## APPROX

On Approximate Envy-Freeness for Indivisible Chores and Mixed Resources	
<i>Umang Bhaskar, A. R. Sricharan, and Rohit Vaish</i> .....	1:1–1:23
Optimal Algorithms for Online $b$ -Matching with Variable Vertex Capacities	
<i>Susanne Albers and Sebastian Schubert</i> .....	2:1–2:18
Bag-Of-Tasks Scheduling on Related Machines	
<i>Anupam Gupta, Amit Kumar, and Sahil Singla</i> .....	3:1–3:16
Hardness of Approximation for Euclidean $k$ -Median	
<i>Anup Bhattacharya, Dishant Goyal, and Ragesh Jaiswal</i> .....	4:1–4:23
Online Directed Spanners and Steiner Forests	
<i>Elena Grigorescu, Young-San Lin, and Kent Quanrud</i> .....	5:1–5:25
Query Complexity of Global Minimum Cut	
<i>Arijit Bishnu, Arijit Ghosh, Gopinath Mishra, and Manaswi Paraashar</i> .....	6:1–6:15
A Constant-Factor Approximation for Weighted Bond Cover	
<i>Eun Jung Kim, Euiwoong Lee, and Dimitrios M. Thilikos</i> .....	7:1–7:14
Truly Asymptotic Lower Bounds for Online Vector Bin Packing	
<i>János Balogh, Ilan Reuven Cohen, Leah Epstein, and Asaf Levin</i> .....	8:1–8:18
Fine-Grained Completeness for Optimization in $P$	
<i>Karl Bringmann, Alejandro Cassis, Nick Fischer, and Marvin Künnemann</i> .....	9:1–9:22
An Estimator for Matching Size in Low Arboricity Graphs with Two Applications	
<i>Hossein Jowhari</i> .....	10:1–10:13
An Optimal Algorithm for Triangle Counting in the Stream	
<i>Rajesh Jayaram and John Kallaugher</i> .....	11:1–11:11
Matching Drivers to Riders: A Two-Stage Robust Approach	
<i>Omar El Housni, Vineet Goyal, Oussama Hanguir, and Clifford Stein</i> .....	12:1–12:22
Secretary Matching Meets Probing with Commitment	
<i>Allan Borodin, Calum MacRury, and Akash Rakheja</i> .....	13:1–13:23
Semi-Streaming Algorithms for Submodular Function Maximization Under $b$ -Matching Constraint	
<i>Chien-Chung Huang and François Sellier</i> .....	14:1–14:18
General Knapsack Problems in a Dynamic Setting	
<i>Yaron Fairstein, Ariel Kulik, Joseph (Seffi) Naor, and Danny Raz</i> .....	15:1–15:18
Min-Sum Clustering (With Outliers)	
<i>Sandip Banerjee, Rafail Ostrovsky, and Yuval Rabani</i> .....	16:1–16:16

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2021).

## ■ Preface

This volume contains the papers presented at the 24th International Conference on Approximation Algorithms for Combinatorial Optimization Problems (APPROX 2021) and the 25th International Conference on Randomization and Computation (RANDOM 2021), which due to COVID-19 were organized as parallel virtual conferences during August 16–18, 2021. APPROX focuses on algorithmic and complexity issues surrounding the development of efficient approximate solutions to computationally difficult problems, and was the 24th in the series. RANDOM is concerned with applications of randomness to computational and combinatorial problems, and was the 25th in the series. Prior to 2003, APPROX took place in Aalborg (1998), Berkeley (1999), Saarbrücken (2000), Berkeley (2001), and Rome (2002), while RANDOM took place in Bologna (1997), Barcelona (1998), Berkeley (1999), Geneva (2000), Berkeley (2001), and Harvard (2002). Since 2003, APPROX and RANDOM have been co-located, taking place in Princeton (2003), Cambridge (2004), Berkeley (2005), Barcelona (2006), Princeton (2007), Boston (2008), Berkeley (2009), Barcelona (2010), Princeton (2011), Boston (2012), Berkeley (2013), Barcelona (2014), Princeton (2015), Paris (2016), Berkeley (2017), Princeton (2018), Boston (2019), and online (2020).

Topics of interest for APPROX and RANDOM are: approximation algorithms, hardness of approximation, small space, sub-linear time and streaming algorithms, online algorithms, approaches that go beyond worst case analysis, distributed and parallel approximation, embeddings and metric space methods, mathematical programming methods, spectral methods, combinatorial optimization, algorithmic game theory, mechanism design and economics, computational geometric problems, approximate learning, design and analysis of randomized algorithms, randomized complexity theory, pseudorandomness and derandomization, random combinatorial structures, random walks/Markov chains, expander graphs and randomness extractors, probabilistic proof systems, random projections and embeddings, error-correcting codes, average-case analysis, smoothed analysis, property testing, and computational learning theory.

The volume contains 27 contributed papers, selected by the APPROX Program Committee out of 62 submissions; and 35 contributed papers, selected by the RANDOM Program Committee out of 84 submissions. We would like to thank all of the authors who submitted papers, the members of the Program Committees, and the external reviewers. We are grateful for the guidance of the steering committees: Jarosław Byrka, Klaus Jansen, Samir Khuller, Monaldo Mastrolili, and László Végh for APPROX, and Oded Goldreich, Raghu Meka, Cris Moore, Anup Rao, Omer Reingold, Dana Ron, Ronitt Rubinfeld, Amit Sahai, Ronen Shaltiel, Alistair Sinclair, and Paul Spirakis for RANDOM.

# On Approximate Envy-Freeness for Indivisible Chores and Mixed Resources

## Abstract

We study the fair allocation of undesirable indivisible items, or *chores*. While the case of desirable indivisible items (or *goods*) is extensively studied, with many results known for different notions of fairness, less is known about the fair division of chores. We study envy-free allocation of chores and make three contributions. First, we show that determining the existence of an envy-free allocation is NP-complete even in the simple case when agents have *binary additive* valuations. Second, we provide a polynomial-time algorithm for computing an allocation that satisfies envy-freeness up to one chore (EF1), correcting a claim in the existing literature. A modification of our algorithm can be used to compute an EF1 allocation for *doubly monotone* instances (where each agent can partition the set of items into objective goods and objective chores). Our third result applies to a *mixed resources* model consisting of indivisible items and a divisible, undesirable heterogeneous resource (i.e., a bad cake). We show that there always exists an allocation that satisfies envy-freeness for mixed resources (EFM) in this setting, complementing a recent result of Bei et al. [22] for indivisible goods and divisible cake.

**2012 ACM Subject Classification** Theory of computation → Algorithmic game theory; Theory of computation → Exact and approximate computation of equilibria; Mathematics of computing → Combinatorial algorithms

**Keywords and phrases** Fair Division, Indivisible Chores, Approximate Envy-Freeness

**Acknowledgements** We thank the anonymous reviewers for helpful comments.

## 1 Introduction

The problem of fairly dividing a set of resources among agents is of central importance in various fields including economics, computer science, and political science. Such problems arise in many settings such as settling border disputes, assigning credit among contributing individuals, rent division, and distributing medical supplies such as vaccines [58]. The theoretical study of fair division has classically focused on *divisible* resources (such as land or clean water), most prominently in the *cake-cutting* literature [28, 61, 60]; here, cake is a metaphor for a heterogeneous resource that can be fractionally allocated. A well-established concept of fairness in this setup is *envy-freeness* [40] which stipulates that no agent envies

another, i.e., prefers the share of another agent to its own. An envy-free division of a divisible, desirable resource (i.e., a cake) is known to exist under general settings [65, 4, 66, 15], and can be efficiently computed for a wide range of utility functions [37, 52, 18, 21].

By contrast, an envy-free solution can fail to exist when the goods are discrete or *indivisible*; important examples include the assignment of course seats at universities [57, 32] and the allocation of public housing units [24]. This has motivated relaxations such as *envy-freeness up to one good* (EF1) where pairwise envy can be eliminated by removing some good from the envied bundle [53, 31]. The EF1 notion enjoys strong theoretical and practical motivation: On the theoretical side, there exist efficient algorithms for computing an EF1 allocation under general, monotone valuations [53]. At the same time, EF1 has also found impressive practical appeal on the popular fair division website *Spliddit* [45] and in course allocation applications [31, 32].

Our focus in this work is on fair allocation of undesirable or negatively-valued indivisible items, also known as *chores*. The chore division problem, introduced by Martin Gardner [44], models scenarios such as distribution of household tasks (e.g., cleaning, cooking, etc.) or the allocation of responsibilities for controlling carbon emissions among countries [67]. For indivisible chores, too, an envy-free allocation could fail to exist, and one of our contributions is to show that determining the existence of such outcomes is NP-complete even under highly restrictive settings (Theorem 2). This negative result prompts us to explore the corresponding relaxation of *envy-freeness up to one chore*, also denoted by EF1, which addresses pairwise envy by removing some chore from the *envious* agent’s bundle.

At first glance, the chore division problem appears to be the “opposite” of the goods problem, and hence one might expect natural adaptation of algorithms that compute an EF1 allocation for goods to also work for chores. This, however, turns out to not be the case.

*Goods vs chores:* Consider the well-known *envy-cycle elimination* algorithm of Lipton et al. [53] for computing an EF1 allocation of indivisible goods. Briefly, the algorithm works by iteratively assigning a good to an agent that is not envied by anyone else. The existence of such an agent is guaranteed by means of resolving cycles in the underlying *envy graph*. (The envy graph of an allocation is a directed graph whose vertices correspond to the agents and there is an edge  $(i, j)$  if agent  $i$  envies agent  $j$ .) When adapted to the chores problem, the algorithm (Algorithm 1) assigns a chore to a “non-envious” agent that has no outgoing edge in the envy graph. Contrary to an existing claim in the literature [10], we observe that this algorithm could fail to find an EF1 allocation even when agents have additive valuations.<sup>1</sup>

► **Example 1 (Envy-cycle elimination algorithm fails EF1 for additive chores).** Consider the following instance with six chores  $c_1, \dots, c_6$  and three agents  $a_1, a_2, a_3$  with additive valuations:

	$c_1$	$c_2$	$c_3$	$c_4$	$c_5$	$c_6$
$a_1$	(-1)	-4	-2	(-3)	0	-1
$a_2$	-2	(-1)	-2	-2	(-3)	-1
$a_3$	-1	-3	(-1)	-1	-3	(-10)

Suppose the algorithm considers the chores in the increasing order of their indices (i.e.,  $c_1, c_2, \dots$ ), and breaks ties among agents in favor of  $a_1$  and then  $a_2$ . No directed cycles appear at any intermediate step during the execution of the algorithm on the above instance.

<sup>1</sup> A recent work by Bérczi et al. [26] shows that this algorithm fails to find an EF1 allocation when agents have non-monotone and non-additive valuations. We show a stronger result, in that the failure in finding an EF1 allocation persists even when agents have additive, monotone nonincreasing valuations.

■ **Algorithm 1** Naïve envy-cycle elimination algorithm.

**Input:** An instance  $\langle N, M, \mathcal{V} \rangle$  with non-increasing valuations

**Output:** An allocation  $A$

```

1 Initialize  $A \leftarrow (\emptyset, \emptyset, \dots, \emptyset)$ 
2 for  $c \in M$  do
3   Choose a sink  $i$  in the envy graph  $G_A$ 
4   Update  $A_i \leftarrow A_i \cup \{c\}$ 
5   while  $G_A$  contains a directed cycle  $C$  do
6      $A \leftarrow A^C$ 
7 return  $A$ 

```

■ **Figure 1** Envy graphs of various allocations in Example 1. A red edge points to the favorite (or most envied) bundle of an agent, while a black edge points to an envied (but not the most envied) bundle.

The resulting allocation, say  $A$ , is given by  $A_1 = \{c_1, c_4\}$ ,  $A_2 = \{c_2, c_5\}$ , and  $A_3 = \{c_3, c_6\}$  (shown as circled entries in the above table). Notice that  $A$  is EF1 and its envy graph is as shown in Figure 1a.

Each node in the envy graph of  $A$  has an outgoing edge (Figure 1a). Therefore, if the algorithm were to allocate another chore after this, it would have to resolve either the cycle  $\{a_1, a_3\}$  or the cycle  $\{a_2, a_3\}$ . Let  $X$  and  $Y$  denote the allocations obtained by resolving the cycles  $\{a_1, a_3\}$  and  $\{a_2, a_3\}$ , respectively (the corresponding envy graphs are shown in Figures 1b and 1c). Although both envy graphs are *acyclic* (and thus admit a “sink” agent), only the allocation  $X$  satisfies EF1; in particular, the pair  $\{a_1, a_3\}$  violates EF1 for  $Y$ .

The above example highlights an important contrast between indivisible goods and chores: For goods, resolving arbitrary envy cycles preserves EF1, whereas for chores, the choice of which envy cycle is resolved matters. This is because when evaluating EF1 for chores, a chore is removed from the envious agent’s bundle. In the envy-cycle resolution step, if a cycle is chosen without caution, then it is possible for an agent to acquire a bundle that, although strictly more preferable, contains no chore that is large enough to compensate for the envy on its own.

A key insight of our work is that there always exists a specific envy cycle – the *top-trading envy cycle* – that can be resolved to compute an EF1 allocation of chores. Our algorithm computes EF1 allocations for *monotone* valuations, and thus provides an analogue of the result of Lipton et al. [53] for the chores setting. Furthermore, a simple modification of our algorithm computes an EF1 allocation for *doubly monotone* instances (Theorem 4), where each agent can partition the items into “objective goods” and “objective chores”, i.e., items with non-negative and negative marginal utility, respectively, for the agent [10]. This class has also been referred to as *itemwise monotone* in the literature [36].

■ **Table 1** EFM existence results for different combinations of indivisible and divisible resources. A ✓ indicates that EFM exists in that setting.

Indivisible \ Divisible	Cake	Bad Cake
Goods	✓ [22]	✓ (Theorem 16)
Chores	✓ for identical rankings (Theorem 17) ✓ for $n + 1$ items (Theorem 18)	

Motivated by this positive observation, we study a *mixed* model, consisting of both divisible as well as indivisible resources. This is a natural model in many settings, e.g., dividing an inheritance that consists of both property and money, or the simultaneous division of chores and rent among housemates. Although the use of payments in fair allocation of indivisible resources has been explored in several works [54, 3, 6, 66, 50, 55, 46, 47, 9, 30, 33], the most general formulation of a model with mixed resources, in our knowledge, is due to Bei et al. [22] who study combined allocation of a divisible *heterogeneous* resource (i.e., a cake) and a set of indivisible goods. This model and its variants are the focus of our work.

Generalizing the set of resources calls for revising the fairness benchmark. While exact envy-freeness still remains out of reach in the mixed model, EF1 can be “too permissive” when only the divisible resource is present. Bei et al. [22] propose a fairness concept called *envy-freeness for mixed goods* (EFM) for indivisible goods and divisible cake, which evaluates fairness with respect to EF1 if the envied bundle only contains indivisible goods, but switches to exact envy-freeness if the envied agent is allocated any cake. They show that an EFM allocation always exists for a mixed instance when agents have additive valuations within as well as across resource types. We note that neither the algorithm of Bei et al. [22] nor its analysis crucially depends on the valuations for the indivisible goods being additive; in fact, their results extend to monotone valuations for the indivisible goods.

We consider the problem of envy-free allocation in mixed instances with doubly monotone indivisible items and bad cake. We extend the definition of EFM naturally to this model, and show that in this model as well, an EFM allocation always exists (Theorem 16). Our work thus extends the results of Bei et al. in two ways – allowing for bad cake as well as doubly monotone indivisible items.

We also study a mixed model with indivisible chores and good cake. This turns out to be quite challenging, because unlike previous cases, one cannot start with an arbitrary EF1 allocation of the indivisible items and then allocate cake to obtain an EFM allocation. We however show the existence of an EFM allocation for two special cases in this model: when each agent has the same ranking over the chores (Theorem 17), and when the number of chores is at most one more than the number of agents (Theorem 18).

## Our Contributions

1. We first show that determining whether an envy-free allocation of chores exists is strongly NP-complete, even in the highly restricted setting when agents have *binary additive* valuations, i.e., when for all agents  $i \in [n]$  and items  $j \in [m]$ ,  $v_{i,j} \in \{-1, 0\}$  (Theorem 2). The analogous problem for indivisible goods with binary valuations is already known to be NP-complete [13, 48].

2. When the fairness goal is relaxed to envy-freeness up to one chore (EF1), we establish efficient computation for instances with chores (Theorem 3), and instances with *doubly monotone* valuations, when each agent  $i$  can partition the set of items into goods  $G_i$  (which always have nonnegative marginal value) and chores  $C_i$  (which always have nonpositive marginal value) (Theorem 4).
3. For a mixed instance consisting of doubly monotone indivisible items and bad cake, we show the existence of an allocation that satisfies the stronger fairness guarantee called *envy-freeness up to a mixed item* (EFM) (Theorem 16). Our result uses our previous theorem for indivisible chores as well as the framework of Bei et al. [22] for the allocation of the divisible item. This complements the result of Bei et al. [22] by showing existence of EFM allocations for mixed instances consisting of both desirable and undesirable items.
4. Lastly, for a mixed instance consisting of indivisible chores and (good) cake (see Section 6.4), we show the existence of an EFM allocation in two special cases: when each agent has the same preference ranking over the set of items (Theorem 17), and when the number of items is at most one more than the number of agents (Theorem 18).

Our results for mixed instances are summarized in Table 1.

## 2 Related Work

As mentioned, fair division has been classically studied for *divisible* resources. For a *heterogeneous*, desirable resource (i.e., a cake), the existence of envy-free solutions is known under mild assumptions [65, 4, 66, 15]. In addition, efficient algorithms are known for computing  $\varepsilon$ -envy-free divisions [60] and envy-free divisions under restricted preferences [37, 52, 18, 21]. For an undesirable heterogeneous resource (a bad cake), too, the existence of an envy-free division is known [59], along with a discrete and bounded procedure for finding such a division [39]. For the case of non-monotone cake (i.e., a real-valued divisible heterogeneous resource), the existence of envy-free outcomes has been shown for specific numbers of agents [62, 56, 7, 8].

Turning to the *indivisible* setting, we note that the sweeping result of Lipton et al. [53] on EF1 for indivisible *goods* has inspired considerable work on establishing stronger existence and computation guarantees in conjunction with other well-studied economic properties [34, 19, 20, 42, 25, 35, 5, 41]. The case of *indivisible chores* has been similarly well studied for a variety of solution concepts such as maximin fair share [12, 17, 14, 49], equitability [43, 2], competitive equilibria with general incomes [63], and envy-freeness [1, 29, 41].

Aziz et al. [10, 11] study a model containing both indivisible goods and chores, wherein *envy-freeness up to an item* (EF1) entails that pairwise envy is bounded by the removal of some good from the envied bundle or some chore from the envious agent's bundle. They show that a variant of the classical round-robin algorithm computes an EF1 allocation under additive utilities, and also claim that a variant of the envy-cycle elimination algorithm [53] returns such allocations for doubly monotone instances (we revisit the latter claim in Example 1). Other fairness notions such as approximate proportionality [10, 11, 16], maximin fair share [51], approximate jealousy-freeness [2], and weaker versions of EF1 [41] have also been studied in this model.

Finally, we note that the model with *mixed resources* comprising of both indivisible and (heterogeneous) divisible parts has been recently formalized by Bei et al. [22], although a special case of their model where the divisible resource is homogenous and desirable (e.g., money) has been extensively studied [54, 3, 6, 66, 50, 55, 46, 47, 9, 30, 33]. Bei et al. [22] showed that when there are indivisible goods and a divisible cake, an allocation satisfying *envy-freeness for mixed goods* (EFM) always exists. Subsequent work considers the maximin fairness notion in the mixed model [23].

### 3 Preliminaries

We consider two kinds of instances: one with purely indivisible items and the other with a mixture of divisible and indivisible items. We will present the preliminaries for instances with purely indivisible items in this section, and defer details for the mixed resources model to Section 6.

#### Problem instance

An *instance*  $\langle N, M, \mathcal{V} \rangle$  of the fair division problem is defined by a set  $N$  of  $n \in \mathbb{N}$  *agents*, a set  $M$  of  $m \in \mathbb{N}$  *indivisible items*, and a *valuation profile*  $\mathcal{V} = \{v_1, v_2, \dots, v_n\}$  that specifies the preferences of every agent  $i \in N$  over each subset of the items in  $M$  via a *valuation function*  $v_i : 2^M \rightarrow \mathbb{R}$ .

#### Marginal valuations

For any agent  $i \in N$  and any set of items  $S \subseteq M$ , the *marginal valuation* of the set  $T \subseteq M \setminus S$  is given by  $v_i(T|S) := v_i(S \cup T) - v_i(S)$ . When the set  $T$  is a singleton (say  $T = \{j\}$ ), we will write  $v_i(j|S)$  instead of  $v_i(\{j\}|S)$  for simplicity.

#### Goods and chores

Given an agent  $i \in N$  and an item  $j \in M$ , we say that  $j$  is a *good* for agent  $i$  if for every subset  $S \subseteq M \setminus \{j\}$ ,  $v_i(j|S) \geq 0$ . We say that  $j$  is a *chore* for agent  $i$  if for every subset  $S \subseteq M \setminus \{j\}$ ,  $v_i(j|S) \leq 0$ , with one of the inequalities strict. Note that for general valuations, an item may neither be a good nor a chore for an agent.

#### Doubly monotone instances

An instance is said to be *doubly monotone* if for each agent, each item is either a good or a chore. That is, each agent  $i$  can partition the items as  $M = G_i \uplus C_i$ , where  $G_i$  are her goods, and  $C_i$  are her chores. Note that an item may be a good for one agent and a chore for another.

#### Monotone instances

A valuation function  $v$  is *monotone non-decreasing* if for any sets  $S \subseteq T \subseteq M$ , we have  $v(T) \geq v(S)$ , and *monotone non-increasing* if for any sets  $S \subseteq T \subseteq M$ , we have  $v(S) \geq v(T)$ . A *monotone goods* instance is one where all the agents have monotone non-decreasing valuations, and a *monotone chores* instance is one where all the agents have monotone non-increasing valuations. We refer to such an instance as a *monotone* if it is clear from context whether we are working with goods or chores.

#### Additive valuations

A well-studied subclass of monotone valuations is that of *additive valuations*, wherein an agent's value of any subset of items is equal to the sum of the values of individual items in the set, i.e., for any agent  $i \in N$  and any set of items  $S \subseteq M$ ,  $v_i(S) := \sum_{j \in S} v_i(\{j\})$ , where we assume that  $v_i(\emptyset) = 0$ . For simplicity, we will write  $v_i(j)$  or  $v_{i,j}$  to denote  $v_i(\{j\})$ .

### Allocation

An *allocation*  $A := (A_1, \dots, A_n)$  is an  $n$ -partition of a subset of the set of items  $M$ , where  $A_i \subseteq M$  is the *bundle* allocated to the agent  $i$  (note that  $A_i$  can be empty). An allocation is said to be *complete* if it assigns all items in  $M$ , and is called *partial* otherwise.

### Envy graph

The *envy graph*  $G_A$  of an allocation  $A$  is a directed graph on the vertex set  $N$  with a directed edge from agent  $i$  to agent  $k$  if  $v_i(A_k) > v_i(A_i)$ , i.e., if agent  $i$  prefers the bundle  $A_k$  over the bundle  $A_i$ .

### Top-trading envy graph

The *top-trading envy graph*  $T_A$  of an allocation  $A$  is a subgraph of its envy graph  $G_A$  with a directed edge from agent  $i$  to agent  $k$  if  $v_i(A_k) = \max_{j \in N} v_i(A_j)$  and  $v_i(A_k) > v_i(A_i)$ , i.e., if agent  $i$  envies agent  $k$  and  $A_k$  is the most preferred bundle for agent  $i$ .

### Cycle-swapped allocation

Given an allocation  $A$  and a directed cycle  $C$  in an envy graph or a top-trading envy graph, the *cycle-swapped allocation*  $A^C$  is obtained by reallocating bundles backwards along the cycle. For each agent  $i$  in the cycle, define  $i^+$  as the agent that she is pointing to in  $C$ . Then,  $A_i^C = A_{i^+}$  if  $i \in C$ , otherwise  $A_i^C = A_i$ .

### Envy-freeness and its relaxations

An allocation  $A$  is said to be

- *envy-free* (EF) if for every pair of agents  $i, k \in N$ , we have  $v_i(A_i) \geq v_i(A_k)$ , and
- *envy-free up to one item* (EF1) if for every pair of agents  $i, k \in N$  such that  $A_i \cup A_k \neq \emptyset$ , there exists an item  $j \in A_i \cup A_k$  such that  $v_i(A_i \setminus \{j\}) \geq v_i(A_k \setminus \{j\})$ .

## 4 Envy-Freeness for Binary Valued Chores

Our first result shows that determining the existence of an envy-free allocation is NP-complete even when agents have binary valuations, i.e., when, for all agents  $i \in N$  and items  $j \in M$ ,  $v_{i,j} \in \{-1, 0\}$  (Theorem 2). If agent valuations are not binary-valued, but are identical, the problem is still (weakly) NP-complete via a straightforward reduction from PARTITION. By contrast, our result establishes strong NP-completeness.

► **Theorem 2.** *Determining whether a given chores instance admits an envy-free allocation is NP-complete even for binary utilities.*

The proof of Theorem 2 can be found in the full version [27] of the paper.

## 5 EF1 For Doubly Monotone Instances

In light of the intractability result in the previous section, we will now explore whether one can achieve approximate envy-freeness (specifically, EF1) for indivisible chores. To this end, we note that the well-known round-robin algorithm (where, in each round, agents take turns in picking their favorite available chore) computes an EF1 allocation when agents have *additive* valuations [11]. In the following, we will provide an algorithm for computing an

■ **Algorithm 2** Top-trading envy-cycle elimination algorithm.

---

**Input:** An instance  $\langle N, M, \mathcal{V} \rangle$  with non-increasing valuations  
**Output:** An allocation  $A$

- 1 Initialize  $A \leftarrow (\emptyset, \emptyset, \dots, \emptyset)$
- 2 **for**  $c \in M$  **do**
- 3     **if** there is no sink in  $G_A$  **then**
- 4          $C \leftarrow$  any cycle in  $T_A$    ▷ if  $G_A$  has no sink, then  $T_A$  must have a cycle (Lemma 6)
- 5          $A \leftarrow A^C$
- 6     Choose a sink  $k$  in the graph  $G_A$
- 7     Update  $A_k \leftarrow A_k \cup \{c\}$
- 8 **return**  $A$

---

EF1 allocation for the much more general class of *monotone valuations*. Thus, our result establishes the analogue of the result of Lipton et al. [53] from the goods-only model for indivisible chores.

### 5.1 An Algorithm for Monotone Chores

As previously mentioned, the algorithm of Lipton et al. [53] computes an EF1 allocation for indivisible goods under monotone valuations. Recall that the algorithm works by assigning, at each step, an unassigned good to an agent who is not envied by anyone else (such an agent is a “source” agent in the underlying envy graph). The existence of such an agent is guaranteed by resolving arbitrary envy cycles in the envy graph until it becomes acyclic. Importantly, resolving an arbitrary envy cycle preserves EF1.

To design an EF1 algorithm for indivisible chores, prior work [10, 11] has proposed the following natural adaptation of this algorithm (see Algorithm 1): Instead of a “source” agent, an unassigned chore is now allocated to a “sink” (i.e., non-envious) agent in the envy graph. The existence of such an agent is once again guaranteed by means of resolving envy cycles. However, as noted in Example 1, resolving *arbitrary* envy cycles could destroy the EF1 property.

To address this gap, we propose to resolve a specific envy cycle that we call the *top-trading envy cycle*. (The nomenclature is inspired from the celebrated top-trading cycle algorithm [64] for finding a core-stable allocation that involves cyclic swaps of the most preferred objects.) Specifically, given a partial allocation  $A$ , we consider a subgraph of the envy graph  $G_A$  that we call the *top-trading envy graph*  $T_A$  whose vertices denote the agents, and an edge  $(i, k)$  denotes that agent  $i$ 's (weakly) most preferred bundle is  $A_k$ .

It is easy to observe that if the envy graph does not have a sink, then the top-trading envy graph  $T_A$  has a cycle (Lemma 6). Thus, resolving top-trading envy cycles (instead of arbitrary envy cycles) also guarantees the existence of a sink agent in the envy graph. More importantly, though, resolving a top-trading envy cycle preserves EF1. Indeed, every agent involved in the top-trading exchange receives its most preferred bundle after the swap, and therefore does not envy anyone else in the next round. The resulting algorithm is presented in Algorithm 2.

► **Theorem 3.** *For a monotone instance with indivisible chores, Algorithm 2 returns an EF1 allocation.*

In Section 5.2, we will discuss a more general result (Theorem 4) that extends the top-trading envy-cycle elimination algorithm to *doubly monotone* instances containing both indivisible goods as well as indivisible chores.

■ **Algorithm 3** An EF1 algorithm for doubly monotone indivisible instances.

---

**Input:** An instance  $\langle N, M, \mathcal{V}, \{G_i\}, \{C_i\} \rangle$  with indivisible items and doubly monotone valuations, where  $G_i$  and  $C_i$  are the set of goods and chores for agent  $i$ , respectively

**Output:** An allocation  $A$

```

1  $A \leftarrow (\emptyset, \emptyset, \dots, \emptyset)$ 
  // Goods Phase
2 for each item  $g \in \cup_i G_i$  do
3    $V^g = \{i \in N \mid g \in G_i\}$  ▷  $V^g$  contains all agents for whom  $g$  is a good
4    $G_A^g =$  the envy graph  $G_A$  restricted to the vertices  $V^g$ 
5   Choose a source  $k$  in the graph  $G_A^g$ 
6   Update  $A_k \leftarrow A_k \cup \{g\}$ 
7   while  $G_A$  contains a directed cycle  $C$  do
8      $A \leftarrow A^C$ 
  // Chores Phase
9 for each item  $c \in \cap_i C_i$  do
10  if there is no sink in  $G_A$  then
11     $C \leftarrow$  any cycle in  $T_A$  ▷ if  $G_A$  has no sink, then  $T_A$  must have a cycle
12     $A \leftarrow A^C$ 
13  Choose a sink  $k$  in the graph  $G_A$ 
14  Update  $A_k \leftarrow A_k \cup \{c\}$ 
15 return  $A$ 

```

---

## 5.2 An Algorithm for Doubly Monotone Instances

For a doubly monotone instance with indivisible items, we now give an algorithm (Algorithm 3) that returns an EF1 allocation. The algorithm runs in two phases. The first phase is for all the items that are a good for at least one agent. For these items, we run the envy-cycle elimination algorithm of Lipton et al. [53], but restricted to the subgraph of agents who consider the item a good. In the second phase, we allocate items that are chores to everybody by running the top-trading envy-cycle elimination algorithm. For a monotone chores-only instance, we recover Algorithm 2 as a special case of Algorithm 3.

► **Theorem 4.** *For a doubly monotone instance with indivisible items, Algorithm 3 returns an EF1 allocation.*

We first provide a brief sketch of the proof: At each step, we maintain the invariant that the partial allocation maintained by the algorithm is EF1. This is certainly true for the goods phase, where any envy created from agent  $i$  to agent  $j$  can always be eliminated by removing a good  $g \in A_j$  (however, unlike in the envy-cycle cancellation for goods-only instances [53], the eliminated item may not be the most recently added one since such an item could be a chore for an envious agent). In the chores phase, any new envy created by adding a chore can be removed by dropping the newly added chore. If we resolve top-trading envy cycles, then none of the agents within the cycle envy any of the agents outside it, since they now have their most preferred bundle. For any agent  $i$  outside the cycle, any envy can be removed by either removing a chore from  $i$  or a good from the envied bundle, since  $i$ 's allocation is unchanged and the bundles remain unbroken.

► **Lemma 5.** *After every step of the goods phase, the partial allocation remains EF1. Further, the goods phase terminates in polynomial time.*

## 1:10 Approximate EF for Indivisible Chores and Mixed Resources

The proof of Lemma 5 closely follows the arguments of Lipton et al. [53]; for completeness, we present a self-contained proof in Appendix A.1. We will now consider the chores phase of the algorithm, and show that if there is no sink in the envy graph  $G_A$ , then there is a cycle in the top-trading envy graph  $T_A$ .

► **Lemma 6.** *Let  $A$  be a partial allocation whose envy graph  $G_A$  does not have a sink. Then, the top-trading envy graph  $T_A$  must have a cycle. Furthermore, such a cycle can be found in polynomial time.*

**Proof.** Since  $G_A$  has no sinks, every vertex in  $G_A$  has outdegree at least one. Thus for all agents  $i$ ,  $i \notin \arg \max_k v_i(A_k)$ . So even in the top-trading envy graph  $T_A$ , each vertex has outdegree at least one. We start at an arbitrary agent and follow an outgoing edge from each successive agent. This gives us a cycle in  $T_A$ . It is easy to see that finding the cycle takes only polynomial time since we encounter each vertex at most once. ◀

We now show that resolving a cycle in the top-trading envy graph  $T_A$  gives an allocation that necessarily has a sink (the existence of such a cycle in  $T_A$  is given by Lemma 6).

► **Lemma 7.** *Let  $A$  be a partial allocation whose top-trading envy graph  $T_A$  contains a cycle. Let  $A'$  denote the allocation obtained by resolving an arbitrary cycle in  $T_A$ . Then the envy graph  $G_{A'}$  of the allocation  $A'$  must have a sink.*

**Proof.** Note that each agent points to its favorite bundle in  $T_A$ . Thus after resolving a cycle in  $T_A$ , all agents who participated in the cycle-swap now have their most preferred bundle in  $A'$  and do not envy any other agent. These agents are sinks in the graph  $G_{A'}$ . ◀

To show that the partial allocation remains EF1 throughout the chores phase, we use Lemmas 8 and 9.

► **Lemma 8.** *In the chores phase, adding a new chore to the allocation (Line 13-14) preserves EF1.*

**Proof.** Suppose at time step  $t$ , the algorithm assigns a new chore (Line 13-14). Suppose before time step  $t$ , our allocation  $A$  was EF1, and the allocation after time step  $t$  is  $A'$ . We show that  $A'$  is EF1 as well. A sink exists in the envy graph  $G_A$  at time step  $t$ , either because there were no top-trading envy cycles when we entered the loop (at Line 9) which implies the existence of a sink, or because we resolved a top-trading envy cycle  $C$  in the previous time step  $t - 1$  (Lines 10-12), in which case all the agents who were a part of the resolved top-trading envy cycle do not envy anyone after the cycle swap, and are sinks in the envy graph  $G_A$ .

Then after time  $t$ , the allocation  $A'$  will be  $A'_k = A_k \cup \{c\}$ , and  $A'_j = A_j$  for all  $j \neq k$ , where  $k$  is a sink in  $G_A$ . Pick two agents  $i$  and  $j$  such that  $i$  envies  $j$  in  $A'$ . If  $i$  did not envy  $j$  in  $A$ , then clearly  $i = k$ . In this case, removing  $c$  from  $A_i$  removes  $i$ 's envy. Suppose  $i$  envied  $j$  in  $A$  as well, and the envy was eliminated by removing  $o \in A_i \cup A_j$ . Then  $i \neq k$  since  $k$  was a sink in the graph  $G_A$ , and so  $v_i(A_i) = v_i(A'_i)$ . If  $o \in A_i$ , then  $v_i(A'_i \setminus \{o\}) \geq v_i(A_j) \geq v_i(A'_j)$ . If  $o \in A_j$ , then  $v_i(A'_i) \geq v_i(A_j \setminus \{o\}) \geq v_i(A_j \cup \{c\} \setminus \{o\})$ , since  $c$  is a chore for all agents. ◀

► **Lemma 9.** *In the chores phase, resolving a top-trading envy cycle (Lines 10-12) preserves EF1.*

**Proof.** Suppose at time step  $t$ , the algorithm resolves a top-trading envy cycle (Line 10-12). Let  $A$  be the allocation before time  $t$ ,  $C$  be the cycle along which the swap happens, and  $A' = A^C$  the allocation obtained by swapping backwards along the cycle. Pick two agents  $i$  and  $j$  such that  $i$  envies  $j$  in  $A'$ . Since every agent in the cycle obtains their favorite bundle,  $i \notin C$ . Thus  $A_i = A'_i$ . Let  $j'$  be the agent such that  $A'_j = A_{j'}$ . Since  $v_i(A'_i) = v_i(A_i)$ ,  $i$  envied  $j'$  before the swap which could be eliminated by removing  $o \in A_i \cup A_{j'}$ . If  $o \in A_i$ , then  $v_i(A'_i \setminus \{o\}) \geq v_i(A'_j)$ . If  $o \in A_{j'}$ , then  $v_i(A'_i) \geq v_i(A'_j \setminus \{o\})$ . Thus removing  $o \in A_i \cup A_{j'}$  eliminates the envy in  $A'$ . ◀

By Lemma 5, the allocation at the beginning of the chores phase is EF1. At every time step  $t$  of the chores phase, the algorithm either assigns a chore to a sink agent or resolves a top-trading envy cycle. Thus Lemma 8 and Lemma 9 together show that the allocation remains EF1 throughout the chores phase. By Lemma 6, finding a cycle in  $T_A$  takes only polynomial time. Since the while-loop executes only once for each chore, the chores phase terminates in polynomial time. This gives us the following lemma:

► **Lemma 10.** *At every step of the chores phase, the allocation remains EF1, and the chores phase terminates in polynomial time.*

The proof of Theorem 4 follows immediately, since by Lemma 10 the allocation at the end of the chores phase is EF1. Thus Algorithm 3 returns an EF1 allocation for a doubly monotone instance. Specialized to instances with only chores, we obtain Theorem 3 as a corollary.

## 6 Approximate Envy Freeness for Mixed Resources

We will now describe the setting with *mixed resources* consisting of both divisible and indivisible parts. This model was recently studied by Bei et al. [22], who introduced the notion of *envy-freeness for mixed goods* (EFM) in the context of a model consisting of indivisible goods and a divisible cake. We generalize this notion to a setting with both goods and chores.

### 6.1 Preliminaries for Instances with Divisible and Indivisible Resources

#### Mixed instance

A mixed instance  $\langle N, M, \mathcal{V}, \cdot, \mathcal{F} \rangle$  is defined by a set of  $n$  agents,  $m$  indivisible items, a valuation profile  $\mathcal{V}$  (over the indivisible items), a divisible resource represented by the interval  $[0, 1]$ , and a family  $\mathcal{F}$  of *density functions* over the divisible resource. The valuations for the indivisible items are as described in Section 3. For the divisible resource, each agent has a *density function*  $f_i : [0, 1] \rightarrow \mathbb{R}$  such that for any measurable subset  $S \subset [0, 1]$ , agent  $i$  values it at  $v_i(S) := \int_S f_i(x) dx$ . When the density function is non-negative for every agent (i.e., for all  $i \in N$ ,  $f_i : [0, 1] \rightarrow \mathbb{R}_{\geq 0}$ ), we will call the divisible resource a “cake”, and for non-positive densities (i.e., for all  $i \in N$ ,  $f_i : [0, 1] \rightarrow \mathbb{R}_{\leq 0}$ ), we will use the term “bad cake”. We do not deal with general real-valued density functions in this work.

#### Allocation

An *allocation*  $A := (A_1, \dots, A_n)$  is given by  $A_i = M_i \cup C_i$ , where  $(M_1, \dots, M_n)$  is an  $n$ -partition of the set of indivisible items  $M$ , and  $(C_1, \dots, C_n)$  is an  $n$ -partition of the divisible resource  $= [0, 1]$ . where  $A_i$  is the *bundle* allocated to the agent  $i$  (note that  $A_i$  can be empty). Given an allocation  $A$ , the *utility* of agent  $i \in N$  for the bundle  $A_i$  is  $v_i(A_i) := v_i(M_i) + v_i(C_i)$ , i.e., utility is additive across resource types.

### Perfect partition

For any  $k \in \mathbb{N}$ , a  $k$ -partition  $C = (C_1, C_2, \dots, C_k)$  of either cake or bad cake is said to be perfect if each agent values all the pieces equally, i.e., for all agents  $i \in N$  and for all pieces of the cake  $j \in [k]$ ,  $v_i(C_j) = \frac{v_i(0)}{k}$ . Note that a perfect allocation of a cake exists even when the agents' valuations are not normalized, since multiplicative scaling of agents' valuations preserves envy-freeness [4]. As in the work of Bei et al. [22], we will assume the existence of a perfect allocation oracle in our algorithmic results.

### Generalized envy graph

The *generalized envy graph*  $\overline{G}_A$  of an allocation  $A$  is a directed graph on the vertex set  $N$ , with a directed edge from agent  $i$  to agent  $k$  if  $v_i(A_k) \geq v_i(A_i)$ . If  $v_i(A_k) = v_i(A_i)$ , then we refer to the edge  $(i, k)$  as an *equality edge*, otherwise we call it an *envy edge*. A *generalized envy cycle* in this graph is a cycle  $C$  that contains at least one envy edge.

### Top-trading generalized envy graph

The *top-trading generalized envy graph*  $\overline{T}_A$  of an allocation  $A$  is a subgraph of  $\overline{G}_A$ , with a directed edge from agent  $i$  to agent  $k$  if  $i \neq k$  and  $v_i(A_k) = \max_{j \in N} v_i(A_j)$ , i.e.,  $A_k$  is one of the most preferred bundles for agent  $i$  in the allocation  $A$ . A generalized envy cycle in this graph is called a *top-trading generalized envy cycle*.

### Envy-freeness for mixed resources (EFM)

We will now discuss the notion of envy-freeness for mixed resources (EFM) that was formalized by Bei et al. [22] in the context of indivisible goods and divisible cake. Our definition extends their formulation to related settings where the indivisible part consists of chores and/or the divisible part is bad cake. The definition below is based on the following idea: Any agent who owns cake should not be envied, any agent who owns bad cake should not envy anyone else, and subject to these conditions, any pairwise envy should be EF1. Formally, an allocation  $A$  is said to be *envy-free for mixed resources* (EFM) if for any pair of agents  $i, k \in N$ , either  $i$  does not envy  $k$  (i.e.,  $v_i(A_i) \geq v_i(A_k)$ ), or all of the following hold: (a)  $i$  does not have bad cake, i.e.,  $v_i(C_i) \geq 0$ , (b)  $k$  does not have cake, i.e.,  $v_i(C_k) \leq 0$ , and (c) the envy from  $i$  to  $k$  is bounded according to EF1, i.e.,  $\exists j \in M_i \cup M_k$  such that  $v_i(A_i \setminus \{j\}) \geq v_i(A_k \setminus \{j\})$ .

## 6.2 Background: Indivisible Goods and Cake

The algorithm of Bei et al. [22] gives an EFM allocation for an instance with additive indivisible goods and cake. The algorithm initially finds an EF1 allocation of the indivisible goods using the envy-cycle elimination algorithm. It then allocates the cake in the following manner: In successive iterations, it tries to find an inclusion-wise maximal *source addable set* of agents, to which cake is then allocated.

► **Definition 11** (Source addable set). *Given a generalized envy graph, a non-empty set of agents  $S \subseteq N$  is a source addable set if (a) there is no envy edge from an agent in  $N$  to an agent in  $S$ , and (b) there is no equality edge from an agent in  $N \setminus S$  to an agent in  $S$ .*

Intuitively, to satisfy the EFM property, an agent that is envied must not get any cake, and an equality edge  $(i, j)$  implies that  $i$ 's value for the cake she gets must be at least her value for the cake that  $j$  gets.

To find a maximal source addable set of agents, the algorithm first resolves all generalized envy cycles in the generalized envy graph  $\overline{G}_A$ . It then removes all agents that are reachable from an envied agent. Bei et al. show that the remaining agents form the unique maximal source addable set. If there are  $k$  agents in this set, then the algorithm finds a perfect  $k$ -partition of the largest prefix of the cake (if  $[a, 1]$  is the remaining unallocated piece of cake, then a prefix of the cake is a piece  $[a, x]$  of the cake where  $a < x \leq 1$ ) such that giving each agent in the set a piece of this partition does not introduce envy towards any agent in the set. This continues until all the cake is allocated.

### 6.3 EFM for Doubly Monotone Indivisible Items and Bad Cake

For an instance with doubly monotone indivisible items and bad cake, we give an algorithm to obtain an EFM allocation (Algorithm 4). First, we run the doubly monotone algorithm (Algorithm 3) on the indivisible instance to obtain an EF1 allocation. We then extend it to an EFM allocation by allocating the bad cake as follows: Our algorithm always allocates prefixes of the bad cake, hence the remaining cake is always an interval  $[a, 1]$  for some  $a \geq 0$ . In each iteration, we first find an inclusion-wise maximal *sink addable set* of agents, defined analogously to the source addable set introduced earlier.

► **Definition 12** (Sink addable set). *Given a generalized envy graph, a non-empty set of agents  $S \subseteq N$  is a sink addable set if (a) there is no envy edge from an agent in  $S$  to an agent in  $N$ , and (b) there is no equality edge from an agent in  $S$  to an agent in  $N \setminus S$ .*

Since we will allocate bad cake to the agents in this set  $S$ , no agent in a sink addable set should envy another agent. Further, an equality edge  $(i, j)$  implies that if  $i$  is in the sink addable set  $S$ ,  $j$  must be in the set as well. We find a maximal sink addable set by first resolving all top-trading generalized envy cycles in the top-trading generalized envy graph  $\overline{T}_A$ , and then using the procedure in Lemma 13. The resolution of top-trading generalized envy cycles does not affect the EFM property, because of the same reasons as in the top-trading envy-cycle elimination algorithm (Section 5).

Once we find the maximal sink addable set  $S$  to which we can allocate bad cake, we need to quantify the amount of bad cake that can be allocated to the agents in  $S$  while still preserving the EFM property. We find the largest loss in utility  $\delta_i$  that an agent  $i \in S$  (who is to be given bad cake) can tolerate before she starts to envy another agent  $j \notin S$  (who is not allocated any bad cake), i.e.,

$$\delta_i = \min_{j \in N \setminus S} v_i(A_i) - v_i(A_j) \text{ for all } i \in S.$$

Note that  $\delta_i > 0$  since there are no envy or equality edges from  $S$  to  $N \setminus S$ . We then find the smallest prefix  $[a, x_{i^*}]$  of the cake, and a perfect  $|S|$ -partition of this prefix, so that if each part is allocated to an agent in  $S$ , then the utility of each agent decreases by at most  $\delta_i$ , and for a particular agent  $i^*$ , her utility goes down by exactly  $\delta_{i^*}$ . By definition of  $\delta_{i^*}$ , a new equality edge arises in the generalized envy graph  $\overline{G}_A$  from agent  $i^* \in S$  to some agent in  $N \setminus S$ . Once we allocate  $[a, x_{i^*}]$  perfectly to all agents in  $S$ , the allocation still remains EFM (Lemma 15), and we only have  $[x_{i^*}, 1]$  of the cake left to allocate. We will establish in Theorem 16 that the algorithm terminates with a polynomial number of such iterations.

We first show that the maximal sink addable set is unique if it exists (Bei et al. [22] show a similar result for source addable sets). All missing proofs can be found in the appendix.

► **Lemma 13.** *Given a partial allocation  $A$ , the maximal sink addable set (if it exists) is unique, and can be found in polynomial time.*

■ **Algorithm 4** Algorithm for EFM with doubly monotone indivisible items and bad cake.

---

**Input:** An instance  $\langle N, M, \mathcal{V}, \mathcal{F} \rangle$  with doubly monotone indivisible items  $M$ , and a divisible bad cake

**Output:** An allocation  $A$

```

1 Run the doubly monotone algorithm to obtain an EF1 allocation  $A = (A_1, A_2, \dots, A_n)$  of  $M$ 
  // Bad cake allocation phase
2 while there is still unallocated cake  $= [a, 1]$  do
3    $\bar{T}_A =$  top-trading generalized envy graph of  $A$ 
4   while there is a top-trading generalized envy cycle  $C$  in  $\bar{T}_A$  do
5      $A \leftarrow A^C$  ▷ This ensures the existence of a sink addable set
6      $S =$  maximal sink addable set for  $A$  ▷ Using Lemmas 13 and 14
7     if  $S = N$  then
8       Find an EF allocation  $(C_1, C_2, \dots, C_n)$  of
9        $A_i = A_i \cup C_i$  for all  $i \in N$ 
10       $\leftarrow \emptyset$ 
11    else
12       $\delta_i = \min_{j \in N \setminus S} v_i(A_i) - v_i(A_j)$  for all  $i \in S$ 
13      if  $v_i() \geq -|S| \cdot \delta_i$  for all  $i \in S$  then
14         $C' \leftarrow$ 
15         $\leftarrow \emptyset$ 
16      else
17         $x_i = \sup \{x \mid v_i([a, x]) \geq -|S| \cdot \delta_i\}$  for all  $i \in S$ 
18         $i^* = \arg \min_{i \in S} x_i$ 
19         $C' \leftarrow [a, x_{i^*}]$ 
20         $\leftarrow [x_{i^*}, 1]$ 
21      Obtain a perfect partition  $(C_1, C_2, \dots, C_{|S|})$  of  $C'$ 
22       $A_i \leftarrow A_i \cup C_i$  for all  $i \in S$ 
23 return  $A$ 

```

---

We now show that once we resolve all top-trading generalized envy cycles, the generalized envy graph  $\bar{G}_A$  contains a sink addable set (and thus a maximal sink addable set).

► **Lemma 14.** *If the top-trading generalized envy graph  $\bar{T}_A$  does not contain any generalized envy cycles, then the generalized envy graph  $\bar{G}_A$  has a sink addable set.*

Once we run the top-trading generalized envy cycle elimination procedure, we are thus guaranteed the existence of a sink addable set. Then, we move to the bad cake allocation procedure. The agents in the set  $S$  are then perfectly allocated a small amount of bad cake while preserving the EFM property. We now show that the partial allocation remains EFM throughout the algorithm.

► **Lemma 15.** *At each step of the bad cake allocation phase, the partial allocation in Algorithm 4 satisfies EFM.*

Finally, we will show that the algorithm terminates, assuming the existence of a perfect partition oracle.

► **Theorem 16.** *Algorithm 4 terminates after  $\mathcal{O}(n^3)$  rounds of the while-loop and returns an EFM allocation.*

## 6.4 Special Case Results with Indivisible Chores and Divisible Cake

While the approach of first allocating the indivisible resources followed by assigning the divisible resource works well for instances with indivisible goods and cake [22], and for instances with doubly monotone indivisible items and bad cake (Theorem 16), extending this approach to an instance with indivisible chores and cake is challenging for the following reason: Suppose, in such an instance, we initially allocate the indivisible chores to satisfy EF1 using the top-trading envy-cycle elimination algorithm. Then we might not be able to proceed with cake allocation, since the algorithm does not guarantee us the existence of a source in the generalized envy graph. In an effort to remedy this, we introduce the component-wise matching algorithm (refer to the full version for details [27]) to obtain an EF1 allocation of additive indivisible chores that does not have any generalized envy cycles. This algorithm ensures that the allocation at the end of indivisible chores stage is generalized envy-cycle free. However, adding even a small amount of cake might once again make the generalized envy graph sourceless, and it is unclear how to proceed at this stage.

Nevertheless, for special cases of this problem, we can prove the existence of an EFM allocation. Restricted to additive valuations of the indivisible chores, we show methods of obtaining an EFM allocation in two cases: 1) when the agents have *identical rankings* of the items (formalized in Appendix A.6), and 2) when the number of items does not exceed the number of agents by more than one, i.e.,  $m \leq n + 1$ . At a high level, the reason we are able to circumvent the aforementioned challenge in these two cases is because the particular EF1 allocation we obtain for indivisible chores in these cases has the property that we can resolve *any* generalized envy cycle that arises during the cake allocation stage. This freedom allows us to execute the algorithm of Bei et al. directly on these instances.

► **Theorem 17.** *For a mixed instance with additive indivisible chores with identical rankings and cake, an EFM allocation exists.*

► **Theorem 18.** *For a mixed instance with  $n$  agents,  $m$  additive indivisible chores and cake where  $m \leq n + 1$ , an EFM allocation exists.*

The proofs of the above two theorems can be found in Appendix A.6 and in the full version [27] of the paper respectively.

## A Appendix

### A.1 Proof of Lemma 5

► **Lemma 5.** *After every step of the goods phase, the partial allocation remains EF1. Further, the goods phase terminates in polynomial time.*

**Proof.** Clearly the empty allocation at the beginning is EF1. Suppose before time step  $t$ , our allocation  $A$  is EF1 (i.e., any envy from agent  $i$  to agent  $j$  can be eliminated by removing an item from  $A_j$ ). Denote the allocation after time step  $t$  by  $A'$ . We will argue that  $A'$  is EF1, and any envy from agent  $i$  to agent  $j$  can be eliminated by removing an item from  $A'_j$ . At every time step, either a good is allocated or an envy cycle is resolved.

Suppose at time step  $t$ , we allocate a new item (Lines 5-6). Note that the graph  $G_A$  is acyclic at this stage. This is because it holds trivially the first time an item is allocated, and in every subsequent execution of the while-loop, we eliminate all envy cycles present (Lines 7-8) before we begin allocating the next item. Thus, the subgraph  $G_A^g$  is acyclic as well, where  $G_A^g$  is the graph  $G_A$  restricted to the agents for whom  $g$  is a good.

Then after time  $t$ , our allocation  $A'$  will be  $A'_k = A_k \cup \{g\}$ , and  $A'_j = A_j$  for all  $j \neq k$ , where  $k$  is a source in  $G_A^g$ . Pick two agents  $i$  and  $j$  such that  $i$  envies  $j$  in  $A'$ . If  $i$  did not envy  $j$  in  $A$ , then clearly  $j$  must be the agent who received the good  $g$  (i.e.,  $j = k$ ) and  $i \in V^g$ . In this case, removing  $g$  from  $A_k$  removes  $i$ 's envy as well. Suppose  $i$  envied  $j$  in  $A$  as well, and the envy was eliminated by removing  $g'$  from  $A_j$ . If  $j = k$  then  $i \notin V^g$  since  $k$  was a source in  $G_A^g$ . Then removing  $g'$  eliminates the envy in  $A'$  as well, since  $v_i(A_k \cup \{g\} \setminus \{g'\}) \leq v_i(A_k \setminus \{g'\})$ . If  $j \neq k$ , then since  $j$ 's bundle remains the same and  $v_i(A'_i) \geq v_i(A_i)$ , the envy can again be eliminated by removing  $g'$  from  $A'_j$ .

Suppose at time  $t$  we resolve an envy cycle (Lines 7-8). Let  $A$  be the allocation before time  $t$ ,  $C$  be the cycle along which the swap happens, and  $A' = A^C$  the allocation obtained by swapping backwards along the cycle. Pick two agents  $i$  and  $j$  such that  $i$  envies  $j$  in  $A'$ . Let  $i'$  and  $j'$  be the agents such that  $A'_i = A_{i'}$  and  $A'_j = A_{j'}$ . Since  $v_i(A'_i) \geq v_i(A_i)$ ,  $i$  envied  $j'$  in the allocation  $A$  before the swap. Suppose this envy was eliminated by removing  $g'$  from  $A_{j'}$ . Then  $v_i(A'_i) \geq v_i(A_i) \geq v_i(A_{j'} \setminus \{g'\})$ , and thus removing  $g'$  from  $A'_j$  eliminates the envy in  $A'$ .

To show that the algorithm terminates in polynomial time, we show that we resolve envy cycles at most a polynomial number of times for each item. Consider a single while-loop for an item, where a cycle swap occurs on the cycle  $C$ . Since the bundles remain unbroken, all agents outside the cycle have the same outdegree in  $G_{A'}$  as in  $G_A$ . An agent  $i$  inside the cycle has strictly lesser outdegree in  $G_{A'}$  compared to  $G_A$ , since the  $(i, i^+)$  edge in  $G_A$  does not translate into a  $(i, i)$  edge in  $G_{A'}$  (since  $i$  gets  $i^+$ 's bundle). Thus the number of envy edges goes down by at least  $|C|$  during each cycle swap, and the while-loop terminates in polynomial time. ◀

### A.2 Proof of Lemma 13

► **Lemma 13.** *Given a partial allocation  $A$ , the maximal sink addable set (if it exists) is unique, and can be found in polynomial time.*

**Proof.** Suppose there were two distinct maximal sink addable sets  $S_1$  and  $S_2$ . Then we show that  $S_1 \cup S_2$  is also a sink addable set, contradicting their maximality. The existence of an envy edge from an agent in  $S_1 \cup S_2$  to an agent in  $N$  contradicts either  $S_1$  or  $S_2$  being a sink addable set. Similarly, an equality edge from an agent in  $S_1 \cup S_2$  to an agent in  $N \setminus S_1 \cup S_2$  contradicts either  $S_1$  or  $S_2$  being a sink addable set. Thus  $S_1 \cup S_2$  is a sink addable set, a contradiction.

To find a maximal sink addable set, say that an agent  $i$  is an *envious* agent if there is an envy edge  $(i, j)$  in the generalized envy graph. Note that by definition a sink addable set cannot contain an envious agent. Let  $T$  be the set of all agents that have a path to an envious agent (i.e., if agent  $r$  is in  $T$ , there exists a path from  $r$  to an envious agent  $i$  in the generalized envy graph along envy and equality edges). Let  $S = N \setminus T$  be the complementary set of agents. We claim that  $S$  is a maximal sink addable set. Clearly, no agent outside  $S$  can be in any sink addable set. To see this, consider any agent  $r \notin S$ , and let  $r$  have a path to an envious agent  $i$ . By the properties of sink addable sets, if  $r$  is in  $S$ , then so must all the agents in the path including  $i$ , but this contradicts the property that a sink addable set cannot contain an envious agent. Now consider an agent  $r$  in  $S$ , and note that  $r$  does not have a path to an envious agent. Since  $r$  is not envious, it does not have an envy edge to any other agent. Further, since all agents outside  $S$  have a path to an envious agent,  $r$  cannot have an (equality or envy) edge to an outside agent. Hence, the set of agents so obtained must be a maximal sink addable set. ◀

### A.3 Proof of Lemma 14

► **Lemma 14.** *If the top-trading generalized envy graph  $\overline{T}_A$  does not contain any generalized envy cycles, then the generalized envy graph  $\overline{G}_A$  has a sink addable set.*

**Proof.** Suppose the top-trading generalized envy graph  $\overline{T}_A$  does not contain any generalized envy cycles. Then each strongly connected component  $C_i$  of the graph  $\overline{T}_A$  contains only equality edges inside it. Let  $C_1$  be a leaf component obtained by Tarjan's algorithm to find strongly connected components (see Section 22.5 of [38]). We claim that  $C_1$  is a sink addable set in the generalized envy graph  $\overline{G}_A$ .

Suppose there was an envy edge from an agent  $i$  in  $C_1$ . Since the top-trading envy graph points to an agent's favorite bundle, there would be an envy edge from  $i$  in the graph  $\overline{T}_A$  as well. Thus  $i$  would not be part of a leaf component of  $\overline{T}_A$ , contradicting that  $i \in C_1$ . Thus all agents in  $C_1$  only have equality edges in  $\overline{G}_A$ .

Suppose now that there was an equality edge from an agent  $i \in C_1$  to an agent  $j \in N \setminus C_1$ . Since  $i$  does not envy any other agent, the edge  $(i, j)$  would be present in  $\overline{T}_A$  as well, contradicting that  $C_1$  is a leaf component of  $\overline{T}_A$ . Thus  $C_1$  is a sink addable set, and thus  $\overline{G}_A$  contains a maximal sink addable set as well. ◀

### A.4 Proof of Lemma 15

► **Lemma 15.** *At each step of the bad cake allocation phase, the partial allocation in Algorithm 4 satisfies EFM.*

**Proof.** The allocation of indivisible items at the start of the algorithm is EF1 and consequently EFM as well. In the generalized top-trading envy graph, suppose we resolve a cycle  $C$ . Then the allocation remains EFM for agents outside the cycle since the bundles are unbroken. Since all agents in the cycle receive their highest valued item, they do not envy any other agent and thus satisfy EFM as well.

In the bad cake allocation stage, if  $N$  is the maximal sink addable set, then there are no envy edges inside the graph  $\overline{G}_A$  and the initial allocation is envy-free. The allocation remains envy-free on adding an EF allocation of the remaining cake to their bundles, and thus the final allocation is EFM as well.

If the maximal sink addable set  $S \subset N$  is a strict subset, then the amount of cake we allocate is chosen such that the EFM property is satisfied. Since every agent in  $S$  is given bad cake, the envy from agents in  $N \setminus S$  remains EFM. By definition of sink addable set,

none of the agents in  $S$  envy anyone before the bad cake allocation. Since we obtain a perfect allocation, none of the agents in  $S$  envy each other after the bad cake allocation as well. Note that the value of the bad cake allocated to each agent in this round is bounded below by  $\delta_i = \min_{j \in N \setminus S} v_i(A_i) - v_i(A_j)$  for all  $i \in S$ . Thus no agent in  $S$  envies an agent in  $N \setminus S$  in the final allocation as well by choice of  $\delta_i$ , and the partial allocation remains EFM throughout the algorithm.  $\blacktriangleleft$

## A.5 Proof of Theorem 16

We will break down the running time analysis into two parts: (1) The number of rounds where the algorithm resolves a top-trading generalized envy cycle, and (2) between any such consecutive rounds, the number of times when the algorithm assigns bad cake to agents in a maximal sink addable set.

Let us start with the first part. Note that assigning bad cake to a maximal sink addable set never creates new envy edges, and resolving a top-trading generalized envy cycle reduces the number of envy edges by at least one. Therefore, following the allocation of the indivisible items, the number of envy edges is a non-increasing function of time. This means that there can be at most  $\mathcal{O}(n^2)$  rounds where a top-trading generalized envy cycle is resolved by the algorithm.

Let us now consider the second part. We will argue that between any consecutive rounds where the algorithm resolves a top-trading generalized envy cycle, there can be at most  $n$  steps where the algorithm allocates bad cake. Observe that if there are no envy edges in the graph, then the maximal sink addable set is the entire set of agents (i.e.,  $S = N$ ), and the algorithm immediately terminates by allocating the entire remaining cake. Otherwise, after each round of adding bad cake, at least one new equality edge is created from  $S$  to  $N \setminus S$ . If this creates a new top-trading generalized envy cycle, then the number of envy edges strictly reduces in the next round. Else, the size of the maximal sink addable set strictly decreases in the next round, implying that there can be at most  $n$  rounds of adding bad cake before the number of envy edges strictly decreases.

Overall, we obtain that the algorithm terminates in  $\mathcal{O}(n^3)$  rounds.

► **Theorem 16.** *Algorithm 4 terminates after  $\mathcal{O}(n^3)$  rounds of the while-loop and returns an EFM allocation.*

**Proof.** By Lemma 15, the allocation returned by the algorithm is EFM. So, it suffices to show that the algorithm executes  $\mathcal{O}(n^3)$  iterations of the while-loop.

First, note that there can be at most  $\mathcal{O}(n^2)$  rounds where the algorithm resolves a top-trading generalized envy cycle. This follows from the following two observations: (a) The number of envy edges never increases during the algorithm, and (b) the number of envy edges strictly decreases by at least one whenever a top-trading generalized envy cycle is resolved. Observation (b) is straightforward. To see why (a) holds, it suffices to argue that adding bad cake does not introduce any new envy edges. Indeed, since we are adding bad cake, none of the agents in the set  $N \setminus S$  (i.e., the agents outside the maximal sink addable set) can develop new envy edges to an agent in  $S$  or  $N \setminus S$ . For each agent in  $S$ , since the amount of cake added is bounded below by  $\delta_i = \min_{j \in N \setminus S} v_i(A_i) - v_i(A_j)$  for all  $i \in S$ , none of the agents in  $S$  have new envy edges to an agent in  $N \setminus S$ . Furthermore, since the allocation is perfect, agents in  $S$  do not end up envying one another. Thus, no new envy edges are created due to the allocation of the bad cake, and therefore we have at most  $\mathcal{O}(n^2)$  rounds of top-trading generalized envy-cycle elimination.

Next, we will argue that between any consecutive cycle-elimination rounds, there can be at most  $n$  steps where the algorithm assigns bad cake to a maximal sink addable set. Note that if at any stage there are no envy edges in the generalized envy graph, then the maximal sink addable set is the entire set of agents (i.e.,  $S = N$ ), and the algorithm terminates immediately after assigning the entire remaining bad cake. So, let us assume for the remainder of the proof that there is always at least one envy edge.

If, for all agents  $i \in S$ , a perfect allocation of the remaining cake  $= [a, 1]$  preserves EFM, then the algorithm terminates in the next step. Else, we mark the point  $x_i$  on the cake for each agent such that after perfectly allocating  $[a, x_i]$ , they have a new equality edge to an agent in  $N \setminus S$ . By choice of  $i^*$  as the agent with minimum value of  $x_i$ , the agent  $i^*$  has a new equality edge to an agent  $j$  in  $N \setminus S$  after this round. If this edge creates a new top-trading generalized envy cycle, then the number of envy edges strictly reduces in the next round. Else, the size of the maximal sink addable set decreases since  $i^*$  now has a path to an envious agent and must therefore be excluded from the maximal sink addable set (additionally, no new agents are added to the sink addable set). Thus, bad cake allocation can occur for at most  $n$  consecutive rounds before the number of envy edges strictly decreases, leading to the desired  $\mathcal{O}(n^3)$  number of rounds.  $\blacktriangleleft$

## A.6 Special Case Results for EFM with Indivisible Chores and Divisible Cake

We first discuss the case of additive indivisible chores with identical rankings and cake. By identical rankings, we mean that all the agents have the same preference order on the indivisible chores, and we can order the chores as  $c_1, c_2, \dots, c_m$  such that  $v_i(c_1) \geq v_i(c_2) \geq \dots \geq v_i(c_m)$  for all agents  $i \in N$ . We assume for simplicity that the number of chores is a multiple of the number of agents. If not, we add an appropriate number of virtual chores that are valued at 0 by every agent, and remove them at the end of the algorithm. Note that this does not affect the EF1 or the EFM property. In this setting, the round-robin algorithm satisfies two desirable properties:

- Let  $(B_1, B_2, \dots, B_n)$  be a partition of the chores given by  $B_i = \{c_j \mid j \equiv i \pmod{n}\}$ . For each of the  $n!$  possible orderings of the agents, under lexicographic tiebreaking of the preferable chores, the round-robin algorithm allocates the same bundle  $B_i$  to the  $i^{\text{th}}$  agent in the ordering, and
- Resolving *any* generalized envy cycle in the allocation obtained from a round-robin instance does not violate EFM.

By lexicographic tiebreaking, we mean that if an agent has many chores of the same value to choose in round-robin, they choose the chore with the lexicographically smallest index.

► **Lemma 19.** *For an additive indivisible chores instance with identical rankings, every ordering of the agents for round-robin allocates the bundle  $B_i = \{c_j \mid j \equiv i \pmod{n}\}$  to the  $i^{\text{th}}$  agent in the ordering when tiebreaking happens lexicographically.*

**Proof.** Order the chores as  $c_1, c_2, \dots, c_m$  in non-increasing order of their value. Suppose that in the execution of the round-robin algorithm, if an agent has many chores that it has the same value for, it chooses the lexicographically smallest chore. We claim that the bundles remain the same regardless of the ordering of the agents.

Suppose the agents were ordered as  $\pi(1), \pi(2), \dots, \pi(n)$  for round-robin. In the first round of the algorithm, we claim that agent  $\pi(i)$  chooses the chore  $c_i$  during the execution. Indeed, since all the agents have the same rankings on the chores, agent  $\pi(1)$  chooses  $c_1$  in the first round (even if there were other chores with the same value,  $c_1$  is lexicographically the

smallest). Inductively, once agents  $\{\pi(1), \pi(2), \dots, \pi(i)\}$  have chosen  $\{c_1, c_2, \dots, c_i\}$ , agent  $\pi(i+1)$  weakly prefers  $c_{i+1}$  over any other chore, and adds it to their bundle because it is the lexicographically smallest chore present. Thus  $\{c_1, c_2, \dots, c_n\}$  are allocated in the first round. By a straightforward induction on the number of rounds, we see that the final allocation is  $A_{\pi(i)} = \{c_j \mid j \equiv i \pmod{n}\}$ . ◀

Note that for every position  $j$  and every agent  $i$ , there is an ordering of the agents such that agent  $i$  is in the  $j^{\text{th}}$  position during the round-robin algorithm (if  $i = j$  consider the identity permutation, else consider the permutation  $(i\ j)$ ). Since the round-robin algorithm always returns an EF1 allocation, this implies the strong property that the partition  $(B_1, B_2, \dots, B_n)$  satisfies EF1 for agent  $i$ , regardless of which bundle is allocated to that agent. Since the agent  $i$  was chosen arbitrarily at the beginning, this gives us the following lemma:

► **Lemma 20.** *For an additive indivisible chores instance with identical rankings, the allocation  $A_{\pi(i)} = B_i$  is an EF1 allocation for any ordering  $\pi$  of the agents, where  $B_i = \{c_j \mid j \equiv i \pmod{n}\}$ .*

Recall from Section 5.1 that the reason we had to restrict ourselves to resolving top-trading envy cycles when searching for an EF1 allocation of monotone indivisible chores was because resolving an arbitrary envy cycle could upset EF1 (Example 1), where an agent might obtain a bundle of higher value during the cycle swap, but the newly acquired bundle might consist of chores with low absolute value. By contrast, we can resolve *any* generalized envy cycle in the case of identical rankings, since the allocation is EF1 regardless of which agent obtains which bundle. Note that this property continues to hold even when we add cake using Bei et al.'s algorithm, since any agent with cake is never envied throughout the algorithm, and any envy present can be eliminated by the removal of one good (in fact, the same good) regardless of the identity of the agent holding a bundle (the valuation is weakly better for bundles with some portion of cake present). Thus, we have the following theorem:

► **Theorem 17.** *For a mixed instance with additive indivisible chores with identical rankings and cake, an EFM allocation exists.*

Using this result, we also show the existence of an EFM allocation when  $n - 1$  of the  $n$  agents have identical rankings. Say the agents are  $\{1, 2, \dots, n\}$ , and the agent  $n$  does not have a ranking identical to the others. Run the round-robin algorithm with the first  $n - 1$  agents and one virtual copy of one of the identical agents, say agent 1. At the end of the round-robin algorithm, allow agent  $n$  to pick their favorite bundle and arbitrarily allocate the remaining bundles between the other agents. Note that since agent  $n$  does not envy anybody at the beginning of cake allocation, and since the cake allocation stage does not create any new envy edges, the final allocation will be EFM for agent  $n$ . For all other agents, the allocation will be EF1 at the beginning of cake allocation (Lemma 20). Since resolving any generalized envy cycle still preserves EFM (Theorem 17), the final allocation will be EFM for the agents  $\{1, 2, \dots, n - 1\}$  as well. Thus we get the following corollary:

► **Corollary 21.** *For a mixed instance with additive indivisible chores with identical rankings for  $n - 1$  agents and cake, an EFM allocation exists. In particular, for two agents, an EFM allocation always exists in this setting.*

This property of being able to resolve any generalized envy cycle can also be obtained when the number of indivisible chores is at most one higher than the number of agents, i.e.,  $m \leq n + 1$ . A proof of Theorem 18 can be found in the full version [27] of the paper.

# Optimal Algorithms for Online $b$ -Matching with Variable Vertex Capacities

## Abstract

We study the  $b$ -matching problem, which generalizes classical online matching introduced by Karp, Vazirani and Vazirani (STOC 1990). Consider a bipartite graph  $G = (S \cup R, E)$ . Every vertex  $s \in S$  is a server with a capacity  $b_s$ , indicating the number of possible matching partners. The vertices  $r \in R$  are requests that arrive online and must be matched immediately to an eligible server. The goal is to maximize the cardinality of the constructed matching. In contrast to earlier work, we study the general setting where servers may have arbitrary, individual capacities. We prove that the most natural and simple online algorithms achieve optimal competitive ratios.

As for deterministic algorithms, we give a greedy algorithm `RELATIVEBALANCE` and analyze it by extending the primal-dual framework of Devanur, Jain and Kleinberg (SODA 2013). In the area of randomized algorithms we study the celebrated `RANKING` algorithm by Karp, Vazirani and Vazirani. We prove that the original `RANKING` strategy, simply picking a random permutation of the servers, achieves an optimal competitiveness of  $1 - 1/e$ , independently of the server capacities. Hence it is not necessary to resort to a reduction, replacing every server  $s$  by  $b_s$  vertices of unit capacity and to then run `RANKING` on this graph with  $\sum_{s \in S} b_s$  vertices on the left-hand side. From a theoretical point of view our result explores the power of randomization and strictly limits the amount of required randomness. From a practical point of view it leads to more efficient allocation algorithms.

Technically, we show that the primal-dual framework of Devanur, Jain and Kleinberg cannot establish a competitiveness better than  $1/2$  for the original `RANKING` algorithm, choosing a permutation of the servers. Therefore, we formulate a new configuration LP for the  $b$ -matching problem and then conduct a primal-dual analysis. We extend this analysis approach to the vertex-weighted  $b$ -matching problem. Specifically, we show that the algorithm `PERTURBEDGREEDY` by Aggarwal, Goel, Karande and Mehta (SODA 2011), again with a sole randomization over the set of servers, is  $(1 - 1/e)$ -competitive. Together with recent work by Huang and Zhang (STOC 2020), our results demonstrate that configuration LPs can be strictly stronger than standard LPs in the analysis of more complex matching problems.

## 1 Introduction

Matching in bipartite graphs is a fundamental problem with numerous applications in computer science. We study the  $b$ -matching problem [13], where the vertices of one set of the bipartition may be matched multiple times. It generalizes the standard matching problem. Furthermore, it models capacitated allocations as well as interesting special cases of the timely AdWords problem.

More specifically, let  $G = (S \cup R, E)$  be a bipartite graph. The vertices of  $S$  are servers. Each server  $s \in S$  has an individual capacity  $b_s$ , indicating the maximum number of possible matching partners. The vertices of  $R$  are requests that have to be assigned to the servers. We consider the online problem where the set  $S$  of servers is known in advance and the requests of  $R$  arrive sequentially one by one. Whenever a new request  $r \in R$  arrives, its incident edges are revealed. The request has to be matched immediately and irrevocably to an eligible server, provided that there is one. The goal is to maximize the number of matching edges.

Prior work on  $b$ -matchings has mostly focused on the case that all servers have the same capacity, i.e.  $b_s = b$ , for all  $s \in S$ . In this paper we study the general setting of individual server capacities, as described above. This setting is particularly relevant in applications. Furthermore, we examine the *vertex-weighted* problem extension, where additionally each server  $s \in S$  has a weight  $w_s$  and the value of every matching edge incident to  $s$  is multiplied by  $w_s$ . The goal is to maximize the total weight of the constructed matching. Again this extension is interesting in allocation problems.

If  $b_s = 1$  for all  $s \in S$ , the  $b$ -matching problem is equal to classic online bipartite matching, which was introduced in a seminal paper by Karp et al. [15] and has received tremendous research interest over the last 30 years. The  $b$ -matching problem models a range of interesting applications. Naturally, the servers can be compute servers that process persistent jobs arriving over time. Furthermore, the servers can be facilities that stream content online, host web pages or store data remotely [5]. More generally, the servers can represent stations in mobile computing, queues in a network switch or even locations in a hash table [2, 5, 9]. Obviously, each server can only handle a limited number of clients.

Another relevant application are the AdWords problem and ad auctions in search engine companies [18]. There is a set of advertisers, each with a daily budget, who wish to link their ads to search keywords and issue respective bids. Queries along with their keywords arrive online and must be allocated instantly to the advertisers. The  $b$ -matching problem models the basic setting where all bids are either 0 or 1. The vertex-weighted extension captures the scenario where all the bids of an advertiser  $s \in S$  have a value of 0 or  $w_s$ .

We analyze the performance of algorithms for the  $b$ -matching problem using competitive analysis. Given an input graph  $G$ , let  $\text{ALG}(G)$  denote the size (or weight) of the matching constructed by an online algorithm  $\text{ALG}$ . Let  $\text{OPT}(G)$  be the corresponding value of an optimal offline algorithm  $\text{OPT}$ . Algorithm  $\text{ALG}$  is  $c$ -competitive if  $\text{ALG}(G) \geq c \cdot \text{OPT}(G)$  holds, for all  $G$ . If  $\text{ALG}$  is a randomized algorithm, then  $\text{ALG}(G)$  has to be replaced by the expected value  $\mathbb{E}[\text{ALG}(G)]$ .

**Related Work.** Straightforward arguments show that any algorithm that matches an incoming request to an eligible server with remaining capacity, if there exists one, is  $\frac{1}{2}$ -competitive. Kalyanasundaram and Pruhs [13] investigate the  $b$ -matching problem if all servers have equal capacity, i.e.  $b_s = b$  for all  $s \in S$ . They present a deterministic  $\text{BALANCE}$  algorithm that matches a new request to an adjacent server whose current load is smallest. Kalyanasundaram and Pruhs prove that  $\text{BALANCE}$  achieves an optimal competitive ratio

of  $1 - 1/(1 + 1/b)^b$ . As  $b$  grows, the latter expression tends to  $1 - 1/e \approx 0.63$ . Azar and Litichevsky [2] give an alternative analysis of the BALANCE algorithm. Chaudhuri et al. [5] and Grove et al. [9] study  $b$ -matchings with a different objective. At any time an algorithm must maintain a matching between the requests that have arrived so far and the servers. The goal is to minimize the total number of switches where a request is reassigned to a different server.

In a famous paper, Karp et al. [15] introduced the online bipartite matching problem. This is a  $b$ -matching problem where all servers have a capacity of 1, i.e. each vertex in the graph may be incident to at most one matching edge. Online bipartite matching has received tremendous research interest over the last years and we only mention the most important results relevant to our work. Again, any algorithm that matches an incoming request to an arbitrary available partner is  $\frac{1}{2}$ -competitive. No deterministic online algorithm can be better than  $\frac{1}{2}$ -competitive. Karp et al. [15] show that an algorithm RANDOM, which matches a request to an available partner chosen uniformly at random, does not achieve a competitiveness greater than  $1/2$ . As a main result they propose the celebrated RANKING algorithm. This strategy initially chooses a random permutation of the vertices in  $S$ . Thereby, each such vertex is assigned a priority or *rank*. Whenever a vertex of  $R$  arrives, it is matched to the eligible vertex of highest rank in  $S$ . Karp et al. prove that RANKING is  $(1 - 1/e)$ -competitive. This ratio is best possible for randomized algorithms [15].

Simplified and alternative analyses of RANKING were provided in [1, 3, 6, 7]. In particular, Devanur et al. [6] developed an elegant primal-dual analysis. Aggarwal et al. [1] defined online vertex-weighted bipartite matching, where each vertex  $s \in S$  has a weight  $w_s$ . Again, all vertices of  $S$  have a capacity of 1. The goal is to maximize the total weight of the constructed matching. Aggarwal et al. [1] devise a generalization of RANKING, named PERTURBED-GREEDY, and prove that it is  $(1 - 1/e)$ -competitive. Devanur et al. [6] analyze this strategy in their compact primal-dual framework. Further work on online bipartite matching considers different input models [8, 12, 14, 16] or refined matching models [10, 17].

The AdWords problem was formally defined by Mehta et al. [18]. They present a deterministic online algorithm that achieves a competitive ratio of  $1 - 1/e$ , under the assumption that the bids are small compared to the advertisers' budgets. No randomized algorithm can obtain a better competitive factor. Buchbinder et al. [4] develop a primal-dual algorithm that attains a competitiveness of  $(1 - 1/c)(1 - R_{\max})$ , where  $c = (1 + R_{\max})^{1/R_{\max}}$  and  $R_{\max}$  is the maximum ratio between the bid of any advertiser and its total budget. Huang et al. [11] give a 0.5016-competitive algorithm, for AdWords without the small-bids assumption.

**Our Contributions.** We present a comprehensive study of the  $b$ -matching problem with variable server capacities. As a main contribution we show that the most natural and simple online algorithms obtain optimal competitive ratios.

First, we concentrate on the unweighted setting, with the objective to maximize the cardinality of the constructed matching. In Section 2 we study deterministic algorithms. We formulate and analyze a strategy RELATIVEBALANCE that assigns an incoming request to an eligible server with minimum *relative load*. The relative load of a server  $s$  is the number requests that are currently matched with  $s$  divided by the capacity  $b_s$ . Thus the algorithm considers which fraction of a server's capacity is already used. This is the most straightforward greedy policy for the setting with variable server capacities. We show that RELATIVEBALANCE achieves a competitive ratio of  $1 - 1/(1 + 1/b_{\min})^{b_{\min}}$ , where  $b_{\min} = \min_s b_s$  is the minimum server capacity. The performance ratio is best possible for deterministic online algorithms.

In order to evaluate RELATIVEBALANCE we conduct a primal-dual analysis. We extend the framework by Devanur et al. [6], this time to analyze a deterministic algorithm different from RANKING. We remark that BALANCE by Kalyanasundaram and Pruhs [13] does not achieve a competitive ratio of  $1 - 1/(1 + 1/b_{\min})^{b_{\min}}$  when using only  $b_{\min}$  spots of each server because OPT may use the additional capacity. Moreover, we would like to add that the results by Buchbinder et al. [4] also imply a deterministic online algorithm with a competitiveness of  $1 - 1/(1 + 1/b_{\min})^{b_{\min}}$  for the  $b$ -matching problem. However, their algorithm is not equal to RELATIVEBALANCE. In fact, their strategy may assign a request to a server not having the smallest relative load and does not necessarily use the full capacity of a server, leaving requests unmatched. This leads to somewhat unintuitive assignments. We give details in Appendix A. Of course, Buchbinder et al. [4] were interested in the general AdWords problem and did not tailor their analysis to  $b$ -matchings.

In Section 3 we study randomized online algorithms. In a first step we examine the RANDOM algorithm, which assigns an incoming request to a random adjacent server with remaining capacity. We prove that the competitive factor of RANDOM is not better than  $1/2$ . The major part of Section 3 investigates the original RANKING algorithm. More specifically, RANKING initially picks a random permutation of the servers. An incoming request is matched to the eligible server of highest rank. We prove that RANKING achieves a competitive ratio of  $1 - 1/e$ , independently of the server capacities. The ratio of  $1 - 1/e$  is best possible for randomized algorithms [18]. Surprisingly, the original RANKING algorithm has an optimal competitiveness for the more complex  $b$ -matching problem. We are not aware of any other generalization of the classical online matching problem where this holds true.

Observe that we can also obtain a competitive ratio of  $1 - 1/e$  using the following reduction to standard online bipartite matching: Replace each server  $s$  with capacity  $b_s$  by exactly  $b_s$  individual vertices of capacity 1. Each request adjacent to  $s$  gets incident edges to each of these  $b_s$  vertices. On the resulting graph with  $\sum_{s \in S} b_s$  vertices on the left-hand side of the bipartition, execute the RANKING algorithm. Such a reduction can also be applied for deterministic online algorithms but only gives a competitive factor of  $1/2$ .

Our result for the original RANKING algorithm, executed on the initial input graph  $G$ , has the following implications. (1) From a theoretical point of view, an interesting question is how much randomness is needed to obtain a competitiveness of  $1 - 1/e$ . Our analysis demonstrates that a straightforward execution of the barely random RANKING strategy attains this ratio. No randomization over the server spots is necessary. (2) In practical applications a ranking of the servers leads to simple and efficient allocation algorithms. With a random permutation of a huge number of server spots, assignments might be difficult, perhaps even impossible to compute.

In our analysis we first demonstrate that the framework by Devanur et al. [6] cannot establish a competitiveness of  $1 - 1/e$  for RANKING, when executed on the original graph  $G$ . It only yields a competitiveness of  $1/2$ . Therefore, as a main technical contribution, we formulate a new configuration linear program (LP) for the  $b$ -matching problem. Using this configuration LP, we then conduct a primal-dual analysis by extending the framework of Devanur et al. [6]. We point out that, for the bipartite matchings with stochastic rewards, Huang and Zhang [10] recently were the first to employ configuration LPs. However, the concrete LPs used in [10] and in this paper are different, apart from a modeling of vertex neighborhoods. Also, the analyses differ so as to obtain the desired performance ratios.

In Section 4 we investigate vertex-weighted  $b$ -matching, with the objective to maximize the total weight of the constructed matching. We focus on randomized strategies and study PERTURBED-GREEDY [1], which was introduced for vertex-weighted online bipartite matching,

where each vertex  $s \in S$  has a capacity of 1. The algorithm, for each  $s \in S$ , computes a rank based on an initial random choice. A request is matched to the eligible vertex  $s \in S$  of highest rank. We investigate PERTURBED-GREEDY for the  $b$ -matching problem when executed on the original input graph  $G$ , without the above reduction of splitting a server  $s$  into  $b_s$  vertices of unit capacity. We extend our analysis approach based on configuration LPs and prove that the algorithm achieves an optimal competitive ratio of  $1 - 1/e$ .

In summary, simple rank-based algorithms that make initial random choices for the servers (but not for the server spots) achieve an optimal competitive ratio of  $1 - 1/e$ , independently of the server capacities. Furthermore, the paper by Huang and Zhang [10] and our work show that configuration LPs can be more powerful than standard LPs in the analysis of more advanced matching problems.

## 2 Deterministic algorithms for maximum-cardinality $b$ -matching

It is easy to verify that an online algorithm that matches a new request to an eligible server with largest remaining capacity does not achieve a competitiveness greater than  $1/2$ .

In the following we present our natural RELATIVEBALANCE algorithm. Let  $load_s$  denote the (absolute) load of a server  $s \in S$ , i.e. the number of requests assigned to  $s$  so far. We define the relative server load as  $l_s := load_s/b_s$ . RELATIVEBALANCE simply assigns incoming requests to an eligible neighbor with minimum relative server load.

### Algorithm 1 RELATIVEBALANCE.

---

```

while a new request  $r \in R$  arrives do
  Let  $N(r)$  denote the set of neighbors of  $r$  with remaining capacity;
  if  $N(r) = \emptyset$  then
    | Do not match  $r$ ;
  else
    | Match  $r$  to  $\arg \min\{l_s : s \in N(r)\}$  (break ties arbitrarily);
  end
end

```

---

We analyze RELATIVEBALANCE by conducting a primal-dual analysis. For this, consider the classical (relaxed) primal and dual LP of maximum cardinality online bipartite  $b$ -matching. Here, we use a primal variable  $m(s, r)$  for each edge  $e = \{s, r\} \in E$ , where  $s \in S$  and  $r \in R$ , indicating whether or not  $e$  is contained in the matching.

$$\begin{aligned}
 \text{Primal: } \max \quad & \sum_{\{s,r\} \in E} m(s, r) \\
 \text{s.t.} \quad & \sum_{r: \{s,r\} \in E} m(s, r) \leq b_s, & (\forall s \in S) \\
 & \sum_{s: \{s,r\} \in E} m(s, r) \leq 1, & (\forall r \in R) \\
 & m(s, r) \geq 0, & (\forall \{s, r\} \in E).
 \end{aligned}$$

$$\begin{aligned}
 \text{Dual: } \min \quad & \sum_{s \in S} b_s \cdot x(s) + \sum_{r \in R} y(r) \\
 \text{s.t.} \quad & x(s) + y(r) \geq 1, & (\forall \{s, r\} \in E) \\
 & x(s), y(r) \geq 0, & (\forall s \in S, \forall r \in R).
 \end{aligned}$$

Devanur et al. [6] developed an elegant framework that unifies the analysis of randomized online algorithms for matching problems. We will extend their framework to analyze our deterministic algorithm RELATIVEBALANCE. Whenever an online algorithm assigns a request  $r$  to a server  $s$ , the gain of 1 in the primal objective function (and thus the size of the matching) is translated into a gain of  $1/c$  in the dual objective function by splitting it across the dual variables  $x(s)$  and  $y(r)$ . Here,  $c$  is a constant that will be maximized during the analysis and will denote the competitive ratio of the algorithm,  $0 < c \leq 1$ . If an arriving request remains unmatched, the dual solution will remain unchanged as well.

It then has to be shown that this can be done in a way such that all the dual constraints are satisfied in the end. Let  $P$  and  $D$  be the value of the constructed primal and dual solution, respectively. By summing over all steps of the algorithm, we get  $P = c \cdot D$ , and thus  $P \geq c \cdot \text{OPT}$ , by weak duality. This implies that the online algorithm is  $c$ -competitive.

In the case without vertex capacities, Devanur et al. [6] show that for the known optimal randomized online algorithms that choose a random value  $x_s \in [0, 1]$  for every server  $s \in S$ , the gain of matching a request  $r$  to  $s$  can be split across  $x(s)$  and  $y(r)$  according to the function  $g(x_s) = e^{x_s - 1}$ . More precisely, in the unweighted scenario, they argue that setting

$$x(s) = \frac{g(x_s)}{c} \quad \text{and} \quad y(r) = \frac{1 - g(x_s)}{c}$$

with  $c = 1 - 1/e$  results in a dual solution that is feasible in expectation.

In our case with vertex capacities, we first have to deal with the fact that a server  $s$  may be assigned multiple requests. Therefore, we increase the value of  $x(s)$  whenever this happens. Moreover, we change the function that determines how the gain is split. Our algorithm uses the relative load of the servers for its matching decisions instead of a ranking based on the random values. Therefore, whenever RELATIVEBALANCE matches a request  $r$  to a server  $s$ , we update

$$\Delta x(s) = \frac{f(l_s)}{c \cdot b_s} \quad \text{and} \quad y(r) = \frac{1 - f(l_s)}{c},$$

where  $f : [0, 1] \rightarrow [0, 1]$  is a monotonically non-decreasing function and  $l_s$  denotes the relative load of  $s$  before the assignment. Observe that this increases the value of the dual solution by exactly  $1/c$  and guarantees  $x(s) \geq 0$  and  $y(r) \geq 0$  for all  $s \in S$  and  $r \in R$ , respectively.

Now, we have to show that  $f$  and  $c$  can be chosen such that this results in a feasible dual solution, i.e.  $x(s) + y(r) \geq 1$  holds for all edges  $\{s, r\} \in E$ . If  $r$  is not matched by RELATIVEBALANCE, then  $y(r) = 0$ . Nonetheless, we know that all of  $r$ 's neighbors had to be fully loaded when  $r$  arrived. Thus, in this case, for all  $b_s$ , we need that

$$x(s) + y(r) = \frac{1}{c \cdot b_s} \sum_{i=0}^{b_s-1} f\left(\frac{i}{b_s}\right) \geq 1. \quad (1)$$

On the other hand, if  $r$  is matched to a server  $s'$  by RELATIVEBALANCE, then we know that  $l_{s'} \leq l_s$  had to hold at the time of  $r$ 's arrival. In this case, it therefore needs to hold that

$$x(s) + y(r) = \frac{1}{c} \left( \frac{1}{b_s} \sum_{i=0}^{load_{s'}-1} f\left(\frac{i}{b_s}\right) + 1 - f\left(\frac{load_{s'}}{b_{s'}}\right) \right) \geq 1, \quad (2)$$

for all ratios  $load_{s'}/b_{s'} \leq load_s/b_s$ . Recall that  $load_{s'}$  and  $load_s$  are absolute server loads.

▷ **Claim 1.** Let  $c := 1 - 1/d$ , where  $d > 1$ . Then,  $f(l_s) = d^{l_s-1}$  satisfies both (1) and (2) if  $d \leq (1 + 1/b_s)^{b_s}$ .

Proof. First, observe that  $d \leq (1 + 1/b_s)^{b_s}$  implies  $d^{\frac{1}{b_s}} - 1 \leq 1/b_s$ . It then follows that

$$\frac{1}{c \cdot b_s} \sum_{i=0}^{b_s-1} f\left(\frac{i}{b_s}\right) = \frac{1}{c \cdot b_s \cdot d} \sum_{i=0}^{b_s-1} \left(d^{\frac{1}{b_s}}\right)^i = \frac{1}{c \cdot b_s \cdot d} \cdot \frac{d-1}{d^{\frac{1}{b_s}}-1} \geq \frac{d-1}{c \cdot b_s \cdot d \cdot \frac{1}{b_s}} = 1.$$

The last step follows from the choice of  $c$ . Moreover, we can show that

$$\begin{aligned} \frac{1}{c} \left( \frac{1}{b_s} \sum_{i=0}^{load_s-1} f\left(\frac{i}{b_s}\right) + 1 - f\left(\frac{load_s}{b_s}\right) \right) &= \frac{1}{c} \left( \frac{1}{b_s \cdot d} \sum_{i=0}^{load_s-1} \left(d^{\frac{1}{b_s}}\right)^i + 1 - d^{load_s/b_s} \right) \\ &= \frac{1}{c} \left( \frac{1}{b_s \cdot d} \cdot \frac{d^{load_s/b_s} - 1}{d^{\frac{1}{b_s}} - 1} + 1 - d^{load_s/b_s} \right) \geq \frac{1}{c} \left( \frac{d^{load_s/b_s} - 1}{d} + 1 - d^{load_s/b_s} \right) \geq \frac{1}{c} \left( 1 - \frac{1}{d} \right) = 1. \quad \triangleleft \end{aligned}$$

We have now shown that the combination of  $f(l_s) := d^{l_s-1}$  with  $c = 1 - 1/d$  yields a feasible dual solution if  $1 < d \leq (1 + 1/b_s)^{b_s}$ , for all  $s \in S$ . Here  $c$  denotes the competitiveness of RELATIVEBALANCE.  $(1 + 1/b_s)^{b_s}$  is a monotonically increasing function for  $b_s > 0$ . The largest possible value for  $d$  is therefore  $(1 + 1/b_{\min})^{b_{\min}}$ , where  $b_{\min} = \min_s b_s$  is the smallest server capacity.

► **Theorem 2.** RELATIVEBALANCE achieves a competitiveness of  $1 - 1/(1 + 1/b_{\min})^{b_{\min}}$ , where  $b_{\min} := \min_{s \in S} b_s$ .

The competitive ratio of  $1 - 1/(1 + 1/b_{\min})^{b_{\min}}$  is optimal for deterministic algorithms: Kalyanasudaram and Pruhs [13] showed that no deterministic online algorithm can achieve a competitiveness greater than  $1 - 1/(1 + 1/b)^b$  if all servers have a uniform capacity equal to  $b$ . We can take their nemesis sequence and add servers with capacity  $b' > b$  that are adjacent to few (or no) extra requests.

### 3 Randomized algorithms for maximum-cardinality $b$ -matching

Karp et al. [15] proposed an algorithm RANDOM, for online bipartite matching, which assigns a newly arriving request to a random eligible neighbor. They showed that RANDOM is not better than  $\frac{1}{2}$ -competitive. We prove that the performance ratio does not improve, for the  $b$ -matching problem, even if all servers have a uniform capacity of  $b \geq 2$ . The material on RANDOM with the proof of the following theorem is given in Appendix B.

► **Theorem 3.** RANDOM does not achieve a competitive ratio better than  $1/2$  for the maximum cardinality online  $b$ -matching problem, even if all server capacities are equal.

The remainder of this section is devoted to the RANKING algorithm. We will prove that the algorithm achieves an optimal competitiveness of  $1 - 1/e$ , for the maximum cardinality online  $b$ -matching problem. Again, we execute RANKING on the original input graph  $G$ . We will work with a version of RANKING (see Alg. 2) that is similar to that in [6]. Note that, importantly, there is a *single* random choice for each server  $s \in S$ . Initially, a  $Z_s \in [0, 1]$  is picked uniformly at random. This value is used as a rank for  $s$ . An incoming request is matched to the eligible server with smallest  $Z$ -value.

First, we argue that the classical primal-dual framework fails here, meaning that it is not able to establish a competitive ratio better than  $1/2$ . As usual, whenever RANKING assigns a request  $r$  to a server  $s$ , we increase  $x(s)$  by and set  $y(r)$  to

$$\Delta x(s) = \frac{g(Z_s)}{c \cdot b_s} \text{ and } y(r) = \frac{1 - g(Z_s)}{c},$$

---

**Algorithm 2** RANKING.
 

---

```

foreach server  $s \in S$  do
  | Pick  $Z_s \in [0, 1]$  uniformly at random;
end
while a new request  $r \in R$  arrives do
  | Let  $N(r)$  denote the set of neighbors of  $r$  with remaining capacity;
  | if  $N(r) = \emptyset$  then
  | | Do not match  $r$ ;
  | else
  | | Match  $r$  to  $\arg \min \{Z_s : s \in N(r)\}$  (break ties consistently);
  | end
end

```

---

respectively. Again,  $g : [0, 1] \rightarrow [0, 1]$  is a monotonically non-decreasing function and  $c$  is a constant that will denote the competitive ratio of the algorithm. Let  $P$  and  $D$  be random variables denoting the value of the random primal and dual solution, respectively. If we were able to show that a combination of  $g$  and  $c$  yields a dual solution that is feasible in expectation, then this would imply a competitive ratio of  $c$ . To see this, create a new (deterministic) dual solution that sets its variables to the expected value of the corresponding variable of the random solution and denote its value by  $D'$ . It then holds that the new dual solution satisfies all dual constraints and thus  $\text{OPT} \leq D' = \mathbb{E}[D]$ . Moreover, the framework yields  $P = c \cdot D$ , always, implying  $\mathbb{E}[P] = c \cdot \mathbb{E}[D] \geq c \cdot \text{OPT}$ .

Now, consider the two input graphs  $G_A$  and  $G_B$  (see Fig. 1). If there was a combination of  $g$  and  $c$  that always yields a dual solution that is feasible in expectation, then this combination also has to satisfy the constraint for the edge  $\{s, r\}$  in both  $G_A$  and  $G_B$  in expectation. In graph  $G_A$ , this means

$$\mathbb{E}[x(s) + y(r)] = \frac{\mathbb{E}[g(Z_s)]}{c \cdot b_s} + \frac{1 - \mathbb{E}[g(Z_s)]}{c} \stackrel{!}{\geq} 1 \iff \mathbb{E}[g(Z_s)] \leq (1 - c) \cdot \frac{b_s}{b_s - 1}.$$

In  $G_B$  however, this means

$$\mathbb{E}[x(s) + y(r)] = b_s \cdot \frac{\mathbb{E}[g(Z_s)]}{c \cdot b_s} + 0 \stackrel{!}{\geq} 1 \iff \mathbb{E}[g(Z_s)] \geq c.$$

Combining these two inequalities yields  $c \leq (1 - c) \cdot \frac{b_s}{b_s - 1}$ . This is equivalent to  $c \leq \frac{b_s}{2b_s - 1}$ , which implies that the best competitive ratio that may be shown for RANKING with this framework approaches  $1/2$  for larger server capacities  $b_s$ .

**Figure 1** Two example input graphs for RANKING. Graph  $G_A$  only consists of a single edge between a server  $s$  and a request  $r$ , whereas  $G_B$  consists of a server  $s$  and its  $b_s + 1$  neighboring requests. Request  $r$  denotes the last arriving request.

Given this fact, we proceed and model the  $b$ -matching problem by a configuration LP. Let  $N_s$  denote the set of neighbors of a server  $s$ . The configuration LP differs from the classical matching LP in that it does not use a variable for every edge  $\{s, r\}$  indicating whether this edge is chosen by the algorithm. Instead it uses a variable  $m(s, N)$ , for every server  $s$  and every subset  $N \subseteq N_s$ , indicating whether this subset is the set of requests matched to  $s$ .

$$\begin{aligned}
 \text{Config LP: } & \max \sum_{s \in S} \sum_{N \subseteq N_s} \min\{|N|, b_s\} \cdot m(s, N) \\
 \text{s.t. } & \sum_{N \subseteq N_s} m(s, N) \leq 1, & (\forall s \in S) \\
 & \sum_{s \in S} \sum_{N \subseteq N_s: r \in N} m(s, N) \leq 1, & (\forall r \in R) \\
 & m(s, N) \geq 0, & (\forall s \in S, \forall N \subseteq N_s).
 \end{aligned}$$

$$\begin{aligned}
 \text{Dual CLP: } & \min \sum_{s \in S} x(s) + \sum_{r \in R} y(r) \\
 \text{s.t. } & x(s) + \sum_{r \in N} y(r) \geq \min\{|N|, b_s\}, & (\forall s \in S, \forall N \subseteq N_s) \\
 & x(s), y(r) \geq 0, & (\forall s \in S, \forall r \in R).
 \end{aligned}$$

Obviously, every valid  $b$ -matching in a graph  $G$  is captured by a solution of the configuration LP. Its optimal solution is an upper bound on the cardinality of the maximum  $b$ -matching in  $G$ . Hence the configuration LP is a suitable primal program for a primal-dual analysis.

We adapt the primal-dual analysis framework. Initially, all primal and dual variables are set to 0. Whenever a new request  $r \in R$  arrives and RANKING assigns it to a server  $s$ , we update the primal variables of  $s$  accordingly, keeping track of the set  $N$  of matching partners. The value of the primal solution increases by 1. Moreover, we update the dual variables

$$\Delta x(s) = \frac{g(Z_s)}{c} \text{ and } y(r) = \frac{1 - g(Z_s)}{c},$$

where  $g : [0, 1] \rightarrow [0, 1]$  is a monotonically non-decreasing function to be determined during the analysis and  $c$  is a constant that will denote the competitive ratio of the algorithm. Note that we now do not have to divide the gain of  $x(s)$  by  $b_s$ , since the dual objective function does not have a factor  $b_s$  before  $x(s)$ . Therefore, we still translate a gain of 1 in the primal solution to a gain of  $1/c$  in the dual solution, guaranteeing that  $P = c \cdot D$ , where  $P$  and  $D$  are the random variables denoting the value of the primal and dual solution, respectively. Similar arguments to before imply that it is sufficient to satisfy all dual constraints in expectation to show a competitive ratio of  $c$ .

Thus, it remains to show is that we can choose  $g$  and  $c$  such that

$$\mathbb{E} \left[ x(s) + \sum_{r \in N} y(r) \right] \geq \min\{|N|, b_s\},$$

for all servers  $s \in S$  and all  $N \subseteq N_s$ . For this, we will need two lemmas similar to the Dominance and Monotonicity Lemmas in [6]. We will consider two executions of RANKING on  $G$  and on  $G \setminus s$ , for some server  $s \in S$ . Here,  $G \setminus s$  denotes the graph induced by the vertex set  $S \setminus \{s\} \cup R$ . We assume that RANKING uses the same  $Z$ -values  $Z_t$  for all servers  $t \in S \setminus \{s\}$  in both executions. Further, let  $r \in R$  be any request in  $G$  and let  $z_r$  be the

$Z$ -value of its matching partner in the  $G \setminus s$  execution. If  $r$  is unmatched, we set  $z_r := 1$  and assign a dummy matching partner. Moreover, let  $y_s(r)$  be the value of  $y(r)$  in the  $G \setminus s$  execution. We impose from now on that  $g(1) = 1$ , which implies  $y_s(r) = (1 - g(z_r))/c$ . We use the idea of *server spots*. A server spot  $s_i$  of a server  $s$ ,  $1 \leq i \leq b_s$ , denotes an individual unit of a server that can accept a request. When RANKING assigns requests to a server  $s$ , we assume without loss of generality that it assigns the  $j$ -th request to the server spot  $s_j$ . A server spot is matched if it has been assigned a request, and unmatched otherwise.

► **Lemma 4.** *At any point during the parallel execution of RANKING on  $G$  and  $G \setminus s$ , the set of unmatched server spots  $U$  in the  $G$  execution forms a superset of the unmatched server spots  $\tilde{U}$  in the  $G \setminus s$  execution. For all server spots  $s'_i \in U \setminus \tilde{U}$ , it holds that  $Z_{s'_i} \geq Z_s$ . If  $Z_{s'} = Z_s$  and  $s' \neq s$ , then  $s$  has a higher priority in the tiebreaking.*

**Proof.** By induction. Initially, the properties trivially hold, since  $U \setminus \tilde{U} = \{s_1, \dots, s_{b_s}\}$  at the start. Then, whenever a new request  $r$  arrives,  $\tilde{U} \subseteq U$  can only be violated if  $r$  is assigned to a server spot  $t_i \in \tilde{U}$  in the  $G$  execution, but  $r$  is not assigned to  $t_i$  in the  $G \setminus s$  execution. There, it is either unmatched or matched to a different server spot, which leads to a contradiction in either case. Since  $t_i \in \tilde{U}$  and  $r$  is a neighbor of the server  $t$ ,  $r$  cannot be unmatched in the  $G \setminus s$  execution. If RANKING chooses a different server spot  $t_j$  for  $r$  in the  $G \setminus s$  execution, then either  $i < j$  or  $i > j$  has to hold.  $i < j$  results in a contradiction because  $t_i \in \tilde{U}$  and we defined that RANKING always chooses the unmatched server spot with smallest index. Furthermore,  $i > j$  also results in a contradiction because  $t_j \in \tilde{U} \subseteq U$  and thus RANKING would have chosen  $t_j$  in the  $G$  execution as well. Moreover, if RANKING assigns  $r$  to a server spot of a different server  $t'$  in the  $G \setminus s$  execution, then  $Z_{t'} \leq Z_t$  has to hold. However,  $\tilde{U} \subseteq U$  implies that this server spot would also be unmatched and available in the  $G$  execution. If  $Z_{t'} < Z_t$ , RANKING would not have chosen an unmatched neighbor with smallest  $Z$ -value in the  $G$  execution, and if  $Z_{t'} = Z_t$ , then the tiebreak would be inconsistent between the two executions.

Moreover, a new server spot  $t'_i$  is only added to  $U \setminus \tilde{U}$  if the matching decision for  $r$  is different in the two execution, i.e. the  $G$  execution assigns  $r$  to some server spot  $t_j \in U \setminus \tilde{U}$  and the  $G \setminus s$  execution assigns  $r$  to  $t'_i \in \tilde{U}$ . Therefore, it has to hold that either  $Z_{t'} > Z_t$  or  $Z_{t'} = Z_t$  and  $t$  has a higher tiebreak priority than  $t'$ . By induction hypothesis,  $Z_t \geq Z_s$  and thus  $Z_{t'} \geq Z_s$ . If  $t' \neq s$  and  $Z_{t'} = Z_t = Z_s$ , then by induction hypothesis  $s$  has a higher tiebreak priority than  $t$ , which in turn has a higher priority than  $t'$ . We conclude that  $s$  has a higher tiebreak priority than  $t'$ . ◀

Hence, if a request  $r$  is unmatched in the  $G$  execution, it is also unmatched in the  $G \setminus s$  execution. If  $r$  gets matched, its matching partner has a  $Z$ -value of at most  $z_r$ . Since  $g$  is non-decreasing with  $g(1) = 1$ , the following statement holds.

► **Corollary 5.** *Given  $Z_t$  for all servers  $t \in S \setminus \{s\}$ ,  $y(r) \geq y_s(r)$  holds for all possible values of  $Z_s$ .*

► **Lemma 6.** *Given  $Z_t$  for all servers  $t \in S \setminus \{s\}$ , let  $z_1 \geq \dots \geq z_k$  be the  $Z$ -values of the matching partners of the  $k = |N_s|$  neighbors of  $s$  in a  $G \setminus s$  execution in non-increasing order. Then, server  $s$  has at least  $\min\{a, b_s\}$  matching partners in an execution of RANKING on  $G$ , where  $a$  is the largest possible integer such that  $Z_s < z_a \leq \dots \leq z_1$ .*

**Proof.** Whenever a neighbor  $r_i$  of  $s$  with  $z_i > Z_s$  arrives and  $s$  still has remaining capacity, then by Lemma 4  $r_i$  will be matched to  $s$ . Among adjacent servers with remaining capacity,  $s$  has the smallest  $Z$ -value and the highest priority in case of ties. ◀

Now, we can finally show how to choose  $g$  and  $c$  such that the dual constraints are satisfied in expectation. Let  $s$  be any server in  $G$  with  $k$  neighbors. Let  $z_i$  be the  $Z$ -value of the matching partner of neighbor  $r_i \in N_s$ ,  $1 \leq i \leq k$ , in the  $G \setminus s$  execution. If  $k < b_s$ , we further define  $z_{k+1} = \dots = z_{b_s} = 0$ . Let  $z'_1 \geq \dots \geq z'_{b_s}$  then be the  $b_s$  largest values of  $\{z_1, \dots, z_{\max\{k, b_s\}}\}$  in non-increasing order. Lemma 6 implies that

$$\mathbb{E} \left[ x(s) \left| \bigwedge_{t \in S \setminus \{s\}} Z_t = z_t \right. \right] \geq \sum_{i=1}^{b_s} \int_0^{z'_i} \frac{g(t)}{c} dt.$$

Moreover, by Corollary 5, it holds for every neighbor  $r \in N_s$  of  $s$

$$\mathbb{E} \left[ y(r) \left| \bigwedge_{t \in S \setminus \{s\}} Z_t = z_t \right. \right] \geq y_s(r) = \frac{1 - g(z_r)}{c},$$

where  $z_r = z_i$  for some  $i$ ,  $1 \leq i \leq k$ . Putting everything together yields

$$\mathbb{E} \left[ x(s) + \sum_{r \in N} y(r) \left| \bigwedge_{t \in S \setminus \{s\}} Z_t = z_t \right. \right] \geq \frac{1}{c} \left( \sum_{i=1}^{b_s} \int_0^{z'_i} g(t) dt + \sum_{r \in N} (1 - g(z_r)) \right).$$

Note that  $\sum_{r \in N} (1 - g(z_r))$  is lower bounded by  $\sum_{i=1}^{\min\{|N|, b_s\}} (1 - g(z'_i))$ , since  $g$  is a non-decreasing function with  $g(1) = 1$  and the  $z'$ -values are an upper bound for the  $z_r$ -values. Plugging this in, we get

$$\begin{aligned} \mathbb{E} \left[ x(s) + \sum_{r \in N} y(r) \left| \bigwedge_{t \in S \setminus \{s\}} Z_t = z_t \right. \right] &\geq \frac{1}{c} \sum_{i=1}^{\min\{|N|, b_s\}} \left( \int_0^{z'_i} g(t) dt + 1 - g(z'_i) \right) \\ &\stackrel{\dagger}{\geq} \min\{|N|, b_s\}. \end{aligned}$$

Observe that the last inequality holds if  $g$  and  $c$  satisfy the following inequality, which is the same inequality that emerges in the analysis of RANKING without server capacities.

$$\int_0^z g(t) dt + 1 - g(z) \geq c, \quad \forall z \in [0, 1]. \quad (3)$$

It is easy to check that the combination of  $g(x) = e^{x-1}$  with  $c = 1 - 1/e$  satisfies (3) and our additional condition  $g(1) = 1$ . By applying the law of total expectation, we finish the proof:

$$\begin{aligned} \mathbb{E} \left[ x(s) + \sum_{r \in N} y(r) \right] &= \int_0^1 \dots \int_0^1 \mathbb{E} \left[ x(s) + \sum_{r \in N} y(r) \left| \bigwedge_{t \in S \setminus \{s\}} Z_t = z_t \right. \right] dz_t \dots dz_{t'} \\ &\geq \int_0^1 \dots \int_0^1 \min\{|N|, b_s\} dz_t \dots dz_{t'} = \min\{|N|, b_s\}. \end{aligned}$$

► **Theorem 7.** RANKING is  $(1 - 1/e)$ -competitive for the maximum-cardinality online  $b$ -matching problem (with variable server capacities).

#### 4 Vertex-weighted $b$ -matching

The work by Buchbinder et al. [4] implies a deterministic online algorithm with an optimal competitiveness of  $1 - 1/(1 + 1/b_{\min})^{b_{\min}}$ . We are not aware of any simpler strategy. Therefore, we focus on randomized algorithms and extend our previous result for RANKING to the vertex-weighted case. We will show that PERTURBED-GREEDY [1] achieves a competitiveness of  $1 - 1/e$  for vertex-weighted  $b$ -matching. Again, we execute the algorithm on the initial input graph  $G$ .

PERTURBED-GREEDY is similar to RANKING; only the definition of ranks differs. For each server  $s \in S$ , a *single* number  $Z_s \in [0, 1]$  is chosen uniformly at random. The rank of  $s$  is  $w_s(1 - g(Z_s))$ , where  $g : [0, 1] \rightarrow [0, 1]$  is a monotonically increasing function that will be set to  $g(x) = e^{x-1}$ .

##### Algorithm 3 PERTURBED-GREEDY.

---

```

foreach server  $s \in S$  do
  | Pick  $Z_s \in [0, 1]$  uniformly at random;
end
while a new request  $r \in R$  arrives do
  | Let  $N(r)$  denote the set of neighbors of  $r$  with remaining capacity;
  | if  $N(r) = \emptyset$  then
  | | Do not match  $r$ ;
  | else
  | | Match  $r$  to  $\arg \max\{w_s(1 - g(Z_s)) : s \in N(r)\}$  (break ties consistently);
  | end
end

```

---

We formulate the configuration LP and its dual for the vertex-weighted  $b$ -matching problem, where we take into account that each matching edge incident to a server  $s$  has a value of  $w_s$ .

$$\begin{aligned}
 \text{Config LP: } \max \quad & \sum_{s \in S} \sum_{N \subseteq N_s} w_s \cdot \min\{|N|, b_s\} \cdot m(s, N) \\
 \text{s.t.} \quad & \sum_{N \subseteq N_s} m(s, N) \leq 1, & (\forall s \in S) \\
 & \sum_{s \in S} \sum_{N \subseteq N_s: r \in N} m(s, N) \leq 1, & (\forall r \in R) \\
 & m(s, N) \geq 0, & (\forall s \in S, \forall N \subseteq N_s).
 \end{aligned}$$

$$\begin{aligned}
 \text{Dual CLP: } \min \quad & \sum_{s \in S} x(s) + \sum_{r \in R} y(r) \\
 \text{s.t.} \quad & x(s) + \sum_{r \in N} y(r) \geq w_s \cdot \min\{|N|, b_s\}, & (\forall s \in S, \forall N \subseteq N_s) \\
 & x(s), y(r) \geq 0, & (\forall s \in S, \forall r \in R).
 \end{aligned}$$

In the primal-dual analysis, we again update the primal variables as well as the dual variables  $x(s)$  and  $y(r)$  whenever PERTURBED-GREEDY matches a request  $r$  to a server  $s$ . We set

$$\Delta x(s) = \frac{w_s g(Z_s)}{c} \quad \text{and} \quad y(r) = \frac{w_s(1 - g(Z_s))}{c}$$

to ensure that the value of the dual solution is always  $1/c$  times the value of the solution for the configuration LP. Here,  $g : [0, 1] \rightarrow [0, 1]$  is a monotonically increasing function and  $c$  is a constant that will be the competitive ratio of the algorithm.

As before, it is sufficient to show that the dual constraints are satisfied in expectation. For this, we have to adapt Lemma 4 and Lemma 6. We consider two execution of PERTURBED-GREEDY on  $G$  and  $G \setminus s$  with the same  $Z$ -values  $Z_t$  for all servers  $t \in S \setminus \{s\}$ . Moreover, denote the neighbors of  $s$  in  $G$  by  $\{r_1, \dots, r_k\} = N_s$  and let  $z_i$ ,  $1 \leq i \leq k$ , be the  $Z$ -value of the matching partner  $\sigma_i$  of request  $r_i$  in the  $G \setminus s$  execution, if  $r_i$  is matched there. If  $r_i$  is unmatched, we set  $z_i := 1$  and assign a dummy matching partner  $\sigma_i$  with  $w_{\sigma_i} := 0$ . Now, further define  $\zeta_i$  as the unique value in  $[0, 1]$  such that

$$w_s (1 - g(\zeta_i)) = w_{\sigma_i} (1 - g(z_i)) ,$$

if it exists. Assuming that  $g$  is a monotonically increasing function with  $g(1) = 1$ , note that such a solution can only not exist if  $w_{\sigma_i} (1 - g(z_i)) > w_s (1 - g(0))$ , in which case we define  $\zeta_i := 0$ . It is easy to see that PERTURBED-GREEDY would prefer server  $s$  over server  $\sigma_i$  if  $Z_s < \zeta_i$ . Moreover, let  $y_s(r_i)$  be the value of  $y(r_i)$  in the  $G \setminus s$  execution. It follows that

$$y_s(r_i) = \frac{w_{\sigma_i} (1 - g(z_i))}{c} \geq \frac{w_s (1 - g(\zeta_i))}{c} .$$

We assume that PERTURBED-GREEDY assigns the  $j$ -th request matched to a server  $s$  to the server spot  $s_j$ .

► **Lemma 8.** *At any point during the parallel execution of PERTURBED-GREEDY on  $G$  and  $G \setminus s$ , it holds that the set of unmatched server spots  $U$  in the  $G$  execution forms a superset of the unmatched server spots  $\tilde{U}$  in the  $G \setminus s$  execution. For all server spots  $s'_i \in U \setminus \tilde{U}$ , it holds that  $w_{s'} (1 - g(Z_{s'})) \leq w_s (1 - g(Z_s))$ . If equality holds and  $s' \neq s$ , then  $s$  has a higher priority in the tiebreaking.*

**Proof.** By induction. The properties trivially hold initially. Then, whenever a new request  $r$  arrives,  $\tilde{U} \subseteq U$  can only be violated if  $r$  is assigned to a server spot  $t_i \in \tilde{U}$  in the  $G$  execution, but  $r$  is not assigned to  $t_i$  in the  $G \setminus s$  execution. There, it is either unmatched or matched to a different server spot, which leads to a contradiction in either case. Since  $t_i \in \tilde{U}$  and  $r$  is a neighbor of the server  $t$ ,  $r$  cannot be unmatched in the  $G \setminus s$  execution. If PERTURBED-GREEDY chooses a different server spot  $t_j$  for  $r$  in the  $G \setminus s$  execution, then either  $i < j$  or  $i > j$  has to hold.  $i < j$  results in a contradiction because  $t_i \in \tilde{U}$  and we defined that PERTURBED-GREEDY always chooses the server spot with smallest index. Furthermore,  $i > j$  also results in a contradiction because  $t_j \in \tilde{U} \subseteq U$  and thus PERTURBED-GREEDY would have chosen  $t_j$  in the  $G$  execution as well. Moreover, if PERTURBED-GREEDY assigns  $r$  to a server spot of a different server  $t'$  in the  $G \setminus s$  execution, then  $w_{t'} (1 - g(Z_{t'})) \geq w_t (1 - g(Z_t))$  has to hold. However,  $\tilde{U} \subseteq U$  implies that this server spot would also be unmatched and available in the  $G$  execution. If  $w_{t'} (1 - g(Z_{t'})) > w_t (1 - g(Z_t))$ , PERTURBED-GREEDY would not have chosen the correct neighbor in the  $G$  execution according to its definition, and if  $w_{t'} (1 - g(Z_{t'})) = w_t (1 - g(Z_t))$ , then the tiebreak would be inconsistent between the two executions.

Moreover, a new server spot  $t'_i$  is only added to  $U \setminus \tilde{U}$  if the matching decision for  $r$  is different in the two execution, i.e. the  $G$  execution assigns  $r$  to some server spot  $t_j \in U \setminus \tilde{U}$  and the  $G \setminus s$  execution assigns  $r$  to  $t'_i \in \tilde{U}$ . Therefore, it has to hold that either  $w_{t'} (1 - g(Z_{t'})) < w_t (1 - g(Z_t))$  or  $w_{t'} (1 - g(Z_{t'})) = w_t (1 - g(Z_t))$  and  $t$  has a higher tiebreak priority than  $t'$ . The induction hypothesis then finishes the proof. ◀

► **Corollary 9.** Given  $Z_t$  for all servers  $t \in S \setminus \{s\}$ ,  $y(r_i) \geq y_s(r_i) \geq w_s(1 - g(\zeta_i))/c$  holds for all  $i$ ,  $1 \leq i \leq k$ , and all possible values of  $Z_s$ .

► **Lemma 10.** Given  $Z_t$  for all servers  $t \in S \setminus \{s\}$ , let  $\zeta_1 \geq \dots \geq \zeta_k$  be the  $\zeta$ -values of the  $k = |N_s|$  neighbors of  $s$  in a  $G \setminus s$  execution in non-increasing order. Then, server  $s$  has at least  $\min\{a, b_s\}$  matching partners in an execution of PERTURBED-GREEDY on  $G$ , where  $a$  is the largest possible integer such that  $Z_s < \zeta_a \leq \dots \leq \zeta_1$ .

**Proof.** Whenever a neighbor  $r_i$  of  $s$  with  $\zeta_i > Z_s$  (note that this implies  $\zeta_i > 0$ ) arrives and  $s$  still has remaining capacity, then Lemma 8 implies that  $r_i$  will be matched to  $s$  since  $w_s(1 - g(Z_s)) > w_s(1 - g(\zeta_i)) = w_{\sigma_i}(1 - g(z_i))$  holds by definition. ◀

We finally show how to choose  $g$  and  $c$  such that the dual constraints are satisfied in expectation. Let  $s$  be any server in  $G$  with  $k$  neighbors. Let  $\zeta_i$  be the  $\zeta$ -value of neighbor  $r_i \in N_s$ ,  $1 \leq i \leq k$ , in the  $G \setminus s$  execution. If  $k < b_s$ , we further define  $\zeta_{k+1} = \dots = \zeta_{b_s} = 0$ . Let  $z'_1 \geq \dots \geq z'_{b_s}$  then be the  $b_s$  largest values of  $\{\zeta_1, \dots, \zeta_{\max\{k, b_s\}}\}$  in non-increasing order. Lemma 10 implies that

$$\mathbb{E} \left[ x(s) \mid \bigwedge_{t \in S \setminus \{s\}} Z_t = z_t \right] = \sum_{i=1}^{b_s} w_s \int_0^{z'_i} \frac{g(t)}{c} dt.$$

Moreover, by Corollary 9, it holds for every neighbor  $r \in N_s$  of  $s$

$$\mathbb{E} \left[ y(r) \mid \bigwedge_{t \in S \setminus \{s\}} Z_t = z_t \right] \geq \frac{w_s(1 - g(\zeta_r))}{c},$$

where  $\zeta_r = \zeta_i$  for some  $i$ ,  $1 \leq i \leq k$ . Putting everything together yields

$$\mathbb{E} \left[ x(s) + \sum_{r \in N} y(r) \mid \bigwedge_{t \in S \setminus \{s\}} Z_t = z_t \right] \geq \frac{w_s}{c} \left( \sum_{i=1}^{b_s} \int_0^{z'_i} g(t) dt + \sum_{r \in N} (1 - g(\zeta_r)) \right).$$

Note that  $\sum_{r \in N} (1 - g(\zeta_r))$  is lower bounded by  $\sum_{i=1}^{\min\{|N|, b_s\}} (1 - g(z'_i))$ , since  $g$  is an increasing function with  $g(1) = 1$  and the  $z'$ -values are an upper bound for the  $\zeta_r$ -values. Plugging this in, we get

$$\begin{aligned} \mathbb{E} \left[ x(s) + \sum_{r \in N} y(r) \mid \bigwedge_{t \in S \setminus \{s\}} Z_t = z_t \right] &\geq \frac{w_s}{c} \sum_{i=1}^{\min\{|N|, b_s\}} \left( \int_0^{z'_i} g(t) dt + 1 - g(z'_i) \right) \\ &\stackrel{!}{\geq} w_s \min\{|N|, b_s\}. \end{aligned}$$

Observe that this holds true if  $g$  and  $c$  fulfill the same inequality (3) as for RANKING. As argued before, it is satisfied for  $g(x) = e^{x-1}$  and  $c = 1 - 1/e$ , which also satisfies our additional constraint  $g(1) = 1$ . Therefore, using the law of total expectation, we conclude that

$$\begin{aligned} \mathbb{E} \left[ x(s) + \sum_{r \in N} y(r) \right] &= \int_0^1 \dots \int_0^1 \mathbb{E} \left[ x(s) + \sum_{r \in N} y(r) \mid \bigwedge_{t \in S \setminus \{s\}} Z_t = z_t \right] dz_t \dots dz_{t'} \\ &\geq \int_0^1 \dots \int_0^1 w_s \min\{|N|, b_s\} dz_t \dots dz_{t'} = w_s \min\{|N|, b_s\}. \end{aligned}$$

► **Theorem 11.** PERTURBED-GREEDY is  $(1 - 1/e)$ -competitive for the vertex-weighted online  $b$ -matching problem (with variable server capacities).

**A Comparison of RELATIVEBALANCE and ALLOCATION**

Consider the algorithm ALLOCATION [4] specialized for maximum cardinality online  $b$ -matching. It is the other known optimal deterministic online algorithm for this problem besides RELATIVEBALANCE.

**Algorithm 4** ALLOCATION.

---

```

Initialize  $x(s) = 0, \forall s \in S$ , and  $y(r) = 0, \forall r \in R$ ;
while a new request  $r \in R$  arrives do
  Let  $N(r)$  denote the set of neighbors  $s$  of  $r$  with  $x(s) < 1$ ;
  if  $N(r) = \emptyset$  then
    Do not match  $r$ ;
  else
    Match  $r$  to  $\arg \min\{x(s) : s \in N(r)\}$  (break ties arbitrarily);
    Update  $y(r) = 1 - x(s)$ ;
    Update  $x(s) = x(s) \cdot \left(1 + \frac{1}{b_s}\right) + \frac{1}{(d-1)b_s}$ ;
  end
end

```

---

The analysis of Buchbinder et al. [4] can be extended to show that ALLOCATION constructs a feasible solution for the classical dual matching LP with its variables  $x(s)$  and  $y(r)$ . Moreover, it can be shown that the size of the constructed matching is at least  $c = 1 - 1/d$  times the value of the constructed dual solution, where  $d = (1 + 1/b_{\min})^{b_{\min}}$ . This implies that ALLOCATION achieves the optimal competitiveness of  $1 - 1/(1 + 1/b_{\min})^{b_{\min}}$ .

Recall that RELATIVEBALANCE matches a request  $r$  to an eligible neighbor with minimum relative server load. In contrast, ALLOCATION matches  $r$  to a neighbor  $s$  with minimum  $x(s)$ , if  $x(s) < 1$ . It can be proven by induction that at any point during the execution of ALLOCATION, a server  $s$  with capacity  $b_s$  and  $load_s$  assigned requests has

$$x(s) = \frac{1}{d-1} \left( \left(1 + \frac{1}{b_s}\right)^{load_s} - 1 \right). \quad (4)$$

This has two consequences: on the one hand, ALLOCATION may choose a different matching partner for  $r$  compared to RELATIVEBALANCE in certain situations, since  $load_s/b_s \leq load_{s'}/b_{s'}$  does not imply  $(1 + 1/b_s)^{load_s} \leq (1 + 1/b_{s'})^{load_{s'}}$ . On the other hand, ALLOCATION considers  $s$  to be full once  $x(s) \geq 1$ . Equation (4) implies that this is the case when

$$\left(1 + \frac{1}{b_s}\right)^{load_s} \geq \left(1 + \frac{1}{b_{\min}}\right)^{b_{\min}}.$$

Observe that this may occur before  $load_s$  becomes  $b_s$ , meaning before  $s$  actually has been assigned  $b_s$  requests. This implies that an unmodified version of ALLOCATION may leave some server spots unused and thus not create a maximal matching.

## B Analysis of RANDOM

We start with a pseudo-code description of RANDOM.

### Algorithm 5 RANDOM.

---

```

while a new request  $r \in R$  arrives do
  Let  $N(r)$  denote the set of neighbors of  $r$  with remaining capacity;
  if  $N(r) = \emptyset$  then
    | Do not match  $r$ ;
  else
    | Match  $r$  to a random  $s \in N(r)$ ;
  end
end

```

---

We extend RANDOM's worst case input graph of the problem without server capacities and show that RANDOM also does not achieve a competitive ratio better than  $\frac{1}{2}$  for the online  $b$ -matching problem, even if all server capacities are equal. Consider a graph with  $n$  servers  $S = \{s_1, \dots, s_n\}$  and  $n$  rounds of requests  $R = R_1 \dot{\cup} \dots \dot{\cup} R_n$ , where  $n = 2k$ . Every server  $s$  has the same capacity  $b_s := b$  and each round contains  $b$  identical requests that all have the same neighbors. The different rounds arrive one after another, such that the first request of  $R_{i+1}$  only arrives after the last request of  $R_i$  arrived,  $1 \leq i < n$ . Requests within the same round can arrive in an arbitrary order. All requests  $r \in R_i$  of the  $i$ -th round are adjacent to server  $s_i$ . This implies that there exists a perfect matching of size  $b \cdot n$  that matches  $R_i$  to  $s_i$ . Moreover, all requests  $r \in R_1 \dot{\cup} \dots \dot{\cup} R_k$  of the first half of rounds are additionally adjacent to all servers  $s_{k+1}, \dots, s_n$  of the second half (see Fig. 2).

**Figure 2** A bad input for RANDOM. There are  $n = 6$  servers, each with capacity  $b = 3$ , and  $n$  rounds of requests, each containing  $b$  identical requests. For clarity, the adjacencies of a round are depicted as a whole. Note that requests still arrive individually one after another and not together with their complete round.

Intuitively, RANDOM performs poorly on this graph since its very unlikely that it makes the correct matching decision for the requests from the first half of rounds, i.e. assigning a request from  $R_i$  to server  $s_i$ . Observe that - irrespective of the matching decision made

by RANDOM for the requests of the first half of rounds - every server of the second half will be assigned exactly  $b$  requests. Let  $X$  be a random variable indicating how many requests were matched to the first half of servers by RANDOM. The size of the constructed matching  $M$  is then  $|M| = b \cdot k + X$ . Therefore, it is possible to compute the expected size of the constructed matching by determining the expected value of  $X$ .

Let  $X_i$ ,  $1 \leq i \leq k$ , be the number of requests assigned to server  $s_i$ . It holds that  $X = \sum_{i=1}^k X_i$ . By design, only requests from  $R_i$  may be assigned to  $s_i$ , for  $1 \leq i \leq k$ . Let  $r$  be any request from such a round  $R_i$  and let  $p_i$  be the probability that RANDOM assigns  $r$  to its perfect matching partner  $s_i$ . Observe that  $p_i$  depends on the number of servers in the second half with remaining capacity. At most  $b \cdot (i - 1) + (b - 1)$  requests arrived before  $r$  ( $r$  may be the last request of  $R_i$ ). Hence at most  $(i - 1)$  of the last  $k$  servers can be full, implying at least  $(k - i + 1)$  eligible neighbors in the second half of servers for all requests from  $R_i$ . Furthermore, server  $s_i$  cannot become full before the last request of  $R_i$  arrives. RANDOM has therefore at least  $(k - i + 2)$  servers to choose from when assigning a request from round  $R_i$ . This yields

$$\mathbb{E}[X] = \sum_{i=1}^k \mathbb{E}[X_i] \leq \sum_{i=1}^k b \cdot p_i \leq b \sum_{i=1}^k \frac{1}{k + 2 - i} = b \sum_{j=2}^{k+1} \frac{1}{j} = b(H_{k+1} - 1) \leq b \ln(k + 1),$$

where  $H_n$  denotes the  $n$ -th harmonic number and the inequality  $H_n \leq \ln(n) + 1$  is used. The size of the perfect matching in this graph is  $b \cdot n$ . Thus, RANDOM achieves a competitive ratio of

$$\frac{\mathbb{E}[|M|]}{b \cdot n} \leq \frac{b \cdot k + b \ln(k + 1)}{b \cdot n} = \frac{1}{2} + \frac{\ln(n/2 + 1)}{n} \xrightarrow{n \rightarrow \infty} \frac{1}{2}.$$

This finishes the proof of Theorem 3.

## Abstract

We consider online scheduling to minimize weighted completion time on related machines, where each *job* consists of several *tasks* that can be concurrently executed. A job gets completed when all its component tasks finish. We obtain an  $O(K^3 \log^2 K)$ -competitive algorithm in the *non-clairvoyant* setting, where  $K$  denotes the number of distinct machine speeds. The analysis is based on dual-fitting on a precedence-constrained LP relaxation that may be of independent interest.

## 1 Introduction

Scheduling to minimize the weighted completion time is a fundamental problem in scheduling. Many algorithms have been developed in both the online and offline settings, and for the cases where machines are identical, related, or unrelated. Most of the work, however, focuses on the setting where each job is a monolithic entity, and has to be processed in a sequential manner.

In this work, we consider the online setting with multiple related machines, where each *job* consists of several *tasks*. These tasks are independent of each other, and can be executed concurrently on different machines. (Tasks can be preempted and migrated.) A job is said to have *completed* when all its component tasks finish processing. We consider the *non-clairvoyant* setting where the algorithm does not know the size of a task up-front, but only when the task finishes processing. Such instances arise in operating system schedulers, where a job and its tasks correspond to a process and its threads that can be executed in parallel. This setting is sometimes called a “*bag of tasks*” (see e.g. [2, 10, 4]).

The bag-of-tasks model can be modeled using precedence constraints. Indeed, each job is modeled as a star graph, where the tasks correspond to the leaves (and have zero weight), and the root is an auxiliary task with zero processing requirement but having weight  $w_j$ . Hence the root can be processed only after all leaf tasks have completed processing. The goal is to minimize total *weighted completion time*. Garg et al. [7] gave a constant-competitive algorithm for this problem for *identical machines*, in a more general setting where tasks form arbitrary precedence DAGs.

### 3:2 Bag-Of-Tasks Scheduling on Related Machines

We extend this result to the setting of *related machines* where machine  $i$  has speed  $s_i$ . By losing a constant factor, we assume that all speeds are powers of some constant  $C$ . Let  $K$  denote the number of distinct machine speeds. In §2, we show that this problem is strictly more challenging than in the identical machines setting:

► **Theorem 1 (Lower Bound).** *Any online non-clairvoyant algorithm has  $\Omega(K)$  competitive ratio for bags-of-tasks on related machines.*

The lower bound arises because we want to process larger tasks on fast machines, but we have no idea about the sizes of the tasks, so we end up clogging the fast machines with small tasks: this issue did not arise when machines were identical. Given the lower bound, we now look for a non-clairvoyant scheduling algorithm with a competitive ratio that depends on  $K$ , the number of distinct speeds. This number may be small in many settings, e.g., when we use commodity hardware of a limited number of types (say, CPUs and GPUs). Our main result is a positive answer to this question:

► **Theorem 2 (Upper Bound).** *The online non-clairvoyant algorithm for bags-of-tasks on related machines has a competitive ratio of §3 is  $O(\min\{K^3 \log^2 K, K + \log n\})$ .*

Our algorithm uses a greedy strategy. Instead of explicitly building a schedule, it assigns (*processing*) rates to tasks at each time  $t$ . Such a rate assignment is called feasible if for every  $k$ , the rate assigned to any subset of  $k$  tasks is at most the total speed of the  $k$  fastest machines. Using an argument based on Hall’s matching theorem, a schedule exists if and only if such a rate assignment can be found. To assign these rates, each alive task gets a “priority”, which is the ratio of the weight of the job containing it to the number of alive tasks of this job. In other words, a task with low weight or with many tasks gets a low priority. We assign feasible rates to alive tasks in a “fair manner”, i.e., we cannot increase the rate of a high priority task by decreasing the rate of a lower priority task. To efficiently find such feasible rates, we use a water-filling procedure.

The analysis proceeds using the popular dual-fitting approach, but we need new ideas: (i) we adapt the precedence-constrained LP relaxation for completion time in [5] to our setting. A naive relaxation would define the completion time of a task as the maximum of the (fractional) completion times of each of the tasks, where the fractional completion time of a task is the sum over times  $t$  of the fraction of the task remaining at this time. Instead, we define  $U_{j,t}$ , for a job  $j$  and time  $t$  as the maximum over all tasks  $v$  for  $j$  of the fraction of  $v$  which remains to be completed at time  $t$ , the completion time of  $j$  as  $\sum_t U_{jt}$ . (See §4 for details.) (ii) Although it is natural to divide the machines into classes based on their speeds, we need a finer partitioning, which drives our setting of dual variables. Indeed, the usual idea of dividing up the job’s weight equally among the tasks that are still alive only leads to an  $O(\log n)$ -competitiveness (see §5). To do better, we first preprocess the instance so that distinct machine speeds differ by a constant factor, but the total processing capacity of a slower speed class is far more than that of all faster machines. Now, at each time, we divide the machines into *blocks*. A constant fraction of the blocks have the property that either the average speed of the machines in the block is close to one of the speed classes, or the total processing capacity of a block is close to that of *all* the machines of a speed class. It turns out that our dual-fitting approach works for accounting the weight of jobs which get processed by such blocks; proving this constitutes the bulk of technical part of the analysis. Finally, we show that most jobs (in terms of weight) get processed by such blocks, and hence we are able to bound the overall weighted completion time. We present the proofs in stages, giving intuition for the new components in each of the sections.

## 1.1 Related Work

Minimizing weighted completion time on parallel machines with precedence constraints has  $O(1)$ -approximation in the *offline* setting: Li [9] improves on [8, 11] to give a  $3.387 + \varepsilon$ -approximation. For *related* machines the precedence constraints make the problem harder: there is an  $O(\log m / \log \log m)$ -approximation [9] improving on a prior  $O(\log K)$  result [5], and an  $\omega(1)$  hardness under certain complexity assumptions [3]. Here  $m$  denotes the number of machines. These results are for offline and hence clairvoyant settings, and do not apply to our setting of non-clairvoyant scheduling.

In the setting of parallel machines, there has been recent work on minimizing weighted completion time in DAG scheduling, where each job consists of a set of tasks with precedence constraints between them given by a DAG [13, 1]. [7] generalized this to the non-clairvoyant setting and gave an  $O(1)$ -competitive algorithm. Our algorithm for the related case is based on a similar water-filling rate assignment idea. Since the machines have different speeds, a set of rates assigned to tasks need to satisfy a more involved feasibility condition. Consequently, its analysis becomes much harder; this forms the main technical contribution of the paper. Indeed, even for the special case considered in this paper where every DAG is a star, we can show a lower bound of  $\Omega(K)$  on the competitive ratio of any non-clairvoyant algorithm. In the full version, we show that any non-clairvoyant algorithm for related machines DAG scheduling must have  $\Omega(\frac{\log m}{\log \log m})$ -competitive ratio.

Our problem also has similarities to open shop scheduling. In open shop scheduling, each job consists of several tasks, where each task  $v$  (for job  $j$ ) needs to be processed on a distinct machine for  $p_{vj}$  amount of time. However, unlike our setting, two tasks for a job cannot be processed simultaneously on different machines. [12] considered open shop scheduling in the offline setting for related machines and gave a  $(2 + \varepsilon)$ -approximation. [6] considered a further generalization of our problem to unrelated machines, where the tasks corresponding to distinct jobs need not be disjoint. They gave a constant-factor approximation algorithm, again offline.

## 1.2 Paper Organization

In this extended abstract, we first give the algorithm in §3, and the linear program in §4. A simpler proof of  $O(K + \log n)$ -competitiveness is in §5. We show  $\text{poly}(K)$ -competitiveness for the case of a single job (which corresponds to makespan minimization) in §6, and then give the complete proof for the general case in §7.

## 2 Problem Statement and the $\Omega(K)$ Hardness

Each job  $j$  has a *weight*  $w_j$  and consists of *tasks*  $T(j) = \{(j, 1), (j, 2), \dots, (j, k_j)\}$  for some  $k_j$ . Each task  $v = (j, \ell)$  has an associated *processing requirement/size*  $p_v = p_{(j, \ell)}$ . The job  $j$  completes when all its associated tasks finish processing. We use letters  $j, j'$ , etc. to denote jobs, and  $v, v'$ , etc. to denote tasks  $(j, \ell)$ .

There are  $m$  machines with speeds  $s_1 \geq s_2 \geq \dots \geq s_m$ . The goal is to minimize the weighted completion time of the jobs. We allow task *preemption* and *migration*, and different tasks of a job can be processed concurrently on different machines. However, a task itself can be processed on at most one machine at any time. In this extended abstract we consider the special case when all release dates are 0, but our results also extend to the more general setting of arbitrary release dates (details in the full version). Let  $S_k := s_1 + \dots + s_k$  denote the total speed of the fastest  $k$  machines. Since we care about the number of *distinct* speeds, we assume there are  $K$  *speed classes*, with speeds  $\sigma_1 > \sigma_2 > \dots > \sigma_K$ . There are  $m_i$  machines having speed  $\sigma_i$ , where  $\sum_i m_i = m$ .

### 3:4 Bag-Of-Tasks Scheduling on Related Machines

► **Assumption 3** (Increasing Capacity Assumption). For parameter  $\gamma \geq 1$ :

- (1) (Falling Speeds.) For each  $\ell$ , we have  $\sigma_i/\sigma_{i+1} \geq 64$ .
- (2) (Increasing Capacity.) For each  $\ell$ , the total processing capacity of speed class  $\ell$  is at least twice that of the previous (faster) speed classes. I.e.,  $m_\ell \sigma_\ell \geq 2(m_1 \sigma_1 + \dots + m_{\ell-1} \sigma_{\ell-1})$ .
- (3) (Speed-up.) The algorithm uses machines that are  $\gamma$  times faster than the adversary's machines.

► **Proposition 4.** An arbitrary instance can be transformed into one satisfying Assumption 3 by losing a factor  $O(\gamma K)$  in the competitive ratio.

**Proof.** (Sketch) For the first part, we round down the speed of each machine to a power of 64. This changes the completion time by at most a factor of 64. The second increasing capacity assumption is not without loss of generality – we greedily find a subset of speed classes by losing  $O(K)$  factor in competitive ratio (see details in Appendix A). Finally, the  $\gamma$ -speedup can only change the competitive ratio by  $\gamma$  factor. ◀

Next we show that any online algorithm has to be  $\Omega(K)$ -competitive even for a single job with the machines satisfying increasing capacity Assumption 3.

► **Proposition 5.** Any online algorithm is  $\Omega(K)$ -competitive even for a single job under increasing capacity Assumption 3.

**Proof.** (Sketch) Consider a single job  $j$  with  $m$  tasks, where  $m$  is the number of machines. For every speed class  $\ell$ , there are  $m_\ell$  tasks of size  $\sigma_\ell$  – call these tasks  $T_\ell(j)$ . Since there is only one job, the objective is to minimize the makespan. The offline (clairvoyant) objective is 1, since all tasks can be assigned to machines with matching speeds. However, any online algorithm incurs a makespan of  $\Omega(K)$ . Here is an informal argument, which can be proved even for randomized algorithms against oblivious adversaries: since there is no way to distinguish between the tasks, the algorithm can at best run all the alive tasks at the same speed. The tasks in  $T_K(j)$  will be the first to finish by time  $\frac{m_K \sigma_K}{\sum_\ell m_\ell \sigma_\ell} \geq \frac{1}{2}$ , where the inequality follows from the increasing capacity assumption. At this time, the processing on tasks from  $T_\ell(j)$  for  $\ell < K$  has been very small, and so tasks in  $T_{K-1}(j)$  will require about 1/2 more units of time to finish, and so on. ◀

## 3 The Scheduling Algorithm

The scheduling algorithm assigns, at each time  $t$ , a rate  $L_v^t$  to each unfinished task  $v$ . The following lemma (whose proof is deferred to the appendix) characterizes rates that correspond to schedules:

► **Lemma 6.** A schedule  $\mathcal{S}$  is feasible if for every time  $t$  and every value of  $k$ :

- (\*) the total rate assigned to any subset of  $k$  tasks is at most  $\gamma \cdot S_k$ .

For each time  $t$ , we now specify the rates  $L_v^t$  assigned to each unfinished task  $v$ . For job  $j$ , let  $T^t(j)$  be the set of tasks in  $T(j)$  which are alive at time  $t$ . Initially all tasks are *unfrozen*. We raise a parameter  $\tau$ , starting at zero, at a uniform speed. The values taken by  $\tau$  will be referred to as *moments*. For each job  $j$  and each task  $v \in T^t(j)$  that is unfrozen, define a *tentative rate* at  $\tau$  to be

$$L_v^t := \frac{w_j}{|T^t(j)|} \cdot \tau. \tag{1}$$

Hence the tentative rates of these unfrozen tasks increase linearly, as long as condition  $(\star)$  is satisfied. However, if  $(\star)$  becomes tight for some subset  $V$  of alive tasks, i.e.,  $\sum_{v \in V} L_v^t = \gamma \cdot S_{|V|}$ , pick a *maximal* set of such tasks and *freeze* them, fixing their rates at their current tentative values. (Observe the factor of  $\gamma$  appears on the right side because we assume the machines in the algorithm to have a speedup of  $\gamma$ .) Now continue the algorithm this way, raising  $\tau$  and the  $L_v^t$  values of remaining unfrozen tasks  $v$  until another subset gets tight, etc., stopping when all jobs are frozen. This defines the  $L_v^t$  rates for each task  $v$  for time  $t$ . By construction, these rates satisfy  $(\star)$ .

### 3.1 Properties of the Rate Assignment

The following claim shows that all alive tasks corresponding to a job get frozen simultaneously.

► **Lemma 7** (Uniform Rates). *For any time  $t$  and any job  $j$ , all its alive tasks (i.e., those in  $T^t(j)$ ) freeze at the same moment  $\tau$ , and hence get the same rate.*

**Proof.** For the sake of contradiction, consider the first moment  $\tau$  where a maximal set  $V$  of tasks contains  $v$  but not  $v'$ , for some job  $j$  with  $v, v' \in T(j)$ . Both  $v, v'$  have been treated identically until now, so  $L_v^t = L_{v'}^t$ . Also, by the choice of  $\tau$ ,  $\sum_{u \in V: u \neq v} L_u^t + L_v^t = \gamma S_{|V|}$ . Since we maintain feasibility at all moments,

$$\sum_{u \in V: u \neq v} L_u^t + L_v^t + L_{v'}^t \leq \gamma S_{|V|+1} \quad \text{and} \quad \sum_{u \in V: u \neq v} L_u^t \leq \gamma S_{|V|-1}.$$

This implies  $L_v^t \geq \gamma s_{|V|}$  and  $L_{v'}^t \leq \gamma s_{|V|+1}$ . Since  $L_v^t = L_{v'}^t$  and  $s_{|V|} \geq s_{|V|+1}$ , all of these must be equal. In that case, by the maximality of set  $V$ , the algorithm should have picked  $V \cup \{v'\}$  instead of  $V$ . ◀

For a task  $v \in T^t(j)$ , define  $\tilde{w}^t(v) := w_j / |T^t(j)|$  to be task  $v$ 's “share” of the weight of job  $j$  at time  $t$ . So if task  $v$  freezes at moment  $\tau$ , then its rate is  $L_v^t = \tilde{w}^t(v) \cdot \tau$ . Let us relate this share for  $v$  to certain averages of the weight. (Proof in Appendix B)

► **Corollary 8.** *Fix a time  $t$ . Let  $V$  be the set of tasks frozen by some moment  $\tau$ . For a task  $v \in V$ ,*

- (i) *if  $V' \subseteq V$  is any subset of tasks which freeze either at the same moment as  $v$ , or after it, then  $\frac{\tilde{w}^t(v)}{s_{|V|}} \geq \frac{w(V')}{S_{|V|}}$ .*
- (ii) *if  $V'' \subseteq V$  is any subset of tasks which freeze either at the same moment as  $v$ , or before it, then  $\frac{\tilde{w}^t(v)}{L_v^t} \leq \frac{\tilde{w}^t(V'')}{\sum_{v' \in V''} L_{v'}^t}$ .*

### 3.2 Defining the Blocks

The rates for tasks alive at any time  $t$  are defined by a sequence of freezing steps, where some group of tasks are frozen: we call these groups *blocks*. By Lemma 7, all tasks in  $T^t(j)$  belong to the same block. The weight  $w(B)$  of block  $B$  is the total weight of jobs whose tasks belong to  $B$ . Let  $B_1^t, B_2^t, \dots$  be the blocks at time  $t$  in the order they were frozen, and  $\tau_1^t, \tau_2^t, \dots$  be the moments at which they froze. Letting  $b_r^t := |B_1^t \cup \dots \cup B_r^t|$ , we get that any task  $v \in B_r^t$  satisfies  $\tau_v^t \cdot w(B_r^t) = \gamma(S_{b_{r+1}^t} - S_{b_r^t})$ .

Each block  $B_r^t$  has an associated set of machines, namely the machines on which the tasks in this block are processed – i.e., the machines indexed  $b_{r-1}^t + 1, \dots, b_r^t$ . We use  $m(B)$  to denote the set of machines associated with a block  $B$ . Since  $|B| = |m(B)|$  and the jobs in  $B$  are processed on  $m(B)$  in a pre-emptive manner at time  $t$ , the rate assigned to any job is at least the slowest speed (and at most the fastest speed) of the machines in  $m(B)$ .

## 4 The Analysis and Intuition

We prove the competitiveness by a dual-fitting analysis: we give a primal-dual pair of LPs, use the algorithm above to give a feasible primal, and then exhibit a feasible dual with value within a small factor of the primal cost.

In the primal LP, we have variables  $x_{ivt}$  for each task  $v$ , machine  $i$ , and time  $t$  denoting the extent of processing done on task  $v$  at machine  $i$  during the interval  $[t, t + 1]$ . Here  $U_{j,t}$  denotes fraction of job  $j$  finished at or after time  $t$ , and  $C_j$  denotes the completion time of job  $j$ .

$$\begin{aligned} \min \sum_j w_j C_j + \sum_{j,t} w_j U_{j,t} \\ U_{j,t} &\geq \sum_{t' \geq t} \sum_i \frac{x_{ivt'}}{p_v} && \forall j, \forall v \in T(j), \forall t \end{aligned} \quad (2)$$

$$C_j \geq \sum_t \sum_i \frac{x_{ivt}}{s_i} \quad \forall j, \forall v \in T(j) \quad (3)$$

$$\sum_i \sum_t \frac{x_{ivt}}{p_v} \geq 1 \quad \forall j, \forall v \in T(j) \quad (4)$$

$$\sum_v \frac{x_{ivt}}{s_i} \leq 1 \quad \forall i, \forall t \quad (5)$$

The constraint (2) is based on precedence-constrained LP relaxations for completion time. Indeed, each job can be thought of as a star graph with a zero size task at the root preceded by all the actual tasks at the leaf. In our LP, for each time  $t$ , we define  $U_{j,t} \in [0, 1]$  to be the maximum over all tasks  $v \in T(j)$  of the fraction of  $v$  that remains (the RHS of (2)), and the completion time of  $j$  is at least the total sum over times  $t$  of  $U_{j,t}$  values. Since we do not explicitly enforce that a task cannot be processed simultaneously on many machines, the first term  $\sum_j w_j C_j$  is added to avoid a large integrality gap. We show feasibility of this LP relaxation (up to factor 2) in §C.

▷ **Claim 9.** For any schedule  $\mathcal{S}$ , there is a feasible solution to the LP of objective value at most  $2 \text{cost}(\mathcal{S})$ .

The linear programming dual has variables  $\alpha_{j,v}, \delta_{j,v}, \delta_{j,v,t}$  corresponding to constraints (4),(3),(2) for every job  $j$  and task  $v \in T(j)$ , and  $\beta_{i,t}$  corresponding to constraints (5) for every machine  $i$  and time  $t$ :

$$\begin{aligned} \max. \sum_{j,v} \alpha_{j,v} - \sum_{i,t} \beta_{i,t} \\ \frac{\alpha_{j,v}}{p_v} \leq \frac{\beta_{i,t}}{s_i} + \sum_{t' \leq t} \frac{\delta_{j,v,t'}}{p_v} + \frac{\delta_{j,v,t}}{s_i} & \quad \forall j, \forall i, \forall t, \forall v \in T(j) \end{aligned} \quad (6)$$

$$\sum_{v \in T(j)} \delta_{j,v} \leq w_j \quad \forall j \quad (7)$$

$$\sum_{v \in T(j)} \delta_{j,v,t} \leq w_j \quad \forall j, t \quad (8)$$

We now give some intuition about these dual variables. The quantity  $\delta_{j,v,t}$  should be thought of the contribution (at time  $t$ ) towards the weighted flow-time of  $j$ . Similarly,  $\delta_{j,v}$  is *global* contribution of  $v$  towards the flow-time of  $v$ . (In the integral case,  $\delta_{j,v}$  would be  $w_j$  for the task which finishes last. If there are several such tasks,  $\delta_{j,v}$  would be non-zero only for such tasks only and would add up to  $w_j$ ). The quantity  $\alpha_{j,v}$  can be thought of as  $v$ 's contribution towards the total weighted flow-time, and  $\beta_{i,t}$  is roughly the queue size at time  $t$  on machine  $i$ . Constraint (6) upper bounds  $\alpha_{j,v}$  in terms of the other dual variables. More intuition about these variables can be found in §4.2.

## 4.1 Simplifying the dual LP

Before interpreting the dual variables, we rewrite the dual LP and add some additional constraints. Define additional variables  $\alpha_{j,v,t}$  for each job  $j$  and task  $v \in T(j)$  and time  $t$ , such that variable  $\alpha_{j,v} = \sum_t \alpha_{j,v,t}$ . We add a new constraint:

$$\sum_{v \in T(j)} \alpha_{j,v,t} \leq w_j. \quad (9)$$

This condition is not a requirement in the dual LP, but we will set  $\alpha_{j,v,t}$  to satisfy it. Assuming this, we set  $\delta_{j,v,t} := \alpha_{j,v,t}$  for all jobs  $j$ , tasks  $v \in T(j)$  and times  $t$ ; feasibility of (9) implies that of (8). Moreover, (6) simplifies to

$$\sum_{t' \geq t} \frac{\alpha_{j,v,t'}}{p_v} \leq \frac{\beta_{i,t}}{s_i} + \frac{\delta_{j,v}}{s_i}.$$

Observe that we can write  $p_v$  as the sum of the rates, and hence as  $p_v = \sum_{t'} L_v^{t'}$ . Since this is at least  $\sum_{t' \geq t} L_v^{t'}$  for any  $t$ , we can substitute above, and infer that it suffices to verify the following condition for all tasks  $v \in T(j)$ , time  $t$ , and time  $t' \geq t$ :

$$\alpha_{j,v,t'} \leq \frac{\beta_{i,t} \cdot L_v^{t'}}{s_i} + \frac{\delta_{j,v} \cdot L_v^{t'}}{s_i}. \quad (10)$$

Henceforth, we ensure that our duals (including  $\alpha_{j,v,t}$ ) satisfy (9),(10) and (7).

## 4.2 Interpreting the Duals and the High-Level Proof Idea

We give some intuition about the dual variables, which will be useful for understanding the subsequent analysis. We set dual variables  $\alpha_{j,v}$  such that for any job  $j$ , the sum  $\sum_{v \in T(j)} \alpha_{j,v}$  is (approximately) the weighted completion of job  $j$ . This ensures that  $\sum_{j,v} \alpha_{j,v}$  is the total weighted completion of the jobs. One way of achieving this is as follows: for every time  $t$  and task-job pair  $(j,v)$  we define  $\alpha_{j,v,t}$  variables such that they add up to be  $w_j$  if job  $j$  is unfinished at time  $t$  (i.e., (9) is satisfied with equality). If  $\alpha_{j,v}$  is set to  $\sum_t \alpha_{j,v,t}$ , then these  $\alpha_{j,v}$  variables would add up to the weighted completion time of  $j$ .

The natural way of defining  $\alpha_{j,v,t}$  is to evenly distribute the weight of  $j$  among all the alive tasks at time  $t$ , i.e., to set  $\alpha_{j,v,t} = \frac{w_j}{T^t(j)}$ . This idea works if we only want to show that the algorithm is  $O(\log n)$ -competitive, but does not seem to generalize if we want to show  $O(K)$ -competitiveness. The reason for this will be clearer shortly, when we discuss the  $\delta_{j,v}$  variables.

Now we discuss  $\beta_{i,t}$  dual variables. We set these variables so that  $\sum_t \beta_{i,t}$  is a constant (less than 1) times the total weighted completion time. This ensures that the objective value of the dual LP is also a constant times the total weighted completion time. A natural idea (ignoring constant factors for now) is to set  $\beta_{i,t} = \frac{w(A^t)}{K m_\ell}$ , where  $A^t$  is the set of alive jobs at time  $t$  and  $\ell$  is the speed class of machine  $i$ . Since we have put an  $\Omega(K)$  term in the denominator of  $\beta_{i,t}$  (and no such term in the definition of  $\alpha_{j,v}$ ), ensuring the feasibility of (6) would require a speed augmentation of  $\Omega(K)$ .

Finally, consider the  $\delta_{j,v}$  dual variables. As (7) suggests, setting  $\delta_{j,v}$  is the same as deciding how to distribute the weight  $w_j$  among the tasks in  $T(j)$ . Notice, however, that this distribution cannot depend on time (unlike  $\alpha_{j,v,t}$  where we were distributing  $w_j$  among all the alive tasks at time  $t$ ). In the ideal scenario, tasks finishing later should get high  $\delta_{j,v}$  values. Since we are in the non-clairvoyant setting, we may want to set  $\delta_{j,v} = \frac{w_j}{|T(j)|}$ . We now argue this can lead to a problem in satisfying (10).

Consider the setting of a single unit-weight job  $j$  initially having  $n$  tasks, and so we set  $\delta_{j,v} = \frac{1}{n}$  for all  $v$ . Say that  $n = m_\ell$  for a large value of  $\ell$ : by the increasing capacity assumption,  $m_\ell \approx m_1 + \dots + m_\ell$ . Now consider a later point in time  $t$  when only  $n'$  tasks

remain, where  $n' = m_{\ell'}$  for some speed class  $\ell' \ll \ell$ . At this time  $t$ , each of the  $n'$  surviving tasks have  $\alpha_{j,v,t} = \frac{1}{n'}$ . But look at the RHS of (10), with machine  $i$  of speed class  $\ell$ . The rate  $L_v^t$  will be very close to  $\sigma_{\ell'}$  (again, by the increasing capacity assumption), and so both the terms would be about  $\frac{\sigma_{\ell'}}{m_{\ell}\sigma_{\ell}}$ . However,  $m_{\ell}\sigma_{\ell}$  could be much larger than  $m_{\ell'}\sigma_{\ell'}$ , and so this constraint will not be satisfied. In fact, we can hope to satisfy (10) at some time  $t$  only if  $n'$  is close to  $n$ , say at least  $n/2$ . When the number of alive tasks drops below  $n/2$ , we need to *redistribute* the weight of  $j$  among these tasks, i.e., we need to increase the  $\delta_{j,v}$  value for these tasks, to about  $\frac{1}{n/2}$ . Since these halving can happen for  $\log n$  steps, we see that (3) is violated by a factor of  $\log n$ . These ideas can be extended to give an  $O(\log n + K)$ -competitive algorithm for arbitrary inputs; see §5 for details. To get a better bound, we need a more careful setting of the dual variables, which we talk about in §6 and §7.

## 5 Analysis I: A Weaker $O(K + \log n)$ Guarantee

We start with a simpler analysis which yields an  $O(K + \log n)$ -competitiveness. This argument will not use the increasing capacity assumption from Assumption 3; however, the result gives a competitiveness of  $O(\max(K, \log n))$  which is logarithmic when  $K$  is small, whereas our eventual result will be  $O(\min(K^{O(1)}, K + \log n))$ , which can be much smaller when  $K \ll \log n$ .

► **Theorem 10.** *The scheduling algorithm in §3 is  $O(K + \log n)$ -competitive.*

**Proof.** For each job  $j$ , we arrange the tasks in  $T(j)$  in descending order of their processing requirements. (This is the opposite of the order in which they finish, since all alive tasks of a job are processed at the same rate.) Say the sequence of the tasks for a job  $j$  is  $v_1, \dots, v_r$ . We partition these tasks into *groups* with exponentially increasing cardinalities:  $T_1(j) := \{v_1\}$ ,  $T_2(j) := \{v_2, v_3\}$ , and  $T_h(j) := \{v_{2^{h-1}}, \dots, v_{2^h-1}\}$  has  $2^{h-1}$  tasks. (Assume w.l.o.g. that  $r + 1$  is a power of 2 by adding zero-sized tasks to  $T(j)$ ). Now we define the dual variables.

**Dual Variables.** Define  $\gamma := 2 \max\{K, \log_2 n\}$ .

- For a time  $t$  and machine  $i$  of speed class  $\ell$ , let  $A^t$  denote the set of active (unfinished) jobs at time  $t$ , and define  $\beta_{i,t} := \frac{w(A^t)}{m_{\ell} \cdot \gamma}$ .
- For job  $j$  and a task  $v \in T_h(j)$  in the  $h$ -th group, define  $\delta_{j,v} := \frac{w_j}{2^{h-1} \cdot \gamma}$ .
- In order to define  $\alpha_{j,v}$ , we first define quantities  $\alpha_{j,v,t}$  for every time  $t$ , and then set  $\alpha_{j,v} := \sum_t \alpha_{j,v,t}$ . At time  $t$ , recall that  $T^t(j)$  is the set of alive tasks of job  $j$ , and define

$$\alpha_{j,v,t} := \frac{w_j}{|T^t(j)|} \cdot \mathbf{1}_{(v \text{ alive at time } t)} = \frac{w_j}{|T^t(j)|} \cdot \mathbf{1}_{(v \in T^t(j))}.$$

This “spreads” the weight of  $j$  equally among its alive tasks.

Having defined the dual variables, we first argue that they are feasible.

► **Lemma 11** (Dual feasibility). *The dual variables defined above always satisfy the constraints (9), (7) and (10) for a speed-up factor  $\gamma \geq 2 \max\{K, \log_2 n\}$ .*

**Proof.** To check feasibility of (7), consider a job  $j$  and observe that

$$\sum_{v \in T(j)} \delta_{j,v} = \sum_h \sum_{v \in T_h(j)} \delta_{j,v} = \sum_h \sum_{v \in T_h(j)} \frac{w_j}{2^{h-1} \cdot \gamma} = \sum_h \frac{w_j}{\gamma} \leq w_j,$$

because  $|T_h(j)| = 2^{h-1}$  and there are at most  $\log_2 n \leq \gamma$  distinct groups. Feasibility of (9) also follows easily. It remains to check (10) for a job  $j$ , task  $v$ , machine  $i$  and times  $t' \leq t$ .

If  $v$  is not alive at time  $t'$ , then  $\alpha_{j,v,t'}$  is 0, and (10) follows trivially. Else,  $v \in T^{t'}(j)$ , and suppose  $v \in T_h(j)$ . This means the jobs in  $T_1(j), \dots, T_{h-1}(j)$  are also alive at time  $t'$ , so  $|T^{t'}(j)| \geq 1 + 2 + \dots + 2^{h-2} + 1 = 2^{h-1}$ . Furthermore, suppose the tasks in  $T^{t'}(j)$  belong to block  $B$  (defined in §3.1), and let  $\ell^*$  be the speed class with the slowest machines among the associated machines  $m(B)$ . Let  $\ell$  denote the speed class of machine  $i$  (considered in (10)). Two cases arise: the first is when  $\ell \geq \ell^*$ , where  $L_v^{t'} \geq \gamma\sigma_{\ell^*} \geq \gamma\sigma_\ell = \gamma s_i$ , so (10) holds because

$$\alpha_{j,v,t'} = \frac{w_j}{|T^{t'}(j)|} \leq \frac{w_j}{2^{h-1}} = \gamma \cdot \delta_{j,v} \leq \frac{\delta_{j,v} \cdot L_v^{t'}}{s_i}.$$

The second case is  $\ell < \ell^*$ : Let  $V \subseteq A^{t'}$  be the set of jobs which are frozen by the moment  $v$  freezes. In other words,  $V$  contains tasks in block  $B$  and the blocks before it. Applying the second statement in Corollary 8 with  $V'' = V$ ,

$$\frac{w_j}{|T^{t'}(v)|L_v^{t'}} \leq \frac{\tilde{w}^t(V)}{\sum_{v' \in V} L_{v'}^{t'}} \leq \frac{w(V)}{\sum_{v' \in V} L_{v'}^{t'}} \leq \frac{w(A^{t'})}{\gamma \cdot m_\ell \sigma_\ell},$$

where the last inequality uses the fact that all machines of speed class  $\ell$  are busy processing jobs in  $V$ . Therefore,

$$\alpha_{j,v,t'} = \frac{w_j}{|T^{t'}(j)|} \leq \frac{w(A^{t'}) \cdot L_v^{t'}}{\gamma \cdot m_\ell \sigma_\ell} \leq \frac{\beta_{i,t} \cdot L_v^{t'}}{s_i},$$

the last inequality using the definition of  $\beta_{i,t}$  and that  $w(A^t) \geq w(A^{t'})$ .  $\blacktriangleleft$

Finally, we show that the dual objective value for this setting of dual variables is close to the primal value. It is easy to check that  $\sum_j \alpha_j = \sum_t w(A^t)$ , which is the total weighted completion time of the jobs. Moreover,

$$\sum_{i,t} \beta_{i,t} = \sum_t \sum_\ell \sum_{i:s_i=\sigma_\ell} \frac{w(A^t)}{m_\ell \gamma} = \frac{K}{\gamma} \cdot \sum_t w(A^t).$$

Since we chose speedup  $\gamma = 2 \max\{K, \log_2 n\}$ , we have  $K \leq \gamma/2$  and the dual objective value  $\sum_{j,v} \alpha_{j,v} - \sum_{i,t} \beta_{i,t}$  is at least half of the total weighted completion time (primal value). This completes the proof of Theorem 10.  $\blacktriangleleft$

## 6 Analysis II: An Improved Guarantee for a Single Job

We want to show that the competitiveness of our algorithm just depends on  $K$ , the number of speed classes. To warm up, in this section we consider the special case of a single job; in §7 we consider the general case. As was shown in Proposition 5, any algorithm has competitive ratio  $\Omega(K)$  even in the case of a single job. We give a matching upper bound using dual fitting for an instance *with a single job*  $j$ , say of weight 1, when the machines satisfy Assumption 3.

► **Theorem 12.** *If the machines satisfy Assumption 3, the scheduling algorithm in §3 is  $O(K^2)$ -competitive for a single job.*

### 6.1 The Intuition Behind the Improvement

The analysis in §5 incurred  $\Omega(\log n)$ -competitive ratio because we divided the execution of the tasks of each job into  $O(\log n)$  *epochs*, where each epoch ended when the number of tasks halved. In each such epoch, we set the  $\delta_{j,v}$  variables by distributing the job's weight evenly among all tasks alive at the beginning of the epoch. A different way to define epochs would

be to let them correspond to the time periods when the number of alive tasks falls in the range  $(m_\ell, m_{\ell+1})$ . This would give us only  $K$  epochs. There is a problem with this definition: as the number of tasks vary in the range  $(m_\ell, m_{\ell+1})$ , the rate assigned to tasks varies from  $\sigma_\ell$  to  $\sigma_{\ell+1}$ . Indeed, there is a transition point  $\tilde{m}_\ell$  in  $(m_\ell, m_{\ell+1})$  such that the rate assigned to the tasks stays close to  $\sigma_{\ell+1}$  as long as the number of tasks lie in the range  $(\tilde{m}_\ell, \sigma_{\ell+1})$ ; but if the number of tasks lie in the range  $(m_\ell, \tilde{m}_\ell)$ , the assigned rate may not stay close to any fixed value. However, in this range, the *total* processing rate assigned to all the tasks stays close to  $m_\ell \sigma_\ell$ .

It turns out that our argument for an epoch (with minor modifications) works as long as one of these two facts hold during an epoch: (i) the total rate assigned to the tasks stays close to  $m_\ell \sigma_\ell$  for some speed class  $\ell$  (even though the number of tasks is much larger than  $m_\ell$ ), or (ii) the actual rate assigned to the tasks stays close to  $\sigma_\ell$ . Thus we can divide the execution of the job into  $2K$  epochs, and get an  $O(K)$ -competitive algorithm. In this section, we prove this for a single job; we extend to the case of multiple jobs in §7 (with a slightly worse competitiveness).

## 6.2 Defining the New Epochs

Before defining the dual variables, we begin with a definition. For each speed class  $\ell$ , define the *threshold*  $\tilde{m}_\ell$  to be the following:

$$\tilde{m}_\ell := \frac{1}{\sigma_{\ell+1}} (\sigma_1 m_1 + \dots + \sigma_\ell m_\ell). \quad (11)$$

The parameter  $\tilde{m}_\ell$  is such that the processing capacity of  $\tilde{m}_\ell$  machines of class  $\ell + 1$  equals the combined processing capacity of machines of class at most  $\ell$ . The increasing capacity assumption implies  $m_\ell < \tilde{m}_\ell < m_{\ell+1}$ , as formalized below:

▷ **Claim 13.** Define  $M_\ell := m_1 + \dots + m_\ell$  and  $\tilde{M}_\ell := M_\ell + \tilde{m}_\ell$ . Under the increasing capacity Assumption 3 and  $\kappa = 2$ , for any speed class  $\ell$ , we have

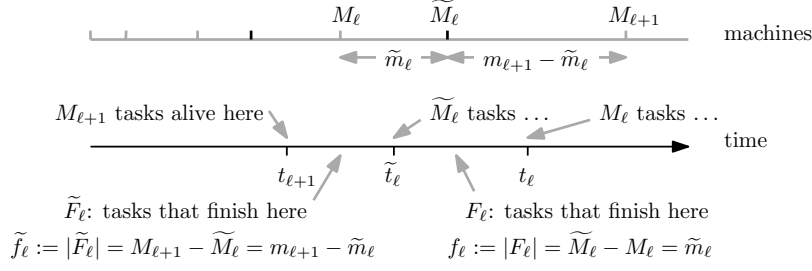

- (a)  $2\tilde{m}_\ell \leq m_{\ell+1}$  and so,  $\tilde{M}_\ell \leq M_{\ell+1}$ ,
- (b)  $\tilde{M}_\ell \geq 2M_\ell$ ,
- (c)  $m_\ell \sigma_\ell \geq \frac{1}{2} \tilde{m}_\ell \sigma_{\ell+1}$ , and
- (d)  $\tilde{m}_\ell \geq 2m_\ell$ .

*Proof.* Fact (a) follows from the increasing capacity assumption and the definition of the threshold, since  $2\tilde{m}_\ell \sigma_{\ell+1} \leq \sigma_{\ell+1} m_{\ell+1}$ . This implies  $\tilde{M}_\ell = M_\ell + \tilde{m}_\ell \leq M_\ell + m_{\ell+1} \leq M_{\ell+1}$ . Proving (b) is equivalent to showing  $\tilde{m}_\ell \geq M_\ell$ , which follows from the definition of  $\tilde{m}_\ell$  and the fact that  $\sigma_{\ell+1} < \sigma_i$  for all  $i \leq \ell$ . The last two statements also follow from the increasing capacity assumption. ◁

We identify a set of  $2K$  *break-points* as follows: for each speed class  $\ell$ , let  $t_\ell$  denote the first time when  $M_\ell$  alive tasks remain. Similarly, let  $\tilde{t}_\ell$  be the first time when exactly  $\tilde{M}_\ell$  alive tasks remain. Note that  $t_{\ell+1} < \tilde{t}_\ell < t_\ell$ . Let  $\tilde{F}_\ell$  be the tasks which finish during  $[t_{\ell+1}, \tilde{t}_\ell]$ , and  $F_\ell$  be those which finish during  $[\tilde{t}_\ell, t_\ell]$ . Let  $\tilde{f}_\ell$  and  $f_\ell$  denote the cardinality of  $\tilde{F}_\ell$  and  $F_\ell$  respectively. Note that  $\tilde{f}_\ell = M_{\ell+1} - \tilde{M}_\ell = m_{\ell+1} - \tilde{m}_\ell$ ,  $f_\ell = \tilde{M}_\ell - M_\ell = \tilde{m}_\ell$ .

▷ **Claim 14.** For any speed class  $\ell$ , we have  $f_\ell \leq \tilde{f}_\ell \leq f_{\ell+1}$ .

*Proof.* The first statement requires that  $\tilde{m}_\ell \leq m_{\ell+1} - \tilde{m}_\ell$ . This is the same as  $2\tilde{m}_\ell \leq m_{\ell+1}$ , which follows from Claim 13 (a). The second statement requires that  $m_{\ell+1} - \tilde{m}_\ell \leq \tilde{m}_{\ell+1}$ , i.e.,  $m_{\ell+1} \leq \tilde{m}_\ell + \tilde{m}_{\ell+1}$ . But  $m_{\ell+1} \leq \tilde{m}_{\ell+1}$  (by Claim 13 (d)), hence the proof. ◁

■ **Figure 1** Defining breakpoints.

Next we set the duals. Although it is possible to directly argue that the delay incurred by the job in each epoch is at most (a constant times) the optimal objective value, the dual fitting proof generalizes to the arbitrary set of jobs.

### 6.3 Setting the Duals

Define the speed-up  $\gamma \geq 2K$ . We set the duals as:

- Define  $\delta_{j,v} := \begin{cases} \frac{1}{2K \cdot f_\ell} & \text{if } v \in F_\ell \\ \frac{1}{2K \cdot \tilde{f}_\ell} & \text{if } v \in \tilde{F}_\ell \end{cases}$ .
- For machine  $i$  of class  $\ell$ , define  $\beta_{i,t} := \frac{1}{2K \cdot m_\ell} \cdot \mathbf{1}_{(\text{not all tasks finished})}$ .
- Finally, as in §5, we define  $\alpha_{j,v,t}$  for each task  $v$  of job  $j$ , and then set  $\alpha_{j,v} := \sum_t \alpha_{j,v,t}$ . To define  $\alpha_{j,v,t}$ , we consider two cases (we use  $n_t$  to denote the number of alive tasks at time  $t$ ):
  1.  $n_t \in [M_\ell, \tilde{M}_\ell]$  for some  $\ell$ : Then  $\alpha_{j,v,t} := (1/n_t) \cdot \mathbf{1}_{(v \text{ alive at time } t)}$ .
  2.  $n_t \in [\tilde{M}_\ell, M_{\ell+1}]$  for some  $\ell$ : Then  $\alpha_{j,v,t} := (1/f_\ell) \cdot \mathbf{1}_{(v \in F_\ell)}$ .

Note the asymmetry in the definition. It arises because in the first case, the *total* speed of machines processing a task is (up to a constant)  $m_\ell \sigma_\ell$ , whereas in the second case the *average* speed of such machines is about  $\sigma_{\ell+1}$ .

► **Lemma 15** (Dual feasibility). *The dual variables defined above always satisfy the constraints (7) and (9), and satisfy constraint (10) for speed-up  $\gamma \geq 2K$ .*

**Proof.** It is easy to check from the definition of  $\delta_{j,v}$  and  $\alpha_{j,v,t}$  that the dual constraints (7) and (9) are satisfied. It remains to verify constraint (10) (re-written below) for any task  $v$ , machine  $i$ , times  $t$  and  $t' \geq t$ .

$$\alpha_{j,v,t'} \leq \frac{L_v^{t'}}{s_i} \cdot (\beta_{i,t} + \delta_{j,v}). \quad ((10) \text{ repeated})$$

As in the definition of  $\alpha_{j,v,t'}$ , there are two cases depending on where  $n_{t'}$  lies. First assume that there is class  $\ell^*$  such that  $M_{\ell^*} \leq n_{t'} < \tilde{M}_{\ell^*}$ . Assume that  $v$  is alive at time  $t'$  (otherwise  $\alpha_{j,v,t'}$  is 0), so  $\alpha_{j,v,t'} = \frac{1}{n_{t'}}$ , where  $n_{t'}$  is the number of alive tasks at time  $t'$ . Being alive at this time  $t'$ , we know that  $v$  will eventually belong to some  $F_\ell$  with  $\ell \leq \ell^*$ , or in some  $\tilde{F}_\ell$  with  $\ell < \ell^*$ . So by Claim 14,  $\delta_{j,v} \geq \frac{1}{2K \cdot f_{\ell^*}}$ . Moreover, let  $i$  be a machine of some class  $\ell$ , so  $s_i = \sigma_\ell$ . Hence, it is enough to verify the following in order to satisfy (10):

$$\frac{1}{n_{t'}} \leq \frac{L_v^{t'}}{\sigma_\ell} \cdot \left( \frac{1}{2K \cdot m_\ell} + \frac{1}{2K \cdot f_{\ell^*}} \right). \quad (12)$$

Two subcases arise, depending on how  $\ell$  and  $\ell^*$  relate – in each we show that just one of the terms on the right is larger than the left.

### 3:12 Bag-Of-Tasks Scheduling on Related Machines

- $\ell^* \geq \ell$ : Since at least  $M_{\ell^*}$  tasks are alive at this time, the total speed assigned to all the alive tasks at time  $t'$  is at least  $\gamma \cdot \sigma_{\ell^*} m_{\ell^*}$ . Therefore,  $L_v^{t'} \geq \frac{\gamma \cdot m_{\ell^*} \sigma_{\ell^*}}{n_{t'}}$ . Now using  $\gamma \geq 2K$ , we get

$$\frac{L_v^{t'}}{2K \cdot m_{\ell} \sigma_{\ell}} \geq \frac{m_{\ell^*} \sigma_{\ell^*}}{m_{\ell} \sigma_{\ell}} \cdot \frac{1}{n_{t'}} \geq \frac{1}{n_{t'}},$$

where the last inequality follows from the increasing capacity assumption.

- $\ell^* \leq \ell - 1$ : The quantity  $L_v^{t'}$  is the total speed of the machines which are busy at time  $t'$ , which is at least  $\gamma(m_1 \sigma_1 + \dots + m_{\ell^*} \sigma_{\ell^*}) = \gamma \cdot \tilde{m}_{\ell^*} \sigma_{\ell^*+1}$ . Again, using  $\gamma \geq 2K$ , we get

$$\frac{L_v^{t'} \cdot n_{t'}}{2K \cdot f_{\ell^*} \sigma_{\ell}} \geq \frac{\tilde{m}_{\ell^*} \sigma_{\ell^*+1}}{f_{\ell^*} \sigma_{\ell}} \geq 1$$

because  $\sigma_{\ell^*+1} \geq \sigma_{\ell}$  and  $\tilde{m}_{\ell^*} = f_{\ell^*}$ .

Thus, (12) is satisfied in both the above subcases.

Next we consider the case when there is a speed class  $\ell^*$  such that  $\tilde{M}_{\ell^*} < n_{t'} \leq M_{\ell^*+1}$ . We can assume that  $v \in F_{\ell^*}$ , otherwise  $\alpha_{j,v,t'}$  is 0; this means  $\delta_{v,j} = \frac{1}{2K \cdot f_{\ell^*}}$ . Since  $\alpha_{j,v,t'} = \frac{1}{f_{\ell^*}} = \frac{1}{m_{\ell^*}}$ , and  $L_v^{t'} \geq \gamma \cdot \sigma_{\ell^*+1}$ , the expression (10) follows from showing

$$\frac{1}{\tilde{m}_{\ell^*}} \leq \frac{\gamma}{\sigma_{\ell}} \cdot \left( \frac{1}{2K \cdot m_{\ell}} + \frac{1}{2K \cdot f_{\ell^*}} \right) \cdot \sigma_{\ell^*+1}. \quad (13)$$

Since  $\gamma \geq 2K$ , we can drop those terms. Again, two cases arise:

- $\ell^* \geq \ell$ : By definition,  $\sigma_{\ell^*+1} \cdot \tilde{m}_{\ell^*} \geq \sigma_{\ell^*} m_{\ell^*} \geq \sigma_{\ell} m_{\ell}$  (by the increasing capacity assumption).
- $\ell^* \leq \ell - 1$ : Since  $f_{\ell^*} = \tilde{m}_{\ell^*}$  and  $\sigma_{\ell} \leq \sigma_{\ell^*+1}$ , this case also follows easily. ◀

**Proof of Theorem 12.** Having checked dual feasibility in Lemma 15, consider now the objective function. For any time  $t$  when at least one task is alive,  $\sum_v \alpha_{j,v,t} = 1$ . Therefore,  $\sum_v \alpha_{j,v}$  is the makespan. Also,  $\sum_i \beta_{i,t} = 1/2$  as long as there are unfinished tasks, so  $\sum_{i,t} \beta_{i,t}$  is half the makespan, and the objective function  $\sum_v \alpha_{j,v} - \sum_{i,t} \beta_{i,t}$  also equals half the makespan. Since we had assumed  $\gamma = O(K)$ -speedup, the algorithm is  $O(K)$ -competitive. ◀

## 7 Analysis III: Proof for $\tilde{O}(K^3)$ Guarantee

We now extend the ideas from the single job case to the general case. We only discuss the proof outline here, and refer the readers to the full version for details. For time  $t$ , let  $A^t$  be the set of alive jobs at time  $t$ . Unlike the single job case where we had only one block, we can now have multiple blocks. While defining  $\alpha_{j,v,t}$  in the single job case, we had considered two cases: (i) the rate assigned to each task stayed close to  $\sigma_{\ell}$  for some class  $\ell$  (this corresponded to  $n_t \in [\tilde{M}_{\ell-1}, M_{\ell})$ ), and (ii) the total rate assigned to each task was close to  $m_{\ell} \sigma_{\ell}$  for speed class  $\ell$  (this corresponded to  $n_t \in [M_{\ell}, \tilde{M}_{\ell})$ ). We extend these notions to blocks as follows: *Simple blocks*: A block  $B$  is said to be *simple* w.r.t. to a speed class  $\ell$  if the average rate assigned to the tasks in  $B$  is close to  $\sigma_{\ell}$ . Similarly a job  $j$  is said to be simple w.r.t. a speed class  $\ell$  if all the alive tasks in it are assigned rates close to  $\sigma_{\ell}$  (recall that all alive tasks in a job are processed at the same rate). All the jobs in a simple block  $B$  may not be simple (w.r.t. the same speed class  $\ell$ ), but we show that a large fraction of jobs (in terms of weight) in  $B$  will be simple. Thus, it is enough to account for the weight of simple jobs in  $B$ . This is analogous to case (i) mentioned above (when there is only one job and tasks in it receive rate

close to  $\sigma_\ell$ ). In §6, we had defined  $\alpha_{j,v,t}$  for such time  $t$  as follows: we consider only those tasks which survive in  $F_\ell$ , and then evenly distribute  $w_j$  among these tasks. The analogous definition here would be as follows: let  $\tau_{\ell,j}$  be the *last* time when  $j$  is simple w.r.t. the speed class  $\ell$ . We define  $\alpha_{j,v,t}$  by evenly distributing  $w_j$  among those tasks in  $v$  which are alive at  $\tau_{\ell,j}$ . We give details in the full version.

*Long blocks:* The total speed of the machines in this block stays close to  $m_\ell \sigma_\ell$  for some speed class  $\ell$ . Again, inspired by the definitions in §6, we assign  $\alpha_{j,v,t}$  for tasks  $v \in B$  by distributing  $w(B)$  to these tasks (in proportion to the rate assigned to them). From the perspective of a job  $j$  which belongs to a long block  $B$  w.r.t. a speed class  $\sigma_\ell$  at a time  $t$ , the feasibility of (6) works out provided for *all* subsequent times  $t'$  when  $j$  again belongs to such a block  $B'$ , we have  $w(B')$  and  $w(B)$  remain close to each other. If  $w(B')$  exceeds (say)  $2w(B)$ , we need to reassign a new set of  $\delta_{j,v}$  values for  $v$ . To get around this problem we require that long blocks (at a time  $t$ ) also have weight at least  $w(A^t)/(10K)$ . With this requirement, the doubling step mentioned above can only happen  $O(\log K)$  times (and so we incur an additional  $O(\log K)$  in the competitive ratio). The details are given in the full version. Blocks which were cheaper than  $w(A^t)/(10K)$  do not create any issue because there can be at most  $K$  of them, and so their total weight is small in comparison to  $w(A^t)$ .

*Short blocks:* Such blocks  $B$  straddle two speed classes, say  $\ell$  and  $\ell + 1$ , but do not contain too many machines of either class (otherwise they will fall into one of the two categories above). We show in the full version that the total weight of such blocks is small compared to  $w(A^t)$ . The intuitive reason is as follows: for any two consecutive short blocks  $B_1$  and  $B_2$ , there must be blocks in between them whose span is much longer than  $B_2$ . Since these blocks freeze before  $B_2$ , their total weight would be large compared to  $w(B_2)$ .

In the overall analysis, we charge short blocks to simple and long blocks, and use dual fitting as indicated above to handle simple and long blocks.

## 8 Discussion

Several interesting problems remain open. (i) Can we close the gap between lower bound of  $\Omega(K)$  and upper bound of  $O(K^3 \log^2 K)$ ? (ii) Can we prove an analogous result for weighted *flow-time* (with speed augmentation)? (iii) Can we generalize this result to the unrelated machines setting? (iv) Our lower bound of  $\Omega(K)$ -competitive ratio relies on non-clairvoyance; can we prove a better bound if the processing times of tasks are known at their arrival times?

## A Missing Proofs of Section 2

► **Proposition 4.** *An arbitrary instance can be transformed into one satisfying Assumption 3 by losing a factor  $O(\gamma K)$  in the competitive ratio.*

**Proof.** We show how to transform the instance so that it satisfies the increasing capacity assumption, while losing only  $O(K)$ -factor in the competitive ratio. For sake of brevity, let  $\kappa$  denote the constant 64.

For a speed class  $\ell$ , let  $C_\ell$  denote  $m_\ell \sigma_\ell$ , i.e., the total processing capacity of the machines in this speed class. Starting from speed class 1, we construct a subset  $X$  of speed classes as follows: if  $\ell$  denotes the last speed class added to  $X$ , then let  $\ell' > \ell$  be the smallest class such that  $C_{\ell'} \geq 2\kappa C_\ell$ . We add  $\ell'$  to  $X$  and continue this process till we have exhausted all the speed classes.

Consider the instance  $\mathcal{I}'$  in which the set of jobs is the same as those in  $\mathcal{I}$ , but there are  $K m_\ell$  machines of speed class  $\ell$  for each  $\ell \in X$ . For a speed class  $\ell \in X$ , let  $C'_\ell$  denote  $2\kappa K m_\ell \sigma_\ell$ , which is at most the total capacity of the speed class  $\ell$  machines in  $\mathcal{I}'$ . Let us now consider the optimal solutions of the two instances. We first observe that  $\text{opt}(\mathcal{I}') \leq \text{opt}(\mathcal{I})$ . Consider two consecutive speed classes  $\ell_1 < \ell_2$  in  $X$ . From the definition of  $X$ , we see that  $C'_{\ell_1} \geq \sum_{l=\ell_1}^{\ell_2-1} C_l$ . Therefore all the processing done by a solution to  $\mathcal{I}$  on machines of speed class  $[\ell_1, \ell_2)$  during a timeslot  $[t, t + 1]$  can be performed on machines of speed class  $\ell_1$  in  $\mathcal{I}'$  during the same timeslot. Therefore,  $\text{opt}(\mathcal{I}') \leq \text{opt}(\mathcal{I})$ .

For the converse statement, it is easy to see that if we give  $2\kappa K$  speedup to each machine in  $\mathcal{I}$ , then the processing capacity of each speed class in  $\mathcal{I}$  is at least that in  $\mathcal{I}'$ . Therefore,  $\text{opt}(\mathcal{I}) \leq 2\kappa K \text{opt}(\mathcal{I}')$ . Therefore, replacing  $\mathcal{I}$  by  $\mathcal{I}'$  will result in  $O(\kappa K)$  loss in competitive ratio. It is also easy to check that  $\mathcal{I}'$  satisfies increasing capacity assumption.

Observe that the conversion from  $\mathcal{I}$  to  $\mathcal{I}'$  can be easily done at the beginning – we just need to identify the index set  $X$ , and use only these for processing. The factor  $K$  loss in competitive ratio is also tight for the instance  $\mathcal{I}$  where all speed classes have the same capacity. ◀

## B

 Missing proofs of Section 3

► **Lemma 6.** *A schedule  $S$  is feasible if for every time  $t$  and every value of  $k$ :*

( $\star$ ) *the total rate assigned to any subset of  $k$  tasks is at most  $\gamma \cdot S_k$ .*

**Proof.** The rates assigned to tasks change only when one of these events happen: (i) a new job  $j$  arrives, (ii) an existing task finishes. Assuming that the job sizes, release dates are integers, we can find a suitable  $\delta > 0$  (which will also depend on the speeds of the machines) such that all the above events happen at integral multiples of  $\delta$ .

Consider an interval  $[t, t + \delta)$ , where  $t$  is an integral multiple of  $\delta$ . We need to show that if  $L_v^t$ 's satisfy the condition ( $\star$ ), then we can build a feasible schedule during  $[t, t + \delta)$ . By feasibility, we mean that each task  $v$  can be processed to an extent of  $\bar{p}_v := L_v^t \cdot \delta$  extent and at any point of time, it gets processed on at most one machine.

We follow a greedy strategy to build the schedule. Suppose we have built the schedule till time  $t' \in [t, t + \delta)$ . At time  $t'$ , we order the tasks in descending order of the remaining processing requirement for this slot (at time  $t$ , each task  $v$  has processing requirement of  $\bar{p}_v$ ). Let the ordered tasks at time  $t'$  be  $v_1, \dots, v_n$ . We schedule  $v_i$  on machine  $i$ .

Suppose for the sake of contradiction, a task  $v^*$  is not able to complete  $\bar{p}_{v^*}$  amount of processing. We first make the following observation:

▷ **Claim 16.** Let  $v$  and  $v'$  be two tasks such that at some time  $t' \in [t, t + \delta)$ , we prefer  $v$  to  $v'$  in the ordering at time  $t'$ . Then if  $v'$  does not complete  $\bar{p}_{v'}$  amount of processing during  $[t, t + \delta)$ , then neither does  $v$ .

*Proof.* Since we prefer  $v$  at time  $t'$ ,  $v$  has more remaining processing time. If we never prefer  $v'$  to  $v$  after time  $t'$ , then  $v$  always has more remaining processing requirement than  $v'$  during this interval. If we prefer  $v'$  to  $v$  at some point of time during  $(t', t + \delta)$ , then it is easy to check that the remaining processing requirements for both  $v$  and  $v'$  will remain the same. The result follows easily from this observation. ◀

Starting from  $\{v^*\}$ , we build a set  $S$  of tasks which has the following property: if  $v \in S$ , then we add to  $S$  all the tasks  $v'$  such that  $v'$  was preferred over  $v$  at some point of time during  $[t, t + \delta)$ . Repeating application of Claim 16 shows that none of these tasks  $v$  complete  $\bar{p}_v$  amount of processing during  $[t, t + \delta)$ . Let  $\bar{m}$  denote  $|S|$ . We note that only tasks in  $S$  would have been processed on the first  $\bar{m}$  machines during  $[t, t + \delta)$  – otherwise, we can add more tasks to  $S$ . Since none of these tasks finish their desired amount of processing during this interval, it follows that

$$\sum_{v \in S} \bar{p}_v \geq \gamma \delta \cdot S_{\bar{m}}.$$

Since  $\bar{p}_v = \delta L_v^t$ , we see that the set of tasks in  $S$  violates ( $\star$ ). This is a contradiction, and so such a task  $v^*$  cannot exist. ◀

► **Corollary 8.** *Fix a time  $t$ . Let  $V$  be the set of tasks frozen by some moment  $\tau$ . For a task  $v \in V$ ,*

- (i) *if  $V' \subseteq V$  is any subset of tasks which freeze either at the same moment as  $v$ , or after it, then  $\frac{\tilde{w}^t(v)}{s|V'|} \geq \frac{w(V')}{S|V'|}$ .*
- (ii) *if  $V'' \subseteq V$  is any subset of tasks which freeze either at the same moment as  $v$ , or before it, then  $\frac{\tilde{w}^t(v)}{L_v^t} \leq \frac{\tilde{w}^t(V'')}{\sum_{v' \in V''} L_{v'}^t}$ .*

### 3:16 Bag-Of-Tasks Scheduling on Related Machines

**Proof.** For any task  $v'$ , let  $\tau_{v'}$  be the value of  $\tau$  at which  $v'$  freezes. We know that

$$\sum_{v' \in V} \tilde{w}^t(v') \cdot \tau_{v'} = \gamma S_{|V|}. \quad (14)$$

Since  $\sum_{v' \in V \setminus \{v\}} \tilde{w}^t(v') \cdot \tau_{v'} \leq \gamma S_{|V|-1}$  by feasibility, it follows that

$$\tilde{w}^t(v) \cdot \tau_v \geq \gamma S_{|V|}. \quad (15)$$

Now for all  $v' \in V'$ , we have  $\tau_{v'} \geq \tau_v$ , so

$$\tilde{w}^t(V') \cdot \tau_v = \sum_{v' \in V'} \tilde{w}^t(v') \cdot \tau_v \leq \sum_{v' \in V'} \tilde{w}^t(v') \cdot \tau_{v'} \leq \sum_{v' \in V} \tilde{w}^t(v') \cdot \tau_{v'} \stackrel{(14)}{=} \gamma S_{|V|}.$$

Hence, the first claim follows:

$$\frac{\tilde{w}^t(v)}{s_{|V|}} \stackrel{(15)}{\geq} \frac{\gamma}{\tau_v} \geq \frac{\tilde{w}^t(V')}{S_{|V|}}.$$

For the second claim,

$$\sum_{v' \in V''} L_{v'}^t = \sum_{v' \in V''} \tilde{w}_{v'}^t \cdot \tau_{v'} \leq \tilde{w}^t(V'') \cdot \tau_v.$$

The claim now follows by the definition  $L_v^t = \tilde{w}^t(v) \cdot \tau_v$ . ◀

## C Missing Proofs of Section 4

▷ **Claim 9.** For any schedule  $\mathcal{S}$ , there is a feasible solution to the LP of objective value at most  $2 \text{cost}(\mathcal{S})$ .

**Proof.** Consider a schedule  $\mathcal{S}$ , and let  $x_{ivt}$  be the extent of processing done on a task  $v$  (belonging to job  $j$ ) during  $[t, t + 1]$  on machine  $i$ . More formally, if the task is processed for  $\varepsilon$  units of time on machine  $i$  during this time slot, then we set  $x_{ivt}$  to  $\varepsilon \cdot s_i$ . Constraint (4) states that every task  $v$  needs to be processed to an extent of  $p_v$ , whereas (5) requires that we cannot do more than  $s_i$  unit of processing in a unit time slot on machine  $i$ . Now we verify (3). Consider a task job  $j$  and a task  $v$  belonging to it. The total processing time of  $v$  is

$$\sum_{i,t} \frac{x_{ivt}}{s_i}. \quad (16)$$

The completion time  $F_j$  of  $j$  is at least the processing time of each of the tasks in it. Finally, we check (2). Define  $F_{j,t}$  to be 1 if  $j$  is alive at time  $t$ . The RHS of this constraint is the fraction of  $v$  which is done after time  $t$ ; and so if this is non-zero, then  $F_{j,t}$  is 1. This shows the validity of this constraint.

In the objective function, the first term is the total weighted completion time of all the jobs. The second term is also the same quantity, because  $F_j$  is equal to  $\sum_{t \geq r_j} F_{j,t}$ . ◁

# Hardness of Approximation for Euclidean $k$ -Median

## Abstract

The Euclidean  $k$ -median problem is defined in the following manner: given a set  $\mathcal{X}$  of  $n$  points in  $d$ -dimensional Euclidean space  $\mathbb{R}^d$ , and an integer  $k$ , find a set  $C \subset \mathbb{R}^d$  of  $k$  points (called centers) such that the cost function  $\Phi(C, \mathcal{X}) \equiv \sum_{x \in \mathcal{X}} \min_{c \in C} \|x - c\|_2$  is minimized. The Euclidean  $k$ -means problem is defined similarly by replacing the distance with squared Euclidean distance in the cost function. Various hardness of approximation results are known for the Euclidean  $k$ -means problem [7, 29, 17]. However, no hardness of approximation result was known for the Euclidean  $k$ -median problem. In this work, assuming the *unique games conjecture* (UGC), we provide the hardness of approximation result for the Euclidean  $k$ -median problem in  $O(\log k)$  dimensional space. This solves an open question posed explicitly in the work of Awasthi et al. [7].

Furthermore, we study the hardness of approximation for the Euclidean  $k$ -means/ $k$ -median problems in the bi-criteria setting where an algorithm is allowed to choose more than  $k$  centers. That is, bi-criteria approximation algorithms are allowed to output  $\beta k$  centers (for constant  $\beta > 1$ ) and the approximation ratio is computed with respect to the optimal  $k$ -means/ $k$ -median cost. We show the hardness of bi-criteria approximation result for the Euclidean  $k$ -median problem for any  $\beta < 1.015$ , assuming UGC. We also show a similar hardness of bi-criteria approximation result for the Euclidean  $k$ -means problem with a stronger bound of  $\beta < 1.28$ , again assuming UGC.

## 1 Introduction

We start by giving the definition of the Euclidean  $k$ -median problem.

► **Definition 1** ( $k$ -median). *Given a set  $\mathcal{X}$  of  $n$  points in  $d$ -dimensional Euclidean space  $\mathbb{R}^d$ , and a positive integer  $k$ , find a set of centers  $C \subset \mathbb{R}^d$  of size  $k$  such that the cost function  $\Phi(C, \mathcal{X}) \equiv \sum_{x \in \mathcal{X}} \min_{c \in C} \|x - c\|$  is minimized.*

The Euclidean  $k$ -means problem is defined similarly by replacing the distance with squared Euclidean distance in the cost function (i.e., replacing  $\|x - c\|$  with  $\|x - c\|^2$ ). These problems are also studied in the discrete setting where the centers are restricted to be chosen from a specific set  $L \subset \mathbb{R}^d$ , also given as input. This is known as the *discrete* version whereas the former version (with  $L = \mathbb{R}^d$ ) is known as the *continuous* version. In the approximation

Leibniz International Proceedings in Informatics

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

setting, the continuous version is not harder than its discrete counterpart since it is known (e.g., [22, 36]) that an  $\alpha$ -approximation for the discrete problem gives an  $\alpha + \varepsilon$  approximation for the continuous version, for arbitrary small constant  $\varepsilon > 0$ , in polynomial time. In this work, we only study the hardness of approximation for continuous version of the problem. The hardness of approximation for the discrete version thus follows from the hardness of approximation of continuous version. In the rest of the paper, we use  $k$ -means/median to implicitly mean *continuous Euclidean  $k$ -means/median* unless specified otherwise <sup>1</sup>.

The relevance of the  $k$ -means and  $k$ -median problems in various computational domains such as resource allocation, big data analysis, pattern mining, and data compression is well known. A significant amount of work has been done to understand the computational aspects of the  $k$ -means/median problems. The  $k$ -means problem is known to be NP-hard even for fixed  $k$  or  $d$  [4, 20, 33, 40]. Similar NP hardness result is also known for the  $k$ -median problem [37]. Even the 1-median problem, popularly known as the *Fermat-Weber* problem [21], is a hard problem and designing efficient algorithms for this problem is a separate line of research in itself – see for e.g. [27, 42, 12, 10, 15]. These hardness barriers motivate approximation algorithms for these problems and a lot of progress have been made in this area. For example, there are various polynomial time approximation schemes (PTASs) known for  $k$ -means and  $k$ -median when  $k$  is fixed (or constant) [36, 28, 22, 14, 25]. Similarly, various PTASs are known for fixed  $d$  [19, 23, 16]. A number of constant factor approximation algorithms are also known for  $k$ -means and  $k$ -median when  $k$  and  $d$  are considered as part of the input. For the  $k$ -means problem, constant approximation algorithms have been given [26, 2], the best being a 6.357 approximation algorithm by Ahmadian *et al.* [2]. On the negative side, there exists a constant  $\varepsilon > 0$  such that there does not exist an efficient  $(1 + \varepsilon)$ -approximation algorithm for the  $k$ -means problem, assuming  $P \neq NP$  [7, 29, 17]. The best-known hardness of approximation result for the  $k$ -means problem is 1.07 due to Cohen-Addad and Karthik [17].

The constant factor approximation algorithms for the  $k$ -median problem are also known [13, 5, 32, 11, 2]. The best known approximation guarantee for  $k$ -median is 2.633 due to Ahmadian *et al.* [2]. On the hardness side, it was known that for general metric spaces, the discrete  $k$ -median problem is hard to approximate within a factor of  $1 + 2/e$  [24]. However, unlike the Euclidean  $k$ -means problem, no hardness of approximation result was known for the Euclidean  $k$ -median problem. Resolving the hardness of approximation for the Euclidean  $k$ -median problem was left as an open problem in the work of Awasthi *et al.* [7]. They asked whether their techniques for proving the inapproximability results for Euclidean  $k$ -means can be used to prove the hardness of approximation result for the Euclidean  $k$ -median problem. From their paper,

*“It would also be interesting to study whether our techniques give hardness of approximation results for the Euclidean  $k$ -median problem.”*

In this work, assuming UGC, we solve this open problem by obtaining the hardness of approximation result for the Euclidean  $k$ -median problem. Following is one of the main results of this work.

► **Theorem 2 (Main Theorem).** *There exists a constant  $\varepsilon > 0$  such that the Euclidean  $k$ -median problem in  $O(\log k)$  dimensional space cannot be approximated to a factor better than  $(1 + \varepsilon)$ , assuming the Unique Games Conjecture.*

<sup>1</sup> In some literature, the Euclidean space implicitly means the dimension is bounded, but in our case the dimension  $d$  can be arbitrarily large

Having established the hardness of approximation results for  $k$ -means and  $k$ -median, the next natural step in the discussion is to allow more flexibility to the algorithm. One possible relaxation is to allow an approximation algorithm to choose more than  $k$  centers, say,  $\beta k$  centers (for some constant  $\beta > 1$ ) and produce a solution that is close to the optimal solution with respect to  $k$  centers. This is known as bi-criteria approximation and the following definition formalizes this notion.

► **Definition 3** ( $(\alpha, \beta)$ -approximation algorithm). *An algorithm  $\mathcal{A}$  is called an  $(\alpha, \beta)$  approximation algorithm for the Euclidean  $k$ -means/ $k$ -median problem if given any instance  $\mathcal{I} = (\mathcal{X}, k)$  with  $\mathcal{X} \subset \mathbb{R}^d$ ,  $\mathcal{A}$  outputs a center set  $F \subset \mathbb{R}^d$  of size  $\beta k$  that has the cost at most  $\alpha$  times the optimal cost with  $k$  centers. That is,*

$$\sum_{x \in \mathcal{X}} \min_{f \in F} \{D(x, f)\} \leq \alpha \cdot \min_{\substack{C \subset \mathbb{R}^d \\ |C|=k}} \left\{ \sum_{x \in \mathcal{X}} \min_{c \in C} \{D(x, c)\} \right\}$$

For the Euclidean  $k$ -means problem,  $D(p, q) \equiv \|p - q\|^2$  and for the  $k$ -median problem  $D(p, q) \equiv \|p - q\|$ .

One expects that as  $\beta$  grows, there would exist efficient  $(\alpha, \beta)$ -approximation algorithms with smaller values of  $\alpha$ . This is indeed observed in the work of Makarychev et al. [35]. For example, their algorithm gives a  $(9 + \varepsilon)$  approximation for  $\beta = 1$ ; 2.59 approximation for  $\beta = 2$ ; 1.4 approximation for  $\beta = 3$ . In other words, the approximation factor of their algorithm decreases as the value of  $\beta$  increases. Furthermore, their algorithm gives a  $(1 + \varepsilon)$ -approximation guarantee with  $O(k \log(1/\varepsilon))$  centers. Bandyapadhyay and Varadarajan [8] gave a  $(1 + \varepsilon)$  approximation algorithm that outputs  $(1 + \varepsilon)k$  centers in constant dimension. There are various other bi-criteria approximation algorithms that use distance-based sampling techniques and achieve better approximation guarantees than their non bi-criteria counterparts [3, 1, 41]. Unfortunately in these bi-criteria algorithms, at least one of  $\alpha, \beta$  is large. Ideally, we would like to obtain a PTAS with a small violation of the number of output centers. More specifically, we would like to address the following question:

*Does the Euclidean  $k$ -means or Euclidean  $k$ -median problem admit an efficient  $(1 + \varepsilon, 1 + \varepsilon)$ -approximation algorithm?*

Note that such type of bi-criteria approximation algorithms that outputs  $(1 + \varepsilon)k$  centers have been extremely useful in obtaining a constant approximation for the *capacitated*  $k$ -median problem [30, 31] for which no true constant approximation is known yet.<sup>2</sup> Therefore, the above question is worth exploring. Note that here we are specifically aiming for a PTAS since the  $k$ -means and  $k$ -median problems already admit a constant factor approximation algorithm. In this work, we give a negative answer to the above question by showing that there exists a constant  $\varepsilon > 0$  such that an efficient  $(1 + \varepsilon, 1 + \varepsilon)$ -approximation algorithm for the  $k$ -means and  $k$ -median problems does not exist assuming the Unique Games Conjecture. The following two theorems state this result more formally.

► **Theorem 4** ( $k$ -median). *For any constant  $1 < \beta < 1.015$ , there exists a constant  $\varepsilon > 0$  such that there is no  $(1 + \varepsilon, \beta)$ -approximation algorithm for the Euclidean  $k$ -median problem in  $O(\log k)$  dimensional space assuming the Unique Games Conjecture.*

<sup>2</sup> In the capacitated  $k$ -median/ $k$ -means problem there is an additional constraint on each center that it cannot serve more than a specified number of clients (or points).

► **Theorem 5** ( $k$ -means). *For any constant  $1 < \beta < 1.28$ , there exists a constant  $\varepsilon > 0$  such that there is no  $(1 + \varepsilon, \beta)$ -approximation algorithm for the Euclidean  $k$ -means problem in  $O(\log k)$  dimensional space assuming the Unique Games Conjecture. Moreover, the same result holds for any  $1 < \beta < 1.1$  under the assumption that  $P \neq NP$ .*

For simplicity, we present the proof of our results in  $O(n)$  dimensional space. However, the results easily extend to  $O(\log k)$  dimensional space using dimensionality reduction techniques of Makarychev *et al.* [34].

**Important note:** We would like to note that assuming  $P \neq NP$ , a similar hardness of approximation result for the Euclidean  $k$ -median problem using different techniques has been obtained independently by Vincent Cohen-Addad, Karthik C. S., and Euiwoong Lee. We came to know about their results through personal communication with the authors. Since their manuscript has not been published online yet, we are not able to add a citation to their work.

In the next subsection, we discuss the known results on hardness of approximation of the  $k$ -means and  $k$ -median problems in more detail.

## 1.1 Related Works

Guha and Khuller proved a  $(1 + \frac{2}{\varepsilon})$  hardness of approximation result for the discrete  $k$ -median problem for the general metric spaces [24]. The first hardness of approximation result for the Euclidean  $k$ -means problem was given by Awasthi *et al.* [7]. They obtained their result using a reduction from Vertex Cover on triangle-free graphs of bounded degree  $\Delta$  to the Euclidean  $k$ -means instances. Their reduction yields a  $(1 + \frac{\varepsilon}{\Delta})$  hardness factor for the  $k$ -means problem for some constant  $\varepsilon > 0$ . Lee *et al.* [29] showed the hardness of approximation of Vertex Cover on triangle-free graphs of bounded degree four. Using  $\Delta = 4$ , they obtained a 1.0013 hardness of approximation for the Euclidean  $k$ -means problem. Subsequently, Cohen-Addad and Karthik [17] improved the hardness of approximation to 1.07 using a modified reduction from the vertex coverage problem instead of a reduction from the vertex cover problem. Moreover, they also gave several improved hardness results for the discrete  $k$ -means/ $k$ -median problems in general and  $\ell_p$  metric spaces. In their more recent work, they also improved the hardness of approximation results for the continuous  $k$ -means/ $k$ -median problem in general metric spaces [18].

Unlike the Euclidean  $k$ -means problem, no hardness of approximation result was known for the Euclidean  $k$ -median problem. In this work, we give hardness of approximation result for the Euclidean  $k$ -median problem assuming the Unique Game Conjecture. As mentioned earlier, in an unpublished work communicated to us through personal communication, Vincent Cohen-Addad, Karthik C. S., and Euiwoong Lee have independently obtained hardness of approximation result for the Euclidean  $k$ -median problem using different set of techniques and under the assumption that  $P \neq NP$ . They also gave bi-criteria hardness of approximation results in  $\ell_\infty$ -metric for the  $k$ -means and  $k$ -median problems [18]. We would like to point out that in the bi-criteria setting, our result is the first hardness of approximation result for the Euclidean  $k$ -means/ $k$ -median problem to the best of our knowledge.

## 1.2 Technical Overview and Contributions

Awasthi *et al.* [7] proved the first hardness of approximation result for the Euclidean  $k$ -means problem. Given any instance  $\mathcal{I} = (\mathcal{X}, k)$  for the Euclidean  $k$ -means problem, they showed that there exists an  $\epsilon > 0$  such that obtaining  $(1 + \epsilon)$ -approximation for Euclidean  $k$ -means

is NP-hard. In this work we build on their techniques to prove the inapproximability result for the Euclidean  $k$ -median problem. First, we describe the reduction employed by Awasthi et al. for the Euclidean  $k$ -means problem and some related results.

*Construction of  $k$ -means instance:* Let  $(G, k)$  be a hard **Vertex Cover** instance where the graph  $G$  has bounded degree  $\Delta$ . Let  $n$  and  $m$  denote respectively the number of vertices and the number of edges in the graph. A  $k$ -means instance  $\mathcal{I} := (\mathcal{X}, k)$  with  $\mathcal{X} \subset \mathbb{R}^n$  is constructed as follows. For every vertex  $i \in V$ , we have an  $n$ -dimensional vector  $x_i \in \{0, 1\}^n$ , which has a 1 at  $i^{\text{th}}$  coordinate and 0 everywhere else. For each edge  $e = (i, j) \in E$ , a point  $x_e := x_i + x_j$  is defined in  $\{0, 1\}^n$ . The set  $\mathcal{X} := \{x_e \mid e \in E\}$  with  $m$  points in  $\mathbb{R}^n$  and parameter  $k$  define the  $k$ -means instance.

Awasthi et al. proved the following theorem based on the above construction [7].

► **Theorem 6** (Theorem 4.1 [7]). *There is an efficient reduction from vertex cover on bounded degree triangle-free graphs to the Euclidean  $k$ -means problem that satisfies the following properties:*

1. *If vertex cover of the instance is  $k$ , then there is a  $k$ -means clustering of cost at most  $(m - k)$ .*
2. *If vertex cover of the instance is at least  $(1 + \varepsilon)k$ , then the cost of optimal  $k$ -means clustering is at least  $(m - k + \delta k)$ .*

Here,  $\varepsilon$  is some fixed constant  $> 0$  and  $\delta = \Omega(\varepsilon)$ .

Awasthi et al. [7] used the following hardness result for the vertex cover problem on bounded degree triangle-free graphs.

► **Theorem 7** (Corollary 5.3 [7]). *Given any unweighted bounded degree triangle-free graph  $G$ , it is NP-hard to approximate **Vertex Cover** within any factor smaller than 1.36.*

Theorem 6 and Theorem 7 together imply that the Euclidean  $k$ -means problem is APX-hard. A formal statement for the same is given as follows (see Section 4 of [7] for the proof of this result).

► **Corollary 8.** *There exists a constant  $\varepsilon' > 0$  such that it is NP-hard to approximate the Euclidean  $k$ -means problem to any factor better than  $(1 + \varepsilon')$ .*

We would like to obtain a similar gap-preserving reduction for the Euclidean  $k$ -median problem. The first obstacle one encounters in this direction is that unlike the 1-mean problem, there does not exist a closed form expression for the 1-median problem, and hence we don't have an exact expression for the optimal 1-median cost. We overcome this barrier by obtaining good upper and lower bounds on the optimal 1-median cost and showing that these bounds suffice for our purpose. More concretely, to upper bound the optimal 1-median cost, we use the centroid as the 1-median and compute the 1-median cost with respect to the centroid. To obtain a lower bound on the 1-median cost of a cluster, we use a decomposition technique to break a cluster into smaller sub-clusters<sup>3</sup> for which we can compute exact or good approximate lower bounds on the 1-median cost. Here we use a simple observation that the optimal 1-median cost of a cluster is at least the sum of the optimal 1-median costs of the sub-clusters. For any sub-cluster that corresponds to a star graph, one can compute the

<sup>3</sup> Since a set of edges in a graph form a cluster of points in the reduction, we use the terms sub-graphs and sub-clusters interchangeably.

exact 1-median cost using our reduction. In order to bound the 1-median cost for sub-clusters that correspond to non-star graphs, we use the following observation crucially: the optimal 1-median cost is preserved under any transformation that preserves the pairwise distances. For non-star graphs, we first employ such a transformation that preserves the 1-median cost and then compute this cost exactly in the projected space. Note that this technique does not give exact 1-median cost for any arbitrary non-star graph, but works only for some *special families* of non-star graphs. The main idea of the decomposition technique is to ensure that only these kinds of non-star graphs are created in the decomposition process. The upper and lower bounds on the 1-median cost, as constructed in the above manner, are used in the completeness and soundness steps of the proof of the reduction, respectively.

The analysis for the completeness part of the reduction is relatively straightforward. If the vertex cover of a graph is  $k$ , then the edges of the graph can be divided into  $k$  star sub-graphs, each of which results in a star cluster in the  $k$ -median instance. The cost for this clustering with  $k$  star clusters can be found using the reduction easily.

In the proof for the soundness part of our reduction, we prove the contrapositive statement that assumes the  $k$ -median clustering cost to be bounded and proves that the vertex cover of the graph is not too large. Our analysis crucially depends on the relation between the vertex cover of a subgraph and the 1-median cost for that subgraph. More specifically, we need to answer the following question. Given a graph with  $r$  edges having vertex cover  $z$ , how does the optimal 1-median cost for that graph behave with respect to  $z$ . For example, for star graphs,  $z = 1$  and the optimal 1-median cost of a star graph on  $r$  edges is exactly  $\sqrt{r(r-1)}$ . For any non-star graph with  $r$  edges, we first show that the optimal 1-median cost of the non-star graph is at least the optimal 1-median cost of a star graph with  $r$  edges. For any non-star graph  $F$  with  $r$  edges, we denote by  $\delta(F)$  the *extra cost* of  $F$ , defined as the difference of the optimal 1-median cost of  $F$  and the optimal 1-median cost of a star graph with  $r$  edges. If we can figure out non-trivial lower bounds for  $\delta(F)$  for different non-star graphs  $F$ , then we would be done. But, figuring out these non-trivial lower bounds that work for any non-star graph is quite a daunting prospect. The way we overcome this in our work is as follows. We characterize the non-star graphs as having maximum matching of size two or more than two, and for each, we relate the *extra cost* of 1-median clustering of that graph with the vertex cover of that graph. We show that the extra cost of a non-star sub-graph is proportional to the number of vertex-disjoint edges in the sub-graph. And since we assume the  $k$ -median cost to be bounded, the number of vertex disjoint edges is also bounded, giving a small vertex cover.

We need one more idea to finish the proof for the soundness part of the reduction. We call a cluster “singleton” if there is only one point in the cluster. Note that any such cluster would cost zero in a  $k$ -median clustering. If there are a large number of singleton clusters, say  $t < k$ , then they pay zero to the cost of the solution, even though those edges have vertex cover  $t$ . We prove a key lemma showing that for any *hard* instance of the vertex cover, the vertex cover of the sub-graph spanned by  $t$  singleton edges is at most  $\frac{2t}{3}$ . We combine these ideas to prove that if  $k$ -median clustering cost is bounded, the vertex cover of the graph cannot be too large.

We also prove the hardness of bi-criteria approximation results for Euclidean  $k$ -means and  $k$ -median problems. The hardness of bi-criteria approximation for Euclidean  $k$ -median is obtained by extending the proof for the hardness of approximation for the Euclidean  $k$ -median problem. We use the same reduction from the vertex cover problem and show that the soundness guarantees hold even if one is allowed to use  $\beta k$  centers, for some  $\beta > 1$ . We also show that similar techniques give the hardness of bi-criteria approximation results for the Euclidean  $k$ -means problem.

## 2 Useful Facts and Inequalities

In this section, we discuss some basic facts and inequalities that we will frequently use in our proofs. First, we note that the Fermat-Weber problem is not difficult for all 1-median instances. We can efficiently obtain 1-median for some special instances. For example, for a set of equidistant points, the 1-median is simply the centroid of the point set. We give a proof of this statement in the next section. Most importantly, we use the following fact and lemma to compute the 1-median cost.

► **Fact 1** ([38]). *For a set of non-collinear points the optimal 1-median is unique.*

► **Lemma 9.** *Let  $A = \{a_1, \dots, a_n\}$  and  $B = \{b_1, \dots, b_n\}$  be any two sets of  $n$  points in  $\mathbb{R}^d$ . If the pairwise distances between points within  $A$  is the same as pairwise distance between points within  $B$ . That is, for all  $i, j \in \{1, \dots, n\}$ ,  $\|a_i - a_j\| = \|b_i - b_j\|$ . Then the optimal 1-median cost of  $A$  is the same as the optimal 1-median cost of  $B$ .*

The proof of Lemma 9 is deferred to Appendix A. We use the above lemma, in vector spaces where it is tricky to compute the optimal 1-median exactly. In such cases, we transform the space to a different vector space, where computing the 1-median is relatively simpler. More specifically, we employ a rigid transformation since it preserves pairwise distances. Next, we give a simple lemma, that is used to prove various bounds related to the quantity  $\sqrt{m(m-1)}$ .

► **Lemma 10.** *Let  $m$  and  $t$  be any positive real numbers greater than one. If  $m \geq t$ , the following bound holds:*

$$m - (t - \sqrt{t(t-1)}) \leq \sqrt{m(m-1)} \leq m - 1/2.$$

**Proof.** The upper bound follows from the sequence of inequalities:  $\sqrt{m(m-1)} < \sqrt{m^2 - m + 1/4} = \sqrt{(m-1/2)^2} = m - 1/2$ . The lower bound follows from the following sequence of inequalities:

$$\sqrt{m(m-1)} = m + m \cdot \left( \sqrt{\frac{m-1}{m}} - 1 \right) \geq m + t \cdot \left( \sqrt{\frac{t-1}{t}} - 1 \right) = m - (t - \sqrt{t(t-1)}).$$

The second inequality holds because  $\frac{a+1}{b+1} \geq \frac{a}{b}$  for  $b \geq a$ . This completes the proof of the lemma. ◀

### 2.1 Preliminaries

Recall that a point in  $\mathcal{X}$  corresponds to an edge of the graph. Therefore, a sub-graph  $S$  of  $G$  corresponds to a subset of points  $\mathcal{X}(S) := \{x_e \mid e \in E(S)\}$  of  $\mathcal{X}$ . We define the 1-median cost of  $\mathcal{X}(S)$  with respect to a center  $c \in \mathbb{R}^n$  as  $\Phi(c, S) \equiv \sum_{x \in \mathcal{X}(S)} \|x - c\|$ . Furthermore, we define the **optimal** 1-median cost of  $\mathcal{X}(S)$  as  $\Phi^*(S)$ . That is,  $\Phi^*(S) \equiv \min_{c \in \mathbb{R}^n} \Phi(c, S)$ . We often use these statements interchangeably, “optimal 1-median cost of a graph  $S$ ” to mean “optimal 1-median cost of the cluster  $\mathcal{X}(S)$ ”.

## 3 Inapproximability of Euclidean k-Median

In this section, we show the inapproximability result of the Euclidean  $k$ -median problem. We obtain this result by showing a gap preserving reduction from Vertex Cover on bounded degree triangle-free graphs to the Euclidean  $k$ -median. For Vertex Cover on bounded degree triangle-free graphs, the inapproximability result is stated in Corollary 13. The corollary simply follows from the following two results of Austrin et al. [6] and Awasthi et al. [7].

► **Theorem 11** (Austrin et al. [6]). *Given any unweighted bounded degree graph  $G = (V, E)$  of maximum degree  $\Delta$ , Vertex Cover can not be approximated within any factor smaller than  $2 - \varepsilon$ , for  $\varepsilon = (2 + o_\Delta(1)) \cdot \frac{\log \log \Delta}{\log \Delta}$  assuming the Unique Games Conjecture.*

In the above theorem,  $\varepsilon$  can be set to arbitrarily small value by taking sufficiently large value of  $\Delta$ .

► **Theorem 12** (Awasthi et al. [7]). *There is a  $(1 + \varepsilon)$ -approximation-preserving reduction from Vertex Cover on bounded degree graphs to Vertex Cover on triangle-free graphs of bounded degree.*

► **Corollary 13.** *Given any unweighted triangle-free graph  $G$  of bounded degree, Vertex Cover can not be approximated within a factor smaller than  $2 - \varepsilon$ , for any constant  $\varepsilon > 0$ , assuming the Unique Games Conjecture.*

Earlier, in Section 1.2, we described the reduction used by Awasthi et al. [7] to construct instances for Euclidean  $k$ -means from a Vertex Cover instance. We use the same construction for the Euclidean  $k$ -median instances. Let  $G = (V, E)$  denote a triangle-free graph of bounded degree  $\Delta$ . Let  $\mathcal{I} = (\mathcal{X}, k)$  denote the Euclidean  $k$ -median instance constructed from  $G$ . We establish the following theorem based on this construction.

► **Theorem 14.** *There is an efficient reduction from Vertex Cover on bounded degree triangle-free graphs with  $m$  edges to the Euclidean  $k$ -median problem that satisfies the following properties:*

1. *If the graph has a vertex cover of size  $k$ , then the  $k$ -median instance has a solution of cost at most  $m - k/2$ .*
2. *If the graph has no vertex cover of size at most  $(2 - \varepsilon) \cdot k$ , then the cost of any  $k$ -median solution on the instance is at least  $m - k/2 + \delta k$ .*

*Here,  $\varepsilon$  is some fixed constant,  $\delta = \Omega(\varepsilon)$ , and  $k \geq$  the size of maximum matching of the graph.*

The graphs with a vertex cover of size at most  $k$  are said to be “Yes” instances and the graphs with no vertex cover of size at most  $(2 - \varepsilon)k$  are said to be “No” instances. Now, the above theorem gives the following inapproximability result for the Euclidean  $k$ -median problem.

► **Corollary 15.** *There exists a constant  $\varepsilon' > 0$  such that the Euclidean  $k$ -median problem can not be approximated to a factor better than  $(1 + \varepsilon')$ , assuming the Unique Games Conjecture.*

**Proof.** Since the hard Vertex Cover instances have bounded degree  $\Delta$ , the maximum matching of such graphs is at least  $\lceil \frac{m}{2\Delta} \rceil$ . First, let us prove this statement. Suppose  $M$  be a matching, that is initially empty, i.e.,  $M = \emptyset$ . We construct  $M$  in an iterative manner. First, we pick an arbitrary edge from the graph and add it to  $M$ . Then, we remove this edge and all the edges incident on it. We repeat this process for the remaining graph until the graph becomes empty. In each iteration, we remove at most  $2\Delta$  edges. Therefore, the matching size of the graph is at least  $\lceil \frac{m}{2\Delta} \rceil$ .

Now, suppose  $k < \frac{m}{2\Delta}$ . Then, the graph does not have a vertex cover of size  $k$  since matching size is at least  $\lceil \frac{m}{2\Delta} \rceil$ . Therefore, such graph instances can be classified as “No” instances in polynomial time. So, they are not the hard Vertex Cover instances. Therefore, we can assume  $k \geq \frac{m}{2\Delta}$  for all the hard Vertex Cover instances. In that case, the second property of Theorem 14, implies that the cost of  $k$ -median instance is  $(m - \frac{k}{2}) + \delta k \geq (1 + \frac{\delta}{2\Delta}) \cdot (m - \frac{k}{2})$ . Thus, the  $k$ -median problem can not be approximated within any factor smaller than  $1 + \frac{\delta}{2\Delta} = 1 + \Omega(\varepsilon)$ . ◀

### 3.1 Completeness

Let  $W = \{v_1, \dots, v_k\}$  be a vertex cover of  $G$ . Let  $S_i$  denote the set of edges covered by  $v_i$ . If an edge is covered by two vertices  $v_i$  and  $v_j$ , then we arbitrarily keep the edge either in  $S_i$  or  $S_j$ . Let  $m_i$  denote the number of edges in  $S_i$ . We define  $\{\mathcal{X}(S_1), \dots, \mathcal{X}(S_k)\}$  as a clustering of the point set  $\mathcal{X}$ . Now, we show that the cost of this clustering is at most  $m - k/2$ . Note that each  $S_i$  forms a star graph centered at  $v_i$ . Moreover, the point set  $\mathcal{X}(S_i)$  forms a regular simplex of side length  $\sqrt{2}$ . We compute the optimal cost of  $\mathcal{X}(S_i)$  using the following lemma.

► **Lemma 16.** *For a regular simplex on  $r$  vertices and side length  $s$ , the optimal 1-median is the centroid of the simplex. Moreover, the optimal 1-median cost is  $s \cdot \sqrt{\frac{r(r-1)}{2}}$ .*

**Proof.** The statement is easy to see for  $r = 1$ . For  $r = 2$ , there are two points  $s$  distance apart. Therefore, the optimal center lies on the line segment joining the two points and the optimal 1-median cost is trivially  $s$ . So, for the rest of the proof, we assume that  $r > 2$ . Suppose  $A = \{a_1, a_2, \dots, a_r\}$  denote the vertex set of a regular simplex. Let  $s$  be the side length of the simplex. Using Lemma 9, we can represent each point  $a_i$  in an  $r$ -dimensional space as follows; we use the same notation to denote the points after such transformations.

$$a_1 := \left( \frac{s}{\sqrt{2}}, 0, \dots, 0 \right), \quad a_2 := \left( 0, \frac{s}{\sqrt{2}}, \dots, 0 \right), \quad \dots, \quad a_r := \left( 0, 0, \dots, \frac{s}{\sqrt{2}} \right)$$

Note that the distance between any  $a_i$  and  $a_j$  is  $s$ , which is the side length of the simplex. Let  $c^* = (c_1, \dots, c_r)$  be an optimal 1-median of point set  $A$ . Then, the 1-median cost is the following:

$$\Phi(c^*, A) = \sum_{i=1}^r \|a_i - c^*\| = \sum_{i=1}^r \left( \sum_{j=1}^r c_j^2 - c_i^2 + \left( \frac{s}{\sqrt{2}} - c_i \right)^2 \right)^{1/2}$$

Suppose  $c_i \neq c_j$  for any  $i \neq j$ . Then, we can swap  $c_i$  and  $c_j$  to create a different median, while keeping the 1-median cost the same. It contradicts the fact that there is only one optimal 1-median, by Fact 1. Therefore, we can assume  $c^* = (c, c, \dots, c)$ . Now, the optimal 1-median cost is:

$$\Phi^*(A) = \Phi(c^*, A) := r \cdot \sqrt{\left( c - \frac{s}{\sqrt{2}} \right)^2 + (r-1) \cdot c^2}$$

The function  $\Phi(c^*, A)$  is strictly convex and attains minimum at  $c = \frac{s}{m \cdot \sqrt{2}}$ , which is the centroid of  $A$ . The optimal 1-median clustering cost is  $\Phi(c^*, A) = s \cdot \sqrt{\frac{r(r-1)}{2}}$ . This completes the proof of the lemma. ◀

The following corollary establishes the cost of a star graph  $S_i$ .

► **Corollary 17.** *Any star graph  $S_i$  with  $r$  edges has the optimal 1-median cost of  $\sqrt{r(r-1)}$*

Using this corollary, we bound the optimal  $k$ -median cost of  $\mathcal{X}$  as follows. Let  $OPT(\mathcal{X}, k)$  denote the optimal  $k$ -median cost of  $\mathcal{X}$ . The following sequence of inequalities proves the first property of Theorem 14.

$$OPT(\mathcal{X}, k) \leq \sum_{i=1}^k \Phi^*(S_i) \stackrel{\text{(Corollary 17)}}{=} \sum_{i=1}^k \sqrt{m_i(m_i - 1)} \stackrel{\text{(Lemma 10)}}{\leq} \sum_{i=1}^k \left( m_i - \frac{1}{2} \right) = m - \frac{k}{2}.$$

### 3.2 Soundness

Now, we prove the second property of Theorem 14. For this, we prove the equivalent contrapositive statement: If the optimal  $k$ -median clustering of  $\mathcal{X}$  has cost at most  $(m - \frac{k}{2} + \delta k)$ , for some constant  $\delta > 0$ , then  $G$  has a vertex cover of size at most  $(2 - \varepsilon)k$ , for some constant  $\varepsilon > 0$ . Let  $\mathcal{C}$  denote an optimal  $k$ -median clustering of  $\mathcal{X}$ . We classify its optimal clusters into two categories: (1) *star* and (2) *non-star*. Let  $F_1, F_2, \dots, F_t$  denote the non-star clusters, and  $S_1, \dots, S_{k-t}$  denote the star clusters. For any star cluster, the vertex cover size is exactly one. Moreover, using Corollary 17, the optimal 1-median cost of any star cluster with  $r$  edges is  $\sqrt{r(r-1)}$ . On the other hand, it may be tricky to exactly compute the vertex cover or the optimal cost of any non-star cluster. Suppose the optimal 1-median cost of a non-star cluster  $F$  on  $r$  edges is given as  $\sqrt{r(r-1)} + \delta(F)$ , where  $\delta(F)$  denotes the *extra-cost* due to a non-star cluster  $F$ . Using this, we define  $\delta(F)$  as the following:

$$\delta(F) \equiv \Phi^*(F) - \sqrt{|F|(|F| - 1)}$$

The following lemmas bound the vertex cover of  $F$  in terms of  $\delta(F)$ .

► **Lemma 18.** *Any non-star cluster  $F$  with a maximum matching of size two has a vertex cover of size at most  $1.62 + (\sqrt{2} + 1)\delta(F)$ .*

► **Lemma 19.** *Any non-star cluster  $F$  with a maximum matching of size at least three has a vertex cover of size at most  $1.8 + (\sqrt{2} + 1)\delta(F)$ .*

These lemmas are the key to proving the main result. We discussed the main proof ideas earlier in Section 1.2; however, due to page-limit, the complete proof is deferred to the full version of the paper [9]. Now, let us see how these lemmas give a vertex cover of size at most  $(2 - \varepsilon)k$ . Let us classify the star clusters into the following two sub-categories:

- (a) Clusters composed of exactly one edge. Let these clusters be:  $P_1, P_2, \dots, P_{t_1}$ .
- (b) Clusters composed of at least two edges. Let these clusters be:  $S_1, S_2, \dots, S_{t_2}$ .

Similarly, we classify the non-star clusters into the following two sub-categories:

- (i) Clusters with a maximum matching of size two. Let these clusters be:  $W_1, W_2, \dots, W_{t_3}$
- (ii) Clusters with a maximum matching of size at least three. Let these clusters be:  $Y_1, Y_2, \dots, Y_{t_4}$

Note that  $t_1 + t_2 + t_3 + t_4$  equals  $k$ . Now, consider the following strategy of computing the vertex cover of  $G$ . Suppose, we compute the vertex cover for every cluster separately. Let  $C_i$  be any cluster, and  $|VC(C_i)|$  denote the vertex cover size of  $C_i$ . Then, the vertex cover of  $G$  can be simply bounded in the following manner:

$$|VC(G)| \leq \sum_{i=1}^{t_1} |VC(P_i)| + \sum_{i=1}^{t_2} |VC(S_i)| + \sum_{i=1}^{t_3} |VC(W_i)| + \sum_{i=1}^{t_4} |VC(Y_i)|$$

However, we can obtain a vertex cover of smaller size using a slightly different strategy. In this strategy, we first compute a minimum vertex cover of all the clusters except single edge clusters  $P_1, P_2, \dots, P_{t_1}$ . Suppose that vertex cover is  $VC'$ . Then we compute a vertex cover for  $P_1, P_2, \dots, P_{t_1}$ . Now, let us see why this strategy gives a vertex cover of smaller size than before. Note that some vertices in  $VC'$  may also cover the edges in  $P_1, \dots, P_{t_1}$ . Suppose there are  $t'_1$  clusters in  $P_1, \dots, P_{t_1}$  that remain uncovered by  $VC'$ . Without loss of generality, assume these clusters to be  $P_1, \dots, P_{t'_1}$ . Now, the vertex cover of  $G$  is bounded in

the following manner:

$$\begin{aligned}
|VC(G)| &\leq |VC\left(\bigcup_{i=1}^{t'_1} P_i\right)| + |VC'| \\
&= |VC\left(\bigcup_{i=1}^{t'_1} P_i\right)| + |VC\left(\left(\bigcup_{j=1}^{t_2} S_j\right) \cup \left(\bigcup_{k=1}^{t_3} W_k\right) \cup \left(\bigcup_{l=1}^{t_4} Y_l\right)\right)| \\
&\leq |VC\left(\bigcup_{i=1}^{t'_1} P_i\right)| + \sum_{i=1}^{t_2} |VC(S_i)| + \sum_{i=1}^{t_3} |VC(W_i)| + \sum_{i=1}^{t_4} |VC(Y_i)|
\end{aligned}$$

Now, we will try to bound the size of the vertex cover of  $P_1 \cup \dots \cup P_{t'_1}$ . Note that we can cover all these single-edge clusters with  $t'_1$  vertices by choosing one vertex per cluster. However, it may be possible to obtain a vertex cover of smaller size if we collectively consider all these clusters. Suppose  $E_P$  denote the set of all edges in  $P_1, \dots, P_{t'_1}$  and  $V_P$  denote the vertex set spanned by them. We define a graph  $G_P = (V_P, E_P)$ . Further, suppose that  $M_P$  is a maximal matching of  $G_P$ . Then, it is easy to see that if  $|M_P| \leq t'_1/3 + 4\delta k$  for some  $\delta > 0$ , we can simply pick both end-points of every edge in  $M_P$ , and it would give a vertex cover of  $G_P$  of size at most  $2t'_1/3 + 8\delta k$ . On the other hand, if  $|M_P| > t'_1/3 + 4\delta k$ , we show that the graph  $G$  admits a vertex cover of size at most  $(2k - 2\delta k)$ . This fact is mentioned in the following lemma. Due to page limit, the proof is deferred to the full version of the paper [9].

► **Lemma 20.** *Let  $\delta > 0$  be any constant and  $G_P$  be as defined above. If  $G_P$  does not have a vertex cover of size  $\leq (\frac{2t'_1}{3} + 8\delta k)$ , then  $G$  has a vertex cover of size at most  $(2k - 2\delta k)$ .*

Based on the above lemma, we will assume that all single edge clusters can be covered with  $(\frac{2t'_1}{3} + 8\delta k) \leq (\frac{2t_1}{3} + 8\delta k)$  vertices; otherwise the graph has a vertex cover of size at most  $(2k - 2\delta k)$  and the soundness proof would be complete. Now, we bound the vertex cover of the entire graph in the following manner.

$$\begin{aligned}
|VC(G)| &\leq |VC\left(\bigcup_{i=1}^{t'_1} P_i\right)| + |VC'| \\
&= |VC\left(\bigcup_{i=1}^{t'_1} P_i\right)| + |VC\left(\left(\bigcup_{j=1}^{t_2} S_j\right) \cup \left(\bigcup_{k=1}^{t_3} W_k\right) \cup \left(\bigcup_{l=1}^{t_4} Y_l\right)\right)| \\
&\leq \sum_{i=1}^{t'_1} |VC(P_i)| + \sum_{i=1}^{t_2} |VC(S_i)| + \sum_{i=1}^{t_3} |VC(W_i)| + \sum_{i=1}^{t_4} |VC(Y_i)| \\
&\leq \left(\frac{2t_1}{3} + 8\delta k\right) + t_2 + \sum_{i=1}^{t_3} \left((\sqrt{2} + 1) \delta(W_i) + 1.62\right) + \sum_{i=1}^{t_4} \left((\sqrt{2} + 1) \delta(Y_i) + 1.8\right), \\
&\hspace{20em} \text{(using Lemmas 18, 19, and 20)} \\
&= (0.67)t_1 + 8\delta k + t_2 + (1.62)t_3 + (1.8)t_4 + (\sqrt{2} + 1) \left(\sum_{i=1}^{t_3} \delta(W_i) + \sum_{i=1}^{t_4} \delta(Y_i)\right)
\end{aligned}$$

Since the optimal cost  $OPT(\mathcal{X}, k) = \sum_{j=1}^k \sqrt{m_j(m_j - 1)} + \sum_{i=1}^{t_3} \delta(W_i) + \sum_{i=1}^{t_4} \delta(Y_i) \leq m - k/2 + \delta k$ ,

we get  $\sum_{i=1}^{t_3} \delta(W_i) + \sum_{i=1}^{t_4} \delta(Y_i) \leq m - k/2 + \delta k - \sum_{j=1}^k \sqrt{m_j(m_j - 1)}$ . We substitute this value in the previous equation, and get the following inequality:

$$|VC(G)| \leq (0.67)t_1 + 8\delta k + t_2 + (1.62)t_3 + (1.8)t_4 + (\sqrt{2} + 1) \cdot \left(m - k/2 - \sum_{j=1}^k \sqrt{m_j(m_j - 1)} + \delta k\right)$$

## 4:12 Hardness of Approximation for Euclidean $k$ -Median

Using Lemma 10, we obtain the following inequalities:

1. For any cluster  $P_j$  with  $|P_j| = 1$ , we have  $\sqrt{|P_j|(|P_j| - 1)} \geq |P_j| - 1$
  2. For any cluster  $S_j$  with  $|S_j| \geq 2$ , we have  $\sqrt{|S_j|(|S_j| - 1)} \geq |S_j| - (2 - \sqrt{2})$
  3. For any cluster  $W_j$  with  $|W_j| \geq 2$ , we have  $\sqrt{|W_j|(|W_j| - 1)} \geq |W_j| - (2 - \sqrt{2})$
  4. For any cluster  $Y_j$  with  $|Y_j| \geq 3$ , we have  $\sqrt{|Y_j|(|Y_j| - 1)} \geq |Y_j| - (3 - \sqrt{6})$
- We substitute these values in the previous equation, and get the following inequality:

$$|VC(G)| \leq (0.67)t_1 + 8\delta k + t_2 + (1.62)t_3 + (1.8)t_4 + (\sqrt{2} + 1) \cdot \left( m - k/2 - \sum_{j=1}^{t_1} (|P_j| - 1) \right. \\ \left. - \sum_{j=1}^{t_2} (|S_j| - (2 - \sqrt{2})) - \sum_{j=1}^{t_3} (|W_j| - (2 - \sqrt{2})) - \sum_{j=1}^{t_4} (|Y_j| - (3 - \sqrt{6})) + \delta k \right)$$

Since the number of edges  $m = \sum_{j=1}^{t_1} |P_j| + \sum_{j=1}^{t_2} |S_j| + \sum_{j=1}^{t_3} |W_j| + \sum_{j=1}^{t_4} |Y_j|$ , we get the following inequality:

$$|VC(G)| \leq (0.67)t_1 + 8\delta k + t_2 + (1.62)t_3 + (1.8)t_4 + (\sqrt{2} + 1) \cdot \left( -k/2 + t_1 + t_2 \cdot (2 - \sqrt{2}) + \right. \\ \left. + t_3 \cdot (2 - \sqrt{2}) + t_4 \cdot (3 - \sqrt{6}) + \delta k \right)$$

We substitute  $k = t_1 + t_2 + t_3 + t_4$ , and obtain the following inequality:

$$|VC(G)| \leq (0.67)t_1 + 8\delta k + t_2 + (1.62)t_3 + (1.8)t_4 + (\sqrt{2} + 1) \cdot \left( \frac{t_1}{2} + \frac{t_2}{10} + \frac{t_3}{10} + \frac{3t_4}{50} + \delta k \right) \\ = (1.88)t_1 + (1.25)t_2 + (1.87)t_3 + (1.95)t_4 + (\sqrt{2} + 9) \delta k \\ < (1.95)k + (\sqrt{2} + 9) \delta k \quad (\text{using } t_3 + t_4 + t_1 + t_2 = k) \\ \leq (2 - \varepsilon)k, \quad \text{for appropriately small constants } \varepsilon, \delta > 0$$

This proves the soundness condition and it completes the proof of Theorem 14. Note that the result holds under the Unique Games Conjecture. To prove the result in a weaker assumption of  $P \neq NP$ , it would require to show that  $|VC(G)| < (1.36)k$  instead of  $|VC(G)| < (1.95)k$ . That would require tighter analysis of the cost of  $k$ -median instances than the one done in this work.

