf}_2(p) \geq \dots \geq \text{Inf}_n(p)$ . The  $\tau$ -critical index of  $p$  is the least  $i$  such that*

$$\text{Inf}_{i+1}(p) \leq \tau^2 \sum_{j=i+1}^n \text{Inf}_j(p).$$

## 3 Derandomizing Meka and Zuckerman's regularity lemma

### 3.1 Overview of [19]'s regularity lemma and its proof

In this subsection we state Meka and Zuckerman's regularity lemma for low-degree polynomials [19], and recall its key elements at a level of detail which will enable us to build on those elements.

► **Lemma 10** (Implicit in the proof of Lemma 5.17 of [19]). *There is a deterministic algorithm which, on input a degree- $d$  polynomial  $p$  and parameters  $\tau, \epsilon, \delta$ , outputs a decision tree of depth*

$$\text{depth}(d, \tau, \epsilon, \delta) := \frac{2^{O(d)}}{\tau^2} \cdot \log\left(\frac{1}{\delta}\right) \log\left(\frac{1}{\epsilon}\right)$$

*with the following property: with probability  $1 - \epsilon$ , a random path down the tree reaches a leaf  $\rho$  such that  $p_\rho$  is either*

1.  $\tau$ -regular, or
2. the PTF  $\text{sign}(p_\rho)$  is  $\delta$ -close to the constant function  $\text{sign}(\mathbf{E}[p_\rho])$ .

*The running time of this tree construction algorithm is  $\text{poly}(n^d, 2^{\text{depth}(d, \tau, \epsilon, \delta)})$ .*

The algorithm of [19] recursively constructs the tree in a sequence of simple “atomic steps”. We now describe how a single atomic step works. Consider a leaf  $\rho$  of the decision tree; initially the leaf  $\rho$  is simply the root of the tree corresponding to the empty restriction. The algorithm behaves differently depending on how large the  $\tau$ -critical index of  $p_\rho$  is:

**Large critical index.** If the polynomial  $p_\rho$  has “large”  $\tau$ -critical index (larger than a parameter  $K$  which is  $2^{O(d)} \log(1/\delta)/\tau^2$ ) then an “atomic step” consists of fixing the  $K$  variables which have the highest influence in  $p_\rho$ , i.e. replacing the current leaf with a complete depth- $K$  decision tree that exhaustively queries those variables. The key to the analysis of this case is the following structural result, which is Lemma 5.2 of [8]:

► **Lemma 11** (restatement of [8]'s Lemma 5.2: Large critical index). *There is a universal constant  $C_1 > 0$  such that the following holds. Let  $p : \{-1, 1\}^n \rightarrow \mathbb{R}$  be a degree- $d$  multilinear polynomial with  $\tau$ -critical index at least  $K := 2^{C_1 d} \log(1/\delta)/\tau^2$ . Then*

$$\Pr_{\rho \leftarrow \{-1, 1\}^{[K]}} [\mathbf{Var}[p_\rho] \leq \delta \mathbf{E}[p_\rho]^2] \geq 2^{-O(d)},$$

*and consequently by Chebyshev's inequality,*

$$\Pr_{\rho \leftarrow \{-1, 1\}^{[K]}} [\text{sign}(p_\rho) \text{ is } \delta\text{-close to } \text{sign}(\mathbf{E}[p_\rho])] \geq 2^{-O(d)}.$$

**Small critical index.** If the polynomial has small  $\tau$ -critical index (smaller than  $K$ ), then an “atomic step” consists of fixing the “head” variables  $[k]$  up to the critical index (again building a complete decision tree over those  $k \leq K$  variables). The key to the analysis of this case is the following structural result, which is Lemma 5.1 of [8]:

► **Lemma 12** (restatement of [8]’s Lemma 5.1: Small critical index). *Let  $p : \{-1, 1\}^n \rightarrow \mathbb{R}$  be a degree- $d$  multilinear polynomial with  $\tau$ -critical index  $k \in [n]$ . Then*

$$\Pr_{\rho \leftarrow \{-1, 1\}^{[k]}} [p_\rho \text{ is } \tau'\text{-regular}] \geq 2^{-O(d)}, \quad \text{where } \tau' \leq 2^{O(d)} \cdot \tau.$$

Given these two results, a relatively straightforward analysis (which is in fact a special case of the analysis we give in the subsequent subsections) shows that after at most  $2^{O(d)} \log(1/\epsilon)$  levels of these “atomic steps”, at most an  $\epsilon$  fraction of paths will not have terminated either in a close-to-constant leaf or a regular leaf.

### 3.2 The high level idea of our approach: Derandomizing each “atomic step” in a bias-preserving manner

The first important technical ingredient of our approach is in the following two lemmas, Lemma 13 and 14, which give *derandomized* versions of Lemma 11 and 12 respectively. Intuitively, these results say that in each of Lemma 11 and 12, rather than considering the uniform distribution over all restrictions fixing  $[K]$  and  $[k]$  respectively, it suffices to consider instead a suitable *pseudorandom* distribution over restrictions.

► **Lemma 13** (Bounded uniformity suffices for Lemma 11: Large critical index). *Let  $p : \{-1, 1\}^n \rightarrow \mathbb{R}$  be a degree- $d$  multilinear polynomial with  $\tau$ -critical index at least  $K := 2^{C_1 d} \log(1/\delta)/\tau^2$ , where  $C_1$  is the universal constant from Lemma 11. Let  $\mathcal{D}$  be a  $4d$ -wise uniform distribution over  $\{-1, 1\}^K$ . Then*

$$\Pr_{\rho \leftarrow \mathcal{D}} [\mathbf{Var}[p_\rho] \leq \delta \mathbf{E}[p_\rho]^2] \geq 2^{-O(d)},$$

and consequently by Chebyshev’s inequality,

$$\Pr_{\rho \leftarrow \mathcal{D}} [\text{sign}(p_\rho) \text{ is } \delta\text{-close to } \text{sign}(\mathbf{E}[p_\rho])] \geq 2^{-O(d)}.$$

► **Lemma 14** (Bounded uniformity suffices for Lemma 12: Small critical index). *Let  $p : \{-1, 1\}^n \rightarrow \mathbb{R}$  be a degree- $d$  multilinear polynomial with  $\tau$ -critical index  $k \in [n]$ . Let  $\mathcal{D}$  be a  $4d$ -wise uniform distribution over  $\{-1, 1\}^k$ . Then*

$$\Pr_{\rho \leftarrow \mathcal{D}} [p_\rho \text{ is } \tau'\text{-regular}] \geq 2^{-O(d)}, \quad \text{where } \tau' \leq 2^{O(d)} \cdot \tau.$$

We prove Lemma 13 in Appendix B.1 and prove Lemma 14 in Appendix B.2. Combining these results with a PRG that fools degree- $d$  PTFs over  $m$  variables (where “ $m$ ” should be thought of as  $\ll n$ ), we establish our bias-preserving derandomized regularity lemma:

► **Theorem 15** (Bias-preserving derandomization of [19]’s regularity lemma, Lemma 10). *Let  $\mathcal{G}_{\text{PTF}}$  be a PRG with seed length  $s(m, d, \eta)$  that*

- (i) *is  $4d$ -wise uniform and*
- (ii)  *$\eta$ -fools degree- $d$  PTFs over  $m$  variables.*

### 37:10 Deterministic Approximate Counting of Polynomial Threshold Functions

There is a deterministic algorithm *BUILD-RESTRICTIONS* which, on input a degree- $d$  polynomial  $p : \{-1, 1\}^n \rightarrow \mathbb{R}$  and parameters  $\epsilon, \delta$ , and  $\tau$ , outputs a collection  $\mathcal{R}$  of restrictions,

$$|\mathcal{R}| \leq \exp(s(m, d, \eta) \cdot 2^{O(d)} \log(\frac{1}{\epsilon}))$$

where

$$m \leq \frac{2^{O(d)}}{\tau^2} \log(\frac{1}{\delta}) \quad \text{and} \quad \eta = \frac{\epsilon}{2^{O(d)} \log(\frac{1}{\epsilon})}$$

with the following property: with probability  $1 - \epsilon$  over a draw  $\rho \leftarrow \mathcal{R}$ , the restricted polynomial  $p_\rho$  is either

1.  $\tau$ -regular, or
2. the PTF  $\text{sign}(p_\rho)$  is  $\delta$ -close to the constant function  $\text{sign}(\mathbf{E}[p_\rho])$ .

Furthermore the collection of restrictions  $\mathcal{R}$  is bias-preserving, in the sense that

$$\left| \mathbf{E}_{\rho \leftarrow \mathcal{R}} \left[ \mathbf{E}_{\mathbf{x} \leftarrow \{-1, 1\}^n} [\text{sign}(p_\rho(\mathbf{x}))] \right] - \mathbf{E}_{\mathbf{x} \leftarrow \{-1, 1\}^n} [\text{sign}(p(\mathbf{x}))] \right| \leq \epsilon. \quad (3)$$

The running time of *BUILD-RESTRICTIONS* is  $\text{poly}(n^d, |\mathcal{R}|)$ .

We prove Theorem 15 in Section 3.3. At a high level, the argument is an extension of the analysis that establishes the original regularity lemma of [19] from Lemma 11 and 12.

In Section 4 we apply Theorem 15 to obtain new deterministic approximate counting results for degree- $d$  Boolean PTFs. We do this by instantiating the pseudorandom generator  $\mathcal{G}_{\text{PTF}}$  using (a slight variant of) the [23] pseudorandom generator, and by using invariance principles and pseudorandom generators for Gaussian PTFs to obtain the required estimates of  $\mathbf{E}_{\mathbf{x} \leftarrow \{-1, 1\}^n} [\text{sign}(p_\rho)]$  for the regular polynomials  $p_\rho$ .

### 3.3 Proof of Theorem 15: Bias-preserving derandomization of [19]'s regularity lemma

We start with a simple fact about bias preservation:

► **Fact 16** (Bias preservation). *Let  $p : \{-1, 1\}^n \rightarrow \mathbb{R}$  be a degree- $d$  polynomial and let  $H \sqcup T$  be a partition of  $[n]$  into two disjoint sets. Let  $\mathcal{D}$  be a pseudorandom distribution over  $\{-1, 1\}^H$  that  $\eta$ -fools degree- $d$  PTFs over the variables in  $H$ . Then*

$$\left| \mathbf{E}_{\substack{\mathbf{x} \leftarrow \{-1, 1\}^H \\ \mathbf{y} \leftarrow \{-1, 1\}^T}} [\text{sign}(p(\mathbf{x}, \mathbf{y}))] - \mathbf{E}_{\substack{\mathbf{z} \leftarrow \mathcal{D} \\ \mathbf{y} \leftarrow \{-1, 1\}^T}} [\text{sign}(p(\mathbf{z}, \mathbf{y}))] \right| \leq \eta. \quad (4)$$

**Proof.** This follows directly from the fact that for any fixed outcome  $y \in \{-1, 1\}^T$ , the function  $\text{sign}(p_y(x)) = \text{sign}(p(x, y))$  is a degree- $d$  PTF over the variables in  $H$  (i.e. the class of degree- $d$  PTFs is closed under restrictions). ◀

The following will be the key subroutine for our algorithm:

► **Lemma 17** (Single atomic step). *Let  $\mathcal{G}_{\text{PTF}}$  be a PRG with seed length  $s(m, d, \eta)$  that*

- (i) *is  $4d$ -wise uniform and*
- (ii)  *$\eta$ -fools degree- $d$  PTFs over  $m$  variables.*

There is a universal constant  $C_2 > 0$  such that the following holds. There is a deterministic algorithm *BUILD-RESTRICTIONS-ATOMIC* which, on input a degree- $d$  polynomial  $p : \{-1, 1\}^n \rightarrow \mathbb{R}$  and parameters  $\delta, \eta$ , and  $\tau$ , outputs a collection  $\mathcal{R}_{\text{atomic}}(p)$  of restrictions,

$$|\mathcal{R}_{\text{atomic}}(p)| \leq \exp(s(m, d, \eta)), \quad m \leq \frac{2^{O(d)}}{\tau^2} \log\left(\frac{1}{\delta}\right)$$

with the following property: with probability  $\geq 2^{-C_2 d}$  over a draw  $\rho \leftarrow \mathcal{R}_{\text{atomic}}(p)$ , the restricted polynomial  $p_\rho$  is either

1.  $\tau$ -regular, or
2. satisfies  $\mathbf{Var}[p_\rho] \leq \delta \mathbf{E}[p_\rho]^2$ , and consequently by Chebyshev's inequality, the PTF  $\text{sign}(p_\rho)$  is  $\delta$ -close to the constant function  $\text{sign}(\mathbf{E}[p_\rho])$ .

Furthermore, this collection of restrictions  $\mathcal{R}_{\text{atomic}}(p)$  is bias-preserving, in the sense that:

$$\left| \mathbf{E}_{\rho \leftarrow \mathcal{R}_{\text{atomic}}(p)} \left[ \mathbf{E}_{\mathbf{x} \leftarrow \{-1, 1\}^n} [\text{sign}(p_\rho(\mathbf{x}))] \right] - \mathbf{E}_{\mathbf{x} \leftarrow \{-1, 1\}^n} [\text{sign}(p(\mathbf{x}))] \right| \leq \eta. \quad (5)$$

The running time of *BUILD-RESTRICTIONS-ATOMIC* is  $\text{poly}(n^d, |\mathcal{R}_{\text{atomic}}(p)|)$ .

**Proof.** Define  $\bar{\tau} := \tau \cdot 2^{-C_3 d}$  where  $C_3 > 0$  is a universal constant that we will set later. The algorithm *BUILD-RESTRICTIONS-ATOMIC* begins by computing  $\text{Inf}_i(p)$  for all  $i \in [n]$ , which can be done deterministically in time  $\text{poly}(n^d)$  via the Fourier formula  $\text{Inf}_i(p) = \sum_{S \ni i} \hat{p}(S)^2$ . With these values, the algorithm then determines whether the  $\bar{\tau}$ -critical index of  $p$  is large (i.e. at least  $K := 2^{C_1 d} \log(1/\delta)/\bar{\tau}^2$  where  $C_1$  is the universal constant from Lemma 11) or small (i.e. at most  $k < K$ ). Let  $H \subseteq [n]$  be the  $K$  most influential variables of  $p$  in the case where  $p$  has large  $\bar{\tau}$ -critical index and the  $k$  most influential ones otherwise, and let  $T := [n] \setminus H$ .

We define  $\mathcal{R}_{\text{atomic}}(p)$  to be the set of all restrictions  $\rho \in \{-1, 1\}^H \times \{*\}^T$  such that  $\rho_H \in \text{range}(\mathcal{G}_{\text{PTF}})$ , where  $\mathcal{G}_{\text{PTF}}$  is a PRG with seed length  $s(|H|, d, \eta)$  that is  $4d$ -wise uniform and  $\eta$ -fools degree- $d$  PTFs over  $\{-1, 1\}^H$ . Note that the size of  $\mathcal{R}_{\text{atomic}}(p)$  is indeed as claimed in the statement of the lemma:

$$|\mathcal{R}_{\text{atomic}}(p)| \leq \exp(s(|H|, d, \eta)),$$

$$\text{where } |H| \leq |\text{range}(\mathcal{G}_{\text{PTF}})| \leq \frac{2^{O(d)}}{\bar{\tau}^2} \log\left(\frac{1}{\delta}\right) = \frac{2^{O(d)}}{\tau^2} \log\left(\frac{1}{\delta}\right).$$

By the  $4d$ -uniformity of  $\mathcal{G}_{\text{PTF}}$  and our definition of  $H$ , it follows from Lemma 13 and 14 that with probability  $\geq 2^{-O(d)}$  over a draw  $\rho \leftarrow \mathcal{R}_{\text{atomic}}$ , the restricted polynomial  $p_\rho$  is either

1.  $(2^{O(d)} \cdot \bar{\tau})$ -regular, or
2. satisfies  $\mathbf{Var}[p_\rho] \leq \delta \mathbf{E}[p_\rho]^2$ , and consequently by Chebyshev's inequality, the PTF  $\text{sign}(p_\rho)$  is  $\delta$ -close to the constant function  $\text{sign}(\mathbf{E}[p_\rho])$ .

We choose the universal constant  $C_3$  to ensure that  $2^{O(d)} \cdot \bar{\tau} = 2^{O(d)} \cdot \tau \cdot 2^{-C_3 d} \leq \tau$ . Finally, using the fact that  $\mathcal{G}_{\text{PTF}}$   $\eta$ -fools degree- $d$  PTFs over  $\{-1, 1\}^H$ , Equation (5) follows from Fact 16 and this completes the proof.  $\blacktriangleleft$

### 3.3.1 Composing single atomic steps: Proof of Theorem 15 given Lemma 17

At a very high level, Theorem 15 follows by recursive applications of Lemma 17. Given a degree- $d$  polynomial  $p$ , *BUILD-RESTRICTIONS* begins by calling the subroutine *BUILD-RESTRICTIONS-ATOMIC* of Lemma 17, which returns a set  $\mathcal{R}_{\text{atomic}}(p) =: \mathcal{R}^{(1)}$  of  $\exp(s(m, d, \eta))$  many restrictions satisfying the conclusion of Lemma 17. We call a restriction

### 37:12 Deterministic Approximate Counting of Polynomial Threshold Functions

$\rho \in \mathcal{R}_{\text{atomic}}(p)$  *good* if  $p_\rho$  is either  $\tau$ -regular or satisfies  $\mathbf{Var}[p_\rho] \leq \delta \mathbf{E}[p_\rho]^2$  (i.e. if  $p_\rho$  satisfies the conclusion of Lemma 17), and we call  $\rho$  *bad* otherwise. By Lemma 17, we have that

$$\Pr_{\rho \leftarrow \mathcal{R}^{(1)}}[\rho \text{ is good}] \geq 2^{-C_2 d}$$

and

$$\left| \mathbf{E}_{\rho \leftarrow \mathcal{R}^{(1)}} \left[ \mathbf{E}_{\mathbf{x} \leftarrow \{-1,1\}^n} [\text{sign}(p_\rho(\mathbf{x}))] \right] - \mathbf{E}_{\mathbf{x} \leftarrow \{-1,1\}^n} [\text{sign}(p(\mathbf{x}))] \right| \leq \eta.$$

BUILD-RESTRICTIONS cycles through all  $\rho \in \mathcal{R}_{\text{atomic}}(p)$  and determines if each is good or bad. Note that this can be done deterministically in overall time  $|\mathcal{R}_{\text{atomic}}(p)| \cdot \text{poly}(n^d)$  via the Fourier formulas  $\text{Inf}_i(q) = \sum_{S \ni i} \hat{q}(S)^2$  and  $\mathbf{Var}(q) = \sum_{S \neq \emptyset} \hat{q}(S)^2$ . For each bad restriction  $\rho$ , BUILD-RESTRICTIONS recursively calls the subroutine BUILD-RESTRICTIONS-ATOMIC on the restricted polynomial  $p_\rho$ , obtaining another set  $\mathcal{R}_{\text{atomic}}(p_\rho)$  of  $\exp(s(m, d, \eta))$  many restrictions satisfying the conclusion of Lemma 17. Consider the overall set of restrictions comprising of the good restrictions in  $\mathcal{R}_{\text{atomic}}(p)$ , along with the the bad  $\rho \in \mathcal{R}_{\text{atomic}}(p)$  extended by those in  $\mathcal{R}_{\text{atomic}}(p_\rho)$ , i.e.

$$\mathcal{R}^{(2)} := \{\rho: \rho \in \mathcal{R}_{\text{atomic}}(p) \text{ is good}\} \cup \{\rho \circ \rho': \rho \in \mathcal{R}_{\text{atomic}}(p) \text{ is bad, } \rho' \in \mathcal{R}_{\text{atomic}}(p_\rho)\}.$$

We have that

$$\begin{aligned} \Pr_{\rho \leftarrow \mathcal{R}^{(2)}}[\rho \text{ is good}] &= 1 - \Pr_{\rho \leftarrow \mathcal{R}^{(2)}}[\rho \text{ is bad}] \\ &= 1 - \Pr_{\rho \leftarrow \mathcal{R}^{(1)}}[\rho \text{ is bad}] \cdot \Pr_{\substack{\rho' \leftarrow \mathcal{R}^{(1)} \\ \rho' \leftarrow \mathcal{R}_{\text{atomic}}(p_\rho)}}[\rho' \text{ is bad} \mid \rho \text{ is bad}] \\ &\geq 1 - (1 - 2^{-C_2 d})^2, \end{aligned}$$

where  $C_2$  is the universal constant from Lemma 17, and

$$\left| \mathbf{E}_{\rho \leftarrow \mathcal{R}^{(2)}} \left[ \mathbf{E}_{\mathbf{x} \leftarrow \{-1,1\}^n} [\text{sign}(p_\rho(\mathbf{x}))] \right] - \mathbf{E}_{\mathbf{x} \leftarrow \{-1,1\}^n} [\text{sign}(p(\mathbf{x}))] \right| \leq 2\eta.$$

Iterating this argument and defining  $\mathcal{R}^{(j)}$  analogously for  $j > 2$ , we have that

$$\Pr_{\rho \leftarrow \mathcal{R}^{(j)}}[\rho \text{ is good}] \geq 1 - (1 - 2^{-C_2 d})^j \tag{6}$$

and

$$\left| \mathbf{E}_{\rho \leftarrow \mathcal{R}^{(j)}} \left[ \mathbf{E}_{\mathbf{x} \leftarrow \{-1,1\}^n} [\text{sign}(p_\rho(\mathbf{x}))] \right] - \mathbf{E}_{\mathbf{x} \leftarrow \{-1,1\}^n} [\text{sign}(p(\mathbf{x}))] \right| \leq j\eta. \tag{7}$$

By choosing  $j = 2^{O(d)} \log(1/\epsilon)$  we can make the RHS of Equation (6) at least  $1 - \epsilon$ , and by our choice of  $\eta = \epsilon/2^{O(d)} \log(1/\epsilon)$  we have that the RHS of Equation (7) is at most  $\epsilon$ . Finally, we note that

$$|\mathcal{R}^{(j)}| \leq \exp(s(m, d, \eta) \cdot j) = \exp(s(m, d, \eta) \cdot 2^{O(d)} \log(\frac{1}{\epsilon}))$$

and this completes the proof of Theorem 15 given Lemma 17. ◀

## 4 Instantiating our derandomized regularity lemma: Proofs of Theorems 1 and 2

### 4.1 The $\mathcal{G}_{\text{PTF}}$ PRG

To apply Theorem 15 we need a PRG  $\mathcal{G}_{\text{PTF}}$  that (i) is  $4d$ -wise uniform, and (ii)  $\eta$ -fools degree- $d$  PTFs over  $\{-1, 1\}^m$ . Since  $m$  (the number of variables) is quite small in Theorem 15, the idea is to use a PRG which has a poor dependence on this parameter but a good dependence on the error parameter  $\eta$  and the degree parameter  $d$ , since we will be able to take advantages of these good dependences on  $\eta$  and  $d$  while not having to “pay too much” for the poor dependence on  $m$ .

As mentioned earlier, the PRG for degree- $d$  PTFs from [23] is well suited to the purpose of achieving item (ii) above with good parameters for us. We recall the performance guarantee of [23]:

► **Theorem 18** (Special case<sup>3</sup> of Theorem 2 of [23]). *There is an efficient explicit PRG with seed length  $2^{O(\sqrt{d \log m})} + \text{polylog}(1/\eta)$  that  $\eta$ -fools the class of degree- $d$  PTFs over  $\{-1, 1\}^m$ .*

Regarding item (i), it is not clear that the [23] PRG is  $4d$ -wise uniform but we can easily augment it to be  $4d$ -wise uniform by simply performing a bitwise XOR with a  $4d$ -wise uniform distribution. The correctness of this is ensured by the following simple lemma:

► **Lemma 19.** *Let  $G_1 : \{-1, 1\}^{s_1} \rightarrow \{-1, 1\}^m$  be a PRG that  $\epsilon$ -fools the class of degree- $d$  PTFs over  $\{-1, 1\}^m$ . Let  $G_2 : \{-1, 1\}^{s_2} \rightarrow \{-1, 1\}^m$  be such that the distribution of  $G_2(\mathbf{r})$  is  $k$ -wise uniform for  $\mathbf{r}$  uniform random over  $\{-1, 1\}^{s_2}$ . Define  $G : \{-1, 1\}^{s_1+s_2} \rightarrow \{-1, 1\}^m$  by*

$$(G(r_1, r_2))_j = (G(r_1))_j \cdot (G(r_2))_j \quad \text{for } j \in [m].$$

*Then (i)  $G$   $\epsilon$ -fools the class of degree- $d$  PTFs over  $\{-1, 1\}^m$ , and (ii)  $G(\mathbf{r}_1, \mathbf{r}_2)$  is  $k$ -wise uniform for  $(\mathbf{r}_1, \mathbf{r}_2)$  uniform random over  $\{-1, 1\}^{s_1+s_2}$ .*

**Proof.** For (i), observe that if  $p(x_1, \dots, x_m)$  is a degree- $d$  polynomial, then for any fixed  $a \in \{-1, 1\}^m$  the function  $q(x_1, \dots, x_m) = p(a_1 x_1, \dots, a_m x_m)$  is also a degree- $d$  polynomial. It follows that for any fixed setting of  $r_1 \in \{-1, 1\}^{s_1}$ , the distribution

$$(G(\mathbf{r}_1, r_2))_{\mathbf{r}_1 \leftarrow \{-1, 1\}^{s_1}} = ((G(\mathbf{r}_1))_1 \cdot (G(r_2))_1, \dots, (G(\mathbf{r}_1))_m \cdot (G(r_2))_m)_{\mathbf{r}_1 \leftarrow \{-1, 1\}^{s_1}}$$

$\epsilon$ -fools the class of degree- $d$  PTFs over  $\{-1, 1\}^m$ , and (i) follows directly from this.

For (ii), similarly observe that if  $\mathbf{X} = (\mathbf{X}_1, \dots, \mathbf{X}_m)$  is a  $k$ -wise uniform random variable over  $\{-1, 1\}^m$  then for any fixed  $a \in \{-1, 1\}^m$ , the random variable  $(a_1 \mathbf{X}_1, \dots, a_m \mathbf{X}_m)$  is also  $k$ -wise uniform. It follows that for any fixed setting of  $r_1 \in \{-1, 1\}^{s_1}$ , the distribution

$$(G(r_1, \mathbf{r}_2))_{\mathbf{r}_2 \leftarrow \{-1, 1\}^{s_2}} = ((G(r_1))_1 \cdot (G(\mathbf{r}_2))_1, \dots, (G(r_1))_m \cdot (G(\mathbf{r}_2))_m)_{\mathbf{r}_2 \leftarrow \{-1, 1\}^{s_2}}$$

is  $k$ -wise uniform, and (ii) follows directly from this. ◀

<sup>3</sup> Theorem 2 of [23] gives a PRG with seed length  $2^{O(\sqrt{\log S})} + \text{polylog}(1/\eta)$  that  $\eta$ -fools the class of size- $S$  Threshold-of- $AC^0$  circuits. The current statement follows as a special case of this by observing that any degree- $d$   $m$ -variable PTF can be viewed as a Threshold-of-AND circuit of size at most  $S = O(m^d)$ , since there are at most  $\binom{m}{0} + \dots + \binom{m}{d}$  many ANDs over at most  $d$  out of  $m$  input variables.

## 37:14 Deterministic Approximate Counting of Polynomial Threshold Functions

Recalling the well-known fact (see e.g. [24]) that there are simple explicit pseudorandom generators with seed length  $O(k \log m)$  that output  $k$ -wise independent distributions over  $\{-1, 1\}^m$ , we get the following corollary of Theorem 18:

► **Corollary 20.** *There is an efficient explicit PRG  $\mathcal{G}_{\text{PTF}}$  with seed length  $s(m, d, \eta) = 2^{O(\sqrt{d \log m})} + \text{polylog}(1/\eta)$  that is  $4d$ -wise uniform and  $\eta$ -fools the class of degree- $d$  PTFs over  $\{-1, 1\}^m$ .*

### 4.2 Proof of Theorem 1

Recall that to prove Theorem 1, we must give a deterministic algorithm for  $\epsilon$ -approximate counting  $n$ -variable degree- $d$  PTFs over Boolean space that runs in time

$$\exp\left(2^{O(d\sqrt{\log(d/\epsilon)})}\right) \cdot n^{2^{O(d)} \cdot \text{poly}(1/\epsilon)}.$$

The algorithm operates in two stages. In the first stage, it runs the BUILD-RESTRICTIONS procedure given in Theorem 15 with its “ $\epsilon$ ” and “ $\delta$ ” parameters both set to  $\epsilon$ , its “ $\tau$ ” parameter set to  $(\epsilon/d)^{O(d)}$ , and  $\mathcal{G}_{\text{PTF}}$  being the PRG given in Corollary 20. With these parameter settings the “ $m$ ” of Theorem 15 is  $m = (d/\epsilon)^{O(d)}$  and the “ $\eta$ ” is  $\eta = \frac{\epsilon}{2^{O(d)} \log(\frac{1}{\epsilon})}$ . Recall that the running time of BUILD-RESTRICTIONS is

$$\begin{aligned} & \text{poly}\left(n^d, \exp\left(s(m, d, \eta) \cdot 2^{O(d)} \log\left(\frac{1}{\epsilon}\right)\right)\right) \\ &= \text{poly}\left(n^d, \exp\left(\left(2^{O(d\sqrt{\log(d/\epsilon)})} + \text{poly}(d, \log(1/\epsilon))\right) \cdot 2^{O(d)} \log\left(\frac{1}{\epsilon}\right)\right)\right) \\ &= \text{poly}\left(n^d, \exp\left(2^{O(d\sqrt{\log(d/\epsilon)})}\right)\right), \end{aligned} \tag{8}$$

and that BUILD-RESTRICTIONS outputs a set  $\mathcal{R}$  of at most

$$\exp\left(s(m, d, \eta) \cdot 2^{O(d)} \log\left(\frac{1}{\epsilon}\right)\right) = \exp\left(2^{O(d\sqrt{\log(d/\epsilon)})}\right)$$

many restrictions.

In the second stage, the algorithm exhaustively iterates over each restriction  $\rho \in \mathcal{R}$ . For each  $\rho \in \mathcal{R}$  it computes a value  $v_\rho$  as follows:

1. First, it computes  $\text{Inf}_i(p_\rho)$  for all variables  $i$  that were not fixed by the restriction  $\rho$  (recall that this can be done deterministically in time  $\text{poly}(n^d)$  via the Fourier formula  $\text{Inf}_i(p_\rho) = \sum_{S \ni i} \hat{p}_\rho(S)^2$ ). It uses these computed influences to determine whether or not  $p_\rho$  is  $\tau$ -regular according to Definition 8 (recall that  $\tau = (\epsilon/d)^{O(d)}$ ).
2. If  $p_\rho$  is  $\tau$ -regular, then it runs the [12] deterministic PRG-based algorithm for Gaussian space (recall Table 2) to obtain a  $\pm\epsilon$ -accurate estimate of  $\mathbf{E}_{\mathbf{g} \sim N(0,1)^n}[\text{sign}(p_\rho(\mathbf{g}))]$ . (Recall that the [12] algorithm takes time  $n^{2^{O(d)} \cdot \text{poly}(1/\epsilon)}$ .) It sets  $v_\rho$  to be the output of this algorithm.
3. Otherwise, if  $p_\rho$  is not  $\tau$ -regular, it simply sets  $v_\rho$  to be the value  $\text{sign}(\mathbf{E}[p_\rho]) = \text{sign}(\hat{p}_\rho(\emptyset)) \in \{-1, 1\}$ .

The final value  $v$  returned by the algorithm is the average over all  $\rho \in \mathcal{R}$  of the values  $v_\rho$ .

From Equation (8) and item (2) above we have that the running time of the algorithm is

$$\exp\left(2^{O(d\sqrt{\log(d/\epsilon)})}\right) \cdot n^{2^{O(d)} \cdot \text{poly}(1/\epsilon)},$$

as claimed in Theorem 1. To conclude the proof it remains only to argue that  $v$  is indeed within an additive  $\pm O(\epsilon)$  of the true value of  $\mathbf{E}_{\mathbf{x} \leftarrow \{-1, 1\}^n}[\text{sign}(p(\mathbf{x}))]$ . Recalling Equation (3)

and the fact that at most an  $\epsilon$  fraction of restrictions  $\rho \in \mathcal{R}$  are such that neither is  $p_\rho$   $\tau$ -regular nor is  $\text{sign}(p_\rho)$   $\delta$ -close (i.e.  $\epsilon$ -close) to the constant function  $\text{sign}(\mathbf{E}[p_\rho])$ , using item (2) above it suffices to show that for every  $\rho$  such that  $p_\rho$  is  $\tau$ -regular, it holds that

$$\left| \mathbf{E}_{\mathbf{g} \sim N(0,1)} [\text{sign}(p_\rho(\mathbf{g}))] - \mathbf{E}_{\mathbf{x} \sim \{-1,1\}^n} [\text{sign}(p_\rho(\mathbf{x}))] \right| \leq O(\epsilon).$$

Since  $p_\rho$  is  $\tau$ -regular, we have that

$$\max_{i \in [n]} \text{Inf}_i(p_\rho) \leq \sqrt{\sum_{j=i}^n \text{Inf}_j(p_\rho)^2} \leq \tau \sum_{j=1}^n \text{Inf}_j(p_\rho) \leq \tau d \cdot \mathbf{Var}[p_\rho],$$

where the last inequality uses that the total influence of a degree- $d$  polynomial is at most  $d$  times its variance. Hence by the invariance principle (Theorem 7), we have that

$$\left| \mathbf{E}_{\mathbf{g} \sim N(0,1)} [\text{sign}(p_\rho(\mathbf{g}))] - \mathbf{E}_{\mathbf{x} \sim \{-1,1\}^n} [\text{sign}(p_\rho(\mathbf{x}))] \right| \leq O(d(\tau d)^{1/8d}) = O(\epsilon)$$

as desired, where the last inequality is by our choice of  $\tau = (\epsilon/d)^{O(d)}$ . This concludes the proof of Theorem 1.  $\blacktriangleleft$

### 4.3 Proof of Theorem 2

To prove Theorem 2, we must give a deterministic algorithm for  $\epsilon$ -approximate counting  $n$ -variable degree- $d$  PTFs over Boolean space that runs in time  $n^{O_{d,\kappa}(1/\epsilon)^\kappa}$ .

The first stage of the algorithm here is identical to the first stage of the algorithm in the previous subsection, with the same parameter settings and running time. The second stage differs only in item (2), where now in the  $\tau$ -regular case we run the [14] deterministic PRG-based algorithm for Gaussian space, which runs in time  $n^{O_{d,\kappa}(1/\epsilon)^\kappa}$ .

The analysis of correctness (showing that the output of this algorithm is  $\pm O(\epsilon)$ -close to the right value) is identical to the previous subsection. The running time of the algorithm is  $\exp(2^{O(d\sqrt{\log(d/\epsilon)})}) \cdot n^{O_{d,\kappa}(1/\epsilon)^\kappa}$ , where we recall that the function of  $d$  and  $1/\kappa$  hidden by the big-Oh notation is very fast-growing, in fact of Ackermann type. We now observe that the first component of the running time,  $\exp(2^{O(d\sqrt{\log(d/\epsilon)})})$ , is asymptotically dominated by the second  $n^{O_{d,\kappa}(1/\epsilon)^\kappa}$  component, which gives us the final claimed  $n^{O_{d,\kappa}(1/\epsilon)^\kappa}$  runtime. We establish this by comparing  $d$  and  $\epsilon$  as follows:

- If  $d$  is less than  $(\log(1/\epsilon))^{1/3}$ , then the first component  $\exp(2^{O(d\sqrt{\log(d/\epsilon)})})$  is less than  $\exp(2^{(\log(1/\epsilon))^{0.9}})$ , whereas the second expression is  $n^{O_{d,\kappa}(1) \cdot (1/\epsilon)^\kappa} \geq \exp(O_{d,\kappa}(1) \cdot (1/\epsilon)^\kappa)$ . For  $(1/\epsilon)^\kappa$  to be as small as  $2^{(\log(1/\epsilon))^{0.9}}$  we would need  $\kappa \leq (\log(1/\epsilon))^{-0.1}$ , but having  $\kappa$  be this small means that the  $O_{d,\kappa}(1)$  factor will make  $O_{d,\kappa}(1) \cdot (1/\epsilon)^\kappa$  much bigger than  $2^{(\log(1/\epsilon))^{0.9}}$ .
  - If  $d$  is larger than  $(\log(1/\epsilon))^{1/3}$ , then the first expression  $\exp(2^{O(d\sqrt{\log(d/\epsilon)})})$  is less than  $\exp(2^{d^3})$ , whereas the second expression is still at least  $\exp(O_{d,\kappa}(1) \cdot (1/\epsilon)^\kappa)$ . Irrespective of the value of  $\kappa$ , the  $O_{d,\kappa}(1)$  in this second expression asymptotically dominates  $\exp(2^{d^3})$ .
- This concludes the proof of Theorem 2.  $\blacktriangleleft$

## A Proof of Fact 6

Let  $p : \{-1, 1\}^n \rightarrow \mathbb{R}$  be a degree- $d$  multilinear polynomial normalized so that  $\mathbf{Var}[p]$  (which is equal to  $\sum_{\emptyset \neq S, |S| \leq d} \hat{p}(S)^2$ ) equals 1, and let  $\mathcal{D}$  be a  $4d$ -wise uniform distribution over  $\{-1, 1\}^n$ . We consider the mean-zero random variable  $p(\mathbf{z}) - \mathbf{E}[p(\mathbf{z})] = p(\mathbf{z}) - \hat{p}(\emptyset)$ , where  $\mathbf{z} \leftarrow \mathcal{D}$ . We have that  $\mathbf{E}[p(\mathbf{z})] = 0$ ,  $\mathbf{E}[p(\mathbf{z})^2] = \mathbf{Var}_{\mathbf{z}}[p(\mathbf{z})] = \mathbf{Var}_{\mathbf{x} \leftarrow \{-1, 1\}^n}[p(\mathbf{x})] = 1$ , and by Corollary 4 (derandomized (2,4)-Hypercontractivity), we further have that  $\mathbf{E}[p(\mathbf{z})^4] \leq 9^d \mathbf{E}[p(\mathbf{z})^2]^2 = 9^d$ . Fact 6 now follows from the following simple fact:

► **Fact 21** ([1], Lemma 3.2). *Let  $A$  be a real valued random variable satisfying  $\mathbf{E}[A] = 0$ ,  $\mathbf{E}[A^2] = 1$  and  $\mathbf{E}[A^4] \leq b$ . Then  $\Pr[A \geq 1/(4\sqrt{b})] \geq 1/(4^4/3b)$ .*

## B Proof of Lemma 13 and Lemma 14

### B.1 Proof of Lemma 13 (derandomized Lemma 5.2 of [8]: large critical index)

We express  $p(x)$  as  $q(x) + r(x) + \mathbf{E}[p]$ , where

$$q(x) = \sum_{S \not\subseteq K} \hat{p}(S) \chi_S(x) \quad \text{and} \quad r(x) = \sum_{\substack{S \subseteq K \\ S \neq \emptyset}} \hat{p}(S) \chi_S(x).$$

[8]'s Lemma 5.2 follows from the following two claims:

1. For every constant  $c$  there is a sufficiently large constant  $C_1$  such that if  $K := 2^{C_1 d} \log(1/\delta)/\tau^2$ , then

$$\mathbf{E}_{\rho \leftarrow \{-1, 1\}^K} [\mathbf{Var}(p_\rho)] \leq \delta \cdot 2^{-cd} \cdot \mathbf{E}_{\rho \leftarrow \{-1, 1\}^K} [r(\rho)^2]. \quad (9)$$

(This is [8]'s Claim 5.6.) Consequently, by Markov's inequality, for all constants  $c$  and  $c'$  we can again choose  $C_1$  to be sufficiently large to ensure that

$$\Pr_{\rho \leftarrow \{-1, 1\}^K} \left[ \mathbf{Var}(p_\rho) \leq \delta \cdot 2^{-cd} \cdot \mathbf{E}_{\rho \leftarrow \{-1, 1\}^K} [r(\rho)^2] \right] \geq 1 - 2^{-c'd}. \quad (10)$$

2. There are constants  $b$  and  $b'$  such that

$$\Pr_{\rho \leftarrow \{-1, 1\}^K} \left[ \mathbf{E}[p_\rho]^2 \geq 2^{-bd} \cdot \mathbf{E}_{\rho \leftarrow \{-1, 1\}^K} [r(\rho)^2] \right] \geq 2^{-b'd}, \quad (11)$$

which follows from an application of Lemma 5.4 of [8].

The proof of Lemma 13 follows [8]’s proof of their Lemma 5.2 almost exactly. The only changes are that:

- the functions  $\rho \mapsto \mathbf{Var}(p_\rho)$  and  $\rho \mapsto r(\rho)^2$  are degree  $2d$  polynomials in  $\rho$ , and hence Equations (9) and (10) both hold for  $\rho$  drawn from any  $2d$ -wise independent distribution over  $\{-1, 1\}^K$ ;
- we use our derandomized version of Lemma 5.4 of [8], namely Fact 6, in place of Lemma 5.4 of [8] to deduce that Equation (11) also holds for  $\rho$  drawn from any  $2d$ -wise independent distribution over  $\{-1, 1\}^K$ .

The rest of the proof is unchanged.

## B.2 Proof of Lemma 14 (derandomized Lemma 5.1 of [8]: small critical index)

The proof of Lemma 14 follows [8]’s proof of their Lemma 5.1 almost exactly. The only changes are that

- we use our derandomized version of (2,4)-Hypercontractivity, namely Corollary 4, in place of (2,4)-Hypercontractivity (Lemma 4.3 of [8], which is used in the line immediately following Equation (5.1) of their paper);
- we use our derandomized version of Lemma 5.4 of [8], namely Fact 6, in place of Lemma 5.4 of [8], which is used two lines after Equation (5.2) of their paper.

The rest of the proof is unchanged.

► **Remark 22 (Motivating our notion of regularity).** Recall from Section 1.4 that the works of [6, 18] use a technically slightly different notion of “regularity.” In those works an  $n$ -variable multivariate polynomial  $p$  is considered to be  $\tau$ -regular if for every  $i \in [n]$  we have that  $\text{Inf}_i(p) \leq \tau \cdot \sum_{i=1}^n \text{Inf}_i(p)$ . Intuitively, we may view this as a notion of “regularity-in- $\ell_\infty$ ”, and the notion used in the current paper and in [8, 19] as a notion of “regularity-in- $\ell_2$ ”.

We remark here that the small critical index case (the subject of Lemma 14 and of Lemma 5.1 of [8]) is the reason why we need to work with the [8] notion of regularity-in- $\ell_2$  given in Definition 8 rather than the regularity-in- $\ell_\infty$  notion used in [6, 18]. In more detail, to handle the small critical index case using the regularity-in- $\ell_\infty$  notion, the analysis of [6, 18] uses an exponential tail bound for degree- $d$  polynomials (the “degree- $d$  Chernoff bound”, see Theorem 9.23 of [21]). However, derandomizing this degree- $d$  Chernoff bound requires  $dq$ -wise uniform distributions, where  $q$  depends on the parameters with which the degree- $d$  Chernoff bound is being applied, and it turns out that because of the way that the [6, 18] arguments employ the degree- $d$  Chernoff bound, this can be prohibitively expensive in our context. In contrast, recall from Section 2.1 that derandomizing Theorem 3 and Fact 5 (which is all that is needed to establish a derandomized version of the small critical index case using the regularity-in- $\ell_2$  notion, as outlined above) can be done using only  $4d$ -wise uniformity.

# Improved Product-Based High-Dimensional Expanders

## Abstract

---

High-dimensional expanders generalize the notion of expander graphs to higher-dimensional simplicial complexes. In contrast to expander graphs, only a handful of high-dimensional expander constructions have been proposed, and no elementary combinatorial construction with near-optimal expansion is known. In this paper, we introduce an improved combinatorial high-dimensional expander construction, by modifying a previous construction of Liu, Mohanty, and Yang (ITCS 2020), which is based on a high-dimensional variant of a tensor product. Our construction achieves a spectral gap of  $\Omega(\frac{1}{k^2})$  for random walks on the  $k$ -dimensional faces, which is only quadratically worse than the optimal bound of  $\Theta(\frac{1}{k})$ . Previous combinatorial constructions, including that of Liu, Mohanty, and Yang, only achieved a spectral gap that is exponentially small in  $k$ . We also present reasoning that suggests our construction is optimal among similar product-based constructions.

## 1 Introduction

Graphs that are sparse but well connected, called expander graphs, have numerous applications in various areas of computer science (see for example [8]). Recently, there has been much interest in generalizing the notion of expansion to higher-dimensional simplicial complexes, beginning with the work of Lineal and Meshulam [12], Meshulam and Wallach [17], and Gromov [7]. While multiple notions of high-dimensional expansion have been introduced (see the survey by Lubotzky [14]), these notions agree in that random simplicial complexes are not good high-dimensional expanders. In contrast, ordinary random graphs are near-optimal expanders with high probability. Therefore constructions of high-dimensional expanders are of particular interest. Early constructions of high-dimensional expanders, namely Ramanujan complexes [16, 15], were quite mathematically involved, whereas more simple and combinatorial constructions have been introduced recently.

In this paper, we introduce a modification of the high-dimensional expander construction of Liu, Mohanty, and Yang [13], which is based on a sort of high-dimensional tensor product. We then show that this modification gives an exponential improvement in the dependence of the  $k$ th order spectral gap on the dimension  $k$ , and we discuss why our results suggest this modification is optimal among constructions with the same general product structure. These results also address a question posed by Liu et al. [13] pertaining to the limitations of their product-based construction.

## 1.1 High-dimensional expanders

A high-dimensional expander is a simplicial complex with certain expansion properties. A **simplicial complex** is a hypergraph with downward-closed hyperedges, called faces. That is, a simplicial complex  $X$  on  $n$  vertices is a collection of faces  $X \subset 2^{[n]}$ , where for any face  $\sigma \in X$ , all subsets of  $\sigma$  are also faces in  $X$ . The **dimension** of a face  $\sigma$  is  $\dim(\sigma) = |\sigma| - 1$ , and the dimension of  $X$  is the maximum dimension of any face in  $X$ . The **1-skeleton** of a simplicial complex is the undirected  $n$ -vertex graph whose edges are given by the 1-dimensional faces. We restrict attention to **pure** simplicial complexes, meaning that every face is contained in a face of maximal dimension.

We consider the notion of high-dimensional expansion introduced by Kaufman and Mass [9], which requires rapid mixing for the high-order “up-down” or “down-up” random walks on simplicial complexes. The  $k$ -dimensional up-down walk on a simplicial complex specifies transition probabilities for a walk that alternates between faces of dimension  $k$  and  $k + 1$ . The 0-dimensional up-down walk is an ordinary lazy random walk on the 1-skeleton of the simplicial complex. Therefore 1-dimensional expanders are just ordinary (spectral) expander graphs. The spectral gaps of higher-order walks are difficult to bound directly, so they are instead typically bounded using a line of work [9, 5, 10, 1], which has shown that a large spectral gap for high-order walks is implied by good local expansion, that is, good spectral expansion of a specific set of graphs that describe the local structure of the simplicial complex. Formal definitions of high-order walks and local expansion are provided in Section 2.

We are interested in constructions of infinite families of high-dimensional expanders with bounded degree and spectral gap for all dimensions. Specifically, for any fixed  $H \geq 1$ , a  **$H$ -dimensional expander family** is a family  $\mathcal{X}$  of  $H$ -dimensional simplicial complexes such that there is no finite upper bound on the number of vertices of elements  $X \in \mathcal{X}$ , and the following two properties hold:

1. Bounded degree: There exists some  $\bar{d} > 0$  such that for every  $X \in \mathcal{X}$ , each vertex in  $X$  belongs to at most  $\bar{d}$  faces.
2. Bounded spectral gap: There exists some  $\underline{\nu} > 0$  such that for every  $X \in \mathcal{X}$  and every  $0 \leq k \leq H - 1$ , the  $k$ -dimensional up-down walk on  $X$  has spectral gap  $\geq \underline{\nu}$ .

In general, the spectral gap of the  $k$ -dimensional up down walk cannot be greater than  $\frac{2}{k+2}$  (see for example Proposition 3.3 of [1]). Our goal is to prove good lower bounds for this spectral gap for specific constructions of  $H$ -dimensional expander families. That is, we are interested in the optimal relationship between dimension and spectral gap, and only require an arbitrary upper bound on degree. This goal differs from the study of expander graphs, and specifically Ramanujan graphs, which focuses on the optimal relationship between degree and spectral gap.

While Kaufman and Mass [9] showed that Ramanujan complexes are high-dimensional expanders, multiple more elementary constructions have since been introduced [3, 4, 2, 13, 11, 6]. However, only three of these constructions [13, 11, 6] provide constant-degree high-dimensional expander families of all dimensions. The construction of Kaufman and Oppenheim [11] and the hyper-regular variant introduced by Friedgut and Iluz [6] are based on coset geometries, and achieve near-optimal expansion in all dimensions. In contrast, the construction of Liu et al. [13] is much more elementary, as it consists of a sort of high-dimensional tensor product between an expander graph and a constant-sized complete simplicial complex. However, this construction has suboptimal expansion in high dimensions. Specifically, Alev and Lau [1] showed that the  $k$ -dimensional up-down walk on the  $H$ -dimensional construction of Liu et al. [13] has spectral gap at least  $\frac{c}{(k+2)^{2k+2}}$ , where  $1 \leq c \leq 2$  is a constant depending on  $H$  and on the expander graph used in the construction. Note that this bound has exponential dependence on  $k$ , in contrast to the optimal linear dependence  $\Omega(\frac{1}{k})$ .

## 1.2 Contributions

In this paper, we present a modification of the high-dimensional expander family of Liu et al. [13], for which we show that the spectral gap of the  $k$ -dimensional up-down walk is at least  $\frac{1}{(1+\log H)(k+2)(k+1)}$ . This quadratic dependence on  $k$  provides an exponential improvement compared to the spectral gap bound of  $\frac{c}{(k+2)2^{k+2}}$  for the construction of Liu et al. [13]. We attain this exponential improvement using the same product structure as Liu et al. [13] while adjusting the weights of faces. Our modified construction also yields improved local expansion in high dimensions. For every  $1 \leq k \leq H - 2$ , we show that the 1-skeleton of the link of any  $k$ -dimensional face in our construction has spectral gap at least  $\frac{k+1}{k+2}$ , an improvement over the analogous bound of  $\frac{1}{2}$  for the construction of Liu et al. [13].

The organization of the remainder of this paper is as follows. Section 2 presents preliminary notions, and Section 3 presents our main construction along with some basic properties. In Section 4, we compute the local expansion of the construction, from which a result of Alev and Lau [1] implies rapid mixing of high-order walks. Section 5 discusses potential generalizations and limitations.

## 2 Background and preliminaries

This section provides basic definitions pertaining to simplicial complexes and high-dimensional expanders, as well as relevant past results.

► **Definition 1.** A *simplicial complex*  $X$  on  $n$  vertices is a subset  $X \subset 2^{[n]}$  such that if  $\sigma \in X$ , then all subsets of  $\sigma$  also belong to  $X$ . Let  $X(k) = \{\sigma \in X : |\sigma| = k + 1\}$ , and let the  *$k$ -skeleton* of  $X$  refer to the simplicial complex  $\bigcup_{\ell \leq k} X(\ell)$ . The elements of  $X(k)$  will be referred to as  *$k$ -dimensional faces*. The *dimension* of a simplicial complex is the maximum dimension of any of its faces, and if each face is contained in a face of maximal dimension, then the complex is *pure*. A *balanced weight function*  $m : X \rightarrow \mathbb{R}_+$  on a pure simplicial complex  $X$  is a function such that for every  $-1 \leq k < \dim(X)$  and every  $\sigma \in X(k)$ ,

$$m(\sigma) = \sum_{\tau : \sigma \subset \tau \in X(k+1)} m(\tau).$$

The 1-skeleton of a simplicial complex  $X$  with balanced weight function  $m$  is the undirected weighted graph  $(X(0), X(1), m)$  that has vertices  $[n] = X(0)$ , edges  $X(1)$ , and edge weights  $m(e)$  for  $e \in X(1)$ . The weighted degree of a vertex  $x$  in this graph is given by the weight  $m(x)$ .

This paper will restrict attention to pure weighted simplicial complexes with balanced weight functions. In this case, the faces and weight function may be defined only on faces of maximal dimension, then propagated downwards, and the following useful formula applies.

► **Lemma 2** ([18]). For every  $H$ -dimensional simplicial complex  $X$ , every  $-1 \leq k \leq H$ , and every  $\sigma \in X(k)$ ,

$$m(\sigma) = (H - k)! \sum_{\tau : \sigma \subset \tau \in X(H)} m(\tau).$$

Just as ordinary expander graph families are specified to have bounded degree, we are interested in families of simplicial complexes satisfying an analogous notion:

► **Definition 3.** A family  $\mathcal{X}$  of simplicial complexes has **bounded degree** if there exists some constant  $\bar{d}$  such that for every  $X \in \mathcal{X}$  and every vertex  $x \in X(0)$ , there are at most  $\bar{d}$  faces in  $X$  that contain  $x$ .

The local properties of a simplicial complex are captured by the links of faces, defined below.

► **Definition 4.** For a simplicial complex  $X$  with weight function  $m$ , the **link**  $X_\sigma$  of any  $\sigma \in X$  is the simplicial complex defined by  $X_\sigma = \{\tau \setminus \sigma : \sigma \subset \tau \in X\}$  with weight function  $m_\sigma(\tau \setminus \sigma) = m(\tau)$ .

A common theme in the study of high-dimensional expanders is the “local-to-global” paradigm, which uses bounds on the expansion of the 1-skeletons of links to prove global expansion properties. To state such local-to-global results, it is first necessary to define graph expansion.

► **Definition 5.** For a graph  $G$ , the adjacency matrix is denoted  $M_G$ , the diagonal degree matrix is denoted  $D_G$ , and the random walk matrix is denoted  $W_G = M_G D_G^{-1}$ . The eigenvalues of the random walk matrix are denoted from greatest to least by  $\omega_i(G) = \omega_i(W_G)$ . The **expansion**, or **spectral gap**, of  $G$  is the quantity  $\nu_2(G) = \nu_2(W_G) = 1 - \omega_2(G)$ .

For any  $n$ -vertex graph  $G$ , all eigenvalues  $\omega_i(W_G)$  of the random walk matrix lie in  $[-1, 1]$ , and  $\omega_1(W_G) = 1$ , so  $0 \leq \nu_2(G) \leq 1 + \frac{1}{n-1}$  because  $\sum_i \omega_i(W_G) = \text{Tr}(W_G) \geq 0$ . Graphs with spectral gaps closer to 1 are considered “better” expanders.

We now introduce a notion of expansion for simplicial complexes.

► **Definition 6.** For  $-1 \leq k \leq H - 2$ , the  **$k$ -dimensional local expansion** of a simplicial complex  $X$  with weight function  $m$  is the value

$$\nu^{(k)}(X) = \min_{\sigma \in X(k)} \nu_2(X_\sigma(0), X_\sigma(1), m_\sigma).$$

The **local expansion** of  $X$  is the minimum of the  $k$ -dimensional local expansion over all  $k \geq 0$ , while the **global expansion** equals the  $(-1)$ -dimensional local expansion.

That is, the  $k$ -dimensional local expansion refers to the lowest expansion of the 1-skeleton of the link of any  $k$ -dimensional face. Note that the terminology  $k$ -dimensional local expansion is nonstandard, but will be useful here. The following result shows that good local expansion in higher dimensions implies good local expansion in lower dimensions.

► **Proposition 7 ([18]).** Let  $X$  be a simplicial complex in which all links of dimension  $\geq 1$  are connected. Then for every  $0 \leq k \leq \dim(X) - 2$ ,

$$\nu^{(k-1)}(X) \geq 2 - \frac{1}{\nu^{(k)}(X)}.$$

In particular, Proposition 7 implies that if  $\nu^{(k)}(X) \geq 1 - \epsilon$ , then  $\nu^{(k-1)}(X) \geq 1 - O(\epsilon)$ .

The definition below presents the high-order random walks on simplicial complexes.

► **Definition 8.** Fix a pure  $H$ -dimensional simplicial complex  $X$ . For  $-1 \leq k \leq H - 1$ , define the **up-step random walk operator**  $W_k^\uparrow \in \mathbb{R}^{X(k+1) \times X(k)}$  so that for  $\sigma \in X(k)$ ,  $\tau \in X(k+1)$ ,

$$W_k^\uparrow(\tau, \sigma) = \begin{cases} \frac{m(\tau)}{m(\sigma)}, & \sigma \subset \tau \in X(k+1) \\ 0, & \text{otherwise} \end{cases}$$

For  $0 \leq k \leq H$ , define the **down-step random walk operator**  $W_k^\downarrow \in \mathbb{R}^{X(k-1) \times X(k)}$  so that for  $\sigma \in X(k), \tau \in X(k-1)$ ,

$$W_k^\downarrow(\tau, \sigma) = \begin{cases} \frac{1}{k+1}, & \sigma \supset \tau \in X(k-1) \\ 0, & \text{otherwise.} \end{cases}$$

Define the **up-down and down-up random walk operators** by  $W_k^{\uparrow\downarrow} = W_{k+1}^\downarrow \circ W_k^\uparrow$  and  $W_k^{\downarrow\uparrow} = W_{k-1}^\uparrow \circ W_k^\downarrow$  respectively.

For context with this definition, consider a 1-dimensional simplicial complex  $X$ , which may be viewed as a weighted, undirected graph. Then the up-step operator  $W_0^\uparrow$  moves from a vertex to an adjacent edge with probability proportional to its weight, while the down-step operator  $W_1^\downarrow$  moves from an edge to either of its vertices with probability  $\frac{1}{2}$ . Thus  $W_0^{\uparrow\downarrow} = W_1^\downarrow \circ W_0^\uparrow$  is the ordinary graph lazy random walk operator, with stationary probability  $\frac{1}{2}$ .

The nonzero elements of the spectra of  $W_k^{\uparrow\downarrow}$  and of  $W_{k+1}^{\downarrow\uparrow}$  are identical. Therefore when studying the expansion of these operators, we restrict attention without loss of generality to  $W_k^{\uparrow\downarrow}$ .

The spectral gap  $\nu_2(W_k^{\uparrow\downarrow})$  gives a measure of high-dimensional expansion. Local expansion, defined above, provides another notion of high-dimensional expansion. The following result, which follows the ‘‘local-to-global’’ paradigm, shows that these two notions are closely related.

► **Theorem 9** ([1]). *Let  $X$  be an  $H$ -dimensional simplicial complex, and let  $W_k^{\uparrow\downarrow}$  refer to the up-down walk operator on  $X$ . Then for every  $0 \leq k \leq H-1$ ,*

$$\nu_2(W_k^{\uparrow\downarrow}) \geq \frac{1}{k+2} \prod_{j=-1}^{k-1} \nu^{(j)}(X).$$

Thus if a simplicial complex has good local expansion, then its high-order walks have large spectral gaps. We apply this result to show our main high-dimensional expansion bound.

The bound in Theorem 9 is nearly tight for good local expanders:

► **Proposition 10** ([1]). *Let  $X$  be an  $H$ -dimensional simplicial complex with at least  $2(H+1)$  vertices, and let  $W_k^{\uparrow\downarrow}$  refer to the up-down walk operator on  $X$ . Then for every  $0 \leq k \leq H-1$ ,*

$$\nu_2(W_k^{\uparrow\downarrow}) \leq \frac{2}{k+2}.$$

The main purpose of this paper is to present a construction of high-dimensional expander families, defined below.

► **Definition 11.** *A family  $\mathcal{X}$  of  $H$ -dimensional simplicial complexes is an  **$H$ -dimensional expander family** if the following conditions hold:*

1. *For every  $n \in \mathbb{N}$ , there exists some  $X \in \mathcal{X}$  with  $|X(0)| \geq n$ .*
2.  *$\mathcal{X}$  has bounded degree.*
3. *For every  $0 \leq k \leq H-1$ , there exists some  $\underline{\nu}_{\mathcal{X},k} > 0$  such that for every  $X \in \mathcal{X}$ , the  $k$ -dimensional up-down walk operator  $W_k^{\uparrow\downarrow}$  on  $X$  satisfies  $\nu_2(W_k^{\uparrow\downarrow}) \geq \underline{\nu}_{\mathcal{X},k}$ .*

We are interested in constructing high-dimensional expander families  $\mathcal{X}$  of all dimensions  $H$  with the up-down walk spectral gaps  $\underline{\nu}_{\mathcal{X},k}$  close to the upper bound in Proposition 10. By Theorem 9, item 3 in Definition 11 is implied by a uniform lower bound on the local expansion  $\nu^{(k)}(X)$  of all  $X \in \mathcal{X}$  for every  $-1 \leq k \leq H-1$ . We use this fact in the analysis of our construction.

### 3 Construction

The following definition introduces the simplicial complex  $Z$  with weight function  $m$  considered in this paper. The construction takes as input an  $n$ -vertex graph  $G$ , which will typically be chosen from a family of expanders, as well as a dimension  $H$  and a parameter  $s \geq H + 1$ , the latter of which will typically be taken as  $s = 2H$ . The parameters  $H$  and  $s$  will typically be treated as fixed values, while  $G$  and  $n$  vary, so that the construction provides a family of  $H$ -dimensional simplicial complexes.

► **Definition 12.** Let  $G = (V(G), E(G), w_G)$  be any connected undirected graph on  $n$  vertices with no self-loops. For positive integers  $H$  and  $s$ , define the  $H$ -dimensional simplicial complex  $Z$  with vertex set  $V(G) \times [s]$  such that

$$Z(H) = \{(v_1, b_1), \dots, (v_{H+1}, b_{H+1})\} \subset V(G) \times [s] : \\ \exists \{u, v\} \in E(G) \text{ s.t. } \{v_1, \dots, v_{H+1}\} = \{u, v\} \text{ and } b_1, \dots, b_{H+1} \text{ are all distinct}\}.$$

Define a weight function  $m$  on  $Z$  so that if  $\sigma = \{(v_1, b_1), \dots, (v_{H+1}, b_{H+1})\} \in Z(H)$  is such that  $|\{i : v_i = u\}| = j$  and  $|\{i : v_i = v\}| = H + 1 - j$  for some edge  $\{u, v\} \in E(G)$ , then let

$$m(\sigma) = \frac{w_G(\{u, v\})}{\binom{H-1}{j-1}}.$$

In words, the  $H$ -dimensional faces of  $Z$  are those sets of the form  $\{(v_1, b_1), \dots, (v_{H+1}, b_{H+1})\}$  such that all  $v_i$  are contained in a single edge of  $G$ , and such that all  $b_i$  are distinct. If the above definition is modified so that the condition  $\{v_1, \dots, v_{H+1}\} = \{u, v\}$  is replaced with  $\{v_1, \dots, v_{H+1}\} \subset \{u, v\}$  and so that  $m(\sigma) = 1$  for all  $H$ -dimensional faces  $\sigma$ , then the resulting simplicial complex  $Q$  is exactly the construction of Liu et al. [13]. The difference between the weight functions of  $Z$  and  $Q$  lead to the key insights of this paper. Also note that here  $G$  may be a weighted graph, whereas Liu et al. [13] only considered complexes  $Q$  derived from unweighted graphs.

If  $G$  is unweighted so that  $w_G(\{u, v\}) = 1$  for all  $\{u, v\} \in E(G)$ , then every  $\sigma \in Z$  has  $(H - 1)!m(\sigma) \in \mathbb{N}$ . Thus  $Z$  may be viewed as an unweighted simplicial complex, meaning that all  $H$ -dimensional faces have the same weight, but where multiple copies of faces are permitted.

The simplicial complex  $Z$  may be viewed as a sort of high-dimensional tensor product of the graph  $G$  and the  $s$ -vertex,  $H$ -dimensional complete complex  $\mathcal{K}_{[s]}$ . In particular, the faces in  $Z(H)$  are exactly those  $(H + 1)$ -element subsets of  $V(G) \times [s]$  for which the projection onto the first component gives an edge in  $G$ , and the projection onto the second component gives a face in  $\mathcal{K}_{[s]}(H)$ . For comparison, an analogous property holds for the ordinary graph tensor product  $G_1 \otimes G_2$ , in which the edges are given by those pairs of elements of  $V(G_1) \times V(G_2)$  whose projection onto either component gives an edge in the respective graph  $G_1$  or  $G_2$ .

Note that as with  $Q$ , the simplicial complex  $Z$  has bounded degree with respect to  $n$  if  $G$  has bounded degree. In particular, fix some values  $H$  and  $s$ , and let  $G$  be chosen from a family of bounded degree graphs. For every  $\{u, v\} \in E(G)$  and  $1 \leq j \leq H$ , by definition

$$|\{\sigma = \{(v_1, b_1), \dots, (v_{H+1}, b_{H+1})\} \in Z(H) : |\{i : v_i = u\}| = j\}| = \binom{s}{H+1} \binom{H+1}{j}. \quad (1)$$

It follows by the definition of  $m$  that both the maximum weight and the maximum number of faces containing any face in  $Z$  are bounded by a constant. Furthermore, the number of faces in  $Z$  grows as  $O(n)$ .

An additional consequence of Equation (1) is that while the cardinality of the set on the left hand side, which equals the sum of the weights of the faces in this set under the weight function of  $Q$ , has an exponential dependence on  $j$ , the sum of the weights of the faces in this set under the weight function of  $Z$  is equal to  $\binom{s}{H+1} \binom{H+1}{j} / \binom{H-1}{j-1}$ , which has only a quadratic dependence on  $j$ . This observation provides some initial intuition for the exponential speedup of high-order walks on  $Z$  compared to  $Q$ .

From here on, the weight function  $m$  and the operators  $W_k^\uparrow, W_k^\downarrow, W_k^{\uparrow\downarrow}, W_k^{\downarrow\uparrow}$  will always refer to  $Z$ , unless explicitly stated otherwise.

### 3.1 Main result

Our main result, shown in Section 4, is stated below.

► **Theorem 13** (Restatement of Corollary 19). *Let  $W_k^{\uparrow\downarrow}$  be the up-down walk operator for the simplicial complex  $Z$  of Definition 12. If  $H \geq 2$ ,  $s \geq 2H$ , and  $n \geq 4$ , then for every  $0 \leq k \leq H - 1$ ,*

$$\nu_2(W_k^{\uparrow\downarrow}) \geq \frac{\nu_2(G)}{(1 + \log H)(k + 2)(k + 1)}.$$

In contrast to this quadratic dependence on  $k$ , Alev and Lau [1] showed that the spectral gap of the  $k$ -dimensional up-down walk on  $Q$  is at least  $\frac{c\nu_2(G)}{(k+2)2^{k+2}}$ , where  $c = c(G, H) \in [1, 2]$  depends on the structure of  $G$ . The discussion in Section 3.3 below provides intuition for why this exponential dependence in  $k$  arises for  $Q$ , and how the adjusted weights in  $Z$  yield the improved quadratic dependence.

Theorem 3.1 implies that for any fixed  $H$  with  $s = 2H$ , if  $G$  is chosen from a family of bounded degree expanders with spectral gap  $\nu > 0$ , the resulting simplicial complexes  $Z$  form a family of  $H$ -dimensional expanders with  $k$ -dimensional up-down walk spectral gap at least  $\frac{\nu}{(1+\log H)(k+2)(k+1)}$ . For comparison, an optimal  $H$ -dimensional expander family, as is given by simplicial complexes with optimal local expansion by Theorem 9, achieves a spectral gap of  $\Omega(\frac{1}{k})$  for the  $k$ -dimensional up-down walk.

### 3.2 Decomposition into permutation-invariant subsets

This section formalizes the intuitive notion that the construction of  $Z$  treats elements of  $[s]$  interchangeably, and introduces some notation to reflect this symmetry. For any  $1 \leq k \leq H + 1$ , the set of  $(k - 1)$ -dimensional faces  $Z(k - 1)$  may be decomposed as follows. For any  $\{u, v\} \in E(G)$  and  $0 \leq j \leq k$ , let

$$Z((j, k - j)_{(u, v)}) = \{ \{(v_1, b_1), \dots, (v_k, b_k)\} \in Z(H) : |\{i : v_i = u\}| = j, |\{i : v_i = v\}| = k - j \}$$

be the set of all  $(k - 1)$ -dimensional faces in  $Z$  that contain  $j$  vertices in  $\{u\} \times [s]$  and  $k - j$  vertices in  $\{v\} \times [s]$ . To remove redundancy when  $j = k$ , let

$$Z((k)_u) = Z((k, 0)_{(u, v)}).$$

Then by construction,

$$Z(k - 1) = \bigsqcup_{u \in V(G)} Z((k)_u) \sqcup \bigsqcup_{\{u, v\} \in E(G), 1 \leq j \leq k - 1} Z((j, k - j)_{(u, v)}).$$

This decomposition simply partitions  $Z$  into faces that differ only by permutations of  $[s]$ :

## 38:8 Improved Product-Based High-Dimensional Expanders

► **Lemma 14.** *For every  $1 \leq k \leq H + 1$ , there is a group action of  $S_{[s]} = \{\text{permutations } \pi : [s] \rightarrow [s]\}$  on the set of faces of  $Z$  given by*

$$\pi(\{(v_1, b_1), \dots, (v_k, b_k)\}) = \{(v_1, \pi(b_1)), \dots, (v_k, \pi(b_k))\}.$$

*The orbits of this action are exactly the sets  $Z((j, k - j)_{(u,v)})$ . The action preserves weights, that is,  $m \circ \pi = m$ .*

**Proof.** The construction of  $Z$  directly implies that for all  $\pi$ , if  $\sigma \in Z$  then  $\pi(\sigma) \in Z$ , so the group action on  $Z$  is well defined. Similarly, for all  $\pi$ , the definition of  $Z((j, k - j)_{(u,v)})$  directly implies that  $\pi(Z((j, k - j)_{(u,v)})) = Z((j, k - j)_{(u,v)})$ . For any  $\sigma = \{(v_1, b_1), \dots, (v_k, b_k)\}$ ,  $\sigma' = \{(v'_1, b'_1), \dots, (v'_k, b'_k)\} \in Z((j, k - j)_{(u,v)})$ , if  $\pi \in S_{[s]}$  is any permutation such that  $\pi(\{b_i : v_i = u\}) = \{b'_i : v'_i = u\}$  and  $\pi(\{b_i : v_i = v\}) = \{b'_i : v'_i = v\}$ , then  $\pi(\sigma) = \sigma'$ . Thus  $Z((j, k - j)_{(u,v)})$  is the orbit of  $\sigma$  under the group action. For any  $\pi$ , to verify that  $m \circ \pi = m$ , note that by definition  $m$  is constant over all values of  $Z((j, H + 1 - j)_{(u,v)})$  for any given  $0 \leq j \leq H + 1$  and  $\{u, v\} \in E(G)$ . Thus for all  $\sigma \in Z(H)$ , the characterization of the orbits above implies that  $m(\pi(\sigma)) = m(\sigma)$ . This equality then extends to  $\sigma$  of any dimension by Lemma 2. ◀

Loosely speaking, Lemma 14 says that elements of  $Z((j, k - j)_{(u,v)})$  may be treated interchangeably, which in particular permits the following definition.

► **Definition 15.** *For all  $1 \leq k \leq H + 1$ ,  $0 \leq j \leq k$ , and  $\{u, v\} \in E(G)$ , choose any  $\sigma \in Z((j, k - j)_{(u,v)})$  and define  $w_{(u,v)}^{(j,k-j)} = m(\sigma)$ . This definition does not depend on the choice of  $\sigma \in Z((j, k - j)_{(u,v)})$  by Lemma 14. To avoid redundancy, also define  $w_{(u,v)}^{(k)} = w_{(u,v)}^{(k,0)}$ .*

Note that  $m$  is defined by letting  $w_{(u,v)}^{(j,H+1-j)} = w_G(\{u, v\}) / \binom{H-1}{j-1}$ . A basic property of these weights is that for any  $1 \leq j \leq k - 1$ , the ratio  $w_{(u,v)}^{(j,k-j)} / w_G(\{u, v\})$  is independent of the choice of edge  $\{u, v\} \in E(G)$ , as is shown below.

► **Lemma 16.** *For all  $2 \leq k \leq H + 1$ ,  $1 \leq j \leq k - 1$ , and  $\{u, v\} \in E(G)$ ,*

$$\frac{w_{(u,v)}^{(j,k-j)}}{w_G(\{u, v\})} = (H + 1 - k)! \sum_{\ell=0}^{H+1-k} \binom{s-k}{\ell} \binom{s-k-\ell}{H+1-k-\ell} \cdot \frac{1}{\binom{H-1}{j+\ell-1}}.$$

**Proof.** For any  $\sigma \in Z((j, k - j)_{(u,v)})$ , any  $H$ -dimensional face  $\tau \supset \sigma$  must satisfy  $\tau \in Z((j + \ell, H + 1 - j - \ell)_{(u,v)})$  for some  $0 \leq \ell \leq H + 1 - k$ . Therefore by Lemma 2,

$$\begin{aligned} \frac{m(\sigma)}{w_G(\{u, v\})} &= \frac{(H + 1 - k)! \sum_{\ell=0}^{H+1-k} \sum_{\sigma \subset \tau \in Z((j+\ell, H+1-j-\ell)_{(u,v)})} m(\tau)}{w_G(\{u, v\})} \\ &= (H + 1 - k)! \sum_{\ell=0}^{H+1-k} \binom{s-k}{\ell} \binom{s-k-\ell}{H+1-k-\ell} \cdot \frac{1}{\binom{H-1}{j+\ell-1}}, \end{aligned}$$

where the final equality holds because there are exactly  $\binom{s-k}{\ell} \binom{s-k-\ell}{H+1-k-\ell}$  elements  $\tau \in Z((j + \ell, H + 1 - j - \ell)_{(u,v)})$  such that  $\tau \supset \sigma$ , and for each one  $m(\tau) = w_{(u,v)}^{(j+\ell, H+1-j-\ell)} = w_G(\{u, v\}) / \binom{H-1}{j+\ell-1}$  by definition. ◀

### 3.3 Relative weights of overlapping faces

The proposition below determines the relative weights of faces of  $Z$  that intersect at all but one of their vertices. This result is used in Section 4 to determine the local expansion of  $Z$ .

► **Proposition 17.** *For all  $1 \leq k \leq H$ ,  $1 \leq j \leq k - 1$ , and  $\{u, v\} \in E(G)$ , it holds that*

$$\frac{w_{(u,v)}^{(j+1,k-j)}}{w_{(u,v)}^{(j,k-j+1)}} = \frac{j}{k-j}.$$

Furthermore,

$$\frac{w_{(u)}^{(k+1)}}{\sum_{v \in N(u)} w_{(u,v)}^{(k,1)}} = k \sum_{i=k+1}^H \frac{1}{i}.$$

**Proof.** Both statements are shown using induction. For the first equality, the base case  $k = H$  follows by the definition of  $w_{(u,v)}^{(j,H+1-j)} = w_G(\{u, v\}) / \binom{H-1}{j-1}$ , so that

$$\frac{w_{(u,v)}^{(j+1,H-j)}}{w_{(u,v)}^{(j,H-j+1)}} = \frac{\binom{H-1}{j-1}}{\binom{H-1}{j}} = \frac{j}{H-j}.$$

For the inductive step, assume for some  $1 \leq k \leq H - 1$  that it holds for all  $1 \leq j \leq k$  that  $w_{(u,v)}^{(j+1,k+1-j)} / w_{(u,v)}^{(j,k+2-j)} = j / (k+1-j)$ . For any  $1 \leq j \leq k-1$  and any  $\sigma \in Z((j+1, k-j)_{(u,v)})$ , by definition any  $(k+1)$ -dimensional face  $\tau \supset \sigma$  is obtained from  $\sigma$  by adding either a vertex in  $\{u\} \times ([s] \setminus \Pi_{[s]}(\sigma))$  or in  $\{v\} \times ([s] \setminus \Pi_{[s]}(\sigma))$ . Therefore

$$\begin{aligned} w_{(u,v)}^{(j+1,k-j)} &= m(\sigma) = \sum_{\sigma \subset \tau \in Z(k+1)} m(\tau) \\ &= \sum_{\sigma \subset \tau \in Z((j+2,k-j)_{(u,v)})} m(\tau) + \sum_{\sigma \subset \tau \in Z((j+1,k-j+1)_{(u,v)})} m(\tau) \\ &= (s-k-1)w_{(u,v)}^{(j+2,k-j)} + w_{(u,v)}^{(j+1,k-j+1)}. \end{aligned} \quad (2)$$

Applying the exact same reasoning to a face  $\sigma' \in Z((j, k-j+1)_{(u,v)})$  gives that

$$w_{(u,v)}^{(j,k-j+1)} = m(\sigma') = (s-k-1)w_{(u,v)}^{(j+1,k-j+1)} + w_{(u,v)}^{(j,k-j+2)}.$$

Therefore

$$\begin{aligned} \frac{w_{(u,v)}^{(j+1,k-j)}}{w_{(u,v)}^{(j,k-j+1)}} &= \frac{(s-k-1)w_{(u,v)}^{(j+2,k-j)} + w_{(u,v)}^{(j+1,k-j+1)}}{(s-k-1)w_{(u,v)}^{(j+1,k-j+1)} + w_{(u,v)}^{(j,k-j+2)}} \\ &= \frac{w_{(u,v)}^{(j+2,k-j)} / w_{(u,v)}^{(j+1,k-j+1)} + 1}{1 + w_{(u,v)}^{(j,k-j+2)} / w_{(u,v)}^{(j+1,k-j+1)}} \\ &= \frac{(j+1)/(k-j) + 1}{1 + (k-j+1)/j} \\ &= \frac{j}{k-j}, \end{aligned}$$

completing the inductive step; note that the third equality above holds by the inductive hypothesis.

## 38:10 Improved Product-Based High-Dimensional Expanders

To show the second equality in the proposition statement, first note that the base case  $k = H$  holds immediately as  $w_{(u)}^{(H+1)} = 0$  because the definition of the complex  $Z$  does not include, or equivalently assigns zero weight, to faces in  $Z((H+1)_{(u)})$ . For the inductive step, assume that for some  $1 \leq k \leq H-1$  it holds that  $w_{(u)}^{(k+2)} / \sum_{v \in N(u)} w_{(u,v)}^{(k+1,1)} = (k+1) \sum_{i=k+2}^H \frac{1}{i}$ . For any  $\sigma \in Z((k+1)_{(u)})$ , by definition any  $(k+1)$ -dimensional face  $\tau \supset \sigma$  is obtained from  $\sigma$  by adding either a vertex in  $\{u\} \times ([s] \setminus \Pi_{[s]}(\sigma))$  or in  $\{v\} \times ([s] \setminus \Pi_{[s]}(\sigma))$  for some  $v \in N(u)$ . Therefore

$$\begin{aligned} w_{(u)}^{(k+1)} = m(\sigma) &= \sum_{\sigma \subset \tau \in Z(k+1)} m(\tau) \\ &= \sum_{\sigma \subset \tau \in Z((k+2)_{(u)})} m(\tau) + \sum_{v \in N(u)} \sum_{\sigma \subset \tau \in Z((k+1,1)_{(u,v)})} m(\tau) \\ &= (s-k-1) \left( w_{(u)}^{(k+2)} + \sum_{v \in N(u)} w_{(u,v)}^{(k+1,1)} \right). \end{aligned}$$

Applying (2) with  $j = k-1$  gives that

$$\sum_{v \in N(u)} w_{(u,v)}^{(k,1)} = (s-k-1) \left( \sum_{v \in N(u)} w_{(u,v)}^{(k+1,1)} + \sum_{v \in N(u)} w_{(u,v)}^{(k,2)} \right).$$

Therefore

$$\begin{aligned} \frac{w_{(u)}^{(k+1)}}{\sum_{v \in N(u)} w_{(u,v)}^{(k,1)}} &= \frac{(s-k-1) \left( w_{(u)}^{(k+2)} + \sum_{v \in N(u)} w_{(u,v)}^{(k+1,1)} \right)}{(s-k-1) \left( \sum_{v \in N(u)} w_{(u,v)}^{(k+1,1)} + \sum_{v \in N(u)} w_{(u,v)}^{(k,2)} \right)} \\ &= \frac{w_{(u)}^{(k+2)} / \left( \sum_{v \in N(u)} w_{(u,v)}^{(k+1,1)} \right) + 1}{1 + \left( \sum_{v \in N(u)} w_{(u,v)}^{(k,2)} \right) / \left( \sum_{v \in N(u)} w_{(u,v)}^{(k+1,1)} \right)} \\ &= \frac{(k+1) \sum_{i=k+2}^H \frac{1}{i} + 1}{1 + 1/k} \\ &= k \sum_{i=k+1}^H \frac{1}{i}, \end{aligned}$$

completing the inductive step; note that the third equality above holds by the inductive hypothesis, and because  $w_{(u,v)}^{(k,2)} = w_{(u,v)}^{(k+1,1)} / k$  for all  $v \in N(u)$  as was shown above. ◀

Proposition 17 provides the key insight for understanding why the spectral gap of the up-down walk on  $Z$  has a quadratic dependence in  $k$ , whereas that of  $Q$  has an exponential dependence. For some  $2 \leq k \leq H$ ,  $1 \leq j \leq k-1$ ,  $\{u, v\} \in E(G)$ , consider an element  $\sigma \in Z((j, k-j)_{(u,v)})$ . Let  $\sigma' \sim W_{k-1}^{\uparrow \downarrow} \mathbf{1}_\sigma$  be the random variable for the face obtained by taking one step in the up-down walk starting at  $\sigma$ . Then  $\sigma' \in Z((j', k-j')_{(u,v)})$  for some  $j' \in \{j+1, j, j-1\}$ . Let  $\Pi_{[s]}(\sigma)$  denote the subset of  $[s]$  obtained by projecting the elements of  $\sigma$  to their second components. If  $j' = j+1$ , then the up step must add some vertex in  $\{u\} \times ([s] \setminus \Pi_{[s]}(\sigma))$  and the down step must remove some vertex in  $(\{v\} \times [s]) \cap \sigma$ , while if  $j' = j-1$  then the up step must add some vertex in  $\{v\} \times ([s] \setminus \Pi_{[s]}(\sigma))$  and the down step must remove some vertex in  $(\{u\} \times [s]) \cap \sigma$ . Thus by the definition of the up- and down-step

transition probabilities,

$$\begin{aligned}\Pr[j' = j + 1] &= \frac{w_{(u,v)}^{(j+1,k-j)}}{w_{(u,v)}^{(j+1,k-j)} + w_{(u,v)}^{(j,k-j+1)}} \cdot \frac{k-j}{k+1} \\ \Pr[j' = j - 1] &= \frac{w_{(u,v)}^{(j,k-j+1)}}{w_{(u,v)}^{(j+1,k-j)} + w_{(u,v)}^{(j,k-j+1)}} \cdot \frac{j}{k+1}.\end{aligned}\tag{3}$$

For the construction  $Q$  of Liu et al. [13], these same expressions hold, but  $w_{(u,v)}^{(j+1,k-j)} = w_{(u,v)}^{(j,k-j+1)}$ , so that when  $j$  is close to 1 or close to  $k$ , the transition probabilities in (3) are heavily skewed to push  $j'$  in the direction of  $k/2$ . It is this property that results in an exponential dependence on  $k$  in the  $k$ th order up-down walk on  $Q$ ; the up-down walk becomes “trapped” in the set of faces contained in  $\{u, v\} \times [s]$ , with the transition probabilities pushing away from the “exit routes”  $Z((k)_{(u)})$  and  $Z((k)_{(v)})$ .

To understand why the weight function  $m$  on  $Z$  resolves this issue, observe that for  $Z$ , Proposition 17 implies that both probabilities in (3) equal  $\frac{j(k-j)}{k(k+1)}$ . Therefore the events  $j' = j + 1$  and  $j' = j - 1$  are equally likely. Thus the up-down walk moves across the sets  $Z((j, k-j)_{(u,v)})$  for  $1 \leq j \leq k-1$  as a lazy random walk on an unweighted, undirected,  $(k-1)$ -vertex path. The mixing time for such a walk grows quadratically in  $k$ , thereby providing intuition for the quadratic dependence in  $k$  for the mixing time of  $W_{k-1}^{\uparrow\downarrow}$ .

The intuition described above can be formalized to bound the mixing time of the high-order walks on  $Z$ . However, the following section takes a different approach by computing the local expansion of  $Z$ , which leads to tighter bounds on  $\nu_2(W_k^{\uparrow\downarrow})$ .

## 4 Local and global expansion

This section analyzes the local and global expansion of  $Z$ , which is then used to bound the mixing time of the up-down random walk using Theorem 9.

► **Theorem 18.** *If  $H \geq 2$ ,  $s \geq 2H$ , and  $n \geq 4$ , then for every  $0 \leq k \leq H - 2$ ,*

$$\nu^{(k)}(Z) = \frac{k+1}{k+2}.$$

Furthermore,

$$\nu^{(-1)}(Z) = \frac{\nu_2(G)}{\sum_{\ell=1}^H 1/\ell} \geq \frac{\nu_2(G)}{1 + \log H}.$$

Note that the local expansion  $\nu^{(k)}(Z)$  for  $k \geq 0$  does not depend on  $G$ . This property stems from the fact that the structure of any given link in  $Z$  depends only on the local structure of  $G$ , that is, on the weights of edges adjacent to a single vertex.

For comparison, the construction  $Q$  of Liu et al. [13] has local expansion  $\nu^{(k)}(Q) = \frac{1}{2}$  in each dimension  $k \geq 0$ , and has global expansion  $\nu^{(-1)}(Q)$  approaching  $\frac{1}{2}\nu_2(G)$  as  $H$  grows large. It was posed as an open question in Liu et al. [13] whether  $\frac{1}{2}$  is a natural barrier for local expansion in graph-product-based constructions. Theorem 18 gives a partial answer to this question, as although  $Z$  sacrifices a factor of  $O(\log H)$  in global expansion compared to  $Q$ , for all  $k \geq 1$  the local expansion  $\nu^{(k)}(Z) = \frac{k+1}{k+2}$  is an improvement on  $\nu^{(k)}(Q) = \frac{1}{2}$ . Section 5 provides a discussion suggesting that further improvements in local expansion are not attainable with a similar graph-product-based construction.

## 38:12 Improved Product-Based High-Dimensional Expanders

The result below applies Theorem 9, shown by Alev and Lau [1], to show that the improvement in local expansion of  $Z$  compared to  $Q$  for  $k \geq 1$  results in an exponential improvement with respect to  $k$  of the spectral gap of the  $k$ th order up-down walk.

► **Corollary 19.** *Let  $W_k^{\uparrow\downarrow}$  be the up-down walk operator for the simplicial complex  $Z$ . If  $H \geq 2$ ,  $s \geq 2H$ , and  $n \geq 4$ , then for all  $0 \leq k \leq H - 1$ ,*

$$\nu_2(W_k^{\uparrow\downarrow}) \geq \frac{\nu_2(G)}{(\sum_{\ell=1}^H 1/\ell)(k+2)(k+1)} \geq \frac{\nu_2(G)}{(1 + \log H)(k+2)(k+1)}.$$

**Proof.** Applying Theorem 9 with Theorem 18 gives that

$$\nu_2(W_k^{\uparrow\downarrow}) \geq \frac{1}{k+2} \cdot \frac{\nu_2(G)}{\sum_{\ell=1}^H 1/\ell} \prod_{j=0}^{k-1} \frac{j+1}{j+2} = \frac{\nu_2(G)}{(\sum_{\ell=1}^H 1/\ell)(k+2)(k+1)}. \quad \blacktriangleleft$$

Because by definition  $W_k^{\uparrow\downarrow}$  has self loop probabilities of  $1/(k+2)$ , for all  $i$  it holds that  $\omega_i(W_k^{\uparrow\downarrow}) \geq -k/(k+2)$ . Therefore assuming that  $G$  is chosen from a family of graphs with bounded ratio of maximum degree to minimum degree, then the mixing time of the random walk  $W_k^{\uparrow\downarrow}$  grows as  $O(\frac{k^2(\log H)(\log n)}{\nu_2(G)})$ .

In contrast, the spectral gap of the  $k$ th order random walk on the construction  $Q$  of Liu et al. [13] was shown in Alev and Lau [1] to grow as  $\Omega(\frac{\nu_2(G)}{k2^k})$ , for a mixing time of  $O(\frac{k2^k \log n}{\nu_2(G)})$ .

### 4.1 Proof of Theorem 18

To prove Theorem 18, we first compute the expansion of the 1-skeleton of every link in  $Z$  in the following lemmas.

► **Lemma 20.** *For every  $2 \leq k \leq H - 1$ ,  $1 \leq j \leq k - 1$ , and  $\{u, v\} \in E(G)$ , every face  $\sigma \in Z((j, k - j)_{(u, v)})$  satisfies*

$$\omega_2(Z_\sigma(0), Z_\sigma(1), m_\sigma) = \frac{1}{k+1}.$$

**Proof.** Following the method of Liu et al. [13], the proof will proceed by identifying the 1-skeleton of each link of  $Z$  with a tensor product of two other graphs, whose spectra can be analyzed independently. For a face  $\sigma \in Z((j, k - j)_{(u, v)})$ , the link  $Z_\sigma$  by definition has vertex set  $Z_\sigma(0) = \{u, v\} \times ([s] \setminus \Pi_{[s]}(\sigma))$  and edge set

$$Z_\sigma(1) = \{\tau \setminus \sigma : \sigma \subset \tau \in Z(k+1)\} = \{(v_1, b_1), (v_2, b_2)\} \subset Z_\sigma(0) : b_1 \neq b_2\}.$$

For such an edge  $\{(v_1, b_1), (v_2, b_2)\}$ , let  $\tau = \sigma \cup \{(v_1, b_1), (v_2, b_2)\}$ , so that the edge's weight  $m(\tau)$  may be one of three possible values:

- If  $v_1 = v_2 = u$ , then  $\tau \in Z((j+2, k-j)_{(u, v)})$ , so  $m(\tau) = w_{(u, v)}^{(j+2, k-j)}$ .
- If  $v_1 = u, v_2 = v$ , then  $\tau \in Z((j+1, k-j+1)_{(u, v)})$ , so  $m(\tau) = w_{(u, v)}^{(j+1, k-j+1)}$ .
- If  $v_1 = v_2 = v$ , then  $\tau \in Z((j, k-j+2)_{(u, v)})$ , so  $m(\tau) = w_{(u, v)}^{(j, k-j+2)}$ .

Therefore letting  $P$  be the 2-vertex graph with adjacency matrix

$$M_P = \begin{pmatrix} w_{(u, v)}^{(j+2, k-j)} & w_{(u, v)}^{(j+1, k-j+1)} \\ w_{(u, v)}^{(j+1, k-j+1)} & w_{(u, v)}^{(j, k-j+2)} \end{pmatrix},$$

then the graph  $(Z_\sigma(0), Z_\sigma(1), m_\sigma)$  described above is exactly given by  $P \otimes K_{[s] \setminus \Pi_{[s]}(\sigma)}$ , where  $K_V$  denotes the complete graph without self-loops on vertex set  $V$ . By Proposition 17, it holds

that  $w_{(u,v)}^{(j+2,k-j)}/w_{(u,v)}^{(j+1,k-j+1)} = (j+1)/(k-j)$  and  $w_{(u,v)}^{(j+1,k-j+1)}/w_{(u,v)}^{(j,k-j+2)} = j/(k-j+1)$ , so the random walk matrix of  $P$  is given by

$$W_P = \frac{1}{k+1} \begin{pmatrix} j+1 & j \\ k-j & k-j+1 \end{pmatrix},$$

whose second eigenvalue is  $1/(k+1)$ , with eigenvector  $(1, -1)^T$ . Thus because 1 is the only positive eigenvalue of  $W_{K_{[s] \setminus \Pi_{[s]}(\sigma)}}$ , it follows that the second eigenvalue of  $W_P \otimes W_{K_{[s] \setminus \Pi_{[s]}(\sigma)}}$  is  $1/(k+1)$ , as desired.  $\blacktriangleleft$

► **Lemma 21.** *If  $s \geq 2H$ , then for every  $1 \leq k \leq H-1$  and  $u \in V(G)$ , every face  $\sigma \in Z((k)_{(u)})$  satisfies*

$$\omega_2(Z_\sigma(0), Z_\sigma(1), m_\sigma) = \frac{1}{k+1}.$$

**Proof.** The proof will proceed similarly to that of Lemma 20. Consider a face  $\sigma \in Z((k)_{(u)})$ , and let  $N(u) = \{v_1, \dots, v_d\}$ . The link  $Z_\sigma$  then has vertex set  $Z_\sigma(0) = (\{u\} \cup N(u)) \times ([s] \setminus \Pi_{[s]}(\sigma))$  and edge set

$$Z_\sigma(1) = \{\tau \setminus \sigma : \sigma \subset \tau \in Z(k+1)\} = \{\{(v, b_1), (v', b_2)\} \subset Z_\sigma(0) : b_1 \neq b_2, |\{v, v'\} \setminus \{u\}| \leq 1\}.$$

For such an edge  $\{(v, b_1), (v', b_2)\}$ , let  $\tau = \sigma \cup \{(v, b_1), (v', b_2)\}$ , so that there are three possible cases for the edge's weight  $m(\tau)$ :

- If  $v = v' = u$ , then  $\tau \in Z((k+2)_{(u)})$ , so  $m(\tau) = w_{(u)}^{(k+2)}$ .
- If  $v = u, v' = v_i$  for some  $i$ , then  $\tau \in Z((k+1, 1)_{(u, v_i)})$ , so  $m(\tau) = w_{(u, v_i)}^{(k+1, 1)}$ .
- If  $v = v' = v_i$  for some  $i$ , then  $\tau \in Z((k, 2)_{(u, v_i)})$ , so  $m(\tau) = w_{(u, v_i)}^{(k, 2)}$ .

Therefore letting  $S$  be the  $(d+1)$ -vertex star graph with adjacency matrix

$$M_S = \begin{pmatrix} w_{(u)}^{(k+2)} & w_{(u, v_1)}^{(k+1, 1)} & w_{(u, v_2)}^{(k+1, 1)} & \dots & w_{(u, v_d)}^{(k+1, 1)} \\ w_{(u, v_1)}^{(k+1, 1)} & w_{(u, v_1)}^{(k, 2)} & 0 & \dots & 0 \\ w_{(u, v_2)}^{(k+1, 1)} & 0 & w_{(u, v_2)}^{(k, 2)} & & \vdots \\ \vdots & \vdots & & \ddots & 0 \\ w_{(u, v_d)}^{(k+1, 1)} & 0 & \dots & 0 & w_{(u, v_d)}^{(k, 2)} \end{pmatrix},$$

it follows that the graph  $(Z_\sigma(0), Z_\sigma(1), m_\sigma)$  is exactly given by  $S \otimes K_{[s] \setminus \Pi_{[s]}(\sigma)}$ . Let  $x = w_{(u)}^{(k+2)} + \sum_{i=1}^d w_{(u, v_i)}^{(k+1, 1)}$ , so that by Proposition 17, the random walk matrix of  $S$  is therefore

$$W_S = \begin{pmatrix} w_{(u)}^{(k+2)}/x & k/(k+1) & k/(k+1) & \dots & k/(k+1) \\ w_{(u, v_1)}^{(k+1, 1)}/x & 1/(k+1) & 0 & \dots & 0 \\ w_{(u, v_2)}^{(k+1, 1)}/x & 0 & 1/(k+1) & & \vdots \\ \vdots & \vdots & & \ddots & 0 \\ w_{(u, v_d)}^{(k+1, 1)}/x & 0 & \dots & 0 & 1/(k+1) \end{pmatrix},$$

Let  $\delta_i \in \mathbb{R}^{d+1}$  denote the  $i$ th basis vector, so that by this expression for  $W_S$ , every vector in the codimension-2 subspace  $\text{span}\{\vec{1}, \delta_1\}^\perp$  is an eigenvector with eigenvalue  $1/(k+1)$ . The

### 38:14 Improved Product-Based High-Dimensional Expanders

final eigenvector in  $\text{span}\{\vec{1}\}^\perp$  is then given by  $(w_{(u)}^{(k+2)} - x, w_{(u,v_1)}^{(k+1,1)}, \dots, w_{(u,v_d)}^{(k+1,1)})^T$ , with eigenvalue

$$\frac{1}{k+1} - \frac{x - w_{(u)}^{(k+2)}}{x} = \frac{1}{k+1} - \frac{1}{1 + (k+1) \sum_{\ell=k+2}^H 1/\ell},$$

where the equality above holds by Proposition 17. Thus  $\omega_2(S) = 1/(k+1)$ . Because  $s \geq 2H$  and  $k \leq H-1$ , it follows that  $|[s] \setminus \Pi_{[s]}(\sigma)| = s - k \geq H+1$ . Therefore the eigenvalues of  $W_{K_{[s] \setminus \Pi_{[s]}(\sigma)}}$  are 1 and  $-1/(s-k-1)$ , with  $0 \leq 1/(s-k-1) \leq 1/H \leq 1/(k+1)$ , so it follows that all eigenvalues of  $W_{K_{[s] \setminus \Pi_{[s]}(\sigma)}}$  that do not equal 1 must have absolute value at most  $1/(k+1)$ . Therefore it follows from  $\omega_2(S) = 1/(k+1)$  that  $\omega_2(S \otimes K_{[s] \setminus \Pi_{[s]}(\sigma)}) = 1/(k+1)$ , as desired.  $\blacktriangleleft$

► **Lemma 22.** For  $1 \leq i \leq n$ , let

$$\tilde{\omega}_i(G) = \frac{1}{\sum_{\ell=1}^H 1/\ell} \omega_i(G) + \left(1 - \frac{1}{\sum_{\ell=1}^H 1/\ell}\right) \quad (4)$$

denote the eigenvalues of a lazy random walk on  $G$ . Then

$$\omega_2(Z(0), Z(1), m) = \max\{\tilde{\omega}_2(G), -\tilde{\omega}_n(G)/(s-1)\}.$$

**Proof.** Consider any  $\tau = \{(u, b_1), (v, b_2)\} \in Z(1)$ . If  $u = v$  then  $\tau \in Z((2)_{(u)})$  so that  $m(\tau) = w_{(u)}^{(2)}$ , while if  $u \neq v$  then  $\tau \in Z((1,1)_{(u,v)})$  so that  $m(\tau) = w_{(u,v)}^{(1,1)}$ . Therefore define  $\tilde{G}$  to be the undirected graph with  $V(\tilde{G}) = V(G)$ ,  $E(\tilde{G}) = E(G) \cup V(G)$ , and with edge weight function  $w_{\tilde{G}}(\cdot)$  given for  $\{u, v\} \in E(G)$  by  $w_{\tilde{G}}(\{u, v\}) = w_{(u,v)}^{(1,1)}$  and  $w_{\tilde{G}}(\{u\}) = w_{(u)}^{(2)}$ . Then the graph  $(Z(0), Z(1), m)$  is exactly given by  $\tilde{G} \otimes K_{[s]}$ . Let  $W_{\tilde{G}}$  denote the random walk matrix of  $\tilde{G}$ , and let  $W'_{\tilde{G}}$  denote  $W_{\tilde{G}}$  with all diagonal entries zeroed out, and let  $W''_{\tilde{G}}$  denote  $W_{\tilde{G}}$  with all non-diagonal entries zeroed out, so that  $W_{\tilde{G}} = W'_{\tilde{G}} + W''_{\tilde{G}}$ . Then for any  $u \in V(G)$ ,

$$W''_{\tilde{G}}(u, u) = \frac{w_{(u)}^{(2)}}{w_{(u)}^{(2)} + \sum_{v \in N(u)} w_{(u,v)}^{(1,1)}} = \frac{1}{1 + \frac{\sum_{v \in N(u)} w_{(u,v)}^{(1,1)}}{w_{(u)}^{(2)}}} = \frac{\sum_{\ell=2}^H \frac{1}{\ell}}{\sum_{\ell=1}^H \frac{1}{\ell}},$$

where the final equality holds by Proposition 17. Therefore  $W''_{\tilde{G}} = (\sum_{\ell=2}^H \frac{1}{\ell} / \sum_{\ell=1}^H \frac{1}{\ell}) I$ . Furthermore, for any  $v \neq u$ ,

$$\begin{aligned} \left(\sum_{\ell=1}^H \frac{1}{\ell}\right) W'_{\tilde{G}}(v, u) &= \frac{w_{(u)}^{(2)} + \sum_{v' \in N(u)} w_{(u,v')}^{(1,1)}}{\sum_{v' \in N(u)} w_{(u,v')}^{(1,1)}} \cdot \frac{w_{(u,v)}^{(1,1)}}{w_{(u)}^{(2)} + \sum_{v' \in N(u)} w_{(u,v')}^{(1,1)}} \\ &= \frac{w_{(u,v)}^{(1,1)}}{\sum_{v' \in N(u)} w_{(u,v')}^{(1,1)}} \\ &= \frac{w_G(\{u, v\})}{\sum_{v' \in N(u)} w_G(\{u, v'\})} \\ &= W_G(v, u), \end{aligned}$$

where the first equality above holds by Proposition 17, and the third equality by Lemma 16. Thus in summary,

$$W_{\tilde{G}} = W'_{\tilde{G}} + W''_{\tilde{G}} = \frac{1}{\sum_{\ell=1}^H 1/\ell} W_G + \left(1 - \frac{1}{\sum_{\ell=1}^H 1/\ell}\right) I,$$

so  $W_{\tilde{G}}$  is simply a lazy instance of the random walk  $W_G$ , and in particular for all  $1 \leq i \leq n$ ,

$$\omega_i(\tilde{G}) = \frac{1}{\sum_{\ell=1}^H 1/\ell} \omega_i(G) + \left(1 - \frac{1}{\sum_{\ell=1}^H 1/\ell}\right) = \tilde{\omega}_i(G).$$

Because the eigenvalues of  $K_{[s]}$  are 1 and  $-1/(s-1)$ , it follows that

$$\omega_2(\tilde{G} \otimes K_{[s]}) = \max\{\omega_2(\tilde{G}), -\omega_n(\tilde{G})/(s-1)\},$$

as desired. ◀

**Proof of Theorem 18.** For every  $0 \leq k \leq H-2$ , each  $\sigma \in Z(k)$  by definition either lies in  $Z((j, k+1-j)_{(u,v)})$  or in  $Z((k+1)_{(u)})$  for some  $1 \leq j \leq k$  and  $\{(u, v)\} \in E(G)$ . Therefore Lemma 20 and Lemma 21 together imply that the link of every  $\sigma \in Z(k)$  has expansion  $\nu_2(Z_\sigma(0), Z_\sigma(1), m_\sigma) = \frac{k+1}{k+2}$ , so

$$\nu^{(k)}(Z) = \frac{k+1}{k+2}.$$

For the global expansion statement, letting  $\tilde{\omega}_i(G)$  be defined as in (4), then by Lemma 22,

$$\nu^{(-1)}(Z) = \nu_2(Z(0), Z(1), m) = 1 - \max\{\tilde{\omega}_2(G), -\tilde{\omega}_n(G)/(s-1)\}.$$

Now because  $n \geq 4$ ,  $H \geq 2$ , and  $s \geq 4$  by assumption, then  $\omega_2(G) \geq -1/3$  and  $\sum_{\ell=1}^H 1/\ell \geq 3/2$ , which implies that  $\tilde{\omega}_2(G) \geq 1/9$  and  $\tilde{\omega}_n(G) \geq -1/3$ , and thus  $\tilde{\omega}_2(G) \geq -\tilde{\omega}_n(G)/(s-1)$ , so

$$\nu^{(-1)}(Z) = 1 - \tilde{\omega}_2(G) = \frac{\nu_2(G)}{\sum_{\ell=1}^H 1/\ell} \geq \frac{\nu_2(G)}{1 + \log H}. \quad \blacktriangleleft$$

## 5 Discussion and future directions

Given the constructions of ordinary expanders using graph products (e.g. [19]), it seems natural to investigate simplicial complex product constructions that yield high-dimensional expanders. From this perspective, the construction  $Q$  of Liu et al. [13] is quite interesting, as it may be viewed as a form of tensor product between a graph  $G$  and the complete simplicial complex on  $s$  vertices. The principal drawback with  $Q$  lies in the exponential dependence of the spectral gap  $\Omega(\frac{\nu_2(G)}{k^{2k}})$  of the up-down walk on the dimension  $k$ . By reducing this dependence to quadratic with a spectral gap of  $\Omega(\frac{\nu_2(G)}{k^2 \log H})$ , the construction  $Z$  greatly improves the mixing time of high-dimensional up-down walks, while maintaining the product-based nature of the construction. However, the optimal spectral gap of the  $k$ th order up-down walk grows as  $\Omega(\frac{1}{k})$ , which is achieved by Ramanujan complexes and by the constructions based on coset geometries of Kaufman and Oppenheim [11] and Friedgut and Iluz [6]. It is therefore natural to ask whether the construction  $Z$  can be further optimized to reduce the quadratic dependence on  $k$  to linear. Below, we suggest a negative answer to this question, by analyzing the implications for local expansion.

The determination of the optimal local expansion for any “graph-product-based construction” was posed as an open question by Liu et al. [13], although no formal definition for a graph-product-based construction was proposed. For concreteness, fix a dimension  $H$ , and let a graph-product-based construction be one such as  $Z$  that takes as input a graph  $G$ , and outputs an  $H$ -dimensional simplicial complex with the same faces as  $Q$ , but with

an arbitrary weight function.<sup>1</sup> The following reasoning suggests that no such construction can improve upon the  $k$ -dimensional local expansion  $\nu^{(k)}(Z) = \frac{k+1}{k+2}$  of  $Z$ . For if some graph-product-based construction  $Z'$  were to satisfy  $\nu^{(k)}(Z') > \frac{k+1+\epsilon}{k+2+\epsilon}$  for some  $\epsilon > 0$  when  $G$  is chosen from a family of  $d$ -regular expanders, then inductively applying Proposition 7 would imply that  $\nu^{(j)}(Z') > \frac{j+1+\epsilon}{j+2+\epsilon}$  for all  $j \leq k$ , so that  $\nu^{(-1)}(Z') > \frac{\epsilon}{1+\epsilon}$ . But as observed in Section 4, the product-based structure ensures that the link of any face of dimension  $\geq 0$  obtains its structure from the structure of the neighborhood of a single vertex in  $G$ , while the entire 1-skeleton of  $Z'$  inherits the global structure of  $G$ . Thus if  $G$  is instead chosen from a family of  $d$ -regular graphs with sufficiently poor expansion, then the 1-skeleton of  $Z'$  will now inherit this poor expansion, so  $\nu^{(-1)}(Z') < \frac{\epsilon}{1+\epsilon}$ . But all  $d$ -regular graphs have the same local structure in the neighborhood of a vertex, so it will still hold that  $\nu^{(k)}(Z') > \frac{k+1+\epsilon}{k+2+\epsilon}$ , and therefore  $\nu^{(-1)}(Z') > \frac{\epsilon}{1+\epsilon}$ , a contradiction.

With  $k$ -dimensional local expansion  $\nu^{(k)} = \frac{k+1}{k+2}$ , the bound from Theorem 9 on the spectral gap of the  $k$ -dimensional up-down walk is at best  $\frac{1}{(k+2)(k+1)}$ . Indeed, a quadratic dependence on  $k$  in mixing time also arose in the discussion in Section 3.3, which shows how for a given edge  $\{u, v\} \in G$ , the  $k$ -dimensional up-down walk on a graph-product-based construction such as  $Z$  proceeds within the faces  $\bigcup_{j=1}^k Z((j, k+1-j)_{(u,v)})$  analogously to a random walk on a  $k$ -vertex path, which has a mixing time of  $\Omega(k^2)$ .<sup>2</sup> These observations suggest that no graph-product-based construction obtains better than a quadratic dependence on  $k$  in the spectral gap of the  $k$ -dimensional up-down walk. It is an interesting open problem to develop alternative combinatorial constructions of high-dimensional expanders that attain the optimal up-down walk spectral gap of  $\Omega(\frac{1}{k})$ .

## Abstract

We show that, for every  $k \geq 2$ , every  $k$ -uniform hypergraph of degree  $\Delta$  and girth at least 5 is efficiently  $(1 + o(1))(k - 1)(\Delta / \ln \Delta)^{1/(k-1)}$ -list colorable. As an application we obtain the currently best deterministic algorithm for list-coloring random hypergraphs of bounded average degree.

## 1 Introduction

In hypergraph coloring one is given a hypergraph  $H(V, E)$  and the goal is to find an assignment of one of  $q$  colors to each vertex  $v \in V$  so that no hyperedge is monochromatic. In the more general *list-coloring* problem, a list of  $q$  allowed colors is specified for each vertex. A graph is  $q$ -list-colorable if it has a list-coloring no matter how the lists are assigned to each vertex. The *list chromatic number*,  $\chi_\ell(H)$ , is the smallest  $q$  for which  $H$  is  $q$ -list colorable.

Hypergraph coloring is a fundamental constraint satisfaction problem with several applications in computer science and combinatorics, that has been studied for over 60 years. In this paper we consider the task of coloring locally sparse hypergraphs and its connection to coloring sparse random hypergraphs.

A hypergraph is *k-uniform* if every hyperedge contains exactly  $k$  vertices. An  $i$ -cycle in a  $k$ -uniform hypergraph is a collection of  $i$  distinct hyperedges spanned by at most  $i(k - 1)$  vertices. We say that a  $k$ -uniform hypergraph has girth at least  $g$  if it contains no  $i$ -cycles for  $2 \leq i < g$ . Note that if a  $k$ -uniform hypergraph has girth at least 3 then every two of its hyperedges have at most one vertex in common.

The main contribution of this paper is to prove the following theorem.

► **Theorem 1.** *Let  $H$  be any  $k$ -uniform hypergraph,  $k \geq 2$ , of maximum degree  $\Delta$  and girth at least 5. For all  $\epsilon > 0$ , there exist a positive constant  $\Delta_{\epsilon,k}$  such that if  $\Delta \geq \Delta_{\epsilon,k}$ , then*

$$\chi_\ell(H) \leq (1 + \epsilon)(k - 1) \left( \frac{\Delta}{\ln \Delta} \right)^{\frac{1}{k-1}}. \quad (1)$$

Furthermore, if  $H$  is a hypergraph on  $n$  vertices then there exists a deterministic algorithm that constructs such a coloring in time polynomial in  $n$ .

Theorem 1 is interesting for a number of reasons. First, it generalizes a well-known result of Kim [20] for coloring graphs of degree  $\Delta$  and girth 5, and it implies the classical theorem of Ajtai, Komlós, Pintz, Spencer and Szemerédi [4] regarding the independence number of  $k$ -uniform hypergraphs of degree  $\Delta$  and girth 5. The latter is a seminal result in combinatorics, with applications in geometry and coding theory [21, 22, 24]. Second, Theorem 1 is tight up to a constant [8]. Note also that, without the girth assumption, the best possible bound [11] on the chromatic number of  $k$ -uniform hypergraphs is  $O(\Delta^{1/(k-1)})$ , i.e., it is asymptotically worse than the one of Theorem 1. For example, there exist graphs of degree  $\Delta$  whose chromatic number is exactly  $\Delta + 1$ . Third, when it applies, Theorem 1 improves upon a result of Frieze and Mubayi [14] regarding the chromatic number of simple hypergraphs, who showed (1) with an unspecified large leading constant (of order at least  $\Omega(k^4)$ ). Finally, Theorem 1 can be used to provide the currently best *deterministic* algorithm for list-coloring random  $k$ -uniform hypergraphs of bounded average degree. We discuss the connection between locally sparse hypergraphs and sparse random hypergraphs with respect to the task of coloring in the following section.

## 1.1 Application to coloring pseudo-random hypergraphs

The random  $k$ -uniform hypergraph  $H(k, n, p)$  is obtained by choosing each of the  $\binom{n}{k}$   $k$ -element subsets of a vertex set  $V$  ( $|V| = n$ ) independently with probability  $p$ . The chosen subsets are the hyperedges of the hypergraph. Note that for  $k = 2$  we have the usual definition of the random graph  $G(n, p)$ . We say that  $H(k, n, p)$  has a certain property  $A$  *almost surely* or *with high probability*, if the probability that  $H \in H(k, n, p)$  has  $A$  tends to 1 as  $n \rightarrow \infty$ .

In this paper we are interested in  $H(k, n, d/\binom{n}{k-1})$ , i.e., the family of random  $k$ -uniform hypergraphs of bounded average degree  $d$ . Specifically, we use Theorem 1 to prove the following theorem.

► **Theorem 2.** *For any constants  $\delta \in (0, 1)$ ,  $k \geq 2$ , there exists  $d_{\delta,k} > 0$  such that for every constant  $d \geq d_{\delta,k}$ , almost surely, the random hypergraph  $H(k, n, d/\binom{n}{k-1})$  can be  $(1 + \delta)(k - 1)(d/\ln d)^{1/(k-1)}$ -list-colored by a deterministic algorithm whose running time is polynomial in  $n$ .*

► **Remark 3.** Note that, for  $k, d$  constants, a very standard argument reveals that distribution  $H(k, n, d/\binom{n}{k-1})$  is essentially equivalent to  $\mathbb{H}(k, n, kdn)$ , namely the uniform distribution over  $k$ -uniform hypergraphs with  $n$  vertices and exactly  $kdn$  hyperedges. Thus, Theorem 2 extends to that model as well.

We note that previous approaches [3, 23, 31] for list-coloring random  $k$ -uniform hypergraphs of bounded average degree  $d$  are either randomized, or require significantly larger lists of colors per vertex in order to succeed. Indeed, to the best of our knowledge, current deterministic approaches require lists of size at least  $O(k^4(d/\ln d)^{1/(k-1)})$ . Moreover, it is believed that *all* efficient algorithms (including randomized ones) require lists of size at least  $(1 + o(1))(k - 1)d/\ln d)^{1/(k-1)}$ , as this bound corresponds to the so-called *shattering*

threshold [1, 7, 15] for coloring sparse random hypergraphs, which is also often referred to as the “algorithmic barrier” [1]. This threshold arises in a plethora of random constraint satisfaction problems, and it corresponds to a precise phase transition in the geometry set of solutions. In all of these problems, we are not aware of any efficient algorithm that works beyond the algorithmic barrier, despite the fact that solutions exist for constraint-densities larger than the one in which the shattering phenomenon appears. We refer the reader to [1, 33] for further details.

In order to prove Theorem 2, we show that random  $k$ -uniform hypergraphs of bounded average degree  $d$  can essentially be treated as hypergraphs of girth 5 and maximum degree  $d$  for the purposes of list-coloring, and then apply Theorem 1. In particular, we identify a pseudo-random family of hypergraphs which we call *girth-reducible*, and show that almost all  $k$ -uniform hypergraphs of bounded average degree belong in this class. Then we show that girth-reducible hypergraphs can be colored efficiently using Theorem 1.

Formally, a  $k$ -uniform hypergraph  $H$  is  $\kappa$ -degenerate if the induced subhypergraph of all subsets of its vertex set has a vertex of degree at most  $\kappa$ . The *degeneracy* of a hypergraph  $H$  is the smallest value of  $\kappa$  for which  $H$  is  $\kappa$ -degenerate. Note that it is known that  $\kappa$ -degenerate hypergraphs are  $(\kappa + 1)$ -list colorable and that the degeneracy of a hypergraph can be computed efficiently by an algorithm that repeatedly removes minimum degree vertices. Indeed, to list-color a  $\kappa$ -degenerate hypergraph we repeatedly find a vertex with (remaining) degree at most  $\kappa$ , assign to it a color that does not appear in any of its neighbors so far, and remove it from the hypergraph. Clearly, if the lists assigned to each vertex are of size at least  $\kappa + 1$  this procedure always terminates successfully.

► **Definition 4.** For  $\delta \in (0, 1)$ , we say that a  $k$ -uniform hypergraph  $H(V, E)$  of average degree  $d$  is  $\delta$ -girth-reducible if its vertex set can be partitioned in two sets,  $U$  and  $V \setminus U$ , such that:

- (a)  $U$  contains all cycles of length at most 4, and all vertices of degree larger than  $(1 + \delta)d$ ;
- (b) subhypergraph  $H[U]$  is  $\left(\frac{d}{\ln d}\right)^{\frac{1}{k-1}}$ -degenerate;
- (c) every vertex in  $V \setminus U$  has at most  $\delta \left(\frac{d}{\ln d}\right)^{\frac{1}{k-1}}$  neighbors in  $U$ .

In words, a hypergraph is  $\delta$ -girth-reducible if its vertex set can be seen as the union of two parts: A “low-degeneracy” part, which contains all vertices of degree more than  $(1 + \delta)d$  and all cycles of lengths at most 4, and a “high-girth” part, which induces a hypergraph of maximum degree at most  $(1 + \delta)d$  and girth 5. Moreover, each vertex in the “high-girth” part has only a few neighbors in the “low-degeneracy” part.

Note that given a  $\delta$ -girth-reducible hypergraph we can efficiently find the promised partition  $(U, V \setminus U)$  as follows. We start with  $U := U_0$ , where  $U_0$  is the set of vertices that either have degree at least  $(1 + \delta)d$ , or they are contained in a cycle of length at most 4. Let  $\partial U$  denote the vertices in  $V \setminus U$  that violate property (c). While  $\partial U \neq \emptyset$ , update  $U$  as  $U := U \cup \partial U$ . The correctness of the process lies in the fact that in each step we add to the current  $U$  a set of vertices that must be in the low-degeneracy part of the hypergraph. Observe also that this process allows us to efficiently check whether a hypergraph is  $\delta$ -girth-reducible.

We prove the following theorem regarding the list-chromatic number of girth-reducible hypergraphs.

► **Theorem 5.** For any constants  $\delta \in (0, 1)$  and  $k \geq 2$ , there exists  $d_{\delta,k} > 0$  such that if  $H$  is a  $\delta$ -girth-reducible,  $k$ -uniform hypergraph of average degree  $d \geq d_{\delta,k}$ , then

$$\chi_\ell(H) \leq (1 + \epsilon)(k - 1) \left(\frac{d}{\ln d}\right)^{\frac{1}{k-1}},$$

where  $\epsilon = 4\delta = O(\delta)$ . Furthermore, if  $H$  is a hypergraph on  $n$  vertices then there exists a deterministic algorithm that constructs such a coloring in time polynomial in  $n$ .

**Proof of Theorem 5.** Let  $\epsilon = 4\delta$ . Given lists of colors of size  $(1 + \epsilon)(k - 1) \left(\frac{d}{\ln d}\right)^{\frac{1}{k-1}}$  for each vertex of  $H$ , we first color the vertices of  $U$  using the greedy algorithm which exploits the low degeneracy of  $H[U]$ . Now each vertex in  $V - U$  has at most  $\delta \left(\frac{d}{\ln d}\right)^{\frac{1}{k-1}}$  forbidden colors in its list as it has at most that many neighbors in  $U$ . We delete these colors from the list. Observe that if we manage to properly color the induced subgraph  $H[V \setminus U]$  using colors from the updated lists, then we are done since every hyperedge with vertices both in  $U$  and  $V \setminus U$  will be automatically “satisfied”, i.e., it cannot be monochromatic. Notice now that the updated list of each vertex still contains at least  $(1 + 3\delta)(k - 1) \left(\frac{d}{\ln d}\right)^{\frac{1}{k-1}}$  colors, for sufficiently large  $d$ . Since the induced subgraph  $H[V \setminus U]$  is of girth at least 5 and of maximum degree at most  $(1 + \delta)d$ , it is efficiently  $(1 + \delta)(k - 1) \left(\frac{(1 + \delta)d}{\ln((1 + \delta)d)}\right)^{\frac{1}{k-1}}$ -list-colorable for sufficiently large  $d$  per Theorem 1. This concludes the proof since  $(1 + \delta)(1 + \delta)^{\frac{1}{k-1}} < (1 + 3\delta)$ . ◀

Moreover, we show that girth-reducibility is a pseudo-random property which is admitted by almost all sparse  $k$ -uniform hypergraphs.

► **Theorem 6.** *For any constants  $\delta \in (0, 1)$ ,  $k \geq 2$ , there exists  $d_{\delta,k} > 0$  such that for every constant  $d \geq d_{\delta,k}$ , almost surely, the random hypergraph  $H(k, n, d/\binom{n}{k-1})$  is  $\delta$ -girth-reducible.*

Theorem 6 follows by simple, although somewhat technical, considerations on properties of sparse random hypergraphs, which are mainly inspired by the results of Alon, Krivelevich and Sudakov [6] and Łuczak [25]. Observe that combining Theorem 6 with Theorem 5 immediately implies Theorem 2.

Overall, the task of coloring locally sparse hypergraphs is inherently related to the average-case complexity of coloring. In particular, in this section we showed that Theorem 1 implies a *robust* algorithm for hypergraph coloring, namely a deterministic procedure that applies to worst-case  $k$ -uniform hypergraphs, while at the same time using a number of colors that is only a  $(k - 1)$ -factor away from the algorithmic barrier for random instances (matching it for  $k = 2$ ). We remark that this application is inspired by recent results that study the connection between local sparsity and efficient randomized algorithms for coloring sparse regular random graphs [26, 2, 10].

## 1.2 Technical overview

The intuition behind the proof of Theorem 1 comes from the following observation, which we explain in terms of graph coloring for simplicity. Let  $G$  be a triangle-free graph of degree  $\Delta$ , and assume that each of its vertices is assigned an arbitrary list of  $q$  colors. Fix a vertex  $v$  of  $G$ , and consider the random experiment in which the neighborhood of  $v$  is properly list-colored randomly. Since  $G$  contains no triangles, this amounts to assigning to each neighbor of  $v$  a color from its list randomly and independently. Assuming that  $q \geq q^* := (1 + \epsilon)\Delta/\ln \Delta$ , the expected number of *available* colors for  $v$ , i.e., the colors from the list of  $v$  that do not appear in any of its neighbors, is at least  $q(1 - 1/q)^\Delta = \omega(\Delta^{\epsilon/2})$ . In fact, a simple concentration argument reveals that the number of available colors for  $v$  in the end of this experiment is at least  $\Delta^{\epsilon/2}$  with probability that goes to 1 as  $\Delta$  grows. To put it differently, as long as  $q \geq q^*$ , the vast majority of valid ways to list-color the neighborhood of  $v$  “leaves enough room” to color  $v$  without creating any monochromatic edges.

A completely analogous observation regarding the ways to properly color the neighborhood of a vertex can be made for  $k$ -uniform hypergraphs. In order to exploit it we employ the so-called *semi-random method*, which is the main tool behind some of the strongest graph coloring results, e.g., [16, 17, 18, 19, 27, 32], including the one of Kim [20]. The idea is to

gradually color the hypergraph in iterations until we reach a point where we can finish the coloring with a simple, e.g., greedy, algorithm. In its most basic form, each iteration consists of the following simple procedure (using graph vertex coloring as a canonical example): Assign to each vertex a color chosen uniformly at random; then uncolor any vertex that receives the same color as one of its neighbors. Using the Lovász Local Lemma [11] and concentration inequalities, one typically shows that, with positive probability, the resulting partial coloring has useful properties that allow for the continuation of the argument in the next iteration. (In fact, using the Moser-Tardos algorithm [29] this approach yields efficient, and often times deterministic [9], algorithms.) Specifically, one keeps track of certain parameters of the current partial coloring and makes sure that, in each iteration, these parameters evolve almost as if the coloring was totally random. For example, recalling the heuristic experiment of the previous paragraph, one of the parameters we would like to keep track of in our case is a lower bound on the number of available colors of each vertex in the hypergraph: If this parameter evolves “randomly” throughout the process, then the vertices that remain uncolored in the end are guaranteed to have a non-trivial number of available colors.

Applications of the semi-random method tend to be technically intense and this is even more so in our case, where we have to deal with constraints of large arity. Large constraints introduce several difficulties, but the most important one is that our algorithm has to control many parameters that interact with each other. Roughly, in order to guarantee the properties that allow for the continuation of the argument in the next iteration, for each uncolored vertex  $v$ , each color  $c$  in the list of  $v$ , and each integer  $r \in [k - 1]$ , we should keep track of a lower bound on the number of adjacent to  $v$  hyperedges that have  $r$  uncolored vertices and  $k - 1 - r$  vertices colored  $c$ . Clearly, these parameters are not independent of each other throughout the process, and so the main challenge is to design and analyze a coloring procedure in which all of them, simultaneously, evolve essentially randomly.

### 1.3 Organization of the paper

The paper is organized as follows. In Section 2 we present the necessary background. In Section 3 we present the algorithm and state the key lemmas for the proof of Theorem 1. (The proofs of these lemmas can be found in the full version of our paper). In Section 4 we prove Theorem 6.

## 2 Background and preliminaries

In this section we give some background on the technical tools that we will use in our proofs.

### 2.1 The Lovász Local Lemma

We will find useful the so-called *lopsided* version of the Lovász Local Lemma [11, 12].

► **Theorem 7.** *Consider a set  $\mathcal{B} = \{B_1, B_2, \dots, B_m\}$  of (bad) events. For each  $B \in \mathcal{B}$ , let  $D(B) \subseteq \mathcal{B} \setminus \{B\}$  be such that  $\Pr[B \mid \bigcap_{C \in S} \overline{C}] \leq \Pr[B]$  for every  $S \subseteq \mathcal{B} \setminus (D(B) \cup \{B\})$ . If there is a function  $x : \mathcal{B} \rightarrow (0, 1)$  satisfying*

$$\Pr[B] \leq x(B) \prod_{C \in D(B)} (1 - x(C)) \quad \text{for all } B \in \mathcal{B} \quad , \quad (2)$$

*then the probability that none of the events in  $\mathcal{B}$  occurs is at least  $\prod_{B \in \mathcal{B}} (1 - x(B)) > 0$ .*

## 39:6 Coloring Locally Sparse Hypergraphs

In particular, we will need the following two corollaries of Theorem 7. For their proofs, the reader is referred to Chapter 19 in [28].

► **Corollary 8.** Consider a set  $\mathcal{B} = \{B_1, \dots, B_m\}$  of (bad) events. For each  $B \in \mathcal{B}$ , let  $D(B) \subseteq \mathcal{B} \setminus \{B\}$  be such that  $\Pr[B \mid \bigcap_{C \in S} \overline{C}] \leq \Pr[B]$  for every  $S \subseteq \mathcal{B} \setminus (D(B) \cup \{B\})$ . If for every  $B \in \mathcal{B}$ :

(a)  $\Pr[B] \leq \frac{1}{4}$ ;

(b)  $\sum_{C \in D(B)} \Pr[C] \leq \frac{1}{4}$ ,

then the probability that none of the events in  $\mathcal{B}$  occurs is strictly positive.

► **Corollary 9.** Consider a set  $\mathcal{B} = \{B_1, B_2, \dots, B_m\}$  of (bad) events such that for each  $B \in \mathcal{B}$ :

(a)  $\Pr[B] \leq p < 1$ ;

(b)  $B$  is mutually independent of a set of all but at most  $\Delta$  of the other events.

If  $4p\Delta \leq 1$  then with positive probability, none of the events in  $\mathcal{B}$  occur.

## 2.2 Talagrand's inequality

We will also need the following version of Talagrand's inequality [30] whose proof can be found in [28].

► **Theorem 10.** Let  $X$  be a non-negative random variable, not identically 0, which is determined by  $n$  independent trials  $T_1, \dots, T_n$ , and satisfying the following for some  $c, r > 0$ :

1. changing the outcome of any trial can affect  $X$  by at most  $c$ , and
2. for any  $s$ , if  $X \geq s$  then there is a set of at most  $w$  trials whose outcomes certify that  $X \geq s$ ,

then for any  $0 \leq t \leq \mathbb{E}[X]$ ,

$$\Pr[|X - \mathbb{E}[X]| > t + 60c\sqrt{w\mathbb{E}[X]}] \leq 4e^{-\frac{t^2}{8c^2w\mathbb{E}[X]}}.$$

## 3 List-coloring high-girth hypergraphs

In this section we describe the algorithm of Theorem 1 and state the key lemmas behind its analysis. As we already explained, our approach is based on the semi-random method. For an excellent exposition both of the method and Kim's result the reader is referred to [28].

We assume without loss of generality that  $\epsilon < \frac{1}{10}$ . Also, it will be convenient to define the parameter  $\delta := (1 + \epsilon)(k - 1) - 1$ , so that the list of each vertex initially has at least  $(1 + \delta)\left(\frac{\Delta}{\ln \Delta}\right)^{\frac{1}{k-1}}$  colors.

We analyze each iteration of our procedure using a probability distribution over the set of (possibly improper) colorings of the uncolored vertices of  $H$  where, additionally, each vertex is either activated or deactivated. We call a pair of coloring and activation bits assignments for the uncolored vertices of hypergraph  $H$  a *state*.

Let  $V_i$  denote the set of uncolored vertices in the beginning of the  $i$ -th iteration. (Initially, all vertices are uncolored.) For each  $v \in V_i$  we denote by  $L_v = L_v(i)$  the list of colors of  $v$  in the beginning of the  $i$ -th iteration. Further, we say that a color  $c \in L_v$  is *available* for  $v$  in a state  $\sigma$  if assigning  $c$  to  $v$  does not cause any hyperedge whose initially uncolored vertices are all activated in  $\sigma$  to be monochromatic.

For each vertex  $v$ , color  $c \in L_v$  and iteration  $i$ , we define a few quantities of interest that our algorithm will attempt to control. Let  $\ell_i(v)$  be the size of  $L_v$ . Further, for each  $r \in [k]$ , let  $D_{i,r}(v, c)$  denote the set of hyperedges  $h$  that contain  $v$  and (i) exactly  $r$  vertices  $\{u_1, \dots, u_r\} \subseteq h \setminus \{v\}$  are uncolored and  $c \in L_{u_j}$  for every  $j \in [r]$ ; (ii) the rest  $k - 1 - r$  vertices other than  $v$  are colored  $c$ . We define  $t_{i,r}(v, c) = |D_{i,r}(v, c)|$ .

As it is common in the applications of the semi-random method, we will not attempt to keep track of the values of  $\ell_i(v)$  and  $t_{i,r}(v, c)$ ,  $r \in [k - 1]$ , for every vertex  $v$  and color  $c$  but, rather, we will focus on their extreme values. In particular, we will define appropriate  $L_i, T_{i,r}$  such that we can show that, for each  $i$ , the following property holds at the beginning of iteration  $i$ :

*Property  $P(i)$ :* For each vertex  $v \in V_i$ , color  $c \in L_v$  and  $r \in [k - 1]$ ,

$$\begin{aligned}\ell_i(v) &\geq L_i, \\ t_{i,r}(v, c) &\leq T_{i,r}.\end{aligned}$$

As a matter of fact, it would be helpful for our analysis (though not necessary) if the inequalities defined in  $P(i)$  were actually tight. Given that  $P(i)$  holds, we can always enforce this stronger property in a straightforward way as follows. First, for each vertex  $v$  such that  $\ell_i(v) > L_i$  we choose arbitrarily  $\ell_i(v) - L_i$  colors from its list and remove them. Then, for each vertex  $v$  and color  $c \in L_i$  such that  $t_{i,r}(v, c) < T_{i,r}$  we add to the hypergraph  $T_{i,r} - t_{i,r}(v, c)$  new hyperedges of size  $r + 1$  that contain  $v$  and  $r$  new “dummy” vertices. (As it will be evident from the proof, we can always assume that  $L_i, T_{i,r}$  are integers, since our analysis is robust to replacing  $L_i, T_{i,r}$  with  $\lfloor L_i \rfloor$  and  $T_{i,r}$  with  $\lceil T_{i,r} \rceil$ .) We assign each dummy vertex a list of  $L_i$  colors:  $L_i - 1$  of them are new and do not appear in the list of any other vertex, and the last one is  $c$ .

► **Remark 11.** Dummy vertices are only useful for the purposes of our analysis and can be removed at the end of the iteration. Indeed, one could use the technique of “equalizing coin flips” instead. For more details see e.g., [28].

Overall, without loss of generality, at each iteration  $i$  our goal will be to guarantee that  $P(i + 1)$  holds assuming  $Q(i)$ .

*Property  $Q(i)$ :* For each vertex  $v \in V_i$ , color  $c \in L_v$  and  $r \in [k - 1]$ ,

$$\begin{aligned}\ell_i(v) &= L_i, \\ t_{i,r}(v, c) &= T_{i,r}.\end{aligned}$$

**An iteration.** For the  $i$ -th iteration we will apply the Local Lemma with respect to the probability distribution induced by assigning to each vertex  $v \in V_i$  a color chosen uniformly at random from  $L_v$  and activating  $v$  with probability  $\alpha = \frac{K}{\ln \Delta}$ , where  $K = (100k^{3k})^{-1}$ . That is, we will apply the Moser-Tardos algorithm in a configuration space consisting of  $2|V_i|$  variables corresponding to the color and activation bit of each variable in  $V_i$ . (We will define the family of bad events for each iteration shortly.)

When the execution of the Moser-Tardos algorithm terminates, we will uncolor some of the vertices in  $V_i$ , to get a new partial coloring. In particular, the partial coloring of the hypergraph, set  $V_{i+1}$ , and the lists of colors for each uncolored vertex in the beginning of iteration  $i + 1$  are induced as follows. Let  $\sigma$  be the output state of the application of the Moser-Tardos algorithm in the  $i$ -th iteration. The list of each vertex  $v$ ,  $L_v(i + 1)$ , is induced from  $L_v(i)$  by removing every non-available color  $c \in L_v(i)$  for  $v$  in  $\sigma$ . We obtain the partial coloring  $\phi$  for the hypergraph and set  $V_{i+1}$  for the beginning of iteration  $i + 1$  by removing the color from every vertex  $v \in V_i$  which is either deactivated or is assigned a non-available for it color in  $\sigma$ .

Overall, the  $i$ -th iteration of our algorithm can be described at a high-level as follows:

1. Apply the Moser-Tardos algorithm to the probability space induced by assigning to each vertex  $v \in V_i$  a color chosen uniformly at random from  $L_v(i)$ , and activating  $v$  with probability  $\alpha$ .

## 39:8 Coloring Locally Sparse Hypergraphs

2. Let  $\sigma$  be the output state of the Moser-Tardos algorithm.
3. For each vertex  $v \in V_i$ , remove any non-available color  $c \in L_v(i)$  in  $\sigma$  to get a list  $L_v(i+1)$ .
4. Uncolor every vertex  $v \in V_i$  that has either received a non-available color or is deactivated in  $\sigma$ , to get a new partial coloring  $\phi$ .

**Controlling the parameters of interest.** Next we describe the recursive definitions for  $L_i$  and  $T_{i,r}$  which, as we already explained, will determine the behavior of the parameters  $\ell_i(v)$  and  $t_{i,r}(v, c)$ , respectively.

Initially,  $L_1 = (1 + \delta) \left(\frac{\Delta}{\ln \Delta}\right)^{\frac{1}{k-1}}$ ,  $T_{1,k-1} = \Delta$  and  $T_{1,r} = 0$  for every  $r \in [k-2]$ . Letting

$$\text{Keep}_i = \prod_{r=1}^{k-1} \left(1 - \left(\frac{\alpha}{L_i}\right)^r\right)^{T_{i,r}}, \quad (3)$$

we define

$$L_{i+1} = L_i \cdot \text{Keep}_i - L_i^{2/3}, \quad (4)$$

$$\begin{aligned} T_{i+1,r} &= \sum_{j=r}^{k-1} \binom{j}{r} T_{i,j} \cdot (\text{Keep}_i (1 - \alpha \text{Keep}_i))^r \left(\frac{\alpha \text{Keep}_i}{L_i}\right)^{j-r} \\ &\quad + 3k^r \alpha^{-r+1} L_i^r \sum_{\ell=1}^{k-1} \frac{T_{i,\ell}}{L_i^{2\ell} (\ln \Delta)^{2\ell}} + \left(\sum_{j=r}^{k-1} \binom{j}{r} \alpha^{j-r} \frac{T_{i,j}}{L_i^{j-r}}\right)^{2/3}. \end{aligned} \quad (5)$$

To get some intuition for the recursive definitions (4), (5), observe that  $\text{Keep}_i$  is the probability that a color  $c \in L_v(i)$  is present in  $L_v(i+1)$  as well. Note further that this implies that the expected value of  $\ell_{i+1}(v, c)$  is  $L_i \cdot \text{Keep}_i$ , a fact which motivates (4). Calculations of similar flavor for  $\mathbb{E}[t_{i+1,r}(v, c)]$  motivate (5).

**The key lemmas.** We are almost ready to state the main lemmas that will guarantee that our procedure eventually reaches a partial list-coloring of  $H$  with favorable properties that will allow us to extend it to a full list-coloring. Before doing so, we need to settle a subtle issue that has to do with the fact that  $t_{i+1,r}(v, c)$  is not sufficiently concentrated around its expectation. To see this, notice for example that  $t_{i+1,1}(v, c)$  drops to zero if  $v$  is assigned  $c$ . (Similarly, for  $r \in \{2, \dots, k-1\}$ , if  $v$  is assigned  $c$  then  $t_{i+1,r}(v, c)$  can be affected by a large amount.) To deal with this problem we will focus instead on variable  $t'_{i+1,r}(v, c)$ , i.e., the number of hyperedges  $h$  that contain  $v$  and (i) exactly  $k-r-1$  vertices of  $h \setminus \{v\}$  are colored  $c$  in the end of iteration  $i$ ; (ii) the rest  $r$  vertices of  $h \setminus \{v\}$  did not retain their color during iteration  $i$  and, further,  $c$  would be available for them if we ignored the color assigned to  $v$ . Observe that if  $c$  is not assigned to  $v$  then  $t_{i+1,r}(v, c) = t'_{i+1,r}(v, c)$  and  $t'_{i+1,r}(v, c) \geq t_{i+1,r}(v, c)$  otherwise.

The first lemma that we prove estimates the expected value of the parameters at the end of the  $i$ -th iteration. Its proof can be found in the full version of our paper.

► **Lemma 12.** *Let  $S_i = \sum_{\ell=1}^{k-1} \frac{T_{i,\ell}}{L_i^{2\ell} (\ln \Delta)^{2\ell}}$  and  $Y_{i,r} = \sum_{j=r}^{k-1} \frac{T_{i,j}}{L_i^j}$ . If  $Q(i)$  holds and for all  $1 < j < i$ ,  $r \in [k-1]$ ,  $L_j \geq (\ln \Delta)^{20(k-1)}$ ,  $T_{i,r} \geq (\ln \Delta)^{20(k-1)}$ , then, for every vertex  $v \in V_{i+1}$  and color  $c \in L_v$ :*

(a)  $\mathbb{E}[\ell_{i+1}(v)] = \ell_i(v) \cdot \text{Keep}_i$ ;

(b)

$$\begin{aligned} \mathbb{E}[t'_{i+1,r}(v, c)] &\leq \sum_{j=r}^{k-1} \binom{j}{r} T_{i,j}(v, c) \cdot (\text{Keep}_i (1 - \alpha \text{Keep}_i))^r \left(\frac{\alpha \text{Keep}_i}{L_i}\right)^{j-r} \\ &\quad + 3k^r \alpha^{-r+1} L_i^r S_i + O(Y_i). \end{aligned}$$

The next step is to prove strong concentration around the mean for our random variables per the following lemma. Its proof can be found in the full version of our paper.

► **Lemma 13.** *If  $Q(i)$  holds and  $L_i, T_{i,r} \geq (\ln \Delta)^{20(k-1)}$ ,  $r \in [k-1]$ , then for every vertex  $v \in V_{i+1}$  and color  $c \in L_v$ ,*

- (a)  $\Pr \left[ |\ell_{i+1}(v) - \mathbb{E}[\ell_{i+1}(v)]| < L_i^{2/3} \right] < \Delta^{-\ln \Delta}$ ;
- (b)  $\Pr \left[ t'_{i+1,r}(v, c) - \mathbb{E}[t'_{i+1,r}(v, c)] > \frac{1}{2} \left( \sum_{j=r}^{k-1} \binom{j}{r} \alpha^{j-r} \frac{T_{i,j}}{L_i^{j-r}} \right)^{2/3} \right] < \Delta^{-\ln \Delta}$ .

Armed with Lemmas 12, 13, a straightforward application of the symmetric Local Lemma, i.e., Corollary 9, reveals the following.

► **Lemma 14.** *With positive probability,  $P(i)$  holds for every  $i$  such that for all  $1 < j < i$ :  $L_j, T_{j,r} \geq (\ln \Delta)^{20(k-1)}$  and  $T_{j,k-1} \geq \frac{1}{10k^2} L_j^{k-1}$ .*

The proof of Lemma 14 can be found in the full version of our paper.

In analyzing the recursive equations (4), (5), it would be helpful if we could ignore the “error terms”. The next lemma shows that this is indeed possible. Its proof can be found in the full version of our paper.

► **Lemma 15.** *Define  $L'_1 = (1 + \delta) \left( \frac{\Delta}{\ln \Delta} \right)^{\frac{1}{k-1}}$ ,  $T'_{1,k-1} = \Delta$ ,  $T'_{1,r} = 0$  for  $r \in [k-2]$ , and recursively define*

$$\begin{aligned} L'_{i+1} &= L'_i \cdot \text{Keep}_i, \\ T'_{i+1,r} &= \sum_{j=r}^{k-1} \binom{j}{r} \left( T'_{i,j} \cdot (\text{Keep}_i \cdot (1 - \alpha \text{Keep}_i))^r \left( \frac{\alpha \text{Keep}_i}{L'_i} \right)^{j-r} \right) \\ &\quad + 3k^r \alpha^{-r+1} L_i^r \sum_{\ell=1}^{k-1} \frac{T_{i,\ell}}{L_i^{2\ell} (\ln \Delta)^{2\ell}}. \end{aligned}$$

*If for all  $1 < j < i$ ,  $L_j \geq (\ln \Delta)^{20(k-1)}$ ,  $T_{j,r} \geq (\ln \Delta)^{20(k-1)}$  for every  $r \in [k-1]$ , and  $T_{j,k-1} \geq \frac{L_j^{k-1}}{10k^2}$ , then*

- (a)  $|L_i - L'_i| \leq (L'_i)^{\frac{5}{6}}$ ;
- (b)  $|T_{i,r} - T'_{i,r}| \leq (T'_{i,r})^{\frac{100r}{100r+1}}$ .

► **Remark 16.** Note that  $\text{Keep}_i$  in Lemma 15 is still defined in terms of  $L_i, T_{i,r}$  and not  $L'_i, T'_{i,r}$ . Note also that in the definition of  $T'_{i+1,r}$ , the second summand is a function of  $T_{i,\ell}, L_i, \ell \in [r-1]$ , and not  $T'_{i,\ell}, L'_i$ .

Using Lemma 15 we are able to prove the following in the full version of our paper.

► **Lemma 17.** *There exists  $i^* = O(\ln \Delta \ln \ln \Delta)$  such that*

- (a) *For all  $1 < i \leq i^*$ ,  $T_{i,r} > (\ln \Delta)^{20(k-1)}$ ,  $L_i \geq \Delta^{\frac{\epsilon/3}{(k-1)(1+\epsilon/2)}}$ , and  $T_{i,k-1} \geq \frac{1}{10k^2} L_i^{k-1}$ ;*
- (b)  *$T_{i^*+1,r} \leq \frac{1}{10k^2} L_{i^*+1}^r$ , for every  $r \in [k-1]$  and  $L_{i^*+1} \geq \Delta^{\frac{\epsilon/3}{(k-1)(1+\epsilon/2)}}$ .*

Lemmas 14, 17 and 18 imply Theorem 1.

► **Lemma 18.** *Let  $\sigma$  be the state promised by Lemma 17. Given  $\sigma$ , we can find a full list-coloring of  $H$  in polynomial time in the number of vertices of  $H$ .*

**Proof of Theorem 1.** We carry out  $i^*$  iterations of our procedure. If  $P(i)$  fails to hold for any iteration  $i$ , then we halt. By Lemmas 14 and 17,  $P(i)$  (and, therefore,  $Q(i)$ ) holds with positive probability for each iteration and so it is possible to perform  $i^*$  iterations. Further, the fact that our LLL application is within the scope of the so-called *variable setting* [29] implies that the deterministic version of the Moser-Tardos algorithm [29, 9] applies and, thus, we can perform  $i^*$  iterations in polynomial time.

After  $i^*$  iterations we can apply the algorithm of Lemma 18 and complete the list-coloring of the input hypergraph.  $\blacktriangleleft$

### 3.1 Proof of Lemma 18

Let  $\mathcal{U}_\sigma$  denote the set of uncolored vertices in  $\sigma$ , and  $\mathcal{U}_\sigma(h)$  the subset of  $\mathcal{U}_\sigma$  that belongs to a hyperedge  $h$ . Our goal is to color the vertices in  $\mathcal{U}_\sigma$  to get a full list-coloring.

Towards that end, let  $L_v = L_v(\sigma)$  denote the list of colors for  $v$  at  $\sigma$ , and  $D_r(v, c) := D_{i^*+1, r}(v, c)$  the set of hyperedges (of size  $t_{i^*+1, r}(v, c)$ ) with  $r$  uncolored vertices in  $\sigma$  whose vertices “compete” for  $c$  with  $v$ , and recall the conclusion of Lemma 17. Let  $\mu$  be the probability distribution induced by giving each vertex  $v \in \mathcal{U}_\sigma$  a color from  $L_v$  uniformly at random. For every hyperedge  $h$  and color  $c \in \bigcap_{u \in h} L_u$  we define  $A_{h, c}$  to be the event that all vertices of  $h$  are colored  $c$ . Let  $\mathcal{A}$  be the family of these (bad) events, and observe that for every  $A_{h, c} \in \mathcal{A}$ :

$$\mu(A_{h, c}) \leq \frac{1}{\prod_{v \in \mathcal{U}_\sigma(h)} |L_v(\sigma)|} < \frac{1}{4}$$

for large enough  $\Delta$ , since  $L_{i^*+1} = L_{i^*+1}(\Delta) \xrightarrow{\Delta \rightarrow \infty} \infty$ .

Moreover, let  $I(A_{h, c})$  denote the set of all bad events  $A_{h', c'}$ , where  $h' \neq h$ , such that either  $\mathcal{U}_\sigma(h) \cap \mathcal{U}_\sigma(h') = \emptyset$ , or  $c'$  is not in the list of colors of the (necessarily unique) uncolored vertex that  $h$  and  $h'$  share. Notice that conditioning on any the non-occurrence of any set  $S \subseteq I(A_{h, c})$  does not increase the probability of  $A_{h, c}$ .

Let  $D(A_{h, c}) := \mathcal{A} \setminus I(A_{h, c})$ . Lemma 18 follows from Corollary 8 (and can be made constructive using the deterministic version of the Moser-Tardos algorithm [29, 9]) as, for every  $A_{h, c} \in \mathcal{A}$ :

$$\begin{aligned} \sum_{A \in D(A_{h, c})} \mu(A) &\leq \sum_{v \in \mathcal{U}_\sigma(h)} \sum_{c' \in L_v} \sum_{r=1}^{k-1} \sum_{h' \in D_r(v, c')} \mu(A_{h', c'}) \\ &= \sum_{v \in \mathcal{U}_\sigma(h)} \sum_{c' \in L_v} \sum_{i=1}^{k-1} \sum_{h' \in D_r(v, c')} \frac{1}{\prod_{u \in \mathcal{U}_\sigma(h')} |L_u|} \\ &\leq \max_{v \in \mathcal{U}_\sigma(h)} \frac{k}{|L_v|} \sum_{c' \in L_v} \sum_{r=1}^{k-1} \frac{|D_r(v, c')|}{L_{i^*+1}^r} \end{aligned} \quad (6)$$

$$\leq \frac{k}{10k^2} \max_{v \in \mathcal{U}_\sigma(h)} \frac{L_{i^*+1}^r \cdot |L_v|}{|L_v| \cdot L_{i^*+1}^r} \quad (7)$$

$$\leq \frac{1}{10} < \frac{1}{4}, \quad (8)$$

for large enough  $\Delta$ , concluding the proof. Note that in (6) we used the facts that every hyperedge has at most  $k$  vertices and  $L_{i^*+1} \geq \Delta^{\frac{\epsilon/3}{(k-1)(1+\epsilon/2)}}$ , and in (7) we used the fact that  $|D_r(v, c')| \leq T_{i^*+1}^r \leq \frac{1}{10k^2} L_{i^*+1}^r$ .

**4 A sufficient pseudo-random property for coloring**

In this section we present the proof of Theorem 6. To do so, we build on ideas of Alon, Krivelevich and Sudakov [6] and show that the random hypergraph  $H(k, n, d/\binom{n}{k-1})$  almost surely admits a few useful features.

The first lemma we prove states that all subgraphs of  $H(k, n, d/\binom{n}{k-1})$  with not too many vertices are sparse and, therefore, of small degeneracy.

► **Lemma 19.** *For every constant  $k \geq 2$ , there exists  $d_k > 0$  such that for any constant  $d \geq d_k$ , the random hypergraph  $H(k, n, d/\binom{n}{k-1})$  has the following property almost surely: Every  $s \leq nd^{-\frac{1}{k-1}}$  vertices of  $H$  span fewer than  $s \left(\frac{d}{(\ln d)^2}\right)^{\frac{1}{k-1}}$  hyperedges. Therefore, any subhypergraph of  $H$  induced by a subset  $V_0 \subset V$  of size  $|V_0| \leq nd^{-\frac{1}{k-1}}$ , is  $k \left(\frac{d}{(\ln d)^2}\right)^{\frac{1}{k-1}}$ -degenerate.*

**Proof.** Letting  $r = \left(\frac{d}{(\ln d)^2}\right)^{\frac{1}{k-1}}$ , we see that the probability that there exists a subset  $V_0 \subset V$  which violates the statement of the lemma is at most

$$\begin{aligned} \sum_{i=r^{\frac{1}{k-1}}}^{nd^{-\frac{1}{k-1}}} \binom{n}{i} \binom{\binom{i}{k}}{\binom{i}{r}} \left(\frac{d}{\binom{n}{k-1}}\right)^{ri} &\leq \sum_{i=r^{\frac{1}{k-1}}}^{nd^{-\frac{1}{k-1}}} \left[ \frac{en}{i} \left(\frac{ei^{k-1}}{r}\right)^r \left(\frac{d}{\binom{n}{k-1}}\right)^{r} \right]^i \tag{9} \\ &\leq \sum_{i=r^{\frac{1}{k-1}}}^{nd^{-\frac{1}{k-1}}} \left[ e^{1+\frac{1}{k-1}} (k-1) \left(\frac{d}{r}\right)^{\frac{1}{k-1}} \left(\frac{ei^{k-1}d}{r\binom{n}{k-1}}\right)^{r-\frac{1}{k-1}} \right]^i \\ &= o(1), \end{aligned}$$

for sufficiently large  $d$ . Note that in the lefthand side of (9) we used the fact that any subset of vertices of size  $s < r^{\frac{1}{k-1}}$  cannot violate the assertion of the lemma, since it can span at most  $s^k < rs$  hyperedges. In deriving the final inequality we used that for any pair of integers  $\alpha, \beta$ , we have that  $\binom{\alpha}{\beta} \geq \left(\frac{\alpha}{\beta}\right)^\beta$ . ◀

Next we show that, as far as the number of vertices of  $H(k, n, d/\binom{n}{k-1})$  that have a constant degree  $c$  is concerned, the degree of each vertex of  $H$  is essentially a Poisson random variable with mean  $d$ .

► **Lemma 20.** *For constants  $c \geq 1$ ,  $k \geq 2$  and  $d$ , let  $X_c$  denote the number of vertices of degree  $c$  in  $H(k, n, d/\binom{n}{k-1})$ . Then, for  $c = O(1)$ , with high probability,*

$$X_c \leq \frac{d^c e^{-d}}{c!} n \left( 1 + O\left(\frac{\log n}{\sqrt{n}}\right) \right).$$

### 39:12 Coloring Locally Sparse Hypergraphs

**Proof.** The lemma follows from standard ideas for estimation of the degree distribution of random graphs (see for example the proof of Theorem 3.3 in [13] for the case  $k = 2$ ). In particular, assume that the vertices of  $H(k, n, d/\binom{n}{k-1})$  are labeled  $1, 2, \dots, n$ . Then,

$$\begin{aligned} \mathbb{E}[X_c] &= n \Pr[\deg(1) = c] \\ &= n \binom{\binom{n-1}{k-1}}{c} \left( \frac{d}{\binom{n}{k-1}} \right)^c \left( 1 - \frac{d}{\binom{n}{k-1}} \right)^{\binom{n-1}{k-1} - c} \\ &\leq n \frac{\binom{\binom{n-1}{k-1}}{c}}{c!} \left( 1 + O\left( \frac{c^2}{\binom{n-1}{k-1}} \right) \right) \left( \frac{d}{\binom{n}{k-1}} \right)^c \exp\left( - \left( \binom{n-1}{k-1} - c \right) \frac{d}{\binom{n}{k-1}} \right) \\ &\leq n \frac{d^c e^{-d}}{c!} \left( 1 + O\left( \frac{1}{n^{k-1}} \right) \right). \end{aligned}$$

To show concentration of  $X_c$  around its expectation, we will use Chebyshev's inequality. In order to do so, we need to estimate  $\Pr[\deg(1) = \deg(2) = c]$ . For  $\ell \in \{0, \dots, c\}$ , let  $E_{1,2}^\ell$  denote the event that there exist exactly  $\ell$  hyperedges that contain both vertices 1 and 2. Then, letting  $p = \frac{d}{\binom{n}{k-1}}$ , we see that

$$\begin{aligned} \Pr[\deg(1) = \deg(2) = c] &\leq \sum_{\ell=0}^c \Pr[E_{1,2}^\ell] \left( \binom{\binom{n-1}{k-1}}{c-\ell} p^c (1-p)^{\binom{n-1}{k-1} - c} \right)^2 \\ &= \sum_{\ell=0}^c \binom{\binom{n-2}{k-2}}{\ell} p^\ell (1-p)^{\binom{n-2}{k-2} - \ell} \left( \binom{\binom{n-1}{k-1}}{c-\ell} p^c (1-p)^{\binom{n-1}{k-1} - c} \right)^2 \\ &= \Pr[\deg(1) = c] \cdot \Pr[\deg(2) = c] \left( 1 + O\left( \frac{1}{n^{k-1}} \right) \right). \end{aligned}$$

Therefore,

$$\begin{aligned} \text{Var}[X_c] &= \sum_{i=1}^n \sum_{j=1}^n (\Pr[\deg(i) = c, \deg(j) = c] - \Pr[\deg(i) = c] \Pr[\deg(j) = c]) \\ &\leq \sum_{i \neq j=1} O\left( \frac{1}{n^{k-1}} \right) + \mathbb{E}[X_c] = An, \end{aligned}$$

for some constant  $A = A(c, d)$ .

Finally, applying the Chebyshev's inequality, we obtain that, for any  $t > 0$ ,

$$\Pr[|X_c - \mathbb{E}[X_c]| \geq t\sqrt{n}] \leq \frac{A}{t^2},$$

and, thus, the proof is concluded by choosing  $t = \log n$ . ◀

Lemma 20 implies the following useful corollary.

► **Corollary 21.** *For any constants  $\delta \in (0, 1)$ ,  $k \geq 2$ ,  $d > 0$ , let  $X = X(\delta, k, d)$  denote the random variable equal to the number of vertices in  $H(k, n, d/\binom{n}{k-1})$  whose degree is in  $[(1 + \delta)d, 3(k-1)^{k-1}d]$ . There exists a constant  $d_\delta > 0$  such that if  $d \geq d_\delta$  then, almost surely,  $X \leq \frac{n}{d^2}$ .*

**Proof.** Let  $X_r$  denote the number of vertices of degree  $r$  in  $H(k, n, d/\binom{n}{k-1})$ . Since  $k, d$  are constants, using Lemma 20 and Stirling's approximation we see that, almost surely,

$$\begin{aligned} \sum_{r=(1+\delta)d}^{3(k-1)^{k-1}d} X_r &\leq n \left(1 + O\left(\frac{\log n}{\sqrt{n}}\right)\right) \sum_{r=(1+\delta)d}^{3(k-1)^{k-1}d} \frac{d^r e^{-d}}{r!} \\ &\leq n(1+\delta) \sum_{r=(1+\delta)d}^{3(k-1)^{k-1}d} \frac{d^r e^{-d}}{\sqrt{2\pi r} \left(\frac{r}{e}\right)^r} \leq \frac{n}{d^2}, \end{aligned}$$

for sufficiently large  $d$  and  $n$ . ◀

Using Lemma 19 and Corollary 21 we show that, almost surely, only a small fraction of vertices of  $H(k, n, d/\binom{n}{k-1})$  have degree that significantly exceeds its average degree.

► **Lemma 22.** *For every constants  $k \geq 2$  and  $\delta \in (0, 1)$ , there exists  $d_{k,\delta} > 0$  such that for any constant  $d \geq d_{k,\delta}$ , all but at most  $\frac{2n}{d^2}$  vertices of the random hypergraph  $H(k, n, d/\binom{n}{k-1})$  have degree at most  $(1+\delta)d$ , almost surely.*

**Proof.** Corollary 21 implies that the number of vertices with degree in the interval  $[(1+\delta)d, 3(k-1)^{k-1}d]$  is at most  $\frac{n}{d^2}$ , for sufficiently large  $d$ .

Suppose now there are more than  $\frac{n}{d^2}$  vertices with degree at least  $3(k-1)^{k-1}d$ . Denote by  $S$  a set containing exactly  $\frac{n}{d^2}$  such vertices. According to Lemma 19, almost surely, the induced subhypergraph  $H[S]$  has at most

$$e(H[S]) \leq \left(\frac{d}{(\ln d)^2}\right)^{\frac{1}{k-1}} |S| = \frac{n}{d^{2-\frac{1}{k-1}} (\ln d)^{\frac{2}{k-1}}}$$

hyperedges. Therefore, the number of hyperedges between the sets of vertices  $S$  and  $V \setminus S$  is at least

$$3(k-1)^{k-1}d|S| - ke(H[S]) \geq \frac{2.9(k-1)^{k-1}n}{d} =: N.$$

However, the probability that  $H(k, n, d/\binom{n}{k-1})$  contains such a subhypergraph is at most

$$\binom{n}{\frac{n}{d^2}} \binom{\frac{n^k}{d^2}}{N} \left(\frac{d}{\binom{n}{k-1}}\right)^N \leq (ed^2)^{\frac{n}{d^2}} \left(\frac{n^k e}{d^2 N} \cdot \frac{d}{\binom{n}{k-1}}\right)^N = o(1),$$

for sufficiently large  $d$ . Note that in deriving the final equality we used that for any pair of integers  $\alpha, \beta$ , we have that  $\binom{\alpha}{\beta} \geq \left(\frac{\alpha}{\beta}\right)^\beta$ . Therefore, almost surely there are at most  $\frac{n}{d^2}$  vertices in  $G$  with degree greater than  $3(k-1)^{k-1}d$ , concluding the proof. ◀

Finally, we show that the neighborhood of a typical vertex of  $H(k, n, d/\binom{n}{k-1})$  is locally tree-like.

► **Lemma 23.** *For every constants  $k \geq 2, \delta \in (0, 1)$ , almost surely, the random hypergraph  $H(k, n, d/\binom{n}{k-1})$  has a subset  $U \subseteq V(H)$  of size at most  $n^{1-\delta}$  such that the induced hypergraph  $H[V \setminus U]$  is of girth at least 5.*

## 39:14 Coloring Locally Sparse Hypergraphs

**Proof.** Let  $Y_2, Y_3, Y_4$ , denote the number of 2-, 3- and 4-cycles in  $H(n, k, d/\binom{n}{k-1})$ , respectively. A straightforward calculation reveals that for  $i \in \{2, 3, 4\}$ :

$$\begin{aligned} \mathbb{E}[Y_i] &\leq \sum_{s=1}^{i(k-1)} \binom{n}{s} \binom{\binom{s}{k-1}}{i} \left( \frac{d}{\binom{n}{k-1}} \right)^i \\ &\leq i(k-1)n^{i(k-1)} \left( \frac{(i(k-1))^{k-1} e^2 (k-1)^{k-1}}{in^{k-1}} \right)^i = O(1). \end{aligned}$$

By Markov's inequality this implies that  $Y_2 + Y_3 + Y_4 \leq n^{1-\sqrt{\delta}}$  almost surely. Denote by  $U$  the union of all 2-, 3- and 4- cycles in  $H$ . Then the induced subhypergraph  $H[V \setminus U]$  has girth at least 5 and, almost surely,  $|U| \leq n^{1-\delta}$ . ◀

We are now ready to prove Theorem 6.

**Proof of Theorem 6.** Our goal will be to find a subset  $U \subset V$  of size  $|U| \leq nd^{-\frac{1}{k-1}}$  that (i) contains all cycles of length at most 4 and every vertex of degree more than  $(1+\delta)d$ ; and (ii) such that, every vertex  $v$  in  $V \setminus U$  has at most  $9k^2 \left( \frac{d}{(\ln d)^2} \right)^{\frac{1}{k-1}} = o\left( \left( \frac{d}{\ln d} \right)^{\frac{1}{k-1}} \right)$  neighbors in  $U$ . Note that in this case, according to Lemma 19,  $H[U]$  is  $k \left( \frac{d}{(\ln d)^2} \right)^{\frac{1}{k-1}}$ -degenerate, concluding the proof assuming  $d$  is sufficiently large. A similar idea has been used in [5, 6, 25].

Towards that end, let  $U_1$  be the set of vertices of degree more than  $(1+\delta)d$ , and  $U_2$  the set of vertices that are contained in a 2-,3- or a 4-cycle. Notice that  $U_1, U_2$ , can be found in polynomial time and, according to Lemmas 22 and 23, the size of  $U_0 := |U_1 \cup U_2|$  is at most  $\frac{3n}{d^2}$  for sufficiently large  $n$  and  $d$ .

We now start with  $U := U_0$  and as long as there exists a vertex  $v \in V \setminus U$  having at least  $9k^2 \left( \frac{d}{(\ln d)^2} \right)^{\frac{1}{k-1}}$  neighbors in  $U$  we do the following. Let  $S_v = \{u_1, u_2, \dots, u_N\}$  be the neighbors of  $v$  in  $U$ . We choose an arbitrary hyperedge  $h$  that contains  $v$  and  $u_1$  and update  $U$  and  $S_v$  by defining  $U := U \cup h$  and  $S_v := S_v \setminus h$ . We keep repeating this operation until  $S_v$  is empty.

This process terminates with  $|U| < nd^{-\frac{1}{k-1}}$  because, otherwise, we would get a subset  $U \subset V$  of size  $|U| = nd^{-\frac{1}{k-1}}$  spanning more than

$$\frac{1}{k} \left( \frac{n}{d^{\frac{1}{k-1}}} - |U_0| \right) \times 9k^2 \left( \frac{d}{(\ln d)^2} \right)^{\frac{1}{k-1}} \times \frac{1}{k} > \frac{n}{d^{\frac{1}{k-1}}} \times \left( \frac{d}{(\ln d)^2} \right)^{\frac{1}{k-1}}$$

hyperedges, for sufficiently large  $d$ . According to Lemma 19 however,  $H$  does not contain any such set almost surely. ◀

---

## Abstract

Let  $M$  be an arbitrary  $n$  by  $n$  matrix of rank  $n - k$ . We study the condition number of  $M$  plus a *low-rank* perturbation  $UV^T$  where  $U, V$  are  $n$  by  $k$  random Gaussian matrices. Under some necessary assumptions, it is shown that  $M + UV^T$  is unlikely to have a large condition number. The main advantages of this kind of perturbation over the well-studied dense Gaussian perturbation, where every entry is independently perturbed, is the  $O(nk)$  cost to store  $U, V$  and the  $O(nk)$  increase in time complexity for performing the matrix-vector multiplication  $(M + UV^T)x$ . This improves the  $\Omega(n^2)$  space and time complexity increase required by a dense perturbation, which is especially burdensome if  $M$  is originally sparse. Our results also extend to the case where  $U$  and  $V$  have rank larger than  $k$  and to symmetric and complex settings. We also give an application to linear systems solving and perform some numerical experiments. Lastly, barriers in applying low-rank noise to other problems studied in the smoothed analysis framework are discussed.

## 1 Introduction

The smoothed analysis framework as introduced by Spielman and Teng aims to explain the performance of algorithms on real world inputs through a hybrid of worst-case and average case analysis [25]. In this framework, we are given an arbitrary input that is then perturbed randomly according to some specified noise model. We apply this framework to study the condition number of a matrix perturbed with low-rank Gaussian noise. The condition number is of interest since it influences the behavior of many algorithms in numerical linear algebra, both in theory and in practice.

To give context to our result, recall that the condition number of a  $n \times n$  matrix  $M$  with singular values  $s_1(M) \geq \dots \geq s_n(M)$  is defined as the ratio  $s_1(M)/s_n(M)$ . Generally, a condition number is “well behaved” if  $s_1(M)/s_n(M) = n^{O(1)}$ . It can be shown that under very mild and natural conditions, we have  $s_1(M) \leq n^{O(1)}$ . For instance, this readily follows from Proposition 6 if the entries are not too large compared to the size of  $M$  or if the entries have sufficient tail concentration far from the origin. Since our random variables are

Gaussians, this easily holds. Therefore, the bulk of the work lies in controlling the *smallest* singular value  $s_n(M)$ . Extending a result of Edelman [11], Sankar, Spielman and Teng showed the following result in [22]:

► **Theorem 1.** *There is a constant  $C > 0$  such that the following holds. Let  $M$  be an arbitrary matrix and let  $N_n$  be a random matrix whose entries are iid Gaussian. Let  $M_n = M + N_n$ . Then for any  $t > 0$ ,*

$$\mathbb{P}(s_n(M_n) \leq t) \leq Cn^{1/2}t.$$

Later, Tao and Vu generalized the above result where the entries of  $N_n$  are independent copies of a general class of random variables that have mean zero and bounded variance [32, 27].

## 1.1 Motivation for low-rank noise

The main drawback of these results is that *every* entry of  $M$  must be perturbed by independent noise. This means that if such a perturbation was carried out in practice, we would need to first draw  $n^2$  random numbers and store them. This is more problematic if  $M$  is sparse to begin with and stored in a data structure utilized for sparse matrices. These observations lead us to ask if we can achieve well-conditioned matrices with **less randomness and less space**. Our results demonstrate the answer is yes by replacing the dense Gaussian ensemble  $N_n$  with a *low-rank* matrix.

To further motivate our work, we note that in the context of smoothed analysis, Theorem 1 is used to explain the phenomenon that matrices encountered in practice frequently have “well behaved” condition number. For instance, many matrices can arise out of empirical observations or measurements which can be subject to some inherent noise.

Similarly, low-rank noise is also natural and arises in many scenarios. Low-rank noise has been studied as a noise model in least squares [33], compressed sensing [8, 18, 10], and imaging [15, 26] to name a few applications. In addition, low-rank noise also arises in many applied sciences model, for instance, see the examples in [1] and references therein where examples are given for the eigenvalue problem  $Mx = x + Ex$ , for a low rank matrix  $E$ , arising in scientific modelling. Furthermore, one of the most frequent properties that matrices in data science possess is having low rank (see [6, 7, 30, 19] and references within). Thus for these matrices, the traditional smoothed analysis viewpoint of having a dense perturbation cannot apply due to their low rank requirement.

Hence, an additional motivation of our work is that studying low-rank noise is a natural step in smoothed analysis which we initiate.

## 1.2 Our results

As stated before, we replace the dense Gaussian perturbation  $N_n$  with a low-rank perturbation. Our main result is the following.

► **Theorem 2** (Theorem 13 simplified). *Let  $1 \leq k \leq n/2$  and  $M$  be a matrix of rank  $n - k$ . Let  $U, V$  be  $n \times k$  matrices with i.i.d.  $\mathcal{N}(0, 1)$  entries. Then*

$$\mathbb{P}\left(s_n(M + UV^T) \leq \frac{\varepsilon}{nk} s_{n-k}(M)\right) \leq C\sqrt{\varepsilon} + \exp(-cn)$$

so long as  $s_{n-k}(M) < n$  for absolute constants  $C, c > 0$ .

Theorem 2 roughly states that if we add a rank  $k$  random perturbation to a rank  $n - k$  matrix, then the smallest  $k$  singular values of the matrix improve. The advantage of our approach is that the matrices  $U, V$  can be stored separately from  $M$  using  $O(nk)$  space. This is especially useful in the case that  $M$  is sparse to begin with and is stored using a data structure optimized for sparse matrices. Furthermore, a matrix vector product operation  $(M + UV^T)x$  can be computed in  $\text{Time}(Mx) + O(nk)$  time where  $\text{Time}(Mx)$  is the time required to compute  $Mx$ . For instance, when  $k = O(1)$ , the extra increase in space and time complexity is only  $O(n)$ . This is a significant improvement in both the space required to store a dense Gaussian random matrix  $G$  and computing  $(M + G)x$  which are both  $\Omega(n^2)$ . We prove Theorem 2 in Section 3 and discuss the dependence on the terms  $s_{n-k}(M)$  and  $\sqrt{\varepsilon}$  which we show is unavoidable (see remarks 17, 18).

Theorem 2 can be generalized in a variety of ways. First, our result carries over to the case where we pick the columns of  $U, V$  to be from a rotationally invariant distribution, such as uniform vectors on the unit sphere. We show that our result also carries over to the case where  $M$  is symmetric and we pick  $U = V$  to preserve symmetry.

It is natural to ask if a broader family of random variables can be used in Theorem 2. In Section 3.1 we show that our result *cannot hold* if we pick the entries of  $U, V$  to be from the Rademacher distribution. This is in contrast to the dense perturbation case where Gaussian random variables can be replaced with a wide variety of other distributions such as sub-Gaussian random variables (which include Rademachers). On the other hand, we can get an analogous statement to Theorem 13 if we allow for complex Gaussian perturbations.

► **Theorem 3** (Theorem 15 simplified). *Let  $1 \leq k \leq n/2$  and  $M$  be a matrix of rank  $n - k$ . Let  $U, V$  be  $n \times k$  complex matrices with real and imaginary parts in each entry drawn independently from  $\mathcal{N}(0, 1/2)$ . Then*

$$\mathbb{P}\left(s_n(M + UV^T) \leq \frac{\varepsilon}{nk} s_{n-k}(M)\right) \leq C\varepsilon + \exp(-cn)$$

so long as  $s_{n-k}(M) < n$  for absolute constants  $C, c > 0$ .

A further natural question to consider is if the low-rank noise model can be studied in other problems in smoothed analysis. In Section B, we highlight the challenges that arise when applying low-rank random perturbations to other well studied problems in smoothed analysis such as the simplex method and  $k$ -means clustering. We show that current analysis methods that work for dense random perturbations for these problems do not carry over to the low-rank case due to the lack of independence.

Lastly, we note that Theorem 2 requires that if the input matrix  $M$  has rank  $n - k$ , then perturbation has rank exactly  $k$ . This condition can be relaxed in a couple of ways; first, if we add a perturbation of rank less than  $k$  then the matrix will be singular so there is nothing to study in this case. On the other hand, adding a rank  $k' > k$  perturbation to a rank  $n - k$  matrix can be thought of as adding a rank  $(k' - k)$  perturbation to a full rank matrix since the original matrix plus a rank  $k$  perturbation will be full rank with probability 1. Then as explained further in Section 4, we can obtain the following result in this case.

► **Theorem 4** (Theorem 20 simplified). *Let  $M$  be a  $n \times n$  real matrix with  $\text{rank}(M) = n$ , smallest singular value  $s_n$ , and  $U, V \in \mathbb{R}^{n \times k}$  have independent  $\mathcal{N}(0, 1)$  coordinates. Then for all  $\varepsilon \in (0, 1)$ ,*

$$\mathbb{P}\left(s_n(M + UV^T) \leq \frac{\varepsilon}{\sqrt{n}}\right) \leq C \left( \sqrt{\varepsilon} \left(1 + \frac{2nk}{s_n}\right) + \frac{1}{(2nk)^{9/4}} + \exp(-cnk) \right).$$

The second way to circumvent Theorem 2 is with the use of Weyl’s perturbation inequality. To see how it applies, consider the case of  $k = 1$ . Decompose  $M = s_n(M)\ell_n r_n^T + M'$  where  $\ell_n, r_n$  are the left and right singular vectors associated with  $s_n(M)$ . Then we can view  $M + uv^T$  as a random perturbation of  $M'$  (which has rank  $n - 1$ ), plus matrix  $s_n(M)\ell_n r_n^T$  whose operator norm is at most  $s_n$ . We can then apply Theorem 2 to  $M'$  to bound  $s_n(M' + UV^T)$  in terms of  $s_{n-1}(M') = s_{n-1}(M)$ , and then incur an additional additive  $s_n(M)$  error by Weyl’s inequality. Since our ideal use case is when  $s_n(M)$  is already negligible, the final bound that we get is comparable to the bound from Theorem 2.

Finally in Section 3.2, we discuss an application of low-rank perturbations to solving large sparse linear systems and in Section A, we present numerical evidence for our low-rank error model.

► **Remark 5.** Note that Theorem 1 and the works of Tao and Vu in [32, 27] both prove a statement of the form  $\mathbb{P}(s_n(M + E) \leq n^{-A}) \leq n^{-B}$  where  $E$  is the perturbation and  $A, B$  are parameters that depend on the random variables comprising the perturbation. Our statements in Theorem 2 is also of similar flavor since it shows that  $\mathbb{P}(s_n(M + E) \leq s_{n-k}(M) n^{-A}) \leq n^{-B}$ . Since the theorems of Sankar, Spielman, and Teng and Tao and Vu have found other applications in smoothed analysis, such as in the analysis of the simplex method and beyond, we envision that our theorem could also find similar applications. We discuss barriers in applying the low-rank noise model to other smoothed analysis problems in Section B.

### 1.3 Previous techniques and our approach

In summary, it is difficult to apply previous techniques in our case since we have *shared randomness* across different rows/columns of the matrix. In more detail, all of the previous techniques used to bound the singular values of a random matrix rely on the controlling the distance between a row to the span of the other rows. To see why this is relevant, imagine a singular matrix. In such a case, it is clear that there must exist a row that lies in the span of the other rows. Therefore, controlling the distance from a row to the span of the other rows gives control over the smallest singular value.

Controlling this geometric quantity boils down to understanding the dot product between a row and the normal vector of the hyperplane spanned by the other rows. Crucially if the rows are independent, we can treat the normal vector of the hyperplane as fixed so this question reduces to the well known Erdos-Littlewood-Offord anti-concentration inequality and its variants which are used in previous works such as [28, 32, 27].

To be more precise, lets consider a high level overview of the proof of Sankar, Spielman, and Teng’s Theorem 1. Fix a vector  $x$  and note that from the identity  $s_n(M_n) = \|M_n^{-1}\|$ , it suffices to give a tail bound on  $\|M_n^{-1}x\|$ . By applying an orthogonal rotation and using the rotational invariance of the Gaussian, we can say that

$$\|M_n^{-1}x\| = \|M_n^{-1}e_1\| = \|c_1\|$$

where  $e_1$  is the first basis vector and  $c_1$  is the first column of  $M_n^{-1}$ . From the equation  $M_n \cdot M_n^{-1} = I$ , it follows that  $\|c_1\| = 1/|w^T r_1|$  where  $r_1$  is the first row of  $M_n$  and  $w^T$  is the normal vector of the span of the rows  $r_2, \dots, r_n$ . Therefore, the proof reduces to understanding the dot product between a random vector  $r_1$ , and another independent vector  $w$ . In the more general case of Tao and Vu [32, 27], more elaborate dot product estimates using the Erdos-Littlewood-Offord inequality are needed.

In our case, if we add a rank 1 perturbation to a matrix, randomness is shared across *all* rows. Therefore, we cannot reduce our problem to understanding the dot product between a random vector and another independent vector since fixing a normal hyperplane of a span

of a subset of rows automatically gives information about the rows not considered in the span due to the shared randomness. Hence, it is tricky to apply the spectrum of existing techniques in our case.

To overcome these barriers, we use a completely different method to prove Theorem 13. We first reduce our problem to adding noise to a diagonal matrix by using rotational invariance. Then we employ linear algebraic tools (rather than probabilistic tools), to get an “explicit” representation of the inverse of a matrix after adding rank  $k$  noise. After arriving at an explicit representation of the inverse, we are able to compute a probabilistic bound on the smallest singular value. Our proof crucially uses the fact that our low-rank perturbations have Gaussian entries whereas the proofs of the dense perturbations carry over in other distributional settings as well. This is not a flaw of our method since it is simply not possible to prove an analogue of our theorems even if the entries of the low-rank perturbations come from sub-Gaussian distributions. We elaborate this point further in Section 3.1.

For Theorem 20 where we add a rank  $k$  random noise to a rank  $n$  matrix, we carefully adapt the geometric ideas utilized in previous approaches as explained above. However to get around the shared randomness between rows, we have to perform some careful conditioning which allows us better control the behavior of the random normal vector  $w$ .

#### 1.4 Why would the perturbed matrix even be full rank?

We briefly address the question of why we even expect low-rank perturbations to improve the condition number. Consider the case where  $D$  is a diagonal matrix of rank  $n - 1$  and we add a random rank 1 Gaussian perturbation  $uv^T$ . Recall the matrix determinant lemma which states that

$$\det(D + uv^T) = \det(D) + v^T \text{adj}(D)u$$

where  $\text{adj}(D)$  is the adjugate matrix of  $D$ . In our case, we can assume that the first  $n - 1$  entries on the diagonal of  $D$  are given by  $s_1(D), \dots, s_{n-1}(D)$  while the last entry is 0. Then, the adjugate matrix is the all zeros matrix except the bottom rightmost entry which is  $s_1(D) \cdots s_{n-1}(D)$ . Therefore,

$$\det(D) + v^T \text{adj}(D)u = (u_n v_n)(s_1(D) \cdots s_{n-1}(D))$$

which is non-zero with probability 1 since  $u_n v_n \neq 0$  with probability 1. Thus, adding a random rank 1 perturbation results in  $D$  not being singular which motivates the question of studying the smallest singular value after a random rank 1 (and more generally low-rank) perturbation.

#### 1.5 Related works

The smoothed analysis framework has been applied to a variety of problems, most notably in analyzing optimization problems such as  $k$ -means [2, 3], the perceptron algorithm [5], and the simplex method [25, 9]. In all of these results, the goal is to show that after an input instance of the problem is suitably perturbed, the algorithm or heuristic runs in polynomial time (the time may depend on the properties of the noise). For a survey of results, see [29, 24, 16] and references within. The analysis used tends to be very problem specific and also heavily dependent on the type of noise added which for a vast majority of cases are dense Gaussian noise.

### Zero preserving noise

The work that is closest in spirit to our work is the zero preserving noise model studied by Spielman, and Teng. It was shown in [22] that if  $M$  is a *symmetric* matrix, then adding an independent Gaussian random variable  $x_{ij}$  to each entry  $M_{ij}$  such that  $i \neq j$ ,  $M_{ij} \neq 0$ , and satisfying  $x_{ij} = x_{ji}$  along with a Gaussian perturbation along the diagonal results in a “well behaved” condition number. However, the main drawback of this result is that it only holds for symmetric matrices and even in this case, a dense perturbation is required if  $M$  is dense to begin with.

### Other works

There are works that use sparse Gaussian perturbations, i.e, their perturbation model is a Gaussian times a Bernoulli random variable with a small parameter. If the Bernoulli random variable has sufficiently small parameter, then with high probability, most of the entries in the perturbation will be zero. The downsides of these methods are that many random variables still need to be drawn and it is not clear if they can show the resulting matrix is well conditioned. For example, Theorem 3.6 in [20] only shows that the singular values of the resulting matrix are *separated* from each other, not that the matrix is well conditioned. In fact, the study of these types of random matrices where entries are sub-Gaussian random variables multiplied by independent Bernoulli variables is still lacking. For instance, the smallest singular value of such family of random matrices was only recently resolved in the highly technical paper of Basak and Rudelson [4].

## 1.6 Notation

We use capital letters as  $A, M$  to denote matrices and lower case letters such as  $x$  for vectors. For a vector  $x$ , the norm  $\|x\|$  is always the Euclidean norm whereas for a matrix  $A$ , the norm  $\|A\|$  always refers to the operator norm (the largest singular value). For a matrix  $A$ , let  $A_S$  denote the sub-matrix of  $A$  which includes the  $i$ th row of  $A$  if and only if  $i \in S$ . The relation  $a \lesssim b$  denotes that  $a$  is less than or equal to  $b$  up to some fixed positive constant and similarly,  $a \simeq b$  denotes that  $a$  and  $b$  are equal up to some fixed positive constant. Unless otherwise indicated, variables  $C, c, C_1, C_2, \dots$  denote positive constants.

## 2 Preliminaries

In this section we enumerate some useful results. First, we recall a classical estimate of the operator norm of a random matrix of Seginer [23]. The following proposition essentially shows that the top singular value of a random matrix is well behaved under mild assumptions. Alternatively, one can also bound the top singular value by the frobenius norm if the random variables populating the matrix have sufficient tail concentration.

► **Proposition 6.** *Let  $M$  be a random  $n \times n$  matrix with entries  $m_{ij}$ . Then,*

$$\mathbb{E}\|M\| = O \left( \mathbb{E} \max_{1 \leq i \leq n} \sqrt{\sum_{j=1}^n m_{ij}^2} + \mathbb{E} \max_{1 \leq j \leq n} \sqrt{\sum_{i=1}^n m_{ij}^2} \right).$$

Next we establish tail bounds for the smallest and largest singular values of real and complex Gaussian matrices.

► **Lemma 7** (Theorem 1 reformulated.). Let  $G \in \mathbb{R}^{k \times k}$  with all entries chosen i.i.d. from  $\mathcal{N}(0, 1)$ . Then

$$\mathbb{P}\left(s_k(G) \leq t_1/\sqrt{k}\right) < Ct_1.$$

for some absolute constant  $C$ .

► **Lemma 8** (Theorem 1.1 in [28]). Let  $G \in \mathbb{C}^{k \times k}$  with all entries chosen with i.i.d. real and imaginary parts from  $\mathcal{N}(0, 1/2)$ . Then

$$\mathbb{P}\left(s_k(G) \leq t_1/\sqrt{k}\right) < t_1^2.$$

► **Lemma 9** (Proposition 2.3 in [21]). Let  $G \in \mathbb{R}^{(n-k) \times k}$  for  $k \leq n/2$  with all entries chosen i.i.d. from  $\mathcal{N}(0, 1)$ . Then

$$\mathbb{P}\left(s_1(G) \geq t_2\sqrt{n-k}\right) < C_1 e^{-C_2 t_2^2 n}.$$

for  $t_2$  larger than some absolute constant, and  $C_1, C_2$  absolute constants.

► **Lemma 10.** Let  $G \in \mathbb{C}^{(n-k) \times k}$  for  $k \leq n/2$  with all entries chosen with i.i.d. real and imaginary parts from  $\mathcal{N}(0, 1/2)$ . Then

$$\mathbb{P}\left(s_1(G) \geq t_2\sqrt{n-k}\right) < 2C_1 e^{-C_2 t_2^2 n}.$$

for  $t_2, C_1, C_2$  as in Lemma 9.

**Proof.** Decompose  $G = A + iB$  and bound  $s_1(G) \leq s_1(A) + s_1(B)$ . Then

$$\begin{aligned} \mathbb{P}\left(s_1(G) \geq t_2\sqrt{2(n-k)}\right) &\leq \mathbb{P}\left(s_1(A) + s_1(B) \geq t_2\sqrt{2(n-k)}\right) \\ &\leq \mathbb{P}\left(s_1(A) \geq \frac{t_2\sqrt{2(n-k)}}{2}\right) + \mathbb{P}\left(s_1(B) \geq \frac{t_2\sqrt{2(n-k)}}{2}\right) \\ &\leq \mathbb{P}\left(s_1(\sqrt{2}A) \geq t_2\sqrt{n-k}\right) + \mathbb{P}\left(s_1(\sqrt{2}B) \geq t_2\sqrt{n-k}\right) \\ &\leq 2C_1 e^{-C_2 t_2^2 n} \end{aligned}$$

where the last inequality follows by Lemma 9 since  $\sqrt{2}A$  and  $\sqrt{2}B$  have real i.i.d.  $\mathcal{N}(0, 1)$  entries. ◀

The following lemma bounds the smallest singular value of a block matrix.

► **Lemma 11.** Let

$$M = \begin{bmatrix} A & B \\ C & D \end{bmatrix}$$

be an  $n \times n$  matrix. Then

$$s_n(M)^{-1} \leq \|A^{-1}\| + \|(M/A)^{-1}\| (1 + \|A^{-1}B\|) (1 + \|CA^{-1}\|)$$

where  $(M/A) = D - CA^{-1}B$  is the Schur complement of  $A$ .

**Proof.** We first use the Schur formula for the inverse of a block matrix:

$$M^{-1} = \begin{bmatrix} A^{-1} + A^{-1}B(M/A)^{-1}CA^{-1} & A^{-1}B(M/A)^{-1} \\ (M/A)^{-1}CA^{-1} & (M/A)^{-1} \end{bmatrix}.$$

The norm of  $M^{-1}$  is upper bounded by the sum of the norms of each of its blocks.

$$\begin{aligned} s_n(M)^{-1} = \|M^{-1}\| &\leq \|A^{-1}\| + \|A^{-1}B\| \|(M/A)^{-1}\| \|CA^{-1}\| \\ &\quad + \|A^{-1}B\| \|(M/A)^{-1}\| \\ &\quad + \|(M/A)^{-1}\| \|CA^{-1}\| \\ &\quad + \|(M/A)^{-1}\| \\ &= \|A^{-1}\| + \|(M/A)^{-1}\| (1 + \|A^{-1}B\|) (1 + \|CA^{-1}\|). \end{aligned} \quad \blacktriangleleft$$

Lastly, we recall that Gaussians are sufficiently anti-concentrated.

► **Proposition 12.** *Let  $x \sim \mathcal{N}(0, 1)$ . Then,  $\mathbb{P}(|x| \leq \varepsilon) = \Theta(\varepsilon)$  for  $\varepsilon$  sufficiently small.*

### 3 Proof of main theorems

The goal of this section is to prove the following theorem and its complex and symmetric analogs.

► **Theorem 13.** *Let  $M$  be an arbitrary matrix of rank  $n - k \geq n/2$ . Let  $U, V$  be  $n \times k$  matrices with i.i.d.  $\mathcal{N}(0, 1)$  entries. Then*

$$\mathbb{P}\left(s_n(M + UV^T) \leq \frac{t_1^2}{k} \min\left(\frac{1}{2}, \frac{s_{n-k}(M)}{4t_2^2(n-k)}\right)\right) \leq C_1 t_1 + C_2 \exp(-C_3 t_2^2 n) \quad (1)$$

for  $t_1 \leq C_4$  and  $t_2 \geq C_5$  for some absolute constants  $C_i, 1 \leq i \leq 5$ .

Our strategy to prove Theorem 13 will reduce general  $M$  to the case of  $M$  nonnegative and diagonal, then express  $s_n(M + UV^T)$  in terms of the singular values of  $M$  and certain sub-matrices of  $U$  and  $V$ , and finally apply tail bounds to said singular values. We start by proving a lemma that allows us to reduce to the case of  $M$  nonnegative and diagonal. As stated in Section 1.3, this is a completely different proof strategy than the one used in previous works.

► **Lemma 14.** *Let  $D = \text{diag}(s_n(M), \dots, s_1(M))$ . Let  $U, V$  be as in Theorem 13. Then the distributions of  $s_n(M + UV^T)$  and of  $s_n(D + UV^T)$  are identical.*

**Proof.** Let  $LDR^T = M$  be the singular value decomposition of  $M$ . Then

$$M + UV^T = LDR^T + UV^T = L(D + L^T UV^T R)R^T.$$

Left- and right- multiplication by unitary matrices preserves singular values so

$$s_n(M + UV^T) = s_n(D + L^T UV^T R).$$

Finally,  $U$  and  $V$  are rotationally invariant, so  $L^T U$  and  $R^T V$  are distributed just as  $U$  and  $V$  are. ◀

Now we proceed to the main proof.

**Proof of Theorem 13.** For any matrix  $T$ , recall that  $T_S$  denotes the sub-matrix of  $T$  which includes the  $i$ th row of  $T$  if and only if  $i \in S$ . Lemma 14 shows that we may assume  $M$  is nonnegative and diagonal without loss of generality. We may write  $M$  and  $M + UV^T$  in block form as

$$M = \begin{bmatrix} 0 & 0 \\ 0 & M' \end{bmatrix} \quad \text{and} \quad M + UV^T = \begin{bmatrix} U_{[k]}V_{[k]}^T & U_{[k]}V_{[n]\setminus[k]}^T \\ U_{[n]\setminus[k]}V_{[k]}^T & M' + U_{[n]\setminus[k]}V_{[n]\setminus[k]}^T \end{bmatrix}$$

where  $M'$  has no zeros on the diagonal. We can use Lemma 11 to upper bound  $s_n(M + UV^T)$ . The factor corresponding to the Schur complement is

$$\left\| \left( M' - U_{[n]\setminus[k]} \left( I - V_{[k]}^T (U_{[k]}V_{[k]}^T)^{-1} U_{[k]} \right) V_{[n]\setminus[k]}^T \right)^{-1} \right\| = \|M'^{-1}\| = s_{n-k}(M)^{-1}$$

since  $I - V_{[k]}^T (U_{[k]}V_{[k]}^T)^{-1} U_{[k]} = 0$ . This is one of the key insights of our proof. Then the resulting bound is

$$\begin{aligned} & s_n(M + UV^T)^{-1} \\ & \leq \frac{1}{s_k(U_{[k]})s_k(V_{[k]}^T)} + \frac{1}{s_{n-k}(M)} \left( 1 + \|(U_{[k]}V_{[k]}^T)^{-1}U_{[k]}V_{[n]\setminus[k]}^T\| \right) \left( 1 + \|U_{[n]\setminus[k]}V_{[k]}^T(U_{[k]}V_{[k]}^T)^{-1}\| \right) \\ & = \frac{1}{s_k(U_{[k]})s_k(V_{[k]}^T)} + \frac{1}{s_{n-k}(M)} \left( 1 + \|V_{[k]}^{-1}V_{[n]\setminus[k]}^T\| \right) \left( 1 + \|U_{[k]}^{-1}U_{[n]\setminus[k]}\| \right) \\ & \leq \frac{1}{s_k(U_{[k]})s_k(V_{[k]}^T)} + \frac{1}{s_{n-k}(M)} \left( 1 + \|V_{[k]}^{-1}\| \|V_{[n]\setminus[k]}^T\| \right) \left( 1 + \|U_{[k]}^{-1}\| \|U_{[n]\setminus[k]}\| \right) \\ & = \frac{1}{s_k(U_{[k]})s_k(V_{[k]}^T)} + \frac{1}{s_{n-k}(M)} \left( 1 + \frac{s_1(V_{[n]\setminus[k]})}{s_k(V_{[k]})} \right) \left( 1 + \frac{s_1(U_{[n]\setminus[k]})}{s_k(U_{[k]})} \right). \end{aligned}$$

Denote events

$$\begin{aligned} \mathcal{E}_1 &= \left( s_1(U_{[n]\setminus[k]}) \leq t_2\sqrt{n-k} \quad \text{and} \quad s_1(V_{[n]\setminus[k]}) \leq t_2\sqrt{n-k} \right), \\ \mathcal{E}_2 &= \left( s_k(U_{[k]}) \geq t_1/\sqrt{k} \quad \text{and} \quad s_k(V_{[k]}) \geq t_1/\sqrt{k} \right). \end{aligned}$$

Conditioning on  $\mathcal{E}_1$  and  $\mathcal{E}_2$ , the above bound becomes

$$s_n(M + UV^T)^{-1} \leq \frac{1}{s_{n-k}(M)} \left( 1 + \frac{t_2}{t_1} \sqrt{(n-k)k} \right)^2 + \frac{k}{t_1^2}.$$

For sufficiently large  $n$  (specifically  $n \geq 6\frac{t_1^2}{k t_2^2}$ ), this becomes

$$s_n(M + UV^T)^{-1} \leq \frac{k}{t_1^2} \left( \frac{2t_2^2(n-k)}{s_{n-k}(M)} + 1 \right) \leq \frac{2k}{t_1^2} \max \left( \frac{2t_2^2(n-k)}{s_{n-k}(M)}, 1 \right)$$

Taking the reciprocal of both sides yields

$$s_n(M + UV^T) \geq \frac{t_1^2}{2k} \min \left( \frac{s_{n-k}(M)}{2t_2^2(n-k)}, 1 \right)$$

The probability that this bound is violated is upper bounded by the probability that at least one of  $\mathcal{E}_1$  or  $\mathcal{E}_2$  fail. We may upper bound this quantity using the union bound:

$$\begin{aligned} \mathbb{P}(\neg\mathcal{E}_1 \vee \neg\mathcal{E}_2) &\leq \mathbb{P}(\neg\mathcal{E}_1) + \mathbb{P}(\neg\mathcal{E}_2) \\ &\leq \mathbb{P}(s_1(U_{[n]\setminus[k]}) \geq t_2\sqrt{n-k}) + \mathbb{P}(s_1(V_{[n]\setminus[k]}) \geq t_2\sqrt{n-k}) \\ &\quad + \mathbb{P}(s_k(U_{[k]}) \leq t_1/\sqrt{k}) + \mathbb{P}(s_k(V_{[k]}) \leq t_1/\sqrt{k}) \\ &\leq 2C_1t_1 + 2C_2e^{-C_3t_2^2n}. \end{aligned}$$

where the last step follows by applying Lemmas 7 and 9 twice each. The factors of 2 can be subsumed into the constants  $C_1$  and  $C_2$  giving the final result.  $\blacktriangleleft$

## 40:10 Smoothed Analysis of the Condition Number Under Low-Rank Perturbations

► **Theorem 15.** Let  $M, t_1, t_2, C_2, C_3$  be as in theorem 13. Let  $U, V$  be  $n \times k$  complex matrices with real and imaginary parts drawn independently from  $\mathcal{N}(0, 1/2)$ . Then

$$\mathbb{P}\left(s_n(M + UV^T) \leq \frac{t_1^2}{k} \min\left(\frac{1}{2}, \frac{s_{n-k}(M)}{4t_2^2(n-k)}\right)\right) \leq 2t_1^2 + C_2 \exp(-C_3 t_2^2 n).$$

Note that the first term on the righthand side is  $2t_1^2$  rather than  $C_1 t_1$  as it was in Theorem 13.

**Proof.** The only place the proof differs from the proof of Theorem 13 is in the upper bound on  $\mathbb{P}(-\mathcal{E}_1)$ . Instead of  $C_1 t_1$ , it is simply  $t_1^2$  by Lemma 8. ◀

► **Remark 16.** Theorems 13 and 15 hold when instead of sampling  $U$  and  $V$  independently, simply set  $U = V$ .

**Proof.** The proof follows almost exactly as before with only a single modification: In Lemma 14, the left- and right- singular vectors of symmetric matrices are the same so  $L = R$  (so  $L^T U = R^T V$ ). Optionally, one may note that events  $\mathcal{E}_1$  and  $\mathcal{E}_2$  are redundant, so one reduces the bound on  $\mathbb{P}(-\mathcal{E}_1 \vee -\mathcal{E}_2)$  by a factor of 2. ◀

► **Remark 17.** Let us briefly mention why the term  $s_{n-k}(M)$  is unavoidable in the statement of Theorem 13. For simplicity, consider  $k = 1$  and suppose that  $M$  is of rank  $n - 1$  and suppose its smallest nonzero singular value is equal to  $\delta$ . After adding a rank 1 term  $uv^T$  to  $M$ , its rank is  $n$  with probability 1. However, if we consider the limit  $\delta \rightarrow 0$ , then  $M + uv^T$  approaches a rank  $n - 1$  matrix meaning  $s_n(M + uv^T) \rightarrow 0$ . Hence, any concentration bound such as (1) must depend on the term  $s_{n-1}$ .

► **Remark 18.** The term  $t_1$  on the right hand side of (1) is also unavoidable. For simplicity, consider the case that  $M \in \mathbb{R}^{n \times n}$  is a diagonal matrix and all the entries are non zero except the last diagonal entry and consider a rank 1 symmetric update. Now after a symmetric rank 1 update, the perturbed matrix is  $M + gg^T$  where  $g \in \mathbb{R}^n$ . The smallest singular value of a symmetric matrix is equivalent to the smallest absolute eigenvalue. From the Raleigh quotient characterization of eigenvalues, we have that

$$\mathbb{P}(s_n(M + gg^T) \leq t^2) \geq \mathbb{P}(|e_n^T(M + gg^T)e_n| \leq t^2).$$

Using the fact that  $Me_n = 0$ , we have

$$\mathbb{P}(|e_n^T(M + gg^T)e_n| \leq t^2) = \mathbb{P}(z^2 \leq t^2)$$

where  $z \in \mathbb{R}$  is a standard normal. Finally,  $\mathbb{P}(z^2 \leq t^2) = \mathbb{P}(|z| \leq t) = \Theta(t)$  from Proposition 12 for  $t$  sufficiently small.

### 3.1 Sub-Gaussian perturbations

Just as Tao and Vu generalized Theorem 1 to the case where more general types of random perturbations beyond Gaussian are used, it is of interest to generalize Theorem 13 to the case where  $U, V$  are from a general family of distributions. A standard choice are mean zero sub-Gaussian distributions since they encompass well known distributions such as the standard Gaussian and  $\pm 1$  (Rademacher) random variables. Surprisingly, we show in this case that we cannot state a general statement like Theorem 13 unless extra assumptions about the fixed matrix  $M$  is made.

► **Lemma 19.** *Let  $u, v \in \mathbb{R}^n$  be vectors with i.i.d. entries that are  $\pm 1$  (Rademacher) with equal probability. There exists a rank  $n - 1$  matrix  $M$  such that with constant probability,  $M + uv^T$  is singular.*

**Proof.** As in the proof of Theorem 13, let  $M = LDR$  and we can say  $s_n(M + uv^T) = s_n(D + (L^T u)(v^T R))$ . In the case that  $u$  and  $v$  are Gaussian, rotational invariance implies that  $L^T u$  and  $v^T R$  are distributed as  $u, v$  respectively. However, this is no longer the case if  $u, v$  have entries coming from general sub-Gaussian distributions, such as  $\pm 1$ . Here, the properties of  $L, R$  can have substantial impact on  $s_n(M + uv^T)$ .

Suppose that the top left entry of  $D$  is 0. Then, if the first row of  $L$  is *sparse*, i.e. has  $O(1)$  non zero entries, then it is possible that the first coordinate of  $L^T u$ ,  $(L^T u)_1$ , is 0 with constant probability and hence the first row of  $D + (L^T u)(v^T R)$  is all 0 which implies that  $M + uv^T$  is still rank  $n - 1$  with constant probability. ◀

Therefore, a general statement such as Theorem 13 in the case of sub-Gaussian distributions is impossible unless extra assumptions are made about the input matrix  $M$ . However, we note that in the  $k = 1$  case, if we *assume* every row of  $L, R$  are *dense* (say have at least a constant fraction of non-zero entries), then the proof of Theorem 13 carries through in the  $\pm 1$  case since the two estimates we need (corresponding to the events  $\mathcal{E}_1$  and  $\mathcal{E}_2$  respectively) are the concentration of the norms of  $L^T u, v^T R$  and each entry being anti-concentrated from 0 which follows from Erdos-Littlewood-Offord type results. It is not clear when such an assumption is natural.

## 3.2 Application to linear systems

We briefly highlight the importance of the condition number in solving systems of linear equations. If we are interested in solving the system  $Ax = b$  where  $A \in \mathbb{R}^{n \times n}$  then the condition number of  $A$  influences both the stability and runtime of linear systems solving. Much of this material is standard and can be found in [31].

**Stability:** If  $\tilde{x}$  denotes the result computed by numerical algorithms to the equation  $Ax = b$  then it is known that the relative error quantity  $\|x - \tilde{x}\|/\|x\|$  satisfies

$$\frac{\|x - \tilde{x}\|}{\|x\|} = O\left(\varepsilon_{\text{machine}} \cdot \frac{s_1(A)}{s_n(A)}\right)$$

where  $\varepsilon_{\text{machine}}$  is the machine precision.

**Runtime:** One of the most widely used algorithms for solving systems of linear equations, especially large sparse ones that arise often in practice, is the conjugate gradient descent method. If the conjugate gradient descent method is run for  $k$  steps, then its convergence scales roughly as

$$\left(\frac{\sqrt{s_1(A)/s_n(A)} - 1}{\sqrt{s_1(A)/s_n(A)} + 1}\right)^k \approx \left(1 - \frac{2}{\sqrt{s_1(A)/s_n(A)}}\right)^k.$$

Therefore, a larger the condition number means more steps of the conjugate gradient descent method are required.

The usefulness of our low-rank error model is further supported by the conjugate gradient descent method. As mentioned previously, this iterative method is mainly used for large sparse systems. Thus, a low-rank perturbation that only requires additional linear space and incurs an additive linear increase in cost per iteration is desirable compared to a dense perturbation which makes the original problem infeasible for large systems.

#### 4 Perturbation beyond rank $k$

In this section, we deal with the case that we add a rank  $k'$  perturbation to a rank  $n - k$  matrix for  $k' > k$ . In such a case, we simply ignore a rank  $k$  portion of the noise and imagine that we are adding a rank  $(k' - k)$  perturbation to a general full-rank matrix. This is valid since the original rank  $k$  matrix plus the rank  $k$  part of the noise will be full rank with probability 1. Our result then is the following.

► **Theorem 20.** *Let  $M$  be a  $n \times n$  real matrix with  $\text{rank}(M) = n > 10$  with smallest singular value  $s_n$ . Let  $U, V \in \mathbb{R}^{n \times k}$  have independent  $\mathcal{N}(0, 1)$  coordinates. Then,*

$$\mathbb{P}(s_n(M + UV^T) \leq 1/t) \leq C \left( \frac{\sqrt{n}}{x_2 \cdot t} \left( 1 + \frac{x_1 \cdot x_3^{1/2} \cdot \sqrt{nk}}{s_n(M)} \right) + \exp(-x_1^2/4) + (2/\pi)^{k/2} x_2^k + \exp(-c x_3) \right) \quad (2)$$

for all  $t > 0$ ,  $x_1 \geq 3\sqrt{2\log(2nk)}$ ,  $x_3 \geq nk$ , and  $x_2 \leq 1$ .

We obtain the following corollary under some natural parameter settings.

► **Corollary 21.** *Let  $M$  be a  $n \times n$  real matrix with  $\text{rank}(M) = n$ , and  $U, V \in \mathbb{R}^{n \times k}$  have independent  $\mathcal{N}(0, 1)$  coordinates. Then for all  $\varepsilon \in (0, 1)$ ,*

$$\mathbb{P}(s_n(M + UV^T) \leq \varepsilon/\sqrt{n}) \leq C \left( \sqrt{\varepsilon} \left( 1 + \frac{3nk\sqrt{\log(2nk)}}{s_n(M)} \right) + \frac{1}{(2nk)^{9/4}} + \exp(-cnk) \right). \quad (3)$$

**Proof.** Set  $t = \sqrt{n}/\varepsilon$ ,  $x_1 = 3\sqrt{\log(2nk)}$ ,  $x_2 = \sqrt{\varepsilon}$ ,  $x_3 = nk$ . ◀

By setting  $\varepsilon$  appropriately, we recover the common “theme” of  $\mathbb{P}(s_n(M + UV^T) \leq n^{-A}) \leq n^{-B}$  as in the case of Theorem 1 and the works of Tao and Vu [32, 27].

We now proceed to prove Theorem 20. Denote  $A = M + UV^T$  and note that  $\text{rank}(A) = n$  with probability 1 so  $A^{-1}$  exists. We observe that (2) reduces to bounding  $\mathbb{P}(\|A^{-1}\| \geq t)$ . Our proof is adapted from the proof of Theorem 1. However, we need to perform a careful conditioning argument to prove the most important part of the argument which is presented in Lemma 23.

We begin by handling the case of a single vector.

► **Lemma 22.** *For any unit vector  $y$ , we have*

$$\mathbb{P}(\|A^{-1}y\|_2 \geq t) \leq C \left( \frac{1}{x_2 \cdot t} \left( 1 + \frac{x_1 \cdot x_3^{1/2} \cdot \sqrt{nk}}{s_n(M)} \right) + \exp(-x_1^2/4) + (2/\pi)^{k/2} x_2^k + \exp(-c x_3) \right)$$

for all  $t > 0$ ,  $x_1 \geq 2\sqrt{\log n}$ ,  $x_3 \geq nk$ , and  $x_2 \leq 1$ .

**Proof.** Let  $Q$  be a rotation that takes  $y$  to  $e_n$  and denote  $QA$  as  $A'$ . Then,

$$\|A^{-1}y\|_2 = \|A^{-1}Q^T e_n\|_2 = \|(QA)^{-1}e_n\|_2 = \|c_n\|_2.$$

where  $c_n$  be the last column of  $(QA)^{-1}$ . From the identity  $A'A'^{-1} = I$ , we have that  $c_n$  is orthogonal to the first  $n - 1$  rows of  $A'$  and has dot product 1 with the last row of  $A'$ . Hence,

$$\|c_n\|_2 = \frac{1}{|\langle w, r^n \rangle|}$$

where  $r^i$  is the  $i$ th row of  $A'$  and  $w$  is the unique unit vector orthogonal to the span of  $\{r^1, \dots, r^{n-1}\}$  (up to to sign). This means that

$$\mathbb{P}(\|A^{-1}y\|_2 \geq t) = \mathbb{P}(\|c_n\|_2 \geq t) = \mathbb{P}(|\langle w, r^n \rangle| \leq 1/t).$$

The last row  $r^n$  of  $A'$  is the sum of the last rows of  $QM$  and  $QUV^T$ . Note that the inner product of  $w$  with the last row of  $QM$  is some fixed parameter; denote it  $r$ . Then  $QU$  is distributed as  $U$  by the rotational invariance of the normal distribution, so the last row of  $QUV^T$  is distributed as  $Vu^n$  where  $u^n \in \mathbb{R}^k$  is a vector of independent Gaussians. Therefore,  $\langle w, r^n \rangle$  is distributed as  $\langle w, Vu^n \rangle + r$ , so it suffices to bound the Levy concentration of  $\langle w, Vu^n \rangle$ . Specifically, we want to show that

$$\sup_{r \in \mathbb{R}} \mathbb{P}(|\langle w, Vu^n \rangle + r| < 1/t) \leq C \left( \frac{1}{x_2 \cdot t} \left( 1 + \frac{x_1 \cdot x_3^{1/2} \cdot \sqrt{nk}}{s_n(M)} \right) + \exp(-x_1^2/4) + (2/\pi)^{k/2} x_2^k + \exp(-c x_3) \right)$$

where the probability is over the realization of  $u^n$  and  $V$ . This readily follows from Lemma 23.  $\blacktriangleleft$

**Proof of Theorem 20.** Let  $s$  be a unit vector chosen uniformly at random from  $\mathcal{S}^{n-1}$ . By Lemma 22, we have

$$\mathbb{P}_{A,s}(\|A^{-1}s\|_2 \geq t/\sqrt{n}) \leq C \left( \frac{1}{x_2 \cdot t/\sqrt{n}} \left( 1 + \frac{x_1 \cdot x_3^{1/2} \cdot \sqrt{nk}}{s_n(M)} \right) + \exp(-x_1^2/4) + (2/\pi)^{k/2} x_2^k + \exp(-c x_3) \right).$$

Now with probability 1, there exists a unique  $y$  such that  $\|A^{-1}y\|_2 = \|A^{-1}\|$ . From Lemma 24, we see that

$$\|A^{-1}s\|_2 \geq \|A^{-1}(y^T s)y\|_2 = |y^T s| \|A^{-1}\|.$$

Therefore we have

$$\begin{aligned} \mathbb{P}_{A,s}(\|A^{-1}s\|_2 \geq t/\sqrt{n}) &\geq \mathbb{P}_{A,s}(\|A^{-1}\| \geq t \text{ and } |s^T y| \geq 1/\sqrt{n}) \\ &= \mathbb{P}(\|A^{-1}\| \geq t) \cdot \mathbb{P}_{A,s}(|s^T y| \geq 1/\sqrt{n} \mid \|A^{-1}\| \geq t). \end{aligned}$$

By the rotational invariance of  $s$ , we have that

$$\mathbb{P}(\|A^{-1}\| \geq t) \cdot \mathbb{P}_{A,s}(|s^T y| \geq 1/\sqrt{n} \mid \|A^{-1}\| \geq t) = \mathbb{P}(\|A^{-1}\| \geq t) \cdot \mathbb{P}(|s^T e_1| \geq 1/\sqrt{n}).$$

From Lemma 25, we have that

$$\mathbb{P}(|s^T e_1| \geq 1/\sqrt{n}) \geq \mathbb{P}(|Z| \geq 1) - 1/n$$

where  $Z \sim \mathcal{N}(0, 1)$ . Altogether, it follows that

$$\begin{aligned} \mathbb{P}(\|A^{-1}\| \geq t) &\leq \frac{\mathbb{P}_{A,s}(\|A^{-1}s\|_2 \geq t/\sqrt{n})}{\mathbb{P}(|Z| \geq 1) - 1/n} \\ &\leq C \left( \frac{1}{x_2 \cdot t/\sqrt{n}} \left( 1 + \frac{x_1 \cdot x_3^{1/2} \cdot \sqrt{nk}}{s_n(M)} \right) + \exp(-x_1^2/4) + (2/\pi)^{k/2} x_2^k + \exp(-c x_3) \right) \end{aligned}$$

for  $n > 10$  as desired.  $\blacktriangleleft$

**► Lemma 23.** Let  $U, V \in \mathbb{R}^{n \times k}$  have independent  $\mathcal{N}(0, 1)$  coordinates. Let  $M \in \mathbb{R}^{n \times n}$  be a matrix with singular values  $s_1 \geq \dots \geq s_n$  and let  $w$  be a vector perpendicular to the first  $n-1$  rows of  $M + UV^T$ . Then for  $x_1 \geq 3\sqrt{\log(2nk)}$ ,  $x_3 \geq nk$ , and  $x_2 \leq 1$ , and all  $t > 0$ ,

$$\sup_{r \in \mathbb{R}} \mathbb{P}(|\langle w, Vu^n \rangle - r| < 1/t) \leq C \left( \frac{1}{x_2 \cdot t} \left( 1 + \frac{x_1 \cdot x_3^{1/2} \cdot \sqrt{nk}}{s_n(M)} \right) + \exp(-x_1^2/4) + (2/\pi)^{k/2} x_2^k + \exp(-c x_3) \right)$$

for some  $C, c > 0$  where  $u^n$  is the last row of  $U$ .

## 40:14 Smoothed Analysis of the Condition Number Under Low-Rank Perturbations

**Proof.** Let  $m^1, \dots, m^n$  be the rows of  $M$  and let  $u^1, \dots, u^n$  be the rows of  $U$ . Then the rows of  $A = M + UV^T$  are given by  $m^i + Vu^i$ . Let  $y$  be the unit vector orthogonal to the span of  $\{m^1, \dots, m^{n-1}\}$ . Consider the following three events:

- $\mathcal{E}_1 =$  event that every entry of  $U$  is at most  $x_1$  in absolute value,
- $\mathcal{E}_2 =$  event that  $\|V^T y\|$  is at least  $x_2$ ,
- $\mathcal{E}_3 =$  event that  $\|V\|^2$  is at most  $x_3$ ,

for  $x_1 \geq 3\sqrt{\log(2nk)}$ ,  $x_3 \geq nk$ , and  $x_2 \leq 1$ . Denote  $\mathcal{E} = \mathcal{E}_1 \cup \mathcal{E}_2 \cup \mathcal{E}_3$ . We now show each of these occurs with high probability. By a standard concentration bound, the maximum of  $nk$  i.i.d. standard Gaussians is strongly concentrated around  $\sqrt{2\log(2nk)}$ . In particular,  $\mathcal{E}_1$  happens with probability at least  $1 - 2\exp(-x_1^2/4)$ . Next, each coordinate of  $V^T y$  is distributed as  $\mathcal{N}(0, 1)$ , and  $\|V^T y\| \geq \|V^T y\|_\infty$ , so we may upper bound  $\mathbb{P}(\mathcal{E}_2^c)$  by  $\mathbb{P}(|g| < x_2)^k$  where  $g$  is  $\mathcal{N}(0, 1)$ . This means  $\mathcal{E}_2$  occurs with probability at least  $1 - (2/\pi)^{k/2} x_2^k$ . Lastly, the event  $\mathcal{E}_3$  happens with probability at least  $1 - \exp(-\Omega(x_3))$  by Lemma 9.

Now fix some realization of  $V$  and  $U$  such that  $\mathcal{E}$  occurs. Suppose for some parameter  $z < \frac{\sqrt{3}}{2} \frac{s_n}{x_1 \cdot \sqrt{nk}}$  that we have  $\|V^T w\| < z$ . We will find a statement which this assumption implies, then take the contrapositive to obtain a lower bound on  $\|V^T w\|$ . From definition of  $w$ , we know

$$\langle w, m^i \rangle + \langle w, Vu^i \rangle = 0$$

for  $1 \leq i \leq n-1$ . We may apply Cauchy-Schwarz to  $\langle w, Vu^i \rangle = \langle V^T w, u^i \rangle$  and use event  $\mathcal{E}_1$  to bound  $\|u^i\|$  and obtain

$$|\langle w, m^i \rangle| \leq \|V^T w\| \cdot \|u^i\| \leq z \cdot x_1 \cdot \sqrt{k}.$$

Decompose  $w = w^\parallel + w^\perp$  where  $w^\parallel$  is in the span of  $m^1, \dots, m^{n-1}$  and  $w^\perp$  is in the orthogonal complement. Write  $w^\parallel = \sum_{i=1}^{n-1} \alpha_i m^i$  for some coefficients  $\alpha_i$ . Then we have

$$\begin{aligned} \|w^\parallel\|^2 &= |\langle w^\parallel, w \rangle| \leq \sum_{i=1}^{n-1} |\alpha_i| \cdot |\langle m^i, w \rangle| \\ &\leq \|\alpha\|_1 \cdot z \cdot x_1 \cdot \sqrt{k} \\ &\leq \|\alpha\| \cdot z \cdot x_1 \cdot \sqrt{nk} \\ &\leq \|w^\parallel\| \frac{z \cdot x_1 \cdot \sqrt{nk}}{s_n} \end{aligned}$$

where  $\alpha$  is the vector of  $\alpha_i$ 's, and the last step follows since  $M$  is non-singular, making  $\alpha$  the unique solution to  $M^T \alpha = w^\parallel$ . Now, note that  $y$  and  $w^\perp$  are parallel, so

$$\|w^\perp\| \|V^T y\| = \|V^T w^\perp\| \leq \|V^T w\| + \|V^T w^\parallel\| \leq z + \|V\| \|w^\parallel\| \leq z \left( 1 + \frac{x_1 \cdot x_3^{1/2} \cdot \sqrt{nk}}{s_n} \right)$$

where the last step follows from  $\mathcal{E}_3$ . From  $z < \frac{\sqrt{3}}{2} \frac{s_n}{x_1 \cdot \sqrt{nk}}$ , we have

$$\|w^\perp\| = \sqrt{1 - \|w^\parallel\|^2} = \sqrt{1 - \left( \frac{z \cdot x_1 \cdot \sqrt{nk}}{s_n} \right)^2} > \frac{1}{2}.$$

Moving  $\|w^\perp\|$  to the right hand side and using  $\mathcal{E}_2$  and the above bound, we arrive at

$$x_2 \leq \|V^T y\| < 2z \left( 1 + x_1 \cdot x_3^{1/2} \cdot \sqrt{nk}/s_n \right).$$

We have thus established the syllogism

$$\|V^T w\| \leq z \leq \frac{\sqrt{3}}{2} \frac{s_n}{x_1 \cdot \sqrt{nk}} \implies \frac{1}{2} \frac{x_2 s_n}{s_n + x_1 \cdot x_3^{1/2} \cdot \sqrt{nk}} < z.$$

By taking the contrapositive and setting  $z = \frac{1}{2} \frac{x_2 s_n}{s_n + x_1 \cdot x_3^{1/2} \cdot \sqrt{nk}}$ , we see that one of the inequalities on the left must fail. It isn't the second one since  $x_2 < \sqrt{3}$ ,  $x_3^{1/2} > 1$ , and  $s_n > 0$ . We therefore conclude our selection of  $z$  lower bounds  $\|V^T w\|$ .

This leads to sufficient anti-concentration. For any fixed vector  $x$ , the distribution of  $\langle x, u^n \rangle$  is the same as  $\mathcal{N}(0, \|x\|^2)$ . So,  $\langle V^T w, u^n \rangle$  for random  $V$  is a mixture of Gaussians, each of which have variance at least  $z^2$  when we condition on  $\mathcal{E}$ . The Levy concentration is thus easily bounded by

$$\sup_{r \in \mathbb{R}} \mathbb{P} \left( |\langle w, V u^n \rangle + r| \leq \frac{1}{t} \mid \mathcal{E} \right) \leq \frac{\sqrt{2/\pi}}{z \cdot t}.$$

The desired bound then follows by incorporating a probability bound on the complement of  $\mathcal{E}$ .  $\blacktriangleleft$

The following lemmas follow easily from basic properties of the SVD and Gaussian random variables so we omit their proof.

► **Lemma 24.** Consider a  $n \times n$  matrix  $M$  and  $u \in \mathcal{S}^{n-1}$  such that  $\|M\| = \|Mu\|_2$ . Then for every  $v \in \mathbb{R}^n$ , we have

$$\|Mv\|_2 \geq |u^T v| \|M\|.$$

► **Lemma 25.** Let  $x$  be a uniformly random vector in  $\mathcal{S}^{n-1}$  and  $Z \sim \mathcal{N}(0, 1)$ . Then for every  $c > 0$ ,

$$\mathbb{P} \left( |x^T e_1| \geq \sqrt{\frac{c}{n}} \right) \geq \mathbb{P}(|Z| \geq \sqrt{c}) - \frac{1}{n}.$$

## A Numerical experiments

In this section, we numerically demonstrate our theoretical results by giving an example of a sparse family of  $n$  by  $n$  matrices that are “poorly” conditioned and whose condition number improves significantly after adding a random Gaussian rank 1 perturbation. We show that this perturbation results in an improvement comparable to what is achieved after adding a dense Gaussian matrix while maintaining a low time complexity for matrix vector product operations.

Our family of  $n$  by  $n$  matrices will be constructed as follows:  $M_n$  will have ones on the anti-diagonal and the first and third off-diagonals above the anti-diagonal. For example,  $M_7$  is displayed below.

$$\begin{bmatrix} 0 & 0 & 0 & 1 & 0 & 1 & 1 \\ 0 & 0 & 1 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

It is shown in [13] that  $M_n$  is ill-conditioned by showing that the magnitude of the smallest eigenvalue of  $M_n$  is of the order  $O(n/C^n)$  where  $C \approx 1.47$  which implies that the smallest singular value of  $M_n$  is also at most  $O(n/C^n)$ . The second smallest eigenvalue on the other hand is a constant.

**Figure 1** (a) Smallest singular values of the original matrix compared against dense and rank 1 perturbations. (b) Time taken to perform a matrix vector product after a dense perturbation and a rank 1 perturbation. The cost for the dense perturbation has a quadratic scaling (slope = 2).

In Figure 1 (a), we show the smallest singular value of  $M_n$  for a range of  $n$  along with the smallest singular values after a dense and rank 1 perturbation. As we can see in the log-log plot, the original values are decaying exponentially while the smallest singular value after the rank 1 perturbation is within a few orders of magnitude of the corresponding value after a dense perturbation. In Figure 1 (b), we show the time taken to perform a matrix vector product after a dense and a rank 1 perturbation. For this task, we used the popular numerical libraries NumPy and SciPy. Since  $M_n$  is sparse, it can be represented in a special sparse format to speed up computations. In the case of a rank 1 perturbation, we only need to store two additional vectors and a matrix vector product  $(M + uv^T)x$  can be performed as

$$(M_n + uv^T)x = M_n x + (v^T x) \cdot u.$$

However, in the case of a dense perturbation, we need to store a dense matrix  $G$  and perform the matrix vector product operation with a vector and a dense matrix resulting in a much slower operation than in the rank 1 case. Indeed, note that the slope of the “Dense” curve in Figure 1 (b) is close to 2 signifying a quadratic increase in time. Overall, we see that in this case, a rank 1 update results in a comparable improvement of the condition number of  $M_n$  while greatly improving the cost to perform a fundamental matrix operation.

## **B** Low-rank noise model for other problems in smoothed analysis

In this section, we outline some of the challenges that arise when applying the rank 1 noise model in other popular problems studied in smoothed analysis. While not a comprehensive survey of all problems, we focus on two of the most studied applications of this framework outside of the condition number. These are the simplex method and  $k$ -means. For these problems, the standard noise model is the dense one where every entry of the input matrix or input set of points respectively, is independently perturbed by a random Gaussian. We highlight some of the challenges that arise when trying to carry out existing proof techniques for these problems using rank 1 noise. This ultimately shows that new ideas are required to bypass the lack of independence as we did for the condition number.

## B.1 Simplex method

The simplex method is one of the most famous applications of the smoothed analysis framework. The goal is to solve a linear program of the form  $\max c^T x$  subject to  $Ax \leq b$  using the simplex method where the entries of  $A \in \mathbb{R}^{m \times n}$  have been perturbed by random noise. Recall that the simplex method operates by moving among the vertices of the polytopes defined by the constrained matrix  $A$ . The geometric operation of moving from one vertex to another is called a pivot operation and the most commonly analyzed pivot operation with respect to smoothed analysis is the shadow vertex pivot method.

Without getting into technical details that will lead us too far afield, we note that the shadow vertex pivoting method requires us to calculate the following bound: let  $a_i$  for  $1 \leq i \leq m$  denote the rows of the matrix  $A$  and let  $W$  be a fixed two dimensional subspace. We wish to bound

$$\mathbb{E}[|\text{edges}(\text{conv}(a_1, \dots, a_m) \cap W)|]$$

where  $\text{conv}(a_1, \dots, a_m)$  is the convex hull of the rows (see [9] for more information).

To calculate the above bound, we essentially need to understand the probability that  $a_j^T \theta \leq t$  for a range of values of  $j$  and some  $t \in \mathbb{R}$  (here  $\theta$  represents the normal vector of the line connecting some two points  $a_i, a_k$ . For the pair  $a_i, a_k$  to be on the convex hull, we need the rest of the points to be on one side of the line). In the case that we add independent noise across the rows, this bound is possible to compute due to independence across  $a_j$ . However, in the case that we add rank 1 noise  $u^T v$  (here  $u \in \mathbb{R}^m, v \in \mathbb{R}^n$ ) to  $A$ , these probabilities become intractable using existing methods since  $a_j$  satisfying  $a_j^T \theta \leq t$  gives us information about all other  $a_{j'}$  for  $j' \neq j$  since randomness is shared across the rows.

Nevertheless, it is possible to get a weak result for the smoothed analysis of the simplex method in our low-rank noise model by using a different pivoting operation. It is shown in [12] that if the rows satisfy a certain *geometric* property, then using a random pivoting rule results in an expected polynomial number of steps for the simplex method to converge.

The geometric property is the following: For any  $I \subseteq [m]$ , and  $j \in [m]$ , if  $a_j$  is not in the span generated by  $a_i, i \in I$ , then the distance from  $a_j$  to this span is at least  $\delta$ . We note that the bound on the expected number of steps depends polynomially on  $1/\delta$  and other parameters. This geometric property reduces to a singular value estimate as follows. For simplicity, lets focus on  $j = 1$  and  $I = \{2, \dots, n-1\}$ . As in Section 1.3, it follows that  $\|A_{[n]}^{-1} e_1\|$  is equal to  $1/|w^T a_1|$  where  $w$  is the normal vector of the span of the rows  $a_2, \dots, a_n$ . Thus, if  $s_n(A_{[n]})$  is “not too small” then  $\|A_{[n]}^{-1} e_1\|$  cannot be “too large” and consequently, the distance from  $a_1$  to the span of  $a_2, \dots, a_n$  is “not too small” (we are intentionally leaving our specific relations for a high level overview). The caveat is that we need the geometric property to hold between  $a_1$  and *every* set of  $n-1$  other vectors. However, since the bound of Theorem 13 only gives us an inverse polynomial probability, we cannot afford the union bound of  $\binom{m}{n}$  unless  $m = n + C$  for some constant  $C$ , which is not a realistic scenario.

Lastly, empirical evidence shows that rank 1 perturbation may not be a suitable if the *original* simplex method (the Dantzig simplex method) is used. In Figure 2, we use the Klee-Minty lower bound [14] for the Dantzig simplex method and add either a dense Gaussian or a rank 1 perturbation to the constraint matrix. We then plot the average number of pivot steps taken over twenty independent trials. It can be seen that a rank 1 perturbation only slightly improves over the exponential number of pivot steps required by the Dantzig simplex method whereas dense perturbations help greatly.

We conclude our discussion with a major open problem.

■ **Figure 2** The Dantzig simplex method applied to the Klee-Minty lower bound and its random perturbations.

► **Open Problem 26.** *Is there a pivoting rule for the simplex method that runs in expected polynomial time if we add random rank 1 noise to the constraint matrix?*

## B.2 *k*-means clustering

Recall that in the *k*-means problem, we are given a set  $X$  of  $n$  points in  $\mathbb{R}^d$  and our goal is to partition the points into  $k$  sets  $S_i$  to minimize the objective

$$\sum_{i=1}^k \sum_{x \in S_i} \|x - \mu_i\|^2$$

where  $\mu_i$  is the mean of the points in  $S_i$ . A common heuristic for this problem, also confusingly known as the *k*-means algorithm, or Lloyd’s method, is to randomly pick an initial set of  $k$  centers, assign each point in  $X$  to its closest center, update the means accordingly, and repeat until convergence. In the smoothed analysis framework, it was shown that if each point in  $X$  is perturbed by an independent Gaussian vector then convergence happens in polynomially many steps [3]. The existing analysis all crucially rely on the following geometric lemma.

► **Lemma 27.** *Let  $x \in \mathbb{R}^d$  be drawn according to a  $d$ -dimensional Gaussian distribution of standard deviation  $\sigma$ , and let  $B$  be the  $d$ -dimensional ball of radius  $\varepsilon$  centered at the origin. Then  $\mathbb{P}(x \in B) \leq (\varepsilon/\sigma)^d$ .*

This lemma roughly states that the probability of a random Gaussian being in any ball of radius  $\varepsilon$  is at most  $\varepsilon^d$ , and is used to union bound over exponentially many events in the smoothed analysis of *k*-means.

