## LIPICs – Leibniz International Proceedings in Informatics

LIPICs is a series of high-quality conference proceedings across all fields in informatics. LIPICs volumes are published according to the principle of Open Access, i.e., they are available online and free of charge.

### *Editorial Board*

- Luca Aceto (*Chair*, Reykjavik University, IS and Gran Sasso Science Institute, IT)
- Christel Baier (TU Dresden, DE)

## ■ Contents

Preface	
<i>Hee-Kap Ahn and Kunihiko Sadakane</i> .....	0:xi
Program Committee	
.....	0:xiii
List of External Reviewers	
.....	0:xv

### Invited Talks

Streaming Pattern Matching	
<i>Tatiana Starikovskaya</i> .....	1:1–1:1
Spanning Properties of Variants of the Delaunay Graph	
<i>Prosenjit Bose</i> .....	2:1–2:1

### Regular Papers

Subquadratic Algorithms for Some 3SUM-Hard Geometric Problems in the Algebraic Decision Tree Model	
<i>Boris Aronov, Mark de Berg, Jean Cardinal, Esther Ezra, John Iacono, and Micha Sharir</i> .....	3:1–3:15
Approximate Maximum Halfspace Discrepancy	
<i>Michael Matheny and Jeff M. Phillips</i> .....	4:1–4:15
The VC-Dimension of Limited Visibility Terrains	
<i>Matt Gibson-Lopez and Zhongxiu Yang</i> .....	5:1–5:17
Clustering with Neighborhoods	
<i>Hongyao Huang, Georgiy Klimenko, and Benjamin Raichel</i> .....	6:1–6:17
Approximating Longest Spanning Tree with Neighborhoods	
<i>Ahmad Biniaz</i> .....	7:1–7:11
Self-Improving Voronoi Construction for a Hidden Mixture of Product Distributions	
<i>Siu-Wing Cheng and Man Ting Wong</i> .....	8:1–8:13
Connected Coordinated Motion Planning with Bounded Stretch	
<i>Sándor P. Fekete, Phillip Keldenich, Ramin Kosfeld, Christian Rieck, and Christian Scheffer</i> .....	9:1–9:16
Enclosing Depth and Other Depth Measures	
<i>Patrick Schneider</i> .....	10:1–10:15
Illuminating the $x$ -Axis by $\alpha$ -Floodlights	
<i>Bengt J. Nilsson, David Orden, Leonidas Palios, Carlos Seara, and Paweł Żyliński</i> .....	11:1–11:12

32nd International Symposium on Algorithms and Computation (ISAAC 2021).