In the next section, we extend the above techniques to give the bi-criteria inapproximability results for the Euclidean  $k$ -median and  $k$ -means problems.

### 4 Bi-criteria Hardness of Approximation

In the previous section, we showed that the  $k$ -median problem cannot be approximated to any factor smaller than  $(1 + \varepsilon)$ , where  $\varepsilon$  is some positive constant. The next step in the *beyond worst-case* discussion is to study the bi-criteria approximation algorithms. That is, we allow the algorithm to choose more than  $k$  centers and analyse whether it produces a solution that is close to the optimal solution with respect to  $k$  centers? Since the algorithm is allowed to output more than  $k$  centers we can hope to get a better approximate solution. An interesting question in this regard would be: *Does there exist a PTAS (polynomial time approximation scheme) for the  $k$ -median/ $k$ -means problem when the algorithm is allowed to choose  $\beta k$  centers for some constant  $\beta > 1$ ?* In other words, is there an  $(1 + \varepsilon, \beta)$ -approximation algorithm? Note that here we compare the cost of  $\beta k$  centers with the optimal cost with respect to  $k$  centers. See Definition 3 in Section 1 for formal definition of  $(\alpha, \beta)$  bi-criteria approximation algorithms.

In this section, we show that even with  $\beta k$  centers, the  $k$ -means/ $k$ -median problems cannot be approximated within any factor smaller than  $(1 + \varepsilon')$ , for some constant  $\varepsilon' > 0$ . The following theorem state this result formally.

► **Theorem 21** (*k*-median). *For any constant  $1 < \beta < 1.015$ , there exists a constant  $\varepsilon > 0$  such that there is no  $(1 + \varepsilon, \beta)$ -approximation algorithm for the Euclidean  $k$ -median problem assuming the Unique Games Conjecture.*

► **Theorem 22** (*k*-means). *For any constant  $1 < \beta < 1.28$ , there exists a constant  $\varepsilon > 0$  such that there is no  $(1 + \varepsilon, \beta)$ -approximation algorithm for the Euclidean  $k$ -means problem assuming the Unique Games Conjecture. Moreover, the same result holds for any  $1 < \beta < 1.1$  under the assumption that  $P \neq NP$ .*

First, let us prove the bi-criteria inapproximability result for the  $k$ -median problem.

### 4.1 Bi-criteria Inapproximability: $k$ -Median

In this subsection, we give a proof of Theorem 21. Let us define a few notations. Suppose  $\mathcal{I} = (\mathcal{X}, k)$  be some  $k$ -median instance. Then,  $OPT(\mathcal{X}, k)$  denote the optimal  $k$ -median cost of  $\mathcal{X}$ . Similarly,  $OPT(\mathcal{X}, \beta k)$  denote the optimal  $\beta k$ -median cost of  $\mathcal{X}$  (or the optimal cost of  $\mathcal{X}$  with  $\beta k$  centers). We use the same reduction as we used in the previous section for showing the hardness of approximation of the  $k$ -median problem. Based on the reduction, we establish the following theorem.

► **Theorem 23.** *There is an efficient reduction from Vertex Cover on bounded degree triangle-free graphs  $G$  (with  $m$  edges) to Euclidean  $k$ -median instances  $\mathcal{I} = (\mathcal{X}, k)$  that satisfies the following properties:*

1. *If  $G$  has a vertex cover of size  $k$ , then  $OPT(\mathcal{X}, k) \leq m - k/2$*
2. *For any constant  $1 < \beta < 1.015$ , there exists constants  $\varepsilon, \delta > 0$  such that if  $G$  has no vertex cover of size  $\leq (2 - \varepsilon) \cdot k$ , then  $OPT(\mathcal{X}, \beta k) \geq m - k/2 + \delta k$ .*

**Proof.** Since the reduction is the same as we discussed in Section 1.2 and 3, we keep all notations the same as before. Also, note that Property 1 in this theorem is the same as Property 1 of Theorem 14. Therefore, the proof is also the same as we did in Section 3.1. Now, we directly move to the proof of Property 2.

The proof is almost the same as we gave in Section 3.2. However, it has some minor differences since we consider the optimal cost with respect to  $\beta k$  centers instead of  $k$  centers. Now, we prove the following contrapositive statement: “For any constants  $1 < \beta < 1.015$  and  $\varepsilon > 0$ , there exists constants  $\varepsilon, \delta > 0$  such that if  $OPT(\mathcal{X}, \beta k) < (m - k/2 + \delta k)$  then  $G$  has a vertex cover of size at most  $(2 - \varepsilon)k$ ”. Let  $\mathcal{C}$  denote an optimal clustering of  $\mathcal{X}$  with  $\beta k$  centers. We classify its optimal clusters into two categories: (1) *star* and (2) *non-star*. Further, we sub-classify the star clusters into the following two sub-categories:

- (a) Clusters composed of exactly one edge. Let these clusters be:  $P_1, P_2, \dots, P_{t_1}$ .
- (b) Clusters composed of at least two edges. Let these clusters be:  $S_1, S_2, \dots, S_{t_2}$ .

Similarly, we sub-classify the non-star clusters into the following two sub-categories:

- (i) Clusters with a maximum matching of size two. Let these clusters be:  $W_1, W_2, \dots, W_{t_3}$
- (ii) Clusters with a maximum matching of size at least three. Let these clusters be:  $Y_1, Y_2, \dots, Y_{t_4}$

Note that  $t_1 + t_2 + t_3 + t_4$  equals  $\beta k$ . Suppose, we first compute a vertex cover of all the clusters except the single edge clusters:  $P_1, \dots, P_{t_1}$ . Let that vertex cover be  $VC'$ . Now, some vertices in  $VC'$  might also cover the edges in  $P_1, \dots, P_{t_1}$ . Suppose there are  $t'_1$  single edge clusters

#### 4:14 Hardness of Approximation for Euclidean k-Median

that remain uncovered by  $VC'$ . Without loss of generality, we assume that these clusters are  $P_1, \dots, P_{t_1}$ . By Lemma 20, we can cover these clusters with  $(\frac{2t_1}{3} + 8\delta k) \leq (\frac{2t_1}{3} + 8\delta k)$  vertices; otherwise the graph would have a vertex cover of size at most  $(2k - \delta k)$ , and the proof of Property 2 would be complete. Now, we bound the vertex cover of the entire graph in the following manner.

$$\begin{aligned} |VC(G)| &\leq \sum_{i=1}^{t_1} |VC(P_i)| + \sum_{i=1}^{t_2} |VC(S_i)| + \sum_{i=1}^{t_3} |VC(W_i)| + \sum_{i=1}^{t_4} |VC(Y_i)| \\ &\leq \left(\frac{2t_1}{3} + 8\delta k\right) + t_2 + \sum_{i=1}^{t_3} ((\sqrt{2} + 1)\delta(W_i) + 1.62) + \sum_{i=1}^{t_4} ((\sqrt{2} + 1)\delta(Y_i) + 1.8), \\ &\hspace{15em} \text{(using Lemmas 18, 19, and 20)} \\ &= (0.67)t_1 + 8\delta k + t_2 + (1.62)t_3 + (1.8)t_4 + (\sqrt{2} + 1) \left( \sum_{i=1}^{t_3} \delta(W_i) + \sum_{i=1}^{t_4} \delta(Y_i) \right) \end{aligned}$$

Since the optimal cost  $OPT(\mathcal{X}, \beta k) = \sum_{j=1}^{\beta k} \sqrt{m_j(m_j - 1)} + \sum_{i=1}^{t_3} \delta(W_i) + \sum_{i=1}^{t_4} \delta(Y_i) \leq m - k/2 + \delta k$ ,

we get  $\sum_{i=1}^{t_3} \delta(W_i) + \sum_{i=1}^{t_4} \delta(Y_i) \leq m - k/2 + \delta k - \sum_{j=1}^{\beta k} \sqrt{m_j(m_j - 1)}$ . We substitute this value in the previous equation, and get the following inequality:

$$|VC(G)| \leq (0.67)t_1 + 8\delta k + t_2 + (1.62)t_3 + (1.8)t_4 + (\sqrt{2} + 1) \cdot \left( m - k/2 - \sum_{j=1}^{\beta k} \sqrt{m_j(m_j - 1)} + \delta k \right)$$

Using Lemma 10, we obtain the following inequalities:

1. For  $P_j$ ,  $\sqrt{m(P_j)(m(P_j) - 1)} \geq m(P_j) - 1$  since  $m(P_j) = 1$
2. For  $S_j$ ,  $\sqrt{m(S_j)(m(S_j) - 1)} \geq m(S_j) - (2 - \sqrt{2})$  since  $m(S_j) \geq 2$
3. For  $W_j$ ,  $\sqrt{m(W_j)(m(W_j) - 1)} \geq m(W_j) - (2 - \sqrt{2})$  since  $m(W_j) \geq 2$
4. For  $Y_j$ ,  $\sqrt{m(Y_j)(m(Y_j) - 1)} \geq m(Y_j) - (3 - \sqrt{6})$  since  $m(Y_j) \geq 3$

We substitute these values in the previous equation, and get the following inequality:

$$\begin{aligned} |VC(G)| &\leq (0.67)t_1 + 8\delta k + t_2 + (1.62)t_3 + (1.8)t_4 + (\sqrt{2} + 1) \cdot \left( m - k/2 - \sum_{j=1}^{t_1} (m(P_j) - 1) + \right. \\ &\quad \left. - \sum_{j=1}^{t_2} (m(S_j) - (2 - \sqrt{2})) - \sum_{j=1}^{t_3} (m(W_j) - (2 - \sqrt{2})) - \sum_{j=1}^{t_4} (m(Y_j) - (3 - \sqrt{6})) + \delta k \right) \end{aligned}$$

Since  $m = \sum_{j=1}^{t_1} m(P_j) + \sum_{j=1}^{t_2} m(S_j) + \sum_{j=1}^{t_3} m(W_j) + \sum_{j=1}^{t_4} m(Y_j)$ , we get the following inequality:

$$\begin{aligned} |VC(G)| &\leq (0.67)t_1 + 8\delta k + t_2 + (1.62)t_3 + (1.8)t_4 + (\sqrt{2} + 1) \cdot \left( -k/2 + t_1 + t_2 \cdot (2 - \sqrt{2}) + \right. \\ &\quad \left. + t_3 \cdot (2 - \sqrt{2}) + t_4 \cdot (3 - \sqrt{6}) + \delta k \right) \\ &= (0.67)t_1 + 8\delta k + t_2 + (1.62)t_3 + (1.8)t_4 + (\sqrt{2} + 1) \cdot \left( \frac{(\beta - 1)k}{2} - \frac{\beta k}{2} + t_1 + t_2 \cdot (2 - \sqrt{2}) + \right. \\ &\quad \left. + t_3 \cdot (2 - \sqrt{2}) + t_4 \cdot (3 - \sqrt{6}) + \delta k \right) \end{aligned}$$

Now, we substitute  $\beta k = t_1 + t_2 + t_3 + t_4$ , and obtain the following inequality:

$$\begin{aligned}
|VC(G)| &\leq (0.67)t_1 + 8\delta k + t_2 + (1.62)t_3 + (1.8)t_4 + (\sqrt{2} + 1) \cdot \left( \frac{(\beta - 1)k}{2} + \frac{t_1}{2} + \frac{t_2}{10} + \frac{t_3}{10} + \frac{3t_4}{50} + \delta k \right) \\
&= (1.88)t_1 + (1.25)t_2 + (1.87)t_3 + (1.95)t_4 + (\sqrt{2} + 1) \cdot \frac{(\beta - 1)k}{2} + (\sqrt{2} + 9) \delta k \\
&< (1.95)\beta k + (\sqrt{2} + 1) \cdot \frac{(\beta - 1)k}{2} + (\sqrt{2} + 9) \delta k && \text{(using } t_3 + t_4 + t_1 + t_2 = \beta k) \\
&< (3.16)\beta k - (1.21)k + (\sqrt{2} + 9) \delta k \\
&\leq (2 - \varepsilon)k, \quad \text{for any } \beta < 1.015 \text{ and appropriately small constants } \varepsilon, \delta > 0
\end{aligned}$$

This proves Property 2 and it completes the proof of Theorem 23.  $\blacktriangleleft$

The following corollary states the main bi-criteria inapproximability result for the  $k$ -median problem.

**► Corollary 24.** *There exists a constant  $\varepsilon' > 0$  such that for any constant  $1 < \beta < 1.015$ , there is no  $(1 + \varepsilon', \beta)$ -approximation algorithm for the  $k$ -median problem assuming the Unique Games Conjecture.*

**Proof.** In the proof of Corollary 15, we showed that  $k \geq \frac{m}{2\Delta}$  for all the hard Vertex Cover instances. Therefore, the second property of Theorem 23, implies that  $OPT(\mathcal{X}, \beta k) \geq (m - \frac{k}{2}) + \delta k \geq (1 + \frac{\delta}{2\Delta}) \cdot (m - \frac{k}{2})$ . Thus, the  $k$ -median problem can not be approximated within any factor smaller than  $1 + \frac{\delta}{2\Delta} = 1 + \Omega(\varepsilon)$ , with  $\beta k$  centers for any  $\beta < 1.015$ .  $\blacktriangleleft$

The proof for the bi-criteria inapproximability of the  $k$ -means problem works in a similar manner. We defer its proof to Appendix B.

---

## A Proof of Lemma 9

► **Lemma 25.** Let  $A = \{a_1, \dots, a_n\}$  and  $B = \{b_1, \dots, b_n\}$  be any two sets of  $n$  points in  $\mathbb{R}^d$ . If the pairwise distances between points within  $A$  is the same as pairwise distance between points within  $B$ . That is, for all  $i, j \in \{1, \dots, n\}$ ,  $\|a_i - a_j\| = \|b_i - b_j\|$ . Then the optimal 1-median cost of  $A$  is the same as the optimal 1-median cost of  $B$ .

Let  $co(A)$  and  $co(B)$  denote the convex hulls of  $A$  and  $B$ , respectively. We split the proof of Lemma 25 in two parts. In the first part (Lemma 26), we show that there exists a distance preserving transformation  $\mathcal{R}$  from  $co(A)$  to  $co(B)$  such that  $\mathcal{R}(a_i) = b_i$  for every  $i \in \{1, \dots, n\}$ . By distance preserving transformation, we mean that for any two points  $x, y \in co(A)$ , the distance  $\|x - y\|$  is preserved after applying the transformation  $\mathcal{R}$ , i.e.,  $\|x - y\| = \|\mathcal{R}(x) - \mathcal{R}(y)\|$ . In the second part (Lemma 27), we show that applying the transformation  $\mathcal{R}$  preserves the optimal 1-median cost of  $A$ .

► **Lemma 26.** Given two sets of points  $A = \{a_1, a_2, \dots, a_n\}$  and  $B = \{b_1, b_2, \dots, b_n\}$  in  $\mathbb{R}^d$  such that  $\|a_i - a_j\| = \|b_i - b_j\|$  for all  $i, j \in \{1, \dots, n\}$ . Then there exists a distance preserving transformation  $\mathcal{R}: co(A) \rightarrow co(B)$  such that  $\mathcal{R}(a_i) = b_i$  for every  $i \in \{1, \dots, n\}$ .

**Proof.** Let  $\mathbf{X}_i$  be a vector<sup>4</sup> defined as  $\mathbf{a}_i - \mathbf{a}_1$  for every  $\mathbf{a}_i \in A$ . Similarly, we define a vector  $\mathbf{Y}_i := \mathbf{b}_i - \mathbf{b}_1$  for every  $\mathbf{b}_i \in B$ . We will use these vectors to define the transformation  $\mathcal{R}$ . For now, note the following property of inner product of  $\mathbf{X}_i$  and  $\mathbf{X}_j$ .

$$\langle \mathbf{X}_i, \mathbf{X}_j \rangle = \langle \mathbf{Y}_i, \mathbf{Y}_j \rangle \quad \text{for every } i, j \in \{1, \dots, n\} \quad (1)$$

The proof of the above property follows from the following sequence of inequalities:

$$\begin{aligned} 2 \cdot \langle \mathbf{X}_i, \mathbf{X}_j \rangle &= \|\mathbf{X}_i\|^2 + \|\mathbf{X}_j\|^2 - \|\mathbf{X}_i - \mathbf{X}_j\|^2 \\ &= \|\mathbf{Y}_i\|^2 + \|\mathbf{Y}_j\|^2 - \|\mathbf{X}_i - \mathbf{X}_j\|^2, & \because \|\mathbf{X}_i\| &= \|\mathbf{a}_i - \mathbf{a}_1\| = \|\mathbf{b}_i - \mathbf{b}_1\| = \|\mathbf{Y}_i\| \\ & & & \text{for every } 1 \leq i \leq n \\ &= \|\mathbf{Y}_i\|^2 + \|\mathbf{Y}_j\|^2 - \|\mathbf{Y}_i - \mathbf{Y}_j\|^2, & \because \|\mathbf{X}_i - \mathbf{X}_j\| &= \|\mathbf{a}_i - \mathbf{a}_j\| = \|\mathbf{b}_i - \mathbf{b}_j\| = \|\mathbf{Y}_i - \mathbf{Y}_j\| \\ &= 2 \cdot \langle \mathbf{Y}_i, \mathbf{Y}_j \rangle \end{aligned}$$

In other words, the triangles  $(a_1, a_i, a_j)$  and  $(b_1, b_i, b_j)$  are congruent for all  $i, j \in \{1, \dots, n\}$ . Therefore, the inner product  $\langle \mathbf{X}_i, \mathbf{X}_j \rangle$  is the same as  $\langle \mathbf{Y}_i, \mathbf{Y}_j \rangle$ .

<sup>4</sup> For better readability, we boldfaced the vector symbols to distinguish them from any scalar quantity.

Now, we describe the transformation  $\mathcal{R}$  from  $co(A)$  to  $co(B)$ . By the definition of  $co(A)$ , any point  $\mathbf{x} \in co(A)$  can be expressed in the form  $\sum_{i=1}^n \lambda_i \cdot \mathbf{a}_i$  for some  $0 \leq \lambda_i \leq 1$  and  $\sum_{i=1}^n \lambda_i = 1$ . Equivalently,  $\mathbf{x}$  can be expressed as  $\mathbf{a}_1 + \sum_{i=2}^n \lambda_i \cdot \mathbf{X}_i$ . For  $\mathbf{x} \in co(A)$ , we define the transformation  $\mathcal{R}$  as  $\mathcal{R}(\mathbf{x}) := \sum_{i=1}^n \lambda_i \cdot \mathbf{b}_i$ . Again,  $\mathcal{R}(\mathbf{x})$  can be equivalently expressed as  $\mathbf{b}_1 + \sum_{i=2}^n \lambda_i \cdot \mathbf{Y}_i$ . It is easy to see that  $\lambda_i \cdot \mathbf{b}_i$  indeed belongs to  $co(B)$  since  $0 \leq \lambda_i \leq 1$  and  $\sum_{i=1}^n \lambda_i = 1$ . Now, we show that  $\mathcal{R}$  is a distance preserving transformation. Let  $\mathbf{x} := \mathbf{a}_1 + \sum_{i=2}^n \lambda_i \cdot \mathbf{X}_i$  and  $\mathbf{y} := \mathbf{a}_1 + \sum_{i=2}^n \gamma_i \cdot \mathbf{X}_i$  be any two points in  $co(A)$ . The following sequence of inequalities prove that  $\|\mathbf{x} - \mathbf{y}\| = \|\mathcal{R}(\mathbf{x}) - \mathcal{R}(\mathbf{y})\|$ .

$$\begin{aligned}
\|\mathbf{x} - \mathbf{y}\|^2 &= (\mathbf{x} - \mathbf{y})^T (\mathbf{x} - \mathbf{y}) \\
&= \left( \sum_{i=2}^n (\lambda_i - \gamma_i) \cdot \mathbf{X}_i \right)^T \cdot \left( \sum_{i=2}^n (\lambda_i - \gamma_i) \cdot \mathbf{X}_i \right) \\
&= \sum_{i=2}^n \sum_{j=2}^n (\lambda_i - \gamma_i) \cdot (\lambda_j - \gamma_j) \cdot \langle \mathbf{X}_i, \mathbf{X}_j \rangle \\
&= \sum_{i=2}^n \sum_{j=2}^n (\lambda_i - \gamma_i) \cdot (\lambda_j - \gamma_j) \cdot \langle \mathbf{Y}_i, \mathbf{Y}_j \rangle, && \text{(using Equation 1)} \\
&= \left( \sum_{i=2}^n (\lambda_i - \gamma_i) \cdot \mathbf{Y}_i \right)^T \cdot \left( \sum_{i=2}^n (\lambda_i - \gamma_i) \cdot \mathbf{Y}_i \right) \\
&= (\mathcal{R}(\mathbf{x}) - \mathcal{R}(\mathbf{y}))^T (\mathcal{R}(\mathbf{x}) - \mathcal{R}(\mathbf{y})) \\
&= \|\mathcal{R}(\mathbf{x}) - \mathcal{R}(\mathbf{y})\|^2
\end{aligned}$$

This proves that  $\mathcal{R}$  is a distance preserving transformation from  $co(A)$  to  $co(B)$ . Moreover, note that  $\mathcal{R}$  is a bijective function. It is possible that a vector  $\mathbf{x} \in co(A)$  has multiple forms, say  $\sum_{i=1}^n \lambda_i \cdot \mathbf{a}_i$  and  $\sum_{i=1}^n \Lambda_i \cdot \mathbf{a}_i$ . Therefore, it appears that  $\mathbf{x}$  maps to different vectors in  $co(B)$ . However, it always maps to the same vector. For the sake of contradiction, assume that  $\mathbf{x}$  maps to two different vectors  $\mathbf{p} := \sum_{i=1}^n \lambda_i \cdot \mathbf{b}_i$  and  $\mathbf{q} := \sum_{i=1}^n \Lambda_i \cdot \mathbf{b}_i$  in  $co(B)$ . Then  $\|\mathbf{p} - \mathbf{q}\| \neq 0$ . It contradicts the fact that  $\mathcal{R}$  is a distance preserving transformation. Similarly, we can show that any two different vectors  $\mathbf{x}, \mathbf{y} \in co(A)$  can not map to the same vector in  $co(B)$ . This proves that  $\mathcal{R}$  is a bijective function.

Furthermore, note that  $\mathcal{R}(\mathbf{a}_i) = \mathbf{b}_i$  for every  $i \in \{1, \dots, n\}$ . To see this, consider  $\lambda_i = 1$  and  $\lambda_j = 0$  for all  $j \in \{1, \dots, n\} \setminus \{i\}$ . Then  $\mathbf{a}_i = \sum_{j=1}^n \lambda_j \cdot \mathbf{a}_j$  and therefore  $\mathcal{R}(\mathbf{a}_i) = \sum_{j=1}^n \lambda_j \cdot \mathbf{b}_j = \mathbf{b}_i$ . This completes the proof of the lemma.  $\blacktriangleleft$

Similar to  $\mathcal{R}$ , we can also define a distance preserving transformation  $\mathcal{R}^{-1}$  from  $co(B)$  to  $co(A)$ . The transformation  $\mathcal{R}^{-1}$  is defined such that for any  $\mathbf{x} = \sum_{i=1}^n \lambda_i \cdot \mathbf{b}_i \in co(B)$ ,

$\mathcal{R}^{-1}(x) = \sum_{i=1}^n \lambda_i \cdot \mathbf{a}_i \in \text{co}(A)$ . Furthermore, as per this definition of  $\mathcal{R}^{-1}$ ,  $\mathcal{R}^{-1}(\mathbf{b}_i) = \mathbf{a}_i$  for every  $i \in \{1, \dots, n\}$ . Now, we show that applying the transformation  $\mathcal{R}$  on  $A$  preserves the optimal 1-median cost of  $A$ .

► **Lemma 27.** *If there exists distance preserving transformations  $\mathcal{R}: \text{co}(A) \rightarrow \text{co}(B)$  and  $\mathcal{R}^{-1}: \text{co}(B) \rightarrow \text{co}(A)$  such that  $\mathcal{R}(\mathbf{a}_i) = \mathbf{b}_i$  and  $\mathcal{R}^{-1}(\mathbf{b}_i) = \mathbf{a}_i$  for every  $i \in \{1, \dots, n\}$ . Then the optimal 1-median cost of  $A$  is the same as the optimal 1-median cost of  $B$ .*

**Proof.** Recall that 1-median cost of an instance  $A$  with respect to a center  $\mathbf{c} \in \mathbb{R}^d$  is denoted by  $\Phi(\mathbf{c}, A) \equiv \sum_{\mathbf{a}_i \in A} \|\mathbf{a}_i - \mathbf{c}\|$ . Let  $\mathbf{c}_1^*$  be the optimal 1-median of  $A$ . Furthermore, we can assume that  $\mathbf{c}_1^* \in \text{co}(A)$  since the optimal 1-median lies in the convex hull of  $A$  (see *e.g.* Remark 2.1 in [39]). Similarly, let  $\mathbf{c}_2^* \in \text{co}(B)$  be the optimal 1-median of  $B$ . Now, we show that  $\Phi(\mathbf{c}_1^*, A) \geq \Phi(\mathbf{c}_2^*, B)$  and  $\Phi(\mathbf{c}_1^*, A) \leq \Phi(\mathbf{c}_2^*, B)$  using the following sequence of inequalities:

$$\begin{aligned} \Phi(\mathbf{c}_1^*, A) &= \sum_{\mathbf{a}_i \in A} \|\mathbf{a}_i - \mathbf{c}_1^*\| \\ &= \sum_{\mathbf{a}_i \in A} \|\mathcal{R}(\mathbf{a}_i) - \mathcal{R}(\mathbf{c}_1^*)\|, && \because \mathcal{R} \text{ preserves the pairwise distances} \\ &= \sum_{\mathbf{b}_i \in B} \|\mathbf{b}_i - \mathcal{R}(\mathbf{c}_1^*)\|, && \because \mathcal{R}(\mathbf{a}_i) = \mathbf{b}_i \\ &\geq \sum_{\mathbf{b}_i \in B} \|\mathbf{b}_i - \mathbf{c}_2^*\|, && \because \mathbf{c}_2^* \text{ is the optimal 1-median of } B \\ &= \Phi(\mathbf{c}_2^*, B) \end{aligned}$$

Similarly, we show that  $\Phi(\mathbf{c}_2^*, B) \geq \Phi(\mathbf{c}_1^*, A)$  as follows:

$$\begin{aligned} \Phi(\mathbf{c}_2^*, B) &= \sum_{\mathbf{b}_i \in B} \|\mathbf{b}_i - \mathbf{c}_2^*\| \\ &= \sum_{\mathbf{b}_i \in B} \|\mathcal{R}^{-1}(\mathbf{b}_i) - \mathcal{R}^{-1}(\mathbf{c}_2^*)\|, && \because \mathcal{R}^{-1} \text{ preserves the pairwise distances} \\ &= \sum_{\mathbf{a}_i \in A} \|\mathbf{a}_i - \mathcal{R}^{-1}(\mathbf{c}_2^*)\|, && \because \mathcal{R}^{-1}(\mathbf{b}_i) = \mathbf{a}_i \\ &\geq \sum_{\mathbf{a}_i \in A} \|\mathbf{a}_i - \mathbf{c}_1^*\|, && \because \mathbf{c}_1^* \text{ is the optimal 1-median of } A \\ &= \Phi(\mathbf{c}_1^*, A) \end{aligned}$$

This proves that  $\Phi(\mathbf{c}_1^*, A) = \Phi(\mathbf{c}_2^*, B)$ . Hence it proves the lemma. ◀

Therefore, Lemma 26 and 27 together proves Lemma 25.

## **B** Bi-criteria Inapproximability: k-means

Here, we again use the same reduction that we used earlier for the  $k$ -median problem in Sections 1.2, 3, and 4.1. Using this, we establish the following theorem.

► **Theorem 28.** *There is an efficient reduction from Vertex Cover on bounded degree triangle-free graphs  $G$  (with  $m$  edges) to Euclidean  $k$ -means instances  $\mathcal{I} = (\mathcal{X}, k)$  that satisfies the following properties:*

1. If  $G$  has a vertex cover of size  $k$ , then  $OPT(\mathcal{X}, k) \leq m - k$
2. For any  $1 < \lambda \leq 2$  and  $\beta < \frac{2}{7} \cdot \left(\lambda + \frac{5}{2}\right)$ , there exists constants  $\varepsilon, \delta > 0$  such that if  $G$  has no vertex cover of size  $\leq (\lambda - \varepsilon) \cdot k$ , then  $OPT(\mathcal{X}, \beta k) \geq m - k + \delta k$ .

This theorem is simply an extension of the result of Awasthi *et al.* [7] to the bi-criteria setting. Now, let us prove this theorem.

## B.1 Completeness

Note that the proof of completeness is already given in [7]. Therefore, we just describe the main components of the proof for the sake of clarity. To understand the proof, let us define some notations used in [7]. Suppose  $F$  is a subgraph of  $G$ . For a vertex  $v \in V(F)$ , let  $d_F(v)$  denote the number of edges in  $F$  that are incident on  $v$ . Note that, the optimal center for 1-means problem is simply the centroid of the point set. Therefore, we can compute the optimal 1-means cost of  $F$ . The following lemma states the optimal 1-means cost of  $F$ .

► **Lemma 29** (Claim 4.3 [7]). *Let  $F$  be a subgraph of  $G$  with  $r$  edges. Then, the optimal 1-means cost of  $F$  is  $\sum_v d_F(v) \left(1 - \frac{d_F(v)}{r}\right)$*

The following corollary bounds the optimal 1-means cost of a star cluster. This corollary is implicitly stated in the proof of Claim 4.4 of [7].

► **Corollary 30.** *The optimal 1-means cost of a star cluster with  $r$  edges is  $r - 1$ .*

Using the above corollary, we give the proof of completeness. Let  $V = \{v_1, \dots, v_k\}$  be a vertex cover of  $G$ . Let  $S_i$  denote the set of edges covered by  $v_i$ . If an edge is covered by two vertices  $i$  and  $j$ , then we arbitrarily keep the edge either in  $S_i$  or  $S_j$ . Let  $m_i$  denote the number of edges in  $S_i$ . We define  $\{\mathcal{X}(S_1), \dots, \mathcal{X}(S_k)\}$  as a clustering of the point set  $\mathcal{X}$ . Now, we show that the cost of this clustering is at most  $m - k$ . Note that each  $S_i$  forms a star graph with its edges sharing the common vertex  $v_i$ . The following sequence of inequalities bound the optimal  $k$ -means cost of  $\mathcal{X}$ .

$$OPT(\mathcal{X}, k) \leq \sum_{i=1}^k \Phi^*(S_i) \stackrel{\text{(Corollary 30)}}{=} \sum_{i=1}^k (m(S_i) - 1) = m - k.$$

## B.2 Soundness

For the proof of soundness, we prove the following contrapositive statement: “For any constant  $1 < \lambda \leq 2$  and  $\beta < \frac{2}{7} \cdot \left(\lambda + \frac{5}{2}\right)$ , there exists constants  $\varepsilon, \delta > 0$  such that if  $OPT(\beta k) \leq (m - k + \delta k)$  then  $G$  has a vertex cover of size at most  $(\lambda - \varepsilon)k$ , for  $\varepsilon = \Omega(\delta)$ .” Let  $\mathcal{C}$  denote an optimal clustering of  $\mathcal{X}$  with  $\beta k$  centers. We classify its optimal clusters into two categories: (1) *star* and (2) *non-star*. Suppose there are  $t_1$  star clusters:  $S_1, \dots, S_{t_1}$ , and  $t_2$  non-star clusters:  $F_1, F_2, \dots, F_{t_2}$ . Note that  $t_1 + t_2$  equals  $\beta k$ . The following lemma bounds the optimal 1-means cost of a non-star cluster.

► **Lemma 31** (Lemma 4.8 [7]). *The optimal 1-means cost of any non-star cluster  $F$  with  $m$  edges is at least  $m - 1 + \delta(F)$ , where  $\delta(F) \geq \frac{2}{3}$ . Furthermore, there is an edge  $(u, v) \in E(F)$  such that  $d_F(u) + d_F(v) \geq m + 1 - \delta(F)$ .*

In the original statement of the lemma in [7], the authors mentioned a weak bound of  $\delta(F) > 1/2$ . However, in the proof of their lemma they have shown  $\delta(F) > 2/3 > 1/2$ . This difference does not matter when we consider inapproximability of the  $k$ -means problem. However, this difference improves the  $\beta$  value in bi-criteria inapproximability of the  $k$ -means problem.

## 4:22 Hardness of Approximation for Euclidean k-Median

► **Corollary 32** ([7]). *Any non-star cluster  $F$  has a vertex cover of size at most  $1 + \frac{5}{2} \cdot \delta(F)$ .*

**Proof.** Suppose  $(u, v)$  be an edge in  $F$  that satisfies the property:  $d_F(u) + d_F(v) \geq m + 1 - \delta(F)$ , by Lemma 31. This means that  $u$  and  $v$  covers at least  $m(F) - \delta(F)$  edges of  $F$ . We pick  $u$  and  $v$  in the vertex cover, and for the remaining  $\delta(F)$  edges we pick one vertex per edge. Therefore,  $F$  has a vertex cover of size at most  $2 + \delta(F)$ . Since  $\delta(F) \geq \frac{2}{3}$ , by Lemma 31, we get  $2 + \delta(F) \leq 1 + \frac{5}{2} \cdot \delta(F)$ . Hence,  $F$  has a vertex cover of size at most  $1 + \frac{5}{2} \cdot \delta(F)$ . This proves the corollary. ◀

Now, the following sequence of inequalities bound the vertex cover size of the entire graph  $G$ .

$$\begin{aligned} |VC(G)| &\leq \sum_{i=1}^{t_1} |VC(S_i)| + \sum_{i=1}^{t_2} |VC(F_i)| \\ &\leq t_1 + \sum_{i=1}^{t_2} \left(1 + \frac{5}{2} \cdot \delta(F_i)\right) \quad (\text{using Corollary 32}) \\ &= t_1 + t_2 + \frac{5}{2} \cdot \sum_{i=1}^{t_2} \delta(F_i) \end{aligned}$$

Since the optimal  $k$ -means cost  $OPT(\mathcal{X}, \beta k) = \sum_{i=1}^{t_1} (m(S_i) - 1) + \sum_{i=1}^{t_2} (m(F_i) - 1 + \delta(F_i)) \leq m - k + \delta k$ , and  $t_1 + t_2 = \beta k$ . Therefore,  $\sum_{i=1}^{t_2} \delta(F_i) \leq (\beta - 1)k + \delta k$ . On substituting this value in the previous equation, we get the following inequality:

$$\begin{aligned} |VC(G)| &\leq t_1 + t_2 + \frac{5}{2} \cdot (\beta - 1)k + \frac{5}{2} \cdot \delta k \\ &= \beta k + \frac{5}{2} \cdot (\beta - 1)k + \frac{5}{2} \cdot \delta k, \quad (\because t_1 + t_2 = \beta k) \\ &\leq (\lambda - \varepsilon)k, \quad \text{for any } \beta < \frac{2}{7} \cdot \left(\lambda + \frac{5}{2}\right) \text{ and appropriately small constants } \varepsilon, \delta > 0 \end{aligned}$$

This proves the soundness condition and thus completes the proof of Theorem 28.

Next, we state a corollary of Theorem 28 that gives the main bi-criteria inapproximability result for the  $k$ -means problem.

► **Corollary 33.** *For any constant  $1 < \beta < 1.28$ , there exists a constant  $\varepsilon' > 0$  such that there is no  $(1 + \varepsilon', \beta)$ -approximation algorithm for the  $k$ -means problem assuming the Unique Games Conjecture. Moreover, the same result holds for any  $1 < \beta < 1.1$  under the assumption that  $P \neq NP$ .*

**Proof.** Suppose Vertex Cover can not be approximated to any factor smaller than  $\lambda - \varepsilon$ , for some constants  $\varepsilon, \lambda > 0$ . In the proof of Corollary 15, we showed that  $k \geq \frac{m}{2\Delta}$  for all the hard Vertex Cover instances. In that case, the second property of Theorem 28 implies that  $OPT(\mathcal{X}, \beta k) \geq (m - k) + \delta k \geq (1 + \frac{\delta}{2\Delta}) \cdot (m - k)$ . Thus, the  $k$ -means problem can not be approximated within any factor smaller than  $1 + \frac{\delta}{2\Delta} = 1 + \Omega(\varepsilon)$ , with  $\beta k$  centers. Now, let us compute the value of  $\beta$  using the value of  $\lambda$ . We know that  $\beta < \frac{2}{7} \cdot \left(\lambda + \frac{5}{2}\right)$ . Consider the following two cases:

- By Corollary 13, Vertex Cover is hard to approximate within any factor smaller than  $2 - \varepsilon$  on bounded degree triangle-free graphs assuming UGC. Hence  $\lambda = 2$  and thus  $\beta < 1.28$  assuming UGC.

- By Theorem 7, Vertex Cover is hard to approximate within any factor smaller than 1.36 on bounded degree triangle-free graphs assuming  $P \neq NP$ . Hence  $\lambda = 1.36$  and thus  $\beta < 1.1$  assuming  $P \neq NP$ .

This completes the proof of the corollary. ◀

## Abstract

We present online algorithms for directed spanners and directed Steiner forests. These are well-studied network connectivity problems that fall under the unifying framework of online covering and packing linear programming formulations. This framework was developed in the seminal work of Buchbinder and Naor (Mathematics of Operations Research, 34, 2009) and is based on primal-dual techniques. Specifically, our results include the following:

- For the *pairwise spanner* problem, in which the pairs of vertices to be spanned arrive online, we present an efficient randomized algorithm with competitive ratio  $\tilde{O}(n^{4/5})$  for graphs with general edge lengths, where  $n$  is the number of vertices of the given graph. For graphs with uniform edge lengths, we give an efficient randomized algorithm with competitive ratio  $\tilde{O}(n^{2/3+\epsilon})$ , and an efficient deterministic algorithm with competitive ratio  $\tilde{O}(k^{1/2+\epsilon})$ , where  $k$  is the number of terminal pairs. To the best of our knowledge, these are the first online algorithms for directed spanners. In the offline version, the current best approximation ratio for uniform edge lengths is  $\tilde{O}(n^{3/5+\epsilon})$ , due to Chlamtáč, Dinitz, Kortsarz, and Laekhanukit (SODA 2017, TALG 2020).
- For the *directed Steiner forest* problem with uniform costs, in which the pairs of vertices to be connected arrive online, we present an efficient randomized algorithm with competitive ratio  $\tilde{O}(n^{2/3+\epsilon})$ . The state-of-the-art online algorithm for general costs is due to Chakrabarty, Ene, Krishnaswamy, and Panigrahi (SICOMP 2018) and is  $\tilde{O}(k^{1/2+\epsilon})$ -competitive. In the offline version, the current best approximation ratio with uniform costs is  $\tilde{O}(n^{26/45+\epsilon})$ , due to Abboud and Bodwin (SODA 2018).

To obtain *efficient* and *competitive* online algorithms, we observe that a small modification of the online covering and packing framework by Buchbinder and Naor implies a polynomial-time implementation of the primal-dual approach with separation oracles, which a priori might perform exponentially many calls to the oracle. We convert the online spanner problem into an online covering problem and complete the rounding-step analysis in a problem-specific fashion.

## 1 Introduction

We study online variants of directed network optimization problems. In an online problem, the input is presented sequentially, one item at a time, and the algorithm is forced to make irrevocable decisions in each step, without knowledge of the remaining part of the input. The performance of the algorithm is measured by its *competitive ratio*, which is the ratio between the value of the online solution and that of an optimal offline solution.

Our main results focus on *directed spanners*, which are sparse subgraphs that approximately preserve pairwise distances between vertices. Spanners are fundamental combinatorial objects with a wide range of applications, such as distributed computation [9, 69], data structures [5, 75], routing schemes [35, 67, 70, 72], approximate shortest paths [18, 41, 42], distance oracles [18, 31, 68], and property testing [8, 22]. For a comprehensive account of the literature, we refer the reader to the excellent survey [2].

We also study related network *connectivity* problems, and in particular on *directed Steiner forests*, which are sparse subgraphs that maintain connectivity between target terminal vertex pairs. Steiner forests are ubiquitously used in a heterogeneous collection of areas, such as multicommodity network design [49, 53], mechanism design and games [30, 63, 64, 73], computational biology [62, 71], and computational geometry [19, 24].

Our approaches are based on covering and packing linear programming (LP) formulations that fall into the unifying framework developed by Buchbinder and Naor [26], using the powerful primal-dual technique [51]. This unifying framework extends across widely different domains, and hence provides a general abstraction that captures the algorithmic essence of all online covering and packing formulations. In our case, to obtain *efficient* competitive algorithms for solving the LPs online, we observe that the algorithms in [26] can be slightly modified to significantly speed up the setting of our applications, in which the algorithm might otherwise make exponentially many calls to a separation oracle. This component is not tailored to the applications studied here and may be of independent interest. In particular, previous approaches solving online covering and packing problems either focus on the competitiveness of the algorithm [4, 12, 16], or manage to leverage the specific structure of the problem for better time efficiency in a somewhat ad-hoc manner [3, 11, 15, 21, 25, 59], while here the solution may be viewed as a more *unified* framework that is also *efficient*.

### 1.1 Our contributions

#### 1.1.1 Directed spanners

Let  $G = (V, E)$  be a directed simple graph with  $n$  vertices. Each edge is associated with its *length*  $\ell : E \rightarrow \mathbb{R}_{\geq 0}$ . The edge lengths are *uniform* if  $\ell(e) = 1$  for all  $e \in E$ . In spanner problems, the goal is to compute a minimum cardinality (number of edges) subgraph in which the distance between terminals is preserved up to some prescribed factor. In the most well-studied setting, called the *directed  $s$ -spanner* problem, there is a fixed value  $s \geq 1$  called the *stretch*, and the goal is to find a minimum cardinality subgraph in which *every* pair of vertices has distance within a factor of  $s$  in the original graph. For low stretch spanners, when  $s = 2$ , there is a tight  $\Theta(\log n)$ -approximation algorithm [44, 65]; when  $s = 3, 4$  both with uniform edge lengths, there are  $\tilde{O}(n^{1/3})$ -approximation algorithms [20, 40]. When  $s > 4$ , the best known approximation factor is  $\tilde{O}(n^{1/2})$  [20]. The problem is hard to approximate within an  $O(2^{\log^{1-\varepsilon} n})$  factor for  $3 \leq s = O(n^{1-\delta})$  and any  $\varepsilon, \delta \in (0, 1)$ , unless  $NP \subseteq DTIME(n^{\text{polylog } n})$  [45].

A more general setting, called the *pairwise spanner* problem [34], and the *client-server* model [22, 44], considers an arbitrary set of terminals  $D = \{(s_i, t_i) \mid i \in [k]\} \subseteq V \times V$ . Each terminal pair  $(s_i, t_i)$  has its own target distance  $d_i$ . The goal is to compute a minimum cardinality subgraph in which for each  $i$ , the distance from  $s_i$  to  $t_i$  is at most  $d_i$ . For the pairwise spanner problem with uniform edge lengths, [34] obtains an  $\tilde{O}(n^{3/5+\epsilon})$ -approximation.

In the online version, the graph is known ahead of time, and the terminal pairs and the corresponding target distances are received one by one in an online fashion. The distance requirement of the arriving terminal pair is satisfied by irrevocably including edges. There are no online algorithms for the pairwise spanner problem that we are aware of, even in the simpler and long-studied case of stretch  $s$  or graphs with uniform lengths.

For graphs with uniform edge lengths, we present the proof outline of the following theorem in Section 2 and refer the reader to the full version [52] for the complete proof.

► **Theorem 1.** *For the online pairwise spanner problem with uniform edge lengths, there exists a deterministic polynomial time algorithm with competitive ratio  $\tilde{O}(k^{1/2+\delta})$  for any constant  $\delta > 0$ .*

Next, we turn to graphs with general edge lengths and derive online algorithms with competitive ratios in terms of  $n$ . We present a generic algorithm (Algorithm 3) used for Theorems 2, 3, 4, 5, 6, and 7. Due to space limitations, we refer the reader to the full version [52] for the complete proof of Theorems 3, 4, and 5.

For graphs with general edge lengths, we show the following in Section 3.1.

► **Theorem 2.** *For the online pairwise spanner problem, there is a randomized polynomial time algorithm with competitive ratio  $\tilde{O}(n^{4/5})$ .*

In one special case, the given graph might have uniform edge lengths, and the diameter is bounded or it is guaranteed that the distances between the terminal pairs are bounded. Let  $d = \max_{i \in [k]} \{d_i\}$  that is known offline be the maximum allowed distance of any pair of terminals in the input. This setting is equivalent to the *d-diameter spanning subgraph* problem introduced in [22].

► **Theorem 3.** *For the online pairwise spanner problem with uniform edge lengths and maximum allowed distance  $d$ , there is a randomized polynomial time algorithm with competitive ratio  $\tilde{O}(d^{1/3}n^{2/3})$ .*

Another special case is where the edge lengths are *quasimetric*. That is, they satisfy the following directed form of the triangle inequality. For any two edges  $u \rightarrow v$  and  $v \rightarrow w$ , there is also an edge  $u \rightarrow w$  such that  $\ell(u, w) \leq \ell(u, v) + \ell(v, w)$ . This setting includes the class of transitive-closure graphs with uniform edge lengths, in which each pair of vertices connected by a directed path is also connected by a directed edge. The offline version of the *transitive-closure spanner* problem was formally defined in [22].

► **Theorem 4.** *For the online pairwise spanner problem where edge lengths are quasimetric, there is a randomized polynomial time algorithm with competitive ratio  $\tilde{O}(n^{2/3})$ .*

In a special case on graphs with uniform edge lengths, for each terminal pair  $(s_i, t_i)$ , there is also an edge  $s_i \rightarrow t_i$  in the given graph. This setting is equivalent to the *all-server spanner* problem introduced in [44].

► **Theorem 5.** *For the online all-server spanner problem with uniform edge lengths, there is a randomized polynomial time algorithm with competitive ratio  $\tilde{O}(n^{2/3})$ .*

## 5:4 Online Directed Spanners and Steiner Forests

For graphs with uniform edge lengths without further assumptions, we use Theorem 1 and the generic algorithm to prove the following theorem in Section 3.2.

► **Theorem 6.** *For the online pairwise spanner problem with uniform edge lengths, there is a randomized polynomial time algorithm with competitive ratio  $\tilde{O}(n^{2/3+\varepsilon})$  for any constant  $\varepsilon \in (0, 1/3)$ .*

### 1.1.2 Directed Steiner forests

In the *directed Steiner forest* problem, we are given a directed graph  $G = (V, E)$  with edge costs  $w : E \rightarrow \mathbb{R}_{\geq 0}$ , and a set of terminals  $D = \{(s_i, t_i) \mid i \in [k]\} \subseteq V \times V$ . The goal is to find a subgraph  $H = (V, E')$  which includes an  $s_i \rightsquigarrow t_i$  path for each terminal pair  $(s_i, t_i)$ , and the total cost  $\sum_{e \in E'} w(e)$  is minimized. The costs are *uniform* when  $w(e) = 1$  for all  $e \in E$ .

In the offline setting with general costs, the best known approximations are  $O(k^{1/2+\varepsilon})$  by Chekuri et al. [32] and  $O(n^{2/3+\varepsilon})$  by Berman et al. [20]. For the special case of uniform costs, there is an improved approximation factor of  $\tilde{O}(n^{26/45+\varepsilon})$  by Abboud and Bodwin [1]. In the online setting, Chakrabarty et al. [28] give an  $\tilde{O}(k^{1/2+\varepsilon})$  approximation for general costs. Their algorithm also extends to the more general buy-at-bulk version. We prove the following in Section 3.3..

► **Theorem 7.** *For the online directed Steiner forest problem with uniform costs, there is a randomized polynomial time algorithm with competitive ratio  $\tilde{O}(n^{2/3+\varepsilon})$  for any constant  $\varepsilon \in (0, 1/3)$ .*

We essentially improve the competitive ratio when the number of terminal pairs is  $\omega(n^{4/3})$ .

### 1.1.3 Summary

We summarize our main results for online pairwise spanners and directed Steiner forests in Table 1 by listing the competitive ratios and contrast them with the corresponding known competitive and approximation ratios. We note that offline  $\tilde{O}(n^{4/5})$ -approximate pairwise spanners for graphs with general edge lengths and offline  $\tilde{O}(k^{1/2+\varepsilon})$ -approximate pairwise spanners for graphs with uniform edge lengths can be obtained by our online algorithms.

■ **Table 1** Summary of the competitive and approximation ratios. Here,  $n$  refers to the number of vertices and  $k$  refers to the number of terminal pairs. We include the known results for comparison. The text in gray refers to known results while the text in black refers to our contributions.

Setting	Pairwise Spanners	Directed Steiner Forests
Offline	$\tilde{O}(n^{4/5})$ (implied by Thm 2)	$\tilde{O}(n^{26/45+\varepsilon})$ (uniform costs) [1]
	$\tilde{O}(n^{3/5+\varepsilon})$ (uniform lengths) [34]	$O(n^{2/3+\varepsilon})$ [20]
	$\tilde{O}(k^{1/2+\varepsilon})$ (uniform lengths, implied by Thm 1)	$O(k^{1/2+\varepsilon})$ [32]
Online	$\tilde{O}(n^{4/5})$ (Thm 2)	$\tilde{O}(k^{1/2+\varepsilon})$ [28]
	$\tilde{O}(n^{2/3+\varepsilon})$ (uniform lengths, Thm 6)	$\tilde{O}(n^{2/3+\varepsilon})$ (uniform costs, Thm 7)
	$\tilde{O}(k^{1/2+\varepsilon})$ (uniform lengths, Thm 1)	

## 1.2 An efficient online covering and packing framework

Before presenting our modification to the unified framework in [26] to obtain efficient online covering and packing LP solvers, we give an overview of the well-known primal-dual framework

for approximating covering and packing LP's online. This framework is the main engine of our application and it is important to establish some context before getting into the application for spanners and Steiner forests. We also introduce a discussion of certain technical nuances that arise for our application, and the small modification we propose to address it. A more formal description, including proofs and fully parameterized theorem statements, is fairly technical and therefore deferred to Appendix C *after* we have used these tools in the context of spanners and Steiner forests.

The primal-dual framework was first developed for the online set cover problem in the seminal work of [4]. The approach was extended to network optimization problems in undirected graphs in [3], then abstracted and generalized to a broad LP-based primal-dual framework in [26]. Our discussion primarily centers around the abstract framework in [26]. A number of previous results in online algorithms, such as ski rental [61] and paging [16], can be recovered from this approach and many new important applications have since been developed, such as the  $k$ -server problem [76]. We refer the reader to the excellent survey by Buchbinder and Naor [27].

These works develop a clean two-step approach to online algorithms based on 1) solving the LP online, and 2) rounding the LP online. Solving the LP online can be done in a generic fashion, while rounding tends to be problem-specific. The setting for the *covering* LP is the following.

$$\text{minimize } \langle \mathbf{c}, x \rangle \text{ over } x \in \mathbb{R}_{\geq 0}^n \text{ s.t. } Ax \geq \mathbf{b}. \quad (1)$$

Here  $A \in \mathbb{R}_{\geq 0}^{m \times n}$  consists of  $m$  covering constraints,  $\mathbf{b} \in \mathbb{R}_{> 0}^m$  is a positive lower bound of the covering constraints, and  $\mathbf{c} \in \mathbb{R}_{> 0}^n$  denotes the positive coefficients of the linear cost function. Each constraint can be normalized, so we focus on covering LP's in the following form.

$$\text{minimize } \langle \mathbf{c}, x \rangle \text{ over } x \in \mathbb{R}_{\geq 0}^n \text{ s.t. } Ax \geq \mathbf{1} \quad (2)$$

where  $\mathbf{1}$  is a vector of all ones.

In the online covering problem, the cost vector  $\mathbf{c}$  is given offline, and each of these covering constraints is presented one by one in an online fashion, that is,  $m$  can be unknown. The goal is to update  $x$  in a non-decreasing manner such that all the covering constraints are satisfied and the objective value  $\langle \mathbf{c}, x \rangle$  is approximately optimal. An important idea in this line of work is to simultaneously consider the dual *packing* problem:

$$\text{maximize } \langle \mathbf{1}, y \rangle \text{ over } y \in \mathbb{R}_{\geq 0}^m \text{ s.t. } A^T y \leq \mathbf{c} \quad (3)$$

where  $A^T$  consists of  $n$  packing constraints with an upper bound  $\mathbf{c}$  given offline.

In the online packing problem, the *columns* of  $A^T$  and the corresponding variables are presented online with value zero, one can either let the arriving variable remain zero, or irrevocably assign a positive value to the arriving variable. The goal is to approximately maximize the objective value  $\langle \mathbf{1}, y \rangle$  with each constraint approximately satisfied.

### 1.2.1 Separation oracles in the online setting

The primal-dual framework in [26] simultaneously solves both LP (2) and LP (3), and crucially uses LP-duality and strong connections between the two solutions to argue that they are both nearly optimal. Here we give a sketch of the LP solving framework for reference in the subsequent discussion. We maintain solutions  $x$  and  $y$  for LP (2) and LP (3), respectively, in an online fashion. The covering solution  $x$  is a function of the packing solution  $y$ . In particular, each coordinate  $x_j$  is exponential in the *load* of the corresponding packing constraint in LP

(3). Both  $x$  and  $y$  are monotonically increasing. The algorithm runs in phases, where each phase corresponds to an estimate for OPT revised over time. Within a phase we have the following. If the new covering constraint  $i \in [m]$ , presented online, is already satisfied, then there is nothing to be done. Otherwise, increase the corresponding coordinate  $y_i$ , which simultaneously increases the  $x_j$ 's based on the magnitude of the coordinate  $a_{ij}$ , where  $a_{ij}$  is the  $i$ -th row  $j$ -th column entry of  $A$ . The framework in [26] increases  $y_i$  until the increased  $x_j$ 's satisfy the new constraint. This naturally extends to the setting when the problem relies on a *separation oracle* to retrieve an unsatisfied covering constraint where the number of constraints can be unbounded [26]. However, while this approach will fix all violating constraints, each individual fix may require a diminishingly small adjustment that cannot be charged off from a global perspective. Consequently the algorithm may have to address exponentially many constraints.

### 1.2.2 A primal-dual bound on separation oracles

Our goal is to adjust the framework to ensure that we only address a polynomial number of constraints (per phase). For many concrete problems in the literature, this issue can be addressed directly based on the problem at hand (discussed in greater detail in Section A). In our setting, we start with a combinatorially defined LP that is not a pure covering problem, and convert it to a covering LP. While having a covering LP is conducive to the online LP framework, the machinery generates a large number of covering constraints that are very unstructured. For example, we have little control over the coefficients of these constraints. This motivates us to develop a more generic argument to bound the number of queries to the separation oracle, based on the online LP framework, more so than the exact problem at hand. Here, when addressing a violated constraint  $i$ , we instead increase the dual variable  $y_i$  until the increased primal variables  $x$  (over-)satisfy the new constraint by a factor of 2. This forces at least one  $x_j$  to be doubled – and in the dual, this means we used up a substantial amount of the corresponding packing constraint. Since the packing solution is already guaranteed to be feasible in each phase by the overall framework, this leads us to conclude that we only ever encounter polynomially many violating constraints.

For our modified online covering and packing framework, we show that 1) the approximation guarantees are identical to those in [26], 2) the framework only encounters polynomially many violating constraints for the online covering problem, and 3) only polynomially many updates are needed for the online packing problem.

► **Theorem 8 (Informal).** *There exists an  $O(\log n)$ -competitive online algorithm for the covering LP (2) which encounters polynomially many violating constraints.*

► **Theorem 9 (Informal).** *Given any parameter  $B > 0$ , there exists a  $1/B$ -competitive online algorithm for the packing LP (3) which updates  $y$  polynomially many times, and each constraint is violated within an  $O(f(A)/B)$  factor ( $f(A)$  is a logarithmic function that depends on the entries in  $A$ ).*

We note that the competitive ratios given in [26] are tight, which also implies the tightness of the modified framework. The number of violating constraints depends not only on the number of covering variables and packing constraints  $n$ , but also on the number of bits used to present the entries in  $A$  and  $\mathbf{c}$ . The formal proof for Theorem 8 is provided in Appendix C, while the formal proof for Theorem 9 provided in the full version [52] is not directly relevant to this work, but may be of independent interest.

### 1.3 High-level technical overview for online network optimization problems

#### 1.3.1 Online pairwise spanners

For this problem, a natural starting point is the flow-based LP approach for offline  $s$ -stretch directed spanners, introduced in [38]. The results of [34] adopt a slight tweak for this approach to achieve an  $\tilde{O}(n/\sqrt{\text{OPT}})$ -approximation, where  $\text{OPT}$  is the size of the optimal solution. With additional ideas, the  $\tilde{O}(n/\sqrt{\text{OPT}})$ -approximation is converted into an  $\tilde{O}(n^{3/5+\varepsilon})$ -approximation for pairwise spanners. One technical obstacle in the online setting is the lack of a useful lower bound for  $\text{OPT}$ . Another challenge is solving the LP for the spanner problem and rounding the solution in an online fashion, particularly as the natural LP is not a covering LP. We address these technical obstacles as discussed below in Section 3. Ultimately we obtain an  $\tilde{O}(n^{4/5})$  competitive ratio for the online setting. The strategy here is to convert the LP for spanners into a covering LP, where the constraints are generated by an *internal* LP. The covering LP previously appeared in [38] implicitly, and in [39] explicitly.

#### 1.3.2 Online pairwise spanners with uniform edge lengths

For the special case of uniform edge lengths, [34] obtains an improved bound of  $\tilde{O}(n^{3/5+\varepsilon})$ . It is natural to ask if the online bound of  $\tilde{O}(n^{4/5})$  mentioned above can be improved as well. Indeed, we obtain an improved bound of  $\tilde{O}(n^{2/3+\varepsilon})$  by replacing the greedy approach in the small  $\text{OPT}$  regime by using the  $\tilde{O}(k^{1/2+\varepsilon})$ -competitive online algorithm discussed in Section 2. This algorithm leverages ideas from [34] in reducing to label cover problems with ideas from the online network design algorithms of [28]. Some additional ideas are required to combine the existing tools and among others we had to formulate a new pure covering LP that can be solved online, to facilitate the transition.

#### 1.3.3 Online Steiner forests with uniform costs

This problem is a special case of the online pairwise spanner problem where the distance requirement for each terminal pair is infinity and the edge lengths are uniform. The online algorithm for this problem has a similar structure to the one for pairwise spanners and similar obstacles to overcome. Before small value of  $\text{OPT}$  gets large, we can leverage the  $\tilde{O}(k^{1/2+\varepsilon})$ -competitive online algorithm or the online buy-at-bulk framework [28] for a better bound than a greedy approach would give, improving the competitive ratio to  $\tilde{O}(n^{2/3+\varepsilon})$ .

## 1.4 Organization

Since the proof of Theorem 1 is the most involved contribution of this work, we start by presenting the proof outline in Section 2 and refer the reader to the full version [52] for the technical proof details. In Section 3, we prove Theorems 2, 6, and 7 by designing a generic online algorithm, which is also used for proving Theorems 3, 4, and 5 in the full version [52]. We show the modified online covering framework in Appendix C, while the modified online packing framework is presented in the full version [52]. We refer the reader to Appendix A for a detailed description of related work and an exposition situating our work in the expansive literature of directed spanners, Steiner forests, and covering and packing problems.

## 2 Online Pairwise Spanners with Uniform Lengths

In this section, we present the proof outline of Theorem 1, namely we design an online algorithm for the pairwise spanner problem with uniform edge lengths with competitive ratio  $\tilde{O}(k^{1/2+\delta})$  for any constant  $\delta > 0$ . We recall that in the *pairwise spanner* problem, we are given a directed graph  $G = (V, E)$  with edge length  $\ell : E \rightarrow \mathbb{R}_{\geq 0}$ , a general set of  $k$  terminals  $D = \{(s_i, t_i) \mid i \in [k]\} \subseteq V \times V$ , and a target distance  $d_i$  for each terminal pair  $(s_i, t_i)$ , the goal is to output a subgraph  $H = (V, E')$  of  $G$  such that for every pair  $(s_i, t_i) \in D$  it is the case that  $d_H(s_i, t_i) \leq d_i$ , i.e. the length of a shortest  $s_i \rightsquigarrow t_i$  path is at most  $d_i$  in the subgraph  $H$ , and we want to minimize the number of edges in  $E'$ . The edge lengths are uniform if  $\ell(e) = 1$  for all  $e \in E$ . In the online setting, the directed graph  $G$  is given offline, while the vertex pairs in  $D \subseteq V \times V$  arrive online one at a time. In the beginning,  $E' = \emptyset$ . Suppose  $(s_i, t_i)$  and its target distance  $d_i$  arrive in round  $i$ , we select some edges from  $E$  and irrevocably add them to  $E'$ , such that in the subgraph  $H = (V, E')$ ,  $d_H(s_i, t_i) \leq d_i$ .

### 2.1 Outline of the proof of Theorem 1

We start by describing the high-level approach of our proof of Theorem 1. While the proof combines ideas of the online buy-at-bulk framework in [28] and of the reduction from the pairwise spanner problem to a connectivity problem in [34], implementing the details require several new ideas. Specifically, we introduce a useful extension of the Steiner problem, called the *Steiner label cover* problem, and our main contribution is an online covering LP formulation for this problem. This approach allows us to not only capture the global approximation property in an online setting, as in [28], but also to handle distance constraints, as in [34]. The entire proof consists of three main ingredients:

1. We first show that there exists an  $O(\sqrt{k})$ -approximate solution consisting of *junction trees*. A junction tree is a subgraph consisting of an in-arborescence and out-arborescence rooted at the same vertex (see also Definition 10).
2. We then show a reduction from the online pairwise spanner problem to the online Steiner label cover problem on a forest with a loss of an  $O(k^{1/2+\delta})$  factor. More precisely, an  $O(\sqrt{k})$  factor comes from the junction tree approximation and an extra  $O(k^\delta)$  factor comes from the *height reduction* technique introduced in [32, 58]. The height reduction technique allows us to focus on low-cost trees of height  $O(1/\delta)$  in order to recover a junction tree approximation.
3. Finally, we show a reduction from the online Steiner label cover problem to the online undirected Steiner forest problem, with a loss of a  $\text{polylog}(n)$  factor. More precisely, we first formulate an online covering LP for the online Steiner label cover instance, then construct an online undirected Steiner forest instance from the LP solution, with a loss of a factor of 2. By [21], the online undirected Steiner forest problem can then be solved deterministically with competitive ratio  $\text{polylog}(n)$ .

Combining these three ingredients results in an  $\tilde{O}(k^{1/2+\delta})$ -competitive algorithm. We provide further intuition below. The detailed description these three ingredients are presented in the full version [52].

#### 2.1.1 Junction tree approximation

Many connectivity problems, including Steiner forests, buy-at-bulk, and spanner problems, are usually solved using *junction trees* introduced in [33].

► **Definition 10.** A junction tree rooted at  $r \in V$  is a directed graph  $G = (V, E)$ , by taking the union of an in-arborescence rooted at  $r$  and an out-arborescence rooted at  $r^2$ . A junction tree solution is a collection of junction trees rooted at different vertices, that satisfies all the terminal distance constraints.

► **Lemma 11.** There exists an  $O(\sqrt{k})$ -approximate junction tree solution for pairwise spanners.

At a high level, the proof of Lemma 11 follows by a standard *density* argument. A *partial solution* is a subgraph that connects a subset of the terminal pairs within the required distances. The density of a partial solution is the ratio between the number of edges used and the number of terminal pairs connected within the required distances. This argument is used for solving offline problems including the Steiner forest problem [20, 32, 46], the buy-at-bulk problem [6], the Client-Server  $s$ -spanner [22] problem, and the pairwise spanner problem [34], by greedily removing low density partial solutions in an iterative manner. Fortunately, this iterative approach also guarantees a nice *global* approximation that consists of junction trees rooted at different vertices, which is amenable in the online setting. The online buy-at-bulk algorithm in [28] is an online version of the junction tree framework for connectivity problems. Our main technical contribution is further modifying the online version of the junction tree framework for problems with distance constraints.

### 2.1.2 Reduction to Steiner label cover

We reduce the pairwise spanner problem to the following extension of Steiner problem termed *Steiner label cover*.

► **Definition 12.** In the Steiner label cover problem, we are given a (directed or undirected) graph  $G = (V, E)$ , non-negative edge costs  $w : E \rightarrow \mathbb{R}_{\geq 0}$ , and a collection of  $k$  disjoint vertex subset pairs  $(S_i, T_i)$  for  $i \in [k]$  where  $S_i, T_i \subseteq V$  and  $S_i \cap T_i = \emptyset$ . Each pair is associated with a relation (set of permissible pairs)  $R_i \subseteq S_i \times T_i$ . The goal is to find a subgraph  $F = (V, E')$  of  $G$ , such that 1) for each  $i \in [k]$ , there exists  $(s, t) \in R_i$  such that there is an  $s \rightsquigarrow t$  path in  $F$ , and 2) the cost  $\sum_{e \in E'} w(e)$  is minimized.

For the online Steiner label cover problem,  $(S_i, T_i)$  and  $R_i$  arrive online, and the goal is to irrevocably select edges to satisfy the first requirement and also approximately minimize the cost.

To reduce to the online Steiner label cover problem, we construct a directed graph  $G'$  that consists of disjoint layered graphs from the given graph  $G = (V, E)$ . Each vertex in  $G'$  is labelled by the distance to (from) the root of a junction tree. This allows us to capture distance constraints by a Steiner label cover instance with distance-based relations. From  $G'$ , we further construct an undirected graph  $H$  which is a forest by the *height reduction* technique [32, 58]. In  $H$ , we define the corresponding Steiner label cover instance, where the terminal vertex sets consist of the leaves, and the solution is guaranteed to be a forest. The Steiner label cover instance on the forest  $H$  has a nice property. For each tree in  $H$ , the terminal vertices can be ordered in a way such that if an *interval* belongs to the relation, then any *subinterval* also belongs to the relation.

<sup>2</sup> A junction tree does not necessarily have a tree structure in directed graphs, i.e. edges in the in-arborescence and edges in the out-arborescence may overlap. Nevertheless, we continue using this term because of historical reasons. A similar notion can also be used for undirected graphs, where a junction tree is indeed a tree.

► **Definition 13.** The ordered Steiner label cover problem on a forest is defined as a special case of the Steiner label cover problem (see Definition 12) with the following properties.

1.  $G$  is an undirected graph consisting of disjoint union of trees  $H_1, H_2, \dots, H_n$  each of which has a distinguished root vertex  $r_j$  where  $j \in [n]$ .
2. For each  $(S_i, T_i)$  and  $R_i$ , and each tree  $H_j$ , the input also includes the orderings  $\prec_{i,j}$  such that:
  - a. For  $S_i^j := S_i \cap H_j$  and  $T_i^j := T_i \cap H_j$ , the ordering  $\prec_{i,j}$  is defined on  $S_i^j \cup T_i^j$ .
  - b. The root  $r_j$  separates  $S_i^j$  from  $T_i^j$ .
  - c. If  $s \in S_i^j$  and  $t \in T_i^j$  are such that  $(s, t) \in R_i$ , then for any  $s' \in S_i^j$  and  $t' \in T_i^j$  such that  $s \preceq_{i,j} s' \prec_{i,j} t' \preceq_{i,j} t$ , we have that  $(s', t') \in R_i$ .

We note that for the online ordered Steiner label cover problem on a forest, besides  $(S_i, T_i)$  and  $R_i$ , the orderings  $\{\succ_{i,j}\}_{j \in [n]}$  also arrive online.

We employ a well-defined mapping between junction trees in  $G$  and forests in  $H$  by paying an  $\tilde{O}(k^{1/2+\delta})$  factor for competitive online solutions. A crucial step for showing Theorem 1 is the following theorem.

► **Theorem 14.** For any constant  $\delta > 0$ , an  $\alpha$ -competitive polynomial time algorithm for online ordered Steiner label cover on a forest implies an  $O(\alpha k^{1/2+\delta})$ -competitive polynomial time algorithm for the online pairwise spanner problem on a directed graph with uniform edge lengths.

At a high level, the online pairwise spanner problem on a directed graph  $G = (V, E)$  with uniform edge lengths reduces to an instance of online Steiner label cover on the forest  $H$  with the following properties.

1.  $H$  consists of disjoint trees  $H_r$  rooted at  $r'$  for each vertex  $r \in V$ .
2.  $|V(H)| = n^{O(1/\delta)}$ ,  $E(H) = n^{O(1/\delta)}$ , and each tree  $H_r$  has depth  $O(1/\delta)$  with respect to  $r'$ .
3. For each arriving terminal pair  $(s_i, t_i)$  with distance requirement  $d_i$ , there is a corresponding pair of terminal sets  $(\hat{S}_i, \hat{T}_i)$  and relation  $\hat{R}_i$  with  $|\hat{R}_i| = n^{O(1/\delta)}$ , where  $\hat{S}_i$  and  $\hat{T}_i$  are disjoint subsets of leaves in  $H$ . Furthermore, we can generate orderings  $\prec_{i,r}$  based on the distance-based relations  $\hat{R}_i$  such that the Steiner label cover instance is an ordered instance on the forest  $H$ .

This technique closely follows the one for solving offline pairwise spanners in [34]. The intermediary problem considered in [34] is the *minimum density Steiner label cover problem*. In this framework, the solution is obtained by selecting the partial solution with the lowest density among the junction trees rooted at different vertices and repeat. In the online setting, to capture the global approximation for pairwise spanners, we construct a forest  $H$  and consider all the possible roots simultaneously.

### 2.1.3 An online algorithm for Steiner label cover on $H$

The goal is to prove the following lemma.

► **Lemma 15.** For the online ordered Steiner label cover problem on a forest (see definition 13), there is a deterministic polynomial time algorithm with competitive ratio  $\text{polylog}(n)$ .

We derive an LP formulation for the Steiner label cover instance on  $H$ . At a high level, the LP minimizes the total edge weight by selecting edges that cover paths with endpoint pairs which belong to the distance-based relation. We show that the LP for Steiner label cover can be converted into an online covering problem, which is efficiently solvable by Theorem 8.

The online rounding is based on the online LP solution for Steiner label cover. Given the online LP solution and the orderings in round  $i$  generated by the distance-based relation  $\hat{R}_i$ , we extract the representative vertex sets  $\tilde{S}_i$  and  $\tilde{T}_i$  from the terminal sets  $\hat{S}_i$  and  $\hat{T}_i$ , respectively, according to orderings  $\prec_{i,r}$  and the contribution of the terminal vertex to the objective of the Steiner label cover LP. We show that the union of cross-products over partitions of  $\tilde{S}_i$  and  $\tilde{T}_i$  (based on the trees in  $H$ ) is a subset of the distance-based relation  $\hat{R}_i$ . This allows us to reduce the online ordered Steiner label cover problem to the online undirected Steiner forest problem by connecting a super source to  $\tilde{S}_i$  and a super sink to  $\tilde{T}_i$ .

This technique closely follows the one for solving offline pairwise spanners in [34]. The main difference is that in the offline pairwise spanner framework, the LP formulation is density-based and considers only one (fractional) junction tree. To globally approximate the online pairwise spanner solution, our LP formulation is based on the forest  $H$  and its objective is the total weight of a (fractional) forest.

The LP for the undirected Steiner forest problem is roughly in the following form.

$$\begin{aligned} \min_x \quad & \sum_{e \in E(H)} w'(e)x_e \\ \text{subject to} \quad & x \text{ supports an } \tilde{S}_i\text{-}\tilde{T}_i \text{ flow of value } 1 \quad \forall i \in [k], \\ & x_e \geq 0 \quad \forall e \in E(H). \end{aligned} \tag{4}$$

Here  $w'$  denotes the edge weights in  $H$ . We show that a solution of the undirected Steiner forest LP (4) recovers a solution for the Steiner label cover LP by a factor of 2. The integrality gap of the undirected Steiner forest LP is  $\text{polylog}(n)$  because the instance can be decomposed into single source Steiner forest instances by the structure of  $H$  [28, 50]. This implies that the online rounding for the Steiner label cover LP can be naturally done via solving the undirected Steiner forest instance online, by using the  $\text{polylog}(n)$ -competitive framework [21].

### 2.1.3.1 Putting it all together

We summarize the overall  $\tilde{O}(k^{1/2+\delta})$ -competitive algorithm for online pairwise spanners when the given graph has uniform edge lengths. The reduction strategy is as follows:

1. Reduce the online pairwise spanner problem on the original graph  $G$  to the online Steiner label cover problem on the directed graph  $G'$  which consists of disjoint layered graphs.
2. Reduce the online Steiner label cover problem on  $G'$  to an online ordered Steiner label cover problem on  $H$ , where  $H$  is a forest.
3. In the forest  $H$ , reduce the online ordered Steiner label cover problem to the online undirected Steiner forest problem.

We note that  $G'$  and  $H$  are constructed offline, while the graph for the final undirected Steiner forest instance is partially constructed online, by adding super sources and sinks and connecting incident edges to the representative leaf vertices online in  $H$ . The pairwise spanner in  $G$  is  $O(\sqrt{k})$ -approximated by junction trees according to Lemma 11. The graph  $G'$  preserves the same cost of the pairwise spanner (junction tree solution) in  $G$ . The solution of the ordered Steiner label cover problem in graph  $H$  is a forest. One can map a forest in  $H$  to junction trees in  $G'$ , via the height reduction technique by losing an  $O(k^\delta)$  factor. Finally, in the forest  $H$ , we solve the undirected Steiner forest instance online and recover an ordered Steiner label cover solution by losing a  $\text{polylog}(n)$  factor. The overall competitive ratio is therefore  $\tilde{O}(k^{1/2+\delta})$ .

### 3 Online Pairwise Spanners

We recall that in the general *pairwise spanner* problem, we are given a directed graph  $G = (V, E)$  with edge length  $\ell : E \rightarrow \mathbb{R}_{\geq 0}$ , a general set of  $k$  terminals  $D = \{(s_i, t_i) \mid i \in [k]\} \subseteq V \times V$ , and a target distance  $d_i$  for each terminal pair  $(s_i, t_i)$ , the goal is to output a subgraph  $H = (V, E')$  of  $G$  such that for every pair  $(s_i, t_i) \in D$  it is the case that  $d_H(s_i, t_i) \leq d_i$ , i.e. the length of a shortest  $s_i \rightsquigarrow t_i$  path is at most  $d_i$  in the subgraph  $H$ , and we want to minimize the number of edges in  $E'$ .

#### 3.1 An $\tilde{O}(n^{4/5})$ -competitive online algorithm for pairwise spanners

In this section, we prove Theorem 2. Recall that in the online setting of the problem, the directed graph  $G$  is given offline, while the vertex pairs in  $D \subseteq V \times V$  arrive online one at a time. In the beginning,  $E' = \emptyset$ . Suppose  $(s_i, t_i)$  and its target distance  $d_i$  arrive in round  $i$ , we select some edges from  $E$  and irrevocably add them to  $E'$ , such that in the subgraph  $H = (V, E')$ ,  $d_H(s_i, t_i) \leq d_i$ . The goal is to approximately minimize the total number of edges added to  $E'$ .

We start with a high-level sketch of an offline algorithm, which we will build on for the online setting. The randomized rounding framework in [20, 34] has two main steps. One step is to solve and round an LP for the spanner problem. The second is to uniformly sample vertices and add the shortest path in-arborescences and out-arborescences rooted at each of the sampled vertices. Terminal pairs are classified as either *thin* or *thick* and are addressed by one of the two steps above accordingly.

In the first step, the rounding scheme based on an LP solution for spanners ensures with high probability that for all thin terminal pairs the distance requirements are met. The second step ensures with high probability that for all thick terminal pairs the distance requirements are met. By selecting an appropriate threshold for classifying the thin and thick pairs, this leads to an  $O(n/\sqrt{\text{OPT}})$ -approximation, where  $\text{OPT}$  is the number of edges in the optimal solution.

The main challenges in adapting this approach to the online setting are as follows: 1)  $\text{OPT}$  can be very small, and 2) the LP for spanners is not naturally a pure covering LP, which makes it difficult to solve online. In the previous work in the offline setting, the small- $\text{OPT}$  case is addressed by sophisticated strategies that appear difficult to emulate online. Instead, we show that the optimal value (however small) is at least the square root of the number of terminal pairs that have arrived. Thus, if  $\text{OPT}$  is small and not many pairs have arrived, we can greedily add a path with the fewest edges subject to the distance requirement for each pair. To overcome the second challenge, we convert the LP for spanners into an equivalent covering LP as in [39], where exponentially many covering constraints are generated by an auxiliary LP. Having transformed the LP into a purely covering one, we can solve the LP online, treating the auxiliary LP as a separation oracle.

##### 3.1.1 A simple $\tilde{O}(n^{4/5})$ -approximate offline algorithm based on [34]

For ease of exposition, we first design a simpler offline algorithm (slightly weaker than the state-of-the-art) that is more amenable to the online setting. This allows us to establish the main ingredients governing the approximation factor in a simpler setting, and then address the online aspects separately. The algorithm leverages the framework developed in [20, 34].

Let  $\mathcal{P}_i$  denote the collection of  $s_i \rightsquigarrow t_i$  paths of length at most  $d_i$  consisting of edges in  $E$ . Let the *local graph*  $G^i = (V^i, E^i)$  be the union of all vertices and edges in  $\mathcal{P}_i$ . A pair  $(s_i, t_i) \in D$  is *t-thick* if  $|V^i| \geq t$ , otherwise  $(s_i, t_i)$  is *t-thin*. Consider the following standard LP relaxation (essentially the one in [38]).

$$\begin{aligned}
& \min_{x,y} && \sum_{e \in E} x_e \\
& \text{subject to} && \sum_{P \in \mathcal{P}_i} y_P \geq 1 && \forall i \in [k], \\
& && \sum_{P|e \in P \in \mathcal{P}_i} y_P \leq x_e && \forall e \in E, \forall i \in [k], \\
& && x_e \geq 0 && \forall e \in E, \\
& && y_P \geq 0 && \forall P \in \mathcal{P}_i \quad \forall i \in [k].
\end{aligned} \tag{5}$$

Herein,  $x_e$  is an indicator of edge  $e$  and  $y_P$  is an indicator of path  $P$ . Suppose we have an integral feasible solution. Then the first set of constraints ensures that there is at least one  $s_i \rightsquigarrow t_i$  path of length at most  $d_i$  selected, and the second set of constraints ensures that if a path  $P$  is selected, then all its edges are selected.

We say that a pair  $(s_i, t_i) \in D$  is *settled* if the selection of edges is such that there exists an  $s_i \rightsquigarrow t_i$  path of length at most  $d_i$ . Applying a simple rounding scheme based on a solution of LP (5) settles the thin pairs with high probability, while sampling enough vertices and adding shortest path in-arborescences and out-arborescences rooted at each sampled vertex ensures with high probability that thick pairs are settled. Let  $\text{OPT}$  be the optimum value of the given pairwise spanner instance. Without loss of generality, we may assume that we know  $\text{OPT}$  since we can guess every value of  $\text{OPT}$  in  $[|E|]$  in the offline setting. Now we are ready to describe Algorithm 1 in [34].

► **Lemma 16.** ([34]) *Algorithm 1 is  $\tilde{O}(n/\sqrt{\text{OPT}})$ -approximate.*

■ **Algorithm 1** Offline pairwise spanner.

- 
- 1:  $E' \leftarrow \emptyset$  and  $t \leftarrow n/\sqrt{\text{OPT}}$ .
  - 2: Solve LP (5) and add each edge  $e \in E$  to  $E'$  with probability  $\min\{1, x_e t \ln n\}$  independently.
  - 3: Obtain a vertex set  $W \subseteq V$  by sampling  $(3n \ln n)/t$  vertices from  $V$  independently and uniformly at random. Add the edges of shortest path in-arborescences and out-arborescences rooted at  $w$  for each  $w \in W$ .
- 

In the all-pairs spanner problem where  $\text{OPT}$  is  $\Omega(n)$ , Algorithm 1 is  $\tilde{O}(\sqrt{n})$ -approximate which matches the state-of-the-art approximation ratio given in [20]. For the pairwise spanner problem, the main challenge is the lack of a nice lower bound for  $\text{OPT}$ . In the offline setting, [34] achieves an  $\tilde{O}(n^{3/5+\epsilon})$ -approximate solution by a careful case analysis when edges have uniform lengths. We give an alternative approach that is amenable to the online setting by considering two cases, where one resolves the issue when  $\text{OPT}$  does not have a nice lower bound, and the other uses a variant of Algorithm 1 given that  $\text{OPT}$  has a nice lower bound. This approach relies on the following observation.

► **Lemma 17.**  $\text{OPT} \geq \sqrt{k}$ .

**Proof.** We observe that when the spanner has  $\ell$  edges, there are at most  $\ell$  source vertices and  $\ell$  sink vertices, so there are at most  $\ell^2$  terminal pairs. Therefore, when the spanner has  $\text{OPT}$  edges, there are at most  $\text{OPT}^2$  terminal pairs, so  $\text{OPT} \geq \sqrt{k}$ . ◀

Now we specify the simple offline algorithm given in Algorithm 2. In the beginning, we set two parameters  $T$  and  $t$  (which we will describe later), and set  $E' = \emptyset$ . An  $s_i \rightsquigarrow t_i$  path is *cheapest feasible* if it meets the distance requirement  $d_i$  by using the minimum number of edges from  $E$ . We note that cheapest feasible paths can be found by Bellman-Ford algorithm.

■ **Algorithm 2** Simple offline pairwise spanner.

- 
- 1: **if**  $k < T$  **then**
  - 2:     Add the edges of a cheapest feasible  $s_i \rightsquigarrow t_i$  path to  $E'$  for each  $i \in [k]$ .
  - 3: **else**
  - 4:     Solve LP (5) and add each edge  $e \in E$  to  $E'$  with probability  $\min\{1, x_e t \ln n\}$  independently.
  - 5:     Obtain a vertex set  $W \subseteq V$  by sampling  $(3n \ln n)/t$  vertices from  $V$  independently and uniformly at random. Add the edges of shortest path in-arborescences and out-arborescences rooted at each vertex  $w \in W$  to  $E'$ .
- 

► **Lemma 18.** *Algorithm 2 is  $\tilde{O}(n^{4/5})$ -approximate when  $T = t = n^{4/5}$ .*

**Proof.** If  $k < n^{4/5}$ , we add the edges of a cheapest feasible  $s_i \rightsquigarrow t_i$  path for each  $(s_i, t_i) \in D$ . Each cheapest feasible  $s_i \rightsquigarrow t_i$  path contains at most  $\text{OPT}$  edges, so the ratio between this solution and  $\text{OPT}$  is  $n^{4/5}$ . If  $k \geq n^{4/5}$ , then  $\text{OPT} \geq n^{2/5}$  by Lemma 17. Let  $\text{LP}^*$  be the optimal objective value of LP (5). The approximation guarantee is

$$\frac{\tilde{O}(t\text{LP}^*) + \tilde{O}(n^2/t)}{\text{OPT}} \leq \frac{\tilde{O}(n^{4/5}\text{OPT}) + \tilde{O}(n^{6/5})}{\text{OPT}} = \tilde{O}(n^{4/5})$$

since the number of edges retained from the rounding scheme is at most  $\tilde{O}(t)\text{LP}^*$  and the number of edges retained by adding arborescences is at most  $2n \cdot 3n \ln n/t$ . This summarizes the simple offline  $\tilde{O}(n^{4/5})$ -approximation algorithm. ◀

### 3.1.2 An $\tilde{O}(n^{4/5})$ -competitive online algorithm

It remains to convert the simple offline algorithm to an online algorithm. We address the two main modifications.

1. We have to (approximately) solve LP (5) online, which is not presented as a covering LP.
2. We have to round the solution of LP (5) online.

For the first modification, LP (5) is converted to an equivalent covering LP (9) (which we show in Appendix B) and approximately solved in an online fashion. For the second modification, we use an online version of the rounding scheme in Algorithm 2, such that the overall probability (from round 1 to the current round) for the edge selection is consistent with the probability based on the online solution of LP (5), by properly scaling the probability based on a conditional argument.

The online algorithm in round  $i$  is given in Algorithm 3. The same structure is used for other variants of the online pairwise spanner problem. In the beginning, we pick a threshold parameter  $T$  and a thickness parameter  $t$ , and set  $E' = \emptyset$ . Let  $x_e^i$  denote the value of  $x_e$  in the approximate solution of LP (9) obtained in round  $i$ . Let  $p_e^i := \min\{1, x_e^i t \ln n\}$ . Algorithm 3 is the online version of Algorithm 2. A key insight is that when we add the arborescences in round  $T$ , it also settles the *future* thick terminal pairs with high probability. With the outline structure of the online algorithm, we prove Theorem 2 in Appendix B.

► **Theorem 2.** *For the online pairwise spanner problem, there is a randomized polynomial time algorithm with competitive ratio  $\tilde{O}(n^{4/5})$ .*

■ **Algorithm 3** Online pairwise spanner.

---

```

1: for an arriving pair  $(s_i, t_i)$  do
2:   Convert the spanner LP (5) to the covering LP (9) and solve LP (9) online.
3:   if  $i < T$  then
4:     Add the edges of a cheapest feasible  $s_i \rightsquigarrow t_i$  path to  $E'$ .
5:   else if  $i = T$  then
6:     Obtain a vertex set  $W \subseteq V$  by sampling  $(3n \ln n)/t$  vertices from  $V$  independently
       and uniformly at random. Add the edges of shortest path in-arborescences and out-
       arborescences rooted at each vertex  $w \in W$  to  $E'$ .
7:     Add each edge  $e$  to  $E'$  independently with probability  $p_e^i$  for each edge  $e \in E \setminus E'$ .
8:   else ▷  $i > T$ 
9:     Add each edge  $e$  to  $E'$  independently with probability  $(p_e^i - p_e^{i-1})/(1 - p_e^{i-1})$  for
       each edge  $e \in E \setminus E'$ .

```

### 3.2 Online pairwise spanners with uniform edge lengths

In this section, we prove Theorem 6.

► **Theorem 6.** *For the online pairwise spanner problem with uniform edge lengths, there is a randomized polynomial time algorithm with competitive ratio  $\tilde{O}(n^{2/3+\varepsilon})$  for any constant  $\varepsilon \in (0, 1/3)$ .*

**Proof.** We employ Algorithm 3 with a slight tweak and set  $T = \lfloor n^{4/3-4\varepsilon} \rfloor$  and  $t = n^{2/3+\varepsilon}$ .

If  $k < T$ , instead of adding edges of a shortest  $s_i \rightsquigarrow t_i$  path, we use Theorem 1 to find an  $\tilde{O}(n^{2/3+\varepsilon})$ -competitive solution.

► **Theorem 1.** *For the online pairwise spanner problem with uniform edge lengths, there exists a deterministic polynomial time algorithm with competitive ratio  $\tilde{O}(k^{1/2+\delta})$  for any constant  $\delta > 0$ .*

For any  $\varepsilon \in (0, 1/3)$ , there exists  $\delta$  such that  $4\delta/(9 + 12\delta) = \varepsilon$ . By picking this  $\delta$ , we have

$$\begin{aligned} \left(\frac{4}{3} - 4\varepsilon\right)\left(\frac{1}{2} + \delta\right) &= \left(\frac{4}{3} - \frac{16\delta}{9 + 12\delta}\right)\left(\frac{1}{2} + \delta\right) = \frac{2}{3} + \frac{4\delta}{3} - \frac{8\delta + 16\delta^2}{9 + 12\delta} \\ &= \frac{2}{3} + \frac{12\delta + 16\delta^2 - 8\delta - 16\delta^2}{9 + 12\delta} = \frac{2}{3} + \frac{4\delta}{9 + 12\delta} = \frac{2}{3} + \varepsilon. \end{aligned}$$

Hence, the ratio between the solution obtained by Theorem 1 and OPT is

$$k^{1/2+\delta} \leq n^{(4/3-4\varepsilon)(1/2+\delta)} = n^{2/3+\varepsilon} = \tilde{O}(n^{2/3+\varepsilon}).$$

By Lemma 17, if  $k \geq T$ , then  $\text{OPT} \geq n^{2/3-2\varepsilon}$ . Let LP be the online integral solution of LP (5) obtained by Algorithm 3. The approximation guarantee is

$$\frac{\tilde{O}(t\text{LP}) + \tilde{O}(n^2/t)}{\text{OPT}} \leq \frac{\tilde{O}(n^{2/3+\varepsilon}\text{OPT}) + \tilde{O}(n^{4/3-\varepsilon})}{\text{OPT}} = \tilde{O}(n^{2/3+\varepsilon}). \quad (6)$$

### 3.3 Online directed Steiner forests with uniform costs

We recall that in this problem, we are given a directed graph  $G = (V, E)$  and a set of terminals  $D = \{(s_i, t_i) \mid i \in [k]\} \subseteq V \times V$ . The goal is to find a minimum cardinality subgraph which includes an  $s_i \rightsquigarrow t_i$  path for each terminal pair  $(s_i, t_i)$ . We show the following theorem.

► **Theorem 7.** *For the online directed Steiner forest problem with uniform costs, there is a randomized polynomial time algorithm with competitive ratio  $\tilde{O}(n^{2/3+\varepsilon})$  for any constant  $\varepsilon \in (0, 1/3)$ .*

**Proof.** In this problem, for each terminal pair  $(s_i, t_i)$ , it suffices to have an  $s_i \rightsquigarrow t_i$  path. Therefore, this problem reduces to the pairwise spanner problem by setting  $d_i = \infty$  for each  $i \in [k]$ . The structure of the online algorithm is the same as that for online pairwise spanners with uniform lengths. We employ Algorithm 3 with a slight tweak and set  $T = \lfloor n^{4/3-4\varepsilon} \rfloor$  and  $t = n^{2/3+\varepsilon}$ . If  $k < T$ , instead of adding edges of a shortest  $s_i \rightsquigarrow t_i$  path, we use Theorem 1 to find an  $\tilde{O}(n^{2/3+\varepsilon})$  competitive solution<sup>3</sup>. If  $k \geq T$ , then the algorithm is  $\tilde{O}(n^{2/3+\varepsilon})$ -competitive by (6). ◀

## 4 Conclusions and Open Problems

In this work, we present the first online algorithm for pairwise spanners with competitive ratio  $\tilde{O}(n^{4/5})$  for general lengths and  $\tilde{O}(n^{2/3+\varepsilon})$  for uniform lengths, and improve the competitive ratio for the online directed Steiner forest problem with uniform costs to  $\tilde{O}(n^{2/3+\varepsilon})$  when  $k = \omega(n^{4/3})$ . We also show an efficient modified framework for online covering and packing. Our work raises several open questions that we state below.

An intriguing open problem is improving the competitive ratio for online pairwise spanners. For graphs with uniform edge lengths, there is a small polynomial gap between the state-of-the-art offline approximation ratio  $\tilde{O}(n^{3/5+\varepsilon})$  and the online competitive ratio  $\tilde{O}(n^{2/3+\varepsilon})$ . For graphs with general edge lengths, we are not aware of any studies about the pairwise spanner problem. Our  $\tilde{O}(n^{4/5})$ -competitive online algorithm intrinsically suggests an  $\tilde{O}(n^{4/5})$ -approximate offline algorithm. As the approach in [34] achieves an  $\tilde{O}(n/\sqrt{\text{OPT}})$ -approximation, we believe that the approximation ratio can be improved for the offline pairwise spanner problem, by judicious case analysis according to the cardinality of OPT.

The state-of-the-art online algorithm for Steiner forests with general costs is  $\tilde{O}(k^{1/2+\varepsilon})$ -competitive [28]. A natural open question is designing an  $o(n)$ -competitive online algorithm when  $k$  is large, and potentially extend this result to the more general buy-at-bulk network design problem. The currently best known offline approximation for Steiner forests with general costs is  $O(n^{2/3+\varepsilon})$  [20], by case analysis that settles thick and thin terminal pairs separately. However, the approach in [20] for settling thin pairs is essentially a greedy procedure which is inherently offline. Our approach utilizes the uniform cost assumption to obtain a useful lower bound for the optimal solution, which is incompatible with general costs. It would be interesting to resolve the aforementioned obstacles and have an  $o(n)$ -competitive online algorithm for directed Steiner forests with general edge costs. One open problem for uniform costs is to improve the competitive ratio, as there is a polynomial gap between the state-of-the-art offline approximation ratio  $\tilde{O}(n^{26/45+\varepsilon})$  and the online competitive ratio  $\tilde{O}(n^{2/3+\varepsilon})$ .

<sup>3</sup> One can also use the  $\tilde{O}(k^{1/2+\delta})$ -competitive online algorithm for graphs with general costs in [28].

## **A** Additional background and related work

A model related to online algorithms is that of streaming algorithms. In the streaming model an input is also revealed sequentially, but the algorithm is only allowed to use some small amount of space, which is sublinear in the length of the stream, and is supposed to maintain an approximate solution. For this model, several papers consider spanner variants, such as undirected or weighted graphs, and additive or multiplicative stretch approximations, and the aim is to build spanners with small size or distortion [17, 48, 60]. In a related direction, spanners have also been studied in the setting of dynamic data structures, where the edges of a graph are inserted or removed one at a time and the goal is to maintain an approximate solution with small update time and space [23, 43]. A relevant model is that of distributed

computation where nodes in the network communicate efficiently to build a solution [36,37,47]. As mentioned earlier, the survey by Ahmed et al. [2] gives a comprehensive account of the vast literature on spanners, and we refer the reader to the references within.

In the buy-at-bulk network design problem [10], each edge is associated with a sub-additive cost function of its *load*. Given a set of terminal demands, the goal is to route integral flows from each source to each sink concurrently to minimize the total cost of the routing. This problem is a generalization of various single-source or multicommodity network connectivity problems, including Steiner trees and Steiner forests, in which the cost function of each edge is a fixed value once allocated. While most problems admit polylogarithmic approximations in either the online or offline setting for undirected networks [11,21,32,55], the problems are much harder for directed networks. In the offline setting, the current best approximation ratio is  $O(k^\epsilon)$  for the directed Steiner tree problem [29,77],  $O(\min\{k^{1/2+\epsilon}, n^{2/3+\epsilon}\})$  for the directed Steiner forest problem [20,32], and  $O(\min\{k^{1/2+\epsilon}, n^{4/5+\epsilon}\})$  for the directed buy-at-bulk problem [6]. In the online setting for directed networks, [28] showed that compared to offline, it suffices to pay an extra polylogarithmic factor, where the polylogarithmic term was later improved by [74]. The main contribution of [28] is essentially bringing the *junction-tree-based* approach into the online setting for connectivity problems. This is the main ingredient that improves the competitive ratio of our online algorithm from  $\tilde{O}(n^{4/5+\epsilon})$  for pairwise spanners to  $\tilde{O}(n^{2/3+\epsilon})$  for Steiner forests. Our approach for online pairwise spanners with uniform edge length combines this ingredient and the offline pairwise spanner framework [34] which tackles hard distance requirements.

As previously mentioned, generating separating constraints with an oracle in the online setting is not new. For example, this arises implicitly in early work on network optimization [3] and the oracle is discussed explicitly in [26]. As a recent example, [56] develops online algorithms for the multistage matroid maintenance problem, which requires solving a covering LP with box constraints online. [56] adjusts the separation oracle to only identify constraints that are violated by at least some constant. Because of the  $\{0,1\}$ -incidence structure of their LP, the sum of primal variables has to increase by a constant to satisfy such a constraint. Meanwhile the box constraints limit the total sum of primal variables to  $O(n)$ . This leads to an  $O(n)$  bound on the number of separating constraints. While there are strong similarities to our approach, one difference is the use of the  $\{0,1\}$ -structure and box constraints to obtain their bound. Our comparably unstructured setting required us to develop an argument independent of concrete features such as these.

Beyond linear objectives, there are other variants of online covering and packing problems, which focus on different objectives with linear constraints. This includes optimizing convex objectives [14] and  $\ell_q$ -norm objectives [74]. Other online problem-dependent variants include for instance mixed covering and packing programs [13], and sparse integer programs [54]. All these frameworks utilize the primal-dual technique, which updates the covering and packing solutions simultaneously with some judiciously selected growth rate, to guarantee nice competitive ratio. Instead, our modified framework focuses on the efficiency of online algorithms for fundamental covering and packing problems, which is amenable to applications with exponential or unbounded number of constraints, where a violating one can be searched by an efficient separation oracle.

## **B** Proof of Theorem 2

► **Theorem 2.** *For the online pairwise spanner problem, there is a randomized polynomial time algorithm with competitive ratio  $\tilde{O}(n^{4/5})$ .*

**Proof.** Suppose in the online setting, there are  $k$  rounds where  $k$  may be unknown. In round  $i \in [k]$ , the pair  $(s_i, t_i)$  and the distance requirement  $d_i$  arrive and we select some new edges from  $E$  to settle  $(s_i, t_i)$ . We run Algorithm 3 by setting  $T = t = \lfloor n^{4/5} \rfloor$ . It suffices to show that 1) LP (5) can be solved online by losing a polylogarithmic factor, and 2) the overall probability of edge selection is consistent with the probability based on the online solution of LP (5).

### B.1 Converting and solving LP (5) online

The goal is to update  $x$  in a non-decreasing manner upon the arrival of the pair  $(s_i, t_i)$  to satisfy all its corresponding constraints, so that the objective value is still approximately optimal. We convert LP (5) into a covering LP as follows.

First, we check in round  $i$ , given the *edge capacity*  $x$ , if there is a (fractional)  $s_i \rightsquigarrow t_i$  path of length at most  $d_i$ . This can be captured by checking the optimum of the following LPs,

$$\max_y \sum_{P \in \mathcal{P}_i} y_P \text{ over } y : \mathcal{P}_i \rightarrow \mathbb{R}_{\geq 0} \text{ s.t. } \sum_{P|e \in P \in \mathcal{P}_i} y_P \leq x_e \text{ for all } e \in E \quad (7)$$

and its dual

$$\min_z \sum_{e \in E} x_e z_e \text{ over } z : E \rightarrow \mathbb{R}_{\geq 0} \text{ s.t. } \sum_{e \in P} z_e \geq 1 \text{ for all } P \in \mathcal{P}_i. \quad (8)$$

We say that  $x$  is *good* if the optimum of LP (7) and LP (8) is at least 1, and it is *bad* otherwise. Namely,  $x$  is good if there is at least one (fractional)  $s_i \rightsquigarrow t_i$  path of length at most  $d_i$ . In LP (8), the feasibility problem is equivalent to the following problem. Given the local graph  $G^i$  and edge weight  $z$ , is there an  $s_i \rightsquigarrow t_i$  path of length at most  $d_i$  and weight less than 1? We note that with uniform lengths, this problem can be solved by Bellman-Ford algorithm with  $d_i$  iterations, which computes the smallest weight among all  $s_i \rightsquigarrow t_i$  paths of length at most  $d_i$  in the local graph  $G^i$ .

Although this bicriteria path problem in general is NP-hard [7], an FPTAS is known to exist [57,66], which gives an approximate separation oracle. We can verify in polynomial time that if there is a path of length at most  $d_i$  and weight less than  $1 - \varepsilon$ . We obtain a solution  $z'$  for LP (8) where each constraint is satisfied by a factor of  $1 - \varepsilon$  and set  $z := z'/(1 - \varepsilon)$  as the solution.

To solve LP (5), suppose in round  $i$ , we are given  $x$ . First, we check if  $x$  is good or bad by approximately solving LP (8). If  $x$  is good, then there exists  $y$  such that  $\sum_{P \in \mathcal{P}_i} y_P \geq 1$ , i.e. the solution is feasible for LP (5), so we move on to the next round. Otherwise,  $x$  is bad, so we increment  $x$  until it becomes good, which implies  $\sum_{e \in E} x_e z_e \geq 1$  for all feasible  $z$  in LP (8). Let  $Z_i$  be the feasible polyhedron of LP (8) in round  $i$ . We derive the following LP (essentially the one in [38,39]) which is equivalent to LP (5), by considering all the constraints of LP (8) from round 1 to round  $k$ .

$$\min_x \sum_{e \in E} x_e \text{ over } x : E \rightarrow \mathbb{R}_{\geq 0} \text{ s.t. } \sum_{e \in E} z_e x_e \geq 1 \text{ for all } i \in [k] \text{ and } z \in Z_i. \quad (9)$$

In round  $i \in [k]$ , the subroutine that approximately solves LP (8) and checks if the optimum is good or not, is the separation oracle used for solving LP (9) online. Here we use Theorem 20 (the formal version of Theorem 8) to show that LP (9) can be solved online in polynomial time by paying an  $O(\log n)$  factor. This requires that both  $\log(1/z_e)$  and  $\log \text{LP}^*$  are polynomial in the number of bits used for the edge lengths, where  $\text{LP}^*$  is the

optimum of LP (9). Clearly,  $\log \text{LP}^* \leq \log |E|$  is in  $\text{poly}(n)$ . For  $\log(1/z_e)$ , the subroutine that approximately solves LP (8) returns an approximate solution  $z$  which is represented by polynomial number of bits used for the edge lengths [57, 66]. By Theorem 20, we have the following Lemma.

► **Lemma 19.** *There exists a polynomial time  $O(\log n)$ -competitive online algorithm for LP (5).*

## B.2 Conditional edge selection

After having a fractional solution of LP (5) in round  $i$  where  $i \geq T = \lfloor n^{4/5} \rfloor$ , we independently pick  $e \in E \setminus E'$  with some scaled probability so that the edge selection is consistent with the probability based on the online solution of LP (5). More specifically, let  $p_e := \min\{1, x_e t \ln n\}$  and let  $p_e^i$  be the value of  $p_e$  in round  $i$ . Let  $\tilde{E}$  be the set of edges where each edge is neither selected while adding cheapest feasible paths prior to round  $T$  nor selected while adding in-arborescences and out-arborescences in round  $T$ . We show that each edge  $e \in \tilde{E}$  has already been selected with probability  $p_e^i$  in round  $i$ . This can be proved by induction. According to Algorithm 3, the base case is round  $T$ , where  $e \in \tilde{E}$  is selected with probability  $p_e^T$ . Now suppose  $i > T$ , if  $e \in \tilde{E}$  has been selected, it is either selected prior to round  $i$  or in round  $i$ . For the former case,  $e$  must have already been selected in round  $i-1$ , with probability  $p_e^{i-1}$  by inductive hypothesis. For the later case, conditioned on  $e$  has not been selected in round  $i-1$ ,  $e$  is selected with probability  $(p_e^i - p_e^{i-1})/(1 - p_e^{i-1})$ . Therefore, in round  $i$ ,  $e$  has been selected with probability  $p_e^{i-1} + (1 - p_e^{i-1}) \cdot \frac{p_e^i - p_e^{i-1}}{1 - p_e^{i-1}} = p_e^i$ , which completes the proof. Intuitively, when  $i > T$ , conditioned on  $e \in \tilde{E}$  was not picked from round 1 to round  $i-1$ , we pick  $e$  with probability  $(p_e^i - p_e^{i-1})/(1 - p_e^{i-1})$  at round  $i$ , so that the overall probability that  $e$  is picked from round 1 to round  $i$  is  $p_e^i$ .

## B.3 Summary

We conclude the proof as follows. The overall algorithm is given in Algorithm 3. For the initialization,  $x$  is a zero vector,  $E'$  is an empty set, and  $T = t = \lfloor n^{4/5} \rfloor$ . The set  $E'$  is the solution. We pay an extra logarithmic factor for solving LP (5) online by Lemma 19. The competitive ratio remains  $\tilde{O}(n^{4/5})$ . ◀

## C Online Covering in Polynomial Time

This section is devoted to proving the formal version of Theorem 8. We recall that the problem of interest is to solve the covering LP (2) online:

$$\text{minimize } \langle \mathbf{c}, x \rangle \text{ over } x \in \mathbb{R}_{\geq 0}^n \text{ s.t. } Ax \geq \mathbf{1}$$

where  $A \in \mathbb{R}_{\geq 0}^{m \times n}$  consists of  $m$  covering constraints,  $\mathbf{1} \in \mathbb{R}_{> 0}^m$  is a vector of all ones treated as the lower bound of the covering constraints, and  $\mathbf{c} \in \mathbb{R}_{> 0}^n$  denotes the positive coefficients of the linear cost function.

In the online covering problem, the cost vector  $\mathbf{c}$  is given offline, and each of these covering constraints is presented one by one in an online fashion, that is,  $m$  can be unknown. In round  $i \in [m]$ ,  $\{a_{ij}\}_{j \in [n]}$  (where  $a_{ij}$  denotes the  $i$ -th row  $j$ -th column entry of  $A$ ) is revealed, and we have to monotonically update  $x$  so that the constraint  $\sum_{j \in [n]} a_{ij} x_j \geq 1$  is satisfied. We always assume that there is at least one positive entry  $a_{ij}$  in each round  $i$ , otherwise constraint  $i$  cannot be satisfied since all the row entries are zeros. The goal is to update  $x$  in a non-decreasing manner and approximately minimize the objective value  $\langle \mathbf{c}, x \rangle$ .

We recall that an important idea in this line of work is to simultaneously consider the dual packing problem:

$$\text{maximize } \langle \mathbf{1}, y \rangle \text{ over } y \in \mathbb{R}_{\geq 0}^m \text{ s.t. } A^T y \leq \mathbf{c}$$

where  $A^T$  consists of  $n$  packing constraints with an upper bound  $\mathbf{c}$  given offline.

The primal-dual framework in [26] simultaneously solves both LP (2) and LP (3), and crucially uses LP-duality and strong connections between the two solutions to argue that they are both nearly optimal. The modified framework closely follows the *guess-and-double* scheme in [26]. Specifically, the scheme runs in phases where each phase estimates a lower bound for the optimum. When the first constraint arrives, the scheme generates the first lower bound

$$\alpha(1) \leftarrow \min_{j \in [n]} \left\{ \frac{c_j}{a_{1j}} \mid a_{1j} > 0 \right\} \leq \text{OPT}$$

where  $c_j$  is the  $j$ -th entry of  $\mathbf{c}$  and OPT is the optimal value of LP (2).

During phase  $r$ , we always assume that the lower bound of the optimum is  $\alpha(r)$  until the online objective  $\langle \mathbf{c}, x \rangle$  exceeds  $\alpha(r)$ . Once the online objective exceeds  $\alpha(r)$ , we start the new phase  $r + 1$  from the current violating constraint<sup>4</sup> (let us call it constraint  $i_{r+1}$ , in particular,  $i_1 = 1$ ), and double the estimated lower bound, i.e.  $\alpha(r + 1) \leftarrow 2\alpha(r)$ . We recall that  $x$  must be updated in a non-decreasing manner, so the algorithm maintains  $\{x_j^r\}$ , which denotes the value of each variable  $x_j$  in each phase  $r$ , and the value of each variable  $x_j$  is actually set to  $\max_r \{x_j^r\}$ .

In Algorithm 4, we describe one round of the modified scheme in phase  $r$ . When a covering constraint  $i$  arrives, we introduce a packing variable  $y_i = 0$ . If the constraint is violated, we increment each  $x_j$  according to an exponential function of  $y_i$  until the constraint is satisfied *by a factor of 2*. This is the main difference between the modified framework and [26], which increments the variables until the constraint is satisfied.

■ **Algorithm 4** Online Covering.

- 
- 1: **for** arriving covering constraint  $i$  **do**
  - 2:      $y_i \leftarrow 0$ . ▷ the packing variable  $y_i$  is used for the analysis
  - 3:     **if**  $\sum_{j=1}^n a_{ij} x_j^r < 1$  **then** ▷ if constraint  $i$  is not satisfied
  - 4:         **while**  $\sum_{j=1}^n a_{ij} x_j^r < 2$  **do** ▷ update until constraint  $i$  is satisfied by a factor of 2
  - 5:             Increase  $y_i$  continuously.
  - 6:             Increase each variable  $x_j^r$  by the following increment function:

$$x_j^r \leftarrow \frac{\alpha(r)}{2nc_j} \exp \left( \frac{\ln(2n)}{c_j} \sum_{k=i_r}^i a_{kj} y_k \right).$$

---

Although the augmentation is in a continuous fashion, it is not hard to implement it in a discrete way for any desired precision by binary search. Therefore, to show that the modified framework is efficient, it suffices to bound the number of violating constraints it will encounter. The performance of the modified scheme is analyzed in Theorem 20 (the formal version of Theorem 8).

---

<sup>4</sup> In [26], the scheme starts all over again from the first constraint. We start from the current violating constraint because it is more amenable when violating constraints are generated by a separation oracle. There is no guarantee for the order of arriving violating constraints in such settings.

► **Theorem 20.** *There exists an  $O(\log n)$ -competitive online algorithm for the covering LP (2) which encounters  $\text{poly}(n, \log \text{OPT}, \log(1/\alpha(1)))$  violating constraints.*

**Proof.** The proof for the  $O(\log n)$ -competitiveness closely follows the one in [26]. Let  $X(r)$  and  $Y(r)$  be the covering and packing objective values, respectively, generated during phase  $r$ . The following claims are used to show that Algorithm 4 is  $O(\log n)$ -competitive.

1.  $x$  is feasible.
2. For each *finished* phase  $r$ ,  $\alpha(r) \leq 4 \ln(2n) \cdot Y(r)$ .
3.  $y$  generated during phase  $r$  is feasible.
4. The sum of the covering objective generated from phase 1 to  $r$  is at most  $2\alpha(r)$ .
5. Let  $r'$  be the last phase, then the covering objective  $\langle \mathbf{c}, x \rangle \leq 2\alpha(r')$ .

From these five claims together with weak duality, we conclude that

$$\langle \mathbf{c}, x \rangle \leq 2\alpha(r') = 4\alpha(r' - 1) \leq 16 \ln(2n) \cdot Y(r' - 1) \leq 16 \ln(2n) \cdot \text{OPT}.$$

Now we show that Algorithm 4 encounters  $\text{poly}(n, \log \text{OPT}, \log(1/\alpha(1)))$  violating constraints. We first show that there are  $O(\log \log n + \log \text{OPT} + \log(1/\alpha(1)))$  phases. The estimated lower bound  $\alpha$  doubles when we start a new phase. Suppose there are  $r'$  phases, then  $\alpha(1) \cdot 2^{r'-1} = O(\log n) \text{OPT}$  because Algorithm 4 is  $O(\log n)$ -competitive. This implies that  $r' = O(\log \log n + \log \text{OPT} + \log(1/\alpha(1)))$ .

In each phase, when a violating constraint arrives, we increment  $x$  so that the constraint is satisfied by a factor of 2. This implies that at least one variable  $x_j$  is doubled.  $x_j = O(\log n) \text{OPT}/c_j$  because  $c_j x_j \leq \langle \mathbf{c}, x \rangle = O(\log n) \text{OPT}$ . At the start of phase  $r$ ,  $x_j = \alpha(r)/(2nc_j) \geq \alpha(1)/(2nc_j)$ . Suppose  $x_j$  has been doubled  $t$  times in phase  $r$ , then

$$\frac{\alpha(1)}{2nc_j} \cdot 2^t \leq \frac{\alpha(r)}{2nc_j} \cdot 2^t \leq x_j = O(\log n) \frac{\text{OPT}}{c_j}$$

which indicates that  $t = O(\log n + \log \text{OPT} + \log(1/\alpha(1)))$ .

There are  $n$  variables and  $r'$  phases, and in each phase, each variable is doubled at most  $t$  times. Therefore, Algorithm 4 encounters  $\text{poly}(n, \log \text{OPT}, \log(1/\alpha(1)))$  violating constraints. ◀

## Abstract

In this work, we resolve the query complexity of global minimum cut problem for a graph by designing a randomized algorithm for approximating the size of minimum cut in a graph, where the graph can be accessed through local queries like DEGREE, NEIGHBOR, and ADJACENCY queries.

Given  $\epsilon \in (0, 1)$ , the algorithm with high probability outputs an estimate  $\hat{t}$  satisfying the following  $(1 - \epsilon)t \leq \hat{t} \leq (1 + \epsilon)t$ , where  $t$  is the size of minimum cut in the graph. The expected number of local queries used by our algorithm is  $\min\{m + n, \frac{m}{\epsilon}\} \text{poly}(\log n, \frac{1}{\epsilon})$  where  $n$  and  $m$  are the number of vertices and edges in the graph, respectively. Eden and Rosenbaum showed that  $\Omega(m/t)$  local queries are required for approximating the size of minimum cut in graphs, but no local query based algorithm was known. Our algorithmic result coupled with the lower bound of Eden and Rosenbaum [APPROX 2018] resolve the query complexity of the problem of estimating the size of minimum cut in graphs using local queries.

Building on the lower bound of Eden and Rosenbaum, we show that, for all  $t \in \mathbb{N}$ ,  $\Omega(m)$  local queries are required to decide if the size of the minimum cut in the graph is  $t$  or  $t - 2$ . Also, we show that, for any  $t \in \mathbb{N}$ ,  $\Omega(m)$  local queries are required to find all the minimum cut edges even if it is promised that the input graph has a minimum cut of size  $t$ . Both of our lower bound results are randomized, and hold even if we can make RANDOM EDGE queries in addition to local queries.

## 1 Introduction

The global minimum cut (denoted MINCUT) of a connected, unweighted, undirected and simple graph  $G = (V, E)$ ,  $|V| = n$  and  $|E| = m$ , is a partition of the vertex set  $V$  into two sets  $S$  and  $V \setminus S$  such that the number of edges between  $S$  and  $V \setminus S$  is minimized. Let  $\text{CUT}(G)$  denote this edge set corresponding to a minimum cut in  $G$ , and  $t$  denote  $|\text{CUT}(G)|$ . The problem is so fundamental that researchers keep coming back to it again and again across different models [23, 22, 27, 25, 28, 1, 29, 14, 12, 13, 21]. The algorithmic landscape for the minimum cut problem has been heavily influenced by Karger and Stein's work [22, 23] and algorithmic solutions for minimum cut across different models [27, 25, 28, 1, 29, 14, 12,

13, 21] \* have revisited their approach [22, 23]. Fundamental graph parameter estimation problems, like estimation of the number of edges [11, 17], triangles [7], cliques [8], stars [18], etc. have been solved in the local and bounded query models [16, 17, 24]. Estimation of the size of MINCUT is also in the league of such fundamental problems to be solved in the model of local queries.

In property testing [15], a graph can be accessed at different granularities – the query oracle can answer properties about graph that are local or global in nature. Local queries involve the relation of a vertex with its immediate neighborhood, whereas, global queries involve the relation between sets of vertices. Recently using a global query, named CUT QUERY [29], the problem of estimating and finding MINCUT was solved, but the problem of estimating or finding MINCUT using local queries has not been solved. The fundamental contribution of our work is to resolve the query complexity of MINCUT using local queries. We resolve both the estimation and finding variants of the problem. To start with, we formally define the query oracle models we would be needing for discussions that follow. Before proceeding further, we note that all the upper and lower bound results in this paper are randomized unless otherwise stated.

**The query oracle models.** We start with the most studied local queries and the random edge query for a graph  $G = (V, E)$  where the vertex set  $V$  is known but the edge set  $E$  is unknown.

- Local Query
  - DEGREE query: given  $u \in V$ , the oracle reports the degree of  $u$  in  $V$ ;
  - NEIGHBOR query: given  $u \in V$  and a positive integer  $i$ , the oracle reports the  $i$ -th neighbor of  $u$ , if it exists; otherwise, the oracle reports  $\perp$ ;
  - ADJACENCY query: given  $u, v \in V$ , the oracle reports whether  $\{u, v\} \in E$ .
- RANDOM EDGE query: The query outputs an uniformly random edge of  $G$ .

Apart from the local queries mentioned, in the last few years, researchers have also used the RANDOM EDGE query [2, 3]. Notice that the randomness will be over the probability space of all edges, and hence, a random edge query is not a local query. This fact is also evident from the work of Eden and Rosenbaum [10]. We use RANDOM EDGE query in conjunction with local queries only for lower bound purposes. The other query oracle relevant for our discussion will be a *global query* called the CUT QUERY proposed by Rubinfeld et al. [29] that was motivated by submodular function minimization. The query takes as input a subset  $S$  of the vertex set  $V$  and returns the size of the cut between  $S$  and  $V \setminus S$  in the graph  $G$ .

**Prologue.** Our motivation for this work is twofold – MINCUT is a fundamental graph estimation problem that needs to be solved in the local query oracle model and the lower bound of Eden and Rosenbaum [9] who extended the seminal work of Blais et al. [5] to develop a technique for proving query complexity lower bounds for graph properties via reductions from communication complexity. Using those techniques, for graphs that can be accessed by only local queries like DEGREE, NEIGHBOR, ADJACENCY and RANDOM EDGE, Eden and Rosenbaum [9] showed that MINCUT admits a lower bound of  $\Omega(m/t)$  in general graphs, where  $m$  and  $t$  are the number of edges and the size of the minimum cut, respectively, in the graph. However, the query complexity of estimating MINCUT (in general graphs)

---

\* The list is to name a few and it is not exhaustive.

has remained elusive as there is no matching upper bound. It is surprising that the query complexity of a fundamental graph problem like MINCUT has not been addressed before Eden and Rosenbaum [9].

In this work, we prove an upper bound of  $\min\{m + n, \frac{m}{t}\} \text{poly}(\log n, \frac{1}{\epsilon})$  for estimating MINCUT using local queries only (and not RANDOM EDGE query). Observe that for  $t \geq 1$ , our upper bound almost matches with the lower bound given by Eden and Rosenbaum [9] if we ignore  $\text{poly}(\log n, \frac{1}{\epsilon})$  term. Note that the case of  $t = 0$  is the CONNECTIVITY problem, where the objective is to decide whether the graph is connected. We build on the lower bound result for *estimating* MINCUT by Eden et al. [9] to show that  $\Omega(m)$  local queries are required if we want to determine the exact size of a MINCUT or find a MINCUT. This result implies that there is a separation between the problem of estimating the size of MINCUT and the problem of finding a MINCUT using local queries. On the other hand, Babai et al. [4] showed that CONNECTIVITY testing has a randomized communication complexity of  $\Omega(n)$ <sup>†</sup>. This implies that any algorithm that solves CONNECTIVITY requires  $\Omega(n/\log n)$  local queries. This is because Alice and Bob can deterministically simulate each local query by communicating at most  $\log n$  bits. We have already discussed that  $\Omega(m)$  local queries are needed to solve CONNECTIVITY. From the lower bounds of  $\Omega(m)$  and  $\Omega(n/\log n)$  for CONNECTIVITY along with the lower bound result of Eden and Rosenbaum [9] for estimating MINCUT, our upper bound result on estimating MINCUT (ignoring  $\text{poly}(\log n, \frac{1}{\epsilon})$  term) is tight - this settles the query complexity of MINCUT using local queries.

Prior to our work, no local query based algorithm existed for MINCUT. But it was Rubinfeld et al. [29] who studied MINCUT for the first time using CUT QUERY, a global query. They showed that there exists a randomized algorithm for finding a MINCUT in  $G$  using  $\tilde{O}(n)$ <sup>‡</sup> CUT QUERY. The deterministic lower bound of  $\Omega(n \log n)$  by Hajnal et al. [20], for CONNECTIVITY in communication complexity, implies that  $\Omega(n)$  CUT QUERY are required by any deterministic algorithm to estimate MINCUT. The randomized lower bound of  $\Omega(n)$  by Babai et al. [4], for CONNECTIVITY in communication complexity, says that  $\Omega(n/\log n)$  CUT QUERY are necessary for any randomized algorithm to estimate MINCUT<sup>§</sup>. So, if we ignore polylogarithmic factors, the upper bound result by Rubinfeld et al. for finding a MINCUT along with the above discussed lower bound result for finding a MINCUT, imply that there is no separation between the problem of estimating size of MINCUT and the problem of finding a MINCUT using CUT QUERY. On a different note, Gaur et al. [19] showed a deterministic lower bound of  $3n/2$  on the number of CUT QUERY for estimating MINCUT.

**Problem statements and results.** We focus on two problems in this work.

Minimum Cut Estimation

**Input:** A parameter  $\epsilon \in (0, 1)$ , and access to an unknown graph  $G$  via local queries

**Output:** A  $(1 \pm \epsilon)$ -approximation to  $|\text{CUT}(G)|$ .

Minimum Cut Finding

**Input:** Access to an unknown graph  $G$  via local queries

**Output:** Find a set  $\text{CUT}(G)$ .

<sup>†</sup> Here the edge set of the graph is partitioned among Alice and Bob. The objective of Alice and Bob is to determine whether the graph is connected by communicating.

<sup>‡</sup>  $\tilde{O}(n)$  hides polylogarithmic terms in  $n$ .

<sup>§</sup> We would like to thank Troy Lee for pointing us to the papers of Hajnal et al. [20] and Babai et al. [4]

Our results are the following.

► **Theorem 1.1** (Minimum cut estimation using local queries). *There exists an algorithm, with DEGREE and NEIGHBOR query access to an unknown graph  $G = (V, E)$ , that solves the minimum cut estimation problem with high probability. The expected number of queries used by the algorithm is  $\min\{m + n, \frac{m}{t}\} \text{poly}(\log n, \frac{1}{\epsilon})$ .*

Building on the lower bound construction of Eden and Rosenbaum [9], we show that no nontrivial query algorithm exists for finding a minimum cut or even estimating the exact size of a minimum cut in graphs.

► **Theorem 1.2** (Lower bound for minimum cut finding, i.e.,  $\text{CUT}(G)$ ). *Let  $m, n, t \in \mathbb{N}$  with  $t \leq n - 1$  and  $2nt \leq m \leq \binom{n}{2}$ <sup>¶</sup>. Any algorithm that has access to DEGREE, NEIGHBOR, ADJACENCY and RANDOM EDGE queries to an unknown graph  $G = (V, E)$  must make at least  $\Omega(m)$  queries in order to find all the edges in a minimum cut of  $G$  with probability  $2/3$ .*

► **Theorem 1.3** (Lower bound for finding the exact size of the minimum cut, i.e.,  $|\text{CUT}(G)|$ ). *Let  $m, n, t \in \mathbb{N}$  with  $2 \leq t \leq n - 2$  and  $2nt \leq m \leq \binom{n}{2}$ . Any algorithm that has access to DEGREE, NEIGHBOR, ADJACENCY and RANDOM EDGE queries to an unknown graph  $G = (V, E)$  must make at least  $\Omega(m)$  queries in order to decide whether  $|\text{CUT}(G)| = t$  or  $|\text{CUT}(G)| = t - 2$  with probability  $2/3$ .*

► **Remark 1.** Local queries show a clear separation in its power in finding MINCUT as opposed to the estimation problem. This is established by using the tight lower bound of minimum cut estimation (viz.  $\Omega(m/t)$  lower bound of Eden and Rosenbaum and our Theorem 1.1) vis-a-vis minimum cut finding as mentioned in our Theorems 1.2 and 1.3 on lower bound for finding  $\text{CUT}(G)$ . As noted earlier, there is no such separation between estimating and finding MINCUT when CUT QUERY is used.

**Notations.** In this paper, we denote the set  $\{1, \dots, n\}$  by  $[n]$ . For ease of notation, we sometimes use  $[n]$  to denote the set of vertices of a graph. We say  $x \geq 0$  is an  $(1 \pm \epsilon)$ -approximation to  $y \geq 0$  if  $|x - y| \leq \epsilon y$ .  $V(G)$  and  $E(G)$  would denote the vertex and edge sets when we want to make the graph  $G$  explicit, else we use  $V$  and  $E$ . For a graph  $G$ ,  $\text{CUT}(G)$  denotes the set of edges in a minimum cut of  $G$ . Let  $A_1, A_2$  be a partition of  $V$ , i.e.,  $V = A_1 \cup A_2$  with  $A_1 \cap A_2 = \emptyset$ . Then,  $\mathcal{C}_G(A_1, A_2) = \{\{u, v\} \in E : u \in A_1 \text{ and } v \in A_2\}$ . The statement *with high probability* means that the probability of success is at least  $1 - \frac{1}{n^c}$ , where  $c$  is a positive constant.  $\tilde{\Theta}(\cdot)$  and  $\tilde{O}(\cdot)$  hides a  $\text{poly}(\log n, \frac{1}{\epsilon})$  term in the upper bound.

**Organization of the paper.** Section 2 discusses the query algorithm for estimating the MINCUT while Section 3 proves lower bounds on finding the MINCUT. Section 4 concludes with a few observations.

## 2 Estimation algorithm

In this Section, we will prove Theorem 1.1. In Section 2.1, we discuss about the intuitions and give the overview of our algorithm. We formalize the intuitions in Section 2.2.

<sup>¶</sup> As mentioned at the beginning of the introduction,  $n, m$  and  $t$  denote the number of vertices, number of edges and the size of MINCUT in  $G$ , respectively.

## 2.1 Overview of our algorithm

We start by assuming that a lower bound  $\hat{t}$  on  $t = |\text{CUT}(G)|$  is known. Later, we discuss how to remove this assumption.

We generate a random subgraph  $H$  of  $G$  by sampling each edge of the graph  $G$  independently with probability  $p = \Theta(\log n / \epsilon^2 \hat{t})$ <sup>||</sup>. Using Chernoff bound, we can show that any particular cut of size  $k$ ,  $k \geq t$ , in  $G$  is *well approximated* in  $H$  with probability at least  $n^{-\Omega(k/\hat{t})}$ . With this idea, consider the following Algorithm, stated informally, for minimum cut estimation.

### Algorithm-Sketch (works with $\hat{t} \leq t$ )

**Step-1:** Generate a random subgraph  $H$  of  $G$  by sampling each edge in  $G$  independently with probability  $p = \Theta(\log n / \epsilon^2 \hat{t})$ . Note that  $H$  can be generated by using  $\tilde{O}(m/\hat{t})$  DEGREE and NEIGHBOR queries in expectation. We will discuss it in Algorithm 1 in Section 2.2.

**Step-2** Determine  $|\text{CUT}(H)|$  and report  $\tilde{t} = \frac{|\text{CUT}(H)|}{p}$  as a  $(1 \pm \epsilon)$ -approximation of  $|\text{CUT}(G)|$ . The number of queries made by the above algorithm is  $\tilde{O}(m/\hat{t})$  in expectation. But it produces correct output only when the vertex partition corresponding to  $\text{CUT}(G)$  and  $\text{CUT}(H)$  are the same. This is not the case always. If we can show that all cuts in  $G$  are approximately preserved in  $H$ , then Algorithm-Sketch produces correct output with high probability. The main bottleneck to prove it is that the total number of cuts in  $G$  can be exponential. A result of Karger (stated in the following lemma) will help us to make Algorithm-Sketch work.

► **Lemma 2.1** (Karger [22]). *For a given graph  $G$  the number of cuts in  $G$  of size at most  $j \cdot |\text{CUT}(G)|$  is at most  $n^{2j}$ .*

Using the above lemma along with Chernoff bound, we can show the following.

► **Lemma 2.2.** *Let  $G$  be a graph,  $\hat{t} \leq t = |\text{CUT}(G)|$  and  $\epsilon \in (0, 1)$ . If  $H(V(G), E_p)$  is a subgraph of  $G$  where each edge in  $E(G)$  is included in  $E_p$  with probability  $p = \min\left\{\frac{200 \log n}{\epsilon^2 \hat{t}}, 1\right\}$  independently, then every cut of size  $k$  in  $G$  has size  $pk(1 \pm \epsilon)$  in  $H$  with probability at least  $1 - \frac{1}{n^{10}}$ .*

The above lemma implies the correctness of Algorithm-Sketch, which is for minimum cut estimation when we know a lower bound  $\hat{t}$  of  $|\text{CUT}(G)|$ . But in general we do not know any such  $\hat{t}$ . To get around the problem, we start guessing  $\hat{t}$  starting from  $\frac{n}{2}$  each time reducing  $\hat{t}$  by a factor of 2. The guessing scheme gives the desired solution due to Lemma 2.2 coupled with the following intuition when  $\hat{t} = \Omega(t \log n / \epsilon^2)$  – if we generate a random subgraph  $H$  of  $G$  by sampling each edge with probability  $p = \Theta(\log n / \epsilon^2 \hat{t})$ , then  $H$  is disconnected with at least a constant probability. So, it boils down to a connectivity check in  $H$ . The intuition is formalized in the following lemma that can be proved using Markov's inequality.

► **Lemma 2.3.** *Let  $G$  be a graph with  $|V(G)| = n$ ,  $\hat{t} \geq \frac{2000 \log n}{\epsilon^2} |\text{CUT}(G)|$  and  $\epsilon \in (0, 1)$ . If  $H(V(G), E_p)$  be a subgraph of  $G$  where each edge in  $E(G)$  is included in  $E_p$  independently with probability  $p = \min\left\{\frac{200 \log n}{\epsilon^2 \hat{t}}, 1\right\}$ , then  $H$  is connected with probability at most  $\frac{1}{10}$ .*

Before moving to the next section, we prove Lemmas 2.2 and 2.3 here.

<sup>||</sup> Though  $p$  can be more than 1 here, we will make it explicit in the formal description

## 6:6 Query Complexity of Global Minimum Cut

**Proof of Lemma 2.2.** If  $p = 1$ , we are done as the graph  $H$  is exactly the same as that of  $G$ . So, without loss of generality assume that the graph  $G$  is connected. Otherwise, the lemma holds trivially as  $|\text{CUT}(G)| = 0$ , i.e.,  $\hat{t} = 0$  and  $p = 1$ . Hence, for the rest of the proof we will assume that  $p = \frac{200 \log n}{\epsilon^2 \hat{t}}$ .

Consider a cut  $\mathcal{C}_G(A_1, A_2)$  of size  $k$  in  $G$ . As we are sampling each edge with probability  $p$ , the expected size of the cut  $\mathcal{C}_H(A_1, A_2)$  is  $pk$ . Using Chernoff bound (see Lemma B.1 in Section B), we get

$$\mathbb{P}(|\mathcal{C}_H(A_1, A_2) - pk| \geq \epsilon pk) \leq e^{-\epsilon^2 pk/3\hat{t}} = n^{-\frac{100k}{3\hat{t}}} \quad (1)$$

Note that here we want to show that every cut in  $G$  is approximately preserved in  $H$ . To do so, we will use Lemma 2.1 along with Equation (1) as follows. Let  $Z_1, Z_2, \dots, Z_\ell$  be the partition of the set of all cuts in  $G$  such that each cut in  $Z_j$  has the number of edges between  $[j \cdot |\text{CUT}(G)|, (j+1) \cdot |\text{CUT}(G)|]$ , where  $\ell \leq \frac{n}{|\text{CUT}(G)|}$  and  $j \leq \ell - 1$ . From Lemma 2.1,  $|Z_j| \leq n^{2j}$ . Consider a particular  $Z_j, j \in [\ell]$ . Using the union bound along with Equation 1, the probability that there exists a cut in  $Z_j$  that is not approximately preserved in  $H$  is at most  $\frac{1}{n^{11}}$ . Taking union bound over all  $Z_j$ 's, the probability that there exists a cut in  $G$  that is not approximately preserved is at most  $\frac{1}{n^{10}}$ .  $\blacktriangleleft$

**Proof of Lemma 2.3.** Let  $\mathcal{C}_G(A_1, A_2)$  be a minimum cut in  $G$ . Observe,  $\mathbb{E}[|\mathcal{C}_H(A_1, A_2)|] = p|\mathcal{C}_G(A_1, A_2)| = p|\text{CUT}(G)|$ . From Markov's inequality, we get  $\mathbb{P}(G \text{ is connected}) \leq \mathbb{P}(|\mathcal{C}_G(A_1, A_2)| \geq 1) \leq \mathbb{E}[|\mathcal{C}_G(A_1, A_2)|] \leq \frac{1}{10}$ .  $\blacktriangleleft$

## 2.2 Formal Algorithm (Proof of Theorem 1.1)

In this Section, the main algorithm for minimum cut estimation is described in Algorithm 3 (ESTIMATOR) that makes multiple calls to Algorithm 2 (VERIFY-GUESS). The VERIFY-GUESS subroutine in turn calls Algorithm 1 (SAMPLE) multiple times.

Given degree sequence of the graph  $G$ , that can be obtained using degree queries, we will first show how to independently sample each edge of  $G$  with probability  $p$  using only NEIGHBOR queries.

■ **Algorithm 1** SAMPLE( $D, p$ ).

---

**Input:**  $D = \{d(i) : i \in [n]\}$ , where  $d(i)$  denotes the degree of the  $i$ -th vertex in the graph  $G$ , and  $p \in (0, 1]$ .

**Output:** Return a subgraph  $H(V, E_p)$  of  $G(V, E)$  where each edge in  $E(G)$  is included in  $E_p$  with probability  $p$ .

Set  $q = 1 - \sqrt{1 - p}$  and  $m = \frac{\sum_{i=1}^n d_i}{2}$ ;

**for** (each  $i \in [n]$ ) **do**

**for** (each  $j \in [d(i)]$  with  $d(i) > 0$ ) **do**

        // Let  $r_j$  be the  $j$ -th neighbor of the  $i$ -th vertex;

        Add the edge  $(i, r_j)$  to the set  $E_p$  with probability  $q$ ;

**end**

**end**

Return the graph  $H(V, E_p)$ .

---

The following lemma proves the correctness of the above algorithm SAMPLE( $D, p$ ).

► **Lemma 2.4.**  $\text{SAMPLE}(D, p)$  returns a random subgraph  $H(V(G), E_p)$  of  $G$  such that each edge  $e \in E$  is included in  $E_p$  independently with probability  $p$ . Moreover, in expectation, the number of NEIGHBOR queries made by  $\text{SAMPLE}(D, p)$  is at most  $2pm$ .

**Proof.** From the description of  $\text{SAMPLE}(D, p)$ , it is clear that the probability that a particular edge  $e \in E(G)$  is added to  $E_p$  with probability  $1 - (1 - p)^2 = p$ .

Observe,  $\mathbb{E}[|E_p|] = pm$ . The bound on the number of NEIGHBOR queries now follows from the fact that  $\text{SAMPLE}(D, p)$  makes at most  $2|E_p|$  many NEIGHBOR queries. ◀

One of the core ideas behind the proof of Theorem 1.1 is that, given an estimate  $\hat{t}$  of  $t$ , we want to efficiently (in terms of number of local queries used by the algorithm) decide if  $\hat{t} \leq t$  or if  $\hat{t} \gtrsim \frac{\log n}{\epsilon^2} \times t$ . Using Algorithm 2, we will show that this can be done using  $\tilde{O}\left(\frac{m}{\hat{t}}\right)$  many NEIGHBOR queries in expectation. Another interesting feature of Algorithm 2 is that, if estimate  $\hat{t} \leq t$ , then Algorithm 2 outputs an estimate which is a  $(1 \pm \epsilon)$ -approximation of  $t$ .

■ **Algorithm 2**  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$ .

---

**Input:**  $D = \{d(i) : i \in [n]\}$ , where  $d(i)$  denotes the degree of the  $i$ -th vertex in the graph  $G$  and  $m = \frac{1}{2} \sum_{i=1}^n d(i) \geq n - 1$ . Also, a guess  $\hat{t}$ , with  $1 \leq \hat{t} \leq \frac{n}{2}$ , for the size of the global minimum cut in  $G$ , and  $\epsilon \in (0, 1)$ .

**Output:** The algorithm should “ACCEPT” or “REJECT”  $\hat{t}$ , with high probability, depending on the following

- If  $\hat{t} \leq |\text{CUT}(G)|$ , then ACCEPT  $\hat{t}$  and also output a  $(1 \pm \epsilon)$ -approximation of  $|\text{CUT}(G)|$
- If  $\hat{t} \geq \frac{200 \log n}{\epsilon^2} |\text{CUT}(G)|$ , then REJECT  $\hat{t}$

Set  $p = \min \left\{ \frac{200 \log^2 n}{\epsilon^2 \hat{t}}, 1 \right\}$ ;

Set  $\Gamma = 100 \log n$  and Call  $\text{SAMPLE}(D, p)$   $\Gamma$  times;

// Let  $H_i(V, E_p^i)$  be the output of  $i$ -th call to  $\text{SAMPLE}(D, p)$ , where  $i \in [\Gamma]$

**if** (at least  $\Gamma/2$  many  $H_i$ 's are disconnected) **then**

  | REJECT  $\hat{t}$

**end**

**else if** (all  $H_i$ 's are connected) **then**

  | ACCEPT  $\hat{t}$ , find  $\text{CUT}(H_i)$  for any  $i \in [\Gamma]$ , and return  $\tilde{t} = \frac{|\text{CUT}(H_i)|}{p}$ .

**end**

**else**

  | Return FAIL.

  | // When we cannot decide between “REJECT” or “ACCEPT” it will return FAIL

**end**

---

The following lemma proves the correctness of Algorithm 2. The lemmas used in proof are Lemmas 2.2, 2.3 and 2.4.

► **Lemma 2.5.**  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  in expectation makes  $\tilde{O}\left(\frac{m}{\hat{t}}\right)$  many NEIGHBOR queries to the graph  $G$  and behaves as follows:

- (i) If  $\hat{t} \geq \frac{200 \log n}{\epsilon^2} |\text{CUT}(G)|$ , then  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  rejects  $\hat{t}$  with probability at least  $1 - \frac{1}{n^9}$ .
- (ii) If  $\hat{t} \leq |\text{CUT}(G)|$ , then  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  accepts  $\hat{t}$  with probability at least  $1 - \frac{1}{n^9}$ . Moreover, in this case,  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  reports an  $(1 \pm \epsilon)$ -approximation to  $\text{CUT}(G)$ .

**Proof.**  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  calls  $\text{SAMPLE}(D, \epsilon)$  for  $\Gamma = 100 \log n$  times with  $p$  being set to  $\min \left\{ \frac{2000 \log n}{\epsilon^2 \hat{t}}, 1 \right\}$ . Recall from Lemma 2.4 that each call to  $\text{SAMPLE}(D, p)$  makes in expectation at most  $2pm$  many  $\text{NEIGHBOR}$  queries, and returns a random subgraph  $H(V, E_p)$ , where each edge in  $E(G)$  is included in  $E_p$  with probability  $p$ . So,  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  makes in expectation  $\mathcal{O}(pm \log n) = \tilde{\mathcal{O}}(m/\hat{t})$  many  $\text{NEIGHBOR}$  queries and generates  $\Gamma$  many random subgraphs of  $G$ . The subgraphs are denoted by  $H_1(V, E_p^1), \dots, H_\Gamma(V, E_p^\Gamma)$ .

- (i) Let  $\hat{t} \geq \frac{2000 \log n}{\epsilon^2} |\text{CUT}(G)|$ . From Lemma 2.3, we have that  $H_i$  will be connected with probability at most  $\frac{1}{10}$ . Observe that in expectation, we get that at least  $\frac{9\Gamma}{10}$  many  $H_i$ 's will be disconnected. By Chernoff bound (see Lemma B.1 in Section B), the probability that at most  $\frac{\Gamma}{2}$  many  $H_i$ 's are disconnected is at most  $\frac{1}{n^{10}}$ . Therefore,  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  rejects any  $\hat{t}$  satisfying  $\hat{t} \geq \frac{2000 \log n}{\epsilon^2} |\text{CUT}(G)|$  with probability at least  $1 - \frac{1}{n^9}$ .
- (ii) Let  $\hat{t} \leq |\text{CUT}(G)|$ . Using Lemma 2.2, we have that every cut of size  $k$  in  $G$  has size  $pk(1 \pm \epsilon)$  in  $H_i$  with probability at least  $1 - \frac{1}{n^{10}}$ . Therefore, with probability at least  $1 - \frac{1}{n^{10}}$ , for all  $i \in [\Gamma]$ , every cut of size  $k$  in  $G$  has size  $pk(1 \pm \epsilon)$  in  $H_i$ . This implies that if  $\hat{t} \leq |\text{CUT}(G)|$  then  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  accepts any  $\hat{t}$  with probability at least  $1 - \frac{1}{n^9}$ . Moreover, for any  $H_i$ , observe that  $\frac{|\text{CUT}(H_i)|}{p}$  is a  $(1 \pm \epsilon)$ -approximation to  $|\text{CUT}(G)|$ . Hence, when  $\hat{t} \leq |\text{CUT}(G)|$ ,  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  also returns a  $(1 \pm \epsilon)$  approximation to  $|\text{CUT}(G)|$  with probability  $1 - \frac{1}{n^9}$ .  $\blacktriangleleft$

$\text{ESTIMATOR}(\epsilon)$  (Algorithm 3) will estimate the size of the minimum cut in  $G$  using  $\text{DEGREE}$  and  $\text{NEIGHBOR}$  queries. The main subroutine used by the algorithm will be  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$ .

The following lemma shows that with high probability  $\text{ESTIMATOR}(\epsilon)$  correctly estimates the size of the minimum cut in the graph  $G$ , and it also bounds the expected number of queries used by the algorithm.

**► Lemma 2.6.**  *$\text{ESTIMATOR}(\epsilon)$  returns a  $(1 \pm \epsilon)$  approximation to  $|\text{CUT}(G)|$  with probability at least  $1 - \frac{1}{n^8}$  by making in expectation  $\min \left\{ m + n, \frac{m}{\epsilon} \right\} \text{poly}(\log n, \frac{1}{\epsilon})$  queries and each query is either a  $\text{DEGREE}$  or a  $\text{NEIGHBOR}$  query to the unknown graph  $G$ .*

**Proof.** Without loss of generality, assume that  $n$  is a power of 2. If  $m < n - 1$  or if there exists a  $i \in [n]$  such that  $d_i = 0$  then the graph  $G$  is disconnected. In this case the algorithm  $\text{ESTIMATOR}(\epsilon)$  makes  $n$   $\text{DEGREE}$  queries and returns the correct answer. Thus we assume that  $m \geq n - 1$ .

First, we prove the correctness and query complexity when the graph is connected, that is,  $t \geq 1$ . Note that  $\text{ESTIMATOR}(\epsilon)$  calls  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  for different values of  $\hat{t}$  starting from  $\frac{n}{2}$ . Recall that  $\kappa = \frac{2000 \log n}{\epsilon^2}$ . For a particular  $\hat{t}$  with  $\hat{t} \geq \kappa t$ ,  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  does not  $\text{REJECT}$   $\hat{t}$  with probability at most  $\frac{1}{n^9}$  by Lemma 2.5 (i). So, by the union bound, the probability that  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  will either  $\text{ACCEPT}$  or  $\text{FAIL}$  for some  $\hat{t}$  with  $\hat{t} \geq \kappa t$ , is at most  $\frac{\log n}{n^9}$ . Hence, with probability at least  $1 - \frac{\log n}{n^9}$ , we can say that  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  rejects all  $\hat{t}$  with  $\hat{t} \geq \kappa t$ .

Observe that, from Lemma 2.5 (ii), the first time  $\hat{t}$  satisfies the following inequality  $\frac{t}{2} < \hat{t} \leq t$ ,  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  will accept  $\hat{t}$  with probability at least  $1 - \frac{1}{n^9}$ . Therefore, for the first time  $\text{VERIFY-GUESS}(D, \hat{t}, \epsilon)$  will either  $\text{ACCEPT}$  or  $\text{FAIL}$ , then  $\hat{t}$  satisfies the following inequality  $\frac{t}{2} < \hat{t} < \kappa t$  with probability at least  $1 - \frac{\log n + 1}{n^9}$ . Let  $\hat{t}_0$  denote the first time  $\text{VERIFY-GUESS}$  returns  $\text{ACCEPT}$  or  $\text{FAIL}$ . From the description of  $\text{ESTIMATOR}(\epsilon)$ , note that, we get  $\hat{t}_u$  by dividing  $\hat{t}_0$  by  $\kappa$ . Note that, with probability at least  $1 - \frac{1 + \log n}{n^9}$ , we have

---

**Algorithm 3** ESTIMATOR( $\epsilon$ ).

---

**Input:** DEGREE and NEIGHBOR query access to an unknown graph  $G$ , and a parameter  $\epsilon \in (0, 1)$ .

**Output:** Either returns a  $(1 \pm \epsilon)$ -approximation to  $t = |\text{CUT}(G)|$  or FAIL

Find the degrees of all the vertices in  $G$  by making  $n$  many DEGREE queries;  
 // Let  $D = \{d(1), \dots, d(n)\}$ , where  $d(i)$  denotes the degree of the  $i$ -th vertex in  $G$ ;  
 If  $\exists i \in [n]$  such that  $d(i) = 0$ , then return  $t = 0$  and QUIT. Otherwise, proceed as follows.

Find  $m = \frac{1}{2} \sum_{i=1}^n d(i)$ . If  $m < n - 1$ , return  $t = 0$  and QUIT. Otherwise, proceed as follows.

Set  $\kappa = \frac{2000 \log n}{\epsilon^2}$

Initialize  $\hat{t} = \frac{n}{2}$ .

**while** ( $\hat{t} \geq 1$ ) **do**

- Call VERIFY-GUESS( $D, \hat{t}, \epsilon$ ).
- if** (VERIFY-GUESS( $D, \hat{t}, \epsilon$ ) returns REJECT) **then**
  - | set  $\hat{t} = \frac{\hat{t}}{2}$  and continue.
- end**
- else**
  - // Note that in this case VERIFY-GUESS( $D, \hat{t}, \epsilon$ ) either returns FAIL or ACCEPT.
  - Set  $\hat{t}_u = \max \left\{ \frac{\hat{t}}{\kappa}, 1 \right\}$ .
  - Call VERIFY-GUESS( $D, \hat{t}_u, \epsilon$ ).
  - if** (VERIFY-GUESS( $D, \hat{t}_u, \epsilon$ ) returns FAIL or REJECT) **then**
    - | return FAIL as the output of ESTIMATOR( $\epsilon$ )
  - end**
  - else**
    - | Let  $\tilde{t}$  be the output of VERIFY-GUESS( $D, \hat{t}_u, \epsilon$ ).
    - | Return  $\tilde{t}$  as the output of ESTIMATOR( $\epsilon$ ).
  - end**

**end**

**Output:** Return that the graph  $G$  is disconnected.

---

$\hat{t}_u < t$ . We then call the procedure VERIFY-GUESS( $D, \hat{t}, \epsilon$ ) with  $\hat{t} = \hat{t}_u$ . By Lemma 2.5 (ii), VERIFY-GUESS( $D, \hat{t}_u, \epsilon$ ) will ACCEPT and report a  $(1 \pm \epsilon)$  approximation to  $t$  with probability at least  $1 - \frac{1}{n^9}$ .

We will now analyze the number of DEGREE and NEIGHBOR queries made by the algorithm. We make an initial  $n$  many queries to construct the set  $D$ . Then at the worst case, we call VERIFY-GUESS( $D, \hat{t}, \epsilon$ ) for  $\hat{t} = \frac{n}{2}, \dots, t'$  and  $\hat{t} = \frac{t'}{\kappa} \geq \frac{t}{2\kappa}$ , where  $\frac{t}{2} < t' < \kappa t$ . It is because VERIFY-GUESS( $D, \hat{t}, \epsilon$ ) accepts  $\hat{t}$  with probability  $1 - \frac{1}{n^9}$  when the first time  $\hat{t}$  satisfy the inequality  $\hat{t} \leq t$ . Hence, by Lemma 2.5 and the facts that  $n \leq \frac{m}{t}$  and  $\hat{t}_u \geq \frac{t}{2\kappa}$  with probability at least  $1 - \frac{\log n + 1}{n^9}$ , in expectation the total number of queries made by the algorithm is at most  $n + \log n \cdot \left(1 - \frac{\log n + 1}{n^9}\right) \cdot \tilde{\mathcal{O}}\left(\frac{2\kappa m}{t}\right) + \log n \cdot \left(\frac{\log n + 1}{n^9}\right) \cdot \tilde{\mathcal{O}}(m) = \tilde{\mathcal{O}}\left(\frac{m}{t}\right)$ .

Note that each query made by ESTIMATOR( $\epsilon$ ) is either a DEGREE or a NEIGHBOR query.

Now we analyze the case when  $t = 0$ . Observe that VERIFY-GUESS( $D, \hat{t}, \epsilon$ ) rejects all  $\hat{t} \geq 1$  with probability  $1 - \frac{\log n}{n^9}$ , and therefore, ESTIMATOR( $\epsilon$ ) will report  $t = 0$ . As we have called

VERIFY-GUESS( $D, \hat{t}, \epsilon$ ) for all  $\hat{t} = \frac{n}{2}, \dots, 1$ , the number of queries made by ESTIMATOR( $\epsilon$ ), in the case when  $t = 0$ , is  $\tilde{\mathcal{O}}(m) + n$ . Note that the additional term of  $n$  in the bound comes from the fact that to compute  $D$ , the algorithm needs to make  $n$  many DEGREE queries. ◀

### 3 Lower bounds

In this Section, we prove Theorems 1.2 and 1.3 using reductions from suitable problems in communication complexity. In Section 3.1, we discuss about two party communication complexity along with the problems that will be used in our reductions. We will discuss the proofs of Theorems 1.2 and 1.3 in Section 3.2.

#### 3.1 Communication Complexity

In two-party communication complexity there are two parties, Alice and Bob, that wish to compute a function  $\Pi : \{0, 1\}^N \times \{0, 1\}^N \rightarrow \{0, 1\} \cup \{0, 1\}^n$  \*\*. Alice is given  $\mathbf{x} \in \{0, 1\}^N$  and Bob is given  $\mathbf{y} \in \{0, 1\}^N$ . Let  $x_i$  ( $y_i$ ) denotes the  $i$ -th bit of  $\mathbf{x}$  ( $\mathbf{y}$ ). While the parties know the function  $\Pi$ , Alice does not know  $\mathbf{y}$ , and similarly Bob does not know  $\mathbf{x}$ . Thus they communicate bits following a pre-decided protocol  $\mathcal{P}$  in order to compute  $\Pi(\mathbf{x}, \mathbf{y})$ . We say a randomized protocol  $\mathcal{P}$  computes  $\Pi$  if for all  $(\mathbf{x}, \mathbf{y}) \in \{0, 1\}^N \times \{0, 1\}^N$  we have  $\mathbb{P}[\mathcal{P}(\mathbf{x}, \mathbf{y}) = \Pi(\mathbf{x}, \mathbf{y})] \geq 2/3$ . The model provides the parties access to common random string of arbitrary length. The cost of the protocol  $\mathcal{P}$  is the maximum number of bits communicated, where maximum is over all inputs  $(\mathbf{x}, \mathbf{y}) \in \{0, 1\}^N \times \{0, 1\}^N$ . The communication complexity of the function is the cost of the most efficient protocol computing  $\Pi$ . For more details on communication complexity see [26]. We now define two functions  $k$ -INTERSECTION and FIND- $k$ -INTERSECTION and discuss their communication complexity. Both these functions will be used in our reductions.

► **Definition 3.1** (FIND- $k$ -INTERSECTION). Let  $k, N \in \mathbb{N}$  such that  $k \leq N$ . Let  $S = \{(\mathbf{x}, \mathbf{y}) \in \{0, 1\}^N \times \{0, 1\}^N : \sum_{i=1}^N x_i y_i = k\}$ . The FIND- $k$ -INTERSECTION function on  $N$  bits is a partial function and is defined as  $\text{FIND-INT}_k^N : S \rightarrow \{0, 1\}^N$ , and is defined as  $\text{FIND-INT}_k^N(\mathbf{x}, \mathbf{y}) = \mathbf{z}$ , where  $z_i = x_i y_i$  for each  $i \in [N]$ .

Note that the objective is that at the end of the protocol Alice and Bob know  $\mathbf{z}$ .

► **Definition 3.2** ( $k$ -INTERSECTION). Let  $k, N \in \mathbb{N}$  such that  $k \leq N$ . Let  $S = \{(\mathbf{x}, \mathbf{y}) : \sum_{i=1}^N x_i y_i = k \text{ or } k - 1\}$ . The  $k$ -INTERSECTION function on  $N$  bits is a partial function denoted by  $\text{INT}_k^N : S \rightarrow \{0, 1\}$ , and is defined as follows:  $\text{INT}_k^N(\mathbf{x}, \mathbf{y}) = 1$  if  $\sum_{i=1}^N x_i y_i = k$  and 0, otherwise.

In communication complexity, the  $k$ -INTERSECTION function on  $N$  bits when  $k = 1$  is known as DISJOINTNESS function on  $N$ . The following lemmas follow easily from the communication complexity of DISJOINTNESS (see [26]).

► **Lemma 3.3.** *Let  $k, N \in \mathbb{N}$  such that  $k \leq cN$  for some constant  $c < 1$ . The randomized communication complexity of FIND- $k$ -INTERSECTION function on  $N$  bits is  $\Omega(N)$ .*

► **Lemma 3.4.** *Let  $k, N \in \mathbb{N}$  such that  $k \leq cN$  for some constant  $c < 1$ . The randomized communication complexity of  $k$ -INTERSECTION function on  $N$  bits ( $\text{INT}_k^N$ ) is  $\Omega(N)$ .*

---

\*\* The co-domain of  $\Pi$  looks odd, as the co-domain is  $\{0, 1\}$  usually. However, we need  $\{0, 1\} \cup \{0, 1\}^n$  to take care of all the problems in communication complexity we discuss in this paper.

### 3.2 Proofs of Theorems 1.2 and 1.3

The proofs of Theorems 1.2 and 1.3 are inspired from the lower bound proof of Eden and Rosenbaum [9] for estimating MINCUT<sup>††</sup>.

**Proof of Theorem 1.2.** We prove by giving a reduction from FIND- $t/2$ -INTERSECTION on  $N$  bits. Without loss of generality assume that  $t$  is even. Let  $\mathbf{x}$  and  $\mathbf{y}$  be the inputs of Alice and Bob. Note that  $\sum_{i=1}^N x_i y_i = t/2$ .

We first discuss a graph  $G_{(\mathbf{x}, \mathbf{y})}(V, E)$  that can be generated from  $(\mathbf{x}, \mathbf{y})$ , such that  $|V| = n$  and  $|E| = m \geq 2nt$ , and works as the “hard” instance for our proof. Note that  $G_{(\mathbf{x}, \mathbf{y})}$  should be such that no useful information about the MINCUT can be derived by knowing only one of  $\mathbf{x}$  and  $\mathbf{y}$ . Let  $s = t + \sqrt{t^2 + (m - nt)/2}$  and  $N = s^2$ . In particular,  $2t \leq s \leq 2t + 3\sqrt{m}$ . Also,  $s \geq \sqrt{m/2}$  and therefore  $s = \Theta(\sqrt{m})$ .

#### The graph $G_{(\mathbf{x}, \mathbf{y})}$ and its properties:

$G_{(\mathbf{x}, \mathbf{y})}$  has the following structure.

- $V = S_A \cup T_A \cup S_B \cup T_B \cup C$  such that  $|S_A| = |T_A| = |S_B| = |T_B| = s$  and  $|C| = n - 4s$ . Let  $S_A = \{s_i^A : i \in [s]\}$  and similarly  $T_A = \{t_i^A : i \in [s]\}$ ,  $S_B = \{s_i^B : i \in [s]\}$  and  $T_B = \{t_i^B : i \in [s]\}$ .
- Each vertex in  $C$  is connected to  $2t$  different vertices in  $S_A$ .
- For  $i, j \in [s]$ : if  $x_{ij} = y_{ij} = 1$ , then  $(s_i^A, t_j^B) \in E$  and  $(s_i^B, t_j^A) \in E$ ; otherwise,  $(s_i^A, t_j^A) \in E$  and  $(s_i^B, t_j^B) \in E$ .

► **Observation 3.5.**  $G_{(\mathbf{x}, \mathbf{y})}$  satisfies the following properties.

**Property-1:** The degree of every vertex in  $C$  is  $2t$ . For any  $v \notin C$ , the neighbors of  $v$  inside  $C$  are fixed irrespective of  $\mathbf{x}$  and  $\mathbf{y}$ ; and the number of neighbors outside  $C$  is  $s \geq 2t$ .

**Property-2:** There are  $t$  edges between the vertex sets  $(C \cup S_A \cup T_A)$  and  $(S_B \cup T_B)$ , and removing them  $G_{(\mathbf{x}, \mathbf{y})}$  becomes disconnected.

**Property-3:** Every pair of vertices  $(S_A \cup T_A \cup C)$  is connected by at least  $3t/2$  edge disjoint paths. Also, every pair of vertices in  $(S_B \cup T_B)$  is connected by at least  $3t/2$  edge disjoint paths.

**Property-4:** The set of  $t$  edges between the vertex sets  $(C \cup S_A \cup T_A)$  and  $(S_B \cup T_B)$  forms the unique global minimum cut of  $G(\mathbf{x}, \mathbf{y})$ ,

**Property-5:**  $x_{ij} = y_{ij} = 1$  if and only if  $(s_i^A, t_j^B)$  and  $(s_i^B, t_j^A)$  are the edges in the unique global minimum cut of  $G_{(\mathbf{x}, \mathbf{y})}$ .

**Proof.** Property-1 and Property-2 directly follow from the construction. Now, we will prove Property-3. We first show that every pair of vertices  $(S_A \cup T_A \cup C)$  is connected by at least  $3t/2$  edge disjoint paths by breaking the analysis into the following cases.

- (i) Consider  $s_i^A, s_j^A \in S_A$ , for  $i, j \in [s]$ . Under the promise that  $\sum_{i=1}^N x_i y_i = t/2$ ,  $s_i^A, s_j^A$  have at least  $s - t \geq 3t/2$  common neighbors in  $T_A$  and thus there are at least  $3t/2$  edge disjoint paths connecting them.
- (ii) Consider  $s_i^A \in S_A$  and  $t_j^A \in T_A$ , for  $i, j \in [s]$ . Let  $s_{j_1}^A, \dots, s_{j_{3t/2}}^A$  be  $3t/2$  distinct neighbors of  $t_j^A$  in  $S_A$ . Since,  $s_i^A$  has  $3t/2$  common neighbors with each  $s_{j_r}^A$ ,  $r \in [3t/2]$ , there is a matching of size  $3t/2$ . Denote this matching by  $(t_{j_r}^A, s_{j_r}^A)$ ,  $r \in [3t/2]$ . Thus  $(s_i^A, t_{j_r}^A), (t_{j_r}^A, s_{j_r}^A), (s_{j_r}^A, t_j^A)$ , for  $r \in [3t/2]$ , forms a set of edge disjoint paths of size  $3t/2$

<sup>††</sup> Note that Eden and Rosenbaum [9] stated the result in terms  $k$ -Edge Connectivity.

## 6:12 Query Complexity of Global Minimum Cut

from  $s_i^A$  to  $t_j^A$ , each of length 3. In case  $s_i^A$  is one of the neighbors of  $t_j^A$ , then one of the  $3t/2$  paths gets reduced to  $(s_i^A, t_j^A)$ , a length 1 path that is edge disjoint from the remaining paths.

- (iii) Consider  $u, v \in C$ . Let  $u_1, \dots, u_{2t} \in S_A$  and  $v_1, \dots, v_{2t} \in S_A$  be the neighbors of  $u$  and  $v$  respectively in  $S_A$ . If for some  $i, j \in [2t]$ ,  $u_i = v_j$  then  $(u, u_i), (u_i, v_j), (v_j, v)$  is a desired path. Thus, assume  $u_i \neq v_j$  for all  $i, j \in [2t]$ . For all  $i \in [2t]$ , since  $u_i$  and  $v_i$  have at least  $3t/2$  common neighbors in  $T_A$  we can find  $3t/2$  edge disjoint paths  $(u_i, t_i^A), (t_i^A, v_i)$ , where  $t_i^A \in T_A$ . Existence of  $3t/2$  edge disjoint paths from  $u \in C$  to  $v \in S_A$  can be proved as in (i). and from  $u \in C$  to  $v \in T_A$  can be proved as in (ii).

Similarly, we can show that every pair of vertices in  $(S_B \cup T_B)$  is connected by  $3t/2$  many edge disjoint paths.

Observe that Property-4 follows from Property-3, and Property-5 follows from the construction of  $G_{(\mathbf{x}, \mathbf{y})}$  and Property-4. ◀

Now, by contradiction assume that there exists an algorithm  $\mathcal{A}$  that makes  $o(m)$  queries to  $G_{(\mathbf{x}, \mathbf{y})}$  and finds all the edges of a global minimum cut with probability  $2/3$ . Now, we give a protocol  $\mathcal{P}$  for FIND- $t/2$ -INTERSECTION on  $N$  bits when the  $\mathbf{x}$  and  $\mathbf{y}$  are the inputs of Alice and Bob, respectively. Note that  $x, y \in \{0, 1\}^N$  such that  $\sum_{i=1}^N x_i y_i = t/2$ .

### Protocol $\mathcal{P}$ for FIND- $t/2$ -INTERSECTION

Alice and Bob run the query algorithm  $\mathcal{A}$  when the unknown graph is  $G_{(\mathbf{x}, \mathbf{y})}$ . Now we explain how they simulate the local queries and random edge query on  $G_{(\mathbf{x}, \mathbf{y})}$  by communication. We would like to note that each query can be answered deterministically.

**DEGREE query:** By Property-1, the degree of every vertex does not depend on the inputs of Alice and Bob, and therefore any degree query can be simulated without any communication.

**NEIGHBOR query:** For  $v \in C$ , the set of  $2t$  neighbors are fixed by the construction. So, any neighbor query involving any  $v \in C$  can be answered without any communication. For  $i \in [s]$  and  $s_i^A \in S_A$ , let  $N_C(s_i^A)$  be the set of fixed neighbors of  $s_i^A$  inside  $C$ . So, by Property-1,  $d(s_i^A) = |N_C(s_i^A)| + s$ <sup>††</sup>. The labels of the neighbors of  $s_i^A$  are such that the first  $|N_C(s_i^A)|$  many neighbors are inside  $C$ , and they are arranged in a fixed but arbitrary order. For  $j \in [s]$ , the  $(|N_C(v)| + j)$ -th neighbor of  $s_i^A$  is either  $t_j^B$  or  $s_j^A$  depending on whether  $x_{ij} = y_{ij} = 1$  or not, respectively. So, any neighbor query involving vertex in  $S_A$  can be answered by 2 bits of communication. Similar arguments also hold for the vertices in  $S_B \cup T_A \cup T_B$ .

**ADJACENCY query:** Observe that each adjacency query can be answered by at most 2 bits of communication, and it can be argued like the NEIGHBOR query.

**RANDOM EDGE query:** By Property-1, the degree of any vertex  $v \in V$  is independent of the inputs of Alice and Bob. Alice and Bob use shared randomness to sample a vertex in  $V$  proportional to its degree. Let  $r \in V$  be the sampled vertex. They again use shared randomness to sample an integer  $j$  in  $[d(v)]$  uniformly at random. Then they determine the  $j$ -th neighbor of  $r$  using NEIGHBOR query. Observe that this procedure simulates a RANDOM EDGE query by using at most 2 bits of communication.

Using the fact that  $G_{(\mathbf{x}, \mathbf{y})}$  satisfies Property-4 and 5, the output of algorithm  $\mathcal{A}$  determines the output of protocol  $\mathcal{P}$  for FIND- $t/2$ -INTERSECTION. As each query of  $\mathcal{A}$  can be simulated

---

<sup>††</sup>  $d(u)$  denotes the degree of the vertex  $u$  in  $G_{(\mathbf{x}, \mathbf{y})}$

by at most two bits of communication by the protocol  $\mathcal{P}$ , the number of bits communicated is  $o(m)$ . Recall that  $N = s^2$  and  $s = \Theta(\sqrt{m})$ . So, the number of bits communicated by Alice and Bob in  $\mathcal{P}$  is  $o(N)$ . This contradicts Theorem 3.3. ◀

**Proof of Theorem 1.3.** The proof of this theorem uses the same construction as the one used in the proof of Theorem 1.2. The “hard” communication problem to reduce from is  $t/2$ -INTERSECTION (see Definition 3.2) on  $N$  bits, where  $N = s^2$  and  $s = \Theta(\sqrt{m})$ . ◀

## 4 Conclusion

Our work first and foremost closes a gap in the query complexity of a fundamental problem of finding a minimum cut using local queries. The strength of our algorithm lies in its simplicity – it uses existing ingredients in a fashion suitable for the query framework. The crucial idea was to ensure that cuts are preserved in a sparsified graph in a query framework. We discuss the application of our approach to other cut problems in Appendix A.

## **A** Application of our approach to other cut problems

**Sublinear time algorithm for Global minimum cut.** For simplicity, the algorithm (Algorithm 3) presented for estimating global minimum cut is  $\tilde{O}(m)$ . But, our algorithm can be adapted to get a sublinear time algorithm (with time complexity  $\tilde{O}\left(\frac{m}{\hat{t}}\right)$ ) for estimating the size of the global minimum cut in the graph. We will sample  $\tilde{O}\left(\frac{m}{\hat{t}}\right)$  random edges with replacement from the graph  $G$  using  $\tilde{O}\left(\frac{m}{\hat{t}}\right)$  using local queries, where  $\hat{t}$  is the guess for the size of the global minimum, rather than sampling each edge with probability  $p = \tilde{O}\left(\frac{1}{\hat{t}}\right)$  as we have done in the Algorithm 2. Observe that, after finding the degrees of all the vertices, a random edge can be generated using  $\mathcal{O}(1)$  local queries. The rest of the algorithm and its analysis can be adapted directly. Therefore, we have the following result.

► **Theorem A.1** (Estimating Global minimum cut in sublinear time). *There exists an algorithm, with DEGREE and NEIGHBOR query access to an unknown graph  $G = (V, E)$ , that solves the minimum cut estimation problem with high probability. With high probability, the time complexity and the query complexity of the algorithm is  $\min \left\{ m + n, \frac{m}{t} \right\} \text{poly} \left( \log n, \frac{1}{\epsilon} \right)$ .*

**Global minimum  $r$ -way cut.** Global minimum  $r$ -cut, for a graph  $G = ([n], E)$ ,  $|V| = n$  and  $|E| = m$ , is a partition of the vertex set  $[n]$  into  $r$ -sets  $S_1, \dots, S_r$  such that the following is minimized:  $|\{i, j\} \in E : \exists k, \ell (k \neq \ell) \in [r], \text{ with } i \in S_k \text{ and } j \in S_\ell\}|$ .

Let  $\text{CUT}_r(G)$  denote the set of edges corresponding to a minimum  $r$ -cut, i.e., the edges that goes across different partitions, and by the size of minimum  $r$ -cut, we mean  $|\text{CUT}_r(G)|$ . The sampling and verification idea used in the proof of Theorem 1.1 can be extended directly, together with [22, Corollary 8.2], to get the following result.

► **Theorem A.2.** *There exists an algorithm, with DEGREE and NEIGHBOR query access to an unknown graph  $G = ([n], E)$ , that with high probability outputs a  $(1 \pm \epsilon)$ -approximation of the size of the minimum  $r$ -cut of  $G$ . The expected number of queries used by the algorithm is  $\min \left\{ m + n, \frac{m}{t_r} \right\} \text{poly} \left( r, \log n, \frac{1}{\epsilon} \right)$ , where  $t_r = |\text{CUT}_r(G)|$ .*

**Minimum cuts in simple multigraphs.** A graph with multiple edges between a pair of vertices in the graph but without any self loops are called *simple multigraphs*. If we have DEGREE and NEIGHBOR query access \* to simple multigraphs then we can directly get the following generalization of Theorem 1.1.

► **Theorem A.3** (Minimum cut estimation in simple multigraphs using local queries). *There exists an algorithm, with DEGREE and NEIGHBOR query access to an unknown simple multigraph  $G = (V, E)$ , that solves the minimum cut estimation problem with high probability. The expected number of queries used by the algorithm is  $\min \left\{ m + n, \frac{m}{t} \right\} \text{poly} \left( \log n, \frac{1}{\epsilon} \right)$ , where  $n$  is the number of vertices in the multigraph,  $m$  is the number of edges in the multigraph and  $t$  is the number of edges in a minimum cut.*

## B Probability Results

► **Lemma B.1** (See [6]). *Let  $X = \sum_{i \in [n]} X_i$  where  $X_i, i \in [n]$ , are independent random variables,  $X_i \in [0, 1]$  and  $\mathbb{E}[X]$  is the expected value of  $X$ . Then*

(i) For  $\epsilon > 0$

$$\Pr[|X - \mathbb{E}[X]| > \epsilon \mathbb{E}[X]] \leq \exp \left( -\frac{\epsilon^2}{3} \mathbb{E}[X] \right).$$

(ii) Suppose  $\mu_L \leq \mathbb{E}[X] \leq \mu_H$ , then for  $0 < \epsilon < 1$

(a)  $\Pr[X > (1 + \epsilon)\mu_H] \leq \exp \left( -\frac{\epsilon^2}{3} \mu_H \right)$ .

(b)  $\Pr[X < (1 - \epsilon)\mu_L] \leq \exp \left( -\frac{\epsilon^2}{2} \mu_L \right)$ .

---

\* For simple multigraphs, we will assume that the neighbors of a vertex are stored with multiplicities.

## Abstract

---

The WEIGHTED  $\mathcal{F}$ -VERTEX DELETION for a class  $\mathcal{F}$  of graphs asks, weighted graph  $G$ , for a minimum weight vertex set  $S$  such that  $G - S \in \mathcal{F}$ . The case when  $\mathcal{F}$  is minor-closed and excludes some graph as a minor has received particular attention but a constant-factor approximation remained elusive for WEIGHTED  $\mathcal{F}$ -VERTEX DELETION. Only three cases of minor-closed  $\mathcal{F}$  are known to admit constant-factor approximations, namely VERTEX COVER, FEEDBACK VERTEX SET and DIAMOND HITTING SET. We study the problem for the class  $\mathcal{F}$  of  $\theta_c$ -minor-free graphs, under the equivalent setting of the WEIGHTED  $c$ -BOND COVER problem, and present a constant-factor approximation algorithm using the primal-dual method. For this, we leverage a structure theorem implicit in [Joret et al., SIDMA'14] which states the following: any graph  $G$  containing a  $\theta_c$ -minor-model either contains a large two-terminal *protrusion*, or contains a constant-size  $\theta_c$ -minor-model, or a collection of pairwise disjoint *constant-sized* connected sets that can be contracted simultaneously to yield a dense graph. In the first case, we tame the graph by replacing the protrusion with a special-purpose weighted gadget. For the second and third case, we provide a weighting scheme which guarantees a local approximation ratio. Besides making an important step in the quest of (dis)proving a constant-factor approximation for WEIGHTED  $\mathcal{F}$ -VERTEX DELETION, our result may be useful as a template for algorithms for other minor-closed families.

## 1 Introduction and main ideas of our results

For a class  $\mathcal{F}$  of graphs, the problem WEIGHTED  $\mathcal{F}$ -VERTEX DELETION asks, given weighted graph  $G = (V, E, w)$ , for a vertex set  $S \subseteq V$  of minimum weight such that  $G - S$  belongs to the class  $\mathcal{F}$ . The WEIGHTED  $\mathcal{F}$ -VERTEX DELETION captures classic graph problems such as WEIGHTED VERTEX COVER and WEIGHTED FEEDBACK VERTEX SET, which corresponds to  $\mathcal{F}$  being the classes of edgeless and acyclic graphs, respectively. A vast literature is devoted to the study of (WEIGHTED)  $\mathcal{F}$ -VERTEX DELETION for various instantiations of  $\mathcal{F}$ , both in approximation algorithms and in parameterized complexity. Much of the work considers a class  $\mathcal{F}$  that is characterized by a set of forbidden (induced) subgraphs [41, 33, 14, 1, 28, 3, 4, 5, 6, 37] or that is minor-closed [22, 16, 18, 20, 31, 19, 30, 8, 2, 23, 21, 44, 11], thus characterized by a (finite) set of forbidden minors.

Lewis and Yannakakis [35] showed that  $\mathcal{F}$ -VERTEX DELETION, the unweighted version of WEIGHTED  $\mathcal{F}$ -VERTEX DELETION, is NP-hard whenever  $\mathcal{F}$  is nontrivial (there are infinitely many graphs in and outside of  $\mathcal{F}$ ) and hereditary (is closed under taking induced subgraphs). It was also long known that  $\mathcal{F}$ -VERTEX DELETION is APX-hard for every non-trivial hereditary class  $\mathcal{F}$  [39]. So, the natural question is for which class  $\mathcal{F}$ , (WEIGHTED)  $\mathcal{F}$ -VERTEX DELETION admits constant-factor approximation algorithms.

When  $\mathcal{F}$  is characterized by a finite set of forbidden induced subgraphs, a constant-factor approximation for WEIGHTED  $\mathcal{F}$ -VERTEX DELETION is readily derived with LP-rounding technique. Lund and Yannakakis [39] conjectured that for  $\mathcal{F}$  characterized by a set of minimal forbidden induced subgraphs, the finiteness of  $\mathcal{F}$  defines the borderline between approximability and inapproximability with constant ratio of  $\mathcal{F}$ -VERTEX DELETION. This conjecture was refuted due to the existence of 2-approximation for WEIGHTED FEEDBACK VERTEX SET [7, 12, 16]. Since then, a few more classes with an infinite set of forbidden induced subgraphs are known to allow constant-factor approximations for  $\mathcal{F}$ -VERTEX DELETION, such as block graphs [1], 3-leaf power graphs [5], interval graphs [14], ptolemaic graphs [6], and bounded treewidth graphs [20, 23]. That is, we are only in the nascent stage when it comes to charting the landscape of (WEIGHTED)  $\mathcal{F}$ -VERTEX DELETION as to constant-factor approximability. In the remainder of this section, we focus on the case where  $\mathcal{F}$  is a minor-closed class.

**Known results on (WEIGHTED)  $\mathcal{F}$ -VERTEX DELETION.** According to Robertson and Seymour theorem, every non-trivial minor-closed graph class  $\mathcal{F}$  is characterized by a finite set, called (*minor*) *obstruction set*, of minimal forbidden minors, called (*minor*) *obstructions* [43]. It is also well-known that  $\mathcal{F}$  has bounded treewidth if and only if one of the obstructions is planar [42]. Therefore, the  $\mathcal{F}$ -VERTEX DELETION for  $\mathcal{F}$  excluding at least one planar graph as a minor can be deemed a natural extension of FEEDBACK VERTEX SET. In this context, it is not surprising that  $\mathcal{F}$ -VERTEX DELETION, for minor-closed  $\mathcal{F}$ , attracted particular attention in parameterized complexity, where Feedback Vertex Set was considered the flagship problem serving as an igniter and a testbed for new techniques.

For every minor-closed  $\mathcal{F}$ , the class of yes-instances to the decision version of  $\mathcal{F}$ -VERTEX DELETION is minor-closed again (for every fixed size of a solution), thus there exists a finite obstruction set for the set of its yes-instances. With a minor-membership test algorithm [26], this implies that  $\mathcal{F}$ -VERTEX DELETION is fixed-parameter tractable. The caveat is, such a fixed-parameter algorithm is non-uniform and non-constructive, and the exponential term in the running time is gigantic. Much endeavour was made to reduce the parametric dependence of such algorithms for  $\mathcal{F}$ -VERTEX DELETION. The case when  $\mathcal{F}$  has bounded treewidth is

now understood well. The corresponding  $\mathcal{F}$ -VERTEX DELETION is known to be solvable in time  $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$  [20, 31] and the single-exponential dependency on  $k$  is asymptotically optimal under the *Exponential Time Hypothesis*<sup>2</sup> [31]. (See also [44] for recent parameterized algorithms for general minor-closed  $\mathcal{F}$ 's).

Turning to approximability, the (unweighted)  $\mathcal{F}$ -VERTEX DELETION can be approximated within a constant-factor when  $\mathcal{F}$  has bounded treewidth, say  $t$ , or equivalently when the obstruction set of  $\mathcal{F}$  contains some planar graph. The first general result in this direction was the randomized  $f(t)$ -approximation of Fomin et al. [20]. Gupta et al. [23] made a further progress with an  $\mathcal{O}(\log t)$ -approximation algorithm. Unfortunately, such approximation algorithms whose approximation ratio depends only on  $\mathcal{F}$  are not known when the input is *weighted*. A principal reason for this is that most of the techniques developed for the unweighted case do not extend to the weighted setting. In this direction, Agrawal et al. [2] presented a randomized  $\mathcal{O}(\log^{1.5} n)$ -approximation algorithm and a deterministic  $\mathcal{O}(\log^2 n)$ -approximation algorithm which run in time  $n^{\mathcal{O}(t)}$  when  $\mathcal{F}$  has treewidth at most  $t$ . It is reported in [2] that an  $\mathcal{O}(\log n \cdot \log \log n)$ -approximation can be deduced from the approximation algorithm of Bansal et al. [8] for the edge deletion variant of WEIGHTED  $\mathcal{F}$ -VERTEX DELETION. For the class  $\mathcal{F}$  of planar graphs, Kawarabayashi and Sidiropoulos [30] presented an algorithm for  $\mathcal{F}$ -VERTEX DELETION with polylogarithmic approximation ratio running in quasi-polynomial time. Beyond this work, no nontrivial approximation algorithm is known for  $\mathcal{F}$  of unbounded treewidth.

Regarding *constant-factor* approximability for WEIGHTED  $\mathcal{F}$ -VERTEX DELETION with minor-closed  $\mathcal{F}$ , only three results are known till now. For the WEIGHTED VERTEX COVER, it was observed early that a 2-approximation can be instantly derived from the half-integrality of LP [40]. The local-ratio algorithm by Bar-Yehuda and Even [10] was presumably the first primal-dual algorithm and laid the groundwork for subsequent development of the primal-dual method.<sup>3</sup> For the WEIGHTED FEEDBACK VERTEX SET, 2-approximation algorithms were proposed using the primal-dual method [7, 12, 16]. Furthermore, a constant-factor approximation algorithm was given for WEIGHTED DIAMOND HITTING SET by Fiorini, Joret, and Pietropaoli [18] in 2010. To the best of our knowledge, no progress is made on approximation with constant ratio for minor-closed  $\mathcal{F}$  since then.

For minor-closed  $\mathcal{F}$  with graphs of bounded treewidth, the known approximation algorithms for (WEIGHTED)  $\mathcal{F}$ -VERTEX DELETION take one of the following two avenues. First, the algorithms in [8, 2, 23] draw on the fact that a graph of constant treewidth has a constant-size separator which breaks down the graph into *smaller* pieces. The measure for smallness is an important design feature of these algorithms. Regardless of the design specification, however, it seems there is an inherent bottleneck to extend these algorithmic strategy to handle weights while achieving a constant approximation ratio; the above results either use an algorithm for the BALANCED SEPARATOR problem that does not admit a constant-factor approximation ratio, under the Small Set Expansion Hypothesis [38], or use a relationship between the size of the separator and the size of resulting pieces that do not hold for weighted graphs.

The second direction is the primal-dual method [10, 7, 12, 16, 18]. The constant-factor approximation of [20] for  $\mathcal{F}$ -VERTEX DELETION is also based on the same core observation of the primal-dual algorithm such as [12]. The 2-approximation for WEIGHTED FEEDBACK

<sup>2</sup> The ETH states that 3-SAT on  $n$  variables cannot be solved in time  $2^{o(n)}$ , see [27] for more details.

<sup>3</sup> In this paper, we consider local-ratio and primal-dual as the same algorithms design paradigm and use the word primal-dual throughout the paper even when the underlying LP is not explicitly given. We refer the reader to the classic survey of Bar-Yehuda et al. [9] for the equivalence.

VERTEX SET became available by introducing a new LP formulation which translates the property “ $G - X$  is a forest” in terms of the *sum of degree contribution* of  $X$ . The idea of expressing the sparsity condition of  $G - X$  in terms of the degree contribution of  $X$  again played the key role in [18] for WEIGHTED DIAMOND HITTING SET. However, the (extended) sparsity inequality of [18] is highly intricate as the LP constraint describes the precise structure of diamond-minor-free graphs (after *taming* the graph via some special protrusion replacer). Therefore, expressing the sparsity condition for other classes  $\mathcal{F}$  with tailor-made LP constraints is likely to be prohibitively convoluted. This implies that a radical simplification of the known algorithm for, say, WEIGHTED DIAMOND HITTING SET will be necessary if one intends to apply the primal-dual method for broader classes.

**Our result and the key ideas.** Let  $\theta_c$  be the graph on two vertices joined by  $c$  parallel edges. The central problem we study is the WEIGHTED  $\mathcal{F}$ -VERTEX DELETION where  $\mathcal{F}$  is the class of  $\theta_c$ -minor-free graphs: a weighted graph  $G = (V, E, w)$  is given as input, and the goal is to find a vertex set  $S$  of minimum weight such that  $G - S$  is  $\theta_c$ -minor-free. We call this particular problem the WEIGHTED  $c$ -BOND COVER problem, as we believe that this nomenclature is more adequate for reasons to be clear in Section 2. Our main result is the following.

► **Theorem 1.** *There is a constant-factor approximation algorithm for WEIGHTED  $c$ -BOND COVER running in uniformly<sup>4</sup> polynomial time.*

Let us briefly recall the classic 2-approximation algorithms for WEIGHTED FEEDBACK VERTEX SET [7, 12]. These algorithms repeatedly delineate a vertex subset  $S$  on which the induced subgraph contains an obstruction (a cycle), and “peel off” a weighted graph on  $S$  from the current weighted graph so that the weight of at least one vertex of the current graph drops to zero. The crux of this approach is to create a weighted graph to peel off (or *design a weighting scheme*) on which every (minimal) feasible solution is consistently an  $\alpha$ -approximate solution. We remark that peeling-off of a weighted graph on  $S$  can be viewed as increasing the dual variable (from zero) corresponding to  $S$  until some dual constraint becomes tight, as articulated in [16].

If one aims to capitalize on the power of the primal-dual method for other minor-closed classes and ultimately for arbitrary  $\mathcal{F}$  with graphs of bounded treewidth, more sophisticated weighting scheme is needed. As we already mentioned, this was successfully done by Fiorini, Joret and Pietropaoli [18] for WEIGHTED DIAMOND HITTING SET, where their primal-dual algorithm is based on an intricate LP formulation. Our primal-dual algorithm diverges from such tactics, and instead use the next structural theorem as a guide for the weighting scheme. Before we present it, we need to define some basic concepts.

Given two disjoint subsets  $X, Y$  of  $V(G)$ , the *edges crossing*  $X$  and  $Y$  is the set of edges with one endpoint in  $X$  and the other in  $Y$ . Notice that  $\theta_c$  is a minor of  $G$  iff  $G$  contains two disjoint connected sets  $X$  and  $Y$  crossed by  $c$  edges of  $G$ . We call the union  $M := X \cup Y$   $\theta_c$ -*model* in  $G$ .

Given a positive integer  $c$ , a  $c$ -*outgrowth* of a graph  $G$  is a triple  $\mathbf{K} = (K, u, v)$  where  $u, v$  are distinct vertices of  $G$ ,  $K$  is a component of  $G \setminus \{u, v\}$ ,  $N_G(V(K)) = \{u, v\}$ , and the graph, denoted by  $K^{(x,y)}$ , obtained from  $G[V(K) \cup \{u, v\}]$  if we remove all edges with endpoints  $u$  and  $v$  is  $\theta_c$ -minor free. The *size* of a  $c$ -outgrowth of  $G$  is the size of  $K$ . A *cluster collection*

<sup>4</sup> We use the term “uniformly polynomial” in order to indicate that a constructive algorithm exists that, for every  $c$ , runs in  $f(c) \cdot n^{O(1)}$  time for some constructible function  $f$ .

of a graph  $G$  is a non-empty collection  $\mathcal{C} = \{C_1, \dots, C_r\}$  of pairwise disjoint non-empty connected subsets of  $V(G)$ . In case  $\bigcup_{C \in \mathcal{C}} C = V(G)$  we say that  $\mathcal{C}$  is a *cluster partition* of  $G$ . The *capacity* of a cluster collection  $\mathcal{C}$  is the maximum number of vertices of a cluster in  $\mathcal{C}$ . We use the notation  $G/\mathcal{C}$  for the multigraph obtained from  $G[\bigcup_{C \in \mathcal{C}} C]$  by contracting<sup>5</sup> all edges in  $G[C_i]$  for each  $i \in \{1, \dots, r\}$ .

► **Theorem 2.** *There is a function  $f_1 : \mathbb{N}^2 \rightarrow \mathbb{N}$  such that, for every two positive integers  $c$  and  $t$ , there is a uniformly polynomial time algorithm that, given as input a graph  $G$ , outputs one of the following:*

1. a  $c$ -outgrowth of size at least  $c$ , or
2. a  $\theta_c$ -model  $M$  of  $G$  of size at most  $f_1(c, t)$ , or
3. a cluster collection  $\mathcal{C}$  of  $G$  of capacity at most  $f_1(c, t)$  such that  $\delta(G/\mathcal{C}) \geq t$ , or
4. a report that  $G$  is  $\theta_c$ -minor free.

(By  $\delta(G)$  we denote the minimum *edge-degree* of a vertex in  $G$ . The *edge-degree* of a vertex  $v$  of  $G$ , denoted by  $\text{edeg}_G(v)$ , is the number of edges that are incident to  $v$ .) A variant of Theorem 2 was originally proved by Joret et al. [29] without the capacity condition on a cluster collection in Case 3. It turns out that imposing the capacity condition of Case 3 is crucial for designing a weighting scheme.

At each iteration, our primal-dual algorithm invokes Theorem 2. Depending on the outcome, the algorithm either runs a *replacer* (defined in Section 2) and reduces the size of a  $c$ -outgrowth, or computes a suitable weighted graph which we call  $\alpha$ -*thin layer* (defined in Section 3), using a suitable weighting scheme, thus reducing the current weight. In both cases, we convert the current weighted graph  $G = (V, E, w)$  into a new weighted graph  $G' = (V', E', w')$  on a strictly smaller number of vertices so that an  $\alpha$ -approximate solution for  $G'$  implies an  $\alpha$ -approximate solution for  $G$  for some particular value of  $\alpha$ .

We stress that the replacer is compatible with any approximation ratio in the sense that the optimal weight of a solution is unchanged and every solution after the replacement can be transformed to a solution that is at least as good. When Theorem 2 reports a constant-sized  $\theta_c$ -model, it is easy to see that a uniformly weighted  $\alpha$ -thin layer suffices. The gist of Theorem 2 is in the third case, which promises a collection of pairwise disjoint *constant-sized* connected sets.

Let us first consider the simplest such case where all connected sets are singletons, namely when  $\delta(G) \geq t$ . It is not difficult to see that, if we consider  $t := 6c$  and under the *edge-degree-proportional* weight function, that is for every  $v \in V(G)$ ,  $w(v) := \text{edeg}_G(v)$ , any feasible solution to WEIGHTED  $c$ -BOND COVER is a 4-approximate solution.

In the general case where we have a collection of pairwise disjoint connected sets, each of size at most  $r$ , the critical observation (Lemma 3) is that if the contraction of these sets yields a graph of minimum edge-degree at least  $t := 8c$ , then a weighting scheme akin to the simple case also works. That is, any feasible solution to WEIGHTED  $c$ -BOND COVER is a  $4r$ -approximate solution. The overall primal-dual framework is summarized in Section 3.

## 2 Preliminary definitions and results

We use  $\mathbb{N}$  for the set of non-negative integers and  $\mathbb{R}_{\geq 0}$  for the set of non-negative reals. Given some  $r \in \mathbb{N}$ , we define  $[r] = \{1, \dots, r\}$ . Given some collection  $\mathcal{A}$  of objects on which the union operation can be defined, we define  $\bigcup \mathcal{A} = \bigcup_{A \in \mathcal{A}} A$ . All graphs we consider are multigraphs

<sup>5</sup> When considering edge contractions we sum up edge multiplicities of multiple edges that are created during the contraction. However, when a loop appears after a contraction, then we suppress it.

## 7:6 Approximation for Weighted Bond Cover

without loops. We denote a graph by  $G = (V, E)$  where  $V$  and  $E$  are its vertex and edge set respectively. A vertex-weighted graph is denoted by  $G = (V, E, w)$  where  $w : V(G) \rightarrow \mathbb{R}_{\geq 0}$  and we say that  $G$  is a  $w$ -weighted graph. We use  $V(G)$  and  $E(G)$  for the vertex set and the edge multiset of  $G$ . We also refer to  $|V(G)|$  as the *size* of  $G$ . If  $X \subseteq V(G)$ , we denote by  $G[X]$  the subgraph of  $G$  induced by  $X$  and by  $G - X$  the graph  $G[V(G) \setminus X]$ . We say that  $X$  is *connected in  $G$*  if  $G[X]$  is connected. A graph  $H$  is a *minor* of a graph  $G$  if  $H$  can be obtained from a subgraph of  $G$  after contracting edges. Given a graph  $H$ , we say that  $G$  is  *$H$ -minor free* if  $G$  does not contain  $H$  as a minor. We denote by  $N_G(v)$  the set of all neighbors of  $v$  in  $G$ .

**Covering bonds.** Let  $G$  be a graph. Given a bipartition  $\{V_1, V_2\}$  of  $V(G)$ , the set of edges crossing  $V_1$  and  $V_2$  is called the *cut* of  $\{V_1, V_2\}$  and an edge set is a *cut* if it is a cut of some vertex bipartition. A minimal non-empty cut is known as a *bond* in the literature. We remark that the bonds of  $G$  are precisely the circuits of the cographic matroid of  $G$ . Given a positive integer  $c$ , a  *$c$ -bond* of a graph  $G$  is any minimal cut of  $G$  of size at least  $c$ . The problem of finding the maximum  $c$  for which a graph  $G$  contains a  $c$ -bond has been examined both from the approximation [25, 15] and the parameterized point of view [17]. Given a set  $S \subseteq V(G)$ , we say that  $S$  is a  *$c$ -bond cover* of  $G$  if  $G - S$  is  $\theta_c$ -minor free. Notice that  $S$  is a  $c$ -bond cover iff  $G \setminus S$  does not contain a  $c$ -bond. Given a weighted graph  $G = (V, E, w)$  with  $w : V(G) \rightarrow \mathbb{R}_{\geq 0}$ , a *minimum weight  $c$ -bond cover* of  $G$  is a  $c$ -bond cover  $S$  where the weight of  $S$ , defined as  $w(S) := \sum_{v \in S} w(v)$ , is minimized.

It is easy to prove that, for every  $c \in \mathbb{N}$ , a graph  $G$  contains  $\theta_c$  as a minor iff it has a  $c$ -bond. This means that when  $\mathcal{F}$  is the class of  $\theta_c$ -minor-free graphs, then WEIGHTED  $\mathcal{F}$ -VERTEX DELETION can be restated as follows.

WEIGHTED  $c$ -BOND COVER

*Input:* a vertex weighted graph  $G = (V, E, w)$ .

*Solution:* a minimum weight  $c$ -bond cover of  $G$ .

**The weighting scheme.** Let  $G$  be a graph and let  $\mathcal{C}$  be a cluster partition of  $G$  of capacity at most  $r$ . Given a cluster  $C \in \mathcal{C}$  we denote by  $\text{ext}_C(C)$  (or simply  $\text{ext}(C)$ ) the set of edges with one endpoint in  $C$  and the other not in  $C$ .

Let now  $G$  be an instance of WEIGHTED  $c$ -BOND COVER for some positive integer  $c$ . We define the vertex weighting function  $w_C : V(G) \rightarrow \mathbb{R}_{\geq 0}$  so that if  $v \in C \in \mathcal{C}$ , then

$$w_C(v) = \frac{|\text{ext}(C)|}{|C|}. \quad (1)$$

When  $\mathcal{C}$  is clear from the context, we simply write  $w$  instead  $w_C$ . The main result of this section is that, with respect to the weight function  $w$  in Equation 1, every  $c$ -bond cover of  $G$  is a  $4r$ -approximation.

► **Lemma 3.** *Let  $c$  be a non negative integer,  $G$  be a graph,  $r$  be a positive integer,  $\mathcal{C}$  be a cluster partition of  $G$  of capacity at most  $r$  and such that  $\delta(G/\mathcal{C}) \geq 8c$ , and  $w : V(G) \rightarrow \mathbb{R}_{\geq 0}$  be a vertex weighting function as in Equation 1. Then for every  $c$ -bond cover  $X$  of  $G$ , it holds that  $\frac{1}{2r} \cdot |E(G/\mathcal{C})| \leq \sum_{v \in X} w(v) \leq 2 \cdot |E(G/\mathcal{C})|$ .*

**Proof.** For the upper bound, note that  $\sum_{v \in X} w(v) = \sum_{v \in X} \frac{|\text{ext}(C)|}{|C|} \leq \sum_{C \in \mathcal{C}} \sum_{v \in C} \frac{|\text{ext}(C)|}{|C|} = \sum_{C \in \mathcal{C}} |\text{ext}(C)| = \sum_{x \in V(G/\mathcal{C})} \text{edeg}_{G/\mathcal{C}}(x) = 2 \cdot |E(G/\mathcal{C})|$ .

For the lower bound, let  $X$  be a  $c$ -bond cover of  $G$  and let  $F = V(G) \setminus X$ ,  $\mathcal{C}_X = \{C \in \mathcal{C} \mid C \cap X \neq \emptyset\}$ , and  $\mathcal{C}_F = \mathcal{C} \setminus \mathcal{C}_X$ . Since  $\delta(G/\mathcal{C}) \geq 8c$ , we obtain that  $|E(G/\mathcal{C})|/2 \geq 2c \cdot |V(G/\mathcal{C})| = 2c \cdot |\mathcal{C}|$ . We claim that  $\sum_{C \in \mathcal{C}_X} |\text{ext}(C)| \geq |E(G/\mathcal{C})|/2$ . Indeed, if this is not the case then, by the fact that  $|E(G/\mathcal{C})| \leq |E(G[F]/\mathcal{C}_F)| + \sum_{C \in \mathcal{C}_X} |\text{ext}(C)|$ , we have that  $|E(G[F]/\mathcal{C}_F)| > |E(G/\mathcal{C})|/2 \geq 2c \cdot |\mathcal{C}| \geq 2c \cdot |\mathcal{C}_F|$  and this last inequality, gives that  $\theta_c$  is a minor of  $G/\mathcal{C}_F$  which is a minor of  $G[F]$ , a contradiction. Here we use the fact that for every  $\theta_c$ -minor free multigraph  $G$ , it holds that  $|E(G)| \leq 2c \cdot |V(G)|$  (following from the main combinatorial result of [36]). Therefore, since each set in  $\mathcal{C}_X$  contains at least one vertex of  $X$ , we obtain  $\sum_{v \in X} w(v) \geq \sum_{C \in \mathcal{C}_X} \frac{|\text{ext}(C)|}{|C|} \geq \frac{1}{r} \sum_{C \in \mathcal{C}_X} |\text{ext}(C)| \geq \frac{|E(G/\mathcal{C})|}{2r}$ , which proves the lower bound.  $\blacktriangleleft$

**Replacing outgrowths.** A  $c$ -outgrowth replacer (hereinafter *replacer*) is a uniformly polynomial-time algorithm which, given a weighted graph  $G = (V, E, w)$  and a  $c$ -outgrowth  $\mathbf{K} = (K, u, v)$  of size at least  $c$ , outputs a weighted graph  $G' = (V', E', w')$  with the following property.

1.  $\mathbf{K}$  is replaced by another  $c$ -outgrowth  $\mathbf{K}' = (K', u, v)$  of size at most  $c - 1$ .
2.  $\text{opt}(G) = \text{opt}(G')$ .
3. Given a  $c$ -bond cover  $S' \subseteq V(G')$ , one can construct in polynomial time a  $c$ -bond cover  $S \subseteq V(G)$  such that  $w(S) \leq w(S')$ .

We now present our  $c$ -outgrowth replacer. Given a  $w$ -weighted graph  $G$ , we denote by  $\text{opt}(G)$  the weight of an optimal solution for WEIGHTED  $c$ -BOND COVER on  $G$ .

**► Lemma 4.** *For every positive  $c \in \mathbb{N}$ , there is a  $c$ -outgrowth replacer. In particular, an  $\alpha$ -approximate solution for  $G'$  implies an  $\alpha$ -approximate solution for  $G$ .*

**Proof.** For  $i \in \{0, \dots, c - 1\}$ , let  $K_i^{(u,v)}$  be the graph obtained from  $K^{(u,v)}$  by adding  $i$  edges connecting  $u$  and  $v$ . Obviously  $K_0^{(u,v)}$  equals  $K^{(u,v)}$ . Let also  $T_i \subseteq V(K)$  be a minimum weight set contained in  $V(K)$  such that  $K_i^{(u,v)} - T_i$  is  $\theta_c$ -minor-free, and  $w_i = w(T_i)$ . Note that  $T_i \subseteq V(K)$  implies that  $T_i$  contains neither  $u$  nor  $v$ . For example,  $T_{c-1}$  is a minimum (internal) vertex cut separating  $u$  and  $v$  in  $K^{(u,v)}$ , and  $w_{c-1} = w(T_{c-1})$  is finite since there is no edge between  $u$  and  $v$  in  $K^{(u,v)}$ . By definition, it holds that  $0 = w_0 \leq w_1 \leq \dots \leq w_{c-1} < \infty$ , and these values can be computed in uniformly polynomial time by using dynamic programming on  $\theta_c$ -minor free graphs (that is bounded treewidth graphs). We also remark that  $T_j$  is a  $c$ -bond cover of  $K_i^{(u,v)}$  for all  $i \leq j$ . We construct the  $c$ -outgrowth  $\mathbf{K}' = (K', u, v)$  so that  $K'^{(u,v)}$  is as follows (see Figure 1).

- $V(K'^{(u,v)}) = \{u, v, x_1, \dots, x_{c-1}\}$  where  $K' = \{x_1, \dots, x_{c-1}\}$ . For each  $1 \leq i \leq c - 1$ , the weight of  $x_i$  is  $w_i$ .
- There are edges  $(u, x_1), (x_1, x_2), \dots, (x_{c-2}, x_{c-1}), (x_{c-1}, v)$ . Additionally for each  $2 \leq i \leq c - 1$ , there is an edge  $(x_i, u)$ .

**■ Figure 1** The construction of the replacement  $c$ -outgrowth  $\mathbf{K}' = (K', u, v)$ .

We observe that for each  $i \in \{0, \dots, c - 1\}$ , the set  $\{x_i\}$  is the minimum weight  $c$ -bond cover of  $K_i^{(u,v)}$ . The next claims are handy (the proof is omitted in this extended abstract).

## 7:8 Approximation for Weighted Bond Cover

▷ **Claim 5.** Let  $(K, u, v)$  be a  $c$ -outgrowth in  $G$  and let  $M = (X, Y)$  be a minimal  $\theta_c$ -model in  $G$ . If  $M$  does not contain  $u$ , then we have  $(X \cup Y) \cap V(K) = \emptyset$ . Furthermore, if  $S$  is a minimal  $c$ -bond cover of  $G$  and if  $S$  contains  $u$  or  $v$ , say  $u$ , then  $S \cap V(K) = \emptyset$ .

▷ **Claim 6.** Let  $Z$  be a  $c$ -bond cover of  $G - V(K)$  and let  $\ell$  be the maximum integer<sup>6</sup> such that  $G - (K \cup Z)$  contains a  $\theta_\ell$ -model with  $u$  and  $v$  in different sets. Then  $Z' = Z \cup T_\ell$  is a  $c$ -bond cover of  $G$ .

We begin with proving the third condition of the replacer. Let  $G'$  be the graph where  $K^{(u,v)}$  is replaced by  $K'^{(u,v)}$ . It suffices to prove the second statement for an arbitrary minimal  $c$ -bond cover  $S' \subseteq V(G')$  of  $G'$ .

First, assume that  $S'$  contains  $u$  or  $v$ , say  $u$ . Claim 5 is applied to  $G'$  verbatim with  $G \leftarrow G'$ ,  $K \leftarrow K'$ ,  $K^{(u,v)} \leftarrow K'^{(u,v)}$ , and we deduce that  $S' \cap V(K') = \emptyset$ . Now we take  $S \leftarrow S'$ , and let us argue that  $S$  is a  $c$ -bond cover of  $G$ . Again Claim 5 implies that if  $G - S$  contains a  $\theta_c$ -model, then one can find one disjoint from  $V(K)$ . This is not possible because  $S = S'$  is a  $c$ -bond cover of  $G - K = G' - K'$ .

Secondly, let us assume that  $S' \cap \{u, v\} = \emptyset$ . Let  $\ell$  be the maximum integer such that  $G' - (K' \cup S')$  contains a  $\theta_\ell$ -model  $M = (X, Y)$  with  $u$  and  $v$  in different sets, say  $u \in X$  and  $v \in Y$ . Clearly  $\ell$  is strictly smaller than  $c$  because  $S'$  is a  $c$ -bond cover of  $G' - K'$ . Note that  $K_\ell'^{(u,v)}$  is obtained from  $G'[X \cup Y \cup V(K')]$  by contracting  $X$  and  $Y$ . Because  $S' \cap V(K')$  is a  $c$ -bond cover of  $G'[X \cup Y \cup V(K')]$ , it is also a  $c$ -bond cover of  $K_\ell'^{(u,v)}$ . Therefore we have  $w_\ell \leq w(S' \cap V(K'))$ .

Let  $S = (S' \setminus V(K')) \cup T_\ell$  be a vertex set of  $G$  and note that  $w(S) \leq w(S')$ . Now applying Claim 6 to  $G$  with  $Z \leftarrow S' \setminus V(K')$  (as a vertex set of  $G$ ), we conclude that  $S$  is a  $c$ -bond cover of  $G$ . This proves the third condition of the replacer, which also establishes  $\text{opt}(G) \leq \text{opt}(G')$  in the second condition of the replacer.

It remains to show  $\text{opt}(G) \geq \text{opt}(G')$ . Consider an optimal  $c$ -bond cover  $S$  of  $G$ , and let  $p$  be the maximum integer such that  $G - (K \cup S)$  contains a  $\theta_p$ -model  $M = (X, Y)$  with  $u$  and  $v$  in different sets. Again we apply Claim 6 with  $G \leftarrow G'$ ,  $Z \leftarrow S \setminus V(K)$  (as a vertex set of  $G'$ ),  $K \leftarrow K'$  and  $T_\ell \leftarrow \{x_p\}$ , and derive that  $(S \setminus V(K)) \cup \{x_p\}$  is a  $c$ -bond cover of  $G'$ . Lastly, observe that  $K_p^{(u,v)}$  is a minor of  $G[X \cup Y \cup V(K)]$ , and because  $S \cap V(K)$  is a  $c$ -bond cover of the latter, it is also a  $c$ -bond cover of the former. Therefore, we have  $w(S \cap V(K)) \geq w_p$ , from which we have  $\text{opt}(G) = w(S) \geq w(S \setminus V(K)) + w_p = w((S \setminus V(K)) \cup \{x_p\}) \geq \text{opt}(G')$ . ◀

### 3 The primal-dual approach

We begin the section by formalizing the notion of  $\alpha$ -thin layer. An  $\alpha$ -thin layer of a weighted graph  $G = (V, E, w)$  is a weighted graph  $H = (V, E, w^\alpha)$  such that the following holds.

- $w^\alpha(v) \leq w(v)$  for every  $v \in V$ ,
- $w^\alpha(v) = w(v)$  for some  $v \in V$ , and
- $w^\alpha(S) \geq (1/\alpha) \cdot w^\alpha(V)$  for any  $c$ -bond cover  $S \subseteq V$  of  $H$ .

We are now ready to prove our main approximation result.

► **Theorem 7.** *There is a uniformly polynomial-time algorithm which, given a positive integer  $c$  and a weighted graph  $G = (V, E, w)$ , computes a  $c$ -bond cover of weight at most  $\alpha \cdot \text{opt}(G)$  for some  $\alpha = \alpha(c)$ .*

<sup>6</sup> If  $u$  and  $v$  are not connected in  $G - (K \cup Z)$ , we let  $\ell = 0$ .

**Proof.** The algorithm initially sets  $G_1 = G$ , and iteratively constructs a sequence of weighted graphs  $G_i = (V_i, E_i, w_i)$  for  $i = 0, 1, \dots$ . At  $i$ -th iteration, we run the algorithm  $\mathcal{A}$  of Theorem 2 for  $t = 8c$ . If  $\mathcal{A}$  detects a  $c$ -outgrowth of size at least  $c$ , then we call the algorithm of Lemma 4, which is clearly a replacer. We run the replacer on  $G_i$  and set  $G_{i+1}$  to be the output of the replacer. If a  $\theta_c$ -model  $M$  of  $G_i$  of size at most  $f_1(c, t)$  is detected by  $\mathcal{A}$ , then let  $\epsilon := \min\{w_i(v) : v \in M\}$  and consider the weighted graph  $H_i = (V_i, E_i, w_i^o)$  with the weight function  $w$  as follows:

$$w_i^o(v) = \begin{cases} \epsilon & \text{if } v \in M \\ 0 & \text{otherwise.} \end{cases}$$

It is obvious that  $H_i$  is an  $\alpha$ -thin layer with  $\alpha = f_1(c, t)$ .

In the third case, note that the cluster collection  $\mathcal{C}$  forms a cluster partition of  $G_i[\mathbf{UC}]$ . Consider the weight function  $w : \mathbf{UC} \rightarrow \mathbb{R}_{\geq 0}$  as in Equation 1 of  $G_i[\mathbf{UC}]$ . Let  $\epsilon := \min\{w_i(v)/w(v) : v \in \mathbf{UC}\}$  and  $H_i = (V_i, E_i, w_i^o)$  be the weighted graph, where

$$w_i^o(v) = \begin{cases} \epsilon \cdot w(v) & \text{if } v \in \mathbf{UC} \\ 0 & \text{otherwise.} \end{cases}$$

Let us verify that  $H_i$  is an  $\alpha$ -thin layer of  $G_i$  for  $\alpha = 4r$ , where  $r = f_1(c, t)$ . It is straightforward to see that the first two requirements of  $\alpha$ -thin layer are met due to the choice of  $\epsilon$ . To check the last requirement, consider an arbitrary  $c$ -bond cover  $S \subseteq V_i$  of  $H_i$ . By Lemma 3, it holds that

$$\frac{\epsilon}{2r} \cdot |E(G_i[\mathbf{UC}]/\mathcal{C})| \leq \sum_{v \in S} w_i^o(v) \leq \sum_{v \in V_i} w_i^o(v) \leq 2\epsilon \cdot |E(G_i[\mathbf{UC}]/\mathcal{C})|,$$

and therefore,

$$\sum_{v \in S} w_i^o(v) \geq \frac{\epsilon}{2r} \cdot |E(G_i[\mathbf{UC}]/\mathcal{C})| \geq \frac{1}{4r} \cdot \sum_{v \in V_i} w_i^o(v).$$

In both the second and the third cases, we set  $G_{i+1}$  to be the weighted graph  $(V_i, E_i, w_i - w_i^o)$  after removing all vertices of weight zero.

Finally, if  $\mathcal{A}$  reports that  $G_i$  is  $\theta_c$ -minor free, then we terminate the iteration. Let  $G = G_1, G_2, \dots, G_\ell$  be the constructed sequence of weighted graph at the end, with  $G_\ell$  being a  $\theta_c$ -minor-free graph. Observe that our algorithm strictly decrease the number of vertices before the  $\ell$ -th iteration, and thus  $\ell \leq n$ .

To establish the main statement, it suffices show that there is a polynomial-time algorithm which produces an  $4r$ -approximate solution for  $G_i$  given an  $4r$ -approximate solution  $T_{i+1}$  for  $G_{i+1}$ , where  $r = f_1(c, t)$  and  $t = 8c$ . This trivially holds if the execution of  $\mathcal{A}$  at  $i$ -th iteration calls the replacer.

Suppose that  $i$ -th iteration produces an  $\alpha$ -thin layer  $H_i = (V_i, E_i, w_i^o)$ , and recall that every  $\alpha$ -thin layer produced in our algorithm satisfies  $\alpha \leq 4r$ . As  $T_{i+1}$  is an  $4r$ -approximate solution for  $G_{i+1}$ , we have

$$\text{opt}(G_{i+1}) \geq (1/4r) \cdot w_{i+1}(T_{i+1}), \quad (2)$$

▷ **Claim 8.**  $T_i := T_{i+1} \cup (V_i \setminus V_{i+1})$  is an  $4r$ -approximate solution for  $G_i$ .

**Proof.** Let  $D_i = V_i \setminus V_{i+1}$ , namely the vertices deleted from  $G_i$  to obtain  $G_{i+1}$ . It is obvious that  $T_{i+1} \cup D_i$  is a feasible solution for  $G_i$ , that is, a  $c$ -bond cover of  $G_i$  because  $G_{i+1} - T_{i+1} = G_i - (T_{i+1} \cup D_i)$  and  $T_{i+1}$  is a  $c$ -bond cover of  $G_{i+1}$ . Let  $Q \subseteq V_i$  be an optimal

## 7:10 Approximation for Weighted Bond Cover

solution for  $G_i$ . Then  $Q$  is a feasible solution for  $H_i$  and  $Q \cap V_{i+1}$  is a feasible solution for  $G_{i+1}$ , therefore

$$w_i^o(Q) \geq (1/4r) \cdot w_i^o(V_i) \text{ and} \quad (3)$$

$$w_{i+1}(Q \cap V_{i+1}) \geq \text{opt}(G_{i+1}), \quad (4)$$

where the inequality 3 is due to the third requirement of  $\alpha$ -thin layer. Furthermore, it holds that

$$w_i(v) = w_i^o(v) + w_{i+1}(v) \quad \text{for each } v \in V_{i+1} \text{ and} \quad (5)$$

$$w_i(v) = w_i^o(v) \quad \text{for each } v \in D_i. \quad (6)$$

Therefore,

$$\begin{aligned} w_i(Q) &= w_i^o(Q) + w_{i+1}(Q \cap V_{i+1}) && \because (5), (6) \\ &\geq (1/4r) \cdot w_i^o(V_i) + \text{opt}(G_{i+1}) && \because (3), (4) \\ &\geq (1/4r) \cdot w_i^o(T_{i+1} \cup D_i) + (1/4r) \cdot w_{i+1}(T_{i+1}) && \because (2) \\ &= (1/4r) \cdot (w_i^o(T_{i+1}) + w_{i+1}(T_{i+1})) + (1/4r) \cdot w_i^o(D_i) \\ &= (1/4r) \cdot w_i(T_{i+1} \cup D_i) && \because (5), (6) \end{aligned}$$

and the claim follows.  $\triangleleft$

We inductively obtain a  $4r$ -approximate solution for  $G_i$ , and finally for the graph  $G_1 = G$ . This finishes the proof.  $\blacktriangleleft$

## 4 Discussion

In this paper we construct a polynomial-time constant-factor approximation algorithm for the WEIGHTED  $\mathcal{F}$ -VERTEX DELETION problem in the case  $\mathcal{F}$  is the class of graphs not containing a  $c$ -bond or, alternatively, the  $\theta_c$ -minor free graphs. The constant-factor of our approximation algorithm is a (constructible) function of  $c$  and the running time is uniformly polynomial. Our results, in case  $c = 2$ , yield a constant-factor approximation for the WEIGHTED FEEDBACK VERTEX SET. Also, a constant-factor approximation for WEIGHTED DIAMOND HITTING SET can easily be derived for the case where  $c = 3$ . For this we apply our results on simple graphs and observe that each time a  $\theta_3$ -minor-model appears, this model, under the absence of multiple edges, should contain 4 vertices and therefore is a minor-model of the diamond  $K_4^-$  (that is  $K_4$  without an edge).

Certainly the general open question is whether WEIGHTED  $\mathcal{F}$ -VERTEX DELETION admits a constant-factor approximation for more general instantiations of the minor-closed class  $\mathcal{F}$ . In this direction, the challenge is to use our approach when the graphs in  $\mathcal{F}$  have bounded treewidth (or, equivalently, if the minor obstruction of  $\mathcal{F}$  contains some planar graph). For this, one needs to extend the structural result of Theorem 2 and, based on this to build a replacer as in Lemma 4.

Given an  $r \in \mathbb{N}$ , an  $r$ -*protrusion* of a graph  $G$  is a set  $X \subseteq V(G)$  such that  $G[X]$  has treewidth at most  $t$  and  $|\partial_G(X)| \leq t$ , where  $\partial_G(X)$  is the set of vertices of  $X$  that are incident to edges not in  $G[X]$ . We conjecture that a possible extension of Theorem 2 might be the following.

**► Conjecture 9.** *There are functions  $f_2 : \mathbb{N}^2 \rightarrow \mathbb{N}$  and  $f_3 : \mathbb{N}^3 \rightarrow \mathbb{N}$  such that, for every  $h$ -vertex planar graph  $H$  and every two positive integers  $t, p$ , there is a uniformly polynomial time algorithm that, given as input a graph  $G$ , outputs one of the following:*

1. an  $f_2(h, t)$ -protrusion  $X$  of size at least  $p$ , or
2. a minor-model of  $H$  of size at most  $f_3(h, t, p)$ , or
3. a cluster collection  $\mathcal{C}$  of  $G$  of capacity at most  $f_3(h, t, p)$  such that  $\delta(G/\mathcal{C}) \geq t$ , or
4. a report that  $G$  is  $H$ -minor free.

Given a proof of some suitable version of Conjecture 9 at hand, cases 1,2, and 3 above can be treated using the method proposed in this paper. In the first case, we need to find a *weighted protrusion replacer* that can replace, in the weighed graph  $G = (V, E, w)$ , the subgraph  $G[X]$  by another one (glued on the same boundary) and create a new weighted graph  $G' = (V', E', w')$  so that an optimal solution has the same weight in both instances. In our case, the role of a protrusion is played by the  $c$ -outgrowth, where  $X$  is the vertex set of  $K^{(u,v)}$  that has treewidth at most  $2c$  and  $|\partial_G(X)| \leq 2$ , i.e.,  $V(K^{(u,v)})$  is a  $2c$ -protrusion of  $G$ . In the case of  $\theta_c$ , the the replacer is given in Lemma 4. The existence of such a replacer in the general case is wide open, first because the boundary  $\partial_G(X)$  has bigger size (depending on  $h$  but perhaps also on  $t$ ) and second, and most important, because we now must deal with *weights* which does not permit us to use any protrusion replacement machinery such as the one used in [20, 19] unweighted version of the problem (based on the, so called, FII-property [13] for more details).

We believe that a possible way to prove Conjecture 9 is to use as departure the proof of the main combinatorial result in [45]. However, in our opinion, the most challenging step is to design a weighted protrusion replacer (or, on the negative side, to provide instantiations of  $H$  where such a replacer does not exist). As such a replacer needs to work on the presence of weights, we suggest that its design might use techniques related to mimicking networks technology [24, 34].

Finally, since our algorithm is based on the primal-dual framework and proceeds by constructing suitable weights for the second and third case where every feasible solution is  $\mathcal{O}(1)$ -approximate, one can ask whether it is possible to *bypass* the need for a replacer and construct suitable weights for the first case. Indeed, the previous approximation algorithms for WEIGHTED FEEDBACK VERTEX SET [7, 12, 16] designed suitable weights even for the case 1 where every *minimal* solution is  $\mathcal{O}(1)$ -approximate. (And used the additional “reverse delete” step at the end to ensure that the final solution remains minimal, for every weighted graph constructed.) In the full version of the paper [32], we show that such weights *cannot exist* for a simple planar graph  $H$ , which suggests that replacers are inherently needed for this class of algorithms for WEIGHTED  $\mathcal{F}$ -VERTEX DELETION.

---

## Abstract

In this work, we consider online  $d$ -dimensional vector bin packing. It is known that no algorithm can have a competitive ratio of  $o(d/\log^2 d)$  in the absolute sense, although upper bounds for this problem have always been presented in the asymptotic sense. Since variants of bin packing are traditionally studied with respect to the asymptotic measure, and since the two measures are different, we focus on the asymptotic measure and prove new lower bounds of the asymptotic competitive ratio. The existing lower bounds prior to this work were known to be smaller than 3, even for very large  $d$ . Here, we significantly improved on the best known lower bounds of the asymptotic competitive ratio (and as a byproduct, on the absolute competitive ratio) for online vector packing of vectors with  $d \geq 3$  dimensions, for every dimension  $d$ . To obtain these results, we use several different constructions, one of which is an adaptive construction with a lower bound of  $\Omega(\sqrt{d})$ . Our main result is that the lower bound of  $\Omega(d/\log^2 d)$  on the competitive ratio holds also in the asymptotic sense. This result holds also against randomized algorithms, and requires a careful adaptation of constructions for online coloring, rather than simple black-box reductions.

## 1 Introduction

We study the classical vector packing problem (VP) [21, 20, 2, 1, 3]. In VP with dimension  $d \geq 2$ , a set of items is given, where every item is a non-zero  $d$ -dimensional vector, whose components are rational numbers in  $[0, 1]$ . This set is to be partitioned into subsets called bins, such that the vector sum of every subset does not exceed 1 in any component. Here, we consider lower bounds on the worst-case performance guarantees of online algorithms for VP. Online algorithms obtain input items one by one, and pack each new item irrevocably before the next item is presented, into an empty (new), or non-empty bin. Such algorithms receive an input as a sequence, while offline algorithms receive an input as a set. An arbitrary optimal offline algorithm, which uses the minimum number of bins for packing the items of the input or instance, is denoted by  $OPT$ . For an input  $L$  and algorithm  $A$ , we let  $A(L)$  denote the number of bins that  $A$  uses to pack  $L$ , also termed the *cost of algorithm  $A$  on input  $L$* . For a randomized algorithm we denote the expected value of the cost of the algorithm  $A$  on input  $L$  as  $\mathbb{E}[A(L)]$ . We also let  $OPT(L)$  denote the number of bins that  $OPT$  uses for a given input  $L$ . The absolute competitive ratio of an algorithm  $A$  is defined as the supremum ratio over the following ratios. These are the ratios for all inputs  $L$ , where the ratio for  $L$  is the ratio between the number of its bins  $A(L)$  and  $OPT(L)$ , the number of the bins of  $OPT$ . The asymptotic competitive ratio is the limit of absolute competitive ratios  $R_K$  when  $K$  tends to infinity, and  $R_K$  takes into account only inputs for which  $OPT$  uses at least  $K$  bins. That is, the asymptotic competitive ratio of  $A$  is:

$$\lim_{K \rightarrow \infty} \sup_{OPT(L) \geq K} \frac{A(L)}{OPT(L)}.$$

For randomized online algorithms the definition for the asymptotic competitive ratio and for the absolute competitive ratio is the same, except that we consider  $\mathbb{E}[A(L)]$  instead of  $A(L)$ . In this paper, we focus mostly on the asymptotic competitive ratio, which is the most natural measure for bin packing algorithms, and we sometimes refer to it by the term *competitive ratio*. When we discuss the absolute competitive ratio, we use this last term explicitly.

Note that VP is defined as a distinct optimization problem for every fixed value of  $d$ . For each such value (which is a dimension), there might be an online algorithm that is the best possible with respect to the absolute competitive ratio (the algorithm whose absolute competitive ratio is minimized), and there might be an online algorithm that is the best possible with respect to the asymptotic competitive ratio. These algorithms may be different. Denote by  $ABS(d)$  the best possible absolute competitive ratio of a deterministic online algorithm for VP with dimension  $d$ , and let  $ASYM(d)$  denote the best possible asymptotic competitive ratio of a deterministic online algorithm for VP with dimension  $d$ . If there are values of  $d$  for which such best possible online algorithms do not exist, we define the corresponding values of  $ABS(d)$  and  $ASYM(d)$  as the infimums of the corresponding ratios, where the infimum is taken over all online algorithms for VP with  $d$  dimensions. Thus, these values are well-defined for all  $d$  even though we currently do not know their values. It is known that these values are mostly linear in  $d$  (see below).

Observe that both  $ABS(d)$  and  $ASYM(d)$  are monotone non-decreasing functions of  $d$ , as we can use the online algorithm with larger dimension in order to pack the lower dimension vectors by simulating a higher dimension input using additional components, which are always set to 0. Furthermore, by the definitions of the asymptotic competitive ratio and the absolute competitive ratio, we conclude that for every  $d$ , we have  $ASYM(d) \leq ABS(d)$ .

In this work, we improve on the known lower bounds of the asymptotic competitive ratio for all fixed values of  $d$  that are at least 3 for online VP. We focus mostly on deterministic

online algorithms, while our main result uses an oblivious adversary and holds also against randomized online algorithm. This also improves the known results for the absolute ratios, that is, we improve upon the state of the art of lower bounding  $\text{ASYM}(d)$  for all  $d \geq 3$ . Our main result is that the order of growth of the asymptotic competitive ratio is  $\Omega\left(\frac{d}{(\log d)^2}\right)$ . Recall that the term asymptotic here, does not refer to the asymptotic growth of  $d$ , but to the asymptotic definition of the competitive ratio, which is the most common measure for bin packing problems. To do that, we present four constructions leading to different lower bounds on  $\text{ASYM}(d)$ . For every specific value of  $d$ , one may use the construction that leads to the largest possible lower bound. In Section 2, we present our results for very large values of  $d$ . That is, we show that for  $d > 16$ , there is a lower bound of  $\frac{d-1}{8(\log_2 d)^3}$  on  $\text{ASYM}(d)$ , and for sufficiently large and fixed values of  $d$ , the lower bound determined for the asymptotic competitive ratio for online VP is  $\frac{d}{2^{11} \cdot (\log_2 d)^2}$ . The lower bounds presented in Section 2 are based on an oblivious adversary. An elaborate explanation for using values of  $d$  that are sufficiently large is also provided in Section 2.

Next, we present the improved lower bounds for relatively small values of  $d$  against deterministic online algorithms. In Section 3, we show a lower bound of at least  $\frac{\lfloor \sqrt{d-1} \rfloor + 2}{2}$  that applies for all fixed values of  $d \geq 2$ . For example, in the case  $d = 14$  we obtain a lower bound of 2.5 on the asymptotic competitive ratio. Then, in Section 4 we show a lower bound of  $\frac{9}{4} = 2.25$  on  $\text{ASYM}(3)$ . Finally, in Section 5, we introduce a lower bound of  $\frac{76}{29} \approx 2.62$  on  $\text{ASYM}(8)$ . The last three constructions, presented in Sections 3, 4, and 5, are based on a technique called adaptive constructions for packing problems, explained in detail below. We note that our lower bound of  $\frac{\lfloor \sqrt{d-1} \rfloor + 2}{2}$  is the largest lower bound that we establish for a large variety of values of  $d$ . This holds even for extremely large values of  $d$  like  $d = 2^{30}$ , for which the value of this lower bound is at least  $2^{14} > 16000$ . Comparing this result to the values of lower bounds presented in Section 2, we find that they are much smaller, and in fact the values resulting from the constructions of that section are not larger than 4972 and 583. Thus, for any reasonable value of  $d$ , the lower bounds obtained based on the adaptive construction method are much better than the ones in Section 2.

The lower bounds on  $\text{ABS}(d)$  established in Azar et al. [2] were not computed explicitly, in the sense that they are only stated as  $\Omega(d^{1-\varepsilon})$  for every  $\varepsilon > 0$ . These lower bounds hold only in the absolute sense, and their order of growth is  $\Omega\left(\frac{d}{(\log_2 d)^2}\right)$ . In order to compare their bounds to our lower bounds on  $\text{ASYM}(d)$ , we examined their proofs. Their lower bounds are basically the deterministic lower bounds on node coloring of graphs where the nodes arrive in an online fashion, thus they are using black-box reductions from the (deterministic) lower bounds of Halldórsson and Szegedy [22]. These black-box reductions are the main reason that lower bounds cannot be obtained on the asymptotic competitive ratio, but only on the absolute competitive ratio, which may be larger (and it is not the standard tool to analyze bin packing problems). Note that we improve the known absolute lower bound for a large number of values of  $d$ . For example, the deterministic lower bound resulting from the construction of [22] for  $d = 60$  is 3.75, while our results imply a lower bound above 4.8 (which holds even in the asymptotic case, and for a slightly lower dimension of 57).

In the work of [22], the part of randomized lower bounds consists of two constructions. In the first one, the value of  $d$  is relatively large, thus we can use Stirling's formula to approximate  $\lceil \log_2 d \rceil!$  with a constant multiplicative error, while the second one holds for all dimensions  $d$ . In Section 2, we use the ideas of Halldórsson and Szegedy [22] to obtain similar lower bounds on the asymptotic competitive ratio of VP. Unlike the work of [2], we do not apply black-box reduction from node coloring. The main motivation for that is that we need a lower bound with respect to a different coloring problem in which we are interested

in *fractional coloring*. Since this variant was not studied before, we cannot use an existing result for it, nor can we use a black-box reduction from it. Instead, we present the lower bound construction for VP. The transition to this fractional coloring is the main tool that we use in order to lift the construction of [2], so that it will allow us to prove a lower bound on the asymptotic competitive ratio for VP. We refer to [11] for a different approach that is based on a black-box reduction from fractional coloring to randomized coloring together with a black-box reduction from the randomized lower bound of [22]. This alternative approach of [11] leads to inferior lower bounds, therefore, we base our result on the approach of [9] instead.

Next, we survey the literature for the bounds of  $\text{ASYM}(d)$ . The special case of  $d = 1$  of VP is simply the bin packing problem (BP), which has been studied for half a century [23, 24]. The current best bounds on  $\text{ASYM}(1)$  (for the online version) are a lower bound of 1.54278 [7] and an upper bound of 1.57829 [5], while  $\text{ABS}(1) = \frac{5}{3}$  [8]. In [4, 6], the authors considered a generalization of BP, known as the Cardinality Constrained Bin Packing (CCBP). CCBP is defined as follows; each item has a scalar size in  $[0, 1]$  (one-dimensional), and in addition, the constraint that the sum of items sizes in each bin does not exceed 1, there is an integer parameter  $k \geq 2$ , such that no bin can have more than  $k$  items. Note that CCBP is a special case of VP with  $d \geq 2$ , by defining a vector for each item, where its first component is the item's size and its second component is  $\frac{1}{k}$  (the other components are zeros). In [6], the authors consider the case of VP with  $d = 2$ , and present its difference from CCBP. They demonstrated that  $\text{ASYM}(2) \geq 2.03731129$  with respect to VP in two dimensions, and thus for all  $d \geq 2$  it was established that  $\text{ASYM}(d) \geq 2.03731129$ , whereas for CCBP there is a 2-competitive algorithm. In [3] it is shown that when  $d$  grows to infinity there is a lower bound that tends to  $e$ , thus  $\lim_{d \rightarrow \infty} \text{ASYM}(d) \geq e$ . It is interesting to note that the lower bound in [3] applies even if all components of all vectors are small. That is, for every small  $\varepsilon > 0$ , where all components are smaller than  $\varepsilon$ , the lower bound of [3] holds, and it holds even when  $\varepsilon$  tends to 0. This matches the upper bound for the very specific case of VP (of small components) established by [1]. Prior to the publications of [3, 6], the lower bounds on  $\text{ASYM}(d)$  were weaker [20, 14, 13].

As for upper bounds on  $\text{ASYM}(d)$ , the best known result [21] is (still) that the First-Fit algorithm has an asymptotic competitive ratio of  $d + 0.7$  for VP in  $d$  dimensions. Prior to that work, there was a slightly weaker bound of  $d + 1$  established by Kou and Markowsky [26]. For the absolute competitive ratio, the resulting bound is also  $d + O(1)$  [21, 26] (an upper bound of  $O(d)$  follows from the simple property that for greedy algorithms, no two bins of the output have a sum of at most 1 in all components). With respect to the literature on VP regarding oblivious adversary, all known upper bounds are using deterministic algorithms, while the lower bound of [3] is the unique lower bound larger than 2 that holds also using oblivious adversary (by applying standard adaptation). The lower bound of [6] is stated only for deterministic algorithms, and the means for adjusting it for use of an oblivious adversary are unknown.

We stress that prior to our work it was unknown whether there is an online algorithm  $A$  for VP for any dimension  $d$  (or for sufficiently large dimensions) such that for every input  $L$ , its cost  $A(L)$  satisfies  $A(L) \leq 3 \cdot \text{OPT}(L) + d$  (where  $d$  is the dimension of the input). This is due to the fact that the known lower bound of  $e$  holds for any additive term, while the non-constant known lower bound uses only  $d$  items for dimension  $d$ .

Vast literature is available on the offline versions of all the problems mentioned above [16, 10, 12, 15, 18, 19, 25, 28]. In particular, similar lower bounds to those of [1] on the absolute approximation ratio for VP (under a certain standard complexity assumption, that

$\text{NP} \neq \text{ZPP}$ ) were observed for the offline scenario [16, 12], also by reductions from coloring problems. The lower bounds are for the absolute measures, since for every dimension  $d$ , the number of items is simply  $d$ . The other bin packing problems discussed here (BP and CCBP) admit polynomial time asymptotic approximation schemes [15, 18, 19, 25], but one can show that unless  $\text{P} = \text{NP}$ , such schemes cannot exist for the absolute cases, and the absolute approximation ratio is at least 1.5. This can serve as evidence that lower bounds for the absolute approximation ratio or the absolute competitive ratio are not sufficient for the analysis of the asymptotic approximation ratio or the asymptotic competitive ratio. In fact, it is true also for online bin packing problems that the absolute measure is different from the asymptotic one. For example, for BP, the best possible absolute competitive ratio is  $\frac{5}{3}$  [8], while the asymptotic competitive ratio is significantly smaller [5]. For CCBP, one example is the parameter  $k = 4$ , for which the best possible absolute competitive ratio is 2 [4, 6], while an improved asymptotic competitive ratio below 2 is known [17].

Omitted proofs will appear in the full version of this work.

## 2 The lower bound for large values of $d$

In this section we consider the cases of very large dimensions. We will prove a lower bound of  $\Omega(\frac{d}{\log^2 d})$  for sufficiently large dimensions  $d$ . Our lower bounds are not smaller than the weaker results of Azar et al. [2], which were established only for the absolute competitive ratio measure (as a function of the dimension, for large enough values of  $d$ ). Here, we consider the stronger measure of the asymptotic competitive ratio, and even prove these lower bounds for randomized algorithms.

The input's sequence presented by the adversary is constructed in  $d$  phases, where each phase consists of  $N$  identical items. The construction uses integer parameter  $\nu$  (which will be chosen later as a function of the number of dimensions), and maintains  $\nu$  classes and  $\mathcal{S}$ , a subset of the  $\nu$  class sets,  $\mathcal{S} \subseteq X = 2^{[\nu]} \setminus \emptyset$  where  $[\nu] = \{1, 2, \dots, \nu\}$ , let  $0 < \epsilon \leq \frac{1}{Nd}$ . The adversary examines the online algorithm's expected values, and associates a class and a set for each phase, which will determine the items' phase components. We denote  $c_j \in [\nu]$ , and  $S_j \in \mathcal{S}$  as the class and the set of the phase  $j$ , respectively.

Formally, at the beginning of phase  $j \in [d]$ , the adversary examines the algorithm's expected assignment and chooses a set  $S_j \in \mathcal{S}$ . The adversary presents  $N$  identical items, where each item component is defined as follows: the items have 1 as their  $j$ th component, all components of indexes larger than  $j$  are 0, while a component of index  $i < j$  is  $\epsilon$  if  $c_i \notin S_j$  and 0 otherwise. Note that the previous phases classes  $c_1, \dots, c_{j-1}$  have been already set. Finally, after examining the expected assignment of these vectors the adversary associates a class  $c_j \in S_j$  for the phase.

First, observe that the non zero components' values are either 1 or  $\epsilon \leq \frac{1}{Nd}$ . Since the number of items is  $Nd$ , a subset of the items cannot be assigned to the same bin, only if exists a component for which there is an item with a value of 1 and another item with a non-zero value. In addition, a construction of this form satisfies that any solution has a cost of at least  $N$  (and of at most  $Nd$ ), regardless of its specific details. Therefore, by letting  $N$  grow to infinity by proving a lower bound for these instances a lower bound on the asymptotic competitive ratio follows. Next, consider a bin  $B$  with a fixed realization of the random bits of the online algorithm (at some point during the lower bound construction). We associate the subset  $S(B) \subseteq [\nu]$  of classes with every such bin, where  $S(B)$  contains the classes of items that are packed into  $B$ , that is,  $\ell \in S(B)$  if there exists at least one phase  $j$  such that  $\ell = c_j$  and an item of phase  $j$  is packed into  $B$ . The set  $S(B)$ , named the associated set of

## 8:6 Lower Bounds for Online Vector Bin Packing

$B$  may be extended later. Intuitively, the adversary chooses a set  $S_j$  and a class  $c_j$  in each phase, in order to increase the (expected) cardinality of the associated set ( $|S(B)|$ ) of the online algorithm bins. Then, by using a corresponding potential function, we will obtain the lower bound of the expected number of bins of the online algorithm. Full details of the adversary's choices are presented later. First, we introduce several properties, which hold for any choice of adversary. The following claim characterizes the possible associated set that an algorithm may pack the items of phase  $j$ .

▷ **Claim 1.** Any algorithm may pack an item of phase  $j$  in bin  $B$ , if and only if it does not contain another item of phase  $j$ , and before the item is added it holds that  $S(B) \subseteq S_j$ .

*Proof.* Two items of the phase  $j$  cannot fit into a common bin, since there is 1 in the  $j$ 'th component of the items. The number of items is  $N \cdot d$ , hence a collection of items fit into a bin, if and only if, no item in the collection has an  $\varepsilon$  component when another item of the collection has a value of 1 at the same component.

Given a bin  $B$ , for any  $\ell \in S(B)$  there exists at least one value  $j'$ , such that an item of phase  $j'$  is assigned to  $B$ , and the class of phase  $j'$  is  $\ell$ . By the construction definition, the  $j'$  component of this item (and the bin  $B$ ) is 1, and if  $\ell \notin S_j$  the  $j'$ th component of items of phase  $j$  is  $\varepsilon$ . Hence, if item of phase  $j$  can be assigned to bin  $B$  then  $\ell \in S_j$ . On the other hand, if  $S(B) \subseteq S_j$  then for any component  $i < j$  of  $B$  which is 1, we have  $c_i \in S(B) \subseteq S_j$ , and by definition the  $j$ 'th phase vector value at component  $i$  is 0. ◁

We observe that there exists a solution which uses at most  $\nu \cdot N$  bins.

▷ **Claim 2.** For any choice of  $c_j, S_j$  there exists an offline solution which uses at most  $\nu \cdot N$  bins.

*Proof.* A solution that opens  $N$  bins for each class and assigns the phase's vector according to the class is a feasible assignment by Claim 1, since for a bin we use to pack in phase  $j$  we have  $S(B) \subseteq \{c_j\}$  and  $c_j \in S_j$  by the algorithm's definition. ◁

Next, we will present an important characterization of the set  $\mathcal{S}$  necessary for the analysis. The set  $\mathcal{S}$  in the construction will depend on a parameters pair  $(\alpha, \beta)$ , and will require that  $(\alpha, \beta)$  would be *satisfiable*.

► **Definition 3.** Given  $\nu$ ,  $(\alpha, \beta)$  is *satisfiable* if there exists a set of subsets  $\mathcal{S} \subseteq X$  such that  $|\mathcal{S}| \geq \alpha$ , and for every pair  $S, S' \in \mathcal{S}$  such that  $S \neq S'$  we have that their symmetric difference  $S \Delta S'$  satisfies  $|S \Delta S'| \geq \beta$ .

The next claim characterizes two satisfiable pairs, which will be used in our lower bound construction.

▷ **Claim 4.** For any  $\nu$ ,  $(\alpha, \beta) = (2^\nu - 1, 1)$  is satisfiable, and if  $\nu$  is sufficiently large then  $(\alpha, \beta) = (2^{\nu/4}, 0.3\nu)$  is satisfiable.

*Proof.* For the first part, consider  $\mathcal{S}$  to be the set  $X$ , which has  $2^\nu - 1$  elements, as required. Each pair of distinct elements represents non-equal subsets of  $[\nu]$ , so that they differ by at least one element. We fix the value of  $\beta$  to 1, in this case.

The second part was proven by [22], which demonstrated that if we pick a random sub-collection of subsets of  $[\nu]$  with  $2^{\lceil \nu/4 \rceil}$  subsets, each consisting of exactly  $\lceil \nu/2 \rceil$  elements of  $[\nu]$  (chosen independently and uniformly at random), then with some positive probability (for large enough value of  $\nu$ ) each pair of these selected subsets satisfies the condition on their symmetric difference. Using the probabilistic method, they were able to prove our claim (deterministically) for large enough values of  $\nu$  (that they have not specified). ◁

For a specific satisfiable pair  $(\alpha, \beta)$  and their corresponding set  $\mathcal{S}$ , and for any associated set  $S(B) \subseteq [\nu]$ , we denote a subset in  $S \in \mathcal{S}$  that *represents*  $B$ , (where  $S$  is represented by  $B$ ) if  $|S \Delta S(B)| \leq \frac{\beta}{5}$ . We will prove that any set is represented by at most a single set in  $\mathcal{S}$ .

▷ **Claim 5.** If for every pair  $S, S' \in \mathcal{S}$  such that  $S \neq S'$  we have  $|S \Delta S'| \geq \beta$  and  $\beta \geq 1$ , then any bin  $B$  is represented by at most one set  $S \in \mathcal{S}$ .