Surprisingly, this lemma *does not* hold in our “rank 1” setting. More precisely, we can prove the following probabilistic bound which is a major impediment to understanding the smoothed complexity of the *k*-means problem with rank 1 noise.

► **Lemma 28.** *Let  $x \in \mathbb{R}^d$  be drawn according to a standard  $d$ -dimensional Gaussian distribution and let  $y \in \mathbb{R}$  be a scalar standard Gaussian random variable. If  $B$  is the  $d$ -dimensional ball of radius  $\varepsilon$  centered at the origin then  $\mathbb{P}(yx \in B) = O(\varepsilon/\sqrt{d})$ .*

Note that  $yx \in \mathbb{R}^d$ . We are considering random variables of this form because if a rank 1 perturbation was added to  $X$ , then each row is perturbed by a random vector of the form  $yx \in \mathbb{R}^d$ . Lemma 28 roughly states that the probability that the random vector  $yx$  is in any ball of radius  $\varepsilon$  only weakly depends on the dimension  $d$ . In particular, we do not get an exponentially small probability afforded by Lemma 27 that enables us to union bound over exponentially many events as in the arguments for the smoothed analysis of  $k$ -means under the standard noise model.

The intuition for Lemma 28 is as follows. First, note that from standard Gaussian concentration, we have  $\|x\| \approx \sqrt{d}$ . Treating this as fixed for now, this means that  $y\|x\|$  is approximately distributed as a scalar Gaussian distribution with variance  $d$ . Therefore, from Proposition 12, it follows that  $\mathbb{P}(|y\|x\| \leq \varepsilon) = \Theta(\varepsilon/\sqrt{d})$ . We now formalize this argument.

**Proof.** Note that  $\|x\|_2^2$  is a chi-squared variable with  $d$  degrees of freedom. From [34], we know that the density of the product  $Z = \|yx\|_2^2 = y^2\|x\|_2^2$  is given by

$$f_Z(z) \simeq \frac{1}{2^{d/2}\Gamma(d/2)} \int_0^\infty \left(x^{d/2-2}e^{-x/2}\right) \left(\frac{1}{\sqrt{z/x}}e^{-z/(2x)}\right) dx.$$

Therefore,

$$\mathbb{P}(\|yx\|_2^2 \leq \varepsilon^2) \simeq \frac{1}{2^{d/2}\Gamma(d/2)} \int_0^{\varepsilon^2} \int_0^\infty \left(x^{d/2-2}e^{-x/2}\right) \left(\frac{1}{\sqrt{z/x}}e^{-z/(2x)}\right) dx dz.$$

We now switch the order of summation which is valid since the integrand is positive. From the definition of the error function, we can check that

$$\int_0^{\varepsilon^2} \frac{1}{\sqrt{z/x}}e^{-z/(2x)} dz \simeq x \cdot \operatorname{erf}(\varepsilon/\sqrt{x}).$$

We now use the estimate  $\operatorname{erf}(t) \leq 2t$  which holds for all  $t \geq 0$ . This gives us

$$\int_0^\infty x^{d/2-1}e^{-x/2}\operatorname{erf}(\varepsilon/\sqrt{x}) dx \lesssim \varepsilon \int_0^\infty x^{d/2-3/2}e^{-x/2} dx = \varepsilon 2^{d/2-1/2}\Gamma(d/2 - 1/2).$$

Finally, noting that  $\Gamma(d/2 - 1/2)/\Gamma(d/2) \lesssim 1/\sqrt{d}$  gives us our desired probability bound. ◀

Note that the above bound is the best that we can hope for. Indeed, we can say that  $\|x\|_2^2 = \Omega(d)$  with probability  $1/2$  so conditioning on this event, we have that  $\Pr(|y\|x\|_2 \leq \varepsilon) = \Omega(\varepsilon/\sqrt{d})$ . We note that Lemma 27 is also required for the smoothed analysis of other Euclidean problems such as a local search heuristic for Euclidean TSP [17].

# Matroid Intersection: A Pseudo-Deterministic Parallel Reduction from Search to Weighted-Decision

Sumanta Ghosh  

Indian Institute of Technology Bombay, India

Rohit Gurjar  

Indian Institute of Technology Bombay, India

---

## Abstract

We study the matroid intersection problem from the parallel complexity perspective. Given two matroids over the same ground set, the problem asks to decide whether they have a common base and its search version asks to find a common base, if one exists. Another widely studied variant is the weighted decision version where with the two matroids, we are given small weights on the ground set elements and a target weight  $W$ , and the question is to decide whether there is a common base of weight at least  $W$ . From the perspective of parallel complexity, the relation between the search and the decision versions is not well understood. We make a significant progress on this question by giving a pseudo-deterministic parallel (NC) algorithm for the search version that uses an oracle access to the weighted decision.

The notion of pseudo-deterministic NC was recently introduced by Goldwasser and Grossman [19], which is a relaxation of NC. A pseudo-deterministic NC algorithm for a search problem is a randomized NC algorithm that, for a given input, outputs a fixed solution with high probability. In case the given matroids are linearly representable, our result implies a pseudo-deterministic NC algorithm (without the weighted decision oracle). This resolves an open question posed by Anari and Vazirani [2].

## 1 Introduction

Most often, a search problem can be efficiently solved using an oracle for a closely related decision problem. For example, if you have access to a decision oracle that tells you whether a given graph has a perfect matching, you can efficiently construct a perfect matching in a given graph using the decision oracle. Such search-to-decision reductions usually involve self-reducibility and make a linear number of oracle calls sequentially. However such reductions do not fit into the framework of parallel complexity, where one can make multiple oracle calls in parallel, but wants poly-logarithmic time complexity. For a more detailed discussion on the difference in parallel complexity of search and decision problems, see [25].

Graph matching and related problems like linear matroid intersection and linear matroid matching were one of the first problems to be studied from the parallel complexity perspective [26, 5]. The decision versions of these problems ask to decide the existence of the respective combinatorial substructures:

- Matching: Does a given graph contain a perfect matching – a set of disjoint edges that cover all the vertices in the graph?
- Linear Matroid Intersection: Given two sets of  $m$  vectors each, is there a set of indices  $B \subseteq [m]$  that corresponds to a basis set in each of the two sets?
- Linear Matroid Matching/Parity: Given a set of pairs of vectors, is there a subset of pairs whose union will give a basis for the union of all pairs?

The search versions of these problems ask for constructing the respective combinatorial substructures (if one exists). The matching problem in bipartite graphs is a special case of all the three problems above (see Figure 1). A bipartite graph is a graph whose vertices can be partitioned into two parts such that every edge connects a vertex from one part to one in the other part. Even in the special case of bipartite matching, the questions of the exact parallel complexity of decision and search and whether decision and search are equivalent in a parallel sense still remain unresolved.

■ **Figure 1** Reductions among the four problems.  $A \rightarrow B$  represents that problem  $A$  reduces to problem  $B$ .

The first efficient randomized parallel algorithms for the three decision problems above followed from the results of Lovász [26]. Lovász gave randomized algorithms for these problems by first reducing these decision questions to testing whether the determinant of a certain symbolic matrix is nonzero, as a polynomial. Then he used the fact that the zeroness of a polynomial can be tested efficiently by just evaluating it at a random point [32, 36, 12, 29]. Hence, the questions were basically reduced to computing determinant of a randomly generated matrix. Interestingly, there are efficient parallel (NC) algorithms for computing the determinant of a matrix [3, 7, 4]. An NC algorithm is one which uses polynomially many parallel processors and takes only polylogarithmic time. Thus, the algorithms of Lovász [26] can be viewed as randomized parallel (RNC) algorithms for the three decision problems. However, this did not imply any parallel algorithms for the search versions.

Randomized parallel (RNC) algorithms for the search versions of these problems were obtained some years later [24, 27, 28]. However, these results did not go via a parallel search-to-decision reduction. Instead, they gave randomized parallel (RNC) reductions from the search version to a variant of the decision problem, namely *weighted decision*. For example, the weighted decision version for perfect matchings asks: given a graph with *small* weights on edges and a target weight  $W$ , is there a perfect matching of weight at most  $W$  (or at least  $W$ ). Here the weight of a perfect matching is defined to be the sum of the

weights of the edges in the perfect matching. It turns out that Lovász's RNC algorithms can be appropriately modified to solve the weighted decision versions as well, when the given weights are small. The search-to-weighted-decision reductions together with the weighted decision algorithms implied randomized parallel search algorithms for the three problems. We elaborate a bit on the reductions.

### Reductions from search to weighted-decision

Karp, Upfal and Wigderson [24] do not explicitly talk about weights, but their reduction is from finding a perfect matching to a subroutine that can be viewed as weighted decision with 0-1 weights on the edges. From the perspective of our current investigation, the result of Mulmuley, Vazirani, and Vazirani [27] is much more interesting. They showed that using the weighted decision oracle, one can compute a perfect matching with just two rounds of parallel calls to the oracle. The crucial ingredient in their algorithm was the powerful Isolation Lemma which states that if the edges of a graph are assigned random weights from a polynomially bounded range uniformly and independently then with high probability, there is a *unique* minimum weight perfect matching in the graph. Once we have such a weight assignment, we can first find the minimum weight  $w^*$  of a perfect matching by calling the weighted decision oracle for each possible target value  $W$  in a polynomially bounded range. Then for each edge  $e$  in parallel, delete  $e$  and ask the oracle if there is a perfect matching of weight at most  $w^*$ . The answer will be no if and only if  $e$  is a part of the unique minimum weight perfect matching. Thus, in two rounds of polynomially many parallel oracle calls, we can compute the unique minimum weight perfect matching.

The amazing thing about the Isolation Lemma is that it applies to not just the family of perfect matchings in a graph, but to arbitrary families of subsets. Thus, the above described search-to-weighted-decision reduction of [27] can be made to work for any problem that admits a similar self-reducibility property. Narayan, Saran, and Vazirani [28] used the same Isolation Lemma based reduction to give RNC algorithms for the search versions of linear matroid intersection and linear matroid matching.

### Derandomization

Since the work of Lovász [26], it has been a big open question to derandomize these results i.e., to find deterministic parallel (NC) algorithms for these problems. While derandomization results have been obtained for the matching problem in many special classes of graphs [11, 35, 10, 20, 1], the question remains open even for bipartite graphs. Only recently, there was a significant progress made when a quasi-NC algorithm was obtained for finding a perfect matching in a bipartite graph [16, 15]. A quasi-NC algorithm runs in polylogarithmic time but can use quasipolynomially ( $2^{\log^{O(1)} n}$ ) many parallel processors, so this result brought the problem quite close to the class NC. Similar quasi-NC algorithms were later obtained for linear matroid intersection [22] and matching in general graphs [34] as well.

In the quest of understanding the deterministic parallel complexity of these problems, an interesting question one can ask is whether there is a deterministic parallel (NC) search-to-decision reduction. An easier question would be to ask for an NC reduction from search to weighted-decision, i.e., derandomizing the reductions of [27, 24, 28] described above. Soon after the quasi-NC result for bipartite matching [16], Goldwasser and Grossman [19] started quite an interesting line of enquiry, where they answered the above question positively for bipartite matching. They observed that the quasi-NC algorithm can be modified to give a deterministic parallel (NC) search-to-weighted-decision reduction for bipartite matching. Their main result was, what they call, a pseudo-deterministic NC algorithm for bipartite matching, which followed from this reduction.

### Pseudo-determinism

The notion of pseudo-deterministic algorithms was introduced by Gat and Goldwasser [17] which is applicable only for search problems. For a given instance of a search problem, a randomized algorithm can possibly give different outputs for different choices of the random seed. Pseudo-deterministic algorithms are randomized algorithms which give a fixed output for a given input with high probability. Note that the earlier described RNC algorithm of [27] for matching is not pseudo-deterministic because for a given graph, it will output different perfect matchings for different possibilities of the randomly chosen weight assignment.

It is not hard to see that if one gives a *deterministic* reduction from a search problem to a decision problem that is known to have a randomized algorithm, then one immediately gets a pseudo-deterministic algorithm for the search problem (see [18, Theorem 2.2]). That is why the NC search-to-weighted-reduction for bipartite matching [19] implied a pseudo-deterministic NC algorithm for bipartite matching, i.e., an RNC algorithm that, for a given graph, outputs the same perfect matching with high probability. One interesting implication of this result is that if one finds an NC algorithm for the weighted-decision of bipartite matching, one will get an NC algorithm for the search version as well.

A natural question arises: can we similarly modify the quasi-NC algorithms for linear matroid intersection [22] and matching in general graphs [34] into NC search-to-weighted-decision reductions, and thus, get pseudo-deterministic NC algorithms for the search versions? It looks quite possible because one can extract out an abstract framework from [19] for converting these quasi-NC algorithms into pseudo-deterministic NC algorithms. But as we discuss below, a straightforward application of this framework does not work out for linear matroid intersection or matching in general graphs. A key step in [19] is to *compute a succinct description* of the set of all (possibly exponentially many) minimum weight perfect matchings in a weighted bipartite graph in NC, given the weighted-decision oracle. However, it is not immediately clear how to solve the analogous question in NC for linear matroid intersection or matching in general graphs. Interestingly, in an earlier work in a different context, Cygan, Gabow, and Sankowski [9] had already solved this question for matching in general graphs. They had designed a procedure based on LP duality to compute a succinct description of the set of all minimum weight perfect matchings, via the weighted-decision oracle. Moreover, as observed in [30], this procedure can also be parallelized using standard techniques. Armed with this heavy hammer, Anari and Vazirani [2] give an NC search-to-weighted-decision reduction, and thus, get a pseudo-deterministic NC algorithm for perfect matching in general graphs. Anari and Vazirani [2] put it as an open question to obtain similar results for linear matroid intersection. In this work, we take up this challenge.

### Our contributions

In the setting of linear matroid intersection, the analogue of a perfect matching is referred as a *common base* – a set of indices that corresponds to a basis in both the sets of vectors. For the weighted version, it is well understood how to succinctly describe the set of minimum or maximum weight common bases, i.e., the minimizing/maximizing face of the common base polytope; see e.g., [31, Chapter 41]. Any face of the common base polytope is characterized by its tight sets. Suppose that  $M_1$  and  $M_2$  are two matroids over the same ground set  $E$ . Then, a subset  $S$  of  $E$  is called a tight set for a maximizing face (of the common base polytope), if for some matroid  $M_i$  the following holds: for every maximum weight common base  $B$ , the set  $S \cap B$  spans the set  $S$ . Note that the number of tight sets of a maximizing face can be exponentially large. However, they are known to have succinct representations. We give a randomized NC algorithm to compute a succinct and unique representation for the tight sets of a maximizing face.

► **Theorem 1** (Informal version of Theorem 5). *There exists a randomized NC algorithm to compute a succinct and unique description for the tight sets of a maximizing face of the common base polytope, given the weighted-decision oracle.*

For a maximizing face of the common base polytope, all the tight sets for some matroid  $M_i$  forms a lattice family, and our description for tight sets is motivated by the succinct representation of lattice families based on the partial order of its prime subsets (also known as irreducible subsets). We construct a digraph in bottom-up fashion, using bases from the maximizing face of the common base polytope, such that it contains the necessary information regarding the tight sets of maximizing face. From this digraph we shall be able to compute the succinct description. See Section 3.1 for more details. Here, we would like to mention that the succinct representation of lattice families using the partial order of its prime subsets is well known and has been used in multiple previous algorithms [31, Chapter 49], [23, 14, 6]. However, all these applications do not fall in the category of parallel computation.

Note that the uniqueness of the description is important because then this RNC algorithm is by default pseudo-deterministic, as there is only one possible output. Once we have designed this heavy hammer, it is relatively easier to combine the procedure of [22] with the abstract framework provided by [19] and obtain a pseudo-deterministic NC search-to-weighted-decision reduction. This leads to our first main result.

► **Theorem 2.** *The search version of the linear matroid intersection problem has a pseudo-deterministic NC algorithm.*

### General Matroid Intersection

Our main technical contributions are applicable to not just linear matroid intersection but also to matroid intersection. In the general matroid intersection problem, instead of two sets of vectors, we are given two matroids on the same ground set and the goal is to find a set of elements that forms a base in each of the two matroids. In this problem, the matroids are not given explicitly but only via a independence or rank oracle. Thus, it does not makes sense to talk about NC or RNC algorithms for this problem. One can however consider a parallel oracle model where we can make polynomially many queries to the oracle in parallel (see [25]). To the best of our knowledge, there is no such parallel algorithm known for the decision or the search version of matroid intersection, even with sub-linear number of rounds of parallel oracle calls. This makes the question all the more interesting whether decision and search are equivalent in a parallel sense.

Interestingly, the search-to-weighted-decision reduction of [28] applies to general matroid intersection as well and can be said to be in RNC. Our results make a significant progress on this question by giving a pseudo-deterministic NC reduction from search to weighted decision. Formally, we can show the following.

► **Theorem 3.** *There is a pseudo-deterministic NC algorithm for finding a common base of two matroids  $M_1$  and  $M_2$  on the same ground set  $E$ , provided that the algorithm has an oracle access to the following decision question: given two matroids with polynomially bound (in  $|E|$ ) weights on the ground set elements and a target weight  $W$ , is there a common base of weight at least  $W$ ? Furthermore, the oracle calls need to be made only for the following pairs of matroids:  $\langle M_1, M_2 \rangle$ ,  $\langle M_1, M_1 \rangle$ , and  $\langle M_2, M_2 \rangle$ .*

Note that in the above theorem, as there is no explicit input, the ground set size is taken as the input size.

## Discussion

There are many natural open questions that are highlighted by our work. The big question is whether there is an NC algorithm for linear matroid intersection. Going to the more general setting, is there some kind of parallel algorithm for matroid intersection? Another question which can generate some new ideas is whether there is an NC reduction from search to decision for linear matroid intersection. For general matroid intersection, it would be interesting to find a parallel search to decision reduction even with the use of randomization.

The third question mentioned in the beginning, that is, linear matroid matching is completely open, in the sense that not even a quasi-NC algorithm is known for it. Given the wide applicability of the Isolation Lemma, the randomized parallel search-to-weighted-decision reduction of Mulmuley, Vazirani, and Vazirani [27] would work for any combinatorial problem with an appropriate self-reducibility property, including NP-hard problems like maximum independent set. An intriguing meta-question is – what is the most general setting where we can find deterministic or pseudo-deterministic parallel search-to-weighted-decision reductions.

## 2 Previous works

We start by briefly describing the techniques of previous works [28, 22, 19] that will be helpful in both comprehending as well as describing our work. Wherever these works talk about a minimization problem, we will describe it in terms of maximization, just for convenience. We will be using the following notations for the two versions of the matroid intersection problem.

- **search-MI**: Given two matroids on a common ground set, compute a common base.
- **weighted-decision-MI**: Given two matroids on the same ground set, polynomially bounded weights on the ground set elements, and a target weight  $W$ , is there a common base of weight at least  $W$ ?

Whenever we are in a setting where the matroids are not given explicitly, we will consider the ground set size as the input size.

The result of Narayanan, Saran, and Vazirani [28] can be interpreted as an RNC reduction from search-MI to weighted-decision-MI. The first step of this reduction is to assign weights to the ground set elements, randomly and independently from a small range. Then from the Isolation Lemma [27], one can say that there is a unique maximum weight common base of the two matroids, with high probability. Here, the *weight of a common base* is defined to be sum of the weights of the elements in the common base. We can first find the maximum weight  $w^*$  of a common base by calling the weighted-decision-MI oracle for each possible target value  $W$  in a small range. Then for each ground set element  $e$  in parallel, increase its weight by one and find out the new maximum weight. The maximum weight increases if and only if  $e$  is a part of the unique maximum weight common base. This way we can find the unique maximum weight common base.

Note that the uniqueness property is crucial for this construction and that is the only place where randomness is needed. And this construction is not pseudo-deterministic because for different choices of random weights, we will get a different maximum weight common base. There has been several efforts to *deterministically* construct a weight assignment in NC that *isolates* a common base, i.e., ensures unique maximum weight common base, but this goal has not been achieved till now. A recent work [22] came quite close to this goal and constructed an isolating weight assignment in quasi-NC. This work generalizes the ideas used to do the same for bipartite matching in [16]. We build on their ideas to construct an isolating weight assignment in pseudo-deterministic NC. We first give a brief description of their result.

### Isolating a common base in quasi-NC

Suppose that  $M_1 = (E, \mathcal{I}_1)$  and  $M_2 = (E, \mathcal{I}_2)$  are two matroids over the same ground set  $E$  where  $\mathcal{B}_1$  and  $\mathcal{B}_2$  are the family of bases of  $M_1$  and  $M_2$ , respectively. Let  $m = |E|$  and  $r_1$  and  $r_2$  be the rank functions of the matroids. The main idea of [22] is to isolate a common base in  $\log m$  rounds, where in each round they significantly reduce the set of maximum weight common bases, and finally bring it down to just one maximum weight common base. In each of these rounds, they deterministically propose a set of  $\text{poly}(m)$  weight assignments, one of which will do the desired reduction in the set of maximum weight common bases. In a round, they have no way of figuring out which one out of these  $\text{poly}(m)$  weight assignments will do the job. So, they have to try all  $\text{poly}(m)^{\log m}$  combinations of these weight assignments. Moreover, for any particular combination, they have to combine the  $\log m$  weight assignments on different scales, which means their weights become as large as  $\text{poly}(m)^{\log m}$ . Due to these two factors, their construction is in quasi-NC and not in NC.

To measure the progress in each round, they need a succinct way to describe the current set of maximum weight common bases. The most convenient way to understand the set of maximum weight common bases is through the *common base polytope*. The common base polytope  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$  is a polytope formed by taking convex hull of the 0-1 indicator vectors of the sets in  $\mathcal{B}_1 \cap \mathcal{B}_2$ . For any weight assignment  $\mathbf{w} \in \mathbb{R}^E$ , the weight of a common base  $B$  is defined as a linear function, and thus, one can obtain the maximum weight common bases by maximizing the function  $\sum_{e \in E} \mathbf{w}_e \mathbf{x}_e$  over  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$ . In particular, the set of maximum weight common bases will always be the set of corners of a face of  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$ .

Edmonds [13] gave a nice description of  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$  using the rank functions  $r_1$  and  $r_2$ . He showed that a point  $\mathbf{x} \in \mathbb{R}^E$  is in  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$  if and only if it satisfies the following constraints:

$$\begin{aligned} \mathbf{x}_e &\geq 0 \quad \forall e \in E, & (1) \\ \mathbf{x}(S) = \sum_{e \in S} \mathbf{x}_e &\leq r_i(S) \quad \forall S \subset E, i = 1, 2, & (2) \\ \mathbf{x}(E) = \sum_{e \in E} \mathbf{x}_e &= r_1(E) = r_2(E). & (3) \end{aligned}$$

The construction in [22] crucially uses the description of the common base polytope  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$ . In terms of the polytope, their construction of the weight assignment is such that in each round, the maximum weight face of  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$  gets significantly smaller and after  $\log m$  rounds, the maximum weight face is simply a corner point. The key notions they introduced to measure the improvement in each iteration are *cycles* with respect to a face and their *circulations* with respect to a weight assignment.

Suppose that  $F$  is a face of  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$ . A subset  $S$  of  $E$  is called a *tight set* of  $M_i$  with respect to  $F$  if the corresponding inequality in (2) is tight for  $F$  i.e, for all  $\mathbf{x} \in F$ ,  $\mathbf{x}(S) = r_i(S)$ . Then [22] showed that for every face  $F$ , we have two partitions of  $E$ , denoted by  $\text{partition}_1[F]$  and  $\text{partition}_2[F]$ , such that every tight set of  $M_i$  with respect to  $F$  is a union of the sets from  $\text{partition}_i[F]$ . The partitions of  $E$  naturally induce a bipartite graph, denoted by  $\mathcal{G}[F]$ , with the left vertex set  $\text{partition}_1[F]$ , the right vertex set  $\text{partition}_2[F]$  and the edge set  $E$ : the edge corresponding to an element  $e \in E$  is incident on the vertex corresponding to a set  $v \in \text{partition}_i[F]$  if and only if  $e \in v$ . A sequence of distinct elements  $(e_1, \dots, e_k)$  from  $E$  is called a *cycle* with respect to  $F$  if it forms a cycle in the graph  $\mathcal{G}[F]$ .

Let  $\mathcal{C}_F$  denotes the set of cycles with respect to a face  $F$  of  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$ . Then [22] showed that for face  $F$ , if  $\mathcal{C}_F = \emptyset$  then  $F$  is a corner point of the polytope  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$ . Their idea was to keep eliminating cycles via appropriate modification of the weight assignment and

get smaller and smaller maximizing face of  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$  to eventually reach a corner point. For a weight assignment  $\mathbf{w}$  on  $E$ , define the *circulation* for a (even length) cycle as the absolute value of the difference of weights in the two sets of alternating edges. Let  $C$  be a cycle, say with respect to  $F = P(\mathcal{B}_1 \cap \mathcal{B}_2)$ , and let  $\mathbf{w}$  be a weight assignment such that the circulation of  $C$  is non-zero w.r.t.  $\mathbf{w}$ . Then they showed that the cycle  $C$  does not appear in the maximizing face with respect to  $\mathbf{w}$ . Now if the weight assignment  $\mathbf{w}$  gives non-zero circulation to *all* the cycles in  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$ , then all the cycles in the maximizing face  $F$  will be eliminated, i.e.  $\mathcal{C}_F = \emptyset$ , and  $F$  will be a corner. However, with polynomially bounded weights, one cannot expect to give nonzero circulation to all the cycles at once, since the number of cycles can be exponentially large.

One of the key ideas in [22, 16] was to eliminate the cycles in rounds. In each round, they double the length of the eliminated cycles and reach to face of a smaller dimension. Thus, in  $\log m$  rounds, one can eliminate all the cycles and reach a corner point of  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$ . They used the fact that if in a graph all the cycles have length greater than  $2^i$ , then there are at most  $m^4$  many cycles of length at most  $2^{i+1}$  [33]. This implies that, at each iteration, we have to give nonzero circulation to at most  $m^4$  many cycles. Using a hashing technique (for example see [16, Lemma 2.3]), one can give nonzero circulation for each of these  $m^4$  many cycles. Formally, Gurjar and Thierauf [21, Lemma 3.11 and 3.12] showed the following property for faces  $F$  (of  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$ ) having no cycle of length  $\leq r$ .

► **Lemma 4.** *Let  $F$  be a face of the polytope  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$  such that  $\mathcal{C}_F$  has no cycle of length  $r$ . Then one can construct a set of  $O(m^6)$  many weight assignments with weights bounded by  $O(m^6)$  in NC such that one of the weight assignment will give nonzero circulation to all the cycles in  $\mathcal{C}_F$  of length at most  $2r$ .*

Now, as described earlier, we consider all possible combinations of weight assignments from different rounds to get a family of  $\text{poly}(m^{\log m})$  many weight assignments with weights bounded by  $\text{poly}(m^{\log m})$  such that for any two matroids on a ground set of size  $m$ , at least one weight assignment isolates a common base.

In this paper, we give a *pseudo-deterministic NC* reduction from search-MI to weighted-decision-MI. This line of work was started by Goldwasser and Grossman [19]. One can extract an abstract framework from [19] with the following two steps to get a pseudo-deterministic NC search-to-weighted-decision reduction: 1) Like [16, 22], an iterative approach of designing an isolating weight assignment family, 2) Succinct representation of the maximum weight faces of the underlying polytope with an RNC algorithm to compute it, assuming the oracle access to the weighted decision. For example, a face of the bipartite matching polytope is completely described by the set edges that participate in some perfect matching in that face, and [19] gives an NC algorithm to compute it using the respective weighted decision oracle.

The faces of the perfect matching polytope for general graphs are more complicated than their bipartite counterpart. Here, any face is described by a maximal laminar family of tight odd cuts. The work of [8, 30] give an NC procedure, with the oracle access to the weight decision problem, to compute a maximal laminar family of tight odd cuts. This result supplies the second ingredient of the [19] framework, which helped [2] give an NC reduction from search to weighted decision for general perfect matching.

Our reduction also follows the abstract framework of [19]. We use the iterative approach developed by [22]. On top of that, we need an RNC algorithm (using the oracle access to weighted-decision-MI) to compute a succinct representation for a maximum weight face of the common base polytope  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$ . However, none of the previous ideas help to answer this question, and we need something completely new.

### 3 Proof techniques

In this section, we briefly describe the proof ideas of our results. Our proofs strongly rely on some structural properties of lattice families over finite sets. Therefore, we briefly discuss the necessary notations and facts about lattice families. For a finite set  $E$ , a family of subsets  $\mathcal{L}$  of  $E$  is called a *lattice family* over  $E$  if it is closed under set union and intersection and for every element  $a \in E$  there exists a set in  $\mathcal{L}$  containing  $a$ . For every element  $a \in E$  there exists a *unique* smallest set in  $\mathcal{L}$  containing  $a$ . Such sets are called as *prime sets* of  $\mathcal{L}$ . All the sets in a lattice family can be written as a union of its prime sets. Every lattice family  $\mathcal{L}$  over  $E$  induces a *unique partition*  $\mathcal{P}$  of  $E$  such that every set in  $\mathcal{L}$  is a disjoint union of sets in  $\mathcal{P}$ . Moreover, the sets in  $\mathcal{P}$  can be written as a sequence  $(S_1, \dots, S_\ell)$  with the following property: for all  $k \in [\ell]$ ,  $\cup_{j=1}^k S_j$  is in  $\mathcal{L}$ . A family  $\mathcal{L}' \subseteq \mathcal{L}$  is called a *sublattice* of  $\mathcal{L}$ , if  $\mathcal{L}'$  is also a lattice family over  $E$ . The partition  $\mathcal{P}$  is a refinement of the partition  $\mathcal{P}'$  induced by  $\mathcal{L}'$ , that is for all  $S \in \mathcal{P}'$ , the sets in  $\mathcal{P}$  having a nonempty intersection with  $S$  form a partition of  $S$ . For proof of these properties, one can see Section 4.2 of the full version.

#### 3.1 Proof Idea of Theorem 1

We discuss a succinct representation for the maximum weight face of the common base polytope and an RNC algorithm to compute it. First, we define some notations. Suppose that  $M_1 = (E, \mathcal{I}_1)$  and  $M_2 = (E, \mathcal{I}_2)$  are two matroids with  $\mathcal{B}_1$  and  $\mathcal{B}_2$  as their family of the bases and  $r_1$  and  $r_2$  as the rank functions, respectively. Let  $m = |E|$ . Let  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$  be the common base polytope of  $M_1$  and  $M_2$  defined by the equations (1), (2), (3), and  $F$  be a face of  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$ . Then a subset  $S$  of  $E$  is called a *tight set* for  $M_i$  (with respect to  $F$ ) if for all  $\mathbf{x} \in F$ ,  $\mathbf{x}(S) = r_i(S)$ . For all  $i \in [2]$ , let  $\text{tight-sets}_i[F]$  denote the family of all tight sets for  $M_i$  with respect to the face  $F$ . Edmonds [13] showed that for all  $i \in [2]$ ,  $\text{tight-sets}_i[F]$  forms a lattice family over  $E$ .

Suppose that  $\mathbf{w}$  is a weight assignment on  $E$ . Let  $F_{\mathbf{w}}$  be the maximizing face of the common base polytope  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$ , with respect to  $\mathbf{w}$ . The face  $F_{\mathbf{w}}$  can be uniquely represented by  $\text{tight-sets}_1[F_{\mathbf{w}}]$  and  $\text{tight-sets}_2[F_{\mathbf{w}}]$ . However, we can not compute them explicitly with our limited computational resources since the size of each family can be exponentially large. On the other hand, since  $\text{tight-sets}_i[F_{\mathbf{w}}]$  is a lattice family over  $E$ , each  $\text{tight-sets}_i[F_{\mathbf{w}}]$  has a succinct representation using partial order defined on its prime sets. More specifically, one can define a pre-order  $\preceq_i$  (that is, reflexive and transitive) on  $E$  as follows: for all  $a, b \in E$ ,  $a \preceq_i b$  if and only if in  $\text{tight-sets}_i[F_{\mathbf{w}}]$ , the prime set containing  $b$  is a subset of the prime set containing  $a$ . The pre-order  $\preceq_i$  gives a succinct representation of  $\text{tight-sets}_i[F_{\mathbf{w}}]$ , that is for every  $S \subseteq E$ ,  $S$  is in  $\text{tight-sets}_i[F_{\mathbf{w}}]$  if and only if  $S$  is transitively closed under  $\preceq_i$ . Such succinct representation for lattice families is well known (see [31, Chapter 49]<sup>1</sup>). For any  $a \in E$ , the transitive closure of  $a$  in  $\preceq_i$  is same as the prime set in  $\text{tight-sets}_i[F_{\mathbf{w}}]$  containing  $a$ . Also, the collection of all maximal subsets of  $E$  which are symmetric under  $\preceq_i$  is same as the partition  $E$  induced by  $\text{tight-sets}_i[F_{\mathbf{w}}]$ . If one consider the digraph representation of  $\prec_i$ , (that is  $(a, b)$  is an edge if and only if  $a \prec_i b$ ) then in  $\text{tight-sets}_i[F_{\mathbf{w}}]$ , the prime set containing  $a$  is same the set of vertices reachable from  $a$  in the digraph and the partition of  $E$  induced by  $\text{tight-sets}_i[F_{\mathbf{w}}]$  is same as the set of strongly connected components. Thus, the prime sets of  $\text{tight-sets}_i[F_{\mathbf{w}}]$  contain all the information

<sup>1</sup> Our definition of  $\preceq_i$  is exactly opposite to the definition used [31, Chapter 49], that is according to their definition,  $a \preceq_i b$  if and only if the prime set containing  $a$  is a subset of the prime set containing  $b$ .

regarding it. In our context, we compute the following succinct objects related to  $F_{\mathbf{w}}$ :  $\text{prime-sets}_i[F_{\mathbf{w}}]$  and  $\text{partition}_i[F_{\mathbf{w}}]$  for all  $i \in [2]$ , where  $\text{prime-sets}_i[F]$  be the set of all primes sets of the lattice family  $\text{tight-sets}_i[F_{\mathbf{w}}]$  and  $\text{partition}_i[F_{\mathbf{w}}]$  denote the partition of  $E$  induced by  $\text{tight-sets}_i[F]$ . Recall from [22, Section 3.3] that the cycles of the bipartite graph induced by  $\text{partition}_1[F_{\mathbf{w}}]$  and  $\text{partition}_2[F_{\mathbf{w}}]$  define the cycles with respect to the face  $F_{\mathbf{w}}$ . And, the tight constraints coming from sets in  $\text{prime-sets}_i[F_{\mathbf{w}}]$  serve as a basis for all the tight constraints from  $\text{tight-sets}_i[F_{\mathbf{w}}]$ . Here, we would like to mention that basis forming families of tight sets are well studied (see [31]). However, to best of our knowledge, no efficient parallel algorithm is known to compute them. Also, the succinct representation of lattices using the partial order of its prime sets has been widely used to design algorithms for different optimization problems. For example, computing optimal stable matching [23], problems in computational geometry [14, 6], submodular function minimization [31, Chapter 49]. However, the context of these applications are very different from parallel computation.

With the above two objects, we also need the following characterization: for all  $i \in [2]$ , there exists a function  $N_i^{F_{\mathbf{w}}}$  from  $\text{partition}_i[F_{\mathbf{w}}]$  to  $\mathbb{Z}_{\geq 0}$  such that a base  $B \in \mathcal{B}_1 \cap \mathcal{B}_2$  is in the face  $F_{\mathbf{w}}$  if and only if for all  $i \in [2]$  and  $S \in \text{partition}_i[F_{\mathbf{w}}]$ , we have  $|S \cap B| = N_i^{F_{\mathbf{w}}}(S)$ . Here, we would like to mention that both the notions of partition and the function  $N_i^{F_{\mathbf{w}}}$  and the criteria we just mentioned were already introduced in [22], but were a bit weaker in the following ways: Our criteria is an exact characterization, however, they showed it for one direction. Our partition has an additional ‘‘chain property’’ ensured by the structural properties of the lattice families. All these additional points will be useful in our proofs. For details see Section 4.5 of the full version and [22, Section 3.2].

Now we briefly discuss about our RNC algorithm to compute  $\text{prime-sets}_i[F_{\mathbf{w}}]$  and  $\text{partition}_i[F_{\mathbf{w}}]$  for all  $i \in [2]$ . One important point is that our algorithm is equipped with the oracle access to **weighted-decision-MI**. Our idea is the following: We first compute a random vertex, equivalently a random base,  $B$  in the face  $F_{\mathbf{w}}$ . The base  $B$  can be computed in RNC using the oracle access to **weighted-decision-MI**. Then iteratively construct a chain of subsets of bases from  $F_{\mathbf{w}}$

$$\{B\} = \mathcal{B}_0 \subseteq \mathcal{B}_1 \subseteq \dots \subseteq \mathcal{B}_\ell$$

such that the minimal face containing  $\mathcal{B}_\ell$  is same as  $F_{\mathbf{w}}$  and  $\ell = \lceil \log m \rceil$ . Next we briefly discuss how to construct the set  $\mathcal{B}_j$  from  $\mathcal{B}_{j-1}$  and compute  $\text{prime-sets}_i[F_{\mathbf{w}}]$  and  $\text{partition}_i[F_{\mathbf{w}}]$  from the set of common bases  $\mathcal{B}_\ell$ .

For all  $j \in \{0, \dots, \ell\}$ , let  $F_j$  denotes the minimal face containing  $\mathcal{B}_j$ . For all  $j \in [\ell]$ , the set  $\mathcal{B}_j$  contains the elements in  $\mathcal{B}_{j-1}$  with the following extra elements: For all  $i \in [2]$ ,  $A \in \text{partition}_i[F_{j-1}]$ , we add a common base  $B_{ij}^{(A)}$  (if it exists) from the face  $F_{\mathbf{w}}$  with the property

$$|A \cap B_{ij}^{(A)}| \neq N_i^{F_{j-1}}(A). \quad (4)$$

We know that for all  $i \in [2]$   $A \in \text{partition}_i[F_{j-1}]$ , every base in  $F_{j-1}$  contains exactly  $N_i^{F_{j-1}}(A)$  many elements from  $A$ . However, our property on  $B_{ij}^{(A)}$  says that we want a base from  $F_{\mathbf{w}}$  which violates that condition, and if exists, we can compute such a base in RNC using the oracle access to **weighted-decision-MI**. Next, we discuss how to compute  $\text{partition}_i[F_j]$  in NC. Note that, after computing  $\text{partition}_i[F_j]$ ,  $N_i^{F_j}$  can be computed in NC by computing  $|B \cap A|$ , for some  $B \in \mathcal{B}_j$ , in parallel for all  $A \in \text{partition}_i[F_j]$ .

The set families  $\text{tight-sets}_i[F_j]$  for all  $i \in [2]$  form lattice families over  $E$ , and given  $B_j$ , we are interested to compute  $\text{prime-sets}_i[F_j]$  and  $\text{partition}_i[F_j]$  in NC. As we mentioned earlier, every lattice family has a digraph representation based on the partial order on primes

sets of lattice family. Given this digraph representation of  $\text{tight-sets}_i[F_j]$ , one can compute  $\text{prime-sets}_i[F_j]$  and  $\text{partition}_i[F_j]$  in NC. However, given  $\mathcal{B}_j$ , it is not clear how to construct the digraph representation of the lattice family  $\text{tight-sets}_i[F_j]$  in NC. We show that, instead of this digraph, it would sufficient for us if we work with a subgraph  $G_i[\mathcal{B}_j]$  defined as follows: the vertex set is same as the ground set  $E$  and for all  $a, b \in E$ ,  $(a, b)$  is an edge of  $G_i[\mathcal{B}_j]$  if and only if

*there exists a base  $B \in \mathcal{B}_j$  such that  $b \in B$  and  $(B \setminus \{b\}) \cup \{a\}$  is also a base of  $M_i$ .*

More specifically, we prove that for every  $a \in E$  the prime set in  $\text{tight-sets}_i[F_j]$  containing  $a$  is same as the set of vertices reachable from  $a$  in  $G_i[F_j]$  and  $\text{partition}_i[F_j]$  is same as the set of strongly connected components in  $G_i[\mathcal{B}_j]$ . Using this characterization, we can compute  $\text{prime-sets}_i[F_j]$  and  $\text{partition}_i[F_j]$  in NC, given the graph  $G_i[\mathcal{B}_j]$ . For more details see Section 6 of the full version. Also, using the weighted decision oracle we can compute  $G_i[\mathcal{B}_j]$  in NC. Thus, given  $\mathcal{B}_j$ ,  $\text{prime-sets}_i[F_j]$  and  $\text{partition}_i[F_j]$  are computable in NC. Here, we would like to mention that constructing directed graphs using base exchange property is a well known technique in matroid literature and has been used in various contexts. For example, one can see the augmenting path based algorithm for matroid intersection in [31, Section 41.2], and some other context in [31, Section 40.3]. The definition of  $G_i[\mathcal{B}_j]$  is very close to the definition used in the second example.

At very high level, this part of our algorithm is doing exactly the opposite of the idea used to construct isolating weight assignment family in [16, 22, 34]. They start from a face of the polytope and iteratively move to the subfaces of smaller dimensions until a corner point is reached. On the other hand, we are starting from a corner point of the face and iteratively reaching bigger faces until we cover the whole face.

Now we give a very brief overview of the correctness of our algorithm. For all  $j \in \{0, 1, \dots, \ell\}$ , since  $F_j$  is a subface of  $F_{\mathbf{w}}$ ,  $\text{tight-sets}_i[F_{\mathbf{w}}]$  is a sublattice of  $\text{tight-sets}_i[F_j]$  for all  $i \in [2]$ . Therefore  $\text{partition}_i[F_j]$  is a refinement of  $\text{partition}_i[F_{\mathbf{w}}]$ , that is for all  $S \in \text{partition}_i[F_{\mathbf{w}}]$ , the sets in  $\text{partition}_i[F_j]$  having nonempty intersection with  $S$  create a partition of  $S$ . Let  $\mathcal{W}_{ij}^{(S)}$  denote the family of sets in  $\text{partition}_i[F_j]$  which have nonempty intersection with  $S \in \text{partition}_i[F_{\mathbf{w}}]$ . As we move from  $(j-1)$ th iteration to  $j$ th iteration, our algorithm satisfies the following property: either the size of the smallest sets in  $\mathcal{W}_{ij}^{(S)}$  satisfying the equation 4 becomes double, or if no such set exists in  $\mathcal{W}_{ij}^{(S)}$ , it becomes equal to  $\{S\}$ . Thus, after  $\ell$ th iteration,  $\text{partition}_i[F_\ell]$  becomes equal to  $\text{partition}_i[F_{\mathbf{w}}]$  for all  $i \in [2]$ . This leads us to prove that  $F_\ell = F_{\mathbf{w}}$ . Therefore,  $\text{prime-sets}_i[F_\ell]$  is also same as  $\text{prime-sets}_i[F_{\mathbf{w}}]$ . In Algorithm 1, we describe all the steps to compute  $\text{prime-sets}_i[F_{\mathbf{w}}]$  and  $\text{partition}_i[F_{\mathbf{w}}]$  for all  $i \in [2]$ . For the detail analysis of the correctness and time complexity of our algorithm see Section 7 of the full version. From the above discussion, we can conclude that

► **Theorem 5.** *Let  $M_1 = (E, \mathcal{I}_1)$  and  $M_2 = (E, \mathcal{I}_2)$  be two matroids with  $\mathcal{B}_1$  and  $\mathcal{B}_2$  be the family of bases, respectively. Let  $\mathbf{w}$  be a weight assignment on  $E$  with polynomially bounded weights, and  $F_{\mathbf{w}}$  be the maximizing face of  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$  with respect to  $\mathbf{w}$ . Then, given  $M_1$ ,  $M_2$  and  $\mathbf{w}$  as inputs, Algorithm 1 computes  $\text{prime-sets}_i[F_{\mathbf{w}}]$  and  $\text{partition}_i[F_{\mathbf{w}}]$  for all  $i \in [2]$  in randomized NC, provided that the algorithm has an oracle access to  $\text{weighted-decision-MI}$ . Furthermore, for all positive integer  $c$ , the success probability of the algorithm can be made at least  $1 - \frac{1}{m^c}$ , where  $m = |E|$ .*

■ **Algorithm 1** Computing prime sets and partitions corresponding to a max-weight face.

**Input:** Two matroids  $M_1 = (E, \mathcal{I}_1)$ ,  $M_2 = (E, \mathcal{I}_2)$ , and a weight assignment  $\mathbf{w} : E \rightarrow \mathbb{Z}_{\geq 0}$ .

**Output:**  $\text{prime-sets}_i[F_{\mathbf{w}}]$  and  $\text{partition}_i[F_{\mathbf{w}}]$  for all  $i \in [2]$ , where  $F_{\mathbf{w}}$  denotes the max-weight face.

**Assumption:** Oracle access to weighted-decision-MI.

```

1: Compute a base  $B$  in  $F_{\mathbf{w}}$ .
2:  $\mathcal{B}_0 \leftarrow \{B\}$ .
3: for all  $i \in [2]$  do in parallel
4:   Compute the graph  $G_i[\mathcal{B}_0]$ .
5:   Let  $F_0$  be the minimal face containing  $\mathcal{B}_0$ .
6:   Compute  $\text{prime-sets}_i[F_0]$ ,  $\text{partition}_i[F_0]$  and  $N_i^{F_0}$ .
7: end for
8: for  $j \leftarrow 1$  to  $\lceil \log m \rceil$  do
9:    $\mathcal{B}_j \leftarrow \mathcal{B}_{j-1}$ .
10:  for all  $i \in [2]$  do in parallel
11:    for all  $A \in \text{partition}_i[F_{j-1}]$  do in parallel
12:      If exists, compute a base  $B_{ij}^{(A)}$  in  $F_{\mathbf{w}}$  such that
      
$$|A \cap B_{ij}^{(A)}| \neq N_i^{F_{j-1}}(A).$$

13:       $\mathcal{B}_j \leftarrow \mathcal{B}_j \cup \{B_{ij}^{(A)}\}$ .
14:    end for
15:  end for
16:  for all  $i \in [2]$  do in parallel
17:    Let  $F_j$  be the minimal face containing  $\mathcal{B}_j$ .
18:    Compute the graph  $G_i[\mathcal{B}_j]$ .
19:    Compute  $\text{prime-sets}_i[F_j]$ ,  $\text{partition}_i[F_j]$  and  $N_i^{F_j}$ .
20:  end for
21: end for
22: return  $\text{prime-sets}_i[F_{\ell}]$  and  $\text{partition}_i[F_{\ell}]$  for  $i \in [2]$  and  $\ell = \lceil \log m \rceil$ .

```

### 3.2 Proof idea of Theorem 3

In this section, we give a proof overview of Theorem 3, which states that there is a pseudo-deterministic NC algorithm for the matroid intersection search problem that uses the weighted-decision oracle. Since the weighted-decision for *linear* matroid intersection can be solved in RNC [28], we get a pseudo-deterministic NC algorithm for the search version of linear matroid intersection, that is, Theorem 2.

Suppose that  $M_1 = (E, \mathcal{I}_1)$  and  $M_2 = (E, \mathcal{I}_2)$  are two matroids with  $\mathcal{B}_1$  and  $\mathcal{B}_2$  as the family of bases, respectively. Let  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$  be the common base polytope of  $M_1$  and  $M_2$ . Let  $\mathbf{w}_0$  be a weight assignment defined as  $\mathbf{w}_0(a) = 1$  for all  $a \in E$ . Then the maximizing face of  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$  with respect to  $\mathbf{w}_0$  is the polytope itself. Let  $m = |E|$  and  $\ell = \lceil \log m \rceil$ . Now our idea is the following: We start from the weight assignment  $\mathbf{w}_0$  and inductively construct a sequence of weight assignments

$$\mathbf{w}_0, \mathbf{w}_1, \dots, \mathbf{w}_{\ell}$$

such that for all  $j \in \{0, 1, \dots, \ell\}$ , the weights in  $\mathbf{w}_j$  are bounded by  $O(m)$  and the length of the shortest cycle with respect to the face  $F_j$  is greater than  $2^j$  where  $F_j$  denotes the

maximizing face with respect to  $\mathbf{w}_j$ . Therefore, the face  $F_\ell$  does not have any cycle, and from [22], it has a unique base. Now using the oracle access to **weighted-decision-MI** the base in  $F_\ell$  can be computed in NC. Next we discuss how to construct  $\mathbf{w}_j$  from  $\mathbf{w}_{j-1}$ .

For all  $j \in \{0, 1, \dots, \ell\}$ , let  $\mathcal{C}_{F_j}$  denotes the set of all cycles with respect to the face  $F_j$ . From the induction hypothesis, for some  $j$ , all the cycles in  $\mathcal{C}_{F_j}$  have length greater than  $2^j$ . Then from [22], there are at most  $m^4$  many cycles of length at most  $2^{j+1}$ . Let  $\mathcal{W}$  be a polynomially large family of weight assignments with polynomially bounded weights such that one of the weight assignments in  $\mathcal{W}$  gives nonzero circulation to all the cycles in  $\mathcal{C}_{F_j}$  of length at most  $2^{j+1}$ . There are well known NC constructions of such a family  $\mathcal{W}$  (see e.g., [16, Lemma 2.3]). For each  $\mathbf{w} \in \mathcal{W}$  we do the following in parallel: combine  $\mathbf{w}_j$  and  $\mathbf{w}$  in decreasing order of precedence. Let  $\mathbf{w}'$  be the combined weight and  $F_{\mathbf{w}'}$  is the maximizing face with respect to it. Now using our RNC algorithm discussed in the previous section, compute  $\text{prime-sets}_i[F_{\mathbf{w}'}]$  and  $\text{partition}_i[F_{\mathbf{w}'}]$  for all  $i \in [2]$ . Now, construct the bipartite graph  $\mathcal{G}[F_{\mathbf{w}'}]$  from  $\text{partition}_1[F_{\mathbf{w}'}]$  and  $\text{partition}_2[F_{\mathbf{w}'}]$  as defined in the description of [22]. The length of the shortest cycles in  $\mathcal{G}[F_{\mathbf{w}'}]$  can be computed in NC. Thus, in NC, we can compute the lexicographically smallest weight assignment  $\mathbf{w} \in \mathcal{W}$  such that the length of the shortest cycles in  $\mathcal{G}[F_{\mathbf{w}'}]$  is greater than  $2^{j+1}$ .

■ **Algorithm 2** Pseudo-deterministic NC algorithm for computing a common base of two matroids.

**Input:** Two matroids  $M_1 = (E, \mathcal{I}_1)$  and  $M_2 = (E, \mathcal{I}_2)$ .

**Output:** A common base of  $M_1$  and  $M_2$ , if exists.

**Assumption:** Oracle access to **weighted-decision-MI**.

```

1:  $\mathbf{w}_0 \leftarrow \mathbf{1}$ .
2: for  $j \leftarrow 1$  to  $\lceil \log m \rceil$  do
3:   Compute a family of weight assignments  $\mathcal{W}$  as promised by Lemma 4.
4:   for all  $\mathbf{w} \in \mathcal{W}$  do in parallel
5:     Combine  $\mathbf{w}_{j-1}$  and  $\mathbf{w}$  with descending order in precedence.
6:     For a  $\mathbf{w} \in \mathcal{W}$ , let  $\mathbf{w}'$  be the combined weight.
7:     Let  $F_{\mathbf{w}'}$  be the maximizing face of  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$  with respect to  $\mathbf{w}'$ .
8:     For all  $i \in [2]$ , compute  $\text{prime-sets}_i[F_{\mathbf{w}'}]$  and  $\text{partition}_i[F_{\mathbf{w}'}]$  using Algorithm 1.
9:     Let  $\mathcal{G}[F_{\mathbf{w}'}]$  be the bipartite graph induced by  $\text{partition}_1[F_{\mathbf{w}'}]$  and  $\text{partition}_2[F_{\mathbf{w}'}]$ .
10:    Compute the length of shortest cycle of  $\mathcal{G}[F_{\mathbf{w}'}]$ .
11:   end for
12:   Take some fixed ordering on  $\mathcal{W}$ , like lexicographic ordering.
13:   Take the smallest  $\mathbf{w}$  such that the length of the shortest cycle in  $\mathcal{G}[F_{\mathbf{w}'}] > 2^j$ .
14:    $\mathbf{w}_j \leftarrow \sum_{i=1}^2 \sum_{S \in \text{prime-sets}_i[F_{\mathbf{w}'}]} \mathbf{1}_S$ .
15: end for
16: Compute the unique common base maximizing  $\mathbf{w}_{\lceil \log m \rceil}$  and output.
```

Next we show how to compute  $\mathbf{w}_{j+1}$  from  $\mathbf{w}'$  such that weights in  $\mathbf{w}_{j+1}$  are bounded by  $O(m)$ . Define  $\mathbf{w}_{j+1}$  as the following:

$$\mathbf{w}_{j+1} = \sum_{i=1}^2 \sum_{S \in \text{prime-sets}_i[F_{\mathbf{w}'}}} \mathbf{1}_S,$$

where  $\mathbf{1}_S \in \mathbb{R}^E$  denotes the indicator vector for the set  $S$ . From the definition, it is clear that weights are bounded by  $2m$ , and can be computed in NC from  $\text{prime-sets}_1[F_{\mathbf{w}'}]$  and  $\text{prime-sets}_2[F_{\mathbf{w}'}]$ . Using the description of  $P(\mathcal{B}_1 \cap \mathcal{B}_2)$ , we can show that every point  $\mathbf{x}$  in

the maximizing face  $F_{j+1}$  must satisfy  $\mathbf{x}(S) = r_i(S)$  for all  $i \in [2]$ ,  $S \in \text{prime-sets}_i[F_{\mathbf{w}'}]$ . This implies that  $\text{prime-sets}_i[F_{\mathbf{w}'}]$  is a subset of  $\text{tight-sets}_i[F_{j+1}]$ . Thus  $\text{tight-sets}_i[F_{\mathbf{w}'}]$  is a subset of  $\text{tight-sets}_i[F_{j+1}]$  since all the sets in a lattice family can be written as a union of its prime sets. This helps us to show that  $F_{\mathbf{w}'}$  is same as  $F_{j+1}$ . Also, one can verify that each step of our algorithm as has a unique answer, therefore it is pseudo-deterministic. In Algorithm 2, we describe the steps of our pseudo-deterministic NC reduction from search-MI to weighted-decision-MI. For the proof of correctness and time complexity analysis of our algorithm, see Section 8 of the full version.

## Abstract

Nisan and Szegedy (CC 1994) showed that any Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  that depends on all its input variables, when represented as a real-valued multivariate polynomial  $P(x_1, \dots, x_n)$ , has degree at least  $\log n - O(\log \log n)$ . This was improved to a tight  $(\log n - O(1))$  bound by Chiarelli, Hatami and Saks (Combinatorica 2020). Similar statements are also known for other Boolean function complexity measures such as Sensitivity (Simon (FCT 1983)), Quantum query complexity, and Approximate degree (Ambainis and de Wolf (CC 2014)).

In this paper, we address this question for *Probabilistic degree*. The function  $f$  has probabilistic degree at most  $d$  if there is a random real-valued polynomial of degree at most  $d$  that agrees with  $f$  at each input with high probability. Our understanding of this complexity measure is significantly weaker than those above: for instance, we do not even know the probabilistic degree of the OR function, the best-known bounds put it between  $(\log n)^{1/2-o(1)}$  and  $O(\log n)$  (Beigel, Reingold, Spielman (STOC 1991); Tarui (TCS 1993); Harsha, Srinivasan (RSA 2019)).

Here we can give a near-optimal understanding of the probabilistic degree of  $n$ -variate functions  $f$ , *modulo* our lack of understanding of the probabilistic degree of OR. We show that if the probabilistic degree of OR is  $(\log n)^c$ , then the minimum possible probabilistic degree of such an  $f$  is at least  $(\log n)^{c/(c+1)-o(1)}$ , and we show this is tight up to  $(\log n)^{o(1)}$  factors.

## 1 Introduction

### 1.1 Background and motivation

Representing Boolean functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  by polynomials is a tried-and-tested technique that has found uses in many areas of Theoretical Computer Science. In particular, such representations have led to important results in Complexity theory [8, 9], Learning theory [19, 11], and Algorithm Design [29].

There are many different kinds of polynomial representations that are useful in various applications. The most straightforward way to represent a Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  by a polynomial is by finding a  $P \in \mathbb{R}[x_1, \dots, x_n]^2$  such that  $P(a) = f(a)$  for all  $a \in \{0, 1\}^n$ . It is a standard fact (say by Möbius Inversion or polynomial interpolation) that any  $f$  has such a representation<sup>3</sup> has degree at most  $n$ , and the smallest degree of such a  $P$  is called the *degree of  $f$*  (or sometimes the *Fourier degree of  $f$*  because of its close relation to the Fourier spectrum of  $f$  [22]), and denoted  $\deg(f)$ .

The degree of  $f$  is an important notion of *complexity* of the function  $f$  and is closely related to a slew of combinatorial measures of Boolean function complexity such as *Sensitivity*, *Decision Tree complexity*, *Quantum Query complexity*, etc. (see, e.g., the survey of Buhrman and de Wolf [10] for a nice introduction). Given a complexity measure  $\mu(\cdot)$  (such as  $\deg(\cdot)$ ) on Boolean functions, a natural question to ask is the following.

► **Question 1.** *How small can  $\mu(f)$  be for a function  $f$  on  $n$  variables?*

To make this question interesting, one must exclude trivial functions like the constant functions, and more generally, functions that depend on just a small subset of their input variables. This brings us to the following definition.

► **Definition 2** (Truly  $n$ -variate Boolean function). *We say that a Boolean function  $f(x_1, \dots, x_n)$  depends on its input variable  $x_i$ , or equivalently that  $x_i$  is influential for  $f$ , if there is an input  $a$  such that flipping the value of the  $i$ th variable at  $a$  changes the value of  $f$  (in this case, we also say that  $x_i$  is influential for  $f$  at  $a$ ). We say that a Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  is truly  $n$ -variate<sup>4</sup> if it depends on all its  $n$  variables.*

A number of results have addressed questions regarding how small complexity measures can be for truly  $n$ -variate Boolean functions.

1. Motivated by problems in Learning theory and PRAM lower bounds, Nisan and Szegedy [21] showed that any truly  $n$ -variate function has degree at least  $\log n - O(\log \log n)$ . Recently, this was improved to  $\log n - O(1)$  by Chiarelli, Hatami and Saks [13]. There are standard examples of Boolean functions (see, e.g., the *Addressing function* defined below) for which this is tight.
2. Ambainis and de Wolf [4] studied the same question for the *approximate degree of  $f$* , which is defined to be the minimum degree of a polynomial  $P$  such that  $|P(a) - f(a)| < 1/3$  for all  $a \in \{0, 1\}^n$ . This complexity measure is closely related to the *quantum query complexity of  $f$*  [10]. Ambainis and de Wolf [4] showed that any truly  $n$ -variate function has approximate degree (and also quantum query complexity)  $\Omega(\log n / \log \log n)$ . They also constructed variants of the Addressing function for which this bound is tight up to constant factors.
3. Such results are also known for more combinatorial complexity measures, such as the *sensitivity* of a Boolean function  $f$ , which is defined as follows. The sensitivity of  $f$  at a point  $a \in \{0, 1\}^n$  is the number of input variables to  $f$  that are influential for  $f$  at  $a$ . The sensitivity of  $f$  is the maximum sensitivity of  $f$  at any input. Simon [25] showed that any truly  $n$ -variate  $f$  has sensitivity at least  $\log n - O(\log \log n)$ . This is also tight up to the  $O(\log \log n)$  additive term (say, for the Addressing function).

<sup>2</sup> We can represent  $f$  as a polynomial over any field, but in this paper, we will work over the reals.

<sup>3</sup> The representation is in fact *unique* if we restrict  $P$  to be *multilinear*, i.e. that no variable has degree more than 1 in  $f$ .

<sup>4</sup> Such functions are also called *non-degenerate* Boolean functions in the literature [25].

We address Question 1 for another well-known polynomial-degree measure called the *Probabilistic degree*. We define this notion first.

► **Definition 3** (Probabilistic polynomial and Probabilistic degree). *Given a Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  and an  $\varepsilon \geq 0$ , an  $\varepsilon$ -error probabilistic polynomial for  $f$  is a random polynomial  $\mathbf{P}$  (with some distribution having finite support) over  $\mathbb{R}[x_1, \dots, x_n]$ <sup>5</sup> such that for each  $a \in \{0, 1\}^n$ ,*

$$\Pr_{\mathbf{P}}[\mathbf{P}(a) \neq f(a)] \leq \varepsilon.$$

(Note that  $\mathbf{P}(a)$  need not be Boolean when  $\mathbf{P}(a) \neq f(a)$ .)

We say that the degree of  $\mathbf{P}$ , denoted  $\deg(\mathbf{P})$ , is at most  $d$  if the probability distribution defining  $\mathbf{P}$  is supported on polynomials of degree at most  $d$ . Finally, we define the  $\varepsilon$ -error probabilistic degree of  $f$ , denoted  $\text{pdeg}_{\varepsilon}(f)$ , to be the least  $d$  such that  $f$  has an  $\varepsilon$ -error probabilistic polynomial of degree at most  $d$ .

In the special case  $\varepsilon = 1/3$ , we omit the subscript in the notation and simply use  $\text{pdeg}(f)$ .

The probabilistic degree is a fundamentally important and well-studied complexity measure of Boolean functions. It was implicitly introduced (in the finite field setting) in a celebrated result of Razborov [23], who showed how to use it to construct low-degree polynomial approximations to small-depth circuits, and hence prove strong circuit lower bounds. The real-valued version was first studied by Beigel, Reingold and Spielman [7] and Tarui [27] who were motivated by other circuit lower bound questions and oracle separations. This measure has since found other applications in complexity theory [5, 8], Pseudorandom generator constructions [9], Learning theory [11], and Algorithm design [29, 1]. Further, in many of these applications (e.g. [5, 9, 1]) we *need* real-valued approximations.

Despite this, however, our understanding of probabilistic degree is much less developed than the other measures above. For instance, near-optimal lower bounds of  $n^{1-o(1)}$  on the probabilistic degree of an explicit Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  were proved only recently by Viola [28], and are only known for a function in the complexity class  $\text{E}^{\text{NP}}$ ; in comparison, the Parity function has degree and approximate degree  $n$ , which is the largest possible. Another example is the OR function on  $n$  variables. It is trivial to estimate the degree of OR (which is  $n$ ) and well-known that its approximate degree is  $\Theta(\sqrt{n})$  [21, 15]. However, its probabilistic degree (over the reals) remains unknown: the best known upper bound is  $O(\log n)$  due to independent results of Beigel et al. [7] and Tarui [27], while the best lower bound is  $(\log n)^{1/2-o(1)}$  due to Harsha and the first author [16]. This indicates that we need better tools to understand probabilistic degree in general and over the reals in particular. This is one of the motivations behind this paper.

Another motivation is to understand the contrast between the setting of real-valued probabilistic polynomials and polynomials over constant-sized finite fields. At a high level, this helps us understand the contrast between circuit complexity classes  $\text{AC}^0$  and  $\text{AC}^0[p]$ , as the former class of circuits has low-degree probabilistic polynomials over the reals [7, 27], while the latter does not [26]. It is easy to show that there are truly  $n$ -variate Boolean functions of constant degree over finite fields (e.g., the parity function is a linear polynomial over the field  $\mathbb{F}_2$ ). It is interesting to ask to what extent such phenomena fail over the reals.

A final motivating reason is to understand more precisely the relationships between probabilistic degree and other complexity measures such as approximate degree. A recent conjecture of Golovnev, Kulikov and Williams [14] shows that porting results for approximate

<sup>5</sup> This can also be defined over other fields.

degree to probabilistic degree would have interesting consequences for De Morgan formula lower bounds. By proving results such as the one in this paper, we hope to be able to prove such connections and hopefully uncover others.

With these motivations in mind, we address Question 1 in the setting of Probabilistic degree. That is, what is the lowest possible probabilistic degree of a truly  $n$ -variate Boolean function? As far as we know, this question has not been addressed before. Putting together Simon's bound on the sensitivity of a truly  $n$ -variate function with known probabilistic degree lower bounds [16], one can show a lower bound of  $(\log \log n)^{1/2-o(1)}$ . This is quite far from the best known upper bounds of  $O(\log n)$ , which hold for say the OR function [7, 27] and the Addressing function defined below in Section 1.3.

## 1.2 Results

Our aim is to prove a result characterizing the minimum possible probabilistic degree of a truly  $n$ -variate Boolean function. However, the gap even just in our understanding of the OR function (as mentioned above) tells us that this may not yet be within reach. What we are able to do is to give a near-complete characterization modulo the gap between known upper and lower bounds for  $\text{pdeg}(\text{OR})$ . *Moreover, the answer is non-trivial: it is not simply  $\text{pdeg}(\text{OR})$ .*

More precisely, our results are the following. Below,  $\text{OR}_n$  denotes the OR function on  $n$  variables. We assume that we have bounds of the form  $\text{pdeg}(\text{OR}_n) = (\log n)^{c \pm o(1)}$  for some  $c > 0$ .

► **Theorem 4.** *Assume that  $\text{pdeg}(\text{OR}_n) \geq (\log n)^{c-o(1)}$  for some  $c > 0$  and all large enough  $n \in \mathbb{N}$ . Then, any truly  $n$ -variate Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  satisfies  $\text{pdeg}(f) \geq (\log n)^{c/(c+1)-o(1)}$ .*

► **Theorem 5.** *Assume that  $\text{pdeg}(\text{OR}_n) \leq (\log n)^{c+o(1)}$  for some  $c > 0$  and all large enough  $n \in \mathbb{N}$ . Then, there exists a truly  $n$ -variate Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  such that  $\text{pdeg}(f) \leq (\log n)^{c/(c+1)+o(1)}$ .*

Thus, we get close-to-matching lower and upper bounds for truly  $n$ -variate Boolean functions assuming close-to-matching lower and upper bounds for the OR function. However, the above statements also imply *unconditional* lower and upper bounds on the probabilistic degrees of truly  $n$ -variate Boolean functions. Using known results that yield  $(\log n)^{(1/2)-o(1)} \leq \text{pdeg}(\text{OR}_n) \leq O(\log n)$  [7, 27, 16], we get

► **Corollary 6.** *Any truly  $n$ -variate Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  satisfies  $\text{pdeg}(f) \geq (\log n)^{(1/3)-o(1)}$ .*

► **Corollary 7.** *There exists a truly  $n$ -variate Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  such that  $\text{pdeg}(f) \leq (\log n)^{(1/2)+o(1)}$ .*

► **Remark 8.** The reader may wonder why we assume lower and upper bounds of the form  $(\log n)^{c \pm o(1)}$  for  $\text{pdeg}(\text{OR}_n)$ . This is because the gaps between the known upper and lower bounds are  $(\log n)^{\Omega(1)}$ , and so it makes sense to use a characterization that shrinks this gap to something relatively insignificant. Furthermore, the best known lower bound on  $\text{pdeg}(\text{OR}_n)$  is of the form  $(\log n)^{1/2-o(1)}$  [16] (more precisely, it is  $\Omega((\log n)/(\log \log n)^{3/2})$ ).

If we instead assume a more precise characterization  $\text{pdeg}(\text{OR}_n) = \Theta((\log n)^c)$ , then going through the proofs of the above theorems would yield a sharper lower bound of  $\Omega((\log n)^{c/(c+1)}/(\log \log n)^2)$  for any truly  $n$ -variate Boolean function and a better upper bound of  $O((\log n)^{c/(c+1)})$  for some truly  $n$ -variate Boolean function.

### 1.3 Proof Outline

Our proof is motivated by two important examples. The first of these is the  $\text{OR}_n$  function which has probabilistic degree at most  $O(\log n)$  by results of [7, 27] and at least  $(\log n)^{(1/2)-o(1)}$  by [16]. The second is the *Addressing function*, which we now define.

The Addressing function  $\text{Addr}_r$  has  $n = r + 2^r$  variables. We think of the input variables as being divided into two parts: there are  $r$  “addressing” variables  $y_1, \dots, y_r$  and  $2^r$  “addressed” variables  $\{z_a \mid a \in \{0, 1\}^r\}$  (the latter part of the input is thus indexed by elements of  $\{0, 1\}^r$ ). On an input  $(a, A) \in \{0, 1\}^r \times \{0, 1\}^{2^r}$ , the output of the function is defined to be  $A_a$  (i.e. the  $a$ th co-ordinate of the vector  $A$ ). The Addressing function satisfies  $\deg(\text{Addr}_r) = r + 1 = O(\log n)$ . This example is quite relevant to this line of work: in particular, it implies that the results of Nisan and Szegedy [21] and Chiarelli et al. [13] stated above are tight, and is also a tight example for Simon’s theorem [25].

We now describe the upper and lower bound proofs, starting with the less technical upper bound.

#### The Upper Bound

Given that we have two natural families of truly  $n$ -variate functions that have degree  $O(\log n)$ , one may suspect that this is the best possible. Indeed this was also our initial conjecture. However, using the ideas of Ambainis and de Wolf [4], we can do better. Ambainis and de Wolf showed that there are truly  $n$ -variate Boolean functions that have *approximate degree*  $O(\log n / \log \log n)$ . Their construction<sup>6</sup> uses a modified Addressing function, where the addressing variables are present in an “encoded” form. While this blows up the size of the first part of the input, this does not affect  $n$  much as the addressing variables take up only a small part of the input. On the other hand, the advantage is that the “decoding” procedure can be performed approximately by a suitable low-degree polynomial: a proof of this uses two famous Quantum algorithms, the *Bernstein-Vazirani algorithm* and *Grover search*, along with the fact that efficient Quantum algorithms yield approximating low-degree polynomials [6]. Putting things together yields an improved approximate degree bound for some  $n$ -variate  $f$ .

We show how to port their construction to the probabilistic degree setting. The first observation is that Grover search, which is essentially an algorithm for computing  $\text{OR}_n$ , is much more “efficient” in the probabilistic degree setting, as  $\text{pdeg}(\text{OR}_n) = O(\log n)$ , while its approximate degree is  $\Omega(\sqrt{n})$  [21]. The second observation is that the Bernstein-Vazirani algorithm, which can be thought of as a decoding algorithm for a suitable error-correcting code, can be replaced by polynomial interpolation. This gives a good idea of why we should also be able to use a similar construction in the probabilistic degree setting. In fact, the better probabilistic degree upper bound for  $\text{OR}_n$  implies that we should be able to get a *better* bound than what is possible for approximate degree. Indeed this is true. By a similar construction, we show that we can construct a truly  $n$ -variate  $f$  with probabilistic degree  $O(\sqrt{\log n})$  *unconditionally*, which is quite a bit better than previous results for any of the above degree measures. If we assume, moreover, that  $\text{pdeg}(\text{OR}_n) \leq (\log n)^{c+o(1)}$ , the same construction yields a function with probabilistic degree  $(\log n)^{c/(c+1)+o(1)}$ .

<sup>6</sup> They actually give two, slightly different, constructions. We use the second one here.

■ **Figure 1** The function  $f(y_1, \dots, y_5, z_1, \dots, z_5)$  is defined by the decision tree on the left (we assume that the left child corresponds to the queried variable taking value 0). When  $z_1, \dots, z_5$  are set i.u.a.r. to  $\mathbf{b}_1, \dots, \mathbf{b}_5$ , we get a random function  $F(y_1, \dots, y_5)$  such that  $F(00000) = \mathbf{b}_1, F(01000) = \mathbf{b}_2, F(01100) = \mathbf{b}_3, F(10000) = \mathbf{b}_4, F(10100) = \mathbf{b}_5$ . After a projection that maps  $y_1 \mapsto y'_1; y_2 \mapsto y'_2; y_3, y_4, y_5 \mapsto y'_3$ , we get the function  $f'$  computed by the tree on the right. This reduces the number of addressing variables to 3. But also note that the variable  $z_5$  is no longer relevant as the path leading to it is inconsistent with the projection. So the number of addressed variables falls to 4.

**The Lower Bound**

Given that the upper bound construction uses the Addressing function as well as the OR function, it is only natural that the lower bound would use the lower bounds for these two families of functions. Our hypothesis already assumes a lower bound of  $(\log n)^{c-o(1)}$  for  $\text{pdeg}(\text{OR}_n)$ . For the addressing function  $\text{Addr}_r$  described above, one can prove an  $\Omega(r) = \Omega(\log n)$  lower bound in the following way. We observe that by setting the  $2^r$  addressed variables uniformly at random, we obtain a uniformly random function on the  $r$  addressing variables. By a counting argument, one can show that a uniformly random Boolean function  $F$  on  $r$  variables has probabilistic degree  $\Omega(r)$  with high probability. In particular, as setting some input variables to constants can only reduce probabilistic degree, this implies that  $\text{pdeg}(\text{Addr}_r) = \Omega(r) = \Omega(\log n)$ . Note that this is tight, as  $\text{deg}(\text{Addr}_r) = r + 1$ .

Our aim is to generalize the above lower bounds enough to prove a lower bound for any truly  $n$ -variate  $f$ . The first informal observation is that the  $\text{OR}_n$  function is the “simplest” function on  $n$  variables to have sensitivity  $n$ . Therefore, it is intuitive that any Boolean function with sensitivity  $n$  should have probabilistic degree at least that of the  $\text{OR}_n$  function. We show that this is true, up to  $(\log n)^{o(1)}$  factors. More generally, we show that any Boolean function  $f$  with sensitivity  $s$  has probabilistic degree at least that of the OR function on  $s$  variables (up to  $(\log s)^{o(1)}$  factors). The proof of this is in the contrapositive: we use a probabilistic degree upper bound for  $f$  to construct a probabilistic polynomial for  $\text{OR}_s$ . The ideas behind this go back to a sampling argument used in the works of Beigel et al. and Tarui [7, 27]. Viewing this argument more abstractly, we can use this to construct a reduction from  $\text{OR}_s$  to  $f$  (for any  $f$  of sensitivity  $s$ ) in the probabilistic degree setting.

The above argument implies a strong lower bound for any  $n$ -variate  $f$  with large sensitivity. In particular, it implies that if  $f$  has sensitivity at least  $s = n^{\Omega(1)}$ , then its probabilistic degree is almost that of the OR function. We now consider the case of functions with small sensitivity (specifically when  $s = n^{o(1)}$ ), which is the most technical part of the proof. By a recent breakthrough result of Huang [18], we also know that  $f$  also has a *decision tree* (we

refer the reader to [10] for the definition of Decision trees) of depth  $d = \text{poly}(s) = n^{o(1)}$ .<sup>7</sup> The prototypical example of such an  $f$  is the Addressing function which has a decision tree of depth  $r + 1 = \lfloor \log n \rfloor + 1$ , which we argued a lower bound for above. The idea, in general, is to find a copy of something like an Addressing function “inside” the function  $f$ .

We illustrate how this argument works by considering a special case of the problem, which is only a small variant of the Addressing function. Assume that a truly  $n$ -variate function  $f$  is computed by a decision tree  $T$  of depth  $d = \text{poly}(\log n)$ . Note that as the function depends on all its variables, each of the underlying  $n$  variables appear in the tree  $T$ . To make things even simpler, assume that we have  $n/2$  “addressing” variables  $y_1, \dots, y_{n/2}$  and  $n/2$  “addressed” variables  $z_1, \dots, z_{n/2}$ . The tree reads  $d - 1$  addressing variables among  $y_1, \dots, y_{n/2}$  in some (possibly adaptive) fashion and then possibly queries one addressed variable, the value of which is output. (See Figure 1 (a).)

How do we argue a lower bound on  $\text{pdeg}(f)$ ? We could try to proceed as above and set the addressed variables  $z_1, \dots, z_{n/2}$  as random to obtain a random function  $\mathbf{F}$  in  $y_1, \dots, y_{n/2}$ . However, this function is not *uniformly* random, as it is sampled using only  $n/2$  random bits, while the number of functions in  $n/2$  variables is  $2^{2^{n/2}}$ . Nevertheless, we can observe that the function  $\mathbf{F}$  does take independent random values at at least  $n/2$  distinct inputs, those which are consistent with  $n/2$  distinct paths in  $T$  leading to the various addressed variables. (See Figure 1 (a).) We could try to lower bound  $\text{pdeg}(\mathbf{F})$  as above.

This leads to the following general question: given a random function  $\mathbf{F} : \{0, 1\}^r \rightarrow \{0, 1\}$  that takes independent and random values at  $M$  distinct inputs in  $\{0, 1\}^r$ , what can we say about the probabilistic degree of  $\mathbf{F}$ ? By a more general counting argument, we are able to show that with high probability, the probabilistic degree of  $\mathbf{F}$  is at least  $\Omega(\log M / \log r)$ . This is easily seen to be tight in the case that  $X$  is, say, a Hamming ball of radius  $R \leq r^{1-\Omega(1)}$ . (In the case that  $M = 2^r$ , this leads to a bound of  $\Omega(r / \log r)$ , nearly matching the claim for random functions that we mentioned above. A tight bound can be obtained in the same way but is harder to state for general  $M$ .)

Given this bound for random functions, we can try to use it in the case of the function  $f$  above. Unfortunately, in this case, both parameters  $r$  and  $M$  are  $n/2$ , and hence we do not get any non-trivial bound. However, we show that we can still reduce to a case where a non-trivial bound is possible (this is where the depth of  $T$  comes in). More precisely, we reduce the number of addressing variables by *projecting* the  $n/2$  addressing variables to a smaller set of  $r'$  variables  $Y' = \{y'_1, \dots, y'_{r'}\}$ . That is, we randomly set each variable  $Y$  to a uniformly random variable in  $Y'$  to get a different function in the variables  $Y' \cup Z$ . This has the effect of reducing the number of addressing variables to  $r'$ . But there is also a potential problem: the projection could also render some of the addressed variables irrelevant, as the paths that lead to them become inconsistent. (See Figure 1 (b).)

Nevertheless, if we choose  $r'$  large enough (something like  $r' = 4d^2$  is enough by the Birthday paradox), the variables of each path are sent to *distinct* variables in  $Y'$  with high probability, which implies that each addressed variable remains relevant with high probability. In particular, there is a projection that maps  $f$  to an “Addressing function” with only  $\text{poly}(\log n)$  addressing variables and  $\Omega(n)$  addressed variables. Now applying the argument for random functions, we get a probabilistic degree lower bound of  $\Omega(\log n / \log \log n)$  for this

<sup>7</sup> Strictly speaking, we do not need to use Huang’s result as we could also use the known polynomial relationship between the decision tree height and the *block sensitivity* of a function [20]. But it is notationally easier to work with sensitivity.

function, nearly matching what we obtained for the Addressing function. As projections do not increase probabilistic degree, the same bound holds for  $f$ , concluding the proof in this special case.<sup>8</sup>

A similar argument can be carried out in the general case by first carefully partitioning the variables into the addressing and addressed variables. We do this by looking at the structure of the decision tree  $T$ . These details are postponed to the formal proof. In general, this argument yields a lower bound of  $\Omega(\log n / \log s)$  on the probabilistic degree of a truly  $n$ -variate function  $f$  with sensitivity at most  $s$ .

Using this lower bound along with the previous lower bound for functions of sensitivity at least  $s$ , and optimizing our choice of  $s$ , yields a lower bound of  $(\log n)^{c/(c+1)-o(1)}$  for any truly  $n$ -variate function  $f$ .

## 2 Preliminaries

### Functions, Restrictions, Projections

Throughout, we work with real-valued functions  $f : \{0, 1\}^n \rightarrow \mathbb{R}$ . Boolean functions (i.e. functions mapping  $\{0, 1\}^n$  to  $\{0, 1\}$ ) are also treated as real-valued. We use boldface notation to denote random variables. A *random function*  $\mathbf{F}$  is a probability distribution over functions.

A *restriction* on  $n$  variables is a map  $\rho : [n] \rightarrow \{0, 1, *\}$ . Given a function  $f : \{0, 1\}^n \rightarrow \mathbb{R}$  and a restriction  $\rho$  on  $n$  variables, we have a natural restricted function  $f_\rho$  defined by setting the  $i$ th input variable to  $f$  to 0, 1 or leaving it as is, depending on whether  $\rho(i)$  is 0, 1 or  $*$  respectively. Note that the function  $f_\rho$  now depends on  $|\rho^{-1}(*)|$  many variables. However, we sometimes also treat  $f_\rho$  as a function of all the original variables that only *depends* on (a subset of) the variables indexed by  $\rho^{-1}(*)$ .

A *projection* from  $n$  variables to  $m$  variables is a map  $\nu : [n] \rightarrow [m]$ . Given a function  $f : \{0, 1\}^n \rightarrow \mathbb{R}$  and a projection  $\nu$  from  $n$  variables to  $m$  variables, we get a function  $f|_\nu : \{0, 1\}^m \rightarrow \mathbb{R}$  by identifying variables of  $f$  that map to the same image under  $\nu$ .

### Some Boolean functions

For any positive integer  $n$ , we use  $\text{OR}_n$ ,  $\text{AND}_n$  and  $\text{Maj}_n$  to denote the OR, AND and Majority functions on  $n$  variables respectively.

► **Fact 9.** *We have the following simple facts about probabilistic polynomials.*

1. (*Interpolation*) Any function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  has an exact multilinear polynomial representation of degree at most  $n$ , i.e.  $\deg(f) := \text{pdeg}_0(f) \leq n$ .
2. (*Shifts and Restrictions*) Fix any  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  and any  $\varepsilon \geq 0$ . Then the function  $g : \{0, 1\}^n \rightarrow \{0, 1\}$  defined by  $g(x) = f(x \oplus y)$  for a fixed  $y \in \{0, 1\}^n$  has the same probabilistic degree as  $f$ , i.e.,  $\text{pdeg}_\varepsilon(g) = \text{pdeg}_\varepsilon(f)$ .  
If  $g : \{0, 1\}^m \rightarrow \{0, 1\}$  is a restriction or a projection of  $f$ , then  $\text{pdeg}_\varepsilon(g) \leq \text{pdeg}_\varepsilon(f)$ .
3. (*Error reduction [16]*) For any  $\delta < \varepsilon \leq 1/3$  and any Boolean function  $f$ , if  $\mathbf{P}$  is an  $\varepsilon$ -error probabilistic polynomial for  $f$ , then  $\mathbf{Q} = M(\mathbf{P}_1, \dots, \mathbf{P}_\ell)$  is a  $\delta$ -error probabilistic polynomial for  $f$  where  $\ell = O(\log(1/\delta)/\log(1/\varepsilon))$ ,  $M$  is the exact multilinear polynomial for  $\text{Maj}_\ell$  and  $\mathbf{P}_1, \dots, \mathbf{P}_\ell$  are independent copies of  $\mathbf{P}$ . In particular, we have  $\text{pdeg}_\delta(f) \leq \text{pdeg}_\varepsilon(f) \cdot O(\log(1/\delta)/\log(1/\varepsilon))$ .

<sup>8</sup> Random projections of this kind have been used recently to prove important results in circuit complexity [17, 12]. However, as far as we know, they have not been used to prove probabilistic degree lower bounds.

4. (Composition) For any Boolean function  $f$  on  $k$  variables and any Boolean functions  $g_1, \dots, g_k$  on a common set of  $m$  variables, let  $h$  denote the natural composed function  $f(g_1, \dots, g_k)$  on  $m$  variables. For  $\varepsilon, \delta_1, \dots, \delta_k \geq 0$ , let  $\mathbf{P}, \mathbf{Q}_1, \dots, \mathbf{Q}_k$  be probabilistic polynomials for  $f, g_1, \dots, g_k$  respectively with errors  $\varepsilon, \delta_1, \dots, \delta_k$  respectively. Then,  $\mathbf{R} = \mathbf{P}(\mathbf{Q}_1, \dots, \mathbf{Q}_k)$  is a probabilistic polynomial for  $h$  with error at most  $\varepsilon + \sum_i \delta_i$ . In particular, for any  $\varepsilon, \delta > 0$ , we have  $\text{pdeg}_{\varepsilon+k\delta}(h) \leq \text{pdeg}_{\varepsilon}(f) \cdot \max_{i \in [k]} \text{pdeg}_{\delta}(g_i)$ .

We will need the following known upper and lower bounds on  $\text{pdeg}(\text{OR}_n)$ .

► **Theorem 10** ([7, 27]).  $\text{pdeg}_{\varepsilon}(\text{OR}_n) = O(\log n \log(1/\varepsilon))$ .

► **Theorem 11** ([16]).  $\text{pdeg}(\text{OR}_n) \geq (\log n)^{1/2-o(1)}$ .

► **Definition 12** (Some Complexity Measures of Boolean functions). Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  be any Boolean function. We use  $D(f)$  to denote the depth of the smallest Decision Tree computing  $f$ .

For  $a \in \{0, 1\}^n$ , we use  $s(f, a)$  to denote the number of  $b \in \{0, 1\}^n$  that can be obtained by flipping a single bit of  $a$  and satisfying  $f(a) \neq f(b)$ . The Sensitivity of  $f$ , denoted  $s(f)$ , is defined to be the maximum value of  $s(f, a)$  as  $a$  ranges over  $\{0, 1\}^n$ .

Huang [18] proved the following breakthrough result recently.

► **Theorem 13** (Huang's Sensitivity theorem [18]). There is an absolute constant  $c_0 > 0$  such that for all large enough  $n$  and all functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ ,  $D(f) \leq s(f)^{c_0}$ .

Strictly speaking, we do not need to use Huang's Sensitivity theorem in what follows as we could also make do with a polynomial relationship between the decision tree height and the *block sensitivity*<sup>9</sup> of  $f$ , which has been known for a long time [20]. However, it is notationally simpler to work with sensitivity.

### 3 The Lower Bound: Proof of Theorem 4

The proof is made up of two lower bounds. We first prove a lower bound on  $\text{pdeg}(f)$  for any function  $f$  that has large sensitivity  $s(f)$ ; this is by a suitable reduction from the case of the OR function. We then prove a lower bound on  $\text{pdeg}(f)$  for any function that depends on all its variables but has small sensitivity; this is by a suitable reduction from a kind of Addressing function. Optimizing over the parameters of the lower bounds will yield the lower bound of the theorem statement.

Throughout this section, we assume that  $\text{pdeg}(\text{OR}_n) \geq (\log n)^{c-o(1)}$  for large enough  $n$ .

#### 3.1 The case of large sensitivity

The main result of this section is the following lower bound on the probabilistic degrees of Boolean functions with large sensitivity.

► **Lemma 14.** Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  be any Boolean function that has sensitivity  $s$ . Then,  $\text{pdeg}(f) \geq (\log s)^{c-o(1)}$ .

<sup>9</sup> The Block sensitivity of a function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  is defined as follows. Given  $a \in \{0, 1\}^n$ , define  $bs(f, a)$  to be the maximum number of pairwise disjoint sets  $B_1, \dots, B_t \subseteq [n]$  such that flipping all the bits indexed by any  $B_i$  in  $a$  results in an input  $b^{(i)}$  such that  $f(a) \neq f(b^{(i)})$ . Then, the block sensitivity of  $f$  is defined to be the maximum value of  $bs(f, a)$  over all inputs  $a \in \{0, 1\}^n$ .

## 42:10 Probabilistic Degree of $N$ -Variate Boolean Function

The above lemma is proved via a probabilistic reduction from the OR function on  $s$  variables to the function  $f$ . This is captured by the following lemma, which shows how a function that has large sensitivity can be used to obtain a probabilistic representation of a large copy of the OR function.

Recall from above that a Boolean function  $h : \{0, 1\}^s \rightarrow \{0, 1\}$  is a restriction of a Boolean function  $g : \{0, 1\}^s \rightarrow \{0, 1\}$  if  $h$  can be obtained by setting some inputs of  $g$  to constants. Though  $h$  no longer depends on the variables that are set to constants, here we still treat  $h$  as a function on all  $s$  variables.

► **Lemma 15.** *Let  $g : \{0, 1\}^s \rightarrow \{0, 1\}$  be any Boolean function such that  $g(0^s) = 0$  and  $g(x) = 1$  for any  $x$  of Hamming weight 1. Then, there exist  $\ell = O(\log s)$  independent random restrictions  $\mathbf{g}_1, \dots, \mathbf{g}_\ell$  of  $g$  such that for any  $a \in \{0, 1\}^s$ ,*

$$\Pr_{\mathbf{g}_1, \dots, \mathbf{g}_\ell} [\text{OR}_\ell(\mathbf{g}_1(a), \dots, \mathbf{g}_\ell(a)) \neq \text{OR}_s(a)] \leq \frac{1}{10}.$$

We interpret the random function  $\text{OR}_\ell(\mathbf{g}_1(a), \dots, \mathbf{g}_\ell(a))$  as a probabilistic representation of the  $\text{OR}_s$  function. The reader may be confused by the fact that the probabilistic representation itself uses an OR function; however, note that this OR function is defined on  $\ell \ll s$  variables and consequently is a much “simpler” function (in particular, for us, what is relevant is that  $\text{pdeg}(\text{OR}_\ell) = O(\log \ell)$  [7, 27] which is much smaller than  $\log s$ ).

The proof of Lemma 15 is closely related to the argument for constructing a probabilistic polynomial for the OR function from [7, 27]. The observation here is that a similar argument can be used to give a probabilistic reduction from  $\text{OR}_s$  to any function  $g$  as above. Due to space constraints, we push the proof of Lemma 15 to the Appendix (Section A). Let us now prove Lemma 14.

**Proof of Lemma 14.** We know that  $f$  has some input of sensitivity  $s$ . Then we note that we may assume  $f(0^n) = 0$  and  $f(0^{j-1}10^{n-j}) = 1$  for  $j \in [s]$ . For let  $a \in \{0, 1\}^n$  such that  $s(f, a) = s$ . If  $f(a) = 1$ , we may replace  $f$  by  $1 - f$ . (Obviously,  $\text{pdeg}_\varepsilon(f) = \text{pdeg}_\varepsilon(1 - f)$ , for all  $\varepsilon \geq 0$ .) So we may assume  $f(a) = 0$ . Now by permuting coordinates if required, we may assume that  $f(\tilde{a}^{(j)}) = 1$ , where  $\tilde{a}^{(j)} := (a_1, \dots, a_{j-1}, 1 - a_j, a_{j+1}, \dots, a_n)$  for all  $j \in [s]$ . Further, if  $a \neq 0^n$ , we may replace  $f$  by  $f'$ , defined as  $f'(x) = f(x \oplus a)$ ,  $x \in \{0, 1\}^n$ . By Fact 9 Item 2,  $\text{pdeg}_\varepsilon(f) = \text{pdeg}_\varepsilon(f')$ , for all  $\varepsilon \geq 0$ . Clearly, we have  $f'(0^n) = 0$  and  $f'(0^{j-1}10^{n-j}) = 1$ , for all  $j \in [s]$ .

So now, by assumption, we have  $f(0^n) = 0$  and  $f(0^{j-1}10^{n-j}) = 1$  for  $j \in [s]$ . Define  $g : \{0, 1\}^s \rightarrow \{0, 1\}$  as  $g(x) = f(x0^{n-s})$ . Then  $g$  satisfies the hypotheses of Lemma 15. Hence, by Lemma 15, there exist  $\ell = O(\log s)$  random restrictions  $\mathbf{g}_1, \dots, \mathbf{g}_\ell$  of  $g$  such that

$$\Pr_{\mathbf{g}_1, \dots, \mathbf{g}_\ell} [\text{OR}_\ell(\mathbf{g}_1(x), \dots, \mathbf{g}_\ell(x)) \neq \text{OR}_s(x)] \leq \frac{1}{10}, \quad \text{for all } x \in \{0, 1\}^s. \quad (1)$$

We use the above representation to devise a probabilistic polynomial for  $\text{OR}_s$ .

Let  $\mathbf{O}$  be any  $(1/10)$ -error probabilistic polynomial for  $\text{OR}_\ell$  and  $\mathbf{G}_1, \dots, \mathbf{G}_\ell$  be any  $(1/10\ell)$ -error probabilistic polynomials for  $\mathbf{g}_1, \dots, \mathbf{g}_\ell$  respectively. Then, by Fact 9 and (1),  $\mathbf{O}(\mathbf{G}_1, \dots, \mathbf{G}_\ell)$  is a  $(1/3)$ -error probabilistic polynomial for  $\text{OR}_s$ .

Note that by Theorem 10, we can choose  $\mathbf{O}$  to have degree at most  $O(\log \ell)$ . Further, by Fact 9, we have  $\text{pdeg}(\mathbf{g}_i) \leq \text{pdeg}(g) \leq \text{pdeg}(f)$  for each  $i \in [\ell]$ . In particular, this implies that we can choose  $\mathbf{G}_i$  to have degree  $O(\text{pdeg}(f) \cdot \log \ell)$  for each  $i \in [\ell]$ . This yields

$$\text{pdeg}(\text{OR}_s) \leq \text{pdeg}(f) \cdot O(\log \ell)^2 = \text{pdeg}(f) \cdot O((\log \log s)^2) = \text{pdeg}(f) \cdot (\log s)^{o(1)}.$$

As  $\text{pdeg}(\text{OR}_s) \geq (\log s)^{c-o(1)}$  by assumption, we get the desired lower bound on  $\text{pdeg}(f)$ . ◀

### 3.2 The case of small sensitivity

We prove the following lemma.

► **Lemma 16.** *Let  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  be a function of sensitivity at most  $s$  that depends on all its  $n$  variables. Then, we have  $\text{pdeg}(f) = \Omega\left(\frac{\log(n/s^{O(1)})}{\log s}\right)$ .*

The proof of the lemma is in two steps. In the first step, we use a counting argument to prove a lower bound on the probabilistic degrees of random functions  $\mathbf{F} : \{0, 1\}^m \rightarrow \{0, 1\}$  which are chosen from a distribution such that for a large subset  $X \subseteq \{0, 1\}^m$ , the random variables  $\{\mathbf{F}(x) \mid x \in X\}$  are independently and uniformly chosen random bits. In the second step, we show how any  $f$  as in the statement of Lemma 16 can be randomly restricted to a random function  $\mathbf{F}$  where the lower bound for random functions applies.

We now state the lower bound for random functions and use it to prove Lemma 16. The lower bound for random functions uses fairly standard ideas and is proved in the appendix (Section B).

► **Lemma 17 (Random function lower bound).** *The following holds for positive integer parameters  $m, M$  and  $d$  such that  $M > m^{10d}$ . Let  $\mathbf{F} : \{0, 1\}^m \rightarrow \{0, 1\}$  be a random function such that for some  $X \subseteq \{0, 1\}^m$  with  $|X| = M$ , the random variables  $(\mathbf{F}(x))_{x \in X}$  are independent and uniformly distributed random bits. Then, we have*

$$\Pr_{\mathbf{F}}[\text{pdeg}_{1/10}(\mathbf{F}) \leq d] < \frac{1}{10}.$$

Let us see how to use Lemma 17 to prove Lemma 16. This proof again breaks into two smaller steps.

**Step 1.** Show that, after a projection,  $f$  turns into something similar to an addressing function, that we will call a *Pseudoaddressing function*.

**Step 2.** Show that any pseudoaddressing function has large probabilistic degree.

As any projection  $g$  of  $f$  satisfies  $\text{pdeg}(g) \leq \text{pdeg}(f)$  (Fact 9), the above implies a lower bound on  $\text{pdeg}(f)$ , hence proving Lemma 16.

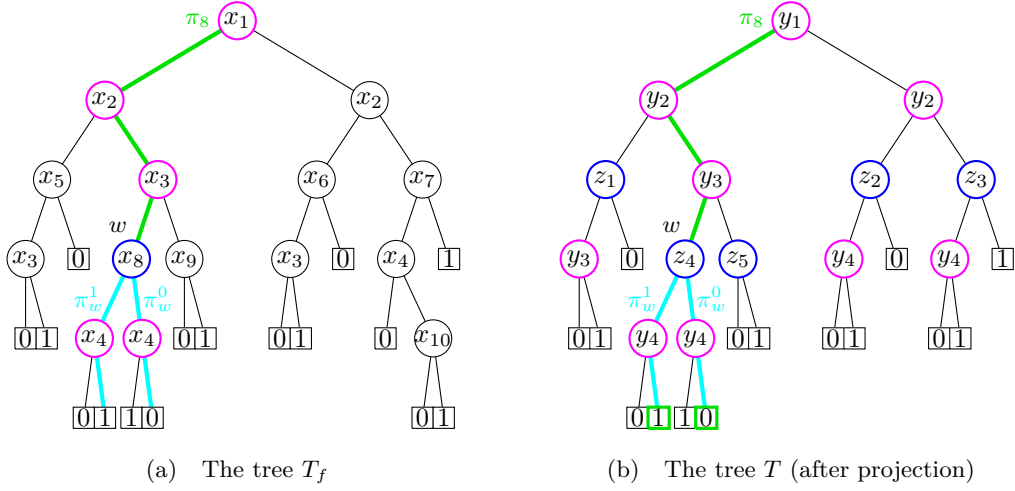

To make the above precise, we need the following definition. We say that a function  $g : \{0, 1\}^{r+t} \rightarrow \{0, 1\}$  is an  $(r, t)$ -*Pseudoaddressing function* if the input variables to  $g$  can be partitioned into two sets  $Y = \{y_1, \dots, y_r\}$  and  $Z = \{z_1, \dots, z_t\}$  and  $g$  can be computed by a decision tree  $T$  with the following properties.

- P1.** For each  $z_j \in Z$ , there are two root-to-leaf paths  $\pi_j^0$  and  $\pi_j^1$  in  $T$  that diverge at a node labeled  $z_j$  and lead to outputs 0 and 1 respectively.
- P2.** All the other nodes on these paths are labeled by variables in  $Y$ , and further these variables take the same values on both paths. In particular,  $\pi_j^0$  and  $\pi_j^1$  differ only on the value of  $z_j$ .

► **Example 18.** Consider the standard Addressing function  $\text{Addr}_r$  on  $n = r + 2^r$  variables as defined in Section 1.3. This function is an  $(r, 2^r)$ -pseudoaddressing function as it can be computed by a decision tree of depth  $r + 1$ , which first queries all the addressing variables to determine  $a \in \{0, 1\}^r$  and then queries and outputs the value of  $z_a$  (the two computational paths querying  $z_a$  give the desired root-to-leaf paths required in the definition above).

In analogy with the Addressing function, given an  $(r, t)$ -pseudoaddressing function as above, we refer to the variables in  $Y$  as the addressing variables and the variables in  $Z$  as the addressed variables.

The two steps of the proof as outlined above can now be formalized as follows.

■ **Figure 2** The decision tree on the left computes a truly 10-variate function  $f(x_1, \dots, x_{10})$ . The paths obtained by concatenating  $\pi_8$  with  $\pi_w^0$  and  $\pi_w^1$  are consistent with each other except for the value of  $x_8$ , the variable queried at node  $w$ . After a projection  $\nu : [10] \rightarrow [9]$  defined by  $\nu(i) = i$  for  $i \leq 9$  and  $\nu(10) = 4$ , we get a tree  $T$ , which computes a  $(4, 5)$ -pseudoaddressing function  $g(y_1, \dots, y_4, z_1, \dots, z_5)$ . Note that each path in  $T$  corresponds to a path in  $T_f$  but not every path in  $T_f$  survives in  $T$  (e.g. the path leading to 0 through the node querying  $x_{10}$  is pruned away, as it is inconsistent with  $\nu$ ).

$\triangleright$  **Claim 19.** Let  $f$  be as in the statement of Lemma 16. Then, there exist  $r \leq s^{O(1)}$  and  $t \geq n/s^{O(1)}$  and a projection  $\nu : [n] \rightarrow [r+t]$  such that  $g = f|_\nu$  is an  $(r, t)$ -pseudoaddressing function.

$\triangleright$  **Claim 20.** Let  $g$  be any  $(r, t)$ -pseudoaddressing function. Then,  $\text{pdeg}(g) = \Omega(\log t / \log r)$ .

As noted above, the above claims immediately imply Lemma 16. We now prove these claims.

**Proof of Claim 19.** We will first outline how to isolate a set of  $n/\text{poly}(s)$  variables that will (almost) be the set of addressed variables. A projection will then be applied to the remaining variables to create the pseudoaddressing function. Let us now see the details.

By Theorem 13, we know that  $f$  has a decision tree  $T_f$  of depth  $d \leq \text{poly}(s)$ . Fix such a tree  $T_f$  of *minimum size*, i.e. with the smallest possible number of leaves. Let  $V = \{x_1, \dots, x_n\}$  denote the input variables of  $f$ .

Any variable  $x_i \in V$  must be queried somewhere in the tree  $T_f$ , as  $f$  depends on all its input variables by assumption. Fix any occurrence of this variable in the decision tree  $T_f$ , and let  $w$  denote the node of  $T_f$  corresponding to this query. (Refer to Figure 2 (a) for an illustration.) Let  $\pi_i$  denote the path from the root of  $T_f$  to  $w$  and let  $T_0$  and  $T_1$  be the subtrees rooted at the left and right children of  $w$ . The decision trees  $T_0$  and  $T_1$  both compute functions of the  $n' < n$  Boolean variables not queried in  $\pi_i$ . Note that these decision trees compute *distinct* functions since otherwise the query made at the vertex  $w$  is unnecessary, and a smaller decision tree than  $T_f$  can be obtained by replacing the subtree rooted at  $w$  by  $T_0$  or by  $T_1$ . This contradicts the minimality of the size of  $T_f$ .

Thus,  $T_0$  and  $T_1$  compute distinct functions. In particular, there is an input  $a \in \{0, 1\}^{n'}$  on which  $T_0$  and  $T_1$  have different outputs; w.l.o.g., assume  $T_0$  and  $T_1$  output 0 and 1 respectively on  $a$ . Let  $\pi_w^0$  and  $\pi_w^1$  be the root-to-leaf paths followed on the input  $a$  in  $T_0$  and

$T_1$  respectively. Note that any variable queried on both  $\pi_w^0$  and  $\pi_w^1$  takes the same value on both paths, as both paths are consistent with the input  $a$ . (Again, see Figure 2 (a) for an example.)

Concatenating each of  $\pi_w^0$  and  $\pi_w^1$  with the path  $\pi_i$  gives us two root-to-leaf paths  $\pi_i^0$  and  $\pi_i^1$  in  $T$  such that

- Q1. The paths  $\pi_i^0$  and  $\pi_i^1$  diverge at the node  $w$  (labelled by variable  $x_i$ ) and lead to outputs 0 and 1 respectively.
- Q2. The two paths agree on all variables other than  $x_i$ , i.e., any other variable that is queried on  $\pi_i^0$  and  $\pi_i^1$  takes the same value on both.

We have such a pair of paths  $\pi_i^0$  and  $\pi_i^1$  for each  $x_i \in V$ . Let  $P_i$  denote the set of all  $j \neq i$  such that  $x_j$  is queried on  $\pi_i^0$  or on  $\pi_i^1$ . Note that  $|P_i| \leq 2d$ .

We claim that we can choose a large subset  $Z' \subseteq [n]$  such that for all  $i \in Z'$ , the set  $P_i$  does not contain any  $j$  where  $j \in Z'$ . To see this, define a graph  $G$  with vertex  $[n]$  and edges between vertices distinct  $i, j \in [n]$  if and only if  $P_i$  contains  $j$  or vice-versa. Since each  $|P_i| \leq 2d$ , it is clear that this graph has average degree at most  $2d$ . By Turán's theorem (see e.g. [3]), this implies that  $G$  has an independent set  $Z'$  of size at least  $n/4d$ . This set  $Z'$  has the required property.

We are now ready to show that the required projection  $\nu$  exists. Let  $r = 10d^2$  and let  $\nu' : [n] \setminus Z' \rightarrow [r]$  be a random map (i.e. the image of each element of the domain is independently and uniformly chosen from  $[r]$ ). We say that an  $i \in Z'$  is *good* if  $\nu'$  is 1-1 on the set  $P_i$ . Let  $\mathcal{G}$  be the set of all good  $i$ , with  $t := |\mathcal{G}|$ . Assume  $\mathcal{G} = \{i_1, \dots, i_t\}$ . We use this to define a random projection  $\nu : [n] \rightarrow [r + t]$  by

$$\nu(i) = \begin{cases} \nu'(i) & \text{if } i \notin Z', \\ 1 & \text{if } i \in Z' \setminus \mathcal{G}, \text{ (here, any } k \in [r] \text{ will do)} \\ r + j & \text{if } i \in \mathcal{G} \text{ and } i = i_j. \end{cases}$$

The random projection defines a random Boolean function  $g$  on  $r + t$  variables. We now show that, with positive probability,  $g$  is an  $(r, n/\text{poly}(s))$ -pseudoaddressing function, where the first  $r$  variables are the addressing variables. This will finish the proof. Note that the projection  $\nu$  applied to the tree  $T_f$  also defines a random decision tree  $T$  computing  $g$ . We will in fact show that  $T$  serves as a witness for the fact that  $g$  is an  $(r, n/\text{poly}(s))$ -pseudoaddressing function (with positive probability).

In fact, this happens whenever  $t = |\mathcal{G}|$  is large enough. More precisely, note that

$$\begin{aligned} \mathbf{E}_{\nu'}[|Z'| - t] &= \sum_{i \in Z'} \Pr_{\nu'}[\nu' \text{ is not 1-1 on } P_i] \leq \sum_{i \in Z'} \sum_{j \neq k \in P_i} \Pr_{\nu'}[\nu'(j) = \nu'(k)] \\ &\leq \sum_{i \in Z'} |P_i|^2 \cdot \frac{1}{r} \leq |Z'| \cdot \frac{(2d)^2}{r} \leq \frac{|Z'|}{2}. \end{aligned}$$

In particular, there is a setting  $\nu'$  of  $\nu'$  such that the corresponding set of good variables  $|\mathcal{G}|$  has size at least  $|Z'|/2$ . Fix this  $\nu'$  and let  $\mathcal{G}, t, \nu, g, T$  be the corresponding fixings of  $\mathcal{G}, t, \nu, g, T$  respectively.

We have  $g = g(y_1, \dots, y_r, z_1, \dots, z_t)$ . Observe that each root-to-leaf path of  $T$  can be identified with a root-to-leaf path of  $T_f$ . Further, a path  $\pi$  of  $T_f$  survives in  $T$  exactly when it is *consistent w.r.t.*  $\nu$ , i.e., if two variables that are set to opposite values in  $\pi$  are not mapped to the same variable by  $\nu$  (see Figure 2 (b) for an example). In particular, if a path  $\pi$  has the property that the variables queried along  $\pi$  are mapped injectively by  $\nu$ , then the path  $\pi$  survives in  $T$ .

## 42:14 Probabilistic Degree of $N$ -Variate Boolean Function

This implies that for any good  $i_j \in \mathcal{G}$ , the corresponding paths  $\pi_{i_j}^0$  and  $\pi_{i_j}^1$  survive in  $T$ . Moreover, as the projection  $\nu$  is injective on the entire set  $P_{i_j}$ , these paths continue to agree with each other on all variables except the variable  $z_j$  queried at the point of their divergence. This gives both properties Q1 and Q2 stated above. As this holds for each  $i_j \in \mathcal{G}$ , we see that  $g$  is indeed an  $(r, t)$ -pseudoaddressing function. Note that  $r = 10d^2 \leq \text{poly}(s)$  and  $t \geq n/4d \geq n/\text{poly}(s)$ . Hence, we have proved the claim.  $\triangleleft$

Proof of Claim 20. The proof is via a reduction to Lemma 17.

Let  $g(y_1, \dots, y_r, z_1, \dots, z_t)$  be an  $(r, t)$ -pseudoaddressing function. Consider the random function  $\mathbf{F}$  on  $\{0, 1\}^r$  obtained by setting the addressed variables  $z_1, \dots, z_t$  to  $\mathbf{b}_1, \dots, \mathbf{b}_t \in \{0, 1\}$  chosen i.u.a.r.. We show that there is an  $X \subseteq \{0, 1\}^r$  of size  $t$  such that the random variables  $(\mathbf{F}(a) : a \in X)$  are independent and uniformly distributed bits. Then, Lemma 17 implies the statement of the claim.

Let us see how  $X$  is defined. Let  $T$  be the decision tree guaranteed for  $g$  by virtue of the fact that it is an  $(r, t)$ -pseudoaddressing function. Further, for any  $z_j$ , let  $\pi_j^0$  and  $\pi_j^1$  be the paths satisfying P1 and P2 above. By P2, we can fix a setting  $a^{(j)} \in \{0, 1\}^r$  to the  $y$ -variables that is consistent with both paths. We set  $X = \{a^{(j)} \mid j \in [t]\}$ .

To analyze  $\mathbf{F}(a^{(j)})$ , note that setting the variables  $z_1, \dots, z_t$  to  $\mathbf{b}_1, \dots, \mathbf{b}_t$  in  $T$  gives us a (random) decision tree  $\mathbf{T}'$  that computes  $\mathbf{F}$ . In particular, the path followed by  $\mathbf{T}'$  on input  $a^{(j)}$  is uniformly chosen among  $\pi_j^0$  and  $\pi_j^1$  depending on the value of  $z_j$ , and hence  $\mathbf{F}(a^{(j)})$  is either  $\mathbf{b}_j$  or  $1 - \mathbf{b}_j$  (exactly which depends on the value of  $z_j$  that is consistent with  $\pi_j^0$  and  $\pi_j^1$ ). In either case, however,  $\mathbf{F}(a^{(j)})$  is a uniformly chosen random bit depending only on  $\mathbf{b}_j$ . Hence, the random variables  $(\mathbf{F}(a^{(j)}) : j \in [t])$  are independent and uniformly distributed.

Thus, Lemma 17 implies that with positive probability,  $\text{pdeg}_{1/10}(\mathbf{F}) = \Omega(\log t / \log r)$ . However, we know by Fact 9 that, as  $\mathbf{F}$  is a restriction of  $g$ ,  $\text{pdeg}_{1/10}(\mathbf{F}) \leq \text{pdeg}_{1/10}(g)$ . Hence, we obtain the same lower bound for  $\text{pdeg}_{1/10}(g)$ . Finally, by error reduction (Fact 9), the same lower bound (up to constant factors) holds for  $\text{pdeg}_{1/3}(g) = \text{pdeg}(g)$ .  $\triangleleft$

### 3.3 Finishing the proof of Theorem 4

Lemma 16 and Lemma 14 imply that

$$\text{pdeg}(f) = \Omega \left( \max \left\{ (\log s)^{c-o(1)}, \frac{\log(n/s^{O(1)})}{\log s} \right\} \right)$$

where  $s$  denotes the sensitivity of  $f$ . The above is minimized for  $s$  so that  $(\log s)^{c+1} = \Theta(\log n)$  (note that this implies that  $s = n^{o(1)}$ ). For this  $s$ , we get

$$\text{pdeg}(f) = \Omega((\log n)^{c/(c+1)-o(1)}) \geq (\log n)^{c/(c+1)-o(1)},$$

proving the theorem.

## 4 The Upper Bound: Proof of Theorem 5

The construction is motivated by and closely follows a construction of Ambainis and de Wolf [2], who used it to prove the existence of a truly  $n$ -variate Boolean function  $f$  whose approximate degree is  $O(\log n / \log \log n)$ . The construction of [2] uses the fact that the approximate degree of the  $\text{OR}_n$  function is  $O(\sqrt{n})$  [15]. Using our assumption that the probabilistic degree of the  $\text{OR}_n$  function is  $(\log n)^{c+o(1)}$  we are able to prove a stronger degree upper bound for probabilistic degree. In particular, Theorem 10 allows us to prove an unconditional upper bound of  $(\log n)^{(1/2)+o(1)}$  on the probabilistic degree of some  $n$ -variable function.

The construction is a variant of the Addressing function, where the addressing bits are replaced by elements of a larger alphabet  $[s]$ , which are themselves presented in an encoded form that allows them to be easily “decoded” by low-degree polynomials. More precisely, we construct the function as follows.

### Construction

Let  $s$  be a power of 2 and let  $H \subseteq \{0, 1\}^s$  be the set of codewords of the Hadamard code. That is, assume  $s = 2^t$  and identify elements of  $\{0, 1\}^s$  with functions  $h : \{0, 1\}^t \rightarrow \{0, 1\}$ . Then  $H$  consists of precisely those elements  $h \in \{0, 1\}^s$  such that  $h$  is a linear function when considered as a mapping from  $\mathbb{F}_2^s$  to  $\mathbb{F}_2$  in the natural way. The set  $H$  contains precisely  $s$  elements, say  $\{h_1, \dots, h_s\}$ .

We define a Boolean function  $f$  on  $n = sr + s^r + 1$  bits as follows. Any input  $a$  is parsed as  $a = (g_1, \dots, g_r, T, b)$ , where  $g_1, \dots, g_r : \{0, 1\}^t \rightarrow \{0, 1\}$ ,  $T : [s]^r \rightarrow \{0, 1\}$  and  $b$  is a single bit. We define  $f$  by

$$f(a) = \begin{cases} T(i_1, \dots, i_r) & \text{if } g_1, \dots, g_r \in H \text{ and } g_1 = h_{i_1}, \dots, g_r = h_{i_r}, \\ b & \text{otherwise.} \end{cases}$$

### Analysis

We have

$$f(g_1, \dots, g_r, T, b) = \sum_{i_1, \dots, i_r \in [s]} 1(g_1 = h_{i_1}, \dots, g_r = h_{i_r}) \cdot T(i_1, \dots, i_r) + (1 - 1(g_1, \dots, g_r \in H)) \cdot b. \quad (2)$$

Here  $1(\mathcal{E})$  for a Boolean predicate  $\mathcal{E}$  takes the value 1 when the Boolean predicate is satisfied and 0 otherwise.

The above implies, in particular, that the function  $f$  is truly  $n$ -variate. To see this, say the variables of  $f$  are

- $x_{j,\alpha}$  ( $j \in [r], \alpha \in \{0, 1\}^t$ ) encoding the entries of the truth tables of  $g_1, \dots, g_r$ . More formally, the variable  $x_{j,\alpha}$  is set to  $g_j(\alpha)$ .
- $y_{i_1, \dots, i_r}$  encoding the entries of  $T$ , and
- $y_0$  which gives the value of  $b$ .

Any variable  $x_{j,\alpha}$  is influential at an input  $(g_1, \dots, g_r, T, b)$  where  $g_1, \dots, g_r$  are  $h_{i_1}, \dots, h_{i_r} \in H$  respectively, and  $b \neq T(i_1, \dots, i_r)$ , which implies that flipping the value of  $x_{j,\alpha}$  at this point changes the output from  $T(i_1, \dots, i_r)$  to  $b$ . The variable  $y_{i_1, \dots, i_r}$  is also influential at the same point. The variable  $y_0$  is influential at any input where not all the  $g_i$  are in  $H$ . Thus, we see that  $f$  is indeed  $n$ -variate.

Now, we will show an upper bound on  $\text{pdeg}(f)$ . This will be done by constructing two polynomials.

- A  $1/3$ -error probabilistic polynomial  $Q(x_{j,\alpha} : j \in [r], \alpha \in \{0, 1\}^t)$  for the Boolean function  $1(g_1, \dots, g_r \in H)$ .
- For each  $i_1, \dots, i_r \in [s]$ , a polynomial  $R_{i_1, \dots, i_r}(x_{j,\alpha} : j \in [r], \alpha \in \{0, 1\}^t)$  such that at input  $(g_1, \dots, g_r) \in H^r$ ,  $R_{i_1, \dots, i_r}(g_1, \dots, g_r) = 1$  if  $g_1 = h_{i_1}, \dots, g_r = h_{i_r}$ , and 0 otherwise. (In other words,  $R_{i_1, \dots, i_r}$  computes a  $\delta$ -function on inputs from  $H^r$ . Note that we do not claim anything if  $(g_1, \dots, g_r) \notin H^r$ .)

## 42:16 Probabilistic Degree of $N$ -Variate Boolean Function

Given the above constructions, the following yields a probabilistic polynomial  $\mathbf{P}$  for  $f$ .

$$\mathbf{P} = \mathbf{Q} \cdot \left( \sum_{i_1, \dots, i_r \in [s]} R_{i_1, \dots, i_r} \cdot y_{i_1, \dots, i_r} \right) + (1 - \mathbf{Q}) \cdot y_0 \quad (3)$$

(The two copies of  $\mathbf{Q}$  are chosen with the same randomness and are *not* independent of each other.) To see that this works, fix any input  $a = (g_1, \dots, g_r, T, b)$ . If  $(g_1, \dots, g_r) \in H^r$ , the term in the parenthesis evaluates to  $T(i_1, \dots, i_r)$  with probability 1. Further,  $\mathbf{Q}(g_1, \dots, g_r)$  evaluates to 1 with probability  $2/3$ . Hence,  $\mathbf{P}(a) = T(i_1, \dots, i_r) = f(a)$  with probability at least  $2/3$ . On the other hand, if  $(g_1, \dots, g_r) \notin H^r$ , then  $\mathbf{Q}(g_1, \dots, g_r)$  evaluates to 0 with probability  $2/3$ . When this event occurs, the first summand evaluates to 0 and the second summand evaluates to  $b$ . Hence,  $\mathbf{P}(a) = b = f(a)$  with probability at least  $2/3$ .

It remains to construct the polynomials  $\mathbf{Q}$  and  $R_{i_1, \dots, i_r}$ . We start with  $\mathbf{Q}$ . Recall that a function  $g : \{0, 1\}^t \rightarrow \{0, 1\}$  lies in  $H$  when it is linear over  $\mathbb{F}_2$ , or equivalently if  $g(\alpha \oplus \beta) \oplus g(\alpha) \oplus g(\beta) = 0$  for every  $\alpha, \beta \in \{0, 1\}^t$ . Thus, the condition that  $g_1, \dots, g_r \in H$  can be rewritten as

$$\bigwedge_{j=1}^r \bigwedge_{\alpha, \beta \in \{0, 1\}^t} (1 \oplus g_j(\alpha \oplus \beta) \oplus g_j(\alpha) \oplus g_j(\beta)).$$

Let  $q(z_1, z_2, z_3)$  be a constant-degree polynomial of 3 Boolean variables that evaluates to  $1 \oplus z_1 \oplus z_2 \oplus z_3$ . Then, the above can be rewritten as  $\bigwedge_{j=1}^r \bigwedge_{\alpha, \beta \in \{0, 1\}^t} q(g_j(\alpha), g_j(\beta), g_j(\alpha \oplus \beta))$ . Thus, we can define the probabilistic polynomial to be

$$\mathbf{Q}(x_{j,\alpha} : j \in [r], \alpha \in \{0, 1\}^t) = \mathbf{Q}_1(q(x_{j,\alpha}, x_{j,\beta}, x_{j,\alpha \oplus \beta}) : j \in [r], \alpha, \beta \in \{0, 1\}^t),$$

where  $\mathbf{Q}_1$  is any probabilistic polynomial for the  $\text{AND}_{r2^{2t}} = \text{AND}_{rs^2}$  function. By assumption,  $\text{pdeg}(\text{OR}_{rs^2})$  and hence, by DeMorgan's laws,  $\text{pdeg}(\text{AND}_{rs^2})$  is at most  $\log(rs^2)^{c+o(1)} = (\log r + \log s)^{c+o(1)}$ .

We now see how to construct  $R_{i_1, \dots, i_r}$  for any fixed  $i_1, \dots, i_r \in [s]$ . Recall the standard fact (see, e.g. [22]) that for  $h_{i_1} \neq h_{i_2} \in H$ , the functions  $\hat{h}_{i_1}, \hat{h}_{i_2} : \{0, 1\}^t \rightarrow \{-1, 1\}$  defined by  $\hat{h}_{i_b}(\alpha) = 1 - 2h_{i_b}(\alpha)$ , for all  $\alpha \in \{0, 1\}^t$  and  $b \in \{1, 2\}$ , are orthogonal to one another, i.e.,  $\sum_{\alpha} \hat{h}_{i_1}(\alpha) \hat{h}_{i_2}(\alpha) = 0$ . Based on this observation, we define the polynomial as follows.

$$R_{i_1, \dots, i_r}(x_{j,\alpha} : j \in [r], \alpha \in \{0, 1\}^t) = \frac{1}{s^r} \prod_{j=1}^r \left( \sum_{\alpha \in \{0, 1\}^t} \hat{h}_{i_j}(\alpha) (1 - 2x_{j,\alpha}) \right).$$

Let us see that this polynomial has the desired properties. Consider input  $(g_1, \dots, g_r) \in H^r$ . Assume  $g_j = h_{i'_j}$  for each  $j \in [r]$ . Then, we have

$$R_{i_1, \dots, i_r}(g_1, \dots, g_r) = \frac{1}{s^r} \prod_{j=1}^r \left( \sum_{\alpha \in \{0, 1\}^t} \hat{h}_{i_j}(\alpha) (1 - 2h_{i'_j}(\alpha)) \right) = \frac{1}{s^r} \prod_{j=1}^r \left( \sum_{\alpha \in \{0, 1\}^t} \hat{h}_{i_j}(\alpha) \hat{h}_{i'_j}(\alpha) \right)$$

and the latter quantity can be seen to be 1 if  $i'_j = i_j$  for all  $j \in [r]$  and 0 otherwise. Thus,  $R_{i_1, \dots, i_r}$  behaves as stipulated. Note that  $\deg(R_{i_1, \dots, i_r}) = r$ .

This concludes the construction of the probabilistic polynomial for  $f$ . The degree of the polynomial thus constructed is at most  $\deg(\mathbf{Q}) + \max_{i_1, \dots, i_r} \deg(R_{i_1, \dots, i_r})$ , which is equal to  $O((\log r + \log s)^{c+o(1)} + r) = O((\log s)^{c+o(1)} + r)$ .

### Parameters

We set  $r = (\log s)^c = t^c$ . This gives a truly  $n$ -variate Boolean function on  $n = O(s^r) = O(2^{t^{1+c}})$  variables with probabilistic degree  $t^{c+o(1)} = (\log n)^{(c/(c+1))+o(1)}$ .

## A Proof of Lemma 15

We will only use restrictions  $g'$  of  $g$  obtained by setting some inputs of  $g$  to 0. The basic observation [7, 27] is the following. For any such restriction  $g' = g_\rho$ , the function  $g'$  always agrees with  $\text{OR}_s$  at the all-zero input. Moreover, if  $a$  is non-zero and has weight  $t > 0$ , then  $g'(a) = \text{OR}_s(a) = 1$  as long as exactly  $t - 1$  of the variables that are set to 1 in  $a$  are fixed to 0 by  $\rho$  (this follows from the fact that  $g$  accepts any input of weight exactly 1). While we cannot always choose a *single* restriction that does this for all possible  $a$ , it is possible to choose a *small number of restrictions* randomly such that for each non-zero  $a$ , at least one of them is guaranteed to work with high probability. We now see the details.

For  $i \in [\log s]$ , let  $\mathcal{D}_i$  be the distribution over subsets of  $[s]$  where we pick each element independently to be in the set with probability  $2^{-i}$ . For a (constant) parameter  $p$  to be chosen later, let  $\mathcal{S}_1^i, \dots, \mathcal{S}_p^i$  be independent random subsets picked from distribution  $\mathcal{D}_i$ . Each such set  $\mathcal{S}_j^i$  is associated with the restriction  $\rho_j^i$  where each variable is set to 0 if it does not belong to  $\mathcal{S}_j^i$ , and left alive (i.e. set to  $*$ ) otherwise. Note that  $\mathbf{g}_j^i := g_{\rho_j^i}$  is a random restriction of  $g$ . Also observe that the total number of such restrictions is  $\ell := p \log s = O(\log s)$ . The final probabilistic representation is the OR of all these  $\mathbf{g}_j^i$ s.

We now prove correctness. Consider any  $a \in \{0, 1\}^s$ . The case when  $a = 0^s$  is easy, as each  $g_j^i$  is obtained by setting some inputs of  $g$  to 0 and hence  $g_j^i(a) = 0$  with probability 1. The same is therefore true for the OR of these functions.

Now assume that  $a \neq 0$ . Thus  $|a| = t \in [s]$ . Fix  $i \in [\log s]$  such that  $t \in (2^{i-1}, 2^i]$ . We will show that, with probability at least 0.9, some  $g_j^i$  evaluates to 1. This will finish the proof.

To see this, let  $S \subseteq [s]$  be the set of coordinates where  $a$  takes value 1. Note that  $g_j^i(a) = g(b_j^i)$  where  $b_j^i$  denotes the indicator vector of  $S_j^i \cap S$ . As  $g(b) = 1$  for any input  $b$  of weight 1, we see that  $g_j^i(a) = 1$  if  $|S_j^i \cap S| = 1$ . Hence, we have

$$\Pr_{g_1^i, \dots, g_p^i} [g_1^i(a) = \dots = g_p^i(a) = 0] \leq \Pr_{S_1^i, \dots, S_p^i} \left[ \bigwedge_{j=1}^p |S_j^i \cap S| \neq 1 \right] = \prod_{j=1}^p \Pr_{S_j^i} [|S_j^i \cap S| \neq 1], \quad (4)$$

where the last equality follows from the independence of the  $S_j^i$ s.

Finally, note that for any  $j$ ,

$$\begin{aligned} \Pr_{S_j^i} [|S_j^i \cap S| = 1] &= \sum_{k \in S} \Pr_{S_j^i} \left[ k \in S_j^i \wedge \bigwedge_{k' \in S \setminus k} k' \notin S_j^i \right] \\ &= t \cdot \frac{1}{2^i} \cdot \left( 1 - \frac{1}{2^i} \right)^{t-1} \geq \frac{1}{2} \cdot \left( 1 - \frac{1}{2^i} \right)^{2^{i-1}-1} \geq \frac{1}{2e}, \end{aligned}$$

where the first inequality follows from the fact that  $t \in (2^{i-1}, 2^i]$  and the second from the standard fact that  $(1 - 1/n)^{n-1} \geq 1/e$ . Plugging the above into (4), we get

$$\Pr_{g_1^i, \dots, g_p^i} [g_1^i(a) = \dots = g_p^i(a) = 0] \leq \left( 1 - \frac{1}{2e} \right)^p \leq \frac{1}{10},$$

for a large enough constant  $p$ . In particular, for this  $p$ , the probability that  $\text{OR}_\ell(g_j^i : i \in [\ell], j \in [p])$  evaluates to 0 is at most 1/10, completing the proof of the lemma.

## B Proof of the Random function lower bound (Lemma 17)

The proof is via a counting argument.

We start with a standard observation, which follows from a simple averaging argument. If  $F : \{0, 1\}^m \rightarrow \{0, 1\}$  has (1/10)-error probabilistic degree  $d$ , then for any probability distribution  $\mu$  over  $\{0, 1\}^m$ , there is a polynomial  $P$  of degree at most  $d$  such that

$$\Pr_{a \sim \mu} [P(a) = F(a)] \geq \frac{9}{10}. \quad (5)$$

Conversely, if there is a probability distribution  $\mu$  such that (5) does not hold for any polynomial of degree at most  $d$ , then  $\text{pdeg}(F) > d$ . We will take the hard distribution to be the uniform distribution over  $X$ .

More precisely, call a function  $g : X \rightarrow \{0, 1\}$  *bad* if there is a polynomial  $P$  of degree at most  $d$  that agrees with  $g$  on at least  $9|X|/10 = 9M/10$  points of  $X$ . Let  $\mathcal{B}$  be the set of bad functions. The reasoning above tells us that

$$\Pr_{\mathbf{F}} [\text{pdeg}_{1/10}(\mathbf{F}) \leq d] \leq \Pr_{\mathbf{F}} [\mathbf{F}|_X \in \mathcal{B}] = \frac{|\mathcal{B}|}{2^M}. \quad (6)$$

where for the latter inequality we have used the fact that the random variables  $(\mathbf{F}(x) : x \in X)$  are independently and uniformly distributed. Hence, it will suffice to bound  $|\mathcal{B}|$  to prove the lemma.

## 42:20 Probabilistic Degree of $N$ -Variate Boolean Function

To bound the size of  $\mathcal{B}$ , it will suffice to give a short encoding of each element of  $\mathcal{B}$ . Fix any  $g \in \mathcal{B}$  and a polynomial  $P$  that agrees with  $g$  on a set  $X' \subseteq X$  such that  $|X'| \geq 9M/10$ . Note that  $g$  can be specified by

1. The set  $X'$ .
2. The set of values of  $g$  on  $X \setminus X'$  (in some pre-determined order).
3. A polynomial  $Q$  of degree at most  $d$  that agrees with  $g$  on  $X'$  (specified as a list of coefficients of monomials).

Note that the number of choices for  $X'$  is at most  $\binom{M}{\leq M/10}$ , which is bounded by  $2^{H(1/10)M}$ , where  $H(\cdot)$  denotes the binary entropy function. Further, the number of possibilities for  $g$  on  $X \setminus X'$  is at most  $2^{|X \setminus X'|} \leq 2^{M/10}$ .

It remains to bound the number of possibilities for  $Q$ . A priori, it is not completely clear how to bound the number of  $Q$  as the coefficients of  $Q$  could be arbitrary real numbers. However, we note that if there is a polynomial  $P$  that agrees with  $g$  on  $X'$ , then there is also a  $Q$  that satisfies this property, and furthermore, the coefficients of  $Q$  are rational numbers of small bit complexity.

Formally, we will use the following lemma, which is an easy consequence of [24, Corollary 3.2d].

► **Lemma 21.** *Consider a system of linear equations  $Ax = b$  over the rational numbers, where  $A$  is an  $p \times q$  Boolean matrix, and  $b \in \{0, 1\}^p$ . Then, if the system has a real solution, it has a rational solution that can be specified (as a list of numerator-denominator pairs in binary) by at most  $10q^3$  bits.*

To use the above lemma, consider the problem of finding a polynomial  $Q$  of degree at most  $d$  that agrees with  $g$  at all points in  $X'$ . The coefficients of such a polynomial  $Q$  solve a linear system of  $p := |X'|$  many linear equations in  $q := \binom{m}{\leq d}$  variables. By the existence of the polynomial  $P$ , this system has a solution. Thus by Lemma 21, we know that there is a solution of bit-complexity at most  $10q^3 \leq m^{4d} < M/10$ . Therefore, we may always choose  $Q$  from the set  $\mathcal{Q}$  of polynomials of bit-complexity (as specified above) at most  $M/10$ . Note that  $|\mathcal{Q}| \leq 2^{M/10}$  by definition.

Overall, this gives a complete specification of any given  $g \in \mathcal{B}$ . More precisely, we have given a 1-1 map  $\tau : \mathcal{B} \rightarrow \mathcal{X} \times \mathcal{S} \times \mathcal{Q}$ , where  $\mathcal{X}$  is the collection of subsets of  $X$  of size at least  $9M/10$ ,  $\mathcal{S}$  is the set of Boolean tuples of length  $M/10$ , and  $\mathcal{Q}$  is the set of polynomials of degree at most  $d$  of bit-complexity at most  $M/10$ . Hence,  $|\mathcal{B}| \leq |\mathcal{X}| \cdot |\mathcal{S}| \cdot |\mathcal{Q}| \leq 2^{M \cdot (H(1/10) + 1/10 + 1/10)} \leq 2^{9M/10}$ . Plugging this into (6), we get

$$\Pr_{\mathbf{F}}[\text{pdeg}_{1/10}(\mathbf{F}) \leq d] \leq \frac{2^{9M/10}}{2^M} < \frac{1}{10}.$$

This finishes the proof of the lemma.

## Abstract

The Swendsen-Wang algorithm is a sophisticated, widely-used Markov chain for sampling from the Gibbs distribution for the ferromagnetic Ising and Potts models. This chain has proved difficult to analyze, due in part to the global nature of its updates. We present optimal bounds on the convergence rate of the Swendsen-Wang algorithm for the complete  $d$ -ary tree. Our bounds extend to the non-uniqueness region and apply to all boundary conditions. We show that the spatial mixing conditions known as *Variance Mixing* and *Entropy Mixing*, introduced in the study of local Markov chains by Martinelli et al. (2003), imply  $\Omega(1)$  spectral gap and  $O(\log n)$  mixing time, respectively, for the Swendsen-Wang dynamics on the  $d$ -ary tree. We also show that these bounds are asymptotically optimal. As a consequence, we establish  $\Theta(\log n)$  mixing for the Swendsen-Wang dynamics for *all* boundary conditions throughout the tree uniqueness region; in fact, our bounds hold beyond the uniqueness threshold for the Ising model, and for the  $q$ -state Potts model when  $q$  is small with respect to  $d$ . Our proofs feature a novel spectral view of the Variance Mixing condition inspired by several recent rapid mixing results on high-dimensional expanders and utilize recent work on block factorization of entropy under spatial mixing conditions.

## 1 Introduction

Spin systems are idealized models of a physical system in equilibrium which are utilized in statistical physics to study phase transitions. A phase transition occurs when there is a dramatic change in the macroscopic properties of the system resulting from a small (infinitesimal in the limit) change in one of the parameters defining the spin system. The macroscopic properties of the system manifest with the persistence (or lack thereof) of long-

range influences. There is a well-established mathematical theory connecting the absence of these influences to the fast convergence of Markov chains. In this paper, we study this connection on the regular tree, known as the *Bethe lattice* in statistical physics [7, 27].

The most well-studied example of a spin system is the *ferromagnetic  $q$ -state Potts model*, which contains the *Ising model* ( $q = 2$ ) as a special case. The Potts model is especially important as fascinating phase transitions (first-order vs. second-order) are now understood rigorously in various contexts [5, 21, 20, 17, 18].

Given a graph  $G = (V, E)$ , configurations of the Potts model are assignments of spins  $[q] = \{1, 2, \dots, q\}$  to the vertices of  $G$ . The parameter  $\beta > 0$  (corresponding to the inverse of the temperature of the system) controls the strength of nearest-neighbor interactions, and the probability of a configuration  $\sigma \in [q]^V$  in the *Gibbs distribution* is such that

$$\mu(\sigma) = \mu_G(\sigma) = \frac{e^{-\beta|D(\sigma)|}}{Z}, \quad (1)$$

where  $D(\sigma) = \{\{v, w\} \in E : \sigma(v) \neq \sigma(w)\}$  denotes the set of bi-chromatic edges in  $\sigma$ , and  $Z$  is the normalizing constant known as the *partition function*.

The *Glauber dynamics* is the simplest example of a Markov chain for sampling from the Gibbs distribution; it updates the spin at a randomly chosen vertex in each step. In many settings, as we detail below, the Glauber dynamics converges exponentially slow at low temperatures (large  $\beta$ ) due to the local nature of its transitions and the long-range correlations in the Gibbs distribution. Of particular interest are thus “global” Markov chains such as the *Swendsen-Wang (SW) dynamics* [49, 23], which update a large fraction of the configuration in each step, thus potentially overcoming the obstacles that hinder the performance of the Glauber dynamics, and with steps that can be efficiently parallelized [4].

The SW dynamics utilizes a close connection between the Potts model and an alternative representation known as the *random-cluster model*. The random-cluster model is defined on subsets of edges and is not a spin system as the weight of a configuration depends on the global connectivity properties of the corresponding subgraph. The transitions of the SW dynamics take a spin configuration, transform it to a “joint” spin-edge configuration, perform a step in the joint space, and then map back to a Potts configuration. Formally, from a Potts configuration  $\sigma_t \in [q]^V$ , a transition  $\sigma_t \rightarrow \sigma_{t+1}$  is defined as follows:

1. Let  $M_t = M(\sigma_t) = E \setminus D(\sigma_t)$  denote the set of monochromatic edges in  $\sigma_t$ .
2. Independently for each edge  $e = \{v, w\} \in M_t$ , keep  $e$  with probability  $p = 1 - \exp(-\beta)$  and remove  $e$  with probability  $1 - p$ . Let  $A_t \subseteq M_t$  denote the resulting subset.
3. In the subgraph  $(V, A_t)$ , independently for each connected component  $C$  (including isolated vertices), choose a spin  $s_C$  uniformly at random from  $[q]$  and assign to each vertex in  $C$  the spin  $s_C$ . This spin assignment defines  $\sigma_{t+1}$ .

There are two standard measures of the convergence rate of a Markov chain. The *mixing time* is the number of steps to get within total variation distance  $\leq 1/4$  of its stationary distribution from the worst starting state. The *relaxation time* is the inverse of the spectral gap of the transition matrix of the chain and measures the speed of convergence from a “warm start”. For approximate counting algorithms the relaxation time is quite useful as it corresponds to the “resample” time [30, 37, 35, 34]; see Section 2 for precise definitions and how these two notions relate to each other.

There has been great progress in formally connecting phase transitions with the convergence rate of the Glauber dynamics. Notably, for the  $d$ -dimensional integer lattice  $\mathbb{Z}^d$ , a series of works established that a spatial mixing property known as *strong spatial mixing (SSM)*

implies  $O(n \log n)$  mixing time of the Glauber dynamics [39, 15, 22]. Roughly speaking, SSM says that correlations decay exponentially fast with the distance and is also known to imply optimal mixing and relaxation times of the SW dynamics on  $\mathbb{Z}^d$  [9, 8]. These techniques utilizing SSM are particular to the lattice and do not extend to *non-amenable* graphs (i.e., those whose boundary and volume are of the same order). The  $d$ -ary complete tree, which is the focus of this paper, is the prime example of a non-amenable graph.

On the regular  $d$ -ary tree, there are two fundamental phase transitions: the *uniqueness* threshold  $\beta_u$  and the *reconstruction* threshold  $\beta_r$ . The smaller of these thresholds  $\beta_u$  corresponds to the uniqueness/non-uniqueness phase transition of the Gibbs measure on the infinite  $d$ -ary tree, and captures whether the worst-case boundary configuration (i.e., a fixed configuration on the leaves of a finite tree) has an effect or not on the spin at the root (in the limit as the height of the tree grows). The second threshold  $\beta_r$  is the reconstruction/non-reconstruction phase transition, marking the divide on whether or not a *random* boundary condition (in expectation) affects the spin of the root.

There is a large body of work on the interplay between these phase transitions and the speed of convergence of the Glauber dynamics on the complete  $d$ -ary tree [41, 40, 6], and more generally on bounded degree graphs [44, 28, 13]. Our main contributions in this paper concern instead the speed of convergence of the SW dynamics on trees, how it is affected by these phase transitions, and the effects of the boundary condition.

Martinelli, Sinclair, and Weitz [40, 41] introduced a pair of spatial mixing (decay of correlation) conditions called *Variance Mixing (VM)* and *Entropy Mixing (EM)* which capture the exponential decay of point-to-set correlations. More formally, the VM and EM conditions hold when there exist constants  $\ell > 0$  and  $\varepsilon = \varepsilon(\ell)$  such that, for every vertex  $v \in T$ , the influence of the spin at  $v$  on the spins of the vertices at distance  $\geq \ell$  from  $v$  in the subtree  $T_v$  rooted at  $v$  decays by a factor of at least  $\varepsilon$ . For the case of VM, this decay of influence is captured in terms of the variance of any function  $g$  that depends only on the spins of the vertices in  $T_v$  at distance  $\geq \ell$  from  $v$ ; specifically, when conditioned on the spin at  $v$ , the conditional variance of  $g$  is (on average) a factor  $\varepsilon$  smaller than the unconditional variance; see Definition 7 in Section 3 for the formal definition. EM is defined analogously, with variance replaced by entropy; see Definition 15.

It was established in [40, 41] that VM and EM imply optimal bounds on the convergence rate of the Glauber dynamics on trees. We obtain optimal bounds for the speed of convergence of the SW dynamics under the same VM and EM spatial mixing conditions.

► **Theorem 1.** *For all  $q \geq 2$  and  $d \geq 3$ , for the  $q$ -state ferromagnetic Ising/Potts model on an  $n$ -vertex complete  $d$ -ary tree, Variance Mixing implies that the relaxation time of the Swendsen-Wang dynamics is  $\Theta(1)$ .*

► **Theorem 2.** *For all  $q \geq 2$  and  $d \geq 3$ , for the  $q$ -state ferromagnetic Ising/Potts model on an  $n$ -vertex complete  $d$ -ary tree, Entropy Mixing implies that the mixing time of the Swendsen-Wang dynamics is  $O(\log n)$ .*

The VM condition is strictly weaker (i.e., easier to satisfy) than the EM condition, but, at the moment, EM is known to hold in the same parameter regimes as VM. The relaxation time bound in Theorem 1 is weaker than the mixing time bound in Theorem 2. We also show that the mixing time in Theorem 2 is asymptotically the best possible.

► **Theorem 3.** *For all  $q \geq 2$ ,  $d \geq 3$  and any  $\beta > 0$ , the mixing time of the SW dynamics on an  $n$ -vertex complete  $d$ -ary tree is  $\Omega(\log n)$  for any boundary condition.*

We remark that the mixing time lower bound in Theorem 3 applies to all inverse temperatures  $\beta$  and all boundary conditions.

The VM and EM conditions are properties of the Gibbs distribution induced by a *specific* boundary condition on the leaves of the tree; this contrasts with other standard notions of decay of correlations such as SSM on  $\mathbb{Z}^d$ . This makes these conditions quite suitable for understanding the speed of convergence of Markov chains under different boundary conditions. For instance, [40, 41] established VM and EM for all boundary conditions provided  $\beta < \max\{\beta_u, \frac{1}{2} \ln(\frac{\sqrt{d}+1}{\sqrt{d}-1})\}$  and for the monochromatic (e.g., all-red) boundary condition for all  $\beta$ . Consequently, we obtain the following results.

► **Theorem 4.** *For all  $q \geq 2$  and  $d \geq 3$ , for the  $q$ -state ferromagnetic Ising/Potts model on an  $n$ -vertex complete  $d$ -ary tree, the relaxation time of the Swendsen-Wang dynamics is  $\Theta(1)$  and its mixing time is  $\Theta(\log n)$  in the following cases:*

1. *the boundary condition is arbitrary and  $\beta < \max\left\{\beta_u, \frac{1}{2} \ln\left(\frac{\sqrt{d}+1}{\sqrt{d}-1}\right)\right\}$ ;*
2. *the boundary condition is monochromatic and  $\beta$  is arbitrary.*

Part (i) of this theorem provides optimal mixing and relaxation times bounds for the SW dynamics under arbitrary boundaries throughout the uniqueness region  $\beta < \beta_u$ . In fact,  $\beta_u < \frac{1}{2} \ln(\frac{\sqrt{d}+1}{\sqrt{d}-1})$  when  $q \leq 2(\sqrt{d} + 1)$  and thus our bound extends to the non-uniqueness region for many combinations of  $d$  and  $q$ . We note that while the value of the uniqueness threshold  $\beta_u$  is known, it does not have a closed form (see [31, 10]). In contrast, the reconstruction threshold  $\beta_r$  is not known for the Potts model [47, 43], but one would expect that part (i) holds for all  $\beta < \beta_r$ ; analogous results are known for the Glauber dynamics for other spin systems where more precise bounds on the reconstruction threshold have been established [6, 45, 48].

Previously, only a  $\text{poly}(n)$  bound was known for the mixing time of the SW dynamics for arbitrary boundary conditions [50, 6]. This  $\text{poly}(n)$  bound holds for every  $\beta$ , but the degree of the polynomial bounding the mixing time is quite large (grows with  $\beta$ ); our bound in part (i) is thus a substantial improvement.

In regards to part (ii) of the theorem, we note that our bound holds for all  $\beta$ , including the whole low-temperature region. The only other case where tight bounds for the SW dynamics are known for the full low-temperature regime is on the geometrically simpler complete graph [25, 12].

Previous (direct) analysis of the speed of convergence of the SW dynamics on trees focused exclusively on the special case of the *free* boundary condition [33, 16], where the dynamics is much simpler as the corresponding random-cluster model is trivial (reduces to independent bond percolation); this was used by Huber [33] to establish  $O(\log n)$  mixing time of the SW dynamics for all  $\beta$  for the special case of the free boundary condition.

We comment briefly on our proof methods next; a more detailed exposition of our approach is provided later in this introduction. The results in [40, 41] use the VM and EM condition to deduce optimal bounds for the relaxation and mixing times of the Glauber dynamics; specifically, they analyze its spectral gap and log-Sobolev constant. Their methods do not extend to the SW dynamics. It can be checked, for example, that the log-Sobolev constant for the SW dynamics is  $\Theta(n^{-1})$ , and thus the best possible mixing time one could hope to obtain with such an approach would be  $O(n \log n)$ . For Theorem 2, we utilize instead new tools introduced by Caputo and Parisi [14] to establish a (block) factorization of entropy. This factorization allows to get a handle on the *modified* log-Sobolev constant for the SW dynamics. For Theorem 1, the main novelty in our approach is a new spectral interpretation of the VM condition that facilitates a factorization of variance, similar to the factorization of entropy from [14]. Lastly, the lower bound from Theorem 3 is obtained by adapting the framework of Hayes and Sinclair [32] to the SW setting using recent ideas from [8].

Finally, we mention that part (ii) of Theorem 4 has interesting implications related to the speed of convergence of random-cluster model Markov chains on trees under the wired boundary condition. That is, all the leaves are connected through external or “artificial” wirings. The case of the wired boundary condition is the most studied version of the random-cluster model on trees (see, e.g., [31, 36]) since, as mentioned earlier, the model is trivial under the free boundary. The random-cluster model, which is parameterized by  $p \in (0, 1)$  and  $q > 0$  (see [24, 1] for its definition), is intimately connected to the ferromagnetic  $q$ -state Potts model when  $q \geq 2$  is an integer and  $p = 1 - \exp(-\beta)$ . In particular, there is a variant of SW dynamics for the random-cluster model (by observing the edge configuration after the second step of the chain).

Another standard Markov chain for the random-cluster model is the heat-bath (edge) dynamics, which is the analog of the Glauber dynamics on spins for random-cluster configurations. Our results for the random-cluster dynamics are the following.

► **Theorem 5.** *For all integer  $q \geq 2$ ,  $p \in (0, 1)$ , and  $d \geq 3$ , for the random-cluster model on an  $n$ -vertex complete  $d$ -ary tree with wired boundary condition, the mixing time of the Swendsen-Wang dynamics is  $O(\log n)$ . In addition, the mixing time of the heat-bath edge dynamics for the random-cluster model is  $O(n \log n)$ .*

To prove these results, we use a factorization of entropy in the joint spin-edge space, as introduced in [8]; they cannot be deduced from the mixing time bounds for the Glauber dynamics for the Potts model in [40, 41].

Our final result shows that while random-cluster dynamics mix quickly under the wired boundary condition, there are random-cluster boundary conditions that cause an exponential slowdown for both the SW dynamics and the heat-bath edge dynamics for the random-cluster model.

► **Theorem 6.** *For all  $q \geq 2$ , all  $d \geq 3$ , consider the random-cluster model on an  $n$ -vertex complete  $d$ -ary tree. Then, there exists  $p \in (0, 1)$  and a random-cluster boundary condition such that the mixing times of the Swendsen-Wang dynamics and of the heat-bath edge dynamics is  $\exp(\Omega(\sqrt{n}))$ .*

We prove this result extending ideas from [11]. In particular, we prove a general theorem that allows us to transfer slow mixing results for the edge dynamics on other graphs to the tree, for a carefully constructed tree boundary condition and a suitable  $p$ . To prove this results we use the random-cluster boundary condition to embed an arbitrary graph  $G$  on the tree; a set with bad conductance for the chain on  $G$  is then lifted to the tree. Theorem 6 then follows from any of the known slow mixing results for the edge dynamics [29, 26, 50].

**Our techniques.** Our first technical contribution is a reinterpretation and generalization of the VM condition as a bound on the second eigenvalue of a certain stochastic matrix which we denote by  $P^\uparrow P^\downarrow$ . The matrices  $P^\uparrow$  and  $P^\downarrow$  are distributional matrices corresponding to the distribution at a vertex  $v$  given the spin configuration of the set  $S_v$  of all its descendants at distance at least  $\ell$  and vice versa. These matrices are inspired by the recent results in [2, 3] utilizing high-dimensional expanders; see Section 3 for their precise definitions.

Our new spectral interpretation of the VM condition allows us to factorize it and obtain an equivalent global variant we call *Parallel Variance Mixing (PVM)*. While the VM condition signifies the exponential decay with distance of the correlations between a vertex  $v$  and the set  $S_v$  (and is well-suited for the analysis of local Markov chains), the PVM condition captures instead the decay rate of set-to-set correlations between the set of all the vertices

at a fixed level of the tree and the set of all their descendants at distance at least  $\ell$ . The PVM condition facilitates the analysis of a block dynamics with a constant number of blocks each of linear volume. We call this variant of block dynamics the *tiled block dynamics* as each block consists of a maximal number of non-intersecting subtrees of constant size (i.e., a *tiling*); see Figure 1. We use the PVM condition to show that the spectral gap of the tiled block dynamics is  $\Omega(1)$ , and a generic comparison between the block dynamics and the SW dynamics yields Theorem 1.

Our proof of Theorem 2 follows a similar strategy. We first obtain a global variant of the EM condition, analogous to the PVM condition but for entropy. For this, we use a recent result of Caputo and Parisi [14]. From this global variant of the EM condition we deduce a factorization of entropy into the even and odd subsets of vertices. (The parity of a vertex is that of its distance to the leaves of the tree.) The even-odd factorization of entropy was recently shown in [8] to imply  $O(\log n)$  mixing of the SW on general biparte graphs.

**Paper organization.** The rest of the paper is organized as follows. Section 2 contains some standard definitions and facts we use in our proofs. In Sections 3 and 4 we prove Theorems 1 and 2, respectively. Our general comparison result between the SW dynamics and the block dynamics, our results for the random-cluster model dynamics, and our lower bound for the SW dynamics (Theorem 3) are proved in the full version of this paper [1].

## 2 Preliminaries

We introduce some notations and facts that are used in the remainder of the paper.

**The Potts model on the  $d$ -ary tree.** For  $d \geq 2$ , let  $\mathbb{T}^d = (\mathbb{V}, \mathbb{E})$  denote the rooted infinite  $d$ -ary tree in which every vertex (including the root) has exactly  $d$  children. We consider the complete finite subtree of  $\mathbb{T}^d$  of height  $h$ , which we denote by  $T = T_h^d = (V(T), E(T))$ . We use  $\partial T$  to denote the external boundary of  $T$ ; i.e., the set of vertices in  $\mathbb{V} \setminus V(T)$  incident to the leaves of  $T$ . We identify subgraphs of  $T$  with their vertex sets. In particular, for  $A \subseteq V(T)$  we use  $E(A)$  for the edges with both endpoints in  $A$ ,  $\partial A$  for the external boundary of  $A$  (i.e., the vertices in  $(T \cup \partial T) \setminus A$  adjacent to  $A$ ), and, with a slight abuse of notation, we write  $A$  also for the induced subgraph  $(A, E(A))$ . When clear from context, we simply use  $T$  for the vertex set  $V(T)$ .

A configuration of the Potts model is an assignment of spins  $[q] = \{1, \dots, q\}$  to the vertices of the graph. For a fixed spin configuration  $\tau$  on the infinite tree  $\mathbb{T}^d$ , we use  $\Omega^\tau = [q]^{T \cup \partial T}$  to denote the set of configurations of  $T$  that agree with  $\tau$  on  $\partial T$ . Hence,  $\tau$  specifies a boundary condition for  $T$ . More generally, for any  $A \subseteq T$  and any  $\eta \in \Omega^\tau$ , let  $\Omega_A^\eta \subseteq \Omega^\tau$  denote the set of configurations of  $T$  that agree with  $\eta$  on  $(T \cup \partial T) \setminus A$ . We use  $\mu_A^\eta$  to denote the Gibbs distribution over  $\Omega_A^\eta$ , so for  $\sigma \in \Omega_A^\eta$  we have

$$\mu_A^\eta(\sigma) := \frac{1}{Z} \exp\left(-\beta \sum_{\{u,v\} \in E(A \cup \partial A)} \mathbb{1}(\sigma_u \neq \sigma_v)\right),$$

where  $Z$  is a normalizing constant (or partition function). For  $\sigma \notin \Omega_A^\eta$ , we set  $\mu_A^\eta(\sigma) = 0$ .

**The tiled block dynamics.** Let  $\mathcal{U} = \{U_1, \dots, U_r\}$  be a collection of subsets (or blocks) such that  $T = \bigcup_i U_i$ . The (heat-bath) block dynamics with blocks  $\mathcal{U}$  is a standard Markov chain for the Gibbs distribution  $\mu_T^\tau$ . If the configuration at time  $t$  is  $\sigma_t$ , the next configuration  $\sigma_{t+1}$  is generated as follows:

■ **Figure 1** An illustration of the sets  $B(v, \ell)$ ,  $B_i^\ell$ , and  $T_j^\ell$ , where  $\ell$  represents the number of levels.

1. Pick an integer  $j \in \{1, 2, \dots, r\}$  uniformly at random;
2. Draw a sample  $\sigma_{t+1}$  from the conditional Gibbs distribution  $\mu_{U_j}^{\sigma_t}$ ; that is, update the configuration in  $U_j$  with a new configuration distributed according to the conditional measure in  $U_j$  given the configuration of  $\sigma_t$  on  $(T \cup \partial T) \setminus U_j$  and the boundary condition  $\tau$ .

We consider a special choice of blocks, where each block is a disjoint union of small subtrees of constant height forming a tiling structure. For  $0 \leq i \leq h + 1$ , let  $L_i$  denote the set of vertices of  $T$  that are of distance exactly  $i$  from the boundary  $\partial T$ ; in particular,  $L_0 = \emptyset$  and  $L_{h+1}$  contains only the root of  $T$ . (It will be helpful to define  $L_i = \emptyset$  for  $i < 0$  or  $i > h + 1$ .) Let  $F_i = \cup_{j \leq i} L_j$  be the set of vertices at distance at most  $i$  from  $\partial T$ ; then  $F_0 = \emptyset$  and  $F_{h+1} = T$ . We further define  $F_i = \emptyset$  for  $i < 0$  and  $F_i = T$  for  $i > h + 1$ . For each  $i \in \mathbb{N}^+$  let

$$B_i^\ell = F_i \setminus F_{i-\ell} = \bigcup_{i-\ell < j \leq i} L_j. \tag{2}$$

In words,  $B_i^\ell$  is the collection of all the subtrees of  $T$  of height  $\ell - 1$  with roots at distance exactly  $i$  from  $\partial T$ ; see Figure 1(b). Finally, for each  $1 \leq j \leq \ell + 1$ , we define

$$T_j^\ell = \bigcup_{0 \leq k \leq \frac{h+\ell-j}{\ell+1}} B_{j+k(\ell+1)}^\ell. \tag{3}$$

The set  $T_j^\ell$  contains all the subtrees of  $T$  whose roots are at distance  $j + k(\ell + 1)$  from  $\partial T$  for some non-negative integer  $k$ ; the height of each subtree (except the top and bottom ones) is  $\ell - 1$ . Also notice that all the subtrees in  $T_j^\ell$  are at (graph) distance at least 2 from each other, and thus they create a tiling pattern over  $T$ . Therefore, we call the block dynamics with blocks  $\mathcal{U} = \{T_1^\ell, \dots, T_{\ell+1}^\ell\}$  the *tilted block dynamics*; see Figure 1(c). The transition matrix of the tiled block dynamics is denoted by  $P_{\text{TB}}$ .

**Mixing and relaxation times.** Let  $P$  be the transition matrix of an ergodic Markov chain over a finite set  $\Phi$  with stationary distribution  $\nu$ . We use  $P^t(X_0, \cdot)$  to denote the distribution of the chain after  $t$  steps starting from  $X_0 \in \Phi$ . The mixing time of  $P$  is defined as  $\tau_{\text{mix}}(P) = \max_{X_0 \in \Phi} \min \{t \geq 0 : \|P^t(X_0, \cdot) - \nu\|_{\text{TV}} \leq 1/4\}$ , where  $\|\cdot\|_{\text{TV}}$  denotes total variation distance.

When  $P$  is reversible, its spectrum is real and we let  $1 = \lambda_1 > \lambda_2 \geq \dots \geq \lambda_{|\Phi|} \geq -1$  denote its eigenvalues ( $1 > \lambda_2$  when  $P$  is irreducible). The *absolute spectral gap* of  $P$  is defined by  $\text{gap}(P) = 1 - \lambda^*$ , where  $\lambda^* = \max\{|\lambda_2|, |\lambda_{|\Phi|}|\}$ . If  $P$  is ergodic (i.e., irreducible and aperiodic), then  $\text{gap}(P) > 0$ , and it is a standard fact that if  $\nu_{\min} = \min_{x \in \Phi} \nu(x)$ , then

$$(\text{gap}(P)^{-1} - 1) \log 2 \leq \tau_{\text{mix}}(P) \leq \text{gap}(P)^{-1} \log(4\nu_{\min}^{-1}); \tag{4}$$

see [38]. The *relaxation time* of the chain is defined as  $\text{gap}(P)^{-1}$ .

**Analytic tools.** We review next some useful tools from functional analysis; we refer the reader to [42, 46] for more extensive background. We can endow  $\mathbb{R}^\Phi$  with the inner product  $\langle f, g \rangle_\nu = \sum_{x \in \Phi} f(x)g(x)\nu(x)$  for two functions  $f, g : \Phi \rightarrow \mathbb{R}$ . The resulting Hilbert space is denoted by  $L_2(\nu) = (\mathbb{R}^\Phi, \langle \cdot, \cdot \rangle_\nu)$  and  $P$  defines an operator from  $L_2(\nu)$  to  $L_2(\nu)$ .

Let  $\mathbf{1} : \Phi \rightarrow \mathbb{R}$  be the constant “all 1” function (i.e.,  $\mathbf{1}(x) = 1 \forall x \in \Phi$ ) and let  $I$  denote the identity mapping over all functions (i.e.,  $If = f$  for all  $f : \Phi \rightarrow \mathbb{R}$ ). We then define:

$$\begin{aligned} \mathbb{E}_\nu(f) &= \sum_{x \in \Phi} f(x)\nu(x) = \langle f, \mathbf{1} \rangle_\nu, \text{ and} \\ \text{Var}_\nu(f) &= \mathbb{E}_\nu(f^2) - \mathbb{E}_\nu(f)^2 = \langle f, (I - \mathbf{1}\nu)f \rangle_\nu \end{aligned}$$

as the expectation and variance of the function  $f$  with respect to (w.r.t.) the measure  $\nu$ . Likewise, for a function  $f : \Omega \rightarrow \mathbb{R}_{\geq 0}$  we define the entropy of  $f$  with respect to  $\nu$  as  $\text{Ent}_\nu(f) = \mathbb{E}_\nu \left[ f \log \left( \frac{f}{\mathbb{E}_\nu(f)} \right) \right]$ .

Often, we will consider  $\nu$  to be the conditional Gibbs distribution  $\mu_A^\eta$  for some  $A \subseteq T$  and  $\eta \in \Omega$ . In those cases, to simplify the notation, we shall write  $\mathbb{E}_A^\eta(f)$  for  $\mathbb{E}_{\mu_A^\eta}(f)$ ,  $\text{Var}_A^\eta(f)$  for  $\text{Var}_{\mu_A^\eta}(f)$ , and  $\text{Ent}_A^\eta(f)$  for  $\text{Ent}_{\mu_A^\eta}(f)$ .

The *Dirichlet form* of a reversible Markov chain with transition matrix  $P$  is defined as

$$\mathcal{E}_P(f, f) = \langle f, (I - P)f \rangle_\nu = \frac{1}{2} \sum_{x, y \in \Phi} \nu(x)P(x, y)(f(x) - f(y))^2, \quad (5)$$

for any  $f : \Phi \rightarrow \mathbb{R}$ . We say  $P$  is *positive semidefinite* if  $\langle f, Pf \rangle_\nu \geq 0$  for all functions  $f : \Phi \rightarrow \mathbb{R}$ . In this case  $P$  has only nonnegative eigenvalues. If  $P$  is positive semidefinite, then the absolute spectral gap of  $P$  satisfies

$$\text{gap}(P) = 1 - \lambda_2 = \inf_{\substack{f: \Phi \rightarrow \mathbb{R} \\ \text{Var}_\nu(f) \neq 0}} \frac{\mathcal{E}_P(f, f)}{\text{Var}_\nu(f)}. \quad (6)$$

### 3 Variance Mixing implies fast mixing: Proof of Theorem 1

We start with the formal definition of the *Variance Mixing (VM)* condition introduced by Martinelli, Sinclair and Weitz [40]. Throughout this section, we consider the Potts model on the  $n$ -vertex  $d$ -ary complete tree  $T = T_h^d$  with a fixed boundary condition  $\tau$ ; hence, for ease of notation we set  $\mu := \mu_T^\tau$  and  $\Omega := \Omega^\tau$ .

For  $v \in T$ , let  $T_v$  denote the subtree of  $T$  rooted at  $v$ . For boundary condition  $\eta \in \Omega$  and a function  $g : \Omega_{T_v}^\eta \rightarrow \mathbb{R}$ , we define the function  $g_v : [q] \rightarrow \mathbb{R}$  as the conditional expectation

$$g_v(a) = \mathbb{E}_{T_v}^\eta [g \mid \sigma_v = a] = \sum_{\sigma \in \Omega_{T_v}^\eta : \sigma_v = a} \mu_{T_v}^\eta(\sigma \mid \sigma_v = a)g(\sigma). \quad (7)$$

In words,  $g_v(a)$  is the conditional expectation of the function  $g$  under the distribution  $\mu_{T_v}^\eta$  given that the root of  $T_v$  (i.e, the vertex  $v$ ) is set to spin  $a \in [q]$ . We also consider the expectation and variance of  $g_v$  w.r.t. the projection of  $\mu_{T_v}^\eta$  on  $v$ . In particular,

$$\begin{aligned} \mathbb{E}_{T_v}^\eta [g_v] &= \sum_{a \in [q]} \mu_{T_v}^\eta(\sigma_v = a)g_v(a) = \mathbb{E}_{T_v}^\eta [g], \text{ and} \\ \text{Var}_{T_v}^\eta [g_v] &= \mathbb{E}_{T_v}^\eta [g_v^2] - \mathbb{E}_{T_v}^\eta [g_v]^2. \end{aligned}$$

For an integer  $\ell \geq 1$ , we define  $B(v, \ell)$  as the set of vertices of  $T_v$  that are at distance less than  $\ell$  from  $v$ ; see Figure 1(a). We say that the function  $g : \Omega_{T_v}^\eta \rightarrow \mathbb{R}$  is independent of the configuration on  $B(v, \ell)$  if for all  $\sigma, \sigma' \in \Omega_{T_v}^\eta$  such that  $\sigma(B(v, \ell)) \neq \sigma'(B(v, \ell))$  and  $\sigma(T_v \setminus B(v, \ell)) = \sigma'(T_v \setminus B(v, \ell))$ , we have  $g(\sigma) = g(\sigma')$ . We can now define VM.

► **Definition 7** (Variance Mixing (VM)). *The Gibbs distribution  $\mu = \mu_T^\tau$  satisfies  $\text{VM}(\ell, \varepsilon)$  if for every  $v \in T$ , every  $\eta \in \Omega$ , and every function  $g : \Omega_{T_v}^\eta \rightarrow \mathbb{R}$  that is independent of the configuration on  $B(v, \ell)$ , we have  $\text{Var}_{T_v}^\eta(g_v) \leq \varepsilon \cdot \text{Var}_{T_v}^\eta(g)$ . We say that the VM condition holds if there exist constants  $\ell$  and  $\varepsilon = \varepsilon(\ell)$  such that  $\text{VM}(\ell, \varepsilon)$  holds.*

The VM condition is a spatial mixing property that captures the rate of decay of correlations, given by  $\varepsilon = \varepsilon(\ell)$ , with the distance  $\ell$  between  $v \in T$  and the set  $T_v \setminus B(v, \ell)$ . To see this, note that, roughly speaking,  $\text{Var}_{T_v}^\eta(g_v)$  is small when  $g_v(a) = \mathbb{E}_{T_v}^\eta[g \mid \sigma_v = a]$  is close to  $g_v(b) = \mathbb{E}_{T_v}^\eta[g \mid \sigma_v = b]$  for every  $a \neq b$ . Since  $g$  is independent of the configuration on  $B(v, \ell)$ , this can only happen if the spin at  $v$ , which is at distance  $\ell$  from  $T_v \setminus B(v, \ell)$ , has only a small influence on the projections of the conditional measures  $\mu_{T_v}^\eta(\cdot \mid \sigma_v = a)$ ,  $\mu_{T_v}^\eta(\cdot \mid \sigma_v = b)$  to  $T_v \setminus B(v, \ell)$ .

It was established in [40, 41] that VM implies optimal mixing of the Glauber dynamics; this was done by analyzing a block dynamics that updates one random block  $B(v, \ell)$  in each step. This block dynamics behaves similarly to the Glauber dynamics since all blocks are of constant size, and there are a linear number of them; see [40, 41] for further details. Our goal here is to establish optimal mixing of global Markov chains, and thus we require a different spatial mixing condition that captures decay of correlations in a more global manner. For this, we introduce the notion of *Parallel Variance Mixing (PVM)*. Recall that for  $0 \leq i \leq h + 1$ ,  $L_i$  is the set all vertices at distance exactly  $i$  from the boundary  $\partial T$ ,  $F_i = \cup_{j \leq i} L_j$ , and  $B_i^\ell = F_i \setminus F_{i-\ell}$ ; see Figures 1(b) and 1(c).

For  $1 \leq i \leq h + 1$ ,  $\eta \in \Omega$  and  $g : \Omega_{F_i}^\eta \rightarrow \mathbb{R}$ , consider the function  $g_{L_i} : [q]^{L_i} \rightarrow \mathbb{R}$  given by

$$g_{L_i}(\xi) = \mathbb{E}_{F_i}^\eta[g \mid \sigma_{L_i} = \xi] = \sum_{\sigma \in \Omega_{F_i}^\eta : \sigma_{L_i} = \xi} \mu_{F_i}^\eta(\sigma \mid \sigma_{L_i} = \xi)g(\sigma),$$

for  $\xi \in [q]^{L_i}$ . That is,  $g_{L_i}(\xi)$  is the conditional expectation of function  $g$  under the distribution  $\mu_{T_v}^\eta$  conditioned on the configuration of the level  $L_i$  being  $\xi$ . Thus, we may consider the expectation and variance of  $g_{L_i}$  w.r.t. the projection of  $\mu_{T_v}^\eta$  to  $L_i$ ; namely,  $\mathbb{E}_{F_i}^\eta[g_{L_i}] = \mathbb{E}_{F_i}^\eta[g]$  and  $\text{Var}_{F_i}^\eta[g_{L_i}] = \mathbb{E}_{F_i}^\eta[g_{L_i}^2] - \mathbb{E}_{F_i}^\eta[g_{L_i}]^2$ . The PVM condition is defined as follows.

► **Definition 8** (Parallel Variance Mixing (PVM)). *The Gibbs distribution  $\mu = \mu_T^\tau$  satisfies  $\text{PVM}(\ell, \varepsilon)$  if for every  $1 \leq i \leq h + 1$ , every  $\eta \in \Omega$ , and every function  $g : \Omega_{F_i}^\eta \rightarrow \mathbb{R}$  that is independent of the configuration on  $B_i^\ell$ , we have  $\text{Var}_{F_i}^\eta(g_{L_i}) \leq \varepsilon \cdot \text{Var}_{F_i}^\eta(g)$ . The PVM condition holds if there exist constants  $\ell$  and  $\varepsilon = \varepsilon(\ell)$  such that  $\text{PVM}(\ell, \varepsilon)$  holds.*

PVM is a natural global variant of VM since  $F_i = \bigcup_{v \in L_i} T_v$  and  $B_i^\ell = \bigcup_{v \in L_i} B(v, \ell)$ . We can show that the two properties are actually equivalent.

► **Theorem 9.** *For every  $\ell \in \mathbb{N}^+$  and  $\varepsilon \in (0, 1)$ , the Gibbs distribution  $\mu$  satisfies  $\text{VM}(\ell, \varepsilon)$  if and only if  $\mu$  satisfies  $\text{PVM}(\ell, \varepsilon)$ .*

In order to show the equivalence between VM and PVM, we introduce a more general spatial mixing condition which we call *General Variance Mixing (GVM)*. We define GVM for general product distributions (see Definition 12) and reinterpret VM and PVM as special cases of this condition. This alternative view of VM and PVM in terms of GVM is quite useful since we can recast the GVM condition as a bound on the spectral gap of a certain Markov chain; this is one key insight in the proof of Theorem 5 and is discussed in detail in Section 3.1.

Now, while VM implies optimal mixing of the Glauber dynamics, we can show that PVM implies a constant bound on the spectral gap of the tiled block dynamics. Recall that this is the heat-bath block dynamics with block collection  $\mathcal{U} = \{T_1^\ell, \dots, T_{\ell+1}^\ell\}$  defined in Section 2.

► **Theorem 10.** *If there exist  $\ell \in \mathbb{N}^+$  and  $\delta \in (0, 1)$  such that  $\mu = \mu_T^\tau$  satisfies  $\text{PVM}(\ell, \varepsilon)$  for  $\varepsilon = \frac{1-\delta}{2(\ell+1)}$ , then the relaxation time of the tiled block dynamics is at most  $2(\ell+1)/\delta$ .*

To prove Theorem 10, we adapt the methods from [40, 41] to our global setting. Our result for the spectral gap of the SW dynamics (Theorem 1) is then obtained through comparison with the tiled block dynamics. We prove the following comparison result between the SW dynamics and a large class of block dynamics, which could be of independent interest.

► **Theorem 11.** *Let  $\mathcal{D} = \{D_1, \dots, D_m\}$  be such that  $D_i \subseteq T$  and  $\cup_{i=1}^m D_i = T$ . Suppose that each block  $D_k$  is such that  $D_k = \cup_{j=1}^{\ell_k} D_{kj}$  where  $\text{dist}(D_{kj}, D_{kj'}) \geq 2$  for every  $j \neq j'$  and let  $\text{vol}(\mathcal{D}) = \max_{k,j} |D_{kj}|$ . Let  $\mathcal{B}_{\mathcal{D}}$  be the transition matrix of the (heat-bath) block dynamics with blocks  $\mathcal{D}$  and let  $\mathbf{SW}$  denote the transition matrix for the SW dynamics. Then,  $\text{gap}(\mathbf{SW}) \geq \exp(-O(\text{vol}(\mathcal{D}))) \cdot \text{gap}(\mathcal{B}_{\mathcal{D}})$ .*

The blocks of the tiled block dynamics satisfy all the conditions in this theorem, and, in addition,  $\text{vol}(\mathcal{D}) = O(1)$ . Hence, combining all the results stated in this section, we see that Theorem 1 from introduction follows.

**Proof of Theorem 1.** Follows from Theorems 9–11. ◀

### 3.1 Equivalence between VM and PVM: Proof of Theorem 9

In this section we establish the equivalence between VM and PVM. We start with the definition of *General Variance Mixing (GVM)*. Let  $\Phi$  and  $\Psi$  be two finite sets and let  $\rho(\cdot, \cdot)$  be an arbitrary joint distribution supported on  $\Phi \times \Psi$ . Denote by  $\nu$  and  $\pi$  the marginal distributions of  $\rho$  over  $\Phi$  and  $\Psi$ , respectively. That is, for  $x \in \Phi$  we have  $\nu(x) = \sum_{y \in \Psi} \rho(x, y)$ , and for  $y \in \Psi$  we have  $\pi(y) = \sum_{x \in \Phi} \rho(x, y)$ . We consider two natural matrices associated to  $\rho$ . For  $x \in \Phi$  and  $y \in \Psi$ , define

$$P^\uparrow(x, y) = \rho(y | x) = \frac{\rho(x, y)}{\nu(x)}, \quad \text{and} \quad P^\downarrow(y, x) = \rho(x | y) = \frac{\rho(x, y)}{\pi(y)}; \quad (8)$$

$P^\uparrow$  is a  $|\Phi| \times |\Psi|$  matrix while  $P^\downarrow$  is a  $|\Psi| \times |\Phi|$  matrix. In addition, observe that  $P^\uparrow P^\downarrow$  and  $P^\downarrow P^\uparrow$  are transition matrices of Markov chains reversible w.r.t.  $\nu$  and  $\pi$ , respectively.

► **Definition 12 (GVM for  $\rho$ ).** *We say that the joint distribution  $\rho$  satisfies  $\text{GVM}(\varepsilon)$  if for every function  $f : \Phi \rightarrow \mathbb{R}$  we have  $\text{Var}_\pi(P^\downarrow f) \leq \varepsilon \cdot \text{Var}_\nu(f)$ .*

One key observation in our proof is that the GVM condition can be expressed in term of the spectral gaps of the matrices  $P^\uparrow P^\downarrow$  and  $P^\downarrow P^\uparrow$ .

► **Lemma 13.** *The joint distribution  $\rho$  satisfies  $\text{GVM}(\varepsilon)$  if and only if  $\text{gap}(P^\uparrow P^\downarrow) = \text{gap}(P^\downarrow P^\uparrow) \geq 1 - \varepsilon$ .*

Before providing the proof of Lemma 13, we recall the definition of the *adjoint operator*. Let  $S_1$  and  $S_2$  be two Hilbert spaces with inner products  $\langle \cdot, \cdot \rangle_{S_1}$  and  $\langle \cdot, \cdot \rangle_{S_2}$  respectively, and let  $K : S_2 \rightarrow S_1$  be a bounded linear operator. The adjoint of  $K$  is the unique operator  $K^* : S_1 \rightarrow S_2$  satisfying  $\langle f, Kg \rangle_{S_1} = \langle K^* f, g \rangle_{S_2}$  for all  $f \in S_1$  and  $g \in S_2$ . When  $S_1 = S_2$ ,  $K$  is called *self-adjoint* if  $K = K^*$ . We can now provide the proof of Lemma 13.

**Proof of Lemma 13.** It is straightforward to check that  $P^\uparrow \mathbf{1} = \mathbf{1}$ ,  $P^\downarrow \mathbf{1} = \mathbf{1}$ ,  $\nu P^\uparrow = \pi$ ,  $\pi P^\downarrow = \nu$ , and that the operator  $P^\uparrow : L_2(\pi) \rightarrow L_2(\nu)$  is the adjoint of the operator  $P^\downarrow : L_2(\nu) \rightarrow L_2(\pi)$ . Hence, both  $P^\uparrow P^\downarrow$  and  $P^\downarrow P^\uparrow$  are positive semidefinite and have the same multiset of non-zero eigenvalues. Now, for  $f : \Phi \rightarrow \mathbb{R}$ , we have

$$\text{Var}_\pi(P^\downarrow f) = \langle P^\downarrow f, (I - \mathbf{1}\pi)P^\downarrow f \rangle_\pi = \langle f, P^\uparrow(I - \mathbf{1}\pi)P^\downarrow f \rangle_\nu = \langle f, P^\uparrow P^\downarrow f \rangle_\nu - \langle f, \mathbf{1}\nu f \rangle_\nu.$$

Therefore,  $\text{Var}_\pi(P^\downarrow f) \leq \varepsilon \cdot \text{Var}_\nu(f)$  holds if and only if

$$\begin{aligned} \langle f, P^\uparrow P^\downarrow f \rangle_\nu - \langle f, \mathbf{1}\nu f \rangle_\nu &\leq \varepsilon \cdot (\langle f, f \rangle_\nu - \langle f, \mathbf{1}\nu f \rangle_\nu) \\ \Leftrightarrow \langle f, (I - P^\uparrow P^\downarrow) f \rangle_\nu &\geq (1 - \varepsilon) \cdot \langle f, (I - \mathbf{1}\nu) f \rangle_\nu \\ \Leftrightarrow \mathcal{E}_{P^\uparrow P^\downarrow}(f, f) &\geq (1 - \varepsilon) \cdot \text{Var}_\nu(f). \end{aligned}$$

The lemma then follows from (6).  $\blacktriangleleft$

We provide next the proof of Theorem 9, which follows from Lemma 13 and interpretations of VM and PVM by GVM. Given  $F = A \cup B \subseteq T$  and  $\eta \in \Omega$ , let  $P^\uparrow = (P_F^\eta)_{A \uparrow B}$  denote the  $q^{|A \setminus B|} \times q^{|B \setminus A|}$  stochastic matrix indexed by the configurations on the sets  $A \setminus B$  and  $B \setminus A$ , such that for  $\xi \in [q]^{A \setminus B}$  and  $\xi' \in [q]^{B \setminus A}$  we have  $P^\uparrow(\xi, \xi') = \mu_F^\eta(\sigma_{B \setminus A} = \xi' \mid \sigma_{A \setminus B} = \xi)$ . In words,  $P^\uparrow$  corresponds to the transition matrix that given the configuration  $\xi$  in  $A \setminus B$  updates the configuration in  $B \setminus A$  from the conditional distribution  $\mu_F^\eta(\cdot \mid \xi)$ . We define in a similar manner the  $q^{|B \setminus A|} \times q^{|A \setminus B|}$  stochastic matrix  $P^\downarrow = (P_F^\eta)_{B \downarrow A}$  where for  $\xi' \in [q]^{B \setminus A}$  and  $\xi \in [q]^{A \setminus B}$  we have  $P^\downarrow(\xi', \xi) = \mu_F^\eta(\sigma_{A \setminus B} = \xi \mid \sigma_{B \setminus A} = \xi')$ .

If we set  $\rho$  to be the marginal of  $\mu_F^\eta$  on  $(A \setminus B) \cup (B \setminus A)$ , then  $\Phi = [q]^{A \setminus B}$ ,  $\Psi = [q]^{B \setminus A}$ , and  $\nu$  and  $\pi$  are the marginals of  $\mu_F^\eta$  on  $A \setminus B$  and  $B \setminus A$ , respectively. Therefore, according to Definition 12, GVM( $\varepsilon$ ) holds for the marginal of  $\mu_F^\eta$  on  $(A \setminus B) \cup (B \setminus A)$  if  $\text{Var}_\pi(P^\downarrow f) \leq \varepsilon \cdot \text{Var}_\nu(f)$  for every function  $f : \Phi \rightarrow \mathbb{R}$ .

Now, note that a function  $g : \Omega_F^\eta \rightarrow \mathbb{R}$  independent of  $B$  only depends on the configuration on  $A \setminus B$ . Thus, for fixed  $\eta$ ,  $g$  induces a function  $f : \Phi \rightarrow \mathbb{R}$ ; in particular,  $\text{Var}_F^\eta(g) = \text{Var}_\nu(f)$ . Moreover, letting  $g_{B \setminus A}(\xi) := \mathbb{E}_F^\eta[g \mid \sigma_{B \setminus A} = \xi]$ , we have  $g_{B \setminus A}(\xi) = P^\downarrow f(\xi)$  for every  $\xi \in \Psi = [q]^{B \setminus A}$ , and so  $\text{Var}_F^\eta(g_{B \setminus A}) = \text{Var}_\pi(P^\downarrow f)$ . Consequently, we arrive at the following equivalences between VM, PVM and GVM.

**► Proposition 14.**

1. The Gibbs distribution  $\mu$  satisfies VM( $\ell, \varepsilon$ ) if and only if for every  $v \in T$  and  $\eta \in \Omega$ , GVM( $\varepsilon$ ) holds for the marginal of  $\mu_{T_v}^\eta$  on  $(T_v \setminus B(v, \ell)) \cup \{v\}$ .
2. The Gibbs distribution  $\mu$  satisfies PVM( $\ell, \varepsilon$ ) if and only if for every  $i$  such that  $1 \leq i \leq h+1$  and  $\eta \in \Omega$ , GVM( $\varepsilon$ ) holds for the marginal of  $\mu_{F_i}^\eta$  on  $(F_i \setminus \cup_{v \in L_i} B(v, \ell)) \cup L_i$ .

To see part 1 simply note that in the notation above, we can set  $F = T_v$ ,  $A = T_v \setminus v$  and  $B = B(v, \ell)$ . For part 2, we set  $F = F_i$ ,  $A = F_{i-1}$  and  $B = B_i^\ell$ .

**Proof of Theorem 9.** From Proposition 14 and Lemma 13, VM( $\ell, \varepsilon$ ) holds if and only if  $\text{gap}(Q_v) \geq 1 - \varepsilon$  for every  $v \in T$  and  $\eta \in \Omega$ , where  $Q_v = (P_{T_v}^\eta)_{B(v, \ell) \downarrow (T_v \setminus v)} (P_{T_v}^\eta)_{(T_v \setminus v) \uparrow B(v, \ell)}$ . Similarly,  $\mu$  satisfies PVM( $\ell, \varepsilon$ ) if and only if  $\text{gap}(Q_{L_i}) \geq 1 - \varepsilon$  for every  $i$  such that  $1 \leq i \leq h+1$  and  $\eta \in \Omega$ , where  $Q_{L_i} = (P_{F_i}^\eta)_{B_i^\ell \downarrow F_{i-1}} (P_{F_i}^\eta)_{F_{i-1} \uparrow B_i^\ell}$ .

Since  $F_i = \bigcup_{v \in L_i} T_v$  and the  $T_v$ 's are at distance at least two from each other,  $\mu_{F_i}^\eta(\sigma_{L_i} = \cdot)$  is a product distribution; in particular  $\mu_{F_i}^\eta(\sigma_{L_i} = \cdot) = \prod_{v \in L_i} \mu_{T_v}^\eta(\sigma_v = \cdot)$  and the chain with transition matrix  $Q_{L_i}$  is a product Markov chain where each component corresponds to  $Q_v$  for some  $v \in L_i$ . A standard fact about product Markov chains, see, e.g., [9, Lemma 4.7], then implies that  $\text{gap}(Q_{L_i}) = \min_{v \in L_i} \text{gap}(Q_v)$  and the result follows.  $\blacktriangleleft$

## 4 Entropy Mixing: Proof of Theorem 2

Let  $E \subseteq T$  denote the set of all *even* vertices of the tree  $T$ , where a vertex is called even if its distance to the leaves is even; let  $O = T \setminus E$  be the set of all odd vertices. We show that EM (i.e., entropy mixing) as defined in [40] implies a factorization of entropy into even and

odd subsets of vertices. This even-odd factorization was recently shown to imply  $O(\log n)$  mixing of the SW dynamics on bipartite graphs [8].

We start with the definition of EM, which is the analog of the VM condition for entropy. Let  $\tau$  be a fixed boundary condition and again set  $\mu := \mu_T^\tau$  and  $\Omega := \Omega^\tau$  for ease of notation. Recall that for  $v \in T$ , we use  $T_v$  for the subtree of  $T$  rooted at  $v$ . Recall that for  $\eta \in \Omega$  and  $g : \Omega_{T_v}^\eta \rightarrow \mathbb{R}$ , we defined the function  $g_v(a) = \mathbb{E}_{T_v}^\eta [g \mid \sigma_v = a]$  for  $a \in [q]$ ; see (7).

► **Definition 15 (Entropy Mixing (EM)).** *The Gibbs distribution  $\mu = \mu_T^\tau$  satisfies  $\text{EM}(\ell, \varepsilon)$  if for every  $v \in T$ , every  $\eta \in \Omega$ , and every function  $g : \Omega_{T_v}^\eta \rightarrow \mathbb{R}$  that is independent of the configuration on  $B(v, \ell)$ , we have  $\text{Ent}_{T_v}^\eta(g_v) \leq \varepsilon \cdot \text{Ent}_{T_v}^\eta(g)$ . The EM condition holds if there exist constants  $\ell$  and  $\varepsilon = \varepsilon(\ell)$  such that  $\text{EM}(\ell, \varepsilon)$  holds.*

Extending our notation from the previous section for the variance functional, for  $A \subseteq T$  and a function  $f : \Omega \rightarrow \mathbb{R}_{\geq 0}$ , we use  $\text{Ent}_A(f)$  for the conditional entropy of  $f$  w.r.t.  $\mu$  given a spin configuration in  $T \setminus A$ ; i.e., for  $\xi \in \Omega$  we have

$$(\text{Ent}_A(f))(\xi) = \text{Ent}_A^\xi(f) = \text{Ent}_\mu[f \mid \sigma_{T \setminus A} = \xi_{T \setminus A}].$$

In particular, we shall write  $\text{Ent}(f) = \text{Ent}_T(f) = \text{Ent}_\mu(f)$ . Notice that  $\text{Ent}_A(f)$  can be viewed as a function from  $[q]^{T \setminus A}$  to  $\mathbb{R}_{\geq 0}$  and  $\mathbb{E}[\text{Ent}_A(f)]$  denotes its mean, averaging over the configuration on  $T \setminus A$ . We state next our even-odd factorization of entropy.

► **Theorem 16.** *If there exist  $\ell \in \mathbb{N}^+$  and  $\varepsilon \in (0, 1)$  such that  $\mu = \mu_T^\tau$  satisfies  $\text{EM}(\ell, \varepsilon)$ , then there exists a constant  $C_{\text{EO}} = C_{\text{EO}}(\ell, \varepsilon)$  independent of  $n$  such that for every function  $f : \Omega \rightarrow \mathbb{R}_{\geq 0}$  we have  $\text{Ent}(f) \leq C_{\text{EO}} (\mathbb{E}[\text{Ent}_E(f)] + \mathbb{E}[\text{Ent}_O(f)])$ .*

Theorem 2 follows immediately.

**Proof of Theorem 2.** By Theorem 16, EM implies the even-odd factorization of entropy, and the results in [8] imply that the mixing time of the SW dynamics is  $O(\log n)$ . ◀

Our main technical contribution in the proof Theorem 2 is thus Theorem 16; namely, that EM implies the even-odd factorization of entropy. To prove Theorem 16, we will first establish entropy factorization for the tiled blocks defined in (3) and (2); see also Figures 1(b) and 1(c). From the tiled block factorization of entropy we then deduce the desired even-odd factorization. This approach is captured by the following two lemmas.

► **Lemma 17.** *If there exist  $\ell \in \mathbb{N}^+$  and  $\varepsilon \in (0, 1)$  such that  $\mu = \mu_T^\tau$  satisfies  $\text{EM}(\ell, \varepsilon)$ , then there exists a constant  $C_{\text{TB}} = C_{\text{TB}}(\ell, \varepsilon)$  independent of  $n$  such that, for every function  $f : \Omega \rightarrow \mathbb{R}_{\geq 0}$ ,  $\text{Ent}(f) \leq C_{\text{TB}} \cdot \sum_{j=1}^{\ell+1} \mathbb{E}[\text{Ent}_{T_j^\ell}(f)]$ .*

► **Lemma 18.** *If for every function  $f : \Omega \rightarrow \mathbb{R}_{\geq 0}$  we have  $\text{Ent}(f) \leq C_{\text{TB}} \cdot \sum_{j=1}^{\ell+1} \mathbb{E}[\text{Ent}_{T_j^\ell}(f)]$ , then there exists  $C_{\text{EO}} = C_{\text{EO}}(C_{\text{TB}}, \ell)$  such that for every function  $f : \Omega \rightarrow \mathbb{R}_{\geq 0}$  we have*

$$\text{Ent}(f) \leq C_{\text{EO}} (\mathbb{E}[\text{Ent}_E(f)] + \mathbb{E}[\text{Ent}_O(f)]).$$

**Proof of Theorem 16.** Follows directly from Lemmas 17 and 18. ◀

We proved a version of Lemma 17 for the variance functional as part of the proof of Theorem 10, and the same argument can then be easily adapted to entropy. We provide next the proof of Lemma 18, which contains the main novelty in our proof of Theorem 16.

**Proof of Lemma 18.** First, we claim that there exists a constant  $C' = C'(\ell)$  such that for every function  $f : \Omega_{B(v,\ell)}^\eta \rightarrow \mathbb{R}_{\geq 0}$  one has the following inequality:

$$\text{Ent}_{B(v,\ell)}^\eta(f) \leq C' \left( \mathbb{E}_{B(v,\ell)}^\eta[\text{Ent}_{B(v,\ell) \cap E}(f)] + \mathbb{E}_{B(v,\ell)}^\eta[\text{Ent}_{B(v,\ell) \cap O}(f)] \right). \quad (9)$$

To deduce (9), consider the even-odd block dynamics  $M$  in  $B(v,\ell)$  with boundary condition  $\eta$  and blocks  $\mathcal{U} = \{E \cap B(v,\ell), O \cap B(v,\ell)\}$ . A simple coupling argument implies that the spectral gap of  $M$  is  $\Omega(1)$ . Then, Corollary A.4 from [19] implies that the log-Sobolev constant  $\alpha(M)$  of  $M$  is  $\Omega(1)$ , which establishes (9) with constant  $C' = O(1/\alpha(M))$ . We note that all bounds and comparisons in this argument are fairly crude, and, in fact, the constant  $C'$  depends exponentially on  $|B(v,\ell)|$ , but it is still independent of  $n$ .

Next, notice that, for any  $\eta \in \Omega$ ,  $\mu_{T_j^\ell}^\eta$  is the product of a collection of distributions on (disjoint) subsets  $B(v,\ell)$ . Lemma 3.2 from [14] allows us to lift the “local” even-odd factorization in each  $B(v,\ell)$  from (9) to a “global” even-odd factorization in  $T_j^\ell$ . Specifically, for every function  $f : \Omega_{T_j^\ell}^\eta \rightarrow \mathbb{R}_{\geq 0}$  we obtain

$$\text{Ent}_{T_j^\ell}^\eta(f) \leq C' \left( \mathbb{E}_{T_j^\ell}^\eta[\text{Ent}_{T_j^\ell \cap E}(f)] + \mathbb{E}_{T_j^\ell}^\eta[\text{Ent}_{T_j^\ell \cap O}(f)] \right).$$

Taking expectation over  $\eta$ , we get

$$\mathbb{E}[\text{Ent}_{T_j^\ell}(f)] \leq C' \left( \mathbb{E}[\text{Ent}_{T_j^\ell \cap E}(f)] + \mathbb{E}[\text{Ent}_{T_j^\ell \cap O}(f)] \right) \leq C' (\mathbb{E}[\text{Ent}_E(f)] + \mathbb{E}[\text{Ent}_O(f)]);$$

the last inequality follows from the fact that  $\text{Ent}_{T_j^\ell}^\eta(f) = \mathbb{E}_E^\eta[\text{Ent}_{T_j^\ell \cap E}(f)] + \mathbb{E}_O^\eta[\text{Ent}_{T_j^\ell \cap O}(f)]$ . Summing up over  $j$ ,

$$\sum_{j=1}^{\ell+1} \mathbb{E}[\text{Ent}_{T_j^\ell}(f)] \leq C'(\ell+1) (\mathbb{E}[\text{Ent}_E(f)] + \mathbb{E}[\text{Ent}_O(f)]),$$

and the result follows by taking  $C_{\text{EO}} = C'(\ell+1)$ . ◀

## Abstract

Using geometric techniques like projection and dimensionality reduction, we show that there exists a randomized sub-linear time algorithm that can estimate the Hamming distance between two matrices. Consider two matrices  $\mathbf{A}$  and  $\mathbf{B}$  of size  $n \times n$  whose dimensions are known to the algorithm but the entries are not. The entries of the matrix are real numbers. The access to any matrix is through an oracle that computes the projection of a row (or a column) of the matrix on a vector in  $\{0, 1\}^n$ . We call this query oracle to be an INNER PRODUCT oracle (shortened as IP). We show that our algorithm returns a  $(1 \pm \epsilon)$  approximation to  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  with high probability by making  $\mathcal{O}\left(\frac{n}{\sqrt{\mathbf{D}_M(\mathbf{A}, \mathbf{B})}} \text{poly}\left(\log n, \frac{1}{\epsilon}\right)\right)$  oracle queries, where  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  denotes the Hamming distance (the number of corresponding entries in which  $\mathbf{A}$  and  $\mathbf{B}$  differ) between two matrices  $\mathbf{A}$  and  $\mathbf{B}$  of size  $n \times n$ . We also show a matching lower bound on the number of such IP queries needed. Though our main result is on estimating  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  using IP, we also compare our results with other query models.

## 1 Introduction

Measuring similarity between entities using a distance function has been a major area of focus in computer science in general and computational geometry in particular [9, 8, 20, 19, 7]. Distance computations require access to the entire data and thus can not escape computations that are linear in time complexity. In this era of big data, seeing the entire data may be too much of an ask and trading precision for a time efficient algorithm is a vibrant area of study in property testing [22]. Testing properties of binary images with sub-linear time algorithms has been a focus of property testing algorithms [27, 26, 11, 24, 10]. Matrices are ubiquitous in the sense that they represent or abstract a whole gamut of structures like adjacency matrices of geometric graphs and visibility graphs, images, experimental data involving 0-1 outcomes, etc. Pairwise distance computations between such matrices is a much-needed programming primitive in image processing and computer vision applications

so much so that the widely used commercial toolbox MATLAB of MathWorks® [1] has an inbuilt function call named `pdist2(·, ·, ·)` [2] for it. Other open source based software packages also have similar primitives [3]. For all these primitives, the matrices need to be known. But in all situations where access to the matrices are restricted (say, because of security, privacy or communication issues) except for an oracle access, we want to know how much the two matrices differ in their entries. Keeping in line with the above, we focus on distance estimation problem between two matrices whose dimensions are known to the algorithm but the entries are unknown; the access to the matrices will be through an oracle. This oracle, though linear algebraic in flavor, has a geometric connotation to it. We hold back the discussion on the motivation of the oracle till Section 1.1.

### Notations

In this paper, we denote the set  $\{1, \dots, t\}$  by  $[t]$  and  $\{0, \dots, t\}$  by  $[[t]]$ . For a matrix  $\mathbf{A}$ ,  $\mathbf{A}(i, j)$  denotes the element in the  $i$ -th row and  $j$ -th column of  $\mathbf{A}$ . Unless stated otherwise,  $\mathbf{A}$  will be a matrix with real entries.  $\mathbf{A}(i, *)$  and  $\mathbf{A}(*, j)$  denote the  $i$ -th row vector and  $j$ -th column vector of the matrix  $\mathbf{A}$ , respectively. Throughout this paper, the number of rows or columns of a square matrix  $\mathbf{A}$  will be  $n$ . Vectors are matrices of order  $n \times 1$  and will be represented using bold face letters. Without loss of generality, we consider  $n$  to be a power of 2. The  $i$ -th coordinate of a vector  $\mathbf{x}$  will be denoted by  $x_i$ . We will denote by  $\mathbf{1}$  the vector with all coordinates 1. Let  $\{0, 1\}^n$  denote the set of  $n$ -dimensional vectors with entries either 0 or 1. By  $\langle \mathbf{x}, \mathbf{y} \rangle$ , we denote the standard inner product of  $\mathbf{x}$  and  $\mathbf{y}$ , that is,  $\langle \mathbf{x}, \mathbf{y} \rangle = \sum_{i=1}^n x_i y_i$ .  $P$  is a  $(1 \pm \varepsilon)$ -approximation to  $Q$  means  $|P - Q| \leq \varepsilon \cdot Q$ . The statement *with high probability* means that the probability of success is at least  $1 - \frac{1}{n^c}$ , where  $c$  is a positive constant.  $\tilde{\Theta}(\cdot)$  and  $\tilde{O}(\cdot)$  hides a poly  $(\log n, \frac{1}{\varepsilon})$  term in the upper bound.  $\|\cdot\|_p$  denotes the usual  $\ell_p$  distance.

## 1.1 Query oracle definition and motivation, problem statements and our results

► **Definition 1.1** (Matrix distance). The *matrix-distance* between two matrices  $\mathbf{A}$  and  $\mathbf{B}$  of size  $n \times n$  is the number of pairwise mismatches and is denoted and defined as

$$D_M(\mathbf{A}, \mathbf{B}) = |\{(i, j) : i, j \in [n], \mathbf{A}(i, j) \neq \mathbf{B}(i, j)\}|.$$

As alluded to earlier, the matrices cannot be accessed directly, the sizes of the matrices are known but the entries are unknown. We will refer to the problem as the *matrix distance* problem. We consider the following query models to solve the matrix distance problem in this paper.

### Query oracles for unknown matrix $\mathbf{A} \in \mathbb{R}^{n \times n}$

The main query oracle access used in this work is based on the inner product of two vectors and is defined as follows:

**INNER PRODUCT (IP):** Given a row index  $i \in [n]$  (or, a column index  $j \in [n]$ ) and a vector  $\mathbf{v} \in \{0, 1\}^n$ , the IP query to  $\mathbf{A}$  reports the value of  $\langle \mathbf{A}(i, *), \mathbf{v} \rangle$  ( $\langle \mathbf{A}(*, j), \mathbf{v} \rangle$ ). If the input index is for row (column), we refer the corresponding query as row (column) IP query.

This linear algebraic oracle access has a geometric connotation to it in terms of *projection* onto Hamming vectors – we exploit this understanding in our work. This oracle access is also motivated from a practical angle. A dot product operation is a fit case for parallelization

using a SINGLE INSTRUCTION MULTIPLE DATA (SIMD) architecture [23]. Modern day GPU processors provide instruction level parallelism. In effect, NVIDIA GPUs that are built on CUDA architecture, provide dot product between two vectors as a single API call [28, 4]. Thus, there exists practical implementation of the query oracle access that we use. There are also examples of programming languages supporting SIMD intrinsics that can compute dot product [5]. There is a caveat though – in terms of resource, more processors are used. For us, in this work, the query complexity is the number of calls to the IP. As mentioned, modern day architectures allow us to convert each IP query to a one cycle computation with more processors used in parallel.

In the power hierarchy of matrix based query oracles, IP surely wields some power vis-a-vis solving certain problems [14]<sup>1</sup>. An obvious question that confronts an algorithm designer is whether a weaker oracle can do the same job at hand (here, computing matrix distance). With that in mind, we define the following two oracles and show that their query complexity lower bounds on the matrix distance problem match the trivial upper bounds. That shows the justification for use of IP.

**MATRIX ELEMENT (ME):** Given two indices  $i, j \in [n]$ , the ME query to  $\mathbf{A}$  returns the value of  $\mathbf{A}(i, j)$ .

**DECISION INNER PRODUCT (DEC-IP):** Given a row index  $i \in [n]$  (or, a column index  $j \in [n]$ ) and a vector  $\mathbf{v} \in \{0, 1\}^n$ , the DEC-IP query to  $\mathbf{A}$  reports whether  $\langle \mathbf{A}(i, *), \mathbf{v} \rangle$  ( $\langle \mathbf{A}(*, j), \mathbf{v} \rangle$ ) = 0. If the input index is for row (column), we refer the corresponding query as row (column) DEC-IP query.

The following remark highlights the relative power of the query oracles.

► **Remark 1.** Each ME query can be simulated by using one DEC-IP oracle, and each DEC-IP oracle can be simulated by using one IP query.

## Our results

Our main result is an algorithm for estimating the distances between two unknown matrices using IP, and the result is formally stated as follows. Unless otherwise mentioned, all our algorithms are randomized.

► **Theorem 1.2** (Main result: Estimating the distance between two arbitrary matrices). *There exists an algorithm that has IP query oracle access to unknown matrices  $\mathbf{A}$  and  $\mathbf{B}$ , takes an  $\varepsilon \in (0, 1)$  as an input, and returns a  $(1 \pm \varepsilon)$  approximation to  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  with high probability, and makes  $\mathcal{O}\left(\left(n/\sqrt{\mathbf{D}_M(\mathbf{A}, \mathbf{B})}\right) \text{poly}\left(\log n, \frac{1}{\varepsilon}\right)\right)$  IP queries.*

We also show that our algorithm (corresponding to the above theorem) is optimal, if we ignore the  $\text{poly}\left(\log n, \frac{1}{\varepsilon}\right)$  term, by showing (in Theorem 4.1) that any algorithm that estimates  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  requires  $\Omega\left(n/\sqrt{\mathbf{D}_M(\mathbf{A}, \mathbf{B})}\right)$  IP queries. For the sake of completeness in understanding the power of IP, we study the matrix distance problem also using two weaker oracle access – ME and DEC-IP. Our results are summarized in Table 1 and they involve both upper and almost matching lower bounds in terms of the number of queries needed. Note that all of our lower bounds hold even if one matrix (say  $\mathbf{A}$ ) is known and both matrices ( $\mathbf{A}$  and  $\mathbf{B}$ ) are symmetric binary matrices.

<sup>1</sup> But the IP defined in this paper is weaker than that defined in [14] – in their case, one is allowed to query for inner product of rows/columns of matrices with vectors in  $\mathbb{R}^n$ .

■ **Table 1** Our results. In this table,  $D = \mathbf{D}_M(\mathbf{A}, \mathbf{B})$ .

Query Oracle	ME	DEC-IP	IP
Upper Bound	$\tilde{O}\left(\frac{n^2}{D}\right)$ (Trivial)	$\tilde{O}\left(\frac{n^2}{D}\right)$ (Trivial)	$\tilde{O}\left(\frac{n}{\sqrt{D}}\right)$ (Theorem 1.2)
Lower Bound	$\Omega\left(\frac{n^2}{D}\right)$ (Corollary 4.3)	$\Omega\left(\frac{n^2}{D}\right)$ (Theorem 4.1)	$\Omega\left(\frac{n}{\sqrt{D}}\right)$ (Theorem 4.2)

► **Remark 2.** Note that an IP query to a matrix  $\mathbf{A}$  answers inner product of a specified row (column) with a given binary vector. However, we will describe subroutines (of the algorithm for estimating the distance between two matrices) that ask for inner product of a specified row (column) with a given vector  $\mathbf{r} \in \{-1, 1\}^n$ . This is not a problem as  $\langle \mathbf{A}(i, *), \mathbf{r} \rangle$  ( $\langle \mathbf{A}(*, j), \mathbf{r} \rangle$ ) can be computed by using two IP queries (with binary vectors)<sup>2</sup>. For simplicity, we refer  $\langle \mathbf{A}(i, *), \mathbf{r} \rangle$  ( $\langle \mathbf{A}(*, j), \mathbf{r} \rangle$ ) also as IP query in our algorithm.

## 1.2 Related work

There are works in property testing and sub-linear geometric algorithms [15, 18, 17, 16]. In the specific problem that we deal with in this paper, to the best of our knowledge, Raskhodnikova [26] started the study of property testing of binary images in the *dense image model*, where the number of 1-pixels is  $\Omega(n^2)$ . The notion of distance between matrices of the same size is defined as the number of pixels (matrix entries) on which they differ. The relative distance is the ratio of the distance and the number of pixels in the image. In this model, Raskhodnikova studies three properties of binary images – connectivity, convexity, and being a half-plane – in the property testing framework. Ron and Tsur [27] studied property testing algorithms in the sparse binary image model (the number of 1-pixels is  $O(n)$ ) for connectivity, convexity, monotonicity, and being a line. The distance measure in this model is defined by the fraction of differing entries taken with respect to the actual number of 1’s in the matrix. As opposed to treating binary images as discrete images represented using pixels as in [27, 26], Berman et al. in [10] and [12] treated them as continuous images and studied the problem of property testing for convexity of 2-dimensional figures with only uniform and independent samples from the input. To the best of our knowledge, computing distances between binary images has not been dealt with in the sub-linear time framework.

### Organization of the paper

We prove Theorem 1.2 (in Section 1.1) through a sequence of results. To prove Theorem 1.2 that estimates the distance between two arbitrary matrices, we need a result that estimates the distance between two symmetric matrices (Lemma 2.1 in Section 2) that in turn needs a result on the estimation of the distance between two symmetric matrices with respect to a parameter  $T$  (Lemma 2.2 in Section 2). Lemma 2.2 is the main technical lemma that uses dimensionality reduction via Johnson Lindenstrauss lemma crucially. The technical overview including the proof idea of Lemma 2.2 is in Section 2.1. The detailed proof idea is in Section 2.2. Using communication complexity, we prove our lower bound results in Section 4. The proof of lemma marked with  $\star$  can be found in the full version of the paper [13].

<sup>2</sup> For  $\mathbf{r} \in \{-1, 1\}^n$ , consider  $\mathbf{v}_1, \mathbf{v}_{-1} \in \{0, 1\}^n$  indicator vectors for +1 and -1 coordinates in  $\mathbf{r} \in \{-1, 1\}^n$ , respectively. Then  $\langle \mathbf{A}(i, *), \mathbf{r} \rangle = \langle \mathbf{A}(i, *), \mathbf{v}_1 \rangle - \langle \mathbf{A}(i, *), \mathbf{v}_{-1} \rangle$ . So,  $\langle \mathbf{A}(i, *), \mathbf{r} \rangle$  can be computed with two IP queries  $\langle \mathbf{A}(i, *), \mathbf{v}_1 \rangle$  and  $\langle \mathbf{A}(i, *), \mathbf{v}_{-1} \rangle$ . Similar argument also holds for  $\langle \mathbf{A}(*, j), \mathbf{r} \rangle$ .

## 2 Matrix-Distance between two symmetric matrices

This section builds up towards a proof of Theorem 1.2 by first giving an algorithm that estimates the matrix-distance between two unknown symmetric matrices (instead of arbitrary matrices as in Theorem 1.2) with high probability. The result is formally stated in Lemma 2.1. In Section 3, we will discuss how this result (stated in Lemma 2.1) can be used to prove Theorem 1.2.

► **Lemma 2.1** (Estimating the distance between two symmetric matrices). *There exists an algorithm  $\text{DIST-SYMM-MATRIX}(\mathbf{A}, \mathbf{B}, \varepsilon)$ , that has IP query access to unknown symmetric matrices  $\mathbf{A}$  and  $\mathbf{B}$ , takes an  $\varepsilon \in (0, \frac{1}{2})$  as an input, and returns a  $(1 \pm \varepsilon)$ -approximation to  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  with high probability, making  $\tilde{O}\left(n/\sqrt{\mathbf{D}_M(\mathbf{A}, \mathbf{B})}\right)$  IP queries.*

First, we prove a parameterized version of the above lemma in Lemma 2.2 where we are given a parameter  $T$  along with an  $\varepsilon \in (0, \frac{1}{2})$  and we can obtain an approximation guarantee on  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  as a function of both  $T$  and  $\varepsilon$ . One can think of  $T$  as a guess for  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$ .

► **Lemma 2.2** ( $(*)$  Estimating the distance between two symmetric matrices w.r.t. a parameter  $T$ ). *There exists an algorithm  $\text{DIST-SYMM-MATRIX-GUESS}(\mathbf{A}, \mathbf{B}, \varepsilon, T)$ , that has IP query access to unknown symmetric matrices  $\mathbf{A}$  and  $\mathbf{B}$ , takes parameters  $T$  and  $\varepsilon \in (0, \frac{1}{2})$  as inputs, and returns  $\hat{d}$  satisfying  $(1 - \frac{\varepsilon}{10}) \mathbf{D}_M(\mathbf{A}, \mathbf{B}) - \frac{\varepsilon}{1600} T \leq \hat{d} \leq (1 + \frac{\varepsilon}{10}) \mathbf{D}_M(\mathbf{A}, \mathbf{B})$  with high probability, and makes  $\tilde{O}\left(n/\sqrt{T}\right)$  queries. Note that here  $T$  is at least a suitable polynomial in  $\log n$  and  $1/\varepsilon$ .*

In Section 2.1, we discuss some preliminary results to prove Lemma 2.2. The proof of Lemma 2.2 is given in Section 2.2. If the guess  $T \leq \mathbf{D}_M(\mathbf{A}, \mathbf{B})$ ,  $\text{DIST-SYMM-MATRIX-GUESS}(\mathbf{A}, \mathbf{B}, \varepsilon, T)$  (as stated in Lemma 2.2) returns a  $(1 \pm \varepsilon)$ -approximation to  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  with high probability. However, this dependence on  $T$  can be overcome to prove Lemma 2.1 by using a standard technique in property testing.

### 2.1 Technical preliminaries to prove Lemma 2.2

The matrix distance  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  can be expressed in terms of the notion of a distance between a row (column) of matrix  $\mathbf{A}$  and a row (column) of matrix  $\mathbf{B}$  as follows:

► **Definition 2.3** (Distance between two rows (columns)). Let  $\mathbf{A}$  and  $\mathbf{B}$  be two matrices of order  $n \times n$ . The distance between the  $i$ -th row of  $\mathbf{A}$  and the  $j$ -th row of  $\mathbf{B}$  is denoted and defined as

$$\mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(j, *)) = |\{k \in [n] : \mathbf{A}(i, k) \neq \mathbf{B}(j, k)\}|,$$

Similarly,  $\mathbf{d}_H(\mathbf{A}(*, i), \mathbf{B}(*, j))$  is the distance between the  $i$ -th column of  $\mathbf{A}$  and the  $j$ -th column of  $\mathbf{B}$ .

► **Observation 2.4** (Expressing  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  as the sum of distance between rows (columns)). Let  $\mathbf{A}$  and  $\mathbf{B}$  be two  $n \times n$  matrices. The matrix distance between  $\mathbf{A}$  and  $\mathbf{B}$  is given by

$$\mathbf{D}_M(\mathbf{A}, \mathbf{B}) = \sum_{i=1}^n \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *)) = \sum_{i=1}^n \mathbf{d}_H(\mathbf{A}(*, i), \mathbf{B}(*, i)).$$

For a given  $i \in [n]$ , we can approximate  $\mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$  and  $\mathbf{d}_H(\mathbf{A}(*, i), \mathbf{B}(*, i))$  using IP queries as stated in Lemma 2.5. This can be shown by an application of the well-known Johnson-Lindenstrauss Lemma [6].

► **Lemma 2.5** (Estimating the distance between rows of  $\mathbf{A}$  and  $\mathbf{B}$ ). *Consider IP access to two  $n \times n$  (unknown) matrices  $\mathbf{A}$  and  $\mathbf{B}$ . There is an algorithm  $\text{DIST-BET-ROWS}(i, \alpha, \delta)$ , that takes  $i \in [n]$  and  $\alpha, \delta \in (0, 1)$  as inputs, and reports a  $(1 \pm \alpha)$ -approximation to  $\mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$  with probability at least  $1 - \delta$ , and makes  $\mathcal{O}\left(\frac{\log n}{\alpha^2} \log \frac{1}{\delta}\right)$  IP queries to both  $\mathbf{A}$  and  $\mathbf{B}$ .*

As it is sufficient for our purpose, in the above lemma, we discussed about estimating the distance between rows of  $\mathbf{A}$  and  $\mathbf{B}$  with the same index. However, we note that, a simple modification to the algorithm corresponding to Lemma 2.5 also works for estimating the distance between any row and/or column pair.

► **Proposition 2.6** (Johnson-Lindenstrauss Lemma). *Let us consider any pair of points  $\mathbf{u}, \mathbf{v} \in \mathbb{R}^N$ . For a given  $\varepsilon \in (0, 1)$  and  $\delta \in (0, 1)$ , there is a map  $f : \mathbb{R}^N \rightarrow \mathbb{R}^d$  such that  $d = \Theta\left(\frac{1}{\varepsilon^2} \log \frac{1}{\delta}\right)$  satisfying the following bound with probability at least  $1 - \delta$ .*

$$(1 - \varepsilon)\|\mathbf{u} - \mathbf{v}\|_2^2 \leq \|f(\mathbf{u}) - f(\mathbf{v})\|_2^2 \leq (1 + \varepsilon)\|\mathbf{u} - \mathbf{v}\|_2^2. \quad (1)$$

► **Remark 3** (An explicit mapping in Johnson-Lindenstrauss Lemma). An explicit mapping  $f : \mathbb{R}^n \rightarrow \mathbb{R}^d$  satisfying Equation 1 is as follows. Consider  $\mathbf{r}_1, \dots, \mathbf{r}_d \in \{-1, 1\}^n$  such that each coordinate of every  $\mathbf{r}_i$  is taken from  $\{-1, 1\}$  uniformly at random. Then for each  $\mathbf{u} \in \{0, 1\}^n$ ,

$$f(\mathbf{u}) = \frac{1}{\sqrt{d}} (\langle \mathbf{u}, \mathbf{r}_1 \rangle, \langle \mathbf{u}, \mathbf{r}_2 \rangle, \dots, \langle \mathbf{u}, \mathbf{r}_d \rangle).$$

### Identity testing between two rows

Now, let us discuss an algorithm where the objective is to decide whether the  $i$ -th row vectors of matrices  $\mathbf{A}$  and  $\mathbf{B}$  are identical. Observe that  $\|\mathbf{A}(i, *) - \mathbf{B}(j, *)\|_2 = 0$  if and only if  $\mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(j, *)) = 0$ . Also notice that, for a function  $f : \mathbb{R}^n \rightarrow \mathbb{R}^d$  satisfying Equation 1,  $\|\mathbf{u} - \mathbf{v}\|_2 = 0$  if and only if  $\|f(\mathbf{u}) - f(\mathbf{v})\|_2 = 0$ . This discussion along with Proposition 2.6 and Remark 3 imply an algorithm (described inside Observation 2.9) that can decide whether corresponding rows of  $\mathbf{A}$  and  $\mathbf{B}$  are identical. Observation 2.9 is stated in a more general form than discussed here. Note that the general form will be needed to show Lemma 2.5. For this purpose, we define the notion of *projecting a vector in  $\{-1, 1\}^n$  onto a set  $S \subseteq [n]$*  as defined below and an observation (Observation 2.8) about evaluating the projection using an IP query.

► **Definition 2.7** (Vector projected onto a set). Let  $\mathbf{A}$  be an  $n \times n$  matrix and  $i \in [n]$ . For a subset  $S \subseteq [n]$ ,  $\mathbf{A}(i, *)|_S \in \mathbb{R}^n$  is defined as the vector having  $\ell$ -th coordinate equals to  $\mathbf{A}(i, \ell)$  if  $\ell \in S$ , and 0, otherwise. Also consider  $\mathbf{r} \in \{-1, 1\}^n$  and a set  $S \subseteq [n]$ . Then the vector  $\mathbf{r}$  projected onto  $S$  is denoted by  $\mathbf{r}|_S \in \{-1, 0, 1\}^n$  and defined as follows: For  $\ell \in [n]$ , the  $\ell$ -th coordinate of  $\mathbf{r}|_S$  is same as that of  $\mathbf{r}$  if  $\ell \in S$ , and 0, otherwise.

► **Observation 2.8.** Let  $\mathbf{A}$  be a  $n \times n$  matrix,  $i \in [n]$ ,  $\mathbf{r} \in \{-1, 1\}^n$  and  $S \subseteq [n]$ . Then  $\langle \mathbf{A}(i, *)|_S, \mathbf{r} \rangle = \langle \mathbf{A}(i, *), \mathbf{r}|_S \rangle$ . That is,  $\langle \mathbf{A}(i, *)|_S, \mathbf{r} \rangle$  can be evaluated by using a IP query  $\langle \mathbf{A}(i, *), \mathbf{r}|_S \rangle$  to matrix  $\mathbf{A}$ .

► **Observation 2.9** (Identity testing between rows of  $\mathbf{A}$  and  $\mathbf{B}$ ). Consider IP access to two  $n \times n$  (unknown) matrices  $\mathbf{A}$  and  $\mathbf{B}$ . There is an algorithm  $\text{IDENTITY}(S, i, \delta)$  that takes  $i \in [n]$ ,  $S \subseteq [n]$  and  $\delta \in (0, 1)$  as inputs, and decides whether  $\mathbf{d}_H(\mathbf{A}(i, *)|_S, \mathbf{B}(i, *)|_S) = 0$  with probability at least  $1 - \delta$ , and makes  $\mathcal{O}\left(\log \frac{1}{\delta}\right)$  IP queries to both  $\mathbf{A}$  and  $\mathbf{B}$ .

**Proof.** Let the vectors  $\mathbf{r}_1, \dots, \mathbf{r}_d \in \{-1, 1\}^n$  be such that each coordinate of every  $\mathbf{r}_j$ ,  $j = 1, \dots, d$ , is taken from  $\{-1, 1\}$  uniformly at random where  $d = \Theta(\log \frac{1}{\delta})$ . Then the algorithm finds  $a_j = \langle \mathbf{A}(i, *)|_S, \mathbf{r}_j \rangle$  and  $b_j = \langle \mathbf{B}(i, *)|_S, \mathbf{r}_j \rangle$  by making one IP query to each of  $\mathbf{A}$  and  $\mathbf{B}$ . This is possible by Observation 2.8. The algorithm makes  $d$  IP queries to each of the matrices  $\mathbf{A}$  and  $\mathbf{B}$ . Take  $\mathbf{a} = \frac{1}{\sqrt{d}}(a_1, \dots, a_d) \in \mathbb{R}^d$  and  $\mathbf{b} = \frac{1}{\sqrt{d}}(b_1, \dots, b_d) \in \mathbb{R}^d$ . By Proposition 2.6 and Remark 3,  $\|\mathbf{a} - \mathbf{b}\|_2 = 0$  if and only if  $\|\mathbf{A}(i, *)|_S, \mathbf{B}(i, *)|_S\|_2 = 0$ . By the definition of distance between a row of one matrix and a row of another matrix (Definition 2.3), note that,  $\|\mathbf{A}(i, *)|_S - \mathbf{B}(j, *)|_S\|_2 = 0$  if and only if  $\mathbf{d}_H(\mathbf{A}(i, *)|_S, \mathbf{B}(j, *)|_S) = 0$ . So, the algorithm finds  $\|\mathbf{a} - \mathbf{b}\|_2$  and, reports  $\|\mathbf{a} - \mathbf{b}\|_2 = 0$  if and only if  $\mathbf{d}_H(\mathbf{A}(i, *)|_S, \mathbf{B}(i, *)|_S) = 0$ . The correctness and query complexity of the algorithm follows from the description itself.  $\blacktriangleleft$

### Estimating the distance between rows induced by a set

Now, consider the algorithm corresponding to Lemma 2.5 (DIST-BET-ROWS( $\cdot, \cdot, \cdot$ )) that can estimate the distance between a row of  $\mathbf{A}$  and a row of  $\mathbf{B}$ . It makes repeated calls to IDENTITY( $\cdot, \cdot, \cdot$ ) in a non-trivial way. Also, algorithm DIST-BET-ROWS( $\cdot, \cdot, \cdot$ ) can be generalized to estimate the distance between a row of  $\mathbf{A}$  and the corresponding row of  $\mathbf{B}$  projected onto the same set  $S \subseteq [n]$ , as stated in the following Lemma.

► **Lemma 2.10** ( $(\star)$  Estimating the distance between rows of  $\mathbf{A}$  and  $\mathbf{B}$  induced by a set  $S \subseteq [n]$ ). Consider IP access to two  $n \times n$  (unknown) matrices  $\mathbf{A}$  and  $\mathbf{B}$ . RESTRICT-DIST-BET-ROWS( $S, i, \alpha, \delta$ ) algorithm, takes  $S \subseteq [n]$ ,  $i \in [n]$  and  $\alpha, \delta \in (0, 1)$  as inputs, and reports a  $(1 \pm \alpha)$ -approximation to  $\mathbf{d}_H(\mathbf{A}(i, *)|_S, \mathbf{B}(i, *)|_S)$  with probability at least  $1 - \delta$ , and makes  $\mathcal{O}\left(\frac{\log n}{\alpha^2} \log \frac{1}{\delta}\right)$  IP queries to both  $\mathbf{A}$  and  $\mathbf{B}$ .

Observe that Lemma 2.5 is a special case of Lemma 2.10 when  $S = [n]$ . Algorithm DIST-BET-ROWS( $i, \alpha, \delta$ ) (corresponding to Lemma 2.5) is directly called as a subroutine from DIST-SYMM-MATRIX-GUESS( $\mathbf{A}, \mathbf{B}, \varepsilon, T$ ). RESTRICT-DIST-BET-ROWS( $S, i, \alpha, \delta$ ) is indirectly called from a subroutine to *sample mismatched element almost uniformly* as explained below.

### Sampling a mismatched element almost uniformly

For a row  $i \in [n]$ , let  $\text{NEQ}(\mathbf{A}, \mathbf{B}, i) = \{j : \mathbf{A}(i, j) \neq \mathbf{B}(i, j)\}$  denote the set of mismatches. Apart from estimating the distance between a row (column) of  $\mathbf{A}$  and the corresponding row (column) of  $\mathbf{B}$ , we can also sample element from  $\text{NEQ}(\mathbf{A}, \mathbf{B}, i)$  *almost uniformly* for any given  $i \in [n]$ .

► **Definition 2.11** (Almost uniform sample). Let  $X$  be a set and  $\alpha \in (0, 1)$ . A  $(1 \pm \alpha)$ -uniform sample from  $X$  is defined as the sample obtained from a distribution  $p$  satisfying  $(1 - \alpha)\frac{1}{|X|} \leq p(x) \leq (1 + \alpha)\frac{1}{|X|}$  for each  $x \in X$ , where  $p(x)$  denotes the probability of getting  $x$  as a sample.

► **Lemma 2.12** ( $(\star)$  Sampling a mismatched element almost uniformly). Consider IP access to two  $n \times n$  (unknown) matrices  $\mathbf{A}$  and  $\mathbf{B}$ . There exists an algorithm APPROX-SAMPLE( $i, \alpha, \delta$ ), that takes  $i \in [n]$  and  $\alpha, \delta \in (0, 1)$  as input, and reports a  $(1 \pm \alpha)$ -uniform sample from the set  $\text{NEQ}(\mathbf{A}, \mathbf{B}, i)$  with probability at least  $1 - \delta$ , and makes  $\mathcal{O}\left(\frac{\log^5 n}{\alpha^2} \log \frac{1}{\delta}\right)$  IP queries to both  $\mathbf{A}$  and  $\mathbf{B}$ .

Note that algorithm APPROX-SAMPLE( $\cdot, \cdot, \cdot$ ) calls repeatedly RESTRICT-DIST-BET-ROWS( $\cdot, \cdot, \cdot$ ). We now have all the ingredients – DIST-BET-ROWS( $i, \alpha, \delta$ ), DIST-SYMM-MATRIX-GUESS( $\mathbf{A}, \mathbf{B}, \varepsilon, T$ ), APPROX-SAMPLE( $i, \alpha, \delta$ ) – to design the final algorithm DIST-SYMM-MATRIX( $\mathbf{A}, \mathbf{B}, \varepsilon$ ).

### Overview of the algorithm

Algorithm  $\text{DIST-SYMM-MATRIX}(\cdot, \cdot, \cdot)$  calls  $\text{DIST-SYMM-MATRIX-GUESS}(\cdot, \cdot, \cdot, \cdot)$  with reduced value of guesses  $O(\log n)$  times to bring down the approximation error of matrix distance within limits. Algorithm  $\text{DIST-SYMM-MATRIX-GUESS}(\mathbf{A}, \mathbf{B}, \varepsilon, T)$  discussed in Lemma 2.2 mainly uses subroutines  $\text{DIST-BET-ROWS}(\cdot, \cdot, \cdot)$  and  $\text{APPROX-SAMPLE}(\cdot, \cdot, \cdot)$  in a nontrivial way. Both of these subroutines use Johnson-Lindenstrauss lemma.

Observe that  $\text{DIST-SYMM-MATRIX-GUESS}(\mathbf{A}, \mathbf{B}, \varepsilon, T)$  estimates  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  where the approximation guarantee is parameterized by  $T$ . By Observation 2.4, we have  $\mathbf{D}_M(\mathbf{A}, \mathbf{B}) = \sum_{i=1}^n \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$ , the sum of the distances among corresponding rows. To estimate  $\sum_{i=1}^n \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$ , our algorithm  $\text{DIST-SYMM-MATRIX-GUESS}(\mathbf{A}, \mathbf{B}, \varepsilon, T)$  considers a partition of the row indices  $[n]$  into buckets such that the row indices  $i$ 's in the same bucket have roughly the same  $\mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$  values. Now the problem boils down to estimating the sizes of the buckets. To do so,  $\text{DIST-SYMM-MATRIX-GUESS}(\mathbf{A}, \mathbf{B}, \varepsilon, T)$  finds a random sample  $\Gamma$  having  $\tilde{O}\left(n/\sqrt{T}\right)$  indices from  $[n]$ , calls  $\text{DIST-BET-ROWS}(i, \cdot, \cdot)$  for each of the sample in  $\Gamma$  and partitions  $\Gamma$  into buckets such that  $i$ 's in the same bucket have roughly the same  $\mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$  values. A *large* bucket is one that contains more than a fixed number of row indices. These steps ensure that the sizes of the *large* buckets are approximated well. Recall that  $\text{APPROX-SAMPLE}(i, \alpha, \delta)$  takes  $i \in [n]$  and  $\alpha, \delta \in (0, 1)$  as input, and reports a  $(1 \pm \alpha)$ -uniform sample from the set  $\text{NEQ}(\mathbf{A}, \mathbf{B}, i)$  with probability at least  $1 - \delta$ . To take care of the *small* buckets,  $\text{DIST-SYMM-MATRIX-GUESS}(\mathbf{A}, \mathbf{B}, \varepsilon, T)$  calls  $\text{APPROX-SAMPLE}(i, \cdot, \cdot)$  for *suitable* number of  $i$ 's chosen uniformly from each large bucket and decides whether the output indices of  $\text{APPROX-SAMPLE}(i, \cdot, \cdot)$  belong to large or small buckets. See the the following section for the technical description of our algorithm.

## 2.2 Proof of Lemma 2.2

Let us consider the following oracle that gives a probabilistic approximate estimate to the distance between the two corresponding rows of  $\mathbf{A}$  and  $\mathbf{B}$ ;  $\mathbf{A}$  and  $\mathbf{B}$  are two unknown  $n \times n$  matrices.

► **Definition 2.13** (Oracle function on the approximate distance between rows). Let  $\beta, \eta \in (0, 1)$ . Oracle  $\mathbb{O}_{\beta, \eta}$  is a function  $\mathbb{O}_{\beta, \eta} : [n] \rightarrow \mathbb{N}$ , which when queried with an  $i \in [n]$ , reports  $\mathbb{O}_{\beta, \eta}(i)$ . Moreover,

$$\mathbb{P}(\text{for every } i \in [n], \mathbb{O}_{\beta, \eta}(i) \text{ is a } (1 \pm \beta)\text{-approximation to } \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))) \geq 1 - \eta.$$

Take  $\beta = \varepsilon/50$  and  $\eta = 1/\text{poly}(n)$  and consider an oracle  $\mathbb{O}_{\beta, \eta}$  as defined above. Also, consider a partitioning of the indices in  $[n]$  into  $t = \Theta\left(\log_{\varepsilon/50} n\right)$  many buckets with respect to  $\mathbb{O}_{\beta, \eta}$  such that the  $i$ 's in the same bucket have *roughly* the same  $\mathbb{O}_{\beta, \eta}(i)$  values. Let  $Y_1, \dots, Y_t \subseteq [n]$  be the resulting buckets with respect to  $\mathbb{O}_{\beta, \eta}$ . Formally, for  $k \in [t]$ ,  $Y_k = \{i \in [n] : (1 + \frac{\varepsilon}{50})^{k-1} \leq \mathbb{O}_{\beta, \eta}(i) < (1 + \frac{\varepsilon}{50})^k\}$ . From the definition of  $\mathbb{O}_{\beta, \eta}$  and the way we are bucketing the elements of  $[n]$ , the following observation follows.