Editors: Hee-Kap Ahn and Kunihiko Sadakane

Leibniz International Proceedings in Informatics

Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

On Geometric Priority Set Cover Problems <i>Aritra Banik, Rajiv Raman, and Saurabh Ray</i> .....	12:1–12:14
The Complexity of Sharing a Pizza <i>Patrick Schnider</i> .....	13:1–13:15
Dynamic Data Structures for $k$ -Nearest Neighbor Queries <i>Sarita de Berg and Frank Staals</i> .....	14:1–14:14
Preference-Based Trajectory Clustering – An Application of Geometric Hitting Sets <i>Florian Barth, Stefan Funke, and Claudius Proissl</i> .....	15:1–15:14
Efficiently Partitioning the Edges of a 1-Planar Graph into a Planar Graph and a Forest <i>Sam Barr and Therese Biedl</i> .....	16:1–16:15
On the Kernel and Related Problems in Interval Digraphs <i>Mathew C. Francis, Pavol Hell, and Dalu Jacob</i> .....	17:1–17:17
Interval Query Problem on Cube-Free Median Graphs <i>Soh Kumabe</i> .....	18:1–18:14
Untangling Circular Drawings: Algorithms and Complexity <i>Sujoy Bhore, Guangping Li, Martin Nöllenburg, Ignaz Rutter, and Hsiang-Yun Wu</i> .....	19:1–19:17
Algorithms and Complexity on Indexing Elastic Founder Graphs <i>Massimo Equi, Tuukka Norri, Jarno Alanko, Bastien Cazaux, Alexandru I. Tomescu, and Veli Mäkinen</i> .....	20:1–20:18
Partitioning $H$ -Free Graphs of Bounded Diameter <i>Christoph Brause, Petr Golovach, Barnaby Martin, Daniël Paulusma, and Siani Smith</i> .....	21:1–21:14
Clique-Based Separators for Geometric Intersection Graphs <i>Mark de Berg, Sándor Kisfaludi-Bak, Morteza Monemizadeh, and Leonidas Theodorou</i> .....	22:1–22:15
Near-Optimal Distance Oracles for Vertex-Labeled Planar Graphs <i>Jacob Ewald, Viktor Fredslund-Hansen, and Christian Wulff-Nilsen</i> .....	23:1–23:14
A Characterization of Individualization-Refinement Trees <i>Markus Anders, Jendrik Brachter, and Pascal Schweitzer</i> .....	24:1–24:14
Truly Subquadratic Exact Distance Oracles with Constant Query Time for Planar Graphs <i>Viktor Fredslund-Hansen, Shay Mozes, and Christian Wulff-Nilsen</i> .....	25:1–25:12
Interval Edge Coloring of Bipartite Graphs with Small Vertex Degrees <i>Anna Małafiejaska, Michał Małafiejski, Krzysztof M. Ociekiewicz, and Krzysztof Pastuszak</i> .....	26:1–26:12
Selected Neighbor Degree Forest Realization <i>Amotz Bar-Noy, David Peleg, Dror Rawitz, and Elad Yehezkel</i> .....	27:1–27:15

MAX CUT in Weighted Random Intersection Graphs and Discrepancy of Sparse Random Set Systems <i>Sotiris Nikolettseas, Christoforos Raptopoulos, and Paul Spirakis</i> .....	28:1–28:16
The Impact of Geometry on Monochrome Regions in the Flip Schelling Process <i>Thomas Bläsius, Tobias Friedrich, Martin S. Krejca, and Louise Molitor</i> .....	29:1–29:17
Piecewise-Linear Farthest-Site Voronoi Diagrams <i>Franz Aurenhammer, Evanthia Papadopoulou, and Martin Suderland</i> .....	30:1–30:11
Effective Resistance and Capacitance in Simplicial Complexes and a Quantum Algorithm <i>Mitchell Black and William Maxwell</i> .....	31:1–31:27
Anonymity-Preserving Space Partitions <i>Úrsula Hébert-Johnson, Chinmay Sonar, Subhash Suri, and Vaishali Surianarayanan</i> .....	32:1–32:16
Impatient PPSZ – A Faster Algorithm for CSP <i>Shibo Li and Dominik Scheder</i> .....	33:1–33:20
Fine-Grained Meta-Theorems for Vertex Integrity <i>Michael Lampis and Valia Mitsou</i> .....	34:1–34:15
Essentially Tight Kernels For (Weakly) Closed Graphs <i>Tomohiro Koana, Christian Komusiewicz, and Frank Sommer</i> .....	35:1–35:15
Filling Crosswords Is Very Hard <i>Laurent Gourvès, Ararat Harutyunyan, Michael Lampis, and Nikolaos Melissinos</i> .....	36:1–36:16
Grid Recognition: Classical and Parameterized Computational Perspectives <i>Siddharth Gupta, Guy Sa’ar, and Meirav Zehavi</i> .....	37:1–37:15
An Improved Approximation Algorithm for the Matching Augmentation Problem <i>Joseph Cheriyan, Robert Cummings, Jack Dippel, and Jasper Zhu</i> .....	38:1–38:17
Multimodal Transportation with Ridesharing of Personal Vehicles <i>Qian-Ping Gu and JiaJian Liang</i> .....	39:1–39:16
Algorithms for Normalized Multiple Sequence Alignments <i>Eloi Araujo, Luiz C. Rozante, Diego P. Rubert, and Fábio V. Martinez</i> .....	40:1–40:16
Separated Red Blue Center Clustering <i>Marzieh Eskandari, Bhavika Khare, and Nirman Kumar</i> .....	41:1–41:13
On the Extended TSP Problem <i>Julián Mestre, Sergey Pupyrev, and Seeun William Umboh</i> .....	42:1–42:14
Probabilistic Analysis of Euclidean Capacitated Vehicle Routing <i>Claire Mathieu and Hang Zhou</i> .....	43:1–43:16
Exact and Approximation Algorithms for Many-To-Many Point Matching in the Plane <i>Sayan Bandyopadhyay, Anil Maheshwari, and Michiel Smid</i> .....	44:1–44:14