*Proof.* Assume for contradiction that a bin  $B$  is represented by two sets  $S_1, S_2 \in \mathcal{S}$ . Recall that  $|S_1 \Delta S_2| \geq \beta$  (by assumption), but  $|S(B) \Delta S_i| \leq \frac{\beta}{5}$  for  $i = 1, 2$  (by the definition of representation). First, consider the elements of  $S_1 \setminus S_2$ . Some of these elements belong to  $S(B)$ , while other do not. Observe that  $(S_1 \setminus S_2) \cap S(B) \subseteq S(B) \Delta S_2$  so  $|(S_1 \setminus S_2) \cap S(B)| \leq \frac{\beta}{5}$ . Since  $(S_1 \setminus S_2) \setminus S(B) \subseteq S(B) \Delta S_1$ , we conclude that  $|(S_1 \setminus S_2) \setminus S(B)| \leq \frac{\beta}{5}$ . Therefore,  $|S_1 \setminus S_2| \leq \frac{2\beta}{5}$ . Similarly (by changing the roles of  $S_1$  and  $S_2$ ) we conclude that  $|S_2 \setminus S_1| \leq \frac{2\beta}{5}$ . Thus,  $|S_1 \Delta S_2| \leq \frac{4\beta}{5}$ , contradicting our assumption about  $\mathcal{S}$ . ◁

We are ready to prove our main lemma, which achieves a lower bound on the expected number of bins opened. We will demonstrate that the adversary may choose a set and a class that will increase the cardinality of the associated sets of the algorithm's bins in every step, which we will capture by using a potential function. Our potential function is the expected value of the sum of  $|S(B)|$  over all bins  $B$  of the algorithm. That is,  $\Phi = \mathbb{E}[\sum_B |S(B)|]$ . Observe that the expected value of the cost of the online algorithm is at most  $\Phi$  and not smaller than  $\frac{\Phi}{\nu}$ , since for any  $B$  it holds that  $|S(B)| \leq \nu$ . Let  $\gamma = \lceil \frac{\beta}{5} \rceil$ , this parameter is chosen to ensure that each associated set of a bin is represented by at most one set  $S \in \mathcal{S}$ .

► **Lemma 6.** For a satisfiable pair  $(\alpha, \beta)$  there exists an adversary strategy, such that the expected number of bins opened by the online algorithm is at least  $\min\{\alpha \cdot N/2, d \cdot \frac{\gamma}{\nu} \cdot \frac{N}{2}\}$ .

*Proof.* We will show that if the expected number of bins before phase  $j$  is less than  $\alpha \cdot N/2$ , then there exists  $S_j, c_j$ , which will increase the potential  $\Phi$  by at least  $\frac{\gamma}{\nu} \cdot \frac{N}{2}$ . The lemma holds since we can perform  $d$  phases, and since the number of bins opened is at least  $\frac{\Phi}{\nu}$ .

Prior to phase  $j$ , we let  $n(S)$  for a set  $S \in \mathcal{S}$  be the expected value of the number of bins (of the online algorithm) that it represents. After the assignment of the  $j$ 'th phase items, we denote by  $\tilde{n}^j(S)$  for a set  $S \in 2^{[\nu]}$  the expected number of bins associated with  $S$  and a  $j$ 'th phase item assigned into it. Note that the adversary may use  $n(S), \tilde{n}^j(S)$  when determining  $S_j, c_j$ , respectively, and that these values do not depend on the realization of the random bits used by the algorithm.

**Determining  $S_j$ .** We obtained  $\sum_{S \in \mathcal{S}} n(S) \leq \alpha \cdot \frac{N}{2}$  through the assumption that the expected number of bins is less than  $\alpha \cdot N/2$ , and since every bin of the algorithm is represented by at most one set. The adversary sets  $S_j \in \mathcal{S}$  such that  $n(S_j)$  is below  $\frac{N}{2}$ , and the existence of  $S_j$  can be guaranteed by the pigeonhole principle.

**Determining  $c_j$ .** The algorithm assigns each item of phase  $j$  to a distinct bin; by linearity of expectation we have,

$$N = \sum_S \tilde{n}^j(S) = \sum_{|S \Delta S_j| < \gamma} \tilde{n}^j(S) + \sum_{|S \Delta S_j| \geq \gamma} \tilde{n}^j(S) \leq \frac{N}{2} + \sum_{|S \Delta S_j| \geq \gamma} \tilde{n}^j(S),$$

where the first inequality is obtained by our choice of  $S_j$ . Therefore, we have

$$N/2 \leq \sum_{|S \Delta S_j| \geq \gamma} \tilde{n}^j(S) \leq \sum_{\ell \in S_j} \frac{\sum_{S: \ell \notin S} \tilde{n}^j(S)}{\gamma},$$

where the second inequality follows, since  $\tilde{n}^j(S) > 0$  only if  $S \subseteq S_j$  by Claim 1, so the same  $S$  will appear at least  $\gamma$  times in the inner summation on the right hand side. The adversary set  $c_j \in S_j$  such that  $\sum_{S:c_j \notin S} \tilde{n}^j(S)$  is above  $\frac{\gamma}{\nu} \cdot \frac{N}{2}$ , the existence of  $c_j$  can be guaranteed by the pigeonhole principle since  $|S_j| \leq \nu$ . Note that the increase in the potential function is exactly  $\sum_{S:c_j \notin S} \tilde{n}^j(S)$ , as required.  $\blacktriangleleft$

## 2.1 Assembling the pieces together

Recall that by Claim 2 the cost of the optimal solution is at most  $\nu \cdot N$ . By Lemma 6 any online algorithm will use at least  $\min\{\alpha \cdot N/2, d \cdot \frac{\gamma}{\nu^2} \cdot \frac{N}{2}\}$  number of bins. This value is maximized if  $d \cdot \frac{\gamma}{\nu^2} \cdot \frac{N}{2} \approx \frac{\alpha N}{2}$ . Thus, we need a method for selecting  $\nu$ , if the dimension  $d$  is given. We will use a value  $\nu$  for which the corresponding pair  $(\alpha, \beta)$  satisfies  $d \geq \frac{\nu^2 \alpha}{\gamma}$  (where  $\gamma$  is determined by  $\beta$ ), and consequently the resulting lower bound would be  $\frac{\alpha}{2\nu}$ .

First, consider the case where  $d$  is relatively small and we use  $(\alpha, \beta) = (2^\nu - 1, 1)$  and thus  $\gamma = 1$ , and  $\nu$  is an integer such that  $\nu^2 \cdot (2^\nu - 1) \leq d$ . It is sufficient to require that  $\nu^2 \cdot 2^\nu \leq d$ , that is satisfied by letting  $\nu = \lfloor \log_2 d - 2 \log_2 \log_2 d \rfloor$ , as for this choice  $\nu^2 2^\nu \leq (\log_2 d)^2 \cdot \frac{d}{(\log_2 d)^2} = d$ . The resulting lower bound is not smaller than

$$\frac{\alpha}{2\nu} \geq \frac{2^{\log_2 d - 2 \log_2 \log_2 d} - 1}{4 \cdot (\log_2 d - 2 \log_2 \log_2 d)} \geq \frac{d - 1}{8(\log_2 d)^3},$$

where the last inequality holds for  $d > 16$ , as for these values of  $d$  we have that  $8 \log_2 \log_2 d < 4 \log_2 d$ .

Next, consider the case where the dimension is higher, and we could use  $(\alpha, \beta) = (2^{\nu/4}, 0.3\nu)$ , and thus  $\gamma = 0.06\nu$ . We pick  $\nu$  as the largest integer such that  $\frac{\alpha \nu^2}{\gamma} \leq d$  that is,  $\alpha \nu = \nu 2^{\nu/4} \leq 0.06 \cdot d$ . Letting  $\nu' = \frac{\nu}{4}$  we will require  $\nu' \cdot 2^{\nu'} \leq 0.015d$ . This condition is satisfied, e.g. for  $\nu' = \lfloor \log_2 d - \log_2 \log_2 d - 7 \rfloor$ , as for this choice of  $\nu'$  we have

$$\nu' \cdot 2^{\nu'} \leq (\log_2 d) \cdot 2^{\log_2 d - \log_2 \log_2 d - 7} = (\log_2 d) \cdot \frac{d}{\log_2 d \cdot 2^7} = \frac{d}{2^7} \leq 0.015d$$

and  $\nu'$  is an integer and thus also  $\nu = 4\nu'$  is integer. The resulting lower bound is

$$\frac{\alpha}{2\nu} = \frac{2^{\nu'}}{8\nu'} \geq \frac{2^{\log_2 d - \log_2 \log_2 d - 8}}{8 \cdot (\log_2 d - \log_2 \log_2 d - 7)} \geq \frac{\frac{d}{\log_2 d}}{2^{11} \cdot \log_2 d} = \frac{d}{2^{11} \cdot (\log_2 d)^2},$$

that holds for large enough values of  $d$ .

Thus, we conclude the construction of this section by the following theorem.

► **Theorem 7.** *For every fixed dimension  $d > 16$ , there is a lower bound of*

$$\frac{d - 1}{8(\log_2 d)^3},$$

*on the asymptotic competitive ratio of online randomized algorithms for VP. For sufficiently large and fixed values of  $d$  the lower bound on the asymptotic competitive ratio is*

$$\frac{d}{2^{11} \cdot (\log_2 d)^2}.$$

### 3 A lower bound for medium sized dimensions

Let  $\alpha, \beta \geq 2$  be the two positive integers such that  $d \geq 2 + \alpha(\beta - 2)$ . Next we show a lower bound of  $\frac{\alpha \cdot \beta}{\alpha + \beta - 2}$  for the corresponding special case. Note that choosing the values  $\alpha = \beta$  results in a lower bound of  $\Omega(\sqrt{d})$  so for very large dimension this result is inferior to the general lower bound we considered earlier. However, the hidden constants in the  $\Omega$  notation are smaller for the current construction leading to better lower bounds for medium sized dimensions.

Let  $N > d$  be a large integer such that  $\frac{N}{\alpha}$  is an integer. Our sequence of items may have up to  $N^3$  items, and we let  $\varepsilon < \frac{1}{N^3}$ . We will use the adaptive construction method to generate a sequence of scalar values where  $a_i$  is the value associated with the  $i$ th item, such that all values are smaller than  $\varepsilon$ , and furthermore the following condition holds. If an item is large, then its value is at least  $N^3$  times larger than the value of a small item. The logical condition that we will use to define small and large items is that a  $d$ -dimensional item is large if it is packed into an empty bin and otherwise it is small. We stress the property that every item of the construction will have a one-dimensional associated value, and we will explain how this value is used in the definition of the  $d$ -dimensional item.

During the adaptive construction, after packing the current item, there will be a value  $\mu < \frac{1}{N} < \frac{1}{2}$ . The value of  $\mu$  may decrease (but cannot increase) after assigning an item. The value  $\mu$  will satisfy the property that the value of every large item that appeared up to (and including) the current iteration is strictly larger than  $\mu$  while for any subset of items  $S$  where  $S$  contains only small items that appear in the instance (both during the prefix and later on) or large items that appear later on in the input sequence, the total value of  $S$  is strictly smaller than  $\mu$ . This is obtained by letting  $\mu$  be the current upper bound on values of items that can still be either small or large at termination, and reducing the length of the interval of possible values in the adaptive construction by a multiplicative factor of  $N^3$  after each item. This is done by using the scheme of [6], and setting the predefined constant mentioned earlier ( $k$ ) to  $N^3$ , this ensure that all such subsets  $S$ , whose number of elements will be less than  $N^3$  (as this will be a valid upper bound on the number of items in the entire construction), will satisfy the requirement. Note that, in the construction all the successive items to a large item must be at least  $N^3$  smaller than this large item since those items could be eventually small.

Our construction will have  $\beta$  phases, and it will be useful to denote by  $\mu_i$  the current value of  $\mu$  at the end of phase  $i$  (i.e., after packing the last item of phase  $i$  and modifying the current interval according to the rules of the adaptive construction). Furthermore, phase  $i$  uses the value  $\mu_{i-1}$ .

The first and last phase have special properties while the intermediate phases ( $\beta - 2$  phases) are all similar. Each phase lasts until the first point in time in which the algorithm has opened  $N$  new bins during this phase. Thus, we will ensure that the total cost of the algorithm is  $N \cdot \beta$ . We also maintain an integer value  $\pi$  denoting the *current component* that is being dealt with, and it has a special role in the construction. We will show later that  $\pi$  will always be an index of a component (i.e.,  $\pi \leq d$ ), even though it is increased frequently. The value  $\pi$  is an index of a component such that items have a very big (and close to 1) component of this index. By increasing  $\pi$ , we change (and increase) the position of this very big component in the construction. This value is initially set as  $\pi = 2$  (while the very first component has a special role during the first phase), and it increases gradually, each time by 1, and it never decreases, as items are being presented. We will see that the value of  $\pi$  never exceeds  $d$ , and during the presentation of items of intermediate phases it will hold that  $\pi \leq d - 1$ .

### The first phase

We construct a sequence of items, where the first component of every vector is  $\frac{1}{N}$  while every other component equals to the value of the current item. Note that this phase ends after at most  $N^2$  items, since any phase ends after the algorithm used  $N$  new bins, every new bin can contain at most  $N$  items of this phase, and there are no bins of previous phases which can be used.

### The $\beta - 2$ intermediate phases

Every such phase will contain at most  $\alpha \cdot N$  items. We keep a counter  $j$  of the index of the phase, where  $j$  is initialized to 2. At the end of phase  $j - 1 \geq 1$  we set  $\mu_{j-1}$  as we described above and we start presenting new items of the  $j$ th phase.

Each item of these  $\beta - 2$  intermediate phases will consist of the following components. All components with indexes smaller than  $\pi$  are equal to 0, the current component with index  $\pi$  is set to  $1 - \mu_{j-1} > \frac{1}{2}$ , and all other components (of larger indexes) are equal to the value of the current item (of the adaptive construction). Recall that a new phase starts whenever the number of new bins during the current phase is  $N$ , and just before starting a new phase we also increase  $\pi$  by 1 (for  $j = 2$ ,  $\pi$  is not increased but it is initialized). However, there are other events where we decide to increase the value of  $\pi$  by 1. These additional events are stated as follows. Whenever the number of large items (according to the adaptive construction) that were packed while the value of  $\pi$  is its current value, is  $\frac{N}{\alpha}$ , we increase the value of  $\pi$  by 1. This is done since the number of large items whose  $\pi$ th component is very big is the maximum possible number. We will show that an increase in the value of  $\pi$  will happen after at most  $N$  consecutive items for which we used the same value of  $\pi$ . This happens either due to the latter rule or due to the end of the phase (since  $\pi$  is always increased due to that event). Before presenting the vectors of the last phase, we prove the main correctness claims regarding the intermediate phases that allow our construction to have the required structure and allow us to prove the claimed lower bound on the asymptotic competitive ratio.

► **Lemma 8.** *The items of phase  $j$  (where  $2 \leq j \leq \beta - 1$ ) cannot be packed into bins that were opened in an earlier phase, that is, bins used first for an item of an earlier phase. Additionally, the value of  $\pi$  remains constant without being increased for at most  $N$  items.*

► **Lemma 9.** *During an intermediate phase, the value of  $\pi$  is increased at most  $\alpha$  times by 1 (including the increase due to the end of the phase).*

We consider the value of  $\pi$  at the beginning of the last phase. By the last lemma, we conclude that just before the moment when phase  $\beta - 1$  ends (the last intermediate phase), we have  $\pi \leq 2 + (\beta - 2) \cdot \alpha + (\beta - 1) \leq d - 1$  and  $\pi$  is increased to a value of at most  $d$  once that phase ends. This final value (of at most  $d$ ) for  $\pi$  was not used as the value of  $\pi$  in the definition of items of any phase (after the very last time that  $\pi$  was increased, no items are defined so it was not used to define an item).

### The last phase

In the last phase we present exactly  $N$  identical items that are defined as follows. In component  $d$  they are equal to  $1 - \mu_{\beta-1}$  and all other components are 0. Observe that every bin that the algorithm has opened in one of the earlier phases has one large item whose  $d$ th component is larger than  $\mu_{\beta-1}$ , and thus the algorithm needs to open  $N$  new bins for these  $N$  items of the last phase.

### Proving the resulting lower bound

Since there are  $\beta$  phases and the algorithm is forced to open  $N$  new bins in every phase, we conclude that the cost of the algorithm is exactly  $N \cdot \beta$ . Since  $N$  could be an arbitrary large integer, in order to prove the lower bound on the asymptotic competitive ratio of the algorithm, it suffices to show that the optimal offline cost is at most  $N \cdot (1 + \frac{\beta-2}{\alpha}) + 1$ . In order to present this proof, we will consider all items of the last phase as small items. We present an offline solution of cost at most  $N \cdot (1 + \frac{\beta-2}{\alpha}) + 1$ . This offline solution will pack all large items into  $N \cdot (\frac{\beta-2}{\alpha}) + 1$  bins, and all small items into a disjoint set of  $N$  bins, and in total we will use at most  $N \cdot (1 + \frac{\beta-2}{\alpha}) + 1$  bins. First, we consider the large items.

► **Lemma 10.** *There is an offline solution that packs all large items into at most  $N \cdot (\frac{\beta-2}{\alpha}) + 1$  bins.*

Next, we consider packing of the small items into  $N$  bins.

► **Lemma 11.** *There is an offline solution that packs all small items into  $N$  bins.*

Thus, we conclude the following result.

► **Theorem 12.** *If  $d \geq \alpha(\beta - 2) + 2$ , then there is no online algorithm for VP whose asymptotic competitive ratio is smaller than  $\frac{\beta}{1 + \frac{\beta-2}{\alpha}} = \frac{\alpha \cdot \beta}{\alpha + \beta - 2}$ .*

For large values of  $d$ , we can use  $\alpha = \beta = \lfloor \sqrt{d-1} \rfloor + 1 \geq \lceil \sqrt{d-1} \rceil$  for which  $\alpha(\beta-2)+2 \leq (\sqrt{d-1} + 1) \cdot (\sqrt{d-1} - 1) + 2 = d - 1 - 1 + 2 = d$  and this lower bound on the asymptotic competitive ratio is  $\frac{\alpha \cdot \beta}{\alpha + \beta - 2} = \frac{\alpha^2}{2\alpha - 2} = \frac{\alpha + 1}{2} + \frac{1}{2(\alpha - 1)} > \frac{\lfloor \sqrt{d-1} \rfloor + 1}{2} + 1 \geq \frac{\sqrt{d-1} + 1}{2} > \frac{\sqrt{d}}{2}$ . However, for small dimensions we could do better. For example for  $d = 98$ , we could pick  $\alpha = 12, \beta = 10$  and the lower bound on the asymptotic competitive ratio is  $\frac{120}{20} = 6$  whereas using  $\alpha = \beta = 10$  the lower bound is  $\frac{100}{18} \approx 5.555$ .

For small dimensions, namely  $d = 6, 7, 9, 10$  and  $11$ , the next estimation can be used. Letting  $\beta = 3$  and  $\alpha = d - 2$ , the lower bound is greater or equal to  $\frac{3\alpha}{\alpha + 1} = \frac{3}{1 + \frac{1}{\alpha}} = \frac{3}{1 + \frac{1}{d-2}}$ . It gives a lower bound of 2.4, 2.5, 2.625, 2.666, and 2.7 for the cases of  $d = 6, 7, 9, 10, 11$ , respectively. We mention several other small values of  $d$ . For  $d = 12$ , we can use  $\alpha = 5$  and  $\beta = 4$  to obtain a lower bound of  $\frac{20}{7} \approx 2.857$ . For  $d = 14$ , we can use  $\alpha = 6$  and  $\beta = 4$  to obtain a lower bound of 3. For  $d = 16$ , we can use  $\alpha = 7$  and  $\beta = 4$  to obtain a lower bound of  $\frac{28}{9} \approx 3.111$ . Improved bounds for the cases  $d = 3, 4, 5, 8$  are presented in the next sections.

## 4 The case $d = 3$

Recall that the known lower bound on the asymptotic competitive ratio for  $d = 2$  is just slightly above 2, and this was the best known constant lower bound for any small value of  $d$  till now. We prove here a lower bound of 2.25 for the case  $d = 3$ , and explain how it can be slightly improved.

We will use an adaptive construction as explained earlier. The construction is based on that of [6].

Let  $K > 1000$  be a large integer, and let  $\varepsilon > 0$  be a small constant (in particular,  $\varepsilon < \frac{1}{K} < 0.001$ ). The input consists of three parts and we describe the parts one by one.

### The first part of the input

Using an adaptive construction of values, we define a sequence of values in  $(0, \varepsilon)$  such that any large value is strictly larger by a multiplicative factor larger than  $10K$  from any small value. The binary condition is that the item is packed into an empty bin by the online algorithm.

## 8:12 Lower Bounds for Online Vector Bin Packing

Thus, an item packed into an empty bin is large, and otherwise the item is small. The number of items will be  $2 \cdot K \cdot N$  for a large integer  $N > 0$ . Letting  $a_1, a_2, \dots, a_{2KN}$  be the sequence of values, the vector for item  $i$  is defined as follows. The first component is  $\frac{1}{K}$ , and each one of the two other components is equal to  $a_i$ . Let  $\gamma$  be a threshold such that if the  $i$ th constructed value is small, it holds that  $0 < a_i < \frac{\gamma}{10K}$  and otherwise  $\gamma < a_i < \varepsilon$ . The input up to this point is denoted by  $I_0$ .

► **Lemma 13.** *The optimal cost for packing  $I_0$  is  $2N$ .*

Let  $X$  denote the number of bins used by the algorithm for the first part of the input and by definition this is also the number of large items. Let  $\mu = \frac{\gamma}{10}$ . Thus, every  $K$  small values have total value below  $\mu$ .

### The second part of the input

For the value of  $\mu$  that is based on the action of the algorithm, we define the next part of the input. There are  $N$  items of each one of the two types:  $(0, 1 - 4 \cdot \mu, \mu)$  and  $(0, \mu, 1 - 4 \cdot \mu)$ . So, in total there are  $2N$  items of these types. The input at this time is called  $I_1$ , i.e.  $I_1$  is the input consisting of the first two parts of the input together.

### Two offline packings of $I_1$

We define two offline packings, for which the first part of the input is packed in a fixed manner. For each possibility of the third part of the input, we will use one of those offline packings that we present here. Consider the first part of the input (the items of  $I_0$ ), and separate small items from large items. Large items are packed such that every bin has  $K$  of them (where one such bin may have a smaller number of these items). The large items require  $\lceil \frac{X}{K} \rceil$  bins. These are feasible bins because none of the components of the sum of any bin is above 1, since no component of any item of the first part is above  $\frac{1}{K}$ . Small items are also packed  $K$  in each bin, and there are at most  $2N$  such bins since the total number of items for the first part is  $2KN$ . The total number of small items is  $2KN - X$ . The first component of the bin has load 1, but the other components have loads below  $\mu$ . Every such bin can also receive one item of each type of the second part. In one packing, we partition the items of the second part into pairs where every pair consists of items of different types. In this offline packing each pair is packed together, these pairs are first packed into bins with  $K$  small items of the first part, and if there are any unpacked items of the second part, they are packed into new bins (also in pairs). In the second packing, every bin gets just one such item of the second part. For both offline packings, the numbers of bins do not exceed  $\frac{X}{K} + 1 + 2N$ .

### The third part of the input

The third part of the input may contain two alternative sets of items. In the first case, leading to the input  $I_{21}$ , there are  $N$  items of the type  $(0, 1 - \mu, 1 - \mu)$ . Every such item is packed into a different bin by any algorithm. In the offline packing, these items are packed first into bins with (at most)  $K$  small items of the first part (but without large items of the first part and without any items of the second part) and then into new bins. The online algorithm cannot combine such items with any item into the same bin, as we will see.

In the second case, leading to the input  $I_{22}$ , there are  $N$  items of each of the types:  $(0, 3\mu, 1 - 2\mu)$ ,  $(0, 1 - 2\mu, 3\mu)$ . No pair of such items can be packed into one bin, but it can

join a bin with (at most)  $K$  small items of the first part and one item of the second part (of the suitable type) but without large items of the first part. It also cannot be packed with an item of the other type of the second part.

This concludes the description of the input construction. Next, we turn our attention to proving the resulting lower bound on the asymptotic competitive ratio for the case  $d = 3$ .

## Proving the resulting lower bound

Here, we prove the following result.

► **Theorem 14.** *There is no online algorithm for the case  $d = 3$  whose asymptotic competitive ratio is smaller than  $\frac{9}{4}$ .*

A very slight improvement over the lower bound which we proved above in Theorem 14 can be obtained as follows, similarly to the known construction for  $d = 2$  [6]. An alternative second part of the input will contain items whose first component is not zero but some multiple of  $\frac{1}{K}$ . The second component will be slightly larger than  $\frac{1}{3}$ , where there will be large items and small items (small items are those that are packed by the algorithm into a bin that cannot receive another item), and all these items have second components larger than  $\frac{1}{3}$ . There may be a third part of the input (in this alternative input), similarly to the construction of [6]. We omit the details as the idea is similar and the improvement is very small. We note that this value of 2.25 is a valid lower bound for the cases  $d \geq 4$  as well. For the case  $d = 5$  we could get the same lower bound by another method in Section 3 as well, where we proved significantly larger values for larger dimensions.

## 5 The case $d = 8$

We consider this special case as well, in order to demonstrate that the asymptotic competitive ratio grows relatively fast with the dimension. We picked the value of  $d = 8$  as for this dimension we are able to exhibit new properties of instances leading to improved lower bounds. Once again the lower bound construction consists of three parts.

### The first part of the input

The first part of the construction is identical to that of the case  $d = 3$ , including the property that the values of  $K$  and  $\varepsilon$  are the same, with the only change that the components equal to  $a_i$  are not just the second and third components, but all components with indexes  $2, 3, \dots, 7$  are equal to  $a_i$ . The first component is still  $\frac{1}{K}$ , while the 8th component is equal to zero. The values  $\gamma$  and  $\mu$  are defined as in the first part of the construction for the case  $d = 3$ .

### The second part of the input

The second part of the input consists of  $6N$  items consisting of six groups each of which has  $N$  vectors, where every  $N$  vectors of a common group are identical. All these vectors have 8th components equal to  $\frac{1}{3}$  and first components equal to zero. The other components are equal to either 0 or to  $1 - 3\mu$ , where every item has exactly one component equal to  $1 - 3\mu$ , and we will call it the large component of the item. We will have the items of group  $j$  (for  $j = 1, 2, \dots, 6$ ) having component  $j + 1$  equal to  $1 - 3\mu$  while all other components (excluding the 8th component) are zero.

### Analyzing the packing of the algorithm at the end of the second part

Before describing the third part of the input, we introduce some notation and properties of the packing of the algorithm at the end of the second part of the input. The items of the second part are defined so that no bin can have more than three such items by the constraint on the 8th component, and all (at most three) items of one bin have distinct large components since  $1 - 3\mu > \frac{1}{2}$ . We will distinguish the cases where a bin contains three, two, or just one item of the second part of the input, introducing notation for their corresponding bin numbers.

For  $j_1, j_2, j_3 \in \{2, 3, 4, 5, 6, 7\}$ , where  $j_1 < j_2 < j_3$ , let  $X_{j_1, j_2, j_3}$  be the number of bins with (exactly) three items of the second part of the input, whose large components are  $j_1, j_2$ , and  $j_3$ . There are 20 such variables. For  $j_4, j_5 \in \{2, 3, 4, 5, 6, 7\}$ , where  $j_4 < j_5$ , let  $Y_{j_4, j_5}$  be the number of bins with (exactly) two items of the second part of the input, whose large components are  $j_4$  and  $j_5$ . There are 15 such variables. For  $j_6 \in \{2, 3, 4, 5, 6, 7\}$ , let  $Z_{j_6}$  be the number of bins with (exactly) one item of the second part of the input, whose large component is  $j_6$ . There are six such variables. Since every bin opened by the algorithm for the first part of the input has a sum of components of items above  $\gamma = 10\mu$  in components  $2, 3, \dots, 7$ , all these bins of the algorithm are new.

The number of bins opened by the algorithm for the first part of the input is denoted by  $Q$  and it satisfies

$$Q \geq 2N .$$

The sum of variables of the form  $X_{j_1, j_2, j_3}$  is denoted by  $X$ , the sum of variables of the form  $Y_{j_4, j_5}$  is denoted by  $Y$ , and the sum of variables of the form  $Z_{j_6}$  is denoted by  $Z$ . That is,  $X = \sum_{j_1, j_2, j_3} X_{j_1, j_2, j_3}$ ,  $Y = \sum_{j_4, j_5} Y_{j_4, j_5}$ , and  $Z = \sum_{j_6} Z_{j_6}$ . By counting the number of items of the second part, we have

$$3X + 2Y + Z = 6N .$$

### The third part of the input

The third part has one of ten possible sets of items, of similar structures. These items have six non-zero components, which are components  $2, 3, \dots, 7$ . Every item has three components whose values are  $2\mu$ , and three components whose values are  $1 - \mu$ . No two such items can be packed into the same bin since the sum of such a component for two items is either  $2\mu + 1 - \mu > 1$  or  $2(1 - \mu) > 1$ . For a triple  $\{2, j_7, j_8\}$  where  $j_7, j_8 \in \{3, 4, 5, 6, 7\}$  are fixed component indexes, and  $j_7 < j_8$ , the input consists of  $N$  items whose components  $2, j_7, j_8$  are equal to  $1 - \mu$  and the components  $\{2, 3, 4, 5, 6, 7\} \setminus \{2, j_7, j_8\}$  are equal to  $2\mu$ , and  $N$  items whose components  $2, j_7, j_8$  are equal to  $2\mu$  and the components  $\{2, 3, 4, 5, 6, 7\} \setminus \{2, j_7, j_8\}$  are equal to  $1 - \mu$ . This completes the construction of the input. Next, we prove the resulting lower bound.

### Proving the resulting lower bound

Recall the decision variables  $X, Y, Z, Q$  whose values are determined by the algorithm but they satisfies the conditions  $Q \geq 2N$  and  $3X + 2Y + Z = 6N$  established above. We first upper bound the optimal offline cost after the third part of the input and then present a lower bound on the maximum cost of the algorithm on these 10 inputs that can be constructed in the third part of the input. As in the proof for  $d = 3$  we can assume  $\frac{Q}{K} \leq 6$ .

► **Lemma 15.** *For each of the ten inputs that can be created at the end of the third part, there is an offline solution whose cost is at most  $2N + 7$ .*

The algorithm can combine into a common bin some items of the third part with items of the second part but it cannot use bins that were used for items of the first part for packing items of the second or third parts. We describe only bins without any items of the first part because any bin of the algorithm containing an item of the first part cannot receive any additional items. We discuss such bins with two or three items of the second part (since bins with just one item can always receive additional items). For a set  $\{2, j_7, j_8\}$ , there may be bins with two items of the second part, where one of the items has a large component in the set  $\{2, j_7, j_8\}$  and the other one has a large component in the set  $\{2, 3, 4, 5, 6, 7\} \setminus \{2, j_7, j_8\}$ . In addition, there may be bins with three items of the second part, where the set of large components is none of the sets  $\{2, j_7, j_8\}$  and  $\{2, 3, 4, 5, 6, 7\} \setminus \{2, j_7, j_8\}$  (comparing them as sets and not as ordered tuples).

By Lemma 15, for large values of  $N$  we find for the asymptotic competitive ratio  $R$  that

$$Q + X + Y + Z \leq 2RN .$$

We introduce two new variables  $Y', X'$  where  $Y'$  is the number of bins of the algorithm with two items of the second part that cannot receive an item of the third part, and  $X'$  is the number of bins of the algorithm with three items of the second part that cannot receive an item of the third part (for the choice of third part, that is, we fix the third part temporarily). Then, by considering this input using the fact that the third part of the input requires packing items into at least  $2N$  bins and we cannot use  $Q + Y' + X'$  of the bins which were opened for the first or second parts, we conclude that

$$Q + Y' + X' + 2N \leq 2RN .$$

We take the sum of the last inequality for all ten options of  $j_7, j_8$ , where the right hand side is  $20RN$ , and the multiplier of  $N$  on the left hand side is  $20N$ . Since we consider all options for the third part of the input, the values  $X'$  and  $Y'$  can have different values, and more precisely, each one has up to ten different values.

We count the multiplier of each variable as follows. Variables of the form  $X_{j_1, j_2, j_3}$  are included in all variables  $X'$  except for the option where  $j_1, j_2, j_3$  are components of equal values, (the algorithm chose exactly the same subset as the one chosen for the third part of the input) which is just one case of the third part. Thus, the multiplier of  $X_{j_1, j_2, j_3}$  is 9. Variables of the form  $Y_{j_4, j_5}$  are included in all variables  $Y'$  except for cases where  $j_4$  and  $j_5$  are components of equal values, which is the case if  $\{j_4, j_5\} \subseteq \{2, j_7, j_8\}$  or  $\{j_4, j_5\} \subseteq \{2, 3, 4, 5, 6, 7\} \setminus \{2, j_7, j_8\}$ . Out of the 15 variables, there are nine such options that are included (in the sense that the bins cannot be used for items of the third part of the input) and six that are not included. Thus, every variable is included in six of the ten partitions, and in this sum of constraints every variable  $Y_{j_4, j_5}$  has a multiplier of 6. We get

$$10Q + 6Y + 9X + 20N \leq 20RN . \tag{1}$$

Using  $3X + 2Y + Z = 6N$  and  $Q + X + Y + Z \leq 2RN$ , we find by subtraction that  $2X + Y - Q \geq 6N - 2RN$  or alternatively

$$9X + 4.5Y - 4.5Q \geq 27N - 9RN .$$

By subtracting the last inequality from (1), we have  $1.5Y + 14.5Q + 47N \leq 29RN$ . Since  $Y \geq 0$  and  $Q \geq 2N$  hold, we establish that  $76N \leq 29RN$  and therefore  $R \geq \frac{76}{29} \approx 2.620689655$  as we summarize in the following theorem.

► **Theorem 16.** *There is no online algorithm for the case  $d = 8$  whose asymptotic competitive ratio is smaller than  $\frac{76}{29} \approx 2.620689655$ .*

## **A** Adaptive constructions for deterministic algorithms

In addition to the lower bound for a general  $d$ , we present lower bounds that achieve better guarantees for relatively small values of  $d$  versus deterministic algorithms. The lower bounds are based on a method that produces a sequence of values with several important properties, and are produced by an adversary according to the algorithm’s behavior. Specifically, we define inputs using a method presented in the past [6]. In this method, a binary condition on the assignment of every item is defined (e.g., whether the item is assigned into a new bin), and it is used by the adversary (who presents the input) for the definition of the properties of the following item. More precisely, the adversary keeps an active interval of (scalar) values (contained in  $(0, 1)$ ), and it modifies the interval after the assignment of every input item by the algorithm. These values are not necessarily the actual sizes of the input items, even in the one-dimensional case, although item sizes are based on them in a simple pre-specified way. This means that the generated value is not necessarily the size of the new input item, nor will it always be equal to a component of its vector. Nevertheless, this generated value is used in the definition of the new item, for example, it may be subtracted from some fixed value, or added to a fixed size.

The number of required items is decided in advance, or (in some cases) an upper bound on the number of required items is provided in advance in cases where the exact number of required items is revealed later on. This number is used to decide upon the initial interval of the values, as well. The initial interval is also based on the required sizes and properties of the values. The initial interval is always defined such that the smallest size is strictly positive and the largest size is sufficiently small.

Input items are presented one by one. After the assignment of an item by the algorithm, the validity of the condition is tested for that item. During the process of input construction, it is ensured (via a process resembling binary search, or geometric binary search) that values corresponding to items satisfying the binary condition are larger by a pre-specified (constant) multiplicative factor than the value of any item not satisfying the binary condition. In this way, the process determines two regions, as explained below. We will call the resulting ranges of values *large* and *small*, where the two ranges are disjoint. Items with large values, i.e., from the large range, are called large, and items with small values, i.e., from the small range, are called small.

## 8:18 Lower Bounds for Online Vector Bin Packing

Note that when an item is presented, its size is defined without any prior knowledge of the assignment, so it is still unknown at that moment whether the binary condition holds for this item. Thus, its value is defined without any knowledge of its dimensions. That knowledge is gained based on the action of the algorithm once the item is packed. Based on the packing, if its value is required to be large, future values will be much smaller, and if its value is required to be small, future values will be much larger.

The construction allows us to define positive values smaller than a given value  $\varepsilon > 0$ , such that for a pre-defined (constant) multiplicative factor  $k$ , any large value is more than  $k$  times larger than any small value. Thus, there is a value  $\gamma < \varepsilon$  such that every small value is smaller than  $\frac{\gamma}{k}$  and every large value is larger than  $\gamma$ . If items are one dimensional, and their sizes are simply these values, it would imply that, for example, an item of size  $1 - \gamma$  can be packed with  $k$  small items, but cannot be packed with one large item into the same bin. Note that in this case large items are also quite small, although not as small as the small items. It is possible to define items differently in one dimension, i.e., not only in the way that their sizes are equal to the values. One option is to use the values as complements of sizes (to 1). Another option is to use an additive term, for example, items can have sizes of  $\frac{1}{3}$  plus the defined value. In this case, one can define a value of  $\varepsilon$  such that  $\frac{1}{3} + \varepsilon < \frac{1}{2}$ , for example. For items that are vectors, one can define a part of the components to be determined based on the corresponding value. For example, it is possible in the case  $d = 5$  that two components will be equal to the value, while three other components are equal to zero.

## Abstract

---

We initiate the study of fine-grained completeness theorems for exact and approximate optimization in the polynomial-time regime.

Inspired by the first completeness results for decision problems in P (Gao, Impagliazzo, Kolokolova, Williams, TALG 2019) as well as the classic class MAXSNP and MAXSNP-completeness for NP optimization problems (Papadimitriou, Yannakakis, JCSS 1991), we define polynomial-time analogues MAXSP and MINSP, which contain a number of natural optimization problems in P, including Maximum Inner Product, general forms of nearest neighbor search and optimization variants of the  $k$ -XOR problem. Specifically, we define MAXSP as the class of problems definable as  $\max_{x_1, \dots, x_k} \#\{(y_1, \dots, y_\ell) : \phi(x_1, \dots, x_k, y_1, \dots, y_\ell)\}$ , where  $\phi$  is a quantifier-free first-order property over a given relational structure (with MINSP defined analogously). On  $m$ -sized structures, we can solve each such problem in time  $O(m^{k+\ell-1})$ . Our results are:

- We determine (a sparse variant of) the Maximum/Minimum Inner Product problem as complete under *deterministic* fine-grained reductions: A strongly subquadratic algorithm for Maximum/Minimum Inner Product would beat the baseline running time of  $O(m^{k+\ell-1})$  for all problems in MAXSP/MINSP by a polynomial factor.
- This completeness transfers to approximation: Maximum/Minimum Inner Product is also complete in the sense that a strongly subquadratic  $c$ -approximation would give a  $(c + \varepsilon)$ -approximation for all MAXSP/MINSP problems in time  $O(m^{k+\ell-1-\delta})$ , where  $\varepsilon > 0$  can be chosen arbitrarily small. Combining our completeness with (Chen, Williams, SODA 2019), we obtain the perhaps surprising consequence that refuting the OV Hypothesis is *equivalent* to giving a  $O(1)$ -approximation for all MINSP problems in faster-than- $O(m^{k+\ell-1})$  time.
- By fine-tuning our reductions, we obtain mild algorithmic improvements for solving and approximating all problems in MAXSP and MINSP, using the fastest known algorithms for Maximum/Minimum Inner Product.

## 1 Introduction

For decades, increasingly strong hardness of approximation techniques have been developed to pinpoint the best approximation guarantees achievable in polynomial time. Among the early successes of the field, we find the MAXSNP completeness theorems by Papadimitriou and Yannakakis [24], giving the first strong evidence against PTASes for MAX-SAT and related problems. Such completeness theorems constitute valuable tools in complexity theory: Generally speaking, proving a problem  $A$  to be complete for a class  $\mathcal{C}$  shows that  $A$  is *the* representing problem for  $\mathcal{C}$ . The precise notion of completeness is typically chosen such that a certain algorithm for  $A$  would yield unexpected algorithms for the whole class  $\mathcal{C}$  – thus establishing that  $A$  is unlikely to admit such an algorithm. However, a completeness result may also open up algorithmic uses. Namely, since any problem in  $\mathcal{C}$  can be reduced to its complete problem  $A$ , we may find (possibly mildly) improved algorithms for all problems in  $\mathcal{C}$  by making algorithmic progress on the single problem  $A$ .

Given this usefulness, it may be surprising that there are currently no completeness results for studying optimization barriers *within the polynomial-time regime*, e.g., for approximability in strongly subquadratic time (in fact, even for studying decision problems, completeness results are an exception rather than the norm, see [29] for a recent survey of the field). Thus, this work sets out to initiate the quest for completeness results for optimization in P, which corresponds to studying the (in-)approximability of problems on large data sets.

### Previous Completeness Results in P

The essentially only known completeness result in fine-grained complexity theory in P is a recent result by Gao, Impagliazzo, Kolokolova, and Williams [18]: The orthogonal vectors problem (OV)<sup>1</sup> is established as complete problem for the class of model-checking first-order properties<sup>2</sup> under fine-grained reductions<sup>3</sup>. From this completeness, they derive in particular:

- **Hardness:** If there are  $\gamma, \delta > 0$  such that OV with moderate dimension  $d = n^\gamma$  can be solved in time  $O(n^{2-\delta})$ , then there is some  $\delta' > 0$  such that all  $(k+1)$ -quantifier first-order properties can be model-checked in time  $O(m^{k-\delta'})$  for  $k \geq 2$ . The negation of this statement's premise is known as the moderate-dimensional OV Hypothesis; the consequence would be very surprising, as model-checking first-order properties is a very general class of problems for which no  $O(m^{k-\delta})$ -time algorithm is known. This result can be seen as support for the moderate-dimensional OV Hypothesis.
- **Algorithms:** Using a stronger notion than fine-grained reductions, Gao et al. also prove that mildly subquadratic algorithms for OV have algorithmic consequences for model-checking first-order properties. Specifically, by combining their reductions with the fastest known algorithm for OV [4, 12], they obtain an  $m^k/2^{\Omega(\sqrt{\log m})}$ -time algorithm for model-checking any  $(k+1)$ -quantifier first-order property.

<sup>1</sup> Given two sets of  $n$  vectors in  $\{0, 1\}^d$ , determine whether there exists a pair of vectors, one of each set, that are orthogonal.

<sup>2</sup> Let  $\phi$  be a first-order property (in prenex normal form) over a relational structure of size  $m$ . Given the structure, determine whether  $\phi$  holds. See Section 2 for details.

<sup>3</sup> For a formal definition of fine-grained reductions, see [11, 18]. For this paper, the reader may think of the following slightly simpler notion: A fine-grained reduction from a problem  $P_1$  with presumed time complexity  $T_1$  to a problem  $P_2$  with presumed time complexity  $T_2$  is an algorithm  $A$  for  $P_1$  that has oracle access to  $P_2$  and whenever we use an  $O(T_2(n)^{1-\delta})$  algorithm for the calls to the  $P_2$ -oracle (for some  $\delta > 0$ ), there is a  $\delta' > 0$  such that  $A$  runs in time  $O(T_1(n)^{1-\delta'})$ .

No comparable fine-grained completeness results are known for polynomial-time optimization problems, raising the question: Can we give completeness theorems also for a general class of optimization problems in P, both for exact and approximate computation?

### Hardness of Approximation in P

Studying the fine-grained approximability of polynomial-time optimization problems (hardness of approximation in P), is a recent and influential trend: After a breakthrough result by Abboud, Rubinfeld, and Williams [3] establishing the *Distributed PCP in P* framework, a number of works gave strong conditional lower bounds, including results for nearest neighbor search [28] or a tight characterization of the approximability of maximum inner product [13, 15]. Further results include work on approximating graph problems [25, 6, 10, 22], the Fréchet distance [7], LCS [1, 2], monochromatic inner product [23], earth mover distance [26], as well as equivalences for fine-grained approximation in P [15, 14, 10]. Related work studies the inapproximability of parameterized problems, ruling out certain approximation guarantees within running time  $f(k)n^{g(k)}$  under parameter  $k$  (such as FPT time  $f(k)$  poly( $n$ ), or  $n^{o(k)}$ ), see [17] for a recent survey.<sup>4</sup>

### An Optimization Class: Polynomial-Time Analogues of MaxSNP

We define a natural and interesting class of polynomial-time optimization problems, inspired by the approach of Gao et al. [18] as well as the classic class MAXSNP introduced by Papadimitriou and Yannakakis [24] to study the approximability of NP optimization problems.

The definition of MAXSNP is motivated by Fagin’s theorem (see, e.g., [20, 19]), which characterizes NP as the family of problems expressible as  $\exists S \forall \bar{y} \exists \bar{z} \phi(\bar{y}, \bar{z}, G, S)$  where  $G$  is a given relational structure,  $\exists S$  ranges over a relational structure  $S$  and  $\forall \bar{y} \exists \bar{z} \phi(\bar{y}, \bar{z}, G, S)$  is a  $\forall^* \exists^*$ -quantified first-order property. A subclass of this is SNP, which consists of those problems expressible without the  $\exists \bar{z}$ -part. Its natural optimization variant is MAXSNP, defined as the set of problems expressible as  $\max_S \#\{\bar{y} : \phi(\bar{y}, G, S)\}$ . Notably, this class of problems contains central optimization problems (MAX-3-SAT, MAX-CUT, etc.), all of which admit a constant-factor approximation in polynomial time. Using a notion of MAXSNP-completeness, Papadimitriou and Yannakakis identified several problems (including MAX-3-SAT and MAX-CUT) as hardest-to-approximate in this class, giving a justification for the lack of a PTAS for these problems.<sup>5</sup>

To study the same type of questions in the polynomial-time regime, the perhaps most natural approach is to restrict the syntax defining MAXSNP problems such that it solely contains polynomial-time problems. Specifically, we replace  $\max_S$  by a maximization over a bounded number of  $k$  variables  $x_1, \dots, x_k$  and restrict the counting operator to tuples  $\bar{y} = (y_1, \dots, y_\ell)$  of bounded length  $\ell$ . The resulting formula  $\max_{x_1, \dots, x_k} \#\{(y_1, \dots, y_\ell) : \phi(x_1, \dots, x_k, y_1, \dots, y_\ell)\}$  can be easily seen (see the full version of the paper [8, Appendix A]) to be solvable in time  $O(m^{k+\ell-1})$ , where  $m$  denotes the problem size. We define  $\text{MAXSP}_{k,\ell}$  to denote the class of these optimization problems and let  $\text{MAXSP} = \bigcup_{k \geq 2, \ell \geq 1} \text{MAXSP}_{k,\ell}$ . Note that here, “SP” stands for “strict P” in analogy to the name “strict NP” of SNP. We refer to Section 2 for more details.

<sup>4</sup> Note that these parameterized inapproximability results do not necessarily apply to the case of a fixed parameter  $k$ , which would correspond to our setting. See [22] for an interesting exception.

<sup>5</sup> A stronger justification was later given by the PCP theorem, establishing inapproximability even under  $P \neq NP$ . In general, these two approaches (approximation-preserving completeness theorems as well as proving inapproximability under established assumptions on exact computation) can result in incomparable hardness of approximation results.

We obtain an analogous minimization class MINSP by replacing max by min everywhere. These classes include interesting problems:

- Vector-definable problems: Let  $\Sigma = \{0, \dots, c\}$  be a fixed alphabet and  $f : \Sigma^k \rightarrow \{0, 1\}$  be an arbitrary Boolean function. Then we can express the following problem: Given sets  $X_1, \dots, X_k$  in  $\Sigma^d$  of vectors, maximize (or minimize)  $\sum_{i=1}^d f(x_1[i], \dots, x_k[i])$  over all  $x_1 \in X_1, \dots, x_k \in X_k$ . Each such problem is definable in MAXSP $_{k,1}$ /MINSP $_{k,1}$ , e.g.:
  - Maximum Inner Product (MAXIP): Given sets  $X_1, X_2 \subseteq \{0, 1\}^d$ , maximize the inner product  $x_1 \cdot x_2$  over  $x_1 \in X_1, x_2 \in X_2$ . To see that this problem is in MAXSP $_{2,1}$ , consider the formula  $\max_{x_1 \in X_1, x_2 \in X_2} \#\{y \in Y : E(x_1, y) \wedge E(x_2, y)\}$ , where  $E(x, y)$  indicates that the  $y$ -th coordinate of  $x$  is equal to 1.
  - Consider minimization with  $k = 2$  and view  $f : \Sigma^2 \rightarrow \{0, 1\}$  as classifying pairs of characters as *similar* (0) or *dissimilar* (1). This expresses the following problem that generalizes the nearest-neighbor problem over the Hamming metric: Given a set of length- $d$  strings over  $\Sigma$ , determine the most similar pair of strings by minimizing the number of dissimilar characters.
  - View  $\Sigma$  as the finite field  $\mathbb{F}_q$  and let  $f(z_1, \dots, z_k) = 1$  iff  $\sum_{i=1}^k z_i \equiv 0 \pmod{q}$ . This gives optimization variants of the  $k$ -XOR problem [21, 16], generalized to arbitrary finite fields.
- Beyond vector-definable problems, in MAXSP $_{2,\ell-2}$  we can express the graph problem of computing, over all edges  $e$ , the maximum number of length- $\ell$  circuits containing  $e$ :

$$\max_{x_1, x_2} \#\{(y_1, \dots, y_{\ell-2}) : E(x_1, x_2) \wedge E(x_2, y_1) \wedge \dots \wedge E(y_{\ell-3}, y_{\ell-2}) \wedge E(y_{\ell-2}, x_1)\}.$$

In fact, MAXSP also contains generalizations of this problem to other pattern graphs than length- $\ell$  circuits (e.g., length- $\ell$  cycles or  $\ell$ -cliques), even arbitrary fixed patterns in *hypergraphs*.

We let  $m$  denote the size of the relational structure, that is, the number of tuples in an explicit representation of all relations. For vector-definable examples, the input can be represented as a relational structure of size  $m = O(nd \log |\Sigma|)$ , which is the natural input size. Note, however, that the relational structure also allows us to succinctly encode *sparse* vectors in very large dimension (such as  $d = \Theta(n)$ ), which is why we often refer to MAXSP and MINSP as describing a *sparse setting*. It is easy to see that each MAXSP or MINSP formula  $\psi$  can be solved in time  $O(m^{k+\ell-1})$  (see [8, Appendix A] in the full version); note that for a fixed  $\psi, k$  and  $\ell$  always denote the number of maximization/minimization and counting variables, respectively. Can we obtain completeness results with respect to improvements over this baseline running time?

### (Sparse) Maximum Inner Product

Our results prove the Maximum Inner Product problem (MAXIP) as representative for the class MAXSP. We will formally introduce two important variants of this problem.

► **Problem 1 (MAXIP).** *Given two sets of  $n$  vectors  $X_1, X_2 \subseteq \{0, 1\}^d$ , the task is to compute the maximum inner product  $\langle x_1, x_2 \rangle = \sum_j x_1[j] \cdot x_2[j]$  for  $x_1 \in X_1, x_2 \in X_2$ .*

When  $d = n^\gamma$  for some (small)  $\gamma > 0$ , we speak of the *moderate-dimensional* MAXIP problem. In this paper, we also use MAXIP in another context, depending on the input format. To make the distinction explicit, let us formally introduce the *Sparse* Maximum Inner Product problem (SPARSE MAXIP):

► **Problem 2 (SPARSE MAXIP).** *Given two sets of  $n$  vectors  $X_1, X_2 \subseteq \{0, 1\}^d$ , sparsely represented as a list of pairs  $(x_i, j)$  which represent the one-coordinates  $x_i[j] = 1$ , the task is to compute the maximum inner product  $\langle x_1, x_2 \rangle$  for  $x_1 \in X_1, x_2 \in X_2$ .*

For moderate-dimensional MAXIP we measure the complexity in  $n$  and for SPARSE MAXIP we measure the complexity in  $m$ , the total number of one-coordinates. We note that SPARSE MAXIP is also special in our setting as this problem can be seen as a member of  $\text{MAXSP}_{2,1}$ . Indeed, SPARSE MAXIP is the same problem as maximizing the formula

$$\psi = \max_{x_1 \in X_1, x_2 \in X_2} \#\{y \in [d] : E(x_1, y) \wedge E(x_2, y)\},$$

where  $E(x_i, y)$  indicates that the  $y$ -th coordinate of  $x_i$  is equal to 1. We also define the (Sparse) Minimum Inner Product problems (MINIP, SPARSE MINIP) as the analogous problems with the task to minimize  $\langle x_1, x_2 \rangle$ .

## 1.1 Our Results

Our first main result is a completeness theorem for exact optimization, establishing Maximum Inner Product as complete for MAXSP (and Minimum Inner Product for MINSIP).

► **Theorem 3** (SPARSE MAXIP is MAXSP-complete). *SPARSE MAXIP is complete for the class MAXSP under fine-grained reductions: If there is some  $\delta > 0$  such that SPARSE MAXIP can be solved in time  $O(m^{2-\delta})$ , then for every  $\text{MAXSP}_{k,\ell}$  formula  $\psi$ , there is some  $\delta' > 0$  such that  $\psi$  can be solved in time  $O(m^{k+\ell-1-\delta'})$ .*

*The analogous statement holds for minimization, if we replace SPARSE MAXIP and MAXSP by SPARSE MINIP and MINSIP, respectively.*

Turning to the approximability of MAXSP and MINSIP, we show how to obtain a fine-grained completeness that even preserves approximation factors (up to an arbitrarily small blow-up). Here and throughout the paper, we say that an algorithm gives a  $c$ -approximation for a maximization problem if it outputs a value in the interval  $[c^{-1} \cdot \text{OPT}, \text{OPT}]$ , where OPT is the optimal value. For minimization, the algorithm computes a value in the interval  $[\text{OPT}, c \cdot \text{OPT}]$ .

► **Theorem 4** (SPARSE MAXIP is MAXSP-complete, (almost) approximation preserving). *Let  $c \geq 1$  and  $\varepsilon > 0$ . If there is some  $\delta > 0$  such that SPARSE MAXIP can be  $c$ -approximated in time  $O(m^{2-\delta})$ , then for every  $\text{MAXSP}_{k,\ell}$  formula  $\psi$ , there is some  $\delta' > 0$  such that  $\psi$  can be  $(c + \varepsilon)$ -approximated in time  $O(m^{k+\ell-1-\delta'})$ .*

*The analogous statement for minimization holds for SPARSE MINIP and MINSIP.*

As a key technical step to obtain Theorems 3 and 4, we prove a *universe reduction* for MAXSP/MINSIP formulas (detailed in Sections 3 and 4.3). Along the way, this universe reduction establishes the following fine-grained equivalence between the sparse and moderate-dimensional settings of MAXIP/MINIP.

► **Theorem 5** (Equivalence between MAXIP and SPARSE MAXIP).

- *There are some  $\gamma, \delta > 0$  such that MAXIP with dimension  $d = n^\gamma$  can be solved in time  $O(n^{2-\delta})$  if and only if there is some  $\delta' > 0$  such that SPARSE MAXIP can be solved in time  $O(m^{2-\delta'})$ .*
- *Let  $c > 1$  and  $\varepsilon > 0$ . If there are some  $\gamma, \delta > 0$  such that MAXIP with dimension  $d = n^\gamma$  can be  $c$ -approximated in time  $O(n^{2-\delta})$  then there is some  $\delta' > 0$  such that SPARSE MAXIP can be  $(c + \varepsilon)$ -approximated in time  $O(m^{2-\delta'})$ . Conversely, if there is some  $\delta > 0$  such that SPARSE MAXIP can be  $c$ -approximated in time  $O(m^{2-\delta})$  then there are some  $\gamma, \delta' > 0$  such that MAXIP with dimension  $d = n^\gamma$  can be  $c$ -approximated in time  $O(n^{2-\delta'})$ .*

*The analogous statements for minimization hold for MINIP.*

We prove Theorems 3, 4 and 5 in Section 4.1.

### Consequences for Hardness of Approximation

As a consequence of the above completeness results and dimension reduction, we obtain the following statements.

- Since Maximum Inner Product and Minimum Inner Product are subquadratic equivalent in moderate dimensions [15, Theorem 1.6], we obtain from Theorems 3 and 5 that a strongly subquadratic algorithm solving moderate-dimensional Maximum Inner Product *exactly* would give a polynomial-factor improvement over the  $O(m^{k+\ell-1})$  running time for all MAXSP and MINSP formulas. This adds an additional surprising consequence of fast Maximum Inner Product algorithms, besides refuting the Orthogonal Vectors Hypothesis.
- There is a  $O(1)$ -approximation beating the quadratic baseline for moderate-dimensional Maximum Inner Product *if and only if* there is a  $O(1)$ -approximation beating the  $O(m^{k+\ell-1})$  time baseline for all MAXSP formulas. To obtain this result combine the fine-grained equivalence of  $O(1)$ -approximation of moderate-dimensional MAXIP and SPARSE MAXIP (Theorem 5) with the completeness of SPARSE MAXIP (Theorem 4). This adds an additional consequence of fast Maximum Inner Product approximation, besides refuting SETH [3, 13].
- In the minimization world, we obtain a tight connection between approximating MINSP formulas and OV: The (moderate-dimensional) OV hypothesis is *equivalent* to the non-existence of a  $O(1)$ -approximation for all MINSP formulas in time  $O(m^{k+\ell-1})$ . To obtain this result, combine the equivalence of moderate-dimensional OV Hypothesis and non-existence of a  $O(1)$ -approximation for moderate-dimensional MINIP [15, Theorem 1.5] with the equivalence of  $O(1)$ -approximation algorithms for moderate-dimensional MINIP and MINSP (Theorem 4 and Theorem 5). Interestingly, this can be seen as additional support for the Orthogonal Vectors Hypothesis.

### Algorithms: Lower-Order Improvements

Since Maximum Inner Product has received significant interest for improved algorithms (see particularly [13, 15]), we turn to the question whether our completeness result also yields lower-order algorithmic improvements for all problems in the class. Indeed, by combining the best known Maximum/Minimum Inner Product algorithms with our reductions, we obtain the following general results for MAXSP and MINSP. We give the proofs for both theorems in Section 4.1.

► **Theorem 6** (Lower-Order Improvement for Exact MAXSP and MINSP). *We can exactly optimize any  $\text{MAXSP}_{k,\ell}$  and  $\text{MINSP}_{k,\ell}$  formula in randomized time  $m^{k+\ell-1}/\log^{\Omega(1)} m$ .*

Interestingly, for constant-factor approximations, a complete shave of logarithmic factors is possible.

► **Theorem 7** (Lower-Order Improvement for Approximate MAXSP and MINSP). *For every constant  $c > 1$ , we can  $c$ -approximate every  $\text{MAXSP}_{k,\ell}$  and  $\text{MINSP}_{k,\ell}$  formula in time  $m^{k+\ell-1}/2^{\Omega(\sqrt{\log m})}$ . For  $\text{MAXSP}_{k,\ell}$  the algorithm is deterministic; for  $\text{MINSP}_{k,\ell}$  it uses randomization.*

## 2 Preliminaries

For an integer  $k \geq 1$ , we set  $[k] = \{1, \dots, k\}$ . Moreover, we write  $\tilde{O}(T) = T \log^{O(1)} T$ .

### First-Order Model-Checking

A *relational structure*  $(X, R_1, \dots, R_r)$  consists of  $n$  objects  $X$  and relations  $R_j \subseteq X^{a_j}$  (of arbitrary arities  $a_j$ ) between these objects. A *first-order formula* is a quantified formula of the form

$$\psi = (Q_1 x_1) \dots (Q_k x_k) \phi(x_1, \dots, x_k),$$

where  $Q_i \in \{\exists, \forall\}$  and  $\phi$  is a Boolean formula over the predicates  $R_j(x_{i_1}, \dots, x_{i_{a_j}})$ . Given a relational structure, the *model-checking problem* (or *query evaluation problem*) is to check whether  $\psi$  holds on the given structure, that is, for  $x_1, \dots, x_k$  ranging over  $X$  and by instantiating the predicates  $R_j(x_{i_1}, \dots, x_{i_{a_j}})$  in  $\phi$  according to the structure,  $\psi$  is valid.

Following previous work in this line of research [18, 9], we assume that the input is represented sparsely – that is, we assume that the relational structure is written down as an exhaustive enumeration of all records in all relations; let  $m$  denote the total number of such entries. This convention is reasonable as this data format is common in the context of database theory and also for the representation of graphs (where it is called the *adjacency list* representation). By ignoring objects not occurring in any relation, we may always assume that  $n \leq O(m)$ .

It is often convenient to assume that each variable  $x_i$  ranges over a separate set  $X_i$ . We can make this assumption without loss generality, by introducing some additional unary predicates.

### MaxSP $_{k,\ell}$ and MinSP $_{k,\ell}$

In analogy to first-order properties with quantifier structure  $\exists^k \forall^\ell$  (with maximization instead of  $\exists$  and counting instead of  $\forall$ ), we now define a class of optimization problems: Let MAXSP $_{k,\ell}$  be the class containing all formulas of the form

$$\psi = \max_{x_1, \dots, x_k, y_1, \dots, y_\ell} \# \phi(x_1, \dots, x_k, y_1, \dots, y_\ell), \quad (1)$$

where, as before,  $\phi$  is a Boolean formula over some predicates of arbitrary arities. We similarly define MINSP $_{k,\ell}$  with “min” in place of “max”. Occasionally, we write OPTSP $_{k,\ell}$  to refer to both of these classes simultaneously, and we write “opt” as a placeholder for either “max” or “min”. In analogy to the model-checking problem for first-order properties, we associate to each formula  $\psi \in \text{OPTSP}_{k,\ell}$  an algorithmic problem:

► **Definition 8** (MAX( $\psi$ ) and MIN( $\psi$ )). *Let  $\psi \in \text{MAXSP}_{k,\ell}$  be as in (1). Given a relational structure on objects  $X$ , the MAX( $\psi$ ) problem is to compute*

$$\text{OPT} = \max_{x_1, \dots, x_k \in X} \#_{y_1, \dots, y_\ell \in X} \phi(x_1, \dots, x_k, y_1, \dots, y_\ell).$$

*We similarly define MIN( $\psi$ ) for  $\psi \in \text{MINSP}_{k,\ell}$ . Occasionally, for  $\psi \in \text{OPTSP}_{k,\ell}$ , we write OPT( $\psi$ ) to refer to both problems simultaneously.*

As before, we usually assume (without loss of generality) that each variable ranges over a separate set:  $x_i \in X_i$ ,  $y_i \in Y_i$ . In particular, as claimed before we can express the SPARSE MAXIP formula

$$\psi = \max_{x_1 \in X_1, x_2 \in X_2} \#\{y \in [d] : E(x_1, y) \wedge E(x_2, y)\}$$

in a way which is consistent with Definition 8 by introducing three unary predicates for  $X_1$ ,  $X_2$  and  $[d]$ . For convenience, we introduce some further notation: For objects  $x_1 \in X_1, \dots, x_k \in X_k$ , we denote by  $\text{Val}(x_1, \dots, x_k) = \#_{y_1, \dots, y_\ell} \phi(x_1, \dots, x_k, y_1, \dots, y_\ell)$  the *value* of  $(x_1, \dots, x_k)$ .

Definition 8 introduces  $\text{MAX}(\psi)$  and  $\text{MIN}(\psi)$  as *exact* optimization problems (i.e., OPT is required to be computed exactly). We say that an algorithm computes a *c-approximation* for  $\text{MAX}(\psi)$  if it computes any value in the interval  $[c^{-1} \cdot \text{OPT}, \text{OPT}]$ . Similarly, a *c-approximation* for  $\text{MIN}(\psi)$  computes any value in  $[\text{OPT}, c \cdot \text{OPT}]$ .

The problem  $\text{OPT}(\psi)$  can be solved in time  $O(m^{k+\ell-1})$  for all  $\text{OPTSP}_{k,\ell}$  formulas  $\psi$ , by a straightforward extension of the model-checking baseline algorithm; see the full version of our paper [8, Appendix A] for details. As this is clearly optimal for  $k + \ell = 2$ , we will often implicitly assume that  $k + \ell \geq 3$  in the following.

As we show in the full version of the paper [8, Appendix B], we can *exactly* solve  $\text{OPTSP}_{k,\ell}$  in time  $O(m^{k+\ell-3/2})$  when  $\ell \geq 2$ . Thus, in the remaining sections we will be working with the *hardest* case  $\ell = 1$ . For convenience we write  $\text{MAXSP}_k := \text{MAXSP}_{k,1}$ , and similarly for  $\text{MINSP}_k$  and  $\text{OPTSP}_k$ . Since for a fixed formula  $\psi \in \text{OPTSP}$ ,  $k$  and  $\ell$  are constants,  $f(k, \ell)$ -factors are hidden in the  $O$ -notation throughout the paper.

### 3 Technical Overview

In this section we give an overview of the main technical ideas used to give our completeness result (Theorem 3). Let  $\psi$  be a  $\text{MAXSP}_{k,\ell}$  formula. We will outline the reduction from  $\text{MAX}(\psi)$  to  $\text{SPARSE MAXIP}$ . Since for  $\ell \geq 2$  we can solve  $\text{MAX}(\psi)$  in time  $O(m^{k+\ell-3/2})$  (see the full version of our paper [8, Appendix B]) we focus on the case of  $\ell = 1$ . The reduction consists of two phases. In the first phase (Appendix A), we reduce  $\psi$  to an intermediate problem called the *Hybrid Problem* which captures the core hardness, but is more restricted. For now, the reader can think of the Hybrid Problem as a vector-definable problem (as introduced in the introduction)  $\max_{x_1 \in X_1, \dots, x_k \in X_k} \sum_{i=1}^d f(x_1[i], \dots, x_k[i])$  with  $X_1, \dots, X_k \subseteq \{0, 1\}^d$ ; we define it formally in Section 4.2. Since a Hybrid Problem is more restricted than the general problem  $\text{MAX}(\psi)$ , the first phase consists of the following 4 steps in which we progressively restrict the shape of  $\psi$ :

1. Remove all *hyperedges*, that is,  $\psi$  no longer contains predicates of arity  $\geq 3$  so an instance of  $\text{MAX}(\psi)$  can be thought of as a graph with parallel (or alternatively, colored) edges.
2. Remove all edges between vertices  $x_i$  and  $x_j$  that we maximize over. We will call these *cross edges*. After this step the only remaining edges are between vertices  $x_i$  and the counting variable  $y$ .
3. Remove all *parallel edges* (or alternatively, colored edges), that is, we combine parallel edges into simple edges.
4. Remove unary predicates, finally turning the  $\text{MAX}(\psi)$  instances into graphs. At this point it becomes simple to rewrite  $\text{MAX}(\psi)$  as a Hybrid Problem.

The second phase of the reduction is to reduce the Hybrid Problem to a  $\text{SPARSE MAXIP}$  instance (Section 4.3). The general idea of this step seems straightforward: For simplicity again let us focus on a vector-definable problem  $\max_{x_1 \in X_1, \dots, x_k \in X_k} \sum_{i=1}^d f(x_1[i], \dots, x_k[i])$  with  $X_1, \dots, X_k \subseteq \{0, 1\}^d$ . We can precisely “cover” each  $f(x_1[i], \dots, x_k[i])$  by at most  $2^k$  summands expressing

$$\sum_{\substack{\alpha_1, \dots, \alpha_k \in \{0,1\} \\ f(\alpha_1, \dots, \alpha_k) = 1}} [(x_1[i], \dots, x_k[i]) = (\alpha_1, \dots, \alpha_k)],$$

where the outer  $[\cdot]$  denotes the Iverson brackets. Observe that each such summand is equivalent to the MAXIP function, *up to complementing some  $x_j[i]$ 's* (i.e. each summand can be expressed as MAXIP by setting  $x_j[i] := 1 - x_j[i]$  whenever  $\alpha_j = 0$ ). The issue, however, is that complementing  $x_j[i]$ 's means complementing a binary relation of size  $O(m)$  (between  $n$  vectors and  $d$  coordinates). Since complementing a sparse relation generally produces a dense relation (here: of size  $\Omega(nd)$ ), this will produce a prohibitively large problem size for the SPARSE MAXIP formulation if  $d$  is large.

The natural approach to overcome this issue is to reduce the dimension of the Hybrid Problem, so that we can afford the complementation step. One challenge in this is that MAXSP formula might have its optimal objective value anywhere in  $\{0, \dots, m^\ell\}$ , but reducing the dimension from  $d \leq m^\ell$  to, say,  $d = m^\gamma$  also reduces the range of possible objective values to  $\{0, \dots, m^\gamma\}$ . It appears counter-intuitive that such a “compression” of objective values should be possible while allowing us to reconstruct the optimum value *exactly*. Perhaps surprisingly, we are able to achieve this by a simple deterministic dimension reduction.

The idea of our dimension reduction is as follows. For concreteness, focus on the SPARSE MAXIP problem. Starting from a SPARSE MAXIP instance  $X_1, X_2 \subseteq \{0, 1\}^d$ , we construct a hash function  $h : \{0, 1\}^d \mapsto \{0, 1\}^{d'}$  with  $d' \ll d$ , which maps every one-entry to  $t$  coordinates in  $[d']$ . More precisely, for every coordinate  $i \in [d]$ , we deterministically choose an auxiliary vector  $w_i \in \{0, 1\}^{d'}$  with exactly  $t$  one-entries for some parameter  $t$ . Then, the hash function is defined as  $h(x) = \bigvee_{i:x[i]=1} w_i$  (here the OR is applied coordinate-wise).

We say that there is a collision between two vectors  $x_1, x_2$  if there are distinct  $i, j \in [d]$  such that  $x_1[i] = x_2[j] = 1$  and the auxiliary vectors  $w_i$  and  $w_j$  share a common one-entry. Ideally, every pair of vectors  $x_1 \in X_1, x_2 \in X_2$  is hashed *perfectly*, meaning that no collision takes place. In that case, it holds that  $\langle h(x_1), h(x_2) \rangle = t \cdot \langle x_1, x_2 \rangle$  and thus also  $\text{OPT}' = t \cdot \text{OPT}$ , where  $\text{OPT}$  and  $\text{OPT}'$  are the objective values of the original and the hashed instance, respectively. However, in reality we cannot expect the hashing to be perfect. Note that nevertheless the difference  $|\langle h(x_1), h(x_2) \rangle - t \cdot \langle x_1, x_2 \rangle|$  is at most the number of collisions between  $x_1$  and  $x_2$ .

We will construct  $h$  in such a way that for all pairs  $x_1, x_2$ , the number of collisions is small, say at most  $C$ . Then by setting  $t > 2C$ , we ensure that  $|t \cdot \text{OPT} - \text{OPT}'| < t/2$  so we can recover  $t \cdot \text{OPT}$  by computing  $\text{OPT}'$  and rounding to the closest multiple of  $t$ . In particular, the optimal pair of vectors in the hashed instance correspond to the pair with maximum inner product in the original instance. Note that we crucially use the fact that MAXIP is expressive enough to *compute the value* of the inner product, which allows us to get rid of the small additive error introduced by the hashing (after rounding).

In Section 4.3 we show that the desired hash function exists and is in fact deterministic: Pick any  $t$  primes  $p_1, \dots, p_t$  of size  $\Theta(t \log t)$  and let  $d' = p_1 + \dots + p_t$ . We identify  $[d']$  with  $\{(i, p_j) : 1 \leq j \leq t, 0 \leq i < p_j\}$  and assign the auxiliary vector  $w_i$  to have one-entries exactly at all coordinates  $(i \bmod p_j, p_j)$ ,  $1 \leq j \leq t$ . A simple calculation shows that with this construction the number of collisions between  $x_1$  and  $x_2$  is at most  $\|x_1\|_1 \cdot \|x_2\|_1 \cdot \log d$ , see Lemma 15. With some additional tricks, we can control this quantity.

Our analysis allows us to even maintain  $c$ -approximate solutions, albeit with an arbitrarily small blow-up due to the small error introduced by rounding. Finding a fully approximation-preserving reduction remains a challenge for future work. Additionally, we need to take great care that our reductions are efficient enough to even transfer  $\log^{0.1} n$ -improvements, to obtain our speed-up for exact optimization (Theorem 6).

### Comparison to Gao et al.'s Work

Our reduction is similar to the work of Gao, Impagliazzo, Kolokolova and Williams [18], showing that the sparse version of Orthogonal Vectors is complete for model checking first-order properties. Here we discuss the key differences.

This first phase of our reduction follows the same structure as in Gao et al., but we simplify the proof significantly: One major difference is that they define a more complicated version of the Hybrid Problem including cross predicates [18, Section 5.2]. Borrowing ideas from [9], we remove the cross predicates at an earlier stage of the reduction (Step 2), which simplifies the remaining Steps 3 and 4. The absence of cross predicates also simplifies the baseline algorithm (see [8, Appendix A] in the full version). More generally, by splitting the reduction into a chain of four steps we cleanly separate the main technical ideas used in the first phase; see Appendix A for more details. In the same spirit we simplify Gao et al.'s improved algorithm [18, Section 9.2] for all problems with more than 1 counting quantifier avoiding their case distinction of 9 different cases by using a simple basis to represent all Boolean functions  $\phi : \{0, 1\}^3 \rightarrow \{0, 1\}$ ; see [8, Appendix B] in the full version.

In the second phase of the reduction, their work faces the same main challenge as ours. Specifically, reducing their Hybrid Problem to OV naively requires complementing a sparse binary relation, possibly resulting in a large dense complement. They solve this issue by designing a similar dimension reduction as ours using a Bloom filter. Naturally their dimension reduction is randomized, but they also provide a derandomization. However, note that there is a crucial difference: They reduce to OV which is a *decision* problem, while we reduce to the *optimization* problem MAXIP. For this reason, the dimension reductions differ in nature: On the one hand, we exploit that MAXIP is more expressive than OV – namely that MAXIP can handle a small number of errors if we round the result, while for OV any introduced error would result in vectors that are not orthogonal anymore. On the other hand, by reducing to OV, Gao et al. do not have to worry about “compressing” the range of possible optimal values, or making the reduction approximation-preserving. For these reasons, their dimension reduction would be unsuitable in our work, and ours would be unsuitable in their work.

## 4 The Reduction

In this section we give the proofs of our main results. The following lemma captures our reduction in all generality. Let  $k$ -MAXIP denote the generalization of the MAXIP problem with the objective to compute  $\max_{x_1 \in X_1, \dots, x_k \in X_k} \langle x_1, \dots, x_k \rangle$ , where  $\langle x_1, \dots, x_k \rangle = \sum_y x_1[y] \cdot \dots \cdot x_k[y]$ . We define  $k$ -MINIP analogously.

► **Lemma 9.** *Let  $s(n) \leq n^{1/6}$  be a nondecreasing function and let  $c \geq 1$  be constant. Assume that  $k$ -MAXIP in dimension  $d = \tilde{O}(s(n)^4 \log^2 n)$  can be  $c$ -approximated in time  $O(n^k/s(n))$ , and let  $\psi$  be an arbitrary  $\text{MAXSP}_k$  formula.*

- *If  $c = 1$  (i.e., we are in the case of exact computation), then  $\text{MAX}(\psi)$  can be exactly solved in time  $O(m^k/s(\sqrt[k+1]{m}))$ .*
- *If  $c > 1$ , then  $\text{MAX}(\psi)$  can be  $(c + \varepsilon)$ -approximated in time  $O(m^k/s(\sqrt[k+1]{m}))$ , for any constant  $\varepsilon > 0$ .*

*The analogous statement holds for  $k$ -MINIP and  $\text{MINSP}_k$ .*

The outline for this section is as follows. First we show how to derive the completeness result (Theorems 3 and 4) and the lower-order improvements (Theorems 6 and 7) from Lemma 9 in Section 4.1. Then we present the proof of Lemma 9, which is carried out in

two phases as explained in the technical overview. In Section 4.2 we formally introduce the intermediate problem called the *Hybrid Problem*. In Section 4.3 we give a fine-grained reduction from the Hybrid Problem to Maximum or Minimum Inner Product (Lemma 14). Finally, in Appendix A we reduce any  $\text{OPT}_{k,\ell}$  formula to the Hybrid Problem (Lemma 17), thus finishing the proof of Lemma 9. We will pay particularly close attention to the exact savings  $s$  in every step.

## 4.1 Consequences

First we derive the completeness Theorems 3 and 4 from Lemma 9.

**Proof of Theorems 3 and 4.** Let  $c \geq 1$  denote the approximation ratio (that is,  $c = 1$  for Theorem 3 and  $c \geq 1$  for Theorem 4). Assuming that SPARSE MAXIP can be  $c$ -approximated in time  $O(m^{2-\delta})$  for some  $\delta > 0$ , we obtain an algorithm for  $c$ -approximating MAXIP in dimension  $d = n^{4\delta/9}$  in time  $O((nd)^{2-\delta}) = O(n^{2-\delta}d^2) = O(n^{2-\delta/9})$ . We also obtain an algorithm for  $c$ -approximating  $k$ -MAXIP in the same dimension in time  $O(n^{k-\delta/9})$  (brute-force all options for the first  $k-2$  vectors, then use the 2-MAXIP algorithm). We can now plug this improved algorithm into our reduction: Setting  $s(n) = n^{\delta/9}/\text{polylog}(n)$  we have that  $k$ -MAXIP in dimension  $d = \tilde{O}(s(n)^4 \log^2 n)$  can be  $c$ -approximated in time  $O(n^k/s(n))$ . Thus, if  $c = 1$  we obtain by Lemma 9 that  $\text{OPT}(\psi)$  can be exactly solved in time  $O(m^k/s(n)^{\frac{1}{k+1}}) = O(m^{k-\beta})$  for  $\beta = \frac{\delta}{9(k+1)} > 0$ . If  $c > 1$ , we obtain that  $\text{OPT}(\psi)$  can be  $(c + \varepsilon)$ -approximated in the same running time, for an arbitrarily small constant  $\varepsilon > 0$ . ◀

Next, we prove Theorem 5.

**Proof of Theorem 5.** The reductions from SPARSE MAXIP to MAXIP and from SPARSE MINIP to MINIP for both the exact and approximate settings are a direct consequence of Lemma 9.

For the other direction, assume there exists some  $\delta > 0$  such that SPARSE MAXIP can be  $c$ -approximated in time  $O(m^{2-\delta})$ . Set  $\gamma := \delta/2$  and observe that any MAXIP instance with  $d = n^\gamma$  yields a SPARSE MAXIP instance of size  $m = O(nd) = O(n^{1+\gamma})$ . Since we can solve this instance in time  $O(m^{2-\delta}) = O(n^{(1+\gamma)(2-\delta)}) = O(n^{(1+\delta/2)(2-\delta)}) = O(n^{2-\delta^2/2})$ , we obtain a  $O(n^{2-\delta'})$ -algorithm for MAXIP with  $d = n^\gamma$  and  $\delta' = \delta^2/2$ . Note that this works for both the exact ( $c = 1$ ) and approximate ( $c > 1$ ) settings. The proof for the minimization case is analogous. ◀

To prove Theorems 6 and 7, we make use of the following state-of-the-art algorithms for MAXIP and MINIP, established in three previous papers [5, 13, 15].

► **Theorem 10** (Improved Algorithms for MAXIP and MINIP [5, 13, 15]).

- $k$ -MAXIP and  $k$ -MINIP in dimension  $d = O(\log^{2.9} n)$  can be exactly solved in randomized time  $O(n^k/\log^{100} n)$  [5].
- For any constant  $c > 1$ ,  $k$ -MAXIP in dimension  $d = 2^{O(\sqrt{\log n})}$  can be  $c$ -approximated in deterministic time  $n^k/2^{\Omega(\sqrt{\log n})}$  [13, Theorem 1.5].
- For any constant  $c > 1$ ,  $k$ -MINIP in dimension  $d = 2^{O(\sqrt{\log n})}$  can be  $c$ -approximated in randomized time  $n^k/2^{\Omega(\sqrt{\log n})}$  [15, Theorem 1.7].

**Proof of Theorems 6 and 7.** To prove Theorem 6, we plug in the first algorithm from Theorem 10 into Lemma 9 and choose  $s(n) = \log^{0.1} n$ . We obtain an exact  $\text{OPTSP}_k$  algorithm in time  $m^k/\log^{\Omega(1)} m$ .

For Theorem 7, we plug the second and third algorithms from Theorem 10 into Lemma 9 and choose  $s(n) = 2^{O(\sqrt{\log n})}$ . We get a  $c$ -approximation for  $\text{OPTSP}_k$  in time  $m^k/2^{\Omega(\sqrt{\log m})}$ , for any constant  $c > 1$ . ◀

Note that only one of these algorithms is deterministic; other known deterministic algorithms are not efficient enough for our reduction<sup>6</sup>.

## 4.2 The Hybrid Problem

We start with another problem definition.

► **Definition 11** (Basic Problem). *Given set families  $\mathcal{S}_1, \dots, \mathcal{S}_k$  over a universe  $U$ , the Basic Maximization Problem of type  $\tau \in \{0, 1\}^k$  is to compute*

$$\text{OPT} = \max_{S_1 \in \mathcal{S}_1, \dots, S_k \in \mathcal{S}_k} \left| \left( \bigcap_{i:\tau[i]=1} S_i \right) \setminus \left( \bigcup_{i:\tau[i]=0} S_i \right) \right|.$$

For example, the Basic Problem of type  $\tau = 11$  is to maximize the common intersection of two sets  $S_1$  and  $S_2$ , the Basic Problem of type  $\tau = 10$  is to maximize the number of elements in  $S_1$  not contained in  $S_2$  and the Basic Problem of type  $\tau = 00$  is to maximize the number of universe elements contained in neither  $S_1$  nor  $S_2$ .

Note that every Basic Problem can be seen as an  $\text{OPTSP}_k$  formula: We introduce objects for all sets  $S_i$  and all universe elements  $u$ , and connect  $S_i$  to  $u$  via an edge  $E(S_i, u)$  if and only if  $u \in S_i$ . Consistent with this analogy, we define  $n$  as the total number of sets  $S_i$  and  $m$  as the total cardinality of all sets  $S_i$  and, as before, study the Basic Problem with respect to the sparsity  $m$ .

► **Definition 12** (Hybrid Problem). *Given set families  $\mathcal{S}_1, \dots, \mathcal{S}_k$  over a universe  $U$ , which is partitioned into  $2^k$  parts  $U = \bigcup_{\tau \in \{0,1\}^k} U_\tau$ , the Hybrid Maximization Problem is to compute*

$$\text{OPT} = \max_{S_1 \in \mathcal{S}_1, \dots, S_k \in \mathcal{S}_k} \sum_{\tau \in \{0,1\}^k} \left| U_\tau \cap \left( \bigcap_{i:\tau[i]=1} S_i \right) \setminus \left( \bigcup_{i:\tau[i]=0} S_i \right) \right|.$$

We similarly define Basic Minimization Problems and define  $\epsilon$ -approximations of Basic Problems in the obvious way. For any  $S_1, \dots, S_k$  and  $\tau \in \{0, 1\}^k$  we denote by  $\text{Val}_\tau(S_1, \dots, S_k)$  the *value* of the Basic Problem constraint of type  $\tau$ :

$$\text{Val}_\tau(S_1, \dots, S_k) := \left| U_\tau \cap \left( \bigcap_{i:\tau[i]=1} S_i \right) \setminus \left( \bigcup_{i:\tau[i]=0} S_i \right) \right|.$$

And we use  $\text{Val}(S_1, \dots, S_k) := \sum_{\tau} \text{Val}_\tau(S_1, \dots, S_k)$  to denote the total value of the sets  $S_1, \dots, S_k$  in a Hybrid Problem instance.

Intuitively, the Hybrid Problem simultaneously optimizes Basic Problem constraints of different types. If we could afford to complement (parts of) the sets  $S_i$ , then there is a straightforward reduction from the Hybrid Problem to a Basic Problem of arbitrary type  $\tau$ : For each constraint of type  $\tau' \neq \tau$ , we simply complement all sets  $S_i$  with  $\tau'[i] \neq \tau[i]$  (more precisely, construct sets  $S'_i$  such that  $U_{\tau'} \cap S'_i = U_{\tau'} \setminus S_i$ ) and reinterpret the  $\tau'$ -constraint as type  $\tau$ . In summary:

<sup>6</sup> Focus on exact  $\text{MAXSP}_k$  for illustration: To obtain the same savings as in Theorem 6, we would need a deterministic algorithm for  $\text{MAXIP}$  in dimension  $d = O(\log^{2.9} n)$  running in time  $O(n^2 / \log^{100} n)$ . However, for this speed-up the current best algorithm [5] requires  $d = O(\log^{1.9} n)$ , so one needs to either improve the algorithm or improve our dimension reduction (Lemma 9) to dimension  $d = \text{poly}(s(n)) \log n$ , say.

► **Observation 13.** *In time  $O(n|U|)$ , any Hybrid Problem instance can be converted into an equivalent Basic Problem instance of arbitrary type  $\tau$ . The sparsity of the constructed instance is up to  $n|U|$ .*

However, being in the sparse setup we cannot tolerate the blow-up in the sparsity. Therefore, in order to efficiently apply Observation 13, we first have to control the universe size  $|U|$ .

### 4.3 Universe Reduction

The goal of this section is to reduce the Hybrid Problem to  $k$ -MAXIP. We give a reduction which closely preserves the savings  $s(n)$  achieved by exact or approximate  $k$ -MAXIP algorithms (losing only polynomial factors in  $s(n)$ ). As a drawback, the reduction slightly worsens the approximation factor, turning a  $c$ -approximation into a  $(c + \varepsilon)$ -approximation.

► **Lemma 14.** *Let  $s(n) \leq n^{1/6}$  be a nondecreasing function and assume that  $k$ -MAXIP in dimension  $d = \tilde{O}(s(n)^4 \log^2 n)$  can be  $c$ -approximated in time  $O(n^k/s(n))$ .*

- *If  $c = 1$  (i.e., we are in the case of exact computation), then the Hybrid Problem can be exactly solved in time  $O(m^k/s(m))$ .*
- *If  $c > 1$ , then the Hybrid Problem can be  $(c + \varepsilon)$ -approximated in time  $O(m^k/s(m))$ , for any constant  $\varepsilon > 0$ .*

*The analogous statement holds for  $k$ -MINIP and  $\text{MINSP}_k$ .*

On a high level, we prove Lemma 14 by first using a deterministic construction to reduce the universe size, and then reducing further to  $k$ -MAXIP as in Observation 13. The following lemma provides our universe reduction in the form of a hash-like function  $h$ .

► **Lemma 15.** *Let  $U$  be a universe and let  $t$  be a parameter. There exists a universe  $U'$  of size at most  $4t^2 \log t$  and a function  $h$  mapping elements in  $U$  to size- $t$  subsets of  $U'$ , such that the following properties hold. By abuse of notation, we write  $h(S) = \bigcup_{u \in S} h(u)$  for sets  $S \subseteq U$ .*

1. (Hashing.) *For all sets  $S \subseteq U$ , it holds that  $|h(S)| \geq t|S| - |S|^2 \log |U|$ .*
2. (Efficiency.) *Evaluating  $h(u)$  takes time  $\tilde{O}(t)$ .*

**Proof.** We start with the construction of  $h$ . By the Prime Number Theorem, there exist  $t$  primes  $p_1, \dots, p_t$  in the interval  $[2t \log t, 4t \log t]$  (for large enough  $t$ , see [27, Corollary 3] for the quantitative version). Let  $U' = \{(i, j) : 1 \leq i \leq t, 0 \leq j < p_i\}$ , then  $|U'| \leq 4t^2 \log t$ . We identify  $U$  with  $[|U|]$  in an arbitrary way and define  $h(u) = \{(i, u \bmod p_i) : 1 \leq i \leq t\}$  for  $u \in U$ .

In order to prove the first property, let us define the *collision number* of two distinct elements  $u, u' \in U$  as  $|h(u) \cap h(u')|$ . It is easy to see that the collision number of any such pair is at most  $\log |U|$ : For any prime  $p_i$ , we have that  $u \bmod p_i = u' \bmod p_i$  if and only if  $p_i$  divides  $u - u'$ . Since  $u - u'$  has absolute value at most  $U$ , there can be at most  $\log |U|$  distinct prime factors  $p_i$  of  $u - u'$ . It follows that  $t|S| - |h(S)| \leq \sum_{u, u' \in S} |h(u) \cap h(u')| \leq |S|^2 \log |U|$ .

Finally, the function can be efficiently evaluated: Computing the primes  $p_1, \dots, p_t$  takes time  $O(t \log t \log \log t)$  using Eratosthenes' sieve, for example. After this precomputation, evaluating  $h(u)$  in time  $O(t)$  is straightforward. ◀

► **Lemma 16 (Universe Reduction).** *Let  $\mathcal{S}_1, \dots, \mathcal{S}_k$  over the universe  $U = \bigcup_{\tau} U_{\tau}$  be a Hybrid Problem instance of maximum set size  $s = \max_{S_i \in \mathcal{S}_i} |S_i|$ , and let  $t$  be a parameter. In time  $\tilde{O}(mt)$  we can compute a number  $\Delta \geq 0$  and a new Hybrid Problem instance  $\mathcal{S}'_1, \dots, \mathcal{S}'_k$  over a small universe  $U' = \bigcup_{\tau} U'_{\tau}$  of size  $|U'| = O(t^2 \log t)$  such that:*

1. The sets  $S_i \in \mathcal{S}_i$  and the sets  $S'_i \in \mathcal{S}'_i$  stand in one-to-one correspondence.
2. For all  $S_1 \in \mathcal{S}_1, \dots, S_k \in \mathcal{S}_k$ , it holds that:

$$|t \cdot \text{Val}(S_1, \dots, S_k) - \text{Val}(S'_1, \dots, S'_k) - \Delta| = O(s^2 \log |U|).$$

**Proof.** We first describe how to construct the new instance. The first goal is to design individual universe reductions for all subuniverses  $U_\tau$ , that is, we construct new universes  $U'_\tau$  and functions  $h_\tau$  mapping  $U_\tau$  to size- $t$  subsets of  $U_\tau$ . We distinguish two cases:

- If  $|U_\tau| \leq 4t \log t$ , then we simply take  $U'_\tau$  as  $t$  copies of  $U_\tau$  and let  $h_\tau$  be the function which maps any element to its  $t$  copies in  $U_\tau$ . It holds that  $|U'_\tau| = t \cdot |U_\tau| \leq 4t^2 \log t$ .
- If  $|U_\tau| > 4t \log t$ , then we apply Lemma 15 with parameter  $t$  to obtain  $U'_\tau$  and  $h_\tau$ . The lemma guarantees that  $|U'_\tau| \leq 4t^2 \log t$ .

Next, we assemble these individual reductions into one. Set  $U' = \bigcup_\tau U'_\tau$ , where we treat the sets  $U'_\tau$  as disjoint. Since in both of the previous two cases we have  $|U_\tau| = O(t^2 \log t)$  it follows that  $|U| = \sum_\tau |U_\tau| = O(t^2 \log t)$ . Let  $h$  be the function which is piece-wise defined by the  $h_\tau$ 's, that is,  $h$  returns  $h_\tau(u)$  on input  $u \in U_\tau$ . Recall the notation  $h(S) = \bigcup_{u \in S} h(u)$ . The new Hybrid Problem instance is constructed by hashing every set  $S_i \in \mathcal{S}_i$  into the smaller universe, that is, we set  $S'_i := h(S_i) \in \mathcal{S}'_i$ . Property 1 is immediate from this construction, and the computation takes time  $\tilde{O}(mt)$ .

It remains to prove Property 2. For the remainder of the proof fix some sets  $S_1, \dots, S_k$  and let  $S = S_1 \cup \dots \cup S_k$  (clearly,  $S$  has size  $O(s)$ ). We start with the (unrealistic) assumption that  $S$  is hashed *perfectly*, that is,  $|h(S)| = t|S|$ . In this case we claim that:

- $t \cdot \text{Val}_\tau(S_1, \dots, S_k) = \text{Val}_\tau(h(S_1), \dots, h(S_k))$  for all  $\tau \neq 0^k$ ,
  - $t \cdot \text{Val}_\tau(S_1, \dots, S_k) = \text{Val}_\tau(h(S_1), \dots, h(S_k)) + \Delta$  for  $\tau = 0^k$ , where  $\Delta := t \cdot |U_{0^k}| - |U'_{0^k}|$ .
- Indeed, if  $S$  is hashed perfectly then we exactly scale the number of satisfying elements by a factor of  $t$  for every type  $\tau \neq 0^k$ . This holds because a satisfying assignment for  $\tau \neq 0^k$  corresponds to some element of the universe  $u \in U_\tau$  for which  $u \in S_i$  for all  $i$ 's such that  $\tau[i] = 1$ . The perfect hashing implies that the element  $u$  in these sets  $S_i$  gets mapped to  $t$  different elements in the new universe, and since there are no collisions these form  $t$  satisfying assignments in the hashed instance. The type  $\tau = 0^k$  is exceptional because each satisfying assignment does not correspond to any  $u \in U_{0^k}$ . Instead, the hashing scales the number of *falsifying* elements of type  $0^k$ ,  $|U_{0^k} \cap S|$ . The number of *satisfying* elements of type  $0^k$ ,  $|U_{0^k} \setminus S|$ , is preserved up to an additive error of exactly  $\Delta$ .

We will now remove the unrealistic assumption that  $h$  is hashed perfectly. The strategy is to define another function  $h^*$  obtained from  $h$  by artificially making the hashing with  $S$  perfect. To that end, we list the elements in  $S$  in an arbitrary order  $s_1, \dots, s_{|S|}$ , and start with the assignment  $h^*(s_j) = h(s_j)$ . As long as there exist indices  $i < j$  such that  $h^*(s_i)$  and  $h^*(s_j)$  share a common element  $z$ , we reassign  $h^*(s_j) := h^*(s_j) \setminus \{z\} \cup \{z'\}$  for some unused universe element  $z' \in U'$ . The function  $h^*$  obtained in this way also maps elements of  $U$  to size- $t$  subsets of  $U'$  and hashes  $S$  perfectly. Let  $Z$  be the set of all pairs of elements  $z$  and  $z'$  that occurred in the process; since there are exactly  $t|S| - |h(S)|$  iterations we have  $|Z| \leq 2t|S| - 2|h(S)|$  and by Lemma 15 it follows that  $|Z| = O(s^2 \log |U|)$ . By the definition of  $h^*$ , it is clear that  $|\text{Val}(h(S_1), \dots, h(S_k)) - \text{Val}(h^*(S_1), \dots, h^*(S_k))| \leq |Z|$ . Therefore, by the previous paragraph (applied with  $h^*$ ) and by an application of the triangle inequality, we obtain:

- $|t \cdot \text{Val}_\tau(S_1, \dots, S_k) - \text{Val}_\tau(h(S_1), \dots, h(S_k))| = O(s^2 \log |U|)$  for all  $\tau \neq 0^k$ ,
- $|t \cdot \text{Val}_\tau(S_1, \dots, S_k) - \text{Val}_\tau(h(S_1), \dots, h(S_k)) - \Delta| = O(s^2 \log |U|)$  for  $\tau = 0^k$ .

The claimed Property 2 is now immediate by summing over all types  $\tau$  and by another application of the triangle inequality.

Finally, it remains to prove that  $\Delta \geq 0$ . There are two cases depending on how the set  $U'_{0^k}$  was constructed: In the first case of the construction we have  $t \cdot |U_{0^k}| = |U'_{0^k}|$  and thus  $\Delta = 0$ . In the second case we have  $|U'_\tau| \leq 4t^2 \log t < t \cdot |U_\tau|$  and thus  $\Delta = t \cdot |U_{0^k}| - |U'_{0^k}| > 0$ . ◀

Having established the universe reduction, we can finally prove Lemma 14.

**Proof of Lemma 14.** The algorithm consists of three steps, which are implemented in the same way for all combinations of maximization versus minimization and exact versus approximate computation.

1. (*Eliminating heavy sets.*) We say that a set  $S_i \in \mathcal{S}_i$  is *heavy* if  $|S_i| > s(m)$ , and *light* otherwise. Our first goal is to eliminate all heavy sets. Since the total cardinality of all sets  $S_i$  is bounded by  $m$ , there can be at most  $O(m/s(m))$  heavy sets. Therefore, we can brute-force over every such set  $S_i$  and solve the remaining Hybrid Problem on  $k - 1$  set families using the baseline algorithm in time  $O(m^{k-1})$ . Afterwards, we can safely remove all heavy sets. Overall, this step takes time  $O(m^k/s(m))$ .
2. (*Reduction to  $k$ -MAXIP or  $k$ -MINIP.*) In the remaining instance we have that  $|S_i| \leq s(m)$  for all sets  $S_i$ . Therefore, we can apply the universe reduction from Lemma 16 (with some parameter  $t$  to be specified in the next step) to obtain an instance  $\mathcal{S}'_1, \dots, \mathcal{S}'_k$  over a smaller universe  $U' = \bigcup_\tau U'_\tau$  of size  $O(t^2 \log t)$ , and an offset  $\Delta \geq 0$ .  
The Hybrid Maximization Problem instance  $\mathcal{S}'_1, \dots, \mathcal{S}'_k$  reduces to  $k$ -MAXIP in the natural way: Recall that  $k$ -MAXIP is the same as the Basic Problem of type  $\tau = 1^k$ . Hence, we can apply Observation 13 to reduce to an instance of  $k$ -MAXIP with  $n = O(m)$  vectors in dimension  $O(t^2 \log t)$  in time  $O(n|U'|) = O(nt^2 \log t)$ . An analogous reduction works for Hybrid Minimization Problems and  $k$ -MINIP.
3. (*Recovering the optimal value.*) Solve (or approximate) the constructed  $k$ -MAXIP instance and let  $\text{ALG}'$  denote the output. Then compute  $\text{ALG} := (\text{ALG}' + \Delta)/t$  and return  $\text{ALG}$  rounded to an integer. The precise way of rounding depends on maximization versus minimization and exact versus approximate, see the following analysis.

Let  $\varepsilon > 0$  be a constant which we will specify later, and set  $t = Cs(m)^2 \log m$  for some sufficiently large constant  $C = C(\varepsilon)$ . Then by Property 2 of Lemma 16 we have

$$\left| \text{Val}(S_1, \dots, S_k) - \frac{\text{Val}(S'_1, \dots, S'_k) + \Delta}{t} \right| = O\left(\frac{s(m)^2 \log m}{t}\right) < \varepsilon.$$

In particular, it holds that

$$\left| \text{OPT} - \frac{\text{OPT}' + \Delta}{t} \right| < \varepsilon, \tag{2}$$

where  $\text{OPT}$  and  $\text{OPT}'$  are the optimal values of the original and the reduced instance, respectively. As the new universe has size  $O(t^2 \log t) = \tilde{O}(s(m)^4 \log m^2)$  as claimed, we can indeed use the efficient  $O(m^k/s(m))$ -time  $k$ -MAXIP or  $k$ -MINIP algorithm in the third step. The total running time is as stated: Recall that  $s(m) \leq m^{1/6}$  and thus all previous steps run in time  $O(m^k/s(m))$ . It remains to argue about the guarantees of the reduction; we need to consider three cases:

- (*Exact maximization or minimization:  $c = 1$ .)* It suffices to set  $\varepsilon < \frac{1}{2}$ . Since we can exactly compute  $\text{ALG}' = \text{OPT}'$ , by rounding  $\text{ALG} = (\text{ALG}' + \Delta)/t$  to the nearest integer, we obtain the only integer in the interval  $((\text{OPT}' + \Delta)/t - \frac{1}{2}, (\text{OPT}' + \Delta)/t + \frac{1}{2})$ , and thus we output  $\text{OPT}$ .

- (Approximate maximization:  $c > 1$ .) We have  $c^{-1}\text{OPT}' \leq \text{ALG}' \leq \text{OPT}'$  and therefore

$$\begin{aligned}\text{ALG} &= \frac{\text{ALG}' + \Delta}{t} \leq \frac{\text{OPT}' + \Delta}{t} \stackrel{(2)}{\leq} \text{OPT} + \varepsilon, \\ \text{ALG} &= \frac{\text{ALG}' + \Delta}{t} \geq \frac{c^{-1}(\text{OPT}' + \Delta)}{t} \stackrel{(2)}{\geq} c^{-1}(\text{OPT} - \varepsilon) \geq c^{-1}\text{OPT} - \varepsilon,\end{aligned}$$

where in the first inequality of the second line we used both  $\text{ALG}' \geq c^{-1}\text{OPT}'$  and  $c > 1$ . From these bounds we derive that the algorithm should return  $\lceil \text{ALG} - \varepsilon \rceil$ . Indeed, as  $\lceil \text{ALG} - \varepsilon \rceil \leq \text{OPT}$  this is always a feasible solution. Moreover, the solution is  $\frac{c}{1-2\varepsilon}$ -approximate: If  $\text{OPT} = 0$ , then  $\lceil \text{ALG} - \varepsilon \rceil = 0$  (if we set  $\varepsilon < \frac{1}{2}$ ). If  $\text{OPT} \geq 1$ , then  $\lceil \text{ALG} - \varepsilon \rceil \geq \frac{1}{c}\text{OPT} - 2\varepsilon \geq \frac{1-2\varepsilon}{c}\text{OPT}$ . Setting  $\varepsilon$  small enough yields approximation ratio  $c + \varepsilon'$ , for any  $\varepsilon' > 0$ .

- (Approximate minimization:  $c > 1$ .) We have  $\text{OPT}' \leq \text{ALG}' \leq c \cdot \text{OPT}'$  and therefore

$$\begin{aligned}\text{ALG} &= \frac{\text{ALG}' + \Delta}{t} \leq \frac{c \cdot \text{OPT}' + \Delta}{t} \leq \frac{c \cdot (\text{OPT} + \Delta)}{t} \stackrel{(2)}{\leq} c \cdot \text{OPT} + c \cdot \varepsilon, \\ \text{ALG} &= \frac{\text{ALG}' + \Delta}{t} \geq \frac{\text{OPT}' + \Delta}{t} \stackrel{(2)}{\geq} \text{OPT} - \varepsilon.\end{aligned}$$

In this case the algorithm should return  $\lfloor \text{ALG} + \varepsilon \rfloor$ . This solution is always feasible as  $\text{OPT} \leq \lfloor \text{ALG} + \varepsilon \rfloor$ . Moreover, the solution is  $c(1+2\varepsilon)$ -approximate: If  $\text{OPT} = 0$ , then  $\lfloor \text{ALG} + \varepsilon \rfloor = 0$  (if we set  $\varepsilon < \frac{1}{2}$ ). If  $\text{OPT} \geq 1$ , then  $\lfloor \text{ALG} + \varepsilon \rfloor \leq c \cdot \text{OPT} + (c+1)\varepsilon \leq c(1+2\varepsilon)\text{OPT}$ . We may again set  $\varepsilon$  small enough to obtain approximation ratio  $c + \varepsilon'$ , for any  $\varepsilon' > 0$ . ◀

## A Reducing $\text{OptSP}_k$ Formulas to the Hybrid Problem

In this section we give the first phase of the reduction, where we reduce  $\text{OPT}(\psi)$  to the Hybrid Problem. The main lemma is the following. As before, let  $s(m) \leq m^{1/6}$  be a nondecreasing function and let  $c \geq 1$  be constant.

► **Lemma 17.** *Let  $k \geq 2$ . If the Hybrid Problem can be  $c$ -approximated in time  $O(m^k/s(m))$ , then  $\text{OPT}(\psi)$  can be  $c$ -approximated in time  $O(m^k/s(\sqrt[k+1]{m}))$ , for any  $\text{OPTSP}_k$  formula  $\psi$ .*

Recall that we only have to deal with  $\text{OPTSP}_k = \text{OPTSP}_{k,1}$  formulas, as any  $\text{OPTSP}_{k,\ell}$  problem with  $\ell > 1$  directly admits an improved algorithm; see [8, Appendix B] in the full version. As explained in Section 3, we prove Lemma 17 by progressively simplifying  $\text{OPT}(\psi)$  in four steps:

1. Remove all *hyperedges*, that is,  $\psi$  no longer contains predicates of arity  $\geq 3$  so an instance of  $\text{OPT}(\psi)$  can be thought of as a (colored) graph.
2. Remove all *cross edges*, that is, edges between vertices  $x_i$  and  $x_j$  that we maximize over.
3. Remove all *parallel edges* (or alternatively, colored edges), that is, we combine parallel edges into simple edges.
4. Remove unary predicates, finally turning the  $\text{OPT}(\psi)$  instances into graphs. At this point it becomes simple to rewrite  $\text{OPT}(\psi)$  as a Hybrid Problem.

### Step 1: Removing Hyperedges

As a first step, we eliminate all *hyperpredicates*, that is, predicates of arity  $\geq 3$ . Formally, we prove the following lemma.

► **Lemma 18.** *Suppose that, for any  $\text{OPTSP}_k$  formula  $\psi$  not containing hyperpredicates,  $\text{OPT}(\psi)$  can be  $c$ -approximated in time  $O(m^k/s(m))$ . Then  $\text{OPT}(\psi)$  can be  $c$ -approximated in time  $O(m^k/s(m))$  for any  $\text{OPTSP}_k$  formula  $\psi$ .*

The proof is quite similar to [18, Section 7]. We start with a technical lemma:

► **Lemma 19.** *Let*

$$\psi = \text{opt}_{x_1, \dots, x_k} \# \left( E(x_i, x_j) \wedge \phi(x_1, \dots, x_k, y) \right),$$

*for some  $i, j \in [k], i \neq j$  and arbitrary  $\phi$ . Then  $\text{OPT}(\psi)$  can be solved exactly in time  $O(m^{k-1/2})$ .*

**Proof.** Let us begin with the simplest case  $k = 2$ . For a vertex  $x$  in the given instance, let  $\deg(x)$  denote the total number of records containing  $x$  over all relations. We distinguish the following three cases:

**Case 1:**  $\deg(x_1) \geq \sqrt{m}$ . We explicitly list all vertices  $x_1$  with  $\deg(x_1) \geq \sqrt{m}$ ; note that there can be at most  $O(\sqrt{m})$  such elements since the sparsity of the  $\text{MAX}(\psi)$  instance is bounded by  $O(m)$ . The remaining  $\text{MAXSP}_1$  formula can be solved in time  $O(m)$  using the baseline algorithm. In total, this step takes time  $O(\sqrt{m}m) = O(m^{3/2})$ .

**Case 2:**  $\deg(x_2) \geq \sqrt{m}$ . By exchanging the roles of  $x_1$  and  $x_2$ , we deal with this case in the same way as case 1.

**Case 3:**  $\deg(x_1) < \sqrt{m}$  and  $\deg(x_2) < \sqrt{m}$ . Assuming that the previous two cases were executed, we can assume that  $\deg(x_1) < \sqrt{m}$  and  $\deg(x_2) < \sqrt{m}$  for all remaining objects  $x_1, x_2$ . We exploit that any non-zero solution  $(x_1, x_2)$  of  $\text{MAX}(\psi)$  satisfies  $E(x_1, x_2)$ : It suffices to maximize over all  $O(m)$  edges  $E(x_1, x_2)$ , counting the number of  $y$ 's satisfying  $\phi$ . Since  $\deg(x_1) < \sqrt{m}$  and  $\deg(x_2) < \sqrt{m}$ , we can enumerate and test all objects  $y$  which are connected to either  $x_1$  or  $x_2$  by some relation in time  $O(\sqrt{m})$ . What remains are objects  $y$  not connected to either  $x_1$  or  $x_2$  by any relation. To account for these missing objects, we can substitute *false* for all non-unary predicates in  $\phi$ ; what remains is a Boolean function over unary predicates over  $y$ . We can precompute the number of  $y$ 's satisfying that function in linear time, so again the total time is  $O(m + m\sqrt{m}) = O(m^{3/2})$ .

It remains to lift this proof to the general case  $k > 2$ . We brute-force over all  $x$ -variables except for  $x_i$  and  $x_j$ . This amounts for a factor  $O(m^{k-2})$  in the running time. What remains is a  $\text{MAXSP}_2$  formula in the shape as before which can be solved exactly in time  $O(m^{3/2})$  by the previous case analysis. In total this takes time  $O(m^{k-2}m^{3/2}) = O(m^{k-1/2})$ . The proof works in exactly the same way for minimization problems. ◀

**Proof of Lemma 18.** Let  $\psi = \max_{x_1, \dots, x_k} \#_y \phi(x_1, \dots, x_k, y)$  be a  $\text{MAXSP}_k$  formula possibly containing some hyperpredicates. We introduce a new binary relation  $N(x_i, x_j)$  defined as follows: For any  $x_i, x_j \in V$  it holds that  $N(x_i, x_j) = \text{true}$  if and only if  $x_i$  and  $x_j$  are connected by some (hyper-)edge. Observe that any (hyper-)edge contributes to at most a constant number of records  $N(x_i, x_j)$ , so we can construct  $N$  in time  $O(m)$  and the sparsity blows up only by a constant factor. We can now rewrite  $\psi$  via

$$\psi_0 = \max_{x_1, \dots, x_k} \#_y \left( \left( \bigwedge_{i \neq j} \bar{N}(x_i, x_j) \right) \wedge \phi_0(x_1, \dots, x_k, y) \right)$$

and

$$\psi_{i,j} = \max_{x_1, \dots, x_k} \#_y \left( N(x_i, x_j) \wedge \phi(x_1, \dots, x_k, y) \right),$$

where  $\phi_0$  is obtained from  $\phi$  by replacing all occurrences of hyperpredicates by *false*. It follows that we can express

$$\text{OPT} = \max\{\text{OPT}_0, \max_{i \neq j} \text{OPT}_{i,j}\},$$

where  $\text{OPT}_0$  is the optimal value of  $\psi_0$ , and  $\text{OPT}_{i,j}$  is the optimal value of  $\psi_{i,j}$ . Observe that  $\psi_0$  is a  $\text{MAXSP}_k$  formula not involving any hyperpredicates, so we can by assumption  $c$ -approximate  $\text{OPT}_0$  in time  $T(m)$ . Moreover, the formulas  $\psi_{i,j}$  are precisely in the shape to apply Lemma 19, so we can compute  $\text{OPT}_{i,j}$  exactly in time  $O(m^{k-1/2})$ . ◀

**Step 2: Removing Cross Edges**

Next, the goal is to remove all binary predicates  $E(x_i, x_j)$  between two  $x$ -variables. Let us call these predicates  $E(x_i, x_j)$  *cross predicates* and the associated entries  $(x_i, x_j)$  *cross edges*.

► **Lemma 20.** *Suppose that, for any  $\text{OPTSP}_k$  formula  $\psi$  not containing hyperpredicates and cross predicates,  $\text{OPT}(\psi)$  can be  $c$ -approximated in time  $O(m^k/s(m))$ . Then  $\text{OPT}(\psi)$  can be  $c$ -approximated in time  $O(m^k/s({}^{k+1}\sqrt{m}))$  for any  $\text{OPTSP}_k$  formula  $\psi$  not containing hyperpredicates.*

**Proof.** Let  $\psi = \max_{x_1, \dots, x_k} \#_y \phi(x_1, \dots, x_k, y)$  and let  $E_1, \dots, E_r$  denote the cross predicates in the given instance. We define

$$\psi_0 := \max_{x_1, \dots, x_k} \#_y \left( \left( \bigwedge_{\ell, i, j} \bar{E}_\ell(x_i, x_j) \right) \wedge \phi_0(x_1, \dots, x_k, y) \right)$$

and

$$\psi_{\ell, i, j} := \max_{x_1, \dots, x_k} \#_y \left( E_\ell(x_i, x_j) \wedge \phi(x_1, \dots, x_k, y) \right),$$

where  $\ell \in [r]$  and  $i \neq j \in [k]$  and  $\phi_0$  is the propositional formula obtained from  $\phi$  by substituting all predicates  $E_\ell(x_i, x_j)$  by *false*. It is easy to verify that

$$\text{OPT} = \max\{\text{OPT}_0, \max_{\ell, i, j} \text{OPT}_{\ell, i, j}\},$$

where  $\text{OPT}_0$  and  $\text{OPT}_{\ell, i, j}$  are the optimal values of  $\text{MAX}(\psi_0)$  and  $\text{MAX}(\psi_{\ell, i, j})$ , respectively. Using Lemma 19, we can compute  $\text{OPT}_{\ell, i, j}$  exactly in time  $O(m^{k-1/2})$  for all  $\ell, i, j$ . It remains to efficiently solve  $\text{MAX}(\psi_0)$  to compute  $\text{OPT}_0$ .

As described before, we can always assume that each variable ranges over a separate set:  $x_i \in X_i, y \in Y$ . We call a vertex  $x_i$  *heavy* if it has degree at least  ${}^{k+1}\sqrt{m}$ , and *light* otherwise. The first step is to eliminate all heavy vertices; there can exist at most  $O(m/{}^{k+1}\sqrt{m})$  many such vertices  $x_i$ . Fixing  $x_i$ , we can solve the remaining problem in time  $O(m^{k-1})$  using the baseline algorithm. We keep track of the optimal solution detected in this way. This precomputation step takes time  $O(m^k/{}^{k+1}\sqrt{m})$  and afterwards we can safely remove all heavy vertices.

Next, partition each set  $X_i$  into several groups  $X_{i,1}, \dots, X_{i,g}$  such that the total degree of all vertices in a group is  $O({}^{k+1}\sqrt{m})$ , and the number of groups is  $g = O(m/{}^{k+1}\sqrt{m})$ . This is implemented by greedily inserting vertices into  $X_{i,j}$  until its total degree exceeds  ${}^{k+1}\sqrt{m}$ . As each vertex inserted in that way is light, we can overshoot by at most  ${}^{k+1}\sqrt{m}$ .

Let  $\psi_1 := \max_{x_1, \dots, x_k} \#_y \phi_0(x_1, \dots, x_k, y)$ ; note that  $\psi_1$  equals  $\psi_0$  except that it disregards the cross predicates. Therefore, by assumption we can  $c$ -approximate  $\text{MAX}(\psi_1)$  in time  $O(m^k/s(m))$ . The algorithm continues as follows:

1. For all combinations  $(j_1, \dots, j_k) \in [g]^k$ , compute a  $c$ -approximation of  $\text{MAX}(\psi_1)$  on the input  $X_{1,j_1}, \dots, X_{k,j_k}$ . We keep track of the  $\binom{k}{2}mn^{k-2} + 1$  combinations with largest values (breaking ties arbitrarily).
2. For any of the top-most  $\binom{k}{2}mn^{k-2} + 1$  combinations  $(j_1, \dots, j_k)$ , solve  $\text{MAX}(\psi_0)$  exactly on  $X_{1,j_1}, \dots, X_{k,j_k}$  using the baseline algorithm. Return the best solution detected in this step or the precomputation phase.

We begin with the correctness of the algorithm. First, the value of any solution  $(x_1, \dots, x_k)$  in  $\text{MAX}(\psi_0)$  is at least as large as its value in  $\text{MAX}(\psi_1)$ . In particular, the optimal solution of  $\text{MAX}(\psi_0)$  has value at least  $\text{OPT}_0$  in  $\text{MAX}(\psi_1)$ . We next establish an upper bound on

the number *false positives*, that is, tuples  $(x_1, \dots, x_k)$  of different value in  $\text{MAX}(\psi_0)$  than in  $\text{MAX}(\psi_1)$ . Observe that any such false positive contains at least one edge  $(x_i, x_j)$  and since there are at most  $m$  edges, at most  $\binom{k}{2}$  choices of  $i, j$  and at most  $n^{k-2}$  choices for the remaining vertices  $x_\ell$ ,  $\ell \neq i, j$ , we can indeed bound the number of false positives by  $\binom{k}{2}mn^{k-2}$ . Thus, if we witness the top-most  $\binom{k}{2}mn^{k-2} + 1$  solutions of  $\text{MAX}(\psi_1)$  in step 1, among these there exists at least one solution of value  $\geq \text{OPT}_0/c$  in  $\text{MAX}(\psi_0)$ .

Finally, let us bound the running time of the above algorithm. Recall that removing heavy vertices accounts for  $O(m^k / \sqrt[k+1]{m})$  time. In step 1, the  $\text{MAX}(\psi_1)$  algorithm is applied  $g^k$  times on instances of size  $O(\sqrt[k+1]{m})$ , which takes time  $O((m/\sqrt[k+1]{m})^k \cdot (\sqrt[k+1]{m})^k / s(\sqrt[k+1]{m})) = O(m^k / s(\sqrt[k+1]{m}))$ . Step 2 runs the baseline algorithm  $mn^{k-2} = O(m^{k-1})$  times on instances of size  $O(\sqrt[k+1]{m})$ , which takes time  $O(m^{k-1}(\sqrt[k+1]{m})^k) = O(m^k / \sqrt[k+1]{m})$ . Thus, the total running time is  $O(m^k / \sqrt[k+1]{m} + m^k / s(\sqrt[k+1]{m}))$ . As  $s(m) \leq m$ , this is as claimed. The proof for the maximization variant is complete and there are only minor adaptations necessary for minimization.  $\blacktriangleleft$

### Step 3: Removing Parallel Edges

After applying the previous steps we can assume that  $\psi$  is an  $\text{OPTSP}_k$  formula not containing hyperedges or cross edges. Let  $E_1, \dots, E_r$  be the binary relations featured in  $\psi$ . We say that  $\psi$  does not have *parallel edges* if  $r = 1$ . In an instance of  $\text{OPT}(\psi)$  with parallel edges, any pair of vertices  $(x_i, y)$  may be connected by up to  $r$  parallel edges, or equivalently by an edge of  $2^r$  possible *colors*. We adopt the second viewpoint for this step: Let  $\chi(x_i, y) := (E_1(x_i, y), \dots, E_r(x_i, y)) \in \{0, 1\}^r$  be the *color* of the edge  $(x_i, y)$  and let  $\chi(x_1, \dots, x_k, y) := (\chi(x_1, y), \dots, \chi(x_k, y)) \in (\{0, 1\}^r)^k$  be the color of the tuple  $(x_1, \dots, x_k, y)$ .

► **Lemma 21.** *Suppose that, for any  $\text{OPTSP}_k$  formula  $\psi$  not containing hyperedges, cross edges and parallel edges,  $\text{OPT}(\psi)$  can be  $c$ -approximated in time  $O(m^k/s(m))$ . Then  $\text{OPT}(\psi)$  can be  $c$ -approximated in time  $O(m^k/s(m))$  for any  $\text{OPTSP}_k$  formula  $\psi$  not containing hyperedges and cross edges.*

**Proof.** Let  $E_1, \dots, E_r$  denote the binary relations featured in the given instance; our goal is to construct a new instance with only a single edge predicate  $E$ . We leave the vertex sets  $X_i$  unchanged and construct  $Y' = \{y_\alpha : y \in Y, \alpha \in (\{0, 1\}^r)^k\}$ , i.e., each vertex  $y \in Y$  is copied  $2^{rk} = O(1)$  times and each copy  $y_\alpha$  is indexed by a  $k$ -tuple of colors  $\alpha = (\alpha_1, \dots, \alpha_k) \in (\{0, 1\}^r)^k$ . For every  $\alpha$  we also introduce a new unary predicate  $C_\alpha$  and assign  $C_\alpha(y_{\alpha'})$  if and only if  $\alpha = \alpha'$ .

Now let  $i \in [k]$  and let  $x_i \in X_i$  and  $y \in Y$  be arbitrary vertices in the original instance. We assign the edges in the constructed instance as follows. If  $\chi(x_i, y) = 0 = (0, \dots, 0)$ , then  $x_i$  and  $y$  are not connected and we do not introduce new edges. So suppose that  $\chi(x_i, y) \neq 0$ . Then we add  $2 \cdot 2^{r(k-1)}$  edges

- $E(x_i, y_\beta)$ , for all  $\beta \in (\{0, 1\}^r)^k$  with  $\beta_i = \chi(x_i, y)$ , and
- $E(x_i, y_\gamma)$ , for all  $\gamma \in (\{0, 1\}^r)^k$  with  $\gamma_i = 0$ .

Clearly the sparsity of the new instance is bounded by  $2 \cdot 2^{r(k-1)}m = O(m)$  plus the contribution of the new unary predicates which is also  $O(m)$ .

Now let  $\psi = \text{opt}_{x_1, \dots, x_k} \#_y \phi(x_1, \dots, x_k)$ . To define an equivalent  $\text{MAXSP}_k$  formula  $\psi'$ , for any  $\alpha \in (\{0, 1\}^r)^k$  let  $\phi_\alpha$  denote the formula obtained from  $\phi$  by substituting  $E_j(x_i, y)$  by *true* if  $\alpha_{i,j} = 1$  and by *false* otherwise. We define  $\psi' = \max_{x_1, \dots, x_k} \#_y \phi'(x_1, \dots, x_k, y)$ ,

where  $\phi'(x_1, \dots, x_k, y)$  is

$$\bigvee_{\alpha \in \{0,1\}^r} \left( \underbrace{C_\alpha(y)}_{(i)} \wedge \underbrace{\left( \bigwedge_{i \in [k]} (E(x_i, y) \iff \alpha_i \neq 0) \right)}_{(ii)} \wedge \underbrace{\phi_\alpha(x_1, \dots, x_k, y)}_{(iii)} \right).$$

As desired, the constructed instance contains only a single binary predicate and no cross or hyperedges. It remains to argue that the value of any tuple  $(x_1, \dots, x_k)$  is not changed by the reduction. Indeed, for all  $y \in Y$  we prove the following two conditions and thereby the claim.

- $\phi'(x_1, \dots, x_k, y_\alpha) = \phi(x_1, \dots, x_k, y)$  for  $\alpha = \chi(x_1, \dots, x_k, y)$ ,
- $\phi'(x_1, \dots, x_k, y_\alpha) = \text{false}$  for all  $\alpha \neq \chi(x_1, \dots, x_k, y)$ .

The first bullet is simple to verify: In the evaluation of  $\phi'(x_1, \dots, x_k, y_\alpha)$  we only have to focus on the  $\alpha$ -disjunct by the constraint (i). The constraint (ii) is satisfied by our construction of  $E$  and therefore only (iii) is decisive:  $\phi'(x_1, \dots, x_k, y_\alpha) = \phi_\alpha(x_1, \dots, x_k, y_\alpha) = \phi(x_1, \dots, x_k, y)$ . Next, focus on the second bullet. For  $\alpha \neq \chi(x_1, \dots, x_k, y)$  there exists some index  $i$  such that  $\alpha_i \neq \chi(x_i, y)$ . By (i), we again only need to consider the  $\alpha$ -disjunct. We now prove that  $E(x_i, y) \iff \alpha_i = 0$  which falsifies (ii) and shows  $\phi'(x_1, \dots, x_k, y_\alpha) = \text{false}$ . On the one hand, if  $\alpha_i \neq 0$  then there is no edge  $E(x_i, y_\alpha)$ , since  $0 \neq \alpha_i \neq \chi(x_i, y)$ . On the other hand, if  $\alpha_i = 0$  then we added an edge  $E(x_i, y_\alpha)$ . ◀

#### Step 4: Removing Unary Predicates

As the final simplification, we eliminate unary predicates and show that the resulting problem can be reduced to the Hybrid Problem.

**Proof of Lemma 17.** By applying the reductions in Lemmas 18, 20 and 21, it suffices to show that any  $\text{OPTSP}_k$  property  $\psi$  not containing hyperpredicates, cross edge predicates and parallel edge predicates can be reduced to the Hybrid Problem. The shape of  $\psi$  is significantly restricted and contains only the following three types of relations: Unary predicates on  $X_1, \dots, X_k$ , unary predicates on  $Y$  and binary predicates of the form  $E(x_i, y)$  for  $i \in [k]$ .

We can assume that there are no unary predicates on  $X_1, \dots, X_k$  as follows: By enumerating all possible assignments of these unary predicates, and by restricting the sets  $X_1, \dots, X_k$  to those vertices matching the current assignment, we create a constant number of instances each without unary predicates on  $X_1, \dots, X_k$ .

This leaves only unary predicates on  $Y$  and the edge predicates  $E(x_i, y)$ . Let  $\psi = \text{opt}_{x_1, \dots, x_k} \#_y \phi(x_1, \dots, x_k, y)$ . Another way to view this problem is associate a Boolean function  $\phi_y : \{0, 1\}^k \rightarrow \{0, 1\}$  to every vertex  $y \in Y$ , which takes as input  $E(x_i, y)$  and does no longer depend on the unary predicates of  $y$ . In that way, we can rewrite the objective as

$$\text{opt}_{x_1, \dots, x_k} \#_y \phi_y(E(x_1, y), \dots, E(x_k, y)).$$

Our goal is now to reinterpret this problem as an instance of the Hybrid Problem. As the universe, we assign

$$U = \left\{ (y, \tau) : y \in Y, \tau \in \{0, 1\}^k \text{ is a satisfying assignment of } \phi_y \right\},$$

along with the partition  $U = \bigcup_{\tau \in \{0,1\}^k} U_\tau$ ,  $U_\tau = U \cap (Y \times \{\tau\})$ . For every vertex  $x_i \in X_i$ , we construct a set  $S_i \in \mathcal{S}_i$  as  $S_i = \{(y, \tau) : E(x_i, y)\} \cap U$ . It is easy to check that the value of every solution is preserved in this way:  $\text{Val}(S_1, \dots, S_k) = \text{Val}(x_1, \dots, x_k)$ . The overhead of this rewriting step is  $O(m)$  and thus negligible in the running time bound. ◀

# An Estimator for Matching Size in Low Arboricity Graphs with Two Applications

---

## Abstract

In this paper, we present a new degree-based estimator for the size of maximum matching in bounded arboricity graphs. When the arboricity of the graph is bounded by  $\alpha$ , the estimator gives a  $\alpha + 2$  factor approximation of the matching size. For planar graphs, we show the estimator does better and returns a 3.5 approximation of the matching size. Using this estimator, we get new results for approximating the matching size of planar graphs in the streaming and distributed models of computation. In particular, in the vertex-arrival streams, we get a randomized  $O(\frac{\sqrt{n}}{\varepsilon^2} \log n)$  space algorithm for approximating the matching size of a planar graph on  $n$  vertices within  $(3.5 + \varepsilon)$  factor. Similarly, we get a simultaneous protocol in the vertex-partition model for approximating the matching size within  $(3.5 + \varepsilon)$  factor using  $O(\frac{n^{2/3}}{\varepsilon^2} \log n)$  communication from each player. In comparison with the previous estimators, the estimator in this paper does not need to know the arboricity of the input graph and improves the approximation factor in the case of planar graphs.

## 1 Introduction

A matching in a graph  $G = (V, E)$  is a subset of edges  $M \subseteq E$  where no two edges in  $M$  share an endpoint. A maximum matching of  $G$  has the maximum number of edges among all possible matchings. Let  $m(G)$  denote the *matching size* of  $G$ , in other words the size of a maximum matching in  $G$ . In this paper, we present algorithms for approximating  $m(G)$  in the sublinear models of computation. In particular, our results are for the vertex-arrival stream model (also known as the adjacency list streams). In the vertex-arrival model, the input stream is an arbitrary ordering of vertex set  $V$ . Additionally, followed by each  $u \in V$  in the stream, the algorithm also gets the list of the neighbors of  $u$ . This is in contrast with the *edge-arrival* version where the input stream is an arbitrary ordering of the edge set  $E$ .

The problem of estimating  $m(G)$  or computing an approximate maximum matching of  $G$  in the data stream model has been studied in several works [14, 13, 10, 6, 17]. Here we focus on algorithms for graphs with bounded arboricity. A graph  $G = (V, E)$  has arboricity bounded by  $\alpha$  if the edge set  $E$  can be partitioned into at most  $\alpha$  forests. A well-known fact (known as the Nash-William theorem [19]) states that a graph has arboricity  $\alpha$ , if and only if every induced subgraph on  $t$  vertices has at most  $\alpha(t - 1)$  number of edges. Graphs with low arboricity cover a wide range of graphs such as graphs with constant degree, planar graphs, and graphs with small tree-widths. In particular planar graphs have arboricity bounded by 3.

A simple reduction from counting distinct elements implies that the exact computation of  $m(G)$  in the data stream model has  $\Omega(n)$  space complexity even for trees and randomized algorithms (see [1] for the lower bound on distinct elements problem.) This negative result has inspired a growing interest in finding estimators for  $m(G)$  that take sublinear space to compute. Specially when the input graph  $G$  has low arboricity, it has been shown by Esfandiari *et al.* [9], and the subsequent works [16, 7, 18, 4], that it is possible to compute  $m(G)$  approximately in  $o(n)$  space by only checking the degree information and the immediate local neighborhood of the vertices (and the edges). This line of research has led to the invent of several *degree-based* estimators for the matching size. In this paper, we design another degree-based estimator for  $m(G)$  in low arboricity graphs that has certain advantages in comparison with the previous works and leads to new algorithmic results. Before describing our estimator we briefly review the previous ideas.

## 1.1 Previous Works

In the following we assume  $G$  has arboricity bounded by  $\alpha$ . Also, unless explicitly stated, all the algorithms mentioned below are randomized.

### Shallow edges, high degree vertices

Esfandiari *et al.* [9] were first to observe that one can approximately characterize the matching size of low arboricity graphs based on the degree information of the vertices and the local neighborhood of the edges. Let  $H$  denote the set of vertices with degree more than  $h = 2\alpha + 3$  and let  $F$  denote the set of edges with both endpoints having degree at most  $h$ . Esfandiari *et al.* have shown that  $m(G) \leq |H| + |F| \leq (5\alpha + 9)m(G)$ . Based on this estimator, the authors in [9] have designed a  $\tilde{O}(\varepsilon^{-2}\alpha n^{2/3})$  space algorithm for approximating  $m(G)$  within  $5\alpha + 9 + \varepsilon$  factor in the edge-arrival model.

### Fractional matchings

By establishing an interesting connection with fractional matchings and the Edmonds Polytope theorem, McGregor and Vorotnikova [16] have shown that the following quantity approximates  $m(G)$  within  $(\alpha + 2)$  factor.

$$(\alpha + 1) \sum_{(u,v) \in E} \min\left\{\frac{1}{\deg(u)}, \frac{1}{\deg(v)}, \frac{1}{\alpha + 1}\right\}.$$

Based on this estimator, the authors in [16] have given a  $\tilde{O}(\varepsilon^{-2}n^{2/3})$  space streaming algorithm (in the edge-arrival model) that approximate  $m(G)$  within  $\alpha + 2 + \varepsilon$  factor. Also in the same work, another degree-based estimator is given that returns a  $\frac{(\alpha+2)^2}{2}$  factor approximation of  $m(G)$ . A notable property of this estimator is that it can be implemented *deterministically* in the vertex-arrival model using only  $O(\log n)$  bits of space.

### $\alpha$ -Last edges

Cormode *et al.* [7] (later revised by McGregor and Vorotnikova [18]) have designed an improved estimator for  $m(G)$  that also depends on a given ordering of the edges. Given a stream of edges  $S = e_1, \dots, e_m$ , let  $E_\alpha(S)$  denote a subset of edges where  $(u, v) \in E_\alpha(S)$  iff the vertices  $u$  and  $v$  both appear at most  $\alpha$  times in  $S$  after the edge  $(u, v)$ . It is shown that  $m(G) \leq |E_\alpha(S)| \leq (\alpha + 2)m(G)$ . Moreover a  $O(\frac{1}{\varepsilon^2} \log^2 n)$  space streaming algorithm is shown that approximates  $|E_\alpha(S)|$  within  $1 + \varepsilon$  factor in the edge-arrival model.

## 1.2 The estimator in this paper

The new estimator is purely based on the degree of the vertices in the graph without any need to have a pre-knowledge of  $\alpha$ . To estimate the matching size, we count the number of what we call *locally superior* vertices in the graph. Consider the following definition.

► **Definition 1.** In graph  $G = (V, E)$ , we call  $u \in V$  a *locally superior vertex* if  $u$  has a neighbor  $v$  such that  $\deg(u) \geq \deg(v)$ . We let  $\ell(G)$  denote the number of locally superior vertices in  $G$ .

We show when the arboricity of  $G$  is bounded by  $\alpha$ ,  $\ell(G)$  approximates  $m(G)$  within  $(\alpha + 2)$  factor (Lemma 2.) This repeats the same bound obtained by the estimators in [16] and [7], however for planar graphs, we prove the approximation factor is at most 3.5 which beats the previous bounds (Lemma 5). This result is the main technical contribution of the paper. As an evidence on the improved approximation quality, consider the 4-regular planar graph on 9 vertices. Both of the estimators in [16] and [7], report 18 as the estimation for  $m(G)$  while the exact answer is 4. It follows their approximation factor is at least 4.5.

As a first application of Lemma 5, we obtain a randomized  $O(\frac{\sqrt{n}}{\varepsilon^2} \log n)$  space streaming algorithm for approximating  $m(G)$  within  $(3.5 + \varepsilon)$  factor in the vertex-arrival model. In terms of approximation factor, this improves over existing sub-linear algorithms [16, 18].

As another application of our estimator, we get a sublinear simultaneous protocol in the *vertex-partition* model for approximating  $m(G)$  when  $G$  is planar. In this model, the vertex set  $V$  is partitioned into  $t$  subsets  $V_1, \dots, V_t$  where each subset is given to a player. Additionally the  $i$ -th player knows the edges on  $V_i$ . The players do not communicate with each other. They only send one message to a *referee* whom at the end computes an approximation of the matching size. (The referee does not get any part of the input.) We assume the referee and the players have a shared source of randomness. Within this setting, we design a protocol that approximates  $m(G)$  within  $3.5 + \varepsilon$  factor using  $O(\frac{n^{2/3}}{\varepsilon^2} \log n)$  communication from each player. Note that for  $t > 3$  and  $t = o(n^{1/3})$ , this result is non-trivial. The best previous result, implicit in the works of [5, 16] computes a  $5 + \varepsilon$  factor approximation using  $\tilde{O}(n^{4/5})$  communication from each player. Also we should mention that, using the estimator in [16], one can get a deterministic simultaneous protocol where each player sends only  $O(\log n)$  bits to the referee. However this protocol computes a 12.5 factor approximation of  $m(G)$ .

## 1.3 Related Works

Kapralov *et al.* [13] have given an estimator for  $m(G)$  when  $G$  is a general graph. Their estimator gives an approximation of  $m(G)$  by looking at the degree information of the vertices in a series of nested subgraphs of  $G$ . The main challenge is implementing the estimator in sublinear space. Based on this estimator, Kapralov *et al.* has shown one can obtain a  $\text{poly}(\log n)$  approximation of  $m(G)$  in  $\text{poly}(\log n)$  space assuming the input edge stream is randomly ordered. There are subsequent works with improved results and analysis [14]. As far as we know, there is no similar result for arbitrarily ordered streams.

There is a large body of works that addresses the problem of finding a matching of near optimal size using  $O(n \cdot \text{poly}(\log n))$  space. This falls within the category of semi-streaming model. See the recent works [12, 3] for the latest results on this.

Maximum matching has also been studied within the context of distributed local algorithms [15] and massively parallel computations [2]. The main objective of these works is to find a large matching of near optimal size in a distributed manner using small number of communication rounds. See the works [8, 11] for related results on graphs with bounded arboricity.

## 2 Graph properties

In the following proofs, we let  $M \subseteq E$  denote a maximum matching in graph  $G$ . When the underlying graph is clear from the context, for the vertex set  $S$ , we use  $N(S)$  to denote the neighbors of the vertices in  $S$  excluding  $S$  itself. For vertex  $u$ , we simply use  $N(u)$  to denote the neighbors of  $u$ . The vertex  $v$  is a neighbor of the edge  $(x, y)$  if  $v$  is adjacent with  $x$  or  $y$ . When  $x$  is paired with  $y$  in the matching  $M$ , abusing the notation, we define  $M(x) = y$ .

► **Lemma 2.** *Let  $G = (V, E)$  be a graph with arboricity  $\alpha$ . We have*

$$m(G) \leq \ell(G) \leq (\alpha + 2)m(G).$$

**Proof.** The left hand side of the inequality is easy to show. For every edge in  $E$ , at least one of the endpoints is locally superior. Since edges in  $M$  are disjoint, at least  $|M|$  number of endpoints must be locally superior. This proves  $m(G) \leq \ell(G)$ .

To show the right hand side, we use a charging argument. Let  $L$  denote the locally superior vertices in  $G$ . Our goal is to show an upper bound on  $|L|$  in terms of  $|M|$  and  $\alpha$ . Let  $X \subseteq L$  be the set of locally superior vertices that are NOT endpoints of a matching edge. The challenge is to prove an upper on  $|X|$ .

The vertices in  $X$  do not contribute to the maximum matching. However all the vertices in  $N(X)$  must be endpoints of matching edges (otherwise  $M$  would not be maximal.) For the same reason, there cannot be an edge between the vertices in  $X$ . To prove an upper bound on  $|X|$ , in the first step, we assign a subset of vertices in  $X$  to edges in  $M$  in a way any target edge gets at most  $\alpha - 1$  locally superior vertices. We do the assignments in the following way.

### The Assignment Procedure

If we find a  $y \in N(X)$  with at most  $\alpha - 1$  neighbors in  $X$ , we assign all the neighbors of  $y$  in  $X$  to the matching edge  $(y, M(y))$ . We repeat this process, every time picking a vertex in  $N(X)$  with less than  $\alpha$  neighbors in  $X$  and do the assignment that we just described, until we cannot find such a vertex in  $N(X)$ . Note that when we assign a locally superior vertex  $x$ , we remove the edges on  $x$  before continuing the procedure.

Here we emphasize the fact that if  $y$  has a neighbor  $x \in X$ , then  $M(y)$  cannot have neighbors in  $X \setminus \{x\}$  (otherwise it would create an augmenting path and contradict with the optimality of  $M$ .)

Let  $X_1 \subseteq X$  be the assigned locally superior vertices and  $M_1 \subseteq M$  be the used matching edges in the assignment procedure. We have

$$|X_1| \leq (\alpha - 1)|M_1|. \tag{1}$$

Let  $X_2 = X \setminus X_1$  be the unassigned vertices in  $X$ . Now we try to prove an upper bound on  $|X_2|$ . For this, we need to make a few observations.

► **Observation 3.** *Let  $Y_2 = N(X_2)$ . The pair  $y$  and  $M(y)$  cannot be both in  $Y_2$ .*

**Proof.** Suppose  $y$  and  $M(y)$  are both in  $N(X_2)$ . Let  $B$  and  $C$  be the neighbors of  $y$  and  $M(y)$  in  $X_2$  respectively. If  $|B \cup C| > 1$ , then one can find an augmenting path of length 3 (with respect to  $M$ .) A contradiction.

On the other hand, if  $|B \cup C| = 1$ , then  $y$  and  $M(y)$  have only a shared neighbor  $x \in X_2$  which means the edge  $e = (y, M(y))$  should have been used by the assignment procedure and as result  $x \in X_1$ . Another contradiction. ◀

► **Observation 4.** *Every vertex  $x \in X_2$  has degree at least  $\alpha + 1$ .*

**Proof.** Consider  $x \in X_2$ . Suppose, for the sake of contradiction,  $\deg(x)$  is  $k$  where  $k \leq \alpha$ . Since  $x$  is a locally superior vertex, there must be a  $y \in N(x)$  with degree at most  $k$  in  $G$ . We know that  $y$  is an endpoint of a matching edge. In the assignments procedure, whenever we used an edge  $e \in M$  all the neighbors of its endpoints (in  $X$ ) were assigned. Since  $x$  is not assigned yet, it means the edge  $(y, M(y))$  has not been used. Consequently  $y$  must have at least  $\alpha$  neighbors in  $X_2$ . Counting the edge  $(y, M(y))$ , we should have  $\deg(y) \geq \alpha + 1$ . A contradiction. ◀

Let  $G' = (X_2 \cup Y_2, E')$  be a bipartite graph where  $E'$  is the set of edges between  $X_2$  and  $Y_2$ . From Observation 4, we have

$$(\alpha + 1)|X_2| \leq |E'|. \quad (2)$$

Since  $G'$  is a subgraph of  $G$ , its arboricity is bounded by  $\alpha$ . As result,

$$|E'| \leq \alpha(|X_2| + |Y_2|). \quad (3)$$

Recall that  $Y_2$  are endpoints of matching edges. Let  $M_2$  be those matching edges. Observation 3 implies that  $|Y_2| = |M_2|$ . As result, combining (2) and (3), we get the following.

$$|X_2| \leq \alpha|Y_2| = \alpha|M_2|. \quad (4)$$

To prove an upper bound on  $|L|$ , we also need to count the locally superior vertices that are endpoints of matching edges. Let  $Z = L \setminus X$ . We have  $|Z| \leq 2|M|$ . Summing up, we get

$$\begin{aligned} |L| &= |X_1| + |X_2| + |Z| \\ &\leq (\alpha - 1)|M_1| + \alpha|M_2| + 2|M| \\ &= \alpha(|M_1| + |M_2|) + 2|M| - |M_1| \\ &\leq (\alpha + 2)|M| - |M_1| \\ &\leq (\alpha + 2)|M| \end{aligned}$$

This proves the lemma. ◀

► **Lemma 5.** *Let  $G = (V, E)$  be a planar graph. We have  $\ell(G) \leq 3.5m(G)$ .*

**Proof.** For planar graphs, similar to what we did in the proof of Lemma 2, we first try to assign some of the vertices in  $X$  to the matching edges using a simple assignment procedure. (Recall that  $X$  is the set of vertices in  $L$  that are not endpoints of edges in  $M$ .)

### The Assignment Procedure

Let  $Y_1 = \emptyset$ . If we find a  $y \in N(X)$  with only 1 neighbor  $x \in X$ , we assign  $x$  to the matching edge  $(y, M(y))$ . Also we add  $y$  to  $Y_1$ . We continue the procedure until we cannot find such a vertex in  $N(X)$ . Note that when we assign a locally superior vertex  $x$ , we remove the edges on  $x$ .

Let  $X_1 \subseteq X$  be the assigned locally superior vertices and  $M_1 \subseteq M$  be the used matching edges in the assignment procedure. Note that  $|Y_1| = |M_1|$ . We have

$$|X_1| \leq |M_1|. \quad (5)$$

## 10:6 An Estimator for Matching Size in Low Arboricity Graphs with Two Applications

Let  $X_2 = X \setminus X_1$ . Using a similar argument that we used for proving Observation 4, we can show every vertex in  $X_2$  has degree at least 3. Also letting  $Y_2 = N(X_2)$ , we observe that  $y \in Y_2$  and  $M(y)$  cannot be both in  $Y_2$  as we noticed in the Observation 3. Let  $M_2 \subseteq M$  be the matching edges with one endpoint in  $Y_2$ . We have  $|Y_2| = |M_2|$ .

Now consider the bipartite graph  $G' = (X_2 \cup Y_2, E')$  where  $E'$  is the set of edges between  $X_2$  and  $Y_2$ . Every planar bipartite graph with  $n$  vertices has at most  $2n - 4$  edges<sup>1</sup>. Since  $G'$  is a bipartite planar graph, it follows,

$$3|X_2| \leq |E'| < 2(|X_2| + |Y_2|) = 2(|X_2| + |M_2|). \quad (6)$$

This shows  $|X_2| < 2|M_2|$ . Letting  $Z = L \setminus X$  and  $M_3 = M \setminus (M_1 \cup M_2)$ , we get

$$|L| = |X_1| + |X_2| + |Z| \leq |M_1| + 2|M_2| + 2|M| \leq 3|M| + |M_2| - |M_3|. \quad (7)$$

This already proves  $|L|$  is bounded by  $4|M|$ . To prove the bound claimed in the lemma, we also show that  $|L| \leq 3|M| + |M_1| + |M_3|$ . Combined with the inequality (7), this proves the lemma.

Let  $Y = Y_1 \cup Y_2$ . Note that  $Y$  are one side of the matching edges in  $M_1 \cup M_2$ . Let  $Y' = \{M(y) \mid y \in Y\}$ . We use a special subset of  $Y'$ , named  $Y''$  which is defined as follows. We let  $Y''$  denote the locally superior vertices in  $Y'$  that have degree 2 or they are adjacent with both endpoints of an edge in  $M_3$ . We make the following observation regarding the vertices in  $Y''$ .

► **Observation 6.** *We can assign each vertex  $y' \in Y''$  to a distinct  $e \in Y_1 \cup M_3$  where  $e$  has no neighbor in  $Y' \setminus \{y'\}$ .*

**Proof.** Consider  $y' \in Y''$ . If  $y'$  is adjacent with both endpoints of an edge  $e = (z, z') \in M_3$ , we assign  $y'$  to  $e$  (when there are multiple edges with this condition we pick one of them arbitrarily.) Note that  $z$  and  $z'$  cannot have neighbors in  $Y'$  other than  $y'$  because otherwise it would create an augmenting path.

Now suppose  $y'$  has degree 2. Since  $y'$  is a locally superior vertex, it must have a neighbor  $z$  of degree at most 2. The neighbor  $z$  cannot be in  $Y_2 \cup X_2$  because the vertices in  $Y_2 \cup X_2$  have degree at least 3. We distinguish between two cases.

- $M(y') \in Y_2$ . In this case,  $z$  cannot be in  $Y_1$  either because the vertices in  $Y_1$  are already of degree 2 without  $y'$ . Also  $z \notin X_1$  because otherwise it would create an augmenting path. The only possibility is that  $z$  is an endpoint of a matching edge in  $M_3$ . We assign  $y'$  to the matching edge  $(z, z') \in M_3$ . Note that  $z'$  cannot have a neighbor in  $Y' \setminus \{y'\}$  because it would create an augmenting path.
- $M(y') \in Y_1$ . Here  $z$  could be in  $X_1$ . If this is the case, then  $M(y')$  cannot have a neighbor in  $Y' \setminus \{y'\}$  because it would create an augmenting path. In this case, we assign  $y'$  to  $M(y')$ . If  $z = M(y')$ , then again we assign  $y'$  to  $M(y')$ . The only remaining possibility is that  $z$  an endpoint of a matching edge in  $M_3$  which we handle it similar to the previous case. ◀

Now, assume we assign the vertices in  $Y''$  to the elements in  $Y_1 \cup M_3$  according to the above observation. Let  $Y'_1 \subseteq Y_1$  and  $M'_3 \subseteq M_3$  be the vertices and edges that were used in the assignment. Let  $Y'''$  be the remaining locally superior vertices in  $Y'$ . Namely,  $Y''' = (L \cap Y') \setminus Y''$ . Before making the final point, we observe that only one endpoint of the

<sup>1</sup> For a short proof of this, combine the Euler's formula  $|V| - |E| + |F| = 2$  with the inequality  $2|E| \geq 4|F|$  caused by each face having at least 4 sides (since there are no odd cycles) and we get  $|E| \leq 2|V| - 4$ .

■ **Figure 1** A demonstration of the construction in the proof of lemmas 2 and 5. Thick edges represent matching edges. The unfilled vertices belong to the set  $Y''$ .

edges in  $M_3$  are adjacent with vertices in  $Y'''$ . Let  $Y_3$  be the endpoint of edges in  $M_3 \setminus M'_3$  that have neighbors in  $Y'''$ . Consider the bipartite graph  $G''(V'', E'')$  where

$$V'' = (X_2 \cup Y''') \cup (Y_2 \cup (Y_1 \setminus Y'_1) \cup Y_3)$$

and  $E''$  is the set of edges between  $X_2$  and  $Y_2$ , and the edges between  $Y'''$  and  $Y_2 \cup (Y_1 \setminus Y'_1) \cup Y_3$ .

Relying on the facts that  $G''$  is a planar bipartite graph,  $Y'''$  is composed of vertices with degree at least 3, and the edges on  $Y'''$  are all in  $E''$ , we have

$$3|X_2| + 3|Y'''| \leq |E''| \leq 2(|X_2| + |Y_2| + |Y_1 \setminus Y'_1| + |Y'''| + |Y_3|).$$

It follows,

$$\begin{aligned} |X_2| + |Y'''| &\leq 2(|Y_2| + |Y_1 \setminus Y'_1| + |Y_3|) \\ &\leq 2(|M_2| + |M_1| - |Y'_1| + |M_3| - |M'_3|) \\ &= 2(|M| - |Y'_1| - |M'_3|) \end{aligned}$$

Since  $|Y''| = |Y'_1| + |M'_3|$ , we get

$$|X_2| + |Y'''| \leq 2|M| - 2|Y''| \quad (8)$$

Let  $Z_1$ ,  $Z_2$  and  $Z_3$  denote the locally superior vertices that are endpoints of matching edges in  $M_1$ ,  $M_2$  and  $M_3$  respectively. From the definition of  $Y''$  and  $Y'''$ , we have

$$|Z_1| + |Z_2| \leq |M_1| + |M_2| + |Y''| + |Y'''| \quad (9)$$

From (8) and (9), we get

$$\begin{aligned} |L| &= |X_1| + |X_2| + |Z_1| + |Z_2| + |Z_3| \\ &\leq |M_1| + |X_2| + (|M_1| + |M_2| + |Y''| + |Y'''|) + 2|M_3| \\ &= 2|M_1| + (|X_2| + |Y'''|) + |M_2| + |Y''| + 2|M_3| \\ &\leq 2|M_1| + |M_2| + 2|M| - |Y''| + 2|M_3| \\ &= 3|M| + |M_1| + |M_3| - |Y''| \\ &\leq 3|M| + |M_1| + |M_3| \end{aligned}$$

This finishes the proof of the lemma. ◀

### 3 Algorithms

We first present a high-level sampling-based estimator for  $\ell(G)$ . Then we show how this estimator can be implemented in the streaming and distributed settings using small space and communication. For our streaming result, we use a combination of the estimator for  $\ell(G)$  and the greedy maximal matching algorithm. For the simultaneous protocol, we use the estimator for  $\ell(G)$  in combination with the edge-sampling primitive in [5] and an estimator in [16].

The high-level estimator (described in Algorithm 1) samples a subset of vertices  $S \subseteq V$  and computes the locally superior vertices in  $S$ . The quantity  $\ell(G)$  is estimated from the scaled ratio of the locally superior vertices in the sample set.

■ **Algorithm 1** The high-level description of the estimator for  $\ell(G)$ .

---

Run the following estimator  $r = \lceil \frac{8}{\varepsilon^2} \rceil$  number of times in parallel. In the end, report the average of the outcomes.

1. Sample  $s$  vertices (uniformly at random) from  $V$  without replacement.
  2. Let  $S$  be the set of sampled vertices.
  3. Compute  $S'$  where  $S'$  is the set of locally superior vertices in  $S$ .
  4. Return  $\frac{n}{s}|S'|$  as an estimation for  $\ell(G)$ .
- 

► **Lemma 7.** *Assuming  $s \geq \frac{n}{\ell(G)}$ , the high-level estimator in Algorithm 1 returns a  $1 + \varepsilon$  factor approximation of  $\ell(G)$  with probability at least  $7/8$ .*

**Proof.** Fix a parallel repetition of the algorithm and let  $X$  denote the outcome of the associated estimator. Assuming an arbitrary ordering on the locally superior vertices, let  $X_i$  denote the random variable associated with  $i$ -th locally superior vertex. We define  $X_i = 1$  if the  $i$ -th locally superior vertex has been sampled, otherwise  $X_i = 0$ . We have  $X = \frac{n}{s} \sum_{i=1}^{\ell(G)} X_i$ . Since  $Pr(X_i = 1) = \frac{s}{n}$ , we get  $E[X] = \ell(G)$ . Further we have

$$\begin{aligned} E[X^2] &= \frac{n^2}{s^2} E\left[\sum_{i,j} X_i X_j\right] = \frac{n^2}{s^2} \left[ \sum_i E[X_i^2] + \sum_{i \neq j} E[X_i X_j] \right] \\ &= \frac{n^2}{s^2} \left[ \frac{s}{n} \ell(G) + \binom{\ell(G)}{2} \frac{s(s-1)}{n(n-1)} \right] \\ &= \frac{n}{s} \ell(G) + \binom{\ell(G)}{2} \frac{n(s-1)}{s(n-1)} \\ &< \frac{n}{s} \ell(G) + \ell^2(G) \end{aligned}$$

Consequently,  $Var[X] = E[X^2] - E^2[X] < \frac{n}{s} \ell(G)$ .

Let  $Y$  be the average of the outcomes of  $r$  parallel and independent repetitions of the basic estimator. We have  $E[Y] = \ell(G)$  and  $Var[Y] < \frac{n}{sr} \ell(G)$ . Using the Chebyshev's inequality,

$$Pr(|Y - E[Y]| \geq \varepsilon E[Y]) \leq \frac{Var[Y]}{\varepsilon^2 E^2[X]} < \frac{n/s}{r \varepsilon^2 \ell(G)}.$$

Setting  $r = \frac{8}{\varepsilon^2}$  and  $s \geq \frac{n}{\ell(G)}$ , the above probability will be less than  $1/8$ . ◀

### 3.1 The streaming algorithm

We first note that we can implement the high-level estimator of Algorithm 1 in the vertex-arrival stream model using  $O(\frac{s}{\epsilon^2} \log n)$  space. Consider a single repetition of the estimator. The sampled set  $S$  is selected in the beginning of the algorithm (before the stream.) This can be done using a reservoir sampling strategy [20] in  $O(|S| \log n)$  space. To decide if  $u \in S$  is locally superior or not, we just need to store  $\deg(u)$  and the minimum degree of the neighbors that are visited so far. Note that when processing a vertex  $v \in V$  and its neighbors, we know if  $v$  is a neighbor of  $u$  or not. Consequently, checking if  $u$  is a locally superior or not takes  $O(\log n)$  bits of space. Therefore the whole space needed to implement a single repetition is  $O(s \log n)$  bits.

The streaming algorithm runs two threads in parallel. In one thread it runs the streaming implementation of Algorithm 1 after setting  $s = \lceil \sqrt{n} \rceil$ . In the other thread, it runs a greedy algorithm to find a maximal matching in the input graph. We stop the greedy algorithm whenever the size of the discovered matching  $F$  exceeds  $\sqrt{n}$ . In the end, if  $|F| < \sqrt{n}$ , we output  $|F|$  as an approximation for  $m(G)$ , otherwise we report the outcome of the first thread.

Note that if  $|F| < \sqrt{n}$ ,  $F$  is a maximal matching in  $G$ . Hence  $|F| \geq \frac{1}{2}m(G)$ . Assume  $|F| \geq \sqrt{n}$ . In this case the algorithm outputs the result of first thread. In this case, by Lemma 2, we know  $\ell(G) \geq \sqrt{n}$ . Consequently, by Lemma 7, the first thread returns a  $1 + O(\epsilon)$  approximation of  $\ell(G)$  and hence it returns a  $3.5 + O(\epsilon)$  approximation of  $m(G)$ . Since the greedy algorithm takes at most  $O(\sqrt{n})$  space, the space complexity of the algorithm is dominated by the space usage of the first thread. We get the following result.

► **Theorem 8.** *Let  $G$  be a planar graph. There is a randomized streaming algorithm in the vertex-arrival model that returns a  $3.5 + \epsilon$  factor approximation of  $m(G)$  using  $O(\frac{\sqrt{n}}{\epsilon^2})$  space.*

### 3.2 A simultaneous communication protocol

In this section we describe a communication protocol for approximating  $m(G)$  in the vertex-partition model. Recall that in this model the vertex set  $V$  is partitioned into  $t$  subsets  $V_1, \dots, V_t$  where the subset  $V_i$  is given to the  $i$ -th player. Additionally the  $i$ -th player knows the edges on the vertices in  $V_i$ . The players do not communicate with each other. They only send one message to a referee whom at the end computes an approximation of the matching size. Also we emphasize the assumption that the referee and the players have a shared source of randomness.

To describe the simultaneous protocol, we consider two cases separately: (a) when the matching size is low; to be precise, when it is smaller than some fixed value  $k = n^{1/3}$ , and (b) when the matching size is high, *i.e.* at least  $\Omega(k)$ . For each case, we describe a separate solution. The overall protocol will be the parallel run of these two solutions along with a sub-protocol to distinguish between the cases.

#### Graphs with large matching size

In the case when matching size is large, similar to what was done in the streaming model, we run an implementation of Algorithm 1 in the given simultaneous model. To see how this is implemented, in the simultaneous model all the players (including the referee) know the sampled set  $S$ . This results from access to the shared randomness. For each  $u \in S$ , the players send the minimum degree of the neighbors of  $u$  in his input to the referee. The player that owns  $u$ , also sends  $\deg(u)$  to the referee. Having received this information, the referee can decide if  $u$  is a locally superior vertex or not. As result, we can implement Algorithm 1 in the simultaneous model using a protocol with  $O(\frac{s}{\epsilon^2} \log n)$  message size.

## 10:10 An Estimator for Matching Size in Low Arboricity Graphs with Two Applications

### Graphs with small matching size

In the case where the matching size is small, we use the edge-sampling method of [5]. Here we review their basic sampling primitive in its general form. Given a graph  $G(V, E)$ , let  $c : V \rightarrow [b]$  be a totally random function that assigns each vertex in  $V$  a random number (color) in  $[b] = \{1, \dots, b\}$ . The set  $\text{Sample}_{b,d,1}$  is a random subset of  $E$  picked in the following way. Given a subset  $K \subseteq [b]$  of size  $d \in \{1, 2\}$ , let  $E_K$  be the edges of  $G$  where the color of their endpoints matches  $K$ . For example when  $K = \{3, 4\}$ , the set  $E_{\{3,4\}}$  contains all edges  $(u, v)$  such that  $\{c(u), c(v)\} = \{3, 4\}$ . For all  $K \subseteq [b]$  of size  $d$ , the set  $\text{Sample}_{b,d,1}$  picks a random edge from  $E_K$ . Finally, the random set  $\text{Sample}_{b,d,r}$  is the union of  $r$  independent instances of  $\text{Sample}_{b,d,1}$ . We have the following lemma from [5] (see Theorems 4 in the reference.)

► **Lemma 9.** *Let  $G = (V, E)$  be a graph. Assuming  $m(G) \leq k$ , with probability  $1 - 1/\text{poly}(k)$ , the random set  $\text{Sample}_{100k,2,O(\log k)}$  contains a matching of size  $m(G)$ .*

Note that, in the simultaneous vertex-partition model, the referee can obtain an instance of  $\text{Sample}_{b,d,1}$  via a protocol with  $O(b^d \log n)$  message size. To see this, using the shared randomness, the players pick the random function  $c : V \rightarrow [b]$ . Let  $E^{(i)}$  be the subset of edges owned by the  $i$ -th player. We have  $E = \bigcup_{i=1}^t E^{(i)}$ . To pick a random edge from  $E_K$  for a given  $K \subseteq [b]$ , the  $i$ -th player randomly picks an edge  $e \in E_K \cap E^{(i)}$  and sends it along with  $|E_K \cap E^{(i)}|$  to the referee. After receiving this information from all the players, the referee can generate a random element of  $E_K$ . Since there are  $O(b^d)$  different  $d$ -subsets of  $[b]$ , the size of the message from a player to the referee is bounded by  $O(b^d \log n)$  bits. Consequently, the referee can produce a rightful instance of  $\text{Sample}_{b,d,r}$  using  $O(rb^d \log n)$  communication from each player.

### How to distinguish between the cases?

For this task, we use a degree-based estimator by McGregor and Vorotnikova [16] described in the following lemma.

► **Lemma 10.** *Let  $G = (V, E)$  be a planar graph. Let  $A'(G) = \sum_{u \in V} \min\{\deg(u)/2, 4 - \deg(u)/2\}$ . We have*

$$m(G) \leq A'(G) \leq 12.5 m(G).$$

It is easy to see that, in the simultaneous vertex-partition model, we can implement this estimator with  $O(\log n)$  bits communication from each player.

### The final protocol

Let  $k = \lceil n^{1/3} \rceil$ . We run the following threads in parallel.

1. A protocol that implements the high-level estimator (Algorithm 1) with  $s = \lceil 12.5n/k \rceil$  as its input parameter according to the discussions above. Let  $z_1$  be the output of this protocol.
2. A protocol to compute an instance of  $\text{Sample}_{b,d,r}$  for  $b = 100k$  and  $d = 2$  and  $r = O(\log k)$ . Let  $z_2$  be the size of maximum matching in the sampled set.
3. A protocol to compute  $A'(G)$ . Let  $z_3$  be the output of this thread.

In the end, if  $z_3 \geq \frac{k}{12.5}$ , the referee outputs  $z_1$  as an approximation for  $m(G)$ , otherwise the referee reports  $z_2$  as the final answer.

► **Theorem 11.** *Let  $G$  be a planar graph on  $n$  vertices. The above simultaneous protocol, with probability  $3/4$ , returns a  $3.5 + O(\varepsilon)$  approximation of  $m(G)$  where each player sends  $O(\frac{n^{2/3}}{\varepsilon^2})$  bits to the referee.*

**Proof.** First we note that by choosing the constants large enough, we can assume the thread (2) errs with probability at most  $1/8$ . If  $z_3 \geq \frac{k}{12.5}$ , then we know  $m(G) \geq \frac{k}{12.5}$ . This follows from Lemma 10. Consequently by Lemma 2, we have  $\ell(G) \geq \frac{k}{12.5}$ . Therefore from Lemma 7, we have  $|z_1 - \ell(G)| \leq \varepsilon \ell(G)$  with probability at least  $7/8$ . It follows from Lemma 5 that  $(1 - \varepsilon)m(G) \leq z_1 \leq (3.5 + 3.5\varepsilon)m(G)$ .

On the other hand, if  $z_3 < \frac{k}{12.5}$ , by Lemma 10 we know that  $m(G)$  must be less than  $k$ . Having this, from Lemma 9, with probability at least  $7/8$ , we get  $z_2 = m(G)$ . In this case the protocol computes the exact matching size of the graph.

The message size of each player is dominated by the cost of the first thread which is  $O(n^{2/3}\varepsilon^{-2} \log n)$ . The total error probability is bounded by  $1/4$ . This finishes the proof. ◀

## 4 Conclusion

In this paper we presented a degree-based estimator for the size of maximum matching in planar graphs. We showed our estimator gives a 3.5 factor approximation of the matching size. This improves the approximation factor of the previous degree-based estimators. We do not have tight examples for our analysis. In fact, we conjecture that  $\ell(G)$  approximates  $m(G)$  within 3 factor when  $G$  is planar.

Using our estimator, we obtained an improved sublinear space algorithm for estimating the matching size in the vertex-arrival streams. We also showed a more efficient simultaneous protocol for estimating the matching size in planar graphs. Unfortunately, the new estimator, in spite of its simplicity, does not immediately lead to one-pass sublinear algorithm in the edge-arrival model. To decide if a vertex is locally superior, we need to know its neighbors and learn their degrees which becomes burdensome in one pass. However, given an extra pass over the stream the same space bound and approximation factor is achievable for the edge-arrival streams as well. It would be interesting to do this without the extra pass.

## Abstract

We present a new algorithm for approximating the number of triangles in a graph  $G$  whose edges arrive as an arbitrary order stream. If  $m$  is the number of edges in  $G$ ,  $T$  the number of triangles,  $\Delta_E$  the maximum number of triangles which share a single edge, and  $\Delta_V$  the maximum number of triangles which share a single vertex, then our algorithm requires space:

$$\tilde{O}\left(\frac{m}{T} \cdot (\Delta_E + \sqrt{\Delta_V})\right)$$

Taken with the  $\Omega\left(\frac{m\Delta_E}{T}\right)$  lower bound of Braverman, Ostrovsky, and Vilenchik (ICALP 2013), and the  $\Omega\left(\frac{m\sqrt{\Delta_V}}{T}\right)$  lower bound of Kallaugher and Price (SODA 2017), our algorithm is optimal up to log factors, resolving the complexity of a classic problem in graph streaming.

## 1 Introduction

Triangle counting is a fundamental problem in the study of graph algorithms, and one of the best studied in the field of graph streams. It arises in the analysis of social networks [5], web graphs [11], and spam detection [3], among other applications. From a theoretical perspective, it is of particular interest as the simplest subgraph counting problem that cannot be solved by considering only *local* information about individual vertices. In other words, counting triangles requires one to aggregate information between pairs of *non-incident* edges.

In this paper, we present an optimal algorithm for counting triangles in the *graph streaming* setting, settling a long line of work on this problem.

## 1.1 Graph Streaming

In the (insertion-only) graph streaming setting, a graph  $G = (V, E)$  is received as a stream of edges  $(\sigma_t)_{t=1}^m$  from its edge set  $E$  in an arbitrary order, and an algorithm is required to output the answer to some problem at the end of the stream, using as little space as possible<sup>1</sup>. Variants on this model include turnstile streaming (in which edges may be deleted as well as inserted), and models that restrict what kind of state the algorithm may maintain.

## 1.2 Triangle Counting in Graph Streams

The theoretical study of graph streaming was initiated by [2], who studied the problem of triangle counting – the problem of estimating the number of three-cliques in a graph. They demonstrated that, in general, sublinear space algorithms cannot exist for this problem; namely, in the worst case any algorithm for triangle counting in a stream must use  $\Omega(n^2)$  bits of space. On the other hand, they also showed that, if one parameterizes in terms of the number of triangles  $T$ , one can often beat this pessimistic lower bound. In particular, they gave an algorithm that uses  $\tilde{O}\left(\frac{mn}{T}\right)^3$  space to count triangles in a graph with  $m$  edges,  $n$  vertices, and  $T$  triangles, based on streaming algorithms for approximating frequency moments.<sup>2</sup> Of course, it is unreasonable to assume that an algorithm knows the number of triangles  $T$  in advance, as this would make counting superfluous. Instead, it will suffice to have constant factor bounds on the parameters in question.<sup>3</sup>

Several years later, the upper bound for this problem was improved to  $\tilde{O}\left(\frac{mn}{T}\right)$  by [7], while [14] gave a (non-comparable) algorithm that samples edges and stores neighborhoods of their endpoints in order to find triangles, achieving  $\tilde{O}\left(\frac{md^2}{T}\right)$  space in graphs with maximum degree  $d$ . Both algorithms were later subsumed by the  $\tilde{O}\left(\frac{md}{T}\right)$  space algorithm of [23].

## 1.3 Additional Graph Parameters for Triangle Counting

Despite the large strides made by the aforementioned algorithms, none of them can achieve sublinear space, even for graphs guaranteed to have as many as  $\Omega(m)$  triangles, without bounding parameters of the graph other than  $m$  and  $T$ . This feature was shown to be necessary by [6], who constructed a family of graphs with either 0 or  $\Omega(m)$  triangles such that distinguishing between the two requires  $\Omega(m)$  space. However, this “hard instance” is an unusual graph – every triangle in it shares a single edge. This motivated the introduction of a new graph parameter  $\Delta_E$ , defined as the maximum number of triangles which share a single edge in  $G$ . When one parameterizes in terms of  $\Delta_E$ , the lower bound of [6] becomes  $\Omega\left(\frac{m\Delta_E}{T}\right)$ . As it happens, the maximum degree of graphs in this family is also  $\Delta_E$ , so in particular this proves [23] to be optimal among algorithms parametrized by only  $m$ ,  $d$ , and  $T$ .

<sup>1</sup> Other properties, such as update time, are also of interest, but space has been the primary object of study in the theory of streaming.

<sup>2</sup> Here we assume the desired approximation is a multiplicative  $(1 \pm \varepsilon)$  with success probability  $\delta$  for some positive constants  $\varepsilon, \delta$ . For most algorithms mentioned here, including our own, the dependence on non-constant  $\varepsilon, \delta$  will go as  $\varepsilon^{-2} \log \delta^{-1}$ . We use  $\tilde{O}(\cdot)$  to suppress logarithmic or polylogarithmic factors in the argument.

<sup>3</sup> One might hope to use these parameters adaptively, giving an algorithm that uses more space the smaller  $T$  is without needing a lower bound at the start. However, this is in general impossible, as a graph stream with few triangles and a graph stream with many triangles may be indistinguishable until the last few updates.

The first algorithm to directly take advantage of the new parameter  $\Delta_E$  was given by [24]. Their algorithm is simple: keep each edge in the stream independently with probability  $p$ , count the number of triangles  $T'$  in the resulting graph, and output  $T'p^{-3}$ . They show that setting  $p = O(\frac{1}{T^{1/3}} + \frac{\Delta_E}{T})$  suffices for an accurate count, and thereby achieve  $\tilde{O}(m(\frac{1}{T^{1/3}} + \frac{\Delta_E}{T}))$  space.

This algorithm has another important feature: it is a *non-adaptive sampling* algorithm – whether it keeps an edge it sees does not depend on the contents of the stream before the edge arrives. This means it can naturally handle *turnstile streams*, streams in which edges may be deleted as well as inserted. In fact, through the use of sketches for  $\ell_0$  sampling (see e.g. [10]) such algorithms may be converted into *linear sketches*, which are algorithms that store only a linear function of their input (when considered as a vector in  $\{0, 1\}^{\binom{V}{2}}$ ).

An improved non-adaptive sampling algorithm was given in [22], which used the technique of coloring vertices with one of  $k$  colors, and keeping all monochromatic edges. This improved the space usage of the algorithm to  $\tilde{O}(m(\frac{1}{\sqrt{T}} + \frac{\Delta_E}{T}))$ . In [17], it was shown (in combination with the existing lower bound of [6]) that this is optimal, even for insertion-only algorithms – for every  $T$  up to  $\Omega(m)$ , a family of graphs exist with  $\Delta_E \leq 1$  and either 0 or  $T$  triangles, such that  $\Omega(\frac{m}{\sqrt{T}})$  space is required to distinguish the two.

However, as with the lower bound of [6], the hard instance from [17] is a rather strange graph: this time every triangle shares a single *vertex*. Also similarly to the lower bound of [6], the bound from [17] weakens as the maximum number of triangles sharing a single vertex, a parameter denoted by  $\Delta_V$ , is restricted. In this case, when parameterized by  $\Delta_V$ , the lower bound becomes  $\Omega(\frac{m\sqrt{\Delta_V}}{T})$ . This was accompanied in [17] by an algorithm that achieves  $\tilde{O}(m(\frac{1}{T^{2/3}} + \frac{\sqrt{\Delta_V}}{T} + \frac{\Delta_E}{T}))$  space, improving on [22] for graphs with  $\Delta_V = o(T)$ .

Subsequently, it was shown in [15] that any linear sketching algorithm for counting triangles requires  $\Omega(\frac{m}{T^{2/3}})$  space, even if every triangle is disjoint from every other and therefore  $\Delta_E = \Delta_V \leq 1$ , and so the [17] algorithm is optimal among linear sketches. By the turnstile streaming-linear sketching equivalence of [20], this suggests that [17] is also optimal among turnstile streaming algorithms.<sup>4</sup>

However, this leaves open the question of how hard triangle counting is for algorithms that are *not* required to handle deletions (i.e., the standard “insertion-only” model). We resolve this question (up to a log factor, as with previous optimality results), by giving an optimal algorithm for triangle counting in insertion-only streams.

## 1.4 Our Algorithm

We give a new algorithm for counting triangles in insertion-only graph streams. For every  $\varepsilon, \delta \in (0, 1)$ , there is an algorithm for insertion-only graph streams that approximates the number of triangles in a graph  $G$  to  $\varepsilon T$  accuracy with probability  $1 - \delta$ , using

$$O\left(\frac{m}{T} \left(\Delta_E + \sqrt{\Delta_V}\right) \log n \frac{\log \frac{1}{\delta}}{\varepsilon^2}\right)$$

bits of space, where  $m$  is the number of edges in  $G$ ,  $T$  the number of triangles,  $\Delta_E$  the maximum number of triangles which share a single edge, and  $\Delta_V$  the maximum number of triangles which share a single vertex.

<sup>4</sup> However, the [20] equivalence depends on rather stringent conditions that a turnstile algorithm must satisfy. In [18], it was shown that relaxing these conditions allows turnstile streaming algorithms for triangle counting that are closer to the result of [14].

## 11:4 An Optimal Algorithm for Triangle Counting in the Stream

■ **Table 1** Best known upper and lower bounds for triangle counting for insertion-only and linear sketching algorithms.  $m$  is the number of edges,  $T$  the number of triangles,  $d$  the maximum degree, and  $\Delta_E, \Delta_V$  are the maximum number of triangles sharing an edge or a vertex respectively. Note that linear sketching upper bounds imply insertion-only upper bounds, while lower bounds are the opposite.

Paper	Space	Model
[23]	$\tilde{O}\left(\frac{md}{T}\right)$	Insertion-only
[6]	$\Omega\left(\frac{m\Delta_E}{T}\right)$	Insertion-only
[17]	$\Omega\left(\frac{m\sqrt{\Delta_V}}{T}\right)$	Insertion-only
[22]	$\tilde{O}\left(m\left(\frac{1}{\sqrt{T}} + \frac{\Delta_E}{T}\right)\right)$	Linear Sketching
[17]	$\tilde{O}\left(m\left(\frac{1}{T^{2/3}} + \frac{\sqrt{\Delta_V}}{T} + \frac{\Delta_E}{T}\right)\right)$	Linear Sketching
[15]	$\Omega\left(\frac{m}{T^{2/3}}\right)$	Linear Sketching
This work	$\tilde{O}\left(\frac{m}{T}(\sqrt{\Delta_V} + \Delta_E)\right)$	Insertion-only

This matches, up to a log factor (and for constant  $\varepsilon, \delta$ ), the lower bounds of [6] and [17]. It subsumes both the algorithm of [17] and the  $\tilde{O}\left(\frac{md}{T}\right)$  algorithm of [23], as in any graph with max degree  $d$ , we have  $\Delta_E \leq d$  and  $\Delta_V \leq \binom{d}{2}$ . This closes the line of work discussed above on the complexity of triangle counting in insertion-only streams.

### 1.5 Other Related Work

In the *multi-pass* streaming setting, an algorithm is allowed to pass over the input stream more than once. [9] shows multipass algorithms take  $\tilde{O}\left(m/\sqrt{T}\right)$  space for arbitrary graphs, giving an algorithm for two passes and a lower bound for a constant number of passes. [19] shows a three pass streaming algorithm using  $O(\sqrt{m} + m^{3/2}/T)$  space. [4] gave a  $O(m^{3/2}/T)$  four pass algorithm.

In the *adjacency-list* model, in which each vertex's list of neighbors is received as a block (and so in particular every edge is seen twice), [21] gave a  $O\left(m/\sqrt{T}\right)$  space one-pass algorithm, while [16] gave  $O(m/T^{2/3})$  space 2-pass algorithm, as well as tight (but conditional on open communication complexity conjectures) lower bounds for both.

The problem has also been studied in the query model, in which case rather than space the concern is minimizing time or query count. While this is a very different setting, similar concerns around mitigating the impact of “heavy” vertices or edges arise. [12] considered triangle counting in this setting, which was extended by [13] to general cliques and [1] to arbitrary constant-size subgraphs.

## 2 Overview of the Algorithm

At a high-level, many triangle counting algorithms in the literature adhere to the following template: **(1)** design a sampling scheme to sample triangles, **(2)** count the number of triangles which survive after this sampling process, **(3)** rescale the number of empirically sampled triangles by the expected fraction of surviving triangles to obtain an unbiased estimator for  $T$ .

As an example, one could sample each edge uniformly with probability  $q$  (this is the approach taken in [24]). Since for a triangle to survive all three of its edges must be sampled, the expected number of triangles that survive is  $Tq^3$ . Thus, rescaling the number of empirically sampled triangles by  $1/q^3$  yields an unbiased estimator. How large must  $q$  be to make this estimator accurate? In order to sample even a single triangle we need  $Tq^3 \geq 1$ , so clearly  $q$  must be at least  $1/T^{1/3}$ . Moreover, if  $\Delta_E$  is the largest number of triangles that share an edge, there might be as few as  $T/\Delta_E$  “heavy” edges such that sampling a triangle requires sampling at least one of them, and so  $q$  must be at least  $\Delta_E/T$ . It turns out that, up to constant factors, this is also sufficient, and so the space needed by this algorithm is  $\tilde{O}\left(m\left(\frac{1}{T^{1/3}} + \frac{\Delta_E}{T}\right)\right)$  bits.

The starting point for our algorithm is the following simple observation, which can be seen as an optimization to the sampling algorithm above. Given three edges  $uv, vw, wu \in E$  arriving in a stream in that order, once the first two edges  $uv, vw$  have been sampled and stored, upon seeing the “completing” edge  $wu$ , we will know that the triangle  $uvw$  exists in  $G$ , and may count it immediately – we get the closing edge of each triangle “for free”. Now for a single triangle to be sampled, we only need to sample the first two edges, and so the probability of finding any given triangle improves to  $q^2$ , allowing a space complexity of  $\tilde{O}\left(m\left(\frac{1}{\sqrt{T}} + \frac{m\Delta_E}{T}\right)\right)$ . However, when  $\Delta_V = o(T)$ , this is still weaker than allowed by the  $\Omega\left(\frac{m}{T}(\sqrt{\Delta_V} + \Delta_E)\right)$  lower bound that results from combining the results of [6, 17].

While the aforementioned algorithm is sub-optimal in general, notice that it does match the lower bounds in the extreme case when  $\Delta_V = T$ , and all triangles share a single vertex. On the other hand, when  $\Delta_V$  is smaller, there are more “fully disjoint” triangles in the graph. Consequentially, we can afford to subsample by *vertices*, as now dropping a single vertex cannot lose too large a fraction of our triangles. We may sample vertices uniformly with some probability  $p$ , and deterministically store all edges adjacent to at least one sampled vertex, again counting a triangle whenever we observe an edge  $wu$  closing a sampled pair  $uv, vw$ . Each such triangle will be counted iff the “first” vertex  $v$  of the triangle is sampled, and these may be divided among as few as  $T/\Delta_V$  “heavy” vertices, so  $p$  must be at least  $\Delta_V/T$ . This again turns out to be sufficient, for a space usage of  $\tilde{O}\left(\frac{m\Delta_V}{T}\right)$  (note that any pair of edges sharing an edge also share a vertex, so  $\Delta_E \leq \Delta_V$ , and thus this does not violate the known lower bounds). While this is an improvement on the aforementioned adaptive edge-sampling scheme for small  $\Delta_V$ , it becomes worse once  $\Delta_V > \sqrt{T}$ .

The crucial insight behind our algorithm is to merge the two aforementioned algorithms with a careful choice of parameterization. Specifically, we sample both edges *and* vertices, before counting triangles that we see closing our sampled wedges. Specifically, we sample vertices  $v \in V$  in the graph with probability  $p \in (0, 1]$ , and then “activate” each edge  $e \in E$  with probability  $q \in (0, 1]$ . When an edge  $uv \in E$  arrives in the stream, we store it iff  $uv$  is active *and* at least one of the vertices  $u$  or  $v$  was sampled. We denote by  $S$  the set of all edges stored by the algorithm. Finally, when a closing edge  $wu$  arrives that completes a triangle with edges  $uv, vw$  that were previously added to  $S$ , we check if the vertex  $v$  at the center of the wedge  $uv, vw$  was sampled, and if so we deterministically increment a counter  $\mathbf{C}$ .

Now observe that, for any given triangle  $uvw$ , the probability that  $uvw$  causes  $\mathbf{C}$  to be incremented is exactly  $pq^2$ . Thus, if we output the quantity  $\mathbf{C}/(pq^2)$  at the end of the stream, we obtain an unbiased estimator for the number of triangles in  $G$ .

Notice that when  $p = 1$  our algorithm reduces to the simpler edge-sampling algorithm stated above. At the other extreme, when  $q = 1$  our algorithm reduces to the vertex sampling algorithm. Intuitively, our choice of the parameters  $p$  and  $q$  are subject to the same constraints faced by the aforementioned edge- and vertex-sampling algorithms. Firstly,  $p$

## 11:6 An Optimal Algorithm for Triangle Counting in the Stream

must be at least  $\Delta_V/T$ , otherwise the algorithm could miss a “heavy” vertex. Furthermore, the product  $pq$  must be at least  $\Delta_E/T$ , to avoid missing “heavy” edges, and  $pq^2$  must be at least  $1/T$  to find any triangles at all. Putting these bounds together, it follows that  $q$  must be at least  $\max\left\{\frac{\Delta_E}{\Delta_V}, \frac{1}{\sqrt{\Delta_V}}\right\}$ .

As with all the algorithms discussed so far, this turns out to also be sufficient – we demonstrate that by fixing the sampling parameters<sup>5</sup>

$$p = \frac{\Delta_V}{T}, \quad q \geq \max\left\{\frac{\Delta_E}{\Delta_V}, \frac{1}{\sqrt{\Delta_V}}\right\}$$

we obtain an algorithm using space  $O\left(\frac{m}{T}(\Delta_E + \sqrt{\Delta_V}) \log n\right)$  which yields an  $O(T^2)$  variance estimator. We may therefore obtain a  $(1 \pm \varepsilon)$  multiplicative estimate with probability  $1 - \delta$  by using  $O\left(\frac{1}{\varepsilon^2} \log \frac{1}{\delta}\right)$  copies of this algorithm.

Consequently one obtains an algorithm matching, up to a log factor, the lower bounds of [6, 17], with optimal space usage in terms of  $m, T, \Delta_E, \Delta_V$ .

### 3 The Triangle Counting Algorithm

Let  $G = (V, E)$  be a graph on  $n$  vertices, received as a stream of undirected edges, adversarially ordered. Let  $m$  be the number of edges in the stream. We write the stream as  $\sigma = (\sigma_i)_{i=1}^m$ , with each  $\sigma_i \in E$ . We use  $T$  to refer to the number of triangles in  $G$ ,  $\Delta_E$  to refer to the maximum number of them sharing a single edge, and  $\Delta_V$  the maximum number sharing a single vertex.

► **Remark 1.** As with all streaming triangle counting algorithms, our algorithm will need to be parametrized by statistics of the graph that cannot be known exactly without trivializing the problem – in our case  $T$ ,  $\Delta_E$ , and  $\Delta_V$ . However, it will not be necessary to know these exactly – an upper bound on  $\Delta_E$ ,  $\Delta_V$  and a lower bound on  $T$  will be sufficient. If these bounds are tight up to a constant, the complexity of our algorithm will be unchanged, otherwise replace the parameters  $T$ ,  $\Delta_E$ ,  $\Delta_V$  with the respective upper and lower bounds.

#### 3.1 Description of the Algorithm

We begin by choosing two hash functions  $\mathbf{f} : V \rightarrow \{0, 1\}$  and  $\mathbf{g} : E \rightarrow \{0, 1\}$ , which will serve as our “vertex sampling” and “edge sampling” functions, respectively. We choose  $\mathbf{f}$  to be pair-wise independent.  $\mathbf{g}$  will only be evaluated at most once for each edge, and so we may choose it to be fully independent. We pick the two functions  $\mathbf{f}, \mathbf{g}$  such that

$$\mathbb{E}[\mathbf{f}(v)] = p$$

for each  $v \in V$  and

$$\mathbb{E}[\mathbf{g}(e)] = q$$

for each  $e \in E$ , where  $p, q$  are parameters to be set later. Such a hash function  $\mathbf{f}$  can be generated by taking a two-wise independent function  $\mathbf{h} : V \rightarrow [M]$ , where  $M = \text{poly}(n)$  is a sufficiently large multiple of  $1/p$ , and setting  $\mathbf{f}(v) = 1$  whenever  $\mathbf{h}(v) \leq pM$  (one can construct  $\mathbf{g}$  similarly using a four-wise independent hash function). Such functions can be generated and stored in at most  $O(\log n)$  bits of space [8].

<sup>5</sup> As mentioned earlier,  $\Delta_E \leq \Delta_V$ , while  $\Delta_V \leq T$  holds trivially. Thus  $p, q$  are valid probabilities.

The algorithm will be simple: sample vertices with probability  $p$ , sample incident edges with probability  $q$ . The formal description is given below in Algorithm 1.

■ **Algorithm 1** Triangle Counting Algorithm.

---

```

1: procedure TRIANGLECOUNTING( $p, q$ )
2:    $S \leftarrow \emptyset$ 
3:    $\bar{\mathbf{T}} \leftarrow 0$ 
4:   for each update  $uv$  do
5:     for  $u \in V$  do
6:       if  $\mathbf{f}(u) > 0 \wedge uv, uw \in S$  then
7:          $\bar{\mathbf{T}} += 1/pq^2$ 
8:       end if
9:     end for
10:    if  $\mathbf{g}(uv)(\mathbf{f}(u) + \mathbf{f}(v)) > 0$  then
11:       $S \leftarrow S \cup \{uv\}$ 
12:    end if
13:  end for
14:  return  $\bar{\mathbf{T}}$ .
15: end procedure

```

---

### 3.2 Analysis of the Algorithm

► **Lemma 2.** *This algorithm uses  $O(mpq \log n)$  bits of space.*

**Proof.** Besides an  $O(\log n)$  sized counter and the hash function  $\mathbf{f}$  ( $\mathbf{g}$  is never evaluated more than once for an edge and thus does not need to be stored), the algorithm maintains a set of edges. Each edge will be kept with probability at most  $2pq$  and takes  $O(\log n)$  space to store, so the result follows. ◀

We will write  $T_{uvw}$  for the variable that is 1 if  $uvw$  is a triangle in  $G$  with its edges arriving in the order  $(uv, uw, vw)$ , and 0 otherwise, and so

$$T = \sum_{(u,v,w) \in V^3} T_{uvw}.$$

We will write  $\bar{\mathbf{T}}_{uvw}$  for the random variable that is  $1/pq^2$  if  $T_{uvw} = 1$  and  $\mathbf{f}(u)\mathbf{g}(uv)\mathbf{g}(uw) = 1$ , and 0 otherwise. We will therefore have

$$\bar{\mathbf{T}} = \sum_{(u,v,w) \in V^3} \bar{\mathbf{T}}_{uvw}.$$

► **Lemma 3.**

$$\mathbb{E}[\bar{\mathbf{T}}] = T.$$

## 11:8 An Optimal Algorithm for Triangle Counting in the Stream

**Proof.** For any  $(u, v, w)$ ,  $\mathbf{f}(u)\mathbf{g}(uv)\mathbf{g}(uw) = 1$  with probability  $pq^2$ , so  $\mathbb{E}[\overline{\mathbf{T}}_{uvw}] = T_{uvw}$ . Therefore,

$$\begin{aligned}\mathbb{E}[\overline{\mathbf{T}}] &= \sum_{(u,v,w) \in V^3} \mathbb{E}[\overline{\mathbf{T}}_{uvw}] \\ &= \sum_{(u,v,w) \in V^3} T_{uvw} \\ &= T\end{aligned}$$

► **Lemma 4.**

$$\text{Var}(\overline{\mathbf{T}}) \leq T/pq^2 + T\Delta_E/pq + T\Delta_V/p.$$

**Proof.** Consider any (ordered) pair of triples  $(u, v, w), (x, y, z) \in V^3$  such that  $T_{uvw}T_{xyz} = 1$ . If  $(u, v, w) = (x, y, z)$ ,  $\overline{\mathbf{T}}_{uvw}\overline{\mathbf{T}}_{xyz} = 1/p^2q^4$  with probability  $pq^2$  and 0 otherwise, so

$$\mathbb{E}[\overline{\mathbf{T}}_{uvw}\overline{\mathbf{T}}_{xyz}] = \mathbb{E}[\overline{\mathbf{T}}_{uvw}^2] = 1/pq^2.$$

At most  $T$  such pairs of triples can exist.

Now, if  $|\{uv, uw\} \cap \{xy, xz\}| = 1$ , then  $u = x$  and so  $\overline{\mathbf{T}}_{uvw}\overline{\mathbf{T}}_{xyz} = 1/p^2q^4$  iff  $\mathbf{f}(u) = 1$  and  $\mathbf{g}(e) = 1$  for all  $e$  in the size-3 set  $\{uv, uw, xy, xz\}$ , which happens with probability  $pq^3$ , and so

$$\mathbb{E}[\overline{\mathbf{T}}_{uvw}\overline{\mathbf{T}}_{xyz}] = 1/pq.$$

Each triangle has at most  $\Delta_E$  other triangles it shares an edge with, so there are at most  $T\Delta_E$  such pairs.

If  $\{uv, uw\} \cap \{xy, xz\} = \emptyset$  but  $u = x$ , then  $\overline{\mathbf{T}}_{uvw}\overline{\mathbf{T}}_{xyz} = 1/p^2q^4$  iff  $\mathbf{f}(u) = 1$  and  $\mathbf{g}(e) = 1$  for all  $e$  in the size-4 set  $\{uv, uw, xy, xz\}$ , which happens with probability  $pq^4$ , and so

$$\mathbb{E}[\overline{\mathbf{T}}_{uvw}\overline{\mathbf{T}}_{xyz}] = 1/p.$$

Each triangle has at most  $\Delta_V$  other triangles it shares a vertex with, so there are at most  $T\Delta_V$  such pairs.

Finally, if  $\{u, v, w\} \cap \{x, y, z\} = \emptyset$ , then  $\overline{\mathbf{T}}_{uvw}\overline{\mathbf{T}}_{xyz} = 1/p^2q^4$  iff  $\mathbf{f}(u) = 1$ ,  $\mathbf{f}(x) = 1$ , and  $\mathbf{g}(e) = 1$  for all  $e$  in the size-4 set  $\{uv, uw, xy, xz\}$ , which happens with probability  $p^2q^4$ , and so

$$\mathbb{E}[\overline{\mathbf{T}}_{uvw}\overline{\mathbf{T}}_{xyz}] = 1.$$

At most  $T^2$  such pairs can exist. Therefore,

$$\begin{aligned}\mathbb{E}[\overline{\mathbf{T}}^2] &= \sum_{(u,v,w) \in V^3} \sum_{(x,y,z) \in V^3} \mathbb{E}[\overline{\mathbf{T}}_{uvw}\overline{\mathbf{T}}_{xyz}] \\ &= \sum_{(u,v,w) \in V^3} \mathbb{E}[\overline{\mathbf{T}}_{uvw}^2] + \sum_{(u,v,w) \in V^3} \left( \sum_{\substack{(x,y,z) \in V^3 \\ |\{uv, uw\} \cap \{xy, xz\}|=1}} \mathbb{E}[\overline{\mathbf{T}}_{uvw}\overline{\mathbf{T}}_{xyz}] + \right. \\ &\quad \left. \sum_{\substack{(x,y,z) \in V^3 \\ \{uv, uw\} \cap \{xy, xz\} = \emptyset \\ u=x}} \mathbb{E}[\overline{\mathbf{T}}_{uvw}\overline{\mathbf{T}}_{xyz}] + \sum_{\substack{(x,y,z) \in V^3 \\ \{u, v, w\} \cap \{x, y, z\} = \emptyset}} \mathbb{E}[\overline{\mathbf{T}}_{uvw}\overline{\mathbf{T}}_{xyz}] \right) \\ &\leq T/pq^2 + T\Delta_E/pq + T\Delta_V/p + T^2\end{aligned}$$

by adding the previously established bounds for all four kinds of pair. The lemma then follows from the fact that  $\text{Var}(\mathbf{T}) = \mathbb{E}[\mathbf{T}^2] - \mathbb{E}[\mathbf{T}]^2 = \mathbb{E}[\mathbf{T}^2] - T^2$ . ◀

We may now prove Theorem 1.4. For every  $\varepsilon, \delta \in (0, 1)$ , there is an algorithm for insertion-only graph streams that approximates the number of triangles in a graph  $G$  to  $\varepsilon T$  accuracy with probability  $1 - \delta$ , using

$$O\left(\frac{m}{T} (\Delta_E + \sqrt{\Delta_V}) \log n \frac{\log \frac{1}{\delta}}{\varepsilon^2}\right)$$

bits of space, where  $m$  is the number of edges in  $G$ ,  $T$  the number of triangles,  $\Delta_E$  the maximum number of triangles which share a single edge, and  $\Delta_V$  the maximum number of triangles which share a single vertex.

**Proof.** We may assume  $\Delta_V$  (more specifically, the upper bound we have on it) is at least 1, as otherwise we already know  $G$  to be triangle-free. By Lemmas 3 and 4, we can set  $p = \Delta_V/T$ ,  $q = \max\{\Delta_E/\Delta_V, 1/\sqrt{\Delta_V}\}$  and run Algorithm 1 to obtain an estimator with expectation  $T$  and variance at most  $3T^2$ . (These will give valid probabilities, as  $\Delta_V \leq T$  by definition, and  $\Delta_E$  is at least  $\Delta_V$ , as any pair of triangles sharing an edge also share a vertex.) By Lemma 2, this will take  $O\left(\frac{m}{T} (\Delta_E + \sqrt{\Delta_V}) \log n\right)$  space.

Repeating this  $36/\varepsilon^2$  times and taking the mean will give an estimator with expectation  $T$  and variance at most  $\varepsilon T^2/2$ . We can then repeat *this*  $O(\log \frac{1}{\delta})$  times and take the median to get an estimator that will be within  $\varepsilon T$  of  $T$  with probability  $1 - \delta$ . ◀

## 4 Conclusion

We resolve the complexity of triangle counting in the insertion-only streaming model, in terms of the well-studied natural graph parameters  $m, T, \Delta_E, \Delta_V$ . The results of [15] resolved this problem for the *linear sketching* model, and a result of [20] states that, under certain conditions, turnstile streaming algorithms are equivalent to linear sketches, suggesting that the algorithm of [17] is optimal for turnstile streams as well. However, [18] showed that an insertion-only algorithm of [14] can be converted into a turnstile streaming algorithm provided that, for instance, the length of the stream is reasonably constrained (with the number of insertions and deletions no more than  $O(1)$  times the final size of the graph). It remains open whether this algorithm can be converted into a turnstile algorithm under such constraints, or whether the bounded-stream turnstile complexity of triangle counting is somewhere between insertion-only and linear sketching.

Another natural question is about the choice of parameters – the algorithm of [22] is optimal in terms of  $m, T$ , and  $\Delta_E$ , but not when the parameter  $\Delta_V$  is considered. Are there natural extensions of the parametrization that allow for better results? The results of [17] include a proof of instance-optimality for a restricted subclass of non-adaptive sampling algorithms, but for more general algorithms it is clear that there are at least *unnatural* extensions of the parametrization that help. For instance, if all the edges of a graph are guaranteed to belong to high-degree vertices, but all the triangles belong to low-degree vertices, a simple filtering strategy allows an improvement.

In particular, the lower bound instances of [6, 17] are both sparse graphs, and so cannot be constructed if  $n$  is constrained to be small relative to  $m$  or  $T$ . For the most dense graphs (with  $\Theta(n^2)$  edges and  $\Theta(n^3)$  triangles) our algorithm and the algorithm of [17] are already trivially optimal up to log factors, since they use only  $\text{polylog}(n)$  bits. However, the complexity landscape for more general dense graphs remains open.

## Abstract

Matching demand (riders) to supply (drivers) efficiently is a fundamental problem for ride-hailing platforms who need to match the riders (almost) as soon as the request arrives with only partial knowledge about future ride requests. A myopic approach that computes an optimal matching for current requests ignoring future uncertainty can be highly sub-optimal. In this paper, we consider a two-stage robust optimization framework for this matching problem where future demand uncertainty is modeled using a set of demand scenarios (specified explicitly or implicitly). The goal is to match the current request to drivers (in the first stage) so that the cost of first stage matching and the worst-case cost over all scenarios for the second stage matching is minimized. We show that this two-stage robust matching is NP-hard under both explicit and implicit models of uncertainty. We present constant approximation algorithms for both models of uncertainty under different settings and show they improve significantly over standard greedy approaches.

## 1 Introduction

Matching demand (riders) with supply (drivers) is a fundamental problem for ride-hailing platforms such as Uber, Lyft and DiDi. These platforms need to continually make efficient matching decisions with only partial knowledge of future ride requests. A common approach in practice is batched matching: instead of matching each request sequentially as it arrives, aggregate the requests for a short amount of time (typically one to two minutes) and match the aggregated requests to available drivers in one batch [42, 33, 44]. However, computing this batch matching myopically without considering future requests can lead to a highly sub-optimal outcome for some subsequent drivers and riders.

Motivated by this shortcoming, and by the possibility of using historical data to hedge against future uncertainty, we study a two-stage framework for matching problems where the future demand uncertainty is modeled as a set of scenarios that are specified explicitly or implicitly. The goal is to compute a matching between the available drivers and the first batch of riders such that the total worst-case cost of first stage and second stage matching

is minimized. More specifically, we consider an adversarial model of uncertainty where the adversary observes the first stage matching of our algorithms and presents a worst-case scenario from the list of specified scenarios in the second stage. We focus on the case where the first stage cost is the average weight of the first stage matching, and the second stage cost is the highest edge weight in the second stage matching. This is motivated by the goal of computing a low-cost first stage matching while also minimizing the worst case waiting time for any rider in any second stage. All the results of this paper hold when the first stage cost is the highest edge weight of the first stage matching. We also study several other metrics in the full version. We consider two common models to describe the uncertainty in the second stage: an *explicit* list of all possible scenarios and an *implicit* description of the scenarios using a cardinality constraint. Two-stage robust optimization is a popular model for hedging against uncertainty [8, 19]. Several combinatorial optimization problems have been studied in this model, including Set Cover, Capacity Planning [7, 11] and Facility Location [22]. While online matching is a classical problem in graph theory, two-stage matching problems with uncertainty, have not been studied extensively. We present related work in Section 1.2.

### 1.1 Our Contributions

**Problem definition.** We consider the following *Two-stage Robust Matching Problem*. We are given a set of drivers  $D$ , a set of first stage riders  $R_1$ , a universe of potential second stage riders  $R_2$  and a set of second stage scenarios  $\mathcal{S} \subseteq \mathcal{P}(R_2)$ <sup>1</sup>. We are given a metric distance  $d$  on  $V = R_1 \cup R_2 \cup D$ . The goal is to find a subset of drivers  $D_1 \subseteq D$  ( $|D_1| = |R_1|$ ) to match all the first stage riders  $R_1$  such that the sum of cost of first stage matching and worst-case cost of second stage matching (between  $D \setminus D_1$  and the riders in the second stage scenario) is minimized. More specifically,

$$\min_{D_1 \subseteq D} \left\{ cost_1(D_1, R_1) + \max_{S \in \mathcal{S}} cost_2(D \setminus D_1, S) \right\}.$$

The first-stage decision is denoted  $D_1$  and its cost is  $cost_1(D_1, R_1)$ . Similarly, the second stage cost for scenario  $S$  is denoted  $cost_2(D \setminus D_1, S)$ , and  $\max\{cost_2(D \setminus D_1, S) \mid S \in \mathcal{S}\}$  is the worst-case cost over all possible scenarios. Let  $|R_1| = m$ ,  $|R_2| = n$ . We denote the objective function for a feasible solution  $D_1$  by

$$f(D_1) = cost_1(D_1, R_1) + \max_{S \in \mathcal{S}} cost_2(D \setminus D_1, S).$$

We assume that there are sufficiently many drivers to satisfy both first and second stage demand. Given an optimal first-stage solution  $D_1^*$ , we denote

$$\begin{aligned} OPT_1 &= cost_1(D_1^*, R_1), & OPT_2 &= \max\{cost_2(D \setminus D_1^*, S) \mid S \in \mathcal{S}\}, \\ OPT &= OPT_1 + OPT_2. \end{aligned}$$

We consider the setting where the first stage cost is the average weight of the matching between  $D_1$  and  $R_1$ , and the second stage cost is the bottleneck matching cost between  $D \setminus D_1$  and  $S$ . The bottleneck matching is the matching that minimizes the longest edge in a maximum cardinality matching between  $D \setminus D_1$  and  $S$ . We refer to this variant as the *Two-Stage Robust Matching Bottleneck Problem (TSRMB)*. Formally, let  $M_1$  be the minimum weight perfect matching between  $R_1$  and  $D_1$ , and given a scenario  $S$ , let  $M_2^S$  be

<sup>1</sup>  $\mathcal{P}(R_2)$  is the power set of  $R_2$ , the set of all subsets of  $R_2$ .

■ **Figure 1** Bipartite graph of drivers and riders in our two-stage matching problem.

the bottleneck matching between the scenario  $S$  and the available drivers  $D \setminus D_1$ , then the cost functions for the TSRMB are:

$$\text{cost}_1(D_1, R_1) = \frac{1}{m} \sum_{(i,j) \in M_1} d(i, j), \quad \text{and} \quad \text{cost}_2(D \setminus D_1, S) = \max_{(i,j) \in M_2^S} d(i, j).$$

The difference between the first and second stage metrics is motivated by the fact that the platform has access to the current requests and can exactly compute the cost of the matching. On the other hand, to ensure the robustness of the solution, we require all second stage assignments to have low waiting times by accounting for the maximum wait time in every scenario. We choose the first stage cost to be the average matching weight instead of the total weight for homogeneity reasons, so that first and second stage costs have comparable magnitudes. The bottleneck objective, i.e., finding a subgraph of a certain kind that minimizes the maximum edge cost in the subgraph, has been considered extensively in the literature [21, 16, 17]. While the main body of this paper will focus on studying TSRMB, we note that all our results hold when the first (resp. second) stage cost is equal to the highest edge weight in the first (resp. second) stage matching. In the full version, we study other variants of cost metrics, including a stochastic variant of TSRMB, and the case where both first and second stage costs are simply the total matching weights.

**Hardness.** We show that TSRMB is NP-hard even for two scenarios and NP-hard to approximate within a factor better than 2 for three scenarios. We also show that even when the scenarios are singletons, the problem is NP-hard to approximate within a factor better than 2. Given these hardness results, we focus on approximation algorithms for the TSRMB problem. A natural candidate is the greedy approach that minimizes only the first stage cost without considering the uncertainty in the second stage. However, we show that this myopic approach can be bad as  $\Omega(m) \cdot OPT$  (See Figure 2.)

**Approximations algorithms.** We consider both explicit and implicit models of uncertainty. For the case of explicit model with two scenarios, we give a constant factor approximation algorithm for TSRMB (Theorem 4). We further generalize the ideas of this algorithm to a

■ **Table 1** Summary of our results, where surplus  $\ell = |D| - |R_1| - k$ .

Uncertainty	Approx	Hardness
Explicit (2 scenarios)	5	NP-Hard
Explicit ( $p$ scenarios)	$O(p^{1.59})$	2
Implicit (surplus $\ell = 0$ )	3	-
Implicit ( $\ell < k$ and $k \leq \sqrt{n/2}$ )	17	2

constant approximation for any fixed number of scenarios (Theorem 6). Our approximation does not depend on the number of first stage riders or the size of scenarios but depends on the number of scenarios. The main idea is to reduce the problem with multiple scenarios to an instance with a single *representative scenario* while losing only a small factor. We then solve the single scenario instance (in polynomial time) to get an approximation for our original problem. The challenge in constructing the representative scenario is to find the right trade-off between capturing the demand of all second stage riders and keeping the cost of this scenario close to the optimal cost of the original instance.

For the implicit model of uncertainty, we consider the setting where we are given a universe of second stage riders  $R_2$  and an integer  $k$ , and any subset of size less than  $k$  can be a scenario. Therefore,  $\mathcal{S} = \{S \subset R_2 \text{ s.t. } |S| \leq k\}$ . The scenarios can be exponentially many in  $k$ , which makes even the evaluation of the cost of a feasible solution challenging and not necessarily achievable in polynomial time. Our analysis depends on the imbalance between supply and demand. In fact, when the number of drivers is very large compared to riders, the problem is less interesting in practice. However, it becomes interesting when the supply and demand are comparable. In this case, drivers might need to be shared between different scenarios. This leads us to define the notion of surplus  $\ell = |D| - |R_1| - k$ , which is the maximum number of drivers that we can afford not to use in a solution. As a warm-up, we first show that if the surplus is equal to zero (all the drivers are used), using any scenario as a representative scenario gives a 3-approximation. The problem becomes significantly more challenging even with a small surplus. We show that under a reasonable assumption on the size of scenarios, there is a constant approximation in the regime when the surplus  $\ell$  is smaller than the demand  $k$  (Theorem 9). Our algorithm is based on finding a clustering of drivers and riders that yields a simplified instance of TSRMB which can be solved within a constant factor. We show that we can cluster the riders into a ball (riders close to each others) and a set of *outliers* (riders far from each others) and apply ideas from the explicit scenario analysis. Finally, since the number of scenarios can be exponential, we construct a set of a polynomial number of proxy scenarios on which we evaluate any feasible solution within a constant approximation. Table 1 summarizes our results. Due to space constraints, we defer some of the proofs to the appendix.

## 1.2 Related Work

*Online bipartite matching.* Finding a maximum cardinality bipartite matching has received a considerable amount of attention over the years. Online matching was first studied by Karp *et al.* [27] in the adversarial model. Since then, many online variants have been studied [37]. This includes AdWords [4, 5, 38], vertex-weighted [1, 6], edge-weighted [20, 31], stochastic matching [12, 35, 39, 13], random vertex arrival [18, 26, 34, 23], and batch arrivals [32, 14, 44]. In the *online bipartite metric matching* variant, servers and clients correspond to points from a metric space, and the objective is to find the minimum weight maximum cardinality

matching. Khullet et al. [29] and Kalyanasundaram and Pruhs [24] provided deterministic algorithms in the adversarial model. In the random arrival model, Meyerson, et al. [40] and Bansal et al. [2] provided poly-logarithmic competitive algorithms. Recently, Raghvendra [41] presented a  $O(\log n)$ -competitive algorithm.

*Two-stage stochastic combinatorial optimization.* Within two-stage stochastic optimization, matching has been studied under various models. Kong and Schaefer [30] and Escoffier et al. [9] studied the stochastic two-stage maximum matching problem. Katriel et al. [28] studied the two-stage stochastic minimum weight maximum matching. Feng and Niazadeh [14] study  $K$ -stage variants of vertex weighted bipartite b-matching and AdWords problems, where online vertices arrive in  $K$  batches. More recently, Feng et al. [15] initiate the study and present online competitive algorithms for vertex-weighted two-stage stochastic matching as well as two-stage joint matching and pricing.

*Two-stage robust combinatorial optimization.* Within two-stage robust optimization, matchings have not been studied extensively. Matuschke et al. proposed a two-stage robust model for minimum weight matching with recourse [36]. Our model for TSRMB is different in three main aspects: i) We use a general class of uncertainty sets to describe the second stage scenarios while in [36] the only information given is the number of second stage vertices. ii) We do not allow any recourse and our first stage matching is irrevocable. iii) Our second stage cost is the bottleneck weight instead of the total weight.

## 2 Preliminaries

### 2.1 NP-hardness

We show that TSRMB is NP-hard under both the implicit and explicit models. In the explicit model, it is NP-hard even for two scenarios and NP-hard to approximate within a factor better than 2 even for three scenarios.

In the explicit model with a polynomial number of scenarios, it is clear that the problem is in NP. However, in the implicit model, the problem can be described with a polynomial size input, but it is not clear that we can compute the total cost in polynomial time since there could be exponentially many scenarios. We show that it is NP-hard to approximate TSRMB in the implicit model within a factor better than 2 even when  $k = 1$ . The proof is presented in Appendix A.

► **Theorem 1.** *In the explicit model of uncertainty, TSRMB is NP-hard even with two scenarios. Furthermore, when the number of scenarios is  $\geq 3$ , there is no  $(2-\epsilon)$ -approximation algorithm for any fixed  $\epsilon > 0$ , unless  $P = NP$ . In the implicit model of uncertainty, even when  $k = 1$ , there is no  $(2-\epsilon)$ -approximation algorithm for TSRMB for any fixed  $\epsilon > 0$ , unless  $P = NP$ .*

### 2.2 Greedy Approach

A natural greedy approach is to choose the optimal matching for the first stage riders  $R_1$  without considering the second stage uncertainty. It can lead to a solution with a total cost that scales linearly with  $m$  (cardinality of  $R_1$ ) while  $OPT$  is a constant, even with one scenario. Consider the line example in Figure 2. We have  $m$  first stage riders and  $m + 1$  drivers alternating on a line with distances 1 and  $1 - \epsilon$ . There is one second stage rider at the right endpoint of the line. The greedy matching minimizes the first stage cost and incurs a total cost of  $(2 - \epsilon)(m + 1)$ , while the optimal cost is equal to 2. Therefore any attempt to have a good approximation needs to consider the second stage riders.

■ **Figure 2** Riders in first stage are depicted as black dots and drivers as black triangles. The second stage rider is depicted as a blue cross.

► **Lemma 2.** *The cost of the Greedy algorithm can be  $\Omega(m) \cdot OPT$ .*

### 2.3 Single Scenario

The *deterministic* version of the TSRMB problem, i.e., when there is only a single scenario in the second stage, can be solved exactly in polynomial time. This is a simple preliminary result which we need for the general case. Denote  $S$  a single second stage scenario. The instance  $(R_1, S, D)$  of TSRMB is then simply given by

$$\min_{D_1 \subset D} \left\{ cost_1(D_1, R_1) + cost_2(D \setminus D_1, S) \right\}.$$

Since the second stage problem is a bottleneck problem [21], the value of the optimal second stage cost  $w$  is one of the edge weights between  $D$  and  $S$ . We iterate over all possible values of  $w$  (at most  $|S| \cdot |D|$  values), delete all edges between  $R_2$  and  $D$  with weights strictly higher than  $w$  and set the weight of the remaining edges between  $S$  and  $D$  to zero. This reduces the problem to finding a minimum weight maximum cardinality matching. We can also use binary search to iterate over the edge weights. We present the details of this algorithm below and refer to it as *TSRMB-1-Scenario* in the rest of this paper.

We define the bottleneck graph of  $w$  to be  $BOTTLENECKG(w) = (R_1 \cup S \cup D, E_1 \cup E_2)$  where  $E_2 = \{(i, j) \in D \times S, d(i, j) \leq w\}$  and  $E_1 = \{(i, j) \in D \times R_1\}$ . Furthermore, we assume that there are  $q$  edges  $\{e_1, \dots, e_q\}$  between  $S$  and  $D$  with weights  $w_1 \leq w_2 \leq \dots \leq w_q$ .

■ **Algorithm 1**  $TSRMB-1-Scenario(R_1, S, D)$ .

**Input:** First stage riders  $R_1$ , scenario  $S$  and drivers  $D$ .

**Output:** First stage decision  $D_1$ .

```

1: for  $i \in \{1, \dots, q\}$  do
2:    $G_i := BOTTLENECKG(w_i)$ .
3:   Set all weights between  $D$  and  $S$  in  $G_i$  to be 0.
4:    $M_i :=$  minimum weight maximum cardinality matching on  $G_i$ .
5:   if  $R_1 \cup S$  is not completely matched in  $M_i$  then
6:     output certificate of failure.
7:   else
8:      $D_1^i :=$  first stage drivers in  $M_i$ .
9:   end if
10: end for
11: return  $D_1 = \arg \min_{D_1^i: 1 \leq i \leq q} \left\{ cost_1(D_1^i, R_1) + cost_2(D \setminus D_1^i, S) \right\}$ .
```

Note that the arg min in the last step of Algorithm 1 is only taken over values of  $i$  for which there was no certificate of failure.

► **Lemma 3.** *TSRMB-1-Scenario gives an optimal solution for the single scenario case.*

**Proof of Lemma 3.** Let  $OPT_1$  and  $OPT_2$  be the first and second stage cost of an optimal solution, and  $i \in \{1, \dots, q\}$  such that  $w_i = OPT_2$ . In this case,  $G_i$  contains all the edges of this optimal solution. By setting all the edges in  $E_2$  to 0, we are able to compute a minimum weight maximum cardinality matching between  $R_1 \cup S$  and  $D$  that matches both  $R_1$  and  $S$  and minimizes the weight of the edges matching  $R_1$ . The first stage cost of this matching is less than  $OPT_1$ , the second stage cost is clearly less than  $OPT_2$  because we only allowed edges with weight less than  $OPT_2$  in  $G_i$ . ◀

We also observe that we can use binary search in Algorithm 1 to iterate over the edge weights. For an iteration  $i$ , a failure to find a minimum weight maximum cardinality matching on  $G_i$  that matches both  $R_1$  and  $S$  implies that we need to try an edge weight higher than  $w_i$ . On the other hand, if  $M_i$  matches  $R_1$  and  $S$  such that  $D_1^i$  gives a smaller total cost, then the optimal bottleneck value is lower than  $w_i$ .

### 3 Explicit Scenarios

#### 3.1 Two scenarios

Our main contribution in this section is a constant approximation algorithm for TSRMB with two scenarios. Our analysis shows that we can reduce the problem to an instance with a single representative scenario by losing a small factor. We then use TSRMB-1-Scenario to solve the single representative scenario case.

Consider two scenarios  $\mathcal{S} = \{S_1, S_2\}$ . First, we can assume without loss of generality that we know the exact value of  $OPT_2$  which corresponds to one of the edges connecting second stage riders  $R_2$  to drivers  $D$  (we can iterate over all the weights of second stage edges). We construct a representative scenario that serves as a proxy for  $S_1$  and  $S_2$  as follows. In the second stage, if a pair of riders  $i \in S_1$  and  $j \in S_2$  is served by the same driver in the optimal solution, then they should be close to each other. Therefore, we can consider a single representative rider for each such pair. While it is not easy to guess all such pairs, we can approximately compute the representative riders by solving a maximum matching on  $S_1 \cup S_2$  with edges less than  $2OPT_2$ . More formally, let  $G_I$  be the induced bipartite subgraph of  $G$  on  $S_1 \cup S_2$  containing only edges between  $S_1$  and  $S_2$  with weight less than or equal to  $2OPT_2$ . We compute a maximum cardinality matching  $M$  between  $S_1$  and  $S_2$  in  $G_I$ , and construct a representative scenario containing  $S_1$  as well as the unmatched riders of  $S_2$ . We solve the single scenario problem on this representative scenario and return its optimal first stage solution. We show in Theorem 4 that this solution leads to a 5-approximation.

■ **Algorithm 2** Two explicit scenarios.

---

**Input:** First stage riders  $R_1$ , two scenarios  $S_1$  and  $S_2$ , drivers  $D$  and value of  $OPT_2$ .

**Output:** First stage decision  $D_1$ .

- 1: Let  $G_I$  be the induced subgraph of  $G$  on  $S_1 \cup S_2$  with only the edges between  $S_1$  and  $S_2$  of weights less than  $2OPT_2$ .
  - 2: Set  $M :=$  maximum cardinality matching between  $S_1$  and  $S_2$  in  $G_I$ .
  - 3: Set  $S_2^{Match} := \{r \in S_2 \mid \exists s \in S_1 \text{ s.t. } (s, r) \in M\}$  and  $S_2^{Unmatch} = S_2 \setminus S_2^{Match}$ .
  - 4: **return**  $D_1 :=$  TSRMB-1-Scenario( $R_1, S_1 \cup S_2^{Unmatch}, D$ ).
- 

▶ **Theorem 4.** *Algorithm 2 yields a solution with total cost less than  $OPT_1 + 5OPT_2$  for TSRMB with 2 scenarios.*

The proof of Theorem 4 relies on the following structural lemma where we show that the set  $D_1$  returned by Algorithm 2 yields a total cost at most  $(OPT_1 + 3OPT_2)$  when evaluated only on the single representative scenario  $S_1 \cup S_2^{Unmatch}$ .

► **Lemma 5.** *Let  $D_1$  be the set of first stage drivers returned by Algorithm 2. Then  $cost_1(D_1, R_1) + cost_2(D \setminus D_1, S_1 \cup S_2^{Unmatch}) \leq OPT_1 + 3OPT_2$ .*

**Proof.** It is sufficient to show the existence of a matching  $M_a$  between  $R_1 \cup S_1 \cup S_2^{Unmatch}$  and  $D$  with a total cost less than  $OPT_1 + 3OPT_2$ . This would imply that the optimal solution  $D_1$  of  $\text{TSRMB-1-Scenario}(R_1, S_1 \cup S_2^{Unmatch}, D)$  has a total cost less than  $OPT_1 + 3OPT_2$  and concludes the proof. We show the existence of  $M_a$  by construction.

**Step 1.** We first match  $R_1$  with their mates in the optimal solution of TSRMB. Hence, the first stage cost of our constructed matching  $M_a$  is  $OPT_1$ .

**Step 2.** Now, we focus on  $S_2^{Unmatch}$ . Let  $S_2^{Unmatch} = S_{12} \cup S_{22}$  be a partition of  $S_2^{Unmatch}$  where  $S_{12}$  contains riders with a distance less than  $2OPT_2$  from  $S_1$  and  $S_{22}$  contains riders with a distance strictly bigger than  $2OPT_2$  from  $S_1$ , where the distance from a set is the minimum distance to any element of the set. A rider in  $S_{22}$  cannot share any driver with a rider from  $S_1$  in the optimal solution of TSRMB, because otherwise, the distance between these riders will be less than  $2OPT_2$  by using the triangle inequality. Therefore we can match  $S_{22}$  to their mates in the optimal solution and add them to  $M_a$ , without using the optimal drivers of  $S_1$ . We pay less than  $OPT_2$  for matching  $S_{22}$ .

**Step 3.** We still need to simultaneously match riders in  $S_1$  and  $S_{12}$  to finish the construction of  $M_a$ . Notice that some riders in  $S_{12}$  might share their optimal drivers with riders in  $S_1$ . We can assume without loss of generality that all riders in  $S_{12}$  share their optimal drivers with  $S_1$  (otherwise we can match them to their optimal drivers without affecting  $S_1$ ). Denote  $S_{12} = \{r_1, \dots, r_q\}$  and  $S_1 = \{s_1, \dots, s_k\}$ . For each  $i \in [q]$  let's say  $s_i \in S_1$  is the rider that shares its optimal driver with  $r_i$ . We show that  $q \leq |M|$ . In fact, every rider in  $S_{12}$  shares its optimal driver with a different rider in  $S_1$ , and is therefore within a distance  $2OPT_2$  from  $S_1$  by the triangle inequality. But since  $S_{12}$  is not covered by the maximum cardinality matching  $M$ , this implies by the maximality of  $M$  that there are  $q$  other riders from  $S_2^{Match}$  that are covered by  $M$ . Hence  $q \leq |M|$ . Finally, let  $\{t_1, \dots, t_q\} \subset S_2^{Match}$  be the mates of  $\{s_1, \dots, s_q\}$  in  $M$ , i.e.,  $(s_i, t_i) \in M$  for all  $i \in [q]$ . Recall that  $d(s_i, t_i) \leq 2OPT_2$  for all  $i \in [q]$ . In what follows, we describe how to match  $S_{12}$  and  $S_1$ :

- (i) For  $i \in [q]$ , we match  $r_i$  to its optimal driver and  $s_i$  to the optimal driver of  $t_i$ . This is possible because the optimal driver of  $t_i$  cannot be the same as the optimal driver of  $r_i$  since both  $r_i$  and  $t_i$  are part of the same scenario  $S_2$ . Therefore, we pay a cost  $OPT_2$  for the riders  $r_i$  and a cost  $3OPT_2$  (follows from the triangle inequality) for the riders  $s_i$  where  $i \in [q]$ .
- (ii) We still need to match  $\{s_{q+1}, \dots, s_k\}$ . Consider a rider  $s_j$  with  $j \in \{q+1, \dots, k\}$ . If the optimal driver of  $s_j$  is not shared with any  $t_i \in \{t_1, \dots, t_q\}$ , then this optimal driver is still available and can be matched to  $s_j$  with a cost less than  $OPT_2$ . If the optimal driver of  $s_j$  is shared with some  $t_i \in \{t_1, \dots, t_q\}$ , then  $s_j$  is also covered by  $M$ . Otherwise  $M$  can be augmented by deleting  $(s_i, t_i)$  and adding  $(r_i, s_i)$  and  $(s_j, t_i)$ . Therefore  $s_j$  is covered by  $M$  and has a mate  $\tilde{t}_j \in S_2^{Match} \setminus \{t_1, \dots, t_q\}$ . Furthermore, the driver assigned to  $\tilde{t}_j$  is still available. We can then match  $s_j$  to the optimal driver of  $\tilde{t}_j$ . Similarly if the optimal driver of some  $s_{j'} \in \{s_{q+1}, \dots, s_k\} \setminus \{s_j\}$  is shared with  $\tilde{t}_j$ , then  $s_{j'}$  is covered by  $M$ . Otherwise  $(r_i, s_i, t_i, s_j, \tilde{t}_j, s_{j'})$  is an augmenting path in  $M$ . Therefore  $s_{j'}$  has a mate in  $M$  and we can match  $s_{j'}$  to the optimal driver of its

mate. We keep extending these augmenting paths until all the riders in  $\{s_{q+1}, \dots, s_k\}$  are matched. Furthermore, the augmenting paths  $(r_i, s_i, t_i, s_j, \tilde{t}_j, s_{j'} \dots)$  starting from two different riders  $r_i \in S_{12}$  are vertex disjoint. This ensures that every driver is used at most once. Again, by the triangle inequality, the edges that match  $\{s_{q+1}, \dots, s_k\}$  in our solution have weights less than  $3OPT_2$ .

Putting it all together, we have constructed a matching  $M_a$  where the first stage cost is exactly  $OPT_1$  and the second-stage cost is less than  $3OPT_2$  since the edges used for matching  $S_1 \cup S_2^{Unmatch}$  in  $M_a$  have a weight less than  $3OPT_2$ . Therefore, the total cost of  $M_a$  is less than  $OPT_1 + 3OPT_2$ . ◀

**Proof of Theorem 4.** Let  $D_1$  be the drivers returned by Algorithm 2. Lemma 5 implies

$$cost_1(D_1, R_1) + cost_2(D \setminus D_1, S_1) \leq OPT_1 + 3OPT_2 \quad (1)$$

and

$$cost_1(D_1, R_1) + cost_2(D \setminus D_1, S_2^{Unmatch}) \leq OPT_1 + 3OPT_2.$$

We have  $S_2 = S_2^{Match} \cup S_2^{Unmatch}$ . If the scenario  $S_2$  is realized, we use the drivers that were assigned to  $S_1$  in the matching constructed in Lemma 5 to match  $S_2^{Match}$ . This is possible with edges of weights less than  $cost_2(D \setminus D_1, S_1) + 2OPT_2$  because  $S_2^{Match}$  is matched to  $S_1$  with edges of weight less than  $2OPT_2$ . Hence,

$$cost_2(D \setminus D_1, S_2) \leq \max \{ cost_2(D \setminus D_1, S_2^{Unmatch}), cost_2(D \setminus D_1, S_1) + 2OPT_2 \},$$

and therefore

$$cost_1(D_1, R_1) + cost_2(D \setminus D_1, S_2) \leq OPT_1 + 5OPT_2. \quad (2)$$

From (1) and (2),  $cost_1(D_1, R_1) + \max_{S \in \{S_1, S_2\}} cost_2(D \setminus D_1, S) \leq OPT_1 + 5OPT_2$ . ◀

■ **Algorithm 3**  $p$  explicit scenarios.

**Input:** First-stage riders  $R_1$ , scenarios  $\{S_1, S_2, \dots, S_p\}$ , drivers  $D$  and value of  $OPT_2$ .

**Output:** First stage decision  $D_1$ .

- 1: Initialize  $\hat{S}_j := S_j$  for  $j = 1, \dots, p$ .
- 2: **for**  $i = 1, \dots, \log_2 p$  **do**
- 3:     **for**  $j = 1, 2, \dots, \frac{p}{2^i}$  **do**
- 4:          $\sigma(j) = j + \frac{p}{2^i}$
- 5:          $M_j :=$  maximum cardinality matching between  $\hat{S}_j$  and  $\hat{S}_{\sigma(j)}$  with edges of weight less than  $2 \cdot 3^{i-1} \cdot OPT_2$ .
- 6:          $\hat{S}_{\sigma(j)}^{Match} := \{r \in \hat{S}_{\sigma(j)} \mid \exists s \in \hat{S}_j \text{ s.t. } (s, r) \in M_j\}$ .
- 7:          $\hat{S}_{\sigma(j)}^{Unmatch} := \hat{S}_{\sigma(j)} \setminus \hat{S}_{\sigma(j)}^{Match}$
- 8:          $\hat{S}_j = \hat{S}_j \cup \hat{S}_{\sigma(j)}^{Unmatch}$ .
- 9:     **end for**
- 10: **end for**
- 11: **return**  $D_1 := \text{TSRMB-1-Scenario}(R_1, \hat{S}_1, D)$ .

### 3.2 Constant number of scenarios

We now consider the case of explicit list of  $p$  scenarios, i.e.,  $\mathcal{S} = \{S_1, S_2, \dots, S_p\}$ . Building upon the ideas from Algorithm 2, we present a  $O(p^{1.59})$ -approximation in this case. The idea is to construct the representative scenario recursively by processing pairs of “scenarios” at each step. Hence, we need  $O(\log_2 p)$  iterations to reduce the problem to an instance of a single scenario. At each iteration, we show that we only lose a multiplicative factor of 3 so that the final approximation ratio is  $O(3^{\log_2 p}) = O(p^{1.59})$ . We present details in Algorithm 3.

The approximation guarantee of our algorithm grows sub-quadratically with  $p$  and it is an interesting question if there exists an approximation that does not depend on the number of scenarios.

► **Theorem 6.** *Algorithm 3 yields a solution with total cost of  $O(p^{1.59}) \cdot OPT$  for TSRMB with an explicit list of  $p$  scenarios.*

**Proof of Theorem 6.** The algorithm reduces the number of considered “scenarios” by half in every iteration, until only one scenario remains. In iteration  $i$ , we have  $\frac{p}{2^{i-1}}$  scenarios that we aggregate in  $\frac{p}{2^i}$  pairs, namely  $(\hat{S}_j, \hat{S}_{\sigma(j)})$  for  $j \in \{1, 2, \dots, \frac{p}{2^i}\}$ . For each pair, we construct a single representative scenario which plays the role of the new  $\hat{S}_j$  at the start of the next iteration  $i + 1$ .

▷ **Claim.** There exists a first stage decision  $D_1^*$ , such that at every iteration  $i \in \{1, \dots, \log_2 p\}$ , we have for all  $j \in \{1, 2, \dots, \frac{p}{2^i}\}$ :

- (i)  $R_1$  can be matched to  $D_1^*$  with a first stage cost of  $OPT_1$ .
- (ii)  $\hat{S}_j \cup \hat{S}_{\sigma(j)}^{Unmatch}$  can be matched to  $D \setminus D_1^*$  with a second stage cost less than  $3^i \cdot OPT_2$ .
- (iii) There exists a matching between  $\hat{S}_{\sigma(j)}^{Match}$  and  $\hat{S}_j$  with edge weights less than  $2 \cdot 3^{i-1} \cdot OPT_2$ .

Proof of the claim. Statement (iii) follows from the definition of  $\hat{S}_{\sigma(j)}^{Match}$  in Algorithm 3. Let's show (i) and (ii) by induction over  $i$ .

- **Initialization:** for  $i = 1$ , let's take any two scenarios  $\hat{S}_j = S_j$  and  $\hat{S}_{\sigma(j)} = S_{\sigma(j)}$ . We know that these two scenarios can be matched to drivers of the optimal solution in the original problem with a cost less than  $OPT_2$ . In the proof of Lemma 5, we show that if we use the optimal first stage decision  $D_1^*$  of the original problem, then we can match  $\hat{S}_j$  and  $\hat{S}_{\sigma(j)}^{Unmatch}$  simultaneously to  $D \setminus D_1^*$  with a cost less than  $3OPT_2$ .
- **Maintenance.** Assume the claim is true for all values less than  $i \leq \log_2 p - 1$ . We show it is true for  $i + 1$ . Since the claim is true for iteration  $i$ , we know that at the start of iteration  $i + 1$ , for  $j \in \{1, \dots, \frac{p}{2^i}\}$ ,  $\hat{S}_j$  can be matched to  $D \setminus D_1^*$  with a cost less than  $3^i \cdot OPT_2$ . We can therefore consider a new TSRMB problem with  $\frac{p}{2^i}$  scenarios, where using  $D_1^*$  as a first stage decision ensures a second stage optimal value less than  $\widehat{OPT}_2 = 3^i \cdot OPT_2$ . By the proof of Lemma 5, and by using  $D_1^*$  as a first stage decision in this problem, we ensure that for  $j \in \{1, \dots, \frac{p}{2^{i+1}}\}$ ,  $\hat{S}_j$  and  $\hat{S}_{\sigma(j)}^{Unmatch}$  can be simultaneously matched to  $D \setminus D_1^*$  with a cost less than  $3\widehat{OPT}_2 = 3^{i+1} \cdot OPT_2$ . ◁

Our claim implies that in the last iteration  $i = \log_2 p$ :

- $R_1$  can be matched to  $D_1^*$  with a first stage cost of  $OPT_1$ .
- $\hat{S}_1$  can be matched to  $D \setminus D_1^*$  with a second stage cost less than  $3^{\log_2 p} \cdot OPT_2$ .

Computing the single scenario solution for  $\hat{S}_1$  will therefore yield a first stage decision  $D_1$  that gives a total cost less than  $OPT_1 + 3^{\log_2 p} \cdot OPT_2$  when the second stage is evaluated on the scenario  $\hat{S}_1$ . We now bound the cost of  $D_1$  on the original scenarios  $\{S_1, \dots, S_p\}$ . Consider a scenario  $S \in \{S_1, \dots, S_p\}$ . The riders in  $S \cap \hat{S}_1$  can be matched to some drivers

in  $D \setminus D_1$  with a cost less than  $OPT_1 + 3^{\log_2 p} \cdot OPT_2$ . As for other riders of  $S \setminus \hat{S}_1$ , they are not part of  $\hat{S}_1$  because they have been matched and deleted at some iteration  $i < \log_2 p$ . Consider riders  $r$  in  $S \setminus \hat{S}_1$  that were matched and deleted from a representative scenario at some iteration, then by statement (iii) in our claim, each  $r$  can be connected to a different rider in  $\hat{S}_1 \setminus (\hat{S}_1 \cap S)$  within a path of length at most

$$\sum_{t=1}^{\log_2 p} 2 \cdot 3^{t-1} \cdot OPT_2 = (3^{\log_2 p} - 1) \cdot OPT_2.$$

We know that  $R_1$  and  $\hat{S}_1$  can be matched respectively to  $D_1$  and  $D \setminus D_1$  with a total cost less than  $OPT_1 + 3^{\log_2 p} \cdot OPT_2$ . Therefore, we can match  $R_1$  and  $S$  respectively to  $D_1$  and  $D \setminus D_1$  with a total cost less than

$$OPT_1 + 3^{\log_2 p} \cdot OPT_2 + (3^{\log_2 p} - 1) \cdot OPT_2 = O(3^{\log_2 p}) \cdot OPT \simeq O(p^{1.59}) \cdot OPT.$$

Therefore, the worst-case total cost of the solution returned by Algorithm 3 is  $O(p^{1.59}) \cdot OPT$ . ◀

## 4 Implicit Scenarios

Consider an implicit model of scenarios  $\mathcal{S} = \{S \subset R_2 \text{ s.t. } |S| \leq k\}$ . While this model is widely used, it poses a challenge because the number of scenarios can be exponential. Therefore, even computing the worst-case second stage cost, for a given first stage solution, might not be possible in polynomial time and we can no longer assume that we can guess  $OPT_2$ . Note that the worst-case scenarios have size exactly  $k$ . Our analysis for this model depends on the balance between supply (drivers) and demand (riders). We define the surplus  $\ell$  as the excess in the number of available drivers for matching first-stage riders and a second-stage scenario:  $\ell = |D| - |R_1| - k$ . As a warm-up, we study the case of no surplus ( $\ell = 0$ ). Then, we address the more general case with a small surplus of drivers.

### 4.1 Warm-up: no surplus

When the number of drivers equals the number of first stage riders plus the size of scenarios (i.e.,  $\ell = 0$ ), we show a 3-approximation by simply solving a single scenario TSRMB with any of the scenarios. In fact, since  $\ell = 0$ , all scenarios are matched to the same set of drivers in the optimal solution. Hence, between any two scenarios, there exists a matching where all edge weights are less than  $2OPT_2$ . So by solving TSRMB with only one of these scenarios, we can recover a solution and bound the cost of the other scenarios within  $OPT_1 + 3OPT_2$  using the triangle inequality. The algorithm and proof are presented below.

■ **Algorithm 4** Implicit scenarios with no surplus.

---

**Input:** First stage riders  $R_1$ , second stage riders  $R_2$ , size  $k$  and drivers  $D$ .

**Output:** First stage decision  $D_1$ .

- 1:  $S_1 :=$  a second stage scenario of size  $k$ .
  - 2:  $D_1 :=$  TSRMB-1-Scenario( $R_1, S_1, D$ ).
  - 3: **return**  $D_1$ .
- 

► **Lemma 7.** *Algorithm 4 yields a solution with total cost less than  $OPT_1 + 3OPT_2$  for TSRMB with implicit scenarios and no surplus.*

## 12:12 Matching Drivers to Riders: A Two-Stage Robust Approach

**Proof of Lemma 7.** Let  $OPT_1$  and  $OPT_2$  be the first and second stage cost of the optimal solution. Let  $f(D_1)$  be the total cost of the solution returned by the algorithm. We claim that  $f(D_1) \leq OPT_1 + 3OPT_2$ . It is clear that  $cost_1(D_1, R_1) + cost_2(D \setminus D_1, S_1) \leq OPT_1 + OPT_2$ . Let  $S \in \mathcal{S}$  be another scenario. Because  $|D| = |R_1| + k$ , the optimal solution uses exactly the same  $k$  drivers to match all the second stage scenarios. This implies that we can use the triangular inequality to find a matching between  $S$  and  $S_1$  of bottleneck cost less than  $2OPT_2$ . Hence for any scenario  $S$ ,

$$\begin{aligned} cost_1(D_1, R_1) + cost_2(D \setminus D_1, S) &\leq cost_1(D_1, R_1) + cost_2(D \setminus D_1, S_1) + 2OPT_2 \\ &\leq OPT_1 + 3OPT_2. \end{aligned} \quad \blacktriangleleft$$

If the surplus is strictly greater than 0, the above procedure can have an approximation ratio of  $\Omega(m)$ . Consider the example in Figure 3, with  $k = 1$  and two second stage riders. The single scenario solution for  $S_1$  uses the optimal second stage driver of  $S_2$ . Hence, if  $S_2$  is realized, the cost of matching  $S_2$  to the closest available driver is  $\Omega(m)$ . Similarly, the single scenario problem for  $S_2$  yields a  $\Omega(m)$  cost for  $S_1$ .

■ **Figure 3** First stage riders are depicted as black dots and drivers as black triangles. The two second stage riders are depicted as blue crosses. Second stage optimum are depicted as solid green edges.  $\mathcal{S} = \{S_1, S_2\}$ ,  $k = 1$  and  $\ell = 1$ .

### 4.2 Small surplus

The TSRMB problem becomes challenging even with a unit surplus. Motivated by this, we focus on the case of a small surplus  $\ell$ . In particular, we assume that  $\ell < k$ , i.e., the excess in the total available drivers is smaller than the size of any scenario. We present a constant approximation algorithm in this regime for the implicit model of uncertainty where the size of scenarios is relatively small with respect to the size of the universe ( $k = O(\sqrt{n})$ ). This technical assumption is needed for our analysis but it is not too restrictive and still captures the regime where the number of scenarios can be exponential. Our algorithm attempts to cluster the second stage riders in different groups (a *ball* and a set of *outliers*) in order to reduce the number of possible worst-case configurations. We then solve a sequence of instances with representative riders from each group. In what follows, we present our construction for these groups of riders.

**Our construction.** First, we show that many riders are contained in a ball with radius  $3OPT_2$ . The center of this ball,  $\delta$ , can be found by selecting the driver with the least maximum distance to its closest  $k$  second-stage riders, i.e.,

$$\delta = \arg \min_{\delta' \in D} \max_{r \in R_k(\delta')} d(\delta', r), \quad (3)$$

where  $R_k(\delta')$  is the set of the  $k$  closest second stage riders to  $\delta'$ . Formally, we have the following lemma. We present the proof in Appendix B.

► **Lemma 8.** *Suppose  $k \leq \sqrt{\frac{n}{2}}$  and  $\ell < k$  and let  $\delta$  be the driver given by (3). Then, the ball  $\mathcal{B}$  centered at  $\delta$  with radius  $3OPT_2$  contains at least  $n - \ell$  second stage riders. Moreover, the distance between any of these riders and any rider in  $R_k(\delta)$  is less than  $4OPT_2$ .*

Now, we focus on the rest of second stage riders. We say that a rider  $r \in R_2$  is an *outlier* if  $d(\delta, r) > 3OPT_2$ . Denote  $\{o_1, o_2, \dots, o_\ell\}$  the farthest  $\ell$  riders from  $\delta$  with  $d(\delta, o_1) \geq d(\delta, o_2) \geq \dots \geq d(\delta, o_\ell)$ . By Lemma 8, the  $n - \ell$  riders in  $\mathcal{B}$  are not outliers and the only potential outliers can be in  $\{o_1, o_2, \dots, o_\ell\}$ . Let  $j^*$  be the threshold such that  $o_1, o_2, \dots, o_{j^*}$  are outliers and  $o_{j^*+1}, \dots, o_\ell$  are not, with the convention that  $j^* = 0$  if there is no outlier. There are  $\ell + 1$  possible values for  $j^*$ . We call each of these possibilities a *configuration*. For  $j = 0, \dots, \ell$ , let  $C_j$  be the configuration corresponding to threshold candidate  $j$ .  $C_0$  is the configuration where there is no outlier and  $C_{j^*}$  is the correct configuration.

■ **Algorithm 5** Implicit scenarios with small surplus and  $k \leq \sqrt{\frac{n}{2}}$ .

---

**Input:** First stage riders  $R_1$ , second stage riders  $R_2$ , size  $k$  and drivers  $D$ .

**Output:** First stage decision  $D_1$ .

- 1: Set  $\delta :=$  driver given by (3).
  - 2: Set  $S_1 :=$  the closest  $k$  second stage riders to  $\delta$ .
  - 3: Set  $S_2 := \{o_1, \dots, o_\ell\}$  the farthest  $\ell$  second stage riders from  $\delta$  ( $o_1$  being the farthest).
  - 4: **for**  $j = 0, \dots, \ell$  **do**
  - 5:      $D_1(j) :=$  TSRMB-1-Scenario( $R_1, S_1 \cup \{o_1 \dots o_j\}, D$ ).
  - 6: **end for**
  - 7: **return**  $D_1 = \arg \min_{D_1(j): j \in \{0, \dots, \ell\}} cost_1(D_1(j), R_1) + \max_{S \in \{S_1, S_2\}} cost_2(D \setminus D_1(j), S)$ .
- 

Recall that  $R_k(\delta)$  are the closest  $k$  second-stage riders to  $\delta$ . For the sake of simplicity, we denote  $S_1 = R_k(\delta)$  and  $S_2 = \{o_1 \dots o_\ell\}$ .  $S_2$  is a feasible scenario since  $\ell < k$ . For every configuration  $C_j$ , we form a representative scenario using  $S_1$  and  $\{o_1 \dots o_j\}$ . We solve TSRMB with this single representative scenario  $S_1 \cup \{o_1 \dots o_j\}$  and denote  $D_1(j)$  the corresponding optimal solution, i.e.,

$$D_1(j) = \text{TSRMB-1-Scenario}(R_1, S_1 \cup \{o_1 \dots o_j\}, D).$$

Since we can not evaluate the cost of  $D_1(j)$  on all scenarios, we use the two proxy scenarios  $S_1$  and  $S_2$ . We show that the candidate  $D_1(j)$  with minimum cost over  $S_1$  and  $S_2$  gives a constant approximation to our original problem. The details are presented in Algorithm 5. We state the result in the next theorem.