► **Observation 2.14** (Bucketing according to an oracle function). Let  $\beta = \varepsilon/50$  and  $\eta \in (0, 1)$ . Consider any oracle  $\mathbb{O}_{\beta, \eta} : [n] \rightarrow \mathbb{R}$  as defined in Definition 2.13. Let  $Y_1, \dots, Y_t$  be the buckets with respect to  $\mathbb{O}_{\beta, \eta}$ . Then

$$\left(1 - \frac{\varepsilon}{50}\right) \mathbf{D}_M(\mathbf{A}, \mathbf{B}) \leq \sum_{k=1}^t |Y_k| \left(1 + \frac{\varepsilon}{50}\right)^k \leq \left(1 + \frac{\varepsilon}{50}\right)^2 \mathbf{D}_M(\mathbf{A}, \mathbf{B})$$

holds with probability at least  $1 - \eta$ .

**Proof.** From Observation 2.4,  $\mathbf{D}_M(\mathbf{A}, \mathbf{B}) = \sum_{i=1}^n \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$ . So, by the definition of  $\mathbb{O}_{\beta, \eta}$  along with  $\beta = \varepsilon/50$ , we have

$$\mathbb{P} \left( \left(1 - \frac{\varepsilon}{50}\right) \mathbf{D}_M(\mathbf{A}, \mathbf{B}) \leq \sum_{i=1}^n \mathbb{O}_{\beta, \eta}(i) \leq \left(1 + \frac{\varepsilon}{50}\right) \mathbf{D}_M(\mathbf{A}, \mathbf{B}) \right) \geq 1 - \eta. \quad (2)$$

As  $Y_1, \dots, Y_t$  are the buckets with respect to  $\mathbb{O}_{\beta, \eta}$ , for  $k \in [t]$ ,  $Y_k = \{i \in [n] : (1 + \frac{\varepsilon}{50})^{k-1} \leq \mathbb{O}_{\beta, \eta}(i) < (1 + \frac{\varepsilon}{50})^k\}$ . So,

$$\sum_{i=1}^n \mathbb{O}_{\beta, \eta}(i) \leq \sum_{k=1}^t |Y_k| \left(1 + \frac{\varepsilon}{50}\right)^k \leq \left(1 + \frac{\varepsilon}{50}\right)^2 \sum_{i=1}^n \mathbb{O}_{\beta, \eta}(i) \quad (3)$$

From Equations 2 and 3, the following holds with probability at least  $1 - \eta$ .

$$\left(1 - \frac{\varepsilon}{50}\right) \mathbf{D}_M(\mathbf{A}, \mathbf{B}) \leq \sum_{k=1}^t |Y_k| \left(1 + \frac{\varepsilon}{50}\right)^k \leq \left(1 + \frac{\varepsilon}{50}\right)^2 \mathbf{D}_M(\mathbf{A}, \mathbf{B}). \quad \blacktriangleleft$$

The above observation roughly says that  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  can be estimated if we can approximate  $|Y_k|$ 's.

### The existence of the oracle

Before the description of the algorithm, we note that our algorithm does not need to know the specific oracle  $\mathbb{O}_{\beta, \eta} : [n] \rightarrow \mathbb{R}$ . The existence of some oracle function  $\mathbb{O}_{\beta, \eta} : [n] \rightarrow \mathbb{R}$  with respect to which  $[n]$  can be partitioned into buckets  $Y_1, \dots, Y_t$  suffices. Our algorithm calls  $\text{DIST-BET-ROWS}(i, \beta, \eta)$  for some  $i$ 's but at most once for each  $i \in [n]$ . Note that  $\text{DIST-BET-ROWS}(i, \beta, \eta)$  is the algorithm (as stated in Lemma 2.5) that returns a  $(1 \pm \beta)$ -approximation to  $\mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$  with probability at least  $1 - \eta$ . So, we can think of  $\mathbb{O}_{\beta, \eta} : [n] \rightarrow \mathbb{R}$  such that  $\mathbb{O}_{\beta, \eta}(i) = \hat{a}_i$ , where  $\hat{a}_i$  is the value returned by  $\text{DIST-BET-ROWS}(i, \beta, \eta)$ , if the algorithm  $\text{DIST-BET-ROWS}(i, \beta, \eta)$  is called (once). Otherwise,  $\mathbb{O}_{\beta, \eta}(i)$  is set to some  $(1 \pm \beta)$ -approximation to  $\mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$ <sup>3</sup>.

### Random sample and bucketing

As has been mentioned in the overview of algorithm in Section 2.1, the problem of estimating matrix distance boils down to estimating the sizes of the buckets  $Y_k$ ,  $k = 1, \dots, t$  and our subsequent action depends on whether the bucket is of *large* or *small* size. But as  $|Y_k|$ 's are unknown, we define a bucket  $Y_k$  to be *large* or *small* depending on the estimate  $|\widehat{Y}_k|$  obtained from a random sample. So, our algorithm starts by taking a random sample  $\Gamma \subseteq [n]$  with replacement, where  $|\Gamma| = \tilde{\mathcal{O}}(n/\sqrt{T})$ , where  $T$  is a guess for  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$ . Now,  $\widehat{Y}_k = Y_k \cap \Gamma$ , the projection of  $Y_k$  on  $\Gamma$ .

For each  $i$  in the random sample  $\Gamma$ , we call  $\text{DIST-BET-ROWS}(i, \beta, \eta)$  (as stated in Lemma 2.5) and let  $\hat{a}_i$  be the output. By Lemma 2.5, for each  $i \in \Gamma$ ,  $\hat{a}_i$  is a  $(1 \pm \frac{\varepsilon}{50})$ -approximation to  $\mathbf{D}_M(\mathbf{A}(i, *), \mathbf{B}(i, *))$  with high probability. Based on the values of  $\hat{a}_i$ 's, we partition the indices in  $\Gamma$  into  $t$  many buckets  $\widehat{Y}_1, \dots, \widehat{Y}_t$  such that  $i \in \Gamma$  is put into  $\widehat{Y}_k$  if and only if  $(1 + \frac{\varepsilon}{50})^{k-1} \leq \hat{a}_i < (1 + \frac{\varepsilon}{50})^k$ . We define a bucket  $Y_k$  to be large or small depending on  $|\widehat{Y}_k| \geq \tau$  or not, where  $\tau = \frac{|\Gamma| \sqrt{\varepsilon T}}{n \cdot 50t}$ .

<sup>3</sup> This instantiation, for  $\mathbb{O}_{\beta, \eta}(i)$ 's for which  $\text{DIST-BET-ROWS}(i, \beta, \eta)$ 's are never called is to complete the description of function  $\mathbb{O}_{\beta, \eta}$ . This has no bearing on our algorithm as well as its analysis.

## 44:10 Distance Between Matrices Using Sublinear Projections on Hamming Cube

So, if  $|Y_k|$  is *large* (roughly say at least  $\sqrt{\varepsilon T}/t$ ), then it can be well approximated from  $|\widehat{Y}_k|$ . However, it will not be possible to estimate  $|Y_k|$  from  $|\widehat{Y}_k|$  if  $|Y_k|$  is *small*. We explain how to take care of  $Y_k$ 's with *small*  $|Y_k|$ .

Let  $L \subseteq [t]$  and  $S \subseteq [t]$  denote the set of indices for large and small buckets, that is,  $L = \{k : Y_k \text{ is large}\}$  and  $S = [t] \setminus L$ . Also, let  $I_L \subseteq [n]$  and  $I_S \subseteq [n]$  denote the set of indices of rows present in large and small buckets, respectively. From Observation 2.4,  $\mathbf{D}_M(\mathbf{A}, \mathbf{B}) = \sum_{i=1}^n \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$ . Let us divide the sum  $\sum_{i=1}^n \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$  into two parts, based on  $I_L$  and  $I_S$ ,  $d_L$

$$d_L = \sum_{i \in I_L} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *)) = \sum_{k \in L} \sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$$

and  $d_S = \sum_{i \in I_S} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *)) = \sum_{k \in S} \sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$ .

That is,  $\mathbf{D}_M(\mathbf{A}, \mathbf{B}) = d_L + d_S$ . In what follows, we describe how our algorithm approximates  $d_L$  and  $d_S$  separately. A pseudocode for algorithm `DIST-SYMM-MATRIX-GUESS`( $\mathbf{A}, \mathbf{B}, \varepsilon, T$ ) can be found in the full version of this paper [13].

### Approximating $d_L$ , the contribution from *large* buckets

We can show in Lemma A.1 (i) and (ii), for each  $k \in L$ ,  $\frac{n}{|I|} |\widehat{Y}_k|$  is a  $(1 \pm \frac{\varepsilon}{50})$ -approximation to  $|Y_k|$  with high probability. Recall that  $d_L = \sum_{k \in L} \sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$ , where  $L$  denotes the set of indices present in large buckets. Our algorithm `DIST-SYMM-MATRIX-GUESS`( $\mathbf{A}, \mathbf{B}, \varepsilon, T$ ) sets  $\widehat{d}_L = \frac{n}{|I|} \sum_{k \in L} |\widehat{Y}_k| (1 + \frac{\varepsilon}{50})^k$  as an estimate for  $d_L$ . Putting everything together, we show in Lemma A.2 that the following holds with high probability.

$$\left(1 - \frac{\varepsilon}{50}\right) d_L \leq \widehat{d}_L \leq \left(1 + \frac{\varepsilon}{50}\right) d_L. \quad (4)$$

### Approximating $d_S$ , the contribution from *small* buckets

$d_S = \sum_{i \in I_S} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$  can not be approximated directly as in the case of  $d_L$ . To get around the problem of estimating the contribution of small buckets, we partition  $\sum_{i \in I_S} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$  into two parts by projecting row vectors  $\mathbf{A}(i, *)$ 's and  $\mathbf{B}(i, *)$ 's onto  $I_L$  and  $I_S$ :

$$d_{SL} = \sum_{i \in I_S} \mathbf{d}_H(\mathbf{A}(i, *)|_{I_L}, \mathbf{B}(i, *)|_{I_L}) \text{ and } d_{SS} = \sum_{i \in I_S} \mathbf{d}_H(\mathbf{A}(i, *)|_{I_S}, \mathbf{B}(i, *)|_{I_S}).$$

So,  $d_S = d_{SL} + d_{SS}$ .

As  $\mathbf{A}$  and  $\mathbf{B}$  are symmetric,  $d_{SL} = d_{LS} = \sum_{i \in I_L} \mathbf{d}_H(\mathbf{A}(i, *)|_{I_S}, \mathbf{B}(i, *)|_{I_S})$ . Hence,  $d_S = d_{LS} + d_{SS}$ . We approximate  $d_S$  by arguing that (i)  $d_{SS}$  is *small*, and (ii)  $d_{LS}$  can be approximated well. Informally speaking, the quantity  $d_{SL}$  is all about looking at the large buckets from the small buckets. But as handling small buckets is problematic as opposed to large buckets, we look at the small buckets from the large buckets. Now, as the matrix is symmetric, these two quantities are the same.

**(i)  $d_{SS}$  is small:** Observe that  $d_{SS}$  can be upper bounded, in terms of  $|I_S|$ , as follows:

$$d_{SS} = \sum_{i \in I_S} \mathbf{d}_H(\mathbf{A}(i, *)|_{I_S}, \mathbf{B}(i, *)|_{I_S}) = |\{(i, j) \in I_S \times I_S : \mathbf{A}(i, j) \neq \mathbf{B}(i, j)\}| \leq |I_S|^2.$$

By the definition of  $I_S$ , it is the set of indices present in small buckets ( $Y_k$ 's with  $|\widehat{Y}_k| \leq \tau$ ). With high probability, for any small bucket  $Y_k$ , we can show that  $|Y_k| \leq \sqrt{\varepsilon T}/40t$ . As there are  $t$  many buckets, with high probability,  $|I_S| = \sum_{k \in S} |Y_k| \leq \frac{n}{|\Gamma|} \tau t \leq \frac{\sqrt{\varepsilon T}}{40}$ . So, with high probability,

$$d_{SS} \leq \frac{\varepsilon T}{1600}. \quad (5)$$

The formal proof of the above equation will be given in Claim A.5.

(ii) **Approximating  $d_{LS}$ :** For  $k \in L$ , the set of indices corresponding to large buckets, let  $d_{LS}^k$  be the contribution of bucket  $Y_k$  to  $d_{LS}$ , that is,  $d_{LS}^k = \sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *)|_{I_S})$ . So,  $d_{LS} = \sum_{k \in L} d_{LS}^k$ , and  $d_{LS}$  can be approximated by approximating  $d_{LS}^k$  for each  $k \in L$ . To approximate  $d_{LS}^k$ , for each  $k \in L$ , we define  $\zeta_k = d_{LS}^k / (\sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *)))$ . We have already argued that  $d_{LS} = \sum_{k \in L} d_{LS}^k$  and recall that  $\sum_{k \in L} \sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *)) = d_L$ . So, intuitively,  $\zeta_k$  denotes the ratio of the contribution of bucket  $Y_k$  to  $d_{LS}$  and the contribution of bucket  $Y_k$  to  $d_L$ . By our bucketing scheme, for each  $i \in Y_k$ ,  $(1 - \frac{\varepsilon}{50})^{k-1} \leq \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *)) \leq (1 + \frac{\varepsilon}{50})^k$ , that is,  $\mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$ 's are roughly the same for each  $i \in Y_k$ . So, any  $d_{LS}^k$  can be approximated by approximating its corresponding  $\zeta_k$ . To do so, we express  $d_{LS}^k$  combinatorially as follows:

$$d_{LS}^k = |\{(i, j) : \mathbf{A}(i, j) \neq \mathbf{B}(i, j) \text{ such that } i \in Y_k \text{ and } j \in I_S\}|.$$

For each  $k \in L$ , our algorithm finds a sample  $Z_k$  of size  $|\widehat{Y}_k|$  many indices from  $\widehat{Y}_k$  with replacement. Then for each  $i \in Z_k$ , our algorithm calls  $\text{APPROX-SAMPLE}(i, \beta, \eta)$ . Recall that  $\text{APPROX-SAMPLE}(i, \beta, \eta)$  (as stated in Lemma 2.12) takes  $i \in [n]$  and  $\beta, \eta \in (0, 1)$  as inputs and returns a  $(1 \pm \beta)$ -uniform sample from the set  $\text{NEQ}(\mathbf{A}, \mathbf{B}, i)$  with probability at least  $1 - \eta$ . Let  $j \in [n]$  be the output of  $\text{NEQ}(\mathbf{A}, \mathbf{B}, i)$ . Then we check whether  $j \in I_S^4$ . Let  $C_k$  be the number of elements  $i \in Z_k$  whose corresponding call to  $\text{APPROX-SAMPLE}(i, \beta, \eta)$  returns a  $j$  with  $j \in I_S$ . Our algorithm takes  $\widehat{\zeta}_k = \frac{C_k}{|\widehat{Y}_k|}$  as an estimate for  $\zeta_k$ . We can show that, (in Lemma A.1 (i) and (ii)), for each  $k \in L$ ,  $\frac{n}{|\Gamma|} |\widehat{Y}_k|$  is a  $(1 \pm \frac{\varepsilon}{50})$ -approximation to  $Y_k$ . Also, when  $T$  is at least a suitable polynomial in  $\log n$  and  $\frac{1}{\varepsilon}$ , we show in Lemma A.1 (iii) and (iv) the followings, respectively:

- $\zeta_k \geq \frac{\varepsilon}{50}$ , then  $\widehat{\zeta}_k$  is a  $(1 \pm \frac{\varepsilon}{40})$ -approximation to  $\zeta_k$  with high probability,
- we show that if  $\zeta_k \leq \frac{\varepsilon}{50}$ , then  $\widehat{\zeta}_k \leq \frac{\varepsilon}{30}$  holds with high probability.

Hence,  $\widehat{d}_{LS} = \frac{n}{|\Gamma|} \sum_{k \in L} \widehat{\zeta}_k |\widehat{Y}_k| (1 + \frac{\varepsilon}{50})^k$  satisfies  $(1 - \frac{\varepsilon}{15}) d_{LS} - \frac{\varepsilon}{25} d_L \leq \widehat{d}_{LS} \leq (1 + \frac{\varepsilon}{15}) d_{LS} + \frac{\varepsilon}{25} d_L$  with high probability. Note that the additive factor in terms of  $d_L$  is due to the way  $\zeta_k$ 's are defined.

In fact our algorithm  $\text{DIST-SYMM-MATRIX-GUESS}(\mathbf{A}, \mathbf{B}, \varepsilon, T)$  sets  $\widehat{d}_S = \widehat{d}_{LS}$ . The intuition behind setting  $\widehat{d}_S = \widehat{d}_{LS}$  is that  $d_S = d_{LS} + d_{SS}$  and  $d_{SS}$  is small. So, with high probability,

$$\left(1 - \frac{\varepsilon}{15}\right) d_{LS} - \frac{\varepsilon}{25} d_L \leq \widehat{d}_S \leq \left(1 + \frac{\varepsilon}{15}\right) d_{LS} + \frac{\varepsilon}{25} d_L. \quad (6)$$

<sup>4</sup> The reason for checking  $j \in I_S$  can be observed from the definition of  $d_{LS}^k = |\{(i, j) : \mathbf{A}(i, j) \neq \mathbf{B}(i, j) \text{ such that } i \in Y_k \text{ and } j \in I_S\}|$ .

## 44:12 Distance Between Matrices Using Sublinear Projections on Hamming Cube

The above will be formally proved in Claim A.6. By Equations 6 and 5, we get  $\widehat{d}_S$  is an estimate for  $d_S$  that satisfies the following with high probability.

$$\left(1 - \frac{\varepsilon}{15}\right) d_S - \frac{\varepsilon T}{1600} - \frac{\varepsilon}{25} d_L \leq \widehat{d}_S \leq \left(1 + \frac{\varepsilon}{15}\right) d_S + \frac{\varepsilon}{25} d_L \quad (7)$$

We will formally show the above equation in Lemma A.3.

### Final output returned by our algorithm $\text{DIST-SYMM-MATRIX-GUESS}(\mathbf{A}, \mathbf{B}, \varepsilon, T)$

Finally, our algorithm returns  $\widehat{d} = \widehat{d}_L + \widehat{d}_S$  as an estimation for  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$ . Recall that  $\mathbf{D}_M(\mathbf{A}, \mathbf{B}) = d_S + d_L$ . From Equations 4 and 7,  $\widehat{d}$  satisfies, with high probability,

$$\left(1 - \frac{\varepsilon}{10}\right) \mathbf{D}_M(\mathbf{A}, \mathbf{B}) - \frac{\varepsilon}{1600} T \leq \widehat{d} \leq \left(1 + \frac{\varepsilon}{10}\right) \mathbf{D}_M(\mathbf{A}, \mathbf{B}).$$

### The query complexity analysis of algorithm $\text{DIST-SYMM-MATRIX-GUESS}(\mathbf{A}, \mathbf{B}, \varepsilon, T)$

Note that the discussed algorithm works when  $T$  is at least a suitable polynomial in  $\log n$  and  $1/\varepsilon$ . Moreover, the algorithm calls each of  $\text{DIST-BET-ROWS}(i, \beta, \eta)$  and  $\text{APPROX-SAMPLE}(i, \beta, \eta)$  for  $\widetilde{\mathcal{O}}\left(n/\sqrt{T}\right)$  times. Note that  $\beta = \varepsilon/50$  and  $\eta = 1/\text{poly}(n)$ . So, the number of IP queries, made by each call to  $\text{DIST-BET-ROWS}(i, \beta, \eta)$  as well as  $\text{APPROX-SAMPLE}(i, \beta, \eta)$ , is  $\widetilde{\mathcal{O}}(1)$  by Lemma 2.5 and 2.12. Hence, the number of IP queries made by our algorithm is  $\widetilde{\mathcal{O}}\left(n/\sqrt{T}\right)$ . The formal proof of the correctness of  $\text{DIST-SYMM-MATRIX-GUESS}(\mathbf{A}, \mathbf{B}, \varepsilon, T)$  is in Appendix A.

## 3 Distance between two arbitrary matrices

In this Section, we prove our main result (stated as Theorem 1.2 in Section 1).

► **Theorem 3.1** (Theorem 1.2 restated). *There exists an algorithm that has IP query access to unknown matrices  $\mathbf{A}$  and  $\mathbf{B}$ , takes an  $\varepsilon \in (0, 1)$  as an input, and returns a  $(1 \pm \varepsilon)$  approximation to  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  with high probability, and makes  $\mathcal{O}\left(\frac{n}{\sqrt{\mathbf{D}_M(\mathbf{A}, \mathbf{B})}} \text{poly}\left(\log n, \frac{1}{\varepsilon}\right)\right)$  queries.*

To prove the above theorem, we use Lemma 2.1 for estimating  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  when both  $\mathbf{A}$  and  $\mathbf{B}$  are symmetric. Let  $\Delta^{\mathbf{A}}$  be a matrix defined as  $\Delta^{\mathbf{A}}(i, j) = \mathbf{A}(i, j)$  if  $i \leq j$ , and  $\Delta^{\mathbf{A}}(i, j) = \mathbf{A}(j, i)$ , otherwise. Also, let  $\Delta_{\mathbf{A}}$  be a matrix defined as  $\Delta_{\mathbf{A}}(i, j) = \mathbf{A}(i, j)$  if  $i \geq j$ , and  $\Delta_{\mathbf{A}}(i, j) = \mathbf{A}(j, i)$ , otherwise. Similarly, we can also define  $\Delta^{\mathbf{B}}$  and  $\Delta_{\mathbf{B}}$  similarly. Observe that  $\Delta^{\mathbf{A}}, \Delta_{\mathbf{A}}, \Delta^{\mathbf{B}}$  and  $\Delta_{\mathbf{B}}$  are symmetric matrices, and

$$\mathbf{D}_M(\mathbf{A}, \mathbf{B}) = \frac{1}{2} [\mathbf{D}_M(\Delta_{\mathbf{A}}, \Delta_{\mathbf{B}}) + \mathbf{D}_M(\Delta^{\mathbf{A}}, \Delta^{\mathbf{B}})].$$

So, we can report a  $(1 \pm \varepsilon)$ -approximation to  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  by finding a  $(1 \pm \frac{\varepsilon}{2})$ -approximation to both  $\mathbf{D}_M(\Delta_{\mathbf{A}}, \Delta_{\mathbf{B}})$  and  $\mathbf{D}_M(\Delta^{\mathbf{A}}, \Delta^{\mathbf{B}})$  with high probability. This is possible, by Lemma 2.1, if we have IP query access to matrices  $\Delta_{\mathbf{A}}, \Delta_{\mathbf{B}}, \Delta^{\mathbf{A}}$  and  $\Delta^{\mathbf{B}}$ . But we do not have IP query access to  $\Delta_{\mathbf{A}}, \Delta_{\mathbf{B}}, \Delta^{\mathbf{A}}$  and  $\Delta^{\mathbf{B}}$  explicitly. However, we can simulate IP query access to matrices  $\Delta_{\mathbf{A}}$  and  $\Delta^{\mathbf{A}}$  ( $\Delta_{\mathbf{B}}$  and  $\Delta^{\mathbf{B}}$ ) with IP query access to matrix  $\mathbf{A}$  ( $\mathbf{B}$ ), respectively as stated and proved in the observation below. Hence, we are done with the proof of Theorem 3.1

► **Observation 3.2.** An IP query to matrix  $\Delta_{\mathbf{A}}$  ( $\Delta^{\mathbf{A}}$ ) can be answered by using two IP queries to matrix  $\mathbf{A}$ . Also, an IP query to  $\Delta_{\mathbf{B}}$  ( $\Delta^{\mathbf{B}}$ ) can be answered by using two IP queries to matrix  $\mathbf{B}$ .

**Proof.** We prove how an IP query to matrix  $\Delta_{\mathbf{A}}$  can be answered by using two IP queries to matrix  $\mathbf{A}$ . Other parts of the statement can be proved similarly.

Consider an IP query  $\langle \Delta_{\mathbf{A}}(i, *), \mathbf{r} \rangle$  to  $\Delta_{\mathbf{A}}$ , where  $i \in [n]$  and  $\mathbf{r} = (r_1, \dots, r_n) \in \mathbb{R}^n$ . Let  $\mathbf{r}^{\leq i}$  and  $\mathbf{r}^{> i}$  in  $\mathbb{R}^n$  be two vectors defined as follows:  $r_j^{\leq i} = r_j$  if  $j \leq i$ , and  $r_j^{\leq i} = 0$ , otherwise.  $r_j^{> i} = r_j$  if  $j > i$ , and  $r_j^{> i} = 0$ , otherwise. Now, we can deduce that

$$\begin{aligned} \langle \Delta_{\mathbf{A}}(i, *), \mathbf{r} \rangle &= \sum_{j=1}^i \Delta_{\mathbf{A}}(i, j) r_j + \sum_{j=i+1}^n \Delta_{\mathbf{A}}(i, j) r_j \\ &= \sum_{j=1}^i \mathbf{A}(i, j) r_j + \sum_{j=i+1}^n \mathbf{A}(j, i) r_j \\ &= \sum_{j=1}^n \mathbf{A}(i, j) r_j^{\leq i} + \sum_{j=1}^n \mathbf{A}(j, i) r_j^{> i} \\ &= \langle \mathbf{A}(i, *), \mathbf{r}^{\leq i} \rangle + \langle \mathbf{A}(*, i), \mathbf{r}^{> i} \rangle \end{aligned}$$

From the above expression, it is clear that an IP query of the form  $\langle \Delta_{\mathbf{A}}(i, *), \mathbf{r} \rangle$  to matrix  $\Delta_{\mathbf{A}}$  can be answered by making two IP queries of the form  $\langle \mathbf{A}(i, *), \mathbf{r}^{\leq i} \rangle$  and  $\langle \mathbf{A}(*, i), \mathbf{r}^{> i} \rangle$  to matrix  $\mathbf{A}$ . ◀

## 4 Lower bound results

In this Section, if we ignore polylogarithmic term, we show that (in Theorem 4.1) our algorithm to estimate  $\mathbf{D}_{\mathbf{M}}(\mathbf{A}, \mathbf{B})$  using IP query is tight. Apart from Theorem 4.1, we also prove that (in Theorem 4.2) the query complexity of estimating  $\mathbf{D}_{\mathbf{M}}(\mathbf{A}, \mathbf{B})$  using DEC-IP is quadratically larger than that of using IP. The results are formally stated as follows. The lower bounds hold even if the matrices  $\mathbf{A}$  and  $\mathbf{B}$  are symmetric matrices, and one matrix (say  $\mathbf{A}$ ) is known and one matrix (say  $\mathbf{B}$ ) is unknown.

► **Theorem 4.1.** *Let  $\mathbf{A}$  and  $\mathbf{B}$  denote the known and unknown (symmetric) matrices, respectively. Also let  $T \in \mathbb{N}$ . Any algorithm having IP query access to matrix  $\mathbf{B}$ , that distinguishes between  $\mathbf{D}_{\mathbf{M}}(\mathbf{A}, \mathbf{B}) = 0$  or  $\mathbf{D}_{\mathbf{M}}(\mathbf{A}, \mathbf{B}) \geq T$  with probability  $2/3$ , makes  $\Omega\left(\frac{n}{\sqrt{T}}\right)$  queries to  $\mathbf{B}$ .*

► **Theorem 4.2.** *Let  $\mathbf{A}$  and  $\mathbf{B}$  denote the known and unknown matrices, respectively. Also let  $T \in \mathbb{N}$ . Any algorithm having DEC-IP query access to matrix  $\mathbf{B}$ , that distinguishes between  $\mathbf{D}_{\mathbf{M}}(\mathbf{A}, \mathbf{B}) = 0$  or  $\mathbf{D}_{\mathbf{M}}(\mathbf{A}, \mathbf{B}) \geq T$  with probability  $2/3$ , makes  $\Omega\left(\frac{n^2}{T}\right)$  queries to  $\mathbf{B}$ .*

Recall that every ME query to a matrix can be simulated by using a DEC-IP. Hence, the following corollary follows.

► **Corollary 4.3.** *Let  $\mathbf{A}$  and  $\mathbf{B}$  denote the known and unknown matrices, respectively. Also let  $T \in \mathbb{N}$ . Any algorithm having ME query access to matrix  $\mathbf{B}$ , that distinguishes between  $\mathbf{D}_{\mathbf{M}}(\mathbf{A}, \mathbf{B}) = 0$  or  $\mathbf{D}_{\mathbf{M}}(\mathbf{A}, \mathbf{B}) \geq T$  with probability  $2/3$ , makes  $\Omega\left(\frac{n^2}{T}\right)$  queries to  $\mathbf{B}$ .*

We prove Theorems 4.1 and 4.2 by using a reduction from a problem known as DISJOINTNESS in two party communication complexity (See Appendix B).

#### 4.1 Proof of Theorem 4.1

Without loss of generality, assume that  $\sqrt{T}$  is an integer that divides  $N$ . We prove the (stated lower bound) by a reduction from  $\text{DISJOINTNESS}_N$  where  $N = n/\sqrt{T}$ . Let  $\mathbf{x}$  and  $\mathbf{y}$  in  $\{0, 1\}^N$  be the inputs of Alice and Bob, respectively. Now consider matrix  $\mathbf{B}$ , that depends on both  $\mathbf{x}$  and  $\mathbf{y}$ , described as follows.

$\mathbf{B}_{11}$	$\mathbf{B}_{12}$	$\mathbf{B}_{13}$
$\mathbf{B}_{21}$	$\mathbf{B}_{22}$	$\mathbf{B}_{23}$
$\mathbf{B}_{31}$	$\mathbf{B}_{32}$	$\mathbf{B}_{33}$

■ **Figure 1** A pictorial illustration of a block matrix  $\mathbf{B}$  considered in the proof of Theorem 4.2, where  $N = 3$ .

#### Description of matrices $\mathbf{A}$ and $\mathbf{B}$

- (i) matrix  $\mathbf{A}$  is the null matrix;
- (ii) matrix  $\mathbf{B}$  is a block diagonal matrix where  $\mathbf{B}_1, \dots, \mathbf{B}_N$  are diagonal blocks of order  $\sqrt{T} \times \sqrt{T}$  (See Figure 2 for an illustration);
- (iii) Consider  $k \in [N]$ . If  $x_k = y_k = 1$ , then  $\mathbf{B}_k(i, j) = 1$  for each  $i, j \in [\sqrt{T}]$ , that is,  $\mathbf{B}_k$  is an all-one matrix. Otherwise,  $\mathbf{B}_k$  is a null matrix.

From the description, matrices  $\mathbf{A}$  and  $\mathbf{B}$  are symmetric matrices. Moreover, if  $\mathbf{x}$  and  $\mathbf{y}$  are disjoint, then all of the  $N$  block matrices are null matrices, that is,  $\mathbf{B}$  is also a null matrix. If  $\mathbf{x}$  and  $\mathbf{y}$  are not disjoint, then there is a  $k \in [N]$  such that  $\mathbf{B}_k$  is an all-one matrix, that is, matrix  $\mathbf{B}$  has at least  $T$  many 1s. Recall that here  $\mathbf{A}$  is a null matrix. Hence,  $\mathbf{D}_M(\mathbf{A}, \mathbf{B}) = 0$  if  $\mathbf{x}$  and  $\mathbf{y}$  are disjoint, and  $\mathbf{D}_M(\mathbf{A}, \mathbf{B}) \geq T$  if  $\mathbf{x}$  and  $\mathbf{y}$  are not disjoint.

Observe that we will be done with the proof for the stated lower bound by arguing that Alice and Bob can generate the answer to any IP query, to matrix  $\mathbf{B}$ , with 2 bits of communication. Consider a row IP query  $\langle \mathbf{B}(i, *), \mathbf{r} \rangle$  to  $\mathbf{B}$  for some  $i \in [n]$  and  $\mathbf{r} \in \{0, 1\}^n$ <sup>5</sup>. From the construction of the matrix  $\mathbf{B}$ , there exists a matrix  $\mathbf{B}_j$ , for some  $j \in [N]$ , that completely determines  $\mathbf{B}(i, *)$ . Also, observe that,  $\mathbf{B}_j$  depends on  $x_j$  and  $y_j$  only. So, Alice and Bob can determine  $\mathbf{B}_j$  (hence  $\mathbf{B}(i, *)$ ) with 2 bits of communication. As  $\mathbf{B}$  is a symmetric matrix, there is no need to consider column IP queries as such queries can be answered by using row IP queries.

#### 4.2 Proof of Theorem 4.2

Here also, we assume that  $\sqrt{T}$  is an integer and  $\sqrt{T}$  divides  $N$ , and prove the stated lower bound by a reduction from  $\text{DISJOINTNESS}_N$  where  $N = n^2/T$ . Let  $\mathbf{x}$  and  $\mathbf{y}$  in  $\{0, 1\}^N$  be the inputs of Alice and Bob, respectively. Now consider matrix  $\mathbf{B}$ , that depends on both  $\mathbf{x}$  and  $\mathbf{y}$ , described as follows. In the following description, consider a canonical mapping  $\phi: [N] \rightarrow \left[ \frac{n}{\sqrt{T}} \right] \times \left[ \frac{n}{\sqrt{T}} \right]$ . Note that  $\phi$  is known to both Alice and Bob apriori.

<sup>5</sup> The proof goes through even if  $\mathbf{r} \in \mathbb{R}^n$ .

■ **Figure 2** A pictorial illustration of a block diagonal matrix  $B$  considered in the proof of Theorem 4.1, where  $N = 3$ .

### Description of matrices $\mathbf{A}$ and $\mathbf{B}$

- (i) matrix  $\mathbf{A}$  is an all 1 matrix;
- (ii) matrix  $\mathbf{B}$  is a block matrix where  $\mathbf{B}_{ij}$ 's  $\left(i, j \in \left[\frac{n}{\sqrt{T}}\right]\right)$  are blocks of order  $\sqrt{T} \times \sqrt{T}$  (See Figure 1 for an illustration);
- (iii) Consider  $k \in [N]$ . If  $x_k = y_k = 1$ , then  $\mathbf{B}_{\phi(k)} = 0$ <sup>6</sup> for each  $i, j \in [\sqrt{T}]$ , that is,  $\mathbf{B}_{\phi(k)}$  is an all 0 matrix. Otherwise,  $\mathbf{B}_{\phi(k)}$  is an all 1 matrix.

From the description, matrices  $\mathbf{A}$  and  $\mathbf{B}$  are symmetric matrices. Moreover, if  $\mathbf{x}$  and  $\mathbf{y}$  are disjoint, then all of the  $N$  block matrices are all 1 matrices, that is,  $\mathbf{B}$  is also an all 1 matrix. If  $\mathbf{x}$  and  $\mathbf{y}$  are not disjoint, then there is (exactly) one  $k \in [N]$  such that  $\mathbf{B}_k$  is a null matrix, that is, matrix  $\mathbf{B}$  has exactly  $T$  many 0s. Recall that here  $\mathbf{A}$  is a null matrix. Hence,  $\mathbf{D}_M(\mathbf{A}, \mathbf{B}) = 0$  if  $\mathbf{x}$  and  $\mathbf{y}$  are disjoint, and,  $\mathbf{D}_M(\mathbf{A}, \mathbf{B}) = T$  if  $\mathbf{x}$  and  $\mathbf{y}$  are not disjoint.

Observe that we will be done with the proof for the stated lower bound by arguing that Alice and Bob can generate the answer to any DEC-IP query, to matrix  $\mathbf{B}$ , with 2 bits of communication. Consider a row DEC-IP query  $\langle \mathbf{B}(i, *), \mathbf{r} \rangle$  to  $\mathbf{B}$  for some  $i \in [n]$  and  $\mathbf{r} \in \{0, 1\}^n$ . Without loss of generality, assume that  $\mathbf{r}$  is not a null matrix, as in this case Alice and Bob can decide  $\langle \mathbf{B}(i, *), \mathbf{r} \rangle = 0$  trivially without any communication. Consider a partition of  $\mathbf{r}$  into  $N/\sqrt{T}$  subvectors  $\mathbf{r}_1, \dots, \mathbf{r}_{n/\sqrt{T}} \in \{0, 1\}^{\sqrt{T}}$  in the natural way (See Figure 1 for an illustration). Now we analyze by making two cases. If two of the  $\mathbf{r}_j$ s are not null vectors, from the construction of the matrix  $\mathbf{B}$ , then  $\langle \mathbf{B}(i, *), \mathbf{r} \rangle > 0$ . So, in this case, Alice and Bob report  $\langle \mathbf{B}(i, *), \mathbf{r} \rangle \neq 0$  without any communication between them. Now consider the case when exactly one of the  $\mathbf{r}_j$  is not a null vector. Once again, from the construction of  $\mathbf{B}$ , deciding whether  $\langle \mathbf{B}(i, *), \mathbf{r} \rangle = 0$  is equivalent to deciding whether a particular block (say  $\mathbf{B}_{xy}$ ) is a null matrix. It is because  $\mathbf{r}$  is not a null vector, and each block in  $\mathbf{B}$  is either a null matrix or an all 1 matrix. Let  $k \in \left[\frac{n}{\sqrt{T}}\right]$  be such that  $\phi(k) = (x, y)$ . Note that  $\mathbf{B}_{xy}$  is a null matrix if and only if  $x_k = y_k = 1$ . So, Alice and Bob can determine whether  $\langle \mathbf{B}(i, *), \mathbf{r} \rangle = 0$  with 2 bits of communication. As  $\mathbf{B}$  is a symmetric matrix, there is no need to consider column DEC-IP queries as such queries can be answered by using row IP queries.

<sup>6</sup> Here we abuse the notation slightly. If  $\phi(k) = (i, j)$ , we denote  $\mathbf{B}_{ij}$  by  $\mathbf{B}_{\phi(k)}$ .

## 5 Conclusion

Recall that in an IP as well as in DEC-IP queries, a vector  $\mathbf{v} \in \{0, 1\}^n$  is given as input along with an index for row or column of an unknown matrix. Let  $\text{IP}_{\mathbb{R}}$  and  $\text{DEC-IP}_{\mathbb{R}}$  be the extension of IP and DEC-IP when  $\mathbf{v}$  is a vector in  $\mathbb{R}^n$ . Now let us have a look into Table 1. The lower bound of  $\Omega(n/\sqrt{D})$ , on the number of IP queries to estimate  $D = \mathbf{D}_M(\mathbf{A}, \mathbf{B})$ , also holds even when we have an access to  $\text{IP}_{\mathbb{R}}$  oracle. This also implies a lower bound of  $\Omega(n/\sqrt{D})$  on the number of DEC-IP queries to solve the problem at hand. But our lower bound proof of  $\Omega(n^2/D)$  on the number of DEC-IP queries does not work when we have access to  $\text{IP}_{\mathbb{R}}$  oracle. So, we leave the following problem as open.

### Open problem

What is the query complexity of estimating  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  when we have  $\text{DEC-IP}_{\mathbb{R}}$  access to matrices  $\mathbf{A}$  and  $\mathbf{B}$ ?

---

**A Formal correctness proof of  $\text{DIST-SYMM-MATRIX-GUESS}(\mathbf{A}, \mathbf{B}, \varepsilon, T)$** 

From the above discussion, we need to only prove for the case when  $T$  is at least a suitable polynomial in  $\log n$  and  $\frac{1}{\varepsilon}$ . The proof (of correctness) is based on the following lemma that can be proved by mainly using Chernoff bound (See Appendix C) and some specific details of the algorithm.

► **Lemma A.1** (Intermediate Lemma needed to prove the correctness). *Let  $\varepsilon \in (0, \frac{1}{2})$ ,  $\beta = \frac{\varepsilon}{50}$  and  $\eta = \frac{1}{\text{poly}(n)}$ . Consider an oracle  $\mathbb{O}_{\beta, \eta} : [n] \rightarrow \mathbb{R}$ , as defined in Definition 2.13, with respect to which algorithm  $\text{DIST-SYMM-MATRIX-GUESS}(\mathbf{A}, \mathbf{B}, \varepsilon, T)$  found  $\widehat{Y}_1, \dots, \widehat{Y}_t \subseteq \Gamma$ . Let  $Y_1, \dots, Y_t$  be the buckets into which  $[n]$  is partitioned w.r.t.  $\mathbb{O}_{\beta, \eta}$ . Then, for  $k \in [t]$ ,*

- (i) *if  $|Y_k| \geq \frac{\sqrt{\varepsilon T}}{50t}$ , then  $\mathbb{P}\left(\left|\frac{n}{|\Gamma|}|\widehat{Y}_k| - |Y_k|\right| \geq \frac{\varepsilon}{50}|Y_k|\right) \leq \frac{1}{\text{poly}(n)}$ ;*
- (ii) *if  $|Y_k| \leq \frac{\sqrt{\varepsilon T}}{50t}$ , then  $\mathbb{P}\left(\frac{n}{|\Gamma|}|\widehat{Y}_k| \geq \frac{\sqrt{\varepsilon T}}{40t}\right) \leq \frac{1}{\text{poly}(n)}$ ;*
- (iii) *if  $\zeta_k \geq \frac{\varepsilon}{50}$ , then  $\mathbb{P}\left(\left|\widehat{\zeta}_k - \zeta_k\right| \geq \frac{\varepsilon}{40}\zeta_k\right) \leq \frac{1}{\text{poly}(n)}$ ;*
- (iv) *if  $\zeta_k \leq \frac{\varepsilon}{50}$ , then  $\mathbb{P}\left(\widehat{\zeta}_k \geq \frac{\varepsilon}{30}\right) \leq \frac{1}{\text{poly}(n)}$ .*

The proof of the above lemma is presented in the full version of this paper [13]. Here, we prove the correctness of algorithm  $\text{DIST-SYMM-MATRIX}(\mathbf{A}, \mathbf{B}, \varepsilon, T)$  via two claims stated below.

► **Lemma A.2** (Approximating  $d_L$ ).  $(1 - \frac{\varepsilon}{50})d_L \leq \widehat{d}_L \leq (1 + \frac{\varepsilon}{50})d_L$  with high probability.

► **Lemma A.3** (Approximating  $d_S$ ).  $(1 - \frac{\varepsilon}{15})d_S - \frac{\varepsilon T}{1600} - \frac{\varepsilon}{25}d_L \leq \widehat{d}_S \leq (1 + \frac{\varepsilon}{15})d_S + \frac{\varepsilon}{25}d_L$ . holds with high probability.

Recall that  $\mathbf{D}_M(\mathbf{A}, \mathbf{B}) = d_L + d_S$ . Assuming that the above two claims hold,  $\widehat{d} = \widehat{d}_L + \widehat{d}_S$  satisfies  $(1 - \frac{\varepsilon}{10})\mathbf{D}_M(\mathbf{A}, \mathbf{B}) - \frac{\varepsilon}{1600}T \leq \widehat{d} \leq (1 + \frac{\varepsilon}{10})\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  with high probability. Note that  $\widehat{d}$  satisfies the requirement for an estimate of  $\mathbf{D}_M(\mathbf{A}, \mathbf{B})$  as stated in Lemma 2.2. Now, it remains to show Lemma A.2 and A.3. We first prove the following claim that follows from our bucketing scheme and will be used in the proofs of Lemma A.2 and A.3. The following claim establishes the connection between the size of a bucket with the sum of the distances between rows (with indices in the same bucket) of matrices  $\mathbf{A}$  and  $\mathbf{B}$ .

► **Claim A.4.**  $\forall k \in [t]$ ,

$$\sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *)) \leq |Y_k| \left(1 + \frac{\varepsilon}{50}\right)^k \leq \left(1 + \frac{\varepsilon}{50}\right) \sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, )),$$

holds with probability at least  $1 - \frac{1}{\text{poly}(n)}$ .

Proof.  $Y_1, \dots, Y_t \subseteq [n]$  be the buckets into which  $[n]$  is partitioned, where

$$Y_k = \{i \in [n] : \left(1 + \frac{\varepsilon}{50}\right)^{k-1} \leq \mathbb{O}_{\beta, \eta}(i) < \left(1 + \frac{\varepsilon}{50}\right)^k\}.$$

So,

$$\text{For each } k \in [t], \sum_{i \in Y_k} \mathbb{O}_{\beta, \eta}(i) \leq |Y_k| \left(1 + \frac{\varepsilon}{50}\right)^k \leq \left(1 + \frac{\varepsilon}{50}\right) \sum_{i \in Y_k} \mathbb{O}_{\beta, \eta}(i) \quad (8)$$

Here  $\beta = \frac{\varepsilon}{50}$  and  $\eta = \frac{1}{\text{poly}(n)}$ .

Oracle  $\mathbb{O}_{\beta, \eta} : [n] \rightarrow \mathbb{R}$  is a function, as defined in Definition 2.13, such that  $\mathbb{O}_{\beta, \eta}(i)$  equals to  $\widehat{a}_i$ , the value returned by  $\text{DIST-BET-ROWS}(i, \beta, \eta)$ , if the algorithm

$\text{DIST-BET-ROWS}(i, \beta, \eta)$  is called (once). Otherwise,  $\mathbb{O}_{\beta, \eta}(i)$  is set to some  $(1 \pm \beta)$ -approximation to  $\mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$ . So, Equation 8 implies that the following holds with probability at least  $1 - \frac{1}{\text{poly}(n)}$ .

$$\forall k \in [t], \sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *)) \leq |Y_k| \left(1 + \frac{\varepsilon}{50}\right)^k \leq \left(1 + \frac{\varepsilon}{50}\right) \sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *)). \blacktriangleleft$$

Now we will show Lemma A.2.

**Proof of Lemma A.2.** Note that  $d_L = \sum_{i \in I_L} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$  and  $\widehat{d}_L = \frac{n}{|\Gamma|} \sum_{k \in L} |\widehat{Y}_k| \left(1 + \frac{\varepsilon}{50}\right)^k$ .

By the definition of  $d_L$  as well as Claim A.4, we get

$$\mathbb{P}\left(d_L \leq \sum_{k \in L} |Y_k| \left(1 + \frac{\varepsilon}{50}\right)^k \leq \left(1 + \frac{\varepsilon}{50}\right) d_L\right) \geq 1 - \frac{1}{\text{poly}(n)}. \quad (9)$$

Recall that, for  $k \in [t]$  in the set  $L$  of large buckets,  $\widehat{Y}_k \geq \tau$ . Here  $\tau = \frac{|\Gamma|}{n} \frac{\sqrt{\varepsilon T}}{40t}$ . By Lemma A.1 (ii) and (i), for each  $k \in L$ ,  $\frac{n}{|\Gamma|} |\widehat{Y}_k|$  is an  $(1 \pm \frac{\varepsilon}{50})$ -approximation to  $|Y_k|$  with probability at least  $1 - \frac{1}{\text{poly}(n)}$ . So, the following holds with probability at least  $1 - \frac{1}{\text{poly}(n)}$ .

$$\left(1 - \frac{\varepsilon}{50}\right) d_L \leq \frac{n}{|\Gamma|} \sum_{k \in L} |\widehat{Y}_k| \left(1 + \frac{\varepsilon}{50}\right)^k \leq \left(1 + \frac{\varepsilon}{50}\right)^2 d_L \quad (10)$$

By the definition of  $\widehat{d}_L$  along with taking  $\varepsilon \in (0, \frac{1}{2})$ , we conclude that

$$\mathbb{P}\left(\left(1 - \frac{\varepsilon}{20}\right) d_L \leq \widehat{d}_L \leq \left(1 + \frac{\varepsilon}{20}\right) d_L\right) \geq 1 - \frac{1}{\text{poly}(n)}. \quad \blacktriangleleft$$

**Proof of Lemma A.3.** Recall that  $d_S = \sum_{i \in I_S} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$  and  $\widehat{d}_S = \frac{n}{|\Gamma|} \sum_{k \in L} \widehat{\zeta}_k \left(1 + \frac{\varepsilon}{50}\right)^k$ . Moreover,  $d_S = d_{SL} + d_{SS}$ , where

$$d_{SL} = \sum_{i \in I_S} \mathbf{d}_H(\mathbf{A}(i, *)|_{I_L}, \mathbf{B}(i, *)|_{I_L}) \text{ and } d_{SS} = \sum_{i \in I_S} \mathbf{d}_H(\mathbf{A}(i, *)|_{I_S}, \mathbf{B}(i, *)|_{I_S}).$$

Also, as  $\mathbf{A}$  and  $\mathbf{B}$  are symmetric matrices,  $d_{SL} = d_{LS} = \sum_{i \in I_L} \mathbf{d}_H(\mathbf{A}(i, *)|_{I_S}, \mathbf{B}(i, *)|_{I_S})$ .

First we show that

► **Claim A.5.**  $\mathbb{P}(d_{SS} \leq \frac{\varepsilon T}{1600}) \geq 1 - \frac{1}{\text{poly}(n)}$ .

Then we show that

► **Claim A.6.**  $\mathbb{P}\left(\left(1 - \frac{\varepsilon}{15}\right) d_{LS} - \frac{\varepsilon}{25} d_L \leq \widehat{d}_S \leq \left(1 + \frac{\varepsilon}{15}\right) d_{LS} + \frac{\varepsilon}{25} d_L\right) \geq 1 - \frac{1}{\text{poly}(n)}$ .

As  $d_S = d_{SS} + d_{LS}$ , the above two claims imply the Lemma, that is, the following holds with probability at least  $1 - \frac{1}{\text{poly}(n)}$ .

$$\left(1 - \frac{\varepsilon}{15}\right) d_S - \frac{\varepsilon T}{1600} - \frac{\varepsilon}{25} d_L \leq \widehat{d}_S \leq \left(1 + \frac{\varepsilon}{15}\right) d_S + \frac{\varepsilon}{25} d_L.$$

So, it remains to show Claims A.5 and A.6.

## 44:20 Distance Between Matrices Using Sublinear Projections on Hamming Cube

Proof of Claim A.5. Note that

$$d_{SS} = \sum_{i \in I_S} \mathbf{d}_H(\mathbf{A}(i, *)|_{I_S}, \mathbf{B}(i, *)|_{I_S}) = |\{(i, j) \in I_S \times I_S : \mathbf{A}(i, j) \neq \mathbf{B}(i, j)\}|,$$

where  $I_S$  denotes the set of indices in the  $Y_k$ 's with  $k \in S$  and  $S$  is the set of small buckets. So,  $|I_S| = \sum_{k \in S} |Y_k|$ . By the definition of  $S$ , for every  $k \in S$ ,  $|\widehat{Y}_k| < \tau = \frac{|\Gamma|}{n} \frac{\sqrt{\varepsilon T}}{50t}$ . By Lemma A.1

(i), we have  $|Y_k| \leq (1 + \frac{\varepsilon}{50}) \frac{n}{|\Gamma|} |\widehat{Y}_k| \leq \frac{\sqrt{\varepsilon T}}{40t}$  with probability at least  $1 - \frac{1}{\text{poly}(n)}$ . This implies that  $|I_S| = \sum_{k \in S} |Y_k| \leq \frac{\sqrt{\varepsilon T}}{40}$  with probability at least  $1 - \frac{1}{\text{poly}(n)}$ . Hence, by the definition of  $d_{SS}$ , we have the following with probability at least  $1 - \frac{1}{\text{poly}(n)}$ .

$$d_{SS} = \sum_{i \in I_S} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *)) \leq |I_S|^2 \leq \frac{\varepsilon T}{1600}. \quad \blacktriangleleft$$

Proof of Claim A.6. Note that  $d_{LS} = \sum_{i \in I_L} \mathbf{d}_H(\mathbf{A}(i, *)|_{I_S}, \mathbf{B}(i, *)|_{I_S})$ . Recall that  $d_{LS} = \sum_{k \in L} d_{LS}^k$ , where  $d_{LS}^k = \sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *)|_{I_S}, \mathbf{B}(i, *)|_{I_S})$ . Also, recall that  $\zeta_k = \frac{d_{LS}^k}{\sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))}$ . So,  $d_{LS}^k = \zeta_k \sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *))$ . Hence,

$$d_{LS} = \sum_{k \in L} \zeta_k \sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *)). \quad (11)$$

By Claim A.4, the following holds with probability at least  $1 - \frac{1}{\text{poly}(n)}$ .

$$\forall k \in [t], \zeta_k \sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *)) \leq \zeta_k |Y_k| \left(1 + \frac{\varepsilon}{50}\right)^k \leq \zeta_k \left(1 + \frac{\varepsilon}{50}\right) \sum_{i \in Y_k} \mathbf{d}_H(\mathbf{A}(i, *), \mathbf{B}(i, *)).$$

Taking sum over all  $k \in L$  and then applying Equation 11, the following holds with probability at least  $1 - \frac{1}{\text{poly}(n)}$ .

$$\mathbb{P}\left(d_{LS} \leq \sum_{k \in L} \zeta_k |Y_k| \left(1 + \frac{\varepsilon}{50}\right)^k \leq \left(1 + \frac{\varepsilon}{50}\right) d_{LS}\right) \geq 1 - \frac{1}{\text{poly}(n)}.$$

Recall that, for  $k \in [t]$  in the set  $L$  of large buckets,  $|\widehat{Y}_k| \geq \tau$ . Here  $\tau = \frac{|\Gamma|}{n} \frac{\sqrt{\varepsilon T}}{40t}$ . By Lemma A.1 (ii) and (i), for each  $k \in L$ ,  $\frac{n}{|\Gamma|} |\widehat{Y}_k|$  is a  $(1 \pm \frac{\varepsilon}{50})$ -approximation to  $|Y_k|$  with probability at least  $1 - \frac{1}{\text{poly}(n)}$ . So,

$$\mathbb{P}\left(\left(1 - \frac{\varepsilon}{50}\right) d_{LS} \leq \frac{n}{|\Gamma|} \sum_{k \in L} \zeta_k |\widehat{Y}_k| \left(1 + \frac{\varepsilon}{50}\right)^k \leq \left(1 + \frac{\varepsilon}{50}\right)^2 d_{LS}\right) \geq 1 - \frac{1}{\text{poly}(n)}. \quad (12)$$

Having the above equation, consider  $\widehat{d}_S = \frac{n}{|\Gamma|} \sum_{k \in L} \widehat{\zeta}_k |\widehat{Y}_k| \left(1 + \frac{\varepsilon}{50}\right)^k$  whose upper and lower bound is to be proved as stated in Claim A.6. Breaking the sum into two parts depending the values of  $\widehat{\zeta}_k$ 's, we have

$$\widehat{d}_S = \frac{n}{|\Gamma|} \sum_{k \in L: \widehat{\zeta}_k \geq \frac{\varepsilon}{50}} \widehat{\zeta}_k |\widehat{Y}_k| \left(1 + \frac{\varepsilon}{50}\right)^k + \frac{n}{|\Gamma|} \sum_{k \in L: \widehat{\zeta}_k < \frac{\varepsilon}{50}} \widehat{\zeta}_k |\widehat{Y}_k| \left(1 + \frac{\varepsilon}{50}\right)^k. \quad (13)$$

We prove the desired upper and lower bound on  $\widehat{d}_S$  separately by using the following observation about upper and lower bounds of the two terms in Equation 13.

► **Observation A.7.**

- (i)  $\frac{n}{|\Gamma|} \sum_{k \in L: \zeta_k \geq \frac{\varepsilon}{50}} \widehat{\zeta}_k \left| \widehat{Y}_k \right| \left(1 + \frac{\varepsilon}{50}\right)^k \leq \left(1 + \frac{\varepsilon}{15}\right) d_{LS}$  with probability  $1 - \frac{1}{\text{poly}(n)}$ .
- (ii)  $\frac{n}{|\Gamma|} \sum_{k \in L: \zeta_k < \frac{\varepsilon}{50}} \widehat{\zeta}_k \left| \widehat{Y}_k \right| \left(1 + \frac{\varepsilon}{25}\right)^k \leq \frac{\varepsilon}{35} d_L$  with probability at least  $1 - \frac{1}{\text{poly}(n)}$ .
- (iii)  $\frac{n}{|\Gamma|} \sum_{k \in L: \zeta_k \geq \frac{\varepsilon}{50}} \widehat{\zeta}_k \left| \widehat{Y}_k \right| \left(1 + \frac{\varepsilon}{50}\right)^k \geq \left(1 - \frac{\varepsilon}{15}\right) d_{LS} - \frac{\varepsilon}{25} d_L$  with probability  $1 - \frac{1}{\text{poly}(n)}$ .

**Proof.**

- (i) By Lemma A.1 (iii), for each  $k \in [t]$  with  $\zeta_k \geq \frac{\varepsilon}{50}$ ,  $\widehat{\zeta}_k$  is a  $(1 \pm \frac{\varepsilon}{40})$ -approximation to  $\zeta_k$  with probability at least  $1 - \frac{1}{\text{poly}(n)}$ . So, with probability at least  $1 - \frac{1}{\text{poly}(n)}$ , we can derive the following.

$$\begin{aligned} \frac{n}{|\Gamma|} \sum_{k \in L: \zeta_k \geq \frac{\varepsilon}{50}} \widehat{\zeta}_k \left| \widehat{Y}_k \right| \left(1 + \frac{\varepsilon}{40}\right)^k &\leq \left(1 + \frac{\varepsilon}{40}\right) \frac{n}{|\Gamma|} \sum_{k \in L: \zeta_k \geq \frac{\varepsilon}{50}} \zeta_k \left| \widehat{Y}_k \right| \left(1 + \frac{\varepsilon}{50}\right)^k \\ &\leq \left(1 + \frac{\varepsilon}{40}\right) \left(1 + \frac{\varepsilon}{50}\right)^2 d_{LS} \quad (\because \text{By Equation 12}) \\ &\leq \left(1 + \frac{\varepsilon}{15}\right) d_{LS}. \end{aligned}$$

- (ii) By Lemma A.1 (iv), for each  $k \in [t]$  with  $\zeta_k < \frac{\varepsilon}{50}$ ,  $\widehat{\zeta}_k$  is at most  $\frac{\varepsilon}{30}$  with probability at least  $1 - \frac{1}{\text{poly}(n)}$ . Hence, the following derivations hold with probability  $1 - \frac{1}{\text{poly}(n)}$ .

$$\begin{aligned} \frac{n}{|\Gamma|} \sum_{k \in L: \zeta_k \geq \frac{\varepsilon}{50}} \zeta_k \left| \widehat{Y}_k \right| \left(1 + \frac{\varepsilon}{50}\right)^k &\leq \frac{\varepsilon}{30} \cdot \frac{n}{|\Gamma|} \sum_{k \in L: \zeta_k < \frac{\varepsilon}{50}} \left| \widehat{Y}_k \right| \left(1 + \frac{\varepsilon}{50}\right)^k \\ &\leq \frac{\varepsilon}{30} \cdot \frac{n}{|\Gamma|} \sum_{k \in L} \left| \widehat{Y}_k \right| \left(1 + \frac{\varepsilon}{50}\right)^k \\ &\leq \frac{\varepsilon}{30} \left(1 + \frac{\varepsilon}{50}\right)^2 d_L \quad (\text{By Equation 10}) \\ &\leq \frac{\varepsilon}{25} d_L \end{aligned}$$

- (iii) Note that

$$\frac{n}{|\Gamma|} \sum_{k \in L: \zeta_k \geq \frac{\varepsilon}{50}} \widehat{\zeta}_k \left| \widehat{Y}_k \right| \left(1 + \frac{\varepsilon}{50}\right)^k \geq \frac{n}{|\Gamma|} \sum_{k \in L} \widehat{\zeta}_k \left| \widehat{Y}_k \right| \left(1 + \frac{\varepsilon}{50}\right)^k - \frac{n}{|\Gamma|} \sum_{k \in L: \zeta_k < \frac{\varepsilon}{50}} \widehat{\zeta}_k \left| \widehat{Y}_k \right| \left(1 + \frac{\varepsilon}{50}\right)^k.$$

By Lemma A.1 (iii), for each  $k \in [t]$  with  $\zeta_k \geq \frac{\varepsilon}{50}$ ,  $\widehat{\zeta}_k$  is a  $(1 \pm \frac{\varepsilon}{40})$ -approximation to  $\zeta_k$  with probability at least  $1 - \frac{1}{\text{poly}(n)}$ . Also, by Observation A.7 (iii),

$\frac{n}{|\Gamma|} \sum_{k \in L: \zeta_k \leq \frac{\varepsilon}{50}} \widehat{\zeta}_k \left| \widehat{Y}_k \right| \left(1 + \frac{\varepsilon}{50}\right)^k \leq \frac{\varepsilon}{25} d_L$  with probability at least  $1 - \frac{1}{\text{poly}(n)}$ . So, we can derive the following with probability at least  $1 - \frac{1}{\text{poly}(n)}$ .

$$\begin{aligned} \frac{n}{|\Gamma|} \sum_{k \in L: \zeta_k \geq \frac{\varepsilon}{50}} \widehat{\zeta}_k \left| \widehat{Y}_k \right| \left(1 + \frac{\varepsilon}{50}\right)^k &\geq \left(1 - \frac{\varepsilon}{40}\right) \frac{n}{|\Gamma|} \sum_{k \in L} \zeta_k \left| \widehat{Y}_k \right| \left(1 + \frac{\varepsilon}{50}\right)^k - \frac{\varepsilon}{25} d_L \\ &\geq \left(1 - \frac{\varepsilon}{40}\right)^2 d_{LS} - \frac{\varepsilon}{25} d_L \quad (\text{By Equation 12}) \\ &\geq \left(1 - \frac{\varepsilon}{15}\right) d_{LS} - \frac{\varepsilon}{25} d_L. \quad \blacktriangleleft \end{aligned}$$

Considering the expression for  $\widehat{d}_S$  in Equation 13 along with Observation A.7 (i) and (ii), we can derive the desired upper bound on  $\widehat{d}_S$  (as follows) that holds with probability at least  $1 - \frac{1}{\text{poly}(n)}$ .

$$\widehat{d}_S \leq \left(1 + \frac{\varepsilon}{15}\right) d_{LS} + \frac{\varepsilon}{25} d_L.$$

## 44:22 Distance Between Matrices Using Sublinear Projections on Hamming Cube

For the lower bound part of  $\widehat{d}_S$ , again consider the expression for  $\widehat{d}_S$  in Equation 13 along with Observation A.7 (iii). We have the following with probability at least  $1 - \frac{1}{\text{poly}(n)}$ .

$$\widehat{d}_S \geq \left(1 - \frac{\varepsilon}{15}\right) d_{LS} - \frac{\varepsilon}{25} d_L. \quad \triangleleft$$

### B Communication complexity

In two-party communication complexity there are two parties, Alice and Bob, that wish to compute a function  $\Pi : \{0, 1\}^N \times \{0, 1\}^N \rightarrow \{0, 1\}$ . Alice is given  $\mathbf{x} \in \{0, 1\}^N$  and Bob is given  $\mathbf{y} \in \{0, 1\}^N$ . Let  $x_i$  ( $y_i$ ) denote the  $i$ -th bit of  $\mathbf{x}$  ( $\mathbf{y}$ ). While the parties know the function  $\Pi$ , Alice does not know  $\mathbf{y}$ , and similarly, Bob does not know  $\mathbf{x}$ . Thus they communicate bits following a pre-decided protocol  $\mathcal{P}$  in order to compute  $\Pi(\mathbf{x}, \mathbf{y})$ . We say a randomized protocol  $\mathcal{P}$  computes  $\Pi$  if for all  $(\mathbf{x}, \mathbf{y}) \in \{0, 1\}^N \times \{0, 1\}^N$  we have  $\mathbb{P}[\mathcal{P}(\mathbf{x}, \mathbf{y}) = \Pi(\mathbf{x}, \mathbf{y})] \geq 2/3$ . The model provides the parties access to common random string of arbitrary length. The cost of the protocol  $\mathcal{P}$  is the maximum number of bits communicated, where maximum is over all inputs  $(\mathbf{x}, \mathbf{y}) \in \{0, 1\}^N \times \{0, 1\}^N$ . The communication complexity of the function is the cost of the most efficient protocol computing  $\Pi$ . For more details on communication complexity, see [25]. We now define DISJOINTNESS function on  $N$  bits and state its two-way randomized communication complexity.

► **Definition B.1.** Let  $N \in \mathbb{N}$ . The DISJOINTNESS $_N$  on  $N$  bits is a function DISJOINTNESS $_N : \{0, 1\}^N \times \{0, 1\}^N \rightarrow \{0, 1\}$  such that DISJOINTNESS $_N(\mathbf{x}, \mathbf{y}) = 0$  if there exists an  $i \in [N]$  such that  $x_i = y_i = 1$ , and 1, otherwise.

► **Proposition B.2.** [25] *The randomized communication complexity of DISJOINTNESS $_N$  is  $\Omega(N)$  even if it is promised that there exists at most one  $i \in [n]$  such that  $x_i = y_i = 1$ .*

### C Probability Results

► **Lemma C.1** (See [21]). *Let  $X = \sum_{i \in [n]} X_i$  where  $X_i, i \in [n]$ , are independent random variables,  $X_i \in [0, 1]$  and  $\mathbb{E}[X]$  is the expected value of  $X$ . Then for  $\epsilon \in (0, 1)$ ,  $\Pr[|X - \mathbb{E}[X]| > \epsilon \mathbb{E}[X]] \leq \exp\left(-\frac{\epsilon^2}{3} \mathbb{E}[X]\right)$ .*

► **Lemma C.2** (See [21]). *Let  $X = \sum_{i \in [n]} X_i$  where  $X_i, i \in [n]$ , are independent random variables,  $X_i \in [0, 1]$  and  $\mathbb{E}[X]$  is the expected value of  $X$ . Suppose  $\mu_L \leq \mathbb{E}[X] \leq \mu_H$ , then for  $0 < \epsilon < 1$ ,*

- (i)  $\Pr[X > (1 + \epsilon)\mu_H] \leq \exp\left(-\frac{\epsilon^2}{3} \mu_H\right)$ .
- (ii)  $\Pr[X < (1 - \epsilon)\mu_L] \leq \exp\left(-\frac{\epsilon^2}{2} \mu_L\right)$ .

## Abstract

Greedy decision tree learning heuristics are mainstays of machine learning practice, but theoretical justification for their empirical success remains elusive. In fact, it has long been known that there are simple target functions for which they fail badly (Kearns and Mansour, STOC 1996).

Recent work of Brutzkus, Daniely, and Malach (COLT 2020) considered the smoothed analysis model as a possible avenue towards resolving this disconnect. Within the smoothed setting and for targets  $f$  that are  $k$ -juntas, they showed that these heuristics successfully learn  $f$  with depth- $k$  decision tree hypotheses. They conjectured that the same guarantee holds more generally for targets that are depth- $k$  decision trees.

We provide a counterexample to this conjecture: we construct targets that are depth- $k$  decision trees and show that even in the smoothed setting, these heuristics build trees of depth  $2^{\Omega(k)}$  before achieving high accuracy. We also show that the guarantees of Brutzkus et al. cannot extend to the agnostic setting: there are targets that are very close to  $k$ -juntas, for which these heuristics build trees of depth  $2^{\Omega(k)}$  before achieving high accuracy.

## 1 Introduction

Greedy decision tree learning heuristics are among the earliest and most basic algorithms in machine learning. Well-known examples include ID3 [28], its successor C4.5 [29], and CART [6], all of which continue to be widely employed in everyday ML applications. These simple heuristics build a decision tree for labeled dataset  $S$  in a greedy, top-down fashion. They first identify a “good” attribute to query as the root of the tree. This induces a partition of  $S$  into  $S_0$  and  $S_1$ , and the left and right subtrees are built recursively using  $S_0$  and  $S_1$  respectively.

In more detail, each heuristic is associated with an *impurity function*  $\mathcal{G} : [0, 1] \rightarrow [0, 1]$  that is concave, symmetric around  $\frac{1}{2}$ , and satisfies  $\mathcal{G}(0) = \mathcal{G}(1) = 0$  and  $\mathcal{G}(\frac{1}{2}) = 1$ . Examples include the binary entropy function  $\mathcal{G}(p) = H(p)$  that is used by ID3 and C4.5, and the Gini

## 45:2 Decision Tree Heuristics Can Fail, Even in the Smoothed Setting

impurity function  $\mathcal{G}(p) = 4p(1-p)$  that is used by CART; Kearns and Mansour [21] proposed and analyzed the function  $\mathcal{G}(p) = 2\sqrt{p(1-p)}$ . For a target function  $f : \mathbb{R}^n \rightarrow \{0, 1\}$  and a distribution  $\mathcal{D}$  over  $\mathbb{R}^n$ , these heuristics build a decision tree hypothesis for  $f$  as follows:

1. *Split*: Query  $\mathbb{1}[x_i \geq \theta]$  as the root of the tree, where  $x_i$  and  $\theta$  are chosen to (approximately) maximize the *purity gain with respect to  $\mathcal{G}$* :

$$\mathcal{G}\text{-purity-gain}_{\mathcal{D}}(f, x_i) := \mathcal{G}(\mathbb{E}[f]) - (\Pr[x_i \geq \theta] \cdot \mathcal{G}(\mathbb{E}[f_{x_i \geq \theta}]) + \Pr[x_i < \theta] \cdot \mathcal{G}(\mathbb{E}[f_{x_i < \theta}])),$$

where the expectations and probabilities above are with respect to randomly drawn labeled examples  $(x, f(x))$  where  $x \sim \mathcal{D}$ , and  $f_{x_i \geq \theta}$  denotes the restriction of  $f$  to inputs satisfying  $x_i \geq \theta$  (and similarly for  $f_{x_i < \theta}$ ).

2. *Recurse*: Build the left and right subtrees by recursing on  $f_{x_i \geq \theta}$  and  $f_{x_i < \theta}$  respectively.
3. *Terminate*: The recursion terminates when the depth of the tree reaches a user-specified depth parameter. Each leaf  $\ell$  of the tree is labeled by  $\text{round}(\mathbb{E}[f_{\ell}])$ , where we associate  $\ell$  with the restriction corresponding to the root-to- $\ell$  path within the tree and  $\text{round}(p) := \mathbb{1}[p \geq \frac{1}{2}]$ .

Given the popularity and empirical success of these heuristics<sup>1</sup>, it is natural to seek theoretical guarantees on their performance:

*Let  $f : \mathbb{R}^n \rightarrow \{0, 1\}$  be a target function and  $\mathcal{D}$  be a distribution over  $\mathbb{R}^n$ . Can we obtain a high-accuracy hypothesis for  $f$  by growing a depth- $k'$  tree using these heuristics, where  $k'$  is not too much larger than  $k$ , the optimal decision tree depth for  $f$ ?* ( $\diamond$ )

### 1.1 Background and prior work

#### A simple and well-known impossibility result

Unfortunately, it has long been known [21, 20] that no such guarantee is possible even under favorable feature and distributional assumptions. Consider the setting of binary features (i.e.  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ ) and the uniform distribution  $\mathcal{U}$  over  $\{0, 1\}^n$ , and suppose  $f$  is the parity of two unknown features  $x_i \oplus x_j$  for  $i, j \in [n]$ . It can be easily verified that for all impurity functions  $\mathcal{G}$ , all features have the same purity gain:  $\mathcal{G}\text{-purity-gain}_{\mathcal{U}}(f, x_{\ell}) = 0$  for all  $\ell \in [n]$ , regardless of whether  $\ell \in \{i, j\}$ . Therefore, these heuristics may build a tree of depth  $\Omega(n)$ , querying irrelevant variables  $x_{\ell}$  where  $\ell \notin \{i, j\}$ , before achieving any nontrivial accuracy. This is therefore an example where the target  $f$  is computable by a decision tree of depth  $k = 2$ , and yet these heuristics may build a tree of depth  $k' = \Omega(n)$  before achieving any nontrivial accuracy.

#### Smoothed analysis

In light of such impossibility results, a line of work has focused on establishing provable guarantees for restricted classes of target functions [13, 25, 7, 3, 2]; we give an overview of these results in Section 1.3.

---

<sup>1</sup> CART and C4.5 were named as two of the “Top 10 algorithms in data mining” by the International Conference on Data Mining (ICDM) community [33]; other algorithms on this list include  $k$ -means,  $k$ -nearest neighbors, Adaboost, and PageRank, all of whose theoretical properties are the subjects of intensive study. C4.5 has also been described as “probably the machine learning workhorse most widely used in practice to date” [32].

The focus of our work is instead on *smoothed analysis* as an alternative route towards evading these impossibility results, an approach that was recently considered by Brutzkus, Daniely, and Malach [8]. Smoothed analysis is by now a standard paradigm for going beyond worst-case analysis. Roughly speaking, positive results in this model show that “hard instances are pathological.” Smoothed analysis has been especially influential in accounting for the empirical effectiveness of algorithms widely used in practice, a notable example being the simplex algorithm for linear programming [31]. The idea of analyzing greedy decision tree learning heuristics through the lens of smoothed analysis is therefore very natural.

A *smoothed product distribution* over  $\{0, 1\}^n$ , a notion introduced by Kalai, Samrodnitsky, and Teng [19], is obtained by randomly and independently perturbing the bias of each marginal of a product distribution. For smoothed product distributions, Brutzkus et al. proved strong guarantees on the performance of greedy decision tree heuristics when run on targets that are *juntas*, functions that depend only on a small number of its features. For a given impurity function  $\mathcal{G}$ , let us write  $\mathcal{A}_{\mathcal{G}}$  to denote the corresponding decision tree learning heuristic.

► **Theorem 1** (Performance guarantee for targets that are  $k$ -juntas [8]). *For all impurity functions  $\mathcal{G}$  and for all target functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  that are  $k$ -juntas, if  $\mathcal{A}_{\mathcal{G}}$  is trained on examples drawn from a smoothed product distribution, it learns a decision tree hypothesis of depth  $k$  that achieves perfect accuracy.*

(Therefore Theorem 1 shows that the smoothed setting enables one to circumvent the impossibility result discussed above, which was based on targets that are 2-juntas.)

Every  $k$ -junta is computable by a depth- $k$  decision tree, but a depth- $k$  decision tree can depend on as many as  $2^k$  variables. Brutzkus et al. left as an open problem of their paper a conjecture that the guarantees of Theorem 1 hold more generally for targets that are depth- $k$  decision trees:

► **Conjecture 2** (Performance guarantee for targets that are depth- $k$  decision trees). *For all impurity functions  $\mathcal{G}$  and for all target functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  that are depth- $k$  decision trees, if  $\mathcal{A}_{\mathcal{G}}$  is trained on examples drawn from a smoothed product distribution, it learns a decision tree hypothesis of depth  $O(k)$  that achieves high accuracy.*

In other words, Conjecture 2 states that for all targets  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ , the sought-for guarantee ( $\diamond$ ) holds if the heuristics are trained on examples drawn from a smoothed product distribution.

## 1.2 This work: Lower bounds in the smoothed setting

Our main result is a counterexample to Conjecture 2. We construct targets that are depth- $k$  decision trees for which all greedy impurity-based heuristics, even in the smoothed setting, may grow a tree of depth  $2^{\Omega(k)}$  before achieving high accuracy. This lower bound is close to being maximally large since Theorem 1 implies an upper bound of  $O(2^k)$ . Our result is actually stronger than just a lower bound in the smoothed setting: our lower bound holds with respect to any product distribution that is balanced in the sense that its marginals are not too skewed.

► **Theorem 3** (Our main result: a counterexample to Conjecture 2; informal). *Conjecture 2 is false: For all  $k = k(n)$ , there are target functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  that are depth- $k$  decision trees such that for all impurity functions  $\mathcal{G}$ , if  $\mathcal{A}_{\mathcal{G}}$  is trained on examples drawn from any balanced product distribution, its decision tree hypothesis does not achieve high accuracy unless it has depth  $2^{\Omega(k)}$ .*

By building on our proof of Theorem 3, we also show that the guarantees of Brutzkus et al. for  $k$ -juntas cannot extend to the agnostic setting:

► **Theorem 4** (Theorem 1 does not extend to the agnostic setting; informal). *For all  $\varepsilon$  and  $k = k(n)$ , there are target functions  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  that are  $\varepsilon$ -close to a  $k$ -junta such that for all impurity functions  $\mathcal{G}$ , if  $\mathcal{A}_{\mathcal{G}}$  is trained on examples drawn from any balanced product distribution, its decision tree hypothesis does not achieve high accuracy unless it has depth  $\varepsilon \cdot 2^{\Omega(k)}$ .*

In particular, there are targets that are  $2^{-\Omega(k)}$ -close to  $k$ -juntas, for which these heuristics have to construct a decision tree hypothesis of depth  $2^{\Omega(k)}$  before achieving high accuracy. Taken together with the positive result of Brutzkus et al., Theorems 3 and 4 add to our understanding of the strength and limitations of greedy decision tree learning heuristics.

Our lower bounds are based on new generalizations of the *addressing function*. Since the addressing function is often a useful extremal example in a variety of settings, we are hopeful that these generalizations and our analysis of them will see further utility beyond the applications of this paper.

### 1.3 Related Work

As mentioned above, there has been a substantial line of work on establishing provable guarantees for greedy decision tree heuristics when run in restricted classes of target functions. Fiat and Pechyony [13] considered the class of read-once DNF formulas and halfspaces; the Ph.D. thesis of Lee [25] considered the class of monotone functions; Brutzkus, Daniely, and Malach [7] considered conjunctions and read-once DNF formulas; recent works of [3, 2] build on the work of Lee and further studied monotone target functions. (All these works focus on the case of binary features and product distributions over examples.)

Kearns and Mansour [21], in one of the first papers to study these heuristics from a theoretical perspective, showed that they can be viewed as boosting algorithms, with internal nodes of the decision tree hypothesis playing the role of weak learners. Their subsequent work with Dietterich [11] provide experimental results that complement the theoretical results of [21]; see also the survey of Kearns [20].

Finally, we mention that decision trees are one of the most intensively studied concept classes in learning theory. The literature on this problem is rich and vast (see e.g. [12, 30, 5, 15, 9, 24, 4, 16, 22, 26, 18, 27, 14, 23, 19, 19, 17, 10, 1]), studying it from a variety of perspectives and providing both positive and negative results. However, the algorithms developed in these works do not resemble the greedy heuristics used in practice, and indeed, most of them are not proper (in the sense of returning a hypothesis that is itself a decision tree).<sup>2</sup>

## 2 Preliminaries

Recall that an impurity function  $\mathcal{G} : [0, 1] \rightarrow [0, 1]$  is concave, symmetric with respect to  $\frac{1}{2}$ , and satisfies  $\mathcal{G}(0) = \mathcal{G}(1) = 0$  and  $\mathcal{G}(\frac{1}{2}) = 1$ . We further quantify the concavity and smoothness of  $\mathcal{G}$  as follows:

<sup>2</sup> Quoting [21], “it seems fair to say that despite their other successes, the models of computational learning theory have not yet provided significant insight into the apparent empirical success of programs like C4.5 and CART.”

► **Definition 5** (Impurity functions).  $\mathcal{G}$  is an  $(\alpha, L)$ -impurity function if  $\mathcal{G}$  is  $\alpha$ -strongly concave and  $L$ -smooth, i.e.,  $\mathcal{G}$  is twice-differentiable and  $\mathcal{G}''(x) \in [-L, -\alpha]$  for every  $x \in [0, 1]$ .

For a boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  and index  $i \in [n]$ , we write  $f_{x_i=0}$  and  $f_{x_i=1}$  to denote the restricted functions obtained by fixing the  $i$ -th input bit of  $f$  to either 0 or 1. Formally, each  $f_{x_i=b}$  is a function over  $\{0, 1\}^n$  defined as  $f_{x_i=b}(x) = f(x^{i \rightarrow b})$ , where  $x^{i \rightarrow b}$  denotes the string obtained by setting the  $i$ -th bit of  $x$  to  $b$ . More generally, a *restriction*  $\pi$  is a list of constraints of form “ $x_i = b$ ” in which every index  $i$  appears at most once. For restriction  $\pi = (x_{i_1} = b_1, x_{i_2} = b_2, \dots)$ , the restricted function  $f_\pi : \{0, 1\}^n \rightarrow \{0, 1\}$  is similarly defined as  $f_\pi(x) = f(x^{i_1 \rightarrow b_1, i_2 \rightarrow b_2, \dots})$ .

► **Definition 6** (Purity gain). Let  $\mathcal{D}$  be a distribution over  $\{0, 1\}^n$  and  $p_i = \Pr_{x \sim \mathcal{D}} [x_i = 1]$ . The  $\mathcal{G}$ -purity gain of querying variable  $x_i$  on boolean function  $f$  is defined as

$$\mathcal{G}\text{-purity-gain}_{\mathcal{D}}(f, x_i) := \mathcal{G} \left( \mathbb{E}_{x \sim \mathcal{D}} [f(x)] \right) - p_i \mathcal{G} \left( \mathbb{E}_{x \sim \mathcal{D}} [f_{x_i=1}(x)] \right) - (1-p_i) \mathcal{G} \left( \mathbb{E}_{x \sim \mathcal{D}} [f_{x_i=0}(x)] \right).$$

In a decision tree, each node  $v$  naturally corresponds to a restriction  $\pi_v$  formed by the variables queried by the ancestors of  $v$  (excluding  $v$  itself). We use  $f_v$  as a shorthand for  $f_{\pi_v}$ . We say that a decision tree learning algorithm is *impurity-based* if, in the tree returned by the algorithm, every internal node  $v$  queries a variable that maximizes the purity gain with respect to  $f_v$ .

► **Definition 7** (Impurity-based algorithms). A decision tree learning algorithm is  $\mathcal{G}$ -impurity-based if the following holds for every  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  and distribution  $\mathcal{D}$  over  $\{0, 1\}^n$ : When learning  $f$  on  $\mathcal{D}$ , the algorithm outputs a decision tree such that for every internal node  $v$ , the variable  $x_i$  that is queried at  $v$  satisfies  $\mathcal{G}\text{-purity-gain}_{\mathcal{D}}(f_v, x_i) \geq \mathcal{G}\text{-purity-gain}_{\mathcal{D}}(f_v, x_j)$  for every  $j \in [n]$ .

The above definition assumes that the algorithm exactly maximizes the  $\mathcal{G}$ -purity gain at every split, while in reality, the purity gains can only be estimated from a finite dataset. We therefore consider an idealized setting that grants the learning algorithm with infinitely many training examples, which, intuitively, strengthens our lower bounds. (Our lower bounds show that in order for an algorithm to recover a good tree – a high-accuracy hypothesis whose depth is close to that of the target – it would need to query a variable that has *exponentially smaller* purity gain than that of the variable with the largest purity gain. Hence, if purity gains are estimated using finitely many random samples as is done in reality, the strength of our lower bounds imply that with extremely high probability, impurity-based heuristics will fail to build a good tree; see Remark 15 for a detailed discussion.)

When a decision tree queries variable  $x_i$  on function  $f$ , it naturally induces two restricted functions  $f_{x_i=0}$  and  $f_{x_i=1}$ . The following lemma states that the purity gain of querying  $x_i$  is roughly the squared difference between the averages of the two functions, up to a factor that depends on the impurity function  $\mathcal{G}$  and the data distribution  $\mathcal{D}$ . We say that a product distribution over  $\{0, 1\}^n$  is  $\delta$ -balanced if the expectation of each of the  $n$  coordinates is in  $[\delta, 1 - \delta]$ .

► **Lemma 8.** For any  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ ,  $\delta$ -balanced product distribution  $\mathcal{D}$  over  $\{0, 1\}^n$  and  $(\alpha, L)$ -impurity function  $\mathcal{G}$ , it holds for  $\kappa = \max \left( \frac{2}{\alpha\delta(1-\delta)}, \frac{L}{8} \right)$  and every  $i \in [n]$  that

$$\frac{1}{\kappa} \leq \frac{\mathcal{G}\text{-purity-gain}_{\mathcal{D}}(f, x_i)}{\left[ \mathbb{E}_{x \sim \mathcal{D}} [f_{x_i=0}(x)] - \mathbb{E}_{x \sim \mathcal{D}} [f_{x_i=1}(x)] \right]^2} \leq \kappa.$$

## 45:6 Decision Tree Heuristics Can Fail, Even in the Smoothed Setting

**Proof of Lemma 8.** Let  $p_i = \Pr_{x \sim \mathcal{D}} [x_i = 1]$  and  $\mu_b = \mathbb{E}_{x \sim \mathcal{D}} [f_{x_i=b}(x)]$  respectively. Then, we have  $\mathbb{E}_{x \sim \mathcal{D}} [f(x)] = p_i \mu_1 + (1 - p_i) \mu_0$ , and the purity gain can be written as

$$\mathcal{G}\text{-purity-gain}_{\mathcal{D}}(f, x_i) = \mathcal{G}(p_i \mu_1 + (1 - p_i) \mu_0) - p_i \mathcal{G}(\mu_1) - (1 - p_i) \mathcal{G}(\mu_0).$$

Since  $\mathcal{G}$  is  $\alpha$ -strongly concave and  $L$ -smooth, the above is bounded between  $\frac{\alpha}{2} \cdot p_i(1 - p_i) \cdot (\mu_0 - \mu_1)^2$  and  $\frac{L}{2} \cdot p_i(1 - p_i) \cdot (\mu_0 - \mu_1)^2$ . Since  $\mathcal{D}$  is  $\delta$ -balanced, we have  $\delta(1 - \delta) \leq p_i(1 - p_i) \leq \frac{1}{4}$ . It follows that

$$\frac{\alpha}{2} \cdot \delta(1 - \delta) \leq \frac{\alpha}{2} \cdot p_i(1 - p_i) \leq \frac{\mathcal{G}\text{-purity-gain}_{\mathcal{D}}(f, x_i)}{(\mu_0 - \mu_1)^2} \leq \frac{L}{2} \cdot p_i(1 - p_i) \leq \frac{L}{8}.$$

Thus, the ratio is bounded between  $1/\kappa$  and  $\kappa$ .  $\blacktriangleleft$

Our lower bounds hold with respect to all  $\delta$ -balanced product distributions. We compare this to the definition of a *c-smoothened*  $\delta$ -balanced product distribution from [8].

**► Definition 9 (Smooth distributions).** A *c-smoothened*  $\delta$ -balanced product distribution is a random product distribution over  $\{0, 1\}^n$  where the marginal for the  $i^{\text{th}}$  bit is 1 with probability  $\hat{p}_i + \Delta_i$  for fixed  $\hat{p}_i \in (\delta + c, 1 - \delta - c)$  and  $\Delta_i$  drawn i.i.d. from  $\text{Uniform}([-c, c])$ .

Since our lower bounds hold against all  $\delta$ -balanced product distributions, it also holds against all *c-smoothened*  $\delta$ -balanced product distributions.

### 3 Proof overview and formal statements of our results

Our goal is to construct a target function that can be computed by a depth- $k$  decision tree, but on which impurity-based algorithms must build to depth  $2^{\Omega(k)}$  or have large error. To do so, we construct a decision tree target  $T$  where the variables with *largest* purity gain are at the *bottom* layer of  $T$  (adjacent to its leaves). Intuitively, impurity-based algorithms will build their decision tree hypothesis for  $T$  by querying all the variables in the bottom layer of  $T$  before querying any of the variables higher up in  $T$ . Our construction will be such that until the higher up variables are queried, it is impossible to approximate the target with any nontrivial error. Summarizing informally, we show that impurity-based algorithms build its decision tree hypothesis for our target by querying variables in exactly the “wrong order”.

The starting point of our construction is the well known *addressing function*. For  $k \in \mathbb{N}$ , the addressing function  $f : \{0, 1\}^{k+2^k} \rightarrow \{0, 1\}$  is defined as follows: Given “addressing bits”  $z \in \{0, 1\}^k$  and “memory bits”  $y \in \{0, 1\}^{2^k}$ , the output  $f(y, z)$  is the  $z^{\text{th}}$  bit of  $y$ , where “ $z^{\text{th}}$  bit” is computed by interpreting  $z$  as a base-2 integer. Note that the addressing function is computable by a decision tree of depth  $k + 1$  that first queries the  $k$  addressing bits, followed by the appropriate memory bit.

For our lower bound, we would like the variables with the highest purity gain to be the memory bits. However, for smoothed product distributions, the addressing bits might have higher purity gain than the memory bits, and impurity-based algorithms might succeed in learning the addressing function. We therefore modify the addressing function by making each addressing bit the parity of multiple new bits. We show that by making each addressing bit the parity of sufficiently many new bits, we can drive the purity gain of these new bits down to the point where the memory bits have the highest purity gain as desired – in fact, larger than the addressing bits by a multiplicative factor of  $e^{\Omega(k)}$ . (Making each addressing bit the parity of multiple new bits increases the depth of the target, so this introduces technical challenges we have to overcome in order to achieve the strongest parameters.)

Our main theorem is formally restated as follows.

► **Theorem 10** (Formal version of Theorem 3). *Fix  $L \geq \alpha > 0$  and  $\delta \in (0, \frac{1}{2}]$ . There are boolean functions  $f_1, f_2, \dots$  such that: (1)  $f_k$  is computable by a decision tree of depth  $O(k/\delta)$ ; (2) For every  $\delta$ -balanced product distribution  $\mathcal{D}$  over the domain of  $f_k$  and every  $(\alpha, L)$ -impurity function  $\mathcal{G}$ , any  $\mathcal{G}$ -impurity based decision tree heuristic, when learning  $f_k$  on  $\mathcal{D}$ , returns a tree that has either depth  $\geq 2^k$  or an  $\Omega(\delta)$  error.*

An extension of our construction and its analysis shows that the guarantees of Brutzkus et al. for targets that are  $k$ -juntas cannot extend to the agnostic setting. Roughly speaking, while our variant of the addressing function from Theorem 10 is far from all  $k$ -juntas, it can be made close to one by fixing most of the memory bits. We obtain our result by showing that our analysis continues to hold under such a restriction.

► **Theorem 11** (Formal version of Theorem 4). *Fix  $L \geq \alpha > 0$ ,  $\delta \in (0, \frac{1}{2}]$  and  $\varepsilon \in (0, 1]$ . There are boolean functions  $f_1, f_2, \dots$  such that for every  $\delta$ -balanced product distribution  $\mathcal{D}$  over the domain of  $f_k$ : (1)  $f_k$  is  $\varepsilon$ -close to an  $O(k/\delta)$ -junta with respect to  $\mathcal{D}$ ; (2) For every  $(\alpha, L)$ -impurity function  $\mathcal{G}$ , any  $\mathcal{G}$ -impurity based decision tree heuristic, when learning  $f_k$  on  $\mathcal{D}$ , returns a tree that has either a depth of  $\Omega(\varepsilon \cdot 2^k)$  or an  $\Omega(1)$  error.*

## 4 Warm-Up: A Weaker Lower Bound

We start by giving a simplified construction that proves a weaker version of Theorem 10, in which the  $O(k/\delta)$  depth in condition (1) is relaxed to  $O(k^2/\delta)$ . For integers  $c, k \geq 1$ , we define a boolean function  $f_{c,k} : \{0, 1\}^{ck^2+2^k} \rightarrow \{0, 1\}$  as follows. The input of  $f_{c,k}$  is viewed as two parts:  $ck^2$  addressing bits  $x_{i,j}$  indexed by  $i \in [k]$  and  $j \in [ck]$ , and  $2^k$  memory bits  $y_a$  indexed by  $a \in \{0, 1\}^k$ . The function value  $f_{c,k}(x, y)$  is defined by first computing  $z_i(x) = \bigoplus_{j=1}^{ck} x_{i,j}$  for every  $i \in [k]$ , and then assigning  $f_{c,k}(x, y) = y_{z(x)}$ .

In other words,  $f_{c,k}$  is a disjoint composition of the  $k$ -bit addressing function and the parity function over  $ck$  bits. Given addressing bits  $x$  and memory bits  $y$ , the function first computes a  $k$ -bit address by taking the XOR of the addressing bits in each group of size  $ck$ , and then retrieves the memory bit with the corresponding address. Clearly,  $f_{c,k}$  can be computed by a decision tree of depth  $ck^2 + 1$  that first queries all the  $ck^2$  addressing bits and then queries the relevant memory bit in the last layer.

### 4.1 Address is Almost Uniform

Drawing input  $(x, y)$  from a distribution  $\mathcal{D}$  naturally defines a distribution over  $\{0, 1\}^k$  of the  $k$ -bit address  $z(x) = (z_1(x), z_2(x), \dots, z_k(x))$ . The following lemma states that when  $\mathcal{D}$  is a  $\delta$ -balanced product distribution, the distribution of  $z(x)$  is almost uniform in the  $\ell_\infty$  sense. Furthermore, this almost uniformity holds even if one of the addressing bits  $x_{i,j}$  is fixed.

► **Lemma 12.** *Suppose that  $c \geq \frac{\ln 5}{\delta}$  and  $\mathcal{D}$  is a  $\delta$ -balanced product distribution over the domain of  $f_{c,k}$ . Then,*

$$\left| \Pr_{(x,y) \sim \mathcal{D}} [z(x) = a] - 2^{-k} \right| \leq 5^{-k}, \forall a \in \{0, 1\}^k.$$

Furthermore, for every  $i \in [k]$ ,  $j \in [ck]$  and  $b \in \{0, 1\}$ ,

$$\left| \Pr_{(x,y) \sim \mathcal{D}} [z(x) = a | x_{i,j} = b] - 2^{-k} \right| \leq 5^{-k}, \forall a \in \{0, 1\}^k.$$

The proof of Lemma 12 uses the following simple fact, which states that the XOR of independent biased random bits is exponentially close to an unbiased coin flip.

► **Lemma 13.** *Suppose that  $x_1, x_2, \dots, x_n$  are independent Bernoulli random variables, each with an expectation between  $\delta$  and  $1 - \delta$ . Then,  $|\Pr[x_1 \oplus x_2 \oplus \dots \oplus x_n = 1] - \frac{1}{2}| \leq \frac{1}{2}(1 - 2\delta)^n \leq \frac{1}{2} \exp(-2\delta n)$ .*

**Proof of Lemma 12.** Since  $z_i(x) = \bigoplus_{j=1}^{ck} x_{i,j}$  and  $\mathcal{D}$  is  $\delta$ -balanced, Lemma 13 gives

$$\left| \Pr_{(x,y) \sim \mathcal{D}} [z_i(x) = 1] - \frac{1}{2} \right| \leq \frac{1}{2} \exp(-2\delta ck) \leq \frac{1}{2} \cdot 5^{-k}.$$

Note that the bits of  $z(x)$  are independent, so  $\Pr_{(x,y) \sim \mathcal{D}} [z(x) = a]$  is given by

$$\prod_{i=1}^k \Pr_{(x,y) \sim \mathcal{D}} [z_i(x) = a_i] \leq \left( \frac{1}{2} + \frac{1}{2} \cdot 5^{-k} \right)^k = 2^{-k} \cdot (1 + 5^{-k})^k \leq 2^{-k} \cdot (1 + (2/5)^k) = 2^{-k} + 5^{-k},$$

where the third step applies  $(1 + x)^k \leq 1 + 2^k x$  for  $x \in [0, 1]$  and integers  $k \geq 1$ . Similarly,

$$\Pr_{(x,y) \sim \mathcal{D}} [z(x) = a] \geq \left( \frac{1}{2} - \frac{1}{2} \cdot 5^{-k} \right)^k \geq 2^{-k} \cdot (1 - 5^{-k})^k \geq 2^{-k} - 5^{-k},$$

where the last two steps apply  $(1 - x)^k \geq 1 - kx$  and  $k \cdot 2^{-k} \leq 1$ . This proves the first part.

The proof of the “furthermore” part is essentially the same, except that conditioning on  $x_{i,j} = b$ ,  $z_i(x)$  becomes the XOR of  $ck - 1$  independent bits and  $b$ . By Lemma 13, we have

$$\left| \Pr_{(x,y) \sim \mathcal{D}} [z_i(x) = 1 | x_{i,j} = b] - \frac{1}{2} \right| \leq \frac{1}{2} \exp(-2\delta(ck - 1)) \leq \frac{1}{2} \exp(-\delta ck) \leq \frac{1}{2} \cdot 5^{-k},$$

and the rest of the proof is the same. ◀

## 4.2 Memory Bits are Queried First

The following technical lemma states that the purity gain of  $f_{c,k}$  is maximized by a memory bit, regardless of the impurity function and the data distribution. Therefore, when an impurity-based algorithm (in the sense of Definition 7) learns  $f_{c,k}$ , the root of the decision tree will always query a memory bit. Furthermore, this property also holds for restrictions of  $f_{c,k}$  as long as the restriction only involves the memory bits.

► **Lemma 14.** *Fix  $L \geq \alpha > 0$  and  $\delta \in (0, \frac{1}{2}]$ . Let  $c_0 = \frac{\ln 5}{\delta}$  and  $k_0 = \frac{\ln(2\kappa)}{\ln(5/4)} + 1$ , where  $\kappa$  is chosen as in Lemma 8. The following holds for every function  $f_{c,k}$  with  $c \geq c_0$  and  $k \geq k_0$ : For any  $(\alpha, L)$ -impurity function  $\mathcal{G}$ ,  $\delta$ -balanced product distribution  $\mathcal{D}$  and restriction  $\pi$  of size  $< 2^k$  that only contains the memory bits of  $f_{c,k}$ , the purity gain  $\mathcal{G}$ -purity-gain $_{\mathcal{D}}((f_{c,k})_{\pi}, \cdot)$  is maximized by a memory bit.*

**Proof of Lemma 14.** Fix  $c \geq c_0$  and  $k \geq k_0$  and shorthand  $f$  for  $f_{c,k}$ . We will prove a stronger claim: with respect to  $f_{\pi}$ , every memory bit (that is not in  $\pi$ ) gives a much higher purity gain than every addressing bit does.

### Purity gain of the memory bits

Fix a memory bit  $y_a$  ( $a \in \{0, 1\}^k$ ) that does not appear in restriction  $\pi$ . Let  $\mu_b = \mathbb{E}_{(x,y) \sim \mathcal{D}} [f_{\pi, y_a=b}(x, y)]$  for  $b \in \{0, 1\}$ . By the law of total expectation,

$$\begin{aligned} \mu_b &= \Pr_{(x,y) \sim \mathcal{D}} [z(x) = a] \cdot \mathbb{E}_{(x,y) \sim \mathcal{D}} [f_{\pi, y_a=b}(x, y) | z(x) = a] \\ &\quad + \Pr_{(x,y) \sim \mathcal{D}} [z(x) \neq a] \cdot \mathbb{E}_{(x,y) \sim \mathcal{D}} [f_{\pi, y_a=b}(x, y) | z(x) \neq a] \\ &= \Pr_{(x,y) \sim \mathcal{D}} [z(x) = a] \cdot b + \Pr_{(x,y) \sim \mathcal{D}} [z(x) \neq a] \cdot \mathbb{E}_{(x,y) \sim \mathcal{D}} [f_{\pi}(x, y) | z(x) \neq a]. \end{aligned}$$

Here the second step holds since  $f_{\pi, y_a=b}(x, y)$  evaluates to  $b$  when the address  $z(x)$  equals  $a$ , and  $f_{\pi, y_a=b}$  agrees with  $f_\pi$  when  $z(x) \neq a$ . Since only the first term above depends on  $b$ , we have

$$|\mu_0 - \mu_1| = \Pr_{(x,y) \sim \mathcal{D}} [z(x) = a] \geq 2^{-k} - 5^{-k} \geq \frac{1}{2} \cdot 2^{-k},$$

where the second step follows from  $c \geq c_0$  and Lemma 12. Finally, by Lemma 8,  $\mathfrak{G}\text{-purity-gain}_{\mathcal{D}}(f_\pi, y_a) \geq \frac{1}{\kappa}(\mu_0 - \mu_1)^2 \geq \frac{1}{4\kappa} \cdot 2^{-2k}$ .

### Purity gain of the addressing bits

Similarly, we fix an addressing bit  $x_{i,j}$  and define the average  $\mu_b = \mathbb{E}_{(x,y) \sim \mathcal{D}} [f_{\pi, x_{i,j}=b}(x, y)]$ . Since  $\mathcal{D}$  is a product distribution,  $\mu_b$  is equal to the conditional expectation  $\mathbb{E}_{(x,y) \sim \mathcal{D}} [f_\pi(x, y) | x_{i,j} = b]$ . Then, by the law of total expectation, we can write  $\mu_b$  as

$$\begin{aligned} \mu_b &= \sum_{a \in \{0,1\}^k} \Pr_{(x,y) \sim \mathcal{D}} [z(x) = a | x_{i,j} = b] \cdot \mathbb{E}_{(x,y) \sim \mathcal{D}} [f_\pi(x, y) | z(x) = a, x_{i,j} = b] \\ &= \sum_{a \in \{0,1\}^k} \Pr_{(x,y) \sim \mathcal{D}} [z(x) = a | x_{i,j} = b] \cdot \mathbb{E}_{(x,y) \sim \mathcal{D}} [f_\pi(x, y) | z(x) = a]. \end{aligned}$$

Here the second step holds since  $f_\pi(x, y)$  and  $x_{i,j}$  are independent conditioning on the address  $z(x)$ ; in other words, once we know the value of  $z(x)$ , it doesn't matter how  $x$  is set in determining the output of  $f$ .

Let  $c_a$  denote  $\mathbb{E}_{(x,y) \sim \mathcal{D}} [f_\pi(x, y) | z(x) = a]$ , and let  $\mathcal{P}_b$  be the distribution of  $z(x)$  conditioning on  $x_{i,j} = b$ . Then,  $\mu_b$  is exactly given by  $\mathbb{E}_{a \sim \mathcal{P}_b} [c_a]$ . Since each  $c_a$  is in  $[0, 1]$ ,  $|\mu_0 - \mu_1|$  is upper bounded by the total variation distance between  $\mathcal{P}_0$  and  $\mathcal{P}_1$ :

$$\begin{aligned} |\mu_0 - \mu_1| &\leq \frac{1}{2} \sum_{a \in \{0,1\}^k} |\mathcal{P}_0(a) - \mathcal{P}_1(a)| \\ &\leq \frac{1}{2} \sum_{a \in \{0,1\}^k} (|\mathcal{P}_0(a) - 2^{-k}| + |\mathcal{P}_1(a) - 2^{-k}|) \\ &\leq \frac{1}{2} \cdot 2^k \cdot 2 \cdot 5^{-k} = (2/5)^k. \end{aligned} \tag{Lemma 12}$$

Finally, applying Lemma 8 shows that  $\mathfrak{G}\text{-purity-gain}_{\mathcal{D}}(f_\pi, x_{i,j}) \leq \kappa(\mu_0 - \mu_1)^2 \leq \kappa \cdot (2/5)^{2k}$ .

Recall that  $k \geq k_0 > \frac{\ln(2\kappa)}{\ln(5/4)}$ , so we have  $\kappa \cdot (2/5)^{2k} < \frac{1}{4\kappa} \cdot 2^{-2k}$ . Therefore, the purity gain of every memory bit outside the restriction is strictly larger than that of any addressing bit, and the lemma follows immediately.  $\blacktriangleleft$

► **Remark 15.** The proof above bounds the purity gain of each memory bit and each addressing bit by  $\Omega((1/2)^{2k})$  and  $O((2/5)^{2k})$  respectively. For Lemma 14 to hold when the purity gains are estimated from a finite dataset, it suffices to argue that each estimate is accurate up to an  $O((2/5)^{2k})$  additive error. By a standard concentration argument, to estimate the purity gains for all restriction  $\pi$  of size  $\leq h$ ,  $2^{O(h+k)}$  training examples are sufficient. When applied later in the proof of Theorem 10, this finite-sample version of Lemma 14 would imply that impurity-based algorithms need to build a tree of depth  $h$  as soon as the sample size reaches  $2^{\Omega(h+k)}$ .

### 4.3 Proof of the Weaker Version

Now we are ready to prove the weaker version of Theorem 10. We will apply Lemma 14 to argue that the tree returned by an impurity-based algorithm never queries an addressing bit (unless all the  $2^k$  memory bits have been queried), and then show that every such decision tree must have an error of  $\Omega(\delta)$ .

**Proof of Theorem 10 (weaker version).** Fix integer  $c \geq \frac{\ln 5}{\delta}$  and consider the functions  $f_{c,1}, f_{c,2}, \dots$ . Since each  $f_{c,k}$  is represented by a decision tree of depth  $ck^2 + 1 = O(k^2/\delta)$ , it remains to show that impurity-based algorithms fail to learn  $f_{c,k}$ . Fix integer  $k \geq k_0$  (where  $k_0$  is chosen as in Lemma 14) and  $\delta$ -balanced product distribution  $\mathcal{D}$  over the domain of  $f_{c,k}$ . In the following, we use shorthand  $f$  for  $f_{c,k}$ .

#### Small trees never query addressing bits

Let  $T$  be the decision tree returned by a  $\mathcal{G}$ -impurity-based algorithm when learning  $f$  on  $\mathcal{D}$ . If  $T$  has depth  $> 2^k$ , we are done, so we assume that  $T$  has depth at most  $2^k$ . We claim that  $T$  never queries the addressing bits of  $f$ . Suppose otherwise, that an addressing bit is queried at node  $v$  in  $T$ , and no addressing bits are queried by the ancestors of  $v$ . Then, the restriction  $\pi_v$  associated with node  $v$  only contains the memory bits of  $f$ . Since  $T$  has depth  $\leq 2^k$ , the size of  $\pi_v$  is strictly less than  $2^k$ . Then, by Lemma 14, the  $\mathcal{G}$ -purity gain with respect to  $f_v$  is maximized by a memory bit. This contradicts the assumption that the algorithm is  $\mathcal{G}$ -impurity-based.

#### Trivial accuracy if no addressing bits are queried

We have shown that  $T$  only queries the memory bits of  $f$ . We may further assume that  $T$  queries *all* the  $2^k$  memory bits before reaching any of its leaves, i.e.,  $T$  is a full binary tree of depth  $2^k$ . This assumption is without loss of generality because we can add dummy queries on the memory bits to the leaves of depth  $< 2^k$ , and label all the resulting leaves with the same bit. This change does not modify the function represented by  $T$ .

Assuming that  $T$  is full, every leaf  $\ell$  of  $T$  is labeled by  $2^k$  bits  $(c_a)_{a \in \{0,1\}^k}$ , meaning that each memory bit  $y_a$  is fixed to  $c_a$  on the root-to- $\ell$  path. The expectation of the restricted function  $f_\ell$  is then given by  $\mu_\ell := \mathbb{E}_{(x,y) \sim \mathcal{D}} [c_{z(x)}]$ . Clearly, the error of  $T$  is minimized when each leaf  $\ell$  is labeled with  $\mathbf{1} [\mu_\ell \geq \frac{1}{2}]$ , and the conditional error when reaching leaf  $\ell$  is  $\min(\mu_\ell, 1 - \mu_\ell)$ .

It remains to show that for a large fraction of leaves  $\ell$ ,  $\mu_\ell$  is bounded away from 0 and 1, so that  $\min(\mu_\ell, 1 - \mu_\ell)$  is large. When leaf  $\ell$  is randomly chosen according to distribution  $\mathcal{D}$ , the corresponding  $\mu_\ell$  is given by

$$\mu_\ell = \sum_{a \in \{0,1\}^k} \Pr_{(x,y) \sim \mathcal{D}} [z(x) = a] \cdot c_a, \quad (1)$$

where  $(c_a)_{a \in \{0,1\}^k}$  are  $2^k$  independent Bernoulli random variables with means in  $[\delta, 1 - \delta]$ .

By Lemma 12 and our choice of  $c \geq c_0$ ,  $\Pr_{(x,y) \sim \mathcal{D}} [z(x) = a] \leq 2 \cdot 2^{-k}$  holds for every  $a \in \{0,1\}^k$ . Thus, each term in (1) is bounded between 0 and  $2 \cdot 2^{-k}$ . Furthermore, since each  $c_a$  has expectation at least  $\delta$ ,  $\mathbb{E}[\mu_\ell] \geq \delta$ . Then, Hoeffding's inequality guarantees that over the random choice of  $(c_a)_{a \in \{0,1\}^k}$ ,  $\mu_\ell \geq \delta/2$  holds with probability at least  $1 - \exp\left(-\frac{2 \cdot (\delta/2)^2}{2^k \cdot (2 \cdot 2^{-k})^2}\right) = 1 - \exp(-2^k \delta^2/8)$ , which is lower bounded by  $2/3$  for all sufficiently large  $k$ . By a symmetric argument,  $\mu_\ell \leq 1 - \delta/2$  also holds with probability  $\geq 2/3$ . Therefore,

with probability  $\geq 1/3$  over the choice of leaf  $\ell$ ,  $\mu_\ell \in [\delta/2, 1 - \delta/2]$  holds and thus the conditional error on leaf  $\ell$  is at least  $\delta/2$ . This shows that the error of  $T$  over distribution  $\mathcal{D}$  is lower bounded by  $\delta/6$ , which completes the proof.  $\blacktriangleleft$

## 5 Proof of Theorem 10

When proving the weaker version of Theorem 10, each hard instance  $f_{c,k}$  has  $\Theta(k^2)$  addressing bits grouped into  $k$  disjoint subsets, and the  $k$ -bit address is defined by the XOR of bits in each subset. We will prove Theorem 10 using a slightly different construction that computes address from  $k$  overlapping subsets of only  $O(k)$  addressing bits.

For integers  $c, k \geq 1$  and a list of  $k$  sets  $S = (S_1, S_2, \dots, S_k)$  where each  $S_i \subseteq [ck]$ , we define a boolean function  $f_{c,k,S} : \{0, 1\}^{ck+2^k} \rightarrow \{0, 1\}$  as follows. The input of  $f_{c,k,S}$  is again divided into two parts:  $ck$  addressing bits  $x_1, x_2, \dots, x_{ck}$  and  $2^k$  memory bits  $y_a$  indexed by a  $k$ -bit address  $a$ . The function value  $f(x, y)$  is computed by taking  $z_i(x) = \bigoplus_{j \in S_i} x_j$  and then  $f(x, y) = y_{z(x)}$ . Clearly,  $f_{c,k,S}$  can be computed by a decision tree of depth  $ck + 1$  that first queries all the  $ck$  addressing bits  $x_1, x_2, \dots, x_{ck}$ , and then queries the relevant memory bit  $y_{z(x)}$ .

Let  $\Delta_{i \in I}^k S_i$  denote the  $k$ -ary symmetric difference of sets  $S_1$  through  $S_k$ , i.e., the set of elements that appear in an odd number of sets. We say that a list of sets  $S = (S_1, S_2, \dots, S_k)$  has *distance*  $d$ , if any non-empty collection of sets has a symmetric difference of size at least  $d$ , i.e.,  $|\Delta_{i \in I}^k S_i| \geq d$  for every non-empty  $I \subseteq [k]$ . In the following, we prove analogs of Lemmas 12 and 14 for function  $f_{c,k,S}$  assuming that  $S$  has a large distance; Theorem 10 would then follow immediately.

**► Lemma 16.** *Suppose that  $\mathcal{D}$  is a  $\delta$ -balanced product distribution over the domain of  $f_{c,k,S}$  and  $S$  has distance  $d \geq \frac{\ln 5}{\delta} \cdot k$ . Then,*

$$\left| \Pr_{(x,y) \sim \mathcal{D}} [z(x) = a] - 2^{-k} \right| \leq 5^{-k}, \forall a \in \{0, 1\}^k.$$

Furthermore, for every  $i \in [ck]$  and  $b \in \{0, 1\}$ ,

$$\left| \Pr_{(x,y) \sim \mathcal{D}} [z(x) = a | x_i = b] - 2^{-k} \right| \leq 5^{-k}, \forall a \in \{0, 1\}^k.$$

We prove Lemma 16 by noting that the distribution of  $z(x)$  has exponentially small Fourier coefficients (except the degree-0 one) under the assumptions, and is thus close to the uniform distribution over  $\{0, 1\}^k$ . More concretely, our goal is to show that, for every  $I \subseteq [k]$  the quantity  $\bigoplus_{i \in I} z_i(x)$  is 1 with probability nearly exactly  $\frac{1}{2}$ . Afterwards, we will show this is sufficient to guarantee that the distribution of  $z(x)$  is close to the uniform distribution.

**Proof of Lemma 16.** Since  $z_i(x) = \bigoplus_{j \in S_i} x_j$ , we have  $\bigoplus_{i \in I} z_i(x) = \bigoplus_{j \in S_I} x_j$  for every  $I \subseteq [k]$ , where  $S_I = \Delta_{i \in I}^k S_i$  is the symmetric difference of the corresponding sets. Since  $S$  has distance  $d$ ,  $|S_I| \geq d$  for every non-empty  $I \subseteq [k]$  and thus  $\bigoplus_{i \in I} z_i(x)$  is the XOR of at least  $d$  independent bits. Note that  $1 - 2 \bigoplus_{i \in I} z_i(x) = \prod_{i \in I} (1 - 2z_i(x))$ . By Lemma 13 and  $d \geq \frac{\ln 5}{\delta} \cdot k$ ,

$$\left| \mathbb{E}_{(x,y) \sim \mathcal{D}} \left[ \prod_{i \in I} (1 - 2z_i(x)) \right] \right| = 2 \cdot \left| \Pr_{(x,y) \sim \mathcal{D}} \left[ \bigoplus_{i \in I} z_i(x) = 1 \right] - \frac{1}{2} \right| \leq \exp(-2\delta d) \leq 5^{-k}. \quad (2)$$

## 45:12 Decision Tree Heuristics Can Fail, Even in the Smoothed Setting

Note that for  $b_1, b_2 \in \{0, 1\}$ , we have  $\mathbb{1}[b_1 = b_2] = \frac{(1-2b_1)(1-2b_2)+1}{2}$ . Therefore, for every  $a \in \{0, 1\}^k$ ,

$$\begin{aligned}
\left| \Pr_{(x,y) \sim \mathcal{D}} [z(x) = a] - 2^{-k} \right| &= \left| \mathbb{E}_{(x,y) \sim \mathcal{D}} \left[ \prod_{i=1}^k \frac{(1-2a_i)(1-2z_i(x)) + 1}{2} \right] - 2^{-k} \right| \\
&= 2^{-k} \left| \sum_{I \subseteq [k]} \mathbb{E}_{(x,y) \sim \mathcal{D}} \left[ \prod_{i \in I} (1-2a_i)(1-2z_i(x)) \right] - 1 \right| \\
&\hspace{15em} \text{(expansion of product and linearity)} \\
&= 2^{-k} \left| \sum_{I \subseteq [k]: I \neq \emptyset} \mathbb{E}_{(x,y) \sim \mathcal{D}} \left[ \prod_{i \in I} (1-2a_i)(1-2z_i(x)) \right] \right| \\
&\hspace{15em} \text{(empty product equals 1)} \\
&\leq 2^{-k} \sum_{I \subseteq [k]: I \neq \emptyset} \left| \prod_{i \in I} (1-2a_i) \right| \cdot \left| \mathbb{E}_{(x,y) \sim \mathcal{D}} \left[ \prod_{i \in I} (1-2z_i(x)) \right] \right| \\
&\hspace{15em} \text{(triangle inequality and linearity)} \\
&= 2^{-k} \sum_{I \subseteq [k]: I \neq \emptyset} \left| \mathbb{E}_{(x,y) \sim \mathcal{D}} \left[ \prod_{i \in I} (1-2z_i(x)) \right] \right| \quad (|1-2a_i| = 1) \\
&\leq 2^{-k} \cdot (2^k - 1) \cdot 5^{-k} < 5^{-k}. \quad \text{(Inequality (2))}
\end{aligned}$$

The proof of the “furthermore” part is the same, except that after conditioning on  $x_i = b$ , each  $\bigoplus_{j \in I} z_j(x)$  is now the XOR of at least  $d - 1$  independent bits, and the remaining proof goes through.  $\blacktriangleleft$

We note that the proof of Lemma 14 depends on the definition of  $z(x)$  only through the application of Lemma 12. Thus, Lemma 16 directly implies the following analog of Lemma 14:

► **Lemma 17.** *Fix  $L \geq \alpha > 0$  and  $\delta \in (0, \frac{1}{2}]$ . Let  $c_0 = \frac{\ln 5}{\delta}$  and  $k_0 = \frac{\ln(2\kappa)}{\ln(5/4)} + 1$ , where  $\kappa$  is chosen as in Lemma 8. The following holds for every function  $f_{c,k,S}$  such that  $k \geq k_0$  and  $S$  has distance  $c_0 k$ : For any  $(\alpha, L)$ -impurity function  $\mathcal{G}$ ,  $\delta$ -balanced product distribution  $\mathcal{D}$  and restriction  $\pi$  of size  $< 2^k$  that only contains the memory bits of  $f_{c,k,S}$ , the purity gain  $\mathcal{G}$ -purity-gain $_{\mathcal{D}}((f_{c,k,S})_{\pi}, \cdot)$  is maximized by a memory bit.*

Finally, we prove Theorem 10 by showing the existence of a set family  $S$  with a good distance.

**Proof of Theorem 10.** Fix  $\delta \in (0, \frac{1}{2}]$ . The Gilbert–Varshamov bound for binary linear codes implies that for some  $c = \Theta(1/\delta)$ , there exists a binary linear code with rate  $\frac{1}{c}$  and relative distance  $\frac{\ln 5}{\delta c}$ . It follows that for every sufficiently large  $k$ , there exists  $S^{(k)} = (S_1^{(k)}, S_2^{(k)}, \dots, S_k^{(k)})$  such that each  $S_i^{(k)} \subseteq [ck]$  and  $S^{(k)}$  has distance  $\frac{\ln 5}{\delta} \cdot k$ . This can be done by using the  $i$ -th basis of the linear code as the indicator vector of subset  $S_i^{(k)}$  for each  $i \in [k]$ .

We prove Theorem 10 using functions  $f_{c,1,S^{(1)}}, f_{c,2,S^{(2)}}, \dots$ . Since each  $f_{c,k,S^{(k)}}$  can be represented by a decision tree of depth  $ck + 1 = O(k/\delta)$ , it remains to prove that impurity-based algorithms fail to learn  $f_{c,k,S^{(k)}}$ . Lemma 17 guarantees that the tree returned by such algorithms either has depth  $> 2^k$ , or never queries any addressing bits. In the latter case, by the same calculation as in the proof of the weaker version, the decision tree must have an  $\Omega(\delta)$  error on distribution  $\mathcal{D}$ .  $\blacktriangleleft$

## 6 Proof of Theorem 11

We prove Theorem 11 using the construction of  $f_{c,k,S}$  in Section 5, where  $S = (S_1, S_2, \dots, S_k)$  is a list of  $k$  subsets of  $[ck]$  and each  $S_i$  specifies how the  $i$ -th bit of the address,  $z_i(x)$ , is computed from the addressing bits  $x_1$  through  $x_{ck}$ . Note that  $f_{c,k,S}$  itself depends on  $\Omega(2^k)$  input bits and is thus not an  $O(k)$ -junta. Nevertheless, we will show that, after we fix most of the memory bits of  $f_{c,k,S}$ , the function is indeed close to a  $(ck)$ -junta with relevant inputs being the  $ck$  addressing bits. Then, as in the proof of Theorem 10, we will argue that impurity-based heuristics still query the (unfixed) memory bits before querying any of the addressing bits, resulting in a tree that is either exponentially deep or far from the target function.

**Proof of Theorem 11.** As in the proof of Theorem 10, we can find functions  $f_{c,1,S^{(1)}}, f_{c,2,S^{(2)}}, \dots$  for some  $c = \Theta(1/\delta)$  such that each  $S^{(k)}$  has distance  $\geq \frac{\ln 5}{\delta} \cdot k$ . We fix a sufficiently large integer  $k$  and shorthand  $f$  for  $f_{c,k,S^{(k)}}$  in the following.

Partition  $\{0, 1\}^k$  into three sets  $A^0$ ,  $A^1$  and  $A^{\text{free}}$  such that  $|A^0| = |A^1|$  and  $\varepsilon \cdot 2^{k-2} \leq |A^{\text{free}}| \leq \varepsilon \cdot 2^{k-1}$ . Consider the restriction  $\pi$  of function  $f$  such that the memory bit  $y_a$  is fixed to be 0 for every  $a \in A^0$  and fixed to be 1 for every  $a \in A^1$ ; the memory bits with addresses in  $A^{\text{free}}$  are left as “free” variables. We will prove the theorem using  $f_\pi$  as the  $k$ -th function in the family.

### $f_\pi$ is close to a junta

Consider the function  $g : \{0, 1\}^{ck+2^k} \rightarrow \{0, 1\}$  defined as  $g(x, y) = \mathbf{1}[z(x) \in A^1]$ , where  $z(x)$  denotes  $(z_1(x), z_2(x), \dots, z_k(x))$  and each  $z_i(x) = \bigoplus_{j \in S_i^{(k)}} x_j$ . Clearly,  $g(x, y)$  only depends on  $x \in \{0, 1\}^{ck}$  and is thus a  $(ck)$ -junta. Furthermore, for every input  $(x, y)$  such that  $z(x) \in A^0$  (resp.  $z(x) \in A^1$ ), both  $f_\pi$  and  $g$  evaluate to 0 (resp. 1). Thus,  $f_\pi$  and  $g$  may disagree only if  $z(x) \in A^{\text{free}}$ . It follows that for every  $\delta$ -balanced product distribution  $\mathcal{D}$ ,

$$\begin{aligned} \Pr_{(x,y) \sim \mathcal{D}} [f_\pi(x, y) \neq g(x, y)] &\leq \Pr_{(x,y) \sim \mathcal{D}} [z(x) \in A^{\text{free}}] \\ &\leq |A^{\text{free}}| \cdot (2^{-k} + 5^{-k}) && \text{(Lemma 16)} \\ &\leq \varepsilon \cdot 2^{k-1} \cdot (2^{-k} + 5^{-k}) < \varepsilon. && (|A^{\text{free}}| \leq \varepsilon \cdot 2^{k-1}) \end{aligned}$$

Therefore,  $f_\pi$  is  $\varepsilon$ -close to an  $O(k/\delta)$ -junta (namely,  $g$ ) with respect to distribution  $\mathcal{D}$ .

### Impurity-based algorithms fail to learn $f_\pi$

Let  $T$  be the decision tree returned by an  $\mathfrak{G}$ -impurity based algorithm when learning  $f_\pi$  on distribution  $\mathcal{D}$ . By Lemma 17,  $T$  must query all the free memory bits with addresses in  $A^{\text{free}}$  before querying any of the addressing bits. Thus, either  $T$  has depth  $> |A^{\text{free}}| = \Omega(\varepsilon \cdot 2^k)$ , or  $T$  only queries the free memory bits of  $f_\pi$ .

In the latter case, we may again assume without loss of generality that  $T$  queries all the free memory bits  $(y_a)_{a \in A^{\text{free}}}$  before reaching any of its leaves, i.e.,  $T$  is a full binary tree of depth  $|A^{\text{free}}|$ . Then, every leaf  $\ell$  naturally specifies  $2^k$  bits  $(c_a)_{a \in \{0,1\}^k}$  defined as

$$c_a = \begin{cases} 0, & a \in A^0, \\ 1, & a \in A^1, \\ b, & a \in A^{\text{free}}, y_a \text{ is fixed to } b \text{ on the root-to-}\ell \text{ path.} \end{cases}$$

## 45:14 Decision Tree Heuristics Can Fail, Even in the Smoothed Setting

Let  $\mu_\ell := \mathbb{E}_{(x,y) \sim \mathcal{D}} [c_{z(x)}]$ . Again, the minimum possible error conditioning on reaching leaf  $\ell$  is  $\min(\mu_\ell, 1 - \mu_\ell)$ , achieved by labeling  $\ell$  with  $\mathbb{1}[\mu_\ell \geq \frac{1}{2}]$ . On the other hand, we have

$$\begin{aligned} \mu_\ell &\geq \Pr_{(x,y) \sim \mathcal{D}} [z(x) \in A^1] \\ &\geq |A^1| \cdot (2^{-k} - 5^{-k}) && \text{(Lemma 16)} \\ &\geq \frac{2^k - |A^{\text{free}}|}{2} \cdot 2^{-(k+1)} && (2|A^1| + |A^{\text{free}}| = 2^k) \\ &\geq \frac{2^k - 2^{k-1}}{2} \cdot 2^{-(k+1)} = \frac{1}{8}, && (|A^{\text{free}}| \leq \varepsilon \cdot 2^{k-1} \leq 2^{k-1}) \end{aligned}$$

and a similar calculation shows  $\mu_\ell \leq \frac{7}{8}$ . We conclude that the error of the decision tree  $T$  over distribution  $\mathcal{D}$  is at least  $\frac{1}{8} = \Omega(1)$ .  $\blacktriangleleft$

## 7 Conclusion

We have constructed target functions for which greedy decision tree learning heuristics fail badly, even in the smoothed setting. Our lower bounds complement and strengthen the parity-of-two-features example discussed in the introduction, which showed that these heuristics fail badly in the non-smoothed setting.

It can be reasonably argued that real-world data sets do not resemble the target functions considered in this paper or the parity-of-two-features example. Perhaps the sought-for guarantee ( $\diamond$ ), while false for certain target functions even in the smoothed setting, is nonetheless true for broad and natural classes of targets? It would be interesting to reexamine, through the lens of smoothed analysis, provable guarantees for restricted classes of functions that have been established. For example, can the guarantees of [3, 2] for monotone target functions and product distributions be further strengthened in the smoothed setting? The target functions considered in this paper, as well as the parity-of-two-features example, are non-monotone.

## Abstract

---

Motivated by the goal of showing stronger structural results about the complexity of learning, we study the learnability of strong concept classes beyond P/poly, such as PSPACE/poly and EXP/poly. We show the following:

1. (Unconditional Lower Bounds for Learning) Building on [31], we prove unconditionally that BPE/poly cannot be weakly learned in polynomial time over the uniform distribution, even with membership and equivalence queries.
2. (Robustness of Learning) For the concept classes EXP/poly and PSPACE/poly, we show unconditionally that worst-case and average-case learning are equivalent, that PAC-learnability and learnability over the uniform distribution are equivalent, and that membership queries do not help in either case.
3. (Reducing Succinct Search to Decision for Learning) For the decision problems  $R_{K_t}$  and  $R_{K_S}$  capturing the complexity of learning EXP/poly and PSPACE/poly respectively, we show a *succinct search to decision* reduction: for each of these problems, the problem is in BPP iff there is a probabilistic polynomial-time algorithm computing circuits encoding proofs for positive instances of the problem. This is shown via a more general result giving succinct search to decision results for PSPACE, EXP and NEXP, which might be of independent interest.
4. (Implausibility of Oblivious Strongly Black-Box Reductions showing NP-hardness of learning NP/poly) We define a natural notion of hardness of learning with respect to oblivious strongly black-box reductions. We show that learning PSPACE/poly is PSPACE-hard with respect to oblivious strongly black-box reductions. On the other hand, if learning NP/poly is NP-hard with respect to oblivious strongly black-box reductions, the Polynomial Hierarchy collapses.

## 1 Introduction

What is the complexity of learning polynomial-size circuits? Despite extensive research on this question, our knowledge is still fairly sparse. For weak concept classes such as decision trees [34, 32], DNFs [34, 27] or even constant-depth circuits with parity gates [12],

reasonably efficient learning algorithms under the uniform distribution are known for various models of learning. For stronger concept classes, learning is believed to be hard, but the evidence for this is not as strong as one might hope. Cryptographic assumptions such as the existence of one-way functions are known to imply that learning polynomial-size circuits is hard [29, 18]. However, we still seem far from showing that PAC-learning polynomial-size circuits is NP-hard - indeed [5] give negative results for certain kinds of black-box reductions to learning.

In this paper, we adopt a fresh perspective of approaching the learnability question from above, i.e. via circuit classes which are more powerful than P/poly. We consider commonly held beliefs about the complexity of learning, and establish these beliefs unconditionally for strong concept classes such as PSPACE/poly and EXP/poly. Of course the very learnability of these concept classes has some unlikely implications, eg., that these classes are approximable by efficient Boolean circuits. The point is that this is still consistent with our complexity-theoretic understanding, and we would like to know what current techniques are capable of proving *unconditionally* about learning. Partly this is to understand the limitations of current techniques, and partly this is to understand what structural properties of the stronger concept classes enable us to show unconditional results about them.

We begin by outlining our main results and comparing them with previous work.

## 1.1 Unconditional Results for Hardness of Learning

Our first set of results deals with unconditional hardness of learning circuit classes. Most complexity theorists believe that learning polynomial-size circuits is unconditionally hard, but of course proving this is at least as hard as the P vs NP problem. We ask: what is the smallest concept class  $\mathcal{C}/\text{poly}^2$  for which we can *prove* learning to be hard? Clearly, if we can prove that  $\mathcal{C}/\text{poly}$  cannot be approximated by efficient circuits, i.e., there does not even *exist* a good hypothesis for all concepts in the class, then hardness of learning follows. This observation implies for example that learning MAEXP is hard, by using known circuit lower bounds for this class [11].

But can we show hardness of learning unconditionally for some concept class where it is consistent with our current understanding of complexity theory that a good hypothesis exists for every concept in the class? We give an affirmative answer by ruling out PAC-learning with membership and equivalence queries unconditionally for the class BPE/poly.

The notion of PAC-learning  $\mathcal{C}/\text{poly}$ , for a uniform class  $\mathcal{C}$  above P such as EXP or BPE, can have different interpretations. Standard definitions for PAC-learning (cf. [30]) consider the task of learning to be efficient if it is polynomial in the size of the target concept over  $n$  inputs (assume that the accuracy  $\varepsilon$  and confidence  $\delta$  are both  $1/\text{poly}(n)$ ) and the hypothesis class is P/poly.<sup>3</sup> The standard definition of PAC-learning in  $\text{poly}(n)$  time using P/poly as its hypothesis class naturally extends to the concept class  $\mathcal{C}/\text{poly}$  as the size of the target concept is *still* polynomial in the input size  $n$ . For the classes  $\mathcal{C}$  we consider, PAC-learnability of  $\mathcal{C}/\text{poly}$  in  $\text{poly}(n)$  time using polynomial-sized hypothesis circuits is still consistent with our current understanding of complexity theory (as we do not have any unconditional average-case lower bounds for  $\mathcal{C}$  against P/poly), and therefore worth studying.

<sup>2</sup> For any uniform complexity class  $\mathcal{C}$ , define the class  $\mathcal{C}/\text{poly}$  as the set of languages  $L$  for which there is a language  $\mathcal{C}$ -machine  $M$  and a family of strings  $\{a_n\}$ , where  $a_n \in \{0, 1\}^{\text{poly}(n)}$ , such that for every  $x \in \{0, 1\}^n$ ,  $x \in L \iff M$  accepts  $(x, a_n)$

<sup>3</sup> In general, the definition requires the hypothesis class  $H$  to be *polynomially evaluable*, which means that there exists an algorithm that on input any instance  $x \in \{0, 1\}^n$  and an encoding of the hypothesis  $h \in H_n$ , outputs the value  $h(x)$  in time polynomial in  $n$  and the size of the hypothesis encoding. It is well known that P/poly is polynomially evaluable.

We say that a class  $\mathcal{C}$  is  $(\varepsilon, \delta)$ -learnable using membership queries over distribution  $\mathcal{D}$  in polynomial time, if there exists a probabilistic polynomial time learning algorithm which given oracle access to any  $f \in \mathcal{C}$ , with probability at least  $1 - \delta$ , outputs a polynomial-sized hypothesis circuit that approximates  $f$  up to an error  $\varepsilon$  over the target distribution  $\mathcal{D}$ . This definition also extends to the case of  $(\varepsilon, \delta)$ -learning using random examples.

BPE/poly can equivalently be defined as the class of languages computable by polynomial-sized circuit families with oracle gates to some function in BPE, with the oracle query size restricted to  $O(n)$ . We prove the unconditional hardness of learning BPE/poly in polynomial time using membership queries even over the uniform distribution using P/poly as the hypothesis class. Hardness of exactly learning BPE/poly with membership and equivalence queries, even using randomized algorithms follows directly from this via [4].

► **Theorem 1.1.** *For every constant  $k \in \mathbb{N}$ , BPE/poly cannot be  $(1/2 - 1/n^k, 1/n)$ -learnt over the uniform distribution using membership queries by randomized learning algorithms running in polynomial time.*

To prove this, we adapt techniques used by [31, 36] to show that randomized PAC-learning algorithms imply circuit lower bounds. [38] show the existence of a PSPACE-Complete function  $f^*$  which is in  $\text{DSPACE}[n]$ , such that  $f^*$  is downward self-reducible and self-correctible (see Appendix A for definitions). Using the techniques of [31], along with the fact that  $f^*$  belongs to BPE, we see that PSPACE collapses to BPP. Using a padding argument and diagonalizing  $\text{DSPACE}[2^{O(n)}]$  against functions which can be approximated by polynomial-sized circuits, we obtain a contradiction to the fact that for every function in BPE/poly, the learner gives a hypothesis circuit which approximates it well.

## 1.2 Robustness for Hardness of Learning

We believe that polynomial-size circuits are hard to learn in a *robust* sense, i.e., that the precise details of the learning model do not matter. Hardness should hold irrespective of whether we consider PAC-learning or learning over the uniform distribution, worst-case learning or average-case learning over some samplable distribution on concepts, and whether or not the learning model is allowed to use membership queries. We do not know how to show that this robustness holds for P/poly, but we are able to show it unconditionally for EXP/poly and PSPACE/poly.

We now consider the class EXP/poly, which can be equivalently defined as the circuit class  $\text{P}^{\text{EXP}}/\text{poly}$  i.e. the class of languages that can be computed by a polynomial sized circuit family with EXP oracle gates.

Showing non-trivial derandomization of BPP, i.e.  $\text{EXP} \neq \text{BPP}$ , is one of the most fundamental questions in complexity theory.<sup>4</sup> We prove that the problem of non-trivial derandomization of BPP is equivalent to the hardness of learning EXP/poly efficiently in most standard models of PAC-learning. In addition, these results extend to not just showing that EXP/poly is hard to learn in the worst-case, but also on average with respect to polynomially samplable distributions over EXP/poly.<sup>5</sup> This also gives us an intriguing situation, where hardness of learning EXP/poly using random examples also implies the hardness of learning EXP/poly using membership queries.

<sup>4</sup> It is worth mentioning that [26] show that  $\text{EXP} \neq \text{BPP}$  is equivalent to the fact that BPP can be derandomized on average in deterministic sub-exponential time (over infinitely many input lengths).

<sup>5</sup> In particular, the results hold for polynomially samplable distribution families over EXP/poly, where for each  $n$ , there exists a distribution in the family over circuit encodings of  $n$ -variate functions in EXP/poly, implicitly defining a distribution on  $n$ -variate functions in EXP/poly (see Remark A.3 for more details.)

The following results are stated for hardness of strong learning. However, they also hold for the setting of weak learnability, by standard equivalences between weak learning and strong learning for PAC-learners [17].

► **Theorem 1.2** (Equivalences for hardness of learning EXP/poly). *The following statements are equivalent.*

1. **Non-trivial derandomization of BPP:**  $\text{EXP} \neq \text{BPP}$ .
2. **Hardness of PAC-learning EXP/poly in the worst-case using random examples:** *There exists  $c \geq 0$ , such that EXP/poly is not  $(1/n^c, 1/20n)$ -PAC-learnable in polynomial time using random examples.*
3. **Hardness of PAC-learning EXP/poly in the worst-case using membership queries:** *There exists  $c \geq 0$ , such that EXP/poly is not  $(1/n^c, 1/20n)$ -PAC-learnable in polynomial time using membership queries.*
4. **Hardness of PAC-learning EXP/poly on average using random examples:** *There exists  $c \geq 0$ , such that EXP/poly is not  $(1/n^c, 1/20n)$ -PAC-learnable in polynomial time on average using random examples, with respect to polynomially samplable distributions over EXP/poly.*
5. **Hardness of PAC-learning EXP/poly on average using membership queries:** *There exists  $c \geq 0$ , such that EXP/poly is not  $(1/n^c, 1/20n)$ -PAC-learnable in polynomial time on average using membership queries, with respect to polynomially samplable distributions over EXP/poly.*

A contrasting result to this is the equivalence between the existence of one-way functions (OWFs) and the hardness of learning P/poly in polynomial time on average with respect to polynomially samplable distributions over P/poly using random examples [25, 8]. Theorem 1.2 not only lends an analogous equivalence between a complexity theoretic assumption that BPP has a non-trivial derandomization and the hardness of learning EXP/poly in polynomial time on average using random examples, but also extends this equivalence to hardness of learning EXP/poly efficiently in the worst-case. Note that showing such an equivalence between the existence of OWFs and hardness of learning P/poly efficiently in the worst-case has been open for decades.<sup>6</sup>

Furthermore, our proof techniques also let us extend all these equivalences to the case where  $\mathcal{C} = \text{PSPACE}$ .

► **Corollary 1.3.** *The following statements are equivalent.*

1.  $\text{PSPACE} \neq \text{BPP}$ .
2. *There exists  $c \geq 0$ , such that PSPACE/poly is not  $(1/n^c, 1/20n)$ -PAC-learnable in polynomial time using random examples (also using membership queries).*
3. *There exists  $c \geq 0$ , such that PSPACE/poly is not  $(1/n^c, 1/20n)$ -PAC-learnable in polynomial time on average using random examples (also using membership queries) with respect to polynomially samplable distributions over PSPACE/poly.*

Essentially, the proof of showing conditional hardness of PAC-learning EXP/poly uses the fact that strongly learning EXP/poly using random examples over the *uniform distribution* implies that  $\text{EXP} = \text{BPP}$ . This also means that the hardest distribution to learn EXP/poly is over the uniform distribution. The same ideas hold for PAC-learning EXP/poly using membership queries too.

---

<sup>6</sup> In particular, we do not know if hardness of learning P/poly efficiently using random examples in the worst-case implies OWFs.

Our techniques used to show these equivalences are inspired from results on uniform derandomization by [26, 38], which were further used by [15, 31] to show circuit lower bounds based on the existence of learning algorithms. We use special properties of functions in EXP and PSPACE like downward self-reducibility and self-correctibility to show that learning these functions would imply a collapse for EXP and PSPACE to BPP.

### 1.3 Reducing Succinct Search to Decision for Learning

Recently, [12] established an important connection between *natural proofs* and *learning*. They showed that natural proofs of strong lower bounds against a circuit class  $\mathcal{C}/\text{poly}$  imply efficient learning algorithms for  $\mathcal{C}/\text{poly}$  over the uniform distribution with membership queries, as long as the class  $\mathcal{C}/\text{poly}$  satisfies some mild closure properties. One way to interpret their result is as an *approximate search to decision* reduction for learning. The decision version of learning polynomial-size circuits is the language MCSP consisting of truth tables of functions that have small circuits, i.e., for which a good hypothesis exists. The search version is to find a small circuit for a positive instance of MCSP. [12] show that if MCSP is polynomial-time decidable (which is implied by the existence of natural proofs against P/poly), then the search version of MCSP can be solved approximately, in the sense that we can efficiently compute a polynomially larger sized circuit that approximates the truth table well.

The language  $R_{Kt}$  (resp.  $R_{KS}$ ) of strings with high Kt complexity (resp. high KS complexity) plays an analogous role to MCSP in the theory of learning EXP/poly (resp. PSPACE/poly). We ask if search to decision reductions can be established for these languages as well. However, it is unclear a priori what it would mean to solve search efficiently for a problem that does not have polynomial-size proofs or witnesses. We introduce the notion of *succinct search*. To efficiently solve a search problem succinctly is to efficiently compute for any YES instance of the problem a circuit that encodes a possibly exponential-size proof for the instance. We use the PCP theorem for NEXP [6] and the Easy Witness Lemma [24] to show that for the classes PSPACE, EXP and NEXP, efficient decidability of the class is equivalent to efficiently solving succinct search for every language in the class. We then use results from [3] to argue that for  $R_{Kt}$  and  $R_{KS}$ , efficient solvability is equivalent to solving succinct search efficiently. Note that this connection is for succinctly solving the search problem *exactly* rather than just for approximate search as in [12].

► **Theorem 1.4** (Equivalence of Succinct Search and Decision for Learning EXP/poly and PSPACE/poly). *Let  $L$  be  $R_{Kt}$  or  $R_{KS}$ .  $L \in \text{BPP}$  iff for each polynomial-time verifier  $V$  for  $L$ , succinct search is efficiently solvable for  $L$  with respect to  $V$ .*

### 1.4 Barriers for Establishing NP-Hardness of Learning

We next look at questions pertaining to hardness of learning classes of the form  $\mathcal{C}/\text{poly}$ , where  $\mathcal{C} \subseteq \text{PH}$ . We only focus on the hardness of PAC-learning  $\mathcal{C}/\text{poly}$  with random examples. In this section, we consider the limitations of proving the NP-hardness of PAC-learning NP/poly, i.e. the class of polynomial size non-deterministic circuits, using random examples, via a black-box reduction from deciding SAT.

Informally, a black-box reduction from problem  $A$  to  $B$ , solves  $A$  given access to any oracle solving  $B$ . Black-box reductions have been ubiquitously used in complexity theory to prove conditional lower bounds. However, for many fundamental questions in complexity theory, there have been results showing why such reductions are limited in power. Various results have conditionally ruled out special-cases of black-box reductions for showing average-case hardness of NP [14, 10], existence of one-way functions [1, 5, 9] and the existence of hitting set generators [22], from hardness of SAT.

For the case of showing hardness of learnability, a  $B$ -adaptive black-box reduction  $R$  from some language  $L$  to PAC-learning a class  $\mathcal{C}$  using random examples is defined by two phases

- The first phase consists of  $B$  adaptive rounds of probabilistic polynomial time algorithms, each of which generates queries to the learner oracle. In more detail, each round uses the input  $z$  to the reduction, fresh randomness and the hypotheses returned by the  $\mathcal{C}$ -learner oracle in the previous rounds, and constructs joint distributions (that serve as example oracles for the learner). It then samples a set of independent labeled examples from each of these distributions as queries to the learner oracle.
- In the second phase, a probabilistic polynomial time algorithm takes all the hypotheses from the first phase and decides whether  $z \in L$ , with high probability.

[5] study the question of the existence of black-box Turing reductions from any language in NP to PAC-learning P/poly using random examples. They consider a strongly black-box reduction, where a reduction is strongly black-box if it runs correctly given any oracle for the learner, as well as the hypotheses output by the learner. For a special case of such a reduction, where the access to the learner and the hypothesis oracles is additionally non-adaptive, they show that such a reduction from SAT to PAC-learning P/poly using random examples collapses NP to CoAM (which implies a collapse of PH to the second level). Additionally, they show that if any language  $L$  reduces to PAC-learning P/poly using random examples via an  $O(1)$ -adaptive black-box reduction, then the hardness of  $L$  implies the existence of an auxiliary-input one-way function (which is a major breakthrough in cryptography).<sup>7</sup>

We define a natural special-case of such a reduction, called an *oblivious* strongly black-box reduction, where the obliviousness of a reduction implies that the queries made to the learner do not depend on the input  $z$  to the reduction, and try to understand its limitations for showing NP-hardness of PAC-learning NP/poly. At a first glance, ruling out oblivious reductions may seem very restrictive, since ideally, one would like to allow reductions whose queries to the learner can depend on the input to the reduction. However, we observe the proof of Corollary 1.3 which shows hardness of PAC-learning PSPACE/poly assuming PSPACE  $\neq$  BPP and reformulate it as an oblivious black-box reduction of the form defined above. In particular, for  $f^*$  being the PSPACE-Complete function given by [38] which is downward self-reducible and self-correctible, we observe that

► **Lemma 1.5.** *There exists an oblivious,  $n$ -adaptive, strongly black-box reduction from deciding  $f^*$  to PAC-learning PSPACE/poly using random examples over the uniform distribution.*

On the other hand, for the case of learning NP/poly using random examples, we show that oblivious strongly black-box reductions from SAT imply a collapse of the polynomial hierarchy. Our main result for the section is

► **Theorem 1.6 (Informal).** *If there exists an oblivious,  $\text{poly}(n)$ -adaptive, strongly black-box reduction from deciding SAT to learning NP/poly using random examples over polynomially samplable distributions, then PH collapses to the third level.*<sup>8</sup>

<sup>7</sup> They also show the impossibility of Karp reductions from SAT to PAC-learning P/poly using random examples, unless NP collapses to SZKA.

<sup>8</sup> We actually show a stronger result that the existence of such a reduction implies that  $\text{NP} \subseteq \text{CoAM}^{\text{poly}}$ , where  $\text{CoAM}^{\text{poly}}$  is the class of languages recognized by constant-round CoAM protocols with advice, where we require proper acceptance/rejection probabilities only when the advice is correct.

Theorem 1.6 implies that standard techniques used for worst-case to average-case reductions, pseudo-random generator constructions from uniform hardness assumptions and in particular, hardness of efficiently PAC-learning classes like PSPACE/poly, cannot be used to show the NP-hardness of PAC-learning NP/poly using random examples.

Theorem 1.6 compares to some previous results in the following way:

- It shows a conditional impossibility result by ruling out a restricted version of adaptive, strongly black-box reductions to learning P/poly using random examples, in contrast to [5], who only rule out fully non-adaptive, strongly black-box reductions, from a slightly weaker assumption ( $\text{NP} \not\subseteq \text{CoAM}$ ).
- Furthermore, the result by [22] which conditionally rules out a non-adaptive black box reduction from deciding SAT to breaking a Hitting Set Generator (HSG), in turn rules out fully non-adaptive, strongly black-box reductions from SAT to learning NP/poly using membership queries over the uniform distribution (by suitably changing the definition of the reduction to the learner).

Indeed, the ideas of [26] can be used to show that hardness of learning NP/poly using membership queries over the uniform distribution, implies the existence of a hitting set generator which hits sufficiently dense circuits. We strengthen this observation by not only extending the reduction to a restricted version of the adaptive case, but also by ruling out a weaker reduction to learning NP/poly with random examples.

- In a similar way, [20] conditionally rule out the existence of mildly adaptive (each query length up to  $n$ , where  $n$  is the length of the input instance, appears in very few levels of adaptivity), strongly black-box reductions from an EXP-Complete problem to learning NP/poly using membership queries (and in fact, learning EXP/poly).

Our result rules out the restricted cases of mildly adaptive, strongly black-box reductions which show the NP-hardness of learning NP/poly using random examples and hence, is a conceptual strengthening of [20], as we rule out a hardness result from a stronger assumption.

- On the other hand, Schapire [37] shows that a *non-uniform* hardness assumption like  $\text{NP/poly} \neq \text{P/poly}$  actually implies the hardness of PAC-learning NP/poly in polynomial time using random examples. They show that if NP/poly is learnable in polynomial time, then there exists an algorithm which takes any  $m$  labeled samples of a target  $f_n \in \text{NP/poly}$ , runs in time  $\text{poly}(m, n)$ , and with high probability, outputs a hypothesis of size  $\text{poly}(n)$  (independent of  $m$ ) that is consistent with all the labeled samples.

In particular, if  $m = 2^n$ , then for every  $f_n \in \text{NP/poly}$ , the algorithm outputs a polynomial-sized hypothesis circuit which computes it correctly on all inputs, thus contradicting the assumption  $\text{NP/poly} \neq \text{P/poly}$ . Note that the result uses that for any  $f_n$ , we get a polynomial-sized circuit that computes it, and in fact, the algorithm runs in  $\text{poly}(m, n) = 2^{O(n)}$  time and is not useful in terms of contradicting a uniform assumption.

It is worth noting that our result has no implications for showing the impossibility of adaptive, black-box NP-hardness reductions which imply the average-case hardness for NP [14, 10], existence of one-way functions [1, 5] or the existence of HSGs [20, 22].

**Overview of the techniques.** The proof of Theorem 1.6 builds on the Feigenbaum-Fortnow [14] protocol, which simulates a type of non-adaptive randomized reduction  $A$  from SAT to an NP problem  $\mathcal{Q}$ , by an AM protocol with polynomial-sized advice, and shows that  $\text{coNP} \subseteq \text{NP/poly}$ .<sup>9</sup>

<sup>9</sup> Their motivation (and [10]) was to rule out certain kinds of non-adaptive, worst-case to average-case black-box reductions for NP.

Suppose that on input  $x$ ,  $A$  makes  $q$  non-adaptive queries to  $\mathcal{Q}$ , sampled independently from certain distribution  $X$ . Very briefly, their AM protocol does the following. For  $K$  large enough, the verifier first generates  $K$  tuples of  $q$  non-adaptive queries by running  $A(x)$  independently  $K$  times. The verifier asks the prover to send a witness to each query which is a YES instance (which it can verify easily). This ensures that the prover cannot cheat if the query is a NO instance and the only way it can cheat is by claiming a YES instance to be a NO instance. Now, if the verifier has the proportion  $p$  of YES instances of  $\mathcal{Q}$  over the distribution  $X$ , then with high probability it knows that the number of YES instances among the  $Kq$  queries is concentrated around  $q \cdot (pK \pm O(\sqrt{K}))$ . The verifier answers with a reject if the number of YES instances is much lesser than  $pqK$ .

The honest prover answers each query correctly (with correct witnesses if necessary) and with high probability, the number of YES instances are close to the expectation. Hence, the verifier can pick any of  $K$  runs of  $A(x)$  using the prover's answers to its queries and the output will be correct with high probability. On the other hand, the cheating prover cannot cheat on more than  $O(q\sqrt{K})$  YES instances, with high probability. If we choose  $K \gg O(q\sqrt{K})$ , then on most of the  $K$  independent runs of  $A$ , all its queries are answered correctly and the reduction gives the correct answer. Thus, if we pick one of the runs at random and get  $A(x)$  by using the prover's answers to its queries, the verifier answers wrongly with low probability.

Consider an oblivious,  $B$ -adaptive, strongly black-box reduction  $R$  from  $L$  to an oracle which learns NP/poly. Suppose we are able to fix  $S_1, \dots, S_t$ , which are sets of labeled examples drawn independently from the joint distributions  $(X_1, f_1(X_1)), \dots, (X_t, f_t(X_t))$  where  $f_1, \dots, f_t \in \text{NP/poly}$ , as the queries made to the learner. Furthermore, let  $h_1, \dots, h_t$  be a set of fixed hypotheses circuits, some of which are used to generate  $S_1, \dots, S_t$ , such that each  $h_i$   $(1 - \varepsilon_0)$ -approximates  $f_i$  over  $X_i$ , for some  $\varepsilon_0 > 0$ . Because  $R$  is strongly black-box, each hypothesis is also accessed as an oracle and we see that  $L$  is decided by the algorithm  $M$  in the second phase, which has access to  $h_1, \dots, h_t$ . Now, the  $t$  oracles to  $M$  can be replaced by a single oracle  $\mathcal{O}$  which takes as input  $i \in [t]$  and  $y \in \{0, 1\}^n$ , and outputs  $h_i(y)$  ( $\mathcal{O}$  can be thought of as a table with  $t$  rows and  $2^n$  columns). We then adapt the techniques of [14] to design an AM protocol for  $L$  with polynomial sized advice, where the verifier expects that the prover answers according to  $\mathcal{O}$ .

The obliviousness of the reduction helps us in fixing the queries made by  $R$ , and implicitly, the corresponding hypotheses output by the oracle. In other words, this helps us fix the proportions of YES instances for each  $f_i$  non-uniformly, as the queries generated to the learner do not depend on the input to the reduction. We do this by inductively fixing the queries made by the reduction starting from the first round of adaptivity. Fixing a "good" polynomial-sized random string  $r^*$  used by the first phase non-uniformly (using Adleman's trick), we first get the queries to the learner made in the first round.

For any other round  $b \geq 2$ , assume that the queries to the learner up to round  $(b - 1)$  and the functionality of the hypothesis oracles used to generate them up to round  $(b - 2)$  are fixed. Using the fact that  $r^*$  is also fixed, we consider the set of all tuples of joint distributions that can be generated in the  $b^{\text{th}}$  round depending on the answers to the oracle queries of the hypotheses seen so far, and arbitrarily choose one of them. Note that, this implicitly fixes the functionality of the hypothesis oracles for the queries generated in round  $b - 1$ . We continue this process and fix all the queries made to the learner by all the rounds from the first phase.

The details of the results from this section have been delegated to Appendix B because of space constraints.

## 1.5 Further Discussion

**Connections to Karp-Lipton Style Theorems.** There is an analogy between our results on implications of learnability and Karp-Lipton style theorems. A Karp-Lipton style theorem for a uniform class  $\mathcal{C}$  gives an unlikely uniform implication of the assumption that  $\mathcal{C}$  has polynomial-size circuits. The original theorem of Karp and Lipton [28] shows such an implication for  $\mathcal{C} = \text{NP}$ : if  $\text{NP} \subseteq \text{P/poly}$ , then  $\Sigma_2 = \Pi_2$ . Karp-Lipton style theorems are now known for many other classes, including  $\mathcal{C} = \text{P}^{\#\text{P}}$  [35],  $\mathcal{C} = \text{PSPACE}$  [6] and  $\mathcal{C} = \text{EXP}$  [6]. In each of these cases,  $\mathcal{C} \subseteq \text{P/poly}$  implies  $\mathcal{C} = \text{MA}$ , applying techniques from the theory of interactive proofs [35, 6].

Similarly, in some of our results (i.e., Theorem 1.1, Theorem 1.2 and Corollary 1.3), we study implications of learnability for classes  $\mathcal{C}/\text{poly}$ , where  $\mathcal{C} = \text{BPE}, \text{EXP}$  or  $\text{PSPACE}$ . Since the learner is required to output a polynomial-size Boolean circuit, the learnability assumption already implies that  $\mathcal{C}$  is approximated by polynomial-size circuits, where the approximation is over the distribution on the examples. We are interested in establishing strong uniform implications of these assumptions, showing that the assumption is actually false in the case  $\mathcal{C} = \text{BPE}$ , and that the assumption implies a simulation of  $\mathcal{C}$  in  $\text{BPP}$  in the other cases. What enables us to show stronger implications than in corresponding Karp-Lipton style theorems is that the learner uniformly produces a good hypothesis by our assumption. However, the learner is assumed to have access to random examples or membership queries which cannot be efficiently simulated - this makes our simulation task more challenging, and we therefore exploit various structural properties of complete languages. We also need to deal with the issue of approximation, while standard Karp-Lipton style theorems have as their antecedent an exact simulation by efficient circuits.

**Open Questions.** One question which stems from our work is to explore the possibility of showing the hardness of PAC-learning  $\text{NP}/\text{poly}$  efficiently using random examples assuming that  $\text{NP} \neq \text{BPP}$ . A potential direction is to consider non black-box reductions for the  $\text{NP}$ -hardness of PAC-learning  $\text{NP}/\text{poly}$ . This viewpoint has lent itself some success in the case of worst-case to average-case reductions [19, 21, 22] and in our case, hardness of efficiently PAC-learning  $\text{EXP}/\text{poly}$ . Indeed, the reduction for  $\text{EXP}/\text{poly}$  only works if the learning algorithm runs in polynomial time, although the reduction still uses the learning algorithm as an oracle.<sup>10</sup> Moreover, [13] show a non black-box reduction from an approximate version of  $\text{MCSP}$  to learning  $\text{P}/\text{poly}$  by sub-exponential-sized circuits (and thus, learning  $\text{NP}/\text{poly}$ ). Note that, it is unclear if approximate  $\text{MCSP}$  is  $\text{NP}$ -hard and this reduction does not imply the  $\text{NP}$ -hardness of PAC-learning  $\text{NP}/\text{poly}$  efficiently.

Another important question is to explore an analogue of the  $\text{PH}$  collapse for learnability. In other words, does polynomial time learnability of  $\text{NP}/\text{poly}$  imply polynomial time learnability of  $\text{PH}/\text{poly}$ ? Note that, under a strong assumption of the existence of a (possibly adaptive and non-relativizable) worst-case to average-case reduction for  $\text{NP}$ , we can use the techniques in Lemma 3.2 along with the downward-self-reducibility of  $\text{SAT}$  to show such a collapse. On the other hand, [23] also shows that there exists an oracle  $O$  with respect to which  $\text{DistNP}^O \subseteq \text{AvgP}^O$  and  $\Sigma_2^O \not\subseteq \text{HeurSIZE}^O[2^{n^\alpha}]$ . Essentially, this result negates the existence of any relativizable reductions which show a statement analogous to the  $\text{PH}$  collapse for average-case algorithms i.e. if  $\text{NP}$  is easy on average, then  $\Sigma_2$  is easy on average too. In a similar spirit, can we prove that no relativizable technique can show that if  $\text{NP}/\text{poly}$  is learnable in polynomial time, then  $\Sigma_2/\text{poly}$  is learnable in polynomial time as well?

<sup>10</sup>For  $\text{EXP}$  to collapse to  $\text{PSPACE}$ , we need the  $\text{EXP}/\text{poly}$  learner to be efficient so that it outputs polynomial-sized hypothesis circuits for any language in  $\text{EXP}$ , and this further implies  $\text{EXP} \subseteq \text{P/poly}$ .

## 2 Unconditional Results for Hardness of Learning

Firstly, we show the hardness of learning BPE/poly over the uniform distribution using membership queries by randomized polynomial time algorithms. The proof of this result uses the following lemma from [31]. Preliminaries and definitions can be found in Appendix A.

► **Lemma 2.1.** *Let  $\mathcal{C}$  be any circuit class,  $s : \mathbb{N} \rightarrow \mathbb{N}$  be a size function and  $f^*$  be the PSPACE-Complete problem from Theorem A.8. There exists constant  $c \in \mathbb{N}$  such that if  $\mathcal{C}[s(n)]$  is learnable up to error  $n^{-c}$  in time  $T(n)$ , then at least one of the following holds :*

- $f^* \notin \mathcal{C}[s(n)]$ .
- $f^* \in \text{BPTIME}[\text{poly}(T(n))]$ .

We also need Lemma A.11 (Appendix A) which proves the existence of functions which cannot be approximated by  $n^{\log n}$ -sized circuits.

**Proof of Theorem 1.1.** Towards a contradiction, assume that there exists constants  $k, d \geq 1$  and a randomized learning algorithm  $A$  which learns BPE/poly in  $O(n^d)$  time over the uniform distribution using membership queries, up to error  $1/2 - 1/n^k$  and confidence  $1/n$ , for every large enough input length  $n$ . By non-uniformly fixing a good random string, we ensure that for every function  $g \in \text{BPE/poly}$ , there exists  $c$  such that  $A$  always outputs a hypothesis circuit of size  $O(n^c)$  which computes  $g$  on at least  $(1/2 + 1/n^k)$ -fraction of  $n$ -length inputs. Thus, for every function in BPE/poly, there exists a family of polynomial-sized circuits  $\{h_n\}_{n \in \mathbb{N}}$  which  $(1/2 + 1/n^k)$ -approximates it, where  $h_i$  is the hypothesis output by the learner on input length  $i$ .

We next show that the existence of such a learner implies the existence of a function in BPE which cannot be  $(1/2 + 1/n^k)$ -approximated by polynomial sized circuits. Consider the PSPACE-Complete function  $f^*$  from Theorem A.8 which is computable in time  $\text{DSPACE}[n]$ .  $f^*$  is in BPE/poly (since  $f^*$  can be computed in E) and we use the learning algorithm for BPE/poly in Lemma 2.1 to see that  $\text{PSPACE} \subseteq \text{BPP}$ . Using a padding argument we observe that  $\text{DSPACE}[2^{O(n)}] \subseteq \text{BPE}$ . From Lemma A.11, we see that there exists a function which cannot be  $(1/2 + 1/n^k)$ -computed by circuits of size  $n^{\log n}$ . We can easily construct a Turing Machine which lexicographically searches for the truth table of a function on  $n$  inputs which cannot be  $(1/2 + 1/n^k)$ -approximated by  $n^{\log n}$  sized circuits in  $2^{O(n)}$  space and answers according to the first one it finds. From this we have that  $\text{DSPACE}[2^{O(n)}]$ , and thus BPE/poly cannot be  $(1/2 + 1/n^k)$ -approximated by  $n^{\log n}$  sized circuits, which leads to a contradiction. ◀

► **Remark 2.2.** [36] show that if for each  $c$ , a circuit class  $\mathcal{C}[n^c]$  is  $(1/2 - 1/n^c, 1/n)$ -learnable using membership queries over the uniform distribution in  $2^n/n^{\omega(1)}$  time, then for each  $c$ , there exists  $L_c \in \text{BPE}$  such that  $L_c \notin \mathcal{C}[n^c]$  (Theorem 12). For any  $c$ , the idea of picking  $\mathcal{C}[n^c] = \text{SIZE}^{\text{BPE}}[n^c]$ , with linear-sized queries to BPE oracles and using the learning algorithm  $A$  which learns BPE/poly in their result to achieve a contradiction (as any function in BPE can be computed by constant sized  $\text{SIZE}^{\text{BPE}}$ -circuits with linear-sized oracle queries) does not work, as [36] crucially uses that  $\mathcal{C}[n^c]$  has to be a subset of  $\text{SIZE}[n^{c'}]$  for some  $c' = O(c)$ .

On the other hand, Theorem 4 in [15] shows that if  $\mathcal{C}$  is learnable using membership queries over the uniform distribution in polynomial time then  $\text{BPE} \not\subseteq \mathcal{C}[\text{poly}(n)]$ . Proving Theorem 1.1 by setting  $\mathcal{C}$  as BPE/poly again does not really work, as [15]'s result only holds true when  $\mathcal{C} = \text{P/poly}$ , as it depends on the collapse of EXP to P/poly.

We next consider hardness of learning E/poly deterministically over the uniform distribution using membership queries. E/poly can equivalently be defined as the class of languages which can be computed by polynomial-sized circuit families with oracle access to some function in E, with the constraint that the oracle queries are of size  $O(n)$ .

We first rule out deterministic *exact* learners for E/poly running in time  $O(2^n/n)$  in Angluin's model of learning [4], i.e. the learners have access to a membership oracle, as well as an equivalence oracle, where the learner presents a hypothesis circuit to the equivalence oracle, receives yes if the hypothesis exactly computes the target concept and receives a counter-example for the hypothesis, otherwise.

We also extend this result to rule out any deterministic learners for E/poly using membership queries, i.e. even learners which can output an approximate hypothesis. In particular, we can show that, for every constant  $\delta \in [0, 1/2 - 1/n)$ , E/poly is hard to learn up to error  $\delta$  over the uniform distribution using membership queries, even by deterministic learning algorithms which run in time  $2^n/n$ . These ideas can also be extended to show similar results for unconditional hardness of learning PSPACE/poly by deterministic polynomial time learners. The proofs follow from simple diagonalization-like arguments such as that used by [31] and can be found in the full version.

### 3 Robustness of Hardness of Learning

In this section, we establish the equivalences in Theorem 1.2 for hardness of learning EXP/poly. We first state the following results necessary for its proof.

► **Lemma 3.1.** *Let  $\text{EXP} = \text{BPP}$ . Then, for every  $c > 0$ , EXP/poly can be  $(1/n^c, 1/20n)$ -PAC-learned using random examples in time polynomial in  $n$ .*

**Proof Sketch.** The proof uses the collapse of EXP into BPP, firstly to observe that EXP/poly is in P/poly. Next, we construct an exponential time procedure which takes as inputs a size parameter  $s(n)$ , a set of examples of length  $n$  and their labels, and outputs a hypothesis circuit of size at most  $s(n)$  which is consistent with the examples, if there exists one, via an exhaustive search. From our assumption, this runs in probabilistic polynomial time. Using an argument based on Occam's razor [30], we obtain a polynomial time learner for P/poly. ◀

► **Lemma 3.2.** *Let  $\text{EXP} \neq \text{BPP}$ . Then, there exists  $c \geq 0$  such that EXP/poly is not  $(1/n^c, 1/20n)$ -learnable in the worst-case using random examples over the uniform distribution in time polynomial in  $n$ .*

**Proof.** Towards a contradiction assume that there exists a constant  $a > 0$  and an  $O(n^a)$ -time learner  $\mathcal{A}$  that  $(1/n^c, 1/20n)$ -learns EXP/poly using random examples over  $U_n$ , for every  $c \geq 0$ . We first show that the existence of the learner  $\mathcal{A}$  for EXP/poly implies that  $\text{EXP} \subseteq \text{P/poly}$ . Let  $g^*$  be an EXP-Complete problem which is self-correctible, whose existence is given by Theorem A.7, with  $c_1 \geq 0$  being the corresponding constant. Use  $\mathcal{A}$  to  $(1/n^{c_1}, 1/20n)$ -learn  $g^*$  using random examples over the uniform distribution. Let  $\mathcal{A}'$  be the algorithm which takes as input  $y \in \{0, 1\}^n$  in addition to the inputs of  $\mathcal{A}$  and runs the learner  $\mathcal{A}$ , following which it returns the evaluation of the hypothesis circuit output by  $\mathcal{A}$  on the input  $y$ . In other words, for every  $n \in \mathbb{N}$ , we have

$$\Pr_{\substack{w \in \{0,1\}^{r(n)} \\ x_1, \dots, x_m \sim U_n}} \left\{ \Pr_{y \sim U_n} \{ \mathcal{A}'(1^n, w, (x_1, g^*(x_1)), \dots, (x_m, g^*(x_m)), y) = g^*(y) \} \geq 1 - 1/n^{c_1} \right\} \\ \geq 1 - 1/20n$$

where both  $r(n)$  and  $m = m(n) = \text{poly}(n)$ .

## 46:12 On the Structure of Learnability Beyond P/Poly

By amplifying the correctness of  $\mathcal{A}'$  using standard techniques, we can then non-uniformly fix the random strings  $w, x_1, \dots, x_m$  and the values of  $g^*$  on each  $x_i$  to get a polynomial sized circuit  $C$ , which takes input  $y \in \{0, 1\}^n$  and outputs the answer of  $\mathcal{A}'$  on the advice string and  $y$ . Thus  $C_n$  agrees with  $g^*$  on at least  $(1 - 1/n^{c_1})$ -fraction of the inputs. Using  $C_n$  with the self-correctibility of  $g^*$  (and fixing another “good” random string non-uniformly in the resulting algorithm), we get a polynomial-sized circuit which computes  $g^*$  on every input and by the EXP-Completeness of  $g^*$ , we see that  $\text{EXP} \subseteq \text{P/poly}$ .

Since  $\text{EXP} \subseteq \text{P/poly}$ , we use Lemma A.9 to observe that  $f^*$  given by Theorem A.8 is now an EXP-Complete problem that is both downward self-reducible and self-correctible. Let  $c_2$  be the constant associated with the self-corrector for  $f^*$ . For any integer  $k$ , given a procedure  $B_k$  which computes  $f^*$  on every instance of size  $k$  with high probability, we use  $\mathcal{A}$  together with the downward self-reduction for  $f^*$ , followed by the self-corrector for  $f^*$  to obtain a procedure  $B_{k+1}$  that computes  $f^*$  on any input of size  $k + 1$ . We use this inductively, to compute  $f^*$  on  $n$  inputs in probabilistic polynomial time.

More precisely, consider the following algorithm  $B_n$  which computes  $f^*$  on a given input  $x$  and does the following. First, it starts with a procedure  $B_{k_0}$ , for a constant  $k_0$ , which can be computed easily using a look-up table. Assuming that we have the procedure  $B_k$  for some input length  $k \leq n$ , we show how to construct the procedure  $B_{k+1}$  inductively. We use the learner  $\mathcal{A}$  to learn the function  $f_{k+1}^*$  up to error  $1/(k+1)^{c_2}$ . For every input  $f^*(y)$  passed to  $\mathcal{A}$ , where  $y$  is a string randomly picked from  $\{0, 1\}^{k+1}$ , we use  $B_k$  with the downward self-reduction of  $f^*$  to compute  $f^*(y)$ .  $\mathcal{A}$  outputs a hypothesis  $h_{k+1}$  which computes  $f_{k+1}^*$  on at least a  $(1 - 1/(k+1)^c)$ -fraction of the inputs with high probability. We now use the self-corrector for  $f^*$  to obtain from  $h_{k+1}$  a procedure  $B_{k+1}$  which is correct on every input of size  $k + 1$  with probability  $1 - \gamma$  (by using standard error reduction arguments), for some  $\gamma > 0$  which we pick later. Repeating this process at most  $n$  times, we obtain  $B_n$  and output  $B_n(x)$ .

First, we show that  $B_n$  outputs  $f^*(x)$  with probability at least  $2/3$ . Let  $d(n)$  be the number of queries made by the DSR to the oracle  $f_{n-1}^*$  in computing  $f^*(x)$  on any input  $x$  of length  $n$ . The idea is that at each stage  $k$ , the procedure  $B_k$  fails only if at least one of  $m(n) \cdot d(n)$  queries answered by  $B_{k-1}$  is incorrect, with probability at most  $m(n)d(n)\gamma \leq 1/20n$  for  $\gamma = 1/20nm(n)d(n)$ , or if  $\mathcal{A}$  fails to output the right hypothesis, with probability at most  $1/20n$ . Thus, the total failure probability at each stage is at most  $1/10n$  and over the  $n$  stages, using the union bound, the total failure probability is at most  $1/10 + \gamma \leq 1/3$ .

We inductively observe that every stage  $B_k$  runs in time  $\text{poly}(k)$ . It is easily seen that  $B_{k_0}$  runs in constant time. Assume that  $B_{k-1}$  runs in  $\text{poly}(k-1)$  time. At stage  $k$ , the time taken to compute  $f^*$  on  $m(k)$  many inputs of length  $k$  is  $O(m(k) \cdot d(k) \cdot \text{poly}(k-1)) \leq \text{poly}(k)$ . After this,  $\mathcal{A}$  takes  $O(k^d)$  time to output  $h_k$  of size at most  $k^d$ , which is used by the  $\text{poly}(k)$ -time self-corrector to compute  $f^*$  on all inputs of size  $k$  with high probability. Thus,  $B_k$  runs in time  $\text{poly}(k) = \text{poly}(n)$ . Since there at most  $n$  stages, the total running time of  $B_n$  is  $\text{poly}(n)$ . This shows that  $f^* \in \text{BPP}$  and contradicts the original assumption. ◀

Using a very similar proof idea, we obtain an analogous statement to Lemma 3.2, but now for worst-case learning  $\text{EXP/poly}$  using membership queries.

► **Lemma 3.3.** *Suppose that  $\text{EXP/poly}$  is  $(1/n^c, 1/20n)$ -learnable in the worst case for every  $c \geq 0$  over the uniform distribution  $U_n$  using membership queries in time  $\text{poly}(n)$ . Then,  $\text{EXP} = \text{BPP}$ .*

Informally (see Appendix A for a formal definition), the task of an  $(\epsilon, \delta)$ -average-case learner for a class  $\mathcal{C}$  over the uniform distribution using random examples, is to  $(\epsilon, \delta)$ -learn an unknown target function which is generated according to a fixed distribution over

$\mathcal{C}$  (defined as an ensemble of distributions over appropriate representations for  $\mathcal{C}$ ). The ideas from Lemma 3.2 can also be extended to show similar implications for the setting of average-case learning EXP/poly using random examples (and membership queries too).

► **Lemma 3.4.** *Suppose that EXP/poly is  $(1/n^c, 1/20n)$ -learnable on average for every  $c \geq 0$  with respect to polynomially samplable distributions over EXP/poly and the uniform distribution  $U_n$  using random examples in time  $\text{poly}(n)$ . Then,  $\text{EXP} = \text{BPP}$ .*

► **Remark 3.5.** In Lemma 3.4, the samplable distributions we consider are over  $\text{SIZE}^{\text{EXP}}[n^k]$ -circuit encodings in  $R_n \subseteq \{0,1\}^{r(n)}$ , where  $r(n) = O(n^{2k+1})$  (see Remark A.3 for more details). In particular, for the distribution  $\mathcal{P}$  over  $\text{SIZE}^{\text{EXP}}[n^k]$  supported only on the function  $g^*$  (or  $f^*$ ) used in the proof of Lemma 3.2, the sampler  $S_{\mathcal{P}}$  takes  $1^{n^k}$  as input and outputs a  $\text{SIZE}^{\text{EXP}}[n^k]$ -circuit encoding of  $g^*$  (or  $f^*$ ) which is just an EXP-oracle gate on  $n$  inputs and this encoding is of size  $O(n^2)$ . The running time of this sampling algorithm is polynomial in the input size.

We use the same ideas as that of Lemma 3.2 to prove that even learning EXP/poly in polynomial time using random examples from the uniform distribution with respect to just these two distributions over EXP/poly, is enough to collapse EXP to BPP.

The formal details of the intermediate results can be found in the full version. We now prove the equivalences for efficiently learning EXP/poly.

**Proof of Theorem 1.2.** The following implications establish the desired equivalences.

$(b) \implies (a), (c) \implies (a)$ : The contrapositives of each of these implications follow from Lemma 3.1. In particular, PAC-learning EXP/poly with error at most  $1/n^c$  for any  $c > 0$  using random examples, implies PAC-learnability of EXP/poly using membership queries, where the queries are just made on the random examples given to the learner.

$(d) \implies (b), (e) \implies (c)$ : Follows from the definitions, since PAC-learning EXP/poly in the worst case in  $\text{poly}(n)$  time using random examples implies PAC-learnability for EXP/poly on average in  $\text{poly}(n)$  time using random examples, for any distribution over EXP/poly. A similar implication holds for learning with membership queries too.

$(a) \implies (b)$ : For any  $c > 0$ , suppose EXP/poly is  $(1/n^c, 1/20n)$  PAC-learnable in polynomial time using random examples over every arbitrary distribution. In particular, this means that EXP/poly can be  $(1/n^c, 1/20n)$ -learnt in polynomial time using random examples over the uniform distribution. The implication follows from the contrapositive of Lemma 3.2.

$(a) \implies (c)$ : Similar to the previous implication, we see that EXP/poly is  $(1/n^c, 1/20n)$ -learnable in polynomial time using membership queries over the uniform distribution. The implication holds from the contrapositive of Lemma 3.3.

$(a) \implies (d), (a) \implies (e)$ : The implications follow from Lemma 3.4 and its corresponding extension to learning on average with membership queries. ◀

The proof of Corollary 1.3 (equivalences for learning PSPACE/poly) follows from the same ideas as Theorem 1.2. In more detail, Lemma 3.1 extends easily as the procedure which searches for a polynomial-sized consistent hypothesis also runs in polynomial space. Lemmas 3.2, 3.3 and 3.4 can also be extended, by learning the downward-self-reducible and self-correctible PSPACE-Complete function  $f^*$  (from Theorem A.8) directly, and using it to compute  $f^*$  on every input.

## 4 Reducing Succinct Search to Decision

The key concepts in this section are verifiability and succinct search. We define verifiers first.

► **Definition 4.1.** *Given language  $L \subseteq \{0, 1\}^*$  and polynomial-time computable relation  $V(\cdot, \cdot)$ , we say that  $V$  is a verifier for  $L$  if for each  $x \in \{0, 1\}^*$ ,  $x \in L$  iff  $\exists y V(x, y)$ .*

*Given language  $L$ , a verifier  $V$  for  $L$ , and function  $f : \mathbb{N} \rightarrow \mathbb{N}$ , we say that  $L$  has  $f(n)$ -size proofs with respect to  $V$ , such that for each  $x \in \{0, 1\}^*$ ,  $x \in L$  implies  $\exists y, |y| \leq f(|x|) : V(x, y)$ . We say that  $L$  has  $f(n)$ -size proofs if there is a verifier  $V$  for  $L$  such that  $L$  has  $f(n)$ -size proofs with respect to  $V$ .*

*Given language  $L$ , a verifier  $V$  for  $L$  and a machine class  $\mathcal{D}$ , we say that  $L$  has  $\mathcal{D}$ -computable proofs with respect to  $V$  if there is a machine  $M \in \mathcal{D}$  such that for each  $x \in \{0, 1\}^*$ ,  $x \in L$  implies  $V(x, M(x))$ . We say that  $L$  has  $\mathcal{D}$ -computable proofs if there is a verifier  $V$  for  $L$  such that  $L$  has  $\mathcal{D}$ -computable proofs with respect to  $V$ .*

Note that NP is the class of languages with polynomial-sized proofs, NEXP is the class of languages with exponential-sized proofs, and for  $\mathcal{D} \in \{\text{EXP}, \text{PSPACE}\}$ ,  $\mathcal{D}$  is the class of languages with  $\mathcal{D}$ -computable proofs (where we abuse notation and use  $\mathcal{D}$  to refer both to a machine class and to the class of languages computable by such machines).

Next we define succinct search. We will assume w.l.o.g. that the proof size for any verifier is a power of 2 - this can be ensured by padding the proof if necessary.

► **Definition 4.2.** *Given language  $L$  and verifier  $V$  for  $L$ , we say that **succinct search is easy** for  $L$  with respect to  $V$  if there is a probabilistic polynomial-time machine  $N$  such that for each  $x \in L$ , there is a  $V$ -proof  $y$  such that with probability  $1 - o(1)$ ,  $\text{tt}(N(x)) = y$ , where for Boolean circuit  $C$ ,  $\text{tt}(C)$  denotes the truth table of the function computed by  $C$ .*

Thus succinct search is easy for  $L$  with respect to a verifier  $V$  if there is a probabilistic polynomial-time machine outputting compressed descriptions of  $V$ -proofs with high probability for any positive instance of  $L$ .

Using the downward self-reducibility of SAT, it is straightforward to see that  $\text{NP} \subseteq \text{BPP}$  iff for each  $L \in \text{NP}$  and for every verifier  $V$  such that  $L$  has poly-size proofs with respect to  $V$ , succinct search is easy for  $L$  with respect to  $V$ . We now show analogous results for PSPACE, EXP and NEXP. First we show for each of these classes that easiness of the class implies easiness of succinct search.

We need the Easy Witness Lemma of Impagliazzo, Kabanets and Wigderson [24].

► **Lemma 4.3** ([24]). *If  $\text{NEXP} \subseteq \text{P/poly}$ , then for each  $L \in \text{NEXP}$  and for each verifier  $V$  for  $L$  such that  $L$  has exponential-size proofs with respect to  $V$ , for each  $x \in L$ , there is a polynomial-size circuit  $C_x$  such that  $V(x, \text{tt}(C_x))$  holds.*

► **Lemma 4.4.** *The following implications hold:*

1. *Let  $\mathcal{D} \in \{\text{PSPACE}, \text{EXP}\}$ . If  $\mathcal{D} = \text{BPP}$ , then for each  $L \in \mathcal{D}$  and for each verifier  $V$  such that  $L$  has  $\mathcal{D}$ -computable proofs with respect to  $V$ , succinct search is easy for  $L$  with respect to  $V$ .*
2. *If  $\text{NEXP} = \text{BPP}$ , then for each  $L \in \text{NEXP}$  and for each verifier  $V$  such that  $L$  has exponential-size proofs with respect to  $V$ , succinct search is easy for  $L$  with respect to  $V$ .*

**Proof.** We establish the first item. Let  $\mathcal{D} \in \{\text{PSPACE}, \text{EXP}\}$ , and assume  $\mathcal{D} = \text{BPP}$ . Let  $L \in \mathcal{D}$  and  $V$  be a verifier for  $L$  such that  $L$  has  $\mathcal{D}$ -computable proofs with respect to  $V$ . We construct a probabilistic poly-time machine  $N$  such that for each input  $x \in L$ , there is a  $V$ -proof  $y$  such that with high probability  $\text{tt}(N(x)) = y$ . Let  $M$  be a  $\mathcal{D}$ -machine outputting  $V$ -proofs for positive instances of  $L$ .

Consider the language  $L' = \{\langle x, i \rangle \mid i^{\text{th}} \text{ bit of } M(x) \text{ is } 1\}$ . Since  $M$  is a  $\mathcal{D}$  machine, we have that  $L' \in \mathcal{D}$ . By assumption,  $\mathcal{D} = \text{BPP}$ , therefore there is a probabilistic poly-time machine  $N'$  deciding  $L'$ . Assume w.l.o.g. that  $N'$  has error at most  $2^{-|y|^2}$  on any input  $y$ . Given input  $x$ ,  $N$  operates as follows. It first computes a probabilistic poly-size circuit  $C'$  simulating  $N'$ . This can be done using the standard efficient conversion of efficient algorithms into small circuits. It then hardwires  $x$  into the first part of the input for  $C'$ , obtaining a circuit  $C'_x$ . It then fixes the random input of the circuit  $C'_x$  to a uniformly generated random string  $r$  to obtain a circuit  $D'_{x,r}$ , which it outputs.

Since the error of  $N'$  is smaller than  $2^{-|y|^2}$  on any input  $y$ , by a simple union bound, with probability  $1 - o(1)$  over the choice of the random string  $r$ ,  $D'_{x,r}$  correctly computes the  $i^{\text{th}}$  bit of  $M(x)$  for each  $i \in [m]$ . For  $x \in L$ ,  $V(x, M(x))$  holds, and therefore  $N$  efficiently solves succinct search for  $L$  with respect to  $V$ .

We establish the second item. Assume  $\text{NEXP} = \text{BPP}$  and let  $L \in \text{NEXP}$  and  $V$  be a verifier for  $L$  such that  $L$  has exponential-size proofs with respect to  $V$ . Since  $\text{NEXP} = \text{BPP}$ , we have that  $\text{NEXP} \subseteq \text{P/poly}$ . By Lemma 4.3, there is a polynomial  $p$  such that for each  $x \in L$ , there is a circuit  $C_x$  of size at most  $p(|x|)$  such that  $V(x, \text{tt}(C_x))$  holds.

Consider the language  $L' = \{\langle x, i \rangle \mid \text{There is a circuit } C \text{ of size } p(|x|) \text{ such that } V(x, \text{tt}(C)) \text{ is } 1, \text{ and the } i^{\text{th}} \text{ bit of the lexicographically first such circuit is } 1\}$ . Clearly  $L' \in \text{EXP}$ , just by enumerating circuits of size  $p(|x|)$  in lexicographic order and finding the first one encoding a  $V$ -proof for  $x$ , if one exists. Since  $\text{EXP} = \text{BPP}$ , there is a probabilistic poly-time machine  $N'$  deciding  $L'$  with error exponentially small. We construct a probabilistic poly-time machine  $N$  as follows: on input  $x$ ,  $N$  runs  $N'$  on  $\{\langle x, i \rangle\}$  for each  $i$  at most the description length of a circuit of size  $p(|x|)$ . It outputs the circuit  $C$  whose description has bit  $i$  set to 1 iff  $N'$  accepts on  $\{\langle x, i \rangle\}$ . Since  $N'$  has error exponentially small, we have that with error exponentially small,  $N$  outputs a circuit  $C$  encoding a  $V$ -proof of  $x$ , and therefore  $N$  efficiently solves succinct search for  $L$  with respect to  $V$ . ◀

For the reverse directions, we use the PCP characterization of  $\text{NEXP}$  [6, 16], where we only require polynomial upper bound on query complexity of the verifier.

► **Theorem 4.5** ([6, 16]). *Let  $L \in \text{NEXP}$ . There is a probabilistic poly-time oracle machine  $V'$  such that:*

1. *For each  $x \in L$ , there is  $y$  of length exponential in  $|x|$  such that  $V'(x)$  accepts with probability at least  $2/3$  when given oracle access to  $y$ .*
2. *For each  $x \notin L$  and for all  $y$ ,  $V'(x)$  accepts with probability at most  $1/3$  when given oracle access to  $y$ .*

We now show that easiness of succinct search implies easiness of decision for any  $L \in \text{NEXP}$ .

► **Lemma 4.6.** *Let  $L \in \text{NEXP}$  and  $V$  be a verifier such that  $L$  has exponential-size proofs with respect to  $V$ . If succinct search is easy for  $L$  with respect to  $V$ , then  $L \in \text{BPP}$ .*

**Proof.** Let  $L \in \text{NEXP}$ . We show that  $L \in \text{BPP}$ . By Theorem 4.5, there is a probabilistic poly-time oracle machine  $V'$  such that if  $x \in L$ , there is  $y$  of length exponential in  $|x|$  for which  $V'$  accepts with high probability on  $x$  when given oracle access to  $y$ , and if  $x \notin L$  rejects with high probability irrespective of the oracle.

Now consider a verifier  $V$  for  $L$  which given input  $x$  and proof  $y$ , accepts iff  $V'(x)$  accepts with oracle  $y$  on a majority of its computation paths. Since succinct search is easy for  $L$  with respect to  $V$ , there is a probabilistic poly-time machine  $N$  such that for input  $x \in L$ , there is a  $V$ -proof  $y$  for  $x$  such that with high probability  $\text{tt}(N(x)) = y$ . We define a probabilistic poly-time machine  $W$  that on input  $x$  simulates  $V'(x)$  as follows. It first runs  $N(x)$  to find a circuit  $C$ . It then runs  $V(x)$ , answering all oracle calls to  $y$  by simulating  $C$  on input corresponding to the bit of  $y$  that is queried. It accepts iff  $V(x)$  accepts.

If  $x \in L$ , by using the assumption that  $N$  solves succinct search,  $W(x)$  accepts with probability close to  $2/3$ . If  $x \notin L$ ,  $W(x)$  rejects with probability close to  $2/3$  since the circuit  $C$  output by  $N(x)$  corresponds to some purported  $V'$ -proof, and every such  $V'$ -proof is rejected with high probability by  $V$  when given oracle access to the proof. ◀

► **Theorem 4.7.** *Let  $\mathcal{D} \in \{\text{PSPACE}, \text{EXP}\}$ .  $\mathcal{D} = \text{BPP}$  iff for each  $L \in \mathcal{D}$  and for each verifier  $V$  for  $L$  such that  $L$  has  $\mathcal{D}$ -computable proofs with respect to  $V$ , succinct search is easy for  $L$  with respect to  $V$ .*

$\text{NEXP} = \text{BPP}$  iff for each  $L \in \text{NEXP}$  and for each verifier  $V$  such that  $L$  has exponential-size proofs with respect to  $V$ , succinct search is easy for  $L$  with respect to  $V$ .

**Proof.** The forward directions of both items follow from Lemma 4.4. The backward direction of the second item follows Lemma 4.6. The backward direction of the first item follows from Lemma 4.6 and the fact that for  $\mathcal{D} \in \{\text{PSPACE}, \text{EXP}\}$ , if  $L \in \mathcal{D}$  and  $V$  is a verifier for  $L$  such that  $L$  has  $\mathcal{D}$ -computable proofs with respect to  $V$ , then  $L \in \text{NEXP}$  and  $L$  has exponential-size proofs with respect to  $V$ . ◀

We now prove Theorem 1.4. Define  $R_{Kt}$  as the language consisting of strings  $x$  such that  $Kt(x) \geq |x|/2$ . Similarly,  $R_{KS}$  is the language consisting of strings  $x$  such that  $KS(x) \geq |x|/2$  [3] (see Appendix A.3 for formal definitions of  $Kt$  and  $KS$  complexity).

► **Theorem 4.8** (Theorem 1.4 stated formally).  $R_{Kt} \in \text{BPP}$  iff for each verifier  $V$  for  $R_{Kt}$  such that  $R_{Kt}$  has  $\text{EXP}$ -computable proofs with respect to  $V$ , succinct search is easy for  $R_{Kt}$  with respect to  $V$ .

$R_{KS} \in \text{BPP}$  iff for each verifier  $V$  for  $R_{KS}$  such that  $R_{KS}$  has  $\text{PSPACE}$ -computable proofs with respect to  $V$ , succinct search is easy for  $R_{KS}$  with respect to  $V$ .

**Proof.** The backward directions of both items follow from Lemma 4.6 and the facts that  $R_{Kt}$  and  $R_{KS}$  are in  $\text{NEXP}$ .

For the forward direction of the first item, we use the result shown in [3] that  $R_{Kt} \in \text{BPP}$  implies  $\text{EXP} = \text{BPP}$ . Combining this with the first item of Lemma 4.4 completes the proof.

For the forward direction of the second item, we use the theorem shown in [3] that  $R_{KS} \in \text{BPP}$  implies  $\text{PSPACE} = \text{BPP}$ . Combining this with the first item of Lemma 4.4 completes the proof. ◀

## A Preliminaries

Let  $\mathcal{F} = \{\mathcal{F}_n\}$ , where  $\mathcal{F}_n$  is set of all Boolean functions over  $\{0, 1\}^n$ , where each  $f_n \in \mathcal{F}_n$  is a function  $f_n : \{0, 1\}^n \rightarrow \{0, 1\}$ . Define  $\text{tt}(f)$  as the truth table of a function  $f_n$  of length  $2^n$ . On the other hand, given a string  $x \in \{0, 1\}^{2^n}$ , define  $\text{fn}(x)$  as the function on  $n$  inputs whose truth table is  $x$ . For every  $n \in \mathbb{N}$ , define  $U_n$  as the uniform distribution over  $\{0, 1\}^n$ .

### A.1 Samplability and Learnability

Let  $\mathcal{C} = \{\mathcal{C}_n\}$ , where  $\mathcal{C}_n \subseteq \mathcal{F}_n$  be a class of functions over  $\{0, 1\}^n$  and  $\mathcal{D} = \{\mathcal{D}_n\}$  be a distribution family over  $\{0, 1\}^*$ , where  $\mathcal{D}_n$  is a distribution over  $\{0, 1\}^n$ .

► **Definition A.1** (Worst-case PAC-learning using random examples). *For any  $0 \leq \epsilon, \delta < 1/2$ , a class  $\mathcal{C}$  is  $(\epsilon, \delta)$ -PAC-learnable in the worst-case using random examples in time  $T(n)$ , if there exists a randomized algorithm  $\mathcal{A}$  such that*

- *For every  $n \in \mathbb{N}$ , for every  $f \in \mathcal{C}_n$ , for every  $\mathcal{D}_n$  over  $\{0, 1\}^n$ ,  $\mathcal{A}$  takes inputs  $1^n, \epsilon, \delta$ , a set of  $m = m(n)$  labeled samples  $(x_1, f(x_1)), \dots, (x_m, f(x_m))$  where each  $x_i \sim \mathcal{D}_n$ , and  $w \in \{0, 1\}^{r(n)}$  as internal randomness.  $\mathcal{A}$  then outputs the description of a circuit  $h$  such that*

$$\Pr_{w \in \{0, 1\}^{r(n)}, x_1, \dots, x_m \sim \mathcal{D}_n} \left\{ \Pr_{y \in \mathcal{D}_n} \{h(y) = f(y)\} \geq 1 - \epsilon \right\} \geq 1 - \delta$$

- *$\mathcal{A}$  runs in time at most  $T(n)$ .*<sup>11</sup>

We can also restrict the learnability to a fixed distribution like the uniform distribution  $U_n$ , where the learner takes random examples chosen over the uniform distribution and hypothesis error is also measured over the uniform distribution. Unless specified otherwise, we use the class of polynomial-sized Boolean circuits P/poly, as the hypothesis class for our learning algorithms.

Furthermore, we can extend this definition to PAC-learning over membership queries by giving the learner  $\mathcal{A}$  oracle access to the function  $f \in \mathcal{C}_n$ , in addition to the random examples drawn from some fixed distribution  $\mathcal{D}_n$  over  $\{0, 1\}^n$ .

To define learnability on average, let  $\mathcal{P} = \{\mathcal{P}_n\}$  be a distribution ensemble over  $\mathcal{C}$ , where  $\mathcal{P}_n$  is a fixed distribution over  $\mathcal{C}_n$ .

► **Definition A.2** (Samplable distributions). *Let  $\mathcal{P}$  be a distribution ensemble over  $\mathcal{C}$ , where for every  $n \in \mathbb{N}$ ,  $\mathcal{P}_n$  is a distribution over the truth tables of  $\mathcal{C}_n$ . Let  $N = 2^n$ . For any non-decreasing function  $S(N) \geq N$ , we say that  $\mathcal{P}$  is samplable in time  $S(N)$ , if there exists a randomized algorithm  $A$  such that for every  $N = 2^n$ , using  $m(N)$  bits of randomness (where  $m(N) \leq S(N)$ ),  $A(1^N, y)$  is distributed identically to  $\mathcal{P}_n$ , where the distribution is over the string  $y$  picked uniformly at random from  $\{0, 1\}^{m(N)}$  and  $A$  runs in time  $S(N)$ .*

*In other words, if  $y$  is picked uniformly at random from  $\{0, 1\}^{m(N)}$  then  $A(1^N, y)$  outputs a truth table from  $\mathcal{C}_n$  which is distributed according to  $\mathcal{P}_n$ . Furthermore, we say that  $\mathcal{P}$  is polynomially samplable if  $S(N) = \text{poly}(N)$ .*

► **Remark A.3.** For the special case where  $\mathcal{C}$  is a class of fixed polynomial sized circuits like  $\text{SIZE}[n^k]$  (or  $\text{SIZE}^{\text{EXP}}[n^k]$ ) for any arbitrary fixed  $k$ , we define a circuit representation scheme for  $\mathcal{C}_n$  given by the set  $R_n \subset \{0, 1\}^{r(n)}$ , where  $r(n) = O(n^k \log n)$ , such that every  $\sigma \in R_n$  is

<sup>11</sup>Note that this immediately implies that  $m(n) \leq T(n)$

a  $\mathcal{C}$ -circuit encoding of a function in  $\mathcal{C}_n$ . Note that this mapping is onto and each function in  $\mathcal{C}_n$  has many representations in  $R_n$ . We also assume that there exists a uniform circuit sequence in  $\mathcal{C}$ , which interprets this encoding as a  $\mathcal{C}$ -circuit and evaluates computations given this encoding.

Now, we can define a distribution ensemble  $\mathcal{P}$  over  $\mathcal{C}$ , where each  $\mathcal{P}_n$  is a distribution over the  $\mathcal{C}$ -circuit encodings, which implicitly defines a distribution over  $\mathcal{C}_n$ . We also define  $S(r(n))$ -samplability of  $\mathcal{P}$ , if there exists a randomized algorithm  $A$  running in time  $S(r(n))$  such that for every  $n \in \mathbb{N}$ ,  $A(1^{r(n)}, y)$  is distributed identically to  $\mathcal{P}_n$ , where the distribution is over the random strings  $y \in \{0, 1\}^{m(n)}$ .

► **Definition A.4** (Average-case learnability [8]). *Let  $\mathcal{C}$  be a class of Boolean functions and  $\mathcal{P} = \{\mathcal{P}_n\}$  be a distribution ensemble over  $\mathcal{C}$ . For any  $0 < \epsilon, \delta < 1/2$ , we say that  $\mathcal{C}$  is  $(\epsilon, \delta)$ -PAC-learnable on average using random examples with respect to  $\mathcal{P}$  in time  $T(n)$ , if there exists a randomized algorithm  $\mathcal{A}$  running in time at most  $T(n)$  such that*

- *For every large enough  $n$ , for any fixed  $f$  drawn according to  $\mathcal{P}_n$ , for every  $\mathcal{D}_n$  over  $\{0, 1\}^n$ ,  $\mathcal{A}$  takes inputs  $1^n, \epsilon, \delta$ , a set of  $m = m(n)$  labeled samples  $(x_1, f(x_1)), \dots, (x_m, f(x_m))$  where each  $x_i \sim \mathcal{D}_n$  and  $w \in \{0, 1\}^*$  (the internal randomness of  $\mathcal{A}$ ) and outputs the description of a circuit  $h$  such that*

$$\Pr_{\substack{f \sim \mathcal{P}_n \\ w \in \{0, 1\}^* \\ x_1, \dots, x_m, y \sim \mathcal{D}_n}} \left\{ \Pr_{y \in \mathcal{D}_n} \{h(y) = f(y)\} \geq 1 - \epsilon \right\} \geq 1 - \delta$$

- *$\mathcal{A}$  runs in time at most  $T(n)$ .*

Furthermore, for any  $0 < \epsilon, \delta < 1/2$ , we say that  $\mathcal{C}$  is  $(\epsilon, \delta)$ -PAC-learnable on average with respect to polynomially samplable distributions over  $\mathcal{C}$  using random examples in time  $T(n)$  if there exists a learning algorithm  $\mathcal{A}$  that runs in time  $T(n)$  such that for every polynomially samplable distribution ensemble  $\mathcal{P}$  over  $\mathcal{C}$ , we have that for every large enough  $n$ ,  $\mathcal{A}$   $(\epsilon, \delta)$ -PAC-learns  $\mathcal{C}_n$  on average using random examples with respect to  $\mathcal{P}_n$ .

We can naturally extend this definition to average-case learning  $\mathcal{C}$  with respect to  $\mathcal{P}$  and a fixed distribution over the examples like  $U_n$ , as well as average-case PAC-learning  $\mathcal{C}$  with membership queries with respect to  $\mathcal{P}$ .

## A.2 Self-Reducibility

In our reductions, we use the following special properties of a function.

► **Definition A.5** (Downward self-reducibility). *A function  $f_n : \{0, 1\}^n \rightarrow \{0, 1\}$  is downward-self-reducible if there is a deterministic polynomial time algorithm  $A$  such that for all  $x \in \{0, 1\}^n$ ,  $A^{f_{n-1}}(x) = f_n(x)$ .*

► **Definition A.6** (Self-Correctibility). *A function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  is said to be self-correctible if there exists a constant  $c \geq 0$  and a probabilistic polynomial-time algorithm  $A$  such that, for every large enough  $n$ , for any function  $\mathcal{O} : \{0, 1\}^n \rightarrow \{0, 1\}$  that agrees with  $f_n$  with probability  $(1 - 1/n^c)$  over the uniform distribution on inputs of length  $n$ , we have that  $\Pr\{A^{\mathcal{O}}(x) = f_n(x)\} \geq 2/3$  for any  $x \in \{0, 1\}^n$ .*

[7] show that any function  $f$  on  $n$  Boolean inputs can be transformed into a function  $f^*$  on  $n$  inputs from a large enough finite field, such that  $f^*$  coincides with  $f$  on the subset  $\{0, 1\}^n$ .

► **Theorem A.7** ([7]). *There exists an EXP-Complete problem  $g^*$  which is self-correctible.*

Furthermore, Trevisan and Vadhan [38] construct a PSPACE-Complete problem which is based on a careful arithmetization and padding of TQBF (using the interactive proof system for PSPACE), which has both these properties.

► **Theorem A.8** ([38]). *There exists a PSPACE-Complete language  $f^* \in \text{DSPACE}[n]$  that is both self-correctible and downward self-reducible (DSR).*

We also use the following results.

► **Lemma A.9.** *If  $\text{EXP} \subseteq \text{P/poly}$ , then  $\text{EXP} = \text{PSPACE}$ . In particular, the function  $f^*$  (from Theorem A.8) is complete for EXP.*

► **Lemma A.10** (Hoeffding's inequality). *Let  $X_1, \dots, X_n$  be independent random variables such that  $0 \leq X_i \leq 1$  for every  $i \in [n]$ . Let  $X = \sum_{i=1}^n X_i$ . Then, for any  $t > 0$ , we have*

$$\Pr\{|X - \mathbf{E}[X]| \geq t\} \leq 2 \exp(-2t^2/n)$$

The following Lemma proves that a random function cannot even be approximated by small-sized circuits and follows from an application of Lemma A.10.

► **Lemma A.11** (Lemma 4 [36]). *For any  $s(n) \geq n$  and  $\delta \in [0, 1/2]$ , we have*

$$\Pr_{f \sim \mathcal{F}_n} \{\exists \text{ circuit of size } \leq s(n) \text{ computing } f \text{ on } \geq (1/2 + \delta)\text{-fraction of the inputs}\} \leq \exp(-\delta^2 2^n + 10s \log s)$$

### A.3 Kolmogorov Complexity

Fix a universal machine  $U$ . Levin [33] defined the following notion of time-bounded Kolmogorov complexity: The  $\text{Kt}$  complexity of a string  $x$  is the minimum  $\text{Kt}(x)$  over  $|p| + \log(t)$  such that  $U(p) = x$  in at most  $t$  steps. It is known [2] that  $\text{Kt}(x)$  is polynomially related to the size of the smallest EXP-oracle circuit computing the function with truth table  $x$  (truncating  $x$  to its longest initial segment with length a power of two).

Similarly,  $\text{KS}(x)$  is the minimum over  $|p| + s$  such that  $U(p) = x$  in at most space  $s$ . It is known [2] that  $\text{KS}(x)$  is polynomially related to the size of the smallest PSPACE-oracle circuit computing the function with truth table  $x$  (truncating  $x$  to its longest initial segment with length a power of two).

Let  $\text{R}_{\text{Kt}}$  be the language consisting of strings  $x$  such that  $\text{Kt}(x) \geq |x|/2$  [3]. Similarly, let  $\text{R}_{\text{KS}}$  be the language consisting of strings  $x$  such that  $\text{KS}(x) \geq |x|/2$  [3].

## B Barriers for Conditional Hardness of Learning

Firstly, we formally define what it means to have a Black-Box Turing reduction from a language  $L$  to a PAC-learning algorithm for a class  $\mathcal{C}$ . Fix the error of the learner to be  $\epsilon = 1/\text{poly}(n)$  (we ignore the confidence parameter, but this only makes our hardness results stronger).

► **Definition B.1** (Turing Reduction to Learning  $\mathcal{C}$ ). *A  $B$ -adaptive black-box reduction from deciding  $L$  to PAC-learning  $\mathcal{C}$  using random examples up to error  $\epsilon$ , is a tuple of probabilistic polynomial time algorithms  $R = (T_1, \dots, T_B, M)$  where  $R$  is given an input  $z \in \{0, 1\}^n$  and randomness  $w \in \{0, 1\}^*$ . For each query,  $R$  constructs a joint distribution  $(X, f(X))$*

## 46:22 On the Structure of Learnability Beyond P/Poly

over  $\{0,1\}^r \times \{0,1\}$  for some  $r \leq n$  and  $f \in \mathcal{C}$ , samples a set  $S = \{(x_i, y_i)\}_{i \leq \text{poly}(n)}$  of independent labeled examples according to  $(X, Y)$  and passes it to the learner. Let  $t(n)$  be the query complexity of each round of adaptivity.  $R$  decides  $z$  by doing the following -

- For each  $1 \leq j \leq B$ ,  $T_j$  gets input  $z$ , fresh random bits from  $w$  and all the  $(j-1) \cdot t(n)$  hypothesis circuits answered for the queries from the previous rounds ( $T_1$  only has  $z$  and randomness  $w$  as input), and outputs  $t(n)$  new queries  $S_{j1}, \dots, S_{jt}$  for the learner, each of which are sets of labeled examples sampled from joint distributions  $(X_{j1}, Y_{j1}), \dots, (X_{jt}, Y_{jt})$ .
- $R$  only has oracle access to the learner.
- $M$  takes as input  $z$ , fresh random bits from  $w$  and the  $B \cdot t(n)$  hypothesis circuits which are the answers made by the learner for all the queries asked by  $T_1, \dots, T_B$ , and outputs the answer.
- The reduction guarantees that if for every oracle  $A$  that is a  $\mathcal{C}$ -circuit learner, if every hypothesis circuit returned by the learner is  $(1 - \varepsilon)$ -close with respect to its corresponding query given to the learner by  $T_1, \dots, T_B$ , then  $M(z) = L(z)$  with high probability over the internal randomness of the reduction  $R$ .

► **Definition B.2.** For any  $B$ -adaptive black-box reduction  $R = (T_1, \dots, T_B)$  from deciding  $L$  to PAC-learning  $\mathcal{C}$  using random examples up to error  $\varepsilon$ , we have

- $R$  is called **strongly black-box**, if  $T_1, \dots, T_B, M$  only have oracle access to the hypothesis circuits and  $M$  decides  $L$  given access to any  $(1 - \varepsilon)$ -close hypothesis circuit answered to each query made by  $T_1, \dots, T_B$ .
- If  $B = 1$ , we call the reduction as **non-adaptive**, and if  $R$  is strongly black-box and  $M$  also makes only non-adaptive queries to the hypotheses circuits, we call the reduction as **fully non-adaptive**.
- $R$  is **oblivious**, if  $T_1, \dots, T_B$  output new queries using only fresh randomness from  $w$  as input and access to the hypotheses generated during the previous rounds. Furthermore,  $M$  accesses each hypothesis using non-adaptively generated, identically distributed queries made from the corresponding distribution over which each hypothesis is guaranteed to be a good approximation. In particular, the obliviousness of the reduction implies the fact that the queries to the learner do not depend on the input  $z$ .

Unless mentioned we think of the query complexity  $t(n) = \text{poly}(n)$ . It is worth to note that since the algorithms  $T_1, \dots, T_B$  are polynomial time algorithms, each joint distribution  $(X, Y)$  must be efficiently samplable.

We first prove Lemma 1.5. This is a reformulation of the proof of Lemma 3.2 used to show hardness of learning PSPACE/poly from a PSPACE-Complete language, into the framework of a black-box reduction.

**Proof of Lemma 1.5.** This is a readaptation of the proof of Corollary 1.3 (via Lemma 3.2). Consider  $R = (T_1, \dots, T_n, M)$  as an  $n$ -adaptive reduction from deciding  $f^*$  to learning PSPACE/poly using random examples over the uniform distribution, where  $T_1, \dots, T_n, M$  are probabilistic polynomial time algorithms which are defined as follows.

For every  $k \leq n$ ,  $T_k$  makes exactly one query to the learner which is the set of examples  $S_k = \{(x_i, y_i)\}_{i \leq \text{poly}(n)}$  drawn from the joint distribution  $(U_k, f^*(U_k))$ , where  $U_k$  is the uniform distribution over  $\{0,1\}^k$ . In the  $k^{\text{th}}$  round of adaptivity,  $T_k$  only makes oracle queries to the hypothesis  $h_{k-1}$  output in the last round. Indeed, let  $h'_{k-1}$  be the oracle circuit which uses  $h_{k-1}$  as an oracle in the self-corrector algorithm for  $f^*$ , and computes  $f^*$  on all  $k-1$  length inputs with high probability. It then outputs a set  $S_k$  of independent labeled samples  $(x_i, y_i)$ , where each  $x_i$  is sampled uniformly at random from  $U_k$  and  $y_i = f^*(x_i)$

computed by using the downward self-reducibility of  $f^*$  with  $h'_{k-1}$ .  $M$  takes the final hypothesis  $h_n$  output by the learner over  $n$  inputs and outputs the value of the self-corrector of  $f^*$  with the oracle  $h_n$ . The correctness of  $R$  and the run-time analyses of  $T_1, \dots, T_n, M$  follow from the proof techniques of Lemma 3.2.

We next show that  $R$  has the required properties. As the self-corrector and the downward self-reduction for  $f^*$  work for any oracle which satisfy the appropriate constraints,  $R$  is correct for any oracle which outputs *any* correct hypothesis for  $f^*$  with respect to the uniform distribution (over different input lengths). Further, it makes only oracle queries to the learner, as well as to all the hypothesis circuits  $h_1, \dots, h_n$ . This makes the reduction strongly black-box. By the property of the self-corrector,  $M$  only makes queries sampled from  $U_n$  to  $h_n$ , which is the same as the query made to the learner. The obliviousness now follows, since only  $f^*$  is learnt in each query, irrespective of the choice of  $z$ . ◀

The main result of the section is the following.

► **Theorem B.3.** *There exists a universal constant  $c > 0$  such that the following holds. For any language  $L$ ,  $\varepsilon_0 = 1/n^c$  and any  $B = \text{poly}(n)$ , if there exists an oblivious,  $B$ -adaptive, strongly black-box reduction from  $L$  to PAC-learning  $\text{NP}/\text{poly}$  using random examples over polynomially samplable distributions up to error  $\varepsilon_0$ , then  $\overline{L} \in \text{AM}^{\text{poly}}$ .*

Recall that the class  $\text{AM}^{\text{poly}}$  refers to the class of languages recognized by constant-round interactive protocols with advice, where we require proper acceptance/rejection probabilities only when the advice is correct. [14] show that  $\text{AM}^{\text{poly}} = \text{NP}/\text{poly}$ . Using Theorem B.3 with  $L = \text{SAT}$ , we get

► **Corollary B.4.** *There exists a universal constant  $c > 0$  such that the following holds. For  $\varepsilon_0 = 1/n^c$  and any  $B = \text{poly}(n)$ , if there exists an oblivious,  $B$ -adaptive, strongly black-box reduction from deciding SAT to learning  $\text{NP}/\text{poly}$  using random examples from polynomially samplable distributions up to error  $\varepsilon_0$ , then  $\text{coNP} \subseteq \text{NP}/\text{poly}$ .*

Corollary B.4 easily implies Theorem 1.6, since  $\text{coNP} \subseteq \text{NP}/\text{poly}$  implies that  $\Sigma_3^P = \Pi_3^P$  [39].

► **Remark B.5.** In addition, we can also extend the proof to the case where  $M$  still makes non-adaptive queries but is not constrained distributionally in its access to all the hypotheses, by directly applying the techniques of [10] for the simulation of  $R$  in  $\text{AM}^{\text{poly}}$ .

The details of the proof of Theorem B.3 can be found in the full version (see Section 1.4 for a sketch).

# The Critical Mean-Field Chayes-Machta Dynamics

## Abstract

The random-cluster model is a unifying framework for studying random graphs, spin systems and electrical networks that plays a fundamental role in designing efficient Markov Chain Monte Carlo (MCMC) sampling algorithms for the classical ferromagnetic Ising and Potts models. In this paper, we study a natural non-local Markov chain known as the *Chayes-Machta dynamics* for the mean-field case of the random-cluster model, where the underlying graph is the complete graph on  $n$  vertices. The random-cluster model is parametrized by an *edge probability*  $p$  and a *cluster weight*  $q$ . Our focus is on the critical regime:  $p = p_c(q)$  and  $q \in (1, 2)$ , where  $p_c(q)$  is the threshold corresponding to the order-disorder phase transition of the model. We show that the mixing time of the Chayes-Machta dynamics is  $O(\log n \cdot \log \log n)$  in this parameter regime, which reveals that the dynamics does not undergo an exponential slowdown at criticality, a surprising fact that had been predicted (but not proved) by statistical physicists. This also provides a nearly optimal bound (up to the  $\log \log n$  factor) for the mixing time of the mean-field Chayes-Machta dynamics in the only regime of parameters where no non-trivial bound was previously known. Our proof consists of a multi-phased coupling argument that combines several key ingredients, including a new local limit theorem, a precise bound on the maximum of symmetric random walks with varying step sizes, and tailored estimates for critical random graphs. In addition, we derive an improved comparison inequality between the mixing time of the Chayes-Machta dynamics and that of the local Glauber dynamics on general graphs; this results in better mixing time bounds for the local dynamics in the mean-field setting.

## 1 Introduction

The *random-cluster model* generalizes classical random graph and spin system models, providing a unifying framework for their study [12]. It plays an indispensable role in the design of efficient Markov Chain Monte Carlo (MCMC) sampling algorithms for the ferromagnetic Ising/Potts model [23, 6, 17] and has become a fundamental tool in the study of phase transitions [1, 11, 10].

The random-cluster model is defined on a finite graph  $G = (V, E)$  with an edge probability parameter  $p \in (0, 1)$  and a cluster weight  $q > 0$ . The set of *configurations* of the model is the set of all subsets of edges  $A \subseteq E$ . The probability of each configuration  $A$  is given by the Gibbs distribution:

$$\mu_{G,p,q}(A) = \frac{1}{Z} \cdot p^{|A|} (1-p)^{|E|-|A|} q^{c(A)}, \quad (1)$$

where  $c(A)$  is the number of connected components in  $(V, A)$  and  $Z := Z(G, p, q)$  is the normalizing factor called the *partition function*.

The special case when  $q = 1$  corresponds to the independent bond percolation model, where each edge of the graph  $G$  appears independently with probability  $p$ . Independent bond percolation is also known as the Erdős-Rényi random graph model when  $G$  is the complete graph.

For integer  $q \geq 2$ , the random-cluster model is closely related to the ferromagnetic  $q$ -state Potts model. Configurations in the  $q$ -state Potts model are the assignments of spin values  $\{1, \dots, q\}$  to the vertices of  $G$ ; the  $q = 2$  case corresponds to the Ising model. A sample  $A \subseteq E$  from the random-cluster distribution can be easily transformed into one for the Ising/Potts model by independently assigning a random spin from  $\{1, \dots, q\}$  to each connected component of  $(V, A)$ . Random-cluster based sampling algorithms, which include the widely-studied Swendsen-Wang dynamics [22], are an attractive alternative to Ising/Potts Markov chains since they are often efficient at “low-temperatures” (large  $p$ ). In this parameter regime, several standard Ising/Potts Markov chains are known to converge slowly.

In this paper we investigate the *Chayes-Machta (CM) dynamics* [9], a natural Markov chain on random-cluster configurations that converges to the random-cluster measure. The CM dynamics is a generalization to non-integer values of  $q$  of the widely studied Swendsen-Wang dynamics [22]. As with all applications of the MCMC method, the primary object of study is the *mixing time*, i.e., the number of steps until the dynamics is close to its stationary distribution, starting from the worst possible initial configuration. We are interested in understanding how the mixing time of the CM dynamics grows as the size of the graph  $G$  increases, and in particular how it relates to the phase transition of the model.

Given a random-cluster configuration  $(V, A)$ , one step of the CM dynamics is defined as follows:

- (i) activate each connected component of  $(V, A)$  independently with probability  $1/q$ ;
- (ii) remove all edges connecting active vertices;
- (iii) add each edge between active vertices independently with probability  $p$ , leaving the rest of the configuration unchanged.

We call (i) the *activation* sub-step, and (ii) and (iii) combined the *percolation* sub-step. It is easy to check that this dynamics is reversible with respect to the Gibbs distribution (1) and thus converges to it [9]. For integer  $q$ , the CM dynamics may be viewed as a variant of the Swendsen-Wang dynamics. In the Swendsen-Wang dynamics, each connected component of  $(V, A)$  receives a random color from  $\{1, \dots, q\}$ , and the edges are updated within each color class as in (ii) and (iii) above; in contrast, the CM dynamics updates the edges of exactly *one* color class. However, note that the Swendsen-Wang dynamics is only well-defined for integer  $q$ , while the CM dynamics is feasible for any real  $q > 1$ . Indeed, the CM dynamics was introduced precisely to allow this generalization.

The study of the interplay between phase transitions and the mixing time of Markov chains goes back to pioneering work in mathematical physics in the late 1980s. This connection for the specific case of the CM dynamics on the complete  $n$ -vertex graph, known as the *mean-field model*, has received some attention in recent years (see [5, 13, 16]) and is the focus of this

paper. As we shall see, the mean-field case is already quite non-trivial, and has historically proven to be a useful starting point in understanding various types of dynamics on more general graphs. We note that, so far, the mean-field is the only setting in which there are tight mixing time bounds for the CM dynamics; all other known bounds are deduced indirectly via comparison with other Markov chains, thus incurring significant overhead [6, 4, 15, 3, 23, 5].

The phase transition for the mean-field random-cluster model is fairly well-understood [8, 20]. In this setting, it is natural to re-parameterize by setting  $p = \zeta/n$ ; the phase transition then occurs at the *critical* value  $\zeta = \zeta_{\text{CR}}(q)$ , where  $\zeta_{\text{CR}}(q) = q$  when  $q \in (0, 2]$  and  $\zeta_{\text{CR}}(q) = 2\left(\frac{q-1}{q-2}\right) \log(q-1)$  for  $q > 2$ . For  $\zeta < \zeta_{\text{CR}}(q)$  all components are of size  $O(\log n)$  with high probability (w.h.p.); that is, with probability tending to 1 as  $n \rightarrow \infty$ . On the other hand, for  $\zeta > \zeta_{\text{CR}}(q)$  there is a unique giant component of size  $\approx \theta n$ , where  $\theta = \theta(\zeta, q)$ . The phase transition is thus analogous to that in  $G(n, p)$  corresponding to the emergence of a giant component.

The phase structure of the mean-field random-cluster model, however, is more subtle and depends crucially on the second parameter  $q$ . In particular, when  $q > 2$  the model exhibits *phase coexistence* at the critical threshold  $\zeta = \zeta_{\text{CR}}(q)$ . Roughly speaking, this means that when  $\zeta = \zeta_{\text{CR}}(q)$ , the set of configurations with all connected components of size  $O(\log n)$ , and set of configurations with a unique giant component, contribute each a constant fraction of the probability mass. For  $q \leq 2$ , on the other hand, there is no phase coexistence.

Phase coexistence at  $\zeta = \zeta_{\text{CR}}(q)$  when  $q > 2$  has significant implications for the speed of convergence of Markov chains, including the CM dynamics. The following detailed connection between the phase structure of the model and the mixing time  $\tau_{\text{mix}}^{\text{CM}}$  of the CM dynamics was recently established in [5, 2, 16]. When  $q > 2$ , we have:

$$\tau_{\text{mix}}^{\text{CM}} = \begin{cases} \Theta(\log n) & \text{if } \zeta \notin [\zeta_{\text{L}}, \zeta_{\text{R}}]; \\ \Theta(n^{1/3}) & \text{if } \zeta = \zeta_{\text{L}}; \\ e^{\Omega(n)} & \text{if } \zeta \in (\zeta_{\text{L}}, \zeta_{\text{R}}), \end{cases} \quad (2)$$

where  $(\zeta_{\text{L}}, \zeta_{\text{R}})$  is the so-called *metastability window*. It is known that  $\zeta_{\text{R}} = q$ , but  $\zeta_{\text{L}}$  does not have a closed form; see [5, 20]; we note that  $\zeta_{\text{CR}}(q) \in (\zeta_{\text{L}}, \zeta_{\text{R}})$  for  $q > 2$ .

When  $q \in (1, 2]$ , there is no metastability window, and the mixing time of the mean-field CM dynamics is  $\Theta(\log n)$  for all  $\zeta \neq \zeta_{\text{CR}}(q)$ . In view of these results, the only case remaining open is when  $q \in (1, 2]$  and  $\zeta = \zeta_{\text{CR}}(q)$ . Our main result shown below concerns precisely this regime, which is particularly delicate and had resisted analysis until now for reasons we explain in our proof overview.

► **Theorem 1.** *The mixing time of the CM dynamics on the complete  $n$ -vertex graph when  $\zeta = \zeta_{\text{CR}}(q) = q$  and  $q \in (1, 2)$  is  $O(\log n \cdot \log \log n)$ .*

A  $\Omega(\log n)$  lower bound is known for the mixing time of the mean-field CM dynamics that holds for all  $p \in (0, 1)$  and  $q > 1$  [5]. Therefore, our result is tight up to the lower order  $O(\log \log n)$  factor, and in fact even better as we explain in Remark 16. The conjectured tight bound when  $\zeta = \zeta_{\text{CR}}(q)$  and  $q \in (1, 2)$  is  $\Theta(\log n)$ . We mention that the  $\zeta = \zeta_{\text{CR}}(q)$  and  $q = 2$  case, which is quite different and not covered by Theorem 1, was considered earlier in [19] for the closely related Swendsen-Wang dynamics, and a tight  $\Theta(n^{1/4})$  bound was established for its mixing time. The same mixing time bound is expected for the CM dynamics in this regime; see Remark 7 for further comments about the  $\zeta = \zeta_{\text{CR}}(q)$ ,  $q = 2$  case.

Our result establishes a striking behavior for random-cluster dynamics when  $q \in (1, 2)$ . Namely, there is no slowdown (exponential or power law) in this regime at the critical threshold  $\zeta = \zeta_{\text{CR}}(q)$ . Note that for  $q > 2$ , as described in (2) above, the mixing time of the

dynamics undergoes an exponential slowdown, transitioning from  $\Theta(\log n)$  when  $\zeta < \zeta_L$ , to a power law at  $\zeta = \zeta_L$ , and to exponential in  $n$  when  $\zeta \in (\zeta_L, \zeta_R)$ . The absence of a critical slowdown for  $q \in (1, 2)$  was in fact predicted by the statistical physics community [14], and our result provides the first rigorous proof of this phenomenon.

Our second result concerns the local *Glauber dynamics* for the random-cluster model. In each step, the Glauber dynamics updates a single edge of the current configuration chosen uniformly at random; a precise definition of this Markov chain is given in the full version of the present paper [7]. In [5], it was established that any upper bound on the mixing time  $\tau_{\text{mix}}^{\text{CM}}$  of the CM dynamics can be translated to one for the mixing time  $\tau_{\text{mix}}^{\text{GD}}$  of the Glauber dynamics, at the expense of a  $\tilde{O}(n^4)$  factor; the  $\tilde{O}$  notation hides polylogarithmic factors. In particular, it was proved in [5] that  $\tau_{\text{mix}}^{\text{GD}} \leq \tau_{\text{mix}}^{\text{CM}} \cdot \tilde{O}(n^4)$ . We provide here an improvement of this comparison inequality.

► **Theorem 2.** *For all  $q > 1$  and all  $\zeta = O(1)$ ,  $\tau_{\text{mix}}^{\text{GD}} \leq \tau_{\text{mix}}^{\text{CM}} \cdot O(n^3(\log n)^2)$ .*

To prove this theorem, we establish a general comparison inequality that holds for any graph, any  $q \geq 1$  and any  $p \in (0, 1)$ ; see the full version of this paper [7] for a precise statement. When combined with the known mixing time bounds for the CM dynamics on the complete graph, Theorem 2 yields that the random-cluster Glauber dynamics mixes in  $\tilde{O}(n^3)$  steps when  $q > 2$  and  $\zeta \notin (\zeta_L, \zeta_R)$ , or when  $q \in (1, 2)$  and  $\zeta = O(1)$ . In these regimes, the mixing time of the Glauber dynamics was previously known to be  $\tilde{O}(n^4)$  and is conjectured to be  $\tilde{O}(n^2)$ ; the improved comparison inequality in Theorem 2 gets us closer to this conjectured tight bound. We note, however, that even if one showed the conjectured optimal bound for the mixing time of the Glauber dynamics, the CM is faster, even if we take into account the computational cost associated to implementing its steps.

We conclude this introduction with some brief remarks about our analysis techniques, which combine several key ingredients in a non-trivial way. Our bound on the mixing time uses the well-known technique of *coupling*: in order to show that the mixing time is  $O(\log n \cdot \log \log n)$ , it suffices to couple the evolutions of two copies of the dynamics, starting from two arbitrary configurations, in such a way that they arrive at the *same* configuration after  $O(\log n)$  steps with probability  $\Omega(1/\log \log n)$ . (The moves of the two copies can be correlated any way we choose, provided that each copy, viewed in isolation, is a valid realization of the dynamics.) Because of the delicate nature of the phase transition in the random-cluster model, combined with the fact that the percolation sub-step of the CM dynamics is critical when  $\zeta = q$ , our coupling is somewhat elaborate and proceeds in multiple phases. The first phase consists of a *burn-in period*, where the two copies of the chain are run independently and the evolution of their largest components is observed until they have shrunk to their “typical” sizes. This part of the analysis is inspired by similar arguments in earlier work [5, 19, 13].

In the second phase, we design a coupling of the activation of the connected components of the two copies which uses: (i) a local limit theorem, which can be thought of as a stronger version of a central limit theorem; (ii) a precise understanding of the distribution of the maximum of symmetric random walks on  $\mathbb{Z}$  with varying step sizes; and (iii) precise estimates for the component structure of random graphs. We develop tailored versions of these probabilistic tools for our setting and combine them to guarantee that the same number of vertices from each copy are activated in each step w.h.p. for sufficiently many steps. This phase of the coupling is the main novelty in our analysis, and allows us to quickly converge to the same configuration.

The rest of the paper is organized as follows. In Section 2, we give a detailed overview of our proof. The proof of the key step in our coupling construction is provided in Section 3; all others proofs are deferred to the full version of this paper [7].

## 2 Proof sketch and techniques

We now give a detailed sketch of the multi-phased coupling argument for proving Theorem 1. We start by formally defining the notions of mixing and coupling times. Let  $\Omega_{\text{RC}}$  be the set of random-cluster configurations of a graph  $G$ ; let  $\mathcal{M}$  be the transition matrix of a random-cluster Markov chain with stationary distribution  $\mu = \mu_{G,p,q}$ , and let  $\mathcal{M}^t(X_0, \cdot)$  be the distribution of the chain after  $t$  steps starting from  $X_0 \in \Omega_{\text{RC}}$ . The  $\varepsilon$ -mixing time of  $\mathcal{M}$  is given by

$$\tau_{\text{mix}}^{\mathcal{M}}(\varepsilon) := \max_{X_0 \in \Omega_{\text{RC}}} \min_{t \geq 0} \{ \|\mathcal{M}^t(X_0, \cdot) - \mu(\cdot)\|_{\text{TV}} \leq \varepsilon \},$$

where  $\|\cdot\|_{\text{TV}}$  denotes total variation distance. In particular, the *mixing time* of  $\mathcal{M}$  is  $\tau_{\text{mix}}^{\mathcal{M}} := \tau_{\text{mix}}^{\mathcal{M}}(1/4)$ .

A *(one step) coupling* of the Markov chain  $\mathcal{M}$  specifies, for every pair of states  $(X_t, Y_t) \in \Omega_{\text{RC}} \times \Omega_{\text{RC}}$ , a probability distribution over  $(X_{t+1}, Y_{t+1})$  such that the processes  $\{X_t\}$  and  $\{Y_t\}$  are valid realizations of  $\mathcal{M}$ , and if  $X_t = Y_t$  then  $X_{t+1} = Y_{t+1}$ . The *coupling time*, denoted  $T_{\text{coup}}$ , is the minimum  $T$  such that  $\Pr[X_T \neq Y_T] \leq 1/4$ , starting from the worst possible pair of configurations in  $\Omega_{\text{RC}}$ . It is a standard fact that  $\tau_{\text{mix}}^{\mathcal{M}} \leq T_{\text{coup}}$ ; moreover, when  $\Pr[X_T = Y_T] \geq \delta$  for some coupling, then  $\tau_{\text{mix}}^{\mathcal{M}} = O(T\delta^{-1})$  (see, e.g., [18]).

We provide first a high level description of our coupling for the CM dynamics. For this, we require the following notation. For a random cluster configuration  $X$ , let  $L_i(X)$  denote the size of the  $i$ -th largest connected component in  $(V, X)$ , and let  $\mathcal{R}_i(X) := \sum_{j \geq i} L_j(X)^2$ ; in particular,  $\mathcal{R}_1(X)$  is the sum of the squares of the sizes of all the components of  $(V, X)$ . Our coupling has three main phases:

1. *Burn-in period*: run two copies  $\{X_t\}, \{Y_t\}$  independently, starting from a pair of arbitrary initial configurations, until  $\mathcal{R}_1(X_T) = O(n^{4/3})$  and  $\mathcal{R}_1(Y_T) = O(n^{4/3})$ .
2. *Coupling to the same component structure*: starting from  $X_T$  and  $Y_T$  such that  $\mathcal{R}_1(X_T) = O(n^{4/3})$  and  $\mathcal{R}_1(Y_T) = O(n^{4/3})$ , we design a two-phased coupling that reaches two configurations with the same component structure as follows:
  - 2a. A two-step coupling after which the two configurations agree on all “large components”;
  - 2b. A coupling that after  $O(\log n)$  additional steps reaches two configurations that will also have the same “small component” structure.
3. *Coupling to the same configuration*: starting from two configurations with the same component structure, there is a straightforward coupling that couples the two configurations in  $O(\log n)$  steps w.h.p.

We proceed to describe each of these phases in detail.

### 2.1 The burn-in period

During the initial phase, two copies of the dynamics evolve independently. This is called a *burn-in period* and in our case consists of three sub-phases.

In the first sub-phase of the burn-in period the goal is to reach a configuration  $X$  such that  $\mathcal{R}_2(X) = O(n^{4/3})$ . For this, we use a lemma from [2], which shows that after  $T = O(\log n)$  steps of the CM dynamics  $\mathcal{R}_2(X_T) = O(n^{4/3})$  with at least constant probability; this holds when  $\zeta = q$  for any initial configuration  $X_0$  and any  $q > 1$ .

► **Lemma 3** ([2], Lemma 3.42). *Let  $q > 1$  and  $\zeta = q$ , and let  $X_0$  be an arbitrary random-cluster configuration. Then, for any constant  $C \geq 0$ , after  $T = O(\log n)$  steps  $\mathcal{R}_2(X_T) = O(n^{4/3})$  and  $L_1(X_T) > Cn^{2/3}$  with probability  $\Omega(1)$ .*

In the second and third sub-phases of the burn-in period, we use the fact that when  $\mathcal{R}_2(X_t) = O(n^{4/3})$ , the number of activated vertices is well concentrated around  $n/q$  (its expectation). This is used to show that the size of the largest component contracts at a constant rate for  $T = O(\log n)$  steps until a configuration  $X_T$  is reached such that  $\mathcal{R}_1(X_T) = O(n^{4/3})$ . This part of the analysis is split into two sub-phases because the contraction for  $L_1(X_t)$  requires a more delicate analysis when  $L_1(X_t) = o(n)$ ; this is captured in the following two lemmas.

► **Lemma 4.** *Let  $\zeta = q$  and  $q \in (1, 2)$ . Suppose  $\mathcal{R}_2(X_0) = O(n^{4/3})$ . Then, for any constant  $\delta > 0$ , there exists  $T = T(\delta) = O(1)$  such that  $\mathcal{R}_2(X_T) = O(n^{4/3})$  and  $L_1(X_T) \leq \delta n$  with probability  $\Omega(1)$ .*

► **Lemma 5.** *Let  $\zeta = q$  and  $q \in (1, 2)$ . Suppose  $\mathcal{R}_2(X_0) = O(n^{4/3})$  and that  $L_1(X_0) \leq \delta n$  for a sufficiently small constant  $\delta$ . Then, with probability  $\Omega(1)$ , after  $T = O(\log n)$  steps  $\mathcal{R}_1(X_T) = O(n^{4/3})$ .*

Lemmas 4 and 5 are proved in the full paper [7]. Combining them with Lemma 3 immediately yields the following theorem.

► **Theorem 6.** *Let  $\zeta = q$ ,  $q \in (1, 2)$  and let  $X_0$  be an arbitrary random-cluster configuration of the complete  $n$ -vertex graph. Then, with probability  $\Omega(1)$ , after  $T = O(\log n)$  steps  $\mathcal{R}_1(X_T) = O(n^{4/3})$ .*

► **Remark 7.** The contraction of  $L_1(X_t)$  established by Lemmas 4 and 5 only occurs when  $q \in (1, 2)$ ; when  $q > 2$  the quantity  $L_1(X_t)$  may increase in expectation, whereas for  $q = 2$  we have  $\mathbb{E}[L_1(X_{t+1}) \mid X_t] \approx L_1(X_t)$ , and the contraction of the size of the largest component is due instead to fluctuations caused by a large second moment. (This is what causes the power law slowdown when  $\zeta = q = 2$ .)

► **Remark 8.** Sub-steps (ii) and (iii) of the CM dynamics are equivalent to replacing the active portion of the configuration by a  $G(m, q/n)$  random graph, where  $m$  is the number of active vertices. Since  $\mathbb{E}[m] = n/q$ , one key challenge in the proofs of Lemmas 4 and 5, and in fact in the entirety of our analysis, is that the random graph  $G(m, q/n)$  is critical or almost critical w.h.p. since  $m \cdot q/n \approx 1$ ; consequently its structural properties are not well concentrated and cannot be maintained for the required  $O(\log n)$  steps of the coupling. This is one of the key reasons why the  $\zeta = \zeta_{\text{CR}}(q) = q$  regime is quite delicate.

## 2.2 Coupling to the same component structure

For the second phase of the coupling, we assume that we start from a pair of configurations  $X_0, Y_0$  such that  $\mathcal{R}_1(X_0) = O(n^{4/3})$ ,  $\mathcal{R}_1(Y_0) = O(n^{4/3})$ . The goal is to show that after  $T = O(\log n)$  steps, with probability  $\Omega(1/\log \log n)$ , we reach two configurations  $X_T$  and  $Y_T$  with the same component structure; i.e.,  $L_j(X_T) = L_j(Y_T)$  for all  $j \geq 1$ . In particular, we prove the following.

► **Theorem 9.** *Let  $\zeta = q$ ,  $q \in (1, 2)$  and suppose  $X_0, Y_0$  are random-cluster configurations such that  $\mathcal{R}_1(X_0) = O(n^{4/3})$  and  $\mathcal{R}_1(Y_0) = O(n^{4/3})$ . Then, there exists a coupling of the CM steps such that after  $T = O(\log n)$  steps  $X_T$  and  $Y_T$  have the same component structure with probability  $\Omega((\log \log n)^{-1})$ .*

Our coupling construction for proving Theorem 9 has two main sub-phases. The first is a two-step coupling after which the two configurations agree on all the components of size above a certain threshold  $B_\omega = n^{2/3}/\omega(n)$ , where  $\omega(n)$  is a slowly increasing function. For convenience and definiteness we set  $\omega(n) = \log \log \log \log n$ . In the second sub-phase we take care of matching the small component structures.

We note that when the same number of vertices are activated from each copy of the chain, we can easily couple the percolation sub-step (with an arbitrary bijection between the activated vertices) and replace the configuration on the active vertices in both chains with the same random sub-graph; consequently, the component structure in the updated sub-graph would be identical. Our goal is thus to design a coupling of the activation of the components that activates the same number of vertices in both copies in every step.

In order for the initial two-step coupling to succeed, certain (additional) properties of the configurations are required. These properties are achieved with a continuation of the initial burn-in phase for a small number of  $O(\log \omega(n))$  steps. For a random-cluster configuration  $X$ , let  $\tilde{\mathcal{R}}_\omega(X) = \sum_{j: L_j(X) \leq B_\omega} L_j(X)^2$  and let  $I(X)$  denote the number of isolated vertices of  $X$ . Our extension of the burn-in period is captured by the following lemma.

► **Lemma 10.** *Let  $\zeta = q$ ,  $q \in (1, 2)$  and suppose  $X_0$  is such that  $\mathcal{R}_1(X_0) = O(n^{4/3})$ . Then, there exists  $T = O(\log \omega(n))$  and a constant  $\beta > 0$  such that  $\tilde{\mathcal{R}}_\omega(X_T) = O(n^{4/3}\omega(n)^{-1/2})$ ,  $\mathcal{R}_1(X_T) = O(n^{4/3})$  and  $I(X_T) = \Omega(n)$  with probability  $\Omega(\omega(n)^{-\beta})$ .*

With these bounds on  $\tilde{\mathcal{R}}_\omega(X_T)$ ,  $\tilde{\mathcal{R}}_\omega(Y_T)$ ,  $I(X_T)$  and  $I(Y_T)$ , we construct the two-step coupling for matching the *large* component structure. The construction crucially relies on a new local limit theorem (Theorem 17). In particular, under our assumptions, when  $\omega(n)$  is small enough, there are few components with sizes above  $B_\omega$ . Hence, we can condition on the event that all of them are activated simultaneously. The difference in the number of active vertices generated by the activation of these large components can then be “corrected” by a coupling of the activation of the smaller components; for this we use our new local limit theorem.

Specifically, our local limit theorem applies to the random variables corresponding to the number of activated vertices from the small components of each copy. We prove it using a result of Mukhin [21] and the fact that, among the small components, there are (roughly speaking) many components of many different sizes. To establish the latter we require a refinement of known random graph estimates (see Lemma 23).

To formally state our result we introduce some additional notation. Let  $\mathcal{S}_\omega(X)$  be the set of connected components of  $X$  with sizes greater than  $B_\omega$ . At step  $t$ , the activation of the components of two random-cluster configurations  $X_t$  and  $Y_t$  is done using a maximal matching  $W_t$  between the components of  $X_t$  and  $Y_t$ , with the restriction that only components of equal size are matched to each other. For an increasing positive function  $g$  and each integer  $k \geq 0$ , define  $\hat{N}_k(t, g) := \hat{N}_k(X_t, Y_t, g)$  as the number of matched pairs in  $W_t$  whose component sizes are in the interval

$$\mathcal{I}_k(g) = \left[ \frac{\vartheta n^{2/3}}{2g(n)^{2k}}, \frac{\vartheta n^{2/3}}{g(n)^{2k}} \right],$$

where  $\vartheta > 0$  is a fixed large constant (independent of  $n$ ).

► **Lemma 11.** *Let  $\zeta = q$ ,  $q \in (1, 2)$  and suppose  $X_0, Y_0$  are random-cluster configurations such that  $\mathcal{R}_1(X_0) = O(n^{4/3})$ ,  $\tilde{\mathcal{R}}_\omega(X_0) = O(n^{4/3}\omega(n)^{-1/2})$ ,  $I(X_0) = \Omega(n)$  and similarly for  $Y_0$ . Then, there exists a two-step coupling of the CM dynamics such that  $\mathcal{S}_\omega(X_2) = \mathcal{S}_\omega(Y_2)$  with probability  $\exp(-O(\omega(n)^9))$ .*

*Moreover,  $L_1(X_2) = O(n^{2/3}\omega(n))$ ,  $\mathcal{R}_2(X_2) = O(n^{4/3})$ ,  $\tilde{\mathcal{R}}_\omega(X_2) = O(n^{4/3}\omega(n)^{-1/2})$ ,  $I(X_2) = \Omega(n)$ ,  $\hat{N}_k(2, \omega(n)) = \Omega(\omega(n)^{3 \cdot 2^{k-1}})$  for all  $k \geq 1$  such that  $n^{2/3}\omega(n)^{-2^{k-1}} \rightarrow \infty$ , and similarly for  $Y_2$ .*

From the first part of the lemma we obtain two configurations that agree on all of their large components, as desired, while the second part guarantees additional structural properties for the resulting configurations so that the next sub-phase of the coupling can also succeed with the required probability.

In the second sub-phase, after the large component are matched, we can design a coupling that activates exactly the same number of vertices from each copy of the chain. To analyze this coupling we use a precise estimate on the distribution of the maximum of symmetric random walks over integers (with steps of different sizes). We are first required to run the chains coupled for  $T = O(\log \omega(n))$  steps, so that certain additional structural properties appear. Let  $M(X_t)$  and  $M(Y_t)$  be the components in the matching  $W_t$  that belong to  $X_t$  and  $Y_t$ , respectively, and let  $D(X_t)$  and  $D(Y_t)$  be the complements of  $M(X_t)$  and  $M(Y_t)$ . Let  $Z_t = \sum_{C \in D(X_t) \cup D(Y_t)} |C|^2$ .

► **Lemma 12.** *Let  $\zeta = q$ ,  $q \in (1, 2)$ . Suppose  $X_0$  and  $Y_0$  are random-cluster configurations such that  $\mathcal{S}_\omega(X_0) = \mathcal{S}_\omega(Y_0)$ , and  $\hat{N}_k(0, \omega(n)) = \Omega(\omega(n)^{3 \cdot 2^{k-1}})$  for all  $k \geq 1$  such that  $n^{2/3} \omega(n)^{-2^{k-1}} \rightarrow \infty$ . Suppose also that  $L_1(X_0) = O(n^{2/3} \omega(n))$ ,  $\mathcal{R}_2(X_0) = O(n^{4/3})$ ,  $\hat{\mathcal{R}}_\omega(X_0) = O(n^{4/3} \omega(n)^{-1/2})$ ,  $I(X_0) = \Omega(n)$ , and similarly for  $Y_0$ .*

*Then, there exists a coupling of the CM steps such that with probability  $e^{-O((\log \omega(n))^2)}$  after  $T = O(\log \omega(n))$  steps:  $\mathcal{S}_\omega(X_T) = \mathcal{S}_\omega(Y_T)$ ,  $Z_T = O(n^{4/3} \omega(n)^{-1/2})$ ,  $\hat{N}_k(T, \omega(n)^{1/2}) = \Omega(\omega(n)^{3 \cdot 2^{k-2}})$  for all  $k \geq 1$  such that  $n^{2/3} \omega(n)^{-2^{k-1}} \rightarrow \infty$ ,  $\mathcal{R}_1(X_T) = O(n^{4/3})$ ,  $I(X_T) = \Omega(n)$ , and similarly for  $Y_T$ .*

The proof of Lemma 12 also uses our local limit theorem (Theorem 17).

The final step of our construction is a coupling of the activation of the components of size less than  $B_\omega$ , so that exactly the same number of vertices are activated from each copy in each step w.h.p.

► **Lemma 13.** *Let  $\zeta = q$ ,  $q \in (1, 2)$  and suppose  $X_0$  and  $Y_0$  are random-cluster configurations such that  $\mathcal{S}_\omega(X_0) = \mathcal{S}_\omega(Y_0)$ ,  $Z_0 = O(n^{4/3} \omega(n)^{-1/2})$ , and  $\hat{N}_k(0, \omega(n)^{1/2}) = \Omega(\omega(n)^{3 \cdot 2^{k-2}})$  for all  $k \geq 1$  such that  $n^{2/3} \omega(n)^{-2^{k-1}} \rightarrow \infty$ . Suppose also that  $\mathcal{R}_1(X_0) = O(n^{4/3})$ ,  $I(X_0) = \Omega(n)$  and similarly for  $Y_0$ . Then, there exist a coupling of the CM steps and a constant  $\beta > 0$  such that after  $T = O(\log n)$  steps,  $X_T$  and  $Y_T$  have the same component structure with probability  $\Omega((\log \log n)^{-\beta})$ .*

We comment briefly on how we prove this lemma. Our starting point is two configurations with the same “large” component structure; i.e.,  $\mathcal{S}_\omega(X_0) = \mathcal{S}_\omega(Y_0)$ . We use the maximal matching  $W_0$  to couple the activation of the large components in  $X_0$  and  $Y_0$ . The small components *not matched* by  $W_0$ , i.e., those counted in  $Z_0$ , are then activated independently. This creates a discrepancy  $\mathcal{D}_0$  between the number of active vertices from each copy. Since  $E[\mathcal{D}_0] = 0$  and  $\text{Var}(\mathcal{D}_0) = \Theta(Z_0) = \Theta(n^{4/3} \omega(n)^{-1/2})$ , it follows from Hoeffding’s inequality that  $\mathcal{D}_0 \leq n^{2/3} \omega(n)^{-1/4}$  w.h.p. To fix this discrepancy, we use the small components *matched* by  $W_0$ . Specifically, under the assumptions in Lemma 13, we can construct a coupling of the activation of the small components so that the difference in the number of activated vertices from the small components from each copy is exactly  $\mathcal{D}_0$  with probability  $\Omega(1)$ . This part of the construction utilizes random walks over the integers; in particular, we use a lower bound for the maximum of such a random walk.

We need to repeat this process until  $Z_t = 0$ ; this takes  $O(\log n)$  steps since  $Z_t \approx (1 - 1/q)^t Z_0$ . However, there are a few complications. First, the initial assumptions on the component structure of the configurations are not preserved for this many steps w.h.p., so we need to relax the requirements as the process evolves. This is in turn possible because the discrepancy  $\mathcal{D}_t$  decreases with each step, which implies that the probability of success of the coupling increases at each step.

Proof of Lemma 10, 12 and 13 is provided in the full version of the present paper [7]. We now indicate how these lemmas lead to a proof of Theorem 9 stated earlier.

**Proof of Theorem 9.** Suppose  $\mathcal{R}_1(X_0) = O(n^{4/3})$  and  $\mathcal{R}_1(Y_0) = O(n^{4/3})$ . It follows from Lemma 10, 11, 12 and 13 that there exists a coupling of the CM steps such that after  $T = O(\log n)$  steps,  $X_T$  and  $Y_T$  could have the same component structure. This coupling succeeds with probability at least

$$\rho = \Omega(\omega(n)^{-\beta_1}) \cdot \exp(-O(\omega(n)^9)) \cdot \exp(-O((\log \omega(n))^2)) \cdot \Omega((\log \log \log n)^{-\beta_2}),$$

where  $\beta_1, \beta_2 > 0$  are constants. Thus,  $\rho = \Omega((\log \log n)^{-1})$ , since  $\omega(n) = \log \log \log \log n$ . ◀

► **Remark 14.** We pause to mention that this delicate coupling for the activation of the components is not required when  $\zeta = q$  and  $q > 2$ . In that regime, the random-cluster model is super-critical, so after the first  $O(\log n)$  steps, the component structure is much simpler, with exactly one large component. On the other hand, when  $\zeta = q$  and  $q \in (1, 2]$  the model is critical, which, combined with the fact mentioned earlier that the percolation sub-step of the dynamics is also critical when  $\zeta = q$ , makes the analysis of the CM dynamics in this regime quite subtle.

### 2.3 Coupling to the same configuration

In the last phase of the coupling, suppose we start with two configurations  $X_0, Y_0$  with the same component structure. We are still required to bound the number of steps until the same configuration is reached. The following lemma from [5] supplies the desired bound.

► **Lemma 15** ([5], Lemma 24). *Let  $q > 1$ ,  $\zeta > 0$  and let  $X_0, Y_0$  be two random-cluster configurations with the same component structure. Then, there exists a coupling of the CM steps such that after  $T = O(\log n)$  steps,  $X_T = Y_T$  w.h.p.*

Combining the results for each of the phases of the coupling, we now prove Theorem 1.

**Proof of Theorem 1.** By Theorem 6, after  $t_0 = O(\log n)$  steps, with probability  $\Omega(1)$ , we have  $\mathcal{R}_1(X_{t_0}) = O(n^{4/3})$  and  $\mathcal{R}_1(Y_{t_0}) = O(n^{4/3})$ . If this is the case, Theorem 9 and Lemma 15 imply that there exists a coupling of the CM steps such that with probability  $\Omega((\log \log n)^{-1})$  after an additional  $t_1 = O(\log n)$  steps,  $X_{t_0+t_1} = Y_{t_0+t_1}$ . Consequently, we obtain that  $\tau_{\text{mix}}^{\text{CM}} = O(\log n \cdot \log \log n)$  as claimed. ◀

► **Remark 16.** The probability of success in Theorem 9, which governs the lower order term  $O(\log \log n)$  in our mixing time bound, is controlled by our choice of the function  $\omega(n)$  for the definition of “large components”. By choosing  $\omega(n)$  that goes to  $\infty$  more slowly, we could improve our mixing time bound to  $O(\log n \cdot g(n))$  where  $g(n)$  is any function that tends to infinity arbitrarily slowly. However, it seems that new ideas are required to obtain a bound of  $O(\log n)$  (matching the known lower bound). In particular, the fact that  $\omega(n) \rightarrow \infty$  is crucially used in some of our proofs. Our specific choice of  $\omega(n)$  yields the  $O(\log n \cdot \log \log n)$  bound and makes our analysis cleaner.

## 3 Coupling to the same component structure: proof of Lemma 11

To prove Lemma 11, we use a local limit theorem to construct a two-step coupling of the CM dynamics that reaches two configurations with the same large component structure. The construction of Markov chain couplings using local limit theorems is not common (see [19] for another example), but it appears to be a powerful technique that may have other interesting applications. We provide next a brief introduction to local limit theorems.

### 3.1 Local limit theorem

Let  $c_1 \leq \dots \leq c_m$  be integers and for  $i = 1, \dots, m$  let  $X_i$  be the random variable that is equal to  $c_i$  with probability  $r \in (0, 1)$ , and it is zero otherwise. Let us assume that  $X_1, \dots, X_m$  are independent random variables. Let  $S_m = \sum_{i=1}^m X_i$ ,  $\mu_m = \mathbb{E}[S_m]$  and  $\sigma_m^2 = \text{Var}(S_m)$ . We say that a *local limit theorem* holds for  $S_m$  if for every integer  $a \in \mathbb{Z}$ :

$$\Pr[S_m = a] = \frac{1}{\sqrt{2\pi}\sigma_m} \exp\left(-\frac{(a - \mu_m)^2}{2\sigma_m^2}\right) + o(\sigma_m^{-1}). \quad (3)$$

We prove, under some conditions, a local limit theorem that applies to the random variables corresponding to the number of active vertices from small components. Recall that for an increasing positive function  $g$  and each integer  $k \geq 0$ , we defined the intervals

$$\mathcal{I}_k(g) = \left[ \frac{\vartheta n^{2/3}}{2g(n)^{2^k}}, \frac{\vartheta n^{2/3}}{g(n)^{2^k}} \right],$$

where  $\vartheta > 0$  is a fixed large constant.

► **Theorem 17.** *Let  $c_1 \leq \dots \leq c_m$  be integers, and suppose  $X_1, \dots, X_m$  are independent random variables such that  $X_i$  is equal to  $c_i$  with probability  $r \in (0, 1)$ , and  $X_i$  is zero otherwise. Let  $g : \mathbb{N} \rightarrow \mathbb{R}$  be an increasing positive function such that  $g(m) \rightarrow \infty$  and  $g(m) = o(\log m)$ . Suppose  $c_m = O(m^{2/3}g(m)^{-1})$ ,  $\sum_{i=1}^m c_i^2 = O(m^{4/3}g(m)^{-1/2})$  and  $c_i = 1$  for all  $i \leq \rho m$ , where  $\rho \in (0, 1)$  is independent of  $m$ . Let  $\ell > 0$  be the smallest integer such that  $m^{2/3}g(m)^{-2^\ell} = o(m^{1/4})$ . If for all  $1 \leq k \leq \ell$ , we have  $|\{i : c_i \in \mathcal{I}_k(g)\}| = \Omega(g(m)^{3 \cdot 2^{k-1}})$ , then a local limit theorem holds for  $S_m = \sum_{i=1}^m X_i$ .*

Theorem 17 follows from a general local limit theorem proved in [21]; a proof is given in the full paper [7]. We next compile a number of (mostly standard) facts about the  $G(n, p)$  random graph model which will be used in our proof of Lemma 11.

### 3.2 Random graphs estimates

We use  $G \sim G(n, p)$  to denote a random graph  $G$  sampled from the standard  $G(n, p)$  model, in which every edge appears independently with probability  $p$ . For a graph  $G$ , with a slight abuse of notation, let  $L_i(G)$  denote the size of the  $i$ -th largest connected component in  $G$ , and let  $\mathcal{R}_i(G) := \sum_{j \geq i} L_j(G)^2$ ; note that the same notation is used for the components of a random-cluster configuration, but it will always be clear from context which case is meant.

► **Lemma 18** ([19], Lemma 5.7). *Let  $I(G)$  denote the number of isolated vertices in  $G$ . If  $np = O(1)$ , then there exists a constant  $C > 0$  such that  $\Pr[I(G) > Cn] = 1 - O(n^{-1})$ .*

► **Lemma 19** ([2], Lemma 2.16). *If  $np > 0$ , we have  $\mathbb{E}[\mathcal{R}_2(G)] = O(n^{4/3})$ .*

► **Lemma 20.** *Let  $G \sim G(n, \frac{1+\varepsilon}{n})$  with  $\varepsilon = o(1)$ . For any positive constant  $\rho \leq 1/10$ , there exist constants  $C \geq 1$  and  $c > 0$  such that if  $\varepsilon^3 n \geq C$ , then*

$$\Pr[|L_1(G) - 2\varepsilon n| > \rho\varepsilon n] = O(\exp(-c\varepsilon^3 n)).$$

For the next results, suppose that  $G \sim G(n, \frac{1+\lambda n^{-1/3}}{n})$ , where  $\lambda = \lambda(n)$  may depend on  $n$ .

► **Lemma 21.** *If  $|\lambda| = O(1)$ , then  $\mathbb{E}[\mathcal{R}_1(G)] = O(n^{4/3})$ .*

All the random graph facts stated so far can be either found in the literature, or follow directly from well-known results. The following lemmas are slightly more refined versions of similar results in the literature.

► **Lemma 22.** *Suppose  $|\lambda| = O(h(n))$  and let  $B_h = n^{2/3}h(n)^{-1}$ , where  $h : \mathbb{N} \rightarrow \mathbb{R}$  is a positive increasing function such that  $h(n) = o(\log n)$ . Then, for any  $\alpha \in (0, 1)$  there exists a constant  $C = C(\alpha) > 0$  such that, with probability at least  $\alpha$ ,*

$$\sum_{j: L_j(G) \leq B_h} L_j(G)^2 \leq Cn^{4/3}h(n)^{-1/2}.$$

► **Lemma 23.** *Let  $S_B = \{j : B \leq L_j(G) \leq 2B\}$  and suppose there exists a positive increasing function  $g$  such that  $g(n) \rightarrow \infty$ ,  $g(n) = o(n^{1/3})$ ,  $|\lambda| \leq g(n)$  and  $B \leq n^{2/3}g(n)^{-2}$ . If  $B \rightarrow \infty$ , then there exists constants  $\delta_1, \delta_2 > 0$  independent of  $n$  such that*

$$\Pr \left[ |S_B| \leq \frac{\delta_1 n}{B^{3/2}} \right] \leq \frac{\delta_2 B^{3/2}}{n}.$$

Finally, the following corollary of Lemma 23 will also be useful. For a graph  $H$ , let  $N_k(H, g)$  be the number of components of  $H$  whose sizes are in the interval  $\mathcal{I}_k(g)$ . We note that with a slight abuse of notation, for a random-cluster configuration  $X$ , we also use  $N_k(X, g)$  for the number of connected components of  $X$  in  $\mathcal{I}_k(g)$ .

► **Lemma 24.** *Let  $m \in (n/2q, n]$  and let  $g$  be an increasing positive function such that  $g(n) = o(m^{1/3})$ ,  $g(n) \rightarrow \infty$  and  $|\lambda| \leq g(m)$ . If  $H \sim G(m, \frac{1+\lambda m^{-1/3}}{m})$ , there exists a constant  $b > 0$  such that, with probability at least  $1 - O(g(n)^{-3})$ ,  $N_k(H, g) \geq bg(n)^{3 \cdot 2^{k-1}}$  for all  $k \geq 1$  such that  $n^{2/3}g(n)^{-2^k} \rightarrow \infty$ .*

The proofs of Lemmas 20-24 are given in the full version of the paper [7].

### 3.3 Proof of Lemma 11

For a random-cluster configuration  $X$ , let  $A(X)$  denote the random variable corresponding to the number of vertices activated by step (i) of the CM dynamics from  $X$ . We provide next the proof of Lemma 11.

**Proof of Lemma 11.** First, both  $\{X_t\}, \{Y_t\}$  perform one independent CM step from the initial configurations  $X_0, Y_0$ . We start by establishing that  $X_1$  and  $Y_1$  preserve the structural properties assumed for  $X_0$  and  $Y_0$ .

By assumption  $\mathcal{R}_1(X_0) = O(n^{4/3})$ , so Hoeffding's inequality implies that the number of activated vertices from  $X_0$  is such that

$$A(X_0) \in I := \left[ n/q - O(n^{2/3}), n/q + O(n^{2/3}) \right]$$

with probability  $\Omega(1)$ . Then, the percolation step is distributed as a

$$G \left( A(X_0), \frac{1 + \lambda A(X_0)^{-1/3}}{A(X_0)} \right)$$

random graph, with  $|\lambda| = O(1)$  with probability  $\Omega(1)$ . Conditioning on this event, from Lemma 18 we obtain that  $I(X_1) = \Omega(n)$  w.h.p. Moreover, from Lemma 21 and Markov's inequality we obtain that  $\mathcal{R}_1(X_1) = O(n^{4/3})$  with probability at least 99/100 and from Lemma 22 that  $\tilde{\mathcal{R}}_\omega(X_1) = O(n^{4/3}\omega(n)^{-1/2})$  also with probability at least 99/100.

We show next that  $X_1$  and  $Y_1$ , in addition to preserving the structural properties of  $X_0$  and  $Y_0$ , also have many connected components with sizes in certain carefully chosen intervals. This fact will be crucial in the design of our coupling. When  $A(X_0) \in I$ , by Lemmas 23 and 24 and a union bound, for all integer  $k \geq 0$  such that  $n^{2/3}\omega(n)^{-2^k} \rightarrow \infty$ ,

## 47:12 The Critical Mean-Field Chayes-Machta Dynamics

$N_k(X_1, \omega) = \Omega(\omega(n)^{3 \cdot 2^{k-1}})$  w.h.p. (Recall, that  $N_k(X_1, \omega)$  denotes the number of connected components of  $X_1$  with sizes in the interval  $\mathcal{I}_k(\omega)$ .) We will also require a bound for the number of components with sizes in the interval

$$J = \left[ \frac{cn^{2/3}}{\omega(n)^6}, \frac{2cn^{2/3}}{\omega(n)^6} \right],$$

where  $c > 0$  is a constant such that  $J$  does not intersect any of the  $\mathcal{I}_k(\omega)$ 's intervals. Let  $W_X$  (resp.,  $W_Y$ ) be the set of components of  $X_1$  (resp.,  $Y_1$ ) with sizes in the interval  $J$ . Lemma 23 then implies that for some positive constants  $\delta_1, \delta_2$  independent of  $n$ ,

$$\Pr \left[ |W_X| \geq \delta_1 n \left( \frac{\omega(n)^6}{cn^{2/3}} \right)^{3/2} \right] \geq 1 - \frac{\delta_2}{n} \left( \frac{cn^{2/3}}{\omega(n)^6} \right)^{3/2} = 1 - O(\omega(n)^{-9}).$$

All the bounds above apply also to the analogous quantities for  $Y_1$  with the same respective probabilities. Therefore, by a union bound, all these properties hold simultaneously for both  $X_1$  and  $Y_1$  with probability  $\Omega(1)$ . We assume that this is indeed the case and proceed to describe the second step of the coupling, in which we shall use each of the established properties for  $X_1$  and  $Y_1$ .

Let  $C_X$  and  $C_Y$  be the set of components in  $X_1$  and  $Y_1$ , respectively, with sizes larger than  $B_\omega$ . (Recall that  $B_\omega = n^{2/3}\omega(n)^{-1}$ , where  $\omega(n) = \log \log \log \log n$ .) Since  $\mathcal{R}_1(X_1) = O(n^{4/3})$ , the total number of components in  $C_X$  is  $O(\omega(n)^2)$ ; moreover, it follows from the Cauchy-Schwarz inequality that the total number of vertices in the components in  $C_X$ , denoted  $\|C_X\|$ , is  $O(n^{2/3}\omega(n))$ ; the same holds for  $C_Y$ .

Without loss of generality, let us assume that  $\|C_X\| \geq \|C_Y\|$ . Let

$$\Gamma = \{C \subset W_Y : \|C_Y \cup C\| \geq \|C_X\|\},$$

and let  $C_{\min} = \arg \min_{C \in \Gamma} \|C_Y \cup C\|$ . In words,  $C_{\min}$  is the smallest subset  $C$  of components of  $W_Y$  so that  $\|C_Y \cup C\| \geq \|C_X\|$ . Since every component in  $W_Y$  has size at least  $cn^{2/3}\omega(n)^{-6}$  and  $|W_Y| = \Omega(\omega(n)^9)$ , the number of vertices in  $W_Y$  is  $\Omega(n^{2/3}\omega(n)^3)$  and so  $\Gamma \neq \emptyset$ . In addition, the number components in  $C_{\min}$  is  $O(\omega(n)^9)$ . Let  $C'_Y = C_Y \cup C_{\min}$  and observe that the number of components in  $C'_Y$  is also  $O(\omega(n)^9)$  and that

$$0 \leq \|C'_Y\| - \|C_X\| \leq 2cn^{2/3}\omega(n)^{-6}.$$

Note that  $\|C_X\| - \|C_Y\|$  may be  $\Omega(n^{2/3}\omega(n))$  (i.e., much larger than  $\|C'_Y\| - \|C_X\|$ ). Hence, if all the components from  $C_Y$  and  $C_X$  were activated, the difference in the number of active vertices could be  $\Omega(n^{2/3}\omega(n))$ . This difference cannot be corrected by our coupling for the activation of the small components. We shall require instead that all the components from  $C'_Y$  and  $C_X$  are activated so that the difference is  $O(n^{2/3}\omega(n)^{-6})$  instead.

We now describe a coupling of the activation sub-step for the second step of the CM dynamics. As mentioned, our goal is to design a coupling in which the same number of vertices are activated from each copy. If indeed  $A(X_1) = A(Y_1)$ , then we can choose an arbitrary bijective map  $\varphi$  between the activated vertices of  $X_1$  and the activated vertices of  $Y_1$  and use  $\varphi$  to couple the percolation sub-step. Specifically, if  $u$  and  $v$  were activated in  $X_1$ , the state of the edges  $\{u, v\}$  in  $X_2$  and  $\{\varphi(u), \varphi(v)\}$  in  $Y_2$  would be the same. This yields a coupling of the percolation sub-step such that  $X_2$  and  $Y_2$  agree on the subgraph update at time 1.

Suppose then that in the second CM step all the components in  $C_X$  and  $C'_Y$  are activated simultaneously. If this is the case, then the difference in the number of activated vertices is  $d \leq 2cn^{2/3}\omega(n)^{-6}$ . We will use a local limit theorem (i.e., Theorem 17) to argue that

there is a coupling of the activation of the remaining components in  $X_1$  and  $Y_1$  such that the total number of active vertices in both copies is the same with probability  $\Omega(1)$ . Since all the components in  $C_X$  and  $C'_Y$  are activated with probability  $\exp(-O(\omega(n)^9))$ , the overall success probability of the coupling will be  $\exp(-O(\omega(n)^9))$ .

Now, let  $x_1, x_2, \dots, x_m$  be the sizes of the components of  $X_1$  that are not in  $C_X$  (in increasing order). Let  $\hat{A}(X_1)$  be the random variable corresponding to the number of active vertices from these components. Observe that  $\hat{A}(X_1)$  is the sum of  $m$  independent random variables, where the  $j$ -th variable in the sum is equal to  $x_j$  with probability  $1/q$ , and it is 0 otherwise. We claim that sequence  $x_1, x_2, \dots, x_m$  satisfies all the conditions in Theorem 17.

First, note that since the number of isolated vertices in  $X_1$  is  $\Omega(n)$ ,  $m = \Theta(n)$  and so  $x_m = O(m^{2/3}\omega(m)^{-1})$ ,  $\sum_{i=1}^m x_i^2 = \hat{R}_\omega(X_1) = O(m^{4/3}\omega(m)^{-1/2})$  and  $x_i = 1$  for all  $i \leq \rho m$ , where  $\rho \in (0, 1)$  is independent of  $m$ . Moreover, since  $N_k(X_1, \omega) \geq \Omega(\omega(n)^{3 \cdot 2^{k-1}})$  for all  $k \geq 1$  such that  $n^{2/3}\omega(n)^{-2^k} \rightarrow \infty$ ,

$$|\{i : x_i \in \mathcal{I}_k(\omega)\}| = \Omega(\omega(m)^{3 \cdot 2^{k-1}}).$$

Since  $N_0(X_1, \omega) = \Omega(\omega(n)^{3/2})$ , we also have

$$\sum_{i=1}^m x_i^2 \geq N_0(X_1, \omega) \cdot \frac{\vartheta^2 n^{4/3}}{4\omega(n)^2} = \Omega(m^{4/3}\omega(m)^{-1/2}).$$

Let  $\mu_X = \mathbb{E}[\hat{A}(X_1)] = q^{-1} \sum_{i=1}^m x_i$  and let

$$\sigma_X^2 = \text{Var}(\hat{A}(X_1)) = q^{-1}(1 - q^{-1}) \sum_{i=1}^m x_i^2 = \Theta(m^{4/3}\omega(m)^{-1/2}).$$

Hence, Theorem 17 implies that  $\Pr[\hat{A}(X_1) = a] = \Omega(\sigma_X^{-1})$  for any  $a \in [\mu_X - \sigma_X, \mu_X + \sigma_X]$ . Similarly, we get  $\Pr[\hat{A}(Y_1) = a] = \Omega(\sigma_Y^{-1})$  for any  $a \in [\mu_Y - \sigma_Y, \mu_Y + \sigma_Y]$ , with  $\hat{A}(Y_1)$ ,  $\mu_Y$  and  $\sigma_Y$  defined analogously for  $Y_1 \setminus C'_Y$ . Note that  $\mu_X - \mu_Y = O(n^{2/3}\omega(n)^{-6})$  and  $\sigma_X, \sigma_Y = \Theta(n^{2/3}\omega(n)^{-1/4})$ . Without loss of generality, suppose  $\sigma_X < \sigma_Y$ . Then for any  $a \in [\mu_X - \sigma_X/2, \mu_Y + \sigma_X/2]$  and  $d = O(n^{2/3}\omega(n)^{-6})$ , we have

$$\min \left\{ \Pr[\hat{A}(X_1) = a], \Pr[\hat{A}(Y_1) = a - d] \right\} = \min \left\{ \Omega(\sigma_X^{-1}), \Omega(\sigma_Y^{-1}) \right\} = \Omega(\sigma_Y^{-1}).$$

Hence, there exists a coupling  $\mathbb{P}$  of  $\hat{A}(X_1)$  and  $\hat{A}(Y_1)$  so that  $\mathbb{P}[\hat{A}(X_1) = a, \hat{A}(Y_1) = a - d] = \Omega(\sigma_Y^{-1})$  for all  $a \in [\mu_X - \sigma_X/2, \mu_Y + \sigma_X/2]$ . Therefore, there is a coupling of  $\hat{A}(X_1)$  and  $\hat{A}(Y_1)$  such that

$$\Pr[\hat{A}(X_1) - \hat{A}(Y_1) = d] = \Omega(\sigma_X/\sigma_Y) = \Omega(1).$$

Putting all these together, we deduce that  $A(X_1) = A(Y_1)$  with probability  $e^{-O(\omega(n)^9)}$ . If this is the case, the edge re-sampling step is coupled bijectively (as described above) so that  $\mathcal{S}_\omega(X_2) = \mathcal{S}_\omega(Y_2)$ .

It remains for us to guarantee the additional desired structural properties of  $X_2$  and  $Y_2$ , which follow straightforwardly from the random graph estimates we stated at the beginning of the section. First note that by Hoeffding's inequality, with probability  $\Omega(1)$ ,

$$\left| A(X_1) - \frac{n}{q} - \frac{(q-1)|C_X|}{q} \right| = O(n^{2/3}).$$

Hence, in the percolation sub-step the active subgraph is replaced by

$$F \sim G \left( A(X_1), \frac{1 + \lambda A(X_1)^{-1/3}}{A(X_1)} \right),$$

where  $|\lambda| = O(\omega(n))$  with probability  $\Omega(1)$  since  $|C_X| = O(n^{2/3}\omega(n))$ . Conditioning on this event, since the components of  $F$  contribute to both  $X_2$  and  $Y_2$ , Lemma 24 implies that w.h.p.  $\hat{N}_k(2, \omega(n)) = \Omega(\omega(n)^{3 \cdot 2^{k-1}})$  for all  $k \geq 1$  such that  $n^{2/3}\omega(n)^{-2^k} \rightarrow \infty$ . Moreover, from Lemma 18 we obtain that  $I(X_2) = \Omega(n)$  w.h.p. From Lemma 19 and Markov's inequality, we obtain that  $\mathcal{R}_2(X_2) = O(n^{4/3})$  with probability at least 99/100 and from Lemma 22 that  $\tilde{\mathcal{R}}_\omega(X_2) = O(n^{4/3}\omega(n)^{-1/2})$  also with probability at least 99/100. All these bounds apply also to the analogous quantities for  $Y_2$  with the same respective probabilities.

Finally, we derive the bound for  $L_1(X_2)$  and  $L_1(Y_2)$ . First, notice  $L_1(F)$  is stochastically dominated by  $L_1(F')$ , where

$$F' \sim G\left(A(X_1), \frac{1 + |\lambda|A(X_1)^{-1/3}}{A(X_1)}\right).$$

Under the assumption that  $|\lambda| = O(\omega(n))$ , if  $|\lambda| \rightarrow \infty$ , then Lemma 20 implies that  $L_1(F') = O(|\lambda|A(X_1)^{2/3}) = O(n^{2/3}\omega(n))$  w.h.p.; otherwise,  $|\lambda| = O(1)$  and by Lemma 21 and Markov's inequality,  $L_1(F') = O(n^{2/3})$  with probability at least 99/100. Thus,  $L_1(F) = O(n^{2/3}\omega(n))$  with probability at least 99/100. We also know that the largest inactivated component in  $X_1$  has size less than  $n^{2/3}\omega(n)^{-1}$ , so  $L_1(X_2) = O(n^{2/3}\omega(n))$  with probability at least 99/100. The same holds for  $Y_2$ . Therefore, by a union bound, all these properties hold simultaneously for both  $X_2$  and  $Y_2$  with probability  $\Omega(1)$ , as claimed.  $\blacktriangleleft$

## Abstract

---

We study the *robust* – à la Chakrabarti, Cormode, and McGregor [STOC’08] – communication complexity of the maximum bipartite matching problem. The edges of an *adversarially* chosen  $n$ -vertex bipartite graph  $G$  are partitioned *randomly* between Alice and Bob. Alice has to send a single message to Bob, using which Bob has to output an approximate maximum matching of  $G$ . We are particularly interested in understanding the best approximation ratio possible by protocols that use a near-optimal message size of  $n \cdot \text{polylog}(n)$ .

The communication complexity of bipartite matching in this setting under an *adversarial* partitioning is well-understood. In their beautiful paper, Goel, Kapralov, and Khanna [SODA’12] gave a  $2/3$ -approximate protocol with  $O(n)$  communication and showed that this approximation is tight unless we allow more than a near-linear communication. The complexity of the robust version, i.e., with a *random* partitioning of the edges, however remains wide open. The best known protocol, implied by a very recent random-order streaming algorithm of the authors [ICALP’21], uses  $O(n \log n)$  communication to obtain a  $(2/3 + \varepsilon_0)$ -approximation for a constant  $\varepsilon_0 \sim 10^{-14}$ . The best known lower bound, on the other hand, leaves open the possibility of all the way up to even a  $(1 - \varepsilon)$ -approximation using near-linear communication for constant  $\varepsilon > 0$ .

In this work, we give a new protocol with a significantly better approximation. Particularly, our protocol achieves a 0.716 expected approximation using  $O(n)$  communication. This protocol is based on a new notion of *distribution-dependent sparsifiers* which give a natural way of sparsifying graphs sampled from a *known* distribution. We then show how to lift the assumption on knowing the graph’s distribution via minimax theorems. We believe this is a particularly powerful method of designing communication protocols and might find further applications.

## 1 Introduction

Consider the following communication game. We have an  $n$ -vertex bipartite graph  $G = (L, R, E)$  whose edges are partitioned into  $E^A$  and  $E^B$  given to Alice and Bob, respectively (both players know  $L$  and  $R$ ). The goal is to compute an approximate maximum matching of  $G$  by Alice sending a single message to Bob and Bob outputting the solution. What is the tradeoff between the size of Alice’s message and the approximation ratio of the output matching, or in other words, the *one-way communication complexity* of bipartite matching?

It is known that  $\Omega(n^2)$  communication is necessary for finding a maximum matching [23] and this is clearly sufficient by Alice sending her entire input. But the situation is more interesting for approximate protocols. A  $1/2$ -approximation with  $O(n)$  communication can be obtained by Alice sending a maximum matching of her input to Bob and  $\Omega(n)$  communication is clearly needed for any constant factor approximation. More interestingly, Goel, Kapralov, and Khanna [25] showed that  $O(n)$  communication even suffices to obtain a  $2/3$ -approximation and that this is the “right” answer: any better approximation requires  $n^{1+\Omega(1/\log \log n)} \gg n \cdot \text{polylog}(n)$  communication.

In this paper, we study a *robust* variant of this problem – à la Chakrabarti, Cormode, and McGregor [18] – wherein the graph  $G$  is still chosen adversarially, but now its edges are instead *randomly partitioned* between the two players, i.e., each edge is independently given to one of the players chosen uniformly at random. This model of random partitioning was introduced in [18] to go beyond the “doubly worst case” analysis of communication games, namely, adversarial inputs and adversarial partitions, and sheds more light into the source of hardness: whether it is due to a pathological partitioning of inputs or rather it holds for most input partitions.

Our main result is a substantial improvement over the  $2/3$ -approximations for adversarial partitions [25] under this random partition model.

► **Result 1** (Formalized in Theorem 17). *There is a randomized one-way protocol with  $O(n)$  communication that achieves an expected  $0.716$ -approximation for the bipartite matching problem under a random partitioning of the input edges between Alice and Bob.*

Prior to our work, the best known approximation ratio achievable for this problem was  $(2/3 + \varepsilon_0)$  for some  $\varepsilon_0 \sim 10^{-14}$ , obtained via the very recent random-order streaming algorithm of the same authors of this paper in [2].

We note that our protocol in this result can be considered *non-explicit*: we show the existence of the protocol rather than explicitly designing the protocol itself (see Section 1.1 for details). Alternatively, the protocol can be found also via a brute-force search in doubly exponential time.

## 1.1 Our Techniques

The  $2/3$ -approximation protocol of [25] (and follow-ups in [3] that simplified it or [37] that extended it to the online batch-arrival model) are all based on finding a suitable subgraph of Alice’s input that preserves large matchings approximately, namely, a matching sparsifier (similar-in-spirit to cut sparsifiers [13, 14]). These subgraphs are defined through a series of graph-theoretic constraints: a novel decomposition into expanding sets (matching skeleton) in [25, 37] (see also [33]), and edge-degree bounded subgraphs in [3] (defined first in [16, 17] for dynamic graph algorithms). We take an entirely different approach in this paper.

The first step of our approach is a way of introducing distributional assumptions about the input, while still solving the problem in its full generality. In particular, in this step, we reduce the general problem to the case that the input graph  $G$  is sampled from some arbitrary but known distribution  $\mathcal{G}$  of graphs. We achieve this via combining several relatively standard ideas specific to the matching problem with an application of Yao’s minimax principle [41] (the so-called “hard direction” of this principle; see Section 5). This is the main *conceptual* step of our approach.

The second step is to design a protocol for the problem assuming that it is additionally given an input distribution  $\mathcal{G}$  of the input graph. We achieve this through a new notion of “distribution-dependent sparsifiers” described below. This is our main *technical* step.

**Distribution-dependent sparsifiers.** Distribution-dependent sparsifiers can be used whenever we know a distribution  $\mathcal{G}$  for inputs of Alice and Bob. In particular, the knowledge of  $\mathcal{G}$  allows us to determine the “importance” of each edge in Alice’s input  $E^A$ : this is the probability that this particular edge belongs to a fixed maximum matching (say, the lexicographically-first maximum matching) of a graph sampled from  $\mathcal{G} \mid E^A$ , i.e., input graphs after conditioning on Alice’s input. The main part of our argument is to show that these importances can be used to sparsify the Alice’s graph to  $O(n)$  edges, while allowing Bob to find a large matching of the entire graph in expectation.

For our analysis of these sparsifiers, we need to show that the edges  $T$  communicated by Alice and the edges  $E^B$  given to Bob combined, include a large matching. We do so by constructing a large fractional matching  $\mathbf{x}$  on the edges in  $T \cup E^B$ . Our construction of  $\mathbf{x}$  is online, in the sense that we decide on the value of  $\mathbf{x}$  induced on  $T$  before sampling Bob’s subgraph  $E^B$  from  $\mathcal{G} \mid E^A$ . Thanks to the fact that Alice picks the edges of  $T$  according to their importance, we can construct  $\mathbf{x}$  on  $T$  such that the fractional value around each vertex  $v$  is equal to the probability that  $v$  is matched in the optimum solution via an edge given to Alice. This is particularly useful because it implies that (i) the size of  $\mathbf{x}$  induced on  $T$  equals the expected number of edges of Alice in an optimum matching, and that (ii) if a vertex is unlikely to be matched via an edge of Alice in the optimum solution, then the fractional matching  $\mathbf{x}$  induced on  $T$  does not occupy this vertex by much, leaving room for the rest of the edges in  $E^B$  to use it.

As a warm-up in Section 3, we show how the ideas above lead to a very simple 0.656-approximate protocol under an *adversarial* partitioning of the input. This is only slightly worse than the optimal  $2/3$ -approximation for this problem, but more importantly, this warm-up conveys the key intuitions behind distribution-dependent sparsifiers and how they are extremely useful for matching in the communication setting. The protocol for our 0.716-approximation in Section 4 for the robust communication model is very similar, but its analysis is more involved and in particular is based on a careful examination of edge importance distributions under a random partitioning.

## 1.2 Further Aspects of Our Results

**Random-order streams.** The one-way communication model in general is strongly motivated by applications to *graph streaming algorithms* [23]. The *robust* communication model, in the same vein, is closely related to *random-order* streaming algorithms wherein the edges of the graph arrive in a random order. In particular, lower bounds in the (robust) communication model directly imply space lower bounds in the (random-order) streaming model [18] and upper bounds are sources of inspiration and stepping stones for designing streaming algorithms (see, e.g., [1, 25, 31] for instances of communication protocols that were turned into streaming algorithms in the context of the matching problem).

Maximum matchings have been studied extensively in random-order streams [1, 2, 15, 22, 24, 34, 35], leading to a  $2/3$ -approximation algorithm of [15] that hit a natural barrier for this problem, and the recent algorithm of [2] that improved this approximation to strictly more than  $2/3$  (for a tiny constant improvement). We hope our ideas in this paper can lead to a significantly-better-than- $2/3$  approximation in random-order streams.

We remark that [2] proves the following robust communication lower bound (and thus a random-order streaming lower bound also): any  $(1 - \Theta(1/\log n))$ -approximation to maximum matching in the robust communication model requires  $n^{1+\Omega(1/\log \log n)} \gg n \cdot \text{polylog}(n)$  communication. Closing the gap between our upper bound and the lower bound of [2] remains a fascinating open question. Finally, we note that our improved protocol also has the following

message: either one should be able to achieve a significantly-better-than- $2/3$  approximation (say, a 0.716-approximation) in random-order streams, or any lower bound technique for proving impossibility of such a result should deviate from the standard two-party communication complexity lower bound approach.

**Non-explicit protocols.** As remarked earlier, the protocol in our main result can be considered non-explicit. Alternatively, the players may need to first spend a doubly-exponential time to find the protocol, and only then they can use it to solve the problem (this is due to the arguments in the first step of our approach and in particular using Yao’s minimax principle). From an algorithmic perspective, this is a weakness of our particular method of protocol design. On the other hand, we find our method particularly strong and insightful from a communication complexity point of view as we shall elaborate below.

Firstly, communication complexity is a non-uniform model of computation with players of unbounded computational power, and the only resource of interest is the communication cost of protocols. In this regard, our protocol uses the “full power” of this model to achieve its approximation ratio using the optimal  $O(n)$  communication.

Secondly, and more importantly, there is a general gap in the study of communication complexity of graph problems: almost all protocols designed in the literature are based on algorithmic tools that are tailored to time-efficient protocols, while all known lower bounds are information-theoretic and hold even for protocols with computationally unbounded players. Can this inconsistent treatment be a contributing factor to the substantial gaps between known upper and lower bounds for various problems, including the robust communication complexity of bipartite matching? If so, then our approach in this paper allows us to explore a wider set of natural protocols for the problems at hand and move toward achieving tight(er) bounds on communication complexity. This will in turn suggest that purely information-theoretic complexity lower bounds cannot prove “strong enough” lower bounds for computationally-efficient algorithms as well. We leave the question of proving communication lower bounds for computationally-efficient protocols, which is the dual approach to our work in this paper, as a very interesting research direction for future work.

### 1.3 Further Related Work

The communication complexity of bipartite matching has been extensively studied from various angles including exact protocols [21, 27, 30], non-deterministic protocols [40], protocols with limited rounds of communication [3, 5, 23, 25, 26], or multi-party protocols [6, 26, 29, 32, 33] to name a few (this is by no means a comprehensive summary of previous results).

The one-way communication complexity of matching, in particular, is directly related to streaming algorithms. In fact, a key motivation in the work of Goel, Kapralov, and Khanna [25] was to determine whether there is a better-than- $1/2$ -approximation algorithm for the matching problem in the streaming model that uses  $\tilde{O}(n)$  space, a longstanding open problem in this area. The lower bound in [25] implies that there is no semi-streaming algorithm with approximation ratio better than  $2/3$ ; this lower bound was later improved by Kapralov to a  $1 - 1/e \approx 0.63$  in [31] and to  $\frac{1}{1+\ln 2} \approx 0.59$  in [32]. Additionally, the communication protocols in [25] were also generalized in the same paper to achieve a  $(1 - 1/e)$ -approximation in vertex-arrival streams.

Finally, we should point out that the work of [25] on the one-way communication complexity of bipartite matching has been quite instrumental and paved the path for various follow-ups including optimal algorithms for vertex-arrival streaming model [25, 31], state-of-the-art lower bounds for streaming matching in both insertion-only streams [31, 32] and

dynamic streams [6, 20], online batch-arrival algorithms [37] and fault-tolerant algorithms [3] for maximum matching, stochastic matching problem [3, 4, 10, 11], and using RS graphs for proving communication lower bounds for other problems such as matrix rank [5, 9], independent sets [7, 19], and reachability [8].

## 2 Preliminaries

**Notation.** For any graph  $G$ , we use  $n$  to denote the number of vertices and  $\mu(G)$  to denote the maximum matching size. A fractional matching  $\mathbf{x}$  on a graph  $G$  is an assignment of values  $x_e$  to the edges  $e$  of  $G$  such that  $x_e \geq 0$  for all edges  $e$  and for each vertex  $v$ ,  $x_v := \sum_{e \ni v} x_e \leq 1$ . We use  $|\mathbf{x}|$  as a shorthand for  $\sum_e x_e$  which is the size of fractional matching  $\mathbf{x}$ .

The following standard fact implies that to show a bipartite graph has an integral matching of size  $\mu$ , it suffices to construct a fractional matching of size  $\mu$  on it.

► **Fact 1.** *Let  $\mathbf{x}$  be a fractional matching of a bipartite graph  $G$ . Then  $G$  has an integral matching of size at least  $|\mathbf{x}|$ .*

**Communication model.** We study the standard two-party communication model of Yao [42] and in particular in the one-way model (see the excellent textbook by Kushilevitz and Nisan [36]). The only slight derivation is that we focus on randomly partitioned inputs, wherein the input graph is still chosen adversarially, but every edge in the graph is sent to one of the players chosen independently and uniformly at random. To our knowledge, this model was first introduced by Chakrabarti, Cormode, and McGregor in [18].

Unless specified otherwise, we assume that protocols are randomized and both players have access to the same *shared* source of randomness, referred to as *public coins*; however, one can always use Newman's theorem [39] to turn public coins into private coins with a negligible overhead. The communication cost of any protocol in this model is the worst-case length of the communicated messages; to be consistent with prior work on this problem in [3, 25, 31, 33], we measure the length of messages in  $\Theta(\log n)$ -bit words as opposed to the more standard convention of bits. Finally, we note that the main resource of interest in this model is the communication and the players are assumed to be *computationally unbounded*.

## 3 Warm-up: A 0.656-Approximation Under Adversarial Partitions

In this section, we describe a one-way protocol for the bipartite matching problem and prove that it achieves an approximation factor of  $(4\sqrt{2}-5) \approx 0.656$  under an *adversarial* partitioning of the edges. While this protocol is slightly worse than the optimal  $2/3$ -approximate protocols in [3, 25] and its analysis shares some similarity with [12], we believe it is still instructive as it acts as a gentle introduction to the ideas used in our main protocol of Section 4.

A key technique introduced in this work is the notion of **distribution-dependent sparsifiers**. For now, let us assume that there is a *known* distribution  $\mathcal{G}$  from which the inputs  $E^A$  and  $E^B$  of Alice and Bob are sampled. Now, suppose Alice has received  $E^A$  as input and plans to send a message to Bob. In order to do this, Alice considers the distribution of inputs conditioned on her input, i.e.,  $\mathcal{G} \mid E^A$ . The message sent by Alice is then a subgraph of her input (the sparsifier), wherein each edge is included depending on the probability that this edge belongs to a fixed maximum matching of a graph sampled from  $\mathcal{G} \mid E^A$ .

Finally, we can lift the assumption on the knowledge of  $\mathcal{G}$  using minimax theorems: distribution-dependent sparsifiers give us a deterministic protocol for *each* distribution of

inputs with approximation ratio at least  $\alpha$  for every distribution; thus, there should also exist a *single* randomized protocol that achieves the same  $\alpha$ -approximation for *all* inputs. See Section 5 for this argument<sup>1</sup>.

### 3.1 The Protocol

We now describe our new distribution-dependent protocol. For the rest of this proof, we assume that Alice and Bob are given the distribution of inputs  $\mathcal{G}$ . For each edge  $e \in E^A$ , we define:

$$a_e := \Pr_{G \sim \mathcal{G}}[e \in \text{MM}(G) \mid E^A], \quad (1)$$

where function  $\text{MM}(\cdot)$  deterministically returns a fixed maximum matching of its input (for instance, the lexicographically-first one, or the one returned by the Hopcroft-Karp algorithm [28]). In words,  $a_e$  is the probability that  $e$  belongs to a fixed maximum matching of a graph  $G$  sampled from  $\mathcal{G}$  conditioned on the input  $E^A$  given to Alice. We are going to treat  $a_e$  as the “importance” of edge  $e$  in  $E^A$ . Observe that since Alice is aware of  $\mathcal{G}$ , she can compute  $a_e$  for each edge  $e \in E^A$ .

**Fractional matching interpretation.** Consider the vector  $\mathbf{a} := \{a_e\}_{e \in E^A}$ . We claim that  $\mathbf{a}$  is a feasible *fractional* matching of  $E^A$ : (i) for every edge  $e \in E^A$ , we have  $a_e \geq 0$  as  $a_e$  is a probability, and (ii) for all vertices  $v$ ,  $a_v := \sum_{e \ni v} a_e \leq 1$  as it can be confirmed that:

$$a_v = \Pr_{G \sim \mathcal{G}}[v \text{ matched in MM}(G) \text{ by edges of } E^A \mid E^A]. \quad (2)$$

This view of  $\mathbf{a}$  presents a natural way of sparsifying Alice’s input. Basically, we can sparsify the support of  $\mathbf{a}$  via the standard cycle-canceling method (see Lemma 2 below) so that instead of (possibly up to)  $\Omega(n^2)$  edges, it will only have  $O(n)$  edges while still preserving the fractional matching of each *vertex* (but not necessarily the edges). This allows us to obtain another fractional matching  $\mathbf{a}'$  that preserves key properties of  $\mathbf{a}$  but is much sparser and thus Alice can simply send this fractional matching directly to Bob.

► **Lemma 2** (Cycle-Canceling Lemma – Folklore). *Let  $\mathbf{f}$  be any fractional matching of  $E^A$ . There is another fractional matching  $\mathbf{f}'$  on  $E^A$  such that:*

- **Sparsification property:** *There are at most  $n - 1$  edges  $e$  in  $E^A$  with  $f'_e > 0$ .*
- **Preserving marginals and size:** *For every vertex  $v$ ,  $f'_v = f_v$ , also implying  $|\mathbf{f}'| = |\mathbf{f}|$ .*

**Proof.** Iteratively take a cycle in the support of  $\mathbf{f}$ , then alternately decrease and increase the value of edges in a way that the minimum value edge gets value zero. Since all cycles are even-length, the fractional matching around each vertices remains unchanged throughout the process. Once there are no more cycles, the remaining fractional matching is a forest with at most  $n - 1$  edges. ◀

We can now formalize the protocol as follows.

By Lemma 2 this protocol requires  $O(n)$  communication (in fact, only  $n - 1$  edges). Thus, it only remains to analyze the approximation ratio of Algorithm 1 in the following.

<sup>1</sup> There is an important subtlety here: distribution-dependent sparsifiers approximate the matching *in expectation* over the choice of graphs in the distribution; in other words, the output matching is close to the optimal matching in expectation. To apply Yao’s minimax principle however, one needs an *instance-wise* approximation for the input graph. Thus, the argument in this part is not a black-box application of minimax theorems.

■ **Algorithm 1** A simple distribution-dependent sparsifier protocol.

- 
- (i) Given edges  $E^A$  as input to Alice, she computes the vector  $\mathbf{a} = \{a_e\}_{e \in E^A}$  using Eq (1); as discussed above,  $\mathbf{a}$  is a valid fractional matching of  $E^A$ .
  - (ii) Alice obtains fractional matching  $\mathbf{a}'$  by running cycle canceling on  $\mathbf{a}$  (Lemma 2) and then sends the edges  $T$  in the support of  $\mathbf{a}'$  to Bob.
  - (iii) Bob, given message  $T$  from Alice and input  $E^B$ , returns a maximum matching of  $E^B \cup T$ .
- 

► **Proposition 3.** *For any input distribution  $\mathcal{G}$  on adversarial partitions, Algorithm 1 achieves a  $4\sqrt{2} - 5 \approx 0.6568$  approximation in expectation and uses  $O(n)$  communication.*

We prove this proposition in the next section.

### 3.2 The Analysis: Proof of Proposition 3

Recall that  $T$  is the support of the fractional matching  $\mathbf{a}'$  that Alice sends to Bob. For the analysis, we only need to show that  $T \cup E^B$  includes a large fractional matching (by Fact 1). To do so, we construct a fractional matching  $\mathbf{x}$  supported on  $T \cup E^B$  in the following way:

$$x_e = \begin{cases} a'_e & \text{if } e \in T, \\ 1 - \max\{a'_u, a'_v\} & \text{if } e = (u, v) \in \text{MM}(G) \cap E^B. \end{cases} \quad (3)$$

Intuitively, once the subgraph  $E^A$  is given to Alice, we immediately commit her fractional matching  $\mathbf{a}'$  to the final fractional matching  $\mathbf{x}$ . Then, after the subgraph  $E^B$  of Bob is revealed, on any edge  $e = (u, v) \in \text{MM}(G) \cap E^B$ , we set  $x_e = 1 - \max\{a'_u, a'_v\}$  which is the largest possible fractional value that does not violate its endpoints' fractional matching constraints due to  $\mathbf{a}'$ .

In what follows, for any choice of  $E^A$ , we lower-bound the ratio  $\mathbf{E}[\|\mathbf{x}\| \mid E^A]$  to  $\mathbf{E}[\mu(G) \mid E^A]$  which implies the approximation ratio of our protocol. We emphasize that  $\mathbf{x}$  is only constructed for the analysis and in the protocol, Bob simply returns a maximum matching of  $T \cup E^B$ .

Consider a maximum matching edge  $uv$  which belongs to the input of Bob, i.e.  $uv \in \text{MM}(G) \cap E^B$  and suppose that  $a'_v > a'_u$ . Observe that in  $\mathbf{x}$ , we set  $x_{uv} = 1 - \max\{a'_u, a'_v\} = 1 - a'_v$ . In this case, we say that vertex  $v$  is *responsible* for edge  $uv$ . Based on this, we define<sup>2</sup>:

$$b_v := \Pr[\exists uv \in \text{MM}(G) \cap E^B \text{ such that } a'_v > a'_u \mid E^A], \quad (4)$$

i.e.,  $b_v$  is the probability that  $v$  is responsible for some edge. We first bound the size of  $\text{MM}(G)$  based on the values  $a_v$  and  $b_v$ .

▷ **Claim 4.**  $\mathbf{E}[\mu(G) \mid E^A] = \sum_v \frac{1}{2} a_v + b_v$ .

*Proof.* We claim that,

- (i)  $\mathbf{E}[\|\text{MM}(G) \cap E^A\| \mid E^A] = \frac{1}{2} \sum_v a_v$ : by the definition of  $a_v$  in Eq (2) and the fact that the number of vertices matched in any matching is twice the size of the matching;
- (ii)  $\mathbf{E}[\|\text{MM}(G) \cap E^B\| \mid E^A] = \sum_v b_v$ : since each responsible vertex has an edge in  $\text{MM}(G) \cap E^B$  and for each such edge, exactly one of its neighbors is responsible.

The claim now follows by adding up the two equations above.  $\triangleleft$

<sup>2</sup> In case of ties, we break ties arbitrarily so that only one vertex is responsible for an edge.

We now also bound the size of  $\mathbf{x}$  based on  $a_v$  and  $b_v$  values.

▷ **Claim 5.** For any vertex  $v$ , define  $g_v := \frac{1}{2}a_v + (1 - a_v)b_v$ . Then,  $\mathbf{E}[|\mathbf{x}| \mid E^A] = \sum_v g_v$ .

*Proof.* By definition,

$$\sum_v g_v = \sum_v \left( \frac{1}{2}a_v + (1 - a_v)b_v \right) = |\mathbf{a}| + \sum_v (1 - a_v)b_v.$$

The first term  $|\mathbf{a}|$  in the sum corresponds to the part of fractional matching  $\mathbf{x}$  constructed on the edges  $T$  sent by Alice, using the fractional matching  $\mathbf{a}'$ , where we have  $|\mathbf{a}'| = |\mathbf{a}|$  by Lemma 2.

It thus remains to prove that contribution of  $\mathbf{x}$  on the remaining edges (i.e. those given to Bob in  $\text{MM}(G) \cap E^B$ ), has expected size  $\sum_v (1 - a_v)b_v$ . This follows from the fact that each vertex  $v$  is responsible for some edge  $uv \in \text{MM}(G) \cap E^B$  with probability  $b_v$  by Eq (4), and that when this happens, we set  $x_{uv} = 1 - a'_v = 1 - a_v$  (as  $a'_v = a_v$  for all  $v$  by Lemma 2). Noting that exactly one of the endpoints of each edge  $e \in \text{MM}(G) \cap E^B$  is responsible for it, we get that  $\mathbf{x}$  on the set of edges given to Bob has expected size exactly  $\sum_v (1 - a_v)b_v$ , completing the proof. ◁

Claims 4 and 5 imply that the approximation factor of Algorithm 1 is

$$\frac{\mathbf{E}[|\mathbf{x}| \mid E^A]}{\mathbf{E}[\mu(G) \mid E^A]} = \frac{\sum_v g_v}{\sum_v \frac{1}{2}a_v + b_v}. \quad (5)$$

To lower bound this ratio, we use Fact 6 below.<sup>3</sup>

► **Fact 6.** For all  $a, b \geq 0$  satisfying  $a + b \leq 1$ , it holds that  $\frac{0.5a + (1-a)b}{0.5a + b} \geq 4\sqrt{2} - 5$ .

Now to use Fact 6 to lower bound the approximation factor, first recall that for each vertex  $v$ , by the definition of  $a_v$  and  $b_v$  in Eq (2) and (4), we have,

$$\begin{aligned} a_v + b_v &\leq \Pr[v \text{ is matched in } \text{MM}(G) \cap E^A \mid E^A] + \Pr[v \text{ is matched in } \text{MM}(G) \cap E^B \mid E^A] \\ &= \Pr[v \text{ is matched in } \text{MM}(G) \mid E^A] \leq 1. \end{aligned}$$

Thus, we can apply Fact 6 and get that for each vertex  $v$ ,  $\frac{g_v}{0.5a_v + b_v} = \frac{0.5a_v + (1-a_v)b_v}{0.5a_v + b_v} \geq 4\sqrt{2} - 5$ . This implies that

$$\frac{\mathbf{E}[|\mathbf{x}| \mid E^A]}{\mathbf{E}[\mu(G) \mid E^A]} \stackrel{(5)}{=} \frac{\sum_v g_v}{\sum_v \frac{1}{2}a_v + b_v} \geq \frac{\sum_v (4\sqrt{2} - 5)(\frac{1}{2}a_v + b_v)}{\sum_v \frac{1}{2}a_v + b_v} = 4\sqrt{2} - 5,$$

which proves Proposition 3 that Algorithm 1 achieves a  $(4\sqrt{2} - 5)$ -approximation.

► **Remark 7.** There are distributions for which the inequality above is actually equality. That is, we have  $\mathbf{E}[|\mathbf{x}| \mid E^A] = (4\sqrt{2} - 5)\mathbf{E}[\mu(G) \mid E^A]$ . Therefore, this analysis based on the construction of fractional matching  $\mathbf{x}$  cannot show an approximation factor better than  $(4\sqrt{2} - 5)$  for this protocol.

That being said, by “scaling” the fractional matching  $\mathbf{a}$  of Alice before sparsifying it, one can in fact achieve a  $(2/3)$ -approximation which is optimal for adversarial partitions with  $O(n)$  communication [25]. We use this scaling idea in our protocol in Section 4.

<sup>3</sup> Mathematica can verify Fact 6; see e.g., this page on WolframAlpha.

## 4 A 0.7167-Approximation Under Random Partitions

In this section, we show that a properly “scaled” variant of our distribution-dependent sparsifier of Section 3 – formalized as Algorithm 2 – achieves a significantly better approximation factor of 0.7167 in expectation, under a *random* partitioning of the edges between the players.

► **Theorem 8.** *There is a deterministic one-way protocol that given any arbitrary but known distribution  $\mathcal{G}$  of input graphs, and a graph  $G$  sampled from  $\mathcal{G}$  partitioned randomly between Alice and Bob, outputs a matching  $M(G)$  in  $G$  such that  $\mathbf{E} |M(G)| \geq 0.7167 \cdot \mathbf{E}[\mu(G)]$ . The protocol requires communicating at most  $n - 1$  edges from Alice to Bob.*

### 4.1 The Protocol

Recall from our Algorithm 1 in Section 3 that Alice, given her subgraph  $E^A$ , first defines a fractional matching  $\mathbf{a}$  on  $E^A$  where for each edge  $e \in E^A$ ,  $a_e = \Pr_{G \sim \mathcal{G}}[e \in \text{MM}(G) \mid E^A]$ , and then applies cycle canceling on  $\mathbf{a}$  and sends the support of the resulting fractional matching  $\mathbf{a}'$  to Bob. Our protocol in this section is very similar, except that instead of applying cycle-canceling on  $\mathbf{a}$ , we first “scale”  $\mathbf{a}$  to obtain another fractional matching  $\mathbf{z}$  and then send the support of cycle-canceled version  $\mathbf{z}'$  of  $\mathbf{z}$  to Bob. To be more precise about what we mean by scaling  $\mathbf{a}$ , let us define:

$$h(x, y) := \min \left\{ \frac{3}{2}, \frac{1}{x}, \frac{1}{y} \right\}. \quad (6)$$

Now for each edge  $e = (u, v) \in E^A$  we define

$$z_e := h(a_v, a_u) \cdot a_e. \quad (7)$$

Noting that  $\mathbf{a}$  is a fractional matching, we get that  $a_v \leq 1$ ,  $a_u \leq 1$ , which implies  $h(a_u, a_v) \geq 1$  and thus  $z_e \geq a_e$ . This means that indeed  $\mathbf{z} = \{z_e\}_{e \in E^A}$  is entry-wise larger than  $\mathbf{a}$ . But can this scaling violate fractional matching constraints, i.e., for some  $v$ ,  $z_v := \sum_{e \ni v} z_e > 1$ ? As a simple consequence of our definition of function  $h$ , it turns out that indeed  $\mathbf{z}$  is still a fractional matching.

► **Observation 9.** *Let  $\mathbf{z}$  be obtained as above, then  $\mathbf{z}$  is a fractional matching of  $E^A$ .*

**Proof.** It is clear that  $\mathbf{z} \geq 0$  since  $z_e \geq a_e \geq 0$  for each edge  $e$ . To see why  $z_v \leq 1$  for all  $v$ , observe that for each edge  $e = (u, v)$ ,  $z_e = h(a_u, a_v)a_e \leq \frac{1}{a_v}a_e$ ; hence  $z_v \leq \frac{1}{a_v} \sum_{e \ni v} a_e = a_v/a_v = 1$ . ◀

Note that the proof of Observation 9 only uses  $h(x, y) \leq \min\{\frac{1}{x}, \frac{1}{y}\}$ . The reason that we defined  $h$  to be  $\min\{\frac{3}{2}, \frac{1}{x}, \frac{1}{y}\}$  will be apparent later when analyzing the approximation.

Our scaled protocol can thus be formalized as follows.

Since the support of  $\mathbf{z}'$  has  $n - 1$  edges, Algorithm 2 only requires communicating  $n - 1$  edges. It thus only remains to analyze its approximation ratio.

### 4.2 The Analysis of Algorithm 2

As in Section 3, to analyze the size of matching  $\text{MM}(T \cup E^B)$  reported by Bob, we construct a large fractional matching  $\mathbf{x}$  on  $T \cup E^B$  and then use the fact that the maximum matching of this graph is at least as large as any fractional matching on it. Our construction of this fractional matching  $\mathbf{x}$  is also in fact the same as our construction in Section 3 with the

■ **Algorithm 2** A scaled distribution-dependent sparsifier protocol.

- 
- (i) Given edges  $E^A$  as input to Alice, she computes the vector  $\mathbf{a} = \{a_e\}_{e \in E^A}$  using Eq (1).
  - (ii) Alice then constructs  $\mathbf{z} = \{z_e\}_{e \in E^A}$  using Eq (7); by Observation 9  $\mathbf{z}$  is a valid fractional matching of  $E^A$ .
  - (iii) Alice obtains a fractional matching  $\mathbf{z}'$  by running cycle canceling on  $\mathbf{z}$  (Lemma 2) and then sends the edges  $T$  in the support of  $\mathbf{z}'$  to Bob.
  - (iv) Bob, given message  $T$  from Alice and input  $E^B$ , returns a maximum matching of  $T \cup E^B$ .
- 

difference that we first commit the sparsified version  $\mathbf{z}'$  of the *scaled* fractional matching  $\mathbf{z}$  to  $\mathbf{x}$ . More formally, we have:

$$x_e := \begin{cases} z'_e & \text{if } e \in T, \\ 1 - \max\{z'_u, z'_v\} & \text{if } e = (u, v) \in \text{MM}(G) \cap E^B. \end{cases}$$

To analyze the size of  $\mathbf{x}$ , we need a few definitions. Definition 11 below for  $b_v$  is equivalent to the definition of  $b_v$  in Section 3, but instead of vector  $\mathbf{a}$ , for each edge  $e \in \text{MM}(G) \cap E^B$  the vertex with higher  $\mathbf{z}$  is made responsible. To be more formal and to avoid ties (for pairs of vertices with  $z_u = z_v$ ) we first define an ordering over the vertices in Definition 10 below and then define  $b_v$ .

► **Definition 10.** *Based on fractional matching  $\mathbf{z}$ , we define a total ordering over the vertex set  $V$  as follows. For any pair of vertices  $u$  and  $v$  with  $z_u \neq z_v$ , we say  $v \succ u$  if  $z_v > z_u$ . For pairs  $u, v$  with  $z_u = z_v$  we break the tie arbitrarily; say  $v \succ u$  if the ID of  $v$  is larger than  $u$ .*

► **Definition 11.** *For each vertex  $v$ , define  $b_v := \Pr[\exists u : uv \in \text{MM}(G) \cap E^B \text{ and } v \succ u \mid E^A]$ .*

Based on this definition of  $b_v$  and similar to Claim 4 of Section 3, we get that:

▷ **Claim 12.**  $\mathbf{E}[\mu(G) \mid E^A] = \sum_v \frac{1}{2}a_v + b_v$ .

Proof. Follows from the same argument in the proof of Claim 4. ◁

The next step is where we start to substantially deviate from the analysis of Section 3. We first give an informal explanation of why a different approach might be needed to analyze Algorithm 2 (the reader may choose to skip this informal explanation and jump to the new analysis after). After that, we formally describe our actual analysis which is based on a notion of “contribution sharing”.

**Informal explanation: why a different analysis is needed.** In Claim 5 of Section 3 we showed  $\mathbf{E}[|\mathbf{x}| \mid E^A] = \sum_v \frac{1}{2}a_v + (1 - a_v)b_v$ , implying intuitively that each vertex  $v$  contributes an expected size of  $g_v = \frac{1}{2}a_v + (1 - a_v)b_v$  to  $\mathbf{x}$ . We then proved the claimed approximation ratio by comparing this contribution  $g_v$  of each vertex  $v$  with  $\frac{1}{2}a_v + b_v$ , which can be thought of as the portion of the benchmark  $\mathbf{E}[\mu(G) \mid E^A] = \sum_v \frac{1}{2}a_v + b_v$  charged to vertex  $v$ .

A straightforward generalization of this framework for analyzing Algorithm 2 would be as follows: It is not hard to see that  $\mathbf{E}[|\mathbf{x}| \mid E^A] = \sum_v \frac{1}{2}z_v + (1 - z_v)b_v$  (the proof follows from a similar argument to Claim 5); thus it suffices to show that the contribution  $g_v = \frac{1}{2}z_v + (1 - z_v)b_v$  of each vertex is large compared to the portion  $\frac{1}{2}a_v + b_v$  of the optimum charged to this vertex. The problem with this type of argument, however, is that it is hard

to measure exactly how the scaling part of Algorithm 2 is useful. In particular, take a vertex  $v$  and suppose that for every neighbor  $u$  of  $v$  in  $E^A$ , it holds that  $a_u = 1$ . This way, for each edge  $e = (v, u) \in E^A$  we would have  $h(a_v, a_u) = 1$  and thus  $z_e = h(a_v, a_u)a_e = a_e$ . That is, the edges of vertex  $v$  are in fact not scaled at all. This would mean that  $z_v = a_v$  and thus  $g_v = \frac{1}{2}z_v + (1 - z_v)b_v = \frac{1}{2}a_v + (1 - a_v)b_v$ , which is not any different from the guarantee we would get for vertex  $v$  without any scaling.

The issue discussed above intuitively implies that in defining the contribution  $g_v$  of each vertex, not only we should take into account the values of  $z_v$  and  $b_v$ , but that in fact the values of  $a_u$  for neighbors  $u$  of  $v$  are also important. Motivated by this, we define  $g_v$  such that intuitively we share the contribution of each vertex with its neighbors. That is, each vertex passes a portion of its contribution to its neighbors, and as a result also receives a portion of the contribution of them. This dynamic allows us to argue that scaling does indeed help our protocol.

**The formal analysis via “contribution sharing”.** Consider function  $\ell(x)$  defined as

$$\ell(x) := \max\left\{\frac{x - 2/3}{6}, 0\right\}. \quad (8)$$

This function  $\ell$  is the sharing function and the reason that is defined this way will be apparent later in the analysis. For each vertex  $v$ , define

$$g_v := \frac{1}{2}z_v + (1 - z_v)b_v - \ell(a_v)a_v + \sum_u \ell(a_u)a_{uv}. \quad (9)$$

The following lemma whose proof is deferred to the full version, states that the expected size of fractional matching  $\mathbf{x}$  conditioned on  $E^A$ , is equal to  $\sum g_v$ . Therefore, intuitively, we can think of  $g_v$  as the amount that vertex  $v$  contributes to the size of  $\mathbf{x}$  in expectation.<sup>4</sup>

► **Lemma 13.**  $\mathbf{E}[|\mathbf{x}| \mid E^A] = \sum_v g_v$ .

To show that  $\mathbf{x}$  tends to be large, Lemma 13 above implies that it suffices to show  $g_v$  is large. The next definition and the lemma that follows it are used for this purpose.

► **Definition 14.** Let  $a, b \in [0, 1]$ . We define:

$$f(a, b, x) := b + \left(\left(\frac{1}{2} - b\right)h(a, x) + \ell(x) - \ell(a)\right) \cdot a \quad \text{and} \quad f(a, b) := \min_{x \in [0, 1]} f(a, b, x),$$

► **Lemma 15.** For any vertex  $v$ , it holds that  $g_v \geq f(a_v, b_v)$ .

The proof of Lemma 15 is also deferred to the full version due to space constraints. This lower bound is particularly useful since  $f(a_v, b_v)$  only depends on the values of  $a_v$  and  $b_v$ , whereas  $g_v$  also depends on  $a_u$  of neighbors  $u$  of  $v$ . Having this, if we in fact prove that  $f(a_v, b_v) \geq \alpha(\frac{1}{2}a_v + b_v)$  for all  $v$ , then we get that Algorithm 2 achieves an approximation ratio of at least  $\alpha$  since

$$\frac{\mathbf{E}[|\mathbf{x}| \mid E^A]}{\mathbf{E}[\mu(G) \mid E^A]} \stackrel{\text{Claim 12, Lemma 13}}{=} \frac{\sum_v g_v}{\sum_v \frac{1}{2}a_v + b_v} \stackrel{\text{Lemma 15}}{\geq} \frac{\sum_v f(a_v, b_v)}{\sum_v \frac{1}{2}a_v + b_v} \geq \frac{\sum_v \alpha(\frac{1}{2}a_v + b_v)}{\sum_v \frac{1}{2}a_v + b_v} \geq \alpha.$$

<sup>4</sup> We note that in fact Lemma 13 holds for *any* possible definition of function  $\ell$ . That is, in the proof of Lemma 13, we do not use the value of  $\ell(x)$  defined in Eq (8).

## 48:12 On the Robust Communication Complexity of Bipartite Matching

Note that up to this point of the analysis, we have not used the fact that the edges are partitioned randomly between Alice and Bob. Therefore, in light of the lower bound of [25] which proves achieving a better-than-(2/3)-approximation for requires  $n^{1+\Omega(1/\log \log n)}$  communication, we get that Algorithm 2 cannot achieve a better-than-(2/3)-approximation under an adversarial partitioning of the input graph. As a result, there should be a choice of  $a_v, b_v$  such that  $f(a_v, b_v) \leq \frac{2}{3}(\frac{1}{2}a_v + b_v)$ . Indeed one can confirm that for  $a_v = \frac{1}{2}$  and  $b_v = \frac{1}{2}$ ,  $f(\frac{1}{2}, \frac{1}{2}) = f(\frac{1}{2}, \frac{1}{2}, 0) = 0.5 = \frac{2}{3}(\frac{1}{2}a_v + b_v)$ .

**How random partitioning helps.** Our main insight in bypassing the  $2/3$ -barrier highlighted above is that for an average vertex  $v$ , it cannot always occur that  $a_v = b_v = \frac{1}{2}$  under a random partitioning. Formally, for a vertex  $u$  chosen uniformly at random from  $V$ ,

$$\mathbf{E}_{u \sim V}[a_u] = \frac{1}{n} \sum_v \mathbf{E}[a_v] = \frac{2}{n} \mathbf{E}[\mathbf{a}] = \frac{2}{n} \mathbf{E}[\text{MM}(G) \cap E^A] \stackrel{(\star)}{=} \frac{2}{n} \cdot \frac{\mathbf{E}[\mu(G)]}{2} = \frac{1}{n} \mathbf{E}[\mu(G)],$$

$$\mathbf{E}_{u \sim V}[b_u] = \frac{1}{n} \sum_v \mathbf{E}[b_v] \stackrel{\text{Definition 11}}{=} \frac{1}{n} \mathbf{E}[\text{MM}(G) \cap E^B] \stackrel{(\star)}{=} \frac{1}{n} \cdot \frac{\mathbf{E}[\mu(G)]}{2} = \frac{1}{2n} \mathbf{E}[\mu(G)],$$

where the equalities marked with  $(\star)$  use the fact that each edge is given to Alice/Bob with probability  $1/2$ . This implies that  $\mathbf{E}[a_u] = 2\mathbf{E}[b_u]$  which formalizes our earlier claim that  $a_u = b_u = \frac{1}{2}$  cannot always happen for an average vertex  $u$ .

To turn the intuition above into an actual analysis of the approximation factor for Algorithm 2 under a random partitioning, we write a factor revealing program formalized as Program 1. We prove that the solution to Program 1 is indeed a lower bound for the approximation ratio of Algorithm 2. The proof can be found in the full version of the paper and is based on our intuition above regarding the relation between  $\mathbf{E}[a_u]$  and  $\mathbf{E}[b_u]$  for a vertex  $u$  chosen at random.

We note that for generality Program 1 is written with a parameter  $p$  which is  $1/2$  (more generally  $p$  can be thought of as the probability that each edge is given to Alice).

► **Lemma 16.** *Let  $r$  be the solution of Program 1 below for  $p = \frac{1}{2}$ ; then  $\mathbf{E}[\mathbf{x}] \geq r \cdot \mathbf{E}[\mu(G)]$ .*

► **Program 1.** A factor revealing (non-linear) program for the performance of Algorithm 2.

$$\begin{aligned} & \text{find} && \text{a distribution } \mathcal{S} \text{ for } (a, b) \text{ over } [0, 1] \times [0, 1] \\ & \text{minimizing} && \mathbf{E}_{\mathcal{S}}[f(a, b)] / \mathbf{E}_{\mathcal{S}}[\frac{1}{2}a + b] \\ & \text{subject to} && \mathbf{E}_{\mathcal{S}}[a] = \frac{2p}{1-p} \mathbf{E}_{\mathcal{S}}[b] \\ & && \Pr_{\mathcal{S}}[a + b \leq 1] = 1 \\ & && \Pr_{\mathcal{S}}[a, b \geq 0] = 1 \end{aligned}$$

In order to find the solution of Program 1, we simplify it and then write a factor revealing LP, showing that  $r \geq 0.7167$  which implies the same bound on the approximation ratio of Algorithm 2. Due to space limits, we omit the details of this step, referring interested readers to the full version of the paper.

## 5 Lifting Knowledge of Distribution via Minimax Theorems

As discussed before, our protocol of Section 4 achieves its claimed approximation guarantee assuming that the input graph  $G$  is drawn from some distribution  $\mathcal{G}$  that is known to the algorithm a priori. In the standard communication complexity model, however, we do not have

access to distribution  $\mathcal{G}$  and the algorithm should work against every possible input graph. In this section, we show how one can use minimax theorems to lift the assumption on knowledge of the distribution  $\mathcal{G}$  in our protocols, without incurring any loss to the approximation guarantee. The following theorem formalizes our main result in the Introduction.

► **Theorem 17.** *There is a randomized one-way protocol that given any arbitrary input graph  $G$  partitioned randomly between Alice and Bob, outputs a matching  $M(G)$  in  $G$  such that  $\mathbf{E} |M(G)| \geq 0.716 \cdot \mu(G)$ . The protocol requires  $O(n)$  communication from Alice to Bob.*

Consider a *deterministic* protocol  $\mathcal{A}$  and let us use  $\mathcal{A}(G^A, G^B)$  to denote the size of the matching returned by the protocol  $\mathcal{A}$  when Alice receives subgraph  $G^A$  and Bob receives subgraph  $G^B$ . Recall that in our discussion of Section 4, we say protocol  $\mathcal{A}$  obtains an  $\alpha$ -approximation if

$$\mathbf{E}_{G \sim \mathcal{G}, (G^A, G^B)} [\mathcal{A}(G^A, G^B)] \geq \alpha \cdot \mathbf{E}_{G \sim \mathcal{G}} [\mu(G)], \quad (10)$$

where here and throughout this section, by subscript  $(G^A, G^B)$  we mean the random process of partitioning the edges of  $G$  into  $G^A$  and  $G^B$  independently and uniformly at random. This guarantee is inherently different from that of Theorem 17. In the following, we first show how one can remedy this part and then give the argument for lifting the assumption on the knowledge of  $\mathcal{G}$ .

**Step 1: Getting an Instance-Wise Approximation Guarantee.** In order to remove the assumption on the knowledge of the distribution  $\mathcal{G}$  we first show that we can slightly modify our protocols to get an *instance-wise* expected approximation guarantee.

► **Lemma 18.** *Suppose that given any input distribution  $\mathcal{G}$  on  $n$ -vertex graphs, there is an  $\alpha$ -approximate maximum matching protocol  $\mathcal{A}$  (i.e.,  $\mathcal{A}$  satisfies Eq (10)) with communication cost  $O(n)$ . For any input distribution  $\mathcal{G}$  and any parameter  $\varepsilon > 0$ , there is another deterministic protocol  $\mathcal{A}'$  with communication cost  $O(\frac{n}{\varepsilon})$  such that*

$$\mathbf{E}_{G \sim \mathcal{G}, (G^A, G^B)} [\mathcal{A}'(G^A, G^B) / \mu(G)] \geq (1 - \varepsilon - o(1)) \cdot \alpha.$$

Due to space constraints, we omit the proof of Lemma 18. However, we note that it is easy to prove if one allows  $O(n \log n / \varepsilon)$  communication instead of  $O(n / \varepsilon)$ . To see this, note that if distribution  $\mathcal{G}$  was such that  $\mu(G)$  was the same in all outcomes of  $G$ , then Lemma 18 would be trivial. Therefore, one can make  $O(\log n / \varepsilon)$  geometrically increasing guesses for the value of  $\mu(G)$ , condition on each separately, and run protocol  $\mathcal{A}$  on them in parallel. In the full version of the paper, we show how one can avoid the extra  $O(\log n)$  factor and achieve this with just  $O(n / \varepsilon)$  communication.

**Step 2: Using Yao's Minimax.** Now that we have an instance-wise approximation guarantee using Lemma 18, we show how one can use Yao's minimax principle [41] to give a single randomized protocol that works against all possible input graphs without knowledge of the distribution  $\mathcal{G}$  from which the graph is drawn. The discussion of this section is essentially a straightforward extension of Yao's minimax principle [41] (see, e.g., [38, Section 2.2] or [36]) for the random partition model. The proof of this proposition is almost identical to that of the original Yao's minimax principle and we claim no novelty for this proof.

► **Proposition 19.** *Let  $C$  and  $\alpha$  be two parameters. Suppose for every distribution  $\mathcal{G}$  on  $n$ -vertex graphs, there exists a deterministic protocol  $\mathcal{A}_{\mathcal{G}}$  with communication cost  $C$  with an instance-wise approximation guarantee  $\mathbf{E}_{G \sim \mathcal{G}, (G^A, G^B)} [\mathcal{A}_{\mathcal{G}}(G^A, G^B) / \mu(G)] \geq \alpha$  where here*

## 48:14 On the Robust Communication Complexity of Bipartite Matching

$(G^A, G^B)$  is a random partitioning of  $G$ . Then, there exists a randomized protocol  $\mathcal{A}_*$  with communication cost  $C$  such that for every graph  $G$ ,  $\mathbf{E}_{\mathcal{A}_*, (G^A, G^B) \sim G}[\mathcal{A}_*(G^A, G^B)] \geq \alpha \mu(G)$ , where the expectation here is taken over both the randomness of the protocol and the random partitioning of the edge-set of  $G$  between the players.

**Proof.** Consider a game between two players called the Input player and the Algorithm player. The set of strategies of the Input player are all bipartite graphs on  $n$  vertices, denoted by  $\mathbb{G}(n)$ , and the set of strategies of the Algorithm player are all deterministic one-way protocols with communication cost  $C$ , denoted by  $\mathbb{P}(C)$ ; for fixed  $n$  and  $C$ , both sets are finite.

For any graph  $G \in \mathbb{G}(n)$  as a strategy of the Input player and deterministic protocol  $\mathcal{A} \in \mathbb{P}(C)$  as the strategy of the Algorithm player, we define:

$$\text{val}(G, \mathcal{A}) := \mathbf{E}_{(G^A, G^B) \sim G}[\mathcal{A}(G^A, G^B)/\mu(G)].$$

On a choice of (pure) strategies  $G$  and  $\mathcal{A}$  by the players, we define the payoff of the Algorithm player as  $\text{val}(G, \mathcal{A})$  and for the Input player as  $-\text{val}(G, \mathcal{A})$ . Alternatively, the Algorithm player would like to maximize  $\text{val}(G, \mathcal{A})$  (by choosing  $\mathcal{A}$ ), while the Input player tries to minimize it (by choosing  $G$ ). Thus, this is a zero-sum game.

Let  $\Delta_G$  denote the set of all distributions on strategies (graphs) of the Input player and  $\Delta_P$  denote the set of all distributions on strategies (deterministic protocols) of the Algorithm player. This way,  $\Delta_G$  and  $\Delta_P$  denote the set of all mixed strategies for the Input player and Algorithm player, respectively. Considering this is a zero-sum game, Von Neumann's Minimax Theorem asserts that,

$$\min_{\mathcal{G} \in \Delta(G)} \max_{\mathcal{A} \in \mathbb{P}(C)} \mathbf{E}_{G \sim \mathcal{G}}[\text{val}(G, \mathcal{A})] = \max_{\mathcal{A}_R \in \Delta_P} \min_{G \in \mathbb{G}(n)} \mathbf{E}_{\mathcal{A} \sim \mathcal{A}_R}[\text{val}(G, \mathcal{A})].$$

Replacing the value of  $\text{val}(G, \mathcal{A})$  with its definition on both sides, we have

$$\min_{\mathcal{G} \in \Delta(G)} \max_{\mathcal{A} \in \mathbb{P}(C)} \mathbf{E}_{G, (G^A, G^B) \sim G} \left[ \frac{\mathcal{A}(G^A, G^B)}{\mu(G)} \right] = \max_{\mathcal{A}_R \in \Delta_P} \min_{G \in \mathbb{G}(n)} \mathbf{E}_{\mathcal{A} \sim \mathcal{A}_R, (G^A, G^B)} \left[ \frac{\mathcal{A}(G^A, G^B)}{\mu(G)} \right]. \quad (11)$$

The LHS in Eq (11) corresponds to picking any possible distribution on inputs and then running the “best” deterministic protocol on this distribution and measuring the instance-wise expected approximation ratio of the protocol. Thus, by the statement of the proposition, the LHS is  $\geq \alpha$ .

The RHS in Eq (11) corresponds to picking any distribution over deterministic protocols, i.e., a (public-coin) randomized protocol, and then running this protocol on the “worst” input graph and measure the expected ratio of the protocol. By the lower bound on LHS and Eq (11), this is at least  $\alpha$ , which means that there exists a randomized protocol  $\mathcal{A}_*$  with communication cost  $C$  (the arg max of RHS in Eq (11)) that achieves an  $\alpha$ -approximation in expectation for every input graph partitioned randomly between Alice and Bob. This concludes the proof.  $\blacktriangleleft$

Theorem 17 now follows immediately from Theorem 8, Lemma 18 and Proposition 19.

## Abstract

We consider the problem of finding an approximate solution to  $\ell_1$  regression while only observing a small number of labels. Given an  $n \times d$  unlabeled data matrix  $X$ , we must choose a small set of  $m \ll n$  rows to observe the labels of, then output an estimate  $\hat{\beta}$  whose error on the original problem is within a  $1 + \varepsilon$  factor of optimal. We show that sampling from  $X$  according to its Lewis weights and outputting the empirical minimizer succeeds with probability  $1 - \delta$  for  $m > O(\frac{1}{\varepsilon^2} d \log \frac{d}{\varepsilon \delta})$ . This is analogous to the performance of sampling according to leverage scores for  $\ell_2$  regression, but with exponentially better dependence on  $\delta$ . We also give a corresponding lower bound of  $\Omega(\frac{d}{\varepsilon^2} + (d + \frac{1}{\varepsilon^2}) \log \frac{1}{\delta})$ .

## 1 Introduction

The standard linear regression problem is, given a data matrix  $X \in \mathbb{R}^{n \times d}$  and corresponding values  $y \in \mathbb{R}^n$ , to find a vector  $\beta \in \mathbb{R}^d$  minimizing  $\|X\beta - y\|_p$ . Least squares regression ( $p = 2$ ) is the most common, but least absolute deviation regression ( $p = 1$ ) is sometimes preferred for its robustness to outliers and heavy-tailed noise. In this paper we focus on  $\ell_1$  regression:

$$\beta^* = \arg \min_{\beta \in \mathbb{R}^d} \|X\beta - y\|_1 \tag{1}$$

But what happens if the unlabeled data  $X$  is cheap but the labels  $y$  are expensive? Can we choose a small subset of indices, only observe the corresponding labels, and still recover a good estimate  $\hat{\beta}$  of the true solution? We would like an algorithm that works with probability  $1 - \delta$  for any input  $(X, y)$ ; this necessitates that our choice of indices be randomized, so the adversary cannot concentrate the noise on them. Formally we define the problem as follows:

► **Problem 1** (Active L1 regression). *There is a known matrix  $X \in \mathbb{R}^{n \times d}$  and a fixed unknown vector  $y$ . A learner interacts with the instance by querying rows indexed  $\{i_k\}_{k \in [m]}$  adaptively, and is shown labels  $\{y_{i_k}\}_{k \in [m]}$  corresponding to the rows queried. The learner must return  $\hat{\beta}$  such that with probability  $1 - \delta$  over the learner’s randomness,*

$$\|X\hat{\beta} - y\|_1 \leq (1 + \varepsilon) \min_{\beta} \|X\beta - y\|_1. \quad (2)$$

Some rows of  $X$  may be more important than others. For example, if one row is orthogonal to all the others, we need to query it to have any knowledge of the corresponding  $y$ ; but if many rows are in the same direction it should suffice to label a few of them to predict the rest.

A natural approach to this problem is to attach some notion of “importance”  $p_1, \dots, p_n$  to each row of  $X$ , then sample rows proportional to  $p_i$ . We can represent this as a “sampling-and-reweighting” sketch  $S \in \mathbb{R}^{m \times n}$ , where each row is  $\frac{1}{p_i} e_i$  with probability proportional to  $p_i$ . This reweighting is such that  $\mathbb{E}_S[\|Sv\|_1] \propto \|v\|_1$  for any vector  $v$ . By querying  $m$  rows we can observe  $Sy$ , and so can output the empirical risk minimizer (ERM)

$$\hat{\beta} := \arg \min \|SX\beta - Sy\|_1. \quad (3)$$

For fixed  $\beta$ ,  $\mathbb{E}_S \|SX\beta - Sy\|_1 \propto \|X\beta - y\|_1$ . The hope is that, if the  $p_i$  are chosen carefully, the ERM  $\hat{\beta}$  will satisfy (2) with relatively few samples. Our main result is that this is true if the  $p_i$  are drawn according to the  $\ell_1$  Lewis weights:

► **Theorem 1** (Informal). *Problem 1 can be solved with  $m = O(\frac{1}{\varepsilon^2} d \log \frac{d}{\varepsilon \delta})$  queries. For constant  $\delta = \Theta(1)$ ,  $m = O(\frac{1}{\varepsilon^2} d \log d)$  suffices.*

Note that, while the model allows for adaptive queries, this algorithm is nonadaptive.

We next show that our sample complexity is near-optimal by demonstrating the following lower bound on the number of queries needed by any algorithm to obtain an accurate estimate. Whether the multiplicative factor of  $\log d$  is necessary is an open question.

► **Theorem 2** (Informal). *Any algorithm satisfying Problem 1 must query  $\Omega(d \log \frac{1}{\delta} + \frac{d}{\varepsilon^2} + \frac{1}{\varepsilon^2} \log \frac{1}{\delta})$  rows on some instances  $(X, y)$ .*

For small  $\delta$ , the upper bound is the product of  $d$ ,  $\frac{1}{\varepsilon^2}$ , and  $\log(1/\delta)$  while the lower bound is the product of each pair.

## 1.1 Related Work

### If all the labels are known

LAD regression cannot be solved in closed form. It can be written as a linear program, but this is relatively slow to solve. One approach to speeding up LAD regression is “sketch-and-solve,” which replaces (1) with (3), which has fewer constraints and so can be solved faster. The key idea here is to acquire regression guarantees by ensuring that  $S$  is a *subspace embedding* for the column space of  $[X \ y]$ .

For a survey on techniques to do this, we direct the reader to [17],[13], [3]. In [17], the emphasis is on *oblivious* sketches – distributions which do not require knowledge of  $[X \ y]$ . On the other hand, [13], [3] discuss sketches that depend on  $[X \ y]$ . Most relevant to us [9], which shows that sampling-and-reweighting matrices  $S$  using Lewis weights of  $[X \ y]$  suffice; we give a simple proof of this in Remark 4. The problem is that *figuring out which labels are important* involves looking at all the labels.

### Active $\ell_2$ regression

Here we return to our setting, where only a subset of the labels is available to us. A number of works have studied this problem, including [6, 7, 8]. The  $\ell_2$  version of the problem was solved optimally in [2], where an algorithm was given using  $O(\frac{d}{\epsilon})$  queries to find  $\hat{\beta}$  satisfying  $\mathbb{E} \left[ \|X\hat{\beta} - y\|_2^2 \right] \leq (1 + \epsilon) \|X\beta^* - y\|_2^2$ . Independent, identical sampling using leverage scores achieves the same guarantee using  $O(d \log d + \frac{d}{\epsilon})$  queries. Note that these results for  $\ell_2$  ERM only work in expectation, while our results hold with high probability.

### Subspace embedding for $\ell_1$ norms

Subspace embeddings for the  $\ell_1$  norm have been studied in a long line of work including [15], [16], [12], [5], and [4], the most recent of which describes an iterative algorithm to approximate *Lewis weights*, which are the analogue of leverage scores for importance sampling preserving  $\ell_1$  norms. The [4] result shows that, for the same  $m = O(\frac{1}{\epsilon^2} d \log \frac{d}{\epsilon \delta})$  sample complexity as given in Theorem 11, a sampler sketch  $S$  based on the Lewis weights of  $X$  will have  $\|SX\beta\|_1 \approx_\epsilon \|X\beta\|_1$  for all  $\beta \in \mathbb{R}^d$ .

### Our approach

At a very high level the goal of this paper is to replace the  $\ell_2$  leverage score analysis of [2] (which looks at the sample complexity of  $\ell_2$  regression in setting of this paper) with the  $\ell_1$  Lewis weight analysis in [4] (which, among other results, demonstrates that i.i.d. importance sampling with Lewis weights results in a subspace embedding). However, the differences between  $\ell_1$  and  $\ell_2$  are significant enough that very little of the [2] proof approach remains.

Per [4], the Lewis weight sampling-and-embedding matrix  $S$  preserves  $\|X\beta\|_1$  for all  $\beta$ . The problem is that it *doesn't* preserve  $\|X\beta - y\|_1$ : if  $y$  has outliers, we have no idea where they are to sample them. In the  $\ell_2$  setting, this difficulty is addressed using the closed-form solution  $\beta^* = X^\dagger y$ , and the fact that the residual vector  $X\beta^* - y$  is orthogonal to the column space of  $X$ . If  $S$  is a subspace embedding it will preserve  $\|X\beta - X\beta^*\| \approx \|S(X\beta - X\beta^*)\|$ , while orthogonality of  $X\beta^* - y$  and  $X\beta^*$  ensures that  $\|S(X\tilde{\beta} - X\beta^*)\| \ll \|S(X\tilde{\beta} - y)\| \approx \|X\tilde{\beta} - y\|$  (here the last approximation is not because of embeddings but rather Markov's inequality). In the  $\ell_1$  setting, not only is  $\beta^*$  not expressible in closed form, but there can be many equally valid minimizers  $\beta^*$  that are far from each other. In Appendix A we show how this approach extends to the  $\ell_1$  setting to give a simple proof of Theorem 1 for a constant factor approximation (i.e.,  $\epsilon = O(1)$ ); but the existence of multiple  $\beta^*$  makes  $\epsilon < 1$  seem unobtainable by this approach.

Instead, we massage the [2] subspace embedding proof into the appropriate form, as we discuss in Section 3. While  $S$  doesn't preserve the total error  $\|X\beta - y\|_1$ , it does preserve *relative* error  $\|X\beta - y\|_1 - \|X\beta^* - y\|_1$ ; the effect of outliers is canceled out, so that this concentrates similarly well to  $\|X\beta - X\beta^*\|_1$ .

### Concurrent work

A very similar set of results appears concurrently and independently in [1]. Their main result is identical to ours, with a similar proof. They also extend the result to  $1 < p < 2$ , but with a significantly weaker  $m = \tilde{O}(d^2/\epsilon^2)$  bound. They do not have the  $\Omega(d \log \frac{1}{\delta})$  lower bound.

## 2 Preliminaries: Subspace Embeddings and Importance Sampling

A key idea used in our analysis is that of a  $\ell_1$  subspace embedding, which is a linear sketch of a matrix that preserves  $\ell_1$  norms within the column space of a matrix:

► **Definition 3** (Subspace Embeddings). *A subspace embedding for the column space of the matrix  $X \in \mathbb{R}^{n \times d}$  is a matrix  $S$  such that for all  $\beta \in \mathbb{R}^d$ ,*

$$\|SX\beta\| = (1 \pm \varepsilon)\|X\beta\|$$

► **Remark 4.** Consider the simpler setting in which we had access to all of  $y$ , but we still want to subsample rows to improve computational complexity. We can view the regression loss  $\|X\beta - y\|_1$  as the  $\ell_1$  norm of the point  $[X \ y] \begin{bmatrix} \beta \\ -1 \end{bmatrix}$  in the column space of  $[X \ y]$ . Indeed, suppose  $\beta^* = \arg \min \|X\beta - y\|_1$  as before and let  $\hat{\beta} = \arg \min \|SX\beta - Sy\|_1$ . Then,  $\hat{\beta}$  solves problem 1 because, for  $\varepsilon < \frac{1}{3}$ ,

$$\|X\hat{\beta} - y\|_1 \leq \frac{1}{1 - \varepsilon} \|SX\hat{\beta} - Sy\|_1 \leq \frac{1}{1 - \varepsilon} \|SX\beta^* - Sy\|_1 \leq \frac{1 + \varepsilon}{1 - \varepsilon} \|X\beta^* - y\|_1 \leq (1 + 4\varepsilon)\|X\beta^* - y\|_1.$$

One way to construct a subspace embedding is by sampling rows and rescaling them appropriately:

► **Definition 5** (Sampling and Reweighting with  $\{p_i\}_{i=1}^n$ ). *For any sequence  $\{p_i\}_{i=1}^n$ , let  $N = \sum_i p_i$ . Then, the sampling-and-reweighting distribution  $\mathcal{S}(\{p_i\}_{i=1}^n)$  over the set of matrices  $S \in \mathbb{R}^{N \times n}$  is such that each row of  $S$  is independently the  $i$ th standard basis vector with probability  $\frac{p_i}{N}$ , scaled by  $\frac{1}{p_i}$ . For any  $k \in [N]$ , let  $i_k$  denote the index such that  $S_{k, i_k} = \frac{1}{p_{i_k}}$ .*

When working in  $\ell_2$ , there is a natural choice for re-weighting: the leverage scores of the rows [17].

► **Definition 6** (Leverage Scores). *The leverage score of the  $i$ th row of a matrix  $X$ ,  $l_i(X)$  is defined as  $x_i^\top (X^\top X)^{-1} x_i$ .*

For  $\ell_1$  subspace embeddings, the analogous weights are the  $\ell_1$  Lewis weights, defined implicitly as the unique weights  $\{w_i(X)\}_{i=1}^n$  that satisfy  $w_i(X) = l_i(WX)$  where  $W$  is a diagonal matrix with  $i$ th diagonal entry  $\frac{1}{\sqrt{w_i(X)}}$ . We will drop the explicit dependence on  $X$  whenever it is clear from context.

► **Definition 7** (Lewis Weights). *The  $\ell_1$  Lewis weights of a matrix  $X$  are the unique weights  $\{w_i\}_{i=1}^n$  that satisfy  $w_i^2 = x_i^\top (\sum_{j=1}^n \frac{1}{w_j} x_j x_j^\top)^{-1} x_i$  for all  $i$ .*

Lewis weights are defined in general for general  $\ell_p$  norms, but we will only need the  $\ell_1$  Lewis weights. For basic properties of Lewis weights, we direct the reader to [4]. Using these definitions, we now state the main consequence of using Lewis weights. This result comes from a line of work on embeddings from subspaces of  $L_1[0, 1]$  to  $\ell_1^m$  such as [15], but is reproduced here similar to how it is presented in [4].

► **Theorem 8** ([4] Theorem 2.3). *Sampling at least  $O(\frac{d \log d}{\varepsilon^2})$  rows according to the  $\ell_1$  Lewis weights  $\{w_i\}_{i=1}^n$  of a matrix  $X \in \mathbb{R}^{n \times d}$  results in a subspace embedding for  $X$  with at least some constant probability. If at least  $O(\frac{d \log \frac{d}{\varepsilon \delta}}{\varepsilon^2})$  rows are sampled, then we have a subspace embedding with probability at least  $1 - \delta$ .*

## 2.1 Properties of Lewis Weights

We will need some properties of Lewis weights, particularly of how they change when the matrix  $X$  is modified.

► **Lemma 9** ([4] Lemma 5.5). *The  $\ell_1$  Lewis weights of a matrix do not increase when rows are added.*

► **Lemma 10.** *Let  $X \in \mathbb{R}^{n \times d}$ , and let  $X' \in \mathbb{R}^{kn \times d}$  be  $X$  stacked on itself  $k$  times, with each row scaled down by  $k$ . Then, each of the Lewis weights is reduced by a factor of  $k$ .*

### 3 Proof Overview

► **Theorem 11.** *Let  $X \in \mathbb{R}^{n \times d}$  have  $\ell_1$  Lewis weights  $\{w_i\}_{i \in [n]}$ , and let  $0 < \varepsilon, \delta < 1$ . Then, for any  $N$  that is at least  $O\left(\frac{d}{\varepsilon^2} \log \frac{d}{\varepsilon \delta}\right)$ , there is a sampling-and-reweighting distribution  $\mathcal{S}(\{p_i\}_{i=1}^n)$  satisfying  $\sum_i p_i = N$  such that for all  $y$ , if  $S \sim \mathcal{S}(\{p_i\}_{i=1}^n)$  and  $\hat{\beta} = \arg \min \|SX\beta - Sy\|_1$ , we have*

$$\|X\hat{\beta} - y\|_1 \leq (1 + \varepsilon) \min_{\beta} \|X\beta - y\|_1$$

with probability  $1 - \delta$ . If  $\delta = O(1)$  is some constant, then  $N$  at least  $O\left(\frac{1}{\varepsilon^2} d \log d\right)$  rows suffice.

#### Regression guarantees from column-space embeddings

As noted in Remark 4, it would suffice to show that  $\|SX\beta - Sy\|_1 \approx \|X\beta - y\|_1$  for all  $\beta$ . The problem is that this is impossible without knowing  $y$ : if one random entry of  $y$  is very large, we would need to sample it to estimate  $\|X\beta - y\|_1$  accurately. However, we don't actually need to estimate  $\|X\beta - y\|_1$ ; we just need to be able to distinguish values of  $\beta$  for which  $\|X\beta - y\|_1$  is far from  $\|X\beta^* - y\|_1$  from values for which it is close. That is, it would suffice to accurately

$$\text{estimate } \|X\hat{\beta} - y\|_1 - \|X\beta^* - y\|_1 \quad \text{with} \quad \|SX\hat{\beta} - Sy\|_1 - \|SX\beta^* - Sy\|_1 \quad (4)$$

for every possible  $\beta$ . In the above example where  $y$  has a single large outlier coordinate, sampling this coordinate or not will dramatically affect *both* terms, but will not affect the difference very much. As such, our key lemma, Lemma 28, states that  $\ell_1$  Lewis weight sampling achieves (4) with high probability. In particular, using at least  $m \geq O\left(\frac{d}{\varepsilon^2} \log \frac{d}{\varepsilon \delta}\right)$  rows we have

$$(\|SX\beta^* - Sy\|_1 - \|SX\beta - Sy\|_1) - (\|X\beta^* - y\|_1 - \|X\beta - y\|_1) < \varepsilon \|X(\beta^* - \beta)\|_1 \quad (5)$$

for all  $\beta$  with probability at least  $1 - \delta$ . We do this by adapting the argument of [4] which shows that  $S$  is a column-space embedding with high probability. We have summarized this argument below.

#### Column-space embedding using Lewis weights ([4])

An important result in [4], which directly implies the high probability subspace embedding, and which will be useful to us later is the following moment bound on deviations of  $\|SX\beta\|_1$ .

## 49:6 L1 Regression with Lewis Weights Subsampling

► **Lemma 12** ([4] Lemma 7.4). *If  $N$  is at least  $O\left(\frac{d}{\varepsilon^2} \log \frac{d}{\varepsilon\delta}\right)$ , and  $S \in \mathbb{R}^{N \times n}$  is drawn from the sampling-and-reweighting distribution  $\mathcal{S}(\{p_i\}_{i=1}^n)$  with  $\sum_i p_i = N$  and  $\{p_i\}_{i=1}^n$  proportional to Lewis weights  $\{w_i\}_{i=1}^n$ , then*

$$\mathbb{E}_S \left[ \left( \max_{\|X\beta\|_1=1} \|SX\beta\|_1 - \|X\beta\|_1 \right)^l \right] \leq \varepsilon^l \delta$$

The proof follows from this chain of inequalities:

$$\begin{aligned} \mathbb{E}_S \left[ \left( \max_{\|X\beta\|_1=1} \|SX\beta\|_1 - \|X\beta\|_1 \right)^l \right] &\stackrel{(A)}{\leq} 2^l \mathbb{E}_{\sigma, S} \left[ \left( \max_{\|X\beta\|_1=1} \left| \sum_k \sigma_k \frac{|x_{i_k}^\top \beta|}{p_{i_k}} \right| \right)^l \right] \\ &\stackrel{(B)}{\leq} 2^l \mathbb{E}_{\sigma, S} \left[ \left( \max_{\|X\beta\|_1=1} \sum_k \sigma_k \frac{x_{i_k}^\top \beta}{p_{i_k}} \right)^l \right] \\ &\stackrel{(C)}{\leq} \varepsilon^l \delta \end{aligned}$$

where the  $\sigma_k$  are independent Rademacher variables, which are  $\pm 1$  with probability  $1/2$  each, and  $p_{i_k}$  is proportional to the  $\ell_1$  Lewis weight of row  $i_k$ . (A) follows by symmetrizing the objective  $F := \max_{\|X\beta\|_1=1} \|SX\beta\|_1 - \|X\beta\|_1$ . (B) follows from a contraction lemma. (C) is shown by constructing a related matrix with bounded Lewis weights and applying Lemma 32 from [15] reproduced below.

► **Lemma 13.** *There exists constant  $C$  such that for any  $X \in \mathbb{R}^{n \times d}$  with all  $\ell_1$  Lewis weights less than  $C \frac{\varepsilon^2}{\log(\frac{n}{\delta})}$  and  $l = \log(2n/\delta)$ , we have*

$$\mathbb{E}_\sigma \left[ \left( \max_{\|X\beta\|_1=1} \left| \sum_{i=1}^n \sigma_i x_i^\top \beta \right| \right)^l \right] \leq \frac{\varepsilon^l \delta}{2} \quad (6)$$

### Regression guarantees using Lewis weight sampling

In this work, we show the following chain of inequalities.

$$\begin{aligned} \mathbb{E}_S \left[ \left( \max_{\|X\beta^* - X\beta\|_1=1} |(\|SX\beta^* - Sy\|_1 - \|SX\beta - Sy\|_1) - (\|X\beta^* - y\|_1 - \|X\beta - y\|_1)| \right)^l \right] \\ &\stackrel{(A)}{\leq} 2^l \mathbb{E}_{S, \sigma} \left[ \left( \max_{\|X\beta^* - X\beta\|_1=1} \left| \sum_k \sigma_k \left( \frac{|x_{i_k}^\top \beta^* - y_{i_k}|}{p_{i_k}} - \frac{|x_{i_k}^\top \beta - y_{i_k}|}{p_{i_k}} \right) \right| \right)^l \right] \\ &\stackrel{(B)}{\leq} 2^{2l+1} \mathbb{E}_{S, \sigma} \left[ \left( \max_{\|X(\beta^* - \beta)\|_1=1} \left| \sum_k \sigma_{i_k} \frac{x_{i_k}^\top}{p_{i_k}} (\beta^* - \beta) \right| \right)^l \right] \\ &\stackrel{(C)}{\leq} \varepsilon^l \delta \end{aligned} \quad (7)$$

Here, for (A), we symmetrize the left hand side of (5) in Lemma 29. For (B), we apply a different contraction lemma, Lemma 30, that allows us to remove  $y$  from our expression, and then end up with the same moment bound for (C). Step (C) is essentially an application of Lemma 32 to  $SX$ , however, because we cannot immediately bound the Lewis weights of  $SX$  to confirm the constraints of the Lemma, we instead construct another matrix  $X''$  which does not significantly alter the right hand side of inequality (7) while having bounded Lewis weights. This is done in Lemmas 33 and 34.

### 3.1 Lower Bounds

We will show that any algorithm must see  $\Omega(d \log \frac{1}{\delta} + \frac{1}{\varepsilon^2} \log \frac{1}{\delta} + \frac{d}{\varepsilon^2})$  labels to return  $\hat{\beta}$  satisfying  $\|X\hat{\beta} - y\|_1 \leq (1 + \varepsilon)\|X\beta^* - y\|_1$  with probability greater than  $1 - \delta$ .

For the lower bound proof it is convenient to consider a *distributional* version of the problem:

► **Problem 2** (Distributional active L1 regression). *There is an unknown joint distribution  $P$  over a finite set  $\mathcal{X} \times \mathcal{Y} \subset \mathbb{R}^d \times \mathbb{R}$ , with  $|\mathcal{Y}| = 2$ . The learner is allowed to adaptively observe  $N$  i.i.d. samples from  $P(\cdot | X = x)$  for the learner's choice of  $N$  values  $x \in \mathcal{X}$ . The learner must return  $\hat{\beta}$  satisfying*

$$\mathbb{E}_{(X,Y) \sim P} [|X^\top \hat{\beta} - Y|] \leq (1 + \varepsilon) \inf_{\beta} \mathbb{E}_{(X,Y) \sim P} [|X^\top \beta - Y|]. \quad (8)$$

with probability at least  $1 - \delta$ .

We begin with a lemma that shows that solving the original, Problem 1, for some  $n$  polynomial in the parameters  $d, \varepsilon, \delta$  is harder than solving the distributional version, Problem 2.

► **Lemma 14.** *A randomized algorithm that solves Problem 1 for  $n = \frac{2}{\varepsilon^2} (\log \frac{2}{\delta} + d \log \frac{3d}{\varepsilon})$  with accuracy  $\varepsilon$  and failure probability  $\delta$  can be used to solve any instance of Problem 2, where  $\mathcal{X}, \mathcal{Y}$ , in the unit  $\ell_\infty$  ball, with accuracy  $6\varepsilon$  and failure probability  $2\delta$ , for small  $\varepsilon$ .*

**Proof.** Let  $n = \frac{8}{\varepsilon^2} (\log \frac{2}{\delta} + d \log \frac{4d}{\varepsilon})$ . Construct an instance of Problem 1 in which the rows of feature matrix  $\mathbf{X}$  and the corresponding label vector  $y$  are drawn i.i.d. from  $P$ . Let  $H$  be the unit  $\ell_\infty$  ball. We have the following:

▷ **Claim 15.** For all  $\beta \in H$ , with probability at least  $1 - \delta$ ,

$$(1 - \varepsilon) \mathbb{E}_{(X,Y) \sim P} [|X^\top \beta - Y|] \leq \frac{1}{n} \|\mathbf{X}\beta - y\|_1 \leq (1 + \varepsilon) \mathbb{E}_{(X,Y) \sim P} [|X^\top \beta - Y|]$$

Let  $\beta^\circ$  denote the minimizer  $\inf_{\beta} \mathbb{E}_{(X,Y) \sim P} [|X^\top \beta - Y|]$ . Let  $\beta^*$  denote the minimizer of the matrix instance  $\inf_{\beta} \|\mathbf{X}\beta - y\|_1$ , and let  $\hat{\beta}$  denote the output of the algorithm on the instance generated. Then we have

$$\begin{aligned} (1 - \varepsilon) \mathbb{E}_{(X,Y) \sim P} [|X^\top \hat{\beta} - Y|] &\leq \frac{1}{n} \|\mathbf{X}\hat{\beta} - y\|_1 \\ &\leq (1 + \varepsilon) \frac{1}{n} \|\mathbf{X}\beta^* - y\|_1 && \text{with probability } 1 - \delta \\ &\leq (1 + \varepsilon) \frac{1}{n} \|\mathbf{X}\beta^\circ - y\|_1 \\ &\leq (1 + \varepsilon)^2 \mathbb{E}_{(X,Y) \sim P} [|X^\top \beta^\circ - Y|] \end{aligned}$$

So with probability  $1 - 2\delta$ ,

$$\mathbb{E}_{(X,Y) \sim P} [|X^\top \hat{\beta} - Y|] \leq (1 + 6\varepsilon) \mathbb{E}_{(X,Y) \sim P} [|X^\top \beta^\circ - Y|]. \quad \blacktriangleleft$$

We then prove lower bounds on the accuracy for any algorithm on Problem 2. We prove three theorems that allow us to show Theorem 26: Theorems 16, 20, and 23. To do this, we make several Claims, which are proved in section 7.1.

In all our lower bounds,  $x$  is a uniform  $e_i$ , and  $y \in \{0, 1\}$  while  $y$  is a Bernoulli random variable. For  $\Omega(\frac{d}{\varepsilon^2})$ , we set  $P(y = 1 | x = e_i)$  to  $\frac{1}{2} + \varepsilon$  uniformly at random independently for each  $i$ ; getting an  $\varepsilon$ -approximate solution requires getting most of the biases correct,

## 49:8 L1 Regression with Lewis Weights Subsampling

which requires  $\frac{1}{\varepsilon^2}$  samples from most of the coordinates  $e_i$ . The  $\Omega(\frac{1}{\varepsilon^2} \log \frac{1}{\delta})$  instance sets  $P(y = 1 | x = e_i)$  to  $\frac{1}{2} + \varepsilon$  with the same bias for each  $i$ ; solving this is essentially distinguishing a  $\varepsilon$  biased coin from a  $-\varepsilon$ -biased coin. Finally, for  $\Omega(d \log \frac{1}{\delta})$  we set  $P(y = 1 | x = e_i) = 0$  except for a random hidden  $i^*$  with  $P(y = 1 | x = e_{i^*}) = \frac{3}{4}$ . Solving this instance requires finding  $i^*$ , but there's a  $\delta$  chance the first  $d \log \frac{1}{\delta}$  queries are all zero.

► **Theorem 16.** *For any  $d \geq 2$  and  $\varepsilon < \frac{1}{10}$ , there exist families  $\mathcal{X} \in \mathbb{R}^d, \mathcal{Y} \in \mathbb{R}$  of inputs and labels respectively such that any algorithm which solves Problem 2 with  $\delta < \frac{1}{4}$  requires at least  $m = \frac{3d}{2000\varepsilon^2}$  samples.*

We take  $\mathcal{X}$  to be the set of standard basis vectors, and the distribution over  $\mathcal{X}$  to be uniform. We will define a set  $\mathcal{B}$  as being a subset of the unit hypercube  $\{-1, 1\}^d$  such that every element is sufficiently far from every other.

▷ **Claim 17.** There is a set  $\mathcal{B} \subset \mathcal{H}$  with  $|\mathcal{B}| \geq 2^{0.2d}$  such that for any two  $\beta_1, \beta_2 \in \mathcal{B}$ , we have  $|\beta_1 - \beta_2| > 0.2d$

Proof. Here we just need an error correcting code with constant rate and constant relative (Hamming) distance. The existence of such a code follows from the Gilbert-Varshamov bound [10]. ◁

Fix some unknown  $\beta^*$ . We will have  $Y = ZX^\top \beta^*$  where  $Z$  is an independent random variable with probability  $\frac{1}{2} + \varepsilon$  of being 1, and  $\frac{1}{2} - \varepsilon$  of being  $-1$ . This completes our description of  $P$ . We define  $l(\beta)$  to be the  $\ell_1$  norm of the residuals for  $\beta$ , that is,  $l(\beta) = \mathbb{E}_{(X,Y) \sim P} [|X^\top \beta - Y|]$ . We have the following properties of  $l(\beta)$ .

▷ **Claim 18.** For  $D, \mathcal{B}$  as chosen above,  $l(\beta^*) = 1 - 2\varepsilon$ .

▷ **Claim 19.** For  $D, \mathcal{B}$  as chosen above, we have for all  $\beta \in \mathcal{B}$ ,  $l(\beta) - l(\beta^*) = \frac{2\varepsilon}{d} \|\beta - \beta^*\|_1$ .

**Proof of Theorem 16.** Suppose some algorithm returns  $\hat{\beta}$  with  $l(\hat{\beta}) < (1 + \frac{\varepsilon}{5})l(\beta^*) \implies \|\beta^* - \hat{\beta}\|_1 < 0.1d$  with probability  $\frac{3}{4}$ . By Fano's inequality,

$$H(\beta^* | \hat{\beta}) < H\left(\frac{1}{4}\right) + \frac{\log |\mathcal{B}| - 1}{4} < 0.05d,$$

and we have a lower bound on the mutual information between the output of our algorithm and the true parameter:  $I(\hat{\beta}; \beta^*) = H(\beta^*) - H(\beta^* | \hat{\beta}) \geq 0.15d$ . For an upper bound on the mutual information after seeing  $m$  samples, we use the data processing inequality.

$$\begin{aligned} I(\beta^*; \hat{\beta}) &\leq I(\beta^*; (Y_i)_{i \in [m]}) \leq \sum_{i=1}^m I(\beta^*; Y_i | (Y_j)_{j \in [i-1]}) \\ &= \sum_{i=1}^m H(Y_i | (Y_j)_{j \in [i-1]}) - H(Y_i | \beta^*, (Y_j)_{j \in [i-1]}) \\ &\leq \sum_{i=1}^m 1 - H(Y_i | \beta^*, I_i) \\ &\leq 4\varepsilon^2 m \end{aligned}$$

Here we have used that

$$\begin{aligned} H(Y_i | \beta^*, (Y_j)_{j \in [i-1]}) &\geq H(Y_i | \beta^*, I_i, (Y_j)_{j \in [i-1]}) \\ &= H(Y_i | \beta^*, I_i) \end{aligned}$$

and that the distribution of  $Y_i$  conditioned on  $\beta^*, I_i$  is just an independent Bernoulli with parameter  $\frac{1}{2} + \varepsilon$  and so

$$\begin{aligned} \sum_{i=1}^m 1 - H(Y_i|\beta^*, I_i) &\leq \sum_{i=1}^m \left[ 1 + \left(\frac{1}{2} + \varepsilon\right) \log\left(\frac{1}{2} + \varepsilon\right) + \left(\frac{1}{2} - \varepsilon\right) \log\left(\frac{1}{2} - \varepsilon\right) \right] \\ &\leq 4\varepsilon^2 m \end{aligned}$$

So  $0.15d \leq I(\beta^*; \hat{\beta}) \leq 4\varepsilon^2 m$ , and so we need  $m \geq \frac{3d}{80\varepsilon^2}$ . The result follows by replacing  $\varepsilon$  with  $5\varepsilon$ .  $\blacktriangleleft$

We can use the same instance to give a high probability lower bound of  $\Omega(\log \frac{1}{\delta}/\varepsilon^2)$ .

► **Theorem 20.** *For any  $d$  and  $\varepsilon < \frac{1}{10}$ , there exist sets  $\mathcal{X} \in \mathbb{R}, \mathcal{Y} \in \mathbb{R}$  of inputs and labels respectively, and a distribution  $P$  on  $\mathcal{X} \times \mathcal{Y}$  such that any algorithm which solves problem 2 requires at least  $m = \frac{1}{4\varepsilon^2} \log \frac{1}{\delta}$  samples.*

**Proof.** Consider two instances, denoted by subscripts (1) and (2) with  $\beta_{(1)}^* = -\mathbb{1}_d$  and  $\beta_{(2)}^* = \mathbb{1}_d$ , where  $\mathbb{1}_d \in \mathbb{R}^d$  is the all-ones vector. Denote by  $P_{(i)}$  the distribution over  $\mathcal{X}, \mathcal{Y}$  for instance (i), and let  $l_{\beta_{(i)}^*}(\beta) = \mathbb{E}_{(X,Y) \sim P_{(i)}}[|X^\top \beta - Y|]$  for  $i \in \{1, 2\}$ .

▷ **Claim 21.** For any  $\beta$ ,  $\max\{l_{\beta_{(1)}^*}(\beta) - l_{\beta_{(1)}^*}(\beta_{(1)}^*), l_{\beta_{(2)}^*}(\beta) - l_{\beta_{(2)}^*}(\beta_{(2)}^*)\} > 2\varepsilon$

From this claim together with Claim 18, we have for some  $i \in \{1, 2\}$ ,  $l_{\beta_{(i)}^*}(\beta) \geq (1 + 2\varepsilon)l_{\beta_{(i)}^*}(\beta_{(i)}^*)$ , for all  $\beta$ .

Denote by  $\hat{\beta}$  the output of the algorithm. Denote by  $\mathbb{P}_{(1)}$  the distribution over outputs by a algorithm interacting instance (1), and by  $\mathbb{P}_{(2)}$  the distribution over outputs by a algorithm interacting instance (2). Denote by  $A$  the event that  $l_{\beta_{(1)}^*}(\hat{\beta}) - l_{\beta_{(1)}^*}(\beta_{(1)}^*) \geq 2\varepsilon$ . Note that under  $A^c$ , we have  $l_{\beta_{(2)}^*}(\hat{\beta}) - l_{\beta_{(2)}^*}(\beta_{(2)}^*) \geq 2\varepsilon$ . Because the algorithm fails with probability at most  $\delta$  on any instance, we have  $2\delta \geq \mathbb{P}_{(1)}(A) + \mathbb{P}_{(2)}(A^c)$ . On the other hand,  $\mathbb{P}_{(1)}(A) + \mathbb{P}_{(2)}(A^c) \geq e^{-D(\mathbb{P}_{(1)}\|\mathbb{P}_{(2)})}$ . We can bound the KL-divergence of the two distributions as an aggregate KL-divergence over the course of acquiring the samples.

► **Theorem 22 (Lemma 15.1, [11]).** *If a learner interacts with two environments (1) and (2) through a policy  $\pi(\cdot|I_1, Y_1, I_2, Y_2, \dots, Y_{i-1})$  which dictates a distribution over actions  $I_i$  conditioned on the past  $(I_1, Y_1, \dots, Y_{i-1})$ , and sees label  $Y_i$  distributed according to some label distribution  $P_{(1), I_i}$  and  $P_{(2), I_i}$ , then the KL-divergence between the output of the learner on instance (1) and (2),  $\mathbb{P}_{(1)}$  and  $\mathbb{P}_{(2)}$  is given by*

$$D(\mathbb{P}_{(1)}\|\mathbb{P}_{(2)}) = \sum_{k=1}^d \mathbb{E}_{(1)} \left[ \sum_{i=1}^N \mathbb{1}\{I_i = k\} \cdot D(P_{(1), I_i}\|P_{(2), I_i}) \right]$$

Now,  $P_{(1), k}$  is a Bernoulli with parameter  $\frac{1}{2} + \varepsilon$ , and  $P_{(2), k}$  is a Bernoulli with parameter  $\frac{1}{2} - \varepsilon$ , so  $D(P_{(1), k}\|P_{(2), k}) \leq 16\varepsilon^2$ , and so we have

$$\begin{aligned} \sum_{k=1}^d \mathbb{E}_{(1)} \left[ \sum_{i=1}^N \mathbb{1}\{I_i = k\} \cdot D(P_{(1), I_i}\|P_{(2), I_i}) \right] &\leq \sum_{k=1}^d \mathbb{E}_{(1)} \left[ \sum_{i=1}^N \mathbb{1}\{I_i = k\} \cdot 16\varepsilon^2 \right] \\ &= 16\varepsilon^2 \cdot \mathbb{E}_{(1)} \left[ \sum_{k=1}^d \sum_{i=1}^N \mathbb{1}\{I_i = k\} \right] = 16\varepsilon^2 m \end{aligned}$$

Putting this together, we have  $\delta \geq e^{-16\varepsilon^2 m} \implies m \geq \frac{1}{16\varepsilon^2} \log \frac{1}{\delta}$ , and the result follows by replacing  $\varepsilon$  with  $\frac{1}{2}\varepsilon$ .  $\blacktriangleleft$

## 49:10 L1 Regression with Lewis Weights Subsampling

► **Theorem 23.** For any  $d \geq 2$ , there exist sets  $\mathcal{X} \in \mathbb{R}^d, \mathcal{Y} \in \mathbb{R}$  of inputs and labels, and a distribution  $P$  on  $\mathcal{X} \times \mathcal{Y}$  such that any algorithm which solves Problem 2, with  $\varepsilon = 1$ , requires at least  $m = \frac{d}{3} \log \frac{1}{8\delta}$  samples.

**Proof.** All logarithms are base 4. Consider instances in which  $\mathcal{X} = \{e_1, e_2, \dots, e_d\}$  where  $e_i$  denotes the  $i$ th standard basis vector and the distribution over  $\mathcal{X}$  is uniform. We take  $Y = ZX^\top \beta^*$  for some  $\beta^*$ , where  $Z$  is an independent Bernoulli random variable which is 1 with probability  $\frac{3}{4}$ , and 0 otherwise. Consider  $d$  instances labelled with subscripts (1), (2),  $\dots$ , ( $d$ ), one in which each of the  $d$  standard basis is  $\beta^*$ , that is,  $\beta_{(i)}^* = e_i$ . Denote by  $\beta_j$  the  $j$ th coordinate of  $\beta$ . For each instance, we have

▷ **Claim 24.** For all  $i \in [d], \beta \in \mathbb{R}^d$ , we have  $\ell_{\beta_{(i)}^*}(\beta) \geq \frac{1}{4d}$  with equality when  $\beta = \beta_{(i)}^*$

We would like our algorithm to return an estimate  $\hat{\beta}$  which satisfies  $\ell_{\beta^*}(\hat{\beta}) < \frac{1}{2d}$ . We first note that any choice of  $\beta$  only succeeds to be this close to the optimal on a single instance.

▷ **Claim 25.** Any  $\beta \in \mathbb{R}^d$  can only satisfy  $\ell_{\beta_{(i)}^*}(\hat{\beta}) < \frac{1}{2d}$  for one  $i \in [d]$ .

So, we may as well enforce that the algorithm return one of  $e_1, e_2, \dots, e_d$ , since any other output can be mapped to one of these to improve the performance of the algorithm.

We will allow our algorithm to sample  $N = \frac{d}{3} \log \frac{1}{\delta}$  rows total. Let  $\mathcal{E}$  be the event that  $Y_1, Y_2, \dots, Y_N$  are all zero. Given any algorithm  $\mathcal{A}$ , let  $F_{\mathcal{A}}$  denote the set of rows it samples fewer than  $\log \frac{1}{\delta}$  times with probability at least  $\frac{1}{2}$ , in event  $\mathcal{E}$ . Because the total number of rows sampled is  $\frac{d}{3} \log \frac{1}{\delta}$ , there must be at least  $\frac{2d}{3}$  rows which are sampled fewer than  $\frac{1}{2} \log \frac{1}{\delta}$  times in expectation.

By Markov's inequality, these rows are sampled fewer than  $\log \frac{1}{\delta}$  times with probability at least  $\frac{1}{2}$ , and are thus all in  $F_{\mathcal{A}}$ . Let  $B_{\mathcal{A}}$  denote the distribution over outputs  $\hat{\beta}$  of  $\mathcal{A}$  in event  $\mathcal{E}$ . Let  $i_{\mathcal{A}} = \arg \min_{j \in F_{\mathcal{A}}} B_{\mathcal{A}}(j)$ . Denote by  $G_{\mathcal{A}}$  the event that row  $i_{\mathcal{A}}$  is sampled fewer than  $\log \frac{1}{\delta}$  times; by construction we have  $\mathbb{P}(G_{\mathcal{A}}) > \frac{1}{2}$ .

The subscripts are explicit because  $F_{\mathcal{A}}, B_{\mathcal{A}}, i_{\mathcal{A}}, \mathbb{P}[G_{\mathcal{A}}]$  are properties of the algorithm and are independent of the instance with which it interacts. Consider the performance of this algorithm against the instance  $\beta_{(i_{\mathcal{A}})}^*$ .

Let  $Y_{(i_{\mathcal{A}}), j, k}$  denote the label returned to the algorithm when it queries  $e_j$  for the  $k$ th time. Let  $T_{(i_{\mathcal{A}})} = \min\{t | Y_{(i_{\mathcal{A}}), i_{\mathcal{A}}, t} = 1\}$ . Denote by  $E_{(i_{\mathcal{A}})}$  the event that  $T_{(i_{\mathcal{A}})} > \log \frac{1}{\delta}$ . Because  $T_{(i_{\mathcal{A}})}$  is a geometric random variable, we have  $\mathbb{P}[E_{(i_{\mathcal{A}})}] > \delta$ .

Now condition on the event  $G_{\mathcal{A}} \cap E_{i_{\mathcal{A}}}$ , which is an event with probability  $\frac{1}{2}\delta$ . Here our algorithm samples  $i_{\mathcal{A}}$  fewer than  $T_{i_{\mathcal{A}}}$  times, so it never sees a 1 and its output distribution is  $B_{\mathcal{A}}$ . It returns  $i \in F_{\mathcal{A}} \setminus \{i_{\mathcal{A}}\}$  with probability at least  $1 - B_{\mathcal{A}}(i_{\mathcal{A}}) \geq 1 - \frac{1}{|F_{\mathcal{A}}|} \geq 1 - \frac{3}{2d} \geq \frac{1}{4}$ . In summary, even after  $\frac{d}{3} \log \frac{1}{\delta}$  queries, no algorithm can return  $\hat{\beta}$  with  $\|X\hat{\beta} - y\| < (1 + \varepsilon)\|X\beta^* - y\|$  with probability greater than  $\frac{1}{8}\delta$ . The result follows by replacing  $\delta$  by  $8\delta$ . ◀

Putting these together we have:

► **Theorem 26.** For any  $d \geq 2, \varepsilon < \frac{1}{10}, \delta < \frac{1}{4}$ , there exist sets  $\mathcal{X} \in \mathbb{R}^d, \mathcal{Y} \in \mathbb{R}$  of inputs and labels, and a distribution  $P$  on  $\mathcal{X} \times \mathcal{Y}$  such that any algorithm which solves Problem 2, with  $\varepsilon = 1$ , requires at least  $m = \Omega(\frac{d}{\varepsilon^2} + \frac{1}{\varepsilon^2} \log \frac{1}{\delta} + d \log \frac{1}{\delta})$  samples.

► **Corollary 27.** Any algorithm that solves Problem 1 takes at least  $\Omega(d \log \frac{1}{\delta} + \frac{d}{\varepsilon^2} + \frac{1}{\varepsilon^2} \log \frac{1}{\delta})$  samples for some  $n = O(\frac{d \log \frac{4}{\delta}}{\varepsilon})$ .

**Proof.** Each of the instances that demonstrate the lower bounds above, in Lemmas 16, 20, and 23, take  $|\mathcal{X}| = d$ , the results follows from Lemma 14. ◀

## 4 Proof of Theorem 11

► **Lemma 28.** *Let  $X \in \mathbb{R}^{n \times d}$  have  $\ell_1$  Lewis weights  $\{w_i\}_{i \in [n]}$ . Then, for any  $N$  that is at least  $O\left(\frac{d}{\varepsilon^2} \log \frac{d}{\varepsilon \delta}\right)$ , there is a sampling-and-reweighting distribution  $\mathcal{S}(\{p_i\}_{i=1}^n)$  satisfying  $\sum_i p_i = N$  such that for all  $y$ , if  $S \sim \mathcal{S}(\{p_i\}_{i=1}^n)$  and  $\beta^* = \arg \min \|X\beta - y\|_1$ , we have for all  $\beta$*

$$(\|SX\beta^* - Sy\|_1 - \|SX\beta - Sy\|_1) - (\|X\beta^* - y\|_1 - \|X\beta - y\|_1) \leq \varepsilon \cdot \|X\beta^* - X\beta\|_1 \quad (9)$$

with probability at least  $1 - \delta$ . Further, for constant  $\delta$ ,  $m = O(d \log d / \varepsilon^2)$  rows suffice.

This lemma is proved for high probability in Section 4.1, and for constant probability in the full version of this paper, [14]. Given this, we can prove the main theorem.

**Proof of Theorem 11.** Applying Lemma 28 to  $\hat{\beta} := \arg \min \|SX\beta - Sy\|_1$ , we get

$$\left(\|SX\beta^* - Sy\|_1 - \|SX\hat{\beta} - Sy\|_1\right) \leq \left(\|X\beta^* - y\|_1 - \|X\hat{\beta} - y\|_1\right) + \varepsilon \cdot \|X\beta^* - X\hat{\beta}\|_1$$

Since  $\hat{\beta}$  is the minimizer of  $\|SX\beta - Sy\|_1$ , the left side is non-negative. So,

$$\begin{aligned} \|X\hat{\beta} - y\|_1 &\leq \|X\beta^* - y\|_1 + \varepsilon \cdot \|X\beta^* - X\hat{\beta}\|_1 \\ &\leq \|X\beta^* - y\|_1 + \varepsilon \cdot (\|X\beta^* - y\|_1 + \|X\hat{\beta} - y\|_1) \end{aligned}$$

Rearranging, and assuming  $\varepsilon < 1/2$ ,

$$\begin{aligned} \|X\hat{\beta} - y\|_1 &\leq \frac{1 + \varepsilon}{1 - \varepsilon} \|X\beta^* - y\|_1 \\ &\leq (1 + 4\varepsilon) \|X\beta^* - y\|_1 \end{aligned}$$

Using  $\varepsilon' = \varepsilon/4$  proves the theorem. ◀

### 4.1 Proof of Lemma 28

This argument is similar to that in Appendix B of [4]. In order to prove Lemma 28, by Markov's inequality, it is sufficient to show that for some  $l$ ,

$$M := \mathbb{E}_S \left[ \left( \max_{\|X\beta^* - X\beta\|_1=1} |(\|SX\beta^* - Sy\|_1 - \|SX\beta - Sy\|_1) - (\|X\beta^* - y\|_1 - \|X\beta - y\|_1)| \right)^l \right] \leq \varepsilon^l \delta$$

To show this, we will symmetrize, then use a contraction lemma to cancel the  $y$  terms. Then, with all the terms being within the column space of  $SX$ , we use the fact that  $S$  is a subspace embedding with high probability. We present two different bounds, one used for the constant probability and one for the high probability cases, but the following intermediate bound is the same for the two:

► **Lemma 29.** *Given a matrix  $X \in \mathbb{R}^{n \times d}$ , let  $\mathcal{S}(\{p_i\}_{i \in [n]})$  be any sampling-and-reweighting distribution, and let  $i_k$  be the row-indices chosen by this sampling matrix such that  $S_{k,i_k} = \frac{1}{p_{i_k}}$ . Let  $\sigma_k$  be independent Rademacher variables that are  $\pm 1$  each with probability 0.5. Then,*

$$M \leq 2^l \mathbb{E}_{S, \sigma} \left[ \left( \max_{\|X\beta^* - X\beta\|_1=1} \left| \sum_k \sigma_k \left( \frac{|x_{i_k}^\top \beta^* - y_{i_k}|}{p_{i_k}} - \frac{|x_{i_k}^\top \beta - y_{i_k}|}{p_{i_k}} \right) \right| \right)^l \right] \quad (10)$$

## 49:12 L1 Regression with Lewis Weights Subsampling

This is essentially standard symmetrization; the proof is in Appendix B. To simplify the expression and eliminate the terms involving the labels, we then use a theorem from [12]:

► **Lemma 30** ([12] Theorem 5). *Let  $\Phi : \mathbb{R}^+ \rightarrow \mathbb{R}^+$  be convex and increasing, and let  $\phi_k : \mathbb{R} \rightarrow \mathbb{R}$  be contractions such that  $\phi_k(0) = 0$  for all  $k$ . Let  $\mathcal{F}$  be a class of functions on  $\{1, 2, 3, \dots, n\}$ , and  $\|g(f)\|_{\mathcal{F}} = \sup_{f \in \mathcal{F}} |g(f)|$ . Then,*

$$\mathbb{E}_{\sigma} \left[ \Phi \left( \frac{1}{2} \left\| \sum_k \sigma_k \phi_k(f(k)) \right\|_{\mathcal{F}} \right) \right] \leq \frac{3}{2} \mathbb{E}_{\sigma} \left[ \Phi \left( \left\| \sum_k \sigma_k f(k) \right\|_{\mathcal{F}} \right) \right]$$

► **Lemma 31.** *For any  $y \in \mathbb{R}^n$ , we have*

$$\begin{aligned} & \mathbb{E}_{S, \sigma} \left[ \left( \max_{\|X\beta^* - X\beta\|_1=1} \left| \sum_k \sigma_k \left( \frac{|x_{i_k}^{\top} \beta^* - y_{i_k}|}{p_{i_k}} - \frac{|x_{i_k}^{\top} \beta - y_{i_k}|}{p_{i_k}} \right) \right| \right)^l \right] \\ & \leq 2^{l+1} \mathbb{E}_{S, \sigma} \left[ \left( \max_{\|X\beta^* - X\beta\|_1=1} \left| \sum_k \sigma_k \left( \frac{x_{i_k}^{\top} \beta^* - x_{i_k}^{\top} \beta}{p_{i_k}} \right) \right| \right)^l \right] \end{aligned} \quad (11)$$

**Proof.** We take  $\Phi(x) = x^l$ , which is convex and increasing for  $l > 1$ , let  $\mathcal{F}$  be the set of functions  $f_{\beta}$  where  $f_{\beta}(k) = \frac{x_{i_k}^{\top} \beta^* - x_{i_k}^{\top} \beta}{p_{i_k}}$  and  $\beta$  satisfies  $\|X\beta^* - X\beta\|_1 = 1$ , and let  $\phi_k$  be defined as

$$\phi_k(z) = \frac{|x_{i_k}^{\top} \beta^* - y_{i_k}|}{p_{i_k}} - \frac{|x_{i_k}^{\top} \beta^* - zp_{i_k} - y_{i_k}|}{p_{i_k}}.$$

This satisfies

$$\phi_k(f_{\beta}(k)) = \phi_k \left( \frac{x_{i_k}^{\top} \beta^* - x_{i_k}^{\top} \beta}{p_{i_k}} \right) = \frac{|x_{i_k}^{\top} \beta^* - y_{i_k}|}{p_{i_k}} - \frac{|x_{i_k}^{\top} \beta - y_{i_k}|}{p_{i_k}}.$$

This is a contraction, since

$$\begin{aligned} |\phi_k(z_1) - \phi_k(z_2)| &= \left| \frac{|x_{i_k}^{\top} \beta^* - z_2 p_{i_k} - y_{i_k}|}{p_{i_k}} - \frac{|x_{i_k}^{\top} \beta^* - z_1 p_{i_k} - y_{i_k}|}{p_{i_k}} \right| \\ &\leq \frac{|z_1 p_{i_k} - z_2 p_{i_k}|}{p_{i_k}} \leq |z_1 - z_2| \end{aligned}$$

Applying Lemma 30 with these parameters, we have

$$\begin{aligned} & \mathbb{E}_{\sigma} \left[ \left( \frac{1}{2} \max_{\|X\beta^* - X\beta\|_1=1} \left| \sum_k \sigma_k \left( \frac{|x_{i_k}^{\top} \beta^* - y_{i_k}|}{p_{i_k}} - \frac{|x_{i_k}^{\top} \beta - \text{true}y_{i_k}|}{p_{i_k}} \right) \right| \right)^l \right] \\ & \leq \frac{3}{2} \mathbb{E}_{\sigma} \left[ \left( \max_{\|X\beta^* - X\beta\|_1=1} \left| \sum_k \sigma_k \left( \frac{x_{i_k}^{\top} \beta^* - x_{i_k}^{\top} \beta}{p_{i_k}} \right) \right| \right)^l \right] \end{aligned}$$

After taking the expectation with respect to  $S$  and multiplying both sides by  $2^l$ , this gives the statement of the lemma. ◀

From here, we use two separate results to show the appropriate row counts for the constant and high probability cases. The constant probability case is left for the full version of this paper, [14].

For high probability row-counts, we use a lemma from [4]:

► **Lemma 32** (8.2, 8.3, 8.4 in [4]). *There exists constant  $C$  such that for any  $X \in \mathbb{R}^{n \times d}$  with all  $\ell_1$  Lewis weights less than  $C \frac{\varepsilon^2}{\log(\frac{n}{\delta})}$  and  $l = \log(2n/\delta)$ , then*

$$\mathbb{E}_\sigma \left[ \left( \max_{\|X\beta\|_1=1} \left| \sum_{i=1}^n \sigma_i x_i^\top \beta \right| \right)^l \right] \leq \frac{\varepsilon^l \delta}{2} \quad (12)$$

We want a similar statement, but for arbitrary matrices, with no bounds placed on the Lewis weights. To do this, we construct a new, related matrix using the following lemma, which is proved in Appendix B:

► **Lemma 33** (Similar to [4] Lemma B.1). *Let  $X$  be any matrix, and let  $W$  be the matrix that has the Lewis weights of  $X$  in the diagonal entries. Let  $N \geq \frac{d}{\varepsilon^2} \log \frac{d}{\varepsilon \delta}$ . There exist constants  $C_1, C_2, C_3$  such that we can construct a matrix  $X'$  such that*

- $X'$  has  $C_1 d N$  rows,
- $X'^\top W'^{-1} X' \succeq X^\top W^{-1} X$ , (where  $W'$  is the matrix that has the Lewis weights of  $X'$  in the diagonal entries),
- $\|X'\beta\|_1 \leq C_2 \|X\beta\|_1$  for all  $\beta$ ,
- the Lewis weights of  $X'$  are bounded by  $\frac{C_3}{N}$ .

► **Lemma 34.** *Consider  $X \in \mathbb{R}^{n \times d}$  with  $\ell_1$  Lewis weights  $w_i$ . Let  $p_i$  be some set of sampling values such that  $N = \sum_i p_i$  and, for some constants  $C, C_1, C_4$ ,*

$$p_i \geq \frac{\log\left(\frac{N+C_1 Nd}{\delta}\right)}{C\varepsilon^2} w_i$$

*Then, if  $N \geq C_4 \frac{d}{\varepsilon^2} \log \frac{d}{\varepsilon \delta}$  and if  $S \sim \mathcal{S}(\{p_i\}_{i \in [n]})$ , then*

$$\mathbb{E}_{S, \sigma} \left[ \left( \max_{\|X\beta\|_1=1} \left| \sum_{k=1}^N \sigma_k \frac{x_{i_k}^\top \beta}{p_{i_k}} \right| \right)^l \right] \leq \frac{\varepsilon^l \delta}{2} \quad (13)$$

**Proof of Lemma 34.** Ideally the Lewis weights of  $SX$  would be bounded by  $C \frac{\varepsilon^2}{\log \frac{N}{\delta}}$  and we could directly apply Lemma 32 to  $SX$  to obtain a bound on the moment. However, we do not know this. Instead, we first construct  $X'$  using  $X$  as described in Lemma 33. We then construct a new matrix  $X''$  by stacking  $X'$  on top of  $SX$ . Define  $W''$  to be the diagonal matrix consisting of the  $\ell_1$  Lewis weights of  $X''$ . Define, for convenience,  $R = N + C_1 Nd$ , which is the number of rows  $X''$  has.

We can bound the term on the left side of (13) by the same term, summing over the rows of  $X''$  instead. That is,

$$\mathbb{E}_{S, \sigma} \left[ \left( \max_{\|X\beta\|_1=1} \left| \sum_{k=1}^N \sigma_k \frac{x_{i_k}^\top \beta}{p_{i_k}} \right| \right)^l \right] \leq \mathbb{E}_{S, \sigma} \left[ \left( \max_{\|X\beta\|_1=1} \left| \sum_{i=1}^R \sigma_i x_i''^\top \beta \right| \right)^l \right]$$

Our goal is to apply Lemma 32 to the right side. To do this, we need to show the correct bound on its Lewis weights, and then have the term be a maximum over  $\|X''\beta\|_1 = 1$ , rather than  $\|X\beta\|_1 = 1$ .

## 49:14 L1 Regression with Lewis Weights Subsampling

**Bounding the Lewis weights of  $X''$ .** By Lemma 9, the  $\ell_1$  Lewis weights of a matrix do not increase when more rows are added. So, the rows in  $X''$  that are from  $X'$  have Lewis weights that are bounded above by  $C_3 \frac{\varepsilon^2}{\log(\frac{d}{\varepsilon\delta})}$ . Further,

$$\begin{aligned} X''^\top W''^{-1} X'' &= \sum_{i=1}^R \frac{1}{w_i''} x_i'' (x_i'')^\top \\ &\succeq \sum_{i=1}^{R-N} \frac{1}{w_k''} x_k'' (x_k'')^\top && \text{since } \sum_{i=kC_1 d^2+1}^N \frac{1}{w_i''} x_i'' (x_i'')^\top \succeq 0 \\ &= X'^\top W'^{-1} X' \succeq X^\top W^{-1} X. \end{aligned}$$

So, any row  $y_i = x_i/p_i$  in  $X''$  that is from  $SX$  satisfies

$$\begin{aligned} w_i''^2 &= y_i^\top (X''^\top W''^{-1} X'')^{-1} y_i \leq y_i^\top (X^\top W^{-1} X)^{-1} y_i = \frac{1}{p_i^2} x_i^\top (X^\top W^{-1} X)^{-1} x_i \\ &\leq \left( \frac{C\varepsilon^2}{\log(\frac{R}{\delta})} \frac{1}{w_i} \right)^2 \cdot w_i^2 = \left( \frac{C\varepsilon^2}{\log(\frac{R}{\delta})} \right)^2 \end{aligned}$$

which means that all of the Lewis weights of  $X''$  are less than the larger of  $C \frac{\varepsilon^2}{\log(\frac{R}{\delta})}$  and  $C_3 \frac{\varepsilon^2}{\log(\frac{d}{\varepsilon\delta})}$ . Now, for small enough  $\varepsilon, \delta$ ,  $\log \frac{R}{\delta} \leq \frac{C}{C_3} \log \frac{d}{\varepsilon\delta}$ , we have the Lewis weight upper bound for all rows of  $X''$  is  $C \frac{\varepsilon^2}{\log(\frac{R}{\delta})}$

**Renormalizing to maximize over  $\|X''\beta\|_1 = 1$ .** If we define the following

$$F := \max_{\|X\beta\|_1=1} \left| \|SX\beta\|_1 - \|X\beta\|_1 \right|$$

then,

$$\|X''\beta\|_1 = \|SX\beta\|_1 + \|X'\beta\|_1 \leq (1 + C_2 + F)\|X\beta\|_1$$

So, we get

$$\begin{aligned} \left( \max_{\|X\beta\|_1=1} \left| \sum_{k=1}^R \sigma_k x_k''^\top \beta \right| \right)^l &\leq (1 + C_2 + F)^l \left( \max_{\|X''\beta\|_1=1} \left| \sum_{k=1}^R \sigma_k x_k''^\top \beta \right| \right)^l \\ &\leq 2^{l-1} ((1 + C_2)^l + F^l) \left( \max_{\|X''\beta\|_1=1} \left| \sum_{k=1}^R \sigma_k x_k''^\top \beta \right| \right)^l \end{aligned}$$

Taking expectations of either side over just the Rademacher variables,

$$\mathbb{E}_\sigma \left[ \left( \max_{\|X\beta\|_1=1} \left| \sum_{k=1}^R \sigma_k x_k''^\top \beta \right| \right)^l \right] \leq 2^{l-1} ((1 + C_2)^l + F^l) \mathbb{E}_\sigma \left[ \left( \max_{\|X''\beta\|_1=1} \left| \sum_{k=1}^R \sigma_k x_k''^\top \beta \right| \right)^l \right]$$

**Applying Lemma 32 to  $X''$ .** Since  $X''$  has  $R$  rows, and the correct Lewis weight bound, we can simply apply Lemma 32 to the right side above

$$\mathbb{E}_\sigma \left[ \left( \max_{\|X\beta\|_1=1} \left| \sum_{k=1}^R \sigma_k x_k''^\top \beta \right| \right)^l \right] \leq 2^{l-1} ((1 + C_2)^l + F^l) \frac{\varepsilon^l \delta}{2}$$

Now, by Lemma 12, we know that  $\mathbb{E}_S[F^l] \leq \varepsilon^l \delta$ . So, taking the expectation with respect to the sampling matrices of either side of the above, we get, for small enough  $\varepsilon, \delta$ ,

$$\mathbb{E}_{S, \sigma} \left[ \left( \max_{\|X\beta\|=1} \left| \sum_{k=1}^{kC_1 d^2 + N} \sigma_k x_k''^\top \beta \right| \right)^l \right] \leq 2^{l-1} ((1 + C_2)^l + \varepsilon^l \delta) \frac{\varepsilon^l \delta}{2} \leq 2^l (1 + C_2)^l \frac{\varepsilon^l \delta}{2}$$

So, solving the problem for  $\varepsilon' = \frac{\varepsilon}{2+2C_2}$  gives the correct bound.  $\blacktriangleleft$

Finally, we can show Lemma 28

**Proof of Lemma 28.** Take  $l = \log(2n/\delta)$ ,  $N = 5 \frac{(1+C_1)C_3}{C} \frac{d}{\varepsilon^2} \log \frac{d}{\varepsilon \delta}$ . Then, we apply Lemma 29, Lemma 31, and Lemma 34 to get

$$M \leq 2^{2l} \varepsilon^l \delta$$

which, solving the problem for  $\varepsilon/4$ , gives the correct bound. Then, applying Markov's inequality, we get that with probability  $\delta$ ,

$$\max_{\|X\beta^* - X\beta\|=1} |(\|SX\beta^* - Sy\|_1 - \|SX\beta - Sy\|_1) - (\|X\beta^* - y\|_1 - \|X\beta - y\|_1)| \leq \varepsilon$$

Finally, scaling up appropriately gives, in generality,

$$|(\|SX\beta^* - Sy\|_1 - \|SX\beta - Sy\|_1) - (\|X\beta^* - y\|_1 - \|X\beta - y\|_1)| \leq \varepsilon \|X\beta^* - X\beta\|_1 \quad \blacktriangleleft$$

## A

 Constant-factor approximation

► **Theorem 35.** Let  $X \in \mathbb{R}^{n \times d}$  have  $\ell_1$  Lewis weights  $\{w_i\}_{i \in [n]}$ . Then, for any  $N$  that is at least  $O(d \log d)$ , there is a sampling-and-reweighting distribution  $\mathcal{S}(\{p_i\}_{i=1}^n)$  satisfying  $\sum_i p_i = N$  such that for all  $y$ , if  $S \sim \mathcal{S}(\{p_i\}_{i=1}^n)$  and  $\hat{\beta} = \arg \min \|SX\beta - Sy\|_1$ , we have

$$\|X\hat{\beta} - y\|_1 \leq 41 \min_{\beta} \|X\beta - y\|_1$$

with probability 0.9.

**Proof.** Since we just want a constant factor approximation, we can take  $\mathcal{S}$  to be the distribution over constant probability Lewis weight  $\ell_1$ -subspace embeddings, so that  $\|X\beta\|_1 \leq 2\|SX\beta\|_1$  with probability at least 0.9. We have

$$\begin{aligned} \|X\hat{\beta} - y\|_1 &\leq \|X\hat{\beta} - X\beta^*\|_1 + \|X\beta^* - y\|_1 \\ &\leq 2\|SX\hat{\beta} - SX\beta^*\|_1 + \|X\beta^* - y\|_1 \\ &\leq 2(\|SX\hat{\beta} - Sy\|_1 + \|SX\beta^* - Sy\|_1) + \|X\beta^* - y\|_1 \\ &\leq 4(\|SX\beta^* - Sy\|_1) + \|X\beta^* - y\|_1 \end{aligned}$$

where in the last inequality, we have used the fact that  $\hat{\beta}$  is the minimizer of  $\|SX\beta - Sy\|_1$ . Now, by Markov's inequality, with probability 0.9,  $\|SX\beta^* - Sy\|_1 \leq 10\|X\beta^* - y\|_1$ . So, we have with probability 0.81,

$$\|X\hat{\beta} - y\|_1 \leq 41\|X\beta^* - y\|_1$$

Since we only used a constant-factor subspace embedding, the row count would be  $O(d \log d)$ . ◀

## B

 Proofs of Lemmas

► **Lemma 10.** Let  $X \in \mathbb{R}^{n \times d}$ , and let  $X' \in \mathbb{R}^{kn \times d}$  be  $X$  stacked on itself  $k$  times, with each row scaled down by  $k$ . Then, each of the Lewis weights is reduced by a factor of  $k$ .

**Proof.** Let  $\{w_i\}_{i=1}^n$  be the Lewis weights of  $X$ , and let  $\{w'_i\}_{i=1}^{kn}$  be the Lewis weights of  $X'$ . Let  $x_i$  be the  $i$ th row of  $X$ , and similarly let  $x'_i$  be the  $i$ th row of  $X'$ . Let the ordering of the rows be such that  $x'_{jn+i} = \frac{1}{k}x_i$  for  $0 \leq j < k$ . Let  $W$  be the diagonal matrix where  $W_{ii} = w_i$ . Since Lewis weights are defined circularly, we just need to check that the suggested weights work, and by uniqueness, they will be correct.

We know that  $w_i^2 = x_i^\top (X^\top W^{-1}X)^{-1}x_i$ . Therefore, if we take  $W'$  to be the diagonal matrix of size  $kn \times kn$ , and set the diagonal entries to be the Lewis weights of  $X$  divided by  $k$ , repeated  $k$  times, then we have

$$X'^\top W'^{-1}X' = \sum_{i=1}^{kn} \frac{1}{w'_i} x'_i x'^\top_i = \sum_{i=1}^{kn} \frac{k}{w_i} x'_i x'^\top_i = k \sum_{i=1}^n \frac{k}{w_i} \cdot \frac{1}{k^2} x_i x_i^\top$$

In the last expression above, we are only summing over the first set of rows in  $X'$ , which are the scaled rows of  $X$ , and then multiplying by  $k$  since they are repeated  $k$  times. Now,

$$k \sum_{i=1}^n \frac{k}{w_i} \cdot \frac{1}{k^2} x_i x_i^\top = \sum_{i=1}^n \frac{1}{w_i} x_i x_i^\top = X^\top W^{-1}X$$

So, finally, for an arbitrary row  $x'_{jn+i}$ , which corresponds to row  $x_i$  in the original matrix, we get its Lewis weight:

$$w'^2_{jn+i} = x'^\top_{jn+i} (X'^\top W'^{-1}X')^{-1} x'_{jn+i} = \frac{1}{k^2} x_i^\top (X^\top W^{-1}X)^{-1} x_i = \frac{w_i^2}{k^2}$$

which proves that our suggested Lewis weights are consistent.  $\blacktriangleleft$

**► Lemma 29.** Given a matrix  $X \in \mathbb{R}^{n \times d}$ , let  $\mathcal{S}(\{p_i\}_{i \in [n]})$  be any sampling-and-reweighting distribution, and let  $i_k$  be the row-indices chosen by this sampling matrix such that  $S_{k,i_k} = \frac{1}{p_{i_k}}$ . Let  $\sigma_k$  be independent Rademacher variables that are  $\pm 1$  each with probability 0.5. Then,

$$M \leq 2^l \mathbb{E}_{S,\sigma} \left[ \left( \max_{\|X\beta^* - X\beta\|=1} \left| \sum_k \sigma_k \left( \frac{|x_{i_k}^\top \beta^* - y_{i_k}|}{p_{i_k}} - \frac{|x_{i_k}^\top \beta - y_{i_k}|}{p_{i_k}} \right) \right| \right)^l \right] \quad (10)$$

**Proof.** We proceed by symmetrization. Since the matrix  $S$  scales the rows by the probability they are picked with, the expectation of  $\|SM\beta\|_1$  is just  $\|M\beta\|_1$ , for any matrix  $M$  and vector  $\beta$ . So, adding or subtracting the same term with a different sampling matrix  $S'$ ,  $(\|S'X\beta^* - S'y\|_1 - \|S'X\beta - S'y\|_1) - (\|X\beta^* - y\|_1 - \|X\beta - y\|_1)$ , is just adding a mean zero term, and since taking the  $l$ th power of a maximum is convex, this can only increase the expectation. That is,

$$\begin{aligned} & \mathbb{E}_{S,S'} \left[ \left( \max_{\|X\beta^* - X\beta\|=1} |(\|SX\beta^* - Sy\|_1 - \|SX\beta - Sy\|_1) - (\|X\beta^* - y\|_1 - \|X\beta - y\|_1)| \right)^l \right] \\ & \leq \mathbb{E}_{S,S'} \left[ \left( \max_{\|X\beta^* - X\beta\|=1} |((\|SX\beta^* - Sy\|_1 - \|SX\beta - Sy\|_1) - (\|X\beta^* - y\|_1 - \|X\beta - y\|_1)) \right. \right. \\ & \quad \left. \left. - ((\|S'X\beta^* - S'y\|_1 - \|S'X\beta - S'y\|_1) - (\|X\beta^* - y\|_1 - \|X\beta - y\|_1)) \right| \right)^l \right] \end{aligned}$$

So, we can bound  $M$  as

$$M \leq \mathbb{E}_{S,S'} \left[ \left( \max_{\|X\beta^* - X\beta\|=1} |(\|SX\beta^* - Sy\|_1 - \|SX\beta - Sy\|_1) - (\|S'X\beta^* - S'y\|_1 - \|S'X\beta - S'y\|_1)| \right)^l \right]$$

## 49:18 L1 Regression with Lewis Weights Subsampling

Let  $i_k$  be the indices chosen by  $S$ , and  $i'_k$  the indices chosen by  $S'$ . Rewriting this as a sum,

$$M \leq \mathbb{E}_{S, S'} \left[ \left( \max_{\|X\beta^* - X\beta\|=1} \left| \sum_k \left( \frac{|x_{i_k}^\top \beta^* - y_{i_k}|}{p_{i_k}} - \frac{|x_{i_k}^\top \beta - y_{i_k}|}{p_{i_k}} \right) - \sum_k \left( \frac{|x_{i'_k}^\top \beta^* - y_{i'_k}|}{p_{i'_k}} - \frac{|x_{i'_k}^\top \beta - y_{i'_k}|}{p_{i'_k}} \right) \right| \right)^l \right]$$

Now, since  $i_k$  and  $i'_k$  are independent and identically distributed, randomly swapping elements from either sum does not change the distribution. This amounts to adding a random sign  $\sigma_k$  to the terms, where  $\sigma_k = \pm 1$  independently with probability  $1/2$ . So,

$$\begin{aligned} M &\leq \mathbb{E}_{S, S', \sigma} \left[ \left( \max_{\|X\beta^* - X\beta\|=1} \left| \sum_k \sigma_k \left( \frac{|x_{i_k}^\top \beta^* - y_{i_k}|}{p_{i_k}} - \frac{|x_{i_k}^\top \beta - y_{i_k}|}{p_{i_k}} \right) - \sum_k \sigma_k \left( \frac{|x_{i'_k}^\top \beta^* - y_{i'_k}|}{p_{i'_k}} - \frac{|x_{i'_k}^\top \beta - y_{i'_k}|}{p_{i'_k}} \right) \right| \right)^l \right] \\ &\leq \mathbb{E}_{S, S', \sigma} \left[ \left( \max_{\|X\beta^* - X\beta\|=1} \left| \sum_k \sigma_k \left( \frac{|x_{i_k}^\top \beta^* - y_{i_k}|}{p_{i_k}} - \frac{|x_{i_k}^\top \beta - y_{i_k}|}{p_{i_k}} \right) \right| + \max_{\|X\beta^* - X\beta\|=1} \left| \sum_k \sigma_k \left( \frac{|x_{i'_k}^\top \beta^* - y_{i'_k}|}{p_{i'_k}} - \frac{|x_{i'_k}^\top \beta - y_{i'_k}|}{p_{i'_k}} \right) \right| \right)^l \right] \\ &\leq 2^l \mathbb{E}_{S, \sigma} \left[ \left( \max_{\|X\beta^* - X\beta\|=1} \left| \sum_k \sigma_k \left( \frac{|x_{i_k}^\top \beta^* - y_{i_k}|}{p_{i_k}} - \frac{|x_{i_k}^\top \beta - y_{i_k}|}{p_{i_k}} \right) \right| \right)^l \right] \end{aligned}$$

Where the final inequality follows from  $(a + b)^l \leq 2^{l-1}(a^l + b^l)$ . Putting these together,

$$M \leq 2^l \mathbb{E}_{S, \sigma} \left[ \left( \max_{\|X\beta^* - X\beta\|=1} \left| \sum_k \sigma_k \left( \frac{|x_{i_k}^\top \beta^* - y_{i_k}|}{p_{i_k}} - \frac{|x_{i_k}^\top \beta - y_{i_k}|}{p_{i_k}} \right) \right| \right)^l \right] \quad (14)$$

◀

► **Lemma 33** (Similar to [4] Lemma B.1). *Let  $X$  be any matrix, and let  $W$  be the matrix that has the Lewis weights of  $X$  in the diagonal entries. Let  $N \geq \frac{d}{\varepsilon^2} \log \frac{d}{\varepsilon \delta}$ . There exist constants  $C_1, C_2, C_3$  such that we can construct a matrix  $X'$  such that*

- $X'$  has  $C_1 d N$  rows,
- $X'^\top W'^{-1} X' \succeq X^\top W^{-1} X$ , (where  $W'$  is the matrix that has the Lewis weights of  $X'$  in the diagonal entries),
- $\|X'\beta\|_1 \leq C_2 \|X\beta\|_1$  for all  $\beta$ ,
- the Lewis weights of  $X'$  are bounded by  $\frac{C_3}{N}$ .

**Proof.** Given matrix  $X$ , we can use Lemma B.1 from [4] to construct a new matrix  $X_1$  that satisfies

- $X_1$  has  $C_1 d^2$  rows,
- $X_1^\top W_1^{-1} X_1 \succeq X^\top W^{-1} X$ , (where  $W_1$  is the matrix that has the Lewis weights of  $X_1$  in the diagonal entries),
- $\|X_1\beta\|_1 \leq C_2 \|X\beta\|_1$  for all  $\beta$ ,
- the Lewis weights of  $X_1$  are bounded by  $\frac{C_3}{d}$ .

So, we can take this matrix and stack it on itself  $k = \frac{N}{d}$  times, while scaling each row down by the same  $k$ . This will be our matrix  $X'$ .  $X'$  will then have  $k = C_1 N d$  rows, which satisfies the first bullet. Also, by Lemma 10, this shrinks the Lewis weights by a factor of  $k$ , which changes the Lewis weight upper bound to  $\frac{C_3}{kd} = \frac{C_3}{N}$  which is what we need. Now, since we are repeating rows  $k$  times, but each row is scaled down by  $k$ , we have  $\|X_1 \beta\|_1 = \|X' \beta\|_1$  for all  $\beta$ . Therefore,  $\|X' \beta\|_1 \leq C_2 \|X \beta\|_1$  for all  $\beta$ . Finally, as in the proof of Lemma 10, we know that since we have duplicated the rows of  $X_1$   $k$  times but scaled them down by  $k$ ,  $X_1^\top W_1^{-1} X_1 = X'^\top W'^{-1} X'$ , and so we are done.  $\blacktriangleleft$

## B.1 Proof of Claims 15, 18, 19, 24, and 25

▷ **Claim 15.** For all  $\beta \in H$ , with probability at least  $1 - \delta$ ,

$$(1 - \varepsilon) \mathbb{E}_{(X,Y) \sim P} [|X^\top \beta - Y|] \leq \frac{1}{n} \|\mathbf{X}\beta - y\|_1 \leq (1 + \varepsilon) \mathbb{E}_{(X,Y) \sim P} [|X^\top \beta - Y|]$$

Proof of Claim 15. By assumption, we know that  $X^\top \beta, Y \in [-1, 1]$ , so,  $|X^\top \beta - Y| \in [0, 2]$ . So, for fixed  $\beta$ , by Hoeffding's on the rows of  $\mathbf{X}\beta - y$ , we have that if  $n \geq \frac{8}{\varepsilon^2} \log \frac{2}{\delta'}$ , then with probability at least  $1 - \delta'$ ,

$$\left(1 - \frac{\varepsilon}{2}\right) \mathbb{E}_{(X,Y) \sim P} [|X^\top \beta - Y|] \leq \frac{1}{n} \|\mathbf{X}\beta - y\|_1 \leq \left(1 + \frac{\varepsilon}{2}\right) \mathbb{E}_{(X,Y) \sim P} [|X^\top \beta - Y|] \quad (15)$$

Now, we construct a  $\frac{\varepsilon}{2d}$ -covering  $S$  of the unit  $\ell_\infty$  ball  $H$ , with fewer than  $\left(\frac{4d}{\varepsilon}\right)^d$  elements, so that for any  $\beta$ , there is some  $\beta_c \in S$  such that  $\|\beta - \beta_c\|_\infty \leq \frac{\varepsilon}{2d}$ . To do this, simply take  $S = \{\beta : \beta_i = k \frac{\varepsilon}{2d}, k \in \mathbb{Z} \cap [-2d/\varepsilon, 2d/\varepsilon]\}$ .

Note that  $\mathbf{X}$  has rows on the hypercube. So, if we denote  $x_{i,j}$  to be the entry of  $\mathbf{X}$  in the  $i$ th row and  $j$ th column, then  $x_{i,j} \in \{-1, 1\}$ . Therefore, for any  $\beta$ ,

$$\|\mathbf{X}\beta\|_1 = \sum_{i=1}^n |x_i^\top \beta| \leq \sum_{i=1}^n \sum_{j=1}^d |x_{i,j} \beta_j| \leq \sum_{i=1}^n \sum_{j=1}^d |\beta_j| \leq nd \|\beta\|_\infty$$

Therefore, we can apply Hoeffding's, as in (15), with  $\delta' = \delta \left(\frac{\varepsilon}{4d}\right)^d$ , and union bound over the set  $S$ , to get that for any  $\beta \in S$ , with probability at least  $1 - \delta$ , (15) holds.

Then, for any  $\beta \in H$ , by the covering property, we can find some  $\beta_c \in S$  such that

$$\|\beta - \beta_c\|_\infty \leq \frac{\varepsilon}{d} \implies \|\mathbf{X}\beta - \mathbf{X}\beta_c\|_1 \leq n\varepsilon. \quad (16)$$

We have

$$\|\mathbf{X}\beta_c - y\|_1 - \|\mathbf{X}\beta_c - \mathbf{X}\beta\|_1 \leq \|\mathbf{X}\beta - y\|_1 \leq \|\mathbf{X}\beta - \mathbf{X}\beta_c\|_1 + \|\mathbf{X}\beta_c - y\|_1$$

So, combining (15) and (16), and dividing by  $n$ , we finally have that if  $n \geq \frac{8}{\varepsilon^2} \left(\log \frac{2}{\delta} + d \log \frac{4d}{\varepsilon}\right)$ , then for all  $\beta \in H$ ,

$$(1 - \varepsilon) \mathbb{E}_{(X,Y) \sim P} [|X^\top \beta - Y|] \leq \frac{1}{n} \|\mathbf{X}\beta - y\|_1 \leq (1 + \varepsilon) \mathbb{E}_{(X,Y) \sim P} [|X^\top \beta - Y|] \quad \triangleleft$$

▷ **Claim 18.** For  $D, \mathcal{B}$  as chosen above,  $l(\beta^*) = 1 - 2\varepsilon$ .

## 49:20 L1 Regression with Lewis Weights Subsampling

Proof of Claim 18. The  $\ell_1$  error for the correct  $\beta$  is given by

$$\begin{aligned}
& \mathbb{E}_{(X,Y) \sim P} |X^\top \beta^* - Y| \\
&= \mathbb{E}_X [E_{Y \sim P(\cdot|X)} |X^\top \beta^* - Y|] && \text{by independence} \\
&= \mathbb{E}_X \left[ \left( \frac{1}{2} + \varepsilon \right) |X^\top \beta^* - X^\top \beta^*| + \left( \frac{1}{2} - \varepsilon \right) |X^\top \beta^* + X^\top \beta^*| \right] \\
&= \mathbb{E}_X [(1 - 2\varepsilon) |X^\top \beta^*|] && \beta^* \in \mathcal{H} \\
&= 1 - 2\varepsilon && \triangleleft
\end{aligned}$$

▷ **Claim 19.** For  $D, \mathcal{B}$  as chosen above, we have for all  $\beta \in \mathcal{B}$ ,  $l(\beta) - l(\beta^*) = \frac{2\varepsilon}{d} \|\beta - \beta^*\|_1$ .

Proof of Claim 19.

$$\begin{aligned}
& \mathbb{E}_{(X,Y) \sim P} |X^\top \beta - Y| \\
&= \mathbb{E}_X [E_{Y \sim P(\cdot|X)} |X^\top \beta - Y|] \\
&= \mathbb{E}_X \left[ \left( \frac{1}{2} + \varepsilon \right) |X^\top \beta - X^\top \beta^*| + \left( \frac{1}{2} - \varepsilon \right) |X^\top \beta + X^\top \beta^*| \right] \\
&= (1 - 2\varepsilon) + 2\varepsilon \mathbb{E}_X [X^\top \beta - X^\top \beta^*] \\
&= (1 - 2\varepsilon) + 2\varepsilon \frac{1}{d} \|\beta - \beta^*\|_1 && \triangleleft
\end{aligned}$$

▷ **Claim 21.** For any  $\beta$ ,  $\max\{\ell_{\beta_{(1)}^*}(\beta) - \ell_{\beta_{(1)}^*}(\beta_{(1)}^*), \ell_{\beta_{(2)}^*}(\beta) - \ell_{\beta_{(2)}^*}(\beta_{(2)}^*)\} > 2\varepsilon$

Proof of Claim 21.

$$\begin{aligned}
l(\beta) + l(\beta) &= 2 - 4\varepsilon + \frac{2\varepsilon}{d} \|\beta_{(1)}^* - \beta\|_1 + \frac{2\varepsilon}{d} \|\beta_{(2)}^* - \beta\|_1 \\
&\geq 2 - 4\varepsilon + \frac{2\varepsilon}{d} \|\beta_{(2)}^* - \beta_{(1)}^*\|_1 \\
&= 2 \\
\implies \max\{\ell_{\beta_{(1)}^*}(\beta) - \ell_{\beta_{(1)}^*}(\beta_{(1)}^*), \ell_{\beta_{(2)}^*}(\beta) - \ell_{\beta_{(2)}^*}(\beta_{(2)}^*)\} &> 2\varepsilon, && \forall \beta \in \mathbb{R}^d \\
&&& \triangleleft
\end{aligned}$$

▷ **Claim 24.** For all  $i \in [d], \beta \in \mathbb{R}^d$ , we have  $\ell_{\beta_{(i)}^*}(\beta) \geq \frac{1}{4d}$  with equality when  $\beta = \beta_{(i)}^*$

Proof of Claim 24.

$$\begin{aligned}
\ell_{\beta_{(i)}^*}(\beta) &= \frac{1}{d} \sum_{j \neq i} |\beta_j| + \frac{\frac{1}{2} + \varepsilon}{d} |1 - \beta_i| + \frac{\frac{1}{2} - \varepsilon}{d} |\beta_i| \\
&\geq \frac{\frac{1}{2} - \varepsilon}{d} (|\beta_i| + |1 - \beta_i|) + \frac{2\varepsilon}{d} |1 - \beta_i| \geq \frac{\frac{1}{2} - \varepsilon}{d} && \triangleleft
\end{aligned}$$

▷ **Claim 25.** Any  $\beta \in \mathbb{R}^d$  can only satisfy  $\ell_{\beta_{(i)}^*}(\hat{\beta}) < \frac{1}{2d}$  for one  $i \in [d]$ .

Proof of Claim 25. Indeed, suppose  $\beta$  was such that  $\ell_{\beta_{(I)}}^*(\beta), \ell_{\beta_{(J)}}^*(\beta) < \frac{1}{2d}$ . Then we must have

$$\begin{aligned}
\frac{1}{2d} &\geq \ell_{\beta_{(I)}}^*(\beta) \\
&= \frac{1}{d} \sum_{j \neq I} |\beta_j| + \frac{\frac{1}{2} - \varepsilon}{d} (|\beta_I| + |1 - \beta_I|) + \frac{2\varepsilon}{d} |1 - \beta_I| \\
&\geq \frac{1}{d} \sum_{j \neq I} |\beta_j| + \frac{\frac{1}{2} - \varepsilon}{d} + \frac{2\varepsilon}{d} |1 - \beta_I| \\
\iff \varepsilon &\geq \sum_{j \neq I} |\beta_j| + 2\varepsilon |1 - \beta_I| \\
&\geq \sum_{j \neq I} |\beta_j| + 2\varepsilon - 2\varepsilon |\beta_I| \\
\iff 2|\beta_I| &\geq \|\beta\|_1 + 2\varepsilon
\end{aligned}$$

Similarly for  $J$ , so we would have  $\|\beta\| \geq |\beta_I| + |\beta_J| \geq \|\beta\|_1 + 2\varepsilon$ . ◁

# Hitting Sets for Orbits of Circuit Classes and Polynomial Families

## Abstract

---

The orbit of an  $n$ -variate polynomial  $f(\mathbf{x})$  over a field  $\mathbb{F}$  is the set  $\{f(A\mathbf{x} + \mathbf{b}) : A \in \text{GL}(n, \mathbb{F}) \text{ and } \mathbf{b} \in \mathbb{F}^n\}$ . In this paper, we initiate the study of explicit hitting sets for the *orbits* of polynomials computable by several natural and well-studied circuit classes and polynomial families. In particular, we give quasi-polynomial time hitting sets for the orbits of:

1. Low-individual-degree polynomials computable by *commutative ROABPs*. This implies quasi-polynomial time hitting sets for the orbits of the *elementary symmetric polynomials*.
2. Multilinear polynomials computable by *constant-width ROABPs*. This implies a quasi-polynomial time hitting set for the orbits of the family  $\{\text{IMM}_{3,d}\}_{d \in \mathbb{N}}$ , which is complete for arithmetic formulas.
3. Polynomials computable by *constant-depth, constant-occur formulas*. This implies quasi-polynomial time hitting sets for the orbits of *multilinear depth-4 circuits with constant top fan-in*, and also polynomial-time hitting sets for the orbits of the *power symmetric* and the *sum-product polynomials*.
4. Polynomials computable by *occur-once formulas*.

## 1 Introduction

Polynomial identity testing (PIT) is a fundamental problem in arithmetic circuit complexity. PIT is the problem of deciding if a given arithmetic circuit computes an identically zero polynomial. It is one of the few natural problems in BPP (in fact, in co-RP) for which we do not know of deterministic polynomial-time algorithms. A probabilistic polynomial-time algorithm for PIT follows from the DeMillo-Lipton-Schwartz-Zippel lemma [15, 71, 78]. PIT has connections to other interesting problems like perfect matching [19, 41, 49, 53, 75], the linear matroid intersection [33, 55], and the maximum rank matrix completion [33, 54]. The deterministic primality testing algorithm in [4] derandomizes a particular instance of PIT over a ring [2]. Also, multivariate polynomial factorization for general circuits can be efficiently reduced to PIT and factoring univariate polynomials [37, 38, 48]. Moreover, derandomizing PIT or the black-box version of PIT<sup>1</sup> is essentially equivalent to proving arithmetic circuit lower bounds.

---

<sup>1</sup> An algorithm for the black-box PIT problem takes as input black-box access to a circuit. The algorithm cannot “see” the circuit but can query it at any point [1, 34, 36, 57]. The black-box PIT problem for a circuit class  $\mathcal{C}$  is also known as the problem of constructing *hitting sets* for  $\mathcal{C}$

In the past two decades, PIT algorithms and hitting set constructions have been studied for various restricted classes/models of circuits. Bounding the read of every variable is a natural restriction that has received a lot of attention. Two constant-read models, viz. *read-once oblivious algebraic branching programs* (ROABPs) and *constant-read* (more generally, *constant-occur*) *formulas*. These models are quiet powerful and capture many interesting circuit classes. A polynomial-time PIT algorithm and a quasi-polynomial time hitting set construction for ROABPs are known [3, 23, 61]. A quasi-polynomial time hitting set construction for multilinear constant-read formulas was given by [10]. [5] obtained polynomial-time constructible hitting sets for constant-depth, constant-occur formulas.

**Hitting sets for orbits.** In this paper, we study hitting set constructions for the *orbits* of ROABPs and constant-occur formulas. The orbit of a polynomial  $f$  is the set of polynomials obtained by applying invertible affine transformations on the variables of  $f$ , i.e., by replacing the variables of  $f$  with linearly independent affine forms. The orbit of a circuit class is the union of the orbits of the polynomials computable by the circuits in the class. Our reasons for studying hitting sets for the orbits of ROABPs and constant-occur formulas are threefold:

1. *The power of orbit closures:* The set of affine projections of an  $n$ -variate polynomial  $f(\mathbf{x})$  over a field  $\mathbb{F}$  is  $\text{aproj}(f) := \{f(A\mathbf{x} + \mathbf{b}) : A \in \mathbb{F}^{n \times n} \text{ and } \mathbf{b} \in \mathbb{F}^n\}$ ; the orbit of  $f$  is the set  $\text{orb}(f) = \{f(A\mathbf{x} + \mathbf{b}) : A \in \text{GL}(n, \mathbb{F}) \text{ and } \mathbf{b} \in \mathbb{F}^n\} \subseteq \text{aproj}(f)$ . Affine projections of polynomials computable by polynomial-size ROABPs or constant-occur formulas have great expressive power. All polynomials computed by algebraic branching programs and arithmetic formulas are affine projections of polynomial width ROABPs and constant ROABPs, respectively. Similarly, all polynomials computed by depth-3 arithmetic circuits (which are quiet powerful [7, 30, 46, 76, 77]) and arithmetic formulas are affine projections of read once formulas. The orbit of  $f$  being a mathematically interesting subset of  $\text{aproj}(f)$ , it is natural to ask if we can construct efficient hitting sets for the orbits of the above-mentioned circuit classes. Moreover,  $\text{orb}(f)$  is not “much smaller” than  $\text{aproj}(f)$ , as the latter is contained in the *orbit closure* of  $f$  if  $\text{char}(\mathbb{F}) = 0$  (see the full version [64] for more details).
2. *Geometry of the circuit classes:* Consider an  $n$ -variate polynomial  $f \in \mathbb{R}[\mathbf{x}]$  and let  $\mathbb{V}(f)$  be the variety (i.e., the zero locus) of  $f$ . The geometry of  $\mathbb{V}(f)$  is preserved by any rigid transformation on  $\mathbb{R}^n$ . Computation of a set  $\mathcal{H} \subseteq \mathbb{R}^n$  that is not contained in  $T(\mathbb{V}(f))$ , for every rigid transformation  $T$ , would have to be “mindful” of the geometry of  $\mathbb{V}(f)$  and oblivious to the choice of the coordinate system. Computing such an  $\mathcal{H}$  is exactly the problem of constructing a hitting set for the polynomials  $\{f(R\mathbf{x} + \mathbf{b}) : R \in O(n, \mathbb{R}) \text{ and } \mathbf{b} \in \mathbb{R}^n\}$ . We can generalize the problem slightly by replacing  $R \in O(n, \mathbb{R})$  with  $A \in \text{GL}(n, \mathbb{R})$ . A hitting set for ROABPs or constant-occur formulas does not immediately give a hitting set for  $\{f(A\mathbf{x} + \mathbf{b}) : A \in \text{GL}(n, \mathbb{R}) \text{ and } \mathbf{b} \in \mathbb{R}^n\}$ , as the definitions of an ROABP and a constant-occur formula are tied to the choice of the coordinate system. It is thus natural to ask if there is anything special about the geometry of  $\mathbb{V}(f)$  which can facilitate efficient constructions of hitting sets for  $\text{orb}(f)$ .
3. *Strengthening existing techniques:* Finally, it is worth investigating whether the techniques used to design hitting sets for ROABPs and constant-occur formulas can be applied or strengthened or combined to give hitting sets for the orbits of these circuit classes.

## 1.1 The models

Unless otherwise stated, we will assume that polynomials are over a field  $\mathbb{F}$ . Read Once Algebraic Branching Programs (ROABPs) are the read once versions of Algebraic Branching Programs defined by Nisan [56]. While Nisan defined ABPs using directed graphs, we use the following equivalent and conventional definition of an ROABP.

► **Definition 1** (ROABP [23]). *An  $n$ -variate, width- $w$  read-once oblivious algebraic branching program (ROABP) is a product of the form  $\mathbf{1}^T \cdot M_1(x_1)M_2(x_2) \cdots M_n(x_n) \cdot \mathbf{1}$ , where  $\mathbf{1}$  is the  $w \times 1$  vector of all ones, and for every  $i \in [n]$ ,  $M_i(x_i)$  is a  $w \times w$  matrix whose entries are in  $\mathbb{F}[x_i]$ .*

► **Definition 2** (Commutative ROABP). *An  $n$ -variate, width- $w$  commutative ROABP is an  $n$ -variate, width- $w$  ROABP  $\mathbf{1}^T \cdot M_1(x_1)M_2(x_2) \cdots M_n(x_n) \cdot \mathbf{1}$ , where for all  $i, j \in [n]$ ,  $M_i(x_i)$  and  $M_j(x_j)$  commute with each other.*

A polynomial  $f$  is  $s$ -sparse if it has at most  $s$  monomials with non-zero coefficients; these monomials will be referred to as the *monomials of  $f$* . A degree- $d$   $s$ -sparse polynomial can be computed by a depth-2 circuit of size  $sd$  as well as by a width- $s$  commutative ROABP.

► **Definition 3** (Occur- $k$  formula [5]). *An occur- $k$  formula is a rooted tree whose leaves are labelled by  $s$ -sparse polynomials and whose internal nodes are sum (+) gates or product-power ( $\times\lambda$ ) gates. Each variable appears in at most  $k$  of the sparse polynomials that label the leaves. The edges feeding into a + gate are labelled by field elements and have 1 as edge weights, whereas the edges feeding into a  $\times\lambda$  gate have natural numbers as edge weights. A leaf node computes the  $s$ -sparse polynomial that labels it. A + gate with inputs from nodes that compute  $f_1, \dots, f_m$  and with the corresponding input edge labels  $\alpha_1, \dots, \alpha_m$ , computes  $\alpha_1 f_1 + \cdots + \alpha_m f_m$ . A  $\times\lambda$  gate with inputs from nodes that compute  $f_1, \dots, f_m$  and with the corresponding input edge weights  $e_1, \dots, e_m$ , computes  $f_1^{e_1} \cdots f_m^{e_m}$ . The formula computes the polynomial that is computed by the root node.*

*The size of an occur- $k$  formula is the weighted sum of all the edges in it (i.e., an edge is counted as many times as its edge weight) plus the sizes of the depth-2 circuits computing the  $s$ -sparse polynomials at the leaves. The depth of an occur- $k$  formula is equal to the depth of the underlying tree plus 2, to account for the depth of the circuits computing the sparse polynomials at the leaves.*

Read- $k$  formulas have been studied intensely in the literature (see Section 1.4). Occur- $k$  formulas generalize read- $k$  formulas in two ways – the leaves are labelled by arbitrary sparse polynomials instead of just variables, and powering gates are included along with the usual sum and product gates. These generalizations help make the occur- $k$  model complete<sup>2</sup>, and capture other interesting circuit classes (such as multilinear depth-4 circuits with constant top fan-in [39, 65]) and polynomial families (such as the power symmetric polynomials). Besides, unlike some prior work [10, 39, 65], there is no restriction of multilinearity on the model. We will identify the variable set  $\mathbf{x} = \{x_1, \dots, x_n\}$  with the column vector  $(x_1 \ x_2 \ \cdots \ x_n)^T$ .

► **Definition 4** (Orbits of polynomials). *Let  $f(\mathbf{x})$  be an  $n$ -variate polynomial over a field  $\mathbb{F}$ . The orbit of  $f$ , denoted by  $\text{orb}(f)$ , is the set  $\{f(A\mathbf{x}) : A \in \text{GL}(n, \mathbb{F})\}$ . The orbit of a set of polynomials  $\mathcal{C}$ , denoted by  $\text{orb}(\mathcal{C})$ , is the union of the orbits of the polynomials in  $\mathcal{C}$ .*

<sup>2</sup> For example, the power symmetric polynomial  $x_1^n + \dots + x_n^n$  cannot be computed by a read- $k$  formula for any  $k < n$ , but it can be computed by an occur-once formula.

The results we present in this paper hold even if we define the orbit of an  $n$ -variate polynomial  $f$  as  $\text{orb}(f) = \{f(A\mathbf{y} + \mathbf{b}) : |\mathbf{y}| = m \geq n, A \in \mathbb{F}^{n \times m} \text{ has rank } n, \text{ and } \mathbf{b} \in \mathbb{F}^n\}$ . However, we work with this slightly conventional definition of  $\text{orb}(f)$  for simplicity of exposition, and because the proofs in the general setting are nearly the same as the proofs we present here. By the “orbit of a circuit class  $\mathcal{C}$ ”, we mean the union of the orbits of the polynomials computable by the circuits in the class  $\mathcal{C}$ . Our main results are efficient constructions of hitting sets for the orbits of commutative ROABPs and constant-width ROABPs (under low individual degree restriction), and the orbits of constant-depth constant-occur formulas and occur-once formulas.

## 1.2 Our results

► **Definition 5** (Hitting set). *Let  $\mathcal{C}$  be a set of  $n$ -variate polynomials. A set of points  $\mathcal{H} \subseteq \mathbb{F}^n$  is a hitting set for  $\mathcal{C}$  if for every non-zero  $f \in \mathcal{C}$ , there is a point  $\mathbf{a} \in \mathcal{H}$  such that  $f(\mathbf{a}) \neq 0$ .*

By a “ $T$ -time hitting set”, we mean that the hitting set can be computed in  $T$  time. The *individual degree* of a monomial is the largest of the exponents of the variables that appear in it. The individual degree of a polynomial is the largest of the individual degrees of its monomials. We are now ready to state our results.

► **Theorem 6** (Hitting sets for the orbits of commutative ROABPs with low individual degree). *Let  $\mathcal{C}$  be the set of  $n$ -variate polynomials with individual degree at most  $d$  that are computable by width- $w$  commutative ROABPs. If  $|\mathbb{F}| > n^2d$ , then a hitting set for  $\text{orb}(\mathcal{C})$  can be computed in  $(nd)^{O(d \log w)}$  time.*

We say an  $n$ -variate polynomial  $f(x_1, x_2, \dots, x_n)$  can be expressed as a sum of  $s$  products of univariates if  $f = \sum_{i \in [s]} \prod_{j \in [n]} f_{i,j}(x_j)$ , where each  $f_{i,j}(x_j)$  is a univariate polynomial in  $x_j$ . This model is subsumed by commutative ROABPs and has found important applications in several other works [30, 63, 66]. The above theorem implies a  $nd^{O(d \log s)}$  time hitting set for this model. As the elementary symmetric polynomials and low individual degree sparse polynomials are special cases of low individual degree sum of products of univariates, we also get quasi-polynomial hitting sets for these models. It turns out though that for the particular case of sparse polynomials it is possible to remove the individual degree restriction from the above theorem. This is due to an independent and simultaneous work by [51]. We state their result next.

► **Theorem 7** (Hitting sets for the orbits of sparse polynomials [51]). *Let  $\mathcal{C}$  be the set of  $n$ -variate,  $s$ -sparse polynomials of degree at most  $d$ . If  $|\mathbb{F}| > nd$  and  $\text{char}(\mathbb{F}) = 0$  or  $> d$ , then a hitting set for  $\text{orb}(\mathcal{C})$  can be computed in  $(nd)^{O(\log s)}$  time.*

The above theorem plays a basic role in the proofs of Theorem 9 and Theorem 10. There, we apply the algebraic independence based analysis from [5, 11] and the Shpilka-Volkovich (SV) generator based argument from [73], respectively, to reduce to the case of constructing hitting sets for the orbits of sparse polynomials. While in the original version of our work [64] we applied Theorem 6 in the base case of the proofs of Theorem 9 and 10, here we plug-in Theorem 7 in the base case. This helps us forgo the low individual degree restriction that was present in these theorems in the original version.

► **Theorem 8** (Hitting sets for the orbits of multilinear constant-width ROABPs). *Let  $\mathcal{C}$  be the set of  $n$ -variate multilinear polynomials that are computable by width- $w$  ROABPs. If  $|\mathbb{F}| > n^{O(w^4)}$ , then a hitting set for  $\text{orb}(\mathcal{C})$  can be computed in  $n^{O(w^6 \cdot \log n)}$  time.*

The theorem gives a quasi-polynomial time hitting set for  $\text{orb}(\text{IMM}_{3,d})$ , which is complete for the class of arithmetic formulas under affine projections (in fact, under  $p$ -projections) [12]. The set of affine projections of  $\text{IMM}_{2,d}$  is also quite rich, despite the fact that there are simple quadratic polynomials that are not in  $\text{aproj}(\text{IMM}_{2,d})$  for *any*  $d$  [8, 62]. This is because hitting sets for  $\text{aproj}(\text{IMM}_{2,d})$  give hitting sets for depth-3 circuits [62]. Moreover,  $\overline{\text{orb}(\text{IMM}_{2,d})}$  captures the orbit closures of arithmetic formulas [13]. The above theorem implies a quasi-polynomial time hitting set for  $\text{orb}(\text{IMM}_{2,d})$ .

► **Theorem 9** (Hitting sets for the orbits of constant-depth, constant-occur formulas). *Let  $\mathcal{C}$  be the set of  $n$ -variate, degree- $D$  polynomials that are computable by depth- $\Delta$ , occur- $k$  formulas of size  $s$ . Let  $R := (2k)^{2\Delta \cdot 2^\Delta}$ . If  $\text{char}(\mathbb{F}) = 0$  or  $> (2ks)^{\Delta^3 R}$ , then a hitting set for  $\text{orb}(\mathcal{C})$  can be computed in  $(nRD)^{O(R(\log R + \Delta \log k + \Delta \log s) + \Delta R)}$  time. If the leaves are labelled by  $b$ -variate polynomials, then a hitting set for  $\text{orb}(\mathcal{C})$  can be computed in  $(nRD)^{O(Rb + \Delta R)}$  time. In particular, if  $\Delta$  and  $k$  are constants, then the hitting sets can be constructed in time  $(nD)^{O(\log s)}$  and  $(nD)^{O(b)}$ , respectively.*

The above theorem gives quasi-polynomial hitting sets for the orbits of two other interesting models viz. multilinear depth-4 circuits with constant top fan-in and the class of polynomials  $C(f_1, \dots, f_m)$ , where  $C$  is a low-degree circuit and  $f_1, \dots, f_m$  are sparse polynomials with bounded transcendence degree [11]. The theorem also yields polynomial-time hitting sets for the orbits of the power symmetric polynomial and the sum-product polynomial  $\text{SP}_{n,D} = \sum_{i \in [n]} \prod_{j \in [D]} x_{i,j}$ . Prior to our work, [47] gave a polynomial-time hitting set for the orbit of power symmetric polynomials using a different argument.

► **Theorem 10** (Hitting sets for the orbits of occur-once formulas). *Let  $\mathcal{C}$  be the set of  $n$ -variate, degree- $D$  polynomials that are computable by occur-once formulas whose leaves are labelled by  $s$ -sparse polynomials. If  $|\mathbb{F}| > nD$  and  $\text{char}(\mathbb{F}) = 0$  or  $> D$ , then a hitting set for  $\text{orb}(\mathcal{C})$  can be computed in  $(nD)^{O(\log n + \log s)}$  time. If the leaves are labelled by  $b$ -variate polynomials, then a hitting set for  $\text{orb}(\mathcal{C})$  can be computed in  $(nD)^{O(\log n + b)}$  time.*

The independent and concurrent work [51] gave (among other results) a quasi-polynomial time hitting set for the orbits of read-once formulas. We note that this result also follows from the second part of the above theorem which is already present in the original version of this work [64]. The proofs of Theorems 9 and 10 can be found in the full version [64].

### 1.3 Proof techniques

Let us briefly discuss the techniques that go into proving the above results.

**Commutative ROABPs with low individual degree.** Theorem 6 is proved by adapting the rank concentration by translation technique of [6] to work for the orbits of commutative ROABPs. Let  $f = \mathbf{1}^T \cdot M_1(x_1)M_2(x_2) \cdots M_n(x_n) \cdot \mathbf{1}$  be a commutative ROABP and  $F = M_1(x_1)M_2(x_2) \cdots M_n(x_n)$ . For any  $A \in \text{GL}(n, \mathbb{F})$ , let  $g = f(A\mathbf{x})$  and  $G = F(A\mathbf{x})$ . Suppose that  $A$  maps  $x_i$  to a linear form  $\ell_i(\mathbf{x})$  for every  $i \in [n]$ , and let  $y_i = \ell_i(\mathbf{x})$ . Then,  $g = \mathbf{1}^T \cdot M_1(y_1)M_2(y_2) \cdots M_n(y_n) \cdot \mathbf{1}$  and  $G = M_1(y_1)M_2(y_2) \cdots M_n(y_n)$ . We show that if  $g \neq 0$ , then there exist *explicit* “low” degree polynomials  $t_1(\mathbf{z}), \dots, t_n(\mathbf{z})$ , where  $\mathbf{z}$  is a “small” set of variables, such that  $g(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z}))$  has a “low” support monomial. This is done by proving that  $G(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z}))$  has low support rank concentration over  $\mathbb{F}(\mathbf{z})$  in the “ $\mathbf{y}$ -variables” (see Section 2.2 for the meaning of low support rank concentration.). That done, we use the assumption that  $f$  has low individual degree to argue that  $g(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z}))$  also has a low support  $\mathbf{x}$ -monomial. This and the fact that  $|\mathbf{z}|$  is small imply that  $g(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z}))$ , when viewed as a polynomial in  $\mathbb{F}[\mathbf{x}, \mathbf{z}]$ , has a low support monomial. Finally, we use the SV generator to hit  $g$ .

Our analysis differs from that in [6] at a crucial point: In [6], it was shown that  $F(\mathbf{x} + \mathbf{t}) = M_1(x_1 + t_1)M_2(x_2 + t_2) \cdots M_n(x_n + t_n)$  has low support rank concentration over  $\mathbb{F}(\mathbf{t})$  if the nonzeroness of every polynomial in a certain collection of polynomials – each in a “small” set of  $\mathbf{t}$ -variables – is preserved. As each polynomial in the collection has “few”  $\mathbf{t}$ -variables, a substitution  $t_i \leftarrow t_i(\mathbf{z})$  that preserves its nonzeroness is relatively easy to construct. But the collection of polynomials that we need to preserve to show low support rank concentration for  $G(\mathbf{x} + \mathbf{t})$  is such that every polynomial in the collection has potentially all the  $\mathbf{t}$ -variables. However, we are able to argue that each of these polynomials still has a low support  $\mathbf{t}$ -monomial. This then helps us construct a substitution  $t_i \mapsto t_i(\mathbf{z})$  that preserves the nonzeroness of these polynomials.

**Multilinear constant-width ROABPs.** Theorem 8 is proved by combining the rank concentration by translation technique of [6] with the merge-and-reduce idea from [23] and [21]. Let  $f = \mathbf{1}^T \cdot M_1(x_1)M_2(x_2) \cdots M_n(x_n) \cdot \mathbf{1}$  be a multilinear, width- $w$  ROABP; here  $M_i(x_i) \in \mathbb{F}^{w \times w}[x_i]$  for all  $i \in [n]$ . Also, let  $F = M_1(x_1)M_2(x_2) \cdots M_n(x_n)$ . For any  $A \in \text{GL}(n, \mathbb{F})$ , let  $g = f(A\mathbf{x})$  and  $G = F(A\mathbf{x})$ . For  $i \in [n]$ , suppose that  $A$  maps  $x_i \mapsto \ell_i(\mathbf{x})$ , where  $\ell_i$  is a linear form, and let  $y_i = \ell_i(\mathbf{x})$  and  $\mathbf{y} = \{y_1, \dots, y_n\}$ . Then,  $g = \mathbf{1}^T \cdot M_1(y_1)M_2(y_2) \cdots M_n(y_n) \cdot \mathbf{1}$  and  $G = M_1(y_1)M_2(y_2) \cdots M_n(y_n)$ . Much like in the case of commutative ROABPs, we show that if  $g \neq 0$ , then there exist explicit “low” degree polynomials  $t_1(\mathbf{z}), \dots, t_n(\mathbf{z})$ , where  $\mathbf{z}$  is a “small” set of variables such that  $G(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z}))$  has “low” support rank concentration in the “ $\mathbf{y}$ -variables”. While in the rank concentration argument for commutative ROABPs the  $\mathbf{x}$ -variables were translated only once, here the translations can be thought of as happening sequentially and in stages. There will be  $\lceil \log n \rceil$  stages with each stage also consisting of multiple translations. After the  $p$ -th stage, the product of any  $2^p$  consecutive matrices in  $G$  will have low support rank concentration in the  $\mathbf{y}$ -variables. Thus, after  $\lceil \log n \rceil$  stages, we will have low support rank concentration in the  $\mathbf{y}$ -variables for  $G(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z}))$ .

As in the case of commutative ROABPs, we show that  $G(\mathbf{x} + \mathbf{t})$  has low support rank concentration if each polynomial in a certain collection of non-zero polynomials in the  $\mathbf{t}$ -variables is kept non-zero by the substitution  $t_i \mapsto t_i(\mathbf{z})$ . However, in this case, it is trickier to show that these polynomials have low support  $\mathbf{t}$ -monomials. We do this by arguing that each such polynomial can be expressed as a ratio of a polynomial that contains a low support  $\mathbf{t}$ -monomial and a product of linear forms in the  $\mathbf{t}$ -variables.

**Constant-depth, constant-occur formulas.** We prove Theorem 9 by combining the algebraic independence based technique in [5] with Theorem 7. Let  $f$  be a constant-depth, constant-occur formula. We first show that it can be assumed without loss of generality that the top-most gate of  $f$  is a  $+$  gate whose fan-in is upper bounded by the occur of  $f$ , say  $k$ . In [5], they were able to upper bound the top fan-in by simply translating a variable by 1 and subtracting the original formula. However, the same idea does not quite work here, because we have only access to a polynomial in the *orbit* of  $f$ . To upper bound the top fan-in, we show that there exists a variable  $x_i$  such that  $\frac{\partial f}{\partial x_i}$  is a constant-depth, constant-occur formula with top fan-in bounded by  $k$ . Then, using the chain rule of differentiation, we show that one can construct a hitting set generator for  $\text{orb}(f)$  from a generator for  $\text{orb}\left(\frac{\partial f}{\partial x_i}\right)$ ; this means that we can shift our attention to  $f' = \frac{\partial f}{\partial x_i}$ , which we shall henceforth refer to as  $f$ .

Let  $f = f_1 + \dots + f_k$ ,  $A \in \text{GL}(n, \mathbb{F})$ ,  $g = f(A\mathbf{x})$ ,  $g = g_1 + \dots + g_k$  where for all  $i \in [k]$ ,  $g_i = f_i(A\mathbf{x})$ . It was shown in [5] that a homomorphism, which is faithful (see Definition 17) to  $f_1, \dots, f_k$ , is a hitting set generator for  $f$ . In our case, this translates to ‘a

homomorphism that is faithful to  $g_1, \dots, g_k$  is a hitting set generator for  $g$ . [5] also showed that the problem of constructing a homomorphism  $\phi$  that is faithful to  $f_1, \dots, f_k$  reduces to constructing a homomorphism  $\psi$  that preserves the determinant of a certain matrix. This matrix is an appropriate sub-matrix of the Jacobian of  $f_1, \dots, f_k$ . Also, it was argued that its determinant is a product of sparse polynomials and so  $\psi$  was obtained from [45]. We use a similar argument, along with the chain rule, to show that the problem of constructing a homomorphism  $\phi$  that is faithful to  $g_1, \dots, g_k$  reduces to constructing a homomorphism  $\psi$  that preserves the determinant of a sub-matrix of the same Jacobian *evaluated at*  $A\mathbf{x}$ . As this determinant is a product of polynomials in the orbit of sparse polynomials, we can use Theorem 7 to construct such a  $\psi$ .

**Occur-once formulas.** We prove Theorem 10 by building upon the arguments in [73] and linking it with Theorem 7. At first, we show two structural results for occur-once formulas. These lemmas are generalizations of similar structural results for read-once formulas shown in [73]. Much like in [73], the structural results help us show that for a “typical” occur-once formula  $f$  with a  $+$  gate as the root node, there exists a variable  $x_i$  such that  $\frac{\partial f}{\partial x_i}$  is a product of occur-once formulas, each of which has at most half as many non-constant leaves as  $f$ . We then use this fact to show that a hitting-set generator for  $\text{orb}(f)$  can be constructed from a generator for  $\text{orb}\left(\frac{\partial f}{\partial x_i}\right)$ . [73] uses the derivatives of  $f$  in a similar way to show that a generator for  $f$  can be constructed from that for  $\frac{\partial f}{\partial x_i}$  using the SV generator (see Definition 12). However, in our case, we want a generator for  $\text{orb}(f)$  and not just for  $f$ . For this reason, we first use the chain rule for derivatives to relate the gradient of a  $g \in \text{orb}(f)$  with that of  $f$ , and then argue that there exists a  $x_j$  such that a generator for  $\text{orb}\left(\frac{\partial f}{\partial x_i}\right)$  is also a generator for  $\frac{\partial g}{\partial x_j}$ . Finally, we use this generator for  $\frac{\partial g}{\partial x_j}$  to construct a generator for  $g$ . The argument then proceeds by induction on the number of non-constant leaves. In the base case, we need a hitting set generator for orbits of sparse polynomials which we get from Theorem 7.

## 1.4 Related work

We give a brief account of known results on PIT and hitting sets for arithmetic circuits. The results on hitting sets for the constant-read models are most relevant to our work here. However, for the sake of completeness, we mention a few other prominent results.

**Constant-read models.** [73] gave a polynomial-time PIT algorithm and a quasi-polynomial time hitting set construction for sums of constantly many *preprocessed* read-once formulas (PROFs). [52] later gave a polynomial time hitting set for the same model. [10] gave a quasi-polynomial time hitting set construction for multilinear *sparse-substituted* read- $k$  formulas, wherein the leaves are replaced by sparse polynomials and every variable appears in at most  $k$  of the sparse polynomials. Observe that the models studied in all three works are special cases of constant occur formulas.

A polynomial-time PIT for ROABPs follows from the PIT algorithm for non-commutative formulas [61]. [23] gave quasi-polynomial time hitting sets for ROABPs, when the order of the variables is known. Building on the rank concentration by translation technique from [6] and the merge-and-reduce idea from [23], [21] gave a quasi-polynomial time hitting set construction for low individual degree ROABPs. Finally, [3] obtained a quasi-polynomial time constructible hitting set for ROABPs using a different and simpler method, namely *basis isolation*, which can be thought of as a generalization of the monomial isolation method in [45]. [32] designed hitting sets for sums of constantly many ROABPs

in quasi-polynomial time; they also gave a polynomial-time PIT algorithm for the same model. Recently, more efficient constructions of hitting sets for ROABPs have been obtained [27], sometimes under additional restrictions on the model such as commutativity and constant-width [31]. For read- $k$  oblivious ABPs, [9] obtained a subexponential-time PIT algorithm.

**Orbits and orbit closures.** A polynomial-time hitting set for the *orbit* of the power symmetric polynomial  $\text{PSym}_{n,d} = x_1^d + \dots + x_n^d$  was given by [47]. As that  $\text{PSym}$  is computable by a depth-2 occur-once formula, Theorem 9 subsumes this result. Our hitting-set construction is different from the one in [47] which involves the Hessian matrix, whereas the proofs here work with just the first order derivatives. Very recently and independent of our work, [51] gave quasi-polynomial time hitting sets for the orbits of sparse polynomials and read-once formulas. For the orbit closures of polynomials that are computable by low-degree, polynomial-size circuits (i.e., VP circuits), [24, 28] gave PSPACE constructions of hitting sets.

**Constant-depth models.** The polynomial-time hitting set construction for depth-2 circuits (i.e., sparse polynomials) in [45] is one of the widely used results in black-box PIT. [16] gave a quasi-polynomial time PIT algorithm for depth-3 circuits with constant top fan-in. Later [44] improved the complexity to polynomial-time. Using ideas developed in [16], and [25], [40, 43, 70] gave polynomial-time constructible hitting sets for depth-3 circuits with constant top fan-in over  $\mathbb{Q}$ . Ultimately, a combination of ideas from the [44] and [25] led to a polynomial-time hitting set construction for the same model over any field [69, 70]. Meanwhile, [42, 66] gave polynomial-time PIT for depth-3 powering circuits. Using ideas from [44] and [66], [63] gave polynomial-time PIT for the sum of a depth-3 circuit with constant top fan-in and a *semi-diagonal* circuit (which is a special kind of a depth-4 circuit). [62] showed that polynomial-time PIT (resp. hitting sets) for  $\text{aproj}(\text{IMM}_{2,d})$  implies polynomial-time PIT (resp. hitting sets) for depth-3 circuits.

A quasi-polynomial time hitting set for set-multilinear depth-3 circuits with known variable-partition was given by [22]. Independently and simultaneously, [6] gave a quasi-polynomial time hitting set for set-multilinear depth-3 circuits with *unknown* variable-partition (and more generally, for constant-depth *pure* formulas [58]) using a different technique, namely *rank concentration by translation*. Set-multilinear depth-3 circuits (in fact, pure formulas) form a subclass of ROABPs. [14] gave subexponential-time hitting sets for multilinear depth-3 and depth-4 formulas (and more generally, for constant-depth multilinear regular formulas) by reducing the problem to constructing hitting sets for ROABPs. For multilinear depth-4 circuits with constant top fan-in, [39] gave a quasi-polynomial time hitting set. This was improved to a polynomial-time hitting set in [65]. Multilinear depth-4 circuits with constant top fan-in form a subclass of depth-4 constant-occur formulas. [5] gave a unifying method based on algebraic independence to design polynomial-time hitting sets for both depth-3 circuits with constant top fan-in and constant-depth, constant-occur formulas. A generalization of depth-3 powering circuits to depth-4 is sums of powers of constant degree polynomials; [20] gave a quasi-polynomial time hitting set for this model. Recently, a sequence of work [59, 60, 72] led to a polynomial-time hitting set for depth-4 circuits with top fan-in at most 3 and bottom fan-in at most 2 via a resolution of a conjecture of [11, 29] on the algebraic rank of the factors appearing in such circuits.

**Edmonds' model.** An important special case of PIT is the following problem: given  $f = \det(A_0 + \sum_{i \in [n]} x_i A_i)$ , where  $A_i \in \mathbb{F}^{n \times n}$  is a rank-1 matrix for every  $i \in [n]$  and  $A_0 \in \mathbb{F}^{n \times n}$  is an arbitrary matrix, check if  $f = 0$  [17]. This case of PIT, played an instrumental

role in devising fast parallel algorithms for several problems such as perfect matching, linear matroid intersection and maximum rank matrix completion [19, 33, 41, 49, 53–55, 75]. A polynomial-time PIT for this model is known [18, 26, 35, 50, 54]. [33] gave a quasi-polynomial time hitting set via a certain derandomization of the Isolation Lemma [53].

We refer the reader to the surveys [67, 68, 74] for more details on some of the results and the models mentioned above.

## 2 Preliminaries

► **Definition 11** (Hitting set generator). *Let  $\mathcal{C}$  be a set of  $n$ -variate polynomials and  $t \in \mathbb{N}$ . A polynomial map  $\mathcal{G} : \mathbb{F}^t \rightarrow \mathbb{F}^n$  is a hitting set generator for  $\mathcal{C}$  if  $\forall f \in \mathcal{C} \setminus \{0\}$ , we have  $f \circ \mathcal{G} \neq 0$ .*

We say the number of variables of  $\mathcal{G}$  is  $t$ , and the degree of  $\mathcal{G}$  – denoted by  $\deg(\mathcal{G})$  – is the maximum of the degrees of the  $n$  polynomials that define  $\mathcal{G}$ . We will denote the  $t$ -variate polynomial  $f \circ \mathcal{G}$  by  $f(\mathcal{G})$ . By treating a matrix  $A \in \mathbb{F}^{n \times n}$  as a linear transformation from  $\mathbb{F}^n$  to  $\mathbb{F}^n$ , we will denote the polynomial map  $A \circ \mathcal{G}$  by  $A\mathcal{G}$  and the  $t$ -variate polynomial  $f \circ A\mathcal{G}$  by  $f(A\mathcal{G})$ . If the defining polynomials of  $\mathcal{G}$  have degree  $d_0$  and the degree of the polynomials in  $\mathcal{C}$  is at most  $D$ , then the degree of  $f(\mathcal{G})$  is at most  $d_0D$ . Thus, if we are given the defining polynomials of  $\mathcal{G}$ , then we can construct a hitting set for  $\mathcal{C}$  in time  $\text{poly}(n, (d_0D)^t)$  using the Schwartz-Zippel lemma, provided also that  $|\mathbb{F}| > d_0D$ .

### 2.1 The Shpilka-Volkovich generator

► **Definition 12** (The Shpilka-Volkovich hitting set generator [73]). *Assume that  $|\mathbb{F}| \geq n$  and let  $\alpha_1, \dots, \alpha_n$  be distinct elements of  $\mathbb{F}$ . For  $i \in [n]$ , let  $L_i(y) := \prod_{j \in [n], j \neq i} \frac{y - \alpha_j}{\alpha_i - \alpha_j}$  be the  $i$ -th Lagrange interpolation polynomial. Then, for  $t \in \mathbb{N}$ , the Shpilka-Volkovich (SV) generator  $\mathcal{G}_t^{SV} : \mathbb{F}^{2t} \rightarrow \mathbb{F}^n$  is defined as  $\mathcal{G}_t^{SV} := \left( \mathcal{G}_t^{(1)}, \dots, \mathcal{G}_t^{(n)} \right)$  where,  $\mathcal{G}_t^{(i)}(y_1, \dots, y_t, z_1, \dots, z_t) = \sum_{k=1}^t L_i(y_k) \cdot z_k$ .*

Notice that  $\deg(\mathcal{G}_t^{(i)}) = n$ , and  $\mathcal{G}_{t+1}^{SV}|_{(y_{t+1}=\alpha_i)} = \mathcal{G}_t^{SV} + \mathbf{e}_i \cdot z_{t+1}$ , where  $\mathbf{e}_i$  is the  $i$ -th standard basis vector of  $\mathbb{F}^n$ . Thus,  $\text{Img}(\mathcal{G}_t^{SV}) \subseteq \text{Img}(\mathcal{G}_{t+1}^{SV})$  and, continuing in this manner,  $\text{Img}(\mathcal{G}_t^{SV}) \subseteq \text{Img}(\mathcal{G}_{t'}^{SV})$  for any  $t' \geq t$ .

► **Observation 13.** *Let  $f \in \mathbb{F}[\mathbf{x}]$  be a non-zero polynomial that depends on only  $b$  of the  $\mathbf{x}$  variables, and  $g \in \text{orb}(f)$ . Then,  $g$  has a monomial of support at most  $b$  and  $g(\mathcal{G}_b^{SV}) \neq 0$ .*

The above observation is proved in the full version [64]. The following observation, which allows us to construct a hitting set generator for  $f$  from a hitting set generator for  $\frac{\partial f}{\partial x_i}$  is used crucially in the proofs of Theorems 9 and 10 and is proved in the full version [64].

► **Observation 14.** *Let  $f \in \mathbb{F}[\mathbf{x}]$  be an  $n$ -variate, degree  $d$  polynomial, and for some  $m \in \mathbb{N}$ , let  $\mathcal{G} : \mathbb{F}^m \rightarrow \mathbb{F}^n$  be a polynomial map of degree at most  $d'$ . If  $|\mathbb{F}| > dd'$  and there is an  $i \in [n]$  such that  $\frac{\partial f}{\partial x_i}(\mathcal{G}) \neq 0$ , then  $f(\mathcal{G} + \mathcal{G}_1^{SV})$  is not a constant.*

### 2.2 Low support rank concentration

Let  $F$  be a polynomial in  $\mathbf{x}$ -variables with coefficients from  $\mathbb{K}^{w \times w}$ , where  $\mathbb{K}$  is a field and  $w \in \mathbb{N}$ . For an  $m \in \mathbb{N}$ , we say that  $F$  has *support- $m$  rank concentration* over  $\mathbb{K}$  if the coefficient of every monomial in  $F$  is in the  $\mathbb{K}$ -span of the coefficients of the monomials of support at most  $m$  in  $F$ . Support of a monomial  $\mathbf{x}^\alpha$  will be denoted as  $\text{Supp}(\mathbf{x}^\alpha)$ . We prove the below observation in the full version [64].

► **Observation 15.** Let  $f = \mathbf{1}^T \cdot M_1(x_1)M_2(x_2) \cdots M_n(x_n) \cdot \mathbf{1} \in \mathbb{F}[\mathbf{x}]$  be computable by an ROABP of width  $w$ , and  $F = M_1(x_1)M_2(x_2) \cdots M_n(x_n)$ . For an  $m \in \mathbb{N}$  and  $t_1(\mathbf{z}), \dots, t_n(\mathbf{z}) \in \mathbb{F}[\mathbf{z}]$ , where  $\mathbf{z}$  is a set of variables different from  $\mathbf{x}$ , suppose that  $F(\mathbf{x} + \mathbf{t}(\mathbf{z})) := M_1(x_1 + t_1(\mathbf{z}))M_2(x_2 + t_2(\mathbf{z})) \cdots M_n(x_n + t_n(\mathbf{z})) \in \mathbb{F}(\mathbf{z})^{w \times w}[\mathbf{x}]$  has support- $m$  rank concentration over  $\mathbb{F}(\mathbf{z})$ . Then,  $f(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z}))$ , when viewed as a polynomial in  $\mathbf{x}$ -variables with coefficients from  $\mathbb{F}[\mathbf{z}]$ , has an  $\mathbf{x}$ -monomial of support at most  $m$ , provided  $f \neq 0$ .

### 2.3 Algebraic rank and faithful homomorphisms

We say that polynomials  $f_1, \dots, f_m \in \mathbb{F}[\mathbf{x}]$  are algebraically independent over  $\mathbb{F}$ , if they do not satisfy any non-trivial polynomial equation over  $\mathbb{F}$ , i.e., for any  $p \in \mathbb{F}[y_1, \dots, y_m]$ ,  $p(f_1, \dots, f_m) = 0$  only if  $p = 0$ . For  $\mathbf{f} = (f_1, \dots, f_m)$ , the transcendence degree (i.e., the algebraic rank) of  $\mathbf{f}$  over  $\mathbb{F}$  is the cardinality of any maximal algebraically independent subset of  $\{f_1, \dots, f_m\}$  over  $\mathbb{F}$ . The notion of algebraic rank is well defined as algebraic independence satisfies the matroid properties.

For  $\mathbf{f} = (f_1, \dots, f_m) \in \mathbb{F}[\mathbf{x}]^m$ , let  $J_{\mathbf{x}}(\mathbf{f})$  denote the Jacobian matrix of  $\mathbf{f}$ . The following well-known lemma relates the transcendence degree of  $\mathbf{f}$  over  $\mathbb{F}$  – denoted by  $\text{tr-deg}_{\mathbb{F}}(\mathbf{f})$  – to the rank of the Jacobian.

► **Lemma 16** (The Jacobian criterion). Let  $\mathbf{f} = (f_1, \dots, f_m) \in \mathbb{F}[\mathbf{x}]^m$  be a tuple of polynomials of degree at most  $D$  and  $\text{tr-deg}_{\mathbb{F}}(\mathbf{f}) = r$ . If  $\text{char}(\mathbb{F}) = 0$  or  $\text{char}(\mathbb{F}) > D^r$ , then  $\text{tr-deg}_{\mathbb{F}}(\mathbf{f}) = \text{rank}_{\mathbb{F}(\mathbf{x})} J_{\mathbf{x}}(\mathbf{f})$ .

► **Definition 17** (Faithful homomorphisms). A homomorphism  $\phi : \mathbb{F}[\mathbf{x}] \rightarrow \mathbb{F}[\mathbf{z}]$  is said to be faithful to  $\mathbf{f} = (f_1, \dots, f_m) \in \mathbb{F}[\mathbf{x}]^m$  if  $\text{tr-deg}_{\mathbb{F}}(\mathbf{f}) = \text{tr-deg}_{\mathbb{F}}(\phi(\mathbf{f}))$ .

► **Lemma 18** (Theorem 2.4 in [5]). If a homomorphism  $\phi : \mathbb{F}[\mathbf{x}] \rightarrow \mathbb{F}[\mathbf{z}]$  is faithful to  $\mathbf{f} = (f_1, \dots, f_m) \in \mathbb{F}[\mathbf{x}]^m$ , then for any  $p \in \mathbb{F}[y_1, \dots, y_m]$ ,  $p(\mathbf{f}) = 0$  if and only if  $p(\phi(\mathbf{f})) = 0$ .

The following lemma was proved in [5, 11].

► **Lemma 19** (Lemma 2.7 of [5]). Let  $\mathbf{f} = (f_1, \dots, f_m)$  be a tuple of polynomials of degree at most  $D$ ,  $\text{tr-deg}_{\mathbb{F}}(\mathbf{f}) \leq r$ , and  $\text{char}(\mathbb{F}) = 0$  or  $> D^r$ . Let  $\psi : \mathbb{F}[\mathbf{x}] \rightarrow \mathbb{F}[\mathbf{z}]$  be a homomorphism such that  $\text{rank}_{\mathbb{F}(\mathbf{z})} J_{\mathbf{x}}(\mathbf{f}) = \text{rank}_{\mathbb{F}(\mathbf{z})} \psi(J_{\mathbf{x}}(\mathbf{f}))$ . Then, the map  $\phi : \mathbb{F}[\mathbf{x}] \rightarrow \mathbb{F}[\mathbf{z}, t, y_1, \dots, y_r]$  that, for all  $i \in [n]$ , maps  $x_i \rightarrow \left( \sum_{j=1}^r y_j t^{ij} \right) + \psi(x_i)$  is faithful to  $\mathbf{f}$ .

We will need the following observation in our proofs. It is proved in the full version [64].

► **Observation 20.** Let  $\mathbf{f} = (f_1, \dots, f_m) \in \mathbb{F}[\mathbf{x}]^m$  be a tuple of polynomials with  $\text{tr-deg}_{\mathbb{F}}(\mathbf{f}) = r$ . For any  $A \in \text{GL}(n, \mathbb{F})$ , let  $g_i = f_i(A\mathbf{x}) \forall i \in [m]$  and  $\mathbf{g} = (g_1, \dots, g_m)$ . Then,  $\text{tr-deg}_{\mathbb{F}}(\mathbf{g}) = r$ .