► **Theorem 9.** *Algorithm 5 yields a solution with total cost less than  $3OPT_1 + 17OPT_2$  for TSRMB with implicit scenarios when  $k \leq \sqrt{\frac{n}{2}}$  and  $\ell < k$ .*

## 12:14 Matching Drivers to Riders: A Two-Stage Robust Approach

Before proving the theorem, we first introduce some notation. For all  $j \in \{0, \dots, \ell\}$ , denote

$$\begin{aligned}\Omega_j &= \text{cost}_1(D_1(j), R_1) \\ \Delta_j &= \text{cost}_2(D \setminus D_1(j), S_1 \cup \{o_1, \dots, o_j\}) \\ \beta_j &= \text{cost}_1(D_1(j), R_1) + \max_{S \in \{S_1, S_2\}} \text{cost}_2(D \setminus D_1(j), S)\end{aligned}$$

Recall that  $f$  the objective function of TSRMB. In particular,

$$f(D_1(j)) = \text{cost}_1(D_1(j), R_1) + \max_{S \in \mathcal{S}} \text{cost}_2(D \setminus D_1(j), S)$$

Our proof is based on the following two claims. Claim 10 establishes a bound on the cost of  $D_1(j^*)$  when evaluated on the proxy scenarios  $S_1$  and  $S_2$  and on all the scenarios in  $\mathcal{S}$ . Recall that  $j^*$  is the threshold index for the outliers as defined earlier in our construction. Claim 11 bounds the cost of  $f(D_1(j))$  for any  $j$ .

▷ **Claim 10.**  $\Omega_{j^*} + \Delta_{j^*} \leq OPT_1 + OPT_2.$  and  $f(D_1(j^*)) \leq OPT_1 + 5OPT_2.$

Proof of Claim 10.

1. In the optimal solution of the original problem,  $R_1$  is matched to a subset  $D_1^*$  of drivers. The scenario  $S_1$  is matched to a set of drivers  $D_{S_1}$  where  $D_1^* \cap D_{S_1} = \emptyset$ . Let  $D_o$  be the set of drivers that are matched to  $o_1, \dots, o_j^*$  in a scenario that contains  $o_1, \dots, o_j^*$ . It is clear that  $D_1^* \cap D_o = \emptyset$ . We claim that  $D_o \cap D_{S_1} = \emptyset$ . In fact, suppose there is a driver  $\rho \in D_o \cap D_{S_1}$ . This implies the existence of some  $o_j$  with  $j \leq j^*$  and some rider  $r \in S_1$  such that  $d(\rho, o_j) \leq OPT_2$  and  $d(\rho, r) \leq OPT_2$ . But then  $d(\delta, o_j) \leq d(\delta, r) + d(r, \rho) + d(\rho, o_j) \leq 3OPT_2$  which contradicts the fact the  $o_j$  is an outlier. Therefore  $D_o \cap D_{S_1} = \emptyset$ . We show that  $D_1^*$  is a feasible first stage solution to the single scenario problem of  $S_1 \cup \{o_1, \dots, o_j^*\}$  with a cost less than  $OPT_1 + OPT_2$ . In fact,  $D_1^*$  can be matched to  $R_1$  with a cost less than  $OPT_1$ ,  $D_{S_1}$  to  $S_1$  and  $D_o$  to  $\{o_1, \dots, o_j^*\}$  with a cost less than  $OPT_2$ . Therefore  $\Omega_{j^*} + \Delta_{j^*} \leq OPT_1 + OPT_2$ .
2. Recall that  $\text{cost}_1(D_1(j^*), R_1) = \Omega_{j^*}$ . Consider a scenario  $S$  and a rider  $r \in S$ . Let  $\mathcal{B}'$  be the set of the  $n - \ell$  closest second stage riders to  $\delta$ . Let  $D_{S_1}(j^*)$  be set of second stage drivers matched to  $S_1$  in the single scenario problem for scenario  $S_1 \cup \{o_1, \dots, o_{j^*}\}$ . Let  $D_o(j^*)$  be the set of second stage drivers matched to  $\{o_1, \dots, o_{j^*}\}$  in the single scenario problem for scenario  $S_1 \cup \{o_1, \dots, o_{j^*}\}$ . Recall that the second stage cost for this single scenario problem is  $\Delta_{j^*}$ . We distinguish three cases:
  - a. If  $r \in \mathcal{B}'$ , then by Lemma 8,  $r$  is connected to every driver in  $D_{S_1}(j^*)$  within a distance less than  $\Delta_{j^*} + 4OPT_2$ .
  - b. If  $r \in \{o_{j^*+1}, \dots, o_\ell\}$ , then  $r$  is connected to every driver in  $D_{S_1}(j^*)$  within a distance less than  $3OPT_2 + OPT_2 + \Delta_{j^*}$ .
  - c. If  $r \in \{o_1, \dots, o_{j^*}\}$  (i.e.,  $r$  an outlier), then  $r$  can be matched to a different driver in  $D_o(j^*)$  within a distance less than  $OPT_2$ .

This means that in every case, we can match  $r$  to a driver in  $D \setminus D_1(j^*)$  with a cost less than  $4OPT_2 + \Delta_{j^*}$ . This implies that

$$\max_{S \in \mathcal{S}} \text{cost}_2(D \setminus D_1(j^*), S) \leq 4OPT_2 + \Delta_{j^*}$$

and therefore

$$\Omega_{j^*} + \max_{S \in \mathcal{S}} \text{cost}_2(D \setminus D_1(j^*), S) \leq \Omega_{j^*} + \Delta_{j^*} + 4OPT_2 \leq OPT_1 + 5OPT_2. \quad \triangleleft$$

▷ **Claim 11.** For all  $j \in \{0, \dots, l\}$  we have,  $\beta_j \leq f(D_1(j)) \leq \max\{\beta_j + 4OPT_2, 3\beta_j + 2OPT_2\}$ .

Proof of Claim 11. Let  $\alpha_j$  be the second stage cost of  $D_1(j)$  on the TSRBM instance with scenarios  $S_1$  and  $S_2$ . Formally,  $\alpha_j = \max_{S \in \{S_1, S_2\}} \text{cost}_2(D \setminus D_1(j), S)$ . Therefore  $\beta_j = \Omega_j + \alpha_j$ .

Let's consider the two sets

$$\begin{aligned} O_1 &= \{r \in \{o_1, \dots, o_\ell\} \mid d(r, \delta) > 2\alpha_j + OPT_2\}. \\ O_2 &= \{o_1, \dots, o_\ell\} \setminus O_1. \end{aligned}$$

Consider  $D_1(j)$  as a first stage decision to TSRMB with scenarios  $S_1$  and  $S_2$ . Let  $\tilde{D}_1 \subset D \setminus D_1(j)$  be the set of drivers that are matched to  $O_1$  when the scenario  $S_2 = \{o_1, \dots, o_\ell\}$  is realized. Similarly, let  $\tilde{D}_2 \subset D \setminus D_1(j)$  be the drivers matched to scenario  $S_1$ . We claim that  $\tilde{D}_1 \cap \tilde{D}_2 = \emptyset$ . Suppose that there exists some driver  $\rho \in \tilde{D}_1 \cap \tilde{D}_2$ , this implies the existence of some  $o \in O_1$  and  $r \in S_1$  such that  $d(\rho, o) \leq \alpha_j$  and  $d(\rho, r) \leq \alpha_j$ . And since  $d(r, \delta) \leq OPT_2$  by definition of  $\delta$  we would have

$$d(o, \delta) \leq d(\rho, o) + d(\rho, r) + d(r, \delta) \leq 2\alpha_j + OPT_2,$$

which contradicts the definition of  $O_1$ . Therefore  $\tilde{D}_1 \cap \tilde{D}_2 = \emptyset$ .

Now consider a scenario  $S \in \mathcal{S}$ . The riders of  $S \cap O_1$  can be matched to  $\tilde{D}_1$  with a bottleneck cost less than  $\alpha_j$ . Recall that by Lemma 8, any rider in  $R_2 \setminus \{o_1, \dots, o_\ell\}$  is within a distance less than  $4OPT_2$  from any rider in  $S_1$ . The riders  $r \in S \setminus \{o_1, \dots, o_\ell\}$  can therefore be matched to any driver  $\rho \in \tilde{D}_2$  within a distance less than

$$d(r, \rho) \leq d(r, S_1) + d(S_1, \rho) \leq 4OPT_2 + \alpha_j.$$

As for riders  $r \in S \cap O_2$ , they can also be matched to any driver  $\rho$  of  $\tilde{D}_2$  within a distance less than

$$d(r, \rho) \leq d(r, \delta) + d(\delta, S_1) + d(S_1, \rho) \leq 2\alpha_j + OPT_2 + OPT_2 + \alpha_j = 3\alpha_j + 2OPT_2.$$

Therefore we can bound the second stage cost

$$\max_{S \in \mathcal{S}} \text{cost}_2(D \setminus D_1(j), S) \leq \max\{\alpha_j + 4OPT_2, 3\alpha_j + 2OPT_2\}$$

and we get that

$$\text{cost}_1(D_1(j), R_1) + \max_{S \in \mathcal{S}} \text{cost}_2(D \setminus D_1(j), S) \leq \max\{\beta_j + 4OPT_2, 3\beta_j + 2OPT_2\}$$

The other inequality  $\beta_j \leq \text{cost}_1(D_1(j), R_1) + \max_{S \in \mathcal{S}} \text{cost}_2(D \setminus D_1(j))$  is trivial. ◁

We are now ready to prove the theorem.

**Proof of Theorem 9.** Suppose Algorithm 5 returns  $D_1(\tilde{j})$  for some  $\tilde{j}$ . From Claim 11 and the minimality of  $\beta_{\tilde{j}}$ :

$$f(D_1(\tilde{j})) \leq \max\{\beta_{\tilde{j}} + 4OPT_2, 3\beta_{\tilde{j}} + 2OPT_2\} \leq \max\{\beta_{j^*} + 4OPT_2, 3\beta_{j^*} + 2OPT_2\}.$$

From Claim 10 and Claim 11, we have  $\beta_{j^*} \leq f(D_1(j^*)) \leq OPT_1 + 5OPT_2$ . We conclude that,

$$f(D_1(\tilde{j})) \leq \max\{OPT_1 + 9OPT_2, 3OPT_1 + 17OPT_2\} = 3OPT_1 + 17OPT_2. \quad \blacktriangleleft$$

## 5 Conclusion

In this paper, we present a new two-stage robust optimization framework for matching problems under both explicit and implicit models of uncertainty. Our problem is motivated by real-life applications in the ride-hailing industry. We study the Two-Stage Robust Matching Bottleneck problem, prove its hardness, and design approximation algorithms under different settings. Our algorithms give a constant approximation if the number of scenarios is fixed, but require additional assumptions when there are polynomially or exponentially many scenarios. It is an interesting question if there exists a constant approximation in the general case that does not depend on the number of scenarios.

## A NP-Hardness proofs for TSRMB

We start by presenting the 3-Dimensional Matching (3-DM) and Set Cover problems, that we use in our reductions to show Theorem 1. Both problems are known to be strongly NP-hard [10, 25].

**title3-Dimensional Matching (3-DM).** Given three sets  $U$ ,  $V$ , and  $W$  of equal cardinality  $n$ , and a subset  $T$  of  $U \times V \times W$ , is there a subset  $M$  of  $T$  with  $|M| = n$  such that whenever  $(u, v, w)$  and  $(u', v', w')$  are distinct triples in  $M$ ,  $u \neq u'$ ,  $v \neq v'$ , and  $w \neq w'$ ?

**Set Cover Problem.** Given a set of elements  $\mathcal{U} = \{1, 2, \dots, n\}$  (called the universe), a collection  $S_1, \dots, S_m$  of  $m$  sets whose union equals the universe and an integer  $p$ .

Question: Is there a set  $C \subset \{1, \dots, m\}$  such that  $|C| \leq p$  and  $\bigcup_{i \in C} S_i = \mathcal{U}$ ?

### Proof of Theorem 1.

**Explicit uncertainty.** Consider an instance of the 3-Dimensional Matching Problem. We can use it to construct (in polynomial time) an instance of TSRMB with 2 scenarios as follows:

- Create two scenarios of size  $n$ :  $S_1 = U$  and  $S_2 = V$ .
- Set  $D = T$ , every driver corresponds to a triple in  $T$ .
- For every  $w \in W$ , let  $d_T(w)$  be the number of sets in  $T$  that contain  $w$ . We create  $d_T(w) - 1$  first stage riders, that are all copies of  $w$ . The total number of first stage riders is therefore  $|R_1| = |T| - n$ .

- For  $(w, e) \in R_1 \times D$ ,  $d(w, e) = \begin{cases} 1 & \text{if } w \in e \\ 3 & \text{otherwise.} \end{cases}$
- For  $(u, e) \in S_1 \cup S_2 \times D$ ,  $d(u, e) = \begin{cases} 1 & \text{if } u \in e \\ 3 & \text{otherwise.} \end{cases}$
- For  $u, v \in R_1 \cup S_1 \cup S_2$ ,  $d(u, v) = \min_{e \in D} d(u, e) + d(v, e)$ .
- For  $e, f \in D$ ,  $d(e, f) = \min_{u \in R_1 \cup S_1 \cup S_2} d(u, e) + d(u, f)$ .

This choice of distances induces a metric graph. We claim that there exists a 3-dimensional matching if and only if there exists a solution to this TSRMB instance with total cost equal to 2. Suppose that  $M = \{e_1, \dots, e_n\} \subset T$  is a 3-Dimensional matching. Let  $e_1, \dots, e_n$  be the drivers that correspond to  $M$  in the TSRMB instance. We show that by using  $D_1 = D \setminus \{e_1, \dots, e_n\}$  as a first stage decision, we ensure that the total cost for the TSRMB instance is equal to 2. For any rider  $u$  in scenario  $S_1$ , by definition of  $M$ , there exists a unique edge  $e_i \in M$  that covers  $u$ . The corresponding driver  $e_i \notin D_1$  can be matched to  $u$  with a distance equal to 1. Furthermore,  $e_i$  cannot be matched to any other rider in  $S_1$  with a cost less than 1. Similarly, for any rider  $v$  in scenario  $S_2$ , since there exists a unique edge  $e_j \in M$  that covers  $v$ , the corresponding driver can be matched to  $v$  with a cost of 1. The second stage cost is therefore equal to 1. As for the first stage cost, we know by definition of  $M$ , that every element  $w \in W$  is covered exactly once. Therefore, for every  $w \in W$ , there exists  $d_T(w) - 1$  edges that contain  $w$  in  $T \setminus M$ . This means that every 1st stage rider can be matched to a driver in  $D_1$  with a cost equal to 1. Hence the total cost of this two-stage matching is equal to 2.

Suppose now that there exists a solution to the TSRMB instance with a cost equal to 2. This means that the first and second stage costs are both equal to 1. Let  $M = \{e_1, \dots, e_n\}$  be the set of drivers used in the second stage of this solution. We show that  $M$  is a 3-dimensional matching. Let  $e_i = (u, v, w)$  and  $e_j = (u', v', w')$  be distinct triples in  $M$ . Since the second stage cost is equal to 1, the driver  $e_i$  (resp.  $e_j$ ) must be matched to  $u$  (resp.  $u'$ ) in  $S_1$ . Since we have exactly  $n$  second stage drivers and  $n$  riders in  $S_1$ , this means that  $e_i$  and  $e_j$  have to be matched to different second stage riders in  $S_1$ . Therefore we get  $u' \neq u$ . Similarly we see that  $v' \neq v$ . Assume now that  $w = w'$ , this means that the TSRMB solution has used two drivers (triples)  $e_i$  and  $e_j$  that contain  $w$  in the second stage. It is therefore impossible to match all the  $d_T(w) - 1$  copies of  $w$  in the first stage with a cost equal to 1. Therefore  $w \neq w'$ . The above construction can be performed in polynomial time of the 3-DM input, and therefore shows that TSRMB with two scenarios is NP-hard.

Now, to show that TSRMB is hard to approximate within a factor better than 2, we consider three scenarios. Consider an instance of 3-DM. We can use it to construct an instance of TSRMB with 3 scenarios as follows:

- Create 3 scenarios of size  $n$ :  $S_1 = U$ ,  $S_2 = V$  and  $S_3 = W$ .
- Set  $D = T$ .
- Create  $|R_1| = |T| - n$  first stage riders.
- For  $(w, e) \in R_1 \times D$ ,  $d(w, e) = 1$ .
- For  $(u, e) \in S_1 \cup S_2 \cup S_3 \times D$ ,  $d(u, e) = \begin{cases} 1 & \text{if } u \in e \\ 3 & \text{otherwise.} \end{cases}$
- For  $u, v \in R_1 \cup S_1 \cup S_2 \cup S_3$ ,  $d(u, v) = \min_{e \in D} d(u, e) + d(v, e)$ .
- For  $e, f \in D$ ,  $d(e, f) = \min_{u \in R_1 \cup S_1 \cup S_2 \cup S_3} d(u, e) + d(u, f)$ .

This choice of distances induces a metric graph. Similarly to the proof of 2 scenarios, we can show that there exists a 3-dimensional matching if and only if there exists a TSRMB solution with cost equal to 2. Furthermore, any solution for this TSRMB instance has

## 12:20 Matching Drivers to Riders: A Two-Stage Robust Approach

either a total cost of 2 or 4 (the first stage cost is always equal to 1). We show that if a  $(2 - \epsilon)$ -approximation (for some  $\epsilon > 0$ ) to the TSRMB exists then 3-Dimensional Matching is decidable. We know that this instance of TSRMB has a solution with total cost equal to 2 if and only if there is a 3-dimensional matching. Furthermore, if there is no 3-dimensional matching, the cost of the optimal solution to TSRMB must be 4. Therefore, if an algorithm guarantees a ratio of  $(2 - \epsilon)$  and a 3-dimensional matching exists, the algorithm delivers a solution with total cost equal to 2. If there is no 3-dimensional matching, then the solution produced by the algorithm has a total cost of 4.

**Implicit uncertainty.** We prove the hardness for  $k = 1$ . We start from an instance of the Set Cover problem and construct an instance of the TSRMB problem. Consider an instance of the decision problem of set cover. We can use it to construct the following TSRMB instance:

- Create  $m$  drivers  $D = \{1, \dots, m\}$ . For each  $j \in \{1, \dots, m\}$ , driver  $j$  corresponds to set  $S_j$ .
- Create  $m - p$  first stage riders,  $R_1 = \{1, \dots, m - p\}$ .
- Create  $n$  second stage riders,  $R_2 = \{1, \dots, n\}$ .
- Set  $\mathcal{S} = \{\{1\}, \dots, \{n\}\}$ . Every scenario is of size 1.

As for the distances between riders and drivers, we define them as follows:

- For  $(i, j) \in R_1 \times D$ ,  $d(i, j) = 1$ .
- For  $(i, j) \in R_2 \times D$ ,  $d(i, j) = \begin{cases} 1 & \text{if } i \in S_j \\ 3 & \text{otherwise.} \end{cases}$
- For  $i, i' \in R_1 \cup R_2$ ,  $d(i, i') = \min_{j \in D} d(i, j) + d(i', j)$ .
- For  $j, j' \in D$ ,  $d(j, j') = \min_{i \in R_1 \cup R_2} d(i, j) + d(i, j')$ .

This choice of distances induces a metric graph. Moreover, every feasible solution to this TSRMB instance has a first stage cost of exactly 1. We show that a set cover of size  $\leq p$  exists if and only if there is a TSRMB solution with total cost equal to 2. Suppose without loss of generality that  $S_1, \dots, S_p$  is a set cover. Then by using the drivers  $\{1, \dots, p\}$  in the second stage, we ensure that every scenario is matched with a cost of 1. This implies the existence of a solution with total cost equal to 2. Now suppose there is a solution to the TSRMB problem with cost equal to 2. Let  $D_2$  be the set of second stage drivers of this solution, then we have  $|D_2| = p$ . We claim that the sets corresponding to drivers in  $D_2$  form a set cover. In fact, since the total cost of the TSRMB solution is equal to 2, the second stage cost is equal to 1. This means that for every scenario  $i \in \{1, \dots, n\}$ , there is a driver  $j \in D_2$  within a distance 1 from  $i$ . Therefore  $i \in S_j$  and  $\{S_j : j \in D_2\}$  is a set cover.

Next we show that if  $(2 - \epsilon)$ -approximation (for some  $\epsilon > 0$ ) to the TSRMB exists then Set Cover is decidable. We know that the TSRMB problem has a solution of cost 2 if and only if there is a set cover of size less than  $p$ . Furthermore, if there is no such set cover, the cost of the optimal solution must be 4. Therefore, if the algorithm guarantees a ratio of  $(2 - \epsilon)$  and there is a set cover of size less than  $p$ , the algorithm delivers a solution with a total cost of 2. If there is no set cover, then clearly the solution produced by the algorithm has a cost of 4. ◀

► **Remark 12.** For  $k \geq 2$ , we can use a generalization of Set Cover to show that the problem is hard for any  $k$ . We use a reduction from the Set MultiCover Problem ([3, 43]) defined below.

**Set MultiCover Problem.** Given a set of elements  $\mathcal{U} = \{1, 2, \dots, n\}$  (called the universe) and a collection  $S_1, \dots, S_m$  of  $m$  sets whose union equals the universe. A “coverage factor” (positive integer)  $k$  and an integer  $p$ . Is there a set  $C \subset \{1, \dots, m\}$  such that  $|C| \leq p$  and for each element  $x \in \mathcal{U}$ ,  $|j \in C : x \in S_j| \geq k$ ?

We can create an instance of TSRMB from a Set MultiCover instance similarly to Set Cover with the exception that  $\mathcal{S} = \{S \subset R_2 \text{ s.t. } |S| = k\}$ . The hardness result follows similarly.

## B Implicit scenarios: small surplus

**Proof of Lemma 8.** Let  $\delta$  be the driver given by (3). We claim that the  $k$  closest riders to  $\delta$  are all within a distance less than  $OPT_2$  from  $\delta$ . Consider  $D_2^*$  to be the  $k + \ell$  drivers left for the second stage in the optimal solution. Every driver in  $D_2^*$  can be matched to a set of different second stage riders over different scenarios. Let us rank the drivers in  $D_2^*$  according to how many different second stage riders they are matched to over all scenarios, in descending order. Formally, let  $D_2^* = \{\delta_1, \delta_2, \dots, \delta_{k+\ell}\}$  and let  $R^*(\delta_i)$  be the second stage riders that are matched to  $\delta_i$  in the optimal solution in some scenario, such that

$$|R^*(\delta_1)| \geq \dots \geq |R^*(\delta_{k+\ell})|.$$

We claim that  $|R^*(\delta_1)| \geq k$ . In fact, we have  $\sum_{i=1}^{k+\ell} |R^*(\delta_i)| \geq n$  because every second stage rider is matched to at least one driver in some scenario. Therefore

$$|R^*(\delta_1)| \geq \frac{n}{k + \ell} \geq \frac{n}{2k} \geq k.$$

We know that all the second stage riders in  $R^*(\delta_1)$  are within a distance less than  $OPT_2$  from  $\delta_1$ . Therefore  $\max_{r \in R_k(\delta_1)} d(\delta_1, r) \leq OPT_2$ . But we know that by definition of  $\delta$ ,

$$\max_{r \in R_k(\delta)} d(\delta, r) \leq \max_{r \in R_k(\delta_1)} d(\delta_1, r) \leq OPT_2$$

This proves that the  $k$  closest second stage riders to  $\delta$  are within a distance less than  $OPT_2$ . Let  $R(\delta)$  be the set of all second stage riders that are within a distance less than  $OPT_2$  from  $\delta$ . Recall that  $R_k(\delta)$  is the set of the  $k$  closest second stage riders to  $\delta$ . In the optimal solution, the scenario  $R_k(\delta)$  is matched to a set of at least new  $k - 1$  drivers  $\{\delta_{i_1}, \dots, \delta_{i_{k-1}}\} \subset D_2^* \setminus \{\delta\}$ . We show a lower bound on the size of  $R(\delta)$  and the number of riders matched to  $\{\delta_{i_1}, \dots, \delta_{i_{k-1}}\}$  over all scenarios in the optimal solution.

$$\triangleright \text{Claim 13. } |R(\delta) \cup \bigcup_{j=1}^{k-1} R^*(\delta_{i_j})| \geq n - \ell$$

*Proof.* Suppose the opposite, suppose that at least  $\ell + 1$  riders from  $R_2$  are not in the union. Let  $F$  be the set of these  $\ell + 1$  riders. Since  $\ell + 1 \leq k$ , we can construct a scenario  $S$  that includes  $F$ . In the optimal solution, and in particular, in the second stage matching of  $S$ , at least one rider from  $F$  needs to be matched to a driver from  $\{\delta, \delta_{i_1}, \dots, \delta_{i_{k-1}}\}$ . Otherwise there are only  $\ell$  second stage drivers left to match all of  $F$ . Therefore there exists  $r \in F$  such that either  $r \in R(\delta)$  or there exists  $j \in \{1, \dots, k - 1\}$  such that  $r \in R^*(\delta_{i_j})$ . This shows that  $r \in R(\delta) \cup \bigcup_{j=1}^{k-1} R^*(\delta_{i_j})$ , which is a contradiction. Therefore, at most  $\ell$  second stage riders are not in the union.  $\triangleleft$

## 12:22 Matching Drivers to Riders: A Two-Stage Robust Approach

▷ **Claim 14.** For any rider  $r \in R(\delta) \bigcup_{j=1}^{k-1} R^*(\delta_{i_j})$ , we have  $d(r, \delta) \leq 3OPT_2$ .

*Proof.* If  $r \in R(\delta)$  then by definition we have  $d(r, \delta) \leq OPT_2$ . Now suppose  $r \in R^*(\delta_{i_j})$  for  $j \in [k-1]$ . Let  $r'$  be the rider from scenario  $R_k(\delta)$  that was matched to  $\delta_{i_j}$  in the optimal solution. Then by the triangular inequality

$$d(r, \delta) \leq d(r, \delta_{i_j}) + d(\delta_{i_j}, r') + d(r', \delta) \leq 3OPT_2. \quad \triangleleft$$

From Claim 14, we see that the ball centered at  $\delta$ , with radius  $3OPT_2$ , contains at least  $n - \ell$  second stage riders in  $R(\delta) \bigcup_{j=1}^{k-1} R^*(\delta_{i_j})$ . This proves the first part of the lemma. The second part is proved in the next claim.

▷ **Claim 15.** For  $r_1 \in R_k(\delta)$  and  $r_2 \in R(\delta) \bigcup_{j=1}^{k-1} R^*(\delta_{i_j})$ , we have  $d(r_1, r_2) \leq 4OPT_2$ .

*Proof.* Let  $r_1 \in R_k(\delta)$ . If  $r_2 \in R(\delta)$  then  $d(r_1, r_2) \leq d(r_1, \delta) + d(\delta, r_2) \leq 2OPT_2$ . If  $r_2 \in R^*(\delta_{i_j})$  for some  $j$ , and  $r'$  is the rider from scenario  $R_k(\delta)$  that was matched to  $\delta_{i_j}$

$$d(r_1, r_2) \leq d(r_1, \delta) + d(\delta, r') + d(r', \delta_{i_j}) + d(\delta_{i_j}, r_2) \leq 4OPT_2. \quad \triangleleft$$

Claim 13 shows that the number of riders included in  $R(\delta) \bigcup_{j=1}^{k-1} R^*(\delta_{i_j})$  is at least  $n - \ell$ . Claim 14 shows that each one of this rider has distance less than  $3OPT_2$  from  $\delta$ . Finally, Claim 15 shows that the distance between any one of this riders and any rider in  $R_k(\delta)$  is less than  $3OPT_2$ . This concludes the proof of Lemma 8. ◀

# Secretary Matching Meets Probing with Commitment

## Abstract

We consider the online bipartite matching problem within the context of stochastic probing with commitment. This is the one-sided online bipartite matching problem where edges adjacent to an online node must be probed to determine if they exist based on edge probabilities that become known when an online vertex arrives. If a probed edge exists, it must be used in the matching. We consider the competitiveness of online algorithms in the adversarial order model (AOM) and the secretary/random order model (ROM). More specifically, we consider an unknown bipartite stochastic graph  $G = (U, V, E)$  where  $U$  is the known set of offline vertices,  $V$  is the set of online vertices,  $G$  has edge probabilities  $(p_e)_{e \in E}$ , and  $G$  has edge weights  $(w_e)_{e \in E}$  or vertex weights  $(w_u)_{u \in U}$ . Additionally,  $G$  has a downward-closed set of probing constraints  $(\mathcal{C}_v)_{v \in V}$ , where  $\mathcal{C}_v$  indicates which sequences of edges adjacent to an online vertex  $v$  can be probed. This model generalizes the various settings of the classical bipartite matching problem (i.e. with and without probing). Our contributions include the introduction and analysis of probing within the random order model, and our generalization of probing constraints which includes budget (i.e. knapsack) constraints. Our algorithms run in polynomial time assuming access to a membership oracle for each  $\mathcal{C}_v$ .

In the vertex weighted setting, for adversarial order arrivals, we generalize the known  $\frac{1}{2}$  competitive ratio to our setting of  $\mathcal{C}_v$  constraints. For random order arrivals, we show that the same algorithm attains an asymptotic competitive ratio of  $1 - 1/e$ , provided the edge probabilities vanish to 0 sufficiently fast. We also obtain a strict competitive ratio for non-vanishing edge probabilities when the probing constraints are sufficiently simple. For example, if each  $\mathcal{C}_v$  corresponds to a patience constraint  $\ell_v$  (i.e.,  $\ell_v$  is the maximum number of probes of edges adjacent to  $v$ ), and any one of following three conditions is satisfied (each studied in previous papers), then there is a conceptually simple greedy algorithm whose competitive ratio is  $1 - \frac{1}{e}$ .

- When the offline vertices are unweighted.
- When the online vertex probabilities are “vertex uniform”; i.e.,  $p_{u,v} = p_v$  for all  $(u, v) \in E$ .
- When the patience constraint  $\ell_v$  satisfies  $\ell_v \in \{1, |U|\}$  for every online vertex; i.e., every online vertex either has unit or full patience.

Finally, in the edge weighted case, we match the known optimal  $\frac{1}{e}$  asymptotic competitive ratio for the classic (i.e. without probing) secretary matching problem.

## 1 Introduction

Stochastic probing problems are part of the larger area of decision making under uncertainty and more specifically, stochastic optimization. Unlike more standard forms of stochastic optimization, it is not just that there is some possible stochastic uncertainty in the set of inputs, stochastic probing problems involve inputs that cannot be determined without probing (at some cost and/or within some constraint) so as to reveal the inputs. Applications of stochastic probing occur naturally in many settings, such as in matching problems where compatibility (for example, in online dating and kidney exchange applications) or legality (for example, a financial transaction that must be authorized before it can be completed) cannot be determined without some trial or investigation. Amongst other applications, the online bipartite stochastic matching problem notably models online advertising where the probability of an edge can correspond to the probability of a purchase in online stores or to pay-per-click revenue in online searching. Commitment reflects the fact that one usually chooses the next probe based on some concept of expected value but in many applications (e.g. kidney exchanges) the cost or invasiveness of probing makes it practically necessary to commit. In some applications, there may be a legal requirement to commit (e.g., if a contract is possibly being offered and commitment is required).

The (*offline*) *stochastic matching* problem was introduced by Chen et al. [9]. In this problem, the input is an adversarially generated *stochastic graph*  $G = (V, E)$  with a probability  $p_e$  associated with each edge  $e$  and a patience (or time-out) parameter  $\ell_v$  associated with each vertex  $v$ . An algorithm probes edges in  $E$  within the constraint that at most  $\ell_v$  edges are probed incident to any particular vertex  $v \in V$ . Also, when an edge  $e$  is probed, it is guaranteed to exist with probability exactly  $p_e$ . If an edge  $(u, v)$  is found to exist, it is added to the matching and then  $u$  and  $v$  are no longer available. The goal is to maximize the expected size of a matching constructed in this way. Chen et al. showed that by probing edges in non-increasing order of edge probability, one attains an approximation ratio of  $1/4$ . The analysis was later improved by Adameczyk [1], who showed that this algorithm in fact attains an approximation ratio of  $1/2$ . This problem can be generalized to vertices or edges having weights.

Mehta and Panigrahi [22] adapted the offline stochastic matching model to online bipartite matching as originally studied in the classical (non-stochastic) adversarial order online model. That is, they consider the setting where the stochastic graph is unknown and online vertices are determined by an adversary. More specifically, they studied the problem in the case of an unweighted stochastic graph  $G = (U, V, E)$  where  $U$  is the set of known offline vertices and the vertices in  $V$  arrive online without knowledge of future online node arrivals. They considered the special case of uniform edge probabilities (i.e.  $p_e = p$  for all  $e \in E$ ) and *unit* patience values, that is  $\ell_v = 1$  for all  $v \in V$ . They considered a greedy algorithm which attains a competitive ratio of  $\frac{1}{2}(1 + (1 - p)^{2/p})$ , which limits to  $\frac{1}{2}(1 + e^{-2}) \approx .567$  as  $p \rightarrow 0$ . Mehta et al. [23] considered the unweighted online stochastic bipartite setting with arbitrary edge probabilities, attaining a competitive ratio of 0.534, and recently, Huang and Zhang [16] additionally handled the case of arbitrary offline vertex weights, while improving this ratio to 0.572. However, as in [22], both [23] and [16] are restricted to unit patience values, and moreover require edge probabilities which are *vanishingly small*<sup>1</sup>. Goyal and Udvani [12] improved on both of these works by showing a 0.596 competitive ratio in the same setting.

---

<sup>1</sup> Vanishingly small edge probabilities must satisfy  $\max_{e \in E} p_e \rightarrow 0$ , where the asymptotics are with respect to the size of  $G$ .

In all our results we will assume *commitment*; that is, when an edge is probed and found to exist, it must be included in the matching (if possible without violating the matching constraint). The patience constraint can be viewed as a simple form of a budget (equivalently, knapsack) constraint for the online vertices. We generalize patience and budget constraints by associating a downward-closed set  $\mathcal{C}_v$  of probing sequences for each online node  $v$  where  $\mathcal{C}_v$  indicates which sequences of edges adjacent to vertex  $v$  can be probed. In the general query and commit framework of Gupta and Nagarajan [14], the  $\mathcal{C}_v$  constraints are the outer constraints.

## 1.1 Preliminaries

An input to the **(online) stochastic matching problem** is a **(bipartite) stochastic graph**, specified in the following way. Let  $G = (U, V, E)$  be a bipartite graph with edge weights  $(w_e)_{e \in E}$  and edge probabilities  $(p_e)_{e \in E}$ . We draw an independent Bernoulli random variable of parameter  $p_e$  for each  $e \in E$ . We refer to this Bernoulli as the **state** of the edge  $e$ , and denote it by  $\text{st}(e)$ . If  $\text{st}(e) = 1$ , then we say that  $e$  is **active**, and otherwise we say that  $e$  is **inactive**. For each  $v \in V$ , denote  $\partial(v)$  as the edges of  $G$  which include  $v$ . Define  $\partial(v)^{(*)}$  as the collection of strings (tuples) formed from the edges of  $\partial(v)$  whose characters (entries) are all distinct. Note that we use string/tuple notation and terminology interchangeably. Each  $v \in V$  has an **online probing constraint**  $\mathcal{C}_v \subseteq \partial(v)^{(*)}$  which is **downward-closed**. That is,  $\mathcal{C}_v$  has the property that if  $e \in \mathcal{C}_v$ , then so is any substring or permutation of  $e$ . Thus, in particular, our setting encodes the case when  $v$  has a patience value  $\ell_v$ , and more generally, when  $\mathcal{C}_v$  corresponds to a matroid or budgetary constraint<sup>2</sup> on  $\partial(v)$ . Note that we will often assume w.l.o.g. that  $E = U \times V$ , as we can always set  $p_{u,v} := 0$ .

A solution to the online stochastic matching problem is an **online probing algorithm**. An online probing algorithm is initially only aware of the identity of the offline vertices  $U$  of  $G$ . We think of  $G$ , as well as the relevant edges probabilities, weights, and probing constraints, as being generated by an adversary. An ordering on  $V$  is then generated either through an adversarial process or uniformly at random. We refer to the former case as the **adversarial order model (AOM)** and the latter case as the **random order model (ROM)**.

Based on whichever ordering is generated on  $V$ , the nodes are then presented to the online probing algorithm one by one. When an online node  $v \in V$  arrives, the online probing algorithm sees all the adjacent edges and their associated probabilities, as well as  $\mathcal{C}_v$ . However, the edge states  $(\text{st}(e))_{e \in \partial(v)}$  remain hidden to the algorithm. Instead, the algorithm must perform a **probing operation** on an adjacent edge  $e$  to reveal/expose its state,  $\text{st}(e)$ . Moreover, the online probing algorithm must **respect commitment**. That is, if an edge  $e = (u, v)$  is probed and turns out to be active, then  $e$  must be added to the current matching, provided  $u$  and  $v$  are both currently unmatched. The probing constraint  $\mathcal{C}_v$  of the online node then restricts which sequences of probes can be made to  $\partial(v)$ . As in the classical problem, an online probing algorithm must decide on a possible match for an online node  $v$  before seeing the next online node. The goal of the online probing algorithm is to return a matching whose expected weight is as large as possible. Since  $\mathcal{C}_v$  may be exponentially large in the size of  $U$ , in order to discuss the efficiency of an online probing algorithm, we work in the **membership oracle model**. That is, upon receiving the online vertex  $v \in V$ , we

<sup>2</sup> In the case of a budget  $B_v$  and edge probing costs  $(b_e)_{e \in \partial(v)}$ , any subset of  $\partial(v)$  may be probed, provided its cumulative cost does not exceed  $B_v$ .

assume the online probing algorithm has access to a **membership oracle**. The algorithm may **query** any string  $e \in \partial(v)^{(*)}$ , thus determining in a single operation whether or not  $e \in \partial(v)^{(*)}$  is in  $\mathcal{C}_v$ .

It is easy to see we cannot hope to obtain a non-trivial competitive ratio against the expected value of an optimal matching of the stochastic graph. Consider a single online vertex with patience 1, and  $k \geq 1$  offline (unweighted) vertices where each edge  $e$  has probability  $\frac{1}{k}$  of being present. The expectation of an online probing algorithm will be at most  $\frac{1}{k}$  while the expected size of an optimal matching will be  $1 - (1 - \frac{1}{k})^k \rightarrow 1 - \frac{1}{e}$ . This example clearly shows that no constant ratio is possible if the patience is sublinear in  $k = |U|$ . Thus, the standard in the literature is to instead benchmark the performance of an online probing algorithm against an *optimal offline probing algorithm*. An **offline probing algorithm** knows  $G = (U, V, E)$ , but initially the edge states  $(\text{st}(e))_{e \in E}$  are hidden. It can adaptively probe the edges of  $E$  in any order, but must satisfy the probing constraints  $(\mathcal{C}_v)_{v \in V}$  at each step of its execution<sup>3</sup>, while respecting commitment; that is, if a probed edge  $e = (u, v)$  turns out to be active, then  $e$  is added to the matching (if possible). The goal of an offline probing algorithm is to construct a matching with optimal weight in expectation. We define the **committal benchmark**  $\text{OPT}(G)$  for  $G$  as the value of an optimal offline probing algorithm. We abuse notation slightly, and also use  $\text{OPT}(G)$  to refer to the *strategy* of the committal benchmark on  $G$ . In the arXiv version of the paper [4], we introduce the stronger **non-committal benchmark**, and indicate which of our results hold against it.

## 1.2 Our Results

We first consider the case when the stochastic graph  $G = (U, V, E)$  has **(offline) vertex weights** – i.e., there exists  $(w_u)_{u \in U}$  such that  $w_{u,v} = w_u$  for each  $v \in N(u)$ , and arbitrary downward-closed probing constraints  $(\mathcal{C}_v)_{v \in V}$ . We consider a *greedy* online probing algorithm. That is, upon the arrival of  $v$ , the probes to  $\partial(v)$  are made in such a way that  $v$  gains as much value as possible (in expectation), provided the currently unmatched nodes of  $U$  are equal to  $R \subseteq U$ . As such, we must follow the probing strategy of the committal benchmark when restricted to the **induced stochastic graph**<sup>4</sup>  $G[\{v\} \cup R]$ , which we denote by  $\text{OPT}(R, v)$  for convenience.

Observe that if  $v$  has unit patience, then  $\text{OPT}(R, v)$  reduces to probing the adjacent edge  $(u, v) \in R \times \{v\}$  such that the value  $w_u \cdot p_{u,v}$  is maximized. Moreover, if  $v$  has unlimited patience, then  $\text{OPT}(R, v)$  corresponds to probing the adjacent edges of  $R \times \{v\}$  in non-increasing order of the associated vertex weights. Building on a result in Purohit et al. [24], Brubach et al. [8] showed how to devise an *efficient* probing strategy for  $v$  whose expected value matches  $\text{OPT}(R, v)$ , for any patience value. Using this probing strategy, they devised an online probing algorithm which achieves a competitive ratio of  $1/2$  for arbitrary patience values. The challenge in extending this competitive ratio to more general probing constraints comes from the fact that it is unclear how to compute  $\text{OPT}(R, v)$  efficiently. We show that this is possible to do when the probing constraints are downward-closed, and provide a primal-dual proof of the following theorem:

<sup>3</sup> Edges  $e \in E^{(*)}$  may be probed in the order specified by  $e$ , provided  $e^v \in \mathcal{C}_v$  for each  $v \in V$ , where  $e^v$  is the substring of  $e$  restricted to edges of  $\partial(v)$ .

<sup>4</sup> Given  $R \subseteq U, V' \subseteq V$ , the induced stochastic graph  $G[R \cup V']$  is formed by restricting the edges weights and probabilities of  $G$  to those edges within  $R \times V'$ . Similarly, each probing constraint  $\mathcal{C}_v$  is restricted to those strings whose entries lie entirely in  $R \times \{v\}$ .

► **Theorem 1.1.** *Suppose the adversary presents a vertex weighted stochastic graph  $G = (U, V, E)$ , with downward-closed probing constraints  $(\mathcal{C}_v)_{v \in V}$ . If  $\mathcal{M}$  is the matching returned by Algorithm 1 when executing on  $G$ , then*

$$\mathbb{E}[w(\mathcal{M})] \geq \frac{1}{2} \cdot OPT(G),$$

*provided the vertices of  $V$  arrive in adversarial order. Moreover, Algorithm 1 can be implemented efficiently in the membership oracle model.*

Since Algorithm 1 is deterministic, the  $1/2$  competitive ratio is best possible for deterministic algorithms in the adversarial arrival setting. One direction is thus to instead consider what can be done if the online probing algorithm is allowed randomization, which has received much attention in the case of unit patience [22, 23, 12, 16]. We instead make partial progress to understanding the performance of Algorithm 1 for downward-closed probing constraints in the ROM setting. However, unlike the adversarial setting, the complexity of the constraints greatly impacts what we are able to prove. The first part of our result is asymptotic in that it yields a good competitive ratio when applied to a stochastic graph whose maximum edge probability  $p_v := \max_{e \in \partial(v)} p_e$  vanishes sufficiently fast relevant to the maximum string length of  $\mathcal{C}_v$ , namely  $c_v := \max_{e \in \mathcal{C}_v} |e|$ , for each  $v \in V$ . Note that the vanishing probability setting is similar in spirit to the small bid to budget assumption in the Adwords problem (see Goyal and Udvani [12] for details). The second part of our result applies to stochastic graphs which we refer to as **rankable**. Roughly speaking, a vertex  $v \in V$  of  $G$  is **rankable**, provided there exists a fixed/non-adaptive ranking  $\pi_v$  of  $\partial(v)$  which can be used to specify the greedy strategy  $OPT(v, R)$  of  $v$ , no matter which vertices  $R \subseteq U$  are available when  $v$  is processed. For example, this includes the well-studied unit patience setting, in which case  $v$  ranks its adjacent edges in non-increasing order of  $(w_u p_{u,v})_{u \in U}$ , as well as when  $G$  is unweighted and has arbitrary patience values, in which case  $v$  ranks its adjacent edges in non-increasing order of edge probability. A stochastic graph is rankable if all its online vertices are rankable. We defer the precise definition to Section 2.

► **Theorem 1.2.** *Suppose Algorithm 1 returns the matching  $\mathcal{M}$  when executing on the vertex weighted stochastic graph  $G = (U, V, E)$  with downward-closed constraints  $(\mathcal{C}_v)_{v \in V}$ , and the vertices of  $V$  arrive u.a.r.. We then have the following two results:*

1. *If  $c_v := \max_{e \in \mathcal{C}_v} |e|$  and  $p_v := \max_{e \in \partial(v)} p_e$ , then*

$$\mathbb{E}[w(\mathcal{M})] \geq \min_{v \in V} (1 - p_v)^{c_v} \cdot \left(1 - \frac{1}{e}\right) \cdot OPT(G).$$

*Thus, if  $c_v \cdot p_v \rightarrow 0$  (as  $|G| \rightarrow \infty$ ) for each  $v \in V$ , then  $\mathbb{E}[w(\mathcal{M})] \geq (1 - o(1))(1 - 1/e) \cdot OPT(G)$ .*

2. *If  $G$  is rankable (which includes the specific cases outlined in the abstract), then*

$$\mathbb{E}[w(\mathcal{M})] \geq \left(1 - \frac{1}{e}\right) \cdot OPT(G).$$

► **Remark 1.3.** The analysis of Algorithm 1 is tight, as an execution of Algorithm 1 corresponds to the seminal Karp et al. [17] RANKING algorithm for unweighted non-stochastic (i.e.,  $p_e \in \{0, 1\}$  for all  $e \in E$ ) bipartite matching.

In the unit patience setting of [22], Mehta and Panigrahi showed that  $.621 < 1 - \frac{1}{e}$  is a randomized inapproximation with regard to guarantees made against LP-std-unit, the LP introduced by [22] to upper bound/relax the committal benchmark in the unit patience

setting. This hardness result led Goyal and Udvani [12] to consider a new unit patience LP that is a tighter relaxation of  $\text{OPT}(G)$  than LP-std-unit, thereby allowing them to prove a  $1 - 1/e$  competitive ratio for the case of **vertex-decomposable**<sup>5</sup> edge probabilities. However, they also discuss the difficulty of extending this result to the case of arbitrary edge probabilities in the context of the Adwords problem with arbitrary budget to bid ratios. It remains open whether a randomized algorithm can attain a competitive ratio of  $1 - 1/e$  against the committal benchmark for adversarial arrivals and arbitrary edge probabilities. A corollary of Theorem 1.2 is that in the ROM setting these difficulties do *not* arise.

► **Corollary 1.4.** *Suppose the adversary presents a vertex weighted stochastic graph  $G = (U, V, E)$ , with unit patience values. If  $\mathcal{M}$  is the matching returned by Algorithm 1 when executing on  $G$ , then*

$$\mathbb{E}[w(\mathcal{M})] \geq \left(1 - \frac{1}{e}\right) \text{OPT}(G),$$

*provided the vertices of  $V$  arrive in random order.*

► **Remark 1.5.** The guarantee of Theorem 1.2 is proven against a new LP relaxation (LP-DP) whose optimum value we denote by  $\text{LPOPT}_{\text{DP}}(G)$ . In the special case when  $G$  has unit patience,  $\text{LPOPT}_{\text{std}}(G) \leq \text{LPOPT}_{\text{DP}}(G)$ . Thus, the 0.621 inapproximation of Mehta and Panigrahi against LP-std-unit does not apply (even for deterministic probing algorithms) to the ROM setting. Corollary 1.4 therefore implies that deterministic probing algorithms in the ROM setting have strictly more power than randomized probing algorithms in the adversarial order model. This contrasts with the classic ROM setting where it is unknown whether a deterministic algorithm can improve upon  $1 - 1/e$ , the optimal competitive attainable by randomized algorithms in the adversarial setting.

We next consider the unknown stochastic matching problem in the most general setting of arbitrary edge weights, and downward-closed probing constraints. Since no non-trivial competitive ratio can be proven in the case of adversarial arrivals, even in the classical setting, we work in the ROM setting. We generalize the matching algorithm of Kesselheim et al. [18] so as to apply to the stochastic probing setting.

► **Theorem 1.6.** *Suppose the adversary presents an edge-weighted stochastic graph  $G = (U, V, E)$ , with downward-closed probing constraints  $(\mathcal{C}_v)_{v \in V}$ . If  $\mathcal{M}$  is the matching returned by Algorithm 2 when executing on  $G$ , then*

$$\mathbb{E}[w(\mathcal{M})] \geq \left(\frac{1}{e} - \frac{1}{|V|}\right) \cdot \text{OPT}(G),$$

*provided the vertices of  $V$  arrive uniformly at random (u.a.r.). Moreover, Algorithm 2 can be implemented efficiently in the membership oracle model.*

► **Remark 1.7.** For context, the previous best known approximation ratio known for the offline bipartite stochastic matching problem with two-sided or one-sided patience is 0.352 due to Adamczyk et al. [3]. Since  $1/e > 0.352$ , Theorem 1.6 in fact improves on this result for the case of one-sided patience, despite the fact that Algorithm 2 works in the unknown graph setting and for more general one-sided probing constraints. Very recently, Brubach et al. [7] proved an approximation ratio of 0.382 for general stochastic graphs.

<sup>5</sup> Vertex-decomposable means that there exists probabilities  $(p_u)_{u \in U}$  and  $(p_v)_{v \in V}$ , such that  $p_{(u,v)} = p_u \cdot p_v$  for each  $(u, v) \in E$ .

### 1.3 Our Technical Contributions

In the vertex weighted setting, the first challenge is to establish a greedy strategy for a single online vertex which runs efficiently for general probing constraints. We provide a dynamic programming based algorithm (DP-OPT) for solving this problem, which builds upon the work of Brubach et al. [8], and before that, Purohit et al. [24] (see Theorem 2.1). In the adversarial arrival setting, we prove a competitive ratio of  $1/2$  by comparing the performance of Algorithm 1 to the dual of LP-DP, an extension of the LP considered by Brubach et al. [8] from patience values to general probing constraints.

We next move to the ROM/secretary setting. In the unit patience setting of Corollary 1.4, DP-OPT reduces to probing a single edge which yields the largest value in expectation, and LP-DP is a relaxation of LP-std-unit (upper bounds its optimum value). While we do not show this, one could work directly with LP-std-unit and follow the primal-dual argument of Devanur et al. [10]. In contrast, Theorem 1.2 applies to downward-closed probing constraints which comes with two main technical challenges. First, Brubach et al. [8] showed that even the offline committal benchmark has a 0.544 inapproximation against the generalization of LP-std-unit to arbitrary patience (LP-std). Moreover, this inapproximation applies to a stochastic graph which is both rankable and has vanishingly small edge probabilities. Thus, Theorem 1.2 cannot be proven by comparing the performance of Algorithm 1 to LP-std and its dual, even for patience values. Our solution is to instead work with LP-DP and its dual, LP-dual-DP. When a match between  $u \in U$  and  $v \in V$  is successfully made, we apply the well-studied cost sharing function  $g(z) := \exp(z - 1)$  to split the weight of  $u$ , as in [10]. However, LP-dual-DP contains variables which do *not* have an analogue in the classical setting. Specifically, the online vertices are associated with exponentially many variables, and we cost share with the offline vertices which were available when  $v$  was matched to  $u$ , opposed to just  $v$  itself. The second main technical challenge is that when moving away from the unit patience setting, the executions of Algorithm 1 become **non-monotonic**. Specifically, while  $v$  may get matched to  $u$ , if a new online vertex  $v^*$  is added to the graph ahead of  $v$ , then  $u$  may not be matched at all. This complicates the analysis, and is the reason the competitive ratio of Theorem 1.2 does not hold unconditionally, as we explain in Section 2.

In the edge weighted setting, upon receiving the online vertices  $V_t := \{v_1, \dots, v_t\}$ , in order to generalize the matching algorithm of Kesselheim et al. [18], Algorithm 2 would ideally probe the edges of  $\partial(v_t)$  suggested by  $\text{OPT}(G_t)$ , where  $G_t := G[U \cup V_t]$  is the induced stochastic graph on  $U \cup V_t$ . However, since we wish for our algorithms to be efficient in addition to attaining optimal competitive ratios, this strategy is not feasible. We instead make use of a new LP (LP-config) recently introduced by the authors in [5] and independently by Brubach et al. in [6, 13] for the special case of patience values, an updated version of [8]. This LP has exponentially many variables which accounts for the many probing strategies available to an arriving vertex  $v$  with probing constraint  $C_v$ . We solve this LP efficiently by using DP-OPT as a deterministic separation oracle for LP-config-dual, the dual of LP-config, in conjunction with the ellipsoid algorithm [26, 11]. This LP closely resembles what the committal benchmark is capable of doing, and thus leads to a probing algorithm with an optimum competitive ratio.

## 2 Vertex Weights

In this section, we define Algorithm 1 and introduce the techniques needed to prove Theorems 1.1 and 1.2. However, for space considerations, we defer the dual-fitting argument used in the adversarial arrival setting of Theorem 1.1 to Appendix B.

Suppose that  $G = (U, V, E)$  is a vertex weighted stochastic graph with weights  $(w_u)_{u \in U}$ . Let us now fix  $s \in V$ , and define  $\text{val}(e)$  to be the expected weight of the edge matched, provided the edges of  $e$  are probed in order, where  $e \in \mathcal{C}_s$ . Observe then the following claim:

► **Theorem 2.1.** *There exists a dynamic programming (DP) based algorithm DP-OPT, which given access to  $G[\{s\} \cup U]$ , computes a tuple  $e' \in \mathcal{C}_s$ , such that  $\text{OPT}(s, U) = \text{val}(e')$ . Moreover, DP-OPT executes in time  $O(|U|^2)$ , assuming access to a membership oracle for the downward-closed constraint  $\mathcal{C}_s$ .*

**Proof of Theorem 2.1.** It will be convenient to denote  $w_{u,s} := w_u$  for each  $u \in U$  such that  $(u, s) \in \partial(s)$ . We first must show that there exists some  $e' \in \mathcal{C}_s$  such that  $\text{val}(e') = \text{OPT}(s, U)$ , where

$$\text{val}(e) := \sum_{i=1}^{|\mathbf{e}|} p_{e_i} w_{e_i} \prod_{j=1}^{i-1} (1 - p_{e_j}), \quad (2.1)$$

for  $e \in \mathcal{C}_s$ , and  $\text{OPT}(s, U)$  is the value of the committal benchmark on  $G[\{s\} \cup U]$ . Since the committal benchmark must respect commitment – i.e., match the first edge to  $s$  which it reveals to be active – it is clear that  $e'$  exists.

Our goal is to now show that  $e'$  can be computed efficiently. Now, for any  $e \in \mathcal{C}_s$ , let  $e^r$  be the rearrangement of  $e$ , based on the non-increasing order of the weights  $(w_e)_{e \in e}$ . Since  $\mathcal{C}_s$  is downward-closed, we know that  $e^r$  is also in  $\mathcal{C}_s$ . Moreover,  $\text{val}(e^r) \geq \text{val}(e)$  (following observations in [24, 8]). Hence, let us order the edges of  $\partial(s)$  as  $e_1, \dots, e_m$ , such that  $w_{e_1} \geq \dots \geq w_{e_m}$ , where  $m := |\partial(s)|$ . Observe then that it suffices to maximize (2.1) over those strings within  $\mathcal{C}_s$  which respect this ordering on  $\partial(s)$ . Stated differently, let us denote  $\mathcal{I}_s$  as the family of subsets of  $\partial(s)$  induced by  $\mathcal{C}_s$ , and define the set function  $f : 2^{\partial(s)} \rightarrow [0, \infty)$ , where  $f(B) := \text{val}(\mathbf{b})$  for  $B = \{b_1, \dots, b_{|B|}\} \subseteq \partial(s)$ , such that  $\mathbf{b} = (b_1, \dots, b_{|B|})$  and  $w_{b_1} \geq \dots \geq w_{b_{|B|}}$ . Our goal is then to efficiently maximize  $f$  over the set-system  $(\partial(s), \mathcal{I}_s)$ . Observe that  $\mathcal{I}_s$  is downward-closed and that we can simulate oracle access to  $\mathcal{I}_s$ , based on our oracle access to  $\mathcal{C}_s$ .

For each  $i = 0, \dots, m - 1$ , denote  $\partial(s)^{>i} := \{e_{i+1}, \dots, e_m\}$ , and  $\partial(s)^{>m} := \emptyset$ . Moreover, define the family of subsets  $\mathcal{I}_s^{>i} := \{B \subseteq \partial(s)^{>i} : B \cup \{e_i\} \in \mathcal{I}_s\}$  for each  $1 \leq i \leq m$ , and  $\mathcal{I}_s^{>0} := \mathcal{I}_s$ . Observe then that  $(\partial(s)^{>i}, \mathcal{I}_s^{>i})$  is a downward-closed set system, as  $\mathcal{I}_s$  is downward-closed. Moreover, we may simulate oracle access to  $\mathcal{I}_s^{>i}$  based on our oracle access to  $\mathcal{I}_s$ .

Denote  $\text{OPT}(\mathcal{I}_s^{>i})$  as the maximum value of  $f$  over constraints  $\mathcal{I}_s^{>i}$ . Observe then that for each  $0 \leq i \leq m - 1$ , the following recursion holds:

$$\text{OPT}(\mathcal{I}_s^{>i}) := \max_{j \in \{i+1, \dots, m\}} (p_{e_j} \cdot w_{e_j} + (1 - p_{e_j}) \cdot \text{OPT}(\mathcal{I}_s^{>j})) \quad (2.2)$$

Hence, given access to the values  $\text{OPT}(\mathcal{I}_s^{>i+1}), \dots, \text{OPT}(\mathcal{I}_s^{>m})$ , we can compute  $\text{OPT}(\mathcal{I}_s^{>i})$  efficiently. Moreover,  $\text{OPT}(\mathcal{I}_s^{>m}) = 0$  by definition. Thus, it is clear that we can use (2.2) to recover an optimal solution to  $f$ . We can define DP-OPT to be a memoization based implementation of (2.2). It is clear DP-OPT can be implemented in the claimed time complexity. ◀

Given  $R \subseteq U$ , consider the induced stochastic graph,  $G[\{s\} \cup R]$  for  $R \subseteq U$  which has probing constraint  $\mathcal{C}_s^R \subseteq \mathcal{C}_v$ , constructed by restricting  $\mathcal{C}_s$  to those strings whose entries all lie in  $R \times \{s\}$ . Moreover, denote the output of executing DP-OPT on  $G[\{s\} \cup R]$  by  $\text{DP-OPT}(s, R)$ . Consider now the following online probing algorithm:

---

**Algorithm 1** Greedy-DP.

**Input:** offline vertices  $U$  with vertex weights  $(w_u)_{u \in U}$ .

**Output:** a matching  $\mathcal{M}$  of active edges of the unknown stochastic graph  $G = (U, V, E)$ .

```

1:  $\mathcal{M} \leftarrow \emptyset$ .
2:  $R \leftarrow U$ .
3: for  $t = 1, \dots, n$  do
4:   Let  $v_t$  be the current online arrival node, with constraint  $\mathcal{C}_{v_t}$ .
5:   Set  $e \leftarrow \text{DP-OPT}(v_t, R)$ 
6:   for  $i = 1, \dots, |e|$  do
7:     Probe  $e_i$ .
8:     if  $\text{st}(e_i) = 1$  then
9:       Add  $e_i$  to  $\mathcal{M}$ , and update  $R \leftarrow R \setminus \{u_i\}$ , where  $e_i = (u_i, v_t)$ .
10: return  $\mathcal{M}$ .

```

---

In general, the behaviour of the committal benchmark, namely  $\text{OPT}(s, R)$ , can change very much, even for minor changes to  $R$ . For instance, if  $R = U$ , then  $\text{OPT}(s, U)$  may probe the edge  $(u, s)$  first – thus giving it highest priority – whereas if  $u^* \in U$  is removed from  $U$  (where  $u^* \neq u$ ),  $\text{OPT}(s, U \setminus \{u^*\})$  may not probe  $(u, v)$  at all (see Example B.1 for an explicit instance of this behaviour). As a result, it is easy to consider an execution of Algorithm 1 on  $G$  where  $v$  is matched to  $u$ , but if a new vertex  $v^*$  is added to  $G$  ahead of  $v$ ,  $u$  is never matched. We thus refer to Algorithm 1 as being non-monotonic. This contrasts with the classical setting, in which the deterministic greedy algorithm in the ROM setting does not exhibit this behaviour, and thus is **monotonic**. The absence of monotonicity isn't problematic in the adversarial setting of Theorem 1.1 because our primal-dual charging assignment does not depend on the order of the online vertex arrivals (see Appendix B). This contrasts with the ROM setting, in which Example B.1 can be extended to show that the cost sharing rule  $g(z) := \exp(z - 1)$  will not work in general. Our approach is thus to restrict our attention to stochastic graphs in which executions of Algorithm 1 are either monotonic, or monotonic with high probability. This leads us to the definition of rankability, which characterizes a large number of settings in which Algorithm 1 is monotonic.

Given a vertex  $v \in V$ , and an ordering  $\pi_v$  on  $\partial(v)$ , if  $R \subseteq U$ , then define  $\pi_v(R)$  to be the longest string constructible by iteratively appending the edges of  $R \times \{v\}$  via  $\pi_v$ , subject to respecting constraint  $\mathcal{C}_v^R$ . More precisely, given  $e'$  after processing  $e_1, \dots, e_i$  of  $R \times \{v\}$  ordered according to  $\pi_v$ , if  $(e', e_{i+1}) \in \mathcal{C}_v^R$ , then update  $e'$  by appending  $e_{i+1}$  to its end, otherwise move to the next edge  $e_{i+2}$  in the ordering  $\pi_v$ , assuming  $i + 2 \leq |R|$ . If  $i + 2 > |R|$ , return the current string  $e'$  as  $\pi_v(R)$ . We say that  $v$  is **rankable**, provided there exists a choice of  $\pi_v$  which depends *solely* on  $(p_e)_{e \in \partial(v)}$ ,  $(w_e)_{e \in \partial(v)}$  and  $\mathcal{C}_v$ , such that for *every*  $R \subseteq U$ , the strings  $\text{DP-OPT}(v, R)$  and  $\pi_v(R)$  are equal. Crucially, if  $v$  is rankable, then when vertex  $v$  arrives while executing Algorithm 1, one can compute the ranking  $\pi_v$  on  $\partial(v)$  and probe the adjacent edges of  $R \times \{v\}$  based on this order, subject to not violating the constraint  $\mathcal{C}_v^R$ . By following this probing strategy, the optimality of DP-OPT ensures that the expected weight of the match made to  $v$  will be  $\text{OPT}(v, R)$ . We consider three (non-exhaustive) examples of rankability:

► **Proposition 2.2.** *Let  $G = (U, V, E)$  be a stochastic graph, and suppose that  $v \in V$ . If  $v$  satisfies either of the following conditions, then  $v$  is rankable:*

1.  $v$  has unit patience or unlimited patience; that is,  $\ell_v \in \{1, |U|\}$ .
2.  $v$  has patience  $\ell_v$ , and for each  $u_1, u_2 \in U$ , if  $p_{u_1, v} \leq p_{u_2, v}$  then  $w_{u_1} \leq w_{u_2}$ .
3.  $G$  is unweighted, and  $v$  has a budget  $B_v$  with edge probing costs  $(b_{u, v})_{u \in U}$ , and for each  $u_1, u_2 \in U$ , if  $p_{u_1, v} \leq p_{u_2, v}$  then  $b_{u_1, v} \geq b_{u_2, v}$ .

## 13:10 Secretary Matching Meets Probing with Commitment

► **Remark 2.3.** Note that the cases of Proposition 2.2 subsume all the settings listed in the abstract. The rankable assumption is similar to assumptions referred to as laminar, agreeable and compatible in other applications.

We refer to the stochastic graph  $G$  as **rankable**, provided all of its vertices are themselves rankable. We emphasize that distinct vertices of  $V$  may each use their own separate rankings of their adjacent edges.

As discussed in Subsection 1.3, the 0.544 inapproximation against LP-std [8] prevents us from proving a performance guarantee against LP-std, even for patience values. We instead upper bound  $\text{OPT}(G)$  using a tighter LP relaxation that comes with the additional benefit of applying to downward-closed probing constraints. For each  $u \in U$  and  $v \in V$ , let  $x_{u,v}$  be a decision variable corresponding to the probability that  $\text{OPT}(G)$  probes the edge  $(u, v)$ .

$$\text{maximize} \quad \sum_{u \in U} \sum_{v \in V} w_u \cdot p_{u,v} \cdot x_{u,v} \quad (\text{LP-DP})$$

$$\text{subject to} \quad \sum_{v \in V} p_{u,v} \cdot x_{u,v} \leq 1 \quad \forall u \in U \quad (2.3)$$

$$\sum_{u \in R} w_u \cdot p_{u,v} \cdot x_{u,v} \leq \text{OPT}(v, R) \quad \forall v \in V, R \subseteq U \quad (2.4)$$

$$x_{u,v} \geq 0 \quad \forall u \in U, v \in V \quad (2.5)$$

Denote  $\text{LPOPT}_{\text{DP}}(G)$  as the optimal value of this LP. Constraint (2.3) can be viewed as ensuring that the expected number of matches made to  $u \in U$  is at most 1. Similarly, (2.4) can be interpreted as ensuring that expected stochastic reward of  $v$ , suggested by the solution  $(x_{u,v})_{u \in U, v \in V}$ , is actually attainable by the committal benchmark. Thus,  $\text{OPT}(G) \leq \text{LPOPT}_{\text{DP}}(G)$  (a formal proof specific to patience values is proven in [8]).

### 2.0.1 Defining the Primal-Dual Charging Schemes

In order to prove Theorems 1.1 and 1.2, we employ primal-dual charging arguments based on the dual of LP-DP. For each  $u \in U$ , define the variable  $\alpha_u$ . Moreover, for each  $R \subseteq U$  and  $v \in V$ , define the variable  $\phi_{v,R}$  (these latter variables correspond to constraint (2.4)).

$$\text{minimize} \quad \sum_{u \in U} \alpha_u + \sum_{v \in V} \sum_{R \subseteq U} \text{OPT}(v, R) \cdot \phi_{v,R} \quad (\text{LP-dual-DP})$$

$$\text{subject to} \quad p_{u,v} \cdot \alpha_u + \sum_{\substack{R \subseteq U: \\ u \in R}} w_u \cdot p_{u,v} \cdot \phi_{v,R} \geq w_u \cdot p_{u,v} \quad \forall u \in U, v \in V \quad (2.6)$$

$$\alpha_u \geq 0 \quad \forall u \in U \quad (2.7)$$

$$\phi_{v,R} \geq 0 \quad \forall v \in V, R \subseteq U \quad (2.8)$$

The dual-fitting argument used to prove Theorem 1.2 has an initial set-up which proceeds similarly to the argument in Devanur et al. [10]. Specifically, first define  $g : [0, 1] \rightarrow [0, 1]$  where  $g(z) := \exp(z - 1)$  for  $z \in [0, 1]$ . We shall use  $g$  to perform our charging/cost sharing. Moreover, recall that given  $v \in V$ , we defined  $c_v := \max_{e \in \mathcal{C}_v} |e|$  and  $p_v := \max_{e \in \partial(v)} p_e$ . Using these definitions, we define  $F = F(G)$ , where

$$F(G) := \begin{cases} 1 - \frac{1}{e} & G \text{ is rankable} \\ (1 - \frac{1}{e}) \cdot \min_{v \in V} (1 - p_v)^{c_v} & \text{otherwise} \end{cases} \quad (2.9)$$

In order to prove Theorem 1.2, we shall prove that Algorithm 1 returns a matching of expected weight at least  $F(G) \cdot \text{LPOPT}_{\text{DP}}(G)$  when executing on the stochastic graph  $G$  in the ROM setting. Clearly, we may assume  $F(G) > 0$ , as otherwise there is nothing to prove, so we shall make this assumption for the rest of the section. Note that  $F(G) \leq 1 - 1/e$  no matter the stochastic graph  $G$ .

For each  $v \in V$ , draw  $Y_v \in [0, 1]$  independently and uniformly at random. We assume that the vertices of  $V$  are presented to Algorithm 1 in a non-decreasing order, based on the values of  $(Y_v)_{v \in V}$ . We now describe how the charging assignments are made while Algorithm 1 executes on  $G$ . First, we initialize a dual solution  $((\alpha_u)_{u \in U}, (\phi_{v,R})_{v \in V, R \subseteq U})$  where all the variables are set equal to 0. Next, we take  $v \in V, u \in U$ , and  $R \subseteq U$ , where  $u \in R$ . If  $R$  consists of the unmatched vertices of  $v$  when it arrives at time  $Y_v$ , then suppose that Algorithm 1 matches  $v$  to  $u$  while making its probes to a subset of the edges of  $R \times \{v\}$ . In this case, we **charge**  $w_u \cdot (1 - g(Y_v))/F$  to  $\alpha_u$  and  $w_u \cdot g(Y_v)/(F \cdot \text{OPT}(v, R))$  to  $\phi_{v,R}$ . Observe that each subset  $R \subseteq U$  is charged at most once, as is each  $u \in U$ . Thus,

$$\mathbb{E}[w(\mathcal{M})] = F \cdot \left( \sum_{u \in U} \mathbb{E}[\alpha_u] + \sum_{v \in V} \sum_{R \subseteq U} \text{OPT}(v, R) \cdot \mathbb{E}[\phi_{v,R}] \right), \quad (2.10)$$

where the expectation is over the random variables  $(Y_v)_{v \in V}$  and  $(\text{st}(e))_{e \in E}$ . If we now set  $\alpha_u^* := \mathbb{E}[\alpha_u]$  and  $\phi_{v,R}^* := \mathbb{E}[\phi_{v,R}]$  for  $u \in U, v \in V$  and  $R \subseteq U$ , then (2.10) implies the following lemma:

► **Lemma 2.4.** *Suppose  $G = (U, V, E)$  is a stochastic graph for which Algorithm 1 returns the matching  $\mathcal{M}$  when presented  $V$  based on  $(Y_v)_{v \in V}$  generated u.a.r. from  $[0, 1]$ . In this case, if the variables  $((\alpha_u^*)_{u \in U}, (\phi_{v,R}^*)_{v \in V, R \subseteq U})$  are defined through the above charging scheme, then*

$$\mathbb{E}[w(\mathcal{M})] = F \cdot \left( \sum_{u \in U} \alpha_u^* + \sum_{v \in V} \sum_{R \subseteq U} \text{OPT}(v, R) \cdot \phi_{v,R}^* \right).$$

We claim the following regarding  $((\alpha_u^*)_{u \in U}, (\phi_{v,R}^*)_{v \in V, R \subseteq U})$ :

► **Lemma 2.5.** *If the online nodes of  $G = (U, V, E)$  are presented to Algorithm 1 based on  $(Y_v)_{v \in V}$  generated u.a.r. from  $[0, 1]$ , then the solution  $((\alpha_u^*)_{u \in U}, (\phi_{v,R}^*)_{v \in V, R \subseteq U})$  is a feasible solution to LP-dual-DP.*

Since LP-DP is a relaxation of the committal benchmark, Theorem 1.2 follows from Lemmas 2.4 and 2.5 in conjunction with weak duality.

## 2.0.2 Proving Dual Feasibility: Lemma 2.5

Let us suppose that the variables  $((\alpha_u)_{u \in U}, (\phi_{v,R})_{v \in V, R \subseteq U})$  are defined as in the charging scheme of Section 2.0.1. In order to prove Lemma 2.5, we must show that for each fixed  $u_0 \in U$  and  $v_0 \in V$ , we have that

$$\mathbb{E}[p_{u_0, v_0} \cdot \alpha_{u_0} + w_{u_0} \cdot p_{u_0, v_0} \sum_{\substack{R \subseteq U: \\ u_0 \in R}} \phi_{v_0, R}] \geq w_{u_0} \cdot p_{u_0, v_0}. \quad (2.11)$$

Our strategy for proving (2.11) first involves the same approach as used in Devanur et al. [10]. Specifically, we define the stochastic graph  $\tilde{G} := (U, \tilde{V}, \tilde{E})$ , where  $\tilde{V} := V \setminus \{v_0\}$  and  $\tilde{G} := G[U \cup \tilde{V}]$ . We wish to compare the execution of the algorithm on the instance  $\tilde{G}$  to its execution on the instance  $G$ . It will be convenient to couple the randomness between these two executions by making the following assumptions:

## 13:12 Secretary Matching Meets Probing with Commitment

1. For each  $e \in \tilde{E}$ ,  $e$  is active in  $\tilde{G}$  if and only if it is active in  $G$ .
2. The same random variables,  $(Y_v)_{v \in \tilde{V}}$ , are used in both executions.

If we now focus on the execution of  $\tilde{G}$ , then define the random variable  $\tilde{Y}_c$  where  $\tilde{Y}_c := Y_{v_c}$  if  $u_0$  is matched to some  $v_c \in \tilde{V}$ , and  $\tilde{Y}_c := 1$  if  $u_0$  remains unmatched after the execution on  $\tilde{G}$ . We refer to the random variable  $\tilde{Y}_c$  as the **critical time** of vertex  $u_0$  with respect to  $v_0$ . We claim the following lower bounds on  $\alpha_{u_0}$  in terms of the critical time  $\tilde{Y}_c$ .

► **Proposition 2.6.**

- If  $G$  is rankable, then  $\alpha_{u_0} \geq (1 - \frac{1}{e})^{-1} w_{u_0} (1 - g(\tilde{Y}_c))$ .
- Otherwise,  $\mathbb{E}[\alpha_{u_0} \mid (Y_v)_{v \in V}, (st(e))_{e \in \tilde{E}}] \geq (1 - \frac{1}{e})^{-1} w_{u_0} (1 - g(\tilde{Y}_c))$ .

► **Remark 2.7.** Note that Proposition 2.6 is the only part of the proof of Theorem 1.2 which is affected by whether or not  $G$  is rankable. We defer the proof of Proposition 2.6 to Appendix B.

By taking the appropriate conditional expectation, we can also lower bound the random variables  $(\phi_{v_0, R})_{\substack{R \subseteq U: \\ u_0 \in R}}$ .

► **Proposition 2.8.**

$$\sum_{\substack{R \subseteq U: \\ u_0 \in R}} \mathbb{E}[\phi_{v_0, R} \mid (Y_v)_{v \in \tilde{V}}, (st(e))_{e \in \tilde{E}}] \geq \frac{1}{F} \int_0^{\tilde{Y}_c} g(z) dz.$$

**Proof of Proposition 2.8.** We first define  $R_{v_0}$  as the unmatched vertices of  $U$  when  $v_0$  arrives (this is a random subset of  $U$ ). We also once again use  $\mathcal{M}$  to denote the matching returned by Algorithm 1 when executing on  $G$ . If we now take a *fixed* subset  $R \subseteq U$ , then the charging assignment to  $\phi_{v_0, R}$  ensures that

$$\phi_{v_0, R} = w(\mathcal{M}(v_0)) \cdot \frac{g(Y_{v_0})}{F \cdot \text{OPT}(v_0, R)} \cdot \mathbf{1}_{[R_{v_0} = R]},$$

where  $w(\mathcal{M}(v_0))$  corresponds to the weight of the vertex matched to  $v_0$  (which is zero if  $v_0$  remains unmatched after the execution on  $G$ ). In order to make use of this relation, let us first condition on the values of  $(Y_v)_{v \in V}$ , as well as the states of the edges of  $\tilde{E}$ ; that is,  $(st(e))_{e \in \tilde{E}}$ . Observe that once we condition on this information, we can determine  $g(Y_{v_0})$ , as well as  $R_{v_0}$ . As such,

$$\mathbb{E}[\phi_{v_0, R} \mid (Y_v)_{v \in V}, (st(e))_{e \in \tilde{E}}] = \frac{g(Y_{v_0})}{F \cdot \text{OPT}(v_0, R)} \mathbb{E}[w(\mathcal{M}(v_0)) \mid (Y_v)_{v \in V}, (st(e))_{e \in \tilde{E}}] \cdot \mathbf{1}_{[R_{v_0} = R]}.$$

On the other hand, the only randomness which remains in the conditional expectation involving  $w(\mathcal{M}(v_0))$  is over the states of the edges adjacent to  $v_0$ . Observe now that since Algorithm 1 behaves optimally on  $G[\{v_0\} \cup R_{v_0}]$ , we get that

$$\mathbb{E}[w(\mathcal{M}(v_0)) \mid (Y_v)_{v \in V}, (st(e))_{e \in \tilde{E}}] = \text{OPT}(v_0, R_{v_0}), \tag{2.12}$$

and so for the *fixed* subset  $R \subseteq U$ ,

$$\mathbb{E}[w(\mathcal{M}(v_0)) \mid (Y_v)_{v \in V}, (st(e))_{e \in \tilde{E}}] \cdot \mathbf{1}_{[R_{v_0} = R]} = \text{OPT}(v_0, R) \cdot \mathbf{1}_{[R_{v_0} = R]}$$

after multiplying each side of (2.12) by the indicator random variable  $\mathbf{1}_{[R_{v_0} = R]}$ . Thus,

$$\mathbb{E}[\phi_{v_0, R} \mid (Y_v)_{v \in V}, (st(e))_{e \in \tilde{E}}] = \frac{g(Y_{v_0})}{F} \mathbf{1}_{[R_{v_0} = R]},$$

after cancellation. We therefore get that

$$\sum_{\substack{R \subseteq U: \\ u_0 \in R}} \mathbb{E}[\phi_{v_0, R} \mid (Y_v)_{v \in V}, (\text{st}(e))_{e \in \tilde{E}}] = \frac{g(Y_{v_0})}{F} \sum_{\substack{R \subseteq U: \\ u_0 \in R}} \mathbf{1}_{[R_{v_0} = R]}.$$

Let us now focus on the case when  $v_0$  arrives before the critical time; that is,  $0 \leq Y_{v_0} < \tilde{Y}_c$ . Up until the arrival of  $v_0$ , the executions of the algorithm on  $\tilde{G}$  and  $G$  proceed identically, thanks to the coupling between the executions. As such,  $u_0$  must be available when  $v_0$  arrives. We interpret this observation in the above notation as saying the following:

$$\mathbf{1}_{[Y_{v_0} < \tilde{Y}_c]} \leq \sum_{\substack{R \subseteq U: \\ u_0 \in R}} \mathbf{1}_{[R_{v_0} = R]}.$$

As a result,

$$\sum_{\substack{R \subseteq U: \\ u_0 \in R}} \mathbb{E}[\phi_{v_0, R} \mid (Y_v)_{v \in V}, (\text{st}(e))_{e \in \tilde{E}}] \geq \frac{g(Y_{v_0})}{F} \mathbf{1}_{[Y_{v_0} < \tilde{Y}_c]}.$$

Now, if we take expectation over  $Y_{v_0}$ , while still conditioning on the random variables  $(Y_v)_{v \in \tilde{V}}$ , then we get that

$$\mathbb{E}[g(Y_{v_0}) \cdot \mathbf{1}_{[Y_{v_0} < \tilde{Y}_c]} \mid (Y_v)_{v \in \tilde{V}}, (\text{st}(e))_{e \in \tilde{E}}] = \int_0^{\tilde{Y}_c} g(z) dz,$$

as  $Y_{v_0}$  is drawn uniformly from  $[0, 1]$ , independently from  $(Y_v)_{v \in \tilde{V}}$  and  $(\text{st}(e))_{e \in \tilde{E}}$ . Thus, after applying the law of iterated expectations,

$$\sum_{\substack{R \subseteq U: \\ u_0 \in R}} \mathbb{E}[\phi_{v_0, R} \mid (Y_v)_{v \in \tilde{V}}, (\text{st}(e))_{e \in \tilde{E}}] \geq \frac{1}{F} \int_0^{\tilde{Y}_c} g(z) dz,$$

and so the claim holds. ◀

With Propositions 2.6 and 2.8, the proof of Lemma 2.5 follows easily (see Appendix B), and so Theorem 1.2 is proven.

### 3 Edge Weights

Let us suppose that  $G = (U, V, E)$  is a stochastic graph with arbitrary edge weights, probabilities and downward-closed probing constraints  $(\mathcal{C}_v)_{v \in V}$ . For each  $k \geq 1$  and  $\mathbf{e} = (e_1, \dots, e_k) \in E^{(k)}$ , define  $g(\mathbf{e}) := \prod_{i=1}^k (1 - p_{e_i})$ . Notice that  $g(\mathbf{e})$  corresponds to the probability that all the edges of  $\mathbf{e}$  are inactive, where  $g(\lambda) := 1$  for the empty string  $\lambda$ . We also define  $\mathbf{e}_{< e_i} := (e_1, \dots, e_{i-1})$  for each  $2 \leq i \leq k$ , which we denote by  $\mathbf{e}_{< i}$  when clear. By convention,  $\mathbf{e}_{< 1} := \lambda$ . Observe then that  $\text{val}(\mathbf{e}) := \sum_{i=1}^{|\mathbf{e}|} p_{e_i} w_{e_i} \cdot g(\mathbf{e}_{< i})$  corresponds to the expected weight of the first active edge if  $\mathbf{e}$  is probed in order of its indices, where  $\text{val}(\lambda) := 0$ .

For each  $v \in V$ , we introduce a decision variable denoted  $x_v(\mathbf{e})$ , which may loosely be interpreted as the likelihood the committal benchmark probes the edges in the order specified

## 13:14 Secretary Matching Meets Probing with Commitment

by  $\mathbf{e} = (e_1, \dots, e_k)$ <sup>6</sup>. With this notation, we express the following LP:

$$\text{maximize} \quad \sum_{v \in V} \sum_{\mathbf{e} \in \mathcal{C}_v} \text{val}(\mathbf{e}) \cdot x_v(\mathbf{e}) \quad (\text{LP-config})$$

$$\text{subject to} \quad \sum_{v \in V} \sum_{\substack{\mathbf{e} \in \mathcal{C}_v: \\ (u,v) \in \mathbf{e}}} p_{u,v} \cdot g(\mathbf{e}_{<(u,v)}) \cdot x_v(\mathbf{e}) \leq 1 \quad \forall u \in U \quad (3.1)$$

$$\sum_{\mathbf{e} \in \mathcal{C}_v} x_v(\mathbf{e}) = 1 \quad \forall v \in V, \quad (3.2)$$

$$x_v(\mathbf{e}) \geq 0 \quad \forall v \in V, \mathbf{e} \in \mathcal{C}_v \quad (3.3)$$

Denote  $\text{LPOPT}_{\text{conf}}(G)$  as the optimal value of LP-config. This LP was developed from insights relevant to both the secretary and prophet settings. Specifically, the DP-OPT algorithm of Theorem 2.1 can be used as a (deterministic) polynomial time separation oracle for the dual of LP-config. This ensures that LP-config can be solved in polynomial time as a consequence of how the ellipsoid algorithm [26, 11] executes (see Theorem A.1 in Appendix A for details). In [5], we prove that LP-config is a relaxation of the committal benchmark. Unlike previous LP relaxations of the committal benchmark, we are not aware of an easy proof of this fact, and we consider it to be a technical contribution.

We now define a *fixed vertex* probing algorithm, called VERTEXPROBE, which is applied to an online vertex  $s$  of an arbitrary stochastic graph (potentially distinct from  $G$ ) with probing constraints  $\mathcal{C}_s$  on  $\partial(s)$ . Specifically, given non-negative values  $(z(\mathbf{e}))_{\mathbf{e} \in \mathcal{C}_s}$  which satisfy  $\sum_{\mathbf{e} \in \mathcal{C}_s} z(\mathbf{e}) = 1$ , draw  $\mathbf{e}'$  with probability  $z(\mathbf{e}')$ . If  $\mathbf{e}' = (e'_1, \dots, e'_k)$  for  $k := |\mathbf{e}'| \geq 1$ , then probe the edges of  $\mathbf{e}'$  in order, and match  $s$  to the first edge revealed to be active. If no such edge exists, or  $\mathbf{e}' = \lambda$ , then return  $\emptyset$ .

► **Lemma 3.1.** *Suppose VERTEXPROBE is passed a fixed online node  $s$  of a stochastic graph, and values  $(z(\mathbf{e}))_{\mathbf{e} \in \mathcal{C}_s}$  which satisfy  $\sum_{\mathbf{e} \in \mathcal{C}_s} z(\mathbf{e}) = 1$ . If for each  $e \in \partial(s)$ ,*

$$\tilde{z}_e := \sum_{\substack{\mathbf{e}' \in \mathcal{C}_v: \\ e \in \mathbf{e}'}} g(\mathbf{e}'_{<e}) \cdot z_v(\mathbf{e}'),$$

*then  $e$  is probed with probability  $\tilde{z}_e$ , and returned by the algorithm with probability  $p_e \cdot \tilde{z}_e$ .*

► **Remark 3.2.** If VERTEXPROBE outputs the edge  $e = (u, s)$  when executing on the fixed node  $s$ , then we say that  $s$  **commits** to the edge  $e = (u, s)$ , or that  $s$  commits to  $u$ .

Returning to the problem of designing an online probing algorithm for  $G$ , let us assume that  $n := |V|$ , and that the online nodes of  $V$  are denoted  $v_1, \dots, v_n$ , where the order is generated *u.a.r.* Denote  $V_t$  as the set of first  $t$  arrivals of  $V$ ; that is,  $V_t := \{v_1, \dots, v_t\}$ . Moreover, set  $G_t := G[U \cup V_t]$ , and  $\text{LPOPT}_{\text{conf}}(G_t)$  as the value of an optimal solution to LP-config (this is a random variable, as  $V_t$  is a random subset of  $V$ ). The following inequality then holds:

► **Lemma 3.3.** *For each  $t \geq 1$ ,  $\mathbb{E}[\text{LPOPT}_{\text{conf}}(G_t)] \geq \frac{t}{n} \text{LPOPT}_{\text{conf}}(G)$ .*

In light of this observation, we design an online probing algorithm which makes use of  $V_t$ , the currently known nodes, to derive an optimal LP solution with respect to  $G_t$ . As such, each time an online node arrives, we must compute an optimal solution for the LP associated to  $G_t$ , distinct from the solution computed for that of  $G_{t-1}$ .

<sup>6</sup> While this is the natural interpretation of the decision variables of LP-config, to the best of our knowledge, formally defining the variables in this way does not lead to a proof that LP-config relaxes the committal benchmark. We discuss this in detail in [5].

■ **Algorithm 2** Unknown Stochastic Graph ROM.

**Input:**  $U$  and  $n := |V|$ .

**Output:** a matching  $\mathcal{M}$  from the (unknown) stochastic graph  $G = (U, V, E)$  of active edges.

---

```

1: Set  $\mathcal{M} \leftarrow \emptyset$ .
2: Set  $G_0 = (U, \emptyset, \emptyset)$ 
3: for  $t = 1, \dots, n$  do
4:   Input  $v_t$ , with  $(w_e)_{e \in \partial(v_t)}$ ,  $(p_e)_{e \in \partial(v_t)}$  and  $\mathcal{C}_{v_t}$ .
5:   Compute  $G_t$ , by updating  $G_{t-1}$  to contain  $v_t$  (and its relevant information).
6:   if  $t < \lfloor n/e \rfloor$  then
7:     Pass on  $v_t$ .
8:   else
9:     Solve LP-config for  $G_t$  and find an optimal solution  $(x_v(e))_{v \in V_t, e \in \mathcal{C}_v}$ .
10:    Set  $e_t \leftarrow \text{VERTEXPROBE}(v_t, \partial(v_t), (x_v(e))_{e \in \mathcal{C}_{v_t}})$ .
11:    if  $e_t = (u_t, v_t) \neq \emptyset$  and  $u_t$  is unmatched then
12:      Add  $e_t$  to  $\mathcal{M}$ .
13: return  $\mathcal{M}$ .

```

---

► **Remark 3.4.** Unlike the algorithm of Kesselheim et al., our algorithm is randomized, and we do not know whether the polytope LP-config always admits an optimum integral solution. We leave it as an interesting open question as to whether or not Algorithm 2 can be derandomized.

Let us consider the matching  $\mathcal{M}$  returned by the algorithm, as well as its weight, which we denote by  $w(\mathcal{M})$ . Set  $\alpha := 1/e$  for clarity, and take  $t \geq \lceil \alpha n \rceil$ . For each  $\alpha n \leq t \leq n$ , define  $R_t$  as the *unmatched vertices* of  $U$  when vertex  $v_t$  arrives. Note that committing to  $e_t = (u_t, v_t)$  is necessary, but not sufficient, for  $v_t$  to match to  $u_t$ . With this notation, we have that  $\mathbb{E}[w(\mathcal{M})] = \sum_{t=\alpha n}^n \mathbb{E}[w(u_t, v_t) \cdot \mathbf{1}_{[u_t \in R_t]}]$ . Moreover, we claim the following:

► **Lemma 3.5.** For each  $t \geq \lceil \alpha n \rceil$ ,  $\mathbb{E}[w(e_t)] \geq LPOPT_{conf}(G)/n$ .

► **Lemma 3.6.** For each  $t \geq \lceil \alpha n \rceil$ , define  $f(t, n) := \lfloor \alpha n \rfloor / (t - 1)$ . In this case,  $\mathbb{P}[u_t \in R_t \mid V_t, v_t] \geq f(t, n)$ , where  $V_t = \{v_1, \dots, v_t\}$  and  $v_t$  is the  $t^{\text{th}}$  arriving node of  $V$ <sup>7</sup>.

The proofs of Lemmas 3.5 and 3.6 mostly follow the analogous claims as proven by Kesselheim et al. in the classic secretary matching problem. We present formal proofs in the arXiv version [4]. With these lemmas, together with the efficient solvability of LP-config, the proof of Theorem 1.6 follows easily (see Appendix C).

## 4 Conclusion and Open Problems

We considered the online stochastic bipartite matching with commitment in a number of different settings establishing several competitive bounds against the committal benchmark. Our work leaves open a number of challenging problems. For context we note that currently, even for the classical (i.e., non-probing) setting,  $1 - \frac{1}{e}$  is the best known ratio for deterministic algorithms operating on unweighted or vertex weighted graphs with random order vertex arrivals. The best known ROM inapproximation of 0.823 (due to Manshadi et al. [21]) comes from the classical i.i.d. unweighted graph setting for a known distribution and applies to randomized as well as deterministic algorithms.

---

<sup>7</sup> Note that since  $V_t$  is a set, conditioning on  $V_t$  only reveals which vertices of  $V$  encompass the first  $t$  arrivals, *not* the order they arrived in. Hence, conditioning on  $v_t$  as well reveals strictly more information.

- What is the best ratio that a deterministic or randomized online algorithm can obtain for *all* vertex weighted stochastic graphs in the ROM setting? That is, what competitive ratio can be achieved without the rankable assumption? Is there an online probing algorithm which can surpass the  $1 - 1/e$  “barrier” with or without the rankable assumption? Here we note that in the classical ROM setting, the RANKING algorithm achieves a 0.696 ratio for unweighted graphs (due to Mahdian and Yan [20]) and a 0.6534 ratio (due to Huang et al. [15]) for vertex weighted graphs. Thus, randomization seems to significantly help in the classical ROM setting.
- What is the best ratio that a randomized online algorithm can obtain for stochastic graphs in the adversarial arrival model? The Mehta and Panigrahi [22] 0.621 inapproximation shows that randomized probing algorithms (even for unweighted graphs and unit patience) cannot achieve a  $1 - 1/e$  performance guarantee against LP-std-unit, however the work of Goyal and Udvani [12] suggests that this is because LP-std-unit is too loose a relaxation of the committal benchmark.
- For edge weighted graphs, can we achieve a  $\frac{1}{e}$  competitive ratio (or any constant ratio) by a combinatorial (and more efficient) algorithm? Our vertex weighted algorithm can be viewed as a truthful online (or random order) posted price mechanism. Can we modify the edge weighted algorithm to be a truthful mechanism thereby generalizing the truthful mechanism of Reiffenhauser [25]? Note that unlike the vertex weighted algorithm, our algorithm for edge weights does not necessarily make an optimal social welfare decision for each online node.

## A Solving LP-config Efficiently

Suppose that we are given an arbitrary stochastic graph  $G = (U, V, E)$ . We contrast LP-config with LP-std, which is defined only when  $G$  has patience values  $(\ell_v)_{v \in V}$ :

$$\begin{array}{ll} \text{maximize} & \sum_{e \in E} w_e \cdot p_e \cdot x_e \end{array} \quad (\text{LP-std})$$

$$\begin{array}{ll} \text{subject to} & \sum_{e \in \partial(u)} p_e \cdot x_e \leq 1 \quad \forall u \in U \end{array} \quad (\text{A.1})$$

$$\sum_{e \in \partial(v)} p_e \cdot x_e \leq 1 \quad \forall v \in V \quad (\text{A.2})$$

$$\sum_{e \in \partial(v)} x_e \leq \ell_v \quad \forall v \in V \quad (\text{A.3})$$

$$0 \leq x_e \leq 1 \quad \forall e \in E. \quad (\text{A.4})$$

Observe that LP-config and LP-std are the same LP in the case of unit patience:

$$\begin{array}{ll} \text{maximize} & \sum_{v \in V} \sum_{e \in \partial(v)} w_e \cdot p_e \cdot x_e \end{array} \quad (\text{LP-std-unit})$$

$$\begin{array}{ll} \text{subject to} & \sum_{e \in \partial(u)} p_e \cdot x_e \leq 1 \quad \forall u \in U \end{array} \quad (\text{A.5})$$

$$\sum_{e \in \partial(v)} x_e \leq 1 \quad \forall v \in V \quad (\text{A.6})$$

$$x_e \geq 0 \quad \forall e \in E \quad (\text{A.7})$$

### A.1 Solving LP-config Efficiently

We now show how LP-config be solved efficiently under the assumptions of Theorem 1.6.

► **Theorem A.1.** *Suppose that  $G = (U, V, E)$  in a stochastic graph with downward-closed probing constraints  $(\mathcal{C}_v)_{v \in V}$ . In the membership oracle model, LP-config is efficiently solvable in  $|G|$ .*

We prove Theorem A.1 by first considering the dual of LP-config. Note, that in the below LP formulation, if  $\mathbf{e} = (e_1, \dots, e_k) \in \mathcal{C}_v$ , then we set  $e_i = (u_i, v)$  for  $i = 1, \dots, k$  for convenience.

$$\begin{aligned}
& \text{minimize} && \sum_{u \in U} \alpha_u + \sum_{v \in V} \beta_v && \text{(LP-config-dual)} \\
& \text{subject to} && \beta_v + \sum_{j=1}^{|\mathbf{e}|} p_{e_j} \cdot g(\mathbf{e}_{<j}) \cdot \alpha_{u_j} \geq \sum_{j=1}^{|\mathbf{e}|} p_{e_j} \cdot w_{e_j} \cdot g(\mathbf{e}_{<j}) && \forall v \in V, \mathbf{e} \in \mathcal{C}_v \\
& && \alpha_u \geq 0 && \forall u \in U \\
& && \beta_v \in \mathbb{R} && \forall v \in V
\end{aligned}$$

Observe that to prove Theorem A.1, it suffices to show that LP-config-dual has a (deterministic) polynomial time separation oracle, as a consequence of how the ellipsoid algorithm [26, 11] executes (see [28, 27, 2, 19] for more detail).

Suppose that we are presented a particular selection of dual variables, say  $(\alpha_u)_{u \in U}$  and  $(\beta_v)_{v \in V}$ , which may or may not be a feasible solution to LP-config-dual. Our separation oracle must determine efficiently whether these variables satisfy all the constraints of LP-config-dual. In the case in which the solution is *infeasible*, the oracle must additionally return a constraint which is violated.

It is clear that we can accomplish this for the non-negativity constraints, so let us fix a particular  $v \in V$  in what follows. We wish to determine whether there exists some  $\mathbf{e} = (e_1, \dots, e_{|\mathbf{e}|}) \in \mathcal{C}_v$ , such that if  $e_i = (u_i, v)$  for  $i = 1, \dots, k$ , then

$$f(\mathbf{e}) := \sum_{j=1}^{|\mathbf{e}|} (w_{e_j} - \alpha_{u_j}) \cdot p_{e_j} \cdot g(\mathbf{e}_{<j}) > \beta_v, \quad (\text{A.8})$$

where  $f(\mathbf{e}) := 0$  if  $\mathbf{e} = \lambda$ .

► **Lemma A.2.** *In the membership oracle model, DP-OPT of Proposition 2.1 can be used to efficiently check whether  $f(\mathbf{e}') > \beta_v$  for some  $\mathbf{e}' \in \mathcal{C}_v$ , provided  $\mathcal{C}_v$  is downward-closed. Moreover, if such a tuple exists, then it can be found efficiently.*

**Proof.** In order to make this statement, it suffices to show how one can use DP-OPT to maximize the function  $f$  efficiently.

Compute  $\tilde{w}_e := w_e - \alpha_u$  for each  $e = (u, v) \in \partial(v)$ , and define  $P := \{e \in \partial(v) : \tilde{w}_e \geq 0\}$ . First observe that if  $P = \emptyset$ , then (A.8) is maximized by the empty-string  $\lambda$ . Thus, for now on assume that  $P \neq \emptyset$ . Since  $\mathcal{C}_v$  is downward-closed, it suffices to consider those  $\mathbf{e} \in \mathcal{C}_v$  whose edges all lie in  $P$ . As such, for notational convenience, let us hereby assume that  $\partial(v) = P$ . Observe then that maximizing  $f$  corresponds to executing DP-OPT on the stochastic graph  $G[U \cup \{v\}]$ , with edge weights replaced by  $(\tilde{w}_e)_{e \in \partial(v)}$ . ◀

## B Proofs and Additions to Section 2

**Proof of Theorem 1.1.** Let  $G = (U, V, E)$  be a vertex weighted stochastic graph, and assume that Algorithm 1 returns the matching  $\mathcal{M}$  when the online vertices of  $G$  are presented to the algorithm in adversarial order.

We now define a charging assignment as Algorithm 1 executes on  $G$ . First, initialize a dual solution  $((\alpha_u)_{u \in U}, (\phi_{v,R})_{v \in V, R \subseteq U})$  where all the variables are set equal to 0. Let us now take  $v \in V, u \in U$ , and  $R \subseteq U$ , where  $u \in R$ . If  $R$  consists of the unmatched vertices when  $v$  it arrives, then suppose that Algorithm 1 matches  $v$  to  $u$  while making its probes to

## 13:20 Secretary Matching Meets Probing with Commitment

a subset of the edges of  $R \times \{v\}$ . In this case, we **charge**  $w_u$  to  $\alpha_u$  and  $w_u/\text{OPT}(v, R)$  to  $\phi_{v,R}$ . Observe that each subset  $R \subseteq U$  is charged at most once, as is each  $u \in U$ . Thus,

$$\mathbb{E}[w(\mathcal{M})] = \frac{1}{2} \cdot \left( \sum_{u \in U} \mathbb{E}[\alpha_u] + \sum_{v \in V} \sum_{R \subseteq U} \text{OPT}(v, R) \cdot \mathbb{E}[\phi_{v,R}] \right), \quad (\text{B.1})$$

where the expectation is over  $(\text{st}(e))_{e \in E}$ . Let us now set  $\alpha_u^* := \mathbb{E}[\alpha_u]$  and  $\phi_{v,R}^* := \mathbb{E}[\phi_{v,R}]$  for  $u \in U, v \in V$  and  $R \subseteq U$ . We claim that  $((\alpha_u^*)_{u \in U}, (\phi_{v,R}^*)_{v \in V, R \subseteq U})$  is a feasible solution to LP-dual-DP. To show this, we must prove that for each fixed  $u_0 \in U$  and  $v_0 \in V$ , we have that

$$\mathbb{E}[p_{u_0, v_0} \cdot \alpha_{u_0} + w_{u_0} \cdot p_{u_0, v_0} \sum_{\substack{R \subseteq U: \\ u_0 \in R}} \phi_{v_0, R}] \geq w_{u_0} \cdot p_{u_0, v_0}. \quad (\text{B.2})$$

We first define  $R_{v_0}$  as the unmatched vertices of  $U$  when  $v_0$  arrives (this is a random subset of  $U$ ). Moreover, define  $\tilde{E} := E \setminus \partial(v_0)$ . We claim the following inequality:

$$\sum_{\substack{R \subseteq U: \\ u_0 \in R}} \mathbb{E}[\phi_{v_0, R} \mid (\text{st}(e))_{e \in \tilde{E}}] = \mathbf{1}_{[u_0 \in R_{v_0}]}$$

To see this, observe that if we take a *fixed* subset  $R \subseteq U$ , then the charging assignment to  $\phi_{v_0, R}$  ensures that

$$\phi_{v_0, R} = w(\mathcal{M}(v_0)) \cdot \frac{1}{\text{OPT}(v_0, R)} \cdot \mathbf{1}_{[R_{v_0} = R]},$$

where  $w(\mathcal{M}(v_0))$  corresponds to the weight of the vertex matched to  $v_0$  (which is zero if  $v_0$  remains unmatched after the execution on  $G$ ). In order to make use of this relation, let us first condition on  $(\text{st}(e))_{e \in \tilde{E}}$ . Observe that once we condition on this information, we can determine  $R_{v_0}$ . As such,

$$\mathbb{E}[\phi_{v_0, R} \mid (\text{st}(e))_{e \in \tilde{E}}] = \frac{1}{\text{OPT}(v_0, R)} \mathbb{E}[w(\mathcal{M}(v_0)) \mid (\text{st}(e))_{e \in \tilde{E}}] \cdot \mathbf{1}_{[R_{v_0} = R]}.$$

On the other hand, the only randomness which remains in the conditional expectation involving  $w(\mathcal{M}(v_0))$  is over  $(\text{st}(e))_{e \in \partial(v_0)}$ . However, since Algorithm 1 behaves optimally on  $G[\{v_0\} \cup R_{v_0}]$ , we get that

$$\mathbb{E}[w(\mathcal{M}(v_0)) \mid (Y_v)_{v \in V}, (\text{st}(e))_{e \in \tilde{E}}] = \text{OPT}(v_0, R_{v_0}), \quad (\text{B.3})$$

and so for the *fixed* subset  $R \subseteq U$ ,

$$\mathbb{E}[w(\mathcal{M}(v_0)) \mid (\text{st}(e))_{e \in \tilde{E}}] \cdot \mathbf{1}_{[R_{v_0} = R]} = \text{OPT}(v_0, R) \cdot \mathbf{1}_{[R_{v_0} = R]}$$

after multiplying each side of (B.3) by the indicator random variable  $\mathbf{1}_{[R_{v_0} = R]}$ . Thus,

$$\mathbb{E}[\phi_{v_0, R} \mid (\text{st}(e))_{e \in \tilde{E}}] = \mathbf{1}_{[R_{v_0} = R]},$$

after cancellation. We therefore get that

$$\sum_{\substack{R \subseteq U: \\ u_0 \in R}} \mathbb{E}[\phi_{v_0, R} \mid (\text{st}(e))_{e \in \tilde{E}}] = \sum_{\substack{R \subseteq U: \\ u_0 \in R}} \mathbf{1}_{[R_{v_0} = R]} = \mathbf{1}_{[u_0 \in R_{v_0}]},$$

as claimed. On the other hand, if we focus on the vertex  $u_0$ , then observe that if  $u_0 \notin R_{v_0}$ , then  $\alpha_{u_0}$  must have been charged  $w_u$ . In other words,  $\alpha_{u_0} \geq w_u \cdot \mathbf{1}_{[u_0 \notin R_{v_0}]}$ . As a result,

$$\mathbb{E}[p_{u_0, v_0} \alpha_{u_0} + w_{u_0} p_{u_0, v_0} \sum_{\substack{R \subseteq U: \\ u_0 \in R}} \phi_{v, R} | (\text{st}(e))_{e \in \tilde{E}}] \geq w_{u_0} p_{u_0, v_0} \cdot \mathbf{1}_{[u_0 \notin R_{v_0}]} + w_{u_0} p_{u_0, v_0} \cdot \mathbf{1}_{[u_0 \in R_{v_0}]},$$

and so (B.2) follows after taking expectations. The solution  $((\alpha_u^*)_{u \in U}, (\phi_{v, R}^*)_{v \in V, R \subseteq U})$  is therefore feasible, and so since  $\text{OPT}(G) \leq \text{LPOPT}_{\text{DP}}(G)$ , the proof is complete after applying weak duality and (B.1).  $\blacktriangleleft$

► **Example B.1.** Let  $G = (U, V, E)$  be a bipartite graph with  $U = \{u_1, u_2, u_3, u_4\}$ ,  $V = \{v\}$  and  $\ell_v = 2$ . Set  $p_{u_1, v} = 1/3$ ,  $p_{u_2, v} = 1$ ,  $p_{u_3, v} = 1/2$ ,  $p_{u_4, v} = 2/3$ . Fix  $\varepsilon > 0$ , and let the weights of offline vertices be  $w_{u_1} = 1 + \varepsilon$ ,  $w_{u_2} = 1 + \varepsilon/2$ ,  $w_{u_3} = w_{u_4} = 1$ . We assume that  $\varepsilon$  is sufficiently small – concretely,  $\varepsilon \leq 1/12$ . If  $R_1 := U$ , then  $\text{OPT}(v, R_1)$  probes  $(u_1, v)$  and then  $(u_2, v)$  in order. On the other hand, if  $R_2 = R_1 \setminus \{v_2\}$ , then  $\text{OPT}(v, R_2)$  does *not* probe  $(u_1, v)$ . Specifically,  $\text{OPT}(v, R_2)$  probes  $(u_3, v)$  and then  $(u_4, v)$ .

**Proof of Proposition 2.6.** For each  $v \in V$ , denote  $R_v^{\text{af}}(G)$  as the unmatched (remaining) vertices of  $U$  right after  $v$  is processed (attempts its probes) in the execution on  $G$ . We emphasize that if a probe of  $v$  yields an active edge, thus matching  $v$ , then this match is excluded from  $R_v^{\text{af}}(G)$ . Similarly, define  $R_v^{\text{af}}(\tilde{G})$  in the same way for the execution on  $\tilde{G}$  (where  $v$  is now restricted to  $\tilde{V}$ ).

We first consider the case when  $G$  is rankable, and so  $F(G) = 1 - 1/e$ . Observe that since the constraints  $(\mathcal{C}_v)_{v \in V}$  are substring-closed, we can use the coupling between the two executions to inductively prove that

$$R_v^{\text{af}}(G) \subseteq R_v^{\text{af}}(\tilde{G}), \quad (\text{B.4})$$

for each  $v \in \tilde{V}$ <sup>8</sup>. Now, since  $g(1) = 1$  (by assumption), there is nothing to prove if  $\tilde{Y}_c = 1$ . Thus, we may assume that  $\tilde{Y}_c < 1$ , and as a consequence, that there exists some vertex  $v_c \in V$  which matches to  $u_0$  at time  $\tilde{Y}_c$  in the execution on  $\tilde{G}$ .

On the other hand, by assumption we know that  $u_0 \notin R_{v_c}^{\text{af}}(\tilde{G})$  and thus by (B.4), that  $u_0 \notin R_{v_c}^{\text{af}}(G)$ . As such, there exists some  $v' \in V$  which probes  $(u_0, v')$  and succeeds in matching to  $u_0$  at time  $Y_{v'} \leq \tilde{Y}_c$ . Thus, since  $g$  is monotone,

$$\alpha_{u_0} \geq \left(1 - \frac{1}{e}\right)^{-1} w_{u_0} \cdot (1 - g(Y_{v'})) \cdot \mathbf{1}_{[\tilde{Y}_c < 1]} \geq \left(1 - \frac{1}{e}\right)^{-1} w_{u_0} \cdot (1 - g(\tilde{Y}_c)),$$

and so the rankable case is complete.

We now consider the case when  $G$  is not rankable. Suppose that  $\mathcal{M}(v_0)$  is the vertex matched to  $v_0$  when the algorithm executes on  $G$ , where  $\mathcal{M}(v_0) := \emptyset$  provided no match is made. Observe then that if no match is made to  $v_0$  in this execution, then the execution proceeds identically to the execution on  $\tilde{G}$ . As a result, we get the following relation:

$$\alpha_{u_0} \geq \frac{w_{u_0}}{F} (1 - g(\tilde{Y}_c)) \cdot \mathbf{1}_{[\mathcal{M}(v_0) = \emptyset]}.$$

Now, let us condition on  $(\text{st}(e))_{e \in \tilde{E}}$  and  $(Y_v)_{v \in V}$ , and recall the definitions of  $p_{v_0} := \max_{e \in \mathcal{C}(v_0)} p_e$  and  $c_{v_0} := \max_{e \in \mathcal{C}_{v_0}} |e|$ . Observe that if every probe involving an edge of

<sup>8</sup> Example B.1 shows why (B.4) will not hold if  $G$  is not rankable.

## 13:22 Secretary Matching Meets Probing with Commitment

$\partial(v_0)$  is inactive, then  $\mathcal{M}(v_0) = \emptyset$ . On the other hand, each probe independently fails with probability at least  $(1 - p_{v_0})$ , and there are at most  $c_{v_0}$  probes made to  $\partial(v_0)$ . Thus,

$$\mathbb{P}[\mathcal{M}(v_0) = \emptyset \mid (\text{st}(e))_{e \in \tilde{E}}, (Y_v)_{v \in V}] \geq (1 - p_{v_0})^{c_{v_0}}$$

Now, since  $F(G) = (1 - 1/e) \cdot \min_{v \in V} (1 - p_v)^{c_v}$ , we get that

$$\mathbb{E}[\alpha_{u_0} \mid (Y_v)_{v \in V}, (\text{st}(e))_{e \in \tilde{E}}] \geq \left(1 - \frac{1}{e}\right)^{-1} w_{u_0} (1 - g(\tilde{Y}_c)),$$

and so the proof is complete.  $\blacktriangleleft$

**Proof of Lemma 2.5.** We first observe that by taking the appropriate conditional expectation, Proposition 2.6 ensures that

$$\mathbb{E}[\alpha_{u_0} \mid (Y_v)_{v \in \tilde{V}}, (\text{st}(e))_{e \in \tilde{E}}] \geq \left(1 - \frac{1}{e}\right)^{-1} w_{u_0} \cdot (1 - g(\tilde{Y}_c)),$$

where the right-hand side follows since  $\tilde{Y}_c$  is entirely determined from  $(Y_v)_{v \in \tilde{V}}$  and  $(\text{st}(e))_{e \in \tilde{E}}$ . Thus, combined with Proposition 2.8,

$$\mathbb{E}[p_{u_0, v_0} \cdot \alpha_{u_0} + w_{u_0} \cdot p_{u_0, v_0} \cdot \sum_{\substack{R \subseteq U: \\ u_0 \in R}} \phi_{v, R} \mid (Y_v)_{v \in \tilde{V}}, (\text{st}(e))_{e \in \tilde{E}}], \quad (\text{B.5})$$

is lower bounded by

$$\left(1 - \frac{1}{e}\right)^{-1} w_{u_0} \cdot p_{u_0, v_0} \cdot (1 - g(\tilde{Y}_c)) + \frac{w_{u_0} p_{u_0, v_0}}{F} \int_0^{\tilde{Y}_c} g(z) dz. \quad (\text{B.6})$$

However,  $g(z) := \exp(z - 1)$  for  $z \in [0, 1]$  by assumption, so

$$(1 - g(\tilde{Y}_c)) + \int_0^{\tilde{Y}_c} g(z) dz = \left(1 - \frac{1}{e}\right),$$

no matter the value of the critical time  $\tilde{Y}_c$ . Thus,

$$\left(1 - \frac{1}{e}\right)^{-1} \left( (1 - g(\tilde{Y}_c)) + \frac{1 - 1/e}{F} \int_0^{\tilde{Y}_c} g(z) dz \right) \geq 1, \quad (\text{B.7})$$

as  $F \leq 1 - 1/e$  by definition (see (2.9)). If we now lower bound (B.6) using (B.7) and take expectations over (B.5), it follows that

$$\mathbb{E}[p_{u_0, v_0} \cdot \alpha_{u_0} + w_{u_0} \cdot p_{u_0, v_0} \cdot \sum_{\substack{R \subseteq U: \\ u_0 \in R}} \phi_{v, R}] \geq w_{u_0} \cdot p_{u_0, v_0}.$$

As the vertices  $u_0 \in U$  and  $v_0 \in V$  were chosen arbitrarily, the proposed dual solution of Lemma 2.5 is feasible, and so the proof is complete.  $\blacktriangleleft$

## C Proofs and Additions to Section 3

**Proof of Theorem 1.6.** Clearly, Algorithm 2 can be implemented efficiently, since LP-config is efficiently solvable. Thus, we focus on proving the algorithm attains the desired asymptotic competitive ratio.

Let us consider the matching  $\mathcal{M}$  returned by the algorithm, as well as its weight, which we denote by  $w(\mathcal{M})$ . Set  $\alpha := 1/e$  for clarity, and take  $t \geq \lceil \alpha n \rceil$ , where we define  $R_t$  to be the *unmatched vertices* of  $U$  when vertex  $v_t$  arrives. Moreover, define  $e_t$  as the edge  $v_t$  commits to, which is the empty-set by definition if no such commitment is made. Observe that

$$\mathbb{E}[w(\mathcal{M})] = \sum_{t=\lceil \alpha n \rceil}^n \mathbb{E}[w(u_t, v_t) \cdot \mathbf{1}_{[u_t \in R_t]}]. \quad (\text{C.1})$$

Fix  $\lceil \alpha n \rceil \leq t \leq n$ , and first observe that  $w(u_t, v_t)$  and  $\{u_t \in R_t\}$  are conditionally independent given  $(V_t, v_t)$ , as the probes involving  $\partial(v_t)$  are independent from those of  $v_1, \dots, v_{t-1}$ . Thus,

$$\mathbb{E}[w(u_t, v_t) \cdot \mathbf{1}_{[u_t \in R_t]} \mid V_t, v_t] = \mathbb{E}[w(u_t, v_t) \mid V_t, v_t] \cdot \mathbb{P}[u_t \in R_t \mid V_t, v_t].$$

Moreover, Lemma 3.6 implies that

$$\mathbb{E}[w(u_t, v_t) \mid V_t, v_t] \cdot \mathbb{P}[u_t \in R_t \mid V_t, v_t] \geq \mathbb{E}[w(u_t, v_t) \mid V_t, v_t] f(t, n),$$

and so  $\mathbb{E}[w(u_t, v_t) \mathbf{1}_{[u_t \in R_t]} \mid V_t, v_t] \geq \mathbb{E}[w(u_t, v_t) \mid V_t, v_t] f(t, n)$ . Thus, by the law of iterated expectations<sup>9</sup>

$$\begin{aligned} \mathbb{E}[w(u_t, v_t) \cdot \mathbf{1}_{[u_t \in R_t]}] &= \mathbb{E}[\mathbb{E}[w(u_t, v_t) \cdot \mathbf{1}_{[u_t \in R_t]} \mid V_t, v_t]] \\ &\geq \mathbb{E}[\mathbb{E}[w(u_t, v_t) \mid V_t, v_t] f(t, n)] = f(t, n) \mathbb{E}[w(u_t, v_t)]. \end{aligned}$$

As a result, using (C.1), we get that

$$\mathbb{E}[w(\mathcal{M})] = \sum_{t=\lceil \alpha n \rceil}^n \mathbb{E}[w(u_t, v_t) \mathbf{1}_{[u_t \in R_t]}] \geq \sum_{t=\lceil \alpha n \rceil}^n f(t, n) \mathbb{E}[w(u_t, v_t)].$$

We may thus conclude that

$$\mathbb{E}[w(\mathcal{M})] \geq \text{LPOPT}_{\text{conf}}(G) \sum_{t=\lceil \alpha n \rceil}^n \frac{f(t, n)}{n},$$

after applying Lemma 3.5. As  $\sum_{t=\lceil \alpha n \rceil}^n f(t, n)/n \geq (1/e - 1/n)$ , the result holds.  $\blacktriangleleft$

<sup>9</sup>  $\mathbb{E}[w(u_t, v_t) \cdot \mathbf{1}_{[u_t \in R_t]} \mid V_t, v_t]$  is a random variable which depends on  $V_t$  and  $v_t$ , and so the outer expectation is over the randomness in  $V_t$  and  $v_t$ .

# Semi-Streaming Algorithms for Submodular Function Maximization Under $b$ -Matching Constraint

## Abstract

We consider the problem of maximizing a submodular function under the  $b$ -matching constraint, in the semi-streaming model. Our main results can be summarized as follows.

- When the function is linear, *i.e.* for the maximum weight  $b$ -matching problem, we obtain a  $2 + \varepsilon$  approximation. This improves the previous best bound of  $3 + \varepsilon$  [12].
- When the function is a non-negative monotone submodular function, we obtain a  $3 + 2\sqrt{2} \approx 5.828$  approximation. This matches the currently best ratio [12].
- When the function is a non-negative non-monotone submodular function, we obtain a  $4 + 2\sqrt{3} \approx 7.464$  approximation. This ratio is also achieved in [12], but only under the simple matching constraint, while we can deal with the more general  $b$ -matching constraint.

We also consider a generalized problem, where a  $k$ -uniform hypergraph is given with an extra matroid constraint imposed on the edges, with the same goal of finding a  $b$ -matching that maximizes a submodular function. We extend our technique to this case to obtain an algorithm with an approximation of  $\frac{8}{3}k + O(1)$ .

Our algorithms build on the ideas of the recent works of Levin and Wajc [12] and of Garg, Jordan, and Svensson [9]. Our main technical innovation is to introduce a data structure and associate it with each vertex and the matroid, to record the extra information of the stored edges. After the streaming phase, these data structures guide the greedy algorithm to make better choices.

## 1 Introduction

Let  $G = (V, E)$  be a multi-graph (with no self-loop) where each vertex  $v \in V$  is associated with a *capacity*  $b_v \in \mathbb{Z}_+$ . A  $b$ -*matching* is a subset of edges  $M \subseteq E$  where each vertex  $v$  has at most  $b_v$  incident edges contained in  $M$ .

In the maximum weight  $b$ -matching problem, edges are given weights  $w : E \rightarrow \mathbb{R}_+$  and we need to compute a  $b$ -matching  $M$  so that  $w(M) = \sum_{e \in M} w(e)$  is maximized. A generalization of the problem is that of maximizing a non-negative *submodular function*  $f : 2^E \rightarrow \mathbb{R}_+$  under

the  $b$ -matching constraint, namely, we look for a  $b$ -matching  $M$  so that  $f(M)$  is maximized. Here we recall the definition of a submodular function:

$$\forall X \subseteq Y \subsetneq E, \forall e \in E \setminus Y, f(X \cup \{e\}) - f(X) \geq f(Y \cup \{e\}) - f(Y).$$

Additionally  $f$  is *monotone* if  $\forall X \subseteq Y \subseteq E, f(X) \leq f(Y)$ , otherwise it is *non-monotone*. Observe that the maximum weight matching is the special case where  $f$  is a linear sum of the weights associated with the edges.

In the traditional offline setting, both problems are extensively studied. The maximum weight  $b$ -matching can be solved in polynomial time [16]; maximizing a non-negative monotone submodular function under  $b$ -matching constraint is NP-hard and the best approximation ratios so far are  $2 + \varepsilon$  and  $4 + \varepsilon$ , for the monotone and non-monotone case, respectively [8].

In this work, we consider the problem in the semi-streaming model [14]. Here the edges in  $E$  arrive over time but we have only limited space (ideally proportional to the output size) and cannot afford to store all edges in  $E$  – this rules out the possibility of applying known offline algorithms.

## 1.1 Our Contribution

We start with the maximum weight ( $b$ -)matching. For this problem, a long series of papers [4, 5, 6, 10, 12, 13, 15, 17] have proposed semi-streaming algorithms, with progressively improved approximation ratios, culminating in the work of Paz and Schwartzman [15], where  $2 + \varepsilon$  approximation is attained, for the simple matching. For the general  $b$ -matching, very recently, Levin and Wajc [12] gave a  $3 + \varepsilon$  approximation algorithm. We close the gap between the simple matching and the general  $b$ -matching.

► **Theorem 1.** *For the maximum weight  $b$ -matching problem, we obtain a  $2 + \varepsilon$  approximation algorithm using  $O(\log_{1+\varepsilon}(W/\varepsilon) \cdot |M_{max}|)$  variables in memory, and another using  $O(\log_{1+\varepsilon}(1/\varepsilon) \cdot |M_{max}| + \sum_{v \in V} b_v)$  variables, where  $M_{max}$  denotes the maximum cardinality  $b$ -matching and  $W$  denotes the maximum ratio between two non-zero weights.*

Next we consider the general case of submodular functions, for whom approximation algorithms have been proposed in [2, 3, 12, 7]. The current best ratios obtained by Levin and Wajc [12] are  $3 + 2\sqrt{2} \approx 5.828$  and  $4 + 2\sqrt{3} \approx 7.464$ , for the monotone and non-monotone functions respectively. We propose an alternative algorithm to achieve the same bounds.

► **Theorem 2.** *To maximize a non-negative submodular function under  $b$ -matching constraint, we obtain algorithms providing a  $3 + 2\sqrt{2} \approx 5.828$  approximation for monotone functions and a  $4 + 2\sqrt{3} \approx 7.464$  approximation for non-monotone functions, using  $O(\log W \cdot |M_{max}|)$  variables, where  $M_{max}$  denotes the maximum cardinality  $b$ -matching and  $W$  denotes the maximum quotient  $\frac{f(e|Y)}{f(e'|X)}$ , for  $X \subseteq Y \subseteq E$ ,  $e, e' \in E$ ,  $f(e'|X) > 0$ .*

It should be pointed out that in [12], for the case of non-monotone functions, their algorithm only works for the simple matching, and it is unclear how to generalize it to the general  $b$ -matching [11], while our algorithm lifts this restriction<sup>1</sup>. Another interesting thing to observe is that even though the achieved ratios are the same and our analysis borrows ideas from [12], our algorithm is not really just the same algorithm disguised under a different form. See Appendix B for a concrete example where the two algorithms behave differently.

<sup>1</sup> However, when the graph is bipartite, this ratio of  $4 + 2\sqrt{3} \approx 7.464$  is already obtained by Garg et al. [9], even for the general  $b$ -matching constraint.

We also consider an extension, where a matroid<sup>2</sup> is imposed on the edges. Specifically, here  $G = (V, E)$  is a  $k$ -uniform hypergraph, where each edge  $e \in E$  contains  $k$  vertices in  $V$ . In addition to the capacities  $b_v$ , a matroid  $\mathcal{M} = (E, \mathcal{I})$  is given. A  $b$ -matching  $M$  is feasible only if  $M$  is an independent set in  $\mathcal{I}$ . The objective here is to find a feasible  $b$ -matching  $M$  that maximizes  $f(M)$  for  $f$  a non-negative submodular function<sup>3</sup>.

To see our problem in a larger context, observe that it is a particular case of the  $(k + 1)$ -matchoid<sup>4</sup>. Using the current best algorithm of Chekuri et al. [3] and Feldman et al. [7], one can obtain  $4(k + 1)$  and  $2(k + 1) + 2\sqrt{(k + 1)(k + 2)} + 1$  for monotone and non-monotone functions, respectively. We obtain the following.

► **Theorem 3.** *To maximize a non-negative submodular function under the  $b$ -matching constraint along with an additional matroid constraint, we design an algorithm providing an approximation ratio bounded by  $\frac{8}{3}k + O(1)$  for both monotone and non-monotone functions, using  $O(\log W \cdot k \cdot \min\{r_{\mathcal{M}}, |M_{\max}|\})$  variables in memory, where  $M_{\max}$  denotes the maximum cardinality  $b$ -matching,  $r_{\mathcal{M}}$  is the rank of the matroid and  $W$  denotes the maximum quotient  $\frac{f(e|Y)}{f(e'|X)}$ , for  $X \subseteq Y \subseteq E$ ,  $e, e' \in E$ ,  $f(e'|X) > 0$ .*

The exact expressions for the approximation ratios are formally stated in Theorems 27 and 29. Given  $k = 2, 3$ , and  $4$ , we obtain the approximation ratios of 13.055, 15.283, and 17.325 for the monotone function. Our ratio is in general better when  $k \geq 3$  compared to the known technique of [3, 7]. When the function is non-monotone, given  $k = 2, 3$ , and  $4$ , we obtain the ratios of 14.857, 17.012, and 18.999, respectively. Our ratio is better when  $k \geq 4$  compared to the known technique of [7].

## 1.2 Our Technique

We use a local-ratio technique to choose to retain or discard a newly arrived edge during the streaming phase. After this phase, a greedy algorithm, according to the reverse edge arrival order, is then applied to add edges one by one into the solution while guaranteeing feasibility.

This is in fact the same framework used in [12, 15]. Our main technical innovation is to introduce a data structure, which takes the form of a set of queues. Such a set of queues is associated with each vertex (and with the imposed matroid). Every edge, if retained, will appear as an element<sup>5</sup> in one of these queues for each of its endpoints (and for the imposed matroid). These queues will guide the greedy algorithm to make better choices and are critical in our improvement over previous results. Here we give some intuition behind these queues. Consider the maximum weight  $b$ -matching problem. Similar to [9], we compute, for every edge, a *gain*. The sum of the gains of the retained edges can be shown to be at least half of the real weight of the unknown optimal matching. The question then boils down

<sup>2</sup> Recall that  $\mathcal{M} = (E, \mathcal{I})$  is a matroid if the following three conditions hold: (1)  $\emptyset \in \mathcal{I}$ , (2) if  $X \subseteq Y \in \mathcal{I}$ , then  $X \in \mathcal{I}$ , and (3) if  $X, Y \in \mathcal{I}$ ,  $|Y| > |X|$ , there exists an element  $e \in Y \setminus X$  so that  $X \cup \{e\} \in \mathcal{I}$ . The sets in  $\mathcal{I}$  are the *independent sets* and the *rank*  $r_{\mathcal{M}}$  of the matroid  $\mathcal{M}$  is defined as  $\max_{X \in \mathcal{I}} |X|$ .

<sup>3</sup> It is natural to ask what if the submodular function is just a linear function. We observe that in this case, our problem reduces to maximizing a weighted rank function (recall that a *weighted rank function* over a matroid  $\mathcal{M}$  is a function  $f : 2^E \rightarrow \mathbb{R}_+$  that such that for  $X \subseteq E$ ,  $f(X) = \max_{Y \subseteq X, Y \in \mathcal{I}} w(Y)$ ), a special case of a monotone submodular function, under the  $b$ -matching constraint. Our algorithm mentioned in Theorem 2 can be trivially generalized to give an approximation ratio of  $k + 1 + 2\sqrt{k}$  for this.

<sup>4</sup> Recall that a  $p$ -matchoid  $\mathcal{M}$  is a collection  $(\mathcal{M}_i = (E_i, \mathcal{I}_i))_{i=1}^s$  of matroids, each defined on some (possibly distinct) subset  $E_i \subseteq E$ , in which each element  $e \in E$  appears in at most  $p$  of the sets  $E_i$ . To see our problem is a  $(k + 1)$ -matchoid, observe that we can define a uniform matroid on each vertex to replace the capacity constraint; as each edge appears in  $k$  vertices, in total it appears in  $k + 1$  matroids.

<sup>5</sup> In this article, we will often use “edge” and “element” interchangeably.

to how to “extract” a matching whose real weight is large compared to these gains of the retained edges. In our queues, the elements are stacked in such a way that the weight of an element  $e$  is the sum of the gains of all the elements preceding  $e$  in any queue containing  $e$ . This suggests that if  $e$  is taken by the greedy algorithm, we can as well ignore all elements that are underneath  $e$  in the queues, as their gains are already “paid for” by  $e$ .

## 2 Maximum Weight $b$ -Matching

### 2.1 Description of the Algorithm

For ease of description, we explain how to achieve 2 approximation, ignoring the issue of space complexity for the moment. We will explain how a slight modification can ensure the desired space complexity, at the expense of an extra  $\varepsilon$  term in the approximation ratio (see Appendix A).

The formal algorithm for the streaming phase is shown in Algorithm 1. We give an informal description here. Let  $S$ , initially empty, be the set of edges that have been stored so far. For each vertex  $v \in V$ , a set  $Q_v = \{Q_{v,1}, \dots, Q_{v,b_v}\}$  of queues are maintained. These queues contain the edges incident to  $v$  that are stored in  $S$  and respect the arrival order of edges (newer edges are higher up in the queues). Each time a new edge  $e$  arrives, we compute its *gain*  $g(e)$  (see Lines 5 and 8). Edge  $e$  is added into  $S$  only if its gain is strictly positive. If this is the case, for each endpoint  $u$  of  $e$ , we put  $e$  in one of  $u$ 's queues (see Lines 6 and 13) and define a *reduced weight*  $w_u(e)$  (Line 11). It should be noted that  $w_u(e)$  will be exactly the sum of the gains of the edges preceding (and including)  $e$  in the queue. We refer to the last element inserted in a queue  $Q$  as the top element of that queue, denoted  $Q.top()$ . To insert an element  $e$  on top of a queue  $Q$ , we use the instruction  $Q.push(e)$ . By convention, for an empty queue  $Q$  we have  $Q.top() = \perp$ . We also set  $w_u(\perp) = 0$ . Notice that each element  $e$  also has, for each endpoint  $v \in e$ , a pointer  $r_v(e)$  to indicate its immediate predecessor in the queue of  $v$ , where it appears.

```

1:  $S \leftarrow \emptyset$ 
2:  $\forall v \in V : Q_v \leftarrow (Q_{v,1} = \emptyset, \dots, Q_{v,b_v} = \emptyset)$  ▷  $b_v$  queues for a vertex  $v$ 
3: for  $e = e_t$ ,  $1 \leq t \leq |E|$  an edge from the stream do
4:   for  $u \in e$  do
5:      $w_u^*(e) \leftarrow \min\{w_u(Q_{u,q}.top()) : 1 \leq q \leq b_u\}$ 
6:      $q_u(e) \leftarrow q$  such that  $w_u(Q_{u,q}.top()) = w_u^*(e)$ 
7:   if  $w(e) > \sum_{u \in e} w_u^*(e)$  then
8:      $g(e) \leftarrow w(e) - \sum_{u \in e} w_u^*(e)$ 
9:      $S \leftarrow S \cup \{e\}$ 
10:   for  $u \in e$  do
11:      $w_u(e) \leftarrow w_u^*(e) + g(e)$ 
12:      $r_u(e) \leftarrow Q_{u,q_u(e)}.top()$  ▷  $r_u(e)$  is the element below  $e$  in the queue
13:      $Q_{u,q_u(e)}.push(e)$  ▷ add  $e$  on the top of the smallest queue

```

---

After the streaming phase, our greedy algorithm, formally described in Algorithm 2, constructs a  $b$ -matching based on the stored set  $S$ .

The greedy proceeds based on the reverse edge arrival order – but with an important modification. Once an edge  $e$  is taken as part of the  $b$ -matching, all edges preceding  $e$  that are stored in the same queue as  $e$  will be subsequently ignored by the greedy algorithm. The variables  $z_e$  are used to mark this fact.

---

**Algorithm 2** Greedy construction phase.
 

---

```

1:  $M \leftarrow \emptyset$ 
2:  $\forall e \in S : z_e \leftarrow 1$ 
3: for  $e \in S$  in reverse order do
4:   if  $z_e = 0$  then continue ▷ skip edge  $e$  if it is marked
5:    $M \leftarrow M \cup \{e\}$ 
6:   for  $u \in e$  do
7:      $c \leftarrow e$ 
8:     while  $c \neq \perp$  do
9:        $z_c \leftarrow 0$  ▷ mark elements below  $e$  in each queue
10:       $c \leftarrow r_u(c)$ 
11: return  $M$ 

```

## 2.2 Analysis for Maximum Weight $b$ -Matching

For analysis, for each discarded element  $e \in E \setminus S$ , we set  $g(e) = 0$  and  $w_u(e) = w_u^*(e)$  for each  $u \in e$ . The *weight* of a queue,  $w_u(Q_{u,i})$ , is defined as the reduced weight of its top element, namely,  $w_u(Q_{u,i}.top())$ . Let  $w_u(Q_u) = \sum_{i=1}^{b_u} w_u(Q_{u,i})$ . We write  $S^{(t)}$  as the value of  $S$  at the end of the iteration  $t$  of the streaming phase, and by convention  $S^{(0)} = \emptyset$ . This notation  $^{(t)}$  will also be used for other sets such as  $Q_u$  and  $Q_{u,i}$ . Through this paper,  $M^{opt}$  will always refer to the best solution for the considered problem.

The following proposition follows easily by induction.

► **Proposition 4.**

- (i) For all  $v \in V$  we have  $g(\delta(v)) = g(\delta(v) \cap S) = w_v(Q_v)$ .
- (ii) The set  $\{Q_{v,q}.top() : 1 \leq q \leq b_v\}$  contains the  $b_v$  heaviest elements of  $S \cap \delta(v)$  in terms of reduced weights.

► **Lemma 5.** At the end of Algorithm 1, for all  $b$ -matching  $M'$  and for all  $v \in V$ , we have  $w_v(Q_v) \geq w_v(M' \cap \delta(v))$ .

**Proof.** By Proposition 4(ii),  $w_v(Q_v)$  is exactly the sum of the reduced weights of the  $b_v$  heaviest elements in  $S \cap \delta(v)$  (which are on top of the queues of  $Q_v$ ). If we can show that for each element  $e = e_t \in M' \setminus S$ ,  $w_u(e_t) \leq \min\{w_v(Q_{v,q}^{[E]}) : 1 \leq q \leq b_v\}$ , the proof will follow. Indeed, as  $e_t$  is discarded, we know that  $w_v(e_t) = \min\{w_v(Q_{v,q}^{(t-1)}) : 1 \leq q \leq b_v\} \leq \min\{w_v(Q_{v,q}^{[E]}) : 1 \leq q \leq b_v\}$ , where the inequality holds because the weight of a queue is monotonically increasing. ◀

► **Lemma 6.**  $2g(S) \geq w(M^{opt})$ .

**Proof.** It is clear that for  $e = \{u, v\}$  we have  $w_u(e) + w_v(e) \geq w(e)$ . Therefore

$$\begin{aligned}
 w(M^{opt}) &\leq \sum_{e=\{u,v\} \in M^{opt}} w_u(e) + w_v(e) = \sum_{u \in V} w_u(M^{opt} \cap \delta(u)) \\
 &\leq \sum_{u \in V} w_u(Q_u) = \sum_{u \in V} g(S \cap \delta(u)) = 2g(S),
 \end{aligned}$$

where the second inequality follows from Lemma 5 and the subsequent equality from Proposition 4(i). The last equality comes from the fact that an edge is incident to 2 vertices. ◀

Recall that  $q_v(e)$  refers to the index of the particular queue in  $Q_v$  where a new edge  $e$  will be inserted (Line 6 of Algorithm 1).

► **Lemma 7.** *Algorithm 2 outputs a feasible  $b$ -matching  $M$  with weight  $w(M) \geq g(S)$ .*

**Proof.** By an easy induction, we know that for a given  $e = e_t \in S$  and  $v \in e$ , we have:

$$w_v(e) = w_v^*(e) + g(e) = \sum_{e' \in Q_{v, q_v(e)}^{(t)}} g(e') \quad \text{and} \quad w(e) = g(e) + \sum_{u \in e} \sum_{e' \in Q_{u, q_u(e)}^{(t-1)}} g(e'). \quad (1)$$

Moreover, observe that  $S \cap \delta(v)$  can be written as a disjoint union of the  $Q_{v, q}$  for  $1 \leq q \leq b_v$ :  $S \cap \delta(v) = \bigcup_{1 \leq q \leq b_v} Q_{v, q}$ . One can also observe that Algorithm 2 takes at most one element in each queue  $Q_{v, i}$ . In fact, an element can be added only if no element above it in any of the queues where it appears has already been added into  $M$ ; and no element below it in the queues can be already part of  $M$  because  $S$  is read in the reverse arrival order. Consequently  $M$  respects the capacity constraint and is thus a feasible  $b$ -matching. We now make a critical claim from which the correctness of the lemma follows easily.

▷ **Claim 8.** Given an edge  $e \in S$ , either  $e \in M$ , or there exists another edge  $e'$  arriving later than  $e$ , such that  $e' \in M$  and there exists a queue belonging to a common endpoint of  $e$  and  $e'$ , which contains both of them.

Observe that if the claim holds, by (1), the gain  $g(e)$  of any edge  $e \in S$  will be “paid” for by some edge  $e' \in M$  and the proof will follow.

To prove the claim, let  $e = \{u, v\}$  and assume that  $e \notin M$ . Consider the two queues  $Q_{u, q_u(e)}$  and  $Q_{v, q_v(e)}$ . The edges stored above  $e$  in these two queues must have arrived later than  $e$  in  $S$  and have thus already been considered by Algorithm 2. The only reason that  $e \notin M$  must be that  $z_e = 0$  when  $e$  is processed, implying that one of these edges was already part of  $M$ . Hence the claim follows. ◀

Lemmas 6 and 7 give the following theorem:

► **Theorem 9.** *Algorithms 1 and 2 provide a 2 approximation for the maximum weight  $b$ -matching problem.*

We refer the readers to Appendix A for the details on how to handle the memory consumption of the algorithm.

► **Remark 10.** It is straightforward to extend our algorithm to a  $k$ -uniform hypergraph, where we can get an approximation ratio of  $k$ . Notice that if the  $k$ -uniform hypergraph is also  $k$ -partite, then the problem becomes that of finding a maximum weight intersection of  $k$  partition matroids. It can be shown that our stored edge set is exactly identical to the one stored by the algorithm of Garg et al. [9]. They have conjectured that for  $k$  arbitrary general matroids, their stored edge set always contains a  $k$  approximation. Our result thus proves their conjecture to be true when all matroids are partition matroids.

## 3 Submodular Function Maximization

### 3.1 Description of the Algorithm

For submodular function maximization, the streaming algorithm, formally described in Algorithm 3, is quite similar to the one for the weighted  $b$ -matching in the preceding section. Here notice that the element weight  $w(e)$  is replaced by the marginal value  $f(e | S)$  (see Lines 7 and 10). We use a similar randomization method to that of Levin and Wajc [12] for non-monotone functions (adding an element to  $S$  only with probability  $p$ , see Lines 8-9), and our analysis will bear much similarity to theirs. The greedy algorithm to build a solution  $M$  from  $S$  is still Algorithm 2.

■ **Algorithm 3** Streaming phase for submodular function maximization.

---

```

1:  $S \leftarrow \emptyset$ 
2:  $\forall v \in V : Q_v \leftarrow (Q_{v,1} = \emptyset, \dots, Q_{v,b_v} = \emptyset)$ 
3: for  $e = e_t, 1 \leq t \leq |E|$  an edge from the stream do
4:   for  $u \in e$  do
5:      $w_u^*(e) \leftarrow \min\{w_u(Q_{u,q}.top()) : 1 \leq q \leq b_u\}$ 
6:      $q_u(e) \leftarrow q$  such that  $w_u(Q_{u,q}.top()) = w_u^*(e)$ 
7:   if  $f(e|S) > \alpha \sum_{u \in e} w_u^*(e)$  then
8:      $\pi \leftarrow$  a random variable equal to 1 with probability  $p$  and 0 otherwise
9:     if  $\pi = 0$  then continue ▷ skip edge  $e$  with probability  $1 - p$ 
10:     $g(e) \leftarrow f(e|S) - \sum_{u \in e} w_u^*(e)$ 
11:     $S \leftarrow S \cup \{e\}$ 
12:    for  $u \in e$  do
13:       $w_u(e) \leftarrow w_u^*(e) + g(e)$ 
14:       $r_u(e) \leftarrow Q_{u,q_u(e)}.top()$ 
15:       $Q_{u,q_u(e)}.push(e)$ 

```

---

Algorithm 3 uses, for  $\alpha = 1 + \varepsilon$ ,  $O(\log_{1+\varepsilon}(W/\varepsilon) \cdot |M_{max}|)$  variables, where  $M_{max}$  denotes the maximum cardinality  $b$ -matching and  $W$  denotes the maximum quotient  $\frac{f(e|Y)}{f(e'|X)}$ , for  $X \subseteq Y \subseteq E$ ,  $e, e' \in E$ ,  $f(e'|X) > 0$  (in Appendix A we explain how to guarantee such space complexity when  $f$  is linear – the general case of a submodular function follows similar ideas).

### 3.2 Analysis for Monotone Submodular Function Maximization

Let  $\alpha = 1 + \varepsilon$ . In this section,  $p = 1$  (so we have actually a deterministic algorithm for the monotone case). The following two lemmas relate the total gain  $g(S)$  with the marginal values  $f(S|\emptyset)$  and  $f(M^{opt}|S)$ .

► **Lemma 11.** *It holds that  $g(S) \geq \frac{\varepsilon}{1+\varepsilon} f(S|\emptyset)$ .*

**Proof.** For an element  $e = e_t \in S$  we have  $f(e|S^{(t-1)}) \geq (1 + \varepsilon) \sum_{u \in e} w_u^*(e)$  so

$$g(e) = f(e|S^{(t-1)}) - \sum_{u \in e} w_u^*(e) \geq f(e|S^{(t-1)}) \left(1 - \frac{1}{1 + \varepsilon}\right),$$

implying that

$$g(S) = \sum_{e \in S} g(e) \geq \sum_{e = e_t \in S} f(e|S^{(t-1)}) \left(1 - \frac{1}{1 + \varepsilon}\right) = \frac{\varepsilon}{1 + \varepsilon} f(S|\emptyset). \quad \blacktriangleleft$$

As in the previous section, if an edge  $e$  is discarded, we assume that  $w_v^*(e) = w_v(e)$  for each  $v \in e$ .

► **Lemma 12.** *It holds that  $2(1 + \varepsilon)g(S) \geq f(M^{opt}|S)$ .*

**Proof.** The only elements  $e = e_t$  missing in  $S$  are the ones satisfying the inequality  $f(e|S^{(t-1)}) \leq (1 + \varepsilon) \sum_{u \in e} w_u^*(e)$ . So by submodularity,

$$\begin{aligned} f(M^{opt}|S) &\leq \sum_{e \in M^{opt} \setminus S} f(e|S) \leq \sum_{e = e_t \in M^{opt} \setminus S} f(e|S^{(t-1)}) \\ &\leq \sum_{e \in M^{opt} \setminus S} (1 + \varepsilon) \sum_{u \in e} w_u^*(e) = (1 + \varepsilon) \sum_{e \in M^{opt} \setminus S} \sum_{u \in e} w_u(e) \end{aligned}$$

$$\begin{aligned}
 &= (1 + \varepsilon) \sum_{u \in V} w_u((M^{opt} \setminus S) \cap \delta(u)) \leq (1 + \varepsilon) \sum_{u \in V} w_u(Q_u) \\
 &\leq 2(1 + \varepsilon)g(S),
 \end{aligned}$$

similar to the proof of Lemma 6.  $\blacktriangleleft$

► **Lemma 13.** *Algorithm 2 outputs a feasible  $b$ -matching with  $f(M) \geq g(S) + f(\emptyset)$ .*

**Proof.** As argued in the proof of Lemma 7,  $M$  respects the capacities and so is feasible. Now, suppose that  $M = \{e_{t_1}, \dots, e_{t_{|M|}}\}$ ,  $t_1 < \dots < t_{|M|}$ . Then

$$f(M) = f(\emptyset) + \sum_{i=1}^{|M|} f(e_{t_i} | \{e_{t_1}, \dots, e_{t_{i-1}}\}) \geq f(\emptyset) + \sum_{i=1}^{|M|} f(e_{t_i} | S^{(t_i-1)}) \geq f(\emptyset) + g(S),$$

as the values  $f(e_{t_i} | S^{(t_i-1)})$  play the same role as the weights in Lemma 7.  $\blacktriangleleft$

► **Theorem 14.** *Algorithms 3 and 2 provide a  $3 + 2\sqrt{2}$  approximation if we set  $\varepsilon = \frac{1}{\sqrt{2}}$ .*

**Proof.** By Lemmas 11 and 12, we derive  $(2 + 2\varepsilon + \frac{1+\varepsilon}{\varepsilon})g(S) \geq f(M^{opt} | S) + f(S | \emptyset) = f(M^{opt} \cup S | \emptyset) \geq f(M^{opt} | \emptyset)$ , where the last inequality is due to the monotonicity of  $f$ . By Lemma 13, the output  $b$ -matching  $M$  guarantees that  $f(M) \geq g(S) + f(\emptyset)$ . As a result,  $(3 + 2\varepsilon + \frac{1}{\varepsilon})f(M) \geq f(M^{opt} | \emptyset) + f(\emptyset) = f(M^{opt})$ . Setting  $\varepsilon = \frac{1}{\sqrt{2}}$  gives the result.  $\blacktriangleleft$

► **Remark 15.** When  $b_v = 1$  for all  $v \in V$  (i.e. simple matching), our algorithm behaves exactly the same as the algorithm of Levin and Wajc [12]. Therefore their tight example also applies to our algorithm. In other words, our analysis of approximation ratio is tight.

### 3.3 Analysis for Non-Monotone Submodular Function Maximization

In this section, we suppose that  $\frac{1}{3+2\varepsilon} \leq p \leq \frac{1}{2}$ .

► **Lemma 16.** *It holds that*

$$\left(2(1 + \varepsilon) + \frac{1 + \varepsilon}{\varepsilon}\right) \mathbb{E}[g(S)] \geq \mathbb{E}[f(S \cup M^{opt} | \emptyset)].$$

**Proof.** From Lemma 11 we have that for any execution of the algorithm (a realization of randomness), the inequality  $\frac{1+\varepsilon}{\varepsilon}g(S) \geq f(S | \emptyset)$  holds, so it is also true in expectation. We will try to prove in the following that  $2(1 + \varepsilon)\mathbb{E}[g(S)] \geq \mathbb{E}[f(M^{opt} | S)]$ , which is the counterpart of Lemma 12.

First, we show that for any  $e \in M^{opt}$ :

$$(1 + \varepsilon)\mathbb{E}\left[\sum_{u \in e} w_u(e)\right] \geq \mathbb{E}[f(e | S)] \tag{2}$$

We will use a conditioning similar to the one used in [12]. Let  $e = e_t \in M^{opt}$ . We consider the event  $A_e = [f(e | S^{(t-1)}) \leq (1 + \varepsilon)\sum_{u \in e} w_u^*(e)]$ . Notice that if  $A_e$  holds,  $e$  is not part of  $S$  and  $w_v^*(e) = w_v(e)$  for each  $v \in e$ . Now by submodularity,

$$\begin{aligned}
 \mathbb{E}[f(e | S) | A_e] &\leq \mathbb{E}[f(e | S^{(t-1)}) | A_e] \leq \mathbb{E}\left[(1 + \varepsilon)\sum_{u \in e} w_u^*(e) | A_e\right] \\
 &= (1 + \varepsilon)\mathbb{E}\left[\sum_{u \in e} w_u(e) | A_e\right]
 \end{aligned}$$

Next we consider the condition  $\overline{A_e}$  (where the edge  $e$  should be added into  $S$  with probability  $p$ ). As  $p \leq \frac{1}{2}$ , and for  $e = e_t = \{u, v\}$  we have  $w_u(e) + w_v(e) = 2f(e | S^{(t-1)}) - w_u^*(e) - w_v^*(e)$  when  $e$  is added to  $S$ , we get

$$\begin{aligned} \mathbb{E} \left[ \sum_{u \in e} w_u(e) | \overline{A_e} \right] &= p \cdot \mathbb{E} \left[ 2f(e | S^{(t-1)}) - \sum_{u \in e} w_u^*(e) | \overline{A_e} \right] + (1-p) \cdot \mathbb{E} \left[ \sum_{u \in e} w_u^*(e) | \overline{A_e} \right] \\ &= 2p \cdot \mathbb{E} \left[ f(e | S^{(t-1)}) | \overline{A_e} \right] + (1-2p) \cdot \mathbb{E} \left[ \sum_{u \in e} w_u^*(e) | \overline{A_e} \right] \\ &\geq 2p \cdot \mathbb{E} \left[ f(e | S^{(t-1)}) | \overline{A_e} \right]. \end{aligned}$$

As a result, for  $p \geq \frac{1}{3+2\varepsilon}$ ,

$$\begin{aligned} (1+\varepsilon) \mathbb{E} \left[ \sum_{u \in e} w_u(e) | \overline{A_e} \right] &\geq 2p(1+\varepsilon) \cdot \mathbb{E} \left[ f(e | S^{(t-1)}) | \overline{A_e} \right] \\ &\geq (1-p) \cdot \mathbb{E} \left[ f(e | S^{(t-1)}) | \overline{A_e} \right] \\ &\geq \mathbb{E} \left[ f(e | S) | \overline{A_e} \right], \end{aligned}$$

where the last inequality holds because with probability  $p$  we have  $f(e | S) = 0$  (as  $e \in S$ ) and with probability  $1-p$ ,  $f(e | S) \leq f(e | S^{(t-1)})$  (by submodularity).

So we have proven inequality (2) and it follows that

$$\begin{aligned} \mathbb{E} [f(M^{opt} | S)] &\leq \sum_{e \in M^{opt}} \mathbb{E} [f(e | S)] \leq (1+\varepsilon) \sum_{e \in M^{opt}} \mathbb{E} \left[ \sum_{u \in e} w_u(e) \right] \\ &= (1+\varepsilon) \sum_{u \in V} \sum_{e \in M^{opt} \cap \delta(u)} \mathbb{E} [w_u(e)] \leq (1+\varepsilon) \sum_{u \in V} \mathbb{E} [w_u(Q_u)] \\ &= 2(1+\varepsilon) \mathbb{E} [g(S)], \end{aligned}$$

where in the last inequality we use the fact that Lemma 5 holds for every realization of randomness.

Now the bounds on  $\mathbb{E} [f(M^{opt} | S)]$  and the bound on  $\mathbb{E} [f(S | \emptyset)]$  argued in the beginning give the proof of the lemma.  $\blacktriangleleft$

Then we will use the following lemma, due to Buchbinder et al. [1]:

► **Lemma 17** (Lemma 2.2 in [1]). *Let  $h : 2^N \rightarrow \mathbb{R}_+$  be a non-negative submodular function, and let  $B$  be a random subset of  $N$  containing every element of  $N$  with probability at most  $p$  (not necessarily independently), then  $\mathbb{E}[h(B)] \geq (1-p)h(\emptyset)$ .*

► **Theorem 18.** *Algorithm 3 run with  $p = \frac{1}{3+2\varepsilon}$  provides a set  $S$ , upon which Algorithm 2 outputs a  $b$ -matching  $M$  satisfying:*

$$\left( \frac{4\varepsilon^2 + 8\varepsilon + 3}{2\varepsilon} \right) \mathbb{E}[f(M)] \geq f(M^{opt}).$$

*This ratio is optimized when  $\varepsilon = \frac{\sqrt{3}}{2}$ , which gives a  $4 + 2\sqrt{3}$  approximation.*

**Proof.** Combining Lemma 13 and Lemma 16,

$$\left( 2(1+\varepsilon) + \frac{1+\varepsilon}{\varepsilon} \right) \mathbb{E}[f(M)] \geq \mathbb{E}[f(S \cup M^{opt})].$$

## 14:10 Semi-Streaming Submodular Function Maximization Under $b$ -Matching Constraint

Now we can apply Lemma 17 by defining  $h : 2^E \rightarrow \mathbb{R}_+$  as, for any  $X \subseteq E$ ,  $h(X) = f(X \cup M^{opt})$  (trivially  $h$  is non-negative and submodular). As any element of  $E$  has the probability of at most  $p$  to appear in  $S$ , we derive  $\mathbb{E}[f(S \cup M^{opt})] = \mathbb{E}[h(S)] \geq (1-p)h(\emptyset) = (1-p)f(M^{opt})$ . Therefore,

$$\left(3 + 2\varepsilon + \frac{1}{\varepsilon}\right) \mathbb{E}[f(M)] \geq \mathbb{E}[f(S \cup M^{opt})] \geq (1-p)f(M^{opt}).$$

As  $p = \frac{1}{3+2\varepsilon}$ , we have

$$\left(\frac{4\varepsilon^2 + 8\varepsilon + 3}{2\varepsilon}\right) \cdot \mathbb{E}[f(M)] \geq f(M^{opt}).$$

This ratio is optimized when  $\varepsilon = \frac{\sqrt{3}}{2}$ , which gives a  $4 + 2\sqrt{3} \approx 7.464$  approximation. ◀

### 4 Matroid-constrained Maximum Submodular $b$ -Matching

In this section we consider the more general case of a  $b$ -matching on a  $k$ -uniform hypergraph and we impose a matroid constraint  $\mathcal{M} = (E, \mathcal{I})$ . A matching  $M \subseteq E$  is feasible only if it respects the capacities of the vertices and is an independent set in  $\mathcal{M}$ .

#### 4.1 Description of the Algorithm

For the streaming phase, our algorithm, formally described in Algorithm 4, is a further generalization of Algorithm 3 in the last section.

We let  $\alpha = 1 + \varepsilon$  and  $\gamma > 1$ . For the matroid  $\mathcal{M}$ , we maintain a set  $Q_{\mathcal{M}} = \{Q_{\mathcal{M},1}, \dots, Q_{\mathcal{M},r_{\mathcal{M}}}\}$ , where  $r_{\mathcal{M}}$  is the rank of  $\mathcal{M}$ , to store the elements (so if an edge  $e$  is part of  $S$ , it appears in a total of  $k+1$  queues,  $k$  of them corresponding to the vertices in  $e$ , and the remaining one corresponding to the matroid).

To facilitate the presentation, we write  $Top(Q_{\mathcal{M}})$  to denote the set of the elements on top of the queues of  $Q_{\mathcal{M}}$ . Lines 8-13 will guarantee that  $Top(Q_{\mathcal{M}})$  is an independent set (in fact a maximum weight base among all elements arrived so far, according to the reduced weights – see Lemma 20). In the end of the algorithm (Lines 26-27), we erase all elements that are not part of  $Top(Q_{\mathcal{M}})$  and let the final output  $S_f$  be simply  $Top(Q_{\mathcal{M}})$ .  $S_f$  is then fed into the greedy, Algorithm 2, to produce the  $b$ -matching. The pointers  $r_v$  are updated (Line 27), so that the queues could be regarded as if they contained only elements of  $S_f$ .

Here we give some intuition. We retain only the elements  $Top(Q_{\mathcal{M}})$  because they are independent (hence any subset of them chosen by the Greedy algorithm), releasing us from the worry that the output is not independent. We set  $\gamma > 1$  to ensure that the gain of new edges in the same queue of  $Q_{\mathcal{M}}$  grows quickly. By doing this,  $Top(Q_{\mathcal{M}})$ , by itself, contributes to a significant fraction of all gains in  $g(S)$  (see Lemma 24). However, an overly large  $\gamma$  causes us to throw away too many edges (see Line 14), thus hurting the final approximation ratio. To optimize, we thus need to choose  $\gamma$  carefully.

The number of variables used by this algorithm is  $O(\min\{k \cdot \log_{\gamma \cdot (1+\varepsilon)}(W/\varepsilon) \cdot r_{\mathcal{M}}, k \cdot \log_{1+\varepsilon}(W/\varepsilon) \cdot |M_{max}|\})$ , where  $M_{max}$  denotes the maximum-cardinality  $b$ -matching  $W$  denotes the maximum quotient  $\frac{f(e|Y)}{f(e'|X)}$ , for  $X \subseteq Y \subseteq E$ ,  $e, e' \in E$ ,  $f(e'|X) > 0$ .

#### 4.2 Analysis for Monotone Submodular Function Maximization

In this section,  $p = 1$ . For each discarded elements  $e \in E \setminus S$ , similarly as before, we set  $w_{\mathcal{M}}(e) = w_{\mathcal{M}}^*(e)$ .

■ **Algorithm 4** Streaming phase for Matroid-constrained Maximum Submodular  $b$ -Matching.

```

---

We introduce some basic facts in matroid theory, e.g., see [16].

► **Proposition 19.** *Given a matroid  $\mathcal{M} = (E, \mathcal{I})$  with weight  $w : E \rightarrow \mathbb{R}_+$ , then*

- (i) *An independent set  $I \in \mathcal{I}$  is a maximum weight base if and only if, for every element  $e \in E \setminus I$ ,  $I \cup \{e\}$  contains a circuit and  $w(e) \leq \min_{e' \in C \setminus \{e\}} w(e')$ .*
- (ii) *If  $I \in \mathcal{I}$ ,  $I \cup \{e\}$  contains a circuit  $C_1$  and  $I \cup \{e'\}$  contains a circuit  $C_2$  and  $C_1$  and  $C_2$  contain a common element  $e'' \in I$ , then there exists another circuit  $C_3 \subseteq (C_1 \cup C_2) \setminus \{e''\}$ .*

► **Lemma 20.** *Let  $\{e_1, \dots, e_t\}$  be the set of edges arrived so far. Then  $Top(Q_{\mathcal{M}}) = Top(Q_{\mathcal{M}}^{(t)})$  forms a maximum weight base in  $\{e_1, \dots, e_t\}$  with regard to the reduced weight  $w_{\mathcal{M}}$ .*

**Proof.** This can be easily proved by induction on the number of edges arrived so far and Proposition 19. ◀

► **Corollary 21.** *At the end of the algorithm,  $w_{\mathcal{M}}(Q_{\mathcal{M}}) \geq w_{\mathcal{M}}(M^{opt})$ .*

## 14:12 Semi-Streaming Submodular Function Maximization Under $b$ -Matching Constraint

The next two lemmas relate the total gain  $g(S)$  with  $f(S | \emptyset)$  and  $f(M^{opt} | S)$ .

► **Lemma 22.** *It holds that  $g(S) \geq \frac{\varepsilon}{1+\varepsilon} f(S | \emptyset)$ .*

**Proof.** Same proof as for Lemma 11. ◀

► **Lemma 23.** *It holds that  $(1 + \varepsilon)(k + \gamma)g(S) \geq f(M^{opt} | S)$ .*

**Proof.** By the same argument as in the proof of Lemma 12, we have

$$\sum_{e \in M^{opt} \setminus S} (1 + \varepsilon) \sum_{u \in e} w_u^*(e) \leq (1 + \varepsilon)k \cdot g(S).$$

Moreover, Corollary 21 shows that  $g(S) = w_{\mathcal{M}}(Q_{\mathcal{M}}) \geq w_{\mathcal{M}}(M^{opt})$  and we know that

$$w_{\mathcal{M}}(M^{opt}) \geq \sum_{e \in M^{opt} \setminus S} w_{\mathcal{M}}(e) = \sum_{e \in M^{opt} \setminus S} w_{\mathcal{M}}^*(e).$$

As a result, we obtain

$$\begin{aligned} f(M^{opt} | S) &\leq \sum_{e \in M^{opt} \setminus S} f(e | S) \leq \sum_{e=e_t \in M^{opt} \setminus S} f(e | S^{(t-1)}) \\ &\leq (1 + \varepsilon) \sum_{e \in M^{opt} \setminus S} \sum_{u \in e} w_u^*(e) + \gamma \cdot w_{\mathcal{M}}^*(e) \\ &\leq (1 + \varepsilon)(k + \gamma)g(S). \end{aligned} \quad \blacktriangleleft$$

The following lemma states that  $S_f$  retains a reasonably large fraction of the gains compared to  $S$ .

► **Lemma 24.** *It holds that  $\left(1 + \frac{1}{\gamma \cdot (1 + \varepsilon) - 1}\right) g(S_f) \geq g(S)$ .*

**Proof.** We have, for all element  $e = e_t \in S_f$ ,

$$\begin{aligned} g(e) &= f(e | S^{(t-1)}) - \sum_{u \in e} w_u^*(e) - w_{\mathcal{M}}^*(e) \\ &\geq (1 + \varepsilon - 1) \sum_{u \in e} w_u^*(e) + (\gamma \cdot (1 + \varepsilon) - 1)w_{\mathcal{M}}^*(e) \\ &\geq (\gamma \cdot (1 + \varepsilon) - 1)w_{\mathcal{M}}^*(e) = (\gamma \cdot (1 + \varepsilon) - 1) \sum_{e' \in Q_{\mathcal{M}, q_{\mathcal{M}}(e)}^{(t-1)}} g(e'). \end{aligned}$$

Recalling that  $q_{\mathcal{M}}(e)$  is the index of the queues in  $Q_{\mathcal{M}}$  where  $e$  is put (see Lines 13 and 25 of Algorithm 4),

$$g(S) = \sum_{e=e_t \in S_f} \left( g(e) + \sum_{e' \in Q_{\mathcal{M}, q_{\mathcal{M}}(e)}^{(t-1)}} g(e') \right) \leq \sum_{e \in S_f} \left( 1 + \frac{1}{\gamma \cdot (1 + \varepsilon) - 1} \right) g(e),$$

and the proof follows. ◀

► **Lemma 25.** *It holds that  $\left(1 + \frac{1}{\gamma \cdot (1 + \varepsilon) - 1}\right) \left((1 + \varepsilon)(k + \gamma) + 1 + \frac{1}{\varepsilon}\right) g(S_f) \geq f(M^{opt} | \emptyset)$ .*

**Proof.** By Lemmas 22 and 23, we have that  $\left((1 + \varepsilon)(k + \gamma) + 1 + \frac{1}{\varepsilon}\right) g(S) \geq f(M^{opt} | S) + f(S | \emptyset) = f(M^{opt} \cup S | \emptyset) \geq f(M^{opt} | \emptyset)$  because  $f$  is monotone. Then we use Lemma 24. ◀

► **Lemma 26.** *With  $S_f$  as input, Algorithm 2 returns a feasible  $b$ -matching  $M$  with  $f(M) \geq g(S_f) + f(\emptyset)$ .*

**Proof.** As argued in Lemma 7,  $M$  respects the capacities. Furthermore, as  $S_f$  is by construction an independent set in  $\mathcal{M}$  and  $M \subseteq S_f \in \mathcal{I}$ , we have  $M \in \mathcal{I}$ . So  $M$  is a feasible  $b$ -matching. Finally, using an analysis similar to the one in the proof of Lemma 13, we have  $f(M) \geq g(S_f) + f(\emptyset)$  (the only difference being that now the “weight”  $f(e_t | S^{(t-1)})$  of an element can be larger than the sum of the gains of the elements below it in the queues, which is not an issue for the analysis). ◀

As a result, we get the following theorem (the same way we obtained Theorem 14):

► **Theorem 27.** *For non-negative monotone submodular functions, Algorithm 4 with  $p = 1$  combined with Algorithm 2 provides a feasible  $b$ -matching such that*

$$\left(1 + \frac{1}{\gamma \cdot (1 + \varepsilon) - 1}\right) \left((1 + \varepsilon)(k + \gamma) + 1 + \frac{1}{\varepsilon}\right) f(M) \geq f(M^{opt}).$$

By setting  $\varepsilon = 1$  and  $\gamma = 2$ , we attain the approximation ratio of  $\frac{4}{3}(2k + 6)$  for all  $k$ .

It is possible to obtain better ratios for a fixed  $k$  by a more careful choice of the parameters  $\varepsilon$  and  $\gamma$ . For instance when  $k = 2, 3$ , and  $4$ , we have the respective ratios of 13.055, 15.283, and 17.325.

### 4.3 Analysis for Non-Monotone Submodular Function Maximization

In this section, we assume  $\frac{1}{1+(k+\gamma)(1+\varepsilon)} \leq p \leq \frac{1}{k+\gamma}$ . The following lemma is the counterpart of Lemma 16, whose proof again uses the technique of conditioning (in a more general form).

► **Lemma 28.** *It holds that  $((1 + \varepsilon)(k + \gamma) + \frac{1+\varepsilon}{\varepsilon}) \mathbb{E}[g(S)] \geq \mathbb{E}[f(S \cup M^{opt} | \emptyset)]$ .*

**Proof.** By Lemma 22, for any realization on randomness, we have  $\frac{1+\varepsilon}{\varepsilon} g(S) \geq f(S | \emptyset)$ , so the inequality also holds in expectation.

We next show that, for any  $e \in M^{opt}$  we have

$$\mathbb{E}[f(e | S)] \leq (1 + \varepsilon) \mathbb{E} \left[ \sum_{u \in e} w_u(e) + \gamma \cdot w_{\mathcal{M}}(e) \right]. \quad (3)$$

Let  $e \in M^{opt}$ . Conditioning on  $A_e = [f(e | S^{(t-1)}) \leq (1 + \varepsilon)(\sum_{u \in e} w_u^*(e) + \gamma \cdot w_{\mathcal{M}}^*(e))]$  (i.e.  $e$  cannot be part of  $S$ ), we have

$$\begin{aligned} \mathbb{E}[f(e | S) | A_e] &\leq \mathbb{E}[f(e | S^{(t-1)}) | A_e] \\ &\leq \mathbb{E} \left[ (1 + \varepsilon) \left( \sum_{u \in e} w_u^*(e) + \gamma \cdot w_{\mathcal{M}}^*(e) \right) | A_e \right] \\ &= (1 + \varepsilon) \mathbb{E} \left[ \sum_{u \in e} w_u(e) + \gamma \cdot w_{\mathcal{M}}(e) | A_e \right]. \end{aligned}$$

For the condition  $\overline{A_e}$ , recall that it means that with probability  $p$ , the edge is added into  $S$  and with probability  $1 - p$ , it is not. So

$$\mathbb{E} \left[ \sum_{u \in e} w_u(e) + \gamma \cdot w_{\mathcal{M}}(e) | \overline{A_e} \right]$$

## 14:14 Semi-Streaming Submodular Function Maximization Under $b$ -Matching Constraint

$$\begin{aligned}
&= p \cdot \mathbb{E} \left[ (k + \gamma)f(e | S^{(t-1)}) - (k + \gamma - 1) \left( \sum_{u \in e} w_u^*(e) \right) - kw_{\mathcal{M}}^*(e) \mid \overline{A_e} \right] \\
&\quad + (1 - p) \cdot \mathbb{E} \left[ \sum_{u \in e} w_u^*(e) + \gamma \cdot w_{\mathcal{M}}^*(e) \mid \overline{A_e} \right] \\
&\geq p \cdot \mathbb{E} \left[ (k + \gamma)f(e | S^{(t-1)}) - (k + \gamma - 1) \left( \sum_{u \in e} w_u^*(e) \right) - (k + \gamma - 1)\gamma \cdot w_{\mathcal{M}}^*(e) \mid \overline{A_e} \right] \\
&\quad + (1 - p) \cdot \mathbb{E} \left[ \sum_{u \in e} w_u^*(e) + \gamma \cdot w_{\mathcal{M}}^*(e) \mid \overline{A_e} \right] \\
&= (k + \gamma) \cdot p \cdot \mathbb{E} \left[ f(e | S^{(t-1)}) \mid \overline{A_e} \right] + (1 - (k + \gamma) \cdot p) \cdot \mathbb{E} \left[ \sum_{u \in e} w_u^*(e) + \gamma \cdot w_{\mathcal{M}}^*(e) \mid \overline{A_e} \right] \\
&\geq (k + \gamma) \cdot p \cdot \mathbb{E} \left[ f(e | S^{(t-1)}) \mid \overline{A_e} \right],
\end{aligned}$$

where in the second step we use the fact that  $\gamma > 1$  and in the last inequality that  $p \leq \frac{1}{k+\gamma}$ . Now as  $p \geq \frac{1}{1+(k+\gamma)(1+\varepsilon)}$ , we have

$$\begin{aligned}
(1 + \varepsilon)\mathbb{E} \left[ \sum_{u \in e} w_u(e) + \gamma \cdot w_{\mathcal{M}}(e) \mid \overline{A_e} \right] &\geq (1 + \varepsilon)(k + \gamma) \cdot p \cdot \mathbb{E} \left[ f(e | S^{(t-1)}) \mid \overline{A_e} \right] \\
&\geq (1 - p) \cdot \mathbb{E} \left[ f(e | S^{(t-1)}) \mid \overline{A_e} \right] \\
&\geq \mathbb{E} \left[ f(e | S) \mid \overline{A_e} \right],
\end{aligned}$$

and we have established (3).

Similar to the proof of Lemma 16 we get

$$\begin{aligned}
\mathbb{E} [f(M^{opt} | S)] &\leq \sum_{e \in M^{opt}} \mathbb{E} [f(e | S)] \\
&\leq (1 + \varepsilon) \sum_{e \in M^{opt}} \mathbb{E} \left[ \sum_{u \in e} w_u(e) \right] + (1 + \varepsilon)\gamma \cdot \mathbb{E}[w_{\mathcal{M}}(M^{opt})] \\
&\leq k(1 + \varepsilon)\mathbb{E}[g(S)] + (1 + \varepsilon)\gamma \cdot \mathbb{E}[w_{\mathcal{M}}(M^{opt})].
\end{aligned}$$

By Lemma 21 we know that for any realization of randomness,  $w_{\mathcal{M}}(M^{opt}) \leq w_{\mathcal{M}}(S_f) = g(S)$ . Thus we get  $\mathbb{E} [f(M^{opt} | S)] \leq (k + \gamma)(1 + \varepsilon)\mathbb{E}[g(S)]$ .

Now the bound on  $\mathbb{E} [f(M^{opt} | S)]$  and the bound on  $\mathbb{E} [f(S | \emptyset)]$  (argued in the beginning of the proof) give us the lemma.  $\blacktriangleleft$

Finally, using Lemma 17 we obtain:

► **Theorem 29.** *For non-negative submodular functions, Algorithm 4 with  $p = \frac{1}{1+(k+\gamma)(1+\varepsilon)}$  combined with Algorithm 2 provides a  $b$ -matching  $M$  independent in  $\mathcal{M}$  such that:*

$$\frac{1 + (k + \gamma)(1 + \varepsilon)}{(k + \gamma)(1 + \varepsilon)} \left( 1 + \frac{1}{\gamma \cdot (1 + \varepsilon) - 1} \right) \left( (1 + \varepsilon)(k + \gamma) + 1 + \frac{1}{\varepsilon} \right) \mathbb{E}[f(M)] \geq f(M^{opt}).$$

Setting  $\varepsilon = 1$  and  $\gamma = 2$  we obtain the ratio of  $\frac{2k+5}{2k+4} \cdot \frac{4}{3} \cdot (2k + 6)$  for all  $k$ .

As in the last section, it is possible to obtain better ratios for a fixed  $k$  by a more careful choice of the parameters  $\varepsilon$  and  $\gamma$ . For instance when  $k = 2, 3$ , and  $4$ , we have the respective ratios of 14.857, 17.012, and 18.999.

## A Making Algorithm 1 Memory-Efficient

We explain how to guarantee the space requirement promised in Theorem 1. In this section,  $w_{\min}$  denotes the minimum non-zero value of the weight of an edge, and  $w_{\max}$  the maximum weight of an edge. Moreover, we set  $W = w_{\max}/w_{\min}$ . We also define  $M_{\max}$  as a given maximum cardinality  $b$ -matching.

Let  $\alpha = (1 + \varepsilon) > 1$ . In Algorithm 5 we add an edge  $e$  to  $S$  only if  $w(e) > \alpha \sum_{u \in e} w_u^*(e)$  (Line 7). For the moment we set  $d = 0$  in our analysis, ignoring Lines 14-16 of the algorithm.

► **Lemma 30.** *The set  $S$  obtained at the end of algorithm 5 when  $d = 0$  guarantees that  $2\alpha g(S) \geq w(M^{\text{opt}})$ .*

■ **Algorithm 5** Streaming phase for weighted matching, memory-efficient.

    queue, it will be removed from  $S$  and from all the queues it appears in

```

---

**Proof.** We proceed as in [9]. Let  $w_\alpha : E \rightarrow \mathbb{R}$  such that  $w_\alpha(e) = w(e)$  for  $e \in S$  and  $w_\alpha(e) = \frac{w(e)}{\alpha}$  for  $e \in E \setminus S$ . We can observe that with the weights  $w_\alpha$ , Algorithm 1 gives the same set  $S$  as Algorithm 5 with the weights  $w$ . We deduce that  $w_\alpha(M^{opt}) \leq 2g(S)$  and then, as  $w \leq \alpha w_\alpha$ , we get  $2\alpha g(S) \geq w(M^{opt})$ . ◀

Hence, using same arguments as in [10, 12] we obtain the following:

► **Theorem 31.** *Algorithm 5 (with  $d = 0$ ) combined with Algorithm 2 gives a  $2 + \varepsilon$  approximation algorithm by using  $O(\log_{1+\varepsilon}(W/\varepsilon) \cdot |M_{max}|)$  variables.*

**Proof.** In a given queue, the minimum non-zero value that can be attained is  $\frac{\varepsilon}{1+\varepsilon} w_{min}$  and the maximum value that can be attained is  $w_{max}$ . As the value of the top element of the queue increases at least by a factor  $1 + \varepsilon$  for each inserted element, a given queue contains at most  $\log_{1+\varepsilon}(W/\varepsilon) + 1$  edges. Hence, a vertex  $v \in V$  contains at most  $\min\{|\delta(v)|, b_v \cdot (\log_{1+\varepsilon}(W/\varepsilon) + 1)\}$  elements of  $S$  at the end of the algorithm.

Then let  $U \subseteq V$  be the set of *saturated* vertices of  $V$  by  $M_{max}$ , *i.e.* the set of vertices  $v \in V$  such that  $|\delta(v) \cap M_{max}| = \min\{|\delta(v)|, b_v\}$ . By construction,  $U$  is a vertex cover and  $\sum_{v \in U} \min\{|\delta(v)|, b_v\} \leq 2|M_{max}|$ . As all edges of  $S$  have at least one endpoint in  $U$ , we get:

$$\begin{aligned}
|S| &\leq \sum_{v \in U} |\delta(v) \cap S| \leq \sum_{v \in U} \min\{|\delta(v)|, b_v \cdot (\log_{1+\varepsilon}(W/\varepsilon) + 1)\} \\
&\leq \sum_{v \in U} \min\{|\delta(v)|, b_v\} \cdot (\log_{1+\varepsilon}(W/\varepsilon) + 1) \leq 2(\log_{1+\varepsilon}(W/\varepsilon) + 1) \cdot |M_{max}|,
\end{aligned}$$

so the memory consumption of the algorithm is  $O(\log_{1+\varepsilon}(W/\varepsilon) \cdot |M_{max}|)$  ◀

Modifying an idea from Ghaffari and Wajc [10] we can further improve the memory consumption of the algorithm, especially if  $W$  is not bounded. For that, set  $\beta = 1 + \frac{2 \log(1/\varepsilon)}{\log(1+\varepsilon)} = 1 + \log_{1+\varepsilon}(1/\varepsilon^2)$  in Algorithm 5 as the maximum size of a queue, and set  $d = 1$  (so that we now consider the whole code).

Consider an endpoint  $u$  of the newly-inserted edge  $e$ . If the queue  $Q_{u,q_u(e)}$  becomes too long (more than  $\beta$  elements), it means the gain  $g(e')$  of the  $\beta + 1$ -th element from the top of the queue (we will call that element  $e'$ ) is very small compared to  $g(e)$ , so we then can “potentially” remove  $e'$  from  $S$  and from the queues without hurting too much  $g(S)$ . In the code, we will mark this edge  $e'$  as *erasable*, so that when  $e'$  will no longer be on top of any queue, it will be removed from  $S$  and all the queues it appears in. To be able to do these eviction operations, the queues have to be implemented with doubly linked lists.

If an edge  $e = \{u, v\}$  is marked as erasable by Algorithm 5 ( $d = 1$ ) because an edge  $e' = \{u, v'\}$  is added to  $S$ , then we say that  $e'$  *evicted*  $e$  (and that  $e$  was *evicted* by  $e'$ ).

► **Lemma 32.** *If  $e = \{u, v\}$  is evicted by  $e' = \{u, v'\}$ , then  $g(e') \geq g(e)/\varepsilon$ .*

**Proof.** We have  $g(e') \geq \varepsilon(w_u^*(e') + w_{v'}^*(e')) \geq \varepsilon w_u^*(e') \geq \varepsilon(1 + \varepsilon)^{\beta-1}g(e) \geq g(e)/\varepsilon$  because after  $e = e_t$  is added to  $Q_{u,q_u(e)}$  we have  $w_u(Q_{u,q_u(e)}^{(t)}) \geq g(e)$  and each time an element is added to  $Q_{u,q_u(e)}$  the value  $w_u(Q_{u,q_u(e)})$  is multiplied at least by  $(1 + \varepsilon)$ . ◀

► **Theorem 33.** *For  $\varepsilon \leq \frac{1}{4}$ , Algorithm 5 with  $d = 1$  combined with Algorithm 2 gives a  $2 + \varepsilon$  approximation algorithm by using  $O(\log_{1+\varepsilon}(1/\varepsilon) \cdot |M_{max}| + \sum_{v \in V} b_v)$  variables.*

**Proof.** For an element  $e$  that was not evicted from  $S$  in Algorithm 5, denote by  $\mathcal{E}_e$  the elements that were evicted by  $e$  directly or indirectly (in a chain of evictions). This set  $\mathcal{E}_e$  contains at most 2 elements that were directly evicted when  $e$  was inserted in  $S$ , and their associated gain is at most  $\varepsilon g(e)$  for each, and at most 4 elements indirectly evicted by  $e$  when these 2 evicted elements were inserted in  $S$ , and their associated gain is at most equal to  $\varepsilon^2 g(e)$  for each, and so on. Then, as  $\varepsilon \leq \frac{1}{4}$ ,

$$\sum_{e' \in \mathcal{E}_e} g(e') \leq \sum_{i=1}^{\infty} (2\varepsilon)^i g(e) \leq 2\varepsilon g(e) \sum_{i=0}^{\infty} (1/2)^i = 4\varepsilon g(e)$$

Therefore, if  $S_0$  denotes the set  $S$  obtained by Algorithm 5 when  $d = 0$  and  $S_1$  denotes the set  $S$  obtained by Algorithm 5 when  $d = 1$ , we get:

$$g(S_0) - g(S_1) \leq 4\varepsilon g(S_1)$$

because the elements inserted in  $S$  are exactly the same for the two algorithms, the only difference being that some elements are missing in  $S_1$  (but these elements were removed when they no longer had any influence on the values of  $w^*$  and thereby no influence on the choice of the elements inserted in  $S$  afterwards). We have then:

$$w(M^{opt}) \leq 2(1 + \varepsilon)g(S_0) \leq 2(1 + \varepsilon)(1 + 4\varepsilon)g(S_1) \leq 2(1 + 6\varepsilon)g(S_1)$$

and Algorithm 2 will provide a  $2(1 + 6\varepsilon)$  approximation of the optimal  $b$ -matching. In fact, the analysis of Algorithm 2 with  $S_1$  as input is almost the same as in the proof of Lemma 7, the only difference being that now the weight of an element is no longer necessarily equal to the sum of the gains of elements below it but can be higher (which is not an issue).

Regarding the memory consumption of the algorithm, one can notice that, using the same notation  $U$  for the set of the elements saturated by  $M_{max}$  as previously, and because there are only up to  $\sum_{v \in V} b_v$  elements on top of the queues that cannot be deleted (and thus these edges are the ones making some queues in  $U$  exceed the limit  $\beta$ ), we obtain:

$$|S| \leq \sum_{v \in V} b_v + \sum_{v \in U} \beta \cdot \min\{|\delta(v)|, b_v\} \leq \sum_{v \in V} b_v + 2\beta \cdot |M_{max}|,$$

and therefore the algorithm uses  $O(\sum_{v \in V} b_v + \log_{1+\varepsilon}(1/\varepsilon) \cdot |M_{max}|)$  variables. ◀

## 14:18 Semi-Streaming Submodular Function Maximization Under $b$ -Matching Constraint

► Remark 34. Ideas presented here for the maximum weight  $b$ -matching can be easily extended to submodular function maximization and for hypergraphs under a matroid constraint, namely for the algorithms presented in Sections 3 and 4.

### **B** Example of Different Behavior Compared to [12]

Here is an example to show the difference of behavior between our algorithm and the one proposed in [12]. Consider a set of four vertices  $V = \{v_1, v_2, v_3, v_4\}$ . We set  $b_{v_1} = 2$  and  $b_{v_i} = 1$  for  $2 \leq i \leq 4$ . Let  $E = \{e_1, e_2, e_3\}$  with  $e_1 = \{v_1, v_2\}$  and  $w(e_1) = 2$ ,  $e_2 = \{v_1, v_3\}$  and  $w(e_2) = 7$ ,  $e_3 = \{v_1, v_4\}$  and  $w(e_3) = 4$ . Using only one dual variable for each vertex, the algorithm of Levin and Wajc [12] takes  $e_1$  and  $e_2$  but discards  $e_3$  because the dual variable  $\phi_{v_1}$  is equal to 4 when  $e_3$  is processed. On the other hand, our algorithm, when processing  $e_3$ , compares  $w(e_3)$  with  $w_{v_1}(e_1) = 2$ . Therefore,  $e_3$  is added into  $S$  and our algorithm provides a  $b$ -matching of weight 11 instead of 9.

# General Knapsack Problems in a Dynamic Setting

## Abstract

The world is dynamic and changes over time, thus any optimization problem used to model real life problems must address this dynamic nature, taking into account the cost of changes to a solution over time. The multistage model was introduced with this goal in mind. In this model we are given a series of instances of an optimization problem, corresponding to different times, and a solution is provided for each instance. The strive for obtaining near-optimal solutions for each instance on one hand, while maintaining similar solutions for consecutive time units on the other hand, is quantified and integrated into the objective function. In this paper we consider the Generalized Multistage  $d$ -Knapsack problem, a generalization of the multistage variants of the Multiple Knapsack problem, as well as the  $d$ -Dimensional Knapsack problem. We present a PTAS for Generalized Multistage  $d$ -Knapsack.

## 1 Introduction

In many optimization settings, the problem of interest is defined over a time horizon in which the actual setting evolves, resulting in changes over time to the problem constraints and the objective function. Thus, even if the optimization problem at hand can be solved efficiently for a single time unit, it may not be clear how to extend this solution to a time-evolving setting.

An example of such a setting comes from the world of cloud management. A cloud provider maintains a data center with servers and offers clients virtual machines having different processing capabilities. Each client demands a virtual machine (with certain properties), and if provided it must pay for it. It would be naïve to assume that the demand of clients is static over time. Factors, such as peak vs. off-hours, and the day of the week, might affect client demand. Also, the cloud provider might either turn off servers to reduce hardware deterioration and electricity usage, or open more servers to meet higher demand. Thus, the optimization problem is partitioned into multiple *stages*, where in each stage there are different constraints and possibly a different optimization goal.

A simple solution is to ignore the dynamicity of the problem, and solve each stage separately and independently of other stages. Thus, profit at each stage is maximized, ignoring the solutions computed for the other stages. Such a solution may result in disgruntled clients, as it can lead to intermittent service between stages. Instead, we will aim for a *multistage* solution that balances between the optimum of each stage, while preserving some continuity between consecutive stages. This will be achieved by incorporating the continuity of the solution into the overall profit.

The multistage model was first introduced by Gupta et al. [18] and Eisenstat et al. [9] to address dynamic environments. Since its introduction, it has received growing attention (examples include [1, 12, 2, 4, 15, 8]). In the multistage model we are given a sequence of instances of an optimization problem. A solution constitutes of a series of solutions, one for each instance.

Two different ideas were used to enforce a balance between single stage optimality and continuity. In [9, 18] a change cost is charged for the dissimilarity of consecutive solutions, while in [4] additional gains were given for their similarity. In the aforementioned cloud management problem, the change cost can be interpreted as installation costs and eviction costs charged when a client is initially served, and then its service is discontinued. The gains can be modeled as increased costs the client is charged to guarantee the continuity of its service.

The cloud management problem described above can be viewed as a multistage problem where the underlying optimization problem is the Multiple Knapsack problem (MKP). In MKP we are given a set of items, each associated with a weight and a profit. Also, we are given a set of bins, each one having a capacity. A feasible solution for MKP is an assignment of items to bins such that the total weight of the items assigned to each bin does not exceed its capacity. The objective is to find a feasible solution maximizing the profit accrued from the assigned items. In the context of the cloud management setting, the items are the virtual machine demands of the clients and the bins are the available servers.

## 1.1 Problem Definition

We study the Generalized Multistage  $d$ -Knapsack problem. We begin with an informal description of the problem. An instance of the problem consists of  $T$  stages, where in each stage we are given an instance of a generalization of the classic knapsack problem. While the instances differ between stages, in all stages the same set of items  $I$  can be packed. The continuity of the solution is enforced by quantifying the similarity of consecutive solutions and integrating it into the objective function.

We quantify continuity by four types of values. The first two values specify gains earned for the similarity of solutions. For example, if an item  $i$  is packed in stages  $t - 1$  and  $t$ , gain  $g_{i,t}^+$  is awarded. Similarly,  $g_{i,t}^-$  is awarded if  $i$  is not packed in  $t - 1$  and  $t$ . The other two values define the cost of changes between consecutive solutions. For example, if an item  $i$  was not packed in stage  $t - 1$ , and it is decided to pack it in stage  $t$ , a change cost of  $c_{i,t}^+$  is charged. Similarly,  $c_{i,t}^-$  is charged if  $i$  is packed in  $t$ , but not in  $t + 1$ .

The packing problem at each stage generalizes the Multiple Knapsack problem, as well as the  $d$ -Dimensional Knapsack problem. In each instance of the problem we are given  $d$  sets of bins, and the weight an item occupies in a bin depends on the set to which the bin belongs to. The profit of an item is accrued once it is assigned to some bin in all  $d$  sets of bins. This problem is called  $d$ -Multiple Knapsack Constraints Problem and is formally defined below.

A Multiple Knapsack Constraint (MKC) is a tuple  $K = (w, B, W)$  defined over a set of items  $I$ . The function  $w : I \rightarrow \mathbb{R}_+$  defines the weight of the items,  $B$  is a set of bins, each equipped with a capacity defined by the function  $W : B \rightarrow \mathbb{R}_+$ . An *assignment* is a

function  $A : B \rightarrow 2^I$ , defining which items are assigned to each of the bins. An assignment is feasible if  $w(A(b)) = \sum_{i \in A(b)} w_i \leq W(b)$  for each bin  $b \in B$ . Similarly, given a tuple of MKCs  $\mathcal{K} = (K_j)_{j=1}^d$  over  $I$ , a tuple of  $d$  assignments  $\mathcal{A} = (A^j)_{j=1}^d$  is feasible for  $\mathcal{K}$  if for each  $j = 1, \dots, d$  assignment  $A^j$  is a feasible assignment for  $K_j$ . We say  $A$  is an assignment of set  $S \subseteq I$  if  $S = \cup_{b \in B} A_b$ .

In  $d$ -Multiple Knapsack Constraints Problem ( $d$ -MKCP), a problem first introduced in [11], we are given a tuple  $(I, \mathcal{K}, p)$ , where  $I$  is a set of items,  $\mathcal{K}$  is a tuple of  $d$  MKCs and  $p : I \rightarrow \mathbb{R}_{\geq 0}$  defines the profit of each item. A feasible solution for  $d$ -MKCP is a set  $S \subseteq I$  and a tuple of feasible assignments  $\mathcal{A}$  (w.r.t  $\mathcal{K}$ ) of  $S$ . The goal is to find a feasible solution that maximizes  $p(S) = \sum_{i \in S} p(i)$ . We note that if there exists an item with negative profit it can be discarded in advance. This fact is used later on, in Section 2.1.

The Generalized Multistage  $d$ -Knapsack problem ( $d$ -GMK), is the multistage model of  $d$ -MKCP. The problem is defined over a time horizon of  $T$  stages as follows. An instance of the problem is a tuple  $((\mathcal{P}_t)_{t=1}^T, g^+, g^-, c^+, c^-)$ , where  $\mathcal{P}_t = (I, \mathcal{K}_t, p_t)$  is a  $d_t$ -MKCP instance with  $d_t \leq d$  for  $t \in [T]$ ,  $g^+, g^- \in \mathbb{R}_+^{I \times [2, T]}$  are the gain vectors and  $c^+, c^- \in \mathbb{R}_+^{I \times [1, T]}$  are the change cost vectors.<sup>1</sup> We use  $g_{i,t}^+$  and  $g_{i,t}^-$  to denote the gain of item  $i$  at stage  $t$ . Similarly, we use  $c_{i,t}^+$  and  $c_{i,t}^-$  to denote the change cost of item  $i$  at stage  $t$ .

A feasible solution for  $d$ -GMK is a tuple  $(S_t, \mathcal{A}_t)_{t=1}^T$ , where  $(S_t, \mathcal{A}_t)$  is a feasible solution for  $\mathcal{P}_t$  (note that  $\mathcal{A}_t$  is a tuple of assignments of  $S_t$ ). Throughout the paper we assume  $S_0 = S_{T+1} = \emptyset$  and denote the objective function of instance  $\mathcal{Q}$  by  $f_{\mathcal{Q}} : I^T \rightarrow \mathbb{R}$ , where

$$f_{\mathcal{Q}}((S_t)_{t=1}^T) = \sum_{t=1}^T \sum_{i \in S_t} p_t(i) + \sum_{t=2}^T \left( \sum_{i \in S_{t-1} \cap S_t} g_{i,t}^+ + \sum_{i \notin S_{t-1} \cup S_t} g_{i,t}^- \right) - \sum_{t=1}^T \left( \sum_{i \in S_t \setminus S_{t-1}} c_{i,t}^+ + \sum_{i \in S_t \setminus S_{t+1}} c_{i,t}^- \right).$$

The goal is to find a feasible solution that maximizes the objective function  $f_{\mathcal{Q}}$ .

A study of  $d$ -GMK reveals it does not admit a constant factor approximation algorithm (see Section 3). We found that in hard instances the change costs are much larger than the profits. Thus we consider an important parameter of the problem, the *profit-cost ratio*. It is defined as the maximum ratio, over all items, between the change cost  $(c^+, c^-)$  and the profit of an item over all stages. It is denoted by  $\phi_{\mathcal{Q}}$  for any instance  $\mathcal{Q}$ , and is formally defined as

$$\phi_{\mathcal{Q}} = \min \left( \left\{ \infty \right\} \cup \left\{ r \geq 0 \mid \forall i \in I, t_1, t_2 \in [T] : \max \{ c_{i,t_1}^+, c_{i,t_1}^- \} \leq r \cdot p_{t_2}(i) \right\} \right)$$

We show that  $d$ -GMK instances where the profit-cost ratio is bounded by a constant admit a PTAS.

We also consider Submodular  $d$ -GMK, a submodular variant of  $d$ -GMK where the profit functions are replaced with monotone submodular set functions. A set function  $p : 2^I \rightarrow \mathbb{R}$  is submodular if for every  $A \subseteq B \subseteq I$  and  $i \in I \setminus B$  it holds that  $p(A \cup \{i\}) - p(A) \geq p(B \cup \{i\}) - p(B)$ . Submodular functions appear naturally in many settings such as coverage [13], matroid rank [5] and cut functions [14]. We use similar techniques to develop the algorithms for  $d$ -GMK and Submodular  $d$ -GMK. Thus, we focus on  $d$ -GMK and defer the formal definition as well as the algorithm for Submodular  $d$ -GMK to the full version of this paper [10].

<sup>1</sup> We use the notations  $[n, m] = \{i \in \mathbb{N} \mid n \leq i \leq m\}$  and  $[n] = [1, n]$  for  $n, m \in \mathbb{N}$ .

Both  $d$ -GMK and Submodular  $d$ -GMK generalize the Multistage Knapsack problem recently considered by Bampis et al. [4]. There are several aspects by which it is generalized. First, handling multiple knapsack constraints as well as  $d$ -dimensional knapsack vs a single knapsack in [4]. Second, the profit earned from assigning items can be described as a submodular function, not only by a modular function. Third, [4] considered only symmetric gains, i.e., the same gain is earned whether an item is assigned or not assigned in consecutive stages. Lastly, change costs were not considered in [4].

## 1.2 Our Results

Our main result is stated in the following theorem.

► **Theorem 1.** *For any fixed  $d \in \mathbb{N}$  and  $\phi \geq 1$  there exists a randomized PTAS for  $d$ -GMK with a profit-cost ratio bounded by  $\phi$ .*

The result uses the general framework of [4], in which the authors first presented an algorithm for instances with bounded time horizon, and then showed how it can be scaled for general instances. To handle bounded time horizons we show an approximation factor preserving reduction (as defined in [22]<sup>2</sup>) from  $d$ -GMK to a generalization of  $q$ -MKCP. The reduction illuminates the relationship between  $d$ -GMK and  $q$ -MKCP. As  $q$ -MKCP admits a PTAS [11], this results in a PTAS for  $d$ -GMK instances with a bounded time horizon.

We note the reduction can be applied to the problem considered in [4] as well. In this case the target optimization problem is  $d$ -dimensional knapsack with a matroid constraint. As the latter problem is known to admit a PTAS [17], this suggests a simpler solution for bounded time horizon in comparison to the one given in [4].

To generalize the result to unbounded time horizon we use an approach similar to [4], though a more sophisticated analysis was required to handle the change costs. The generalization is achieved by cutting the time horizon into sub-instances with a fixed time horizon. Each sub-instance is solved separately, and then the solutions are combined to create a solution for the full instance. Handling change costs is trickier as cutting an instance may lead to an excessive charge of change costs at the cut points. We must compensate for these additional costs, or we will not be able to bound the value of the solution.

The results for the modular variant generalizes the PTAS for Multistage Knapsack [4]. For  $d \geq 2$ , we cannot expect better results as even  $d$ -KP, also generalized by  $d$ -GMK, does not admit an *efficient* PTAS (EPTAS). Theorem 2 shows an EPTAS cannot be obtained for 1-GMK as well

► **Theorem 2.** *Unless  $W[1] = FPT$ , there is no EPTAS for 1-GMK, even if the length of the time horizon is  $T = 2$ , the set of bins in each MKC contains one bin and there are no change costs.*

The theorem is proved using a simple reduction from 2-dimensional knapsack. Bampis et al. [4] considered a similar withered down instance and proved that even if the gains are symmetric (i.e.,  $g_{i,t}^+ = g_{i,t}^-$ ) a *Fully* PTAS (FPTAS) does not exist for the problem.

Using a reduction from multidimensional knapsack we show that 1-GMK, in its general form, cannot be approximated to any constant factor.

► **Theorem 3.** *For any  $d \geq 1$ , there is no polynomial time approximation algorithm for  $d$ -GMK with a constant approximation ratio, unless  $NP = ZPP$ .*

---

<sup>2</sup> A formal definition is provided in Appendix A for completeness

This result justifies our study of the special cases of  $d$ -GMK in which the profit-cost ratio is bounded by a constant.

The techniques used to develop the algorithm for  $d$ -GMK can be adjusted slightly to produce an approximation algorithm for Submodular  $d$ -GMK. The complete details are given in the full version of this paper [10].

► **Theorem 4.** *For any fixed  $d \in \mathbb{N}$  and  $\epsilon > 0$  there exists a randomized  $(1 - \frac{1}{e} - \epsilon)$ -approximation algorithm for Submodular  $d$ -GMK.*

In the submodular variant one cannot hope for vast improvement over our results as the algorithm is almost tight. This is due to the hardness results for submodular maximization subject to a cardinality constraint presented by Nemhauser and Wolsey [20].

### 1.3 Related Work

In the multistage model we are given a series of instances of an optimization problem, and we search for a solution which optimizes each instance while maintains some similarity between solutions. Many optimization problem were considered under this framework. These include matching [2, 7], clustering [8], subset sum [3], vertex cover [15] and minimum  $s - t$  path [16].

The multistage model was first presented by both Eisenstat et al. [9] and Gupta et al. [18]. In [9] the Multistage Facility Location problem was considered, where the underlying metric in which clients and facility reside changes over time. A logarithmic approximation algorithm was presented for two variants of the problem; the hourly opening costs where the opening cost of a facility is charged at each stage in which it is open, and the fixed opening costs where a facility is open at all stages after its opening costs is paid. A logarithmic hardness result was also presented for the fixed opening costs variant. An et al. [1] improved the result for the hourly opening costs variant and presented a constant factor approximation. Fairstein et al. [12] proved that the logarithmic hardness result does not hold if only the client locations change over time and the facilities are static.

As mentioned, the multistage model was also introduced by Gupta et al. [18], where the Multistage Matroid Maintenance (MMM) problem was considered. In MMM we are given a set of elements equipped with costs that change over time. In addition, we are given a matroid. The goal is to select a base of minimum costs at each stage whilst minimizing the cost of the difference of bases selected for consecutive stages. Gupta et al. [18] presented a logarithmic approximation algorithm for the problem, as well as fitting lower bound, proving this result is tight.

### Organization

Section 2 provides the approximation schemes from Theorem 1. Hardness results are presented in Section 3.

## 2 Approximation Scheme for $d$ -GMK

In this section we derive the approximation scheme for  $d$ -GMK with bounded profit-cost ratio. In Section 2.1 we show how a PTAS for instances with bounded time horizon can be obtain via a reduction to a variant of  $d$ -MKCP. Subsequently, in Section 2.2 we show how the algorithm for bounded time horizon can be used to approximate general instance.

## 2.1 Bounded Time Horizon

In this section we provide a reduction from an instance of  $q$ -GMK to a generalization of  $d$ -MKCP (for specific values of  $d$  and  $q$ ). The generalization was presented in [11] and is called  $d$ -MKCP With A Matroid Constraint ( $d$ -MKCP+) and is defined by a tuple  $(I, \mathcal{K}, p, \mathcal{I})$ , where  $(I, \mathcal{K}, p)$  forms an instance of  $d$ -MKCP. Also, the set  $\mathcal{I} \subseteq 2^I$  defines a matroid<sup>3</sup> constraint. A feasible solution for  $d$ -MKCP+ is a set  $S \in \mathcal{I}$  and a tuple of feasible assignments  $\mathcal{A}$  (w.r.t  $\mathcal{K}$ ) of  $S$ . The goal is to find a feasible solution which maximizes  $\sum_{i \in S} p(i)$ . The following definition presents the construction of the reduction.

► **Definition 5.** Let  $\mathcal{Q} = ((\mathcal{P}_t)_{t=1}^T, g^+, g^-, c^+, c^-)$  be an instance of  $d$ -GMK, where  $\mathcal{P}_t = (I, \mathcal{K}_t, p_t)$  and  $\mathcal{K}_t = (K_{t,j})_{j=1}^{d_t}$ . Define  $R(\mathcal{Q}) = (E, \tilde{\mathcal{K}}, \tilde{p}, \mathcal{I})$  where

- $E = I \times 2^{[T]}$
- $\mathcal{I} = \{S \subseteq E \mid \forall i \in I: |S \cap (\{i\} \times 2^{[T]})| \leq 1\}$
- For  $t \in [T], j \leq d_t$  set MKC  $\tilde{K}_{t,j} = (\tilde{w}_{t,j}, B_{t,j}, W_{t,j})$  over  $E$ , where  $K_{t,j} = (w_{t,j}, B_{t,j}, W_{t,j})$  and

$$\tilde{w}_{t,j}((i, D)) = \begin{cases} w_{t,j}(i) & t \in D \\ 0 & \text{otherwise} \end{cases}$$

- For  $t = 1, \dots, T, d_t < j \leq d$  set MKC  $\tilde{K}_{t,j} = (w_0, \{b\}, W_0)$  over  $E$ , where  $w_0 : 2^E \rightarrow \{0\}$ ,  $W_0(b) = 0$  and  $b$  is an arbitrary bin (object).
- $\tilde{\mathcal{K}} = (\tilde{K}_{t,j})_{t \in [T], j \in [d]}$ .
- The objective function  $\tilde{p}$  is defined as follows.

$$\tilde{p}(S) = \sum_{(i,D) \in S} \left( \sum_{t \in D} p_t(i) + \sum_{t \in D: t-1 \in D} g_{i,t}^+ + \sum_{t \notin D: t-1 \notin D} g_{i,t}^- - \sum_{t \in D: t-1 \notin D} c_{i,t}^+ - \sum_{t \in D: t+1 \notin D} c_{i,t}^- \right)$$

Each element  $(i, D) \in E$  states the subset of stages in which item  $i$  is assigned. I.e.,  $i$  is only assigned in stages  $t \in D$ . Thus any solution should include at most one element  $(i, D)$  for each  $i \in I$ . This constraint is fully captured by the partition matroid constraint defined by the set of independent sets  $\mathcal{I}$ . Finally, if an element  $(i, D)$  is selected, we must assign  $i$  in each MKC  $K_{t,j}$  for  $j \in [d_t], t \in D$ . This is captured by the weight function  $\tilde{w}$ , as an element  $(i, D)$  weighs  $w_{t,j}(i)$  if and only if  $t \in D$  (otherwise its weight is zero and it can be assigned for “free”).

► **Lemma 6.** For any  $d$ -GMK instance  $\mathcal{Q}$  with time horizon  $T$ , it holds that  $R(\mathcal{Q})$  is a  $dT$ -MKCP+ instance.

**Proof.** Let  $\mathcal{Q} = ((\mathcal{P}_t)_{t=1}^T, g^+, g^-, c^+, c^-)$  be an instance of  $d$ -GMK, where  $\mathcal{P}_t = (I, \mathcal{K}_t, p_t)$  and  $\mathcal{K}_t = (K_{t,j})_{j=1}^{d_t}$ . Also, let  $R(\mathcal{Q}) = (E, \tilde{\mathcal{K}}, \tilde{p}, \mathcal{I})$  be the reduced instance of  $\mathcal{Q}$  as defined in Definition 5. It is easy to see that the set  $\mathcal{I}$  is the independent sets of a partition matroid, as for each item  $i$  at most one element  $(i, D)$  can be chosen. Thus,  $\mathcal{I}$  is the family of independent sets of a matroid as required.

Next,  $\mathcal{K}$  defines a tuple of MKCs, so all that is left to prove is that  $\tilde{p}$  is non-negative and modular. For each element  $(i, D) \in E$  we can define a fixed value

$$v((i, D)) = \sum_{t \in D} p_t(i) + \sum_{t \in D: t-1 \in D} g_{i,t}^+ + \sum_{t \notin D: t-1 \notin D} g_{i,t}^- - \sum_{t \in D: t-1 \notin D} c_{i,t}^+ + \sum_{t \in D: t+1 \notin D} c_{i,t}^-$$

It immediately follows that  $\tilde{p}(S) = \sum_{e \in S} v(e)$  and that  $\tilde{p}$  is modular. As stated in Section 1.1, elements with negative values are discarded in advance such that  $\tilde{p}$  is also non-negative. ◀

<sup>3</sup> A formal definition for matroid can be found in [21]

► **Lemma 7.** *Let  $\mathcal{Q}$  be an instance of  $d$ -GMK with time horizon  $T$ . For any feasible solution  $(S_t, \mathcal{A}_t)_{t=1}^T$  of  $\mathcal{Q}$  there exists a feasible solution  $(S, (\tilde{A}_{t,j})_{t \in [T], j \in [d]})$  of  $R(\mathcal{Q})$  such that  $f_{\mathcal{Q}}((S_t)_{t=1}^T) = \tilde{p}(S)$ .*

**Proof.** Let  $\mathcal{Q} = ((\mathcal{P}_t)_{t=1}^T, g^+, g^-, c^+, c^-)$  be an instance of  $d$ -GMK, where  $\mathcal{P}_t = (I, \mathcal{K}_t, p_t)$  and  $\mathcal{K}_t = (K_{t,j})_{j=1}^{d_t}$ . Also, let  $R(\mathcal{Q}) = (E, \tilde{\mathcal{K}}, \tilde{p}, \mathcal{I})$  be the reduced instance of  $\mathcal{Q}$ , where  $\tilde{\mathcal{K}} = (\tilde{K}_{t,j})_{t \in [T], j \in [d]}$  and  $\tilde{K}_{t,j} = (\tilde{w}, B_{t,j}, W_{t,j})$  (see Definition 5). Consider some feasible solution  $(S_t, \mathcal{A}_t)_{t=1}^T$  for  $\mathcal{Q}$ , where  $\mathcal{A}_t = (A_{t,j})_{j=1}^{d_t}$ . In the following we define a solution  $(S, (\tilde{A}_{t,j})_{t \in [T], j \in [d]})$  for  $R(\mathcal{Q})$ . Let

$$S = \{(i, D) \mid i \in I, D = \{t \in [T] \mid i \in S_t\}\}$$

It can be easily verified that  $S \in \mathcal{I}$ . The value of the subset  $S$  is

$$\begin{aligned} \tilde{p}(S) &= \\ & \sum_{(i,D) \in S} \left( \sum_{t \in D} p_t(i) + \sum_{t \in D: t-1 \in D} g_{i,t}^+ + \sum_{t \notin D: t-1 \notin D} g_{i,t}^- - \sum_{t \in D: t-1 \notin D} c_{i,t}^+ - \sum_{t \in D: t+1 \notin D} c_{i,t}^- \right) = \\ & \sum_{t=1}^T \sum_{i \in S_t} p_t(i) + \sum_{t=2}^T \left( \sum_{i \in S_{t-1} \cap S_t} g_{i,t}^+ + \sum_{i \notin S_{t-1} \cup S_t} g_{i,t}^- \right) - \sum_{t=1}^T \left( \sum_{i \in S_t \setminus S_{t-1}} c_{i,t}^+ + \sum_{i \in S_t \setminus S_{t+1}} c_{i,t}^- \right) = \\ & f_{\mathcal{Q}}((S_t)_{t=1}^T). \end{aligned}$$

Next, for each  $t \in [T], j \in [d]$  we present an assignment  $\tilde{A}_{t,j}$  of  $S$ . Consider the following two cases:

1. If  $j > d_t$ , recall  $\tilde{K}_{t,j} = (w_0, \{b\}, W_0)$  where  $w_0(i, D) = 0$  for all  $(i, D) \in E$  and  $W_0(b) = 0$ . We define  $\tilde{A}_{t,j}$  by  $\tilde{A}_{t,j}(b) = S$ . It thus holds that  $w_0(\tilde{A}_{t,j}(b)) = 0 = W_0$ . That is,  $\tilde{A}_{t,j}$  is feasible.
2. If  $j \leq d_t$ , let  $b^* \in B_{t,j}$  be some unique bin in  $B_{t,j}$  and define assignment  $\tilde{A}_{t,j} : B_{t,j} \rightarrow 2^E$  by

$$\begin{aligned} \tilde{A}_{t,j}(b) &= \left( A_{t,j}(b) \times 2^{[T]} \right) \cap S & \forall b \in B_{t,j} \setminus \{b^*\} \\ \tilde{A}_{t,j}(b^*) &= \left( \left( A_{t,j}(b^*) \times 2^{[T]} \right) \cap S \right) \cup \{(i, D) \in S \mid t \notin D\} \end{aligned} \quad (1)$$

The assignment  $\tilde{A}_{t,j}$  is a feasible assignment w.r.t  $\tilde{K}_{t,j}$  since for each bin  $b \in B_{t,j}$  it holds that

$$\sum_{(i,D) \in \tilde{A}_{t,j}(b)} \tilde{w}_{t,j}((i, D)) = \sum_{i \in A_{t,j}(b)} w_{t,j}(i) \leq W_{t,j}(b)$$

Let  $(i, D) \in S$ . If  $i \in S_t$  there is  $b \in B_{t,j}$  such that  $i \in A_{t,j}(b)$ , hence  $(i, D) \in \tilde{A}_{t,j}(b)$  by (1). If  $i \notin S_t$  then  $t \notin D$  and thus  $(i, D) \in \tilde{A}_{t,j}(b^*)$ . Overall, we have  $S \subseteq \bigcup_{b \in B_{t,j}} \tilde{A}_{t,j}(b)$ .

By (1) it follows that  $S \supseteq \bigcup_{b \in B_{t,j}} \tilde{A}_{t,j}(b)$  as well, thus  $S = \bigcup_{b \in B_{t,j}} \tilde{A}_{t,j}(b)$ . I.e.,  $\tilde{A}_{t,j}$  is an assignment of  $S$ .

Note that the assignments can be constructed in polynomial time. We can conclude that  $(S, (\tilde{A}_{t,j})_{t \in [T], j \in [d]})$  is a feasible solution for  $R(\mathcal{Q})$ , and its value is  $f_{\mathcal{Q}}((S_t)_{t=1}^T)$ . ◀

► **Lemma 8.** *Let  $\mathcal{Q}$  be an instance of  $d$ -GMK (with arbitrary time horizon  $T$ ). For any feasible solution  $(S, (\tilde{A}_{t,j})_{t \in [T], j \in [d]})$  for  $R(\mathcal{Q})$  a feasible solution  $(S_t, \mathcal{A}_t)_{t=1}^T$  for  $\mathcal{Q}$  such that  $f_{\mathcal{Q}}((S_t)_{t=1}^T) = \tilde{f}(S)$  can be constructed in polynomial time.*

## 15:8 General Knapsack Problems in a Dynamic Setting

The proof of Lemma 8 is similar to the proof of Lemma 7, thus it is deferred to Appendix A.

For any  $d$ -GMK instance with a fixed time horizon  $T$ , the reduction  $R(\mathcal{Q})$  can be constructed in polynomial (as  $|E| = |I| \cdot 2^{|T|}$ ). The next corollary follows from this observation and lemmas 7 and 8.

► **Corollary 9.** *For any fixed  $T \in \mathbb{N}$ , there exists an approximation factor preserving reduction from  $d$ -GMK with a time horizon bounded by  $T$  to  $dT$ -MKCP+.*

In [11] a PTAS for  $d$ -MKCP+ is presented. Thus, the next lemma follows from the above corollary.

► **Lemma 10.** *For any fixed  $T \in \mathbb{N}$  there exists a randomized PTAS for  $d$ -GMK with a time horizon bounded by  $T$ .*

### 2.2 General Time Horizon

In this section we present an algorithm for  $d$ -GMK with a general time horizon  $T$ . This is done by cutting the time horizon at several stages into sub-instances. Each sub-instance is optimized independently and then the solutions are combined to create a solution for the complete instance. A somewhat similar technique was used in [4]. However, they considered a model without change costs which is much simpler. Our analysis is more delicate as it requires local consideration of the assignment of each item to ensure that any additional costs charged are covered by profit and gains earned.

Given an instance  $\mathcal{Q} = ((\mathcal{P}_t)_{t=1}^T, g^+, g^-, c^+, c^-)$  we define a sub-instance for the sub-range  $[t_1, t_2]$ , denoted throughout this section by  $((\mathcal{P}_t)_{t=t_1}^{t_2}, g^+, g^-, c^+, c^-)$  without shifting or truncating the gain and change costs vectors. For example, for  $t \in [t_1, t_2]$  gain  $g_{i,t}^+$  is earned for assigning item  $i$  in stages  $t$  and  $t+1$ . Also, observe that stages  $t_1 - 1$  and  $t_2 + 1$  are outside the scope of the instance. Thus, when evaluating a solution for the sub-instance it is assumed that  $S_{t_1-1} = S_{t_2+1} = \emptyset$ .

Given an integer  $T \in \mathbb{N}$ , a set of *cut points*  $U = \{u_0, \dots, u_k\}$  of  $T$  is a set of integers such that for every  $j = 0, \dots, k-1$  it holds that  $u_j < u_{j+1}$  and  $1 = u_0 < u_k = T + 1$ .

► **Definition 11.** *Let  $\mathcal{Q} = ((\mathcal{P}_t)_{t=1}^T, g^+, g^-, c^+, c^-)$  be an instance of  $d$ -GMK, where  $\mathcal{P}_t = (I, \mathcal{K}_t, p_t)$ . Also, let  $U = \{u_0, \dots, u_k\}$  be a set of cut points. The tuple of  $d$ -GMK instances  $\mathcal{Q}_U = \left( (\mathcal{P}_t)_{t=u_j}^{u_{j+1}-1}, g^+, g^-, c^+, c^- \right)_{j=0}^{k-1}$  is defined as the cut instances of  $\mathcal{Q}$  w.r.t  $U$ .*

► **Definition 12.** *Let  $\mathcal{Q}$  be an instance of  $d$ -GMK,  $U = \{u_0, \dots, u_k\}$  be a set of cut points and  $\mathcal{Q}_U$  be the respective cut instances. Also, let  $\left( (S_t, \mathcal{A}_t)_{t=u_j}^{u_{j+1}-1} \right)_{j=0}^{k-1}$  be a tuple of feasible solutions for the tuple of cut instances  $\mathcal{Q}_U$ . Then, the solution  $(S_t, \mathcal{A}_t)_{t=1}^T$  for  $\mathcal{Q}$  is called a cut solution.*

The next corollary elaborates on the relationship between a cut solution and the cut instance solutions from which it is constructed.

► **Corollary 13.** *Given any  $d$ -GMK instance  $\mathcal{Q}$ , cut points  $U$ , cut instances  $\mathcal{Q}_U$  and feasible solutions for the cut instances, the respective cut solution is a feasible solution for  $\mathcal{Q}$ , and its value is at least the sum of values of the solutions for the cut instances.*

The proof of the corollary is fairly simple, and is deferred to Appendix A. We are now ready to present the algorithm for  $d$ -GMK with general time horizon length.

---

**Algorithm 1** General Time Horizon.

- 
- Input :**  $0 < \epsilon < \frac{1}{4}$ ,  $\phi \geq 1$ , a  $d$ -GMK instance  $\mathcal{Q}$  with time horizon  $T$  such that  $\phi_{\mathcal{Q}} \leq \phi$ , and  $\alpha$ -approximation algorithm  $A$  for  $d$ -GMK with time horizon  $T \leq \frac{2\phi}{\epsilon^2}$ .
- 1 Set  $\mu = \frac{\epsilon^2}{\phi}$ .
  - 2 **for**  $j = 1, \dots, \frac{1}{\mu}$  **do**
  - 3     Set  $U_j = \left\{ \frac{a}{\mu} + j - 1 \mid a \in \mathbb{N}, a \geq 1, \frac{a}{\mu} + j - 1 \leq T - \frac{1}{\mu} \right\} \cup \{1, T + 1\}$ .
  - 4     Find a solution for each cut instance in  $\mathcal{Q}_{U_j}$  using algorithm  $A$  and set  $\mathcal{S}_j$  as the respective cut solution.
  - 5 **Return** the solution  $\mathcal{S}_j$  which maximizes the objective function  $f_{\mathcal{Q}}$ .
- 

Before analysing the algorithm we present several definitions and lemmas that are essential for the proof. First, we start by reformulating the solution. Instead of describing the assignment of items by the tuple  $(S_t)_{t=1}^T$ , we define a new set of elements  $E = I \times [T] \times [T]$ , where each element  $(i, t_1, t_2) \in E$  states that item  $i$  is assigned in the interval  $[t_1, t_2]$ . Given a feasible solution  $(S_t, \mathcal{A}_t)_{t=1}^T$  for  $\mathcal{Q}$  we denote the representation of  $(S_t)_{t=1}^T$  as a subset of  $E$  by  $E((S_t)_{t=1}^T)$  and it is equal to

$$E((S_t)_{t=1}^T) = \{(i, t_1, t_2) \in E \mid \forall t \in [t_1, t_2] : i \in S_t \text{ and } i \notin S_{t_1-1} \cup S_{t_2+1}\}.$$

If  $\tilde{S} = E((S_t)_{t=1}^T)$ , we define the reverse mapping as  $\tilde{S}(t) = \{i \in I \mid \exists(i, t_1, t_2) \in \tilde{S} : t \in [t_1, t_2]\} = S_t$ . Now, we can define a solution for  $d$ -GMK using our new representation as  $(\tilde{S}, \mathcal{A}_t)_{t=1}^T$ .

► **Definition 14.** The value,  $v(e)$ , of element  $e = (i, t_1, t_2)$  is defined as the total value earned from assigning  $i$  in the range  $[t_1, t_2]$  minus the change costs charge for assigning and discarding it. Formally,

$$v(e) = \sum_{t=t_1}^{t_2} p_t(i) + \sum_{t=t_1+1}^{t_2} g_{i,t}^+ - c_{i,t_1}^+ - c_{i,t_2}^-$$

The value of solution  $\tilde{S} \subseteq E$  for  $d$ -GMK instance  $\mathcal{Q}$  is  $\sum_{e \in \tilde{S}} v(e) + \sum_{t=2}^T \sum_{i \notin \tilde{S}(t-1) \cup \tilde{S}(t)} g_{i,t}^-$  and it is equal to  $f_{\mathcal{Q}}((\tilde{S}(t))_{t=1}^T)$ .

In Algorithm 1 we consider a solution for a tuple of cut instances created by cutting an instance at a set of cut points. Here we consider the opposite action, the effect of cutting a solution at these cut points. We start by considering a single cut point.

► **Definition 15.** Given an element  $e = (i, t_1, t_2)$  and a cut point  $u \in (t_1, t_2]$  we define the outcome of cutting  $e$  at  $u$  as the set of intervals  $u(e) = \{(i, t_1, u-1), (i, u, t_2)\}$ . Also, the loss caused by cutting  $e$  at  $u$  is defined as the difference between the value of  $e$  and the sum of value of elements in  $u(e)$ . It is denoted by  $\ell(e, u)$  and is equal to

$$\ell(e, u) = v(e) - \sum_{e' \in u(e)} v(e') = g_{i,u}^+ + c_{i,u}^+ + c_{i,u-1}^- \quad (2)$$

We can similarly extend the definition to include more than one cut point as follows.

► **Definition 16.** Given a set of cut points  $U = \{u_0, u_1, \dots, u_k\}$  and an element  $e = (i, t_1, t_2)$  define  $U(e)$  as the set of elements created by cutting the  $e$  at all cut points in  $U$ . Formally,

$$U((i, t_1, t_2)) = \left\{ (i, \max\{t_1, u_{r-1}\}, \min\{u_r - 1, t_2\}) \mid r \in [k] \text{ and } [u_{r-1}, u_r - 1] \cap [t_1, t_2] \neq \emptyset \right\}$$

## 15:10 General Knapsack Problems in a Dynamic Setting

Consider the following example as a demonstration of the above definition. If  $e = (i, t_1, t_2)$  and  $(t_1, t_2) \cap U_j = \{u_2, u_3\}$ , then  $U_j(e) = \{(i, t_1, u_2 - 1), (i, u_2, u_3 - 1), (i, u_3, t_2)\}$ .

The definition of loss caused by cutting an element can be extended to a set of cut points  $U$ . If element  $e = (i, t_1, t_2)$  is cut by a of cut points  $U$  the loss is

$$\ell(e, U) = v(e) - \sum_{e' \in U(e)} v(e') = \sum_{u \in U \cap (t_1, t_2]} (g_{i,u}^+ + c_{i,u}^+ + c_{i,u-1}^-) = \sum_{u \in U \cap (t_1, t_2]} \ell(e, u) \quad (3)$$

since only gains  $g^+$  are lost due to cutting as well as change cost for splitting an assignment into two intervals. This means that even if an element is cut multiple times, the loss due to each cut point can be considered separately.

► **Lemma 17.** *Let  $0 < \epsilon < \frac{1}{4}$ ,  $\phi \geq 1$  and  $A$  be an  $\alpha$ -approximation algorithm for  $d$ -GMK with time horizon  $T \leq \frac{2\phi}{\epsilon^2}$ . Also, let  $\mathcal{Q}$  be an instance of  $d$ -GMK such that  $\phi_{\mathcal{Q}} \leq \phi$ . Algorithm 1 approximates  $\mathcal{Q}$  within a factor of  $(1 - \epsilon)\alpha$ .*

**Proof.** Let  $\mathcal{Q} = ((P_t)_{t=1}^T, g^+, g^-, c^+, c^-)$  be an instance of  $d$ -GMK with time horizon  $T$  and profit-cost ratio  $\phi_{\mathcal{Q}} \leq \phi$ . We assume for simplicity  $\phi$  is integral. Let  $0 < \epsilon < \frac{1}{4}$  and  $\mu = \frac{\epsilon^2}{\phi}$ . Also, let  $A$  be an  $\alpha$ -approximation algorithm for  $d$ -GMK with time horizon  $T' \leq \frac{2\phi}{\epsilon^2} = \frac{2}{\mu}$ . Note, if  $T \leq \frac{2}{\mu}$ , the cut points set  $U_0$  is an empty set, and in this case  $A$  returns an  $\alpha$ -approximation solution for  $\mathcal{Q}$  as required.

Let  $U_j = \{u_1^j, \dots, u_{k_j}^j\}$  for  $j = 1, \dots, \frac{1}{\mu}$ . We show that there exists a set of cut points  $U_j$  and a tuple of solutions  $\left( (S_t, \mathcal{A}_t)_{t=u_r^j}^{u_{r+1}^j-1} \right)_{r=0}^{k_j-1}$  for each cut instance in  $\mathcal{Q}_{U_j} = (q_j^r)_{r=0}^{k_j-1}$ , such that the sum of values of the solutions,  $\sum_{r=0}^{k_j-1} f_{q_j^r} \left( (S_t)_{t=u_r^j}^{u_{r+1}^j-1} \right)$ , is sufficiently large. From Corollary 13 it follows that the value of a cut solution is larger than the sum of its parts (due to lost gains and change costs saved if an item is assigned in adjacent instances). Thus, this also proves that the maximum cut solution found is sufficiently large as well.

Let  $(S_t^*, \mathcal{A}_t^*)_{t=1}^T$  be an optimal solution for  $\mathcal{Q}$ , and let  $\tilde{S}^* = E \left( (S_t^*)_{t=1}^T \right)$ . We partition  $\tilde{S}^*$  into two subsets by the length of the interval they describe. Formally,  $X = \left\{ (i, t_1, t_2) \in \tilde{S}^* \mid t_2 - t_1 < \frac{\phi}{\epsilon} \right\}$  and  $Y = \tilde{S}^* \setminus X$ . So  $X$  contains short intervals, and  $Y$  contains long intervals.

Define  $\tilde{S}_j$  as the subset of elements longer than  $\phi$  in  $\cup_{e \in Y} U_j(e)$  as well as short elements  $e \in X$  that are not cut by  $U_j$ . I.e.,

$$\tilde{S}_j = \{e \in X \mid U_j(e) = \{e\}\} \cup \bigcup_{e \in Y} \{(i, t_1, t_2) \in U_j(e) \mid t_2 - t_1 \geq \phi\}$$

At each stage  $t \in [T]$  it holds that  $\tilde{S}_j(t) \subseteq S_t^*$ . Thus there exists a tuple of assignments, denoted by  $\mathcal{A}_t^j$ , such that  $(\tilde{S}_j, \mathcal{A}_t^j)_{t=1}^T$  is a feasible solution for  $\mathcal{Q}$ . We partition set  $\tilde{S}_j$  as follows. Let  $\tilde{S}_{j,r} = \left\{ (i, t_1, t_2) \in \tilde{S}_j \mid [t_1, t_2] \subseteq [u_r^j, u_{r+1}^j - 1] \right\}$ . It holds that  $\tilde{S}_j = \cup_{r=0}^{k_j-1} \tilde{S}_{j,r}$  as each element  $(i, t_1, t_2)$  is contained in exactly one interval  $[u_r^j, u_{r+1}^j - 1]$ . Thus  $\left( (\tilde{S}_{j,r}, \mathcal{A}_t^j)_{t=u_r^j}^{u_{r+1}^j-1} \right)_{r=0}^{k_j-1}$  is a tuple of feasible solutions for the cut instances in  $\mathcal{Q}_{U_j}$  such that  $(\tilde{S}_{j,r}, \mathcal{A}_t^j)_{t=u_r^j}^{u_{r+1}^j-1}$  is a solution for the  $r$ -th instance. The value of all elements in the defined solutions for the cut instances is

$$\sum_{r=0}^{k_j-1} \sum_{e \in \tilde{S}_{j,r}} v(e) = \sum_{e \in \tilde{S}_j} v(e) = \sum_{e \in X: U_j(e) = \{e\}} v(e) + \sum_{e \in Y} \sum_{e' = (i, t_1, t_2) \in U_j(e): t_2 - t_1 \geq \phi} v(e')$$

Thus, after including the value of gains  $g^-$  earned by solutions  $\tilde{S}_{j,r}$ , we can bound the total value of optimal solutions for all cut instances  $\mathcal{Q}_{U_j}$  by

$$\sum_{e \in X: U_j(e) = \{e\}} v(e) + \sum_{e \in Y} \sum_{\substack{e' = (i, t_1, t_2) \in U_j(e): \\ t_2 - t_1 \geq \phi}} v(e') + \sum_{\substack{t \in [u_r^j + 1, u_{r+1}^j - 1]: \\ u_r^j \in U_j}} \sum_{i \notin \tilde{S}_{j,r}(t-1) \cup \tilde{S}_{j,r}(t)} g_{i,t}^- \quad (4)$$

We define  $\mathcal{B}$  as the total sum of values of optimal solutions for the cut instances  $(\mathcal{Q}_{U_j})_{j=1}^{\frac{1}{\mu}}$ . By utilizing Equation (4) we can bound  $\mathcal{B}$  as follows.

$$\begin{aligned} \mathcal{B} &\geq \sum_{j=1}^{\frac{1}{\mu}} \sum_{r=0}^{k_j-1} \left( \sum_{e \in \tilde{S}_{j,r}} v(e) + \sum_{t \in [u_r^j + 1, u_{r+1}^j - 1]: u_r^j \in U_j} \sum_{i \notin \tilde{S}_{j,r}(t-1) \cup \tilde{S}_{j,r}(t)} g_{i,t}^- \right) \\ &= \sum_{j=1}^{\frac{1}{\mu}} \sum_{e \in \tilde{S}_j} v(e) + \sum_{j=1}^{\frac{1}{\mu}} \sum_{t \in [2, T] \setminus U_j} \sum_{i \notin \tilde{S}_j(t-1) \cup \tilde{S}_j(t)} g_{i,t}^- \\ &= \sum_{e \in X} \sum_{j \in [\frac{1}{\mu}]: U_j(e) = \{e\}} v(e) + \sum_{e \in Y} \sum_{j=1}^{\frac{1}{\mu}} \sum_{e' = (i, t_1, t_2) \in U_j(e): t_2 - t_1 \geq \phi} v(e') \\ &\quad + \sum_{j=1}^{\frac{1}{\mu}} \sum_{t \in [2, T] \setminus U_j} \sum_{i \notin \tilde{S}_j(t-1) \cup \tilde{S}_j(t)} g_{i,t}^- \end{aligned} \quad (5)$$

We bound the value of each of the three terms separately by comparing it to the value of the optimal solution.

Consider the first term, value earned from short elements, i.e., elements  $e = (i, t_1, t_2) \in X$ . It holds that  $e \in \tilde{S}_j$  if and only if  $U_j(e) = \{e\}$  which means that  $(t_1, t_2] \cap U_j = \emptyset$ . Since for every  $j_1 \neq j_2$  it holds that  $U_{j_1} \cap U_{j_2} = \{1, T+1\}$  and since there are  $\frac{1}{\mu}$  sets of cut point, for each element  $e \in X$  it holds that  $e \in \tilde{S}_j$  for at least  $\frac{1}{\mu} - \frac{\phi}{\epsilon}$  values of  $j \in [\frac{1}{\mu}]$ . Thus,

$$\sum_{e \in X} \sum_{j \in [\frac{1}{\mu}]: U_j(e) = \{e\}} v(e) \geq \left( \frac{1}{\mu} - \frac{\phi}{\epsilon} \right) \sum_{e \in X} v(e) = \frac{1}{\mu} (1 - \epsilon) \sum_{e \in X} v(e) \quad (6)$$

Next, we bound the second term, the value earned from long elements,  $e \in Y$ . Consider the set of cut points  $U_j$ . Two operators are applied to each long element. First, it is cut and the subset  $U_j(e)$  is defined. Second, short elements are discarded from  $U_j(e)$ . The resulting subset is  $\{(i, t_1, t_2) \in U_j(e) \mid t_2 - t_1 \geq \phi\}$  and therefore we would like to bound the difference

$$\sum_{e \in Y} \left( v(e) - \sum_{e' \in \{(i, t_1, t_2) \in U_j(e) \mid t_2 - t_1 \geq \phi\}} v(e') \right)$$

Consider an element  $e = (i, t_1, t_2) \in Y$  cut by cut points set  $U_j$ . As shown in Equation (3), the loss caused by cutting  $e$  at cut point  $u \in (t_1, t_2]$  is independent of other cuts that are applied to  $e$  and is equal to  $\ell(e, u)$ . Thus we can consider each cut point separately.

As mentioned above, if  $e = (i, t_1, t_2) \in Y$ , the second operator discards elements  $e' \in U_j(e)$  that are short. Since the distance between each pair of cut points in  $U_j$  is at least  $\frac{1}{\mu} = \frac{\phi}{\epsilon^2} > \phi$ , each such short element  $e'$  is either  $(i, t_1, u)$  or  $(i, u, t_2)$  for some unique cut point  $u \in U_j$ . In addition, it must hold that either  $u - t_1 < \phi$  or  $t_2 - u < \phi$ . We associate the value lost by discarding  $e'$  to this unique cut point  $u$ .

## 15:12 General Knapsack Problems in a Dynamic Setting

Let  $e = (i, t_1, t_2) \in Y$  and  $u \in U_j$  be a cut point such that  $u \in (t_1, t_2]$ , i.e.,  $u$  cuts  $e$ . There are three cases to consider.

1. If  $u - t_1 < \phi$ , element  $e' = (i, t_1, u - 1) \in U_j(e)$  is discarded and a loss of  $v(e')$  is associated with  $u$  in addition to  $\ell(e, u)$ . Thus the total loss is at most

$$\begin{aligned} v(e') + \ell(e, u) &= \sum_{t=t_1}^{u-1} p_t(i) + \sum_{t=t_1+1}^{u-1} g_{i,t}^+ - c_{i,t_1}^+ - c_{i,u-1}^- + g_{i,u}^+ + c_{i,u}^+ + c_{i,u-1}^- \leq \\ &\leq \sum_{t=t_1}^{u-1} p_t(i) + \sum_{t=t_1+1}^u g_{i,t}^+ + c_{i,u-1}^+ \leq \sum_{t=t_1}^{u+\phi-1} p_t(i) + \sum_{t=t_1+1}^{u+\phi-1} g_{i,t}^+ \end{aligned}$$

where the equality is due to Equation (2) and the last inequality is due to the profit-cost ratio.

2. If  $t_2 - u < \phi$ , element  $e' = (i, u, t_2) \in U_j(e)$  is discarded and a loss of  $v(e')$  is associated with  $u$  in addition to  $\ell(e, u)$ . Thus the total loss is at most

$$\begin{aligned} v(e') + \ell(e, u) &= \sum_{t=u}^{t_2} p_t(i) + \sum_{t=u+1}^{t_2} g_{i,t}^+ - c_{i,u}^+ - c_{i,t_2}^- + g_{i,u}^+ + c_{i,u}^+ + c_{i,u-1}^- \leq \\ &\leq \sum_{t=u}^{t_2} p_t(i) + \sum_{t=u}^{t_2} g_{i,t}^+ + c_{i,u-1}^- \leq \sum_{t=u-\phi}^{t_2} p_t(i) + \sum_{t=u-\phi+1}^{t_2} g_{i,t}^+ \end{aligned}$$

where the equality is due to Equation (2) and the last inequality is due to the profit-cost ratio.

3. If  $t_2 - u \geq \phi$  and  $u - t_1 \geq \phi$ , no elements are discarded from  $U_j(e)$ . Thus the only loss is  $\ell(e, u)$  and can be bounded by

$$\ell(e, u) = g_{i,u}^+ + c_{i,u}^+ + c_{i,u-1}^- \leq \sum_{t=u-\phi}^{u+\phi-1} p_t(i) + \sum_{t=u-\phi+1}^{u+\phi-1} g_{i,t}^+$$

Overall we can bound the loss induced by cutting long elements at cut points  $U_j$  (due to loss  $\ell(e, u)$  and discarded short elements) by

$$\sum_{(i, t_1, t_2) \in Y} \sum_{u \in (t_1, t_2] \cap U_j} \left( \sum_{t=\max\{t_1, u-\phi\}}^{\min\{t_2, u+\phi-1\}} p_t(i) + \sum_{t=\max\{t_1+1, u-\phi+1\}}^{\min\{t_2, u+\phi-1\}} g_{i,t}^+ \right)$$

This means that the total value gained from elements that were originally in  $Y$  is

$$\begin{aligned} &\sum_{e \in Y} \sum_{j=1}^{\frac{1}{\mu}} \sum_{e'=(i, t_1, t_2) \in u(e, U_j): t_2 - t_1 \geq \phi} v(e') \geq \\ &\frac{1}{\mu} \sum_{e \in Y} v(e) - \sum_{j=1}^{\frac{1}{\mu}} \sum_{(i, t_1, t_2) \in Y} \sum_{u \in [t_1+1, t_2] \cap U_j} \left( \sum_{t=\max\{t_1, u-\phi\}}^{\min\{t_2, u+\phi-1\}} p_t(i) + \sum_{t=\max\{t_1+1, u-\phi+1\}}^{\min\{t_2, u+\phi-1\}} g_{i,t}^+ \right) \geq \\ &\frac{1}{\mu} \sum_{e \in Y} v(e) - \sum_{(i, t_1, t_2) \in Y} \sum_{u \in [t_1+1, t_2]} \left( \sum_{t=\max\{t_1, u-\phi\}}^{\min\{t_2, u+\phi-1\}} p_t(i) + \sum_{t=\max\{t_1+1, u-\phi+1\}}^{\min\{t_2, u+\phi-1\}} g_{i,t}^+ \right) \geq \\ &\frac{1}{\mu} \sum_{e \in Y} v(e) - 2\phi \sum_{(i, t_1, t_2) \in Y} \left( \sum_{t \in [t_1, t_2]} p_t(i) + \sum_{t \in [t_1+1, t_2]} g_{i,t}^+ \right) \end{aligned}$$

where the second inequality follows from the fact that for every  $j_1 \neq j_2$  it holds that  $U_{j_1} \cap U_{j_2} = \{1, T+1\}$ . The last inequality is due to the fact that the profit and gains of element  $(i, t_1, t_2)$  is lost at stage  $t \in [t_1, t_2]$  if it is cut by a cut point  $u$  such that  $|u - t| \leq \phi$ . Thus, its value is lost in at most  $2\phi$  instances. Due to the profit-cost ratio, for each long element  $e = (i, t_1, t_2) \in Y$  it holds that

$$c_{i,t_1}^+ + c_{i,t_2}^- \leq 2\phi \cdot \frac{\sum_{t=t_1}^{t_2} p_t(i) + \sum_{t=t_1+1}^{t_2} g_{i,t}^+}{t_2 - t_1} \leq \epsilon \cdot \sum_{t=t_1}^{t_2} p_t(i) + \epsilon \cdot \sum_{t=t_1+1}^{t_2} g_{i,t}^+$$

By substituting  $4\phi(c_{i,t_1}^+ + c_{i,t_2}^-) \leq 4\phi\epsilon \left( \sum_{t=t_1}^{t_2} p_t(i) + \sum_{t=t_1+1}^{t_2} g_{i,t}^+ \right)$  we get that

$$\begin{aligned} & \frac{1}{\mu} \sum_{e \in Y} v(e) - 2\phi \sum_{(i,t_1,t_2) \in Y} \left( \sum_{t=t_1}^{t_2} p_t(i) + \sum_{t=t_1+1}^{t_2} g_{i,t}^+ \right) = \\ & \sum_{(i,t_1,t_2) \in Y} \left( \frac{1}{\mu} \left( \sum_{t=t_1}^{t_2} p_t(i) + \sum_{t=t_1+1}^{t_2} g_{i,t}^+ - c_{i,t_1}^+ - c_{i,t_2}^- \right) - 2\phi \left( \sum_{t=t_1}^{t_2} p_t(i) + \sum_{t=t_1+1}^{t_2} g_{i,t}^+ \right) \right) \geq \\ & \sum_{(i,t_1,t_2) \in Y} \left( \left( \frac{1}{\mu} - 2\phi - 4\phi\epsilon \right) \left( \sum_{t=t_1}^{t_2} p_t(i) + \sum_{t=t_1+1}^{t_2} g_{i,t}^+ \right) - \left( \frac{1}{\mu} - 4\phi \right) (c_{i,t_1}^+ + c_{i,t_2}^-) \right) \geq \\ & \left( \frac{1}{\mu} - 2\phi - 4\phi\epsilon \right) \sum_{e \in Y} v(e) \geq \left( \frac{1}{\mu} - \frac{\phi}{\epsilon} \right) \sum_{e \in Y} v(e) \end{aligned}$$

where the last inequality follows the fact that  $\epsilon < \frac{1}{4}$ . Overall, we get that

$$\sum_{e \in Y} \sum_{j=1}^{\frac{1}{\mu}} v(e') \geq \left( \frac{1}{\mu} - \frac{\phi}{\epsilon} \right) \sum_{e \in Y} v(e) \quad (7)$$

Lastly, we bound the third term, gains  $g^-$  earned in all cut instance solutions. Consider a cut point set  $U_j$  and gain  $g_{i,t}^-$  earned in solution  $\tilde{S}^*$ , i.e.,  $i \notin S_{t-1}^* \cup S_t^*$ . Therefore, any element  $(i, t_1, t_2)$  such that  $t \in [t_1, t_2]$  or  $t-1 \in [t_1, t_2]$  is not in  $\tilde{S}_j$ . Thus, unless  $t \in U_j$ , gain  $g_{i,t}^-$  is earned in  $\tilde{S}_j$  and in some solution  $\tilde{S}_{j,r} \subseteq \tilde{S}_j$  such that  $t \in [u_r^j, u_{r+1}^j - 1]$  and  $u_r^j \in U_j$ . Again, we can use the fact that for every  $j_1 \neq j_2$  it holds that  $U_{j_1} \cap U_{j_2} = \{1, T+1\}$  and get that

$$\sum_{j=1}^{\frac{1}{\mu}} \sum_{t \in [2, T] \setminus U_j} \sum_{i \notin \tilde{S}_j(t-1) \cap \tilde{S}_j(t)} g_{i,t}^- \geq \left( \frac{1}{\mu} - 1 \right) \sum_{t=1}^T \sum_{i \notin \tilde{S}^*(t-1) \cap \tilde{S}^*(t)} g_{i,t}^- \quad (8)$$

By substituting inequalities (6),(7) and (8) in Inequality (5) we get that

$$\mathcal{B} \geq \left( \frac{1}{\mu} - \frac{\phi}{\epsilon} \right) \left( \sum_{e \in \tilde{S}^*} v(e) + \sum_{t \in [2, T]} \sum_{i \notin \tilde{S}^*(t-1) \cap \tilde{S}^*(t)} g_{i,t}^- \right) = \left( \frac{1}{\mu} - \frac{\phi}{\epsilon} \right) f_{\mathcal{Q}}((S_t^*)_{t=1}^T)$$

For each set of values, their average is smaller or equal to their maximum value. Thus there must exist at least one set of cut points  $U_{j^*}$  such that the sum of values of the solutions  $(\tilde{S}_{j^*,r}^*)_{r=0}^{k_j-1}$  for its cut instances,  $\mathcal{Q}_{U_{j^*}}$ , is at least  $\mu \cdot \mathcal{B}$ , the average value of a set of solutions for a set of cut instance  $\mathcal{Q}_{U_j}$  (for  $j = 1, \dots, \frac{1}{\mu}$ ). We get that

$$\sum_{e \in \tilde{S}_{j^*}} v(e) + \sum_{t \in [2, T]} \sum_{i \notin \tilde{S}_{j^*}(t-1) \cap \tilde{S}_{j^*}(t)} g_{i,t}^- \geq \mu \mathcal{B} = (1 - \epsilon) f_{\mathcal{Q}}((S_t^*)_{t=1}^T)$$

## 15:14 General Knapsack Problems in a Dynamic Setting

At iteration  $j^*$ , in which Algorithm 1 considers the cut instances  $\mathcal{Q}_{U_{j^*}}$ , algorithm  $A$  provides an approximate solution for each cut instance. Thus the value of the solution returned by  $A$  for the  $r$ -th cut instance is at least

$$\alpha \cdot \left( \sum_{e \in \tilde{S}_{j^*,r}} v(e) + \sum_{t \in [u_r^j+1, u_{r+1}^j-1]: u_r^j \in U_j, i \notin \tilde{S}_{j^*,r}^{(t-1)} \cup \tilde{S}_{j^*,r}^{(t)}} g_{i,t}^- \right)$$

Summing over all cut instances in  $\mathcal{Q}_{U_{j^*}}$  provides a solution with value at least

$$\alpha \cdot \left( \sum_{e \in \tilde{S}_{j^*}} v(e) + \sum_{t \in [2,T]} \sum_{i \notin \tilde{S}_{j^*}^{(t-1)} \cap \tilde{S}_{j^*}^{(t)}} g_{i,t}^- \right) \geq (1 - \epsilon) \cdot \alpha \cdot f_{\mathcal{Q}}((S_t^*)_{t=1}^T) \quad \blacktriangleleft$$

The correctness of Theorem 1 follows immediately from Theorem 17 and Lemma 10.

### 3 Hardness Results

In this section we present two hardness results for 1-GMK. First, we show no constant approximation ratio exists for 1-GMK (with unbounded profit-cost ratio), even if there is only one bin per stage. Then, we show that even if we wither down the model by removing the change costs, limiting the time horizon length to  $T = 2$ , and only having a single bin per stage, the problem still does not admit an EPTAS.

The above results are proved by showing an approximation preserving reduction from  $d$ -Dimensional Knapsack ( $d$ -KP) and Multidimensional Knapsack. For  $d \in \mathbb{N}$ , in  $d$ -KP we are given a set of items  $I$ , each equipped with a profit  $p_i$ , as well as a  $d$ -dimensional weight vector  $\bar{w}^i \in [0, 1]^d$ . We denote  $j$ -th coordinate of  $\bar{w}^i$  by  $\bar{w}_j^i$ . In addition, we are given a single bin equipped with a  $d$ -dimensional capacity vector  $\bar{W} \in \mathbb{R}_{\geq 0}^d$ . A subset  $S \subseteq I$  is a feasible solution if  $\sum_{i \in S} \bar{w}^i \leq \bar{W}$ . The objective is to find a feasible solution  $S$  which maximizes  $\sum_{i \in S} p_i$ .

The Multidimensional Knapsack problem is the generalization of  $d$ -KP in which  $d$  is not fixed. That is, the input for the problem is a  $d$ -KP instance for some  $d \in \mathbb{N}$ . The solutions and their values are the solution and values of the  $d$ -KP instance.

Note that  $d$ -KP is a special case of  $d$ -MKCP, where the set of MKCs is  $\mathcal{K} = (K_j)_{j=1}^d$ . The  $j$ -th MKC is  $K_j = (w_j, B_j, W_j)$ , where  $w_j(i) = \bar{w}_j^i$ ,  $B_j = \{b\}$  and  $W_j(b) = \bar{W}_j$ , where  $\bar{W}_j$  is the  $j$ -th coordinate of the capacity vector  $\bar{W}$ . Finally, the profit function  $p: I \rightarrow \mathbb{R}_{\geq 0}$  is defined as  $p(i) = p_i$  for any  $i \in I$ . For simplicity we will use this notation for  $d$ -KP and Multidimensional Knapsack throughout this section.

► **Lemma 18.** *There is an approximation preserving reduction from the Multidimensional Knapsack problem to 1-GMK with a single bin in each stage.*

**Proof.** Let  $\mathcal{Q} = (I, \mathcal{K}, p)$  be an instance of Multidimensional Knapsack, where  $\mathcal{K} = (K_j)_{j=1}^d$ . We define an instance of 1-GMK as follows. Define  $T = d$ , and for  $j = 1, \dots, d$  define  $\mathcal{P}_j = (I, (K_j), h)$  with  $h(i) = \frac{p(i)}{d}$  for all  $i \in I$ . The gains vectors are defined as zero vectors,  $g^+ = g^- = \vec{0}$ . Finally, we define the change cost vectors. For all  $i \in I$  we set

$$c_{i,t}^+ = \begin{cases} p(i) & t \in [2, d] \\ 0 & \text{otherwise.} \end{cases}, \quad c_{i,t}^- = \begin{cases} p(i) & t \in [1, d-1] \\ 0 & \text{otherwise.} \end{cases}$$

The tuple  $\tilde{\mathcal{Q}} = ((\mathcal{P}_t)_{t=1}^d, g^+, g^-, c^+, c^-)$  is a 1-GMK instance with time horizon  $T = d$ .

Let  $(S, \mathcal{A})$  be a feasible solution for  $\mathcal{Q}$ , where  $\mathcal{A} = (A_j)_{j=1}^d$ . We can easily construct a solution for  $\tilde{\mathcal{Q}}$  by setting  $\mathcal{A}_j = (A_j)$  for  $j = 1, \dots, d$ . Then,  $(S_t, \mathcal{A}_t)_{t=1}^d$ , where  $S_j = S$  for  $j = 1, \dots, d$ , is a solution for  $\tilde{\mathcal{Q}}$ . Note that all items are either assigned or not assigned in all stages. Thus the value of the solution is

$$f_{\tilde{\mathcal{Q}}}((S_t)_{t=1}^d) = \sum_{t=1}^d h(S_t) - \sum_{t=1}^T \left( \sum_{i \in S_t \setminus S_{t+1}} c_{i,t}^- + \sum_{i \in S_t \setminus S_{t-1}} c_{i,t}^+ \right) = d \cdot h(S) = p(S)$$

The solution is also feasible as for every  $j \in [d]$  it holds that  $A_j$  is a feasible assignments for MKC  $K_j$ .

Next, let  $(S_t, \mathcal{A}_t)_{t=1}^d$  be a feasible solution for  $\tilde{\mathcal{Q}}$ , where  $\mathcal{A}_j = (\tilde{A}_j)$  for  $j = 1, \dots, d$ . For  $j = 1, \dots, d$  let  $B_j = \{b_j\}$ . We define the selected items set as  $S = \bigcap_{j \in [d]} S_j$  and define the assignments accordingly,  $A_j(b_j) = S$  for  $j = 1, \dots, d$  and  $\mathcal{A} = (A_j)_{j=1}^d$ . Consider some  $j \in [s]$ , the assignment  $A_j$  is feasible as  $A_j(b_j) \subseteq \tilde{A}_j(b_j)$  and

$$\sum_{i \in A_j(b_j)} w_j(i) \leq \sum_{i \in \tilde{A}_j(b_j)} w_j(i) \leq W_j(b_j)$$

The value of the solution is

$$p(S) = d \cdot h(S) \geq \sum_{t=1}^d h(S_t) - \sum_{t=1}^T \left( \sum_{i \in S_t \setminus S_{t+1}} c_{i,t}^- + \sum_{i \in S_t \setminus S_{t-1}} c_{i,t}^+ \right) = f_{\tilde{\mathcal{Q}}}((S_t)_{t=1}^d)$$

where the inequality follows from the construction of  $\tilde{\mathcal{Q}}$ . Furthermore, note that  $S$  can be constructed in polynomial time, which concludes the proof.  $\blacktriangleleft$

In [6] Chekuri and Kahanna showed that Multidimensional Knapsack does not admit any constant approximation ratio unless  $NP = ZPP$ . Theorem 3 follows immediately from the hardness result of [6] and Lemma 18.

We now proceed to the second hardness result.

**► Lemma 19.** *There is an approximation preserving reduction from 2-Dimensional Knapsack problem to 1-GMK with time horizon  $T = 2$ , no change costs and a single bin per stage.*

**Proof.** Let  $\mathcal{Q} = (I, \mathcal{K}, p)$  be an instance of 2-dimensional knapsack, where  $\mathcal{K} = (K_1, K_2)$ . Also, since  $p$  is modular, it holds that  $p(S) = \sum_{i \in S} p_i$ .

We define an instance of 1-GMK as follows. Set  $T = 2$ ,  $\mathcal{P}_1 = (I, (K_1), h)$  and  $\mathcal{P}_2 = (I, (K_2), h)$ , where  $h$  is the zero function, i.e.,  $h : I \rightarrow \{0\}$  such that  $\forall i \in I$  it holds that  $h(i) = 0$ . Since there are only two stages, gains exists only for stage for  $t = 2$ . Set  $g_{i,2}^+ = p(i)$  and  $g_{i,2}^- = 0$  for each item  $i \in I$ . Finally, we set the change cost vectors as  $c^+ = c^- = \vec{0}$ . The tuple  $\tilde{\mathcal{Q}} = ((\mathcal{P}_1, \mathcal{P}_2), g^+, g^-, c^+, c^-)$  is a 1-GMK instance with time horizon  $T = 2$ . Note that since all profits, change costs and gains  $g^-$  are zero we can write the objective function as

$$f_{\tilde{\mathcal{Q}}}((S_1, S_2)) = \sum_{i \in S_1 \cap S_2} g_{i,2}^+.$$

Let  $(S, \mathcal{A})$  be a feasible solution for  $\mathcal{Q}$ , where  $\mathcal{A} = (A_1, A_2)$ . We can easily construct a solution for the  $\tilde{\mathcal{Q}}$  by setting  $\mathcal{A}_1 = (A_1)$  and  $\mathcal{A}_2 = (A_2)$ . Then,  $(S_t, \mathcal{A}_t)_{t=1}^2$ , where  $S_1 = S_2 = S$ , is a solution for  $\tilde{\mathcal{Q}}$ . Note that all items are either assigned in both stages or not assigned in both stages. Thus the value of the solution is

$$f_{\tilde{\mathcal{Q}}}((S, S)) = \sum_{i \in S_1 \cap S_2} g_{i,2}^+ = \sum_{i \in S} g_{i,2}^+ = \sum_{i \in S} p_i = p(S)$$

## 15:16 General Knapsack Problems in a Dynamic Setting

The solution is also feasible as  $A_1$  and  $A_2$  are feasible assignments of  $K_1$  and  $K_2$  (respectively).

Next, let  $(S_t, \mathcal{A}_t)_{t=1}^2$  be a feasible solution for  $\tilde{\mathcal{Q}}$ , where  $\mathcal{A}_1 = (\tilde{A}_1)$  and  $\mathcal{A}_2 = (\tilde{A}_2)$ . Let  $B_1 = \{b_1\}$  and  $B_2 = \{b_2\}$ . We define the selected items set as  $S = S_1 \cap S_2$  and define the assignments accordingly,  $A_1(b_1) = A_2(b_2) = S$  and  $\mathcal{A} = (A_1, A_2)$ . Assignment  $A_1$  is feasible as  $A_1(b_1) \subseteq \tilde{A}_1(b_1)$  and

$$\sum_{i \in A_1(b_1)} w_1(i) \leq \sum_{i \in \tilde{A}_1(b_1)} w_1(i) \leq W_1(b_1)$$

A similar statement shows that assignment  $A_2$  is feasible as well. The value of the solution is

$$p(S) = \sum_{i \in S} p(i) = \sum_{i \in S} g_{i,2}^+ = \sum_{i \in S_1 \cap S_2} g_{i,2}^+ = f_{\tilde{\mathcal{Q}}}((S, S))$$

which concludes the proof. ◀

In [19] Kulik and Shachnai showed that there is no EPTAS for 2-KP unless  $W[1] = FPT$ . Theorem 2 follows immediately from the hardness result of [19] and Lemma 19.

## A Omitted Proofs and Definition

► **Definition 20.** Let  $\Pi_1, \Pi_2$  be two maximization problems. An approximation factor preserving reduction from  $\Pi_1$  to  $\Pi_2$  consists of two polynomial time algorithms  $f, g$  such that for any two instances  $I_1$  of problem  $\Pi_1$  and  $I_2 = f(I_1)$  of problem  $\Pi_2$  it holds that

- $I_2 \in \Pi_2$  and  $OPT_{\Pi_2}(I_2) \geq OPT_{\Pi_1}(I_1)$ .
- for any solution  $s_2$  for  $I_2$ , solution  $s_1 = g(I_1, s_2)$  is a solution for  $I_1$  and  $obj_{\Pi_1}(I_1, s_1) \geq obj_{\Pi_2}(I_2, s_2)$ .

where  $OPT_{\Pi}(I)$  is the value of an optimal solution for instance  $I$  of problem  $\Pi$ , and  $obj_{\Pi}(I, s)$  is the value of solution  $s$  for instance  $I$  of problem  $\Pi$ .

**Proof of Lemma 8.** Let  $\mathcal{Q} = ((\mathcal{P}_t)_{t=1}^T, g^+, g^-, c^+, c^-)$  be an instance of  $d$ -GMK, where  $\mathcal{P}_t = (I, \mathcal{K}_t, p_t)$  and  $\mathcal{K}_t = (K_{t,j})_{j=1}^{d_t}$ . Also, let  $R(\mathcal{Q}) = (E, \tilde{\mathcal{K}}, \tilde{p}, \mathcal{I})$  be the reduced instance of  $\mathcal{Q}$ . and  $(S, (\tilde{A}_{t,j})_{t \in [T], j \in [d]})$  be a feasible solution for  $R(\mathcal{Q})$ . We define the solution  $(S_t, \mathcal{A}_t)_{t=1}^T$  for  $\mathcal{Q}$  as follows. For every stage  $t$  we set  $S_t = \{i \in I \mid \exists (i, D) \in S : t \in D\}$ . For every  $t = 1, \dots, T$ ,  $j = 1, \dots, d_t$  and bin  $b \in B_{t,j}$  (the set of bins in MKC  $K_{t,j}$ ) let  $A_{t,j}(b) = \{i \in I \mid \exists (i, D) \in \tilde{A}_{t,j}(b) : t \in D\}$ . Observe that the sets  $(S_t)_{t=1}^T$  and assignments  $(A_{t,j})_{t \in [T], j \in [d_t]}$  can be constructed in polynomial time as at most  $|I|$  elements can be chosen due to the matroid constraint. The assignment  $A_{t,j}$  is an assignment of  $S_t$  since

$$S_t = \{i \in I \mid \exists (i, D) \in S : t \in D\} = \bigcup_{b \in B_{t,j}} \{i \in I \mid (i, D) \in \tilde{A}_{t,j}(b) : t \in D\} = \bigcup_{b \in B_{t,j}} A_{t,j}(b),$$

where the second equality follows the feasibility of the solution for  $R(\mathcal{Q})$ . In addition,  $A_{t,j}$  is

## 15:18 General Knapsack Problems in a Dynamic Setting

a feasible assignment for MKC  $K_{t,j}$  since for every bin  $b \in B_{t,j}$  it holds that

$$\sum_{i \in A_{t,j}(b)} w_{t,j}(i) = \sum_{(i,D) \in \tilde{A}_{t,j}(b): t \in D} \tilde{w}_{t,j}((i,D)) = \sum_{(i,D) \in \tilde{A}_{t,j}(b)} \tilde{w}_{t,j}((i,D)) \leq W_{t,j}(b)$$

Thus  $(S_t, \mathcal{A}_t)_{t=1}^T$  is a feasible solution for  $\mathcal{Q}$ .

Lastly, consider the value of the solution for  $\mathcal{Q}$ . It holds that

$$\begin{aligned} f_{\mathcal{Q}}((S_t)_{t=1}^T) &= \\ &= \sum_{t=1}^T \sum_{i \in S_t} p_t(i) + \sum_{t=2}^T \left( \sum_{i \in S_{t-1} \cap S_t} g_{i,t}^+ + \sum_{i \notin S_{t-1} \cup S_t} g_{i,t}^- \right) - \sum_{t=1}^T \left( \sum_{i \in S_t \setminus S_{t-1}} c_{i,t}^+ + \sum_{i \in S_t \setminus S_{t+1}} c_{i,t}^- \right) = \\ &= \sum_{(i,D) \in S} \left( \sum_{t \in D} p_t(i) + \sum_{t \in D: t-1 \in D} g_{i,t}^+ + \sum_{t \notin D: t-1 \notin D} g_{i,t}^- - \sum_{t \in D: t-1 \notin D} c_{i,t}^+ - \sum_{t \in D: t+1 \notin D} c_{i,t}^- \right) = \\ &= \tilde{p}(S) \end{aligned}$$

◀

**Proof of Corollary 13.** Let  $\mathcal{Q}$  be an instance of  $d$ -GMK,  $U$  be a set of cut points. Also, let  $\mathcal{Q}_U = (q_j)_{j=0}^{k-1} = \left( (\mathcal{P}_t)_{t=u_j}^{u_{j+1}-1}, g^+, g^-, c^+, c^- \right)_{j=0}^{k-1}$  be the corresponding tuple of cut instances, and  $\left( (S_t, \mathcal{A}_t)_{t=u_j}^{u_{j+1}-1} \right)_{j=0}^{k-1}$  be a tuple of feasible solutions for the cut instances.

We define the solution  $(S_t, \mathcal{A}_t)_{t=1}^T$  for  $\mathcal{Q}$ . It is easy to see that the assignments  $\mathcal{A}_t$  to  $\mathcal{K}_t$  are all feasible assignments of  $S_t$ . In addition, it holds that

$$\begin{aligned} f_{\mathcal{Q}}((S_t)_{t=1}^T) &= \\ &= \sum_{t=1}^T p_t(S_t) + \sum_{t=2}^T \left( \sum_{i \in S_{t-1} \cap S_t} g_{i,t}^+ + \sum_{i \notin S_{t-1} \cup S_t} g_{i,t}^- \right) - \sum_{t=1}^T \left( \sum_{i \in S_t \setminus S_{t+1}} c_{i,t}^- + \sum_{i \in S_t \setminus S_{t-1}} c_{i,t}^+ \right) \geq \\ &= \sum_{j=0}^{k-1} \left( \sum_{t=u_j}^{u_{j+1}-1} p_t(S_t) + \sum_{t=u_{j+1}}^{u_{j+1}-1} \left( \sum_{i \in S_{t-1} \cap S_t} g_{i,t}^+ + \sum_{i \notin S_{t-1} \cup S_t} g_{i,t}^- \right) \right. \\ &\quad \left. - \sum_{t=u_{j+1}}^{u_{j+1}-1} \left( \sum_{i \in S_t \setminus S_{t+1}} c_{i,t}^- + \sum_{i \in S_t \setminus S_{t-1}} c_{i,t}^+ \right) - \sum_{i \in S_{u_{j+1}-1}} c_{i,u_{j+1}}^- - \sum_{i \in S_{u_j}} c_{i,u_j}^+ \right) = \\ &= \sum_{j=0}^{k-1} f_{q_j} \left( (S_t)_{t=u_j}^{u_{j+1}-1} \right) \end{aligned}$$

where  $f_{q_j}$  is the objective functions of cut instance  $q_j$ . This proves that a cut solution has a higher value than the sum of solutions for cut instance from which it was created. ◀

## Abstract

We give a constant factor polynomial time pseudo-approximation algorithm for min-sum clustering with or without outliers. The algorithm is allowed to exclude an arbitrarily small constant fraction of the points. For instance, we show how to compute a solution that clusters 98% of the input data points and pays no more than a constant factor times the optimal solution that clusters 99% of the input data points. More generally, we give the following bicriteria approximation: For any  $\epsilon > 0$ , for any instance with  $n$  input points and for any positive integer  $n' \leq n$ , we compute in polynomial time a clustering of at least  $(1 - \epsilon)n'$  points of cost at most a constant factor greater than the optimal cost of clustering  $n'$  points. The approximation guarantee grows with  $\frac{1}{\epsilon}$ . Our results apply to instances of points in real space endowed with squared Euclidean distance, as well as to points in a metric space, where the number of clusters, and also the dimension if relevant, is arbitrary (part of the input, not an absolute constant).

## 1 Introduction

We consider min-sum  $k$ -clustering. This is the problem of partitioning an input dataset of  $n$  points into  $k$  clusters with the objective of minimizing the sum of intra-cluster pairwise distances. We consider primarily the prevalent setting of instances of points in  $\mathbb{R}^d$  endowed with a distance function equal to the squared Euclidean distance (henceforth referred to as the  $\ell_2^2$  case). Our results apply also to the case of instances of points endowed with an explicit metric (henceforth referred to as the metric case). Note that we consider  $k$  (and  $d$ , if relevant) to be part of the input, rather than an absolute constant. In these and similar cases we give polynomial time approximation algorithms that cluster all but a negligible constant fraction

## 16:2 Min-Sum Clustering (With Outliers)

of outliers at a cost that is at most a constant factor larger than the optimum clustering. More specifically, for any  $\epsilon > 0$ , if the optimum we compete against is required to cluster any number  $n' \leq n$  of points, our algorithm clusters at least  $(1 - \epsilon)n'$  points and at most  $n'$  points, and pays a constant factor more than the optimum for  $n'$  points. The constant depends on  $\epsilon$ .

Clustering in general is a fundamental question in unsupervised learning. The question originated in the social sciences and now is widely applicable in data analysis and machine learning, in areas including bioinformatics, computer vision, pattern recognition, signal processing, fraud/spam/fake news filtering, and market/population segmentation. Clustering is also a list of fundamental discrete optimization problems in computational geometry that have been studied for decades by theoreticians, in particular (but not exclusively) as simple non-convex targets of machine learning. Some clustering problems, notably centroid-based criteria such as  $k$ -means, have been studied extensively. We currently have a fairly tight analysis of their complexity in the worst case (e.g. [4, 42, 1, 20]) and under a wide range of restrictive conditions: low dimension (e.g., [33, 21, 30]) fixed  $k$  (e.g. [41, 27, 17, 26]), various notions of stability (e.g. [44, 7, 40, 5, 22]), restrictive models of computation (e.g., [16, 3, 15, 14]), etc., as well as practically appealing heuristics (e.g., Lloyd's iteration, local search) and supportive theoretical justification (e.g., some of the afore-mentioned papers and also [6, 38]). Theoretical understanding of density-based clustering criteria, and in particular min-sum clustering, is far less developed. There are clearly cases in practice where, for instance, min-sum clustering coincides far better with the intuitive clustering objective than standard centroid-based criteria. A simple illustrative example is the case of separating two concentric dense rings of points in the plane. Moreover, min-sum clustering satisfies Kleinberg's consistency axiom, whereas a fairly large class of centroid-based criteria including  $k$ -means and  $k$ -median do not satisfy this axiom [39, 47]. However, the state-of-the-art for computing min-sum clustering remains inferior to alternatives. Min-sum  $k$ -clustering is NP-hard in the  $\ell_2^2$  case (e.g., using arguments from [4]), and also for the metric case (see [29]), even for  $k = 2$ . In the  $\ell_2^2$  case, it can be solved in polynomial time if both  $d$  and  $k$  are absolute constants [35]. In the metric case with arbitrary  $k$ , approximating min-sum clustering to within a factor better than 1.415 is NP-hard [31, 19]. If  $k$  is a fixed constant, the problem admits a PTAS, both in the  $\ell_2^2$  case and in the metric case [28]; see also [32, 36, 43, 45] for previous work in this vein. Hassin and Or [34] gave a 2-factor approximation algorithm for the metric penalized  $k$ -min-sum problem where  $k$  is a constant. If  $k = o(\log n / \log \log n)$ , then there is a constant factor approximation algorithm for the  $\ell_2^2$  case [23]. In the metric case, assuming that  $k = o(\log n / \log \log n)$  and the instance satisfies a certain clusterability/stability condition, a partition close to optimal can be computed in polynomial time [8, 9] (see also [46] for some applications and experimental results in this vein). We note that practical applications often require the number of clusters i.e.,  $k$  too many, so the above restrictions on  $k$  are unrealistic in those cases. In the worst case, and under no restrictions on the instance, the best known approximation guarantee known is an  $O(\log n)$  approximation algorithm [13] for the metric case. This improves upon a slightly worse and much earlier guarantee [12]. In both papers, the factor is derived from representing the input metric space approximately as a convex combination of hierarchically separated tree (HST) metrics [10, 11, 25]. This incurs logarithmic distortion, which is asymptotically tight in the worst case. In HST metrics, min-sum clustering can be approximated to within a constant factor. Thus, a fundamental challenge of the study of min-sum clustering is to eliminate the gap between the hardness of approximation lower bound of 1.415 and the approximation guarantee upper bound of  $O(\log n)$ . We show that a constant factor approximation is possible, if one is willing to regard as outliers a small fraction of the input dataset. For the  $\ell_2^2$  case, we are not aware of any previous non-trivial guarantee for  $k \gg \log n / \log \log n$ .

Our results are derived using a reduction from min-sum clustering to a centroid-based criterion with (soft) capacity constraints. This can be done exactly in the  $\ell_2^2$  case, and approximately in the metric case, though to get polynomial time algorithms we use an approximation in both cases. This reduction underlies also some of the above-mentioned previous results on min-sum clustering. The outcome of this reduction is a  $k$ -median or  $k$ -means problem with non-uniform capacities. If we are aiming for a constant factor approximation then we can afford to violate the capacities by a constant factor. There are nice results on approximating  $k$ -median with non-uniform capacities, for instance [24]. Unfortunately, these results do not seem applicable here, because their input is a metric space. The reduction, even for the metric case, does not generate a metric instance of capacitated  $k$ -median (the triangle inequality is violated unboundedly). Nevertheless, we do draw some ideas from this literature. Our min-sum clustering algorithm is based on the well-trodden path of using the primal-dual schema repeatedly to search for a good Lagrange multiplier in lagrangian relaxation of the problem (see [37] for the origin of this method). The dual program has a variable for every data point, and a constraint for every possible cluster. The dual ascent process requires detection of constraints that become tight. In our case, this is a non-trivial problem, which we solve only approximately. As usual, the dual values are used to “buy” the opening of the clusters that become tight, and we have to contend with points contributing simultaneously to multiple clusters. This is done, as usual, by creating a conflict graph among the tight clusters and choosing an independent set in this graph. However, in our case there are unusual complications. The connection cost is a distance (not a metric in the  $\ell_2^2$  case, but this is a minor concern) multiplied by the cardinality of the cluster. If there is a conflict between a large cluster and some small clusters, we have the following dilemma. If we open the large cluster, the unclustered points in the small clusters may lack dual “money” to connect to the large cluster; they can only afford the distance multiplied by the cardinality of their small cluster. If, on the other hand, we open (some or all of) the small clusters, assigning the unclustered points in the large cluster to those small clusters might inflate their cardinality by a super-constant factor, leaving all points with insufficient funds to connect to the inflated clusters.

We resolve this dilemma as follows (using in part some ideas from [18]). We open larger clusters first, so if a cluster is not opened, it is smaller than the conflicting cluster that blocked it. Unclustered points are not assigned to the blocking cluster, but rather aggregated around each blocking cluster to form their own clusters of appropriate cardinality. We use approximate cardinality, in scales which are powers of a constant  $b$ . As we require the Lagrange multiplier preserving (LMP) property, we must have sufficient “funds” to pay the opening costs in full (but can settle for paying just a fraction of the connection cost). This is possible if in a scale of, say,  $b^p$  we have, say, at least  $b^{2+p}$  unclustered points in clusters of scaled cardinality  $b^p$  (each set of roughly this size can afford to open its own cluster). If a blocking cluster is blocking fewer points in this scale, we can’t afford to cluster them and must discard them as outliers. This is the primary source of the excess outliers.

As usual, the search for a good Lagrange multiplier may end with two integer primal solutions, one with fewer than  $k$  clusters and one with more than  $k$  clusters, whose convex combination is a feasible fractional bipoint solution to the  $k$ -clustering problem. In our case, as we already may have to give up on some outliers, we can simply output either the  $< k$  solution or the  $k$  largest clusters in the  $> k$  solution. We point out that these extra outliers can be avoided by using a more sophisticated “rounding” of the bipoint solution, but given our loss in the primal-dual phase, it would not improve meaningfully our guarantees.

The above description sums up the algorithm in the case that  $n' = n$ . Our result also extends to the case that the optimal solution is also allowed to discard some outliers (we may have to discard some more). The main additional issue in the case  $n' < n$  is that in the primal-dual phase we may open a cluster that brings the number of clustered points from below  $n'$  to above  $n'$ . In this case, some points in this last cluster need to be discarded, but then the remaining clustered points might have insufficient “funds” to open the last cluster. If we have many clusters, we can afford to eliminate the smallest cluster, declaring its points as outliers, and use the dual values of the points in that cluster to pay for opening the last one. If there is a small number of clusters, we may assume that the primal-dual phase opened less than  $k$  clusters (to ensure this property, if  $k$  is a small constant, we employ the known PTAS; thus we can assume that  $k$  is large). Our approach in this case draws from [2], where a similar issue is addressed in the case of the sum-of-radii  $k$ -clustering problem. Though the questions are quite different, we use a similar idea of computing a (slightly) non-Lagrange multiplier preserving approximation to the lagrangian relaxation. The LMP property is regularly used in the argument that the bipoint solution is both feasible and cheap; the approach we adopt requires an extra argument to bound the cost of a bipoint solution that incorporates a non-LMP solution.

The rest of the paper is organized as follows. Section 2 introduces some basic definitions and claims. Section 3 describes the algorithm. Section 4 analyzes the algorithm. For conciseness, the paper presents the  $\ell_2^2$  case. Our main result is Theorem 8. The metric case is essentially identical, and is briefly explained in Theorem 9. We note that we made no effort to optimize the constant factor guarantees, throughout the paper.

## 2 Definitions and Preliminary Claims

Consider an instance of min-sum clustering that is defined by a set of points  $X \subset \mathbb{R}^d$  and a target number of clusters  $k \in \mathbb{N}$ . Let  $n = |X|$ . The cost of a cluster  $Y \subset X$  is

$$\text{cost}(Y) = \frac{1}{2} \cdot \sum_{x,y \in Y} \|x - y\|_2^2.$$

The center of mass (or mean) of  $Y$  is  $\text{cm}(Y) = \frac{1}{|Y|} \cdot \sum_{x \in Y} x$ . The following proposition is a well-known fact (for instance, see [35]).

► **Proposition 1.** *The following assertions hold for every finite set  $Y \subset \mathbb{R}^d$ .*

1. *The center of mass  $\text{cm}(Y)$  is the unique minimizer of  $\sum_{x \in Y} \|x - y\|_2^2$  over  $y \in \mathbb{R}^d$ .*
2.  *$\text{cost}(Y) = |Y| \cdot \sum_{x \in Y} \|x - \text{cm}(Y)\|_2^2$ .*

A *min-sum  $k$ -clustering* of  $X$  is a partition of  $X$  into  $k$  disjoint subsets  $X_1, X_2, \dots, X_k$  that minimizes over all possible partitions

$$\sum_{i=1}^k \text{cost}(X_i) = \sum_{i=1}^k |X_i| \cdot \sum_{x \in X_i} \|x - \text{cm}(X_i)\|_2^2.$$

In the version allowing outliers, we are given a target  $n' \leq n$  of the number of points to cluster, and we are required that  $|\bigcup_{i=1}^k X_i| \geq n'$ . Clearly, the version without outliers is a special case of the version with outliers with  $n' = n$ . Let  $\text{opt}(X, n', k)$  denote the optimal min-sum cost of clustering  $n'$  points in  $X$  into  $k$  clusters. Formally, we can express the goal

as a problem of optimizing an exponential size integer program:

$$\begin{aligned}
& \text{minimize} && \sum_{Y \subset X} \text{cost}(Y) \cdot z_Y \\
& \text{s.t.} && \sum_{Y \ni x} z_Y + w_x \geq 1 \quad \forall x \in X \\
& && \sum_{Y \subset X} z_Y \leq k \\
& && \sum_{x \in X} w_x \leq n - n' \\
& && z_Y \in \{0, 1\} \quad \forall Y \subset X \\
& && w_x \in \{0, 1\} \quad \forall x \in X.
\end{aligned} \tag{1}$$

Fix  $b \in \mathbb{N}$ ,  $b > 1$ . For  $i \in \mathbb{N}$ , let  $\text{floor}_b(i) = b^{\lfloor \log_b i \rfloor}$ . For  $Y \subset X$ , let  $\text{ctr}(Y)$  be a reference point that we set for now as  $\text{ctr}(Y) = \text{cm}(Y)$ . Define

$$\text{cost}_b(Y) = \text{floor}_b(|Y|) \cdot \sum_{y \in Y} \|y - \text{ctr}(Y)\|_2^2.$$

In other words, (assuming  $\text{ctr}(Y) = \text{cm}(Y)$ ) we revise  $\text{cost}(Y)$  by rounding  $|Y|$  down to the nearest power of  $b$ . Thus,  $\frac{1}{b} \cdot \text{cost}(Y) < \text{cost}_b(Y) \leq \text{cost}(Y)$ . We relax the integer program (1) as follows ( $b$  to be determined later):

$$\begin{aligned}
& \text{minimize} && \sum_{Y \subset X} \text{cost}_b(Y) \cdot z_Y \\
& \text{s.t.} && \sum_{Y \ni x} z_Y + w_x \geq 1 \quad \forall x \in X \\
& && \sum_{Y \subset X} z_Y \leq k \\
& && \sum_{x \in X} w_x \leq n - n' \\
& && z_Y \geq 0 \quad \forall Y \subset X \\
& && w_x \geq 0 \quad \forall x \in X.
\end{aligned} \tag{2}$$

Then, following a well-traveled path, we lagrangify the constraint on the number of clusters to get the following lagrangian relaxation ( $\lambda$  denotes the unknown Lagrange multiplier).

$$\begin{aligned}
& \text{minimize} && \sum_{Y \subset X} \text{cost}_b(Y) \cdot z_Y + \lambda \cdot (\sum_{Y \subset X} z_Y - k) \\
& \text{s.t.} && \sum_{Y \ni x} z_Y + w_x \geq 1 \quad \forall x \in X \\
& && \sum_{x \in X} w_x \leq n - n' \\
& && z_Y \geq 0 \quad \forall Y \subset X \\
& && w_x \geq 0 \quad \forall x \in X.
\end{aligned} \tag{3}$$

For fixed  $\lambda$ , this is a linear program, and its dual is:

$$\begin{aligned}
& \text{maximize} && \sum_{x \in X} \alpha_x - \gamma \cdot (n - n') - \lambda \cdot k \\
& \text{s.t.} && \sum_{x \in Y} \alpha_x \leq \lambda + \text{cost}_b(Y) \quad \forall Y \subset X \\
& && 0 \leq \alpha_x \leq \gamma \quad \forall x \in X.
\end{aligned} \tag{4}$$

Notice that the linear program (3) can be interpreted as a relaxation of the “facility location” version of the problem, with  $\lambda$ -uniform cluster opening costs.

► **Lemma 2.** *For any  $\lambda$ , the optimal value of the linear program (4) is a lower bound on the optimal value of the integer program (1).*

**Proof.** Consider any optimal solution  $(z, w)$  to the integer program (1). Notice that we may assume that  $\sum_{Y \subset X} z_Y = k$ , otherwise we can split some clusters to get exactly  $k$  of them. Splitting clusters cannot increase the cost of the solution. This is also a feasible solution to the linear program (3). Moreover, the Lagrange term  $\lambda \cdot (\sum_{Y \subset X} z_Y - k)$  zeroes out, and  $\sum_{Y \subset X} \text{cost}_b(Y) \cdot z_Y \leq \sum_{Y \subset X} \text{cost}(Y) \cdot z_Y$ . By weak duality, the value of any feasible solution to the dual program (4) is a lower bound on the value of any feasible solution to the linear program (3). ◀

## 16:6 Min-Sum Clustering (With Outliers)

An obvious issue with the dual program (4) is that the number of constraints is exponential in  $n$ . We want to construct a dual solution by growing the dual variables, however, it is not clear how to detect new tight dual constraints without enumerating over the  $\exp(n)$  number of constraints. We now address this issue. First consider the following fact.

► **Proposition 3.** *Let  $Y$  be a finite set of points in  $\mathbb{R}^d$ . There exists  $y \in Y$  such that  $\sum_{x \in Y} \|x - y\|_2^2 \leq 2 \cdot \sum_{x \in Y} \|x - \text{cm}(Y)\|_2^2$ . (We note that the factor of 2 can be improved to  $1 + \epsilon$ , for any  $\epsilon > 0$ , using the center of mass of  $O(1/\epsilon^2)$  points in  $Y$ , e.g. [35, 28].)*

**Proof sketch.** Notice that for every  $y \in \mathbb{R}^d$ ,

$$\sum_{x \in Y} \|x - y\|_2^2 \leq \sum_{x \in Y} \|x - \text{cm}(Y)\|_2^2 + |Y| \cdot \|y - \text{cm}(Y)\|_2^2$$

(see [44]). Thus, by picking  $y \in Y$  that minimizes  $\|y - \text{cm}(Y)\|_2^2$ , the proposition follows. ◀

An immediate consequence of Proposition 3 is that  $\mathcal{F} = X$  is a set of  $n$  points in  $\mathbb{R}^d$ , such that for every  $Y \subset X$  there exists a point  $c_Y \in \mathcal{F}$  such that

$$\sum_{x \in Y} \|x - \text{cm}(Y)\|_2^2 \leq \sum_{x \in Y} \|x - c_Y\|_2^2 \leq 2 \cdot \sum_{x \in Y} \|x - \text{cm}(Y)\|_2^2. \quad (5)$$

(We can improve the factor of 2 to any constant  $1 + \epsilon$  by increasing the size of  $\mathcal{F}$  to  $n^{O(1/\epsilon^2)}$ .) Now, given  $\mathcal{F}$ , set initially  $\text{ctr}(Y) = c_Y$  for all  $Y \subset X$ . Notice that this puts  $\text{cost}_b(Y) = \text{floor}_b(|Y|) \cdot \sum_{y \in Y} \|y - c_Y\|_2^2$ . We consider the following revised dual program.

$$\begin{aligned} & \text{maximize} && \sum_{x \in X} \alpha_x - \gamma \cdot (n - n') - \lambda \cdot k \\ & \text{s.t.} && \sum_{x \in Y} \alpha_x \leq \lambda + \text{floor}_b(|Y|) \cdot \sum_{x \in Y} \|x - y\|_2^2 \quad \forall Y \subset X, \forall y \in Y \\ & && 0 \leq \alpha_x \leq \gamma \quad \forall x \in X. \end{aligned} \quad (6)$$

► **Lemma 4.** *For any  $\lambda$ , the optimal value of the linear program (6) is at most twice the optimal value of the integer program (1).*

**Proof.** The dual of the linear program (6) is

$$\min \left\{ \sum_{Y \subset X} \sum_{y \in Y} \text{floor}_b(|Y|) \cdot \sum_{x \in Y} \|x - y\|_2^2 \cdot z_{Y,y} + \lambda \cdot \left( \sum_{Y \subset X} \sum_{y \in Y} z_{Y,y} - k \right) : \right. \\ \left. \forall x \in X, \sum_{Y \ni x} \sum_{y \in Y} z_{Y,y} + w_x \geq 1 \wedge \sum_{x \in X} w_x \leq n - n' \wedge z, w \geq 0 \right\} \quad (7)$$

Consider an optimal clustering of any  $n'$  points in  $X$  into  $k$  disjoint clusters  $Y_1, Y_2, \dots, Y_k$ . For all  $Y \subset X$ , set  $z_{Y,y}$  to be the indicator that  $Y$  is a cluster in this list and  $y = c_Y$ . Also, for all  $x \in X$  set  $w_x$  to be the indicator that  $x$  is not clustered. Clearly, this is a feasible solution to the linear program (7), so its value is an upper bound on the optimal value of the linear program (6). The Lagrange term vanishes as there are exactly  $k$  non-zero values  $Z_{Y,y}$ . Thus, the upper bound is

$$\sum_{j=1}^k \text{floor}_b(|Y_j|) \cdot \sum_{x \in Y_j} \|x - c_{Y_j}\|_2^2 \leq 2 \cdot \sum_{j=1}^k \text{floor}_b(|Y_j|) \cdot \sum_{x \in Y_j} \|x - \text{cm}(Y_j)\|_2^2 \leq 2 \cdot \sum_{j=1}^k \text{cost}(Y_j),$$

where the first inequality uses Equation (5). ◀

In the primal-dual procedure, there is an active set  $\text{active} \subset X$  of points for which it is safe to raise the dual variable  $\alpha_x$  for all  $x \in \text{active}$ . We need to detect when a new dual constraint becomes tight and requires the removal of the points that are involved from active. This can be done in polynomial time for the revised dual program (6) as follows. For every  $y \in X$  and for every  $j \in \{0, 1, 2, \dots, \log_b \text{floor}_b(n)\}$ , we check if there exists  $Y \subset X$  that satisfies (i)  $y \in Y$ ; (ii)  $Y \cap \text{active} \neq \emptyset$ ; (iii)  $\log_b \text{floor}_b(|Y|) = j$ ; (iv)  $\sum_{x \in Y} \alpha_x \geq \lambda + b^j \cdot \sum_{x \in Y} \|x - y\|_2^2$ . In order to do this, consider the set of points  $C_{y,j} = \{x \in X : \alpha_x \geq b^j \cdot \|x - y\|_2^2\}$ , and sort  $C_{y,j}$  by nonincreasing order of  $\alpha_x - b^j \cdot \|x - y\|_2^2$ .

► **Lemma 5.** *There exists a choice of  $Y, y, j$  that satisfies (i)–(iv) iff there exists a choice of  $y, j$  such that  $|C_{y,j}| \geq b^j$  and  $C_{y,j} \cap \text{active} \neq \emptyset$  and first  $\min\{|C_{y,j}|, b^{j+1} - 1\}$  points in the above order that include  $y$  and at least one point from active are a set satisfying (i)–(iv).*

**Proof.** Clearly the existence of  $y, j$  such that  $C_{y,j}$  has the listed properties implies the existence of  $Y, y, j$  that satisfy (i)–(iv). As for the other direction, consider  $Y, y, j$  that satisfy (i)–(iv). Clearly  $y \in C_{y,j}$ . Suppose that there exists a point  $x \in Y \setminus C_{y,j}$ . Then, putting  $Y' = Y \setminus \{x\}$  and  $j' = \log_b \text{floor}_b(|Y'|) \leq j$ , we have that  $Y', y, j'$  also satisfy (i)–(iv). Thus, we may assume that  $Y \subset C_{y,j}$ . Now, choice in lemma of a subset of  $C_{y,j}$  subject to conditions (i)–(iii) maximizes  $\sum_{x \in Y} (\alpha_x - b^j \cdot \|x - y\|_2^2)$ . Thus, this subset also satisfies (iv). ◀

There are  $O(n \log n)$  pairs  $y, j$ . Listing and sorting each  $C_{y,j}$  takes at most  $O(n \log n)$  operations. Listing the candidate  $Y \subset C_{y,j}$  and checking it takes  $O(|C_{y,j}|)$  operations. Thus, finding a new tight constraint can be done in polynomial time. (Trivially, we can discretize the increase of the dual variables and/or use binary search to find the increase that causes a new constraint to become tight. As we're dealing with squared Euclidean distance, if the input consists of finite precision rational numbers, then all computed values are finite precision rational numbers.)

### 3 The Algorithm

We now describe the following three-phase primal-dual algorithm (Algorithm 1: PRIMAL-DUAL, refer page 9) that can be used to solve the facility location version of min-sum clustering. In addition to the pointset  $X$ , the cluster opening cost  $\lambda$ , and the target number of points  $n'$ , the algorithm also gets a (sufficiently large, TBD) parameter  $b$  that governs the excess number of discarded outliers in its output. Throughout the algorithm, sets of points  $Y \subset X$  will maintain values  $\text{card}_b(Y)$  and  $\text{ctr}(Y)$ . Clearly, we cannot do this explicitly and efficiently for every set  $Y \subset X$ . We use Lemma 5 and its consequences to implement the operations that we need, without storing explicitly these values for more than  $n$  sets. This affects only the first phase of the algorithm. For  $x \in X$  and  $Y \subset X$ , we denote throughout the paper  $d(x, Y) = b^{\text{card}_b(Y)} \cdot \|x - \text{ctr}(Y)\|_2^2$ . This is interpreted according to the relevant values of  $\text{card}_b(Y)$  and  $\text{ctr}(Y)$ .

Phase 1 constructs a dual solution and collects candidate clusters. During phase 1, a point  $x$  is either active or inactive. Initially, for all  $x \in X$ , we set  $\alpha_x$  to 0, and we set  $x$  to be active. The set of candidate clusters preclusters is empty. We raise all active  $x$  at a uniform rate, and pause to change the status of points and clusters if one of the following events happens.

- There exists an active  $x \in X$  and a cluster  $Y \in \text{preclusters}$  such that  $\alpha_x \geq d(x, Y)$ . In this case, replace  $Y$  by  $Y \cup \{x\}$  in preclusters. The new cluster in preclusters inherits the  $\text{card}_b$  and  $\text{ctr}$  values from  $Y$ . Also set  $x$  to be inactive.

## 16:8 Min-Sum Clustering (With Outliers)

- There exists  $Y \subset X$  that contains an active point and  $y \in Y$  such that the dual constraint associated with the pair  $Y, y$  is tight. Explicitly,

$$\sum_{x \in Y} \alpha_x \geq \lambda + \text{cost}_b(Y),$$

where we set  $\text{card}_b(Y) = \log_b \text{floor}_b(|Y|)$  and  $\text{ctr}(Y) = y$ . In this case, add an inclusion-wise minimal such  $Y$  to preclusters and set all  $x \in Y$  to be inactive (and set  $\text{card}_b(Y)$  and  $\text{ctr}(Y)$  as stated above).

The first phase ends as soon as the number of active  $x \in X$  drops to  $n - n'$  or lower. If this number drops below  $n - n'$ , we do not add the last cluster  $Y_{\text{last}}$  to preclusters, but keep it separately. Note that each new tight constraint causes at least one point  $x \in X$  to become inactive, hence the number of sets  $Y$  that require storing explicitly their parameters  $\text{card}_b(Y)$  and  $\text{ctr}(Y)$  is at most  $n' \leq n$ .

In phase 2, we trim the set of candidate clusters and assign points uniquely to the clusters in the trimmed list, as follows. Note that we need the parameters  $\text{card}_b$  and  $\text{ctr}$  only for clusters for which these values were stored explicitly in phase 1. Define a conflict graph on the clusters in preclusters. Two clusters  $Y_1, Y_2 \in \text{preclusters}$  are connected by an edge in the conflict graph iff there exists  $x \in Y_1 \cap Y_2$  such that  $\alpha_x > \max\{d(x, Y_1), d(x, Y_2)\}$ . In other words, the edge  $\{Y_1, Y_2\}$  indicates that there is  $x \in Y_1 \cap Y_2$  that contributes to the opening cost  $\lambda$  of both  $Y_1$  and  $Y_2$ . Next, take a lexicographically maximal independent set  $\mathcal{I}$  in the conflict graph, ordering preclusters by non-increasing order of  $\text{card}_b(Y)$ , breaking ties arbitrarily. We group the points clustered in preclusters into meta-clusters of the form  $(Y, Y')$ , where  $Y \in \mathcal{I}$  indicates the meta-cluster, and  $Y'$  is a set of points. (Thus, the entire meta-cluster associated with  $Y$  is  $\cup_{(Y, Y') \in \text{metaclusters}} Y'$ .) In particular, for  $Y \in \mathcal{I}$ , we put  $(Y, Y) \in \text{metaclusters}$ . Any remaining points in preclusters are added as follows. If  $Y' \notin \mathcal{I}$ , then let  $Y''$  be the set of remaining points in  $\{x \in Y' : \alpha_x = \max_{y \in Y'} \alpha_y\}$ , and let  $Y \in \mathcal{I}$  be such that  $Y$  precedes  $Y'$  in the order on preclusters and  $\{Y, Y'\}$  is an edge. Add  $(Y, Y'')$  to metaclusters, with  $\text{card}_b(Y'') = \text{card}_b(Y')$  and  $\text{ctr}(Y'') = \text{ctr}(Y)$ . Finally, if the number of assigned points to metaclusters is less than  $n'$ , then we add  $(Y_{\text{last}}, Y)$  to metaclusters, where  $Y$  is a set of previously unclustered points from  $Y_{\text{last}}$  of the cardinality needed to complete the number of clustered point to  $n'$ . (Notice that at least  $n'$  points are clustered in preclusters  $\cup \{Y_{\text{last}}\}$ , so this is possible.)

Phase 3 determines the final output clustering of the points. For every meta-cluster  $(Y, \cdot)$  and for every integer  $p \leq \text{card}_b(Y)$ , let  $n_{Y,p}$  denote the number of points  $x \in X$  such that there exists  $(Y, Y') \in \text{metaclusters}$  with  $Y' \ni x$  and  $\text{card}_b(Y') = p$ . We open clusters as follows. For  $p = \text{card}_b(Y)$ , we open  $\max\{1, \lfloor \frac{n_{Y,p-2} + n_{Y,p-1} + n_{Y,p}}{b^{2+p}} \rfloor\}$  clusters and assign all the points counted in  $n_{Y,p-2}, n_{Y,p-1}, n_{Y,p}$  to these clusters, as evenly as possible.

► **Lemma 6.** *The number of points in each such cluster is at most  $2b^{2+p}$ , and if  $Y \neq Y_{\text{last}}$  then this number is at least  $b^p$ .*

**Proof.** If we open one cluster, then clearly  $n_{Y,p-2} + n_{Y,p-1} + n_{Y,p} < 2b^{2+p}$ . If we open  $s > 1$  clusters, then we must have  $sb^{2+p} \leq n_{Y,p-2} + n_{Y,p-1} + n_{Y,p} < (s+1)b^{2+p}$ . Thus, the number of points in each cluster is between  $b^{2+p}$  and  $(1 + 1/s)b^{2+p}$ . Clearly for every set  $Y \neq Y_{\text{last}}$ ,  $(Y, Y) \in \text{metaclusters}$ , and by the definition of  $p = \text{card}_b(Y)$ , it holds that  $|Y| \geq b^p$ . ◀

For  $p < \text{card}_b(Y) - 2$ , we open  $\lfloor \frac{n_{Y,p}}{b^{2+p}} \rfloor$  clusters. If this number is at least 1, we assign all the points counted in  $n_{Y,p}$  to these clusters, as evenly as possible. If this number is 0, we discard all the points counted in  $n_{Y,p}$  as outliers.

► **Lemma 7.** *In this step, if no cluster is opened then number of points that are discarded is less than  $b^{2+p}$ , else the number of points in each cluster is at least  $b^{2+p}$  and less than  $2b^{2+p}$ .*

**Proof.** The assertion is trivial. ◀

## 16:10 Min-Sum Clustering (With Outliers)

We are now ready to define our min-sum  $k$ -clustering algorithm (Algorithm 2: MIN-SUM-CLUSTERING refer page 10). If  $k \leq \frac{4}{\epsilon}$ , we can run a PTAS or a constant factor approximation for fixed  $k$  (for instance [28, 23]).<sup>1</sup> Otherwise, our algorithm follows the general schema of the lagrangian relaxation method. Let  $\delta > 0$  be determined later. We run the procedure PRIMALDUAL on various values of  $\lambda$ , and if the smallest returned cluster for a particular value of  $\lambda$  which is denoted as  $Y_{\min, \lambda}$  has at most  $\frac{\epsilon}{3} \cdot n'$  points, we remove this cluster. Using binary search on the Lagrange multiplier  $\lambda$ , we find two values  $\lambda_1 < \lambda_2$ , with  $\lambda_2 - \lambda_1 < \delta$ , that satisfy the following property. The above process (running PRIMALDUAL, then removing the smallest cluster if it's sufficiently small) returns  $k_1 > k$  clusters (denoted as clusters<sub>1</sub>) for  $\lambda = \lambda_1$ , and  $k_2 \leq k$  clusters (denoted as clusters<sub>2</sub>) for  $\lambda = \lambda_2$ . If  $\frac{k-k_2}{k_1-k_2} \geq 1 - \frac{\epsilon}{4}$ , we output the  $k$  largest clusters in the solution for  $\lambda_1$  (i.e. from clusters<sub>1</sub>), and otherwise we output the solution for  $\lambda_2$  (i.e. from clusters<sub>2</sub>).

<sup>1</sup> These papers consider only the case without outliers. The PTAS in [28] enumerates over cluster sizes and approximate cluster centers, then computes an optimal assignment of the data points to the approximate centers, given the corresponding cluster sizes. Clearly, the algorithm can be adapted trivially to handle the case with outliers by modifying the target sum of cluster sizes.

► **Theorem 8.** *The execution of **procedure** `MINSUMCLUSTERING`( $X, k, n', \epsilon$ ) computes a clustering of  $X' \subset X$  into  $k$  clusters such that  $|X'| \in [(1 - \epsilon)n', n']$ , and the total cost of the clustering of  $X'$  is at most  $O\left(\frac{1}{\epsilon^3}\right) \cdot \text{opt}(X, n', k)$ . The time complexity of this computation is  $\text{poly}(n, \log(1/\epsilon), \log \Delta)$ , where  $\Delta$  is ratio of largest to non-zero smallest  $\|\cdot\|_2^2$  distance in  $X$ .*

**Proof.** The performance guarantee is an immediate consequence of Corollary 11 below. The running time is a straightforward analysis of the code. ◀

► **Theorem 9.** *The same claim applies to instances of points in a metric space  $(X, \text{dist})$ , with  $\text{dist}$  replacing  $\|\cdot\|_2^2$  in the code and in the claim.*

**Proof sketch.** The  $\|\cdot\|_2^2$  distance can be replaced by any metric distance  $\text{dist}$  in all claims starting from Proposition 3. The proofs sometime require minor changes. In particular, in Lemma 13, the factor  $\frac{1}{9}$  can be improved to  $\frac{1}{3}$  on account of the triangle inequality, and this improves all the other constants that depend on it. ◀

## 4 Proofs

In this section we analyze the min-sum  $k$ -clustering algorithm. The analysis builds on the following guarantees of the primal-dual schema.

► **Theorem 10.** *For every  $\epsilon \in (0, 1]$  there exists a constant  $c = c_\epsilon$  such that the following holds. Let clusters be the output of **procedure** `PRIMALDUAL`( $X, \lambda, n', b$ ), and let  $\alpha$  be the dual solution computed during the execution of this procedure. Set  $\gamma = \max_{x \in X} \alpha_x$ . Then,*

1.  $(\alpha, \gamma)$  is a feasible solution to the dual program (6).
2.  $\sum_{Y \in \text{clusters}} |Y| \in [(1 - \frac{\epsilon}{3})n', n']$ .
3.  $c \cdot (|\text{clusters}| - 1) \cdot \lambda + \sum_{Y \in \text{clusters}} \text{cost}(Y) \leq c \cdot \sum_{Y \in \text{clusters}} \sum_{x \in Y} \alpha_x$ .

► **Corollary 11.** *Let clusters be the output of **procedure** `MINSUMCLUSTERING`. Then, the following assertions hold:*

1.  $|\text{clusters}| \leq k$ .
2.  $\sum_{Y \in \text{clusters}} |Y| \in [(1 - \epsilon)n', n']$ .
3.  $\sum_{Y \in \text{clusters}} \text{cost}(Y) \leq \frac{8(c+1)}{\epsilon} \cdot \text{opt}(X, n', k)$ .

**Proof.** The first assertion follows directly from the definition of the procedure.

For the second assertion, let  $\lambda_i, \text{clusters}_i$  (where  $i = 1, 2$ ) be the values that determine the output of the procedure. By Theorem 10,  $\sum_{Y \in \text{clusters}_i} |Y| \geq (1 - \frac{\epsilon}{3})n'$ . If  $Y_{\min, \lambda_i}$  is removed from  $\text{clusters}_i$ , then  $|Y_{\min, \lambda_i}| \leq \frac{\epsilon}{3} \cdot n'$ . Thus, if  $i = 2$  then clearly the assertion holds. If  $i = 1$ , then  $\rho_1 \geq 1 - \frac{\epsilon}{4}$ . Therefore,

$$k_1 \leq \frac{1}{\rho_1} \cdot k \leq \left(1 + \frac{\epsilon}{4 - \epsilon}\right) \cdot k \leq \left(1 + \frac{\epsilon}{3}\right) \cdot k.$$

Thus, the procedure removes from the output at most a fraction of  $\frac{\epsilon}{3}$  of the clusters in  $\text{clusters}_1$ . As the removed clusters are the smallest, they contain at most  $\frac{\epsilon}{3} \cdot n'$  points.

As for the third assertion, consider the two solutions  $\text{clusters}_1, \text{clusters}_2$  that are used to determine the procedure's output. For  $i = 1, 2$ , let  $\alpha_i, \text{preclusters}_i$  be the output of `PRIMALDUALPHASE1` during the computation of  $\text{clusters}_i$ . Put  $\gamma_i = \max_{x \in X} \alpha_{i,x}$ . Let

$$(\alpha, \gamma) = \rho_1(\alpha_1, \gamma_1) + (1 - \rho_1)(\alpha_2, \gamma_2).$$

Clearly,  $(\alpha, \gamma)$  is a feasible solution to the dual LP (6) with the constant  $\lambda = \rho_1 \lambda_1 + (1 - \rho_1) \lambda_2$ . Notice that there are exactly  $n - n'$  points that are not included in  $\text{preclusters}_i$ . Each point

## 16:12 Min-Sum Clustering (With Outliers)

$x \in X$  which is not included in preclusters $_i$  has  $\alpha_{i,x} = \gamma_i$ . (Notice that all the points that are excluded are active. This is true even for points that are discarded from the last tight cluster that gets included in preclusters $_i$ .) So, the value of the solution  $(\alpha, \gamma)$  is

$$\begin{aligned}
2 \cdot \text{opt}(X, n', k) &\geq \sum_{x \in X} \alpha_x - (n - n')\gamma - \lambda k \\
&= \rho_1 \cdot \left( \sum_{x \in X} \alpha_{1,x} - (n - n')\gamma_1 - \lambda k_1 \right) + (1 - \rho_1) \cdot \left( \sum_{x \in X} \alpha_{2,x} - (n - n')\gamma_2 - \lambda k_2 \right) \\
&= \rho_1 \cdot \left( \sum_{Y \in \text{preclusters}_1} \sum_{x \in Y} \alpha_{1,x} - \lambda k_1 \right) + (1 - \rho_1) \cdot \left( \sum_{Y \in \text{preclusters}_2} \sum_{x \in Y} \alpha_{2,x} - \lambda k_2 \right) \\
&\geq \rho_1 \cdot \left( \sum_{Y \in \text{preclusters}_1} \sum_{x \in Y} \alpha_{1,x} - \lambda_1 k_1 \right) + (1 - \rho_1) \cdot \left( \sum_{Y \in \text{preclusters}_2} \sum_{x \in Y} \alpha_{2,x} - \lambda_2 k_2 \right) \\
&\quad - \delta \cdot (k_1 + k_2),
\end{aligned}$$

where the first inequality follows from Lemma 4, and the first equality uses the fact that  $k = \rho_1 k_1 + (1 - \rho_1)k_2$ .

For  $i = 1, 2$  consider the final value of clusters $_i$ . By definition,  $k_i$  is one less than the number of clusters returned from **procedure** PRIMALDUAL, so by Theorem 10,

$$\sum_{Y \in \text{clusters}_i} \text{cost}(Y) \leq c \cdot \left( \sum_{Y \in \text{clusters}_i} \sum_{x \in Y} \alpha_x - k_i \cdot \lambda_i \right).$$

In particular, the right-hand side is non-negative. Notice that if  $\rho_1 \geq 1 - \frac{\epsilon}{4}$ , then clearly  $\rho_1 > \frac{\epsilon}{4}$  and the cost of the output clustering is at most  $\sum_{Y \in \text{clusters}_1} \text{cost}(Y)$ . Similarly, if  $\rho_1 < 1 - \frac{\epsilon}{4}$ , then  $1 - \rho_1 > \frac{\epsilon}{4}$  and the cost of the output clustering is at most  $\sum_{Y \in \text{clusters}_2} \text{cost}(Y)$ . Either way, we get that the cost of the clustering is at most  $\frac{8c}{\epsilon} \cdot \text{opt}(X, n', k) + \frac{4\delta}{\epsilon} \cdot (k_1 + k_2) \leq \frac{8(c+1)}{\epsilon} \cdot \text{opt}(X, n', k)$ .  $\blacktriangleleft$

Next we analyze primal-dual algorithm and prove Theorem 10. The notation follows Algorithm 1.

► **Lemma 12.** *At the end of executing **procedure** PRIMALDUALPHASE1, for every  $Y \in$  preclusters and for every  $x \in Y$ , we have that  $\alpha_x \geq d(x, Y)$ .*

**Proof.** When  $Y$  is added to preclusters then there exists  $y \in Y$  and  $j = \log_b \text{floor}_b(|Y|)$  such that  $Y \subset C_{y,j}$ . We set  $\text{card}_b(Y) = j$  and  $\text{ctr}(Y) = y$ , so by the definition of  $C_{y,j}$  the lemma holds. If a point  $x$  is later added to  $Y$ , the condition for doing it is that  $\alpha_x \geq d(x, Y)$ .  $\blacktriangleleft$

► **Lemma 13.** *At the end of executing **procedure** PRIMALDUALPHASE2, the following assertions hold:*

1.  $\sum_{(Y, Y') \in \text{metaclusters}} |Y'| = n'$ .
2. For every  $(Y, Y') \in \text{metaclusters}$  and for every  $x \in Y'$ , we have that  $\alpha_x \geq \frac{1}{9} \cdot d(x, Y')$ .

**Proof.** The first assertion holds as the points that are clustered in metaclusters are all the points that are clustered in preclusters plus some of the points clustered in  $Y_{\text{last}}$ . The number of such points is at most  $n'$  without  $Y_{\text{last}}$ , and at least  $n'$  with  $Y_{\text{last}}$ . The algorithm takes from  $Y_{\text{last}}$  exactly the number of points needed to complete the number in preclusters to  $n'$ .

For the second assertion, consider  $(Y, Y') \in \text{metaclusters}$  and  $x \in Y'$ . If  $Y = Y'$ , then Lemma 12 guarantees the assertion. Otherwise, consider  $Y'' \in \text{preclusters}$  that caused  $(Y, Y')$  to be added to metaclusters. In particular,  $Y' \subset Y''$ ,  $\text{card}_b(Y') = \text{card}_b(Y'') \leq \text{card}_b(Y)$ , and

there exists  $z \in Y \cap Y''$  such that  $\alpha_z > \max\{d(z, Y), d(z, Y'')\}$ . By the choice of  $Y'$  in the algorithm,  $\alpha_x = \max_{x' \in Y''} \alpha_{x'}$ , so it must be that  $\alpha_z \leq \alpha_x$ . Notice that by Lemma 12,

$$\alpha_x \geq d(x, Y'') = b^{\text{card}_b(Y'')} \cdot \|x - \text{ctr}(Y'')\|_2^2.$$

$$\begin{aligned} \text{Also, } \alpha_z &> \max\{b^{\text{card}_b(Y)} \cdot \|z - \text{ctr}(Y)\|_2^2, b^{\text{card}_b(Y'')} \cdot \|z - \text{ctr}(Y'')\|_2^2\} \\ &\geq b^{\text{card}_b(Y')} \cdot \max\{\|z - \text{ctr}(Y)\|_2^2, \|z - \text{ctr}(Y'')\|_2^2\}. \end{aligned}$$

$$\begin{aligned} \text{Thus, } d(x, Y') &= b^{\text{card}_b(Y')} \cdot \|x - \text{ctr}(Y)\|_2^2 \\ &\leq b^{\text{card}_b(Y')} \cdot (\|x - \text{ctr}(Y'')\|_2 + \|z - \text{ctr}(Y'')\|_2 + \|z - \text{ctr}(Y)\|_2)^2 \\ &\leq 9 \cdot \alpha_x. \end{aligned} \quad \blacktriangleleft$$

Let clusters be the output of **procedure** PRIMALDUALPHASE3. Recall that every cluster  $Z \in \text{clusters}$  is derived in some iteration indexed by  $(Y, \cdot) \in \text{metaclusters}$ . It holds that either  $Z \subset Y_{\max}$  or  $Z \subset Y_p$  for some  $p < \text{card}_b(Y) - 2$ . Notice that in the latter case,  $Y \neq Y_{\text{last}}$ . We will set implicitly  $\text{card}_b(Z)$  as follows.

$$\text{card}_b(Z) = \begin{cases} \text{card}_b(Y) & Z \subset Y_{\max}, \\ p & Z \subset Y_p, p < \text{card}_b(Y) - 2. \end{cases}$$

We will also set implicitly  $\text{ctr}(Z) = \text{ctr}(Y)$ .

► **Lemma 14.** *If  $Z \subset Y_p$  for some  $p < \text{card}_b(Y) - 2$ , then  $\sum_{x \in Z} \alpha_x \geq b \cdot \lambda$ . The same is true if  $Z \subset Y_{\max}$ ,  $Y \neq Y_{\text{last}}$ , and  $|Y_{\max}| \geq b^{2+\text{card}_b(Y)}$ .*

**Proof.** Consider  $x \in Z \subset Y_p$ ,  $p < \text{card}_b(Y) - 2$ . There is a pair  $(Y, Y')$  in metaclusters such that  $p = \text{card}_b(Y') < \text{card}_b(Y) - 2$ , and  $x \in Y'$ . Moreover, there is  $Y'' \in \text{preclusters}$  such that  $Y' \subset Y''$  and  $\text{card}_b(Y'') = p$  and  $\alpha_x = \max_{y \in Y''} \alpha_y$ . By the definition of  $\text{card}_b$ , we have that  $|Y''| < b^{1+p}$ . Therefore,  $\alpha_x > \frac{\lambda}{b^{1+p}}$ . By Lemma 7,  $|Z| \geq b^{2+p}$ , hence the conclusion.

A similar argument applies to  $Z \subset Y_{\max}$ , assuming that  $|Y_{\max}| \geq b^{2+\text{card}_b(Y)}$ . In this case, if  $Z \supset Y$  then we have  $\sum_{x \in Y} \alpha_x \geq \lambda$ . As  $|Y| < b^{1+\text{card}_b(Y)}$ ,  $Z$  also contains more than  $b^{2+\text{card}_b(Y)} - b^{1+\text{card}_b(Y)} = b^{2+\text{card}_b(Y)} \cdot (1 - \frac{1}{b})$  points from pairs  $(Y, Y') \in \text{metaclusters}$ ,  $Y' \neq Y$ . By the argument for  $Y_p$ , for each such point  $x$  we have  $\alpha_x > \frac{\lambda}{b^{1+\text{card}_b(Y')}} > \frac{\lambda}{b^{1+\text{card}_b(Y)}}$ . Overall, we get that  $\sum_{x \in Z} \alpha_x > \lambda + b^{2+\text{card}_b(Y)} \cdot (1 - \frac{1}{b}) \cdot \frac{\lambda}{b^{1+\text{card}_b(Y)}} = b \cdot \lambda$ . If  $Z$  does not contain  $Y$ , then the argument for  $Y_p$  holds. ◀

► **Lemma 15.** *For every  $Z \in \text{clusters}$ ,  $\text{cost}(Z) \leq 2b^2 \cdot \sum_{x \in Z} d(x, Z)$ .*

**Proof.** We have  $\text{cost}(Z) = |Z| \cdot \sum_{x \in Z} \|x - \text{cm}(Z)\|_2^2 \leq |Z| \cdot \sum_{x \in Z} \|x - \text{ctr}(Y)\|_2^2$ . By Lemmas 6 and 7,  $|Z| \leq 2b^2 \cdot \text{card}_b(Z)$ . ◀

**Proof of Theorem 10.** First, consider the feasibility of  $(\alpha, \gamma)$ . Clearly,  $\gamma$  is set in the theorem to satisfy the constraints that include it. Regarding the constraints that involve only  $\alpha$ , we prove that they are satisfied throughout the execution of **procedure** PRIMALDUALPHASE1. The proof is by induction on the number of inactive points. Clearly, the initial  $\alpha$  is feasible. Now, suppose that  $\alpha$  is feasible for some number of inactive points, and consider the next step when this number increases and a set  $A \subset \text{active}$  is removed from active (we will use active here to denote the set before the removal of  $A$ ). Let  $\alpha'$  denote the values of the dual variables just before  $A$  is removed from active. If there exist  $Y \subset X$  and  $y \in Y$  such that the constraint for the pair  $Y, y$  is violated, then clearly  $Y \cap \text{active} \neq \emptyset$ , otherwise the same constraint would

## 16:14 Min-Sum Clustering (With Outliers)

have been violated by the solution  $\alpha$ , as  $\alpha$  and  $\alpha'$  differ only on active. But then there is some intermediate value  $\alpha''$  such that  $\alpha''_x = \alpha_x$  for all  $x \notin \text{active}$  and  $\alpha_x \leq \alpha''_x < \alpha'_x$  for all  $x \in \text{active}$ , which causes this constraint (or another constraint involving active points) to become tight. Therefore, at least one point would have been removed from active before we reach the values  $\alpha'$ , in contradiction with our assumptions. Next, consider number of points clustered in the output clusters of **procedure** PRIMALDUAL. Clearly, **procedure** PRIMALDUALPHASE2 clusters in metaclusters exactly  $n'$  points. Some of these points are discarded by **procedure** PRIMALDUALPHASE3. Consider some  $(Y, \cdot) \in \text{metaclusters}$ . By Lemma 7, number of points discarded from these clusters is less than

$$\sum_{p < \text{card}_b(Y) - 2} b^{2+p} = \frac{b^{\text{card}_b(Y)} - b^2}{b - 1}.$$

On the other hand, all the points in  $Y_{\max}$  are clustered in clusters, as  $Y \neq Y_{\text{last}}$  in this case. Clearly, the number of points in  $Y_{\max}$  is at least  $|Y| \geq b^{\text{card}_b(Y)}$ . Thus, less than  $\frac{1}{b-1} \cdot n' \leq \epsilon \cdot n'$  points get discarded. Finally, let's consider the cost of the clustering. Let  $Z \in \text{clusters}$  be a cluster that satisfies the conditions of Lemma 14. Then,

$$\begin{aligned} \sum_{x \in Z} \alpha_x - \lambda &> \frac{b-1}{b} \cdot \sum_{x \in Z} \alpha_x \\ &\geq \frac{b-1}{9b} \cdot \sum_{x \in Z} d(x, Z) \\ &\geq \frac{b-1}{18b^3} \cdot \text{cost}(Z), \end{aligned}$$

where the first inequality follows from Lemma 14, the second inequality follows from Lemma 13, and the third inequality follows from Lemma 15. The remaining clusters are sets  $Y_{\max}$  with  $|Y_{\max}| < b^{2+\text{card}_b(Y)}$  and a subset of  $Y_{\text{last}}$ . Consider a cluster  $Y_{\max} \in \text{clusters}$ . We have that

$$\sum_{x \in Y_{\max}} \alpha_x - \lambda = \sum_{x \in Y} \alpha_x - \lambda + \sum_{x \in Y_{\max} \setminus Y} \alpha_x \geq \sum_{x \in Y} d(x, Y) + \frac{1}{9} \cdot \sum_{x \in Y_{\max} \setminus Y} d(x, Y) \geq \frac{1}{18b^2} \cdot \text{cost}(Y_{\max}).$$

Finally, if there's a cluster  $Z \subset Y_{\text{last}}$ , then

$$\sum_{x \in Z} \alpha_x \geq \frac{1}{9} \cdot \sum_{x \in Z} d(x, Y_{\max}) \geq \frac{1}{18b^2} \cdot \text{cost}(Z).$$

Thus, we can set  $c = c_\epsilon = \frac{18b^3}{b-1} = \frac{18(1+\epsilon)^3}{\epsilon^2}$ . ◀

## Abstract

An ordering constraint satisfaction problem (OCSP) is given by a positive integer  $k$  and a constraint predicate  $\Pi$  mapping permutations on  $\{1, \dots, k\}$  to  $\{0, 1\}$ . Given an instance of OCSP( $\Pi$ ) on  $n$  variables and  $m$  constraints, the goal is to find an ordering of the  $n$  variables that maximizes the number of constraints that are satisfied, where a constraint specifies a sequence of  $k$  distinct variables and the constraint is satisfied by an ordering on the  $n$  variables if the ordering induced on the  $k$  variables in the constraint satisfies  $\Pi$ . Ordering constraint satisfaction problems capture natural problems including “Maximum acyclic subgraph (MAS)” and “Betweenness”.

In this work we consider the task of approximating the maximum number of satisfiable constraints in the (single-pass) streaming setting, where an instance is presented as a stream of constraints. We show that for every  $\Pi$ , OCSP( $\Pi$ ) is approximation-resistant to  $o(n)$ -space streaming algorithms, i.e., algorithms using  $o(n)$  space cannot distinguish streams where almost every constraint is satisfiable from streams where no ordering beats the random ordering by a noticeable amount. This space bound is tight up to polylogarithmic factors. In the case of MAS our result shows that for every  $\epsilon > 0$ , MAS is not  $1/2 + \epsilon$ -approximable in  $o(n)$  space. The previous best inapproximability result only ruled out a  $3/4$ -approximation in  $o(\sqrt{n})$  space.

Our results build on recent works of Chou, Golovnev, Sudan, Velingker, and Velusamy who show tight, linear-space inapproximability results for a broad class of (non-ordering) constraint satisfaction problems (CSPs) over arbitrary (finite) alphabets. Our results are obtained by building a family of appropriate CSPs (one for every  $q$ ) from any given OCSP, and applying their work to this family of CSPs. To convert the resulting hardness results for CSPs back to our OCSP, we show that the hard instances from this earlier work have the following “small-set expansion” property: If the CSP instance is viewed as a hypergraph in the natural way, then for every partition of the hypergraph into small blocks most of the hyperedges are incident on vertices from distinct blocks. By exploiting this combinatorial property, in combination with the hardness results of the resulting families of CSPs, we give optimal inapproximability results for all OCSPs.

## 1 Introduction

In this work we consider the complexity of “approximating” “ordering constraint satisfaction problems (OCSPs)” in the “streaming setting”. We introduce these notions below before describing our results.

### 1.1 Orderings and Constraint Satisfaction Problems

In this work we consider optimization problems where the solution space is all possible orderings of  $n$  variables. The Travelling Salesperson Problem and most forms of scheduling fit this framework, though our work considers a more restricted class of problems, namely *ordering constraint satisfaction problems (OCSPs)*. OCSPs as a class were first defined by Guruswami, Håstad, Manokaran, Raghavendra, and Charikar [10]. To describe them here, we first set up some notation and terminology, and then give some examples.

We let  $[n]$  denote the set  $\{0, \dots, n-1\}$  and  $S_n$  denote the set of permutations on  $[n]$ , i.e., the set of bijections  $\sigma : [n] \rightarrow [n]$ . We sometimes use  $[\sigma(0) \sigma(1) \dots \sigma(n-1)]$  to denote  $\sigma : [n] \rightarrow [n]$ . The solution space of ordering problems is  $S_n$ , i.e., an *assignment* to  $n$  variables is given by  $\sigma \in S_n$ . Given  $k$  distinct integers  $a_0, \dots, a_{k-1}$  we define  $\text{ord}(a_0, \dots, a_{k-1})$  to be the unique permutation in  $S_k$  which sorts  $a_0, \dots, a_{k-1}$ . In other words,  $\text{ord}(a_0, \dots, a_{k-1})$  is the unique permutation  $\pi \in S_k$  such that  $a_{\pi(0)} < \dots < a_{\pi(k-1)}$ . A *k-ary ordering constraint function* is given by a predicate  $\Pi : S_k \rightarrow \{0, 1\}$ . An *ordering constraint application* on  $n$  variables is given by a constraint function  $\Pi$  and a  $k$ -tuple  $\mathbf{j} = (j_0, j_1, \dots, j_{k-1}) \in [n]^k$  where the  $j_i$ 's are distinct. In the interest of brevity we will often skip the term “ordering” below and further refer to constraint functions as “functions” and constraint applications as “constraints”. A constraint  $(\Pi, \mathbf{j})$  is *satisfied* by an assignment  $\sigma \in S_n$  if  $\Pi(\text{ord}(\sigma|_{\mathbf{j}})) = 1$ , where  $\sigma|_{\mathbf{j}}$  is the  $k$ -tuple  $(\sigma(j_0), \dots, \sigma(j_{k-1})) \in [n]^k$ .

A *maximum ordering constraint satisfaction problem*,  $\text{Max-OCSP}(\Pi)$ , is specified by a single ordering constraint function  $\Pi : S_k \rightarrow \{0, 1\}$ , for some positive integer arity  $k$ . An *instance* of  $\text{Max-OCSP}(\Pi)$  on  $n$  variables is given by  $m$  constraints  $C_0, \dots, C_{m-1}$  where  $C_i = (\Pi, \mathbf{j}(i))$ , i.e., the application of the function  $\Pi$  to the variables  $\mathbf{j}(i) = (j(i)_0, \dots, j(i)_{k-1})$ . (We omit  $\Pi$  from the description of a constraint  $C_i$  when clear from context.) The *value* of an ordering  $\sigma \in S_n$  on an instance  $\Psi = (C_0, \dots, C_{m-1})$ , denoted  $\text{val}_\Psi(\sigma)$ , is the fraction of constraints satisfied by  $\sigma$ , i.e.,  $\text{val}_\Psi(\sigma) = \frac{1}{m} \sum_{i \in [m]} \Pi(\text{ord}(\sigma|_{\mathbf{j}(i)}))$ . The optimal value of  $\Psi$  is defined as  $\text{val}_\Psi = \max_{\sigma \in S_n} \{\text{val}_\Psi(\sigma)\}$ .

The simplest, and arguably most interesting, problem which fits the  $\text{Max-OCSP}$  framework is the *maximum acyclic subgraph (MAS)* problem. In this problem, the input is a directed graph on  $n$  vertices, and the goal is to find an ordering of the vertices which maximize the number of forward edges. A simple depth-first search algorithm can decide whether a given graph  $G$  has a *perfect* ordering (i.e., one which has *no* back edges); however, Karp [17], in his famous list of 21 NP-complete problems, proved the NP-completeness of deciding whether, given a graph  $G$  and a parameter  $k$ , there exists an ordering of the vertices such that at least  $k$  edges are forward. For our purposes, MAS can be viewed as a 2-ary  $\text{Max-OCSP}$  problem, by defining the ordering constraint predicate  $\Pi_{\text{MAS}} : S_2 \rightarrow \{0, 1\}$  given by  $\Pi_{\text{MAS}}([0 \ 1]) = 1$  and  $\Pi_{\text{MAS}}([1 \ 0]) = 0$ , and associating vertices with variables and edges with constraints. Indeed, an edge/constraint  $(u, v)$  (where  $u, v \in [n]$  are distinct variables/vertices) will be satisfied by an assignment/ordering  $\sigma \in S_n$  iff  $\Pi_{\text{MAS}}(\text{ord}(\sigma|_{(u,v)})) = 1$ , or equivalently, iff  $\sigma(u) < \sigma(v)$ .

A second natural  $\text{Max-OCSP}$  problem is the *maximum betweenness (MaxBtw)* problem. This is a 3-ary OCSP in which an ordering  $\sigma$  satisfies a constraint  $(u, v, w)$  iff  $\sigma(v)$  is between  $\sigma(u)$  and  $\sigma(w)$ , i.e., iff  $\sigma(u) < \sigma(v) < \sigma(w)$  or  $\sigma(u) > \sigma(v) > \sigma(w)$ , and the goal is again

to find the maximum number of satisfiable constraints. This is given by the constraint satisfaction function  $\Pi_{\text{BtwN}} : S_3 \rightarrow \{0, 1\}$  given by  $\Pi_{\text{BtwN}}([0\ 1\ 2]) = 1, \Pi_{\text{BtwN}}([2\ 1\ 0]) = 1$ , and  $\Pi_{\text{BtwN}}(\pi) = 0$  for all other  $\pi \in S_3$ . The complexity of maximizing betweenness was originally studied by Opatrný [21], who proved that even deciding whether a set of betweenness constraints is perfectly satisfiable is NP-complete.

## 1.2 Approximability

In this work we consider the *approximability* of ordering constraint satisfaction problems. We say that a (randomized) algorithm  $A$  is an  $\alpha$ -*approximation algorithm* for Max-OCSP( $\Pi$ ) if for every instance  $\Psi$ ,  $\alpha \cdot \text{val}_\Psi \leq A(\Psi) \leq \text{val}_\Psi$  with probability at least  $2/3$  over the internal coin tosses of  $A$ . Thus our approximation factors  $\alpha$  are numbers in the interval  $[0, 1]$ .

Given  $\Pi : S_k \rightarrow \{0, 1\}$  let  $\rho(\Pi) = \frac{|\{\pi \in S_k \mid \Pi(\pi) = 1\}|}{k!}$  denote the probability that  $\Pi$  is satisfied by a random ordering. Every instance  $\Psi$  of Max-OCSP( $\Pi$ ) satisfies  $\text{val}_\Psi \geq \rho(\Pi)$  and thus the trivial algorithm that always outputs  $\rho(\Pi)$  is a  $\rho(\Pi)$ -approximation algorithm for Max-OCSP( $\Pi$ ). Under what conditions it is possible to beat this trivial approximation is a major open question.

For MaxBtwN, the trivial algorithm is a  $\frac{1}{3}$ -approximation. Chor and Sudan [4] showed that  $(\frac{47}{48} + \epsilon)$ -approximating MaxBtwN is NP-hard, for every  $\epsilon > 0$ . The  $\frac{47}{48}$  factor was improved to  $\frac{1}{2}$  by Austrin, Manokaran, and Wenner [1]. For MAS, the trivial algorithm is a  $\frac{1}{2}$ -approximation. Newman [20] showed that  $(\frac{65}{66} + \epsilon)$ -approximating MAS is NP-hard, for every  $\epsilon > 0$ . [1] improved the  $\frac{65}{66}$  to  $\frac{14}{15}$ , and Bhangale and Khot [2] further improved the factor to  $\frac{2}{3}$ .

We could hope that for every nontrivial nontrivial Max-OCSP( $\Pi$ ), it is NP-hard to even  $(\rho(\Pi) + \epsilon)$ -approximate Max-OCSP( $\Pi$ ) for any constant factor  $\epsilon > 0$ . This property is called *approximation resistance* (and we define it more carefully in the setting of streaming algorithms below). Approximation resistance based on NP-hardness is known for certain constraint satisfaction problems which do not fall under the Max-OCSP framework; this includes the seminal result of Håstad [13] that it is NP-hard to  $(\frac{7}{8} + \epsilon)$ -approximate Max3AND for any  $\epsilon > 0$ . But as far as we know, such results are lacking for *any* Max-OCSP problem.

Given this situation, Guruswami, Håstad, Manokaran, Raghavendra, and Charikar [10] proved the “next best thing”: assuming the unique games conjecture (UGC) of Khot [18], every Max-OCSP( $\Pi$ ) is approximation-resistant. But the question of proving approximation resistance for polynomial-time algorithms without relying on unproven assumptions such as UGC and  $P \neq NP$  remains unsolved. Towards this goal, in this work, we consider the approximability of Max-OCSP’s in the (*single-pass*) *streaming model*, which we define below.

## 1.3 Streaming algorithms

A (single-pass) streaming algorithm is defined as follows. An instance  $\Psi = (C_0, \dots, C_{m-1})$  of Max-OCSP( $\Pi$ ) is presented as a stream of constraints with the  $i$ th element of the stream being  $\mathbf{j}(i)$  where  $C_i = (\Pi, \mathbf{j}(i))$ . A streaming algorithm  $A$  updates its state with each element of the stream and at the end produces the output  $A(\Psi) \in [0, 1]$  (which is supposed to estimate  $\text{val}_\Psi$ ). The measure of complexity of interest to us is the space used by  $A$  and in particular we distinguish between algorithms that use space polylogarithmic in the input length and space that grows polynomially ( $\Omega(n^\delta)$  for  $\delta > 0$ ) in the input length.

We say that a problem Max-OCSP( $\Pi$ ) is *approximable (in the streaming setting)* if we can beat the trivial  $\rho(\Pi)$ -approximation algorithm by a positive constant factor. Specifically Max-OCSP( $\Pi$ ) is said to be *approximable* if for every  $\delta > 0$  there exists  $\epsilon > 0$  and a space  $O(n^\delta)$  algorithm  $A$  that is a  $(\rho(\Pi) + \epsilon)$ -approximation algorithm for Max-OCSP( $\Pi$ ), We say Max-OCSP( $\Pi$ ) is *approximation-resistant (in the streaming setting)* otherwise.

In recent years, investigations into CSP approximability in the streaming model have been strikingly successful, resulting in tight characterizations of streaming approximability for many problems [19, 14, 15, 12, 11, 16, 8, 6, 7, 5]. Most of these papers studied approximability, not of *ordering* CSPs, but of “non-ordering CSPs” where the variables can take values in a finite alphabet. ([12] and [11] are the exceptions, and we will discuss them below.) While single-pass streaming algorithms are a weaker model than general polynomial-time algorithms, we do remark that nontrivial approximations for many problems are possible in the streaming setting. In particular, the Max2AND problem is (roughly)  $\frac{4}{9}$ -approximable in the streaming setting (whereas the trivial approximation is a  $\frac{1}{4}$ -approximation) [8].

## 1.4 Main result and comparison to prior and related works

► **Theorem 1** (Main theorem). *For every  $k \in \mathbb{N}$  and every  $\Pi : \mathcal{S}_k \rightarrow \{0, 1\}$ , Max-OCSP( $\Pi$ ) is approximation resistant in the (single-pass) streaming setting. In particular for every  $\epsilon > 0$ , every  $(\rho(\Pi) + \epsilon)$ -approximation algorithm  $A$  for Max-OCSP( $\Pi$ ) requires  $\Omega(n)$  space.*

In particular our theorem implies that MAS is not  $1/2 + \epsilon$ -approximable in  $o(n)$  space for every  $\epsilon > 0$ , and MaxBtwn is not  $1/3 + \epsilon$ -approximable. Theorem 1 is restated in Section 3 along with several necessary lemmas; it follows readily from these lemmas and its proof is omitted.

Theorem 1 parallels the classical result of [10], who prove that Max-OCSP( $\Pi$ ) is approximation resistant with respect to *polynomial-time* algorithms, for every  $\Pi$ , assuming the unique games conjecture. In our setting of streaming algorithms, the only problem that seems to have been previously explored in the literature was MAS, and even in this case a tight approximability result was not known.

In the case of MAS, Guruswami, Velingker, and Velusamy [12] proved that for every  $\epsilon > 0$ , MAS is not  $(\frac{7}{8} + \epsilon)$ -approximable in  $o(\sqrt{n})$  space using a gadget reduction from the Boolean hidden matching problem [9]. A stronger  $o(\sqrt{n})$ -space,  $3/4$ -approximation hardness for MAS is indicated in the work of Guruswami and Tao [11], who prove streaming bounds for unique games, a “non-ordering” CSP problem, and suggest a reduction from unique games to MAS.

As far as we know, our result is the first tight approximability result for Max-OCSP( $\Pi$ ) for *any* non-constant  $\Pi$  in  $\Omega(n^\delta)$  space for any  $\delta > 0$ , and it yields tight approximability results for *every*  $\Pi$  in *linear* space. We remark that this linear space bound is also optimal (up to logarithmic factors); similarly to the observation in [5] for non-ordering CSPs, Max-OCSP( $\Pi$ ) values can be approximated arbitrarily well in  $\tilde{O}(n)$  space by subsampling  $O(n)$  constraints from the input instance and then solving the Max-OCSP( $\Pi$ ) problem on this subinstance exactly.<sup>1</sup>

Chakrabarti, Ghosh, McGregor, and Vorotnikova [3] recently also studied directed graph ordering problems (e.g., acyclicity testing,  $(s, t)$ -connectivity, topological sorting) in the streaming setting. For the problems that considered in [3], their work gives *super-linear* space lower bounds even for multi-pass streaming algorithms. Note that for our problems an  $\tilde{O}(n)$  upper bound holds, suggesting that their problems are not OCSPs. Indeed this is true, but one of the problems considered is close enough to MAS to allow a more detailed comparison. The specific problem is the *minimum feedback arc set* (MFAS) problem, the goal of which is to output the fractional size of the smallest set of edges whose removal

<sup>1</sup> This assumes a definition of streaming complexity which makes no restriction on time complexity. Of course, if we restrict to polynomial time, then assuming the unique games conjecture, no nontrivial approximation will be possible.

produces an acyclic subgraph. In other words, the sum of MFAS value of a graph and the MAS value of the graph is exactly one. [3] proved that for every  $\kappa > 1$ ,  $\kappa$ -approximating<sup>2</sup> the MFAS value requires  $\Omega(n^2)$  space in the streaming setting (for a single pass, and more generally  $\Omega(n^{1+\Omega(1/p)})/p^{O(1)}$  space for  $p$  passes). Note that such lower bounds are obtained using instances with optimum MFAS values that are  $o(1)$ . Thus the MAS values in the same graph are  $1 - o(1)$  (even in the **NO** instances) and thus these results usually do not imply any hardness of approximation for MAS.

## 1.5 Techniques

Our general approach is to start with a hardness result for CSPs over alphabets of size  $q$  (i.e., constraint satisfaction problems where the variables take values in  $[q]$ ), and then to reduce these CSPs to the OCSF at hand. While this general approach is not new, the optimality of our results seems to come from the fact that we choose the CSP problem carefully, and are able to get optimal hardness results for problems of our choice thanks to a general result of Chou, Golovnev, Sudan, Velingker and Velusamy [5]. Thus whereas previous approaches towards proving hardness of MAS, for example, were unable to get optimal hardness results for MAS despite starting with optimal hardness results of the source (unique games), by choosing our source problem more carefully we manage to get optimal hardness results. In the remainder of this section, we describe and motivate this approach towards proving the approximation-resistance of Max-OCSF's.

### 1.5.1 Special case: The intuition for MAS

We start by describing our proof technique for the special case of the MAS problem. In this section, for readability, we (mostly) use the language of graphs, edges, and vertices instead of instances, constraints, and variables.

Similarly to earlier work in the setting of streaming approximability (e.g., [14]), we prove inapproximability of MAS by exhibiting a pair of distributions, which we denote  $\mathcal{G}^Y$  and  $\mathcal{G}^N$ , satisfying the following two properties:

1.  $\mathcal{G}^Y$  and  $\mathcal{G}^N$  are “indistinguishable” to streaming algorithms (to be defined formally below).
2. (With high probability)  $\mathcal{G}^Y$  has high MAS values ( $\approx 1$ ) and  $\mathcal{G}^N$  has low MAS values ( $\approx \frac{1}{2}$ ).

The existence of such distributions would suffice to establish the theorem: there cannot be any streaming approximation for MAS, since any such algorithm would be able to distinguish these distributions. But how are we to actually construct distributions  $\mathcal{G}^Y$  and  $\mathcal{G}^N$  satisfying these properties?

The strategy which has proved successful in past work for proving streaming approximation resistance of other varieties of CSPs was roughly to let the  $\mathcal{G}^N$  graphs be completely random, while  $\mathcal{G}^Y$  graphs are sampled with “hidden structure”, which is essentially a very good assignment. Then, one would show that streaming algorithms cannot detect the existence of such hidden structure, via a reduction to a communication game (typically a variant of Boolean hidden matching [9, 24]). In our setting, we might hope that the hidden structure could simply be an ordering; that is, we could hope to define  $\mathcal{G}^Y$  by first sampling a random ordering of the vertices, then sampling edges which go forward with respect to this ordering, and then perhaps adding some noise. But unfortunately, we lack the techniques to prove communication lower bounds when orderings are the hidden structure.

<sup>2</sup> For minimization problems a  $\kappa$  approximation is one whose value is at least the minimum value and at most  $\kappa$  times larger than the minimum. Thus approximation factors are larger than 1.

Hence, instead of seeking a direct proof of an indistinguishability result, in this paper, we turn back to earlier indistinguishability results proven in the context of *non-ordering CSPs*. In this setting, variables take on values in an alphabet  $[q]$ , and constraints specify allowed values of subsets of the variables. In particular, two distinct variables may take on the same value in  $[q]$ , whereas in the ordering setting, every variable in  $[n]$  must get a distinct value in  $[n]$ . (See Subsection 4.1 for a formal definition.) We will set  $q$  to be a large constant, carefully design a non-ordering CSP function, employ past results (i.e., [5]) to characterize its streaming inapproximability, examine the  $\mathcal{G}^Y$  and  $\mathcal{G}^N$  graphs created in the reduction, and then show that  $\mathcal{G}^N$  graphs have low MAS values while the hidden structure in the  $\mathcal{G}^Y$  graphs – even if it isn’t an ordering per se – guarantees high MAS values.

Why would we expect such an idea to work out, and how do we properly choose the non-ordering CSP constraint function? To begin, this constraint function will be a 2-ary function  $f : [q]^2 \rightarrow \{0, 1\}$ . Let  $\text{Max-CSP}(f)$  denote the non-ordering CSP problem of maximizing the number of  $f$  constraints satisfied by an assignment  $\mathbf{b} \in [q]^n$ . We will view an input graph  $G$  simultaneously as an instance of MAS and as an instance of  $\text{Max-CSP}(f)$ , with the same underlying set of edges/constraints. For a graph  $G$ , let  $\text{val}_G$  denote its MAS value and  $\overline{\text{val}}_G$  its value in  $\text{Max-CSP}(f)$ . We will choose  $f$  so that the indistinguishable hard distributions  $\mathcal{G}^Y$  and  $\mathcal{G}^N$  (originating from the reduction of [5]) have the following four properties:

1. With high probability over  $G \sim \mathcal{G}^Y$ ,  $\overline{\text{val}}_G \approx 1$ .
2. With high probability over  $G \sim \mathcal{G}^N$ ,  $\overline{\text{val}}_G \approx \frac{1}{2}$ .
3. For all  $G$ ,  $\text{val}_G \geq \overline{\text{val}}_G$ .
4. With high probability over  $G \sim \mathcal{G}^N$ ,  $\text{val}_G$  is not much larger than  $\overline{\text{val}}_G$ .

Together, these items will suffice to prove the theorem since item 2 and item 4 together imply that with high probability over  $G \sim \mathcal{G}^N$ ,  $\text{val}_G \approx \frac{1}{2}$ , while item 1 and item 3 together imply that with high probability over  $G \sim \mathcal{G}^Y$ ,  $\text{val}_G \approx 1$ .

Concretely, we setup the non-ordering CSP function as follows. Recall that  $\Pi_{\text{MAS}}([0\ 1]) = 1$  while  $\Pi_{\text{MAS}}([1\ 0]) = 0$ . We define the constraint function  $f_{\text{MAS}}^q : [q]^2 \rightarrow \{0, 1\}$  by  $f_{\text{MAS}}^q(x, y) = 1$  iff  $x < y$ . Note that  $f_{\text{MAS}}^q$  is supported on  $\frac{q(q-1)}{2} \approx \frac{1}{2}$  pairs in  $[q]^2$ . We first show that [5]’s results imply that  $\text{Max-CSP}(f_{\text{MAS}}^q)$  is approximation-resistant, and pick  $\mathcal{G}^Y$  and  $\mathcal{G}^N$  as the **YES** and **NO** distributions witnessing this result. This immediately yields item 1 and item 2 above. It remains to prove item 4 and item 3. In the remainder of this subsection, we sketch the proofs; see Figure 1 for a visual depiction, and Section 4 for the formal proofs.

Towards item 3, we take advantage of the fact that  $\text{Max-CSP}(f_{\text{MAS}}^q)$  captures a “ $q$ -coarsening” of MAS. We consider an arbitrary  $\text{Max-CSP}(f_{\text{MAS}}^q)$ -assignment  $\mathbf{b} \in [q]^n$  for a graph  $G$ , which assigns to the  $i$ -th vertex a value  $b_i \in [q]$ . We construct an ordering of  $G$ ’s vertices by first placing the “block” of vertices assigned value 0, then the block of vertices assigned 1, etc., finally placing the vertices assigned value  $q - 1$ . (Within any particular block, the vertices may be ordered arbitrarily.) Now whenever an edge  $(u, v)$  is satisfied by  $\mathbf{b}$  when viewing  $G$  as an instance of  $\text{Max-CSP}(f_{\text{MAS}}^q)$  – that is, whenever  $b_v > b_u$  – the same edge will be satisfied by our constructed ordering when viewing  $G$  as an instance of MAS. Hence  $\text{val}_G \geq \overline{\text{val}}_G$ .

Towards item 4, we can no longer use the results of [5] as a black box. Instead, we show that the graphs  $\mathcal{G}^N$  are “small partition expanders” in a specific sense: any partition of the constraint graph into  $q$  roughly equal sized blocks has very few edges, specifically a  $o(1)$  fraction, which lie *within* the blocks. Now, we think of an ordering  $\sigma \in S_n$  variables as dividing the  $n$  variables into  $q$  blocks with variables  $\sigma(0), \dots, \sigma(n/q - 1)$  being in the first block,  $\sigma(n/q), \dots, \sigma(2n/q - 1)$  being in the second block and so on. Whenever an edge  $(u, v)$  is satisfied by  $\sigma$  when viewing  $G$  as an instance of MAS, it will also be satisfied by our

constructed ordering when viewing  $G$  as an instance of  $\text{Max-CSP}(f_{\text{MAS}}^q)$ , unless  $u$  and  $v$  end up in the same block; but by the small partition expansion condition, this happens only for  $o(1)$  fraction of the edges. Hence  $\text{val}_G \leq \overline{\text{val}}_G + o(1)$ .

We remark in passing that our notion of coarsening is somewhat similar to, but not the same as, that used in previous works, notably [10]. In particular the techniques used to compare the OCSP value (before coarsening) with the non-ordering CSP value (after coarsening) are somewhat different: Their analysis involves more sophisticated tools such as influence of variables and Gaussian noise stability. The proof of item 4 in our setting, in contrast, uses a more elementary analysis of the type common with random graphs. Finally, we remark that in the rest of the paper, in the interest of self-containedness, our construction will “forget” about  $\text{Max-CSP}(f_{\text{MAS}}^q)$ , define the distributions  $\mathcal{G}^Y$  and  $\mathcal{G}^N$  explicitly, and treat  $\overline{\text{val}}_G$  simply as an artifact of the analysis which calculates the MAS values of  $\mathcal{G}^Y$  and  $\mathcal{G}^N$ , but we hope that this discussion has motivated the construction.

## 1.5.2 Extending to general ordering CSPs

Extending the idea to other OCSPs involves two additional steps. Given the constraint function  $\Pi$  (of arity  $k$ ) and positive integer  $q$ , we define  $f_{\Pi}^q$  analogously to  $f_{\text{MAS}}^q$ . We then explicitly describe the **YES** and **NO** distributions of  $\text{Max-CSP}(f_{\Pi}^q)$  which the general theorem of [5] shows are indistinguishable to  $o(n)$  space algorithms. Crucial to this application is the observation that  $f_{\Pi}^q$  is a “ $1 - k - 1/q$ -wide” function, where  $f_{\Pi}^q$  is  $\omega$ -wide if there exists a vector  $\mathbf{v} = (v_0, \dots, v_{k-1}) \in [q]^k$  such that for an  $\omega$ -fraction of  $a \in [q]$ , we have  $f_{\Pi}^q(v_0 + a, \dots, v_{k-1} + a) = 1$ . This would allow us to conclude that  $\text{Max-CSP}(f_{\Pi}^q)$  is hard to approximate to within factor of roughly  $\rho/\omega$ , though as in the special case of MAS we do not use this result explicitly.<sup>3</sup> Instead, the second step of our proof replicates item 4 above. We give an analysis of the partition expansion in the **NO** instances arising from the construction in [5]. Specifically we show that the constraint hypergraph is now a “small partition hypergraph expander”, in the sense that any partition into  $q$  roughly equal sized blocks would have very few hyperedges that contain even two vertices from the same block. With these two additional ingredients in place, and following the same template as in the hardness for MAS, we immediately get the approximation resistance of  $\text{Max-OCSP}(\Pi)$  for general  $\Pi$ .

### 1.5.2.1 This version

Our current results improve on a previous version of this paper [23] that gave only  $\Omega(\sqrt{n})$  space lower bounds for all OCSPs. Our improvement to  $\Omega(n)$  space lower bounds comes by invoking the more recent results of [5], whereas our previous version used the strongest lower bounds for CSPs that were available at the time from an earlier work of Chou, Golovnev, Sudan, and Velusamy [7]. The results of [7] are quantitatively weaker for the problems considered in [5], though their results apply to a broader collection of problems. Interestingly for our application, which covers *all* OCSPs, the narrower set of problems considered in [5] suffices. We also note that the proof in this version of our paper is more streamlined thanks to the notion of “wide” constraints introduced and used in [5].

We omit some proofs in this conference version due to space constraints; see the relevant sections in our full version [22].

<sup>3</sup> Indeed, the “width” observation is involved in the proof of item 1 and item 2 even in the MAS case (with  $k = 2$ ).

### 1.5.2.2 Organization of the rest of the paper

In Section 2 we introduce some notation we use and background material. In Section 3 we prove our main theorem, Theorem 1. In this section we also introduce two distributions on Max-OCSP( $\Pi$ ) instances, the **YES** distribution and the **NO** distribution, and state lemmas asserting that these distributions are concentrated on instances with high, and respectively low, OCSP value; and that these distributions are indistinguishable to single-pass small space streaming algorithms. We prove the lemmas on the OCSP values in Section 4, and describe the indistinguishability lemma in Section 5.

## 2 Preliminaries and definitions

### 2.1 Basic notation

Some of the notation we use is already introduced in Subsection 1.1. Here we introduce some more notation we use.

The *support* of an ordering constraint function  $\Pi : \mathcal{S}_k \rightarrow \{0, 1\}$  is the set  $\text{supp}(\Pi) = \{\pi \in \mathcal{S}_k \mid \Pi(\pi) = 1\}$ .

Addition of elements in  $[q]$  is implicitly taken modulo  $q$ .

Throughout this paper we will be working with  $k$ -uniform *ordered* hypergraphs, or simply  $k$ -hypergraphs, defined in the sequel. Given a finite set  $V$ , an (ordered, self-loop-free)  $k$ -hyperedge  $e = (v_1, \dots, v_k)$  is a sequence of  $k$  distinct elements  $v_1, \dots, v_k \in V$ . We stress that the ordering of vertices within an edge is important to us. An (ordered, self-loop-free, multi-)  $k$ -hypergraph  $G = (V, E)$  is given by a set of vertices  $V$  and a multiset  $E = E(G) \subseteq V^k$  of  $k$ -hyperedges. A  $k$ -hyperedge  $\mathbf{e}$  is *incident* on a vertex  $v$  if  $v$  appears in  $\mathbf{e}$ . Let  $\Gamma(\mathbf{e}) \subseteq V$  denote the set of vertices to which a  $k$ -hyperedge  $\mathbf{e}$  is incident, and let  $m = m(G)$  denote the number of  $k$ -hyperedges in  $G$ .

A  $k$ -hypergraph is a  $k$ -*hypermatching* if it has the property that no pair of (distinct)  $k$ -hyperedges is incident on the same vertex. For  $\alpha \leq \frac{1}{k}$ , an  $\alpha$ -*partial  $k$ -hypermatching* is a  $k$ -hypermatching which contains  $\alpha n$   $k$ -hyperedges. We let  $\mathcal{H}_{k,n,\alpha}$  denote the uniform distribution over all  $\alpha$ -partial  $k$ -hypermatchings on  $[n]$ .

A vector  $\mathbf{b} = (b_0, \dots, b_{n-1}) \in [q]^n$  may be viewed as a  $q$ -*partition* of  $[n]$  into *blocks*  $\mathbf{b}^{-1}(0), \dots, \mathbf{b}^{-1}(q-1)$ , where the  $i$ -th block  $\mathbf{b}^{-1}(i)$  is defined as the set of indices  $\{j \in [n] : b_j = i\}$ . Given  $\mathbf{b} = (b_0, \dots, b_{n-1}) \in [q]^n$  and an indexing vector  $\mathbf{j} = (j_0, \dots, j_{k-1}) \in [n]^k$ , we define  $\mathbf{b}|_{\mathbf{j}} = (b_{j_0}, \dots, b_{j_{k-1}})$ .

Given an instance  $\Psi$  of Max-OCSP( $\Pi$ ) on  $n$  variables, we define the *constraint hypergraph*  $G(\Psi)$  to be the  $k$ -hypergraph on  $[n]$ , where each  $k$ -hyperedge corresponds to a constraint (given by the exact same  $k$ -tuple). We also let  $m(\Psi)$  denote the number of constraints in  $\Psi$  (equiv., the number of  $k$ -hyperedges in  $G(\Psi)$ ).

### 2.2 Concentration bound

We also require the following form of *Azuma's inequality*, a concentration inequality for submartingales. For us the following form, for Boolean-valued random variables with bounded conditional expectations taken from Kapralov and Krachun [16], is particularly convenient.

► **Lemma 2** ([16, Lemma 2.5]). *Let  $X_0, \dots, X_{m-1}$  be (not necessarily independent)  $\{0, 1\}$ -valued random variables, such that for some  $p \in (0, 1)$ ,  $\mathbb{E}[X_i \mid X_0, \dots, X_{i-1}] \leq p$  for every  $i \in [m]$ . Then if  $\mu := pm$ , for every  $\nu > 0$ ,*

$$\Pr[X_0 + \dots + X_{m-1} \geq \mu + \nu] \leq \exp\left(-\frac{1}{2} \cdot \frac{\nu^2}{\mu + \nu}\right).$$

### 3 The streaming space lower bound

In this section we restate our main theorem, and state the lemmas which are necessary for its proof.

► **Theorem 1** (Main theorem). *For every  $k \in \mathbb{N}$  and every  $\Pi : \mathcal{S}_k \rightarrow \{0, 1\}$ ,  $\text{Max-OCSP}(\Pi)$  is approximation resistant in the (single-pass) streaming setting. In particular for every  $\epsilon > 0$ , every  $(\rho(\Pi) + \epsilon)$ -approximation algorithm  $A$  for  $\text{Max-OCSP}(\Pi)$  requires  $\Omega(n)$  space.*

Our lower bound is proved, as is usual for such statements, by showing that no small space algorithm can “distinguish” **YES** instances with OCSP value at least  $1 - \epsilon/2$ , from **NO** instances with OCSP value at most  $\rho(\Pi) + \epsilon/2$ . Such a statement is in turn proved by exhibiting two families of distributions, the **YES** distributions and the **NO** distributions, and showing these are indistinguishable. Specifically we choose some parameters  $q, T, \alpha$  and a permutation  $\pi \in \mathcal{S}_k$  carefully and define two distributions  $\mathcal{G}^Y = \mathcal{G}_{q,n,\alpha,T}^{Y,\pi}(\Pi)$  and  $\mathcal{G}^N = \mathcal{G}_{q,n,\alpha,T}^N(\Pi)$ . We claim that for our choice of parameters  $\mathcal{G}^Y$  is supported on instances with value at least  $1 - \epsilon/2$  – this is asserted in Lemma 5. Similarly we claim that  $\mathcal{G}^N$  is mostly supported (with probability  $1 - o(1)$ ) on instances with value at most  $\rho(\Pi) + \epsilon/2$  (see Lemma 6). Finally we assert in Lemma 7 that any algorithm that distinguishes  $\mathcal{G}^Y$  from  $\mathcal{G}^N$  with “advantage” at least  $1/8$  (i.e., accepts  $\Psi \sim \mathcal{G}^Y$  with probability  $1/8$  more than  $\Psi \sim \mathcal{G}^N$ ) requires  $\Omega(n)$  space.

#### 3.1 Distribution of hard instances

For  $\ell, k \in [q]$ , define the  $k$ -tuple of “contiguous” values  $\mathbf{v}_q^{(\ell)} = (\ell, \dots, \ell + k - 1) \in [q]^k$ . Crucially, since the addition here is taken modulo  $q$ , we may have  $\ell + k - 1 < \ell$  and in particular  $\text{ord}(\mathbf{v}_q^{(\ell)})$  may not be the identity.

For a  $k$ -tuple  $\mathbf{a} = (a_0, \dots, a_{k-1})$  and a permutation  $\pi \in \mathcal{S}_k$ , define the *permuted*  $k$ -tuple  $\mathbf{a}_\pi$  as  $(a_{\pi^{-1}(0)}, \dots, a_{\pi^{-1}(k-1)})$ . In particular, we have  $(\mathbf{v}_q^{(\ell)})_\pi = (\pi^{-1}(0) + \ell, \dots, \pi^{-1}(k-1) + \ell)$ . We define  $\mathbf{a}_\pi$  in this way because:

► **Proposition 3.** *If  $\mathbf{a}$  is a  $k$ -tuple of distinct integers, then  $\text{ord}(\mathbf{a}_\pi) = \text{ord}(\mathbf{a}) \circ \pi$  (where  $\circ$  denotes composition of permutations).*

**Proof.** Recall that  $\text{ord}(\mathbf{a})$  is the unique permutation  $\tau$  such that  $a_{\tau(0)} < \dots < a_{\tau(k-1)}$ . Let  $\tau = \text{ord}(\mathbf{a})$ , and let  $\sigma = \text{ord}(\mathbf{a}_\pi)$ , so that  $\sigma$  is the unique permutation such that  $a_{\sigma(\pi^{-1}(0))} < \dots < a_{\sigma(\pi^{-1}(k-1))}$ . Then  $\tau = \sigma \circ \pi^{-1}$ . Hence  $\tau \circ \pi = \sigma$ , as desired. ◀

We now formally define our **YES** and **NO** distributions for  $\text{Max-OCSP}(\Pi)$ .

► **Definition 4** ( $\mathcal{G}_{q,n,\alpha,T}^{Y,\pi}(\Pi)$  and  $\mathcal{G}_{q,n,\alpha,T}^N(\Pi)$ ). *For  $k \in \mathbb{N}$  and  $\Pi : \mathcal{S}_k \rightarrow \{0, 1\}$ , let  $q, n, T \in \mathbb{N}$ ,  $\alpha > 0$ , and let  $B = N$  or  $B = (Y, \pi)$  for some  $\pi \in \text{supp}(\Pi)$ . We define the distribution  $\mathcal{G}_{q,n,\alpha,T}^B$ , over  $n$ -variable  $\text{Max-OCSP}(\Pi)$  instances, as follows:*

1. *Sample a uniformly random  $q$ -partition  $\mathbf{b} = (b_0, \dots, b_{n-1}) \in [q]^n$ .*
2. *Sample  $T$  hypermatchings independently  $\tilde{G}_0, \dots, \tilde{G}_{T-1} \sim \mathcal{H}_{k,n,\alpha}$ .*
3. *For each  $t \in [T]$ , do the following:*
  - *Let  $G_t$  be an empty  $k$ -hypergraph on  $[n]$ .*
  - *For each  $k$ -hyperedge  $\tilde{\mathbf{e}} = (j_0, \dots, j_{k-1}) \in E(\tilde{G}_t)$ :*
    - *(YES) If  $B = (Y, \pi)$ , and there exists  $\ell \in [q]$  such that  $\mathbf{b}|_j = (\mathbf{v}_q^{(\ell)})_\pi$ , add  $\tilde{\mathbf{e}}$  to  $G_t$  with probability  $\frac{1}{q}$ .*
    - *(NO) If  $B = N$ , add  $\tilde{\mathbf{e}}$  to  $G_t$  with probability  $\frac{1}{q^k}$ .*

## 17:10 Streaming Approximation Resistance of Every Ordering CSP

4. Let  $G := G_0 \cup \dots \cup G_{T-1}$ .
5. Return the Max-OCSP( $\Pi$ ) instance  $\Psi$  on  $n$  variables given by the constraint hypergraph  $G$ .

We say that an algorithm **ALG** achieves advantage  $\delta$  in distinguishing  $\mathcal{G}_{q,n,\alpha,T}^{Y,\pi}(\Pi)$  from  $\mathcal{G}_{q,n,\alpha,T}^N(\Pi)$  if there exists an  $n_0$  such that for all  $n \geq n_0$ , we have

$$\left| \Pr_{\Psi \sim \mathcal{G}_{q,n,\alpha,T}^{Y,\pi}(\Pi)} [\mathbf{ALG}(\Psi) = 1] - \Pr_{\Psi \sim \mathcal{G}_{q,n,\alpha,T}^N(\Pi)} [\mathbf{ALG}(\Psi) = 1] \right| \geq \delta.$$

We make several remarks on this definition. Firstly, note that the constraints within  $\mathcal{G}_{q,n,\alpha,T}^{Y,\pi}(\Pi)$  and  $\mathcal{G}_{q,n,\alpha,T}^N(\Pi)$  do not directly depend on  $\Pi$ . We still parameterize the distributions by  $\Pi$ , since they are formally distributions over Max-OCSP( $\Pi$ ) instances;  $\Pi$  also determines the set of allowed permutations  $\pi$  in the **YES** case as well as the underlying arity  $k$ . However, we will omit the parameterization ( $\Pi$ ) when clear from context. Secondly, we note that when sampling an instance from  $\mathcal{G}_{q,n,\alpha,T}^N$ , the partition  $\mathbf{b}$  has no effect, and so  $\mathcal{G}_{q,n,\alpha,T}^N$  is completely random. Hence these instances fit into the standard paradigm for streaming lower bounds of “random graphs vs. random graphs with hidden structure”. Finally, we observe that the number of constraints in both distributions is distributed as a sum of  $m = n\alpha T$  independent Bernoulli( $\frac{1}{q^k}$ ) random variables.

In the following section we state lemmas which highlight the main properties of the distributions above. See Figure 1 in Appendix A for a visual interpretation of the distributions in the case of MAS.

### 3.2 Statement of key lemmas

Our first lemma shows that  $\mathcal{G}^Y$  is supported on instances of high value.

► **Lemma 5** ( $\mathcal{G}^Y$  has high Max-OCSP( $\Pi$ ) values). *For every ordering constraint satisfaction function  $\Pi$ , every  $\pi \in \text{supp}(\Pi)$  and  $\Psi \sim \mathcal{G}_{q,n,\alpha,T}^{Y,\pi}$ , we have  $\text{val}_\Psi \geq 1 - \frac{k-1}{q}$  (i.e., this occurs with probability 1).*

We sketch the proof of Lemma 5 in Subsection 4.2. Next we assert that  $\mathcal{G}^N$  is supported mostly on instances of low value.

► **Lemma 6** ( $\mathcal{G}^N$  has low Max-OCSP( $\Pi$ ) values). *For every  $k$ -ary ordering constraint function  $\Pi : \mathcal{S}_k \rightarrow \{0, 1\}$ , and every  $\epsilon > 0$ , there exists  $q_0 \in \mathbb{N}$  and  $\alpha_0 \geq 0$  such that for all  $q \geq q_0$  and  $\alpha \leq \alpha_0$ , there exists  $T_0 \in \mathbb{N}$  such that for all  $T \geq T_0$ , for sufficiently large  $n$ , we have*

$$\Pr_{\Psi \sim \mathcal{G}_{q,n,\alpha,T}^N} \left[ \text{val}_\Psi \geq \rho(\Pi) + \frac{\epsilon}{2} \right] \leq 0.01.$$

We discuss, and partially prove, Lemma 6 in Subsection 4.3. We note that this lemma is more technically involved than Lemma 5 and this is the proof that needs the notion of “small partition expanders”. Finally the following lemma asserts the indistinguishability of  $\mathcal{G}^Y$  and  $\mathcal{G}^N$  to small space streaming algorithms and is discussed in Section 5. We remark that this lemma follows directly from the work of [5].

► **Lemma 7**. *For every  $q, k \in \mathbb{N}$  there exists  $\alpha_0(k) > 0$  such that for every  $T \in \mathbb{N}$ ,  $\alpha \in (0, \alpha_0(k)]$  the following holds: For every  $\Pi : \mathcal{S}_k \rightarrow \{0, 1\}$  and  $\pi \in \text{supp}(\Pi)$ , every streaming algorithm **ALG** distinguishing  $\mathcal{G}_{q,n,\alpha,T}^{Y,\pi}$  from  $\mathcal{G}_{q,n,\alpha,T}^N$  with advantage  $1/8$  for all lengths  $n$  uses space  $\Omega(n)$ .*

Assuming Lemma 5, Lemma 6, and Lemma 7 the proof of Theorem 1 is straightforward and is omitted.

## 4 Bounds on Max-OCSP( $\Pi$ ) values of $\mathcal{G}^Y$ and $\mathcal{G}^N$

The goal of this section is to discuss, and at least partially prove, our technical lemmas which lower bound the Max-OCSP( $\Pi$ ) values of  $\mathcal{G}_{q,n,\alpha,T}^{Y,\pi}$  (Lemma 5) and upper bound the Max-OCSP( $\Pi$ ) values of  $\mathcal{G}_{q,n,\alpha,T}^N$  (Lemma 6).

### 4.1 CSPs and coarsening

In preparation for proving the lemmas, we recall the definition of (non-ordering) *constraint satisfaction problems* (CSPs), whose solution spaces are  $[q]^n$  (as opposed to  $\mathcal{S}_n$ ), and define an operation called *q-coarsening* on Max-OCSP's, which restricts the solution space from  $\mathcal{S}_n$  to  $[q]^n$ .

A *maximum constraint satisfaction problem*, Max-CSP( $f$ ), is specified by a single constraint function  $f : [q]^k \rightarrow \{0, 1\}$ , for some positive integer  $k$ . An *instance* of Max-CSP( $f$ ) on  $n$  variables is given by  $m$  constraints  $C_0, \dots, C_{m-1}$  where  $C_i = (f, \mathbf{j}(i))$ , i.e., the application of the function  $f$  to the variables  $\mathbf{j}(i) = (j(i)_0, \dots, j(i)_{k-1})$ . (Again,  $f$  is omitted when clear from context.) The *value* of an assignment  $\mathbf{b} \in [q]^n$  on an instance  $\Phi = (C_0, \dots, C_{m-1})$ , denoted  $\overline{\text{val}}_{\Phi}^q(\mathbf{b})$ , is the fraction of constraints satisfied by  $\mathbf{b}$ , i.e.,  $\overline{\text{val}}_{\Phi}^q(\mathbf{b}) = \frac{1}{m} \sum_{i \in [m]} f(\mathbf{b}|_{\mathbf{j}(i)})$ , where (recall)  $\mathbf{b}|_{\mathbf{j}} = (b_{j_0}, \dots, b_{j_{k-1}})$  for  $\mathbf{b} = (b_0, \dots, b_{n-1})$ ,  $\mathbf{j} = (j_0, \dots, j_{k-1})$ . The optimal value of  $\Phi$  is defined as  $\overline{\text{val}}_{\Phi}^q = \max_{\mathbf{b} \in [q]^n} \{\overline{\text{val}}_{\Phi}^q(\mathbf{b})\}$ .

► **Definition 8** (*q-coarsening*). Let  $\Pi$  be a  $k$ -ary Max-OCSP and let  $q \in \mathbb{N}$ . The *q-coarsening* of  $\Pi$  is the  $k$ -ary Max-CSP problem Max-CSP( $f_{\Pi}^q$ ) where we define  $f_{\Pi}^q : [q]^k \rightarrow \{0, 1\}$  as follows: For  $\mathbf{a} \in [q]^k$ ,  $f_{\Pi}^q(\mathbf{a}) = 1$  iff the entries in  $\mathbf{a}$  are all distinct and  $\Pi(\text{ord}(\mathbf{a})) = 1$ . The *q-coarsening* of an instance  $\Psi$  of Max-OCSP( $\Pi$ ) is the instance  $\Phi$  of Max-CSP( $f_{\Pi}^q$ ) given by the identical collection of constraints.

The following lemma captures the idea that coarsening restricts the space of possible solutions; compare to Lemma 15 below.

► **Lemma 9.** If  $q \in \mathbb{N}$ ,  $\Psi$  is an instance of Max-OCSP( $\Pi$ ), and  $\Phi$  is the *q-coarsening* of  $\Psi$ , then  $\text{val}_{\Psi} \geq \overline{\text{val}}_{\Phi}^q$ .

**Proof.** We will show that for every assignment  $\mathbf{b} \in [q]^n$  to  $\Phi$ , we can construct an assignment  $\sigma \in \mathcal{S}_n$  to  $\Psi$  such that  $\text{val}_{\Psi}(\sigma) \geq \overline{\text{val}}_{\Phi}^q(\mathbf{b})$ . Consider an assignment  $\mathbf{b} \in [q]^n$ . Let  $\sigma$  be the ordering on  $[n]$  given by placing the blocks  $\mathbf{b}^{-1}(0), \dots, \mathbf{b}^{-1}(q-1)$  in order (within each block, we enumerate the indices arbitrarily). Consider any constraint  $C = \mathbf{j} = (j_0, \dots, j_{k-1})$  in  $\Phi$  which is satisfied by  $\mathbf{b}$  in  $\Phi$ . Since  $f_{\Pi}^q(\mathbf{b}|_{\mathbf{j}}) = 1$ , by definition of  $f_{\Pi}^q$  we have that  $\Pi(\text{ord}(\mathbf{b}|_{\mathbf{j}})) = 1$  and  $b_{j_0}, \dots, b_{j_{k-1}}$  are distinct. The latter implies, by construction of  $\sigma$ , that  $\text{ord}(\mathbf{b}|_{\mathbf{j}}) = \text{ord}(\sigma|_{\mathbf{j}})$ . Hence  $\Pi(\text{ord}(\sigma|_{\mathbf{j}})) = 1$ , so  $\sigma$  satisfies  $C$  in  $\Psi$ . Hence  $\text{val}_{\Psi}(\sigma) \geq \overline{\text{val}}_{\Phi}^q(\mathbf{b})$ . ◀

### 4.2 $\mathcal{G}^Y$ has high Max-OCSP( $\Pi$ ) values

In this section, we prove Lemma 5, which states that the Max-OCSP( $\Pi$ ) values of instances  $\Psi$  drawn from  $\mathcal{G}_{q,n,\alpha,T}^{Y,\pi}$  are large. Note that we prove a bound for *every* instance  $\Psi$  in the support of  $\mathcal{G}_{q,n,\alpha,T}^{Y,\pi}$ , although it would suffice for our application to prove that such a bound holds with high probability over the choice of  $\Psi$ .

To prove Lemma 5, if  $\Phi$  is the *q-coarsening* of  $\Psi$ , by Lemma 9, it suffices to show that  $\overline{\text{val}}_{\Phi}^q \geq 1 - \frac{k-1}{q}$ . One natural approach is to consider the *q-partition*  $\mathbf{b} = (b_0, \dots, b_{n-1}) \in [q]^n$  sampled when sampling  $\Psi$  and view  $\mathbf{b}$  as an assignment to  $\Phi$ . Consider any constraint

## 17:12 Streaming Approximation Resistance of Every Ordering CSP

$C = \mathbf{j} = (j_0, \dots, j_{k-1})$  in  $\Psi$ ; by the definition of  $\mathcal{G}^{Y, \pi}$  (Definition 4), we have  $\mathbf{b}|_{\mathbf{j}} = (\mathbf{v}_q^{(\ell)})_{\pi}$  for some (unique)  $\ell \in [q]$ , which we term the *identifier* of  $C$  (recall, we defined  $\mathbf{v}_q^{(\ell)}$  as the  $k$ -tuple  $(\ell, \dots, \ell + k - 1) \in [q]^k$ ). In other words,  $\mathbf{b}|_{\mathbf{j}} = (\mathbf{v}_q^{(\ell)})_{\pi}$ . Hence,  $C$  is satisfied by  $\mathbf{b}$  iff  $\Pi(\text{ord}((\mathbf{v}_q^{(\ell)})_{\pi})) = 1$ . By Proposition 3 above,  $\text{ord}((\mathbf{v}_q^{(\ell)})_{\pi}) = \text{ord}(\mathbf{v}_q^{(\ell)}) \circ \pi$ . Hence a sufficient condition for  $\mathbf{b}$  to satisfy  $C$  (which is in fact necessary in the case  $|\text{supp}(\Pi)| = 1$ ) is that  $\text{ord}(\mathbf{v}_q^{(\ell)}) = [0 \dots k - 1]$  (since then  $\text{ord}((\mathbf{v}_q^{(\ell)})_{\pi}) = \pi$ ); this happens iff  $C$ 's identifier  $\ell \in \{0, \dots, q - k\}$ . Unfortunately, when sampling the constraints  $C$ , we might get “unlucky” and get a sample which over-represents the constraints  $C$  with identifier  $\ell \in \{q - k + 1, \dots, q - 1\}$ . We can resolve this issue using “shifted” versions of  $\mathbf{b}$ ;<sup>4</sup> the proof is omitted here.

### 4.3 $\mathcal{G}^N$ has low Max-OCSP( $\Pi$ ) values

In this section, we prove Lemma 6, which states that the Max-OCSP( $\Pi$ ) value of an instance drawn from  $\mathcal{G}^N$  does not significantly exceed the random ordering threshold  $\rho(\Pi)$ , with high probability.

Using concentration bounds (i.e., Lemma 2), one could show that a fixed solution  $\sigma \in \mathcal{S}_n$  satisfies more than  $\rho(\Pi) + \frac{1}{q}$  constraints with probability which is exponentially small in  $n$ . However, taking a union bound over all  $n!$  permutations  $\sigma$  would cause an unacceptable blowup in the probability. Instead, to prove Lemma 6, we take an indirect approach, involving bounding the Max-CSP value of the  $q$ -coarsening of a random instance and bounding the gap between the Max-OCSP value and the  $q$ -coarsened Max-CSP value. To do this, we define the following notions of small set expansion for  $k$ -hypergraphs:

► **Definition 10** (Lying on a set). *Let  $G = (V, E)$  be a  $k$ -hypergraph. Given a set  $S \subseteq V$ , a  $k$ -hyperedge  $\mathbf{e} \in E$  lies on  $S$  if it is incident on two (distinct) vertices in  $S$  (i.e., if  $|\Gamma(\mathbf{e}) \cap S| \geq 2$ ).*

► **Definition 11** (Congregating on a partition). *Let  $G = (V, E)$  be a  $k$ -hypergraph. Given a  $q$ -partition  $\mathbf{b} \in [q]^n$ , a  $k$ -hyperedge  $\mathbf{e} \in E$  congregates on  $\mathbf{b}$  if it lies on one of the blocks  $\mathbf{b}^{-1}(i)$ .*

We denote by  $N(G, S)$  the number of  $k$ -hyperedges of  $G$  which lie on  $S$ .

► **Definition 12** (Small set hypergraph expansion (SSHE) property). *A  $k$ -hypergraph  $G = (V, E)$  is a  $(\gamma, \delta)$ -small set hypergraph expander (SSHE) if it has the following property: For every subset  $S \subseteq V$  of size at most  $\gamma|V|$ ,  $N(G, S) \leq \delta|E|$  (i.e., the number of  $k$ -hyperedges in  $E$  which lie on  $S$  is at most  $\delta|E|$ ).*

► **Definition 13** (Small partition hypergraph expansion (SPHE) property). *A  $k$ -hypergraph  $G = (V, E)$  is a  $(\gamma, \delta)$ -small partition hypergraph expander (SPHE) if it has the following property: For every partition  $\mathbf{b} \in [q]^n$  where each block  $\mathbf{b}^{-1}(i)$  has size at most  $\gamma|V|$ , the number of  $k$ -hyperedges in  $E$  which congregate on  $\mathbf{b}$  is at most  $\delta|E|$ .*

In the context of Figure 1 in Appendix A, the SPHE property says that for *any* partition with small blocks, there cannot be too many “orange” edges.

Having defined the SSHE and SPHE properties, we now sketch the proof of Lemma 6. The full proof is omitted.

<sup>4</sup> Alternatively, in expectation,  $\overline{\text{val}}_{\Phi}^q(\mathbf{b}) = 1 - \frac{k-1}{q}$ . Hence with probability at least  $\frac{99}{100}$ ,  $\overline{\text{val}}_{\Phi}^q(\mathbf{b}) \geq 1 - \frac{100(k-1)}{q}$  by Markov's inequality; this suffices for a “with-high-probability” statement.

**Proof sketch of Lemma 6.** For sufficiently large  $q$ , with high probability, the Max-CSP value of the  $q$ -coarsening of a random Max-OCSP( $\Pi$ ) instance drawn from  $\mathcal{G}_q^N$  is not much larger than  $\rho(\Pi)$  (Lemma 20 below). The constraint hypergraph for a random Max-OCSP( $\Pi$ ) instance drawn from  $\mathcal{G}_q^N$  is a good SSHE with high probability (Lemma 18 below). Hypergraphs which are good SSHEs are also (slightly worse) SPHEs (Lemma 14 below). Finally, if the constraint hypergraph of a Max-OCSP( $\Pi$ ) instance is a good SPHE, its Max-OCSP( $\Pi$ ) value cannot be much larger than its  $q$ -coarsened Max-CSP value (Lemma 15 below); intuitively, this is because if we “coarsen” an optimal ordering  $\sigma$  for the Max-OCSP by lumping vertices together in small groups to get an assignment  $\mathbf{b}$  for the coarsened Max-CSP, we can view this assignment  $\mathbf{b}$  as a partition on  $V$ , and for every  $k$ -hyperedge in  $G(\Psi)$  which does not congregate on this partition, the corresponding constraint in  $\Psi$  is satisfied. ◀

We remark that the bounds on Max-CSP values of coarsened random instances (Lemma 20 below) and on SSHE in random instances (Lemma 18 below) both use concentration inequalities (i.e., Lemma 2) and union bound over a space of size only  $(O_\epsilon(1))^n$  (the space of all solutions to the coarsened Max-CSP and the space of all small subsets of  $[n]$ , respectively); this lets us avoid the issue of union-bounding over the entire space  $S_n$  directly.

In the remainder of this section, we describe the necessary lemmas.

▶ **Lemma 14** (Good SSHEs are good SPHEs). *For every  $\gamma, \delta > 0$ , if a  $k$ -hypergraph  $G = (V, E)$  is a  $(\gamma, \delta)$ -SSHE, then it is a  $(\gamma, \delta(\frac{2}{\gamma} + 1))$ -SPHE.*

**Proof.** Omitted. ◀

▶ **Lemma 15** (Coarsening roughly preserves value in SPHEs). *Let  $\Psi$  be a Max-OCSP( $\Pi$ ) instance on  $n$  variables. Suppose that the constraint hypergraph of  $\Psi$  is a  $(\gamma, \delta)$ -SPHE. Let  $\Phi$  be the  $q$ -coarsening of  $\Psi$ . Then for sufficiently large  $n$ , if  $q \geq \frac{2}{\gamma}$ ,*

$$\text{val}_\Psi \leq \overline{\text{val}}_\Phi^q + \delta.$$

**Proof.** We will show that for every assignment  $\sigma \in S_n$  to  $\Psi$ , we can construct an assignment  $\mathbf{b} = (b_0, \dots, b_{n-1}) \in [q]^n$  to  $\Phi$  such that  $\text{val}_\Psi(\sigma) \leq \overline{\text{val}}_\Phi^q(\mathbf{b}) + \delta$ . Fix  $\sigma \in S_n$ . Define  $\mathbf{b} \in [q]^n$  by  $b_i = \lfloor \sigma(i) / \lfloor \gamma n \rfloor \rfloor$  for each  $i \in [n]$ . Observe that since  $\sigma(i) \leq n - 1$ , we have  $b_i \leq \lfloor (n - 1) / \lfloor \gamma n \rfloor \rfloor < q$ , hence  $\mathbf{b}$  is a valid assignment to  $\Phi$ . Also,  $\mathbf{b}$  has the property that for every  $i, j \in [n]$ , if  $\sigma(i) < \sigma(j)$  then  $b_i \leq b_j$ ; we call this *monotonicity* of  $\mathbf{b}$ .

View  $\mathbf{b}$  as a  $q$ -partition and consider the constraint hypergraph of  $\Psi$  (which is the same as the constraint hypergraph of  $\Phi$ ). Call a constraint  $C = (j_0, \dots, j_{k-1})$  *good* if it is both satisfied by  $\sigma$ , and the  $k$ -hyperedge corresponding to it does not congregate on  $\mathbf{b}$ . If  $C$  is good, then  $b_{j_0}, \dots, b_{j_{k-1}}$  are all distinct; together with monotonicity of  $\mathbf{b}$ , we conclude that if  $C$  is good, then  $\text{ord}(\mathbf{b}|_C) = \text{ord}(\sigma(j_0), \dots, \sigma(j_{k-1}))$ .

Finally, we note that each block in  $\mathbf{b}$  has size at most  $\gamma n$  by definition; hence by the SPHE property of the constraint hypergraph of  $\Psi$ , at most  $\delta$ -fraction of the constraints of  $\Psi$  correspond to  $k$ -hyperedges which congregate on  $\mathbf{b}$ . Since  $\text{val}_\Psi(\sigma)$  fraction of the constraints of  $\Psi$  are satisfied by  $\sigma$ , at least  $(\text{val}_\Psi(\sigma) - \delta)$ -fraction of the constraints of  $\Psi$  are good, and hence  $\mathbf{b}$  satisfies at least  $(\text{val}_\Psi(\sigma) - \delta)$ -fraction of the constraints of  $\Phi$ , as desired. ◀

The construction in this lemma was called *coarsening* the assignment  $\sigma$  by [10] (cf. [10, Definition 4.1]).

We also include the following helpful lemma, which lets us restrict to the case where our sampled Max-OCSP( $\Pi$ ) instance has many constraints.

## 17:14 Streaming Approximation Resistance of Every Ordering CSP

► **Lemma 16** (Most instances in  $\mathcal{G}^N$  have many constraints). *For every  $n, \alpha, \gamma > 0$ , and  $q \in \mathbb{N}$ ,*

$$\Pr_{\Psi \sim \mathcal{G}_{q,n,\alpha,T}^N} \left[ m(\Psi) \leq \frac{n\alpha T}{2q^k} \right] \leq \exp \left( -\frac{n\alpha T}{8q^k} \right).$$

**Proof.** The number of constraints in  $\Psi$  is distributed as the sum of  $n\alpha T$  independent Bernoulli( $1/q^k$ ) random variables. The desired bound follows by applying the Chernoff bound. ◀

### 4.3.1 $\mathcal{G}^N$ is a good SSHE with high probability

Recall that for a  $k$ -hypergraph  $G = (V, E)$  and  $S \subseteq V(G)$ , we define  $N(G, S)$  to be the number of  $k$ -hyperedges in  $G$  that lie on  $S$ , and for an  $k$ -hyperedge  $\mathbf{e} \in E$ , we define  $\Gamma(\mathbf{e}) \subseteq V$  as the set of vertices incident on  $\mathbf{e}$ .

► **Lemma 17** (Random hypermatchings barely lie on small sets). *For every  $n$  and  $\alpha, \gamma > 0$  with  $\alpha \leq \frac{1}{2k}$ , and every subset  $S \subseteq [n]$  of at most  $\gamma n$  vertices, we have*

$$\Pr_{G \sim \mathcal{H}_{k,n,\alpha}} [N(G, S) \geq 8k^2\gamma^2\alpha n] \leq \exp(-\gamma^2\alpha n).$$

**Proof.** Label the hyperedges of  $G$  as  $\mathbf{e}_0, \dots, \mathbf{e}_{\alpha n-1}$ . For  $i \in [\alpha n]$ , let  $X_i$  be the indicator for the event that  $\mathbf{e}_i$  lies on  $S$ . We have  $N(G, S) = X_0 + \dots + X_{\alpha n-1}$ .

We first bound  $\mathbb{E}[X_i \mid X_0, \dots, X_{i-1}]$  for each  $i$ . Conditioned on  $\mathbf{e}_0, \dots, \mathbf{e}_{i-1}$ , the  $k$ -hyperedge  $\mathbf{e}_i$  is uniformly distributed over the set of all  $k$ -hyperedges on  $[n] \setminus (\Gamma(\mathbf{e}_0) \cup \dots \cup \Gamma(\mathbf{e}_{i-1}))$ . It suffices to union-bound, over distinct pairs  $j_1 < j_2 \in \binom{[k]}{2}$ , the probability that the  $j_1$ -st and  $j_2$ -nd vertices of  $\mathbf{e}_i$  are in  $S$  (conditioned on  $X_0, \dots, X_{i-1}$ ). We can sample the  $j_1$ -st and  $j_2$ -nd vertices of  $\mathbf{e}_i$  first (uniformly over remaining vertices outside of  $S$ ) and then sample the remaining vertices (uniformly over remaining vertices). Hence we have the upper-bound

$$\mathbb{E}[X_i \mid X_0, \dots, X_{i-1}] \leq \binom{k}{2} \cdot \frac{|S|(|S|-1)}{(n-ki)(n-ki-1)} \leq \left( \frac{|S|}{n-k\alpha n} \right)^2 \leq 4k^2\gamma^2,$$

since  $\alpha \leq \frac{1}{2k}$ .

Now, we apply the concentration bound in Lemma 2 to conclude that:

$$\Pr_{G \sim \mathcal{H}_{k,n,\alpha}} [X_0 + \dots + X_{\alpha n-1} \geq 8k^2\gamma^2\alpha n] \leq \exp(-2k^2\gamma^2\alpha n) \leq \exp(-\gamma^2\alpha n). \quad \blacktriangleleft$$

► **Lemma 18.** *For every  $n, \alpha, \gamma > 0$ , and  $q \in \mathbb{N}$  with  $\alpha \leq \frac{1}{2k}$ ,*

$$\Pr_{\Psi \sim \mathcal{G}_{q,n,\alpha,T}^N} \left[ G(\Psi) \text{ is not a } (\gamma, 8k^2\gamma^2)\text{-SSHE} \mid m(\Psi) \geq \frac{n\alpha T}{2q^k} \right] \leq \exp \left( -\left( \frac{\gamma^2\alpha T}{2q^k} - \ln 2 \right) n \right).$$

**Proof.** Let  $\alpha_0, \dots, \alpha_{T-1} \geq 0$  be such that  $\frac{\alpha T}{2q^k} \leq \alpha_0 + \dots + \alpha_{T-1} \leq \alpha T$ . It suffices to prove the bound, for every such sequence  $\alpha_0, \dots, \alpha_{T-1}$ , conditioned on the event that for every  $i \in [T]$ ,  $m(G_i) = \alpha_i n$  (where  $G_i$  is defined as in Definition 4). This is equivalent to simply sampling each  $G_i \sim \mathcal{H}_{k,n,\alpha_i}$  independently.

Fix any set  $S \subseteq [n]$  of size at most  $\gamma n$ . Applying Lemma 17, and the fact that each hypermatching  $G_i$  in  $G$  is sampled independently, we conclude that

$$\begin{aligned} & \Pr_{\Psi \sim \mathcal{G}_{q,n,\alpha,T}^N} [\exists i \in [T] \text{ s.t. } N(G_i, S) \geq 8k^2\gamma^2\alpha_i n \mid \forall i \in [T], m(G_i) = \alpha_i n] \\ & \leq \exp(-\gamma^2(\alpha_0 + \dots + \alpha_{T-1})n) \\ & \leq \exp\left(-\frac{\gamma^2\alpha T n}{2q^k}\right). \end{aligned}$$

Hence by averaging, the total fraction of  $k$ -hyperedges in  $G$  which lie on  $S$  is at most  $8k^2\gamma^2$ . Taking the union-bound over the  $\leq 2^n$  possible subsets  $S \subseteq [n]$  gives the desired bound.  $\blacktriangleleft$

### 4.3.2 $\mathcal{G}^N$ has low coarsened Max-CSP( $f_{\Pi}^q$ ) values with high probability

For  $G \sim \mathcal{H}_{k,n,\alpha}$ , we define an instance  $\Phi(G)$  of Max-CSP( $f_{\Pi}^q$ ) on  $n$  variables  $x_0, \dots, x_{n-1}$  naturally as follows: for each  $k$ -hyperedge  $\mathbf{j} = (j_0, \dots, j_{k-1}) \in E(G) \subseteq [n]^k$ , we add the constraint  $\mathbf{j}$  to  $\Phi(G)$ .

► **Lemma 19** (Satisfiability of random instances of Max-CSP( $f_{\Pi}^q$ )). *For every  $n, \alpha, \eta > 0$ , and  $\mathbf{b} \in [q]^n$ ,*

$$\Pr_{G \sim \mathcal{H}_{k,n,\alpha}} [\text{val}_{\Phi(G)}^f(\mathbf{b}) \geq \rho(\Pi) + \eta] \leq \exp\left(-\left(\frac{\eta^2\alpha}{2(\rho(\Pi) + \eta)}\right)n\right).$$

**Proof.** Omitted.  $\blacktriangleleft$

► **Lemma 20.** *For every  $n$  and  $\alpha, \eta > 0$ ,*

$$\begin{aligned} & \Pr_{\Psi \sim \mathcal{G}_{q,n,\alpha,T}^N} \left[ \text{val}_{\Phi}^f \geq \rho(\Pi) + \eta, \text{ where } \Phi \text{ is the } q\text{-coarsening of } \Psi \mid m(\Psi) \geq \frac{n\alpha T}{2q^k} \right] \\ & \leq \exp\left(-\left(\frac{\eta^2\alpha T}{4(\rho(\Pi) + \eta)q^k} - \ln q\right)n\right). \end{aligned}$$

**Proof.** Identical to the proof of Lemma 18 (using Lemma 19 instead of Lemma 17), but now union-bounding over a set of size  $q^n$  (i.e., the set of possible assignments  $\mathbf{b} \in [q]^n$  for  $\Phi$ ).  $\blacktriangleleft$

## 5 Streaming indistinguishability of $\mathcal{G}^Y$ and $\mathcal{G}^N$

In this section we remark on the proof of Lemma 7 (although the full proof is omitted). This indistinguishability follows directly from the work of [5], who introduce a  $T$ -player communication problem called *implicit randomized mask detection (IRMD)*. Once we properly situate our instances  $\mathcal{G}^Y$  and  $\mathcal{G}^N$  within the framework of [5], Lemma 7 follows immediately.

We first recall their definition of the IRMD problem, and state their lower bound. The following definition is based on [5, Definition 3.1]. In [5] the IRMD game is parametrized by two distributions  $\mathcal{D}_Y$  and  $\mathcal{D}_N$ , but hardness is proved for a specific pair of distributions which suffices for our purpose; these distributions will thus be “hardcoded” into the definition we give.

► **Definition 21** (Implicit randomized mask detection (IRMD) problem). *Let  $q, k, n, T \in \mathbb{N}, \alpha \in (0, 1/k)$  be parameters. In the  $\text{IRMD}_{\alpha,T}$  game, there are  $T$  players, indexed from 0 to  $T - 1$ , and a hidden partition encoded by a random  $\mathbf{b} \in [q]^n$ . The  $t$ -th player has two inputs:*

## 17:16 Streaming Approximation Resistance of Every Ordering CSP

(a.)  $M_t \in \{0,1\}^{\alpha kn \times n}$ , the hypermatching matrix corresponding to a uniform  $\alpha$ -partial  $k$ -hypermatching on  $n$  vertices (i.e., drawn from  $\mathcal{H}_{n,\alpha}$ ), and (b.) a vector  $\mathbf{z}_t \in [q]^{\alpha kn}$  that can be generated from one of two different distributions:

- (**YES**)  $\mathbf{z}_t = M_t \mathbf{b} + \mathbf{y}_t \pmod{q}$  where  $\mathbf{y}_t \in [q]^{\alpha kn}$  is of the form  $\mathbf{y}_t = (\mathbf{y}_{t,0}, \dots, \mathbf{y}_{t,\alpha n-1})$  and each  $\mathbf{y}_{t,i} \in [q]^k$  is sampled as  $(a, \dots, a)$  where  $a$  is sampled uniformly from  $[q]$ .
- (**NO**)  $\mathbf{z}_t = M_t \mathbf{b} + \mathbf{y}_t \pmod{q}$  where  $\mathbf{y}_t \in [q]^{\alpha kn}$  is of the form  $\mathbf{y}_t = (\mathbf{y}_{t,0}, \dots, \mathbf{y}_{t,\alpha n-1})$  and each  $\mathbf{y}_{t,i} \in [q]^k$  is sampled as  $(a_0, \dots, a_{k-1})$  where each  $a_j$  is sampled uniformly and independently from  $[q]$ .

This is a one-way game where the  $t$ -th player can send a private message to the  $(t+1)$ -st player after receiving a message from the previous player. The goal is for the  $(T-1)$ -st player to decide whether the  $\{\mathbf{z}_t\}$  have been chosen from the **YES** or **NO** distribution, and the advantage of a protocol is defined as

$$\left| \Pr_{\text{YES case}} [\text{the } (T-1)\text{-st player outputs } 1] - \Pr_{\text{NO case}} [\text{the } (T-1)\text{-st player outputs } 1] \right|.$$

Note that the definition of the IRMD problem does not depend on an underlying family of constraints. Nevertheless, we are able to leverage its hardness to prove Lemma 7 (and indeed, all hardness results in [5] itself stem from hardness for the IRMD problem). The following theorem from [5] gives a lower bound on the communication complexity of the IRMD problem:

► **Theorem 22** ([5, Theorem 3.2]). *For every  $q, k \in \mathbb{N}$  and  $\delta \in (0, 1/2)$ ,  $\alpha \in (0, 1/k)$ ,  $T \in \mathbb{N}$  there exists  $n_0 \in \mathbb{N}$  and  $\tau \in (0, 1)$  such that the following holds. For all  $n \geq n_0$ , every protocol for  $\text{IRMD}_{\alpha, T}$  on  $n$  vertices with advantage  $\delta$  requires  $\tau n$  bits of communication.*

We use this hardness result to prove Lemma 7, via a standard communication-to-streaming reduction from IRMD. Our proof is based on the reduction given by [5, Theorem 4.3], which introduces a notion called the *width* of a constraint family, which we briefly discuss. For our purposes, it suffices to define the width  $\omega(f) \in [0, 1]$  of a single constraint  $f : [q]^k \rightarrow \{0, 1\}$  as

$$\omega(f) = \max_{\mathbf{b} \in [q]^k} \left\{ \Pr_{\ell \in [q]} [f(\mathbf{b} + \ell) = 1] \right\},$$

where  $\mathbf{b} + \ell$  denotes adding  $\ell$  to each component of  $\mathbf{b}$ . [5, Theorem 4.3] states that for every  $f$  and  $\epsilon > 0$ ,  $\text{Max-CSP}(f)$  cannot be  $(\rho(f)/\omega(f) + \epsilon)$ -approximated by a sublinear-space single-pass streaming algorithm, where  $\rho(f) = \Pr_{\mathbf{b} \in [q]^k} [f(\mathbf{b}) = 1]$  is the random assignment value for  $f$ . (The approximation ratio  $\rho(f)/\omega(f)$  is derived from the fact that the **NO** instances in the reduction have values close to  $\rho(f)$ , while the **YES** instances have values close to  $\omega(f)$ .) Hence whenever  $\omega(f)$  is close to 1,  $\text{Max-CSP}(f)$  is difficult to approximate. In our setting, we have  $\omega(f_{\Pi}^q) \geq 1 - \frac{k-1}{q}$ ; indeed, simply take  $\mathbf{b} = (\pi^{-1}(0), \dots, \pi^{-1}(k-1))$ , and then for any  $\ell \in \{0, \dots, q-k\}$ , we have  $f_{\Pi}^q(\mathbf{b} + \ell) = 1$  (by the same reasoning as in Subsection 4.2). The fact that  $\omega(f_{\Pi}^q) \approx 1$  for large  $q$  is precisely what enables us to apply [5]'s lower bounds to get optimal lower bounds in our setting.

---

**A** Example hard instances for MAS

(a) Constraint graph of a sample MAS instance drawn from  $\mathcal{G}^Y$ .

(b) Constraint graph of a sample MAS instance drawn from  $\mathcal{G}^N$ .

**Figure 1** The constraint graphs of MAS instances which could plausibly be drawn from  $\mathcal{G}^Y$  and  $\mathcal{G}^N$ , respectively, for  $q = 5$  and  $n = 12$ . Recall that MAS is a binary Max-OCSP with ordering constraint function  $\Pi$  supported only on  $[0\ 1]$ . According to the definition of  $\mathcal{G}^Y$  (see Definition 4, with  $\pi = [0\ 1]$ ), instances are sampled by first sampling a  $q$ -partition  $\mathbf{b} = (b_0, \dots, b_{n-1}) \in [q]^n$ , and then sampling some edges; every sampled edge  $(u, v)$  must satisfy  $b_v = b_u + 1 \pmod{q}$ . On the other hand, there are no requirements on  $(b_u, b_v)$  for instances sampled from  $\mathcal{G}^N$ . Above, the blocks of the partition  $\mathbf{b}$  are labelled  $0, \dots, 4$ , and the reader can verify that the edges satisfy the appropriate requirements. We also color the edges in a specific way: We color an edge  $(u, v)$  green, orange, or red if  $b_v > b_u$ ,  $b_v = b_u$ , or  $b_v < b_u$ , respectively. This visually suggests important elements of our proofs that  $\mathcal{G}^Y$  has MAS values close to 1 and  $\mathcal{G}^N$  has MAS values close to  $\frac{1}{2}$  (for formal statements, see Lemma 5 and Lemma 6, respectively). Specifically, in the case of  $\mathcal{G}^Y$ , if we arbitrarily arrange the vertices in each block, we will get an ordering in which every green edge is satisfied, and we expect all but  $\frac{1}{q}$  fraction of the edges to be satisfied (i.e., all but those which go from block  $q - 1$  to block 0). On the other hand, if we executed a similar process in  $\mathcal{G}^N$ , the resulting ordering would satisfy all green edges and some subset of the orange edges; together, in expectation, these account only for  $\frac{q(q+1)}{2q^2} = \frac{q+1}{2q} \approx \frac{1}{2}$  fraction of the edges.

## Abstract

In a hierarchical clustering problem the task is to compute a series of mutually compatible clusterings of a finite metric space  $(P, \text{dist})$ . Starting with the clustering where every point forms its own cluster, one iteratively merges two clusters until only one cluster remains. Complete linkage is a well-known and popular algorithm to compute such clusterings: in every step it merges the two clusters whose union has the smallest radius (or diameter) among all currently possible merges. We prove that the radius (or diameter) of every  $k$ -clustering computed by complete linkage is at most by factor  $O(k)$  (or  $O(k^2)$ ) worse than an optimal  $k$ -clustering minimizing the radius (or diameter). Furthermore we give a negative answer to the question proposed by Dasgupta and Long [6], who show a lower bound of  $\Omega(\log(k))$  and ask if the approximation guarantee is in fact  $\Theta(\log(k))$ . We present instances where complete linkage performs poorly in the sense that the  $k$ -clustering computed by complete linkage is off by a factor of  $\Omega(k)$  from an optimal solution for radius and diameter. We conclude that in general metric spaces complete linkage does not perform asymptotically better than single linkage, merging the two clusters with smallest inter-cluster distance, for which we prove an approximation guarantee of  $O(k)$ .

## 1 Introduction

The  $k$ -clustering problem asks for a partition of a point set in a metric space into  $k$  subsets (or clusters). To measure whether the data is clustered well, one option is to pick a center for every cluster and compute the maximum distance between a point and the center of its cluster. This objective is to be minimized and is known as  $k$ -center. A problem which is independent of the choice of centers is the  $k$ -diameter problem, where we want to minimize the maximum distance between two points lying in the same cluster. Observe that  $k$ -center and  $k$ -diameter are related to each other in the sense that for a fixed set  $P$  the cost of an optimal  $k$ -diameter clustering on  $P$  is at most twice the cost of an optimal  $k$ -center clustering, which again costs at most as much as an optimal  $k$ -diameter clustering. There are other

objectives to measure the quality of a clustering where every point contributes to the cost of the clustering, for example *k-median* and *k-means*. Here we want to minimize the cost which equals the sum over all (squared) distances between a point and the center of its cluster.

The *k*-center problem is NP-hard to approximate with factor  $\alpha < 2$  [12, 14]. This bound is tight, as both Gonzalez [7] and Hochbaum and Shmoys [13] show. Gonzalez's 2-approximation algorithm is a simple, but elegant greedy approach. Starting with an arbitrary point  $p_1 \in P$ , one constructs an enumeration  $P = \{p_1, \dots, p_{|P|}\}$  by successively choosing as  $p_{i+1}$  a point from  $P$  whose minimum distance to any point from  $\{p_1, \dots, p_i\}$  is maximal. Assigning every point from  $P$  to its closest neighbor among  $p_1, \dots, p_k$  (the centers) yields a 2-approximation for the *k*-center problem for all  $k = 1, \dots, |P|$ . One can prove that the resulting clustering is also a 2-approximation to *k*-diameter. Another greedy approach is the reverse greedy algorithm, which starts with all data points as centers and iteratively removes a center such that the objective stays as small as possible. Hershkowitz and Kehne [11] show that this algorithm computes an  $\Theta(k)$ -approximation. Observe that both greedy algorithms compute an *incremental clustering* where the centers of a *k*-clustering are also centers of an *l*-clustering if  $l \geq k$ .

Gonzalez's algorithm [7] allows to compute good clusterings, even if one does not previously know an appropriate value for *k*. However, even successive clusterings computed by Gonzalez's algorithm and reverse greedy can be radically different and so it can be difficult to compare them and select one that seems appropriate for the task.

Another greedy approach known as *complete linkage* starts with every point in its own cluster and consecutively merges two clusters whose union has the smallest radius (or diameter when considering the *k*-diameter objective) among all possible cluster pairs. If we proceed like this until only one cluster remains, we also obtain a *k*-clustering for any possible  $1 \leq k \leq |P|$ . However, this time, the resulting clusterings are also *hierarchically compatible*: for all  $l \geq k$  the *l*-clustering is a refinement of the *k*-clustering. This makes it easier to compare such clusterings with each other and to choose an appropriate *k*-clustering. Also, this additional hierarchical structure is interesting in and of itself. Famous examples include phylogenetic trees that represent the relationship between animal species in biology.

A series of such hierarchically compatible clusterings  $\mathcal{C}_1, \dots, \mathcal{C}_{|P|}$  (with  $\mathcal{C}_k$  being a *k*-clustering for all *k*) forms a *hierarchical clustering*. Complete linkage is a common and popular bottom-up approach to compute these and can be generalized to fit any *k*-clustering objective, resulting in so called *agglomerative clustering* methods. For hierarchical *k*-means this is Wards method [16].

To evaluate a hierarchical clustering  $\mathcal{C}_1, \dots, \mathcal{C}_{|P|}$  we refer to the underlying *k*-clusterings: it is an  $\alpha$ -*approximation* if the cost of  $\mathcal{C}_k$  is at most  $\alpha$  times that of an optimal *k*-clustering for all  $1 \leq k \leq |P|$ .

**Related work.** For hierarchical *k*-center and *k*-diameter, constant factor approximations are known. For both problems Dasgupta and Long [6] and Charikar et al. [4] give a polynomial-time 8-approximation. In [15] Lin et al. introduce the concept of nesting. Using this technique, every approximation algorithm to a *k*-clustering objective that satisfies their nesting property can be converted into an algorithm for its hierarchical version. Especially *k*-median and *k*-means satisfy this property and thus (in combination with the currently best constant factor approximations for *k*-median [3] and *k*-means [2]), polynomial time constant factor approximations do indeed exist for the hierarchical *k*-median/*k*-means problem. Yet the resulting guarantees are relatively high ( $\approx 56$  for *k*-median and  $\approx 3662$  for *k*-means). Nesting can also be applied to *k*-center/*k*-diameter but does not improve upon the 8-approximation.

As optimal  $k$ -clusterings are not necessarily hierarchically compatible, even assuming unlimited computation power 1-approximations do not exist in general. Das and Kenyon-Mathieu [5] give an instance for the diameter and Großwendt [10] for the radius where the best hierarchical clustering is a 2-approximation. Using the concept of nesting by Lin et al. [15], Großwendt [10] proves an existential upper bound of 4 for hierarchical  $k$ -center.

However, greedy algorithms are more common in practical applications. There exist several theoretical results on upper and lower bounds on the approximation factor for complete linkage. For metrics induced by norms in  $\mathbb{R}^d$ , especially the Euclidean metric, Ackermann et al. [1] prove that, assuming the dimension  $d$  to be constant, complete linkage computes for both the  $k$ -center and  $k$ -diameter objective an  $O(\log(k))$  approximation. This was later improved by Großwendt and Röglin [8] to  $O(1)$ . Both works distinguish between two variants of  $k$ -center: one where centers must be from the set  $P$  and the second where they can be arbitrary points chosen from the whole space  $\mathbb{R}^d$ . In the first case the approximation factor shown in [1, 8] depends linearly on  $d$  and in the second case exponentially on  $d$ . For the  $k$ -diameter problem it even depends doubly exponentially on the dimension. Furthermore Ackermann et al. prove for the  $l_p$ -metric with  $1 \leq p < \infty$  a lower bound of  $\Omega(\sqrt[p]{\log(d)})$  for complete linkage for  $k$ -diameter and  $k$ -center with centers drawn from  $P$  [1].

Little is known about complete linkage in general metric spaces. Dasgupta and Long show in [6] that the lower bound is in  $\Omega(\log(k))$ . With an approach to upper bound the increase in cost by a complete linkage merge, which we borrow from [1], we obtain in a relatively straightforward manner an upper bound of  $O(\log(|P| - k))$  for complete linkage for  $k$ -center.

There exist few results for agglomerative clustering regarding other objectives. Großwendt et al. [9] analyze Ward's method for  $k$ -means, and show that if the clusters of an optimal  $k$ -means clustering are sufficiently far apart, Ward's method computes a 2-approximation and under some additional assumptions in fact reconstructs the optimal clustering.

**Our Results.** We study upper and lower bounds for the complete linkage algorithm in general metric spaces for the  $k$ -center and  $k$ -diameter objective. For  $k$ -center in general metric spaces it is reasonable to assume that centers can be only drawn from  $P$  and thus we only consider this variant. Our main results are:

- A lower bound of  $\Omega(k)$  for complete linkage for  $k$ -center and  $k$ -diameter, which improves the currently highest lower bound of  $\Omega(\log(k))$  by Dasgupta and Long [6] significantly.
- An upper bound of  $O(k)$  for  $k$ -center and an upper bound of  $O(k^2)$  for  $k$ -diameter, which are to the best of the authors' knowledge the first non-trivial upper bounds for complete linkage in general metric spaces.

The lower bound  $\Omega(k)$  is surprising as it shows that complete linkage does not perform asymptotically better than single linkage, which merges the two clusters with smallest distance to each other (the distance of two clusters is the smallest distance between two of their points). Dasgupta and Long [6] prove a lower bound of  $\Omega(k)$  for single linkage and we show that the approximation factor is in fact  $\Theta(k)$ . As single linkage is not designed to minimize the radius or diameter of emerging clusters, it is a natural assumption that it performs worse than complete linkage. However our results show that this assumption is generally not true. It is even still open if complete linkage for  $k$ -diameter performs as good as single linkage, as we are only able to prove an upper bound of  $O(k^2)$ .

**Techniques.** One of the biggest and most well-known issues concerning single linkage is that of chaining. If there is a sequence of points  $x_1, \dots, x_k \in P$  with  $\text{dist}(x_i, x_{i+1})$  relatively small for all  $i$ , then single linkage might merge all of them together, despite the resulting cluster

■ **Figure 1** On the left we see two  $k$ -center clusters with radius  $r$  whose centers lie in the same optimal cluster. The radius of the merged cluster is at most  $r + 2x$ . On the right we have a similar situation for  $k$ -diameter but the merged cluster has diameter at most  $2d + x$ .

being quite large. Dasgupta and Long show with their lower bound of  $\Omega(\log k)$  that a similar process of chaining can also occur when executing complete linkage. They give the example of points placed on a regular  $(k \times k)$ -grid with a spacing of 1. The distance is given by the sum of the discrete metric on the horizontal axis and the logarithm of the absolute value of the vertical axis. That is,  $\text{dist}((x, y), (x', y')) = \mathbf{1}_{x \neq x'} + \log_2(1 + |y - y'|)$ . Now, although an optimal clustering just consists of the individual rows of the grid, complete linkage might reproduce the columns instead (assuming that  $k$  is a power of 2): iteratively go from top to bottom and merge vertically neighboring clusters. Every such iteration halves the number of clusters and, due to the logarithm, only increases the cost by 1, just as when merging along the rows. Of course, we would have to pay only once to merge horizontally, whereas we have to pay  $\log_2 k$  times to merge vertically, but complete linkage cannot distinguish between these two cases. In fact, one can shift the vertical placement by arbitrarily small values to ensure that complete linkage always chooses the bad case.

We have to heavily modify the example to improve upon this  $\log_2 k$  factor. The fundamental problem is this: a vertical merge is only allowed to increase the cost by 1 to tie it with any horizontal merge, whereas the number of rows occupied by a cluster (and thus its diameter) doubles. We raise the lower bound by constructing an instance on which complete linkage iteratively merges diagonally shifted clusters. This process of merging clusters is much slower and does not require us to introduce a logarithmic scaling: merging one such cluster into the other incurs a cost of 1, while at the same time increasing the number of occupied rows only by one. The instance that we describe later is successively built from smaller components that exhibit exactly this behaviour, while ensuring that any such merge does not pay for the whole row.

Following the work of Ackermann et al. [1] one can show for complete linkage an upper bound of  $\log(|P| - k)$  for  $k$ -center. This comes from the following easy property, which is true for the radius but cannot be transferred to diameter: Suppose the optimal  $k$ -center solution  $\mathcal{O}$  has cost  $x$ . In a complete linkage clustering consisting of more than  $k$  clusters two of its centers must lie in the same optimal cluster and therefore are at distance  $\leq 2x$  to each other. Thus the merge that is performed by complete linkage increases the cost by at most  $2x$ . However if we replace  $k$ -center by  $k$ -diameter we see that the cost is more than doubled in the worst case (see Figure 1), which is not enough to obtain an upper bound polynomial in  $k$ . Thus we introduce another perspective on the cost of a cluster. A cluster is good if its cost is small enough in comparison to the number of optimal clusters from  $\mathcal{O}$  which it intersects. As  $\mathcal{O}$  consists of  $k$  clusters this already implies a sufficiently small upper bound for good clusters. For all remaining clusters we show that their number is small enough. This approach leads to an upper bound of  $O(k^2)$  for  $k$ -diameter and, in combination with the  $\log(|P| - k)$  upper bound, an upper bound of  $O(k)$  for  $k$ -center.

## 2 Preliminaries

Let  $(P, \text{dist})$  be a metric space with  $n$  points and  $1 \leq k \leq n$ . The  $k$ -center problem asks for a partition of  $P$  into  $k$  clusters  $\mathcal{C} = \{C_1, \dots, C_k\}$ . The cost of cluster  $C_i$  is given by  $\text{cost}(C_i) = \min_{c \in C_i} \max_{x \in C_i} \text{dist}(x, c)$  while the cost of the clustering  $\mathcal{C}$  is  $\text{cost}(\mathcal{C}) = \max_{i=1, \dots, k} \text{cost}(C_i)$  and is to be minimized.

In the  $k$ -diameter problem we also have to find a partition of  $P$  into  $k$  clusters  $\mathcal{C} = \{C_1, \dots, C_k\}$  and minimize the overall cost. However, we replace the cost of a cluster  $C_i$  by  $\text{cost}(C_i) = \max_{x, y \in C_i} \text{dist}(x, y)$ . For both the  $k$ -center and the  $k$ -diameter problem we denote by  $\mathcal{O}_k$  an arbitrary but fixed *optimal clustering*.

We study the hierarchical version of the above problems, where we ask for a  $k$ -clustering  $\mathcal{C}_k$  of  $P$  for every  $1 \leq k \leq n$ . The clusterings must be *hierarchically compatible*, which means that  $\mathcal{C}_{k-1}$  is obtained from  $\mathcal{C}_k$  by merging two of its clusters, i.e., for all  $2 \leq k \leq n$  there are  $A, B \in \mathcal{C}_k$  such that  $\mathcal{C}_{k-1} = \mathcal{C}_k \setminus \{A, B\} \cup \{A \cup B\}$ . A sequence of such  $k$ -clusterings  $(\mathcal{C}_k)_{k=1}^n$  is called a *hierarchical clustering*. We say that it is an  $\alpha$ -approximation if  $\text{cost}(\mathcal{C}_k) \leq \alpha \text{cost}(\mathcal{O}_k)$  for all  $1 \leq k \leq n$ . Thus the task is to find a hierarchical clustering which is a good approximation to the optimal solution on every level  $k$ .

A common class of approaches for computing such hierarchical clusterings are *agglomerative linkage algorithms*. As outlined above, a hierarchical clustering can be computed in a bottom-up fashion, where pairs of clusters are merged successively. Agglomerative linkage procedures do exactly that, with the choice of clusters to be merged at every step given by a linkage function. Such a linkage function maps all possible pairs of disjoint clusters onto  $\mathbb{R}_+$  and the algorithm chooses one pair that minimizes this value: Suppose that we have already constructed  $\mathcal{C}_k$  and are using the linkage function  $f$ . Then  $\mathcal{C}_{k-1}$  is given by merging a pair  $A \neq B \in \mathcal{C}_k$  with  $f(A, B) = \min_{A' \neq B' \in \mathcal{C}_k} f(A', B')$ . As already stated, the two linkage functions we are interested in are:

- Single linkage:  $(A, B) \mapsto \text{dist}(A, B) = \min_{(a, b) \in A \times B} \text{dist}(a, b)$ .
- Complete linkage:  $(A, B) \mapsto \text{cost}(A \cup B)$ .

To analyze the performance of the respective agglomerative algorithms we often consider the smallest clustering from  $(\mathcal{C}_k)_{k=1}^n$  (in terms of the number of clusters) whose cost does not exceed a given bound. This perspective is already used by Großwendt and Röglin [8] and allows a better handling of the cost. For any  $x \geq 0$  let  $t_{\leq x} = \min\{k \mid \text{cost}(\mathcal{C}_k) \leq x\}$  and set  $\mathcal{H}_x = \mathcal{C}_{t_{\leq x}}$ . Observe that  $\mathcal{H}_x$  is the smallest clustering from  $(\mathcal{C}_k)_{k=1}^n$  with cost at most  $x$ . Thus it has the useful property that every merge of two clusters in  $\mathcal{H}_x$  results in a clustering of cost more than  $x$ . Furthermore, for a cluster  $C \subseteq P$  and an optimal  $k$ -clustering  $\mathcal{O} = \mathcal{O}_k$  we denote by  $\mathcal{O}_C = \{O \in \mathcal{O} \mid O \cap C \neq \emptyset\}$  the set of all optimal  $k$ -clusters hit by  $C$ .

## 3 Approximation Guarantee of Single Linkage

As outlined in [6] there are clustering instances where single linkage builds chains yielding the lower bound  $\Omega(k)$  on the approximation factor. We show in Appendix A that this is the worst case scenario, as in fact single linkage computes an  $O(k)$ -approximation for hierarchical  $k$ -center/ $k$ -diameter.

► **Theorem 1.** *Let  $(\mathcal{C}_k)_{k=1}^n$  be the hierarchical clustering computed by single linkage on  $(P, \text{dist})$  and let  $\mathcal{O}_k$  be an optimal clustering for  $k$ -center or  $k$ -diameter, respectively. We have for all  $1 \leq k \leq n$*

1.  $\text{cost}(\mathcal{C}_k) \leq (2k + 2) \cdot \text{cost}(\mathcal{O}_k)$  for the  $k$ -center cost
2.  $\text{cost}(\mathcal{C}_k) \leq 2k \cdot \text{cost}(\mathcal{O}_k)$  for the  $k$ -diameter cost.

■ **Figure 2** The progression of the first 5 components  $K_1, \dots, K_5$ . The gray sets indicate points on the same level and form the optimal clusters. When analyzing the instance for the radius, the encircled points in the  $K_2$  and  $K_4$  component indicate their optimal centers.

#### 4 Lower Bounds for Complete Linkage

In the following we show that complete linkage performs asymptotically as bad as single linkage in the worst case. That is, for every  $k \in \mathbb{N}$  we provide an instance  $P_k$  on which the diameter and radius of a  $k$ -clustering computed by complete linkage is off by a factor of  $\Omega(k)$  from the cost of an optimal solution. This improves upon the previously known lower bound of  $\Omega(\log_2(k))$  established by Dasgupta and Long. Recall from the introduction that one of the big problems preventing an improved lower bound was that any horizontal merge already paid for all the involved rows. As such, for the worst case, one was only allowed to merge vertically, but this can be done at most  $\log_2(k)$  times. We improve upon this by inductively constructing an instance from smaller components that are diagonally shifted to produce bigger ones. Merging two such diagonally shifted components incurs an additional cost of 1, while ensuring at the same time that this does not pay for any future merges of parallel components.

A  $k$ -component  $K_k = (G_k, \phi_k)$  is a combination of a graph  $G_k = (V_k, E_k)$  and a mapping  $\phi_k : V_k \rightarrow \{1, \dots, k\}$ . The mapping is necessary for the construction of the component and later on determines an optimal  $k$ -clustering on  $P_k$ . We refer to  $\phi_k(x)$  as the *level* of  $x$ . The other part of the component is an undirected graph  $G_k$ , referred to as a  $k$ -graph, on  $2^{k-1}$  points with edge weights in  $\mathbb{N}$  that describe the distances between the levels.

The 1-component  $K_1$  consists of a single point  $x$  with  $\phi_1(x) = 1$ . All higher components are constructed inductively from this 1-component. Given the  $(k - 1)$ -component  $K_{k-1}$  we construct  $K_k$  as follows: Let  $K_{k-1}^{(0)}$  and  $K_{k-1}^{(1)}$  be two copies of the  $(k - 1)$ -component  $K_{k-1}$ . For the  $k$ -graph  $G_k$  we first take the disjoint union of the graphs  $G_{k-1}^{(0)}$  and  $G_{k-1}^{(1)}$ . This already yields all the points of  $G_k$ . For the  $k$ -mapping  $\phi_k$  we set  $\phi_k(x) = \phi_{k-1}^{(i)}(x) + i$  for  $x \in V(G_{k-1}^{(i)}) \subset V(G_k)$ . That is, in the first copy the levels stay the same, whereas in the second all levels are shifted by 1. Finally, to complete  $G_k$ , we add one edge of weight  $k - 1$  from the unique point  $s \in V(G_k)$  with  $\phi_k(s) = 1$  to the unique point  $t \in V(G_k)$  with  $\phi_k(t) = k$ . The progression of the first five components is given in Figure 2.

The instance  $P_k$  is now constructed from the  $k$ -component as follows: Let  $K_k^{(1)}, \dots, K_k^{(k+1)}$  be  $k+1$  copies of  $K_k$ . Take the disjoint union of the corresponding  $k$ -graphs  $G_k^{(1)}, \dots, G_k^{(k+1)}$  and connect them by adding edges  $\{x, y\}$  of weight 1 for every two points  $x \in V(G_k^{(i)})$  and  $y \in V(G_k^{(j)})$  with  $\phi_k^{(i)}(x) = \phi_k^{(j)}(y)$ . Note that the sets of points from the same level constitute cliques of diameter and radius 1 and form an optimal solution of cost 1. To simplify notation we omit the indices and write  $\phi_k(x)$  to denote the level of a point  $x \in V(G_k^{(j)}) \subset V(P_k)$ . The distance between two points in  $V(P_k)$  is given by the length of a shortest path.

Let  $(\mathcal{C}_{k'})_{k'=1}^n$  be the clustering produced by complete linkage on  $(V(P_k), \text{dist})$  minimizing the radius or diameter. Recall that  $\mathcal{C}_{k'-1}$  arises from  $\mathcal{C}_{k'}$  by merging two clusters  $A, B \in \mathcal{C}_{k'}$  that minimize the radius or diameter of  $A \cup B$ . Remember that  $t_{\leq x} = \min\{k' \mid \text{cost}(\mathcal{C}_{k'}) \leq x\}$  and that  $\mathcal{H}_x = \mathcal{C}_{t_{\leq x}}$  denotes the smallest clustering with cost smaller or equal to  $x$ . We show in the following two subsections that  $\mathcal{H}_{k-1}$  consists exactly of the  $k+1$  different  $k$ -graphs that make up the instance resulting in the following theorem.

► **Theorem 2.** *For every  $k \in \mathbb{N}$  there exists an instance  $(V(P_k), \text{dist})$  on which complete linkage, minimizing either diameter or radius, computes a solution of diameter  $k$  or radius  $\frac{k}{2}$ , respectively, whereas the cost of an optimal solution is 1.*

### 4.1 A Lower Bound for Diameter-Based Cost

We start with the analysis for diameter-based costs and after that move on to radius-based costs.

► **Lemma 3.** *The distance between two points  $x, y \in V(P_k)$  is at least as big as the difference in levels  $|\phi_k(x) - \phi_k(y)|$ .*

**Proof.** By the inductive construction of the components, an edge of weight  $w$  can cross at most  $w$  levels. Hence the distance between  $x$  and  $y$  is at least  $|\phi_k(x) - \phi_k(y)|$ . ◀

Consider an  $\ell$ -graph  $G_\ell$ . Instead of talking about the cluster  $V(G_\ell)$  in  $(V(P_k), \text{dist})$  we slightly abuse our notation and see  $G_\ell$  as a cluster with  $\text{cost}(G_\ell) = \max_{x, y \in V(G_\ell)} \text{dist}(x, y)$ , i.e., the diameter of  $V(G_\ell)$ . Using the previous lemma we can show inductively that the diameter of any  $\ell$ -graph in  $P_k$  is  $\ell - 1$ .

► **Lemma 4.** *Let  $G_\ell$  be an  $\ell$ -graph contained in  $P_k$ . We have  $\text{cost}(G_\ell) = \ell - 1$ .*

**Proof.** We prove the upper bound  $\text{cost}(G_\ell) \leq \ell - 1$  by induction. The 1-graphs are points and so the claim follows trivially for  $\ell = 1$ . Assume now that we have shown the claim for  $\ell - 1$ . Let  $s, t \in V(G_\ell)$  be points such that  $\text{dist}(s, t) = \text{cost}(G_\ell)$ . If these points lie in the same graph, say  $G_{\ell-1}^{(0)}$ , of the two  $(\ell - 1)$ -graphs  $G_{\ell-1}^{(0)}$  and  $G_{\ell-1}^{(1)}$  that make up  $G_\ell$ , then

$$\text{cost}(G_\ell) = \text{dist}(s, t) \leq \text{cost}(G_{\ell-1}^{(0)}) \leq \ell - 2 < \ell - 1$$

by induction and we are done. Otherwise we may assume that  $s \in V(G_{\ell-1}^{(0)})$  and  $t \in V(G_{\ell-1}^{(1)})$ . This leaves us with another case analysis. If  $s$  is the unique point with level 1 and  $t$  is the unique point in level  $\ell$  in  $G_\ell$  then we are again done, since by construction there exists an edge between  $s$  and  $t$  of weight  $\ell - 1$ . Otherwise one of  $s$  or  $t$  must share a level with a point not in the same  $(\ell - 1)$ -graph as themselves. Without loss of generality we may assume that  $s$  lies in the same level as some  $u \in V(G_{\ell-1}^{(1)})$ . By induction  $\text{dist}(u, t) \leq \ell - 2$  and so

$$\text{cost}(G_\ell) = \text{dist}(s, t) \leq \text{dist}(s, u) + \text{dist}(u, t) \leq 1 + \ell - 2 = \ell - 1.$$

This concludes the proof of the upper bound  $\text{cost}(G_\ell) \leq \ell - 1$ .

To see the lower bound  $\text{cost}(G_\ell) \geq \ell - 1$ , we apply Lemma 3 to the unique point  $s$  with level 1 and the unique point  $t$  with level  $\ell$  in  $G_\ell$ . This shows that  $\text{cost}(G_\ell) \geq \text{dist}(s, t) \geq \ell - 1$ . ◀

The goal now is to show that complete linkage actually reconstructs these graphs as clusters. We already computed the cost of an  $\ell$ -graph and now it is left to observe that merging two  $\ell$ -graphs costs at least  $\ell$ .

► **Lemma 5.** *Complete linkage might merge clusters on  $(V(P_k), \text{dist})$  in such a way that for all  $\ell \leq k$ , the clustering  $\mathcal{H}_{\ell-1}$  consists exactly of the  $\ell$ -graphs that make up  $P_k$ .*

**Proof.** We again prove the claim by induction. Complete linkage always starts with every point in a separate cluster. Since those are exactly the 1-graphs and any merge costs at least 1, the claim follows for  $\ell = 1$ . Suppose now that  $\mathcal{H}_{\ell-1}$  consists exactly of the  $\ell$ -graphs of the instance. Since we are dealing with integer weights, any new merge increases the cost by at least 1 and so we may merge all pairs of  $\ell$ -graphs that form the  $(\ell + 1)$ -graphs. These are cheapest merges as they altogether increase the cost from  $\ell - 1$  to  $\ell$  (see Lemma 4). To finish the proof we are left to show that at this point there are no more free merges left. Take any two  $(\ell + 1)$ -graphs  $G_{\ell+1} \neq G'_{\ell+1}$  contained in the current clustering. If they do not exactly cover the same levels, then the distance between the point in the lowest level to the point in the highest level is strictly more than  $\ell$  by Lemma 3. Hence, we can assume that they share the same levels, say level  $\lambda$  up to level  $\ell + \lambda$ . Denote by  $s$  the unique point in  $V(G_{\ell+1})$  with  $\phi_k(s) = \lambda$  and by  $t$  the unique point in  $V(G'_{\ell+1})$  with  $\phi_k(t) = \ell + \lambda$ . A shortest path connecting  $s$  and  $t$  must contain an edge  $\{u, w\}$  with  $u \in V(G_{\ell+1})$  and  $w \in V(P_k) \setminus V(G_{\ell+1})$ . Such an edge either weights at least  $\ell + 1$  or weights 1 and connects points in the same level, i.e.,  $\phi_k(u) = \phi_k(w)$ . In the first case we directly obtain  $\text{dist}(s, t) \geq \ell + 1$ . In the second case we use Lemma 3 and obtain

$$\begin{aligned} \text{dist}(s, t) &= \text{dist}(s, u) + \text{dist}(u, w) + \text{dist}(w, t) \\ &\geq |\phi_k(s) - \phi_k(u)| + 1 + |\phi_k(w) - \phi_k(t)| \\ &= |\phi_k(s) - \phi_k(t)| + 1 \\ &= \ell + 1. \end{aligned}$$

It follows that  $\mathcal{H}_\ell$  consists exactly of the  $(\ell + 1)$ -graphs that make up  $P_k$ . ◀

**Proof of Theorem 2 (diameter).** Lemma 5 shows that  $\mathcal{H}_{k-1}$  can consist of all the  $k$ -graphs that make up  $P_k$ . There are exactly  $k + 1$  of them and so there is one merge remaining to get a  $k$ -clustering. By definition of  $\mathcal{H}_{k-1}$ , this last merge increases the cost by at least 1 and so the  $k$ -clustering produced by complete linkage costs at least  $k$ , whereas the optimal clustering consisting of the  $k$  individual levels costs 1. ◀

## 4.2 A Lower Bound for Radius-Based Costs

We show that the instance  $(V(P_k), \text{dist})$  also yields a lower bound of  $k/2$  for radius-based costs. This requires some additional work, as we now also have to keep track of the centers that induce an optimal radius. For an  $\ell$ -graph  $G_\ell$  we again slightly abuse the notation and talk about  $G_\ell$  as a cluster with  $\text{cost}(G_\ell) = \min_{c \in V(G_\ell)} \max_{x \in V(G_\ell)} \text{dist}(c, x)$ , the radius of  $V(G_\ell)$ .

To prove Lemma 6 we show that there is a point in  $P_k$  for which the following holds:

- For all but one of the  $\ell$ -graphs that constitute  $G_{2\ell}$  we can find a point that we can reach by an edge of weight 1. Since the diameter of these graphs is  $\ell - 1$ , this is sufficient.
- The remaining  $\ell$ -graph lies in the same  $(\ell + 1)$ -graph as our point and so we are again done by considering the diameter. Also there are no points that induce a smaller radius, since the diameter of  $G_{2\ell}$  is already  $2\ell - 1$ .

► **Lemma 6.** *Let  $G_{2\ell}$  be any of the  $2\ell$ -graphs that constitute  $P_k$  for  $1 \leq \ell \leq \frac{k}{2}$  arbitrary. Then it holds that  $\text{cost}(G_{2\ell}) = \ell$  and furthermore, all optimal centers that induce this cost are themselves already contained in  $G_{2\ell}$  (and not in any other  $2\ell$ -graph).*

**Proof.** By Lemma 4 we know that the diameter of  $G_{2\ell}$  is  $2\ell - 1$ . Thus the radius of  $G_{2\ell}$  is at least  $\ell$ . To show the upper bound of  $\ell$  suppose that  $G_{2\ell}$  covers the levels  $\lambda$  up to  $\lambda + 2\ell - 1$  in  $P_k$ . Consider the unique  $(\ell + 1)$ -graph  $H_{\ell+1}$  contained in  $G_{2\ell}$  covering the levels  $\lambda + \ell - 1$  to  $\lambda + 2\ell - 1$ . Let  $c$  be the unique point in  $H_{\ell+1}$  with level  $\lambda + \ell - 1$ . By Lemma 4 the diameter of  $H_{\ell+1}$  is  $\ell$ , so any point in  $H_{\ell+1}$  is at distance  $\leq \ell$  to  $c$ . Consider now a point  $x \in V(G_{2\ell}) \setminus V(H_{\ell+1})$  and the  $\ell$ -graph  $H_\ell$  containing  $x$ . We claim that  $H_\ell$  contains a point  $y$  with level  $\lambda + \ell - 1$ . If this is not true then  $H_\ell$  covers the levels  $\lambda + \ell$  up to  $\lambda + 2\ell - 1$  and therefore also contains the unique point in  $G_{2\ell}$  with level  $\lambda + 2\ell - 1$ . This is not possible as the unique point in  $G_{2\ell}$  with level  $\lambda + 2\ell - 1$  is already contained in  $H_{\ell+1}$ . So using that the diameter of  $H_\ell$  is  $\ell - 1$  and  $\phi_k(c) = \phi_k(y)$  we obtain

$$\text{dist}(c, x) \leq \text{dist}(c, y) + \text{dist}(y, x) \leq 1 + (\ell - 1) = \ell.$$

Now we prove that all optimal centers must be contained in  $G_{2\ell}$ . For all points  $c \in V(P_k) \setminus V(G_{2\ell})$  we have to show that  $\max_{x' \in V(G_{2\ell})} \text{dist}(c, x') \geq \ell + 1$ . Suppose that  $\phi_k(c) \leq \lambda + \ell - 1$ . Let  $x$  be the unique point in  $G_{2\ell}$  with level  $\lambda + 2\ell - 1$ , we claim that  $\text{dist}(c, x) \geq \ell + 1$ . Consider a shortest path between  $c$  and  $x$  and let  $\{u, w\}$  be an edge on this path with  $u \in V(P_k) \setminus V(G_{2\ell})$  and  $w \in V(G_{2\ell})$ . By construction  $\{u, w\}$  either weights at least  $2\ell$  in which case

$$\text{dist}(c, x) \geq 2\ell \geq \ell + 1$$

or it weights 1 and  $\phi_k(u) = \phi_k(w)$ , so

$$\begin{aligned} \text{dist}(c, x) &= \text{dist}(c, u) + \text{dist}(u, v) + \text{dist}(v, x) \\ &\geq |\phi_k(c) - \phi_k(u)| + 1 + |\phi_k(w) - \phi_k(x)| \\ &= |\phi_k(c) - \phi_k(x)| + 1 \\ &\geq \ell + 1. \end{aligned}$$

In case  $\phi_k(c) \geq \lambda + \ell$  we can prove analogously that  $\text{dist}(c, y) \geq \ell + 1$  for the unique point  $y$  in  $G_{2\ell}$  with level  $\lambda$ . This finishes the proof. ◀

Now we make sure that complete linkage completely reconstructs these components. In particular we show that merging  $2\ell$ -graphs which cover the same levels increases the cost of our solution. Here we make use of the fact that sets of optimal centers for any pair of  $2\ell$ -graphs do not intersect. Lemma 7 ensures that the cost indeed increases.

► **Lemma 7.** *Let  $C, D$  be two subsets of  $V(P_k)$  with  $\text{cost}(C) = \text{cost}(D)$ . Let  $Z(C)$  and  $Z(D)$  denote the set of all optimal centers for  $C$  respectively  $D$ . If  $Z(C) \cap Z(D) = \emptyset$  then  $\text{cost}(C \cup D) > \text{cost}(C)$ .*

**Proof.** Let  $x \in V(P_k)$ . Since  $Z(C) \cap Z(D) = \emptyset$  this point can be an optimal center for at most one of the sets. Assume without loss of generality that  $x \notin Z(D)$ . We have

$$\max_{y \in C \cup D} \text{dist}(y, x) \geq \max_{y \in D} \text{dist}(y, x) > \text{cost}(D) = \text{cost}(C)$$

So we have for all  $x \in V(P_k)$  that  $\max_{y \in C \cup D} \text{dist}(y, x) > \text{cost}(C)$  which proves the lemma. ◀

Now, with this we can prove that the merging behavior of complete linkage reconstructs our components. Observe that Theorem 2 is an immediate consequence of Corollary 8.

► **Corollary 8.** *Complete linkage might merge clusters in  $(V(P_k), \text{dist})$  in such a way, that for  $1 \leq \ell \leq \frac{k}{2}$ , the clustering  $\mathcal{H}_\ell$  consists exactly of the  $2\ell$ -graphs that make up  $P_k$ .*

**Proof.** The proof is an analogous induction to Lemma 5. Consider the case  $\ell = 1$ . The first merge increases the cost to 1. Observe by Lemma 6 that the cost of a 2-graph is 1. Furthermore, the same lemma shows that the sets of optimal centers for any pair of 2-graphs do not intersect and so, as shown in Lemma 7 any further merge necessarily has to increase the cost. Hence  $\mathcal{H}_1$  consists exactly of the 2-graphs.

Assume now that the claim holds for  $\mathcal{H}_\ell$ . The induction step works essentially the same as the base case. Any merge will increase the cost of the solution by at least 1 by definition of  $\mathcal{H}_\ell$  and so we might as well merge all  $2\ell$ -graphs that together compose a  $(2\ell + 2)$ -graph as this is a cheapest choice (Lemma 6). Furthermore, any additional merge would increase the cost to at least  $\ell + 2$  (again by Lemma 7) and so  $\mathcal{H}_{\ell+1}$  consist of the  $(2\ell + 2)$ -graphs. ◀

Notice that in our analysis we decided which clusters will be merged by complete linkage whenever it has to choose between two merges of the same cost. However with some adjustments on the instance  $P_k$  we can show a lower bound of  $\Omega(k)$  for both, diameter and radius, for any behavior of complete linkage on ties. For more details we refer to Appendix B.

## 5 An Upper Bound for Complete Linkage

Even though complete linkage is often used when it comes to computing a hierarchical clustering, there are no known non-trivial upper bounds for its approximation guarantee in general metric spaces, to the best of the authors' knowledge. We give an upper bound for complete linkage for hierarchical  $k$ -center and hierarchical  $k$ -diameter.

### 5.1 An Upper Bound for Radius-Based Cost

We show that the approximation ratio of the radius of any  $k$ -clustering  $\mathcal{C}_k$  produced by complete linkage relative to an optimal  $k$ -center clustering is in  $O(k)$ .

► **Theorem 9.** *Let  $(\mathcal{C}_k)_{k=1}^n$  be the hierarchical clustering computed by complete linkage on  $(P, \text{dist})$  optimizing the radius. For all  $1 \leq k \leq n$  the radius cost  $\text{cost}(\mathcal{C}_k)$  is upper bounded by  $O(k) \text{cost}(\mathcal{O}_k)$ , where  $\mathcal{O}_k$  is an optimal  $k$ -center clustering.*

To simplify the notation we fix an arbitrary  $k$  and assume that the optimal  $k$ -clustering  $\mathcal{O} = \mathcal{O}_k$  has cost  $\text{cost}(\mathcal{O}) = \frac{1}{2}$ . The latter is possible without loss of generality by scaling the metric appropriately.

We split the proof of Theorem 9 into two parts. In the first, we derive a crude upper bound for the increasing cost of clusterings produced during the execution of complete linkage. This part follows the work of Ackermann et al. [1], who use the same bound to estimate the cost of some few merge steps. Proposition 12 shows that the difference in cost between  $\mathcal{C}_k$  and  $\mathcal{C}_t$  for  $t > k$  is at most  $\lceil \log(t - k) \rceil + 1$ . That is,  $\text{cost}(\mathcal{C}_k) \leq \lceil \log(t - k) \rceil + 1 + \text{cost}(\mathcal{C}_t)$  holds for all  $1 \leq k < t \leq n$ . A clustering  $\mathcal{C}_t$  whose cost we can estimate directly (i.e. without referring to any other clustering) thus yields a proper upper bound for  $\text{cost}(\mathcal{C}_k)$ . Ideally, this clustering should consist of relatively few clusters (so that  $\lceil \log(t - k) \rceil$  is small), while at the same time not being too expensive. Of course, however, these criteria oppose each other. Naively choosing the initial clustering  $\mathcal{C}_t = \mathcal{C}_n$  is not good enough. Although its cost is minimal, the number of clusters is too high, only yielding an upper bound of  $\text{cost}(\mathcal{C}_k) \leq \lceil \log(n - k) \rceil + 1$ . In the second part of the proof we thus set out to find a different clustering to start from.

### Part 1: An estimate of the relative difference in cost

When dealing with radii, any merge done by complete linkage previous to reaching a  $k$ -clustering increases the cost by at most  $2 \text{cost}(\mathcal{O}) = 1$  (Figure 1). This is due to the fact that the centers of two of those clusters are contained in the same optimal cluster.

We show that complete linkage clusterings at times  $t_{\leq x}$  and  $t_{\leq x+1}$  can have at most  $k$  clusters in common. All other clusters from  $\mathcal{H}_x$  are merged in  $\mathcal{H}_{x+1}$ .

► **Lemma 10.** *For all  $x \geq 0$  the clustering  $\mathcal{H}_{x+1}$  contains at most  $k$  clusters of cost at most  $x$ . In particular, it holds that  $|\mathcal{H}_{x+1} \cap \mathcal{H}_x| \leq k$ .*

**Proof.** Assume on the contrary that there exist  $k+1$  pairwise different clusters  $D_1, \dots, D_{k+1}$  at time  $t_{\leq x+1}$  of cost at most  $x$ . Denote by  $d_i \in D_i$  a point that induces the smallest radius, i.e.  $\text{cost}(D_i) = \max_{d \in D_i} \text{dist}(d, d_i)$  for all  $i$ . Then two of these points, say  $d_1$  and  $d_2$ , have to be contained in the same optimal cluster  $O \in \mathcal{O}$ . Hence, we know that

$$\text{cost}(D_1 \cup D_2) \leq 1 + \max_{i \in \{1,2\}} \text{cost}(D_i) \leq 1 + x$$

because  $\text{dist}(d_1, d_2) \leq 2 \text{cost}(O) \leq 2 \text{cost}(\mathcal{O}) = 1$  and  $\text{cost}(D_i) \leq x$  for  $i = 1, 2$ . This contradicts the definition of  $\mathcal{H}_{x+1}$ , as  $D_1$  and  $D_2$  can still be merged without pushing the cost beyond  $x+1$ . ◀

With this we can upper bound  $|\mathcal{H}_{x+i}|$  in terms of  $|\mathcal{H}_x|$  for all  $i \in \mathbb{N}$ . The proof of Corollary 11 can be found in Appendix C.

► **Corollary 11.** *For all  $i \in \mathbb{N}_+$  and  $x \geq 0$  it holds that  $|\mathcal{H}_{x+i}| \leq k + \frac{1}{2^i}(|\mathcal{H}_x| - k)$ .*

► **Proposition 12.** *For all  $k < t \leq n$  it holds that  $\text{cost}(\mathcal{C}_k) \leq \lceil \log(t - k) \rceil + 1 + \text{cost}(\mathcal{C}_t)$ .*

**Proof.** Let  $x = \text{cost}(\mathcal{C}_t)$ , so that  $\mathcal{H}_x$  consists of at most  $t$  clusters. Applying Corollary 11 with  $i = \lceil \log(t - k) \rceil + 1$  then shows that

$$|\mathcal{H}_{x+i}| < k + \frac{1}{t - k}(|\mathcal{H}_x| - k) \leq k + 1.$$

That is,  $\mathcal{H}_{x+i}$  emerges from  $\mathcal{C}_k$  by merging some (or none) of its clusters and we can conclude that  $\text{cost}(\mathcal{C}_k) \leq \text{cost}(\mathcal{H}_{x+i}) \leq x + i = \text{cost}(\mathcal{C}_t) + \lceil \log(t - k) \rceil + 1$ . ◀

### Part 2: A cheap clustering with few clusters

Suppose that there exists a complete linkage clustering  $\mathcal{C}_t$  for some  $t > k$  with  $t \in O(2^k)$  clusters and  $\text{cost}(\mathcal{C}_t) \in O(k)$ . Then applying Proposition 12 shows that

$$\text{cost}(\mathcal{C}_k) \in \log(O(2^k)) + 1 + O(k) = O(k) = O(k) \text{cost}(\mathcal{O})$$

and Theorem 9 is proven (recall that  $\text{cost}(\mathcal{O}) = \frac{1}{2}$ ). We show that  $\mathcal{C}_t = \mathcal{H}_{4k+2}$  is a sufficiently good choice. To estimate the size of  $\mathcal{H}_{4k+2}$ , we distinguish between active and inactive clusters. Remember that  $\mathcal{O}_C = \{O \in \mathcal{O} \mid O \cap C \neq \emptyset\}$  is the set of optimal clusters hit by  $C$ .

► **Definition 13.** *We call a cluster  $C \in \mathcal{H}_x$  active, if  $\text{cost}(C) \leq 4 \cdot |\mathcal{O}_C|$ , or if there exists an active cluster  $C' \in \mathcal{H}_{x-1}$  such that  $\mathcal{O}_C \subseteq \mathcal{O}_{C'}$ . Otherwise,  $C$  is called inactive.*

## 18:12 Upper and Lower Bounds for Complete Linkage in General Metric Spaces

The behavior that makes complete linkage more difficult to analyze than single linkage is that the former sometimes merges clusters that are quite far apart. That is, contrary to single linkage, complete linkage can produce clusters that are very expensive relative to the number of optimal clusters hit by them. We mark such clusters as inactive and count them directly the first time they are created. We will see that the number of such clusters is small. However the number of active clusters is potentially large, but if the cost of the clustering reaches  $4k + 2$ , this number can also be bounded as we see in the following lemma.

► **Lemma 14.** *There are at most  $2^k$  active clusters in  $\mathcal{H}_{4k+2}$ .*

**Proof.** Notice that at time  $t_{\leq 4k+2}$  there cannot exist two active clusters  $C_1$  and  $C_2$  with  $\mathcal{O}_{C_1} \subseteq \mathcal{O}_{C_2}$ . Indeed, since  $C_2$  hits all the optimal clusters hit by  $C_1$  we get that

$$\text{cost}(C_1 \cup C_2) \leq \text{cost}(C_2) + 1 \leq 4|\mathcal{O}_{C_2}| + 1 \leq 4k + 1$$

and so  $C_1$  and  $C_2$  would have been merged in  $\mathcal{H}_{4k+2}$ . Now, if there are more than  $2^k$  active clusters in  $\mathcal{H}_{4k+2}$ , then at least two of them must hit exactly the same set of optimal clusters. Since we have just ruled this out, the lemma follows. ◀

We estimate the number of inactive clusters, by looking at the circumstances under which they arise. As it happens, at each step there are not many clusters whose merge yields an inactive cluster.

► **Lemma 15.** *There are at most  $4k^2 + k$  inactive clusters in  $\mathcal{H}_{4k+2}$ .*

**Proof.** Let  $m_x$  be the number of inactive clusters in  $\mathcal{H}_x$ . We show that the recurrence relation  $m_x \leq m_{x-1} + k$  holds for any  $x \in \mathbb{N}$ . In that case  $m_{4k+2} \leq (4k+1)k = 4k^2 + k$  since  $m_1 = 0$  and we are done.

To prove the recurrence relation first fix some arbitrary  $x \in \mathbb{N}$  and let  $D \in \mathcal{H}_x$  be an inactive cluster. Let  $D_1, \dots, D_\ell \in \mathcal{H}_{x-1}$  be the clusters whose merge results in  $D$ . We show that none of them can be active at time  $t_{\leq x-1}$  and have cost at least  $x - 2$ . Since this only leaves few possible clusterings, we get the recurrence inequality given above. Suppose that for one of the clusters, say  $D_i$ , it holds that  $4 \cdot |\mathcal{O}_{D_i}| \geq \text{cost}(D_i) \geq x - 2$ . Right away, notice that  $|\mathcal{O}_{D_i}| < |\mathcal{O}_D|$  since otherwise  $D$  would also be active by definition. But then

$$\text{cost}(D) \leq x \leq \text{cost}(D_i) + 2 \leq 4|\mathcal{O}_{D_i}| + 2 < 4(|\mathcal{O}_{D_i}| + 1) \leq 4|\mathcal{O}_D|$$

contradicts the assumption of  $D$  being inactive. As such, we know that all  $D_i$  ( $i = 1, \dots, \ell$ ) must be inactive or have cost less than  $x - 2$ . In other words, each inactive cluster in  $\mathcal{H}_x$  descends from the set

$$\{D \in \mathcal{H}_{x-1} \mid D \text{ is inactive}\} \cup \{D \in \mathcal{H}_{x-1} \mid \text{cost}(D) < x - 2\}.$$

The cardinality of the set on the left is  $m_{x-1}$  and, by Lemma 10, the cardinality of the set on the right is at most  $k$ . This proves the claim. ◀

► **Corollary 16.**  *$\mathcal{H}_{4k+2}$  consists of at most  $2^k + 4k^2 + k$  clusters.*

Notice that Theorem 9 is an immediate consequence of Corollary 16 and Proposition 12.

## 5.2 An Upper Bound for Diameter-Based Cost

The main challenge in proving an upper bound on the approximation guarantee of complete linkage when replacing the  $k$ -center objective by the  $k$ -diameter objective is to deal with the possibly large increase of cost after a merge step (see Figure 1).

For some arbitrary but fixed  $k$  let  $\mathcal{O}$  denote an optimal  $k$ -diameter solution and assume that  $\text{cost}(\mathcal{O}) = 1$  from now on. To motivate our approach consider the clustering  $\mathcal{H}_1$  computed by complete linkage at time  $t_{\leq 1}$ . Observe that every optimal cluster can fully contain at most one cluster from  $\mathcal{H}_1$ , as the union of such clusters would cost at most 1. Now, consider the graph  $G = (V, E)$  with  $V = \mathcal{O}$  and edges  $\{A, B\} \subset V$  for every cluster  $C \in \mathcal{H}_1$  intersecting  $A$  and  $B$ . If there is such an edge  $\{A, B\}$ , then the cost of merging  $A$  and  $B$  is upper bounded by 3. We can go even further and consider the merge of all optimal clusters in a connected component of  $G$ . Suppose the size of the connected component is  $m$ , then the resulting cluster costs at most  $2m - 1$ . There are two extreme cases in which we could end up: if  $E = \emptyset$ , then  $\mathcal{H}_1 = \mathcal{O}$  and complete linkage has successfully recovered the optimal solution. On the other hand, if  $G$  is connected, then merging all points costs at most  $2k - 1$  and we get an  $O(k)$ -approximative solution. The remaining cases are more difficult to handle. We proceed by successively adding edges between optimal clusters, while maintaining the property that for a connected component  $Z$  in  $G$  merging  $\cup_{A \in V(Z)} A$  costs at most  $|V(Z)|^2$ . This leads to an upper bound of  $k^2$  for all clusters  $C$  constructed by complete linkage with  $C \subset \cup_{A \in V(Z)} A$ . We show that the number of clusters which do not admit this property is sufficiently small, such that in the end, we are able to prove that  $\mathcal{H}_{k^2}$  consists of at most  $k$  clusters. This immediately leads the following theorem.

► **Theorem 17.** *Let  $(\mathcal{C}_k)_{k=1}^n$  be the hierarchical clustering computed by complete linkage on  $(P, \text{dist})$  optimizing the diameter. For all  $1 \leq k \leq n$  the diameter cost  $\text{cost}(\mathcal{C}_k)$  is upper bounded by  $k^2 \text{cost}(\mathcal{O}_k)$ , where  $\mathcal{O}_k$  is an optimal  $k$ -diameter clustering.*

Essential for this section is a sequence of *cluster graphs*  $G_t = (V_t, E_t)$  for  $t = 1, \dots, k^2$  constructed directly on the set  $V_t = \mathcal{O}$  of optimal  $k$ -clusters. We start with the cluster graph  $G_1$  that contains edges  $\{A, B\}$  for every two vertices  $A, B \in V_1 = \mathcal{O}$  that are hit by a common cluster from  $\mathcal{H}_1$ . To this we successively add edges based on a vertex labeling in order to create the remaining cluster graphs  $G_2, \dots, G_{k^2}$ . The labeling distinguishes vertices as being either *active* or *inactive*. We denote the set of active vertices in  $V_t$  by  $V_t^a$  and the set of inactive ones by  $V_t^i$ . In the beginning ( $t = 1$ ) the inactive vertices are set to precisely those that are isolated:  $V_1^i = \{O \in V_1 \mid \delta_{G_1}(O) = \emptyset\}$ . For  $t \geq 2$ , the labeling is outlined in Definition 18. Over the course of time, active vertices may become inactive, but inactive vertices never become active again.

Given a labeling for  $V_{t+1}$ , we construct  $G_{t+1}$  from  $G_t$  by adding additional edges: If there are two active vertices  $A, B \in V_{t+1}^a$  that are both hit by a common cluster from  $\mathcal{H}_{t+1}$ , we add an edge  $\{A, B\}$  to  $E_{t+1}$ .

► **Definition 18.** *Let  $A \in V_{t+1}$  be an arbitrary optimal cluster and  $Z_A$  the connected component in  $G_t$  that contains  $A$ . We call  $A$  inactive (i.e.,  $A \in V_{t+1}^i$ ) if  $\lceil \text{cost}(Z_A) \rceil \leq t$ , and active otherwise. Here, and in the following  $\text{cost}(Z_A) = \text{cost}(\cup_{B \in V(Z_A)} B)$  denotes the cost of merging all optimal clusters contained in  $V(Z_A)$ .*

Thus if a connected component in  $G_t$  has small cost, then all vertices in this component become inactive in  $G_{t+1}$  by definition. We state the following useful properties of inactive vertices in  $(G_t)_{t=1}^{k^2}$ .

► **Lemma 19.** *If  $Z$  is a connected component in  $G_{t+1}$  with  $V(Z) \cap V_{t+1}^i \neq \emptyset$ , then*

1.  $Z$  is also a connected component in  $G_t$  and  $\lceil \text{cost}(Z) \rceil \leq t$ ,
  2. we have  $V(Z) \subseteq V_{t+1}^i$ , i.e., all vertices in  $Z$  become inactive at the same time.
- Moreover we have  $V_t^i \subseteq V_{t+1}^i$ , so once vertices become inactive, they stay inactive. Equivalently,  $V_{t+1}^a \subseteq V_t^a$ .

**Proof.** Take any inactive vertex  $A \in V_{t+1}^i \cap V(Z)$  and consider the connected component  $Z_A$  in  $G_t$  containing  $A$ . By Definition 18, we have that  $\lceil \text{cost}(Z_A) \rceil \leq t$  and so all other vertices in  $Z_A$  have to be in  $V_{t+1}^i$  as well. We observe that  $E_{t+1} \setminus E_t$  only contains edges between vertices from  $V_{t+1}^a$  by construction. This shows  $Z = Z_A$ .

It is left to show that inactive vertices stay inactive. For  $t = 1$  the inactive vertices  $V_1^i$  are already connected components with cost at most 1. As such, they remain inactive at step  $t = 2$ . For  $t \geq 2$ , consider an inactive vertex  $A \in V_t^i$  and the connected component  $Z \subseteq G_t$  containing it. We showed previously that  $V(Z) \subseteq V_t^i$  and so  $Z$  is also a connected component in  $G_{t+1}$  with  $\lceil \text{cost}(Z) \rceil \leq t - 1 < t$  and thus  $A \in V(Z) \subseteq V_{t+1}^i$ . ◀

► **Definition 20.** *Let  $C \in \mathcal{H}_t$  for some fixed  $t \in \mathbb{N}$ . We define  $\mathcal{I}_t = \{C \in \mathcal{H}_t \mid \mathcal{O}_C \cap V_t^i \neq \emptyset\}$  as the set of all clusters in  $\mathcal{H}_t$  which hit at least one inactive vertex of  $G_t$ . We call these clusters inactive and all clusters from  $\mathcal{H}_t \setminus \mathcal{I}_t$  active.*

We prove the following easy property about active clusters.

► **Lemma 21.** *If  $C \in \mathcal{H}_t \setminus \mathcal{I}_t$ , then  $G_t[\mathcal{O}_C]$  forms a clique. In particular there exists a connected component in  $G_t$  that fully contains  $\mathcal{O}_C$ .*

**Proof.** By definition of  $\mathcal{I}_t$ ,  $\mathcal{O}_C$  must consist exclusively of active vertices. Since all of them are hit by  $C \in \mathcal{H}_t$  there exists an edge  $\{A, B\} \in E_t$  for every pair  $A, B \in \mathcal{O}_C$ . In other words,  $G_t[\mathcal{O}_C]$  forms a clique and the claim follows. ◀

This does not necessarily hold for an inactive cluster  $C \in \mathcal{I}_t$ . As  $C$  contains at least one inactive vertex, the connected component  $Z$  which contains this vertex does not grow. If later on complete linkage merges  $C$  with another cluster the result is an inactive cluster which may hit vertices outside of  $Z$ . So  $G_{t'}$  does not reflect the progression of  $C$  for  $t' \geq t$ . However, the number of such clusters cannot exceed  $|V_t^i|$ .

► **Lemma 22.** *The number of inactive clusters in  $\mathcal{H}_t$  is at most the number of inactive vertices at time  $t$ . That is,  $|\mathcal{I}_t| \leq |V_t^i|$  holds for all  $t \in \mathbb{N}$ .*

**Proof.** We prove the claim by showing that the following inductive construction defines a family of injective mappings  $\phi_t : \mathcal{I}_t \rightarrow V_t^i$ :

- Let  $C \in \mathcal{I}_1$  be an inactive cluster. By definition  $C$  thus has to intersect an inactive optimal cluster  $A \in V_1^i$ . Actually, there can only be one such cluster, as any other optimal cluster that is hit would induce an edge incident to  $A$  in  $G_1$ , making it active. Set  $\phi_1(C) = A$ , so that  $\mathcal{O}_C = \{\phi_1(C)\}$ .
- For  $t > 1$  and  $C \in \mathcal{I}_t$  we distinguish two cases: If there is no cluster in  $\mathcal{I}_{t-1}$  that is a subset of  $C$ , we pick an arbitrary but fixed  $A \in \mathcal{O}_C \cap V_t^i$  and set  $\phi_t(C) = A$ . Otherwise, we know that  $C$  must descend from some cluster  $D \in \mathcal{I}_{t-1}$  and we can set  $\phi_t(C) = \phi_{t-1}(D)$ . Since  $\phi_{t-1}(D) \in V_{t-1}^i \subseteq V_t^i$  by Lemma 19, this shows that  $\phi_t$  really maps into  $V_t^i$ .

Suppose that there exist two inactive clusters  $C, D \in \mathcal{I}_1$  that are mapped to the same inactive vertex  $A \in V_1^i$ . Then, by the construction of  $\phi_1$ ,  $\mathcal{O}_C = \{A\} = \mathcal{O}_D$  shows that  $C$  and  $D$  are actually fully contained in the same optimal cluster. The optimal cluster has diameter at most 1 and so  $C$  and  $D$  would have already been merged in  $\mathcal{H}_1$ . As this is not possible,  $\phi_1$  has to be injective.

Now, let  $t \geq 2$  be arbitrary and assume  $\phi_{t-1}$  to be injective. We show that in that case  $\phi_t$  also has to be injective. Suppose on the contrary, that there exist two different clusters  $C, D \in \mathcal{I}_t$  with  $\phi_t(C) = \phi_t(D)$ . We distinguish three cases.

**Case 1:** Both  $C$  and  $D$  descend from (i.e., contain) clusters  $C', D' \in \mathcal{I}_{t-1}$  with  $\phi_t(C) = \phi_{t-1}(C')$  and  $\phi_t(D) = \phi_{t-1}(D')$ , respectively. Then  $\phi_{t-1}(C') = \phi_t(C) = \phi_t(D) = \phi_{t-1}(D')$  entails that  $C' = D'$ , since  $\phi_{t-1}$  is assumed to be injective. Clearly,  $C' = D'$  cannot end up being a subset of two different clusters in  $\mathcal{I}_t$  and so we end up in a contradiction.

**Case 2:** Neither  $C$  nor  $D$  descend from a cluster in  $\mathcal{I}_{t-1}$ . In other words,  $C$  and  $D$  fully descend from clusters in  $\mathcal{H}_{t-1} \setminus \mathcal{I}_{t-1}$  and so there exist clusters  $C', D' \in \mathcal{H}_{t-1} \setminus \mathcal{I}_{t-1}$  contained in  $C$  and  $D$ , respectively, such that  $A = \phi_t(C) = \phi_t(D) \in \mathcal{O}_{C'} \cap \mathcal{O}_{D'}$ . Applying Lemma 21 yields the existence of a connected component  $Z$  in  $G_{t-1}$  with  $V(Z) \supset \mathcal{O}_{C'} \cup \mathcal{O}_{D'}$ . We show that this connected component has cost at most  $t-1$ . In that case,  $C'$  and  $D'$  should have already been merged in  $\mathcal{H}_{t-1}$ ; a contradiction. To show that  $\text{cost}(Z) \leq t-1$ , consider the connected component  $Z'$  in  $G_t$  containing  $A = \phi_t(C) = \phi_t(D) \in \mathcal{O}_C \cap \mathcal{O}_D \cap V_t^i$ . Since  $A$  was chosen from a subset of  $V_t^i$ , we know from Lemma 19 that  $Z'$  is also a connected component in  $G_{t-1}$  with  $\text{cost}(Z') \leq t-1$ . Now,  $A \in V(Z) \cap V(Z')$  shows that  $Z = Z'$  and so we are done.

**Case 3:**  $D$  contains a cluster  $D' \in \mathcal{I}_{t-1}$ , so that  $\phi_t(D) = \phi_{t-1}(D') \in V_{t-1}^i$ , whereas  $C$  does not. (The symmetric case with the roles of  $C$  and  $D$  swapped is left out.) Since  $C$  fully descends from  $\mathcal{H}_{t-1} \setminus \mathcal{I}_{t-1}$ , we know that  $\mathcal{O}_C \subseteq V_{t-1}^a$ . But this already yields a contradiction:  $V_{t-1}^a \ni \phi_t(C) = \phi_t(D) = \phi_{t-1}(D') \in V_{t-1}^i$ .

This covers all possible cases, with each one ending in a contradiction. Hence  $\phi_t$  has to be injective and by induction this holds for all  $t \in \mathbb{N}$ .  $\blacktriangleleft$

Active clusters from  $\mathcal{H}_t$  are nicely represented by the graph  $G_t$  as it is shown in Lemma 21. We can indirectly bound the cost of active clusters by bounding the cost of the connected components they are contained in.

► **Lemma 23.** *Let  $Z$  be a connected component in  $G_t$ . If  $V(Z) \subset V_t^a$ , we have  $\text{cost}(Z) \leq |V(Z)|^2$ .*

**Proof.** Again, we prove this via an induction over  $t$ . For  $t = 1$  and  $A, B \in V(Z)$  we want to upper bound the distance between  $p \in A$  and  $q \in B$ . Let  $A = Q_1, \dots, Q_s = B$  be a simple path connecting  $A$  and  $B$  in  $Z$ . We know by definition of  $G_1$  that for  $j = 1, \dots, s-1$  there is a pair of points  $p_j \in Q_j$  and  $q_j \in Q_{j+1}$  with  $\text{dist}(p_j, q_j) \leq 1$ . Using the triangle inequality we obtain

$$\begin{aligned} \text{dist}(p, q) &\leq \text{dist}(p, p_1) + \sum_{j=1}^{s-2} (\text{dist}(p_j, q_j) + \text{dist}(q_j, p_{j+1})) \\ &\quad + \text{dist}(p_{s-1}, q_{s-1}) + \text{dist}(q_{s-1}, q) \\ &\leq 2s - 1. \end{aligned}$$

Here we use that  $q_j$  and  $p_{j+1}$  are in the same optimal cluster, thus the distance between those points is at most one.

Since  $V(Z)$  contains only active vertices we have  $|V(Z)| \geq 2$ . Using the above upper bound on the distance between two points in  $\bigcup_{A \in V(Z)} A$  we obtain

$$\text{cost}(Z) \leq 2|V(Z)| - 1 \leq |V(Z)|^2.$$

## 18:16 Upper and Lower Bounds for Complete Linkage in General Metric Spaces

For  $t > 1$  let  $Z_1, \dots, Z_u$  denote the connected components in  $G_{t-1}$  with  $V(Z) = \bigcup_{j=1}^u V(Z_j)$ . Let  $j, j' \in \{1, \dots, u\}$ . We observe that  $V(Z_j) \subset V(Z) \subset V_t^a \subset V_{t-1}^a$ . Thus we obtain by induction that

$$\text{cost}(Z_j) \leq |V(Z_j)|^2. \quad (1)$$

Suppose that  $\lceil \text{cost}(Z_j) \rceil \leq t - 1$ . Then  $V(Z_j) \subset V_t^i$  by definition, which is a contradiction to  $V(Z) \cap V_t^i = \emptyset$ . So we must have

$$t \leq \lceil \text{cost}(Z_j) \rceil. \quad (2)$$

Combining (1) and (2) we obtain

$$t \leq \sqrt{\lceil \text{cost}(Z_j) \rceil \lceil \text{cost}(Z_{j'}) \rceil} \leq \sqrt{|V(Z_j)|^2 |V(Z_{j'})|^2} = |V(Z_j)| |V(Z_{j'})|. \quad (3)$$

For  $A, B \in V(Z)$  we want to upper bound the distance between  $p \in A$  and  $q \in B$ . Let  $A = Q_1, \dots, Q_s = B$  be a simple path connecting  $A$  and  $B$  in  $Z$  which enters and leaves every connected component  $Z_j$  for  $j \in \{1, \dots, u\}$  at most once. We divide the path into several parts such that every part lies in one connected component from  $\{Z_1, \dots, Z_u\}$ . Let  $1 = m_1 < m_2 < \dots < m_l = s$  such that  $Q_{m_j}, \dots, Q_{m_{j+1}-1}$  lie in one connected component  $Z^{(j)} \in \{Z_1, \dots, Z_u\}$  and  $Z^{(j)} \neq Z^{(j+1)}$  for all  $j \in \{1, \dots, l\}$ . Since  $(Q_{m_{j-1}}, Q_{m_j}) \in E_t$  we know that there exists a cluster in  $\mathcal{H}_t$  that intersects  $Q_{m_{j-1}}$  and  $Q_{m_j}$ , thus there is a pair of points  $p_j \in Q_{m_{j-1}}$  and  $q_j \in Q_{m_j}$  such that  $\text{dist}(p_j, q_j) \leq t$ . We obtain

$$\begin{aligned} \text{dist}(p, q) &\leq \sum_{j=1}^{l-1} (\text{cost}(Z^{(j)}) + \text{dist}(p_j, q_j)) + \text{cost}(Z^{(l)}) \leq \sum_{j=1}^l (|V(Z^{(j)})|^2 + t) \\ &\leq \left( \sum_{j=1}^l |V(Z^{(j)})| \right)^2 = |V(Z)|^2. \end{aligned}$$

For the second inequality we use (1) and  $\text{dist}(p_j, q_j) \leq t$ . For the third inequality we use (3). So we obtain the claimed upper bound on the cost of  $Z$ .  $\blacktriangleleft$

We see that a connected component in  $G_{k^2}$  cannot contain two active clusters, yielding the following upper bound.

**► Lemma 24.** *At time  $t \leq k^2$  the number of active clusters is less than or equal to the number of active vertices. In other words,  $|\mathcal{H}_{k^2} \setminus \mathcal{I}_{k^2}| \leq |V_{k^2}^a|$ .*

**Proof.** By Lemma 21 we know that every cluster  $C \in \mathcal{H}_{k^2} \setminus \mathcal{I}_{k^2}$  is fully contained in a connected component  $Z_C$  from  $G_{k^2}$ . We show that mapping any such  $C$  to an arbitrary vertex in  $Z_C$  yields an injective map  $\varphi : \mathcal{H}_{k^2} \setminus \mathcal{I}_{k^2} \hookrightarrow V_{k^2}^a$ . First, notice that  $\varphi$  is well-defined: If  $Z_C$  contains an inactive vertex, then all its vertices are inactive (Lemma 19), contradicting the choice of  $C$  as active.

Suppose now that there are two different clusters  $C, C' \in \mathcal{H}_{k^2} \setminus \mathcal{I}_{k^2}$  that are mapped to the same vertex  $\varphi(C) = \varphi(C')$ . Then the connected components  $Z_C$  and  $Z_{C'}$ , in which they are embedded, already have to coincide ( $Z_C = Z_{C'}$ ). But we have just shown (Lemma 23), that  $\text{cost}(Z_C) \leq |V(Z_C)|^2 \leq k^2$  and so  $C$  and  $C'$  would have already been merged in  $\mathcal{H}_{k^2}$ . As such the images of both cannot coincide and the map is injective.  $\blacktriangleleft$

Together with the bound for the number of inactive clusters we are now able to prove the theorem.

**Proof of Theorem 17.** Using Lemma 22&24 we obtain  $|\mathcal{H}_{k^2}| = |\mathcal{H}_{k^2} \setminus \mathcal{I}_{k^2}| + |\mathcal{I}_{k^2}| \leq |V_{k^2}^a| + |V_{k^2}^i| = k$ , yielding  $\text{cost}(\mathcal{C}_k) \leq \text{cost}(\mathcal{H}_{k^2}) \leq k^2 \text{cost}(\mathcal{C}_k)$ .  $\blacktriangleleft$

## A Single Linkage

Let  $(\mathcal{C}_k)_{i=1}^n$  be the hierarchical clustering computed by single linkage on  $(P, \text{dist})$ . Recall that  $\mathcal{C}_{k-1}$  arises from  $\mathcal{C}_k$  by merging two clusters  $A, B \in \mathcal{C}_k$  that minimize  $\text{dist}(A, B)$ .

We first compare the radius of  $\mathcal{C}_k$  to the cost of an optimal  $k$ -center clustering  $\mathcal{O}$ . We introduce a graph  $G$  whose vertices are the optimal clusters  $V(G) = \mathcal{O}$  and whose edges  $E(G) = \{\{O, O'\} \subseteq \mathcal{O} \mid \text{dist}(O, O') \leq 2 \text{cost}(\mathcal{O})\}$  connect all pairs of optimal clusters  $O, O' \in \mathcal{O}$  with distance at most twice the optimal radius.

We make a similar construction to compare the diameter of  $\mathcal{C}_k$  to the cost of an optimal  $k$ -diameter clustering  $\mathcal{O}'$ . We consider the graph  $G'$  with  $V(G') = \mathcal{O}'$  where two clusters in  $\mathcal{O}'$  are connected via an edge if their distance is at most  $\text{cost}(\mathcal{O}')$ .

## 18:18 Upper and Lower Bounds for Complete Linkage in General Metric Spaces

To estimate the cost of a single linkage cluster  $C \in \mathcal{C}_k$  we look at the optimal clusters hit by  $C$ . The next lemma shows that for any two points in  $C$  we can find a path connecting them that passes through a chain of optimal clusters with distance at most  $2 \text{cost}(\mathcal{O})$  or  $\text{cost}(\mathcal{O}')$  when considering the radius or diameter, respectively. One can already anticipate that this gives an upper bound of  $O(k)$  on the radius or diameter of any such cluster  $C$ . In Figure 3 we see an example of such a cluster  $C$  and the optimal clusters hit by  $C$ .

► **Lemma 25.** *Let  $C \in \mathcal{C}_t$  be a cluster computed by single linkage at a time step  $t \geq k$ . Then the graphs  $G[\mathcal{O}_C]$  and  $G'[\mathcal{O}'_C]$  induced by the vertex set of optimal clusters hit by  $C$  are connected.*

**Proof.** We prove the lemma for  $G[\mathcal{O}_C]$  by induction. At the beginning ( $t = n$ ) the lemma obviously holds, since any cluster contained in  $\mathcal{C}_n$  is a point and thus hits only one single optimal cluster. Assume now that the claim holds for  $t > k$ . By the pigeonhole principle there must exist two clusters  $C, C' \in \mathcal{C}_t$  with two points  $c \in C$  and  $c' \in C'$  lying in the same optimal cluster  $O \in \mathcal{O}$ . We know that  $\text{dist}(C, C') \leq 2 \text{cost}(O) \leq 2 \text{cost}(\mathcal{O})$ . But this value is exactly the objective that single linkage minimizes, so we know in particular that this upper bound also holds for the distance between the clusters  $D, D'$  chosen by single linkage. Combining this with the induction hypothesis that both  $G[\mathcal{O}_D]$  and  $G[\mathcal{O}_{D'}]$  are connected finishes the proof. One proves analogously that  $G'[\mathcal{O}'_C]$  is connected. ◀

As we see in Figure 3 this already yields an upper bound of  $2k \text{cost}(\mathcal{O}')$  on the diameter of  $C$ . We estimate the radius of  $C$  by looking at the paths going through optimal clusters in  $\mathcal{O}_C$  that are at distance at most  $2 \text{cost}(\mathcal{O})$  from one another. Choosing the center appropriately and uncoiling these paths in our original space  $P$  yields our upper bound of  $(2k + 2) \text{cost}(\mathcal{O})$ .

► **Theorem 1.** *Let  $(\mathcal{C}_k)_{k=1}^n$  be the hierarchical clustering computed by single linkage on  $(P, \text{dist})$  and let  $\mathcal{O}_k$  be an optimal clustering for  $k$ -center or  $k$ -diameter, respectively. We have for all  $1 \leq k \leq n$*

1.  $\text{cost}(\mathcal{C}_k) \leq (2k + 2) \cdot \text{cost}(\mathcal{O}_k)$  for the  $k$ -center cost
2.  $\text{cost}(\mathcal{C}_k) \leq 2k \cdot \text{cost}(\mathcal{O}_k)$  for the  $k$ -diameter cost.

**Proof.** We prove the statement for  $k$ -center. Fix an arbitrary time step  $1 \leq k \leq n$  and denote  $\mathcal{O} = \mathcal{O}_k$ . Let  $C \in \mathcal{C}_k$  be an arbitrary cluster and  $P$  a longest simple path in  $G[\mathcal{O}_C]$ . Choose as center for  $C$  an arbitrary vertex  $c \in C \cap O$  from an optimal cluster  $O$  lying in the middle of  $P$ . Note that by this choice every other vertex in  $G[\mathcal{O}_C]$  is reachable from  $O$  by a path of length at most  $\frac{k}{2}$ . Uncoiling such paths in  $P$  gives us an upper bound of  $2(k + 1) \text{cost}(\mathcal{O})$  for the distance between  $c$  and any other point  $z \in C$  as follows: If  $O_z \in \mathcal{O}$  is the optimal cluster containing  $z$ , then by choice of  $O$ , there exists a path  $O = O_1, \dots, O_{\ell+1} = O_z$  in  $G[\mathcal{O}_C]$  of length  $\ell \leq \frac{k}{2}$  connecting them. That means, for each  $i = 1, \dots, \ell$  there exist points  $x_i \in O_i, y_{i+1} \in O_{i+1}$  such that  $\text{dist}(x_i, y_{i+1}) \leq 2 \text{cost}(\mathcal{O})$ . Hence

$$\begin{aligned} \text{dist}(c, z) &\leq \text{dist}(c, x_1) + \sum_{i=1}^{\ell-1} (\text{dist}(x_i, y_{i+1}) + \text{dist}(y_{i+1}, x_{i+1})) \\ &\quad + \text{dist}(x_\ell, y_{\ell+1}) + \text{dist}(y_{\ell+1}, z) \\ &\leq 2(2\ell + 1) \text{cost}(\mathcal{O}) \leq 2(k + 1) \text{cost}(\mathcal{O}). \end{aligned}$$

Using Lemma 25 one proves the statement for  $k$ -diameter analogously. ◀

■ **Figure 3** Cluster  $C$  hits the optimal clusters  $A_1, \dots, A_\ell$  with  $\text{dist}(A_i, A_{i+1}) \leq 2 \text{cost}(\theta)$  when considering the radius on the left and  $\text{dist}(A_i, A_{i+1}) \leq \text{cost}(\theta')$  when considering the diameter on the right. In the left picture, we see that choosing center  $c$  in  $A_{\lceil \frac{\ell}{2} \rceil}$  leads to radius  $\leq 2(\ell + 1) \text{cost}(\theta)$ . Similarly the diameter of  $C$  in the right picture is at most  $2\ell \text{cost}(\theta)$ .

## B A Lower Bound for Complete Linkage without Bad Ties

In this section we focus on modifying the instance  $(V(P_k), \text{dist})$  such that merging two  $\ell$ -graphs  $G_\ell, G'_\ell$  which are part of the same  $(\ell + 1)$ -graph is slightly cheaper than performing any other merge in a clustering consisting of all  $\ell$ -graphs.

### B.1 Diameter-Based Cost

We explain how to adjust the construction of the  $k$ -components for the diameter. Let  $\epsilon \in (0, \frac{1}{2})$ . The definition of  $K_1$  stays the same. As before a  $k$ -component is constructed from two copies  $K_{k-1}^{(0)}, K_{k-1}^{(1)}$  of the  $(k - 1)$ -component by taking the disjoint union of the corresponding graphs and increasing the level of each point in  $K_{k-1}^{(1)}$  by one. Here we do not add an edge of weight  $k - 1$  between the unique point  $s \in V(G_{k-1}^{(0)})$  with level 1 and  $t \in V(G_{k-1}^{(1)})$  with level  $k$ . Instead we complete  $G_k$  by adding edges of weight  $(k - 1)(1 - \epsilon)$  between  $x \in V(G_{k-1}^{(0)})$  and  $y \in V(G_{k-1}^{(1)})$  if they are not on the same level, i.e.,  $\phi_k(x) \neq \phi_k(y)$ .

The instance  $P_k$  is then constructed from  $k$ -copies  $K_k^{(1)}, \dots, K_k^{(k)}$  of the  $k$ -component  $K_k$ . We take the disjoint union of the corresponding  $k$ -graphs  $G_k^{(1)}, \dots, G_k^{(k)}$  and connect them by adding edges  $\{x, y\}$  of weight 1 for every two points  $x \in V(G_k^{(i)})$  and  $y \in V(G_k^{(j)})$  with  $\phi_k^{(i)}(x) = \phi_k^{(j)}(y)$ .

We show that the clustering computed by complete linkage on  $(V(P_k), \text{dist})$  at time  $t_{\leq \ell(1-\epsilon)}$  consists exactly of the  $(\ell + 1)$ -graphs that make up the instance.

► **Lemma 26.** *The distance between two points  $x, y \in V(P_k)$  is at least  $|\phi_k(x) - \phi_k(y)|(1 - \epsilon)$ .*

**Proof.** By the inductive construction of the components, an edge which crosses  $w$  levels costs at least  $w(1 - \epsilon)$ . Hence the distance between  $x$  and  $y$  is at least  $|\phi_k(x) - \phi_k(y)|(1 - \epsilon)$ . ◀

As before we use the previous lemma to show that the diameter of any  $\ell$ -graph in  $P_k$  is  $(\ell - 1)(1 - \epsilon)$ .

► **Lemma 27.** *Let  $G_\ell$  be an  $\ell$ -graph contained in  $P_k$ . We have  $\text{cost}(G_\ell) = (\ell - 1)(1 - \epsilon)$ .*

**Proof.** We prove the upper bound  $\text{cost}(G_\ell) \leq (\ell - 1)(1 - \epsilon)$  by induction. The 1-graphs are points and so the claim follows trivially for  $\ell = 1$ . Assume now that we have shown the claim for  $\ell - 1$ . Let  $G_\ell$  be an  $\ell$ -graph and  $s, t \in V(G_\ell)$  points such that  $\text{cost}(G_\ell) = \text{dist}(s, t)$ . If

## 18:20 Upper and Lower Bounds for Complete Linkage in General Metric Spaces

these points lie in the same graph, say  $G_{\ell-1}^{(0)}$ , of the two  $(\ell-1)$ -graphs  $G_{\ell-1}^{(0)}$  and  $G_{\ell-1}^{(1)}$  that make up  $G_\ell$ , then

$$\text{dist}(s, t) \leq \text{cost}(G_{\ell-1}^{(0)}) \leq (\ell-2)(1-\epsilon) < (\ell-1)(1-\epsilon)$$

by induction and we are done. Otherwise we may assume that  $s \in V(G_{\ell-1}^{(0)})$  and  $t \in V(G_{\ell-1}^{(1)})$ . We distinguish two cases. If  $\phi_k(s) = \phi_k(t)$  these points are connected by an edge of weight one by construction. Notice that an  $\ell$ -graph does not contain points with the same level if  $\ell \leq 2$ . Using  $\epsilon \leq \frac{1}{2}$  and  $\ell \geq 3$  we obtain

$$\text{dist}(s, t) = 1 \leq (\ell-1)(1-\epsilon).$$

If  $s$  and  $t$  are on different levels there is an edge of weight  $(\ell-1)(1-\epsilon)$  between  $s$  and  $t$  by construction. Thus we obtain in all cases

$$\text{cost}(G_\ell) = \text{dist}(s, t) \leq (\ell-1)(1-\epsilon).$$

To see the lower bound  $\text{cost}(G_\ell) \geq (\ell-1)(1-\epsilon)$ , we apply Lemma 26 to the unique point  $s \in V(G_\ell)$  with  $\phi_\ell(s) = 1$  and the unique point  $t \in V(G_\ell)$  with  $\phi_\ell(t) = \ell$ . This shows that  $\text{cost}(G_\ell) \geq \text{dist}(s, t) \geq (\ell-1)(1-\epsilon)$ . ◀

We show that complete linkage must reconstruct these components as clusters.

► **Lemma 28.** *Complete linkage must merge clusters on  $(V(P_k), \text{dist})$  in such a way that for all  $\ell < k$ , the clustering  $\mathcal{H}_{\ell(1-\epsilon)}$  consists exactly of the  $(\ell+1)$ -graphs that make up  $P_k$ .*

**Proof.** We prove the claim by induction. Complete linkage always starts with every point in a separate cluster. Since those are exactly the 1-graphs and any merge of two points costs at least  $(1-\epsilon)$ , the claim follows for  $\ell = 0$ . Suppose now that  $\mathcal{H}_{(\ell-1)(1-\epsilon)}$  consists exactly of the  $\ell$ -graphs of the instance. Consider two  $\ell$ -graphs  $G_\ell \neq G'_\ell$  contained in the current clustering. We compute the cost of merging  $G_\ell$  with  $G'_\ell$ . For this purpose we distinguish whether they are contained in the same  $(\ell+1)$ -graph or not.

**Case 1:** If they are contained in the same  $(\ell+1)$ -graph  $G_{\ell+1}$  merging  $G_\ell$  with  $G'_\ell$  results in  $G_{\ell+1}$ . We obtain by Lemma 27, that  $\text{cost}(G_{\ell+1}) = \ell(1-\epsilon)$ .

**Case 2:** If they are not contained in the same  $(\ell+1)$ -graph, we show that merging  $G_\ell$  with  $G'_\ell$  costs more than  $\ell(1-\epsilon)$ . We make the following observations.

1. The edges connecting  $x \in V(G_\ell)$  and  $y \in V(G'_\ell)$  with  $\phi_k(x) \neq \phi_k(y)$  are of weight  $\geq (\ell+1)(1-\epsilon)$ .
2. There exist  $s \in V(G_\ell)$  and  $t \in V(G'_\ell)$  with  $|\phi_k(s) - \phi_k(t)| \geq \ell-1$ .

The last observation follows from the fact that each of the graphs contains two points whose difference in levels is exactly  $\ell-1$ .

We prove that  $\text{dist}(s, t) > \ell(1-\epsilon)$  and therefore merging  $G_\ell$  with  $G'_\ell$  costs more than  $\ell(1-\epsilon)$ . Any shortest path connecting  $s$  and  $t$  in  $P_k$  must contain an edge  $\{u, w\}$  between a point  $u \in V(G_\ell)$  and a point  $w \in V(G'_\ell)$ . By above observation this edge is either of weight  $\geq (\ell+1)(1-\epsilon)$  or  $u$  and  $w$  are on the same level and the edge is of weight 1. In the first case we conclude

$$\text{dist}(s, t) \geq (\ell+1)(1-\epsilon) > \ell(1-\epsilon).$$

In the second case we obtain that

$$\begin{aligned}
\text{dist}(s, t) &= \text{dist}(s, u) + 1 + \text{dist}(w, t) \\
&\geq |\phi_k(s) - \phi_k(u)|(1 - \epsilon) + 1 + |\phi_k(w) - \phi_k(t)|(1 - \epsilon) \\
&= |\phi_k(s) - \phi_k(t)|(1 - \epsilon) + 1 \\
&\geq (\ell - 1)(1 - \epsilon) + 1 \\
&> \ell(1 - \epsilon).
\end{aligned}$$

We see that  $\mathcal{H}_{\ell(1-\epsilon)}$  must consist exactly of the  $(\ell + 1)$ -graphs of  $P_k$ .  $\blacktriangleleft$

Lemma 28 shows that  $\mathcal{H}_{(k-1)(1-\epsilon)}$  consists of all the  $k$ -graphs that make up  $P_k$ . There are exactly  $k$  of them, thus the  $k$ -clustering produced by complete linkage costs  $(k - 1)(1 - \epsilon)$ .

► **Corollary 29.** *However the tie-breaks are resolved, complete linkage computes a  $k$ -clustering on  $(V(P_k), \text{dist})$  with diameter  $(k - 1)(1 - \epsilon)$  while the optimal  $k$ -clustering has diameter 1.*

## B.2 Radius-Based Cost

We explain how to adjust the construction of the  $k$ -components for the radius. Let  $\epsilon \in (0, \frac{1}{2})$ . The definition of  $K_1$  does not change. As before a  $k$ -component is constructed from two copies  $K_{k-1}^{(0)}, K_{k-1}^{(1)}$  of the  $(k - 1)$ -component by taking the disjoint union of the corresponding graphs and increasing the level of each point in  $K_{k-1}^{(1)}$  by one. We complete  $G_k$  by adding edges between  $x \in V(G_{k-1}^{(0)})$  and  $y \in V(G_{k-1}^{(1)})$  if  $\phi_k(x) \neq \phi_k(y)$  and we assign this edge a weight of  $\lceil \frac{k}{2} \rceil (1 - \epsilon)$  if  $|\phi_k(x) - \phi_k(y)| \leq \lceil \frac{k}{2} \rceil - 1$  and otherwise a weight of  $|\phi_k(x) - \phi_k(y)|(1 - \epsilon)$ .

As before the instance  $P_k$  is constructed from  $k$ -copies  $K_k^{(1)}, \dots, K_k^{(k)}$  of the  $k$ -component  $K_k$ . We take the disjoint union of the corresponding  $k$ -graphs  $G_k^{(1)}, \dots, G_k^{(k)}$  and connect them by adding edges  $\{x, y\}$  of weight 1 for every two points  $x \in V(G_k^{(i)})$  and  $y \in V(G_k^{(j)})$  with  $\phi_k^{(i)}(x) = \phi_k^{(j)}(y)$ . We observe that Lemma 26 still holds on the adjusted instance. Also notice that the diameter of an  $\ell$ -graph is still upper bounded by  $(\ell - 1)(1 - \epsilon)$ .

► **Lemma 30.** *Let  $G_{2\ell}$  be any of the  $2\ell$ -graphs that constitute  $P_k$  for  $1 \leq \ell \leq \frac{k}{2}$ . It holds that  $\text{cost}(G_{2\ell}) = \ell(1 - \epsilon)$ . Furthermore let  $G'_{2\ell}$  be a second  $2\ell$ -graph which is not contained in the same  $2(\ell + 1)$ -graph as  $G_{2\ell}$ . Any cluster containing  $G_{2\ell}$  and  $G'_{2\ell}$  costs at least  $\ell(1 - \epsilon) + 1$ .*

**Proof.** We know that  $G_{2\ell}$  contains points  $s$  and  $t$  with  $|\phi_k(s) - \phi_k(t)| = 2\ell - 1$ . Thus for any  $x \in V(P_k)$  we have  $\max\{|\phi_k(s) - \phi_k(x)|, |\phi_k(t) - \phi_k(x)|\} \geq \ell$ . By Lemma 26 we know that  $\max\{\text{dist}(s, x), \text{dist}(t, x)\} \geq \ell(1 - \epsilon)$  and therefore  $\text{cost}(G_{2\ell}) \geq \ell(1 - \epsilon)$ .

To prove the upper bound suppose that  $G_{2\ell}$  covers the levels  $\lambda$  up to  $\lambda + 2\ell - 1$  in  $P_k$ . Consider the unique  $(\ell + 1)$ -graph  $H_{\ell+1}$  contained in  $G_{2\ell}$  covering the levels  $\lambda + \ell - 1$  to  $\lambda + 2\ell - 1$ . Let  $c$  be the unique point in  $H_{\ell+1}$  with level  $\lambda + \ell - 1$ . Remember that the diameter of  $H_{\ell+1}$  is at most  $\ell(1 - \epsilon)$ , so any point in  $H_{\ell+1}$  is at distance  $\leq \ell(1 - \epsilon)$  to  $c$ . Consider now a point  $x \in V(G_{2\ell}) \setminus V(H_{\ell+1})$ . We know that  $\phi_k(x) < \lambda + 2\ell - 1$ . Thus  $|\phi_k(x) - \phi_k(c)| \leq \ell - 1$ . By construction there exists an edge of weight at most  $\ell(1 - \epsilon)$  between  $x$  and  $c$  and thus  $\text{dist}(x, c) \leq \ell(1 - \epsilon)$ .