## 3 Hitting sets for the orbits of commutative ROABPs

**The strategy.** (Recap) Let  $f = \mathbf{1}^T \cdot M_1(x_1)M_2(x_2) \cdots M_n(x_n) \cdot \mathbf{1}$  be a width- $w$  commutative ROABP; here  $M_i(x_i) \in \mathbb{F}^{w \times w}[x_i]$  for all  $i \in [n]$ . Also, let  $F = M_1(x_1)M_2(x_2) \cdots M_n(x_n)$ . For any  $A \in \text{GL}(n, \mathbb{F})$ , let  $g = f(A\mathbf{x})$  and  $G = F(A\mathbf{x})$ . For  $i \in [n]$ , suppose that  $A$  maps  $x_i \mapsto \ell_i(\mathbf{x})$ , where  $\ell_i$  is a linear form, and let  $y_i = \ell_i(\mathbf{x})$  and  $\mathbf{y} = \{y_1, \dots, y_n\}$ . Then,  $g = \mathbf{1}^T \cdot M_1(y_1)M_2(y_2) \cdots M_n(y_n) \cdot \mathbf{1}$  and  $G = M_1(y_1)M_2(y_2) \cdots M_n(y_n)$ . We will show that if  $g \neq 0$ , then there exist explicit “low” degree polynomials  $t_1(\mathbf{z}), \dots, t_n(\mathbf{z})$ , where  $\mathbf{z}$  is a “small” set of variables such that  $g(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z}))$  has a “low” support monomial. This

will be done by proving that  $G(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z}))$  has low support rank concentration in the “ $\mathbf{y}$ -variables”. Applying Observation 15, we will get that  $g(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z}))$  has a low support  $\mathbf{y}$ -monomial. This will then imply that  $g(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z}))$  has a low support  $\mathbf{x}$ -monomial, provided  $f$  has low individual degree. Finally, we will plug in the SV generator to preserve the non-zerosness of  $g$ . More precisely, we will prove the following theorem at the end of Section 3.2.

► **Theorem 21.** *Let  $f$  be an  $n$ -variate polynomial with individual degree at most  $d$  that is computable by a width- $w$  commutative ROABP. If  $|\mathbb{F}| \geq n$ , then  $\mathcal{G}_{(2^{\lceil \log w^2 \rceil}(d+1)+1)}^{SV}$  is a hitting set generator for  $\text{orb}(f)$ .*

**Notations and conventions.** In the analysis, we will treat  $t_1(\mathbf{z}), \dots, t_n(\mathbf{z})$  as formal variables  $\mathbf{t} = (t_1, \dots, t_n)$  while always keeping in mind the substitution map  $t_i \mapsto t_i(\mathbf{z})$ . For  $i \in [n]$ , let  $r_i = \ell_i(\mathbf{t})$ . For  $S \subseteq [n]$ , define  $\mathbf{r}_S = \{r_i : i \in S\}$ . The  $\mathbb{F}$ -linear independence of  $\ell_1, \dots, \ell_n$  allows us to treat  $\mathbf{y}$  and  $\mathbf{r}$  as sets of formal variables. Notice that in this notation,  $G(\mathbf{x} + \mathbf{t}) = M_1(y_1 + r_1)M_2(y_2 + r_2) \cdots M_n(y_n + r_n)$ . Let  $\mathbb{A}$  denote the matrix algebra  $\mathbb{F}^{w \times w}$ . For  $i \in [n]$ , let  $M_i(y_i) = \sum_{e_i=0}^d u_{i,e_i} y_i^{e_i}$ , where  $u_{i,e_i} \in \mathbb{A}$  and  $M_i(y_i + r_i) = \sum_{b_i=0}^d v_{i,b_i} y_i^{b_i}$ , where  $v_{i,b_i} \in \mathbb{A}[r_i] \subset \mathbb{A}[\mathbf{t}]$ . As  $f$  is a commutative ROABP,  $M_1(y_1), \dots, M_n(y_n)$  commute with each other and hence  $u_{i,e_i}$  and  $u_{j,e_j}$  also commute for  $i \neq j$ . The following observation, which we prove in the full version [64], implies that  $v_{i,e_i}$  and  $v_{j,e_j}$  also commute for  $i \neq j$ .

► **Observation 22.** *For every  $i \in [n]$  and  $b_i, e_i \in \{0, \dots, d\}$ ,  $v_{i,b_i} = \sum_{e_i=0}^d \binom{e_i}{b_i} \cdot r_i^{e_i - b_i} \cdot u_{i,e_i}$  and  $u_{i,e_i} = \sum_{b_i=0}^d \binom{b_i}{e_i} \cdot (-r_i)^{b_i - e_i} \cdot v_{i,b_i}$ , where  $\binom{a}{b} = 0$  if  $a < b$ .*

For a set  $S = \{i_1, i_2, \dots, i_{|S|}\} \subseteq [n]$ , where  $i_1 < i_2 < \dots < i_{|S|}$ , the vector  $(b_{i_1}, b_{i_2}, \dots, b_{i_{|S|}})$  will be denoted by  $(b_i : i \in S)$ . Let  $\text{Supp}(\mathbf{b})$  denote the support of the vector  $\mathbf{b}$  which is defined as the number of non-zero elements in it. Define the parameter  $m := 2 \lceil \log w^2 \rceil + 1$ .

### 3.1 The goal: low support rank concentration

We set ourselves the goal of proving that there exist explicit degree- $n$  polynomials  $t_1(\mathbf{z}), \dots, t_n(\mathbf{z})$ , where  $|\mathbf{z}| = 2m$ , such that  $G(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z})) = M_1(y_1 + r_1)M_2(y_2 + r_2) \cdots M_n(y_n + r_n) \in \mathbb{A}[r_1, \dots, r_n][\mathbf{y}]$  has support- $(m - 1)$  rank concentration over  $\mathbb{F}(\mathbf{z})$  in the  $\mathbf{y}$ -variables. We will show in this and the next section that this happens if all polynomials in a certain collection of non-zero polynomials  $\{h_S(\mathbf{r}_S) : S \subseteq \binom{[n]}{m}\} \subseteq \mathbb{F}[r_1, \dots, r_n]$ , remain non-zero under the substitution  $t_i \mapsto t_i(\mathbf{z})$ . The following lemma, proved in the full version [64], will help us achieve this goal.

► **Lemma 23.** *Let  $G, \mathbf{t}, \mathbf{z}, \mathbf{y}$  and  $\mathbf{r}_S$  be as defined above. Suppose that the following two conditions are satisfied:*

1. *For every  $S \subseteq \binom{[n]}{m}$  and  $(b_i : i \in S) \in \{0, \dots, d\}^m$ , there is a non-zero polynomial  $h_S(\mathbf{r}_S)$  such that  $h_S(\mathbf{r}_S) \cdot \prod_{i \in S} v_{i,b_i} \in \mathbb{F}[\mathbf{t}]$ -span  $\left\{ \prod_{i \in S} v_{i,b'_i} : \text{Supp}(b'_i : i \in S) < m \right\}$ .*
  2. *There exists a substitution  $t_i \mapsto t_i(\mathbf{z})$  that keeps  $h_S(\mathbf{r}_S)$  non-zero for all  $S \subseteq \binom{[n]}{m}$ .*
- Then, for every  $\mathbf{b} = (b_i : i \in [n]) \in \{0, \dots, d\}^n$ ,*

$$\prod_{i \in [n]} v_{i,b_i} \in \mathbb{F}(\mathbf{z})\text{-span} \left\{ \prod_{i \in [n]} v_{i,b'_i} : \text{Supp}(b'_i : i \in [n]) < m \right\},$$

*and  $G(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z}))$  has support- $(m - 1)$  rank concentration over  $\mathbb{F}(\mathbf{z})$  in  $\mathbf{y}$ -variables.*

### 3.2 Achieving rank concentration

We will now see how to satisfy conditions 1 and 2 of Lemma 23 such that  $\deg_{\mathbf{r}_S}(h_S(\mathbf{r}_S)) \leq md^{m+1}$ ,  $t_i(\mathbf{z})$  is an explicit degree- $n$  polynomial, and  $|\mathbf{z}| = 2m$ . Assume wlog that  $S = [m]$ . For  $\mathbf{b} = (b_1, \dots, b_m)$  and  $\mathbf{e} = (e_1, \dots, e_m)$  in  $\{0, \dots, d\}^m$ , define  $\binom{\mathbf{b}}{\mathbf{e}} := \prod_{i \in [m]} \binom{b_i}{e_i}$ , where,  $\binom{b_i}{e_i} = 0$  if  $b_i < e_i$ . Also, let  $v_{\mathbf{b}} := \prod_{i \in [m]} v_{i, b_i}$  and  $u_{\mathbf{e}} := \prod_{i \in [m]} u_{i, e_i}$ . Define  $\mathbf{r} := (-r_1, \dots, -r_m)$ ,  $\mathbf{r}^{\mathbf{b}} := \prod_{i \in [m]} (-r_i)^{b_i}$  and  $\mathbf{r}^{-\mathbf{e}} := \prod_{i \in [m]} (-r_i)^{-e_i}$ . We now define some vectors and matrices by fixing an arbitrary order on the elements of  $\{0, \dots, d\}^m$ .

Let  $V := (v_{\mathbf{b}} : \mathbf{b} \in \{0, \dots, d\}^m)$  and  $U := (u_{\mathbf{e}} : \mathbf{e} \in \{0, \dots, d\}^m)$ ;  $V$  is a row vector in  $\mathbb{A}[\mathbf{r}]^{(d+1)^m}$  whereas  $U$  is a row vector in  $\mathbb{A}^{(d+1)^m}$ . Let  $C := \text{diag}(\mathbf{r}^{\mathbf{b}} : \mathbf{b} \in \{0, \dots, d\}^m)$  and  $D := \text{diag}(\mathbf{r}^{-\mathbf{e}} : \mathbf{e} \in \{0, \dots, d\}^m)$ ; both  $C$  and  $D$  are  $(d+1)^m \times (d+1)^m$  diagonal matrices. Let  $M$  be a  $(d+1)^m \times (d+1)^m$  matrix whose rows and columns are indexed by  $\mathbf{b} \in \{0, \dots, d\}^m$  and  $\mathbf{e} \in \{0, \dots, d\}^m$  respectively. The entry of  $M$  indexed by  $(\mathbf{b}, \mathbf{e})$  contains  $\binom{\mathbf{b}}{\mathbf{e}}$ . We now make the following claim which is proved in the full version [64].

▷ **Claim 24.** Let  $U, V, C, M$  and  $D$  be as defined above. Then,  $U = VCMD$ .

In [6], a very similar equation was called the *transfer equation* and we will refer to  $U = VCMD$  by the same name. Let  $F := \{\mathbf{b} \in \{0, \dots, d\}^m : \text{Supp}(\mathbf{b}) = m\}$ ; clearly,  $|F| = d^m$ . Also, let us call the set of all vectors  $(n_{\mathbf{e}} : \mathbf{e} \in \{0, \dots, d\}^m) \in \mathbb{F}^{(d+1)^m}$  for which  $\sum_{\mathbf{e} \in \{0, \dots, d\}^m} n_{\mathbf{e}} u_{\mathbf{e}} = 0$  the *null space* of  $U$ . Then, we have the following lemma.

► **Lemma 25.** *There are vectors  $\{\mathbf{n}_{\mathbf{b}} : \mathbf{b} \in F\}$  in the null space of  $U$  such that the following holds: Let  $N$  be the  $(d+1)^m \times d^m$  matrix whose rows are indexed by  $\mathbf{e} \in \{0, \dots, d\}^m$  and whose columns are indexed by  $\mathbf{b} \in F$  and whose column indexed by  $\mathbf{b}$  is  $\mathbf{n}_{\mathbf{b}}$ . Then, the square matrix  $[CMDN]_F$  is invertible, where  $[CMDN]_F$  is the sub-matrix of  $CMDN$  consisting of only those rows of  $CMDN$  that are indexed by  $\mathbf{b} \in F$ .*

We need the value of  $m$  in the proof of the lemma which is given in Appendix A. For now, observe that  $\det([CMDN]_F) \in \mathbb{F}[\mathbf{r}]$ : Every entry of  $[CMDN]_F$  is a  $\mathbb{F}$ -linear combination of some entries of the matrix  $CMD$ . The entry of  $CMD$  indexed by  $(\mathbf{b}, \mathbf{e})$  is  $\binom{\mathbf{b}}{\mathbf{e}} \cdot \mathbf{r}^{\mathbf{b}} \cdot \mathbf{r}^{-\mathbf{e}}$ , which is non-zero only if  $b_i \geq e_i$  for all  $i \in [m]$ . In this case,  $\mathbf{r}^{\mathbf{b}} \cdot \mathbf{r}^{-\mathbf{e}}$  is a monomial in the  $\mathbf{r}$ -variables. Thus,  $\det([CMDN]_F)$  – which is a polynomial in the entries of  $[CMDN]_F$  – is a polynomial in the  $\mathbf{r}$ -variables. This observation leads to the following corollary of the above lemma, which immediately gives a way to satisfy condition 1 of Lemma 23.

► **Corollary 26.** *Let  $h(\mathbf{r}) := \det([CMDN]_F)$ . Then, for every  $\mathbf{b} \in F$ ,*

$$h(\mathbf{r}) \cdot v_{\mathbf{b}} \in \mathbb{F}[\mathbf{t}]\text{-span} \{v_{\mathbf{b}'} : \mathbf{b}' \in \{0, \dots, d\}^m \text{ and } \text{Supp}(\mathbf{b}') < m\}.$$

The above corollary is proved in the full version [64]. The following claim about  $h(\mathbf{r})$  gives us a way to satisfy condition 2 of Lemma 23. It's proof can be found in the full version [64].

▷ **Claim 27.** The polynomial  $h(\mathbf{r})$ , when viewed as a polynomial in the  $\mathbf{t}$ -variables after setting  $r_i = \ell_i(\mathbf{t})$ , has a  $\mathbf{t}$ -monomial of support at most  $m$ .

By substituting  $\mathcal{G}_m^{SV}$  for  $\mathbf{t}$ , the polynomial  $h(\mathbf{r})$  remains non-zero, satisfying condition 2. The number of variables in  $\mathcal{G}_m^{SV}$ , i.e.,  $|\mathbf{z}| = 2m$  and its degree is  $n$ . The proofs of Theorems 21 and 6 using Lemma 23 can be found in Appendix A.

#### 4 Hitting sets for the orbits of multilinear constant-width ROABPs

**The strategy.** (Recap) Let  $f = \mathbf{1}^T \cdot M_1(x_1)M_2(x_2) \cdots M_n(x_n) \cdot \mathbf{1}$  be a multilinear, width- $w$  ROABP; here  $M_i(x_i) \in \mathbb{F}^{w \times w}[x_i]$  for all  $i \in [n]$ . Also, let  $F = M_1(x_1)M_2(x_2) \cdots M_n(x_n)$ . For any  $A \in \text{GL}(n, \mathbb{F})$ , let  $g = f(A\mathbf{x})$  and  $G = F(A\mathbf{x})$ . For  $i \in [n]$ , suppose that  $A$  maps  $x_i \mapsto \ell_i(\mathbf{x})$ , where  $\ell_i$  is a linear form, and let  $y_i = \ell_i(\mathbf{x})$  and  $\mathbf{y} = \{y_1, \dots, y_n\}$ . Then,  $g = \mathbf{1}^T \cdot M_1(y_1)M_2(y_2) \cdots M_n(y_n) \cdot \mathbf{1}$  and  $G = M_1(y_1)M_2(y_2) \cdots M_n(y_n)$ . Just like in the previous section, we will show that if  $g \neq 0$ , then there exist explicit “low” degree polynomials  $t_1(\mathbf{z}), \dots, t_n(\mathbf{z})$ , where  $\mathbf{z}$  is a “small” set of variables such that  $G(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z}))$  has “low” support rank concentration in the “ $\mathbf{y}$ -variables”. While in the rank concentration argument in the previous section the  $\mathbf{x}$ -variables were translated only once, here the translations can be thought of as happening sequentially and in stages. There will be  $\lceil \log n \rceil$  stages with each stage also consisting of multiple translations. After the  $p$ -th stage, the product of any  $2^p$  consecutive matrices in  $G$  will have low support rank concentration in the  $\mathbf{y}$ -variables. Thus, after  $\lceil \log n \rceil$  stages, we will have low support rank concentration in the  $\mathbf{y}$ -variables for  $G(x_1 + t_1(\mathbf{z}), \dots, x_n + t_n(\mathbf{z}))$ .

**Notations and conventions.** Much like in the previous section, we will first translate the  $\mathbf{x}$ -variables by the  $\mathbf{t}$ -variables and then substitute the  $\mathbf{t}$ -variables by low degree polynomials in a small set of variables. We will translate the  $\mathbf{x}$ -variables by  $\lceil \log n \rceil$  groups of  $\mathbf{t}$ -variables,  $\mathbf{t}_1, \dots, \mathbf{t}_{\lceil \log n \rceil}$ . For all  $p \in \lceil \log n \rceil$ , the group  $\mathbf{t}_p$  will have  $\mu := w^2 + \lceil \log w^2 \rceil$  sub-groups of  $\mathbf{t}$ -variables,  $\mathbf{t}_{p,1}, \dots, \mathbf{t}_{p,\mu}$ . For all  $p \in \lceil \log n \rceil$  and  $q \in [\mu]$ ,  $\mathbf{t}_{p,q} := \{t_{p,q,1}, \dots, t_{p,q,n}\}$ . Thus, finally the translation will look like  $x_i \rightarrow x_i + \sum_{p \in \lceil \log n \rceil, q \in [\mu]} t_{p,q,i}$  for all  $i \in [n]$ . Finally, we will substitute the  $\mathbf{t}$ -variables as  $t_{p,q,i} \mapsto s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(i)}$ , where  $\beta_{p,q}(i)$  will be fixed later in the analysis. Let  $r_{p,q,i} := \ell_i(\mathbf{t}_{p,q})$ ; notice that for all  $i \in [n]$ ,  $y_i$  is translated as  $y_i \rightarrow y_i + \sum_{p \in \lceil \log n \rceil, q \in [\mu]} \ell_i(\mathbf{t}_{p,q}) = y_i + \sum_{p \in \lceil \log n \rceil, q \in [\mu]} r_{p,q,i}$ .

For the purpose of analysis, we will think of the translation as happening sequentially in the order  $\mathbf{t}_{1,1}, \dots, \mathbf{t}_{1,\mu}, \mathbf{t}_{2,1}, \dots, \mathbf{t}_{2,\mu}, \dots, \mathbf{t}_{n,1}, \dots, \mathbf{t}_{n,\mu}$ , i.e., we will first translate by  $\mathbf{t}_{1,1}$ , then by  $\mathbf{t}_{1,2}$ , and so on. We denote the order thus imposed on the set  $\{(p, q) : p \in \lceil \log n \rceil, q \in [\mu]\}$  by  $\prec$ .

For a set  $S = \{i_1, i_2, \dots, i_{|S|}\} \subseteq [n]$ , where  $i_1 < i_2 < \dots < i_{|S|}$ , the vector  $(b_{i_1}, b_{i_2}, \dots, b_{i_{|S|}})$  will be denoted by  $(b_i : i \in S)$ . Let  $\text{Supp}(\mathbf{b})$  denote the support of the vector  $\mathbf{b}$  which is defined as the number of non-zero elements in it. The inductive argument given on the next two subsections is inspired by the “merge-and-reduce” idea from [21, 23].

#### 4.1 Low support rank concentration: an inductive argument

In this and the next sections, we will prove the following lemma. Let  $\mathbb{A} := \mathbb{F}^{w \times w}$ .

► **Lemma 28.** *There exist  $\{\beta_{p,q}(i) : p \in \lceil \log n \rceil, q \in [\mu], i \in [n]\} \subset \mathbb{Z}_{\geq 0}$ , such that when we treat  $G(x_1 + \sum_{p \in \lceil \log n \rceil, q \in [\mu]} s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(1)}, \dots, x_n + \sum_{p \in \lceil \log n \rceil, q \in [\mu]} s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(n)})$ , as a polynomial in the  $\mathbf{y}$ -variables over  $\mathbb{A}[r_{p,q,i} : p \in \lceil \log n \rceil, q \in [\mu], i \in [n]]$ , has support- $\mu$  rank concentration in  $\mathbf{y}$ -variables over  $\mathbb{F}(s_{p,q}, z_{p,q} : p \in \lceil \log n \rceil, q \in [\mu])$ . The  $\beta_{p,q}(i)$ s can be found in time  $n^{O(w^4)}$  and each  $\beta_{p,q}(i) \leq n^{O(w^4)}$ .*

We will prove this lemma by induction on  $(p, q)$ . Let us call  $\beta_{p,q}(i)$ s *efficiently computable and good* if they can be found in time  $n^{O(w^4)}$  and each  $\beta_{p,q}(i) \leq n^{O(w^4)}$ . Precisely, the induction hypothesis is as follows.

## 50:14 Hitting Sets for Orbits of Circuit Classes and Polynomial Families

**Induction hypothesis.** Just before translating by  $\mathbf{t}_{p^*,q^*}$ -variables, assume that there exist efficiently computable and good  $\{\beta_{p,q}(i) : (p,q) \prec (p^*,q^*)\}$  such that the product of any  $2^{p^*}$  consecutive matrices in

$$G \left( x_1 + \sum_{(p,q) \prec (p^*,q^*)} s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(1)}, \dots, x_n + \sum_{(p,q) \prec (p^*,q^*)} s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(n)} \right)$$

has support- $(2\mu - (q^* - 1))$  rank concentration over  $\mathbb{F}(s_{p,q}, z_{p,q} : (p,q) \prec (p^*,q^*))$  in  $\mathbf{y}$ -variables.

**Base case.** In the base case,  $(p^*,q^*) = (1,1)$ . Observe that we can assume that  $w \geq 2$ ; if  $w = 1$ , then  $g$  is a product of univariates and the existence of a polynomial time hitting set follows from Observation 13. For any  $w \geq 2$ ,  $2 \leq 2\mu$ . As a product of any two consecutive matrices in  $G$  has support  $2 \leq 2\mu$  rank concentration in the  $\mathbf{y}$ -variables over  $\mathbb{F}$ , the base case is satisfied.

**Induction step.** We need to show that there exist  $\{\beta_{p^*,q^*}(i) : i \in [n]\}$  which are efficiently computable and good, such that after translating by  $\mathbf{t}_{p^*,q^*}$  and substituting  $t_{p^*,q^*,i} \rightarrow s_{p^*,q^*} \cdot z_{p^*,q^*}^{\beta_{p^*,q^*}(i)}$ , the product of any  $2^{p^*}$  consecutive matrices in

$$G \left( x_1 + \sum_{(p,q) \preceq (p^*,q^*)} s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(1)}, \dots, x_n + \sum_{(p,q) \preceq (p^*,q^*)} s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(n)} \right)$$

has support- $(2\mu - q^*)$  rank concentration in the  $\mathbf{y}$ -variables over  $\mathbb{F}(s_{p,q}, z_{p,q} : (p,q) \preceq (p^*,q^*))$ . If  $q^* < \mu$ , then this would mean that the induction hypothesis holds immediately before translation by  $\mathbf{t}_{p^*,q^*+1}$ . Otherwise, if  $q^* = \mu$ , then the following easy-to-verify observation implies that the induction hypothesis holds immediately before translation by  $\mathbf{t}_{p^*+1,1}$ .

► **Observation 29.** Suppose that  $\{\beta_{p,q}(i) : (p,q) \preceq (p^*,\mu)\}$  are such that the product of any  $2^{p^*}$  consecutive matrices in

$$G \left( x_1 + \sum_{(p,q) \preceq (p^*,\mu)} s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(1)}, \dots, x_n + \sum_{(p,q) \preceq (p^*,\mu)} s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(n)} \right)$$

has support- $\mu$  rank concentration in  $\mathbf{y}$ -variables over  $\mathbb{F}(s_{p,q}, z_{p,q} : (p,q) \preceq (p^*,\mu))$ . Then the product of any  $2^{p^*+1}$  consecutive matrices in

$$G \left( x_1 + \sum_{(p,q) \preceq (p^*,\mu)} s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(1)}, \dots, x_n + \sum_{(p,q) \preceq (p^*,\mu)} s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(n)} \right)$$

has support- $2\mu$  rank concentration in the  $\mathbf{y}$ -variables over  $\mathbb{F}(s_{p,q}, z_{p,q} : (p,q) \preceq (p^*,\mu))$ .

Simplifying notations for the ease of exposition. By focusing on the induction step, we will henceforth denote  $\mathbb{F}(s_{p,q}, z_{p,q} : (p,q) \prec (p^*,q^*))$  by  $\mathbb{F}$ , and for all  $i \in [n]$ ,

$$M_i \left( y_j + \sum_{(p,q) \prec (p^*,q^*)} \ell_i \left( s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(1)}, \dots, s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(n)} \right) \right)$$

by  $M_i(y_i)$ ,  $t_{p^*,q^*,i}$  by  $t_i$ ,  $r_{p^*,q^*,i}$  by  $r_i$ ,  $s_{p^*,q^*}$  by  $s$ ,  $z_{p^*,q^*}$  by  $z$  and  $\beta_{p^*,q^*}(i)$  by  $\beta(i)$ .

Without loss of generality, we shall consider the product  $M_1(y_1 + r_1) \cdots M_m(y_m + r_m)$  of the first  $m = 2^{p^*}$  matrices. Our goal is to show that there exist efficiently computable and good  $\{\beta(i) : i \in [m]\}$  such that after substituting  $t_i \rightarrow s \cdot z^{\beta(i)}$ , the above product has support- $(2\mu - q^*)$  rank concentration in the  $\mathbf{y}$ -variables over  $\mathbb{F}(s, z)$  assuming that  $M_1(y_1) \cdots M_m(y_m)$  has support- $(2\mu - (q^* - 1))$  rank concentration in the  $\mathbf{y}$ -variables over  $\mathbb{F}$ .

## 4.2 Details of the induction step

**Recalling some notations.** Before we show how to achieve rank concentration, let us recall some notations defined in Section 3. While in Section 3, the individual degree is  $d$ , here the individual degree is 1 and so, we modify the definitions accordingly.  $\mathbb{A}$  is used to denote the matrix algebra  $\mathbb{F}^{w \times w}$ . For  $i \in [m]$ ,  $M_i(y_i) = \sum_{e_i=0}^1 u_{i,e_i} y_i^{e_i}$ , where  $u_{i,e_i} \in \mathbb{A}$  and  $M_i(y_i + r_i) = \sum_{b_i=0}^1 v_{i,b_i} y_i^{b_i}$ , where  $v_{i,b_i} \in \mathbb{A}[r_i] \subset \mathbb{A}[\mathbf{t}]$ . For  $\mathbf{b} = (b_1, \dots, b_m)$  and  $\mathbf{e} = (e_1, \dots, e_m)$  in  $\{0, 1\}^m$ ,  $\binom{\mathbf{b}}{\mathbf{e}} := \prod_{i \in [m]} \binom{b_i}{e_i}$ . Also,  $v_{\mathbf{b}} := \prod_{i \in [m]} v_{i,b_i}$  and  $u_{\mathbf{e}} := \prod_{i \in [m]} u_{i,e_i}$ . Moreover,  $\mathbf{r} := (-r_1, \dots, -r_m)$ ,  $\mathbf{r}^{\mathbf{b}} := \prod_{i \in [m]} (-r_i)^{b_i}$  and  $\mathbf{r}^{-\mathbf{e}} := \prod_{i \in [m]} (-r_i)^{-e_i}$ . Let  $\mathbf{t} := (t_1, \dots, t_n)$ .

The following vectors and matrices are defined by fixing an arbitrary order on the elements of  $\{0, 1\}^m$ .  $V := (v_{\mathbf{b}} : \mathbf{b} \in \{0, 1\}^m)$  and  $U := (u_{\mathbf{e}} : \mathbf{e} \in \{0, 1\}^m)$ ;  $V$  is a row vector in  $\mathbb{A}[\mathbf{r}]^{2^m}$  whereas  $U$  is a row vector in  $\mathbb{A}^{2^m}$ . Both  $C := \text{diag}(\mathbf{r}^{\mathbf{b}} : \mathbf{b} \in \{0, 1\}^m)$  and  $D := \text{diag}(\mathbf{r}^{-\mathbf{e}} : \mathbf{e} \in \{0, 1\}^m)$  are  $2^m \times 2^m$  diagonal matrices. Finally,  $M$  is a  $2^m \times 2^m$  numeric matrix whose rows and columns were indexed by  $\mathbf{b} \in \{0, 1\}^m$  and  $\mathbf{e} \in \{0, 1\}^m$ , respectively. The entry of  $M$  indexed by  $(\mathbf{b}, \mathbf{e})$  contains  $\binom{\mathbf{b}}{\mathbf{e}}$ . The proof of the following transfer equation is same as the proof of Claim 24.

▷ **Claim 30.** Let  $U, V, C, M$  and  $D$  be as defined above. Then,  $U = VCMD$ .

Let  $F := \{\mathbf{b} \in \{0, 1\}^m : \text{Supp}(\mathbf{b}) > 2\mu - q^*\}$ . Also, recall that the the *null space* of  $U$  is the set of all vectors  $(n_{\mathbf{e}} : \mathbf{e} \in \{0, 1\}^m) \in \mathbb{F}^{2^m}$  for which  $\sum_{\mathbf{e} \in \{0, 1\}^m} n_{\mathbf{e}} u_{\mathbf{e}} = 0$ . We have the following lemma.

► **Lemma 31.** *There are vectors  $\{\mathbf{n}_{\mathbf{b}} : \mathbf{b} \in F\}$  in the null space of  $U$  such that the following holds: Let  $N$  be the  $2^m \times |F|$  matrix whose rows are indexed by  $\mathbf{e} \in \{0, 1\}^m$  and whose columns are indexed by  $\mathbf{b} \in F$  and whose  $\mathbf{b}$ -th column is  $\mathbf{n}_{\mathbf{b}}$ . Then, the square matrix  $[CMDN]_F$  is invertible, where  $[CMDN]_F$  is the sub-matrix of  $CMDN$  consisting of only those rows of  $CMDN$  that are indexed by  $F$ . Also,  $\det([CMDN]_F) \in \mathbb{F}[\mathbf{r}] \subset \mathbb{F}[\mathbf{t}]$  can be expressed as the ratio of a polynomial in  $\mathbb{F}[\mathbf{t}]$  that contains a monomial of degree at most  $2w^2\mu$  in the  $\mathbf{t}$ -variables and a product of linear forms in  $\mathbb{F}[\mathbf{t}]$ .*

The proof of this lemma, which uses the value of  $\mu$ , is given in the full version [64]. We now complete the induction step using this lemma. As  $\det([CMDN]_F)$  is a polynomial in  $\mathbb{F}[\mathbf{r}]$  we get the following corollaries.

► **Corollary 32.** *Let  $h(\mathbf{r}) := \det([CMDN]_F)$ . Then, for every  $\mathbf{b} \in F$ ,*

$$h(\mathbf{r}) \cdot v_{\mathbf{b}} \in \mathbb{F}[\mathbf{t}]\text{-span} \{v_{\mathbf{b}'} : \mathbf{b}' \in \{0, 1\}^m \text{ and } \text{Supp}(\mathbf{b}') \leq 2\mu - q^*\}. \quad (1)$$

**Proof.** Same as the proof of Corollary 26. ◀

► **Corollary 33.** *Suppose  $\{\beta(i) : i \in [n]\}$  are such that the substitution  $t_i \mapsto s \cdot z^{\beta(i)}$  keeps all non-zero polynomials in  $\mathbb{F}[\mathbf{t}]$  containing a monomial of degree at most  $2w^2\mu$  in the  $\mathbf{t}$ -variables non-zero. Then, the product  $M_1(y_1 + r_1) \cdots M_m(y_m + r_m)$  has support- $(2\mu - q^*)$  rank concentration in the  $\mathbf{y}$ -variables over  $\mathbb{F}(s, z)$  after substituting  $t_i \rightarrow s \cdot z^{\beta(i)}$ .*

**Proof.** Multiply both sides of (1) by  $(h(\mathbf{r}))^{-1}$  after substituting  $t_i \mapsto s \cdot z^{\beta(i)}$ . ◀

The following claim, proved in the full version [64], allows us to compute  $\{\beta(i) : i \in [n]\}$  efficiently.

▷ **Claim 34.** There exist  $\{\beta(i) : i \in [n]\}$  such that the substitution  $t_i \mapsto s \cdot z^{\beta(i)}$  keeps all non-zero polynomials in  $\mathbb{F}[\mathbf{t}]$  containing a monomial of degree at most  $2w^2\mu$  in the  $\mathbf{t}$ -variables non-zero. Moreover, we can find all the  $\beta(i)$  in time  $n^{O(w^4)}$  and each  $\beta(i) \leq n^{O(w^4)}$ .

This completes the induction step. Lemma 28 and Theorem 8 are proved in Appendix B.

## 5 Conclusion

In this paper, we have given efficient hitting sets for orbits of several well-studied circuit classes such as commutative ROABPs and constant-width ROABPs (under the low individual degree restriction), and constant-depth constant-occur formulas and occur-once formulas. In the process, we have obtained efficiently constructible hitting sets for the orbits of the elementary symmetric and power symmetric and sum-product polynomials as well as the iterated matrix multiplication polynomials of width-3, which is a complete family of polynomials for arithmetic formulas under  $p$ -projections. The hitting set problem for the orbits of these circuit classes and polynomial families is interesting as their affine projections capture much larger circuit classes and orbits are a natural and dense subset of the set of affine projections. However, the following questions still remain open:

- **Removing the low individual degree restriction.** The low individual degree restriction is natural as it subsumes the multilinear case. However, it would be ideal if we get rid of this limitation of our results. In particular, can we give an efficient hitting-set construction for the orbits of general commutative ROABPs and constant-width ROABPs?
- **Lower bound and hitting set for the orbits of ROABPs.** We would also like to remove the requirements of commutativity and constant-width from our results on hitting sets for the orbits of ROABPs. It is worth noting that an explicit hitting set for the orbits of ROABPs implies a lower bound for the same model computing some explicit polynomial [1]. To our knowledge, no explicit lower bound is known for the orbits of ROABPs. Can we prove such a lower bound first?
- **Hitting sets for the orbits of Det and IMM.** The determinant (Det) and the iterated matrix multiplication (IMM) polynomial families are complete for the class of algebraic branching programs under  $p$ -projections. Can we design efficiently constructible hitting sets for the orbits of Det and IMM?

---

## A Missing proofs from Section 3

### A.1 Proof of Lemma 25

The entries of  $U$ , the columns of  $M$ , the rows and columns of  $D$ , and the rows of  $N$  are indexed by  $\mathbf{e} \in \{0, \dots, d\}^m$ . Impose an order  $\prec$ , say the lexicographical order, on the indices  $\mathbf{e} \in \{0, \dots, d\}^m$  of  $U$  and the other three matrices. Pick the *minimal* basis of the space spanned by the entries of  $U$  according to this order, i.e., consider the entries of  $U$  in the order dictated by  $\prec$  while forming the basis. Let  $\mathcal{B} := \{\mathbf{e} \in \{0, \dots, d\}^m : u_{\mathbf{e}} \text{ is in the minimal basis of } U \text{ w.r.t. } \prec\}$ .

**Construction of the matrix  $N$ .** The columns of  $N$  are indexed by  $\mathbf{b} \in F$ . We will now specify a set of column vectors  $\{\mathbf{n}_{\mathbf{b}} : \mathbf{b} \in F\}$  in the null space of  $U$  such that the column of  $N$  indexed by  $\mathbf{b} \in F$  is  $\mathbf{n}_{\mathbf{b}}$ . There are two cases for  $\mathbf{b} \in F$ :

**Case 1:**  $\mathbf{b} \in F \setminus \mathcal{B}$ . In this case,  $u_{\mathbf{b}}$  is dependent on  $\{u_{\mathbf{e}} : \mathbf{e} \in \mathcal{B} \text{ and } \mathbf{e} \prec \mathbf{b}\}$ . Pick this dependence vector as  $\mathbf{n}_{\mathbf{b}}$ .

**Case 2:**  $\mathbf{b} \in F \cap \mathcal{B}$ . Let there be  $p$  such  $\mathbf{b}$ , where  $p \leq |\mathcal{B}| \leq w^2$ . For a set  $E \subseteq [m]$  and  $\mathbf{b} \in \{0, \dots, d\}^m$ , let  $(\mathbf{b})_E$  denote the vector obtained by projecting  $\mathbf{b}$  to the coordinates in  $E$ . Roughly speaking, the following claim which is proved in the full version [64] says that each of these  $p$  vectors has a “small signature” that differentiates it from the other  $p - 1$  vectors.

▷ **Claim 35.** There exists a way of numbering all  $\mathbf{b} \in F \cap \mathcal{B}$  as  $\mathbf{b}_1, \dots, \mathbf{b}_p$  and there exist non-empty sets  $E_1, \dots, E_p \subseteq [m]$ , each of size at most  $\log p \leq \log w^2$  such that for all  $k \in [p - 1]$ ,

$$(\mathbf{b}_k)_{E_k} \neq (\mathbf{b}_\ell)_{E_k} \quad \forall \ell \in \{k + 1, \dots, p\} \quad (2)$$

We will call  $E_k$  the *signature* of  $\mathbf{b}_k$  for  $k \in [p]$ . The following claim tells us that for each vector  $\mathbf{b}_k$ , there is a vector that is not in  $\mathcal{B}$  and has support at most  $m - 1$ , but agrees with  $\mathbf{b}_k$  on its signature and so in some sense can be used as a proxy for  $\mathbf{b}_k$ .

▷ **Claim 36.** For every  $k \in [p]$ , there exists a vector  $\mathbf{b}'_k \in \{0, \dots, d\}^m \setminus (F \cup \mathcal{B})$  such that  $(\mathbf{b}'_k)_{E_k} = (\mathbf{b}_k)_{E_k}$  and also  $\mathbf{b}'_k$  and  $\mathbf{b}_k$  agree on all locations where  $\mathbf{b}'_k$  is non-zero.

A proof of the above claim is provided in the full version [64]. We will now use the above two claims to construct  $\mathbf{n}_{\mathbf{b}_k}$  for all  $k \in [p]$ . We will use  $\mathbf{b}'_k$  from Claim 36 as a proxy for  $\mathbf{b}_k$ . Notice that  $u_{\mathbf{b}'_k}$  is dependent on  $\{u_{\mathbf{e}} : \mathbf{e} \in \mathcal{B} \text{ and } \mathbf{e} \prec \mathbf{b}'_k\}$ . Let this dependence vector be  $\mathbf{n}_{\mathbf{b}_k}$ . This completes the construction of  $N$ . We will now show that  $[CMDN]_F$  is an invertible matrix.

**$[CMDN]_F$  is invertible.** As  $C$  is a diagonal matrix with non-zero entries, it is sufficient to show that  $[MDN]_F = [M]_F DN$  is an invertible matrix, where  $[M]_F$  is the sub-matrix of  $M$  consisting of only those rows of  $M$  that are indexed by  $\mathbf{b} \in F$ . The following claim lets us simplify the structure of  $[M]_F$  so that it becomes easier to argue that  $[M]_F DN$  is invertible.

▷ **Claim 37.** There is a row operation matrix  $R \in \text{GL}(d^m, \mathbb{F})$  with  $\det(R) = 1$  such that  $R[M]_F$  has the following structure: The rows of  $R[M]_F$  are indexed by  $\mathbf{b} = (b_1, \dots, b_m) \in F$  and its columns by  $\mathbf{e} = (e_1, \dots, e_m) \in \{0, \dots, d\}^m$ . Its entry indexed by  $(\mathbf{b}, \mathbf{e})$  is non-zero if and only if for all  $i \in [m]$ ,  $b_i = e_i$  if  $e_i \neq 0$ . All the non-zero entries of  $R[M]_F$  are  $\pm 1$ .

The above claim is proved in the full version [64]. Because of this claim, showing that  $R[M]_F DN$  is invertible would suffice. Just like we did with  $M$ , we also impose the order  $\prec$  on the columns of  $R[M]_F$  that are indexed by  $\mathbf{e} \in \{0, \dots, d\}^m$ . Recall that the rows of  $R[M]_F$  and the columns of  $N$  are indexed by  $\mathbf{b} \in F$ . We order these indices as follows: we keep the indices  $\mathbf{b} \in F \setminus \mathcal{B}$  before  $\mathbf{b}_1, \dots, \mathbf{b}_p$ . We will treat  $\mathbf{r}^{-\mathbf{e}}$  as a monomial in  $(-r_1)^{-1}, \dots, (-r_m)^{-1}$  “variables” and impose the order  $\prec$  on the monomials in these variables. Let  $A := \{\mathbf{b} : \mathbf{b} \in F \setminus \mathcal{B}\} \cup \{\mathbf{b}'_1, \dots, \mathbf{b}'_p\}$ ; notice that  $|A| = |F|$ . Also, the elements of  $A$  are ordered as the elements of  $F$  but with  $\mathbf{b}'_k$  replacing  $\mathbf{b}_k$  for  $k \in [p]$ . Then, from the Cauchy-Binet formula and the construction of the matrix  $N$ ,  $\det(R[M]_F DN)$  equals

$$\det([R[M]_F]_{\bullet, A}) [N]_A \cdot \prod_{\mathbf{e} \in A} \mathbf{r}^{-\mathbf{e}} + \text{lower order monomials in the } (-r_1)^{-1}, \dots, (-r_m)^{-1}.$$

Here  $[R[M]_F]_{\bullet, A}$  denotes the restriction of  $R[M]_F$  to the columns indexed by  $\mathbf{e} \in A$ , and  $[N]_A$  denotes the restriction of  $N$  to the rows indexed by  $\mathbf{e} \in A$ . Thus to show that  $R[M]_F DN$  (and therefore  $[CMDN]_F$ ) is invertible, the following two claims, both of which are proved in the full version [64], suffice.

▷ **Claim 38.**  $[N]_A$  is an identity matrix.

▷ **Claim 39.** The matrix  $[R[M]_F]_{\bullet, A}$  is an upper triangular matrix with 1 or  $-1$  entries on the diagonal.

## A.2 Proof of Theorem 21

Let  $f = \mathbf{1}^T \cdot M_1(x_1)M_2(x_2) \cdots M_n(x_n) \cdot \mathbf{1}$  be a width- $w$  commutative ROABP having individual degree at most  $d$ ; here  $M_i \in \mathbb{F}^{w \times w}[x_i]$  for all  $i \in [n]$ . Also, let  $F = M_1(x_1)M_2(x_2) \cdots M_n(x_n)$ . For any  $A \in \text{GL}(n, \mathbb{F})$ , let  $g = f(\mathbf{Ax})$  and  $G = F(\mathbf{Ax})$ . Suppose that  $A$  maps  $x_i \mapsto \ell_i(\mathbf{x})$  and let  $y_i = \ell_i(\mathbf{x})$  for all  $i \in [n]$ . Then,  $g = \mathbf{1}^T \cdot M_1(y_1)M_2(y_2) \cdots M_n(y_n) \cdot \mathbf{1}$  and

$G = M_1(y_1)M_2(y_2) \cdots M_n(y_n)$ . In Sections 3.1 and 3.2, we have shown that  $G(\mathbf{x} + \mathcal{G}_m^{SV})$  has support- $(m-1)$  rank concentration (for  $m = 2 \lceil \log w^2 \rceil + 1$ ) over  $\mathbb{F}(\mathbf{z})$  in the  $\mathbf{y}$ -variables; the  $\mathbf{z}$ -variables are the variables introduced by the  $\mathcal{G}_m^{SV}$  generator. From Observation 15, if  $g(\mathbf{x}) \neq 0$ , then  $g(\mathbf{x} + \mathcal{G}_m^{SV})$ , when viewed as a polynomial over  $\mathbb{F}[\mathbf{z}]$  in the  $\mathbf{y}$ -variables (this we can do as  $g(\mathbf{x} + \mathcal{G}_m^{SV}) = \mathbf{1}^T \cdot G(\mathbf{x} + \mathcal{G}_m^{SV}) \cdot \mathbf{1}$ , and  $G(\mathbf{x} + \mathcal{G}_m^{SV})$  can be viewed as a polynomial over  $\mathbb{A}[\mathbf{z}]$  in the  $\mathbf{y}$ -variables), has a  $\mathbf{y}$ -monomial of support at most  $m-1$ . Let the  $\mathbf{y}$ -degree of this monomial be  $D'$ . As the individual degree of every  $\mathbf{x}$ -variable in  $f$  is at most  $d$ , the individual degree of every  $\mathbf{y}$ -variable in  $g$  is also at most  $d$ . Thus,  $D' \leq (m-1)d$ . As the homogeneous component of  $g(\mathbf{x} + \mathcal{G}_m^{SV})$  of  $\mathbf{y}$ -degree  $D'$  is non-zero, the homogeneous component of  $g(\mathbf{x} + \mathcal{G}_m^{SV})$  (now viewed as polynomial over  $\mathbb{F}[\mathbf{z}]$  in the  $\mathbf{x}$ -variables) of  $\mathbf{x}$ -degree  $D'$  must also be non-zero, since  $\ell_1, \dots, \ell_n$  are linearly independent. This means that  $g(\mathbf{x} + \mathcal{G}_m^{SV})$ , when viewed as a polynomial over  $\mathbb{F}[\mathbf{z}]$  in the  $\mathbf{x}$ -variables, has an  $\mathbf{x}$ -monomial of support (in fact, degree) at most  $D' \leq (m-1)d$ . Thus,  $g(\mathcal{G}_{(m-1)d}^{SV} + \mathcal{G}_m^{SV}) \neq 0$ . Now, it follows directly from the definition of the SV generator that  $\mathcal{G}_{(m-1)d}^{SV} + \mathcal{G}_m^{SV} = \mathcal{G}_{m+(m-1)d}^{SV}$  and so  $g(\mathcal{G}_{m+(m-1)d}^{SV}) \neq 0$ . Replacing  $m$  by its value  $2 \lceil \log w^2 \rceil + 1$  proves the theorem. Note that the SV generator needs  $|\mathbb{F}| \geq n$ .

### A.3 Proof of Theorem 6

Let  $f$  be an  $n$ -variate polynomial computed by a width- $w$  commutative ROABP of individual degree at most  $d$ , and  $g \in \text{orb}(f)$ . Then, from Theorem 21,  $g(\mathcal{G}_{(2 \lceil \log w^2 \rceil (d+1)+1)}^{SV}) \neq 0$  whenever  $g \neq 0$ . Now,  $\mathcal{G}_{(2 \lceil \log w^2 \rceil (d+1)+1)}^{SV}$  has  $2(2 \lceil \log w^2 \rceil (d+1) + 1)$  variables, and is of degree  $n$ . So  $g(\mathcal{G}_{(2 \lceil \log w^2 \rceil (d+1)+1)}^{SV})$  also has  $2(2 \lceil \log w^2 \rceil (d+1) + 1)$  variables. Since the individual degree of  $f$  is at most  $d$ , the  $\deg(f) = \deg(g) \leq nd$ . So the degree of  $g(\mathcal{G}_{(2 \lceil \log w^2 \rceil (d+1)+1)}^{SV})$  is at most  $n^2d$ . Thus, as  $|\mathbb{F}| > n^2d$ , a hitting set for  $g$  can be computed in time  $(n^2d + 1)^{(2 \lceil \log w^2 \rceil (d+1)+1)} = (nd)^{O(d \log w)}$ .

## B Missing proofs from Section 4

### B.1 Proof of Lemma 31

The entries of  $U$ , the columns of  $M$ , the rows and columns of  $D$ , and the rows of  $N$  are indexed by  $\mathbf{e} \in \{0, 1\}^m$ . Impose the degree lexicographic order, denoted by  $\prec_{\text{dlex}}$ , on the indices  $\mathbf{e} \in \{0, 1\}^m$  of  $U$  and the other three matrices (by identifying  $\mathbf{e}$  with an  $m$ -variate monomial). Pick the *minimal* basis of the space spanned by the entries of  $U$  according to this order, i.e., consider the entries of  $U$  in the order dictated by  $\prec_{\text{dlex}}$  while forming the basis. Let  $\mathcal{B} := \{\mathbf{e} \in \{0, 1\}^m : u_{\mathbf{e}} \text{ is in the minimal basis of } U \text{ w.r.t. } \prec_{\text{dlex}}\}$ .

► **Observation 40.** *By the induction hypothesis, for every  $\mathbf{e} \in F \cap \mathcal{B}$ ,  $\text{Supp}(\mathbf{e}) = 2\mu - (q^* - 1)$ .*

**Construction of the matrix  $N$ .** The columns of  $N$  are indexed by  $\mathbf{b} \in F$ . We will now specify a set of column vectors  $\{\mathbf{n}_{\mathbf{b}} : \mathbf{b} \in F\}$  in the null space of  $U$  such that the column of  $N$  indexed by  $\mathbf{b} \in F$  is  $\mathbf{n}_{\mathbf{b}}$ . There are two cases for  $\mathbf{b} \in F$ :

**Case 1:**  $\mathbf{b} \in F \setminus \mathcal{B}$ . In this case,  $u_{\mathbf{b}}$  is dependent on  $\{u_{\mathbf{e}} : \mathbf{e} \in \mathcal{B} \text{ and } \mathbf{e} \prec_{\text{dlex}} \mathbf{b}\}$ . Pick this dependence vector as  $\mathbf{n}_{\mathbf{b}}$ .

**Case 2:**  $\mathbf{b} \in F \cap \mathcal{B}$ . Let there be  $p$  such  $\mathbf{b}, \mathbf{b}_1, \dots, \mathbf{b}_p$ , where  $p \leq |\mathcal{B}| \leq w^2$ . For a set  $E \subseteq [m]$  and  $\mathbf{b} \in \{0, 1\}^m$ , let  $(\mathbf{b})_E$  denote the vector obtained by projecting  $\mathbf{b}$  to the coordinates

in  $E$ . Roughly speaking, the following claim, which is proved in the full version [64], says that each of these  $p$  vectors has a “small signature” that differentiates it from the other  $p - 1$  vectors.

- ▷ **Claim 41.** There exist sets  $E_1, \dots, E_p \subseteq [m]$ , each of size  $w^2 - 1$  such that for all  $k \in [p]$ ,
1.  $\text{Supp}((\mathbf{b}_k)_{E_k}) = w^2 - 1$ ,
  2.  $(\mathbf{b}_k)_{E_k} \neq (\mathbf{b}_\ell)_{E_k} \forall \ell \neq k$ .

As before, we will call  $E_k$  the signature of  $\mathbf{b}_k$ . The following claim tells us that for each vector  $\mathbf{b}_k$ , there is a vector that is not in  $\mathcal{B}$  and has support less than  $2\mu - (q^* - 1)$ , but agrees with  $\mathbf{b}_k$  on its signature and so in some sense can be used as a proxy for  $\mathbf{b}_k$ .

- ▷ **Claim 42.** For every  $k \in [p]$ , there exists a vector  $\mathbf{b}'_k \in \{0, 1\}^m \setminus (F \cup \mathcal{B})$  such that  $(\mathbf{b}'_k)_{E_k} = (\mathbf{b}_k)_{E_k}$  and also  $\mathbf{b}'_k$  and  $\mathbf{b}_k$  agree on all locations where  $\mathbf{b}'_k$  is non-zero.

Proof. Similar to the proof of Claim 36. ◁

We will now use the above two claims to construct  $\mathbf{n}_{\mathbf{b}_k}$  for all  $k \in [p]$ . We will use  $\mathbf{b}'_k$  from Claim 42 as a proxy for  $\mathbf{b}_k$ . Notice that  $u_{\mathbf{b}'_k}$  is dependent on  $\{u_{\mathbf{e}} : \mathbf{e} \in \mathcal{B} \text{ and } \mathbf{e} \prec_{\text{dlex}} \mathbf{b}'_k\}$ . Let this dependence vector be  $\mathbf{n}_{\mathbf{b}_k}$ . This completes the construction of  $N$ . We will now show that  $[CMDN]_F$  is invertible. In fact, we will show that  $\det([CMDN]_F)$  is the ratio of a polynomial in  $\mathbb{F}[\mathbf{t}]$  which contains a monomial of degree at most  $2w^2\mu$  and a product of a bunch of non-zero linear forms in  $\mathbb{F}[\mathbf{t}]$ .

**$[CMDN]_F$  is invertible.** Let  $[M]_F$  be the restriction of  $M$  to the rows indexed by  $F$ , and  $[C]_F$  the restriction of  $C$  to the rows and columns indexed by  $F$ .

► **Observation 43.** *The matrix  $[M]_F$  has the following structure: The rows of  $[M]_F$  are indexed by  $\mathbf{b} = (b_1, \dots, b_m) \in F$  and its columns by  $\mathbf{e} = (e_1, \dots, e_m) \in \{0, 1\}^m$ . Its entry indexed by  $(\mathbf{b}, \mathbf{e})$  is non-zero if and only if for all  $i \in [m]$ ,  $b_i = e_i$  if  $e_i \neq 0$ . All non-zero entries are 1.*

We order the indices  $\mathbf{b} \in F$  as follows: Let  $F_0 := \{\mathbf{b} \in F : \text{Supp}(\mathbf{b}) > 2\mu - (q^* - 1)\}$  and  $F_1 := \{\mathbf{b} \in F : \text{Supp}(\mathbf{b}) = 2\mu - (q^* - 1)\}$ . We first keep the  $\mathbf{b} \in F_0$  in (descending) degree lexicographic order<sup>3</sup>, followed by  $\mathbf{b} \in F_1 \setminus \mathcal{B}$  in (reverse) lexicographic order<sup>4</sup>, and then  $\mathbf{b}_1, \dots, \mathbf{b}_p$ . Also, let  $A := (F \setminus \mathcal{B}) \uplus \{\mathbf{b}'_1, \dots, \mathbf{b}'_p\}$ . Notice that  $|A| = |F|$ . Also, the elements of  $A$  are ordered as the elements of  $F$  but with  $\mathbf{b}'_k$  replacing  $\mathbf{b}_k$  for  $k \in [p]$ . For any  $S \subseteq \{0, 1\}^m$  of size  $|S| = |F|$ , let  $[M]_{F,S}$  denote the restriction of  $[M]_F$  to the columns indexed by  $\mathbf{e} \in S$ , and  $[N]_S$  denote the restriction of  $N$  to the rows indexed by  $\mathbf{e} \in S$ . Now,

$$\begin{aligned} \det([CMDN]_F) &= \det([C]_F) \det([M]_F D N) \\ &= \prod_{\mathbf{b} \in F} \mathbf{r}^{\mathbf{b}} \cdot \left( \sum_{\substack{S \subseteq A \uplus \mathcal{B} \\ |S| = |F|}} \det([M]_{F,S}) \cdot \det([N]_S) \cdot \prod_{\mathbf{e} \in S} \mathbf{r}^{-\mathbf{e}} \right) \\ &= \prod_{\mathbf{b} \in F} \mathbf{r}^{\mathbf{b}} \cdot \left( \sum_{\substack{S \subseteq A \uplus \mathcal{B} \\ |S| = |F|}} \det([M]_{F,S}) \cdot \det([N]_S) \cdot \prod_{\mathbf{e} \in S \cap A} \mathbf{r}^{-\mathbf{e}} \cdot \prod_{\mathbf{e} \in S \cap \mathcal{B}} \mathbf{r}^{-\mathbf{e}} \right) \end{aligned}$$

<sup>3</sup> i.e.,  $\mathbf{b}$  comes before  $\hat{\mathbf{b}}$  if  $\text{Supp}(\mathbf{b}) > \text{Supp}(\hat{\mathbf{b}})$ , or if  $\text{Supp}(\mathbf{b}) = \text{Supp}(\hat{\mathbf{b}})$  and  $\hat{\mathbf{b}} \prec_{\text{lex}} \mathbf{b}$ .

<sup>4</sup> i.e.,  $\mathbf{b}$  comes before  $\hat{\mathbf{b}}$  if  $\hat{\mathbf{b}} \prec_{\text{lex}} \mathbf{b}$ .

$$= \prod_{\mathbf{b} \in F} \mathbf{r}^{\mathbf{b}} \cdot \prod_{\mathbf{e} \in A \uplus \mathcal{B}} \mathbf{r}^{-\mathbf{e}} \cdot \left( \sum_{\substack{S \subseteq A \uplus \mathcal{B} \\ |S|=|F|}} \det([M]_{F,S}) \cdot \det([N]_S) \cdot \prod_{\mathbf{e} \in A \setminus S} \mathbf{r}^{\mathbf{e}} \cdot \prod_{\mathbf{e} \in \mathcal{B} \setminus S} \mathbf{r}^{\mathbf{e}} \right),$$

where the second equality follows from the Cauchy-Binet formula and the third equality from the fact that for any  $S \not\subseteq A \uplus \mathcal{B}$ ,  $\det([N]_S) = 0$ . Now, notice that  $\prod_{\mathbf{b} \in F} \mathbf{r}^{\mathbf{b}} \cdot \prod_{\mathbf{e} \in A \uplus \mathcal{B}} \mathbf{r}^{-\mathbf{e}}$  is the reciprocal of a product of non-zero linear forms in  $\mathbf{t}$ -variables, as  $F \subseteq A \uplus \mathcal{B}$ . We shall now prove that

$$\sum_{\substack{S \subseteq A \uplus \mathcal{B} \\ |S|=|F|}} \det([M]_{F,S}) \cdot \det([N]_S) \cdot \prod_{\mathbf{e} \in A \setminus S} \mathbf{r}^{\mathbf{e}} \cdot \prod_{\mathbf{e} \in \mathcal{B} \setminus S} \mathbf{r}^{\mathbf{e}} \quad (3)$$

has a  $\mathbf{t}$ -monomial of degree at most  $w^2(2\mu - (q^* - 1))$ .

▷ **Claim 44.**  $[N]_A$  is an identity matrix.

Proof. Same as that of Claim 38. ◁

▷ **Claim 45.** The matrix  $[M]_{F,A}$  is an upper triangular matrix with ones on the diagonal.

The proof of the above claim is provided in the full version [64].

▷ **Claim 46.**  $\det([M]_{F,A}) \cdot \det([N]_A) \cdot \prod_{\mathbf{e} \in \mathcal{B} \setminus A} \mathbf{r}^{\mathbf{e}} = \prod_{\mathbf{e} \in \mathcal{B}} \mathbf{r}^{\mathbf{e}} \neq 0$  and has  $\mathbf{t}$ -degree at most  $2w^2\mu$ .

Proof.  $\det([M]_{F,A}) \cdot \det([N]_A) \cdot \prod_{\mathbf{e} \in \mathcal{B} \setminus A} \mathbf{r}^{\mathbf{e}} = \prod_{\mathbf{e} \in \mathcal{B}} \mathbf{r}^{\mathbf{e}} \neq 0$  follows from Claims 44 and 45 and the fact that  $A \cap \mathcal{B}$  is empty. For every  $\mathbf{e} \in \mathcal{B}$ ,  $\deg_{\mathbf{t}}(\mathbf{r}^{\mathbf{e}}) \leq 2\mu - (q^* - 1)$ . So,  $\deg_{\mathbf{t}}(\prod_{\mathbf{e} \in \mathcal{B}} \mathbf{r}^{\mathbf{e}}) \leq w^2 \cdot (2\mu - (q^* - 1)) \leq 2w^2\mu$ , as  $|\mathcal{B}| \leq w^2$ . ◁

▷ **Claim 47.** For any  $S \subseteq A \uplus \mathcal{B}$  such that  $|S| = |F|$  and  $\det([N]_S)$  is non-zero, there is a one-to-one correspondence between  $A \setminus S$  and  $S \cap \mathcal{B}$  such that if  $\mathbf{e} \in A \setminus S$  corresponds to  $\mathbf{e}' \in S \cap \mathcal{B}$ , then  $\mathbf{e}' \prec_{\text{dlex}} \mathbf{e}$ .

The above claim, which is proved in the full version [64], implies that for every  $S \in A \uplus \mathcal{B}$  of size  $|F|$ , either  $\det([M]_{F,S}) \cdot \det([N]_S) \cdot \prod_{\mathbf{e} \in A \setminus S} \mathbf{r}^{\mathbf{e}} \cdot \prod_{\mathbf{e} \in \mathcal{B} \setminus S} \mathbf{r}^{\mathbf{e}}$  is 0, or  $\prod_{\mathbf{e} \in \mathcal{B}} \mathbf{r}^{\mathbf{e}} \prec_{\text{dlex}} \prod_{\mathbf{e} \in A \setminus S} \mathbf{r}^{\mathbf{e}} \cdot \prod_{\mathbf{e} \in \mathcal{B} \setminus S} \mathbf{r}^{\mathbf{e}}$ . Hence,  $\prod_{\mathbf{e} \in \mathcal{B}} \mathbf{r}^{\mathbf{e}}$  is the smallest  $\mathbf{r}$ -monomial in the polynomial given in (3) w.r.t.  $\prec_{\text{dlex}}$  order, and so, the homogeneous component of this polynomial that has the same  $\mathbf{r}$ -degree as that of  $\prod_{\mathbf{e} \in \mathcal{B}} \mathbf{r}^{\mathbf{e}}$  survives. Now, from Claim 46 and the fact that  $\ell_1, \dots, \ell_n$  are linearly independent, the polynomial in (3) has a  $\mathbf{t}$ -monomial of degree  $\leq 2w^2\mu$ .

## B.2 Proof of Lemma 28

So far we have proved that there exist  $\{\beta_{p,q}(i) : p \in [\lceil \log n \rceil], q \in [\mu], i \in [n]\}$ , such that  $G \left( x_1 + \sum_{p \in [\lceil \log n \rceil], q \in [\mu]} s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(1)}, \dots, x_n + \sum_{p \in [\lceil \log n \rceil], q \in [\mu]} s_{p,q} \cdot z_{p,q}^{\beta_{p,q}(n)} \right)$  has support- $\mu$  rank concentration in the  $\mathbf{y}$ -variables over  $\mathbb{F}(s_{p,q}, z_{p,q} : p \in [\lceil \log n \rceil], q \in [\mu])$ . Moreover, for each  $(p, q)$ , we can find all  $\beta_{p,q}(i)$  in time  $n^{O(w^4)}$  and each  $\beta_{p,q}(i) \leq n^{O(w^4)}$ . However, since the algorithm that follows from [45] is oblivious, the  $\beta_{p,q}(i)$  found for some fixed  $(p, q)$  can be used for all values of  $(p, q)$ . This proves the lemma.

### B.3 Proof of Theorem 8

Let  $f = \mathbf{1}^T \cdot M_1(x_1)M_2(x_2) \cdots M_n(x_n) \cdot \mathbf{1}$  be a multilinear width- $w$  ROABP; here  $M_i(x_i) \in \mathbb{F}^{w \times w}[x_i]$  for all  $i \in [n]$ . Also, let  $F = M_1(x_1)M_2(x_2) \cdots M_n(x_n)$ . For any  $A \in \text{GL}(n, \mathbb{F})$ , let  $g = f(A\mathbf{x})$  and  $G = F(A\mathbf{x})$ . For  $i \in [n]$ , suppose that  $A$  maps  $x_i \mapsto \ell_i(\mathbf{x})$ , where  $\ell_i$  is a linear form, and let  $y_i = \ell_i(\mathbf{x})$  and  $\mathbf{y} = \{y_1, \dots, y_n\}$ . Then,  $g = \mathbf{1}^T \cdot M_1(y_1)M_2(y_2) \cdots M_n(y_n) \cdot \mathbf{1}$  and  $G = M_1(y_1)M_2(y_2) \cdots M_n(y_n)$ . Let  $\mu = w^2 + \lceil \log w^2 \rceil$ . From Lemma 28, there exist polynomials, say  $t_1, \dots, t_n$ , in  $\mathbb{F}[s_{p,q}, z_{p,q} : p \in [\lceil \log n \rceil], q \in [\mu]]$  of degree at most  $n^{O(w^4)}$  such that  $G(x_1 + t_1, \dots, x_n + t_n)$  has support- $\mu$  rank concentration in the  $\mathbf{y}$ -variables over  $\mathbb{F}(\{s_{p,q}, z_{p,q}\}_{p,q})$ . Moreover, these polynomials can be computed in time  $n^{O(w^4)}$ . Suppose that  $g \neq 0$ . Then, from Observation 15,  $g(x_1 + t_1, \dots, x_n + t_n)$  has a support- $\mu$ ,  $\mathbf{y}$ -monomial when viewed as a polynomial over  $\mathbb{F}[\{s_{p,q}, z_{p,q}\}_{p,q}]$  in the  $\mathbf{y}$ -variables. Since  $f$  is multilinear, as seen in the proof of Theorem 21,  $g(x_1 + t_1, \dots, x_n + t_n)$  has a support- $\mu$ ,  $\mathbf{x}$ -monomial. Thus,  $g(\mathcal{G}_\mu^{SV} + (t_1, \dots, t_n)) \neq 0$ . Now,  $g(\mathcal{G}_\mu^{SV} + (t_1, \dots, t_n))$  is a polynomial in  $2\mu + \mu \cdot \lceil \log n \rceil$  variables over  $\mathbb{F}$ . Also, its degree is at most  $n^{O(w^4)}$ . So, if  $|\mathbb{F}| > n^{O(w^4)}$ , a hitting set for  $g$  can be computed in time  $n^{O(w^4 \cdot \mu \cdot \log n)} = n^{O(w^6 \cdot \log n)}$ . This, along with the time required to compute  $t_1, \dots, t_n$ , still gives a  $n^{O(w^6 \cdot \log n)}$ -time hitting set for  $g$ .

# Sampling Multiple Edges Efficiently

## Abstract

We present a sublinear time algorithm that allows one to sample multiple edges from a distribution that is pointwise  $\epsilon$ -close to the uniform distribution, in an *amortized-efficient* fashion. We consider the adjacency list query model, where access to a graph  $G$  is given via degree and neighbor queries.

The problem of sampling a single edge in this model has been raised by Eden and Rosenbaum (SOSA 18). Let  $n$  and  $m$  denote the number of vertices and edges of  $G$ , respectively. Eden and Rosenbaum provided upper and lower bounds of  $\Theta^*(n/\sqrt{m})$  for sampling a single edge in general graphs (where  $O^*(\cdot)$  suppresses  $\text{poly}(1/\epsilon)$  and  $\text{poly}(\log n)$  dependencies). We ask whether the query complexity lower bound for sampling a single edge can be circumvented when multiple samples are required. That is, can we get an improved amortized per-sample cost if we allow a preprocessing phase? We answer in the affirmative.

We present an algorithm that, if one knows the number of required samples  $q$  in advance, has an overall cost that is sublinear in  $q$ , namely,  $O^*(\sqrt{q} \cdot (n/\sqrt{m}))$ , which is strictly preferable to  $O^*(q \cdot (n/\sqrt{m}))$  cost resulting from  $q$  invocations of the algorithm by Eden and Rosenbaum.

Subsequent to a preliminary version of this work, Tětek and Thorup (arXiv, preprint) proved that this bound is essentially optimal.

## 1 Introduction

The ability to select edges uniformly at random in a large graph or network, namely *edge sampling*, is an important primitive, interesting both from a theoretical perspective in various models of computation (e.g., [19, 2, 3, 1, 13, 12, 7, 4, 15]), and from a practical perspective in the study of real-world networks (e.g., [20, 22, 31, 6, 27]). We consider the task of outputting edges from a distribution that is close to uniform; more precisely, the output distribution on edges will be *pointwise*  $\epsilon$ -close to the uniform distribution, so that each edge will be returned with probability in  $[\frac{1-\epsilon}{m}, \frac{1+\epsilon}{m}]$ . Note that this is a stronger notion than the more standard

notion of  $\epsilon$ -close to uniform in *total variation distance* (TVD).<sup>1</sup> We consider this task in the sublinear setting, specifically, in the adjacency list query model, where the algorithm can perform uniform vertex queries, as well as degree and neighbor queries.

Three recent algorithms have been presented for this problem in the adjacency list model. The first, by Eden and Rosenbaum [13], is an  $O^*(n/\sqrt{m})$  query complexity<sup>2</sup> algorithm that works in general graphs.<sup>3</sup> This was later refined by Eden, Ron, and Rosenbaum [7] to an  $O^*(m\alpha/n)$  algorithm for graphs that have arboricity<sup>4</sup> at most  $\alpha$  (where it is assumed that  $\alpha$  is given as input to the algorithm). Finally, in [26], Tětek and Thorup combined techniques from the previous two works and presented the state of the art algorithm for sampling a single edge. This algorithm exponentially improves on the dependency in  $1/\epsilon$  compared to the algorithm by [13]. All of these algorithms were also shown to be essentially optimal if one is interested in outputting a *single* edge sample. Naively, to sample  $q$  edges in general graphs, one can invoke the [26] algorithm  $q$  times, with expected complexity  $O^*(q \cdot (n/\sqrt{m}))$ . In this paper, we prove that this query complexity can be improved to  $O^*(\sqrt{q} \cdot (n/\sqrt{m}))$ . That is, we prove that there exists an algorithm with a better *amortized* query complexity.

## 1.1 Results

We present an algorithm that returns an edge from a distribution that is pointwise  $\epsilon$ -close to uniform, and efficiently supports many edge sample invocations. Assuming one knows in advance the number of required edge samples  $q$ , the overall cost of  $q$  edge samples is  $O^*(q \cdot (n/\sqrt{m}) + q) = O^*(q \cdot (n/\sqrt{m}))$ , where the equality is since we can assume that  $q = O(n^2/m)$ .<sup>5</sup> Subsequent to a preliminary version of this work, Tětek and Thorup [26, Theorem 15] proved that the above result is essentially optimal.

Our algorithm is based on two procedures: a preprocessing procedure that is invoked once, and a sampling procedure which is invoked whenever an edge sample is requested. There is a trade-off between the preprocessing cost and per-sample cost of the sampling procedure. Namely, for a trade-off parameter  $x \geq 1$ , which can be given as input to the algorithm, the preprocessing query complexity is  $O^*(n^2/(m \cdot x))$  and the per-sample cost of the sampling procedure is  $O(x/\epsilon)$ .

► **Theorem 1.1 (Informal).** *Let  $G$  be a graph over  $n$  vertices and  $m$  edges. Assume access to  $G$  is given via the adjacency list query model. There exists an algorithm that, given an approximation parameter  $\epsilon$  and a trade-off parameter  $x$ , has two procedures: a preprocessing procedure, and a sampling procedure. The sampling procedure outputs an edge from a distribution that is pointwise  $\epsilon$ -close to uniform. The preprocessing procedure has  $O^*(n^2/(m \cdot x))$  expected query complexity, and the expected per-sample query complexity of the sampling procedure is  $O(x/\epsilon)$ .*

As mentioned previously, this result is essentially optimal, due to a lower bound by Tětek and Thorup [26].

<sup>1</sup> See Section 1.1 for a detailed discussion comparing TVD-closeness to pointwise closeness.

<sup>2</sup> We note that in all the mentioned algorithms the running time is asymptotically equal to the query complexity, and therefore we limit the discussion to query complexity.

<sup>3</sup> Throughout the paper  $O^*(\cdot)$  is used to suppresses  $\text{poly}(\log n/\epsilon)$  dependencies.

<sup>4</sup> The arboricity of a graph is the minimal number of forests required to cover its edge set.

<sup>5</sup> Observe that if the number of required samples  $q$  exceeds  $n^2/m$ , then one can simply perform  $O(n^2 \log n/m)$  uniform pair queries and with high probability recover all edges in the graph. Hence, we can assume that  $q \leq n^2/m$ , and so the term  $q$  does not asymptotically affect the complexity.

► **Theorem 1.2** (Theorem 15 in [26], restated). *Let  $\epsilon$  be some small constant  $0 < \epsilon < 1$ . Any algorithm that samples  $q$  edges from a distribution that is pointwise  $\epsilon$ -close to uniform in the adjacency list query model must perform  $\Omega(\sqrt{q} \cdot (n/\sqrt{m}))$  queries.*

To better understand how the complexity of our upper bound compares to what was previously known, we give some possible instantiations. First, setting  $x = n/\sqrt{m}$  implies a preprocessing phase with  $O^*(n/\sqrt{m})$  queries and a cost of  $O(n/\sqrt{m})$  per sample, thus recovering the bounds of [13]. Second, setting  $x = 1$  implies a preprocessing phase with  $O(n^2/m)$  queries and a cost of  $O(1/\epsilon)$  per sample. This can be compared to the naive approach of querying the degrees of all the vertices in the graph, and then sampling each vertex with probability proportional to its degree and returning an edge incident to the sampled vertex.<sup>6</sup> Hence, the naive approach yields an  $O(n)$  preprocessing cost and  $O(1)$  per-sample cost while our algorithm with  $x = 1$  yields an  $O^*(n^2/m) = O^*(n/d_{\text{avg}})$  preprocessing and  $O(1/\epsilon)$  per-sample cost, where  $d_{\text{avg}}$  denotes the average degree of the graph.

For a concrete example, consider the case where  $m = \Theta(n)$  and  $q = O(\sqrt{n})$  edge samples are required. Setting  $x = n^{1/4}$  gives an overall cost of  $n^{3/4}$  for sampling  $q$  edges, where previously this would have required  $O(n)$  queries (by either the naive approach, or performing  $O(\sqrt{n})$  invocations of the  $O^*(n/\sqrt{m}) = O^*(\sqrt{n})$  algorithm of [26]). In general, if the number of queries  $q$  is known in advance, then setting  $x = \frac{n/\sqrt{m}}{\sqrt{q}}$ , yields that sampling  $q$  edges has an overall cost of  $O^*(\sqrt{q} \cdot (n/\sqrt{m}))$ , where previously this would have required  $O^*(q \cdot (n/\sqrt{m}))$  queries resulting from  $q$  invocations of the algorithm by [26]. We discuss some more concrete applications in the following section.

### From the augmented model to the general query model

Recently, it has been suggested by Aliakbarpour et al. [3] to consider query models that also provide queries for uniform edge samples, and multiple algorithms have since been developed for this model, e.g., [4, 15, 5, 28].

Currently, for “transferring” results in models that allow uniform edge samples back to models that do not allow such queries in a black-box manner,<sup>7</sup> one must either (1) pay a multiplicative cost of  $O^*(n/\sqrt{m})$  per query (replacing each edge sample query in an invocation of the [13] algorithm for sampling edges), (2) pay an additive cost of  $O(n)$  (using the naive approach described above), or (3) pay an additive cost of  $O^*(n^2/m)$  if pair queries<sup>8</sup> are allowed.<sup>9</sup>

For example, the works by Assadi, Kapralov and Khanna [4], Fichtenberger, Gao and Peng [15], and Biswas, Eden and Rubinfeld [5] give algorithms that rely on edge samples for the tasks of approximately counting and uniformly sampling arbitrary subgraphs in sublinear time. Specifically, these works assume the *augmented* query model which allows for vertex, degree, neighbor, pair as well as uniform edge samples queries. When only vertex, degree, neighbor and pair queries (without uniform edge samples) are provided, this is referred to as the *general* query model [21]. Currently, there are no dedicated algorithms for these tasks in the general model, that does not allow edge samples. For approximating the number of 4-cycles, denoted  $\#C_4$ , the algorithms of [4, 15] have query complexity of  $O^*(m^2/\#C_4)$ .

<sup>6</sup> Indeed, the naive approach returns an edge from a distribution that is *exactly* uniform.

<sup>7</sup> This is true for results for which pointwise-close to uniform edge samples are sufficient, as in the case in all the current sublinear results that rely on edge samples (that we know of).

<sup>8</sup> Pair queries return whether there is an edge between two vertices in the graph.

<sup>9</sup> As one can sample *all* edges in the graph with high probability using  $O^*(n^2/m)$  uniform pair queries (by the coupon collector’s argument), and then return from the set of sampled edges.

## 51:4 Sampling Multiple Edges Efficiently

For a graph with  $m = O(n)$  edges and  $\#C_4 = \Theta(n^{3/2})$  4-cycles, this results in an  $O^*(\sqrt{n})$  query complexity in the augmented model. Using our algorithm, we can set  $q = O(\sqrt{n})$ , and approximately count the number of  $\#C_4$ 's in  $O^*(n^{3/4})$  queries in the general query model, where previously to our results this would have cost  $O(n)$  queries. We note that this “black-box” transformation from the augmented model to the general query model is not guaranteed to be optimal in terms of the resulting complexity in the general model. Indeed, dedicated algorithms for counting and sampling stars and cliques in the general model, prove that this is not the case [18, 9, 11, 10, 8, 28]. Nonetheless, to the best of our knowledge, no other results are currently known for subgraphs apart from stars or cliques, and so this approach provides the only known algorithms for arbitrary subgraph counting and sampling in the general model.

### Pointwise vs. TVD

A more standard measure of distance between two distributions  $P$  and  $Q$  is the total variation distance (TVD),  $d_{TV}(P, Q) = \frac{1}{2} \sum_{x \in \Omega} |P(x) - Q(x)|$ . Observe that this is a strictly weaker measure. That is, pointwise-closeness implies closeness in TVD. Thus our algorithm immediately produce a distribution that is TVD close to uniform. However, being close to a distribution in TVD, does not imply pointwise-closeness.<sup>10</sup> Furthermore, in various settings, this weaker definition is not sufficient, as is the case in some of the applications we mentioned previously. For instance, the uniform edge samples in the algorithms of [4, 15] cannot be replaced in a black-box manner by edge samples that are only guaranteed to be close to uniform in TVD. For a concrete example, consider the task of approximately counting the number of triangles. Let  $G = A \cup B$  be a graph, where  $A$  is a bipartite subgraph over  $(1 - \epsilon)m$  edges, and  $B$  is a clique over  $\epsilon m$  edges. An algorithm that returns a uniformly distributed edge in  $A$  is close in TVD to uniform over the entire edge set of  $G$ . However, it does not allow one to correctly approximate the number of triangles in  $G$ , as the algorithm will never return an edge from the clique, which is where all the triangles reside.

## 1.2 Technical Overview

Sampling (almost) uniformly distributed edges is equivalent to sampling vertices with probability (almost) proportional to their degree  $\frac{d(v)}{2m}$ .<sup>11</sup> Hence, from now on we focus on the latter task.

Consider first the following naive procedure for sampling vertices with probability proportional to their degree. Assume that  $d_{\max}$ , the maximum degree in the graph is known. Query a vertex uniformly at random and return it with probability  $\frac{d(v)}{d_{\max}}$ ; otherwise, return fail. Then each vertex is sampled with probability  $\frac{d(v)}{n \cdot d_{\max}}$ . Therefore, if we repeatedly invoke the above until a vertex is returned, then each vertex is returned with probability  $\frac{d(v)}{2m}$ , as desired. However, the expected number of attempts until a vertex is returned is  $O(\frac{n \cdot d_{\max}}{m})$  (since the overall success probability of a single attempt is  $\sum_{v \in V} \frac{d(v)}{n \cdot d_{\max}} = \frac{2m}{n \cdot d_{\max}}$ ), which could be as high as  $O(\frac{n^2}{m})$  when  $d_{\max} = \Theta(n)$ .

<sup>10</sup> E.g., a distribution that ignores  $\epsilon/2$ -fraction of the edges and is uniform on the rest is close in TVD to uniform, but clearly it is not pointwise close.

<sup>11</sup> Since if every  $v$  is sampled with probability in  $(1 \pm \epsilon) \frac{d(v)}{2m}$ , performing one more uniform neighbor query from  $v$  implies that each specific edge  $(v, w)$  in the graph is sampled with probability in  $(1 \pm \epsilon) \cdot \frac{1}{2m}$ .

Our idea is to partition the graph vertices into *light* and *heavy*, according to some degree threshold  $\tau$ , that will play a similar role to that of  $d_{\max}$  in the naive procedure above. Our algorithm has two procedures, a preprocessing procedure and a sampling procedure. The preprocessing procedure is invoked once in the beginning of the algorithm, and the sampling procedure is invoked every time an edge sample is requested. In the preprocessing procedure we construct a data structure that will later be used to sample heavy vertices. In the sampling procedure, we repeatedly try to sample a vertex, each time either a light or a heavy with equal probability, until a vertex is returned. To sample light vertices, we invoke the above simple procedure with  $\tau$  instead of  $d_{\max}$ . Namely, sample a uniform random vertex  $v$ , if  $d(v) \leq \tau$ , return it with probability  $\frac{d(v)}{\tau}$ . To sample heavy vertices, we use the data structure constructed by the preprocessing procedure as will be detailed shortly.

In the preprocessing procedure, we sample a set  $S$  of  $O\left(\frac{n}{\tau} \cdot \frac{\log n}{\epsilon^2}\right)$  vertices uniformly at random. We then construct a data structure that allows to sample edges incident<sup>12</sup> to  $S$  uniformly at random. It holds that with high probability for every heavy vertex  $v$ , its number of neighbors in  $S$ , denoted  $d_S(v)$ , is close to its expected value,  $d(v) \cdot \frac{|S|}{n}$ . Also, it holds that with high probability the sum of degrees of the vertices in  $S$ , denoted  $d(S)$ , is close to its expected value,  $2m \cdot \frac{|S|}{n}$ . Hence, to sample heavy vertices, we first sample an edge  $(u, v)$  incident to  $S$  uniformly at random (without loss of generality  $u \in S$ ) and then we check if the second endpoint  $v$  is heavy. If so, we return  $v$ , and otherwise we fail. By the previous discussion on the properties of  $S$ , it holds that every heavy vertex is sampled with probability approximately  $\frac{d_S(v)}{d(S)} \approx \frac{d(v)}{2m}$ .

### 1.3 Comparison to Previous Work

For the sake of this discussion assume that  $\epsilon$  is some small constant. Most closely related to our work, is the algorithm of [13]. Their algorithm also works by partitioning the graph's vertices to *light* and *heavy* vertices according to their some degree threshold  $\theta$ . Their method of sampling light edges is identical to ours: one simply samples a vertex uniformly at random, and keeps it with probability  $d(v)/\theta$ . In our algorithm,  $\tau$  is the degree threshold for light and heavy vertices, so that  $\tau$  and  $\theta$  plays the same role. The difference between our works is in the sampling of heavy vertices. To sample heavy vertices, the algorithm of [13] tries to reach heavy vertices by sampling light vertices, and then querying one of their neighbors uniformly at random. For this approach to output heavy vertices with almost equal probability to light vertices,  $\theta$  must be set to  $\Omega(\sqrt{m})$ . Our approach for sampling heavy vertices is different, and relies on the preprocessing phase, which later allows us to reach heavy vertices with  $O(1)$  queries. This allows us, in a sense, to decouple the dependence of the threshold  $\tau$  and the success probability of sampling light vertices. Hence, we can allow to set the degree threshold  $\tau$  to smaller values, which results in a more efficient per-sample complexity (at a cost of a preprocessing step).

The algorithm of [7] also outputs a uniformly distributed single edge, however in graphs with bounded arboricity  $\alpha$ . Here too the algorithm first defines light vertices, setting the threshold to  $\Theta(\alpha)$ . Sampling heavy edge is then performed by starting at light vertices as before, but taking longer random walks of length  $\ell$ , for  $\ell$  chosen uniformly in  $[\log n]$ . This method was later used by Tětek [26] to exponentially improve the dependence in  $\epsilon$  of sampling a single edge in the general setting. It is an interesting open question whether there exists an algorithm for sampling multiple edges in bounded arboricity graphs which has better complexity than the algorithm of this work.

<sup>12</sup>We say that an edge  $(u, v)$  is incident to  $S$  if either  $u$  or  $v$  are in  $S$ .

## 1.4 Further Related Work

We note that some of the related works were already mentioned, but we list them again for the sake of completeness.

### Sampling edges in the adjacency list model

As discussed previously, the most related work to ours is that of [13] for sampling a single edge from an almost uniform distribution in general graphs in  $O^*(n/\sqrt{m})$  expected time. This was later refined by Eden, Rosenbaum and Ron [7] to an  $O^*(n\alpha/m)$  expected time algorithm in bounded arboricity graphs, where a bound  $\alpha$  on the arboricity of the graph at question is also given as input to the algorithm.<sup>13</sup> Recently, Tětek and Thorup [26] proved that the dependency in  $\epsilon$  in the algorithm of [13] could be improved from  $1/\sqrt{\epsilon}$  to  $\log(1/\epsilon)$ . They further proved (subsequent to our work) that given additional access to what they refer to as hash-based neighbor queries, there exists an algorithm for sampling multiple edges (with and without replacement) from the exactly uniform distribution in  $O^*(\sqrt{q} \cdot (n/\sqrt{m}))$  time.

### The augmented edge samples model

In [3], Aliakbarpour et al. suggested a query model which allows access to uniform edge samples and degree queries. In this model they presented an algorithm for approximately counting the number of  $s$ -stars in expected time  $O^*(m/\#H^{1/s})$ , where  $\#H$  denotes the number of  $s$ -stars in the graph. In [4], Assadi, Kapralov and Khanna considered the combined power of neighbor, degree, pair and uniform vertex and edge samples. In this model, they presented an algorithm that approximates the number of occurrences of any arbitrary subgraph  $H$  in a graph  $G$  in expected time  $O^*(m^{\rho(H)}/\#H)$ , where  $\rho(H)$  is the fractional edge cover<sup>14</sup> of  $H$ , and  $\#H$  is the number of occurrences of  $H$  in  $G$ . In the same model, Fichtenberger, Gao, and Peng [15] simplified the above algorithm and proved the same complexity for the additional task of sampling a uniformly distributed copy of  $H$ . Recently, Biswas, Eden and Rubinfeld [5], parameterized the complexity of counting and sampling arbitrary subgraph by what they refer to as the decomposition cost of  $H$ , improving the above results for a large family of subgraphs  $H$ . In [28], Tětek considers this model in the context of approximately counting triangles in the super-linear regime.

### Sampling from networks

Sampling from networks is a very basic primitive that is used in a host of works for studying networks' parameters (e.g., [20, 22, 31, 6, 27]). Most approaches for efficiently sampling edges from networks are random walk based approaches, whose complexity is proportional to the mixing time of the network, e.g., [22, 16, 25, 24]. We note that our approach cannot be directly compared with that of the random walk based ones, as the query models are different: The adjacency list query model assumes access to uniform vertex queries and one can only query one neighbor at a time, while random walk based approaches usually only assume access to arbitrary seed vertices and querying a node reveals its set of neighbors. Furthermore, while in theory the mixing time of a graph can be of order  $O(n)$ , in practice,

<sup>13</sup>Note that since for all graphs  $\alpha \leq \sqrt{m}$ , this results is always at least as good as the previous one.

<sup>14</sup>The fractional edge cover of a graph is minimum weight assignment of weights to the graph's edges, so that the sum of weights over the edges incident to each vertex is at least 1.

social networks tend to have smaller mixing times [24], making random walk based approaches very efficient. Still, denoting the mixing time of the network by  $t_{mix}$ , such approaches require one to perform  $\Omega(t_{mix})$  queries in order to obtain *each* new sample, thus leaving the question of a more efficient amortized sampling procedure open.

## 2 Preliminaries

Let  $G = (V, E)$  be an undirected simple graph over  $n$  vertices. We consider the adjacency list query model, which assumes the following set of queries:

- **Uniform vertex queries:** which return a uniformly distributed vertex in  $V$ .
- **Degree queries:**  $deg(v)$ , which return the degree of the queried vertex.
- **Neighbor queries**  $nbr(v, i)$  which return the  $i^{\text{th}}$  neighbor of  $v$ , if one exists and  $\perp$  otherwise.

We sometimes say that we perform a “uniform neighbor query” from some vertex  $v$ . This can be simply implemented by choosing an index  $i \in [d(v)]$  uniformly at random, and querying  $nbr(v, i)$ .

Throughout the paper we consider each edge from both endpoints. That is, each edge  $\{u, v\}$  is considered as two oriented edges  $(u, v)$  and  $(v, u)$ . Abusing notation, let  $E$  denote the set of all oriented edges, so that  $m = |E| = \sum_{v \in V} d(v)$  and  $d_{\text{avg}} = m/n$ . Unless stated explicitly otherwise, when we say an “edge”, we refer to oriented edges.

For a vertex  $v \in V$  we denote by  $\Gamma(v)$  the set of  $v$ 's neighbors. For a set  $S \subseteq V$  we denote by  $E(S)$  the subset of edges  $(u, v)$  such that  $u \in S$ , and by  $m(S)$  the sum of degrees of all vertices in  $S$ , i.e.  $m(S) = |E(S)| = \sum_{v \in S} d(v)$ . For every vertex  $v \in V$  and set  $S \subseteq V$ , we denote by  $d_S(v)$  the degree of  $v$  in  $S$ ,  $d_S(v) = |\Gamma(v) \cap S|$ .

We consider the following definition of  $\epsilon$ -pointwise close distributions:

► **Definition 1** (Definition 1.1 in [13]). *Let  $Q$  be a fixed probability distribution on a finite set  $\Omega$ . We say that a probability distribution  $P$  is pointwise  $\epsilon$ -close to  $Q$  if for all  $x \in \Omega$ ,*

$$|P(x) - Q(x)| \leq \epsilon Q(x), \quad \text{or equivalently} \quad P(X) \in (1 \pm \epsilon)Q(X).$$

If  $Q = U$ , the uniform distribution on  $\Omega$ , then we say that  $P$  is pointwise  $\epsilon$ -close to uniform.

## 3 Multiple Edge Sampling

As discussed in the introduction, our algorithm consists of a preprocessing procedure that creates a data structure that enables one to sample heavy vertices, and a sampling procedure that samples an almost uniformly distributed edge. Also recall that our procedures are parameterized by a value  $x$  which allows for a trade-off between the preprocessing complexity and the per-sample complexity. Namely, allowing per-sample complexity of  $O(x/\epsilon)$ , our preprocessing procedure will run in time  $O^*(n/(d_{\text{avg}} \cdot x))$ . If one knows the number of queries,  $q$ , then setting  $x = \frac{n/\sqrt{m}}{\sqrt{q}}$  yields the optimal trade-off between the preprocessing and the sampling.

### 3.1 Preprocessing

In this section we present our preprocessing procedure that will later allow us to sample heavy vertices. The procedure and its analysis are similar to the procedure Sample-degrees-typical of Eden, Ron, and Seshadhri [11].

## 51:8 Sampling Multiple Edges Efficiently

The input parameters to the procedure are  $n$ , the number of vertices in the graph,  $x$ , the trade-off parameter,  $\delta$ , a failure probability parameter, and  $\epsilon$ , the approximation parameter. The output is a data structure that, with probability at least  $1 - \delta$ , allows one to sample heavy vertices with probability (roughly) proportional to their degree.

We note that we set  $\bar{x} = \min\{x, \sqrt{n/\bar{d}_{\text{avg}}}\}$  since for values  $x = \Omega(\sqrt{n/\bar{d}_{\text{avg}}})$  it is better to simply use the  $O^*(\sqrt{n/\bar{d}_{\text{avg}}})$  per-sample algorithm of [13]. We shall make use of the following theorems.

► **Theorem 3.1** (Theorem 1.1 of [17], restated.). *There exists an algorithm that, given query access to a graph  $G$  over  $n$  vertices and  $m$  edges, an approximation parameter  $\epsilon \in (0, \frac{1}{2})$ , and a failure parameter  $\delta \in (0, 1)$ , returns a value  $\bar{m}$  such that with probability at least  $1 - \delta$ ,  $\bar{m} \in [(1 - \epsilon)m, m]$ . The expected query complexity and running time of the algorithm are  $O(\frac{n}{\sqrt{m}} \cdot \frac{\log^2 n}{\epsilon^{2.5}})$ .*

► **Theorem 3.2** (Section 4.2 and Lemma 17 in [14], restated.). *For a set  $S$  of size at least  $\frac{n}{\sqrt{m}} \cdot \frac{34}{\epsilon}$ , it holds that with probability at least  $5/6$ ,  $m(S)/s > \frac{1}{2} \cdot (1 - \epsilon) \cdot d_{\text{avg}}$ .*

► **Theorem 3.3** (A data structure for a discrete distribution (e.g., [29, 30, 23])). *There exists an algorithm that receives as input a discrete probability distribution  $P$  over  $\ell$  elements, and constructs a data structure that allows one to sample from  $P$  in linear time  $O(\ell)$ .*

### Preprocessing $(n, \epsilon, \delta, x)$

1. Invoke the algorithm of [17]<sup>a</sup> to get an estimate  $\bar{d}_{\text{avg}}$  of the average degree  $d_{\text{avg}}$ .
2. Let  $\bar{x} = \min\left\{x, \sqrt{n/\bar{d}_{\text{avg}}}\right\}$ .
3. Let  $t = \lceil \log_3(\frac{3}{\delta}) \rceil$ , and let  $\tau = \frac{\bar{x} \cdot \bar{d}_{\text{avg}}}{\epsilon}$ .
4. For  $i = 1$  to  $t$  do:
  - a. Let  $S_i$  be a multiset of  $s = \frac{n}{\tau} \cdot \frac{35 \log(6nt/\delta)}{\epsilon^2}$  vertices chosen uniformly at random.
  - b. Query the degrees of all the vertices in  $S_i$  and compute  $m(S_i) = \sum_{v \in S_i} d(v)$ .
5. Let  $S$  be the first set  $S_i$  such that  $\frac{m(S_i)}{s} \in [\frac{1}{4} \cdot \bar{d}_{\text{avg}}, 12 \cdot \bar{d}_{\text{avg}}]$ .
  - a. If no such set exists, then **return fail**.
  - b. Else, set up a data structure<sup>b</sup>  $D(S)$  that supports sampling each vertex  $v \in S$  with probability  $\frac{d(v)}{m(S)}$ .
6. Let  $\bar{\gamma} = \frac{m(S)}{\bar{d}_{\text{avg}} \cdot |S|}$ .
7. **Return**  $(\bar{\gamma}, \tau, \bar{x}, D(S))$ .

<sup>a</sup> See Theorem 3.1

<sup>b</sup> See Theorem 3.3

The following definitions will be useful in order to prove the lemma regarding the performance of the **Preprocessing** procedure.

► **Definition 2.** *We say that a sampled set  $S \subseteq V$  is  $\epsilon$ -good if the following two conditions hold:*

- *For every heavy vertex  $v \in V_{>\tau}$ ,  $d_S(v) \in (1 \pm \epsilon)|S| \cdot \frac{d(v)}{n}$ .*
- *$\frac{m(S)}{s} \in [\frac{1}{4} \cdot d_{\text{avg}}, 12 \cdot d_{\text{avg}}]$ .*

► **Definition 3.** *We say that  $\bar{d}_{\text{avg}}$  is an  $\epsilon$ -good estimate of  $d_{\text{avg}}$  if  $\bar{d}_{\text{avg}} \in [(1 - \epsilon)d_{\text{avg}}, d_{\text{avg}}]$ .*

► **Lemma 4.** Assume query access to a graph  $G$  over  $n$  vertices,  $\epsilon \in (0, \frac{1}{2})$ ,  $\delta \in (0, 1)$ , and  $x \geq 1$ . The procedure **Preprocessing** $(n, \epsilon, \delta, x)$ , with probability at least  $1 - \delta$ , returns a tuple  $(\bar{\gamma}, \tau, \bar{x}, D(S))$  such that the following holds.

- $D(S)$  is a data structure that supports sampling a uniform edge in  $E(S)$ , for an  $\epsilon$ -good set  $S$ , as defined in Definition 2.
- $\bar{x} \in [1, \sqrt{n/\bar{d}_{\text{avg}}}]$ ,  $\tau = \frac{\bar{x} \cdot \bar{d}_{\text{avg}}}{\epsilon}$ , and  $\bar{\gamma} = \frac{m(S)}{\bar{d}_{\text{avg}} \cdot |S|}$ , where  $\bar{d}_{\text{avg}}$  is an  $\epsilon$ -good estimate of  $d_{\text{avg}}$ , as defined in Definition 3.

The expected query complexity and running time of the procedure are  $O\left(\max\left\{\frac{n}{d_{\text{avg}} \cdot x}, \sqrt{\frac{n}{\bar{d}_{\text{avg}}}}\right\} \cdot \frac{\log^2(n \log(1/\delta)/\delta)}{\epsilon}\right)$ .

**Proof.** We start with proving that with probability at least  $1 - \delta$  the set  $S$  chosen in Step 5 is a good set. Namely, that (1)  $\frac{m(S)}{|S|} \in [\frac{1}{4} \cdot \bar{d}_{\text{avg}}, 12 \cdot \bar{d}_{\text{avg}}]$ , and that (2) for all heavy vertices  $v \in V_{>\tau}$ ,  $d_S(v) \in (1 \pm \epsilon)s \cdot \frac{d(v)}{n}$ .

By Theorem 1.1 of [17] (see Theorem 3.1), with probability at least  $1 - \frac{\delta}{3}$ ,  $\bar{d}_{\text{avg}}$  is an  $\epsilon$ -good estimate of  $d_{\text{avg}}$ , that is

$$(1 - \epsilon)d_{\text{avg}} \leq \bar{d}_{\text{avg}} \leq d_{\text{avg}}. \quad (1)$$

We henceforth condition on this event, and continue to prove the latter property. Fix an iteration  $i \in [t]$ . Observe that  $\mathbb{E}\left[\frac{m(S_i)}{s}\right] = d_{\text{avg}}$ . By Markov's inequality,<sup>15</sup> equation (1), and the assumption that  $\epsilon \in (0, \frac{1}{2})$ ,

$$\Pr\left[\frac{m(S_i)}{s} > 12 \cdot \bar{d}_{\text{avg}}\right] \leq \frac{d_{\text{avg}}}{12 \cdot \bar{d}_{\text{avg}}} \leq \frac{1}{12(1 - \epsilon)} \leq \frac{1}{6}.$$

Recall that  $s = \frac{n}{\tau} \cdot \frac{35 \log(6nt/\delta)}{\epsilon^2}$ ,  $\tau = \frac{\bar{x} \cdot \bar{d}_{\text{avg}}}{\epsilon}$ , and  $\bar{x} \leq \sqrt{n/\bar{d}_{\text{avg}}}$  and that we condition on  $\bar{d}_{\text{avg}} \geq (1 - \epsilon)d_{\text{avg}}$ . Thus,  $\tau \leq \frac{\sqrt{m}}{\epsilon}$ , and  $s \geq \frac{34}{\epsilon} \cdot \frac{n}{\sqrt{m}}$ . Therefore, by Lemma 17 in [14] (see Theorem 3.2), for every  $i$ , it holds that

$$\Pr\left[\frac{m(S_i)}{s} \leq \frac{1}{2} \cdot (1 - \epsilon) d_{\text{avg}}\right] \leq \frac{1}{6}. \quad (2)$$

By equations (1), (2), and the assumption that  $\epsilon \in (0, \frac{1}{2})$ ,

$$\Pr\left[\frac{m(S_i)}{s} < \frac{1}{4} \cdot \bar{d}_{\text{avg}}\right] \leq \Pr\left[\frac{m(S_i)}{s} \leq \frac{1}{2} \cdot (1 - \epsilon) d_{\text{avg}}\right] \leq \frac{1}{6}$$

By the union bound, for every specific  $i$ ,

$$\Pr\left[\frac{m(S_i)}{s} < \frac{1}{4} \cdot \bar{d}_{\text{avg}} \quad \text{or} \quad \frac{m(S_i)}{s} > 12 \cdot \bar{d}_{\text{avg}}\right] \leq \frac{1}{3}.$$

Hence, the probability that for all the selected multisets  $\{S_i\}_{i \in [t]}$ , either  $\frac{m(S_i)}{s} < \frac{1}{4} \cdot \bar{d}_{\text{avg}}$  or  $\frac{m(S_i)}{s} > 12 \cdot \bar{d}_{\text{avg}}$  is bounded by  $\frac{1}{3^t} = \frac{\delta}{3}$  (recall  $t = \lceil \log_3(\frac{3}{\delta}) \rceil$ ). Therefore, with probability at least  $1 - \frac{2\delta}{3}$ , it holds that  $\frac{m(S)}{s} \in [\frac{1}{4} \cdot \bar{d}_{\text{avg}}, 12 \cdot \bar{d}_{\text{avg}}]$ , and the procedure does not return *fail* in Step 5a.

<sup>15</sup> Markov's inequality: if  $X$  is a non-negative random variable and  $a > 0$ ,  $P(X \geq a) \leq \frac{E(X)}{a}$ .

## 51:10 Sampling Multiple Edges Efficiently

Next, we prove that there exists a high-degree vertex  $v \in V_{>\tau}$  such that  $d_S(v) \notin (1 \pm \epsilon)s \cdot \frac{d(v)}{n}$  with probability at most  $\frac{\delta}{3}$ . Fix an iteration  $i \in [t]$ , and let  $S_i = \{u_1, \dots, u_s\}$  be the sampled set. For any fixed high-degree vertex  $v \in V_{>\tau}$  and for some vertex  $u \in V$ , let

$$\chi^v(u) = \begin{cases} 1 & u \text{ is a neighbor of } v \\ 0 & \text{otherwise} \end{cases}.$$

Observe that  $\mathbb{E}_{u \in V} [\chi^v(u)] = \frac{d(v)}{n}$ , and that  $d_{S_i}(v) = \sum_{j \in [s]} \chi^v(u_j)$ . Thus,  $\mathbb{E}[d_{S_i}(v)] = s \cdot \frac{d(v)}{n}$ . Since the  $\chi^v(u)$  variables are independent  $\{0, 1\}$  random variables, by the multiplicative Chernoff bound,<sup>16</sup>

$$\Pr \left[ \left| d_{S_i}(v) - \frac{s \cdot d(v)}{n} \right| \geq \epsilon \cdot \frac{s \cdot d(v)}{n} \right] \leq 2 \exp \left( -\frac{\epsilon^2 \cdot s \cdot d(v)}{3n} \right) \leq \frac{\delta}{3nt}, \quad (3)$$

where the last inequality is by the assumption that  $\epsilon \in (0, \frac{1}{2})$ , the setting of  $s = \frac{n}{\tau} \cdot \frac{35 \log(6nt/\delta)}{\epsilon^2}$ , and since we fixed a heavy vertex  $v$  so that  $d(v) \geq \tau$ . By taking a union bound over all high-degree vertices, it holds that there exists  $v \in V_{>\tau}$  such that  $d_{S_i}(v) \notin (1 \pm \epsilon) \frac{s \cdot d(v)}{n}$  with probability at most  $\frac{\delta}{3t}$ .

Hence, with probability at least  $1 - \delta$ ,  $D(S)$  is a data structure of a good set  $S$ . Moreover, by steps 2, 6, and 3 in the procedure **Preprocessing**( $n, \epsilon, \delta, x$ ) it holds that  $\bar{x} \in \left[ 1, \sqrt{n/\bar{d}_{\text{avg}}} \right]$ ,

$\bar{\gamma} = \frac{m(S)}{\bar{d}_{\text{avg}} \cdot |S|}$ , and  $\tau = \frac{\bar{x} \cdot \bar{d}_{\text{avg}}}{\epsilon}$  respectively. By equation (1),  $\bar{d}_{\text{avg}}$  is an  $\epsilon$ -good estimate for  $d_{\text{avg}}$ .

We now turn to analyze the complexity. By [17] (see Theorem 3.1), the query complexity and running time of step 1 is  $O\left(\frac{n}{\sqrt{m}} \cdot \frac{\log^2(n)}{\epsilon^{2.5}}\right)$ . The expected query complexity and running time of the for loop are  $O(t \cdot s) = O\left(\frac{n}{\bar{d}_{\text{avg}} \cdot \bar{x}} \cdot \frac{\log^2(n \log(1/\delta)/\delta)}{\epsilon}\right)$ , where the equality holds by the setting of  $s, t$  and since the expected value of  $\bar{d}_{\text{avg}}$  is  $d_{\text{avg}}$ . Step 5 takes  $O(t)$  time. By [29, 30, 23] (see Theorem 3.3), the running time of step 5b is  $O(s)$ . All other steps takes  $O(1)$  time. Hence, the expected query complexity and running time are dominated by the for loop. By the setting of  $\bar{x} = \min\{x, \sqrt{n/\bar{d}_{\text{avg}}}\}$  we have  $O(s \cdot t) = O\left(\frac{n}{\bar{d}_{\text{avg}} \cdot \bar{x}} \cdot \frac{\log^2(n \log(1/\delta)/\delta)}{\epsilon}\right) = O\left(\max\left\{\frac{n}{\bar{d}_{\text{avg}} \cdot x}, \sqrt{\frac{n}{\bar{d}_{\text{avg}}}}\right\} \cdot \frac{\log^2(n \log(1/\delta)/\delta)}{\epsilon}\right)$  which proves the claim.  $\blacktriangleleft$

### 3.2 Sampling an edge

In this section we present our sampling procedures. The following definition and claim will be useful in our analysis.

► **Definition 5.** Let  $\tau$  be a degree threshold. Let  $V_{\leq\tau} = \{v \in V \mid d(v) \leq \tau\}$ , and let  $V_{>\tau} = V \setminus V_{\leq\tau}$ . We refer to  $V_{\leq\tau}$  and  $V_{>\tau}$  as the sets of light vertices and heavy vertices, respectively. Let  $E_{\leq\tau} = \{(u, v) \mid u \in V_{\leq\tau}\}$  and  $E_{>\tau} = \{(u, v) \mid u \in V_{>\tau}\}$ .

► **Definition 6.** If the procedure **Preprocessing**( $n, \epsilon, \delta, x$ ) returns a tuple  $(\bar{\gamma}, \tau, \bar{x}, D(S))$  such that the following items of Lemma 4 hold, then we say that this invocation is successful.

- $D(S)$  is a data structure that supports sampling a uniform edge in  $E(S)$ , for an  $\epsilon$ -good set  $S$ , as defined in Definition 2.
- $\bar{x} \in [1, \sqrt{n/\bar{d}_{\text{avg}}}]$ ,  $\tau = \frac{\bar{x} \cdot \bar{d}_{\text{avg}}}{\epsilon}$ , and  $\bar{\gamma} = \frac{m(S)}{\bar{d}_{\text{avg}} \cdot |S|}$ , where  $\bar{d}_{\text{avg}}$  is an  $\epsilon$ -good estimate of  $d_{\text{avg}}$ , as defined in Definition 3.

<sup>16</sup> Multiplicative Chernoff bound: if  $X_1, \dots, X_n$  are independent random variables taking values in  $\{0, 1\}$ , then for any  $0 \leq \delta \leq 1$ ,  $\Pr \left[ \left| \sum_{i \in [n]} X_i - \mu \right| \geq \delta \mu \right] \leq 2e^{-\frac{\delta^2 \mu}{3}}$  where  $\mu = \mathbb{E} \left[ \sum_{i \in [n]} X_i \right]$ .

▷ **Claim 7.** Let  $\gamma = \frac{m(S)}{d_{\text{avg}} \cdot |S|}$  and  $\bar{\gamma} = \frac{m(S)}{d_{\text{avg}} \cdot |S|}$ . If  $S$  is an  $\epsilon$ -good set, as in Definition 2, and  $\bar{d}_{\text{avg}}$  is an  $\epsilon$ -good estimate of  $d_{\text{avg}}$ , as in Definition 3, then it holds that  $\bar{\gamma} \in [1/4, 12]$  and that  $\gamma \in [(1 - \epsilon)\bar{\gamma}, \bar{\gamma}]$ .

*Proof.* By the assumption that  $S$  is an  $\epsilon$ -good set, it holds that  $\frac{m(S)}{|S|} \in [\frac{1}{4} \cdot \bar{d}_{\text{avg}}, 12 \cdot \bar{d}_{\text{avg}}]$ . Therefore,  $\bar{\gamma} \in [\frac{1}{4}, 12]$ . By the assumption that  $\bar{d}_{\text{avg}}$  is an  $\epsilon$ -good estimate of  $d_{\text{avg}}$ , namely  $\bar{d}_{\text{avg}} \in [(1 - \epsilon)d_{\text{avg}}, d_{\text{avg}}]$ , it holds that  $\gamma \in [(1 - \epsilon)\bar{\gamma}, \bar{\gamma}]$ . ◁

### 3.2.1 The sampling procedures

We now present the two procedures for sampling light edges and heavy edges.

**Sample-Uniform-Edge** ( $\bar{\gamma}, \tau, \bar{x}, D(S), \epsilon$ )

1. While **True** do:
  - a. Sample uniformly at random a bit  $b \leftarrow \{0, 1\}$ .
  - b. If  $b = 0$  invoke **Sample-Light**( $\bar{\gamma}, \tau$ ).
  - c. Otherwise, invoke **Sample-Heavy**( $\tau, D(S), \bar{x}, \epsilon$ ).
  - d. If an edge  $(v, u)$  was returned, then **return**  $(v, u)$ .

**Sample-Light** ( $\bar{\gamma}, \tau$ )

1. Sample a vertex  $v \in V$  uniformly at random and query for its degree.
2. If  $d(v) > \tau$  **return fail**.
3. Query a uniform neighbor of  $v$ . Let  $u$  be the returned vertex.
4. **Return**  $(v, u)$  with probability  $\frac{d(v)}{\tau} \cdot \frac{1}{4\bar{\gamma}}$ , otherwise **return fail**.

**Sample-Heavy** ( $\tau, D(S), \bar{x}, \epsilon$ )

1. Sample from the data structure  $D(S)$  a vertex  $v \in S$  with probability  $\frac{d(v)}{m(S)}$ .
2. Sample uniform neighbor of  $v$ . Let  $u$  be the returned vertex.
3. If  $d(u) \leq \tau$  **return fail**.
4. Sample uniform neighbor of  $u$ . Let  $w$  be the returned vertex.
5. **Return**  $(u, w)$  with probability  $\epsilon/4\bar{x}$ , otherwise **return fail**.

Our procedure for sampling an edge **Sample-Uniform-Edge** gets as input a tuple  $(\bar{\gamma}, \tau, \bar{x}, D(S))$  which is the output of the procedure **Preprocessing**. Our guarantees on the resulting distribution of edge samples rely on the preprocessing being successful (see Definition 6), which happens with probability at least  $1 - \delta$ .

► **Lemma 8.** *Assume that **Preprocessing** has been invoked successfully, as defined in Definition 6. The procedure **Sample-Light**( $\bar{\gamma}, \tau$ ) returns an edge in  $E_{\leq \tau}$  such that each edge is returned with probability  $\frac{\epsilon|S|}{4n \cdot \bar{x} \cdot m(S)}$ . The query complexity and running time of the procedure are  $O(1)$ .*

**Proof.** Let  $(v, u)$  be a fixed edge in  $E_{\leq \tau}$ .

$$\begin{aligned} \Pr[(v, u) \text{ returned}] &= \Pr[(v \text{ is sampled in Step 1) and } (u \text{ sampled in Step 3}) \\ &\quad \text{and } ((v, u) \text{ returned in Step 4})] \\ &= \frac{1}{n} \cdot \frac{1}{d(v)} \cdot \frac{d(v)}{\tau \cdot 4\bar{\gamma}}. \end{aligned}$$

## 51:12 Sampling Multiple Edges Efficiently

Note that by Claim 7,  $1/4\bar{\gamma} \leq 1$  and therefore, Step 4 is valid and the above holds. Hence, by the setting of  $\tau = \frac{\bar{x} \cdot \bar{d}_{\text{avg}}}{\epsilon}$  and  $\bar{\gamma} = \frac{m(S)}{d_{\text{avg}} \cdot |S|}$ ,

$$\Pr[(v, u) \text{ is returned}] = \frac{1}{n \cdot \tau \cdot 4\bar{\gamma}} = \frac{\epsilon \cdot |S|}{4n \cdot \bar{x} \cdot m(S)}.$$

The procedure performs at most one degree query and one uniform neighbor query. All other operations take constant time. Therefore, the query complexity and running time of the procedure are constant.  $\blacktriangleleft$

► **Lemma 9.** *Assume that **Preprocessing** has been invoked successfully, as defined in Definition 6. The procedure **Sample-Heavy**( $\tau, D(S), \bar{x}, \epsilon$ ) returns an edge in  $E_{>\tau}$  such that each edge is returned with probability  $\frac{(1 \pm \epsilon)\epsilon|S|}{4n \cdot \bar{x} \cdot m(S)}$ . The query complexity and running time of the procedure are  $O(1)$ .*

**Proof.** Let  $(u, w)$  be an edge in  $E_{>\tau}$ . We first compute the probability that  $u$  is sampled in Step 2. Recall, the data structure  $D(S)$  supports sampling a vertex  $v$  in  $S$  with probability  $\frac{d(v)}{m(S)}$ . The probability that  $u$  is sampled in Step 2 is equal to the probability that a vertex  $v \in S$  which is a neighbor of  $u$  is sampled in step 1, and  $u$  is the selected neighbor of  $v$  in Step 2. Namely,

$$\Pr[u \text{ is sampled in Step 2}] = \sum_{v \in S \cap \Gamma(u)} \frac{d(v)}{m(S)} \cdot \frac{1}{d(v)} = \sum_{v \in S \cap \Gamma(u)} \frac{1}{m(S)} = \frac{d_S(u)}{m(S)}.$$

By the assumption that **Preprocessing** has been invoked successfully, so that  $S$  is  $\epsilon$ -good, and because  $u \in V_{>\tau}$ ,

$$d_S(u) \in (1 \pm \epsilon) \cdot |S| \cdot \frac{d(u)}{n}.$$

Hence, the probability that  $(u, w)$  is returned by the procedure is

$$\begin{aligned} \Pr[(u, w) \text{ is returned}] &= \Pr[(u \text{ sampled in Step 2}) \text{ and } (w \text{ sampled in Step 5}) \\ &\quad \text{and } ((u, w) \text{ returned in Step 5})] \\ &= \frac{d_S(u)}{m(S)} \cdot \frac{1}{d(u)} \cdot \frac{\epsilon}{4\bar{x}} \in \frac{(1 \pm \epsilon)|S| \cdot \frac{d(u)}{n} \cdot \epsilon}{m(S) \cdot d(u) \cdot 4\bar{x}} = \frac{(1 \pm \epsilon)\epsilon|S|}{4n \cdot \bar{x} \cdot m(S)}. \end{aligned}$$

The procedure performs one degree query and two neighbor queries, and the rest of the operations take constant time. Hence the query complexity and running time are constant.  $\blacktriangleleft$

We are now ready to prove the formal version of Theorem 1.1.

► **Theorem 3.4.** *There exists an algorithm that gets as input query access to a graph  $G$ ,  $n$ , the number of vertices in the graph,  $\epsilon \in (0, \frac{1}{2})$ , an approximation parameter,  $\delta \in (0, 1)$ , a failure parameter, and  $x > 1$ , a trade-off parameter. The algorithm has a preprocessing procedure and a sampling procedure.*

*The preprocessing procedure has expected query complexity  $O\left(\max\left\{\frac{n}{d_{\text{avg}} \cdot x}, \sqrt{\frac{n}{d_{\text{avg}}}}\right\} \cdot \frac{\log^2(n \log(1/\delta)/\delta)}{\epsilon}\right)$ , and it succeeds with probability at least  $1 - \delta$ . If the preprocessing procedure succeeds, then each time the sampling procedure is invoked it returns an edge such that the distribution on returned edges is  $2\epsilon$ -point-wise close to uniform, as defined in Definition 1. Each invocation of the sampling procedure has expected  $O(\bar{x}/\epsilon)$  query and time complexity.*

**Proof.** By 9, the procedure **Preprocessing** procedure succeeds with probability at least  $1 - \delta$ . Furthermore, it has expected running time and query complexity as stated.

Condition on the event that the invocation of **Preprocessing** was successful. Let  $P$  denote the distribution over the returned edges by the procedure **Sample-Uniform-Edge**. By Lemma 2.3 in [13], in order to prove that  $P$  is pointwise  $2\epsilon$ -close to uniform, it suffices to prove that for every two edges  $e, e'$  in the graph,  $\frac{P(e)}{P(e')} \in (1 \pm 2\epsilon)$ . By Lemma 8, every light edge  $e$  is returned with probability  $\frac{\epsilon \cdot |S|}{4n \cdot \bar{x} \cdot m(S)}$ . By Lemma 9, every heavy edge  $e'$  is returned with probability  $\frac{(1 \pm \epsilon)\epsilon |S|}{4n \cdot \bar{x} \cdot m(S)}$ . Therefore, for every two edges  $e, e'$  in the graph,  $\frac{P(e)}{P(e')} \in (1 \pm 2\epsilon)$ .

Next, we prove a lower bound on the success probability of a single invocation of the while loop in Step 1 in **Sample-Uniform-Edge**.

$$\begin{aligned} \Pr[\text{an edge is returned}] &= \frac{1}{2} \Pr[\text{Sample-Light returns an edge}] \\ &\quad + \frac{1}{2} \Pr[\text{Sample-Heavy returns an edge}] \\ &\geq \frac{1}{2} |E_{\leq \tau}| \cdot \frac{\epsilon \cdot |S|}{4n \cdot \bar{x} \cdot m(S)} + \frac{1}{2} \cdot |E_{> \tau}| \cdot \frac{(1 - \epsilon)\epsilon \cdot |S|}{4n \cdot \bar{x} \cdot m(S)} \\ &\geq \frac{1}{2} \cdot \frac{(1 - \epsilon) \cdot \epsilon |S| \cdot m}{4n \cdot \bar{x} \cdot m(S)} = \frac{(1 - \epsilon)\epsilon}{8\gamma \bar{x}} \geq \frac{\epsilon}{192x}, \end{aligned}$$

where the second inequality is due to Claim 7, i.e.  $\gamma \leq 12$ . Hence, the expected number of invocations until an edge is returned is  $O(\bar{x}/\epsilon)$ . ◀

## Abstract

The Forrelation problem, first introduced by Aaronson [1] and Aaronson and Ambainis [2], is a well studied computational problem in the context of separating quantum and classical computational models. Variants of this problem were used to give tight separations between quantum and classical query complexity [2]; the first separation between poly-logarithmic quantum query complexity and bounded-depth circuits of super-polynomial size, a result that also implied an oracle separation of the classes BQP and PH [15]; and improved separations between quantum and classical communication complexity [12]. In all these separations, the lower bound for the classical model only holds when the advantage of the protocol (over a random guess) is more than  $\approx 1/\sqrt{N}$ , that is, the success probability is larger than  $\approx 1/2 + 1/\sqrt{N}$ . This is unavoidable as  $\approx 1/\sqrt{N}$  is the correlation between two coordinates of an input that is sampled from the Forrelation distribution, and hence there are simple classical protocols that achieve advantage  $\approx 1/\sqrt{N}$ , in all these models.

To achieve separations when the classical protocol has smaller advantage, we study in this work the XOR of  $k$  independent copies of (a variant of) the Forrelation function (where  $k \ll N$ ). We prove a very general result that shows that any family of Boolean functions that is closed under restrictions, whose Fourier mass at level  $2k$  is bounded by  $\alpha^k$  (that is, the sum of the absolute values of all Fourier coefficients at level  $2k$  is bounded by  $\alpha^k$ ), cannot compute the XOR of  $k$  independent copies of the Forrelation function with advantage better than  $O\left(\frac{\alpha^k}{N^{k/2}}\right)$ . This is a strengthening of a result of [8], that gave a similar statement for  $k = 1$ , using the technique of [15]. We give several applications of our result. In particular, we obtain the following separations:

**Quantum versus Classical Communication Complexity.** We give the first example of a partial Boolean function that can be computed by a simultaneous-message quantum protocol with communication complexity  $\text{polylog}(N)$  (where Alice and Bob also share  $\text{polylog}(N)$  EPR pairs), and such that, any classical randomized protocol of communication complexity at most  $\tilde{o}(N^{1/4})$ , with any number of rounds, has quasipolynomially small advantage over a random guess. Previously, only separations where the classical protocol has polynomially small advantage were known between these models [10, 12].

**Quantum Query Complexity versus Bounded Depth Circuits.** We give the first example of a partial Boolean function that has a quantum query algorithm with query complexity  $\text{polylog}(N)$ , and such that, any constant-depth circuit of quasipolynomial size has quasipolynomially small advantage over a random guess. Previously, only separations where the constant-depth circuit has polynomially small advantage were known [15].

## 1 Introduction

Several recent works used Fourier analysis to prove lower bounds for computing (variants of) the Forrelation (partial) function of [1, 2], in various models of computation and communication [15, 8, 12]. These works show that for many computational models, when analyzing the success probability of computing the Forrelation function, it's sufficient to bound the contribution of Fourier coefficients at level 2, ignoring all other Fourier coefficients [15, 8]. This holds for any computational model that is closed under restrictions and is proved by analyzing the Forrelation distribution as a distribution resulting from a certain random walk, rather than analyzing it directly.

While this is a powerful technique, it could only be used to bound computations of the Forrelation function with advantage (over a random guess) larger than  $\approx 1/\sqrt{N}$ , that is, computations with success probability larger than  $\approx 1/2 + 1/\sqrt{N}$ . Roughly speaking, this is because the bound on the Fourier coefficients at level 2 of the Forrelation function is  $\approx O(1/\sqrt{N})$ . We note that while ruling out protocols with advantage larger than  $1/\sqrt{N}$  is satisfactory in many cases, an advantage of  $1/\sqrt{N}$  is often viewed as non-negligible and it is often desirable to rule out protocols with negligible (sub-polynomially small) advantage as well.

In this work, we study the XOR of  $k$  independent copies of the Forrelation function of [15] (where  $k < o(N^{1/50})$ ). We show that for many computational models, when analyzing the success probability of computing the XOR of  $k$  independent copies of the Forrelation function, it's sufficient to bound the contribution of Fourier coefficients at level  $2k$ , ignoring all other Fourier coefficients. Our proof builds on the techniques of [15], and followup works [8, 12], by analyzing a “product” of  $k$  random walks, one for each of the independent copies of the Forrelation function. This can be viewed as a random walk with a  $k$ -dimensional time variable.

Consequently, we obtain a very general lower bound that shows that any family of Boolean functions that is closed under restrictions, whose Fourier mass at level  $2k$  is bounded by  $\alpha^k$  (that is, for every function in the family, the sum of the absolute values of all Fourier coefficients at level  $2k$  is bounded by  $\alpha^k$ ), cannot compute the XOR of  $k$  independent copies of the Forrelation function with advantage better than  $O\left(\frac{\alpha^k}{N^{k/2}}\right)$ , that is, with success probability larger than  $\frac{1}{2} + O\left(\frac{\alpha^k}{N^{k/2}}\right)$ . This is a strengthening of a result of [8], that gave a similar statement for  $k = 1$ , using the technique of [15]. While bounding the advantage of protocols for the XOR of  $k$  independent copies of a problem is often non-trivial, our result gives a very general way to do that for the special case of Forrelation.

We note that the requirement that the family of Boolean functions is closed under restrictions is satisfied by essentially all non-uniform computational models. The requirement of having a good bound on the Fourier mass at level  $2k$  is satisfied by several central and well-studied computational models (see for example [7] for a recent discussion). In particular, we focus in this work on three such models: communication complexity, query complexity (decision trees) and bounded-depth circuits. We note that our result is valid for any  $k < N^c$ , for some constant  $c > 0$ , and hence it can be used to prove lower bounds for circuits/protocols with exponentially small advantage, in all these models. However, for the applications of separating quantum and classical computational models, we take  $k$  to be poly-logarithmic in  $N$ , so that we have quantum protocols of poly-logarithmic cost. We use our main theorem to give several separations between quantum and classical computational models.

## 1.1 Communication Complexity

Quantum versus classical separations in communication complexity have been studied for more than two decades in numerous works. We briefly summarize the history of quantum advantage in communication complexity of partial functions, that is most relevant for us: First, Buhrman, Cleve and Wigderson proved an exponential separation between zero-error simultaneous-message quantum communication complexity (without entanglement) and classical deterministic communication complexity [4]. For the bounded-error model, Raz showed an exponential separation between two-way quantum communication complexity and two-way randomized communication complexity [14]. Gavinsky et al (building on Bar-Yossef et al [3]) gave an exponential separation between one-way quantum communication complexity and one-way randomized communication complexity [11]. Klartag and Regev gave an exponential separation between one-way quantum communication complexity and two-way randomized communication complexity [16]. The state of the art separation, by Gavinsky, gave an exponential separation between simultaneous-message quantum communication complexity (with entanglement) and two-way randomized communication complexity [10]. An alternative proof for Gavinsky's result was recently given by [12], as a followup to [15, 8], and had the additional desired property that in the quantum protocol, the time complexity of all the players is poly-logarithmic.

## Our Result

In all these works, the lower bounds for classical communication complexity only hold when the advantage of the protocol (over a random guess) is more than  $\approx 1/\sqrt{N}$ , that is, the success probability is larger than  $\approx 1/2 + 1/\sqrt{N}$ .

In this work, we give a partial Boolean function that can be computed by a simultaneous-message quantum protocol with communication complexity  $\text{polylog}(N)$  (where Alice and Bob also share  $\text{polylog}(N)$  EPR pairs), and such that, any classical randomized protocol of communication complexity at most  $\tilde{o}(N^{1/4})$ , with any number of rounds, has quasipolynomially small advantage over a random guess. This qualitatively matches the results of [10, 12] and has the additional desired property that the lower bound for the classical communication protocol holds for quasipolynomially small advantage, rather than polynomially small advantage. Moreover, as in [12], the quantum protocol in our upper bound has the additional property of being *efficiently implementable*, in the sense that it can be described by quantum circuits of size  $\text{polylog}(N)$ , with oracle access to the inputs.

To prove this result we use the XOR of  $k$  independent copies of the Forrelation function, lifted to communication complexity using XOR as the gadget [13], as in [12]. The quantum upper bound is simple. For the classical lower bound, we use ideas from [12] to bound the

level- $2k$  Fourier mass. This, along with our main theorem implies the desired separation. Our bounds for the level- $2k$  Fourier mass may be interesting in their own right and are proved in Section 7.

## Related Work

We note that an exponential separation between **two-way** quantum communication complexity and two-way randomized communication complexity, with quasipolynomially small advantage, can be proved by a combination of several previous results, as follows:

Start with an existing separation between quantum and classical query complexity, such as the one of [2]. Use Drucker's XOR lemma for randomized decision tree [9] to get a separation between quantum and classical query complexity, where the classical protocol has quasipolynomially small advantage. Finally, use the recent lifting theorem of [5] to lift the result to communication complexity. To the best of our knowledge, this separation was not previously observed.

It follows from these works that there exists a function computable in the quantum two-way model in communication complexity  $\text{polylog}(N)$ , for which randomized protocols of cost  $\tilde{o}(\sqrt{N})$  have at most quasipolynomially small advantage. While the lower bound is for cost  $\tilde{o}(\sqrt{N})$  protocols, which is quantitatively stronger than our lower bound for cost  $\tilde{o}(N^{1/4})$  protocols, the quantum upper bound in this result seems to require two rounds of communication, while our function is computable in the simultaneous model when Alice and Bob share entanglement.

## 1.2 Bounded Depth Circuits

Separations of quantum query complexity and bounded-depth classical circuit complexity have been studied in the context of oracle separations of the classes BQP and PH. An example of a partial Boolean function (Forrelation) that has a quantum query algorithm with query complexity  $\text{polylog}(N)$ , and such that, any constant-depth circuit of quasipolynomial size has polynomially small advantage over a random guess, was given in [15]. This result implied an oracle separation of the classes BQP and PH.

Here, we give the first example of a partial Boolean function (XOR of  $k$  copies of Forrelation) that has a quantum query algorithm with query complexity  $\text{polylog}(N)$ , and such that, any constant-depth circuit of quasipolynomial size has **quasipolynomially** small advantage over a random guess.

For the proof, we use our main theorem, together with Tal's bounds on the level- $2k$  Fourier mass of bounded-depth circuits [17].

## 1.3 Decision Trees

The query complexity model (also known as black box model or decision-tree complexity) has played a central role in the study of quantum computational complexity. Quantum advantages in query complexity (decision trees) have been demonstrated for partial functions in various settings and numerous works. For example, Aaronson and Ambainis [2] showed that the Forrelation problem can be solved by one quantum query, while its randomized query complexity is  $\Omega(\sqrt{N}/\log N)$ .

For classical randomized query complexity, there is a known XOR lemma, proved by Drucker [9]. In particular, Theorem 1.3 of [9], along with the result of [2] gives a partial function (XOR of  $\text{polylog}(N)$  copies of Forrelation) that can be computed by a quantum query algorithm with  $\text{polylog}(N)$  queries, while every classical randomized algorithm that makes  $\tilde{o}(N^{1/2})$  queries, has quasipolynomially small advantage.

Our main theorem implies a different proof for this result, using Tal’s recent bounds on the level- $2k$  Fourier mass of decision trees [18].

### 1.4 The Main Theorem

Our functions are obtained by taking an XOR of several copies of a variant of the Forrelation problem, as defined in [15].

Let  $N = 2^n$  for sufficiently large  $n \in \mathbb{N}$ . Let  $k \in \mathbb{N}$  be a parameter. We assume that  $k = o(N^{1/50})$ . Let  $\epsilon = \frac{1}{60k^2 \ln N}$  be a parameter.

Let  $H_N$  denote the  $N \times N$  normalized Hadamard matrix whose entries are either  $-\frac{1}{\sqrt{N}}$  or  $\frac{1}{\sqrt{N}}$ . Let

$$f_{\text{orr}}(z) := \frac{1}{N} \langle z_2, H_N z_1 \rangle$$

denote the *Forrelation* of a vector  $z = (z_1, z_2)$ , where  $z_1, z_2 \in \mathbb{R}^N$ . The **Forrelation Decision Problem** is the partial Boolean function  $F : \{-1, 1\}^{2N} \rightarrow \{-1, 1\}$  defined at  $z \in \{-1, 1\}^{2N}$  by

$$F(z) := \begin{cases} -1 & \text{if } f_{\text{orr}}(z) \geq \epsilon/2 \\ 1 & \text{if } f_{\text{orr}}(z) \leq \epsilon/4 \\ \text{undefined} & \text{otherwise} \end{cases}$$

The  $\oplus^k$  **Forrelation Decision Problem**  $F^{(k)} : \{-1, 1\}^{2kN} \rightarrow \{-1, 1\}$  is defined as the XOR of  $k$  independent copies of  $F$ . More precisely, for every  $z_1, \dots, z_k \in \{-1, 1\}^{2N}$ , let

$$F^{(k)}(z_1, \dots, z_k) := \prod_{j=1}^k F(z_j).$$

For our separation results, we take the function  $F^{(k)}$ , where  $k = \lceil \log^2 N \rceil$ . For our communication complexity separation we take the lift of  $F^{(k)}$  with XOR as the gadget. The quantum upper bounds in all these separation results are quite simple. Moreover, all the quantum algorithms in our upper bounds have the additional advantage of being *efficiently implementable*, in the sense that they can be described by quantum circuits of size  $\text{polylog}(N)$ , with oracle access to the inputs.

Our main contribution is the classical lower bound. Towards this, our main theorem provides an upper bound on the maximum correlation of  $F^{(k)}$  with any family of Boolean functions, in terms of the maximum level- $2k$  Fourier mass of a function in the family.

► **Main Theorem (Informal).** *There exist two distributions,  $\sigma_0^{(k)}$  and  $\sigma_1^{(k)}$ , on the NO and YES instances of  $F^{(k)}$ , respectively, with the following property. Let  $\mathcal{H}$  be a family of Boolean functions, each of which maps  $\{-1, 1\}^{2kN}$  into  $[-1, 1]$ . Assume that  $\mathcal{H}$  is closed under restrictions. For  $H \in \mathcal{H}$ , let  $L_{2k}(H) := \sum_{|S|=2k} |\widehat{H}(S)|$ . Let  $\alpha \in \mathbb{R}$  be such that  $\alpha^k := \sup_{H \in \mathcal{H}} (L_{2k}(H), 1)$ . Then, for every  $H \in \mathcal{H}$ ,*

$$\left| \mathbb{E}_{z \sim \sigma_0^{(k)}} [H(z)] - \mathbb{E}_{z \sim \sigma_1^{(k)}} [H(z)] \right| \leq O\left(\frac{\alpha^k}{N^{k/2}}\right)$$

Our main theorem implies that functions in  $\mathcal{H}$  cannot correlate with  $F^{(k)}$  by more than  $\frac{1}{2} + O\left(\frac{\alpha^k}{N^{k/2}}\right)$ . For the applications, we instantiate  $\mathcal{H}$  with the class of functions computed by classical protocols of small cost.

## 1.5 Overview of Proof of the Main Theorem for $k = 2$

Our proof builds on the techniques of [15], and followup works [8, 12], which, in turn, used a key idea from [7]. We will now give an overview of the proof of the Main Theorem for the special case  $k = 2$ , where one can already see most of the key ideas.

We start by recalling the hard distributions for  $k = 1$ , as in [15]. The **distribution  $\mathcal{U}$  on no instances** of  $F$  is the uniform distribution  $U_{2N}$  on  $\{-1, 1\}^{2N}$ . It can be shown that a bit string drawn uniformly at random almost always has low Forrelation. The **distribution  $\mathcal{G}$  on yes instances** of  $F$  is the Gaussian distribution with mean 0 and covariance matrix  $\epsilon \begin{bmatrix} \mathbb{I}_N & H_N \\ H_N & \mathbb{I}_N \end{bmatrix}$ . It can be shown that a vector drawn from this distribution almost always has high Forrelation (at least  $\epsilon/2$ ). Although  $\mathcal{G}$  is not a distribution over  $\{-1, 1\}^{2N}$ , this can be fixed (by probabilistically rounding the values) and we ignore this issue in the proof overview.

Our hard distributions for  $k \geq 2$  are obtained by naturally lifting these distributions. The **distribution  $\mu_0$  on no instances** of  $F^{(2)}$  is  $\frac{1}{2}(\mathcal{U} \times \mathcal{U} + \mathcal{G} \times \mathcal{G})$ . The **distribution  $\mu_1$  on yes instances** is  $\frac{1}{2}(\mathcal{U} \times \mathcal{G} + \mathcal{G} \times \mathcal{U})$ . It can be shown that these distributions indeed have almost all their mass on the YES and NO instances of  $F^{(2)}$ , respectively.

Throughout this proof, we identify functions in  $\mathcal{H}$  with their unique multilinear extensions. Using this identification, it follows that for all  $H \in \mathcal{H}$  and  $z_0 \in \mathbb{R}^{4N}$ , we have  $\mathbb{E}_{z \sim \mathcal{U}}[H(z_0 + (z, 0))] = \mathbb{E}_{z \sim \mathcal{U}}[H(z_0 + (0, z))] = \mathbb{E}_{z \sim \mathcal{U}^2}[H(z_0 + z)] = H(z_0)$ .

### Bounding the Advantage of $H$ in Distinguishing $p \cdot \mu_0$ and $p \cdot \mu_1$ , for Small $p$

As in [15, 8], in order to show that functions in  $\mathcal{H}$  can't distinguish between  $\mu_0$  and  $\mu_1$ , we first show that they can't distinguish between  $p \cdot \mu_0$  and  $p \cdot \mu_1$ , for small  $p$ . We show that for every  $H \in \mathcal{H}$ , and  $p \leq \frac{1}{2N}$ ,

$$\begin{aligned} \left| \mathbb{E}_{z \sim p \cdot \mu_0} [H(z)] - \mathbb{E}_{z \sim p \cdot \mu_1} [H(z)] \right| &\triangleq \frac{1}{2} \left| \mathbb{E}_{\substack{z_1 \sim p \cdot \mathcal{G} \\ z_2 \sim p \cdot \mathcal{G}}} [H(z_1, z_2) - H(z_1, 0) - H(0, z_2) + H(0, 0)] \right| \\ &\leq p^4 \cdot O\left(\frac{L_4(H)}{N}\right) + O(p^6 N^{1.5}) \end{aligned}$$

This claim is analogous to Claim 20 from [8]. For sufficiently small  $p$ , the second term in the R.H.S. of the inequality is negligible, compared to the first term. To prove this inequality, we use the Fourier expansion of  $H$  in the L.H.S. and bound the difference between the moments of  $p \cdot \mu_0$  and  $p \cdot \mu_1$ . We show that  $p \cdot \mu_0$  and  $p \cdot \mu_1$  agree on moments of degree less than 4, so these moments don't contribute to the difference. We then show that the contribution of the moments of degree 4 is  $L_4(H) \cdot O\left(\frac{p^4}{N}\right)$  and the contribution of moments of higher degrees is  $O(p^6 N^{1.5})$ .

**Bounding the Advantage of  $H(z_0 + z)$  in Distinguishing  $p \cdot \mu_0$  and  $p \cdot \mu_1$ , for Small  $p$**

Next, as in [15, 8], we show a similar statement for the function  $H(z_0 + z)$  of  $z$ , where  $z_0$  is not too large. We show that for every  $H \in \mathcal{H}$ , and every  $z_0 \in [-1/2, 1/2]^{2kN}$  and  $p \leq \frac{1}{2N}$ ,

$$\begin{aligned} & \left| \frac{1}{2} \mathbb{E}_{\substack{z_1 \sim p \cdot \mathcal{G} \\ z_2 \sim p \cdot \mathcal{G}}} [H(z_0 + (z_1, z_2)) - H(z_0 + (z_1, 0)) - H(z_0 + (0, z_2)) + H(z_0)] \right| \\ & \leq p^4 \cdot O\left(\frac{L_4(H)}{N}\right) + O(p^6 N^{1.5}) \end{aligned} \tag{1}$$

The proof of this inequality is similar to the proof of Claim 19 of [8], using key ideas from [7], and relies on the multilinearity of functions in  $\mathcal{H}$  and the closure of  $\mathcal{H}$  under restrictions.

**A Random Walk with Two-Dimensional Time Variable**

This is the main place where our proof differs from the one of [15] and followup works [8, 12]. In all these works the Forrelation distribution was ultimately analyzed as the distribution obtained by a certain random walk. Here, we consider a product of two random walks, which can also be viewed as a random walk with two-dimensional time variable.

Let  $T = 16N^4$  and  $p = \frac{1}{\sqrt{T}}$ . Let  $z_1^{(1)}, z_2^{(1)}, \dots, z_1^{(T)}, z_2^{(T)} \sim p \cdot \mathcal{G}$  be independent samples. Let  $t = (t_1, t_2)$  for  $t_1, t_2 \in \{0, \dots, T\}$ . Let  $z^{\leq(t)} := \left(\sum_{i=1}^{t_1} z_1^{(i)}, \sum_{i=1}^{t_2} z_2^{(i)}\right)$ . Note that  $z^{\leq(t)}$  is distributed according to  $(p\sqrt{t_1} \cdot \mathcal{G}) \times (p\sqrt{t_2} \cdot \mathcal{G})$ . In particular,  $z^{\leq(T,T)}$  is distributed according to  $\mathcal{G} \times \mathcal{G}$ . This implies that

$$(*) := \mathbb{E}_{z \sim \mu_0} [H(z)] - \mathbb{E}_{z \sim \mu_1} [H(z)] \triangleq \frac{1}{2} \mathbb{E} \left[ H(z^{\leq(T,T)}) - H(z^{\leq(T,0)}) - H(z^{\leq(0,T)}) + H(0,0) \right]$$

We now rewrite (\*) as follows.

$$(*) = \frac{1}{2} \sum_{\substack{t_1 \in [T] \\ t_2 \in [T]}} \mathbb{E} \left[ H(z^{\leq(t_1, t_2)}) - H(z^{\leq(t_1-1, t_2)}) - H(z^{\leq(t_1, t_2-1)}) + H(z^{\leq(t_1-1, t_2-1)}) \right] \tag{2}$$

The last equation follows by a two-dimensional telescopic cancellation, as depicted in Figure 1. This turns out to be a powerful observation. Note that for every fixed  $t = (t_1, t_2)$ , the random variable  $z^{\leq(t)} - z^{\leq(t-(1,1))} \triangleq (z_1^{(t_1)}, z_2^{(t_2)})$  is distributed according to  $p \cdot \mathcal{G}^2$ , by construction. We can thus apply Inequality(1), setting  $z_0 = z^{\leq(t-(1,1))}$ . This, along with the Triangle-Inequality implies that

$$\begin{aligned} |(*)| & \leq \frac{1}{2} \sum_{\substack{t_1 \in [T] \\ t_2 \in [T]}} \left| \mathbb{E} \left[ H(z^{\leq(t_1, t_2)}) - H(z^{\leq(t_1-1, t_2)}) - H(z^{\leq(t_1, t_2-1)}) + H(z^{\leq(t_1-1, t_2-1)}) \right] \right| \\ & \leq \frac{1}{2} \sum_{\substack{t_1 \in [T] \\ t_2 \in [T]}} \left( p^4 \cdot O\left(\frac{L_4(H)}{N}\right) + O(p^6 N^{1.5}) \right) \quad \text{by Inequality (1)} \\ & = O\left(\frac{L_4(H)}{N}\right) + o\left(\frac{1}{N}\right) \quad \text{since } T = 16N^4 = \frac{1}{p^2} \end{aligned}$$

This completes the proof overview for  $k = 2$ , albeit with many details left out.

■ **Figure 1** Consider the  $(T + 1) \times (T + 1)$  grid whose vertices are indexed by  $v \in (\{0\} \cup [T])^2$ . Each vertex  $v$  is labelled by  $H(z^{\leq (v)})$ . Each rectangle has a sign on its vertices as defined in Figure 1 and the label of a rectangle is the sum of signed labels of its vertices. The sum of labels of all  $1 \times 1$  rectangles equals the label of the larger  $T \times T$  rectangle. This is exactly the content of Equation (2).

## 1.6 Organization of the Paper

In the appendix, we present a formal description of our main results. The proofs can be found in the full version of the paper.

## 1.7 Related Work

Independently of our result, [6] demonstrated PRGs with polylogarithmic dependence on seed length, for a large class of boolean functions. Their result builds on the framework of [7, 8, 15] and constructs improved PRGs by leveraging level- $k$  Fourier bounds.

## A Formal Description of the Main Results

### Notation

For  $n \in \mathbb{N}$ , we use  $[n]$  to denote the set  $\{1, 2, \dots, n\}$ . We typically use  $N$  to refer to  $2^n$ . For a set  $S \subseteq [n]$ , let  $\bar{S} := [n] \setminus S$  denote the complement of  $S$ . For sets  $S \subseteq [n], T \subseteq [m]$ , we typically use  $S \times T := \{(s, t) : s \in S, t \in T\}$  denote the set product of  $S$  and  $T$ . Sometimes, we use the notation  $(S, T)$ . Note that the map  $(i, j) \rightarrow m(i-1) + j$  is a bijection between  $[n] \times [m]$  and  $[nm]$ . Using this identification,  $S \times T$  is a subset of  $[nm]$ . We identify subsets  $S \subseteq [n]$  with their  $\{0, 1\}$  indicator vector, that is, the vector  $S \in \{0, 1\}^n$  such that for each  $j \in [n]$ ,  $S_j = 1$  if and only if  $j \in S$ .

Let  $v \in \mathbb{R}^n$ . For  $i \in [n]$ , we refer to the  $i$ -th coordinate of  $v$  by  $v_i$  or  $v(i)$ . For  $x, y \in \mathbb{R}^n$ , let  $x \cdot y \in \mathbb{R}^n$  be the pointwise product between  $x$  and  $y$ . This is the vector whose  $i$ -th coordinate is  $x_i y_i$ , for every  $i \in [n]$ . Let  $\langle x, y \rangle$  denote the real inner product between  $x$  and  $y$ . For  $x, y \in \{0, 1\}^n$ , let  $\langle x, y \rangle_2 := \sum_{i=1}^n x_i y_i \pmod 2$  denote the mod 2 inner product between  $x$  and  $y$ . We use  $\mathbb{I}_n$  to denote the  $n \times n$  identity matrix. We use  $0$  to denote the zero vector in arbitrary dimensions.

### Distributions

For a probability distribution  $D$ , let  $x \sim D$  denote a random variable  $x$  sampled according to  $D$ . For distributions  $D_1$  and  $D_2$ , we use  $D_1 \times D_2$  to denote the product distribution defined by sampling  $(x, y)$  where  $x \sim D_1$  and  $y \sim D_2$  are sampled independently. For  $n \in \mathbb{N}$  and a distribution  $D$ , let  $D^n$  denote the product of  $n$  distributions, each of which is  $D$ . Let  $\mu \in \mathbb{R}^n$  be a vector and  $\Sigma \in \mathbb{R}^{n \times n}$  be a positive semi-definite matrix. We use  $\mathcal{N}(\mu, \Sigma)$  to refer to the  $n$ -dimensional Gaussian distribution with mean  $\mu$  and covariance matrix  $\Sigma$ . Let  $U_n$  denote the uniform distribution on  $\{-1, 1\}^n$ . For a distribution  $D$  over  $\mathbb{R}^n$  and  $a \in \mathbb{R}^n$ , let  $a + D$  refer to the distribution obtained by sampling  $z \sim D$  and returning  $z + a$ . For  $P \in \mathbb{R}^n$  and a distribution  $D$  over  $\mathbb{R}^n$ , let  $P \cdot D$  denote the distribution obtained by sampling  $x \sim D$  and returning  $P \cdot x$ . For  $p \in \mathbb{R}$ , we use  $p \cdot D$  to denote the distribution obtained by sampling  $x \sim D$  and returning  $px$ . For  $I \subseteq [n]$ , let  $\hat{D}(I) := \mathbb{E}_{z \sim D} [\prod_{i \in I} z_i]$  refer to the  $I$ -th moment of  $D$ .

### Fourier Analysis

We refer to  $\{-1, 1\}^n$  as the Boolean hypercube in  $n$  dimensions. Let  $\mathcal{F} := \{f : \{-1, 1\}^n \rightarrow \mathbb{R}\}$  denote the real vector space of all Boolean functions on  $n$  variables. There is an inner product on this space as follows. For  $f, g \in \mathcal{F}$ , let  $\langle f, g \rangle := \mathbb{E}_{x \sim U_n}[f(x)g(x)]$ . For every  $S \subseteq [n]$ , there is a character function  $\chi_S : \{-1, 1\}^n \rightarrow \{-1, 1\}$  defined at  $x \in \{-1, 1\}^n$  by  $\chi_S(x) := \prod_{i \in S} x_i$ . The set of character functions  $\{\chi_S\}_{S \subseteq [n]}$  forms an orthonormal basis for  $\mathcal{F}$ . For  $f \in \mathcal{F}$  and  $S \subseteq [n]$ , let  $\widehat{f}(S) := \langle f, \chi_S \rangle$  denote the  $S$ -th Fourier coefficient of  $f$ . Note that for all  $f \in \mathcal{F}$ , we have  $f = \sum_{S \subseteq [n]} \widehat{f}(S) \chi_S$ . For  $f \in \mathcal{F}$ , the multilinear extension of  $f$  is the unique multilinear polynomial  $\widehat{f} : \mathbb{R}^n \rightarrow \mathbb{R}$  which agrees with  $f$  on  $\{-1, 1\}^n$ . For every  $S \subseteq [n]$ , the multilinear extension of  $\chi_S$  is the monomial  $\prod_{i \in S} x_i$ . This implies that the multilinear extension of  $f \in \mathcal{F}$  is  $\sum_{S \subseteq [n]} \widehat{f}(S) \prod_{i \in S} x_i$ . Henceforth, we identify Boolean functions with their multilinear extensions. With this identification, it can be shown that functions in  $\mathcal{F}$  which map  $\{-1, 1\}^n$  into  $[-1, 1]$  also map  $[-1, 1]^n$  into  $[-1, 1]$ . For  $f, g \in \mathcal{F}$ , let  $f * g \in \mathcal{F}$  be defined at  $z \in \{-1, 1\}^n$  by  $(f * g)(z) := \mathbb{E}_{x \sim U_n}[f(x)g(x \cdot z)]$ . It can be shown that for all  $S \subseteq [n]$ , we have  $\widehat{f * g}(S) = \widehat{f}(S)\widehat{g}(S)$ .

### Level- $k$ Fourier Mass

For  $f \in \mathcal{F}$  and  $k \in \{0, \dots, n\}$ , let  $L_k(f) := \sum_{|S|=k} |\widehat{f}(S)|$  denote the level- $k$  Fourier mass of  $f$ . For a family  $\mathcal{H} \subseteq \mathcal{F}$  of Boolean functions, let  $L_k(\mathcal{H}) := \sup_{H \in \mathcal{H}} L_k(H)$ .

## A.1 The Forrelation Problem

Let  $k, N \in \mathbb{N}$  be parameters, where  $N = 2^n$  for some  $n \in \mathbb{N}$ . We assume that  $k = o(N^{1/50})$ . Fix a parameter  $\epsilon = \frac{1}{60k^2 \ln N}$ . Let  $\mathcal{U}$  refer to  $U_{2N}$ .

### Hadamard Matrix

The Hadamard matrix  $H_N$  of size  $N$  is an  $N \times N$  matrix. The rows and columns are indexed by strings  $a$  and  $b$  respectively where  $a, b \in \{0, 1\}^n$  and the  $(a, b)$ -th entry of  $H_N$  is defined to be  $\frac{1}{\sqrt{N}}(-1)^{\langle a, b \rangle_2}$ . Equivalently,

$$H_N(a, b) := \begin{cases} \frac{-1}{\sqrt{N}} & \text{if } \sum_{i=1}^n a_i b_i \equiv 1 \pmod{2} \\ \frac{+1}{\sqrt{N}} & \text{if } \sum_{i=1}^n a_i b_i \equiv 0 \pmod{2} \end{cases}$$

### The Forrelation Function

The Forrelation Function  $f_{\text{orr}} : \mathbb{R}^{2N} \rightarrow \mathbb{R}$  is defined as follows. Let  $z \in \mathbb{R}^{2N}$  and  $x, y \in \mathbb{R}^N$  be such that  $z = (x, y)$ . Then,

$$f_{\text{orr}}(z) := \frac{1}{N} \langle x, H_N y \rangle$$

### The $\oplus^k$ Forrelation Decision Problem

► **Definition 1** (The  $\oplus^k$  Forrelation Decision Problem). *The Forrelation Decision Problem is the partial Boolean function  $F : \{-1, 1\}^{2N} \rightarrow \{-1, 1\}$  defined as follows. For  $z \in \{-1, 1\}^{2N}$ ,*

let

$$F(z) := \begin{cases} -1 & \text{if } \text{forr}(z) \geq \epsilon/2 \\ 1 & \text{if } \text{forr}(z) \leq \epsilon/4 \\ \text{undefined} & \text{otherwise} \end{cases}$$

The  $\oplus^k$  Forrelation Decision Problem  $F^{(k)} : \{-1, 1\}^{2kN} \rightarrow \{-1, 1\}$  is defined as the XOR of  $k$  independent copies of  $F$ . To be precise, for every  $z_1, \dots, z_k \in \{-1, 1\}^{2N}$ , let

$$F^{(k)}(z_1, \dots, z_k) := \prod_{j=1}^k F(z_j)$$

### The Gaussian Forrelation Distribution $\mathcal{G}$

► **Definition 2.** Let  $\mathcal{G}$  denote the Gaussian distribution over  $\mathbb{R}^{2N}$  defined by the following process.

1. Sample  $x_1, \dots, x_N \sim \mathcal{N}(0, \epsilon)$  independently.
2. Let  $x = (x_1, \dots, x_N)$  and  $y = H_N x$ .
3. Output  $(x, y)$ .

The distribution  $\mathcal{G}$  can be equivalently expressed as  $\mathcal{N}\left(0, \epsilon \begin{bmatrix} \mathbb{I}_N & H_N \\ H_N & \mathbb{I}_N \end{bmatrix}\right)$ .

### A.2 Hard Distributions over $\mathbb{R}^{2kN}$

Let  $\mathcal{P}, \mathcal{Q}$  be two probability distributions on the domain  $\mathbb{D} := \mathbb{R}^{2N}$ . Let  $S \subseteq [k]$ . We define  $\mathcal{P}^S \mathcal{Q}^{\bar{S}}$  to be the distribution on  $\mathbb{D}^k$  defined by sampling  $x = (x_1, \dots, x_k)$  where  $x_1, \dots, x_k \in \mathbb{D}$  are sampled as follows.

$$\text{For each } j \in [k], \text{ independently sample } \begin{cases} x_j \sim \mathcal{P} & \text{if } j \in S \\ x_j \sim \mathcal{Q} & \text{if } j \in \bar{S} \end{cases}$$

► **Definition 3.** Let  $\mathcal{G}$  be the distribution in Definition 2 and  $\mathcal{U} = U_{2N}$ . Define a pair of distributions  $\mu_0^{(k)}, \mu_1^{(k)}$  on  $\mathbb{R}^{2kN}$  as follows.

$$\mu_0^{(k)} := \frac{1}{2^{k-1}} \sum_{\substack{S \subseteq [k] \\ |S| \text{ is even}}} \mathcal{G}^S \mathcal{U}^{\bar{S}} \quad \text{and} \quad \mu_1^{(k)} := \frac{1}{2^{k-1}} \sum_{\substack{S \subseteq [k] \\ |S| \text{ is odd}}} \mathcal{G}^S \mathcal{U}^{\bar{S}}$$

### A.3 Rounding Distributions to the Boolean Hypercube

Let  $\text{trnc} : \mathbb{R} \rightarrow [-1, 1]$  denote the truncation function, whose action on  $a \in \mathbb{R}$  is given by

$$\text{trnc}(a) = \begin{cases} \text{sign}(a) & \text{if } a \notin [-1, 1] \\ a & \text{otherwise} \end{cases}$$

For  $l \in \mathbb{R}$ , we also use  $\text{trnc} : \mathbb{R}^l \rightarrow [-1, 1]^l$  to refer to the function that applies the above truncation function coordinate-wise.

► **Definition 4.** Let  $\mu$  be any distribution on  $\mathbb{R}^M$ . We define the rounded distribution  $\tilde{\mu}$  on  $\{-1, 1\}^M$  as follows.

1. Sample  $z \sim \mu$ .

## 52:12 Lower Bounds for XOR of Forrelations

2. For each coordinate  $i \in [M]$ , independently, let  $z'_i = 1$  with probability  $\frac{1+\text{trnc}(z_i)}{2}$  and  $z'_i = -1$  with probability  $\frac{1-\text{trnc}(z_i)}{2}$ .
  3. Output  $z' = (z'_1, \dots, z'_M)$ .
- Let  $z_0 \in \mathbb{R}^M$  and  $\mu$  be the distribution whose support is  $\{z_0\}$ . We use  $\tilde{z}_0$  to refer to  $\tilde{\mu}$ .

### A.4 The Forrelation Distribution

Let  $k \in \mathbb{N}$ . Let  $\tilde{\mu}_0^{(k)}$  and  $\tilde{\mu}_1^{(k)}$  (respectively  $\tilde{\mathcal{G}}$ ) be distributions over  $\{-1, 1\}^{2kN}$  (respectively  $\{-1, 1\}^{2N}$ ) generated from rounding  $\mu_1^{(k)}$  and  $\mu_0^{(k)}$  (respectively  $\mathcal{G}$ ) according to Definition 4. Observe that we may alternatively define  $\tilde{\mu}_0^{(k)}$  and  $\tilde{\mu}_1^{(k)}$  as follows.

► **Definition 5.** Let  $\mathcal{G}$  be as in Definition 2 and  $\mathcal{U} = U_{2N}$ . Let

$$\tilde{\mu}_0^{(k)} := \frac{1}{2^{k-1}} \sum_{\substack{S \subseteq [k] \\ |S| \text{ is even}}} \tilde{\mathcal{G}}^S \mathcal{U}^{\bar{S}} \quad \text{and} \quad \tilde{\mu}_1^{(k)} := \frac{1}{2^{k-1}} \sum_{\substack{S \subseteq [k] \\ |S| \text{ is odd}}} \tilde{\mathcal{G}}^S \mathcal{U}^{\bar{S}}$$

We refer to  $\tilde{\mu}_1^{(1)} \triangleq \tilde{\mathcal{G}}$  as the Forrelation Distribution.

We show that the distributions  $\tilde{\mu}_1^{(k)}$  and  $\tilde{\mu}_0^{(k)}$  put considerable mass on the YES and NO instances of  $F^{(k)}$ , respectively, where  $F^{(k)}$  is the  $\oplus^k$  Forrelation Decision Problem as in Definition 1.

► **Lemma 6.** Let  $\tilde{\mu}_0^{(k)}$  and  $\tilde{\mu}_1^{(k)}$  be distributions as in Definition 5 and  $F^{(k)}$  be the  $\oplus^k$  Forrelation Decision Problem as in Definition 1. Then,

$$\mathbb{P}_{z \sim \tilde{\mu}_0^{(k)}} [F^{(k)}(z) = 1] \geq 1 - O\left(\frac{k}{N^{6k^2}}\right) \quad \text{and} \quad \mathbb{P}_{z \sim \tilde{\mu}_1^{(k)}} [F^{(k)}(z) = -1] \geq 1 - O\left(\frac{k}{N^{6k^2}}\right)$$

### A.5 Closure under Restrictions

► **Definition 7.** Let  $a \in \{-1, 1, 0\}^M$ . Let  $\rho_a : \mathbb{R}^M \rightarrow \mathbb{R}^M$  be a restriction defined as follows. For  $v \in \mathbb{R}^M$ , let  $\rho_a(v) \in \mathbb{R}^M$  be such that for all  $j \in [M]$ ,

$$(\rho_a(v))(j) := \begin{cases} v(j) & \text{if } a(j) = 0 \\ a(j) & \text{otherwise} \end{cases}$$

For a function  $F : \{-1, 1\}^M \rightarrow \mathbb{R}$ , the restricted function  $F \circ \rho_v : \{-1, 1\}^M \rightarrow \mathbb{R}$  is defined at  $z \in \{-1, 1\}^M$  by  $(F \circ \rho_v)(z) := F(\rho_v(z))$ .

We say that a family  $\mathcal{H}$  of Boolean functions in  $M$  variables is closed under restrictions if for all restrictions  $v \in \{-1, 1, 0\}^M$  and  $H \in \mathcal{H}$ , the restricted function  $H \circ \rho_v$  is in  $\mathcal{H}$ .

## B The Main Result

Let  $N \in \mathbb{N}$  be a parameter describing the input size. We will assume that  $N$  is a sufficiently large power of 2. Let  $k \in \mathbb{N}$ . We assume that  $k = o(N^{1/50})$ . Let  $\epsilon = \frac{1}{60k^2 \ln N}$  be the parameter defining  $\mathcal{G}$  as before.

► **Theorem 8.** Let  $\mathcal{H}$  be a family of Boolean functions on  $2kN$  variables, each of which maps  $\{-1, 1\}^{2kN}$  into  $[-1, 1]$ . Assume that  $\mathcal{H}$  is closed under restrictions. Let  $\tilde{\mu}_0^{(k)}, \tilde{\mu}_1^{(k)}$  be the distributions over  $\{-1, 1\}^{2kN}$  as in Definition 5. Then, for every  $H \in \mathcal{H}$ ,

$$\left| \mathbb{E}_{z \sim \tilde{\mu}_0^{(k)}} [H(z)] - \mathbb{E}_{z \sim \tilde{\mu}_1^{(k)}} [H(z)] \right| \leq O\left(\frac{L_{2k}(\mathcal{H})}{N^{k/2}}\right) + o\left(\frac{1}{N^{k/2}}\right)$$

► **Definition 9.** Let  $\tilde{\mu}_0^{(k)}, \tilde{\mu}_1^{(k)}$  be as in Definition 5. Let  $\sigma_0^{(k)}$  (respectively  $\sigma_1^{(k)}$ ) be obtained by conditioning  $\tilde{\mu}_0^{(k)}$  on being a NO (respectively YES) instance of  $F^{(k)}$ .

► **Corollary 10.** Under the same hypothesis as Theorem 8, for every  $H \in \mathcal{H}$

$$\left| \mathbb{E}_{z \sim \sigma_0^{(k)}} [H(z)] - \mathbb{E}_{z \sim \sigma_1^{(k)}} [H(z)] \right| \leq O\left(\frac{L_{2k}(\mathcal{H})}{N^{k/2}}\right) + o\left(\frac{1}{N^{k/2}}\right)$$

## B.1 Applications to Quantum versus Classical Separations

### Query Complexity Separations

► **Lemma 11.** Let  $D : \{-1, 1\}^{2kN} \rightarrow \{-1, 1\}$  be a deterministic decision tree of depth  $d \geq 1$ . Then,

$$\left| \mathbb{E}_{z \sim \sigma_0^{(k)}} [D(z)] - \mathbb{E}_{z \sim \sigma_1^{(k)}} [D(z)] \right| \leq \left( \frac{O(d \log(kN))}{N^{1/2}} \right)^k$$

► **Theorem 12.**  $F^{(k)}$  can be computed in the bounded-error quantum query model with  $O(k^5 \log^2 N \log k)$  queries. However, every randomized decision tree of depth  $\tilde{O}(\sqrt{N})$  has a worst-case success probability of at most  $\frac{1}{2} + \exp(-\Omega(k))$ .

Setting  $k = \lceil \log^c N \rceil$  for  $c \in \mathbb{N}$  in Theorem 12 gives us an explicit family of partial functions that are computable by quantum query algorithms of cost  $\tilde{O}(\log^{5c+2} N)$ , however every randomized query algorithm of cost  $\tilde{O}(N^{\frac{1}{2}})$  has at most  $\frac{1}{2^{\Omega(\log^c N)}}$  advantage over random guessing.

### Communication Complexity Separations

► **Definition 13** (The  $\oplus^k$  Forrelation Communication Problem  $F^{(k)} \circ \text{XOR}$ ). Alice is given  $x$  and Bob is given  $y$  where  $x, y \in \{-1, 1\}^{2kN}$ . Let  $F^{(k)}$  be as in Definition 1. Their goal is to compute the partial function  $F^{(k)}(x \cdot y)$ .

► **Lemma 14.** Let  $C : \{-1, 1\}^{2kN} \times \{-1, 1\}^{2kN} \rightarrow \{-1, 1\}$  be any deterministic protocol of communication complexity  $c$ . Then,

$$\left| \mathbb{E}_{\substack{x \sim U_{2kN} \\ z \sim \sigma_0^{(k)}}} [C(x, x \cdot z)] - \mathbb{E}_{\substack{x \sim U_{2kN} \\ z \sim \sigma_1^{(k)}}} [C(x, x \cdot z)] \right| \leq O\left(\frac{(c + 8k)^{2k}}{N^{k/2}}\right)$$

► **Theorem 15.**  $F^{(k)} \circ \text{XOR}$  can be solved in the quantum simultaneous with entanglement model with  $O(k^5 \log^3 N \log k)$  bits of communication, when Alice and Bob share  $O(k^5 \log^3 N \log k)$  EPR pairs. However, any randomized protocol of cost  $\tilde{O}(N^{1/4})$  has a worst-case success probability of at most  $\frac{1}{2} + \exp(-\Omega(k))$ .

Setting  $k = \lceil \log^c N \rceil$  for  $c \in \mathbb{N}$  in Theorem 15 gives us an explicit family of partial functions that are computable by quantum simultaneous protocols of cost  $\tilde{O}(\log^{5c+3} N)$  when Alice and Bob share  $\tilde{O}(\log^{5c+3} N)$  EPR pairs, however every interactive randomized protocol of cost  $\tilde{O}(N^{\frac{1}{4}})$  has at most  $\frac{1}{2^{\Omega(\log^c N)}}$  advantage over random guessing.

## Circuit Complexity Separations

► **Lemma 16.** *Let  $C : \{-1, 1\}^{2kN} \rightarrow \{-1, 1\}$  be an AC0 circuit of depth  $d \geq 1$  and size  $s$ . Then,*

$$\left| \mathbb{E}_{z \sim \sigma_0^{(k)}} [C(z)] - \mathbb{E}_{z \sim \sigma_1^{(k)}} [C(z)] \right| \leq \left( \frac{O(\log^{2d-2}(s))}{N^{1/2}} \right)^k$$

► **Theorem 17.** *The distributions  $\sigma_1^{(k)}$  and  $\sigma_0^{(k)}$  can be distinguished by a bounded-error quantum query protocol with  $O(k^5 \log^2 N \log k)$  queries with  $2/3$  advantage. However, every constant depth circuit of size  $o\left(\exp\left(N^{\frac{1}{4(d-1)}}\right)\right)$  can distinguish these distributions with at most  $\exp(-\Omega(k))$  advantage.*

Setting  $k = \lceil \log^c N \rceil$  for  $c \in \mathbb{N}$  in Theorem 17 gives us an explicit family of distributions that are distinguishable by cost  $\tilde{O}(\log^{5c+2} N)$  quantum query algorithms, however every constant depth circuit of quasipolynomial size can distinguish them with at most  $\frac{1}{2^{\Omega(\log^c N)}}$  advantage.

# Fourier Growth of Structured $\mathbb{F}_2$ -Polynomials and Applications

## Abstract

We analyze the *Fourier growth*, i.e. the  $L_1$  Fourier weight at level  $k$  (denoted  $L_{1,k}$ ), of various well-studied classes of “structured”  $\mathbb{F}_2$ -polynomials. This study is motivated by applications in pseudorandomness, in particular recent results and conjectures due to [9, 10, 8] which show that upper bounds on Fourier growth (even at level  $k = 2$ ) give unconditional pseudorandom generators.

Our main structural results on Fourier growth are as follows:

- We show that any symmetric degree- $d$   $\mathbb{F}_2$ -polynomial  $p$  has  $L_{1,k}(p) \leq \Pr[p = 1] \cdot O(d)^k$ . This quadratically strengthens an earlier bound that was implicit in [33].
- We show that any read- $\Delta$  degree- $d$   $\mathbb{F}_2$ -polynomial  $p$  has  $L_{1,k}(p) \leq \Pr[p = 1] \cdot (k\Delta d)^{O(k)}$ .
- We establish a composition theorem which gives  $L_{1,k}$  bounds on disjoint compositions of functions that are closed under restrictions and admit  $L_{1,k}$  bounds.

Finally, we apply the above structural results to obtain new unconditional pseudorandom generators and new correlation bounds for various classes of  $\mathbb{F}_2$ -polynomials.

## 1 Introduction

### 1.1 Background: $L_1$ Fourier norms and Fourier growth

Over the past several decades, Fourier analysis of Boolean functions has emerged as a fundamental tool of great utility across many different areas within theoretical computer science and mathematics. Areas of application include (but are not limited to) combinatorics, the theory of random graphs and statistical physics, social choice theory, Gaussian geometry and the study of metric spaces, cryptography, learning theory, property testing, and many branches of computational complexity such as hardness of approximation, circuit complexity, and pseudorandomness. The excellent book of O’Donnell [29] provides a broad introduction. In this paper we follow the notation of [29], and for a Boolean-valued function  $f$  on  $n$  Boolean variables and  $S \subseteq [n]$ , we write  $\widehat{f}(S)$  to denote the Fourier coefficient of  $f$  on  $S$ .

Given the wide range of different contexts within which the Fourier analysis of Boolean functions has been pursued, it is not surprising that many different quantitative parameters of Boolean functions have been analyzed in the literature. In this work we are chiefly interested in the  $L_1$  Fourier norm at level  $k$ :

► **Definition 1** ( $L_1$  Fourier norm at level  $k$ ). *The  $L_1$  Fourier norm of a function  $f: \{-1, 1\}^n \rightarrow \{0, 1\}$  at level  $k$  is the quantity*

$$L_{1,k}(f) := \sum_{S \subseteq [n]: |S|=k} |\widehat{f}(S)|.$$

For a function class  $\mathcal{F}$ , we write  $L_{1,k}(\mathcal{F})$  to denote  $\max_{f \in \mathcal{F}} L_{1,k}(f)$ .

As we explain below, strong motivation for studying the  $L_1$  Fourier norm at level  $k$  (even for specific small values of  $k$  such as  $k = 2$ ) is given by exciting recent results in unconditional pseudorandomness. More generally, the notion of *Fourier growth* is a convenient way of capturing the  $L_1$  Fourier norm at level  $k$  for every  $k$ :

► **Definition 2** (Fourier growth). *A function class  $\mathcal{F} \subseteq \{f: \{-1, 1\}^n \rightarrow \{0, 1\}\}$  has Fourier growth  $L_1(a, b)$  if there exist constants  $a$  and  $b$  such that  $L_{1,k}(\mathcal{F}) \leq a \cdot b^k$  for every  $k$ .*

The notion of Fourier growth was explicitly introduced by Reingold, Steinke, and Vadhan in [33] for the purpose of constructing pseudorandom generators for space-bounded computation (though we note that the Fourier growth of DNF formulas was already analyzed in [26], motivated by applications in learning theory). In recent years there has been a surge of research interest in understanding the Fourier growth of different types of functions [38, 19, 11, 22, 17, 39, 36, 16]. One strand of motivation for this study has come from the study of quantum computing; in particular, bounds on the Fourier growth of  $\text{AC}^0$  [38] were used in the breakthrough result of Raz and Tal [31] which gave an oracle separation between the classes BQP and PH. More recently, in order to achieve an optimal separation between quantum and randomized query complexity, several researchers [39, 1, 36] have studied the Fourier growth of decision trees, with the recent work of [36] obtaining optimal bounds. Analyzing the Fourier growth of other classes of functions has also led to separations between quantum and classical computation in other settings [16, 17, 18].

Our chief interest in the current paper arises from a different line of work which has established powerful applications of Fourier growth bounds in pseudorandomness. We describe the relevant background, which motivates a new conjecture that we propose on Fourier growth, in the next subsection.

## 1.2 Motivation for this work: Fourier growth, pseudorandomness, $\mathbb{F}_2$ -polynomials, and the CHLT conjecture

### 1.2.1 Pseudorandom generators from Fourier growth bounds

Constructing explicit, unconditional pseudorandom generators (PRGs) for various classes of Boolean functions is an important goal in complexity theory. In the recent work [9], Chattopadhyay, Hatami, Hosseini, and Lovett introduced a novel framework for the design of such PRGs. Their approach provides an explicit pseudorandom generator for any class of functions that is closed under restrictions and has bounded Fourier growth:

► **Theorem 3** (PRGs from Fourier growth: Theorem 23 of [9]). *Let  $\mathcal{F}$  be a family of  $n$ -variable Boolean functions that is closed under restrictions and has Fourier growth  $L_1(a, b)$ . Then there is an explicit pseudorandom generator that  $\epsilon$ -fools  $\mathcal{F}$  with seed length  $O(b^2 \log(n/\epsilon)(\log \log n + \log(a/\epsilon)))$ .*

Building on Theorem 3, in [10] Chattopadhyay, Hatami, Lovett, and Tal showed that in fact it suffices to have a bound just on  $L_{1,2}(\mathcal{F})$  in order to obtain an efficient PRG for  $\mathcal{F}$ :

► **Theorem 4** (PRGs from  $L_1$  Fourier norm bounds at level  $k = 2$ : Theorem 2.1 of [10]). *Let  $\mathcal{F}$  be a family of  $n$ -variable Boolean functions that is closed under restrictions and has  $L_{1,2}(\mathcal{F}) \leq t$ . Then there is an explicit pseudorandom generator that  $\epsilon$ -fools  $\mathcal{F}$  with seed length  $O((t/\epsilon)^{2+o(1)} \cdot \text{polylog}(n))$ .*

Observe that while Theorem 4 requires a weaker structural result than Theorem 3 (a bound only on  $L_{1,2}(\mathcal{F})$  as opposed to  $L_{1,k}(\mathcal{F})$  for all  $k \geq 1$ ), the resulting pseudorandom generator is quantitatively weaker since it has seed length polynomial rather than logarithmic in the error parameter  $1/\epsilon$ . Even more recently, in [8] Chattopadhyay, Gaitonde, Lee, Lovett, and Shetty further developed this framework by interpolating between the two results described above. They showed that a bound on  $L_{1,k}^1$  for any  $k \geq 3$  suffices to give a PRG, with a seed length whose  $\epsilon$ -dependence scales with  $k$ :

► **Theorem 5** (PRGs from  $L_1$  Fourier norm bounds up to level  $k$  for any  $k$ : Theorem 4.3 of [8]). *Let  $\mathcal{F}$  be a family of  $n$ -variable Boolean functions that is closed under restrictions and has  $L_{1,k}(\mathcal{F}) \leq b^k$  for some  $k \geq 3$ . Then there exists a pseudorandom generator that  $\epsilon$ -fools  $\mathcal{F}$  with seed length  $O\left(\frac{b^{2+\frac{4}{k-2}} \cdot k \cdot \text{polylog}(\frac{n}{\epsilon})}{\epsilon^{k-2}}\right)$ .*

### 1.2.2 $\mathbb{F}_2$ -polynomials and the CHLT conjecture

The works [9] and [10] highlighted the challenge of proving  $L_{1,k}$  bounds for the class of bounded-degree  $\mathbb{F}_2$ -polynomials as being of special interest. Let

$\text{Poly}_{n,d} :=$  the class of all  $n$ -variate  $\mathbb{F}_2$ -polynomials of degree  $d$ .

It follows from Theorem 4 that even proving

$$L_{1,2}(\text{Poly}_{n,\text{polylog}(n)}) \leq n^{0.49} \tag{1}$$

---

<sup>1</sup> In fact, they showed that a bound on the weaker quantity  $M_{1,k}(f) := \max_{x \in \{-1,1\}^n} |\sum_{|S|=k} \widehat{f}(S)x^S|$  suffices.

would give nontrivial PRGs for  $\mathbb{F}_2$ -polynomials of polylog( $n$ ) degree, improving on [5, 24, 41]. By the classic connection (due to Razborov [32]) between such polynomials and the class  $\text{AC}^0[\oplus]$  of constant-depth circuits with parity gates, this would also give nontrivial PRGs, of seed length  $n^{1-c}$ , for  $\text{AC}^0[\oplus]$ . This would be a breakthrough improvement on existing results, which are poor either in terms of seed length [15] or in terms of explicitness [12].

The authors of [10] in fact conjectured the following bound, which is much stronger than Equation (1):

► **Conjecture 6** ([10]). *For all  $d \geq 1$ , it holds that  $L_{1,2}(\text{Poly}_{n,d}) = O(d^2)$ .*

### 1.2.3 Extending the CHLT conjecture

Given Conjecture 6, and in light of Theorem 5, it is natural to speculate that an even stronger result than Conjecture 6 might hold. We consider the following natural generalization of the [10] conjecture, extending it from  $L_{1,2}(\text{Poly}_{n,d})$  to  $L_{1,k}(\text{Poly}_{n,d})$ :

► **Conjecture 7**. *For all  $d, k \geq 1$ , it holds that  $L_{1,k}(\text{Poly}_{n,d}) = O(d)^k$ .*

The work [10] proved that  $L_{1,1}(\text{Poly}_{n,d}) \leq 4d$ , and already in [9] it was shown that  $L_{1,k}(\text{Poly}_{n,d}) \leq (2^{3d} \cdot k)^k$ , but to the best of our knowledge no other results towards Conjecture 6 or Conjecture 7 are known.

Given the apparent difficulty of resolving Conjecture 6 and Conjecture 7 in the general forms stated above, it is natural to study  $L_{1,2}$  and  $L_{1,k}$  bounds for specific subclasses of degree- $d$   $\mathbb{F}_2$ -polynomials. This study is the subject of our main structural results, which we describe in the next subsection.

## 1.3 Our results: Fourier bounds for structured $\mathbb{F}_2$ -polynomials

Our main results show that  $L_{1,2}$  and  $L_{1,k}$  bounds of the flavor of Conjecture 6 and Conjecture 7 indeed hold for several well-studied classes of  $\mathbb{F}_2$ -polynomials, specifically *symmetric*  $\mathbb{F}_2$ -polynomials and *read- $\Delta$*   $\mathbb{F}_2$ -polynomials. We additionally prove a composition theorem that allows us to combine such polynomials (or, more generally, any polynomials that satisfy certain  $L_{1,k}$  bounds) in a natural way and obtain  $L_{1,k}$  bounds on the resulting combined polynomials.

Before describing our results in detail, we pause to briefly explain why (beyond the fact that they are natural mathematical objects) such “highly structured” polynomials are attractive targets of study given known results. It has been known for more than ten years [2, Lemma 2] that for any degree  $d < (1 - \epsilon)n$ , a *random*  $\mathbb{F}_2$ -polynomial of degree  $d$  (constructed by independently including each monomial of degree at most  $d$  with probability  $1/2$ ) is extremely unlikely to have bias larger than  $\exp(-n/d)$ . It follows that as long as  $d$  is not too large, a random degree- $d$  polynomial  $p$  is overwhelmingly likely to have  $L_{1,k}(p) = o_n(1)$ , which is much smaller than  $d^k$ . (To verify this, consider the polynomials  $p_S$  obtained by XORing  $p$  with the parity function  $\sum_{i \in S} x_i$ . Note that the bias of  $p_S$  is the Fourier coefficient of  $(-1)^p$  on  $S$ . Now apply [2, Lemma 2] to each polynomial  $p_S$ , and sum the terms.)

Since the conjectures hold true for random polynomials, it is natural to investigate highly structured polynomials.

### 1.3.1 Symmetric $\mathbb{F}_2$ -polynomials

A *symmetric*  $\mathbb{F}_2$ -polynomial over  $x_1, \dots, x_n$  is one whose output depends only on the Hamming weight of its input  $x$ . Such a polynomial of degree  $d$  can be written in the form

$$p(x) := \sum_{k=0}^d c_k \sum_{|S|=k, S \subseteq [n]} \prod_{i \in S} x_i,$$

where  $c_0, \dots, c_d \in \{0, 1\}$ . While symmetric polynomials may seem like simple objects, their study can sometimes lead to unexpected discoveries; for example, a symmetric, low-degree  $\mathbb{F}_2$ -polynomial provided a counterexample to the “Inverse conjecture for the Gowers norm” [25, 20].

We prove the following upper bound on the  $L_1$  Fourier norm at level  $k$  for any symmetric polynomial:

► **Theorem 8.** *Let  $p(x_1, \dots, x_n)$  be a symmetric  $\mathbb{F}_2$ -polynomial of degree  $d$ . Then  $L_{1,k}(p) \leq \Pr[p = 1] \cdot O(d)^k$  for every  $k$ .*

We note that if  $d = n$  and  $p$  is the AND function, then an easy computation shows that  $L_{1,k}(p) = \Pr[p = 1] \cdot \binom{d}{k}$ . Moreover, in Appendix A we show that this implies that the upper bounds conjectured in Conjecture 7 are best possible for any constant  $k$ . Theorem 8 verifies the [10] conjecture (Conjecture 6), and even the generalized version Conjecture 7, for the class of symmetric polynomials.

Theorem 8 provides a quadratic sharpening of an earlier bound that was implicit in [33] (as well as providing the “correct” dependence on  $\Pr[p = 1]$ ). In [33] Reingold, Steinke and Vadhan showed that any function  $f$  computed by an oblivious, read-once, regular branching program of width  $w$  has  $L_{1,k}(f) \leq (2w^2)^k$ . It follows directly from a result of [3] (Lemma 15 below) that any symmetric  $\mathbb{F}_2$ -polynomial  $p$  of degree  $d$  can be computed by an oblivious, read-once, regular branching program of width at most  $2d$ , and hence the [33] result implies that  $L_{1,k}(p) \leq 8^k d^{2k}$ .

### 1.3.2 Read- $\Delta$ $\mathbb{F}_2$ -polynomials

For  $\Delta \geq 1$ , a *read- $\Delta$*   $\mathbb{F}_2$ -polynomial is one in which each input variable appears in at most  $\Delta$  monomials. The case  $\Delta = 1$  corresponds to the class of *read-once polynomials*, which are simply sums of monomials over disjoint sets of variables; for example, the polynomial  $x_1x_2 + x_3x_4$  is read-once whereas  $x_1x_2 + x_1x_4$  is read-twice. Read-once polynomials have been studied from the perspective of pseudorandomness [23, 27, 22, 14] as they capture several difficulties in improving Nisan’s generators [28] for width-4 read-once branching programs.

We show that the  $L_{1,k}$  Fourier norm of read- $\Delta$  polynomials is polynomial in  $d$  and  $\Delta$ :

► **Theorem 9.** *Let  $p(x_1, \dots, x_n)$  be a read- $\Delta$  polynomial of degree  $d$ . Then  $L_{1,k}(p) \leq \Pr[p = 1] \cdot O(k)^k \cdot (d\Delta)^{8k}$ .*

[22] showed that read-once polynomials satisfy an  $L_{1,k}$  bound of  $O(d)^k$  for every  $k$ , but we are not aware of previous bounds on even the  $L_1$  Fourier norm at level  $k = 2$  for read- $\Delta$  polynomials, even for  $\Delta = 2$ .

As any monomial with degree  $\Omega(\log n)$  vanishes under a random restriction with high probability, we have the following corollary which applies to polynomials of any degree.

► **Corollary 10.** *Let  $p(x_1, \dots, x_n)$  be a read- $\Delta$  polynomial. Then  $L_{1,k}(p) \leq O(k)^{9k} \cdot (\Delta \log n)^{8k}$ .*

### 1.3.3 A composition theorem

The upper bounds of Theorem 8 and Theorem 9 both include a factor of  $\Pr[p = 1]$ . (We observe that negating  $p$ , i.e. adding 1 to it, does not change its  $L_{1,2}$  or  $L_{1,k}$  and keeps  $p$  symmetric (respectively, read- $\Delta$ ) if it was originally symmetric (respectively, read- $\Delta$ ), and hence in the context of those theorems we can assume that this  $\Pr[p = 1]$  factor is at most  $1/2$ .) Level- $k$  bounds that include this factor have appeared in earlier works for other classes of functions [30, 4, 11, 39, 18], and have been used to obtain high-level bounds for other classes of functions [11, 39, 18] and to extend level- $k$  bounds to more general classes of functions [22]. Having these  $\Pr[p = 1]$  factors in Theorem 8 and Theorem 9 is important for us in the context of our composition theorem, which we now describe. We begin by defining the notion of a *disjoint composition* of functions:

► **Definition 11.** Let  $\mathcal{F}$  be a class of functions from  $\{-1, 1\}^m$  to  $\{-1, 1\}$  and let  $\mathcal{G}$  be a class of functions from  $\{-1, 1\}^\ell$  to  $\{-1, 1\}$ . Define the class  $\mathcal{H} = \mathcal{F} \circ \mathcal{G}$  of disjoint compositions of  $\mathcal{F}$  and  $\mathcal{G}$  to be the class of all functions from  $\{-1, 1\}^{m\ell}$  to  $\{-1, 1\}$  of the form

$$h(x^1, \dots, x^m) = f(g_1(x^1), \dots, g_m(x^m)),$$

where  $g_1, \dots, g_m \in \mathcal{G}$  are defined on  $m$  disjoint sets of variables and  $f \in \mathcal{F}$ .

As an example of this definition, the class of *block-symmetric* polynomials (i.e. polynomials whose variables are divided into blocks and are symmetric within each block but not overall) are a special case of disjoint compositions where  $\mathcal{G}$  is taken to be the class of symmetric polynomials. We remark that block-symmetric polynomials are known to correlate better with parities than symmetric polynomials in certain settings [21].

We prove a composition theorem for upper-bounding the  $L_1$  Fourier norm at level  $k$  of the disjoint composition of any classes of functions that are closed under restriction and admit a  $L_{1,k}$  bound of the form  $\Pr[f = 1] \cdot a \cdot b^k$ :

► **Theorem 12.** Let  $g_1, \dots, g_m \in \mathcal{G}$  and let  $f \in \mathcal{F}$ , where  $\mathcal{F}$  is closed under restrictions. Suppose that for every  $1 \leq k \leq K$ , we have

1.  $L_{1,k}(f) \leq \Pr[f = 1] \cdot a_{\text{out}} \cdot b_{\text{out}}^k$  for every  $f \in \mathcal{F}$ , and
2.  $L_{1,k}(g) \leq \Pr[g = 1] \cdot a_{\text{in}} \cdot b_{\text{in}}^k$  for every  $g \in \mathcal{G}$ .

Then for every  $\pm 1$ -valued function  $h \in \mathcal{H} = \mathcal{F} \circ \mathcal{G}$ , we have that

$$L_{1,K}(h) \leq \Pr[h = 1] \cdot a_{\text{out}} \cdot (a_{\text{in}} b_{\text{in}} b_{\text{out}})^K.$$

See the full version of this paper for a slightly sharper bound. We remark that Theorem 12 does not assume any  $\mathbb{F}_2$ -polynomial structure for the functions in  $\mathcal{F}$  or  $\mathcal{G}$  and thus may be of broader utility.

## 1.4 Applications of our results

Our structural results imply new pseudorandom generators and correlation bounds.

### 1.4.1 Pseudorandom generators

Combining our Fourier bounds with the polarizing framework, we obtain new PRGs for read-few polynomials. The following theorem follows from applying Theorem 5 with some  $k = \Theta(\log n)$  and the  $L_{1,k}$  bound in Corollary 10.

► **Theorem 13.** *There is an explicit pseudorandom generator that  $\epsilon$ -fools read- $\Delta$   $\mathbb{F}_2$ -polynomials with seed length  $\text{poly}(\Delta, \log n, \log(1/\epsilon))$ .*

For constant  $\epsilon$ , this improves on a PRG by Servedio and Tan [34], which has a seed length of  $2^{O(\sqrt{\log(\Delta n)})}$ . (Note that read- $\Delta$  polynomials are also  $(\Delta n)$ -sparse.) We are not aware of any previous PRG for read-2 polynomials with  $\text{polylog}(n)$  seed length.

Note that the OR function has  $L_1$  Fourier norm  $O(1)$ . By expressing a DNF in the Fourier expansion of OR in its terms, it is not hard to see that the same PRG also fools the class of read- $\Delta$  DNFs (and read- $\Delta$  CNFs similarly) [35].

### 1.4.2 Correlation bounds

Exhibiting explicit Boolean functions that do not *correlate* with low-degree polynomials is a fundamental challenge in complexity. Perhaps surprisingly, this challenge stands in the way of progress on a striking variety of frontiers in complexity, including circuits, rigidity, and multiparty communication complexity. For a survey of correlation bounds and discussions of these connections we refer the reader to [40, 42, 44].

For polynomials of degree larger than  $\log_2 n$ , the state-of-the-art remains the lower bound proved by Razborov and Smolensky in the 1980s' [32, 37], showing that for any degree- $d$  polynomial  $p$  and an explicit function  $h$  (in fact, majority) we have:

$$\Pr[p(x) = h(x)] \leq 1/2 + O(d/\sqrt{n}).$$

Viola [43] recently showed that upper bounds on  $L_{1,k}(\mathcal{F})$  imply correlation bounds between  $\mathcal{F}$  and an explicit function  $h_k$  that is related to majority and is defined as

$$h_k(x) := \text{sgn}\left(\sum_{|S|=k} x^S\right).$$

In particular, proving Conjecture 6 or related conjectures implies new correlation bounds beating Razborov–Smolensky. The formal statement of the connection is given by the following theorem.

► **Theorem 14** (Theorem 1 in [43]). *For every  $k \in [n]$  and  $\mathcal{F} \subseteq \{f: \{0, 1\}^n \rightarrow \{-1, 1\}\}$ , there is a distribution  $D_k$  on  $\{0, 1\}^n$  such that for any  $f \in \mathcal{F}$ ,*

$$\Pr_{x \sim D_k} [f(x) = h_k(x)] \leq \frac{1}{2} + \frac{e^k}{2\sqrt{\binom{n}{k}}} L_{1,k}(\mathcal{F}).$$

For example, if  $k = 2$  and we assume that the answer to Conjecture 6 is positive, then the right-hand side above becomes  $1/2 + O(d^2/n)$ , which is a quadratic improvement over the bound by Razborov and Smolensky.

Therefore, Theorems 8 and 9 imply correlation bounds between these polynomials and an explicit function that are better than  $O(d/\sqrt{n})$  given in [32, 37]. We note that via a connection in [41], existing PRGs for these polynomials already imply strong correlation bounds between these polynomials and the class of NP. Our results apply to more general classes via the composition theorem, where it is not clear if previous techniques applied. For a concrete example, consider the composition of a degree- $(n^\alpha)$  symmetric polynomial with degree- $(n^\alpha)$  read- $(n^\alpha)$  polynomials. Theorem 12 shows that such polynomial has  $L_{1,2} \leq n^{O(\alpha)}$ . For a sufficiently small  $\alpha = \Omega(1)$ , we again obtain correlation bounds improving on Razborov–Smolensky.

## 1.5 Related work

We close this introduction by discussing a recent work of Girish, Tal and Wu [18] on parity decision trees that is related to our results.

Parity decision trees are a generalization of decision trees in which each node queries a parity of some input bits rather than a single input bit. The class of depth- $d$  parity decision trees is a subclass of  $\mathbb{F}_2$  degree- $d$  polynomials, as such a parity decision tree can be expressed as a sum of products of sums over  $\mathbb{F}_2$ , where each product corresponds to a path in the tree (and hence gives rise to  $\mathbb{F}_2$ -monomials of degree at most  $d$ ). The Fourier spectrum of parity decision trees was first studied in [4], which obtained a level-1 bound of  $O(\sqrt{d})$ . This bound was recently extended to higher levels in [18], showing that any depth- $d$  parity decision tree  $T$  over  $n$  variables has  $L_{1,k}(T) \leq d^{k/2} \cdot O(k \log n)^k$ .

## 2 Our techniques

We now briefly explain the approaches used to prove our results. We note that each of these results is obtained using very different ingredients, and hence the results can be read independently of each other.

### 2.1 Symmetric polynomials (Theorem 8, Section 4)

The starting point of our proof is a result from [3], which says that degree- $d$  symmetric  $\mathbb{F}_2$ -polynomials only depend on the Hamming weight of their input modulo  $m$  for some  $m$  (a power of two) which is  $\Theta(d)$ . Given this, since  $p(x)$  takes the same value for all strings  $x$  with the same weights  $\ell \bmod m$ , to analyze  $L_{1,k}(p)$  it suffices to analyze  $\mathbf{E}[(-1)^{x_1+\dots+x_k}]$  conditioned on  $x$  having Hamming weight exactly  $\ell \bmod m$ .

We bound this conditional expectation by considering separately two cases depending on whether or not  $k \leq n/m^2$ . For the case that  $k \leq n/m^2$ , we use a (slight sharpening of a) result from [6], which gives a bound of  $m^{-k}e^{-\Omega(n/m^2)}$ . In the other case, that  $k \geq n/m^2$ , in Lemma 17 we prove a bound of  $O(km/n)^k$ . This is established via a careful argument that gives a new bound on the Kravchuk polynomial in certain ranges (see the full version of the paper for more details), extending and sharpening similar bounds that were recently established in [13] (the bounds of [13] would not suffice for our purposes).

In each of the above two cases, summing over all the  $\binom{n}{k}$  coefficients gives the desired bound of  $O(m)^k = O(d)^k$ .

### 2.2 Read- $\Delta$ polynomials (Theorem 9, Section 5)

Writing  $f := (-1)^p$  for an  $\mathbb{F}_2$ -polynomial  $p$ , we observe that the coefficient  $\hat{f}(S)$  is simply the bias of  $p_S(x) := p(x) + \sum_{i \in S} x_i$ . Our high-level approach is to decompose the read-few polynomial  $p_S$  into many disjoint components, then show that each component has small bias. Since the components are disjoint, the product of these biases gives an upper bound on the bias of  $p_S$ .

In more detail, we first partition the variables according to the minimum degree  $t_i$  of the monomials containing each variable  $x_i$ . Then we start decomposing  $p_S$  by collecting all the monomials in  $p$  containing  $x_i$  to form the polynomial  $p_i$ . We observe that the larger  $t_i$  is, the more likely  $p_i$  is to vanish on a random input, and therefore the closer  $p_i + x_i$  is to being unbiased. For most  $S$ , we can pick many such  $p_i$ 's ( $i \in S$ ) from  $p$  so that they are disjoint. For the remaining polynomial  $r$ , because  $\Delta$  and  $d$  are small, we can further decompose  $r$  into

many disjoint polynomials  $r_i$ . Finally, our upper bound on  $|\widehat{f}(S)|$  will be the magnitude of the product of the biases of the  $p_i$ 's and  $r_i$ 's. We note that our decomposition of  $p$  uses the structure of  $S$ ; and so the upper bound on  $\widehat{f}(S)$  depends on  $S$  (see Lemma 18). Summing over each  $|\widehat{f}(S)|$  gives our upper bound.

### 2.3 Composition theorem (Theorem 12, Section 6)

As a warmup, let us first consider directly computing a degree-1 Fourier coefficient  $\widehat{h}(\{(i, j)\})$  of the composition. Since the inner functions  $g_i$  depend on disjoint variables, by writing the outer function  $f$  in its Fourier expansion, it is not hard to see that

$$\widehat{h}(\{(i, j)\}) = \sum_{S \ni i} \widehat{f}(S) \prod_{\ell \in S \setminus \{i\}} \mathbf{E}[g_\ell] \cdot \widehat{g}_i(\{j\}).$$

When the  $g_i$ 's are balanced, i.e.  $\mathbf{E}[g_i] = 0$ , we have  $\widehat{h}(\{(i, j)\}) = \widehat{f}(\{i\})\widehat{g}_i(\{j\})$ , and it follows that  $L_{1,1}(h) \leq L_{1,1}(\mathcal{F})L_{1,1}(\mathcal{G})$ . To handle the unbalanced case, we apply an idea from [9] that lets us relate  $\sum_{S \ni i} \widehat{f}(S) \prod_{\ell \in S \setminus \{i\}} \mathbf{E}[g_\ell]$  to the average of  $\widehat{f}_R(\{i\})$ , for some suitably chosen random restriction  $R$  on  $f$  (see Claim 20). As  $\mathcal{F}$  is closed under restrictions, we can apply the  $L_{1,1}(\mathcal{F})$  bound on  $f_R$ , which in turns gives a bound on  $\sum_{S \ni i} \widehat{f}(S) \prod_{\ell \in S \setminus \{i\}} \mathbf{E}[g_\ell]$  in terms of  $L_{1,1}(\mathcal{F})$  and  $\mathbf{E}[g_i]$ .

Bounding  $L_{1,k}(h)$  for  $k \geq 2$  is more complicated, as each  $\widehat{h}(S)$  involves  $\widehat{f}(J)$  and  $\widehat{g}_i(T)$ 's, where the sets  $J$  and  $T$  have different sizes. We provide more details in Section 6.

## 3 Preliminaries

**Notation.** For a string  $x \in \{0, 1\}^n$  we write  $|x|$  to denote its Hamming weight  $\sum_{i=1}^n x_i$ . We use  $\mathcal{X}_w$  to denote  $\{x : |x| = w\}$ , the set of  $n$ -bit strings with Hamming weight  $w$ , and  $\mathcal{X}_{\ell \bmod m} = \bigcup_{w:w \equiv \ell \bmod m} \mathcal{X}_w = \{x : |x| \equiv \ell \bmod m\}$ .

We recall that for an  $n$ -variable Boolean function  $f$ , the *level- $k$  Fourier  $L_1$  norm* of  $f$  is

$$L_{1,k}(f) = \sum_{S \subseteq [n]: |S|=k} |\widehat{f}(S)|.$$

We note that a function  $f$  and its negation have the same  $L_{1,k}$  for  $k \geq 1$ . Hence we can often assume that  $\Pr[f = 1] \leq 1/2$ , or replace the occurrence of  $\Pr[f = 1]$  in a bound by  $\min\{\Pr[f = 1], \Pr[f = 0]\}$  for a  $\{0, 1\}$ -valued function  $f$  (or by  $\min\{\Pr[f = 1], \Pr[f = -1]\}$  for a  $\{-1, 1\}$ -valued function). If  $f$  is a  $\{-1, 1\}$ -valued function then  $\frac{1 - \mathbf{E}[f]}{2}$  is equal to  $\min\{\Pr[f = 1], \Pr[f = -1]\}$ , and we will often write  $\frac{1 - \mathbf{E}[f]}{2}$  for convenience.

Unless otherwise indicated, we will use the letters  $p, q, r$ , etc. to denote  $\mathbb{F}_2$ -polynomials (with inputs in  $\{0, 1\}^n$  and outputs in  $\{0, 1\}$ ) and the letters  $f, g, h$ , etc. to denote general Boolean functions (where the inputs may be  $\{0, 1\}^n$  or  $\{-1, 1\}^n$  and the outputs may be  $\{0, 1\}$  or  $\{-1, 1\}$  depending on convenience). We note that changing from  $\{0, 1\}$  outputs to  $\{-1, 1\}$  outputs only changes  $L_{1,k}$  by a factor of 2.

We use standard multilinear monomial notation as follows: given a vector  $\beta = (\beta_1, \dots, \beta_n)$  and a subset  $T \subseteq [n]$ , we write  $\beta^T$  to denote  $\prod_{j \in T} \beta_j$ .

#### 4 $L_{1,k}$ bounds for symmetric polynomials

In this section we prove Theorem 8, which gives an upper bound on  $L_{1,k}(p)$  for any symmetric  $\mathbb{F}_2$ -polynomial  $p$  of degree  $d$ , covering the entire range of parameters  $1 \leq k, d \leq n$ .

##### 4.1 Proof idea

As the polynomial  $p$  is symmetric, its Fourier coefficient  $\widehat{p}(S)$  only depends on  $|S|$ , the size of  $S$ . Hence to bound  $L_{1,k}$  it suffices to analyze the coefficient  $\widehat{p}(\{1, \dots, k\}) = \mathbf{E}_{x \sim \{0,1\}^n} [p(x)(-1)^{x_1 + \dots + x_k}]$ .

Our proof uses a result from [3] (Lemma 15 below), which says that degree- $d$  symmetric  $\mathbb{F}_2$ -polynomials only depend on the Hamming weight of their input modulo  $m$  for some  $m = O(d)$ . Given this, since  $p(x)$  takes the same value for strings  $x$  with the same weights  $\ell \bmod m$ , we can in turn bound each  $\mathbf{E}[(-1)^{x_1 + \dots + x_k}]$  conditioned on  $x$  having Hamming weight exactly  $\ell \bmod m$ , i.e.  $x \in \mathcal{X}_{\ell \bmod m}$ . We consider two cases depending on whether or not  $k \leq n/m^2$ . If  $k \leq n/m^2$ , we can apply a (slight sharpening of a) result from [6], which gives a bound of  $m^{-k} e^{-\Omega(n/m^2)}$ . If  $k \geq n/m^2$ , in Lemma 17 we prove a bound of  $O(km/n)^k$ . In each case, summing over all the  $\binom{n}{k}$  coefficients gives the desired bound of  $O(m)^k = O(d)^k$ .

We now give some intuition for Lemma 17, which upper bounds the magnitude of the ratio

$$\mathbf{E}_{x \sim \mathcal{X}_{\ell \bmod m}} [(-1)^{x_1 + \dots + x_k}] = \frac{\sum_{x \in \mathcal{X}_{\ell \bmod m}} (-1)^{x_1 + \dots + x_k}}{|\mathcal{X}_{\ell \bmod m}|} \quad (2)$$

by  $O(km/n)^k$ . Let us first consider  $k = 1$  and  $m = \Theta(\sqrt{n})$ . As most strings  $x$  have Hamming weight within  $[n/2 - \Theta(\sqrt{n}), n/2 + \Theta(\sqrt{n})]$ , it is natural to think about the weight  $|x|$  in the form of  $n/2 + m\mathbb{Z} + \ell'$ . It is easy to see that the denominator is at least  $\Omega(2^n/\sqrt{n})$ , so we focus on bounding the numerator. Consider the quantity  $\sum_{x \in \mathcal{X}_{n/2+s}} \mathbf{E}[(-1)^{x_1}]$  for some  $s$ . As we are summing over all strings of the same Hamming weight, we can instead consider  $\sum_{x \in \mathcal{X}_{n/2+s}} \mathbf{E}_{i \sim [n]} [(-1)^{x_i}]$ . For any string of weight  $n/2 + s$ , it is easy to see that

$$\mathbf{E}_{i \sim [n]} [(-1)^{x_i}] = (1/2 - s/n) - (1/2 + s/n) = -2s/n. \quad (3)$$

Therefore, in the  $k = 1$  case we get that

$$\left| \mathbf{E}_{x \sim \mathcal{X}_{\ell \bmod m}} [(-1)^{x_1 + \dots + x_k}] \right| \leq 2 \sum_c \binom{n}{n/2 + cm + \ell'} \frac{|cm + \ell'|}{n}.$$

Using the fact that  $\binom{n}{n/2 + cm + \ell'}$  is exponentially decreasing in  $|c|$ , in the full version of the paper we show that this is at most  $O(2^n/n)$ . So the ratio in (2) is at most  $O(1/\sqrt{n})$ , as desired, when  $k = 1$ .

However, already for  $k = 2$ , a direct (but tedious) calculation shows that

$$\mathbf{E}_{i < j} [(-1)^{x_i + x_j}] = \frac{4s^2 - 2ns + n}{n(n-1)}, \quad (4)$$

which no longer decreases in  $s$  like in (3). Nevertheless, we observe that this is bounded by  $O(1/n + (|s|/n)^2)$ , which is sufficient for bounding the ratio by  $O(1/n)$ . Building on this, for any  $k$  we obtain a bound of  $2^{O(k)}((k/n)^{k/2} + (|s|/n))^k$  in the full version of the paper, and by a more careful calculation we are able to obtain the desired bound of  $O(km/n)^k$  on Equation (2).

### 4.2 Proof of Theorem 8

We now prove the theorem. We will use the following result from [3], which says that degree- $d$  symmetric  $\mathbb{F}_2$ -polynomials only depend on their input's Hamming weight modulo  $O(d)$ .

► **Lemma 15** (Theorem 2.4 in [3],  $p = 2$ ). *Let  $p: \{0, 1\}^n \rightarrow \{0, 1\}$  be a symmetric  $\mathbb{F}_2$ -polynomial of degree  $d$ , where  $m/2 \leq d < m$  and  $m$  is a power of two. Then  $p(x)$  only depends on  $|x| \bmod m$ .*

We will also use two bounds on the biases of parities under the uniform distribution over  $\mathcal{X}_{\ell \bmod m}$ , one holds for  $k \leq n/(2d)^2 \leq n/m^2$  (Claim 16) and the other for  $k \geq n/(2d)^2 \geq n/(4m^2)$  (Lemma 17). Claim 16 is essentially taken from [6]. However, the statement in [6] has a slightly worse bound; so in the full version of the paper we explain the changes required to give the bound of Claim 16. The proof of Lemma 17 involves bounding the magnitude of Kravchuk polynomials. As it is somewhat technical we defer its proof to the full version of the paper.

▷ **Claim 16** (Lemma 10 in [6]). For every  $1 \leq k \leq n/m^2$  and every integer  $\ell$ ,

$$2^{-n} \left| \sum_{x \in \mathcal{X}_{\ell \bmod m}} (-1)^{x_1 + \dots + x_k} \right| \leq m^{-(k+1)} e^{-\Omega(n/m^2)},$$

while for  $k = 0$ ,

$$\left| 2^{-n} |\mathcal{X}_{\ell \bmod m}| - 1/m \right| \leq m^{-1} e^{-\Omega(n/m^2)}.$$

► **Lemma 17.** *For  $k \geq n/(4m^2)$ , we have*

$$\binom{n}{k} \cdot \max_{\ell} \left| \frac{\sum_{x \in \mathcal{X}_{\ell \bmod m}} (-1)^{x_1 + \dots + x_k}}{|\mathcal{X}_{\ell \bmod m}|} \right| \leq O(m)^k.$$

We now use Claim 16 and Lemma 17 to prove Theorem 8.

**Proof of Theorem 8.** As  $p$  is symmetric, all the level- $k$  coefficients are the same, so it suffices to give a bound on  $\widehat{p}(\{1, 2, \dots, k\})$ . Let  $\tilde{p}: \{0, \dots, n\} \rightarrow \{0, 1\}$  be the function defined by  $\tilde{p}(|x|) := p(x_1, \dots, x_n)$ . By Lemma 15, we have  $\tilde{p}(\ell) = \tilde{p}(\ell \bmod m)$  for some  $d < m \leq 2d$  where  $m$  is a power of 2. Using the definition of  $\widehat{p}(\{1, \dots, k\})$ , we have

$$\begin{aligned} |\widehat{p}(\{1, \dots, k\})| &= \left| \mathbf{E}_{x \sim \{0,1\}^n} [p(x) (-1)^{x_1 + \dots + x_k}] \right| \\ &= \left| \sum_{\ell=0}^{m-1} \tilde{p}(\ell) \frac{|\mathcal{X}_{\ell \bmod m}|}{2^n} \cdot \frac{\sum_{x \in \mathcal{X}_{\ell \bmod m}} (-1)^{x_1 + \dots + x_k}}{|\mathcal{X}_{\ell \bmod m}|} \right| \\ &\leq \mathbf{E}[p] \cdot \max_{0 \leq \ell \leq m-1} \left| \frac{\sum_{x \in \mathcal{X}_{\ell \bmod m}} (-1)^{x_1 + \dots + x_k}}{|\mathcal{X}_{\ell \bmod m}|} \right|, \end{aligned}$$

where we use the shorthand  $\mathbf{E}[p] = \mathbf{E}_{x \sim \{0,1\}^n} [p(x)]$  in the last step.

When  $k \leq n/(2d)^2 \leq n/m^2$ , by Claim 16 (using the first bound for the numerator and the second  $k = 0$  bound for the denominator) we have

$$\max_{0 \leq \ell \leq m-1} \left| \frac{\sum_{x \in \mathcal{X}_{\ell \bmod m}} (-1)^{x_1 + \dots + x_k}}{|\mathcal{X}_{\ell \bmod m}|} \right| \leq \frac{m^{-(k+1)} e^{-\Omega(n/m^2)}}{m^{-1} (1 - e^{-\Omega(n/m^2)})} \leq O(1) \cdot m^{-k} e^{-\Omega(n/m^2)},$$

## 53:12 Fourier Growth of Structured $\mathbb{F}_2$ -Polynomials and Applications

where the last inequality holds because  $1 \leq k \leq n/m^2$  and hence the  $(1 - e^{-\Omega(n/m^2)})$  factor in the denominator of the left-hand side is  $\Omega(1)$ . Hence, summing over all the  $\binom{n}{k}$  level- $k$  coefficients, we get that

$$L_{1,k}(p) \leq \mathbf{E}[p] \cdot \binom{n}{k} \cdot O(1) \cdot m^{-k} e^{-\Omega(n/m^2)} \leq \mathbf{E}[p] \cdot O(1) \cdot m^k \left(\frac{ne}{km^2}\right)^k e^{-\Omega(n/m^2)} \leq \mathbf{E}[p] \cdot O(m)^k,$$

where the last inequality is because for constant  $c$ , the function  $(x/k)^k e^{-cx}$  is maximized when  $x = k/c$ , and is  $O(1)^k$ .

When  $k \geq n/(2d)^2 \geq n/(4m^2)$ , by Lemma 17 we have

$$L_{1,k}(p) \leq \mathbf{E}[p] \cdot \binom{n}{k} \max_{0 \leq \ell \leq m-1} \left| \frac{\sum_{x \in \mathcal{X}_{\ell \bmod m}} (-1)^{x_1 + \dots + x_k}}{|\mathcal{X}_{\ell \bmod m}|} \right| \leq \mathbf{E}[p] \cdot O(m)^k. \quad \blacktriangleleft$$

### 5 $L_{1,k}$ bounds for read- $\Delta$ polynomials

In this section we prove our  $L_{1,k}$  bounds for read-few polynomials, proving Theorem 9.

#### 5.1 Proof idea

We first observe that for  $f = (-1)^p$ , the Fourier coefficient  $\widehat{f}(S)$  is simply the bias of the  $\mathbb{F}_2$ -polynomial  $p_S(x) := p(x) + \sum_{i \in S} x_i$ . Assuming that  $p_S$  depends on all  $n$  variables, by a simple greedy argument we can collect  $n/\text{poly}(\Delta, d)$  polynomials in  $p_S$  so that each of them depends on disjoint variables, and it is not hard to show that the product of the biases of these polynomials upper bounds the bias of  $p_S$ . From this is easy to see that any read- $\Delta$  degree- $d$  polynomial has bias  $\exp(2^{-d}n/\text{poly}(\Delta, d))$ . However, this quantity is too large to sum over  $\binom{n}{k}$  coefficients.

Our next idea (Lemma 18) is to give a more refined decomposition of the polynomial  $p$  by inspecting the variables  $x_i : i \in S$  more closely. Suppose the variables  $x_i : i \in S$  are far apart in their dependency graph (see the definition of  $G_p$  below), as must indeed be the case for most of the  $\binom{n}{k}$  size- $k$  sets  $S$ . Then we can collect all the monomials containing each  $x_i$  to form a polynomial  $p_i$ , and these  $p_i$ 's will depend on disjoint variables. Moreover, if every monomial in  $p_i$  has high degree (see the definition of  $V_t(p)$  below), then  $p_i = 0$  with high probability and therefore  $p_i + x_i$  is almost unbiased. Therefore, we can first collect these  $p_i$  and  $x_i$  from  $p_S$ ; then, for the remaining  $m \geq |S| \cdot \text{poly}(\Delta, d)$  monomials in  $p_S$ , as before we collect  $m/\text{poly}(\Delta, d)$  polynomials  $r_i$  so that they depend on disjoint variables, but this time we collect these monomials using the variables in  $V_t(p)$ , and give an upper bound in terms of the size  $|V_t(p)|$ . Multiplying the biases of the  $p_i + x_i$ 's and the bias of  $r$  gives our refined upper bound on  $\widehat{f}(S)$  in Lemma 18.

#### 5.2 Proof of Theorem 9

We now proceed to the actual proof. We first define some notions that will be used throughout our arguments. For a read- $\Delta$  degree- $d$  polynomial  $p$ , we define  $V_t(p) : t \in [d]$  and  $G_p$  as follows.

For every  $t \in [d]$ , define

$$V_t(p) := \{i \in [n] : \text{the minimum degree of the monomials in } p \text{ containing } x_i \text{ is } t\}.$$

Note that the sets  $V_1(p), \dots, V_d(p)$  form a partition of the input variables  $p$  depends on.

Define the undirected graph  $G_p$  on  $[n]$ , where  $i, j \in [n]$  are adjacent if  $x_i$  and  $x_j$  both appear in the same monomial in  $q$ . Note that  $G_p$  has degree at most  $\Delta d$ . For  $S \subseteq [n]$ , we use  $N_{=d}(S)$  to denote the indices that are at distance exactly  $d$  to  $S$  in  $G_p$ , and use  $N_{\leq d}(S)$  to denote  $\bigcup_{j=0}^d N_{=j}(S)$ .

We first state our key lemma, which gives a refined bound on each  $\widehat{f}(S)$  stronger than the naive bound sketched in the first paragraph of the ‘‘Proof Idea’’ above, and use it to prove Theorem 9. Due to lack of space, we defer its proof to the full version of the paper.

► **Lemma 18** (Main lemma for read- $\Delta$  polynomials). *Let  $p(x_1, \dots, x_n)$  be a read- $\Delta$  degree- $d$  polynomial. Let  $S \subseteq [n], |S| \geq \ell$  be a subset containing some  $\ell$  indices  $i_1, \dots, i_\ell \in S$  whose pairwise distances in  $G_p$  are at least 4, and let  $t_1, \dots, t_\ell \in [d]$  be such that each  $i_j \in V_{t_j}(p)$ . Let  $f = (-1)^p$ . Then*

$$|\widehat{f}(S)| \leq O(1)^{|S|} \cdot \Delta^\ell \prod_{j \in [\ell]} \left( 2^{-t_j} \exp \left( -\frac{2^{-t_j} |V_{t_j}(p)|}{\ell \cdot (\Delta d)^4} \right) \right).$$

**Proof of Theorem 9.** Using a reduction given in the proof of [7, Lemma 2.2], it suffices to prove the same bound without the acceptance probability factor, i.e. to prove that for every  $1 \leq k \leq n$ ,

$$L_{1,k}(p) \leq O(k)^k \cdot (\Delta d)^{8k}.$$

As [7] did not provide an explicit statement of the reduction, for completeness we provide a self-contained statement and proof in Lemma 22 in Appendix A.

For every subset  $S \subseteq [n]$  of size  $k$ , there exists an  $\ell \leq k$  and  $i_1, \dots, i_\ell \in S$  such that their pairwise distances in  $G_p$  are at least 4, each  $i_j \in V_{t_j}(p)$  for some  $t_j \in [d]$ , and each of the remaining  $k - \ell$  indices in  $S$  is within distance at most 3 to some  $i_j$ .

Fix any  $i_1, \dots, i_\ell$ , and let us bound the number of subsets  $S \subseteq [n]$  of size  $k$  that can contain  $i_1, \dots, i_\ell$ . Because  $|N_{\leq 3}(j)| \leq (\Delta d)^3 + (\Delta d)^2 + \Delta d + 1 \leq 4(\Delta d)^3$  for every  $j \in [n]$ , the remaining  $k - \ell$  indices of  $S$  can appear in at most

$$\begin{aligned} \sum_{j_1 + \dots + j_\ell = k - \ell} \prod_{b \in [\ell]} \binom{4(\Delta d)^3}{j_b} &= \binom{4\ell(\Delta d)^3}{k - \ell} \\ &\leq (4(\Delta d)^3)^k \cdot e^{k - \ell} \left( \frac{\ell}{k - \ell} \right)^{k - \ell} \\ &\leq (e\Delta d)^{3k} \end{aligned}$$

different ways, where the equality uses the Vandermonde identity, the first inequality uses  $\binom{n}{k} \leq (en/k)^k$ , and the last one uses  $\left(\frac{\ell}{k - \ell}\right)^{k - \ell} \leq \left(1 + \frac{\ell}{k - \ell}\right)^{k - \ell} \leq e^\ell$  and  $4e < e^3$ . Therefore, by Lemma 18,

$$\begin{aligned} \sum_{S: |S|=k} |\widehat{f}(S)| &\leq \sum_{\ell=1}^k \sum_{t \subseteq [d]^\ell} \left[ \left( \prod_{j \in [\ell]} |V_{t_j}(p)| \right) \cdot (e\Delta d)^{3k} \cdot O(1)^k \Delta^\ell \prod_{j' \in [\ell]} \left( 2^{-t_{j'}} \exp \left( -\frac{2^{-t_{j'}} |V_{t_{j'}}(p)|}{\ell(\Delta d)^4} \right) \right) \right] \\ &\leq O(1)^k \cdot (\Delta d)^{3k} \sum_{\ell=1}^k \Delta^\ell \sum_{t \subseteq [d]^\ell} \prod_{j \in [\ell]} \left( 2^{-t_j} |V_{t_j}(p)| \exp \left( -\frac{2^{-t_j} |V_{t_j}(p)|}{\ell(\Delta d)^4} \right) \right) \\ &\leq O(1)^k \cdot (\Delta d)^{3k} \sum_{\ell=1}^k \Delta^\ell \cdot d^\ell \cdot (\ell(\Delta d)^4)^\ell \\ &\leq O(k)^k \cdot (\Delta d)^{3k} \cdot (\Delta d)^{5k} \\ &= O(k)^k \cdot (\Delta d)^{8k}, \end{aligned}$$

where the third inequality is because the function  $x \mapsto xe^{-x/c}$  is maximized when  $x = c$ . This completes the proof. ◀

## 6 $L_{1,k}$ bounds for disjoint compositions

In this section we give  $L_{1,k}$  bounds on *disjoint compositions* of functions, proving Theorem 12.

### 6.1 Proof idea

Before proving Theorem 12, we briefly describe the main ideas of the proof. For a subset  $J \subseteq [m]$ , let  $\partial_J f$  denote the  $J$ -th derivative of  $f$ , which can be expressed as

$$\partial_J f(x_1, \dots, x_m) := \sum_{T \supseteq J} \widehat{f}(T) x^{T \setminus J}.$$

Note that  $\widehat{f}(J) = \partial_J f(\vec{0})$ .

Let us begin by considering the task of bounding  $L_{1,1}(h) = \sum_{(i,j) \in [m] \times [\ell]} |\widehat{h}\{(i,j)\}|$ . Let  $\beta = (\beta_1, \dots, \beta_m)$ , where  $\beta_i := \mathbf{E}[g_i]$ . Using the Fourier expansion of  $f$ , we have

$$\widehat{h}\{(i,j)\} = \sum_{S \subseteq [m]} \widehat{f}(S) \mathbf{E} \left[ \prod_{k \in S} g_k(x_k) \cdot x_{i,j} \right].$$

If  $S \not\ni i$ , then the expectation is zero, because  $\prod_{k \in S} g_k(x_k)$  and  $x_{i,j}$  are independent and  $\mathbf{E}[x_{i,j}] = 0$ . So, we have

$$\widehat{h}\{(i,j)\} = \sum_{S \ni i} \widehat{f}(S) \beta^{S \setminus \{i\}} \cdot \widehat{g}_i(\{j\}) = \partial_i f(\beta) \cdot \widehat{g}_i(\{j\}).$$

If the functions  $g_i$  are balanced, i.e.  $\mathbf{E}[g_i] = 0$  for all  $i$ , then we would have  $\beta = \vec{0}$ , and

$$\widehat{h}\{(i,j)\} = \partial_i f(\vec{0}) \cdot \widehat{g}_i(\{j\}) = \widehat{f}(\{i\}) \widehat{g}_i(\{j\}).$$

So in this case we have

$$L_{1,1}(h) = \sum_{i \in [m], j \in [\ell]} |\widehat{h}\{(i,j)\}| = \sum_{i \in [m]} \sum_{j \in [\ell]} |\widehat{f}(\{i\}) \widehat{g}_i(\{j\})| = \sum_{i \in [m]} |\widehat{f}(\{i\})| \sum_{j \in [\ell]} |\widehat{g}_i(\{j\})|$$

and we can apply our bounds on  $L_{1,1}(\mathcal{F})$  and  $L_{1,1}(\mathcal{G})$  to  $\sum_{i \in [m]} \widehat{f}(\{i\})$  and  $\sum_{j \in [\ell]} \widehat{g}_i(\{j\})$  respectively. Specializing to the case  $g_1 = \dots = g_m$ , we have

▷ **Claim 19.** Suppose  $g_1 = g_2 = \dots = g_m =: g$  and  $\mathbf{E}[g] = 0$ . Then  $L_{1,1}(h) = L_{1,1}(f)L_{1,1}(g)$ .

In general the  $g_i$ 's may not all be the same and may not be balanced, and so it seems unclear how we can apply our  $L_{1,1}(\mathcal{F})$  bound on  $\sum_{i \in [m]} \partial_i f(\beta_1, \dots, \beta_m)$  when  $\beta \neq \vec{0}$ . To deal with this, in Claim 20 below we apply a clever idea introduced in [9] that lets us relate  $f(\beta)$  at a nonzero point  $\beta$  to the average of  $f_{R_\beta}(\vec{0})$ , where  $f_{R_\beta}$  is  $f$  with some of its inputs fixed by a random restriction  $R_\beta$ . As  $\mathcal{F}$  is closed under restrictions, we have that  $f_{R_\beta} \in \mathcal{F}$  and we can apply the  $L_{1,1}(\mathcal{F})$  bound on  $\sum_i \partial_i f_{R_\beta}(\vec{0})$ , which in turn gives a bound on  $\sum_{i \in [m]} \partial_i f(\beta_1, \dots, \beta_m)$ .

Bounding  $L_{1,K}(h)$  for  $K \geq 2$  is more complicated, as now each  $\widehat{h}(S)$  involves many  $\widehat{f}(J)$  and  $\widehat{g}_i(T)$ 's, where the sets  $J$  and  $T$  have different sizes. So one has to group the coefficients carefully.

### 6.2 Useful notation

For a set  $S \subseteq [m] \times [\ell]$ , let  $S|_f := \{i \in [m] : (i, j) \in S \text{ for some } j \in [\ell]\}$  be the “set of first coordinates” that occur in  $S$ , and let  $S|i := \{j \in [\ell] : (i, j) \in S\}$ . Note that if  $(i, j) \in S$ , then  $i \in S|_f$  and  $j \in S|i$ . Let  $\beta$  denote the vector  $(\beta_1, \dots, \beta_m)$ , where  $\beta_i := \mathbf{E}[g_i]$  for each  $i \in [m]$ . For a set  $J = \{i_1, \dots, i_{|J|}\} \subseteq [m]$  and  $f = f(y_1, \dots, y_m)$ , we write  $\partial_J f$  to denote  $\frac{\partial^{|J|} f}{\partial y_{i_1} \dots \partial y_{i_{|J|}}}$ . Since  $\partial_J y^T = \mathbb{1}(T \supseteq J) y^{T \setminus J}$ , by the multilinearity of  $f$  we have that

$$\partial_J f(\beta) = \sum_{T \supseteq J} \widehat{f}(T) \beta^{T \setminus J}. \tag{5}$$

### 6.3 The random restriction $R_\beta$

Given  $\beta \in [-1, 1]^m$ , let  $R_\beta$  be the random restriction which is the randomized function from  $\{-1, 1\}^m$  to  $\{-1, 1\}^m$  whose  $i$ -th coordinate is (independently) defined by

$$R_\beta(y)_i := \begin{cases} \text{sgn}(\beta_i) & \text{with probability } |\beta_i| \\ y_i & \text{with probability } 1 - |\beta_i|. \end{cases}$$

Note that we have

$$\mathbf{E}_{R_\beta, y} [R_\beta(y)_i] = \mathbf{E}_{R_\beta} [R_\beta(\vec{0})_i] = \beta_i.$$

Define  $f_{R_\beta}(y)$  to be the (randomized) function  $f(R_\beta(y))$ . By the multilinearity of  $f$  and independence of the  $R_\beta(y)_i$  we have

$$\mathbf{E}_{R_\beta, y} [f_{R_\beta}(y)] = \mathbf{E}_{R_\beta} [f_{R_\beta}(\vec{0})] = f(\beta).$$

The following claim relates the two derivatives  $\partial_S f(\beta)$  and  $\partial_S f_{R_\beta}(\vec{0}) = \widehat{f_{R_\beta}}(S)$ .

▷ Claim 20.

$$\partial_S f(\beta) = \prod_{i \in S} \frac{1}{1 - |\beta_i|} \cdot \mathbf{E}_{R_\beta} [\partial_S f_{R_\beta}(\vec{0})] = \prod_{i \in S} \frac{1}{1 - |\beta_i|} \cdot \mathbf{E}_{R_\beta} [\widehat{f_{R_\beta}}(S)].$$

Proof. Due to lack of space, we defer the proof to the full version of the paper. ◁

We can use Claim 20 to express each coefficient of  $h$  in terms of the coefficients of  $f$  and  $g_i$ .

► **Lemma 21.** For  $S \subseteq [m] \times [\ell]$ , we have  $\widehat{h}(S) = \prod_{i \in S|_f} \widehat{g}_i(S|i) \cdot \prod_{i \in S|_f} \frac{1}{1 - |\beta_i|} \cdot \mathbf{E}_{R_\beta} [\widehat{f_{R_\beta}}(S|_f)]$ .

Proof. Due to lack of space, we defer the proof to the full version of the paper. ◀

### 6.4 Proof of Theorem 12

By Lemma 21,  $L_{1,K}(h)$  is equal to

$$\sum_{S \subseteq [m] \times [\ell] : |S|=K} |\widehat{h}(S)| = \sum_{S \subseteq [m] \times [\ell] : |S|=K} \left| \prod_{i \in S|_f} \widehat{g}_i(S|i) \cdot \prod_{i \in S|_f} \frac{1}{1 - |\beta_i|} \cdot \mathbf{E}_{R_\beta} [\widehat{f_{R_\beta}}(S|_f)] \right|.$$

We enumerate all the subsets  $S \subseteq [m] \times [\ell]$  of size  $K$  in the following order: For every  $|J| = k \in [K]$  out of the  $m$  blocks of  $\ell$  coordinates, we enumerate all possible combinations

### 53:16 Fourier Growth of Structured $\mathbb{F}_2$ -Polynomials and Applications

of the (disjoint) nonempty subsets  $\{S_i : i \in J\}$  in those  $k$  blocks whose sizes sum to  $K$ . Rewriting the summation above in this order, we obtain

$$\begin{aligned} \sum_{S \subseteq [m] \times [\ell] : |S|=K} |\widehat{h}(S)| &= \sum_{k=1}^K \sum_{\substack{J \subseteq [m] \\ |J|=k}} \sum_{\substack{w \subseteq [\ell]^J \\ |J|=k}} \sum_{\substack{\{S_i\}_{i \in J} \subseteq [\ell]^J \\ \forall i \in J : |S_i|=w_i}} \left| \prod_{i \in J} \widehat{g}_i(S_i) \prod_{i \in J} \frac{1}{1-|\beta_i|} \mathbf{E}_{R_\beta} [\widehat{f_{R_\beta}}(J)] \right| \\ &\leq \sum_{k=1}^K \sum_{\substack{J \subseteq [m] \\ |J|=k}} \sum_{\substack{w \subseteq [\ell]^J \\ |J|=k}} \sum_{\substack{\{S_i\}_{i \in J} \subseteq [\ell]^J \\ \forall i \in J : |S_i|=w_i}} \prod_{i \in J} |\widehat{g}_i(S_i)| \prod_{i \in J} \frac{1}{1-|\beta_i|} \left| \mathbf{E}_{R_\beta} [\widehat{f_{R_\beta}}(J)] \right|. \end{aligned} \quad (6)$$

Since  $L_{1,w_i}(g_i) \leq \frac{1-|\beta_i|}{2} \cdot a_{\text{in}} \cdot b_{\text{in}}^{w_i}$ , for every  $\{w_i\}_{i \in J}$  such that  $\sum_{i \in J} w_i = K$ , we have

$$\sum_{\substack{\{S_i\}_{i \in J} \subseteq [\ell]^J : i \in J \\ \forall i \in J : |S_i|=w_i}} \prod_{i \in J} |\widehat{g}_i(S_i)| = \prod_{i \in J} L_{1,w_i}(g_i) \leq \prod_{i \in J} \left( \frac{1-|\beta_i|}{2} a_{\text{in}} b_{\text{in}}^{w_i} \right) = b_{\text{in}}^K a_{\text{in}}^{|J|} \prod_{i \in J} \frac{1-|\beta_i|}{2}.$$

Plugging the above into (6), we get that

$$\begin{aligned} \sum_{S \subseteq [m] \times [\ell] : |S|=K} |\widehat{h}(S)| &\leq b_{\text{in}}^K \sum_{k=1}^K a_{\text{in}}^k \sum_{\substack{J \subseteq [m] \\ |J|=k}} \sum_{\substack{w \subseteq [\ell]^J \\ \sum_{i \in J} w_i = K}} \prod_{i \in J} \left( \frac{1-|\beta_i|}{2} \cdot \frac{1}{1-|\beta_i|} \cdot \left| \mathbf{E}_{R_\beta} [\widehat{f_{R_\beta}}(J)] \right| \right) \\ &= b_{\text{in}}^K \sum_{k=1}^K \left( \frac{a_{\text{in}}}{2} \right)^k \sum_{\substack{J \subseteq [m] \\ |J|=k}} \left| \mathbf{E}_{R_\beta} [\widehat{f_{R_\beta}}(J)] \right| \sum_{\substack{w \subseteq [\ell]^J \\ \sum_{i \in J} w_i = K}} 1 \\ &\leq b_{\text{in}}^K \sum_{k=1}^K \left( \frac{a_{\text{in}}}{2} \right)^k \binom{K-1}{k-1} \sum_{\substack{J \subseteq [m] \\ |J|=k}} \left| \mathbf{E}_{R_\beta} [\widehat{f_{R_\beta}}(J)] \right|, \end{aligned} \quad (7)$$

where the last inequality is because for every subset  $J \subseteq [m]$ , the set  $\{w \subseteq [\ell]^J : \sum_{i \in J} w_i = K\}$  has size at most  $\binom{K-1}{|J|-1}$ . We now bound  $|\mathbf{E}_{R_\beta} [\widehat{f_{R_\beta}}(J)]|$ . Since for every restriction  $R_\beta$ , we have  $f_{R_\beta} \in \mathcal{F}$  (by the assumption that  $\mathcal{F}$  is closed under restrictions), it follows that

$$L_{1,k}(f_{R_\beta}) \leq \frac{1 - |\mathbf{E}_y[f_{R_\beta}(y)]|}{2} a_{\text{out}} b_{\text{out}}^k \leq \frac{1 - \mathbf{E}_y[f_{R_\beta}(y)]}{2} a_{\text{out}} b_{\text{out}}^k.$$

So

$$\begin{aligned} \sum_{J \subseteq [m], |J|=k} \left| \mathbf{E}_{R_\beta} [\widehat{f_{R_\beta}}(J)] \right| &\leq \mathbf{E}_{R_\beta} [L_{1,k}(f_{R_\beta})] \\ &\leq \frac{1 - \mathbf{E}_{R_\beta, y} [f_{R_\beta}(y)]}{2} a_{\text{out}} b_{\text{out}}^k \\ &= \frac{1 - \mathbf{E}[h]}{2} a_{\text{out}} b_{\text{out}}^k. \end{aligned}$$

Continuing from (7), we get

$$\begin{aligned} \sum_{S \subseteq [m] \times [\ell]: |S|=K} |\widehat{h}(S)| &\leq \frac{1 - \mathbf{E}[h]}{2} \cdot b_{\text{in}}^K \cdot \sum_{k=1}^K \left(\frac{a_{\text{in}}}{2}\right)^k \cdot \binom{K-1}{k-1} \cdot a_{\text{out}} b_{\text{out}}^k \\ &= \frac{1 - \mathbf{E}[h]}{2} \cdot a_{\text{out}} \cdot b_{\text{in}}^K \cdot \frac{a_{\text{in}} b_{\text{out}}}{2} \left(1 + \frac{a_{\text{in}} b_{\text{out}}}{2}\right)^{K-1} \\ &\leq \frac{1 - \mathbf{E}[h]}{2} \cdot a_{\text{out}} \cdot (a_{\text{in}} b_{\text{in}} b_{\text{out}})^K. \end{aligned}$$

where the last equality used the binomial theorem. Applying the same argument to  $-h$  lets us replace  $\frac{1 - \mathbf{E}[h]}{2}$  with  $\frac{1 + \mathbf{E}[h]}{2}$ , concluding the proof of Theorem 12.  $\blacktriangleleft$

## A Reduction to bound without acceptance probability

In this section, we show that given any  $L_{1,k}$  Fourier norm bound on a class of functions that is closed under XOR on disjoint variables, such a bound can be automatically “upgraded” to a refined bound that depends on the acceptance probability:

► **Lemma 22.** *Let  $\mathcal{F}$  be a class of  $\{-1, 1\}$ -valued functions such that for every  $f \in \mathcal{F}$ , the XOR of disjoint copies of  $f$  (over disjoint sets of variables) also belongs to  $\mathcal{F}$ . If  $L_{1,k}(\mathcal{F}) \leq b^k$ , then for every  $f \in \mathcal{F}$  it holds that  $L_{1,k}(f) \leq 2e \cdot \frac{1-|\mathbf{E}[f]|}{2} \cdot b^k$ .*

**Proof.** Suppose not, and let  $f \in \mathcal{F}$  be such that  $L_{1,k}(f) > 2e \cdot \frac{1-|\mathbf{E}[f]|}{2} \cdot b^k$ . We first observe that since  $L_{1,k}(\mathcal{F}) \leq b^k$ , it must be the case that  $1 - |\mathbf{E}[f]| \leq 1/e$ . Let  $\alpha := \frac{1-|\mathbf{E}[f]|}{2} \in [0, \frac{1}{2e}]$  so that  $|\mathbf{E}[f]| = 1 - 2\alpha \geq 1 - 1/e$ . Let  $f^{\oplus t}$  be the XOR of  $t$  disjoint copies of  $f$  on  $tn$  variables, where the integer  $t$  is to be determined below. By our assumption, we have  $f^{\oplus t} \in \mathcal{F}$  and thus

$$\begin{aligned}
 L_{1,k}(f^{\oplus t}) &\geq \binom{t}{1} \cdot L_{1,0}(f)^{t-1} \cdot L_{1,k}(f) && \text{(by disjointness)} \\
 &= t \cdot (1 - 2\alpha)^{t-1} \cdot L_{1,k}(f) && (L_{1,0}(f) = \mathbf{E}[f]) \\
 &> t \cdot (1 - 2\alpha)^{t-1} \cdot 2e \cdot \alpha \cdot b^k =: \Lambda(t).
 \end{aligned}$$

### 53:20 Fourier Growth of Structured $\mathbb{F}_2$ -Polynomials and Applications

We note that if  $\alpha = 0$  then  $|\mathbf{E}[f]| = 1$ , so all the Fourier weight of  $f$  is on the constant coefficient, and hence the claimed inequality holds trivially. So we subsequently assume that  $0 < \alpha \leq \frac{1}{2e}$ . Let  $t^* := \frac{1}{-\ln(1-2\alpha)} > 0$ . It is easy to verify that  $\Lambda(t)$  is increasing when  $t \leq t^*$ , and is decreasing when  $t \geq t^*$ .