It is left to show that any cluster containing  $G_{2\ell}$  and  $G'_{2\ell}$  costs at least  $\ell(1 - \epsilon) + 1$ . Let  $y \in V(P_k)$  and let  $H_{2(\ell+1)}$  be the  $2(\ell + 1)$ -graph containing  $y$ . Assume without loss of generality that  $G_{2\ell}$  is not contained in  $H_{2(\ell+1)}$ . Let  $x \in V(G_{2\ell})$  be a point with  $|\phi_k(x) - \phi_k(y)| \geq \ell$ . We claim that  $\text{dist}(x, y) \geq (\ell - 1)(1 - \epsilon) + 1$ . A shortest path connecting  $x$  and  $y$  must contain an edge  $\{u, w\}$  with  $u \in V(P_k) \setminus V(H_{2(\ell+1)})$  and  $w \in V(H_{2(\ell+1)})$ . We

## 18:22 Upper and Lower Bounds for Complete Linkage in General Metric Spaces

know by construction that either  $\phi_k(u) = \phi_k(w)$ , or the edge weights at least  $(\ell + 2)(1 - \epsilon)$ . In the first case we use Lemma 26 and obtain

$$\begin{aligned} \text{dist}(x, y) &= \text{dist}(x, u) + \text{dist}(u, w) + \text{dist}(w, y) \\ &\geq |\phi_k(x) - \phi_k(u)|(1 - \epsilon) + 1 + |\phi_k(w) - \phi_k(y)|(1 - \epsilon) \\ &= |\phi_k(x) - \phi_k(y)|(1 - \epsilon) + 1 \\ &\geq \ell(1 - \epsilon) + 1 \end{aligned}$$

and in the second case we obtain

$$\text{dist}(x, y) \geq (\ell + 2)(1 - \epsilon) \geq \ell(1 - \epsilon) + 1. \quad \blacktriangleleft$$

This immediately leads the following results.

► **Corollary 31.** *Complete linkage must merge clusters on  $(V(P_k), \text{dist})$  in such a way that for all  $1 \leq \ell \leq \frac{k}{2}$ , the clustering  $\mathcal{H}_{\ell(1-\epsilon)}$  consists exactly of the  $2\ell$ -graphs that make up  $P_k$ .*

► **Corollary 32.** *However the tie-breaks are resolved, complete linkage computes a  $k$ -clustering on  $(V(P_k), \text{dist})$  with radius  $\frac{k}{2}(1 - \epsilon)$ , while the optimal  $k$ -clustering has radius 1.*

### C An Upper Bound for Radius-Based Cost

► **Corollary 11.** *For all  $i \in \mathbb{N}_+$  and  $x \geq 0$  it holds that  $|\mathcal{H}_{x+i}| \leq k + \frac{1}{2^i}(|\mathcal{H}_x| - k)$ .*

**Proof.** First, we consider what happens when we increase the cost by 1. We fix an arbitrary  $x' \geq 0$ . Lemma 10 shows that at most  $k$  clusters from  $\mathcal{H}_{x'}$  are left untouched, while the remaining  $|\mathcal{H}_{x'}| - k$  clusters have to be merged with at least one other cluster (thus at least halving the number of those clusters) to get to  $\mathcal{H}_{x'+1}$ . This yields a bound of

$$|\mathcal{H}_{x'+1}| \leq k + \frac{1}{2}(|\mathcal{H}_{x'}| - k).$$

Now, the case for general  $i \in \mathbb{N}$  follows by a straightforward induction. We have just shown that the claim is true for  $i = 1$ , where we set  $x' = x$ . For the induction step suppose that

$$|\mathcal{H}_{x+i-1}| \leq k + \frac{1}{2^{i-1}}(|\mathcal{H}_x| - k).$$

Substituting this into the inequality

$$|\mathcal{H}_{x+i}| \leq k + \frac{1}{2}(|\mathcal{H}_{x+i-1}| - k),$$

derived from the first part of our proof with  $x' = x + i - 1$ , yields

$$|\mathcal{H}_{x+i}| \leq k + \frac{k + \frac{1}{2^{i-1}}(|\mathcal{H}_x| - k) - k}{2} = k + \frac{1}{2^i}(|\mathcal{H}_x| - k)$$

as claimed. ◀

## Abstract

We study two-pass streaming algorithms for Maximum Bipartite Matching (MBM). All known two-pass streaming algorithms for MBM operate in a similar fashion: They compute a maximal matching in the first pass and find 3-augmenting paths in the second in order to augment the matching found in the first pass. Our aim is to explore the limitations of this approach and to determine whether current techniques can be used to further improve the state-of-the-art algorithms. We give the following results:

We show that every two-pass streaming algorithm that solely computes a maximal matching in the first pass and outputs a  $(2/3 + \epsilon)$ -approximation requires  $n^{1+\Omega(\frac{1}{\log \log n})}$  space, for every  $\epsilon > 0$ , where  $n$  is the number of vertices of the input graph. This result is obtained by extending the Ruzsa-Szemerédi graph construction of [Goel et al., SODA'12] so as to ensure that the resulting graph has a close to perfect matching, the key property needed in our construction. This result may be of independent interest.

Furthermore, we combine the two main techniques, i.e., subsampling followed by the GREEDY matching algorithm [Konrad, MFCS'18] which gives a  $2 - \sqrt{2} \approx 0.5857$ -approximation, and the computation of *degree-bounded semi-matchings* [Esfandiari et al., ICDMW'16][Kale and Tirodkar, APPROX'17] which gives a  $\frac{1}{2} + \frac{1}{12} \approx 0.5833$ -approximation, and obtain a meta-algorithm that yields Konrad's and Esfandiari et al.'s algorithms as special cases. This unifies two strands of research. By optimizing parameters, we discover that Konrad's algorithm is optimal for the implied class of algorithms and, perhaps surprisingly, that there is a second optimal algorithm. We show that the analysis of our meta-algorithm is best possible. Our results imply that further improvements, if possible, require new techniques.

## 1 Introduction

In the *semi-streaming model* for processing large graphs, an  $n$ -vertex graph is presented to an algorithm as a sequence of its edges in arbitrary order. The algorithm makes one or few passes over the input stream and maintains a memory of size  $O(n \text{ polylog } n)$ .

The semi-streaming model has been extensively studied since its introduction by Feigenbaum et al. in 2004 [11], and various graph problems, including matchings, independent sets, spanning trees, graph sparsification, subgraph detection, and others are known to admit semi-streaming algorithms (see [23] for an excellent survey). Among these problems, the Maximum Matching problem and, in particular, its bipartite version, the Maximum Bipartite Matching (MBM) problem, have received the most attention (see, for example, [11, 22, 1, 20, 13, 16, 8, 15, 19, 12, 5, 10, 2, 4, 17]).

**Algorithm 1** GREEDY Matching.

---

**Input:** Graph  $G = (A, B, E)$

- 1:  $M \leftarrow \emptyset$
- 2: **for each** edge  $e \in E$  (arbitrary order)
- 3:     **if**  $M \cup \{e\}$  is a matching
- 4:          $M \leftarrow M \cup \{e\}$
- 5: **return**  $M$

---

**Algorithm 2** GREEDY <sub>$d$</sub>  Semi-Matching.

---

**Input:** Graph  $G = (A, B, E)$ , integer  $d$

- 1:  $S \leftarrow \emptyset$
- 2: **for each** edge  $ab \in E$  (arbitrary order)
- 3:     **if**  $\deg_S(a) = 0$  **and**  $\deg_S(b) < d$
- 4:          $S \leftarrow S \cup \{ab\}$
- 5: **return**  $S$

---

In this paper, we focus on MBM. The currently best one-pass semi-streaming algorithm for MBM is the GREEDY matching algorithm (depicted in Algorithm 1). GREEDY processes the edges of a graph in arbitrary order and inserts the current edge into an initially empty matching if possible. It produces a maximal matching, which is known to be at least half the size of a maximum matching, and constitutes a  $\frac{1}{2}$ -approximation semi-streaming algorithm for MBM. It is a long-standing open question whether GREEDY is optimal for the class of semi-streaming algorithms or whether an improved approximation ratio is possible. Progress has been made on the lower bound side ([13, 16, 17]), ruling out semi-streaming algorithms with approximation ratio better than  $\frac{1}{1+\ln 2} \approx 0.5906$  [17].

Konrad et al. [20] were the first to show that an approximation ratio better than  $\frac{1}{2}$  can be achieved if two passes over the input are allowed, and further successive improvements [15, 8, 19] led to a two-pass semi-streaming algorithm with an approximation factor of  $2 - \sqrt{2} \approx 0.58578$  [19] (see Table 1 for an overview of two-pass algorithms for MBM).

**Table 1** Two-pass semi-streaming algorithms for Maximum Bipartite Matching.

Approximation Factor	Reference	Comment
$\frac{1}{2} + 0.019$	Konrad et al. [20]	randomized
$\frac{1}{2} + \frac{1}{16} = 0.5625$	Kale and Tirodkar [15]	deterministic
$\frac{1}{2} + \frac{1}{12} \approx 0.5833$	Esfandiari et al. [8]	deterministic
$2 - \sqrt{2} \approx 0.5857$	Konrad [19]	randomized

All known two-pass streaming algorithms proceed in a similar fashion. In the first pass, they run GREEDY in order to compute a maximal matching  $M$ . In the second pass, they pursue different strategies to compute additional edges  $F$  that allow them to increase the size of  $M$ . Two techniques for computing the edge set  $F$  have been used:

1. **Subsampling and Greedy** [19] (see also [20]): Given a bipartite graph  $G = (A, B, E)$  and a first-pass maximal matching  $M$ , they first subsample the edges  $M$  with probability  $p$  and obtain a matching  $M' \subseteq M$ . Then, in the second pass, they compute GREEDY matchings  $M_L$  and  $M_R$  on subgraphs  $G_L = G[A(M') \cup \overline{B(M)}]$  and  $G_R = G[\overline{A(M)} \cup B(M')]$ , respectively, where  $A(M')$  are the matched  $A$ -vertices in  $M'$ ,  $\overline{B(M)}$  are the unmatched  $B$  vertices, and  $B(M')$  and  $\overline{A(M)}$  are defined similarly. It can be seen that if  $M$  is relatively small, then  $M' \cup M_L \cup M_R$  contains many disjoint 3-augmenting paths. Setting  $p = \sqrt{2} - 1$  yields the approximation factor  $2 - \sqrt{2}$ .
2. **Semi-matchings and Greedy <sub>$d$</sub>**  [15, 8]: Given a bipartite graph  $G = (A, B, E)$  and a first-pass maximal matching  $M$ , the second pass consists of finding *degree- $d$ -constrained semi-matchings*  $S_L$  and  $S_R$  on subgraphs  $G_L = G[A(M) \cup \overline{B(M)}]$  and  $G_R = G[\overline{A(M)} \cup B(M)]$ , respectively, using the algorithm GREEDY <sub>$d$</sub>  (as depicted in Algorithm 2). A degree- $d$ -constrained semi-matching in a bipartite graph is a subset of edges  $S \subseteq E$  such

that  $\deg_S(a) \leq 1$  and  $\deg_S(b) \leq d$ , for every  $a \in A$  and  $b \in B$  or vice versa<sup>1</sup>. Similar to the method above, it can be seen that if the matching  $M$  is relatively small,  $M \cup S_L \cup S_R$  contains many disjoint 3-augmenting paths. The setting  $d = 3$  yields the approximation factor  $\frac{1}{2} + \frac{1}{12}$ .

**Our Results.** In this paper, we explore the limitations of this approach and investigate whether current techniques can be used to further improve the state-of-the-art.

Our first result is a limitation result on the approximation factor achievable by algorithms that follow the scheme described above:

► **Theorem 1 (simplified).** *Every two-pass semi-streaming algorithm for MBM that solely runs GREEDY in the first pass has an approximation factor of at most  $\frac{2}{3}$ .*

Our result builds upon a result by Goel et al. [13] who proved that the lower bound of Theorem 1 applies to one-pass streaming algorithms. Their construction relies on the existence of dense *Ruzsa-Szemerédi* graphs with large induced matchings, i.e., bipartite  $2n$ -vertex graphs  $G = (A, B, E)$  with  $|A| = |B| = n$  whose edge sets can be partitioned into disjoint induced matchings such that each matching is of size at least  $(\frac{1}{2} - \delta)n$ , for some small  $\delta$ . Our construction requires similarly dense RS graphs with equally large matchings, however, in addition to these properties, our RS graphs must contain a *near-perfect* matching, i.e., a matching that matches all but a small constant fraction of the vertices. To this end, we augment the RS graph construction by Goel et al.: We show that, for each induced matching  $M$  in Goel et al.'s construction, we can add a matching  $M'$  to the construction without violating the induced matching property such that  $M \cup M'$  forms a near-perfect matching. We believe this result may be of independent interest.

Next, we combine the subsampling and semi-matching techniques and give a meta-algorithm that yields Konrad's and Esfandiari et al.'s algorithms as special cases, thereby unifying two strands of research. Our meta-algorithm is parameterised by a sampling probability  $0 < p \leq 1$  and an integral degree bound  $d \geq 1$ . First, as in the subsampling technique, the edges of the first-pass matching  $M$  are subsampled independently with probability  $p$ , which yields a subset  $M' \subseteq M$ . Next, as in the semi-matching technique, incomplete semi-matchings  $S_L$  and  $S_R$  with degree bounds  $d$  are computed, however, now in the subgraphs  $G'_L = G[A(M') \cup \overline{B(M)}]$  and  $G'_R = G[\overline{A(M)} \cup B(M')]$ . The algorithm then outputs the largest matching among the edges  $M \cup S_L \cup S_R$ .

As our second result, we establish the approximation factor of our meta-algorithm:

► **Theorem 2 (simplified).** *Combining the subsampling and semi-matching techniques yields a two-pass semi-streaming algorithm for MBM with approximation factor*

$$\begin{cases} \frac{1}{2} + (\frac{1}{d+p} - \frac{1}{2d}) \cdot p, & \text{if } p \leq d(\sqrt{2} - 1) \\ \frac{1}{2} + \frac{d-p}{6d+2p}, & \text{otherwise,} \end{cases}$$

(ignoring lower order terms) that succeeds with high probability.

Interestingly, two parameter settings maximize the approximation factor in Theorem 2, achieving the ratio  $2 - \sqrt{2}$  (see Figure 1). This is achieved by setting  $d = 1$  and  $p = \sqrt{2} - 1$  which recovers Konrad's algorithm, and by setting  $d = 2$  and  $p = 2\sqrt{2} - 2$  which gives a new algorithm. The setting  $d = 3$  and  $p = 1$  yields the slightly weaker bound  $\frac{1}{2} + \frac{1}{12} \approx 0.5833$  and recovers Esfandiari et al.'s algorithm.

<sup>1</sup> The usual definition of a semi-matching requires  $\deg_S(a) = 1$ , for every  $a \in A$  (e.g. [9, 21]). This property is not required here, and, for ease of notation, we stick to this term.

■ **Figure 1** Approximation factors for different settings of  $d$ .

We also show that the analysis of our meta-algorithm is tight, by giving instances on which our meta-algorithm does not perform better than the claimed bound (**Theorem 12**).

**Discussion.** Our results demonstrate that new techniques are needed in order to improve on the  $(2 - \sqrt{2})$  approximation factor. However, one may wonder whether  $2 - \sqrt{2}$  is the best approximation ratio achievable by the class of two-pass matching algorithms that solely computes a maximal matching in the first pass. As pointed out by Kapralov [17], his techniques for establishing the  $\frac{1}{1+\ln 2}$  lower bound for one-pass algorithms can probably also be applied to a construction by Huang et al. [14], which would then show that  $2 - \sqrt{2}$  is the best approximation factor achievable by one-pass semi-streaming algorithms for MBM. It is unclear whether a first-pass GREEDY matching could be embedded in the resulting construction without affecting its hardness, however, if possible, this would render Konrad’s algorithm optimal for the considered class of two-pass streaming algorithms.

**Further Related Work.** Besides two passes over the input, improvements over the GREEDY algorithm can also be obtained under the assumption that the input stream is in random order. Assadi and Behnezhad [2] recently showed that an approximation factor of  $\frac{2}{3} + \epsilon$  can be obtained, for some fixed small but constant  $\epsilon > 0$ , building on Bernstein’s breakthrough result [5], and improving on previous algorithms [5, 10, 19, 20]. In insertion-deletion streams, where previously inserted edges may be deleted again, space  $\tilde{\Theta}(n^{2-3\epsilon})$  is necessary [7] and sufficient [3, 6] for computing a  $n^\epsilon$ -approximation (see also [18]).

**Outline.** We first give notation and definitions in Section 2. Subsequently, we show in Section 3 that every two-pass semi-streaming algorithm that solely runs GREEDY in the first pass cannot have an approximation ratio of  $\frac{2}{3} + \epsilon$ , for any  $\epsilon > 0$ . Our main algorithmic result, i.e., the combination of subsampling and  $\text{GREEDY}_d$ , is presented in Section 4. Finally, we conclude in Section 5.

## 2 Preliminaries

Let  $G = (A, B, E)$  be a bipartite graph with  $V = A \cup B$  and  $|V| = n$ . For  $F \subseteq E$  and  $v \in V$ , we write  $\text{deg}_F(v)$  to denote the degree of vertex  $v$  in subgraph  $(A, B, F)$ . For any  $U \subseteq V$  and  $F \subseteq E$ ,  $U(F)$  denotes the set of vertices in  $U$  which are the endpoints of edges in  $F$ , and we denote its complement by  $\overline{U(F)} = U \setminus U(F)$ . For a subset of vertices  $U \subseteq V$ , we write  $G[U]$

for the subgraph of  $G$  induced by  $U$ . For any edges  $e, f \in E$ ,  $e$  is *incident* to  $f$  if they share an endpoint. We say that  $e$  and  $f$  are *vertex-disjoint* if  $e$  is not incident to  $f$ . Lastly, for any two sets  $X$  and  $Y$ , we define  $X \oplus Y := (X \setminus Y) \cup (Y \setminus X)$  as their symmetric difference.

A *matching* in  $G$  is a subset  $M \subseteq E$  of vertex-disjoint edges. It is *maximal* if every  $e \in E \setminus M$  is incident to an edge in  $M$ . We denote by  $\mu(G)$  the *matching number* of  $G$ , i.e., the cardinality of a largest matching. A *maximum matching* is one of size  $\mu(G)$ . Additionally,  $M$  is called an *induced matching* if the edge set of the subgraph of  $G$  induced by  $V(M)$  is exactly  $M$ .

**Wald's Equation.** We require the following well-known version of *Wald's Equation*:

► **Lemma 3.** *Let  $X_1, X_2, \dots$  be a sequence of non-negative random variables with  $\mathbb{E}[X_i] \leq \tau$ , for all  $i \leq T$ , and let  $T$  be a random stopping time for the sequence with  $\mathbb{E}[T] < \infty$ . Then:*

$$\mathbb{E}\left[\sum_{i=1}^T X_i\right] \leq \tau \cdot \mathbb{E}[T] .$$

### 3 Lower Bound

We now prove that every two-pass streaming algorithm for MBM with approximation factor  $\frac{2}{3} + \epsilon$ , for any  $\epsilon > 0$ , that solely runs GREEDY in the first pass requires space  $n^{1+\Omega(\frac{1}{\log \log n})}$ . To this end, we adapt the lower bound by Goel et al. [13], which we discuss first.

#### 3.1 Goel et al.'s Lower Bound for One-pass Algorithms

Goel et al.'s lower bound is proved in the *one-way two-party communication framework*. Two parties, denoted Alice and Bob, each hold subsets  $E_1$  and  $E_2$ , respectively, of the input graph's edges. Alice sends a single message to Bob who, upon receipt, outputs a large matching. Goel et al. showed that there is a distribution  $\lambda$  over input graphs so that every deterministic communication protocol with constant distributional error over  $\lambda$  and approximation factor  $\frac{2}{3} + \epsilon$ , for any  $\epsilon > 0$ , requires a message of length  $n^{1+\Omega(\frac{1}{\log \log n})}$ . A similar result then applies for randomized constant error protocols by Yao's Lemma [25], and the well-known connection between streaming algorithms and one-way communication protocols allows us to translate this lower bound to a lower bound on the space requirements of constant error one-pass streaming algorithms.

Goel et al.'s construction is based on the existence of a dense Ruzsa-Szemerédi graph:

► **Definition 4** (Ruzsa-Szemerédi Graph). *A bipartite graph  $G = (A, B, E)$  is an  $(r, t)$ -Ruzsa-Szemerédi graph (RS graph in short) if the edge set  $E$  can be partitioned into  $t$  disjoint matchings  $M_1, M_2, \dots, M_t$  such that, for every  $i$ , (1)  $|M_i| \geq r$ ; and (2)  $M_i$  is an induced matching in  $G$ .*

They give a construction for a family of  $((\frac{1}{2} - \delta)n, n^{\Omega(\frac{1}{\log \log n})})$ -RS graphs, for any small constant  $\delta > 0$ , on  $2n$  vertices (with  $|A| = |B| = n$ ) that we will extend further below.

Their hard input distribution  $\lambda$  for the two-party communication setting is displayed in Figure 2. Observe that the graphs  $G \sim \lambda$  are such that  $\mu(G) \geq \frac{3}{2}N$  since the matching  $M_X^* \cup M_Y^* \cup \widehat{M}_s$  is of this size.

Goel et al. prove the following hardness result:

► **Theorem 5.** *For any small  $\epsilon > 0$ , every deterministic  $(\frac{2}{3} + \epsilon)$ -approximation one-way two-party communication protocol with constant distributional error over  $\lambda$  requires a message of size  $n^{1+\Omega(\frac{1}{\log \log n})}$ , where  $n$  is the number of vertices in the input graph.*

1. Let  $G^{RS} = (A, B, E)$  be an  $(r, t)$ -RS graph with  $|A| = |B| = N$  and  $r = (\frac{1}{2} - \delta) \cdot N$ , for some  $\delta > 0$ , and  $t = N^{\Omega(\frac{1}{\log \log N})}$ .
  2. For every  $i \in [t]$ , let  $\widehat{M}_i \subseteq M_i$  be a uniform random subset of size  $(\frac{1}{2} - 2\delta) \cdot N$  and let  $E_1 = \cup_{i=1}^t \widehat{M}_i$ .
  3. Let  $X$  and  $Y$  each be disjoint sets of  $(\frac{1}{2} + \delta) \cdot N$  vertices, which are also disjoint from  $A \cup B$ . Choose uniformly at random a special index  $s \in [t]$ .
  4. Let  $M_X^*$  and  $M_Y^*$  be arbitrary perfect matchings between  $X$  and  $\overline{B(M_s)}$ , and  $Y$  and  $\overline{A(M_s)}$ , respectively. Then, let  $E_2 = M_X^* \cup M_Y^*$ .
  5. Finally,  $G = (A \cup X, B \cup Y, E_1 \cup E_2)$  which has  $n = (3 + 2\delta) \cdot N$  vertices.
- Alice is given edges  $E_1$  and Bob is given edges  $E_2$ .

■ Figure 2 Hard input distribution  $\lambda$ .

### 3.2 Our Lower Bound Construction

In the following, we extend Goel et al.’s lower bound to the two-pass situation where a GREEDY matching is computed in the first pass. To this end, we need to augment Alice and Bob’s inputs, as defined by distribution  $\lambda$ , by a maximal matching  $M$  in the input graph  $G \sim \lambda$ , which then results in a distribution  $\lambda^+$ . Observe that if we place the edges of  $M$  at the beginning of the input stream, then running GREEDY in the first pass recovers exactly the matching  $M$ . Hence, when abstracting the second pass as a two-party communication problem, both Alice and Bob already know the matching  $M$ . Our main argument then is as follows: We will show that any two-party protocol under distribution  $\lambda^+$  can also be used for solving the distribution  $\lambda$  with the same distributional error, message size, and similar approximation factor. The hardness of Theorem 5, therefore, carries over.

#### 3.2.1 Ruzsa-Szemerédi Graphs with Near-Perfect Matchings

Adding a maximal matching  $M$  to Alice’s and Bob’s input requires care since we need to ensure that the hardness of the construction is preserved. Our construction requires that the underlying RS graph contains a near-perfect matching, which is a property that is not guaranteed by Goel et al.’s RS graph construction.

We therefore augment Goel et al.’s construction by complementing every induced matching,  $M_i$ , with a vertex-disjoint counterpart,  $M'_i$ , without destroying the RS graph properties. Then, since  $M_i$  and  $M'_i$  are vertex-disjoint,  $M_i \cup M'_i$  constitutes a matching, and, since both  $M_i$  and  $M'_i$  each already match nearly half of the vertices,  $M_i \cup M'_i$  constitutes a near-perfect matching in our family of RS graphs.

We will now present Goel et al.’s RS graph construction and then discuss how the additional matchings  $M'_i$  can be added to the construction.

#### Goel et al.’s Ruzsa-Szemerédi Graph Construction

For an integer  $m$ , let  $X = Y = [m^2]^m$  be the vertex sets of a bipartite graph, and let  $N = |X| = |Y| = m^{2m}$  denote their cardinalities. Every induced matching  $M_I$  of Goel et al.’s RS graph construction is indexed by a subset of coordinates  $I \subset [m]$  of size  $\frac{\delta m}{6}$ , for some small  $\delta > 0$ . Then, the edges  $M_I$  are defined by means of a colouring of the vertices  $X$  and  $Y$  (which depends on  $I$ ), that we discuss first.

■ **Figure 3** One group of the partitioned number line of natural numbers.

**Colouring the Vertex Sets.** Let  $w = \frac{(2+\delta)m}{3}$ . Then, define a partition of the natural numbers into groups of size  $w$  such that, for all  $k \in \mathbb{N}_0$ ,

$$\begin{aligned}
 R_k &= \left[ kw, kw + \frac{m}{3} \right) && \text{where } |R_k| = \frac{m}{3}, \\
 W_k &= \left[ kw + \frac{m}{3}, kw + \frac{m}{3} + \frac{\delta m}{6} \right) && \text{where } |W_k| = \frac{\delta m}{6}, \\
 B_k &= \left[ kw + \frac{m}{3} + \frac{\delta m}{6}, kw + \frac{2m}{3} + \frac{\delta m}{6} \right) && \text{where } |B_k| = \frac{m}{3}, \\
 W'_k &= \left[ kw + \frac{2m}{3} + \frac{\delta m}{6}, (k+1)w \right) && \text{where } |W'_k| = \frac{\delta m}{6}.
 \end{aligned}$$

See Figure 3 for an illustration.

Given  $I$ , let  $L_s = \{\vec{x} \in [m^2]^m : \sum_{i \in I} x_i = s\}$  represent a layer of vectors in  $[m^2]^m$  where the 1-norm of their subvectors<sup>2</sup> w.r.t.  $I$  is  $s$ , for all  $s \in \mathbb{N}_0$ . Next, colour the vectors in each  $L_s$  either red if  $s \in R_k$ , blue if  $s \in B_k$ , or white if  $s \in W_k \cup W'_k$ , for some  $k \in \mathbb{N}_0$ . Doing this gives the following coloured strips for any  $k \in \mathbb{N}_0$  (see Figure 4):

$$R(k) = \bigcup_{\forall s \in R_k} L_s, \quad W(k) = \bigcup_{\forall s \in W_k} L_s, \quad B(k) = \bigcup_{\forall s \in B_k} L_s \quad \text{and} \quad W'(k) = \bigcup_{\forall s \in W'_k} L_s.$$

Next, these strips are grouped together by colour, as follows:

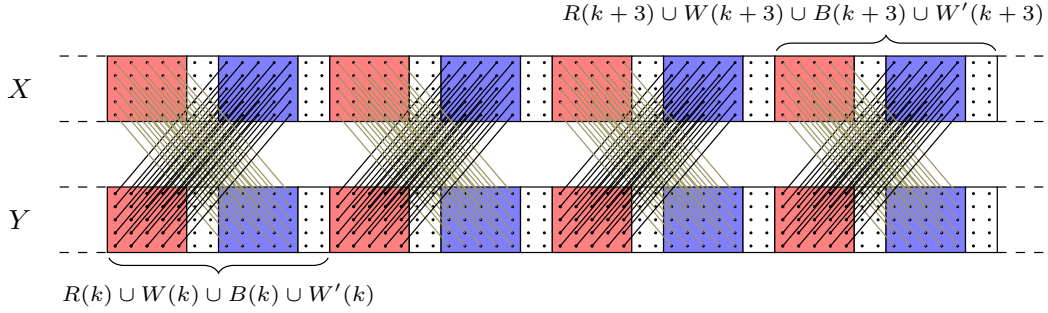

$$R = \bigcup_{\forall k \in \mathbb{N}_0} R(k), \quad W = \bigcup_{\forall k \in \mathbb{N}_0} W(k), \quad B = \bigcup_{\forall k \in \mathbb{N}_0} B(k) \quad \text{and} \quad W' = \bigcup_{\forall k \in \mathbb{N}_0} W'(k).$$

We now define the colours of the vertices  $X$  and  $Y$  as follows: A vertex  $\vec{z} \in X \cup Y$  is coloured red if  $\vec{z} \in R$ , blue if  $\vec{z} \in B$ , and white if  $\vec{z} \in W \cup W'$ . Let  $R^X = R \cap X$  and define  $B^X, W^X, W'^X, R^Y, B^Y, W^Y, W'^Y$  similarly.

**Definition of the Induced Matchings.** Goel et al. construct the edges of the induced matching  $M_I$  by pairing every blue vertex  $\vec{b} \in B^X$  with each coordinate greater than  $\frac{2}{\delta} + 1$  to a red vertex  $\vec{r} \in R^Y$ , such that  $\vec{r} = \vec{b} - (\frac{2}{\delta} + 1) \cdot \vec{1}_I$ , where  $\vec{1}_I$  is the characteristic vector of set  $I$ . See Figure 4 for an illustration.

Goel et al. show that  $M_I$  is large, i.e.,  $|M_I| \geq (\frac{1}{2} - \delta) \cdot N - o(N)$ . Observe that any two distinct indexing sets  $I$  and  $J$  produce their own vertex colourings and matchings  $M_I$  and  $M_J$ . They prove that, as long as the index sets  $I$  and  $J$  have a sufficiently small intersection (at most  $(\frac{5\delta}{12})(\frac{\delta m}{6})$ ),  $M_I$  and  $M_J$  are induced matchings w.r.t. to each other. Hence, they show the existence of a large family  $\mathcal{T}$ , with  $|\mathcal{T}| = N^{\Omega(\frac{1}{\log \log N})}$ , of subsets  $I \subset [m]$  whose pairwise intersections are of size at most  $(\frac{5\delta}{12})(\frac{\delta m}{6})$ . Then, the matchings of the RS graph are identified as the matchings  $M_I$ , for every  $I \in \mathcal{T}$ .

<sup>2</sup> A subvector in this context is the result of a trivial mapping of the vector to a lower dimensional subspace.

■ **Figure 4** Illustration of the vertex colouring and induced matchings for a fixed  $I$ . The black edges are  $M_I$  and the gold ones are  $M'_I$ .

### Extending Goel et al.'s Construction

For every indexing set  $I \in \mathcal{T}$  and respective matching  $M_I$  of Goel et al.'s construction, we symmetrically construct an additional matching  $M'_I$  by pairing every blue vertex in  $Y$  (instead of  $X$ ),  $\vec{b} \in B^Y$ , with each coordinate greater than  $\frac{2}{\delta} + 1$ , to a red vertex in  $X$ ,  $\vec{r} \in R^X$ , such that  $\vec{r} = \vec{b} - (\frac{2}{\delta} + 1) \cdot \vec{1}_I$ . See Figure 4 for an illustration.

We immediately see that, by virtue of being symmetrical,  $|M'_I| = |M_I| (\geq (\frac{1}{2} - \delta) \cdot N - o(N))$ .

Furthermore, by construction,  $M'_I$  and  $M_I$  are vertex-disjoint matchings, hence  $M_I \cup M'_I$  is a matching, and, taking their respective sizes into account,  $M_I \cup M'_I$  is a near-perfect matching as required. Since, for any distinct  $I, J \in \mathcal{T}$ ,  $M_I$  and  $M_J$  are induced matchings w.r.t. each other, the symmetrical nature of our additional matchings implies the same for  $M'_I$  and  $M'_J$ . However, showing that  $M_I$  and  $M'_J$  are induced with respect to each other is not immediately clear. Fortunately, Goel et al.'s proof already implicitly shows this, and, for completeness, we reproduce the decisive argument:

► **Lemma 6.** *Given two distinct sets of indices  $I$  and  $J$  such that  $|I \cap J| \leq (\frac{5\delta}{12})(\frac{\delta m}{6})$ , no edge in  $M_I$  is induced by  $M'_J$ , for any small enough  $\delta > 0$ .*

**Proof.** Let  $\vec{b} \in B^X$  be matched to  $\vec{r} \in R^Y$  by  $M_I$ , i.e.,  $\vec{b} - \vec{r} = (\frac{2}{\delta} + 1) \cdot \vec{1}_I$ . If the edge  $(\vec{b}, \vec{r})$  is induced by  $M'_J$ , then one endpoint is coloured blue and the other red in the colouring of  $X$  and  $Y$  with respect to  $J$ . Hence,  $\vec{b}$  and  $\vec{r}$  are separated by a single white strip (see Figure 4) and

$$|\sum_{j \in J} (\vec{b} - \vec{r})_j| \geq \frac{\delta m}{6}. \quad (1)$$

On the other hand,

$$|\sum_{j \in J} (\vec{b} - \vec{r})_j| = |\sum_{j \in J} ((\frac{2}{\delta} + 1) \cdot \vec{1}_I)_j| = (\frac{2}{\delta} + 1) \cdot |I \cap J| \leq (\frac{5}{6} + \frac{5\delta}{12})(\frac{\delta m}{6}),$$

which contradicts Equation 1 for small enough  $\delta$ . ◀

We thus obtain the following theorem:

► **Theorem 7.** *For any small enough constant  $\delta > 0$ , there exists a family of bipartite  $(r, t)$ -Ruzsa-Szemerédi graphs where  $|A| = |B| = N$ ,  $r = (\frac{1}{2} - \delta) \cdot N$ , and  $t = N^{\Omega(\frac{1}{\log \log N})}$  such that there are  $N^{\Omega(\frac{1}{\log \log N})}$  disjoint near-perfect matchings each of size exactly  $(1 - 2\delta) \cdot N$ .*

1. Let  $G^{RS}$  be an RS graph as in Theorem 7. Fix some induced matching  $M_i$  and let  $M_i \cup M'_i$  be its near-perfect matching of size  $(1 - 2\delta) \cdot N$ .
  2. Let  $F$  be an arbitrary set of  $2\delta N$  additional edges such that  $P = M_i \cup M'_i \cup F$  is a perfect matching in  $G^{RS}$ .
  3. Consider distribution  $\lambda$  constructed using RS graph  $G^{RS} \setminus (M_i \cup M'_i)$ .
  4. For every  $G = (V, E) \sim \lambda$ , let  $P_G = M_i \cup M'_i \cup (F \setminus E)$  (to avoid multi-edges) and add  $P_G$  to  $G$  to obtain the input graph  $G^+$ .
- The edges  $P \cup E_1$  are given to Alice and the edges  $P \cup E_2$  are given to Bob (recall that  $E_1$  and  $E_2$  are defined in distribution  $\lambda$ ).

■ **Figure 5** Hard input distribution  $\lambda^+$ .

### 3.2.2 Lower Bound Proof

Equipped with RS graphs with near-perfect matchings and input distribution  $\lambda$ , we now define our hard input distribution  $\lambda^+$ , see Figure 5.

We are now ready to prove our main lower bound theorem:

► **Theorem 8.** *For any  $\epsilon > 0$ , every deterministic  $(\frac{2}{3} + \epsilon)$ -approximation one-way communication protocol with constant distributional error over  $\lambda^+$  for MBM requires a message of size  $n^{1+\Omega(\frac{1}{\log \log n})}$ , where  $n$  is the number of vertices in the input graph.*

**Proof.** Let  $\gamma^+$  be a deterministic  $(\frac{2}{3} + \epsilon)$ -approximation protocol that solves distribution  $\lambda^+$  with constant distributional error. Given  $\gamma^+$ , we will now define a protocol  $\gamma$  that solves distribution  $\lambda$  with the same communication cost, same error, and approximation ratio strictly better than  $\frac{2}{3}$ . Invoking Theorem 5 then proves our result.

The protocol  $\gamma$  is easy to obtain: Observe that  $P$  in distribution  $\lambda^+$  is the same for every sampled input graph  $G^+ \sim \lambda^+$ . Hence, in protocol  $\gamma$ , Alice and Bob first make sure that the edges  $P$  are included in their inputs. This is achieved by Alice adding the edges  $P \setminus E_1 = P_G$  to her input, and Bob adding the edges  $P$  to his input. In doing so, Alice and Bob's input is equivalently distributed to choosing an input graph  $G^+$  from  $\lambda^+$ . Alice and Bob can, therefore, run protocol  $\gamma^+$  which produces an output matching  $M_{\text{out}}^+$ . Bob then outputs the largest matching  $M_{\text{out}}$  among the edges  $M_X^* \cup M_Y^* \cup (M_{\text{out}}^+ \setminus P_G)$  as the output of the protocol  $\gamma$ .

Next, we will argue that  $|M_{\text{out}}| \geq |M_{\text{out}}^+| - |F| = |M_{\text{out}}^+| - 2\delta N$ . We can construct a matching  $\tilde{M}$  of this size as follows: First, add every edge  $e \in M_{\text{out}}^+$  that is not contained in  $P$  to  $\tilde{M}$ . Second, for every edge  $e \in M_{\text{out}}^+ \cap (M_i \cup M'_i)$ , we insert the incident edge to  $e$  that is contained in  $M_X^* \cup M_Y^*$  into  $\tilde{M}$  (notice that these incident edges always exist except for edges from the special induced matching). This implies that  $|M_{\text{out}}| \geq |\tilde{M}| \geq |M_{\text{out}}^+| - |F|$ .

Recall that  $\mu(G) \geq \frac{2}{3}N$  and, since  $G$  is a subgraph of  $G^+$ ,  $\mu(G^+) \geq \mu(G)$ . This implies that  $N \leq \frac{2}{3}\mu(G^+)$ . Since  $\gamma^+$  is a  $(\frac{2}{3} + \epsilon)$ -approximation protocol, we have  $|M_{\text{out}}^+| \geq (\frac{2}{3} + \epsilon)\mu(G^+)$ , and thus:

$$|M_{\text{out}}| \geq |M_{\text{out}}^+| - 2\delta N \geq (\frac{2}{3} + \epsilon)\mu(G^+) - 2\delta \frac{2}{3}\mu(G^+) = (\frac{2}{3} + \epsilon - \frac{4}{3}\delta)\mu(G^+).$$

Hence, setting  $\delta < \frac{3}{4}\epsilon$  in distribution  $\lambda$  yields a protocol with approximation ratio strictly above  $\frac{2}{3}$ . This, however, implies that  $\gamma$  requires a message of length  $n^{1+\Omega(\frac{1}{\log \log n})}$  (Theorem 5), and since the message sent in  $\gamma$  and  $\gamma^+$  is equivalent, the result follows. ◀

Applying Yao's Lemma and the usual connection between streaming algorithms and one-way communication protocols, we obtain our main lower bound result:

■ **Algorithm 3** Finding Augmenting Paths.

**Input:** A stream of edges  $\pi$  of a bipartite graph  $G = (A, B, E)$ , a maximal matching  $M$  in  $G$ ,  $p \in (0, 1]$  and  $d \in \mathbb{N}^+$ .

- 1: Let  $M' \subseteq M$  be a random subset such that  $\forall e \in M, \Pr[e \in M'] = p$
- 2: Let  $G'_L = G[A(M') \cup \overline{B(M)}]$  and  $G'_R = G[\overline{A(M)} \cup B(M')]$
- 3: Denote by  $\pi_{G'_L}$  ( $\pi_{G'_R}$ ) the substream of  $\pi$  of edges of  $G'_L$  ( $G'_R$ , respectively)
- 4:  $S_L \leftarrow \text{GREEDY}_d(\pi_{G'_L})$  such that  $\deg_{S_L}(a) \leq 1$ , for every  $a \in A(M')$ , and  $\deg_{S_L}(b) \leq d$ , for every  $b \in \overline{B(M)}$
- 5:  $S_R \leftarrow \text{GREEDY}_d(\pi_{G'_R})$  such that  $\deg_{S_R}(b) \leq 1$ , for every  $b \in B(M')$ , and  $\deg_{S_R}(a) \leq d$ , for every  $a \in \overline{A(M)}$
- 6:  $\mathcal{P} \leftarrow \{ab', ab, a'b : ab' \in S_L, ab \in M', a'b \in S_R\}$
- 7: **return** A largest subset  $\mathcal{Q} \subseteq \mathcal{P}$  of vertex-disjoint paths.

► **Theorem 1.** For any  $\epsilon > 0$ , every (possibly randomised) two-pass streaming algorithm for MBM with approximation ratio  $\frac{2}{3} + \epsilon$  that solely computes a GREEDY matching in the first pass requires  $n^{1+\Omega(\frac{1}{\log \log n})}$  space, where  $n$  is the number of vertices in the graph.

## 4 Algorithm

In this section, we combine the subsampling approach as used by Konrad [19] and the semi-matching approach as used by Esfandiari et al. [8] and Kale and Tirodkar [15] in order to find many disjoint 3-augmenting paths, see Algorithm 3.

The input to Algorithm 3 is a stream of edges  $\pi$  of a bipartite graph  $G = (A, B, E)$ , a maximal matching  $M$  in  $G$  (e.g., computed in a first pass by GREEDY), a sampling probability  $p$ , and an integral degree bound  $d$ . First, each edge of  $M$  is included in  $M'$  with probability  $p$ . Then, while processing the stream, degree- $d$ -bounded semi-matchings  $S_L$  and  $S_R$  are computed using the algorithm  $\text{GREEDY}_d$  (see Algorithm 2 in Section 1). The algorithm then returns a largest subset of vertex-disjoint 3-augmenting paths  $\mathcal{Q}$ . We can thus obtain a matching of size  $|M| + |\mathcal{Q}|$ .

### 4.1 Analysis of Algorithm 3

The main task in analysing Algorithm 3 is to bound the sizes of  $S_L$  and  $S_R$  from below. A bound that holds in expectation for the case  $d = 1$  was previously proved by Konrad et al. [20], and a high probability result (for  $d = 1$ ) was later obtained by Konrad [19]. We also first give a bound that holds in expectation (Lemma 9), which is achieved by extending the original proof by Konrad et al. [20]. Our extension, however, is non-trivial as it requires a very different progress measure. Then, following Konrad [19], we obtain a high probability version in Lemma 10.

We also remark that Lemmas 9 and 10 are stated in a more general context, however, it is not hard to see that they capture the situation of the computations of  $S_L$  and  $S_R$  in subgraphs  $G'_L$  and  $G'_R$ , respectively.

► **Lemma 9.** Let  $G = (A, B, E)$  be a bipartite graph,  $\pi$  an arbitrarily ordered stream of its edges,  $p \in (0, 1]$ , and  $d \in \mathbb{N}^+$ . Let  $A' \subseteq A$  be a random subset such that  $\forall a \in A, \Pr[a \in A'] = p$ , and let  $d$  be the degree bound of the  $B$  vertices. Let  $H = G[A' \cup B]$  and denote by  $\pi_H$  the substream of  $\pi$  consisting of the edges in  $H$ . Then,

$$\mathbb{E}_{A'}[|\text{GREEDY}_d(\pi_H)|] \geq \frac{d}{d+p} \cdot p \cdot \mu(G).$$

**Proof.** Let  $M^*$  be a fixed maximum matching in  $G$  and let  $M_H^* := \{ab \in M^* : a \in A'\}$  be the subset of edges incident to  $A'$ .

**Game Setup.** Consider the following game: On selection of an edge by  $\text{GREEDY}_d(\pi_H)$ , the edge *attacks* the (at most two) incident edges of  $M_H^*$  and deals damage to them. Initially, the damage of every edge in  $M_H^*$  is 0, and the maximum damage of each such edge is 1. A damage below 1 means that the edge could still be selected by the algorithm. A damage equal to 1 implies that the edge can no longer be selected.

Denote by  $S_i$  the first  $i$  edges selected by  $\text{GREEDY}_d(\pi_H)$  and let  $ab$  be the  $(i + 1)^{\text{th}}$  edge selected. The way damage is dealt is as follows:

- If there is an edge  $a'b \in M_H^*$  such that  $a' \notin A(S_{i+1})$  then attack edge  $a'b$  by adding  $\frac{1}{d}$  damage to it;
- If there is an edge  $ab' \in M_H^*$  then attack edge  $ab'$  by adding  $1 - \frac{\deg_{S_i}(b')}{d}$  damage to it, maxing out the damage to 1.

Observe that the maximum damage an edge selected by  $\text{GREEDY}_d(\pi_H)$  can inflict is at most  $1 + \frac{1}{d}$  (applying both cases to the two incident optimal edges). Furthermore, observe that the maximum damage every edge in  $M_H^*$  receives is 1, and, indeed, at the end of the algorithm, every edge in  $M_H^*$  has damage 1.

**Applying Wald's Equation.** Denote by  $s$  the cardinality of the semi-matching computed by  $\text{GREEDY}_d(\pi_H)$  and let  $X_1, X_2, \dots, X_s$  be the sequence of edges selected. Define the random variable  $Y_i$  to be the damage dealt by edge  $X_i$ . Let  $T$  be the smallest  $i$  such that  $\sum_{j=1}^i Y_j = |M_H^*|$  holds. Observe that  $T$  is a random stopping time. To apply the version of Wald's Equation presented in Lemma 3, we need to show that  $\mathbb{E}[T]$  is finite and find a value  $\tau$  such that, for all  $i \leq T$ ,  $\mathbb{E}[Y_i] \leq \tau$  holds:

The expected stopping time  $\mathbb{E}[T]$  is finite since  $T \leq s$  always holds by the end of the algorithm, i.e., the total damage dealt is  $|M_H^*|$ . Finding  $\tau$  is less obvious. By definition, the damage  $Y_i$  dealt by any edge  $X_i$  is either 0,  $\frac{1}{d}, \dots, 1$  or  $1 + \frac{1}{d}$ . Hence, we obtain the following:

$$\mathbb{E}[Y_i] \leq \Pr[Y_i \leq 1] \cdot 1 + \underbrace{\Pr\left[Y_i = 1 + \frac{1}{d}\right]}_q \cdot \left(1 + \frac{1}{d}\right) = (1 - q) \cdot 1 + q \cdot \left(1 + \frac{1}{d}\right) = 1 + \frac{q}{d}.$$

It remains to bound  $\Pr[Y_i = 1 + \frac{1}{d}] (= q)$ . Let  $X_i = ab$ . Then, by definition of the game, the event  $Y_i = 1 + \frac{1}{d}$  only happens if there exists an edge  $a'b \in M_H^*$  such that  $a' \notin A(S_i)$ . In this case,  $ab$  inflicts a damage of 1 on edge  $a'b$ . However, observe that since  $a' \notin A(S_i)$ , the random choice as to whether  $a' \in A'$  and thus whether  $a'b \in M_H^*$  had not needed to occur yet (principle of deferred decision). Hence, we obtain:

$$\Pr[Y_i = 1 + \frac{1}{d}] \leq \Pr[a' \in A'] = p.$$

Having shown that  $\mathbb{E}[T]$  is finite and  $\mathbb{E}[Y_i] \leq 1 + \frac{p}{d}$  for all  $i \leq T$ , we can apply Wald's Equation (Lemma 3) and we obtain  $\mathbb{E}[\sum_{j=1}^T Y_j] \leq (1 + \frac{p}{d})\mathbb{E}[T]$ . Finally, since  $\mathbb{E}[\sum_{j=1}^T Y_j] = \mathbb{E}[|M_H^*|] = p \cdot \mu(G)$  and  $T \leq s = |\text{GREEDY}_d(\pi_H)|$ , it follows that

$$\mathbb{E}\left[\sum_{j=1}^T Y_j\right] = p \cdot \mu(G) \leq \left(1 + \frac{p}{d}\right) \cdot \mathbb{E}[T] \leq \left(1 + \frac{p}{d}\right) \cdot \mathbb{E}[|\text{GREEDY}_d(\pi_H)|],$$

which implies the result. ◀

## 19:12 On Two-Pass Streaming Algorithms for Maximum Bipartite Matching

Next, we follow the approach by Konrad [19] to strengthen Lemma 9 and obtain the following high probability result (see Appendix A for the proof):

► **Lemma 10.** *Let  $G = (A, B, E)$  be a bipartite graph,  $\pi$  be any arbitrary stream of its edges,  $p \in (0, 1]$  and  $d \in \mathbb{N}^+$ . Let  $A' \subseteq A$  be a random subset such that  $\forall a \in A, \Pr[a \in A'] = p$ , let  $d$  be the degree bound of the  $B$  vertices and let  $H = G[A' \cup B]$ . Then, the following holds with probability at least  $1 - 2\mu(G)^{-18}$ :*

$$|\text{GREEDY}_d(\pi_H)| \geq \frac{d}{d+p} \cdot p \cdot \mu(G) - o(\mu(G)).$$

Equipped with Lemma 10, we are now ready to bound the number of augmenting paths found by Algorithm 3.

► **Lemma 11.** *Suppose that  $|M| = (\frac{1}{2} + \epsilon)\mu(G)$ . Then, with probability  $1 - \mu(G)^{-16}$ , the number of vertex-disjoint 3-augmenting paths  $|\mathcal{Q}|$  found by Algorithm 3 is at least:*

$$|\mathcal{Q}| \geq \left(\frac{1-2\epsilon}{d+p} - \frac{1+2\epsilon}{2d}\right) \cdot p \cdot \mu(G) - o(\mu(G)).$$

**Proof.** Let  $M^*$  be a fixed maximum matching in  $G$ . In this proof, we will refer to the quantities used by Algorithm 3. First, using a Chernoff bound for independent Poisson trials, we see that  $|M'| = p \cdot |M| \pm O(\sqrt{|M| \ln |M|})$  with probability at least  $1 - |M|^{-C}$  for an arbitrarily large constant  $C$ .

Consider the subgraphs  $G_L = G[A(M) \cup \overline{B(M)}]$  and  $G_R = G[\overline{A(M)} \cup B(M)]$ .  $M \oplus M^*$  contains  $(\frac{1}{2} - \epsilon)\mu(G)$  vertex-disjoint augmenting paths where each path starts and ends with an edge in  $G_L \cup G_R$ . This implies that

$$\mu(G_L) + \mu(G_R) \geq 2\left(\frac{1}{2} - \epsilon\right)\mu(G) = (1 - 2\epsilon)\mu(G). \quad (2)$$

Following Konrad [19], we will argue next that

$$|\mathcal{P}| \geq |S_L| + |S_R| - |M'|. \quad (3)$$

Observe that there are  $|M'| - |S_L|$  vertices of  $|M'|$  that are not incident to an edge in  $S_L$ , and similarly,  $|M'| - |S_R|$  vertices of  $|M'|$  that are not incident to an edge in  $S_R$ . Hence, there are at least  $|M'| - (|M'| - |S_L|) - (|M'| - |S_R|) = |S_L| + |S_R| - |M'|$  edges of  $|M'|$  that are incident to both an edge from  $S_L$  and  $S_R$ . We thus obtain that there are at least  $|\mathcal{P}| \geq |S_L| + |S_R| - |M'|$  3-augmenting paths.

Next, Esfandiari et al. (Lemma 6 in [8]) consider a similar structure to  $\mathcal{P}$  and argue that there is at least a  $d$ -fraction of augmenting paths in  $\mathcal{P}$  that are vertex-disjoint, and, hence,

$$|\mathcal{Q}| \geq \frac{1}{d}|\mathcal{P}|. \quad (4)$$

Using Lemma 10 and Inequalities 2, 3, and 4, we obtain:

$$\begin{aligned} |\mathcal{Q}| &\geq \frac{1}{d}(|S_L| + |S_R| - |M'|) \\ &\geq \frac{1}{d}\left(\frac{d}{d+p} \cdot p \cdot (1 - 2\epsilon)\mu(G) - o(\mu(G)) - p \cdot \left(\frac{1}{2} + \epsilon\right)\mu(G) - O(\sqrt{\mu(G) \ln \mu(G)})\right) \\ &= \left(\frac{1-2\epsilon}{d+p} - \frac{1+2\epsilon}{2d}\right) \cdot p \cdot \mu(G) - o(\mu(G)). \end{aligned}$$

Using the union bound, the error of the algorithm is bounded by  $|M|^{-C} + 2\mu(G)^{-18} \leq \mu(G)^{-16}$ . ◀

1. Let  $A_{\text{in}} = \{a_{\text{in}}^1, a_{\text{in}}^2, \dots, a_{\text{in}}^N\}$ ,  $A_{\text{out}} = \{a_{\text{out}}^1, \dots, a_{\text{out}}^N\}$ ,  $B_{\text{in}} = \{b_{\text{in}}^1, \dots, b_{\text{in}}^N\}$ , and  $B_{\text{out}} = \{b_{\text{out}}^1, \dots, b_{\text{out}}^N\}$  be sets of vertices, for some integer  $N$ .
2. Let  $M = \{a_{\text{in}}^i b_{\text{in}}^i : 1 \leq i \leq N\}$  be a perfect matching between  $A_{\text{in}}$  and  $B_{\text{in}}$ . Let  $G_L = (A_{\text{in}}, B_{\text{out}}, E_L)$  be a semi-complete graph such that  $a_{\text{in}}^i b_{\text{out}}^j \in E_L \Leftrightarrow i \geq j$ , and let  $G_R = (A_{\text{out}}, B_{\text{in}}, E_R)$  be a semi-complete graph such that  $a_{\text{out}}^i b_{\text{in}}^j \in E_R \Leftrightarrow i \geq j$ .
3. Our bipartite hard instance graph is defined as  $G = (A_{\text{in}} \cup A_{\text{out}}, B_{\text{in}} \cup B_{\text{out}}, M \cup E_L \cup E_R)$  and has  $n = 4N$  vertices.
4. Finally, let  $\pi$  be a stream of its edges where the edges of  $M$  arrive first followed by the edges  $E_L$  and  $E_R$ . The edges in  $E_L$  are ordered so that  $a_{\text{in}}^i b_{\text{out}}^j$  arrives before  $a_{\text{in}}^{i'} b_{\text{out}}^{j'}$  only if  $i > i'$ , or  $i = i'$  and  $j < j'$ . Similarly, the edges in  $E_R$  are ordered so that  $a_{\text{out}}^i b_{\text{in}}^j$  arrives before  $a_{\text{out}}^{i'} b_{\text{in}}^{j'}$  only if  $i > i'$ , or  $i = i'$  and  $j < j'$ .

■ **Figure 6** Hard input instance  $G$  for Algorithm 3.

We are now ready to state our main algorithmic result:

► **Theorem 2.** *For every  $p \in (0, 1]$  and every integral  $d \geq 1$ , there is a two-pass semi-streaming algorithm for MBM with approximation factor*

$$\begin{cases} \frac{1}{2} + \left(\frac{1}{d+p} - \frac{1}{2d}\right) \cdot p - o(1), & \text{if } p \leq d(\sqrt{2} - 1) \\ \frac{1}{2} + \frac{d-p}{6d+2p} - o(1), & \text{otherwise,} \end{cases}$$

that succeeds with high probability (in  $\mu(G)$ , where  $G$  is the input graph). The settings ( $d = 1, p = \sqrt{2} - 1$ ) and ( $d = 2, p = 2(\sqrt{2} - 1)$ ) maximize the approximation factor to  $2 - \sqrt{2} - o(1)$ .

**Proof.** Let  $M$  be a maximal matching such that  $|M| = (\frac{1}{2} + \epsilon)\mu(G)$ , for some  $0 \leq \epsilon \leq \frac{1}{2}$  and some bipartite graph  $G = (A, B, E)$  with a stream  $\pi$  of its edges. Let  $\mathcal{Q}$  be the disjoint augmenting paths found by Algorithm 3 on input  $\pi, M, p$  and  $d$ . Then, augmenting  $M$  with  $\mathcal{Q}$  yields a matching of size  $|M| + |\mathcal{Q}|$ . By Lemma 11, the following inequality holds with high probability:

$$|M| + |\mathcal{Q}| \geq \left(\frac{1}{2} + \epsilon\right)\mu(G) + \left(\frac{1-2\epsilon}{d+p} - \frac{1+2\epsilon}{2d}\right) \cdot p \cdot \mu(G) - o(\mu(G)). \quad (5)$$

We distinguish two cases:

1. If  $p \leq d(\sqrt{2} - 1)$  then  $\epsilon = 0$  minimizes the RHS of Inequality 5, and we obtain the claimed bound by plugging the value  $\epsilon = 0$  into the inequality.
2. If  $p \geq d(\sqrt{2} - 1)$  (only possible if  $d \in \{1, 2\}$ ) then  $\epsilon = \frac{d-p}{6d+2p}$  minimizes the RHS of Inequality 5, and we obtain the claimed bound by plugging the value  $\epsilon = \frac{d-p}{6d+2p}$  into the inequality.

It can be seen that, for a fixed  $d$ , the maximum is obtained if  $p = \min\{d\sqrt{2} - d, 1\}$ , and the values  $d \in \{1, 2\}$  yield the claimed bound of  $2 - \sqrt{2} - o(1)$  (see Figure 1 in Section 1). ◀

## 4.2 Optimality of the Analysis

We will show now that our analysis of Algorithm 3 is best possible. To this end, we define a worst-case input graph  $G$  in Figure 6, and prove in Theorem 12 that Algorithm 3 does not perform better on  $G$  than predicted by our analysis. See Figure 7 for an illustration.

Observe that  $M$  is a maximal matching in  $G$ , and if we run GREEDY in the first pass on  $\pi$  then  $M$  would be returned. Let  $M_L^* = \{a_{\text{in}}^i b_{\text{out}}^i : 1 \leq i \leq N\}$  and  $M_R^* = \{a_{\text{out}}^i b_{\text{in}}^i : 1 \leq i \leq N\}$ . Then,  $M_L^*$  is a perfect matching in  $G_L$ ,  $M_R^*$  is a perfect matching in  $G_R$ , and  $M_L^* \cup M_R^*$  is a perfect matching in  $G$ .

■ **Figure 7** Algorithm 3 on a hard input instance with  $N = 7$ ,  $d = 3$  and  $p = 0.5$ .

► **Theorem 12.** *Algorithm 3 with parameters  $d \geq 1$  and  $0 < p \leq 1$  on input  $G$  received via stream  $\pi$  and maximal matching  $M$  finds at most*

$$\left( \left( \frac{1}{d+p} - \frac{1}{2d} \right) \cdot p + o(1) \right) \mu(G)$$

*augmenting paths with high probability. This renders our analysis of Algorithm 3 best possible when  $p \leq d\sqrt{2} - d$ .*

**Proof.** In this proof, we will refer to the quantities used by Algorithm 3, that is,  $M'$  (the edges of  $M$  subsampled with probability  $p$ ),  $S_L$  and  $S_R$ .

We will use the following claim in our proof:

▷ **Claim 13.** With high probability, for every pair  $i, j \in [N]$  with  $i \leq j$ , we have

$$|\{a_{\text{in}}^k b_{\text{in}}^k \in M' \mid i \leq k \leq j\}| = p \cdot (j - i) \pm o(N).$$

*Proof.* This claim is easy to prove. Indeed, for any fixed  $i, j \in [N]$  with  $i \leq j$ , the statement above follows directly from the Chernoff bound. Using the union bound over all pairs  $i, j \in [N]$ , the claim follows. ◁

From now on, we condition on the event that the statement in Claim 13 holds.

Let  $A'_{\text{in}} = A(M')$  and let  $B'_{\text{in}} = B(M')$ . We will first argue that, for two different vertices  $a_{\text{in}}^i, a_{\text{in}}^j \in A'_{\text{in}}$  with  $i < j$ , if  $a_{\text{in}}^i \in A(S_L)$  then  $a_{\text{in}}^j \in A(S_L)$  also holds. Indeed, suppose that this was not the case. Let  $b_{\text{out}}^k$  be the partner of  $a_{\text{in}}^i$  in  $S_L$ . Observe that the edges  $a_{\text{in}}^i b_{\text{out}}^k, a_{\text{in}}^j b_{\text{out}}^k \in E_L$ , and, in particular, the edge  $a_{\text{in}}^j b_{\text{out}}^k$  arrives before the edge  $a_{\text{in}}^i b_{\text{out}}^k$  in  $\pi$ . Hence, edge  $a_{\text{in}}^j b_{\text{out}}^k$  would have been selected, a contradiction. A similar argument holds for vertices  $b_{\text{out}}^i, b_{\text{out}}^j \in B_{\text{out}}$  with  $i > j$ ; if  $\deg_{S_L}(b_{\text{out}}^i) \geq 1$  then  $\deg_{S_L}(b_{\text{out}}^j) = d$ .

Let  $i_{\text{min}}$  be the smallest index such that  $a_{\text{in}}^{i_{\text{min}}} \in A(S_L)$ . We will now argue that  $i_{\text{min}} \geq \frac{pN}{p+d} - o(N)$ . Observe that the vertices  $A'_{\text{in}}$  are matched in order from the largest to smallest index, and each matched vertex in  $A'_{\text{in}}$  is matched only once. The vertices in  $B_{\text{out}}$  are matched from the smallest to largest index, and each matched vertex is matched  $d$  times (except possibly the last such matched vertex). Consider the last edge  $a_{\text{in}}^{i_{\text{min}}} b_{\text{out}}^q$  inserted into  $S_L$ . Then,  $q \leq i_{\text{min}}$ , and, thus,  $|B(S_L)| \leq i_{\text{min}}$ . By Claim 13 (applied with  $j = N$ ), we have

$|A(S_L)| \geq p \cdot (N - i_{\min}) - o(N)$  with high probability. Since  $|A(S_L)|$  is matched to  $B(S_L)$  in  $S_L$ , and each  $B$ -vertex is matched at most  $d$  times, we obtain  $|A(S_L)| \leq d \cdot |B(S_L)|$ , and, hence:

$$p \cdot (N - i_{\min}) - o(N) \leq |A(S_L)| \leq d \cdot |B(S_L)| \leq d \cdot i_{\min} ,$$

which implies  $i_{\min} \geq \frac{pN}{p+d} - o(N)$ .

Let  $i_{\max}$  be the largest index such that  $b_{\text{in}}^{i_{\max}} \in B(S_R)$ . Using a similar argument as above, we see that  $i_{\max} \leq \frac{dN}{p+d} + o(N)$ .

Let  $M'' = \{a_{\text{in}}^i b_{\text{in}}^i \in M' : i_{\min} \leq i \leq i_{\max}\}$  be the subset of augmentable edges, i.e., edges for which there exists a left wing in  $S_L$  and a right wing in  $S_R$ . Then, by Claim 13, we have

$$|M''| \leq p \cdot (i_{\max} - i_{\min}) + o(N) \leq \frac{p(d-p)N}{p+d} + o(N) .$$

All but constantly many vertices in  $A(M'')$  share the same neighbour in  $S_L$  with  $d-1$  other vertices of  $A(M'')$ . Hence, at most a  $d$ -fraction (plus up to the constantly many exceptions, which disappear in the  $o(N)$  term) of  $M''$  can be augmented simultaneously. Using  $N = \frac{1}{2}\mu(G)$ , we obtain the following bound on the number of edges that can be augmented simultaneously:

$$\frac{1}{d}|M''| \leq \frac{1}{d} \left( \frac{p(d-p)N}{p+d} + o(N) \right) = \left( \left( \frac{1}{d+p} - \frac{1}{2d} \right) \cdot p + o(1) \right) \mu(G) . \quad \blacktriangleleft$$

## 5 Conclusion

In this paper, we studied the class of two-pass semi-streaming algorithms for MBM that solely compute a GREEDY matching in the first pass. We showed that algorithms of this class cannot have an approximation ratio of  $\frac{2}{3} + \epsilon$ , for any  $\epsilon > 0$ . We also combined the two dominant techniques that have previously been used for designing such algorithms and discovered another algorithm that matches the state-of-the-art approximation factor of  $2 - \sqrt{2} \approx 0.58578$ .

We conclude with two open problems. First, we are particularly interested in whether there exists a one-pass semi-streaming algorithm that is able to augment a maximal matching so as to yield an approximation ratio above  $2 - \sqrt{2}$ . Second, is there a two-pass semi-streaming algorithm for MBM that improves on the approximation factor of  $2 - \sqrt{2}$  and operates differently in the first pass to the class of algorithms considered in this paper?

## A

 Strengthening Lemma 9

Following [19], we use tail inequalities for martingales to strengthen Lemma 9 and give a high probability result. The proof of Lemma 10 uses the *Azuma-Hoeffding's Inequality* [24, Theorem 12.4]:

► **Lemma 14** (Azuma-Hoeffding's Inequality). *Let  $Z_0, Z_1, \dots, Z_n$  be a martingale such that  $\forall k \geq 0, |Z_{k+1} - Z_k| \leq c_k$ . Then,  $\forall t \geq 0$  and any  $\lambda > 0$ ,*

$$\Pr[|Z_t - Z_0| \geq \lambda] \leq 2 \exp\left(\frac{-\lambda^2}{2 \sum_{k=0}^{t-1} c_k^2}\right).$$

► **Lemma 10.** *Let  $G = (A, B, E)$  be a bipartite graph,  $\pi$  be any arbitrary stream of its edges,  $p \in (0, 1]$  and  $d \in \mathbb{N}^+$ . Let  $A' \subseteq A$  be a random subset such that  $\forall a \in A, \Pr[a \in A'] = p$ , let  $d$  be the degree bound of the  $B$  vertices and let  $H = G[A' \cup B]$ . Then, the following holds with probability at least  $1 - 2\mu(G)^{-18}$ :*

$$|\text{GREEDY}_d(\pi_H)| \geq \frac{d}{d+p} \cdot p \cdot \mu(G) - o(\mu(G)).$$

**Proof.** Let  $X_1, X_2, \dots, X_s$  be the sequence of random variables representing the edges selected by  $\text{GREEDY}_d(\pi_H)$  with the source of randomness from the choice of  $A'$ . Define  $Y := |\text{GREEDY}_d(\pi_H)|$ . Then, we define the random variables  $Z_i := \mathbb{E}[Y | X_1, \dots, X_i]$  for all  $i = 0, \dots, s$  to be the corresponding Doob Martingale, and let  $Z_i = Z_{i-1}$ , for every  $i > s$ . Notice that  $Z_s = Y$  and  $Z_0 = \mathbb{E}[Y] \geq \frac{d}{d+p} \cdot p \cdot \mu(G)$  by Lemma 9. Now, we will show that any deviation of  $Y$  from its expectation,  $|Z_s - Z_0|$ , is small with high probability.

To that end, we first need to bound  $|Z_{i+1} - Z_i|$  for all  $i \geq 0$ . Notice that  $|Z_{i+1} - Z_i| = 0$  for all  $i \geq s$ . Next, we will argue that  $|Z_{i+1} - Z_i| \leq 1$  for all  $i < s$ . Indeed, for any fixed first  $i$  edges added to the semi-matching, any two different choices for  $X_{i+1}$  yield two potentially different semi-matchings  $S_1, S_2$ , respectively, such that  $S_1 \oplus S_2$  consists of at most one alternating path. Hence, the two semi-matchings differ by at most one edge, which proves the claim.

Then, we have that  $s = Y \leq d \cdot \mu(H) \leq d \cdot \mu(G)$  and it follows that  $|Z_{i+1} - Z_i| \leq 1$  for all  $i \leq d \cdot \mu(G)$  and  $|Z_{i+1} - Z_i| = 0$  for all  $i > d \cdot \mu(G)$ . Finally, by applying Azuma-Hoeffding's Inequality (see Lemma 14), we finalise the proof:

$$\Pr\left[|Z_s - Z_0| \geq 6\sqrt{d\mu(G) \ln \mu(G)}\right] \leq 2\mu(G)^{-18},$$

where  $|Z_s - Z_0| = |Y - \mathbb{E}[Y]|$ . ◀

## Abstract

In the Demand Strip Packing problem (DSP), we are given a time interval and a collection of tasks, each characterized by a processing time and a demand for a given resource (such as electricity, computational power, etc.). A feasible solution consists of a schedule of the tasks within the mentioned time interval. Our goal is to minimize the peak resource consumption, i.e. the maximum total demand of tasks executed at any point in time.

It is known that DSP is NP-hard to approximate below a factor  $3/2$ , and standard techniques for related problems imply a (polynomial-time) 2-approximation. Our main result is a  $(5/3 + \varepsilon)$ -approximation algorithm for any constant  $\varepsilon > 0$ . We also achieve best-possible approximation factors for some relevant special cases.

## 1 Introduction

Consider the following scenario: we are given a time interval and a collection of tasks, where each task is characterized by a processing time (no longer than the time interval) and a demand for a given resource. A feasible solution consists of a schedule of all the tasks within the mentioned time interval, and our goal is to minimize the peak resource consumption, i.e. the maximum total demand of tasks scheduled at any point in time. It is easy to imagine concrete applications of this scenario; for example, the considered resource might be electricity, bandwidth along a communication channel, or computational power.

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

The above scenario can be naturally formalized via the following DEMAND STRIP PACKING problem (DSP). We interpret the time interval as a path graph  $G = (V, E)$  with  $W$  edges, where each edge is interpreted as a time slot where we can start to process a task. Let  $\mathcal{I} = \{1, \dots, n\}$  be the set of tasks, where task  $i$  has integer *processing time* (or *width*)  $w(i) \in [1, W]$  and integer *demand* (or *height*)  $h(i) \geq 0$ . A feasible solution (or *schedule* of the tasks) consists of a subpath  $P(i)$  of  $G$  for each  $i \in \mathcal{I}$  containing precisely  $w(i)$  edges. Our goal is to minimize the peak resource consumption (or simply *peak*) which is defined as

$$\max_{e \in E} \sum_{i \in \mathcal{I}: e \in P(i)} h(i).$$

A problem closely related to DSP is the GEOMETRIC STRIP PACKING problem (GSP)<sup>1</sup>, which can be interpreted as a variant of DSP with an extra geometric packing constraint. Here we are given an axis-aligned half-strip of integer width  $W$  (and unbounded height) and a collection of open rectangles (or tasks), where each rectangle  $i$  has integer width  $w(i) \in [1, W]$  and integer height  $h(i) \geq 0$ . Our goal is to find an axis-aligned non-overlapping packing of all the rectangles within the strip that minimizes the peak height, i.e. the maximum height spanned by any rectangle. Notice that one can reinterpret DSP as a variant of GSP, where the processing time and demand of each task correspond to the width and height of a rectangle, resp. (this also motivated our notation). A critical difference w.r.t. GSP however is that DSP does not require to pack such rectangles geometrically<sup>2</sup>.

Obviously, a feasible solution to GSP induces a feasible solution to DSP of no larger peak. The converse is however not true (see Figure 1), and consequently it makes sense to design algorithms specifically for DSP. We remark that there are applications that are better formalized by GSP than by DSP. In particular, this happens when each task requires a contiguous and fixed portion of the considered resource. For example, we might need to allocate consecutive frequencies or memory locations to each task: changing this allocation over time might be problematic. Another natural application of GSP is cutting rectangular pieces from a roll of some raw material (e.g., paper, metal, or leather). However, for other applications, the geometric constraint in GSP does not seem to be necessary, and hence it makes sense to drop it (i.e., to rather consider DSP): this might lead to better solutions, possibly via simpler and/or more efficient algorithms. Consider for example the minimization of the peak energy consumption in smart-grids [31, 44, 39].

A straightforward reduction to the NP-complete PARTITION problem (similar to the one known for GSP, see also [43]) shows that DSP is NP-hard to approximate below a factor  $3/2$ . Constant approximation algorithms for DSP are given in [43, 45]. However, a better 2-approximation can be obtained by applying an algorithm by Steinberg [42] which was developed for GSP: the reason is that Steinberg uses area-based lower bounds that extend directly from GSP to DSP.

## 1.1 Our Results and Techniques

Our main result is as follows<sup>3</sup>.

► **Theorem 1.** *For any constant  $\varepsilon > 0$ , there is a polynomial-time deterministic  $(5/3 + \varepsilon)$ -approximation algorithm for DSP.*

<sup>1</sup> GSP is usually simply called STRIP PACKING in the literature. We added the word “geometric” to better highlight the differences between the two problems.

<sup>2</sup> Or, equivalently, we can split such rectangles into unit-width vertical slices, and then pack such slices geometrically so that slices of the same rectangle appear consecutively in a horizontal sense.

<sup>3</sup> The same result as in Theorem 1 was achieved independently in [15]; their approach is however substantially different from ours.

(a) DSP solution of peak 4 whose corresponding optimal GSP solution has peak 5.

(b) SQUARE-DSP solution of peak 11 whose corresponding optimal GSP solution has peak at least 12.

■ **Figure 1** Gap instances between DSP and GSP.

The above approximation ratio matches the best-known result for GSP from Harren et al. [23], achieved using dynamic programming based techniques to place almost all the rectangles except for a set of very small total area, followed by a careful and quite involved case distinction to pack these remaining rectangles. However, we remark that our algorithm is entirely different, and in particular it does not compute a geometric packing of tasks/rectangles. Furthermore, our analysis is substantially simpler. Notice that the result in [23] does *not* imply a  $(5/3 + \varepsilon)$ -approximation for DSP since some lower bounds used in their proofs do not hold necessarily for DSP.

We also achieve improved approximation algorithms for relevant special cases of DSP. We obtain a PTAS for the special case where the demand of each task is much lower than the optimal peak  $OPT$ . This captures applications where each job consumes a relatively small amount of the available resource (think about the electricity consumption of large-scale systems such as cities or countries).

► **Theorem 2.** *Given  $\varepsilon > 0$  small enough, there exists  $\delta > 0$  and a polynomial time algorithm such that, given an instance of DSP with optimal value  $OPT$  and consisting solely of tasks having height at most  $\delta \cdot OPT$ , it computes a  $(1 + O(\varepsilon))$ -approximate solution.*

Motivated by the special case of GSP and related problems where all rectangles are squares, we also study the special case of DSP where  $h(j) = w(j)$  for all tasks (the SQUARE-DSP problem). The  $3/2 - \varepsilon$  hardness of approximation extends to this case (see Appendix A), and we are still able to show that there is a gap between DSP and GSP (see Figure 1b and Section 5). However, in this case, we are able to provide an optimal  $3/2$ -approximation. We defer the proof of the following theorem to the full version of the paper [17].

► **Theorem 3.** *There is a deterministic polynomial-time  $3/2$ -approximation for SQUARE-DSP.*

At a high level, our approach is based on a classification of tasks into groups depending on their heights and widths. We carefully schedule some groups first, so that their *demand profile* has a convenient structure. Here, by demand profile we simply mean the total demand of the already scheduled tasks over each edge. The structure of the demand profile allows us to pack the remaining groups (intuitively, on top of such profile) in a convenient way. We critically exploit the fact that, differently from GSP, we only care about the total demand on each edge. This allows us to adapt techniques from Bin Packing or Makespan Minimization (see Lemmas 6 and 12).

## 1.2 Related Work

GSP generalizes famous problems such as Makespan Minimization on identical machines [12] (here all the rectangles have width 1 and  $W$  corresponds to the number of processors) or Bin Packing [13] (here all the rectangles have height 1 and the height of the solution corresponds to the number of bins). Consequently, it is known that for any  $\varepsilon > 0$ , there is no  $(3/2 - \varepsilon)$ -approximation for the problem unless  $P=NP$ . The first non-trivial approximation algorithm for GSP, with an approximation ratio of 3, was given by Baker, Coffman, and Rivest [5]. After a series of very technical and involved refinements [14, 41, 40, 42, 24], the current best approximation factor for the problem is  $(5/3 + \varepsilon)$  due to Harren et al. [23]. GSP has been also studied in the pseudopolynomial setting, i.e., when  $W = n^{O(1)}$  [30, 38, 1, 20, 25, 28, 27] and in the asymptotic setting, i.e. when the optimal value is assumed to be large [32, 29]. In both cases, approximation algorithms and almost matching lower bounds have been developed.

There is a very rich line of research on generalizations and variants of DSP such as online versions [34, 35], tasks with availability constraints or time windows [45, 44, 31], a mixture of preemptable and non-preemptable tasks [39] or generalized cost functions based on the demand at each edge [10, 35]. The variant of DSP with the extra feature of interrupting the tasks is known as STRIP PACKING WITH SLICING, for which there exists an FPTAS [3]; on the other hand, the case of DSP is still hard to approximate by a factor better than  $3/2$  as noted by Tang et al. [43].

Another problem closely related to DSP is PARALLEL JOB SCHEDULING. Here we are given a set of jobs and  $m$  machines, where each job is characterized by a processing time and a number of machines where the job must be processed simultaneously (these machines do not need to be contiguous), and the goal is to minimize the makespan. The same hardness of approximation applies in this case, but interestingly an almost tight  $(3/2 + \varepsilon)$ -approximation algorithm has been developed [26] and also a pseudopolynomial  $(1 + \varepsilon)$ -approximation is known [30]. See [16] for a comprehensive survey on the problem and its many variants.

It is also worth mentioning another case where the distinction between geometric and demand-based packing plays a substantial role: the UNSPLITTABLE FLOW ON A PATH problem (UFP) [4, 22, 7, 21] and the STORAGE ALLOCATION problem (SAP) [36, 37]. In both problems, we are given a path graph with edge capacities, and tasks specified by a subpath, a demand (or height), and a profit. In both problems, the goal is to select a maximum profit subset of tasks that can be *packed* while respecting edge capacities. For UFP, analogously to DSP, we require that the total demand of the selected tasks on each edge  $e$  is at most the capacity of  $e$ . For SAP, analogously to GSP, we interpret each task as a rectangle (with the width given by its number of edges) and, intuitively, we need to pack such rectangles non-overlappingly below the capacity profile. Notice that, differently from DSP and GSP, here the path associated with each task is fixed in the input. Furthermore, not all the tasks need to be packed.

Finally, in the DYNAMIC STORAGE ALLOCATION problem (DSA) the setting is analogous to SAP but, similarly to GSP, we are asked for an embedding of all the rectangles minimizing the peak height, i.e. the maximum height reached by any rectangle (in particular, there are no edge capacities). Notice that in DSA a lower bound is provided by the peak demand, i.e. the maximum over the edges  $e$  of the sum of the heights of rectangles whose path uses  $e$ . Buchsbaum et al. [9] studied in detail the relation between the optimal peak height and the peak demand, providing examples where these values differ by a constant factor. The authors also present a  $(2 + \varepsilon)$ -approximation for DSA that provides guarantees even when compared with the peak demand.

### 1.3 Organization

We start by introducing in Section 2 some useful definitions and known results. As a warm-up, in Section 3 we present a very simple 2-approximation for DSP that allows us to illustrate part of our ideas. Then in Section 4 we present our main result, namely a  $(5/3 + \varepsilon)$ -approximation for DSP. Finally, in Section 5 we provide details about the gap instances in Figure 1. The results for special cases of DSP (Theorems 2 and 3) can be found in Appendix B and the full version of this paper [17] respectively.

## 2 Preliminaries

Let  $e_1, \dots, e_W$  be the edges of  $G$  from left to right. Recall that a feasible solution or schedule  $P(\cdot)$  specifies a subpath  $P(i)$  of  $G$  of length  $w(i)$  for each task  $i$ . Sometimes it is convenient to consider a *partial* schedule  $P(\cdot)$  which specified the path of a subset  $\mathcal{I}'$  of tasks only (it is convenient to consider  $P(i)$  as an *empty path* for the remaining tasks). We call this a schedule of  $\mathcal{I}'$ .

Let us define, for a given subset  $\mathcal{I}'$  of tasks,  $h_{\max}(\mathcal{I}') := \max_{i \in \mathcal{I}'} h(i)$  and  $h(\mathcal{I}') := \sum_{i \in \mathcal{I}'} h(i)$ . We define analogously  $w_{\max}(\mathcal{I}')$  and  $w(\mathcal{I}')$  w.r.t. widths. Let also  $a(\mathcal{I}') := \sum_{i \in \mathcal{I}'} a(i)$ , where  $a(i) := h(i) \cdot w(i)$  corresponds to the *area* of task  $i$ . We will start by showing a couple of simple lower bounds for the optimal peak  $OPT$  that will be used extensively along this work.

► **Proposition 4.**  $OPT \geq \max\{h_{\max}(\mathcal{I}), \sum_{i \in \mathcal{I}: w(i) > W/2} h(i), a(\mathcal{I})/W\}$ .

**Proof.** Since the total demand of any edge used by the task of largest height is at least  $h_{\max}(\mathcal{I})$ , it holds that  $OPT \geq h_{\max}(\mathcal{I})$ . Also notice that, in any scheduling, the tasks of width larger than  $W/2$  use the edge  $e_{\lceil W/2 \rceil}$ , being then the total demand of this edge (and consequently  $OPT$ ) at least  $\sum_{i \in \mathcal{I}: w(i) > W/2} h(i)$ . Finally, the last bound follows from an averaging argument and the fact that the sum over the edges of the total demand on each edge is equal to  $a(\mathcal{I})$ . ◀

### 2.1 Demand Profile and Left-Pushing

Consider a schedule  $P(\cdot)$  of  $\mathcal{I}' \subseteq \mathcal{I}$ . We define the *demand profile*  $h(P)$  of  $P(\cdot)$  as the vector that stores for each edge  $e$  the total demand  $\sum_{i \in \mathcal{I}': e \in P(i)} h(i)$  of the tasks whose path contains  $e$  (if the path of  $i$  is not specified, then  $i$  does not contribute to the demand profile). Since  $W$  can be exponential in  $n$ , we need to store the demand profile in a more efficient way. This can be done by noticing that the number of times the total demand changes from an edge to the next one is at most  $2n$  (when a task starts or finishes). Hence we just need to store the edges where the demand profile changes value and the corresponding demand. In particular, we can efficiently store the demand profile. Furthermore, we can efficiently update it, e.g., when augmenting an existing schedule by specifying the path  $P(i)$  of one more task  $i$ , or when we modify the value of some  $P(i)$  by *shifting* tasks as we will discuss later.

Given a schedule  $P(\cdot)$  of  $\mathcal{I}' \subseteq \mathcal{I}$  and  $i \in \mathcal{I}'$ , a *left-shifting* of  $i$  in  $P(\cdot)$  is the operation of replacing  $P(i)$  with the path  $P'(i)$  of length  $w(i)$  that starts one edge to the left of  $P(i)$ . Clearly, this operation is allowed only if  $P(i)$  does not start at the leftmost edge of  $G$ . Consider a schedule  $P(\cdot)$  with peak  $\pi$ , and let  $\pi' \geq \pi$ . A  $\pi'$ -*left-pushing* of  $P(\cdot)$  is the operation of iteratively performing left-shiftings in any order until it is not possible to continue while guaranteeing that the peak is always at most  $\pi'$ . We will critically use left-pushings in our algorithms. Notice that a left-pushing can be computed in polynomial time (see Appendix B for some more details).

Intuitively, left-pushing accumulates the demand over the first edges while inducing a non-increasing demand profile to the right. For a node  $t^*$  of the path and a value  $Q \geq 0$ , we will say that a (possibly partial) schedule  $P(\cdot)$  is  $(Q, t^*)$ -sorted if the corresponding demand on the edges to the left of  $t^*$  is at least  $Q$  and on the edges to the right of  $t^*$  the demand profile is non-increasing (see Figure 2); if  $t^*$  is the leftmost node we just say that the schedule is sorted. Our algorithms will first schedule some tasks and then perform a left-pushing. After that, it will be possible to schedule the remaining tasks in a convenient way thanks to the properties of the resulting demand profile.

## 2.2 Container-based Scheduling

Similar to recent work on related rectangle packing problems (e.g., [18, 6]), we will exploit a *container-based* scheduling approach. A *container*  $C$  can be interpreted as an artificial task, with its own width  $w(C)$  (i.e. a number of edges) and height  $h(C)$ . Furthermore, it is classified as *vertical* or *horizontal*, with a meaning which is explained later. The containers are scheduled as usual tasks in a DSP instance (in particular by defining a path  $P(C)$  for each container  $C$ ), with the goal of minimizing the peak  $\pi$ . We also define a packing of tasks into containers  $C$  respecting the following constraints: if  $C$  is vertical, the tasks  $\mathcal{I}(C)$  packed into  $C$  must have height at most  $h(C)$  and total width at most  $w(C)$ ; if  $C$  is horizontal, tasks  $\mathcal{I}(C)$  must have width at most  $w(C)$  and total height at most  $h(C)$ . Intuitively, the tasks packed into a vertical (resp., horizontal) container induce a geometric packing of the rectangles associated with each task into the rectangle corresponding to the container, where the task rectangles are packed non-overlappingly one next to the other (resp., one on top of the other). Any such packing and scheduling of containers naturally induces a schedule of the tasks: if  $C$  is horizontal, tasks  $\mathcal{I}(C)$  are all scheduled starting on the leftmost edge of  $P(C)$ . Otherwise, tasks  $\mathcal{I}(C)$  are scheduled one after the other starting at the leftmost edge of  $P(C)$ . It is hopefully clear to the reader that the demand profile of such a schedule of the tasks is dominated by the demand profile of the containers' schedule. In particular, if the latter has peak  $\pi$ , then the corresponding schedule of the tasks has a no larger peak.

The general strategy is then as follows: we first show that there exists a convenient packing of tasks into a constant number of containers and that there exists a scheduling  $P^*(\cdot)$  of these containers with a small peak  $\pi$ . We also require that these containers are *guessable*, meaning that we can guess their sizes by exploring a polynomial number of options. Once we guessed the correct set of containers, a  $\pi$ -left-pushing of  $P^*(\cdot)$  can be computed by brute force (since they are constantly many tasks). Finally, we pack tasks into containers, inducing a schedule of the tasks with peak  $\pi$ .

This final step can be performed (almost completely) via a reduction to the GENERALIZED ASSIGNMENT problem (GAP). Recall that in GAP we are given a set of  $k$  bins, where each bin  $j$  has an associated capacity  $C_j \geq 0$ , and a set of  $n$  items. For each item  $i$  and bin  $j$ , the input specifies a size  $s_{ij} \geq 0$  and a profit  $p_{ij} \geq 0$  of item  $i$  w.r.t. bin  $j$ . A feasible solution assigns each item to some bin so that the total size of the items assigned to each bin  $j$  is at most  $C_j$ . Our goal is to maximize the total profit associated with this assignment. GAP admits a PTAS in the case of a constant number of bins (see Section E.2 in [19]).

► **Lemma 5.** *For any constant  $\varepsilon' > 0$ , given a set of tasks  $\mathcal{I}'$  that can be packed into a given set of containers of constant cardinality, there is a polynomial-time algorithm to pack  $\mathcal{I}'' \subseteq \mathcal{I}'$  with  $a(\mathcal{I}'') \geq (1 - \varepsilon')a(\mathcal{I}')$  into the mentioned containers.*

**Proof.** We define a GAP instance as follows: we create one bin per container, where the capacity of the bin is equal to the width of the container if it is vertical or the height of the container if it is horizontal. For each task  $i$  we define an item that has uniform profit equal

to its area  $a(i)$  over all the bins. Given a task  $i$  and a vertical (resp., horizontal) container  $j$ , the size  $s_{ij}$  of  $i$  into bin  $j$  is set to  $w(i)$  (resp.,  $h(i)$ ) if task  $i$  can be packed into container  $j$  according to the mentioned rules. Otherwise we set  $s_{ij} = +\infty$ . The claim follows by applying the aforementioned PTAS for GAP with parameter  $\varepsilon'$ . ◀

Notice that the above lemma allows us to pack all the tasks but a subset of small total area, hence we need to schedule somehow such *leftover* tasks. This is not necessarily a trivial task; indeed, such tasks, though of small area, might have large height, and hence scheduling them on top of the rest might substantially increase the peak. To circumvent this issue we will identify special containers reserved for tasks of large height where we will be able to pack all such tasks with no leftovers. We will then apply the PTAS from Lemma 5 only to the remaining tasks and containers.

### 3 A Simple 2-Approximation for DSP

In order to introduce part of our ideas, in this section, we present a simple 2-approximation for DSP. As mentioned before, a 2-approximation can also be achieved via Steinberg's algorithm [42], however, that algorithm is substantially more complex (not surprisingly since it computes a *geometric packing* of tasks interpreted as rectangles like in GSP).

The following lemma exploits a modification of Next-Fit-Decreasing [13], the well-known approximation algorithm for Bin Packing.

► **Lemma 6.** *Let  $P(\cdot)$  be a sorted schedule of  $\mathcal{I}' \subseteq \mathcal{I}$  with peak at most  $\pi$ . For  $\mathcal{I}'' := \mathcal{I} \setminus \mathcal{I}'$ , assume that:*

- $\pi \geq h_{\max}(\mathcal{I}'') + \max\{a(\mathcal{I})/W, h_{\max}(\mathcal{I}'')\}$ ,
- $w_{\max}(\mathcal{I}'') \leq W/2$ , and
- $(W - w_{\max}(\mathcal{I}''))(\pi - h_{\max}(\mathcal{I}'')) + w_{\max}(\mathcal{I}'') \cdot h_{\max}(\mathcal{I}'') \geq a(\mathcal{I})$ .

*Then it is possible to compute in polynomial time a schedule of  $\mathcal{I}$  having peak at most  $\pi$ .*

**Proof.** By slightly abusing notation, we will next use an edge label  $e$  also to denote the position  $i$  of  $e$  in the sequence  $e_1, \dots, e_W$  of edges from left to right. We do not modify the schedule of  $\mathcal{I}'$  and schedule the remaining tasks  $\mathcal{I}''$  as follows. Let us fix an arbitrary order for tasks in  $\mathcal{I}''$ , and let us initially define  $e^{check}$  to be the leftmost edge. We scan completely the list of tasks  $\mathcal{I}''$  and, if the current task  $i$  can be scheduled starting on edge  $e^{check}$  while maintaining a peak of at most  $\pi$ , we do that and remove  $i$  from  $\mathcal{I}''$ ; otherwise, we keep  $i$  in  $\mathcal{I}''$  and try with the next task. Once we consider the final task, we update  $e^{check}$  to be the leftmost edge to the right of the current  $e^{check}$  whose demand is different from the demand of the current  $e^{check}$ . We iterate the procedure on the new  $e^{check}$  until all tasks are scheduled or we identify a task  $i$  which cannot be scheduled.

First, notice that we update  $e^{check}$  at most  $|\mathcal{I}'|$  times, and after each time, we iterate through at most  $|\mathcal{I}''|$  tasks, so the running time is polynomial in the size of the input. It is also not difficult to see that with this procedure, the demand profile from  $e^{check}$  to its right is always non-increasing (restricted to these edges, scheduling a task is equivalent to summing up two non-decreasing profiles), and none of the remaining tasks can fit in any one of the edges to the left of  $e^{check}$  (as we actually tried to place them there but it was not possible). Notice also that, if this procedure manages to schedule all the tasks, then the claimed peak is automatically achieved. So we will assume by contradiction that this is not the case.

Let  $i$  be a task that could not be scheduled. This could only happen due to  $i$  being too wide for the current edge  $e^{check}$  where it should be scheduled (and hence for any subsequent edge). This implies that  $e^{check} > W - w(i)$  and hence there are more than  $W - w(i)$  edges

## 20:8 Approximation Algorithms for Demand Strip Packing

having demand larger than  $\pi - h(i)$ . Thus the total area of the scheduled tasks plus task  $i$  is strictly larger than

$$A(h(i), w(i)) := (W - w(i)) \cdot (\pi - h(i)) + h(i) \cdot w(i).$$

This expression is decreasing both as a function of  $h(i)$  and as a function of  $w(i)$ . Indeed,

$$\frac{\partial}{\partial h(i)} A(h(i), w(i)) = 2w(i) - W \leq 0, \text{ and } \frac{\partial}{\partial w(i)} A(h(i), w(i)) = 2h(i) - \pi \leq 0,$$

where we used the fact that, by assumption,  $w(i) \leq \frac{W}{2}$  and  $\pi \geq 2h_{\max}(\mathcal{I}'') \geq 2h(i)$ . We conclude that

$$A(h(i), w(i)) \geq A(h_{\max}(\mathcal{I}''), w_{\max}(\mathcal{I}'')) = (W - w_{\max}(\mathcal{I}''))(\pi - h_{\max}(\mathcal{I}'')) + w_{\max}(\mathcal{I}'') \cdot h_{\max}(\mathcal{I}'') \geq a(\mathcal{I}),$$

where in the last inequality we used the third assumption. This is a contradiction since a subset of tasks would have area strictly larger than the total area  $a(\mathcal{I})$ . ◀

We are now ready to provide a simple 2-approximation.

► **Corollary 7.** *There exists a deterministic 2-approximation for DSP.*

**Proof.** Let  $\mathcal{I}$  be an instance of DSP. We will first schedule the tasks  $\mathcal{I}'$  having width larger than  $W/2$  starting on the leftmost edge. Let  $\mathcal{I}'' := \mathcal{I} \setminus \mathcal{I}'$ . This partial schedule is sorted and has peak  $\sum_{i \in \mathcal{I}'} h(i) \leq M := \max\{h_{\max}(\mathcal{I}), \sum_{i \in \mathcal{I}'} h(i), a(\mathcal{I})/W\}$ . Recall that, by Proposition 4,  $M \leq OPT$ . Define  $\pi = 2M$ , and observe that

$$(\pi - h_{\max}(\mathcal{I}''))(W - w_{\max}(\mathcal{I}'')) + h_{\max}(\mathcal{I}'') \cdot w_{\max}(\mathcal{I}'') \geq M \cdot (W/2) + M \cdot (W/2) = M \cdot W \geq a(\mathcal{I}).$$

Thus we can apply Lemma 6 with parameter  $\pi = 2M$ . This provides a schedule with peak at most  $2M \leq 2OPT$ . ◀

In the following sections, we will extend the approach in the above 2-approximation as follows. We will first compute a feasible solution of some given peak that includes all the tasks having height larger than some threshold and width larger than some threshold. Then we will left-push this schedule to add some structure to the demand profile. Finally, we schedule the remaining tasks by means of a generalization of Lemma 6 (Lemma 12) which considers  $(Q, t^*)$ -sorted schedules (rather than just sorted ones).

### 4 A $(5/3 + \varepsilon)$ -Approximation for DSP

In this section we will prove Theorem 1. In order to attain the claimed result, we will provide first some useful definitions and preprocessing lemmas.

Let us assume that the optimal value  $OPT$  is known to the algorithm (this assumption can be dropped by approximately guessing this value, introducing an extra  $(1 + \varepsilon)$  factor in the approximation). We start by classifying the tasks in the instance according to their widths and heights (see Figure 2). Let  $\mu, \delta, \mu < \delta \leq \varepsilon$ , be two constant parameters to be fixed later. We say that a task  $i$  is:

- *tall* if  $h(i) > \frac{2}{3}OPT$ ,
- *large* if  $h(i) \in (\delta OPT, \frac{2}{3}OPT]$  and  $w(i) > \varepsilon W$ ,
- *horizontal* if  $h(i) \leq \mu OPT$  and  $w(i) > \varepsilon W$ ,
- *narrow* if  $h(i) \leq \frac{2}{3}OPT$  and  $w(i) \leq \varepsilon W$ , or
- *medium* if  $h(i) \in (\mu OPT, \delta OPT]$  and  $w(i) > \varepsilon W$ .

■ **Figure 2** (Left) Classification of the tasks according to Section 4. (Right) Representation of a  $(Q, t^*)$ -sorted demand profile.

We denote by  $\mathcal{T}, \mathcal{L}, \mathcal{H}, \mathcal{N}$  and  $\mathcal{M}$  the sets of tall, large, horizontal, narrow and medium tasks respectively. Recall that the general idea of our approach is to show that we can schedule almost every task in a constant number of containers, which in turn can be enumerated in polynomial time by brute force. In the rest of this section, we basically show the existence of such a solution for most of the previously described classes. More precisely, we argue that the optimal schedule can be rearranged so as to define constantly many containers to pack all the tasks in  $\mathcal{T} \cup \mathcal{L}$  while increasing the peak of the solution by at most an additive  $\frac{2}{3}OPT$  term (see Lemma 9). We then show that a subset of the tasks in  $\mathcal{H}$  can be scheduled in  $\mathcal{O}(1)$  containers such that the left-over from this class has a very small area compared  $W \cdot OPT$  (see Lemma 10). Then, it is not difficult to show that the left-over from  $\mathcal{H}$  can be placed in a single container with a very small height. We also prove that all the tasks in  $\mathcal{M}$  can be packed in a single container of small height by showing how to choose the parameters  $\mu$  and  $\delta$  (see Lemma 8). This leads in conclusion to a container-based scheduling for  $\mathcal{I} \setminus \mathcal{N}$  of peak  $(\frac{5}{3} + 7\varepsilon)OPT$  (see Lemma 11). Finally, we present a method to schedule every task in  $\mathcal{N}$  on top of the previous solution without increasing its peak by using a greedy approach (see Lemma 12).

We first deal with the medium tasks. As the following lemma states, it is possible to choose  $\mu$  and  $\delta$  in such a way that the two parameters differ by a large factor and the total height of medium tasks is small.

► **Lemma 8.** *Given a polynomial-time computable function  $f : (0, 1) \rightarrow (0, 1)$ , with  $f(x) < x$ , and any constant  $\varepsilon \in (0, 1)$ , we can compute in polynomial time a set  $\Delta$  of  $\frac{2}{\varepsilon^2}$  many positive real numbers upper bounded by  $\varepsilon$ , such that there is at least one number  $\delta \in \Delta$  so that, by choosing  $\mu = f(\delta)$ , one has  $a(\mathcal{M}) \leq \varepsilon^2 \cdot OPT \cdot W$  (hence  $h(\mathcal{M}) \leq \varepsilon OPT$ ).*

**Proof.** Let  $y_1 = \varepsilon$  and, for each  $j \in \{1, \dots, |\Delta|\}$ , define  $y_{j+1} = f(y_j)$ . For each  $j \leq |\Delta|$ , let  $I_j = \{i \in \mathcal{I} : h(i) \in [y_{j+1}, y_j]\}$ . Note that  $y_j$ 's are decreasing since  $f(x) < x$ . Observe that  $I_{j'}$  is disjoint from  $I_{j''}$  for every  $j' \neq j''$ , and the total area of tasks in  $\bigcup I_j$  is at most  $W \cdot OPT$ . Thus, there exists a value  $\bar{j}$  such that the total area of the tasks in  $I_{\bar{j}}$  is at most  $\frac{2OPT \cdot W}{|\Delta|} = \varepsilon^2 \cdot OPT \cdot W$ . Choosing  $\delta = y_{\bar{j}}$  and  $\mu = y_{\bar{j}+1}$  verifies all the conditions of the lemma as in that case  $\mathcal{M} \subseteq I_{\bar{j}}$ . Notice that, since every task in  $\mathcal{M}$  has width at least  $\varepsilon W$ , we have that  $h(\mathcal{M}) \leq \varepsilon OPT$ . ◀

Function  $f$  will be given later. From now on, we will assume that  $\mu$  and  $\delta$  are chosen according to Lemma 8. Notice that this implies that  $\mu, \delta = O_\varepsilon(1)$ . The rest of this section is organized as follows. In Section 4.1 we define a container-based scheduling of  $\mathcal{T} \cup \mathcal{L}$ . In Section 4.2 we extend this in order to include also  $\mathcal{H}$ . In Section 4.3 we schedule the remaining tasks and prove Theorem 1.

#### 4.1 Containers for Tall and Large Tasks

In this section, we define a packing of tall and large tasks into a constant number of guessable containers. This packing can be computed exactly, i.e. with no leftovers (in particular, we will not use Lemma 5 to compute such packing). To that aim, we will exploit the following structural result.

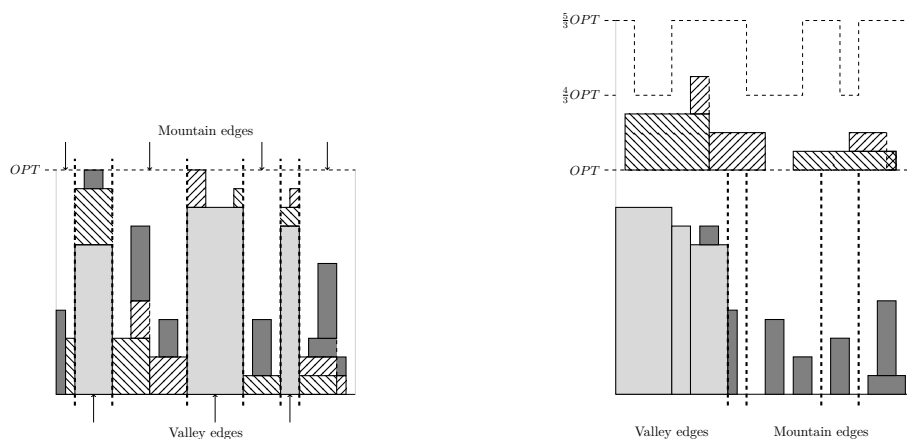

► **Lemma 9.** *Let  $P(\cdot)$  be an optimal schedule of  $\mathcal{I}$  (hence with peak  $OPT$ ). There exists a packing  $P'(\cdot)$  with peak at most  $\frac{5}{3}OPT$  satisfying that all the tall tasks are scheduled one after the other starting on the leftmost edge in non-increasing order of height.*

**Proof.** Let  $\mathcal{T}$  be the tall tasks (having height larger than  $\frac{2}{3}OPT$ ). Notice that the paths of these tasks in  $P(\cdot)$  need to be edge disjoint. Let us classify the edges into *valley edges* if some task in  $\mathcal{T}$  uses that edge in  $P(\cdot)$  and *mountain edges* otherwise (see also Figure 3a). We let  $\mathcal{I}_{mnt}$  be the (*mountain*) tasks whose path in  $P(\cdot)$  consists solely of mountain edges,  $\mathcal{I}_{vll}$  be the (*valley*) tasks whose path in  $P(\cdot)$  consists solely of valley edges (notice that this set includes  $\mathcal{T}$ ), and  $\mathcal{I}_{crs} := \mathcal{I} \setminus (\mathcal{I}_{vll} \cup \mathcal{I}_{mnt})$  the remaining (*crossing*) tasks.

We next define a modified partial schedule  $P'(\cdot)$  of  $\mathcal{I}_{vll} \cup \mathcal{I}_{mnt}$  as follows. Let us reorder the edges of the path (and the tasks accordingly) so that valley edges appear to the left and mountain edges appear to the right in the path (maintaining their relative order). Furthermore, we rearrange the valley edges so that tasks in  $\mathcal{T}$  are scheduled from left to right in non-increasing order of height. Observe that by construction  $\mathcal{I}_{mnt}$  are scheduled on  $W - w(\mathcal{T})$  edges (i.e. the total number of mountain edges). Since we temporarily removed crossing tasks, this induces a feasible packing of  $\mathcal{I}_{vll} \cup \mathcal{I}_{mnt}$ . The resulting packing  $P'(\cdot)$  clearly has a peak of at most  $OPT$ .

Consider next the schedule  $P(\cdot)$  restricted to  $\mathcal{I}_{crs}$ . We claim that this schedule has peak at most  $\frac{2}{3}OPT$ . Indeed, notice first that the demand of valley edges is at most  $\frac{1}{3}OPT$ . Consider next a mountain edge  $e$ . Let  $e_\ell$  be the rightmost valley edge to the left of  $e$  (if any), and define  $e_r$  symmetrically to the right of  $e$ . Any task in  $\mathcal{I}_{crs}$  using  $e$  must also use  $e_\ell$  or  $e_r$  (or both). Hence the total demand on  $e$  is at most the total demand on  $e_\ell$  plus the total demand on  $e_r$ , thus at most  $\frac{2}{3}OPT$ . The claim follows by combining the schedule of  $\mathcal{I}_{crs}$  (taken from  $P(\cdot)$ ) with the above schedule  $P'(\cdot)$  of  $\mathcal{I}_{vll} \cup \mathcal{I}_{mnt}$  (see also Figure 3b). ◀

We will next assume that tall tasks are scheduled as in the above lemma. By increasing the peak by  $\varepsilon OPT$  (up to  $(\frac{5}{3} + \varepsilon)OPT$ ), one can define a set of  $O_\varepsilon(1)$  (tall) containers where such tasks can be packed (respecting the mentioned order and with no leftovers). Consider the demand profile of tall tasks in the considered schedule, and round it to the next multiple of  $\varepsilon OPT$ . Consider the tasks  $\mathcal{T}_k$  corresponding to the value  $k \cdot \varepsilon OPT$  in the rounded profile. Notice that these tasks are scheduled consecutively along some path  $P_k$ . We create a vertical container  $C_k$  of height  $k \cdot \varepsilon OPT$  and width  $|E(P_k)|$ , pack  $\mathcal{T}_k$  into  $C_k$ , and schedule  $C_k$  on  $P_k$ . Clearly, we need to create at most  $1/\varepsilon$  containers. Notice also that the dimensions of these containers can be guessed in polynomial time since there is a constant number of options for the height, and the widths correspond to the total width of a subsequence of tall tasks in the considered ordering by non-increasing height (breaking ties arbitrarily).

(a) A scheduling of peak  $OPT$ . Light gray rectangles correspond to tasks in  $\mathcal{T}$ , dark gray ones represent mountain and valley tasks, and dashed ones the crossing tasks.

(b) Structured solution having peak at most  $\frac{5}{3}OPT$ , where tasks in  $\mathcal{T}$  are placed one next to the other, starting at the leftmost edge and sorted non-increasingly by height.

■ **Figure 3** Depiction of the proof of Lemma 9.

It remains to consider large tasks. Since they are at most  $\frac{1}{\varepsilon\delta} = O_\varepsilon(1)$  many, it is sufficient to define a distinct (large) container for each one of them and pack the large tasks accordingly. We schedule the large containers exactly as in the solution guaranteed by Lemma 9. Clearly tall and large containers can be scheduled together with a peak of at most  $(\frac{5}{3} + \varepsilon)OPT$  by the above construction.

## 4.2 Containers for Horizontal Tasks

In this section, we define a packing of horizontal tasks into a constant number of guessable containers. These containers can be scheduled together with the tall and large containers with small enough peaks. This will induce a convenient schedule of non-narrow tasks.

Let us focus on the schedule of tall and large containers with a peak of at most  $(\frac{5}{3} + \varepsilon)OPT$  from the previous section. Consider now the demand profile of such container schedule. Since the demand profile of tall containers has at most  $1/\varepsilon = O_\varepsilon(1)$  jumps, and the demand profile of large containers has at most  $2/(\varepsilon\delta) = O_\varepsilon(1)$  jumps, then the overall demand profile has  $O_\varepsilon(1)$  jumps.

Assume next that horizontal tasks are scheduled as in Lemma 9: notice that such tasks can be scheduled with the tall and large containers without increasing the peak. This implies that the demand profile of horizontal tasks is upper bounded (on each coordinate) by the difference between  $(\frac{5}{3} + \varepsilon)OPT$  and the demand profile of tall and large containers (see Figure 4). Under these conditions, it is possible to build containers for horizontal tasks, using the standard linear grouping technique, as the following lemma shows.

► **Lemma 10.** *Suppose there exists a schedule of  $\mathcal{H}$  such that its demand profile is upper bounded (vectorially) by a demand profile  $D$  with  $O_\varepsilon(1)$  jumps. Then there exists a container packing for  $\mathcal{H}$  into  $O_\varepsilon(1)$  horizontal guessable containers with demand profile upper bounded by  $D$  plus  $4\varepsilon OPT$  on each coordinate.*

**Proof.** Let us assume by now that horizontal tasks are *horizontally sliced*, meaning that each task  $i$ , having height  $h(i)$  and width  $w(i)$ , is replaced by  $h(i)$  sibling slices, which are tasks of width  $w(i)$  and height 1. The schedule of the slices is the same as for the corresponding task.

■ **Figure 4** The demand profile of tall and large tasks in the schedule obtained from Lemma 9 has  $O_\epsilon(1)$  jumps, bounding the profile of (sliced) horizontal tasks (on top).

In order to reduce the possible number of distinct slice widths to a constant, we will use the technique of linear grouping while increasing the final peak by at most  $2\epsilon OPT$ . We start by considering all the slices in a pile, one on top of the other and sorted non-increasingly by width from bottom to top (and putting sibling slices consecutively). Since these slices have a width at least  $\epsilon W$  and total area at most  $OPT \cdot W$ , the pile has total height at most  $\frac{1}{\epsilon} OPT$ . Starting from the bottom, we partition the pile into groups  $G_1, \dots, G_q$  of height exactly  $\epsilon OPT$  (except possibly for  $G_q$  which may have a smaller height). We remove from the solution the slices in  $G_1$  and any slice in  $G_2$  which used to have a sibling slice in  $G_1$ , and temporarily remove the corresponding tasks. Observe that we are removing the tasks whose slices are fully contained in  $G_1$  plus at most one extra task. In particular, the total height of the removed tasks is at most  $(\epsilon + \mu)OPT \leq 2\epsilon OPT$  (here we use  $\mu \leq \epsilon$ ).

Next, we round up the widths of the remaining slices as follows: for  $i = 2, \dots, q$ , the width of slices (still) in  $G_i$  are rounded to the smallest width of any slice originally in  $G_{i-1}$ . We call this set of slices the rounded slices, and next focus on packing them. Notice that rounded slices have at most  $1/\epsilon^2$  distinct widths. This also induces a matching between each rounded slice  $a$  and a distinct original slice  $b$ , so that  $w(b) \geq w(a)$ . In particular, we can schedule each such  $a$  starting on the first edge of  $P(b)$  without increasing the overall peak.

Now we left-shift the horizontal slices in the solution as much as possible while still obtaining a schedule whose demand profile is upper bounded by  $D$ . Let  $e$  be the starting edge of some slice  $S$  at the end of the process. Notice that one of the following cases holds: (1)  $D$  increases on edge  $e$  (including as a special case when  $e$  is the leftmost edge of  $G$ ) or (2) the edge  $f$  to the left of  $e$  is the ending edge of some other slice  $S'$ . Indeed otherwise it would be possible to left-shift  $S$  while respecting all the constraints. This implies that the possible positions for the starting edge of any slice can be obtained by considering the  $O_\epsilon(1)$  edges where  $D$  increases and then adding the total width of a few slices. Notice that there are at most  $1/\epsilon^2$  such widths, and we can sum up at most  $1/\epsilon$  of them (since horizontal slices have widths at least  $\epsilon W$ ). Altogether, the number of possible starting edges for the slices is  $O_\epsilon(1)$ .

Consider the leftmost possible such edge  $e$  and all the rounded slices  $S_e$  starting on  $e$  in this left-shifted schedule. We partition  $S_e$  by width  $w$ , and for each such width  $w$  and corresponding set of slices  $S_{e,w}$ , we construct a horizontal container of width  $w$  and height  $h(S_{e,w})$  where we pack  $S_{e,w}$ . We repeat this procedure for each possible starting edge  $e$ ,

obtaining in the end  $K \leq O_\varepsilon(1)$  containers in total where we packed all the rounded slices. Notice that the width of each container is the width of some rounded slice, which in turn is the width of some task. Hence the widths of the containers are guessable in the usual sense.

We next turn the above packing of rounded slices into a feasible packing of tasks (into the same containers). First of all, we repack the rounded slices as follows. We consider all the slices  $S_w$  of a given width  $w$  in any order where sibling slices appear consecutively, and all the containers  $C_w$  of that width in any order. We pack each slice  $s \in S_w$  in the first container  $C \in C_w$  where  $s$  still fits. Notice that  $h(S_w) = h(C_w)$  by construction, hence we repack all rounded slices this way. Next we consider the tasks  $i$  whose slices are all contained in the *same* container  $C$ , and pack  $i$  into  $C$ . By construction this packing is feasible. We add the tasks which are not packed this way to the set of removed tasks defined earlier. We round up the heights of the containers to the next multiple of  $\frac{\varepsilon}{K}OPT$ , hence making such heights guessable. This way the peak increases at most by  $\varepsilon OPT$ .

Consider the set of removed tasks. Recall that the tasks removed in the initial rounding phase have total height at most  $2\varepsilon OPT$ . In the following packing phase, we remove at most one task per container, hence these removed tasks have height at most  $K \cdot \mu \cdot OPT \leq \varepsilon OPT$ . Here we assume that  $\mu \leq \varepsilon/K$ : this can be achieved by choosing  $f(x) = x/K$  in Lemma 8. Hence the removed tasks altogether have total height at most  $3\varepsilon OPT$ : we pack these tasks in one extra (guessable) horizontal container of width  $W$  and height  $3\varepsilon OPT$ . ◀

From the above construction it is possible to derive a schedule of non-narrow tasks of small enough peak.

► **Lemma 11.** *It is possible to compute in polynomial-time a feasible schedule of  $\mathcal{I} \setminus \mathcal{N}$  with peak at most  $(\frac{5}{3} + 7\varepsilon) OPT$ .*

**Proof.** Consider the guessable containers for tall, large, and horizontal tasks and the corresponding schedule as described before. This schedule has a peak of at most  $(\frac{5}{3} + \varepsilon)OPT + 4\varepsilon OPT$ . By Lemma 8 the medium tasks fit into a horizontal container of width  $W$  and height  $\varepsilon OPT$ . Altogether this leads to a packing of  $\mathcal{L} \cup \mathcal{T} \cup \mathcal{H} \cup \mathcal{M} = \mathcal{I} \setminus \mathcal{N}$  into  $O_\varepsilon(1)$  guessable containers that can be scheduled with peak at most  $(\frac{5}{3} + 6\varepsilon)OPT$ .

It is easy to pack  $\mathcal{L} \cup \mathcal{T} \cup \mathcal{M}$  into the corresponding containers. For  $\mathcal{H}$  we apply Lemma 5 with  $\varepsilon' = \varepsilon^2$  to assign the horizontal tasks to them, obtaining a set of horizontal unplaced tasks of an area at most  $\varepsilon^2 \cdot W \cdot OPT$  (hence of total height at most  $\varepsilon OPT$ ). The latter tasks can be placed into an extra horizontal container of height  $\varepsilon OPT$  and width  $W$ . The resulting set of containers can be scheduled with a peak at most  $(\frac{5}{3} + 7\varepsilon)OPT$ , and such a schedule can be efficiently computed as already discussed. ◀

### 4.3 Scheduling Narrow Tasks

At this point it just remains to schedule the narrow tasks. For this goal we need the following generalization of Lemma 6 that considers  $(Q, t^*)$ -sorted partial schedules. Recall that for a node  $t^*$  of the path and a value  $Q \geq 0$ , a schedule is  $(Q, t^*)$ -sorted if the demand to the left of  $t^*$  is at least  $Q$ , and to the right of  $t^*$  the demand profile is non-increasing.

► **Lemma 12.** *Let  $\mathcal{I}$  be an instance of DSP and  $\alpha > 0$ . Suppose we are given a  $((1 + \alpha)OPT, t^*)$ -sorted schedule of  $\mathcal{I}' \subseteq \mathcal{I}$ . Let  $\mathcal{I}'' := \mathcal{I} \setminus \mathcal{I}'$  and assume that:*

- *The peak of the schedule is at most  $\pi$ , with  $\pi \geq (1 + \alpha)OPT + h_{\max}(\mathcal{I}'')$ , and*
- *$w_{\max}(\mathcal{I}'') \leq \frac{\alpha}{2(\alpha+1)}W$ .*

*Then it is possible to compute in polynomial time a schedule of  $\mathcal{I}$  with peak at most  $\pi$ .*

## 20:14 Approximation Algorithms for Demand Strip Packing

**Proof.** By overloading notation, let  $t^*$  also denote the number of edges to the left of  $t^*$ . Notice first that  $W - t^* \geq 2w_{\max}(\mathcal{I}'')$ . Indeed otherwise, since the input schedule is  $((1 + \alpha)OPT, t^*)$ -sorted, the total area of the tasks in  $\mathcal{I}'$  would be at least

$$t^* \cdot (1 + \alpha)OPT > (W - 2w_{\max}(\mathcal{I}''))(1 + \alpha)OPT \geq W \cdot OPT$$

which is not possible. Roughly speaking, to prove the desired claim, we will apply Lemma 6 to the demand profile induced by the edges to the right of  $t^*$ . In more detail, we consider a new instance defined by a path with  $\tilde{W} = W - t^*$  edges and a set of tasks  $\tilde{\mathcal{I}}$  consisting of  $\tilde{\mathcal{I}}'' := \mathcal{I}''$  plus a set  $\tilde{\mathcal{I}}'$  of  $\tilde{W}$  tasks having width 1 and, for each edge  $e$  to the right of  $t^*$ , height equal to the total demand on edge  $e$  in the original schedule for  $\mathcal{I}'$ . To see that the required hypotheses are satisfied, notice that by scheduling the tasks in  $\tilde{\mathcal{I}}'$  one next to the other sorted non-increasingly by height we obtain a sorted partial schedule of a peak at most  $\pi$ , where

$$\pi \geq h_{\max}(\mathcal{I}'') + (1 + \alpha)OPT \geq h_{\max}(\tilde{\mathcal{I}}'') + \max\{a(\tilde{\mathcal{I}})/\tilde{W}, h_{\max}(\tilde{\mathcal{I}}'')\}.$$

The last inequality above holds since  $a(\tilde{\mathcal{I}}) \leq OPT \cdot W - a(\mathcal{I}') \leq OPT(W - (1 + \alpha)t^*)$ . Finally, we notice that  $w_{\max}(\tilde{\mathcal{I}}'') \leq \tilde{W}/2$ , and

$$\begin{aligned} & (\tilde{W} - w_{\max}(\tilde{\mathcal{I}}''))(\pi - h_{\max}(\tilde{\mathcal{I}}'')) + w_{\max}(\tilde{\mathcal{I}}'') \cdot h_{\max}(\tilde{\mathcal{I}}'') \\ \geq & (\tilde{W} - w_{\max}(\tilde{\mathcal{I}}''))(1 + \alpha)OPT \\ = & OPT(W - t^*(1 + \alpha)) + \alpha W \cdot OPT - w_{\max}(\mathcal{I}'')(1 + \alpha)OPT \\ \geq & a(\tilde{\mathcal{I}}) + \alpha W \cdot OPT - \frac{\alpha}{2}W \cdot OPT \geq a(\tilde{\mathcal{I}}). \end{aligned}$$

Hence all the conditions of Lemma 6 apply. Given that the demand profile of the partial schedule for  $\tilde{\mathcal{I}}$  is the same as the demand profile induced by the edges to the right of  $t^*$  in the original schedule for  $\mathcal{I}'$ , we can schedule  $\mathcal{I}''$  on top of the input schedule without exceeding the peak  $\pi$ .  $\blacktriangleleft$

We now have all the ingredients to prove Theorem 1.

**Proof of Theorem 1.** Consider the schedule of  $\mathcal{I} \setminus \mathcal{N}$  with peak at most  $\pi := (\frac{5}{3} + 7\varepsilon)OPT$  provided by Lemma 11. We perform a  $\pi$ -left-pushing of this schedule, however without left-shifting any tall task. Let us prove that this partial schedule of  $\mathcal{I}' := \mathcal{I} \setminus \mathcal{N}$  satisfies all the required properties of Lemma 12 with parameter  $\pi$ . First of all, there exists a node  $t^*$  for which (1) every edge to the left of  $t^*$  (if any) has demand larger than  $(1 + 7\varepsilon)OPT$ , and (2) the demand profile to the right of  $t^*$  is non-increasing. Indeed, if (1) does not hold, then there exists an edge having demand less than  $(1 + 7\varepsilon)OPT$  and the following edge has demand larger than  $(1 + 7\varepsilon)OPT$ . But this means that some task which is not tall can be left-shifted (as there can be only one tall task per edge); similarly, if (2) does not hold, there is a pair of contiguous edges to the right of  $t^*$  where the demand strictly increases from left to right. But since the tall tasks are sorted non-increasingly by height, this implies that there exists a task that is not tall that can be left-shifted. In conclusion, the solution is  $((1 + 7\varepsilon)OPT, t^*)$ -sorted and also  $w_{\max}(\mathcal{N}) \leq \varepsilon W \leq \frac{7\varepsilon}{2(1+7\varepsilon)}W$  for  $\varepsilon$  small enough. Since  $\pi \geq (1 + 7\varepsilon)OPT + h_{\max}(\mathcal{N})$ , by Lemma 12 we obtain a feasible schedule of peak at most  $\pi$ . The claim follows by scaling  $\varepsilon$  appropriately.  $\blacktriangleleft$

■ **Figure 5** If we assume by contradiction that some optimal solution of height 4 for the GSP instance described in Lemma 13 exists, it must have this structure.

## 5 Comparison between DSP and GSP

In this Section we provide instances where a gap between the optimal values they achieve interpreted as DSP and GSP instances can be observed. First we discuss the general case and then the case of SQUARE-DSP. It is worth noticing that, for the general case, an analogous proof can be derived from the results in [8].

► **Lemma 13.** *There exists an instance of DSP with optimal peak 4 such that the corresponding GSP instance has optimal peak 5.*

**Proof.** Consider the following DSP instance  $\mathcal{I}$ , where  $W = 7$  and the set of tasks consists of the following eight elements (see Figure 1a for a depiction):

- Two tasks of width 2 and height 3 (tasks 1 and 2 in the figure),
- Two tasks of width 4 and height 1 (tasks 3 and 4 in the figure),
- One task of width 3 and height 1 (task 5 in the figure),
- One task of width 1 and height 1 (task 6 in the figure), and
- Two tasks of width 1 and height 2 (tasks 7 and 8 in the figure).

As it is possible to see in Figure 1a, the optimal solution has peak 4 (since  $OPT \geq a(\mathcal{I})/W = 4$ ). We will show now that there is no solution for the corresponding GSP instance of height 4, which would conclude the proof.

Suppose by contradiction that there exists a solution to the corresponding GSP instance of height 4. Let us imagine for the sake of presentation that we draw a grid of unit-size cells over the rectangular region  $[0, 7] \times [0, 4]$ , defining four rows of height 1 and seven columns of width 1. First of all, notice that in any feasible packing of the rectangles into the region, rectangles 1 and 2 cannot be touching the top (resp. bottom) boundary of the region at the same time. If that is the case, then the rectangles 3 and 4 do not fit in the region as they cannot be placed in the same row and none of them fits in the rows which are partially occupied by rectangles 1 and 2. So let us assume w.l.o.g. that rectangle 1 touches the top boundary and rectangle 2 touches the bottom boundary. Since they both partially occupy the middle rows of the region, rectangles 3 and 4 must be placed one touching the bottom boundary and the other touching the top boundary. This implies that rectangle 5 has to be placed in one of the middle rows (in the other rows there is just one cell free), forcing us to place rectangles 1 and 2 one touching the left boundary and the other touching the right boundary (see Figure 5). Suppose rectangle 5 is assigned to the second row from bottom to top (the other case being symmetric). Then in the two topmost rows we have to pack two rectangles of height 2 plus a rectangle of width 4 which is not possible as their total width is larger than the space left due to rectangle 1. This contradicts the fact that there is a feasible solution for the GSP instance  $\mathcal{I}$  of height 4. ◀

## 20:16 Approximation Algorithms for Demand Strip Packing

Now we will prove that even for the case of square tasks, the optimum packing for the two problems of SQUARE-DSP and SQUARE-GSP can exhibit a gap.

► **Lemma 14.** *There exists an instance of SQUARE-DSP such that the optimal schedule has peak 11 but every feasible solution for the corresponding SQUARE-GSP instance has height at least 12.*

**Proof.** Consider a SQUARE-DSP with  $W = 13$  and containing the following set  $\mathcal{I}$  of tasks (see Figure 1b for a depiction):

- Two tasks of height/width 6 (tasks 1 and 2 in the figure),
- Two tasks of height/width 5 (tasks 3 and 4 in the figure),
- One task of height/width 3 (task 5 in the figure),
- Two tasks of height/width 2 (tasks 6 and 7 in the figure), and
- Four tasks of height/width 1 (tasks 8, 9, 10 and 11 in the figure).

Since  $a(\mathcal{I}) = 11 \cdot 13$ , we have that  $OPT \geq 11$ . Figure 1b shows that the optimal peak is at most 11 and hence it is exactly 11.

Assume by contradiction that there exists a feasible packing for the corresponding SQUARE-GSP instance of height at most 11. Consider  $\mathcal{K}$  to be the region  $[0, 0] \times [13, 11]$  in the plane, and let  $(x_i, y_i)$  be the coordinate of the bottom-left corner of task  $i$  in the solution. Notice that  $\mathcal{K}$  must be completely filled with tasks.

We can assume that  $x_1 \leq x_2$ , and since tasks 1 and 2 have height 6 and the height of  $\mathcal{K}$  is 11, it must hold that  $x_1 \leq x_2 + 6$ . Hence, w.l.o.g. there are two cases to consider:

- $x_1 = 0$  and  $x_2 = 6$ :

In this case the region  $[12, y_2] \times [13, y_2 + 6]$  can only contain squares of size 1, and they cannot fill the region completely, so this case cannot happen.

- $x_1 = 0$  and  $x_2 = 7$ :

We show that  $y_1, y_2 \in \{0, 5\}$ ; Assume that  $y_1 \notin \{0, 5\}$ . Then tasks 2, 3 and 4 must be packed inside the region  $[6, 0] \times [13, 11]$  since they can not be packed above or below task 1. Since  $a(j_2) + a(j_3) + a(j_4) > 77$ , this is not possible, hence proving the claim.

Note that if  $y_1 = y_2$  then, similarly to the previous case, the area in  $[6, y_1] \times [7, y_1 + 6]$  can only contain tasks of size 1 and they cannot fill this region completely. So we can assume that  $(x_1, y_1) = (0, 0)$  and  $(x_2, y_2) = (7, 5)$ .

Now every remaining rectangle is either packed in  $[6, 0] \times [13, 5]$  or in  $[0, 6] \times [7, 11]$ . However, among tasks 3, 4 and 5, it is not possible to place two of them in one of the previously mentioned rectangular region together, contradicting the existence of a feasible solution of height 11. ◀

## A Hardness of Approximation for Square-DSP

For several rectangle packing problems it is usually the case that they are NP-hard (or APX-hard) even when restricted to instances consisting solely of squares [33]. This holds also for DSP, as the following theorem shows.

► **Theorem 15.** *For any  $\varepsilon > 0$ , there exists no polynomial-time  $(3/2 - \varepsilon)$ -approximation algorithm for SQUARE-DSP unless  $NP = P$ .*

In order to prove this result, we show a gap-producing reduction from the NP-complete BALANCED PARTITION problem, formally defined as follows.

► **Definition 16** (BALANCED PARTITION). *In an instance of the BALANCED PARTITION problem, we are given a set of  $2n$  positive integers  $A = \{a_1, a_2, \dots, a_{2n}\}$ . The goal is to decide whether there exists a partitioning of  $A$  into  $A_1$  and  $A_2$  such that  $|A_1| = |A_2| = n$ , and the sum of the numbers in each of the two sets is equal to a target value  $B = \left(\sum_{j=1}^{2n} a_j\right) / 2$ .*

We start first by proving that the BALANCED PARTITION problem is NP-complete. This result is folklore by now but, for the sake of completeness, we bring a complete proof.

► **Theorem 17.** *BALANCED PARTITION is NP-complete.*

**Proof.** We will reduce the PARTITION problem to the balanced variant in polynomial time. Given an instance  $\mathcal{I}$  of the PARTITION problem with  $n$  numbers  $a_1, a_2, \dots, a_n$ , we construct an instance  $\mathcal{I}'_k$  of the BALANCED PARTITION problem for each  $k \in \{1, 2, \dots, \lfloor n/2 \rfloor\}$ . Let  $C$  be  $(\sum_{j=1}^n a_j) + 1$ . For each  $k$ , the instance  $\mathcal{I}'_k$  is defined as follows. Let  $\mathcal{I}'_k$  have all the initial numbers,  $a_1, a_2, \dots, a_n$ . Add the set **dummy** of  $n - 2k + 2$  extra numbers where **dummy** =  $\{\alpha, \beta_1, \beta_2, \dots, \beta_{n-2k+1}\}$  in which  $\alpha = (n - 2k + 1)C$  and  $\beta_i = C$  for each  $i \in [n - k + 1]$ . We claim that  $\mathcal{I}$  is a *Yes* instance of the PARTITION problem if and only if at least one  $\mathcal{I}'_k$  is a *Yes* instance of the BALANCED PARTITION problem.

**Completeness.** Assume that  $\mathcal{I}$  is a *Yes* instance of the PARTITION problem. Let  $S_1$  and  $S_2$  be the two sets of equal sum, say  $B$ . These sets may not necessarily have the same cardinality. With sum renumbering, assume that  $S_1 = \{a_1, a_2, \dots, a_k\}$  and  $S_2 = \{a_{k+1}, a_{k+2}, \dots, a_n\}$  for some  $k \in [\lfloor n/2 \rfloor]$ . It is easy to see that the instance  $\mathcal{I}'_k$  of the BALANCED PARTITION problem is a *Yes* instance, since we can make the sets  $S'_1 = \{a_1, a_2, \dots, a_k, \beta_1, \beta_2, \dots, \beta_{n-2k+1}\}$  and  $S'_2 = \{a_{k+1}, a_{k+2}, \dots, a_n, \alpha\}$  both with the sum  $B + (n - 2k + 1)C$  and cardinality  $n - k + 1$ .

**Soundness.** Now assume that  $\mathcal{I}$  is a *No* instance of the PARTITION problem. We claim that no  $\mathcal{I}'_k$  can be a *Yes* instance of the BALANCED PARTITION problem either. For the sake of contradiction, assume  $\mathcal{I}'_k$  is a *Yes* instance with two partitions  $S'_1$  and  $S'_2$  of the same sum and cardinality. Note that if no  $\beta_i$  is placed in the same set as  $\alpha$ , we reach a contradiction since we then can find two sets  $S_1 = \{a_1, a_2, \dots, a_k\}$  and  $S_2 = \{a_{k+1}, a_{k+2}, \dots, a_n\}$  of the same sum of the original PARTITION instance  $\mathcal{I}$ . So with some renumbering, we can assume we have  $S'_1 = \{a_1, a_2, \dots, a_{k'}, \alpha, \beta_1, \beta_2, \dots, \beta_\ell\}$  and  $S'_2 = \{a_{k'+1}, a_{k'+2}, \dots, a_n, \beta_{\ell+1}, \beta_{\ell+2}, \dots, \beta_{n-2k+1}\}$  for some  $k'$  and  $\ell$  in which:

$$\sum_{j=1}^{k'} a_j + (n - 2k + 1)C + \ell \cdot C = \sum_{j=k'+1}^n a'_j + (n - 2k + 1 - \ell)C.$$

This implies that

$$2\ell \cdot C = \sum_{j=k'+1}^n a'_j - \sum_{j=1}^{k'} a_j \leq \sum_{j=k'+1}^n a'_j < C,$$

which is a contradiction. ◀

**Proof of Theorem 15.** Assume an instance  $\mathcal{I}$  of the BALANCED PARTITION problem is given. Based in this instance, we define an instance  $\mathcal{I}'$  of SQUARE-DSP. Let  $a_{max}$  denote the maximum value among the integers in  $A$ . Define  $C$  as  $1/\varepsilon \cdot \sum_{j=1}^{2n} a_j$ , where  $\varepsilon$  is chosen such that  $1/\varepsilon$  is a large but constant integer. Note that  $C > 1/\varepsilon \cdot a_{max}$ . Let  $\mathcal{I}'$  have  $2n$  tasks, where each task  $i$  has width and height  $C + a_i$  for  $i \in [2n]$ . Our goal is to schedule the  $2n$  tasks into a path of  $W = n \cdot C + B$  edges while minimizing the peak. Based on the hardness of the BALANCED PARTITION problem, we show that it is hard to distinguish between the case where an schedule with peak  $2C(1 + \varepsilon)$  exists and the case where the minimum peak is larger than  $3(C + 1) - \varepsilon$ .

**Completeness.** Assume that  $\mathcal{I}$  is a *Yes* instance, meaning that a partitioning  $A = A_1 \dot{\cup} A_2$  exists that satisfies the cardinality and sum constraints. Define two shelves of squares,  $S_i = \{j | a_j \in A_i\}$  for  $i = 1, 2$ , and schedule them starting at the leftmost edge. The width of each shelf is equal to  $n \cdot C + B$  and the peak is at most  $2 \cdot (C + a_{max}) < 2C(1 + \varepsilon)$ .

**Soundness.** Now, consider a No instance  $\mathcal{I}$ . We claim that, for the corresponding SQUARE-DSP instance, no schedule with peak smaller than or equal to  $3(C+1) - \varepsilon$  exists. For the sake of contradiction, assume that it is the case. Since the size of each task is at least  $C+1$ , it means that in the optimal solution for  $\mathcal{I}'$ , no three tasks use the same edge. Also, the total width of the tasks is  $2W = 2(nC + b)$ , so no edge can have less than two tasks. This allows us to split the tasks  $S$  into two sets  $S_1$  and  $S_2$ . We start at the leftmost edge and pick one of the two tasks placed on this edge arbitrarily and put in  $S_1$ . Since every edge has exactly two tasks, immediately to the right of this task at least one another task must start. We put it in  $S_1$  as well and proceed until we reach the rightmost edge, breaking ties arbitrarily along the way. We set  $S_2 = S \setminus S_1$ . It remains to show that each set has exactly  $n$  tasks. Assume otherwise; let  $S_1$  be composed of tasks  $s_1, \dots, s_{n+k}$ , and  $S_2$  be the tasks  $s_{n+k+1}, \dots, s_{2n}$  for some  $k$ ,  $1 \leq k \leq n$ . Since the tasks are placed one next to the other in each shelf, we have that  $(n+k)C + \sum_{j=1}^{n+k} a_j = (n-k)C + \sum_{j'=n+k+1}^{2n} a_{j'}$ . Therefore  $\sum_{j'=n+k+1}^{2n} a_{j'} \geq 2k \cdot C$ , which is a contradiction for any value of  $k > 0$  by our choice of  $C$ .

As a result, assuming that  $\text{NP} \neq \text{P}$ , no polynomial-time algorithm can approximate the SQUARE-DSP problem within a factor of  $\frac{3(C+1)-\varepsilon}{2C(1+\varepsilon)} = 3/2 - \varepsilon'$ , for some  $\varepsilon' = O(\varepsilon)$ . ◀

## B A PTAS for DSP with short tasks

In this section we will prove Theorem 2 restated below.

► **Theorem 2.** *Given  $\varepsilon > 0$  small enough, there exists  $\delta > 0$  and a polynomial time algorithm such that, given an instance of DSP with optimal value  $OPT$  and consisting solely of tasks having height at most  $\delta \cdot OPT$ , it computes a  $(1 + O(\varepsilon))$ -approximate solution.*

Before proving the result in detail we provide a couple of required technical lemmas regarding the computation of  $\pi$ -left-pushing of a given schedule  $P(\cdot)$ . First of all, we prove that such a solution can be indeed computed efficiently.

► **Lemma 18.** *Given a feasible schedule  $P(\cdot)$  with peak  $\pi$  for an instance  $\mathcal{I}$ , one can compute a  $\pi'$ -left-pushing of  $P(\cdot)$ , with  $\pi' \geq \pi$ , in polynomial time.*

**Proof.** Let  $1, \dots, n$  be the tasks sorted according to their starting edge in  $P(\cdot)$  from left to right. Let  $S_i$  be the starting edge of task  $i$ . First, inductively, we compute a  $\pi'$ -left-pushing of  $\mathcal{I} \setminus \{n\}$  and do not left-shift task  $n$ . Since we only left-shifted the tasks, the demand on the edges from  $S_n$  to  $e_W$  cannot increase. Thus, we reach a feasible solution such that its peak does not exceed  $\pi'$ . Now we compute the starting time of task  $n$ ,  $s^*$ , if we left-shift this task as much as possible. Note that  $s^*$  can only be either the leftmost edge or some edge  $e$  such that some previous task finishes next to the left of  $e$ , as otherwise at least one more unit of left-shifting is possible for task  $n$ . Now, using this fact, we have at most  $n$  possibilities for  $s^*$  and we can compute this value in polynomial time. Note that if we call the obtained schedule as  $P'(\cdot)$ , then  $P'(\cdot)$  is indeed a  $\pi'$ -left-pushing of  $P(\cdot)$ . ◀

The following lemma summarizes the useful properties we can get when computing a left-pushing.

► **Lemma 19.** *Given a feasible schedule  $P(\cdot)$  with peak  $\pi$  for an instance  $\mathcal{I}$ , the  $\pi'$ -left-pushing of  $P(\cdot)$  for  $\pi' \geq \pi$ , let us say  $P'(\cdot)$ , satisfies the following properties:*

1. *There exists a node  $t^*$  such that  $P'(\cdot)$  is  $(\pi' - h_{\max}(\mathcal{I}), t^*)$ -sorted, and*
2. *every  $i \in \mathcal{I}$  has a starting edge in  $\mathcal{E}'$  of the form  $\sum_{j \in \mathcal{I}'} w(j)$  for some  $\mathcal{I}' \subseteq \mathcal{I} \setminus \{i\}$  (0 if  $\mathcal{I}'$  is empty).*

**Proof.** We now show a proof of the two properties:

1. Suppose that there exists a node  $k$  such that the demand on the edge to the left of  $k$  is smaller than  $\pi' - h_{\max}(\mathcal{I})$  and the demand on the edge to the right of  $k$  is larger than  $\pi' - h_{\max}(\mathcal{I})$ . This implies that some task starts at the edge to the right of  $k$ , but then it is possible to left-shift this task without surpassing the threshold of  $\pi'$  which is a contradiction. At this point we know that there exists  $k'$  such that every edge to the left of  $k'$  has demand larger than  $\pi' - h_{\max}(\mathcal{I})$ , and let  $k^*$  be the rightmost such node. Similarly to the previous case, if after  $k^*$  there exists a node  $k$  such that the load to the left of  $k$  is smaller than the demand to the right of  $k$ , then again there must exist a task starting to the right of  $k$  and, since their demands are at most  $\pi' - h_{\max}(\mathcal{I})$ , left-shifting such task does not violate the threshold of  $\pi'$  which is a contradiction.

2. Suppose there exists a task not satisfying the claim, and let  $i$  be the leftmost such task in  $P'(\cdot)$ . It is easy to see that  $i$  cannot start at the leftmost edge and also that the demand on the edge just to the left of  $P'(i)$  is larger than  $\pi' - h(i)$  as otherwise a left-shifting of  $i$  is possible. Due to  $i$  being the leftmost task, no task  $i'$  can finish just to the left of  $P'(i)$ , as otherwise the number of edges before  $P'(i)$  would be the sum of some widths in  $\mathcal{I}$  plus  $w(i')$ , thus fulfilling the claim for  $i$ . This implies that every task using the edge just to the left of  $P'(i)$  must also use edge  $P'(i)$ . But then the total demand just to the left of  $P'(i)$  would be at most the total demand on  $P'(i)$  minus  $h(i)$ , which is at most  $\pi' - h(i)$ . ◀

We can now proceed with the proof of Lemma 2, where at some point in the proof we will make use of the following concentration bound which was proved in [11].

► **Lemma 20** (Calinescu et al. [11]). *Let  $X_1, X_2, \dots, X_n$  be independent random variables and let  $0 \leq \beta_1, \beta_2, \dots, \beta_n \leq 1$  be real numbers, where for each  $i = 1, 2, \dots, n$ ,  $X_i = \beta_i$  with probability  $p_i$  and  $X_i = 0$  otherwise. Let  $X = \sum_{i=1}^n X_i$  and  $\mu = \mathbb{E}[X]$ . Then*

1. *The variance of  $X$ ,  $\sigma^2(X)$ , is at most  $\mu$ , and*
2. *For any  $0 < \lambda < \sqrt{\mu}$ ,  $\mathbb{P}[X > \mu + \lambda\sqrt{\mu}] < e^{-\frac{\lambda^2}{2}(1-\lambda/\sqrt{\mu})}$ .*

**Proof of Theorem 2.** Let  $\delta > 0$  be a constant that we will specify later. We will partition the tasks into two sets according to their widths: we will say that a task  $i$  is *horizontal* if  $w(i) > \delta \cdot W$  and otherwise we will say it is *narrow*. Consider by now only the horizontal tasks in  $\mathcal{I}$ , and assume that the value  $OPT$  is known. Thanks to Lemma 19, by computing an  $OPT$ -left-pushing of the optimal solution, we know there exists a set  $\mathcal{E}_H \subseteq E$  that can be computed in polynomial time such that the starting edge of every task belongs to  $\mathcal{E}_H$ . Indeed, edges in  $\mathcal{E}_H$  correspond to the sum of widths of some horizontal tasks, implying that the number of widths in the sum must be at most  $\frac{1}{\delta}$ . Hence, all the possible starting edges are of the form  $\sum_{i \in \mathcal{I}'} w(i)$  where  $|\mathcal{I}'| \leq \frac{1}{\delta}$ . The set  $\mathcal{E}_H$  consisting of these edges has size at most  $n^{1/\varepsilon-1}$  and can clearly be computed in polynomial time.

With the following integer program we can compute a feasible solution corresponding to a  $OPT$ -left-pushing of some scheduling for these tasks. We define a variable  $x_{i,k}$  for each task  $i$  and starting edge  $k$  in the previously computed set  $\mathcal{E}_H$  (if task  $i$  cannot be scheduled starting at edge  $k$  this variable is not considered):

$$\begin{array}{ll}
 \min & \lambda \\
 \text{s.t.} & \sum_{k \in \mathcal{E}_H} x_{i,k} = 1 \quad \forall i \text{ horizontal} \\
 & \sum_{i \text{ hor.}} \sum_{k' \in \mathcal{E}_H(i,q)} h(i) \cdot x_{i,k'} \leq OPT \quad \forall q \in \mathcal{E}_H \\
 & x_{i,k} \in \{0, 1\} \quad \forall i \text{ horizontal, } k \in \mathcal{E}_H,
 \end{array}$$

where, given  $i \in \mathcal{I}$  and  $q \in \{1, \dots, W\}$ ,  $\mathcal{E}_H(i, e)$  is the set of edges  $k \in \mathcal{E}_H$  such that, if  $i$  has  $k$  as starting edge, then it uses edge  $e$ . In other words, the second family of constraints is ensuring that the total demand of the constructed solution is at most  $OPT$  in every edge (which can be done with polynomially many constraints thanks to the size of  $\mathcal{E}_H$ ).

We will consider the canonical linear relaxation of the formulation, and let  $\vec{x}$  be an optimal solution to this LP (which can be computed in polynomial time). In order to derive a feasible solution we will use *Randomized Rounding with Alterations*, a technique previously used in similar settings for Packing and Scheduling problems [11, 36, 2]. In a first stage, for each task  $i$ , we will sample one starting edge  $k$  according to the probability distribution induced by  $\{x_{i,k}\}_{k \in \mathcal{E}_H}$ . Now, in a second stage, we scan the starting edges  $k$  from left to right, and the sampled tasks  $i$  starting at node  $k$  according to the sample in any order, and we add  $i$  to the current solution as long as the obtained peak is no more than  $(1 + \varepsilon)OPT$ . Observe that this is a dependent rounding where each task  $i$  is finally scheduled in the solution with marginal probability at most  $x_{i,k}$ .

Suppose we are applying the previous procedure, and let  $k$  be a fixed edge in that order. Let  $\tilde{X}_{i,k} \in \{0, 1\}$  be equal to 1 if and only if  $i$  is scheduled starting at edge  $k$  in the first stage, and similarly we define  $\tilde{Y}_{i,k}$  to be 1 if and only if  $i$  is scheduled starting at edge  $k$  in the second stage. Notice that  $\tilde{Y}_{i,k} \leq \tilde{X}_{i,k}$  deterministically. By stochastic domination, we have that

$$\mathbb{P} \left[ \sum_{i \text{ hor.}} \sum_{k \in \mathcal{E}_H(i, q)} \tilde{Y}_{i,k} \cdot h(i) > (1 + \varepsilon)OPT \right] \leq \mathbb{P} \left[ \sum_{i \text{ hor.}} \sum_{k \in \mathcal{E}_H(i, q)} \tilde{X}_{i,k} \cdot h(i) > (1 + \varepsilon)OPT \right].$$

To upper bound the latter quantity we will consider two cases:

- If  $\mu \leq \frac{3}{4\delta}$ , then we can use Chebyshev's inequality for the variable  $Z := \sum_{i \text{ hor.}} \frac{\tilde{X}_{i,k} \cdot h(i)}{\delta OPT}$  (notice that thanks to Lemma 20 it holds that  $\sigma(Z) \leq \sqrt{\mu}$ ), from where we obtain that

$$\begin{aligned} \mathbb{P} \left[ \sum_{i \text{ hor.}} \sum_{k \in \mathcal{E}_H(i, q)} \tilde{X}_{i,k} \cdot h(i) > (1 + \varepsilon)OPT \right] &= \mathbb{P} \left[ Z > \frac{1 + \varepsilon}{\delta} \right] \\ &\leq \mathbb{P} \left[ |Z - \mu| > \left( \frac{1 + \varepsilon}{\delta} - \frac{3}{4\delta} \right) \cdot \frac{\sigma(Z)}{\sqrt{\mu}} \right] \\ &\leq \frac{16\mu\delta^2}{(1 + 4\varepsilon)^2} \leq \varepsilon \end{aligned}$$

for  $\delta \leq \frac{\varepsilon}{4}$ .

- If  $\mu > \frac{3}{4\delta}$ , we first set  $\lambda = \frac{1 + \varepsilon - \mu\delta}{\delta\sqrt{\mu}}$  so that  $\mu + \lambda\sqrt{\mu} = \frac{1 + \varepsilon}{\delta}$ . Notice that  $\mu = \sum_{i \text{ hor.}} \frac{x_{i,k} \cdot h(i)}{\delta OPT} \leq \frac{1}{\delta}$  due to the constraints in the LP.

Now, it is not difficult to see that  $\lambda$  is decreasing as a function of  $\mu$ , implying that  $\lambda \geq \frac{1 + 4\varepsilon}{\sqrt{12\delta}}$ . Furthermore, we have that  $1 - \frac{\lambda}{\sqrt{\mu}} = 2 - \frac{1 + \varepsilon}{\delta\mu} \geq \frac{2}{3}$ , and thus also  $\lambda < \sqrt{\mu}$ . Now we can use Lemma 20 applied to the variables  $\{X_{i,k}h(i)/(\delta OPT)\}_{i \text{ hor.}}$  and their sum  $Z$  and obtain

$$\begin{aligned} \mathbb{P} \left[ \sum_{i \text{ hor.}} \sum_{k \in \mathcal{E}_H(i, q)} \tilde{X}_{i,k} \cdot h(i) > (1 + \varepsilon)OPT \right] &= \mathbb{P} [Z > \mu + \lambda\sqrt{\mu}] \\ &< e^{-\frac{\lambda^2}{2}(1 - \lambda/\sqrt{\mu})} \\ &< e^{-\frac{2}{9} \frac{(1 + 4\varepsilon)^2}{12\delta^2}} \leq \varepsilon \end{aligned}$$

for  $\delta \leq \frac{(1 + 4\varepsilon)^2}{54} \ln \frac{1}{\varepsilon}$ .

## 20:24 Approximation Algorithms for Demand Strip Packing

This implies that we get a solution with peak at most  $(1 + \varepsilon)OPT$  and the probability that a task is not scheduled is at most  $\varepsilon$ . As a consequence, in expectation the total area of tasks that were not placed is at most  $\varepsilon W \cdot OPT$ , and hence using Markov's inequality we get that the probability that these tasks have area larger than  $2\varepsilon W \cdot OPT$  is at most  $\frac{1}{2}$ . Thus, if the area of these tasks is at most  $2\varepsilon W \cdot OPT$  and since their heights are at most  $\delta \cdot OPT$ , we can place them into a rectangular region of height  $4\varepsilon OPT$  and width  $W$  using Corollary 7. If the area guarantee is not satisfied then we repeat the whole process to ensure it as, in expectation, a constant number of times only is required.

Now we will include the set  $\mathcal{N}$  of narrow tasks into the solution by applying Lemma 12 with parameter  $\pi = (1 + 5\varepsilon)OPT$ . Consider a  $\pi$ -left-pushing of the solution. Thanks to Lemma 19, there exists a node  $t^*$  such that the obtained schedule is  $(\pi, t^*)$ -sorted. Furthermore, it is not difficult to see that  $\pi \geq (1 + 4\varepsilon)\frac{a(\mathcal{I})}{W} + h_{\max}(\mathcal{I}'')$  and  $w_{\max}(\mathcal{N}) \leq \varepsilon W \leq \frac{4\varepsilon}{2(4\varepsilon+1)}$  for  $\varepsilon \leq 1/4$ , hence satisfying the requirements of the lemma. This way, we obtain a feasible scheduling with peak at most  $(1 + 5\varepsilon)OPT$ .

Finally, in order to avoid knowing the value of  $OPT$ , we can approximately guess it using any constant approximation (such as Corollary 7) and define a constant number of candidates. ◀

## Abstract

---

We study the Nonpreemptive Peak Demand Minimization (NPDM) problem, where we are given a set of jobs, specified by their processing times and energy requirements. The goal is to schedule all jobs within a fixed time period such that the peak load (the maximum total energy requirement at any time) is minimized. This problem has recently received significant attention due to its relevance in smart-grids. Theoretically, the problem is related to the classical strip packing problem (SP). In SP, a given set of axis-aligned rectangles must be packed into a fixed-width strip, such that the height of the strip is minimized. NPDM can be modeled as strip packing with slicing and stacking constraint: each rectangle may be cut vertically into multiple slices and the slices may be packed into the strip as individual pieces. The stacking constraint forbids solutions where two slices of the same rectangle are intersected by the same vertical line. Nonpreemption enforces the slices to be placed in contiguous horizontal locations (but may be placed at different vertical locations).

We obtain a  $(5/3 + \epsilon)$ -approximation algorithm for the problem. We also provide an asymptotic efficient polynomial-time approximation scheme (AEPTAS) which generates a schedule for almost all jobs with energy consumption  $(1 + \epsilon)\text{OPT}$ . The remaining jobs fit into a thin container of height 1. The previous best result for NPDM was a 2.7 approximation based on FFDH [41]. One of our key ideas is providing several new lower bounds on the optimal solution of a geometric packing, which could be useful in other related problems. These lower bounds help us to obtain approximative solutions based on Steinberg's algorithm in many cases. In addition, we show how to split schedules generated by the AEPTAS into few segments and to rearrange the corresponding jobs to insert the thin container mentioned above.

## 1 Introduction

Recent years have seen a substantial increase in the demand of electricity, due to rapid urbanization, economic growth and new modes of electrical energy consumption (e.g., electric cars). Traditionally, electricity generation, transmission, and distribution relied on building infrastructure to support the peak load, when the demand for electricity is maximum. However, the peak is rarely achieved and thus more demands can be accommodated using the inherent flexibility of scheduling of certain jobs. E.g., the energy requirements for HVAC units, electric vehicles, washers and dryers, water heaters, etc. can be met with a flexible scheduling of these appliances. Smart-grids [48, 32, 45] are next-generation cyber-physical systems that couple digital communication systems on top of the existing grid infrastructure for such efficient utilization of power, e.g., by shifting users' demand to off-peak hours in order to reduce peak load.

Future smart-grids are expected to obtain demand requirements for a time period and schedule the jobs such that the peak demand is minimized. Recently, this problem has received considerable attention [3, 37, 40, 42, 12]. Each job can also be modeled as a rectangle, with desired power demand as height and required running time as width. This gives a geometric optimization problem where the goal is to pack the slices of the rectangles into a strip of width as the time period. The goal is to minimize the maximum height of the packing. There is another additional *stacking constraint* requiring that no vertical line may intersect two slices from the same rectangle.

In this paper, we study this problem known as Nonpreemptive Peak Demand Minimization (NPDM). Formally, we are given a set of jobs  $\mathcal{J}$ . Each job  $j \in \mathcal{J}$  has a processing time  $p(j) \in \mathbb{N}$  (also called width) and an energy requirement  $e(j) \in \mathbb{N}$  (also called height). Furthermore, we are given a deadline  $D \in \mathbb{N}$ . All the jobs are available from the time 0 and have to be finished before the deadline  $D$ . A schedule  $\sigma$  of the jobs  $\mathcal{J}$  assigns each job a starting time  $\sigma(j) \in \mathbb{N}$  such that it is finished before the deadline, i.e.,  $c(j) := \sigma(j) + p(j) \leq D$ . The total energy consumption at a time  $\tau \in \{0, \dots, D\}$  is given by  $e(\tau) := \sum_{j \in \mathcal{J}, \sigma(j) \leq \tau < \sigma(j) + p(j)} e(j)$ . The objective is to minimize the peak of energy consumption, i.e., minimize  $T_\sigma := \max_{\tau \in \{0, \dots, D-1\}} e(\tau)$ .

NPDM can be viewed as a variant of strip packing problem, where we are allowed to slice the rectangles vertically and the slices must be packed in contiguous horizontal positions (but may be placed at different vertical positions). In the classical strip packing problem, we are given a set of rectangles as well as a bounded-width strip and the objective is to find a non-overlapping, axis-aligned packing of all rectangles into the strip so as to minimize the height of the packing. A simple reduction from the PARTITION problem shows a lower bound of  $3/2$  for polynomial-time approximation for the problem. In 1980, Baker et al. [4] first gave a 3-approximation algorithm. Later Coffman et al. [31] introduced two simple shelf-based algorithms: Next Fit Decreasing Height (NFDH), First Fit Decreasing Height (FFDH), with approximation ratios as 3 and 2.7, respectively. Sleator [46] gave a 2.5-approximation. Thereafter, Steinberg [47] and Schiermeyer [44] independently improved the approximation ratio to 2. Afterwards, Harren and van Stee [21] obtained a 1.936-approximation. The present best approximation is  $(5/3 + \varepsilon)$ , due to Harren et al. [20].

Alamdari et al. [3] studied a variant where we allow preemption of jobs, also known as two-dimensional strip packing with slicing and stacking constraints (2SP-SSC), or preemptive offline cost optimal scheduling problem (P-OCOSP) [41]. They showed this variant to be NP-hard and obtained an FPTAS. They also studied several shelf-based algorithms and provide a practical polynomial time algorithm that allows only one preemption per job. Ranjan et al. [42] have proposed a practical  $4/3$ -approximation algorithm for this problem.

For NPDM, Tang et al. [48] first proposed a 7-approximation algorithm. Yaw et al. [49] showed that NPDM is NP-hard to approximate within a factor better than  $3/2$ . They have given a 4-approximation for a special case when all jobs require the same execution time. Ranjan et al. [40], have proposed a 3-approximation algorithms for NPDM. They [41] also proposed an FFDH-based 2.7-approximation algorithm for a mixed variant where some jobs can be preempted and some can not be preempted.

**Our Contributions.** We obtain improved approximation algorithms for NPDM.<sup>1</sup> Note that the optimal solutions of sliced strip packing/NPDM and strip packing can be quite different. In fact, in [9] an example with a ratio  $5/4$  is presented. Thus, the techniques from strip packing do not always translate directly to our problem. We exploit the property that, due to slicing, we can separately guess regions (*profile*) for packing of jobs with large energy demand (*tall* jobs) and jobs with large time requirements (*wide* jobs). We show that we can remove a small amount of jobs with large energy demand so that we can approximately guess the optimal profile of jobs with large processing time so that their starting positions come from a set containing a constant number of values. This helps us to show the existence of a structured solution that we can pack near-optimally using linear programs. This shows the existence of an asymptotic efficient polynomial-time approximation scheme (AEPTAS):

► **Theorem 1.** *For any  $\varepsilon > 0$ , there is an algorithm that schedules all jobs such that the peak load is bounded by  $(1 + \varepsilon)\text{OPT} + e_{\max}$ , where  $e_{\max}$  denotes the maximal energy demand among the given jobs. The time complexity of this algorithm is bounded by  $\mathcal{O}(n \log(n)) + 1/\varepsilon^{1/\varepsilon^{\mathcal{O}(1/\varepsilon)}}$ .*

In fact, we show a slightly stronger result here, providing a schedule for almost all jobs  $\mathcal{J} \setminus \mathcal{C}$  with peak energy demand bounded by  $(1 + \varepsilon)\text{OPT}$  plus a schedule for the remaining jobs  $\mathcal{C}$  with peak energy demand  $e_{\max}$  and schedule length  $\lambda D$  for a sufficiently small  $\lambda \in [0, 1]$ .

Using the AEPTAS and Steinberg’s algorithm[47], we obtain our main result:

► **Theorem 2.** *For any  $\varepsilon > 0$ , there is a polynomial-time  $(5/3 + \varepsilon)$ -approximation algorithm for NPDM.*

Previously, in strip packing (and related problems) the lower bound on the optimal packing height is given based on the height of the tallest job or the total area of all jobs [47, 44]. One of our main technical contributions is to show several additional lower bounds on the optimal load. These bounds may be helpful in other related geometric problems. In fact, these can be helpful to simplify some of the analyses of previous algorithms. Using these lower bounds, we show, intuitively, that if there is a large amount of energy consuming jobs (or time consuming jobs) we can obtain a good packing using Steinberg’s algorithm. Otherwise, we start with the packing from AEPTAS and modify the packing to obtain a packing within  $(5/3 + \varepsilon)$ -factor of the optimal. This repacking utilizes novel insights about the structure of the packing that precedes it, leading to a less granular approach when repacking.

**Related Work.** Strip packing has also been studied under asymptotic approximation. The seminal work of Kenyon and Rémila [34] provided an APTAS with an additive term  $\mathcal{O}(e_{\max}/\varepsilon^2)$ , where  $e_{\max}$  is the height of the tallest rectangle. The latter additive term was subsequently improved to  $e_{\max}$  by Jansen and Solis-Oba [28]. Pseudo-polynomial time algorithm for strip packing has received recent attention [39, 18, 2, 22]. Finally, Jansen and

<sup>1</sup> The same result as in Theorem 1 was achieved independently in [15]; their approach is however substantially different from ours.

Rau [27] gave an almost tight pseudo-polynomial time  $(5/4 + \varepsilon)$ -approximation algorithm. Recently, Galvez et al. [14] gave a tight  $(3/2 + \varepsilon)$ -approximation algorithm for a special case when all rectangles are skewed (each has either width or height  $\leq \delta D$ , where  $\delta \in (0, 1]$  is a small constant).

A related problem is non-contiguous multiple organization packing [10], where the width of each rectangle represents a demand for a number of concurrent processors. This is similar to sliced strip packing, however, the slices need to be horizontally aligned to satisfy concurrency. Several important scheduling problems are related, such as multiple strip packing [27], malleable task scheduling [23], parallel task scheduling [29], moldable task scheduling [24, 25], etc.

Several geometric packing problems are well-studied in combinatorial optimization. In two-dimensional bin packing, we are given a set of rectangles and the goal is to pack all rectangles into the minimum number of unit square bins. This well-studied problem [5, 26] is known to admit no APTAS [6], unless  $P=NP$ , and the present best approximation ratio is 1.406 [7]. Another related problem is two-dimensional geometric knapsack [30, 17], where each rectangle has an associated profit and we wish to pack a maximum profit subset of rectangles in a given square knapsack. The present best approximation ratio for the problem is 1.89 [16]. These problems are also studied under guillotine cuts [8, 36, 35] where all jobs can be cut out by a recursive sequence of end-to-end cuts. There are several other important related problems such as maximum independent set of rectangles [1], unsplittable flow on a path [19], storage allocation problem [38], etc. We refer the readers to [13] for a survey.

The following result from [47] will be a crucial subroutine in our algorithms.

► **Theorem 3** (Steinberg's Algorithm [47]). *Steinberg's algorithm packs a set of rectangular objects  $\mathcal{R}$  into a rectangular container of height  $a$  and width  $b$  in polynomial time, if and only if the following inequalities hold:*

$$e_{\max} \leq a, \quad p_{\max} \leq b, \quad 2 \sum_{r \in \mathcal{R}} e(r)p(r) \leq ab - (2e_{\max} - a)_+(2p_{\max} - b)_+, \quad (\text{Steinberg Cond.})$$

where  $x_+ = \max\{x, 0\}$ ,  $p_{\max}$  is the maximal width of a rectangle, and  $e_{\max}$  is the maximal height of a rectangle,  $e(r)$  represents the height of a rectangle and  $p(r)$  represents the width of a rectangle.

**General Approach.** The general idea of our  $(5/3 + \varepsilon)$ -approximation algorithm is as follows: If the jobs that are large in at least one of the two dimensions have a sufficiently large total amount of work, a  $(5/3 + \varepsilon)$ -approximation can be achieved by placing these jobs in a structured manner and using Steinberg's algorithms to place the residual jobs. We describe two of these cases in Section 2.

Otherwise, we know that the total amount of work of these jobs not too large. In this case, we find a schedule  $\sigma_1$  that schedules almost all the jobs using an energy demand of at most  $(1 + \mathcal{O}(\gamma))\text{OPT}$ . The residual jobs are contained in an extra schedule  $\sigma_2$  of length  $\gamma D$  and peak energy demand bounded by  $T$ . These schedules are generated using the algorithm described Section 4 in the proof of Theorem 10. Note that we have to choose  $\gamma \in \mathcal{O}_\varepsilon(1)$  small enough, in order to meet the requirements for the next step.

Given these schedules, we find a rescheduling argument, where we rearrange the schedule  $\sigma_1$  such that we can add the schedule  $\sigma_2$  while increasing the peak energy demand by at most  $(2/3)T$ . This repacking argument is described in Section 3 in the proof of Theorem 7.

**Notation.** For an instance  $I = (\mathcal{J}, D)$ , we denote by  $\text{OPT}(I)$  (or just  $\text{OPT}$ ) the optimal energy consumption peak. For some set of jobs  $\mathcal{J}$  we define  $\text{work}(\mathcal{J}) = \sum_{i \in \mathcal{J}} p(i)e(i)$ , the total processing time as  $p(\mathcal{J}) = \sum_{i \in \mathcal{J}} p(i)$ , as well as the total energy demand as  $e(\mathcal{J}) = \sum_{i \in \mathcal{J}} e(i)$ . With the additional notation of  $\mathcal{J}_{P(i)} = \{i \in \mathcal{J} \mid P(i)\}$  as a restriction of  $\mathcal{J}$  using the predicate  $P$ . E.g., we may express the energy demand of jobs of  $\mathcal{J}$  which have a processing time of at least  $D/2$  by  $e(\mathcal{J}_{p(i) \geq D/2})$ . Furthermore, given a set of jobs  $\mathcal{J}$ , we denote  $p_{\max}(\mathcal{J}) := \max_{i \in \mathcal{J}} p(i)$  and  $e_{\max}(\mathcal{J}) := \max_{i \in \mathcal{J}} e(i)$  and write  $e_{\max}$  and  $p_{\max}$  if the set of jobs is clear from the context. We say a job  $i$  that is placed at  $\sigma(i)$  overlaps a point in time  $\tau$  if and only if  $\sigma(i) \leq \tau < \sigma(i) + p(i)$ . The set  $\mathcal{J}(\tau)$  denotes the set of jobs that overlap the point in time  $\tau$ . Additionally, we introduce segments  $S$  of the schedule which refer to time intervals and container  $C$  which can be seen as sub schedules. The starting point of a time interval  $S$  will be denoted by  $\sigma(S)$  and its endpoint as  $c(S)$ . On the other hand, a container  $C$  has a length (time), which is denoted as  $p(C)$ , and a bound on the energy demand  $e(C)$ . If these containers are scheduled, they get a start point  $\sigma(C)$ , which is added to the start point of any job scheduled in  $C$ .

## 2 Cases solved with Steinberg's algorithm

In this section, we first bound the peak energy demand from below and then use Steinberg's algorithm to handle some cases. Two obvious lower bounds are the energy demand of the most energy demanding job  $e_{\max}$  and the bound given by the total amount of work of the jobs, i.e.,  $\text{OPT} \geq \max\{e_{\max}, \text{work}(\mathcal{J})/D\}$ . Another simple lower bound is the total energy demand of jobs longer than  $D/2$ , since they have to be scheduled in parallel. This gives us the first lower bound on  $\text{OPT}$  and we call it  $T_1 := \max\{e_{\max}, \text{work}(\mathcal{J})/D, e(\mathcal{J}_{p(i) > D/2})\}$ . In the following, we will present three more complex lower bounds. The next bound is related to the items with a large energy demand. We denote this lower bound as

$$T_2 := \min\{T \mid p(\mathcal{J}_{e(i) \geq T/3}) + p(\mathcal{J}_{e(i) \geq 2T/3}) \leq 2D \wedge p(\mathcal{J}_{e(i) \geq T/2}) \leq D\}.$$

The next two lower bounds depend on the ratio of long jobs and jobs with large energy demand. For a given  $k \in [n]$ , we define  $\mathcal{J}_k$  to be the set of the  $k$  jobs with the largest energy demand in  $\mathcal{J}$  and  $\mathcal{J}'_k$  to be the set of the  $k$  jobs with the largest energy demand in  $\mathcal{J} \setminus \mathcal{J}_{p(i) > D/2}$ . Let  $i_k$  and  $i'_k$  be the jobs with the smallest energy demand in  $\mathcal{J}_k$  and  $\mathcal{J}'_k$ , respectively. We define:

$$T_{3,a} := \max\{\min\{e(i_k) + e(\mathcal{J}_{p(i) > D - p(\mathcal{J}_k)/2} \setminus \mathcal{J}_k), 2e(i_k)\} \mid k \in \{1, \dots, n\}, p(\mathcal{J}_k) \leq D\},$$

$$T_{3,b} := \max\{\min\{e(i'_k) + e(\mathcal{J}_{p(i) > D - p(\mathcal{J}'_k)/2}), 2e(i'_k)\} \mid k \in \{1, \dots, n\}, p(\mathcal{J}'_k) \leq D\},$$

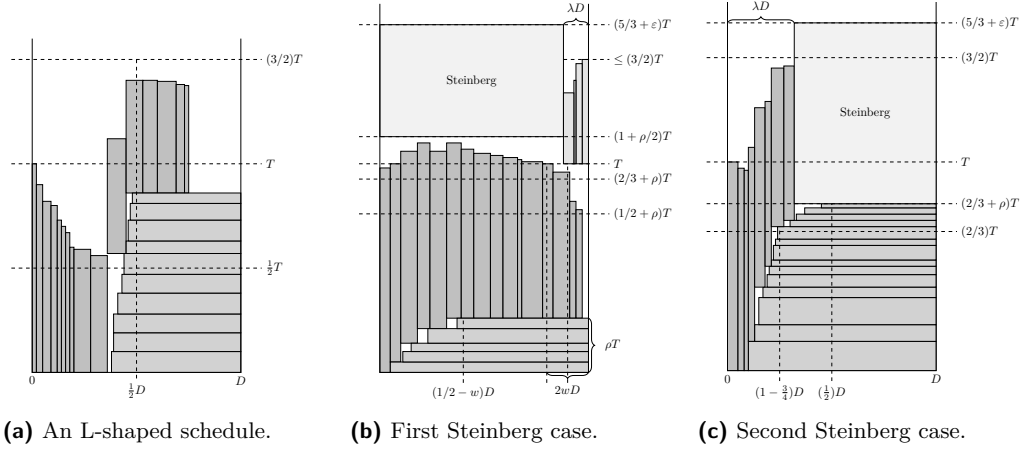

and  $T_3 = \max\{T_{3,a}, T_{3,b}\}$ .

Finally, define  $\mathcal{J}_k$  as the set of the  $k$  jobs with largest energy demand,  $\mathcal{J}_{D,k} := \mathcal{J}_{p(i) > (\max\{D - p(\mathcal{J}_k), D/2\})} \setminus \mathcal{J}_k$ . Let  $i_k$  be the job with the smallest energy demand in  $\mathcal{J}_k$ , then define

$$T_4 := \max\{\min\{2e(i_k), e(i_k) + e(\mathcal{J}_{D,k})/2\} \mid k \in \{1, \dots, n\}, p(\mathcal{J}_k) \leq D\}.$$

► **Theorem 4.** *Given an instance  $I = (\mathcal{J}, D)$ , the value  $T := \max\{T_1, T_2, T_3, T_4\}$  is a lower bound on  $\text{OPT}(I)$ . The value of  $T$  can be found in  $\mathcal{O}(n \log(n))$ .*

This lower bound on  $\text{OPT}$  helps us to identify two cases, that can be solved by scheduling jobs that are large in at least one of the two dimensions in a sorted manner, while the other jobs are scheduled using Steinberg's algorithm. We prove this and the following two theorems in the appendix.

■ **Figure 1** Subfigure 1a shows one possible L-shaped schedule, where  $\mathcal{J}_{\text{seq}}$  contains all the jobs with energy demand larger than  $T/2$  and  $\mathcal{J}_D$  contains all the jobs with processing time larger than  $D/2$ . Subfigure 1b shows a schedule in the case that  $p(\mathcal{J}_{e(i) > (2/3)T}) \geq (1 - w)D$ . Subfigure 1c shows a schedule in the case that  $e(\mathcal{J}_{p(i) > (3/4)D}) \geq (2/3)T$ .

▶ **Theorem 5 (First Steinberg Case).** Let  $T := \max\{T_1, T_2, T_3, T_4\}$  be the lower bound on OPT as defined above. If  $p(\mathcal{J}_{e(j) > (2/3)T}) \geq (1 - (3/4)\varepsilon)D$ , there is a polynomial time algorithm to place all jobs inside a schedule with peak energy demand at most  $(5/3 + \varepsilon)T$ .

▶ **Theorem 6 (Second Steinberg Case).** Let  $T$  be the lower bound on OPT defined as above. If  $e(\mathcal{J}_{p(i) \geq (3/4)D}) > (2/3)T$ , then there is a polynomial time algorithm that places all the jobs inside the area  $[0, D] \times [0, (5/3)T]$ .

### 3

 $(5/3 + \varepsilon)$ -Approximation

This section inspects schedules generated by the AEPTAS from Theorem 10, more closely. The AEPTAS generates a schedule that fits almost all jobs into an amount of work of peak energy demand  $T \leq (1 + \varepsilon)\text{OPT}$ . Left out of the schedule is a set of jobs that has a very small total processing time, where each job can have an energy demand up to OPT. As such, this set of jobs can be fit into a strip of energy demand OPT and processing time  $\gamma D$  for some  $\gamma > 0$ . Since we aim to generate a schedule of peak energy demand  $(5/3 + \varepsilon)\text{OPT}$ , it does not suffice to simply place this set atop the generated schedule, as this would result in a peak energy demand of  $2\text{OPT}$ . Instead, we must find some area in the generated schedule, inside of which we can remove jobs such that an energy demand of  $\text{OPT}/3$  for a processing time of  $\lambda D$  is empty, where  $\lambda \in [0, 1]$  is a small constant depending on  $\varepsilon$ . Once we have achieved this, and placed the jobs removed by this procedure in a way that does not intersect this strip, we can then place the strip of energy demand OPT at exactly that place, resulting in a schedule of peak energy demand  $(5/3 + \varepsilon)\text{OPT}$ . If none of the previously mentioned cases (as in Theorem 5 and 6, that can be solved using Steinberg's algorithm) apply, then the following Theorem combined with Theorem 10 proves Theorem 2.

▶ **Theorem 7.** Let  $\varepsilon \in (0, 1/3]$ ,  $\varepsilon' \leq (3/5)\varepsilon$  and  $\gamma \leq (3/40)\varepsilon$ . Given an instance  $I$  with  $e(\mathcal{J}_{p(j) > (3/4)D}) \leq (2/3)T'$  and  $p(\mathcal{J}_{e(j) > (2/3)T'}) \leq (1 - (3/4)\varepsilon)D$ , for  $T' = \max\{T_1, T_2, T_3, T_4\}$  and a schedule  $\sigma$  (e.g. generated by the APTAS) where almost all jobs are placed such that the peak energy demand is  $T \leq (1 + \varepsilon')\text{OPT}$ , and the residual jobs inside an additional box  $C_\gamma$  of energy demand  $T$  and processing time  $\gamma D$ , we can find a restructured schedule that places all the jobs up to a schedule with peak energy demand of at most  $(5/3 + \varepsilon)\text{OPT}$ .

■ **Figure 2** Splitting the given schedule into segments at time points  $\tau_1 = \frac{D}{8}$ ,  $\tau_2 = \frac{(15-24\gamma)D}{64}$ ,  $\tau_3 = \frac{(9+11\gamma)D}{32}$ ,  $\tau_4 = \frac{(3+2\gamma)D}{8}$  and  $\tau_5 = \frac{D}{2}$ .

**Proof.** From the schedule  $\sigma$ , we will generate a new schedule  $\sigma'$ . Some jobs will be shifted to new starting positions  $\sigma'$ . Other jobs  $j$  that are not mentioned in this proof keep their original starting positions, i.e.,  $\sigma'(j) = \sigma(j)$ .

If the schedule contains a job  $j$  with processing time  $p(j) \in [\gamma, (1-2\gamma)D]$  and energy demand  $e(j) \in [(1/3)T, (2/3)T]$ , we proceed as follows to make room for  $C_\gamma$  by shifting job  $j$ : Since  $p(j) \leq (1-2\gamma)D$  it holds that  $\max\{\sigma(j), D - (\sigma(j) + p(j))\} \geq \gamma D$ . Let us, w.l.o.g., assume that  $\sigma(j) \leq D - (\sigma(j) + p(j))$ , otherwise we mirror the schedule at  $D/2$ . We shift the job  $j$  completely to the right (by at least  $\gamma D$ ) such that it is positioned at  $\sigma'(j) := D - p(j)$ . This increases the peak energy demand to at most  $(5/3)T$ . Now the schedule between  $\sigma(j)$  and  $\sigma(j) + \gamma D$  has an energy demand of at most  $(2/3)T$ . We place the box  $C_\gamma$  at  $\sigma(j)$ . Since the box has an energy demand of at most  $T$ , the resulting schedule still has a peak energy demand of at most  $(5/3)T \leq (5/3 + \varepsilon)\text{OPT}$ .

If such a job does not exist, we search for segments that are not overlapped by jobs with energy demand larger than  $(2/3)T$ . We split the schedule into segments at the times  $\tau_1 = \frac{D}{8}$ ,  $\tau_2 = \frac{(15-24\gamma)D}{64}$ ,  $\tau_3 = \frac{(9+11\gamma)D}{32}$ ,  $\tau_4 = \frac{(3+2\gamma)D}{8}$  and  $\tau_5 = \frac{D}{2}$  as well at  $\tau'_i = D - \tau_i$  for  $i \in \{1, 2, 3, 4\}$  and set  $\tau_0 = 0$ . We number the resulting segments in increasing order from 0 to  $D/2$  and from  $D$  to  $D/2$  such that similar segments on both sides get the same number, see Figure 2. For  $k \in \{1, 2, 3, 4, 5\}$ , we denote by  $\sigma(S_k)$  ( $= \tau_{k-1}$ ) the start-time of a segment, by  $c(S_k)$  ( $= \tau_k$ ) the end-time of the segment and by  $p(S_k)$  ( $= \tau_k - \tau_{k-1}$ ) the processing time of the segment  $S_k$ . Since  $p(\mathcal{J}_{e(j) > (2/3)T}) \leq (1 - (3/4)\varepsilon)D$ , we know, by pigeonhole principle, that in one of these segments a total time of at least  $(3/4)\varepsilon D/10 \geq (3/40)\varepsilon D \geq \gamma D$  is not overlapped by these jobs.

Let  $S_{l,k_1}$  be the earliest such strip, and  $S_{r,k_2}$  the latest (they might be the same) such that  $k_1, k_2 \in \{1, 2, 3, 4, 5\}$  represent the index of the strips  $S_1, \dots, S_5$ . In the next step, we modify the start- and end-times of  $S_{l,k_1}$  such that it starts at the end of a job with energy demand at least  $(2/3)T$  or at 0. We denote the shifted start times as  $\sigma'(\cdot)$  and the shifted completion time as  $c'(\cdot)$ . If the start-time of  $S_{l,k_1}$ , i.e.  $\tau_{k-1}$  intersects a job  $j$  with  $e(j) \geq (2/3)T$ , we define  $\sigma'(S_{l,k_1}) := \sigma(j) + p(j) \leq c(S_{l,k_1}) - \gamma D$ . Otherwise if  $k_1 \neq 1$ , we find the last job  $j$  ending before  $\sigma(S_{l,k_1})$  with  $e(j) \geq (2/3)T$  and define  $\sigma'(S_{l,k_1}) := \sigma(j) + p(j) \geq \sigma(S_{l,k_1}) - \gamma D$  and shift the end-time of  $S_{l,k_1}$  by the same amount. Note that, since  $S_{l,k_1}$  is the first strip with at least  $\gamma D$  time not occupied by jobs with energy demand larger than  $(2/3)T$ , the starting time of  $S_{l,k_1}$  is reduced by at most  $\gamma D$ , while the processing time of the segment is not increased. Finally, if the end-time of  $S_{l,k_1}$  intersects a job  $j$  that has an energy demand larger than  $(2/3)T$ , we reduce it to  $c'(S_{l,k_1}) := \sigma(j)$  and call the modified segment  $S'_{l,k_1}$ . These modifications never decrease the total time that is not overlapped by jobs with energy demand larger than  $(2/3)T$  in  $S_{l,k_1}$ . We do the same but mirrored for  $S_{r,k_2}$  resulting in a modified segment  $S'_{r,k_2}$ . For an illustration of this procedure, see Figure 3. If  $D - c(S'_{r,k_2}) \leq \sigma(S'_{l,k_1})$ , we mirror the schedule such that  $\sigma'(j) = D - c(j)$ . We denote by  $S'_k$

■ **Figure 3** An illustration of the border shifting procedure. The original borders are indicated by  $\tau_{i-1}$  and  $\tau_i$ . As  $\tau_{i-1}$  is not intersected by a job with energy demand larger than  $(2/3)T$  we shift  $\sigma(S'_k)$  to an earlier point in time, such that the job with energy demand larger than  $(2/3)T$   $\pi_1$  ends at the exact same time. We then shift  $c(S'_k)$  by the same amount. The shifted  $c(S'_k)$  may intersect a job with energy demand larger than  $(2/3)T$   $\pi_2$ , indicated by the dotted line, and in this case we shift the border further such that  $c(S'_k) = \sigma(\pi_2)$  holds.

the segment in  $\{S'_{l,k_1}, S'_{r,k_2}\}$  that appears first in this new schedule, where  $k = \min\{k_1, k_2\}$  represents the original number of the chosen segment. As a consequence of this mirroring if  $k \geq 2$ , we ensured there exists a job  $j$  with  $e(j) > (2/3)T$  and  $c(S'_k) \leq \sigma(j) \leq D - \sigma(S'_k)$ . Additionally, we know about the start and endpoints of this segment that  $\tau_{k-1} - \gamma D \leq \sigma(S'_k)$  and  $p(S'_k) \leq \tau_k - \tau_{k-1}$ .

We aim to remove jobs from  $S'_k$ , such that the peak energy consumption reached inside  $S'_k$  is bounded by  $(2/3)T$ . We categorize the jobs to be removed in three classes; first the set of jobs  $\mathcal{J}_{\text{cont}}$  that are wholly contained in  $S'_k$  due to the earlier shifting and have an energy demand less than  $(2/3)T$ , second the set of jobs that have an energy demand larger than  $(2/3)T$ , and finally the set of jobs intersecting one of the time points  $\sigma(S'_k)$  or  $c(S'_k)$ . First, we remove  $\mathcal{J}_{\text{cont}}$  from the segment and schedule them inside a container that has an energy demand of at most  $(2/3)T$  and length at most  $3p(S'_k)$ .

► **Lemma 8.** *The jobs  $\mathcal{J}_{\text{cont}}$  can be scheduled inside a container  $C_{\text{cont}}$  of energy demand  $(2/3)T$  and processing time  $3p(S'_k) \leq D/2$ .*

**Proof.** First note that  $\text{work}(\mathcal{J}_{\text{cont}}) \leq p(S'_k)T$ , since the peak energy demand in  $\sigma$  is bounded by  $T$ . We place these jobs using Steinberg's algorithm. Recall that this procedure allows us to place a set of rectangles  $\mathcal{R}$  into a container of size  $a \cdot b$  as long as the following conditions are met:  $p_{\max}(\mathcal{J}) \leq a$ ,  $e_{\max}(\mathcal{J}) \leq b$ ,  $2 \cdot \text{work}(\mathcal{J}) \leq (ab - (2e_{\max}(\mathcal{J}) - T)_+)(2p_{\max}(\mathcal{J}) - D)_+$ . Setting our values for  $b = 3p(S'_k)$  and  $a = (2/3)T$  yields the desired property. Clearly no job wholly contained in a segment of processing time  $p(S'_k)$  can have a processing time greater than  $p(S'_k)$ . Furthermore, the maximum energy demand of any job in  $\mathcal{J}_{\text{cont}}$  is  $(2/3)T$ . Finally, we have:

$$\begin{aligned}
 2 \cdot \text{work}(\mathcal{J}_{\text{cont}}) &\leq 3p(S'_k) \cdot (2/3)T - (2p(S'_k) - 3p(S'_k))_+ \cdot (2(2/3)T - (2/3)T)_+ \\
 &= (ab - (2e_{\max}(\mathcal{J}) - b)_+(2p_{\max}(\mathcal{J}) - a)_+) \quad \blacktriangleleft
 \end{aligned}$$

In the next step, we consider the jobs with energy demand larger than  $(2/3)T$ . By construction of the strip, we know that the total processing time of jobs with energy demands larger than  $(2/3)T$  is bounded by  $p(S'_k) - \gamma D$ . We remove all these jobs from the strip and combine them with the extra container  $C_\gamma$  of energy demand at most  $T$  and processing time  $\gamma D$  to a new container called  $C_{\text{tall}}$ . It has an energy demand of at most  $T$  and a processing time of at most  $p(S'_k)$ .

After this step, the only jobs remaining inside the area of  $S'_k$  are the jobs that overlap the borders of  $S'_k$ . If the peak energy demand in  $S'_k$  is lower than  $(2/3)T$ , we place the container  $C_{\text{tall}}$  inside the strip  $S'_k$  as well as the container  $C_{\text{cont}}$  right of  $D/2$  and are done. Otherwise, we have to remove jobs that overlap the borders of the strip  $S'_k$  until the peak energy demand in  $S'_k$  is bounded by  $(2/3)T$ . The jobs we choose to remove are dependent on the position of the strip. The following lemma helps to see how these jobs can be shifted without increasing the peak energy demand of the schedule too much.

► **Lemma 9.** *Consider a schedule  $\sigma$  with peak energy demand bounded by  $T$  and a time  $\bar{\tau}$ , as well as a subset of jobs  $\mathcal{J}_{\text{Move}} \subseteq \mathcal{J}(\bar{\tau})$  with  $e(\mathcal{J}_{\text{Move}}) \leq a \cdot T$  for some  $a \in [0, 1]$ . Let  $\tau$  be the smallest value  $\sigma(j)$  for  $j \in \mathcal{J}_{\text{Move}}$ . Consider the schedule  $\sigma'$ , where all the jobs in  $\mathcal{J}_{\text{Move}}$  are delayed such that they end at  $D$ , i. e.,  $\sigma'(j) = D - p(j)$  for all  $\mathcal{J}_{\text{Move}}$  and  $\sigma'(j) = \sigma(j)$  for all other jobs.*

*In the schedule  $\sigma'$  before of  $D/2 + \tau/2$ , the peak energy demand is bounded by  $T$ , while after of  $D/2 + \tau/2$  the peak energy demand is bounded by  $(1 + a)T$ .*

**Proof.** If the energy demand of the schedule  $\sigma'$  is larger than  $T$  at a position  $\tau'$ , it has to be because one of the jobs in  $\mathcal{J}_{\text{Move}}$  overlaps it. Hence, that peak energy demand is bounded by  $(1 + a)T$ , since we shifted jobs with total energy demand bounded by  $aT$ . Let  $j$  be one of the shifted jobs. If  $\sigma'(j) > D/2 + \tau/2$ , the energy demand of the schedule before of  $D/2 + \tau/2$  cannot be influenced by this job. Therefore, assume that  $D - p(j) = \sigma'(j) \leq D/2 + \tau/2$ . As a consequence,  $p(j) \geq D/2 - \tau/2$ . Since  $\sigma(j) \leq \tau$  it holds that  $\sigma(j) + p(j) \geq D/2 + \tau/2$ . Thus before time  $D/2 + \tau/2$ , the job  $j$  overlaps its previous positions and cannot increase the peak energy demand above  $T$ . ◀

We choose which of the overlapping jobs to shift depending if  $k = 1$  or  $k \neq 1$ . Remember that none of the borders of  $S'_k$  overlap a job that has an energy demand larger than  $(2/3)T$ , and assume for the following, that there is a point inside  $S'_k$  where the total energy demand of overlapping jobs is larger than  $(2/3)T$ .

**Case 1:  $k = 1$ .** Consider the time  $\tau = c(S'_1) \leq D/8$  and the set of jobs  $\mathcal{J}(\tau)$  that are intersected by this line. We know that the total energy demand of jobs with processing time greater than  $(3/4)D$  is bounded by  $(2/3)T$ . Let  $\mathcal{J}_{\text{Move}}$  be the set of jobs generated as follows: Greedily take the jobs with the largest energy demand from  $\mathcal{J}(\tau) \setminus \mathcal{J}_{p(j) > (3/4)D}$ , until either all the jobs from  $\mathcal{J}(\tau) \setminus \mathcal{J}_{p(j) > (3/4)D}$  are contained in  $\mathcal{J}_{\text{Move}}$  or  $e(\mathcal{J}_{\text{Move}}) \in [(1/3)T, (2/3)T]$ . In this process, we never exceed  $(2/3)T$  since, if there is a job with energy demand larger than  $(1/3)T$  in  $\mathcal{J}(\tau) \setminus \mathcal{J}_{p(j) > (3/4)D}$ , we choose it first and immediately stop. We delay the jobs in  $\mathcal{J}_{\text{Move}}$  to new start positions  $\sigma'$  such that for each job  $j \in \mathcal{J}_{\text{Move}}$  we have that  $c'(j) := \sigma'(j) + p(j) = D$ . Note that  $\sigma'(j) \geq (1/4)D$  for each  $j \in \mathcal{J}_{\text{Move}}$  and therefore no longer overlaps  $c(S'_1)$ . Furthermore, we know by Lemma 9 that before  $D/2$  the peak energy demand is bounded by  $T$ , while after  $D/2$  the peak energy demand is bounded by  $(5/3)T$ . Furthermore, the peak energy demand inside  $S'_1$  is bounded by  $(2/3)T$ .

Since  $S'_1$  has a processing time of at most  $D/8$ , we know by Lemma 8 that  $\mathcal{J}_{\text{cont}}$  can be placed inside a container  $C_{\text{cont}}$  with energy demand at most  $(2/3)T$  and processing time bounded by  $3D/8$ . Therefore, we can schedule this container at  $D/8$  and know that it is finished before  $D/2$ . Finally, we schedule the container  $C_{\text{tall}}$  at  $\sigma'(C_{\text{tall}}) = 0$ . The peak energy demand of the resulting schedule is bounded by  $(5/3)T$ . See Figure 4a for the repacking procedure.

## 21:10 Peak Demand Minimization via Sliced Strip Packing

■ **Figure 4** Illustration of the steps in the proof of Theorem 7. Note that the set  $\mathcal{J}_{\text{Move}}$  is delayed such that the jobs end at  $D$ . The containers  $C_{\text{tall}}$  and  $C_{\text{cont}}$  are placed such that they do not intersect. For 4b and 4c, the jobs  $j_v$  are placed in the same manner, and the job  $j_r$  is denoted.

**Case 2:  $k \neq 1$ .** In this case, the borders of the considered strip can be overlapped from both sides. Furthermore, we know that the left border of  $S'_k$  is right of  $D/8 - \gamma D \geq \gamma D$ .

Consider the largest total energy demand of jobs that are intersected by any vertical line through  $S'_k$  and denote this energy demand as  $T_{S'_k}$ . Since there is a job  $j_l$  with energy demand larger than  $(2/3)T$  with  $\sigma(j_l) + p(j_l) = \sigma(S'_k)$ , we know that the total energy demand of jobs intersecting  $\sigma(S'_k)$  can be at most  $(1/3)T$ . Next, consider the closest job  $j_r$  that starts after  $c(S'_k)$  and has an energy demand larger than  $(2/3)T$ . By the choice of  $S'_k$ , we know that such a job must exist and that  $\sigma(j_r) \leq D - \sigma(S'_k)$ , by the choice of  $S'_k$  out of  $S'_{k_1,l}$  and  $S'_{k_2,r}$ . Furthermore, we know that the total energy demand of jobs intersecting the vertical line at  $\sigma(j_r)$  is bounded by  $(1/3)T$ .

Hence the jobs that overlap the vertical line at  $\sigma(j_r)$  and the jobs that overlap the vertical line at  $\sigma(S'_k)$  add a total energy demand of at most  $(2/3)T$  to  $T_{S'_k}$ . Let us now consider the jobs  $\mathcal{J}_M$  that overlap the time  $c(S'_k)$  but neither the time  $\sigma(S'_k)$  nor the time  $\sigma(j_r)$ . Each of them has a processing time of at most  $D - \sigma(S'_k) - \sigma(j_r) \leq D - 2\sigma(S'_k)$ . Hence when delaying their start points such that  $\sigma'(j) = D - p(j)$ , they no longer overlap the time  $c(S'_k)$  since  $p(S'_k) \leq \sigma(S'_k)$  for each  $k \in \{2, 3, 4, 5\}$ .

We greedily take jobs from  $\mathcal{J}_M$  that have the earliest starting point until we have all jobs from  $\mathcal{J}_M$  or we have a total energy demand of at least  $(1/3)T$ . If the total energy demand of the chosen jobs is larger than  $(2/3)T$ , the last job  $j_v$  has an energy demand of at least  $(1/3)T$ . Since it has a processing time lower than  $(1 - 2\gamma)D$ , it has to have a processing time of at most  $\gamma D$ . We remove this job and place it later, while we shift all the others to new positions  $\sigma'$  such that  $\sigma'(j) = D - p(j)$  for each of the taken jobs  $j$ . We call the set of shifted jobs  $\mathcal{J}_{\text{Move}}$ .

Furthermore, since  $\mathcal{J}_{\text{Move}}$  has a total energy demand of at most  $(2/3)T$  and a starting point right of  $\sigma(S'_k)$ , we know by Lemma 9 that the peak energy demand right of  $D/2 + \sigma(S'_k)/2$  is bounded by  $(5/3)T$  while left of  $D/2 + \sigma(S'_k)/2$  it is bounded by  $T$ .

Let  $\sigma(j_l)$  be the starting time of the last taken job. Before  $\sigma(j_l)$  (in  $S'_k$ ) there is no longer a job from  $\mathcal{J}_M$ , and, hence inside in the strip  $S'_k$  that is left of  $\sigma(j_l)$ , the peak energy demand is bounded by  $(2/3)T$ . On the other hand, after  $\sigma(j_l)$  (in  $S'_k$ ) we either have removed jobs with total energy demand at least  $(1/3)T$ , or all the jobs from  $\mathcal{J}_M$  and hence the schedule there can have a total energy demand of at most  $(2/3)T$  as well. Therefore, we can place the container  $C_{\text{tall}}$  inside  $S'_k$  without increasing the energy demand above  $(5/3)T$ .

The container  $C_{\text{cont}}$  and the job  $j_v$  remain to be placed. For  $k \in \{2, 3\}$ , we set  $C_{\text{cont}}$  at  $\sigma'(C_{\text{cont}}) = c(S'_k)$  and the job  $\sigma'(j_v) = 0$ , while for  $k \in \{4, 5\}$ , we set  $\sigma'(C_{\text{cont}}) = 0$  and  $\sigma'(j_v) = c(S'_k)$ . We will now see, for each segment, that the peak energy demand of  $(5/3)T$  is not exceeded by this new schedule.

First note that  $p(j_v) \leq \gamma D \leq D/8 - \gamma D$  and hence does not intersect  $S'_2$ , when scheduled at  $\sigma'(j_v) = 0$ . Similarly, it is more narrow than  $S'_5$  and  $\sigma(S'_5)/2$ , and hence fits right of  $S'_4$  and  $S'_5$  without increasing the schedule more than  $(5/3)T$ .

Let us now check the conditions for  $C_{\text{cont}}$ : For  $k \in \{2, 3\}$ , we have to ensure that  $c(S'_k) + p(C_{\text{cont}})/2 \leq D/2 + \sigma(S'_k)$ , while for  $k \in \{4, 5\}$  we have to prove that  $p(C_{\text{cont}}) \leq \sigma(S'_k)$ . It holds that  $p(S'_2) \leq \frac{(15-24\gamma)D}{64} - \frac{D}{8} = \frac{(7-24\gamma)D}{64}$  and hence  $p(C_{\text{cont}}) \leq 3 \left( \frac{(7-24\gamma)D}{64} \right)$ . Therefore,  $c(S'_2) + p(C_{\text{cont}}) \leq \frac{D}{2} + \frac{\sigma(S'_2)}{2}$ . Furthermore,  $p(S'_3) \leq \frac{(9+14\gamma)D}{32} - \frac{(15-24\gamma)D}{64} = \left( \frac{3}{64} + \frac{52\gamma}{32} \right) D$  and hence  $p(C_{\text{cont}}) \leq 3 \left( \frac{3}{64} + \frac{52\gamma}{32} \right) D$ . Therefore,  $c(S'_3) + p(C_{\text{cont}}) \leq \frac{(9+14\gamma)D}{32} + 3 \left( \frac{3}{64} + \frac{52\gamma}{32} \right) D = \frac{(27+184\gamma)D}{64}$ , while  $D/2 + \sigma(S'_3)/2 \geq D/2 + \left( \frac{15-24\gamma}{64} - \gamma \right) D/2 = \left( \frac{79}{128} - \frac{11}{8}\gamma \right) D$ . As a consequence,  $c(S'_3) + p(C_{\text{cont}}) \leq D/2 + \sigma(S'_3)/2$ , since  $\gamma \leq 1/40 \leq 25/392$ .

Finally, we have  $p(S'_4) \leq \frac{(3+2\gamma)D}{8} - \frac{(9+14\gamma)D}{32} = \frac{(3-6\gamma)D}{32}$ . Hence,  $p(C_{\text{cont}}) \leq 3 \left( \frac{(3-6\gamma)D}{32} \right) = \frac{(9+14\gamma)D}{32} - \gamma D \leq \sigma(S'_4)$ . While it holds that  $p(S'_5) \leq \frac{D}{2} - \frac{(3+2\gamma)D}{8} = \frac{(1+2\gamma)D}{8}$ . Therefore,  $p(C_{\text{cont}}) \leq 3 \cdot \frac{(1+2\gamma)D}{8} = \frac{(3+6\gamma)D}{8} = \frac{(1+2\gamma)D}{8} - \gamma D \leq \sigma(S'_5)$ .

For a visual representation of this repacking procedure see Figure 4. In all the cases the generated schedule has a height of at most  $(5/3)T \leq (5/3)(1 + \varepsilon')\text{OPT} \leq (5/3 + \varepsilon)\text{OPT}$ . ◀

## 4 AEPTAS for NPDM

In this section, we will prove the following theorem.

► **Theorem 10.** *Let  $\varepsilon > 0$ . There is an algorithm that places almost all jobs such that the peak energy demand is bounded by  $T' := (1 + \mathcal{O}(\varepsilon))\text{OPT}$ . For the residual jobs, we can choose one of the following containers for them to be placed in:  $C_1$  with processing time  $\varepsilon D$  and energy demand  $T'$  or a container  $C_2$  with processing time  $D$  and energy demand  $e_{\max}$ . The time complexity of this algorithm is bounded by  $\mathcal{O}(n \log(n)/\varepsilon) + 1/\varepsilon^{1/\varepsilon^{\mathcal{O}(1/\varepsilon)}}$ .*

The statement, in fact, gives two variants of the algorithm. The first variant where all residual jobs are placed in  $C_1$  is used in our  $5/3 + \varepsilon$  approximation algorithm, where the second variant with all residual jobs in  $C_2$  can be used to obtain the AEPTAS by setting  $\sigma(C_2) = 0$ . The described algorithm follows the dual-approximation framework. We describe an algorithm that given a bound on the schedule peak energy demand  $T$  computes a schedule with peak energy demand  $(1 + \mathcal{O}(\varepsilon))T' + e_{\max}$  or decides correctly that there is no schedule with peak energy demand at most  $T'$ . This algorithm then can be called in binary search fashion with values  $T$  between  $T' = \max\{T_1, T_2, T_3, T_4\}$  and  $\max\{2\text{work}(\mathcal{J})/D, 2e_{\max}\}$ , using only multiples of  $\varepsilon T'$ . Note that if  $e_{\max} \leq \mathcal{O}(\varepsilon^3 T')$ , we can use the algorithm in [11] to find an  $(1 + \varepsilon)\text{OPT} + \mathcal{O}(\log(1/\varepsilon)/\varepsilon \cdot \varepsilon^3 T') = (1 + \mathcal{O}(\varepsilon))\text{OPT}$  approximation. Hence we can assume that  $e_{\max} > \mathcal{O}(\varepsilon^3 T')$ .

### Classification of Jobs

Given two values  $\delta$  and  $\mu$  with  $\mu < \delta$ , we partition the jobs into five sets: large, horizontal, vertical, small, and medium sized jobs. We define  $\mathcal{J}_{\text{large}} := \{i \in \mathcal{J} | e(i) \geq \delta T', p(i) > \delta D\}$ ,  $\mathcal{J}_{\text{hor}} := \{i \in \mathcal{J} | e(i) < \mu T', p(i) > \delta D\}$ ,  $\mathcal{J}_{\text{ver}} := \{i \in \mathcal{J} | e(i) \geq \delta T', p(i) < \mu D\}$ ,  $\mathcal{J}_{\text{small}} := \{i \in \mathcal{J} | e(i) < \mu T', p(i) < \mu D\}$ , and  $\mathcal{J}_{\text{medium}} := \mathcal{J} \setminus (\mathcal{J}_{\text{large}} \cup \mathcal{J}_{\text{hor}} \cup \mathcal{J}_{\text{ver}} \cup \mathcal{J}_{\text{small}})$ .

► **Lemma 11.** *In  $\mathcal{O}(n + 1/\varepsilon^2)$  operations it is possible to find values  $\geq \varepsilon^{\mathcal{O}(1/\varepsilon^2)}$  for  $\delta$  and  $\mu$  such that  $\text{work}(\mathcal{J}_{\text{medium}}) \leq (\varepsilon^2/4)DT$  and  $\mu \leq c\varepsilon^5\delta$  for any given constant  $c$ .*

**Proof.** Consider the sequence  $\rho_0 := \varepsilon^5/4$ ,  $\rho_{i+1} := c\rho_i\varepsilon^3$ . Due to the pigeonhole principle, there exists an  $i \in \{0, \dots, 8/\varepsilon^2\}$  such that when defining  $\delta := \sigma_i$  and  $\mu := \sigma_{i+1}$  the total amount of work of the medium sized jobs is bounded by  $(\varepsilon^2/4)DT$ , because each job appears only in two possible sets of medium jobs. We have  $\delta \geq \mu \geq \varepsilon^{\mathcal{O}(1/\varepsilon^2)}$ . ◀

## 21:12 Peak Demand Minimization via Sliced Strip Packing

► **Lemma 12.** [43] *We can round the energy demands  $e(i)$  of the vertical and large jobs to multiples  $k_i \varepsilon \delta T$  with  $k_i \in \{1/\varepsilon, \dots, 1/\varepsilon \delta\}$  such that the number of different demands is bounded by  $O(1/\varepsilon^2 \log(1/\delta))$ . This rounding increases the optimal energy demand by at most  $2\varepsilon T$*

### Profile for vertical jobs

In the following we will dismiss the medium jobs from the schedule. Given an optimal schedule, we partition the schedule into  $1/\gamma$  segments of processing time  $\gamma D$ , for a constant  $\gamma \in \mathcal{O}_\varepsilon(1)$ . Given a schedule of jobs  $J$ , we define profile of  $J$  to be  $\{(x, y) | y = \sum_{j \in J | \sigma(j) \leq x \leq \sigma(j) + p(j)} e(j), 0 \leq x \leq D, \}$ . Energy demand of profile of jobs  $J$  at time  $t$  is  $\mathcal{E}_J(t) := \sum_{j \in J | \sigma(j) \leq t \leq \sigma(j) + p(j)} e(j)$ . Now consider the profile of large and horizontal jobs. Let  $\tilde{J} := \mathcal{J}_{large} \cup \mathcal{J}_{hor}$ . We search for the segments where the maximal energy demand of the profile of large and horizontal jobs and the minimal energy demand of this profile differs more than  $\varepsilon T$ , i.e., if in segment  $S := (t_a, t_b)$ ,  $|\max_{t \in S} \mathcal{E}_{\tilde{J}}(t) - \min_{t \in S} \mathcal{E}_{\tilde{J}}(t)| \geq \varepsilon T$ , then we remove all vertical and small jobs from these segments fractionally, i.e., we slice jobs, which are cut by the borders of the segment.

▷ **Claim 1.** Let  $\mathcal{J}_{rem}$  be the set of removed vertical and small jobs. Then  $\text{work}(\mathcal{J}_{rem})$  is bounded by  $\mathcal{O}(\gamma/\varepsilon \delta) \cdot D \cdot T$ .

*Proof.* Note that the energy demand of the profile of horizontal or large jobs only changes, when horizontal or large jobs end or start. The large and horizontal jobs have a total energy demand of at most  $T/\delta$  since they have a processing time of at least  $\delta D$  and the total area of the schedule is bounded by  $T \cdot D$ . Hence there can be at most  $2(T/\delta)/\varepsilon T = \mathcal{O}(1/\varepsilon \delta)$  segments, where the energy demand of the profile changes more than  $\varepsilon T$ . As a result, the total area of the removed vertical jobs can be bounded by  $\mathcal{O}(1/\varepsilon \delta) \cdot (\gamma D \cdot T)$ . ◁

▷ **Claim 2 (Size of  $\gamma$ ).** In the case of container  $C_1$ , we can choose  $\gamma \in \mathcal{O}(\varepsilon \delta \lambda)$  such that we can schedule the removed vertical jobs fractionally inside a container  $C_{1,1/4}$  of processing time  $p(C_1)/4$  and energy demand  $e(C_1)$ . Otherwise, we can choose  $\gamma \in \mathcal{O}(\varepsilon^4 \delta)$  such that we can schedule the removed vertical jobs fractionally inside a container  $C_{2,1/4}$  of processing time  $p(C_2)/4$  and energy demand  $e(C_2)$ .

*Proof.* Let  $k \in \{1, 2\}$  depending on the chosen container. First we place all the jobs  $\mathcal{J}_{rem,tall}$ , i.e., jobs in  $\mathcal{J}_{rem}$  with energy demand larger than  $e(C_{k,1/4})/2$  next to each other. The total processing time of these jobs is bounded by  $2 \cdot \text{work}(\mathcal{J}_{rem,tall})/e(C_{k,1/4})$ . Next, we place the residual jobs  $\mathcal{J}_{rem,res} := \mathcal{J}_{rem} \setminus \mathcal{J}_{rem,tall}$ , which have an energy demand of at most  $e(C_{k,1/4})/2$ . We take slices of processing time 1 of the jobs and place them on top of each other until the energy demand  $e(C_{k,1/4})/2$  is reached. Since each job has an energy demand of at most  $e(C_{k,1/4})/2$  the energy demand  $e(C_{k,1/4})$  is not exceeded. The total processing time of this schedule is bounded by  $2\text{work}(\mathcal{J}_{rem,res})/e(C_{k,1/4}) + 1 \leq \mathcal{O}(\gamma/(\varepsilon \delta) \cdot D \cdot T)/e(C_{k,1/4})$ . Hence, for  $C_{1,1/4}$  the total processing time is bounded by  $\mathcal{O}(\gamma/(\varepsilon \delta) \cdot D \cdot T)/T = \mathcal{O}(\gamma/(\varepsilon \delta))D$ . Hence, when choosing  $\gamma \in \mathcal{O}(\lambda \varepsilon \delta)$  for a suitable constant, the total processing time of this schedule is bounded by  $p(C_1)/4$ . Otherwise, for container  $C_{2,1/4}$  the total processing time is bounded by  $\mathcal{O}((\gamma/(\varepsilon \delta) \cdot D \cdot T)/\varepsilon^3 T) = \mathcal{O}(\gamma/\varepsilon^4 \delta)D$ . Hence, when choosing  $\gamma \in \mathcal{O}(\varepsilon^4 \delta)$  for a suitable constant, the total processing time of this schedule is bounded by  $p(C_2)/4$ . ◁

### Algorithm to place the vertical, small, and medium jobs

In the algorithm, we first round the energy demands of the vertical jobs to at most  $\mathcal{O}(1/\varepsilon^2 \cdot \log(1/\delta)) = (1/\varepsilon)^{\mathcal{O}(1)}$  sizes using Lemma 12 (geometric rounding).

Afterward, we guess for each of the  $1/\gamma$  segments the energy demand reserved for the vertical and small jobs rounding up to the next multiple of  $\varepsilon T$ , adding at most one more  $\varepsilon T$  to the energy demand of the schedule. There are at most  $\mathcal{O}((1/\varepsilon)^{1/\gamma})$  possible guesses. Furthermore, we introduce one segment  $\top$  of energy demand  $\lceil e(C_k)/(\varepsilon T) \rceil \cdot \varepsilon T$  and processing time  $p(C_k)/4$  ( $k \in \{1, 2\}$ ) for the set of removed vertical jobs. Let  $S_{ver}$  be the set of all introduced segments, and for each  $s \in S_{ver}$  let  $e_{s,ver}$  be the energy demand reserved for vertical and small jobs. Note that for each  $s \in S_{ver}$  there exists an  $i \in \{0, \dots, 1/\varepsilon + 3\}$  such that  $e_{s,ver} = i\varepsilon T$ . Furthermore, let  $S_{ver,e}$  be the set of segments that have exactly energy demand  $e$  and let  $p(S_{ver,e})$  be their total processing time.

To place the vertical jobs into the segments  $S_{ver}$ , we use a configuration LP. Let  $C = \{a_\eta : \eta | \eta \in \{e(j) | j \in \mathcal{J}_{ver}\}\}$  be a configuration for vertical jobs, where  $a_\eta$  denotes the multiplicity with which the energy demand  $\eta$  is contained in  $C$ . We denote by  $e(C) := \sum_{\eta \in \{e(j) | j \in \mathcal{J}_{ver}\}} a_\eta \cdot \eta$  the energy total demand of  $C$ , and by  $\mathcal{C}_e$  the set of configurations with energy demand at most  $e$ . Furthermore, for a given configuration  $C$  we denote by  $a_\eta(C)$  the number of jobs contained in  $C$  that have an energy demand of  $\eta$ . Since each vertical job has a energy demand of at least  $\delta T$ , there are at most  $(1/\varepsilon)^{\mathcal{O}(1/\delta)}$  different configurations. Consider the following linear program:

$$\sum_{C \in \mathcal{C}_{i\varepsilon T}} x_{C,i} = p(S_{ver,i\varepsilon T}) \quad \forall i \in \{1, \dots, 1/\varepsilon + 3\} \quad (1)$$

$$\sum_{s \in S} \sum_{C \in \mathcal{C}_{e_{s,ver}}} a_\eta(C) x_{C,s} = \sum_{j \in \mathcal{J}_{ver}, e(j)=\eta} p(j) \quad \forall \eta \in \{e(j) | j \in \mathcal{J}_{ver}\} \quad (2)$$

$$x_{C,i} \geq 0 \quad \forall C \in \mathcal{C}, i \in \{1, \dots, 1/\varepsilon\} \quad (3)$$

The variable  $x_{C,i}$  represents the processing-time of configuration  $C$  inside segments  $s \in S_{ver}$  with reserved energy capacity  $e_{s,ver} = i\varepsilon T$ . The first equation ensures that the total processing-time assigned to configurations inside segments with a certain energy capacity does not exceed the total processing time of these segments. The second equation ensures that each job is fully scheduled. More precisely, that the total processing time of jobs with a certain energy demand is covered by the configurations. A basic solution has at most  $(1/\varepsilon + |\{e(j) | j \in \mathcal{J}_{ver}\}| + 1) = (1/\varepsilon)^3$  nonzero components. We can solve the above linear program by guessing the set of non zero components and then solving the resulting LP in  $((1/\varepsilon)^{\mathcal{O}(1/\delta)})^{(1/\varepsilon)^3}$  time.

To place the vertical jobs, we first fill them greedily inside the configurations (slicing when the corresponding configuration slot is full) and afterwards place the configurations inside the schedule, slicing the jobs at the segment borders. For each nonzero component we have one configuration that contains at most  $2/\delta$  fractionally placed vertical jobs on top of each other, which have a total energy demand of at most  $2T'$ . Additionally, for each segment we have the same amount of fractional jobs. Hence total area of fractionally placed jobs can be bounded by  $\mu D \cdot 2T \cdot ((1/\varepsilon)^3 + 1/\gamma)$ . If we choose  $C_1$  this can be bounded by  $\mathcal{O}(\mu/(\lambda\varepsilon\delta))DT \leq \lambda DT/8$ , since  $\mu = c\varepsilon\delta\lambda^2$  and otherwise by  $\in \mathcal{O}(\mu D \cdot T/(\varepsilon^5\delta)) \leq DT/8$ , since  $\mu = c\varepsilon^5\delta$  for a suitable small constant  $c$ . We remove the fractionally placed jobs  $\mathcal{J}_{frac}$ .

Next, we place the small jobs inside the empty area that can appear above each configuration for vertical jobs. Note that there are at most  $((1/\varepsilon)^{\mathcal{O}(1)} + 1/\gamma)$  configurations and the free area inside these configurations has at least the size of the total area of the small jobs. As a consequence, we have at most  $2/\gamma$  rectangular areas to place the small jobs, which have a total area, which is at least the size of the small jobs. We use the NFDH algorithm to place these jobs inside the boxes until no other job fits inside.

## 21:14 Peak Demand Minimization via Sliced Strip Packing

Assume we could not place all the small jobs inside these boxes. When considering the area of free energy in each box, there are three parts that contribute to it. First, each box can have a free strip at its end, which has a processing time of at most  $\mu D$ . The total area of free energy contributed by this strip is bounded by  $(2/\gamma)\mu D \cdot 2T$ . Second, each box can have a free strip of energy demand at most  $\mu T$  on the top because otherwise, another line of jobs would have fitted inside this box. Since there are no boxes on top of each other, we can bound the total area of free energy inside this strip by  $\mu T \cdot D$ . Finally, there can be free energy between the shelves of the jobs generated by the NFDH algorithm. This total free energy is bounded by the energy demand of the tallest job times the processing time of the widest box, i.e.,  $\mu T \cdot \gamma D$ . Hence the total area of free energy inside the boxes is bounded by  $5\mu D \cdot T \cdot \gamma + D \cdot \mu T$ . Since  $\gamma \in \mathcal{O}(1/\varepsilon^5\delta)$  and we have chosen  $\mu \leq c\delta\varepsilon^6$  for a suitable small constant  $c \in \mathbb{Q}$ , the total work of the remaining small jobs  $\mathcal{J}_{small,res}$ , which could not be placed is bounded by  $\varepsilon TD$ .

We place the residual small jobs  $\mathcal{J}_{small,res}$  on top of the schedule using NFDH. This adds an energy demand of at most  $2\varepsilon T$  to the schedule. Next we place the medium jobs. We start all the medium jobs, that have a processing time larger than  $p(C_k)/4$  with Steinberg's algorithm inside a box of energy demand at most  $\mathcal{O}(\varepsilon)T$  and processing time  $D$ . This is possible since they have processing time in  $(\varepsilon D, D]$  and therefore each has an energy demand of at most  $\mathcal{O}(\varepsilon)T$  because their total work is bounded by  $(\varepsilon^2/4)DT$ . The residual jobs (that might have a processing time larger than  $\varepsilon T$ ) are placed inside the first half of the container using Steinberg's algorithm. The later half of the container is filled with the extra box for vertical jobs defined for the LP and the fractionally scheduled jobs. The extra box has a width of at most  $p(C_k)/4$ . Since the fractionally placed vertical jobs  $\mathcal{J}_{frac}$  have an area of at most  $\varepsilon(C_k) \cdot p(C_k)/8$  and each has a width of at most  $\mu D < p(C_k)/8$ , we can use Steinberg's algorithm to place them inside the last quarter of the container  $C_k$ .

### Placement of horizontal jobs

In this section, we first reduce the number of possible starting points for horizontal jobs and then use a linear program to place the jobs in the schedule.

First step: use geometric grouping to reduce the number of processing times of horizontal jobs. At a loss of at most  $2\varepsilon T$  in the approximation ratio, we can reduce the number of processing times of horizontal jobs to  $\mathcal{O}(\log(1/\delta)/\varepsilon)$  using geometric grouping (see [33, Theorem 2] by Karmarkar and Karp). These rounded jobs can be placed fractionally instead of the original jobs and an extra box of energy demand at most  $\mathcal{O}(\varepsilon)T$ . In this fractional packing, the horizontal jobs are sliced along the axis of the processing-time, i.e., different fractions of a job might have different starting points, but a fraction that is started, will not be interrupted and require the same amount of energy during its procession. We denote the rounded processing-time of a job  $j$  as  $p'(j)$ .

In the next step, we will reduce the number of starting points of the large and fractionally placed horizontal jobs without exceeding the given profile. Remember, we know the profile of large and horizontal jobs with precision  $\varepsilon T$  for the segments of processing time  $\gamma D$ .

▷ **Claim 3.** Without loss in the approximation ratio, we can reduce the number of different starting points of rounded horizontal and large jobs to  $(1/\varepsilon)^{\mathcal{O}(1/\varepsilon)}$ .

*Proof.* Consider the large and horizontal jobs starting in the first segment. Since this segment has a processing time of  $\gamma D \leq \delta D$ , there can be no job ending in this segment. Hence this segment is maximally filled at the point  $\gamma D$ . We can shift the start point of each job in this segment to 0 and we will not change the maximal energy demand of this segment.

Now consider a job  $i \in \mathcal{J}_{hor} \cup \mathcal{J}_{large}$  starting in the second segment. If there is no horizontal or large job ending before the start of  $i$ , we can shift the start point of  $i$  to  $\gamma D$  without changing the maximal filling energy demand in this segment. However, if there is a job  $j \in \mathcal{J}_{hor} \cup \mathcal{J}_{large}$  ending before  $i$  in this segment, we can not shift this job to  $\gamma D$  since then  $i$  and  $j$  overlap, which they did not before. This could change the maximal energy demand of the profile in this segment. Nevertheless, if  $j$  is the last job ending before  $i$ , we can shift  $i$  to the left, such that  $i$  starts at the endpoint of  $j$ .

We iterate this shifting with all segments and all jobs in  $\mathcal{J}_{hor} \cup \mathcal{J}_{large}$ . As a result, all jobs start either at a multiple of  $\gamma D$ , or they start at an endpoint of an other job in  $\mathcal{J}_{hor} \cup \mathcal{J}_{large}$ . Therefore, we can describe the set of possible starting points for jobs in  $\mathcal{J}_{hor} \cup \mathcal{J}_{large}$  as  $S_{hor,large} := \{l\gamma D + \sum_{j=1}^{1/\delta} p(i_j) \mid l \in \{0, 1, \dots, 1/\gamma\}, i_j \in \mathcal{J}_{hor} \cup \mathcal{J}_{large} \forall j \in \{1, \dots, 1/\delta_w\}\}$ . It holds that  $|S_{hor,large}| \leq (1/\gamma) \cdot (\log(1/\delta)/\epsilon)^{1/\delta} = (1/\epsilon)^{(1/\epsilon)^{\mathcal{O}(1/\epsilon)}}$ .  $\triangleleft$

$\triangleright$  **Claim 4.** At a loss of at most  $\mathcal{O}(\epsilon T)$  in the approximation ratio, we can reduce the number of *used* starting points for rounded horizontal jobs to  $\mathcal{O}(1/\epsilon\delta)$ .

*Proof.* We partition the set of horizontal jobs by their processing time into  $\mathcal{O}(\log(1/\delta))$  sets  $\mathcal{J}_{hor}^l := \{i \in \mathcal{J}_{hor} \mid D/2^l < p(i) \leq D/2^{l-1}\}$ . For each of these sets, we will reduce the number of starting positions to  $2^l/\epsilon^2$ . We partition the schedule into  $2^l$  segments of processing time  $D/2^l$ . Each job from the set  $\mathcal{J}_{hor}^l$  has a processing time larger than  $D/2^l$  and hence it starts in an other segment as it ends. We consider for each segment all the horizontal jobs of the set  $\mathcal{J}_{hor}^l$  ending in this segment and sort them by increasing starting position. Let  $e_{l,i}$  be the energy demand of the stack of jobs in  $\mathcal{J}_{hor}^l$  ending in the  $i$ -th segment. We partition the stack into  $1/\epsilon$  layers of energy demand  $\epsilon e_{l,i}$  and slice the horizontal jobs overlapping the layer borders. We remove all the jobs in the bottom most layer and shift the jobs from the layers above to the left, such that they start at the latest original start position from the layer below. We repeat this procedure for each segment. By this shift, we reduce the total number of starting positions from jobs from the set  $\mathcal{J}_{hor}^l$  to  $2^l/\epsilon$ . The total energy demand of the jobs we removed is bounded by  $\epsilon e(\mathcal{J}_{hor}^l)$ . Since these jobs have a processing time of at most  $D/2^{l-1}$ , we can schedule  $2^{l-1}$  of these jobs after one another (horizontally), without violating the deadline. Hence, when scheduling these jobs fractionally, we add at most  $\epsilon e(\mathcal{J}_{hor}^l)/2^{l-1}$  to the schedule. Note that since all the jobs in set  $\mathcal{J}_{hor}^l$  have a processing time of at least  $D/2^l$ , it holds that  $\sum_{l=1}^{\lceil \log(1/\delta) \rceil} e(\mathcal{J}_{hor}^l)/2^l \leq T$  and, hence, we add at most  $\sum_{l=1}^{\lceil \log(1/\delta) \rceil} \epsilon e(\mathcal{J}_{hor}^l)/2^{l-1} \leq 2\epsilon T$  to the energy demand of the schedule, when scheduling the removed horizontal jobs. The total number of starting positions is bounded by  $\sum_{l=1}^{\lceil \log(1/\delta) \rceil} 2^l/\epsilon = (2^{\lceil \log(1/\delta) \rceil + 1} - 1)/\epsilon \in \mathcal{O}(1/\delta_w \epsilon)$ .  $\triangleleft$

### Algorithm to place horizontal and large jobs

To place the jobs in  $\mathcal{J}_{hor} \cup \mathcal{J}_{large}$ , we first guess the starting positions of the large jobs  $\mathcal{J}_{large}$  in  $\mathcal{O}(|S_{hor,large}|^{|\mathcal{J}_{large}|}) = (1/\epsilon)^{(1/\epsilon)^{\mathcal{O}(1/\epsilon)}}$ . Note that this guess affects the energy demand that is left for horizontal jobs. Next we guess which  $\mathcal{O}(1/\epsilon\delta)$  starting points in  $S_{hor,large}$  will be used after the shifting due to Claim 4. There are at most  $|S_{hor,large}|^{\mathcal{O}(1/\epsilon\delta)} = (1/\epsilon)^{(1/\epsilon)^{\mathcal{O}(1/\epsilon)}}$  possible guesses total. We call the set of guessed starting points  $\bar{S}_{h,l}$ . For each starting point in  $\bar{S}_{h,l}$ , we calculate the residual total energy demand, that is left after the guess for the large jobs. For a given  $s \in \bar{S}_{h,l}$  let  $e_{s,hor}$  be this residual total energy demand.

Consider the following linear program for horizontal jobs:

$$\begin{aligned}
\sum_{\rho \in \{p'(j) | j \in \mathcal{J}_{hor}\}} \sum_{\substack{s' \in \bar{S}_{h,l} \\ s' \leq s < s' + \rho}} x_{\rho, s'} &\leq e_{s, hor} && \forall s \in \bar{S}_{h,l} \\
\sum_{s \in \bar{S}_{h,l}} x_{\rho, s} &= \sum_{j \in \mathcal{J}_{hor}, p'(j) = \rho} e(j) && \forall \rho \in \{p'(j) | j \in \mathcal{J}_{hor}\} \\
x_{\rho, s} &\geq 0 && \forall s \in \bar{S}_{h,l}, \rho \in \{p'(j) | j \in \mathcal{J}_{hor}\}
\end{aligned}$$

The variable  $x_{\rho, s}$  denotes the total energy demand of jobs with rounded processing time  $\rho$  starting at  $s$ . The first equation ensures that the energy capacity at a starting time  $s$  is not exceeded by the jobs starting at or overlapping  $s$ . The second equation ensures that the total energy requirement of jobs with rounded processing time  $\rho$  is covered by energy demand of jobs with this processing time started in the schedule.

A basic solution to this linear program has at most  $|\bar{S}_{h,l}| + |\mathcal{J}_{hor}| = \mathcal{O}(1/\varepsilon\delta)$  non zero components. We can guess the non zero components in at most  $(|\bar{S}_{h,l}| \cdot |\mathcal{J}_{hor}|)^{|\bar{S}_{h,l}| + |\mathcal{J}_{hor}|} = (1/\varepsilon)^{\mathcal{O}(1/\varepsilon)}$ . Furthermore, we can guess their value with precision  $\mu T$  in at most  $(1/\mu)^{|\bar{S}_{h,l}| + |\mathcal{J}_{hor}|} = (1/\varepsilon)^{\mathcal{O}(1/\varepsilon)}$  guesses. Scheduling all the horizontal jobs integral and the error due to the precision add at most  $2\mu T \cdot (|\bar{S}_{h,l}| + |\mathcal{J}_{hor}|)$  to the peak energy demand. Note that  $2\mu T \cdot (|\bar{S}_{h,l}| + |\mathcal{J}_{hor}|) \leq \mathcal{O}(\varepsilon)T'$  since  $\mu \leq \mathcal{O}(\varepsilon^2\delta)$ .

After this step, we either have scheduled all given jobs or have decided that it is not possible for the given guess of  $T$  and the profile. If it is not possible for any profile, we have to increase  $T$ . If we have found a schedule, we try the next smaller value for  $T$ . Each of the steps has increased the peak energy demand by at most  $\mathcal{O}(\varepsilon)T$  above  $T$ . Besides of the job classification and rounding, each step of the algorithm is bounded by  $(1/\varepsilon)^{\mathcal{O}(1/\varepsilon)}$ . Therefore, the described algorithms fulfills the claims of Theorem 10.

## 5 Conclusion

In this paper, we presented an AEPTAS with additive term  $e_{\max}$  as well as a  $(5/3 + \varepsilon)$ -approximation for Nonpreemptive Peak Demand Minimization (NPDM). Since the lower bound for approximation algorithms for this problem is known to be  $3/2$ , this leaves a small gap between the lower bound and the approximation guarantee. Closing this gap is an interesting open question for further research, especially since for the related strip packing problem the same gap is yet to be resolved.

## A Proof of Theorem 4

**Proof:**  $T_2 \leq \text{OPT}(I)$ .

► **Lemma 13.** *It holds that  $p(\mathcal{J}_{e(i) > (1/3)\text{OPT}}) + p(\mathcal{J}_{e(i) > (2/3)\text{OPT}}) \leq 2D$  and  $p(\mathcal{J}_{e(i) > (1/2)\text{OPT}}) \leq D$ .*

**Proof.** Note that jobs with energy demand larger than  $(1/3)\text{OPT}$  cannot intersect the same vertical line as jobs with energy demand larger than  $(2/3)\text{OPT}$  in an optimal schedule. Furthermore, each vertical line through an optimal schedule can intersect at most two jobs with energy demand larger than  $(1/3)\text{OPT}$ . Moreover, no vertical line can intersect two jobs from the set  $\mathcal{J}_{e(i) > (1/2)\text{OPT}}$ . The claim is a consequence. ◀

► **Corollary 14.** *The smallest value  $T$  such that  $p(\mathcal{J}_{e(i) > (1/3)T}) + p(\mathcal{J}_{e(i) > (2/3)T}) \leq 2D$  and  $p(\mathcal{J}_{e(i) > T/2}) \leq D$  is a lower bound for  $\text{OPT}$ .*

**Proof.** By Lemma 13, we know that  $p(\mathcal{J}_{e(i) > (1/3)\text{OPT}}) + p(\mathcal{J}_{e(i) > (2/3)\text{OPT}}) \leq 2D$  and obviously we have  $p(\mathcal{J}_{e(i) > \text{OPT}/2}) \leq D$ . Therefore, the smallest value such that  $p(\mathcal{J}_{e(i) > (1/3)T}) + p(\mathcal{J}_{e(i) > (2/3)T}) \leq 2D$  and  $p(\mathcal{J}_{e(i) > T/2}) \leq D$  has to be a lower bound on  $\text{OPT}$ . ◀

## 21:20 Peak Demand Minimization via Sliced Strip Packing

Note that we can find this smallest value in  $\mathcal{O}(n \log n)$  by starting with  $T = T_1$  and as long as  $p(\mathcal{J}_{e(i) \geq 1/3T}) + p(\mathcal{J}_{e(i) \geq 2/3T}) > 2D$  or  $p(\mathcal{J}_{e(i) > T/2}) > D$  update  $T$  as follows: For  $l \in [0, 1]$ , denote by  $e_l$  the energy demand of the smallest job in  $\mathcal{J}_{e(i) > l \cdot T}$  and set  $T := \min\{3e_{1/3}, (3/2)e_{2/3}, 2e_{1/2}\}$ . This iteratively excludes one job from one of the three sets. We denote this lower bound as

$$T_2 := \min\{T \mid p(\mathcal{J}_{e(i) \geq T/3}) + p(\mathcal{J}_{e(i) \geq 2T/3}) \leq 2D \wedge p(\mathcal{J}_{e(i) \geq T/2}) \leq D\}.$$

► **Lemma 15.** *Let  $w' \in [0, 1/2)$ . Then*

$$p(\mathcal{J}_{e(i) > (2/3)T_2}) > (1 - w')D \Rightarrow p(\mathcal{J}_{e(i) \in ((1/3)T_2, (2/3)T_2]}) \leq 2w'D.$$

**Proof.** We know that  $p(\mathcal{J}_{e(i) > (1/3)T_2}) + p(\mathcal{J}_{e(i) > (2/3)T_2}) \leq 2D$ . Because  $\mathcal{J}_{e(i) > (2/3)T_2} \subseteq \mathcal{J}_{e(i) > (1/3)T_2}$  and  $p(\mathcal{J}_{e(i) > (2/3)T_2}) > (1 - w')D$ , it holds that  $p(\mathcal{J}_{e(i) \in ((1/3)T_2, (2/3)T_2]}) \leq 2w'D$ . ◀

**Proof:  $T_3 \leq \text{OPT}(I)$ .** Next, we obtain a bound based on a set of jobs that do not overlap vertically in a given optimal schedule.

► **Lemma 16.** *Consider an optimal schedule and let  $\mathcal{J}_{\text{seq}}$  be a set of jobs such that no pair of jobs  $i, i' \in \mathcal{J}_{\text{seq}}$  overlaps vertically, i.e.,  $\sigma(i) + p(i) \leq \sigma(i')$  or  $\sigma(i') + p(i') \leq \sigma(i)$ . Furthermore, define  $\mathcal{J}_w := \mathcal{J}_{p(i) > (D - p(\mathcal{J}_{\text{seq}})/2)} \setminus \mathcal{J}_{\text{seq}}$ . Then there exists a vertical line through the schedule that intersects a job in  $\mathcal{J}_{\text{seq}}$  and all the jobs in  $\mathcal{J}_w$ .*

**Proof.** First note that  $(D - p(\mathcal{J}_{\text{seq}})/2) \geq D/2$ . Consider the vertical strip between  $p(\mathcal{J}_{\text{seq}})/2$  and  $(D - p(\mathcal{J}_{\text{seq}}))/2$ . Each job in  $\mathcal{J}_w$  completely overlaps this strip. Furthermore, either the strip itself contains a job in  $\mathcal{J}_{\text{seq}}$ , in which case the claim is trivially true, or on each position on both sides of the strip there is a job from  $\mathcal{J}_{\text{seq}}$ . Assume the latter case. Since the jobs in  $\mathcal{J}_w$  have a time demand strictly larger than  $(D - p(\mathcal{J}_{\text{seq}})/2)$ , there exists an  $\sigma > 0$  such that the vertical line at  $(D - p(\mathcal{J}_{\text{seq}})/2) + \sigma$  as well is overlapped by all the jobs in this set. Since this line intersects also a job from the set  $\mathcal{J}_{\text{seq}}$ , the claim follows. ◀

► **Corollary 17.** *Let  $\mathcal{J}_{\text{seq}}$  be a set of jobs such that  $p(\mathcal{J}_{\text{seq}}) \leq D$  and consider  $\mathcal{J}_w := \mathcal{J}_{p(i) > D - p(\mathcal{J}_{\text{seq}})/2} \setminus \mathcal{J}_{\text{seq}}$ . Furthermore let  $i_\perp \in \mathcal{J}_{\text{seq}}$  be the job with the smallest energy demand. Then it holds that  $\min\{e(i_\perp) + e(\mathcal{J}_w), 2e(i_\perp)\} \leq \text{OPT}$ .*

**Proof.** Consider an optimal solution. If two jobs from the set  $\mathcal{J}_{\text{seq}}$  intersect the same vertical line,  $2e(i_\perp)$  is obviously a lower bound on OPT. On the other hand, if in any optimal schedule there does not exist a pair of jobs from  $\mathcal{J}_{\text{seq}}$  that overlap the same vertical line, we know by Lemma 16 that there exists a job in  $\mathcal{J}_{\text{seq}}$  that overlaps with all the jobs in  $\mathcal{J}_w$  and therefore  $\text{OPT} \geq e(i_\perp) + e(\mathcal{J}_w)$  in this case. ◀

From Corollary 17, we derive a lower bound on OPT. For a given  $k \in [n]$ , we define  $\mathcal{J}_k$  to be the set of the  $k$  jobs with the largest energy demand in  $\mathcal{J}$  and  $\mathcal{J}'_k$  to be the set of the  $k$  jobs with the largest energy demand in  $\mathcal{J} \setminus \mathcal{J}_{p(i) > D/2}$ . Let  $i_k$  and  $i'_k$  be the jobs with the smallest energy demand in  $\mathcal{J}_k$  and  $\mathcal{J}'_k$ , respectively. We define:

$$T_{3,a} := \max\{\min\{e(i_k) + e(\mathcal{J}_{p(i) > D - p(\mathcal{J}_k)/2} \setminus \mathcal{J}_k), 2e(i_k)\} \mid k \in \{1, \dots, n\}, p(\mathcal{J}_k) \leq D\},$$

$$T_{3,b} := \max\{\min\{e(i'_k) + e(\mathcal{J}_{p(i) > D - p(\mathcal{J}'_k)/2}), 2e(i'_k)\} \mid k \in \{1, \dots, n\}, p(\mathcal{J}'_k) \leq D\},$$

and finally  $T_3 = \max\{T_{3,a}, T_{3,b}\}$ . Note that  $\mathcal{J}'_k$  and  $\mathcal{J}_{p(i) > D - p(\mathcal{J}'_k)/2}$  are disjoint, since  $\mathcal{J}'_k$  contains only jobs with processing time at most  $D/2$  and  $\mathcal{J}_{p(i) > D - p(\mathcal{J}'_k)/2}$  contains only jobs with processing time larger than  $D/2$ , and hence, by Corollary 17,  $T_3$  is a lower bound on OPT. For this lower bound, we prove the following property.

► **Lemma 18.** *Let  $T = \max\{T_1, T_2, T_3\}$ ,  $w \in (0, 1/2)$  and  $h \in (1/2, 1]$  as well as  $\mathcal{J}_h := \mathcal{J}_{e(i) \geq hT}$  and  $\mathcal{J}_w := \mathcal{J}_{p(i) > (1/2+w/2)D} \setminus \mathcal{J}_h$ . It holds that*

$$p(\mathcal{J}_h) \geq (1-w)D \Rightarrow e(\mathcal{J}_w) \leq (1-h)T.$$

**Proof.** Since  $T \geq T_2$ , it holds that  $p(\mathcal{J}_h) \leq D$ . By construction of  $T_3$  for each job  $j \in \mathcal{J}_h$ , it holds that  $e(j) + e(\mathcal{J}_{p(i) > D - p(\mathcal{J}_{e(i) \geq e(j)})/2} \setminus \mathcal{J}_{e(i) \geq e(j)}) \leq T_3$ , because  $2e(j) > T_3$  (and  $T_3 \geq \min\{2e(j), e(j) + e(\mathcal{J}_{p(i) > D - p(\mathcal{J}_{e(i) \geq e(j)})/2} \setminus \mathcal{J}_{e(i) \geq e(j)})\}$ ). Furthermore, note that  $\mathcal{J}_h = \mathcal{J}_{e(i) \geq e(j)}$  for the job  $j$  with the smallest energy demand in  $\mathcal{J}_h$ .

Therefore, if  $p(\mathcal{J}_h) \geq (1-w)D$ , it holds that  $\mathcal{J}_{p(i) > D - (1-w)D/2} \subseteq \mathcal{J}_{p(i) > D - p(\mathcal{J}_h)/2}$  and hence,

$$\begin{aligned} hT + e(\mathcal{J}_w) &= hT + e(\mathcal{J}_{p(i) > D - (1-w)D/2} \setminus \mathcal{J}_h) \\ &\leq e(j) + e(\mathcal{J}_{p(i) > D - p(\mathcal{J}_h)/2} \setminus \mathcal{J}_h) \leq T_3 \leq T. \end{aligned} \quad \blacktriangleleft$$

► **Lemma 19.** *Let  $T = \max\{T_1, T_2, T_3\}$ ,  $w \in (1/2, 1]$  and  $h \in (1/2, 1]$  as well as  $\mathcal{J}_w := \mathcal{J}_{p(i) \geq wD}$  and  $\mathcal{J}_h := \mathcal{J}_{e(i) > hT} \setminus \mathcal{J}_{p(i) > D/2}$ . It holds that*

$$e(\mathcal{J}_w) > (1-h)T \Rightarrow p(\mathcal{J}_h) \leq 2(1-w)D.$$

**Proof.** Let  $e(\mathcal{J}_w) > (1-h)T$ . Since for each job in  $\mathcal{J}_h$  it holds that  $e(i) > T/2 \geq T_{3,b}/2$ , by definition of  $T_{3,b}$ , for each  $j \in \mathcal{J}_h$  it holds that  $e(j) + e(\mathcal{J}_{p(i) > D - p(\mathcal{J}_{e(i) \geq e(j)})/2}) \leq T$ . Therefore for the smallest job  $j \in \mathcal{J}_h$ , it holds that  $e(j) + e(\mathcal{J}_{p(i) > D - p(\mathcal{J}_h)/2}) \leq T$ .

For contradiction assume that  $p(\mathcal{J}_h) > 2(1-w)D$ . Note that in this case  $D - p(\mathcal{J}_h)/2 < wD$  and hence  $e(\mathcal{J}_{p(i) > D - p(\mathcal{J}_h)/2}) \geq e(\mathcal{J}_D) > (1-h)T$ . As a consequence  $e(j) + e(\mathcal{J}_{p(i) > D - p(\mathcal{J}_h)/2}) > hT + (1-h)T = T$ , a contradiction.  $\blacktriangleleft$

**Proof:  $T_4 \leq \text{OPT}(I)$ .**

► **Lemma 20.** *Consider an optimal schedule and let  $\mathcal{J}_{\text{seq}} \subseteq \mathcal{J}$  be a set of jobs such that no pair of jobs  $j, j' \in \mathcal{J}_{\text{seq}}$  overlaps vertically, i.e.,  $\sigma(j) + p(j) \leq \sigma(j')$  or  $\sigma(j') + p(j') \leq \sigma(j)$ . Let  $\mathcal{J}_D \subseteq \mathcal{J}_{p(j) > (\max\{D - p(\mathcal{J}_{\text{seq}}), D/2\})} \setminus \mathcal{J}_{\text{seq}}$ . Then there exists a vertical line through the schedule that intersects a job in  $\mathcal{J}_{\text{seq}}$  and a subset  $\mathcal{J}_{W'} \subseteq \mathcal{J}_D$  with  $e(\mathcal{J}'_D) \geq e(\mathcal{J}_D)/2$ .*

**Proof.** First, we consider the trivial cases. If a job from  $\mathcal{J}_{\text{seq}}$  overlaps the vertical line at  $D/2$  the claim is trivially true, since all the jobs from  $\mathcal{J}_D$  overlap  $D/2$ . On the other hand, if all the jobs in  $\mathcal{J}_{\text{seq}}$  are left or right of  $D/2$ , it holds that  $p(\mathcal{J}_{\text{seq}}) \leq D/2$  and one of the jobs has a distance of at most  $D/2 - p(\mathcal{J}_{\text{seq}})$  from  $D/2$ . This job has to be overlapped by all the jobs from  $\mathcal{J}_D$  since they have a width larger than  $D - p(\mathcal{J}_{\text{seq}})$ .

Otherwise, consider the vertical line  $L_l$  through the right border of the rightmost job from  $\mathcal{J}_{\text{seq}}$  that is left of  $D/2$  and the vertical line  $L_r$  through the left border of the leftmost job from  $\mathcal{J}_{\text{seq}}$  that is right of  $D/2$ . Note that  $L_l$  and  $L_r$  have a distance of at most  $(D - p(\mathcal{J}_{\text{seq}}))$ . Consider the set  $\mathcal{J}_{D,l} \subseteq \mathcal{J}_D$  that is intersected by the vertical line  $L_l$ . Note that the residual jobs in  $\mathcal{J}_{D,r} := \mathcal{J}_D \setminus \mathcal{J}_{D,l}$  all overlap the vertical line at  $L_l + (D - p(\mathcal{J}_{\text{seq}})) \geq L_r$  and hence  $L_r$  as well. Since  $\mathcal{J}_{D,r} \cup \mathcal{J}_{D,l} = \mathcal{J}_D$ , one of the two sets has an energy demand of at least  $e(\mathcal{J}_D)/2$ . Finally, note that there exists a small enough  $\sigma > 0$  such that  $L_l - \sigma$  and  $L_r + \sigma$  overlap the same set of wide jobs as  $L_l$  and  $L_r$  as well as the corresponding job in  $\mathcal{J}_{\text{seq}}$ .  $\blacktriangleleft$

► **Corollary 21.** *Let  $\mathcal{J}_{\text{seq}}$  be a set of jobs such that  $p(\mathcal{J}_{\text{seq}}) \leq D$  and consider  $\mathcal{J}_D := \mathcal{J}_{p(i) > (\max\{D - p(\mathcal{J}_{\text{seq}}), D/2\})} \setminus \mathcal{J}_{\text{seq}}$ . Furthermore let  $i_\perp \in \mathcal{J}_{\text{seq}}$  be the job with the smallest energy demand. Then it holds that  $\min\{e(i_\perp) + e(\mathcal{J}_D)/2, 2e(i_\perp)\} \leq \text{OPT}$ .*

**Proof.** Consider an optimal solution. If two jobs from the set  $\mathcal{J}_{\text{seq}}$  intersect the same vertical line,  $2e(i_{\perp})$  is obviously a lower bound on OPT. Otherwise, if in any optimal schedule there does not exist a pair of jobs from  $\mathcal{J}_{\text{seq}}$  that overlap the same vertical line, we know by Lemma 20 that there exists a job in  $\mathcal{J}_{\text{seq}}$  that overlaps with a set  $\mathcal{J}'_D \subseteq \mathcal{J}_D$  such that  $e(\mathcal{J}'_D) \geq e(\mathcal{J}_D)/2$  and therefore  $\text{OPT} \geq e(i_{\perp}) + e(\mathcal{J}_D)/2$  in this case.  $\blacktriangleleft$

Define  $\mathcal{J}_k$  as the set of the  $k$  jobs with largest energy demand. Furthermore, define  $\mathcal{J}_{D,k} := \mathcal{J}_{p(i) > (\max\{D-p(\mathcal{J}_k), D/2\})} \setminus \mathcal{J}_k$ . Let  $i_k$  be the job with the smallest energy demand in  $\mathcal{J}_k$ . We define the value  $T_4$ , which by Corollary 21 is a lower bound for OPT as follows:

$$T_4 := \max\{\min\{2e(i_k), e(i_k) + e(\mathcal{J}_{D,k})/2\} \mid k \in \{1, \dots, n\}, p(\mathcal{J}_k) \leq D\}.$$

Given two disjoint sets of jobs  $\mathcal{J}_{\text{seq}}$  and  $\mathcal{J}_D$ , we say they are placed *L-shaped*, if the jobs  $i \in \mathcal{J}_D$  are placed such that  $\sigma(i) + p(i) = D$ , while the jobs in  $\mathcal{J}_{\text{seq}}$  are sorted by energy demand and placed left-aligned most demanding to the left, see Figure 1a.

► **Lemma 22.** *Let  $T = \max\{T_1, T_2, T_3, T_4\}$ . If we place  $\mathcal{J}_{\text{seq}} := \mathcal{J}_{e(i) > T/2}$  and  $\mathcal{J}_D := \mathcal{J}_{p(i) > D/2} \setminus \mathcal{J}_{\text{seq}}$  L-shaped, the schedule has a height of at most  $T + e(\mathcal{J}_D)/2 \leq (3/2)\text{OPT}$ .*

**Proof.** Consider a vertical line  $L$  through the generated schedule. If  $L$  does not intersect a job from  $\mathcal{J}_{\text{seq}}$ , the intersected jobs have a height of at most  $e(\mathcal{J}_D) \leq T$ . Otherwise, let  $i_L \in \mathcal{J}_{\text{seq}}$  and  $\mathcal{J}_{W,L} \subseteq \mathcal{J}_D$  be the jobs intersected by  $L$  and define  $\mathcal{J}_{\text{seq},L} := \mathcal{J}_{e(i) \geq e(i_L)}$ . Note that by definition of the schedule, it holds that  $\mathcal{J}_{W,L} \subseteq \mathcal{J}_{p(i) > (\max\{D-p(\mathcal{J}_{\text{seq},L}), D/2\})} \setminus \mathcal{J}_{\text{seq},L}$ . Since  $e(i_L) > T_4/2$ , it holds that  $T_4 \geq e(i_L) + e(\mathcal{J}_{W,L})/2$ , by definition of  $T_4$ . As a consequence  $e(i_L) + e(\mathcal{J}_{W,L}) \leq T + e(\mathcal{J}_{W,L})/2 \leq T + e(\mathcal{J}_D)/2 \leq (3/2)\text{OPT}$ .  $\blacktriangleleft$

## B Proof of Theorem 5 (First Steinberg Case)

**Proof.** We place jobs that are very time consuming or very energy demanding in an ordered fashion, while the residual jobs will be placed using Steinberg's Algorithm, see Figure 1b. We define  $\mathcal{J}_D := \mathcal{J}_{p(j) > (1/2+w)D} \setminus \mathcal{J}_{e(j) > T/2}$  to be the set of jobs with large processing times excluding jobs with large energy demands. We place each job  $j \in \mathcal{J}_D$  such that  $\sigma(j) = D - p(j)$ . All the jobs in  $\mathcal{J}_{e(j) > T/2}$  are sorted by energy demand and placed left aligned, most demanding first inside the schedule area. Let  $\rho := e(\mathcal{J}_D)/T$  and let  $e_{(1-2w)D}$  denote the energy demand of the job in  $\mathcal{J}_{e(j) > T/2}$  at position  $(1-2w)D$ . Then  $e_{(1-2w)D} \geq (2/3)T$ . By Lemma 18 and the choice of  $T$ , we know that  $e_{(1-2w)D} + e(\mathcal{J}_D) \leq T \leq \text{OPT}$  and hence  $\rho \leq (1/3)$ . Let  $L$  be a vertical line though the schedule, that is at or strictly left of  $(1/2-w)D$  and intersects a job from  $\mathcal{J}_{e(j) > T/2}$  and all the jobs from  $\mathcal{J}_D$ . By Lemma 22 at and left of  $L$  the peak energy demand of the schedule is bounded by  $(1 + \rho/2)T$ . On the other hand, right of  $L$  the energy demand of the schedule does not increase compared to  $L$ . As a consequence, the peak energy demand in the current schedule is bounded by  $(1 + \rho/2)T \leq (7/6)T$ . Furthermore, we know that right of  $(1-2w)D$  the schedule has a peak energy demand of at most  $T$ . Consider the set of jobs  $\mathcal{J}_{e(j) \in ((1/3)T, (1/2)T]}$ . By Lemma 15 we know  $p(\mathcal{J}_{e(j) \in ((1/3)T, (1/2)T]}) \leq 2w \cdot D$ , since  $\mathcal{J}_{e(j) > (2/3)T} \geq (1-w)D$ . Now we consider two cases.

**Case A.** If  $\varepsilon \leq \rho/2$ , we place all the jobs in  $\mathcal{J}_M := \mathcal{J}_{e(j) \in ((1/3)T, (1/2)T]}$  right-aligned next to each other inside the strip. Since they have an energy demand of at most  $(1/2)T$  and right of  $(1-2w)D$  the schedule has a peak energy demand of at most  $T$ , the peak energy demand of  $(5/3)T$  is not exceeded after adding these jobs. Define  $\lambda := p(\mathcal{J}_M)/D$ . Now at each point on the x-axis between 0 and  $a := (1-\lambda)D$  the schedule has an energy demand of at most

$(1 + \rho/2)T$ , and, therefore, we can use an energy demand of  $b := (2/3 - \rho/2 + \varepsilon)T$  to place the residual jobs. Let  $\mathcal{J}_{res}$  denote the set of residual jobs that still have to be placed. Note that each job in  $\mathcal{J}_{res}$  has an energy demand of at most  $(1/3)T$  and a processing time of at most  $(1/2 + w)D$  and the total area of these jobs can be bound by

$$\begin{aligned} \text{work}(\mathcal{J}_{res}) &\leq DT - (2/3)T \cdot (1 - w)D - \rho T \cdot (1/2 + w)D - (1/3)T \cdot \lambda D \\ &= (1/3 + (2/3)w - \rho(1/2 + w) - \lambda/3)DT, \end{aligned}$$

and hence  $2\text{work}(\mathcal{J}_{res}) \leq (2/3 + (4/3)w - \rho(1 + 2w) - (2/3)\lambda)DT$ . On the other hand, it holds that

$$\begin{aligned} &ab - (2p_{\max} - a)_+(2e_{\max} - b)_+ \\ &= (2/3 - \rho/2 + \varepsilon)T(1 - \lambda)D \\ &\quad - ((2(1/2 + w) - (1 - \lambda))D)_+((2(1/3) - (2/3 - \rho/2 + \varepsilon))T)_+ \\ &= (2/3 - \rho/2 + \varepsilon - (2/3)\lambda + (\rho/2 - \varepsilon)\lambda - (2w + \lambda)_+(\rho/2 - \varepsilon)_+)DT \\ &= (2/3 + \varepsilon(1 + 2w) - (1/2 + w)\rho - (2/3)\lambda)DT, \end{aligned}$$

since  $\rho/2 - \varepsilon \geq 0$ . Hence Steinberg's condition is fulfilled if  $(4/3)w - \rho(w + 1/2) \leq \varepsilon(1 + 2w)$ , which is true since  $w \leq (3/4)\varepsilon$ .

**Case B.** On the other hand, if  $\rho/2 < \varepsilon$ , it holds that  $(2/3 + \varepsilon - \rho/2)/2 \geq 1/3$ , and we consider the set  $\mathcal{J}_M := \mathcal{J}_{e(j) \in ((2/3 + \varepsilon - \rho/2)/2)T, (1/2)T]}$ , instead of the set  $\mathcal{J}_{e(j) \in ((1/3)T, (1/2)T]}$ , and place it right-aligned. Again, we define  $\lambda := p(\mathcal{J}_M)$ . Now, each job in  $\mathcal{J}_{res}$  has an energy demand of at most  $(1/3 + \varepsilon/2 - \rho/4)T$  and a processing time of at most  $(1/2 + w)D$ . The total area of these jobs can be bounded by

$$\begin{aligned} \text{work}(\mathcal{J}_{res}) &\leq DT - (2/3)T \cdot (1 - w)D - \rho T \cdot (1/2 + w)D - (1/3 + \varepsilon/2 - \rho/4)T \cdot \lambda D \\ &= (1/3 + (2/3)w - \rho(1/2 + w) - \lambda(1/3 + \varepsilon/2 - \rho/4))DT, \end{aligned}$$

and hence  $2\text{work}(\mathcal{J}_{res}) \leq (2/3 + 4/3w - \rho(1 + 2w) - (2/3 + \varepsilon - \rho/2)\lambda)DT$ . On the other hand, it holds that

$$\begin{aligned} &ab - (2p_{\max} - a)_+(2e_{\max} - b)_+ \\ &= (2/3 - \rho/2 + \varepsilon)T(1 - \lambda)D - (2(1/2 + w)D - (1 - \lambda)D)_+(2(1/3 + \varepsilon/2 - \rho/4)T \\ &\quad - (2/3 - \rho/2 + \varepsilon)T)_+ \\ &= (2/3 + \varepsilon - \rho/2 - (2/3 - \rho/2 + \varepsilon)\lambda)DT, \end{aligned}$$

Hence, Steinberg's condition is fulfilled if  $(4/3 - 2\rho)w - \rho/2 \leq \varepsilon$ , which is true since  $w \leq (3/4)\varepsilon$ .

Therefore, in both cases we use Steinberg's algorithm to place the jobs  $\mathcal{J}_{res}$  inside a rectangular container  $C$  of height  $(2/3 + \varepsilon - \rho)T$  and width  $(1 - \lambda)D$ , which in turn is positioned at  $\sigma(C) = 0$ . ◀

## C Proof of Theorem 6 (Second Steinberg Case)

**Proof.** In the first step, we place all the jobs in  $\mathcal{J}_D := \mathcal{J}_{p(j) > D/2}$  and  $\mathcal{J}_{seq} := \mathcal{J}_{e(j) > T/2} \setminus \mathcal{J}_D$  L-shaped. By Lemma 22 the resulting schedule has a peak energy demand of at most  $(3/2)\text{OPT}$ . Let  $e(\mathcal{J}_D) := (2/3 + \rho)T$  and  $p(\mathcal{J}_{seq}) := \lambda D$ . By Lemma 19, we know that, since  $e(\mathcal{J}_{p(j) \geq (3/4)D}) > (2/3)T$ , that  $\lambda D \leq 2(D - (3/4)D) = D/2$ .

## 21:24 Peak Demand Minimization via Sliced Strip Packing

The total amount of work  $\text{work}(\mathcal{J}_{res})$  of the residual jobs is bounded by

$$\text{work}(\mathcal{J}_{res}) \leq DT - (3/4)D \cdot (2/3)T - (1/2)D \cdot \rho T - \lambda D \cdot (1/2)T = (1/2 - \rho/2 - \lambda/2)DT.$$

On the other hand, there is a rectangular area with time  $a := (1 - \lambda)D$  and energy  $b := ((5/3) - (2/3 + \rho))T = (1 - \rho)T \geq (1/2)T$  where we can place the residual jobs. We will place the residual jobs into this area using Steinberg's algorithm. This is possible if the Steinberg's condition  $2\text{work}(\mathcal{J}_{res}) \leq ab - (2 \cdot p_{\max}(\mathcal{J}_{res}) - a)_+(2 \cdot e_{\max}(\mathcal{J}_{res}) - b)_+$  is fulfilled and each job fits inside the schedule area. Since  $p_{\max}(\mathcal{J}_{res}) \leq D/2 \leq a$  and  $e_{\max}(\mathcal{J}_{res}) \leq T/2 < b$ , it holds that

$$\begin{aligned} & ab - (2 \cdot p_{\max}(\mathcal{J}_{res}) - a)_+(2 \cdot e_{\max}(\mathcal{J}_{res}) - b)_+ \\ &= (1 - \lambda)D \cdot (1 - \rho)T - (D - (1 - \lambda)D)_+(T - (1 - \rho)T)_+ \\ &= (1 - \lambda - \rho)D \cdot T \\ &= 2(1/2 - \rho/2 - \lambda/2)DT \geq 2\text{work}(\mathcal{J}_{res}). \end{aligned}$$

The condition is fulfilled, and we can use the free rectangular area to place the residual jobs. ◀

## Abstract

In the *Two-dimensional Bin Packing (2BP)* problem, we are given a set of rectangles of height and width at most one and our goal is to find an axis-aligned nonoverlapping packing of these rectangles into the minimum number of unit square bins. The problem admits no APTAS and the current best approximation ratio is 1.406 by Bansal and Khan [SODA'14]. A well-studied variant of the problem is *Guillotine Two-dimensional Bin Packing (G2BP)*, where all rectangles must be packed in such a way that every rectangle in the packing can be obtained by recursively applying a sequence of end-to-end axis-parallel cuts, also called *guillotine cuts*. Bansal, Lodi, and Sviridenko [FOCS'05] obtained an APTAS for this problem. Let  $\lambda$  be the smallest constant such that for every set  $I$  of items, the number of bins in the optimal solution to G2BP for  $I$  is upper bounded by  $\lambda \text{opt}(I) + c$ , where  $\text{opt}(I)$  is the number of bins in the optimal solution to 2BP for  $I$  and  $c$  is a constant. It is known that  $4/3 \leq \lambda \leq 1.692$ . Bansal and Khan [SODA'14] conjectured that  $\lambda = 4/3$ . The conjecture, if true, will imply a  $(4/3 + \varepsilon)$ -approximation algorithm for 2BP. According to convention, for a given constant  $\delta > 0$ , a rectangle is *large* if both its height and width are at least  $\delta$ , and otherwise it is called *skewed*. We make progress towards the conjecture by showing  $\lambda = 4/3$  for *skewed instance*, i.e., when all input rectangles are skewed. Even for this case, the previous best upper bound on  $\lambda$  was roughly 1.692. We also give an APTAS for 2BP for skewed instance, though general 2BP does not admit an APTAS.

## 1 Introduction

Two-dimensional Bin Packing (2BP) is a well-studied problem in combinatorial optimization. It finds numerous applications in logistics, databases, and cutting stock. In 2BP, we are given a set of  $n$  rectangular items and square bins of side length 1. The  $i^{\text{th}}$  item is characterized by its width  $w(i) \in (0, 1]$  and height  $h(i) \in (0, 1]$ . Our goal is to find an axis-aligned nonoverlapping packing of these items into the minimum number of square bins of side length 1. There are two well-studied variants: (i) where the items cannot be rotated, and (ii) they can be rotated by 90 degrees.

As is conventional in bin packing, we focus on asymptotic approximation algorithms. For any optimization problem, the asymptotic approximation ratio (AAR) of algorithm  $\mathcal{A}$  is defined as  $\lim_{m \rightarrow \infty} \sup_{I: \text{opt}(I)=m} (\mathcal{A}(I)/\text{opt}(I))$ , where  $\text{opt}(I)$  is the optimal objective value and  $\mathcal{A}(I)$  is the objective value of the solution output by algorithm  $\mathcal{A}$ , respectively, on input  $I$ . Intuitively, AAR captures the algorithm's behavior when  $\text{opt}(I)$  is large. We call a

bin packing algorithm  $\alpha$ -asymptotic-approximate iff its AAR is at most  $\alpha$ . An Asymptotic Polynomial-Time Approximation Scheme (APTAS) is an algorithm that accepts a parameter  $\varepsilon$  and has AAR of  $(1 + \varepsilon)$ .

2BP is a generalization of classical 1-D bin packing problem [24, 15]. However, unlike 1-D bin packing, 2BP does not admit an APTAS unless  $P=NP$  [5]. In 1982, Chung, Garey, and Johnson [13] gave an approximation algorithm with AAR 2.125 for 2BP. Caprara [9] improved the AAR to  $T_\infty (\approx 1.691)$ . After a series of works [4, 25, 7], the AAR was gradually improved to  $1 + \ln(1.5) + \varepsilon \approx 1.405$  (for both the rotational and non-rotational versions of 2BP). The best-known lower bounds on the AAR for 2BP are  $1 + 1/3792$  and  $1 + 1/2196$  [11], for the versions with and without rotations, respectively.

In the context of geometric packing, guillotine cuts are well-studied and heavily used in practice [41]. The notions of *guillotine cuts* and *k-stage packing* were introduced by Gilmore and Gomory in their seminal paper [22] on the cutting stock problem. In *k-stage packing*, the items can be separated from each other using *k* stages of axis-parallel end-to-end cuts, also called guillotine cuts, where in each stage, either all cuts are vertical or all cuts are horizontal. In each stage, each rectangular region obtained in the previous stage is considered separately and can be cut again using guillotine cuts. Note that in the cutting process we change the orientation (vertical or horizontal) of the cuts  $k - 1$  times. 2-stage packing, also called *shelf packing*, has been studied extensively. A packing is called *guillotinable* iff it is a *k-stage packing* for some integer *k*. See Figure 1 for examples. Caprara et al. [10] gave an APTAS for 2-stage 2BP. Bansal et al. [8] showed an APTAS for guillotine 2BP.

■ **Figure 1** Examples of guillotinable and non-guillotinable packing.

The presence of an APTAS for guillotine 2BP raises an important question: can the optimal solution to guillotine 2BP be used as a good approximate solution to 2BP? Formally, let  $\text{opt}(I)$  and  $\text{opt}_g(I)$  be the minimum number of bins and the minimum number of guillotinable bins, respectively, needed to pack items  $I$ . Let  $\lambda$  be the smallest constant such that for some constant  $c$  and for every set  $I$  of items, we get  $\text{opt}_g(I) \leq \lambda \text{opt}(I) + c$ . Then  $\lambda$  is called the Asymptotic Price of Guillotinability (APoG). It is easy to show that

$\text{APoG} \geq 4/3$ <sup>1</sup>. Bansal and Khan [7] conjectured that  $\text{APoG} = 4/3$ . If true, this would imply a  $(4/3 + \varepsilon)$ -asymptotic-approximation algorithm for 2BP [8]. However, the present upper bound on  $\text{APoG}$  is only  $T_\infty$  ( $\approx 1.691$ ), due to Caprara’s HDH algorithm [9] for 2BP, which produces a 2-stage packing.

APTASes are known for some special cases for 2BP, such as when all items are squares [5] or when all rectangles are small in both dimensions [14]. Another important class is *skewed* rectangles. We say that a rectangle is  $\delta$ -large if, for some constant  $\delta > 0$ , its width and height are more than  $\delta$ ; otherwise, the rectangle is  $\delta$ -skewed. We just say that a rectangle is large or skewed when  $\delta$  is clear from the context. An instance of 2BP is skewed if all the rectangles in the input are skewed. Skewed instances are important in geometric packing (see Section 1.1). This special case is practically relevant [18]: e.g., in scheduling, it captures scenarios where no job can consume a significant amount of a shared resource (energy, memory space, etc.) for a significant amount of time. Even for skewed instance for 2BP, the best known AAR is 1.406 [7]. Also, for skewed instance, the best known upper bound on  $\text{APoG}$  is  $T_\infty \approx 1.691$ .

## 1.1 Related Works

Multidimensional packing problems are fundamental in combinatorial optimization [12]. Vector packing (VP) is another variant of bin packing, where the input is a set of vectors in  $[0, 1]^d$  and the goal is to partition the vectors into the minimum number of parts (bins) such that in each part, the sum of vectors is at most 1 in every coordinate. The present best approximation algorithm attains an AAR of  $(0.807 + \ln(d + 1))$  [6] and there is a matching  $\Omega(\ln d)$ -hardness [37]. Generalized multidimensional packing [33, 32] generalizes both geometric and vector packing.

In two-dimensional strip packing (2SP) [14, 40], we are given a set of rectangles and a bounded width strip. The goal is to obtain an axis-aligned nonoverlapping packing of all rectangles such that the height of the packing is minimized. The best-known approximation ratio for 2SP is  $5/3 + \varepsilon$  [23] and it is NP-hard to obtain better than  $3/2$ -approximation. However, there exist APTASes for the problem [28, 26]. In two-dimensional knapsack (2GK) [27], the rectangles have associated profits and our goal is to pack the maximum profit subset into a unit square knapsack. The present best polynomial-time (resp. pseudopolynomial-time) approximation ratio for 2GK is 1.809 [20] (resp.  $4/3$  [21]). These geometric packing problems have also been studied for  $d$ -dimensions ( $d \geq 2$ ) [39].

2SP and 2GK are also well-studied under guillotine packing. Seiden and Woeginger [38] gave an APTAS for guillotine 2SP. Khan et al. [29] recently gave a pseudopolynomial-time approximation scheme for guillotine 2GK. Recently, guillotine cuts [35] have received attention due to their connection with the maximum independent set of rectangles (MISR) problem [2]. In MISR, we are given a set of possibly overlapping rectangles and the goal is to find the maximum cardinality set of rectangles so that there is no pairwise overlap. It was noted in [30, 1] that for any set of  $n$  non-overlapping axis-parallel rectangles, if there is a guillotine cutting sequence separating  $\alpha n$  of them, then it implies a  $1/\alpha$ -approximation for MISR.

Skewed instance is an important special case in these problems. In some problems, such as MISR and 2GK, if all items are  $\delta$ -large then we can solve them exactly in polynomial time. So, the inherent difficulty of these problems lies in skewed instances. For VP, hard instances are again skewed, e.g., Bansal, Eliáš and Khan [6] showed that hard instances for 2-D VP

<sup>1</sup> Consider a set  $I$  of items containing  $2m$  rectangles of width 0.6 and height 0.4 and  $2m$  rectangles of width 0.4 and height 0.6. Then  $\text{opt}(I) = m$  and  $\text{opt}_g(I) = \lceil 4m/3 \rceil$ .

(for a class of algorithms called *rounding based algorithms*) are skewed instances, where one dimension is  $1 - \varepsilon$  and the other dimension is  $\varepsilon$ . Galvez et al. [18] recently studied strip packing when all items are skewed. For skewed instances, they showed  $(3/2 - \varepsilon)$  hardness of approximation and a matching  $(3/2 + \varepsilon)$ -approximation algorithm. For 2GK, when the height of each item is at most  $\varepsilon^3$ , a  $(1 - 72\varepsilon)$ -approximation algorithm is known [17].

## 1.2 Our Contributions

We study 2BP for the special case of  $\delta$ -skewed rectangles, where  $\delta \in (0, 1/2]$  is a constant.

First, we make progress towards the conjecture [7] that  $\text{APoG} = 4/3$ . Even for skewed rectangles, we only knew  $4/3 \leq \text{APoG} \leq T_\infty (\approx 1.691)$ . We resolve the conjecture for skewed rectangles, by giving lower and upper bounds of roughly  $4/3$  when  $\delta$  is a small constant.

Specifically, we give an algorithm for 2BP, called  $\text{skewed4Pack}_\varepsilon$ , that takes a parameter  $\varepsilon \in (0, 1)$  as input. For a set  $I$  of  $\delta$ -skewed rectangles, we show that when  $\delta$  and  $\varepsilon$  are close to 0,  $\text{skewed4Pack}_\varepsilon(I)$  outputs a 4-stage packing of  $I$  into roughly  $4 \text{opt}(I)/3 + O(1)$  bins.

► **Theorem 1.** *Let  $I$  be a set of  $\delta$ -skewed items, where  $\delta \in (0, 1/2]$ . Then  $\text{skewed4Pack}_\varepsilon(I)$  outputs a 4-stage packing of  $I$  in time  $O((1/\varepsilon)^{O(1/\varepsilon)} + n \log n)$ . Furthermore, the number of bins used is at most  $(4/3)(1 + 8\delta)(1 + 7\varepsilon) \text{opt}(I) + (8/\varepsilon^2) + 30$ .*

The lower bound of  $4/3$  on APoG can be extended to skewed items. We formally prove this in Appendix D. Hence, our bounds are tight for skewed items. Our result indicates that to improve the bounds on APoG in the general case, we should focus on  $\delta$ -large items.

Our other main result is an APTAS for 2BP for skewed items. Formally, we give an algorithm for 2BP, called  $\text{skewedCPack}$ , and show that for every constant  $\varepsilon \in (0, 1)$ , there exists a constant  $\delta \in (0, \varepsilon)$  such that the algorithm has an AAR of  $1 + \varepsilon$  when all items in the input are  $\delta$ -skewed rectangles.  $\text{skewedCPack}$  can be extended to the rotational version of 2BP. The best-known AAR for 2BP is  $1 + \ln(1.5) + \varepsilon$ . Our result indicates that to improve upon algorithms for 2BP, one should focus on  $\delta$ -large items.

In Section 3, we describe the  $\text{skewed4Pack}$  algorithm and prove Theorem 1. In Section 4, we describe the  $\text{skewedCPack}$  algorithm and prove that it has an AAR of  $1 + \varepsilon$ .

## 2 Preliminaries

Let  $[n] := \{1, 2, \dots, n\}$ , for  $n \in \mathbb{N}$ . For a rectangle  $i$ , its area  $a(i) := w(i)h(i)$ . For a set  $I$  of rectangles, let  $a(I) := \sum_{i \in I} a(i)$ . An *axis-aligned packing* of an item  $i$  in a bin is specified by a pair  $(x(i), y(i))$ , where  $x(i), y(i) \in [0, 1]$ , so that  $i$  is placed in the region  $[x(i), x(i) + w(i)] \times [y(i), y(i) + h(i)]$ . A packing of rectangles in a bin is called *nonoverlapping* iff for any two distinct items  $i$  and  $j$ , the rectangles  $(x(i), x(i) + w(i)) \times (y(i), y(i) + h(i))$  and  $(x(j), x(j) + w(j)) \times (y(j), y(j) + h(j))$  are disjoint. Equivalently, items may only intersect at their boundaries.

**Next-Fit Decreasing Height (NFDH).** NFDH [14] is a simple algorithm for 2SP and 2BP. We will use the following results on NFDH (cf. Appendix B in [31]).

► **Lemma 2.** *Let  $I$  be a set of items where each item  $i$  has  $w(i) \leq \delta_W$  and  $h(i) \leq \delta_H$ . NFDH can pack  $I$  into a bin of width  $W$  and height  $H$  if  $a(I) \leq (W - \delta_W)(H - \delta_H)$ .*

► **Lemma 3.** *NFDH uses less than  $(2a(I) + 1)/(1 - \delta)$  bins to pack  $I$  when  $h(i) \leq \delta$  for each item  $i$  and less than  $2a(I)/(1 - \delta) + 3$  bins when  $w(i) \leq \delta$  for each item  $i$ .*

If we swap the coordinate axes in NFDH, we get the Next-Fit Decreasing Width (NFDW) algorithm. Analogs of the above results hold for NFDW.

**Slicing Items.** We will consider variants of 2BP where some items can be *sliced*. Formally, slicing a rectangular item  $i$  using a horizontal cut is the operation of replacing  $i$  by two items  $i_1$  and  $i_2$  such that  $w(i) = w(i_1) = w(i_2)$  and  $h(i) = h(i_1) + h(i_2)$ . Slicing using vertical cut is defined analogously. Allowing some items to be sliced may reduce the number of bins required to pack them.

Variants of 2SP where items can be sliced using vertical cuts find applications in resource allocation problems [3, 16, 19]. Many packing algorithms [28, 25, 8] solve the sliceable version of the problem as a subroutine.

### 3 Guillotunable Packing of Skewed Rectangles

An item is called  $(\delta_W, \delta_H)$ -skewed iff its width is at most  $\delta_W$  or its height is at most  $\delta_H$ . In this section, we consider the problem of obtaining tight upper and lower bounds on APoG for  $(\delta_W, \delta_H)$ -skewed items. We will describe the `skewed4Pack` algorithm and prove Theorem 1.

#### 3.1 Packing With Slicing

Before describing `skewed4Pack`, let us first look at a closely-related variant of this problem, called the *sliceable 2D bin packing problem*, denoted as S2BP. In this problem, we are given two sets of rectangular items,  $\widetilde{W}$  and  $\widetilde{H}$ , where items in  $\widetilde{W}$  have width more than  $1/2$ , and items in  $\widetilde{H}$  have height more than  $1/2$ .  $\widetilde{W}$  is called the set of wide items and  $\widetilde{H}$  is called the set of tall items. We are allowed to *slice* items in  $\widetilde{W}$  using horizontal cuts and slice items in  $\widetilde{H}$  using vertical cuts, and our task is to pack  $\widetilde{W} \cup \widetilde{H}$  into the minimum number of bins without rotating the items.

We first describe a  $4/3$ -asymptotic-approximation algorithm for S2BP, called `greedyPack`, that outputs a 2-stage packing. Later, we will use `greedyPack` to design `skewed4Pack`.

We assume that the bin is a square of side length 1. Since we can slice items, we allow items in  $\widetilde{W}$  to have height more than 1 and items in  $\widetilde{H}$  to have width more than 1.

For  $X \subseteq \widetilde{W}$ ,  $Y \subseteq \widetilde{H}$ , let  $\text{hsum}(X) := \sum_{i \in X} h(i)$ ;  $\text{wsum}(Y) := \sum_{i \in Y} w(i)$ ;  $\text{wmax}(X) := \max_{i \in X} w(i)$  if  $X \neq \emptyset$ , and 0 if  $X = \emptyset$ ;  $\text{hmax}(Y) := \max_{i \in Y} h(i)$  if  $Y \neq \emptyset$ , and 0 if  $Y = \emptyset$ .

In the algorithm `greedyPack`( $\widetilde{W}, \widetilde{H}$ ), we first sort items  $\widetilde{W}$  in decreasing order of width and sort items  $\widetilde{H}$  in decreasing order of height. Suppose  $\text{hsum}(\widetilde{W}) \geq \text{wsum}(\widetilde{H})$ . Let  $X$  be the largest prefix of  $\widetilde{W}$  of total height at most 1, i.e., if  $\text{hsum}(\widetilde{W}) > 1$ , then  $X$  is a prefix of  $\widetilde{W}$  such that  $\text{hsum}(X) = 1$  (slice items if needed), and  $X = \widetilde{W}$  otherwise. Pack  $X$  into a bin such that the items touch the right edge of the bin. Then we pack the largest possible prefix of  $\widetilde{H}$  into the empty rectangular region of width  $1 - \text{wmax}(X)$  in the left side of the bin. We call this a type-1 bin. See Figure 2a for an example. If  $\text{hsum}(\widetilde{W}) < \text{wsum}(\widetilde{H})$ , we proceed analogously in a coordinate-swapped way, i.e., we first pack tall items in the bin and then pack wide items in the remaining space. Call this bin a type-2 bin. We pack the rest of the items into bins in the same way.

▷ **Claim 4.** `greedyPack`( $\widetilde{W}, \widetilde{H}$ ) outputs a 2-stage packing of  $\widetilde{W} \cup \widetilde{H}$  in  $O(m + |\widetilde{W}| \log |\widetilde{W}| + |\widetilde{H}| \log |\widetilde{H}|)$  time, where  $m$  is the number of bins used. It slices items in  $\widetilde{W}$  by making at most  $m - 1$  horizontal cuts and slices items in  $\widetilde{H}$  by making at most  $m - 1$  vertical cuts.

Since items in  $\widetilde{W}$  have width more than  $1/2$ , no two items can be placed side-by-side. Hence,  $\lceil \text{hsum}(\widetilde{W}) \rceil = \text{opt}(\widetilde{W}) \leq \text{opt}(\widetilde{W} \cup \widetilde{H})$ . Similarly,  $\lceil \text{wsum}(\widetilde{H}) \rceil \leq \text{opt}(\widetilde{W} \cup \widetilde{H})$ . So, if all bins have the same type, `greedyPack` uses  $\max(\lceil \text{hsum}(\widetilde{W}) \rceil, \lceil \text{wsum}(\widetilde{H}) \rceil) = \text{opt}(\widetilde{W} \cup \widetilde{H})$  bins. We will now focus on the case where some bins have type 1 and some have type 2.

(a) A type-1 bin produced by `greedyPack`. Wide items are packed on the right. Tall items are packed on the left.

(b) A type-2 bin produced by `greedyPack`. Tall items are packed above. Wide items are packed below.

(c) A type-1 bin in the packing of  $\widehat{I}$  computed by `skewed4Pack` (see Section 3.2). The packing contains 5 tall containers in 2 tall shelves and 18 wide containers in 8 wide shelves.

► **Definition 5.** In a type-1 bin, let  $X$  and  $Y$  be wide and tall items, respectively. The bin is called full iff  $\text{hsum}(X) = 1$  and  $\text{wsum}(Y) = 1 - \text{wmax}(X)$ . Similarly define full for type 2.

We first show that full bins pack items of large total area, and then show that if some bins have type 1 and some have type 2, then there are at most 2 non-full bins. This helps us upper-bound the number of bins used by `greedyPack`( $\widetilde{W}, \widetilde{H}$ ) in terms of  $a(\widetilde{W} \cup \widetilde{H})$ .

► **Lemma 6.** Let there be  $m_1$  type-1 full bins, containing items  $J_1$ . Then  $m_1 \leq 4a(J_1)/3 + 1/3$ .

**Proof.** In the  $j^{\text{th}}$  full bin of type 1, let  $X_j$  be the items from  $\widetilde{W}$  and  $Y_j$  be the items from  $\widetilde{H}$ . Let  $\ell_j := \text{wmax}(X_j)$  if  $j \leq m_1$  and  $\ell_{m_1+1} := 1/2$ . Since all items have their larger dimension more than  $1/2$ ,  $\ell_j \geq 1/2$  and  $\text{hmax}(Y_j) > 1/2$ , for any  $j \in [m_1]$ .

$a(X_j) \geq \ell_{j+1}$ , since  $X_j$  has height 1 and width at least  $\ell_{j+1}$ .  $a(Y_j) \geq (1 - \ell_j)/2$ , since  $Y_j$  has width  $1 - \ell_j$  and height more than  $1/2$ . So,  $a(J_1) = \sum_{j=1}^{m_1} (a(X_j) + a(Y_j)) \geq \sum_{j=1}^{m_1} (\ell_{j+1} + (1 - \ell_j)/2) \geq \sum_{j=1}^{m_1} ((\ell_{j+1}/2) + (1/4) + (1/2) - (\ell_j/2)) \geq (3m_1 - 1/4)$ . In the above inequalities, we used  $\ell_{j+1} \geq 1/2$  and  $\ell_1 \leq 1$ .

Therefore,  $m_1 \leq 4a(J_1)/3 + 1/3$ . ◀

An analog of Lemma 6 can be proven for type-2 bins. Lemma 6 implies that very few full bins can have items of total area significantly less than  $3/4$ .

Suppose `greedyPack`( $\widetilde{W}, \widetilde{H}$ ) uses  $m$  bins. After  $j$  bins are packed, let  $A_j$  be the height of the remaining items in  $\widetilde{W}$  and  $B_j$  be the width of the remaining items in  $\widetilde{H}$ . Let  $t_j$  be the type of the  $j^{\text{th}}$  bin (1 for type-1 bin, 2 for type-2 bin). So  $t_j = 1 \iff A_{j-1} \geq B_{j-1}$ .

We first show that  $|A_{j-1} - B_{j-1}| \leq 1 \implies |A_j - B_j| \leq 1$ , i.e., once  $|\text{hsum}(\widetilde{W}) - \text{wsum}(\widetilde{H})|$  becomes at most 1 during `greedyPack`, it continues to stay at most 1. Next, we show that  $t_j \neq t_{j+1} \implies |A_{j-1} - B_{j-1}| \leq 1$ , i.e., if all bins don't have the same type, then  $|\text{hsum}(\widetilde{W}) - \text{wsum}(\widetilde{H})|$  eventually becomes at most 1 during `greedyPack`. In the first non-full bin, we use up all the wide items or all the tall items. We will show that the remaining items have total height or total width at most 1, so we have at most 2 non-full bins.

In the  $j^{\text{th}}$  bin, let  $a_j$  be the height of items from  $\widetilde{W}$  and  $b_j$  be the width of items from  $\widetilde{H}$ . Hence, for all  $j \in [m]$ ,  $A_{j-1} = A_j + a_j$  and  $B_{j-1} = B_j + b_j$ .

► **Lemma 7.**  $|A_{j-1} - B_{j-1}| \leq 1 \implies |A_j - B_j| \leq 1$ .

**Proof.** W.l.o.g., assume  $A_{j-1} \geq B_{j-1}$ . So,  $t_j = 1$ . Suppose  $a_j < b_j$ . Then  $a_j < 1$ , so we used up  $\widetilde{W}$  in the  $j^{\text{th}}$  bin. Therefore,  $A_j = 0 \implies A_{j-1} = a_j < b_j \leq b_j + B_j = B_{j-1}$ , which contradicts. Hence,  $a_j \geq b_j$ . As  $0 \leq (A_{j-1} - B_{j-1}), (a_j - b_j) \leq 1$ , we get  $A_j - B_j = (A_{j-1} - B_{j-1}) - (a_j - b_j) \in [-1, 1]$ . ◀

► **Lemma 8.**  $t_j \neq t_{j+1} \implies |A_{j-1} - B_{j-1}| \leq 1$ .

**Proof.** W.l.o.g., assume  $t_j = 1$  and  $t_{j+1} = 2$ . Then

$$A_{j-1} \geq B_{j-1} \text{ and } A_j < B_j \implies B_{j-1} \leq A_{j-1} < B_{j-1} + a_j - b_j \implies A_{j-1} - B_{j-1} \in [0, 1]. \blacktriangleleft$$

► **Lemma 9.** *If all bins don't have the same type, then there can be at most 2 non-full bins.*

**Proof.** Let there be  $p$  full bins. Assume w.l.o.g. that in the  $(p+1)^{\text{th}}$  bin, we used up all items from  $\widetilde{W}$  but not  $\widetilde{H}$ . Hence,  $A_{p+1} = 0$  and  $\forall i \geq p+2, t_i = 2$ . Since all bins don't have the same type,  $\exists k \leq p+1$  such that  $t_k = 1$  and  $t_{k+1} = 2$ . By Lemmas 7 and 8, we get  $|A_{p+1} - B_{p+1}| \leq 1$ , implying  $B_{p+1} \leq 1$ . Hence, the  $(p+1)^{\text{th}}$  bin will use up all tall items, implying at most 2 non-full bins. ◀

► **Theorem 10.** *The number of bins  $m$  used by `greedyPack` is at most  $\max(\lceil \text{hsum}(\widetilde{W}) \rceil, \lceil \text{wsum}(\widetilde{H}) \rceil, \frac{4}{3}a(\widetilde{W} \cup \widetilde{H}) + \frac{8}{3})$ .*

**Proof.** If all bins have the same type, then  $m \leq \max(\lceil \text{hsum}(\widetilde{W}) \rceil, \lceil \text{wsum}(\widetilde{H}) \rceil)$ .

Let there be  $m_1$  (resp.  $m_2$ ) full bins of type 1 (resp. type 2) and let  $J_1$  (resp.  $J_2$ ) be the items inside those bins. Then by Lemma 6, we get  $m_1 \leq 4a(J_1)/3 + 1/3$  and  $m_2 \leq 4a(J_2)/3 + 1/3$ . Hence,  $m_1 + m_2 \leq 4a(\widetilde{W} \cup \widetilde{H})/3 + 2/3$ . If all bins don't have the same type, then by Lemma 9, there can be at most 2 non-full bins, so `greedyPack`( $\widetilde{W}, \widetilde{H}$ ) uses at most  $4a(\widetilde{W} \cup \widetilde{H})/3 + 8/3$  bins. ◀

### 3.2 The `skewed4Pack` Algorithm

We now return to the 2BP problem. `skewed4Pack` is an algorithm for 2BP takes as input a set  $I$  of rectangular items and a parameter  $\varepsilon \in (0, 1)$  where  $\varepsilon^{-1} \in \mathbb{Z}$ . It outputs a 4-stage bin packing of  $I$ . `skewed4Pack` has the following outline:

- A. Use linear grouping [15, 28] to round up the width or height of each item in  $I$ . This gives us a new instance  $\widehat{I}$ .
- B. Pack  $\widehat{I}$  into  $1/\varepsilon^2 + 1$  shelves, after *slicing* some items. A shelf is a rectangular region with width or height more than  $1/2$  and is fully packed, i.e., the area of items in a shelf equals the area of the shelf. If we treat each shelf as an item, we get a new instance  $\widetilde{I}$ .
- C. Compute a packing of  $\widetilde{I}$  into bins, after possibly slicing some items, using `greedyPack`.
- D. Repack most items of  $\widehat{I}$  without slicing into the shelves. We will prove that the remaining items have very small area, so they can be packed separately using NFDH.

**A. Item Classification and Rounding.** Define  $W := \{i \in I : h(i) \leq \delta_H\}$  and  $H := I - W$ . Items in  $W$  are called *wide* and items in  $H$  are called *tall*. Let  $W^{(L)} := \{i \in W : w(i) > \varepsilon\}$  and  $W^{(S)} := W - W^{(L)}$ . Similarly, let  $H^{(L)} := \{i \in H : h(i) > \varepsilon\}$  and  $H^{(S)} := H - H^{(L)}$ .

We will use *linear grouping* [15, 28] to round up the widths of  $W^{(L)}$  and the heights of  $H^{(L)}$  to get items  $\widehat{W}^{(L)}$  and  $\widehat{H}^{(L)}$ , respectively. By Claim 27 in Appendix A, items in  $\widehat{W}^{(L)}$  have at most  $1/\varepsilon^2$  distinct widths and items in  $\widehat{H}^{(L)}$  have at most  $1/\varepsilon^2$  distinct heights.

Let  $\widehat{W} := \widehat{W}^{(L)} \cup W^{(S)}$ ,  $\widehat{H} := \widehat{H}^{(L)} \cup H^{(S)}$ ,  $\widehat{I} := \widehat{W} \cup \widehat{H}$ . For  $\widehat{X} \subseteq \widehat{I}$ , let  $\text{fopt}(\widehat{X})$  be the minimum number of bins needed to pack  $\widehat{X}$  when items in  $\widehat{X} \cap \widehat{W}^{(L)}$  can be sliced using horizontal cuts, items in  $\widehat{X} \cap \widehat{H}^{(L)}$  can be sliced using vertical cuts, and items in  $\widehat{X} \cap (W^{(S)} \cup H^{(S)})$  can be sliced both vertically and horizontally. The following lemma follows from Lemma 28 in Appendix A.

► **Lemma 11.**  $\text{fopt}(\widehat{I}) < (1 + \varepsilon) \text{opt}(I) + 2$ .

**B. Creating Shelves.** We will use ideas from Kenyon and Rémila’s 2SP algorithm [28] to pack  $\widehat{I}$  into *shelves*. Roughly, we solve a linear program to compute an optimal strip packing of  $\widehat{W}$ , where the packing is 3-stage. The first stage of cuts gives us shelves and the second stage gives us containers. From each shelf, we trim off space that doesn’t belong to any container. See Section 3.3 for details. Let  $\widetilde{W}$  be the shelves thus obtained. Analogously, we can pack items  $\widehat{H}$  into shelves  $\widetilde{H}$ . Shelves in  $\widetilde{W}$  are called *wide shelves* and shelves in  $\widetilde{H}$  are called *tall shelves*. Let  $\widetilde{I} := \widetilde{W} \cup \widetilde{H}$ . We can interpret each shelf in  $\widetilde{I}$  as a rectangular item. We allow slicing  $\widetilde{W}$  and  $\widetilde{H}$  using horizontal cuts and vertical cuts, respectively. In Section 3.3, we prove the following facts.

► **Lemma 12.**  *$\widetilde{I}$  has the following properties: (a)  $|\widetilde{W}| \leq 1 + 1/\varepsilon^2$  and  $|\widetilde{H}| \leq 1 + 1/\varepsilon^2$ ; (b) Each item in  $\widetilde{W}$  has width more than  $1/2$  and each item in  $\widetilde{H}$  has height more than  $1/2$ ; (c)  $a(\widetilde{I}) = a(\widehat{I})$ ; (d)  $\max(\lceil \text{hsum}(\widetilde{W}) \rceil, \lceil \text{wsum}(\widetilde{H}) \rceil) \leq \text{fopt}(\widehat{I})$ .*

**C. Packing Shelves into Bins.** So far, we have packed  $\widehat{I}$  into shelves  $\widetilde{W}$  and  $\widetilde{H}$ . We will now use  $\text{greedyPack}(\widetilde{W}, \widetilde{H})$  to pack the shelves into bins. By Claim 4, we get a 2-stage packing of  $\widetilde{W} \cup \widetilde{H}$  into  $m$  bins, where we make at most  $m - 1$  horizontal cuts in  $\widetilde{W}$  and at most  $m - 1$  vertical cuts in  $\widetilde{H}$ . The horizontal cuts (resp. vertical cuts) increase the number of wide shelves (resp. tall shelves) from at most  $1 + 1/\varepsilon^2$  to at most  $m + 1/\varepsilon^2$ . By Theorem 10, Lemma 12(d) and Lemma 12(c), we get  $m \leq \max(\lceil \text{hsum}(\widetilde{W}) \rceil, \lceil \text{wsum}(\widetilde{H}) \rceil, \frac{4}{3}a(\widetilde{I}) + \frac{8}{3}) \leq \frac{4}{3}\text{fopt}(\widehat{I}) + \frac{8}{3}$ .

**D. Packing Items into Containers.** So far, we have a packing of shelves into  $m$  bins, where the shelves contain slices of items  $\widehat{I}$ . We will now repack a large subset of  $\widehat{I}$  into the shelves without slicing  $\widehat{I}$ . See Figure 2c for an example output. We do this using a standard greedy algorithm. See Appendix B for details of the algorithm and proof of the following lemma.

► **Lemma 13.** *Let  $P$  be a packing of  $\widetilde{I}$  into  $m$  bins, where we made at most  $m - 1$  horizontal cuts in wide shelves and at most  $m - 1$  vertical cuts in tall shelves. Then we can (without slicing) pack a large subset of  $\widehat{I}$  into the shelves in  $P$  such that the unpacked items (also called discarded items) from  $\widetilde{W}$  have total area less than  $\varepsilon \text{hsum}(\widetilde{W}) + \delta_H(1 + \varepsilon)(m + 1/\varepsilon^2)$ , and the unpacked items from  $\widetilde{H}$  have area less than  $\varepsilon \text{wsum}(\widetilde{H}) + \delta_W(1 + \varepsilon)(m + 1/\varepsilon^2)$ .*

We pack wide discarded items into new bins using NFDH and pack tall discarded items into new bins using NFDW. Finally, we prove the performance guarantee of  $\text{skewed4Pack}_\varepsilon(I)$ .

► **Lemma 14.** *Let  $I$  be a set of  $(\delta_W, \delta_H)$ -skewed items. Then  $\text{skewed4Pack}_\varepsilon(I)$  outputs a 4-stage packing of  $I$  in time  $O((1/\varepsilon)^{O(1/\varepsilon)} + n \log n)$  and uses less than  $\alpha(1 + \varepsilon)\text{opt}(I) + 2\beta$  bins, where  $\Delta := \frac{1}{2} \left( \frac{\delta_H}{1 - \delta_H} + \frac{\delta_W}{1 - \delta_W} \right)$ ,  $\alpha := \frac{4}{3}(1 + 4\Delta)(1 + 3\varepsilon)$ ,  $\beta := \frac{2\Delta(1 + \varepsilon)}{\varepsilon^2} + \frac{10}{3} + \frac{19\Delta}{3} + \frac{16\Delta\varepsilon}{3}$ .*

**Proof.** The discarded items are packed using NFDH or NFDW, which output a 2-stage packing. Since  $\text{greedyPack}$  outputs a 2-stage packing of the shelves and the packing of items into the shelves is a 2-stage packing, the bin packing of non-discarded items is a 4-stage packing. The time taken by  $\text{skewed4Pack}$  is at most  $O((1/\varepsilon)^{O(1/\varepsilon)} + n \log n)$ .

Suppose  $\text{greedyPack}$  uses at most  $m$  bins. By Theorem 10,  $m \leq 4\text{fopt}(\widehat{I})/3 + 8/3$ . Let  $W^d$  and  $H^d$  be the items discarded from  $W$  and  $H$ , respectively. By Lemma 13 and Lemma 12(d),  $a(W^d) < \varepsilon \text{fopt}(\widehat{I}) + \delta_H(1 + \varepsilon)(m + 1/\varepsilon^2)$  and  $a(H^d) < \varepsilon \text{fopt}(\widehat{I}) + \delta_W(1 + \varepsilon)(m + 1/\varepsilon^2)$ .

By Lemmas 3 and 11, the number of bins used by `skewed4Pack $_{\varepsilon}$ (I)` is less than

$$\begin{aligned} & m + \frac{2a(W^d) + 1}{1 - \delta_H} + \frac{2a(H^d) + 1}{1 - \delta_W} \\ & \leq (1 + 4\Delta(1 + \varepsilon))m + 4\varepsilon(1 + \Delta) \text{fopt}(\widehat{I}) + 2(1 + \Delta) + 4\Delta(1 + \varepsilon)/\varepsilon^2 \\ & \leq \alpha \text{fopt}(\widehat{I}) + 2(\beta - 1) < \alpha(1 + \varepsilon) \text{opt}(I) + 2\beta. \end{aligned} \quad \blacktriangleleft$$

Now we conclude with the proof of Theorem 1.

**Proof of Theorem 1.** This is a simple corollary of Lemma 14, where  $\delta \leq 1/2$  gives us  $\Delta \leq 2\delta$ ,  $\alpha(1 + \varepsilon) \leq (4/3)(1 + 8\delta)(1 + 7\varepsilon)$ , and  $\beta \leq 4/\varepsilon^2 + 15$ .  $\blacktriangleleft$

### 3.3 Creating Shelves

Here we will describe how to obtain shelves  $\widetilde{W}$  and  $\widetilde{H}$  from items  $\widehat{W}$  and  $\widehat{H}$ , respectively. Let  $\text{opt}_{\text{SP}}(\widehat{W})$  denote the optimal strip packing of  $\widehat{W}$  where items in  $\widehat{W}$  can be sliced using horizontal cuts. Then  $\text{fopt}(\widehat{W}) = \lceil \text{opt}_{\text{SP}}(\widehat{W}) \rceil$ . Hence, we will now try to compute a near-optimal strip packing of  $\widehat{W}$ .

Define a horizontal configuration  $S$  as a tuple  $(S_0, S_1, S_2, \dots)$  of  $1/\varepsilon^2 + 1$  non-negative integers, where  $S_0 \in \{0, 1\}$  and  $\sum_{j=1}^{1/\varepsilon^2} S_j w_j \leq 1$ . For any horizontal line at height  $y$  in a strip packing of  $\widehat{W}$ , the multiset of items intersecting the line corresponds to a configuration.  $S_0$  indicates whether the line intersects items from  $W^{(S)}$ , and  $S_j$  is the number of items from  $\widehat{W}_j^{(L)}$  that the line intersects. Let  $\mathcal{S}$  be the set of all horizontal configurations. Let  $N := |\mathcal{S}|$ .

To obtain an optimal packing, we need to determine the height of each configuration. This can be done with the following linear program.

$$\begin{aligned} & \min_{x \in \mathbb{R}^N} \sum_{S \in \mathcal{S}} x_S \\ & \text{where } \sum_{S \in \mathcal{S}} S_j x_S = h(\widehat{W}_j^{(L)}) \quad \forall j \in [1/\varepsilon^2] \\ & \text{and } \sum_{S: S_0=1} \left( 1 - \sum_{j=1}^{1/\varepsilon^2} S_j w_j \right) x_S = a(W^{(S)}) \\ & \text{and } x_S \geq 0 \quad \forall S \in \mathcal{S} \end{aligned}$$

Let  $x^*$  be an optimal extreme-point solution to the above LP. This gives us a packing where the strip is divided into rectangular regions called *shelves* that are stacked on top of each other. Each shelf has a configuration  $S$  associated with it and has height  $h(S) := x_S^*$  and contains  $S_j$  *containers* of width  $w_j$ . Containers of width  $w_j$  only contain items from  $\widehat{W}_j^{(L)}$ , and we call them *type- $j$*  containers. If  $S_0 = 1$ ,  $S$  also contains a container of width  $1 - \sum_{j=1}^{1/\varepsilon^2} S_j w_j$  that contains small items. We call this container a *type-0* container. Each container is fully filled with items. Let  $w(S)$  denote the width of shelf  $S$ , i.e., the sum of widths of all containers in  $S$ . Note that if  $S_0 = 1$ , then  $w(S) = 1$ . Otherwise,  $w(S) = \sum_{j=1}^{1/\varepsilon^2} S_j w_j$ .

► **Lemma 15.**  $x^*$  contains at most  $1/\varepsilon^2 + 1$  positive entries.

**Proof sketch.** Follows by applying Rank Lemma<sup>2</sup> to the linear program.  $\blacktriangleleft$

<sup>2</sup> Rank Lemma: the number of non-zero variables in an extreme-point solution to a linear program is at most the number of non-trivial constraints [34, Lemma 2.1.4].

► **Lemma 16.**  $x_S^* > 0 \implies w(S) > 1/2$ .

**Proof.** Suppose  $w(S) \leq 1/2$ . Then we could have split  $S$  into two parts by making a horizontal cut in the middle and packed the parts side-by-side, reducing the height of the strip by  $x_S^*/2$ . But that would contradict the fact that  $x^*$  is optimal. ◀

Treat each shelf  $S$  as an item of width  $w(S)$  and height  $h(S)$ . Allow each such item to be sliced using horizontal cuts. This gives us a new set  $\widetilde{W}$  of items such that  $\widetilde{W}$  can be packed inside  $\widetilde{W}$ . By applying an analogous approach to  $\widetilde{H}$ , we get a new set  $\widetilde{H}$  of items. Let  $\widetilde{I} := \widetilde{W} \cup \widetilde{H}$ . We call the shelves of  $\widetilde{W}$  *wide shelves* and the shelves of  $\widetilde{H}$  *tall shelves*. The containers in wide shelves are called *wide containers* and the containers in tall shelves are called *tall containers*.

► **Lemma 12.**  $\widetilde{I}$  has the following properties: (a)  $|\widetilde{W}| \leq 1 + 1/\varepsilon^2$  and  $|\widetilde{H}| \leq 1 + 1/\varepsilon^2$ ; (b) Each item in  $\widetilde{W}$  has width more than  $1/2$  and each item in  $\widetilde{H}$  has height more than  $1/2$ ; (c)  $a(\widetilde{I}) = a(\widehat{I})$ ; (d)  $\max(\lceil \text{hsum}(\widetilde{W}) \rceil, \lceil \text{wsum}(\widetilde{H}) \rceil) \leq \text{fopt}(\widehat{I})$ .

**Proof.** Lemma 15 implies (a) and Lemma 16 implies (b).  $a(\widehat{I}) = a(\widetilde{I})$  as the shelves are tightly packed. Since  $x^*$  is an optimal solution to the linear program,  $\lceil \text{hsum}(\widetilde{W}) \rceil = \lceil \sum_{S \in \mathcal{S}} x_S^* \rceil = \lceil \text{opt}_{\text{SP}}(\widehat{W}) \rceil = \text{fopt}(\widehat{W}) \leq \text{fopt}(\widehat{I})$ . Similarly,  $\lceil \text{wsum}(\widetilde{H}) \rceil = \text{fopt}(\widehat{H}) \leq \text{fopt}(\widehat{I})$ . ◀

## 4 Almost-Optimal Bin Packing of Skewed Rectangles

In this section, we will describe the algorithm `skewedCPack`. `skewedCPack` takes as input a set  $I$  of items and a parameter  $\varepsilon \in (0, 1/2]$ , where  $\varepsilon^{-1} \in \mathbb{Z}$ . We will prove that `skewedCPack` has AAR  $1 + 20\varepsilon$  when  $\delta$  is sufficiently small. `skewedCPack` works roughly as follows:

1. Invoke the subroutine `round`( $I$ ) (cf. Section 4.1). `round`( $I$ ) returns a pair  $(\widetilde{I}, I_{\text{med}})$ . Here  $I_{\text{med}}$ , called the set of *medium items*, has low total area, so we can pack it in a small number of bins.  $\widetilde{I}$ , called the set of *rounded items*, is obtained by rounding up the width or height of each item in  $I - I_{\text{med}}$ , so that  $\widetilde{I}$  has properties that help us pack it easily.
2. Compute the optimal *fractional compartmental* bin packing of  $\widetilde{I}$  (we will define *fractional* and *compartmental* later).
3. Use this packing of  $\widetilde{I}$  to obtain a packing of  $I$  that uses slightly more number of bins.

To bound the AAR of `skewedCPack`, we will prove a structural theorem (Section 4.2), which says that the optimal fractional compartmental packing of  $\widetilde{I}$  uses close to  $\text{opt}(I)$  bins.

### 4.1 Classifying and Rounding Items

We now describe the algorithm `round` and show that its output satisfies important properties.

First, we will find a set  $I_{\text{med}} \subseteq I$  and positive constants  $\varepsilon_1$  and  $\varepsilon_2$  such that  $a(I_{\text{med}}) \leq \varepsilon a(I)$ ,  $\varepsilon_2 \ll \varepsilon_1$ , and  $I - I_{\text{med}}$  is  $(\varepsilon_2, \varepsilon_1]$ -free, i.e., no item in  $I - I_{\text{med}}$  has its width or height in the interval  $(\varepsilon_2, \varepsilon_1]$ . Then we can remove  $I_{\text{med}}$  from  $I$  and pack it separately into a small number of bins using NFDH. We will see that the  $(\varepsilon_2, \varepsilon_1]$ -freeness of  $I - I_{\text{med}}$  will help us pack  $I - I_{\text{med}}$  efficiently. Specifically, we require  $\varepsilon_1 \leq \varepsilon$ ,  $\varepsilon_1^{-1} \in \mathbb{Z}$ , and  $\varepsilon_2 = f(\varepsilon_1)$ , where  $f(x) := \varepsilon x / (104(1 + 1/(\varepsilon x))^{2/x-2})$ . We explain this choice of  $f$  in Section 4.3.4. Intuitively, such an  $f$  ensures that  $\varepsilon_2 \ll \varepsilon_1$  and  $\varepsilon_2^{-1} \in \mathbb{Z}$ . For `skewedCPack` to work, we require  $\delta \leq \varepsilon_2$ . Finding such an  $I_{\text{med}}$  and  $\varepsilon_1$  is a standard technique [25, 7], so we defer the details to Appendix C.1.

Next, we classify the items in  $I - I_{\text{med}}$  into three disjoint classes:

- Wide items:  $W := \{i \in I : w(i) > \varepsilon_1 \text{ and } h(i) \leq \varepsilon_2\}$ .
- Tall items:  $H := \{i \in I : w(i) \leq \varepsilon_2 \text{ and } h(i) > \varepsilon_1\}$ .
- Small items:  $S := \{i \in I : w(i) \leq \varepsilon_2 \text{ and } h(i) \leq \varepsilon_2\}$ .

We will now use *linear grouping* [15, 28] to round up the widths of items  $W$  and the heights of items  $H$  to get items  $\widetilde{W}$  and  $\widetilde{H}$ , respectively. By Claim 27 in Appendix A, items in  $\widetilde{W}$  have at most  $1/(\varepsilon\varepsilon_1)$  distinct widths and items in  $\widetilde{H}$  have at most  $1/(\varepsilon\varepsilon_1)$  distinct heights. Let  $\widetilde{I} := \widetilde{W} \cup \widetilde{H} \cup S$ .

► **Definition 17** (Fractional packing). *Suppose we are allowed to slice wide items in  $\widetilde{I}$  using horizontal cuts, slice tall items in  $\widetilde{I}$  using vertical cuts and slice small items in  $\widetilde{I}$  using both horizontal and vertical cuts. For any  $\widetilde{X} \subseteq \widetilde{I}$ , a bin packing of the slices of  $\widetilde{X}$  is called a fractional packing of  $\widetilde{X}$ . The optimal fractional packing of  $\widetilde{X}$  is denoted by  $\text{fopt}(\widetilde{X})$ .*

► **Lemma 18.**  $\text{fopt}(\widetilde{I}) < (1 + \varepsilon) \text{opt}(I) + 2$ .

**Proof.** Directly follows from Lemma 28 in Appendix A. ◀

## 4.2 Structural Theorem

We will now define compartmental packing and prove the structural theorem, which says that the number of bins in the optimal fractional compartmental packing of  $\widetilde{I}$  is roughly equal to  $\text{fopt}(\widetilde{I})$ .

We first show how to *discretize* a packing, i.e., we show that given a fractional packing of items in a bin, we can remove a small fraction of tall and small items and shift the remaining items leftwards so that the left and right edges of each wide item belong to a constant-sized set  $\mathcal{T}$ , where  $|\mathcal{T}| \leq (1 + 1/\varepsilon\varepsilon_1)^{2/\varepsilon_1 - 2}$ . Next, we define *compartmental* packing and show how to convert a discretized packing to a compartmental packing.

For any rectangle  $i$  packed in a bin, let  $x_1(i)$  and  $x_2(i)$  denote the  $x$ -coordinates of its left and right edges, respectively, and let  $y_1(i)$  and  $y_2(i)$  denote the  $y$ -coordinates of its bottom and top edges, respectively. Let  $R$  be the set of distinct widths of items in  $\widetilde{W}$ . Given the way we rounded items,  $|R| \leq 1/\varepsilon\varepsilon_1$ . Recall that  $\varepsilon_1 \leq \varepsilon \leq 1/2$  and  $\varepsilon_1^{-1}, \varepsilon^{-1} \in \mathbb{Z}$ .

► **Theorem 19.** *Given a fractional packing of items  $\widetilde{J} \subseteq \widetilde{I}$  into a bin, we can remove tall and small items of total area less than  $\varepsilon$  and shift some of the remaining items to the left such that for every wide item  $i$ , we get  $x_1(i), x_2(i) \in \mathcal{T}$ .*

**Proof.** For wide items  $u$  and  $v$  in the bin, we say that  $u \prec v$  iff the right edge of  $u$  is to the left of the left edge of  $v$ . Formally  $u \prec v \iff x_2(u) \leq x_1(v)$ . We call  $u$  a *predecessor* of  $v$ . A sequence  $[i_1, i_2, \dots, i_k]$  such that  $i_1 \prec i_2 \prec \dots \prec i_k$  is called a *chain* ending at  $i_k$ . For a wide item  $i$ , define  $\text{level}(i)$  as the number of items in the longest chain ending at  $i$ . Formally,  $\text{level}(i) := 1$  if  $i$  has no predecessors, and  $(1 + \max_{j \prec i} \text{level}(j))$  otherwise. Let  $W_j$  be the items at level  $j$ , i.e.,  $W_j := \{i : \text{level}(i) = j\}$ . Note that the level of an item can be at most  $1/\varepsilon_1 - 1$ , since each wide item has width more than  $\varepsilon_1$ .

We will describe an algorithm for discretization. But first, we need to introduce two recursively-defined set families  $(S_1, S_2, \dots)$  and  $(T_0, T_1, \dots)$ . Let  $T_0 := \{0\}$  and  $t_0 := 1$ . For any  $j > 0$ , define  $t_j := (1 + 1/\varepsilon\varepsilon_1)^{2j}$ ,  $\delta_j := \varepsilon\varepsilon_1/t_{j-1}$ ,  $S_j := T_{j-1} \cup \{k\delta_j : k \in \mathbb{Z}, 0 \leq k < 1/\delta_j\}$ ,  $T_j := \{x + y : x \in S_j, y \in R \cup \{0\}\}$ . Note that  $\forall j > 0$ , we have  $T_{j-1} \subseteq S_j \subseteq T_j$  and  $\delta_j^{-1} \in \mathbb{Z}$ . Define  $\mathcal{T} := T_{1/\varepsilon_1 - 1}$ .

Our discretization algorithm proceeds in stages, where in the  $j^{\text{th}}$  stage, we apply two transformations to the items in the bin, called *strip-removal* and *compaction*.

**Strip-removal:** For each  $x \in T_{j-1}$ , consider a strip of width  $\delta_j$  and height 1 in the bin whose left edge has coordinate  $x$ . Discard the slices of tall and small items inside the strips.

**Compaction:** Move all tall and small items as much towards the left as possible (imagine a gravitational force acting leftwards on the tall and small items) while keeping the wide items fixed. Then move each wide item  $i \in W_j$  leftwards till  $x_1(i) \in S_j$ .

## 22:12 Geometric Bin Packing with Skewed Items

Observe that the algorithm maintains the following invariant: *after  $k$  stages, for each  $j \in [k]$ , each item  $i \in W_j$  has  $x_1(i) \in S_j$  (and hence  $x_2(i) \in T_j$ ). This ensures that after the algorithm ends,  $x_1(i), x_2(i) \in \mathcal{T}$ . All that remains to prove is that the total area of items discarded during strip-removal is at most  $\varepsilon$  and that compaction is always possible.*

► **Lemma 20.** *For all  $j \geq 0$ ,  $|T_j| \leq t_j$ .*

**Proof by induction.**  $|T_0| = t_0 = 1$ , so the base case holds. Now assume  $|T_{j-1}| \leq t_{j-1}$ . Then

$$|T_j| \leq (|R| + 1)|S_j| \leq \left(\frac{1}{\varepsilon\varepsilon_1} + 1\right) \left(|T_{j-1}| + \frac{1}{\delta_j}\right) \leq \left(\frac{1}{\varepsilon\varepsilon_1} + 1\right)^2 t_{j-1} = t_j. \quad \blacktriangleleft$$

Therefore,  $|\mathcal{T}| \leq t_{1/\varepsilon_1 - 1} = (1 + 1/\varepsilon\varepsilon_1)^{2/\varepsilon_1 - 2}$ .

► **Lemma 21.** *Discarded items (across all stages) have total area less than  $\varepsilon$ .*

**Proof.** In the  $j^{\text{th}}$  stage, we create  $|T_{j-1}|$  strips, and each strip has total area at most  $\delta_j$ . Therefore, the area discarded in the  $j^{\text{th}}$  stage is at most  $|T_{j-1}|\delta_j \leq t_{j-1}\delta_j = \varepsilon\varepsilon_1$ . Since there can be at most  $1/\varepsilon_1 - 1$  stages, we discard a total area of less than  $\varepsilon$  across all stages. ◀

► **Lemma 22.** *Compaction always succeeds, i.e., in the  $j^{\text{th}}$  stage, while moving item  $i \in W_j$  leftwards, no other item will block its movement.*

**Proof.** Let  $i \in W_j$ . Let  $z$  be the  $x$ -coordinate of the left edge of the strip immediately to the left of item  $i$ , i.e.,  $z := \max(\{x \in T_{j-1} : x \leq x_1(i)\})$ . For any wide item  $i'$ , we have  $x_2(i') \leq x_1(i) \iff i' \prec i \iff \text{level}(i') \leq j - 1$ . By our invariant, we get  $\text{level}(i') \leq j - 1 \implies x_2(i') \in T_{j-1} \implies x_2(i') \leq z$ . Therefore, for every wide item  $i'$ ,  $x_2(i') \notin (z, x_1(i)]$ .

In the  $j^{\text{th}}$  strip-removal, we cleared the strip  $[z, z + \delta_j] \times [0, 1]$ . If  $x_1(i) \in [z, z + \delta_j]$ , then  $i$  can freely move to  $z$ , and  $z \in T_{j-1} \subseteq S_j$ . Since no wide item has its right edge in  $(z, x_1(i)]$ , if  $x_1(i) > z + \delta_j$ , all the tall and small items whose left edge lies in  $[z + \delta_j, x_1(i)]$  will move leftwards by at least  $\delta_j$  during compaction. Hence, there would be an empty space of width at least  $\delta_j$  to the left of item  $i$ . Therefore, we can move  $i$  leftwards to make  $x_1(i)$  a multiple of  $\delta_j$ , and then  $x_1(i)$  would belong to  $S_j$ . ◀

Hence, compaction always succeeds and we get  $x_1(i), x_2(i) \in \mathcal{T}$  for each wide item  $i$ . ◀

► **Definition 23 (Compartmental packing).** *Consider a packing of some items into a bin. A compartment  $C$  is defined as a rectangular region in the bin satisfying the following properties:*

- $x_1(C), x_2(C) \in \mathcal{T}$ .
- $y_1(C), y_2(C)$  are multiples of  $\varepsilon_{\text{cont}} := \varepsilon\varepsilon_1/6|\mathcal{T}|$ .
- $C$  does not contain both wide items and tall items.
- If  $C$  contains tall items, then  $x_1(C)$  and  $x_2(C)$  are consecutive values in  $\mathcal{T}$ .

*If a compartment contains a wide item, it is called a wide compartment. Otherwise it is called a tall compartment. A packing of items into a bin is called compartmental iff there is a set of non-overlapping compartments in the bin such that each wide or tall item lies completely inside some compartment, and there are at most  $n_W := 3(1/\varepsilon_1 - 1)|\mathcal{T}| + 1$  wide compartments and at most  $n_H := (1/\varepsilon_1 - 1)|\mathcal{T}|$  tall compartments in the bin. A packing of items into multiple bins is called compartmental iff each bin is compartmental.*

Note that small items can be packed both inside and outside compartments.

The following lemma states that a discretized packing can be converted to a compartmental packing. It can be proved using standard techniques (e.g., Section 3.2.3 in [36]). See Appendix G.2 in [31] for a formal proof.

► **Lemma 24.** *If  $x_1(i), x_2(i) \in \mathcal{T}$  for each wide item  $i$  in a bin, then by removing wide and small items of area less than  $\varepsilon$ , we can get a compartmental packing of the remaining items.*

► **Theorem 25.** *For a set  $\tilde{I}$  of  $\delta$ -skewed rounded items, define  $\text{fcopt}(\tilde{I})$  as the number of bins in the optimal fractional compartmental packing<sup>3</sup> of  $\tilde{I}$ . Then  $\text{fcopt}(\tilde{I}) < (1 + 4\varepsilon) \text{fopt}(\tilde{I}) + 2$ .*

**Proof.** Consider a fractional packing of  $\tilde{I}$  into  $m := \text{fopt}(\tilde{I})$  bins. From each bin, we can discard items of area at most  $2\varepsilon$  and get a compartmental packing of the remaining items by Theorem 19 and Lemma 24.

Let  $X$  be the set of wide and small discarded items and let  $Y$  be the set of tall discarded items. For each item  $i \in X$ , if  $w(i) \leq 1/2$ , slice it using a horizontal cut in the middle and place the pieces horizontally next to each other to get a new item of width  $2w(i)$  and height  $h(i)/2$ . Repeat until  $w(i) > 1/2$ . Now pack the items in bins by stacking them one-over-the-other so that for each item  $i \in X$ ,  $x_1(i) = 0$ . This will require less than  $2a(X) + 1$  bins, and the packing will be compartmental.

Similarly, we can get a compartmental packing of  $Y$  into  $2a(Y) + 1$  bins. Since  $a(X \cup Y) < 2\varepsilon m$ , we will require less than  $4\varepsilon m + 2$  bins. Therefore, the total number of compartmental bins used to pack  $\tilde{I}$  is less than  $(1 + 4\varepsilon)m + 2$ . ◀

### 4.3 Packing Algorithm

We now describe the `skewedCPack` algorithm for packing a set  $I$  of  $n$   $\delta$ -skewed items.

1. **Classifying and Rounding Items** (see Section 4.1): Compute  $(\tilde{I}, I_{\text{med}}) := \text{round}(I)$ . Recall that  $I_{\text{med}}$ , called the set of *medium items*, has low total area, and  $\tilde{I}$ , called the set of *rounded items*, is obtained by rounding up the width or height of each item in  $I - I_{\text{med}}$ .
2. **Enumerating Packing of Compartments:** Compute all possible packings of empty compartments into at most  $n$  bins.
3. **Fractionally Packing Items into Compartments:** For each packing  $P$  of empty compartments, fractionally pack  $\tilde{I}$  into  $P$  using a linear program.
4. **Converting a Fractional Packing to a Non-Fractional Packing:** Discard a small set  $D \subseteq \tilde{I}$  of items and use an extreme-point solution to the linear program to non-fractionally pack  $\tilde{I} - D$  into  $P$ .
5. Pack  $I_{\text{med}} \cup D$  into bins using NFDH.

See Figure 3 for a visual overview of `skewedCPack`. We describe steps 2, 3 and 4 in Sections 4.3.1–4.3.3, respectively. In Section 4.3.4, we bound the AAR of `skewedCPack`.

#### 4.3.1 Enumerating Packing of Compartments

We will now describe a subroutine, called `iterPackings`( $\tilde{I}$ ), that outputs all packings of empty compartments into at least  $\lceil a(\tilde{I}) \rceil$  bins and at most  $n$  bins. A packing of empty compartments in a bin is called a *configuration*. We will first enumerate all configurations and then output multisets of configurations of cardinality ranging from  $\lceil a(\tilde{I}) \rceil$  to  $n$ .

<sup>3</sup> A *fractional compartmental packing* of  $\tilde{I}$  is a fractional packing of  $\tilde{I}$  that is also compartmental.

■ **Figure 3** Major steps of `skewedCPack` after rounding  $I$ .

There can be at most  $n_W := 3(1/\varepsilon_1 - 1)|\mathcal{T}| + 1$  wide compartments in a bin. Each wide compartment can have  $(1/\varepsilon_{\text{cont}})^2$   $y$ -coordinates of the top and bottom edges and at most  $|\mathcal{T}|^2/2$   $x$ -coordinates of the left and right edges, where  $\varepsilon_{\text{cont}} := \varepsilon\varepsilon_1/6|\mathcal{T}|$ . The rest of the space is for tall compartments. Therefore, the number of configurations is at most

$$n_C := ((1/\varepsilon_{\text{cont}})^2|\mathcal{T}|^2/2)^{n_W} \leq \left(\frac{3|\mathcal{T}|^2}{\varepsilon\varepsilon_1}\right)^{6|\mathcal{T}|/\varepsilon_1} \leq \left(1 + \frac{1}{\varepsilon\varepsilon_1}\right)^{\left(1 + \frac{1}{\varepsilon\varepsilon_1}\right)^{2/\varepsilon_1+1}}.$$

Since each configuration can have at most  $n$  bins, the number of combinations of configurations is at most  $(n+1)^{n_C}$ . Therefore, we can output all possible bin packings of empty compartments in  $O(n^{n_C})$  time. This completes the description of `iterPackings`.

### 4.3.2 Fractionally Packing Items into Compartments

For each bin packing  $P$  of empty compartments, we will try to fractionally pack the items into the bins. To do this, we will create a feasibility linear program, called  $\text{FP}(\tilde{I}, P)$ , that is feasible iff wide and tall items in  $\tilde{I}$  can be packed into the compartments in  $P$ . If  $\text{FP}(\tilde{I}, P)$  is feasible, then small items can also be fractionally packed since  $P$  contains at least  $a(\tilde{I})$  bins.

Let  $w'_1, w'_2, \dots, w'_p$  be the distinct widths of wide compartments in  $P$ . Let  $U_j$  be the set of wide compartments in  $P$  having width  $w'_j$ . Let  $h(U_j)$  be the sum of heights of the compartments in  $U_j$ . By Definition 23, we know that  $p \leq |\mathcal{T}|^2/2$ . Let  $w_1, w_2, \dots, w_r$  be the distinct widths of items in  $\tilde{W}$  (recall that  $\tilde{W}$  is the set of wide items in  $\tilde{I}$ ). Let  $\tilde{W}_j$  be the items in  $\tilde{W}$  having width  $w_j$ . Let  $h(\tilde{W}_j)$  be the sum of heights of all items in  $\tilde{W}_j$ . By Claim 27, we get  $r \leq 1/\varepsilon\varepsilon_1$ .

Let  $C := [C_0, C_1, \dots, C_r]$  be a vector, where  $C_0 \in [p]$  and  $C_j \in \mathbb{Z}_{\geq 0}$  for  $j \in [r]$ .  $C$  is called a *wide configuration* iff  $w(C) := \sum_{j=1}^r C_j w_j \leq w'_{C_0}$ . Intuitively, a wide configuration  $C$  represents a set of wide items that can be placed side-by-side into a compartment of width  $w'_{C_0}$ . Let  $\mathcal{C}$  be the set of all wide configurations. Then  $|\mathcal{C}| \leq p/\varepsilon_1^r$ , which is a constant. Let  $\mathcal{C}_j := \{C \in \mathcal{C} : C_0 = j\}$ .

To pack  $\tilde{W}$  into wide compartments, we must determine the height of each configuration. Let  $x \in \mathbb{R}_{\geq 0}^{|\mathcal{C}|}$  be a vector where  $x_C$  denotes the height of configuration  $C$ . Then  $\tilde{W}$  can be packed into wide compartments according to  $x$  iff  $x$  is a feasible solution to the following

feasibility linear program, named  $\text{FP}_W(\tilde{I}, P)$ :

$$\begin{aligned} \sum_{C \in \mathcal{C}} C_j x_C &\geq h(\tilde{W}_j) \quad \forall j \in [r] && (\tilde{W}_j \text{ should be covered}) \\ \sum_{C \in \mathcal{C} \text{ and } C_0=j} x_C &\leq h(U_j) \quad \forall j \in [p] && (C_j \text{ should fit in } U_j) \\ x_C &\geq 0 \quad \forall C \in \mathcal{C} \end{aligned}$$

Let  $x^*$  be an extreme point solution to  $\text{FP}_W(\tilde{I}, P)$  (if  $\text{FP}_W(\tilde{I}, P)$  is feasible). By Rank Lemma<sup>4</sup>, at most  $p + r$  entries of  $x^*$  are non-zero. Since the number of variables and constraints is constant,  $x^*$  can be computed in constant time.

Let  $\tilde{H}$  be the set of tall items in  $\tilde{I}$ . Items in  $\tilde{H}$  have at most  $1/\varepsilon\varepsilon_1$  distinct heights. Let there be  $q$  distinct heights of tall compartments in  $P$ . By Definition 23, we get  $q \leq 1/\varepsilon_{\text{cont}} = 6|\mathcal{T}|/\varepsilon\varepsilon_1$ . We can similarly define *tall configurations* and define a feasibility linear program for tall items, named  $\text{FP}_H(\tilde{I}, P)$ .  $\tilde{H}$  can be packed into tall compartments in  $P$  iff  $\text{FP}_H(\tilde{I}, P)$  is feasible. Let  $y^*$  be an extreme point solution to  $\text{FP}_H(\tilde{I}, P)$ . Then  $y^*$  can be computed in constant time and  $y^*$  has at most  $q + 1/\varepsilon\varepsilon_1$  positive entries.

Hence,  $\tilde{I}$  can be packed into  $P$  iff  $\text{FP}(\tilde{I}, P) := \text{FP}_W(\tilde{I}, P) \wedge \text{FP}_H(\tilde{I}, P)$  is feasible. The solution  $(x^*, y^*)$  shows us how to split each compartment into *shelves*, where each shelf corresponds to a configuration  $C$  and the shelf can be split into  $C_j$  *containers* of width  $w_j$  and one container of width  $w'_{C_0} - w(C)$ . Let there be  $m$  bins in  $P$ . After splitting the configurations across compartments, we get at most  $p + q + 2/\varepsilon\varepsilon_1 + m(n_W + n_H)$  shelves.

### 4.3.3 Converting a Fractional Packing to a Non-Fractional Packing

Consider a packing  $P$  of empty compartments into  $m$  bins. Let  $x^*$  and  $y^*$  be extreme-point solutions to  $\text{FP}_W(\tilde{I}, P)$  and  $\text{FP}_H(\tilde{I}, P)$ , respectively (assuming  $\tilde{I}$  can fit into  $P$ ). Then  $(x^*, y^*)$  gives us a fractional compartmental packing of  $\tilde{I}$  into  $m$  bins. We now show how to convert this to a non-fractional compartmental packing by removing some items from  $\tilde{I}$ .

Formally, we give an algorithm called  $\text{greedyCPack}(\tilde{I}, P, x^*, y^*)$ . It returns a pair  $(Q, D)$ , where  $Q$  is a (non-fractional) compartmental bin packing of items  $\tilde{I} - D$ , where the compartments in the bins are as per  $P$ .  $D$  is called the set of discarded items.

$\text{greedyCPack}$  is based on standard techniques. We prove in Appendix C.2 that

$$a(D) < \frac{52|\mathcal{T}|\varepsilon_2}{\varepsilon_1} m + 4\varepsilon_2 \left( \frac{|\mathcal{T}|^2}{2} + \frac{6|\mathcal{T}|}{\varepsilon\varepsilon_1} + \frac{2}{\varepsilon\varepsilon_1} \right). \quad (1)$$

We give an outline of  $\text{greedyCPack}$  here and defer the details to Appendix C.2.

1. For each  $j$ , iteratively assign wide items from  $\tilde{W}_j$  to a container of width  $w_j$ . When the total height of assigned items exceeds the height of the container, discard the last-assigned item and switch to a new container and repeat.
2. Similarly assign tall items to tall containers.
3. Identify rectangular regions where we can pack small items:
  - For each configuration  $C$ , there is a free region of width  $w'_{C_0} - w(C)$  and height  $x^*_C$  in a wide compartment. Similarly, we get free regions in tall compartments.

<sup>4</sup> Rank Lemma: the number of non-zero variables in an extreme-point solution to a linear program is at most the number of non-trivial constraints [34, Lemma 2.1.4].

- In each bin, the number of compartments is constant, so the space outside compartments be divided into a constant number of rectangular regions (see Lemma 29).  
Pack most of the small items into these free regions using NFDH. Discard the rest.

#### 4.3.4 Summary

See Appendix C.3 for a precise description of `skewedCPack`.

Recall the function  $f$  from Section 4.1. Since  $\varepsilon_2 := f(\varepsilon_1)$ , we get

$$\varepsilon_2 = f(\varepsilon_1) = \frac{\varepsilon\varepsilon_1}{104(1 + 1/\varepsilon\varepsilon_1)^{2/\varepsilon_1-2}} \leq \frac{\varepsilon\varepsilon_1}{104|\mathcal{T}|}. \quad (2)$$

The last inequality follows from the fact that  $|\mathcal{T}| \leq (1 + 1/\varepsilon\varepsilon_1)^{2/\varepsilon_1-2}$ .

► **Theorem 26.** *The number of bins used by `skewedCPackε( $\tilde{I}$ )` is less than*

$$(1 + 20\varepsilon) \text{opt}(I) + \frac{1}{13} \left(1 + \frac{1}{\varepsilon\varepsilon_1}\right)^{2/\varepsilon_1-2} + 23.$$

**Proof.** In an optimal fractional compartmental bin packing of  $\tilde{I}$ , let  $P^*$  be the corresponding packing of empty compartments into bins. Hence,  $P^*$  contains  $m := \text{fcopt}(\tilde{I})$  bins. Since `iterPackings( $\tilde{I}$ )` iterates over all bin packings of compartments,  $P^* \in \text{iterPackings}(\tilde{I})$ . Since wide and tall items in  $\tilde{I}$  can be packed into the compartments of  $P^*$ , we get that  $x^*$  and  $y^*$  are not null. By Lemma 3, the number of bins used by NFDH to pack  $I_{\text{med}} \cup D$  is less than  $2a(I_{\text{med}} \cup D)/(1 - \delta) + 3 + 1/(1 - \delta)$ . Therefore, the number of bins used by `skewedCPack( $I$ )` is less than

$$\begin{aligned} & m + \frac{2a(I_{\text{med}} \cup D)}{1 - \delta} + 3 + \frac{1}{1 - \delta} \\ & < m + \frac{2\varepsilon}{1 - \delta}a(I) + \frac{2\varepsilon_2}{1 - \delta} \left( \frac{52|\mathcal{T}|}{\varepsilon_1}m + 4 \left( \frac{|\mathcal{T}|^2}{2} + \frac{6|\mathcal{T}| + 2}{\varepsilon\varepsilon_1} \right) \right) + 3 + \frac{1}{1 - \delta} \\ & \hspace{15em} \text{(by Equation (1) and } a(I_{\text{med}}) \leq \varepsilon a(I)) \\ & = \left(1 + \frac{104\varepsilon_2|\mathcal{T}|}{\varepsilon_1(1 - \delta)}\right) m + \frac{2\varepsilon}{1 - \delta}a(I) + 3 + \frac{1}{1 - \delta} + \frac{8\varepsilon_2}{1 - \delta} \left( \frac{|\mathcal{T}|^2}{2} + \frac{6|\mathcal{T}| + 2}{\varepsilon\varepsilon_1} \right) \\ & = \left(1 + \frac{\varepsilon}{1 - \delta}\right) m + \frac{2\varepsilon}{1 - \delta}a(I) + 3 + \frac{1}{13(1 - \delta)} \left( \frac{\varepsilon\varepsilon_1|\mathcal{T}|}{2} + 19 + \frac{2}{|\mathcal{T}|} \right). \end{aligned}$$

(by Equation (2))

By Theorem 25 and Lemma 18, we get

$$m = \text{fcopt}(\tilde{I}) < (1 + 4\varepsilon) \text{fopt}(\tilde{I}) + 2 < (1 + 4\varepsilon)(1 + \varepsilon) \text{opt}(I) + 4 + 8\varepsilon.$$

Therefore, the number of bins used by `skewedCPack( $I$ )` is less than

$$\begin{aligned} & \left( (1 + 4\varepsilon)(1 + \varepsilon) \left(1 + \frac{\varepsilon}{1 - \delta}\right) + \frac{2\varepsilon}{1 - \delta} \right) \text{opt}(I) \\ & \quad + (4 + 8\varepsilon) \left(1 + \frac{\varepsilon}{1 - \delta}\right) + 3 + \frac{1}{13(1 - \delta)} \left( \frac{\varepsilon\varepsilon_1|\mathcal{T}|}{2} + 19 + \frac{2}{|\mathcal{T}|} \right) \\ & \leq (1 + 20\varepsilon) \text{opt}(I) + \frac{1}{13} \left(1 + \frac{1}{\varepsilon\varepsilon_1}\right)^{2/\varepsilon_1-2} + 23. \end{aligned} \quad \text{(since } \delta \leq \varepsilon_1 \leq \varepsilon \leq 1/2)$$

## A Linear Grouping

In this section, we describe the *linear grouping* technique [15, 28] for wide and tall items.

Let  $\varepsilon$  and  $\varepsilon_1$  be constants in  $(0, 1)$ . Let  $W$  be a set of items where each item has width more than  $\varepsilon_1$ . We will describe an algorithm, called `lingroupWide` that takes  $W$ ,  $\varepsilon$  and  $\varepsilon_1$  as input and returns the set  $\widehat{W}$  as output, where  $\widehat{W}$  is obtained by increasing the width of each item in  $W$ . `lingroupWide`( $W, \varepsilon, \varepsilon_1$ ) first arranges the items  $W$  in decreasing order of width and stacks them one-over-the-other (i.e., the widest item in  $W$  is at the bottom). Let  $h_L$  be the height of the stack. Let  $y(i)$  be the  $y$ -coordinate of the bottom edge of item  $i$ . Split the stack into sections of height  $\varepsilon\varepsilon_1 h_L$  each. For  $j \in [1/\varepsilon\varepsilon_1]$ , let  $w_j$  be the width of the widest item intersecting the  $j^{\text{th}}$  section from the bottom, i.e.,

$$w_j := \max(\{w(i) : i \in W \text{ and } (y(i), y(i) + h(i)) \cap ((j-1)\varepsilon\varepsilon_1 h_L, j\varepsilon\varepsilon_1 h_L) \neq \emptyset\}).$$

Round up the width of each item  $i$  to the smallest  $w_j$  that is at least  $w(i)$  (see Figure 4). Let  $W_j$  be the items whose width got rounded to  $w_j$  and let  $\widehat{W}_j$  be the resulting rounded items. (There may be ties, i.e., there may exist  $j_1 < j_2$  such that  $w_{j_1} = w_{j_2}$ . In that case, define  $W_{j_2} := \widehat{W}_{j_2} = \emptyset$ . This ensures that all  $W_j$  are disjoint.) Finally, define  $\widehat{W} := \bigcup_j \widehat{W}_j$ .

■ **Figure 4** Example invocation of `lingroupWide` for  $\varepsilon = \varepsilon_1 = 1/2$ .

We can similarly define the algorithm `lingroupTall`. Let  $H$  be a set of items where each item has height more than  $\varepsilon_1$ . `lingroupTall` that takes  $H$ ,  $\varepsilon$  and  $\varepsilon_1$  as input and returns  $\widehat{H}$ , where  $\widehat{H}$  is obtained by increasing the height of each item in  $H$ .

▷ **Claim 27.** Items in `lingroupWide`( $W, \varepsilon, \varepsilon_1$ ) have at most  $1/(\varepsilon\varepsilon_1)$  distinct widths. Items in `lingroupTall`( $H, \varepsilon, \varepsilon_1$ ) have at most  $1/(\varepsilon\varepsilon_1)$  distinct heights.

► **Lemma 28.** *Let  $W$ ,  $H$  and  $S$  be sets of items, where items in  $W$  have width more than  $\varepsilon_1$  and items in  $H$  have height more than  $\varepsilon_1$ . Let  $\widehat{W} := \text{lingroupWide}(W, \varepsilon, \varepsilon_1)$  and  $\widehat{H} := \text{lingroupTall}(H, \varepsilon, \varepsilon_1)$ . If we allow slicing items in  $\widehat{W}$  and  $\widehat{H}$  using horizontal and vertical cuts, respectively, then we can pack  $\widehat{W} \cup \widehat{H} \cup S$  into less than  $(1 + \varepsilon) \text{opt}(W \cup H \cup S) + 2$  bins.*

**Proof.** (cf. Appendix C in [31]) ◀

## B skewed4Pack: Packing Items into Containers

► **Lemma 13.** *Let  $P$  be a packing of  $\widetilde{I}$  into  $m$  bins, where we made at most  $m - 1$  horizontal cuts in wide shelves and at most  $m - 1$  vertical cuts in tall shelves. Then we can (without slicing) pack a large subset of  $\widehat{I}$  into the shelves in  $P$  such that the unpacked items (also called discarded items) from  $\widehat{W}$  have total area less than  $\varepsilon \text{hsum}(\widehat{W}) + \delta_H(1 + \varepsilon)(m + 1/\varepsilon^2)$ , and the unpacked items from  $\widehat{H}$  have area less than  $\varepsilon \text{wsum}(\widehat{H}) + \delta_W(1 + \varepsilon)(m + 1/\varepsilon^2)$ .*

**Proof.** For each  $j \in [1/\varepsilon^2]$ , number the type- $j$  wide containers arbitrarily, and number the items in  $\widehat{W}_j^{(L)}$  arbitrarily. Now greedily assign items from  $\widehat{W}_j^{(L)}$  to the first container  $C$  until the total height of the items exceeds  $h(C)$ . Then move to the next container and repeat. As per the constraints of the linear program, all items in  $\widehat{W}_j^{(L)}$  will get assigned to some type- $j$  wide container. Similarly, number the type-0 wide containers arbitrarily and number the items in  $W^{(S)}$  arbitrarily. Greedily assign items from  $W^{(S)}$  to the first container  $C$  until the total area of the items exceeds  $a(C)$ . Then move to the next container and repeat. As per the constraints of the linear program, all items in  $W^{(S)}$  will get assigned to some type-0 wide container. Similarly, assign all items from  $\widehat{H}$  to tall containers.

Let  $C$  be a type- $j$  wide container and  $\widehat{J}$  be the items assigned to it. If we discard the last item from  $\widehat{J}$ , then the items can be packed into  $C$ . The area of the discarded item is at most  $w(C)\delta_H$ . Let  $C$  be a type-0 wide container and  $\widehat{J}$  be the items assigned to it. Arrange the items in  $\widehat{J}$  in decreasing order of height and pack the largest prefix  $\widehat{J}' \subseteq \widehat{J}$  into  $C$  using NFDW (Next-Fit Decreasing Width).

Discard the items  $\widehat{J} - \widehat{J}'$ . By Lemma 2,  $a(\widehat{J} - \widehat{J}') < \varepsilon h(C) + \delta_H w(C) + \varepsilon \delta_H$ . Therefore, for a wide shelf  $S$ , the total area of discarded items is less than  $\varepsilon h(S) + \delta_H(1 + \varepsilon)$ .

After slicing the shelves in  $\widetilde{I}$  to get  $P$ , we get at most  $m + 1/\varepsilon^2$  wide shelves and at most  $m + 1/\varepsilon^2$  tall shelves. Therefore, the total area of discarded items from  $W$  is less than  $\varepsilon \text{hsum}(\widehat{W}) + \delta_H(1 + \varepsilon)(m + 1/\varepsilon^2)$ , and the total area of discarded items from  $H$  is less than  $\varepsilon \text{wsum}(\widehat{H}) + \delta_W(1 + \varepsilon)(m + 1/\varepsilon^2)$ . ◀

## C Details of skewedCPack

### C.1 Removing Medium Items

Let  $T := \lceil 2/\varepsilon \rceil$ . Let  $\mu_0 = \varepsilon$ . For  $t \in [T]$ , define  $\mu_t := f(\mu_{t-1})$  and define

$$J_t := \{i \in I : w(i) \in (\mu_t, \mu_{t-1}] \text{ or } h(i) \in (\mu_t, \mu_{t-1}]\}.$$

Let  $r := \text{argmin}_{t=1}^T a(J_t)$ ,  $I_{\text{med}} := J_r$ ,  $\varepsilon_1 := \mu_{r-1}$ . Each item belongs to at most 2 sets  $J_t$ , so

$$a(I_{\text{med}}) = \min_{t=1}^T a(J_t) \leq \frac{1}{T} \sum_{t=1}^T a(J_t) \leq \frac{2}{\lceil 2/\varepsilon \rceil} a(I) \leq \varepsilon a(I).$$

### C.2 Converting a Fractional Packing to a Non-Fractional Packing

► **Lemma 29.** *Let there be a set  $I$  of rectangles packed inside a bin. Then there is a polynomial-time algorithm that can decompose the empty space in the bin into at most  $3|I| + 1$  rectangles by making horizontal cuts only.*

**Proof.** Extend the top and bottom edge of each rectangle leftwards and rightwards till they hit another rectangle or an edge of the bin. This decomposes the empty region into rectangles  $R$ . See Figure 5.

For each rectangle  $i \in I$ , the top edge of  $i$  is the bottom edge of a rectangle in  $R$ , the bottom edge of  $i$  is the bottom edge of two rectangles in  $R$ . Apart from possibly the rectangle in  $R$  whose bottom edge is at the bottom of the bin, the bottom edge of every rectangle in  $R$  is either the bottom or top edge of a rectangle in  $I$ . Therefore,  $|R| \leq 3|I| + 1$ . ◀

■ **Figure 5** Horizontal cuts partition empty space around the 3 items into 9 rectangular regions.

Let  $(Q, D) := \text{greedyCPack}(\tilde{I}, P, x^*, y^*)$ , where  $P$  is a packing of empty compartments into  $m$  bins. We will describe  $\text{greedyCPack}$  and show that

$$a(D) < \frac{52|\mathcal{T}|\varepsilon_2}{\varepsilon_1}m + 4\varepsilon_2 \left( \frac{|\mathcal{T}|^2}{2} + \frac{6|\mathcal{T}|}{\varepsilon\varepsilon_1} + \frac{2}{\varepsilon\varepsilon_1} \right).$$

For a configuration  $C$  in a wide compartment, there is a container of width  $w'_{C_0} - w(C)$  available for packing small items. Hence, there are  $p + q + 2/\varepsilon\varepsilon_1 + m(n_W + n_H)$  containers available inside compartments for packing small items. By Lemma 29, we can partition the space outside compartments into at most  $m(3(n_W + n_H) + 1)$  containers. Therefore, the total number of containers available for packing small items is at most

$$m_S := (p + q + 2/\varepsilon\varepsilon_1) + m(4(n_W + n_H) + 1) \leq \left( \frac{|\mathcal{T}|^2}{2} + \frac{6|\mathcal{T}|}{\varepsilon\varepsilon_1} + \frac{2}{\varepsilon\varepsilon_1} \right) + \frac{16|\mathcal{T}|}{\varepsilon_1}m.$$

Greedy assign small items to small containers, i.e., keep assigning small items to a container till the area of items assigned to it is at least the area of the container, and then resume from the next container. Each small item will get assigned to some container. For each container  $C$ , pack the largest possible prefix of the assigned items using the Next-Fit Decreasing Height (NFDH) algorithm. By Lemma 2, the area of unpacked items would be less than  $\varepsilon_2 + \delta + \varepsilon_2\delta$ . Summing over all containers, we get that the unpacked area is less than  $(\varepsilon_2 + \delta + \varepsilon_2\delta)m_S \leq 3\varepsilon_2m_S$ .

For each  $j$ , greedily assign wide items from  $\tilde{W}_j$  to containers of width  $w_j$ , i.e., keep assigning items till the height of items exceeds the height of the container. Each wide item will get assigned to some container. Then discard the last item from each container. For each shelf in a wide compartment having configuration  $C$ , the total area of items we discard is at most  $\delta w(C)$ . Similarly, we can discard tall items of area at most  $\delta h(C)$  from each shelf in a tall compartment having configuration  $C$ .

## 22:22 Geometric Bin Packing with Skewed Items

Hence, across all configurations, we discard wide and tall items of area at most

$$\delta((p + q + 2/\varepsilon\varepsilon_1) + m(n_W + n_H)) \leq \delta \left( \frac{|\mathcal{T}|^2}{2} + \frac{6|\mathcal{T}|}{\varepsilon\varepsilon_1} + \frac{2}{\varepsilon\varepsilon_1} \right) + \frac{4\delta|\mathcal{T}|}{\varepsilon_1} m.$$

Therefore, for  $(Q, D) := \text{greedyCPack}(\tilde{I}, P, x^*, y^*)$ , we get

$$a(D) < \frac{52|\mathcal{T}|\varepsilon_2}{\varepsilon_1} m + 4\varepsilon_2 \left( \frac{|\mathcal{T}|^2}{2} + \frac{6|\mathcal{T}|}{\varepsilon\varepsilon_1} + \frac{2}{\varepsilon\varepsilon_1} \right).$$

## D Lower Bound on APoG

In this section, we prove a lower bound of roughly  $4/3$  on the APoG for skewed rectangles.

► **Lemma 30.** *Let  $m$  and  $k$  be positive integers and  $\varepsilon \in (0, 1)$ . Let  $J$  be a set of items packed into a bin, where each item has the longer dimension equal to  $(1 + \varepsilon)/2$  and the shorter dimension equal to  $(1 - \varepsilon)/2k$ . If the bin is guillotine-separable, then  $a(J) \leq 3/4 + \varepsilon/2 - \varepsilon^2/4$ .*

**Proof sketch.** For an item packed in the bin, if the height is  $(1 - \varepsilon)/2k$ , call it a wide item, and if the width is  $(1 - \varepsilon)/2k$ , call it a tall item. Let  $W$  be the set of wide items in  $J$ .

We can rearrange the items in the bin so that all wide items touch the left edge of the bin and all tall items touch the bottom edge of the bin. See Appendix E in [31] for a formal proof and Figure 6 for an example.

Therefore, the square region of side length  $(1 - \varepsilon)/2$  at the top-right corner of the bin is empty. Hence, the area occupied in each bin is at most  $3/4 + \varepsilon/2 - \varepsilon^2/4$ . ◀

■ **Figure 6** Structuring a guillotine-separable packing.

► **Theorem 31.** Let  $m$  and  $k$  be positive integers and  $\varepsilon \in (0, 1)$ . Let  $I$  be a set of  $4mk$  items, where  $2mk$  items have width  $(1 + \varepsilon)/2$  and height  $(1 - \varepsilon)/2k$ , and  $2mk$  items have height  $(1 + \varepsilon)/2$  and width  $(1 - \varepsilon)/2k$ . Let  $\text{opt}(I)$  be the number of bins in the optimal packing of  $I$  and  $\text{opt}_g(I)$  be the number of bins in the optimal guillotinable packing of  $I$ . Then

$$\frac{\text{opt}_g(I)}{\text{opt}(I)} \geq \frac{4}{3}(1 - \varepsilon).$$

This holds true even if items in  $I$  are allowed to be rotated.

**Proof.** For an item  $i \in I$ , if  $h(i) = (1 - \varepsilon)/2k$ , call it a wide item, and if  $w(i) = (1 - \varepsilon)/2k$ , call it a tall item. Let  $W$  be the set of wide items and  $H$  be the set of tall items.

Partition  $W$  into groups of  $k$  elements. In each group, stack items one-over-the-other. This gives us  $2m$  containers of width  $(1 + \varepsilon)/2$  and height  $(1 - \varepsilon)/2$ . Similarly, get  $2m$  containers of height  $(1 + \varepsilon)/2$  and height  $(1 - \varepsilon)/2$  by stacking items from  $H$  side-by-side. We can pack 4 containers in one bin, so  $I$  can be packed into  $m$  bins. See Figure 7 for an example. Therefore,  $\text{opt}(I) \leq m$ .

■ **Figure 7** Packing  $4k$  items in one bin. Here  $k = 7$ .

We will now show a lower-bound on  $\text{opt}_g(I)$ . In any guillotine-separable packing of  $I$ , the area occupied by each bin is at most  $3/4 + \varepsilon/2 - \varepsilon^2/4$  (by Lemma 30). Note that  $a(I) = m(1 - \varepsilon^2)$ . Therefore,

$$\begin{aligned} \text{opt}_g(I) &\geq \frac{m(1 - \varepsilon^2)}{3/4 + \varepsilon/2 - \varepsilon^2/4} \\ \implies \frac{\text{opt}_g(I)}{\text{opt}(I)} &\geq \frac{4}{3} \times \frac{1 - \varepsilon^2}{1 + 2\varepsilon/3 - \varepsilon^2/3} = \frac{4}{3} \times \frac{1 - \varepsilon}{1 - \varepsilon/3} \geq \frac{4}{3}(1 - \varepsilon). \end{aligned}$$

## Abstract

The main focus of this paper is radius-based (supplier) clustering in the two-stage stochastic setting with recourse, where the inherent stochasticity of the model comes in the form of a budget constraint. We also explore a number of variants where additional constraints are imposed on the first-stage decisions, specifically matroid and multi-knapsack constraints.

Our eventual goal is to provide results for supplier problems in the most general distributional setting, where there is only black-box access to the underlying distribution. To that end, we follow a two-step approach. First, we develop algorithms for a restricted version of each problem, in which all possible scenarios are explicitly provided; second, we employ a novel *scenario-discarding* variant of the standard *Sample Average Approximation (SAA)* method, in which we crucially exploit properties of the restricted-case algorithms. We finally note that the scenario-discarding modification to the SAA method is necessary in order to optimize over the radius.

## 1 Introduction

Stochastic optimization, first introduced in the work of Beale [2] and Dantzig [5], provides a way for modeling uncertainty in the realization of the input data. In this paper, we give approximation algorithms for a family of problems in stochastic optimization, and more precisely in the *2-stage recourse model* [22]. Our formal problem definitions follow.

We are given a set of clients  $\mathcal{C}$  and a set of facilities  $\mathcal{F}$ , in a metric space characterized by a distance function  $d$ . We let  $n = |\mathcal{C}|$  and  $m = |\mathcal{F}|$ . Our paradigm unfolds in two stages. In the first, each  $i \in \mathcal{F}$  has a cost  $c_i^I$ , but at that time we do not know which clients from  $\mathcal{C}$  will need service, and we only have a description of the distribution  $\mathcal{D}$  that governs the arrivals of clients later on. In the second stage, a *scenario*  $A \subseteq \mathcal{C}$  is realized with probability  $p_A$  according to  $\mathcal{D}$ , and now each  $i \in \mathcal{F}$  has a cost  $c_i^A$ . The clients of the realized scenario are precisely those that will require service from the facilities of  $\mathcal{F}$ . Using only the description of the distribution  $\mathcal{D}$ , we can proactively open a set of facilities  $F_I$  in *stage-I*. Subsequently, when a scenario  $A$  arrives in *stage-II*, we can augment the already constructed solution by opening some additional facilities  $F_A$ .

Throughout the paper, the objective function we minimize is the *maximum covering distance or radius*. Let  $d(j, S) = \min_{i \in S} d(i, j)$  for any  $j \in \mathcal{C}$  and for any  $S \subseteq \mathcal{F}$ . We then ask for  $F_I$  and  $F_A$ , such that  $d(j, F_I \cup F_A) \leq R$  for every  $A$  that materializes and all  $j \in A$ , **for the minimum  $R$  possible**. Furthermore, the expected opening cost of the returned solution is required to be at most some given budget  $B$ , i.e.,  $\sum_{i \in F_I} c_i^I + \mathbb{E}_{A \sim \mathcal{D}} \left[ \sum_{i \in F_A} c_i^A \right] \leq B$ . We call this problem *Two-Stage Stochastic Supplier* or **2S-Sup** for short.

Finally, we assume that for every  $j \in \mathcal{C}$  we have  $\Pr_{A \sim \mathcal{D}}[j \in A] > 0$ ; note that if this is not the case, then the presence of  $j$  in the input is completely redundant.

**Additional Stage-I Constraints.** Beyond the basic version of the problem, we also consider variants where there are additional hard constraints on the set of chosen stage-I facilities.

In *Two-Stage Stochastic Matroid Supplier* or **2S-MatSup** for short, the input also includes a matroid  $\mathcal{M} = (\mathcal{F}, \mathcal{I})$ , where  $\mathcal{I} \subseteq 2^{\mathcal{F}}$  is the family of independent sets of  $\mathcal{M}$ . In this case, we additionally require  $F_I \in \mathcal{I}$ .

In *Two-Stage Stochastic Multi-knapsack Supplier* or **2S-MuSup** for short,  $L$  additional knapsack constraints are imposed on  $F_I$ . Specifically, we are given budgets  $W_\ell \geq 0$  and weights  $f_i^\ell \geq 0$  for every  $i \in \mathcal{F}$  and every integer  $\ell \in [L]$ , such that the stage-I facilities should satisfy  $\sum_{i \in F_I} f_i^\ell \leq W_\ell$  for every  $\ell \in [L]$ . We also call a **2S-MuSup** instance *discrete*, if all weights  $f_i^\ell$  are integers, and for such an instance we further define a parameter  $\Lambda = \prod_{\ell=1}^L W_\ell$ .

**Modeling the Stage-I Distributional Knowledge.** To complete the description of a two-stage problem, one needs to define how knowledge of the distribution  $\mathcal{D}$  is represented in stage-I.

The most general representation is the *black-box* model [20, 8, 17, 14, 19], where we only have access to an oracle that can sample scenarios  $A$  according to  $\mathcal{D}$ . In this model, every time a scenario  $A$  is revealed, either through the oracle or through an actual data realization, we also learn the facility-cost vector  $c^A$  associated with it. We also consider the more restricted *polynomial-scenarios* model [18, 11, 16, 7], where all scenarios  $A$ , together with their occurrence probabilities  $p_A$  and their corresponding facility-cost vectors  $c^A$ , are explicitly provided.

We use the suffixes **BB** and **Poly** to distinguish these settings. For example, **2S-Sup-BB** is the previously defined **2S-Sup** in the black-box model.

In both distributional settings, our algorithms must have runtime polynomial in  $n, m$ . For the polynomial-scenarios case, the runtime should also be polynomial in the number of explicitly provided scenarios.

## 1.1 Motivation

To our knowledge, we are the first to consider this type of radius minimization problems in the two-stage stochastic paradigm. Regarding clustering problems in this regime, most prior work has focused on *Facility Location* [18, 20, 16, 17, 9, 14, 19]. On similar lines, [1] studies a stochastic  $k$ -center variant, where points arrive independently, *but each point only needs to get covered with some given probability*. Moreover, **2S-Sup** is the natural two-stage counterpart of the well-known **Knapsack-Supplier** problem [10]. **Knapsack-Supplier** has a 3-approximation, which is also the best ratio possible unless  $P=NP$  [10].

To see a practical application for our problems, consider healthcare resource allocation, when trying to mitigate a disease outbreak through the preventive placement of testing sites. Suppose that  $\mathcal{F}$  corresponds to potential locations that can host a testing center (e.g., hospitals, private clinics, university labs),  $\mathcal{C}$  to populations that can be affected by a possible disease outbreak, and each scenario  $A \in \mathcal{D}$  to which populations suffer the outbreak. Since immediate testing is of utmost importance, a central decision maker may prepare testing sites, such that under every scenario, each infected population has the closest possible access to a testing center. Assembling these sites in advance, i.e., in stage-I, has multiple benefits; for example, the necessary equipment and materials might be much cheaper and easier to obtain before the onset of the disease. Furthermore, the choice to minimize the maximum covering distance, as opposed to the opening cost, would reflect a policy valuing societal welfare more than economic performance.

In addition, there may be further constraints on  $F_I$ , irrespective of the stage-II decisions, which cannot be directly reduced to the budget  $B$ . For instance, we might have a constraint on the total number of personnel we want to occupy prior to the outbreak of the disease, assuming that facility  $i$  requires  $f_i$  people to keep it operational during the waiting period. To our knowledge, this is the first time additional stage-I constraints are studied in the two-stage stochastic regime.

## 1.2 Our Generalization Scheme and Comparison with Previous Results

Our ultimate goal is to devise algorithms for the black-box setting. As is usual in two-stage stochastic problems, we do this in three steps. First, we develop algorithms for the less complicated polynomial-scenarios model. Second, we sample a small number of scenarios from the black-box oracle and use our polynomial-scenarios algorithms to (approximately) solve the problems on them. Finally, we extrapolate this solution to the original black-box problem. This overall methodology is called *Sample Average Approximation (SAA)*.

Unfortunately, standard SAA approaches [21, 4] cannot be directly applied in radius minimization problems. On a high level, the obstacle here is that we need to compute the true cost of the approximate solution, something that is impossible using already existing results. Because this is a delicate technical issue, we refer the reader to Appendix A for an in-depth discussion.

**Our Sampling Framework.** Since the optimal black-box radius  $R^*$  is always the distance between a client and a facility, there are at most  $nm$  different options for it. Thus, we consider each separately, and assume for now that we work with a specific guess  $R$ . Given

this, we sample some  $N$  scenarios from the oracle, and let  $Q = \{S_1, S_2, \dots, S_N\}$  be that sampled set. We then run our polynomial-scenarios  $\eta$ -approximation algorithms on  $Q$ , which are guaranteed to provide solutions that cover each client within distance  $\eta R$ . Crucially, we show that if  $R \geq R^*$  and  $N$  is chosen appropriately, these solutions have cost at most  $(1 + \epsilon)B$  on  $Q$ , for any  $\epsilon > 0$ . Hence, in the end we keep the minimum guess for  $R$  whose cost over the samples is at most  $(1 + \epsilon)B$ .

For this minimum guess  $R$  (which obviously satisfies  $R \leq R^*$ ), the polynomial-scenarios algorithm returned a stage-I set  $F_I$ , and a stage-II set  $F_{S_v}$  for each  $S_v \in Q$ . **Our polynomial-scenarios algorithms are also designed to satisfy two additional key properties.** First, given  $F_I$  and any  $A \notin Q$ , there is an *efficient* process to *extend* the algorithm's output to a stage-II solution  $F_A$  with  $d(j, F_I \cup F_A) \leq \eta R$  for all  $j \in A$ . Second, irrespective of  $Q$ , the set  $\mathcal{S}$  of possible black-box solutions the extension process might produce, has only exponential size as a function of  $n$  and  $m$  (by default, it could have size  $2^{m|\mathcal{D}|}$ , and note that  $\mathcal{D}$  may be exponentially large or even uncountably infinite). **We call algorithms satisfying these properties *efficiently generalizable*.**

After using the extension process to construct a solution for every  $A$  that materializes, there is a final *scenario-discarding* step to our framework. Specifically, for some given  $\alpha \in (0, 1)$ , we first determine a threshold value  $T$  corresponding to the  $\lceil \alpha |Q| \rceil^{\text{th}}$  costliest scenario of  $Q$ . Then, if for an arriving  $A$  the computed set  $F_A$  has stage-II cost more than  $T$ , we perform no stage-II openings by setting  $F_A = \emptyset$  (i.e., we “give up” on  $A$ ). This step coupled with the bounds on  $|\mathcal{S}|$  ensure that the overall opening cost of our solution is at most  $(1 + \epsilon)B$ . At this point, note that discarding implies that there may exist scenarios  $A$  with  $d(j, F_I \cup F_A) > \eta R$  for some  $j \in A$ . However, we show such scenarios occur with probability at most  $\alpha$ , and the latter can be made inverse polynomially small.

### 1.3 Outline and Contributions

In Section 2, we present our generalization scheme. We summarize it as follows:

► **Theorem 1.** *Suppose we have an efficiently generalizable,  $\eta$ -approximation algorithm for the polynomial-scenarios variant of any of the problems we study. Let  $\mathcal{S}$  be the set of all potential black-box solutions its extension process may produce. Then, for any  $\gamma, \epsilon, \alpha \in (0, 1)$  and with  $\mathcal{O}\left(\frac{1}{\epsilon\alpha} \log\left(\frac{nm|\mathcal{S}|}{\gamma}\right) \log\left(\frac{nm}{\gamma}\right)\right)$  samples, we compute a radius  $R$  and a black-box solution  $F_I, F_A$  for all  $A \in \mathcal{D}$ :*

1.  $F_I$  satisfies the stage-I specific constraints of the problem (matroid or multiknapsack).
2. With probability at least  $1 - \gamma$ , we have  $R \leq R^*$  and  $\sum_{i \in F_I} c_i^I + \mathbb{E}_{A \sim \mathcal{D}}[\sum_{i \in F_A} c_i^A] \leq (1 + \epsilon)B$ , where  $R^*$  the optimal radius of the black-box variant.
3. With probability at least  $1 - \gamma$ , there holds  $\Pr_{A \sim \mathcal{D}}[d(j, F_I \cup F_A) \leq \eta R, \forall j \in A] \geq 1 - \alpha$ .

► **Theorem 2.** *We provide the following efficiently generalizable algorithms:*

- A 3-approximation for **2S-Sup-Poly** with  $|\mathcal{S}| \leq (n + 1)!$ .  
For the black-box case, the sample complexity of Theorem 1 is  $\tilde{O}\left(\frac{n}{\epsilon\alpha}\right)$ .
- A 5-approximation for **2S-MatSup-Poly** with  $|\mathcal{S}| \leq 2^m n!$ .  
For the black-box case, the sample complexity of Theorem 1 is  $\tilde{O}\left(\frac{m+n}{\epsilon\alpha}\right)$ .
- A 5-approximation for discrete instances of **2S-MuSup-Poly**, with  $|\mathcal{S}| \leq 2^m$  and runtime  $\text{poly}(n, m, \Lambda)$ . In the black-box case, the sample complexity of Theorem 1 is  $\tilde{O}\left(\frac{m}{\epsilon\alpha}\right)$ .

Here,  $\tilde{O}()$  hides  $\text{polylog}(n, m, 1/\gamma)$  terms. The 3-approximation for **2S-Sup-Poly** is presented in Section 3. It relies on a novel LP rounding technique, not used in clustering problems before. Notably, its approximation ratio matches the lower bound of the non-stochastic counterpart [10] (**Knapsack Supplier**), something very rare in the two-stage

paradigm. The 5-approximation for **2S-MatSup-Poly** is presented in Section 4. It relies on solving an auxiliary LP, whose optimal solution is guaranteed to be integral. The 5-approximation for **2S-MuSup-Poly** is presented in Appendix C, and is based on a reduction to a deterministic supplier problem with outliers. Specifically, if we view stage-I as consisting of a deterministic robust problem, stage-II is interpreted as trying to cover all outliers left over by stage-I.

**The main advantages of our generalization scheme are.**

1. Unlike standard SAA approaches [4, 21], it can handle problems based on the maximum-radius objective function.
2. The approximation ratio  $\eta$  is preserved with high probability during the generalization. By contrast, in typical two-stage problems, the approximation ratio usually gets inflated when generalizing the polynomial-scenarios setting to the black-box one.
3. The adaptive selection of  $T$  yields crisp sample bounds in terms of  $\alpha$  and  $\epsilon$ . By contrast, simpler non-adaptive approaches (e.g.,  $T = \frac{B}{\alpha}$ ) would still give the same guarantees, but the dependence of the sample bounds on  $\alpha$ ,  $\epsilon$  would be worse ( $\frac{1}{\epsilon^2\alpha^2}$  compared to  $\frac{1}{\epsilon\alpha}$  as we achieve). This adaptive thresholding may also be of independent interest; for instance, we conjecture that it might be able to improve the sample complexity in the SAA analysis of [4].

**Remark 1.** There is an important connection between the design of our generalization scheme and the design of our polynomial-scenarios approximation algorithms.

In any SAA approach, the sample complexity necessarily depends on the set of possible actions over which the generalization is performed. In Theorem 1, the sample bounds are given in terms of the *cardinality* of  $\mathcal{S}$ . Following the lines of [21], it may be possible to replace this dependence with a notion of dimension of the underlying convex program. However, such general bounds would lead to *significantly* larger complexities, consisting of very high order polynomials of  $n$ ,  $m$ .

On the other hand, all of our polynomial-scenarios algorithms are carefully designed, so that the *cardinality* of  $\mathcal{S}$  itself is small. *Indeed, one of the major contributions of this work is to show that this property can still be satisfied for sophisticated approximation algorithms using complex LP rounding.* Consequently, we can use simple generalization bounds. Besides being clear and intuitive, these lead to a much lower dependence on  $n, m$  for the sample complexity (see Theorem 2). To our knowledge, these are the first examples of non-trivial approximation algorithms for two-stage stochastic problems via directly bounding the size of the solution set  $\mathcal{S}$ .

**Remark 2.** If we assume that the maximum stage-II cost of any facility is bounded by some polynomial value  $\Delta$ , then we could use standard SAA results directly for our problems. Alternatively, we can use a variant of our generalization scheme (without scenario-discarding) getting refined sample bounds. A simple modification of our Section 2 analysis yields Theorem 3. However, this additional assumption on the cost function is much stronger than what is typically used in the two-stage stochastic literature, and so our scheme aims at tackling the most general case.

► **Theorem 3.** *Suppose we have an efficiently generalizable,  $\eta$ -approximation algorithm for the polynomial-scenarios variant of any of the problems we study. Let  $\mathcal{S}$  be the set of all possible black-box solutions its extension process can produce. Then, for any  $\gamma, \epsilon \in (0, 1)$  and*

■ **Algorithm 1** GreedyCluster( $\mathcal{Q}, R, g$ ).

```

 $H \leftarrow \emptyset;$ 
for each  $j \in \mathcal{Q}$  in non-increasing order of  $g(j)$  do
     $H \leftarrow H \cup \{j\};$ 
    for each  $j' \in \mathcal{Q}$  with  $G_{j,R} \cap G_{j',R} \neq \emptyset$  do
         $\pi(j') \leftarrow j, \mathcal{Q} \leftarrow \mathcal{Q} \setminus \{j'\};$ 
    end
end
Return  $(H, \pi)$ ;
    
```

---

with  $\mathcal{O}\left(\frac{m\Delta}{\epsilon} \log\left(\frac{nm|S|}{\gamma}\right) \log\left(\frac{nm}{\gamma}\right)\right)$  samples, we get a radius  $R$  and a black-box solution  $F_I, F_A$  for all  $A \in \mathcal{D}$ :

1.  $F_I$  satisfies the stage-I specific constraints of the problem (matroid or multiknapsack).
2. With probability at least  $1-\gamma$ , we have  $R \leq R^*$  and  $\sum_{i \in F_I} c_i^I + \mathbb{E}_{A \sim \mathcal{D}}[\sum_{i \in F_A} c_i^A] \leq (1+\epsilon)B$ , where  $R^*$  the optimal radius of the black-box variant.
3. With probability one, we have  $d(j, F_I \cup F_A) \leq \eta R$  for all  $j \in A \in \mathcal{D}$ .

In particular, with our polynomial-scenarios approximation algorithms, the sample bounds of **2S-Sup**, **2S-MatSup** and **2S-MuSup** are  $\tilde{O}\left(\frac{nm\Delta}{\epsilon}\right)$ ,  $\tilde{O}\left(\frac{(n+m)m\Delta}{\epsilon}\right)$  and  $\tilde{O}\left(\frac{m^2\Delta}{\epsilon}\right)$  respectively.

## 1.4 Notation and Important Subroutines

For  $k \in \mathbb{N}$ , we use  $[k]$  to denote  $\{1, 2, \dots, k\}$ . Also, for a vector  $\alpha = (\alpha_1, \alpha_2, \dots, \alpha_k)$  and a subset  $X \subseteq [k]$ , we use  $\alpha(X)$  to denote  $\sum_{i \in X} \alpha_i$ . For a client  $j$  and  $R \geq 0$ , we define  $G_{j,R} = \{i \in \mathcal{F} : d(i, j) \leq R\}$ ,  $i_{j,R}^I = \arg \min_{i \in G_{j,R}} c_i^I$  and  $i_{j,R}^A = \arg \min_{i \in G_{j,R}} c_i^A$  for any  $A$ .

We repeatedly use a key subroutine named GreedyCluster(), shown in Algorithm 1. Its input is a set of clients  $\mathcal{Q}$ , a target radius  $R$ , and an ordering function  $g : \mathcal{Q} \mapsto \mathbb{R}$ . Its output is a set  $H \subseteq \mathcal{Q}$  along with a mapping  $\pi : \mathcal{Q} \mapsto H$ . The goal of this subroutine is to sparsify the given input  $\mathcal{Q}$ , by greedily choosing a set of representative clients  $H$ .

► **Observation 4.** For  $(H, \pi) = \text{GreedyCluster}(\mathcal{Q}, R, g)$ , the following two properties hold: (i) for all  $j, j' \in H$  with  $j \neq j'$ , we have  $G_{j,R} \cap G_{j',R} = \emptyset$ ; and (ii) for all  $j \in \mathcal{Q}$  with  $j' = \pi(j)$ , we have  $G_{j,R} \cap G_{j',R} \neq \emptyset$ ,  $d(j, j') \leq 2R$ , and  $g(j') \geq g(j)$ .

## 2 Generalizing to the Black-Box Setting

Let  $\mathcal{P}$  be any of the two-stage problems we consider, with polynomial-scenarios variant **P-Poly** and black-box variant **P-BB**. Moreover, suppose that we have an  $\eta$ -approximation algorithm  $\text{AlgP}$  for **P-Poly**, which we intend to use to solve **P-BB**. Before we proceed to our generalization scheme, we present some important definitions and assumptions.

As a starting point, assume we are given a radius demand  $R$ ; we later discuss how to optimize over this. Hence, we denote a **P-BB** problem instance by the tuple  $\mathcal{J} = (\mathcal{C}, \mathcal{F}, \mathcal{M}_I, c^I, B, R)$ , where  $\mathcal{C}$  is the set of clients,  $\mathcal{F}$  the set of facilities  $i$ , each with stage-I cost  $c_i^I$ ,  $\mathcal{M}_I \subseteq 2^{\mathcal{F}}$  the set of legal stage-I openings (representing the stage-I specific constraints of  $\mathcal{P}$ ),  $B$  the budget, and  $R$  the given covering demand. In addition, there is an underlying distribution  $\mathcal{D}$ , where each scenario  $A \in \mathcal{D}$  appears with some unknown probability  $p_A$ . Our only means of access to  $\mathcal{D}$  is via a sampling oracle. Finally, when a scenario  $A \in \mathcal{D}$  is revealed, we also learn the corresponding facility costs  $c_i^A$ .

► **Definition 5.** We define a strategy  $s$  to be a tuple  $(F_I^s, F_A^s \mid A \in \mathcal{D})$  of facility sets, where  $A$  ranges over  $\mathcal{D}$ . The set  $F_I^s$  represents the facilities  $s$  opens in stage-I, and  $F_A^s$  denotes the facilities  $s$  opens in stage-II, when the arriving scenario is  $A$ . In other words, a strategy is a just potential solution to  $\mathcal{P}$ -**BB**.

► **Assumption 6.** For any strategy  $s$  and  $A \in \mathcal{D}$ , the value  $c^A(F_A^s)$  has a continuous CDF. We can assume this w.l.o.g.; we simply add a dummy facility  $i_d$  in the input, and for all  $s$  and  $A \in \mathcal{D}$ , we include  $i_d$  in the original  $F_A^s$ . Then,  $c_{i_d}^A$  is set to be some infinitesimal smooth noise. Also,  $B$  and  $\mathcal{M}_I$  can trivially be extended to account for  $i_d$ . Finally, the assumption implies that for a finite set of scenarios  $Q$ , the values  $c^A(F_A^s)$  for all  $A \in Q$  are distinct with probability 1.

We say that a given instance  $\mathfrak{J}$  is *feasible* for  $\mathcal{P}$ -**BB**, if there exists a strategy  $s^*$  satisfying:

$$F_I^{s^*} \in \mathcal{M}_I, \quad c^I(F_I^{s^*}) + \sum_{A \in \mathcal{D}} p_A c^A(F_A^{s^*}) \leq B, \quad \forall j \in A \in \mathcal{D} \quad d(j, F_I^{s^*} \cup F_A^{s^*}) \leq R$$

For  $\mathcal{P}$ -**Poly**, consider an instance  $\mathfrak{J} = (\mathcal{C}, \mathcal{F}, \mathcal{M}_I, Q, \vec{q}, \vec{c}, B, R)$ , where  $\mathcal{C}, \mathcal{F}, \mathcal{M}_I, B, R$  are as in the  $\mathcal{P}$ -**BB** setting,  $Q$  is the set of provided scenarios,  $\vec{c}$  the vector of stage-I and stage-II explicitly given costs, and  $\vec{q}$  the vector of occurrence probabilities  $q_A$  of each  $A \in Q$ . We say that the instance  $\mathfrak{J}$  is *feasible* for  $\mathcal{P}$ -**Poly**, if there exist sets  $F_I \subseteq \mathcal{F}$  and  $F_A \subseteq \mathcal{F}$  for every  $A \in Q$ , such that:

$$F_I \in \mathcal{M}_I, \quad c^I(F_I) + \sum_{A \in Q} q_A c^A(F_A) \leq B, \quad \forall j \in A \in Q \quad d(j, F_I \cup F_A) \leq R$$

We also write  $F$  for the overall collection of sets  $F_I$  and  $F_A : A \in Q$ .

► **Definition 7.** An algorithm  $\text{Alg}\mathcal{P}$  is a valid  $\eta$ -approximation algorithm for  $\mathcal{P}$ -**Poly**, if given any problem instance  $\mathfrak{J} = (\mathcal{C}, \mathcal{F}, \mathcal{M}_I, Q, \vec{q}, \vec{c}, B, R)$ , one of the following two cases holds:

- (A) If  $\mathfrak{J}$  is feasible for  $\mathcal{P}$ -**Poly**, then  $\text{Alg}\mathcal{P}$  returns a collection of sets  $F$  with  $F_I \in \mathcal{M}_I$ ,  $c^I(F_I) + \sum_{A \in Q} q_A c^A(F_A) \leq B$  and  $\forall j \in A \in Q \quad d(j, F_I \cup F_A) \leq \eta R$ .
- (B) If  $\mathfrak{J}$  is not feasible for  $\mathcal{P}$ -**Poly**, then the algorithm either returns “INFEASIBLE”, or returns a collection of sets  $F$  satisfying the properties presented in A.

► **Definition 8.** A valid  $\eta$ -approximation algorithm  $\text{Alg}\mathcal{P}$  for  $\mathcal{P}$ -**Poly** is efficiently generalizable, if for every instance  $\mathfrak{J} = (\mathcal{C}, \mathcal{F}, \mathcal{M}_I, Q, \vec{q}, \vec{c}, B, R)$  for which it returns a solution  $F$ , there is an efficient procedure that implicitly extends this to a strategy  $\bar{s}$ , and satisfies:

- (I) Given any  $A \in \mathcal{D}$ , it returns a set  $F_A^{\bar{s}} \subseteq \mathcal{F}$ , with  $d(j, F_I^{\bar{s}} \cup F_A^{\bar{s}}) \leq \eta R$  for all  $j \in A$ .
- (II)  $F_I^{\bar{s}} = F_I$  and  $F_A^{\bar{s}} = F_A$  for every  $A \in Q$ .
- (III) Given  $\mathfrak{J}$ , let  $\mathcal{S}$  be the set of all possible strategies that are potentially achievable using the extension procedure for any set  $Q$ . Then  $|\mathcal{S}| \leq t_{\mathcal{P}}(n, m)$  for some function  $t_{\mathcal{P}}(n, m)$ , with  $\log(t_{\mathcal{P}}(n, m)) = \text{poly}(n, m)$ .

Note that property III is not trivial, since by default  $|\mathcal{S}| \leq 2^{m|\mathcal{D}|}$ , and  $|\mathcal{D}|$  can be exponentially large or even uncountably infinite.

The first step of our generalization is based on sampling a set  $Q$  of scenarios from  $\mathcal{D}$ , and then applying the efficiently-generalizable  $\text{Alg}\mathcal{P}$  on  $Q$ . When running the latter, we also increase the available budget to  $(1 + \epsilon)B$ , for some  $\epsilon > 0$ . The purpose of this step is to verify whether or not the given instance of  $\mathcal{P}$ -**BB** is feasible, and to achieve this we may have to repeat it a polynomial number of times. See Algorithm 2 for the full details.

**Algorithm 2** Determining Feasibility for  $\mathcal{P}$ -BB.

---

**Input :** Parameters  $\epsilon, \gamma, \alpha \in (0, 1)$ ,  $N \geq 1$  and a  $\mathcal{P}$ -BB instance  
 $\mathfrak{J} = (\mathcal{C}, \mathcal{F}, \mathcal{M}_I, c^I, B, R)$ .

**If**  $\exists j \in \mathcal{C} : d(j, \mathcal{F}) > R$  **then** return “INFEASIBLE”; // For points not sampled

**for**  $h = 1, \dots, \left\lceil \log_{\frac{13}{12}}(1/\gamma) \right\rceil$  **do**

Draw  $N$  independent samples from the oracle, obtaining set  $Q = \{S_1, \dots, S_N\}$ ;  
 Let  $\vec{c}$  the vector containing  $c^I$  and the stage-II facility-cost vectors of all  $S_v \in Q$ ;  
 For every  $S_v \in Q$  set  $q_{S_v} \leftarrow 1/N$ ;  
**if**  $\text{AlgP}(\mathcal{C}, \mathcal{F}, \mathcal{M}_I, Q, \vec{q}, \vec{c}, (1 + \epsilon)B, R)$  returns  $F$  **then**

Let  $T$  be the  $\lceil \alpha N \rceil^{\text{th}}$  largest value of  $c^{S_v}(F_{S_v})$  among all scenarios in  $Q$ ;  
 Return  $(F, T)$ ;

**end**

**end**

Return “INFEASIBLE”;

---

If Algorithm 2 returns “INFEASIBLE”, then our approach would deem that  $\mathfrak{J}$  is not feasible for  $\mathcal{P}$ -BB. Otherwise, let  $F$  be the solution returned by  $\text{AlgP}$  at the last “successful” iteration of the while loop. Because  $\text{AlgP}$  is efficiently-generalizable, we can apply its extension procedure to any arriving scenario, and therefore implicitly construct a strategy  $\bar{s}$ . By the properties of  $\text{AlgP}$  and II, I, we have  $F_I^{\bar{s}} \in \mathcal{M}_I$  and  $d(j, F_I^{\bar{s}} \cup F_A^{\bar{s}}) \leq \eta R$  for every  $A \in \mathcal{D}$  and  $j \in A$ .

However, we are not yet done. The second step of our generalization framework consists of slightly modifying the strategy  $\bar{s}$ . For that reason, we use the value  $T$  returned by Algorithm 2, which corresponds to the  $\lceil \alpha N \rceil^{\text{th}}$  largest value  $c^{S_v}(F_{S_v}^{\bar{s}})$  among all  $S_v \in Q$ , with  $Q$  the sampled set in the last iteration of the while loop ( $F_{S_v}^{\bar{s}} = F_{S_v}$  by II). Note here that Assumption 6 ensures that the choice of  $T$  is well-defined.

If now an arriving scenario  $A$  has  $c^A(F_A^{\bar{s}}) > T$ , we will perform no stage-II opening. This modification eventually constructs a new strategy  $\hat{s}$ , with  $F_I^{\hat{s}} = F_I^{\bar{s}}$ ,  $F_A^{\hat{s}} = \emptyset$  when  $c^A(F_A^{\bar{s}}) > T$ , and  $F_A^{\hat{s}} = F_A^{\bar{s}}$  if  $c^A(F_A^{\bar{s}}) \leq T$ . The latter strategy will determine our final opening actions, and hence we need to analyze its *opening cost*  $C(\hat{s})$  over  $\mathcal{D}$ , and the probability with which it does not return an  $\eta$ -approximate solution. Regarding the latter, note that when  $F_A^{\hat{s}} \neq F_A^{\bar{s}}$ , we can no longer guarantee an approximation ratio of  $\eta$  as implied by property I for  $\bar{s}$ .

► **Lemma 9.** *If instance  $\mathfrak{J}$  is feasible for  $\mathcal{P}$ -BB and  $N \geq 1/\epsilon$ , then with probability at least  $1 - \gamma$  Algorithm 2 does not terminate with “INFEASIBLE”.*

**Proof.** By rescaling, we assume w.l.o.g. that  $B = 1$ . Also, the cost of any strategy  $s$  over  $\mathcal{D}$  is given by  $C(s) = c^I(F_I^s) + \sum_{A \in \mathcal{D}} p_A c^A(F_A^s)$ . For any specific execution of the while loop in Algorithm 2, let  $Y_v^s$  be the second-stage cost of  $s$  on sample  $S_v$ . Finally, for a fixed  $s$  the random variables  $Y_v^s$  are independent, and the empirical cost of  $s$  on  $Q$  is  $\hat{C}(s) = c^I(F_I^s) + \frac{1}{N} \sum_{v=1}^N Y_v^s$ .

If  $\mathfrak{J}$  is feasible, then there exists some strategy  $s^*$  satisfying  $F_I^{s^*} \in \mathcal{M}_I$  and  $d(j, F_I^{s^*} \cup F_A^{s^*}) \leq R$  for every  $A \in \mathcal{Q}$  and  $j \in A$ . We will also show that  $\hat{C}(s^*) \leq (1 + \epsilon)B$  with probability at least  $1/13$ . In this case, the restriction of  $s^*$  to  $Q$  verifies that  $(\mathcal{C}, \mathcal{F}, \mathcal{M}_I, Q, \vec{q}, \vec{c}, (1 + \epsilon)B, R)$  is feasible for  $\mathcal{P}$ -Poly. Thus, since  $\text{AlgP}$  is a valid  $\eta$ -approximation for  $\mathcal{P}$ -Poly, it will not return “INFEASIBLE”.

As  $s^*$  is feasible for  $\mathfrak{J}$  we have  $C(s^*) \leq B$ , implying  $\mathbb{E}[Y_v^{s^*}] = \sum_{A \in \mathcal{D}} p_A \cdot c^A(F_A^{s^*}) \leq B = 1$  for all samples  $v$ . By Lemma 20 with  $\delta = \epsilon BN$ , this yields

$$\Pr \left[ \sum_{v=1}^N Y_v^{s^*} < \mathbb{E} \left[ \sum_{v=1}^N Y_v^{s^*} \right] + \epsilon BN \right] \geq \min \left\{ \frac{\epsilon BN}{1 + \epsilon BN}, \frac{1}{13} \right\}$$

When  $N \geq \frac{B}{\epsilon} = \frac{1}{\epsilon}$ , we see that  $\epsilon BN / (1 + \epsilon BN) \geq 1/13$ . Hence, with probability at least  $1/13$  we have  $\sum_{v=1}^N Y_v^{s^*} < \mathbb{E}[\sum_{v=1}^N Y_v^{s^*}] + \epsilon BN$ , in which case we get  $\hat{C}(s^*) \leq (1 + \epsilon)B$  as shown below:

$$\begin{aligned} \hat{C}(s^*) &= c^I(F_I^{s^*}) + \frac{1}{N} \sum_{v=1}^N Y_v^{s^*} \leq c^I(F_I^{s^*}) + \frac{1}{N} \sum_{v=1}^N \mathbb{E}[Y_v^{s^*}] + \epsilon B \\ &\leq c^I(F_I^{s^*}) + \sum_{A \in \mathcal{D}} p_A \cdot c^A(F_A^{s^*}) + \epsilon B \leq (1 + \epsilon)B \end{aligned}$$

So each iteration terminates successfully with probability at least  $1/13$ . To bring the error probability down to at most  $\gamma$ , we repeat the process for  $\left\lceil \log_{\frac{13}{12}}(1/\gamma) \right\rceil$  iterations.  $\blacktriangleleft$

Let  $\mathcal{T}$  be the event that Algorithm 2 terminates **without returning** “INFEASIBLE”, and  $\mathcal{T}_h$  the event that Alg $\mathcal{P}$  found a solution  $F$  at the  $h^{\text{th}}$  iteration of the while loop. We denote by *Invalid* the event that Algorithm 2 returns an invalid output; specifically, if  $\mathcal{T}$  occurs, *Invalid* is the event of having  $C(\hat{s}) > (1 + 2\epsilon)B$ , otherwise it is the event of mistakenly deciding that  $\mathfrak{J}$  is not feasible. Let now  $Q_h$  be the set of scenarios sampled at the  $h^{\text{th}}$  iteration of Algorithm 2, and for any strategy  $s$  let  $T_s^h$  be the  $\lceil \alpha N \rceil^{\text{th}}$  largest value  $c^{S_v}(F_{S_v}^s)$  among all  $S_v \in Q_h$ . We then denote by  $\mathcal{E}_h$  the event that for all  $s \in \mathcal{S}$ , we have  $\Pr_{A \sim \mathcal{D}}[c^A(F_A^s) > T_s^h] \geq \frac{\alpha}{4}$ . Finally, note that due to III the set  $\mathcal{S}$  is deterministically given in the event  $\mathcal{E}_h$ .

► **Lemma 10.** For any  $\gamma, \alpha \in (0, 1)$  and  $N = \mathcal{O}\left(\frac{1}{\alpha} \log\left(\frac{t_{\mathcal{P}}(n, m)}{\gamma}\right)\right)$ , we have  $\Pr[\bar{\mathcal{E}}_h] \leq \gamma / (\log_{\frac{13}{12}}(\frac{1}{\gamma}) + 1)$ .

**Proof.** Focus on a specific iteration  $h$ . Consider a strategy  $s \in \mathcal{S}$ , and for each  $S_v \in Q_h$  let  $X_v$  be an indicator random variable that is 1 iff  $c^{S_v}(F_{S_v}^s) > T_s^h$ . Also let  $X = \sum_{v=1}^N X_v$ , and note that by Assumption 6 we have  $X = \lceil \alpha N \rceil - 1$ . This implies that the empirical probability of scenarios with stage-II cost more than  $T_s^h$  is  $q_s^h = (\lceil \alpha N \rceil - 1)/N$ . Finally, let  $p_s^h = \Pr_{A \sim \mathcal{D}}[c^A(F_A^s) > T_s^h]$ .

If  $p_s^h \geq \alpha$  then we immediately get  $\Pr[p_s^h < \alpha/4] = 0$ . Therefore, assume that  $p_s^h < \alpha$ . If  $N \geq 4/\alpha$  then we have:

$$q_s^h - \frac{\alpha}{2} = \frac{\lceil \alpha N \rceil - 1}{N} - \frac{\alpha}{2} \geq \frac{\alpha N - 1}{N} - \frac{\alpha}{2} = \frac{\alpha}{2} - \frac{1}{N} \geq \frac{\alpha}{2} - \frac{\alpha}{4} = \frac{\alpha}{4}$$

Hence, if  $p_s^h \geq q_s^h - \frac{\alpha}{2}$  and  $N \geq 4/\alpha$ , we get  $p_s^h \geq \frac{\alpha}{4}$ . Using Lemma 22 with  $p_s^h < \alpha$ ,  $\delta = \alpha/2$  and  $N = \frac{8}{\alpha} \log\left(\frac{t_{\mathcal{P}}(n, m)}{\gamma} (\log_{\frac{13}{12}}(\frac{1}{\gamma}) + 1)\right) \geq 4/\alpha$  yields the following:

$$\Pr[p_s^h < \frac{\alpha}{4}] \leq \Pr[p_s^h < q_s^h - \alpha/2] \leq e^{-\left(\frac{t_{\mathcal{P}}(n, m)}{\gamma} (\log_{\frac{13}{12}}(\frac{1}{\gamma}) + 1)\right)} = \frac{\gamma}{t_{\mathcal{P}}(n, m) (\log_{\frac{13}{12}}(1/\gamma) + 1)}$$

A union bound over all  $s \in \mathcal{S}$  and property III will finally give  $\Pr[\bar{\mathcal{E}}_h] \leq \gamma / (\log_{\frac{13}{12}}(\frac{1}{\gamma}) + 1)$ .  $\blacktriangleleft$

► **Theorem 11.** For any  $\epsilon, \gamma, \alpha \in (0, 1)$  and  $N = \mathcal{O}\left(\frac{1}{\epsilon \alpha} \log\left(\frac{t_{\mathcal{P}}(n, m)}{\gamma}\right)\right)$ ,  $\Pr[\text{Invalid}] \leq 3\gamma$ .

## 23:10 Approximating Two-Stage Stochastic Supplier Problems

**Proof.** Using the definition of the Invalid event and Lemmas 9, 10 we get the following.

$$\begin{aligned}
\Pr[\text{Invalid}] &= \Pr[\text{Invalid} \mid \bar{\mathcal{T}}] \Pr[\bar{\mathcal{T}}] + \Pr[\text{Invalid} \mid \mathcal{T}] \Pr[\mathcal{T}] \leq \gamma + \sum_h \Pr[\text{Invalid} \wedge \mathcal{T}_h] \\
&= \gamma + \sum_h \left( \Pr[\text{Invalid} \wedge \mathcal{T}_h \mid \mathcal{E}_h] \Pr[\mathcal{E}_h] + \Pr[\text{Invalid} \wedge \mathcal{T}_h \mid \bar{\mathcal{E}}_h] \Pr[\bar{\mathcal{E}}_h] \right) \\
&\leq 2\gamma + \sum_h \Pr[\text{Invalid} \wedge \mathcal{T}_h \wedge \mathcal{E}_h] \tag{1}
\end{aligned}$$

For each  $s \in \mathcal{S}$ , let  $t_s$  be value such that  $\Pr_{A \sim \mathcal{D}}[c^A(F_A^s) > t_s] = \frac{\alpha}{4}$ . Note that the existence of  $t_s$  is guaranteed by Assumption 6. Further, for each  $s \in \mathcal{S}$ ,  $A \in \mathcal{D}$ , define  $\tilde{c}^A(F_A^s)$  to be  $c^A(F_A^s)$  if  $c^A(F_A^s) \leq t_s$ , and 0 otherwise. In addition, for an iteration  $h$  let  $Y_{v,h}^s$  be a random variable denoting the second-stage  $\tilde{c}$  cost of  $s$  for the  $v$ -th sample of  $h$ , and  $Z_{v,h}^s$  be an indicator random variable that is 1 iff the original second-stage cost of  $s$  on the  $v$ -th sample of  $h$  is greater than  $t_s$ . We use the following cost functions:

$$\hat{C}_h(s) = c^I(F_I^s) + \frac{1}{N} \sum_{v=1}^N Y_{v,h}^s + \frac{t_s}{N} \sum_{v=1}^N Z_{v,h}^s \quad \text{and} \quad \tilde{C}(s) = c^I(F_I^s) + \sum_{A \in \mathcal{D}} p_A \cdot \tilde{c}^A(F_A^s)$$

Also, if  $p_s = \Pr_{A \sim \mathcal{D}}[c^A(F_A^s) > t_s]$ , then  $\mathbb{E}[\hat{C}_h(s)] = \tilde{C}(s) + p_s t_s$ . Finally, let  $\hat{C}_h^{II}(s) = \hat{C}_h(s) - c^I(F_I^s)$  and  $\tilde{C}^{II}(s) = \tilde{C}(s) - c^I(F_I^s)$ .

Now observe that if  $\text{Invalid} \wedge \mathcal{T}_h \wedge \mathcal{E}_h$  occurs, then there must exist some  $s \in \mathcal{S}$  with  $\hat{C}_h(s) \leq (1 + \epsilon)B$  and  $\tilde{C}(s) > (1 + 2\epsilon)B$ . Specifically we have  $\hat{C}_h(\bar{s}) \leq (1 + \epsilon)B$  and  $\tilde{C}(\bar{s}) > (1 + 2\epsilon)B$ . To see why  $\hat{C}_h(\bar{s}) \leq (1 + \epsilon)B$  is true, note that under this event AlgP finds a solution in iteration  $h$ . The empirical cost of this solution (which corresponds to a restriction of  $\bar{s}$ ) is at most  $(1 + \epsilon)B$ , and the pruning based on the value  $t_s$  can only decrease this cost. Regarding  $\tilde{C}(\bar{s}) > (1 + 2\epsilon)B$ , under  $\text{Invalid} \wedge \mathcal{T}_h \wedge \mathcal{E}_h$  we at first have  $C(\hat{s}) > (1 + 2\epsilon)B$ . In addition,  $\tilde{C}(\bar{s}) \leq C(\hat{s})$ , because by the definitions of  $t_s$  and  $\mathcal{E}_h$  we have  $t_s \geq T_s^h$ . Hence, we upper bound the probability of  $\text{Invalid} \wedge \mathcal{T}_h \wedge \mathcal{E}_h$  as follows:

$$\begin{aligned}
\Pr[\text{Invalid} \wedge \mathcal{T}_h \wedge \mathcal{E}_h] &\leq \Pr[\exists s \in \mathcal{S} : \hat{C}_h(s) \leq (1 + \epsilon)B \wedge \tilde{C}(s) > (1 + 2\epsilon)B] \\
&\leq \Pr[\exists s \in \mathcal{S} : \hat{C}_h(s) \leq (1 + \epsilon)B \wedge \tilde{C}(s) + p_s t_s > (1 + 2\epsilon)B + p_s t_s] \\
&\leq \Pr[\exists s \in \mathcal{S} : \hat{C}_h(s) \leq (1 + \epsilon)B \wedge \mathbb{E}[\hat{C}_h(s)] > (1 + 2\epsilon)B + p_s t_s] \\
&\leq \Pr[\exists s \in \mathcal{S} : \hat{C}_h^{II}(s) \leq (1 - \delta_s) \mathbb{E}[\hat{C}_h^{II}(s)]] \\
&\leq \sum_{s \in \mathcal{S}} \Pr \left[ \hat{C}_h^{II}(s) \leq (1 - \delta_s) \mathbb{E}[\hat{C}_h^{II}(s)] \right] \\
&= \sum_{s \in \mathcal{S}} \Pr \left[ N \cdot \hat{C}_h^{II}(s) / t_s \leq (1 - \delta_s) N \cdot \mathbb{E}[\hat{C}_h^{II}(s)] / t_s \right] \tag{2}
\end{aligned}$$

In the above we defined  $\delta_s$  such that  $\delta_s \geq \frac{\epsilon + p_s t_s}{1 + 2\epsilon + p_s t_s}$ , and also we made use of  $B = 1$  and  $\mathbb{E}[\hat{C}_h(s)] = \tilde{C}(s) + p_s t_s > 1 + 2\epsilon + p_s t_s$ . Applying Lemma 21 gives

$$\Pr \left[ N \cdot \hat{C}_h^{II}(s) / t_s \leq (1 - \delta_s) N \cdot \mathbb{E}[\hat{C}_h^{II}(s)] / t_s \right] \leq e^{-\frac{N(\epsilon + p_s t_s)^2}{2t_s(1 + 2\epsilon + p_s t_s)}} \tag{3}$$

We now focus on the quantity  $\frac{(\epsilon + p_s t_s)^2}{2t_s(1 + 2\epsilon + p_s t_s)}$ , and consider two distinct cases for  $p_s t_s$ .

- Suppose  $p_s t_s \geq \epsilon$ . Then  $\frac{(\epsilon + p_s t_s)^2}{2t_s(1 + 2\epsilon + p_s t_s)} \geq \frac{p_s^2 t_s^2}{2t_s(1 + 3p_s t_s)} \geq \frac{p_s}{2} \frac{p_s t_s}{1 + 3p_s t_s} \geq \frac{\epsilon \cdot p_s}{2(1 + 3\epsilon)}$ , where the last inequality follows because  $x/(1 + 3x)$  is increasing and in our case  $x \geq \epsilon$ .

- Suppose  $p_s t_s < \epsilon$ . Then  $\frac{(\epsilon + p_s t_s)^2}{2t_s(1+2\epsilon+p_s t_s)} \geq \frac{\epsilon^2}{2t_s(1+3\epsilon)} \geq \frac{\epsilon \cdot p_s}{2(1+3\epsilon)}$ , where in the last inequality we used the fact that in this case  $t_s < \epsilon/p_s$ .

Therefore, by definition of  $p_s$ , we have  $\frac{(\epsilon + p_s t_s)^2}{2t_s(1+2\epsilon+p_s t_s)} \geq \frac{\epsilon \cdot \alpha}{8(1+3\epsilon)}$  in every case. Plugging that in (3), (2), and setting  $N = \frac{8(1+\epsilon)}{\epsilon \alpha} \log\left(\frac{t_{\mathcal{P}}(n,m)}{\gamma} (\log_{\frac{13}{12}}(\frac{1}{\gamma}) + 1)\right)$  gives  $\Pr[\text{Invalid} \wedge \mathcal{T}_h \wedge \mathcal{E}_h] \leq \gamma / (\log_{\frac{13}{12}}(\frac{1}{\gamma}) + 1)$ . Finally, using this in (1) gives the desired error probability of at most  $3\gamma$ . ◀

► **Theorem 12.** For any  $\gamma, \alpha \in (0, 1)$  and  $N = \mathcal{O}\left(\frac{1}{\alpha} \log\left(\frac{t_{\mathcal{P}}(n,m)}{\gamma}\right)\right)$ , the solution strategy  $\hat{s}$  satisfies  $\Pr_{A \sim \mathcal{D}}[d(j, F_I^{\hat{s}} \cup F_A^{\hat{s}}) \leq \eta R, \forall j \in A] \geq 1 - 2\alpha$  with probability at least  $1 - \gamma$ .

**Proof.** Consider some iteration  $h$  and strategy  $s \in \mathcal{S}$ . Let  $p_s^h = \Pr_{A \sim \mathcal{D}}[c^A(F_A^s) > T_s^h]$ , and  $\mathcal{B}_s^h$  the event of having  $p_{T_s^h} > 2\alpha$ . Suppose that  $p_s^h > \alpha$ , otherwise  $\mathcal{B}_s^h$  cannot occur. Let  $X_v$  an indicator random variable that is 1 iff  $s$  has stage-II cost larger than  $T_s^h$  in the  $v$ -th sample. Also, let  $X = \sum_{v=1}^N X_v$ , and recall that  $X = \lceil \alpha N \rceil - 1 \leq \alpha N$ . Moreover, we have  $\mathbb{E}[X] = p_s^h N$  and notice that  $2X > \mathbb{E}[X]$  implies  $p_s^h < 2\alpha$ . Using Lemma 21 with  $\delta = 1/2$  we get  $\Pr[X \leq \mathbb{E}[X]/2] \leq e^{-p_s^h N/8}$ . Because  $p_s^h > \alpha$ , setting  $N = \frac{8}{\alpha} \log\left(\frac{t_{\mathcal{P}}(n,m)}{\gamma} (\log_{\frac{13}{12}}(\frac{1}{\gamma}) + 1)\right)$  gives  $\sum_h \sum_{s \in \mathcal{S}} \Pr[\mathcal{B}_s^h] \leq \gamma$ . ◀

Finally, by optimizing over the radius, we get our main generalization result:

► **Theorem 13.** Assume we have an efficiently generalizable  $\eta$ -approximation for  $\mathcal{P}$ -Poly. Then, using  $\mathcal{O}\left(\frac{1}{\epsilon \alpha} \log\left(\frac{nm \cdot t_{\mathcal{P}}(n,m)}{\gamma}\right) \log \frac{nm}{\gamma}\right)$  samples, we obtain a strategy  $\hat{s}$  and a radius  $R$ , such that with probability at least  $1 - \mathcal{O}(\gamma)$  the following hold: (i)  $C(\hat{s}) \leq (1 + 2\epsilon)B$ , (ii)  $F_I^{\hat{s}} \in \mathcal{M}_I$ ; (iii)  $R \leq R^*$ , where  $R^*$  is the optimal radius for  $\mathcal{P}$ -BB; (iv)  $\Pr_{A \sim \mathcal{D}}[d(j, F_I^{\hat{s}} \cup F_A^{\hat{s}}) \leq \eta R, \forall j \in A] \geq 1 - 2\alpha$ .

**Proof.** Because  $R^*$  is the distance between some facility and some client, there are at most  $nm$  alternatives for it. Thus, we can run Algorithm 2 for all possible  $nm$  target radius values, using error parameter  $\gamma' = \frac{\gamma}{nm}$ . We then return the smallest radius that did not yield “INFEASIBLE”. By a union bound over all radius choices, the probability of the *Invalid* event in any of them is at most  $3\gamma$ . Thus, with probability at least  $1 - 3\gamma$ , the chosen radius  $R$  satisfies  $R \leq R^*$ , and the opening cost of the corresponding strategy is at most  $(1 + 2\epsilon)B$ . Finally, for the returned strategy Theorem 12 holds as well, and the sample bound accounts for all iteration of Algorithm 2.

Additionally, note that we do not need fresh samples for each radius guess  $R$ ; we can draw an appropriate number of samples  $N$  upfront, and test all guesses in “parallel” with the same data. ◀

In light of Theorem 13 and the generic search step for the radius  $R$ , we assume for all our  $\mathcal{P}$ -poly problems that a target radius  $R$  is given explicitly.

We conclude with some final remarks. At first, III guarantees  $N = \text{poly}(n, m, \frac{1}{\epsilon}, \frac{1}{\alpha}, \log \frac{1}{\gamma})$ . Also, the probability  $2\alpha$  of not returning an  $\eta$ -approximate solution can be made inverse polynomially small, without affecting the polynomial nature of the sample complexity.

### 3 Approximation Algorithm for 2S-Sup-BB

In this section we tackle **2S-Sup-BB**, by first designing a 3-approximation algorithm for **2S-Sup-Poly**, and then proving that the latter is efficiently generalizable.

**Algorithm 3** Correlated LP-Rounding Algorithm for **2S-Sup-Poly**.

---

Solve LP (4)-(6) to get a feasible solution  $y^I, y^A : A \in Q$ ;  
**if** no feasible LP solution exists **then**  
     | Return “INFEASIBLE”;  
**end**  
 $(H_I, \pi^I) \leftarrow \text{GreedyCluster}(\mathcal{C}, R, g^I)$ , where  $g^I(j) = y^I(G_j)$  ;  
**for** each scenario  $A \in Q$  **do**  
     |  $(H_A, \pi^A) \leftarrow \text{GreedyCluster}(A, R, g^A)$ , where  $g^A(j) = -y^I(G_{\pi^I(j)})$  ;  
**end**  
 Order the clients of  $H_I$  as  $j_1, j_2, \dots, j_h$  such that  $y^I(G_{j_1}) \leq y^I(G_{j_2}) \leq \dots \leq y^I(G_{j_h})$ ;  
 Consider an additional “dummy” client  $j_{h+1}$  with  $y^I(G_{j_{h+1}}) > y^I(G_{j_\ell})$  for all  $\ell \in [h]$ ;  
**for** all integers  $\ell = 1, 2, \dots, h+1$  **do**  
     |  $F_I^\ell \leftarrow \{i_{j_k}^I \mid j_k \in H_I \text{ and } y^I(G_{j_k}) \geq y^I(G_{j_\ell})\}$ ;  
     **for** each  $A \in Q$  **do**  
         |  $F_A^\ell \leftarrow \{i_j^A \mid j \in H_A \text{ and } F_I^\ell \cap G_{\pi^I(j)} = \emptyset\}$ ;  
     **end**  
     |  $S_\ell \leftarrow c^I(F_I^\ell) + \sum_{A \in Q} p_A \cdot c^A(F_A^\ell)$ ;  
**end**  
 Return  $F_I^{\ell^*}, F_A^{\ell^*} : A \in Q$  such that  $\ell^* = \arg \min_\ell S_\ell$ ;  

---

**3.1 A 3-Approximation Algorithm for 2S-Sup-Poly**

We are given a list of scenarios  $Q$  together with their probabilities  $p_A$  and cost vectors  $c^A$ , a target radius  $R$ , and let  $G_j = G_{j,R}$ ,  $i_j^I = i_{j,R}^I$ ,  $i_j^A = i_{j,R}^A$  for every  $j \in \mathcal{C}$  and  $A \in Q$ . Consider LP (4)-(6).

$$\sum_{i \in \mathcal{F}} y_i^I \cdot c_i^I + \sum_{A \in Q} p_A \sum_{i \in \mathcal{F}} y_i^A \cdot c_i^A \leq B \quad (4)$$

$$\sum_{i \in G_j} (y_i^I + y_i^A) \geq 1, \quad \forall j \in A \in Q \quad (5)$$

$$0 \leq y_i^I, y_i^A \leq 1 \quad (6)$$

Constraint (4) captures the total expected cost, and constraint (5) the fact that for all  $A \in Q$ , every  $j \in A$  must have an open facility within distance  $R$  from it. In addition, note that if the LP is infeasible, then there cannot be a solution of radius at most  $R$  for the given **2S-Sup-Poly** instance. The rounding algorithm appears in Algorithm 3.

**► Theorem 14.** For any scenario  $A \in Q$  and every  $j \in A$ , we have  $d(j, F_I^{\ell^*} \cup F_A^{\ell^*}) \leq 3R$ .

**Proof.** Focus on some  $A \in Q$ . Recall that  $d(j, \pi^I(j)) \leq 2R$  and  $d(j, \pi^A(j)) \leq 2R$  for any  $j \in A$ . For  $j \in H_A$  the statement is clearly true, because either  $G_{\pi^I(j)} \cap F_I^{\ell^*} \neq \emptyset$  or  $G_j \cap F_A^{\ell^*} \neq \emptyset$ . So consider some  $j \in A \setminus H_A$ . If  $G_{\pi^A(j)} \cap F_A^{\ell^*} \neq \emptyset$ , then any facility  $i \in G_{\pi^A(j)} \cap F_A^{\ell^*}$  will be within distance  $3R$  from  $j$ . If on the other hand  $G_{\pi^A(j)} \cap F_A^{\ell^*} = \emptyset$ , then our algorithm guarantees  $G_{\pi^I(\pi^A(j))} \cap F_I^{\ell^*} \neq \emptyset$ . Further, the stage-II greedy clustering yields  $g^A(\pi^A(j)) \geq g^A(j) \implies y^I(G_{\pi^I(j)}) \geq y^I(G_{\pi^I(\pi^A(j))})$ . Therefore, from the way we formed  $F_I^{\ell^*}$  and the fact that  $G_{\pi^I(\pi^A(j))} \cap F_I^{\ell^*} \neq \emptyset$ , we infer that  $G_{\pi^I(j)} \cap F_I^{\ell^*} \neq \emptyset$ . The latter ensures that  $d(j, G_{\pi^I(j)} \cap F_I^{\ell^*}) \leq 3R$ . ◀

**► Theorem 15.** The opening cost  $S_{\ell^*}$  of Algorithm 3 is at most  $B$ .

■ **Algorithm 4** Generalization Procedure for **2S-Sup-Poly**.

---

**Input :** Returned sets  $F_I, F_A : A \in Q$  and inner execution details of Algorithm 3  
 Let  $\bar{s}$  the strategy we will define, and for the stage-I actions set  $F_I^{\bar{s}} \leftarrow F_I$ ;  
 Suppose scenario  $A \in \mathcal{D}$  arrived in the second stage;  
 For every  $j \in A$  set  $g(j) \leftarrow -y^I(G_{\pi^I(j)})$ , where  $y^I, \pi^I$  are the LP solution vector and stage-I mapping computed in Algorithm 3;  
 $(H_A, \pi^A) \leftarrow \text{GreedyCluster}(A, R, g)$ ;  
 $F_A^{\bar{s}} \leftarrow \{i_j^A \mid j \in H_A \text{ and } F_I \cap G_{\pi^I(j)} = \emptyset\}$ ;

---

**Proof.** Consider the following process to generate a random solution: we draw a random variable  $\beta$  uniformly from  $[0, 1]$ , and then set  $F_I^\beta = \{i_j^I \mid j \in H_I \text{ and } y^I(G_j) \geq \beta\}$ ,  $F_A^\beta = \{i_j^A \mid j \in H_A \text{ and } F_I \cap G_{\pi^I(j)} = \emptyset\}$  for all  $A \in Q$ . For each possible draw for  $\beta$ , the resulting sets  $F_I^\beta, F_A^\beta$  correspond to sets  $F_I^\ell, F_A^\ell$  for some integer  $\ell \in [h+1]$ . Hence, in order to show the existence of an  $\ell$  with  $S_\ell \leq B$ , it suffices to show  $\mathbb{E}_{\beta \sim [0,1]}[c^I(F_I^\beta) + \sum_{A \in Q} p_A \cdot c^A(F_A^\beta)] \leq B$ .

We start by calculating the probability of opening a given facility  $i_j^I$  with  $j \in H_I$  in stage-I. This will occur only if  $\beta \leq y^I(G_j)$ , and so  $\Pr[i_j^I \text{ is opened at stage-I}] \leq \min(y^I(G_j), 1)$ . Therefore, due to  $G_j \cap G_{j'} = \emptyset$  for all distinct  $j, j' \in H_I$ , we get:

$$\mathbb{E}_{\beta \sim [0,1]}[c^I(F_I^\beta)] \leq \sum_{j \in H_I} c_{i_j^I}^I \cdot y^I(G_j) \leq \sum_{i \in \mathcal{F}} y_i^I \cdot c_i^I \quad (7)$$

Moreover, for any  $j \in H_A$  and any  $A \in Q$  we have  $\Pr[i_j^A \text{ is opened at stage-II} \mid A] = 1 - \min(y^I(G_{\pi^I(j)}), 1) \leq 1 - \min(y^I(G_j), 1) \leq y^A(G_j)$ . The first inequality results from the greedy clustering of stage-I that gives  $y^I(G_{\pi^I(j)}) \geq y^I(G_j)$ , and the second follows from (5). Thus, due to  $G_j \cap G_{j'} = \emptyset$  for all distinct  $j, j' \in H_A$ , we get:

$$\mathbb{E}_{\beta \sim [0,1]}[c^A(F_A^\beta)] \leq \sum_{j \in H_A} c_{i_j^A}^A \cdot y^A(G_j) \leq \sum_{i \in \mathcal{F}} y_i^A \cdot c_i^A \quad (8)$$

Combining (7), (8) and (4) gives  $\mathbb{E}_{\beta \sim [0,1]}[c^I(F_I^\beta)] + \sum_{A \in Q} p_A \cdot \mathbb{E}_{\beta \sim [0,1]}[c^A(F_A^\beta)] \leq B$ . ◀

### 3.2 Generalizing to the Black-Box Setting

To show that Algorithm 3 fits the framework of Section 2, we must show that it is efficiently generalizable as in Definition 8. For one thing, it is obvious that Algorithm 3 satisfies the properties of Definition 7, and therefore is a valid 3-approximation. Hence, we only need a process to efficiently extend its output to any arriving scenario  $A \in \mathcal{D}$ , where  $\mathcal{D}$  the black-box distribution. This is demonstrated in Algorithm 4, which mimics the stage-II actions of Algorithm 3. Here we crucially exploit the fact that the stage-II decisions of Algorithm 3 only depend on information from the LP about stage-I variables.

Since Algorithm 4 exactly imitates the stage-II actions of Algorithm 3, it is easy to see that property II is satisfied. Further, the arguments in Theorem 14 would still apply, and eventually guarantee  $d(j, F_I^{\bar{s}} \cup F_A^{\bar{s}}) \leq 3R$  for all  $j \in A$  and any  $A \in \mathcal{D}$ , thus verifying property I. To conclude, we only need to prove III. Let  $\mathcal{S}_K$  the set of strategies achievable via Algorithm 4.

► **Lemma 16.** *Algorithm 3 satisfies property III with  $|\mathcal{S}_K| \leq (n+1)!$ .*

■ **Algorithm 5** Rounding Algorithm for **2S-MatSup-Poly**.

---

Solve LP (9)-(12) to get a feasible solution  $y^I, y^A$  for all  $A \in Q$ ;  
**if** no feasible LP solution exists **then**  
 | Return “INFEASIBLE”;  
**end**  
 $(H_I, \pi^I) \leftarrow \text{GreedyCluster}(\mathcal{C}, R, g^I)$  where  $g^I(j) = y^I(G_j)$  ;  
 Let  $g^{II} : \mathcal{C} \mapsto [n]$  be some fixed and given bijective mapping;  
**for** each scenario  $A \in Q$  **do**  
 |  $(H_A, \pi^A) \leftarrow \text{GreedyCluster}(A, R, g^{II})$  ;  
**end**  
 Solve LP (13)-(16) and get an optimal integral solution  $z^*$ , such that  
 $z_i^* \in \{0, 1\} \forall i \in \mathcal{F}$ ;  
 $F_I \leftarrow \{i \in \mathcal{F} \mid z_i^* = 1\}$ ;  
 $F_A \leftarrow \{i_j^A \in \mathcal{F} \mid j \in H_A \text{ and } G_{\pi^I(j)} \cap F_I = \emptyset\}$  for every  $A \in Q$ .

---

**Proof.** The constructed final strategy is determined by 1) the sorted order of  $y^I(G_j)$  for all  $j \in \mathcal{C}$ , and 2) a minimum threshold  $\ell'$  such that  $G_{j_{\ell'}} \cap F_I \neq \emptyset$  with  $j_{\ell'} \in H_I$ . Given those, we know exactly what  $H_I$  and  $H_A$  for every  $A \in \mathcal{D}$  will be, as well as  $F_I$  and  $F_A$  for every  $A \in \mathcal{D}$ . The set of all possible such options is also independent  $Q$ . Since there are  $n!$  total possible orderings for the  $y^I(G_j)$  values, and the threshold parameter  $\ell'$  can take at most  $n + 1$  values, we get  $|\mathcal{S}_K| \leq (n + 1)!$ . ◀

■ **4 Approximation Algorithm for 2S-MatSup-BB**

The outline of this section is similar to that of Section 3. We begin with a 5-approximation algorithm for **2S-MatSup-Poly**, and then show that it is also efficiently generalizable.

**4.1 A 5-Approximation Algorithm for 2S-MatSup-Poly**

We are given a radius  $R$ , and a list of scenarios  $Q$  together with their probabilities  $p_A$  and cost vectors  $c^A$ . Moreover, assume that  $r_{\mathcal{M}}$  is the rank function of the input matroid  $\mathcal{M} = (\mathcal{F}, \mathcal{I})$ . We also use the notation  $G_j = G_{j,R}$ , and  $i_j^A = i_{j,R}^A$  for every  $j \in \mathcal{C}$  and  $A \in Q$ . Consider LP (9)-(12).

$$\sum_{i \in \mathcal{F}} y_i^I \cdot c_i^I + \sum_{A \in Q} p_A \sum_{i \in \mathcal{F}} y_i^A \cdot c_i^A \leq B \quad (9)$$

$$\sum_{i \in G_j} (y_i^I + y_i^A) \geq 1, \quad \forall j \in A \in Q \quad (10)$$

$$\sum_{i \in U} y_i^I \leq r_{\mathcal{M}}(U), \quad \forall U \subseteq \mathcal{F} \quad (11)$$

$$0 \leq y_i^I, y_i^A \leq 1 \quad (12)$$

Compared to LP (4)-(6), the only difference lies in constraint (11), which exactly represents the stage-I matroid requirement. Hence, it is a valid relaxation for the problem. Although the LP has an exponential number of constraints, it can be solved in polynomial time via the Ellipsoid algorithm, with a separation oracle based on minimizing a submodular function [13].

Assuming LP feasibility, our algorithm (presented in full detail in Algorithm 5), begins with two greedy clustering steps, one for each stage, that produce sets  $H_I, H_A : A \in Q$  with

corresponding mappings  $\pi^I$  and  $\pi^A$ . We then set up and solve the auxiliary LP shown in (13)-(16), and use this solution to determine sets  $F_I$  and  $F_A$ .

$$\text{minimize } \sum_{i \in \mathcal{F}} z_i \cdot c_i^I + \sum_{A \in Q} p_A \sum_{j \in H_A} c_{i_j^A}^A (1 - z(G_{\pi^I(j)})) \quad (13)$$

$$\text{subject to } z(G_j) \leq 1, \forall j \in H_I \quad (14)$$

$$z(U) \leq r_{\mathcal{M}}(U), \forall U \subseteq \mathcal{F} \quad (15)$$

$$0 \leq z_i \leq 1 \quad (16)$$

► **Lemma 17.** *If LP (9)-(12) is feasible, then the optimal solution  $z^*$  of the auxiliary LP (13)-(16) has objective function value at most  $B$ , and is integral (i.e. for all  $i \in \mathcal{F}$  we have  $z_i^* \in \{0, 1\}$ ).*

**Proof.** Solution  $z^*$  is integral since the LP (13)-(16) is the intersection of two matroid polytopes, namely, the polytope corresponding to  $\mathcal{M}$ , and a partition matroid polytope over all  $G_j$  with  $j \in H_I$ . (Recall that sets  $G_j$  for  $j \in H_I$  are pairwise disjoint.)

Now let  $y^I, y^A$  be a feasible solution of (9)-(12). For all  $j \in H_I$  with  $y^I(G_j) \leq 1$ , set  $z_i = y_i^I$  for all  $i \in G_j$ . For all  $j \in H_I$  with  $y^I(G_j) > 1$ , set  $z_i = y_i^I / y^I(G_j)$  for all  $i \in G_j$ . For the rest of the facilities set  $z_i = 0$ . This solution obviously satisfies (14). Also, because  $y^I$  satisfies (11) and  $z_i \leq y_i^I$  for all  $i$ , we know that  $z$  satisfies (15) too. Finally, regarding the objective function:

$$\sum_{i \in \mathcal{F}} z_i \cdot c_i^I \leq \sum_{i \in \mathcal{F}} y_i \cdot c_i^I \quad (17)$$

For the second-stage cost we then get:

$$\begin{aligned} \sum_{A \in Q} p_A \sum_{j \in H_A} c_{i_j^A}^A (1 - z(G_{\pi^I(j)})) &\leq \sum_{A \in Q} p_A \sum_{\substack{j \in H_A: \\ y^I(G_{\pi^I(j)}) \leq 1}} c_{i_j^A}^A (1 - y^I(G_{\pi^I(j)})) \\ &\leq \sum_{A \in Q} p_A \sum_{\substack{j \in H_A: \\ y^I(G_{\pi^I(j)}) \leq 1}} c_{i_j^A}^A (1 - y^I(G_j)) \\ &\leq \sum_{A \in Q} p_A \sum_{\substack{j \in H_A: \\ y^I(G_{\pi^I(j)}) \leq 1}} c_{i_j^A}^A y^A(G_j) \leq \sum_{A \in Q} p_A \sum_{i \in \mathcal{F}} y_i^A c_i^A \quad (18) \end{aligned}$$

The second line follows from the stage-I greedy clustering, which ensures  $y^I(G_{\pi^I(j)}) \geq y^I(G_j)$  for all  $j \in \mathcal{C}$ . The last line is due to (10), and the fact that for all  $A \in Q$  and all distinct  $j, j' \in H_A$  we have  $G_j \cap G_{j'} = \emptyset$ . Finally, combining (9), (17) and (18) we get the desired bound on the cost. ◀

► **Theorem 18.** *For the sets  $F_I, F_A : A \in Q$  returned by Algorithm 5 the following three properties hold: (i)  $F_I \in \mathcal{I}$ , (ii)  $c^I(F_I) + \sum_{A \in Q} p_A c^A(F_A) \leq B$ , and (iii)  $d(j, F_I \cup F_A) \leq 5R$  for all  $j \in A \in Q$ .*

**Proof.** (i) is obvious, since  $z^*$  satisfies constraint (15). For (ii), the opening cost of the solution coincides with the value of the objective (13) for  $z^*$ , and hence by Lemma 17 it is at most  $B$ .

For (iii), consider  $A \in Q$ , and recall that  $d(j, \pi^I(j)) \leq 2R$  and  $d(j, \pi^A(j)) \leq 2R$  for any  $j \in A$ . For  $j \in H_A$  the bound (iii) holds, because either  $G_{\pi^I(j)} \cap F_I \neq \emptyset$  or  $G_j \cap F_A \neq \emptyset$ . So suppose that  $j \in A \setminus H_A$ . If  $G_{\pi^A(j)} \cap F_A \neq \emptyset$ , then any facility  $i \in G_{\pi^A(j)} \cap F_A$  will be within distance  $3R$  from  $j$ . If on the other hand  $G_{\pi^A(j)} \cap F_A = \emptyset$ , then there exists  $i \in G_{\pi^I(\pi^A(j))} \cap F_I$ . Therefore,  $d(i, j) \leq d(i, \pi^I(\pi^A(j))) + d(\pi^I(\pi^A(j)), \pi^A(j)) + d(\pi^A(j), j) \leq 5R$ . ◀

**Algorithm 6** Generalization Procedure for 2S-MatSup-Poly.
 

---

**Input:** Returned sets  $F_I, F_A : A \in Q$  and inner execution details of Algorithm 5  
 Let  $\bar{s}$  the strategy we will define, and for the stage-I actions set  $F_I^{\bar{s}} \leftarrow F_I$ ;  
 Suppose scenario  $A \in \mathcal{D}$  arrived in the second stage;  
 Let  $\pi^I$  the stage-I mapping and  $g^{II}$  the bijective function, both used in Algorithm 5;  
 Set  $(H_A, \pi^A) \leftarrow \text{GreedyCluster}(A, R, g^{II})$ ;  
 Open the set  $F_A^{\bar{s}} = \{i_j^A \mid j \in H_A \text{ and } F_I \cap G_{\pi^I(j)} = \emptyset\}$ ;

---

## 4.2 Generalizing to the Black-Box Setting

It is clear that Algorithm 5 satisfies Definition 7, and therefore is a valid 5-approximation. Consider now Algorithm 6 to efficiently extend its output to any arriving scenario  $A \in \mathcal{D}$ . Since Algorithm 6 exactly imitates the stage-II actions of Algorithm 5, it is easy to see that property II is satisfied. Furthermore, the arguments in Theorem 18 would still go through, and eventually guarantee  $d(j, F_I^{\bar{s}} \cup F_A^{\bar{s}}) \leq 5R$  for all  $j \in A$  and any  $A \in \mathcal{D}$ , thus verifying property I. To conclude, we only need to prove III. Let  $\mathcal{S}_M$  the set of strategies achievable via Algorithm 6.

► **Lemma 19.** *Algorithm 5 satisfies property III with  $|\mathcal{S}_M| = 2^m \cdot n!$ .*

**Proof.** Since  $g^{II}$  can be thought of as part of the input,  $\bar{s}$  depends only on 1) the set  $F_I$  returned by Algorithm 5, and 2) the sorted order of  $y^I(G_j)$  for all  $j \in \mathcal{C}$ , which ultimately dictates the mapping  $\pi^I$ . Given those, we can determine the stage-II openings for every possible scenario  $A \in \mathcal{D}$ . These options do not depend on scenarios  $Q$ . The total number of possible outcomes for  $F_I$  is  $2^m$ , and the total number of orderings for the clients of  $\mathcal{C}$  is  $n!$ . Hence,  $|\mathcal{S}_M| = 2^m \cdot n!$ . ◀

## **A** Applying the Standard SAA Method in Supplier Problems

Consider the standard two-stage stochastic setting. In the first stage, we are allowed to take some proactive actions and commit to an anticipatory part of the solution  $x$ , which will incur some cost  $c(x)$ . In the second stage, a scenario  $A$  is sampled from the distribution  $\mathcal{D}$ , and we can take some *stage-II* recourse actions  $y_A$  with cost  $f_A(x, y_A)$ . If  $X$  is the set of stage-I actions and  $Y$  the set of recourse actions, the goal is to find a solution  $x^* \in X$  to minimize  $f(x) = c(x) + \mathbb{E}_{A \sim \mathcal{D}}[q_A(x)]$ , where  $q_A(x) = \min_{y \in Y} \{f_A(x, y) \mid (x, y) \text{ is a valid solution for } A\}$ .

**The Standard SAA Method.** Consider minimizing  $f(x)$  in the black-box model. If  $S$  is a set of scenarios sampled from the black-box oracle, let  $\hat{f}(x) = c(x) + (\sum_{A \in S} q_A(x))/|S|$  be the empirical estimate of  $f(x)$ . Also, let  $x^*$  and  $\bar{x}$  be the minimizers of  $f(x)$  and  $\hat{f}(x)$  respectively.

The work [21] shows that if  $f(x)$  is modeled as a convex program, then for any  $\epsilon, \gamma \in (0, 1)$  and with  $|S| = \text{poly}(n, m, \lambda, \epsilon, 1/\gamma)$ , we have  $f(\bar{x}) \leq (1 + \epsilon)f(x^*)$  with probability at least  $1 - \gamma$  ( $\lambda$  is the maximum multiplicative factor by which an element's cost is increased in

stage-II). An alternate proof of this appeared in [4], which also covered the case of  $f(x)$  being an integer program. Moreover, [4] proves that if  $\bar{x}$  is an  $\alpha$ -approximate minimizer of  $\hat{f}(x)$ , then a slight modification to the sampling still gives  $f(\bar{x}) \leq (\alpha + \epsilon)f(x^*)$  with probability at least  $1 - \gamma$ .

The result of [4] further implies that the black-box model can be effectively reduced to the polynomial-scenarios one, via the following process. Assuming that  $f(x)$  corresponds to the integer program modeling our problem, first find an  $\alpha$ -approximate minimizer  $\bar{x}$  of  $\hat{f}(x)$ , and treat  $\bar{x}$  as the stage-I actions. Then, given any arriving  $A$ , re-solve the problem using any known  $\rho$ -approximation algorithm for the non-stochastic counterpart, with  $\bar{x}$  as a fixed part of the solution. This process eventually leads to an overall approximation ratio of  $\alpha\rho + \epsilon$ .

**Roadblocks for the Standard SAA Analysis in Supplier Problems.** A natural way to fit our models within the existing framework, is to first assume knowledge of the optimal radius  $R^*$  and then use the opening cost as the objective function  $f_{R^*}(x)$ , by turning the radius requirement into a simple covering constraint. In other words, we set  $f_{R^*}(x) = c^I(x) + \mathbb{E}_{A \sim \mathcal{D}}[q_{A,R^*}(x)]$  with  $q_{A,R^*}(x) = \min_y \{c^A(y) \mid (x, y) \text{ covers all } j \in A \text{ within distance } R^*\}$ . Note that  $f_{R^*}(x)$  may represent both the convex and the integer program corresponding to the underlying problem.

To avoid any overhead in the approximation ratio (from re-solving the problem in stage-II), one should apply SAA to the function  $f_{R^*}(x)$  corresponding to the convex program describing the problem (the roadblock described here trivially extends to the case of  $f_{R^*}(x)$  being an integer function as well). If there exists a rounding that turns the empirical minimizer  $\bar{x}_{R^*}$  into a solution that covers each client within distance  $\alpha R^*$ , while also having an opening cost of at most  $f_{R^*}(\bar{x}_{R^*})$ , we get the desired result because  $f_{R^*}(\bar{x}_{R^*}) \leq (1 + \epsilon)f_{R^*}(x_{R^*}^*)$  and  $f_{R^*}(x_{R^*}^*) \leq B$ . With slight modifications, all our polynomial-scenarios algorithms can be interpreted as such rounding procedures.

Nonetheless, we still have to identify a good guess for  $R^*$ , **and this constitutes an unavoidable roadblock in applying standard SAA** in supplier problems. Since  $R^*$  is one of  $nm$  alternative options, one can test each of those individually. Hence, assume we work with some guess  $R$ , and define the corresponding cost functions  $f_R, \hat{f}_R$  with minimizers  $x_R^*, \bar{x}_R$  respectively. Observe that  $R$  is a good guess iff  $f_R(x_R^*) \leq (1 + \mathcal{O}(\epsilon))B$ , since in this way vanilla SAA combined with our rounding procedures yields an opening cost of  $f_R(\bar{x}_R) \leq (1 + \epsilon)f_R(x_R^*)$ , and minimizing over the radius is just a matter of finding the minimum good guess. However, because  $f_R(x)$  is not efficiently computable, the only way to test if  $R$  is a good guess, is through  $\hat{f}_R(x)$ . Unfortunately, empirically estimating  $f_R(x)$  within an  $(1 + \epsilon)$  factor may require a super-polynomial number of samples [12]. The reason for this is the existence of scenarios with high stage-II cost appearing with small probability, which drastically increase the variance of  $\hat{f}_R(x)$ . **On a high level, the obstacle in supplier problems stems from the need to not only find a minimizer  $\bar{x}_R$ , but also compute its corresponding value  $f_R(\bar{x}_R)$ .** This makes it impossible to know which guesses  $R$  are good, and consequently there is no way to optimize over the radius.

Finally, note that if the stage-II cost of every scenario is polynomially bounded, the variance of  $\hat{f}_R(x)$  is also polynomial, and standard SAA arguments go through without difficulties. However, this assumption is much stronger than is typically used for the two-stage stochastic model.

## B Auxiliary Lemmas

► **Lemma 20** ([6]). *Let  $X_1, \dots, X_K$  be non-negative independent random variables, with expectations  $\mu_1, \dots, \mu_K$  respectively, where  $\mu_k \leq 1$  for every  $k$ . Let  $X = \sum_{k=1}^K X_k$ , and let  $\mu = \sum_{k=1}^K \mu_k = \mathbb{E}[X]$ . Then for every  $\delta > 0$  we have  $\Pr[X < \mu + \delta] \geq \min\{\frac{\delta}{1+\delta}, \frac{1}{13}\}$ .*

The two following lemmas are standard Chernoff bounds.

► **Lemma 21.** *Let  $X_1, X_2, \dots, X_K$  be independent random variables with  $X_k \in [0, 1]$  for every  $k$ . For  $X = \sum_{k=1}^K X_k$  with  $\mu = \mathbb{E}[X]$  and any  $\delta > 0$ , we have  $\Pr[X \leq (1 - \delta)\mu] \leq e^{-\frac{\mu\delta^2}{2}}$ .*

► **Lemma 22.** *Let  $X_1, X_2, \dots, X_K$  be independent Bernoulli random variables with parameter  $p$ . Let  $X = \sum_{k=1}^K X_k$  the corresponding binomial random variable. If for the realization of  $X$  we have  $X = qK$ , then for any  $\delta > 0$  we have  $\Pr[p < q - \delta] \leq e^{-K\delta^2/2p}$ .*

## C Approximation Algorithm for 2S-MuSup-BB

To tackle this, we construct an efficiently generalizable algorithm for **2S-MuSup-Poly**, via an intriguing reduction to a non-stochastic clustering problem with outliers. Specifically, if we view stage-I as consisting of a deterministic robust problem, stage-II is interpreted as covering all outliers left over by stage-I. Formally, we use the following robust problem:

**Robust Weighted Multi-Knapsack-Supplier.** We are given a set of clients  $\mathcal{C}$  and a set of facilities  $\mathcal{F}$ , in a metric space with distance function  $d$ . The input also includes parameters  $V, R \in \mathbb{R}_{\geq 0}$ , and for every client  $j \in \mathcal{C}$  an associated weight  $v_j \in \mathbb{R}_{\geq 0}$ . In addition, we have the same types of multi-knapsack constraints as in **2S-MuSup**: there are  $L$  in total budgets  $W_\ell$ , and every facility  $i \in \mathcal{F}$  has costs  $f_i^\ell$  for  $\ell \in [L]$ . The goal is to choose a set of facilities  $S \subseteq \mathcal{F}$ , such that  $\sum_{j \in \mathcal{C}: d(j,S) > R} v_j \leq V$  and  $f^\ell(S) \leq W_\ell$  for every  $\ell \in [L]$ . Clients  $j$  with  $d(j, S) > R$  are called outliers. Finally, an instance of this problem is called *discrete*, if the values  $f_i^\ell$  are all integers.

We first show that any  $\rho$ -approximation for **Robust Weighted Multi-Knapsack-Supplier** can be used in order to get an efficiently generalizable  $(\rho + 2)$ -approximation algorithm for **2S-MuSup-Poly**. In addition, we argue that already existing work [3, 15] gives a 3-approximation for discrete instances of **Robust Weighted Multi-Knapsack-Supplier**, thus leading to an efficiently generalizable 5-approximation for discrete instances of **2S-MuSup-Poly**.

### C.1 Reducing 2S-MuSup-Poly to Robust Weighted Multi-Knapsack-Supplier

We first suppose that the costs  $c_i^j$  are polynomially bounded integers, and claim that this restriction will be removed when we generalize to the black-box setting. Once more, let  $Q$  be a set of provided scenarios,  $R$  a target radius, and  $G_j = G_{j,R}$ ,  $i_j^A = i_{j,R}^A$  for all  $j \in \mathcal{C}$  and  $A \in Q$ . Furthermore, suppose that we have a  $\rho$ -approximation algorithm  $RW$  for **Robust Weighted Multi-Knapsack-Supplier**. For a feasible instance  $\mathcal{J}'$  of the latter problem,  $RW$  returns a solution  $S$  satisfying all knapsack constraints and also  $\sum_{j \in \mathcal{C}: d(j,S) > \rho R} v_j \leq V$ . Otherwise, it either returns “INFEASIBLE”, or again a solution with the previous properties.

If the provided instance  $\mathcal{J}$  of **2S-MuSup-Poly** is feasible, the first step in tackling the problem is figuring out the portion of the budget, say  $B_I$ , that is used in the first stage of a

**Algorithm 7** Approximation Algorithm for **2S-MuSup-Poly**.

---

```

Let  $g^{II} : \mathcal{C} \mapsto [n]$  be some fixed and given bijective mapping;
for each scenario  $A \in Q$  do
    |  $(H_A, \pi^A) \leftarrow \text{GreedyCluster}(A, R, g^{II});$ 
end
Construct instance  $\mathcal{J}'$  of Robust Weighted Multi-Knapsack-Supplier as
discussed;
if  $RW(\mathcal{J}') = \text{"INFEASIBLE"}$  then
    | Return "INFEASIBLE";
end
 $F_I \leftarrow RW(\mathcal{J}')$ ; // Stage-I facilities
for each scenario  $A \in Q$  do
    |  $F_A \leftarrow \{i_j^A \mid j \in H_A \text{ with } d(j, F_I) > \rho R\}$ ; // Stage-II facilities
end
    
```

---

feasible solution. Since the costs  $c_i^I$  are polynomially bounded integers, we can guess  $B_I$  in polynomial time through solving the problem for all different alternatives for it. So from this point on, assume w.l.o.g. that we have the correct  $B_I$ , and also let  $B_{II} = B - B_I$ .

Algorithm 7 shows how to use  $RW$  to approximate **2S-MuSup-Poly**. It begins with greedy clustering steps for each  $A$ , and given  $H_A, \pi^A$  it constructs an instance  $\mathcal{J}'$  of **Robust Weighted Multi-Knapsack-Supplier** as follows.  $\mathcal{C}, \mathcal{F}, d$ , and  $R$  are the same for both problems. For all  $j \in \mathcal{C}$  we set  $v_j = \sum_{A \in Q: j \in H_A} p_A \cdot c_{i_j^A}^A$  and also  $V = B_{II}$ . Finally, the instance  $\mathcal{J}'$  has  $L' = L + 1$  knapsack constraints, where the first  $L$  are the stage-I constraints of **2S-MuSup-Poly** ( $f^\ell(S) \leq W_\ell$ ), and the last is  $c^I(S) \leq B_I$ .

► **Lemma 23.** *If the original **2S-MuSup-Poly** instance  $\mathcal{J}$  is feasible, then the **Robust Weighted Multi-Knapsack-Supplier** instance  $\mathcal{J}'$  is also feasible.*

**Proof.** Consider some feasible solution  $F_I^*, F_A^*$  for **2S-MuSup-Poly**. We claim that  $F_I^*$  is a valid solution for  $\mathcal{J}'$ . It clearly satisfies the  $L$  knapsack constraints of the form  $f^\ell(F_I^*) \leq W_\ell$ , and if our guess  $B_I$  is the right one, it also satisfies  $c^I(F_I^*) \leq B_I$ . Now, for any  $A \in Q$ , any client  $j \in H_A$  with  $d(j, F_I^*) > R$  must be covered by some facility  $x_j^A \in G_j \cap F_A^*$ . Since  $B_{II}$  is the second-stage portion of the budget used by  $F_I^*, F_A^*$ , and  $G_{j'} \cap G_{j''} = \emptyset$  for all distinct  $j', j'' \in H_A$  we have:

$$B_{II} \geq \sum_A p_A \sum_{i \in F_A^*} c_i^A \geq \sum_A p_A \sum_{\substack{j \in H_A: \\ d(j, F_I^*) > R}} c_{x_j^A}^A \geq \sum_A p_A \sum_{\substack{j \in H_A: \\ d(j, F_I^*) > R}} c_{i_j^A}^A = \sum_{\substack{j \in \mathcal{C}: \\ d(j, F_I^*) > R}} v_j$$

This implies that  $S = F_I^*$  satisfies the constraint  $\sum_{j: d(j, S) > R} v_j \leq B_{II}$  of instance  $\mathcal{J}'$ . ◀

► **Theorem 24.** *Algorithm 7 is a valid  $(\rho + 2)$ -approximation for **2S-MuSup-Poly**.*

**Proof.** First of all, Lemma 23 guarantees that if the given instance of **2S-MuSup-Poly** is feasible, we will get a solution  $F_I, F_A$ . By specification of  $RW$ ,  $c^I(F_I) \leq B_I$  and  $f^\ell(F_I) \leq W_\ell$  for every  $\ell$ . The stage-II cost  $C_{II}$  of this solution is given by:

$$C_{II} = \sum_A p_A \sum_{\substack{j \in H_A: \\ d(j, F_I) > \rho R}} c_{i_j^A}^A = \sum_{\substack{j \in \mathcal{C}: \\ d(j, F_I) > \rho R}} v_j \leq B_{II},$$

■ **Algorithm 8** Generalization Procedure for **2S-MuSup-Poly**.

---

**Input :** Returned sets  $F_I, F_A : A \in Q$  and inner execution details of Algorithm 7  
 Let  $\bar{s}$  the strategy we will define, and for the stage-I actions set  $F_I^{\bar{s}} \leftarrow F_I$ ;  
 Suppose scenario  $A$  arrived in the second stage;  
 $(H_A, \pi^A) \leftarrow \text{GreedyCluster}(A, R, g^{II})$ , where  $g^{II}$  the bijective function used in  
 Algorithm 7;  
 Open the set  $F_A^{\bar{s}} \leftarrow \{i_j^A \mid j \in H_A \text{ and } d(j, F_I) > \rho R\}$ ;

---

where the last inequality follows because  $F_I$  is the output of  $RW(\mathcal{J}')$ .

Consider now a  $j \in A$  for some  $A \in Q$ . The distance of  $j$  to its closest facility will be at most  $d(\pi^A(j), F_I \cup F_A) + d(j, \pi^A(j))$ . Since  $\pi^A(j) \in H_A$ , there will either be a stage-I open facility within distance  $\rho R$  from it, or we perform a stage-II opening in  $G_{\pi(j)}$ , which results in a covering distance of at most  $R$ . Also, by the greedy clustering step, we have  $d(j, \pi^A(j)) \leq 2R$ . So in the end we get  $d(j, F_I \cup F_A) \leq (\rho + 2)R$ . ◀

By combining Algorithm 7 with existing 3-approximation algorithms for **Robust Weighted Multi-Knapsack-Supplier**, we get the following result:

► **Theorem 25.** *There is a 5-approximation algorithm for discrete instances of **2S-MuSup-Poly**, where additionally all  $c_i^I$  are polynomially bounded integers. The runtime of it is  $\text{poly}(n, m, \Lambda)$ .*

**Proof.** The results of [3] give a 3-approximation for discrete instances of **Robust Weighted Multi-Knapsack-Supplier**, when  $v_j = 1$  for all  $j$ . The work of [15] extends this to allow arbitrary  $v_j$  values. Note that by our assumption that the values  $c^I$  are polynomially bounded integers, the instance  $\mathcal{J}'$  is discrete, and hence the algorithm of [15] can be utilized in Algorithm 7 and give a 5-approximation for **2S-Sup-Poly**. Finally, given the results in [3, 15], the runtime of the whole process will be  $\text{poly}(n, m, \Lambda)$ . ◀

## C.2 Generalizing to the Black-Box Setting

Since the algorithm of Section C.1 is a valid  $(\rho + 2)$ -approximation, consider the process in Algorithm 8, which efficiently extends its output to any arriving scenario  $A \in \mathcal{D}$ .

Because Algorithm 8 exactly mimics the stage-II actions of Algorithm 7, it is easy to see that property II is satisfied. Further, the arguments of Theorem 24 would still ensure  $d(j, F_I \cup F_A) \leq (\rho + 2)R$  for every  $j \in A$  and  $A \in \mathcal{D}$ , thus guaranteeing property I. To conclude, we again only need to prove property III. Let  $\mathcal{S}_{MK}$  the set of strategies achievable via Algorithm 8.

► **Lemma 26.** *Algorithm 7 satisfies property III with  $|\mathcal{S}_{MK}| = 2^m$ .*

**Proof.** The returned final strategy depends solely on the set  $F_I$ . Given that, we can exactly determine all possible stage-II openings, since every  $H_A$  for  $A \in \mathcal{D}$  can be computed using the fixed function  $g^{II}$ . There are  $2^m$  choices for  $F_I$ , and therefore  $|\mathcal{S}_{MK}| = 2^m$ . Finally, it is easy to see that the set  $\mathcal{S}_{MK}$  is independent of  $Q$ . ◀

Our algorithm for **2S-MuSup-Poly** requires the values  $c_i^I$  to be polynomially bounded integers. As we show next, this assumption can be removed by a standard rescaling trick:

## 23:22 Approximating Two-Stage Stochastic Supplier Problems

► **Theorem 27.** *Suppose that the  $c_i^I$  are arbitrary numbers. By appropriate cost-quantization for any  $\epsilon \in (0, 1)$ , Algorithm 7 can be modified to give a solution  $F_I, F_A : A \in Q$  for **2S-MuSup-Poly**, where  $d(j, F_I \cup F_A) \leq (\rho + 2)R$  for all  $A \in Q, j \in A$ , and also  $c^I(F_I) + \sum_{A \in Q} p_A c^A(F_A) \leq (1 + \epsilon)B$ .*

**Proof.** For convenience, let us assume that  $B = 1$ , and suppose that all facilities have  $c_i^I \leq B = 1$  (as otherwise they can never be opened). Given some  $\epsilon > 0$ , let us define  $q = \epsilon/m$ , and form new costs by  $\tilde{c}_i^I = \lceil c_i^I/q \rceil, \tilde{c}_i^A = c_i^A/q, B' = B(1 + \epsilon)/q$ . The costs  $\tilde{c}_i^I$  are at most  $\lceil 1/q \rceil$ , and hence are polynomially-bounded integers. Therefore, the reduction of Section C.1 can be applied.

Suppose now that  $F_I, F_A$  is a solution to the original instance of **2S-MuSup-Poly**, with opening cost at most  $B$ . For the modified cost of this solution we then have:

$$\tilde{c}^I(F_I) + \sum_A p_A \tilde{c}^A(F_A) \leq (c^I(F_I) + \sum_A p_A c^A(F_A))/q + \sum_{i \in \mathcal{F}} 1 \leq B/q + m \leq B'$$

Thus,  $F_I, F_A$  is also a solution to the modified instance, implying that the latter is feasible. Hence, consider any solution  $\tilde{F}_I, \tilde{F}_A$  to the modified instance, that we would get after running Algorithm 7 with the new costs; its opening cost in the original instance is  $c^I(\tilde{F}_I) + \sum_A p_A c^A(\tilde{F}_A) \leq q\tilde{c}^I(\tilde{F}_I) + q\sum_A p_A \tilde{c}^A(\tilde{F}_A) \leq qB' = B(1 + \epsilon)$ . Therefore, since  $\tilde{F}_I, \tilde{F}_A$  is a  $(\rho + 2)$ -approximate solution, we get the desired result. ◀

Note that applying our generalization framework on this solution would make the overall cost over  $\mathcal{D}$  be at most  $(1 + \mathcal{O}(\epsilon))(1 + \epsilon)B = (1 + \mathcal{O}(\epsilon))B$ , which implies that in the black-box setting we do not need the initial assumption for the costs  $c_i^I$ .

### C.3 Connections to 2S-MatSup

Suppose we define our non-stochastic robust problem as having one knapsack and one matroid constraint, instead of  $L$  knapsack constraints. Then the reduction of Section C.1 would yield a  $(\rho + 2)$ -approximation for **2S-MatSup-Poly** in the exact same manner, where  $\rho$  the ratio of the algorithm used to solve the corresponding deterministic outliers problem.

A result of [3, Theorem 16] gives a 3-approximation for this outliers problem, which in turn would give a 5-approximation for **2S-MatSup-Poly**. However, the algorithm obtained in this way would be randomized (its solution may not be a valid one), would only work for polynomially bounded values  $v_j$ , and would also be significantly more complex than the algorithm of Section 4.

# Fast Approximation Algorithms for Bounded Degree and Crossing Spanning Tree Problems

## Abstract

We develop fast approximation algorithms for the minimum-cost version of the Bounded-Degree MST problem (BD-MST) and its generalization the Crossing Spanning Tree problem (CROSSING-ST). We solve the underlying LP to within a  $(1 + \epsilon)$  approximation factor in near-linear time via the multiplicative weight update (MWU) technique. This yields, in particular, a near-linear time algorithm that outputs an estimate  $B$  such that  $B \leq B^* \leq \lceil (1 + \epsilon)B \rceil + 1$  where  $B^*$  is the minimum-degree of a spanning tree of a given graph. To round the fractional solution, in our main technical contribution, we describe a fast near-linear time implementation of swap-rounding in the spanning tree polytope of a graph. The fractional solution can also be used to sparsify the input graph that can in turn be used to speed up existing combinatorial algorithms. Together, these ideas lead to significantly faster approximation algorithms than known before for the two problems of interest. In addition, a fast algorithm for swap rounding in the graphic matroid is a generic tool that has other applications, including to TSP and submodular function maximization.

## 1 Introduction

Spanning trees in graphs are a fundamental object of study and arise in a number of settings. Efficient algorithms for finding a minimum-cost spanning tree (MST) in a graph are classical. In a variety of applications ranging from network design, TSP, phylogenetics, and others, one often seeks to find a spanning tree with additional constraints. An interesting and well-known problem in this space is the BOUNDED-DEGREE SPANNING TREE (BD-ST) problem in which the goal is to find a spanning tree in a given graph  $G = (V, E)$  that minimizes the maximum degree in the tree. We refer to the minimum-cost version of BD-ST as BD-MST where one seeks a spanning tree of minimum cost subject to a given degree bound  $B$  on the vertices. The decision version of BD-ST (Given  $G, B$  is there a spanning tree with maximum degree  $B$ ?) is already NP-Complete for  $B = 2$  since it captures the Hamilton-Path problem. In an influential paper, Fürer and Raghavachari [24], building on earlier work of Win [49],

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

described a simple local-search type algorithm that runs in  $\tilde{O}(mn)$  time (here  $m$  is number of edges and  $n$  number of nodes) that outputs a spanning tree with degree at most  $B + 1$ , or certifies that  $G$  does not have a spanning tree with degree at most  $B$  (we use  $\tilde{O}$  notation to suppress poly-logarithmic factors in  $n, m, 1/\epsilon$  for notational simplicity). Their algorithm, in fact, works even in the non-uniform setting where each vertex  $v$  has a specified degree bound  $B_v$ . The Fürer-Raghavachari result spurred a substantial line of work that sought to extend their clean result to the minimum-cost setting. This was finally achieved by Singh and Lau [43] who described a polynomial-time algorithm that outputs a tree  $T$  such that the degree of each  $v$  in  $T$  is at most  $B_v + 1$  and the cost of the tree is at most  $\text{OPT}$ . Their algorithm is based on iterative rounding of a natural LP relaxation. We refer the reader to [35, 13, 28, 43, 22] for several ideas and pointers on BD-ST and BD-MST.

Motivated by several applications, Bilo et al. [9] defined the CROSSING SPANNING TREE problem (CROSSING-ST). In CROSSING-ST the input is a graph  $G = (V, E)$ , a collection of cuts  $C_1, C_2, \dots, C_k$ , and integers  $B_1, B_2, \dots, B_k$ . Each cut  $C_i$  is a subset of the edges though in many applications we view  $C_i$  as  $\delta_G(S_i)$  for some  $S_i \subset V$  (where  $\delta_G(S_i) = \{uv \in E \mid u \in S_i, v \in V \setminus S_i\}$  is the standard definition of a cut set with respect to  $S_i$ ). The goal is to find a spanning tree  $T$  such that  $|E(T) \cap C_i| \leq B_i$ , that is,  $T$  crosses each cut  $C_i$  at most  $B_i$  times. It is easy to see that BD-ST is a special case of CROSSING-ST where the cuts correspond to singletons. We refer to the min-cost version of CROSSING-ST as CROSSING-MST. CROSSING-ST gained substantial prominence in the context of the asymmetric traveling salesman problem (ATSP) – Asadpour et al. [5] showed the importance of thin spanning trees for approximating ATSP and obtained an  $O(\log n / \log \log n)$ -approximation (now we have constant factor approximations for ATSP via other methods [46, 47]). Motivated by the thin tree conjecture and its applications to ATSP (see [5, 2]) and other technical considerations, researchers have studied CROSSING-ST, its generalization to the matroid setting, and various special cases [20, 8, 7, 37, 36]. The best known approximation algorithms for CROSSING-ST and its special cases have mainly relied on the natural LP relaxation. For general CROSSING-ST the best known approximation ratio is  $\min\{O(\log k / \log \log k), (1 + \epsilon)B + O(\log k / \epsilon^2)\}$ . A variety of sophisticated and interesting rounding techniques have been designed for CROSSING-ST and its special cases. An outstanding open problem is whether CROSSING-ST admits a constant factor approximation via the natural LP relaxation. This is challenging due its implications for the thin tree conjecture.

Most of the focus on BD-MST and CROSSING-ST has been on the quality of the approximation. The best known approximation bounds rely on LP relaxations and complex rounding procedures. The overall running times are very large polynomials in the input size and are often unspecified. In this paper we are interested in the design of *fast* approximation algorithms for BD-MST, CROSSING-ST and related problems. In recent years there has been significant progress in designing fast, and often near-linear time, approximation algorithms for a number of problems in discrete and combinatorial optimization. This has been led by, and also motivated, synergy between continuous/convex optimization, numerical linear algebra, dynamic data structures, sparsification techniques, and structural results, among several others. For BD-ST with uniform degree, Duan, He and Zhang [22] described a combinatorial algorithm that for any given  $\epsilon > 0$ , runs in  $O(m \log^7 n / \epsilon^7)$  time, and either outputs a spanning tree with degree  $(1 + \epsilon)B + O(\log n / \epsilon^2)$  or reports that there does not exist a tree with maximum degree  $\leq B$ . This paper is partly motivated by the goal of improving their results: dependence on  $\epsilon$ , a better approximation, handling non-uniform bounds, cost, CROSSING-MST, and connection to the LP relaxation.

A second motivation for this paper is to develop a fast algorithm for swap-rounding in the spanning tree polytope. It is a dependent rounding technique that has several applications ranging from TSP to submodular function maximization (see [20, 26, 17, 23]). The question of developing a fast swap-rounding procedure for spanning trees was explicitly raised in [17] in the context of Metric-TSP.

## 1.1 Results

In this paper we develop fast approximation algorithms for BD-MST, CROSSING-MST and related problems in a unified fashion via broadly applicable methodology based on the LP relaxation. We consider the following problem with general packing constraints. The input to this problem is an undirected graph  $G = (V, E)$ , a non-negative edge-cost vector  $c : E \rightarrow \mathbb{R}_+$ , a non-negative matrix  $A \in [0, 1]^{k \times m}$ , and a vector  $b \in [1, \infty)^k$ . The goal is to find a spanning tree  $T$  of minimum cost such that  $A\mathbf{1}_T \leq b$  where  $\mathbf{1}_T \in \{0, 1\}^m$  is the characteristic vector of the edge set of  $T$ . This is a special case of a more general problem considered in [20]: min-cost matroid base with packing constraints. Here we restrict attention to spanning trees (graphic matroid). We refer to this slightly more general problem also as CROSSING-MST.

Our first result is a near-linear time algorithm to approximately solve the underlying LP relaxation for CROSSING-MST. For a multigraph  $G$  we let  $\mathcal{T}(G)$  denote the set of all spanning trees of  $G$  and let  $\text{ST}(G)$  denote the spanning tree polytope of  $G$  (which is the convex hull of the characteristic vectors  $\{\mathbf{1}_T \mid T \in \mathcal{T}(G)\}$ ).

► **Theorem 1.** *Let  $G = (V, E)$  be a multigraph with  $m$  edges and  $n$  nodes and consider the linear program  $\min\{c^T x : Ax \leq b, x \in \text{ST}(G)\}$  where  $A \in [0, 1]^{k \times m}$ ,  $b \in [1, \infty)^k$ ,  $c \in [0, \infty)^m$ . Let  $N$  be the maximum of  $m$  and number of non-zeroes in  $A$ . There is a randomized polynomial time algorithm that for any given  $\epsilon \in (0, 1/2]$  runs in  $\tilde{O}(N/\epsilon^2)$  time and with high probability either correctly certifies that the LP is infeasible or outputs a solution  $y \in \text{ST}(G)$  such that  $c^T y \leq (1 + \epsilon)\text{OPT}$  and  $Ay \leq (1 + \epsilon)b$  where  $\text{OPT}$  is the minimum value of a feasible solution.*

► **Remark 2.** We describe a randomized algorithm for the sake of simplicity, however we believe that a deterministic algorithm with similar guarantees can be obtained via ideas in [16].

Solving the LP relaxation quickly enables to estimate the optimum integer solution *value* via existing rounding results [43, 20, 8, 7, 37, 36]. For instance, when specialized to BD-ST, we obtain a near-linear time algorithm to estimate the optimum value arbitrarily closely (modulo the additive 1).

► **Corollary 3.** *There is a randomized  $\tilde{O}(m/\epsilon^2)$ -time algorithm that outputs a value  $B$  such that  $B \leq B^* \leq \lceil (1 + \epsilon)B \rceil + 1$  where  $B^*$  is the minimum maximum degree over all spanning trees (that is,  $B^* = \min_{T \in \mathcal{T}(G)} \max_{v \in V} \deg_T(v)$  where  $\deg_T(v)$  is the degree of  $v$  in  $T$ ).*

Our second result shows the utility of the LP solution to sparsify the original graph  $G$ .

► **Theorem 4.** *Let  $x \in \text{ST}(G)$  be such that  $Ax \leq b$  for a matrix  $A \in [0, 1]^{k \times m}$  and  $b \in [1, \infty)^k$ . Consider a random subgraph  $G' = (V, E')$  of  $G$  obtained by picking each edge  $e \in G$  with probability  $\alpha_e := \min\{1, \frac{36 \log(k+m)}{\epsilon^2} \cdot x_e\}$ . Then with high probability the following hold: (i)  $|E'| = O(n \ln(k+m)/\epsilon^2)$  (ii) there exists a fractional solution  $z \in \text{ST}(G)$  in the support of  $G'$  such that  $Az \leq (1 + 3\epsilon)b$ .*

One can run a combinatorial algorithm such as the Fürer-Raghavchari algorithm [24] on the sparse graph rather than on the original graph  $G$ . This yields the following corollary which improves the  $\tilde{O}(mn)$  running time substantially when  $G$  is dense.

► **Corollary 5.** *There is a randomized algorithm for BD-ST that given a graph  $G$  on  $n$  nodes runs in  $\tilde{O}(n^2/\epsilon^2)$  time, and with high probability outputs a spanning tree  $T$  with maximum degree  $\lceil(1 + \epsilon)B^*\rceil + 2$  where  $B^*$  is the optimal degree bound.*

► **Remark 6.** Corollaries 3 and 5 can be generalized to the non-uniform degree version of BD-ST. Input is  $G$  and degree bounds  $B_v, v \in V$ , and the algorithm either decides that there is no spanning tree satisfying the degree bounds or outputs a tree that approximately satisfies them.

Our final result is a fast algorithm to round the LP solution. Several different rounding strategies have been developed for BD-MST and CROSSING-MST and they yield different guarantees and take advantage of the special structure of the given instance. Iterated rounding has been one of the primary and powerful techniques, however it requires basic feasible solutions to the LP relaxation; it seems far from obvious how to obtain fast algorithms with comparable guarantees and is a challenging open problem. We are here interested in *oblivious randomized rounding* strategies that take a point  $x \in \text{ST}(G)$  and round it to a random spanning tree  $T \in \mathcal{T}(G)$  such that the coordinates of the resulting random edge vector are *negatively correlated*<sup>1</sup>. Negative correlation implies concentration for linear constraints as shown by Panconesi and Srinivasan [38]. These strategies, when combined with the LP solution, yield bicriteria approximation algorithms for CROSSING-MST of the form  $(1 + \epsilon, \min\{O(\log k / \log \log k)b_i, (1 + \epsilon)b_i + O(\log k)/\epsilon^2\})$  where the first part is the approximation with respect to the cost and the second part with respect to the packing constraints. For CROSSING-ST and CROSSING-MST these are currently the best known approximation ratios (although special cases such as BD-MST admit much better bounds). Several dependent randomized rounding techniques achieving negative correlation in the spanning tree polytope are known: maximum entropy rounding [5], pipage rounding and *swap rounding* [20]. These rounding techniques generally apply to matroids and have several other applications. In this paper we show that given  $x \in \text{ST}(G)$ , one can swap-round  $x$  to a spanning tree in near-linear time provided it is given in an implicit fashion; alternately one can obtain an implicit *approximate* representation  $x'$  of  $x$  and then apply an efficient swap-rounding on  $x'$ . Since swap-rounding is a flexible procedure and does not generate a unique distribution, a precise technical statement requires more formal notation and we refer the reader to Section 3. Here we state a theorem in a general form so that it can be used in other contexts.

► **Theorem 7.** *Let  $G = (V, E)$  be a multigraph with  $m$  edges and let  $x \in [0, 1]^m$ . For any  $\epsilon \in (0, 1/2)$  there is a randomized algorithm that runs in  $\tilde{O}(m/\epsilon^2)$  time and either correctly decides that  $x \notin \text{ST}(G)$  or outputs a random vector  $T = (X_1, X_2, \dots, X_m) \in \{0, 1\}^m$  such that (i)  $T$  is the characteristic vector of a spanning tree of  $G$  (ii)  $\mathbb{E}[X_i] \leq (1 + \epsilon)x_i$  for  $1 \leq i \leq m$  and (iii)  $X_1, X_2, \dots, X_m$  are negatively correlated. In particular  $T$  is obtained as a swap-rounding of a vector  $y$  such that  $y \leq (1 + \epsilon)x$ .*

Combining Theorems 1 and 7 and existing results on swap rounding [20] we obtain the following. The approximation ratio matches the best known for CROSSING-MST and the algorithm runs in near-linear time.

<sup>1</sup> A collection of  $\{0, 1\}$  random variables  $X_1, X_2, \dots, X_r$  are negatively correlated if, for all subsets  $S \subseteq [r]$ ,  $\mathbb{E}[\prod_{i \in S} X_i] \leq \prod_{i \in S} \mathbb{E}[X_i]$  and  $\mathbb{E}[\prod_{i \in S} (1 - X_i)] \leq \prod_{i \in S} (1 - \mathbb{E}[X_i])$ .

► **Corollary 8.** *For the feasibility version of CROSSING-MST, there is a randomized algorithm that runs in near-linear time and outputs a spanning tree  $T$  such that*

$$A\mathbb{1}_T \leq \min\{O(\log k / \log \log k)b_i, (1 + \epsilon)b_i + O(\log k)/\epsilon^2\}$$

*with high probability. For the cost version of CROSSING-MST, there is a randomized algorithm that outputs a*

$$(1 + \epsilon, \min\{O(\log k / \log \log k)b_i, (1 + \epsilon)b_i + O(\log k)/\epsilon^2\})$$

*bicriteria approximation with probability  $\Omega(\epsilon)$ . After  $\tilde{O}(1/\epsilon)$  independent repetitions of this algorithm, we can obtain the same guarantees with high probability.*

Our algorithm, when specialized to BD-ST and BD-MST is more general than the one in [22] in terms of handling cost and non-uniform degrees. In addition we obtain a very close estimate of  $B^*$ , a much better dependence on  $\epsilon$ , and also obtain an approximation of the form  $O(\log n / \log \log n)B^*$  which is better than  $(1 + \epsilon)B^* + O(\log n)/\epsilon^2$  for small  $B^*$ .

We mainly focused on BD-MST and a high-level result for CROSSING-MST. One can obtain results for related problems that involve multiple costs, lower bounds in addition to upper bounds, and other applications of swap-roundings. We discuss these in more detail in Section A.

## 1.2 Overview of main ideas

Faster approximation algorithms for LPs that arise in combinatorial optimization have been developed via several techniques. We follow a recent line of work [16, 18, 39, 14] that utilizes features of the multiplicative weight update (MWU) method and data structures to speed up *implicit* LPs. In particular, the LP for CROSSING-MST that we seek to solve can be addressed by the randomized MWU algorithm from [18] and data structures for dynamic MST [29]. The overall approach follows some ideas from past work [16]. The sparsification result is inspired by recent applications of similar ideas [16, 15, 11] and utilizes Karger’s theorem on random sampling for packing disjoint bases in matroids [30].

Our main novel contribution is Theorem 7 which we believe is of independent interest beyond the applications outlined here. Dependent randomized rounding techniques have had many spectacular applications. In particular maximum entropy rounding in the spanning tree polytope gave a strong impetus to this line of work via its applications to ATSP [5] and metric-TSP [27]. Swap-rounding is a simpler scheme to describe and analyze, and suffices for several applications that only require negative correlation. However, all the known dependent rounding schemes are computationally expensive. Recent work has led to fantastic progress in sampling spanning trees [4], however the bottleneck for maximum entropy rounding is to compute, from a given point  $x \in \text{ST}(G)$ , the maximum entropy distribution with marginals equal to  $x$ ; polynomial time (approximation) algorithms exist for this [5, 44] but they are rather slow. Swap-rounding [20] requires one to decompose  $x \in \text{ST}(G)$  (or more generally a point in the matroid base polytope) into a convex combination of spanning trees; that is we write  $x = \sum_{T \in \mathcal{T}} \lambda_T \mathbb{1}_T$  such that  $\sum_T \lambda_T = 1$  and  $\lambda_T \geq 0, T \in \mathcal{T}$ . This is a non-trivial problem to do exactly. The starting point here is a theorem in [16] that shows that one can solve this decomposition problem *approximately* and deterministically in near-linear time via a reduction to the problem of spanning tree packing; this is done via MWU techniques. The near-linear time algorithm implies that any  $x \in \text{ST}(G)$  can be decomposed efficiently into an *implicit* convex decomposition of total size  $\tilde{O}(m/\epsilon^2)$  where  $\epsilon$  is the approximation parameter in the decomposition. To store the convex combination  $\sum_{i=1}^h \lambda_i \mathbb{1}_{T_i}$  implicitly, we store the

first tree  $T_1$  explicitly and to obtain  $T_{i+1}$  from  $T_i$  for  $i \in [h-1]$ , we store the edges in the symmetric difference of  $T_{i+1}$  and  $T_i$ . The size of the decomposition is then the sum of the sizes of the symmetric differences and the size of  $T_1$ . We give a more formal definition of an implicit decomposition in Section 3.2. We show in this paper that this implicit sparse decomposition is well-suited to the swap-rounding algorithm. We employ a divide-and-conquer strategy with appropriate tree data structures to obtain an implementation that is near-linear in the size of the implicit decomposition. Putting these ingredients together yields our result.<sup>2</sup>

The seemingly fortuitous connection between the MWU based algorithm for packing spanning trees and its implicit representation leading to a fast algorithm for swap-rounding is yet another illustration of the synergy between tools coming together in the design of fast algorithms.

### 1.3 Other related work

We overview some known results on CROSSING-ST and CROSSING-MST and special cases. BD-MST can be viewed as a special case of CROSSING-MST where each edge participates in 2 constraints. Bansal et al. [8] showed that if each edge participates in at most  $\Delta$  constraints of  $A$  (and  $A$  is a binary matrix) then one can obtain a  $(1, b + \Delta - 1)$ -approximation generalizing the BD-MST result; this was further extended to matroids by Lau, Kiraly and Singh [33]. It is shown in [7] that for CROSSING-ST one cannot obtain a purely additive approximation better than  $O(\sqrt{n})$  via the natural LP relaxation. For this they use a reduction from discrepancy minimization; it also implies, via the hardness result in [12] for discrepancy, that it is NP-Hard to obtain a purely additive  $o(\sqrt{n})$  bound. Bansal et al. [7] consider the *laminar* case of CROSSING-MST where the cuts form a laminar family and obtained a  $(1, b + O(\log n))$  approximation via iterative rounding (this problem generalizes BD-MST). Olver and Zenklusen [37] consider chain-constrained CROSSING-ST which is a further specialization when the laminar family is a chain (a nested family of cuts). For this special case they obtained an  $O(1)$ -factor approximation in the unit cost setting; Linhares and Swamy [36] considered the min-cost version and obtained an  $(O(1), O(1))$ -approximation. [37] also showed that even in the setting of chain-constrained CROSSING-ST, it is NP-Hard to obtain a purely additive bound better than  $c \log n / \log \log n$  for some fixed constant  $c$ .

Dependent randomized rounding has been an active area of research with many applications. Pipage rounding, originally developed by Ageev and Sviridenko [1] in a deterministic way, was generalized to the randomized setting by Srinivasan [45] and by Gandhi et al. [25] and [10, 20] and has led to a number of applications. Maximum entropy rounding satisfies additional properties beyond negative correlation and this is important in applications to metric-TSP (see [27] and very recent work [31, 32]). There has been exciting recent progress on sampling spanning trees and bases in matroids and we refer the reader to some recent work [41, 3, 4] for further pointers. Concentration bounds via dependent rounding can also be obtained without negative correlation (see [21] for instance) and recent work of Bansal [6] combines iterative rounding with dependent rounding in a powerful way.

---

<sup>2</sup> In an earlier version of the paper (see [19]) we described our fast swap rounding using two ideas. The first was a fast near-linear time algorithm to merge two spanning trees using the link-cut tree data structure. We were unaware of prior work of Ene and Nguyễn [23] that had already given such an algorithm in the context of fast algorithms for submodular function maximization in graphic matroids. In this version of the paper we use their algorithm as a black box. We focus on our second idea which exploits the implicit representation. We thank Alina Ene and Huy Nguyễn for pointing out to us their fast algorithm for merging two trees.

Fast approximation algorithms for solving positive LPs and SDPs has been an extensive area of research starting from the early 90s. Lagrangean relaxation techniques based on MWU and other methods have been extensively studied in the past, and continue to provide new insights and results for both explicit and implicit problems. Recent work based on a convex optimization perspective has led to a number of new results and improvements. It is infeasible to do justice to this extensive research area and we refer the reader to two recent PhD theses [40, 48]. Spectacular advances in fast algorithms based on the Laplacian paradigm, interior point methods, cutting plane methods, spectral graph theory, and several others have been made in the recent past and is a very active area of research with frequent ongoing developments.

## Organization

Section 2 introduces some relevant notation, technical background and tree data structures that we rely on. Section 3 describes our fast swap-rounding algorithm and proves Theorem 7. Section 4 describes the sparsification process of Theorem 4. Section 5 discusses the LP relaxation for CROSSING-ST and Theorem 1. Section A brings together results from previous sections to prove some of the corollaries stated in the introduction and provides details of some extensions and related problems.

## 2 Preliminaries and notation

For a set  $S$ , we use the convenient notation  $S - i$  to denote  $S \setminus \{i\}$  and  $S + i$  to denote  $S \cup \{i\}$ .

### Matroids

We discuss some basics of matroids to establish some notation as well as present some useful lemmas that will be used later. A *matroid*  $\mathcal{M}$  is a tuple  $(N, \mathcal{I})$  with  $\mathcal{I} \subseteq 2^N$  satisfying the following three properties: (1)  $\emptyset \in \mathcal{I}$ , (2) if  $A \in \mathcal{I}$  and  $B \subseteq A$ , then  $B \in \mathcal{I}$ , and (3) if  $A, B \in \mathcal{I}$  such that  $|A| < |B|$  then there exists  $b \in B \setminus A$  such that  $A + b \in \mathcal{I}$ . We refer to the sets in  $\mathcal{I}$  as *independent sets* and say that maximal independent sets are *bases*. The *rank* of  $\mathcal{M}$  is the size of a base. For a set  $A \subseteq 2^N$ , we refer to  $r_{\mathcal{M}}(A) = \max\{|S| : S \subseteq A, S \in \mathcal{I}\}$  as the *rank* of  $A$ .

A useful notion that we utilize in our fast implementation of swap rounding is that of contraction of a matroid. We say that the *contraction* of  $e$  in  $\mathcal{M}$  results in the matroid  $\mathcal{M}/e = (N - e, \{I \subseteq N - e : I + e \in \mathcal{I}\})$  if  $r_{\mathcal{M}}(\{e\}) = 1$  and  $\mathcal{M}/e = (N - e, \{I \subseteq N - e : I \in \mathcal{I}\})$  if  $r_{\mathcal{M}}(\{e\}) = 0$ . This definition extends naturally to contracting subsets  $A \subseteq N$ . It can be shown that contracting the elements of  $A$  in any order results in the same matroid, which we denote as  $\mathcal{M}/A$ .

The following statements are standard results in the study of matroids (e.g. see [42]). The following theorem is important in the analysis of swap rounding. It is often called the strong base exchange property of matroids.

► **Theorem 9.** *Let  $\mathcal{M} = (N, \mathcal{I})$  be a matroid and let  $B, B'$  be bases. For  $e \in B \setminus B'$ , there exists  $e' \in B' \setminus B$  such that  $B - e + e' \in \mathcal{I}$  and  $B' - e' + e \in \mathcal{I}$ .*

The next lemma shows that if one contracts elements of an independent set in a matroid, bases in the contracted matroid can be used to form bases in the initial matroid.

► **Lemma 10.** *Let  $\mathcal{M} = (N, \mathcal{I})$  be a matroid and let  $A \in \mathcal{I}$ . Let  $B_A$  be a base in  $\mathcal{M}/A$ . Then  $A \cup B_A$  is a base in  $\mathcal{M}$ .*

### A forest data structure

We need a data structure to represent a forest that supports the necessary operations we need to implement randomized swap rounding in Section 3. The data structure mainly needs to facilitate the contraction of edges, including being able to recover the identity of the original edges after any number of contractions. We enable this by enforcing that when the data structure is initialized, every edge  $e$  is accompanied with a unique identifier. This identifier will be associated with the edge regardless of the edge's endpoints changing due to contraction. The implementation of this step is important to guarantee a fast running time.

The data structure is initialized via the function `init`, which takes as input the vertices, edges, and unique edge identifiers of the forest. `init` initializes an adjacency list  $A$ , stores a mapping  $f$  of edges to their unique edge identifiers, and creates a disjoint-set data structure  $R$  where every vertex initially is in its own set. The operation `contract` contracts an edge  $uv$  in the forest by identifying the vertices  $u$  and  $v$  as the same vertex. This requires choosing  $u$  or  $v$  to be the new representative (suppose we choose  $u$  without loss of generality), merging the sets corresponding to  $u$  and  $v$  in  $R$  while making  $u$  the representative of the set in  $R$ , and modifying the adjacency list  $A$  to reflect the changes corresponding to contracting  $uv$  and making  $u$  the representative. After an edge is contracted, the vertex set changes. We need to support the ability to obtain the edge identifier of an edge in the contracted forest. The data structure maintains  $f$  under edge contractions and returns unique identifiers with the operation `orig-edge`. Given an edge  $uv$  that was in the contracted forest at some point in the past, we also need to support the ability to obtain the edge in the vertex set of the current contracted forest. We do this using  $R$ , which stores all of the vertices that have been contracted together in disjoint sets. This operation is supported by the operation `represented-edge`. Finally, we can copy the graph via the operation `copy`, which simply enumerates over the vertices, edges, and stored unique identifiers of the edges to create a new data structure.

The following lemma formalizes the preceding description of the data structure. We leave the formal details of a specific implementation and the proof of the following lemma for the full version.

► **Lemma 11.** *Let  $F = (V, E)$  be a forest and for all  $e \in E$ , let  $id(e)$  be the unique identifier of  $e$ . The data structure can be initialized via a call to `init` in  $\tilde{O}(|V|)$  time. For  $i = 0, 1, \dots, k$ , let  $F_i = (V_i, E_i)$  be the forest after  $i$  calls to `contract`, so  $F_0 = F$  and  $F_k$  is the current state of the forest. The data structure supports the following operations.*

- `orig-edge( $e$ )`: *input is an edge  $e \in E_k$ . Output is the identifier  $id(e)$  that was provided when  $e$  was added to the data structure. Running time is  $\tilde{O}(1)$ .*
- `represented-edge( $e$ )`: *input is two vertices  $u, v \in V_i$  for some  $i = 0, 1, \dots, k$ . Output is the pair  $\{u_r, v_r\}$ , where  $u_r$  and  $v_r$  are the vertices in  $V_k$  that correspond to  $u$  and  $v$  in the contracted forest  $F_k$ . Running time is  $O(1)$ .*
- `contract( $uv, z \in \{u, v\}$ )`: *input is two vertices  $u, v \in V_k$ . The operation contracts  $uv$  in  $E_k$ , setting the new vertex in  $F_{k+1} = (V_{k+1}, E_{k+1})$  to be  $\{u, v\} \setminus \{z\}$ . The amortized running time is  $\tilde{O}(\deg_{F_k}(z))$ .*
- `copy()`: *output is a forest data structure with vertices  $V_k$  and edges  $E_k$  along with the stored edge identifiers. Running time is  $\tilde{O}(|V_k|)$ .*

<pre> merge-bases(<math>\delta, B, \delta', B'</math>)   while <math>B \setminus B' \neq \emptyset</math> do     <math>e \leftarrow</math> arbitrary element of <math>B \setminus B'</math>     <math>e' \leftarrow</math> element of <math>B' \setminus B</math> such that <math>B - e + e' \in \mathcal{I}</math> and <math>B' - e' + e \in \mathcal{I}</math>     <math>b \leftarrow 1</math> with probability <math>\frac{\delta}{\delta + \delta'}</math> and 0 otherwise     if <math>b = 1</math> then       <math>B \leftarrow B - e + e'</math>     else       <math>B' \leftarrow B' - e' + e</math>     end if   end while   return <math>B</math> </pre>

■ **Figure 1** The randomized swap rounding algorithm from [20].

### 3 Fast swap rounding in the spanning tree polytope

Randomized swap rounding, developed in [20], is a dependent rounding scheme for rounding a fractional point  $x$  in the base polytope of a matroid to a random base  $X$ . The rounding preserves expectation in that  $\mathbb{E}[X] = x$ , and more importantly, the coordinates of  $X$  are negatively correlated. In this section we prove Theorem 7 on a fast algorithm for swap-rounding in the spanning tree polytope. We begin by describing swap-rounding.

#### 3.1 Randomized swap rounding

Let  $\mathcal{M} = (N, \mathcal{I})$  be a matroid and let  $\mathcal{P}$  be the base polytope of  $\mathcal{M}$  (convex hull of the characteristic vectors of the bases of  $\mathcal{M}$ ). Any  $x \in \mathcal{P}$  can be written as a finite convex combination of bases:  $x = \sum_{i=1}^h \delta_i \mathbb{1}_{B_i}$ . Note that this combination is not necessarily unique. As in [20], we give the original algorithm for randomized swap rounding via two routines. The first is `merge-bases`, which takes as input two bases  $B, B'$  and two real values  $\delta, \delta' \in (0, 1)$ . If  $B = B'$  the algorithm outputs  $B$ . Otherwise the algorithm finds a pair of elements  $e, e'$  such that  $e \in B \setminus B'$  and  $e' \in B' \setminus B$  where  $B - e + e' \in \mathcal{I}$  and  $B' - e' + e \in \mathcal{I}$ . For such  $e$  and  $e'$ , we say that they are a *valid exchange pair* and that we *swap*  $e$  with  $e'$ . The existence of such elements is guaranteed by the strong base exchange property of matroids in Theorem 9. The algorithm randomly retains  $e$  or  $e'$  in both bases with appropriate probability and this increases the intersection size of  $B$  and  $B'$ . The algorithm repeats this process until  $B = B'$ . The overall algorithm `swap-round` utilizes `merge-bases` as a subroutine and repeatedly merges the bases until only one base is left. A formal description is in Figure 1 along with the pseudocode for `merge-bases`.

It is shown in [20] that swap-rounding generates a random base/extreme point  $X \in \mathcal{P}$  (note that the extreme points of  $\mathcal{P}$  are characteristic vectors of bases) such that  $\mathbb{E}[X] = x$  and the coordinates  $X_1, X_2, \dots, X_n$  (here  $|N| = n$ ) are negatively correlated. We observe

that swap-rounding does not lead to a unique probability distribution on the bases (that depends only  $x$ ). First, as we already noted, the convex decomposition of  $x$  into bases is not unique. Second, both **merge-bases** and **swap-round** are non-deterministic in their choices of which element pairs to swap and in which order to merge bases in the convex decomposition. The key property for negative correlation, as observed in [20], is to view the generation of the final base  $B$  as a vector-valued martingale (which preserves expectation in each step) that changes only two coordinates in each step. Another rounding strategy, namely pipage rounding, also enjoys this property. Nevertheless swap-rounding is a meta algorithm that has certain clearly defined features. The flexibility offered by **merge-bases** and **swap-round** are precisely what allow for faster implementation in specific settings.

We say that  $\bar{B} \stackrel{d}{=} \text{merge-bases}(\delta, B, \delta', B')$  if for some non-deterministic choice of valid exchange pairs in the algorithm,  $\bar{B}$  is the random output of **merge-bases** $(\delta, B, \delta', B')$ . Similarly we say that  $B \stackrel{d}{=} \text{swap-round}(\delta_1, B_1, \dots, \delta_h, B_h)$  if  $B$  is the random output of the **swap-round** process for some non-deterministic choice of the order in which bases are merged and some non-deterministic choices in the merging of bases. It follows from [20] that if  $B \stackrel{d}{=} \text{swap-round}(\delta_1, B_1, \dots, \delta_h, B_h)$  then  $B$  satisfies the property that  $\mathbb{E}[B] = x$  and coordinates of  $B$  are negatively correlated.

### 3.2 Setup for fast implementation in graphs

Let  $G = (V, E)$  be a multigraph with  $|V| = n$  and  $|E| = m$  and let  $x \in \text{ST}(G)$  be a fractional spanning tree. Swap rounding requires decomposing  $x$  into a convex combination of spanning trees. This step is itself non-trivial; existing algorithms have a high polynomial dependence on  $n, m$ . Instead we will settle for an *approximate* decomposition that has some very useful features. We state a theorem (in fact a corollary of a theorem) from [16] in a slightly modified form suitable for us.

► **Theorem 12** (Paraphrase of Corollary 1.2 in [16]). *Given a graph  $G = (V, E)$  with  $n = |V|$  and  $m = |E|$  and a rational vector  $x \in [0, 1]^m$  there is a deterministic polynomial-time algorithm that runs in  $\tilde{O}(m/\epsilon^2)$  time and either correctly reports that  $x \notin \text{ST}(G)$  or outputs an implicit convex decomposition of  $z$  into spanning trees such that  $z \leq (1 + \epsilon)x$ .*

The MWU algorithm behind the preceding theorem outputs a convex decomposition of  $z = \sum_{i=1}^h \delta_i \mathbf{1}_{T_i}$  for  $h = \tilde{O}(m/\epsilon^2)$  but in an implicit fashion. It outputs  $T = T_1$  and a sequence of tuples  $(\delta_i, E_i, E'_i)$  where  $T_{i+1} = T_i - E_i + E'_i$  for  $1 \leq i < h$  and has the property that  $\sum_{i=1}^{h-1} (|E_i| + |E'_i|) = \tilde{O}(m/\epsilon^2)$ . Thus the convex decomposition of  $z$  is rather sparse and near-linear in  $m$  for any fixed  $\epsilon > 0$ . We will take advantage of this and swap-round  $z$  via this implicit convex decomposition. For many applications of interest, including **CROSSING-MST**, the fact that we randomly round  $z$  instead of  $x$  does not make much of a difference in the overall approximation since  $x$  itself in our setting is the output of an approximate LP solver.

► **Remark 13.** The output of the approximate LP solver based on MWU for **CROSSING-MST** has the implicit decomposition as outlined in the preceding paragraph. However, for the sake of a self-contained result as stated in Theorem 7, we use the result from [16] which also has the advantage of being deterministic.

The rest of the section describes a fast implementation for **swap-round**. The algorithm is based on a divide and conquer strategy for implementing **swap-round** when the convex combination is described in an implicit and compact fashion. An important ingredient is a fast black-box implementation of **merge-bases**. For this we use the following result; as we remarked earlier, an earlier version of this paper obtained a similar result.

► **Theorem 14** (Ene and Nguyễn [23]). *Let  $T$  and  $T'$  be spanning trees of a graph  $G = (V, E)$  with  $|V| = n$  and  $E = T \cup T'$  and let  $\delta, \delta' \in (0, 1)$ . There exists an algorithm `fast-merge` such that  $\text{fast-merge}(\delta, T, \delta', T') \stackrel{d}{=} \text{merge-bases}(\delta, T, \delta', T')$  and the call to `fast-merge` runs in  $O(n \log^2 n)$  time.*

### 3.3 Fast implementation of swap-round

In this subsection the goal is to prove the following theorem.

► **Theorem 15.** *Let  $\sum_{i=1}^h \delta_i \mathbb{1}_{T_i}$  be a convex combination of spanning trees of the graph  $G = (V, E)$  where  $n = |V|$ . Let  $T$  be a spanning tree such that  $T = T_1$  and let  $\{(E_i, E'_i)\}_{i=1}^{h-1}$  be a sequence of sets of edges such that  $T_{i+1} = T_i - E_i + E'_i$  for all  $i \in [h-1]$  and  $E_i \cap E'_i = \emptyset$  for all  $i \in [h-1]$ . Then there exists an algorithm that takes as input  $T$ ,  $\{(E_i, E'_i)\}_{i=1}^{h-1}$ , and  $\{\delta_i\}_{i=1}^h$  and outputs a tree  $T_S$  such that  $T_S \stackrel{d}{=} \text{swap-round}(\delta_1, T_1, \dots, \delta_h, T_h)$ . The running time of the algorithm is  $\tilde{O}(n + \gamma)$  time where  $\gamma = \sum_{i=1}^{h-1} (|E_i| + |E'_i|)$ .*

#### A divide and conquer approach

We consider the swap rounding framework in the setting of arbitrary matroids for simplicity. We work with the implicit decomposition of the convex combination of bases  $\sum_{i=1}^h \delta_i \mathbb{1}_{B_i}$  of the matroid  $\mathcal{M} = (N, \mathcal{I})$ , as described in Theorem 15. That is, the input is a base  $B$  such that  $B = B_1$ , a sequence of sets of elements  $\{(E_i, E'_i)\}_{i=1}^{h-1}$  such that  $B_{i+1} = B_i - E_i + E'_i$  and  $E_i \cap E'_i = \emptyset$  for all  $i \in [h-1]$ , and the sequence of coefficients  $\{\delta_i\}_{i=1}^h$ .

The pseudocode for our divide and conquer algorithm `divide-and-conquer-swap` is given in Figure 2. The basic idea is simple. We *imagine* constructing an explicit convex decomposition  $B_1, B_2, \dots, B_h$  from the implicit one. The high-level idea is to recursively apply swap rounding to  $B_1, \dots, B_{h/2}$  to create a base  $B$ , and similarly create a base  $B'$  by recursively applying swap rounding to  $B_{h/2+1}, \dots, B_h$ , and then merging  $B$  and  $B'$ . The advantage of this approach is manifested in the implicit case. To see this, we observe that in  $\text{merge-bases}(\delta, B, \delta', B')$ , the intersection  $B \cap B'$  is always in the output, and this implies that the intersection  $\bigcap_{i=1}^h B_i$  will always be in the output of  $\text{swap-round}(\delta_1, B_1, \dots, \delta_h, B_h)$ . Therefore, at every recursive level, we simply contract the intersection prior to merging any bases. Note that this is slightly complicated by the fact that the input is an implicit representation. However, we note that  $B \cap \bigcup_{i=1}^{h-1} (E_i \cup E'_i) = B \setminus \bigcap_{i=1}^h B_i$  as  $E_i \cup E'_i = B_i \Delta B_{i+1}$  for all  $i \in [h-1]$  where  $S \Delta U$  denotes the symmetric difference of the sets  $S, U$  (see full version for more details). (We note later how the contraction of elements helps in the running time when specializing to the graphic matroid.) After contracting the intersection, the algorithm recursively calls itself on the first  $h/2$  bases and the second  $h/2$  bases, then merges the output of the two recursive calls via `merge-bases`. With the given implicit representation, this means that the input to the first recursive call is  $B_1, \{(E_i, E'_i)\}_{i=1}^{h/2-1}, \{\delta_i\}_{i=1}^{h/2}$  and the input to the second recursive call is  $B_{h/2+1}, \{(E_i, E'_i)\}_{i=h/2+1}^{h-1}, \{\delta_i\}_{i=h/2+1}^h$  (note we can easily construct  $B_{h/2+1}$  via the implicit representation). The underlying matroid in the call to `merge-bases` is the matroid  $\mathcal{M}$  with the intersection  $\bigcap_{i=1}^h B_i$  contracted.

The following lemma shows that `divide-and-conquer-swap` is a proper implementation of `swap-round`. We leave the details of the proof for the full version of the paper.