We choose  $t = \lceil t^* \rceil$ . Since  $\alpha \leq \frac{1}{2e} < \frac{e-1}{2e} \approx 0.3161$ , we have  $t^* > 1$  and thus

$$\begin{aligned} L_{1,k}(f^{\oplus t}) &> \Lambda(\lceil t^* \rceil) \geq \Lambda(t^* + 1) = \left( \frac{1}{-\ln(1-2\alpha)} + 1 \right) \cdot (1-2\alpha)^{-\frac{1}{\ln(1-2\alpha)}} \cdot 2e \cdot \alpha \cdot b^k \\ &= \left( \frac{2\alpha}{-\ln(1-2\alpha)} + 2\alpha \right) \cdot b^k \geq b^k, \end{aligned}$$

where the last inequality holds for every  $\alpha \in (0, \frac{e-1}{2e}]$  and can be checked via elementary calculations. This contradicts  $L_{1,k}(\mathcal{F}) \leq b^k$ , and the lemma is proved.  $\blacktriangleleft$

# Candidate Tree Codes via Pascal Determinant Cubes

## Abstract

Tree codes are combinatorial structures introduced by Schulman [23] as key ingredients in interactive coding schemes. Asymptotically-good tree codes are long known to exist, yet their explicit construction remains a notoriously hard open problem. Even proposing a plausible construction, without the burden of proof, is difficult and the defining tree code property requires structure that remains elusive. To the best of our knowledge, only one candidate appears in the literature, due to Moore and Schulman [19].

We put forth a new candidate for an explicit asymptotically-good tree code. Our construction is an extension of the vanishing rate tree code by Cohen-Haeupler-Schulman [7], and its correctness relies on a conjecture that we introduce on certain Pascal determinants indexed by the points of the Boolean hypercube. Furthermore, using the vanishing distance tree code by Gelles *et al.* [12] enables us to present a construction that relies on an even weaker assumption. We furnish evidence supporting our conjecture through numerical computation, combinatorial arguments from planar path graphs and based on well-studied heuristics from arithmetic geometry.

## 1 Introduction

Coding theory addresses the problem of communication over an imperfect channel. In the classic setting studied in the seminal work of Shannon [26], Alice wishes to communicate a message to Bob over a channel that may induce errors. The question then is: how should Alice encode her message so that if the amount of errors is not excessive, Bob can recover her message? Around the same time, Hamming [14] introduced the notion of an error-correcting code. A function  $C: \Sigma^k \rightarrow \Sigma^n$  is an *error-correcting code* with distance  $\delta$  if for every distinct  $x, y \in \Sigma^k$ , the respective images  $C(x), C(y)$  have relative Hamming distance at least  $\delta$ . rate of information transmission  $\rho = \frac{k}{n}$  and the fraction of errors corrected (roughly  $\delta/2$ ) are competing quantities with a tradeoff between them. Among the most basic questions in coding theory is to obtain explicit *asymptotically good codes*, that is, codes over fixed  $\Sigma$  with constant distance  $\delta > 0$  and constant rate  $\rho > 0$ . By “explicit” we mean that  $C$  can be evaluated in time  $\text{poly}(n)$ . Justensen [15] was the first to devise such an explicit construction. Since then, several explicit constructions have appeared, including using algebraic geometry codes [28] and expander graphs [27].

While error-correcting codes can be used to solve the problem of sending a single message from Alice to Bob over an imperfect channel, in some settings, the two parties interact with each other, sending multiple messages where a message depends on previous messages that were exchanged. Interactive coding addresses the subtler problem of enabling such dynamic interaction over an imperfect channel. In this far more challenging setting, standard codes do not offer a satisfactory solution.

Tree codes are powerful combinatorial structures, defined by Schulman [23, 25] as key ingredients for achieving interactive coding schemes. They play a role analogous to that error-correcting codes take in the single message setting. Tree codes, as their name suggests, are trees with certain distance properties. To give the formal definition, we set some notation. Let  $T$  be a rooted binary tree that is endowed with an edge coloring from some ambient color set (or alphabet)  $\Sigma$ . For vertices  $u, v$  of equal depth let  $w$  be their least common ancestor and denote the distance, in edges, from  $u$  to  $w$  by  $\ell$ . Let  $p_u, p_v \in \Sigma^\ell$  be the sequences of colors on the path from  $w$  to  $u$  and to  $v$ , respectively. We define  $h(u, v)$  to be the relative Hamming distance between  $p_u$  and  $p_v$ . Informally,  $h(u, v)$  measures the distance between the two color sequences obtained by following the paths from the root to each of  $u$  and  $v$ , excluding the “non-interesting” common prefix. A tree code is any coloring that has a lower bound on this quantity. Formally,

► **Definition 1** (Tree codes [23]). *Let  $T$  be the complete rooted binary tree of depth  $n$ . The tree  $T$ , together with an edge-coloring of  $T$  by a color set  $\Sigma$  is called a tree code with distance  $\delta$  if for every pair of vertices  $u, v$  with equal depth it holds that  $h(u, v) \geq \delta$ .*

It is not clear at all that there exists a universal constant  $\delta > 0$  such that for every  $n$  there exists a depth- $n$  tree code with distance  $\delta$ . Namely, it is not clear that there is a family of tree codes  $(T_n)_{n \in \mathbb{N}}$ , where  $T_n$  has depth  $n$ , such that the color set  $\Sigma$  is common to all trees in the family, and every  $T_n$  has distance  $\delta$ . We refer to such a family as a tree code with distance  $\delta$  over the color set  $\Sigma$ .

Three different proofs were provided by Schulman, showing that for any constant  $\delta < 1$  there exists a tree code with alphabet size  $|\Sigma| = O_\delta(1)$  achieving distance  $\delta$ . More recently, based on Schulman’s ideas, it was shown that there is a tree code with only 4 colors, having positive distance (in particular, distance  $\delta = 0.136$ ) [8] and, moreover, 3 colors do not suffice to guarantee any constant distance  $\delta > 0$ . All of these proofs rely on the probabilistic method and thus are not explicit. The problem of constructing asymptotically-good tree codes has drawn substantial attention [24, 6, 19, 21, 12, 7, 20], but has endured as a difficult challenge.

Given this difficulty, it is natural to construct, for a given distance parameter  $\delta > 0$ , a family of tree codes  $(T_n)_{n \in \mathbb{N}}$  for which  $T_n$  is allowed to use some  $c(n)$  number of colors. The goal is to obtain an asymptotically slowly-growing function  $c$ . Note that constructing a tree code family with  $c(n) = 2^n$  colors is trivial. Indeed, having so many colors at hand, one can encode the entire path leading to a vertex on the edge preceding it, yielding distance  $\delta = 1$ . In an unpublished manuscript, Evans, Klugerman and Schulman [24] constructed a tree code with  $c(n) = n^{O_\delta(1)}$  colors. The state-of-the-art construction [7] achieves  $c(n) = (\log n)^{O_\delta(1)}$ . See [20] for alternative constructions achieving the same parameters as well as decoding algorithms, and [4] for an account relating [7] and [21].

Despite this progress, constructing asymptotically-good tree codes is wide open. Curiously, even candidate constructions are rare. This is mostly because a tree code is *not* a pseudorandom object. Its defining property requires structure that remains elusive. For this reason, even proposing a plausible construction, without the burden of proof, requires further insight and is not an easy task. To the best of our knowledge, there is a single candidate in the literature, due to Moore and Schulman [19]. The construction’s distance property relies on an intriguing open conjecture about certain exponential sums that the authors introduce. The Moore-Schulman conjecture was verified computationally for small instances, and the hope is that these represent the general case.

## 1.1 Our Contribution

In this work we put forth a candidate construction of asymptotically-good tree codes. Namely, for some universal constant  $c \geq 1$  and for every integer  $n \geq 1$  we give an explicit construction of a depth- $n$  binary tree code with  $c$  colors. The distance of the tree code is bounded below by some constant  $\delta > 0$ , independent of  $n$ , provided a conjecture that we introduce on certain Pascal determinants associated with the points of the Boolean hypercube holds. We give independent supporting evidence for our conjecture: first through the combinatorics of planar path graphs underlying our construction and then based on well-studied heuristics from arithmetic geometry. Furthermore, we verify the conjecture computationally on small values.

Our candidate tree code is an extension of the [7] construction. We set the stage in Section 2 with a discussion of [7] followed by a description of our contributions in Section 3. Underlying the [7] construction is a key online uncertainty principle for the Newton basis: a consequence of non-vanishing of Pascal (binomial) sub-matrix determinants, proved by invoking the combinatorial Lindström-Gessel-Viennot lemma. These determinants are in fact positive numbers growing exponentially with the depth of the tree, forcing the [7] construction to require poly-logarithmic number of colors. With the intent of reducing the number of colors, one may try to work modulo a prime in hopes the non-vanishing is still preserved. In Section 3.1 we reason the contrary is true: it is unlikely to work for primes small enough to guarantee a constant number of colors. There are exponentially many Pascal sub-matrix determinants, at least one of which is likely to vanish “accidentally” modulo the chosen prime.

Our main technical contribution is an extension of the [7] construction, which we present as a candidate asymptotically-good tree code. The construction extends ideas of [7] and further makes use of the vanishing-distance tree code by Gelles *et al.* [12], which allows us to relax our assumption. An informal description of the main ideas is in Section 3.3 with a formal treatment of the more intricate aspects deferred to Section 5. In our construction, the role of each Pascal sub-matrix determinant is recast as a bundle of Pascal sub-matrix determinants, parametrized by points on the Boolean hypercube of high enough dimension (hence the term “Pascal determinant cube” in the title). We then work modulo a prime  $p$  of appropriate size. Instead of worrying about a determinant vanishing modulo  $p$ , we only have to worry about the whole associated cube of Pascal determinants vanishing modulo  $p$ . Informed by computation, combinatorics and arithmetic, we formulate the Conjecture 4 in Section 3.2 that the cube of determinants never vanishes modulo our chosen prime. We prove that if the conjecture (or even an asymptotic version of it, Conjecture 5) holds then our construction is indeed asymptotically good.

In Appendix A, we investigate our conjecture through a combinatorial lens. Each determinant bundle in the conjecture can be encoded as an integer polynomial whose evaluation at the points of the Boolean hypercube gives the bundle. Through the Lindström-

Gessel-Viennot lemma, in Appendix A.1 we prove that the polynomial never vanishes on any point of the Boolean hypercube. For the conjecture to fail, all these exponentially many evaluations must be divisible by our chosen prime number, which we reason is likely impossible for our chosen parameters. This very scenario is reformulated in terms of Boolean functions in Appendix A.2, by multi-linearizing the aforementioned polynomial. Conjecture 4 is then rephrased as the non vanishing of an  $\mathbb{F}_p$ -valued Boolean function, furthering our belief in the conjecture.

In Appendix B, we look to deep results from arithmetic geometry to claim the plausibility of our conjecture. If the hypersurface of zeroes of the aforementioned polynomial encoding the bundle of determinants intersects with the Boolean hypercube generically, our conjecture holds true. Following Fouvry [10], we investigate this intersection deploying Katz-Laumon exponential sums. The bounds on Katz-Laumon sums and Fouvry's point counting technique fall short of quantitatively proving our conjecture. Yet, we show they suffice to prove a nontrivial relaxation of our conjecture: with the Boolean hypercube extended to hypercubes of side length  $\approx p^{3/4}$ . Despite falling short of proving our conjecture, the methods are illuminating and suggest there are no arithmetic obstructions to our conjecture.

## 1.2 Recent Developments

Since posting our report online, there have been several exciting developments. Brakerski, Kalai and Saxena [5] published a major advancement on the use of tree codes in interactive coding. They demonstrate how a tree code with an efficient encoding algorithm suffices in obtaining efficient and deterministic interactive coding schemes against adversarial errors. In particular, they completely eliminate the necessity of the tree code possessing an efficient decoding algorithm. Our candidate tree code clearly has an efficient encoding algorithm and seamlessly fits their needs. Therefore, proving our tree codes are indeed asymptotically good would immediately imply efficient and deterministic interactive coding schemes.

Pudlák gleaned an abstraction of our construction and reduced the problem of constructing asymptotically good tree codes to constructing block matrices of the following form [22]. Consider an  $n$  by  $n$  block matrix whose entries are 2 by 1 column vector blocks. Say it is triangular, meaning all blocks above the diagonal are  $\begin{pmatrix} 0 \\ 0 \end{pmatrix}$  vectors. For every  $k$  by  $k$  block sub matrix (where the sorted column indices are never ahead of the row indices), Pudlák demands that the  $2k$  by  $k$  matrix induced by forgetting the block structure is full rank. This rank criterion is a relaxation of our determinant bundle non vanishing. Pudlák further proves that random triangular block matrices with entries from a finite field of size quadratic in  $n$  satisfy the rank criterion with high probability. Explicit deterministic construction of such block matrices beckons, with our construction being the only currently proposed candidate.

## 2 Cohen-Haeupler-Schulman Tree Codes

For the sequel, it is convenient to think of a tree code as an online version of a regular error correcting code. Recall that a tree code consists of a complete rooted, depth- $n$  binary tree in which each edge is labeled by a symbol from an alphabet  $\Sigma$ . This naturally induces a one-to-one mapping assigning each binary string  $s$  to a path starting at the root, where  $s$  indicates which child is taken in each of the steps. Such a path maps to a string over  $\Sigma$ , namely, the concatenation of symbols along the path. This way, a tree code  $T$  encodes any binary string  $s$  into an equally long string  $T(s)$  over  $\Sigma$ . This encoding has the online property because the encoding of any prefix does not depend on later symbols. Thus, one

can view a binary tree code as an online function  $T : \{0, 1\}^n \rightarrow \Sigma^n$ . It is useful to consider input alphabets other than binary (which corresponds to a larger arity of the tree). In [7], the input symbols are elements of  $\mathbb{Z}$  rather than  $\{0, 1\}$ .

The distance property of a tree code can be phrased as follows when viewed as a function  $T : \Sigma_{\text{in}}^n \rightarrow \Sigma_{\text{out}}^n$ . For every pair of distinct strings  $m = (m_0, \dots, m_{n-1})$ ,  $m' = (m'_0, \dots, m'_{n-1})$ ,  $c$  being the least integer such that  $m_c \neq m'_c$ , the following holds. For every  $\ell \in [0, n - c]$  (for integers  $a < b$  we write  $[a, b]$  for  $\{a, a + 1, \dots, b - 1\}$ ) the strings  $(T(m)_c, \dots, T(m)_{c+\ell})$ ,  $(T(m')_c, \dots, T(m')_{c+\ell})$  are at Hamming distance at least  $\delta(\ell + 1)$ .

**The Newton basis.** [7] makes use of the Newton basis for real polynomials. This basis consists of polynomials of the form  $\binom{x}{k} \in \mathbb{R}[x]$  for  $k \in \mathbb{N}$ , where  $\binom{x}{k} = \frac{x(x-1)\dots(x-(k-1))}{k!}$ . It is easy to verify that for every  $d \in \mathbb{N}$ , the set  $\{\binom{x}{k} \mid k = 0, 1, \dots, d\}$  forms a basis for the space of univariate real polynomials of degree at most  $d$ . The feature which makes the Newton basis suitable for constructing tree codes unlike, say the standard basis, is its online nature with respect to  $\mathbb{N}$ . Let  $m_0, \dots, m_t \in \mathbb{R}$ . Let  $f(x) = \sum_{i=0}^t a_i x^i$  be the least degree polynomial that interpolates on the points  $(0, m_0), \dots, (t, m_t)$ . Then, generally, given a new point  $(t + 1, m_{t+1})$ , the least degree polynomial,  $g(x) = \sum_{i=0}^{t+1} b_i x^i$ , that interpolates on  $(0, m_0), \dots, (t + 1, m_{t+1})$  will have a completely different sequence of coefficients (i.e.,  $a_i \neq b_i$ ). By contrast, using the Newton basis, the coefficients that were already “recorded” stay intact given the new point  $(t + 1, m_{t+1})$ . More precisely, if  $f(x) = \sum_{i=0}^t \gamma_i \binom{x}{i}$  then  $g(x) = f(x) + \gamma_{t+1} \binom{x}{t+1}$  for some  $\gamma_{t+1} \in \mathbb{R}$ . Thus, for every  $t$ , the coefficient  $\gamma_t$  is determined by  $m_0, m_1, \dots, m_t$ . Another convenient property of the Newton basis, not shared by the standard basis, is that if  $m_0, \dots, m_t$  are all integers, so are the coefficients  $\gamma_0, \dots, \gamma_t$ .

**The [7] tree code over the integers.** In [7], for every integer  $n \geq 1$  a function  $\text{TC}_{\mathbb{Z}} : \mathbb{Z}^n \rightarrow (\mathbb{Z} \times \mathbb{Z})^n$  is constructed as follows. Given  $m = (m_0, \dots, m_{n-1}) \in \mathbb{Z}^n$ , let  $f \in \mathbb{R}[T]$  be the least degree real polynomial that interpolates on  $(0, m_0), \dots, (n - 1, m_{n-1})$ . Expand  $f$  in the Newton basis  $f(T) = \sum_{t=0}^{n-1} \gamma_t \binom{T}{t}$ . With this notation, for every  $t \in [0, n)$ , define  $\text{TC}_{\mathbb{Z}}(m)_t = (m_t, \gamma_t)$ . In words, at time  $t$ , both the  $t^{\text{th}}$  input symbol is outputted as well as the “new” coefficient  $\gamma_t$ .

**Analysis.** To argue about the distance of  $\text{TC}_{\mathbb{Z}}$ , using the fact that it is  $\mathbb{R}$ -linear, one has to prove that if  $c \in [0, n)$  is the least integer for which  $m_c \neq 0$  then for every  $\ell \in [0, n - c)$ , at least  $\delta$ -fraction of the indices in  $[c, c + \ell]$  satisfies that  $\text{TC}_{\mathbb{Z}}(m)_t$  is nonzero (as a pair). If we write, for  $d \in [0, n)$ ,  $f_d(T) = \sum_{t=0}^d \gamma_t \binom{T}{t}$  then the number of non-zeros in the sequence  $\gamma_c, \gamma_{c+1}, \dots, \gamma_{c+\ell}$  is precisely the sparsity of  $f_{c+\ell}$  in the Newton basis. This, together with the fact that for every  $i \leq t$ ,  $m_i = f_t(i)$ , implies that to “break” the construction  $\text{TC}_{\mathbb{Z}}$ , one must come up with a sparse polynomial  $f_{c+\ell}$ , with respect to the Newton basis, that has many roots in  $I = \{c, c + 1, \dots, c + \ell\}$ . Indeed, if  $f_{c+\ell}$  is not sparse, then many of the  $\gamma$ -entries of  $(\text{TC}_{\mathbb{Z}}(m)_t)_{t \in I}$  will be nonzero. On the other hand, if  $f_{c+\ell}$  has only few roots in  $I$  then many of the  $m$ -entries are nonzero. To this end, the main lemma proved in [7] is a bound on the numbers of distinct integral roots a real polynomial can have as a function of its sparsity in the Newton basis.

► **Lemma 2** ([7]). *Let  $f \in \mathbb{R}[T]$  be a nonzero polynomial of sparsity  $s \geq 1$  in the Newton basis. Let  $c \geq 0$  be the least integer such that  $f(c) \neq 0$ . Then,  $f$  has at most  $s - 1$  distinct roots in  $[c, \infty) \cap \mathbb{N}$ .*

Lemma 2 implies that if the sparsity of  $f_{c+\ell}$  is  $s$  then there can be at most  $s - 1$  zeros among the  $m$ -entries of  $\{\text{TC}_{\mathbb{Z}}(m)_t\}_{t \in I}$ , establishing  $\text{TC}_{\mathbb{Z}}$  has distance at least  $\frac{1}{2}$ .

**The Lindström-Gessel-Viennot Lemma.** Lemma 2 is proved using a corollary of the Lindström-Gessel-Viennot Lemma. Let  $\mathbf{t} = (t_1, \dots, t_s)$ ,  $\mathbf{c} = (c_1, \dots, c_s)$  be strictly increasing sequences of non-negative integers. Let  $M_{\mathbf{t}, \mathbf{c}}$  be the  $s \times s$  matrix whose  $(i, j)^{\text{th}}$  entry is given by  $\binom{t_i}{c_j}$ . We write  $\mathbf{c} \leq \mathbf{t}$  if  $c_i \leq t_i$  for every  $i \in [s]$ .

► **Lemma 3** ([13], Corollary 2).  $\mathbf{c} \leq \mathbf{t} \iff \det M_{\mathbf{t}, \mathbf{c}} \neq 0$ .

For more recent treatments of the LGV Lemma see [1], Chapter 5.4 or [2], Chapter 25. This lemma is in fact much older, and we invite the reader to look at the appendix of [7] for more information regarding the history of this lemma.

**The binary tree code.** To reduce the alphabet to binary, [7] proves that if for every  $t$ ,  $|m_t| \leq 2^k$  for some  $k$  then  $|\gamma_t| \leq 2^{t+k}$ . Given a binary string  $m = (m_0, \dots, m_{n-1})$ , partition  $m$  to  $\sqrt{n}$  consecutive blocks of length  $\sqrt{n}$ , and interpret each block as a non-negative integer  $M_i$  of size at most  $2^{\sqrt{n}}$ . At this point, the tree code over the integers  $\text{TC}_{\mathbb{Z}} : \mathbb{N}^{\sqrt{n}} \rightarrow (\mathbb{Z} \times \mathbb{Z})^{\sqrt{n}}$  can be applied to  $M_0, \dots, M_{\sqrt{n}-1}$ . By the above bound,  $|\gamma_t| \leq 2^{t+\sqrt{n}} \leq 2^{2\sqrt{n}}$ . Hence, an output symbol  $(m_t, \gamma_t)$  can be encoded using  $3\sqrt{n}$  bits. Of course, these bits cannot be output on the fly as one must write a symbol only after all of the  $\sqrt{n}$  bits of the corresponding input symbol have been read. This creates a “lag” of length  $\sqrt{n}$  that can be resolved by using a depth- $\sqrt{n}$  tree code which is obtained recursively. As the recursive depth is  $O(\log \log n)$  and since for every bit read one writes  $O(1)$  bits per recursive call, the number of bits written per input bit is  $O(\log \log n)$ . Hence, the poly( $\log n$ ) alphabet size.

### 3 Our Contribution

#### 3.1 The Unlikeliness of an LGV-Like Lemma Over Small Fields

The reason that the [7] construction is not asymptotically-good is that their tree code is constructed over the integers, and the alphabet reduction that is invoked has a cost that is exponential in the depth of the recursion. The recursion’s depth is directly affected by the magnitude of the  $\gamma_t$  symbols which, unfortunately, are exponential in  $t$ . Taking  $\sqrt{n}$ -length blocks yields the best trade-off, resulting in depth  $O(\log \log n)$ .

One can show that resorting to such recursion could have been avoided if the construction was carried over a prime field  $\mathbb{F}_p$  with  $p = \text{poly}(n)$ . That is, instead of outputting  $\gamma_t$ , output its reduction modulo  $p$ . To be precise, for the construction to work, one must take  $p \geq n$  due to other considerations. However, as long as  $p < n^e$  for some constant  $e$ , standard techniques can be used to obtain an asymptotically-good binary tree code, where the constant  $e$  will affect the rate of the resulted tree.

A very similar approach to this was raised by Pudlák [21]. On this, we quote a sentence from the conclusion part of [21]: “This seems to be a very difficult problem and we do not dare to conjecture that  $p$  may be of polynomial size”. At this point, Pudlák suggests studying restricted cases for which small fields suffice and try to base tree code constructions on such results, but we digress.

In consensus with Pudlák, we too believe that the approach of working over  $\mathbb{F}_p$  as suggested above is not likely to work. That is, it seems very plausible to us that the LGV Lemma does not have an analog over a field of size poly( $n$ ). More precisely, we suspect that for every constant  $e \geq 1$ , there exists  $n_0 = n_0(e)$  such that for every  $n \geq n_0$  and  $p \leq n^e$ , there exists a pair  $\mathbf{t}, \mathbf{c} \in [0, n]^s$ , for some  $s \in [n]$ , satisfying  $\mathbf{c} \leq \mathbf{t}$ , such that  $\det M_{\mathbf{t}, \mathbf{c}} \equiv_p 0$ .

To get some intuition as to why we believe this is the case, fix some prime  $p$  and  $s \in [n]$ . There are between  $\binom{n}{s}$  and  $\binom{n}{s}^2$  pairs of sequences  $\mathbf{t}, \mathbf{c}$  to consider. Unless some structure is present, one would expect that roughly  $\frac{1}{p}$ -fraction of pairs  $\mathbf{t}, \mathbf{c}$  would satisfy  $p \mid \det M_{\mathbf{t}, \mathbf{c}}$ .

By that heuristic, we do not expect that  $p$  can be taken much smaller than  $\binom{n}{s}$ . As we are interested in  $s$  that can be as large as  $\Omega(n)$ , this heuristic points against the existence of a “good” prime  $p = 2^{o(n)}$ , let alone  $p = \text{poly}(n)$ .

This heuristic is supported by a computational search that we carried. Let  $\mathcal{P}_1 : \mathbb{N} \rightarrow \mathbb{N}$  be the function that maps  $n \in \mathbb{N}$  to the least prime  $p$  that satisfies the following property. For every  $s \in [n]$  and strictly increasing sequences  $\mathbf{c} = (c_1, \dots, c_s), \mathbf{t} = (t_1, \dots, t_s) \in [0, n]^s$  with  $\mathbf{c} \leq \mathbf{t}$  it holds that  $\det M_{\mathbf{t}, \mathbf{c}} \not\equiv_p 0$ . Informally,  $\mathcal{P}_1$  maps  $n$  to the smallest prime  $p$  that is “good” for  $n$ . An exhaustive search we have conducted for hundreds of computer hours seems to suggest that  $\mathcal{P}_1(n)$  grows exponentially with  $n$ .

■ **Table 1** Values of  $\mathcal{P}_1(n)$  obtained using a computer search.

$n$	6	7	8	9	10	11	12	13	14	15	16
$\mathcal{P}_1(n)$	13	17	47	89	241	641	2,687	6,521	15,401	74,257	> 250,000

Since posting our preprint online, Karingula and Lovett [16] consider the non singularity of submatrices of triangular matrices modulo  $p$  in a different context. They too arrive at our conclusion, in fact, conjecturing a stronger claim ([16], Conjecture 1.5): for every triangular integer matrix, a fraction of the determinants (corresponding to index sequences  $\mathbf{t}, \mathbf{c}$ , as above) are likely to vanish modulo  $p$  unless the field size  $p$  grows exponentially.

### 3.2 A Conjecture

The informal heuristic presented above makes the point that no  $\text{poly}(n)$ -size prime is likely to work against all  $\exp(n)$  many pairs of sequences as we have no evidence for a structural phenomenon to support the seemingly unlikely alternative. The main contribution of this work is a tree code construction—a variant of [7]—whose distance analysis relies on what we believe is a plausible statement which we put forth as a conjecture. To formally state our conjecture some preparation is required.

As before, let  $\mathbf{c} = (c_1, \dots, c_s), \mathbf{t} = (t_1, \dots, t_s) \in [0, n]^s$  be a pair of strictly increasing sequences with  $\mathbf{c} \leq \mathbf{t}$ . For symbolic variables  $X_1, \dots, X_s$ , define the  $s \times s$  (symbolic) matrix  $M_{\mathbf{t}, \mathbf{c}}(X_1, \dots, X_s)$  whose  $(i, j)$ <sup>th</sup> entry is given by  $\binom{X_i + t_i}{c_j}$ . Define  $\Phi_{\mathbf{t}, \mathbf{c}}(X_1, \dots, X_s) \triangleq \det M_{\mathbf{t}, \mathbf{c}}(X_1, \dots, X_s) \in \mathbb{Z}[X_1, \dots, X_s]$ . For a prime  $p$ , let  $\Phi_{\mathbf{t}, \mathbf{c}}^p(X_1, \dots, X_s) \in \mathbb{F}_p[X_1, \dots, X_s]$  denote the reduction of  $\Phi_{\mathbf{t}, \mathbf{c}}$  at  $p$ . That is, every coefficient of  $\Phi_{\mathbf{t}, \mathbf{c}}$  is taken modulo  $p$  to form  $\Phi_{\mathbf{t}, \mathbf{c}}^p$ . With this notation, to ensure that the [7] tree code works over  $\mathbb{F}_p$ , one must establish that  $\Phi_{\mathbf{t}, \mathbf{c}}^p(0, \dots, 0) \neq 0$  for all  $\mathbf{t}, \mathbf{c}$  in question. Put differently, the [7] construction fails if for some pair  $\mathbf{t}, \mathbf{c}$  as above,  $\Phi_{\mathbf{t}, \mathbf{c}}^p$  evaluates to 0 at the origin. Our main contribution is an explicit construction which fails only if  $\Phi_{\mathbf{t}, \mathbf{c}}^p$  evaluates to 0 on the *entire* Boolean hypercube  $\{0, 1\}^s$ . Equivalently, our construction is asymptotically-good if

$$\exists(x_1, \dots, x_s) \in \{0, 1\}^s \quad \Phi_{\mathbf{t}, \mathbf{c}}(x_1, \dots, x_s) \not\equiv_p 0. \tag{3.1}$$

#### 3.2.1 Preliminary Informal Discussion on the Plausibility of Equation (3.1)

To start with, consider a very informal point of view on the plausibility of Equation (3.1), a discussion similar in spirit to the one conducted for arguing against the plausibility of taking the [7] construction over  $\mathbb{F}_p$ . Heuristically, and very informally, one may think of the  $2^s$  conditions in Equation (3.1) as  $2^s$  trials that are “generated by  $s$  independent

random variables”  $X_1, \dots, X_s$ . Unless some structural obstruction is in place, the “event” in Equation (3.1) is expected to have probability of about  $p^{-s}$ . Continuing this informal line of reasoning, by a union bound, one would expect that for a choice of  $p$  satisfying  $p^{-s} \binom{n}{s}^2 \ll \frac{1}{n}$ , Equation (3.1) holds for every pair  $\mathbf{t}, \mathbf{c} \in [0, n]^s$ , for every  $s \in [n]$ . The latter holds by taking  $p \gg n^3$ .

Another informal argument supporting the validity of Equation (3.1) is as follows. Note that  $\Phi_{\mathbf{t}, \mathbf{c}}$  has total degree  $d \leq sn \leq n^2$ . In fact, as we only care about  $\Phi_{\mathbf{t}, \mathbf{c}}$  restricted to  $\{0, 1\}^s$ , we may assume that  $\Phi_{\mathbf{t}, \mathbf{c}}$  is multi-linear and so  $d \leq s \leq n$ . One can show that for  $p > n$ ,  $\Phi_{\mathbf{t}, \mathbf{c}}^p$  is a nonzero polynomial; thus, by Schwartz-Zippel,  $\Phi_{\mathbf{t}, \mathbf{c}}^p$  has at most  $\frac{d}{p} \leq \frac{n}{p}$  fraction of roots in  $\mathbb{F}_p^s$ . By taking, say,  $p \geq n^2$ , the roots of  $\Phi_{\mathbf{t}, \mathbf{c}}$  occupy at most  $\frac{1}{\sqrt{p}}$ -fraction of  $\mathbb{F}_p^s$ . Now, for the heuristic part, one may conjecture that  $\{0, 1\}^s$  “looks random” to the zero set  $V_{\mathbf{t}, \mathbf{c}}$  of  $\Phi_{\mathbf{t}, \mathbf{c}}$ . As a weak consequence,  $\{0, 1\}^s$  is not contained in  $V_{\mathbf{t}, \mathbf{c}}$ , which is the content of Equation (3.1).

### 3.2.2 The Conjecture

There is one small technical issue we need to address before presenting our formal conjecture. Note that if  $t_{i+1} = t_i + 1$  for some  $i$  then  $\Phi_{\mathbf{t}, \mathbf{c}}(x_1, \dots, x_s) = 0$  whenever  $x_i = 1$  and  $x_{i+1} = 0$  for the simple reason that two of the rows of  $M_{\mathbf{t}, \mathbf{c}}(x_1, \dots, x_s)$  are identical. Informally, from the heuristic point of view discussed above, when  $t_{i+1} = t_i + 1$ , the events associated with the variables  $X_i, X_{i+1}$  are dependent. To exclude these trivial roots of  $\Phi_{\mathbf{t}, \mathbf{c}}(x_1, \dots, x_s)$  we assume in the conjecture (and guarantee in the construction) that  $\mathbf{t}, \mathbf{c}$  only have even entries. In Appendix A.1 we prove that, having done so,  $\Phi_{\mathbf{t}, \mathbf{c}}$  has no root in  $\{0, 1\}^s$ . That is, when considering  $\mathbf{t}, \mathbf{c}$  with even entries,  $\Phi_{\mathbf{t}, \mathbf{c}}(x_1, \dots, x_s) \neq 0$  for every  $(x_1, \dots, x_s) \in \{0, 1\}^s$ , and so it is only the reduction modulo  $p$  that may yield roots. With this, we are finally ready to state our conjecture.

► **Conjecture 4** (The Pascal determinant cubes (PDC) conjecture). *There exists a universal constant  $e_p \geq 1$  such that for every integer  $n \geq 1$  and prime  $p \geq n^{e_p}$  the following holds. For every  $s \in [n]$  and a pair of strictly increasing sequences  $\mathbf{t} = (t_1, \dots, t_s), \mathbf{c} = (c_1, \dots, c_s) \in ([0, n] \cap 2\mathbb{Z})^s$  satisfying  $\mathbf{c} \leq \mathbf{t}$ ,  $\exists (x_1, \dots, x_s) \in \{0, 1\}^s \quad \Phi_{\mathbf{t}, \mathbf{c}}^p(x_1, \dots, x_s) \neq 0$ .*

### 3.2.3 Experiments Supporting Conjecture 4

To support Conjecture 4 and, more fundamentally, to verify that there is no “structure” obstructing our heuristic arguments, we ran a computer search. Let  $\mathcal{P}_2 : \mathbb{N} \rightarrow \mathbb{N}$  be the function that maps  $n \in \mathbb{N}$  to the least prime  $p$  that satisfies the following property. For every  $s \in [n]$ , and every pair of strictly increasing sequences  $\mathbf{t} = (t_1, \dots, t_s), \mathbf{c} = (c_1, \dots, c_s) \in ([0, n] \cap 2\mathbb{Z})^s$  satisfying  $\mathbf{c} \leq \mathbf{t}$ , it holds that  $\Phi_{\mathbf{t}, \mathbf{c}}^p(x_1, \dots, x_s) \neq 0$  for some  $(x_1, \dots, x_s) \in \{0, 1\}^s$ . Informally,  $\mathcal{P}_2$  maps  $n$  to the least prime that is “good” for  $n$  in our conjecture. In comparison with  $\mathcal{P}_1$ , for every  $\mathbf{t}, \mathbf{c}$  in question,  $\mathcal{P}_1$  provides  $\Phi_{\mathbf{t}, \mathbf{c}}^p$  a single trial by evaluating it over the origin, while  $\mathcal{P}_2$  evaluates it over the entire Boolean hypercube of dimension  $s$ , and accepts the smallest prime that for every such  $\mathbf{t}, \mathbf{c}$ ,  $\Phi_{\mathbf{t}, \mathbf{c}}^p$  doesn’t vanish on at least one of its points.

An exhaustive search we have conducted, spanned over hundreds of computer hours, verifies at least for small numbers, that unlike  $\mathcal{P}_1(n)$ , the function  $\mathcal{P}_2(n)$  grows very slowly with  $n$ . In fact, the data collected in Table 2 shows that for  $7 \leq n \leq 30$ ,  $\mathcal{P}_2(n)$  equals the least prime number  $p \geq n - 1$ .<sup>1</sup>

<sup>1</sup> This is tight, namely, for every  $n \geq 7$ ,  $\mathcal{P}_2(n) \geq n - 1$ . Indeed, take  $p < n - 1$  a prime. If  $p \geq 5$ , consider

■ **Table 2** Values of  $\mathcal{P}_2(n)$  obtained using a computer search. Note that for an even  $n$ ,  $\mathcal{P}_2(n) = \mathcal{P}_2(n - 1)$  as  $\mathbf{t}, \mathbf{c}$  have even entries. Thus, only the data of odd  $n$ 's is collected.

$n$	5	7	9	11	13	15	17	19	21	23	25	27	29
$\mathcal{P}_2(n)$	3	7	11	11	13	17	17	19	23	23	29	29	29

We do not expect  $\mathcal{P}_2(n)$  to grow so slowly and we certainly do not expect it to have such a simple formula. While we could not compute  $\mathcal{P}_2(n)$  for  $n > 29$ , we were able to show that  $\mathcal{P}_2(127) > 131$  by eliminating the first two “potential” primes 127, 131. To see that, say,  $\mathcal{P}_2(127) \neq 131$  we invite the diligent reader to verify that  $\mathbf{c} = (0, 4, 10)$ ,  $\mathbf{t} = (64, 68, 74)$  yields a counterexample. That is,

$$\left| \begin{pmatrix} 64 + x_1 \\ 0 \\ 68 + x_2 \\ 0 \\ 74 + x_3 \\ 0 \end{pmatrix} \begin{pmatrix} 64 + x_1 \\ 4 \\ 68 + x_2 \\ 4 \\ 74 + x_3 \\ 4 \end{pmatrix} \begin{pmatrix} 64 + x_1 \\ 10 \\ 68 + x_2 \\ 10 \\ 74 + x_3 \\ 10 \end{pmatrix} \right| \equiv_{131} 0$$

for every  $(x_1, x_2, x_3) \in \{0, 1\}^3$ .

### 3.2.4 Asymptotic Version of Conjecture 4

For the informal heuristic argument used in Section 3.2.1 the point made is that while the number of “tests”  $(\mathbf{t}, \mathbf{c})$  grows exponentially with  $s$ , so does the number of “trials”  $(x_1, \dots, x_s)$ . Thus, when considering such a heuristic,  $s$  is thought of as an asymptotic parameter. However, Conjecture 4 is stated for every  $s \geq 1$ . While it may very well be the case that our conjecture holds as is, we prefer to base our construction on a more robust conjecture that avoids the possible “irregularities” that may be present for small values of  $s$ .

A natural relaxation is to bound  $s$  from below by some parameter  $s_0$  that is may even be allowed to grow with  $n$ . However, note that this should be done with some care. Indeed, if Conjecture 4 can be falsified for some value  $s$ , it is immediately false for larger values of  $s$ . To see this, take the counterexample  $\mathbf{c} = (c_1, \dots, c_s)$ ,  $\mathbf{t} = (t_1, \dots, t_s) \in [0, n]^s$  and consider  $\mathbf{c}' = (c_1, \dots, c_s, c_{s+1})$ ,  $\mathbf{t}' = (t_1, \dots, t_s, t_{s+1}) \in [0, n]^s$  where  $c_{s+1}, t_{s+1}$  are chosen so that  $t_s < c_{s+1} \leq t_{s+1}$ . Observe that this has the effect of “embedding”  $M_{\mathbf{t}, \mathbf{c}}(X_1, \dots, X_s)$  as the top-left sub matrix of  $M_{\mathbf{t}', \mathbf{c}'}(X_1, \dots, X_{s+1})$ . Furthermore, all but the lowest entry of the rightmost column are 0. In particular,

$$\Phi_{\mathbf{t}', \mathbf{c}'}(X_1, \dots, X_{s+1}) = \begin{pmatrix} t_{s+1} + X_{s+1} \\ c_{s+1} \end{pmatrix} \cdot \Phi_{\mathbf{t}, \mathbf{c}}(X_1, \dots, X_s).$$

Thus, if  $\Phi_{\mathbf{t}, \mathbf{c}}$  vanishes on  $\{0, 1\}^s$  then  $\Phi_{\mathbf{t}', \mathbf{c}'}$  vanishes on  $\{0, 1\}^{s+1}$ .

The “correct” way of formalizing a relaxation of Conjecture 4 in which only sufficiently large  $s$  are of interest is to restrict to pairs  $\mathbf{t}, \mathbf{c}$  for which not only  $s \geq s_0$  but also  $t_1 \geq c_{s_0}$ . Observe that under this condition, counterexamples of size less than  $s_0$  cannot be embedded as in the above discussion. We state below a variant of Conjecture 4 on which our candidate constructions rely. However, when discussing our conjecture we do not distinguish between Conjecture 4 and Conjecture 5 unless such a distinction is essential.

---

the sequences  $\mathbf{t} = (0, p + 1)$  and  $\mathbf{c} = (0, 4)$ . Note that  $\Phi_{\mathbf{t}, \mathbf{c}}^p(x_1, x_2) = \binom{p+1+x_2}{4}$ , and that  $p$  divides both  $\binom{p+1}{4}$  and  $\binom{p+2}{4}$ . For  $p = 2, 3$  one can use  $\mathbf{t} = (0, 2p)$ ,  $\mathbf{c} = (0, 2)$ . By Table 2, the assertion is false for  $n < 7$ .

► **Conjecture 5** (Asymptotic PDC conjecture). *There exist universal constants  $e_p, e_s \geq 1$  such that for every integer  $n \geq 1$  and prime  $p \geq n^{e_p}$  the following holds. For every  $s \geq s_0 \triangleq (\log n)^{e_s}$  and every pair of strictly increasing sequences  $\mathbf{t} = (t_1, \dots, t_s), \mathbf{c} = (c_1, \dots, c_s) \in ([0, n) \cap 2\mathbb{Z})^s$  satisfying  $\mathbf{t} \geq \mathbf{c}$  and  $t_1 \geq c_{s_0}$ , it holds that  $\exists (x_1, \dots, x_s) \in \{0, 1\}^s$   $\Phi_{\mathbf{t}, \mathbf{c}}^p(x_1, \dots, x_s) \neq 0$ .*

We will overcome this relaxation with the aid of the explicit tree code by Gelles *et al.* [12], which will provide some structure to the polynomials we need to analyze to prove the correctness of our construction.

### 3.2.5 Structural Factors of $\Phi_{\mathbf{t}, \mathbf{c}}$ and Its Linearization

Conjecture 4 only concerns with the evaluation of  $\Phi_{\mathbf{t}, \mathbf{c}}$  at the Boolean hypercube which, recall, we prove never vanishes in Appendix A.1. But, as defined,  $\Phi_{\mathbf{t}, \mathbf{c}}$  does not encode this in any way. In this section, we identify and remove certain factors of  $\Phi_{\mathbf{t}, \mathbf{c}}$  that are, in a sense, “outside” the Boolean hypercube, and so are of no interest to us.

For sequences  $\mathbf{t}, \mathbf{c}$  as in Conjecture 4, consider the matrix  $M_{\mathbf{t}, \mathbf{c}}(X_1, \dots, X_s)$ . Take distinct  $i, j \in [s]$  with  $i > j$ . The substitution  $X_i = X_j + t_j - t_i$  turns the  $i^{\text{th}}$  and  $j^{\text{th}}$  rows identical, resulting in an identically zero determinant. By Hilbert’s Nullstellensatz,  $X_i - X_j + t_i - t_j$  divides  $\Phi_{\mathbf{t}, \mathbf{c}}(X_1, \dots, X_s)$  in  $\mathbb{Q}[X_1, \dots, X_s]$ . Therefore the determinant polynomial is of the form

$$\Phi_{\mathbf{t}, \mathbf{c}}(X_1, \dots, X_s) = \Xi_{\mathbf{t}, \mathbf{c}}(X_1, \dots, X_s) \cdot \prod_{i>j} (X_i - X_j + t_i - t_j)$$

for some polynomial  $\Xi_{\mathbf{t}, \mathbf{c}}[X_1, \dots, X_s] \in \mathbb{Q}[X_1, \dots, X_s]$ . In fact, by Gauss’s lemma for GCD domains,  $\Xi_{\mathbf{t}, \mathbf{c}}[X_1, \dots, X_s]$  is in  $\mathbb{Z}[X_1, \dots, X_s]$  since  $\Phi_{\mathbf{t}, \mathbf{c}}$  and the structural factor are both primitive. Thus, we can consider reduction modulo a prime  $p$ . Since  $t_i, t_j$  are distinct even numbers in  $[0, n)$ , the structural factors do not vanish at any point of the Boolean hypercube, even when reduced modulo a prime  $p > n$ . Therefore, studying the zeros of  $\Phi_{\mathbf{t}, \mathbf{c}}^p$  in the Boolean hypercube is equivalent to studying those of  $\Xi_{\mathbf{t}, \mathbf{c}}$ , even modulo a prime  $p > n$ .

Observe that the linearization of the univariate polynomial  $\binom{X+t}{c}$ , for  $c \geq 1$  takes the nice form  $\binom{X+t}{c} = \binom{t}{c-1}X + \binom{t}{c}$  as can be seen using Pascal’s identity. In Appendix A.2 we take these ideas a step further and obtain a reformulation of Conjecture 4 which, informally, states that a certain polynomial  $\Psi_{\mathbf{t}, \mathbf{c}}^p$  is nonzero (as an element of the ring  $\mathbb{F}_p[X_1, \dots, X_s]$ ). That is to say, while the [7] tree code fails over  $\mathbb{F}_p$  if a certain polynomial has a root at the origin, via its reformulation, Conjecture 4 is false only if a certain polynomial is the zero polynomial. An asymptotic version, equivalent to Conjecture 5 is immediate.

In Appendix B we suggest a stronger variant of Conjecture 4 and further study the plausibility of Conjecture 4 and its stronger variant based on deep results in arithmetic geometry. In particular, we reason about the distribution of values attain by  $\Phi_{\mathbf{t}, \mathbf{c}}$  on the Boolean hypercube by considering the exponential sum  $\sum_{(x_1, \dots, x_s) \in \{0, 1\}^s} \zeta_p^{\Phi_{\mathbf{t}, \mathbf{c}}(x_1, \dots, x_s)}$ , where  $\zeta_p$  is a  $p^{\text{th}}$  root of unity in  $\mathbb{C}$ , and collect computational data that appear in a longer version of the paper [3]. However, we wrap up this preliminary discussion on our conjecture and its variants. In the next section we go back to the problem of constructing tree codes, and give an informal presentation of our construction and its analysis, based on Conjecture 4 or, more precisely, based on the asymptotic variant, Conjecture 5.

### 3.3 The Candidate Tree Code

Our candidate construction is a variant of the construction discussed in Section 2. In fact, for obtaining distance larger than  $\frac{1}{2}$ , [7] modified their original construction so that at time  $t$ , not one but some  $r \geq 1$  number of evaluations of the “current” polynomial  $f_t$  is recorded. This enabled them to achieve distance  $1 - \frac{1}{r+1}$ . Our candidate construction is closely related to that variant. We make use of this idea of multiple evaluations not for improving the distance, but rather for relaxing the analysis so that it is plausible that the reduction modulo a small prime  $p$  yields non-vanishing distance and, in particular, follows by Conjecture 5.

Recall, however, that Conjecture 5 holds only for pairs of length  $s \geq s_0$  for which  $t_1 \geq c_{s_0}$ . Therefore, we need to introduce some mechanism to the construction so that its correctness does not rely on the behaviour when applied with small values of  $s$  (nor on invalid pairs). To this end, we make use of an explicit tree code construction by [12]. For every  $n \geq 1$ , an explicit tree code  $\text{TC}' : [n^2]^n \rightarrow [2n^2]^n$  having distance  $\frac{1}{\log n}$  is given (see Corollary 11 for a precise statement). Although  $\text{TC}'$  has a vanishing distance, it suffices for our needs as we will not use  $\text{TC}'$  directly for arguing about the distance; rather, we invoke  $\text{TC}'$  to guarantee some structure on the polynomials we need to analyze.

Take  $p > 2n^2$  a prime, and think of  $\text{TC}' : [n^2]^n \rightarrow \mathbb{F}_p^n$  in the natural way. Our construction proceeds as follows. Given  $m = (m_0, m_1, \dots, m_{n-1}) \in [n^2]^n$  we first apply  $\text{TC}'$  to obtain  $(\gamma_0, \gamma_2, \gamma_4, \dots, \gamma_{2(n-1)}) = \text{TC}'(m)$ . For  $t \in [0, n)$ , we define  $f_t(T) \in \mathbb{F}_p[T]$  by  $f_t(T) = \sum_{i=0}^t \gamma_{2i} \binom{T}{2i}$ . At time  $t \in [0, n)$ , our tree code  $\text{TC} : [n^2]^n \rightarrow (\mathbb{F}_p^3)^n$  outputs  $\text{TC}(m)_t = (\gamma_{2t}, f_t(2t), f_t(2t+1))$ . As mentioned, as the alphabet is of size  $\text{poly}(n)$ , standard techniques can then be used to obtain an explicit binary tree code with comparable parameters. We thus have,

► **Theorem 6.** *Assume that Conjecture 5 holds with parameters  $e_p, e_s$ . Then, there exist  $c = c(e_p, e_s) \in \mathbb{N}$  and  $\delta = \delta(e_p, e_s) \in (0, 1)$  such that the following holds. For every  $n \in \mathbb{N}$  there exists an explicit tree code  $\text{TC} : \{0, 1\}^n \rightarrow [c]^n$  with distance  $\delta$ .*

#### 3.3.1 Sketch of the Analysis

As for the analysis, consider distinct  $m = (m_0, m_1, \dots, m_{n-1})$ ,  $m' = (m'_0, m'_1, \dots, m'_{n-1})$ , and let  $c \in [0, n)$  be the least integer for which  $m_c \neq m'_c$ . By the property of  $\text{TC}'$  we get that for every  $\ell \in [0, n - c)$ , when restricted to  $[c, c + \ell]$ , the strings  $\gamma = \text{TC}'(m)$ ,  $\gamma' = \text{TC}'(m')$  are of distance  $s \geq \frac{\ell}{\log n}$ . In particular, when considering  $\ell \geq (\log n)^e$  for some constant  $e > 1$ , we have that  $s \geq (\log n)^{e-1}$ . Let us assume this bound on  $\ell$  for the moment. Observe now that, by construction,  $s$  is precisely the sparsity of the polynomial  $g(T) = f_{c+\ell}(T) - f'_{c+\ell}(T)$  with respect to the Newton basis. Thus, we can write  $g(T) = \sum_{j=1}^s \gamma''_{2c_j} \binom{T}{2c_j}$ , where  $c = c_1 < c_2 < \dots < c_s \leq c + \ell < n$  and  $\gamma''_{2c_j} = \gamma_{2c_j} - \gamma'_{2c_j}$ .

We wish to bound the number of integers  $t \in [c, c + \ell]$  for which  $g(2t) = g(2t+1) = 0$  as indeed for every such  $t$ ,  $\text{TC}(m)_t$  and  $\text{TC}(m')_t$  agree when projected to the last two entries of the triplet. To get a bound of  $b$  on such indices  $t$ , the natural approach is to assume the existence of some  $t_1 < t_2 < \dots < t_b$  in  $[c, c + \ell]$  with  $g(2t_i) = g(2t_i + 1) = 0$  for every  $i \in [b]$ , and try to get a contradiction via Conjecture 5 for a sufficiently large value  $b$ . Recall, however, that for the conjecture it is required that  $\mathbf{t} \geq \mathbf{c}$  which is not necessarily the case. In [7] this technical issue is resolved by observing that one can restrict to the longest prefixes  $(c_1, c_2, \dots, c_{s_1})$ ,  $(t_1, t_2, \dots, t_{s_1})$  of the original sequences for which  $c_i \leq t_i$  for every  $i \in [s_1]$ . Such  $s_1$  exists as  $c_1 \leq t_1$ .

Our analysis is somewhat trickier as we can only invoke Conjecture 5 starting from some  $s_0$  (and under some restriction on the pair). In particular, in the notation of Conjecture 5, we have  $s_0 = (\log(2n))^{e_s}$ , and it may very well be the case that the longest prefix length

## 54:12 Candidate Tree Codes via Pascal Determinant Cubes

$s_1 < s_0$ . To overcome this, and to satisfy the hypothesis of Conjecture 5, we first prove a bound of  $s$  on the number of  $t_i$ 's in  $[c_{s_0}, c + \ell]$  rather than in  $[c, c + \ell]$ . This can be done based on Conjecture 5 using a similar argument to that of [7] who invoke the LGV Lemma.

To bound the number of the remaining  $t_i$ 's, namely, those in  $[c, c_{s_0}]$  we bound the length of this interval. Had  $c_1, \dots, c_{s_0}$  been arbitrary, the interval's length could have been unbounded. However, recall that by construction,  $c_1, \dots, c_{s_0}$  are the indices in  $[c, c_{s_0}]$  for which  $\text{TC}'(m), \text{TC}'(m')$  disagree. Since  $\text{TC}'$  has distance  $\frac{1}{\log n}$  it follows that  $s_0 \geq \frac{c_{s_0} - c}{\log n}$ , and so the interval's length is bounded by  $c_{s_0} - c \leq s_0 \log n \leq (\log(2n))^{e_s+1}$ . Hence, the total number of  $t_i$ 's is bounded by  $s + (\log(2n))^{e_s+1}$ , and so the distance between  $\text{TC}(m)$  and  $\text{TC}(m')$  when restricted to  $[c, c + \ell]$  is at least  $\max(s, \ell - (s + (\log(2n))^{e_s+1}))$ . By taking  $\ell$  sufficiently large, the latter approaches  $\frac{\ell}{3}$ .

In the discussion above, we assumed  $\ell$  is sufficiently large. In particular,  $\ell > \ell_0 = (\log n)^e$  for some constant  $e$ . To resolve this "lag", namely, to handle also smaller values of  $\ell$ , we use a standard technique in which an explicit tree code of length  $O(\ell_0)$  is concatenated with the construction above.

### 4 Preliminaries

Let  $n \geq 1$  be an integer and  $\Sigma$  some (finite or infinite) set. For a string  $x = (x_1, \dots, x_n) \in \Sigma^n$  and integers  $1 \leq a \leq b \leq n$ , we let  $x_{[a,b]}$  denote the substring  $(x_a, \dots, x_b)$ . Given  $x, y \in \Sigma^n$ , we write  $\text{dist}(x, y)$  for their Hamming distance. For an integer  $n \geq 1$  write  $[n]$  for  $\{1, 2, \dots, n\}$ . For integers  $a < b$  we denote  $[a, b) = \{a, a + 1, \dots, b - 1\}$ . We use the conventions that the natural numbers are  $\mathbb{N} = \{0, 1, 2, \dots\}$ , and that  $\binom{a}{b} = 0$  for integers  $0 \leq a < b$ .

Tree codes, as their name suggest, are trees with certain distance properties. However, as discussed in Section 2, we use an equivalent definition of tree codes that more explicitly specifies their online characteristic. Recall that a function  $f: \Sigma_{\text{in}}^n \rightarrow \Sigma_{\text{out}}^n$  is said to be *online* if for every  $i \in [n]$  and  $x \in \Sigma_{\text{in}}^n$ ,  $f(x)_i$  is determined by  $x_1, \dots, x_i$ . For a pair of distinct  $x, y \in \Sigma^n$ , we define  $\text{split}(x, y)$  as the least integer  $s \in [n]$  such that  $x_s \neq y_s$ .

► **Definition 7** ([23]). *An online function  $\text{TC}: \Sigma_{\text{in}}^n \rightarrow \Sigma_{\text{out}}^n$  is a tree code with distance  $\delta$  if for every distinct  $x, y \in \Sigma_{\text{in}}^n$ , with  $s = \text{split}(x, y)$ , and every  $\ell \in [0, n - s)$ ,*

$$\text{dist}(\text{TC}(x)_{[s, s+\ell]}, \text{TC}(y)_{[s, s+\ell]}) \geq \delta(\ell + 1).$$

*We refer to  $n$  as the depth of  $\text{TC}$ . We refer to  $\Sigma_{\text{in}}, \Sigma_{\text{out}}$  as the input alphabet and output alphabet, respectively.*

We are interested in some further properties of tree codes.

► **Definition 8.** *Let  $\text{TC}: \Sigma_{\text{in}}^n \rightarrow \Sigma_{\text{out}}^n$  be a tree code.*

- *We say that  $\text{TC}$  is a binary tree code if  $\Sigma_{\text{in}} = \{0, 1\}$ .*
- *We say that  $\text{TC}$  is explicit if it can be evaluated on every input  $m \in \Sigma_{\text{in}}^n$  in polynomial time in the bit complexity of  $m$ .*

### 5 Proof of Theorem 6

In this section we present our candidate tree code and prove Theorem 6. Our construction is obtained in several steps, where the main part is to construct a relaxation of tree codes, called a lagged tree code. Informally, this is a tree code whose distance property holds only after a certain time interval.

► **Definition 9** ([7]). *An online function  $\text{TC} : \Sigma_{\text{in}}^n \rightarrow \Sigma_{\text{out}}^n$  is a lagged tree code with lag  $\ell_0$  and distance  $\delta$  if for every distinct  $x, y \in \Sigma_{\text{in}}^n$ , with  $s = \text{split}(x, y)$ , and every  $\ell \in [\ell_0, n - s]$ ,*

$$\text{dist}(\text{TC}(x)_{[s, s+\ell]}, \text{TC}(y)_{[s, s+\ell]}) \geq \delta(\ell + 1).$$

Note that a tree code is a lagged tree code with lag parameter  $\ell_0 = 0$ . It is straightforward to transform any lag- $\ell_0$  tree code to a tree code using a second tree code of length  $O(\ell_0)$ . Our construction of lagged tree codes, given below by Proposition 12, has lag  $\ell_0 = \text{poly}(\log n)$ . A result by Braverman [6] provides, for every constant  $\varepsilon \in (0, 1)$  and integer  $m$  an asymptotically-good tree code of length  $m$  in time  $2^{O(m^\varepsilon)}$ . Thus, asymptotically-good tree codes of length  $\ell_0$  can be obtained in time  $\text{poly}(n)$ . The obtained tree code (as well as the lagged tree code that is given by Proposition 12) is over a  $\text{poly}(n)$ -size alphabet. It is well-known how to reduce the alphabet to binary, obtaining tree codes with comparable parameters (see, e.g., [21], Proposition 3.1).

In light of the discussion above, we turn to present our candidate construction of  $\text{poly}(\log n)$ -lagged tree codes over  $\text{poly}(n)$ -size alphabet. Our construction makes use of a tree code construction by [12].

► **Lemma 10** (Lemma 5.1 in [12]). *There exists an absolute constant  $k_0 \in \mathbb{N}$  such that the following hold for every  $\varepsilon > 0$  and integers  $k, n \in \mathbb{N}$  such that  $\frac{k_0 \cdot \log n}{\varepsilon} \leq k \leq n$ . There exists an explicit tree code  $C : \Sigma_{\text{in}}^k \rightarrow \Sigma_{\text{out}}^k$  with  $\Sigma_{\text{in}} = \{0, 1\}^{\frac{\log n}{\varepsilon}}$ ,  $\Sigma_{\text{out}} = \{0, 1\}^{\frac{\log n}{\varepsilon} + 1}$ , rate  $\rho' = \frac{1}{1 + \varepsilon / \log n}$  and relative distance at least  $\delta' = \frac{1}{1 + 2 \log(n) / \varepsilon}$ .*

The following is a straightforward corollary of Lemma 10 obtained by taking  $\varepsilon = \frac{1}{2}$ . Note that the factors of 4 and 8 in the alphabet size of  $\text{TC}'$  in Corollary 11 are for obtaining a tree code for every  $n$ , not just a power of two as in Lemma 10.

► **Corollary 11.** *There exists a universal constant  $n_0 \geq 1$  such that for every integer  $n \geq n_0$  there exists an explicit tree code  $\text{TC}' : [4n^2]^n \rightarrow [8n^2]^n$  with distance  $\delta = \frac{1}{5 \log n}$ .*

Given an integer  $n \geq n_0$  we proceed as follows. Let  $p$  be the least prime number larger than  $\max(8n^2, (2n)^{e_p})$ , where  $e_p$  is the constant from Conjecture 5. By Corollary 11, there exists an explicit tree code  $\text{TC}' : [4n^2]^n \rightarrow [8n^2]^n$  with distance  $\frac{1}{5 \log n}$ . As  $p > 8n^2$  we can embed the output symbols of  $\text{TC}'$  in  $\mathbb{F}_p$  by identifying them with the field elements  $1, \dots, 8n^2$  of  $\mathbb{F}_p$ . Hence, we may think of  $\text{TC}'$  as a function of the form  $\text{TC}' : [4n^2]^n \rightarrow \mathbb{F}_p^n$ .

Define the function  $\text{TC} : [4n^2]^n \rightarrow (\mathbb{F}_p^3)^n$  as follows. Let  $m = (m_0, m_1, \dots, m_{n-1}) \in [4n^2]^n$ . Compute  $\text{TC}'(m) = (\gamma_0, \gamma_2, \gamma_4, \dots, \gamma_{2(n-1)}) \in \mathbb{F}_p^n$ . For  $t = 0, 1, \dots, n-1$  define the polynomial  $f_t(T) \in \mathbb{F}_p[T]$  by

$$f_t(T) = \sum_{i=0}^t \gamma_{2i} \binom{T}{2i}. \tag{5.1}$$

Finally, for  $t = 0, 1, \dots, n-1$ , define

$$\text{TC}(m)_t = (\gamma_{2t}, f_t(2t), f_t(2t+1)). \tag{5.2}$$

► **Proposition 12.** *Assume that Conjecture 5 holds with parameters  $e_p, e_s$ . Then,  $\text{TC}$  as defined in Equation (5.2) is an  $\ell_0$ -lagged tree code, where  $\ell_0 = 15(\log(2n))^{e_s+1}$ , having distance  $\frac{1}{3}$  and rate at least  $\frac{1}{2 \max(2, e_p)}$ .*

**Proof.** That the rate is bounded below by  $\frac{1}{2 \max(2, e_p)}$  is a straightforward calculation. We turn to analyze the distance. Note that  $\text{TC}$  is not linear and so, for the distance analysis, we consider two distinct messages. Let  $m = (m_0, \dots, m_{n-1}) \in [4n^2]^n$  and  $m' = (m'_0, \dots, m'_{n-1}) \in [4n^2]^n$

## 54:14 Candidate Tree Codes via Pascal Determinant Cubes

distinct. Let  $0 \leq c \leq n-1$  be the least integer for which  $m_c \neq m'_c$ , and let  $\ell \in [\ell_0, n-c)$ . Denote

$$\begin{aligned}\gamma &= (\gamma_0, \gamma_2, \dots, \gamma_{2(n-1)}) = \text{TC}'(m), \\ \gamma' &= (\gamma'_0, \gamma'_2, \dots, \gamma'_{2(n-1)}) = \text{TC}'(m').\end{aligned}$$

Since  $\text{TC}'$  has distance  $\frac{1}{5 \log n}$  it holds that

$$\begin{aligned}s &\triangleq \text{dist} \left( \gamma_{[c, c+\ell]}, \gamma'_{[c, c+\ell]} \right) \\ &= \text{dist} \left( (\gamma_{2c}, \gamma_{2(c+1)}, \dots, \gamma_{2(c+\ell)}), (\gamma'_{2c}, \gamma'_{2(c+1)}, \dots, \gamma'_{2(c+\ell)}) \right) \\ &\geq \frac{\ell+1}{5 \log n}.\end{aligned}$$

As  $\ell \geq \ell_0$  we have that  $s > s_0$ , where  $s_0 \triangleq (\log(2n))^{e_s}$ . Similarly to Equation (5.1), we define for  $t = 0, 1, \dots, n-1$  the polynomial  $f'_t(T) \in \mathbb{F}_p[T]$  by

$$f'_t(T) = \sum_{i=0}^t \gamma'_{2i} \binom{T}{2i}.$$

Observe that  $s$  is precisely the sparsity of  $f_{c+\ell}(T) - f'_{c+\ell}(T)$  with respect to the Newton basis. Let  $c \leq c_1 < c_2 < \dots < c_s \leq c+\ell$  be all the integers such that  $\gamma_{2c_j} \neq \gamma'_{2c_j}$  for every  $j \in [s]$ . As  $\text{TC}'$  is a tree code (with nonzero distance)  $\gamma_{2c} = \text{TC}'(m)_c \neq \text{TC}'(m')_c = \gamma'_{2c}$ , and so  $c_1 = c$ . By denoting  $\gamma''_i = \gamma_i - \gamma'_i$ , one can write the polynomial  $f_{c+\ell}(T) - f'_{c+\ell}(T)$  as

$$g(T) = \sum_{j=1}^s \gamma''_{2c_j} \binom{T}{2c_j}.$$

Define  $Z = \{t \in [c, c+\ell] \mid g(2t) = g(2t+1) = 0\}$ .

▷ **Claim 13.** Assuming Conjecture 5,  $|Z \cap [c_{s_0}, c+\ell]| < s$ .

*Proof.* Assume by way of contradiction that there are distinct integers  $t_1, \dots, t_s \in [c_{s_0}, c+\ell]$  such that

$$\forall i \in [s] \quad g(2t_i) = g(2t_i+1) = 0. \quad (5.3)$$

Assume further that  $t_1 < \dots < t_s$ . Let  $s_1 \in \{s_0, s_0+1, \dots, s\}$  be the largest integer with the property that for every  $i \in \{s_0, s_0+1, \dots, s_1\}$ ,  $t_i \geq c_i$ . Note that  $s_1$  is well-defined as  $t_{s_0} \geq c_{s_0}$  (and so the maximum is taken over a non-empty, finite, set). Let  $M(X_1, \dots, X_{s_1})$  be the  $s_1 \times s_1$  matrix whose  $(i, j)^{\text{th}}$  entry is

$$M_{i,j}(X_1, \dots, X_{s_1}) = \begin{pmatrix} X_i + 2t_i \\ 2c_j \end{pmatrix},$$

where  $X_1, \dots, X_{s_1}$  are formal variables. Let  $\Phi \in \mathbb{F}_p[X_1, \dots, X_{s_1}]$  be the polynomial that is given by  $\Phi(X_1, \dots, X_{s_1}) = \det M(X_1, \dots, X_{s_1})$ . Denote  $\mathbf{t} = (2t_1, \dots, 2t_{s_1})$  and  $\mathbf{c} = (2c_1, \dots, 2c_{s_1})$ . Note that  $\Phi$  as defined above is precisely  $\Phi_{\mathbf{t}, \mathbf{c}}^p$  in the notation of Conjecture 5. Clearly,  $\mathbf{t}, \mathbf{c} \in ([0, 2n) \cap 2\mathbb{Z})^{s_1}$ . We turn to show that  $\mathbf{c} \leq \mathbf{t}$ . Indeed, for  $i \in \{s_0, s_0+1, \dots, s_1\}$  we have that  $t_i \geq c_i$  by the definition of  $s_1$ . Moreover, recall that for every  $i \in [s]$ ,  $t_i \geq c_{s_0}$ , and so, for  $i < s_0$  we have that  $t_i \geq c_{s_0} > c_i$ . Recall that  $p \geq (2n)^{e_p}$ ,  $s_1 \geq s_0 = (\log(2n))^{e_s}$ , and  $2t_1 \geq 2c_{s_0}$ . Thus, the hypothesis of Conjecture 5 is met with  $s, n$  in the notation

the conjecture taken to be  $s_1$  and  $2n$  in our notation, respectively. Therefore, assuming the validity of Conjecture 5 we conclude the existence of  $(x_1, \dots, x_{s_1}) \in \{0, 1\}^{s_1}$  such that  $\Phi(x_1, \dots, x_{s_1}) \neq 0$  in  $\mathbb{F}_p$ .

We now use  $(x_1, \dots, x_{s_1})$  to get a contradiction. Let  $\Gamma \in \mathbb{F}_p^{s_1}$  be the vector with  $i^{\text{th}}$  entry  $\Gamma_i = \gamma''_{2c_i}$ . Observe that  $\Gamma$  is a nonzero vector. To see this, consider its first entry  $\Gamma_1 = \gamma''_{2c_1} = \gamma'_{2c}$ . Recall that  $\gamma''_{2c} = \gamma_{2c} - \gamma'_{2c}$ . As  $\text{TC}'$  is a tree code (with distance larger than 0) and since  $m_c \neq m'_c$  we have that  $\gamma_{2c} = \text{TC}'(m)_c \neq \text{TC}'(m')_c = \gamma'_{2c}$ . Thus,  $\Gamma_1 \neq 0$ .

Since  $\Phi(x_1, \dots, x_{s_1}) \neq 0$  we have that  $M(x_1, \dots, x_{s_1})$  is nonsingular, and therefore  $M(x_1, \dots, x_{s_1})\Gamma$  is a nonzero vector. Let then  $i \in [s_1]$  be such that  $(M(x_1, \dots, x_{s_1})\Gamma)_i \neq 0$ . Note that

$$(M(x_1, \dots, x_{s_1})\Gamma)_i = \sum_{j=1}^{s_1} \gamma''_{2c_j} \binom{x_i + 2t_i}{2c_j}. \quad (5.4)$$

Assume for the moment that  $s_1 < s$ . As  $i \leq s_1$  we have that  $i < s$  and so we may refer to  $t_{i+1}$ . As  $x_i \in \{0, 1\}$ , we have that  $2t_i + x_i \leq 2t_i + 1 < 2t_{i+1}$ . Hence, as  $i \leq s_1$ ,  $2t_i + x_i < 2t_{s_1+1}$ . By the definition of  $s_1$  we have that  $t_{s_1+1} < c_{s_1+1}$ , and so  $2t_i + x_i < 2c_{s_1+1}$ . Hence,  $\binom{x_i + 2t_i}{2c_j} = 0$  for all  $j \in \{s_1 + 1, \dots, s\}$ . Thus,

$$\sum_{j=1}^{s_1} \gamma''_{2c_j} \binom{x_i + 2t_i}{2c_j} = \sum_{j=1}^s \gamma''_{2c_j} \binom{x_i + 2t_i}{2c_j} = g(2t_i + x_i). \quad (5.5)$$

Equation (5.5) trivially follows also when  $s_1 = s$ , and so it holds in general, namely, without any assumption on  $s_1$ . Equations (5.4) and (5.5) together imply that

$$g(2t_i + x_i) = (M(x_1, \dots, x_{s_1})\Gamma)_i \neq 0$$

which, as  $x_i \in \{0, 1\}$ , stands in contradiction to Equation (5.3), and thus proving the claim.  $\triangleleft$

$\triangleright$  **Claim 14.**  $|Z| \leq s + 5(\log(2n))^{e_s+1}$ .

*Proof.* As  $\text{TC}'$  is a tree code with distance  $\frac{1}{5 \log n}$ , we have that

$$\begin{aligned} s_0 &= \text{dist} \left( (\gamma_{2c_1}, \gamma_{2(c_1+1)}, \dots, \gamma_{2c_{s_0}}), (\gamma'_{2c_1}, \gamma'_{2(c_1+1)}, \dots, \gamma'_{2c_{s_0}}) \right) \\ &= \text{dist} \left( \text{TC}'(m)_{[c_1, c_{s_0}]}, \text{TC}'(m')_{[c_1, c_{s_0}]} \right) \\ &\geq \frac{c_{s_0} - c_1 + 1}{5 \log n} \\ &\geq \frac{c_{s_0} - c}{5 \log n}. \end{aligned}$$

Now,  $s_0 = (\log(2n))^{e_s}$ , and so

$$c_{s_0} - c \leq 5(\log n)(\log(2n))^{e_s} \leq 5(\log(2n))^{e_s+1}.$$

This, together with Claim 13, implies that

$$\begin{aligned} |Z| &\leq (c_{s_0} - c) + |Z \cap [c_{s_0}, c + \ell]| \\ &\leq s + 5(\log(2n))^{e_s+1}. \end{aligned} \quad \triangleleft$$

$\triangleright$  **Claim 15.** For every  $t \in [c, c + \ell]$  and  $x \in \{0, 1\}$ ,

$$g(2t + x) = f_t(2t + x) - f'_t(2t + x).$$

## 54:16 Candidate Tree Codes via Pascal Determinant Cubes

Proof. Recall that  $c_1, \dots, c_s$  are precisely the indices in  $[c, c + \ell]$  for which  $\gamma$  and  $\gamma'$  disagree. More precisely, for  $i \in [c, c + \ell]$ ,  $\gamma_{2i} \neq \gamma'_{2i}$  if and only if  $i \in \{c_1, \dots, c_s\}$ . Hence, for every  $t \in [c, c + \ell]$  and  $x \in \{0, 1\}$ ,

$$\begin{aligned} f_t(2t+x) - f'_t(2t+x) &= \sum_{i=0}^t (\gamma_{2i} - \gamma'_{2i}) \binom{2t+x}{2i} \\ &= \sum_{\substack{j \in [s] \\ c_j \leq t}} \gamma''_{2c_j} \binom{2t+x}{2c_j} \\ &= \sum_{j=1}^s \gamma''_{2c_j} \binom{2t+x}{2c_j} \\ &= g(2t+x), \end{aligned}$$

where the penultimate equality follows since  $\binom{2t+x}{2c_j} = 0$  for every  $j \in [s]$  for which  $c_j > t$ . Indeed, if  $c_j > t$  then  $2c_j \geq 2t + 2$  and so  $\binom{2t}{2c_j} = \binom{2t+1}{2c_j} = 0$ .  $\triangleleft$

By Claim 15,  $t \in Z$  if and only if the last two entries of  $\text{TC}(m)_t$ , namely,  $f_t(2t), f_t(2t+1)$ , agree with the corresponding entries,  $f'_t(2t), f'_t(2t+1)$ , of  $\text{TC}(m')_t$ . As the third entry of  $\text{TC}(m)$  and  $\text{TC}(m')$ , when restricted to  $[c, c + \ell]$ , disagree on exactly  $s$  indices, we have that the number of indices  $t \in [c, c + \ell]$  for which  $\text{TC}(m)_t \neq \text{TC}(m')_t$  (as a triplet) is bounded below by

$$\begin{aligned} \max(s, \ell + 1 - |Z|) &\geq \max(s, \ell + 1 - s - 5(\log(2n))^{e_s+1}) \\ &\geq \frac{\ell - 5(\log(2n))^{e_s+1} + 1}{2} \\ &\geq \frac{\ell + 1}{3}, \end{aligned}$$

where the last inequality follows since  $\ell \geq \ell_0 = 15(\log(2n))^{e_s+1}$ .  $\blacktriangleleft$

## A Combinatorics Corroborating Conjecture 4

### A.1 Non-Vanishing of $\Phi_{t,c}$ on the Boolean Hypercube

In this section we prove that the integer polynomial  $\Phi_{t,c}$  as in Conjecture 4 does not vanish on any point of the Boolean hypercube. To this end, we make use of ideas similar to those used by [7] to prove that  $\Phi_{t,c}$  has no root at the origin. Fix sequences  $t, c$  as in Conjecture 4 for the remainder of this section. Consider a directed acyclic graph  $G = (V, E)$  with edge weights  $\{w(e) \mid e \in E\}$  coming from a commutative ring with identity, along with two ordered vertex sets  $\mathcal{R} = \{R_1, R_2, \dots, R_d\}, \mathcal{C} = \{C_1, C_2, \dots, C_d\} \subseteq V$  of the same cardinality  $d$ . Associated to it is the path matrix  $M$ : the square matrix indexed by  $R, C$  with the  $R \in \mathcal{R}, C \in \mathcal{C}$  entry  $M_{R,C} \triangleq \prod_{P: R \rightarrow C} w(P)$  where the product is taken over all paths  $P$  from  $R$  to  $C$  and the weight  $w(P)$  is the product of edge weights in the path  $P$ . Paths of length 0 are included and given the weight 1. A path system  $\mathcal{P}$  from  $\mathcal{R}$  to  $\mathcal{C}$  consists of a permutation  $\sigma \in S_d$  and a set of paths  $\{P_i : R_i \rightarrow C_{\sigma(i)} \mid i \in [d]\}$ . Let  $\text{sgn}(\mathcal{P})$  denote the sign of  $\sigma$  and  $w(\mathcal{P})$  denote the product of the weights  $\prod_{i=1}^d w(P_i)$ . The path system is called vertex disjoint if its set of paths are vertex disjoint. The LGV Lemma is the expression for the determinant of the path matrix  $M$  in terms of the underlying path graph

$$\det(M) = \sum_{\substack{\text{vertex disjoint} \\ \text{path systems } \mathcal{P}}} \text{sgn}(\mathcal{P})w(\mathcal{P}).$$

Gessel and Viennot applied it to path graphs cut out from the square lattice and proved the non vanishing theorem for determinants of Pascal submatrices. We next show a non vanishing of determinants central to our construction using the same path graph but with vertices relabelled.

► **Lemma 16.** For all strictly increasing non negative integer sequences  $\mathbf{c} = (c_1, \dots, c_s), \mathbf{t} = (t_1, \dots, t_s)$  such that  $\mathbf{c} \leq \mathbf{t}$  and  $t_i$  is even for all  $i \in [s]$ , and  $\forall (x_1, x_2, \dots, x_s) \in \{0, 1\}^s$ ,

$$\Phi_{\mathbf{t}, \mathbf{c}}(x_1, \dots, x_s) \neq 0.$$

**Proof.** Fix numbers  $c_1, \dots, c_s, t_1, \dots, t_s, x_1, \dots, x_s$  as in the statement. Consider the directed acyclic graph below with unit edge weights and distinguished (in red) vertex subsets  $\{R_1, R_2, \dots, R_s\}$  and  $\{C_1, C_2, \dots, C_s\}$ . The  $(t_1 + x_1)^{th}$  vertex on the first column is labelled  $R_1$ , the  $(t_2 + x_2)^{th}$  vertex on the first column is labelled  $R_2$  and so on. The labels  $R_i$ s are well defined, for  $(t_i + x_i)$ s are distinct as  $t_i$ s are even and  $x_i$ s are in  $\{0, 1\}$ . The  $c_1^{th}$  vertex on the diagonal is labelled  $C_1$ , the  $c_2^{th}$  vertex on the diagonal is labelled  $C_2$  and so on. To illustrate,  $t_1 = 4, x_1 = 0, c_1 = 3$  in the diagram. The horizontal edges are directed from left to right and the vertical edges from bottom to top.

Since all the edge weights are 1, the  $(i, j)^{th}$  entry  $M_{i,j}$  of the path matrix is the number of paths  $P_{t_i+x_i, c_j}$  from  $R_i$  to  $C_j$ . This satisfies the two term recurrence  $P_{t_i+x_i, c_j} = P_{t_i+x_i-1, c_j-1} + P_{t_i+x_i-1, c_j}$  as evident from the picture on the right. This is Pascal's identity for binomials. The boundary conditions  $\binom{t_i+x_i}{0} = 1$  and  $\binom{t_i+x_i}{c_i} = 1$  for  $t_i + x_i = c_i$  are consistent with the path formulation. We conclude that the associated path matrix is  $M_{\mathbf{t}, \mathbf{c}} = \left\{ \binom{t_i+x_i}{c_j} \mid i, j \in [s] \right\}$ , whose determinant  $\Phi_{\mathbf{t}, \mathbf{c}}(x_1, \dots, x_s)$  is in question. The planar geometry forces all vertex disjoint path systems to have the identity permutation, which has sign 1. Hence the determinant is a positive number provided there is at least one vertex disjoint path system. By the condition  $t_i + x_i \geq c_i$  for all  $i$ , there is at least one, namely for each  $R_i \rightarrow C_i$ , traverse  $c_i$  edges right before turning up. ◀

## A.2 Reformulation of Conjecture 4

In this section we provide a reformulation of Conjecture 4. Fix sequences  $\mathbf{t}, \mathbf{c}$  as in Conjecture 4. Consider the variety  $X_{\mathbf{t}, \mathbf{c}}$  of intersection of the hypercube and the hypersurface generated by  $\Phi_{\mathbf{t}, \mathbf{c}}$ . The variety  $X_{\mathbf{t}, \mathbf{c}}$  is generated by the ideal

$$\mathcal{I}_{\mathbf{t}, \mathbf{c}} := \langle \Phi_{\mathbf{t}, \mathbf{c}}(X_1, X_2, \dots, X_s), X_1^2 - X_1, \dots, X_s^2 - X_s \rangle.$$

Clearly, the intersection variety is zero dimensional (or empty), since the hypercube is zero dimensional and  $\Phi_{\mathbf{t}, \mathbf{c}}$  is nonzero. The degree of the polynomial defining the hypersurface can be reduced through the relations carving out the hypercube as follows. Let  $\Psi_{\mathbf{t}, \mathbf{c}}(X_1, X_2, \dots, X_s) \in \mathbb{Z}[X_1, X_2, \dots, X_s]$  be the unique lift of

$$\Phi_{\mathbf{t}, \mathbf{c}}[X_1, X_2, \dots, X_s] \text{ mod } \langle X_1^2 - X_1, X_2^2 - X_2, \dots, X_s^2 - X_s \rangle$$

with degree in each variable at most 1. Informally,  $\Psi_{\mathbf{t}, \mathbf{c}}$  is merely  $\Phi_{\mathbf{t}, \mathbf{c}}$  with every indeterminate  $X_i^*$  replaced by  $X_i$ . The  $*$  in the superscript denotes some positive exponent. Since  $\Phi_{\mathbf{t}, \mathbf{c}}$  is nonzero, so is  $\Psi_{\mathbf{t}, \mathbf{c}}$ . The respective hypersurfaces generated by  $\Phi_{\mathbf{t}, \mathbf{c}}$  and  $\Psi_{\mathbf{t}, \mathbf{c}}$  have the same intersection with the Boolean hypercube and hence we can work with either. We will proceed with  $\Psi_{\mathbf{t}, \mathbf{c}}$  as it has the form

$$\Psi_{\mathbf{t}, \mathbf{c}}(X_1, X_2, \dots, X_s) = \sum_{b=(b_1, b_2, \dots, b_s) \in \{0, 1\}^s} a_b X_1^{b_1} X_2^{b_2} \dots X_s^{b_s}$$

familiar to Boolean functional analysts with possibly smaller degrees. Further, restricting to the Boolean cube removed the structural factors that concerned us in Section 3.2.5 from  $\Psi_{\mathbf{t}, \mathbf{c}}$ . Let  $\Psi_{\mathbf{t}, \mathbf{c}}^p \in \mathbb{F}_p[X_1, X_2, \dots, X_s]$  be the reduction of  $\Psi_{\mathbf{t}, \mathbf{c}}$  modulo the prime  $p$ .

Conjecture 4 amounts to  $\Psi_{\mathbf{t},\mathbf{c}}^p$  being a nonzero polynomial. This is, at least one of the coefficients  $a_b \bmod p, b \in \{0,1\}^s$  is nonzero. Equivalently, at least one of the evaluations  $\Psi_{\mathbf{t},\mathbf{c}}^p(e), e \in \{0,1\}^s \subset \mathbb{F}_p^s$  is nonzero. Below we choose to reformulate the asymptotic version, Conjecture 5.

► **Conjecture 17** (Conjecture 5 reformulated). *There exist universal constants  $e_p, e_s \geq 1$  such that for every integer  $n \geq 1$ , prime  $p \geq n^{e_p}$ , and  $s \geq (\log n)^{e_s}$  the following holds. For every pair of strictly increasing sequences  $\mathbf{t} = (t_1, \dots, t_s), \mathbf{c} = (c_1, \dots, c_s) \in ([0, n] \cap 2\mathbb{Z})^s$  satisfying  $\mathbf{c} \leq \mathbf{t}$ , it holds that  $\Psi_{\mathbf{t},\mathbf{c}}^p(X_1, X_2, \dots, X_s)$  is nonzero.*

## B Arithmetic Geometry Heuristics Supporting Conjecture 4

We laboured through the whole previous section trying to argue that the restriction  $\Psi_{\mathbf{t},\mathbf{c}}$  to the Boolean hypercube of  $\Phi_{\mathbf{t},\mathbf{c}}$  is not identically zero modulo our chosen prime  $p$ . Our starting observation in this section is that the reduction  $\Phi_{\mathbf{t},\mathbf{c}}^p$  of  $\Phi_{\mathbf{t},\mathbf{c}}$  is non zero, since  $\Phi_{\mathbf{t},\mathbf{c}}$  is primitive (it is apparent from the defining equation that the highest total degree term of  $\Phi_{\mathbf{t},\mathbf{c}}$  is monic). Therefore, the zeroes of  $\Phi_{\mathbf{t},\mathbf{c}}^p$  define a hypersurface (that is, of codimension 1). We study the intersection of the Boolean hypercube sitting inside  $\mathbb{F}_p^s$  with this hypersurface using arithmetic geometry. Our analysis falls short of proving Conjecture 4 owing the failure to control some error terms. But we will prove Conjecture 4 holds when relaxed to accommodate hypercubes of side length growing with  $p$ .

It is convenient to be ambitious and target stronger versions of Conjecture 4 (or its asymptotic variant, Conjecture 5) which, arguably, are even more natural. First, the distribution of values obtained by evaluating  $\Phi_{\mathbf{t},\mathbf{c}}^p$  on the Boolean hypercube  $\{0,1\}^s$ , for any  $\mathbf{t}, \mathbf{c}$  in question, is fairly balanced when  $p$  is taken sufficiently large compared to  $n$ . More precisely, we postulate the following conjecture.

► **Conjecture 18** (Strong form, value distribution). *There exist universal constants  $e_p, e_s \geq 1$  and  $\beta \in (0, 1)$  such that for every integer  $n \geq 1$ , prime  $p \geq n^{e_p}$ , and  $s \geq (\log n)^{e_s}$  the following holds. For every pair of strictly increasing sequences  $\mathbf{t} = (t_1, \dots, t_s), \mathbf{c} = (c_1, \dots, c_s) \in ([0, n] \cap 2\mathbb{Z})^s$  satisfying  $\mathbf{c} \leq \mathbf{t}$ , it holds that*

$$\left| \sum_{(x_1, \dots, x_s) \in \{0,1\}^s} \zeta_p^{\Phi_{\mathbf{t},\mathbf{c}}(x_1, \dots, x_s)} \right| \leq 2^{\beta s}, \quad (\text{B.1})$$

where  $\zeta_p$  is a  $p^{\text{th}}$  root of unity in  $\mathbb{C}$ .

When the prime  $p$  exceeds the height of  $\Phi_{\mathbf{t},\mathbf{c}}$ , the sum concentrates in a wedge above the positive real axis disturbing the equidistribution. Despite not stating explicitly, we are only interested in (and only claim the conjecture) when  $p$  is small compared to the height of  $\Phi_{\mathbf{t},\mathbf{c}}$ . What really concerns us is the distribution of zeroes

$$\Phi_{\mathbf{t},\mathbf{c}}(\mathbb{F}_p, 2) := \left\{ (x_1, x_2, \dots, x_s) \in \{0,1\}^s \subset \mathbb{F}_p^s \mid \Phi_{\mathbf{t},\mathbf{c}}^p(x_1, x_2, \dots, x_s) = 0 \right\}$$

of  $\Phi_{\mathbf{t},\mathbf{c}}^p$  on the Boolean hypercube; suggesting another strengthening of Conjecture 5.

► **Conjecture 19** (Strong form, point count). *There exist universal constants  $e_p, e_s \geq 1$  and  $\beta \in (0, 1)$  such that for every integer  $n \geq 1$ , prime  $p \geq n^{e_p}$ , and  $s \geq (\log n)^{e_s}$  the following holds. For every pair of strictly increasing sequences  $\mathbf{t} = (t_1, \dots, t_s), \mathbf{c} = (c_1, \dots, c_s) \in ([0, n] \cap 2\mathbb{Z})^s$  satisfying  $\mathbf{c} \leq \mathbf{t}$ , it holds that  $|\Phi_{\mathbf{t},\mathbf{c}}(\mathbb{F}_p, 2)| \leq 2^{\beta s}$ .*

We have gathered some data using a computer program to shed some more light on the exponential sum in Conjecture 18, presented in a longer version of the paper [3].

### B.1 Pascal Determinant Hypersurfaces

Using arithmetic geometry, we next argue for the rarity of zeroes as stated in Conjecture 19. We start with the most naive yet convincing argument. Before addressing the intersection with the Boolean hypercube, consider the  $\mathbb{F}_p$ -rational points  $\Phi_{\mathbf{t},\mathbf{c}}(\mathbb{F}_p) := \left\{w \in \mathbb{F}_p \mid \Phi_{\mathbf{t},\mathbf{c}}^p(w) = 0\right\}$  on the hypersurface of dimension  $s - 1$  and degree  $\leq ns$  in isolation. The Schwartz-Zippel Lemma implies  $|\Phi_{\mathbf{t},\mathbf{c}}(\mathbb{F}_p)| \leq nsp^{s-1}$ . If  $\Phi_{\mathbf{t},\mathbf{c}}^p$  is irreducible or if it has only a few (say  $N_{\mathbf{t},\mathbf{c}}^p$ ) irreducible components, the Lang-Weil bound gives the improved estimate [18]

$$|\Phi_{\mathbf{t},\mathbf{c}}(\mathbb{F}_p) - N_{\mathbf{t},\mathbf{c}}^p p^{s-1}| = (ns - 1)(ns - 2)p^{s-3/2} + O(nsp^{s-2}).$$

With the unimportant structured factors removed from  $\Phi_{\mathbf{t},\mathbf{c}}$ , the remaining  $\Xi_{\mathbf{t},\mathbf{c}}$  (which is also primitive, by Gauss’s lemma) also has non zero reduction  $\Xi_{\mathbf{t},\mathbf{c}}^p$ . It is not always irreducible. For instance, if the index sets  $\mathbf{t}, \mathbf{c}$  are such that  $c_j < t_{j+1}$  for some  $j$ , then the vertex disjoint paths connecting the first  $j$  vertices are decoupled from the rest: resulting in a factorization of  $\Xi_{\mathbf{t},\mathbf{c}}$ . But for the factorization induced by such decouplings, the reduction  $\Xi_{\mathbf{t},\mathbf{c}}^p$  is likely to be irreducible. Better still, if (the homogenization of)  $\Xi_{\mathbf{t},\mathbf{c}}^p$  is irreducible and defines a smooth projective variety, then deep results arising from Deligne’s proof of the Weil conjectures [9, Théorème 8.1] imply the full “square root cancellation”

$$|\Xi_{\mathbf{t},\mathbf{c}}(\mathbb{F}_p) - p^{s-1}| = O(b_{s-1} p^{\frac{s-1}{2}})$$

where  $b_{s-1} \leq \frac{1}{2}s(s+1)(sn)^s$  is the  $s - 1$ th Betti number. To derive our heuristic estimate, Schwartz-Zippel will suffice. For ease of exposition, we will use  $\Phi_{\mathbf{t},\mathbf{c}}$  in the ensuing analysis, even though  $\Xi_{\mathbf{t},\mathbf{c}}^p$  offers some minor gains degree wise. In spirit, the probability  $\Phi_{\mathbf{t},\mathbf{c}}^p$  is zero at a point in  $\mathbb{F}_p^s$  is centred at  $\frac{N_{\mathbf{t},\mathbf{c}}^p}{p}$  with an error term depending on the smoothness. Irrespective of the smoothness, the error term is negligible compared to the estimate for  $p$  a big enough polynomial in  $n$ . We hypothesise that the hypersurface intersects generically with the Boolean hypercube and the number of intersection points is bounded as

$$|\Phi_{\mathbf{t},\mathbf{c}}(\mathbb{F}_p, 2)| \approx |\Phi_{\mathbf{t},\mathbf{c}}(\mathbb{F}_p)| \left(\frac{2}{p}\right)^s. \tag{B.2}$$

By the Schwartz-Zippel lemma

$$|\Phi_{\mathbf{t},\mathbf{c}}(\mathbb{F}_p, 2)| \approx |\Phi_{\mathbf{t},\mathbf{c}}(\mathbb{F}_p)| \left(\frac{2}{p}\right)^s = O\left(\frac{ns2^s}{p}\right) \tag{B.3}$$

suggesting Conjecture 19 holds for  $p > n^2$ .

### B.2 Katz-Laumon Sums and Point Counting in Hypercubes

Through arithmetic geometric bounds on exponential sums, we argue our determinant hypersurfaces intersect generically with the Boolean hypercube. We show Conjecture 4 holds when relaxed to allow hypercubes of length (larger than 2) growing with the prime. Quantitatively, the bounds attained fall short of proving Conjecture 4. Yet, the methods are illuminating and suggest there are no arithmetic obstructions to our conjectures.

The key ingredient is the Katz-Laumon sum [17]. Building on Grothendieck’s foundational trace formula for  $\ell$ -adic cohomology and Deligne’s proof of the Weil conjectures, Katz and Laumon studied certain trigonometric sums over arbitrary high dimensional varieties over finite fields, parametrized by auxiliary points. They proved square root cancellation without any strong geometric assumption (such as smoothness) on the variety, for almost all choices

of the parameter. Fouvry [10] and Fouvry-Katz [11] extended Katz and Laumon's theorem to obtain a stratified theorem. Fouvry applied Katz-Laumon sums to count points of a variety on hypercubes (Boolean or more general). Fouvry and Katz extended this approach and proved better bounds provided more is assumed about the geometry of the variety. We adapt these techniques to bound the intersection of our hypersurfaces  $\Phi_{t,c}(\mathbb{F}_p)$  with Boolean hypercubes as (a proof of the bound is in a longer version of the paper [3])

$$|\Phi_{t,c}(\mathbb{F}_p, 2)| = \left(\frac{2}{p}\right)^s |\Phi_{t,c}(\mathbb{F}_p)| + O\left(p^{(s-1)/2}(\log p)^s + \frac{2^{s-1} \log p}{\sqrt{p}}\right). \quad (\text{B.4})$$

The constant hidden in the asymptotic  $O$  notation may depend on  $s$ , but this dependence will be subsumed and removed in Equation (B.5). Our ultimate goal is to claim the right hand side is strictly less than  $2^s$ , which would prove Conjecture 4. However,  $p^{(s-1)/2}$  is too large and muddies the estimate. The bounds are good enough if the hypercube side length is extended to  $b > 2$ , since Fouvry [10] shows for every  $\Phi_{t,c}$ , for large enough  $p$ ,

$$|\Phi_{t,c}(\mathbb{F}_p, b)| = \left(\frac{b}{p}\right)^s |\Phi_{t,c}(\mathbb{F}_p)| + O\left(p^{(s-1)/2}(\log p)^s + \frac{b^{s-1} \log p}{\sqrt{p}}\right). \quad (\text{B.5})$$

From the Schwartz-Zippel lemma bound Equation (B.3) on  $|\Phi_{t,c}(\mathbb{F}_p)|$ ,

$$|\Phi_{t,c}(\mathbb{F}_p, b)| \leq \frac{ns2^s}{p} + O\left(p^{(s-1)/2}(\log p)^s + \frac{b^{s-1} \log p}{\sqrt{p}}\right).$$

For  $b \gg p^{3/4}$ ,  $|\Phi_{t,c}(\mathbb{F}_p, b)| \ll b^s$ . Fouvry's theorem applies to arbitrary varieties and the "for large enough  $p$ " clause is primarily in place to ensure the defining polynomials do not identically vanish modulo  $p$ . To us,  $\Phi_{t,c}^p$  is non zero, so the bounds should hold uniformly for all  $p$ . Therefore, with some work to ensure uniformity of bounds, these methods prove Conjecture 19 when relaxed to Boolean cubes of length growing  $b \gg p^{3/4}$ . A proof is deferred to the full version of this paper.

We believe the large error term in Equation (B.4) and Fouvry's theorem Equation (B.5) to be artefacts of proof techniques and not intrinsic to the quantities. The primary lesson we advocate from these arithmetic geometric techniques is qualitative and not quantitative. There should be no arithmetic obstruction to equidistribution of the zeroes of the hypersurfaces defined by our determinant polynomials in the Boolean hypercube, as claimed in the strong form of our conjecture.

# Towards a Decomposition-Optimal Algorithm for Counting and Sampling Arbitrary Motifs in Sublinear Time

## Abstract

We consider the problem of sampling and approximately counting an arbitrary given motif  $H$  in a graph  $G$ , where access to  $G$  is given via queries: degree, neighbor, and pair, as well as uniform edge sample queries. Previous algorithms for these tasks were based on a decomposition of  $H$  into a collection of odd cycles and stars, denoted  $D^*(H) = \{O_{k_1}, \dots, O_{k_q}, S_{p_1}, \dots, S_{p_\ell}\}$ . These algorithms were shown to be optimal for the case where  $H$  is a clique or an odd-length cycle, but no other lower bounds were known.

We present a new algorithm for sampling arbitrary motifs which, up to  $\text{poly}(\log n)$  factors, is always at least as good, and for most graphs  $G$  is strictly better. The main ingredient leading to this improvement is an improved uniform algorithm for sampling stars, which might be of independent interest, as it allows to sample vertices according to the  $p$ -th moment of the degree distribution.

Finally, we prove that this algorithm is *decomposition-optimal* for decompositions that contain at least one odd cycle. These are the first lower bounds for motifs  $H$  with a nontrivial decomposition, i.e., motifs that have more than a single component in their decomposition.

## 1 Introduction

The problems of counting and sampling small motifs in graphs are fundamental algorithmic problems with many applications. Small motifs statistics are used for the study and characterization of graphs in multiple fields, including biology, chemistry, social networks and many others (see e.g., [36, 30, 21, 33, 32, 43, 28, 35, 38, 41, 31]). From a theoretical perspective, the complexity of the best known classical algorithms for exactly enumerating small motifs such as cliques and paths of length  $k$ , grows exponentially with  $k$  [42, 9]. On the more applied side, there is an extensive study of practical algorithms for approximate motif counting (e.g., [39, 5, 34, 1, 27, 12, 7, 24]). We study the problems of approximate motif counting and uniform sampling in the *sublinear-time* setting, where sublinear is with respect to the size of the graph. We consider the *augmented query model*, introduced by [2], where the allowed queries are degree, neighbor and pair queries as well as uniform edge sample queries.<sup>1</sup> We note that the model which only allows for the first three types of queries is referred to as the *general graph query model*, introduced by [29].

The problems of approximate counting and uniformly sampling of *arbitrary motifs* of constant size in sublinear-time have seen much progress recently, through the results of Assadi, Kapralov and Khanna [3], and Fichtenberger, Gao and Peng [23]. The algorithms of [3, 23] both start by computing an optimal (in a sense that will be clear shortly) decomposition of the motif  $H$  into vertex-disjoint odd cycles and stars, defined next.

**A decomposition into odd cycles and stars.** A decomposition  $D$  of a motif (graph)  $H$  into a collection of vertex disjoint small cycles and stars  $\{O_{k_1}, \dots, O_{k_q}, S_{p_1}, \dots, S_{p_\ell}\}$  is valid if all vertices of  $H$  belong to either a star or an odd cycle in the collection. Each decomposition can be associated with a weight function  $f_D : E \rightarrow \{0, \frac{1}{2}, 1\}$  which assigns weight 1 to edges of its star components, weight  $1/2$  to edges of its odd cycle components and weight 0 to all other edges in  $H$ . See figure 1 for an illustration. Hence, each decomposition  $\{O_{k_1}, \dots, O_{k_q}, S_{p_1}, \dots, S_{p_\ell}\}$  has value  $\rho(D) = \sum_{e \in H} f_D(e) = \sum_{i=1}^q k_i/2 + \sum_{j=1}^{\ell} p_j$ , where throughout the paper  $k_i$  and  $p_j$  denote the length and number of petals in the  $i^{\text{th}}$  cycle and  $j^{\text{th}}$  star, respectively, in  $D^*(H)$ . For every  $H$ , its optimal decomposition value is  $\rho(H) = \min_D \{\rho(D)\}$ , and a decomposition  $D$  is said to be *optimal* for  $H$  if  $\rho(D) = \rho(H)$ . We fix (one of) the optimal decomposition of  $H$ , and denote it by  $D^*(H)$ . In [3], it is shown that an optimal decomposition of a motif  $H$  can be computed in polynomial time in  $|H|$ .<sup>2</sup>

The algorithm in [23] has expected running time <sup>3</sup>  $O\left(\frac{m^{\rho(H)}}{n}\right)$  for the task of uniformly

<sup>1</sup> Degree queries return the degree of the queried vertex, neighbor queries with index  $i \leq d(v)$  return the  $i^{\text{th}}$  neighbor of the queried vertex, pair queries return whether there is an edge between the queried pair of vertices, and uniform edge queries return a uniformly distributed edge in the graph.

<sup>2</sup> We note that  $\rho(H)$  is equal to the fractional edge cover value of  $H$ : the fractional edge cover value of a motif (graph)  $H$  is the solution to the following minimization problem. Minimize  $\sum_{e \in E} f(e)$  under the constraint that for every  $v \in H$ ,  $\sum_{e \ni v} f(e) \geq 1$ . In [3], the decomposition is computed by first computing an optimal fractional cover. However, as there exists a mapping between fractional edge covers to decompositions which preserves their value, we choose to define  $\rho(H)$  according to the minimal valid decomposition value.

<sup>3</sup> Throughout the paper, unless stated otherwise, the query complexity of the mentioned sublinear-time algorithms is the same as the minimum between their running time and  $\min\{n + m, m \log n\}$ . This is true since any algorithm can simply query the entire graph and continue computation locally. Querying the entire graph can either be performed by querying the neighbors of all vertices (which takes  $O(n + m)$  queries), or by performing  $m \log n$  uniform edge samples, which, with high probability, return all edges in the graph (note that we do not care about isolated vertices, as we assume the motif  $H$  is connected). Hence, we focus our attention on the running time complexity.

■ **Figure 1** An example of an optimal decomposition of a motif  $H$  into odd cycles and stars. The orange edges have weight  $1/2$ , the red edges have weight  $1$ , and the dotted edges have zero weight.

sampling a copy of  $H$ , where  $\bar{h}$  is the number of copies of  $H$  in  $G$ , and  $m$  is the number of oriented edges<sup>4</sup> in  $G$ . The algorithm in [3] for the  $(1 \pm \epsilon)$ -approximation task has the same complexity up to  $\text{poly}(\epsilon, |H|, \log n)$  factors, where  $n$  is the number of vertices in  $G$ .

## 1.1 Our results

We present improved upper and lower bounds for the tasks of estimating and sampling any arbitrary motif in a graph  $G$  in sublinear time (with respect to the size of  $G$ ). First, we give a new, essentially optimal, star-sampler for graphs. We also show that with few modifications, the star-sampler can be adapted to an optimal  $\ell_p$  sampler, which might be of independent interest. Based on this sampler, as well as an improved sampling approach, we present our main algorithm for sampling a uniformly distributed copy of any given motif  $H$  in a graph  $G$ . Our algorithm's complexity is parameterized by what we refer to as the *decomposition-cost* of  $H$  in  $G$ , denoted  $\text{DECOMP-COST}(G, H, D^*(H))$ . We further show that our motif sampling algorithm can be used to obtain a  $(1 \pm \epsilon)$ -estimate of the motif at question (with an overhead of an  $O(1/\epsilon^2)$  factor). As we shall see, our result is always at least as good as previous algorithms for these problems (up to a  $\log n \log \log n$  term), and greatly improves upon them for various interesting graph classes, such as random graphs and bounded arboricity graphs.

We then continue to prove that for any motif whose optimal decomposition contains at least one odd cycle, this bound is *decomposition-optimal*: we show that for every decomposition  $D$  that contains at least one odd cycle, there exists a motif  $H_D$  (with optimal decomposition  $D$ ) and a family of graphs  $\mathcal{G}$  so that in order to sample a uniformly distributed copy of  $H$  (or to approximate  $\bar{h}$ ) in a uniformly chosen graph in  $\mathcal{G}$ , the number of required queries is  $\Omega(\min\{\text{DECOMP-COST}(G, H, D^*(H)), m\})$  in expectation.

We start by describing the upper bound.

### 1.1.1 Optimal star/ $\ell_p$ -sampler

Our first contribution is an improved algorithm, *Sample-a-Star*, for sampling a (single) star uniformly at random, and its variant for sampling vertices according to the  $p^{\text{th}}$  moment. For a vertex  $v$ , we let  $\bar{s}_p(v) = \binom{d(v)}{p}$ , if  $d(v) \geq p$ , and otherwise,  $\bar{s}_p(v) = 0$ . We let  $\bar{s}_p = \sum_{v \in V} \bar{s}_p(v)$  denote the number of  $p$ -stars in the graph. We will also be interested in the closely related value of the  $p^{\text{th}}$  moment of the degree distribution,  $\bar{\mu}_p = \sum_{v \in V} d(v)^p$ .

<sup>4</sup> Throughout the paper we think of every edge  $\{u, v\}$  as two oriented edges  $(u, v)$  and  $(v, u)$ , and let  $m$  denote the number of oriented edges.

► **Theorem 1.** *There exists a procedure, **Sample-a-Star**, that given query access to a graph  $G$ , and a constant factor estimate of  $\bar{s}_p$ , returns a uniformly distributed  $p$ -star in  $G$ . The expected query complexity and running time of the procedure are  $O\left(\min\left\{\frac{m \cdot n^{p-1}}{\bar{s}_p}, \frac{m}{\bar{s}_p^{1/p}}\right\}\right)$  where  $\bar{s}_p$  denotes the number of  $p$ -stars in  $G$ .*

We note that a constant factor estimate of  $\bar{s}_p$  can be obtained by invoking one of the algorithms in [17, 2], in expected query complexity  $\tilde{O}\left(\min\left\{\frac{m \cdot n^{p-1}}{\bar{s}_p}, \frac{m}{\bar{s}_p^{1/p}}\right\}\right)$ . Therefore, if such an estimate is not known in advance, then it could be computed, with probability at least  $2/3$ , by only incurring a  $\log n$  factor to the expected time complexity.

We will also show a variant of **Sample-a-Star**, denoted **Sublinear- $\ell_p$ -Sampler**, that gives an optimal  $\ell_p$ -sampler for any integer  $p \geq 2$  in sublinear time. That is, **Sublinear- $\ell_p$ -Sampler** allows to sample according to the  $p^{\text{th}}$  moment of the degree distribution, so that every vertex  $v \in V$  is returned by it with probability  $d(v)^p / \bar{\mu}_p$ . The question of sampling according to the  $p^{\text{th}}$  moment for various values of  $p$  has been studied extensively in the streaming model where  $\ell_p$  samplers have found numerous applications, see, e.g., the recent survey by Cormode and Hossein [11] and the references therein. Therefore we hope it could find applications in the sublinear-time setting that go beyond subgraph sampling.

► **Theorem 2.** *There exists an algorithm, **Sublinear- $\ell_p$ -Sampler**, that returns a vertex  $v \in V$ , so that each  $v \in V$  is returned with probability  $d(v)^p / \bar{\mu}_p$ . The expected running time of the algorithm is  $O\left(\min\left\{\frac{m \cdot n^{p-1}}{\bar{\mu}_p}, \frac{m}{\bar{\mu}_p^{1/p}}\right\}\right)$ .*

Observe that for every value of  $p$ ,  $\bar{s}_p < \bar{\mu}_p$ . Furthermore, Since  $m$  and  $\bar{\mu}_p^{1/p}$  are simply the  $\ell_1$  and  $\ell_p$  norms of the degree distribution of  $G$ , it holds that  $\bar{\mu}_p^{1/p}$  is smaller than  $m$ , and could be as small as  $m/n^{1-1/p}$ . Therefore,  $\bar{\mu}_p^{1/p} < m \Leftrightarrow \bar{\mu}_p^{p-1/p} < m^{p-1}$ . and it follows that

$$m \cdot \min\left\{n^{p-1}, \bar{s}_p^{(p-1)/p}\right\} \leq m \cdot \bar{s}_p^{(p-1)/p} < m \cdot \bar{\mu}_p^{(p-1)/p} \leq m \cdot m^{p-1} = m^p. \quad (1)$$

Hence, not accounting for the  $O(\log n \log \log n)$  term, the expected complexity  $\tilde{O}(m \cdot \min\{n^{p-1}, \bar{s}_p^{(p-1)/p}\} / \bar{s}_p)$  of **Sample-a-Star** strictly improves upon the  $O(m^p / \bar{s}_p)$  expected complexity of the star-sampling algorithm by [23]. Accounting for that term, our algorithm is preferable when either  $d_{\text{avg}} = \omega(\log n \log \log n)$  or  $m / \bar{s}_p^{1/p} = \omega(\log n)$ .

Furthermore, the complexity of **Sample-a-Star** matches the complexities of the star approximation algorithms by [26, 2], thus proving that uniformly sampling and approximately counting stars in the augmented model have essentially the same complexity. Finally, the construction of the lower bound for the estimation variant by [26] proves that **Sample-a-Star** and **Sublinear- $\ell_p$ -Sampler** are essentially optimal.

### 1.1.2 An algorithm for sampling and estimating arbitrary motifs

Given the above star sampler, we continue to describe our main contribution: an algorithm, **Sample- $H$** , that for any graph  $G$  and given motif  $H$ , outputs a uniformly distributed copy of  $H$  in  $G$ .

To sample a copy of  $H$  we first sample copies of all basic components in its decomposition  $D^*(H)$ , and then check if they can be extended to a copy of  $H$  in  $G$ . Therefore, it will be useful to define the costs of these sampling operations.

► **Notation 3** (Basic components, counts and costs). Let  $H$  be a motif, and let  $D^*(H) = \{O_{k_1}, \dots, O_{k_q}, S_{p_1}, \dots, S_{p_\ell}\}$  be an optimal decomposition of  $H$ . We refer to the odd cycles and stars in  $D^*(H)$  as the basic components of the decomposition (or sometimes, abusing notation, of  $H$ ). We use the notation  $\{C_i\}_{i \in [r]}$ , to denote the set of all components in  $D^*(H)$ ,  $\{C_i\}_{i \in [r]} = D^*(H)$ , where  $r = q + \ell$ .

For every basic component  $C_i$  in  $D^*(H) = \{C_i\}_{i \in [r]}$ , we denote the number of copies of  $C_i$  in  $G$  as  $\bar{c}_i$  and refer to it as the count of  $C_i$ . Similarly,  $\bar{o}_k$  and  $\bar{s}_p$  denote the number of copies of length  $k$  odd cycles and  $p$ -stars in  $G$ , respectively.

We also define the sampling cost (or just cost in short) of  $C_i$  to be:

$$\text{cost}(C_i) = \begin{cases} m^{k/2}/\bar{o}_k & C_i = O_k \\ \min \left\{ \frac{m \cdot n^{p-1}}{\bar{s}_p}, \frac{m}{\bar{s}_p^{1/p}} \right\} & C_i = S_p \end{cases}.$$

Observe that indeed, by Theorem 1, sampling a single  $p$ -star in  $G$  takes  $\text{cost}(S_p) = \min \left\{ \frac{m \cdot n^{p-1}}{\bar{s}_p}, \frac{m}{\bar{s}_p^{1/p}} \right\}$  queries in expectation, and by [23, Lemma 3.1], sampling a single  $O_k$  odd cycle takes  $\text{cost}(O_k) = m^{k/2}/\bar{o}_k$  queries in expectation.

► **Notation 4** (Decomposition-cost). For a motif  $H$ , an optimal decomposition  $D^*(H)$  of  $H$ , and a graph  $G$ , the decomposition cost of  $H$  in  $G$ , denoted  $\text{DECOMP-COST}(G, H, D^*(H))$  is

$$\text{DECOMP-COST}(G, H, D^*(H)) = \max_{i \in [r]} \{\text{cost}(C_i)\} \cdot \frac{\prod \bar{c}_i}{\bar{\mathbf{h}}}.$$

Note that the motif  $H$  determines the counts of  $\bar{\mathbf{h}}$  and its decomposition  $D^*(H)$  determines what are the basic component counts in  $G$  that are relevant to the sampling cost.

► **Theorem 5.** Let  $G$  be a graph over  $n$  vertices and  $m$  edges, and let  $H$  be a motif such that  $D^*(H) = \{O_{k_1}, \dots, O_{k_q}, S_{p_1}, \dots, S_{p_\ell}\} = \{C_i\}_{i \in [r]}$ . There exists an algorithm, **Sample- $H$** , that returns a copy of  $H$  in  $G$ . With probability at least  $1 - 1/\text{poly}(n)$ , the returned copy is uniformly distributed in  $G$ . The expected query complexity of the algorithm is

$$O(\min \{\text{DECOMP-COST}(G, H, D^*(H)), m\}) \cdot \log n \log \log n.$$

In the full version of this paper ([8]), we prove that with slight modifications to the sampling algorithm we can obtain a  $(1 \pm \epsilon)$ -approximation algorithm for  $\bar{\mathbf{h}}$ , with the same expected query complexity and running time up to a multiplicative factor of  $O(1/\epsilon^2)$ .

**Comparison to previous bounds.** We would like to compare our algorithm's expected complexity stated in Theorem 5, to the expected complexity  $O\left(\frac{m^{\rho(H)}}{\bar{\mathbf{h}}}\right)$  of the counting and sampling algorithms by [3] and [23], respectively, where recall that for an optimal decomposition  $D^*(H) = \{O_{k_1}, \dots, O_{k_q}, S_{p_1}, \dots, S_{p_\ell}\}$  of  $H$ ,  $\rho(H) = \sum_{i \in [q]} k_i/2 + \sum_{i \in [\ell]} p_i$ .

Recalling Equation 1, and plugging in the costs of the basic components and the decomposition cost, defined in Notations 3 and 4, respectively, we get that for any graph  $G$  and motif  $H$ ,

$$\begin{aligned} \text{DECOMP-COST}(G, H, D^*(H)) &= \max_{i \in [r]} \{\text{cost}(C_i)\} \cdot \frac{\prod \bar{c}_i}{\bar{\mathbf{h}}} \\ &= \max_{i \in [r]} \{\text{cost}(C_i)\} \cdot \frac{\prod_{i \in [q]} \bar{o}_{k_i} \cdot \prod_{i \in [\ell]} \bar{s}_{p_i}}{\bar{\mathbf{h}}} \end{aligned}$$

$$\begin{aligned} &\leq \frac{\prod_{i \in [q]} m^{k_i/2} \cdot \prod_{i \in [\ell]} m \cdot (\min\{n^{p_i-1}, \bar{s}_{p_i}^{(p_i-1)/p_i}\})}{\bar{h}} \\ &< \frac{\prod_{i \in [q]} m^{k_i/2} \cdot \prod_{i \in [\ell]} m^p}{\bar{h}} = \frac{m^{\rho(H)}}{\bar{h}}. \end{aligned}$$

Therefore, as long as  $D^*(H)$  contains at least one star, and not accounting for the term  $O(\log n \log \log n)$ , our algorithm is preferable to the previous one, as we save a factor of at least  $d_{\text{avg}}^{p-1}$  for each  $p$ -star in  $D^*(H)$ .

Moreover, the complexity of our sampling algorithm is parameterized by the *actual* counts of the basic components  $O_{k_1}, \dots, O_{k_q}, S_{p_1}, \dots, S_{p_\ell}$  of the graph  $G$  at hand, rather than by the maximal possible counts of these components, respectively  $m^{k_1/2}, \dots, m^{k_q/2}, m^{p_1}, \dots, m^{p_\ell}$ , as is in previous algorithms. For example, if the max component cost is due to the odd cycle of length  $k_1$ , we get

$$O^* \left( \frac{m^{k_1/2} \cdot \bar{o}_{k_2} \cdot \dots \cdot \bar{o}_{k_q} \cdot \bar{s}_{p_1} \cdot \dots \cdot \bar{s}_{p_\ell}}{\bar{h}} \right) \text{ vs. } O^* \left( \frac{m^{k_1/2} \cdot m^{k_2/2} \cdot \dots \cdot m^{k_q/2} \cdot m^{p_1} \cdot \dots \cdot m^{p_\ell}}{\bar{h}} \right)$$

of the previous algorithms. Importantly, this parameterization arises *only* in the analysis, while the algorithm itself is very simple, and does not depend on prior knowledge of the actual values of these counts.

**Improved results for various graph classes.** Our parameterization immediately implies improved results in various interesting graph classes. For example, for sparse Erdős-Rényi random graphs  $\mathcal{G}(n, d/n)$ , the expected count of  $k$ -odd cycles is  $\Theta(d^k)$ , and of  $p$ -stars is  $\Theta(n \cdot d^p)$ . Hence, if we consider for example a motif  $H$  that is composed of a triangle connected to a 5-petals star, our algorithm has expected complexity  $O^* \left( \frac{m^{2.5} \cdot d^4}{\bar{h}} \right)$ , while the algorithms in [3, 23] have expected complexity  $O \left( \frac{m^{6.5}}{\bar{h}} \right)$ . In another example, for graphs of bounded arboricity<sup>5</sup>  $\alpha$ , the number of  $k$ -odd cycles is upper bounded<sup>6</sup> by  $\alpha \cdot m^{(k-1)/2}$ . Therefore, in the case that  $G$  has, e.g., constant arboricity, we save a multiplicative factor of  $\sqrt{m^q}$  or  $\sqrt{m^{q-1}}$ , depending on whether the max cost component is due to a star or an odd cycle, respectively (recall that  $q$  is the number of odd cycles in the decomposition).

### 1.1.3 Lower bound for estimating and sampling general motifs

In the full version, we prove the following lower bound, which states that for every decomposition  $D$  that contains at least one odd cycle component and every realizable value of DECOMP-COST, there exists a motif  $H_D$  such that  $D$  is an optimal decomposition of  $H_D$ , and for which our upper bound is optimal.

► **Theorem 6.** *For any decomposition  $D$  that contains at least one odd cycle, and for every  $n$  and  $m$  and realizable value  $DC$  of DECOMP-COST, there exists a motif  $H_D$ , with optimal decomposition  $D$ , and a family of graphs  $\mathcal{G}$  over  $n$  vertices and  $m$  edges, for which the following holds. For every  $G \in \mathcal{G}$ ,  $\text{DECOMP-COST}(G, H_D, D) = DC$ , and the expected query complexity of sampling (whp) a uniformly distributed copy of  $H_D$  in a uniformly chosen  $G \in \mathcal{G}$  is  $\Omega(DC)$ .*

<sup>5</sup> The arboricity of a graph  $G$  is the minimal number of forests required to cover the edge set of  $G$ .

<sup>6</sup> In a graph  $G$  with arboricity  $\alpha$  there exists an acyclic ordering of the graph's vertices, such that each vertex has  $O(\alpha)$  vertices exceeding it in the order. We can attribute each  $k$ -cycles in the graph to its first vertex in that ordering. It then holds that each vertex has at most  $(d^+(v))^2 \cdot m^{(k-3)/2}$  attributed cycles, and it follows that  $\bar{o}_k \leq \alpha \cdot m^{(k-1)/2}$ , where  $d^+(v)$  is the number of neighbors of  $v$  that exceed it in the aforementioned ordering.

Prior to this work, the only known lower bounds for the tasks of uniformly sampling or approximately counting motifs  $H$  that were either a clique [19], a single odd cycle [3], or a single star [26, 2, 19]. The above theorem provides the first lower bounds for motifs with non-trivial decompositions. Furthermore, even though our bounds are only *decomposition-optimal* (that is, they do not hold for *any* motif  $H$ ), each decomposition  $D$  corresponds to at least one motif  $H_D$  (generally, there are multiple valid ones), for which our bounds are tight.

In order to prove Theorem 6, we actually prove a stronger theorem, which relies on a technical notion of *good counts*, formally stated in Definition 17 in the full version.

► **Theorem 7.** *For any decomposition  $D = \{O_{k_1}, \dots, O_{k_q}, S_{p_1}, \dots, S_{p_\ell}\} = \{C_i\}_{i \in [r]}$  that contains at least one odd cycle component, for every  $n, m, \bar{\mathbf{h}}$  and a set of good counts,  $\{\bar{c}_i\}_{i \in [r]} = \{\bar{o}_{k_1}, \dots, \bar{o}_{k_q}, \bar{s}_{p_1}, \dots, \bar{s}_{p_\ell}\}$ , as defined in Definition 17 of the full version, the following holds. There exists a motif  $H_D$ , with an optimal decomposition  $D$ , and a family of graphs  $\mathcal{G}$  over  $n$  vertices and  $m$  edges, as follows. For every  $G \in \mathcal{G}$ , the basic component counts are as specified by  $\{\bar{c}_i\}_{i \in [r]}$ , the number of copies of  $H_D$  is  $\bar{\mathbf{h}}$ , and the expected query complexity of sampling (whp) a uniformly distributed copy of  $H_D$  in a uniformly chosen  $G \in \mathcal{G}$  is*

$$\Omega \left( \min \left\{ \max_{i \in [r]} \{ \text{cost}(C_i) \} \cdot \frac{\prod_i \bar{c}_i}{\bar{\mathbf{h}}}, m \right\} \right).$$

In the full version, we first prove that Theorem 6 follows from Theorem 7. Theorem 7 is essentially a substantial refinement of Theorem 6, in the following sense. Not only that for any decomposition cost we can match the lower bound (as stated in Theorem 6), but we can match it for a large variety of *specific* setting of the basic counts (as long as they are good, as stated in Theorem 7). While Theorem 7 does not state that the lower bound holds for *any* setting of the counts  $\{\bar{c}_i\}_{i \in [r]}$ , as we discuss in the full version, some of the constraints on these counts are unavoidable. It remains an open question whether this set of constraints can be weakened, or perhaps more interestingly, whether, given that a set of constraints that is *not good*, can a better upper bound be devised.

## 1.2 Organization of the paper

We give some preliminaries in Section 2. The discussion on additional related works on sublinear motif counting and sampling is deferred to Appendix A. In Section 3 we give a high level overview of our techniques. We present our algorithms for uniformly sampling stars and arbitrary motifs  $H$  in Section 4. Due to page limitation, the full details of the  $\ell_p$ -sampler, approximation algorithm, as well as the decomposition-optimal lower bounds are deferred to the full version of this paper [8].

## 2 Preliminaries and Notation

Let  $G = (V, E)$  be a simple undirected graph. We let  $n$  denote the number of vertices in the graph. We think of every edge  $\{u, v\}$  in the graph as two *oriented* edges  $(u, v)$  and  $(v, u)$ , and slightly abuse notation to let  $m$  denote the number of oriented edges, so that  $m = \sum_{v \in V} d(v) = 2|E|$ , and  $d_{\text{avg}} = m/n$ . Unless explicitly stated otherwise, when we say “edge” we mean an oriented edge. We let  $d(v)$  denote the degree of a given vertex. We let  $[r]$  denote the set of integers 1 through  $r$ .

**The augmented query model.** We consider the augmented query model which allows for the following queries. (1) A degree query,  $deg(v)$ , returns the degree of  $v$ ,  $d(v)$ ; (2) An  $i^{\text{th}}$  neighbor query,  $Nbr(v, i)$  returns the  $i^{\text{th}}$  neighbor of  $v$  if  $i \leq d(v)$ , and otherwise returns FAIL; (3) A pair query,  $pair(u, v)$ , returns whether  $(u, v) \in E$ ; and (4) Uniform edge query returns a uniformly distributed (oriented) edge in  $E$ .

**A decomposition into odd cycles and stars.** Given a motif  $H$ , the result in [3] is parameterized by the *fractional edge cover number*  $\rho(H)$ . The fractional edge cover number is the optimal solution to the *linear programming relaxation* of the integer linear program (ILP) for the minimum edge cover of  $H$ : The ILP allows each edge to take values in  $\{0, 1\}$ , under the constraint that the sum of edge values incident to any vertex  $v$  is at least 1. The LP relaxation allows values in  $[0, 1]$  instead, and  $\rho(H)$  is the minimum possible sum of all the (fractional) values. In [3], the authors strengthen an existing result by Atserias, Grohe and Marx [4], in order to prove that there always exists an optimal solution as follows. All of the weight (i.e., non zero edges) is supported on (the edges of) vertex-disjoint odd cycles and stars, where each odd cycle edge has weight  $1/2$ , and each star edge has weight 1. Consequently, the corresponding optimal solution of the LP for a given graph  $H$  is equivalent to a decomposition of  $H$  into a collection of vertex-disjoint odd cycles and stars, denoted  $D^*(H) = \{O_{k_1}, \dots, O_{k_q}, S_{p_1}, \dots, S_{p_\ell}\}$ . See Figure 1 for an illustration.

Generally, the motif we aim to sample (or approximate its counts) will be denoted by  $H$ , and the corresponding decomposition will be  $\mathcal{D}(H) = \{O_{k_1}, \dots, O_{k_q}, S_{p_1}, \dots, S_{p_\ell}\} = \{C_i\}_{i \in r}$  for  $r = q + \ell$ . We use a convention of using  $O_{k_i}$  to refer to the  $i^{\text{th}}$  decomposition component which is an odd cycle of size  $k_i$ , and  $S_{p_i}$  to refer to the  $i^{\text{th}}$  star component, which is a star with  $p_i$  petals. We use  $\bar{o}_k$  and  $\bar{s}_p$  denote the number of  $k$ -cycles and  $p$ -stars in  $G$  respectively, and we use  $\bar{h}$  to denote the number of copies of  $H$  in  $G$ .

Next, we formally define the fractional edge cover of a graph (or motif), and the resulting decomposition. We note that in this paper we will be interested in the decomposition of the motif  $H$ , and not the graph  $G$ .

► **Definition 8** (Fractional edge cover). *A fractional edge cover of a graph is a function  $f : E \rightarrow \mathbb{R}_{\geq 0}$  such that for every  $v \in V$ ,  $\sum_{e \ni v} f(e) \geq 1$ . We say that the cost of a given edge cover  $f$  is  $\sum_{e \in E} f(e)$ . For any graph (motif)  $H$ , its fractional edge cover value is the minimum cost over all of its fractional edge covers, and we denote this value by  $\rho(H)$ . An optimal edge-cover of  $H$  is any edge cover of  $H$  with cost  $\rho(H)$ .*

► **Lemma 9** (Lemma 4 in [3]). *Any graph (motif)  $H$  admits an optimal fractional edge cover  $x^*$ , whose support, denoted  $SUPP(x^*)$ , is a collection of vertex-disjoint odd cycles and stars, such that:*

- for every odd cycle  $C \in SUPP(x^*)$ , for every  $e \in C$ ,  $x^*(e) = 1/2$ .
- for every  $e \in SUPP(x^*)$  that does not belong to an odd cycle,  $x^*(e) = 1$ .

► **Definition 10** (Decomposition into odd-cycles and stars). *Given an optimal fractional edge-cover  $x^*$  as in Lemma 9, let  $\{O_{k_1}, \dots, O_{k_q}\}$  be the odd-cycles in the support of  $x^*$ , and let  $\{S_{p_1}, \dots, S_{p_\ell}\}$  be the stars. We refer to  $D^*(H) := \{O_{k_1}, \dots, O_{k_q}, S_{p_1}, \dots, S_{p_\ell}\}$  as an (optimal) decomposition of  $H$ .*

Given a graph (motif)  $H$ , its fractional edge cover value and an optimal decomposition can be computed efficiently:

► **Theorem 11** (Lemma 4 and Section 3 in [3]). *For any graph  $H$ , its fractional edge cover value  $\rho(H)$  and an optimal decomposition  $D^*(H)$  can be computed in polynomial time in  $|H|$ .*

### 3 Overview of Our Results and Techniques

We start with describing the ideas behind our upper bound result.

#### 3.1 An algorithm for sampling arbitrary motifs

We take the same approach as that of [23], of sampling towards estimating, but improve on the query complexity of their bound using two ingredients. The first is an improved star sampler, and the second is an improved sampling approach.

**Improved star sampler.** The algorithm of [23] tries to sample  $p$ -stars by sampling  $p$  edges uniformly at random, and checking if they form a star (by simply checking if all  $p$  edges agree on their first endpoint). Hence, each  $p$ -star is sampled with probability  $1/m^p$ . Our first observation is that it is more efficient to sample a *single* edge  $(u, v)$  and then sample  $p - 1$  neighbors of  $v$  uniformly at random, by drawing  $(p - 1)$  indices  $i_1, \dots, i_p$  in  $[d(v)]$  uniformly at random, and performing neighbor queries  $(v, i_j)$  for every  $j \in [p - 1]$ . However, this sampling procedure introduces biasing towards stars that are incident to lower degree endpoints. If we were also given an upper bound  $d_{ub}$  on the maximal degree in the graph, i.e., a value  $d_{ub}$  such that  $d_{max} \leq d_{ub}$ , where  $d_{max}$  is the maximum degree in  $G$ , then we could overcome the above biasing, by “unifying” all the degrees in the graph to  $d_{ub}$ . Specifically, this unification of degrees is achieved by querying the  $i^{\text{th}}$  neighbor of a vertex, where  $i$  is chosen uniformly at random in  $[d_{ub}]$ , rather than in  $[d(v)]$ .<sup>7</sup> By repeating this process  $p - 1$  times, we get that each specific copy of a  $p$ -star is sampled with equal probability  $\frac{1}{m \cdot (d_{ub})^{p-1}}$ . Observe that this is always preferable to  $1/m^p$ , i.e.  $\frac{1}{m \cdot (d_{ub})^{p-1}} > \frac{1}{m^p}$ , since for every graph  $G$ ,  $d_{ub} < m$ . While we are not given such a bound on the maximal degree, letting  $\bar{s}_p$  denote the number of  $p$ -stars in  $G$ , it always holds that  $d_{max} \leq \min\{n, \bar{s}_p^{1/p}\}$  (since every vertex with degree  $d > p$  contributes  $d^p$  to  $\bar{s}_p$ ). Hence, we can use the existing algorithms for star approximations by [26, 2, 17] in order to first get an estimate  $\hat{s}_p$  of  $\bar{s}_p$ , and then use this estimate to get an upper bound  $d_{ub}$  on  $d_{max}$  by setting  $d_{ub} = \min\{n, \hat{s}_p^{1/p}\}$ .

**An improved sampling approach.** In order to describe the second ingredient for improving over the bounds of [23], we first recall their algorithm. In the first step, their algorithm simultaneously attempts to sample a copy of each odd cycle and star in the decomposition of  $H$ . Then if all individual sampling attempt succeed, the algorithm proceeds to check if the sampled copies are connected in  $G$  in a way that is consistent with the non-decomposition edges of  $H$ . However, it is easy to see that this approach is wasteful. Even if all but one of the simultaneous sampling attempts of the first step succeed, the algorithm starts over. For example, if  $D^*(H)$  consists of a star and a triangle, then in the first step their algorithm attempts to sample simultaneously a star and a triangle, and in the case that, say, a triangle is sampled but the star sampling attempt fails, then the sampled triangle is discarded, and the algorithm goes back to the beginning of the first step.

To remedy this, in the first step our algorithm invokes the star- and odd-cycle samplers for every basic component in  $D^*(H)$ , until all samplers return an *actual* copy of of the requested component. This ensures that we proceed to the next step of verifying  $H$  only once we have actual copies of all the basic components. We then continue to check if these copies can be

<sup>7</sup> This is effectively equivalent to rejection sampling where first  $v$  is “kept” with probability  $d(v)/d_{ub}$ , and then a neighbor of  $v$  is sampled uniformly at random.

extended to a copy of  $H$  in  $G$ , as before. While this is a subtle change, it is exactly what allows us to replace the dependency in the maximum number of potential copies of the basic components, to a dependency in the actual number of copies in  $G$ .

We note that for motifs  $H$  whose decomposition has repeating smaller sub-motifs, our sampling approach can be used recursively, which can be more efficient. That is, instead of decomposing  $H$  to its most basic components, stars and odd-cycles, we can consider decomposing it to collections of more complex components. For example, if  $H$  has such a collection  $H_1 \subset H$  that is repeated more than once, then it is more beneficial to first try and sample all of the copies of  $H_1$  (as well as the other components of  $H$ ) and only then try to extend these copies to  $H$ . The sampling of the  $H_1$  copies can then be performed by a recursive call to the motif sampler. It can be shown that for any repeated motif  $H_1$  in the decomposition of  $H$ , applying the recursive sampling process results in an improved upper bound.

### From sampling to estimating

In order to obtain a  $(1 \pm \epsilon)$ -estimate of  $\bar{h}$ , we can use the sampling algorithm as follows. Consider a single sampling attempt in which we first sample all basic components of  $D^*(H)$  (at some cost  $Q$ ), and then perform all pair queries between the components to check if the sampled components induce a copy of  $H$  (at cost  $O(|H|^2)$ ). By the above description such an attempt succeeds with probability that depends on the counts of the basic components of  $D^*(H)$  and on the count  $\bar{h}$ . Hence we can think of the success probability of each attempt as a coin toss with bias  $p$ , where  $p$  depends only on the counts of the components and  $\bar{h}$ . By standard concentration bounds, using  $\Theta(1/(p\epsilon^2))$  sampling attempts, we can compute a  $(1 \pm \epsilon)$ -estimate  $\hat{p}$  of  $p$ . Since we can also get  $(1 \pm \epsilon)$ -multiplicative estimates of the counts of each basic component without asymptotically increasing the running time, we can deduce from  $\hat{p}$  a  $(1 \pm \Theta(\epsilon))$ -estimate of  $\bar{h}$ . See the full version for more details.

## 3.2 Decomposition-optimal lower bounds

**Theorem 6 follows from Theorem 7.** To prove Theorems 6 and 7, we first explain why given Theorem 7, Theorem 6 follows. We then describe at a high level a family of graphs  $\mathcal{G}$  in which sampling copies of a given motif is hard.

At a high level, Theorem 7 states that given (1) a decomposition  $D$  and (2) a set of good counts  $\{\bar{c}_i\}_{i \in [r]}$ , we can construct (3) a motif  $H_D$  (such that  $D$  is an optimal decomposition of  $H_D$ ) and (4) a family of graphs  $\mathcal{G}$  such that expected number of queries required to sampling copies of  $H_D$  in  $\mathcal{G}$  is

$$\max_{i \in [r]} \{cost(C_i)\} \cdot \frac{\prod \bar{c}_i}{\bar{h}}.$$

Theorem 6 states that given (a) a decomposition  $D$  and (b) a (realizable) decomposition cost DC, that there exists (c) a motif  $H_D$  and (d) a family of graphs for which the decomposition-cost of  $G, D$  and  $H_D$  is DC, and sampling copies of  $H_D$  in graphs of  $\mathcal{G}$  requires  $\Omega(\text{DC})$  queries.

To prove that Theorem 6 follows from Theorem 7, we then prove that given (a) and (b), we can specify a set of counts which both satisfies  $\text{DC} = \max_{i \in [r]} \{cost(C_i)\} \cdot \frac{\prod \bar{c}_i}{\bar{h}}$  and which is good. Since the set of counts is good, we can invoke Theorem 7, and get that there exists a motif  $H_D$  and a family of graphs in which it is hard to sample copies of  $H_D$ . Therefore, in the rest of the section we focus our attention on the proof of Theorem 7.

**Ideas behind the proof of Theorem 7.** Given a graph decomposition  $D$ , values  $n, m, \bar{h}$  and a set of counts  $\bar{c}_1, \dots, \bar{c}_r$  of its basic components, our lower bound proof starts by defining a motif  $H_D$ , and a family of graphs  $\mathcal{G}$  such that the following holds.

- The optimal decomposition of  $H_D$  is  $D$ ;
- For every  $G \in \mathcal{G}$  and  $O_{k_i}, S_{p_j} \in D$ , their number of copies in  $G$  is  $\Theta(\bar{o}_{k_i})$  and  $\Theta(\bar{s}_{p_j})$ , respectively;
- The number of copies of  $H$  in  $G$  is  $\Theta(\bar{h})$
- Sampling a uniformly distributed copy of  $H_D$  in a uniformly chosen  $G$  in  $\mathcal{G}$ , requires  $\Omega(\min\{m, DC\})$  queries in expectation.

There are several challenges in proving our lower bound. First, as they are very general and work for any given decomposition  $D$  that contains at least one odd cycle, there are many sub cases that need to be dealt with separately, depending on the mixture of components in  $D$ . Second, the lower bound term does not only depend on the different counts, but also on the relations between them, which determines the component that maximizes  $\text{cost}(C_i)$ . As mentioned previously, our lower bound only holds for the case that the max cost is due to an odd cycle component. It remains an open question whether a similar lower bound can be proven for the case that the max cost is due to a star, or whether in that case a better algorithm exists. The authors suspect the latter option. Third, as in most previous lower bounds for motif sampling and counting, we prove the hardness of the task by “hiding” a constant fraction of the copies of  $H_D$ , so that the existence of these copies depends on a small set of crucial edges. That is, we prove that we can construct the family of graphs  $\mathcal{G}$ , such that for every  $G \in \mathcal{G}$ , a specific set of  $t$  crucial edges, for some small  $t$  that depends on the basic counts and  $\bar{h}$ , contributes  $\Theta(\bar{h})$  copies of  $H_D$ . We then prove that detecting these edges requires many queries (this is formalized by a reduction from a variant of the SET-DISJOINTNESS communication complexity problem, based on the framework of [19]). This approach of constructing many copies of  $H_D$  which all depend on small set of crucial edges, leads the construction of the graphs  $\mathcal{G}$  to contain very dense components, which in turn causes correlations between the counts of the different components. A significant challenge is therefore to define the motif  $H_D$  and the graphs of  $\mathcal{G}$  in a way that satisfies all given counts simultaneously.

In each graph  $G$  in the hard family  $\mathcal{G}$ , we have a corresponding “gadget” to each of the components of  $D$ . Let  $k_1$  denote (one of) the maximum-cost odd-cycle components. For each odd-cycle component  $O_{k_i}$  for  $k_i \neq k_1$ , we define either a **few-cycles-gadget** or a **cycle-gadget** that induce  $\bar{o}_{k_i}$  odd cycles of length  $k_i$  according to the relation between  $k_i$  and  $k_1$ . For each star component  $S_{p_j}$  we define a **star-gadget** that induces  $\bar{s}_{p_j}$  many  $p_j$ -stars. The maximum-cost cycle component  $O_{k_1}$  has a different gadget, a **CC-gadget**. This gadget is used to hide the set of  $t$  crucial edges, and allows us to parameterize the complexity in terms of the cost  $\text{cost}\{O_{k_1}\}$ .

To formally prove the lower bound we make use the framework introduced in [19], which uses reductions from communication complexity problems to motif sampling and counting problems in order to prove hardness results of these latter tasks. This allows us to prove that one cannot, with high probability, witness an edge from the set of  $t$  hidden edges, unless  $\Omega(m/t)$  queries are performed. This in turn implies that one cannot, with high probability, witness a copy of  $H_D$  contributed by these edges. Hence, we obtain a lower of  $\Omega(m/t)$  for the task of outputting a uniformly sampling. Setting  $t$  appropriately gives the desired bound.

## 4 Upper Bounds for Sampling Arbitrary Motifs

In this section we present our improved sampling algorithm. Recall that our upper bound improvement has two ingredients, an improved star sampler, and an improved sampling approach. We start with presenting the improved star sampling algorithm.

### 4.1 An optimal ( $\ell_p$ ) star-sampler

Our star sampling procedure assumes that it gets as a parameter a value  $\hat{s}_p$  which is a constant-factor estimate of  $\bar{s}_p$ . This value can be obtained by invoking one of the star estimation algorithm of [2, 17].

► **Lemma 12** ([2], Theorem 1). *Given query access to a graph  $G$  and an approximation parameter  $\epsilon$ , there exists an algorithm, *Moment-Estimator*, that returns a value  $\hat{s}_p$ , such that with probability at least  $2/3$ ,  $\hat{s}_p \in [\bar{s}_p, 2\bar{s}_p]$ . The expected query complexity and running time  $O\left(\min\left\{m, \min\left\{\frac{m \cdot n^{p-1}}{\bar{s}_p}, \frac{m}{\bar{s}_p^{1/p}}\right\} \cdot \log \log n\right\}\right)$ .*

Given an estimate  $\hat{s}_p$  on  $\bar{s}_p$ , our algorithm sets an upper bound<sup>8</sup>  $d_{ub}$  on the maximal degree,  $d_{ub} = \min\{n, \hat{s}_p\}$ . It then tries to sample a copy of a  $p$ -star as follows. In each sampling attempt it samples a single edge  $(v_0, v_1)$ , and then performs  $p - 1$  neighbor queries  $nbr(v_0, i_j)$  for  $j = 2 \dots p$ , where each  $i_j$  is chosen independently and uniformly at random from  $[d_{ub}]$ . In order to ensure that the sampled neighbors are distinct, and to avoid multiplicity issues, a  $p$ -star is returned only if its petals are sampled in ascending order of ids. In every such sampling attempt, each specific  $p$ -star is therefore sampled with equal probability  $\frac{1}{m \cdot d_{ub}^{p-1}}$ .

Hence, invoking the above  $\frac{m \cdot d_{ub}^{p-1}}{\bar{s}_p}$  times, in expectation, returns a uniformly distributed copy of a  $p$ -star.

**Sample-a-Star**( $p, n, \hat{s}_p$ )

1. Let  $d_{ub} = \min\{n, (c_p \cdot \hat{s}_p)^{1/p}\}$  for a value  $c_p$  as specified in the proof of Theorem 1.
2. While **TRUE**:
  - a. Perform a uniform edge query, and denote the returned edge  $(v_0, v_1)$ .
  - b. Choose  $p-1$  indices  $i_2, \dots, i_p$  uniformly at random in  $[d_{ub}]$  (with replacement).
  - c. For every  $j \in [2..p]$ , query the  $i_j^{\text{th}}$  neighbor of  $v_0$ . Let  $v_2, \dots, v_p$  be the returned vertices, if all queries returned a neighbor. Otherwise break.
  - d. If  $id(v_2) < id(v_3) < \dots < id(v_p)$ , then **return**  $(v_0, v_1, \dots, v_p)$ .

► **Theorem 13.** *Assume that  $\hat{s}_p \in [\bar{s}_p, c \cdot \bar{s}_p]$  for some small constants  $c$ . The procedure **Sample-a-Star**( $p, \hat{s}_p$ ) returns a uniformly distributed  $p$ -star in  $G$ . The expected query complexity of the procedure is  $O\left(\min\left\{\frac{m \cdot n^{p-1}}{\bar{s}_p}, \frac{m}{\bar{s}_p^{1/p}}\right\}\right)$ .*

**Proof.** Let  $c_p$  denote the minimal value such that for every  $k \in [n]$ ,  $c_p \cdot \binom{k}{p} \geq k^p$  (note that  $c_p = \Theta(p!)$ ). Then  $\bar{s}_p = \sum_{v \in V} \binom{d(v)}{p} > \binom{d_{max}}{p} \geq d_{max}^p / c_p$ , and by the assumption on  $\hat{s}_p$ ,  $d_{max} < (c_p \cdot \bar{s}_p)^{1/p} \leq (c_p \cdot \hat{s}_p)^{1/p}$ . It follows by the setting of  $d_{ub} = \min\{n, (c_p \cdot \hat{s}_p)^{1/p}\}$  in Step 1, that  $d_{ub} \geq d_{max}$ .

<sup>8</sup> Observe that  $d_{max}$  is  $d_{max} = \max_v d(v)$ , while  $d_{ub}$  is simply a bound on  $d_{max}$ , so that  $d_{max} \leq d_{ub}$ .

Consider a specific copy  $\bar{S}_p = (a_0, a_1, \dots, a_p)$  of a  $p$ -star in  $G$ , where  $a_0$  is the star center and  $a_1$  through  $a_p$  are its petals in ascending id order. In each iteration of the while loop, the probability that  $\bar{S}_p$  is returned is

$$\begin{aligned} \Pr[\bar{S}_p \text{ is returned}] &= \Pr[(a_0, a_1) \text{ is sampled in Step 2a}] \\ &\quad \cdot \Pr[a_2, \dots, a_p \text{ are sampled in Step 2b}] \\ &= \frac{1}{m} \cdot \frac{1}{d_{ub}^{p-1}}. \end{aligned} \tag{2}$$

Note the the last equality crucially depends on  $d(v) \leq d_{max} \leq d_{ub}$  for all  $v \in V$ . (Indeed, if there exists a vertex  $v$  with degree  $d(v) > d_{ub}$ , then some of its incident stars will have zero probability of being sampled.) Hence, each copy is sampled with equal probability, implying that the procedure returns a uniformly distributed copy of a  $p$ -star.

We now turn to bound the expected query complexity. It follows from Equation 2 and the setting of  $d_{ub}$ , that the success probability of a single invocation of the while loop is  $\frac{\bar{s}_p}{m \cdot d_{ub}^{p-1}}$ . Hence, the expected number of invocations is  $\frac{m \cdot d_{ub}^{p-1}}{\bar{s}_p}$ . It follows that, for a constant  $p$ , the expected number of invocations is

$$O\left(\frac{m \cdot \min\{n, (c_p \cdot \bar{s}_p)^{1/p}\}^{p-1}}{\bar{s}_p}\right) = O\left(\min\left\{\frac{m \cdot n^{p-1}}{\bar{s}_p}, \frac{m}{\bar{s}_p^{1/p}}\right\}\right).$$

Since the query complexity and running time of a single invocation of the while loop are constant, the above is also a bound on the expected query complexity and running time of the while loop.  $\blacktriangleleft$

In the full version of this paper, we explain how algorithm **Sample-a-Star** can be slightly modified to produce an  $\ell_p$ -sampler, **Sublinear- $\ell_p$ -Sampler** as specified in Theorem 2.

## 4.2 General motif sampler

Our algorithm for sampling uniform copies of a motif  $H$  in a graph  $G$  relies on the above star sampler, and the odd cycle sampler of [23].

► **Lemma 14** (Lemma 3.3 in [23], restated). *There exists a procedure that, given a parameter  $k$  and an estimate  $\hat{m} \in [m, 2m]$ , samples each specific copy of an odd cycle of length  $k$  with probability  $1/m^{k/2}$ .*

It follows that by repeatedly invoking the procedure above until an odd cycle is returned we can get an odd cycle sampling algorithm.

► **Corollary 15.** *There exists a procedure, **Sample-Odd-Cycle**, that, given an estimate  $\hat{m} \in [m, 2m]$ , returns a uniformly distributed copy of an odd cycle of length  $k$ . The expected query complexity is  $O\left(\min\left\{m \log n, n + m, \frac{m^{k/2}}{\bar{o}_k}\right\}\right)$ , where  $\bar{o}_k$  denotes the number of odd cycles of length  $k$  in  $G$ .*

We also use the following algorithm from [25] to obtain an estimate of  $m$ .

► **Theorem 16** ([25], Theorem 1, restated). *There exists an algorithm that, given query access to a graph  $G$ , the number of vertices  $n$ , and a parameter  $\epsilon$ , returns a value  $\tilde{m}$ , such that with probability at least  $2/3$ ,  $\tilde{m} \in [m, (1 + \epsilon)m]$ . The expected query complexity and running time of the algorithm is  $O(n/\sqrt{m}) \cdot (\log \log n/\epsilon^2)$ .*

Our motif sampling algorithm invokes the star-sampler and odd-cycles-sampler for each of the star and odd-cycles components in  $D^*(H)$ , respectively. Once actual copies of all the components are sampled, it checks whether they form a copy of  $H$  in  $G$ , using  $O(|H|^2) = O(1)$  additional pair queries.

**Sample- $H$  ( $H, n$ )**

1. Compute a 2-factor estimate  $\hat{m}$  of  $m$  by invoking the algorithm of [25] with  $\epsilon = 1/2$  for  $10 \log n$  times, and letting  $\hat{m}$  be the median of the returned values.
2. Compute an optimal decomposition of  $H$ ,  $D^*(H) = \{O_{k_1}, \dots, O_{k_q}, S_{p_1}, \dots, S_{p_\ell}\}$ .
3. For every  $S_{p_i}$  in  $D$ , invoke algorithm **Moment-Estimator** with  $\epsilon = 1/2$  and  $r = p_i$  for  $t = 10 \log(n \cdot \ell)$  times to get  $t$  estimates of  $\bar{s}_{p_i}$ . Let  $\hat{s}_{p_i}$  be the median value among the  $t$  received estimates of each  $S_{p_i}$ .
4. While **True**:
  - a. For every  $i \in [q]$  do:
    - i. Invoke **Sample-Odd-Cycle**( $k_i, \hat{m}$ ), and let  $\bar{O}_i$  be the returned odd cycle.
  - b. For every  $i \in [\ell]$  do:
    - i. Invoke **Sample-a-Star**( $p_i, n, \hat{s}_{p_i}$ ), and let  $\bar{S}_i$  be the returned  $s_j$ -star.
  - c. Perform  $O(|H|^2)$  pair queries to verify whether the set of components  $\{\bar{O}_1, \dots, \bar{O}_q, \bar{S}_1, \dots, \bar{S}_\ell\}$  can be extended to a copy of  $H$  in  $G$ .
  - d. If a copy of  $H$  is discovered, then **return** it.
  - e. If the number of queries performed exceeds  $n + \hat{m}$ , then query all edges of the graph<sup>a</sup> and output a uniformly distributed copy of  $H$ .

<sup>a</sup> by either performing  $n + 2m$  degree and neighbor queries, or  $10m \log n$  uniform edge queries

We are now ready to prove our main upper bound theorem, which we recall here.

► **Theorem 17.** *Let  $G$  be a graph over  $n$  vertices and  $m$  edges, and let  $H$  be a motif such that  $D^*(H) = \{O_{k_1}, \dots, O_{k_q}, S_{p_1}, \dots, S_{p_\ell}\} = \{C_i\}_{i \in [r]}$ . There exists an algorithm, **Sample- $H$** , that returns a copy of  $H$  in  $G$ . With probability at least  $1 - 1/\text{poly}(n)$ , the returned copy is uniformly distributed in  $G$ . The expected query complexity of the algorithm is*

$$O(\min\{\text{DECOMP-COST}(G, H, D^*(H)), m\}) \cdot \log n \log \log n.$$

**Proof.** By Theorem 16, when invoked with a value  $\epsilon = 1/2$ , the edge estimation algorithm of [25] returns a value  $\tilde{m}$  such that, with probability at least  $2/3$ ,  $\tilde{m} \in [m, 1.5m]$ . Hence, with probability at least  $1 - 1/3n^2$ , the median value  $\hat{m}$  of the  $10 \log n$  invocations is such that  $\hat{m} \in [m, 1.5m]$ . We henceforth condition on this event.

We next prove that with probability at least  $1 - 1/3n^2$ , all the computed  $\hat{s}_{p_i}$  values are good estimates of  $\bar{s}_{p_i}$ . By Lemma 12, for a fixed  $p_i$ , with probability at least  $2/3$ , the value returned from **Moment-Estimator** is in  $[\hat{s}_{p_i}, 1.5 \cdot \hat{s}_{p_i}]$ . Therefore, the probability that the median value of the  $t = 10 \log(n\ell)$  invocations in Step 3 is outside this range is at most  $1/(3\ell n^2)$ . Hence, taking a union bound over all  $i \in [\ell]$ , with probability at least  $1 - 1/3n^2$ , for every  $i \in [\ell]$ ,  $\hat{s}_{p_i} \in [\bar{s}_{p_i}, 1.5 \cdot \bar{s}_{p_i}]$ . We henceforth condition on this event as well.

Fix a copy  $H'$  of  $H$  in  $G$ , and let  $O'_1, \dots, O'_q, S'_1, \dots, S'_\ell$  be its cycles and stars, corresponding to those of  $D^*(H)$ . By Corollary 15, for each  $O'_i$ , its probability of being returned in Step 4(a)i is  $1/\bar{o}_{k_i}$ . Similarly, by Lemma 1, for each  $S'_i$ , its probability of being returned in Step 4(b)i is  $1/\bar{s}_{p_i}$ . Therefore, in the case that the number of queries does not exceed  $\hat{m}$ , in every iteration

of the loop, each specific copy of  $H$  is returned with equal probability  $\frac{1}{\prod_{i=1}^q \bar{o}_{k_i} \cdot \prod_{i=1}^{\ell} \bar{s}_{p_i}}$ .<sup>9</sup> Hence, once a copy of  $H$  is returned, it is uniformly distributed in  $G$ . In the case that the number of queries exceeds  $\hat{m}$ , the algorithm either performs  $n + 2m$  queries to query all the neighbors of all vertices, or  $10m \log n$  queries, in order to discover all edges with high probability. In the former case, the entire graph  $G$  is known. In the latter case, by the coupon collector analysis, the probability that all edges are known at the end of the process is at least  $1 - 1/3n^2$ . Hence, with probability at least  $1 - 1/3n^2$ , at the end of this process, a uniformly distributed copy of  $H$  is returned.

It remains to bound the query complexity. By Lemma 12, Step 3 takes  $\sum_{p_i} t \cdot \min \left\{ \frac{m \cdot n^{p_i-1}}{\bar{s}_{p_i}}, \frac{m}{\bar{s}_{p_i}^{1/p_i}} \right\} \cdot \log n \log \log n$  queries in expectation. By the above discussion, it holds that the expected number of invocations of the while loop is  $\frac{\prod_{i=1}^q \bar{o}_{k_i} \cdot \prod_{i=1}^{\ell} \bar{s}_{p_i}}{\bar{h}}$ . Furthermore, by Lemma 1, the expected query complexity of sampling each  $S_{p_i}$  is  $\min \left\{ \frac{m \cdot n^{p_i-1}}{\bar{s}_{p_i}}, \frac{m}{\bar{s}_{p_i}^{1/p_i}} \right\}$ . By Lemma 15, the expected running time of each invocation of the  $k_i$ -cycle sampler is  $O \left( \frac{m^{k_i/2}}{\bar{o}_{k_i}} \right)$ . The complexity of Step 4c is  $O(|H|^2) = O(1)$  queries, and is subsumed by the complexity of the other steps. Hence, the expected cost of each invocation of the while loop is

$$\max_{i \in [q]} \left\{ \frac{m^{k_i/2}}{\bar{o}_{k_i}} \right\} + \max_{i \in [\ell]} \left\{ \min \left\{ \frac{m}{\bar{s}_{p_i}^{1/p_i}}, \frac{m \cdot n^{p_i-1}}{\bar{s}_{p_i}} \right\} \right\} = \max_{i \in [q]} \left\{ \frac{m^{k_i/2}}{\bar{o}_{k_i}} \right\} + \min \left\{ \frac{m}{\bar{s}_p^{1/p}}, \frac{m \cdot n^{p-1}}{\bar{s}_p} \right\},$$

where the equality holds since the maximum of the second term is always achieved by the largest star in the decomposition,  $S_p$ . Also, due to Step 4e and the assumption on  $\hat{m}$ , the query complexity of algorithm is always bounded by  $O(\min\{m \log n, n + m\})$ . Therefore, the overall expected query complexity is the minimum between  $O(\min\{m \log n, n + m\})$  and

$$\begin{aligned} & O \left( \left( \max_{i \in [q]} \left\{ \frac{m^{k_i/2}}{\bar{o}_{k_i}} \right\} + \min \left\{ \frac{m \cdot n^{p-1}}{\bar{s}_p}, \frac{m}{\bar{s}_p^{1/p}} \right\} \cdot \log n \log \log n \right) \cdot \frac{\prod_{i \in [r]} \bar{c}_i}{\bar{h}} \right) \\ &= O \left( \min \left\{ \max_{i \in [r]} \{ \text{cost}(C_i) \} \cdot \frac{\prod \bar{c}_i}{\bar{h}}, m \right\} \cdot \log n \log \log n \right) \\ &= O \left( \min \{ \text{DECOMP-COST}(G, H, D^*(H)), m, n \} \cdot \log n \log \log n \right), \end{aligned}$$

as claimed.  $\blacktriangleleft$

## A Related Work

We note that some of the works were mentioned before, but we repeat them here for the sake of completeness. Over the past decade, there has been a growing body of work investigating the questions of approximately counting and sampling motifs in sublinear time. These questions were considered for various motifs  $H$ , classes of  $G$ , and query models.

The study of sublinear time estimation of motif counts was initiated by the works of Feige [22] and of Goldreich and Ron [25] on approximating the average degree in general graphs. Feige [22] investigated the problem of estimating the average degree of a graph, denoted  $d_{\text{avg}}$ , when given query access to the degrees of the vertices. By performing a careful variance analysis, Feige proved that  $O\left(\sqrt{n/d_{\text{avg}}}/\epsilon\right)$  queries are sufficient in order to obtain a  $(\frac{1}{2} - \epsilon)$ -approximation of  $d_{\text{avg}}$ . He also proved that a better approximation ratio cannot be achieved in sublinear time using only degree queries. The same problem was then considered by Goldreich and Ron [25]. Goldreich and Ron proved that an  $(1 + \epsilon)$ -approximation can be achieved with  $O\left(\sqrt{n/d_{\text{avg}}}\right) \cdot \text{poly}(1/\epsilon, \log n)$  queries, if neighbor queries are also allowed. Building on these ideas, Gonen et al. [26] considered the problem of approximating the number of  $s$ -stars in a graph. Their algorithm only assumed neighbor and degree queries. In [2], Aliakbarpour, Biswas, Gouleakis, Peebles, and Rubinfeld and Yodpinyanee considered the same problem of estimating the number of  $s$ -stars in the augmented edge queries model, which allowed them to circumvent the lower bounds of [26] for this problem. In [17], Eden, Ron and Seshadhari again considered this problem, and presented improved bound for the case where the graph  $G$  has bounded arboricity. In [13, 16, 18], Eden, Ron and Seshadhari considered the problems of estimating the number of  $k$ -cliques in general and in bounded arboricity graphs, in the general graph query model, and gave matching upper and lower bounds. In [40], Tětek considers both the general and the augmented query models for approximately counting triangles in the super-linear regime. In [19], Eden and Rosenbaum presented a framework for proving motif counting lower bounds using reduction from communication complexity, which allowed them to reprove the lower bounds for all of the variants listed above.

In [20, 14], Eden and Rosenbaum and Ron has initiated the study of sampling motifs (almost) uniformly at random. They considered the general graph query model, and presented upper and matching lower bounds up to  $\text{poly}(\log n/1/\epsilon)$  factors, for the task of sampling edges almost uniformly at random, both for general graphs and bounded arboricity graphs. Recently, Tětek and Thorup [37] presented an improved analysis which reduced the dependency in

$\epsilon$  to  $\log(1/\epsilon)$ . This result implies that for all practical applications, the edge sampler is essentially as good as a truly uniform sampler. They also proved that given access to what they refer to as hash-based neighbor queries, there exists an algorithm that samples from the exact uniform distribution. The authors of [14] also raised the question of approximating vs. sampling complexity, and gave preliminary results that there exists motifs  $H$  (triangles) and classes of graphs  $G$  (bounded arboricity graphs) in which approximating the number of  $H$ 's is strictly easier than sampling an almost uniformly distributed copy of  $H$ . This question was very recently resolved by them, proving a separation for the tasks of counting and uniformly sampling cliques in bounded arboricity graphs [15].

A significant result was achieved recently, when Assadi, Kapralov and Khanna gave an algorithm for approximately counting the number of copies of any given general  $H$ , in the edge queries augmented query model. They also gave a matching lower bound for the case that  $H$  is an odd cycle. Fichtenberger, Gao and Peng presented a cleaner algorithm with a much simplified analysis for the same problem, that also returns a uniformly distributed copy of  $H$ .

Another query model was suggested recently by Beame et al. [6], which assumes access to only *independent set* (IS) queries or *bipartite independent set* (BIS) queries. Inspired by group testing, IS queries allow to ask whether a given set  $A$  is an independent set, and BIS queries allow to ask whether two sets  $A$  and  $B$  have at least one edge between them. In this model they considered the problem of estimating the average degree and gave an  $O(n^{2/3}) \cdot \text{poly}(\log n)$  algorithm using IS queries, and  $\text{poly}(\log n)$  algorithm using BIS queries. Chen, Levi and Waingarten [10] later improved the first bound to  $O(n/\sqrt{m}) \cdot \text{poly}(\log n)$  and also proved it to be optimal.

## Abstract

In this work, we present an abstract framework for some algebraic error-correcting codes with the aim of capturing codes that are list-decodable to capacity, along with their decoding algorithm. In the polynomial ideal framework, a code is specified by some ideals in a polynomial ring, messages are polynomials and their encoding is the residue modulo the ideals. We present an alternate way of viewing this class of codes in terms of linear operators, and show that this alternate view makes their algorithmic list-decodability amenable to analysis.

Our framework leads to a new class of codes that we call *affine Folded Reed-Solomon codes* (which are themselves a special case of the broader class we explore). These codes are common generalizations of the well-studied Folded Reed-Solomon codes and Univariate Multiplicity codes, while also capturing the less-studied Additive Folded Reed-Solomon codes as well as a large family of codes that were not previously known/studied.

More significantly our framework also captures the algorithmic list-decodability of the constituent codes. Specifically, we present a unified view of the decoding algorithm for ideal-theoretic codes and show that the decodability reduces to the analysis of the distance of some related codes. We show that good bounds on this distance lead to capacity-achieving performance of the underlying code, providing a unifying explanation of known capacity-achieving results. In the specific case of affine Folded Reed-Solomon codes, our framework shows that they are list-decodable up to capacity (for appropriate setting of the parameters), thereby unifying the previous results for Folded Reed-Solomon, Multiplicity and Additive Folded Reed-Solomon codes.

## 1 Introduction

Reed-Solomon codes are obtained by evaluations of polynomial of degree less than  $k$  at  $n$  distinct points in a finite field  $\mathbb{F}$ . Folded-Reed-Solomon (FRS) codes are obtained by evaluating a polynomial at  $sn$  (carefully chosen) points that are grouped into  $n$  bundles of size  $s$  each, and then viewing the resulting  $sn$  evaluations as  $n$  elements of  $\mathbb{F}^s$ . Multiplicity codes are obtained by evaluating the polynomial, and  $s - 1$  of its derivatives and again viewing the resulting  $sn$  evaluations as  $n$  elements of  $\mathbb{F}^s$ .

This “bundling” (or folding, as it is called for FRS codes) in FRS codes and Multiplicity codes may be viewed at best as a harmless operation – it does not hurt the rate and (relative) distance of a code which is already optimal in these parameters. But far from merely being harmless, in the context algorithmic list-decoding, bundling has led to remarkable improvements and to two of the very few explicit capacity achieving codes in the literature. Indeed the only other codes that achieve list-decoding capacity algorithmically and do not use one of the above codes as an ingredient are the Folded Algebraic-Geometric codes, which also use bundling. Despite this central role, the bundling operation is not well-understood algebraically. Indeed it seems like an “ad hoc” operation rather than a principled one. Unearthing what bundling is and understanding when and why it turns out to be so powerful is the primary goal of this work, and we make some progress towards this.

Turning to the algorithms for list-decoding the above codes close to capacity, there are two significantly different ones in the literature. A (later) algorithm due to Guruswami and Wang [6]<sup>1</sup> which seems more generalizable, and the original algorithm of Guruswami and Rudra [3] which is significantly more challenging to apply to multiplicity codes (see [9]). In both cases, while the algorithm for FRS works in all (reasonable) settings, the algorithms for multiplicity codes only work when the characteristic of the field is larger than the degrees of the polynomials in question. Looking more closely at FRS codes, part of the careful choice of bundling in FRS codes is to pick each bundle to be a geometric progression. If one were to switch this to an arithmetic progression, then one would get a less-studied family codes called the Additive-FRS. It turns out the Additive-FRS codes are also known to be list-decodable to capacity but only via the original algorithm. Thus, the short summary of algorithmic list-decoding is that there is no short summary! Algorithms tend to work but we need to choose carefully and read the fine print.

The goal of this paper is to provide a unifying algebraic framework that (a) captures bundling algebraically, (b) captures most of the algorithmic success also algebraically, leaving well-defined parts for combinatorial analysis and (c) leads to new codes that also achieve capacity. In this work we use basic notions from linear algebra and polynomial rings to present a unifying definition (see Definitions 3.1 and 4.4) that captures the codes very generally, and also the decoding ability (see Theorem 1.1). We elaborate on these below.

### Polynomial ideal codes

Our starting point is what we term “polynomial ideal codes”. A *polynomial ideal code* over a finite field  $\mathbb{F}$  and parameters  $k, s$  is specified by  $n$  pairwise relatively prime monic polynomials  $E_0(X), \dots, E_{n-1}(X) \in \mathbb{F}[X]$  of degree equal to  $s$ .<sup>2</sup> The encoding maps a message  $p \in \mathbb{F}^k$

<sup>1</sup> We note that the Guruswami-Wang algorithm is inspired by an idea due to Vadhan [12, Theorem 5.24] that shows that it suffices to interpolate a polynomial  $Q$  which is linear in the  $y$ -variables. However, the algorithm from [12] is not applicable to our setting since it uses polynomial factorization as well as analysis tools that are specific to Reed-Solomon codes. The further simplifications developed in [6] are key to the applicability in our setting.

<sup>2</sup> Here  $\mathbb{F}[X]$  refers to the ring of univariate polynomials in the variable  $X$  over the field  $\mathbb{F}$  while  $\mathbb{F}_{<k}[X]$  refers to the vector-space of polynomials in  $\mathbb{F}[X]$  of degree strictly less than  $k$ .

(interpreted as a polynomial of degree less than  $k$ ) to  $n$  symbols as follows:

$$\begin{aligned} \mathbb{F}_{<k}[X] &\longrightarrow (\mathbb{F}_{<s}[X])^n \\ p(X) &\longmapsto (p(X) \pmod{E_i(X)})_{i=0}^{n-1} \end{aligned}$$

The codes described above, Reed-Solomon, FRS, Multiplicity and Additive-FRS, are all examples of polynomial ideal codes. For Reed-Solomon codes, this is folklore knowledge: the evaluation point  $a_i$  corresponds to going mod  $E_i(X) = (X - a_i)$ . For any bundling of the Reed-Solomon codes this follows by taking product of the corresponding polynomials. For multiplicity codes of order  $s$ , the evaluation of a polynomial and its derivatives at  $a_i$  corresponds to going modulo  $E_i(X) = (X - a_i)^s$ .

The abstraction of polynomial ideal codes is not new to this work. Indeed Guruswami, Sahai and Sudan [4, Appendix A] already proposed these codes as a good abstraction of algebraic codes. Their framework is even more general, in particular they even consider non-polynomial ideals such as in  $\mathbb{Z}$ . They suggest algorithmic possibilities but do not flesh out the details. In this work we show that polynomial ideal codes, as we define them, are indeed list-decodable up to the Johnson radius. We note that the proof involves some steps not indicated in the previous work but for the most part this confirms the previous thinking.

The abstraction above also captures “bundling” (or folding) nicely - we get them by choosing  $E_i(X)$  to be a product of some  $E_{ij}(X)$ . But the above abstraction thus far fails to capture the capacity-achieving aspects of the codes (i.e., the benefits of this bundling) and the decoding algorithms. This leads us to the two main *novel* steps of this paper:

- We present an alternate viewpoint of polynomial ideal *codes* in terms of *linear operators*.
- We abstract the Guruswami-Wang linear-algebraic list-decoding *algorithm* in terms of *linear operators*.

The two sets of “linear operators”, in the codes and in the decoding algorithm, are not the same. But the linearity of both allows them to interact nicely with each other. We elaborate further below after introducing them.

### Linear operator codes

In this work, a linear operator is an  $\mathbb{F}$ -linear function  $L : \mathbb{F}[X] \rightarrow \mathbb{F}[X]$ . A *linear operator code* is characterized by a family of linear operators  $\mathcal{L} = (L_0, \dots, L_{s-1})$ , a set  $A = \{a_0, \dots, a_{n-1}\} \subseteq \mathbb{F}$  of evaluation points and  $k$  a degree parameter such that  $k \leq s \cdot n$ . The corresponding linear operator code, denoted by  $LO_k^A(\mathcal{L})$ , is given as follows:

$$\begin{aligned} \mathbb{F}_{<k}[X] &\longrightarrow (\mathbb{F}^s)^n \\ p(X) &\longmapsto (\mathcal{L}(p)(a_i))_{i=0}^{n-1} \end{aligned}$$

Linear operator codes easily capture polynomial ideal codes. For instance, the multiplicity codes are linear operator codes wherein the linear operators are the successive derivative operators. But they are also too general – even if we restrict the operators to map  $\mathbb{F}_{<k}[X]$  to itself, an operator allows  $k^2$  degrees of freedom.

We narrow this broad family by looking subfamilies of linear operators and codes. The specific subfamily we turn are what we call “ideal linear operators”. We say that linear operators  $L_0, \dots, L_{s-1}$  are *ideal linear operators* with respect to a set  $A$  of evaluation points if for every  $a \in A$ , the vector space

$$I^a(\mathcal{L}) = \{p \in \mathbb{F}[X] \mid \mathcal{L}(p)(a) = \bar{0}\}$$

is an ideal. (When the set of evaluation points is clear from context, we drop the phrase “with respect to  $A$ ”.) Linear operator codes corresponding to ideal linear operators are called *ideal linear operator codes* (see Definitions 4.1 and 4.4 for precise definitions).

It is not hard to see that a family of linear operators  $\mathcal{L} = (L_0, \dots, L_{s-1})$  has the ideal property if it satisfies the following *linearly-extendibility* property: There exists a matrix  $M(X) \in \mathbb{F}[X]^{s \times s}$  such that for all  $p \in \mathbb{F}[X]$  we have

$$\mathcal{L}(X \cdot p(X)) = M(X) \cdot \mathcal{L}(p(X)).$$

This motivates yet another class of linear operators and code: We say that an operator family  $\mathcal{L}$  is a *linearly-extendible linear operator* if such a matrix  $M(X)$  exists and the resulting code is said to be a *linearly-extendible linear operator code* (see Definitions 4.2 and 4.4 for precise definitions).

It turns out that these three definitions of codes – polynomial ideal codes, ideal linear operator codes and linearly-extendible linear operator codes – are equivalent (see Propositions 4.6 and 4.8 and Corollary 4.9). And while the notion of polynomial ideal codes captures the codes mentioned thus far naturally, the equivalent notion of linearly-extendible codes provides a path to understanding the applicability of the linear-algebraic list-decoding algorithm of Guruswami and Wang.

While it is not the case that every linearly-extendible linear operator code (and thus every polynomial ideal code) is amenable to this list-decoding algorithm, it turns out that one can extract a nice sufficient condition on the linear-extendibility for the algorithm to be well-defined. This allows us to turn the question of list-decodability into a quantitative one – how many errors can be corrected. And the linear operator framework now converts this question into analyzing the rank of an associated matrix.

The sufficient condition we extract is the following: we say that an operator  $L : \mathbb{F}[X] \rightarrow \mathbb{F}[X]$  is degree-preserving if  $\deg_X(Lf) \leq \deg_X(f)$  for all  $f \in \mathbb{F}[X]$ . Observe that any degree-preserving linear operator when restricted to  $\mathbb{F}_{<k}[X]$  can be represented by an upper-triangular matrix in  $\mathbb{F}^{k \times k}$ . A family of linear operators obtained by repeated iteration,  $\mathcal{L} = (L = L^0, L = L^1, L^2, \dots, L^{s-1})$  is called an *iterative* family. We associate with any degree-preserving family  $\mathcal{L} = (L_0, \dots, L_{s-1})$  of linear operators a simple matrix in  $\mathbb{F}^{s \times k}$  called  $\text{Diag}(\mathcal{L})$ , whose  $i$ th row is the diagonal of  $L_i$  and consider the code in  $\mathbb{F}^k$  generated by  $\text{Diag}(\mathcal{L})$ .

The following theorem now shows that for any degree-preserving iterative linearly-extendible operator codes, lower bound on the distance of  $\text{Diag}(\mathcal{L})$  yields an upper bound on the list size obtained by the Guruswami-Wang algorithm, even when the number of errors approaches  $(1 - \text{rate})$  of the code.

► **Theorem 1.1.** *Suppose  $L : \mathbb{F}[X] \rightarrow \mathbb{F}[X]$  is a degree-preserving linear operator and  $A$  a set of evaluation points such that for  $\mathcal{L} = (L^0, L^1, \dots, L^{s-1})$  the corresponding code  $\mathcal{C}$  is a linearly-extendible linear operator code. Furthermore, if the matrix  $\text{Diag}(\mathcal{L}) \in \mathbb{F}^{s \times k}$  formed by stacking the diagonals of the  $s$  linear operators as the rows is the generator matrix of a code with distance  $1 - \frac{\ell}{k}$ , then,  $\mathcal{C}$  is list-decodable up to the distance  $1 - \frac{k}{(s-m+1)n} - \frac{1}{m}$  with list size  $q^\ell$  for any  $1 \leq m \leq s$ .*

We remark that our actual theorem is more general (see Theorem 5.2) where we further separate the role of linear operators used to build the code, from those that seed the decoding algorithm. But it immediately implies Theorem 1.1 above, which in turn already suffices to capture the capacity achieving decodability of FRS, multiplicity and additive-FRS codes. Regarding the aspect of the need to lower bound the distance of the code generated by

$\text{Diag}(\mathcal{L})$ , to bound the list size of the codes, we stress that for each of these codes the lower bound on the distance follows from fairly simple arguments. Indeed the generality of the arguments allows us to capture broader families of codes uniformly, as described next.

### A Common Generalization

Our framework leads very naturally to a *new* class of codes that we call the *Affine Folded Reed-Solomon* (Affine-FRS) codes: these are codes defined by ideals of the form  $\prod_{i=0}^{s-1} (X - \ell^{(i)}(a))$  where  $\ell(z) = \alpha z + \beta$  is any linear form and  $\ell^{(i)}(z) = \underbrace{\ell(\ell \dots \ell(z) \dots)}_{i \text{ times}}$ . These codes generalize

all the previously considered codes: The case  $\ell(z) = \gamma z$  are the FRS codes, the case  $\ell(z) = z$  are the Multiplicity codes, and the case  $\ell(z) = z + \beta$  are the Additive FRS codes!

► **Theorem 1.2** (Informal statement – see Theorem A.8). *Let  $\ell$  be any linear form such that either  $\text{ord}(\ell) \geq k$  or  $(\text{char}(\mathbb{F}) \geq k \text{ and } \beta \neq 0)$ <sup>3</sup>. Then the Affine-FRS codes corresponding to the linear form  $\ell$  are list-decodable up to capacity.*

Previously, even for the special case of the Additive FRS codes, list-decodability close to capacity was only achieved by the more involved algorithm of Guruswami & Rudra [3] and Kopparty [9] (see paragraph on Additive Folding and Footnote 4 in [2, Section III]). (A similar approach can be extended to cover the case of  $\text{ord}(\ell) \geq k$  in Theorem 1.2: however, it seems difficult to do so for the case when  $\text{ord}(\ell)$  is small.)

Thus, our Affine-FRS codes lead to the first common abstraction of the three codes as well as the first common algorithm for solving the list-decoding problem for these codes. (Furthermore, this algorithm is linear-algebraic.)<sup>4</sup> Arguably thus, even if the Affine-FRS codes had been studied previously, it is not clear that the ability to decode them for every choice of  $\ell(z)$  would be obvious.

## Organization

The rest of the paper is organized as follows. We begin with some preliminaries in Section 2. We then formally define polynomial ideal codes and linear operator codes in Sections 3 and 4 respectively. In Section 5, we discuss list-decoding algorithms for polynomial ideal codes. We first present the list-decoding algorithm for *all* polynomial ideal codes up to the Johnson radius in Section 5.1 and then the list-decoding algorithm beyond the Johnson radius for special families of linear operator codes in Section 5.2. Finally, we conclude by demonstrating how these results can be used to show that several well-known families of codes (Folded Reed-Solomon, multiplicity, additive Folded Reed-Solomon codes) as well as their common generalization affine folded Reed-Solomon achieve list-decoding capacity in Appendix A.

Throughout the paper, we skip the proofs of various claims due to space constraints. We refer the interested reader to the full version of the paper [1] for the complete proofs.

## 2 Notations and Preliminaries

We start with some notations that we follow in the rest of this paper.

- For a natural number  $n$ ,  $[n]$  denotes the set  $\{0, 1, \dots, n-1\}$ .
- $\mathbb{F}$  denotes a field.

<sup>3</sup>  $\text{ord}(\ell)$  refers to the smallest positive integer  $u$  such that  $\ell^{(u)}(z) = z$ .

## 56:6 Ideal-Theoretic Explanation of Capacity-Achieving Decoding

- For  $a, b, i, j \in \mathbb{Z}$ , where  $a, b, i, j \geq 0$  the bivariate monomial  $X^i Y^j$  is said to have  $(a, b)$ -weighted degree at most  $d$  if  $ai + bj \leq d$ .  $N(a, b)$  denotes the number of bivariate monomials of  $(1, a)$ -weighted degree at most  $b$ .
- For  $a, b \in \mathbb{Z}$ , a bivariate polynomial  $Q(X, Y)$  is said to have  $(a, b)$ -weighted degree at most  $d$ , if it is supported on monomials of  $(a, b)$ -weighted degree at most  $d$ .
- We say that a function  $f(n) : \mathbb{N} \rightarrow \mathbb{N}$  is **poly**( $n$ ), if there are constants  $c, n_0 \in \mathbb{N}$  such that for all  $n \geq n_0$ ,  $f(n) \leq n^c$ .
- $\mathbb{F}[X]$  is the ring of univariate polynomials with coefficients in  $\mathbb{F}$ , and for every  $k \in \mathbb{N}$ ,  $\mathbb{F}_{<k}[X]$  denotes the set of polynomials in  $\mathbb{F}[X]$  of degree strictly less than  $k$ .
- For a multivariate polynomial  $f(X_0, X_1, \dots, X_{n-1}) \in \mathbb{F}[X_0, X_1, \dots, X_{n-1}]$ ,  $\deg_{X_i}(f)$  denotes the degree of  $f$ , when viewing it as a univariate in  $X_i$ , with coefficients in the polynomial ring on the remaining variables over the field  $\mathbb{F}$ .

### Estimates on $N(a, b)$

We rely on the following simple lemma to estimate the number of bivariate monomials with  $(1, a)$ -weighted degree at most  $b$ . See the full version [1] for the proof.

► **Lemma 2.1.** *For every  $a, b \in \mathbb{N}$ , let  $N(a, b)$  denote the number of bivariate monomials with  $(1, a)$ -weighted degree at most  $b$ . Then, the following are true.*

1.  $N(a - 1, b) \geq b^2/2a$ .
2. For every  $\eta \in \mathbb{N}$ , if  $a$  divides  $b$ , then

$$N(a, b) - N(a, b - a\eta) - \eta(b - a\eta + 1) = a\eta(\eta + 1)/2.$$

### Johnson radius

► **Theorem 2.2** (List decoding up to Johnson radius). *Let  $q \in \mathbb{N}$  be a natural number. Any code with block length  $n$  and relative distance  $\delta$  over an alphabet of size  $q$  is (combinatorially) list decodable from  $(1 - \sqrt{1 - \delta})$  fraction of errors with list size at most  $n^2 q \delta$ .*

We have the following bound for codes, referred to popularly as the *Singleton bound* [11], though the bound appears earlier in the works of Joshi [7] and Komamiya [8].

► **Theorem 2.3** (Komamiya-Joshi-Singleton bound). *The rate  $R$  and the relative distance  $\delta$  of a code satisfy  $R + \delta \leq 1 + o(1)$ .*

In particular, for codes which lie on the Komamiya-Joshi-Singleton bound, we have that they are combinatorially list decodable from  $1 - \sqrt{R} - o(1)$  fraction errors with polynomial list size.

### List-decoding upto capacity

► **Definition 2.4** (List-decoding Capacity). *Consider a family of codes  $\mathcal{C} = \{C_1, \dots, C_n, \dots\}$  where  $C_n$  has rate  $\rho_n$  and block length  $n$  with alphabet  $\Sigma_n$ . Then,  $\mathcal{C}$  is said to achieve list-decoding capacity if  $\forall \varepsilon > 0$  there exists an  $n_0$  such that  $\forall n \geq n_0$  and all received words  $w \in \Sigma_n$ , there exists at most a polynomial number of codewords  $c \in C_n$  such that  $\delta(c, w) \leq (1 - \rho_n(1 + \varepsilon))$ .*

*Further, if there exists an efficient algorithm for finding all these codewords, then,  $\mathcal{C}$  is said to achieve list-decoding capacity efficiently. Ideally, we want to keep  $\Sigma_n$  as small as possible.*

### Chinese remainder theorem

We also rely on the following version of the Chinese Remainder Theorem for the polynomial ring.

► **Theorem 2.5.** *Let  $E_0(X), E_1(X), \dots, E_{s-1}(X)$  be univariate polynomials of degree equal to  $d$  over a field  $\mathbb{F}$  such that for every distinct  $i, j \in [s]$ ,  $E_i$  and  $E_j$  are relatively prime. Then, for every  $s$ -tuple of polynomials  $(r_0(X), \dots, r_{s-1}(X)) \in \mathbb{F}[X]^s$  such that each  $r_i$  is of degree strictly less than  $d$  (or zero), there is a unique polynomial  $p(X) \in \mathbb{F}[X]$  of degree at most  $d^s - 1$  such that for all  $i \in [s]$ ,*

$$p(X) = r_i(X) \pmod{E_i(X)}.$$

### Polynomial ideals

► **Definition 2.6.** *A subset  $I \subseteq \mathbb{F}[X]$  of polynomials is said to be an ideal if the following are true.*

- $0 \in I$ .
- For all  $p(X), q(X) \in I$ ,  $p + q \in I$ .
- For every  $p(X) \in I$  and  $q(X) \in \mathbb{F}[X]$ ,  $p(X) \cdot q(X) \in I$ .

For the univariate polynomial ring  $\mathbb{F}[X]$ , we also know that every ideal  $I$  is principal, i.e. there exists a polynomial  $p(X) \in I$  such that

$$I = \{p(X)q(X) : q(X) \in \mathbb{F}[X]\}.$$

## 3 Polynomial ideal codes

In this section, we discuss polynomial ideal codes in more detail, and see how this framework captures some of the well studied families of algebraic error correcting codes.

We start with the formal definition of polynomial ideal codes.

► **Definition 3.1 (polynomial ideal codes).** *Given a field  $\mathbb{F}$ , parameters  $s, k$  and  $n$  satisfying  $k < s \cdot n$ , the polynomial ideal code is specified by a family of  $n$  polynomials  $E_0, \dots, E_{n-1}$  in the ring  $\mathbb{F}[X]$  of univariate polynomials over the field  $\mathbb{F}$  satisfying the following properties.*

1. For all  $i \in [n]$ , polynomial  $E_i$  has degree exactly  $s$ .
2. The  $E_i$ 's are monic polynomials.
3. The polynomials  $E_i$ 's are pairwise relatively prime.

The encoding of the polynomial ideal code maps is as follows:

$$\begin{aligned} \mathbb{F}_{<k}[X] &\longrightarrow (\mathbb{F}_{<s}[X])^n \\ p(X) &\longmapsto (p(X) \pmod{E_i(X)})_{i=0}^{n-1} \end{aligned}$$

As is clear from the definition, polynomial ideal codes are linear over  $\mathbb{F}$  and have rate  $k/sn$  and relative distance  $(1 - (k - 1)/sn)$ . Since the sum of rate and relative distance satisfy the Komamiya-Joshi-Singleton bound, these codes are maximal-distance separable (MDS) codes.

We note that in general,  $E_i$ 's need not have the same degree, but for notational convenience, we work in the setting when each of them is of degree equal to  $s$ . We also note that these codes continue to be well defined even if the  $E_i$ 's are not relatively prime. In this case, the condition,  $k < s \cdot n$  is replaced by  $k$  being less than the degree of the lowest common multiple of  $E_0, E_1, \dots, E_{n-1}$ . However, the distance of the code suffers in this case, and such codes need not approach the Komamiya-Joshi-Singleton bound. We now observe that some of the standard and well studied family of algebraic error correcting codes are in fact instances of polynomial ideal codes for appropriate choice of  $E_0, E_1, \dots, E_{n-1}$ .

### 3.1 Some well known codes via polynomial ideals

The message space for all these codes is identified with univariate polynomials of degree at most  $k - 1$  in  $\mathbb{F}[X]$ . We assume that the underlying field  $\mathbb{F}$  is of size at least  $n$  for this discussion, else, we work over a large enough extension of  $\mathbb{F}$ .

#### Reed-Solomon Codes

Let  $a_0, a_1, \dots, a_{n-1}$  be  $n$  distinct elements of  $\mathbb{F}$ . In a Reed-Solomon code, we encode a message polynomial  $p(X) \in \mathbb{F}[X]_{<k}$  by its evaluation on  $a_0, a_1, \dots, a_{n-1}$ . To view these as a polynomial ideal code, observe that  $p(a_i) = p(X) \pmod{(X - a_i)}$ . Thus, we can set the polynomials  $E_i(X)$  in Definition 3.1 to be equal to  $(X - a_i)$  for each  $i \in [n]$ . Thus,  $s = 1$ . Clearly, the  $E_i$ 's are relatively prime since  $a_0, a_1, \dots, a_{n-1}$  are distinct.

#### Folded Reed-Solomon Codes [3]

Let  $\gamma \in \mathbb{F}_q^*$  be an element of multiplicative order at least  $s$ , i.e.  $\gamma^0, \gamma, \dots, \gamma^{s-1}$  are all distinct field elements. Further, let the set of evaluation points be  $A = \{a_0, \dots, a_{n-1}\}$  such that for any two distinct  $i$  and  $j$  the sets  $\{a_i, a_i\gamma, \dots, a_i\gamma^{s-1}\}$  and  $\{a_j, a_j\gamma, \dots, a_j\gamma^{s-1}\}$  are disjoint. In a Folded Reed-Solomon code, with block length  $n$  and folding parameter  $s$  is defined by the following encoding function.

$$p(X) \mapsto \left( p(a_i), p(a_i\gamma^1), \dots, p(a_i\gamma^{s-1}) \right)_{i=0}^{n-1}$$

Thus, these are codes over the alphabet  $\mathbb{F}^s$ .

To view these as polynomial ideal codes, we set  $E_i(X) = \prod_{j=0}^{s-1} (X - a_i\gamma^j)$ . Clearly, each such  $E_i$  is a polynomial of degree equal to  $s$ , and since for any two distinct  $i$  and  $j$  the sets  $\{a_i, a_i\gamma, \dots, a_i\gamma^{s-1}\}$  and  $\{a_j, a_j\gamma, \dots, a_j\gamma^{s-1}\}$  are disjoint, the polynomials  $E_0, E_1, \dots, E_{n-1}$  are all relatively prime.

To see the equivalence between these two viewpoints observe that  $p(a_i\gamma^j) = p(X) \pmod{(X - a_i\gamma^j)}$ . Moreover,  $(X - a_i\gamma^j)$  are all relatively prime as  $j$  varies in  $[s]$  for every  $i \in [n]$ . Thus, by the Chinese Remainder Theorem over  $\mathbb{F}[X]$ , there is a bijection between remainders of a polynomial modulo  $\{(X - a_i\gamma^j) : j \in [s]\}$  and the remainder modulo the product  $E_i = \prod_{j \in [s]} (X - a_i\gamma^j)$  of these polynomials.

#### Additive Folded Reed-Solomon Codes [3]

Additive Folded Reed-Solomon codes are a variant of the Folded Reed-Solomon codes defined above. Let  $\mathbb{F}_q$  have characteristic at least  $s$  and let  $\beta \in \mathbb{F}_q^*$ . Further, let the set of evaluation points be  $A = \{a_0, \dots, a_{n-1}\}$  where  $a_i - a_j \notin \{0, \beta, 2\beta, \dots, (s-1)\beta\}$  for distinct  $i$  and  $j$ . Here,  $s$  denotes the folding parameter. The encoding is defined as follows.

$$p(X) \mapsto \left( p(a_i), p(a_i + \beta), \dots, p(a_i + \beta(s-1)) \right)_{i=0}^{n-1}$$

Thus, these are also codes over the alphabet  $\mathbb{F}^s$ .

To view these as polynomial ideal codes, we set  $E_i(X) = \prod_{j=0}^{s-1} (X - a_i + \beta j)$ . Clearly, each such  $E_i$  is a polynomial of degree equal to  $s$ , and since  $a_i - a_j \notin \{0, \beta, 2\beta, \dots, (s-1)\beta\}$  for distinct  $i$  and  $j$ , the polynomials  $E_0, E_1, \dots, E_{n-1}$  are all relatively prime.

To see the equivalence between the two definitions, the argument is again identical to that for Folded Reed-Solomon codes discussed earlier in this section. We just observe  $(X - a_i + \beta j)$  are all relatively prime  $j$  varies in  $[s]$  for every  $i \in [n]$ , and thus by the Chinese Remainder

Theorem over  $\mathbb{F}[X]$ , there is a bijection between remainders of a polynomial modulo  $\{(X - a_i + \beta j) : j \in [s]\}$  and the remainder modulo the product  $E_i = \prod_{j \in [s]} (X - a_i + \beta j)$  of these polynomials.

### Univariate Multiplicity Codes [10]

Univariate multiplicity codes, or simply multiplicity codes are a variant of Reed-Solomon, where in addition to the evaluation of the message polynomial at every  $a_i$ , we also give the evaluation of its derivatives of up to order  $s - 1$ . While they can be defined over all fields, for the exposition in this paper, we consider these codes over fields  $\mathbb{F}$  of characteristic at least  $sn$ . Moreover, we also work with the standard derivatives (from analysis), as opposed to Hasse derivatives which is typically the convention in coding theoretic context. Let  $a_0, a_1, \dots, a_{n-1} \in \mathbb{F}$  be distinct field elements.

The encoding is defined as follows.

$$p(X) \mapsto \left( p(a_i), \frac{\partial p}{\partial X}(a_i), \dots, \frac{\partial^{s-1} p}{\partial X^{s-1}}(a_i) \right)_{i=0}^{n-1}$$

Here,  $\frac{\partial^j p}{\partial X^j}$  denotes the (standard)  $j$ th order derivative of  $p$  with respect to  $X$ .

To view these as polynomial ideal codes, we set  $E_i(X) = (X - a_i)^s$ . Clearly, each such  $E_i$  is a polynomial of degree equal to  $s$ , and since  $a_i$ 's are all distinct, these polynomials  $E_0, E_1, \dots, E_{n-1}$  are all relatively prime.

The equivalence of these two definitions follows from an application of Taylor's theorem to univariate polynomials, which says the following.

$$\begin{aligned} p(X) &= p(a_i + X - a_i) \\ &= p(a_i) + (X - a_i) \frac{\partial p}{\partial X}(a_i) + \dots + \frac{1}{(s-1)!} (X - a_i)^{s-1} \frac{\partial^{s-1} p}{\partial X^{s-1}}(a_i) + (X - a_i)^s \cdot q(X) \end{aligned}$$

for some polynomial  $q(X) \in \mathbb{F}[X]$ . Thus,

$$p(X) \pmod{(X - a_i)^s} = p(a_i) + (X - a_i) \frac{\partial p}{\partial X}(a_i) + \dots + \frac{1}{(s-1)!} (X - a_i)^{s-1} \frac{\partial^{s-1} p}{\partial X^{s-1}}(a_i).$$

Therefore,  $p(X) \pmod{(X - a_i)^s}$  we can *read* off the evaluations of the derivatives of  $p$  of order up to  $s - 1$  at  $a_i$  by explicitly writing  $p(X) \pmod{(X - a_i)^s}$  as a polynomial in  $(X - a_i)$  (via interpolation for instance), and reading off the various coefficients. Similarly, using the above expression, given the evaluation of all the derivatives of order up to  $s - 1$  of  $p$  at  $a_i$ , we can also reconstruct  $p(X) \pmod{(X - a_i)^s}$ .

### Affine Folded Reed-Solomon Codes

We now describe a common generalization of the codes defined above, which we call Affine Folded Reed-Solomon Codes. Fix integers  $k, n, q$  with  $n \leq q$ . Let  $\alpha \in \mathbb{F}_q^*$  and  $\beta \in \mathbb{F}_q$  such that the multiplicative order of  $\alpha$  is  $u$ . Further, define  $\ell(X) = \alpha X + \beta$  and

$$\ell^{(i)}(X) = \underbrace{\ell(\ell \dots \ell(X))}_{i \text{ times}} = \alpha^i X + \beta \cdot \sum_{j=0}^{i-1} \alpha^j = \alpha_i X + \beta_i.$$

In fact, if  $\alpha \neq 1$ , i.e,  $u > 1$  then,  $\beta_u = \beta \cdot \sum_{j=0}^{u-1} \alpha^j = 0$  and hence  $\ell^{(u)}(X) = \ell^{(0)}(X)$ . Let  $\text{ord}(\ell)$  denote the smallest positive integer  $t$  such that  $\ell^{(t)}(X) = X$ . The message space of the Affine Folded Reed-Solomon code of degree  $k$  with block length  $n$  and folding

## 56:10 Ideal-Theoretic Explanation of Capacity-Achieving Decoding

parameter  $s$  is polynomials of degree at most  $k - 1$  over  $\mathbb{F}[X]$ , i.e.,  $\mathbb{F}_{<k}[X]$  where  $\mathbb{F} = \mathbb{F}_q$ . Let the set of evaluation points be  $A = \{a_0, \dots, a_{n-1}\}$  such that for distinct  $i, j$  the sets  $\{\ell^{(0)}(a_i), \dots, \ell^{(s-1)}(a_i)\}$  and  $\{\ell^{(0)}(a_j), \dots, \ell^{(s-1)}(a_j)\}$  are disjoint.

The encoding function of Affine Folded Reed-Solomon Codes is given as: (Recall that  $t = \text{ord}(\ell)$ ; let  $s = v \cdot t + r$  where  $r < t$ .)

$$p(X) \mapsto \left( \begin{array}{cccccc} p(\ell^{(0)}(a_i)) & \frac{\partial p}{\partial X}(\ell^{(0)}(a_i)) & \dots & \frac{\partial^{v-1} p}{\partial X^{v-1}}(\ell^{(0)}(a_i)) & \frac{\partial^v p}{\partial X^v}(\ell^{(0)}(a_i)) & \\ \vdots & \vdots & \dots & \vdots & \vdots & \\ \vdots & \vdots & \dots & \vdots & \vdots & \frac{\partial^v p}{\partial X^v}(\ell^{(r-1)}(a_i)) \\ p(\ell^{(t-1)}(a_i)) & \frac{\partial p}{\partial X}(\ell^{(t-1)}(a_i)) & \dots & \frac{\partial^{v-1} p}{\partial X^{v-1}}(\ell^{(t-1)}(a_i)) & & \end{array} \right)_{i=0}^{n-1}.$$

Thus, these are also codes over the alphabet  $\mathbb{F}^s$ .

To view these as polynomial ideal codes we set

$$E_i(X) = \prod_{j=0}^{s-1} (X - \alpha_j a_i - \beta_j) = \prod_{j=0}^{r-1} (X - \ell^{(j)}(a_i))^{v+1} \cdot \prod_{j=r}^{t-1} (X - \ell^{(j)}(a_i))^v.$$

For the choice of  $A$  as above, the polynomials  $E_i = E(X, a_i)$  are pairwise co-prime. Similar to the previous cases of Folded/Additive Reed-Solomon and Multiplicity codes we have a bijection between the remainders of a polynomial modulo  $E_i$  and the encoding of the polynomial at  $a_i$ .

### 3.2 An alternate definition

We now discuss an alternate definition of polynomial ideal codes; the advantage being that this definition ties together the polynomials  $E_0, E_1, \dots, E_{n-1}$  into a single bivariate polynomial. This would be useful later on when we discuss the connection between polynomial ideal codes and linear operator codes.

► **Definition 3.2** (polynomial ideal codes (in terms of bivariate polynomials)). *Given a field  $\mathbb{F}$ , parameters  $s, k$  and  $n$  satisfying  $k < s \cdot n$ , the polynomial ideal code is specified by a bivariate polynomial  $E(X, Y)$  over the field  $\mathbb{F}$  and a set of  $n$  field elements  $a_0, a_1, \dots, a_{n-1}$  in  $\mathbb{F}$  satisfying the following properties.*

1.  $\deg_X E(X, Y) = s$ .
2.  $E(X, Y)$  is a monic polynomial in the variable  $X$ .
3. The polynomials  $E(X, a_i)$ 's are pairwise relatively prime.

*Since  $E$  is monic and has (exact) degree  $s$  in the variable  $X$ , any polynomial  $p \in \mathbb{F}[X]$  has the following unique representation.*

$$p(X) = Q^{(p)}(X, Y) \cdot E(X, Y) + R^{(p)}(X, Y) \quad \text{where } \deg_X(R^{(p)}(X, Y)) < s.$$

*The encoding of the polynomial ideal code maps  $p$  as follows:*

$$\begin{aligned} \mathbb{F}_{<k}[X] &\longrightarrow (\mathbb{F}_{<s}[X])^n \\ p(X) &\longmapsto \left( R^{(p)}(X, a_i) \right)_{i=0}^{n-1}. \end{aligned}$$

The equivalence of Definitions 3.1 and 3.2 is not hard to see. We summarize this in the simple observation below.

► **Observation 3.3.** *Definitions 3.1 and 3.2 are equivalent.*

**Proof.** Given a code as per Definition 3.1, we can view this as a code according to Definition 3.2 by picking  $n$  distinct  $a_0, a_1, \dots, a_{n-1} \in \mathbb{F}$  (or in a large enough extension of  $\mathbb{F}$  of size at least  $n$ ) and use standard Lagrange interpolation to find a bivariate polynomial  $E(X, Y)$  such that for every  $i \in [n]$ ,

$$E(X, a_i) = E_i.$$

More precisely, we define  $E(X, Y)$  as follows.

$$E(X, Y) := \sum_{i \in [n]} \left( \prod_{j \in [n] \setminus \{i\}} \frac{(Y - a_j)}{(a_j - a_i)} \right) \cdot E_i(X).$$

Clearly,  $E(X, a_i)$ 's are relatively prime, and their degree in  $X$  equals  $s$  and  $E(X, Y)$  is monic in  $X$ . The equivalence of the encoding function also follows immediately from the definitions.

The other direction is even simpler. Given a code as per Definition 3.2, we can view this as a code as per Definition 3.1 by just setting  $E_i(X)$  to be equal to  $E(X, a_i)$  for every  $i \in [n]$ . The condition on the degree of  $E_i$  and their relative primality follows immediately from the fact that  $E(X, Y)$  is monic in  $X$  of degree  $s$ , and  $E(X, a_i)$ 's are relatively prime. Once again, the encoding map can be seen to be equivalent in both the cases. ◀

From Observation 3.3 and the discussion in Section 3.1, the Reed-Solomon codes, Folded Reed-Solomon codes, Additive Folded Reed-Solomon codes and Multiplicity codes can also be viewed as polynomial ideal codes as per Definition 3.2.

- **Reed-Solomon codes:** We take  $E(X, Y)$  to be equal to  $(X - Y)$ , the set of points  $a_0, \dots, a_{n-1}$  remain the same.
- **Folded Reed-Solomon codes:** We take  $E(X, Y) = \prod_{j \in [s]} (X - \gamma^j Y)$  and the set of evaluation points  $a_0, \dots, a_{n-1}$  are set as before, and  $\gamma \in \mathbb{F}^*$  is an element of high enough order.
- **Additive Folded Reed-Solomon codes:** We take  $E(X, Y) = \prod_{j \in [s]} (X - Y + \beta j)$  and the set of evaluation points  $a_0, \dots, a_{n-1}$  are set as before. Recall that  $\mathbb{F}$  is taken to be a field of characteristic at least  $s$  for these codes.
- **Multiplicity codes:** We take  $E(X, Y)$  to be equal to  $(X - Y)^s$ , the set of points  $a_0, \dots, a_{n-1}$  are distinct.
- **Affine Folded Reed-Solomon codes:** We take  $E(X, Y) = \prod_{i=0}^{s-1} (X - \ell^{(i)}(Y))$  where  $\ell(Y) = \alpha Y + \beta$  with  $\alpha \in \mathbb{F}_q^*$  and  $\beta \in \mathbb{F}_q$ . Recall that the set of evaluation points  $A = \{a_0, \dots, a_{n-1}\}$  is such that for distinct  $i, j$  the sets  $\{\ell^{(0)}(a_i), \dots, \ell^{(s-1)}(a_i)\}$  and  $\{\ell^{(0)}(a_j), \dots, \ell^{(s-1)}(a_j)\}$  are disjoint.

It follows immediately from these definitions that all the desired properties in Definition 3.2 are indeed satisfied. We skip the remaining details.

## 4 Linear operator codes

In this section, we give an alternate viewpoint of polynomial ideal codes in terms of codes defined based on linear operators on the ring of polynomials.

► **Definition 4.1** (linear operators). *Let  $\mathcal{L} = (L_0, \dots, L_{s-1})$  be a of  $s$  linear operators where each  $L_i : \mathbb{F}[X] \rightarrow \mathbb{F}[X]$  is a  $\mathbb{F}$ -linear operator over the ring  $\mathbb{F}$ . For any  $f \in \mathbb{F}[X]$ , it will be convenient to denote by  $\mathcal{L}(f)$  the (row) vector  $(L_0(f), \dots, L_{s-1}(f)) \in \mathbb{F}[X]^s$ .*

## 56:12 Ideal-Theoretic Explanation of Capacity-Achieving Decoding

Given any such family  $\mathcal{L}$  and element  $a \in \mathbb{F}$ , define

$$I^a(\mathcal{L}) = \{p(X) \in \mathbb{F}[X] \mid \mathcal{L}(p)(a) = \bar{0}\}.$$

If the family  $\mathcal{L}$  of linear operators family and the set of field elements  $A \subseteq \mathbb{F}$  further satisfy the property that  $I^a(\mathcal{L})$  is an ideal for each  $a \in A$ , we refer to the family  $\mathcal{L}$  as an ideal family of linear operators with respect to  $A$ .

In this case, since  $\mathbb{F}[X]$  is a principal ideal domain, for each  $a \in A$ ,  $I^a(\mathcal{L}) = \langle E^a(\mathcal{L})(X) \rangle$  for some monic polynomial  $E^a(\mathcal{L}) \in F[X]$ .

We now define a special condition on the family of linear operators  $\mathcal{L}$  which will help us capture when  $I^a(\mathcal{L})$  forms an ideal.

► **Definition 4.2** (linearly-extendible linear operators). *The family  $\mathcal{L}$  of linear operators is said to be linearly-extendible if there exists a matrix  $M(X) \in \mathbb{F}[X]^{s \times s}$  such that for all  $p \in F[X]$  we have*

$$\mathcal{L}(X \cdot p(X)) = M(X) \cdot \mathcal{L}(p(X)). \quad (1)$$

We give two examples to illustrate the definition:

- Let  $L_0(f(X)) = f(X)$  and  $L_1(f(X)) = f'(X)$  where  $f'$  is the formal derivative of  $f$ . Then, by the product rule  $L_1(Xf(X)) = X \cdot f'(X) + f(X)$ . Hence, in this case  $M(X) = \begin{pmatrix} X & 0 \\ 1 & X \end{pmatrix}$ .
- Let  $L_0(f(X)) = f(X)$  and  $L_1(f(X)) = f(\gamma X)$  where  $\gamma \in \mathbb{F}_q$  is non-zero. Then, we have  $L_1(Xf(X)) = \gamma X f(\gamma X)$ . Hence, in this case  $M(X) = \begin{pmatrix} 1 & 0 \\ 0 & \gamma X \end{pmatrix}$ .

► **Observation 4.3.** *Suppose  $\mathcal{L}$  is linearly-extendible and  $M(X)$  is the corresponding matrix from Equation (1).*

- *For any  $j \geq 0$  we have  $\mathcal{L}(X^j \cdot p(X)) = (M(X))^j \cdot \mathcal{L}(p(X))$ . Thus, by linearity we have that for any  $q \in \mathbb{F}[X]$ :*

$$\mathcal{L}(q(X) \cdot p(X)) = q(M(X)) \cdot \mathcal{L}(p(X)).$$

*For instance if  $q(X) = X^j$  then  $\mathcal{L}(X^j \cdot p(X)) = (M(X))^j \cdot \mathcal{L}(p(X))$ .*

- *The family  $\mathcal{L}$  is completely specified by  $\mathcal{L}(1)$  and  $M(X)$ . In other words,  $\mathcal{L}(p(X)) = p(M(X)) \cdot \mathcal{L}(1)$ .*
- *For every set  $A$  of evaluation points,  $\mathcal{L}$  is an ideal family of linear operators with respect to  $A$ . This is because if at a point  $a$  we have  $\mathcal{L}(p)(a) = 0$  then  $\mathcal{L}(Xp)(a) = (M(X) \cdot \mathcal{L}(p(X)))(a) = M(X = a) \cdot \mathcal{L}(p)(a) = 0$ . This means that if  $p(X) \in I^a(\mathcal{L})$  then  $Xp(X) \in I^a(\mathcal{L})$ , and hence by linearity for any  $q(X) \in \mathbb{F}[X]$  we have  $q(X) \cdot p(X) \in I^a(\mathcal{L})$ .*

► **Definition 4.4** (linear operator codes). *Let  $\mathcal{L} = (L_0, \dots, L_{s-1})$  be a family of linear operators,  $A = \{a_1, \dots, a_n\} \subseteq \mathbb{F}$  be a set of evaluation points and  $k$  a degree parameter such that  $k \leq s \cdot n$ . Then the linear operator code generated by  $\mathcal{L}$  and  $A$ , denoted by  $LO_k^A(\mathcal{L})$ , is given as follows:*

$$\begin{aligned} \mathbb{F}_{<k}[X] &\longrightarrow (\mathbb{F}^s)^n \\ p(X) &\longmapsto (\mathcal{L}(p)(a_i))_{i=1}^n. \end{aligned}$$

- *If  $\mathcal{L}$  is an ideal family of linear operators with respect to  $A$  where the polynomials  $E_i := E^{a_i}(\mathcal{L})$ , which are the monic generator polynomials for the ideals  $I^{a_i}(\mathcal{L})$ , further satisfy the following:*

1. *For all  $i \in [n]$ , polynomial  $E_i$  has degree exactly  $s$ .*
2. *The polynomials  $E_i$ 's are pairwise relatively prime.*

Then the linear operator code is said to be an ideal linear operator code and denoted by  $ILO_k^A(\mathcal{L})$ .

- If the ideal linear operator code  $ILO_k^A(\mathcal{L})$  further satisfies that  $\mathcal{L}$  is linearly-extendible, then the ideal linear operator code is said to be a linearly-extendible linear operator code, denoted by  $LELO_k^A(\mathcal{L})$ .

► **Remark 4.5.** The rate of the  $LO_k^A(\mathcal{L})$  code is  $k/sn$ . Further, if the code is an ideal linear operator code, i.e.,  $ILO_k^A(\mathcal{L})$ , then its distance is  $1 - \frac{k-1}{sn}$ . Hence,  $ILO_k^A(\mathcal{L})$  is an MDS code.

► **Proposition 4.6.** Any polynomial ideal code is a linearly-extendible linear operator code.

See the full version [1] for a proof.

► **Remark 4.7.** (degree preserving) If the bivariate polynomial  $E(X, Y)$  has total degree  $s$ , then, the linear operator in the  $LELO$  code obtained above has the property that  $\deg_X L_i(X^j) \leq j$ : in fact,  $\deg_X L_i(X^j) \leq j - i$ .

► **Proposition 4.8.** Any ideal linear operator code is a polynomial ideal code.

**Proof.** Consider an ideal linear operator code  $ILO_k^A(\mathcal{L})$ . For any polynomial  $p(X) \in \mathbb{F}[X]$  and a point  $a_i \in A$ , giving  $\mathcal{L}(p(X))(a)$  is equivalent to giving  $p(X) \bmod \langle E_i \rangle$  where  $\langle E_i \rangle = I^{a_i}(\mathcal{L})$ . However, the  $E_i$ s readily satisfy Definition 3.1. ◀

Now, we state a corollary which further corroborates the notion of linear-extendibility.

► **Corollary 4.9** (Equivalence of  $ILO$  and  $LELO$ ). From Propositions 4.6 and 4.8 it follows that every ideal linear operator code is also a linearly-extendible linear operator code.

Below we state some well known codes in their linear operator descriptions (a more formal treatment is given in *Appendix A*):

- **Reed-Solomon Codes:** Let  $A = \{a_0, \dots, a_{n-1}\}$  be distinct elements in  $\mathbb{F}_q$ . These are  $LELO_{\mathcal{L}, A}$  where  $\mathcal{L} = (I)$ . That is the encoding of the message polynomial  $p(X) \in \mathbb{F}_{<k}[X]$  at a point  $a$  is  $L(f(X))(a) = f(a)$ .
- **Folded Reed-Solomon Codes:** Let  $\gamma \in \mathbb{F}_q^*$  with multiplicative order at least  $s$ .  $FRS[k, n]$  with folding parameter  $s$  are linearly-extendible linear operator codes  $LELO_{\mathcal{L}, A}$  where:
  - $\mathcal{L} = (L_0, \dots, L_{s-1})$  with  $L_1(f(X)) = f(\gamma Y)$  for  $f(X) \in \mathbb{F}_q[X]$  and  $L_i = L_1^i$  for  $i \in \{0, 1, \dots, s-1\}$ .
  - For the above family of operators  $M(X)$  is given by  $M(X)_{ij} = \gamma^i X \cdot \mathbb{I}[i = j]$  for  $i, j \in [s]$ .
  - The set of evaluation points is  $A = \{a_0, \dots, a_{n-1}\}$  where for any two distinct  $i$  and  $j$  the sets  $\{a_i, a_i\gamma, \dots, a_i\gamma^{s-1}\}$  and  $\{a_j, a_j\gamma, \dots, a_j\gamma^{s-1}\}$  are disjoint.
- **Multiplicity Codes:** Then,  $MULT[k, n]$  codes of order  $s$  are linearly-extendible linear operator codes  $LELO_{\mathcal{L}, A}$  where:
  - $\mathcal{L} = (L_0, \dots, L_{s-1})$  with  $L_1(f(X)) = \frac{\partial f(X)}{\partial X}$  for  $f(X) \in \mathbb{F}_q[X]$  and  $L_i = L_1^i$  for  $i \in \{0, 1, \dots, s-1\}$ .
  - For the above family of operators  $M(X)$  is given by  $M(X)_{ij} = X \cdot \mathbb{I}[i = j] + i \cdot \mathbb{I}[i-1 = j]$  for  $i, j \in [s]$ .
  - The set of evaluation points is  $A = \{a_0, \dots, a_{n-1}\}$  where  $a_i$ s are all distinct.
- **Additive Folded Reed-Solomon Codes:** Let  $\beta \in \mathbb{F}_q$  be a non-zero element and the characteristic of  $\mathbb{F}_q$  be at least  $s$ . Then, Additive- $FRS[k, n]$  codes with folding parameter  $s$  are linearly-extendible linear operator codes  $LELO_{\mathcal{L}, A}$  where:

## 56:14 Ideal-Theoretic Explanation of Capacity-Achieving Decoding

- $\mathcal{L} = (L_0, \dots, L_{s-1})$  with  $L_1(f(X)) = f(X + \beta)$  for  $f(X) \in \mathbb{F}_q[X]$  and  $L_i = L_1^i$  for  $i \in \{0, 1, \dots, s-1\}$ .
- For the above family of operators  $M(X)$  is given by  $M(X)_{ij} = (X + i\beta) \cdot \mathbb{I}[i = j]$  for  $i, j \in [s]$ .
- The set of evaluation points is  $A = \{a_0, \dots, a_{n-1}\}$  where  $a_i - a_j \notin \{0, \beta, 2\beta, \dots, (s-1)\beta\}$  for distinct  $i$  and  $j$ .
- **Affine Folded Reed-Solomon Codes:** Let  $\alpha \in \mathbb{F}_q^*$  and  $\beta \in \mathbb{F}_q$ . Further, let  $\ell(X) = \alpha X + \beta$  with  $\text{ord}(\ell) = u$ . Then Affine-FRS $[k, n]$  codes with folding parameter  $s$  are linearly-extendible codes  $LELO_{\mathcal{L}, A}$  described below. (See Observation A.7 for more details.)  
 Define  $D_1 : \mathbb{F}[X] \rightarrow \mathbb{F}[X]$  as  $D_1(f(X)) = \frac{\partial f(X)}{\partial X}$  and  $S_1 : \mathbb{F}[X] \rightarrow \mathbb{F}[X]$  as  $S_1(f(X)) = f(\ell(X))$ . Further, for  $i \geq 0$  let  $D_i = D_1^i$  and  $S_i = S_1^i$ . Recall, that the order of  $\alpha$  is  $u$ . For any integer  $r \in [s]$  let  $r = r_1 u + r_0$ , with  $r_0 < u$ , be the unique representation of  $r$ .
  - Define  $L_r : \mathbb{F}[X] \rightarrow \mathbb{F}[X]$  as  $L_r(f(X)) = S_{r_0}(D_{r_1} f(X))$ . Set  $\mathcal{L} = (L_0, \dots, L_{s-1})$ . Clearly,  $\mathcal{L}$  is a family of linear operators.
  - $L_r(Xf) = S_{r_0}(D_{r_1} f) = S_{r_0}(r_1 \cdot D_{r_1-1} f + X \cdot D_{r_1} f) = r_1 \cdot L_{r-u} f + S_{r_0}(X) \cdot L_r f$ : hence,  $\mathcal{L}$  is a set of linearly-extendible linear operators.
  - The set of evaluation points  $A = \{a_0, \dots, a_{n-1}\}$  is such that for distinct  $i, j$  the sets  $\{\ell^{(0)}(a_i), \dots, \ell^{(s-1)}(a_i)\}$  and  $\{\ell^{(0)}(a_j), \dots, \ell^{(s-1)}(a_j)\}$  are disjoint.

### 5 List-decoding of polynomial ideal codes

In this section, we discuss the list-decoding of polynomial ideal codes.

#### 5.1 List-decoding up to to the Johnson radius

We first observe that polynomial ideal codes are list decodable in polynomial time, up to the Johnson radius.

► **Theorem 5.1.** *Let  $k, s, n \in \mathbb{N}$  be such that  $k < sn$  and  $s < k - 1$ . Let  $E_0(X), E_1(X), \dots, E_{n-1}(X) \in \mathbb{F}[X]$  be relatively prime monic polynomials of degree equal to  $s$  each. Let  $\text{Enc} : \mathbb{F}_{<k}[X] \rightarrow (\mathbb{F}_{<s}[X])^n$  be the encoding function defined as*

$$p(X) \mapsto (p(X) \pmod{E_i(X)})_{i=0}^{n-1}.$$

*Then, there is an algorithm, which takes as input a received word  $\mathbf{c} = (\mathbf{c}_0, \mathbf{c}_1, \dots, \mathbf{c}_n) \in \mathbb{F}_{<s}[X]^n$  and for every  $\varepsilon > 0$  outputs all polynomials  $f \in \mathbb{F}_{<k}[X]$  such that  $\text{Enc}(f)$  and  $\mathbf{c}$  agree on at least  $(k/sn)^{1/2} + \varepsilon$  fraction of coordinates in time  $\text{poly}(n, 1/\varepsilon)$ .*

Observe that the rate of this code is  $k/sn$  and distance is  $1 - (k-1)/sn$ , and thus Theorem 5.1 gives us an algorithmic analog of Theorem 2.2 for these codes.

The list decoding algorithm for polynomial ideal codes is an (almost immediate) extension of an algorithm of Guruswami, Sahai and Sudan [4] for list decoding codes based on Chinese Remainder Theorem to this setting. This algorithm, in turn, relies on ideas in an earlier algorithm of Guruswami and Sudan [5] for list decoding Reed-Solomon codes up to the Johnson radius.

As noted in the introduction, most of the ideas for the proof of Theorem 5.1 were already there in the work of Guruswami, Sahai and Sudan [4] and all we do in this section is to flush out some of the details. Due to space constraints, we refer the interested reader to full version [1] for details.

## 5.2 List-decoding beyond the Johnson radius

In this section, we use the linear operator viewpoint of polynomial ideal codes to study their list-decodability beyond the Johnson radius. We show that if the family of linear operators  $\mathcal{L}$  and the evaluation points satisfy some further properties, then the linear operator code is list-decodable all the way up to the distance of the code.

Let  $\mathcal{G} = (G_0, \dots, G_{m-1})$  and  $\mathcal{T} = (T_0, T_1, \dots, T_{r-1})$  be two families of linear operators such that  $G_i : \mathbb{F}[X] \rightarrow \mathbb{F}[X]$  and  $\mathcal{T}$  is a linearly-extendible family of linear operators. We say that the pair  $(\mathcal{T}, \mathcal{G})$  *list-composes* in terms of  $\mathcal{L}$  at the set of evaluation points  $A$  if we have the following. For every linear operator  $G \in \mathcal{G}$  and field element  $a \in A$ , there exists a linear function  $h_{G,a} : \mathbb{F}^s \rightarrow \mathbb{F}^r$  such that for every polynomial  $f \in \mathbb{F}[X]$  we have

$$\mathcal{T}(G(f))(a) = h_{G,a}(\mathcal{L}(f)(a)).$$

► **Theorem 5.2.** *If  $LO_k^A(\mathcal{L})$  is a linear operator code and there exists two families of linear operators  $\mathcal{G} = (G_0, \dots, G_{m-1})$  and  $\mathcal{T} = (T_0, \dots, T_{r-1})$  such that*

1.  $(\mathcal{T}, A)$  forms a linearly-extendible linear operator code  $LELO_{k+nr/m}^A(\mathcal{T})$
  2. The pair  $(\mathcal{T}, \mathcal{G})$  list-composes in terms of  $\mathcal{L}$  at the set of evaluation points
  3.  $\mathcal{G}$  is degree-preserving
  4.  $\text{Diag}(\mathcal{G}) \in \mathbb{F}^{|\mathcal{G}| \times k}$  is the generator matrix of a code with distance  $k - \ell$ .
- Then,  $LO_k^A(\mathcal{L})$  is list-decodable up to the distance  $1 - \frac{k}{rn} - \frac{1}{m}$  with list size  $q^\ell$ .

This theorem clearly implies Theorem 1.1. We refer the interested reader to the full version of the paper [1] for the proof.

## A Example of Codes Achieving List-Decoding Capacity

In this section we will use Theorem 5.2 to (re)prove the list-decoding capacity of the Folded Reed-Solomon codes, multiplicity codes and additive Folded Reed-Solomon codes. We then introduce a common generalization of all these codes, which we refer to as affine Folded Reed-Solomon codes and prove the list-decoding up to capacity of these codes.

### A.1 Folded Reed-Solomon (*FRS*) Codes

Fix integers  $k, n, q$  with  $n \leq q$ . Fix  $\gamma \in \mathbb{F}_q^*$  of multiplicative order at least  $s$ . The message space of the  $FRS_s^\gamma[k, n]$  code with folding parameter  $s$  is polynomials of degree at most  $k-1$  over  $\mathbb{F}[X]$ , i.e.,  $\mathbb{F}_{<k}[X]$  where  $\mathbb{F} = \mathbb{F}_q$ . Then, *FRS* codes are linearly-extendible linear operator codes  $LELO_{\mathcal{L}, A}$  where:

- $\mathcal{L} = (L_0, \dots, L_{s-1})$  with  $L_1(f(X)) = f(\gamma X)$  for  $f(X) \in \mathbb{F}_q[X]$  and  $L_i = L_1^i$  for  $i \in \{0, 1, \dots, s-1\}$ .
- For the above family of operators  $M(X)$  is given by  $M(X)_{ij} = \gamma^i X \cdot \mathbb{I}[i = j]$  for  $i, j \in [s]$ .
- The set of evaluation points is  $A = \{a_0, \dots, a_{n-1}\}$  where for any two distinct  $i$  and  $j$  the sets  $\{a_i, a_i\gamma, \dots, a_i\gamma^{s-1}\}$  and  $\{a_j, a_j\gamma, \dots, a_j\gamma^{s-1}\}$  are disjoint.

► Remark A.1.

1. Recall that the bivariate polynomial  $E(X, Y)$  corresponding to the polynomial ideal code representation is  $E(X, Y) = \prod_{i=0}^{s-1} (X - \gamma^i Y)$ .
2. For the choice of  $A$  as above, the rate of the code is  $\frac{k}{sn}$  and its distance is  $1 - \frac{k-1}{sn}$  as the polynomials  $E_i = E(X, a_i)$  are pairwise co-prime.

► **Theorem A.2** ([6]). *Let  $\gamma \in \mathbb{F}_q^*$  be an element of order at least  $k$ . Further, let  $A = \{a_0, \dots, a_{n-1}\}$  be a set of evaluation points where for any two distinct  $i$  and  $j$  the sets  $\{a_i, a_i\gamma, \dots, a_i\gamma^{s-1}\}$  and  $\{a_j, a_j\gamma, \dots, a_j\gamma^{s-1}\}$  are disjoint. For every  $\varepsilon > 0$  there exists  $s$  large enough ( $s \geq \Omega(1/\varepsilon^2)$ ) such that  $FRS_s^\gamma[k, n]$  at the set of evaluation points  $A$  can be efficiently list-decoded up to distance  $1 - \frac{k}{sn} - \varepsilon$ .*

**Proof.** We will prove this by applying Theorem 5.2. Set  $\mathcal{G} = (L_0, \dots, L_{m-1})$  for some integer  $m < s$  to be set later and  $\mathcal{T} = (T_0, \dots, T_{r-1})$  with  $r = s - m + 1$  and  $T_i = L_i$ .

Theorem 5.2-Item 1: Clearly,  $(\mathcal{T}, A)$  forms a linearly-extendible linear operator code  $LELO_{k+nr/m}^A(\mathcal{T})$  which is  $FRS_r^\gamma[k + nr/m, n]$  at the set of evaluation points  $A$ .

Theorem 5.2-Item 2: For all  $G_i \in \mathcal{G}$ ,  $T_j \in \mathcal{T}$  and  $a \in A$ , we have that for every polynomial  $f \in \mathbb{F}[X]$ :  $T_j(G_i(f))(a) = L_{i+j}(f)(a)$ . Notice that  $L_{i+j} \in \mathcal{L}$  as  $i + j \leq s - 1$ .

Theorem 5.2-Item 3:  $G_i(x^j) = \gamma^{ij} y^j$ , and hence  $\mathcal{G}$  is degree preserving.

Theorem 5.2-Item 4: The matrix  $\text{Diag}(\mathcal{G})$  is given by  $\text{Diag}(\mathcal{G})_{ij} = \gamma^{ij}$  for  $i \in [m]$  and  $j \in [k]$ . Hence, as long as  $\gamma$  has order at least  $k$  this is the generator matrix of  $RS[m-1, k]$  and hence its distance is  $k - m + 1$ .

Thus  $FRS_s^\gamma[k, n]$  can be efficiently list-decoded up to distance  $1 - \frac{k-1}{rn} - \frac{1}{m}$  with list size  $q^{m-1}$ . By choosing a large enough  $m$  and  $s$  we can ensure that  $1 - \frac{k-1}{rn} - \frac{1}{m} > 1 - \frac{k}{sn} - \varepsilon$ . ◀

## A.2 Multiplicity (*MULT*) Codes

Fix integers  $k, n, q$  with  $n \leq q$ . The message space of the  $MULT_s[k, n]$  code of order  $s$  is polynomials of degree at most  $k-1$  over  $\mathbb{F}[X]$ , i.e.,  $\mathbb{F}_{<k}[X]$  where  $\mathbb{F} = \mathbb{F}_q$ . Then,  $MULT_s[k, n]$  codes are linearly-extendible linear operator codes  $LELO_{\mathcal{L}, A}$  where:

- $\mathcal{L} = (L_0, \dots, L_{s-1})$  with  $L_1(f(X)) = \frac{\partial f(X)}{\partial X}$  for  $f(X) \in \mathbb{F}_q[X]$  and  $L_i = L_1^i$  for  $i \in \{0, 1, \dots, s-1\}$ .
- For the above family of operators  $M(X)$  is given by  $M(X)_{ij} = X \cdot \mathbb{I}[i = j] + i \cdot \mathbb{I}[i-1 = j]$  for  $i, j \in [s]$ .
- The set of evaluation points is  $A = \{a_0, \dots, a_{n-1}\}$  where  $a_i$ s are all distinct.

► Remark A.3.

1. Recall that the bivariate polynomial  $E(X, Y)$  corresponding to the polynomial ideal code representation is  $E(X, Y) = (X - Y)^s$ .
2. For the choice of  $A$  as above,  $MULT_s[k, n]$  is a code with rate  $\frac{k}{sn}$  and distance  $1 - \frac{k-1}{sn}$  as the polynomials  $E_i = E(X, a_i)$  are pairwise co-prime.

► **Theorem A.4** ([6]). *Let the characteristic of  $\mathbb{F}_q$  be at least  $\max(s, k)$ . Further, let the set of evaluation points be  $A = \{a_0, \dots, a_{n-1}\}$  where  $a_i$ s are all distinct. Then, for every  $\varepsilon > 0$  there exists  $s$  large enough ( $s \geq \Omega(1/\varepsilon^2)$ ) such that  $MULT_s[k, n]$  can be efficiently list-decoded up to distance  $1 - \frac{k}{sn} - \varepsilon$ .*

**Proof.** We will again appeal to Theorem 5.2. Set  $\mathcal{G} = (G_0, \dots, G_{m-1})$  where  $G_i = \frac{X^i}{i!} \cdot L_i$  for  $i \in \{0, 1, \dots, m-1\}$  for some integer  $m < s$  to be set later and  $\mathcal{T} = (T_0, \dots, T_{r-1})$  with  $r = s - m + 1$  and  $T_i = L_i$ .

Theorem 5.2-Item 1: Clearly,  $(\mathcal{T}, A)$  forms a linearly-extendible linear operator code  $LELO_{k+nr/m}^A(\mathcal{T})$  which is  $MULT_r[k + nr/m, n]$  of order  $r$  at the set of evaluation points  $A$ .

Theorem 5.2-Item 2: For all  $G_i \in \mathcal{G}$ ,  $T_j \in \mathcal{T}$  and  $a \in A$ , we have that for every polynomial  $f \in \mathbb{F}[X]$ :

$$T_j(G_i(f))(a) = \left( \sum_{b=0}^j \binom{j}{b} \binom{i}{b} \cdot (b!/i!) \cdot X^{i-b} L_{i+b}(f) \right)(a).$$

Notice that the above expression only involves  $L_i$ s where  $i < s$ .

Theorem 5.2-Item 3:  $G_i(X^j) = \binom{j}{i} \cdot X^j$ , and hence  $\mathcal{G}$  is degree preserving.

Theorem 5.2-Item 4: The matrix  $\text{Diag}(\mathcal{G})$  is given by  $\text{Diag}(\mathcal{G})_{ij} = \binom{j}{i}$  for  $i \in [m]$  and  $j \in [k]$ . This matrix can be transformed via elementary row operations to a  $RS[m, k]$  generator matrix with points of evaluations as  $0, 1, \dots, k-1$ ; thus, as long as the characteristic of  $\mathbb{F}_q$  is at least  $k$  we have that the distance of  $\text{Diag}(\mathcal{G})$  is  $k - m + 1$ .

Thus  $MULT_s[k, n]$  can be efficiently list-decoded up to distance  $1 - \frac{k-1}{rn} - \frac{1}{m}$  with list size  $q^{m-1}$ . By choosing a large enough  $m$  and  $s$  we can ensure that  $1 - \frac{k-1}{rn} - \frac{1}{m} > 1 - \frac{k}{sn} - \varepsilon$ . ◀

## A.3 Additive Folded Reed-Solomon (Additive-FRS) Codes

Fix integers  $k, n, q$  with  $n \leq q$ . Let  $\beta \in \mathbb{F}_q$  be a non-zero element and characteristic of  $\mathbb{F}_q$  is at least  $s$ . The message space of the Additive-FRS $_s^\beta[k, n]$  code with folding parameter  $s$  is polynomials of degree at most  $k-1$  over  $\mathbb{F}[X]$ , i.e.,  $\mathbb{F}_{<k}[X]$  where  $\mathbb{F} = \mathbb{F}_q$ . Then, Additive-FRS $_s^\beta[k, n]$  codes are linearly-extendible linear operator codes  $LELO_{\mathcal{L}, A}$  where:

- $\mathcal{L} = (L_0, \dots, L_{s-1})$  with  $L_1(f(X)) = f(X + \beta)$  for  $f(X) \in \mathbb{F}_q[X]$  and  $L_i = L_1^i$  for  $i \in \{0, 1, \dots, s-1\}$ .

## 56:18 Ideal-Theoretic Explanation of Capacity-Achieving Decoding

- For the above family of operators  $M(X)$  is given by  $M(X)_{ij} = (X + i\beta) \cdot \mathbb{I}[i = j]$  for  $i, j \in [s]$ .
- The set of evaluation points is  $A = \{a_0, \dots, a_{n-1}\}$  where  $a_i - a_j \notin \{0, \beta, 2\beta, \dots, (s-1)\beta\}$  for distinct  $i$  and  $j$ .

► Remark A.5.

1. Recall that the bivariate polynomial  $E(X, Y)$  corresponding to the polynomial ideal code representation is  $E(X, Y) = \prod_{i=0}^{s-1} (X - Y - i\beta)$ .
2. For the choice of  $A$  as above, Additive-FRS $_s^\beta[k, n]$  is a code with rate  $\frac{k}{sn}$  and distance  $1 - \frac{k-1}{sn}$  as the polynomials  $E_i = E(X, a_i)$  are pairwise co-prime.

► **Theorem A.6.** *Let the characteristic of  $\mathbb{F}_q$  be at least  $\max(s, k)$  and  $\beta \in \mathbb{F}_q$  be a non-zero element. Further, let the set of evaluation points  $A = \{a_0, \dots, a_{n-1}\}$  be such that  $a_i - a_j \notin \{0, \beta, 2\beta, \dots, (s-1)\beta\}$  for distinct  $i$  and  $j$ . Then, for every  $\varepsilon > 0$  there exists  $s$  large enough ( $s \geq \Omega(1/\varepsilon^2)$ ) such that Additive-FRS $_s^\beta[k, n]$  over the set of evaluation points  $A$  can be efficiently list-decoded up to distance  $1 - \frac{k}{sn} - \varepsilon$ .*

**Proof.** We will again appeal to Theorem 5.2. To define  $\mathcal{G} = (G_0, \dots, G_{m-1})$  for some integer  $m < s$ , we need the following definitions. Let  $B \in \mathbb{F}_q^{m \times m}$  be a matrix where  $B_{ij} = (j)^i$  for  $i, j \in [m]$ , i.e, the transpose of the Vandermonde matrix at the points  $\{0, 1, \dots, m-1\}$ : these points are distinct since the characteristic of the field is at least  $k$ . Further, let  $\mathbf{b}_i \in \mathbb{F}_q^m$  be a vector such that  $B\mathbf{b}_i = e_i$  for  $i \in [m]$  where  $e_i$ s are the standard basis vectors:  $\mathbf{b}_i$ s exist because  $B$  is full rank. Now, define  $G_i = X^i \cdot \sum_{c=0}^{m-1} \mathbf{b}_i(c)L_c$  for  $i \in [m]$ . Set  $\mathcal{T} = (T_0, \dots, T_{r-1})$  with  $r = s - m + 1$  and  $T_i = L_i$ .

Theorem 5.2-Item 1: Clearly,  $(\mathcal{T}, A)$  forms a linearly-extendible linear operator code  $LELO_{k+nr/m}^A(\mathcal{T})$  which is Additive-FRS $_r^\beta[k + nr/m, n]$  with folding parameter  $r$  at the set of evaluation points  $A$ .

Theorem 5.2-Item 2: For all  $G_i \in \mathcal{G}$ ,  $T_j \in \mathcal{T}$  and  $a \in A$ , we have that for every polynomial  $f \in \mathbb{F}[X]$ :

$$\begin{aligned} T_j(G_i(f))(a) &= T_j \left( X^i \cdot \sum_{c=0}^{m-1} \mathbf{b}_i(c)L_c \right) (a) \\ &= \left( (X + j\beta)^i \cdot \sum_{c=0}^{m-1} \mathbf{b}_i(c)L_{c+j} \right) (a). \end{aligned}$$

Notice that the above expression only involves  $L_i$ s where  $i < s$ . Theorem 5.2-Item 3:

$$\begin{aligned} G_i(X^j) &= X^i \cdot \sum_{c=0}^{m-1} \mathbf{b}_i(c)L_c(X^j) \\ &= X^i \cdot \sum_{c=0}^{m-1} \mathbf{b}_i(c)(X + c\beta)^j \\ &= X^i \cdot \sum_{c=0}^{m-1} \mathbf{b}_i(c) \sum_{h \leq j} \binom{j}{h} X^h \cdot (c\beta)^{j-h} \\ &= X^i \cdot \left( \binom{j}{i} \beta^i X^{j-i} + \sum_{h \leq j-m} \alpha_h X^h \right) \end{aligned}$$

(this is because  $B\mathbf{b}_i = e_i$  which means that for  $h > j - m$  we have  $\sum_{c=0}^{m-1} \mathbf{b}_i(c) \cdot (c)^{j-h} = \mathbb{I}[j - h = i]$ ;  $\alpha_n$  are field constants)

$$= \binom{j}{i} \beta^{i-1} X^j + \dots,$$

and hence  $\mathcal{G}$  is degree preserving.

Theorem 5.2-Item 4: By the above, the matrix  $\text{Diag}(\mathcal{G})$  is given by  $\text{Diag}(\mathcal{G})_{ij} = \binom{j}{i} \beta^i$  for  $i \in [m]$  and  $j \in [k]$ . Up to scaling this is the same code as  $\text{Diag}(\mathcal{G})$  in Theorem A.4: and hence, if the characteristic of the field is at least  $k$  then its distance is  $k - m + 1$ .

Thus Additive-FRS $_s^\beta[k, n]$  can be efficiently list-decoded up to distance  $1 - \frac{k-1}{rn} - \frac{1}{m}$  with list size  $q^{m-1}$ . By choosing a large enough  $m$  and  $s$  we can ensure that  $1 - \frac{k-1}{rn} - \frac{1}{m} > 1 - \frac{k}{sn} - \varepsilon$ . ◀

### A.4 Affine Folded Reed-Solomon (Affine-FRS) Codes

We first recall the definition of Affine-FRS codes. Fix integers  $k, n, q$  with  $n \leq q$ . Let  $\alpha \in \mathbb{F}_q^*$  and  $\beta \in \mathbb{F}_q$  such that the multiplicative order of  $\alpha$  is  $u$ . Further, define  $\ell(X) = \alpha X + \beta$  and

$$\ell^{(i)}(X) = \underbrace{\ell(\ell \dots \ell(X))}_{i \text{ times}} = \alpha^i X + \beta \cdot \sum_{j=0}^{i-1} \alpha^j = \alpha_i X + \beta_i.$$

In fact, if  $\alpha \neq 1$ , i.e.,  $u > 1$  then,  $\ell^{(u)}(X) = \ell^{(0)}(X)$ . Let  $\text{ord}(\ell)$  denote the smallest positive integer  $t$  such that  $\ell^{(t)}(z) = z$ . The message space of the Affine-FRS $_s^{\alpha, \beta}[k, n]$  code with folding parameter  $s$  is polynomials of degree at most  $k - 1$  over  $\mathbb{F}[X]$ , i.e.,  $\mathbb{F}_{<k}[X]$  where  $\mathbb{F} = \mathbb{F}_q$ . Let the set of evaluation points be  $A = \{a_0, \dots, a_{n-1}\}$  such that for distinct  $i, j$  the sets  $\{\ell^{(0)}(a_i), \dots, \ell^{(s-1)}(a_i)\}$  and  $\{\ell^{(0)}(a_j), \dots, \ell^{(s-1)}(a_j)\}$  are disjoint. Then, Affine-FRS $_s^{\alpha, \beta}[k, n]$  codes are polynomial ideal codes where:

- The bivariate polynomial  $E(X, Y)$  corresponding to the polynomial ideal code representation is  $E(X, Y) = \prod_{i=0}^{s-1} (X - \alpha_i Y - \beta_i)$ .
- For the choice of  $A$  as above, Affine-FRS $_s^{\alpha, \beta}[k, n]$  is a code with rate  $\frac{k}{sn}$  and distance  $1 - \frac{k-1}{sn}$  as the polynomials  $E_i = E(X, a_i)$  are pairwise co-prime.

We will now recall the description of Affine-FRS codes in terms of linear operators which will be helpful while list-decoding. Define  $D_1 : \mathbb{F}[X] \rightarrow \mathbb{F}[X]$  as  $D_1(f(X)) = \frac{\partial f(X)}{\partial X}$  and  $S_1 : \mathbb{F}[X] \rightarrow \mathbb{F}[X]$  as  $S_1(f(X)) = f(\ell(X))$ . Further, for  $i \geq 0$  let  $D_i = D_1^i$  and  $S_i = S_1^i$ . Recall, that the order of  $\alpha$  is  $u$ . For any integer  $r \in [s]$  let  $r = r_1 u + r_0$ , with  $r_0 < u$ , be the unique representation of  $r$ . Then, define  $L_r : \mathbb{F}[X] \rightarrow \mathbb{F}[X]$  as  $L_r(f(X)) = S_{r_0}(D_{r_1} f(X))$ . Set  $\mathcal{L} = (L_0, \dots, L_{s-1})$ . Clearly,  $\mathcal{L}$  is a family of linear operators. Further,  $L_r(Xf) = S_{r_0}(D_{r_1} Xf) = S_{r_0}(r_1 \cdot D_{r_1-1} f + X \cdot D_{r_1} f) = r_1 \cdot L_{r-u} f + S_{r_0}(X) \cdot L_r f$ ; hence,  $\mathcal{L}$  is a set of linearly-extendible linear operators.

▶ **Observation A.7.** *If  $u > 1$  then at an evaluation point  $a \in \mathbb{F}_q$  the following pieces of information are the same:*

- $f(X) \bmod \prod_{i=0}^{s-1} (X - \alpha_i a - \beta_i)$
- $\mathcal{L}(f)(a)$ .

Hence, if  $u > 1$ , then, Affine-FRS $_s^{\alpha, \beta}[k, n]$  at the points of evaluation  $A$  is  $LELO_{\mathcal{L}, A}$ .

▶ **Theorem A.8.** *For every  $\varepsilon > 0$ , there exists a large enough  $s$  such that the follow holds. Let  $\mathbb{F}_q$  be a field,  $k$  a parameter and  $\ell(X) = \alpha \cdot X + \beta$  such that  $\alpha \in \mathbb{F}_q^*$  and  $\beta \in \mathbb{F}_q$ . Furthermore, let the evaluation points  $A = \{a_0, \dots, a_{n-1}\}$  be such that for distinct  $i, j$  the sets  $\{\ell^{(0)}(a_i), \dots, \ell^{(s-1)}(a_i)\}$  and  $\{\ell^{(0)}(a_j), \dots, \ell^{(s-1)}(a_j)\}$  are disjoint. Then, if either:*

## 56:20 Ideal-Theoretic Explanation of Capacity-Achieving Decoding

■  $\text{ord}(\ell) \geq k$  or

■  $\text{char}(\mathbb{F}_q) > k$  and  $\beta \neq 0$

holds, Affine-FRS $_{s}^{\alpha, \beta}[k, n]$  over the set of evaluation points  $A$  can be efficiently list-decoded up to distance  $1 - \frac{k}{sn} - \varepsilon$ .

**Proof.** We will again appeal to Theorem 5.2. Let  $u$  be the multiplicative order of  $\alpha$ . Let  $v = \lfloor s/u \rfloor$ .

**Case  $\text{ord}(\ell) \geq k$ .** This means that  $u \geq k$ . This is similar to decoding FRS codes. We skip the details.

Henceforth, we assume that  $\text{char}(\mathbb{F}_q) \geq k$  and  $\beta \neq 0$ .

**Case  $u = 1$ .** This is the same case as for Additive-FRS codes. Thus, by Theorem A.6 we are done.

**Case  $u > 1$  and  $v \geq \sqrt{s}$ .** (This case is similar to  $MULT_v[k, n]$ .)

Define  $\mathcal{G} = (G_0, \dots, G_{m-1})$  for some integer  $m < s$ , as  $G_i(f) = (X^i/i!) \cdot D_i f$ . Let  $r = (v - m)u$  and set  $\mathcal{T} = \{L_0, L_1, \dots, L_{r-1}\}$ .

Theorem 5.2-Item 1: Clearly,  $(\mathcal{T}, A)$  forms a linearly-extendible linear operator code  $LELO_{k+nr/m}^A(\mathcal{T})$  which is Affine-FRS $_r^{\alpha, \beta}[k + nr/m, n]$  at the set of evaluation points  $A$ .

Theorem 5.2-Item 2: For all  $G_i \in \mathcal{G}$ ,  $T_j \in \mathcal{T}$  and  $a \in A$  we have that for every polynomial  $f \in \mathbb{F}[X]$ :

$$\begin{aligned} T_j(G_i(f))(a) &= \left( S_{j_0} D_{j_1} \left( \frac{X^i}{i!} \cdot D_i(f) \right) \right) (a) \\ &= \left( S_{j_0} \sum_{b=0}^{j_1} \binom{j_1}{b} \binom{i}{b} \cdot (b!/i!) \cdot X^{i-b} D_{i+b}(f) \right) (a) \\ &= \left( \sum_{b=0}^{j_1} \binom{j_1}{b} \binom{i}{b} \cdot (b!/i!) \cdot (S_{j_0} X^{i-b}) \cdot L_{j_0+(i+b)u}(f) \right) (a). \end{aligned}$$

Notice that the above expression only involves  $L_i$ s where  $i < s$ .

Theorem 5.2-Items 3 and 4: are identical to the corresponding items in Theorem A.4.

Thus Affine-FRS $_s^{\beta}[k, n]$  can be efficiently list-decoded up to distance  $1 - \frac{k-1}{rn} - \frac{1}{m}$  with list size  $q^{m-1}$ . By choosing a large enough  $m$  and  $s$  we can ensure that  $1 - \frac{k-1}{rn} - \frac{1}{m} > 1 - \frac{k}{sn} - \varepsilon$ .

**Case  $u > \sqrt{s}$ .** (This case is similar to Additive-FRS $_u^{\beta}[k, n]$ .) As in Theorem A.6, to define  $\mathcal{G} = (G_0, \dots, G_{m-1})$  for some integer  $m < u$ , we need the following definitions. Let  $B \in \mathbb{F}_q^{m \times m}$  be a matrix where  $B_{ij} = (\beta(\alpha^j - 1)/(\alpha^j))^i$  for  $i, j \in [m]$ , i.e, the transpose of the Vandermonde matrix at the points  $\{\beta(\alpha^j - 1)/(\alpha^j) \mid j \in [m]\}$ : these points are distinct since the order of  $u$  is at least  $m$ . Further, let  $\mathbf{b}_i \in \mathbb{F}_q^m$  be a vector such that  $B\mathbf{b}_i = e_i$  for  $i \in [m]$  where  $e_i$ s are the standard basis vectors:  $\mathbf{b}_i$ s exist because  $B$  is full rank.

Define  $\mathcal{G} = (G_0, \dots, G_{m-1})$  for some integer  $m < s$ , as  $G_i = X^i \cdot \sum_{c=0}^{m-1} b_i(c) S_c$ . Let  $r = s - m + 1$  and set  $\mathcal{T} = \{L_0, \dots, L_{r-1}\}$ .

Theorem 5.2-Item 1: Clearly,  $(\mathcal{T}, A)$  forms a linearly-extendible linear operator code  $LELO_{k+nr/m}^A(\mathcal{T})$  which is Affine-FRS $_r^{\alpha, \beta}[k + nr/m, n]$  at the set of evaluation points  $A$ .

Theorem 5.2-Item 2: For all  $G_i \in \mathcal{G}$ ,  $T_j \in \mathcal{T}$  and  $a \in A$  we have that for every polynomial  $f \in \mathbb{F}[X]$ :

$$\begin{aligned}
T_j(G_i(f))(a) &= \left( S_{j_0} D_{j_1} \left( X^i \cdot \sum_{c=0}^{m-1} b_i(c) S_c f \right) \right) (a) \\
&= \left( S_{j_0} \sum_{b=0}^{j_1} \binom{j_1}{b} \binom{i}{b} \cdot (b!) \cdot X^{i-b} D_b \left( \sum_{c=0}^{m-1} b_i(c) S_c f \right) \right) (a) \\
&= \left( S_{j_0} \sum_{b=0}^{j_1} \binom{j_1}{b} \binom{i}{b} \cdot (b!) \cdot X^{i-b} \left( \sum_{c=0}^{m-1} (b_i(c) \alpha_c^b) S_c D_b f \right) \right) (a) \\
&= \left( S_{j_0} \sum_{b=0}^{j_1} \binom{j_1}{b} \binom{i}{b} \cdot (b!) \cdot X^{i-b} \left( \sum_{c=0}^{m-1} (b_i(c) \alpha_c^b) L_{bu+cf} \right) \right) (a).
\end{aligned}$$

Notice that the above expression only involves  $L_i$ s where  $i < s$ .

Theorem 5.2-Items 3 and 4: follow almost identically to the corresponding items in Theorem A.6.

Thus Affine-FRS $_s^\beta[k, n]$  can be efficiently list-decoded up to distance  $1 - \frac{k-1}{rn} - \frac{1}{m}$  with list size  $q^{m-1}$ . By choosing a large enough  $m$  and  $s$  we can ensure that  $1 - \frac{k-1}{rn} - \frac{1}{m} > 1 - \frac{k}{sn} - \varepsilon$ . ◀

# Visible Rank and Codes with Locality

## Abstract

We propose a framework to study the effect of local recovery requirements of codeword symbols on the dimension of linear codes, based on a combinatorial proxy that we call *visible rank*. The locality constraints of a linear code are stipulated by a matrix  $H$  of  $\star$ 's and 0's (which we call a "stencil"), whose rows correspond to the local parity checks (with the  $\star$ 's indicating the support of the check). The visible rank of  $H$  is the largest  $r$  for which there is a  $r \times r$  submatrix in  $H$  with a unique generalized diagonal of  $\star$ 's. The visible rank yields a field-independent combinatorial lower bound on the rank of  $H$  and thus the co-dimension of the code.

We point out connections of the visible rank to other notions in the literature such as unique restricted graph matchings, matroids, spanoids, and min-rank. In particular, we prove a rank-nullity type theorem relating visible rank to the rank of an associated construct called *symmetric spanoid*, which was introduced by Dvir, Gopi, Gu, and Wigderson [5]. Using this connection and a construction of appropriate stencils, we answer a question posed in [5] and demonstrate that symmetric spanoid rank cannot improve the currently best known  $\tilde{O}(n^{(q-2)/(q-1)})$  upper bound on the dimension of  $q$ -query locally correctable codes (LCCs) of length  $n$ . This also pins down the efficacy of visible rank as a proxy for the dimension of LCCs.

We also study the  $t$ -Disjoint Repair Group Property ( $t$ -DRGP) of codes where each codeword symbol must belong to  $t$  disjoint check equations. It is known that linear codes with 2-DRGP must have co-dimension  $\Omega(\sqrt{n})$  (which is matched by a simple product code construction). We show that there are stencils corresponding to 2-DRGP with visible rank as small as  $O(\log n)$ . However, we show the second tensor of any 2-DRGP stencil has visible rank  $\Omega(n)$ , thus recovering the  $\Omega(\sqrt{n})$  lower bound for 2-DRGP. For  $q$ -LCC, however, the  $k$ 'th tensor power for  $k \leq n^{o(1)}$  is unable to improve the  $\tilde{O}(n^{(q-2)/(q-1)})$  upper bound on the dimension of  $q$ -LCCs by a polynomial factor. Inspired by this and as a notion of intrinsic interest, we define the notion of *visible capacity* of a stencil as the limiting visible rank of high tensor powers, analogous to Shannon capacity, and pose the question whether there can be large gaps between visible capacity and algebraic rank.

## 1 Introduction

The notion of *locality* in error-correcting codes refers to the concept of recovering codeword symbols as a function of a small number of other codeword symbols. Local decoding requirements of various kinds have received a lot of attention in coding theory, due to both their theoretical and practical interest. For instance,  $q$ -query locally correctable codes (LCCs) aim to recover any codeword symbol as a function of  $q$  other codeword symbols in a manner

robust to a constant fraction of errors. On the other hand, locally recoverable codes (LRCs), in their simplest incarnation, require each codeword symbol to be a function of some  $\ell$  other codeword symbols, allowing local recovery from any single erasure.<sup>1</sup>

LCCs have been extensively studied in theoretical computer science, and have connections beyond coding theory to topics such as probabilistically checkable proofs and private information retrieval. We refer the reader to [31] and the introduction of [13] for excellent surveys on LCCs and their connections. LRCs were motivated by the need to balance global fault tolerance with extremely efficient repair of a small number of failed storage nodes in modern large-scale distributed storage systems [12]. They have led to intriguing new theoretical questions, and have also had significant practical impact with adoption in large scale systems such as Microsoft Azur [17] and Hadoop [25].

Let us define the above notions formally, in a convenient form that sets up this work. We will restrict attention to linear codes in this work, i.e., subspaces  $C$  of  $\mathbb{F}_q^n$  for some finite field  $\mathbb{F}_q$ . In this case, the  $i$ 'th symbol  $c_i$  of every codeword  $c = (c_1, \dots, c_n) \in C$  can be recovered as a function of the symbols  $c_j$ , for indices  $j$  in a (minimal) subset  $R_i \subset [n] \setminus \{i\}$ , iff  $c_i$  and  $\{c_j \mid j \in R_i\}$  satisfy a linear check equation, or in other words, there is a dual codeword whose support equals  $\{i\} \cup R_i$ . The set  $R_i$  is called a *repair group* for the  $i$ 'th codeword symbol (other terminology used in the literature includes regenerating sets and recovery sets).

The  $q$ -LCC property, for a fixed number of queries  $q$  and growing  $n$ , corresponds to having  $\Omega(n)$  disjoint groups of size  $\leq q$  for each position  $i \in [n]$ , or equivalently  $\Omega(n)$  dual codewords of Hamming weight at most  $(q + 1)$  whose support includes  $i$  and are otherwise disjoint. The  $\ell$ -LRC corresponds to having a dual codeword of Hamming weight at most  $(\ell + 1)$  whose support includes  $i$ , for each  $i \in [n]$ . A property that interpolates between these extremes of a single repair group and  $\Omega(n)$  disjoint repair groups is the Disjoint Repair Group Property ( $t$ -DRGP) where we require  $t$  disjoint repair groups for each position  $i \in [n]$  (equivalently  $t$  dual codewords whose support includes  $i$  but are otherwise disjoint).

There is an exponentially large gap between upper and lower bounds on the trade-off between code dimension and code length for  $q$ -LCCs. The best known code constructions have dimension only  $O((\log n)^{q-1})$  (achieved by generalized Reed-Muller codes or certain lifted codes [14]), whereas the best known upper bound on the dimension of  $q$ -LCCs is much larger and equals  $\widetilde{O}(n^{(q-2)/(q-1)})$  [19, 29, 18]<sup>2</sup>. Narrowing this huge gap has remained open for over two decades.

In contrast the best possible dimension of a  $\ell$ -LRC is easily determined to be  $\lfloor \frac{\ell n}{\ell+1} \rfloor$ .<sup>3</sup> However, for  $t$ -DRGP, there are again some intriguing mysteries. For 2-DRGP, we have tight bounds – the minimum possible redundancy (co-dimension) equals  $\sqrt{2n} \pm \Theta(1)$ . The lower bound is established via very elegant proofs based on the polynomial method [30] or rank arguments [24]. However, for fixed  $t > 2$ , we do not know better lower bounds, and the best known constructions have co-dimension  $\approx t\sqrt{n}$  [6]. There are better constructions known for some values of  $t = n^{\Theta(1)}$  [8, 20]. A lower bound on the co-dimension of  $c(t)\sqrt{n}$  for some function  $c(t)$  that grows with  $t$  seems likely, but has been elusive despite various attempts, and so far for any fixed  $t$ , the bound for  $t = 2$  is the best known.

<sup>1</sup> There is also a distance requirement on LRCs to provide more global error/erasure resilience.

<sup>2</sup> The  $\widetilde{O}(\cdot)$  and  $\widetilde{\Omega}(\cdot)$  are used to suppress factors poly-logarithmic in  $n$ .

<sup>3</sup> In this case, a more interesting trade-off is a Singleton-type bound that also factors in the distance of the code [12].

This work was motivated in part by these major gaps in our knowledge concerning  $q$ -LCCs and  $t$ -DRGPs. Our investigation follows a new perspective based on *visible rank* (to be defined soon), which is a combinatorial proxy for (linear-algebraic) rank that we believe is of broader interest. This is similar in spirit to a thought-provoking recent work [5] that introduced a combinatorial abstraction of spanning structures called *spanoids*<sup>4</sup> to shed light on the limitations of current techniques to prove better upper bounds on the dimension of  $q$ -LCCs. They noted that current techniques to bound LCC dimension apply more generally to the associated spanoids, which they showed could have rank as large as  $\tilde{\Omega}(n^{(q-2)/(q-1)})$ . Therefore to improve the LCC bound one needs techniques that are more specific than spanoids and better tailored to the LCC setting. One such possibility mentioned in [5] is to restrict attention to *symmetric spanoids*, which have a natural symmetry property that linear LCCs imply.

Our visible rank notion turns out to be intimately related to symmetric spanoids via a rank-nullity type theorem (Theorem 14). While technically simple in hindsight, it offers a powerful viewpoint on symmetric spanoids which in particular resolves a question posed in [5] – we show that symmetric spanoids are also too coarse a technique to beat the  $\tilde{O}(n^{(q-2)/(q-1)})$  upper bound on  $q$ -LCC dimension.

## 1.1 Stencils and visible rank

With the above backdrop, we now proceed to describe the setup we use to study these questions, based on the rank of certain matrix templates which we call “stencils.” We can represent the support structure of the check equations (i.e., dual codewords) governing a locality property by an  $n$ -column matrix of 0’s and  $\star$ ’s. For each check equation involving the  $i$ ’th symbol and a repair group  $R_i \subset [n] \setminus \{i\}$ , we place a row in the stencil with  $\star$ ’s precisely at  $R_i \cup \{i\}$  (i.e., with  $\star$ ’s at the support of the associated dual codeword). For the  $\ell$ -LRC property for instance, an associated stencil would be an  $n \times n$  matrix with  $\star$ ’s on the diagonal and  $\ell$  other  $\star$ ’s in each row. For  $q$ -LCC, we would have a  $\delta n^2 \times n$  matrix whose rows are split into  $n$  groups with the rows in the  $i$ ’th group having a  $\star$  in the  $i$ ’th column and  $q$  other  $\star$ ’s in disjoint columns.

The smallest co-dimension of linear codes over a field  $\mathbb{F}$  with certain locality property is, by design, the minimum rank  $\text{rk}_{\mathbb{F}}(H)$  of the associated stencil  $H$  when the  $\star$ ’s are replaced by arbitrary nonzero entries from  $\mathbb{F}$ . In this work, our goal is to understand this quantity via field oblivious methods based only on the combinatorial structure of the stencil of  $\star$ ’s.

The tool we put forth for this purpose is the *visible rank* of  $H$ , denoted  $\text{vrk}(H)$  and defined to be the largest  $r$  for which there is a  $r \times r$  submatrix of  $H$  that has exactly one general diagonal whose entries are all  $\star$ ’s. By the Leibniz formula, the determinant of such a submatrix is nonzero for any substitution of nonzero entries for the  $\star$ ’s. Thus  $\text{rk}_{\mathbb{F}}(H) \geq \text{vrk}(H)$  for every field  $\mathbb{F}$ .

Our goal in this work is to understand the interrelationship between visible rank and the co-dimension of linear codes under various locality requirements. This can shed further light on the bottleneck in known techniques to study trade-offs between locality and code dimension, and optimistically could also lead to better constructions.

---

<sup>4</sup> We defer a precise description of spanoids, along with their strong connection to visible rank, to Section 2.4.

## 1.2 Visible rank and Locality

For  $\ell$ -LRCs, a simple greedy argument shows that its associated parity-check stencil  $H$  satisfies  $\text{vrk}(H) \geq n/(\ell + 1)$ . Thus visible rank captures the optimal trade-off between code dimension and locality  $\ell$ .

For  $q$ -LCCs with  $q \geq 3$ , an argument similar to (in fact a bit simpler than and implied by) the one for spanoids in [5] shows that the stencil corresponding to  $q$ -LCCs has visible rank at least  $n - \tilde{O}(n^{(q-2)/(q-1)})$ , showing an upper bound of  $\tilde{O}(n^{(q-2)/(q-1)})$  on the dimension of  $q$ -LCCs. We show that visible rank suffers the same bottleneck as spanoids in terms of bounding the dimension of  $q$ -LCCs.

► **Theorem 1.** *For  $q \geq 3$ , there exist  $n$ -column stencils  $H$  with  $\star$ 's structure compatible with  $q$ -LCCs for which  $\text{vrk}(H) \leq n - \tilde{\Omega}(n^{(q-2)/(q-1)})$ .*

Through the precise connection we establish between visible rank and symmetric spanoids, this shows the same limitation for symmetric spanoids, thus answering a question posed in [5].

For the  $t$ -DRGP property, we focus on the  $t = 2$  case, with the goal of finding a combinatorial substitute for the currently known  $\Omega(\sqrt{n})$  lower bounds on co-dimension [30, 8] which are algebraic. Unfortunately, we show that visible rank, in its basic form, is too weak in this context.

► **Theorem 2.** *There exist  $2n \times n$  stencils  $H$  with  $\star$ 's structure compatible with 2-DRGP for which  $\text{vrk}(H) \leq O(\log n)$ .*

## 1.3 Visible rank and tensor powers

In view of Theorem 2, we investigate avenues to get better bounds out of the visible rank approach. Specifically, we study the visible rank of tensor powers of the matrix. It turns out that the visible rank is super-multiplicative:  $\text{vrk}(H \otimes H) \geq \text{vrk}(H)^2$ , while on the other hand algebraic rank is sub-multiplicative, so higher tensor powers could yield better lower bounds on the rank. Indeed, we are able to show precisely this for 2-DRGP:

► **Theorem 3.** *For every  $2n \times n$  stencil  $H$  with  $\star$ 's structure compatible with 2-DRGP, we have  $\text{vrk}(H \otimes H) \geq \Omega(n)$ , and thus  $\text{rk}_{\mathbb{F}}(H) \geq \Omega(\sqrt{n})$  for every field  $\mathbb{F}$ .*

On the other hand, for  $q$ -LCCs with  $q \geq 3$ , we show that higher tensor powers suffer the same bottleneck as Theorem 1.

► **Theorem 4.** *For  $q \geq 3$ , there exist  $n$ -column stencils  $H$  with  $\star$ 's structure compatible with  $q$ -LCCs for which  $\text{vrk}(H^{\otimes k})^{1/k} \leq n - \tilde{\Omega}(n^{(q-2)/(q-1)})/k$  for any integer  $k$ . In particular even for  $k = n^{o(1)}$ , we get no polynomial improvements to the current upper bounds on dimension of  $q$ -LCCs.*

## 1.4 Visible capacity

Given the super-multiplicativity of visible rank under tensor powers, and drawing inspiration from the Shannon capacity of graphs, we put forth the notion of *visual capacity* of a matrix  $H$  of 0's and  $\star$ 's, defined as  $\Upsilon(H) := \sup_k \text{vrk}(H^{\otimes k})^{1/k}$ . The visual capacity is also a field oblivious lower bound on algebraic rank  $\text{rk}_{\mathbb{F}}(H)$  for any field  $\mathbb{F}$ . It is not known whether there are stencils that exhibit a gap between visible capacity and its minimum possible  $\text{rk}_{\mathbb{F}}(H)$  over all fields  $\mathbb{F}$ .

The proofs of our results are technically simple, once the framework is set up. Our contributions are more on the conceptual side, via the introduction and initial systematic study of visible rank and its diverse connections. Our inquiry also raises interesting questions and directions for future work, some of which are outlined in Section 7, including the relationship between visible capacity and algebraic rank.

## 1.5 Connections and related work

Studying the interplay between the combinatorial structure of a matrix and its rank is a natural quest that arises in several contexts. See Chapter 3 of [26] for a survey of works on lower bounding the algebraic rank. For works specific to codes with locality, the work of [3] analyzed the combinatorial properties of design matrices over the reals to improve bounds on LCCs over the real numbers, although the methods used are particular to the field of reals and do not carry over to any field.

Visible rank in particular turns out to have a diverse array of connections, some of which we briefly discuss here. The connection to spanoids, that we already mentioned, is described in more detail in Section 2.4.

**Uniquely restricted matchings.** Given a stencil  $H \in \{0, \star\}^{m \times n}$ , there is a canonical bipartite graph  $G$  between the rows and columns of  $H$ , where a row connects to a column if and only if their shared entry has a star. Visual rank has a nice graph-theoretic formulation: it turns out (see Section 2.3) that a submatrix of  $H$  has a unique general diagonal of  $\star$ 's iff the corresponding induced subgraph has a unique perfect matching. Such induced bipartite graphs are known in the literature as *Uniquely Restricted Matchings (URMs)* and have been extensively studied [11, 9, 16, 22, 27, 7]. They were first introduced in [11], wherein they proved that computing the maximum URM of a bipartite graph is NP-complete. It was later shown in [22] that  $n^{1/3-o(1)}$  approximations of the maximum URM is also NP-hard unless  $\text{NP} = \text{ZPP}$  and additionally that the problem of finding the maximum URM is APX-complete.

**Matroids.** One can encode any matroid into a stencil. Recall that a circuit of a matroid is a minimal dependent set – that is, a dependent set whose proper subsets are all independent (the terminology reflects the fact that in a graphic matroid, the circuits are cycles of the graph). Given a matroid  $\mathcal{M}$  on universe  $[n]$  and a set  $\mathcal{C} = \{C_1, \dots, C_m\}$  of circuits of  $\mathcal{M}$ , we consider a  $m \times n$  stencil  $H$  where the entry at  $(i, j)$  is a  $\star$  if and only if  $j \in C_i$ . For this matrix, one can show that a collection of visibly independent columns (see Section 2.2 for the definition of visible independence) is an independent set in the dual matroid. Therefore, we have  $\text{rk}(\mathcal{M}) + \text{vrk}(H) \leq n$  – this also follows from our rank-nullity theorem for symmetric spanoids as one can associate a symmetric spanoid with any matroid (the collection of sets in Definition 13 will just be the circuits of the matroid).

**Min-rank.** The minimum possible rank of a square  $0\text{-}\star$  stencil over assignments to the  $\star$ 's from some field has been well studied in combinatorics.<sup>5</sup> For example, we have Haemers' classic bound on independent set of a graph and its applications to Shannon capacity [15].

<sup>5</sup> There is a slight difference in the minrank setup, in that the  $\star$ 's can take any value including 0, except the  $\star$ 's on the diagonal which must take nonzero values.

Note that in this case we are using a linear-algebraic tool to understand a combinatorial quantity, whereas visible rank goes the other way, serving as a combinatorial proxy for a linear-algebraic quantity. Recent interest in minrank has included their characterization of the most efficient linear index codes [2]. The minrank of stencils corresponding to  $n$ -vertex random Erdős-Rényi graphs was recently shown to be  $\Theta(n/\log n)$  over any field that is polynomially bounded [10].

**Matrix Rigidity.** Given a square matrix  $A \in \mathbb{F}^{n \times n}$  and a natural number  $r \leq n$ , the *rigidity* of  $A$  is the minimal number of entries that one can perturb in  $A$  so that its rank becomes at most  $r$ . Matrix rigidity was introduced in the seminal work [28] and since then had expansive research on constructing explicit rigid matrices. See [23] for a recent survey on matrix rigidity and related connections. The visible rank provides a combinatorial guarantee on the rank of a matrix, and that conjures up the possibility of constructing explicit rigid matrices by finding explicit stencils whose visible rank is robust to small amounts of corruptions of its entries.

**Incidence Theorems.** Given an  $m \times n$  matrix  $A$  over the field  $\mathbb{F}$  with rank  $r$ , one can decompose  $A = MN$  where  $M$  and  $N$  are  $m \times r$  and  $r \times n$  matrices. If we consider the rows of  $M$  as hyperplanes over the projective plane  $\mathbb{P}\mathbb{F}^{r-1}$  of dimension  $(r-1)$  and the columns of  $N$  as points in  $\mathbb{P}\mathbb{F}^{r-1}$ , then the stencil of  $A$  defines a point-hyperplane incidence over  $\mathbb{P}\mathbb{F}^{r-1}$ . In particular, when  $r = 3$ , the stencil of  $A$  defines a point-line incidence over the field  $\mathbb{F}$ . Thus studying the combinatorial properties of a stencil whose  $\mathbb{F}$ -rank (see Definition 6) is at most 3 is equivalent to studying the combinatorics of point-line incidences over the field  $\mathbb{F}$ . For more on incidence theorems, see [4] for an excellent survey in the area.

**Communication complexity.** The visible rank provides a connection between deterministic and nondeterministic communication complexity [21]. For a communication problem  $f : X \times Y \rightarrow \{0, 1\}$ , define the stencil  $H_f \in \{0, \star\}^{X \times Y}$  by  $H_f(x, y) = \star$  if  $f(x, y) = 0$  and  $M_f(x, y) = 0$  if  $f(x, y) = 1$ . Then it is known that  $D(f) \leq (\log_2 \text{vrk}(H_f)) \cdot (N(f) + 1)$  where  $D(f)$  and  $N(f)$  are respectively the deterministic and nondeterministic communication complexity of  $f$  [21, Thm 3.5].

## 1.6 Organization

We begin in Section 2 by formally introducing the notations and terminology for stencils, and establishing some simple but very useful combinatorial facts about visible rank. We use these to show that there are  $q$ -LCC stencils for  $q \geq 3$  with visible rank at most  $n - \tilde{\Omega}(n^{(q-2)/(q-1)})$  (Section 3), and the existence of a 2-DRGP stencil with visible rank of at most  $O(\log n)$  (Section 4). In Section 5, we introduce a tensor product operation on stencils and prove various properties about them. In Section 6, we utilize tensor powers to show that the rank of a 2-DRGP over any field  $\mathbb{F}$  is at least  $\sqrt{n}$ , which asymptotically matches the current best lower bounds on  $t$ -DRGP codes. We also show that for  $q$ -LCC stencils, the tensor powers at the  $k$ 'th level for  $k \leq \text{polylog}(n)$  do not yield better lower bounds on the rank than the ones obtained from the visible rank. Finally, in Section 7, we discuss further directions and questions inspired by this work.

## 2 Stencils and their visible rank

In this section, we will be formally setting up the model of stencils and all the associated definitions and notations. We denote  $[n]$  to be the set  $\{1, 2, \dots, n\}$ . For any matrix  $H \in \{0, \star\}^{m \times n}$ , we denote it as a *stencil*. For an  $m \times n$  stencil  $H$ , we denote its entry in the  $i$ 'th row and  $j$ 'th column by  $H[i, j]$ . Any restriction to the specific sub-collection of the rows and columns of  $H$  is said to be a *sub-stencil* of  $H$ . For given sets  $A$  and  $B$ , a stencil  $H$  is said to be an  $A \times B$  if it is an  $|A| \times |B|$  stencil along with an associated indexing of the rows by  $A$  and the columns by  $B$ . Given a square stencil  $M \in \{0, \star\}^{n \times n}$ , a *general diagonal* of  $M$ , is a collection of entries  $\{M[1, \pi(1)], \dots, M[n, \pi(n)]\}$  where  $\pi$  is a permutation on  $[n]$ . We say that a general diagonal is a *star diagonal* if all its  $n$  entries are  $\star$ 's.

### 2.1 Algebraic witnesses of stencils

Instantiating a code with the locality properties stipulated by a stencil amounts to filling its  $\star$ 's with field entries, or realizing an algebraic witness as defined below.

► **Definition 5** (Algebraic witness). *For field  $\mathbb{F}$  and stencil  $H \in \{0, \star\}^{m \times n}$ , a matrix  $W \in \mathbb{F}^{m \times n}$  is said to be an  $\mathbb{F}$ -witness of  $H$  if it satisfies the property that  $W[i, j] \neq 0$  if and only if  $H[i, j] = \star$ . More generally, any  $\mathbb{F}$ -witness of  $H$  is said to be an algebraic witness of  $H$ .*

We stress that every  $\star$  in the stencil  $H$  must be replaced by a *nonzero* entry from  $\mathbb{F}$  and cannot be zero. Of the possible algebraic witnesses for  $H$ , we will be primarily focused in this paper on the algebraic witnesses that attain the smallest feasible rank, which leads us to the following definition.

► **Definition 6** (Rank). *Given an  $m \times n$  stencil  $H$ , the  $\mathbb{F}$ -rank of  $H$  is the smallest natural number  $r$  such that there exists a field  $\mathbb{F}$  and an  $\mathbb{F}$ -witness  $W \in \mathbb{F}^{m \times n}$  whose rank is equal to  $r$ . We denote the value  $r$  by  $\text{rk}_{\mathbb{F}}(H)$ .*

### 2.2 Visible Rank

In this section, we introduce our notion of the *visible rank* of a stencil. The main motivation of introducing the visible is to be able to determine the most optimal lower bound on the rank of a matrix with only the knowledge of knowing the support of a matrix and nothing else about the values of that support.

Consider a square matrix  $A \in \mathbb{F}^{n \times n}$ , and suppose we are interested in determining if it is full rank. A natural approach would be to inspect its determinant. From the Leibniz formula, we know that  $\det(A) = \sum_{\pi \in S_n} \prod_{i=1}^n (-1)^{\text{sgn}(\pi)} A_{i, \pi(i)}$ , where  $S_n$  denotes the symmetric group of order  $n$  and  $\text{sgn}(\pi)$  denotes the sign of a permutation  $\pi$ . From Leibniz formula, notice that  $\det(A)$  is a linear combination of the nonzero general diagonals of  $A$ . If our hope is to obtain  $\det(A) \neq 0$  without any knowledge of the values of the support of  $A$ , one way to guarantee it is to say that  $A$  has exactly one nonzero general diagonal. In such a case, we can guarantee that  $\det(A) \neq 0$ . As when  $A$  has more than one general diagonal, there is no guarantee if  $\det(A) \neq 0$  without inspecting the values of the support of  $A$ .

From the previous discussion, it seems natural to define the notion of a rank on stencils as follows.

► **Definition 7** (Visibly Full Rank). *For a square stencil  $M \in \{0, \star\}^{n \times n}$ , we say that  $M$  is visibly full rank if  $M$  has exactly one star diagonal. That is, a general diagonal whose entries are all  $\star$ 's.*

Of course, in most cases, when we are given a matrix  $A \in \mathbb{F}^{m \times n}$ , we would be interested in determining its rank. One way to define the rank of the matrix  $A$  is to say that  $\text{rank}(A)$  is the size of the largest square submatrix in  $A$  that is full-rank. From this viewpoint, it seems clear to define the rank of a stencil in a similar fashion.

► **Definition 8** (Visible Rank). *For a stencil  $H \in \{0, \star\}^{m \times n}$ , the visible rank of  $H$ , denoted  $\text{vrk}(H)$ , is the largest square sub-stencil in  $H$  that is visibly full rank.*

We also say that a set of  $k$  columns in  $H$  is *visibly independent* if there exists a  $k \times k$  sub-stencil within these  $k$  columns that is visibly full rank. Of course, not all full-rank square matrices  $A \in \mathbb{F}^{m \times n}$  necessarily have exactly one nonzero general diagonal, but all squares that have exactly one nonzero general diagonal are necessarily full-rank. Thus if we are interested in determining  $\text{rank}(A)$  by finding the size of the largest square submatrix in  $A$  that is full-rank, we can instead search for the largest square submatrix in  $A$  that has exactly one nonzero general diagonal. Since that square submatrix has rank at most the rank of  $A$ , this leads us to the following proposition.

► **Proposition 9.** *Given a field  $\mathbb{F}$  and stencil  $H \in \{0, \star\}^{m \times n}$ , we have  $\text{rk}_{\mathbb{F}}(H) \geq \text{vrk}(H)$ .*

### 2.3 Combinatorial properties of visible rank

In this subsection, we will be proving some properties about visible rank. In particular, we will show that any visibly independent stencil  $M$  is permutationally equivalent to an upper triangular stencil, and from this observation, we will be able to upper bound the visible rank by the largest rectangle of zeros in the stencil, which will be our main tool in our constructions of  $q$ -LCC and  $t$ -DRGP stencils. We also show an upper bound on the rank of a stencil by the maximum number of zeros in each row.

Given two stencils  $H_1, H_2 \in \{0, \star\}^{m \times n}$ , we say that  $H_1$  is *permutationally equivalent* to  $H_2$  if there are permutations  $\pi : [m] \rightarrow [m]$  and  $\sigma : [n] \rightarrow [n]$  such that  $H_1[i, j] = H_2[\pi(i), \sigma(j)]$  for all  $i \in [m]$  and  $j \in [n]$ . For such  $H_1$  and  $H_2$ , we introduce the notation  $H_2 = (H_1)_{\pi, \sigma}$  to say that  $H_2$  is obtained from  $H_1$  by permuting the rows with the permutation  $\pi$  and the columns by the permutation  $\sigma$  (We remark that row permutations commute with column permutations).

► **Lemma 10.** *Let  $M \in \{0, \star\}^{n \times n}$  be visibly full rank. Then there exists permutations  $\pi$  and  $\sigma$  on  $[n]$  such that  $N := M_{\pi, \sigma}$  is an upper triangular stencil. That is,  $N[i, i] = \star$  and  $N[i, j] = 0$  for all  $i, j \in [n]$  with  $i > j$ .*

**Proof.** First, we claim that for any visibly full rank stencil  $M \in \{0, \star\}^{n \times n}$ , there exists a row in  $M$  with exactly one star. Indeed, assume (for the sake of a contradiction) that such a row doesn't exist. Since no row can be all zeros in  $M$ , then each row has at least two  $\star$ 's. Index the rows of  $M$  by  $R = \{r_1, \dots, r_n\}$  and the columns by  $C = \{c_1, \dots, c_n\}$ . Let  $G = (R, C, S)$  be a bipartite graph on the rows and columns of  $M$  with edges  $S$ , where  $S$  is the set of  $\star$ 's in  $M$ . Because  $M$  is visibly independent,  $G$  has a unique perfect matching. Moreover, by our initial assumption,  $d_G(v) \geq 2$  for all  $v \in R$ . Thus if we color the edges of the unique

matching of  $G$  red and all remaining edges of  $G$  blue, then by the fact that  $d_G(v) \geq 2$  for all  $v \in R$ , we can find an alternating cycle  $C$  with red edges  $R_C$  and blue edges  $B_C$ . Since  $R_C$  and  $B_C$  match the same vertex sets, then replacing the edges in  $R_C$  with those of  $B_C$  in the unique matching will produce another matching, but that's a contradiction as  $G$  has a unique perfect matching. This proves our claim.

Next, we proceed by induction on  $n$ . The base case  $n = 1$  is immediate to see. As for the induction step, we know by the previous claim that there exists some row in  $M$  with exactly one  $\star$ . Thus we can find a permutationally equivalent matrix  $M'$  of  $M$  with the  $n$ 'th row having exactly one  $\star$  at the  $n$ 'th column. Because  $M$  is visibly independent, then so is  $M'$ . Moreover, any general diagonal in  $M'$  must contain  $M[n, n]$ . This means that the  $(n - 1) \times (n - 1)$  minor  $M'_0$ , which is obtained by deleting row  $n$  and column  $n$  of  $M'$ , is visibly independent. By our induction hypothesis, we can permute the rows and columns of  $M'_0$  to make it upper triangular, and thus we conclude that  $M$ 's rows and columns can be permuted to make it upper triangular. ◀

Thus we can characterize all visibly full rank matrices, and that help us obtain the following upper bound on the visible rank.

► **Lemma 11.** *Given an  $m \times n$  stencil  $H$ , if there are natural numbers  $a, b$  such that  $H$  has no  $a \times b$  sub-stencil of zeros, then we have  $\text{vrk}(H) < a + b$ .*

**Proof.** Assume (for the sake of a contradiction) that  $H$  has a  $(a + b) \times (a + b)$  square sub-stencil  $H_0$  that is visibly independent. By Lemma 10, we know that  $H_0$  is permutationally equivalent to an  $(a + b) \times (a + b)$  upper triangle. Since such triangle has a  $a \times b$  sub-stencil of zeros, we arrive to a contradiction. ◀

We also provide an upper bound on the rank of a stencil by the maximum number of zeros in each rows.

► **Proposition 12.** *For any  $m \times n$  stencil  $H$ . If each row of  $H$  has at most  $d$  zeros, then we have that  $\text{rk}_{\mathbb{F}}(H) \leq d + 1$  for all fields  $\mathbb{F}$  such that  $|\mathbb{F}| \geq n$ .*

**Proof.** Pick a field  $|\mathbb{F}| \geq n$ . Label the columns of  $H$  by pairwise distinct entries  $a_1, \dots, a_n \in \mathbb{F}$ . For row  $i$ , let the columns that are zero along row  $i$  be  $Z_i \subseteq \{a_1, \dots, a_n\}$ . Consider the polynomial  $p_i(x) := \prod_{a \in Z_i} (x - a)$ . Notice that  $p_i$  evaluates to zero on  $Z_i$ . On everywhere else, it evaluates to a nonzero value. Thus the matrix  $E \in \mathbb{F}^{m \times n}$  defined by  $E_{ij} = p_i(a_j)$  is an  $\mathbb{F}$ -witness of  $H$ . Moreover, since  $|Z_i| \leq d$  for each  $i \in [m]$ , then we know that the monomials  $\{1, x, \dots, x^d\}$  span the polynomials  $\{p_1, \dots, p_m\}$ . This shows that  $\text{rank}(E) \leq d + 1$  and thus  $\text{rk}_{\mathbb{F}}(H) \leq d + 1$ . ◀

We remark that the bound  $|\mathbb{F}| \geq n$  is crucial for Proposition 12. Consider the stencil  $D \in \{0, \star\}^{n \times n}$  that has  $\star$ 's everywhere except on the diagonal. Such a stencil has a visible rank of 2, but one can show that its rank over  $\mathbb{F}_2$  is at least  $n - 1$ .

## 2.4 A Rank-Nullity Type Theorem Between Stencils and Symmetric Spanoids

In this subsection, we formally setup spanoids and prove a rank-nullity type theorem between symmetric spanoids and stencils.

A *spanoid*  $\mathcal{S}$  is a collection of inference rules in the form of pairs  $(S, i)$ , which are written in the form  $S \rightarrow i$ , where  $S \subseteq [n]$  and  $i \in [n]$ . The objective in spanoids is to determine the size of the smallest subset  $B \subseteq [n]$  such that one can use the inference rules of  $\mathcal{S}$  to obtain all of  $[n]$ . Spanoids were introduced in [5] as an abstraction of LCCs, wherein they proved that the spanoid analog of  $q$ -LCCs satisfy the upper bound  $\tilde{O}(n^{(q-2)/(q-1)})$  on the rank. Moreover, they also showed that there are  $q$ -LCC spanoids for which their rank is  $\tilde{\Omega}(n^{(q-2)/(q-1)})$ .

Let us setup the definitions needed for spanoids. A derivation in  $\mathcal{S}$  of  $i \in [n]$  from a set  $T \subseteq [n]$  is a sequence of sets  $T_0 = T, T_1, \dots, T_r$  satisfying  $T_j = T_{j-1} \cup \{i_j\}$  for some  $i_j \in [n]$ ,  $j \in [r]$ , and with  $i_r = i$ . Further, for every  $j \in [r]$ , there is a rule  $(S_{j-1}, i_j)$  in  $\mathcal{S}$  for some  $S_{j-1} \subseteq T_{j-1}$ . The *span* of a set  $T \subseteq [n]$ , denoted  $\text{span}_{\mathcal{S}}(T)$ , is the set of all  $i \in [n]$  for which there is a derivation of  $i$  from  $T$ . The rank of a spanoid, denoted  $\text{rank}(\mathcal{S})$ , is the size of the smallest set  $T \subseteq [n]$  such that  $\text{span}_{\mathcal{S}}(T) = [n]$ . Finally, we define symmetric spanoids below.

► **Definition 13** (Symmetric Spanoids). *A spanoid  $\mathcal{S}$  over  $[n]$  is a symmetric spanoid if there are a collection of sets  $\{S_1, \dots, S_m\}$  so that the inference rules of  $\mathcal{S}$  are of the form  $S_j \setminus \{i\} \rightarrow \{i\}$  for any  $i \in S_j$  and  $j \in [m]$ .*

Now we may proceed to prove our theorem that relates the rank of symmetric spanoids with the visible rank of an associated stencil.

► **Theorem 14.** *For any symmetric spanoid  $\mathcal{S}$  over  $[n]$  with  $m$  sets, there exists a canonical stencil  $H$  of size  $m \times n$  such that for any collection of columns  $C \subseteq [n]$  in  $H$ , they are visibly independent if and only if  $\text{span}_{\mathcal{S}}([n] \setminus C) = [n]$ . Moreover, we have  $\text{vrk}(H) + \text{rank}(\mathcal{S}) = n$ .*

**Proof.** Define  $H[i, j] = \star$  if  $j \in S_i$  and zero otherwise. We claim that such  $H$  satisfies the conditions. Indeed, suppose that the columns  $C = \{c_1, \dots, c_k\}$  are visibly independent. Then that means there are rows  $r_1, \dots, r_k$  so that the  $k \times k$  sub-stencil formed by these columns and rows is visibly full rank. Denote this matrix as  $H_C$ . By Lemma 10, we can find permutations  $\pi, \sigma$  over  $[k]$  such that the matrix  $H'_C := H_{\pi, \sigma}$  is upper triangular. In terms of spanoids, that means  $c_{\sigma(i)} \in S_{r_{\pi(i)}}$  and  $S_{r_{\pi(i)}} \subseteq [n] \setminus \{c_{\sigma(1)}, \dots, c_{\sigma(i-1)}\}$  for all  $i \in [k]$ . We can rewrite the last set containment as  $S_{r_{\pi(i)}} \subseteq ([n] \setminus C) \cup \{c_{\sigma(i)}, \dots, c_{\sigma(k)}\}$ . Thus we apply the inference rules  $S_{r_{\pi(k)}} \setminus c_{\sigma(k)} \rightarrow c_{\sigma(k)}, S_{r_{\pi(k-1)}} \setminus c_{\sigma(k-1)} \rightarrow c_{\sigma(k-1)}, \dots, S_{r_{\pi(1)}} \setminus c_{\sigma(1)} \rightarrow c_{\sigma(1)}$  in that order with the set  $[n] \setminus C$ , to deduce that the set  $[n] \setminus C$  spans the set  $[n]$  in  $\mathcal{S}$ . Thus  $\text{span}_{\mathcal{S}}([n] \setminus C) = [n]$ .

Now, suppose that  $\text{span}_{\mathcal{S}}([n] \setminus C) = [n]$ . Then that means that we can find sets  $S_{i_1}, \dots, S_{i_k}$  and a permutation  $\sigma$  over  $[k]$  such that  $c_{\sigma(j)} \in S_{i_j}$  and we can apply the inference rules  $S_{i_1} \setminus \{c_{\sigma(1)}\} \rightarrow c_{\sigma(1)}, \dots, S_{i_k} \setminus \{c_{\sigma(k)}\} \rightarrow c_{\sigma(k)}$  in that order. That implies then that  $S_{i_j} \subseteq ([n] \setminus C) \cup \{c_{\sigma(1)}, \dots, c_{\sigma(j)}\}$ . In terms of the stencil  $H$ , that means  $H[i_j, \sigma(j)] = \star$  and  $H[i_\ell, \sigma(j)] = 0$  for  $\ell < j$ . Thus the  $k \times k$  sub-stencil  $H'$  that is restricted to the columns  $c_{\sigma(1)}, \dots, c_{\sigma(k)}$  and rows  $i_1, \dots, i_k$  in that order forms a lower triangular stencil, which is permutationally equivalent to an upper triangular stencil. Thus we deduce that the set of columns  $C$  is visibly independent.

Now, for any set  $S \subseteq [n]$  such that  $\text{span}_{\mathcal{S}}(S) = [n]$ , we know that  $[n] \setminus S$  is visibly independent in  $H$ . Thus  $n - |S| \leq \text{vrk}(H)$ . Since this holds for any such set  $S$ , then we deduce that  $\text{rank}(\mathcal{S}) + \text{vrk}(H) \geq n$ . On the other hand, for any collection of columns  $C$  in  $H$  that is visibly independent, we know that  $\text{span}_{\mathcal{S}}([n] \setminus C) = [n]$ . This implies  $n - |C| \geq \text{rank}(\mathcal{S})$ . Since this holds for any visibly independent set of columns  $C$  in  $H$ , then we find that  $n \geq \text{rank}(\mathcal{S}) + \text{vrk}(H)$ . Hence  $\text{rank}(\mathcal{S}) + \text{vrk}(H) = n$ . ◀

### 3 Constructing $q$ -LCC Stencils

In this section, we define  $q$ -LCC stencils and construct  $q$ -LCC stencils whose visible rank achieves the known lower bounds up to polylog factors.

► **Definition 15** ( $q$ -LCC Stencils). For  $\delta > 0$ , a  $\delta n^2 \times n$  stencil  $H$  whose rows are labelled by  $[n] \times [\delta n]$  is said to be a  $q$ -LCC stencil if  $H[(i, j), i] = \star$  for all  $(i, j) \in [n] \times [\delta n]$ . Moreover, for every  $k \in [n] \setminus \{i\}$ , the collection of entries  $\{M[(i, 1), k], \dots, M[(i, t), k]\}$  has at most one star, and the number of  $\star$ 's in each row of  $H$  is at most  $q + 1$ .

Now we proceed to prove our main theorem for this section.

► **Theorem 16.** For  $q \geq 3$ , there exists a  $q$ -LCC stencil  $M$  for which  $\text{vrk}(M) \leq n - \tilde{\Omega}\left(n^{(q-2)/(q-1)}\right)$ .

**Proof.** For  $(i, j) \in [n] \times [\delta n]$ . Define  $r_j^i := \{k \in [n] : H[(i, j), k] = \star\}$  to be the support of row  $(i, j)$ , and let  $G_i := \{r_j^i : j \in [\delta n]\}$  be the  $\delta n$  groups for column  $i$ . We shall show that by picking the groups  $G_i$  uniformly at random, the visible rank will at most be  $n - n^{(q-2)/(q-1)}/\log n$  with high probability.

Consider natural numbers  $s > k$  where  $s = n^{\frac{q-2}{q-1}}$  and  $k = s/\log n = n^{\frac{q-2}{q-1}}/\log n$ . Let  $E_{s,k}$  be the event that there aren't any  $(s - k) \times (n - s)$  sub-stencils in  $H$  that are all zeros. We shall show that  $E_{s,k}$  occurs with high probability, which will yield an upper bound of  $n - k$  on the visible rank via Lemma 11. We will use an equivalent form of the event  $E_{s,k}$ , which is the event that there are no  $s - k$  rows in  $H$  whose union of supports is at most  $s$ . Now, consider a collection of columns  $C$  of size  $s$  and a collection of  $s - k$  rows  $R$ , where  $R$  and  $C$  denote the collection of their supports. Enumerate  $R \cap G_i = \{r_1^i, \dots, r_{a_i}^i\}$ . By the chain rule, the definition of  $G_i$ , and the independence of the  $G_i$ 's, we find that

$$\begin{aligned} \Pr \left[ \bigwedge_{r \in R} r \subseteq C \right] &= \prod_{i=1}^n \Pr \left[ \bigwedge_{r \in R \cap G_i} r \subseteq C \right] \\ &= \prod_{i=1}^n \prod_{j=1}^{a_i} \Pr \left[ r_j^i \subseteq C \mid r_k^i \subseteq C \text{ for } k \in [j - 1] \right] \\ &= \prod_{i=1}^n \prod_{j=1}^{a_i} \Pr \left[ r_j^i \setminus \{i\} \subseteq C \setminus \{r_1^i, \dots, r_{j-1}^i\} \mid r_k^i \subseteq C \text{ for } k \in [j - 1] \right] \\ &= \prod_{i=1}^n \prod_{j=1}^{a_i} \frac{\binom{s-(j-1)q-1}{q}}{\binom{n-(j-1)q-1}{q}} \leq \left( \frac{\binom{s-1}{q}}{\binom{n-1}{q}} \right)^{s-k} \leq \left( \frac{s}{n} \right)^{q(s-k)} \end{aligned}$$

Therefore, from the definition of  $E_{s,k}$ , by applying a Union Bound over all possible collections of columns  $C$  of size  $s$  and  $s - k$  collections of rows  $R$  and use the bound  $\binom{a}{b} \leq \left(\frac{ea}{b}\right)^b$ , we

deduce that

$$\begin{aligned}
\Pr[E_{s,k}] &\leq \binom{n}{s} \binom{\delta ns}{s-k} \left(\frac{s}{n}\right)^{q(s-k)} \leq \left(\frac{en}{s}\right)^s \left(\frac{e\delta ns}{s-k}\right)^{s-k} \left(\frac{s}{n}\right)^{q(s-k)} \\
&= \left(\frac{en}{s}\right)^k \left(\frac{e^2 \delta s^{q-1}}{\left(1 - \frac{k}{s}\right) n^{q-2}}\right)^{s-k} \\
&= \left(en^{1/(q-1)}\right)^k \left(\frac{e^2 \delta}{\left(1 - \frac{1}{\log n}\right)}\right)^{n^{\frac{q-2}{q-1}} \left(1 - \frac{1}{\log n}\right)}
\end{aligned}$$

Thus for small enough  $\delta < e^{-2}$ , the quantity above becomes  $\exp\left(-\Omega(n^{(q-2)/(q-1)})\right)$ . Thus we can find a  $q$ -LCC stencil  $M$  such that no  $s-k$  rows whose support is entirely contained within  $s$  columns. That is equivalent to saying that there is no  $(s-k) \times (n-s)$  sub-stencil that is all zeros. By Lemma 11, we therefore conclude that  $\text{vrk}(M) < n-k = n - \Omega\left(n^{\frac{q-2}{q-1}}/\log n\right)$ . ◀

#### 4 $t$ -DRGP Stencils

We now define the stencils that capture the requirement of each codeword symbol having  $t$  disjoint recovery groups.

► **Definition 17** ( $t$ -DRGP Stencils). *A  $tn \times n$  stencil  $H$  whose rows are labelled by  $[n] \times [t]$  is said to be a  $t$ -DRGP stencil if  $H[(i, j), i] = \star$  for all  $(i, j) \in [n] \times [t]$ . Moreover, for every  $k \in [n] \setminus \{i\}$ , the collection of entries  $\{M[(i, 1), k], \dots, M[(i, t), k]\}$  has at most one star.*

Now we proceed to prove our main theorem for this section.

► **Theorem 18.** *For any fixed natural number  $t \geq 2$ , there exists a  $t$ -DRGP stencil  $H$  satisfying  $\text{vrk}(H) \leq O(t^2 \log n)$ .*

**Proof.** Consider a random  $t$ -DRGP stencil  $H$  as follows: define the set of entries  $S_{i,j} := \{(i, s), j \mid s \in [t]\}$ . Set for each  $i \neq j \in [n]$ , set all of the entries  $S_{i,i}$  to be  $\star$ 's, and uniformly sample an entry from  $S_{i,j}$  to be a  $\star$  while everything else in  $S_{i,j}$  is set to be zero.

We will show that  $\text{vrk}(H) \leq c_1 \log n$  occurs with high probability. Indeed, fix  $k \in \mathbb{N}$ . Given any square sub-stencil  $H_0$  of  $H$  of size  $k$ , we have by Lemma 10 that if  $H_0$  is visibly independent, then we must have at least  $\binom{k}{2}$  zeros. Let this set of entries be  $Z \subseteq ([n] \times [t]) \times [n]$ . Since  $Z$  must all be zeros, then we deduce that  $Z \subseteq \cup_{i \neq j} S_{i,j}$ . Since each  $S_{i,j}$  has size  $t$ , then  $Z$  has at least  $\binom{k}{2}/t$  entries, each of which belongs to an  $S_{i,j}$  that is different than the other. That is, for each  $i \neq j \in [n]$  such that  $Z \cap S_{i,j} \neq \emptyset$ , arbitrarily pick an entry  $e \in Z \cap S_{i,j}$ , and let  $T$  be those set of entries. Then we know that  $T \geq \binom{k}{2}/t$ . Moreover, the events that the entries in  $T$  are zero are all independent, with each having a chance of at most  $1 - 1/t$  of being zero. Thus the chance that  $Z$  is all-zeros is at most  $(1 - 1/t)^{\binom{k}{2}/t}$ . By a Union Bound over all possible such  $Z$ 's, which is enumerated over all  $(k!)^2$  different permutations of the rows and columns, we deduce that

$$\Pr[H_0 \text{ is visibly independent}] \leq (k!)^2 \left(1 - \frac{1}{t}\right)^{\frac{\binom{k}{2}}{t}} \leq \left(k^2 \left(1 - \frac{1}{t}\right)^{\frac{k-1}{2t}}\right)^k.$$

And by applying another Union Bound over all such  $H_0$ , we find that

$$\Pr[\text{vrk}(H) \geq k] \leq \binom{tn}{k} \binom{n}{k} \left( k^2 \left( 1 - \frac{1}{t} \right)^{\frac{k-1}{2t}} \right)^k \leq \left( k^2 t n^2 \left( 1 - \frac{1}{t} \right)^{\frac{k-1}{2t}} \right)^k.$$

Picking  $k = 6t^2 \ln n + 1$  makes the right hand side less than 1 for large enough  $n$ . ◀

## 5 Tensor Products

In this section, we will be introducing a tensor product operation on stencils and explore its properties. Given the natural tensor product  $A \otimes B$  for matrices  $A$  and  $B$ , notice that the support of  $A \otimes B$  is determined completely by the support of the matrices  $A$  and  $B$ . As a consequence of this observation, we will be able to define the stencil of  $A \otimes B$  based solely on the stencils of  $A$  and  $B$ . This leads us to our definition of a tensor product over stencils.

► **Definition 19** (Tensor product). *Given an  $A_1 \times B_1$  stencil  $H_1$  and an  $A_2 \times B_2$  stencil  $H_2$ , let  $H_1 \otimes H_2$  be a  $(A_1 \times A_2) \times (B_1 \times B_2)$  stencil such that*

$$(H_1 \otimes H_2)[(a_1, a_2), (b_1, b_2)] = \begin{cases} \star & \text{if } H_1[a_1, b_1] \text{ and } H_2[a_2, b_2] \text{ both equal } \star, \\ 0 & \text{if at least one of } H_1[a_1, b_1] \text{ and } H_2[a_2, b_2] \text{ equals } 0. \end{cases}$$

We remark that our tensor product follows similar properties as the natural tensor product for matrices, such as associativity and non-commutativity.

### 5.1 Algebraic witnesses of tensor products

In this subsection, we will be proving that any algebraic witnesses of the stencils  $H_1$  and  $H_2$  is also an algebraic witness of  $H_1 \otimes H_2$ . This will therefore show us that the  $\mathbb{F}$ -rank is a *sub-multiplicative* function with respect to the tensor product.

► **Proposition 20.** *Let  $M$  and  $N$  be matrices over a field  $\mathbb{F}$  who are  $\mathbb{F}$ -witnesses to stencils  $H_1, H_2$ , respectively. Then  $M \otimes N$  is an  $\mathbb{F}$ -witness of  $H_1 \otimes H_2$ .*

**Proof.** For every entry in  $H_1 \otimes H_2$ , we know that  $(H_1 \otimes H_2)[(i_1, i_2), (j_1, j_2)]$  is a  $\star$  if and only if  $H_1[i_1, j_1]$  and  $H_2[i_2, j_2]$  are both  $\star$ 's. This holds if and only if  $M_{i_1 j_1}$  and  $N_{i_2 j_2}$  are both nonzero. Because  $(M \otimes N)_{(i_1, i_2), (j_1, j_2)} = M_{i_1 j_1} N_{i_2 j_2}$ , then the entry  $(M \otimes N)_{(i_1, i_2), (j_1, j_2)}$  is nonzero if and only if  $M_{i_1 j_1}$  and  $N_{i_2 j_2}$  are both nonzero. Thus  $M \otimes N$  is an  $\mathbb{F}$ -witness of  $H_1 \otimes H_2$ . ◀

By applying Proposition 20 on the  $\mathbb{F}$ -witnesses of  $H_1$  and  $H_2$  with the smallest ranks, we deduce the following corollary.

► **Corollary 21.** *For a field  $\mathbb{F}$ , we have the inequality  $rk_{\mathbb{F}}(H_1)rk_{\mathbb{F}}(H_2) \geq rk_{\mathbb{F}}(H_1 \otimes H_2)$*

### 5.2 Visible rank and tensor products

In this subsection, we will show that the tensor product of two visibly full rank stencils is also visibly full rank. This will therefore show us that the visible rank is *super-multiplicative* with respect to the tensor product. We will also show an upper bound on the visible rank of the tensor product with respect to the visible rank of one of the stencils.

► **Proposition 22.** *Given visibly independent matrices  $A$  and  $B$  of size  $n$ , their tensor  $A \otimes B$  is also visibly independent.*

**Proof.** By Lemma 10, we know that there are permutations  $\pi_A, \sigma_A, \pi_B, \sigma_B$  on  $[n]$  such that the stencils  $A_0 = (A)_{\pi_A, \sigma_A}$  and  $B_0 = (B)_{\pi_B, \sigma_B}$  are both upper triangular stencils. Moreover, we see that  $A_0 \otimes B_0 = (A \otimes B)_{(\pi_A, \pi_B), (\sigma_A, \sigma_B)}$ . Therefore, it suffices for us to show that  $A_0 \otimes B_0$  is an upper triangular stencil.

Consider the lexicographical ordering on  $[n] \times [n]$ . When  $(i_1, i_2) > (j_1, j_2)$ , then we know that one of the inequalities  $i_1 > j_1$  and  $i_2 > j_2$  must hold, which means one of  $A_0[i_1, j_1]$  or  $B_0[i_2, j_2]$  must be a zero. This proves that  $(A_0 \otimes B_0)[(i_1, i_2), (j_1, j_2)] = 0$  whenever  $(i_1, i_2) > (j_1, j_2)$ . As for when  $(i_1, i_2) = (j_1, j_2)$ , then we immediately know that  $(A_0 \otimes B_0)[(i_1, i_2), (i_1, i_2)] = \star$  as  $A_0[i_1, i_1] = B_0[i_2, i_2] = \star$ . Hence  $A_0 \otimes B_0$  is an upper triangular stencil with respect to the lexicographical ordering. ◀

Given stencils  $H_1$  and  $H_2$ , we know by Proposition 22 that the tensor product of any of their visibly full rank sub-stencils will also be visibly full rank in  $H_1 \otimes H_2$ . This yields us the following corollary.

► **Corollary 23.** *For stencils  $H_1$  and  $H_2$ , We have the inequality  $\text{vrk}(H_1 \otimes H_2) \geq \text{vrk}(H_1)\text{vrk}(H_2)$ .*

Lastly, we end this subsection with an upper bound on the visible rank of  $H_1 \otimes H_2$ .

► **Proposition 24.** *For stencils  $H_1$  and  $H_2$  of sizes  $m_1 \times n_1$  and  $m_2 \times n_2$ , respectively, We have the inequality  $\text{vrk}(H_1 \otimes H_2) \leq \text{vrk}(H_1)n_2$ .*

**Proof.** Consider a visibly full rank substencil  $M$  in  $H_1 \otimes H_2$  of size  $k \times k$ . By Lemma 10, we can find a  $k \times k$  permutationally equivalent matrix  $M'$  of  $M$ . Let the columns and rows of  $M'$  be indexed as  $(a_1, b_1), \dots, (a_k, b_k)$  and  $(c_1, d_1), \dots, (c_k, d_k)$ . Define  $b_{\max}$  to be the most frequent column of  $H_2$  in  $\{b_1, \dots, b_k\}$ . Let  $I := \{i_1, \dots, i_s\}$  be the indices such that  $b_{i_j} = b_{\max}$ . We know that  $s \geq k/n_2$  by definition of  $b_{\max}$ . Moreover, the substencil  $M_0$  of  $M'$  attained by taking the rows and columns with index in  $I$  is upper triangular. Since  $M'[(c_{i_j}, d_{i_j}), (a_{i_j}, b_{\max})] = \star$ , then  $H_2[d_{i_j}, b_{\max}] = \star$  for all  $j \in [s]$ . Because  $M_0$  is upper triangular, then if we consider the  $s \times s$  substencil  $N_1$  in  $H_1$  with columns and rows  $\{a_{i_1}, \dots, a_{i_s}\}$  and  $\{c_{i_1}, \dots, c_{i_s}\}$ , we deduce that  $N_1$  is upper triangular. Thus  $\text{vrk}(H_1) \geq \text{vrk}(N_1) = s \geq k/n_2$ . Hence  $n_2 \text{vrk}(H_1) \geq k$  for any visibly full rank  $k \times k$  substencil  $M$  in  $H_1 \otimes H_2$ . ◀

### 5.3 Visible rank of the tensor powers

Naturally, one would be interested in tensoring a stencil  $H$  with itself several times and examine such a stencil.

► **Definition 25 (Tensor power).** *Given an  $m \times n$  stencil  $H$ , the  $k$ 'th tensor of  $H$  is the  $m^k \times n^k$  stencil  $H^{\otimes k}$  defined as  $H^{\otimes k} := \underbrace{H \otimes H \otimes \dots \otimes H}_{k \text{ times}}$ .*

By combining all the results from the previous subsections, we obtain the following corollary.

► **Corollary 26.** *For a natural number  $k$  and an  $m \times n$  stencil  $H$ , we have the inequality*

$$\text{rk}_{\mathbb{F}}(H) \geq \text{rk}_{\mathbb{F}}(H^{\otimes k})^{1/k} \geq \text{vrk}(H^{\otimes k})^{1/k} \geq \text{vrk}(H)$$

*Moreover, we also have the inequality  $\text{vrk}(H^{\otimes k}) \leq n^{k-1} \text{vrk}(H)$ .*

From the previous corollary, we can see that by consider the visible rank of the higher tensor powers of a stencil  $H$ , one might hope to attain better lower bounds on the  $\mathbb{F}$ -rank. Naturally, one would define the highest possible bound achieved through this vein.

► **Definition 27 (Visible Capacity).** *The visible capacity of a stencil  $H$ , denoted as  $\Upsilon(H)$ , is defined as  $\Upsilon(H) := \sup_k \text{vrk}(H^{\otimes k})^{1/k}$ .*

By Corollary 26, we deduce that  $\text{rk}_{\mathbb{F}}(H) \geq \Upsilon(H)$  over any field  $\mathbb{F}$ . It is not known to us if there are stencils for which there is a gap between its visible capacity and all its  $\mathbb{F}$ -ranks. We leave the discussion of this point to Question 1 in Section 7.

## 6 Tensor Powers of Stencils for 2-DRGP Codes and $q$ -LCCs

In this section, we will be considering the tensor product in the previous section and use it to analyze the visible rank of the tensor powers of 2-DRGP and  $q$ -LCC stencils to see if they might yield better lower bounds on the rank via Corollary 26.

### 6.1 2-DRGP stencils

In this subsection, we prove that the second tensor power of an arbitrary 2-DRGP stencil has a large visible rank.

► **Theorem 28.** *For any 2-DRGP stencil  $H$ , we have  $\text{vrk}(H \otimes H) \geq n$ .*

**Proof.** We cite [24, 30] for the proof of this part. We will follow the notations given in [30] closely. While both proofs show that  $\text{rk}_{\mathbb{F}}(H) \geq \sqrt{2n} - O(1)$ , we will prove that  $\text{rk}_{\mathbb{F}}(H) \geq \sqrt{n}$  by showing that  $\text{vrk}(H \otimes H) \geq n$  and then applying Corollary 26. We rewrite their proofs in terms of tensor powers.

Consider the  $n \times n$  sub-stencil  $D$  in  $H \otimes H$  whose columns are  $(1, 1), \dots, (n, n)$  and whose rows are  $((1, 1), (1, 2)), \dots, ((n, 1), (n, 2))$ . We claim that  $D$  has  $\star$ 's along the diagonal and zero everywhere else, which implies that it is visibly full rank. Indeed, the entry  $D[((i, 1), (i, 2)), (j, j)]$  equals  $\star$  if and only if both  $H[(i, 1), j]$  and  $H[(i, 2), j]$  are  $\star$ 's. Since  $H$  is a 2-DRGP stencil, this happens precisely when  $i = j$ . Thus  $D$  is a diagonal stencil. ◀

Thus by Corollary 26, we obtain a lower bound  $\text{rk}_{\mathbb{F}}(H) \geq \sqrt{n}$  for any field  $\mathbb{F}$ . On the other hand, the best known lower bounds yield  $\text{rk}_{\mathbb{F}}(H) \geq \sqrt{2n} - O(1)$ , and so one might be interested in achieving this lower bound through the viewpoint of tensor products. In order to improve the lower bound that we have, we first have to translate our proof into linear-algebraic terms.

Given a field  $\mathbb{F}$ , suppose that we have an  $\mathbb{F}$ -witness  $A$  of the 2-DRGP stencil  $H$  whose rank is  $r$ . Decompose  $A = MN$  where  $M$  is an  $2n \times r$  matrix and  $N$  is an  $r \times n$  matrix. Denote the  $i$ 'th column of  $N$  by  $w_i$ . Then the proof of Theorem 28 is equivalent to saying that the tensors  $\{w_i \otimes w_i\}_{i=1}^n$  are linearly independent. Since they live in a space  $\mathbb{F}^r \otimes \mathbb{F}^r$ , then we obtain the inequality  $r^2 \geq n$ , which gives us the same lower bound as we obtained

in Theorem 28. Now, if one is more careful about the vector space, one can notice that the tensors  $\{w_i \otimes w_i\}_{i=1}^n$  belong to the space of *symmetric* tensors, which has a dimension of  $\binom{r+1}{2}$ . Thus we obtain the inequality  $\binom{r+1}{2} \geq n$ , which gives us  $r \geq \sqrt{2n} - O(1)$ .

## 6.2 $q$ -LCC stencils

In this subsection, we will show that the visible ranks of the  $k$ 'th tensor power of a  $q$ -LCC stencil would not improve the current bound of  $n - \tilde{\Omega}(n^{(q-2)/(q-1)})$  in Theorem 16 for  $k \leq \text{polylog}(n)$ . More generally, we will show that the visible rank of small tensor powers could be not significantly bigger than the visible rank for the regime of high-rate stencils.

► **Proposition 29.** *Let  $H$  be an  $m \times n$  stencil whose visible rank is at most  $n - s$ . For any fixed natural number  $k$ , we have  $\text{vrk}(H^{\otimes k})^{1/k} \leq n - \frac{s}{k}$ .*

**Proof.** By Corollary 26 and the inequality  $(1 - x)^{1/k} \leq 1 - \frac{x}{k}$  for  $x \geq 0$ , we have that

$$\text{vrk}(H^{\otimes k})^{1/k} \leq \left(n^{k-1} \text{vrk}(H)\right)^{1/k} \leq \left(n^{k-1}(n - s)\right)^{1/k} = n \left(1 - \frac{s}{n}\right)^{1/k} \leq n \left(1 - \frac{s}{kn}\right) = n - \frac{s}{k}. \blacktriangleleft$$

From Proposition 29, we notice that looking at the visible rank of the  $n^{o(1)}$  level tensor powers of a  $q$ -LCC stencil would not improve the current bounds on  $q$ -LCCS by a polynomial factor. We state it more formally in the following corollary.

► **Corollary 30.** *Let  $H$  be a  $q$ -LCC stencil whose visible rank is at most  $n - \tilde{\Omega}(n^{(q-2)/(q-1)})$ . For any natural number  $k$ , we have  $\text{vrk}(H^{\otimes k})^{1/k} \leq n - \tilde{\Omega}(n^{(q-2)/(q-1)})/k$ .*

## 7 Further Directions and Discussion

Stencils provide an initial framework toward combinatorial methods for effectively lower bounding the rank of a matrix. However, we have seen the limitations of the visible rank with 2-DRGP stencils as well as small tensor powers of  $q$ -LCC stencils. We leave the reader with questions that remain open about the current framework and possibilities of imposing further restrictions on the model to obtain sharper lower bounds on the rank.

1. While we may have shown that the  $k$ 'th tensor power of a  $q$ -LCC does not yield better lower bounds for  $k \leq n^{o(1)}$ , this does not rule out the possibility that the visible capacity might yield better lower bounds. In fact, we do not know if there are any stencils for which the visible capacity does not match the lowest possible rank for the stencil. In other words, does there exist a stencil  $H$  such that  $\text{rk}_{\mathbb{F}}(H) > \Upsilon(H)$  for every field  $\mathbb{F}$ ?
2. Random 2-DRGP patterns have shown an exponential gap between the visible ranks of the first and second tensor powers, but one might be curious to see an exponential separation between the visible ranks of the  $(t - 1)$ 'th and  $t$ 'th tensor powers. Formally speaking, for every natural number  $t$  greater than 1, does there exist a  $m \times n$  stencil  $H$  and a constant  $c > 0$  such that  $\text{vrk}(H^{\otimes i}) = O(\log^{ci} n)$  for  $i = 1, 2, \dots, t - 1$  while  $\text{vrk}(H^{\otimes t}) = \Omega(n)$ ? Such a phenomena holds with Shannon capacity [1].
3. In this paper, we shown a polynomial gap between  $\text{rk}_{\mathbb{F}}(H)$  and  $\text{vrk}(H)$  by proving that there are 2-DRGP stencils  $H$  with  $\text{vrk}(H) = O(\log n)$  and  $\text{rk}_{\mathbb{F}}(H) = \Omega(\sqrt{n})$ . On the other hand, can there also be a similar polynomial gap with the quantities  $n - \text{rk}_{\mathbb{F}}(H)$  and  $n - \text{vrk}(H)$ ? From Proposition 29, we have seen that the visible ranks of the  $k$ 'th tensor

power for  $k \leq n^{o(1)}$  would not suffice to show this polynomial gap. Nonetheless, it still leaves the possibility of using the visible capacity to showing this polynomial gap, but we do not know of any methods that can lower bound the visible capacity other than the visible ranks of finite tensor powers. Note that this question is the symmetric spanoid version of Question 2 posed in [5].

## Abstract

---

Motivated by the derandomization of space-bounded computation, there has been a long line of work on constructing pseudorandom generators (PRGs) against various forms of read-once branching programs (ROBPs), with a goal of improving the  $O(\log^2 n)$  seed length of Nisan’s classic construction [33] to the optimal  $O(\log n)$ .

In this work, we construct an explicit PRG with seed length  $\tilde{O}(\log n)$  for constant-width ROBPs that are *monotone*, meaning that the states at each time step can be ordered so that edges with the same labels never cross each other. Equivalently, for each fixed input, the transition functions are a monotone function of the state. This result is complementary to a line of work that gave PRGs with seed length  $O(\log n)$  for (ordered) *permutation* ROBPs of constant width [7, 26, 12, 37], since the monotonicity constraint can be seen as the “opposite” of the permutation constraint.

Our PRG also works for monotone ROBPs that can read the input bits in any order, which are strictly more powerful than read-once  $AC^0$ . Our PRG achieves better parameters (in terms of the dependence on the depth of the circuit) than the best previous pseudorandom generator for read-once  $AC^0$ , due to Doron, Hatami, and Hoza [13].

Our pseudorandom generator construction follows Ajtai and Wigderson’s approach of iterated pseudorandom restrictions [1, 18]. We give a randomness-efficient width-reduction process which proves that the branching program simplifies to an  $O(\log n)$ -junta after only  $O(\log \log n)$  independent applications of the Forbes–Kelley pseudorandom restrictions [16].

## 1 Introduction

Branching programs are a fundamental model in computational complexity, capturing both space-bounded computation and circuit classes. In this paper, we study a restricted class of branching programs we call *monotone*, giving a new pseudorandom generator for their read-once version.

### 1.1 Monotone Branching Programs

First we recall the standard definition of a layered branching program:

► **Definition 1.** For  $w, n, s \in \mathbb{N}$ , a (layered) branching program (BP)  $B$  on  $n$  variables, with length  $s$  and width  $w$ , or an  $[n, s, w]$  BP, is specified by a start state  $v_0 \in [w]$ , a set of accept states  $V_{\text{acc}} \subseteq [w]$ , a sequence of variable indices  $i_1, \dots, i_s \in [n]$ , and sequence of transition functions  $E_j: \{0, 1\} \times [w] \rightarrow [w]$  for  $j = 1, \dots, s$ .

A branching program  $B$  as above naturally defines a function  $B: \{0, 1\}^n \rightarrow \{0, 1\}$ : Start at the starting state  $v_0$ , and then for  $j = 1, \dots, s$ , read the input bit  $x_{i_j}$  and then transition to state  $v_j = E_j(x_{i_j}, v_{j-1})$ . The branching program accepts ( $B(x) = 1$ ) if  $v_n \in V_{\text{acc}}$  and rejects ( $B(x) = 0$ ) otherwise.

$B$  is a read-once branching program, or an  $[n, w]$  ROBP, if  $s = n$  and  $i_1, \dots, i_s$  is a permutation of  $[n]$ . If this is the identity permutation (i.e. the variables are read in order), then we say  $B$  is an ordered branching program.

A layered branching program  $B$  has an associated directed graph. The vertex set has  $s+1$  layers of  $w$  vertices each. For each  $j = 1, \dots, s$ , layer  $j$  is labelled with an input variable, namely  $x_{i_j}$ , and there are two edges, labelled 0 and 1, going from each vertex  $v$  in layer  $j$  to vertices layer  $j+1$ , namely  $E_j(0, v)$  and  $E_j(1, v)$ .

We now introduce the model of *monotone* programs that we consider.

► **Definition 2 (monotone branching program (MBP)).** We say a BP  $B$  is monotone if for every  $j \in [s]$  and  $\sigma \in \{0, 1\}$ , the  $j$ -th transition function with input bit restricted to  $\sigma$ , denoted  $E_j^\sigma \triangleq E_j(\sigma, \cdot): [w] \rightarrow [w]$ , is a monotone function according to the standard ordering of  $[w]$ , i.e. if  $v \geq v'$ , then  $E_j^\sigma(v) \geq E_j^\sigma(v')$ .

That is, put differently, if we draw the layered graph as an  $w \times (s+1)$  grid, then whenever we consider the edges associated with a fixed input  $x$ , there are no edges crossing. We will refer to BPs that are both monotone and read once as read-once MBPs.

It is important to note that this definition only requires monotonicity with respect to the *state* of the branching program; MBPs can easily compute functions that are non-monotone as a function of their *input* (as we will see below). We remark that the definition of read-once MBPs as defined here is different from the notion of *locally monotone* studied in [10]. Importantly, the latter property is not preserved under restrictions and hence is less nice structurally. The read-once definition also coincides with the notion of *monotone ROBPs* as defined in [31], if we require all reject states to precede the accepting ones in the last layer.<sup>1</sup> However, the formulation above is more convenient for us.

<sup>1</sup> In fact, for the sake of constructing PRGs, we can remove this requirement by replacing  $\varepsilon$  with  $\varepsilon/w$ .

## 1.2 Monotone Branching Programs and $AC^0$

Recall Barrington’s celebrated theorem that constant-width branching programs are equivalent in power to  $NC^1$  circuits [2]. However, when we restrict to *monotone* branching programs, then they become equivalent in power to the much weaker  $AC^0$  circuits. Our model of monotone branching programs is closely related to the models of planar branching programs studied in [3, 4] and the following can be deduced from their results:<sup>2</sup>

► **Theorem 3** (corollary of [4]). *A sequence of functions  $f_n : \{0, 1\}^n \rightarrow \{0, 1\}$  is in  $AC^0$  if and only if it is computable by a constant-width MBP of polynomial length.*

In this paper, our focus is on read-once MBPs. We prove that these are *strictly stronger* than read-once  $AC^0$ :

► **Proposition 4.**

1. *If a sequence of functions  $f_n : \{0, 1\}^n \rightarrow \{0, 1\}$  is in read-once  $AC^0$ , then it can be computed by constant-width read-once MBP. Moreover, if  $f_n$  can be computed in depth  $w$  read-once  $AC^0$ , then it can be computed by width  $w + 1$  read-once MBPs.*
2. *For every  $n \geq 3$ , there exists a function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  computable by a width 3 read-once MBP, but not computable by any read-once De Morgan formula (regardless of depth).*

Item 1 is proven in the same way as the easier direction of Theorem 3, noting that if we start with a read-once  $AC^0$  circuit, we end up with a read-once MBP. Item 2 is proven by showing that simple functions, like checking whether the input contains at least two ones cannot be computed by a read-once De Morgan formula, but can be computed by width three MBPs. We give the proof for Item 2 in Section 4.

Thus, constant-width read-once MBPs form an intermediate class between read-once  $AC^0$  and  $AC^0$ .<sup>3</sup>

## 1.3 Pseudorandom Generators for Read-Once Branching Programs

A longstanding quest in complexity theory is to understand the power of randomness in relation to space complexity. A central challenge in this direction is to construct pseudorandom generators for read-once branching programs.

In this work we study the question of designing explicit PRGs for small-width ROBPs.

► **Definition 5.** *Given a class of functions  $\mathcal{F} : \{0, 1\}^n \rightarrow \{0, 1\}$ , a function  $G : \{0, 1\}^r \rightarrow \{0, 1\}^n$  is a PRG for  $\mathcal{F}$  with error  $\varepsilon$  if for any  $f \in \mathcal{F}$ , we have*

$$\left| \Pr_{y \in_u \{0, 1\}^r} [f(G(y)) = 1] - \Pr_{x \in_u \{0, 1\}^n} [f(x) = 1] \right| \leq \varepsilon.$$

*We call  $r$  the seed length of the generator and the generator is explicit if its output can be computed in polynomial time (in  $n$ ). We often say  $G$   $\varepsilon$ -fools  $\mathcal{F}$ .*

<sup>2</sup> In an earlier version of our paper [15], we claimed Theorem 3 as a new contribution. Kristoffer Hansen then explained to us how the result follows from [3]. More precisely, there are simple gadget reductions to show that a constant-width monotone branching program according to our definition can be simulated by a planar branching program according to the definition of [3]. Thus the result of [3] establishing the equivalence of the latter with  $AC^0$  implies the “if” direction of Theorem 3. The “only if” direction is much easier, and amounts to observing that the standard simulation of  $AC^0$  by constant-width branching programs yields a monotone program. For completeness, we provide a direct and self-contained proof of both directions of Theorem 3 in Appendix A.

<sup>3</sup> Both inclusions are strict, since there are functions in  $AC^0$  that cannot be computed by circuits of size smaller than  $n^4$ , and the proof of Theorem 3 shows that any constant-width read-once MBP can be simulated by an  $AC^0$  circuit of size  $O(n^3)$ .

Designing *pseudorandom generators* against ordered ROBPs has received a lot of attention and is intimately connected to the question of understanding the power of randomness vs. space. It has also found a number of applications beyond derandomizing space. ([29, 35, 21, 24, 25, 19] are just few examples.)

The best known PRGs for ordered ROBPs to date are those of Nisan [33] and Impagliazzo–Nisan–Wigderson [23] which give seed length  $O(\log^2 n)$  when  $w = n^{O(1)}$  and  $\varepsilon = 1/n^{O(1)}$ . However, even for width four and constant error their construction requiring seed length  $O(\log^2 n)$  is still the best. Improving on this seed length, even for constant width, has been a longstanding barrier. We do have better PRGs for various special classes of ROBPs that are independently interesting:

- Braverman, Rao, Raz, and Yehudayoff [7] construct PRGs with  $\tilde{O}(\log n)$  seed length for constant-width ordered *regular* branching programs and  $\varepsilon = 1/\text{poly}(\log n)$ . Regular branching programs are a special class of ROBPs where we require the structural condition that each vertex has the same in-degree in the underlying layered graph.
- Starting with the work of Koucký, Nimbhorkar, and Pudlák [26], several works [12, 37, 22] have achieved a seed length of  $O(\log n)$  (with no  $\log \log n$  factors) for the further restricted model of ordered *permutation branching programs*. In these, we require that at each layer  $j$ , and for each symbol  $\sigma$ , the transition function  $E_i^\sigma$  is a permutation of  $[w]$ .
- Meka, Reingold, and Tal [30] construct PRGs with  $\tilde{O}(\log n)$  seed length for width three ordered ROBPs and  $\varepsilon = 1/\text{poly}(\log n)$ , as well as for unordered ones with  $\varepsilon = 1/\text{poly}(\log \log n)$ .
- [16] gave a PRG that is significantly different from that of [33, 23] and achieves seed length  $O(\log^3 n)$  for polynomial width and  $\tilde{O}(\log^2 n)$  for constant-width ROBPs (again, even unordered).

## 1.4 Our Main Result

We give an explicit PRG with seed length  $\tilde{O}(\log(n/\varepsilon))$  for read-once MBPs.

► **Theorem 6** (see Section 3.2). *For any positive integers  $n$ ,  $w \leq n$ , and  $\varepsilon \in (0, 1/2)$ , there is an explicit PRG that  $\varepsilon$ -fools  $[n, w]$  read-once MBPs (even unordered ones) with seed length  $O(w^2 \log(n/\varepsilon) \cdot (\log \log(n/\varepsilon))^2)$ .*

We believe that fooling read-once MBPs is an important (and clearly necessary) step toward breaking the  $O(\log^2 n)$ -barrier for constant-width ROBPs. The class of (ordered) branching programs that we understand best from the perspective of pseudorandomness is that of *permutation branching programs*, thanks to the aforementioned works of [7, 26, 12, 37, 22], all of which obtain their results by showing that the Impagliazzo–Nisan–Wigderson [23] pseudorandom generator can be analyzed better for such programs. Monotone BPs can be seen as the extreme opposite of permutation BPs: the only monotone function  $E: [w] \rightarrow [w]$  that is also a permutation is the identity. Thus the only layers a monotone BP can share with a permutation BP are redundant (can be eliminated from the branching program without changing its functionality). Furthermore, in stark contrast to the case of ordered permutation branching programs, it is known that instantiations of the classical constructions of [33, 23] with  $\tilde{O}(\log n)$  seed length provably do not work against ordered MBPs of width 3 [8].

Technically, our arguments build on the paradigm of using random restrictions for fooling ROBPs as studied in the works of [18, 34, 38, 11, 20, 28, 10, 16, 30, 27, 13, 14]. This gives more evidence that this approach can perhaps lead to  $\tilde{O}(\log n)$  seed length for constant-width ROBPs. Our analysis introduces the idea of exploiting *width reduction* combined with *alphabet reduction* that could be useful for the general problem.

By Proposition 4, the PRG of Theorem 6 is also a PRG for read-once De Morgan formulas. For read-once  $\text{AC}^0$ , corresponding to width  $w = O(1)$ , it achieves a better dependence on the width  $w$  than the previous generator for read-once  $\text{AC}^0$ , which has a seed of length  $\log(n/\varepsilon) \cdot O(w \log \log(n/\varepsilon))^{2w+2}$  for depth- $w$  formulas [13] (our dependence on  $w$  is  $w^2$ ). For read-once formulas of arbitrary depth, the best PRG prior to our work was the PRG of Forbes and Kelley [16], which has seed length  $O(\log(n/\varepsilon) \log^2 n)$ . Thus, the PRG of Theorem 6 attains better seed length for read-once formulas that have depth up to  $w = o\left(\frac{\log n}{\log \log(n/\varepsilon)}\right)$ .

We note that constructing PRGs that are not sensitive to the ordering of the bits in which the input is read is a natural question. First, fooling read-once  $\text{AC}^0$ , for example, is inherently an unordered task. But also, PRGs for ROBPs that follows the “classical” and successful seed recycling approach due to Nisan (e.g., [33, 23, 26, 7, 6]) heavily depends on the ordering of the bits. In fact, Tzur [39] proved that Nisan’s PRG can in fact be distinguished from uniform by an unordered constant width branching program (see also [5]). Thus, the hope is that PRGs that are not sensitive to the ordering will help make progress on the problem of fooling ordered ROBPs with seed length  $o(\log^2 n)$ .

## 1.5 Techniques

We proceed by giving an overview of the construction of our PRG and of the techniques we use.

### 1.5.1 The Iterated Restrictions Approach

We construct our PRG using the *iterated pseudorandom restrictions* approach, pioneered by Ajtai and Wigderson [1] and further developed by Gopalan et al. [18]. That is, we pseudorandomly assign values to a pseudorandomly chosen subset of the variables, and then repeat the process until we assigned values to all variables. Intuitively, designing a pseudorandom restriction for some function  $f$  is easier than fooling  $f$  outright, because designing a pseudorandom restriction amounts to fooling a “smoothed out” version of  $f$  [18], or equivalently, designing a PRG that would fool  $f$  after some noise was added [20]. Previous works that used this approach include PRGs for unordered ROBPs [34, 10, 16], PRGs for width-3 ROBPs [18, 38, 30], PRGs for bounded-depth read-once formulas [18, 11, 13, 14], and PRGs for arbitrary-order product tests [20, 28, 27].

Following the iterated restrictions approach, we need our pseudorandom distribution  $X$  over restrictions to satisfy two key properties. The first property is that the restriction should approximately *preserve the expectation* of the function. i.e., in expectation over  $X$ , the restricted function  $f|_X$  should have approximately the same bias as  $f$  itself, i.e.  $\mathbb{E}_X[\mathbb{E}_U[f|_X(U)]] \approx \mathbb{E}_U[f(U)]$ , where  $U$  denotes the uniform distribution on the appropriate number of bits. This feature ensures that after sampling the restriction  $X$ , our remaining task is simply to fool  $f|_X$ . The second property is the *simplification* property. That is, we want that the restricted function, for a typical restriction, should be in a sense simpler than  $f$  itself. Clearly, simplifying  $f$  would make it easier to fool.

To achieve the first property of preserving the expectation, we follow Forbes and Kelley [16], who constructed a simple pseudorandom distribution over restrictions that approximately preserves the expectation of any constant-width ROBP. In the Forbes–Kelley distribution, we determine which coordinates stay alive in an almost  $k$ -wise independent manner, and sample the fixed coordinates using a small-bias space. This distribution, per a single restriction, can be sampled using  $\tilde{O}(\log(n/\varepsilon))$  uniform bits. Next, we proceed to discuss how to achieve the simplification property.

### 1.5.2 Iterative Width Reduction

In our setting, we design our restrictions in a way that fits nicely with the [16] distribution. Thus, the remaining challenge is indeed to ensure that such restrictions *simplify* constant width monotone ROBPs. In [16], the measure of complexity was simply the number of remaining unset variables. That is, Forbes and Kelley argued that after applying  $O(\log n)$  independent pseudorandom restrictions, with high probability, all variables are set, and hence there is nothing left to fool. Such an analysis gives seed length of  $\tilde{O}(\log(n/\varepsilon) \cdot \log n)$ , and recent works used more sophisticated measures of complexity to show that for more restricted classes of bounded width ROBPs, one can reach a function which is simple enough after only  $O(\log \log n)$  independent pseudorandom restrictions [18, 30, 13, 14]. In this work, we continue this line of research, and show that after  $O(\log \log n)$  iterations, roughly speaking, the width of the ROBP decreases by 1.

Since the construction and analysis of PRG will not depend on the ordering of the input bits, for simplicity we will describe it here assuming that the monotone ROBP  $B$  is ordered (to avoid the indexing  $i_j$  of input variables). Before getting to the construction, we highlight the key concept of *colliding layers* in a branching program, which was also paramount in [8, 36, 38, 10, 30]. We say that a BP layer  $i$  is a collision one, if there exist two edges with the same label  $\sigma$  that are mapped to the same vertex, i.e.  $E_i^\sigma$  is not a permutation. We say a collision is *realized* if a restriction fixes  $x_i$  to  $\sigma$ , and thus effectively introduces a layer with smaller width. The property of monotone BPs we use is that every non-identity layer is a collision one, and crucially, that this property is preserved under restrictions.

Another technical, yet powerful, component of our analysis is treating a branching program with edges labeled 0 and 1, i.e., over the alphabet  $\{0, 1\}$ , as a branching program over a much larger alphabet. Expressing the branching program over a larger alphabet preserves monotonicity and allows us to reduce the width of the BP in some cases. In fact, we will treat both the width and the alphabet size as progress measures.

Towards describing our iterative simplifying process, express our ROBP  $B$ , over  $\{0, 1\}$ , as a branching program over  $\Sigma = \{0, 1\}^\ell$  in the straightforward way, where  $\ell$  will start out as  $O(\log(n/\varepsilon))$  and eventually will be reduced to  $O(\log \log(n/\varepsilon))$ . Each “layer” is now a function from  $\Sigma \times [w]$  to  $[w]$ . Initially, moving to a larger alphabet only makes our task more difficult, but the generality will be useful as we induct on the width below (i.e. even if we start out with a width  $w$  program with alphabet  $\{0, 1\}$ , the argument below will force us to handle width  $w - 1$  programs having alphabet  $\{0, 1\}^{O(\log(n/\varepsilon))}$ ).

We iteratively apply the following two observations.

1. **Realizing a collision.** After a suitable pseudorandom restriction  $X^1$ , in every sequence of  $\exp(O(\ell)) \cdot \log(n/\varepsilon) = \exp(O(\ell))$  collision layers, we will have a collision in one of these layers. As each layer in a read-once MBP is either an identity layer or a collision layer, and this remains true also after transitioning to a larger alphabet, we can deduce that after  $X^1$  every  $C^\ell$  consecutive nontrivial layers contains a layer of width at most  $w - 1$ , for a sufficiently large constant  $C$ .
2. **Alphabet reduction.** After a suitable pseudorandom restriction  $X^2$ , up to a few “unruly” layers, we can shrink the alphabet size of  $B$  so that all layers are effectively over  $\{0, 1\}^{\ell/2}$ . Specifically, we can assume that in every sequence of  $C^\ell$  consecutive layers of alphabet size  $B$ , all but  $O(\log(n/\varepsilon))$  of them will have their alphabet size reduced to  $\{0, 1\}^{\ell/2}$ .

Both  $X^1$  and  $X^2$  will consist of almost  $k$ -wise independent distributions on  $\{0, 1, \star\}$  where  $\star$  represents the bits not assigned by the restriction and we take  $X^1$  to have  $\star$ -probability  $1/2$  and  $X^2$  to have a smaller, yet still constant,  $\star$ -probability.

Equipped with the above two observations, aiming at reducing the width of  $B$ , we apply, independently, the above  $X^1$  and  $X^2$  for  $t = O(\log \log(n/\varepsilon))$  iterations. After the first application of  $X^1$ , we can write  $B$  as  $B = B_1 \circ \dots \circ B_r$ , each  $B_i$  is of length at most  $C^\ell$  over an  $\ell$ -bit alphabet, starting and ending in a layer of width  $w - 1$ . Then the first application of  $X^2$  will reduce the alphabet of each of the  $B_i$ -s to consist of  $\ell/2$  bits, except for  $O(\log(n/\varepsilon))$  unruly layers within each  $B_i$ . The second application of  $X^1$  will now create collisions every  $C^{\ell/2}$  non-unruly layers, refining the program further into  $B = B'_1 \circ \dots \circ B'_{r'}$ , where each  $B'_i$  is of length at most  $C^{\ell/2}$  over an  $\ell/2$ -bit alphabet (except for  $O(\log(n/\varepsilon))$  unruly layers), starting and ending with a layer of width  $w - 1$ . The second of application of  $X^2$  will then reduce the alphabet size of each  $B'_i$  to at most  $\ell/4$  except for  $O(\log(n/\varepsilon))$  additional unruly layers within each  $B'_i$ . In general, each iteration *reduces the distance* between consecutive layers of width  $w - 1$  and *reduces the alphabet size*, except for increasing the number of unruly layers by  $O(\log(n/\varepsilon))$  within each interval. Finally after  $t = O(\log \log(n/\varepsilon))$  iterations, we will have an alphabet where each symbol consists of  $\ell^* = O(\log \log(n/\varepsilon))$  bits, so the distance between width  $w - 1$  layers is at most  $C^{\ell^*} = \text{poly}(\log(n/\varepsilon))$ . Even including the unruly layers, we can now view our as a width  $w - 1$  read-once MBP over  $\Sigma' = \{0, 1\}^{\text{poly}(\log(n/\varepsilon))}$ .

Before we can repeat the above process and reduce the width from  $w - 1$  to  $w - 2$ , etc., we need to reduce  $\Sigma'$  back to  $\Sigma = \{0, 1\}^{O(\log(n/\varepsilon))}$ . We can achieve this by an additional alphabet reduction using an almost  $k$ -wise independent distribution with  $\star$ -probability  $1/\text{poly} \log(n/\varepsilon)$  suffices.

Recall that due to [16], we can set the above restrictions to preserve the expectation of our original  $B$ , up to a small error. Hence, with seed of length  $\tilde{O}(\log(n/\varepsilon))$  we can both preserve the expectation and reduce the width by 1. Applying this  $w - 1$  times, with high probability our program will be very simple – a function depending on only  $O(\log(n/\varepsilon))$  bits (i.e. a junta), which is fooled by an almost  $O(\log(n/\varepsilon))$ -wise independent distribution.

All in all, our construction consists of commonly used primitives for PRGs: pseudorandom restrictions in which both the choice of live variables and the the choice of fixed coordinates are sampled from an almost  $k$ -wise independent distributions, with varying parameters. The analysis of iterative width reduction via resorting to larger alphabets is new, and we believe can be of use for designing PRGs for other models of computation. Naturally, there are some additional subtleties in the analysis and the choice of parameters, which we leave to the complete analysis in Section 3.

## 2 Preliminaries

We denote by  $U_n$  the uniform distribution over  $\{0, 1\}^n$ . Suppose  $\mathcal{C}$  is a class of functions in  $\{0, 1\}^n \rightarrow \mathbb{R}$  and  $G$  is a distribution over  $\{0, 1\}^n$ . We say that  $G$   $\varepsilon$ -fools  $\mathcal{C}$  if for every  $f \in \mathcal{C}$  it holds that  $|\mathbb{E}[f(G)] - \mathbb{E}[f(U_n)]| \leq \varepsilon$ . Recall that a PRG  $\varepsilon$ -fooling  $\mathcal{C}$  is a function  $G: \{0, 1\}^s \rightarrow \{0, 1\}^n$  such that  $G(U_s)$   $\varepsilon$ -fools  $\mathcal{C}$ . As a shorthand, we often write  $\mathbb{E}[f]$  to denote  $\mathbb{E}[f(U_n)]$ , and omit the subscript  $n$  when the number of input bits is clear from context.

### 2.1 Branching Programs

We extend the definition of branching programs from Definition 1 to large alphabets. We do so by grouping together at most  $\ell$  consecutive bits in a single edge-layer of the program. The main advantage in such a transformation is that we can potentially express a width  $w$  program over  $\{0, 1\}$  as a width  $w' < w$  program over  $\{0, 1\}^\ell$ . This will be crucial in our analysis.

We say that a *read-once branching program* (ROBP)  $B$  is a  $[n, w']_\ell$  ROBP if  $B$  can be written as a directed layered graph with  $m+1$  layers (for some  $m \leq n$ ) denoted  $V_1, \dots, V_{m+1}$ . Each  $V_i$  consists of at most  $w'$  many vertices. Furthermore, there exists a partition of  $[n]$  to disjoint subsets  $S_1, \dots, S_m \subseteq [n]$  of size at most  $\ell$  each, and between every consecutive layers of vertices  $V_i$  and  $V_{i+1}$  there exists a set of directed edges such that any vertex in  $V_i$  has  $2^{|S_i|}$  edges going towards  $V_{i+1}$ . We can treat the  $i$ -th layer of edges as a transition function  $E_i: \{0, 1\}^{S_i} \times [w'] \rightarrow [w']$  between  $V_i$  and  $V_{i+1}$ . Namely, for each  $\sigma \in \{0, 1\}^{S_i}$  we have the function  $E_i^\sigma \triangleq E_i(\sigma, \cdot): [w'] \rightarrow [w']$  that is defined in the natural way by following the edges labeled  $\sigma$  from  $V_i$  to  $V_{i+1}$ . Such a program naturally describes a read-once computation on  $x \in \{0, 1\}^n$ , where in the  $i$ -th step we follow the edge marked with  $x_{S_i} \in \{0, 1\}^{S_i}$  from a vertex in  $V_i$  to a vertex in  $V_{i+1}$ . We often denote  $\ell$  as the *alphabet length* of  $B$  and  $2^\ell$  as the *alphabet size* of  $B$ .

We say that an  $[n, w']_\ell$  ROBP is monotone if for every  $i \in [m]$ , its  $i$ -th layer  $E_i$  satisfies the following. For any  $\sigma \in \{0, 1\}^{S_i}$  and distinct  $x_1, x_2 \in [w']$ ,  $x_1 \geq x_2$  implies  $E_i^\sigma(x_1) \geq E_i^\sigma(x_2)$ . We say  $E_i$  is an *identity layer* if for any  $\sigma \in \{0, 1\}^{S_i}$  it holds that  $E_i^\sigma$  is the identity function. We say that  $E_i$  is a *collision layer* if there exists  $\sigma \in \{0, 1\}^{S_i}$  such that  $E_i^\sigma$  contains a collision, i.e., there exist distinct  $x_1, x_2 \in [w']$  such that  $E_i^\sigma(x_1) = E_i^\sigma(x_2)$ . We will make use of the following key observation.

▷ **Claim 7.** In a read-once MBP, every layer is either an identity layer or a collision layer.

As noted above, our techniques will also hold for the unordered setting, so we may assume that the bits of  $x$  are permuted by some permutation  $\pi \in S_n$ , i.e., the  $i$ -th layer of the program follow the edge marked by  $x_{\pi(i)}$ . Since we are in the unordered setting we can assume without loss of generality that there are no identity layers in the program, by skipping these layers.

Observe that if an (unordered)  $[n, w]$  ROBP  $B$  over  $\{0, 1\}$  has  $m+1$  of its  $n+1$  vertex-layers with width at most  $w'$  and of distance at most  $\ell$  apart, then we can write  $B$  as a  $[n, w']_\ell$  ROBP  $B'$ . Furthermore, if  $B$  is monotone so is  $B'$ .

## 2.2 $k$ -Wise and $\delta$ -Biased Distributions

We say that a random variable  $Y \sim \{0, 1\}^n$  is  $\delta$ -biased if it  $\delta$ -fools all parity functions. Namely, if for any nonempty  $I \subseteq [n]$  it holds that

$$\left| \Pr \left[ \bigoplus_{i \in I} Y_i = 1 \right] - \frac{1}{2} \right| \leq \delta.$$

There are explicit constructions of  $\delta$ -biased distributions over  $\{0, 1\}^n$  that can be sampled efficiently with  $O(\log n + \log \frac{1}{\delta})$  truly random bits [32].

► **Lemma 8** (Vazirani's XOR Lemma, See e.g., [17, Section 1]). *Let  $Y \sim \{0, 1\}^n$  be a  $\delta$ -biased distribution, and let  $S \subseteq [n]$ . Then,  $|Y_S - U_{|S|}| \leq 2^{|S|/2} \cdot \delta$ .*

For  $p \in [0, 1]$ , we denote by  $\text{Bernoulli}(p)^{\otimes n}$  the distribution over  $\{0, 1\}^n$  where the bits are i.i.d. and each bit has expectation  $p$ . We say that  $Z \sim \{0, 1\}^n$  is  $\gamma$ -almost  $k$ -wise independent with marginals  $p$  if for every set  $I \subseteq [n]$  satisfying  $|I| \leq k$  it holds that  $|Z_I - \text{Bernoulli}(p)^{\otimes |I|}| \leq \gamma$ . We can sample such distributions efficiently.

▷ **Claim 9** (see, e.g., in [14]). For any positive integers  $n, k, C$ , and any  $\gamma > 0$ , there is an explicit  $\gamma$ -almost  $k$ -wise independent distribution with marginals  $p = 2^{-C}$  that can be sampled efficiently with  $O(Ck + \log \frac{1}{\gamma} + \log \log n)$  truly random bits.

Moreover, we have good tail bounds for almost  $k$ -wise distribution.

► **Lemma 10** (following [9, 38]). *Let  $X_1, \dots, X_n$  be  $\gamma$ -almost  $k$ -wise independent random variables over  $\{0, 1\}$  with marginals  $q$ , and let  $\alpha > 0$ . Then, for an even  $k \leq qn$ ,*

$$\Pr \left[ \left| \sum_{i \in [n]} X_i - qn \right| \geq \alpha qn \right] \leq \left( \frac{16k}{\alpha^2 qn} \right)^{k/2} + 2k\gamma \left( \frac{1}{\alpha q} \right)^k.$$

► **Corollary 11.** *Let  $X'_1, \dots, X'_n$  be  $\gamma$ -almost  $k$ -wise independent random variables over  $\{0, 1\}$  with marginals  $\geq q$ . Then, for an even  $k \leq qn$ ,*

$$\Pr \left[ \sum_{i \in [n]} X'_i = 0 \right] \leq \left( \frac{16k}{qn} \right)^{k/2} + 2k\gamma \left( \frac{1}{q} \right)^k.$$

**Proof.** Take  $X_i = X'_i \wedge Y_i$  where  $Y_i$  is a coin toss with  $\Pr[Y_i = 1] = q/\mathbb{E}[X'_i]$ . We have that  $\mathbb{E}[X_i] = q$ , and that  $X_1, \dots, X_n$  are  $\gamma$ -almost  $k$ -wise independent with marginals  $q$ . Applying Lemma 10 with  $\alpha = 1$  implies that

$$\Pr \left[ \sum_{i \in [n]} X_i = 0 \right] \leq \left( \frac{16k}{qn} \right)^{k/2} + 2k\gamma \left( \frac{1}{q} \right)^k.$$

The proof is complete since  $\Pr \left[ \sum_{i \in [n]} X'_i = 0 \right] \leq \Pr \left[ \sum_{i \in [n]} X_i = 0 \right]$ . ◀

### 2.3 Restrictions and Pseudorandom Restrictions

A *restriction* is a string  $x \in \{0, 1, \star\}^n$ . Intuitively,  $x_i = \star$  means the  $i$ -th coordinate has not been set by the restriction. A restriction  $x$  can be specified by two strings  $y, z \in \{0, 1\}^n$  where  $z$  determines the  $\star$  locations and  $y$  determines the assigned values in the non- $\star$  locations. Namely, we define  $\text{Res}: \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1, \star\}^n$  by

$$\text{Res}(y, z)_i = \begin{cases} \star & z_i = 1, \\ y_i & z_i = 0. \end{cases}$$

We define a *composition* operation on restrictions, by

$$(x \circ x')_i = \begin{cases} x_i & x_i \neq \star, \\ x'_i & \text{otherwise.} \end{cases}$$

For a function  $f$  on  $\{0, 1\}^n$ , the restricted function  $f|_x$  on  $\{0, 1\}^n$  is defined by  $f|_x(x') = f(x \circ x')$ .

We will repeatedly use the following fact.

▷ **Claim 12.** Let  $B$  be a read-once MBP of length  $n$ , and let  $x \in \{0, 1, \star\}^n$  be any restriction. Then,  $B|_x$  is a read-once MBP.

Given a function  $f: \{0, 1\}^n \rightarrow \mathbb{R}$  and a distribution  $X \sim \{0, 1, \star\}^n$ , we say that  $X$  *preserves the expectation* of  $f$  with error  $\varepsilon$  if  $|\mathbb{E}[f|_X(U)] - \mathbb{E}[f]| \leq \varepsilon$ .

Forbes and Kelley showed that pseudorandom restrictions preserve the expectation of constant-width ROBPs. We give a “with high probability” version of their result, proved in [14].

► **Lemma 13** ([16], restated). *There exists a constant  $c \geq 1$  such that the following holds for any positive integers  $n, w$ , and  $\eta > 0$ . Let  $Z$  be a  $\gamma$ -almost  $k$ -wise independent distribution over  $\{0, 1\}^n$ , where  $k \geq c \log \frac{nw}{\eta}$  and  $\gamma \leq 2^{-k}$ . Let  $Y$  be a  $\delta$ -biased distribution over  $\{0, 1\}^n$ , where  $\log \frac{1}{\delta} \geq cwk \log \log n$ . Then, for any  $[n, w, \{0, 1\}]$  BP  $B$  it holds that with probability at least  $1 - \eta$  over  $z \sim Z$ ,*

$$\left| \mathbb{E}_{Y,U} [B|_{\text{Res}(Y,z)}(U)] - \mathbb{E}[B] \right| \leq \eta.$$

For  $X \sim \{0, 1, \star\}^n$  and a positive integer  $t$ , we denote by  $X^{\text{ot}}$  the distribution over  $\{0, 1, \star\}^n$  obtained by drawing independent samples  $x^{(1)}, \dots, x^{(t)} \sim X$  and composing them, namely  $x = x^{(1)} \circ \dots \circ x^{(t)}$ . We record two easy claims.

▷ **Claim 14.** Let  $\mathcal{F} \subseteq \{0, 1\}^n \rightarrow \mathbb{R}$  be some function class which is closed under restrictions. Then, if  $X$  preserves the expectation of every  $f \in \mathcal{F}$  with error  $\varepsilon$ , then  $X^{\text{ot}}$  preserves the expectation of every  $f \in \mathcal{F}$  with error  $t \cdot \varepsilon$ .

▷ **Claim 15.** Let  $X = \text{Res}(Y, Z)$  where  $Y \sim \{0, 1\}^n$  and  $Z$  is  $\gamma$ -almost  $k$ -wise independent with marginals  $p$ . Then, for any positive integer  $t$ , the distribution of the  $\star$  positions in  $X^{\text{ot}}$  is  $(t\gamma)$ -almost  $k$ -wise independent with marginals  $p^t$ .

Finally, we turn to define the notion of realizing a collision, in which a restriction “hits” a symbol in a collision layer that indeed causes a collision.

► **Definition 16** (realizing a collision). *Let  $B$  be an  $[n, w]_\ell$  ROBP and let  $E_i : \{0, 1\}^{S_i} \times [w] \rightarrow [w]$  be a collision layer in  $B$  for some  $i \in [n]$ . We say a string  $(y, z) \in \{0, 1\}^n \times \{0, 1\}^n$  realizes a collision in  $E_i$  if for any symbol  $\sigma \in \{0, 1\}^{S_i}$  consistent with the restriction  $\text{Res}(y, z)$  (i.e.,  $\sigma_j = y_j$  for all  $j \in S_i$  with  $z_j = 0$ ) we have that  $E_i^\sigma$  contains a collision (i.e.  $E_i^\sigma(v) = E_i^\sigma(v')$  for two distinct states  $v, v'$ ). We say  $(y, z)$  realizes a collision in  $B$  if it realizes a collision in some layer  $E_i$ .*

We will always use the special case where a collision is realized by  $z_{S_i} = 0^{|S_i|}$  and  $E_i^{y_{S_i}}$  having a collision.

### 3 PRGs for Constant-Width Read-Once MBPs

We set forth two auxiliary lemmas that will serve as the building blocks for our iterative argument.

The first claim states that in a read-once MBP with enough colliding layers from  $[w]$  to  $[w]$ , each depending on at most  $\ell$  bits, it is likely that one of the layers will realize a collision under a pseudorandom restriction. The second claim will help us implement *alphabet reduction* as outlined in the introduction.

► **Lemma 17** (realizing a collision). *Let  $\ell \in \mathbb{N}$  and  $m \geq 16^\ell$ . For  $i = 1, \dots, m$ , let  $E_i : \{0, 1\}^{S_i} \times [w] \rightarrow [w]$  where  $S_1, \dots, S_m \subseteq [n]$  are disjoint sets of size at most  $\ell$ . Suppose that each  $E_i$  is a collision layer. Let  $Y, Z \sim \{0, 1\}^n$  be  $\gamma$ -almost  $k$ -wise independent distributions, for  $\ell \leq k \leq 2^\ell/16$ . Then,*

$$\Pr_{Z,Y} [\exists i : (Y, Z) \text{ realizes a collision in } E_i] \geq 1 - 2^{-k/2} - \gamma \cdot 8^k.$$

**Proof.** For  $j \in [m]$  let  $\mathcal{E}_j$  be the event that  $z_{S_j} = 0^{|S_j|}$  and  $y_{S_j} = \sigma_j$ , where  $\sigma_j$  is an arbitrary choice of a string for which  $E_j^{\sigma_j}$  collides. Observe that when  $\mathcal{E}_j$  occurs,  $(Y, Z)$  realizes a collision in  $E_j$ . Thus, it suffices to lower bound the probability that some of the  $\mathcal{E}_j$  occurs.

The key observation is that the events  $\mathcal{E}_1, \dots, \mathcal{E}_m$  are  $2\gamma$ -almost  $k/\ell$ -wise independent with marginals  $\geq 4^{-\ell}$ . Indeed, for any test that depends on  $k/\ell$  of the events  $\mathcal{E}_1, \dots, \mathcal{E}_m$ , the test can be written as a function of  $k$  bits from  $Y$  and  $k$  bits from  $Z$ , and since any  $k$  bits from  $Y$  are  $\gamma$ -almost uniform and any  $k$  bits of  $Z$  are  $\gamma$ -almost uniform, we get that the test is fooled by the distribution with error at most  $2\gamma$ . Since on the uniform distribution  $z_{S_i} = 0^{|S_i|}$  and  $y_{S_i} = \sigma_i$  has probability  $4^{-|S_i|} \geq 4^{-\ell}$ , we get that  $\mathcal{E}_1, \dots, \mathcal{E}_m$  are  $2\gamma$ -almost  $k/\ell$ -wise independent with marginals  $\geq 4^{-\ell}$ .

By Corollary 11,

$$\begin{aligned} \Pr \left[ \sum_{j=1}^m 1_{\mathcal{E}_j} = 0 \right] &\leq \left( \frac{16k/\ell}{4^{-\ell} 16^\ell} \right)^{k/2\ell} + 4(k/\ell)\gamma \left( \frac{1}{4^{-\ell}} \right)^{k/\ell} \\ &\leq (2^\ell/4^\ell)^{k/2\ell} + \gamma \cdot 2^\ell \cdot (4^\ell)^{k/\ell} \leq 2^{-k/2} + \gamma \cdot 8^k. \end{aligned}$$

Thus, we get

$$\Pr_{Z,Y} [\exists i : (Y, Z) \text{ realizes a collision in } E_i] \geq \Pr \left[ \sum_{j=1}^m 1_{\mathcal{E}_j} > 0 \right] \geq 1 - 2^{-k/2} + \gamma \cdot 8^k. \quad \blacktriangleleft$$

► **Lemma 18** (alphabet reduction). *For every constant  $C > 1$  there exists a constant  $p \in (0, 1)$  such that the following holds. Let  $\ell \in \mathbb{N}$  and  $m \leq C^\ell$ . For  $i = 1, \dots, m$ , let  $E_i: \{0, 1\}^{S_i} \times [w] \rightarrow [w]$  where  $S_1, \dots, S_m \subseteq [n]$  are disjoint sets of size at most  $\ell$ . Let  $Z \sim \{0, 1\}^n$  be a  $\gamma$ -almost  $k$ -wise independent distribution with marginals  $p$ , for  $k \geq \ell$ . For  $j = 1, \dots, m$  let  $B_j$  be the indicator that  $Z_{S_j}$  has more than  $\ell/2$  ones. Then,*

$$\Pr \left[ \sum_{j=1}^m B_j \geq \frac{k}{\ell} \right] \leq C^k \cdot \gamma + 2^{-k}$$

**Proof.** Fix a set  $T \subseteq [m]$  of size  $t = \frac{k}{\ell}$ . For  $j \in T$ , let  $B_j(z)$  be the indicator random variable that is 1 if and only if  $z_{S_j}$  has more than  $\frac{\ell}{2}$  ones. We bound  $\Pr_Z[\forall j \in T : B_j(Z) = 1]$ . Note that this event depends only on  $k$  bits of  $Z$  and thus

$$\Pr_Z[\forall j \in T, B_j(Z) = 1] \leq \Pr_U[\forall j \in T : B_j(U) = 1] + \gamma.$$

To bound the probability of  $\forall j \in T, B_j(U)$  we note that each  $B_j$  happens with probability at most  $\binom{\ell}{\ell/2} p^{\ell/2} \leq 2^\ell p^{\ell/2}$  and that  $k/\ell$  of these events happen simultaneously with probability at most  $(2^\ell p^{\ell/2})^{k/\ell} = 2^k p^{k/2}$ .

Taking the union-bound over all subsets, we get the probability there exists  $T \subseteq [m]$  of size  $t$  for which  $B_j = 1$  for every  $j \in T$  is at most

$$\binom{C^\ell}{t} \left( \gamma + 2^k p^{k/2} \right) \leq C^{\ell t} \cdot \left( \gamma + 2^k p^{k/2} \right) = C^k \cdot \gamma + 2^{-k},$$

for  $p = \frac{1}{16C^2}$ . ◀

### 3.1 Width Reduction

► **Lemma 19.** *Let  $B$  be an  $[n, w]_\ell$  read-once MBP, and let  $\varepsilon > 0$ . Let  $k = \max(\ell, 4 \log(2n/\varepsilon))$  and  $\gamma = 32^{-k}$ . Set  $t = \log(\ell/\log(16k))$ . Also, for every  $j \in [t]$ ,*

■ *Let  $Y_1^j \sim \{0, 1\}^n$  and  $Z_1^j \sim \{0, 1\}^{\ell n}$  be  $\gamma$ -almost  $k$ -wise independent distribution;*

## 58:12 PRGs for Read-Once Monotone Branching Programs

- Let  $Y_2^j \sim \{0, 1\}^n$  be any distribution; and,
- Let  $Z_2^j \sim \{0, 1\}^n$  be a  $\gamma$ -almost  $k$ -wise independent distribution with marginal probability  $p$  as obtained from Lemma 18 for the constant  $C = 16$ .

For every  $j \in [t]$  we denote the  $j$ -th restriction as

$$X^j = X^{j,1} \circ X^{j,2} = \text{Res}(Y_1^j, Z_1^j) \circ \text{Res}(Y_2^j, Z_2^j),$$

and we set the pseudorandom restriction  $\bar{X} = X^1 \circ \dots \circ X^t$ .

Then, with probability at least  $1 - \varepsilon$  over  $\bar{x} \sim \bar{X}$ ,  $B|_{\bar{x}}$  can be written as an  $[n, w - 1]_{\ell'}$  read-once MBP for  $\ell' = O(k^9)$ .

**Proof.** Consider  $\ell_0 = \ell, \ell_1 = \ell/2, \dots, \ell_t = \ell/2^t$ . Note that for all  $i$  we have  $\ell_i \leq k \leq 2^{\ell_i}/16$ . Denote  $\Sigma^{(0)} = \Sigma$  and  $\ell_0 = \ell$ . Consider the pseudorandom restriction  $X^{1,1}$ , denoting  $A^1 = B|_{X^{1,1}}$ . By Lemma 17, followed by a union bound, we get that with probability at least

$$1 - n \cdot \left(2^{-k/2} + \gamma \cdot 8^k\right) \geq 1 - \varepsilon/2n,$$

every  $16^{\ell_0}$  consecutive layers of  $A^1$  contains a layer of vertices of width  $w - 1$ .<sup>4</sup> In the following, we condition on the event mentioned in the previous sentence. After the restriction we identify all layers of width  $w - 1$  and decompose the program to a concatenation of subprograms starting and ending with width at most  $w - 1$ . That is, we can write  $A^1$  as  $A_1^1 \circ \dots \circ A_r^1$ , where  $A_i^1$  has initial and final width at most  $w - 1$ , and length at most  $16^{\ell_0}$  over alphabet  $\Sigma^{(0)} = \{0, 1\}^{\ell_0}$ .

Next, consider the application of  $X^{1,2}$  on  $A^1 = A_1^1 \circ \dots \circ A_r^1$ . By Lemma 18 and a union bound, with probability at least

$$1 - n(16^k \gamma + 2^{-k}) \geq 1 - \varepsilon/2n,$$

we can reduce the alphabet in each  $A_i^1|_{X^{1,2}}$  to  $\Sigma^{(1)} = \{0, 1\}^{\ell_0/2}$ , except for  $k/\ell_0 \leq k$  “unruly” wide layers whose alphabet is a subset of  $\{0, 1\}^{\ell_0}$ . To sum up, after the first restriction, with probability at least  $1 - \varepsilon/n$ ,  $B^1 = B|_{X^1}$  can be written as a read-once MBP  $\tilde{B}_1^1 \circ \dots \tilde{B}_r^1$ , such that for every subprogram  $\tilde{B}_i^1$ : (i) starts and ends with width  $w - 1$  (ii) has at most  $16^{\ell_0}$  good layers with alphabet length  $\leq \ell_1$ , and (iii) has up to  $k$  unruly layers with alphabet length  $\leq \ell_0$ .

We show by induction on  $j$  that, with probability at least  $1 - \varepsilon j/n$ , after the  $j$ -th restriction  $B^j = B|_{X^1 \circ \dots \circ X^j}$  can be written as  $\tilde{B}_1^j \circ \dots \tilde{B}_{r_j}^j$ , such that for every subprogram  $\tilde{B}_i^j$ :

- Starts and ends with width  $w - 1$ ,
- Has at most  $16^{\ell_{j-1}}$  good layers with alphabet length  $\leq \ell_j$ , and,
- Has up to  $jk$  unruly layers with alphabet length  $\leq \ell_0$ .

Assume this to be the case for some  $j < t$ , we show how to prove it to be the case for  $j + 1$ . We denote by  $A^{j+1} = B^j|_{X^{j+1,1}}$ . By Lemma 17, with probability at least  $1 - n \cdot (2^{-k} + \gamma \cdot 8^k) \geq 1 - \varepsilon/2n$ , every  $16^{\ell_j}$  consecutive good layers of  $B^{j+1}$  realizes a collision in  $A^{j+1}$ . We write  $A^{j+1}$  as

$$A_1^{j+1} \circ \dots \circ A_{r_{j+1}}^{j+1},$$

<sup>4</sup> Observe that if  $16^{\ell_0} > n$  we may not apply Lemma 17. However, then the statement that “every  $16^{\ell_0}$  consecutive layers of  $A^1$  contains a layer of vertices of width  $w - 1$ ” is always true.

where each subprogram  $A_i^{j+1}$ : (i) starts and ends with width  $w - 1$ , (ii) has at most  $16^{\ell_j}$  good layers with alphabet length  $\leq \ell_j$ , and (iii) has up to  $jk$  unruly layers with alphabet length  $\leq \ell_0$ . To see Item (iii) note that the partition to subprograms is a refinement of the previous partition and thus cannot increase the maximal number of “unruly” layers in a subprogram.

Applying  $X^{j+1,2}$ , by Lemma 18, with probability at least  $1 - n(16^k\gamma + 2^{-k}) \geq 1 - \varepsilon/2n$ , in each subprogram  $A_i^{j+1}$  we can reduce the alphabet to  $\Sigma_{j+1} = \{0, 1\}^{\ell_{j+1}}$  except for at most the previous  $jk$  unruly layers and potentially  $k$  new unruly layers.

Overall, with probability at least  $1 - t\varepsilon/n \geq 1 - \varepsilon$ , the branching program  $B^t$  can be written as  $B^t = B_1^t \circ \dots \circ B_{r_t}^t$ , where  $B_i^t$  starts and ends with width  $w - 1$ , has at most  $16^{\ell_{t-1}}$  good layers and at most  $kt$  unruly layers. Thus, each  $B_i^t$  is a function of at most

$$16^{\ell_{t-1}} \cdot \ell_t + kt \cdot \ell_0 \leq k \cdot 16^{2(4+\log(k))} + k^3 = O(k^9)$$

bits. We can merge all bits participating in  $B_i^t$  to a single symbol in  $\Sigma' = \{0, 1\}^{\ell'}$  where  $\ell' = O(k^9)$ . We can thus write  $B^t$  as an  $[n, w - 1]_{\ell'}$  read-once MBP. ◀

As a second step, we reduce the alphabet size from  $\text{poly}(\log(n/\varepsilon))$  down to  $O(\log(n/\varepsilon))$ .

► **Lemma 20.** *Let  $\varepsilon > 0$ ,  $k = 4 \log(n/\varepsilon)$ ,  $\gamma = 1/(16\ell)^k$ . Let  $B$  be an  $[n, w]_{\ell}$  read-once MBP. Let  $Z$  be a  $\gamma$ -almost  $k$ -wise independent distribution over  $\{0, 1\}^n$  with marginals  $p_2 = 1/2\ell$ ; Let  $Y$  be any distribution over  $\{0, 1\}^n$ . Let  $X = \text{Res}(Y, Z)$ .*

*Then, with probability at least  $1 - \varepsilon$  over  $\bar{x} \sim \bar{X}$ ,  $B|_{\bar{x}}$  can be written as an  $[n, w]_k$  read-once MBP.*

**Proof.** Let  $z \sim Z$ . As in Lemma 18, for each layer  $j$  let  $B_j$  be the indicator random variable that is 1 if and only if  $z_j$  has more than  $k$  ones. By the union bound,

$$\Pr_Z [B_j = 1] \leq \binom{\ell}{k} \cdot (p_2^k + \gamma) \leq \ell^k p_2^k + \ell^k \cdot \gamma \leq 2 \cdot 2^{-k}.$$

Union bounding over all layers, the probability that we failed to reduce the alphabet size to  $2^k$  in any of the layers is at most  $1 - 2n2^{-k} \geq 1 - \varepsilon$ . ◀

### 3.2 Putting It Together

Our process will apply a sequence of  $w - 1$  restrictions sampled using Lemma 13, reducing the program width one at a time, with high probability, while preserving the acceptance probability.

Let  $c$  be a large enough constant. Set  $k = c \log(nw/\varepsilon)$  and  $t = \log(k)$ . Set  $\gamma = 1/(ck^9)^k$  and  $\delta = \min\{\gamma/2^k, 2^{-cwk \log \log n}\}$ . Set  $C = 16$ ,  $p_1 = \frac{1}{16C^2}$  and  $p_2 = \frac{1}{ck^9}$ .

For  $i \in [w - 2]$  and for  $j \in [t]$ :

- Let  $X^{i,j,1} = \text{Res}(Y^{i,j,1}, Z^{i,j,1})$  be a restriction from Lemma 13 with parameters  $k$ ,  $\gamma$  and  $\delta$  as above. We have that  $Y^{i,j,1}$  is a  $\delta$ -biased distribution, which is also a  $\gamma$ -almost  $k$ -wise independent distribution (due to Lemma 8). We have that  $Z^{i,j,1}$  is  $\gamma$ -almost  $k$ -wise independent (with marginals  $1/2$ ).
- Let  $X^{i,j,2} = \text{Res}(Y^{i,j,2}, Z^{i,j,2})$  be a composition of  $\log(1/p_1) = O(1)$  restrictions from Lemma 13 with parameters  $k$ ,  $\gamma$  and  $\delta$  as above. We have that  $Y^{i,j,2}$  is a  $\delta$ -biased distribution, which is also a  $\gamma$ -almost  $k$ -wise independent distribution. By Claim 15 we have that  $Z^{i,j,2}$  is  $\log(1/p_1)\gamma$ -almost  $k$ -wise independent with marginals  $p_1$ .

## 58:14 PRGs for Read-Once Monotone Branching Programs

- Let  $\tilde{X}^i = \text{Res}(\tilde{Y}^i, \tilde{Z}^i)$  be a composition of  $\log(1/p_2) = O(\log \log(nw/\varepsilon))$  restrictions from Lemma 13 with parameters  $k, \gamma$  and  $\delta$  as above. By Claim 15 we have that  $\tilde{Z}^i$  is  $\log(1/p_2)\gamma$ -almost  $k$ -wise independent with marginals  $p_2$ .

We define  $X^{i,j} = (X^{i,j,1} \circ X^{i,j,2})$  and  $X^i = (X^{i,1} \circ X^{i,2} \circ \dots \circ X^{i,t}) \circ \tilde{X}^i$ . And finally,  $X = X^1 \circ X^2 \circ \dots \circ X^{w-1}$ . Let  $S \sim \{0, 1\}^n$  be a  $\varepsilon$ -almost  $k$ -wise independent distribution. Our PRG  $G$  is given by

$$G = X \circ S.$$

Let  $s = s(n, w, \varepsilon)$  be the seed length required to sample from  $G$ . Following the seed lengths of the above primitives in Section 2, we can give the following bound.

▷ Claim 21. It holds that  $s = O(w^2 \log(n/\varepsilon) \cdot (\log \log(n/\varepsilon))^2)$ .

▷ Claim 22.  $G$  fools width- $w$  read-once MBPs of length  $n$  with error at most  $4\varepsilon n$ .

Proof. Let  $B$  be an  $[n, w]_1$  read-once MBP, which can also be written as an  $[n, w]_k$  read-once MBP by grouping every  $k$ -consecutive layers. Note that this transformation preserves monotonicity. Since our restriction is picked as a  $m = O(t \cdot w + w \log k) \leq n$  compositions of restrictions that each maintain the acceptance probability of the ROBP up to error  $\varepsilon$  (Lemma 13), we see that

$$\left| \mathbb{E}_{X,U}[B|_X(U)] - \mathbb{E}_U[B(U)] \right| \leq \varepsilon \cdot n.$$

It remains to show that  $\mathbb{E}_{X,U}[B|_X(U)] \approx \mathbb{E}_{X,S}[B|_X(S)]$ . For that we show that with high probability  $B|_X$  can be expressed as a  $[n, 1]_k$  read-once MBP. Let  $E = E(\bar{X})$  be the union of the following bad events:

- There exists an  $i \in [w-1]$  such that  $(X^{i,1} \circ X^{i,2} \circ \dots \circ X^{i,t})$  fails to reduce the width, in the sense of Lemma 19.
- There exists an  $i \in [w-1]$  such that  $\tilde{X}^i$  fails to reduce the alphabet size from  $O(k^9)$  to  $k$ , in the sense of Lemma 20.

By Lemmas 19 and 20,  $\Pr[E] \leq 2w\varepsilon$ . Note that in the case that  $E$  does not occur, we have that  $B|_X$  is a  $[n, 1]_k$  ROBP or in other words that it is a junta that depends on at most  $k$  bits. In such a case,  $B|_X$  will be  $\varepsilon$ -fooled by  $S$ . Overall we have

$$\begin{aligned} \left| \mathbb{E}_{X,U}[B|_X(U)] - \mathbb{E}_{X,S}[B|_X(S)] \right| &\leq \Pr[E] + \Pr[\bar{E}] \cdot \left| \mathbb{E}_X \left[ \mathbb{E}_U[B|_X(U)] - \mathbb{E}_S[B|_X(S)] \mid \bar{E} \right] \right| \\ &\leq 2w\varepsilon + \varepsilon. \end{aligned}$$

Combining both estimates we see that

$$\left| \mathbb{E}_G[B(G)] - \mathbb{E}_U[B(U)] \right| \leq \varepsilon \cdot (n + 2w + 1) \leq 4\varepsilon n. \quad \triangleleft$$

► **Theorem 23.** *Let  $n \in \mathbb{N}$ ,  $\varepsilon' > 0$  and  $w \leq n$ . There exists a generator  $G$  that fools width- $w$  read-once MBPs of length  $n$ , with error at most  $\varepsilon'$  and seed-length  $O(w^2 \cdot \log(n/\varepsilon') \cdot (\log \log(n/\varepsilon'))^2)$ .*

**Proof.** Apply Claim 22 and Claim 21 with  $\varepsilon = \varepsilon'/4n$ . ◀

## 4 Relation to Read-Once $AC^0$

In this section we study the relation between constant-width read-once MBPs and read-once  $AC^0$ :

► **Proposition 4.**

1. If a sequence of functions  $f_n: \{0,1\}^n \rightarrow \{0,1\}$  is in read-once  $AC^0$ , then it can be computed by constant-width read-once MBP. Moreover, if  $f_n$  can be computed in depth  $w$  read-once  $AC^0$ , then it can be computed by width  $w + 1$  read-once MBPs.
2. For every  $n \geq 3$ , there exists a function  $f: \{0,1\}^n \rightarrow \{0,1\}$  computable by a width 3 read-once MBP, but not computable by any read-once De Morgan formula (regardless of depth).

First, we establish Item 1 of Proposition 4 by observing that the known implication, that read-once  $AC^0$  formulas can be computed by constant-width ROBPs, yields a monotone ROBP.

► **Lemma 24.** *Let  $f: \{0,1\}^n \rightarrow \{0,1\}$  be a function computable by a read-once, depth- $w$   $AC^0$  formula. Then,  $f$  can also be computed by an  $[n, w + 1]$  read-once MBP.*

**Proof.** We prove the claim by induction on the depth  $w$ , and further prove that the ‘accept’ states in our read-once MBP are above the ‘reject’ states (that is, if  $s$  is an accept state and  $s'$  is a reject state then  $s \geq s'$ ). For  $w = 1$ ,  $f$  computes either the disjunction or the conjunction of at most  $s$  literals. This can clearly be done by an  $[n, s, 2]$  read-once MBP, if we set state 2 to be an accept state (and so state 1 is a reject one).

Next, fix some  $f$  computable by a formula  $F: \{0,1\}^n \rightarrow \{0,1\}$  of depth  $w > 1$  and size  $s$ , and assume that its top gate is an AND gate (the other case is similar). We denote the subformulas feeding into the top gate as  $F_1, \dots, F_m$ , and these are on disjoint variables because the formula is read-once. By the induction’s hypothesis, each subformula  $F_i$  is computable by a width  $w$  read-once MBP over its variables with the accept states being on top.

To construct  $B$  that computes  $F$ , we can concatenate the  $B_i$ -s and add another “sudden reject” level at level  $s = 1$ .<sup>5</sup> The starting vertex of  $B$  is the starting vertex of  $B_1$ . Whenever a computation of some  $B_i$ , for some  $i < m$ , reaches its final layer, we rewire the edges in that layer to either the sudden reject level, if  $B_i$  did not reach an accepting vertex, or to the starting vertex of  $B_{i+1}$ . The accept vertices of  $B$  are the accept vertices of  $B_m$ . Note that this transformation preserves the ordering between accepts and reject states, since  $B_m$  does.

The fact that  $B$  computes  $f$  readily follows, and  $B$  is read-once because the  $B_i$ -s are on disjoint variables. To argue that monotonicity is preserved, simply observe that the rewiring preserves the order: In the AND case, accept vertices are rewired to the next starting vertex, which is indeed above the sudden reject level, to which all reject vertices are rewired. The OR case is similar. ◀

We now prove Item 2 of Proposition 4, giving a family of functions computable by read-once MBPs but not by read-once formulas. Our proof also gives a new characterization of read-once formulas.

<sup>5</sup> In a sudden reject level, each vertex transitions to the same level with both its edges, and the last vertex in that level is a reject vertex. When the top gate is an OR gate, we would replace the sudden reject level with a sudden accept level at  $s = w + 1$ , and make the last vertex of the sudden accept level an accepting vertex.

► **Lemma 25.** *For every  $n \geq 3$ , there exists a function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  computable by a width 3 read-once MBP, but not computable by any read-once De Morgan formula (regardless of depth).*

**Proof.** We first give a property of functions computable by read-once formulas. Given  $g : \{0, 1\}^m \rightarrow \{0, 1\}$  and  $b \in \{0, 1\}$ , let  $W_b(g) \in \{0, \dots, m\}$  denote the size of the smallest set of coordinates  $I \subseteq [m]$  for which there exists a  $z \in \{0, 1\}^{|I|}$  such that for every  $x \in \{0, 1\}^m$  it holds that  $x_I = z$  implies  $g(x) = b$ .

► **Lemma 26.** *Let  $g : \{0, 1\}^n \rightarrow \{0, 1\}$  be a function computable by a read-once De Morgan formula. Then,  $W_0(g) \cdot W_1(g) \leq n$ .*

Roughly speaking, this lemma says that for a function computable by a read-once formula, we can either find a short witness for it being 0, or a short witness for it being 1. In particular, it cannot be highly resilient.

**Proof.** We prove the lemma by induction on the formula's depth  $d$ . For  $d = 1$ ,  $g$  is either an AND of literals or an OR of literals. For the AND function,  $W_0(\text{AND}) = 1$  and  $W_1(\text{AND}) = n$ . For the OR function,  $W_0(\text{OR}) = n$  and  $W_1(\text{OR}) = 1$ . Thus, indeed,  $W_0(g) \cdot W_1(g) \leq n$ .

Assume our lemma holds for formulas of depth  $d \geq 1$ , and let  $g$  be some formula of depth  $d + 1$ , say with an AND top gate, so  $g = \text{AND}(f_1, \dots, f_k)$ , each  $f_i : \{0, 1\}^{n_i} \rightarrow \{0, 1\}$  is a depth- $d$  formula. In this case,  $W_0(g) = \min_{j \in [k]} W_0(f_j)$  and  $W_1(g) = \sum_{i \in [k]} W_1(f_i)$ . By our induction's hypothesis, we get that

$$W_0(g) \cdot W_1(g) = \left( \min_{j \in [k]} W_0(f_j) \right) \cdot \sum_{i \in [k]} W_1(f_i) \leq \sum_{i \in [k]} W_0(f_i) \cdot W_1(f_i) \leq \sum_{i \in [k]} n_i = n.$$

The case of an OR top gate is analogous. ◀

Now, our function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  will simply be the  $\text{Thr}_2^n$  function, that returns 1 if and only if the Hamming weight of the input string  $x \in \{0, 1\}^n$  is at least 2. There,  $W_1(f) = 2$  and  $W_0(f) = n - 1$ , so it is not computable by read-once formulas, however  $f$  is computable by a simple width-3 read-once MBP. ◀

We note that we can also construct balanced functions  $f$  separating read-once MBPs from read-once De Morgan formulas. In particular,  $f = \text{AND}_m \circ \text{Thr}_2^w$  for  $m = O(2^w/w)$  (which resembles the Tribes function) has this property. More generally, one can consider, say,  $\text{Thr}_2$ , as a “gadget” to construct richer families of read-once MBPs not computable by read-once formulas.

---

## **A** Monotone Branching Programs and $\text{AC}^0$ Circuits

In this section we give a self-contained proof of the equivalence between constant width MBPs and  $\text{AC}^0$  circuits, proving Theorem 3:

► **Theorem 3** (corollary of [4]). *A sequence of functions  $f_n : \{0, 1\}^n \rightarrow \{0, 1\}$  is in  $\text{AC}^0$  if and only if it is computable by a constant-width MBP of polynomial length.*

First we note that the “if” direction follows from Lemma 24.

► **Lemma 27.** *Let  $f: \{0,1\}^n \rightarrow \{0,1\}$  be a function computable by a (read-many)  $AC^0$  formula of depth  $w$  and size  $s$ . Then,  $f$  can also be computed by an  $[n, s, w + 1]$  MBP.*

(Here take the *size* of an  $AC^0$  formula to be the number of leaves.)

**Proof.** Let  $F(x_1, \dots, x_n)$  be depth- $w$   $AC^0$  formula of size  $s$ . Then by putting distinct variables on the leaves of  $F$  we obtain a read-once  $AC^0$  formula  $G(y_1, \dots, y_s)$  on  $s$  variables such that  $F(x_1, \dots, x_n) = G(\sigma_1 x_{i_1}, \dots, \sigma_s x_{i_s})$  where  $i_1, \dots, i_s \in [n]$  and  $\sigma_1, \dots, \sigma_s \in \{\pm 1\}$  (referring to whether or not the variable is negated at each leaf). By Lemma 24, there is a read-once MBP  $B(y_1, \dots, y_s)$  of width  $w + 1$  computing  $G$ . Then,  $B(\sigma_1 x_{i_1}, \dots, \sigma_s x_{i_s})$  is a (read-many) MBP of width  $w + 1$  and length  $s$  computing  $F$ . ◀

The result naturally extends to  $AC^0$  circuits, due to the standard transformation expressing a size  $s$  depth  $w$   $AC^0$  circuit as a size  $s^w$  depth  $w$   $AC^0$  formula.

► **Corollary 28.** *Let  $f: \{0,1\}^n \rightarrow \{0,1\}$  be a function computable by a depth- $w$   $AC^0$  circuit of size  $s$ . Then,  $f$  can also be computed by an  $[n, s^w, w + 1]$  MBP.*

Next, we give the other direction of Theorem 3. Similarly to the other direction, we start by showing that *read-once* MBPs can be simulated by (read-many)  $AC^0$ :

► **Lemma 29.** *Let  $f: \{0,1\}^n \rightarrow \{0,1\}$  be a function computable by a read-once MBP of width  $w$ . Then,  $f$  can also be computed by a circuit of depth  $O(w)$  and size  $O(w^4 n^3)$ .*

**Proof.** We prove this lemma by induction on the width. For  $w = 1$  the claim is trivial. Fix some  $w > 1$  and let  $B$  be an  $[n, w]$  read-once MBP. We define two BPs,  $B^u$  and  $B^\ell$ , each of width  $w - 1$ , as follows.

- For  $B^u$ , we remove the first level of vertices (that is, removing state number 1 in each layer) and reroute edges that go into state 1 to state 2. Formally, each transition  $U_i^b: \{2, \dots, w\} \rightarrow \{2, \dots, w\}$  of  $B^u$  is defined by  $U_i^b(x) = \max\{E_i^b(x), 2\}$ , for  $E_i^b: [w] \rightarrow [w]$  being the corresponding transition of  $B$ .
- Similarly, for  $B^\ell$ , we remove the last level of vertices: Each transition  $L_i^b: [w - 1] \rightarrow [w - 1]$  of  $B^\ell$  is defined by  $L_i^b(x) = \min\{E_i^b(x), w - 1\}$ .

Notice that these transformations preserve monotonicity. Roughly speaking, our goal is to first argue that at each transition,  $B$  acts the same as either  $B^u$  or  $B^\ell$ , depending on whether  $B$  last reached the state 1 or the state  $w$ . Then, we show that we can efficiently detect, given any layer  $j$  and an input  $x$ , if indeed  $B(x)$  passed through the state 1 or through the state  $w$  before reaching the layer  $j$ .

Let  $s_0$  be the starting vertex of  $B$ , and denote  $u_0 = \max\{s_0, 2\}$  and  $\ell_0 = \min\{s_0, w - 1\}$ . Given some input  $x \in \{0,1\}^n$ , we consider the computation path of all three BPs on  $x$ . Towards this end, denote by  $s_1, \dots, s_n \in [w]$  the states that  $x$  traverses in  $B$ ,  $u_1, \dots, u_n \in \{2, \dots, w\}$  the states that  $x$  traverses in  $B^u$  and  $\ell_1, \dots, \ell_n \in [w - 1]$  the states that  $x$  traverses in  $B^\ell$ . First, observe that:

▷ **Claim 30.** For every  $i \in [n]$ ,  $u_i \geq s_i \geq \ell_i$ .

The above claim readily follows by induction on  $i$ , using the monotonicity property. Next, we argue:

▷ **Claim 31.** For every  $i \in [n]$ , let  $j \leq i$  be the largest integer such that  $s_j \in \{1, w\}$ , if it exists. Thus, if  $s_j = w$  then  $u_i = s_i$  and if  $s_j = 1$  then  $\ell_i = s_i$ .

Proof. Fix some  $i \in [n]$  and assume that  $j \leq i$  is the largest integer such that  $s_j \in \{1, w\}$ , say  $s_j = 1$ . By Claim 30, we must also have  $\ell_j = 1$ . Then by induction, we also have  $\ell_{j'} = s_{j'}$  for all  $j' = j, j+1, \dots, i$ , because the only way in which the transition in  $B^\ell$  and  $B$  can differ is if  $s_{j'} = w$ , which by assumption does not occur in this interval.  $\triangleleft$

Hence, for each layer  $i$ , we know that either  $s_i = u_i$  or  $s_i = \ell_i$ , and we know which is the case by looking at the last place the original path reached either 1 or  $w$ .

By our induction's hypothesis, for every  $i \in [n]$  and  $s \in \{2, \dots, w\}$  there exists a circuit  $C_{i,s}^u: \{0, 1\}^n \rightarrow \{0, 1\}$  such that  $C_{i,s}^u(x) = 1$  if and only if  $B^u$  reached the state  $s$  after reading  $x_1, \dots, x_i$ . Similarly, there exists a circuit  $C_{i,s}^\ell$  that detects whether  $B^\ell$  reached  $s \in [w-1]$  in the  $i$ -th layer upon traversing with  $x$ . Using these circuits, for each  $s \in [w]$ , we will construct a circuit  $C_s(x)$  that determined whether  $s_n = s$ .

The construction goes as follows. The circuit will determine the last  $j$  where there was a “switch” between the two cases of Claim 31, i.e., the smallest  $j \in [n]$  such that  $s_j \in \{1, w\}$  and for every  $k \geq j$  it holds that  $s_k \in \{2, \dots, w-1\} \cup \{s_j\}$ . Observe that if  $s_j = 1$  then  $s_{j-1} = u_{j-1}$ , so  $E_j^{x_j}(u_{j-1}) = 1$ . Afterward, we keep following  $B^\ell$ , i.e.,  $s_k = \ell_k$  and so  $E_{k+1}^{x_{k+1}}(\ell_k) \neq w$  for all  $k \geq j$ . The converse also holds. Namely,  $E_j^{x_j}(u_{j-1}) = 1$  implies that  $s_j = \ell_j = 1$  (since  $\ell_{j-1} \leq u_{j-1}$  and the program is monotone) and  $E_{k+1}^{x_{k+1}}(\ell_k) \neq w$  for all  $k \geq j$  implies that indeed  $s_{k+1} = \ell_{k+1}$ . Thus, the predicate

$$P_L(x) = \left( \bigvee_{j \in [n]} \left( (E_j^{x_j}(u_{j-1}) = 1) \wedge \bigwedge_{k \geq j} (E_{k+1}^{x_{k+1}}(\ell_k) \neq w) \right) \right) \vee \left( u_1 \neq w \wedge \bigwedge_{k \geq 1} E_k^{x_k}(\ell_k) \neq w \right)$$

evaluates to 1 if and only if the largest integer  $j \leq n$  such that  $s_j \in \{1, w\}$  has  $s_j = 1$ , or  $s_j$  never equals  $w$  (and hence  $s_n = \ell_n$ ). Following the same reasoning,

$$P_U(x) = \left( \bigvee_{j \in [n]} \left( (E_j^{x_j}(\ell_{j-1}) = w) \wedge \bigwedge_{k \geq j} (E_{k+1}^{x_{k+1}}(u_k) \neq 1) \right) \right) \vee \left( \ell_1 \neq 1 \wedge \bigwedge_{k \geq 1} E_k^{x_k}(u_k) \neq 1 \right)$$

evaluates to 1 if and only if the largest integer  $j \leq n$  such that  $s_j \in \{1, w\}$  has  $s_j = w$ , or  $s_j$  never equals 1 (and hence  $s_n = u_n$ ).

We now wish to compute  $P_L: \{0, 1\}^n \rightarrow \{0, 1\}$  by a shallow circuit. Determining  $u_{j-1}$  can be done by querying  $C_{j-1,s}^u(x)$  for each  $s \in \{2, \dots, w\}$ . Similarly, determining  $\ell_k$  can be done by querying  $C_{k,s}^\ell(x)$  for each  $s \in [w-1]$ . The functions  $E_j^b$  and  $E_{k+1}^b$ , for each  $b \in \{0, 1\}$ , are determined solely by  $B$  and can be hardwired. Letting  $\text{size}(w-1)$  and  $\text{depth}(w-1)$  be the size and depth upper bound for the circuits guaranteed to us by the hypothesis, we can bound  $\text{size}(P_L)$  by  $2nw \cdot \text{size}(w-1) + O(wn^2)$  and  $\text{depth}(P_L)$  by  $\text{depth}(w-1) + O(1)$ . The same bounds for  $P_U: \{0, 1\}^n \rightarrow \{0, 1\}$  also hold.

Equipped with circuits  $C_L$  and  $C_U$  computing  $P_L$  and  $P_U$  respectively, we are ready to compute  $B$ . Indeed, all that is left is to determine whether  $s_n = \ell_n$  or  $s_n = u_n$  and invoke the relevant circuit from the previous level. This incurs additional constant depth and  $O(wn)$  size. Overall, the size and depth of  $C$  satisfies the recurrence relations  $\text{size}(w) = O(nw) \cdot \text{size}(w-1) + O(wn^2)$  and  $\text{depth}(w) = \text{depth}(w-1) + O(1)$ . As  $\text{size}(1) = O(n)$  and  $\text{depth}(1) = O(1)$ , this gives us depth  $O(w)$  and size  $w^{O(w)} \cdot n^w$ .

We can improve the size of the circuit by a dynamic programming approach. For  $1 \leq a \leq b \leq w$ , let  $B^{[a,b]}$  be the ROBP in which we keep only the levels  $a, \dots, b$  and rewire edges accordingly. Namely, we replace each  $E_i^\sigma(x)$  with  $\max\{a, \min\{b, E_i^\sigma(x)\}\}$ . Observe that for when  $a < b$ ,  $(B^{[a,b]})^\ell = B^{[a,b-1]}$  and  $(B^{[a,b]})^u = B^{[a+1,b]}$ .

For every  $1 \leq a \leq b \leq w$  and  $s \in \{a, \dots, b\}$ , let  $X_i^{a,b,s}$  be the indicator which is 1 if and only if upon reading the first  $i$  bits of  $x$ , the program  $B^{[a,b]}$  reached the state  $s$ . Note that there are at most  $w^3 \cdot n$  such indicators overall.

Fix some integer  $\Delta \in \{0, \dots, w-1\}$ . We can compute the values

$$\mathcal{I}_\Delta = \left\{ X_i^{a,a+\Delta,s} : a \in [w-\Delta], s \in [a, a+\Delta], i \in [n] \right\}$$

in the following manner. For  $\Delta = 0$ , all indicators are true. For  $\Delta \geq 1$ , assume we already computed the values

$$\mathcal{I}_{\Delta-1} = \left\{ X_i^{a,a+\Delta-1,s} : a \in [w-(\Delta-1)], s \in [a, a+\Delta-1], i \in [n] \right\}.$$

Thus, to compute a single indicator from  $\mathcal{I}_\Delta$  given  $\mathcal{I}_{\Delta-1}$ , we can use the above recurrence relations, as each  $\ell_i$  and  $u_i$  correspond to some indicator from  $\mathcal{I}_{\Delta-1}$ . This takes  $O(wn^2)$  size and  $O(1)$  depth. Computing the entire  $\mathcal{I}_\Delta$  thus takes  $O(w^3n^3)$  size and  $O(1)$  depth. Overall, computing  $\blacktriangleleft$

Similarly to the proof of Lemma 27, we can handle the read-many case by noting that a read-many MBP of length  $s$  can be obtained from a read-once MBP on  $s$  variables by a variable substitution. This gives us the “only if” direction of Theorem 3:

► **Corollary 32.** *Let  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  be a function computable by an  $[n, s, w]$  MBP for  $s \geq n$ . Then,  $f$  can also be computed by a circuit of depth  $O(w)$  and size  $O(w^4s^3)$ .*

# On the Power of Choice for $k$ -Colorability of Random Graphs

## Abstract

In an  $r$ -choice Achlioptas process, random edges are generated  $r$  at a time, and an online strategy is used to select one of them for inclusion in a graph. We investigate the problem of whether such a selection strategy can shift the  $k$ -colorability transition; that is, the number of edges at which the graph goes from being  $k$ -colorable to non- $k$ -colorable.

We show that, for  $k \geq 9$ , two choices suffice to delay the  $k$ -colorability threshold, and that for every  $k \geq 2$ , six choices suffice.

## 1 Introduction

In studying the evolution of a random graph, a field launched by the seminal paper of Erdős and Rényi [7], one starts from an empty graph, and adds edges one by one, generating each one independently and uniformly at random. In this context, a common object of study is the size of the graph at which some property of interest changes. For instance, if we are interested in  $k$ -colorability, there will eventually be some edge whose addition changes the graph from being  $k$ -colorable to non- $k$ -colorable.

The  $k$ -colorability transition threshold conjecture states that there is a particular threshold  $d(k)$  such that, almost surely, the  $k$ -colorability transition occurs when  $G$  has average degree approximately  $d(k)$ ; more precisely, when the average degree lies between  $(1 - \varepsilon)d(k)$  and  $(1 + \varepsilon)d(k)$ , for any fixed  $\varepsilon > 0$ . Substantial progress has been made on pinning down this transition threshold, especially by Achlioptas and Naor [2] and by Coja-Oghlan and Vilenchik [5], culminating in a rather precise formula for the asymptotics of  $d(k)$  for large  $k$ . However, for fixed  $k \geq 3$ , the conjecture remains open.

An interesting twist on the evolution of the random graph was proposed by Achlioptas in 2001: Suppose that *two* random edges are sampled at each step in the construction of  $G$ , and an online algorithm selects one of them, which is then added to  $G$ . A more general version of this process proposes  $r$  random edges in each step, from which the algorithm selects one. After  $m$  edges have been chosen in this way, how different can the resulting graph be from the usual Erdős-Rényi random graph  $G(n, m)$ ?

Earlier work on the “power of choice” to affect the outcome of random processes has investigated questions like load-balancing in balls and bins models, scheduling, routing and more; for more, see the excellent survey by Richa, Mitzenmacher and Sitaraman [10]. More specifically, Achlioptas processes have been studied in the context of formation of the giant component in a random graph [3, 4, 13, 11], and the satisfiability threshold for random boolean formulas [12, 6, 9]. In each of these cases, the upshot has been that fairly simple heuristics are capable of shifting the thresholds to a significant extent. However, the heuristics and their analyses remain fairly problem-specific.

The main contribution of the present work is a proof that, for every  $k \geq 2$ , there exist fairly simple choice strategies that significantly delay the  $k$ -coloring threshold, given a constant number of choices for each edge. Our proof leverages existing upper and lower bounds on the  $k$ -colorability threshold, and works even if the  $k$ -Colorability Threshold Conjecture turns out to be false. More precisely, we establish the following result.

► **Theorem 1.** *For every  $k \geq 2$ , there exist  $2 \leq r \leq 6$ , an explicit edge selection strategy for the  $r$ -choice Achlioptas process, and a real number  $d$  such that, if  $G$  is the graph produced by running our strategy for  $dn/2$  steps, and  $H$  is an Erdős-Rényi random graph with the same number of edges, then  $G$  is almost surely  $k$ -colorable and  $H$  is almost surely not  $k$ -colorable. In particular,  $r = 2$  choices suffice for  $k = 2$  and  $k \geq 9$ ,  $r = 3$  suffices for all  $k \neq 3$ , and  $r = 6$  suffices for all  $k$ .*

If, rather than delaying, one wants to *hasten* the  $k$ -colorability threshold, this can be done very easily by “densifying” the graph, an idea used in [6] to hasten the  $k$ -SAT threshold for random boolean formulas. Unlike our main result, this technique easily extends to any monotone graph property that has a sharp threshold in the Erdős-Rényi model. More precisely,

► **Observation 2.** *Let  $P$  be any graph property that is monotone in the sense that  $P(G)$  implies  $P(G')$  for every subgraph  $G'$  of  $G$ . Then, if the threshold conjecture is true for  $P$ , we can lower the threshold using  $r$  choices, whenever  $r \geq 2$ . Moreover, even without the threshold conjecture for  $P$ , if there exist real numbers  $0 < \alpha_1 < \alpha_2$  such that  $P$  almost surely holds for  $G(n, \alpha_1 n)$ , and almost surely fails to hold for  $G(n, \alpha_2 n)$ , then there exists  $r = r(\alpha_1, \alpha_2)$  and  $d = d(\alpha_1, \alpha_2)$ , and an explicit edge selection strategy for the  $r$ -choice Achlioptas process, such that, if  $G$  is the graph produced by running our strategy for  $dn/2$  steps, and  $H$  is an Erdős-Rényi random graph with the same number of edges, then  $H$  almost surely has property  $P$ , and  $G$  almost surely does not. In the case when  $P$  is  $k$ -colorability,  $r = 2$  choices suffices to lower the  $k$ -coloring threshold when  $k = 2$  or  $k \geq 12$ ,  $r = 3$  suffices when  $k \geq 6$ ,  $r = 4$  suffices when  $k \neq 4$ , and  $r = 5$  suffices for all  $k$ .*

The interested reader may refer to Appendix A for additional details.

## 1.1 Strategy for Delaying the $k$ -Colorability Transition

Our basic strategy for delaying the  $k$ -colorability transition is to try to create a large bipartite subgraph. This can be achieved very simply by, *ab initio*, partitioning the vertex set into two equal parts, and then by choosing, whenever possible, a *crossing edge*, that is, one whose endpoints lie in both sides of the partition. As we shall see, this extremely simple heuristic suffices to establish Theorem 1 when  $k \geq 6$ , and with slight modifications, for  $k \leq 5$  as well.

For intuition about why this approach works, think about what happens in the limit as  $r$  becomes very large. Since the probability of being offered all non-crossing edges in a particular step is less than  $2^{-r}$ , by choosing crossing edges whenever possible, our graph

becomes “more and more bipartite” as  $r$  increases. Indeed, when  $r = 3 \log n$ ,  $G$  will almost surely become a complete bipartite graph before it is forced to include any non-crossing edges! Obviously, this is a huge delay to any of the  $k$ -colorability thresholds, which all take place after linearly many edges.

For more intuition, consider the case when  $k$  is very large, but  $r \geq 2$  is constant. We expect about a  $2^{-r}$  fraction of the edges to be non-crossing, and hence the average degree of the graph induced by one side of  $G$  will be about  $2^{-r}$  times the average degree of  $G$ . Since, asymptotically for large  $k$ , we know that the  $k$ -colorability occurs somewhere around  $d \approx 2k \ln(k)$ , (See Theorem 3 for a more precise statement.) which is a nearly-linear function, this tells us that each side of  $G$  should need almost  $2^r$  times fewer colors than  $G(n, m)$ . Hence, if we color the two sides with disjoint sets of colors, so that the crossing edges cannot cause any monochromatic edges, we would expect to need almost  $2^{r-1}$  times fewer colors to color our graph than a random graph with the same average degree.

The above approach works as stated for  $k \geq 6$ . For smaller values of  $k$ , it is necessary to improve the above strategy by adding an additional “filtering” step that checks to see whether the edge proposed by the basic strategy would create an obstacle to  $k$ -coloring; in this case, we make a different edge choice. This is the most technical part of the paper, particularly the case  $k = 3$ , for which the filtering algorithm is fairly complicated.

For  $k = 4$  and  $k = 5$ , since we are splitting the colors among the two sides of  $G$ , at least one side gets only two colors. This is a bit of a special case because, unlike with more colors, two-coloring does not have a sharp phase transition at a particular average degree. Instead, the transition for  $G(n, d/n)$  is spread out over the range  $0 < d < 1$ . However, as we shall see, for Achlioptas processes, it is possible to delay this threshold until the emergence of a giant component at  $d = 1$  (and even beyond!).

For  $k = 3$ , we need a further modification to our plan as outlined above. With only three colors, one side of the graph would only get one color, and would need to remain empty of edges! Since this is clearly impossible, we modify our plan of prescribing disjoint sets of colors for the two sides of the graph. Instead, we allow one of the three colors to be used on both sides. As will be seen, this complicates both the edge selection process and its analysis, and increases the number of choices we need, to  $r = 6$ .

We point out an interesting qualitative difference between the problem of delaying the  $k$ -coloring threshold and that of delaying the  $k$ -SAT threshold. Earlier work on delaying the  $k$ -SAT threshold, in particular by Perkins [9] and by Dani et al. [6], took advantage of the fact that, with enough choices, the 2-SAT threshold can be shifted past the  $k$ -SAT threshold. The analogous statement for  $k$ -coloring would require us to keep our graph bipartite past the formation of a giant component. Although Bohman and Frieze [3] showed that it is possible to delay the formation of a giant component, it obviously cannot be delayed past  $d = 2$ , and indeed, as shown by Bohman, Frieze and Wormald [4, Theorem 1(d)], not past  $d = 1.93$ . After a linear-size giant component has formed, each step of our Achlioptas process has a constant probability that all  $r$  offered edges will fall within the giant component, and moreover all violate bipartiteness. Thus, there is no hope of keeping the graph 2-colorable past the 3-colorability threshold, for any constant (or indeed sub-logarithmic) number of choices. This “fragility” of the property of 2-colorability may provide some intuition for the increased difficulty of our attempts to shift the  $k$ -colorability threshold for small values of  $k$ .

## 1.2 Organization of the Paper

The remainder of the paper is divided into numbered sections. For the most part, each section introduces one or two new ideas that are needed for a particular range of the number of colors,  $k$ . Many of the sections depend on concepts introduced in earlier sections, so it is easiest to read them in order.

In Section 2 (Preliminaries), we introduce various notation and terminology, as well as stating the key results from past work that we will need for our work. In Section 3 we formally state the PreferCrossing strategy, and show how it can be used directly to raise the  $k$ -colorability threshold for  $k \geq 6$ . In Section 4, we handle the case  $k = 2$  by showing that odd cycles (indeed all cycles) can be delayed until a giant component forms, and that this idea can be combined with previous work on delaying the birth of the giant component. In Section 5, we handle the cases  $k = 4$  and  $k = 5$ . These are treated separately from the large  $k$  cases because now one of the two sides will be colored using only two colors, which requires the cycle-avoidance technique developed in Section 4. In Section 6, we handle the hardest case:  $k = 3$ , which involves a significant extension to the technique for avoiding cycles introduced in Section 4. In Section 7, we show how an improved bound on the 3-coloring transition threshold, due to Achlioptas and Moore [1], can be used to reduce the number of choices we need for  $k = 9$  from 3 to 2.

Finally, Appendix A presents a proof of Observation 2, about hastening the transition for (almost) any monotone graph property.

## 2 Preliminaries

Let  $V$  be a fixed vertex set, of size  $n$ . In the rest of the paper, unless otherwise specified, whenever we use asymptotic notations such as big-O and little-O, these refer to limits as  $n \rightarrow \infty$ , while all the other key parameters, namely, average degree  $\bar{d}$ , number of choices,  $r$ , and number of colors,  $k$ , are held constant. When we state that something happens “almost surely,” we mean that the corresponding event has probability  $1 - o(1)$ .

When we talk about the Erdős-Rényi random graph,  $G(n, m)$ , we assume that  $m$  independent random edges are sampled from  $\binom{V}{2}$ , with replacement. Edges are undirected and self-loops are not allowed.

In an  $r$ -choice Achlioptas process, at each step,  $r$  independent random edges are sampled from  $\binom{V}{2}$ , with replacement. An online algorithm, which we call a “strategy” is used to select one of these edges for inclusion in the edge set of the graph, which is initially empty. We allow duplicate edges both in the set of proposed edges, as well as the graph itself. However, observe that, when the total number of edges is linear in  $n$ , and  $r = O(1)$ , the expected number of duplicate edges seen during the entire process is  $O(1)$ . Consequently, in this range of parameters, it should be easy to see that very similar results hold even when duplicate edges are not allowed.

### Key Results from Prior Work

The following result is due to Achlioptas and Naor [2, See Lemma 3 and Proposition 4]

► **Theorem 3** (Achlioptas and Naor). *Suppose  $k$  is a positive integer, and  $d < 2(k-1) \ln(k-1)$ . Then, almost surely,  $G(n, dn/2)$  is  $k$ -colorable. If, instead,  $d > (2k-1) \ln(k)$ , then, almost surely,  $G(n, dn/2)$  is not  $k$ -colorable.*

For notational convenience, we introduce a shorthand for the upper and lower bounds on the transition threshold from Theorem 3.

► **Definition 4.** *For  $k$  a positive integer, denote*

$$L_k = 2(k-1) \ln(k-1) \quad \text{and} \quad U_k = (2k-1) \ln(k).$$

Subsequent work by Coja-Oghlan and Vilenchik [5] established an asymptotically sharper bound, pinning down the chromatic number for a set of degrees having asymptotic density one. However, their bounds are only stated asymptotically in  $k$ , and do not lead to improved bounds for fixed values of  $k$ .

For the case  $k = 3$ , Achlioptas and Moore [1] proved a tighter lower bound on the 3-colorability threshold by analysing the success probability of a naive 3-coloring algorithm using the differential equations method.

► **Theorem 5** (Achlioptas and Moore). *Almost all graphs with average degree 4.03 are 3-colorable.*

Although Theorem 3 is sharp enough to derive most of our bounds, we will need Theorem 5 in order to shift the transition threshold for  $k = 7$  using  $r = 3$  choices, and  $k = 9$  using only  $r = 2$  choices. We note that future improvements to the bounds on the  $k$ -coloring transition thresholds for  $G(n, m)$  might produce further improvements to our bounds.

For the cases whose analysis involve 2-coloring, we will make use of past work on accelerating or delaying the formation of the giant component. We start with a classical result of Erdős and Rényi:

► **Theorem 6.** *When  $d < 1$ , almost surely, all connected components of  $G(n, dn/2)$  have size  $O(\log n)$ , but when  $d > 1$ , almost surely,  $G(n, dn/2)$  has a “giant” component of size  $\Theta(n)$ .*

Bohman and Frieze [3] showed that, in an Achlioptas process, it is possible to delay this threshold, inspiring many related papers. The following result is due to Spencer and Wormald [13].

► **Theorem 7.** *There exists an edge selection strategy for the 2-choice Achlioptas process, in which, almost surely, the largest component size is still  $O(\log n)$  after the inclusion of  $dn/2$  edges, where  $d = 1.6587$ .*

The details of Spencer and Wormald’s elegant algorithm will not be important in the present work. In Section 4 we will show how to modify their strategy to additionally delay  $G$ ’s first cycle until the giant component forms, but these modifications treat the original strategy as a black box. We note that, in the same paper, Spencer and Wormald presented another strategy for hastening the arrival of giant component, causing it to appear at average degree  $d = 0.6671$ .

### 3 Main Idea, Many Colors

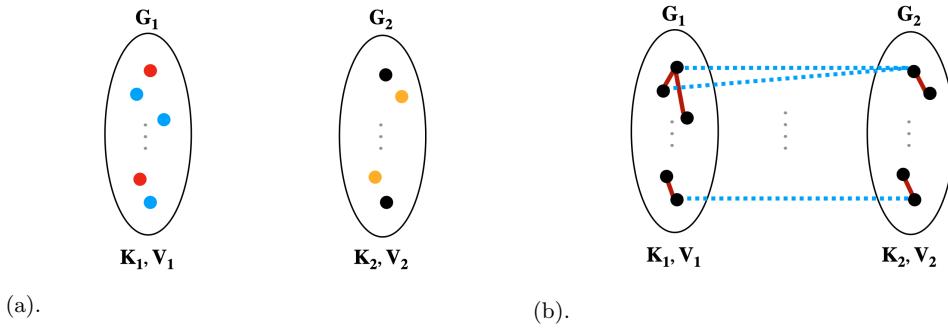

Our general approach to delaying the  $k$ -colorability threshold is to partition both the vertex and color sets into two parts, and then to assign a disjoint set of colors to each side of the graph. The intuition for this was already discussed in Section 1.1. We now formalize some of these ideas.

Let  $V$  be the set of vertices and  $K$  the set of colors. Then  $|V| = n$  and  $|K| = k$ . We will partition  $V$  into disjoint subsets  $V_1$  and  $V_2$ , called “sides,” each of size  $n/2$ . (Since we are interested in the asymptotic behaviour in  $n$  we do not need to worry about its parity.)

We also partition  $K$  into disjoint sets  $K_1$  and  $K_2$ . When we color the graph, we will use colors in  $K_i$  to color side  $V_i$ . Most of the time we will partition the set of colors so that  $|K_1| = \lfloor k/2 \rfloor$  and  $|K_2| = \lceil k/2 \rceil$ , although we will have some occasions to deviate from this.

We will use an Achlioptas process to build a graph  $G$  with  $m$  edges on  $V$ .  $G_1$  and  $G_2$  will denote the subgraphs of  $G$  induced by  $V_1$  and  $V_2$ . By abuse of notation, we will also refer to the graphs obtained partway through the Achlioptas process as  $G$ ,  $G_1$  and  $G_2$ .

Based on the partition  $V = V_1 \sqcup V_2$ , we classify the possible edges into two types:

■ **Figure 1** Illustration for: (a) Disjoint color sets  $K_1$  and  $K_2$ , and vertex sets  $V_1$  and  $V_2$  assigned to  $G_1$  and  $G_2$ , respectively; and (b) Types of edges using solid lines for non-crossing edges and dashed lines for crossing edges.

- **a crossing edge:** An (undirected) edge  $\{u, v\}$  with  $u \in V_1$  and  $v \in V_2$ .
- **a non-crossing edge on side  $i$ , or an edge in  $G_i$  :** An (undirected) edge  $\{u, v\}$  where both  $u, v \in V_i$ .

Note that since we are using disjoint sets of colors for  $V_1$  and  $V_2$ , a crossing edge is never violated by a coloring.

Each edge offered to us in the Achlioptas process is sampled uniformly at random from all  $\binom{n}{2}$  pairs of vertices. The probability of a single offered edge being a crossing edge is

$$\frac{\binom{n/2}{2}}{\binom{n}{2}} = \frac{1}{2} + \frac{1}{2(n-1)} = 1/2 + o(1) \approx 1/2$$

while for  $i = 1, 2$ , the probability of a single offered edge being a non-crossing edge on side  $i$  is

$$\frac{\binom{n/2}{2}}{\binom{n}{2}} = \frac{1}{4} - \frac{1}{4(n-1)} = 1/4 - o(1) \approx 1/4$$

Let  $r$  denote the number of edges offered to the algorithm at each step of the Achlioptas process. As a reminder, each edge is sampled independently and uniformly from  $\binom{V}{2}$ . We use the following strategy to select an edge at every step, unless stated otherwise:

► **Strategy 1. PreferCrossing**  
*Select the first crossing edge, if any. Otherwise, select the first edge.*

Note that in the event that no crossing is available, the selected edge is equally likely to be on either side, and is a uniformly random edge conditioned on being on the side it is.

Let  $m$  be the total number of edges inserted into  $G$ , so the average degree of  $G$  is  $\bar{d} = 2m/n$ . For  $i \in \{1, 2\}$ , let  $\bar{d}_i$  denote the average degree of the graph  $G_i$ .

We use the PreferCrossing strategy to choose the edge to be inserted into  $G$  at each step. A non-crossing edge is inserted only if all  $r$  candidate edges are non-crossing, so the probability of inserting a non-crossing edge is at most  $1/2^r$ . Also, in this case we insert the first edge, which is equally likely to be on either side. So the probability of inserting an edge into  $G_i$  is  $1/2^{r+1}$ .

It follows that in expectation, there are  $m/2^{r+1}$  edges in each  $G_i$  and the rest are crossing edges. Using this we can calculate the expected average degrees on the two sides as follows:

$$\mathbb{E}[\bar{d}_i] < \frac{2m/2^{r+1}}{n/2} = \left(\frac{2m}{n}\right) \frac{1}{2^r} = \frac{\bar{d}}{2^r}$$

By the Law of Large Numbers, it follows that, almost surely,

$$\bar{d}_i < (1 + o(1)) \frac{\bar{d}}{2^r}. \tag{1}$$

Now, since whichever of the three classes of edge (crossing, non-crossing on side 1, non-crossing on side 2) the PreferCrossing strategy selects, the edge is uniformly random within that class, it follows that, conditioned on  $\bar{d}_1$  and  $\bar{d}_2$ ,  $G_1$  and  $G_2$  are uniformly random graphs with that number of edges. Therefore, assuming each  $\bar{d}_i$  is below a known lower bound on the  $k_i$ -colorability transition, it will follow that each  $G_i$  is almost surely  $k_i$ -colorable, and hence  $G$  is  $(k_1 + k_2)$ -colorable. If, additionally,  $\bar{d}$  is greater than a known upper bound on the  $k$ -colorability threshold, and  $k = k_1 + k_2$ , we will have shifted the  $k$ -colorability transition threshold.

Theorem 3 tells us that for  $\kappa \geq 3$ , the  $\kappa$ -colorability transition threshold (if it exists) lies between  $L_\kappa$  and  $U_\kappa$  (see Definition 4.) Additionally, we will sometimes also use the improved lower bound  $L'_3 = 4.03$  from Theorem 5

Since the expression for  $L_\kappa$  is monotone, the graphs  $G_i$  are  $k_i$ -colorable (and hence  $G$  is  $k$ -colorable) until  $\bar{d}_1 = \bar{d}_2 = \min\{L_{k_1}, L_{k_2}\}$ . It therefore makes sense to split the colors as evenly as possible. We will set  $k_1 = \lfloor k/2 \rfloor$ ,  $k_2 = \lceil k/2 \rceil$ . Then  $G_1$  and  $G_2$  are  $k_1$ - and  $k_2$ -colorable respectively until  $\bar{d}_1 = \bar{d}_2 = L_{\lfloor k/2 \rfloor}$

Now, we know from Eq. (1) that

$$\bar{d} \geq 2^r \bar{d}_1 \geq 2^r L_{\lfloor k/2 \rfloor}$$

and we will have delayed the  $k$ -colorability transition if this exceeds  $U_k$

Since  $L_k$  and  $U_k$  are both asymptotically equal to  $2k \ln k$ , this shows that for sufficiently large  $k$  two choices suffice to raise the  $k$ -colorability threshold. Indeed, using Mathematica to solve the inequalities

$$2^r L_{\lfloor k/2 \rfloor} \geq U_k$$

for  $r = 2, 3$  and 4, we see that

- two choices suffice for even  $k \geq 10$  and odd  $k \geq 13$
- three choice suffice for even  $k \geq 6$  and odd  $k \geq 9$  and
- four choices suffice for  $k = 7$ .

Moreover, if we use the improved lower bound  $L'_3 = 4.03$ , instead of  $L_3$  for the case of  $k = 7$ , then we see that

$$8L'_3 = 8 \times 4.03 = 32.24 > 25.3 = U_7$$

so that three choices suffice  $k = 7$ . This establishes Theorem 1 for  $k \geq 6$ , except for the cases  $k = 9$  and  $k = 11$ .

For  $k = 9, 11$  we have established that three choices suffice, but we want to show that in fact we only need two. We will tackle the case  $k = 11$  here and leave  $k = 9$  for Section 7.

When  $k = 11$ , we allocate five colors to side 1, and six colors to side 2. The five-colorability of  $G_1$  is only guaranteed until  $\bar{d}_1 = 8 \ln 4 \approx 11.09$ . With  $r = 2$  choices, at this point  $\bar{d}$  is about 44.36, smaller than  $20 \ln 10 = 46.05$ , so that although  $G$  is 11-colorable, so is

## 59:8 Power of Choice for $k$ -Colorability

$G(n, m = 44.36n/2)$ , so we have not shifted the threshold. In order to increase  $\bar{d}$  past  $U_{11} = 21 \ln 11 = 50.356$ , we note that  $\bar{d}_2$  is *also* about 11.09, since we are equally likely to add a non-crossing edge to side 2 as to side 1. But  $\bar{d}_2$  is allowed to go to  $10 \ln 5 \approx 16.09$  before we can no longer guarantee the 6-colorability of  $G_2$ . This means we have a fair bit of slack to favor  $G_2$  when adding non-crossing edges. Suppose we put a  $\varphi < 1/2$  fraction of the non-crossing edges into  $G_1$  and a  $(1 - \varphi)$  fraction of them into  $G_2$ . What should  $\varphi$  be to ensure the best outcome? Note that we need  $\varphi \geq 2^{-r}$ , since if all the non-crossing choices are on side 1, then we cannot add an edge in side 2. However, subject to this constraint, we are adding  $m\varphi/2^r$  edges to  $G_1$  and  $m(1 - \varphi)/2^r$  edges to  $G_2$  in expectation. But this means that  $\mathbb{E}[\bar{d}_1] = \bar{d}\varphi/2^{r-1}$  and  $\mathbb{E}[\bar{d}_2] = \bar{d}(1 - \varphi)/2^{r-1}$ . Since these random variables stay close to their expectations, it follows that  $\bar{d}_1$  and  $\bar{d}_2$  are in the ratio  $\varphi/(1 - \varphi)$ . Now, it is best if we can arrange it so that both  $G_1$  and  $G_2$  lose their guarantee of colorability at the same time (so that there is no slack). But this means

$$\frac{L_5}{L_6} = \frac{\varphi}{1 - \varphi}$$

But this means we should set

$$\varphi = \frac{L_5}{L_5 + L_6} = \frac{11.09}{11.09 + 16.09} \approx \frac{2}{5}$$

Since  $2/5 > 1/4$ , it is possible to achieve a  $2/5 - 3/5$  split of the non-crossing edges, when there are two choices.

Finally, what does this make the average degree of the graph  $G$  at the time when 11-colorability can no longer be guaranteed?? Since

$$\bar{d} \approx \frac{2^{r-1}\bar{d}_1}{\varphi} \approx \frac{2^{r-1}\bar{d}_2}{1 - \varphi}$$

when  $r = 2$  and  $\varphi = 2/5$  we get

$$\bar{d} \approx \frac{2L_5}{2/5} = 55.45 > 50.356 = U_{11}.$$

Thus two choices suffice to raise the 11-colorability threshold.

To write down an *explicit* edge selection strategy, note that if when we are not forced to take an edge on a particular side, we toss a biased coin that selects side 1 with probability  $\gamma$ , then the overall probability of adding an edge to side 1 conditioned on adding a non-crossing edge is  $1/4 + \gamma/2$ . Since we want this to be  $2/5$  we should set  $\gamma = 3/10$ . Here is the strategy we use.

► **Strategy 2. BiasedPreferCrossing for  $k = 11$**

*Given two edges, select the first crossing edge, if any.*

*Otherwise if both non crossing edges are on the same side, select the first one*

*Otherwise there is one edge offered on each side. Select the one on side 1 with probability 0.3, and the one on side 2 with probability 0.7.*

## 4 Emergence of Giant component and Emergence of Cycles

The case  $k = 2$  differs from larger  $k$  in one very important way: namely, the  $k$ -Colorability Threshold Conjecture is false when  $k = 2$ ; for  $G(n, p)$  where  $p = d/n$ , rather than a sharp transition from colorable to non-colorable at a critical value of  $d$ , instead this transition is spread across the whole range  $0 < d < 1$ .

To see this, we observe that the expected number of triangles is  $\binom{n}{3}p^3 \approx d^3/6$ , which is a positive constant for all  $0 < d < 1$ . It is not much harder to prove that the probability that at least one triangle exists is also  $\Theta(1)$  whenever  $d = \Theta(1)$ , and hence the probability that  $G(n, p)$  is not 2-colorable is bounded away from zero.

On the other hand, it is also not hard to prove that, as long as  $p < (1 - \epsilon)/n$ ,  $G(n, p)$  is a forest with probability bounded below by a constant, and hence the probability that  $G(n, p)$  is 2-colorable is also bounded away from zero. In other words, the transition from  $G(n, d/n)$  being almost surely 2-colorable to being almost surely not 2-colorable is not sharp, but is rather spread over the entire interval  $0 < d < 1$ .

Even though there isn't a sharp threshold for 2-colorability in  $G(n, p)$ , we will prove in this section that, given  $r = 2$  choices, we can both create a sharp threshold, and shift it.

Two-colorability is of course, equivalent to the absence of odd cycles, and it turns out that the presence of odd cycles—indeed, of any cycles—is intimately linked with the emergence of the giant component.

Consider a 2-choice Achlioptas process, using the following, very simple, edge selection rule:

► **Strategy 3. SimpleAvoidCycles**

*Select the first edge, unless it would create a cycle, in which case, select the second edge.*

SimpleAvoidCycles manages to avoid the emergence of cycles until the average degree is 1, the threshold for the emergence of the giant component. On the other hand, once a giant component forms, it very quickly grows to size  $\omega(\sqrt{n})$ , at which point it is almost certain that a pair of edges will be offered within  $o(n)$  steps, both of which lie within the giant component. Therefore it is not possible to avoid cycles for more than a few steps after the formation of a giant component. Thus, with two choices, this very simple heuristic results in a sharp threshold for the emergence of cycles (and similarly for odd cycles, a.k.a. non-2-colorability).

#### 4.1 Analysis of SimpleAvoidCycles

As before, let  $m = dn/2$ , where  $d < 1$ . Consider the graph  $G' = G(n, m')$ , where  $m' = m + \log n$ .

For our purposes,  $G(n, m')$  means the graph obtained from sampling  $m'$  independent edges uniformly from  $\binom{n}{2}$  (with replacement).

► **Lemma 8.** *The number of edges of  $G'$  contained in one or more cycles is  $o(\log n)$ , almost surely.*

**Proof.** This is a standard result, so we present an abbreviated proof. The expected number of cycles of length  $k$  in the  $G(n, p)$  model is

$$\binom{n}{k} \frac{k!}{2k} p^k < \frac{(np)^k}{2k}.$$

Since each  $k$ -cycle contains  $k$  edges, it follows that the expected number of edges in  $k$ -cycles is less than  $(np)^k/2$ . If we set  $np = 1 - \epsilon$  and sum over all  $k \geq 3$ , we get

$$\sum_{k=3}^n \frac{(1 - \epsilon)^k}{2} < \sum_{k=3}^{\infty} \frac{(1 - \epsilon)^k}{2} = \frac{(1 - \epsilon)^3}{2\epsilon} = O(1).$$

We omit the details of the comparison between the  $G(n, m)$  model and the  $G(n, p)$  model, which are standard. Since the expected number of edges in cycles is  $O(1)$ , whereas  $\log(n)$  tends to infinity, by Markov's inequality it is almost certain that the actual number of edges in cycles is  $o(\log n)$ . ◀

► **Lemma 9.** *The probability that any of the edges  $e_{m+1}, \dots, e_{m'}$  are contained in a cycle of  $G'$  is  $O(\log(n)/n)$ .*

**Proof.** Since, by Lemma 8, the expected number of edges in cycles is  $O(1)$ , and since the  $m'$  edges of  $G'$  are identically distributed, it follows that each edge  $e_j$  has probability  $O(1/m')$  to be part of a cycle. Hence, by linearity of expectation and Markov's inequality, the probability that any of the edges  $e_{m+1}, \dots, e_{m'}$  is part of a cycle is  $O((m' - m)/m') = O(\log(n)/n)$ . ◀

► **Theorem 10.** *For  $d < 1$ , SimpleAvoidCycles outputs a cycle-free graph, almost surely.*

**Proof.** We couple the  $m$  choices made by SimpleAvoidCycles with the edges chosen in  $G(n, m')$ . For each  $1 \leq i \leq m$ , let  $e_i$  be the first edge offered to SimpleAvoidCycles. For each  $j$ 'th edge rejected by SimpleAvoidCycles, we let  $e_{m+j}$  be the second edge offered to SimpleAvoidCycles. When  $j$  is greater than the number of edges rejected by SimpleAvoidCycles, we let  $e_{m+j}$  be a uniformly random edge, chosen independently from all others.

Our first observation is that the sequence of edges  $e_1, \dots, e_{m'}$  is uniformly random in  $\binom{[n]}{m'}$ . This is because each  $e_j$  is uniformly random, conditioned on  $e_1, \dots, e_{j-1}$ .

Now, suppose the output of SimpleAvoidCycles contains a cycle. This means that at least one of the “second edges” chosen by SimpleAvoidCycles is contained in a cycle in the output of SimpleAvoidCycles. This implies that either SimpleAvoidCycles rejected more than  $m' - m$  first edges, in which case  $e_1, \dots, e_m$  contains more than  $m' - m$  cycles, and hence so does  $G'$ . This is unlikely by Lemma 8. Or SimpleAvoidCycles rejected fewer than  $m' - m$  edges, but one of the second edges formed a cycle in its output, which is a subgraph of  $G'$ . But Lemma 9 bounds the probability of this event. Applying the union bound to these two events, we get the desired upper bound on the probability that the output of SimpleAvoidCycles contains a cycle. ◀

## 4.2 Avoiding Cycles Longer

Next we will show how to keep  $G$  a forest as long as the average degree is less than 1.6587, the threshold from Theorem 7. More generically, we will show how, if any strategy for a 2-choice Achlioptas process can delay the giant component until average degree  $d$ , we can tweak it to additionally keep  $G$  a forest up to the same average degree threshold. We will refer to this strategy as DelayGiant. To be more precise, we will assume that, for every  $d' < d$ , DelayGiant run for  $d'n/2$  steps almost surely outputs a graph whose components all have  $O(n^{1/4})$  vertices.

First, we argue that, without loss of generality, DelayGiant can be assumed to have the following two properties:

1. If exactly one of the two offered edges make a cycle, DelayGiant selects it.
2. In this case, the subsequent behavior of DelayGiant is independent of the second, unselected edge.

The first property is obvious, since if an edge forms a cycle, adding it to  $G$  does not increase any of the component sizes; therefore it dominates any edge that doesn't form a cycle. The second property is less obvious, but the idea is that any strategy can be made “forgetful” by making it resample any state information it might be maintaining, from its conditional

distribution, conditioned on the edges it has accepted so far. It follows from the Law of Total Probability that this does not change the distribution of the output. An algorithm that is forgetful in this sense, and satisfies property 1, necessarily satisfies property 2 as well. The motivation for property 2 is that it will allow us to apply the Principle of Deferred Decisions to the edges chosen by our strategy in steps when it deviates from DelayGiant's choices.

Now our strategy for delaying the appearance of the first cycle in  $G$  can be described in one sentence:

► **Strategy 4. AvoidCycles**

*Select the edge chosen by the DelayGiant algorithm, unless it would form a cycle, in which case, select the other edge.*

► **Theorem 11.** *For  $d < 1.6587$ , with high probability, the 2-choice Achlioptas process run for  $m = dn/2$  steps using strategy AvoidCycles outputs a cycle-free graph.*

Consider a run of the DelayGiant algorithm. Let  $\{(e_1, e'_1), (e_2, e'_2) \dots (e_m, e'_m)\}$  be the edges that are offered to the algorithm during this run. Let  $G_i$  be the graph produced by DelayGiant after the first  $i$  steps, *i.e.*  $G_i$  has  $i$  edges, one out of each pair  $(e_j, e'_j)$ ,  $1 \leq j \leq i$ . Let

$$S := \{i \mid \text{neither of the edges } e_i, e'_i \text{ forms a cycle when added to } G_{i-1}\}$$

Let DelayGiant' be an algorithm that emulates DelayGiant on the steps in  $S$ , but adds no edge on the  $m - |S|$  steps when DelayGiant would add a cycle-forming edge. Let  $G'_i$  be the intermediate graph produced by DelayGiant' after  $i$  steps. Note that for all  $i$ ,  $G'_i$  is a spanning forest of  $G_i$ .

By assumption, almost surely, all the components of  $G_m$  have size  $o(n^{1/4})$ . Hence also, for all  $1 \leq i \leq m$ , the components of  $G_i$ , and therefore also  $G'_i$  have size  $O(n^{1/4})$ . Now, consider an arbitrary forest all of whose components are of size at most  $t$ . We make two observations:

► **Observation 12.** *Let  $G$  be a graph, all of whose components are of size at most  $t$ . Then the probability that adding one random edge to  $G$  creates a cycle is at most  $\frac{t-1}{n-1}$ .*

► **Observation 13.** *Let  $G$  be a graph, all of whose components are of size at most  $t$ . Add any  $\ell$  edges to  $G$ . Then, the largest component of the resulting graph has size at most  $\ell t$*

Applying Observation 12 inductively to each  $G'_i$ , with  $t = O(n^{1/4})$ , we see that the expected number of steps on which DelayGiant' adds no edge,  $\mathbb{E}[m - |S|]$ , is at most  $m \left( \frac{t-1}{n-1} \right)$ , which is  $O(n^{1/4})$ .

When DelayGiant' has run for  $m$  steps, the resulting graph  $G'_m$  is a forest with  $|S|$  edges, whose components are size  $O(n^{1/4})$ . Let DelayGiant'' be the algorithm that runs DelayGiant' and then expands  $G'_m$  to a graph with  $m$  edges by adding  $m - |S| = O(n^{1/4})$  uniformly random edges. Applying Observation 13, the components of this graph have size at most  $O(n^{1/2})$ . Since each of the  $O(n^{1/4})$  random edges to be added has at most  $O(n^{-1/2})$  chance of forming a cycle, by Markov's inequality, the probability that this graph contains a cycle is at most  $O(n^{-1/4})$ . Thus, the graph produced by DelayGiant'' is almost surely a forest.

The proof of Theorem 11 will be complete once we establish the following Lemma, relating AvoidCycles to DelayGiant''.

► **Lemma 14.** *AvoidCycles is better at avoiding cycles than DelayGiant'', i.e., for every  $m$ ,*

$$\mathbb{P}(\text{AvoidCycles is cycle-free after } m \text{ edges}) \geq \mathbb{P}(\text{DelayGiant'' is cycle-free after } m \text{ edges}).$$

**Proof.** It will suffice to couple the choices made by the two algorithms in such a way that each edge chosen by DelayGiant'' is either the same as the one chosen by AvoidCycles, or forms a cycle. Consider the edge chosen by AvoidCycles at a particular timestep  $i \in [m] \setminus S$ . Also, let  $A_i$  denote the set of all possible edges that would form a cycle if added to  $G_{i-1}$ , and let  $B_i = \binom{n}{2} \setminus A_i$ . We apply the principle of deferred decisions to the edges  $(e_i, e'_i)$ . Conditioned on  $G_{i-1}$  and the event that  $i \notin S$ , the distribution of  $(e_i, e'_i)$  is uniform in  $(A_i \cup B_i)^2 \setminus B_i^2$ . This means that the edge selected by AvoidCycles in step  $i$  has a conditional distribution which is uniform in  $A_i$  with probability  $\frac{|A_i|}{|A_i|+2|B_i|}$  and uniform in  $B_i$  with probability  $\frac{2|B_i|}{|A_i|+2|B_i|}$ .

Let us compare this distribution with that of a uniformly random edge. A uniformly random edge is uniform in  $A_i$  with probability  $\frac{|A_i|}{|A_i|+|B_i|}$ , and uniform in  $B_i$  with probability  $\frac{|B_i|}{|A_i|+|B_i|}$ . Now, observing that

$$\frac{a}{a+2b} < \frac{a}{a+b}$$

whenever  $a, b > 0$ , we see that the edge selected by AvoidCycles can be coupled with the uniformly random edge so that either the two edges are either equal, or the edge selected by AvoidCycles is in  $B_i$  and the uniformly random edge is in  $A_i$ . Since an edge in  $A_i$  would have formed a cycle even at step  $i$ , it definitely forms a cycle when added to the final result of DelayGiant.

Moreover, conditioned on the edges  $e_1, \dots, e_m$ , the deferred edges  $e_{m+j}$  are fully independent, since Property 2 tells us that DelayGiant does not take the identities of previously rejected edges into account when making its decisions. Thus, the sequence of edges  $e_{m+1}, \dots, e_{m'}$  is less likely to make a cycle than a sequence of  $m' - m$  uniformly random edges. It follows that there is a coupling between the output of AvoidCycles and DelayGiant'' such that the graphs produced are always identical except when DelayGiant'' contains at least one cycle. ◀

## 5 Four or Five Colors

When we get down to fewer than six colors, the basic PreferCrossing strategy runs into some difficulties, since at least one of the sides has fewer than three colors. This is problematic because even at low edge densities,  $G(n, m)$  has a constant chance of having an odd cycle and therefore cannot be two-colored. This means that the subgraph  $G_i$  of  $G$  on the side with only two colors will stop being two-colorable even before it has a linear number of edges. Fortunately, as we saw in the previous section, given a choice of two edges to choose from, we can avoid the appearance of cycles and keep the graph two-colorable until it reaches an average degree of about 1.6587.

When  $k = 4$ , we partition  $V$  into two sides as usual, and assign two of the four colors to each side. We prefer crossing edges as usual, and select a crossing edge whenever we are offered one. If there are at least three edges to choose from, and we are not offered any crossing edges, then at least two of the offered non-crossing edges are on the same side, and we have some room to be selective about the edge we are adding, and avoid cycles in the graph. Note that either side is equally likely to have two or more edges, and conditioned on the side, the edge choices are uniformly random from that side.

Here is an explicit description of the edge-selection strategy used:

► **Strategy 5. PreferCrossing with Two-sided Cycle Avoidance (PCTCA)**

Choose  $r = 3$  edges independently and uniformly at random

if there are any crossing edges then

| Select the first crossing edge.

else

| Let  $G_i$  be the side with more candidate edges

| Select the edge chosen by AvoidCycles on  $G_i$ .

end

Using the above edge selection strategy, we can show that

► **Theorem 15.** *Three choices suffice to increase the 4-colorability threshold.*

**Proof.** Let  $m$  be the total number of edges inserted into  $G$ , so the average degree of  $G$  is  $\bar{d} = 2m/n$ . For  $i \in \{1, 2\}$ , let  $\bar{d}_i$  denote the average degree of the graph  $G_i$ .

The probability of inserting a crossing edge into  $G$  is  $7/8$ . When there are no crossing edges, the chance that a particular side has two edge choices is  $1/16$ . We choose one of the two or more offered edges using the AvoidCycles strategy so that for  $i \in \{1, 2\}$  the expected number of edges inserted into  $G_i$  is  $m/16$ . Thus  $\mathbb{E}[\bar{d}_i] = \frac{2m/16}{n/2} = \frac{\bar{d}}{8}$ , and as usual,

$$\bar{d}_i \leq (1 + o(1))\bar{d}/8$$

Since we are using the AvoidCycles strategy to insert edges into  $G_1$  and  $G_2$ , by Theorem 11 we can push  $\bar{d}_1$  to 1.6587 before  $G_i$  stops being two-colorable. At that point,

$$\bar{d} = 8 \times 1.6587 = 13.2696 > 9.704 = 7 \ln 4 = U_4$$

so that  $G$  is 4-colorable at a density where  $G(n, m)$  isn't, and we have shifted the threshold. ◀

When  $k = 5$  we assign two colors to  $G_1$  and three colors to  $G_2$ . Again, we choose crossing edges whenever we can; if there are  $r = 3$  choices we can do this about  $7/8$  of the time.

What happens when we can't choose a crossing edge? Half the time, there will be two edges offered on side 1 and we can use AvoidCycles to choose one of them. If we choose an edge on side 2 the other half the time, then we will have  $\bar{d}_1 = \bar{d}_2 = \bar{d}/8$  and as we know from the four-colorability analysis above, we can push this up to  $\bar{d}_1 = 1.6587$  and  $\bar{d} = 13.2696$  before the 2-coloring on  $G_1$  breaks down. But  $13.2696 < 14.485 = 9 \ln 5 = U_5$  so we haven't shifted the 5-colorability threshold. Of course, at this point,  $\bar{d}_2$  is also only 1.6587, and has a lot of slack before it reaches  $L'_3 = 4.03$ , or even  $L_3 = 2.77$ .

So we want to use a biased strategy that favors choosing edges from side 2 when no crossing edges are available. We could figure out the optimal bias that makes both sides reach their limits at the same time, as we did in the  $k = 11$  case. Instead we opt for the following simple explicit strategy.

► **Strategy 6. PreferCrossing with One-sided Cycle Avoidance (PCOCA)**

Choose  $r = 3$  edges independently and uniformly at random

if there are any crossing edges then

| Select the first crossing edge.

else

| if the first two edges are both in  $V_1^2$  then

| | Select one of them according to *AvoidCycles*, run on  $G_1$

| else

| | (In this case at least one edge is in  $V_2^2$ )

| | Select the first edge in  $V_2^2$ .

| end

end

► **Theorem 16.** *Three choices suffice to increase the 5-colorability threshold.*

**Proof.** Let  $m$  be the total number of edges inserted into  $G$  so the average degree of  $G$  is  $\bar{d} = 2m/n$ . Similarly, for  $i \in \{1, 2\}$ , let  $\bar{d}_i$  denote the average degree of the graph  $G_i$ .

The probability of choosing a crossing edge is  $7/8$ . The probability of choosing an edge on side 1 is  $(1/4)(1/4)(1/2) = 1/32$ , and the probability of choosing an edge on side 2 is  $3/32$ . Then  $\mathbb{E}[\bar{d}_1] = \bar{d}/16$  and  $\mathbb{E}[\bar{d}_2] = 3\bar{d}/16$

If we set  $m = 8n$  then  $\bar{d} = 16 > U_5$  is a density at which  $G(n, m)$  is not 5-colorable. On the other hand if  $\bar{d} = 16$  in  $G$  constructed using PCOCA, then  $\bar{d}_1 = 1 < 1.6586$  and  $\bar{d}_2 = 3 < 4.03 = L'_3$ , so that  $G_1$  is two-colorable,  $G_2$  is 3-colorable and hence  $G$  is 5-colorable. ◀

## 6 Three Colors

For  $k = 3$ , we face a new challenge to our approach, namely: there is no longer any hope of using disjoint color sets to color the two sides of our graph. Instead, we try to make the color sets as disjoint as possible. Specifically, we try to color  $G$  using red and yellow for the first side, and blue and yellow for the second side. Although the crossing edges may cause problems now, at least the only bad color assignment for a crossing edge is (yellow, yellow). We call this kind of 3-coloring a  $(Y, *)$ -coloring, since the non-yellow colors are determined by their side.

Note that this specific type of coloring can be found in linear time, since it is a special case of Constrained Graph 3-Coloring, which is reducible to 2-SAT (see [8, Problem 5.6]). Here is our strategy:

► **Strategy 7. PreferCrossingButCheck (PCBC)**

Choose  $r = 6$  edges independently and uniformly at random.

Let  $e$  be the edge chosen by the *PreferCrossing* heuristic.

Check whether  $G \cup \{e\}$  remains  $(Y, *)$ -colorable. If it is, select  $e$ . Otherwise, select the first edge other than  $e$ .

We note that with an appropriate data structure, all  $m$  of the colorability checks can be performed in combined expected time  $O(n)$ . However, since our goal is just to show that the colorability transition can be shifted, we leave the details as an exercise.

We claim that, when  $r = 6$ , the output of PCBC is almost surely  $(Y, *)$ -colorable. To see this, observe that, in order for a greedy approach to coloring to fail, the graph must have a cycle of length  $2k + 1$  with edges (in order)  $(e_1, e_2, \dots, e_{2k+1})$ , where the  $k$  even edges  $e_{2i}$  are all non-crossing. This is analogous to the fact that a graph fails to be 2-colorable if and only if it has an odd cycle. However, note that in the case of 2-coloring, the criterion is “if and only if,” whereas here there is only an implication; the cycle is only guaranteed to cause a problem if we start by coloring the wrong vertex yellow. We call a cycle of this type a “bad odd cycle.”

► **Proposition 17.** *Let  $d > 0$ . Let  $G$  be the output of an Achlioptas process with  $r$  choices, running the PreferCrossing heuristic, for  $dn/2$  steps. Also suppose that  $d^2 < 2^r$ . Then the expected number of edges contained in bad odd cycles of  $G$  is  $O(1)$ .*

**Proof.** Note that, for every vertex  $v$ , the expected degree is  $d$ , but the expected number of non-crossing edges incident with  $v$  is  $d2^{-r}$ . With a little work we can see that the expected number of walks of length  $2k$  starting at a particular node, in which all the even steps are along non-crossing edges is at most  $d^k(d2^{-r})^k$ . In order to complete such a walk to a cycle of length  $2k + 1$ , we need a particular edge to be present, which is an event of probability at most  $d/(n/2)$ . Since there are  $n$  possible starting points for our walk, this gives the following bound on the number of edges contained in a bad odd cycle:

$$n \sum_{k \geq 1} \frac{d}{n/2} (d^2 2^{-r})^k (2k + 1) = 2d \sum_{k \geq 1} \sum_{k \geq 1} (2k + 1) (d^2 2^{-r})^k,$$

which since  $d^2 < 2^r$ , is a convergent sum. ◀

Thus, in expectation, PCBC deviates from the choices made by PreferCrossing on only  $O(1)$  steps. Denote this number of steps by  $m' - m$ . On the steps when it deviates, it takes the first alternative edge. Since PreferCrossing makes its edge choice based only on which edges are crossing or not, this alternative edge must be uniformly random, conditioned on whether it is a crossing edge or not. It follows that PCBC succeeds at least as often as a variant PCBC' that, instead of taking each rejected edge from PreferCrossing, instead adds one uniformly random crossing edge and one uniformly random non-crossing edge.

PCBC', in turn, will almost surely perform at least as well as another variant, PCBC'', which, instead of adding one uniformly random crossing edge, and one uniformly random non-crossing edge, instead adds  $C2^r$  edges chosen by an Achlioptas process running the PreferCrossings strategy, where  $C \rightarrow \infty$ . But now, observe that PCBC'' is just PreferCrossings run for  $m'' = m + o(n)$  steps, with all of its bad odd cycles from the first  $m$  steps broken up. Since PreferCrossings run for  $m''$  steps still has, in expectation,  $O(1)$  edges involved in bad odd cycles, and these edges are uniformly randomly distributed among the  $m'$  steps, the probability that any of them occur in the last  $m'' - m$  steps is  $O((m'' - m)/m'') = o(1)$ . Hence the output of PCBC'' almost surely has no bad odd cycles, and is therefore  $(Y, *)$ -colorable. Since by our earlier remarks, PCBC almost surely performs at least as well as PCBC'', this establishes the result.

## 7 Two choices for 9 colors

In Section 3 as part of a unified analysis for  $k \geq 6$  we showed that three choices were enough to raise the 9-colorability threshold. In this section we will show that in fact just two choices suffice. Surprisingly, this result involves a more uneven split of the colors, with three colors

reserved for  $V_1$  and six for  $V_2$ . This helps partly because, for  $k = 3$ , the improved lower bound  $L'_3 = 4.03$  of Theorem 5 is significantly better than the bound of Theorem 3.

The main idea is to use a biased PreferCrossing strategy which favors the six color side when a non-crossing edge is forced. We have two choices, so we will be putting in a non-crossing edge only a fourth of the time. Conditioned in that, we want to make the colorability on the two sides break at roughly the same time. As we saw before, this means that we should add edges to side 1 (with three colors) with probability  $\varphi$ , where

$$\frac{\varphi}{1 - \varphi} = \frac{L'_3}{L_6} = \frac{4.03}{16.094} \approx \frac{1}{4}$$

from which we get that  $\varphi$  should be approximately  $1/5$ ... and that is a problem. If the probability of selecting an edge from side 1 conditioned on a non-crossing edge is  $1/5$ , then the overall probability is  $1/20$ , but this is not achievable with two choices, since there is a  $1/16$  chance that both edges are on side 1!

So where does that leave us? It turns out that we can still tweak this to make it work. From the beginning, we have made the *a priori* division of the vertex set into two equal sized disjoint subsets because that maximizes our ability to put in crossing edges. But having found ourselves in a situation where we want to put in fewer edges into side one than is possible, the obvious solution seems to be to make side one smaller. So let's start over, and partition  $V$  into disjoint sets  $V_1$  and  $V_2$ , where  $|V_1| = \alpha n$  and  $|V_2| = (1 - \alpha)n$ . It turns out that  $\alpha = 0.47$  works well. With this parameter setting, we choose crossing edges whenever possible, and failing that, edges in  $G_2$ , with edges in  $G_1$  as a last resort. This leads to average degrees  $\bar{d}_1 = 0.1038\bar{d}$  and  $\bar{d}_2 = 0.3830\bar{d}$ . Since  $0.1038U_9 \leq L_3$  and  $0.3830U_9 \leq L_6$ , this shows that we have shifted the 9-coloring threshold with  $r = 2$  choices.

## Appendix A: Hastening the threshold

Here we present a sketch of the proof of Observation 2. Since the choice strategy and the proof technique are exactly the same as in [6], we omit most of the details.

**Proof Sketch for Observation 2.** The choice strategy is to favor some vertex set  $S$ , where  $|S| = \gamma n$ . For instance, let  $S = \{1, 2, \dots, \gamma n\}$ . By always choosing a random edge in  $\binom{S}{2}$  when one is available, we find that the induced graph on  $S$  is uniformly random, but denser than  $G$  as a whole, having average degree asymptotically equal to  $(1 - (1 - \gamma^2)^r)/\gamma$  times the average degree of  $G$ . Choosing  $\gamma$  to maximize this expression, we obtain the desired choice strategy. For instance, setting  $\gamma = 1/\sqrt{r}$ , we can see that  $(1 - (1 - \gamma^2)^r)/\gamma = \Theta(\sqrt{r})$ , which tends to infinity. This shows that the favored subgraph can be made arbitrarily more dense than  $G$ , thus bridging the gap between any upper and lower bounds on the threshold. ◀

# Memory-Sample Lower Bounds for Learning Parity with Noise

## Abstract

In this work, we show, for the well-studied problem of learning parity under noise, where a learner tries to learn  $x = (x_1, \dots, x_n) \in \{0, 1\}^n$  from a stream of random linear equations over  $\mathbb{F}_2$  that are correct with probability  $\frac{1}{2} + \varepsilon$  and flipped with probability  $\frac{1}{2} - \varepsilon$  ( $0 < \varepsilon < \frac{1}{2}$ ), that any learning algorithm requires either a memory of size  $\Omega(n^2/\varepsilon)$  or an exponential number of samples.

In fact, we study memory-sample lower bounds for a large class of learning problems, as characterized by [8], when the samples are noisy. A matrix  $M : A \times X \rightarrow \{-1, 1\}$  corresponds to the following learning problem with error parameter  $\varepsilon$ : an unknown element  $x \in X$  is chosen uniformly at random. A learner tries to learn  $x$  from a stream of samples,  $(a_1, b_1), (a_2, b_2) \dots$ , where for every  $i$ ,  $a_i \in A$  is chosen uniformly at random and  $b_i = M(a_i, x)$  with probability  $1/2 + \varepsilon$  and  $b_i = -M(a_i, x)$  with probability  $1/2 - \varepsilon$  ( $0 < \varepsilon < \frac{1}{2}$ ). Assume that  $k, \ell, r$  are such that any submatrix of  $M$  of at least  $2^{-k} \cdot |A|$  rows and at least  $2^{-\ell} \cdot |X|$  columns, has a bias of at most  $2^{-r}$ . We show that any learning algorithm for the learning problem corresponding to  $M$ , with error parameter  $\varepsilon$ , requires either a memory of size at least  $\Omega\left(\frac{k \cdot \ell}{\varepsilon}\right)$ , or at least  $2^{\Omega(r)}$  samples. The result holds even if the learner has an exponentially small success probability (of  $2^{-\Omega(r)}$ ). In particular, this shows that for a large class of learning problems, same as those in [8], any learning algorithm requires either a memory of size at least  $\Omega\left(\frac{(\log |X|) \cdot (\log |A|)}{\varepsilon}\right)$  or an exponential number of noisy samples.

Our proof is based on adapting the arguments in [21, 8] to the noisy case.

in the streaming setting. In addition to being a natural question in learning theory and complexity theory, lower bounds in this model also have direct applications to bounded storage cryptography [20, 26, 16, 25, 11, 13, 6, 12]. [24] conjectured that any algorithm for learning parities of size  $n$  (that is, learning  $x \in \{0, 1\}^n$  from a stream of random linear equations in  $\mathbb{F}_2$ ) requires either a memory of size  $\Omega(n^2)$  or an exponential number of samples. This conjecture was proven in [20] and in follow up works, this was generalized to learning sparse parities in [16] and more general learning problems in [21, 17, 19, 8, 2, 5, 18, 23, 9, 4, 10].

In this work, we extend this line of work to *noisy* Boolean function learning problems. In particular, we consider the well-studied problem of learning parity under noise (LPN). In this problem, a learner wants to learn  $x \in \{0, 1\}^n$  from independent and uniformly random linear equations in  $\mathbb{F}_2$  where the right hand sides are obtained by independently flipping the evaluation of an unknown parity function with probability  $\frac{1}{2} - \varepsilon$ . Learning Parity with Noise (LPN) is a central problem in Learning and Coding Theory (often referred to as decoding random linear codes) and has been extensively studied. Even without memory constraints, coming up with algorithms for the problem has proven to be challenging and the current state-of-the-art for solving the problem is still the celebrated work of Blum, Kalai and Wasserman [3] that runs in time  $2^{O(n/\log_2(n))}$ . Over time, the hardness of LPN (and its generalization to non-binary finite fields) has been used as a starting point in several hardness results [14, 7] and constructing cryptographic primitives [1]. On the other hand, lower-bounds for the problem are known only in restricted models such as Statistical Query Learning<sup>1</sup> [15].

Learning under noise is at least as hard as learning without noise and thus, memory-sample lower bounds for parity learning [20] holds for learning parity under noise too. It is natural to ask – can we get better space lower bounds for learning parities under noise? In this work, we are able to strengthen the memory lower bound to  $\Omega(n^2/\varepsilon)$  for parity learning with noise.

Our results actually extend to a broad class of learning problems – under noise. As in [21] and follow up works, we represent a learning problem using a matrix. Let  $X, A$  be two finite sets (where  $X$  represents the concept-class that we are trying to learn and  $A$  represents the set of possible samples). Let  $M : A \times X \rightarrow \{-1, 1\}$  be a matrix. The matrix  $M$  represents the following learning problem with error parameter  $\varepsilon$  ( $0 < \varepsilon < \frac{1}{2}$ ): An unknown element  $x \in X$  was chosen uniformly at random. A learner tries to learn  $x$  from a stream of samples,  $(a_1, b_1), (a_2, b_2) \dots$ , where for every  $i$ ,  $a_i \in A$  is chosen uniformly at random and  $b_i = M(a_i, x)$  with probability  $\frac{1}{2} + \varepsilon$ .

## 1.1 Our Results

We use extractor-based characterization of the matrix  $M$  to prove our lower bounds, as done in [8]. Our main result can be stated as follows (Corollary 19): Assume that  $k, \ell, r$  are such that any submatrix of  $M$  of at least  $2^{-k} \cdot |A|$  rows and at least  $2^{-\ell} \cdot |X|$  columns, has a bias of at most  $2^{-r}$ . Then, any learning algorithm for the learning problem corresponding to  $M$  with error parameter  $\varepsilon$  requires either a memory of size at least  $\Omega(k \cdot \ell/\varepsilon)$ , or at least  $2^{\Omega(r)}$  samples. Thus, we get an extra factor of  $\frac{1}{\varepsilon}$  in the space lower bound for all the bounds on learning problems that [8] imply, some of which are as follows (see [8] for details on why the corresponding matrices satisfy the extractor-based property):

---

<sup>1</sup> The SQ model does not seem to distinguish between noisy and noiseless variants of parity learning and yields the same lower bound in both cases.

1. **Parities with noise:** A learner tries to learn  $x = (x_1, \dots, x_n) \in \{0, 1\}^n$ , from (a stream of) random linear equations over  $\mathbb{F}_2$  which are correct with probability  $\frac{1}{2} + \varepsilon$  and flipped with probability  $\frac{1}{2} - \varepsilon$ . Any learning algorithm requires either a memory of size  $\Omega(n^2/\varepsilon)$  or an exponential number of samples.
2. **Sparse parities with noise:** A learner tries to learn  $x = (x_1, \dots, x_n) \in \{0, 1\}^n$  of sparsity  $\ell$ , from (a stream of) random linear equations over  $\mathbb{F}_2$  which are correct with probability  $\frac{1}{2} + \varepsilon$  and flipped with probability  $\frac{1}{2} - \varepsilon$ . Any learning algorithm requires:
  - a. Assuming  $\ell \leq n/2$ : either a memory of size  $\Omega(n \cdot \ell/\varepsilon)$  or  $2^{\Omega(\ell)}$  samples.
  - b. Assuming  $\ell \leq n^{0.9}$ : either a memory of size  $\Omega(n \cdot \ell^{0.99}/\varepsilon)$  or  $\ell^{\Omega(\ell)}$  samples.
3. **Learning from noisy sparse linear equations:** A learner tries to learn  $x = (x_1, \dots, x_n) \in \{0, 1\}^n$ , from (a stream of) random sparse linear equations, of sparsity  $\ell$ , over  $\mathbb{F}_2$ , which are correct with probability  $\frac{1}{2} + \varepsilon$  and flipped with probability  $\frac{1}{2} - \varepsilon$ . Any learning algorithm requires:
  - a. Assuming  $\ell \leq n/2$ : either a memory of size  $\Omega(n \cdot \ell/\varepsilon)$  or  $2^{\Omega(\ell)}$  samples.
  - b. Assuming  $\ell \leq n^{0.9}$ : either a memory of size  $\Omega(n \cdot \ell^{0.99}/\varepsilon)$  or  $\ell^{\Omega(\ell)}$  samples.
4. **Learning from noisy low-degree equations:** A learner tries to learn  $x = (x_1, \dots, x_n) \in \{0, 1\}^n$ , from (a stream of) random multilinear polynomial equations of degree at most  $d$ , over  $\mathbb{F}_2$ , which are correct with probability  $\frac{1}{2} + \varepsilon$  and flipped with probability  $\frac{1}{2} - \varepsilon$ . We prove that if  $d \leq 0.99 \cdot n$ , any learning algorithm requires either a memory of size  $\Omega\left(\binom{n}{\leq d} \frac{n}{d \cdot \varepsilon}\right)$  or  $2^{\Omega(n/d)}$  samples (where  $\binom{n}{\leq d} = \binom{n}{0} + \binom{n}{1} + \dots + \binom{n}{d}$ ).
5. **Low-degree polynomials with noise:** A learner tries to learn an  $n'$ -variate multilinear polynomial  $p$  of degree at most  $d$  over  $\mathbb{F}_2$ , from (a stream of) random evaluations of  $p$  over  $\mathbb{F}_2^{n'}$ , which are correct with probability  $\frac{1}{2} + \varepsilon$  and flipped with probability  $\frac{1}{2} - \varepsilon$ . We prove that if  $d \leq 0.99 \cdot n'$ , any learning algorithm requires either a memory of size  $\Omega\left(\binom{n'}{\leq d} \cdot \frac{n'}{d \cdot \varepsilon}\right)$  or  $2^{\Omega(n'/d)}$  samples.