► **Lemma 16.** *Let  $\sum_{i=1}^h \delta_i \mathbb{1}_{B_i}$  be a convex combination of bases in the matroid  $\mathcal{M}$  and  $\{(E_i, E'_i)\}_{i=1}^{h-1}$  be a sequence of elements such that  $B_{i+1} = B_i - E_i + E'_i$  and  $E_i \cap E'_i = \emptyset$  for all  $i$ . Then  $\text{swap-round}(\delta_1, B_1, \dots, \delta_h, B_h) \stackrel{d}{=} \text{divide-and-conquer-swap}(B_1, \{(E_i, E'_i)\}_{i=1}^{h-1}, \{\delta_i\}_{i=1}^h)$ .*

```

divide-and-conquer-swap( $B, \{(E_i, E'_i)\}_{i=s}^{t-1}, \{\delta_i\}_{i=s}^t$ )
  if  $s = t$  then
    return  $B$ 
  end if
   $\ell \leftarrow \max \left\{ \ell' \in \{s, s+1, \dots, t\} : \sum_{i=s}^{\ell'-1} |E_i| \leq \frac{1}{2} \sum_{i=s}^{t-1} |E_i| \right\}$ 
   $\hat{B} \leftarrow B \cap \bigcup_{i=s}^{\ell-1} (E_i \cup E'_i)$ 
   $\hat{B}_C \leftarrow \hat{B}$ 
  for  $i$  from  $s$  to  $\ell$  do
     $\hat{B}_C \leftarrow \hat{B}_C - E_i + E'_i$ 
  end for
   $\hat{B}_L \leftarrow \text{divide-and-conquer-swap}(\hat{B}, \{(E_i, E'_i)\}_{i=s}^{\ell-1}, \{\delta_i\}_{i=s}^{\ell})$ 
   $\hat{B}_R \leftarrow \text{divide-and-conquer-swap}(\hat{B}_C, \{(E_i, E'_i)\}_{i=\ell+1}^{t-1}, \{\delta_i\}_{i=\ell+1}^t)$ 
   $\hat{B}_M \leftarrow \text{merge-bases}(\sum_{i=s}^{\ell} \delta_i, \hat{B}_L, \sum_{i=\ell+1}^t \delta_i, \hat{B}_R)$ 
  return  $\hat{B}_M \cup (B \setminus \bigcup_{i=s}^{\ell-1} (E_i \cup E'_i))$ 

```

■ **Figure 2** A divide-and-conquer implementation of swap rounding with an implicit representation.

### A fast implementation of divide-and-conquer-swap for spanning trees

The pseudocode for our fast implementation `fast-swap` of `divide-and-conquer-swap` is given in Figure 4.

As in `divide-and-conquer-swap`, the algorithm `fast-swap` contracts the intersection of the input. Suppose we contract the intersection  $\bigcap_{i=1}^h T_i$  in  $T_j$  and call this contracted tree  $\hat{T}_j$ . Then  $|\hat{T}_j| \leq |T_j \setminus \bigcap_{i=1}^h T_i|$ . A simple argument shows that  $T_j \setminus \bigcap_{i=1}^h T_i \subseteq \bigcup_{i=1}^{h-1} (T_i \Delta T_{i+1}) = \bigcup_{i=1}^{h-1} (E_i \cup E'_i)$  (see full version for more details). Thus, the size of the contracted tree is bounded by the size of the implicit representation  $\gamma := \sum_{i=1}^{h-1} |E_i| + |E'_i|$ . One can write a convex combination of bases in any matroid using the implicit representation, and contraction could even be implemented quickly as is the case in the graphic matroid. The main point for improving the running time is having an implementation of `merge-bases` that runs in time proportional to the size of the *contracted* matroid. This is key to the speedup achieved for the graphic matroid. `fast-merge` runs in time proportional to the size of the input trees, which have been contracted to have size  $O(\min\{n, \gamma\})$ , which yields a running time of  $\tilde{O}(\min\{n, \gamma\})$ . This speedup at every recursive level combined with the divide-and-conquer approach of `fast-swap` is sufficient to achieve a near-linear time implementation of `swap-round`.

Recall that as we are working with contracted trees, an edge in the contracted trees might have different endpoints than it did in the initial trees. The identifiers of edges do not change, regardless of whether the endpoints of the edge change due to contraction of edges in a tree. We therefore will refer to id's of edges throughout the algorithm `fast-swap` to work from contracted edges back to edges in the initial trees. This extra bookkeeping will mainly be handled implicitly.

Contraction of the intersection of the input trees in `fast-swap` using only the implicit representation is handled by the algorithm `shrink-intersection` and we give the pseudocode in Figure 3. Consider spanning trees  $T_s, T_{s+1}, \dots, T_t$ . The input to `shrink-intersection` is  $T_s$  and a sequence of sets of edges  $\{(E_i, E'_i)\}_{i=s}^{t-1}$  such that  $T_{i+1} = T_i - E_i + E'_i$  and  $E_i \cap E'_i = \emptyset$  for  $i \in \{s, s+1, \dots, t-1\}$ . Then `shrink-intersection` contracts  $\bigcap_{i=s}^t T_i$  in  $T_s$ . It is then easy to see that one can compute the intersection via the edges  $\{(E_i, E'_i)\}_{i=s}^{t-1}$  as  $\bigcap_{i=s}^t T_i = T_s \setminus \bigcup_{i=s}^{t-1} (E_i \cup E'_i)$  (see full version for more details). Let  $\hat{T}_s$  be  $T_s$  with  $\bigcap_{i=s}^t T_i$

```

shrink-intersection( $T, \{(E_i, E'_i)\}_{i=s}^{t-1}$ )
 $\hat{T} \leftarrow T.\text{copy}()$ 
for  $e \in T \setminus \bigcup_{i=s}^{t-1} (E_i \cup E'_i)$  do
     $uv \leftarrow \hat{T}.\text{represented-edge}(e)$ 
    assume  $\deg_{\hat{T}}(u) \leq \deg_{\hat{T}}(v)$  (otherwise rename)
     $\hat{T}.\text{contract}(uv, u)$ 
end for
let  $id(e)$  denote the unique identifier of an edge  $e$ 
for  $i$  from  $s$  to  $t - 1$  do
     $\hat{E}_i \leftarrow \bigcup_{e \in E_i} (\hat{T}.\text{represented-edge}(e), id(e))$ 
     $\hat{E}'_i \leftarrow \bigcup_{e \in E'_i} (\hat{T}.\text{represented-edge}(e), id(e))$ 
end for
return  $(\hat{T}, \{(\hat{E}_i, \hat{E}'_i)\}_{i=s}^{t-1})$ 

```

■ **Figure 3** A subroutine used in our fast implementation **fast-swap** of randomized swap rounding; used to implicitly contract the trees of the given convex combination.

contracted. The vertex set of  $\hat{T}_s$  is different than the vertex set of  $T_s$ . Then as the sets of edges  $E_i$  and  $E'_i$  for all  $i$  are defined on the vertices in  $T_s$ , we need to map the endpoints of edges in  $E_i$  to the new vertex set of  $\hat{T}_s$ . Using the data structure presented in Lemma 11, this is achieved using the operations **represented-edge** and **orig-edge**, which handle mapping the edge to its new endpoints and maintaining the edge identifier, respectively.

The following lemma shows that **shrink-intersection** indeed contracts the intersection of the trees via the implicit representation. We leave the details of the proof for the full version.

► **Lemma 17.** *Let  $T_1, \dots, T_h$  be spanning trees and let  $\{(E_i, E'_i)\}_{i=1}^{h-1}$  be a sequence of edge sets defined on the same vertex set such that  $T_{i+1} = T_i - E_i + E'_i$  and  $E_i \cap E'_i = \emptyset$  for all  $i \in [h-1]$ . Contract  $\bigcap_{i=1}^h T_i$  in  $T_1, \dots, T_h$  to obtain  $\hat{T}_1, \dots, \hat{T}_h$ , respectively.*

*Let  $n_{T_1} = |T_1|$  and  $\gamma = \sum_{i=1}^{h-1} (|E_i| + |E'_i|)$ . Then **shrink-intersection** $(T_1, \{(E_i, E'_i)\}_{i=1}^{h-1})$  runs in time  $\tilde{O}(n_{T_1} + \gamma)$  and outputs  $(\hat{T}, \{(\hat{E}_i, \hat{E}'_i)\}_{i=1}^{h-1})$  where  $\hat{T} = \hat{T}_1$  and  $\hat{T}_{i+1} = \hat{T}_i - \hat{E}_i + \hat{E}'_i$  for all  $i \in [h-1]$ . Moreover,  $|E_i| = |\hat{E}_i|$  and  $|E'_i| = |\hat{E}'_i|$  for all  $i \in [h-1]$  and  $|\hat{T}| \leq \min\{n_{T_1}, \gamma\}$ .*

We use the algorithm in Theorem 14 for **merge-bases**. In **fast-swap**, the two trees that are merged  $\hat{T}_L$  and  $\hat{T}_R$  are the return values of the two recursive calls to **fast-swap**. The algorithm at this point has explicit access to the adjacency lists of both  $\hat{T}_L$  and  $\hat{T}_R$ , which are used as input to the algorithm **fast-merge**. The output of **fast-merge** will be the outcome of merging the two trees  $\hat{T}_L$  and  $\hat{T}_R$ , which are edges of potentially contracted trees from the original convex combination. We can use the operation **orig-edge** of the forest data structure of Lemma 11 for  $\hat{T}_L$  and  $\hat{T}_R$  to obtain the edges from the trees of the original convex combination. This extra bookkeeping will be handled implicitly.

We next prove that **fast-swap** is implementing **swap-round** and that it runs in near-linear time.

► **Lemma 18.** *Let  $\sum_{i=1}^h \delta_i \mathbb{1}_{T_i}$  be a convex combination of spanning trees of the graph  $G = (V, E)$  where  $n = |V|$ . Let  $T$  be a spanning tree such that  $T = T_1$  and let  $\{(E_i, E'_i)\}_{i=1}^{h-1}$  be a sequence of sets of edges such that  $T_{i+1} = T_i - E_i + E'_i$  and  $E_i \cap E'_i = \emptyset$  for all  $i \in [h-1]$ .*

*Then **fast-swap** $(T, \{(E_i, E'_i)\}_{i=1}^{h-1}, \{\delta_i\}_{i=1}^h) \stackrel{d}{=} \text{swap-round}(\delta_1, T_1, \dots, \delta_h, T_h)$  and the call to **fast-swap** runs in  $\tilde{O}(n_T + \gamma)$  time where  $n_T = |T|$  and  $\gamma = \sum_{i=1}^{h-1} (|E_i| + |E'_i|)$ .*

```

fast-swap( $T, \{(E_i, E'_i)\}_{i=s}^{t-1}, \{\delta_i\}_{i=s}^t$ )
  if  $s = t$  then
    return  $T$ 
  end if
   $\ell \leftarrow \max \left\{ \ell' \in \{s, s+1, \dots, t\} : \sum_{i=s}^{\ell'-1} |E_i| \leq \frac{1}{2} \sum_{i=s}^{t-1} |E_i| \right\}$ 
   $(\hat{T}, \{(\hat{E}_i, \hat{E}'_i)\}_{i=s}^{t-1}) \leftarrow \text{shrink-intersection}(T, \{(E_i, E'_i)\}_{i=s}^{t-1})$ 
   $\hat{E}_C \leftarrow E(\hat{T})$ 
  for  $i$  from  $s$  to  $\ell$  do
     $\hat{E}_C \leftarrow \hat{E}_C - \hat{E}_i + \hat{E}'_i$ 
  end for
   $\hat{T}_C \leftarrow \text{init}(V(\hat{T}), \hat{E}_C)$ 
   $\hat{T}_L \leftarrow \text{fast-swap}(\hat{T}, \{(\hat{E}_i, \hat{E}'_i)\}_{i=s}^{\ell-1}, \{\delta_i\}_{i=s}^{\ell})$ 
   $\hat{T}_R \leftarrow \text{fast-swap}(\hat{T}_C, \{(\hat{E}_i, \hat{E}'_i)\}_{i=\ell+1}^{t-1}, \{\delta_i\}_{i=\ell+1}^t)$ 
   $\hat{T}_M \leftarrow \text{fast-merge}(\sum_{i=s}^{\ell} \delta_i, \hat{T}_L, \sum_{i=\ell+1}^t \delta_i, \hat{T}_R)$ 
  return  $\hat{T}_M \cup (T \setminus \bigcup_{i=s}^{t-1} (E_i \cup E'_i))$ 
    
```

■ **Figure 4** A fast implementation of randomized swap rounding from [20].

**Proof.** One can immediately see `fast-swap` is an implementation of `divide-and-conquer-swap`. There are some bookkeeping details that are left out of the implementation, such as maintaining the set of edges returned by `fast-merge`, but these are easily handled. Lemma 16 shows that  $\text{divide-and-conquer-swap}(\delta_1, T_1, \dots, \delta_h, T_h) \stackrel{d}{=} \text{swap-round}(\delta_1, T_1, \dots, \delta_h, T_h)$ , implying  $\text{fast-swap}(T, \{(E_i, E'_i)\}_{i=1}^{h-1}, \{\delta_i\}_{i=1}^h) \stackrel{d}{=} \text{swap-round}(\delta_1, T_1, \dots, \delta_h, T_h)$ .

Now we prove the running time bound. Let  $R(n_T, \gamma)$  denote the running time of the call to `fast-swap`( $T, \{(E_i, E'_i)\}_{i=1}^{h-1}, \{\delta_i\}_{i=1}^h$ ). By Lemma 17, the running time of the call to `shrink-intersection` is  $\tilde{O}(n_T + \gamma)$ . Let  $(\hat{T}, \{(\hat{E}_i, \hat{E}'_i)\}_{i=1}^{h-1})$  be the output of `shrink-intersection`. Lemma 17 also guarantees that  $\gamma = \sum_{i=1}^{h-1} |\hat{E}_i| + |\hat{E}'_i|$  and  $|\hat{T}| \leq \min\{n_T, \gamma\}$ . Then by Lemma 11, constructing  $\hat{T}_C$  requires  $\tilde{O}(n_{\hat{T}} + \gamma)$  time. As the size of  $\hat{T}_L$  and  $\hat{T}_R$  is the same as  $\hat{T}$  and  $\hat{T}_C$ , the call to `fast-merge` runs in  $\tilde{O}(n_T + \gamma)$  time by Theorem 14. The time it takes to compute the returned tree is  $\tilde{O}(n_T + \gamma)$  as we have enough time to scan all of  $T$  and  $\bigcup_{i=1}^{h-1} (E_i \cup E'_i)$ . So the total time excluding the recursive calls is  $(n_T + \gamma) \cdot \alpha$  for where  $\alpha = O(\log^c(n_T + \gamma))$  for some fixed integer  $c$ .

As for the recursive calls, first define  $\gamma(s, t) := \sum_{i=s}^t (|E_i| + |E'_i|)$ . Then the running time of the first recursive call is  $R(n_{\hat{T}}, \gamma(1, \ell-1))$  and the second recursive call is  $R(n_{\hat{T}_C}, \gamma(\ell+1, h-1))$ . By choice of  $\ell$ , we always have that  $\gamma(1, \ell-1) \leq \frac{\gamma}{2}$ . As  $\ell$  is the largest integer such that  $\gamma(1, \ell-1) \leq \frac{\gamma}{2}$ , then  $\gamma(1, \ell) > \frac{\gamma}{2}$ . Therefore, we have  $\gamma(\ell+1, h-1) = \gamma - \gamma(1, \ell) < \frac{\gamma}{2}$ . Combining this with the fact that `shrink-intersection` guarantees that  $|\hat{T}| \leq \min\{n_T, \gamma\}$  and  $|\hat{T}_C| \leq \min\{n_T, \gamma\}$ , we have

$$R(n_T, \gamma) \leq 2R(\min\{n_T, \gamma\}, \gamma/2) + \alpha \cdot (n_T + \gamma).$$

Note that  $R(n_T, \gamma) = O(1)$  when  $n_T = O(1)$  and  $\gamma = O(1)$ .

We claim that  $R(a, b) \leq \alpha\beta \cdot (a + 8b \log b)$  is a valid solution to this recurrence for some sufficiently large but fixed constant  $\beta \geq 1$ . By choosing  $\beta$  sufficiently large it is clear that it holds for the base case. To prove the inductive step we see the following:

$$R(a, b) \leq 2R(\min\{a, b\}, b/2) + \alpha \cdot (a + b) \leq 2[\alpha\beta \cdot (\min\{a, b\} + 4b \log(b/2))] + \alpha \cdot (a + b).$$

Hence we need to verify that

$$2[\alpha\beta(\min\{a, b\} + 4b \log(b/2))] + \alpha \cdot (a + b) \leq \alpha\beta \cdot (a + 8b \log b). \quad (1)$$

Since  $\beta \geq 1$ , rearranging, it suffices to verify that

$$2 \min\{a, b\} + 8b \log(b/2) + b \leq 8b \log b.$$

As  $8b \log b - 8b \log(b/2) = 8b$  and  $2 \min\{a, b\} + b \leq 3b$ , this proves (1) and therefore  $R(n_T, \gamma) \leq \alpha\beta(n_T + 8\gamma \log \gamma) = \tilde{O}(n_T + \gamma)$ . This concludes the proof.  $\blacktriangleleft$

The proof of Theorem 7 then follows by combining Theorem 12 (and remarks after the theorem statement) and Theorem 15.

## 4 Sparsification via the LP Solution

Let  $G = (V, E)$  be a graph on  $n$  nodes and  $m$  edges and let  $x$  be a point in  $\text{ST}(G)$ . In this section we discuss Theorem 4, which shows that, via random sampling, one can obtain a sparse point  $x' \in \text{ST}(G)$  from  $x$ . The random sampling approximately preserves linear constraints and thus one can use this technique to obtain sparse LP solutions to the packing problems involving spanning tree (and more generally matroid) constraints. The sampling and analysis rely on Karger's well-known work on random sampling for packing disjoint bases in matroids. We paraphrase the relevant theorem.

► **Theorem 19** (Corollary 4.12 from [30]). *Let  $\mathcal{M}$  be a matroid with  $m$  elements and non-negative integer capacities on elements such that  $\mathcal{M}$  has  $k$  disjoint bases. Suppose each copy of a capacitated element  $e$  is sampled independently with probability  $p \geq 18(\ln m)/(k\epsilon^2)$  yielding a matroid  $\mathcal{M}(p)$ . Then with high probability the number of disjoint bases in  $\mathcal{M}(p)$  is in  $[(1 - \epsilon)pk, (1 + \epsilon)pk]$ .*

We restate Theorem 4 for the reader's convenience. We leave the details of the proof to the full version.

► **Theorem 20.** *Let  $x \in \text{ST}(G)$  be a rational vector such that  $Ax \leq b$  for a matrix  $A \in [0, 1]^{r \times m}$  and  $b \in [1, \infty)^r$ . Consider a random subgraph  $G' = (V, E')$  of  $G$  obtained by picking each edge  $e \in G$  with probability  $\alpha_e := \min\{1, \frac{36 \log(r+m)}{\epsilon^2} \cdot x_e\}$ . Then with high probability the following hold: (i)  $|E'| = O(n \ln(r+m)/\epsilon^2)$  (ii) there exists a fractional solution  $z \in \text{ST}(G)$  in the support of  $G'$  such that  $Az \leq (1 + 3\epsilon)b$ .*

► **Remark 21.** For problems that also involve costs, we have a fractional solution  $\mathbf{x}$  and an objective  $\sum_e c_e x_e$ . Without loss of generality we can assume that  $c_e \in [0, 1]$  for all  $e$ . The preceding proof shows that the sparse graph obtained by sampling supports a fractional solution  $\mathbf{z}$  such that  $\mathbb{E}[\sum_e c_e z_e] \leq (1 + \epsilon) \sum_e c_e x_e$ . Further,  $\sum_e c_e z_e \leq (1 + 3\epsilon) \sum_e c_e x_e$  holds with high probability as long as  $\max_e c_e \leq \sum_e c_e x_e$ . This condition may not hold in general but can be typically guaranteed in the overall algorithm by guessing the largest cost edge in an optimum integer solution.

► **Remark 22.** The proof in the preceding theorem also shows that with high probability the graph  $G'$  is connected and satisfies the property that  $A\mathbf{1}_{E'} \leq O(\log n/\epsilon^2)b$ . Thus any spanning tree of  $G'$  satisfies the constraints to a multiplicative  $O(\log n)$ -factor by fixing  $\epsilon$  to a small constant. This is weaker than the guarantee provided by swap-rounding.

## 5 Fast approximation scheme for solving the LP relaxation

In this section, we discuss Theorem 1, which gives a fast approximation scheme to solve the LP relaxation for CROSSING-ST. We recall the LP for CROSSING-ST.

$$\begin{aligned} \min \quad & \sum_{e \in E} c_e y_e \\ \text{subject to} \quad & Ay \leq b \\ & y \in \text{ST}(G) \end{aligned} \tag{P}$$

Note that even the feasibility problem (whether there exists  $y \in \text{ST}(G)$  such that  $Ay \leq b$ ) is interesting and important. We will mainly focus on the feasibility LP and show how we can incorporate costs in the full version of the paper. We recast the feasibility LP as a pure packing LP using an implicit formulation with an exponential number of variables. This is for technical convenience and to more directly apply the framework from [18]. For each tree  $T \in \mathcal{T}(G)$  we have a variable  $x_T$  and we consider the problem of packing spanning trees.

$$\begin{aligned} \text{maximize} \quad & \sum_{T \in \mathcal{T}} x_T \\ \text{subject to} \quad & \sum_{T \in \mathcal{T}} (A\mathbf{1}_T)_i \cdot x_T \leq b_i, \quad \forall i \in [k] \\ & x_T \geq 0, \quad \forall T \in \mathcal{T} \end{aligned} \tag{C}$$

The following is easy to establish from the fact that  $y \in \text{ST}(G)$  iff  $y$  can be written as a convex combination of the characteristic vectors of spanning trees of  $G$ .

► **Observation 23.** *There exists a feasible solution  $y$  to  $\mathcal{P}$  iff there exists a feasible solution  $x$  to  $\mathcal{C}$  with value at least 1. Further, if  $x$  is a feasible solution to  $\mathcal{C}$  with value  $(1 - \epsilon)$  there exists a solution  $y$  such that  $y \in \text{ST}(G)$  and  $Ay \leq \frac{1}{1-\epsilon}b$ .*

$\mathcal{C}$  is a pure packing LP, albeit in *implicit* form. In the full version of the paper, we show how to approximately solve the LP using MWU techniques and in particular we use the randomized MWU framework from [18] for positive LPs. The full version reviews the MWU framework and shows how to apply it along with other implementation details to achieve the concrete run times that we claim in Theorem 1.

---

## A Putting things together and extensions

In the main body of the paper we discussed the main technical results corresponding to Theorems 1, 4, and 7. In this section we give formal proofs of the corollaries stated in Section 1. In addition, we also describe some extensions and other related results that follow from the ideas in the preceding sections.

### A.1 Proofs of corollaries

We start with Corollary 3.

**Proof of Corollary 3.** Let  $G = (V, E)$  be the input graph with  $m$  edges and  $n$  vertices and let  $\epsilon > 0$ . Consider the LP relaxation to test whether  $G$  has a spanning tree with degree at most a given parameter  $B'$ . Theorem 1 implies that there exists a randomized algorithm that, with high probability, either correctly determines that there is no feasible solution to the LP, or outputs a fractional spanning tree  $y \in \text{ST}(G)$  such that  $\sum_{e \in \delta(v)} y_e \leq (1 + \epsilon)B'$  for all  $v$ . Using the algorithm, we can do binary search over the integers from 2 to  $n - 1$  to find the smallest value  $B$  for which the algorithm outputs a solution. We will focus on the scenario where the algorithm from Theorem 1 is correct in each of the  $O(\log n)$  calls in the binary search procedure; this happens with high probability. For the value of  $B$  found in the binary search, let  $y \in \text{ST}(G)$  be the solution that is output; we have  $\sum_{e \in \delta(v)} y_e \leq (1 + \epsilon)B$  for all  $v$ . Since the approximate LP solver correctly reported infeasibility for all  $B' < B$ , we have  $B - 1 < B^*$ , which implies  $B \leq B^*$ . As there is a feasible fractional spanning tree  $y$  such that  $\sum_{e \in \delta(v)} y_e \leq \lceil (1 + \epsilon)B \rceil$  for all  $v$ , the result of [43] implies that  $B^* \leq \lceil (1 + \epsilon)B \rceil + 1$ .

Regarding the run time, each call to the algorithm in Theorem 1 takes  $\tilde{O}(m/\epsilon^2)$  time since  $N = O(m)$  in the setting of BD-ST. Binary search adds only an  $O(\log n)$  multiplicative-factor overhead, leading to the claimed running time. ◀

We next prove Corollary 5. The algorithm described in the corollary takes advantage of Theorem 4 to sparsify the input graph, then runs the Fürer-Raghavachari algorithm [24].

**Proof of Corollary 5.** We will assume that the input is a graph  $G = (V, E)$  with  $m$  edges and  $n$  vertices. Let  $\epsilon > 0$ . As in the proof of Corollary 3, we can use Theorem 1 and binary search to find in  $\tilde{O}(\frac{m}{\epsilon^2})$  time, with high probability, a fractional spanning tree  $x \in \text{ST}(G)$  such that  $\sum_{e \in \delta(v)} x_e \leq (1 + \epsilon)B^*$  for all  $v \in V$ . By Theorem 4, we can use random

sampling based on  $x$  to obtain a subgraph  $G' = (V, E')$  of  $G$  such that with high probability we have  $|E'| = O(\frac{n \log(n+m)}{\epsilon^2})$  and there exists a fractional solution  $z \in \text{ST}(G)$  in the support of  $G'$  such that  $\sum_{e \in \delta(v)} z_e \leq (1 + 3\epsilon)(1 + \epsilon)B^* \leq (1 + 7\epsilon)B^*$  for all  $v \in V$  (for sufficiently small  $\epsilon$ ). The result of [43] implies there exists a spanning tree  $T$  in  $G'$  such that  $\max_{v \in V} \deg_T(v) \leq \lceil (1 + 7\epsilon)B^* \rceil + 1$ . For a graph  $H$  on  $n$  vertices and  $m$  edges, the algorithm of [24] runs in  $\tilde{O}(mn)$  time and outputs a spanning tree  $T$  such that the maximum degree of  $T$  is at most  $\text{OPT}(H) + 1$ , where  $\text{OPT}(H) = \min_{T \in \mathcal{T}(H)} \max_{v \in V} \deg_T(v)$ . Thus, the algorithm of [24] when applied to  $G'$ , outputs a spanning tree with degree at most  $\lceil (1 + 7\epsilon)B^* \rceil + 2$ , and runs in  $\tilde{O}(\frac{n^2}{\epsilon^2})$  time. ◀

We now prove Corollary 8. This corollary combines the LP solver of Theorem 1 and the fast implementation of randomized swap rounding of Theorem 7 to give a fast algorithm for CROSSING-MST.

**Proof of Corollary 8.** Let  $G = (V, E)$  be the input graph and  $\epsilon > 0$ . We want to solve  $\min\{c^T x : Ax \leq b, x \in \text{ST}(G)\}$ . By Theorem 1, there exists a randomized algorithm that runs in  $\tilde{O}(N/\epsilon^2)$  time and with high probability certifies the LP is infeasible or outputs  $y \in \text{ST}(G)$  such that  $c^T y \leq (1 + \epsilon)\text{OPT}$  and  $Ay \leq (1 + \epsilon)b$ . We then apply the fast implementation of randomized swap rounding of Theorem 7 to  $y$ , which runs in  $\tilde{O}(m/\epsilon^2)$  time and outputs a spanning tree  $T$ . If we only considered the feasibility version (i.e. find  $x \in \text{ST}(G)$  such that  $Ax \leq b$ ), then the existing results on swap rounding [20] imply that  $A\mathbf{1}_T \leq \min\{O(\log k / \log \log k)b, (1 + \epsilon)b + O(\log k)/\epsilon^2\}$  with high probability. In the cost version, [20] implies that  $A\mathbf{1}_T \leq \min\{O(\log k / \log \log k)b, (1 + \epsilon)b + O(\log k)/\epsilon^2\}$  with high probability, and  $\mathbb{E}[c^T \mathbf{1}_T] \leq \sum_e c^T x$ . Thus, the cost is preserved only in expectation. We can, however, apply Markov's inequality and conclude that  $\Pr[c^T \mathbf{1}_T \geq (1 + \epsilon)c^T x] \leq \frac{1}{1 + \epsilon} \leq 1 - \frac{\epsilon}{2}$  (for  $\epsilon$  sufficiently small). For a suitable choice of the high probability bound, we have that  $A\mathbf{1}_T \leq \min\{O(\log k / \log \log k)b, (1 + \epsilon)b + O(\log k)/\epsilon^2\}$  and  $c^T \mathbf{1}_T \leq (1 + \epsilon)c^T x$  with probability at least  $\frac{\epsilon}{2} - \frac{1}{2n^2}$ . We can assume that  $\epsilon > \frac{1}{n^2}$ , for otherwise the  $\frac{1}{\epsilon^2}$  dependence in the run time of the approximate LP algorithm is not meaningful; one can use other techniques including an exact LP solver. Thus, with probability at least  $\frac{\epsilon}{4}$ , we have  $c^T \mathbf{1}_T \leq (1 + O(\epsilon))c^T x \leq (1 + O(\epsilon))\text{OPT}$  and  $A\mathbf{1}_T \leq \min\{O(\log k / \log \log k)b, (1 + \epsilon)b + O(\log k)/\epsilon^2\}$ . To boost the  $\frac{\epsilon}{4}$  probability of success, we can repeat the rounding algorithm  $O(\frac{\log n}{\epsilon})$  times independently; with high probability, one of the trees will yield the desired bicriteria approximation. ◀

### Non-uniform degree bounds

We briefly sketch some details regarding Remark 6. First, we note that the algorithm for solving the LP relaxation handles the non-uniform degree bound case in  $\tilde{O}(m/\epsilon^2)$  time. It either certifies that the given bounds are infeasible or outputs a fractional solution with degree at most  $(1 + \epsilon)B_v$  for each  $v$ . We can then apply the result in [43] to know that there exists a spanning tree  $T$  in which the degree of each  $v$  is at most  $\lceil (1 + \epsilon)B_v \rceil + 1$ . We can apply sparsification from Theorem 4 to the fractional solution to obtain a sparse subgraph that contains a near-optimal fractional solution. It remains to observe that the Fürer-Raghavachari algorithm can be used even in the non-uniform setting via a simple reduction to the uniform setting. This was noted in prior work [34, 43] and we provide the details in the full version of the paper. This results in an  $\tilde{O}(n^2/\epsilon^2)$  time algorithm that either decides that the given non-uniform degree bounds are infeasible or outputs a spanning tree in which the degree of each node  $v$  is at most  $\lceil (1 + \epsilon)B_v \rceil + 2$ .

## A.2 Extensions and related problems

We focused mainly on BD-ST, BD-MST and CROSSING-MST. Here we briefly discuss related problems that have also been studied in the literature to which some of the ideas in this paper apply.

### Estimation of value for special cases of CROSSING-MST

As we remarked in Section 1, various special cases of CROSSING-MST have been studied. For some of these special cases one can obtain a constant factor violation in the constraint [37, 36]. We highlight one setting. One can view BD-MST as a special case of CROSSING-MST where the matrix  $A$  is a  $\{0, 1\}$ -matrix with at most 2 non-zeroes per column (since an edge participates in only two degree constraints); the result in [43] has been extended in [33] (see also [8]) to show that if  $A$  is a  $\{0, 1\}$ -matrix with at most  $\Delta$  non-zeroes per column, then the fractional solution can be rounded such that the cost is not violated and each constraint is violated by at most an additive bound of  $(\Delta - 1)$ . Theorem 1 allows us to obtain a near-linear time algorithm to approximate the LP. Combined with the known rounding results, this gives estimates of the integer optimum solution in near-linear time. Thus, the bottleneck in obtaining a solution, in addition to the value, is the rounding step. Finding faster iterated rounding algorithms is an interesting open problem even in restricted settings.

### Multiple cost vectors

In some applications one has multiple different cost vectors on the edges, and it is advantageous to find a spanning tree that simultaneously optimizes these costs. Such multi-criteria problems have been studied in several contexts. Let  $c_1, c_2, \dots, c_r$  be  $r$  different cost vectors on the edges (which we assume are all non-negative). In this setting it is typical to assume that we are given bounds  $B_1, B_2, \dots, B_r$  and the goal is to find a spanning tree  $T \in \mathcal{T}(G)$  satisfying the packing constraints such that  $c_j(T) \leq B_j$  for  $j \in [r]$ . We can easily incorporate these multiple cost bounds as packing constraints and solve the resulting LP relaxation via techniques outlined in Section 5. Once we have the LP solution we note that swap-rounding is oblivious to the objective, and hence preserves each cost in expectation. With additional standard tricks one can guarantee that the costs can be preserved to within an  $O(\log r)$  factor while ensuring that the constraints are satisfied to within the same factor guaranteed in Corollary 8.

### Lower bounds

BD-MST has been generalized to the setting where there can also be lower bounds on the degree constraints of each vertex. [43] and [33] showed that the additive degree bound guarantees for BD-MST can be extended to the setting with lower bounds in addition to upper bounds. One can also consider such a generalization in the context of CROSSING-MST. The natural LP relaxation for such a problem with both lower and upper bounds is of the form  $\min\{c^T x : Ax \leq b, A'x \geq b', x \in \text{ST}(G)\}$  where  $A, A' \in [0, 1]^{k \times m}$ ,  $b, b' \in [1, \infty)^k$ ,  $c \in [0, \infty)^m$ . Here  $A$  corresponds to upper bounds (packing constraints) and  $A'$  corresponds to lower bounds (covering constraints). This mixed packing and covering LP can also be solved approximately in near-linear time by generalizing the ideas in Section 5. Sparsification as well as swap-rounding can also be applied since they are oblivious to the constraints once the LP is solved. The guarantees one obtains via swap rounding are based on negative correlation and concentration bounds. They behave slightly differently for lower bounds. One obtains a tree  $T$  such that  $A\mathbf{1}_T \leq (1 + \epsilon)b + O(\log k)/\epsilon^2$  and  $A'\mathbf{1}_T \geq (1 - \epsilon)b' - O(\log k)/\epsilon^2$  with high probability. As in the other cases, the LP solution proves the existence of good integer solutions based on the known rounding results.

## Abstract

---

A classical branch of graph algorithms is graph transversals, where one seeks a minimum-weight subset of nodes in a node-weighted graph  $G$  which intersects all copies of subgraphs  $F$  from a fixed family  $\mathcal{F}$ . Many such graph transversal problems have been shown to admit polynomial-time approximation schemes (PTAS) for *planar* input graphs  $G$ , using a variety of techniques like the shifting technique (Baker, J. ACM 1994), bidimensionality (Fomin et al., SODA 2011), or connectivity domination (Cohen-Addad et al., STOC 2016). These techniques do not seem to apply to graph transversals with parity constraints, which have recently received significant attention, but for which no PTASs are known.

In the *even-cycle transversal* (ECT) problem, the goal is to find a minimum-weight hitting set for the set of even cycles in an undirected graph. For ECT, Fiorini et al. (IPCO 2010) showed that the integrality gap of the standard covering LP relaxation is  $\Theta(\log n)$ , and that adding sparsity inequalities reduces the integrality gap to 10.

Our main result is a primal-dual algorithm that yields a  $47/7 \approx 6.71$ -approximation for ECT on node-weighted planar graphs, and an integrality gap of the same value for the standard LP relaxation on node-weighted planar graphs.

## 1 Introduction

Transversal problems in graphs have received a significant amount of attention from the perspective of algorithm design. Such problems take as input a node-weighted graph  $G$ , and seek a minimum-weight subset  $S$  of nodes which intersect all graphs  $F$  from a fixed graph family  $\mathcal{F}$  that appears as subgraph in  $G$ . A prominent example in this direction is the fundamental FEEDBACK VERTEX SET (FVS) problem, where  $\mathcal{F}$  is the class of all cycles. FVS is one of Karp's 21 NP-complete problems [17]. It admits a 2-approximation in polynomial time [2, 5], which cannot be improved to a  $(2 - \varepsilon)$ -approximation for any  $\varepsilon > 0$  assuming the Unique Games Conjecture [18].

Recently, several graph transversal problems have been revisited in the presence of additional parity constraints [19, 21, 20, 23]. The natural parity variants of FVS are ODD CYCLE TRANSVERSAL (OCT) and EVEN CYCLE TRANSVERSAL (ECT), where one wishes to intersect the odd-length and even-length cycles of the input graph  $G$ , respectively. approximability of these problems is much less understood than that of FVS: for OCT, only an  $\mathcal{O}(\sqrt{\log n})$ -approximation is known [1], and for ECT, only a 10-approximation is known [21].

Planar graphs are a natural subclass of graphs in which to consider graph transversal problems. The interest goes back to Baker’s shifting technique [3], which yielded a PTAS for VERTEX COVER in planar graphs (where  $\mathcal{F}$  is the single graph consisting of an edge). The technique was generalized by Demaine et al. [8], who gave EPTASs for graph transversal problems satisfying a certain bidimensionality criterion, including FVS in *unweighted* planar graphs. That result was later extended to yield an EPTAS for FVS in unweighted  $H$ -minor free graphs [13], for any fixed graph  $H$ . In *edge-weighted* planar graphs, PTAS are known for edge-weighted STEINER FOREST and OCT [4, 16, 10].

On *node-weighted* planar graphs, the situation appears to be more complex. First, the existence of a PTAS for FVS on node-weighted planar graphs was a long-standing open question which was resolved only recently in a paper of Cohen-Addad et al. [7]. The authors presented a PTAS for FVS in node-weighted planar graphs, crucially exploiting the fact that the treewidth of  $G - S$  is bounded for feasible solutions  $S$ . The existence of an EPTAS for FVS in node-weighted planar graphs is still open.

To deal with cycle transversal problems (in node-weighted planar graphs) which are more complex than FVS, Goemans and Williamson [14] first proposed a primal-dual based framework. Their framework requires the cycle family  $\mathcal{F}$  to satisfy a certain uncrossing property. The latter property can be seen to be satisfied by OCT, DIRECTED FVS in directed planar graphs, and SUBSET FVS, which seeks a minimum-cost node set hitting all cycles containing a node from a given node set  $T$ . For those problems, the authors obtained 3-approximations<sup>1</sup>. The framework by Berman and Yaroslavtsev [14] also yields a 3-approximation for STEINER FOREST in node-weighted planar graphs [9, 22]. Berman and Yaroslavtsev [6] later improved the approximation factor for the same class of uncrossable cycle transversal problems from 3 to 2.4. For none of those problems, though, the existence of a PTAS is known.

The main question driving our work is whether the framework of Goemans and Williamson [14] (and its improvement by Berman and Yaroslavtsev [6]) can be extended to cycle transversal problems that do not satisfy uncrossability. In this paper we focus on ECT in node-weighted planar graphs as a natural such problem: even cycles are not uncrossable, and hence the frameworks by Goemans and Williamson [14] does not apply. Furthermore, the framework of Cohen-Addad et al. [7] requires that contracting edges only reduces the solution value, which is not the case for even cycles either. For *unweighted* planar graphs, it is still possible to obtain an EPTAS for ECT, by building on the work of Fomin et al. [12]. Their main result are EPTASs for bidimensional problems, which ECT is not (as contracting edges can change the parity of cycles). Yet, to obtain their result, they show that any transversal problem that satisfies the “ $\nu$ -transversability” and “reducibility” conditions has an EPTAS on  $H$ -minor free graphs (cf. [12, Theorem 1]). Both conditions are met by unweighted ECT<sup>2</sup>, which thus admits an EPTAS on  $H$ -minor free graphs. For ECT on node-weighted planar graphs, though, reducibility fails, and the existence of a PTAS is unknown. The currently best result for ECT is a 10-approximation, which was given by Fiorini et al. [11] for general graphs. They showed that the integrality gap of the standard covering LP relaxation for ECT is  $\Theta(\log n)$ , but that adding sparsity inequalities reduces the integrality gap to 10. No better than 10-approximation is known for ECT in node-weighted planar graphs.

<sup>1</sup> 18/7-approximations were claimed but later found to be incorrect [6].

<sup>2</sup>  $\nu$ -transversability follows from as graphs without even cycles have treewidth 2, and reducibility from unit weights and connectedness of the to-be-hit subgraphs  $F$ .

### 1.1 Our results

We prove an improved approximation algorithm for ECT in node-weighted planar graphs.

► **Theorem 1.** *ECT has an efficient  $47/7 \approx 6.71$ -approximation on node-weighted planar graphs.*

This improves the previously best 10-approximation by Fiorini et al. [11] for planar graphs.

Our algorithm takes as input a node-weighted planar graph  $G$  with node weights  $c_v \in \mathbb{N}$  for each  $v \in V(G)$ . We then employ a primal-dual algorithm that is based on the following natural covering LP for ECT and its dual, where  $\mathcal{C}$  denotes the set of even cycles in  $G$ :

$$\begin{array}{l|l}
 \min c^T x & \max \mathbb{1}^T y \\
 \text{(P}_{\text{ECT}}) \text{ s.t. } x(C) \geq 1 \quad \forall C \in \mathcal{C} & \text{s.t. } \sum_{C \in \mathcal{C}, v \in C} y_C \leq c_v \quad \forall v \in V(G) \\
 x \geq 0 & \text{(D}_{\text{ECT}}) \\
 & y \geq 0
 \end{array}$$

Fiorini et al. [11] proved that the integrality gap of this LP is  $\Theta(\log n)$ . Our main result is an improved integrality gap of this LP for ECT in planar graphs:

► **Theorem 2.** *The integrality gap of the LP (P<sub>ECT</sub>) is at most  $47/7 \approx 6.71$  in planar graphs.*

### 1.2 Our approach

Designing a primal-dual algorithm is far from trivial, as the imposed parity constraints rule out a direct application of the framework proposed by Goemans and Williamson [14]. Unlike in their work, *face-minimal even cycles* (even cycles containing a minimal set of faces in their interior) are not necessarily faces, and may thus overlap. Indeed, increasing the dual variables of face-minimal even cycles does not yield a constant-factor approximation in general.

Consider Figure 1, and let  $F$  be the inner face that is only incident to blue and black nodes. For an even number of 5-cycles surrounding  $F$ ,  $F$  is the only face-minimal even cycle

■ **Figure 1** The bottom path has odd length, and the number of length-5 faces at the top is even.

in the graph. Using only  $F$  for the dual increase, even including a reverse-delete step, leaves one blue node of each 5-cycle. Yet, an optimal solution would take a single red and blue node from one 5-cycle.

To circumvent this impediment, we establish strong structural properties of planar graphs related to ECT. Those properties along with results from matching theory allow us to algorithmically find a large set of pairwise face-disjoint even cycles whose dual variables we can then increment. Even with this set of cycles found, it remains technically challenging to bound the integrality gap. For this purpose, we first use the structure of minimal hitting sets of our graph to associate each such set with a hitting set in a subdivision of the so called 2-compression of our graph; the latter is a certain minor that we define in detail shortly. We then show that faces that are contained in even cycles we increment are incident to few

nodes on average. Crucial in this step is a technical result that is implicit in the work of Berman and Yaroslavtsev [6]. Eventually, this approach leads to an integrality gap of  $47/7$ , and an algorithm with the same approximation guarantee.

Due to space constraints, we defer proofs of statements marked by  $(\star)$  to the full version of the paper [15].

## 2 Primal-dual algorithm for ECT on node-weighted planar graphs

We describe a primal-dual, constant-factor approximation for ECT on node-weighted planar graphs. Our algorithm borrows some ideas from Fiorini et al. [11] for the DIAMOND HITTING SET (DHS) problem, which seeks a minimum-cost set of nodes in a node-weighted graph  $G$  that hits all *diamonds* (sub-divisions of the graph consisting of three parallel edges). For DHS, Fiorini et al. [11] employ a primal-dual algorithm to prove that the natural covering LP ( $P_{\text{ECT}}$ ) (where  $\mathcal{C}$  is replaced by the set of diamonds) has integrality gap  $\Theta(\log n)$ . We develop several new ideas to obtain a constant integrality gap.

We now outline the ideas of our primal-dual approach. Consider a planar input graph  $G$  with node costs  $c_v \in \mathbb{N}$  for each  $v \in V(G)$ . Given feasible dual solution  $y$  to ( $D_{\text{ECT}}$ ), let the *residual cost* of node  $v \in V(G)$  be  $c_v - \sum_{C \in \mathcal{C}, v \in C} y_C$ . Our primal-dual method begins with a trivial feasible dual solution  $y = \mathbb{0}$ , and the empty, infeasible hitting set  $S = \emptyset$ .

Then, in each iteration, we increase  $y_C$  for all  $C$  in some carefully chosen subset  $\mathcal{C}' \subseteq \mathcal{C}$  of even cycles, while maintaining dual feasibility, and until some *primary condition* is achieved. A common such primary condition is that some dual node-constraint becomes *tight* in the increase process, and hence the corresponding node ends up having residual cost 0.

When this happens, we add the node to  $S$ . Once  $S$  is a feasible ECT, our algorithm ends its first phase, and executes a problem-specific *reverse-delete* procedure. Here, we consider all nodes in  $S$  in reverse order of addition to  $S$ , and we delete such a node if the feasibility of  $S$  is maintained. We will later describe a subtle and crucial refinement of this reverse-delete procedure. Call the resulting final output of the algorithm  $S'$ .

During our algorithm, we will use the term *hitting set* to refer to  $S$ , and during the analysis we will use the term *hitting set* to refer to  $S'$ . We will say a hitting set is *feasible* if it is a feasible ECT, and refer to nodes of the hitting set as *hit nodes*.

In the next subsections, we will fill in the details of the algorithm, and analyze the cost of  $S'$  compared to the value of an optimal solution. We begin by defining the concept of “blended inequalities” and necessary graph compression operations. Blended inequalities were used by Fiorini et al. [11], and our definitions follow their’s closely.

### 2.1 Blended inequalities and compression

A *block* of  $G$  is an inclusion-maximal 2-connected subgraph of  $G$ . The *block graph* of  $G$  is the bipartite graph  $B_G$  with bipartition  $V(B_G) = B_1 \cup B_2$ , where  $B_1$  are the blocks of  $G$ ,  $B_2$  are the cut nodes of  $G$ , and  $(b_1, b_2) \in B_1 \times B_2$  is an edge if  $b_2$  is a node of  $b_1$ .

Let  $S$  be a partial solution to the given ECT instance at some point during the execution of our algorithm. Let  $G^S$  be the corresponding residual graph that we obtain from  $G - S$  by deleting all nodes that do not lie on even cycles. Our primal-dual algorithm first looks for an even cycle  $C$  in  $G^S$  such that at most two nodes of  $C$  have neighbours outside  $C$ . If such a cycle  $C$  is found, we increment its dual variable  $y_C$  until a node becomes tight. The reason for doing this is that such  $C$  will pay for at most two hit nodes, which we will show later.

If there is no even cycle  $C$  in  $G^S$  such that at most two nodes of  $C$  have neighbours outside  $C$ , we successively compress the residual graph  $G^S$  using two types of graph compression. To this end, first note that any minimal solution will only contain one node in the

interior of any induced path in  $G^S$ . Suppose we contract some path  $P$  of  $G^S$  of length at least 2 down to an edge  $e$ . Choosing a node in the interior of  $P$  is “equivalent” to choosing the edge  $e$ . This is the motivation for the 1-compression.

Suppose we contract two  $u$ - $v$  paths  $P_1, P_2$  with lengths of different parity down to edges  $e_1, e_2$ , respectively. We will find it helpful to think of these edges as a single *twin* edge between  $u$  and  $v$  whose parity is *flexible*. This is the motivation for the 2-compression.

Formally, we will successively compress  $G^S$  as follows:

- Obtain the 1-compression  $G_1^S$  of  $G^S$  by repeatedly *folding* degree-2 nodes  $v$ , as long as they exist, which means to delete  $v$  and adding the edge  $uw$  between its neighbors  $u, w$ .
- Note that no pair of nodes in  $G_1^S$  is connected by more than two edges. Obtain  $\bar{G}_1^S$  from  $G_1^S$  by replacing each pair of parallel edges by a *twin* edge. In  $\bar{G}_1^S$ , we now once again fold degree-2 nodes as long as those exist. The resulting graph is the 2-compression  $G_2^S$  of  $G^S$ .

See Figure 2 for examples of 1- and 2-compression of a graph. In the following, we will omit the superscript  $S$  from  $G_1^S, \bar{G}_1^S,$  and  $G_2^S$  if this is clear from the context. Let  $G_3$  be obtained from  $G_2$  by replacing every edge of  $G_2$  with a path of length two. If a twin edge was replaced, call the two edges of the path added *twin edges*. By an abuse of notation, we call a cycle of  $G_1, G_2$  or  $G_3$  even if it contains a twin edge, or if its preimage in  $G$  is even.

■ **Figure 2** The graph  $G$  and its 1- and 2-compression  $G_1$  and  $G_2$ .

In the following, we will sometimes call the subgraph  $Q$  of  $G$  whose contraction yields a subgraph  $R$  of  $G_2$  the *preimage* of  $R$ . If  $R$  is an edge, call  $Q$  a *piece*, and say  $Q$  *corresponds* to  $R$ . Furthermore, call  $u, v$  *ends* of  $Q$  and other nodes of  $Q$  *internal nodes*. If the edge was twin, call the piece *twin*, otherwise, call the piece *single*. The blocks of a piece are cycles and paths, and the block graph of a piece is a path. Each cycle of a piece is called an *elementary cycle*. For an elementary cycle  $C$ , call its two nodes  $u_C$  and  $v_C$  with neighbours outside  $C$  *branch nodes*. Call the two  $u_C - v_C$ -paths  $P_1, P_2$  in  $C$  the *handles* of  $C$ , which form the *handle pair*  $(P_1, P_2)$ . For an illustration, see the red and light blue edges in Figure 2.

The reason for defining  $G_3$  is that intuitively selecting a node inside a piece corresponds to selecting the edge corresponding to the piece in  $G_2$ . It will be simpler for us if our hitting set consists of only nodes, so we subdivide each edge of  $G_2$ . Suppose that  $S$  is the partial (and infeasible) hitting set for the cycles in  $\mathcal{C}$  at some point during the algorithm. Further, assume that  $G^S$  has even cycles, but none with at most two outside neighbours. In this case, if an even cycle  $C'$  in  $G^S$  contains an internal node of some piece  $Q$ , then  $C' \cap Q$  is a path between the ends of  $Q$ ; see Figure 3. It follows that  $C'$  has the form  $v_1 P_1 v_2 P_2 \dots v_k P_k v_1$ , where for  $i = 1, \dots, k$  nodes  $v_i, v_{i+1 \bmod k}$  are ends of some piece  $Q_i$ , and  $P_i$  is a  $v_i - v_{i+1}$  path in  $Q_i$ . For  $i = 1, \dots, k$ , pieces  $Q_i, Q_j$  for  $i \neq j$  are disjoint except for their ends.

■ **Figure 3** The light blue cycle in  $G$  has two  $u$ - $t$  paths lying in different pieces of  $G$ ; the dashed path has odd length.

We say that  $C'$  in  $G^S$  corresponds to cycle  $C = (v_1, \dots, v_k)$  in  $G_2^S$ . For such  $C$ , its *blended inequality* is

$$\sum_v a_v^C x_v \geq 1, \tag{*}$$

where  $a_v^C \in \{0, 1/2, 1\}$  for all nodes  $v$ , and where the support of  $a^C$  is contained in the node set of the preimage of  $C$ . We next provide a precise definition of the coefficients of (\*). With those, one can show that (\*) is dominated by a convex combination of inequalities  $x(C) \geq 1$  in  $(P_{ECT})$ .

Consider an elementary cycle of the preimage of  $C$  and let  $h_1, h_2$  be its two handles. For each of these handles, we define its residual cost as the smallest residual cost of any of its internal nodes. Suppose that the residual cost of  $h_2$  is at most that of  $h_1$ . We will also call  $h_1$  the *dominant*, and  $h_2$  the *non-dominant* handle of this cycle. As an invariant, our algorithm maintains that the designation of dominant and non-dominant handles of an elementary cycle does not change throughout the algorithm's execution.

Suppose first that the residual cost of  $h_1$  is strictly larger than that of  $h_2$ . In this case, let  $a_v^C = 1$  for all internal nodes of handle  $h_1$ , and let  $a_v^C = 0$  of the internal nodes of  $h_2$ . If the residual cost of both handles is the same, we let  $a_v^C = 1/2$  on internal nodes of both handles.

In certain cases, we need to *correct the parity* of the constructed inequality. This is necessary if  $a^C$  as defined above is 0,1 (i.e., if all elementary cycles of  $C$  have a strictly dominant handle), and if the cycle formed by all dominant handles is odd. In this case, we pick an arbitrary elementary cycle on  $C$ , and declare it *special*. For this special cycle, we then set  $a_v^C = 1$  for the internal nodes on *both* handles. Following the same reasoning as Fiorini et al. [11] for DHS, we can show the following for ECT:

► **Lemma 3.** *Each feasible point of our LP  $(P_{ECT})$  satisfies any blended inequality.*

In our algorithm, we assume that inequalities (\*) are part of  $(P_{ECT})$ . Throughout the algorithm, we increase dual variables  $y_{\otimes}$  of such inequalities.

We will sometimes say that variable  $y_{\otimes}$  (or cycle  $C$ ) *pays for*  $\sum_{v \in S'} a_v^C$  hit nodes. It is well-known (see, e.g., Goemans and Williamson [14]) that if during any iteration dual variables for a family of blended inequalities are incremented uniformly, and the dual variables pay for  $\alpha$  hit nodes (of  $S'$ ) on average, then the final solution produced by the algorithm is  $\alpha$ -approximate.

The motivation for blended inequalities is to pay for no more than one node in each piece. Consider the example in Figure 1. Here, the bottom black dashed path is odd, there are an even number of handle pairs in the top part, and  $\varepsilon$  is small. Suppose we set  $a_v^C = 1/2$

on internal nodes of each handle. If we were to increment the inequality  $(\otimes)$ , all the blue nodes of weight 1 would become tight, and after reverse-delete, the algorithm would keep one blue node for each handle pair. However, selecting a red node and a blue node would be a cheaper solution. This could be achieved by setting  $a_v^C = 1$  for red and black nodes, and  $a_v^C = 0$  on blue nodes, until the residual costs of the red nodes become 1, and afterwards setting  $a_v^C = 1/2$  on internal nodes of each handle.

During its execution, the algorithm carefully chooses a family of even cycles  $\mathcal{C}$  in  $G_2^S$  and increments the dual variables of certain blended inequalities for each  $C \in \mathcal{C}$  until a node becomes tight, or the blended inequality changes; i.e. the residual costs of two handles of a handle pair, which were previously not equal, become equal.

In their primal-dual algorithms for cycle transversal problems with uncrossing property, Goemans and Williamson [14] started with the infeasible “hitting set”  $S = \emptyset$ . While  $S$  is infeasible, the dual variables for faces of the residual digraph that are cycles are incremented. A reverse-delete step is applied at the end. The authors show that tight examples for their algorithm feature so called *pocket* subgraphs. Not surprisingly, the improved algorithm of Berman and Yaroslavtsev [6] has to pay special attention to these pockets to obtain the improvement in performance guarantee.

## 2.2 Pockets and their variants

The following definition of crossing cycles was elementary to the approach by Goemans and Williamson [14] for cycle transversal problems in planar graphs.

► **Definition 4.** *In an embedded planar graph, two cycles  $C_1, C_2$  cross if  $C_i$  contains an edge intersecting the interior of the region bounded by  $C_{3-i}$ , for  $i = 1, 2$ . That is, the plane curve corresponding to the embedding of the edge in the plane intersects the interior of the region of the plane bounded by  $C_{3-i}$ . A set of cycles  $\mathcal{C}$  is laminar if no two elements of  $\mathcal{C}$  cross.*

Next, we formally define pockets, and we also introduce the new notion of “pseudo-pockets”, the lack of which will help us “cover” our graph with even cycles.

► **Definition 5.** *Let  $G$  be a graph and let  $\mathcal{C}$  be a collection of cycles in  $G$ . A pseudo-pocket of  $(G, \mathcal{C})$  is a connected subgraph  $G'$  of  $G$  which contains a cycle such that at most two nodes of  $G'$  have neighbours outside  $G'$ . A pocket of  $(G, \mathcal{C})$  is a pseudo-pocket that contains a cycle of  $\mathcal{C}$ . A pocket is minimal if it contains no pocket as a proper induced subgraph.*

■ **Figure 4** (a) Graph formed by red nodes is a pocket. (b) Crossing cycles in red and black.

## 2.3 Identifying families of even cycles via tilings

The  $12/5$ -approximation algorithm of Berman and Yaroslavtsev [6] for DIRECTED FVS in node-weighted planar digraphs  $G$  proceeds roughly as follows.

It starts with the empty hitting set  $S = \emptyset$ . As long as  $S$  is not a hitting set for the directed cycles of  $G$ , it first looks for a pocket  $H$  of the residual digraph  $G^S$ , that is the digraph obtained from  $G - S$  by deleting all nodes not on a directed cycle. It then increments the dual variables for the set of face minimal directed cycles of  $H$ , which happen to be faces. It then adds any nodes that become tight to  $S$ . Once  $S$  is feasible, the algorithm performs a reverse deletion step.

As pointed out, in our setting, face-minimal even cycles may not be faces, and may cross. Following Berman and Yaroslavtsev [6], we wish to “cover” our residual graph with face-minimal even cycles which do not cross, we call this a “tiling”; see Figure 5 iii). As we will see, this tiling allows us to identify the dual variables to increase. Let us formalize the correspondence between edges of the dual between odd faces and even faces.

► **Definition 6.** *Let  $H$  be a plane graph without pseudo-pockets. For each face  $f$  of  $H$ , let  $v_f$  be the corresponding node of the planar dual  $H^*$ . A tile of  $H$  is an even cycle  $C$  of  $H$  bounding one or two faces. If  $C$  is a single face  $f$ , we say that  $C$  corresponds to the node  $v_f$ . If  $C$  bounds two faces  $f$  and  $g$ , we say that  $C$  corresponds to the edge  $v_f v_g \in E(H^*)$ . We say that nodes  $v_f, v_g$  and the faces  $f, g$  are covered by the tile.*

For a node  $v$  of  $H^*$ , let  $f_v \subset E(H)$  be the edges on the boundary of the corresponding face of  $H$ . Denote by  $h_\infty$  the node of  $H^*$  corresponding to the infinite face.

Given  $wh_\infty \in E(H^*)$ , a cycle  $C^1 \subset E(H)$  corresponds to  $wh_\infty$  if  $C^1$  is a cycle of  $f_w \Delta f_{h_\infty}$ , or  $C^1 = C' \Delta f_w$  and  $C'$  is a cycle of  $f_w \Delta f_{h_\infty}$ . We also call such a cycle  $C^1$  a tile and say that  $C^1$  covers  $h_\infty, w$ , and the corresponding faces.

Given a matching  $E' \subset E(H^*)$  and  $V' \subset V(H^*)$ , with  $E' = \{e_1, \dots, e_\ell\}$  and  $V' = \{v_1, \dots, v_t\}$ , a set of tiles  $\mathcal{T} = \{C_1, \dots, C_{\ell+t}\}$  corresponds to  $E' \cup V'$  if  $C_i$  corresponds to  $e_i$  for  $i = 1, \dots, \ell$  and  $C_{j+\ell}$  corresponds to  $v_j$  for  $j = 1, \dots, t$ .

In Figure 5 i), cycle  $C$  bounds two faces  $f$  and  $g$ ; see also Figure 5 ii).

■ **Figure 5** Diagrams i) and ii) show cycles in green and corresponding edges of the dual graph in red. (i) The red edge corresponds to the symmetric difference of two finite faces. (ii) The red edge corresponds to the symmetric difference of a finite and infinite face. Diagrams iii) and iv) show a tiling indicated by the boundaries of the various finite regions in white, light grey, etc and the corresponding matching.

► **Definition 7.** *For a plane graph  $H$ , a set  $\mathcal{T}$  of tiles is a pseudo-tiling if no face of  $H$  is covered by more than one tile. If the node  $v_{h_\infty}$  corresponding to the infinite face of  $H$  is not covered by  $\mathcal{T}$ , we call  $\mathcal{T}$  a tiling.*

Certain tilings are particularly desirable; we will define these the next.

► **Definition 8.** *Let  $\alpha \in (0, 1)$ . A tiling is  $\alpha$ -quasi-perfect if it covers all even finite faces, a  $\beta$ -fraction of odd finite faces of  $G^S$ , and a  $\psi$ -fraction of the finite faces of  $G^S$  are even, where  $\beta(1 - \psi) + 2\psi \geq \alpha$ .*

Let  $C$  be an even cycle in  $G_2^S$ , and recall that we say that  $C$  pays for  $\sum_{v \in S} a_v^C$  hit nodes. For an even cycle in a tiling consisting of two faces, we bound the number of hit nodes it pays for by the number of hit nodes each face pays for.

We will show that a finite face of our graph intersects at most  $18/7$  hit nodes on average (over all finite faces). Ideally, we would want to cover all faces by a tiling. Then an even cycle of our tiling is incident to at most  $36/7$  hit nodes on average, twice the amount a face of our graph intersects on average. Alas, tilings covering all faces need not always exist. Thus, we try to find a tiling that covers as many finite faces as possible. Suppose that we find a tiling  $\mathcal{T}$  that covers a set  $\mathcal{T}_{\text{Faces}}$  of finite faces consisting of  $\alpha$ -fraction of the finite faces of our graph. It follows that a face of  $\mathcal{T}_{\text{Faces}}$  will be incident to at most  $18/7\alpha$  hit nodes on average, and so an even cycle of the tiling  $\mathcal{T}$  is incident to at most  $36/7\alpha$  hit nodes on average. Intuitively, even faces pay for fewer hit nodes than even cycles containing two faces, so it is good if a tiling contains many even faces. The motivation for quasi-perfect tilings is that it is good if a large fraction of faces are covered by the tiling and if the tiling contains a lot of even faces. We prove the following key result in Appendix A.

► **Theorem 9.** *Let  $H$  be a 2-compression of some planar graph  $G$ , that has an even cycle and contains no pockets. Then  $H$  has a  $2/3$ -quasi-perfect tiling.*

## 2.4 The algorithm in detail

We formally state our algorithm. It takes as input a planar graph  $G$  with cost function  $c : V(G) \rightarrow \mathbb{N}$ . Let  $\mathcal{C}(G)$  be the set of even cycles of  $G$ , and let  $\text{opt}(G, c)$  be the minimum cost of an *even cycle transversal* of  $G$ , which is a set of nodes intersecting each cycle in  $\mathcal{C}(G)$ .

As we will see, the algorithm returns an even cycle transversal  $S$  of  $G$  whose cost is at most  $(47/7)\text{opt}(G, c)$ . We start with the empty candidate  $S := \emptyset$ . In each iteration, the algorithm looks for an even cycle  $C$  in the residual graph  $G^S$  such that at most two nodes of  $C$  have outside neighbours. If we find such  $C$ , increment the variable  $y_C$  until a node becomes tight. If no such cycle exists, the algorithm computes the 2-compression of  $G^S$ , and in it, we find an inclusion-minimal pocket  $H$  of  $G_2^S$ . Using Theorem 9, we find a  $2/3$ -quasi-perfect tiling  $\mathcal{T}_H$  of  $H$  and increments the dual variables for the blended inequalities for each  $C \in \mathcal{T}_H$ . The algorithm then adds all nodes  $X$  that became tight to our candidate hitting set  $S$ .

During an iteration, for each handle pair  $(Q_1, Q_2)$  for which the set  $X$  of nodes that became tight contains a node in the interior of each handle, our algorithm will choose two nodes  $a, b \in X$  with  $a$  in the interior of  $Q_1$  and  $b$  in the interior of  $Q_2$  and define  $(a, b)$  to be a *node pair*. For instance, in Figure 2 if  $v$  and  $v'$  are the only nodes added during some iteration then the algorithm would define  $(v, v')$  to be a node pair. For a set of nodes  $X$  added during the same iteration, nodes in a pair are considered to be added *before* any node not in a pair.

At the end of the algorithm, we perform a non-trivial reverse-delete procedure. Formally, let  $w_1, \dots, w_\ell$  be the nodes of  $S$  in the order they were added to  $S$  by the algorithm, where for nodes  $w_i, w_j$  that were added during the same iteration if  $w_i$  is in a pair and  $w_j$  is not, then  $i < j$ . That is, for reverse-delete purposes, nodes not in a pair are considered for deletion first. For  $p = \ell, \ell - 1, \dots, 1$ , if  $w_p$  is not in a node pair, then if  $S \setminus \{w_p\}$  is a feasible ECT, the algorithm deletes  $w_p$  from  $S$ ; otherwise, it does not. If  $w_p$  is in a node pair  $(w_p, w')$ , then if  $S \setminus \{w_p, w'\}$  is a feasible hitting set, then delete both  $w_p, w'$  from  $S$ ; else, keep both  $w_p, w'$ .

The intuition behind the caveat in our reverse-delete step is that node pairs are often very useful to keep, because they disconnect a piece. Consider the example in Figure 6. There is a piece with green nodes of cost 2, and an odd number of length-5 faces with red and blue

## 25:10 Hitting Weighted Even Cycles in Planar Graphs

■ **Algorithm 2.1** EvenCycleTransversal( $G, c$ ).

---

**Input** : A planar graph  $G$  with node costs  $c : V(G) \rightarrow \mathbb{N}$ .

---

striped nodes of cost 1. The black nodes have cost infinity. The bottom dashed path has odd length. In the 2-compression shown on the right, all length-5 faces in the figure belong to one piece. Suppose the blended inequality chooses the length-5 face with the green nodes as the special cycle, and increments the blended inequality for this graph. One sees that the red, blue striped and green nodes become tight simultaneously.

To see that reverse delete orders need to be chosen carefully, consider the following adversarial ordering: in reverse delete, consider the two green nodes other than  $v$  first, then consider the red nodes, and then consider one blue striped node on each handle. Finally, consider the remaining blue striped nodes. One can see that the algorithm would end up with  $v$  and one blue striped node per handle, which is significantly more costly than the optimum which selects the solution consisting of one red and one blue striped node on a handle pair. This completes the description of our approximation algorithm for ECT, whose complete pseudo-code is given as Algorithm 2.1.

■ **Figure 6** The red and blue striped nodes have weight 1, black nodes have infinite weight and green nodes have cost 2. The bottom dashed black path has odd length. The number of length-5 faces at the top is assumed to be even.

## 2.5 Analysis of approximation ratio

We claim the algorithm to be a  $47/7$ -approximation for ECT on node-weighted planar graphs.

Fix an input planar graph  $G$  with node costs  $c_v \in \mathbb{N}$ . Consider a set  $S \subseteq V(G)$  of nodes and a node  $v \in S$ . A cycle  $C$  is a *pseudo-witness cycle* for  $v$  with respect to  $S$  if  $C \cap S = \{v\}$ . If  $C$  is additionally even, then  $C$  is a *witness cycle* for  $v$ . Note that if  $S$  is an inclusion-minimal ECT for  $G$ , then there is a set  $W_v$  of witness cycles for each node in  $v \in S$ . If the reverse-delete procedure does not delete any node of  $S$ , then each node not in a pair has a witness cycle and for each pair, at least one of the nodes in the pair has a witness cycle.

The analyses of the algorithms by Goemans and Williamson [14] and by Berman and Yaroslavtsev [6] for SUBSET FVS on planar graphs rely crucially on the fact that, each node of an inclusion-wise minimal solution has a witness cycle. Goemans and Williamson [14] showed that one can find a laminar collection  $\mathcal{A}$  of witness cycles. Laminar families are well-known to have a natural tree representation. The key argument of both algorithms is that for each *leaf cycle*  $C$  of the laminar family, one can increment the dual variable of at least one face contained in the region defined by  $C$ . Further, this dual variable pays only for the hit node that  $C$  is a witness of. This is used to argue that a large portion of the dual variables they incremented pay for a single hit node. An additional bound on how many nodes the other dual variables pay for is proven exploiting the sparsity of planar graphs.

For ECT, however, we do not have laminar witness cycles. Instead, we must extend the analysis of Berman and Yaroslavtsev [6] to find a set of laminar pseudo-witness cycles.

Consider some time  $\bar{t}$  during the algorithm when applied to  $(G, c)$ . Let  $S_{\bar{t}}$  be the current hitting set and  $G^{S_{\bar{t}}}$  the residual graph. Let  $\{\sum_{v \in V(G)} a_v^C \geq 1\}_{C \in \mathcal{L}}$  be the set of inequalities of the increased dual variables. Here,  $\mathcal{L}$  will be either a single cycle of  $G^{S_{\bar{t}}}$ , or a tiling of  $G_2^{S_{\bar{t}}}$ . We wish to show that the primal increase rate towards the final set  $S'$  at time  $\bar{t}$ ,  $\sum_{C \in \mathcal{L}} \sum_{v \in S'} a_v^C$  is at most  $47/7$  times the dual increase rate  $|\mathcal{L}|$ .

If the algorithm incremented  $y_C$ , where  $C$  was a cycle of  $G$  for which at most two nodes have outside neighbours, then the inequality we increase is  $\sum_{v \in C} x_v \geq 1$ . As  $S'$  is minimal under reverse-delete,  $|C \cap S'| \leq 2$ , and hence the primal increase rate  $\sum_{v \in S'} a_v^C = |C \cap S'|$  is at most twice the dual increase rate 1.

Otherwise, if the algorithm did not increment  $y_C$ , then there is no cycle  $C$  of  $G^{S_{\bar{t}}}$  such that at most two nodes of  $C$  have neighbours outside  $C$ . Hence, the set of increased inequalities are the blended inequalities of a tiling  $\mathcal{T}_H$  of an inclusion-minimal pocket  $H$  of  $G_2^{S_{\bar{t}}}$ . For a cycle  $C$  of  $G_2^{S_{\bar{t}}}$ , let  $\sum_{v \in V(G^{S_{\bar{t}}})} a_v^C \geq 1$  be the blended inequality  $C$  (see Equation  $\circledast$ ).

Recall that informally speaking, we wish to pay for at most one hit node inside a piece. To do this, we need the following theorem which generalizes a result by Fiorini et al. [11, Theorem 5.7] and tells us the structure of a minimal solution within a piece.

► **Theorem 10.** *Let  $S'$  be the output of Algorithm 2.1 on input  $(G, c)$ . Consider an edge  $uw \in E(G_2^{S_i})$  on the even cycle whose dual variable we increase, and let  $Q$  be the piece corresponding to  $uw$  in  $G$ . Then exactly one of the following occurs:*

- (C1)  $S'$  contains no internal node of  $Q$ ,
- (C2)  $S'$  contains exactly one node of  $Q$ , and this node is a cut-node of  $Q$ ,
- (C3)  $S'$  contains exactly two nodes of  $Q$ , and they belong to opposite handles of a cycle of  $Q$ ,
- (C4)  $S'$  contains exactly one node per elementary cycle of  $Q$ , each belonging to the interior of some handle of the corresponding cycle.

**Proof.** If  $S'$  contains two nodes  $a$  and  $b$  in the interiors of different handles of a pair, then since removing both  $a$  and  $b$  disconnects  $u$  from  $w$  in  $Q$ , our algorithm would delete all other nodes of  $V(Q) \setminus \{u, w\}$  from  $S'$ . If  $u$  or  $w$  were in  $S'$ , then our algorithm would delete both  $a$  and  $b$ . Thus,  $u, w \notin S'$ , and case (C3) holds.

Similarly, if  $S'$  contains a cut node  $z$ , then since removing  $z$  disconnects from  $u$  from  $v$  in  $Q$ , our algorithm would delete all other nodes of  $V(Q) \setminus \{u, v\}$  from  $S'$ . If  $u$  or  $w$  were in  $S'$ , then our algorithm would delete  $z$ . Thus,  $u, w \notin S'$ , and case (C2) holds.

If  $u$  or  $w$  is in  $S'$ , then for any  $r \in S' \cap (V(Q) \setminus \{u, w\})$  there cannot be an even cycle of  $G$  which intersects  $S'$  only at  $r$  as such a cycle would have to go through  $u$  or  $w$ , and thus  $S'$  contains no internal node of  $Q$  and case (C1) holds.

Assume that cases (C1), (C2) and (C3) do not hold, so  $u, w \notin S'$ . Let  $(P_1, P_2)$  be a handle pair on  $Q$  such that  $P_1$  contains a hit node  $t$  in its interior and  $P_2$  does not. Suppose that  $Y_1, Y_2$  was another handle pair with no hit node on either of  $Y_1$  or  $Y_2$ . By our deletion procedure, there must be an even cycle  $C$  which intersects  $S'$  at  $t$  only. Such a cycle  $C$  uses the handle  $P_1$  and one handle  $Y_i$  of the pair  $Y_1, Y_2$ . Let  $C'$  be the cycle obtained from  $C$  by replacing the paths  $P_1$  and  $Y_i$  in  $C$  by the paths  $P_2$  and  $Y_{3-i}$ . Since the lengths of different handles of a pair have different parity,  $C'$  is even. Since  $P_2, Y_1$  and  $Y_2$  contain no nodes of  $S'$ ,  $C'$  contains no nodes of  $S'$ , which is a contradiction. Since a handle can only contain one hit node of  $S'$ , this implies that case (C4) holds. ◀

Given a hitting set  $S'$  output by Algorithm 2.1, we wish to construct a corresponding hitting set for  $G_3^{S_i}$  such that the primal increase rate of any particular blended inequality (with respect to  $S'$ ) is equals the number of nodes of  $S'_3$  on the corresponding cycle of  $G_3^{S_i}$ .

► **Definition 11.** *Let  $S'$  be a hitting set output by Algorithm 2.1. The corresponding hitting set for  $G_3^{S_i}$  is the set  $S'_3 \subset V(G_3^{S_i})$  obtained by first taking the nodes of  $S' \cap V(G_3^{S_i})$ . Now, consider an edge  $uv$  of  $G_2^{S_i}$  with corresponding piece  $P$ . Replace  $uv$  by the path  $uw_p v$  in  $G_3^{S_i}$ , and add  $w_p$  to  $S'_3$  if  $P - S'$  has two components.<sup>3</sup>*

▷ **Claim 12.** Let  $C$  be the preimage of an even cycle in  $G_2^{S_i}$ , and  $C_3$  the corresponding cycle in  $G_3^{S_i}$ . We claim  $\sum_{v \in S'} a_v^C \leq |C_3 \cap S'_3| + 1$ . Further, if  $C$  does not contain a twin edge, then  $\sum_{v \in S'} a_v^C \leq |C_3 \cap S'_3|$ .

**Proof.** Define  $b^C$  as follows: For a handle pair, while one handle has greater residual cost than the other set  $b_v^C = 1$  for  $v$  on the handle of greater residual cost  $b_v^C = 0$  on internal nodes of the other handle (change  $b^C$  whenever residual costs become equal). Otherwise,  $b_v^C = 1/2$  on internal nodes of both handles. In short,  $b_v^C$  are the coefficients  $a_v^C$  if we had not redefined  $a_v^C = 1$  for nodes on the special cycle.

<sup>3</sup> Note that the minimality of  $S'$  implies that removing  $S'$  from  $P$  yields at most two connected components.

Let  $uw \in E(G_2^{S_i})$ ,  $Q$  be the preimage of  $uw$  in  $G^{S_i}$  and  $uw_Qw$  be the subdivision of  $uw$  in  $G_3^{S_i}$ . Let  $S'_3$  be the corresponding hitting set of  $S'$  for  $G_3^{S_i}$ . We claim  $\sum_{v \in S' \cap (Q \setminus \{u,w\})} b_v^C = |S'_3 \cap \{w_Q\}|$ . We decide which case of Theorem 10 is satisfied by  $uw$  and  $S'$ .

- If  $uw$  and  $S'$  satisfy (C1), then  $\sum_{v \in S' \cap (Q \setminus \{u,w\})} b_v^C = 0$ . Since  $S'$  contains no internal node of  $Q$ ,  $Q \setminus S$  is connected, and hence  $S'_3$  does not contain  $w_Q$ . Hence  $\sum_{v \in S' \cap (Q \setminus \{u,w\})} b_v^C = |S'_3 \cap \{w_Q\}|$ .
- If  $uw$  and  $S'$  satisfy (C2) or (C3), then  $S'$  does not contain either end node of  $Q$ , and contains either a single cut node of  $Q$ , or exactly two nodes of  $Q$  in the interiors of two handles of a handle pair of  $Q$ . Thus,  $S' \cap Q$  consists either of a single node  $v$  for which  $b_v^C = 1$ , or two nodes  $j, k$  for which  $b_j^C = b_k^C = 1/2$ , and so  $\sum_{v \in S' \cap Q} b_v^C = 1$ .

In case (C2) or (C3),  $Q \setminus S'$  is disconnected, so  $|S'_3 \cap \{w_Q\}| = 1$ . Hence,  $\sum_{v \in S' \cap (Q \setminus \{u,w\})} b_v^C = |S'_3 \cap \{w_Q\}|$ .

- Suppose  $S'$  satisfies (C4). Suppose, for sake of contradiction that, Algorithm 2.1 added a node pair  $(\ell', m)$  on some handle pair  $(P_1, P_2)$  of  $Q$ . It then follows from the reverse-delete step that the final solution  $S'$  contains both  $\ell'$  and  $m$ , or none of them. Since we do not contain a node pair, the deletion procedure of Algorithm 2.1 implies the algorithm did not add a node pair with nodes in  $Q$ . Hence, throughout the algorithm, for each handle pair  $(P_1, P_2)$  of  $Q$ , the handle  $P_i$ , which contains a hit node in its interior must have strictly less residual cost than the other. Hence  $b_v^C = 0$  on handle  $P_i$ . This implies

$$\sum_{v \in (V(Q) \setminus \{u,w\})} b_v^C = 0 . \tag{1}$$

Thus  $\sum_{v \in S' \cap (Q \setminus \{u,w\})} b_v^C = |S'_3 \cap \{w_Q\}|$ .

Let  $C = v_1 v_2 \dots v_\ell v_1$ . Let  $Q_i$  be the piece corresponding to  $v_i v_{i+1 \bmod \ell}$ . Let  $q_i$  be the node resulting from subdividing  $v_i v_{i+1 \bmod \ell}$  in  $G_2^{S_i}$  to obtain  $G_3^{S_i}$ . Let  $C_3 := v_1 q_1 v_2, q_2, \dots, v_\ell q_\ell$  the cycle corresponding to  $C$  in  $G_3^{S_i}$ . We showed

$$\sum_{v \in S' \cap (Q_i \setminus \{u,w\})} b_v^C = |S'_3 \cap \{q_i\}| . \tag{2}$$

Summing (2) for  $i = 1, \dots, \ell$  yields  $\sum_{v \in S' \cap (\cup_{i=1}^{\ell} Q_i \setminus \{v_1, v_2, \dots, v_\ell\})} b_v^C = |\{q_1, q_2, \dots, q_\ell\} \cap C_3|$ .

Noting  $b_{v_i}^C = 1$  for each  $i$  and  $b_v^C = 0$  for  $v \notin \cup_{j=1}^{\ell} Q_j$ , yields

$$\sum_{v \in S'} b_v^C = |C_3 \cap S'_3| . \tag{3}$$

Let us now relate  $a_v^C$  to  $b_v^C$ . If  $C$  has no twin edge, then the blended inequality coefficients  $a_v^C$  are equal to  $b_v^C$ , therefore  $\sum_{v \in S} a_v^C = |C_3 \cap S'_3|$ .

In general,  $C$  may contain a twin edge. In this case,  $a_v^C$  differs from  $b_v^C$  only in the interior of the handles  $H_1, H_2$  of the special cycle: then either  $b_v^C = \frac{1}{2}$  in the interior of  $H_1$  and  $H_2$ , or  $b_v^C = 0$  in the interior of the dominant handle, and  $b_v^C = a_v^C$  everywhere else.

If  $b_v^C = \frac{1}{2}$  in the interior of  $H_1$  and  $H_2$ , then note from Theorem 10 there are at most two nodes of  $S'$  on  $H_1 \cup H_2$ . Thus,  $\sum_{v \in S} a_v^C \leq \sum_{v \in S} b_v^C + 1$ .

Otherwise,  $b_v^C = 0$  in the interior of the dominant handle, and  $b_v^C = a_v^C$  everywhere else. Since  $S$  contains at most one node from the dominant handle  $\sum_{v \in S} a_v^C \leq \sum_{v \in S} b_v^C + 1$ . Thus,  $\sum_{v \in S} a_v^C \leq |C_3 \cap S'_3| + 1$  completing the proof.  $\triangleleft$

To show that  $|C_3 \cap S'_3| + 1$  is small on average we need the fact that  $S'_3$  is a minimal ECT, which is stated in the following remark.

## 25:14 Hitting Weighted Even Cycles in Planar Graphs

► **Remark 13.** Let  $S'$  be the output of Algorithm 2.1 on input  $(G, c)$ . Let  $S'_3$  be the corresponding hitting set for  $G_3^{S'_i}$  in Definition 11. Then each  $v \in S'_3$  has a witness cycle.

For a node  $h$  and cycle  $C$ , denote by  $C \circ h$  that  $h$  lies on  $C$ .

► **Definition 14.** Let  $\mathcal{R}$  be a set of cycles of a graph  $G$ , and let  $S \subset V(G)$ . The debit graph for  $\mathcal{R}$  and  $S$  is the bipartite graph  $\mathcal{D}_G = (\mathcal{R} \cup S, E)$  with edges  $E_{\mathcal{R}} = \{(C, s) \in \mathcal{R} \times S \mid C \circ s\}$ .

Given an embedding of  $G$  and a set  $\mathcal{R}$  of faces of  $G$ , we can obtain an embedding of  $\mathcal{D}_G$  by placing a node  $v_M$  inside the face  $R$  for each  $R \in \mathcal{R}$ . This shows the following observation.

► **Observation 15** ([14, 6]). *If  $\mathcal{R}$  is a set of faces of  $G$ , then the debit graph is planar.*

Note that for  $\mathcal{R}$  a set of cycles, a cycle  $R \in \mathcal{R}$ , the number of nodes  $|R \cap S|$  that  $R$  pays for in the hitting set is the degree of  $R$  in the debit graph.

Recall the definition of the SUBSET FVS problem, which seeks a minimum-weight node set  $X$  which intersects all cycles from  $\mathcal{C}_T$ , the collection of cycles in  $G$  which contain some node from a given set  $T \subseteq V(G)$ . Observe that each node of  $S'_3$  has a witness cycle in  $G_3^{S'_i}$ ; therefore, it is an inclusion-minimal hitting set for the collection  $\mathcal{C}_T$  with  $T = S'_3$ . Goemans and Williamson [14, Lemma 4.2] showed that any inclusion-minimal hitting set for  $\mathcal{C}_T$  has a laminar set of witness cycles, which implies that there is a laminar set of pseudo-witness cycles  $\mathcal{A}$  for hitting set  $S'_3$ .

► **Proposition 16** ([14, Lemma 4.2 specialized for SUBSET FVS]). *Let  $G'$  be a planar graph and let  $T \subseteq V(G')$ . Let  $\mathcal{C}_T$  be the set of cycles of  $G'$  containing at least one node of  $T$ , and let  $X$  be an inclusion-minimal hitting set for  $\mathcal{C}_T$ . Then there is a laminar set of cycles  $\mathcal{A} = \{A_x \mid x \in X\}$ , satisfying  $A_x \in \mathcal{C}_T$  and  $A_x \cap X = \{x\}$ .*

Applying Proposition 16 to  $G' = G_3$  and  $X = T = S'_3$  implies there is a laminar set  $\mathcal{A} = \{A_x \mid x \in S'_3\}$  of cycles satisfying  $A_x \cap S'_3 = \{x\}$ . In other words,  $\mathcal{A}$  is a laminar set of pseudo-witness cycles for  $S'_3$ . Note that cycles of  $\mathcal{A}$  may not be even, hence they may be pseudo-witness cycles for  $S'_3$ , but not necessarily witness cycles for nodes of  $S'_3$ .

Recall that, during the current iteration, our algorithm incremented the blended inequalities of the cycles in a  $2/3$ -quasi-perfect tiling  $\mathcal{T}_H$  of  $H$ . Recall  $H$  is an inclusion-minimal pocket of  $G_2^{S'_i}$ . By abuse of notation, let  $\mathcal{T}_H$  be the corresponding cycles of  $G_3^{S'_i}$ . Let  $\mathcal{D}$  be the debit graph formed using  $G_3^{S'_i}$ , the cycle set  $\mathcal{T}_H$  and hitting set  $S'_3$ .

Obtain graph  $\mathcal{D}'$  from  $\mathcal{D}$  by replacing each even cycle  $C$  containing two faces with the two faces that compose it. To be precise, construct  $\mathcal{D}'$  by first taking all nodes of  $S'_3$  and all faces of  $H$  that lie inside some even cycle of  $\mathcal{T}_H$  as the vertex set. For each edge  $(C, v) \in E(\mathcal{D})$ , if the cycle  $C$  consist of two faces  $f_1, f_2$  add the edges  $(f_1, v)$  and  $(f_2, v)$  to  $\mathcal{D}'$ , otherwise add the edge  $(C, v)$  to  $\mathcal{D}'$  (see Figure 7). Delete isolated vertices from  $\mathcal{D}'$ . If  $f_i$  is not incident to any hit nodes  $v$ , we remove  $f_i$  from  $\mathcal{D}'$ . Let  $\mathcal{T}_{\text{Faces}(H)}$  be the “face nodes” of  $\mathcal{D}'$ . Let  $\mathcal{F}_{\text{all}(H)}$  denote the finite faces of  $H$ . Let  $\mathcal{F}_H$  denote the set of finite faces of  $H$  that contain a hit node. Observe that  $M \cap S'_3 = \emptyset$  for each  $M \in \mathcal{F}_{\text{all}(H)} \setminus \mathcal{F}_H$ . Now

$$\begin{aligned} \sum_{M \in \mathcal{T}_H} |M \cap S'_3| &\leq \sum_{M \in \mathcal{T}_{\text{Faces}(H)}} |M \cap S'_3| \\ &\leq \sum_{M \in \mathcal{F}_{\text{all}(H)}} |M \cap S'_3| - |\mathcal{F}_H \setminus \mathcal{T}_{\text{Faces}(H)}| = \sum_{M \in \mathcal{F}} |M \cap S'_3| - |\mathcal{F}_H \setminus \mathcal{T}_{\text{Faces}(H)}|. \end{aligned} \quad (4)$$

■ **Figure 7** Left: A possible debit graph  $\mathcal{D}$  with the cycles of the tiling in Figure 5. Right: the graph  $\mathcal{D}'$  obtained by replacing each cycle with the faces that compose it.

■ **Figure 8** A graph consisting of a tessellation of the plane with twice as many triangles as dodecagons. None of the triangles are adjacent, so a maximum tiling covers only the even dodecagons.

The first inequality holds, because for each cycle  $C$  consisting of two faces  $f_1$  and  $f_2$  we have  $|C \cap S'_3| \leq |f_1 \cap S'_3| + |f_2 \cap S'_3|$ . The second inequality holds, because each face of  $\mathcal{F}_H$  contains a hit node, and so  $|C \cap S'_3| \geq 1$  for each  $C \in \mathcal{F}_H$ . The last inequality holds, because by definition  $|M \cap S'_3| = 0$  for all  $M \in \mathcal{F}_{\text{all}(H)} \setminus \mathcal{F}_H$ .

If our tiling covers  $2/3$  of all finite faces, then  $|\mathcal{T}_{\text{Faces}(H)}| \leq 2|\mathcal{T}_H|$  and  $(2/3)|\mathcal{F}_H| \leq |\mathcal{T}_{\text{Faces}(H)}|$ , so  $|\mathcal{F}_H| \leq 3|\mathcal{T}_H|$ . Alas, one can show that a tiling that covers  $2/3$  of all finite faces does not always exist; see Figure 8. To overcome this impediment, we will show that  $|\mathcal{F}_H| \leq 3|\mathcal{T}_H|$  holds for a  $2/3$ -quasi-perfect tiling. Suppose that our  $2/3$ -quasi-perfect tiling covers a  $b$ -fraction of the odd faces in  $\mathcal{F}_H$ , and a  $c$ -fraction of the faces in  $\mathcal{F}_H$  which are even. Let  $\mathcal{F}_{\text{even}(H)}$  be the even finite faces of  $\mathcal{F}_H$ . Then, as  $\mathcal{F}_H \setminus \mathcal{F}_{\text{even}(H)}$  are the odd faces of  $\mathcal{F}_H$ , and  $\mathcal{T}_{\text{Faces}(H)} \setminus \mathcal{F}_{\text{even}(H)}$  are the odd faces covered by our tiling, it holds that  $b|\mathcal{F}_H \setminus \mathcal{F}_{\text{even}(H)}| = |\mathcal{T}_{\text{Faces}(H)} \setminus \mathcal{F}_{\text{even}(H)}|$ . Simplifying, we get

$$b|\mathcal{F}_H| + (1 - b)|\mathcal{F}_{\text{even}(H)}| \leq |\mathcal{T}_{\text{Faces}(H)}| \leq 2|\mathcal{T}_H| - |\mathcal{F}_{\text{even}(H)}| .$$

By rearranging, we get  $b|\mathcal{F}_H \setminus \mathcal{F}_{\text{even}(H)}| + 2|\mathcal{F}_{\text{even}(H)}| \leq 2|\mathcal{T}_H|$ . Noting that  $b(1 - c) + 2c \geq 2/3$ , and rearranging once more, yields

$$\frac{2}{3}|\mathcal{F}_H| \leq b|\mathcal{F}_H \setminus \mathcal{F}_{\text{even}(H)}| + 2|\mathcal{F}_{\text{even}(H)}| \leq |\mathcal{T}_{\text{Faces}(H)}| \leq 2|\mathcal{T}_H| .$$

Noting that  $|\mathcal{F}_{\text{even}(H)}|/|\mathcal{F}_H| = c$  and  $b(1 - c) + 2c \geq 2/3$ , we get

$$3|\mathcal{T}_H| \geq \frac{3}{2}(b(1 - c) + 2c)|\mathcal{F}_H| \geq |\mathcal{F}_H| . \tag{5}$$

By (4), in order to bound  $\sum_{M \in \mathcal{T}_H} |M \cap S'_3|$ , it suffices to bound  $\sum_{M \in \mathcal{F}} |M \cap S'_3|$ . To do this, we prove the following extension of the work by Berman and Yaroslavtsev [6, Theorem 4.1].

## 25:16 Hitting Weighted Even Cycles in Planar Graphs

► **Theorem 17.** *Let  $H$  be an inclusion-wise minimal pocket of  $G$ . Let  $S \subset V(G)$  be a set of nodes with some set  $\mathcal{A}$  of laminar pseudo-witness cycles. Let  $\mathcal{R}$  be a set of finite faces of  $H$  such that each cycle of  $\mathcal{A}$  contains a face of  $\mathcal{R}$  in its interior. Then  $\sum_{M \in \mathcal{R}} |M \cap S| \leq \frac{18}{7} |\mathcal{R}|$ .*

We defer the proof of Theorem 17 to Subsection A.1.

Let  $\mathcal{A}$  be a set of laminar witness cycles for  $S'_3$ . If we were to set  $\mathcal{R} = \mathcal{F}_H$  (the set of finite faces of  $H$  incident to a hit node), then each cycle  $A \in \mathcal{A}$  contains a face of  $\mathcal{R}$  in its interior, namely any face inside  $A$  that is incident to the hit node of  $S'_3$  on  $A$ . Thus,  $S'_3, \mathcal{A}$  and  $\mathcal{R}$  meet the conditions of Theorem 17.

To recap, we wish to bound the primal increase rate  $\sum_{M \in \mathcal{T}_H} \sum_{v \in S} a_v^M$ , so we analyze the expression  $\sum_{M \in \mathcal{T}_H} |M \cap S'_3|$ . Recall from Claim 12 that  $\sum_{v \in S} a_v^M$  is at most one more than  $|M \cap S'_3|$  and  $\sum_{v \in S} a_v^M = |M \cap S'_3|$  if  $M$  contains no twin edge. We bound  $\sum_{M \in \mathcal{T}_H} |M \cap S'_3|$  by looking at the quantity  $\sum_{M \in \mathcal{F}_H} |M \cap S'_3|$ , because  $\mathcal{F}_H$  fits the conditions of Theorem 17. One could then use  $|\mathcal{F}_H| \leq 3|\mathcal{T}_H|$  (by (5)), to bound  $\sum_{M \in \mathcal{T}_H} \sum_{v \in S} a_v^M$  in terms of the dual increase rate  $|\mathcal{T}_H|$ . We will use  $3|\mathcal{T}_H| \geq \frac{3}{2}(b(1-c) + 2c)|\mathcal{F}_H|$  to obtain a stronger bound.

Let  $\mathcal{T}$  be our 2/3-quasi-perfect tiling from Theorem 9. Recall from Definition 8 that the fraction  $\beta$  of odd finite faces that are covered by the tiling, and the fraction  $\psi$  of finite faces of  $H$ , that are even satisfy  $\beta(1-\psi) + 2\psi \geq \alpha$ . Let  $\mathcal{A}$  be a set of pseudo-witness cycles in  $H$  for  $S'_3$ , the corresponding set for the hitting set  $S'$  returned by our algorithm. Define  $\mathcal{R} = \mathcal{F}_H$ . We have that every cycle of  $\mathcal{A}$  contains a face of  $\mathcal{R}$  in its interior. Thus,  $\mathcal{R}, \mathcal{A}$  and  $S'_3$  satisfy the conditions of Theorem 17. Therefore,

$$\sum_{M \in \mathcal{T}_H} |M \cap S'_3| \leq \left( \sum_{M \in \mathcal{F}_H} |M \cap S'_3| \right) - |\mathcal{F}_H \setminus \mathcal{T}_{\text{Faces}(H)}| \leq \frac{18}{7} |\mathcal{F}_H| - |\mathcal{F}_H \setminus \mathcal{T}_{\text{Faces}(H)}|. \quad (6)$$

Note that  $\sum_{v \in S} a_v^M \leq |M \cap S|$ , unless  $M$  contains a twin edge. If  $M \in \mathcal{T}$  is the disjoint union of two odd faces which share an edge, then  $M$  will not contain a twin edge. That is,  $M$  can only contain a twin edge if  $M \in \mathcal{F}_{\text{even}(H)}$ , so  $M$  is an even face then. So

$$\sum_{M \in \mathcal{T}_H} \sum_{v \in S} a_v^M \leq \sum_{M \in \mathcal{T}_H} |M \cap S| + |\mathcal{F}_{\text{even}(H)}| \leq \frac{18}{7} |\mathcal{F}_H| - |\mathcal{F}_H \setminus \mathcal{T}_{\text{Faces}(H)}| + |\mathcal{F}_{\text{even}(H)}|. \quad (7)$$

Recall that  $c = |\mathcal{F}_{\text{even}(H)}|/|\mathcal{F}_H|$  is the fraction of finite faces of  $\mathcal{F}_H$  which are even, and that  $b = |\mathcal{T}_{\text{Faces}(H)} \setminus \mathcal{F}_{\text{even}(H)}|/|\mathcal{F}_H \setminus \mathcal{F}_{\text{even}(H)}|$  is the fraction of odd finite faces of  $\mathcal{F}_H$  covered by our tiling. Note that

$$\begin{aligned} |\mathcal{F} \setminus \mathcal{T}_{\text{Faces}(H)}| &= |\mathcal{F}_H \setminus \mathcal{F}_{\text{even}(H)}| - |\mathcal{T}_{\text{Faces}(H)} \setminus \mathcal{F}_{\text{even}(H)}| \\ &= |\mathcal{F} \setminus \mathcal{F}_{\text{even}(H)}| - b|\mathcal{F}_H \setminus \mathcal{F}_{\text{even}(H)}| = (1-b)(1-c)|\mathcal{F}_H|. \end{aligned}$$

We now recall (5), by which  $3|\mathcal{T}_H| \geq \frac{3}{2}(b(1-c) + 2c)|\mathcal{F}_H|$ .

Substituting these bounds for  $|\mathcal{F}_H|$  and  $|\mathcal{F}_H \setminus \mathcal{T}_{\text{Faces}(H)}|$  into (7), we obtain

$$\begin{aligned} \sum_{M \in \mathcal{T}_H} \sum_{v \in S} a_v^M &\leq c|\mathcal{F}_H| + \frac{18}{7} \left( \frac{2}{b(1-c) + 2c} |\mathcal{T}_H| \right) - (1-b)(1-c)|\mathcal{F}_H| \\ &= \frac{2c}{b(1-c) + 2c} |\mathcal{T}_H| + \frac{18}{7} \left( \frac{2}{b(1-c) + 2c} |\mathcal{T}_H| \right) - \frac{2(1-b)(1-c)}{b(1-c) + 2c} |\mathcal{T}_H|. \end{aligned}$$

If we maximize the right-hand side factor  $\frac{2c}{(b(1-c)+2c)} + \frac{36}{7(b(1-c)+2c)} - \frac{2(1-b)(1-c)}{(b(1-c)+2c)}$  subject to  $b(1-c) + 2c \geq 2/3$ , we obtain that the right-hand side is bounded by  $\frac{47}{7} |\mathcal{T}_H|$ .

This completes the proof of Theorem 1 modulo the proof of Theorem 9; i.e., the fact that large quasi-perfect tilings can be computed efficiently. We deal with this in the appendix.

**A** Obtaining a 2/3-quasi-perfect tiling

We now show how to find the 2/3-quasi perfect tiling in line 8 of Algorithm 2.1. The following result states that the minimal pockets picked by the algorithm have such tilings.

► **Theorem 9.** *Let  $H$  be a 2-compression of some planar graph  $G$ , that has an even cycle and contains no pockets. Then  $H$  has a 2/3-quasi-perfect tiling.*

To prove this theorem we will use the following lemma.

► **Lemma 18.** *For any set  $S$ , any pseudo-pocket contained in  $G_2^S$  contains an even cycle.*

**Proof.** Informally speaking, the proof will show that any pseudo-pocket without even cycles contains an odd cycle for which only two nodes have outside neighbours; this, however, cannot appear in the 2-compression, as we would have replaced this cycle by an edge in  $G_2^S$ .

Suppose, for sake of contradiction, that  $G_2^S$  contained a pseudo-pocket  $Q$  without even cycles. Since each node of  $Q$  is in an even cycle of  $G_2$  and  $Q$  contains no even cycle,  $Q$  contains exactly two nodes  $u$  and  $v$  with neighbours outside  $Q$ , and each node of  $Q$  lies on a  $u$ - $v$  path of  $Q$ . Let  $B_u$  and  $B_v$  be the blocks of  $Q$  containing  $u$  and  $v$  in the block graph  $\mathcal{B}$  of  $Q$ , respectively (see Figure 9).

If  $\mathcal{B}$  is not a path, then there would be some block  $B_1$  that does not lie on a  $B_u$ - $B_v$  path in  $\mathcal{B}$ , and thus there would be a node of  $B_1$  that would not lie on a  $u$ - $v$  path in  $Q$  – a contradiction. Hence,  $\mathcal{B}$  is a path. Let  $B$  be a block of  $Q$ . Suppose for a contradiction

■ **Figure 9** Graph  $Q$  consisting of blocks labelled  $B_1, B_2, B_3, B_4, B_u, B_v$ . Block  $B_1$  depicted in blue contains nodes not on any  $u$ - $v$  path, which is a contradiction.

that  $B$  contains a cycle  $C$  and a node  $v'$  of  $C$  with a neighbour  $u' \in V(B)$  outside  $C$ . Since  $v'$  is not a cut node, there is a path  $P$  from  $u'$  to  $C \setminus v'$ . Construct the  $u'$ - $v'$  path  $P'$  from  $P$  by traversing  $P$  from  $u'$  to the first node  $w'$  of  $C \setminus v'$  and appending to that a  $w'$ - $v'$  path in  $C$ . Since  $Q$  contains no even cycles, the cycles  $P' \cup v'u'$  and  $C$  are odd. Then the cycle formed by the edges  $E(C) \Delta E(P' \cup v'u')$ , that is edges of  $C$  or  $P' \cup v'u'$ , but not both, has length  $|E(C)| + |E(P' \cup v'u')| - 2|E(C) \cap E(P' \cup v'u')|$  which is even, and hence a contradiction. Thus if  $B$  contains a cycle then it does not contain nodes outside the cycle, or put simply  $B$  is a cycle. Since we assume  $B$  contains no even cycles,  $B$  is an odd cycle. Thus, the blocks of  $Q$  are odd cycles or edges. Since  $Q$  contains at least one cycle, there is an odd cycle  $C'$ . Since  $\mathcal{B}$  is a path,  $C'$  contains 2 nodes  $a$  and  $b$  with neighbours outside  $C'$ . However,  $G_2^S$

cannot contain such an odd cycle, as that we would have contracted the two  $a$ - $b$  paths of  $C'$  to parallel edges and then replaced them by a twin edge; see Figure 10. This completes the proof. ◀

■ **Figure 10** Cycle is replaced by an edge in 2-compression.

For any set  $S$ , if  $G_3^S$  contained a pseudo-pocket  $Q$  without even cycles, then  $Q$  was obtained from a subgraph  $Q'$  of  $G_2^S$  by subdividing edges. Then  $Q'$  would be a pseudo-pocket of  $G_2^S$  without even cycles. This contradicts Lemma 18. This shows the following corollary.

► **Corollary 19.** *For any set  $S$ , any pseudo-pocket of  $G_3^S$  contains an even cycle.*

Recall from Definition 6 and the paragraph afterwards, that a pseudo-tiling of our graph corresponds to the union of a matching of the dual graph and a set of even faces. A tiling corresponds to the union of a matching of the dual graph not containing any edge incident to the infinite face and a set of even finite faces. Under this correspondence, the existence of large pseudo-tilings is a much more natural thing to prove. Let us first formally define a large pseudo-tiling.

► **Definition 20.** *Let  $\alpha \in (0, 1)$ . A pseudo-tiling  $\mathcal{T}$  is  $\alpha$ -pseudo-perfect if it covers all even faces (including the infinite face if it is even) and a  $\beta$ -fraction of the odd faces, and a  $\psi$ -fraction of the faces of  $H$  are even, where  $\beta(1 - \psi) + 2\psi \geq \alpha$ .*

We will first prove the existence of large pseudo-perfect pseudo-tilings. We fix an embedding of  $H$ . For any multigraph  $W$ , let  $\text{oc}(W)$  be the number of odd components of  $W$ . Recall pseudo-tilings correspond to matchings. Our proof will use Tutte’s Theorem stated below, which informally speaking, says that the absence of a large matching implies the existence of a small set of vertices whose removal results in a graph with a large number of connected components of odd size.

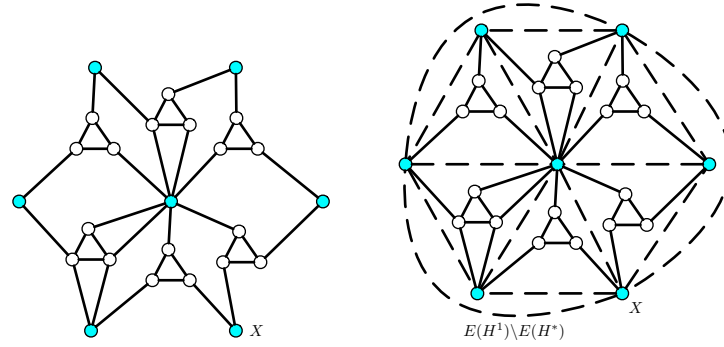

► **Theorem 21 (Tutte’s Theorem).** *For any graph  $G$ , the number of nodes of  $G$  which are not covered by a maximum size matching of  $G$  is at most*

$$\text{oc}(G \setminus X) - |X| . \tag{8}$$

*for some  $X \subset V(G)$ . Further, if some node  $v \in V(G)$  is covered by every maximum matching of  $G$ , then (8) holds for some  $X \subset V(G)$  containing  $v$ .*

The main idea of why such large pseudo-perfect pseudo-tilings should exist is that by Tutte’s Theorem, the absence of a large pseudo-tiling implies that for some set  $X$  of nodes of the dual graph  $H^*$ , the set of odd components of  $H^* \setminus X$  is large relative to  $|X|$ .

Construct a new graph  $H^1$  as follows. Start with the graph  $H^*$  and add as many edges as possible between nodes of  $X$  while preserving planarity and not creating any faces of length two (see Figure 11). We will show that each odd component of  $H^1 \setminus X$  lies in a different face of  $H^1[X]$  and that  $H^1$  contains at most two faces of length two. Thus using Euler’s formula,  $|E(H^1[X])| \leq 3|V(H^1[X])| - 4$ ,  $H^1[X]$  does not have too many edges. The crucial observation is that since each odd component of  $H^1 \setminus X$  lies in a different face of  $H^1[X]$ , each

■ **Figure 11** The graph  $H^*$  with set  $X \subset V(H^*)$  (depicted in blue) on the left. On the right, the graph  $H^1$  obtained from  $H^*$  by adding edges (dashed) between  $X$ .

node  $x \in X$  is adjacent to more other nodes of  $X$  in  $H^1$  than there are odd components of  $H^1 \setminus X$  which contain a neighbour of  $x$ . By facial region, we mean the region of the plane bounded by a face. We will also show there are at most two odd components  $J_1, J_2$  for which at most two nodes of  $X$  have neighbours in  $J_i$ . We can then show that the number of odd components is at most  $2/3$  the number of edges of  $H^1[X]$  plus  $\frac{2}{3}$ , which will contradict that the set of odd components is large.

► **Lemma 22** ( $\star$ ). *Let  $H$  be as in Algorithm 2.1, that is,  $H$  is a minimal pocket of  $G_2^S$ . Then  $H$  has a  $2/3$ -pseudo-perfect pseudo-tiling.*

So let  $\mathcal{T}$  be a  $2/3$ -pseudo-perfect pseudo-tiling of  $H$ . Let  $\beta'$  be the fraction of odd faces of  $H$  which are covered by  $\mathcal{T}$ , and let  $\psi'$  be the fraction of even faces of  $H$ . Next, we will show that if  $\mathcal{T}$  covers more faces than a maximum tiling of  $H$ , then  $\mathcal{T}$  satisfies a slightly stronger condition than  $2/3$ -pseudo-perfect, namely,  $\beta'(1 - \psi')|V(H^*)| + 2\psi'|V(H^*)| \geq \frac{2}{3}|V(H^*)| + \frac{4}{3}$ . Formally, this means:

► **Lemma 23** ( $\star$ ). *Let  $H$  be as in Algorithm 2.1, that is,  $H$  is a minimal pocket of  $G_2^S$ . Suppose that any maximum size pseudo-tiling of  $H$  covers the infinite face. Then  $H$  has a pseudo-tiling covering a  $\beta'$ -fraction of all odd faces such that*

$$\beta'(1 - \psi')|V(H^*)| + 2\psi'|V(H^*)| \geq \frac{2}{3}|V(H^*)| + \frac{4}{3}. \quad (9)$$

► **Theorem 24**. *Let  $H$  be an inclusion-minimal pocket of  $G_2^S$ . Then we can obtain  $2/3$ -quasi-perfect tiling of  $H$  in polynomial time.*

**Proof.** We first show that  $H$  admits a  $2/3$ -quasi-perfect tiling. Let us show that if some tiling  $\mathcal{T}$  is  $2/3$ -pseudo-perfect, then it is  $2/3$ -quasi-perfect. Let  $\beta'$  be the fraction of odd faces of  $H$  that are covered by  $\mathcal{T}$  and  $\psi'$  the fraction of faces of  $H$ , that are even. As  $\mathcal{T}$  is  $2/3$ -pseudo-perfect, it covers all even faces. Since  $\mathcal{T}$  is a tiling, the infinite face is odd. As the number of even finite faces is  $\psi'|V(H^*)|$ , so  $\frac{\psi'|V(H^*)|}{|V(H^*)|-1}$  is the fraction of finite faces of  $H$  that are even.  $(1 - \psi')|V(H^*)|$  is the number of odd faces of  $H$ , so  $\beta'(1 - \psi')|V(H^*)|$  is the number of odd faces of  $H$  covered by  $\mathcal{T}$ . Since the infinite face is odd,  $(1 - \psi')|V(H^*)| - 1$  is the number of odd finite faces. Thus  $\frac{\beta'(1 - \psi')|V(H^*)|}{(1 - \psi')|V(H^*)| - 1}$  is the fraction of odd finite faces of  $H$  covered by  $\mathcal{T}$ . Since

$$\begin{aligned}
 & \frac{\beta'(1-\psi')|V(H^*)|}{(1-\psi')|V(H^*)|-1} \left(1 - \frac{\psi'|V(H^*)|}{|V(H^*)|-1}\right) + \frac{2\psi'|V(H^*)|}{|V(H^*)|-1} \\
 = & \frac{\beta'(1-\psi')|V(H^*)|}{(1-\psi')|V(H^*)|-1} (1-\psi') + 2\psi' + \left(2 - \frac{\beta'(1-\psi')|V(H^*)|}{(1-\psi')|V(H^*)|-1}\right) \left(\psi' - \frac{\psi'|V(H^*)|}{|V(H^*)|-1}\right) \\
 \leq & \frac{\beta'(1-\psi')|V(H^*)|}{(1-\psi')|V(H^*)|-1} (1-\psi') + 2\psi' \leq \frac{2}{3},
 \end{aligned}$$

it holds that  $\mathcal{T}$  is  $2/3$ -quasi-perfect.

If there is a maximum size pseudo-tiling that is also a tiling, then it follows from Lemma 22 that such a tiling is  $2/3$ -quasi-perfect.

Otherwise, if no pseudo-tiling exists, the largest pseudo-tiling is larger than the largest tiling. Let  $\mathcal{T}$  be a maximum size pseudo-tiling.

If the infinite face of  $\mathcal{T}$  is even, consider the tiling  $\mathcal{T}'$  obtained by removing the infinite face from  $\mathcal{T}$ . Let  $\psi^{(1)} := (\psi'|V(H^*)|-1)/(|V(H^*)|-1)$  be the fraction of finite faces of  $H$  which are even. As the infinite face is even,  $\beta'$  is the fraction of odd finite faces of  $H$  which are covered by  $\mathcal{T}'$ . It holds that

$$\begin{aligned}
 \beta'(1-\psi^{(1)})(|V(H^*)|-1) + 2\psi^{(1)}(|V(H^*)|-1) &= \beta'|V(H^*)|(1-\psi') + \psi'|V(H^*)|-1 \\
 &\geq \frac{2}{3}|V(H^*)| + \frac{4}{3} - 1 = \frac{2}{3}(|V(H^*)|-1).
 \end{aligned}$$

So  $\mathcal{T}'$  is  $2/3$ -quasi-perfect.

If the infinite face is odd, consider the tiling  $\mathcal{T}'$  obtained by removing the even cycle covering the infinite face from  $\mathcal{T}$ . Let  $\psi^{(2)} := \psi'|V(H^*)|/(|V(H^*)|-1)$  be the fraction of finite faces of  $H$  that are even. At least  $\beta'|V(H^*)|-2$  of the finite faces of  $H$  are covered by  $\mathcal{T}'$  so the fraction  $\beta''$  of finite odd faces of  $H$  that are covered satisfies  $\beta'' \geq (\beta'|V(H^*)|-1)/(1-\psi^{(2)})(|V(H^*)|-1)$ . Therefore,

$$\begin{aligned}
 \beta''(1-\psi^{(2)})(|V(H^*)|-1) + 2\psi^{(2)}(|V(H^*)|-1) &\geq (\beta'|V(H^*)|-1) + 2c|V(H^*)| \\
 &\geq \frac{2}{3}|V(H^*)| + \frac{4}{3} - 1 = \frac{2}{3}(|V(H^*)|-1).
 \end{aligned}$$

Hence also in this case,  $\mathcal{T}'$  is  $2/3$ -quasi-perfect.

Finally, since a tiling corresponds to the union of a matching and a set of even faces, finding a maximum tiling of  $H$  corresponds to finding a maximum matching of the odd finite faces of  $H$ . Computing such a maximum matching can be done in polynomial time. ◀

## A.1 Proof of Theorem 17

In this section we will prove Theorem 17. Let  $G, H, \mathcal{R}, S, \mathcal{A}$  be as in the statement of Theorem 17. Let  $\mathcal{D}_G$  be the debit graph of  $G$  with respect to  $S$ .

We introduce the notion of “balance”, which captures for subsets  $\mathcal{R}' \subseteq \mathcal{R}$  of cycles are incident to more or less than  $18/7$  nodes of  $S$  on average.

► **Definition 25.** For each subset  $\mathcal{R}' \subseteq \mathcal{R}$ , its balance  $\text{bal}(\mathcal{R}')$  is the quantity  $|\mathcal{R}'| - \frac{7}{18}|E'_{\mathcal{R}}|$ .

Our proof follows the same methodology as Berman and Yaroslavtsev [6]. First, it shows a pseudo-witness cycle that is not a face and is minimally so, that is any pseudo-witness cycle lying in the finite region bounded by it is a face, has balance at least  $1 - \frac{7}{18}$ . Then it uses this to apply a reduction on  $G$ . We will use the following result of theirs.

■ **Figure 12** Pseudo-witness cycles  $C_1, \dots, C_5$  divide  $H$  into regions  $R_0, R_1, \dots, R_5$ .

► **Proposition 26** ([6, Lemma 4.3]). *Let  $W$  be a planar graph,  $\hat{S}$  be a set of nodes of  $W$  and  $Q \subset \hat{S}$  be a set of nodes of  $W$  that we call outer nodes. Let  $\mathcal{R}_W$  be a set of faces of  $W$  such that each non-outer node of  $\hat{S} \cap W$  has a pseudo-witness cycle in  $\mathcal{R}_W$ . If  $W$  contains a  $\leq 2$  outer nodes, then  $\text{bal}(\mathcal{R}_W) \geq 1 - \frac{7}{18}a$ .*

If all nodes of a pseudo-witness cycle  $A$  are contained in  $H$ , call  $A$  a *hierarchical* pseudo-witness cycle. Otherwise, call  $A$  a *crossing* pseudo-witness cycle. Denote the set of crossing pseudo-witness cycles by  $\hat{\mathcal{A}}$ . We are now ready to complete the proof of Theorem 17. We begin by reductions on our instance  $(G, H, \mathcal{R}, \mathcal{A}, S)$  which simplify our instance and do not increase the balance. If after applying this reduction our instance has positive balance, then our instance had positive balance before the reduction. We define the reduction below.

► **Definition 27.** *We define the following reduction on our instance  $(G, H, \mathcal{R}, \mathcal{A}, S)$ . If  $H$  contains a hierarchical pseudo-witness cycle  $A$  that is not a face of  $\mathcal{R}$ , delete all nodes, edges and faces of  $\mathcal{R}$  inside  $A$  from  $H$  and add  $A$  to  $\mathcal{R}$ . If  $H$  does not contain a hierarchical witness cycle, we call the instance  $(G, H, \mathcal{R}, \mathcal{A}, S)$  reduced.*

Let  $\mathcal{R}_C$  be the faces in  $\mathcal{R}$  contained in the region bounded by  $C$ . Let  $H^1, \mathcal{R}^1$  be the result of applying the reduction in Definition 27 on  $H, \mathcal{R}$ . The balance of  $H^1, \mathcal{R}^1$  is equal to

$$\begin{aligned} & |(\mathcal{R} \setminus \mathcal{R}_C) \cup \{C\}| - \sum_{M \in (\mathcal{R} \setminus \mathcal{R}_C) \cup \{C\}} |M \cap S| \\ &= |\mathcal{R}| - \sum_{M \in \mathcal{R}} |M \cap S| - (|\mathcal{R}_C| + 1 - (\sum_{M \in \mathcal{R}_C} |M \cap S|) + 1) = \text{bal}(H) + 1 - \text{bal}(\mathcal{R}_C) - \frac{7}{18}. \end{aligned}$$

That is to say, the reduction changes the balance by  $1 - \text{bal}(\mathcal{R}_C) - \frac{7}{18}$ , which by Proposition 26 is non-positive. Thus, if after applying the reduction in Definition 27, our instance has positive balance then it initially had positive balance. We know apply the reduction in Definition 27 until our instance is reduced, for simplicity we will continue to call this graph  $H$ .

The crossing pseudo-witness cycles  $\hat{\mathcal{A}}$  partition  $H$  into *regions*, see Figure 12. That is, consider the subgraph  $K \subset H$  consisting of nodes and edges lying on a witness cycle of  $\hat{\mathcal{A}}$  or on the outside face of  $H$ . The regions are defined as the portions of the plane bounded by the finite faces of  $K$ . Define a *subpocket* [6] as the subgraph of  $H$  consisting of the nodes and edges lying in or on the boundary of a region.

► **Proposition 28** ([6]). *The regions that the set of crossing cycles  $\hat{\mathcal{A}}$  partition the plane into satisfy the following. For each region, there is a set  $\tilde{\mathcal{A}}$  of at most two pseudo-witness cycles of  $\hat{\mathcal{A}}$  such that each node bounding the region either does not lie on a pseudo-witness cycle in  $\tilde{\mathcal{A}}$  or lies on a cycle of  $\tilde{\mathcal{A}}$ .*

By the reduction described in Definition 27 each non-crossing cycle of  $\mathcal{A}$  is a face. Since by Proposition 28, the outside face of each subpocket  $W$  contains nodes from at most two crossing pseudo-witness cycles, and contains all nodes that belong to pseudo-witness cycles lie on the outside face, there are at most two hit nodes of  $W$  whose pseudo-witness is not a face and they must lie on the outside face of  $W$ . Hence, each subpocket satisfies the conditions of Proposition 26 and hence has positive balance. Thus,  $H$  has positive balance, that is,  $0 \leq |\mathcal{R}| - \frac{7}{18}|E_{\mathcal{R}}| = |R| - \sum_{M \in R} |M \cap S|$ . Rearranging,  $\sum_{M \in R} |M \cap S| \leq \frac{18}{7}|\mathcal{R}|$ , which completes the proof of Theorem 17.  $\blacktriangleleft$

# Revenue Maximization in Transportation Networks

## Abstract

We study the joint optimization problem of pricing trips in a transportation network and serving the induced demands by routing a fleet of available service vehicles to maximize revenue. Our framework encompasses applications that include traditional transportation networks (e.g., airplanes, buses) and their more modern counterparts (e.g., ride-sharing systems). We describe a simple combinatorial model, in which each edge in the network is endowed with a curve that gives the demand for traveling between its endpoints at any given price. We are supplied with a number of vehicles and a time budget to serve the demands induced by the prices that we set, seeking to maximize revenue. We first focus on a (preliminary) special case of our model with unit distances and unit time horizon. We show that this version of the problem can be solved optimally in polynomial time. Switching to the general case of our model, we first present a two-stage approach that separately optimizes for prices and routes, achieving a logarithmic approximation to revenue in the process. Next, using the insights gathered in the first two results, we present a constant factor approximation algorithm that jointly optimizes for prices and routes for the supply vehicles. Finally, we discuss how our algorithms can handle capacitated vehicles, impatient demands, and selfish (wage-maximizing) drivers.

## 1 Introduction

The increasing popularity of ride-sharing systems has inspired renewed interest on questions of pricing and routing transportation requests in networks [2, 4, 6, 12, 16]. Typically, such ride sharing platforms have an abundance of data at their disposal, which offers them a good understanding of the market. These data offer insights which can lead to reasonable estimates of the supply of drivers expected at a given time, as well as the number of customers who would be interested in taking a given trip at a given time and price. Similar data is available for more traditional transportation companies, such as airlines and bus agencies. In all these settings it is natural to ask the question:

*How do we maximize revenue in a transportation network, given a) a supply of vehicles and b) demand curves for the possible trips?*

This question appears at face value to be (primarily) a pricing problem. While this is true to a large extent, there is a latent scheduling/routing aspect of how one can serve these demands with an available supply of vehicles. This connection implies that any approach in this setting has to address difficulties encountered both in pricing and in routing problems.

Various efforts have been made at tackling aspects of pricing and routing in ride-sharing platforms. These include queueing approaches [4], mechanism design [6, 12, 16], and Markov chain models [2]. In this work we formulate and study a simple combinatorial model of the

TRANSPORTATION NETWORK PRICING problem. In our model, the problem is studied on a graph where distances are symmetric (i.e., the distance from node  $u$  to node  $v$  is the same as the distance from node  $v$  to node  $u$ ) but demands are asymmetric (i.e., the demand from node  $u$  to node  $v$  at a price  $p$  is not necessarily the same as the demand from node  $v$  to node  $u$  at the same price  $p$ ). We consider this assumption to be reasonable in real world scenarios but also note that our results hold within a constant approximation when the distance between any  $u$  and  $v$  is within constant bounds of the distance between  $v$  and  $u$ . An available supply of  $k$  vehicles can move from node to node in the graph serving demands in the process.

It is not hard to observe that pricing decisions are interconnected with routing decisions. Knowing how many times vehicles will travel from  $u$  to  $v$  gives insights on how to price the trip from  $u$  to  $v$ . In such a case, we would want to charge as much as possible while still maintaining a demand high enough to utilize the vehicles that make the trip. Similarly, knowing that a specific trip has a large number of customers who are willing to travel at a high price hints that we should send a large number of vehicles their way. This interconnection makes the problem challenging and interesting.

## 1.1 Our Contributions

In Section 3 we attempt to disentangle the pricing component from the routing aspect and understand their difficulties separately. We explore the pricing and supply assignment aspect by abstracting away the routing component in a special case of the model. We show that this pricing and assignment version of the problem can be solved in polynomial time. In Section 4, we transition to the general graph model and present an approach that handles pricing and routing as separate stages, achieving a logarithmic approximation to the revenue in the process. In Section 5, applying the insights gathered in the first two, we bring the pricing and routing components back together in a joint optimization stage and provide a constant factor approximation algorithm for general graphs. In Section 6 of the paper we explain how our solution can handle selfish drivers with a small loss in the approximation factor. In Section 7, we show that our techniques generalize to the setting where edges have different demands depending on the time of the day, a setting that can also handle impatient demands that disappear after a certain period. Finally, in Section 8, we discuss how the capacitated version of the problem reduces to the unit capacity case.

## 1.2 Related Work

Various previous works study pricing in ride-sharing systems. The papers most closely related to ours are [6, 16] who also study a network with price dependent demand curves and seek to maximize revenue. A significant difference in our model is that we consider a general network with arbitrary distances as opposed to the unit distances studied in these two models. The work in [6] considers an infinite supply setting and proves that price discrimination can significantly improve revenue over uniform pricing. The work in [16] considers drivers with preferences for one location over the other and takes a mechanism design approach to achieve incentive compatibility. We note that in our final section we also consider a special, well-motivated, form of driver preferences: wage maximization.

Other papers study more dynamic aspects of ride-sharing platforms such as spatial imbalance and temporal variation [12], dynamic pricing [8], Markov models [2], and queueing models [4]. Other studies focus on market segmentation [1, 3] and car pooling aspects [14].

On the routing side, our work is related to the vehicle routing problem [10, 11] and, more closely, to prize collecting traveling salesperson problems in graphs. Most relevant is work on the *orienteering* problem, the best known algorithms for variants of which are given in [15] and [9]. The work in [15] achieves a 2 approximation for single path orienteering on undirected graphs via a primal-dual algorithm. The work in [9] presents dynamic programming based algorithms, following up on work in [5, 7]. A particular result from [7] that is relevant in our proofs is that undirected orienteering with  $k$  paths can be approximated within a factor 3.

## 2 Model and Preliminaries

In this section we define the specifics of TRANSPORTATION NETWORK PRICING.

Consider a set of locations  $V$  and the possible trips between them  $E = V \times V$ . Let  $l_e$  be the length (in time) of trip  $e \in E$ . We assume trip times are symmetric and  $l_e = l_{e'}$  for  $e = (u, v)$  and  $e' = (v, u)$ . For each trip  $e$ , we are also given a demand curve  $d_e(p)$  that gives the number of agents who are willing to pay a price  $p$  for trip  $e$ . Naturally, we assume that  $d_e(p)$  is a non-increasing function of  $p$ . For convenience, for each trip  $e$ , we also define the price curve

$$p_e(d) = \max\{p \mid d_e(p) \geq d\}$$

as the maximum price  $p$  such that at least  $d$  agents are willing to pay  $p$  for the trip  $e$ . To serve these demands, we have a supply of  $k$  service vehicles who can move from location to location and transport the demands. The total trips a service vehicle can make are limited by a time horizon  $T$  which is an upper bound on the total length of trips a service vehicle can do. For simplicity and without loss of generality we assume that all edge lengths, demand values, and possible prices are integers.

A solution consists of: (a) a price  $q_e$  for each trip  $e$  and (b) a path  $P_i$  of length at most  $T$  for each service vehicle  $i$ . A path is a sequence of trips  $P = \{e_1, e_2, \dots, e_m\}$  such that the destination of trip  $e_j$  is the source of trip  $e_{j+1}$ . The set of service vehicle paths induces a supply  $s_e$  for trip  $e$ , defined as the number of times  $e$  appears in all paths (note that a path might repeat  $e$  multiple times). The revenue for trip  $e$  is then equal to:

$$r_e = q_e \min\{s_e, d_e(q_e)\}.$$

Our objective is to provide prices and paths that maximize the total revenue:

$$R = \sum_{e \in E} r_e.$$

We assume throughout the paper that the number of agents  $k$  and the time horizon  $T$  are both polynomial in the size of the graph  $G$ . We will design (approximation) algorithms that are polynomial in  $k$ ,  $T$ , and the size of the graph. Figure 1 illustrates a simple instance of the TRANSPORTATION NETWORK PRICING problem and its optimal solution.

A key component of our algorithms is the *revenue function* of an edge  $e \in V \times V$  that expresses the maximum amount of revenue that can be obtained from the edge  $e$  for a given supply. Mathematically, we define

$$r_e(\ell) = \max_{0 \leq j \leq \ell} \{j \cdot p_e(j)\}$$

■ **Figure 1** An instance of the TRANSPORTATION NETWORK PRICING problem. Each edge in the digraph represents a trip  $e$  of unit length. The maps labeling each edge represent the corresponding price curve, for instance,  $p_{(u,v)}(1) = 20$  and  $p_{(u,v)}(2) = 15$ . For a time horizon of  $T = 3$  and  $k = 3$  service vehicles, the figure illustrates an optimal solution that assigns two vehicles to the path  $\langle (u, v), (v, w), (w, u) \rangle$  and one vehicle to the path  $\langle (u, v), (v, x), (x, u) \rangle$  for a total revenue of 82.

### 3 Node Model: One Trip Per Vehicle

We begin with a warm-up setting in which each vehicle only makes one trip and our decisions amount to pricing edges and assigning vehicles to them. To fit this framework in our model, we can think of the special case with unit edge lengths and a unit time horizon. Since edges have no interaction with each other in this setting, we may equivalently think of them as simply unconnected nodes. For ease of notation, for this special case, we define a demand curve  $d_i(\cdot)$  for each node  $i$ . The price curve  $p_i(\cdot)$  and revenue curve  $r_i(\cdot)$  are defined similarly. We term this special case as the TRANSPORTATION NODE PRICING PROBLEM. We show that the problem is poly-time solvable.

► **Theorem 1.** *TRANSPORTATION NODE PRICING can be solved in polynomial time when the number  $k$  of service vehicles is polynomial in the size of the graph.*

**Proof.** Consider an arbitrary ordering of the nodes. Let  $\text{Opt}(i, j)$  denote the revenue extracted by the optimal solution for the first  $i$  nodes with  $j$  vehicles. Thus  $\text{Opt}(n, k)$  denotes the revenue extracted by the optimal solution for an instance. The following recurrence shows how one can compute this optimal solution via dynamic programming.

$$\text{Opt}(i, j) = \max_{\ell \in \{0, \dots, j\}} \{ \text{Opt}(i - 1, j - \ell) + r_i(\ell) \} \tag{1}$$

Intuitively, the recurrence searches over all possible number of vehicles to assign to the  $i^{\text{th}}$  node and solves the residual problem optimally. While  $\text{Opt}(n, k)$  only yields the optimal revenue, it is also easy to obtain the actual optimal solution by tracing the path taken by the dynamic program. ◀

As a side-note, we prove that the problem is NP-Hard when  $k$  is super-polynomial. We note though that a FPTAS is possible with an approach similar to the one for KNAPSACK.

► **Theorem 2.** *TRANSPORTATION NODE PRICING is NP-Hard.*

**Proof.** We will prove this by reducing KNAPSACK to our problem. The KNAPSACK problem has a collection of  $n$  items with sizes  $s_i$  and values  $v_i$  for  $i = 1, 2, \dots, n$  and a knapsack of size  $B$ . The goal is to pack items of total size at most  $B$  and maximize the total value picked.

Our reduction is as follows. For each item  $i$ , we construct a node  $i$  with the following demands: for a given large number  $L$ , the demand for the trip to  $i$  is one when the price is  $LS_i v_i$  and  $LS_i$  when the price is  $v_i$ . There are no others interested in the trip to  $i$ . In other words, we set  $r_i(1) = LS_i v_i$  and  $r(LS_i + 1) = LS_i v_i + v_i$ . The total supply of vehicles is  $k = n + LB$ .

Observe that in the induced TRANSPORTATION NODE PRICING instance there are, in effect, two possible prices for each node: either set price  $p_i = LS_i v_i$  and serve the unique customer at that price, or set  $p_i = v_i$  and serve all  $LS_i + 1$  customers. This means we have the option to either extract total revenue  $LS_i v_i$  spending supply 1 or spend an additional supply of  $LS_i$  to extract an extra  $v_i$ . When  $L$  is high enough, it is clear that any optimal solution spends the first  $n$  of the  $n + LB$  supply units to secure the  $LS_i v_i$  from every node, before considering any of the additional  $v_i$ 's. Then the solution will have to allocate the remaining  $LB$  supply units to get additional revenue  $v_i$  from any node  $i$  to which it allocates  $LS_i$ . This is precisely the original KNAPSACK problem where all the sizes are scaled by  $L$ , which implies that any optimal solution to this TRANSPORTATION NODE PRICING instance recovers an optimal solution to the corresponding KNAPSACK instance. ◀

#### 4 Separate Price & Route Optimization

In this section we consider the general TRANSPORTATION NETWORK PRICING model and present an approach that first attempts to determine prices and then to compute routes for the supply vehicles. We show that this algorithm achieves a logarithmic approximation. This section is of interest in itself, but also a warm-up for various aspects we will encounter in our main technical result in the next section (a constant approximation for the same problem that jointly optimizes for prices and routes) such as a reduction to the UNDIRECTED ORIENTEERING PROBLEM:

► **Definition 3.** *In the UNDIRECTED ORIENTEERING problem we are given an undirected graph  $G = (V, E)$  with costs on the edges and values on the nodes, and a cost budget  $T$ . We seek to find  $k$  paths each of cost at most  $T$  that maximize the total value of nodes visited.*

Our algorithm proceeds in two steps as follows:

*Guess a revenue target and set prices accordingly.* We guess a target revenue  $\tilde{r} \in \mathbb{R}$  and attempt to extract a revenue of  $\tilde{r}$  from each edge  $e$  in the network. For every edge  $e$ , set the price that would achieve the revenue target  $\tilde{r}$  with the smallest supply possible. If  $\tilde{r}$  is not achievable on some edge  $e$ , give up on  $e$  and set an infinite price.

*Construct and solve an undirected orienteering instance.* Since prices have been determined, each crossing of an edge by a supply vehicle extracts a known revenue. We formulate and solve an UNDIRECTED ORIENTEERING instance based on this information. Good constant factor approximation algorithms are known for UNDIRECTED ORIENTEERING, something that is the raison d'être of the graph transformation we perform in this stage. In more detail, we construct an auxiliary undirected graph in which we move the value from edges (i.e., the trips in the transportation graph) to new nodes that we introduce between the trip's endpoints. Every time such a node is visited will represent the corresponding trip being performed once. Hence, the value of such a node is equal to the price set for the corresponding trip. The edge lengths in the auxiliary graph are scaled so that the paths returned by the orienteering algorithm can be converted into sequences of trips in the original network.

## 4.1 Price Setting

Our algorithm begins with a guess  $\tilde{r}$  that is the revenue we will try to extract from every edge (i.e., every trip) in the network. Let  $\mathcal{R} = \{r_e(\ell)\}_{e \in E, 0 \leq \ell \leq kT}$  denote the set of all possible revenue values that can be extracted from any edge (note that no trip can be made more than  $kT$  times even if all service vehicles perform that one trip). The algorithm will ultimately be run for all possible guesses  $\tilde{r} \in \mathcal{R}$ . Since  $|\mathcal{R}| \leq n^2 kT$ , trying all possible revenues in  $\mathcal{R}$  can be done in polynomial time.

Once  $\tilde{r}$  is fixed, the price that we should set at any edge  $e$  can be computed as follows. Let  $s_e = \min\{\ell : r_e(\ell) \geq \tilde{r}\}$  be the minimum supply we need to extract value  $\tilde{r}$  at  $e$ . Then  $q_e = p_e(s_e)$  is the price we set for edge  $e$ . We now make the following claim.

► **Lemma 4.** *Let  $(q^*, P^*)$  be an optimal solution with  $q^*$  the vector of prices and  $P^*$  the paths of the service vehicles. Also, let  $\tilde{r}$  be the guess that, with induced prices  $\tilde{q}$  and the same paths  $P^*$ , maximizes the revenue among all guesses. The revenue extracted by solution  $(\tilde{q}, P^*)$  is an  $H_m$ -approximation to the revenue extracted by the solution  $(q^*, P^*)$ , where  $m$  is the number of edges in the graph and  $H_m$  the  $m$ -th harmonic number.*

**Proof.** Order the edges as  $1, 2, \dots, m$ , in order of non-increasing revenue extracted in  $(q^*, P^*)$ . Call these revenues  $r_1^*, r_2^*, \dots, r_m^*$ . Consider the guess  $\tilde{r} = r_j^*$  for our algorithm. Fix the paths  $P^*$  and set the price that achieves  $\tilde{r}$  in each edge  $e$  (or infinite price if not possible) as per our algorithm. Consider any edge  $e \leq j$ . We know that  $\tilde{r} = r_j^*$  is achievable on these edges, since the optimal solution extracts at least that on each one. Moreover, we have enough supply to achieve  $r_j^*$  on these edges, since  $P^*$  allocates enough supply for at least that much. Hence, when the guess is  $\tilde{r} = r_j^*$ , the solution  $(\tilde{q}, P^*)$  extracts value at least  $j r_j^*$ .

Let  $j^* = \arg \max_j \{j r_j^*\}$  be the guess that yields the maximum value. Thus, we have  $j^* r_{j^*}^* \geq j' r_{j'}^*$ , for all  $j' = 1, 2, \dots, m$ . Then:

$$R^* = \sum_{j'=1}^m r_{j'}^* \leq \sum_{j'=1}^m \frac{j^* r_{j^*}^*}{j'} = H_m j^* r_{j^*}^* \leq H_m R,$$

with  $R^*$  the optimal revenue and  $R$  the revenue of  $(\tilde{q}, P^*)$ . This proves the lemma.

We also proceed to prove that this factor is tight. Consider the case when  $r_j^* = 1/j$ . Every  $j r_j^*$  is unit, whereas their sum is  $H_m$ . ◀

## 4.2 Construction of the Orienteering Instance

Given the prices fixed in the previous stage of the algorithm, our goal is to route the  $k$  supply vehicles so that they can extract as much value as possible. This task is similar to the UNDIRECTED ORIENTEERING problem, for which a 2-approximation algorithm exists [15]. The main difference in our setting is that the values are on the trips between nodes and not on the nodes. Moreover, these trips are directed. We now describe a transformation to the graph that handles these issues with a small loss in approximation.

We construct an undirected graph  $H = (N, A)$  with values on the nodes and costs on the edges as follows. We begin with the nodes of the input transportation network  $V$ . All these nodes have value 0. For every ordered pair of nodes  $e = (u, v) \in E$ , we construct  $\min\{kT, d_e(q_e)\}$  nodes  $z_e^i, i = 1, 2, \dots, \min\{kT, d_e(q_e)\}$ , with value  $q_e$ , i.e., the price of the trip from  $u$  to  $v$ . For every such node  $z_e^i$ , we add an (undirected) edge between it and  $u$  and an (undirected) edge between it and  $v$ . Both these edges have length equal to  $l_e$ , the length of the trip from  $u$  to  $v$ . Figure 2 shows an example of the construction of the orienteering instance.

■ **Figure 2** Construction of the orienteering instance with fixed prices.

► **Lemma 5.** *Every path of length at most  $T^*$  in the input graph  $G$  that extracts revenue  $R$  can be expressed as a path of length at most  $2T^*$  in  $H$  that picks value  $R$ .*

**Proof.** Let  $P$  be a path of length at most  $T^*$  in  $G$ . Consider the order in which nodes are visited by the path  $P$  in  $G$ . We visit the same nodes in the same order in the graph  $H$  to obtain a path  $P'$ . The  $i^{\text{th}}$  time we cross an edge from  $u$  to  $v$  (in  $G$ ), we go via the intermediate node  $z_e^i$  in  $H$ . For  $i$  larger than  $d_e(q_e)$ , we go via any of the intermediate nodes (since they all have already been visited). Since the original path  $P$  in  $G$  has length at most  $T^*$ , and every edge  $e = (u, v)$  of length  $l_e$  in  $G$  corresponds to a walk  $(u \rightarrow z_e^i \rightarrow v)$  of length  $2l_e$  in  $H$ , the new path  $P'$  in  $H$  has a total length of at most  $2T^*$ . Let us now compute the value picked up by the path  $P'$  in  $H$ . Let  $s_e$  be the number of times that path  $P$  passes through edge  $e$ . Then, by definition, the total revenue extracted by  $P$  is given by:

$$R = \sum_e q_e \min\{s_e, d_e(q_e)\}.$$

On the other hand, for every edge  $e = (u, v)$  in  $G$ , by construction the path  $P'$  passes through  $\min\{s_e, d_e(q_e)\}$  distinct intermediate vertices ( $z_e^i$ ) each having value  $q_e$ . Thus path  $P'$  picks up value at least  $R$  in  $H$ . ◀

► **Lemma 6.** *Every path of length at most  $\tilde{T}$  in graph  $H$  that picks value  $R$  can be expressed as a path of length at most  $\tilde{T}$  in  $G$  that extracts at least revenue  $R$ .*

**Proof.** Let  $P'$  be a path in  $H$  of length at most  $\tilde{T}$  that picks value  $R$ . Let  $v$  be the first vertex on path  $P'$ . Then the path  $P'$  departs from node  $v$ , visits an intermediate node  $z_e^i$  (where  $e = (u, v)$  or  $e = (v, u)$ ) and either returns back to  $v$  or moves to the opposite node  $u$ . In the former case, it pays a cost of  $2l_e$  and extracts value  $q_e$ . We can construct a path  $P$  in  $G$  in exactly the same way as follows - starting from node  $v$ , visit node  $u$  and come back to  $v$  paying a total cost of  $2l_e$  (since lengths are symmetric) and extracting at least  $q_e$  revenue. In the latter case  $P'$  visits  $v \rightarrow z_e^i \rightarrow u$  and again pays a cost of  $2l_e$  and extracts a revenue of  $q_e$  (unless of course all intermediate nodes  $z_e^i$  have already been visited earlier). In this case, if  $e = (v, u)$ , then we simply cross from node  $v$  to node  $u$  in the path  $P$  to earn revenue  $q_e$  and a cost of only  $l_e$ . On the other hand, if  $e = (u, v)$ , then in path  $P$ , we first take edge  $(v, u)$ , then take  $(u, v)$ , and then again take  $(v, u)$  so that we end up on the same node on both  $P$  and  $P'$ . In this step, path  $P$  extracts a revenue of at least  $q_e$  but pays a cost of  $3l_e$ .

Let  $P'_{\text{rev}}$  denote a path in  $H$  that is the reverse of  $P'$ , i.e., it visits the same set of nodes but in the reverse order. Let  $P_{\text{rev}}$  be the path in  $G$  constructed as above starting from  $P'_{\text{rev}}$ . By construction, both  $P$  and  $P_{\text{rev}}$  extract a revenue of at least  $R$ . However, since for any

step  $v \rightarrow z_e^i \rightarrow u$  in  $P'$ , exactly one of  $P$  and  $P_{\text{rev}}$  pay a cost of  $l_e$  while the other pays  $3l_e$ . Thus, we have:

$$\text{length}(P) + \text{length}(P_{\text{rev}}) = \sum_e 4l_e = 2\text{length}(P')$$

and hence at least one of  $P$  and  $P_{\text{rev}}$  have length of at most  $\tilde{T}$ , proving the lemma. ◀

► **Lemma 7.** *For a set of fixed prices, solving the UNDIRECTED ORIENTEERING problem on graph  $H$  with budget  $T$  and translating the paths of graph  $H$  to paths of graph  $G$  as in Lemma 6, gives a 6-approximation to revenue.*

**Proof.** By Lemma 5 we get that each one of the optimal paths in  $G$  can be expressed as a path of length at most  $2T$  in  $H$ . We solve UNDIRECTED ORIENTEERING with a budget of  $T$ . We note that the optimal solution with budget  $T$  will have at least half the value of the optimal solution with budget  $2T$  since we can simply take the better half. This implies the optimal solution for the instance we solve will have value at least half the optimal revenue. By the fact that UNDIRECTED ORIENTEERING with  $k$  paths can be solved within a 3-approximation, our paths in  $H$  will be within 6 of the optimal revenue. Applying Lemma 6 completes the proof. ◀

Putting Lemma 4 with Lemma 7 together, we get the main theorem of the section. More precisely, Lemma 4 suggests that some prices given by our first stage are such that the optimal paths for them will give an  $H_m$ -approximation to revenue. Lemma 7 proves that, when we try these prices, we will find paths that approximate the optimal paths within a factor 6. We then get the following theorem.

► **Theorem 8.** *Our separate pricing & routing optimization algorithm gives a  $6H_m$ -approximation to revenue, where  $m$  is the number of edges.*

## 5 Joint Price and Route Optimization

In this section we use the insights obtained in the previous two sections to come up with a joint pricing and routing optimization algorithm. The algorithm in effect combines the main ideas of the previous two approaches to price and route at the same time. The algorithm proceeds in the following stages.

*Concave approximate revenue curve construction.* First, we process all demand curves to obtain the corresponding revenue functions  $r_e(\ell)$  (recall that these give the maximum possible revenue that can be achieved at edge  $e$  with supply  $\ell$ ), which in turn we process to obtain *approximate* revenue functions  $\hat{r}_e(\ell)$  that are concave. We prove that we can always find a concave function that satisfies  $r_e(\ell) \leq \hat{r}_e(\ell) \leq 2r_e(\ell)$  for every  $\ell$ . The main reason for performing this step is that the concave approximate revenue functions  $\hat{r}_e(\ell)$  satisfy the nice property that the marginal increase:

$$\Delta \hat{r}_e(\ell) = \hat{r}_e(\ell) - \hat{r}_e(\ell - 1)$$

that is caused by the  $\ell$ -th supply on edge  $e$  is decreasing. This proves useful when we place these marginal contributions as values to be collected from a graph in the second stage. We will also refer to  $\hat{r}_e(\cdot)$  as the *perceived* revenue.

*Auxiliary graph construction.* The main idea of the second stage of our algorithm is to construct an auxiliary graph that, similarly to our approach in the previous section, a) is undirected, b) has values only on nodes, and c) there is an equivalence between paths in the

auxiliary graph and sequences of trips in the input transportation network. Again, the value is moved from edge  $e$ , to a collection of nodes  $z_e^i, i = 1, 2, \dots, kT$ , that are introduced between its endpoints. This time however, the values of these nodes are not the same. Instead, the value of  $z_e^\ell$  is precisely the marginal perceived revenue  $\Delta \hat{r}_e(\ell)$ . The transformation of edge lengths is exactly as in the previous section. We then proceed as in the previous section, to solve the induced UNDIRECTED ORIENTEERING instance and translate the paths of the auxiliary graph  $H$  to paths of the input graph  $G$ . Once this is done, the paths induce supplies on the edges which we can use to infer the prices.

### 5.1 Concave Approximate Revenue Functions

As we also discussed in the preliminary node model, we can express the maximum revenue we can extract from an edge, given supply  $\ell$ , as:

$$r_e(\ell) = \max_{0 \leq j \leq \ell} \{jp_e(j)\},$$

with  $p_e(j)$  the maximum price that induces demand at least  $j$ . As can be seen in Figure 3, we note that  $r_e(\cdot)$  need not be a concave function.

However, we can define a concave function  $\hat{r}_e(\cdot)$  as the concave envelope of  $r_e(\cdot)$ . In other words,  $\hat{r}_e(\cdot)$  is the lowest-valued concave function such that  $\hat{r}_e(\ell) \geq r_e(\ell)$ . Concretely, let  $[\ell_1, \ell_2]$  be a maximal interval such that the function  $r_e(\cdot)$  in this interval is bounded above by the linear interpolation of  $r_e(\ell_1)$  and  $r_e(\ell_2)$ . Then  $\forall \ell \in [\ell_1, \ell_2]$ ,  $\hat{r}_e(\ell)$  is obtained by linearly interpolating between  $(\ell_1, r_e(\ell_1))$  and  $(\ell_2, r_e(\ell_2))$ , i.e.,

$$\hat{r}_e(\ell) = \left( \frac{r_e(\ell_2) - r_e(\ell_1)}{\ell_2 - \ell_1} \right) (\ell - \ell_1) + r_e(\ell_1)$$

■ **Figure 3** Example revenue function and its concave approximation. The bold line shows the original revenue function  $r_e(\cdot)$  for some edge  $e$ , and the green dashed line shows its concave approximation  $\hat{r}_e(\cdot)$ .

We now show that  $\hat{r}_e(\cdot)$  point-wise approximates  $r_e(\cdot)$  within a factor of 2.

▷ **Claim 9.** For all  $0 \leq \ell \leq k$ ,  $\hat{r}_e(\ell) \leq 2r_e(\ell)$

Proof. Let  $[\ell_1, \ell_2]$  be a maximal interval such that  $\hat{r}_e(\ell) > r_e(\ell), \forall \ell \in (\ell_1, \ell_2)$ . Note that by definition of  $\ell_2$ , we have  $r_e(\ell_2) = \ell_2 p_e(\ell_2)$ . Otherwise, if  $r_e(\ell_2) = jp_e(j)$  for some  $j < \ell_2$ , then we have  $r_e(\ell_2) = r_e(j)$  and we cannot have  $\hat{r}_e(j) > r_e(j)$ . Now, since  $p_e(\cdot)$  is a non-increasing function, we have

$$r_e(\ell_1) = \max_{0 \leq j \leq \ell_1} \{jp_e(j)\} \geq \ell_1 p_e(\ell_2) \tag{2}$$

Hence, we have the following,

$$\frac{r_e(\ell_2) - r_e(\ell_1)}{\ell_2 - \ell_1} \leq \frac{r_e(\ell_2) - \ell_1 p_e(\ell_2)}{\ell_2 - \ell_1} \quad (3)$$

$$= \frac{\ell_2 p_e(\ell_2) - \ell_1 p_e(\ell_2)}{\ell_2 - \ell_1} = p_e(\ell_2) \quad (4)$$

Now, for any  $\ell \in (\ell_1, \ell_2)$ , by definition of  $\hat{r}_e(\cdot)$  we have,

$$\hat{r}_e(\ell) = \left( \frac{r_e(\ell_2) - r_e(\ell_1)}{\ell_2 - \ell_1} \right) (\ell - \ell_1) + r_e(\ell_1) \quad (5)$$

$$\leq p_e(\ell_2)(\ell - \ell_1) + r_e(\ell_1) \quad (6)$$

$$\leq 2 \max\{\ell p_e(\ell_2), r_e(\ell_1)\} \quad (7)$$

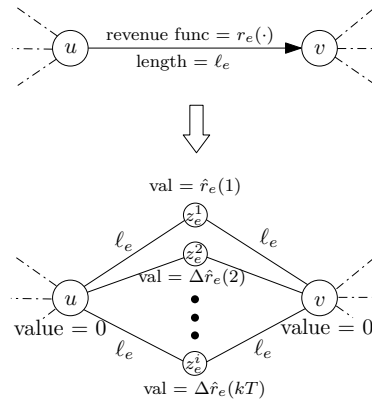

However, since the revenue function  $r_e(\cdot)$  is non-decreasing and the price function  $p_e(\cdot)$  is non-increasing, we have

$$r_e(\ell) \geq \max\{\ell p_e(\ell_2), r_e(\ell_1)\} \quad (8)$$

The claim now follows from equations (7) and (8).  $\triangleleft$

## 5.2 Construction of the Orienteering Instance

As in the previous section, we will construct an undirected graph  $H = (N, A)$  with values on the nodes and costs on the edges. Here also, we begin with the nodes of the input transportation network  $V$  which again have value 0. For every ordered pair of nodes  $e = (u, v) \in E$ , we construct  $kT$  nodes  $z_e^i, i = 1, 2, \dots, kT$ . The value of  $z_e^i$  is  $\Delta \hat{r}_e(i)$ , i.e., the marginal increase in perceived total revenue (as given by the concave approximate revenue functions  $\hat{r}_e(\cdot)$ ) offered by the  $i$ -th trip from  $u$  to  $v$ . For every such node  $z_e^i$ , we add an (undirected) edge between it and  $u$  and an (undirected) edge between it and  $v$ . Both these edges have length equal to  $\ell_e$ , the length of the trip from  $u$  to  $v$ . Figure 4 shows an example of the construction of the orienteering instance.

■ **Figure 4** Construction of the orienteering instance with approximate revenues.

► **Lemma 10.** *Every path of length at most  $T^*$  in the input graph  $G$  that extracts perceived revenue  $R$  can be expressed as a path of length at most  $2T^*$  in  $H$  that picks value  $R$ .*

**Proof.** Let  $P$  be a path in  $G$  of length at most  $T^*$  that extracts a perceived revenue of  $R$ . We construct a path  $P'$  in  $H$  as follows - when  $P$  uses the edge  $(u, v)$  for the  $i^{\text{th}}$  time, our path in  $H$  moves from node  $u$  to node  $v$  via the intermediate node  $z_{(u,v)}^i$ . Thus, if  $P$  passes through an edge  $e$  exactly  $l$  times to extract a perceived revenue of  $\hat{r}_e(l)$ , the path  $P'$  also picks up a value of  $\sum_{i=1}^l \Delta \hat{r}_e(i) = \hat{r}_e(l)$ . Thus  $P'$  also picks up a total value of  $R$ . The length argument follows precisely as in Lemma 5.  $\blacktriangleleft$

► **Lemma 11.** *Every path of length at most  $\tilde{T}$  in graph  $H$  that picks value  $R$  can be expressed as a path of length at most  $\tilde{T}$  in  $G$  that extracts perceived revenue at least  $R$ .*

**Proof.** The path construction and length arguments follow exactly as in Lemma 6. The revenue argument is as follows: Say the path  $P'$  in  $H$  visits  $x$  intermediate nodes corresponding to edge  $e = (u, v)$ . Then our constructed path  $P$  in  $G$  crosses edge  $e$  at least  $x$  times and extracts a perceived revenue of at least  $\hat{r}_e(x)$ . On the other hand, since  $\Delta \hat{r}_e(\cdot)$  is the non-increasing, the value earned by  $P'$  from edge  $e$  is at most  $\sum_{i=1}^x \Delta \hat{r}_e(i) = \hat{r}_e(x)$ .  $\blacktriangleleft$

Lemmas 10 and 11 together imply that the UNDIRECTED ORIENTEERING problem with  $k$  paths is equivalent to the TRANSPORTATION NETWORK PRICING problem with concave revenue functions up to a factor of 2 in the approximation ratio. We can thus directly use a 3-approximation algorithm for UNDIRECTED ORIENTEERING as in Lemma 7 to obtain a 6-approximation to the TRANSPORTATION NETWORK PRICING with concave revenue functions. However, since arbitrary revenue functions can be approximated within a factor of 2 by concave functions, Claim 9 then yields our main result.

► **Theorem 12.** *Our joint pricing & routing optimization algorithm gives a 6-approximation to revenue for concave revenue functions and a 12-approximation to revenue for general revenue functions.*

## 6 Selfish drivers

An additional layer of complexity in the ride-sharing context is added by the fact that drivers are independent and will not follow the paths dictated by our algorithm when this is not the behavior that maximizes their total wages. In this section we discuss the presence of selfish drivers in the TRANSPORTATION NETWORK PRICING setting. We assume that wages are a fixed  $\alpha$  fraction of the revenue (i.e., the drivers and the platform share the earnings with a fixed ratio) and argue that, for any given prices, letting the drivers reach an equilibrium is within a factor 2 of the optimal path selections. In this sense, with a small loss in the approximation factor, we may use our algorithms to compute prices assuming the drivers will comply, advertise them, and let the drivers reach an equilibrium.

For the purposes of our argument, we will need to introduce some additional notation and definitions. First, for simplicity of exposition, we set  $\alpha = 1$ , i.e., assume the drivers receive all revenue. Let  $x_e^i$  be the number of times driver  $i$  crosses edge  $e$  and  $x^i = (x_e^i)_{e \in E}$  the vector for driver  $i$  over all edges which we will refer to as the driver's *strategy*. Let  $x$  be the vector of all driver strategies. Let  $d_e$  be the demand under the current price vector (note that, for simplicity, we have dropped dependence of  $d_e$  on  $q_e$  in the notation, since prices are considered fixed throughout this section) and  $s_e(x)$  the supply under  $x$ . We are now ready to define the (expected) wage of  $i$  on  $e$  as:

$$w_e^i(x) = x_e^i q_e \min \left\{ 1, \frac{d_e}{x_e} \right\}.$$

## 26:12 Revenue Maximization in Transportation Networks

The interpretation of this expression is that  $i$  has probability 1 to get a ride (and hence a payment of  $q_e$ ) every time she crosses the edge when the demand is at least the supply and probability  $d_e/x_e$  when the demand is less than the supply. Another interpretation is that drivers share the total revenue on the edge  $r_e = q_e \min\{s_e(x), d_e\}$  proportionally to the number of times they cross it.

A collection of strategies is a *Nash equilibrium* when for every driver  $i$ , it is the case that a unilateral deviation to some other vector  $y^i$ , induced by a different path selection will not increase her total wages:

$$\sum_{e \in E} w_e^i(x) \geq \sum_{e \in E} w_e^i(x^{-i}, y^i), \quad \forall y^i.$$

The *price of anarchy* is the ratio of the total wages in the optimal solution over the total wages in the worst Nash equilibrium. We get the following observation.

► **Observation 13.** *The price of anarchy in the TRANSPORTATION NETWORK PRICING problem after prices have been fixed is 2.*

**Proof.** The upper bound follows by the fact that the game we have described is a utility game with a submodular utility function (since the drivers cover demands with their path selections). The upper bound then follows from the main result in [18].

The lower bound follows from the following simple instance of the TRANSPORTATION NODE PRICING submodel. Node 1 has a single demand which is priced at  $1 + \epsilon$ . Node 2 has  $1/\epsilon$  demands priced at  $\epsilon$ . There are  $1/\epsilon$  drivers in the game. If all of them head to node 1, their expected wage will be  $\epsilon + \epsilon^2$ , which is larger than the  $\epsilon$  they can get from a ride at node 2. Hence, this is a Nash equilibrium with total wages  $1 + \epsilon$ . The optimal solution assigns 1 driver to node 1 and the rest of them to node 2 for total wages 2. ◀

Hence, we reach the conclusion that, in the presence of selfish drivers, our approximation will be a factor 2 away of the ones achieved by our algorithms, i.e., we achieve a 2-approximation using our joint price and route optimization algorithm.

## 7 Transportation Network Pricing with Dynamic Demands

In this section we consider a natural extension of the TRANSPORTATION NETWORK PRICING problem where the demands on an edge can now vary as a function of time. We let  $d_e(p, t)$  denote the demand on edge  $e$  at time  $t$  when the price is  $p$ . The demand that applies is determined at the moment in time when an agent starts traversing an edge. For ease of notation, we assume that the lengths on edges are specified in the units of time. Since all edge lengths are integral we can assume that the demand changes only at integral time steps. In this section we prove the following theorem.

► **Theorem 14.** *The Transportation Network pricing problem with dynamic demands can be solved in time polynomial in  $n, k$ , and  $T$  to obtain an approximation of  $O(\log n)$ .*

To obtain the best possible result, we proceed in two steps. In step 1, we reduce the TRANSPORTATION NETWORK PRICING WITH DYNAMIC DEMAND problem to single agent TRANSPORTATION NETWORK ROUTING WITH UNIT TIME WINDOWS. In step 2, we reduce the single agent TRANSPORTATION NETWORK ROUTING WITH UNIT TIME WINDOWS problem to DIRECTED ORIENTEERING WITH UNIT TIME WINDOWS problem. In the end, we obtain an approximation factor of  $O(\log n)$ .

## 7.1 Step 1: Transportation Network Pricing to Transportation Network Routing

This reduction is similar to section 5.2. We present an additional step where we reduce the problem from  $k$  agents to a single agent.

First since the demand varies with time, we redevelop some of the notation to depend on time. The price curve  $p_e(d, t) = \max\{p \mid d_e(p, t) \geq d\}$  is the price at which the demand is at least  $d$ . The revenue from assigning  $l$  agents to edge  $e$  at time  $t$  is  $r_e(l, t) = \max_{0 \leq j \leq l} \{j p_e(j, t)\}$ . We approximate the revenue curve using a concave function  $\hat{r}_e(t, i)$  constructed similar to Lemma 9 with the guarantee that  $r_e(l, t) \leq \hat{r}_e(l, t) \leq 2r_e(l, t)$ .

Using the concave revenue functions  $\hat{r}$ , we reduce the problem to one of constructing paths on a graph. We will call this the Transportation Network Routing with Unit Time Windows problem.

► **Definition 15.** *In TRANSPORTATION NETWORK ROUTING WITH UNIT TIME WINDOWS problem, we are given a directed graph  $G(V, E)$  with values  $v_e$  and time window of unit length  $[t_e, t_e + 1]$  associated with each edge. The goal is to find  $k$  paths such that each path has length at most  $T$  and the sum of values  $v_e$  of all edges that appear in at least one path is maximized. The value  $v_e$  on an edge is only collected if the path starts on the edge  $e$  during the time window  $[t_e, t_e + 1]$ . If the same edge  $e$  appears in multiple paths, its value  $v_e$  is collected only once.*

Given our input instance  $G = (V, E)$  of the TRANSPORTATION NETWORK PRICING WITH DYNAMIC DEMANDS problem, we construct an instance  $G' = (V, E')$  of the TRANSPORTATION NETWORK ROUTING WITH UNIT TIME WINDOWS problem as follows. This graph has the same set of vertices  $V$ . For each edge  $(u, v)$  in the original graph  $G$ , we construct  $kT$  parallel edges between  $u$  and  $v$ . The value of the  $(l, t)$ 'th edge for  $l \in \{0, 1, \dots, k\}$  and  $t \in 0, 1, \dots, T - 1$  is  $\Delta \hat{r}(l, t) = \hat{r}(l, t + 1) - \hat{r}(l, t)$ . Then similar arguments as section 5.2 guarantee that an  $\alpha$ -approximation to TRANSPORTATION NETWORK ROUTING WITH UNIT TIME WINDOWS problem yields a  $2\alpha$ -approximation to TRANSPORTATION NETWORK PRICING WITH DYNAMIC DEMANDS. Note that since the paths map one-to-one in time between the two instances the time windows do not create any new challenge.

Next we show that an approximation algorithm for the TRANSPORTATION NETWORK ROUTING WITH TIME WINDOWS problem with one agent can be used to obtain a slightly worse approximation for  $k$  agents. The proof is similar to an analogous result by [7] for orienteering problem.

► **Theorem 16.** *An  $\alpha$ -approximation algorithm for the transportation network problem with time windows for a single agent can be used to obtain an  $(\alpha + 1)$ -approximation for the transportation network problem with time windows for  $k$  agents.*

**Proof.** Given an  $\alpha$ -approximation algorithm for the transportation network problem for a single agent, we use it repeatedly to solve the problem for  $k$  agents. After the algorithm has selected path  $A_i$  for the  $i$ 'th agent. We set the value on all edges used by the path  $A_i$  to zero before calling the algorithm for the next agent. This ensures that all paths constructed by the algorithm are edge disjoint. Let  $O = (O_1, O_2, \dots, O_k)$  denote the optimal solution with  $k$  agents decomposed into the  $k$  agents' paths. Let  $\Delta_i$  denote the edges from path  $O_i$  that have already been used by some path  $A_j$  (where  $j < i$ ) by algorithm before path  $A_i$  is chosen. There is a feasible path using all the edges of  $O_i \setminus \Delta_i$ . Thus we have that  $v(A_i) \geq \frac{1}{\alpha} \{v(O_i) - v(\Delta_i)\}$ . Summing these over all agents,  $\alpha v(A) \geq v(O) - v(\Delta)$ . Moreover  $v(\Delta) \leq v(A)$ . Hence we conclude that  $(\alpha + 1)v(A) \geq v(O)$ . ◀

With this result, it suffices to obtain an approximation for the TRANSPORTATION NETWORK ROUTING WITH TIME WINDOWS problem for a single agent.

## 7.2 Step 2: Transportation Network Routing to Directed Orienteering

We next reduce TRANSPORTATION NETWORK ROUTING WITH TIME WINDOWS to directed orienteering with fixed start locations and unit time windows.

► **Definition 17.** *In DIRECTED ORIENTEERING WITH UNIT TIME WINDOWS AND FIXED START we are given a directed graph  $G = (V, E)$  with costs on the edges and values on the nodes, and a cost budget  $T$ . There is also a time-window of unit length associated with each node. The value from a node is only collected if it is visited within the time window. We seek to find a path of cost at most  $T$  that starts at node  $s \in V$  such that the value collected is maximized.*

This problem can be solved in polynomial time to obtain an approximation of  $O(\log n)$ . This follows from [9] that provide an approximation of  $O(\alpha)$  where  $\alpha$  is approximation for directed orienteering, [13] that provides an  $O(\beta \log n)$  approximation for directed orienteering where  $\beta$  is the integrality gap for asymmetric TSP, and [17] that provides a constant factor integrality gap for asymmetric TSP.

We start with the TRANSPORTATION NETWORK ROUTING instance  $G' = (V, E')$  with length  $l_e$ , value  $v_e$  and unit time window  $[t_e, t_e + 1]$  associated with each edge. We construct a directed graph  $H = (N, A)$  with values on the nodes and costs on the edges. The set of vertices  $N = V \cup I$ . The set  $V$  is the set of original vertices. The set  $I$  is the set of *intermediate* vertices, with one vertex  $z_e$  for each edge  $e$  in  $E'$ . In the graph  $H$ , for each edge  $e = (u, v) \in E'$ , we add an edge  $(u, z_e)$  of length  $l_e$  and an edge  $(z_e, v)$  of length zero. We associate value  $v_e$  and time window  $[t_e + l_e, t_e + l_e + 1]$  with each intermediate node  $z_e$  and value 0 with nodes in  $V$ .

We prove the following lemmas to obtain the final result:

► **Lemma 18.** *Any path of length at most  $T^*$  in graph  $G'$  that picks value  $V$  can be expressed as a path of length  $T^*$  in  $H$  that picks value  $V$*

**Proof.** Consider edge  $e = (u, v)$  in the path. We map it to the edges  $(u, z_e), (z_e, v)$ . The path collects the value if it starts traversing the edge during  $[t_e, t_e + 1]$ . In the orienteering instance the path will get to the intermediate node  $z_e$  in time window  $[t_e + l_e, t_e + l_e + 1]$  so the same value  $v_e$  can be collected. ◀

For mapping a solution in graph  $H$  to a solution in graph  $G'$  the main blocker is that the path may start or end at one of the  $z_e$  nodes. To tackle this we call the orienteering problem with a fixed start node. We prove the following lemma.

► **Lemma 19.** *Given a path of length  $T^*$  that starts at a node a non-intermediate node  $s$  in  $H$  and collects value  $V$ , we can construct a path of length  $T^*$  in the graph  $G'$  with value  $V$  starting at node  $s$  in graph  $G'$*

**Proof.** If the path in  $H$  ends at an intermediate node  $z_e$ , it can be extended to the next non-intermediate node without increasing its length. We can assume that the path begins and ends in non-intermediate nodes. After that there is one-to-one mapping between the portions of the path. An intermediate node  $z_e$  only connects to the end node  $v$  of the edge  $e$ . So we can always find pairs of segments  $(u, z_e), (z_e, v)$  in the path. These can be mapped to  $e = (u, v)$  in graph  $G'$ . The value  $v_e$  is the same, the lengths of the segments are the same and the time window  $[t_e + l_e, t_e + l_e + 1]$  in the graph  $H$  maps to  $[t_e, t_e + 1]$  which is precisely when the constructed path will begin traversing edge  $e$ . ◀

To complete the proof of Theorem 14, we need to call the orienteering subroutine with all possible start nodes in the set  $V$ . We can choose the best solution among those and it will be an  $O(\log n)$ -approximation to the optimal solution to the SINGLE AGENT TRANSPORTATION NETWORK ROUTING problem. Trying different start nodes does not degrade the running time by more than a factor of  $n$ .

## 8 Capacitated Vehicles

For the sake of simplicity, we have studied the problem in terms of unit capacity vehicles that can serve a single demand when crossing an edge. We now explain that a simple transformation can reduce the capacitated version of the problem where each vehicle can serve up to a fixed number  $c$  of demands to the unit capacity case. The main idea is as follows: We will transform any given demand curve into an equivalent one such that a) for any given price, the number of buyers that is willing to buy is a multiple of  $c$  and b) the revenue functions remain intact. Achieving that would then allow us to change the units of measurement by a factor  $c$  and have each unit of demand correspond to a number of buyers equal to the vehicle capacity, in effect recovering the unit capacity model. Note that the revenue functions that give the optimal revenue of an edge as a function of the supply assigned to it are the only input given to our main algorithms. This implies our approximation results are preserved by such a reduction.

Consider a given price curve  $p_e(\cdot)$ . For any given integer  $s$ , let,

$$\rho_s = \max_{(s-1)c < d \leq s \cdot c} d \cdot p_e(d), \quad (9)$$

be the maximum revenue obtained when using exactly  $s$  service vehicles. Our modified curve is such that:

$$\hat{d}_e(p) = s \cdot c, \text{ for all } p \in \left( \frac{\rho_{s+1}}{(s+1)c}, \frac{\rho_s}{s \cdot c} \right]. \quad (10)$$

The following lemma proves that the modified demand curve is well defined.

► **Lemma 20.**

$$\frac{\rho_{s+1}}{(s+1)c} \leq \frac{\rho_s}{s \cdot c}.$$

**Proof.** Note that  $\rho_s \geq p_e(s \cdot c)s \cdot c$ , since using  $d = s \cdot c$  is an option in (9). Also,  $\rho_{s+1} \leq p_e(s \cdot c)(s+1)c$ , since the highest price for which supply  $s+1$  is needed is at most  $p_e(s \cdot c)$  and the highest demand for which supply  $s+1$  is needed is  $(s+1)c$ . The two inequalities can be combined to give:

$$\frac{\rho_{s+1}}{(s+1)c} \leq p_e(s \cdot c) \leq \frac{\rho_s}{s \cdot c},$$

which completes the proof. ◀

The demand curve (10) by definition satisfies the property that only a multiple of  $c$  buyers will show up under any price. Then, the  $j$ -th such group of  $c$  buyers can be replaced with a single buyer with value  $\rho_j/j$ . By Lemma 20 these  $\rho_j/j$  values are nonincreasing, as necessary for demand curves. Moreover, the optimal revenue obtained by any given number of supply vehicles remains the same, which suggests the revenue curves are unchanged and our transformation is completed as desired.

## Abstract

---

A *connected partition* is a partition of the vertices of a graph into sets that induce connected subgraphs. Such partitions naturally occur in many application areas such as road networks, and image processing. In these settings, it is often desirable to partition into a fixed number of parts of roughly of the same size or weight. The resulting computational problem is called Balanced Connected Partition (BCP). The two classical objectives for BCP are to maximize the weight of the smallest, or minimize the weight of the largest component. We study BCP on  $c$ -claw-free graphs, the class of graphs that do not have  $K_{1,c}$  as an induced subgraph, and present efficient  $(c - 1)$ -approximation algorithms for both objectives. In particular, for 3-claw-free graphs, also simply known as claw-free graphs, we obtain a 2-approximation. Due to the claw-freeness of line graphs, this also implies a 2-approximation for the edge-partition version of BCP in general graphs.

A harder connected partition problem arises from demanding a connected partition into  $k$  parts that have (possibly) heterogeneous target weights  $w_1, \dots, w_k$ . In the 1970s Györi and Lovász showed that if  $G$  is  $k$ -connected and the target weights sum to the total size of  $G$ , such a partition exists. However, to this day no polynomial algorithm to compute such partitions exists for  $k > 4$ . Towards finding such a partition  $T_1, \dots, T_k$  in  $k$ -connected graphs for general  $k$ , we show how to efficiently compute connected partitions that at least approximately meet the target weights, subject to the mild assumption that each  $w_i$  is greater than the weight of the heaviest vertex. In particular, we give a 3-approximation for both the lower and the upper bounded version i.e. we guarantee that each  $T_i$  has weight at least  $\frac{w_i}{3}$  or that each  $T_i$  has weight most  $3w_i$ , respectively. Also, we present a both-side bounded version that produces a connected partition where each  $T_i$  has size at least  $\frac{w_i}{3}$  and at most  $\max(\{r, 3\})w_i$ , where  $r \geq 1$  is the ratio between the largest and smallest value in  $w_1, \dots, w_k$ . In particular for the balanced version, i.e.  $w_1 = w_2 = \dots = w_k$ , this gives a partition with  $\frac{1}{3}w_i \leq w(T_i) \leq 3w_i$ .

## 1 Introduction

Partitioning a graph into connected subgraphs is a problem that arises in many application areas such as parallel processing, road network decomposition, image processing, districting problems, and robotics [34, 35, 4, 1, 39]. Often in these applications, it is required to find a partition into a specified number  $k$  of connected subgraphs. For instance, in the parallel processing applications, the number of processors is restricted, and in robotics applications, the number of robots available is restricted. Formally, we call a partition  $T_1, T_2, \dots, T_k$  of the vertex set of graph, a *connected ( $k$ -)partition*, if the subgraph induced by the vertices in  $T_i$  is connected for each  $1 \leq i \leq k$ .

The typical modeling objective in such connected partition problems is to balance sizes among the  $k$  parts. Sometimes one needs to consider a vertex-weighted generalization e.g. weights representing the required amount of work at the entity corresponding to the vertex. The two classical balancing objectives for such  $k$ -partitions are to maximize the total weight of the lightest part, or to minimize the weight of the heaviest part. These objectives yield the following two versions of the *balanced connected partition problem* (BCP).

MAX-MIN BCP (MIN-MAX BCP)

*Input:* A vertex-weighted graph  $G = (V, E, w)$  where  $w : V \rightarrow \mathbb{N}$ , and  $k \in \mathbb{N}$ .

*Task:* Find a connected  $k$ -partition  $T_1, \dots, T_k$  of  $G$  maximizing  $\min_{i \in [k]} w(T_i)$  (minimizing  $\max_{i \in [k]} w(T_i)$  resp.).

On general graphs, both variants of BCP are NP-hard [5], and hence the problems have been mostly studied from the viewpoint of approximation algorithms [6, 8, 9, 11, 12]. Most of the known results are for small values of  $k$ , and there are some results also for special classes like grid graphs or graphs of bounded treewidth (see related work section for further details). The currently best known polynomial-time approximation for general graphs for any  $k$  is a 3-approximation for both MAX-MIN and MIN-MAX BCP by Casel et. al. [6].

Intuitively, an obstacle for getting a balanced connected partition is a large induced star, i.e. a tree with one internal node and  $c$  leaves, denoted by  $K_{1,c}$ . We say a graph is  *$c$ -claw-free* or  *$K_{1,c}$ -free* if it does not contain an induced  $K_{1,c}$  as subgraph. For such graphs, we give a very efficient  $(c - 1)$ -approximation algorithm for both the min-max and max-min objective. In particular by setting  $c = 3$ , we get a 2-approximation on  $K_{1,3}$ -free graphs, better known as *claw-free graphs*.

Claw free graphs have been widely studied by Seymour and Chudnovsky in a series of seven papers under the name *Claw-free graphs I-VII* ([14]-[20]), who also provide a structure theorem for these graphs [21]. Some interesting examples of such graphs are line graphs, proper circular interval graphs and de-Bruijn graphs [22]. Apart from their structural properties, claw-free graphs have been studied in the context of obtaining efficient algorithms for several interesting problems, see e.g. [27, 24, 23].

Although, for  $c > 3$  our algorithm gives a worse guarantee than the algorithm by Casel et. al. [6], we note that their algorithm runs in  $\mathcal{O}(\log(X^*)k^2|V||E|)$  time for MAX-MIN BCP and in  $\mathcal{O}(\log(X^*)|V||E|(\log \log X^* \log(|V|w_{\max}) + k^2))$  time for MIN-MAX BCP, where  $X^*$  denotes the optimum value and  $w_{\max} := \max_{v \in V} w(v)$  the maximum weight of a vertex, whereas our algorithms give an  $\mathcal{O}(\log(X^*)|E|)$  runtime for MAX-MIN BCP and an  $\mathcal{O}(|E|)$  runtime for MIN-MAX BCP. Moreover, our algorithms are less technical and hence much easier to implement. We prove the following statements.

► **Theorem 1.** *Given a vertex-weighted  $K_{1,c}$ -free graph  $G = (V, E, w)$  and  $k \in \mathbb{N}$ , a  $(c - 1)$ -approximation for MIN-MAX BCP can be computed in  $\mathcal{O}(|E|)$  time.*

► **Theorem 2.** *Given a vertex-weighted  $K_{1,c}$ -free graph  $G = (V, E, w)$  and  $k \in \mathbb{N}$ , a  $(c - 1)$ -approximation for MAX-MIN BCP can be computed in time  $\mathcal{O}(\log(X^*)|E|)$ , where  $X^*$  is the optimum value.*

Since line graphs are  $K_{1,3}$ -free, these results directly imply efficient approximations for the following edge-partition versions of BCP. A  $k$ -partition of the edges of a graph, is called a *connected edge  $k$ -partition*, if the subgraph induced by the edges in each part is connected. In the problem Min-Max (Max-Min) balanced connected edge partition (BCEP), one searches for a connected edge  $k$ -partition of an edge-weighted graph minimizing the maximum (resp. maximizing the minimum) weight of the parts. This problem is equivalent to finding a connected  $k$ -partition of the vertices in the line graph of the input graph. The best known approximation for BCEP is for graphs with no edge weight larger than  $w(G)/2k$ . For such graphs, [13] give an algorithm that finds a connected edge  $k$ -partition, such that the weight of the heaviest subgraph is at most twice as large as the weight of the lightest subgraph, implying a 2-approximation for MIN-MAX and MAX-MIN BCEP. In comparison, our algorithms achieve the same approximation guarantee without restrictions on the edge weights.

► **Corollary 3.** *MIN-MAX BCEP and MAX-MIN BCEP have 2-approximations in polynomial time.*

An extension of BCP is demanding for fixed (possibly heterogeneous) size targets for each of the  $k$  parts. More precisely, given a graph  $G$  and  $w_1, \dots, w_k$  with  $\sum_{i=1}^k w_i = n$ , the task is to find a partition  $T_1, \dots, T_k$  where each  $T_i$  has size  $w_i$  and induces a connected subgraph. Such a connected  $k$ -partition with the fixed target weights exists for  $G$  only if  $G$  meets certain structural properties; a  $K_{1,3}$  for example has no connected 2-partition  $T_1, T_2$  with  $|T_1| = |T_2| = 2$ . A characterization of when such a connected partition always exists was independently proved by Györi [26] and Lovász [32]: They showed that in any  $k$ -connected graph a connected  $k$ -partition satisfying the target weights always exists. This result is the famous Györi-Lovász Theorem (GL theorem, for short):

► **Theorem 4** (Györi-Lovász Theorem [26, 32]). *Given a  $k$ -connected graph  $G = (V, E, w)$ ,  $n_1, \dots, n_k \in \mathbb{N}$  such that  $\sum_{i=1}^k n_i = |V|$ , and  $k$  terminal vertices  $t_1, \dots, t_k \in V$ , there exists a connected  $k$ -partition  $T_1, \dots, T_k$  of  $V$  such that for each  $i \in [k]$ ,  $|T_i| = n_i$  and  $t_i \in T_i$ .*

Recently, the theorem was generalized to vertex-weighted graphs as:

► **Theorem 5** (Weighted Györi-Lovász Theorem [7, 10, 28]). *Given a vertex-weighted  $k$ -connected graph  $G = (V, E, w)$ ,  $w_1, \dots, w_k \in \mathbb{N}$  such that  $\sum_{i=1}^k w_i = w(V)$ , and  $k$  terminal vertices  $t_1, \dots, t_k$ , there exists a connected  $k$ -partition  $T_1, \dots, T_k$  of  $V$  such that  $w_i - w_{\max} < w(T_i) < w_i + w_{\max}$ , and  $t_i \in T_i$  for each  $i \in [k]$ , where  $w_{\max}$  is the largest vertex weight.*

We refer to the partition guaranteed by the (weighted) GL theorem as *GL partition*. We will however not consider the terminal vertices in the GL partitions in this work.

The GL theorem has found some applications in the field of algorithms. Chen et. al. [10] use it for proving the existence of low-congestion *confluent flows* in  $k$ -connected graphs. Further, Löwenstein et. al. [33] and Chandran et. al. [7] use it for finding spanning trees with low *spanning tree congestion*. Perhaps, the reason why such a strong combinatorial statement has not found further applications is that we do not know how to efficiently compute GL

partitions. About five decades after the discovery of the GL theorem, polynomial time algorithms for finding a GL partition (even in the unweighted case without terminals) are only known for  $k \leq 4$  [37, 38, 28]. The fastest algorithm for general  $k$  takes  $\Omega(2^n)$  time [7, 29]. Neither are there any impossibility results to exclude efficient computability of such partitions. Even when  $k$  is part of the input, a polynomial time algorithm is not ruled out.

The absence of efficient algorithms for finding exact GL partitions motivates finding GL-style partitions that approximately satisfy the weight targets. In this paper we present polynomial time algorithms for such approximations. First we give an algorithm for a “half-bounded” GL partition, in the sense that we can guarantee an approximate upper or lower bound on the weight of the parts.

► **Theorem 6.** *Let  $G = (V, E, w)$  be a  $k$ -connected vertex-weighted graph and  $w_1, \dots, w_k \in \mathbb{N}$  with  $\sum_{i=1}^k w_i = w(G)$ , and  $\min_{i \in [k]} w_i \geq \max_{v \in V} w(v)$ . A connected  $k$ -partition  $T_1, \dots, T_k$  of  $V$  such that either  $w(T_i) \geq \frac{1}{3}w_i$  for every  $i \in [k]$  (lower-bound version) or  $w(T_i) \leq 3w_i$  for every  $i \in [k]$  (upper-bound version) can be computed in time  $\mathcal{O}(k|V|^2|E|)$ .*

We then extend this result to a lower and upper bounded partition.

► **Theorem 7.** *Let  $G = (V, E, w)$  be a  $k$ -connected vertex-weighted graph and  $w_1, \dots, w_k \in \mathbb{N}$  with  $\sum_{i=1}^k w_i = w(G)$ , and  $\min_{i \in [k]} w_i \geq \max_{v \in V} w(v)$ , and  $r := \frac{\max_{i \in [k]} w_i}{\min_{j \in [k]} w_j}$ . Then, a connected  $k$ -partition  $T_1, \dots, T_k$  of  $V$  such that  $\frac{1}{3}w_i \leq w(T_i) \leq \max\{r, 3\}w_i$  for every  $i \in [k]$  can be found in time  $\mathcal{O}(k|V|^2|E|)$ .*

In particular, Theorem 7 implies the following approximately balanced partition of  $k$ -connected graphs.

► **Corollary 8.** *Let  $G = (V, E, w)$  be a  $k$ -connected vertex-weighted graph such that  $w(G) \geq k \max_{v \in V} w(v)$ . Then, a connected  $k$ -partition  $T_1, \dots, T_k$  of  $V$  such that  $\frac{1}{3} \left\lfloor \frac{w(G)}{k} \right\rfloor \leq w(T_i) \leq 3 \left\lceil \frac{w(G)}{k} \right\rceil$  for every  $i \in [k]$  can be found in time  $\mathcal{O}(k|V|^2|E|)$ .*

To the best of our knowledge, these are the first polynomial time algorithms that *approximate* the GL theorem. We believe that such an efficient approximation will result in the theorem being used for developing algorithms in the future. Especially, we are hopeful that the both-side approximation for balanced connected partition of  $k$ -connected graphs will find applications. We remark, however that for the above mentioned applications of confluent flows and spanning tree congestion, the terminal vertices are essential and hence our algorithms cannot be used. An interesting future direction would be to extend our results to the setting with terminals.

Observe that Corollary 8 in some sense yields a 3-approximation simultaneously for MIN-MAX and MAX-MIN BCP in  $k$ -connected graphs. In this regard, it is interesting to note that the  $+/-w_{\max}$  slack given in the weighted GL theorem is enough to retain hardness in the following sense: even for  $k = 2$ , MIN-MAX BCP and MAX-MIN BCP remain strongly NP-hard when restricted to 2-connected graphs; and the corresponding hardness-proof given in [8] also constructs an instance with  $w(G) \geq k \max_{v \in V} w(v)$ . This hardness can be extended to  $k$ -connected graphs for any fixed  $k \geq 2$  (see [8][Theorem 3] for more details).

Lastly, we point out that this paper is only a short version and refer the reader for more technical details and complete proofs to the full version of it.

## 1.1 Related work

Both variants of BCP were first introduced for trees [36, 31]. Under this restriction, a linear time algorithm was provided for both variants in [25]. This is particularly important since different heuristics transform the original instance to a tree to efficiently solve the problem, see [13, 39]. For both variants of BCP, a 3-approximation is given in [6], which is the best known approximation in polynomial time. With respect to lower bounds, it is known that there exists no approximation for MAX-MIN BCP with a ratio below  $6/5$ , unless  $P = NP$  [8]. For the unweighted case, a  $\frac{k}{2}$ -approximation for MIN-MAX BCP with  $k \geq 3$ , is given in [11].

Balanced connected partitions for fixed small values of  $k$ , denoted  $BCP_k$ , have also been studied extensively. The restriction  $BCP_2$ , i.e. balanced connected bipartition, is already NP-hard [5]. On the positive side, a  $\frac{4}{3}$ -approximation for MAX-MIN  $BCP_2$  is given in [12], and in [11] this result is used to derive a  $\frac{5}{4}$ -approximation for MIN-MAX  $BCP_2$ . Considering tripartitions, MAX-MIN  $BCP_3$  and MIN-MAX  $BCP_3$  can be approximated with ratios  $\frac{5}{3}$  and  $\frac{3}{2}$ , respectively [9].

Regarding special graph classes, BCP has been investigated in grid graphs and series-parallel graphs. While it was shown that BCP is NP-hard for arbitrary grid graphs [2], the MAX-MIN BCP can be solved in polynomial time for ladders, i.e., grid graphs with two rows [3]. For the class of series-parallel graphs, Ito et. al. [30] observed that BCP remains weakly NP-hard (by a simple reduction from the Partition problem) and gave a pseudo-polynomial-time algorithm for both variants of BCP. They also showed that their algorithm can be extended to graphs with bounded tree-width.

The GL Theorem was independently proved by Györi [26] and Lovász [32]. Györi used an elementary graph theoretic approach while Lovász used ideas from topology. Lovász's proof also works for directed graphs. The Györi-Lovász Theorem is extended to weighted directed graphs by Chen et. al. [10] and Györi's original proof was generalized to weighted undirected graphs by Chandran et. al. [7]. Both papers only gave upper bounds of  $w_i + w_{\max}$  on the weight of partition  $T_i$  and did not provide any lower bounds. Later Hoyer [28] showed that the method of Chandran et. al. [7] can be also extended to give the lower bound  $w_i - w_{\max}$ , even for directed graphs. Polynomial algorithms to also compute GL partitions are only known for the particular cases  $k = 2, 3, 4$  [37, 38, 28] and all  $k \geq 5$  are still open.

## 2 Preliminaries

By  $\mathbb{N}$  we denote the natural numbers without zero. We use  $[k]$  to denote the set  $\{1, \dots, k\}$ .

All the graphs that we refer to in this paper are simple, finite and connected. Consider a graph  $G = (V, E)$ . We denote by  $V(G)$  and  $E(G)$  the set of vertices and edges of  $G$  respectively, and if the graph we refer to is clear, we may simply write  $V$  and  $E$ . For a set of vertex sets  $\mathcal{S} \subseteq 2^V$  we use  $V(\mathcal{S})$  to denote  $\bigcup_{S \in \mathcal{S}} S$ . We denote an edge  $e = \{u, v\} \in E(G)$  by  $uv$  and the neighborhood of a vertex  $v \in V$  in  $G$  by  $N_G(v) = \{u \in V \mid uv \in E(G)\}$ . Similarly we denote the neighborhood of a vertex set  $V' \subseteq V$  in  $G$  by  $N_G(V')$ , that is  $\bigcup_{v \in V'} N_G(v) \setminus V'$ . We may omit the subscript  $G$  when the graph is clear from the context. We use  $\Delta(G)$  to denote the maximum degree of  $G$ .

We denote a *vertex-weighted graph* by  $G = (V, E, w)$  where  $w$  is a function assigning integer weights to vertices  $w: V \rightarrow \mathbb{N}$ , and  $V$  and  $E$  are vertex and edge sets. We denote by  $w_{\min}$  and by  $w_{\max}$ ,  $\min_{v \in V} w(v)$  and  $\max_{v \in V} w(v)$ , respectively. For any  $V' \subseteq V$ , we use  $w(V')$  to denote the sum of weights of the vertices in  $V'$ . For a subgraph  $H$  of  $G$  we use  $w(H)$  to denote  $w(V(H))$ , and refer to it as the *weight of the subgraph*  $H$ . For a rooted tree  $T$  and a vertex  $x$  in  $T$ , we use  $T_x$  to denote the rooted subtree of  $T$  rooted at  $x$ .

For  $V' \subseteq V$  we denote by  $G[V']$  the graph induced by  $V'$ , i.e.  $G[V'] = (V', E')$  with  $E' = E \cap (V' \times V')$ . For vertex-weighted graphs, induced subgraphs inherit the vertex-weights given by  $w$ . For  $V' \subseteq V$  we also use  $G - V'$  to denote the subgraph  $G[V \setminus V']$ . Similarly, if  $V'$  is a singleton  $\{v\}$  we also write  $G - v$ . For graphs  $G_1$  and  $G_2$ , we use  $G_1 \cup G_2$  to denote the graph on vertices  $V(G_1) \cup V(G_2)$  with edge set  $E(G_1) \cup E(G_2)$ .

Let  $\mathcal{U} = \{U_1, \dots, U_r\}$  be such that each  $U_i \subseteq V(G)$ . We call  $\mathcal{U}$  a *connected packing* of  $V(G)$  if each  $G[U_i]$  is connected, and the sets in  $\mathcal{U}$  are pairwise disjoint. A connected packing  $\mathcal{U}$  is called *connected vertex partition* (CVP) of  $V$ , if also  $\cup_{i=1}^r U_i = V(G)$ . We denote a CVP that has  $k$  vertex sets as  $\text{CVP}_k$ . For any  $\mathcal{U}' \subseteq \mathcal{U}$ , we define  $V(\mathcal{U}') := \cup_{U' \in \mathcal{U}'} U'$ , and the weight  $w(\mathcal{U}') := w(V(\mathcal{U}'))$ . Let  $\mathcal{I}$  be an interval. If  $\mathcal{U}$  is a CVP and  $w(U_i) \in \mathcal{I}$  for all  $i \in [r]$ , then we say that  $\mathcal{U}$  is an  $\mathcal{I}$ -connected vertex ( $r$ -)partition ( $\mathcal{I}$ -CVP $_k$  or just  $\mathcal{I}$ -CVP) of  $V$ . If  $\mathcal{U}$  is a connected-packing and  $w(U_i) \in \mathcal{I}$  for all  $i \in [r]$ , then we say that  $\mathcal{U}$  is a  $\mathcal{I}$ -connected packing of  $V$ .

### 3 Approximation for BCP on $c$ -claw-free graphs

In this section we give an idea of how to prove Theorems 1 and 2 by giving a  $(c - 1)$ -approximation for MAX-MIN BCP and MIN-MAX BCP on  $K_{1,c}$ -free graphs. We assume  $c \geq 3$  as  $c \leq 2$  gives trivial graph classes. We first show that a connected partition for  $K_{1,c}$ -free graphs with parts of size in  $[\lambda, (c - 1)\lambda]$  for some fixed  $\lambda$  can be found in linear time. For MAX-MIN BCP, this algorithm has to be called many times while doing a binary search for the optimum value. We point out that it is not difficult to adapt these algorithms to unconnected graphs achieving the same approximation results.

Exploiting that each vertex in any DFS-tree of a  $K_{1,c}$ -free graph has at most  $c - 1$  children, we can carefully extract connected components of a fixed size while also maintaining a DFS-tree for the remaining graph. Also, this can be done very efficiently, as stated in the following result.

► **Lemma 9.** *Given a  $K_{1,c}$ -free graph  $G$  and a DFS-tree of  $G$ . For any  $w(G) \geq \lambda \geq w_{\max}$ , there is an algorithm that finds a connected vertex set  $S$  such that  $\lambda \leq w(S) < (c - 1)\lambda$  and  $G - S$  is connected, in  $\mathcal{O}(|V|)$  time. Furthermore, the algorithm finds a DFS-tree of  $G - S$ .*

We use `BalancedPartition` to denote the algorithm that exhaustively applies Lemma 9. Observe that `BalancedPartition` produces a connected partition  $S_1, \dots, S_m$  where  $w(S_i) \in [\lambda, (c - 1)\lambda]$  for every  $i \in [m - 1]$  and  $w(S_m) < (c - 1)\lambda$  in linear time, where the achieved runtime follows by saving already processed subtrees.

Theorem 1 now follows from running `BalancedPartition` with  $\lambda = \max\{w_{\max}, \frac{w(G)}{k}\}$ . Note that this choice of  $\lambda$  is a trivial lower bound for the optimum value.

As already mentioned, to prove Theorem 2, we first need to find an input parameter  $\lambda$  for Algorithm `BalancedPartition` that provides the desired  $(c - 1)$ -approximation.

Let  $(G, k)$  be an instance of MAX-MIN BCP, where  $G$  is a  $K_{1,c}$ -free graph. Let  $X^*$  be the optimal value for the instance  $(G, k)$ . For any given  $X \leq w(G)/k$ , we design an algorithm that either gives a  $[\lfloor X/(c - 1) \rfloor, \infty)$ -CVP $_k$ , or reports that  $X > X^*$ . Note that  $X^* \leq w(G)/k$ . Once we have this procedure in hand, a binary search for the largest  $X$  in the interval  $(0, \lceil w(G)/k \rceil]$  for which we find a  $[\lfloor X/(c - 1) \rfloor, \infty)$ -CVP $_k$  can be used to obtain an approximate solution for MAX-MIN BCP.

**Algorithm MaxMinApx.** First remove all vertices of weight more than  $\lambda = \lfloor X/(c - 1) \rfloor$  and save them in  $H$ . Then save the connected components of weight less than  $\lambda$  in  $\mathcal{Q}$ .

Let  $\mathcal{V} = \{V_1, \dots, V_\ell\}$  be the connected components of  $G - (H \cup V(\mathcal{Q}))$ . Apply algorithm `BalancedPartition` on each  $G[V_i]$  with  $\lambda$  as input parameter to obtain  $\mathcal{S}^i = \{S_1^i, \dots, S_{m_i}^i\}$  for every  $i \in [\ell]$ . If for some  $i \in [\ell]$  the weight  $w(S_{m_i}^i)$  is less than  $\lambda$ , then merge this vertex set with  $S_{m_i-1}^i$  and accordingly update  $\mathcal{S}^i$ . Further, compute a  $(\lambda, \infty)$ -CVP $_{|H|}$   $\mathcal{S}^H$  of  $G[H \cup V(\mathcal{Q})]$  as follows: for each  $h \in H$ , we have a set  $S^h \in \mathcal{S}^H$  with  $h \in S^h$ ; we add each  $Q \in \mathcal{Q}$  to some  $S^h$  such that  $h \in N(Q)$ . Let  $\mathcal{S} = \mathcal{S}^H \cup \bigcup_{i=1}^{\ell} \mathcal{S}^i$ . If  $|\mathcal{S}| \geq k$ , then merge connected sets arbitrarily in  $\mathcal{S}$  until  $|\mathcal{S}| = k$  and return  $\mathcal{S}$ . If  $|\mathcal{S}| < k$ , report that  $X > X^*$ .

We point out that a  $[\lambda, \infty)$ -CVP $_j$  with  $j > k$ , can easily be transformed to a  $[\lambda, \infty)$ -CVP $_k$ , since the input graph is connected. It is not hard to see that if algorithm `MaxMinApx` returns  $\mathcal{S}$  then this is a  $[\lambda, \infty)$ -CVP $_k$  of  $V$ . The most complicated part of proving that `MaxMinApx` works correctly is showing that if it terminates with  $|\mathcal{S}| < k$  and reports  $X > X^*$  that this is indeed true.

► **Lemma 10.** *If Algorithm `MaxMinApx` terminates with  $|\mathcal{S}| < k$ , then  $X > X^*$ .*

**Proof.** Let  $H, \mathcal{Q}, \mathcal{V} = \{V_1, \dots, V_\ell\}$  be the computed vertices and connected vertex sets in the algorithm for  $\lambda = \lfloor X/(c-1) \rfloor$ , respectively. Recall that  $w(V_i) \geq \lambda$  for every  $V_i \in \mathcal{V}$  and  $w(Q) < \lambda$  for every  $Q \in \mathcal{Q}$ . Let  $\mathcal{S}^* = \{S_1^*, \dots, S_k^*\}$  be an optimal solution of  $(G, k)$ , i.e.,  $\mathcal{S}^*$  is an  $[X^*, \infty)$ -CVP $_k$  of  $V$ . Consider the sets  $\mathcal{V}^{H \cup \mathcal{Q}} := \{S_i^* \in \mathcal{S}^* \mid S_i^* \cap (H \cup V(\mathcal{Q})) \neq \emptyset\}$ ,  $\mathcal{V}^1 := \{S_i^* \in \mathcal{S}^* \mid S_i^* \cap V_1 \neq \emptyset\} \setminus \mathcal{V}^{H \cup \mathcal{Q}}$ ,  $\dots$ ,  $\mathcal{V}^\ell := \{S_i^* \in \mathcal{S}^* \mid S_i^* \cap V_\ell \neq \emptyset\} \setminus \mathcal{V}^{H \cup \mathcal{Q}}$ . We claim that these sets are a partition of  $\mathcal{S}^*$ . This follows directly from the fact that  $H$  separates all  $V_i \in \mathcal{V}$  and all  $Q \in \mathcal{Q}$  from each other. That is, for an  $i \in [k]$  and  $j \in [\ell]$  the connected vertex set  $S_i^*$  with  $S_i^* \cap V_j \neq \emptyset$  and  $S_i^* \cap V \setminus V_j \neq \emptyset$  contains at least one  $h \in H$  and hence  $S_i^* \in \mathcal{V}^{H \cup \mathcal{Q}}$ . Otherwise, if  $S_i^* \subseteq V_j$ , then  $S_i^* \in \mathcal{V}^j$ .

Suppose `MaxMinApx` terminates with  $|\mathcal{S}| < k$  although  $X \leq X^*$ . We show that  $|\mathcal{V}^{H \cup \mathcal{Q}}| \leq |H|$  and  $|\mathcal{V}^i| \leq |\mathcal{S}^i|$  for every  $i \in [\ell]$ , implying that  $|\mathcal{S}^*| \leq |H| + \sum_{i=1}^{\ell} |\mathcal{S}^i| = |\mathcal{S}| < k$ , which contradicts  $|\mathcal{S}^*| = k$ .

First, we show  $|\mathcal{V}^{H \cup \mathcal{Q}}| \leq |H|$ . For this, it is sufficient to prove that  $S_i^* \cap H \neq \emptyset$  for each  $S_i^* \in \mathcal{V}^{H \cup \mathcal{Q}}$  as  $\mathcal{S}^*$  is a partition of  $V$ . We prove this by contradiction. Suppose there is an  $S_i^* \in \mathcal{V}^{H \cup \mathcal{Q}}$ , such that  $S_i^* \cap H = \emptyset$ . This implies that  $S_i^* \subseteq Q$  for some  $Q \in \mathcal{Q}$ , since  $H$  separates every  $Q \in \mathcal{Q}$  from every other  $Q' \in \mathcal{Q} \setminus \{Q\}$  and from the vertices  $V \setminus (H \cup V(\mathcal{Q}))$ . Thus,  $w(S_i^*) \leq w(Q) < \lambda$  by the definition of  $\mathcal{Q}$  and therefore  $w(S_i^*) < \lambda = \lfloor X/(c-1) \rfloor \leq \lfloor X^*/(c-1) \rfloor$ , contradicting  $\min_{i \in [k]} w(S_i^*) = X^*$ .

It remains to show that  $|\mathcal{V}^i| \leq |\mathcal{S}^i|$  for every  $i \in [\ell]$ . Fix an  $i \in [\ell]$  and let  $G[V_i]$  with  $\lambda$  be the input when calling algorithm `BalancedPartition`. Observe that the input is valid, since  $G[V_i]$  is connected by definition and  $w(G[V_i]) \geq \lambda \geq \max_{v \in V_i} w(v)$  as  $H$  contains all vertices that have weight more than  $\lambda$ . Algorithm `BalancedPartition` provides a CVP  $\mathcal{S}^i = \{S_1^i, \dots, S_{m_i}^i\}$  of  $V_i$  with  $w(S_j^i) \in [\lambda, (c-1)\lambda)$  for every  $j \in [m_i-1]$  and  $w(S_{m_i}^i) < (c-1)\lambda$ . Consider  $\mathcal{S}^i$  before merging, i.e. we do not merge  $S_{m_i}^i$  to  $S_{m_i-1}^i$  in the algorithm `MaxMinApx` if  $w(S_{m_i}^i) < \lambda$ . That is,  $w(S_{m_i}^i) < \lambda$  is possible, and we need to show  $|\mathcal{V}^i| \leq m_i - 1 = |\mathcal{S}^i| - 1$ . Observe for  $\mathcal{S}^* \in \mathcal{V}^i$  that  $\mathcal{S}^* \subseteq V_i$ , i.e.  $\sum_{j=1}^{m_i} w(S_j^i) \geq \sum_{\mathcal{S}^* \in \mathcal{V}^i} w(\mathcal{S}^*)$ . As a result, we have  $|\mathcal{S}^i|X \geq |\mathcal{S}^i|(c-1)\lambda > \sum_{j=1}^{m_i} w(S_j^i) \geq \sum_{\mathcal{S}^* \in \mathcal{V}^i} w(\mathcal{S}^*) \geq |\mathcal{V}^i|X^*$ . Consequently, by  $X \leq X^*$  we obtain  $|\mathcal{V}^i| < |\mathcal{S}^i|$ , which leads to  $|\mathcal{V}^i| \leq |\mathcal{S}^i| - 1$ . ◀

## 4 Approximation of the Györi-Lovász Theorem for $k$ -connected Graphs

Our algorithms for the approximate GL theorems are based mainly on the following combinatorial lemma concerning certain vertex separators, that leads to useful structures in

$k$ -connected graphs. Let  $G = (V, E, w)$  be a connected vertex-weighted graph and let  $\lambda$  be an integer. We say  $s \in V$  is a  $\lambda$ -separator if all connected components of  $G - \{s\}$  weigh less than  $\lambda$ . We say  $G$  is  $\lambda$ -dividable if there is a  $[\lambda, \infty)$ -CVP<sub>2</sub> of  $V$ .

► **Lemma 11** ([6]). *Let  $G = (V, E, w)$  be a connected vertex-weighted graph and let  $\lambda > w_{\max}$  be an integer. If  $w(G) > 3(\lambda - 1)$ , then either  $G$  is  $\lambda$ -dividable or there is a  $\lambda$ -separator. Furthermore, finding the connected vertex sets in case  $G$  is  $\lambda$ -dividable and finding the  $\lambda$ -separator in the other case can be done in  $\mathcal{O}(|V||E|)$  time.*

#### 4.1 Bounded Partition for $k$ -connected Graphs

In this section, we give an algorithm for computing approximate GL partitions with one-side approximation bound (either lower bound or upper bound), thus proving Theorem 6. For this, we first use the following theorem, from which Theorem 6 follows as below.

► **Theorem 12.** *Let  $G = (V, E, w)$  be a  $k$ -connected vertex-weighted graph and let  $w_1, \dots, w_k \in \mathbb{N}$  with  $\sum_{i=1}^k w_i = w(G)$ , and  $\min_{i \in [k]} w_i \geq \max_{v \in V} w(v)$ . A set of connected vertex sets  $\mathcal{T} = \{T_1, \dots, T_\ell\}$  with  $\ell \leq k$  and  $\alpha w_i \leq w(T_i) \leq 3\alpha w_i$  for every  $i \in [\ell]$  can be computed in time  $\mathcal{O}(k|V|^2|E|)$ . Moreover, if  $\ell < k$ , then  $\mathcal{T}$  is also a CVP of  $V$ .*

By Theorem 12 we can derive Theorem 6 using  $\alpha = 1/3$  and  $\alpha = 1$  for the lower bound and upper bounded version, respectively.

In the following we always assume that  $w_1, \dots, w_k$  is sorted in descending order. To now give the algorithm proving Theorem 12, we make use of Lemma 11. For this, we first need to ensure that  $w_{\max} < \alpha w_k$ . Therefore, we perform a preprocessing step until we reach an instance that satisfies  $w_{\max} < \alpha w_k$ . Suppose  $w_{\max} \geq \alpha w_\ell$ , where  $\ell$  is the smallest index in  $[k]$  that satisfies this inequality. We remove a vertex  $v_{\max}$  with  $w(v_{\max}) = w_{\max}$  from  $G$  and  $w_\ell$  from  $\mathcal{W}$ . Further, we set  $T_\ell = \{v_{\max}\}$  and consider the set for index  $\ell$  to be finished, i.e., we now aim to find a set  $\mathcal{T} = \{T_1, \dots, T_{\ell-1}, T_{\ell+1}, \dots, T_k\}$  according to  $\mathcal{W} = \{w_1, \dots, w_{\ell-1}, w_{\ell+1}, \dots, w_k\}$ . Observe that since we only deleted one vertex,  $G$  now is at least  $(k - 1)$ -connected, and  $|\mathcal{W}| = k - 1$ . Note that since  $w_{\max} \leq w_k \leq w_\ell \leq 3\alpha w_\ell$ , we have  $w(T_\ell) \in [\alpha w_\ell, 3\alpha w_\ell]$  as required. Also, we obtain  $w(G) \geq \sum_{w_j \in \mathcal{W}} w_j$  after removing  $w_\ell$  from  $\mathcal{W}$  and  $v_{\max}$  from  $G$ .

After this preprocessing, we can assume that we have a  $k$ -connected graph  $G = (V, E, w)$  and natural numbers  $w_1, \dots, w_k$  sorted in descending order, where  $\sum_{i=1}^k w_i \leq w(G)$  and  $w_{\max} < \alpha w_k$ .

On such a graph  $G$  we then gradually build a packing  $\mathcal{T}$  with the help of Lemma 11. During our algorithm to build  $\mathcal{T}$  we ensure that at each step  $\mathcal{T} = \{T_1, T_2, \dots, T_{i-1}\}$  where each  $T_j \in \mathcal{T}$  is a connected vertex set with weight in  $[\alpha w_j, 3\alpha w_j]$  for each  $j \in [i - 1]$ . We then search in the remaining graph for the next set  $T_i$  and always use  $\overline{G}$  to denote the graph  $G \setminus V(\mathcal{T})$ . We say a connected subgraph is  $i$ -small if it has weight less than  $\alpha w_i$  and  $i$ -big otherwise. In case we reach a situation, where  $\overline{G}$  has no connected component that is  $i$ -big, we have to alter the already built sets  $T_1, T_2, \dots, T_{i-1}$  to build  $T_i$ . For this, we use  $\mathcal{T}_a$  to denote the set of all  $T_j \in \mathcal{T}$  that have no  $(\alpha w_j)$ -separator, and  $\mathcal{T}_b$  to denote the set of all  $T_j \in \mathcal{T}$  that have an  $(\alpha w_j)$ -separator. For  $T_j \in \mathcal{T}_b$  with an  $(\alpha w_j)$ -separator  $s$  we use  $C(T_j)$  to denote the connected components of  $G[T_j \setminus \{s\}]$  (if there is more than one  $(\alpha w_j)$ -separator, fix one of them arbitrarily). The following Algorithm BoundedGL formally explains our routine to build  $\mathcal{T}$ .

**Algorithm BoundedGL**

1. Initialize  $\mathcal{T} := \emptyset$  as container for the desired connected-vertex-packing  $T_1, \dots, T_k$  of  $G$  and initialize  $i := 1$  as an increment-variable.
2. While  $\overline{G} = G \setminus V(\mathcal{T})$  is not the empty graph: //main loop
  - a. Find a connected vertex set  $T_i$  having weight in  $[\alpha w_i, 3\alpha w_i]$ , add  $T_i$  to  $\mathcal{T}$ , and increment  $i$  by one. If  $i = k + 1$  then terminate the algorithm.  
// See Lemma 14 for correctness of this step
  - b. While  $\overline{G}$  is not empty and has no  $i$ -big connected component: //inner loop  
Pick an  $i$ -small connected component  $Q$  of  $\overline{G}$ . Pick a  $T_j \in \mathcal{T}$  such that either  $T_j \in \mathcal{T}_a$  and  $Q$  has an edge to  $T_j$  (Case 1), or  $T_j \in \mathcal{T}_b$  and  $Q$  has an edge to some component  $Q' \in C(T_j)$  (Case 2). // The occurrence of at least one of these cases is shown in Lemma 15.  
If  $w(T_j \cup Q) \leq 3\alpha w_j$  then update  $T_j$  to  $T_j \cup Q$ . Otherwise:
    - i. Case 1 ( $T_j \in \mathcal{T}_a$ ): Apply the following **Divide-routine** on  $T_j \cup Q$ : Use Lemma 11 to compute a  $[\alpha w_j, \infty)$ -CVP<sub>2</sub>  $V_1, V_2$  of  $T_j \cup Q$ . Set  $T_j = V_2$  (i.e.  $V_1$  goes to  $\overline{G}$ ).
    - ii. Case 2 ( $T_j \in \mathcal{T}_b$ ): remove  $Q'$  from  $T_j$  (i.e.  $Q'$  goes back to  $\overline{G}$ ) if  $T_j \cup Q$  is not  $\alpha w_j$ -dividable. Otherwise, apply divide routine on  $T_j \cup Q$ .

To prove the correctness of the algorithm, we will show that the following invariant is maintained.

► **Lemma 13.** *Algorithm BoundedGL maintains a packing  $\mathcal{T} = \{T_1, T_2, \dots, T_{i-1}\}$  where each  $T_j \in \mathcal{T}$  is a connected vertex set having weight in  $[\alpha w_j, 3\alpha w_j]$ .*

Towards proving this we use the following fact.

► **Lemma 14.** *Whenever the divide routine in algorithm BoundedGL is to be executed, there is at least one  $i$ -big component in  $\overline{G}$ .*

**Proof.** When  $i = 1$  i.e. in the first main loop iteration, this holds because  $\overline{G} = G$  is connected and  $\alpha w_1 \leq w_1 \leq \sum_{i=1}^k w_i \leq w(G)$ . For the subsequent iterations, the divide routine is only applied after the inner loop is terminated which only happens if either  $\overline{G}$  is empty or has an  $i$ -big component. In case  $\overline{G}$  is empty, then the algorithm terminates. So, if the algorithm applies the divide routine in the inner loop, then  $\overline{G}$  has an  $i$ -big component. ◀

**Proof of Lemma 13.** We increment  $i$  only in Step 2a. Before incrementing  $i$ , we add  $T_i$  to  $\mathcal{T}$  while ensuring that  $w(T_i) \in [\alpha w_i, 3\alpha w_i]$  and  $G[T_i]$  is connected. In Lemma 14, we prove that whenever the divide routine is about to be executed, there is an  $i$ -big component in  $\overline{G}$ , ensuring the existence of such a  $T_i$ . Once a  $T_j$  is added to  $\mathcal{T}$ , it is then modified only in Step 2b. So let us look into how it gets modified in Step 2b. If the condition  $w(T_j \cup Q) \leq 3\alpha w_j$  is satisfied then it is clear that the new  $T_j = T_j \cup Q$  also satisfies the weight constraints. Since  $Q$  has an edge to  $T_j$  and  $T_j$  and  $Q$  each were connected, it is also clear that the new  $T_j$  remains connected. So now consider the case when  $w(T_j \cup Q) > 3\alpha w_j$ . In Case 1 ( $T_j \in \mathcal{T}_a$ ), we call the divide routine and the new  $T_j$  is the set  $V_2$  returned by the routine. The set  $V_2$  is connected due to the property of the divide routine. To see that it also satisfies the weight constraints, observe that  $w(V_1 \cup V_2)$  is at most  $4\alpha w_j$  as  $w(T_j)$  was at most  $3\alpha w_j$  and  $w(Q) < \alpha w_j \leq \alpha w_j$ . Since  $w(V_1), w(V_2) \geq \alpha w_j$ , we then have  $w(V_2) \in [\alpha w_j, 3\alpha w_j]$ . So it only remains to consider Case 2 ( $T_j \in \mathcal{T}_b$ ). The case when  $T_j \cup Q$  is  $\alpha w_j$ -dividable is analog to Case 1. We know  $w(Q') < \alpha w_j$  by definition. Also, since  $w(T_j \cup Q)$  was more than  $3\alpha w_j$  and  $w(Q) < \alpha w_j$ , we have that  $w(T_j)$  was at least  $2\alpha w_j$ . Thus the new  $T_j = T_j \setminus Q'$  has weight in  $[\alpha w_j, 3\alpha w_j]$ . Also, the new  $T_j$  is connected by the definition of  $Q'$ . ◀

It is clear from the algorithm that termination occurs only if  $\overline{G}$  is empty or  $i = k + 1$ . Then using Lemma 13, it is clear that  $\mathcal{T}$  contains the required packing as claimed in Theorem 12, provided that Step 2b runs correctly and the inner loop terminates, which we prove in the two lemmas below.

► **Lemma 15.** *In Step 2b at least Case 1 or Case 2 occurs.*

**Proof.** Suppose Case 1 does not occur i.e.,  $Q$  does not have an edge to any  $T_j \in \mathcal{T}_a$ . For  $T_j \in \mathcal{T}_b$ , let  $s_j$  denote the fixed  $(\alpha w_j)$ -separator vertex. Since  $G$  is  $k$ -connected and  $|\mathcal{T}| < k$ , there is an edge from  $Q$  to at least one vertex in  $\bigcup_{T_j \in \mathcal{T}_b} T_j \setminus \{s_j\}$ . Thus, Case 2 occurs. ◀

► **Lemma 16.** *The inner loop runs correctly and terminates after at most  $|V|^2$  iterations.*

**Proof.** The occurrence of one of the two cases in Step 2b is shown in Lemma 15. For the correctness of Case 1, observe that we can use Lemma 11 to divide  $T_j \cup Q$ , as  $T_j \cup Q$  cannot have an  $(\alpha w_j)$ -separator (this would give an  $(\alpha w_j)$ -separator for  $T_j$  implying that  $T_j \in \mathcal{T}_b$ ). It remains to prove that the inner loop terminates as claimed. If Step 2(b)i is executed, then an  $i$ -big component is created in  $\overline{G}$  as  $\overline{G}$  now contains  $V_1$  returned by the divide-routine, and hence the loop is terminated. The same yields if we apply the divide routine in Step 2(b)ii. So, suppose the inner loop never executes the divide routine. In the other cases, either a connected component is deleted from  $\overline{G}$  or new vertices are added to a connected component in  $\overline{G}$ . Also note that new connected components are not introduced to  $\overline{G}$  and vertices are not deleted from existing connected components (except when the whole connected component is removed; also, two or more connected components may merge due to the introduction of new vertices to  $\overline{G}$ ). Thus, after  $|V|^2$  iterations either there is an  $i$ -big component or  $\overline{G}$  is empty. ◀

It is tempting to think that one could use Theorem 12 to derive a CVP  $\mathcal{T} = \{T_1, \dots, T_k\}$  such that  $\alpha w_i \leq w(T_i) \leq 3\alpha w_i$  for each  $i \in [k]$ . If Algorithm **BoundedGL** terminates with  $\ell < k$ , then  $\mathcal{T}$  is a partition of the vertices in  $G$ , and we only have trouble with the lower bound on  $T_j$  for  $\ell < j \leq k$ . Otherwise, if it terminates with  $\ell = k$ , then  $\mathcal{T}$  satisfies all lower bounds, but might not be a partition. Assigning the remaining vertices in  $G$  to turn  $\mathcal{T}$  into a CVP in this case might yield violations of the upper bound. Since  $\alpha = 1$  yields the first, and  $\alpha = \frac{1}{3}$  the second case, one might think that choosing the correct  $\alpha$  in between would result in a CVP with  $\ell = k$ . Unfortunately, Algorithm **BoundedGL** does not have a monotone behaviour w.r.t.  $\alpha \in (\frac{1}{3}, 1)$  in the sense that for two values  $\frac{1}{3} < \alpha_1 < \alpha_2 < 1$ , the case  $\ell = k$  for  $\alpha_1$  does not imply  $\ell = k$  for  $\alpha_2$ . Thus, even if we could prove the existence of an optimal value for  $\alpha$ , we have no way to search for it.

## 4.2 Both-side Bounded Partition for $k$ -connected Graphs

In this section, we give the algorithms to derive Theorem 7 by providing a both-side bounded approximate GL partition. For achieving a simultaneous lower and upper bounded partition, as a starting point, we apply Theorem 12 with  $\alpha = \frac{1}{3}$  obtaining a lower and upper bounded packing  $\mathcal{T} = \{T_1, \dots, T_k\}$  with  $\frac{1}{3}w_i \leq w(T_i) \leq w_i$  for every  $i \in [k]$ . As long as  $\mathcal{T}$  is not a CVP of  $V$  yet, we transfer a subset of the remaining vertices  $V \setminus V(\mathcal{T})$  through a path in an auxiliary graph to elements in  $\mathcal{T}$ , while making sure that for each  $i$ ,  $\frac{1}{3}w_i \leq w(T_i) \leq \max\{r, 3\}w(T_i)$ . We call one such transfer a *transferring-iteration*. We define  $\mathcal{T}^* := \{T_1, T_2, \dots, T_j\}$  where  $j$  is the smallest number such that  $w(T_i) \geq w_i$  for  $i \in [j]$  and  $w(T_{j+1}) < w_{j+1}$ . In case of  $w_a = w_b$  and  $w(T_a) \geq w_a$ , but  $w(T_b) < w_b$  we assume that  $a < b$ . Note that this is easily realizable by a relabeling of indices. Observe that  $\mathcal{T}^* = \emptyset$  if  $w(T_1) < w_1$ . As a measure of progress,

we guarantee in each transferring-iteration that either the cardinality of  $\mathcal{T}^*$  increases, or the number of vertices in  $V(\mathcal{T})$  increases. Also, the cardinality of  $\mathcal{T}^*$  is non-decreasing throughout the algorithm. Note that if  $T_i \in \mathcal{T}^*$  for all  $i$ , then it follows that  $w(T_i) = w_i$  for all  $i$  and moreover,  $\mathcal{T}$  is a CVP.

Let  $\mathcal{T} = \{T_1, \dots, T_k\}$  be a connected packing of  $V$  in  $G$  with  $w(T_i) \leq \max\{r, 3\}w_i$  for every  $i \in [k]$ . We use  $\mathcal{Q}$  to denote the vertex sets forming the connected components of  $G[V \setminus V(\mathcal{T})]$ . We define  $\mathcal{T}^+ := \{T_i \in \mathcal{T} \mid w(T_i) \geq w_i\}$  and  $\mathcal{T}^- := \mathcal{T} \setminus \mathcal{T}^+$ . Note that  $\mathcal{T}^* \subseteq \mathcal{T}^+$ . Analogous to section 4.1, we define  $\mathcal{T}_a^+$  as the set of  $T_i \in \mathcal{T}^+$  that do *not* have a  $w_i$ -separator vertex and  $\mathcal{T}_b^+$  to be the ones in  $\mathcal{T}^+$  having a  $w_i$ -separator. For  $T_i \in \mathcal{T}_b^+$ , we use  $s(T_i)$  to denote its  $w_i$ -separator (if there are multiple we fix one arbitrarily) and  $C(T_i)$  to denote the vertex sets forming the connected components of  $G[T_i \setminus \{s(T_i)\}]$ . We say a vertex  $v \in V$  or a vertex set  $V' \subseteq V$  is  $\mathcal{T}$ -assigned if  $v \in V(\mathcal{T})$  or  $V' \subseteq V(\mathcal{T})$ , respectively. That is, the set of  $\mathcal{T}$ -assigned vertices is  $V(\mathcal{T})$  and  $V(\mathcal{Q})$  is the set of *not*  $\mathcal{T}$ -assigned vertices. We say  $\mathcal{T}$  is *pack-satisfied* if  $|\mathcal{T}| = k$ , each  $T_j \in \mathcal{T}$  is connected,  $w(T_j) \in [\frac{1}{3}w_j, \max\{r, 3\}w_j]$ , and the vertex sets in  $\mathcal{T}$  are pairwise disjoint.

We define the *transfer-graph*  $H = (\mathcal{V}_H, E_H)$  as  $\mathcal{V}_H := (\bigcup_{T \in \mathcal{T}_b^+} C(T)) \cup \mathcal{T}_a^+ \cup \mathcal{T}^- \cup \mathcal{Q}$  and  $E_H := \{(V_1, V_2) \in \binom{\mathcal{V}_H}{2} \mid N_G(V_1) \cap V_2 \neq \emptyset\}$ .

#### Algorithm DoubleBoundedGL

1. Apply Theorem 12 with  $\alpha = \frac{1}{3}$  on  $G$  to obtain a connected packing  $\mathcal{T} = \{T_1, \dots, T_k\}$  with  $w(T_i) \geq \frac{1}{3}w_i$  for every  $i \in [k]$ .
2. While  $\mathcal{Q} \neq \emptyset$ :
  - a. Find a minimal path in  $H$  from  $\mathcal{Q}$  to  $\mathcal{T}^-$ . Let this path be  $P_Q^{T_i}$  where  $Q \in \mathcal{Q}$  and  $T_i \in \mathcal{T}^-$ .  
*// Note that all vertices in  $P_Q^{T_i}$  except the start and end vertex are in  $\mathcal{T}_a^+ \cup \bigcup_{T \in \mathcal{T}_b^+} C(T)$  by minimality of the path.*
  - b. Execute the **TransferVertices** routine given below, which augments vertices through the path  $P_Q^{T_i}$  such that  $\mathcal{T}$  stays pack-satisfied, and either  $|\mathcal{T}^*|$  increases, or  $|\mathcal{T}^*|$  remains the same and the number of  $\mathcal{T}$ -assigned vertices increases.

We need some more notations for describing the **TransferVertices** routine. For  $\mathcal{V}'_H \subseteq \mathcal{V}_H$  and  $\mathcal{T}' \subseteq \mathcal{T}$  we define  $\mathcal{T}'(\mathcal{V}'_H)$  as the set  $\{T_i \in \mathcal{T}' \mid V(T_i) \cap V(\mathcal{V}'_H) \neq \emptyset\}$ . For  $H' \subseteq H$  we define  $\mathcal{T}'(H') := \mathcal{T}'(\mathcal{V}_H(H'))$ , and  $V(H') := V(\mathcal{V}_H(H'))$ . With  $|P_Q^{T_i}|$  we denote the length of the path  $P_Q^{T_i}$ , i.e. the number of edges in  $P_Q^{T_i}$ . We define  $P_Q^\ell$  as the vertex with distance  $\ell$  to  $Q$  in  $P_Q^{T_i}$ , where  $P_Q^0 = Q$ , and define  $T(P_Q^\ell)$  for  $\ell \in [|P_Q^{T_i}|]$  as the function which returns  $T_j$  with  $P_Q^\ell \subseteq T_j$ . For  $\mathcal{T}' \subseteq \mathcal{T}$  we define  $I(\mathcal{T}') := \{i \mid T_i \in \mathcal{T}'\}$ .

The **TransferVertices** routine transfers vertices through the path  $P_Q^{T_i}$ . Our input is a pack-satisfied  $\mathcal{T}$  and a  $P_Q^{T_i}$  path according to Step 2b in algorithm **DoubleBoundedGL**. By the minimality of the path  $P_Q^{T_i}$ , it is clear that  $V_H(P_Q^{T_i}) \setminus \{Q, T_i\} \subseteq \mathcal{T}_a^+ \cup \bigcup_{T \in \mathcal{T}_b^+} C(T)$ . That is, except for the destination  $T_i$  we run only through vertex sets from  $\mathcal{T}^+$  in  $\mathcal{T}(P_Q^{T_i})$ . Roughly, our goal is to transfer vertices of  $V(P_Q^{T_i} - T_i)$  to  $T_i$ , thereby changing the division of the vertex sets  $\mathcal{T}(P_Q^{T_i})$  and preserving the vertex sets in  $\mathcal{T}^*$ .

We often need to do a *truncate* operation on sets  $T_j$  with  $w(T_j) > \max\{r, 3\}w_j$ . We mean by *truncate*  $T_j$  that we remove vertices from  $T_j$  until  $w_j \leq w(T_j) \leq \max\{r, 3\}w_j$  such that  $T_j$  remains connected. This can be done by removing a non-separator vertex from  $T_j$  until the weight drops below  $\max\{r, 3\}w(T_j)$ . Note that any connected graph has at least one non-separator vertex. Since  $w_{\max} \leq w_j$  we know that the weight does not decrease below  $w_j$  during the last deletion.

**Algorithm TransferVertices**

1. Initialize  $X := Q$  and let  $u = \min(I(\mathcal{T}^-))$ .
2. For  $\ell = 1$  to  $|P_Q^{\mathcal{T}^i}|$  do:
  - a. Let  $T_j = T(P_Q^\ell)$ .
  - b. If  $w(X) \geq w_u$ : set  $T_u = X$ . Truncate  $T_u$  if necessary and terminate the algorithm.
  - c. If  $w(X \cup T_j) \leq \max\{r, 3\}w_j$ : update  $T_j$  to  $X \cup T_j$  and terminate the algorithm.
  - d. If  $T_j \notin \mathcal{T}^*$ : Set  $T'_j = T_j \cup X$ ,  $T_j = T_u$  and  $T_u = T'_j$ . Truncate  $T_j$  and  $T_u$  if necessary and terminate the algorithm.
  - e. If  $T_j \in \mathcal{T}_a^+$ : divide  $T_j \cup X$  into connected vertex sets  $V_1, V_2$  with  $w(V_1), w(V_2) \geq w_j$  using the construction given by Lemma 11. Set  $T_j = V_1$  and  $T_u = V_2$ . Truncate  $T_j$  and  $T_u$  if necessary and terminate the algorithm.
  - f. We know  $T_j \in \mathcal{T}_b^+ \cap \mathcal{T}^*$ . Set  $X = X \cup P_Q^\ell$  and remove  $P_Q^\ell$  from  $T_j$ .

## Abstract

---

Three decades ago, Nisan constructed an explicit pseudorandom generator (PRG) that fools width- $n$  length- $n$  read-once branching programs (ROBPs) with error  $\varepsilon$  and seed length  $O(\log^2 n + \log n \cdot \log(1/\varepsilon))$  [19]. Nisan’s generator remains the best explicit PRG known for this important model of computation. However, a recent line of work starting with Braverman, Cohen, and Garg [6, 8, 10, 22] has shown how to construct *weighted* pseudorandom generators (WPRGs, aka pseudorandom pseudodistribution generators) with better seed lengths than Nisan’s generator when the error parameter  $\varepsilon$  is small.

In this work, we present an explicit WPRG for width- $n$  length- $n$  ROBPs with seed length  $O(\log^2 n + \log(1/\varepsilon))$ . Our seed length eliminates  $\log \log$  factors from prior constructions, and our generator completes this line of research in the sense that further improvements would require beating Nisan’s generator in the standard constant-error regime. Our technique is a variation of a recently-discovered reduction that converts moderate-error PRGs into low-error WPRGs [10, 22]. Our version of the reduction uses averaging samplers.

We also point out that as a consequence of the recent work on WPRGs, any randomized space- $S$  decision algorithm can be simulated deterministically in space  $O(S^{3/2}/\sqrt{\log S})$ . This is a slight improvement over Saks and Zhou’s celebrated  $O(S^{3/2})$  bound [23]. For this application, our improved WPRG is not necessary.

## 1 Introduction

### 1.1 Derandomization

Randomization is a versatile technique in algorithm design. However, random bits are not always available. Therefore, we would like to deterministically simulate randomized algorithms as efficiently as possible. In this paper, we focus on space efficiency. After fixing its input, the output of a small-space algorithm as a function of its random bits can be computed by a *read-once branching program* (ROBP).

► **Definition 1.1** (ROBP). *A width- $w$  length- $n$  ROBP is a directed graph consisting of  $n + 1$  layers of vertices  $V_0, \dots, V_n$  with  $w$  vertices in each layer. For each  $i \in [n]$ , each vertex in  $V_{i-1}$  has two outgoing edges labeled 0 and 1 leading to  $V_i$ . On input  $x \in \{0, 1\}^n$ , the program*

starts at a designated start vertex  $v_{\text{start}} \in V_0$ , then reads the bits  $x_1, \dots, x_n$  in order and traverses the corresponding edges. The program accepts or rejects depending on whether the final vertex in this path is a designated accept vertex  $v_{\text{acc}} \in V_n$ . In this way, the program computes a function  $f: \{0, 1\}^n \rightarrow \{0, 1\}$ .

Arguably, the most important case is  $w = n$ , which captures  $(\log n)$ -space randomized algorithms that always halt. To derandomize such an algorithm, we would like to estimate the expectation of the corresponding ROBP on a uniform random input.

## 1.2 Pseudorandom Generators

The traditional approach to derandomization is to design a *pseudorandom generator* (PRG).

► **Definition 1.2** (PRG). Let  $\mathcal{F}$  be a class of functions  $f: \{0, 1\}^n \rightarrow \{0, 1\}$ . An  $\varepsilon$ -PRG for  $\mathcal{F}$  is a function  $G: \{0, 1\}^r \rightarrow \{0, 1\}^n$  such that for every  $f \in \mathcal{F}$ ,

$$\left| \mathbb{E}_{x \in \{0, 1\}^r} [f(G(x))] - \mathbb{E}_{x \in \{0, 1\}^n} [f(x)] \right| \leq \varepsilon.$$

Here  $r$  is the seed length of  $G$ .

By the probabilistic method, there exists a (nonexplicit) PRG for width- $n$  length- $n$  ROBPs with seed length  $O(\log(n/\varepsilon))$ . A corresponding explicit<sup>1</sup> construction would imply a complete derandomization of space-bounded computation ( $\mathbf{L} = \mathbf{BPL}$ ), because we could deterministically estimate the expectation of a given ROBP  $f$  by computing  $2^{-r} \cdot \sum_{x \in \{0, 1\}^r} f(G(x))$ . Babai, Nisan, and Szegedy designed the first explicit PRG for width- $n$  length- $n$  ROBPs [4], with seed length

$$2^{O(\sqrt{\log n})} \cdot \log(1/\varepsilon).$$

In a subsequent breakthrough [19], Nisan designed a PRG with a much better seed length of

$$O(\log^2 n + \log n \cdot \log(1/\varepsilon)).$$

## 1.3 Weighted PRGs

In the decades since Nisan's work [19], despite intense effort, the problem of designing PRGs for width- $n$  length- $n$  ROBPs has stubbornly resisted further attacks. Nisan's PRG [19] remains the best explicit PRG known for this model. However, PRGs are not the only possible approach to derandomization. Braverman, Cohen, and Garg recently introduced an intriguing generalization of PRGs called *weighted pseudorandom generators* (WPRGs), aka *pseudorandom pseudodistribution generators* [6].

► **Definition 1.3** (WPRG). Let  $\mathcal{F}$  be a class of functions  $f: \{0, 1\}^n \rightarrow \{0, 1\}$ . An  $\varepsilon$ -WPRG for  $\mathcal{F}$  is a pair of functions  $(G, \rho)$ , where  $G: \{0, 1\}^r \rightarrow \{0, 1\}^n$  and  $\rho: \{0, 1\}^r \rightarrow \mathbb{R}$ , such that for every  $f \in \mathcal{F}$ ,

$$\left| \mathbb{E}_{x \in \{0, 1\}^r} [\rho(x) \cdot f(G(x))] - \mathbb{E}_{x \in \{0, 1\}^n} [f(x)] \right| \leq \varepsilon.$$

Here  $r$  is the seed length of  $(G, \rho)$ . If  $\rho$  maps  $\{0, 1\}^r \rightarrow [-K, K]$ , we say the WPRG is  $K$ -bounded.

<sup>1</sup> We say that a function  $G: \{0, 1\}^r \rightarrow \{0, 1\}^n$  is *explicit* if it can be computed in space  $O(r)$ . More precisely, we are considering a family of functions indexed by one or more parameters (e.g.,  $n$  and  $\varepsilon$ ). The algorithm for computing  $G$  is given both the parameters and the input to  $G$ .

A standard (“unweighted”) PRG is the case  $\rho(x) \equiv 1$ . Just like an unweighted PRG, a WPRG for ROBPs can be used to estimate the expectation of a given ROBP  $f$ , because we can compute  $2^{-r} \cdot \sum_{x \in \{0,1\}^r} \rho(x) \cdot f(G(x))$ . As long as  $r$  is small and  $G$  and  $\rho$  are both efficiently computable, this is still an efficient derandomization. Thus, optimal WPRGs for ROBPs would immediately imply  $\mathbf{L} = \mathbf{BPL}$ . Furthermore, WPRGs imply *hitting set generators* (HSGs).

► **Definition 1.4 (HSG).** *Let  $\mathcal{F}$  be a class of functions  $f: \{0,1\}^n \rightarrow \{0,1\}$ . An  $\varepsilon$ -HSG for  $\mathcal{F}$  is a function  $G: \{0,1\}^r \rightarrow \{0,1\}^n$  such that for every  $f \in \mathcal{F}$ ,*

$$\mathbb{E}_{x \in \{0,1\}^r} [f(G(x))] \geq \varepsilon \implies \exists x \in \{0,1\}^r, f(G(x)) = 1.$$

If  $(G, \rho)$  is an  $\varepsilon$ -WPRG for  $\mathcal{F}$ , then  $G$  is an  $\varepsilon'$ -HSG for  $\mathcal{F}$  for any  $\varepsilon' > \varepsilon$  [6]. HSGs have been studied since the 80s [2], but prior to Braverman, Cohen, and Garg’s work [6], no explicit HSG for width- $n$  length- $n$  ROBPs was known that was any better than Nisan’s PRG (except when  $\varepsilon$  is *extremely* small; see Table 1). For these reasons, it was exciting when Braverman, Cohen, and Garg presented an explicit WPRG that fools width- $n$  length- $n$  ROBPs [6] with seed length

$$\tilde{O}(\log^2 n + \log(1/\varepsilon)),$$

which is better than Nisan’s PRG’s seed length when  $\varepsilon \ll 1/\text{poly}(n)$ .

Admittedly, Braverman, Cohen, and Garg’s result [6] did not yet imply an improved derandomization of space-bounded computation, but still, their innovative and complex work provides valuable insights. The additional flexibility in the definition of a WPRG means that WPRGs can be easier to construct compared to unweighted PRGs. In fact, in one setting (unbounded-width permutation ROBPs with a single accept vertex), Pyne and Vadhan recently showed that there is an explicit WPRG [22] with a seed length that is *provably impossible* to attain by unweighted PRGs [12], a testament to the power of the WPRG approach to derandomization.

Subsequent to Braverman, Cohen, and Garg’s work [6], Chattopadhyay and Liao gave a simpler WPRG construction [8] that fools width- $n$  length- $n$  ROBPs with the improved seed length

$$\tilde{O}(\log^2 n) + O(\log(1/\varepsilon)). \tag{1}$$

Very recently, Cohen, Doron, Renard, Sberlo, and Ta-Shma [10] and Pyne and Vadhan [22] independently obtained an even simpler WPRG that fools width- $n$  length- $n$  ROBPs with seed length

$$O(\log^2 n) + \tilde{O}(\log(1/\varepsilon)). \tag{2}$$

(These last two constructions and analyses are nearly identical [10, 22].)

## 1.4 Main Result: An Improved WPRG

In this work, we present another WPRG for ROBPs with a better seed length.

► **Theorem 1.5.** *For any  $w, n \in \mathbb{N}$  and  $\varepsilon > 0$ , there is an explicit  $\varepsilon$ -WPRG for width- $w$  length- $n$  ROBPs with seed length  $O(\log(wn) \log n + \log(1/\varepsilon))$ . Furthermore, the WPRG is  $\text{poly}(1/\varepsilon)$ -bounded.*

■ **Table 1** Known PRGs, WPRGs, and HSGs for width- $n$  length- $n$  ROBPs. As a reminder, PRG  $\implies$  WPRG  $\implies$  HSG.

Seed length	Type of generator	Reference
$\tilde{O}(\sqrt{n}) + O(\log(1/\varepsilon))$	HSG	[2] <sup>2</sup>
$2^{O(\sqrt{\log n})} \cdot \log(1/\varepsilon)$	PRG	[4]
$O(\log^2 n + \log(1/\varepsilon) \cdot \log n)$	PRG	[19]
$\tilde{O}(\log^2 n + \log(1/\varepsilon))$	WPRG	[6]
$O(\log^2 n + \log(1/\varepsilon))$	HSG	[14]
$\tilde{O}(\log^2 n) + O(\log(1/\varepsilon))$	WPRG	[8]
$O(\log^2 n) + \tilde{O}(\log(1/\varepsilon))$	WPRG	[10, 22]
$O(\log^2 n + \log(1/\varepsilon))$	WPRG	This work
$O(\log n + \log(1/\varepsilon))$	PRG	Optimal (non-explicit)

When  $w = n$ , our WPRG has seed length  $O(\log^2 n + \log(1/\varepsilon))$ , giving the “best of both worlds” compared to Equations (1) and (2). Our WPRG is the first to achieve seed length  $O(\log^2 n)$  with error  $n^{-\log n}$ . Furthermore, our WPRG represents the completion of the research project of designing WPRGs for width- $n$  length- $n$  ROBPs while focusing on the seed length’s dependence on  $\varepsilon$  [6, 8, 10, 22]. After all, even an HSG must have seed length at least  $\Omega(\log(1/\varepsilon))$ , so obtaining a better WPRG for width- $n$  length- $n$  ROBPs requires beating Nisan’s generator in the traditional, challenging constant-error regime. (That being said, see Section 5.)

Our WPRG generalizes some other recent work on the small- $\varepsilon$  regime. Hoza and Zuckerman constructed an explicit  $\varepsilon$ -HSG for width- $n$  length- $n$  ROBPs with seed length  $O(\log^2 n + \log(1/\varepsilon))$  [14], which follows also from our WPRG. Meanwhile, Cheng and Hoza gave a deterministic algorithm for estimating  $\mathbb{E}[f] \pm \varepsilon$  in space  $O(\log^2 n + \log(1/\varepsilon))$  given query access to a constant-width ROBP  $f$  [9]; Theorem 1.5 immediately implies such an algorithm for the more general case of polynomial-width ROBPs.

## 1.5 Derandomization that Beats the Saks-Zhou Bound

Next we turn to the general problem of derandomizing space- $S$  decision algorithms, whether by PRGs, WPRGs, HSGs, or any other method. Early work [24, 16, 5] showed that these algorithms can be simulated deterministically in space  $O(S^2)$  (in fact these early papers show how to simulate more powerful models). Saks and Zhou gave an improved simulation that runs in space  $O(S^{3/2})$  [23], which has remained unbeaten for decades. We point out that as a consequence of the recent progress on WPRGs, it is now possible to slightly improve the bound.

► **Theorem 1.6.** *For any function  $S(N) \geq \log N$ , we have*

$$\mathbf{BSPACE}(S) \subseteq \mathbf{DSPACE}\left(\frac{S^{3/2}}{\sqrt{\log S}}\right).$$

<sup>2</sup> For any  $w \in \mathbb{N}$ , Ajtai, Komlos, and Szemerédi designed an explicit  $(1/w)$ -HSG for width- $w$  length- $n$  ROBPs where  $n = O(\log^2 w / \log \log w)$  with optimal seed length  $O(\log w)$  [2]. Turning things around, for any  $n \in \mathbb{N}$  and  $\varepsilon > 0$ , we can let  $w = 2\sqrt{n \log n} / \varepsilon$  and get an explicit  $\varepsilon$ -HSG for width- $w$  length- $n$  ROBPs (hence also for width- $n$  length- $n$  ROBPs) with seed length  $O(\sqrt{n \log n} + \log(1/\varepsilon))$ .

(We use  $N$  to denote the input length, reserving  $n$  to denote the length of an ROBP. Recall that  $\mathbf{BPSPACE}(S)$  is the class of languages that can be decided by randomized algorithms that run in space  $O(S)$  and always halt.<sup>3</sup>) Admittedly,  $O(S^{3/2}/\sqrt{\log S})$  is barely any better than Saks and Zhou’s  $O(S^{3/2})$  bound [23]. However, we hope that Theorem 1.6 might break a “psychological barrier” by demonstrating that the Saks-Zhou algorithm [23] has room for improvement.

Our improved WPRG is not necessary for proving Theorem 1.6. Instead, Theorem 1.6 follows by combining several prior works [23, 3, 17, 8, 10, 22].

## 1.6 Overview of Proofs

### 1.6.1 Overview of our Improved WPRG

The proof of Theorem 1.5 is similar to the recent WPRG constructions by Cohen et al. and Pyne and Vadhan [10, 22]. Say we would like to fool some width- $n$  length- $n$  ROBP  $f$  with low error  $\varepsilon \ll 1/\text{poly}(n)$ . The starting point is a PRG  $G$  that fools ROBPs with moderate error  $1/\text{poly}(n)$ . Building on work by Ahmadinejad, Kelner, Murtagh, Peebles, Sidford, and Vadhan [1], Cohen et al. and Pyne and Vadhan [10, 22] showed a bound of the form

$$\left| \mathbb{E}[f] - \sum_{i=1}^K \sigma_i \cdot \mathbb{E}[f(A_i)] \right| \leq \varepsilon, \quad (3)$$