## 1.2 Techniques

Our proof follows the proof of [21, 8] very closely and builds on that proof. We extend the extractor-based result of [8] to the noisy case and a straightforward adaptation to its proof gives the stronger lower bound for the noisy case (which reflects on the strength of the current techniques). The main contribution of this paper is not a technical one but establishing stronger space lower bounds for a well-studied problem of learning parity with noise, using the current techniques.

## 1.3 Discussion and Open Problem

Let's look at a space upper bound for the problem of learning parity with noise, that is, a learner tries to learn  $x \in \{0, 1\}^n$  from a stream of samples of the form  $(a, b)$ , where  $a \in \{0, 1\}^n$  is chosen uniformly at random and  $b = a \cdot x$  with probability  $\frac{1}{2} + \varepsilon$  and  $b = 1 - a \cdot x$  with probability  $\frac{1}{2} - \varepsilon$  (here,  $a \cdot x$  represents the inner product of  $a$  and  $x$  in  $\mathbb{F}_2$ , that is,  $a \cdot x = \sum_i a_i x_i \pmod{2}$ ).

### Upper Bound

Consider the following algorithm  $A$ : Store the first  $m = O(n/\varepsilon^2)$  samples. Check for every  $x' \in \{0, 1\}^n$ , if for at least  $(\frac{1}{2} + \frac{\varepsilon}{2})$  fraction of the samples  $(a_1, b_1), \dots, (a_m, b_m)$ ,  $a_i \cdot x'$  agrees with  $b_i$ . Output the first  $x'$  that satisfies the check. In expectation,  $a_i \cdot x$  would agree with  $b_i$  for  $(\frac{1}{2} + \varepsilon)$  fraction of the samples, and otherwise for  $x' \neq x$ , in expectation,  $a_i \cdot x'$  would

agree with  $b_i$  for half the samples. Therefore, for large enough  $m$ , using Chernoff bound and a union bound, with high probability  $(1 - o(1))$  over the  $m$  samples,  $x'$  satisfies the check if and only if  $x' = x$ , and  $A$  outputs the correct answer under such an event.  $A$  uses  $O(n/\varepsilon^2)$  samples and  $O(n^2/\varepsilon^2)$  bits of space.

In this paper, we prove that any algorithm that learns parity with noise from a stream of samples (as defined above) requires  $\Omega(n^2/\varepsilon)$  bits of space or exponential number of samples. Improving the lower bound to match the upper bound (or vice versa) is a fascinating open problem and we conjecture that the upper bound is tight. As each sample gives at most  $O(\varepsilon^2)$  bits of information about  $x$ , we can at least show that a learning algorithm requires  $O(n/\varepsilon^2)$  samples to learn  $x$  (which corresponds to using  $O(n^2/\varepsilon^2)$  bits of space if each sample is stored).

► **Conjecture 1.** *Any learner that tries to learn  $x \in \{0, 1\}^n$  from a stream of samples of the form  $(a, b)$ , where  $a \in \{0, 1\}^n$  is chosen uniformly at random and  $b = a \cdot x$  with probability  $\frac{1}{2} + \varepsilon$  and  $b = 1 - a \cdot x$  with probability  $\frac{1}{2} - \varepsilon$ , requires either  $\Omega(n^2/\varepsilon^2)$  bits of memory or  $2^{\Omega(n)}$  samples.*

The proof of the conjecture, if true, would lead to new technical insights (beyond extractor-based techniques) into proving time-space (or memory-sample) lower bounds for learning problems.

## 1.4 Outline of the Paper

In Section 2, we establish certain notations and definitions, which are borrowed from [21, 8]. We give a proof overview in Section 3 and prove the main theorem in Section 4.

## 2 Preliminaries

Denote by  $\mathcal{U}_X : X \rightarrow \mathbb{R}^+$  the uniform distribution over  $X$ . Denote by  $\log$  the logarithm to base 2. For a random variable  $Z$  and an event  $E$ , we denote by  $\mathbb{P}_Z$  the distribution of the random variables  $Z$ , and we denote by  $\mathbb{P}_{Z|E}$  the distribution of the random variable  $Z$  conditioned on the event  $E$ .

### Viewing a Learning Problem, with error $\frac{1}{2} - \varepsilon$ , as a Matrix

Let  $X, A$  be two finite sets of size larger than 1. Let  $n = \log_2 |X|$  and  $n' = \log_2 |A|$ .

Let  $M : A \times X \rightarrow \{-1, 1\}$  be a matrix. The matrix  $M$  corresponds to the following learning problem with error parameter  $\varepsilon$  ( $0 < \varepsilon < \frac{1}{2}$ ). There is an unknown element  $x \in X$  that was chosen uniformly at random. A learner tries to learn  $x$  from samples  $(a, b)$ , where  $a \in A$  is chosen uniformly at random, and  $b = M(a, x)$  with probability  $\frac{1}{2} + \varepsilon$  and  $b = -M(a, x)$  with probability  $\frac{1}{2} - \varepsilon$ . That is, the learning algorithm is given a stream of samples,  $(a_1, b_1), (a_2, b_2) \dots$ , where each  $a_t$  is uniformly distributed, and  $b_t = M(a_t, x)$  with probability  $\frac{1}{2} + \varepsilon$  and  $b_t = -M(a_t, x)$  with probability  $\frac{1}{2} - \varepsilon$ .

### Norms and Inner Products

Let  $p \geq 1$ . For a function  $f : X \rightarrow \mathbb{R}$ , denote by  $\|f\|_p$  the  $\ell_p$  norm of  $f$ , with respect to the uniform distribution over  $X$ , that is:

$$\|f\|_p = \left( \mathbf{E}_{x \in_R X} [|f(x)|^p] \right)^{1/p}.$$

For two functions  $f, g : X \rightarrow \mathbb{R}$ , define their inner product with respect to the uniform distribution over  $X$  as

$$\langle f, g \rangle = \mathbf{E}_{x \in_R X} [f(x) \cdot g(x)].$$

For a matrix  $M : A \times X \rightarrow \mathbb{R}$  and a row  $a \in A$ , we denote by  $M_a : X \rightarrow \mathbb{R}$  the function corresponding to the  $a$ -th row of  $M$ . Note that for a function  $f : X \rightarrow \mathbb{R}$ , we have  $\langle M_a, f \rangle = \frac{(M \cdot f)_a}{|X|}$ . Here,  $M \cdot f$  represents the matrix multiplication of  $M$  with  $f$ .

## $L_2$ -Extractors and $L_\infty$ -Extractors

► **Definition 2** ( $L_2$ -Extractor). *Let  $X, A$  be two finite sets. A matrix  $M : A \times X \rightarrow \{-1, 1\}$  is a  $(k, \ell)$ - $L_2$ -Extractor with error  $2^{-r}$ , if for every non-negative  $f : X \rightarrow \mathbb{R}$  with  $\frac{\|f\|_2}{\|f\|_1} \leq 2^\ell$  there are at most  $2^{-k} \cdot |A|$  rows  $a$  in  $A$  with*

$$\frac{|\langle M_a, f \rangle|}{\|f\|_1} \geq 2^{-r}.$$

Let  $\Omega$  be a finite set. We denote a distribution over  $\Omega$  as a function  $f : \Omega \rightarrow \mathbb{R}^+$  such that  $\sum_{x \in \Omega} f(x) = 1$ . We say that a distribution  $f : \Omega \rightarrow \mathbb{R}^+$  has min-entropy  $k$  if for all  $x \in \Omega$ , we have  $f(x) \leq 2^{-k}$ .

► **Definition 3** ( $L_\infty$ -Extractor). *Let  $X, A$  be two finite sets. A matrix  $M : A \times X \rightarrow \{-1, 1\}$  is a  $(k, \ell \sim r)$ - $L_\infty$ -Extractor if for every distribution  $p_x : X \rightarrow \mathbb{R}^+$  with min-entropy at least  $(\log(|X|) - \ell)$  and every distribution  $p_a : A \rightarrow \mathbb{R}^+$  with min-entropy at least  $(\log(|A|) - k)$ ,*

$$\left| \sum_{a' \in A} \sum_{x' \in X} p_a(a') \cdot p_x(x') \cdot M(a', x') \right| \leq 2^{-r}.$$

## Branching Program for a Learning Problem

In the following definition, we model the learner for the learning problem that corresponds to the matrix  $M$ , by a *branching program*, as done by previous papers starting with [20].

► **Definition 4. Branching Program for a Learning Problem:** *A branching program of length  $m$  and width  $d$ , for learning, is a directed (multi) graph with vertices arranged in  $m + 1$  layers containing at most  $d$  vertices each. In the first layer, that we think of as layer 0, there is only one vertex, called the start vertex. A vertex of outdegree 0 is called a leaf. All vertices in the last layer are leaves (but there may be additional leaves). Every non-leaf vertex in the program has  $2|A|$  outgoing edges, labeled by elements  $(a, b) \in A \times \{-1, 1\}$ , with exactly one edge labeled by each such  $(a, b)$ , and all these edges going into vertices in the next layer. Each leaf  $v$  in the program is labeled by an element  $\tilde{x}(v) \in X$ , that we think of as the output of the program on that leaf.*

**Computation-Path:** *The samples  $(a_1, b_1), \dots, (a_m, b_m) \in A \times \{-1, 1\}$  that are given as input, define a computation-path in the branching program, by starting from the start vertex and following at step  $t$  the edge labeled by  $(a_t, b_t)$ , until reaching a leaf. The program outputs the label  $\tilde{x}(v)$  of the leaf  $v$  reached by the computation-path.*

**Success Probability:** *The success probability of the program is the probability that  $\tilde{x} = x$ , where  $\tilde{x}$  is the element that the program outputs, and the probability is over  $x, a_1, \dots, a_m, b_1, \dots, b_m$  (where  $x$  is uniformly distributed over  $X$  and  $a_1, \dots, a_m$  are uniformly distributed over  $A$ , and for every  $t$ ,  $b_t = M(a_t, x)$  with probability  $\frac{1}{2} + \varepsilon$  and  $-M(a_t, x)$  with probability  $\frac{1}{2} - \varepsilon$ ).*

A learning algorithm, using  $m$  samples and a memory of  $s$  bits, can be modeled as a branching program<sup>2</sup> of length  $m$  and width  $2^{O(s)}$ . Thus, we will focus on proving width-length tradeoffs for any branching program that learns an extractor-based learning problem with noise, and such tradeoffs would translate into memory-sample tradeoffs for the learning algorithms.

### 3 Overview of the Proof

The proof adapts the extractor-based time-space lower bound of [8] to the *noisy* case, which in turn built on [21] that gave a general technique for proving memory-samples lower bounds. We recall the arguments in [21, 8] for convenience.

Assume that  $M$  is a  $(k', \ell')$ - $L_2$ -extractor with error  $2^{-r'}$ , and let  $r = \min\{k', \ell', r'\}$ . Let  $B$  be a branching program for the noisy learning problem that corresponds to the matrix  $M$ . We want to prove that  $B$  has at least  $2^{\Omega(r)}$  length or requires at least  $2^{\Omega(\frac{k'\ell'}{\varepsilon})}$  width (that is, any learning algorithm solving the learning problem corresponding to the matrix  $M$  with error parameter  $\varepsilon$ , requires either  $\Omega(\frac{k'\ell'}{\varepsilon})$  memory or exponential number of samples). Assume for a contradiction that  $B$  is of length  $m = 2^{cr}$  and width  $d = 2^{c\frac{k'\ell'}{\varepsilon}}$ , where  $c > 0$  is a small constant.

We define the *truncated-path*,  $\mathcal{T}$ , to be the same as the computation-path of  $B$ , except that it sometimes stops before reaching a leaf. Roughly speaking,  $\mathcal{T}$  stops before reaching a leaf if certain “bad” events occur. Nevertheless, we show that the probability that  $\mathcal{T}$  stops before reaching a leaf is negligible, so we can think of  $\mathcal{T}$  as almost identical to the computation-path.

For a vertex  $v$  of  $B$ , we denote by  $E_v$  the event that  $\mathcal{T}$  reaches the vertex  $v$ . We denote by  $\Pr(v) = \Pr(E_v)$  the probability for  $E_v$  (where the probability is over  $x, a_1, \dots, a_m, b_1, \dots, b_m$ ), and we denote by  $\mathbb{P}_{x|v} = \mathbb{P}_{x|E_v}$  the distribution of the random variable  $x$  conditioned on the event  $E_v$ . Similarly, for an edge  $e$  of the branching program  $B$ , let  $E_e$  be the event that  $\mathcal{T}$  traverses the edge  $e$ . Denote,  $\Pr(e) = \Pr(E_e)$ , and  $\mathbb{P}_{x|e} = \mathbb{P}_{x|E_e}$ .

A vertex  $v$  of  $B$  is called *significant* if

$$\|\mathbb{P}_{x|v}\|_2 > 2^{\ell'} \cdot 2^{-n}.$$

Roughly speaking, this means that conditioning on the event that  $\mathcal{T}$  reaches the vertex  $v$ , a non-negligible amount of information is known about  $x$ . In order to guess  $x$  with a non-negligible success probability,  $\mathcal{T}$  must reach a significant vertex. Lemma 6 shows that the probability that  $\mathcal{T}$  reaches any significant vertex is negligible, and thus the main result follows.

To prove Lemma 6, we show that for every fixed significant vertex  $s$ , the probability that  $\mathcal{T}$  reaches  $s$  is at most  $2^{-\Omega(k'\ell'/\varepsilon)}$  (which is smaller than one over the number of vertices in  $B$ ). Hence, we can use a union bound to prove the lemma.

The proof that the probability that  $\mathcal{T}$  reaches  $s$  is extremely small is the main part of the proof. To that end, we use the following functions to measure the progress made by the branching program towards reaching  $s$ .

<sup>2</sup> The lower bound holds for randomized learning algorithms because a branching program is a non-uniform model of computation, and we can fix a *good* randomization for the computation without affecting the width.

Let  $L_i$  be the set of vertices  $v$  in layer- $i$  of  $B$ , such that  $\Pr(v) > 0$ . Let  $\Gamma_i$  be the set of edges  $e$  from layer- $(i-1)$  of  $B$  to layer- $i$  of  $B$ , such that  $\Pr(e) > 0$ . Let

$$\mathcal{Z}_i = \sum_{v \in L_i} \Pr(v) \cdot \langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle^{k'/2\varepsilon},$$

$$\mathcal{Z}'_i = \sum_{e \in \Gamma_i} \Pr(e) \cdot \langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^{k'/2\varepsilon}.$$

We think of  $\mathcal{Z}_i, \mathcal{Z}'_i$  as measuring the progress made by the branching program, towards reaching a state with distribution similar to  $\mathbb{P}_{x|s}$ .

We show that each  $\mathcal{Z}_i$  may only be negligibly larger than  $\mathcal{Z}_{i-1}$ . Hence, since it's easy to calculate that  $\mathcal{Z}_0 = 2^{-\frac{2nk'}{2\varepsilon}}$ , it follows that  $\mathcal{Z}_i$  is close to  $2^{-\frac{2nk'}{2\varepsilon}}$ , for every  $i$ . On the other hand, if  $s$  is in layer- $i$  then  $\mathcal{Z}_i$  is at least  $\Pr(s) \cdot \langle \mathbb{P}_{x|s}, \mathbb{P}_{x|s} \rangle^{\frac{k'}{2\varepsilon}}$ . Thus,  $\Pr(s) \cdot \langle \mathbb{P}_{x|s}, \mathbb{P}_{x|s} \rangle^{\frac{k'}{2\varepsilon}}$  cannot be much larger than  $2^{-2n\frac{k'}{2\varepsilon}}$ . Since  $s$  is significant,  $\langle \mathbb{P}_{x|s}, \mathbb{P}_{x|s} \rangle^{\frac{k'}{2\varepsilon}} > 2^{(2\ell' - 2n)\frac{k'}{2\varepsilon}}$  and hence  $\Pr(s)$  is at most  $2^{-\Omega(\frac{k'\ell'}{\varepsilon})}$ .

The proof that  $\mathcal{Z}_i$  may only be negligibly larger than  $\mathcal{Z}_{i-1}$  is done in two steps: Claim 17 shows by a simple convexity argument that  $\mathcal{Z}_i \leq \mathcal{Z}'_i$ . The hard part, that is done in Claim 15 and Claim 16, is to prove that  $\mathcal{Z}'_i$  may only be negligibly larger than  $\mathcal{Z}_{i-1}$ .

For this proof, we define for every vertex  $v$ , the set of edges  $\Gamma_{out}(v)$  that are going out of  $v$ , such that  $\Pr(e) > 0$ . Claim 15 shows that for every vertex  $v$ ,

$$\sum_{e \in \Gamma_{out}(v)} \Pr(e) \cdot \langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^{k'/2\varepsilon}$$

may only be negligibly higher than

$$\Pr(v) \cdot \langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle^{k'/2\varepsilon}.$$

For the proof of Claim 15, which is the hardest proof in the paper, we follow [21, 8] and consider the function  $\mathbb{P}_{x|v} \cdot \mathbb{P}_{x|s}$ . We first show how to bound  $\|\mathbb{P}_{x|v} \cdot \mathbb{P}_{x|s}\|_2$ . We then consider two cases: If  $\|\mathbb{P}_{x|v} \cdot \mathbb{P}_{x|s}\|_1$  is negligible, then  $\langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle^{k'/2\varepsilon}$  is negligible and doesn't contribute much, and we show that for every  $e \in \Gamma_{out}(v)$ ,  $\langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^{k'/2\varepsilon}$  is also negligible and doesn't contribute much. If  $\|\mathbb{P}_{x|v} \cdot \mathbb{P}_{x|s}\|_1$  is non-negligible, we use the bound on  $\|\mathbb{P}_{x|v} \cdot \mathbb{P}_{x|s}\|_2$  and the assumption that  $M$  is a  $(k', \ell')$ - $L_2$ -extractor to show that for almost all edges  $e \in \Gamma_{out}(v)$ , we have that  $\langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^{k'/2\varepsilon}$  is very close to  $\langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle^{k'/2\varepsilon}$ . Only an exponentially small  $(2^{-k'})$  fraction of edges are “bad” and give a significantly larger  $\langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^{k'/2\varepsilon}$ . In the noiseless case, any “bad” edge can increase  $\langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle$  by a factor of 2 in the worst case, and hence [8] raised  $\langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle$  and  $\langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle$  to the power of  $k'$ , as it is the largest power for which the contribution of the “bad” edges is still small (as their fraction is  $2^{-k'}$ ). But in the noisy case, any “bad” edge can increase  $\langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle$  by a factor of at most  $(1 + 2\varepsilon)$  in the worst case, and thus, we can afford to raise  $\langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle$  and  $\langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle$  to the power of  $k'/2\varepsilon$ . *This is where our proof differs from that of [8].*

This outline oversimplifies many details. To make the argument work, we force  $\mathcal{T}$  to stop at significant vertices and whenever  $\mathbb{P}_{x|v}(x)$  is large, that is, at significant values, as done in previous papers. And we force  $\mathcal{T}$  to stop before traversing some edges, that are so “bad” that their contribution to  $\mathcal{Z}'_i$  is huge and they cannot be ignored. We show that the total probability that  $\mathcal{T}$  stops before reaching a leaf is negligible.

## 4 Main Result

► **Theorem 5.** Let  $\frac{1}{100} < c < \frac{\ln 2}{3}$ . Fix  $\gamma$  to be such that  $\frac{3c}{\ln 2} < \gamma^2 < 1$ . Let  $X, A$  be two finite sets. Let  $n = \log_2 |X|$ . Let  $M : A \times X \rightarrow \{-1, 1\}$  be a matrix which is a  $(k', \ell')$ - $L_2$ -extractor with error  $2^{-r'}$ , for sufficiently large<sup>3</sup>  $k', \ell'$  and  $r'$ , where  $\ell' \leq n$ . Let

$$r := \min \left\{ \frac{r'}{2}, \frac{(1-\gamma)k'}{2}, \frac{(1-\gamma)\ell'}{2} - 1 \right\}. \quad (1)$$

Let  $B$  be a branching program, of length at most  $2^r$  and width at most  $2^{c \cdot k' \cdot \ell' / \varepsilon}$ , for the learning problem that corresponds to the matrix  $M$  with error parameter  $\varepsilon$ . Then, the success probability of  $B$  is at most  $O(2^{-r})$ .

**Proof.** We recall the proof in [8, 21] and adapt it to the noisy case. Let

$$k := \frac{\gamma \ln 2}{2\varepsilon} k' \quad \text{and} \quad \ell := \gamma \ell' / 3. \quad (2)$$

Our proof differs from [8] starting with Claim 10, which allows us to set  $k$  to a larger value of  $\frac{\gamma \ln 2}{2\varepsilon} k'$  instead of  $\gamma(\ln 2)k'$  as set in [8]. Note that by the assumption that  $k', \ell'$  and  $r'$  are sufficiently large, we get that  $k, \ell$  and  $r$  are also sufficiently large. Since  $\ell' \leq n$ , we have  $\ell + r \leq \frac{\gamma \ell'}{3} + \frac{(1-\gamma)\ell'}{2} < \frac{\ell'}{2} \leq \frac{n}{2}$ . Thus,

$$r < n/2 - \ell. \quad (3)$$

Let  $B$  be a branching program of length  $m = 2^r$  and width<sup>4</sup>  $d = 2^{c \cdot k' \cdot \ell' / \varepsilon}$  for the learning problem that corresponds to the matrix  $M$  with error parameter  $\varepsilon$ . We will show that the success probability of  $B$  is at most  $O(2^{-r})$ .

### 4.1 The Truncated-Path and Additional Definitions and Notation

We will define the **truncated-path**,  $\mathcal{T}$ , to be the same as the computation-path of  $B$ , except that it sometimes stops before reaching a leaf. Formally, we define  $\mathcal{T}$ , together with several other definitions and notations, by induction on the layers of the branching program  $B$ .

Assume that we already defined the truncated-path  $\mathcal{T}$ , until it reaches layer- $i$  of  $B$ . For a vertex  $v$  in layer- $i$  of  $B$ , let  $E_v$  be the event that  $\mathcal{T}$  reaches the vertex  $v$ . For simplicity, we denote by  $\Pr(v) = \Pr(E_v)$  the probability for  $E_v$  (where the probability is over  $x, a_1, \dots, a_m, b_1, \dots, b_m$ ), and we denote by  $\mathbb{P}_{x|v} = \mathbb{P}_{x|E_v}$  the distribution of the random variable  $x$  conditioned on the event  $E_v$ .

There will be three cases in which the truncated-path  $\mathcal{T}$  stops on a non-leaf  $v$ :

1. If  $v$  is a, so called, significant vertex, where the  $\ell_2$  norm of  $\mathbb{P}_{x|v}$  is non-negligible. (Intuitively, this means that conditioned on the event that  $\mathcal{T}$  reaches  $v$ , a non-negligible amount of information is known about  $x$ ).
2. If  $\mathbb{P}_{x|v}(x)$  is non-negligible. (Intuitively, this means that conditioned on the event that  $\mathcal{T}$  reaches  $v$ , the correct element  $x$  could have been guessed with a non-negligible probability).
3. If  $(M \cdot \mathbb{P}_{x|v})(a_{i+1})$  is non-negligible. (Intuitively, this means that  $\mathcal{T}$  is about to traverse a “bad” edge, which is traversed with a non-negligibly higher or lower probability than probability of traversal under uniform distribution on  $x$ ).

Next, we describe these three cases more formally.

<sup>3</sup> By “sufficiently large” we mean that  $k', \ell', r'$  are larger than some constant that depends on  $\gamma$ .

<sup>4</sup> width lower bound is vacuous for  $\varepsilon < 2^{-r/2}$  as regardless of the width,  $\Omega(n/\varepsilon^2) > 2^r$  samples are needed to learn.

## Significant Vertices

We say that a vertex  $v$  in layer- $i$  of  $B$  is **significant** if

$$\|\mathbb{P}_{x|v}\|_2 > 2^\ell \cdot 2^{-n}.$$

## Significant Values

Even if  $v$  is not significant,  $\mathbb{P}_{x|v}$  may have relatively large values. For a vertex  $v$  in layer- $i$  of  $B$ , denote by  $\text{Sig}(v)$  the set of all  $x' \in X$ , such that,

$$\mathbb{P}_{x|v}(x') > 2^{2\ell+2r} \cdot 2^{-n}.$$

## Bad Edges

For a vertex  $v$  in layer- $i$  of  $B$ , denote by  $\text{Bad}(v)$  the set of all  $\alpha \in A$ , such that,

$$|(M \cdot \mathbb{P}_{x|v})(\alpha)| \geq 2^{-r'}.$$

## The Truncated-Path $\mathcal{T}$

We define  $\mathcal{T}$  by induction on the layers of the branching program  $B$ . Assume that we already defined  $\mathcal{T}$  until it reaches a vertex  $v$  in layer- $i$  of  $B$ . The path  $\mathcal{T}$  stops on  $v$  if (at least) one of the following occurs:

1.  $v$  is significant.
2.  $x \in \text{Sig}(v)$ .
3.  $a_{i+1} \in \text{Bad}(v)$ .
4.  $v$  is a leaf.

Otherwise,  $\mathcal{T}$  proceeds by following the edge labeled by  $(a_{i+1}, b_{i+1})$  (same as the computational-path).

## 4.2 Proof of Theorem 5

Since  $\mathcal{T}$  follows the computation-path of  $B$ , except that it sometimes stops before reaching a leaf, the success probability of  $B$  is bounded (from above) by the probability that  $\mathcal{T}$  stops before reaching a leaf, plus the probability that  $\mathcal{T}$  reaches a leaf  $v$  and  $\tilde{x}(v) = x$ .

The main lemma needed for the proof of Theorem 5 is Lemma 6 that shows that the probability that  $\mathcal{T}$  reaches a significant vertex is at most  $O(2^{-r})$ .

► **Lemma 6.** *The probability that  $\mathcal{T}$  reaches a significant vertex is at most  $O(2^{-r})$ .*

Lemma 6 is proved in Section 4.3. We will now show how the proof of Theorem 5 follows from that lemma.

Lemma 6 shows that the probability that  $\mathcal{T}$  stops on a non-leaf vertex, because of the first reason (i.e., that the vertex is significant), is small. The next two claims imply that the probabilities that  $\mathcal{T}$  stops on a non-leaf vertex, because of the second and third reasons, are also small. We defer the proofs to Appendix A (proved as in [8]).

▷ **Claim 7.** If  $v$  is a non-significant vertex of  $B$  then

$$\Pr_x[x \in \text{Sig}(v) \mid E_v] \leq 2^{-2r}.$$

## 60:10 Memory-Sample Lower Bounds for Learning Parity with Noise

▷ **Claim 8.** If  $v$  is a non-significant vertex of  $B$  then

$$\Pr_{a_{i+1}} [a_{i+1} \in \text{Bad}(v)] \leq 2^{-2r}.$$

We can now use Lemma 6, Claim 7 and Claim 8 to prove that the probability that  $\mathcal{T}$  stops before reaching a leaf is at most  $O(2^{-r})$ . Lemma 6 shows that the probability that  $\mathcal{T}$  reaches a significant vertex and hence stops because of the first reason, is at most  $O(2^{-r})$ . Assuming that  $\mathcal{T}$  doesn't reach any significant vertex (in which case it would have stopped because of the first reason), Claim 7 shows that in each step, the probability that  $\mathcal{T}$  stops because of the second reason, is at most  $2^{-2r}$ . Taking a union bound over the  $m = 2^r$  steps, the total probability that  $\mathcal{T}$  stops because of the second reason, is at most  $2^{-r}$ . In the same way, assuming that  $\mathcal{T}$  doesn't reach any significant vertex (in which case it would have stopped because of the first reason), Claim 8 shows that in each step, the probability that  $\mathcal{T}$  stops because of the third reason, is at most  $2^{-2r}$ . Again, taking a union bound over the  $2^r$  steps, the total probability that  $\mathcal{T}$  stops because of the third reason, is at most  $2^{-r}$ . Thus, the total probability that  $\mathcal{T}$  stops (for any reason) before reaching a leaf is at most  $O(2^{-r})$ .

Recall that if  $\mathcal{T}$  doesn't stop before reaching a leaf, it just follows the computation-path of  $B$ . Recall also that by Lemma 6, the probability that  $\mathcal{T}$  reaches a significant leaf is at most  $O(2^{-r})$ . Thus, to bound (from above) the success probability of  $B$  by  $O(2^{-r})$ , it remains to bound the probability that  $\mathcal{T}$  reaches a non-significant leaf  $v$  and  $\tilde{x}(v) = x$ . Claim 9 shows that for any non-significant leaf  $v$ , conditioned on the event that  $\mathcal{T}$  reaches  $v$ , the probability for  $\tilde{x}(v) = x$  is at most  $2^{-r}$ , which completes the proof of Theorem 5.

▷ **Claim 9.** If  $v$  is a non-significant leaf of  $B$  then

$$\Pr[\tilde{x}(v) = x \mid E_v] \leq 2^{-r}.$$

Refer to Appendix A for the proof (proved as in [8]). This completes the proof of Theorem 5. ◀

### 4.3 Proof of Lemma 6

**Proof.** We need to prove that the probability that  $\mathcal{T}$  reaches any significant vertex is at most  $O(2^{-r})$ . Let  $s$  be a significant vertex of  $B$ . We will bound from above the probability that  $\mathcal{T}$  reaches  $s$ , and then use a union bound over all significant vertices of  $B$ . Interestingly, the upper bound on the width of  $B$  is used only in the union bound.

#### The Distributions $\mathbb{P}_{x|v}$ and $\mathbb{P}_{x|e}$

Recall that for a vertex  $v$  of  $B$ , we denote by  $E_v$  the event that  $\mathcal{T}$  reaches the vertex  $v$ . For simplicity, we denote by  $\Pr(v) = \Pr(E_v)$  the probability for  $E_v$  (where the probability is over  $x, a_1, \dots, a_m, b_1, \dots, b_m$ ), and we denote by  $\mathbb{P}_{x|v} = \mathbb{P}_{x|E_v}$  the distribution of the random variable  $x$  conditioned on the event  $E_v$ .

Similarly, for an edge  $e$  of the branching program  $B$ , let  $E_e$  be the event that  $\mathcal{T}$  traverses the edge  $e$ . Denote,  $\Pr(e) = \Pr(E_e)$  (where the probability is over  $x, a_1, \dots, a_m, b_1, \dots, b_m$ ), and  $\mathbb{P}_{x|e} = \mathbb{P}_{x|E_e}$ .

▷ **Claim 10.** For any edge  $e = (v, u)$  of  $B$ , labeled by  $(a, b)$ , such that  $\Pr(e) > 0$ , for any  $x' \in X$ ,

$$\mathbb{P}_{x|e}(x') = \begin{cases} 0 & \text{if } x' \in \text{Sig}(v) \\ \mathbb{P}_{x|v}(x')(1 + 2\varepsilon) \cdot c_e^{-1} & \text{if } x' \notin \text{Sig}(v) \text{ and } M(a, x') = b \\ \mathbb{P}_{x|v}(x')(1 - 2\varepsilon) \cdot c_e^{-1} & \text{if } x' \notin \text{Sig}(v) \text{ and } M(a, x') \neq b \end{cases}$$

where  $c_e$  is a normalization factor that satisfies,

$$c_e \geq 1 - 4 \cdot 2^{-2r}.$$

Proof. Let  $e = (v, u)$  be an edge of  $B$ , labeled by  $(a, b)$ , and such that  $\Pr(e) > 0$ . Since  $\Pr(e) > 0$ , the vertex  $v$  is not significant (as otherwise  $\mathcal{T}$  always stops on  $v$  and hence  $\Pr(e) = 0$ ). Also, since  $\Pr(e) > 0$ , we know that  $a \notin \text{Bad}(v)$  (as otherwise  $\mathcal{T}$  never traverses  $e$  and hence  $\Pr(e) = 0$ ).

If  $\mathcal{T}$  reaches  $v$ , it traverses the edge  $e$  if and only if:  $x \notin \text{Sig}(v)$  (as otherwise  $\mathcal{T}$  stops on  $v$ ) and  $a_{i+1} = a$ ,  $b_{i+1} = b$ . Therefore, by Bayes' rule, for any  $x' \in X$ ,

$$\mathbb{P}_{x|e}(x') = \begin{cases} 0 & \text{if } x' \in \text{Sig}(v) \\ \mathbb{P}_{x|v}(x')(1 + 2\varepsilon) \cdot c_e^{-1} & \text{if } x' \notin \text{Sig}(v) \text{ and } M(a, x') = b \\ \mathbb{P}_{x|v}(x')(1 - 2\varepsilon) \cdot c_e^{-1} & \text{if } x' \notin \text{Sig}(v) \text{ and } M(a, x') \neq b \end{cases}$$

where  $c_e$  is a normalization factor, given by

$$\begin{aligned} c_e &= \sum_{\{x' : x' \notin \text{Sig}(v) \wedge M(a, x') = b\}} \mathbb{P}_{x|v}(x')(1 + 2\varepsilon) \\ &\quad + \sum_{\{x' : x' \notin \text{Sig}(v) \wedge M(a, x') \neq b\}} \mathbb{P}_{x|v}(x')(1 - 2\varepsilon) \\ &= (1 + 2\varepsilon) \cdot \Pr_x[(x \notin \text{Sig}(v)) \wedge (M(a, x) = b) \mid E_v] \\ &\quad + (1 - 2\varepsilon) \cdot \Pr_x[(x \notin \text{Sig}(v)) \wedge (M(a, x) \neq b) \mid E_v]. \end{aligned}$$

Since  $v$  is not significant, by Claim 7,

$$\Pr_x[x \in \text{Sig}(v) \mid E_v] \leq 2^{-2r}.$$

Since  $a \notin \text{Bad}(v)$ ,

$$\left| \Pr_x[M(a, x) = 1 \mid E_v] - \Pr_x[M(a, x) = -1 \mid E_v] \right| = |(M \cdot \mathbb{P}_{x|v})(a)| \leq 2^{-r'},$$

and hence for every  $b' \in \{-1, 1\}$ ,

$$\Pr_x[M(a, x) = b' \mid E_v] \geq \frac{1}{2} - 2^{-r'}.$$

Hence, by the union bound,

$$c_e \geq (1 + 2\varepsilon) \cdot (\frac{1}{2} - 2^{-r'} - 2^{-2r}) + (1 - 2\varepsilon) \cdot (\frac{1}{2} - 2^{-r'} - 2^{-2r}) \geq 1 - 4 \cdot 2^{-2r}$$

(where the last inequality follows since  $r \leq r'/2$ , by Equation (1)).  $\triangleleft$

### Bounding the Norm of $\mathbb{P}_{x|s}$

We will show that  $\|\mathbb{P}_{x|s}\|_2$  cannot be too large. Towards this, we will first prove that for every edge  $e$  of  $B$  that is traversed by  $\mathcal{T}$  with probability larger than zero,  $\|\mathbb{P}_{x|e}\|_2$  cannot be too large. We defer the proofs of the following claims to Appendix A (proved as in [8]).

▷ **Claim 11.** For any edge  $e$  of  $B$ , such that  $\Pr(e) > 0$ ,

$$\|\mathbb{P}_{x|e}\|_2 \leq 4 \cdot 2^\ell \cdot 2^{-n}.$$

▷ **Claim 12.**

$$\|\mathbb{P}_{x|s}\|_2 \leq 4 \cdot 2^\ell \cdot 2^{-n}.$$

## 60:12 Memory-Sample Lower Bounds for Learning Parity with Noise

### Similarity to a Target Distribution

Recall that for two functions  $f, g : X \rightarrow \mathbb{R}^+$ , we defined

$$\langle f, g \rangle = \mathbf{E}_{z \in_R X} [f(z) \cdot g(z)].$$

We think of  $\langle f, g \rangle$  as a measure for the similarity between a function  $f$  and a target function  $g$ . Typically  $f, g$  will be distributions.

▷ Claim 13.

$$\langle \mathbb{P}_{x|s}, \mathbb{P}_{x|s} \rangle > 2^{2\ell} \cdot 2^{-2n}.$$

Proof. Since  $s$  is significant,

$$\langle \mathbb{P}_{x|s}, \mathbb{P}_{x|s} \rangle = \|\mathbb{P}_{x|s}\|_2^2 > 2^{2\ell} \cdot 2^{-2n}. \quad \triangleleft$$

▷ Claim 14.

$$\langle \mathcal{U}_X, \mathbb{P}_{x|s} \rangle = 2^{-2n},$$

where  $\mathcal{U}_X$  is the uniform distribution over  $X$ .

Proof. Since  $\mathbb{P}_{x|s}$  is a distribution,

$$\langle \mathcal{U}_X, \mathbb{P}_{x|s} \rangle = 2^{-2n} \cdot \sum_{z \in X} \mathbb{P}_{x|s}(z) = 2^{-2n}. \quad \triangleleft$$

### Measuring the Progress

For  $i \in \{0, \dots, m\}$ , let  $L_i$  be the set of vertices  $v$  in layer- $i$  of  $B$ , such that  $\Pr(v) > 0$ . For  $i \in \{1, \dots, m\}$ , let  $\Gamma_i$  be the set of edges  $e$  from layer- $(i-1)$  of  $B$  to layer- $i$  of  $B$ , such that  $\Pr(e) > 0$ . Recall that  $k = \frac{\gamma \ln 2}{2\varepsilon} k'$  (Equation (2)).

For  $i \in \{0, \dots, m\}$ , let

$$\mathcal{Z}_i = \sum_{v \in L_i} \Pr(v) \cdot \langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle^k.$$

For  $i \in \{1, \dots, m\}$ , let

$$\mathcal{Z}'_i = \sum_{e \in \Gamma_i} \Pr(e) \cdot \langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^k.$$

We think of  $\mathcal{Z}_i, \mathcal{Z}'_i$  as measuring the progress made by the branching program, towards reaching a state with distribution similar to  $\mathbb{P}_{x|s}$ .

For a vertex  $v$  of  $B$ , let  $\Gamma_{out}(v)$  be the set of all edges  $e$  of  $B$ , that are going out of  $v$ , such that  $\Pr(e) > 0$ . Note that

$$\sum_{e \in \Gamma_{out}(v)} \Pr(e) \leq \Pr(v).$$

(We don't always have an equality here, since sometimes  $\mathcal{T}$  stops on  $v$ ).

The next four claims show that the progress made by the branching program is slow.

▷ **Claim 15.** For every vertex  $v$  of  $B$ , such that  $\Pr(v) > 0$ ,

$$\sum_{e \in \Gamma_{out}(v)} \frac{\Pr(e)}{\Pr(v)} \cdot \langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^k \leq \langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle^k \cdot (1 + 2^{-r})^k + (2^{-2n+2})^k.$$

*Proof.* If  $v$  is significant or  $v$  is a leaf, then  $\mathcal{T}$  always stops on  $v$  and hence  $\Gamma_{out}(v)$  is empty and thus the left hand side is equal to zero and the right hand side is positive, so the claim follows trivially. Thus, we can assume that  $v$  is not significant and is not a leaf.

Define  $P : X \rightarrow \mathbb{R}^+$  as follows. For any  $x' \in X$ ,

$$P(x') = \begin{cases} 0 & \text{if } x' \in \text{Sig}(v) \\ \mathbb{P}_{x|v}(x') & \text{if } x' \notin \text{Sig}(v) \end{cases}$$

Note that by the definition of  $\text{Sig}(v)$ , for any  $x' \in X$ ,

$$P(x') \leq 2^{2\ell+2r} \cdot 2^{-n}. \quad (4)$$

Define  $f : X \rightarrow \mathbb{R}^+$  as follows. For any  $x' \in X$ ,

$$f(x') = P(x') \cdot \mathbb{P}_{x|s}(x').$$

By Claim 12 and Equation (4),

$$\|f\|_2 \leq 2^{2\ell+2r} \cdot 2^{-n} \cdot \|\mathbb{P}_{x|s}\|_2 \leq 2^{2\ell+2r} \cdot 2^{-n} \cdot 4 \cdot 2^\ell \cdot 2^{-n} = 2^{3\ell+2r+2} \cdot 2^{-2n}. \quad (5)$$

By Claim 10, for any edge  $e \in \Gamma_{out}(v)$ , labeled by  $(a, b)$ , for any  $x' \in X$ ,

$$\mathbb{P}_{x|e}(x') = \begin{cases} 0 & \text{if } x' \in \text{Sig}(v) \\ \mathbb{P}_{x|v}(x')(1 + 2\varepsilon) \cdot c_e^{-1} & \text{if } x' \notin \text{Sig}(v) \text{ and } M(a, x') = b \\ \mathbb{P}_{x|v}(x')(1 - 2\varepsilon) \cdot c_e^{-1} & \text{if } x' \notin \text{Sig}(v) \text{ and } M(a, x') \neq b \end{cases}$$

where  $c_e$  is a normalization factor that satisfies,

$$c_e \geq 1 - 4 \cdot 2^{-2r}.$$

Therefore, for any edge  $e \in \Gamma_{out}(v)$ , labeled by  $(a, b)$ , for any  $x' \in X$ ,

$$\mathbb{P}_{x|e}(x') \cdot \mathbb{P}_{x|s}(x') = f(x') \cdot (1 + 2\varepsilon \cdot b \cdot M(a, x')) \cdot c_e^{-1}$$

and hence, we have

$$\begin{aligned} \langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle &= \mathbf{E}_{x' \in \mathcal{R}X} [\mathbb{P}_{x|e}(x') \cdot \mathbb{P}_{x|s}(x')] = \mathbf{E}_{x' \in \mathcal{R}X} [f(x') \cdot (1 + 2\varepsilon \cdot b \cdot M(a, x')) \cdot c_e^{-1}] \\ &= (\|f\|_1 + 2\varepsilon \cdot b \cdot \langle M_a, f \rangle) \cdot (c_e)^{-1} \\ &< (\|f\|_1 + 2\varepsilon |\langle M_a, f \rangle|) \cdot (1 + 2^{-2r+3}) \end{aligned} \quad (6)$$

(where the last inequality holds by the bound that we have on  $c_e$ , because we assume that  $k', \ell', r'$  and thus  $r$  are sufficiently large).

We will now consider two cases:

**Case I:**  $\|f\|_1 < 2^{-2n}$ . In this case, we bound  $|\langle M_a, f \rangle| \leq \|f\|_1$  (since  $f$  is non-negative and the entries of  $M$  are in  $\{-1, 1\}$ ) and  $(1 + 2^{-2r+3}) < 2$  (since we assume that  $k', \ell', r'$  and thus  $r$  are sufficiently large) and obtain for any edge  $e \in \Gamma_{out}(v)$ ,

$$\langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle < 4 \cdot 2^{-2n}.$$

Since  $\sum_{e \in \Gamma_{out}(v)} \frac{\Pr(e)}{\Pr(v)} \leq 1$ , Claim 15 follows, as the left hand side of the claim is smaller than the second term on the right hand side.

## 60:14 Memory-Sample Lower Bounds for Learning Parity with Noise

**Case II:**  $\|f\|_1 \geq 2^{-2n}$ . For every  $a \in A$ , define

$$t(a) = \frac{|\langle M_a, f \rangle|}{\|f\|_1}.$$

By Equation (6),

$$\langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^k < \|f\|_1^k \cdot (1 + 2\varepsilon \cdot t(a))^k \cdot (1 + 2^{-2r+3})^k. \quad (7)$$

Note that by the definitions of  $P$  and  $f$ ,

$$\|f\|_1 = \mathbf{E}_{x' \in_{RA} X} [f(x')] = \langle P, \mathbb{P}_{x|s} \rangle \leq \langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle.$$

Note also that for every  $a \in A$ , there is at most one edge  $e_{(a,1)} \in \Gamma_{out}(v)$ , labeled by  $(a, 1)$ , and at most one edge  $e_{(a,-1)} \in \Gamma_{out}(v)$ , labeled by  $(a, -1)$ , and we have

$$\frac{\Pr(e_{(a,1)})}{\Pr(v)} + \frac{\Pr(e_{(a,-1)})}{\Pr(v)} \leq \frac{1}{|A|},$$

since  $\frac{1}{|A|}$  is the probability that the next sample read by the program is  $a$ . Thus, summing over all  $e \in \Gamma_{out}(v)$ , by Equation (7),

$$\sum_{e \in \Gamma_{out}(v)} \frac{\Pr(e)}{\Pr(v)} \cdot \langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^k < \langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle^k \cdot \mathbf{E}_{a \in_{RA} A} \left[ (1 + 2\varepsilon \cdot t(a))^k \right] \cdot (1 + 2^{-2r+3})^k. \quad (8)$$

It remains to bound

$$\mathbf{E}_{a \in_{RA} A} \left[ (1 + 2\varepsilon \cdot t(a))^k \right], \quad (9)$$

using the properties of the matrix  $M$  and the bounds on the  $\ell_2$  versus  $\ell_1$  norms of  $f$ .

By Equation (5), the assumption that  $\|f\|_1 \geq 2^{-2n}$ , Equation (1) and Equation (2), we get

$$\frac{\|f\|_2}{\|f\|_1} \leq 2^{3\ell+2r+2} \leq 2^{\ell'}.$$

Since  $M$  is a  $(k', \ell')$ - $L_2$ -extractor with error  $2^{-r'}$ , there are at most  $2^{-k'} \cdot |A|$  rows  $a \in A$  with  $t(a) = \frac{|\langle M_a, f \rangle|}{\|f\|_1} \geq 2^{-r'}$ . We bound the expectation in Equation (9), by splitting the expectation into two sums

$$\mathbf{E}_{a \in_{RA} A} \left[ (1 + 2\varepsilon \cdot t(a))^k \right] = \frac{1}{|A|} \cdot \sum_{a : t(a) \leq 2^{-r'}} (1 + 2\varepsilon \cdot t(a))^k + \frac{1}{|A|} \cdot \sum_{a : t(a) > 2^{-r'}} (1 + 2\varepsilon \cdot t(a))^k. \quad (10)$$

We bound the first sum in Equation (10) by  $(1 + 2\varepsilon \cdot 2^{-r'})^k$ . As for the second sum in Equation (10), we know that it is a sum of at most  $2^{-k'} \cdot |A|$  elements, and since for every  $a \in A$ , we have  $t(a) \leq 1$ , we have

$$\frac{1}{|A|} \cdot \sum_{a : t(a) > 2^{-r'}} (1 + 2\varepsilon \cdot t(a))^k \leq 2^{-k'} \cdot (1 + 2\varepsilon)^k \leq 2^{-k'} e^{2\varepsilon k} \leq 2^{-2r}$$

(where in the last inequality we used Equations (1) and (2)). Overall, using Equation (1) again, we get

$$\mathbf{E}_{a \in_{RA} A} \left[ (1 + 2\varepsilon \cdot t(a))^k \right] \leq (1 + 2\varepsilon \cdot 2^{-r'})^k + 2^{-2r} \leq (1 + 2^{-2r})^{k+1}. \quad (11)$$

Substituting Equation (11) into Equation (8), we obtain

$$\begin{aligned} \sum_{e \in \Gamma_{out}(v)} \frac{\Pr(e)}{\Pr(v)} \cdot \langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^k &< \langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle^k \cdot (1 + 2^{-2r})^{k+1} \cdot (1 + 2^{-2r+3})^k \\ &< \langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle^k \cdot (1 + 2^{-r})^k \end{aligned}$$

(where the last inequality uses the assumption that  $r$  is sufficiently large). This completes the proof of Claim 15.  $\triangleleft$

The following three claims use Claim 15 to quantify the progress over the layers and we defer the proofs to Appendix A (proved as in [8]).

▷ **Claim 16.** For every  $i \in \{1, \dots, m\}$ ,

$$\mathcal{Z}'_i \leq \mathcal{Z}_{i-1} \cdot (1 + 2^{-r})^k + (2^{-2n+2})^k.$$

▷ **Claim 17.** For every  $i \in \{1, \dots, m\}$ ,

$$\mathcal{Z}_i \leq \mathcal{Z}'_i.$$

▷ **Claim 18.** For every  $i \in \{1, \dots, m\}$ ,

$$\mathcal{Z}_i \leq 2^{4k+2r} \cdot 2^{-2k \cdot n}.$$

## Proof of Lemma 6

We can now complete the proof of Lemma 6. Assume that  $s$  is in layer- $i$  of  $B$ . By Claim 13,

$$\mathcal{Z}_i \geq \Pr(s) \cdot \langle \mathbb{P}_{x|s}, \mathbb{P}_{x|s} \rangle^k > \Pr(s) \cdot (2^{2\ell} \cdot 2^{-2n})^k = \Pr(s) \cdot 2^{2\ell \cdot k} \cdot 2^{-2k \cdot n}.$$

On the other hand, by Claim 18,

$$\mathcal{Z}_i \leq 2^{4k+2r} \cdot 2^{-2k \cdot n}.$$

Thus, using Equation (1) and Equation (2), we get

$$\Pr(s) \leq 2^{4k+2r} \cdot 2^{-2\ell \cdot k} \leq 2^{\frac{2k'}{\varepsilon}} \cdot 2^{-\frac{\gamma^2 \ln 2}{3\varepsilon} (k' \ell')}.$$

Recall that we assumed that the width of  $B$  is at most  $2^{ck' \ell' / \varepsilon}$  for some constant  $c < \ln 2/3$ , and that the length of  $B$  is at most  $2^r$ . Recall that we fixed  $\gamma$  such that  $\gamma^2(\ln 2)/3 > c$ . Taking a union bound over at most  $2^r \cdot 2^{ck' \ell' / \varepsilon} \leq 2^{k'} \cdot 2^{ck' \ell' / \varepsilon}$  significant vertices of  $B$ , we conclude that the probability that  $\mathcal{T}$  reaches any significant vertex is at most  $2^{-\Omega(k' \ell' / \varepsilon)}$ . Since we assume that  $k'$  and  $\ell'$  are sufficiently large,  $2^{-\Omega(k' \ell' / \varepsilon)}$  is certainly at most  $2^{-k'}$ , which is at most  $2^{-r}$ .  $\triangleleft$

► **Corollary 19.** *Let  $X, A$  be two finite sets. Let  $M : A \times X \rightarrow \{-1, 1\}$  be a matrix. Assume that  $k, \ell, r \in \mathbb{N}$  are large enough and such that any submatrix of  $M$  of at least  $2^{-k} \cdot |A|$  rows and at least  $2^{-\ell} \cdot |X|$  columns, has a bias of at most  $2^{-r}$ .*

*Then, any learning algorithm for the learning problem corresponding to  $M$  with error parameter  $\varepsilon$ , requires either a memory of size at least  $\Omega\left(\frac{k \cdot \ell}{\varepsilon}\right)$ , or at least  $2^{\Omega(r)}$  samples. The result holds even if the learner has an exponentially small success probability (of  $2^{-\Omega(r)}$ ).*

Corollary follows from the equivalence between  $L_2$ -Extractors and  $L_\infty$ -Extractors (up to constant factors) observed in [8].

## A Omitted Proofs from Section 4

**Proof of Claim 7.** Since  $v$  is not significant,

$$\mathbf{E}_{x' \sim \mathbb{P}_{x|v}} [\mathbb{P}_{x|v}(x')] = \sum_{x' \in X} [\mathbb{P}_{x|v}(x')]^2 = 2^n \cdot \mathbf{E}_{x' \in \mathbb{R}X} [\mathbb{P}_{x|v}(x')] \leq 2^{2\ell} \cdot 2^{-n}.$$

Hence, by Markov's inequality,

$$\Pr_{x' \sim \mathbb{P}_{x|v}} [\mathbb{P}_{x|v}(x') > 2^{2r} \cdot 2^{2\ell} \cdot 2^{-n}] \leq 2^{-2r}.$$

Since conditioned on  $E_v$ , the distribution of  $x$  is  $\mathbb{P}_{x|v}$ , we obtain

$$\Pr_x [x \in \text{Sig}(v) \mid E_v] = \Pr_x [(\mathbb{P}_{x|v}(x) > 2^{2r} \cdot 2^{2\ell} \cdot 2^{-n}) \mid E_v] \leq 2^{-2r}. \quad \blacktriangleleft$$

**Proof of Claim 8.** Since  $v$  is not significant,  $\|\mathbb{P}_{x|v}\|_2 \leq 2^\ell \cdot 2^{-n}$ . Since  $\mathbb{P}_{x|v}$  is a distribution,  $\|\mathbb{P}_{x|v}\|_1 = 2^{-n}$ . Thus,

$$\frac{\|\mathbb{P}_{x|v}\|_2}{\|\mathbb{P}_{x|v}\|_1} \leq 2^\ell \leq 2^{\ell'}.$$

Since  $M$  is a  $(k', \ell')$ - $L_2$ -extractor with error  $2^{-r'}$ , there are at most  $2^{-k'} \cdot |A|$  elements  $\alpha \in A$  with

$$|\langle M_\alpha, \mathbb{P}_{x|v} \rangle| \geq 2^{-r'} \cdot \|\mathbb{P}_{x|v}\|_1 = 2^{-r'} \cdot 2^{-n}$$

The claim follows since  $a_{i+1}$  is uniformly distributed over  $A$  and since  $k' \geq 2r$  (Equation (1)).  $\blacktriangleleft$

**Proof of Claim 9.** Since  $v$  is not significant,

$$\mathbf{E}_{x' \in \mathbb{R}X} [\mathbb{P}_{x|v}(x')] \leq 2^{2\ell} \cdot 2^{-2n}.$$

Hence, for every  $x' \in X$ ,

$$\Pr[x = x' \mid E_v] = \mathbb{P}_{x|v}(x') \leq 2^\ell \cdot 2^{-n/2} \leq 2^{-r}$$

since  $r \leq n/2 - \ell$  (Equation (3)). In particular,  $\Pr[\tilde{x}(v) = x \mid E_v] \leq 2^{-r}$ .  $\blacktriangleleft$

## 60:18 Memory-Sample Lower Bounds for Learning Parity with Noise

**Proof of Claim 11.** Let  $e = (v, u)$  be an edge of  $B$ , labeled by  $(a, b)$ , and such that  $\Pr(e) > 0$ . Since  $\Pr(e) > 0$ , the vertex  $v$  is not significant (as otherwise  $\mathcal{T}$  always stops on  $v$  and hence  $\Pr(e) = 0$ ). Thus,

$$\|\mathbb{P}_{x|v}\|_2 \leq 2^\ell \cdot 2^{-n}.$$

By Claim 10, for any  $x' \in X$ ,

$$\mathbb{P}_{x|e}(x') = \begin{cases} 0 & \text{if } x' \in \text{Sig}(v) \\ \mathbb{P}_{x|v}(x')(1 + 2\varepsilon) \cdot c_e^{-1} & \text{if } x' \notin \text{Sig}(v) \text{ and } M(a, x') = b \\ \mathbb{P}_{x|v}(x')(1 - 2\varepsilon) \cdot c_e^{-1} & \text{if } x' \notin \text{Sig}(v) \text{ and } M(a, x') \neq b \end{cases}$$

where  $c_e$  is a normalization factor that satisfies,

$$c_e \geq 1 - 4 \cdot 2^{-2r} > \frac{1}{2}.$$

(where the last inequality holds because we assume that  $k', \ell', r'$  and thus  $r$  are sufficiently large.) Thus,  $\|\mathbb{P}_{x|e}\|_2 \leq c_e^{-1} \cdot (1 + 2\varepsilon) \|\mathbb{P}_{x|v}\|_2 \leq 4 \cdot 2^\ell \cdot 2^{-n}$ . ◀

**Proof of Claim 12.** Let  $\Gamma_{in}(s)$  be the set of all edges  $e$  of  $B$ , that are going into  $s$ , such that  $\Pr(e) > 0$ . Note that

$$\sum_{e \in \Gamma_{in}(s)} \Pr(e) = \Pr(s).$$

By the law of total probability, for every  $x' \in X$ ,

$$\mathbb{P}_{x|s}(x') = \sum_{e \in \Gamma_{in}(s)} \frac{\Pr(e)}{\Pr(s)} \cdot \mathbb{P}_{x|e}(x'),$$

and hence by Jensen's inequality,

$$\mathbb{P}_{x|s}(x')^2 \leq \sum_{e \in \Gamma_{in}(s)} \frac{\Pr(e)}{\Pr(s)} \cdot \mathbb{P}_{x|e}(x')^2.$$

Summing over  $x' \in X$ , we obtain,

$$\|\mathbb{P}_{x|s}\|_2^2 \leq \sum_{e \in \Gamma_{in}(s)} \frac{\Pr(e)}{\Pr(s)} \cdot \|\mathbb{P}_{x|e}\|_2^2.$$

By Claim 11, for any  $e \in \Gamma_{in}(s)$ ,

$$\|\mathbb{P}_{x|e}\|_2^2 \leq (4 \cdot 2^\ell \cdot 2^{-n})^2.$$

Hence,  $\|\mathbb{P}_{x|s}\|_2^2 \leq (4 \cdot 2^\ell \cdot 2^{-n})^2$ . ◀

**Proof of Claim 16.** By Claim 15,

$$\begin{aligned} \mathcal{Z}'_i &= \sum_{e \in \Gamma_i} \Pr(e) \cdot \langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^k = \sum_{v \in L_{i-1}} \Pr(v) \cdot \sum_{e \in \Gamma_{out}(v)} \frac{\Pr(e)}{\Pr(v)} \cdot \langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^k \\ &\leq \sum_{v \in L_{i-1}} \Pr(v) \cdot \left( \langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle^k \cdot (1 + 2^{-r})^k + (2^{-2n+2})^k \right) \\ &= \mathcal{Z}_{i-1} \cdot (1 + 2^{-r})^k + \sum_{v \in L_{i-1}} \Pr(v) \cdot (2^{-2n+2})^k \\ &\leq \mathcal{Z}_{i-1} \cdot (1 + 2^{-r})^k + (2^{-2n+2})^k \end{aligned}$$

◀

**Proof of Claim 17.** For any  $v \in L_i$ , let  $\Gamma_{in}(v)$  be the set of all edges  $e \in \Gamma_i$ , that are going into  $v$ . Note that

$$\sum_{e \in \Gamma_{in}(v)} \Pr(e) = \Pr(v).$$

By the law of total probability, for every  $v \in L_i$  and every  $x' \in X$ ,

$$\mathbb{P}_{x|v}(x') = \sum_{e \in \Gamma_{in}(v)} \frac{\Pr(e)}{\Pr(v)} \cdot \mathbb{P}_{x|e}(x'),$$

and hence

$$\langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle = \sum_{e \in \Gamma_{in}(v)} \frac{\Pr(e)}{\Pr(v)} \cdot \langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle.$$

Thus, by Jensen's inequality,

$$\langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle^k \leq \sum_{e \in \Gamma_{in}(v)} \frac{\Pr(e)}{\Pr(v)} \cdot \langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^k.$$

Summing over all  $v \in L_i$ , we get

$$\begin{aligned} \mathcal{Z}_i &= \sum_{v \in L_i} \Pr(v) \cdot \langle \mathbb{P}_{x|v}, \mathbb{P}_{x|s} \rangle^k \\ &\leq \sum_{v \in L_i} \Pr(v) \cdot \sum_{e \in \Gamma_{in}(v)} \frac{\Pr(e)}{\Pr(v)} \cdot \langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^k \\ &= \sum_{e \in \Gamma_i} \Pr(e) \cdot \langle \mathbb{P}_{x|e}, \mathbb{P}_{x|s} \rangle^k \\ &= \mathcal{Z}'_i. \end{aligned} \quad \blacktriangleleft$$

**Proof of Claim 18.** By Claim 14,  $\mathcal{Z}_0 = (2^{-2n})^k$ . By Claim 16 and Claim 17, for every  $i \in \{1, \dots, m\}$ ,

$$\mathcal{Z}_i \leq \mathcal{Z}_{i-1} \cdot (1 + 2^{-r})^k + (2^{-2n+2})^k.$$

Hence, for every  $i \in \{1, \dots, m\}$ ,

$$\mathcal{Z}_i \leq (2^{-2n+2})^k \cdot (m+1) \cdot (1 + 2^{-r})^{km}.$$

Since  $m = 2^r$ ,

$$\mathcal{Z}_i \leq 2^{-2k \cdot n} \cdot 2^{2k} \cdot (2^r + 1) \cdot e^k \leq 2^{-2k \cdot n} \cdot 2^{4k+2r}. \quad \blacktriangleleft$$

# Testing Hamiltonicity (And Other Problems) in Minor-Free Graphs

## Abstract

In this paper we provide sub-linear algorithms for several fundamental problems in the setting in which the input graph excludes a fixed minor, i.e., is a minor-free graph. In particular, we provide the following algorithms for minor-free unbounded degree graphs.

1. A tester for Hamiltonicity with two-sided error with  $\text{poly}(1/\epsilon)$ -query complexity, where  $\epsilon$  is the proximity parameter.
2. A local algorithm, as defined by Rubinfeld et al. (ICS 2011), for constructing a spanning subgraph with almost minimum weight, specifically, at most a factor  $(1 + \epsilon)$  of the optimum, with  $\text{poly}(1/\epsilon)$ -query complexity.

Both our algorithms use partition oracles, a tool introduced by Hassidim et al. (FOCS 2009), which are oracles that provide access to a partition of the graph such that the number of cut-edges is small and each part of the partition is small. The polynomial dependence in  $1/\epsilon$  of our algorithms is achieved by combining the recent  $\text{poly}(d/\epsilon)$ -query partition oracle of Kumar-Seshadhri-Stolman (ECCC 2021) for minor-free graphs with degree bounded by  $d$ .

For bounded degree minor-free graphs we introduce the notion of *covering partition oracles* which is a relaxed version of partition oracles and design a  $\text{poly}(d/\epsilon)$ -time covering partition oracle for this family of graphs. Using our covering partition oracle we provide the same results as above (except that the tester for Hamiltonicity has one-sided error) for minor-free bounded degree graphs, as well as showing that any property which is monotone and additive (e.g. bipartiteness) can be tested in minor-free graphs by making  $\text{poly}(d/\epsilon)$ -queries.

The benefit of using the covering partition oracle rather than the partition oracle in our algorithms is its simplicity and an improved polynomial dependence in  $1/\epsilon$  in the obtained query complexity.

## 1 Introduction

The family of minor-free graphs has been at the focus of attention ever since the theory of graph minors began many decades ago and has been drawing much attention in the field of computer science as well. Aside from being an important family that includes natural families of graphs such as planar graphs, it also has the appeal that some hard graph problems become easy when restricted to this family of graphs (e.g. Graph Isomorphism [15]).

Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Minor-free graphs have been extensively studied also in the realm of sublinear algorithms and in particular property testing (see e.g. [4, 5, 29, 21, 17, 3, 10, 18, 7, 6, 19, 20]). In particular, in the general-graph model [30] where there is much less body of work, compared to the bounded-degree graph model [11] and the dense graph model [13], these graphs draw attention as they allow for better characterization compared to general unbounded degree graphs. A notable example is the result by Czumaj and Sohler [7] who recently gave a full characterization of properties that can be tested with one-sided error with query complexity that is independent of the size of the graph (i.e. *testable*). They showed that the latter is possible if and only if testing the property can be reduced to testing for a finite family of finite forbidden subgraphs. This raises the question regarding the testability of properties that can not be reduced to testing for a finite family of finite forbidden subgraphs when we allow the tester to have two-sided error. A well known example of such property is the property of being Hamiltonian.

Another question, which is also relevant for bounded degree graphs, is whether we can obtain algorithms with query complexity which is only polynomial in  $1/\epsilon$  where  $\epsilon$  is the proximity parameter. Newman and Sohler [29] showed that any property of bounded degree hyperfinite graphs and in particular minor-free graphs is testable. Their algorithm learns the graph up to modifications of  $\epsilon dn$  edges with query complexity which is super-polynomial in  $d$  and  $\epsilon$ . While this approach works for all properties of graphs, more efficient testers can be obtained for specific properties of graphs. In particular, properties of graphs which are monotone and additive can be tested by using  $O(d/\epsilon)$  queries to a partition oracle, a tool introduced by Hassidim et al. [14]. Thus, an implication of the recent  $\text{poly}(d/\epsilon)$ -query partition oracle of Kumar-Seshadhri-Stolman [20] is that monotone and additive properties are testable with  $\text{poly}(d/\epsilon)$ -queries. Thus the question of designing testers with  $\text{poly}(1/\epsilon)$ -queries remains open for properties which are not monotone or not additive, as the property of being Hamiltonian.

An additional motivation for studying Hamiltonicity in minor-free graphs is, as shown by Yoshida-Ito [33] and Goldreich [12], that it can not be tested with sublinear query complexity in general bounded degree graphs.

## 1.1 Our Results

All our algorithms work under the promise that the input graph is minor-free.

### 1.1.1 Testing Hamiltonicity

In the general graph model, we provide an algorithm for approximating the distance from Hamiltonicity up to an additive error of  $\epsilon n$  where  $n$  denotes the number of vertices in the input graph with query complexity which is  $\text{poly}(1/\epsilon)$  and time complexity which is exponential in  $\text{poly}(1/\epsilon)$ . This also implies a tolerant tester with two-sided error for testing Hamiltonicity with the same complexities.

In the bounded-degree graph model, we provide an algorithm for testing Hamiltonicity with one-sided error with query complexity which is  $\text{poly}(d/\epsilon)$ , where  $d$  denotes the bound on the degree, and time complexity which is exponential in  $\text{poly}(d/\epsilon)$ .

### 1.1.2 Local algorithm for constructing spanning subgraphs of almost optimum weight

In the general graph model, we provide a local algorithm for constructing a sparse spanning subgraph of weight at most  $(1 + \epsilon)\text{OPT}$  where  $\text{OPT}$  denotes the weight of the MST of the input graph. The algorithm receives as parameters  $\epsilon$  and an upper bound,  $W$ , on the maximum weight of an edge in the graph. Moreover, the number of edges of the output graph that do not belong to the MST of the input graph<sup>1</sup> is  $O(\epsilon n/W)$ . The query complexity and time complexity of the algorithm is  $\text{poly}(W/\epsilon)$ . We note that in addition to incidence queries our algorithm also use random neighbour queries.

In the bounded-degree graph model, we provide a simpler algorithm with the same guarantees whose query complexity and time complexity is  $\text{poly}(dW/\epsilon)$ , where the polynomial of the complexity is somewhat improved compared to the algorithm for graphs of unbounded degree.

### 1.1.3 Testing monotone and additive properties of graphs

We prove that any property which is monotone (closed under removal of edges and vertices) and additive (closed under the disjoint union of graphs) can be tested in the bounded degree model with  $\text{poly}(d/\epsilon)$ -query complexity under the promise that the input graph is minor-free. The same result was recently shown independently by Kumar-Seshadhri-Stolman [20]. While in [20] they use partition oracles in the proof, we use a relaxed notion of partition oracles (which we introduce in this paper) and consequently obtain a somewhat improved polynomial dependence in the query complexity and a simpler algorithm.

## 1.2 Our algorithms for minor-free unbounded degree graphs

### 1.2.1 Testing Hamiltonicity

We begin by proving that the distance from Hamiltonicity of any graph  $G = (V, E)$  equals the size of the minimum path cover of  $G$  minus 1, where a path cover of a graph is a set of disjoint paths such that each  $v \in V$  belongs to exactly one path (see Claim 11).

We then prove that if we remove  $O(\epsilon|V|)$  edges from  $G$  as well as edges that are incident to  $O(\epsilon|V|)$  vertices in  $G$  then the distance from Hamiltonicity may be increased by (at most)  $O(\epsilon|V|)$  (see Claims 12 and 13).

Thus, in order to obtain an approximation, with an additive error of  $O(\epsilon|V|)$ , to the size of the minimum path cover of  $G$  (and hence to its distance from Hamiltonicity) it suffices to obtain such approximation to the size of the minimum path cover of  $\hat{G}$  where  $\hat{G}$  is defined as follows. We obtain  $\hat{G}$  from  $G$  by first removing the edges incident to vertices of high degree, which we refer to as *heavy* vertices, then running the partition oracle on the resulting graph and then removing the cut-edges of the partition. An approximation to the size of the minimum path cover of  $\hat{G}$  can be obtained by sampling vertices u.a.r. from  $V$  and computing the size of the minimum path cover of their connected component in  $\hat{G}$ .

Since we obtain an approximation algorithm for the distance from being Hamiltonian we also obtain a tolerant tester with two-sided error for this property.

<sup>1</sup> Without loss of generality we assume that the weights of the edges are distinct and hence that there is a unique MST.

### 1.2.2 Constructing spanning subgraphs with almost optimum weight

We present our algorithm as a global algorithm and prove its correctness. Thereafter, we describe the local implementation of this global algorithm.

Our global algorithm proceeds as follows. In the first step, the algorithm adds all the edges between *heavy* vertices to the edges of the constructed spanning subgraph,  $E'$ , where a heavy vertex is defined to be a vertex of degree greater than some threshold.

It then runs the partition oracle on the graph induced on the vertices that are not heavy, i.e., *light* vertices and adds all the cut-edges of the partition to  $E'$ .

In the second step, each part of the partition is partitioned into subparts by running a controlled variant of Borůvka's algorithm for finding an MST on each part independently. The edges spanning the sub-parts are then added to  $E'$ . Then, for each each sub-part, the algorithm adds a single edge to a single heavy vertex which is adjacent to the sub-part (assuming there is one).

We prove that all the edges added in the second step belong to the minimum spanning forest (MSF) of a graph which is  $O(\epsilon/W_G)$ -close to  $G$ , where  $W_G$  denotes the maximum weight of an edge in  $G$ . Additionally we prove that if we remove  $O(\epsilon|V|/W_G)$  edges from  $G$ , then the weight of the minimum spanning forest (MSF) may increase by (at most)  $O(\epsilon|V|)$ .

The second step partitions the vertices of the graph into *clusters* and *isolated parts*, where isolated parts are parts that are not adjacent to any heavy vertex, and the clusters are defined as follows. Each cluster contains a single heavy vertex, which we refer to as the *center* of the cluster and sub-parts that are adjacent in the constructed graph to the center (each sub-part is adjacent to at most a single center).

In the third step the algorithm adds edges to  $E'$  between pairs of cluster that are adjacent to each other. For every edge  $\{u, v\}$  which is adjacent to two different clusters,  $A$  and  $B$ , the algorithm runs another algorithm that samples edges incident to  $A$  and  $B$  and returns the lightest one. The edge  $\{u, v\}$  is added to  $E'$  if it is lighter than the returned edge.

We note that the algorithm that samples edges incident to a pair of specific clusters,  $A$  and  $B$  may not sample sufficient number of edges or may not return any edge (this is likely when the degree of both centers is large compared to the number of edges which are incident to both  $A$  and  $B$ ). In the analysis which is adapted from [28], we show that nonetheless, w.h.p. the number of edges added in the third step is sufficiently small. The main idea is to consider the graph in which each cluster is contracted into a single vertex and then to analyse the sampling algorithm with respect to this graph which is also minor-free and hence has bounded arboricity<sup>2</sup>. The bounded arboricity of the contracted graph ensures that w.h.p. the sampling algorithm samples enough edges which are incident to  $A$  and  $B$  as long as the cut between these clusters is sufficiently large. On the other hand, if this is not the case then we show that we can afford to add to  $E'$  all the edges in the cut.

The local implementation of the above-mention global algorithm is quite straightforward and is presented in Section B.7.

## 1.3 Our algorithms for minor-free bounded degree graphs

### 1.3.1 Covering partition oracles

We introduce a relaxed version of partition oracles which we call *covering partition oracles* and design such an oracle for minor-free graphs with query complexity  $\text{poly}(d/\epsilon)$ . Given query access to a graph  $G = (V, E)$  and parameter  $\epsilon$  a partition oracle provides access to

---

<sup>2</sup> The arboricity of a graph is the minimum number of forests into which its edges can be partitioned.

a partition of  $V$ ,  $\mathcal{P}$ , such that the size of each part of  $\mathcal{P}$  is small (usually  $\text{poly}(1/\epsilon)$ ), the number of cut-edges of  $\mathcal{P}$  is at most  $\epsilon|V|$  (w.h.p.) and  $\mathcal{P}$  is determined only by  $G$  and the randomness of the oracle. On query  $v \in V$  the oracle returns the part of  $v$  in  $\mathcal{P}$ .

A covering partition oracle has the same guarantees only that the requirement to return the part of  $v$  on query  $v \in V$  is relaxed as follows. On query  $v \in V$  the oracle is required to return a (small) subset  $S$  such that  $S$  contains the part of  $v$  in  $\mathcal{P}$ .

Our covering partition oracle builds on a central theorem from the recent work of [19]. The theorem states that for any minor-free bounded degree graph there exists a partition of the graph into small parts with small number of cut-edges such that for each part of the partition,  $P$ , there exists a vertex,  $s \in V$ , such that if we perform sufficiently many (polynomial in  $1/\epsilon$ ) lazy random walks from  $s$  then w.h.p. we encounter all the vertices in  $P$ . Building on this theorem we prove that the simple algorithm that on query  $v \in V$  performs a set of lazy random walks from  $v$  (of different lengths) and then performs a set of lazy random walks from each endpoint of these walks is a covering partition oracle.

The algorithms described in Subsections 1.3.2-1.3.4, use our covering partition oracle.

We note that since a partition oracle is a special case of a covering partition oracle (with stronger guarantees) all our algorithms for bounded degree graphs also work when one replaces calls to the covering partition oracle by calls to a partition oracle.

As mentioned above, the use of covering partition oracles has two benefits. The first benefit is that the implementation of the covering partition oracles is much simpler and the second benefit is that the query complexity per oracle query is better (though both our covering partition oracle and the partition oracle of [20] have query complexity which is  $\text{poly}(d/\epsilon)$ ), which consequently affects the query complexity of the algorithms.

Another conceptual benefit in introducing covering partition oracles is that for some families of graphs the gap in the query complexity can be more dramatic. To give a concrete example consider  $(\epsilon, \rho(\epsilon))$ -hyperfinite graphs<sup>3</sup>. It is straightforward to obtain a covering partition oracle with query complexity  $O(d^{\rho(\epsilon)})$  for this family of graphs while the best known partition oracle for this family has query complexity which is  $O(2^{d^{\rho(c\epsilon^3)}})$  [14], where  $c$  is some constant. We note that all our algorithms for bounded degree graphs work for any family of graphs for which there is a covering partition oracle (including  $(\epsilon, \rho(\epsilon))$ -hyperfinite graphs).

### 1.3.2 Testing Hamiltonicity

In addition to relating the distance from Hamiltonicity of any graph  $G = (V, E)$  to the size of its minimum path cover, as mentioned above, we also prove that given a subset  $S \subset V$ , if the size of the minimum path cover of  $G[S]$  is greater than the number of edges in the cut of  $S$  and  $V \setminus S$  then  $G$  is not Hamiltonian. Using this claim it becomes straightforward to design a one-sided error tester for Hamiltonicity that uses  $O(1/\epsilon)$  queries to a partition oracle. We prove that it suffices to use the same number of queries to the covering partition oracle. We note that in this case there is a trade-off between the query complexity and time complexity. In particular while using the covering partition oracle rather than the partition oracle results in a better polynomial dependence of the query complexity it also results in a worse polynomial dependence in the exponent of the running time (in both cases the running time is exponential in  $\epsilon^{-1}$  since we find the size of the minimum path cover by brute force<sup>4</sup>).

<sup>3</sup> Let  $\rho$  be a function from  $\mathbb{R}_+$  to  $\mathbb{R}_+$ . A graph  $G = (V, E)$  is  $(\epsilon, \rho(\epsilon))$ -hyperfinite if for every  $\epsilon > 0$  it is possible to remove  $\epsilon|V|$  edges of the graph such that the remaining graph has connected components of size at most  $\rho(\epsilon)$ .

<sup>4</sup> Finding the minimum path cover is APX-hard since (as noted by Chandra Chekuri at stackexchange.com [16]) we can reduce the TSP-path problem in metrics with distances 1 and 2 to it. The latter problem is APX-hard [9]).

### 1.3.3 Constructing spanning subgraphs with almost optimum weight

As mentioned-above, given a weighted graph  $G = (V, E, w)$  if we remove  $O(\epsilon|V|/W_G)$  edges from  $G$  then the weight of the MSF of the resulting graph may increase by at most  $O(\epsilon|V|)$  compared to the weight of  $G$ . Thus given access to a partition of  $V$  such that the subgraph induced on each part is connected and the number of cut-edges is  $O(\epsilon|V|/W_G)$  we can proceed as follows. For each part of the partition we add to  $E'$  the edges of the MST of the subgraph induced on this part. In addition, we add to  $E'$  the cut-edges of the partition. Consequently, the total weight of the edges in  $E'$  is greater than the weight of the MST of  $G$  by at most  $O(\epsilon|V|/W_G)$ . Hence, if on query  $\{u, v\}$  we query the partition oracle on  $u$  and  $v$  then it is possible to determine whether  $\{u, v\} \in E'$  where  $E'$  is constructed as described above with respect to the partition of the oracle. We prove that the same approach works when we preform the same queries to the covering partition oracle.

### 1.3.4 Testing monotone and additive properties

One of the main applications of the partition oracle is a general reduction for testing monotone and additive properties of bounded degree minor-free graphs. The idea of the reduction (from testing to the partition oracle) is to sample  $O(d/\epsilon)$  vertices and for each vertex  $v$  in the sample to test whether the subgraph induced on the part of  $v$  has the properties. The tester accepts iff all sampled parts pass the test. We prove that the same reduction works when we replace the queries to the partition oracle by queries to the covering partition oracle.

## 1.4 Organization

Due to space limitations, an extended section on related work as well as omitted proofs and details of Section 3 appear in the appendix.

## 2 Preliminaries

In this section we introduce several definitions and some known results that will be used in the following sections. Unless stated explicitly otherwise, we consider simple graphs, that is, with no self-loops and no parallel edges.

Let  $G = (V, E)$  be a graph over  $n$  vertices. Each vertex  $v \in V$  has an id,  $id(v)$ , where there is a full order over the ids.

The total order over the vertices induces a total order (ranking)  $\rho$  over the edges of the graph in the following straightforward manner:  $\rho((u, v)) < \rho((u', v))$  if and only if  $\min\{u, v\} < \min\{u', v'\}$  or  $\min\{u, v\} = \min\{u', v'\}$  and  $\max\{u, v\} < \max\{u', v'\}$  (recall that  $V = [n]$ ). Thus, given a weighted graph, we may assume without loss of the generality that the weights of the edges are unique by breaking ties according to the order over the edges.

For a subset of vertices  $X$ , we let  $G[X]$  denote the subgraph of  $G$  induced by  $X$ .

When we consider bounded degree graphs, we consider the bounded-degree graph model [11]. The graphs we consider have a known degree bound  $d$ , and we assume we have query access to their incidence-lists representation. Namely, for any vertex  $v$  and index  $1 \leq i \leq d$  it is possible to obtain the  $i^{\text{th}}$  neighbor of  $v$  (where if  $v$  has less than  $i$  neighbors, then a special symbol is returned). If the graph is edge-weighted, then the weight of the edge is returned as well. When we consider graphs with unbounded degree we consider the general graph model [30] equipped with an additional type of query: random neighbor query. Namely, when we query any given vertex  $v$  a random neighbor of  $v$  is returned <sup>5</sup>.

<sup>5</sup> We note that we do not use the random neighbor query in our tester for Hamiltonicity.

For a graph  $G = (V, E)$  and two sets of vertices  $V_1, V_2 \subseteq V$ , we let  $E^G(V_1, V_2)$  denote the set of edges in  $G$  with one endpoint in  $V_1$  and one endpoint in  $V_2$ . That is  $E(V_1, V_2) \stackrel{\text{def}}{=} \{(v_1, v_2) \in E : v_1 \in V_1, v_2 \in V_2\}$ . If  $G$  is clear from the context we may omit it from the notation.

A tester with two-sided error for a property  $\mathcal{P}$  receives a parameter  $\epsilon$  and query access to a graph  $G = (V, E)$  and has the following guarantees. If  $G \in \mathcal{P}$  then the tester accepts with probability at least  $2/3$ . If  $G$  is  $\epsilon$ -far<sup>6</sup> from  $\mathcal{P}$  then the tester rejects with probability at least  $2/3$ . A tester with one-sided error accepts  $G \in \mathcal{P}$  with probability 1.

## 2.1 Partition oracles and covering partition oracles

► **Definition 1.** For  $\epsilon \in (0, 1]$ ,  $k \geq 1$  and a graph  $G = (V, E)$ , we say that a partition  $\mathcal{P} = (V_1, \dots, V_t)$  of  $V$  is an  $(\epsilon, k)$ -partition (w.r.t.  $G$ ), if the following conditions hold:

1. For every  $1 \leq i \leq t$  it holds that  $|V_i| \leq k$ ;
2. For every  $1 \leq i \leq t$  the subgraph induced by  $V_i$  in  $G$  is connected;
3. The total number of edges whose endpoints are in different parts of the partition is at most  $\epsilon|V|$  (that is,  $|\{(v_i, v_j) \in E : v_i \in V_j, v_j \in V_j, i \neq j\}| \leq \epsilon|V|$ ).

Let  $G = (V, E)$  be a graph and let  $\mathcal{P}$  be a partition of  $V$ . We denote by  $g_{\mathcal{P}}$  the function from  $v \in V$  to  $2^V$  (the set of all subsets of  $V$ ), that on input  $v \in V$ , returns the subset  $V_{\ell} \in \mathcal{P}$  such that  $v \in V_{\ell}$ . We denote the set of cut-edges of  $\mathcal{P}$  by  $E_{\mathcal{P}}^G = \{(u, v) \in E : g_{\mathcal{P}}(v) \neq g_{\mathcal{P}}(u)\}$  (we may omit  $G$  from the notation when it is clear from the context).

► **Definition 2** ([14]). An oracle  $\mathcal{O}$  is a partition oracle if, given query access to the incidence-lists representation of a graph  $G = (V, E)$ , the oracle  $\mathcal{O}$  provides query access to a partition  $\mathcal{P} = (V_1, \dots, V_t)$  of  $V$ , where  $\mathcal{P}$  is determined by  $G$  and the internal randomness of the oracle. Namely, on input  $v \in V$ , the oracle returns  $g_{\mathcal{P}}(v)$  and for any sequence of queries,  $\mathcal{O}$  answers consistently with the same  $\mathcal{P}$ . An oracle  $\mathcal{O}$  is an  $(\epsilon, k)$ -partition oracle with respect to a class of graphs  $\mathcal{C}$  if the partition  $\mathcal{P}$  it answers according to has the following properties.

1. For every  $V_{\ell} \in \mathcal{P}$ ,  $|V_{\ell}| \leq k$  and the subgraph induced by  $V_{\ell}$  in  $G$  is connected.
2. If  $G$  belongs to  $\mathcal{C}$ , then  $|E_{\mathcal{P}}| \leq \epsilon|V|$  with high constant probability, where the probability is taken over the internal coin flips of  $\mathcal{O}$ .

We consider the following relaxation of Definition 2.

► **Definition 3.** An oracle  $\mathcal{O}$  is a covering partition oracle if, given query access to the incidence-lists representation of a graph  $G = (V, E)$ , the oracle  $\mathcal{O}$ , on input  $v \in V$ , returns a subset  $S \subseteq V$  such that  $g_{\mathcal{P}}(v) \subseteq S$  where  $\mathcal{P}$  is a partition of  $V$  determined by  $G$  and the internal randomness of the oracle. For any sequence of queries,  $\mathcal{O}$  answers consistently according to the same  $\mathcal{P}$ . An oracle  $\mathcal{O}$  is an  $(\epsilon, k)$ -covering partition oracle with respect to a class of graphs  $\mathcal{C}$  if the following conditions hold.

1. On every query, the subgraph induced by the subset returned by  $\mathcal{O}$ ,  $S$ , is connected and  $|S| \leq k$ .
2. If  $G$  belongs to  $\mathcal{C}$ , then w.h.p.,  $|E_{\mathcal{P}}| \leq \epsilon|V|$ , where the probability is taken over the internal coin flips of  $\mathcal{O}$ .

<sup>6</sup> In the bounded degree model, a graph  $G = (V, E)$  is said to be  $\epsilon$ -far from a property  $\mathcal{P}$  if for every graph  $G' = (V, E') \in \mathcal{P}$  of maximum degree  $d$  it holds that the symmetric difference between  $E$  and  $E'$  has cardinality which is greater than  $\epsilon \cdot d|V|/2$ . In the general graph model, a graph  $G = (V, E)$  is said to be  $\epsilon$ -far from a property  $\mathcal{P}$  if for every graph  $G' = (V, E') \in \mathcal{P}$  it holds that the symmetric difference between  $E$  and  $E'$  has cardinality which is greater than  $\epsilon \cdot \max\{|E|, |E'|\}$ .

## 2.2 Graph minors

Recall that a graph  $R$  is called a *minor* of a graph  $G$  if  $R$  is isomorphic to a graph that can be obtained by zero or more edge contractions on a subgraph of  $G$ . A graph  $G$  is  *$R$ -minor-free* if  $R$  is not a minor of  $G$ . We next quote two results that will play a central role in this work.

► **Fact 4.** *Let  $R$  be a fixed graph with  $r$  edges. For every  $R$ -minor-free graph  $G = (V, E)$  it holds that:*

1.  $|E| \leq r \cdot |V|$ ;
2.  $E$  can be partitioned into at most  $r$  forests.

Unless stated otherwise, in all our algorithms, we assume that the input graph is  $R$ -minor-free graph where  $R$  is a fixed graph with  $r$  edges (we could receive  $r$  as a parameter but we make this assumption for the sake of brevity).

## 2.3 Hamiltonian path and minimum path cover

► **Definition 5** (Hamiltonian path). *A Hamiltonian path in  $G = (V, E)$  is a path between two vertices of  $G$  that visits each vertex of  $G$  exactly once.*

► **Definition 6** (minimum path cover). *Given an undirected graph  $G = (V, E)$ , a path cover is a set of disjoint paths such that every vertex  $v \in V$  belongs to exactly one path. The minimum path cover of  $G$  is a path cover of  $G$  having the least number of paths.*

## 2.4 Local algorithms for constructing sparse spanning subgraphs

► **Definition 7** ([28]). *An algorithm  $\mathcal{A}$  is a local sparse spanning graph (LSSG) algorithm if, given  $n \geq 1$ ,  $\epsilon > 0$ , and query access to the incidence-lists representation of a connected graph  $G = (V, E)$  over  $n$  vertices, it provides oracle access to a subgraph  $G' = (V, E')$  of  $G$  such that:*

1.  $G'$  is connected.
2.  $|E'| \leq (1 + \epsilon) \cdot n$  with high constant probability<sup>7</sup>, where  $E'$  is determined by  $G$  and the internal randomness of  $\mathcal{A}$ .

More specifically, on query  $u, v \in E$ ,  $\mathcal{A}$  returns whether  $(u, v) \in E'$ , and for any sequence of edges,  $\mathcal{A}$  answers consistently with the same  $G'$ .

An algorithm  $\mathcal{A}$  is an LSSG algorithm for a family of graphs  $\mathcal{C}$  if the above conditions hold, provided that the input graph  $G$  belongs to  $\mathcal{C}$ .

► **Definition 8** ([26]). *A local algorithm for  $(1 + \epsilon)$ -approximating the minimum weight spanning graph of a graph  $G = (V, E, w)$  with positive weights and  $\min_{e \in E} w(e) \geq 1$ , is a local algorithm for  $(1 + \epsilon)$ -sparse spanning graph of  $G = (V, E, w)$  for which the following holds:  $\sum_{e \in E'} w(e) \leq (1 + \epsilon)\alpha$ , where  $\alpha$  is the weight of a minimum weight spanning tree of  $G$ .*

For a graph  $G = (V, E, w)$  we define  $W_G = \max_{e \in E} w(e)$  (when it is clear from the context, we sometimes omit the subscript  $G$ ). We denote by  $\text{MSF}(G)$  the set of edges the minimum-spanning-forest of  $G$  (as mentioned above we assume without loss of generality that all weights are distinct and thus the minimum-spanning-forest is unique). For a connect weighted graph we denote by  $\text{MST}(G)$  the set of edges the minimum-spanning-forest of  $G$ . For a subset of edges  $S \subseteq E$ , we define  $w(S) \stackrel{\text{def}}{=} \sum_{e \in S} w(e)$ .

<sup>7</sup> In some papers the required success probability is high, i.e. at least  $1 - 1/\Omega(n)$ .

Our algorithms build on the following rules.

1. The *cut rule* states that for any cut of the graph (a cut is a partition of the vertices into two sets), the lightest edge that crosses the cut must be in the MST.
2. The *cycle rule* states that if we have a cycle, the heaviest edge on that cycle cannot be in the MST.

### 3 Algorithms for minor-free graphs with unbounded degrees

#### 3.1 Testing Hamiltonicity

In this section we prove the following Theorem.

► **Theorem 9.** *Given query access to an input graph  $G = (V, E)$  where  $G$  is a minor-free unbounded degree graph and parameters  $\epsilon$  and  $|V|$ , there exists an algorithm that accepts  $G$  with probability at least  $2/3$  if  $G$  is  $\epsilon/2$ -close to being Hamiltonian and rejects  $G$  with probability at least  $2/3$  if  $G$  is  $\epsilon$ -far from being Hamiltonian. The query complexity of the algorithm is  $\text{poly}(1/\epsilon)$  and the running time is exponential in  $\text{poly}(1/\epsilon)$ .*

Theorem 9 is a direct consequence of following claim (which is proved in the sequel).

▷ **Claim 10.** Given an input graph  $G = (V, E)$  which is a minor-free graph, and parameter  $\epsilon$ , Algorithm 1 outputs a value  $x$  such that with high constant probability  $\delta_{\text{HAM}}(G) - \epsilon|V| \leq x \leq \delta_{\text{HAM}}(G) + \epsilon|V|$ .

We next state a couple of claims which we use in the proof of Claim 10.

▷ **Claim 11.** Let  $G = (V, E)$  be a graph and let  $k$  be the size of a minimum path cover of  $G$ . Then the distance of  $G$  for being Hamiltonian,  $\delta_{\text{HAM}}(G)$ , is  $k - 1$ .

▷ **Claim 12.** Let  $G = (V, E)$  be a graph and let  $F \subseteq E$  be a subset of edges. Then

$$\delta_{\text{HAM}}(G) \leq \delta_{\text{HAM}}(G') \leq \delta_{\text{HAM}}(G) + |F|,$$

where  $G' = (V, E')$  and  $E' = E \setminus F$ .

▷ **Claim 13.** Let  $G = (V, E)$  be a graph and let  $S \subseteq V$  be a subset of vertices. Then

$$\delta_{\text{HAM}}(G) \leq \delta_{\text{HAM}}(G') \leq \delta_{\text{HAM}}(G) + 2|S|,$$

where  $G' = (V, E')$  and  $E'$  is the set of edges in  $E$  that are not incident to vertices in  $S$ .

Proof of Claim 10. Let  $\mathcal{P}$  denote the partition for which the partition oracle executed in Step 3(a)i answers according to. With high constant probability  $|E_{\mathcal{P}}| \leq \frac{\epsilon|V|}{4}$ . Let  $E_1$  denote this event.

Let  $G' = (V, E')$  be the graph such that  $E'$  is the set of edges that are not incident to vertices in  $H$  and are not in  $E_{\mathcal{P}}$ . By Claims 12 and 13,

$$\delta_{\text{HAM}}(G) \leq \delta_{\text{HAM}}(G') \leq \delta_{\text{HAM}}(G) + |E_{\mathcal{P}}| + 2|H|.$$

By Markov's inequality and Fact 4,  $|H| \leq \frac{\epsilon|V|}{4}$ . We prove that, conditioned that  $E_1$  occurs, Algorithm 1 outputs with high constant probability a  $(1 + \epsilon)$ -approximation to  $\delta_{\text{HAM}}(G')$ .

For each  $v \in V$  define the random variable  $x_v$  as defined in Step 3 of Algorithm 1. Let  $T \in \mathcal{P}$  be a part in  $\mathcal{P}$ , then  $\sum_{v \in T} x_v = k$  where  $k$  is the minimum path cover of  $G[T]$ . Thus  $\sum_{v \in V} x_v$  is the minimum path cover of  $G'$ . Since for every  $v \in V$ ,  $x_v \in (0, 1]$ , it follows by

## 61:10 Testing Hamiltonicity (And Other Problems) in Minor-Free Graphs

■ **Algorithm 1** Approximating the distance to Hamiltonicity in minor-free, unbounded degree, graphs.

**Input:** Oracle access to a minor-free, unbounded-degree, graph  $G = (V, E)$

**Output:**  $(1 + \epsilon)$ -approximation to  $\delta_{\text{HAM}}(G)$

1. Define  $\Delta \stackrel{\text{def}}{=} 8c(h)/\epsilon$ ,  $H$  to be the set of vertices of degree greater than  $\Delta$ , and  $L \stackrel{\text{def}}{=} V \setminus H$ .
2. Sample a set  $S$  of  $y = \Theta(1/\epsilon^2)$  vertices u.a.r.
3. For each vertex  $v \in S$ :
  - a. If  $v \in L$  then:
    - i. Query the partition oracle on  $v$  with parameter  $\epsilon/4$  w.r.t. the graph  $G[L]$ .  
Let  $S_v$  denote the returned set.
    - ii. Set  $x_v = k/|S_v|$  where  $k$  is the size of the minimum path cover of  $G[S_v]$ .
  - b. Otherwise, set  $x_v = 1$ .
4. Output  $\frac{\sum_{v \in S} x_v}{|S|} \cdot |V|$ .

the additive Chernoff's bound that with high constant probability  $\left| \frac{\sum_{v \in S} x_v}{|S|} - \frac{\sum_{v \in V} x_v}{|V|} \right| \leq \frac{\epsilon}{4}$ .  
Thus, with high constant probability,

$$\delta_{\text{HAM}}(G) - \frac{\epsilon|V|}{4} \leq \frac{\sum_{v \in S} x_v}{|S|} \cdot |V| \leq \delta_{\text{HAM}}(G) + \epsilon|V|,$$

as desired. ◁

### 3.2 A Local algorithm for constructing a spanning subgraph with almost optimum weight

In this section we prove the following theorem.

► **Theorem 14.** *There exists a local algorithm for  $(1 + \epsilon)$ -approximating the minimum weight spanning graph for the family of unbounded degree minor-free graphs, with positive weights and minimum weight which is at least 1. The query complexity and time complexity of the algorithm is  $\text{poly}(W/\epsilon)$  where  $W$  is an upper bound on the maximum weight. The algorithm receives  $\epsilon$  and  $W$  as parameters.*

▷ **Claim 15.** Let  $G = (V, E, w)$  be a weighted graph and let  $G' = (V, E', w)$  be a graph such that  $E' = E \setminus S$  where  $S \subseteq E$ . Then  $w(\text{MSF}(G')) \leq w(\text{MSF}(G)) + |S|W_G$ . Moreover,  $|\text{MSF}(G') \setminus \text{MSF}(G)| \leq |S|$ .

We next describe our algorithm from a global point of view.

#### 3.2.1 The global algorithm

Our global algorithm, which is listed in Algorithm 2, proceeds as follows. In Step 2, the algorithm adds all the edges between *heavy* vertices to  $E'$  where a heavy vertex is defined to be a vertex of degree greater than  $\Delta \stackrel{\text{def}}{=} 6r^2W/\epsilon$ .

It then runs the partition oracle on the graph induced on the *light* vertices, namely vertices that are not heavy, and adds all the cut-edges of the partition,  $\mathcal{P}$ , to  $E'$  (Step 4).

■ **Algorithm 2** Global algorithm for approximated-MST in unbounded-degree minor-free graphs.

**Input:** parameters  $\epsilon$  and  $W$  and access to a minor-free graph  $G = (V, E)$ .

**Output:**  $G = (V, E')$  which is an approximated-MST of  $G$ .

1. Let  $H$  denote the set of all vertices of degree greater than  $\Delta$  and let  $L = V \setminus H$ .
2. Add all the edges of  $G[H]$  to  $E'$ .
3. Run the partition oracle with parameter  $\epsilon/(6W)$  on all vertices in  $G[L]$ . Let  $\mathcal{P}$  denote the resulting partition.
4. Add all the edges in  $E_{\mathcal{P}}$  to  $E'$ .
5. For each  $S \in \mathcal{P}$ :
  - a. Run Algorithm 4 and let  $F = (S, A)$  denote the returned graph.
  - b. Add the edges in  $A$  to  $E'$ .
  - c. For each connected component of  $F$ ,  $C$ :
    - i. Add to  $E'$  the lightest edges which is adjacent to  $C$  and  $H$  (if such edge exists).
6. For each  $v \in H$ , define the *cluster* of  $v$ , denoted by  $\mathcal{C}(v)$ , to be subset of vertices that contains  $v$  and all the vertices in sub-parts  $B$  such that there exists an edge in  $E'$  that is incident to  $v$  and a vertex in  $B$ .  $v$  is referred to as the *center* of the cluster.
7. For each edges  $\{u, v\} \in E$  such that  $u$  and  $v$  belong to different clusters:
  - a. Run Algorithm 3 and add  $\{u, v\}$  to  $E'$  if it is lighter than the edge returned by the algorithm or if it returned null.
8. Return  $G' = (V, E')$ .

Step 5 consists of two parts. In Sub-step 5a the algorithm runs Algorithm 4 on each part in  $\mathcal{P}$ . Algorithm 4 partitions the parts into connected sub-parts by performing a controlled variant of Borůvka's algorithm. The edges added in Sub-step 5a are the edges that span the sub-parts. In Sub-step 5c, for each sub-part, the algorithm adds a single edge to a single vertex in  $H$  which is adjacent to the sub-part (assuming there is one).

This partitions the vertices of the graph into *clusters* and *isolated parts*, namely, parts in  $\mathcal{P}$  that are not adjacent to any vertex in  $H$ . Each cluster contains a single heavy vertex, which we refer to as the *center* of the cluster and sub-parts that are connected by a single edge to the center.

In Step 7 the algorithm adds edges to  $E'$  between pairs of clusters that are adjacent to each other in  $G' = (V, E \setminus E_{\mathcal{P}})$ . For every edge  $\{u, v\}$  which is adjacent to two different clusters,  $A$  and  $B$ , the algorithm runs Algorithm 3 which samples edges incident to  $A$  and  $B$  and returns the lightest one. The edge  $\{u, v\}$  is added to  $E'$  if it is lighter than the edge returned by Algorithm 3 (or if the algorithm returned null).

We note that we do not have direct access to uniform samples of edges incident to a pair of specific clusters,  $A$  and  $B$ . In fact, it could be the case that Algorithm 3 does not return any edge (this is likely when the degree of both centers is large compared to the number of edges which are incident to both  $A$  and  $B$ ). By adapting the analysis in [28], we show that nonetheless, w.h.p. the number of edges added in Step 7 is sufficiently small.

This concludes the description of the global algorithm. The proof of correctness as well as the local implementation (Algorithm 8) are deferred to the appendix.

## 61:12 Testing Hamiltonicity (And Other Problems) in Minor-Free Graphs

■ **Algorithm 3** Return sampled lightest edge.

**Input:**  $a \in H$  and  $b \in H$ .

**Output:** The sampled lightest edge between  $\mathcal{C}(a)$  and  $\mathcal{C}(b)$

1. Initially  $A = \emptyset$  and let  $x$  be an upper bound on the size of the parts returned by the partition oracle when executed with parameter  $\epsilon/(6W)$ .
2. Sample a set,  $S$ , of  $\tilde{\Theta}(W^2 r^3 x \Delta / \epsilon^2)$  edges incident to  $a$ .
3. For each  $\{a, u\} \in S$  do:
  - a. If  $u \in H$  then add it to  $A$  if and only if  $u = b$ .
  - b. Otherwise, find the part of  $u$  and the sub-parts of this part.
  - c. For each sub-part find its center.
  - d. Add to  $A$  all the edges between the sub-part of  $u$  and sub-parts that belong to  $\mathcal{C}(b)$ .
4. Repeat Steps 2-3 where  $a$  and  $b$  switch roles.
5. Return the lightest edge in  $A$  (if  $A = \emptyset$  then return null).

■ **Algorithm 4** Partition into sub-parts.

**Input:** Access to the input graph  $G = (V, E)$  and a subset  $S \subseteq L$  such that  $G[S]$  is connected.

**Output:** A graph  $F = (S, A)$  such that each connected component of  $F$  is a sub-part of  $S$

1. Initially every vertex in  $S$  is in its own sub-part (a singleton) and  $A = \emptyset$ .
2. We say a sub-part  $B$  is *active* if the lightest in  $E^G(B, S \setminus B)$  is lighter than the lightest edge in  $E^G(B, H)$  or if  $E^G(B, H) = \emptyset$ .
3. While there are still active sub-parts do:
  - a. Each active sub-part  $B$  selects the lightest edge in  $E^G(B, S \setminus B)$ , denoted by  $e_B$ .
  - b. For each active sub-part,  $B$ , add  $e_B$  to  $A$
  - c. Update the new sub-parts to be the connected components of the graph  $F = (S, A)$  (each connected component is a sub-part).
4. Return  $F$ .

## 4 Algorithms for minor-free graphs with bounded degrees

### 4.1 Covering partition oracle

In this section we prove the following theorem.

► **Theorem 16.** *Algorithm 5 is an  $(\epsilon, \text{poly}(\epsilon^{-1}))$ -covering-partition oracle for minor-free bounded degree graphs with query complexity  $\text{poly}(\epsilon^{-1})$ . Specifically, the size of the sets returned by the oracle is  $O(\epsilon^{-640} \log^2(1/\epsilon))$ .*

We begin with a couple of definitions and lemmas from [20] that we build on.

► **Definition 17** ([20]). *Given  $\mathbf{x} \in (\mathbb{R}^+)^{|V|}$  and parameter  $\xi \in [0, 1]$ , the  $\xi$ -clipped vector  $\text{cl}(\mathbf{x}, \xi)$  is the lexicographically least vector  $\mathbf{y}$  optimizing the program:  $\min \|\mathbf{y}\|_2$ , subject to  $\|\mathbf{x} - \mathbf{y}\|_1 \leq \xi$  and  $\forall v \in V, \mathbf{y}(v) \leq \mathbf{x}(v)$ .*

► **Lemma 18** ([20]). *There is an absolute constant  $\alpha$  such that the following holds. Let  $H$  be a graph on  $r$  vertices. Suppose  $G$  is a  $H$ -minor-free graph. Then for any  $h \geq \alpha r^3$ , there exists at least  $(1 - 1/h)n$  vertices such that  $\|\text{cl}(\mathbf{p}_{v,\ell}, 3/8)\|_2^2 \geq h^{-7}$ .*

Given two parameters  $\epsilon \in [0, 1/2]$ , and a graph  $R$  on  $r \geq 3$  vertices. The length of the random walk is  $\ell = \alpha r^3 + \lceil \epsilon^{-20} \rceil$  where  $\alpha$  is some absolute constant.

► **Theorem 19** ([20]). *Suppose there are at least  $(1 - 1/\ell^{1/5})n$  vertices  $s$  s.t.  $\|\text{cl}(\mathbf{p}_{s,\ell}, 1/4)\|_2^2 > \ell^{-c}$ . Then, there is a partition  $\{P_1, P_2, \dots, P_b\}$  of the vertices s.t.:*

1. For each  $P_i$ , there exists  $s \in V$  such that:  $\forall v \in P_i, \sum_{t < 10\ell^{c+1}} p_{s,t}(v) \geq 1/8\ell^{c+1}$ .
2. The total number of edges crossing the partition is at most  $8dn\sqrt{c\ell^{-1/5} \log \ell}$ .

► **Corollary 20.** *Let  $G = (V, E)$  be a graph which is  $R$ -minor-free where  $R$  is a graph on  $r$  vertices. There exists a partition  $\{P_1, P_2, \dots, P_b\}$  of the  $V$  such that:*

1. For each  $P_i$ , there exists  $s \in V$  such that:  $\forall v \in P_i, \sum_{t < 10\ell^8} p_{s,t}(v) \geq 1/8\ell^8$ .
2. The total number of edges crossing the partition is at most  $\epsilon dn$ .

**Proof.** We first note that  $8dn\sqrt{c\ell^{-1/5} \log \ell} \leq \epsilon dn$  for sufficiently large constant  $\alpha$ .

By Lemma 18 there exist at least  $(1 - 1/\ell)n$  vertices such that  $\|\text{cl}(\mathbf{p}_{v,\ell}, 3/8)\|_2^2 \geq \ell^{-7}$ . Thus the corollary follows from the facts that  $(1 - 1/\ell)n \geq (1 - 1/\ell^{1/5})n$  and  $\|\text{cl}(\mathbf{p}_{s,\ell}, 1/4)\|_2^2 \geq \|\text{cl}(\mathbf{p}_{s,\ell}, 3/8)\|_2^2$ . ◀

■ **Algorithm 5** Covering-partition oracle.

**Input:**  $v \in V$ .

**Output:** A subset  $S$  which covers the part of  $v$ .

1. For every  $t < 10\ell^8$  perform  $x \stackrel{\text{def}}{=} \Theta(\ell^8 \log \ell)$  random walks of length  $t$  from  $v$ .
2. Let  $R$  denote the endpoints of the random walks performed in the previous step.
3. For every vertex  $r \in R$ , for every  $t < 10\ell^8$ , perform  $x$  random walks of length  $t$  from  $r$ .
4. Let  $S$  denote the set of all vertices encountered by the random walks performed in Step 1 and Step 3.
5. Return  $S$ .

**Proof of Theorem 16.** Let  $G = (V, E)$  be a graph which is  $R$ -minor-free where  $R$  is a graph over  $r$  vertices. Consider the partition of  $V$ ,  $\mathcal{P} = \{P_1, P_2, \dots, P_b\}$  as defined in Corollary 20 when we take the proximity parameter to be  $\epsilon/2$ . We shall define another partition  $\mathcal{P}'$  which is a refinement of  $\mathcal{P}$  such that Algorithm 5 returns for every  $v \in V$ , a subset  $S$  such that  $P' \subseteq S$  where  $P'$  denotes the part of  $v$  in  $\mathcal{P}'$ . Thereafter, we shall prove that, w.h.p., the number of cut-edges of  $\mathcal{P}'$  is not much greater than the number of cut-edges of  $\mathcal{P}$ .

For every  $v \in V$ , we say that  $v$  *fails* if Algorithm 5, when queried on  $v$ , does not return  $S$  such that  $P^v \subseteq S$ , where  $P^v$  denotes the part of  $v$  in  $\mathcal{P}$ . We define  $\mathcal{P}'$  as follows. For every  $v \in V$ , if there exists  $u \in P^v$  such that  $u$  fails, then the part of  $v$  in  $\mathcal{P}'$  is defined to be the singleton  $\{v\}$  (namely, the entire part  $P^v$  is partitioned into singletons in  $\mathcal{P}'$ ). Otherwise, it is defined to be  $P^v$ .

We next show that w.h.p. the cut-edges of  $\mathcal{P}'$  is at most  $\epsilon d|V|$ . For every  $v$ , the probability that  $v$  fails is at most  $p \stackrel{\text{def}}{=} \ell^{-c_1}$  for an appropriate setting of  $x$  (with accordance to the Theta-notation), where  $c_1$  is a constant that will be determined later. Let  $y = \ell^{c_2}$  be an upper bound on the number of vertices in the parts of  $\mathcal{P}$ , where  $c_2$  is a constant.<sup>8</sup>

<sup>8</sup> Clearly, since for each  $P_i$ , there exists  $s \in V$  such that:  $\forall v \in P_i, \sum_{t < 10\ell^8} p_{s,t}(v) \geq 1/8\ell^8$ , it follows that  $y \leq 10\ell^8 \cdot 8\ell^8$ .

## 61:14 Testing Hamiltonicity (And Other Problems) in Minor-Free Graphs

For every  $v \in V$ , define the random variable  $X_v$  as follows. If  $v$  fails then  $X_v = |P_v|/y$  and otherwise  $X_v = 0$ . Clearly  $y \cdot \sum_{v \in V} X_v \geq |\mathcal{P}'| - |\mathcal{P}|$ . Note that  $\{X_v\}_{v \in V}$  are independent random variables ranging in  $[0, 1]$ .

For every  $v \in V$ , we define the random variable  $Y_v$  as follows. With probability  $p$ ,  $Y_v = 1$  and otherwise  $X_v = 0$ . Clearly,  $Y_v$  dominates  $X_v$ . Since  $\{Y_v\}_{v \in V}$  are identical independent random variables, it follows by the multiplicative Chernoff's bound that w.h.p.  $y \cdot \sum_{v \in V} Y_v \leq y \cdot |V| \cdot 2p$ .

Since for sufficiently large  $c_1$ ,  $p \leq \frac{\epsilon}{4y}$ , it follows that w.h.p.  $|\mathcal{P}'| - |\mathcal{P}| \leq \epsilon|V|/2$ . Thus, the number of cut-edges in  $\mathcal{P}'$  is greater than the number of cut-edges in  $\mathcal{P}$  by at most  $\epsilon d|V|/2$  (recall that the algorithm refines  $\mathcal{P}$  by decomposing entire parts into singletons). ◀

### 4.2 Testing Hamiltonicity

In this section we prove the following theorem.

► **Theorem 21.** *Given query access to an input graph  $G = (V, E)$  where  $G$  is a minor-free bounded degree graph and a parameters  $\epsilon$  and  $|V|$ , Algorithm 6 accepts  $G$  with probability 1 if  $G$  is Hamiltonian and rejects  $G$  with probability at least  $2/3$  if  $G$  is  $\epsilon$ -far from being Hamiltonian. The query complexity of the algorithm is  $\text{poly}(d/\epsilon)$  and the running time is exponential in  $\text{poly}(d/\epsilon)$ .*

The correctness of Algorithm 6 builds on the following claim which, given  $S \subset V$ , bounds the size of a minimum path cover in  $G[S]$  by the size of the cut of  $S$ .

▷ **Claim 22.** Let  $G = (V, E)$  be a graph and let  $S \subset V$  be a subset of vertices of  $G$ . Let  $k$  be the size of a minimum path cover in  $G[S]$ . If  $k - 1 > |E(S, V \setminus S)|/2$ , then there is no Hamiltonian path in  $G$ . Moreover, any Hamiltonian path in  $G$  must include at least  $2(k - 1)$  edges from  $E(S, V \setminus S)$ .

*Proof.* Let  $G = (V, E)$  be a graph. Assume toward contradiction that there exists Hamiltonian path in  $G$ ,  $\mathcal{H} = (v_1, v_2, \dots, v_{|V|})$  and a subset  $S \subset V$  such that  $k - 1 > |E(S, V \setminus S)|/2$ , where  $k$  is the size of a minimum path cover in  $G[S]$ . Let  $\mathcal{P}'_S$  denote the set of all maximal sub-paths of  $\mathcal{H}$  in  $G[S]$ . In order to connect the sub-paths in  $\mathcal{P}'_S$  it must hold that  $\mathcal{H}$  leaves and returns to  $G[S]$  at least  $2(\mathcal{P}'_S - 1)$  times, each time using a different edge. Thus,  $|E(S, V \setminus S)| \geq 2(|\mathcal{P}'_S| - 1)$ . Since  $\mathcal{P}'_S$  is a path cover of  $G[S]$  it follows that  $|\mathcal{P}'_S| \geq k$ , thus,  $|E(S, V \setminus S)| \geq 2(k - 1)$ , in contradiction to our assumption. Hence the claim follows. ◀

We next list our algorithm and prove its correctness.

**Proof of Theorem 21.** By Claim 22, Algorithm 6 never rejects graphs which are Hamiltonian.

Let  $G$  be a minor-free bounded degree graph which is  $\epsilon$ -far from being Hamiltonian. We shall prove that Algorithm 6 rejects  $G$  with probability at least  $2/3$ . Let  $\mathcal{P}$  denote the partition that the oracle, executed in Step 2a, answers according to. With high constant probability, it holds that  $|E_{\mathcal{P}}| \leq \frac{\epsilon|V|}{6}$ . Let  $E_1$  denote the event that this conditions holds.

Let  $\mathcal{F}$  denote the set of parts,  $S$ , in  $\mathcal{P}$ , such that  $E(S, V \setminus S) = \emptyset$  or for which the size of the minimum path cover of  $G[S]$  is greater  $|E(S, V \setminus S)|/2 + 1$

Assume towards contradiction that  $E_1$  occurs and that  $|\mathcal{F}| < \epsilon|V|/(2x)$  where  $x$  is an upper bound on the number of vertices in each part of  $\mathcal{P}$ . We next show that  $\delta_{\text{HAM}}(G) \leq \epsilon|V|$  in contradiction to our assumption.

For each part  $S \in \mathcal{F}$  we construct a path over  $S$  that visits each vertex in  $S$  exactly once by adding at most  $|S| - 1 \leq x - 1$  edges to  $G$ .

■ **Algorithm 6** Testing Hamiltonicity in minor-free, bounded degree, graphs.

**Input:** Oracle access to a minor-free, bounded-degree, graph  $G = (V, E)$

**Output:** Tests if  $G$  is Hamiltonian with one-sided error.

1. Sample a subset,  $S \subseteq V$ , of  $y \stackrel{\text{def}}{=} \Theta(x/\epsilon)$  vertices, uniformly at random, where  $x$  is an upper bound on the size of the sets returned by the covering partition oracle when execute with parameter  $\epsilon/6$ .
2. For each  $v \in S$  do:
  - a. Query the covering partition oracle on  $v$  with parameter  $\epsilon/6$ , and let  $S_v$  denote the returned set.
  - b. If  $E(S_v, V \setminus S_v) = \emptyset$  then return REJECT.
  - c. For each subset  $T \subseteq S_v$  such that  $G[T]$  is connected, find the size of the minimum path cover of  $T$  and return REJECT if it is greater than  $|E(T, V \setminus T)|/2 + 1$ .

For each part  $S \in \mathcal{P} \setminus \mathcal{F}$ , let  $\mathcal{C}_S$  denote a minimum path cover of  $G[S]$ . We construct a path over  $S$  that visits each vertex in  $S$  exactly once by adding at most  $|\mathcal{C}_S| - 1 \leq |E(S, V \setminus S)|/2$  edges to  $G$ .

We then connect all the paths induced on the different parts of  $\mathcal{P}$  by adding at most  $|\mathcal{P}| = |\mathcal{F}| + |\mathcal{P} \setminus \mathcal{F}|$  edges.

Overall the number of edges added is at most:

$$|\mathcal{F}| \cdot (x - 1) + |E_{\mathcal{P}}| + |\mathcal{F}| + |\mathcal{P} \setminus \mathcal{F}| \leq |\mathcal{F}| \cdot x + 3|E_{\mathcal{P}}| < \epsilon|V|,$$

where the first inequality follows from the fact that  $|\mathcal{P} \setminus \mathcal{F}| \leq 2|E_{\mathcal{P}}|$  as for each  $S \in \mathcal{P} \setminus \mathcal{F}$  it holds that  $E(S, V \setminus S) \cap E_{\mathcal{P}} \neq \emptyset$  and each edge in  $E_{\mathcal{P}}$  is adjacent to at most 2 parts in  $\mathcal{P}$ .

Thus, if  $\delta_{\text{HAM}(G)} > \epsilon|V|$  and  $E_1$  occurs then  $|\mathcal{F}| \geq \epsilon|V|/(2x)$ . Thus, the number of vertices in parts that belong to  $\mathcal{F}$  is at least  $\epsilon|V|/(2x)$ , which implies that  $G$  is rejected w.h.p. either in Step 2b or in Step 2c of Algorithm 6, as desired. ◀

### 4.3 Local algorithms for constructing a spanning subgraph with almost optimum weight

In this section we prove the following theorem.

► **Theorem 23.** *Algorithm 7 is a local algorithm for  $(1 + \epsilon)$ -approximating the minimum weight spanning graph for minor-free graphs, with high constant success probability and time and query complexity  $\text{poly}(W, d, \epsilon^{-1})$ .*

**Proof.** Let  $\mathcal{P}$  denote the partition that the oracle, executed in Step 1, answers according to. With high constant probability, it holds that  $|E_{\mathcal{P}}| \leq \epsilon|V|/W$ . Let  $E_1$  denote the event that this conditions holds. We claim that the number edges for which Algorithm 7 returns YES for which both endpoints belong to the same part is at most  $|V| - 1$ . To see this consider a part  $T \in \mathcal{P}$  and a cycle  $C$  in  $G[T]$ . Let  $\{u, v\}$  denote the heaviest edge in the cycle. When queried on  $u$  and  $v$  the covering partition oracle returns sets  $S_u$  and  $S_v$  such that  $T \subseteq S_u \cup S_v$ . Thus the cycle  $C$  is contained in  $G[S_u \cup S_v]$ . Therefore the algorithm returns NO on  $\{u, v\}$  in Step 3. By the cycle rule the number of edges in  $G[T]$  for which the algorithm returns YES is exactly  $|T| - 1$ .

Hence conditioned on  $E_1$ , the total number of edges for which Algorithm 7 returns YES is at most  $(|V| - 1) + \epsilon|V|/W$ .

## 61:16 Testing Hamiltonicity (And Other Problems) in Minor-Free Graphs

By the cycle rule, any edge,  $e$ , for which Algorithm 7 returns NO does not belong to the MST of  $G$ . Since the MST consists of exactly  $|V| - 1$  edges, it follows that, conditioned on  $E_1$ , the number of edges that do not belong to the MST and for which Algorithm 7 returns YES is at most  $\epsilon|V|/W$  as desired. ◀

■ **Algorithm 7** Local algorithm for approximated-MST in bounded-degree minor-free graphs.

**Input:**  $\{u, v\} \in E$  and parameters  $\epsilon$  and  $W$ .

**Output:** YES if  $\{u, v\}$  belongs to the approximated-MST and NO otherwise.

1. Perform a query  $u$  and a query  $v$  to the covering-partition oracle with parameter  $\epsilon/W$ . Let  $S_u$  and  $S_v$  denote the subsets returned by the oracle, respectively.
2. Find the subgraph induced on  $S_u \cup S_v$ , denoted by  $G[S_u \cup S_v]$ .
3. Return NO if and only if  $\{u, v\}$  is the heaviest edge on any cycle in  $G[S_u \cup S_v]$ .

### 4.4 Testing monotone and additive properties

► **Theorem 24.** *Any property of graphs which is monotone (closed under removal of edges and vertices) and additive (closed under the disjoint union of graphs) can be tested with one-sided error in minor-free graphs with bounded degree  $d$  with query complexity which is  $\text{poly}(d/\epsilon)$  where  $\epsilon$  is the proximity parameter.*

**Proof.** Let  $\mathcal{T}$  be a property of graphs which is monotone and additive. We propose the following algorithm for testing  $\mathcal{P}$  on an input graph  $G$  which is a minor-free graphs of degree bounded by  $d$ . Sample a set of  $O(d/\epsilon)$  vertices,  $S$ , uniformly at random and run the covering partition oracle on each  $v \in S$  with parameter  $\epsilon/2$ .

For each  $v \in S$ , let  $S_v$  denote the set returned by the covering partition oracle when queried on  $v$ . Return ACCEPT iff for all  $v \in S$ ,  $G[S_v]$  has the property  $\mathcal{T}$ .

If  $G$  has the property  $\mathcal{T}$  then since  $\mathcal{T}$  is monotone it follows that for all  $v \in S$ ,  $G[S_v]$  has the property  $\mathcal{T}$  as well.

Let  $\mathcal{P}$  denote the partition that the covering partition oracle answers according to. With high constant probability  $|E_{\mathcal{P}}| \leq \epsilon|V|/2$ . Let  $E_1$  denote the event that this condition holds. If  $G$  is  $\epsilon$ -far from having the property  $\mathcal{T}$  then, conditioned on  $E_1$ ,  $G' = (V, E \setminus E_{\mathcal{P}})$  is  $(\epsilon/2)$ -far from having the property  $\mathcal{T}$ .

Thus we need to remove at least  $\epsilon|V|/2$  edges from  $G'$  to obtain the property  $\mathcal{T}$ . By the additivity and monotonicity of  $\mathcal{T}$  it follows that  $G'$  has the property  $\mathcal{T}$  if and only if for every  $T \in \mathcal{P}$ ,  $G[T]$  has the property  $\mathcal{T}$ . Thus, there are at least  $\epsilon|V|/2$  edges, and hence at least  $\epsilon|V|/(2d)$  vertices, that belong to parts,  $T \in \mathcal{P}$  such that  $G[T]$  does not have the property  $\mathcal{T}$ . Hence, with high constant probability the algorithm sample one of these vertices and rejects  $G$ . This concludes the proof. ◀

## **A** Related Work

### A.1 Partition Oracles

Partition oracles were introduced by Hassidim et al. [14] as a tool for approximating parameters and testing properties of minor-free bounded degree graphs. The query complexity of the partition oracle of [14] is exponential in  $1/\epsilon$ . The query complexity was later improved in [25] to be quasi-polynomial in  $1/\epsilon$ . Very recently, Kumar-Seshadhri-Stolman [20] obtained a partition oracle with query complexity which is polynomial in  $1/\epsilon$ .

Edelman et al. [8] obtained a partition oracle with query complexity polynomial which is in  $1/\epsilon$  for graphs with bounded treewidth.

### A.2 Testing Hamiltonicity

Yoshida and Ito [33] and more recently Goldreich [12] proved a linear (in the number of vertices) lower bound for testing Hamiltonicity (even with two-sided error) in bounded degree graphs. Adler and Köhler [1] provided a deterministic construction of families of graphs for which testing Hamiltonicity with one-sided error requires linear number of queries.

### A.3 Testing properties of minor-free graphs

Newman and Sohler [29] showed that any property of hyperfinite graphs and in particular minor-free graphs can be tested with query complexity that depends only on  $1/\epsilon$  and  $d$  where  $d$  is a bound on the maximum degree. In fact, they proved a stronger claim, that a minor-free graph can be learned up to a precision of  $\epsilon dn$  edges with such query complexity. However, although the query complexity of their canonical tester is independent of  $n$  it is super-polynomial in  $d/\epsilon$ .

For minor-free graphs of unbounded degrees, Czumaj et al. [6] obtained an algorithm whose query complexity depends only on  $1/\epsilon$  for testing Bipartiteness. More recently, this result was generalized by Czumaj and Sohler [7] who proved that any property of minor-free graphs can be tested with one-sided error with query complexity that depends only on  $1/\epsilon$  if and only if it can be reduced to testing for a finite family of finite forbidden subgraphs. Czumaj et al. [6] also provide a canonical tester for testing  $H$ -subgraph freeness for any fixed  $H$  with query complexity that is independent of  $n$ , however super polynomial in  $1/\epsilon$ .

It was shown that for other restrictive families of graphs of unbounded degree that every property is testable with query complexity which is at most polylogarithmic in  $n$  [21, 17, 3]. Specifically, Kusumoto and Yoshida [21] proved that any property of forests can be tested with query complexity  $\text{poly}(\log n)$  and that testing Isomorphism of forests requires  $\Omega(\sqrt{\log n})$ . This result was generalized in Babu-Khoury-Newman [3] for  $k$ -outerplanar graphs.

### A.4 Local algorithms for constructing sparse spanning subgraphs

The model of *local computation algorithms* as considered in this work, was defined by Rubinfeld et al. [32] (see also Alon et al. [2] and survey in [23]). The problem of constructing sparse spanning subgraphs in this model was studied in several papers [26, 24, 25, 22, 31, 28]. This problem is a special case of constructing an  $\epsilon$ -almost MST in which the weights of all the edges are identical.

For restricted families of graphs, it was shown that the complexity of the problem is independent of  $n$ . Specifically, it was shown in [24] that for families of graph that are, roughly speaking, sufficiency non-expanding, one can provide an algorithm with query complexity that is independent of  $n$  (however, super-exponential in  $1/\epsilon$ ). This is achieved by simulating a localized version of Kruskal's algorithm. On the negative side, it was also shown in [24] that for graphs with expansion properties that are a little better, there is *no local algorithm* that inspects a number of edges that is independent of  $n$ .

In [28] there is an algorithm for locally constructing sparse spanning subgraphs in minor-free, unbounded degree, graphs with query complexity and time complexity which are polynomial in  $d$  and  $1/\epsilon$ . Thus our algorithm for unbounded degree graphs generalizes this result for the weighted case.

In [26, 27] it was shown that a spanning subgraph of almost optimum weight can be constructed locally in minor-free graph with degree bounded by  $d$  with query complexity and time complexity which are quasi-polynomial in  $d$ ,  $1/\epsilon$  and  $W$  where  $W$  is the maximum weight of an edge. Thus our algorithm for unbounded degree graphs generalizes this result to unbounded degree graphs and improves the complexity of the upper bound from quasi-polynomial to polynomial in  $d$ ,  $1/\epsilon$  and  $W$ .

## **B** Omitted proofs and details

### **B.1** Proof of Claim 11

Let  $G = (V, E)$  be a graph and let  $\mathcal{C} = \{P_1, \dots, P_k\}$  be a minimum path cover of  $G$ .

We first prove that  $\delta_{\text{HAM}}(G) \leq k - 1$ . For every  $1 \leq i \leq k - 1$  we add an edge which connects the end-vertex of  $P_i$  to the start-vertex of  $P_{i+1}$ . Thus, by adding  $k - 1$  edges we constructed a Hamiltonian path in  $G$ .

We next prove that  $\delta_{\text{HAM}}(G) \geq k - 1$ . By definition, there exist  $\delta_{\text{HAM}}(G)$  edges such that when added to  $G$ ,  $G$  becomes Hamiltonian. Let  $E'$  denote a set of  $\delta_{\text{HAM}}(G)$  such edges and let  $G' = (V, E \cup E')$  be the graph resulting from adding these edges to  $G$ . Let  $\mathcal{H} = (s_1, \dots, s_{|V|})$  denote a Hamiltonian path in  $G'$ . After we remove back the edges in  $E'$  we break  $\mathcal{H}$  into  $|E'| + 1$  connected components (each edge we remove adds an additional connected component), i.e. into  $|E'| + 1$  paths. Thus the size of the minimum path cover of  $G$  is at most  $|E'| + 1 = \delta_{\text{HAM}}(G) + 1$ . Thus  $k \leq \delta_{\text{HAM}}(G) + 1$  and so  $\delta_{\text{HAM}}(G) \geq k - 1$  as desired.

### **B.2** Proof of Claim 12

The claim that  $\delta_{\text{HAM}}(G) \leq \delta_{\text{HAM}}(G')$  follows from the fact that the distance from being Hamiltonian can not decrease when we remove edges.

Let  $\mathcal{C}$  be a minimum path cover of  $G$ . By Claim 11,  $\delta_{\text{HAM}}(G) = |\mathcal{C}| - 1$ . Now consider removing the edges in  $F$  one by one and how this affects the number of paths in  $\mathcal{C}$ . After removal of a single edge, the number of paths may increase by at most one. Thus, after removing all the edges in  $F$  the paths in  $\mathcal{C}$  break into at most  $|\mathcal{C}| + |F|$  paths. Thus the size of the minimum path cover of  $G'$  is at most  $|\mathcal{C}| + |F|$ . By claim 11,  $\delta_{\text{HAM}}(G') \leq |\mathcal{C}| + |F| - 1 = \delta_{\text{HAM}}(G) + |F|$ , as desired.

### **B.3** Proof of Claim 13

The proof of this claim is similar to the proof of Claim 12.

The claim that  $\delta_{\text{HAM}}(G) \leq \delta_{\text{HAM}}(G')$  follows from the fact that the distance from being Hamiltonian can not decrease when we remove edges.

Let  $\mathcal{C}$  be a minimum path cover of  $G$ . By Claim 11,  $\delta_{\text{HAM}}(G) = |\mathcal{C}| - 1$ . Now consider removing the edges adjacent to vertices in  $S$  vertex by vertex and how this affects the number of paths in  $\mathcal{C}$ . After removal of edges incident to a specific vertex, the number of paths may increase by at most two. This follows from the fact that each vertex  $v$  belongs to exactly one path,  $P$ , and the fact that when the edges incident to  $v$  are removed,  $P$  may break into at most 3 different paths. Thus, after removing all the edges incident to vertices in  $S$  the paths in  $\mathcal{P}$  break into at most  $|\mathcal{C}| + 2|S|$  paths. Thus the size of the minimum path cover of  $G'$  is at most  $|\mathcal{C}| + 2|S|$ . By claim 11,  $\delta_{\text{HAM}}(G') \leq |\mathcal{C}| + 2|S| - 1 = \delta_{\text{HAM}}(G) + 2|S|$ , as desired.

## B.4 Proof of Claim 15

We claim that  $\text{MSF}(G) \subseteq \text{MSF}(G') \cup S$ . To see this observe that for every edge  $e \in E' \setminus \text{MSF}(G')$ , it holds, by the cycle rule, that there exists a cycle in  $G'$  such that  $e$  is the heaviest edges in this cycle. Thus, these edges are not in  $\text{MSF}(G)$  either (because all the cycles in  $G'$  exist in  $G$  as well).

Since the number of connected components in  $G$  is at most the number of connected components in  $G'$  it holds that  $|\text{MSF}(G')| \leq |\text{MSF}(G)|$ . Thus,

$$|\text{MSF}(G) \setminus \text{MSF}(G')| \geq |\text{MSF}(G') \setminus \text{MSF}(G)|. \quad (1)$$

Since  $\text{MSF}(G) \subseteq \text{MSF}(G') \cup S$  it holds that  $\text{MSF}(G) \setminus \text{MSF}(G') \subseteq S$ . Thus,

$$|\text{MSF}(G) \setminus \text{MSF}(G')| \leq |S|. \quad (2)$$

It follows from Equations 1 and 2 that  $|\text{MSF}(G') \setminus \text{MSF}(G)| \leq |S|$ . Thus, the claim follows from the bound on the maximum weight of an edge in  $G$ .

## B.5 Correctness of Algorithm 2

▷ **Claim 25.** With high constant probability, the number of edges added to  $E'$  in steps 2 and 4 of Algorithm 2 is at most  $\epsilon|V|/(3W)$ .

*Proof.* With high constant probability  $|E_{\mathcal{P}}| \leq \epsilon|V|/(6W)$ . Since  $G$  is minor-free it follows by Fact 4 and Markov's inequality the number of edges in  $G[H]$  is at most  $\epsilon|V|/(6W)$ . The claim follows. ◁

▷ **Claim 26.** All edges added to  $E'$  in step 5 of Algorithm 2 belong to  $\text{MSF}(\hat{G})$  where  $\hat{G} = (V, E \setminus E_{\mathcal{P}})$ .

*Proof.* Let  $S \in \mathcal{P}$  and let  $F = (S, A)$  denote the graph returned by Algorithm 4.

We first prove that all the edges in  $A$  belong to  $\text{MSF}(\hat{G})$ . Since each sub-part  $B$  of  $S$  is active (see Step 2 of Algorithm 4) as long as the lightest edge in  $E^G(B, S \setminus B)$  is lighter than the lightest edge in  $E^G(B, H)$  it follows that  $e_B$  (see Step 3a of Algorithm 4) is the lightest edge in  $E^{\hat{G}}(B, V \setminus B)$ . Thus, all the edges of  $A$  belong to  $\text{MSF}(\hat{G})$  by the cut rule (see Subsection 2.4).

We next prove that for each connected component of  $F$ ,  $C$ , the lightest edge which is adjacent to  $C$  and  $H$  (if such edge exists) is in  $\text{MSF}(\hat{G})$ . We first note that we only need to consider  $S$  such that  $E^G(S, H) \neq \emptyset$ . In this case each connected component of  $F$ ,  $C$ , is adjacent to at least one vertex in  $H$ . Since  $C$  is not active it follows that lightest edge which is adjacent to  $C$  and  $H$  is the lightest edge in the cut of  $C$  in  $\hat{G}$ . Thus the claim follows from the cut rule. This concludes the proof of the claim. ◁

In the proof of the following claim we closely follow the analysis in [28] (see proof in Subsection B.6).

## 61:22 Testing Hamiltonicity (And Other Problems) in Minor-Free Graphs

▷ **Claim 27.** Let  $U$  denote the set of edges in  $E'$  that are incident to two different clusters (namely, each endpoint belongs to a different cluster). With probability  $1 - 1/\Omega(|V|)$ ,  $|U| \leq \epsilon|V|/(3W)$ .

▷ **Claim 28.** Let  $G = (V, E)$  be a connected minor-free graph, then with high constant probability the graph returned by Algorithm 2,  $G' = (V, E')$ , is connected and  $\sum_{e \in E'} w(e) \leq (1 + \epsilon)\text{OPT}$ , where OPT is the weight of a minimum weight spanning tree of  $G$ .

*Proof.* We begin by proving  $G'$  is connected. To see this observe that each vertex either belongs to a cluster or to a subset  $S \in \mathcal{P}$  such that  $E^G(S, H) = \emptyset$ .

By construction, the subgraph induced on each cluster in  $G'$  is connected. For any two clusters which are connected by an edge the lightest edge that connects the clusters belongs to  $E'$ . This follows from Step 7 in Algorithm 2. If  $E^G(S, H) = \emptyset$  then  $G'[S]$  is connected by Algorithm 2, as all sub-parts of  $S$  remain active throughout the entire execution of the algorithm. Moreover, all the edges in  $E^G(S, V \setminus S)$  are in  $E'$  as well. Thus  $G'$  is connected. The claim regarding the weight of the edges of  $G'$  follows from Claim 15 and Claims 25-27.  $\triangleleft$

### B.6 Proof of Claim 27

For each cluster  $B$ , we charge to  $B$  a subset of the edges incident to  $B$  so that the union of all the charged edges (over all clusters) contains  $U$ . Our goal is to show that with probability  $1 - 1/\Omega(n)$ , the total number of charged edges is at most  $\epsilon|V|/(3W)$ .

Let  $\tilde{G} = (V, \hat{E})$  be such that  $\hat{E} = E \setminus E_{\mathcal{P}}$ . Consider the auxiliary graph, denoted  $\tilde{G}$ , that results from contracting each cluster  $B$  and isolated parts in  $\hat{G}$  into a *mega-vertex* in  $\tilde{G}$ , which we denote by  $v(B)$ . For each pair of clusters  $B$  and  $B'$  such that  $E^{\hat{G}}(B, B')$  is non-empty, there is an edge  $(v(B), v(B'))$  in  $\tilde{G}$ , which we refer to as a *mega edge*, and whose weight is  $|E^{\hat{G}}(B, B')|$ . Since  $G$  is minor-free, so is  $\tilde{G}$ . By Fact 4, which bounds the arboricity of minor-free graphs, we can partition the mega-edges of  $\tilde{G}$  into  $r$  forests. Consider orienting the mega-edges of  $\tilde{G}$  according to this partition (from children to parents in the trees of these forests), so that each mega-vertex has at most  $r$  outgoing mega-edges. For cluster  $B$  and a cluster  $B'$  such that  $(v(B), v(B'))$  is an edge in  $\tilde{G}$  that is oriented from  $v(B)$  to  $v(B')$ , we shall charge to  $B$  a subset of the edges in  $E^{\hat{G}}(B, B')$ , as described next.

Let  $x$  be an upper bound on the size of parts returned by the partition oracle when executed with parameter  $\epsilon/(6W)$ . Thus  $x$  is an upper bound on the size of part in the partition  $\mathcal{P}$  of  $G[\mathcal{L}]$ . Let  $E^b(B, B')$  denote the subset of edges in  $E^{\hat{G}}(B, B')$  that are the  $(\epsilon/(9rW)) \cdot |E(B, B')|$  lightest edges of  $E(B, B')$ . We charge all the edges in  $E^b(B, B')$  to  $B$ . The rationale is that for these edges it is likely that the algorithm won't sample an edge in  $E^{\hat{G}}(B, B')$  which is lighter. The total number of such edges is at most  $(\epsilon/(9rW)) \cdot |E| \leq \epsilon|V|/(9W)$ .

For a light vertex  $y$  let  $\text{subpart}(y)$  denote the subpart of  $y$ . Let  $u$  be the center of the cluster  $B$ , and let  $N^b(u, B')$  be the set of vertices,  $y \in N(u)$ , such that:

$$(y \in B' \text{ and } (u, y) \in E^b(B, B')) \text{ or } (\exists(y', z) \in E^b(B, B') \text{ s.t. } y' \in \text{subpart}(y)) .$$

That is,  $N^b(u, B')$  is the subset of neighbors of  $u$  such that if Algorithm 3 selects one of them in Step 2, then it obtains an edge in  $E^b(B, B')$ . We consider two cases.

**First case:**  $|N^b(u, B')|/|N(u)| < \epsilon^2/(162W^2r^3x\Delta)$ . In this case we charge all edges in  $E^{\hat{G}}(B, B')$  to  $B$ . For each part  $\text{subpart}(y)$  such that  $y \in N^b(u, B')$  there are at most  $|\text{subpart}(y)| \cdot \Delta$  edges  $(y', z) \in E^b(B, B')$  for which  $y' \in \text{subpart}(y)$ . Therefore, in this case

$|E^b(B, B')| \leq x\Delta \cdot |N^b(u, B')| \leq N(u) \cdot \epsilon^2/(162W^2r^3)$  and hence  $|E(B, B')| < (9rW/\epsilon) \cdot \epsilon^2/(162W^2r^3) \cdot N(u)$ . It follows that the total number of charged edges of this type is at most  $(\epsilon/(18rW)) \cdot 2|E| \leq \epsilon n/(9W)$ .

**Second case:**  $|N^b(u, B')|/|N(u)| \geq \epsilon^2/(162W^2r^3x\Delta)$ . For each  $u$  and  $B'$  that fall under this case we define the set of edges  $Y(u, B') = \{(u, v) : v \in N^b(u, B')\}$  and denote by  $Y$  the union of all such sets (over all such pairs  $u$  and  $B'$ ). Edges in  $Y$  are charged to  $B$  if and only if they belong to  $U$  and are incident to a vertex in  $B$ . Fix an edge in  $Y$  that is incident to  $B$ , and note that the selection of neighbors of  $u$  is done according to a  $t$ -wise independent distribution for  $t > 4q$ , where  $q$  is the sample size set in Step 2 of the Algorithm 3. Therefore, the probability that the edge belongs to  $U$  is upper bounded by  $(1 - \epsilon^2/(162W^2r^3x\Delta))^q$ , which by the setting of  $q$ , is at most  $p = \epsilon/(18Wr)$  (for sufficiently large constant w.r.t. the Theta notation).

We next show, using Chebyshev's inequality, that w.h.p., the number of edges in  $Y$  that are in  $U$  is at most  $2p|E|$ . For  $y \in Y$ , define  $J_y$  to be an indicator variable that is 1 if and only if  $y \in F$ . Then for a fixed  $y \in Y$ ,  $E[J_y] \leq p$  and  $\{J_y\}$  are pairwise independent (this is due to the fact that the samples of every pair of edges are pairwise independent). Therefore, by Chebyshev's inequality,

$$\Pr \left[ \sum_{y \in Y} J_y \geq 2p|E| \right] \leq \frac{\text{Var}[\sum_{y \in Y} J_y]}{(p|E|)^2} = \frac{\sum_{y \in Y} \text{Var}(J_y)}{(p|E|)^2} \leq \frac{p(1-p)|E|}{(p|E|)^2} = \frac{1-p}{p|E|} = \frac{1}{\Omega(n)},$$

and the proof of Claim 27 is completed.

► **Remark 29.** The random seed that Algorithm 2 uses consists of two parts. The first part is for running the partition oracle. The second part is for selecting random neighbors in Step 2 of Algorithm 3. Since the selection of neighbors is according to a  $t$ -wise independent distribution we obtain that a random seed of length  $\tilde{O}(\log n)$  is sufficient.

## B.7 The local implementation of Algorithm 2

Algorithm 8 is the local implementation of Algorithm 2 and is listed next.

■ **Algorithm 8** Local algorithm for approximated-MST in unbounded-degree minor-free graphs.

**Input:**  $\{u, v\} \in E$ .

**Output:** YES if  $\{u, v\}$  belongs to the approximated-MST and NO otherwise.

1. If both  $u$  and  $v$  are in  $H$  return YES.
2. If both  $u$  and  $v$  are light:
  - a. Query the partition oracle on  $u$  and  $v$  and return YES if they belong to different parts.
  - b. Find the sub-parts of  $u$  and  $v$  by running Algorithm 4.
  - c. If  $u$  and  $v$  are in the same sub-part:
    - i. Return YES if  $\{u, v\}$  is in the set of edges returned by Algorithm 4 (when running on  $u$ ).
    - ii. Otherwise, return NO.
  - d. Otherwise, set  $C_u$  to be the center of  $u$  and  $C_v$  to be the center of  $v$ .
  - e. If  $C_u = C_v$  return NO.
3. Otherwise, if  $u$  is light and  $v$  is heavy (and analogously if  $v$  is light and  $u$  is heavy) then:
  - a. Find the sub-part of  $u$  and set  $C_u$  to be the center of this sub-part
  - b. Set  $C_v = v$
4. Run Algorithm 3 on  $C_u$  and  $C_v$  and return YES if the edge  $\{u, v\}$  is lighter than the edge returned by the algorithm. Otherwise, return NO.

# Parallel Repetition for the GHZ Game: A Simpler Proof

## Abstract

We give a new proof of the fact that the parallel repetition of the (3-player) GHZ game reduces the value of the game to zero polynomially quickly. That is, we show that the value of the  $n$ -fold GHZ game is at most  $n^{-\Omega(1)}$ . This was first established by Holmgren and Raz [18]. We present a new proof of this theorem that we believe to be simpler and more direct. Unlike most previous works on parallel repetition, our proof makes no use of information theory, and relies on the use of Fourier analysis.

The GHZ game [15] has played a foundational role in the understanding of quantum information theory, due in part to the fact that quantum strategies can win the GHZ game with probability 1. It is possible that improved parallel repetition bounds may find applications in this setting.

Recently, Dinur, Harsha, Venkat, and Yuen [7] highlighted the GHZ game as a simple three-player game, which is in some sense maximally far from the class of multi-player games whose behavior under parallel repetition is well understood. Dinur et al. conjectured that parallel repetition decreases the value of the GHZ game exponentially quickly, and speculated that progress on proving this would shed light on parallel repetition for general multi-player (multi-prover) games.

## 1 Introduction

The focus of this paper is multi-player games, and in particular their asymptotic behavior under parallel repetition.

Multi-player games consist of a one-round interaction between a referee and  $k$  players. In this interaction, the referee first samples a “query”  $(q_1, \dots, q_k)$  from some joint query distribution  $\mathcal{Q}$ , and for each  $i$  sends  $q_i$  to the  $i^{\text{th}}$  player. The players are required to respectively produce “answers”  $a_1, \dots, a_k$  without communicating with one another (that is, each  $a_i$  is a function only of  $q_i$ ) and they are said to *win* the game if  $(q_1, \dots, q_k, a_1, \dots, a_k)$  satisfy some predicate  $W$  that is fixed and associated with the game.

Suppose that a game  $G$  has the property that the maximum probability with which players can win is  $1 - \epsilon$ , no matter what strategy they use. This quantity is called the *value* of  $G$ . The parallel repetition question [13] asks

*How well can the players concurrently play in  $n$  independent copies of  $G$ ?*

More precisely, consider the following  $k$ -player game, which we call the  $n$ -wise parallel repetition of  $G$  and denote by  $G^n$ :

1. The referee samples, for each  $i \in [n]$  independently, query tuples  $(q_1^i, \dots, q_k^i) \sim \mathcal{Q}$ . We refer to the index  $i$  as a *coordinate* of the parallel repeated game.
2. The  $j^{\text{th}}$  player is given  $(q_j^1, \dots, q_j^n)$  and is required to produce a tuple  $(a_j^1, \dots, a_j^n)$ .
3. The players are said to win in coordinate  $i$  if  $(q_1^i, \dots, q_k^i, a_1^i, \dots, a_k^i)$  satisfies  $W$ . They are said to win (without qualification) if they win in every coordinate  $i \in [n]$ .

One might initially conjecture that the value of  $G^n$  is  $(1 - \epsilon)^n$ . However, this turns out not to be true [14, 9, 12, 25], as players may benefit from correlating their answers across different coordinates. Still, Raz showed that if  $G$  is a two-player game, then the value of  $G^n$  is  $2^{-\Omega(n)}$ , where the  $\Omega$  hides a game-dependent constant [23, 17]. Tighter results, based on the value of the initial game are also known [8, 5]. For many applications, such bounds are qualitatively as good as the initial flawed conjecture.

Games involving three or more players have proven more difficult to analyze, and the best known general bound on their parallel repeated value is due to Verbitsky [26]. This bound states that the value of  $G^n$  approaches 0, but the bound is *extremely* weak (it shows that the value is at most  $\frac{1}{\alpha(n)}$ , where  $\alpha$  denotes an inverse Ackermann function). The weakness of this bound is generally conjectured to reflect limitations of current proof techniques rather than a fundamental difference in the behavior of many-player games. In the technically incomparable but related *no-signaling setting* however, Holmgren and Yang showed that three-player games genuinely behave differently than two-player games [19]. Specifically, they showed that there exists a three-player game with “no-signaling value” bounded away from 1 such that no amount of parallel repetition reduces the no-signaling value at all.

Parallel repetition is a mathematically natural operation that we find worthy of study in its own right. At the same time, parallel repetition bounds have found several applications in theoretical computer science (see this survey by [24]). For example, parallel repetition of 2 player games shares intimate connections with multi-player interactive proofs [4], probabilistically checkable proofs and hardness of approximation [3, 10, 16], geometry of foams [11, 20, 1], quantum information [6], and communication complexity [22, 2]. Recent work also shows that strong parallel repetition for a particular class of multiprover games implies new time lower bounds on Turing machines that can take advice [21].

Dinur et al. [7] describe a restricted class of multi-player games for which Raz’s approach generalizes (giving exponential parallel bounds). Specifically, they consider games whose query distribution satisfies a certain connectivity property. For games outside this class,

Verbitsky’s bound was the best known. Dinur et al. highlighted one simple three-player game, called the GHZ game [15], that in some sense is maximally far from the aforementioned tractable class of multi-player games. In the GHZ game, the players’ queries are  $(q_1, q_2, q_3)$  chosen uniformly at random from  $\{0, 1\}^3$  such that  $q_1 \oplus q_2 \oplus q_3 = 0$ , and the players’ goal is to produce  $(a_1, a_2, a_3)$  such that  $a_1 \oplus a_2 \oplus a_3 = q_1 \vee q_2 \vee q_3$ . Dinur et al. conjectured that parallel repetition decreases the value of the GHZ game exponentially quickly, and speculated that progress on proving this would shed light on parallel repetition for general games. The GHZ game has also played a foundational role in the understanding of quantum information theory, due in part to the fact that quantum strategies can win the GHZ game with probability 1. It is possible that improved parallel repetition bounds will find applications in this setting as well.

In a recent work, Holmgren and Raz [18] proved the following polynomial upper bound on the parallel repetition of the GHZ game:

► **Theorem 1.** *The value of the  $n$ -wise repeated GHZ game is at most  $n^{-\Omega(1)}$ .*

Our main contribution is a different proof of this theorem that, in our view, is significantly simpler and more direct than the proof of [18]. Like [18], we actually do not rely on any properties of the GHZ game other than its query distribution, and in particular we do not rely on specifics of the win condition. Furthermore, unlike most previous works on parallel repetition, our proof makes no use of information theory, and instead relies on the use of Fourier analysis.

## 1.1 Technical Overview

Let  $\mathcal{P}$  denote the distribution of queries in the  $n$ -wise parallel repeated GHZ game. Let  $\alpha = \Theta(1/n^\varepsilon)$  for a small constant  $\varepsilon > 0$  and  $E = E_1 \times E_2 \times E_3$  be any product event with significant probability under  $\mathcal{P}$ , i.e.,  $\mathcal{P}(E) \geq \alpha$ . The core of our proof is establishing that for a random coordinate  $i \in [n]$ , the query distribution  $\mathcal{P}|E$  ( $\mathcal{P}$  conditioned on  $E$ ) is mildly hard in the  $i^{\text{th}}$  coordinate. That is, given queries sampled from  $\mathcal{P}|E$ , the players’ maximum winning probability in the  $i^{\text{th}}$  coordinate is bounded away from 1. Using standard arguments from the parallel repetition literature, this will imply an inverse polynomial bound for the value of the  $n$ -fold GHZ game. The difficulty, as usual, is that the  $n$  different queries in  $\mathcal{P}|E$  may not be independent.

Our approach at a high level is to:

1. Identify a class  $\mathcal{D}$  of simple distributions (over queries for the  $n$ -wise repeated GHZ game) such that it is easy to analyze (in step 3 below) which coordinates are hard for any given  $D \in \mathcal{D}$ . By hard, we mean that the players’ maximum winning probability in the  $i^{\text{th}}$  coordinate is  $\frac{3}{4}$ .
2. Approximate  $\mathcal{P}|E$  by a convex combination of distributions from  $\mathcal{D}$ . That is, we write

$$\mathcal{P}|E \approx \sum_j p_j D_j,$$

where  $\{D_j\}$  are distributions in  $\mathcal{D}$ ,  $p_j$  are non-negative reals summing to 1, and  $\approx$  denotes closeness in total variational distance.

3. Show that in the above convex combination, “most” of the  $D_i$  have many hard coordinates. More precisely, if we sample  $j$  with probability  $p_j$ , then the expected fraction of coordinates in which  $D_j$  is hard is at least a constant (say  $1/3$ ).

Completing this approach implies that if  $i \in [n]$  is uniformly random, then the  $i^{\text{th}}$  coordinate of  $\mathcal{P}|E$  can be won with probability at most  $1 - \Omega(1)$ . We elaborate on each of these steps below.

### Bow Tie Distributions

For our class of “simple” distributions  $\mathcal{D}$ , we introduce the notion of a “bow tie” distribution. We then define  $\mathcal{D}$  to be the set of all bow tie distributions. A bow tie is a set  $B$  of the form

$$\left\{ \begin{array}{l} (x_0, y_0, z_0), \\ (x_0, y_1, z_1), \\ (x_1, y_0, z_1), \\ (x_1, y_1, z_0) \end{array} \right\} \subseteq (\mathbb{F}_2^n)^3$$

such that for each  $(x, y, z)$  in  $B$ , we have  $x + y + z = 0$ . In particular this requires that  $x_0 + x_1 = y_0 + y_1 = z_0 + z_1$ . A bow tie distribution is the uniform distribution on a bow tie. Our name of “bow tie” is based on the fact that bow ties are thus determined by  $\{(x_0, y_0), (x_0, y_1), (x_1, y_0), (x_1, y_1)\}$ , which we sometimes view as a set of edges in a graph. In this case, bow ties are special kinds of  $K_{2,2}$  subgraphs, where  $K_{2,2}$  denotes the complete bipartite graph.

The main property of a bow tie distribution  $D$  is that for every coordinate  $i$  for which  $(x_0)_i \neq (x_1)_i$  (equivalently  $(y_0)_i \neq (y_1)_i$ , or  $(z_0)_i \neq (z_1)_i$ ), the  $i^{\text{th}}$  coordinate of  $D$  is as hard as the GHZ game (i.e. players cannot produce winning answers for the  $i^{\text{th}}$  coordinate with probability more than  $\frac{3}{4}$ ). This follows by “locally embedding” the (unrepeated) GHZ query distribution into the  $i^{\text{th}}$  coordinate of  $D$  as follows. We first swap  $x_0 \leftrightarrow x_1$ ,  $y_0 \leftrightarrow y_1$ ,  $z_0 \leftrightarrow z_1$  as necessary to ensure that

$$(x_0)_i = (y_0)_i = (z_0)_i = 0. \quad (1)$$

An even number of swaps are required to do this by the assumption that  $x_0 + y_0 + z_0 = 0$ , and bow ties are invariant under an even number of such swaps. Thus Equation (1) is without loss of generality. Suppose  $\bar{f}_1, \bar{f}_2, \bar{f}_3 : \mathbb{F}_2^n \rightarrow \mathbb{F}_2$  comprise a strategy for the  $i^{\text{th}}$  coordinate of  $D$ . Then a strategy  $f_1, f_2, f_3 : \mathbb{F}_2 \rightarrow \mathbb{F}_2$  for the basic (unrepeated) GHZ game can be constructed as

$$\begin{aligned} f_1(b) &= \bar{f}_1(x_b) \\ f_2(b) &= \bar{f}_2(y_b) \\ f_3(b) &= \bar{f}_3(z_b). \end{aligned}$$

The winning probability of this strategy is the same as the winning probability of  $\bar{f}_1, \bar{f}_2, \bar{f}_3$  in the  $i^{\text{th}}$  coordinate because  $((x_{b_1})_i, (y_{b_2})_i, (z_{b_3})_i) = (b_1, b_2, b_3)$ . Hence both probabilities are at most  $3/4$ .

### Approximating $\mathcal{P}|E$ by Bow Ties

We now sketch how to approximate  $\mathcal{P}|E$  by a convex combination of bow tie distributions, where  $E$  is a product event  $E_1 \times E_2 \times E_3$ . We assume for now that the non-zero Fourier coefficients of each  $E_j$  are small. We will return to this assumption at the end of the overview – it turns out to be nearly without loss of generality.

We show that  $\mathcal{P}|E$  is close in total variational distance to the distribution obtained by sampling a *uniformly random* bow tie  $B \subseteq E$ , and then outputting a random element of  $B$ . The latter distribution is equivalent to sampling  $(x, y, z)$  with probability proportional to the number of bow ties  $B \subseteq E$  that contain  $(x, y, z)$ . This number is

$$\begin{cases} \left( \sum_{z' \in \mathbb{F}_2^n} E_1(y + z') E_2(x + z') E_3(z') \right) - 1 & \text{if } (x, y, z) \in \text{supp}(\mathcal{P}|E) \\ 0 & \text{otherwise,} \end{cases} \quad (2)$$

where we identify  $E_1, E_2$ , and  $E_3$  with their indicator functions. Note that we are subtracting 1 to cancel the term corresponding to  $z' = z$ .

Intuitively, the fact that all  $E_j$  have small Fourier coefficients means that they look random with respect to linear functions. Thus, one might guess that the above sum is close to  $2^n \cdot \mu(E_1)\mu(E_2)\mu(E_3)$  for most  $(x, y, z) \in \text{supp}(\mathcal{P}|E)$ , where  $\mu(S) = |S|/2^n$  denotes the measure of  $S$  under the uniform distribution on  $\mathbb{F}_2^n$ . If “close to” and “most” have the right meanings, then this would imply that our distribution is close in total variational distance to  $\mathcal{P}|E$  as desired.

Our full proof indeed establishes this. More precisely, we view Equation (2) as a vector indexed by  $(x, y, z)$  and establish bounds on that vector’s  $\ell_1$  and  $\ell_2$  norms as a criterion for near-uniformity. In the process our proof repeatedly uses the following claims (see Lemma 16). For all sets  $S, T \subseteq \mathbb{F}_2^n$  that are sufficiently large, we have

$$\mathbb{E}_{\substack{z \sim \mathbb{F}_2^n \\ x \sim \mathbb{F}_2^n}} [S(x) \cdot T(x+z) \cdot E_3(z)] \approx \mu(S) \cdot \mu(T) \cdot \mu(E_3)$$

and

$$\mathbb{E}_{z \sim \mathbb{F}_2^n} \left[ \left( \mathbb{E}_{x \sim \mathbb{F}_2^n} [S(x) \cdot E_2(x+z)] \right)^2 \cdot E_3(z) \right] \approx \mu(S)^2 \cdot \mu(E_2)^2 \cdot \mu(E_3).$$

### Most Bow Ties are Hard in Many Coordinates

For the final step of our proof, we need to show that the distribution of bow ties analyzed in the previous step produces (with high probability) bow ties that differ in many coordinates.

We begin by parameterizing a bow tie by  $(x_0, y_0, x_0 \oplus x_1)$  and noting that in the previous step, we essentially showed that  $E$  contains  $2^{3n-O(\log n)}$  different bow ties. The  $O(\log n)$  term in the exponent arises from the fact that the events  $\{E_j\}$  have density in  $\mathbb{F}_2^n$  that is inverse polynomial in  $n$ . A simple counting argument then shows that for a random bow tie, the min-entropy of  $x_0 \oplus x_1$  is close to  $n$ . This means that  $x_0 \oplus x_1$  is close to the uniform distribution in the sense that any event occurring with probability  $p$  under the uniform distribution occurs with probability  $p \cdot n^{O(1)}$  under the distribution of  $x_0 \oplus x_1$ . Thus we can finally apply a Chernoff bound to deduce that with all but  $2^{-\Omega(n)}$  probability,  $x_0 \oplus x_1$  has Hamming weight at least  $n/3$ .

In other words, a bow tie sampled uniformly at random differs in at least a  $\frac{1}{3}$  fraction of coordinates. By the main property of bow ties, this implies that the corresponding bow tie distribution is hard on a  $\frac{1}{3}$  fraction of coordinates (indeed, the same set of coordinates).

### Handling General Events

For general (product) events  $E = E_1 \times E_2 \times E_3$  (where the sets  $\{E_i\}$  need not have small Fourier coefficients), we can partition the universe  $\mathbb{F}_2^n \times \mathbb{F}_2^n \times \mathbb{F}_2^n$  into parts  $\pi$  such that for most of the parts  $\pi$ , the event  $E$  restricted to  $\pi$  has the structure that we already analyzed. For this to make sense, we ensure several properties of the partition. First,  $\pi$  should be a product set ( $\pi = \pi_1 \times \pi_2 \times \pi_3$ ) so that  $E \cap \pi$  is a product set as well, i.e.  $E \cap \pi$  has the form  $\tilde{E}_1 \times \tilde{E}_2 \times \tilde{E}_3$ . Second, each  $\pi_i$  should be an affine subspace of  $\mathbb{F}_2^n$  so that we can do Fourier analysis with respect to this subspace. Finally  $\pi_1, \pi_2$ , and  $\pi_3$  should all be affine shifts of the *same* linear subspace so that the set  $\{(x, y, z) \in \pi : x + y + z = 0\}$  has the same Fourier-analytic structure as the parallel repeated GHZ query set  $\{(x, y, z) \in (\mathbb{F}_2^{n'})^3 : x + y + z = 0\}$  for some  $n' < n$ .

We prove the existence of such a partition with  $n'$  not too small ( $n' = n - o(n)$ ) by a simple iterative approach, which is similar to [18].

## 1.2 Comparison to [18]

Our proof has some similarity to [18] – in particular, both proofs partition  $(\mathbb{F}_2^n)^3$  into subspaces according to Fourier-analytic criteria and analyze these subspaces separately – but the resemblance ends there. In fact, there are fundamental high-level differences between the two proofs.

The biggest qualitative difference is that our high-level approach decomposes any conditional distribution  $\mathcal{P}|E$  into components (bow tie distributions) for which many coordinates are hard. [18] takes an analogous approach, but it establishes a weaker result that differs in the order of quantifiers: it first fixes a strategy  $f$ , and then decomposes  $\mathcal{P}|E$  into components such that  $f$  performs poorly on many coordinates of many components. This difference is due to the fact that [18] uses uniform distributions on high-dimensional affine spaces as their basic “hard” distributions. It is not in general possible to express  $\mathcal{P}|E$  as a convex combination of such distributions (for example if each  $E_j$  is a uniformly random subset of  $\mathbb{F}_2^n$ ). Instead, [18] expresses  $\mathcal{P}|E$  as a convex combination of “pseudo-affine” distributions. This significantly complicates their proof, and we avoid this complication entirely by our use of bow tie distributions, which are novel to this work.

The remainder of our proof (the analysis of hardness within each part of the partition) is entirely different.

## 2 Notation & Preliminaries

A significant portion of these preliminaries is taken verbatim from [18].

We write  $\exp(t)$  to denote  $e^t$  for  $t \in \mathbb{R}$ .

Let  $n \in \mathbb{N}$ . For a vector  $v \in \mathbb{R}^n$  and  $i \in [n]$ , we write  $v(i)$  or  $v^i$  to denote the  $i$ -th coordinate of  $v$ . For  $p \in \mathbb{N}$ , we write  $\|v\|_p \stackrel{\text{def}}{=} \left( \sum_{i \in [n]} |v(i)|^p \right)^{1/p}$  to denote the  $\ell_p$  norm of  $v$ .

For  $z \in \{0, 1\}^*$ ,  $\text{hwt}(z) \stackrel{\text{def}}{=} \|z\|_1$  denotes the Hamming weight of  $z$ .

We crucially rely on the Cauchy-Schwarz inequality.

► **Fact 2 (Cauchy-Schwarz).** *Let  $k \in \mathbb{N}$  and  $a_1, \dots, a_k, b_1, \dots, b_k \in \mathbb{R}$ . Then,  $\sum_{i=1}^k |a_i \cdot b_i| \leq \sqrt{\sum_{i=1}^k a_i^2} \cdot \sqrt{\sum_{i=1}^k b_i^2}$ .*

### 2.1 Set Theory

Let  $\Omega$  be a universe. By a partition of  $\Omega$ , we mean a collection of pairwise disjoint subsets of  $\Omega$ , whose union equals  $\Omega$ . If  $\Pi$  is a partition of  $\Omega$  and  $\omega$  is an element of  $\Omega$ , we will write  $\Pi(\omega)$  to denote the (unique) element of  $\Pi$  that contains  $\omega$ . Thus, we can view  $\Pi$  as a function  $\Pi : \Omega \rightarrow 2^\Omega$ .

For a set  $S \subseteq \Omega$ , we identify  $S$  with its indicator function  $S : \Omega \rightarrow \{0, 1\}$  defined at  $\omega \in \Omega$  by

$$S(\omega) = \begin{cases} 1 & \text{if } \omega \in S \\ 0 & \text{otherwise.} \end{cases}$$

For sets  $S, T \subseteq \Omega$  such that  $T \neq \emptyset$ , we use  $S|_T \subseteq T$  to denote the set  $S \cap T$  when viewed as a subset of  $T$ . In particular,  $S|_T$  is an indicator function from  $T$  to  $\{0, 1\}$ .

## 2.2 Probability Theory

### Probability Distributions

Let  $P$  be a distribution over a universe  $\Omega$ . We sometimes think of  $P$  as a vector in  $\mathbb{R}^{|\Omega|}$  whose value in coordinate  $\omega \in \Omega$  is  $P(\omega)$ . In particular, we use  $\|P - Q\|_1$  to denote the  $\ell_1$  norm of the vector  $P - Q \in \mathbb{R}^{|\Omega|}$ , where  $P$  and  $Q$  are probability distributions. We use  $\omega \sim P$  to denote a random element  $\omega$  distributed according to  $P$ . We use  $\text{supp}(P) = \{\omega \in \Omega : P(\omega) > 0\}$  to denote the support of the distribution  $P$ .

### Random Variables

Let  $\Sigma$  be any alphabet. We say that  $X : \Omega \rightarrow \Sigma$  is a  $\Sigma$ -valued random variable. If  $\Sigma = \mathbb{R}$ , we say that the random variable is real-valued. If  $X$  is a real-valued random variable, the expectation of  $X$  under  $P$  is denoted  $\mathbb{E}_{\omega \sim P}[X(\omega)]$ . Often, the underlying distribution  $P$  is implicit, in which case we simply use  $\mathbb{E}[X]$ . If  $X$  is a  $\Sigma$ -valued random variable and  $P$  is a probability distribution, we write  $P_X$  or  $X(P)$  to denote the induced probability distribution of  $X$  under  $P$ , i.e.,  $P_X(\sigma) = (X(P))(\sigma) \stackrel{\text{def}}{=} P(X = \sigma)$  for all  $\sigma \in \Sigma$ . In particular, we say that  $X$  is distributed according to  $P_X$  and we use  $\sigma \sim X(P)$  to denote a random variable  $\sigma$  distributed according to  $P_X$ . The distribution  $P$  is often implicit, and we identify  $X$  with the underlying distribution  $P_X$ .

### Events

We refer to subsets of  $\Omega$  as events. We use standard shorthand for denoting events. For instance, if  $X$  is a  $\Sigma$ -valued random variable and  $x \in \Sigma$ , we write  $X = x$  to denote the event  $\{\omega \in \Omega : X(\omega) = x\}$ . Similarly, for a subset  $F \subseteq \Sigma$ , we write  $X \in F$  to denote the event  $\{\omega \in \Omega : X(\omega) \in F\}$ . We use  $P(E)$  to denote the probability of  $E$  under  $P$ . When  $P$  is implicit, we use the notation  $\Pr(E)$  to denote  $P(E)$ .

### Conditional Probabilities

Let  $E \subseteq \Omega$  be an event with  $P(E) > 0$ . Then the conditional distribution of  $P$  given  $E$  is denoted  $(P|E) : \Omega \rightarrow \mathbb{R}$  and is defined to be

$$(P|E)(\omega) = \begin{cases} P(\omega)/P(E) & \text{if } \omega \in E \\ 0 & \text{otherwise.} \end{cases}$$

If  $E$  is an event, we write  $P_{X|E}$  as shorthand for  $(P|E)_X$ .

### Measure under Uniform Distribution

For any set  $S \subseteq \Omega$ , we sometimes identify  $S$  with the uniform distribution over  $S$ . In particular, we use  $x \sim S$  to denote  $x$  sampled according to the uniform distribution on  $S$ . For  $S, \pi \subseteq \Omega$  such that  $\pi \neq \emptyset$ , we use  $\mu_\pi(S) = \frac{|S \cap \pi|}{|\pi|}$  to denote the measure of  $S$  under the uniform distribution over  $\pi$ . When  $\pi = \Omega$ , we omit the subscript and simply use  $\mu(S)$ .

## 2.3 Fourier Analysis

### Fourier Analysis over Subspaces

For any (finite) vector space  $\mathcal{V}$  over  $\mathbb{F}_2$ , the character group of  $\mathcal{V}$ , denoted  $\widehat{\mathcal{V}}$ , is the set of group homomorphisms mapping  $\mathcal{V}$  (viewed as an additive group) to  $\{-1, 1\}$  (viewed as a

## 62:8 Parallel Repetition for the GHZ Game: A Simpler Proof

multiplicative group). Each such homomorphism is called a character of  $\mathcal{V}$ . For functions mapping  $\mathcal{V} \rightarrow \mathbb{R}$ , we define the inner product

$$\langle f, g \rangle \stackrel{\text{def}}{=} \mathbb{E}_{x \sim \mathcal{V}} [f(x)g(x)].$$

The character group of  $\mathcal{V}$  forms an orthonormal basis under this inner product. We refer to the all-ones functions  $\chi : \mathcal{V} \rightarrow \{-1, 1\}$ ,  $\chi \equiv 1$  as the *trivial character* or the *zero character* and denote this by  $\chi = \emptyset$ .

For all characters  $\chi \neq \emptyset$ , since  $\langle \chi, \emptyset \rangle = 0$ , we have  $\mathbb{E}_{x \sim \mathcal{V}} [\chi(x)] = 0$ , in particular,  $\chi(\mathcal{V})$  is a uniform  $\{\pm 1\}$ -random variable. Let  $\emptyset \neq S \subseteq \mathcal{V}$  be a set. Then  $\mu_{\mathcal{V}}(S) \triangleq \frac{|S \cap \mathcal{V}|}{|\mathcal{V}|} = \widehat{S}(\emptyset)$ , where we identify  $S$  with its indicator function  $S : \mathcal{V} \rightarrow \{0, 1\}$  as mentioned before. For  $\chi \in \widehat{\mathcal{V}}$ , we have  $\mathbb{E}_{x \sim S} [\chi(x)] = \frac{\widehat{S}(\chi)}{\widehat{S}(\emptyset)}$ .

► **Fact 3.** *Given a choice of basis for  $\mathcal{V}$ , there is a canonical isomorphism between  $\mathcal{V}$  and  $\widehat{\mathcal{V}}$ . Specifically, if  $\mathcal{V} = \mathbb{F}_2^n$ , then the characters of  $\mathcal{V}$  are the functions of the form*

$$\chi_{\gamma}(v) = (-1)^{\gamma \cdot v}$$

for  $\gamma \in \mathbb{F}_2^n$ .

► **Definition 4.** *For any function  $f : \mathcal{V} \rightarrow \mathbb{R}$ , its Fourier transform is the function  $\widehat{f} : \widehat{\mathcal{V}} \rightarrow \mathbb{R}$  defined by*

$$\widehat{f}(\chi) \stackrel{\text{def}}{=} \langle f, \chi \rangle = \mathbb{E}_{x \sim \mathcal{V}} [f(x)\chi(x)].$$

Since the characters of  $\mathcal{V}$  are orthonormal and  $\mathcal{V}$  is finite, we can deduce that  $f$  is equal to  $\sum_{\chi \in \widehat{\mathcal{V}}} \widehat{f}(\chi) \cdot \chi$ .

► **Theorem 5 (Plancherel).** *For any  $f, g : \mathcal{V} \rightarrow \mathbb{R}$ ,*

$$\langle f, g \rangle = \sum_{\chi \in \widehat{\mathcal{V}}} \widehat{f}(\chi) \cdot \widehat{g}(\chi).$$

An important special case of Plancherel's theorem is Parseval's theorem:

► **Theorem 6 (Parseval).** *For any  $f : \mathcal{V} \rightarrow \mathbb{R}$ ,*

$$\mathbb{E}_{x \sim \mathcal{V}} [f(x)^2] = \sum_{\chi \in \widehat{\mathcal{V}}} \widehat{f}(\chi)^2.$$

### Fourier Analysis over Affine Subspaces

Fix any subspace  $\mathcal{V} \subseteq \mathbb{F}_2^n$  and a vector  $a \in \mathbb{F}_2^n$ . Let  $\mathcal{U} = a + \mathcal{V}$  denote the affine subspace obtained by shifting  $\mathcal{V}$  by  $a$ . For every function  $f : \mathcal{V} \rightarrow \mathbb{R}$ , we associate it with a function  $f_a : \mathcal{U} \rightarrow \mathbb{R}$  defined by  $f_a(x) = f(x + a)$  for all  $x \in \mathcal{U}$ . This is a bijective correspondence between the set of functions from  $\mathcal{U}$  to  $\mathbb{R}$  and the set of functions from  $\mathcal{V}$  to  $\mathbb{R}$ . Under this association, we can identify  $\chi \in \widehat{\mathcal{V}}$  with  $\chi_a : \mathcal{U} \rightarrow \{-1, 1\}$  where  $\chi_a(x) = \chi(x + a)$  for all  $x \in \mathcal{U}$ . This defines an orthonormal basis  $\widehat{\mathcal{U}}_a := \{\chi_a : \mathcal{U} \rightarrow \{-1, 1\} \mid \chi \in \widehat{\mathcal{V}}\}$  for the vector space of functions from  $\mathcal{U}$  to  $\mathbb{R}$ . We call this the Fourier basis for  $\mathcal{U}$  with respect to  $a$ . This basis depends on the choice of the shift  $a \in \mathcal{U}$ . However, for all possible shifts  $b \in \mathcal{U}$  and character functions  $\chi \in \widehat{\mathcal{V}}$ , the functions  $\chi_a$  and  $\chi_b$  only differ by a sign. To see this, observe that

$$\chi_a(x) = \chi(a + x) = \chi(b + x) \cdot \chi(a + b) = \chi_b(x) \cdot \chi(a + b)$$

We will sometimes ignore the subscript and simply use  $\chi \in \widehat{\mathcal{V}}$  to index functions in the Fourier basis of  $\mathcal{U}$ . This is particularly the case when the properties we are dealing are independent of choice of basis (for example, the absolute values of Fourier coefficients of a function).

## 2.4 Multi-Player Games

In parallel repetition we often work with Cartesian product sets of the form  $(\mathcal{X}_1 \times \cdots \times \mathcal{X}_k)^n$ . For these sets, we will use subscripts to index the inner product and superscripts to index the outer product. That is, for  $\mathcal{X} = \mathcal{X}_1 \times \cdots \times \mathcal{X}_k$  we view elements  $x$  of  $\mathcal{X}^n$  as tuples  $(x_1, \dots, x_k)$ , where  $x_i \in \mathcal{X}_i^n$ . We use  $x_i^j$  or  $x_i(j)$  to refer to the  $j^{\text{th}}$  coordinate of  $x_i$ . We use  $x^j$  to denote the vector  $(x_1^j, \dots, x_k^j)$ .

If  $\{E_i \subseteq \mathcal{X}_i\}_{i \in [k]}$  is a collection of subsets, we write  $E_1 \times \cdots \times E_k$  to denote the set  $\{x \in \mathcal{X} : \forall i \in [k], x_i \in E_i\}$ . We say that  $f : (\mathcal{X}_1 \times \cdots \times \mathcal{X}_k)^n \rightarrow (\mathcal{Y}_1 \times \cdots \times \mathcal{Y}_k)^n$  is a product function if  $f = f_1 \times \cdots \times f_k$  for some functions  $f_i : \mathcal{X}_i^n \rightarrow \mathcal{Y}_i^n$ .

► **Definition 7 (Multi-player Games).** A  $k$ -player game is a tuple  $(\mathcal{X}, \mathcal{Y}, Q, W)$ , where  $\mathcal{X} = \mathcal{X}_1 \times \cdots \times \mathcal{X}_k$  and  $\mathcal{Y} = \mathcal{Y}_1 \times \cdots \times \mathcal{Y}_k$  are finite sets,  $Q$  is a probability measure on  $\mathcal{X}$ , and  $W : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1\}$  is a “winning” predicate. We refer to  $Q$  as the query distribution or the input distribution of the game.

► **Definition 8 (Deterministic Strategies).** A deterministic strategy for a  $k$ -player game  $\mathcal{G} = (\mathcal{X}, \mathcal{Y}, Q, W)$  is a function  $f = f_1 \times \cdots \times f_k$  where each  $f_i : \mathcal{X}_i \rightarrow \mathcal{Y}_i$ . The success probability of  $f$  in  $\mathcal{G}$  is denoted and defined as

$$\text{val}(\mathcal{G}, f) \stackrel{\text{def}}{=} \Pr_{x \sim Q} [W(x, f(x)) = 1].$$

The most important quantity associated with a game is the maximum probability with which the game can be “won”.

► **Definition 9.** The value of a  $k$ -player game  $\mathcal{G} = (\mathcal{X}, \mathcal{Y}, Q, W)$ , denoted  $\text{val}(\mathcal{G})$ , is the maximum, over all deterministic strategies  $f$ , of  $\text{val}(\mathcal{G}, f)$ .

It is often easier to construct *probabilistic* strategies for a game, i.e. strategies in which players may use shared and/or individual randomness in computing their answers.

► **Definition 10 (Probabilistic Strategies).** Let  $\mathcal{G} = (\mathcal{X}, \mathcal{Y}, Q, W)$  be a  $k$ -player game. A probabilistic strategy for  $\mathcal{G}$  is a distribution  $\mathcal{F}$  of deterministic strategies for  $\mathcal{G}$ . The success probability of  $\mathcal{F}$  in  $\mathcal{G}$  is denoted and defined as

$$\text{val}(\mathcal{G}, \mathcal{F}) \stackrel{\text{def}}{=} \Pr_{\substack{x \sim Q \\ f \sim \mathcal{F}}} [W(x, f(x)) = 1].$$

A standard averaging argument implies that for every game, probabilistic strategies cannot achieve better success probability than deterministic strategies:

► **Fact 11.** Replacing “deterministic strategies” by “probabilistic strategies” in Definition 9 yields an equivalent definition.

The main operation on multi-player games that we consider in this paper is parallel repetition:

## 62:10 Parallel Repetition for the GHZ Game: A Simpler Proof

► **Definition 12** (Parallel Repetition). Given a  $k$ -player game  $\mathcal{G} = (\mathcal{X}, \mathcal{Y}, Q, W)$ , its  $n$ -fold parallel repetition, denoted  $\mathcal{G}^n$ , is defined as the  $k$ -player game  $(\mathcal{X}^n, \mathcal{Y}^n, Q^n, W^n)$ , where  $W^n(x, y) \stackrel{\text{def}}{=} \bigwedge_{j=1}^n W(x^j, y^j)$ . For  $x \in \mathcal{X}^n$ , we refer to  $x_i \in \mathcal{X}_i^n$  as the input to the  $i$ -th player.

To bound the value of parallel repeated games, it is helpful to analyze the probability of winning in a particular instance of the game under various modified query distributions.

► **Definition 13** (Value in  $j^{\text{th}}$  coordinate). If  $\mathcal{G} = (\mathcal{X}, \mathcal{Y}, Q, W^n)$  is a game (with a product winning predicate), the value of  $\mathcal{G}$  in the  $j^{\text{th}}$  coordinate for  $j \in [n]$ , denoted  $\text{val}^{(j)}(\mathcal{G})$ , is the value of the game  $(\mathcal{X}, \mathcal{Y}, Q, W')$ , where  $W'(x, y) = W(x^j, y^j)$ .

► **Definition 14** (Game with Modified Query Distribution). Let  $\mathcal{G} = (\mathcal{X}, \mathcal{Y}, Q, W)$  be a game. For a probability measure  $P$  on  $\mathcal{X}$ , we write  $\mathcal{G}|P$  to denote the game  $(\mathcal{X}, \mathcal{Y}, P, W)$ . For an event  $E$  on  $\mathcal{X}$ , we write  $\mathcal{G}|E$  to denote the game  $(\mathcal{X}, \mathcal{Y}, Q_E, W)$ .

### 2.5 GHZ Distribution

Let  $\mathcal{X} = \mathcal{X}_1 \times \mathcal{X}_2 \times \mathcal{X}_3$  and  $\mathcal{Y} = \mathcal{Y}_1 \times \mathcal{Y}_2 \times \mathcal{Y}_3$  where  $\mathcal{X}_i = \mathcal{Y}_i = \mathbb{F}_2$ . Let  $Q$  denote the uniform distribution over  $\{(0, 0, 0), (0, 1, 1), (1, 0, 1), (1, 1, 0)\}$ . Define  $W : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1\}$  at  $x \in \mathcal{X}, y \in \mathcal{Y}$  by  $W(x, y) = 1$  if and only if  $x_1 \vee x_2 \vee x_3 = y_1 + y_2 + y_3 \pmod{2}$ . The GHZ game refers to the 3-player game  $(\mathcal{X}, \mathcal{Y}, Q, W)$ , which has value  $3/4$ . The  $n$ -fold repeated GHZ game refers to the  $n$ -fold parallel repetition of  $(\mathcal{X}, \mathcal{Y}, Q, W)$ . Our parallel repetition results easily generalize with any other (constant-sized) answer alphabet  $\mathcal{Y}'$  and any predicate  $W'$ , as long as the game  $(\mathcal{X}, \mathcal{Y}', Q, W')$  has value less than 1.

We typically use  $X = (X_1, X_2, X_3) \in \mathcal{X}^n$  to denote a random variable distributed according to  $Q^n$  where  $X_i \in \mathcal{X}_i^n$  denotes the input to the  $i$ -th player.

## 3 Partitioning into Pseudorandom Subspaces

We make use of the notion of affine partition similar to the one defined in [18]. We say that  $\Pi$  is an affine partition of  $(\mathbb{F}_2^n)^3$  of codimension at most  $d$  if  $\Pi$  is a partition on  $(\mathbb{F}_2^n)^3$  and:

- Each part  $\pi \in \Pi$  has the form  $a_\pi + \mathcal{V}_\pi^3$  where  $\mathcal{V}_\pi$  is a subspace of  $\mathbb{F}_2^n$  and  $a_\pi \in (\mathbb{F}_2^n)^3$ , and
- Each  $\mathcal{V}_\pi$  has codimension at most  $d$ .

The main take-away from this section is Proposition 15, which states the following: Given the query distribution to the  $n$ -fold GHZ game, and a product event  $E \subseteq (\mathbb{F}_2^n)^3$  with large enough probability mass, we can find an affine partition  $\Pi$  of  $(\mathbb{F}_2^n)^3$  such that on a typical part  $\pi \in \Pi$ , the non-zero Fourier coefficients of the indicator functions  $E_1|_{\pi_1}, E_2|_{\pi_2}, E_3|_{\pi_3}$  are small. Recall that  $E_i|_{\pi_i} : \pi_i \rightarrow \{0, 1\}$  is the indicator function of the set  $E_i \cap \pi_i \subseteq \pi_i$ .

Formally, the proposition is as follows:

► **Proposition 15.** Let  $\mathcal{P} = Q^n$ . Let  $E = E_1 \times E_2 \times E_3 \subseteq (\mathbb{F}_2^n)^3$  be such that  $\mathcal{P}(E) = \alpha$ . For all  $\delta > 0$ , there exists an affine partition  $\Pi$  of  $(\mathbb{F}_2^n)^3$  of codimension at most  $\frac{3}{\delta^3}$  such that the following holds. With probability at least  $1 - \frac{\delta}{\alpha}$  over  $\pi \sim \Pi(\mathcal{P}|E)$ , for all  $i \in [3]$  and non-zero  $\chi \in \widehat{\mathcal{V}}$ , we have  $\left| \widehat{E_i|_{\pi_i}}(\chi) \right| \leq \delta$ , where  $\pi$  is of the form  $\pi_1 \times \pi_2 \times \pi_3$  for affine shifts  $\pi_1, \pi_2, \pi_3$  of some subspace  $\mathcal{V}$  of  $\mathbb{F}_2^n$ .

Recall that  $\Pi(\mathcal{P}|E)$  is the distribution induced by sampling  $x \sim \mathcal{P}|E$  and outputting the part of  $\Pi$  to which  $x$  belongs. Note that in the statement of the proposition, we don't specify a choice of Fourier basis for  $\pi_i$ . This is because for any set  $S \subseteq \pi_i$ , the quantity  $\left| \widehat{S}(\chi_{a_i}) \right|$  is

independent of choice of  $a_i \in \pi_i$  so we simply write  $|\widehat{S}(\chi)|$ . The proof of Proposition 15 is similar in nature to the proof of Lemma 6.2 in [18], but is much simpler and is presented in the full version of the paper.

#### 4 Key Fourier Analytic Lemmas

We crucially make use of the following lemma, the proof of which can be found in the full version of the paper.

► **Lemma 16.** *Let  $\mathcal{V} \subseteq \mathbb{F}_2^n$  be a subspace and  $a_1, a_2, a_3 \in \mathbb{F}_2^n$  be such that  $a_1 + a_2 + a_3 = 0$ . Let  $\pi = \pi_1 \times \pi_2 \times \pi_3$  where  $\pi_i = a_i + \mathcal{V}$ . Let  $A \subseteq \pi_1, B \subseteq \pi_2, C \subseteq \pi_3$  be sets such that for all non-zero  $\chi \in \widehat{\mathcal{V}}$ , we have  $|\widehat{C}(\chi)| \leq \delta_1$ . Then,*

$$\left| \mathbb{E}_{\substack{z \sim \pi_3 \\ x \sim \pi_1}} [A(x) \cdot B(x+z) \cdot C(z)] - \mu_{\pi_1}(A) \cdot \mu_{\pi_2}(B) \cdot \mu_{\pi_3}(C) \right| \leq \delta_1.$$

If furthermore for all non-zero  $\chi \in \widehat{\mathcal{V}}$ , we have  $|\widehat{B}(\chi)| \leq \delta_2$ , then

$$\left| \mathbb{E}_{z \sim \pi_3} \left[ \left( \mathbb{E}_{x \sim \pi_1} [A(x) \cdot B(x+z)] \right)^2 \cdot C(z) \right] - \mu_{\pi_1}(A)^2 \cdot \mu_{\pi_2}(B)^2 \cdot \mu_{\pi_3}(C) \right| \leq \delta_2^2 + \delta_1.$$

Recall from Section 2.2 that  $\mu_{\pi_i}(S) \triangleq \frac{|S \cap \pi_i|}{|\pi_i|}$ . In the statement of this lemma, we don't specify a choice of Fourier basis for  $\pi_2$  and  $\pi_3$ . Since the properties  $|\widehat{C}(\chi_{a_3})| \leq \delta_1$  and  $|\widehat{B}(\chi_{a_2})| \leq \delta_2$  are independent of the choice of  $a_2$  and  $a_3$ , we simply write  $|\widehat{C}(\chi)| \leq \delta_1$  and  $|\widehat{B}(\chi)| \leq \delta_2$ .

#### 5 Main Proof

We use the following Parallel Repetition Criterion which is similar to, but weaker than the one from [18] for the GHZ game and has a slightly simpler proof.

Let  $\mathcal{G}$  refer to the  $n$ -fold parallel repetition of the GHZ game. Let  $\mathcal{P} = \mathcal{Q}^n$ .

► **Lemma 17 (Parallel Repetition Criterion).** *Let  $c \in (0, 1]$  be a constant and  $\rho(n) : \mathbb{N} \rightarrow \mathbb{R}$  be a function such that  $\rho(n) \geq \exp(-n)$ . Suppose for all large  $n \in \mathbb{N}$  and all subsets  $E_1, E_2, E_3 \subseteq \mathbb{F}_2^n$  such that  $\mathcal{P}(E) \geq \rho(n)$  where  $E = E_1 \times E_2 \times E_3$ , we have  $\mathbb{E}_{i \sim [n]} [\text{val}^{(i)}(\mathcal{G}|E)] \leq 1 - c$ . Then,*

$$\text{val}(\mathcal{G}) \leq \rho(n)^{\Omega(1)}.$$

This lemma is proved in [18] under the weaker assumption that there is *some* coordinate  $i \in [n]$  for which  $\text{val}^{(i)}(\mathcal{G}|E) \leq 1 - c$ . The proof is slightly simpler under our stronger assumption that  $\mathbb{E}_{i \sim [n]} [\text{val}^{(i)}(\mathcal{G}|E)] \leq 1 - c$ . We prove this in Appendix A.1.

Given this criterion, our goal of showing an inverse polynomial bound for  $\text{val}(\mathcal{G})$  reduces to showing the following. Let  $E = E_1 \times E_2 \times E_3$  be any event such that  $\mathcal{P}(E) = \alpha \geq \frac{1}{n^{1/100}}$  and  $n$  be large enough. It suffices to show that  $\mathbb{E}_{i \sim [n]} [\text{val}^{(i)}(\mathcal{G}|E)] \leq 0.95$ . We do this as follows.

Let  $\delta = \frac{\alpha^{20}}{n^{1/40}}$ . Proposition 15 implies the existence of a partition  $\Pi$  of  $(\mathbb{F}_2^n)^3$  into affine subspaces of codimension at most  $O\left(\frac{1}{\delta^3}\right) = o(n)$  such that:

## 62:12 Parallel Repetition for the GHZ Game: A Simpler Proof

- Every  $\pi \in \Pi$  is of the form  $a + \mathcal{V}^3$  where  $\mathcal{V} \subseteq \mathbb{F}_2^n$  is a subspace and  $a \in (\mathbb{F}_2^n)^3$ .
- With probability at least  $1 - \frac{\delta}{\mathcal{P}(E)} \geq 1 - o(1)$  over  $\pi \sim \Pi(\mathcal{P}|E)$ , we have  $\left| \widehat{E_i|_{\pi_i}}(\chi) \right| \leq \delta$  for all  $i \in [3]$  and non-zero  $\chi \in \widehat{\mathcal{V}}$ , where  $\mathcal{V}$  is the subspace of  $\mathbb{F}_2^n$  for which  $\pi$  is an affine shift of  $\mathcal{V}^3$ .

Under the distribution  $\Pi(\mathcal{P}|E)$ , the probability that  $\pi$  is sampled equals  $\frac{(\mathcal{P}|\pi)(E) \cdot \mathcal{P}(\pi)}{\mathcal{P}(E)}$  by Bayes' rule. This implies that the probability that  $\pi \sim \Pi(\mathcal{P}|E)$  satisfies  $(\mathcal{P}|\pi)(E) \leq \mathcal{P}(E)/10$  is at most  $1/10$ . We will focus on  $\pi = \pi_1 \times \pi_2 \times \pi_3$  that satisfy both these properties, namely, the measure of  $E$  under  $\mathcal{P}|\pi$  is significant, furthermore, for all  $i \in [3]$ , all non-zero Fourier coefficients of the sets  $E_i$  restricted to  $\pi_i$  are small.

► **Definition 18.** *We say that  $\pi$  is good if*

$$(\mathcal{P}|\pi)(E) \geq \alpha/10, \text{ and for all non-zero } \chi \in \widehat{\mathcal{V}} \text{ and } i \in [3], \text{ we have } \left| \widehat{E_i|_{\pi_i}}(\chi) \right| \leq \delta. \quad (3)$$

By a union bound, a random  $\pi \sim \Pi(\mathcal{P}|E)$  will be good with probability at least  $1 - \frac{1}{10} - \frac{\delta}{\alpha}$ . Fix any such good  $\pi = \pi_1 \times \pi_2 \times \pi_3 \in \Pi$ , and let  $\mathcal{V}$  be the subspace such that  $\pi$  is an affine shift of  $\mathcal{V}^3$ .

For all  $z \in E_3 \cap \pi_3$ , define a (partial) matching  $M_z$  between  $\pi_1$  and  $\pi_2$  as follows. For  $x \in \pi_1 \cap E_1, y \in \pi_2 \cap E_2, z \in \pi_3 \cap E_3$  such that  $x + y = z$ , put an edge  $(x, y)$ . Let  $L_z$  (resp.  $R_z$ ) be the left (resp. right) endpoints of  $M_z$ . Let  $G = \cup_{z \in E_3 \cap \pi_3} M_z$  be the bipartite graph between  $\pi_1$  and  $\pi_2$  obtained by combining edges from the matchings for  $z \in E_3 \cap \pi_3$ . Let  $E(G)$  denote the set of edges in  $G$ . For every edge  $e \in E(G)$ , we can identify  $e$  with a valid input to the  $n$ -fold GHZ game that is contained in  $E \cap \pi$ . Namely, we associate  $(x_0, y_0) \in E(G)$  to the input  $(x_0, y_0, x_0 + y_0) \in \text{supp}(\mathcal{P}) \cap E \cap \pi$ . This is a bijective correspondence because of the way we defined the graph  $G$ . Under this correspondence, the uniform distribution over edges of  $G$  corresponds to the distribution  $\mathcal{P}|E, \pi$ . We now introduce the important notion of a bow tie.

► **Definition 19 (Bow Tie).** *We say that a subset of edges  $b \subseteq E(G)$  is a bow tie if  $b = \{x_0, x_1\} \times \{y_0, y_1\}$  for some  $x_0 \neq x_1 \in \pi_1, y_0 \neq y_1 \in \pi_2$  such that  $x_0 + y_0 = x_1 + y_1$  (or equivalently  $x_0 + y_1 = x_1 + y_0$ ). Alternatively, for  $z_0 = x_0 + y_0$  and  $z_1 = x_0 + y_1$ , we have  $(x_i, y_j, z_k) \in \text{supp}(\mathcal{P})$  for all  $(i, j, k) \in \text{supp}(\mathcal{Q})$ .*

Let  $b = \{x_0, x_1\} \times \{y_0, y_1\}$  be a bow tie. As before, we identify  $b$  with the indicator vector  $b \in \{0, 1\}^{E(G)}$  of the edges of  $b$ , that is,  $b(e) = 1$  iff  $e \in \{(x_i, y_j) : i, j \in \{0, 1\}\}$ . We use  $\tilde{b}$  to denote the uniform distribution on the edges of the bow tie, when viewed as inputs to the  $n$ -fold GHZ game. More precisely,  $\tilde{b}$  denotes the uniform distribution on  $\{(x_i, y_j, x_i + y_j) \mid i, j \in \{0, 1\}\}$ .

We say that  $b$  differs in the  $i$ -th coordinate for  $i \in [n]$  if  $x_0(i) \neq x_1(i)$ , or equivalently,  $y_0(i) \neq y_1(i)$ , or equivalently,  $z_0(i) \neq z_1(i)$ .

Let  $b$  be a bow tie and  $I \subseteq [n]$  be the coordinates on which  $b$  differs. The following claim shows that  $\text{val}^{(i)}(\mathcal{G}\tilde{b}) \leq 3/4$  for all  $i \in I$ . The proof is deferred to Appendix A.2

▷ **Claim 20.** Let  $b = \{x_0, x_1\} \times \{y_0, y_1\}$  be a bow tie. Let  $I \subseteq [n]$  be the subset of coordinates on which  $b$  differs. Then,  $\text{val}^{(i)}(\mathcal{G}\tilde{b}) \leq 3/4$  for all  $i \in I$ .

Let  $B$  denote the set of all bow ties. Consider the distribution on edges defined by first sampling a uniformly random bow tie from  $B$ , and then a uniformly random edge from the bow tie. We now provide an alternate description of this distribution. For each  $z \in E_3 \cap \pi_3$ , define  $1_z \in \{0, 1\}^{|E(G)|}$  as follows. For each  $e = (x, y) \in E(G)$ , define  $1_z(e) = 1$  if  $x$  and  $y$

are both matched in  $M_z$  but not to each other, and define  $1_z(e) = 0$  otherwise. Alternatively,  $1_z$  is the indicator of the set  $((L_z \times R_z) \setminus M_z) \cap E(G)$ . Let  $v := \mathbb{E}_{z \sim E_3 \cap \pi_3}[1_z]$ . Note that  $v$  has  $|E(G)|$  coordinates, each of which have non-negative values, so  $v$  induces a distribution on  $E(G)$ . Consider this distribution  $\tilde{v} = \frac{v}{\|v\|_1}$  on  $E(G)$  defined by normalizing  $v$ . We show that this distribution is an alternate description of the aforementioned distribution.

▷ **Claim 21.**  $v = |E_3 \cap \pi_3|^{-1} \cdot (\sum_{b \in B} b)$ . In particular, we can think of the distribution  $\tilde{v} := \frac{v}{\|v\|_1}$  on  $E(G)$  as obtained by sampling a uniformly random bow tie  $b$  in  $G$  and outputting a uniformly random edge of  $b$ .

The proof of this is deferred to Appendix A.3. Our goal now is to show that the distribution  $\tilde{v}$  is close to the uniform distribution over edges of  $G$ . To do so, we study some properties of  $G$ . Observe that  $|E(G)| \triangleq |\mathcal{V}|^2 \cdot \mathbb{E}_{\substack{x \sim \pi_1 \\ z \sim \pi_3}}[E_1(x) \cdot E_2(x+z) \cdot E_3(z)]$ . We apply Lemma 16 with parameters  $A = E_1 \cap \pi_1, B = E_2 \cap \pi_2, C = E_3 \cap \pi_3$ . Since  $\pi \in \text{supp}(\Pi(\mathcal{P}|E))$ , the set  $\pi \cap \text{supp}(\mathcal{P})$  is non-empty, therefore, we may choose  $a \in \text{supp}(\mathcal{P})$  so that  $\pi = a + \mathcal{V}^3$ . This, along with Equation (3) implies that the first hypothesis of Lemma 16 is satisfied. Lemma 16 implies that

$$\left| |E(G)| - |\mathcal{V}|^2 \cdot \mu_{\pi_1}(E_1) \cdot \mu_{\pi_2}(E_2) \cdot \mu_{\pi_3}(E_3) \right| \leq |\mathcal{V}|^2 \cdot \delta. \quad (4)$$

We make use of the following bounds on the  $\ell_1$  and  $\ell_2$  norms of  $v$ . The proofs of these are by Fourier analysis and are deferred to Appendices A.4 and A.5.

▷ **Claim 22.**

$$\begin{aligned} \|v\|_1 &\geq |\mathcal{V}|^2 \cdot (\mu_{\pi_1}(E_1)^2 \cdot \mu_{\pi_2}(E_2)^2 \cdot \mu_{\pi_3}(E_3) - 3 \cdot \delta) \\ &\quad - |\mathcal{V}| \cdot (\mu_{\pi_1}(E_1) \cdot \mu_{\pi_2}(E_2) + 2 \cdot \delta \cdot \mu_{\pi_3}(E_3)^{-1}) \end{aligned} \quad (5)$$

▷ **Claim 23.**

$$\|v\|_2^2 \leq |\mathcal{V}|^2 \cdot \left( \mu_{\pi_1}(E_1)^3 \cdot \mu_{\pi_2}(E_2)^3 \cdot \mu_{\pi_3}(E_3) + 10 \cdot \sqrt{\delta} \right) \quad (6)$$

We now bound  $\|\tilde{v}\|_2 = \frac{\|v\|_2}{\|v\|_1}$  by plugging in appropriate bounds on  $\delta$  and dividing Equation (6) by Equation (5). Our choice of  $\delta = \alpha^{20}/n^{1/40}$ , and our assumption that  $\alpha/10 \leq (\mathcal{P}|\pi)(E)$  (which in turn is at most  $\min_{i \in [3]} (\mu_{\pi_i}(E_i))$ ) implies that  $\delta$  is much smaller than any  $\mu_{\pi_i}(E_i)$ . In particular, we highlight that

$$\begin{aligned} \sqrt{\delta} &= o(\mu_{\pi_1}(E_1)^3 \cdot \mu_{\pi_2}(E_2)^3 \cdot \mu_{\pi_3}(E_3)) \\ \delta &= o(\mu_{\pi_1}(E_1)^2 \cdot \mu_{\pi_2}(E_2)^2 \cdot \mu_{\pi_3}(E_3)) \\ \delta &= o(\mu_{\pi_1}(E_1) \cdot \mu_{\pi_2}(E_2) \cdot \mu_{\pi_3}(E_3)) \end{aligned}$$

Furthermore, since  $|\mathcal{V}| = 2^{\Omega(n)}$  and  $1 \geq \mu_{\pi_i}(E_i) = \Omega(\alpha) = n^{-O(1)}$ , we have

$$|\mathcal{V}| \cdot \mu_{\pi_1}(E_1) \cdot \mu_{\pi_2}(E_2) = o(|\mathcal{V}|^2 \cdot \mu_{\pi_1}(E_1)^2 \cdot \mu_{\pi_2}(E_2)^2 \cdot \mu_{\pi_3}(E_3)).$$

Thus the dominant term on the right-hand side of Equation (5) is  $|\mathcal{V}|^2 \cdot \mu_{\pi_1}(E_1)^2 \cdot \mu_{\pi_2}(E_2)^2 \cdot \mu_{\pi_3}(E_3)$ , and the dominant term on the right-hand side of Equation (6) is  $|\mathcal{V}|^2 \cdot \mu_{\pi_1}(E_1)^3 \cdot \mu_{\pi_2}(E_2)^3 \cdot \mu_{\pi_3}(E_3)$ . More precisely, we have

$$\|v\|_1 \geq (1 - o(1)) \cdot |\mathcal{V}|^2 \cdot \mu_{\pi_1}(E_1)^2 \cdot \mu_{\pi_2}(E_2)^2 \cdot \mu_{\pi_3}(E_3) \quad (7)$$

$$\|v\|_2^2 \leq (1 + o(1)) \cdot |\mathcal{V}|^2 \cdot \mu_{\pi_1}(E_1)^3 \cdot \mu_{\pi_2}(E_2)^3 \cdot \mu_{\pi_3}(E_3). \quad (8)$$

This implies that

$$\|\tilde{v}\|_2^2 = \frac{\|v\|_2^2}{\|v\|_1^2} \leq \frac{1 + o(1)}{|\mathcal{V}|^2 \cdot \mu_{\pi_1}(E_1) \cdot \mu_{\pi_2}(E_2) \cdot \mu_{\pi_3}(E_3)} \quad (9)$$

In comparison, Equation (4) gave that

$$|E(G)| \in (1 \pm o(1)) \cdot |\mathcal{V}|^2 \cdot \mu_{\pi_1}(E_1) \cdot \mu_{\pi_2}(E_2) \cdot \mu_{\pi_3}(E_3).$$

Thus we can rewrite Equation (9) as

$$\|\tilde{v}\|_2 \leq \frac{1 + o(1)}{\sqrt{|E(G)|}} \quad (10)$$

This, together with the fact that by construction  $\|\tilde{v}\|_1 = 1$ , is sufficient to deduce that  $\tilde{v}$  is close to the “uniform distribution” vector  $\tilde{u} \stackrel{\text{def}}{=} (\frac{1}{|E(G)|}, \dots, \frac{1}{|E(G)|})$ . More formally, we have:

► **Fact 24.** *Suppose that  $\tilde{v} \in \mathbb{R}^m$  is an  $m$ -dimensional vector such that  $\|\tilde{v}\|_1 = 1$ , and  $\|\tilde{v}\|_2 = \frac{1+\beta}{\sqrt{m}}$  for some  $\beta \in [0, 1]$ . Then*

$$\|\tilde{v} - \tilde{u}\|_1 \leq \sqrt{3\beta},$$

where  $\tilde{u}$  denotes the vector  $(\frac{1}{m}, \dots, \frac{1}{m})$ .

The proof of Fact 24 is deferred to Appendix A.6

Applying Fact 24 to Equation (10) shows that  $d_{\text{TV}}(\tilde{v}, \tilde{u}) = o(1)$ . In other words, a uniformly random edge of a uniformly random bow tie is distributed close to uniformly on  $E(G)$ .

We now show that a typical bow tie differs in a considerable fraction of coordinates.

▷ **Claim 25.**  $\Pr_{\substack{i \sim [n] \\ b \sim B}}[b \text{ differs in } i\text{-th coordinate}] \geq 1/3 - o(1)$ .

The proof of Claim 25 is deferred to Appendix A.7.

Claim 20, along with Claim 25 implies that  $\Pr_{\substack{i \sim [n] \\ b \sim B}}[\text{val}^{(i)}(\mathcal{G}|\tilde{b}) \leq 3/4] \geq 1/3 - o(1) \geq 0.3$ . For those  $i \in [n]$  and  $b \in B$  such that  $b$  doesn't differ at the  $i$ -th coordinate, we bound  $\text{val}^{(i)}(\mathcal{G}|\tilde{b})$  by 1. This, along with Claim 21 implies that  $\mathbb{E}_{i \sim [n]} \left[ \text{val}^{(i)}(\mathcal{G}|\tilde{v}) \right] \leq \mathbb{E}_{\substack{i \sim [n] \\ b \sim B}}[\text{val}^{(i)}(\mathcal{G}|\tilde{b})] \leq 0.75 \times 0.3 + 1 \times 0.7 \leq 0.925$ . Since  $d_{\text{TV}}(\tilde{u}, \tilde{v}) \leq o(1)$  and  $\tilde{u}$  corresponds to  $\mathcal{P}|\pi, E$ , this implies that  $\mathbb{E}_{i \sim [n]} \left[ \text{val}^{(i)}(\mathcal{G}|\pi, E) \right] = 0.925 + o(1) \leq 0.93$ . Since  $\pi \sim \Pi(\mathcal{P}|E)$  is good with probability at least  $1 - \delta \cdot \alpha^{-1} - 1/10 \geq 0.9 - o(1) \geq 0.8$ , we have  $\mathbb{E}_{i \sim [n]} \left[ \text{val}^{(i)}(\mathcal{G}|E) \right] \leq \mathbb{E}_{\substack{i \sim [n] \\ \pi \sim \Pi(\mathcal{P}|E)}} \left[ \text{val}^{(i)}(\mathcal{G}|E, \pi) \right] \leq 0.8 \times 0.93 + 0.2 \times 1 < 0.95$ . This, along with Lemma 17 completes the proof.

## A Appendix

### A.1 Proof of Lemma 17

**Proof of Lemma 17.** Let  $\mathcal{P} = \mathcal{Q}^n$ . Choose the largest integer  $m \geq 0$  such that  $32^{-m} \geq \rho(n) \cdot \frac{2}{c}$ . Note that  $m = \Theta(\log(1/\rho(n)))$ . Fix any deterministic product strategy  $\bar{f} = (\bar{f}_1, \bar{f}_2, \bar{f}_3)$  for the players where  $\bar{f}_i : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^n$  denotes the strategy for the  $i$ -th player. Let  $Y_i = \bar{f}_i(X_i) \in \mathbb{F}_2^n$  denote the output of player  $i$  on input  $X_i$ . Let  $\{j_1, \dots, j_m\} \subseteq [n]$  be a set of coordinates. Let  $W_i$  denote the event of winning the GHZ game in the  $j_i$ -th coordinate under the strategy  $\bar{f}$  and let  $W_{\leq i} := W_1 \wedge \dots \wedge W_i$ . Observe that

$$\text{val}(\mathcal{G}, \bar{f}) \leq \prod_{i=0}^{m-1} \Pr[W_{i+1} \mid W_{\leq i}].$$

We show how to construct a sequence of coordinates so that every term in the above product is at most  $1 - c/2$ . This would imply that  $\text{val}(\mathcal{G}) \leq (1 - c/2)^{\Theta(\log(1/\rho(n)))} = \rho(n)^{\Omega(1)}$ . Fix any  $i \in \{0, \dots, m-1\}$  and assume that we have found  $j_1, \dots, j_i$ . Let  $X \sim \mathcal{P}$  and  $X_{\leq i}$  denote  $X$  restricted to the coordinates  $\{j_1, \dots, j_i\}$ . Let  $Y_{\leq i}$  denote the outputs of the players restricted to the coordinates  $\{j_1, \dots, j_i\}$ . Let  $Z_{\leq i} = (X_{\leq i}, Y_{\leq i})$ . Since  $W_{\leq i}$  is a function of  $Z_{\leq i}$ , we have

$$\begin{aligned} \Pr[W_{i+1} \mid W_{\leq i}] &= \mathbb{E}_{z_{\leq i} \sim Z_{\leq i} \mid W_{\leq i}} [\Pr[W_{i+1} \mid Z_{\leq i} = z_{\leq i}]] \\ &\leq \mathbb{E}_{z_{\leq i} \sim Z_{\leq i} \mid W_{\leq i}} [\text{val}^{(j_{i+1})}(\mathcal{G} \mid Z_{\leq i} = z_{\leq i})]. \end{aligned} \quad (11)$$

Let  $F = F(z_{\leq i})$  denote the event that  $\mathcal{P}[Z_{\leq i} = z_{\leq i} \mid W_{\leq i}] \geq \frac{c}{2} \cdot \frac{1}{N}$  where  $N = 32^i \geq \text{supp}(Z_{\leq i})$ . We argue that  $F$  occurs with probability at least  $1 - c/2$ . This is because we are sampling  $z_{\leq i}$  with probability  $\mathcal{P}[Z_{\leq i} = z_{\leq i} \mid W_{\leq i}]$ , hence the measure of  $z_{\leq i}$  for which  $\mathcal{P}[Z_{\leq i} = z_{\leq i} \mid W_{\leq i}] \leq \frac{c}{2} \cdot \frac{1}{N}$  is at most  $\frac{c}{2}$ . Fix any  $z_{\leq i}$  such that  $F$  holds. Our choice of  $m$  implies that  $\frac{1}{N} \cdot \frac{c}{2} \geq \rho(n)$ . Note that we can express the distribution  $\mathcal{P} \mid Z_{\leq i} = z_{\leq i}$  as  $\mathcal{P} \mid E$  where  $E = E_1 \times E_2 \times E_3$  for  $E_1, E_2, E_3 \subseteq \mathbb{F}_2^n$  and  $\mathcal{P}(E) \geq \rho(n)$ . The hypothesis of Lemma 17 implies that  $\mathbb{E}_{j \sim [n]} [\text{val}^{(j)}(\mathcal{G} \mid Z_{\leq i} = z_{\leq i})] \leq 1 - c$ . This implies that

$$\begin{aligned} \mathbb{E}_{\substack{z_{\leq i} \sim Z_{\leq i} \mid W_{\leq i} \\ j \sim [n]}} [\text{val}^{(j)}(\mathcal{G} \mid Z_{\leq i} = z_{\leq i})] &\leq \Pr_{z_{\leq i} \sim Z_{\leq i} \mid W_{\leq i}} [\neg F] \\ &\quad + \mathbb{E}_{\substack{z_{\leq i} \sim Z_{\leq i} \mid W_{\leq i}, F \\ j \sim [n]}} [\text{val}^{(j)}(\mathcal{G} \mid Z_{\leq i} = z_{\leq i})] \\ &\leq \frac{c}{2} + 1 - c = 1 - \frac{c}{2}. \end{aligned}$$

By linearity of expectation, we can fix a  $j \in [n]$  such that  $\mathbb{E}_{z_{\leq i} \sim Z_{\leq i} \mid W_{\leq i}} [\text{val}^{(j)}(\mathcal{G} \mid Z_{\leq i} = z_{\leq i})] \leq 1 - \frac{c}{2}$ . Note that  $j \notin \{j_1, \dots, j_i\}$  since we already win the game on these coordinates. This, along with Equation (11) completes the proof.  $\blacktriangleleft$

### A.2 Proof of Claim 20

**Proof of Claim 20.** Let  $i \in I$ . Since the bow tie  $b$  differs in the  $i$ -th coordinate, we have

$$\{x_0(i), x_1(i)\} = \{y_0(i), y_1(i)\} = \{z_0(i), z_1(i)\} = \{0, 1\}.$$

We may thus assume without loss of generality that  $x_0(i) = y_0(i) = 0$ . Define embeddings  $\phi_1 : \mathbb{F}_2 \rightarrow \{x_0, x_1\}$ ,  $\phi_2 : \mathbb{F}_2 \rightarrow \{y_0, y_1\}$  and  $\phi_3 : \mathbb{F}_2 \rightarrow \{z_0, z_1\}$  at  $a \in \mathbb{F}_2$  by  $\phi_1(a) = x_a$ ,  $\phi_2(a) = y_a$  and  $\phi_3(a) = z_a$ . It follows for all  $a \in \{0, 1\}$  and  $j \in [3]$ , we have  $(\phi_j(a))(i) = a$ . In particular, for  $\phi = \phi_1 \times \phi_2 \times \phi_3$ , the distribution  $\phi(\mathcal{Q})$  is exactly the distribution  $\tilde{b}$ . Given any strategies  $\bar{f}_1, \bar{f}_2, \bar{f}_3 : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^n$  for the players for the  $n$ -fold GHZ game restricted to the query distribution  $\tilde{b}$ , the functions  $\phi_1, \phi_2, \phi_3$  induce a strategy for the GHZ game as follows. Define  $f_j : \mathbb{F}_2 \rightarrow \mathbb{F}_2$  by  $f_j(a) = (\bar{f}_j(\phi_j(a)))(i)$ . The success probability of the strategy  $f_1 \times f_2 \times f_3$  on the distribution  $\mathcal{Q}$  is exactly the success probability in the  $i$ -th coordinate of the strategy  $\bar{f}_1 \times \bar{f}_2 \times \bar{f}_3$  on the distribution  $\tilde{b}$ . It follows that  $\text{val}^{(i)}(\mathcal{G}|\tilde{b}) \leq 3/4$ .  $\triangleleft$

### A.3 Proof of Claim 21

Proof of Claim 21. Fix any  $e \in E(G)$ ,  $e = (x_0, y_0)$ . This implies that  $x_0 \in E_1 \cap \pi_1$ ,  $y_0 \in E_2 \cap \pi_2$  and  $z_0 := x_0 + y_0 \in E_3 \cap \pi_3$ . Note that  $v(e) = \Pr_{z \sim E_3 \cap \pi_3} [(x_0, y_0) \in (L_z \times R_z) \setminus M_z]$ . For any  $z_1 \in E_3 \cap \pi_3$ ,

$$\begin{aligned} e \in (L_{z_1} \times R_{z_1}) \setminus M_{z_1} &\iff x_0 + z_1 \in E_2 \cap \pi_2, y_0 + z_1 \in E_1 \cap \pi_1, z_1 \neq z_0 \\ &\iff x_0, x_1 \in E_1 \cap \pi_1, y_0, y_1 \in E_2 \cap \pi_2, z_1 \neq z_0 \in E_3 \cap \pi_3 \\ &\text{where } x_1 := y_0 + z_1, y_1 := x_0 + z_1 \\ &\iff \{x_0, x_1\} \times \{y_0, y_1\} \text{ is a bow tie} \\ &\text{where } x_1 := y_0 + z_1, y_1 := x_0 + z_1. \end{aligned}$$

This implies that for all  $e = (x_0, y_0) \in E(G)$  and  $z_1 \in E_3 \cap \pi_3$ , we have  $1_{z_1}(e) = 1$  if and only if  $b = \{x_0, x_1\} \times \{y_0, y_1\}$  is a bow tie. Observe that as we vary  $z_1 \in E_3 \cap \pi_3$ , we obtain all possible bow ties that contain the edge  $e$ , i.e. the bow ties  $b$  for which  $b(e) \neq 0$ . This implies that  $v \triangleq \mathbb{E}_{z_1 \sim E_3 \cap \pi_3} [1_z] = |E_3 \cap \pi_3|^{-1} \cdot (\sum_{b \in B} b)$ .  $\triangleleft$

### A.4 Proof of Claim 22

For ease of notation, we define weight functions as follows.

► **Definition 26** (Weight functions). Let  $\mathcal{P} = \mathcal{Q}^n$ . For  $z \in \pi_3$ , let

$$\text{wt}_\pi(z) := \Pr_{X \sim \mathcal{P}} [(X_1 \in E_1 \text{ and } X_2 \in E_2) | (X \in \pi \text{ and } X_3 = z)] = \mathbb{E}_{x \sim \pi_1} [E_1(x)E_2(x+z)].$$

Proof of Claim 22. Let  $z \in E_3 \cap \pi_3$ . Note that  $\text{wt}_\pi(z) = \mu_{\pi_1}(L_z) = \mu_{\pi_2}(R_z)$ . Observe that  $\|1_z\|_1 = |E(G) \cap (L_z \times R_z) \setminus M_z|$ . We apply Lemma 16 with parameters  $A = L_z \cap \pi_1$ ,  $B = R_z \cap \pi_2$ ,  $C = E_3 \cap \pi_3$ . The first hypothesis of Lemma 16 is satisfied due to Equation (3). Lemma 16 implies that

$$\begin{aligned} |E(G) \cap (L_z \times R_z)| &\triangleq |\mathcal{V}|^2 \cdot \mathbb{E}_{\substack{z' \sim \pi_3 \\ x \sim \pi_1}} [L_z(x) \cdot R_z(x+z') \cdot E_3(z')] \\ &\geq |\mathcal{V}|^2 \cdot (\mu_{\pi_1}(L_z) \cdot \mu_{\pi_2}(R_z) \cdot \mu_{\pi_3}(E_3) - \delta) \\ &\triangleq |\mathcal{V}|^2 \cdot (\text{wt}_\pi(z)^2 \cdot \mu_{\pi_3}(E_3) - \delta). \end{aligned}$$

Similarly,  $|M_z| \triangleq |\mathcal{V}| \cdot \mathbb{E}_{x \sim \pi_1} [E_1(x) \cdot E_2(x+z)] = |\mathcal{V}| \cdot \text{wt}_\pi(z)$ . We apply Lemma 16 with parameters  $A = E_1$ ,  $B = E_2$ ,  $C = E_3$ . All the hypothesis are satisfied due to Equation (3). Lemma 16, along with conditioning  $z \sim \pi_3$  on  $z \in E_3$  implies that

$$\left| \mathbb{E}_{z \sim E_3 \cap \pi_3} [\text{wt}_\pi(z)^2] - \mu_{\pi_1}(E_1)^2 \cdot \mu_{\pi_2}(E_2)^2 \right| \leq 2 \cdot \delta \cdot \mu_{\pi_3}(E_3)^{-1}. \quad (12)$$

## 62:18 Parallel Repetition for the GHZ Game: A Simpler Proof

$$\left| \mathbb{E}_{z \sim E_3 \cap \pi_3} [\text{wt}_\pi(z)] - \mu_{\pi_1}(E_1) \cdot \mu_{\pi_2}(E_2) \right| \leq 2 \cdot \delta \cdot \mu_{\pi_3}(E_3)^{-1}.$$

Substituting this in the previous inequalities and taking an expectation over  $z \sim E_3 \cap \pi_3$ ,

$$\begin{aligned} \|v\|_1 &= \mathbb{E}_{z \sim E_3 \cap \pi_3} [\|1_z\|_1] = \mathbb{E}_{z \sim E_3 \cap \pi_3} [|E(G) \cap (L_z \times R_z)| - |M_z|] \\ &\geq |\mathcal{V}|^2 \cdot \left( \mathbb{E}_{z \sim E_3 \cap \pi_3} [\text{wt}_\pi(z)^2] \cdot \mu_{\pi_3}(E_3) - \delta \right) \\ &\quad - |\mathcal{V}| \cdot \mathbb{E}_{z \sim E_3 \cap \pi_3} [\text{wt}_\pi(z)] \\ &\geq |\mathcal{V}|^2 \cdot (\mu_{\pi_1}(E_1)^2 \cdot \mu_{\pi_2}(E_2)^2 \cdot \mu_{\pi_3}(E_3) - 3 \cdot \delta) \\ &\quad - |\mathcal{V}| \cdot (\mu_{\pi_1}(E_1) \cdot \mu_{\pi_2}(E_2) + 2 \cdot \delta \cdot \mu_{\pi_3}(E_3)^{-1}). \quad \blacktriangleleft \end{aligned}$$

### A.5 Proof of Claim 23

Proof of Claim 23. Define  $\text{wt}_\pi(\cdot)$  as in the proof of Claim 22. Let  $z, z' \in E_3 \cap \pi_3$ . Observe that  $\langle 1_z, 1_{z'} \rangle = |E(G) \cap ((L_z \cap L_{z'}) \times (R_z \cap R_{z'})) \setminus (M_z \cup M_{z'})|$ . We apply Lemma 16 with parameters  $A = L_z \cap L_{z'} \cap \pi_1$ ,  $B = R_z \cap R_{z'} \cap \pi_2$  and  $C = E_3 \cap \pi_3$ . The first hypothesis is satisfied due to Equation (3). Lemma 16 implies that

$$\begin{aligned} \langle 1_z, 1_{z'} \rangle &= |E(G) \cap ((L_z \cap L_{z'}) \times (R_z \cap R_{z'})) \setminus (M_z \cup M_{z'})| \\ &\leq |\mathcal{V}|^2 \cdot (\mu_{\pi_1}(L_z \cap L_{z'}) \cdot \mu_{\pi_2}(R_z \cap R_{z'}) \cdot \mu_{\pi_3}(E_3) + \delta). \end{aligned}$$

Taking an expectation over  $z' \sim E_3 \cap \pi_3$  and applying Cauchy-Schwartz yields that

$$\begin{aligned} &\mathbb{E}_{z' \sim E_3 \cap \pi_3} [\langle 1_z, 1_{z'} \rangle] \\ &\leq |\mathcal{V}|^2 \cdot \mathbb{E}_{z' \sim E_3 \cap \pi_3} [\mu_{\pi_1}(L_z \cap L_{z'}) \cdot \mu_{\pi_2}(R_z \cap R_{z'}) \cdot \mu_{\pi_3}(E_3) + \delta] \\ &\leq |\mathcal{V}|^2 \cdot \left( \sqrt{\mathbb{E}_{z' \sim E_3 \cap \pi_3} [\mu_{\pi_1}(L_z \cap L_{z'})^2]} \cdot \sqrt{\mathbb{E}_{z' \sim E_3 \cap \pi_3} [\mu_{\pi_2}(R_z \cap R_{z'})^2]} \cdot \mu_{\pi_3}(E_3) + \delta \right). \end{aligned}$$

Observe that  $\mu_{\pi_1}(L_z \cap L_{z'}) = \mathbb{E}_{x \sim \pi_1} [L_z(x) E_2(x + z')]$  for all  $z' \in E_3 \cap \pi_3$ . We now apply Lemma 16 with parameters  $A = L_z \cap \pi_1$ ,  $B = E_2 \cap \pi_2$ ,  $C = E_3 \cap \pi_3$ . All the hypotheses are satisfied due to Equation (3). Lemma 16, along with the aforementioned observation implies that

$$\left| \mathbb{E}_{z' \sim E_3 \cap \pi_3} [\mu_{\pi_1}(L_z \cap L_{z'})^2] - \mu_{\pi_1}(L_z)^2 \cdot \mu_{\pi_2}(E_2)^2 \right| \leq 2 \cdot \delta \cdot \mu_{\pi_3}(E_3)^{-1}.$$

An analogous inequality holds for  $|R_z \cap R_{z'}|$ . Substituting this in the previous inequality and using the fact that  $\sqrt{a+b} \leq \sqrt{a} + \sqrt{b}$ , we have

$$\begin{aligned} &\mathbb{E}_{z' \sim E_3 \cap \pi_3} [\langle 1_z, 1_{z'} \rangle] \\ &\leq |\mathcal{V}|^2 \cdot \left( \left( \mu_{\pi_1}(L_z) \cdot \mu_{\pi_2}(E_2) + \sqrt{\frac{2 \cdot \delta}{\mu_{\pi_3}(E_3)}} \right) \cdot \left( \mu_{\pi_2}(R_z) \cdot \mu_{\pi_1}(E_1) + \sqrt{\frac{2 \cdot \delta}{\mu_{\pi_3}(E_3)}} \right) \cdot \mu_{\pi_3}(E_3) \right. \\ &\quad \left. + \delta \right) \\ &\leq |\mathcal{V}|^2 \cdot \left( \mu_{\pi_1}(L_z) \cdot \mu_{\pi_2}(R_z) \cdot \mu_{\pi_1}(E_1) \cdot \mu_{\pi_2}(E_2) \cdot \mu_{\pi_3}(E_3) + 8 \cdot \sqrt{\delta} \right) \\ &= |\mathcal{V}|^2 \cdot \left( \text{wt}_\pi(z)^2 \cdot \mu_{\pi_1}(E_1) \cdot \mu_{\pi_2}(E_2) \cdot \mu_{\pi_3}(E_3) + 8 \cdot \sqrt{\delta} \right). \end{aligned}$$

We now take an expectation over  $z \sim E_3 \cap \pi_3$  and use Equation (12) to conclude that

$$\mathbb{E}_{z, z' \sim E_3 \cap \pi_3} [\langle 1_z, 1_{z'} \rangle] \leq |\mathcal{V}|^2 \cdot \left( \mu_{\pi_1}(E_1)^3 \cdot \mu_{\pi_2}(E_2)^3 \cdot \mu_{\pi_3}(E_3) + 10 \cdot \sqrt{\delta} \right). \quad \blacktriangleleft$$

## A.6 Proof of Fact 24

**Proof of Fact 24.**

$$\begin{aligned}
 \|\tilde{v} - \tilde{u}\|_2^2 &= \langle \tilde{v} - \tilde{u}, \tilde{v} - \tilde{u} \rangle \\
 &= \|\tilde{v}\|_2^2 + \|\tilde{u}\|_2^2 - 2\langle \tilde{u}, \tilde{v} \rangle \\
 &= \frac{1 + 2\beta + \beta^2}{m} + \frac{1}{m} - \frac{2}{m} \\
 &= \frac{2\beta + \beta^2}{m} \leq \frac{3\beta}{m}.
 \end{aligned}$$

Finally, we bound the  $\ell_1$  distance in terms of the  $\ell_2$  distance:

$$\|\tilde{v} - \tilde{u}\|_1 \leq \|\tilde{v} - \tilde{u}\|_2 \cdot \sqrt{m} \leq \sqrt{3\beta}. \quad \blacktriangleleft$$

## A.7 Proof of Claim 25

**Proof of Claim 25.** It suffices to show that a random  $b \sim B$  differs in less than  $n/3$  coordinates with probability at most  $2^{-\Omega(n)} = o(1)$ .

The Chernoff bound implies that  $\Pr_{x_0, x_1 \sim \mathbb{F}_2^n} [\text{hwt}(x_0 + x_1) < n/3] \leq 2^{-\Omega(n)}$ . We condition on  $x_0, x_1 \in \pi_1$  to conclude that  $\Pr_{x_0, x_1 \sim \pi_1} [\text{hwt}(x_0 + x_1) < n/3] \leq 2^{-\Omega(n)} \cdot \frac{2^{2n}}{|\mathcal{V}|^2}$ .

Let  $b = \{x_0, x_1\} \times \{y_0, y_1\}$  be a bow tie. By definition, we have  $y_1 = x_0 + x_1 + y_0$ . In particular, the bow tie  $b$  is uniquely identified by  $x_0, x_1, y_0$ . This implies that the probability that a random  $b \sim B$  differs in less than  $n/3$  coordinates is precisely

$$\begin{aligned}
 &\frac{|\mathcal{V}|^3}{|B|} \Pr_{\substack{x_0, x_1 \sim \pi_1 \\ y_0 \sim \pi_2 \\ y_1 = x_0 + x_1 + y_0}} [\{x_0, x_1\} \times \{y_0, y_1\} \in B \text{ and } \text{hwt}(x_0 + x_1) < n/3] \\
 &\leq \frac{|\mathcal{V}|^3}{|B|} \Pr_{x_0, x_1 \sim \pi_1} [\text{hwt}(x_0 + x_1) < n/3] \\
 &\leq \frac{|\mathcal{V}|^3}{|B|} \cdot 2^{-\Omega(n)} \cdot \frac{2^{2n}}{|\mathcal{V}|^2}
 \end{aligned}$$

Recall that  $v = \mathbb{E}_{z \sim E_3 \cap \pi_3} [1_z] = \frac{1}{\mu_{\pi_3}(E_3) \cdot |\mathcal{V}|} \sum_{z \in E_3 \cap \pi_3} 1_z$ , where for each  $e$ ,  $\sum_{z \in E_3 \cap \pi_3} 1_z(e)$  equals the number of bow ties containing the edge  $e$ . Since each bow tie contains 4 edges, we have that  $\|v\|_1 = \frac{4}{\mu_{\pi_3}(E_3) \cdot |\mathcal{V}|} \cdot |B|$ . Then, equation (7) implies that

$$|B| \geq \frac{1}{8} \cdot |\mathcal{V}|^3 \cdot \mu_{\pi_1}(E_1)^2 \cdot \mu_{\pi_2}(E_2)^2 \cdot \mu_{\pi_3}(E_3)^2 \geq \frac{1}{8} \cdot |\mathcal{V}|^3 \cdot \alpha^6.$$

This implies that  $\frac{|\mathcal{V}|^3}{|B|} \leq 8/\alpha^6$ . Recall that  $\alpha \geq n^{-O(1)}$  and the co-dimension of  $\mathcal{V}$  is  $o(n)$ . This implies that  $\frac{2^{2n}}{|\mathcal{V}|^2} = 2^{o(n)}$ . This along with the above calculation implies that the probability that a uniformly random  $b \sim B$  differs in less than  $n/3$  coordinates is at most  $\frac{8 \cdot 2^{-\Omega(n)}}{\alpha^6} \cdot 2^{o(n)} = 2^{-\Omega(n)}$ . This completes the proof.  $\triangleleft$