Augmenting Graphs to Minimize the Radius <i>Joachim Gudmundsson, Yuan Sha, and Fan Yao</i> .....	45:1–45:20
Linear-Time Approximation Scheme for $k$ -Means Clustering of Axis-Parallel Affine Subspaces <i>Kyungjin Cho and Eunjin Oh</i> .....	46:1–46:13
Feedback Vertex Set on Geometric Intersection Graphs <i>Shinwoo An and Eunjin Oh</i> .....	47:1–47:12
Streaming Algorithms for Graph $k$ -Matching with Optimal or Near-Optimal Update Time <i>Jianer Chen, Qin Huang, Iyad Kanj, Qian Li, and Ge Xia</i> .....	48:1–48:17
Making Three out of Two: Three-Way Online Correlated Selection <i>Yongho Shin and Hyung-Chan An</i> .....	49:1–49:17
Tight Competitive Analyses of Online Car-Sharing Problems <i>Ya-Chun Liang, Kuan-Yun Lai, Ho-Lin Chen, and Kazuo Iwama</i> .....	50:1–50:14
Skeletons and Minimum Energy Scheduling <i>Antonios Antoniadis, Gunjan Kumar, and Nikhil Kumar</i> .....	51:1–51:16
Machine Covering in the Random-Order Model <i>Susanne Albers, Waldo Gálvez, and Maximilian Janke</i> .....	52:1–52:16
Nearly-Tight Lower Bounds for Set Cover and Network Design with Deadlines/Delay <i>Noam Touitou</i> .....	53:1–53:16
Cryptographic Hardness Under Projections for Time-Bounded Kolmogorov Complexity <i>Eric Allender, John Gouwar, Shuichi Hirahara, and Caleb Robelle</i> .....	54:1–54:17
Identity Testing Under Label Mismatch <i>Clément L. Canonne and Karl Wimmer</i> .....	55:1–55:17
Unique-Neighbor-Like Expansion and Group-Independent Cossystolic Expansion <i>Tali Kaufman and David Mass</i> .....	56:1–56:17
Group Evacuation on a Line by Agents with Different Communication Abilities <i>Jurek Czyzowicz, Ryan Killick, Evangelos Kranakis, Danny Krizanc, Lata Narayanan, Jaroslav Opatrny, Denis Pankratov, and Sunil Shende</i> .....	57:1–57:24
Lower Bounds for Induced Cycle Detection in Distributed Computing <i>François Le Gall and Masayuki Miyamoto</i> .....	58:1–58:19
Distributed Approximations of $f$ -Matchings and $b$ -Matchings in Graphs of Sub-Logarithmic Expansion <i>Andrzej Czygrinow, Michał Hanćkowiak, and Marcin Witkowski</i> .....	59:1–59:13
Inverse Suffix Array Queries for 2-Dimensional Pattern Matching in Near-Compact Space <i>Dhrumil Patel and Rahul Shah</i> .....	60:1–60:14
Dynamic Boolean Formula Evaluation <i>Rathish Das, Andrea Lincoln, Jayson Lynch, and J. Ian Munro</i> .....	61:1–61:19

Shortest Beer Path Queries in Outerplanar Graphs <i>Joyce Bacic, Saeed Mehrabi, and Michiel Smid</i> .....	62:1–62:16
Space-Efficient Algorithms for Reachability in Directed Geometric Graphs <i>Sujoy Bhore and Rahul Jain</i> .....	63:1–63:17
Repetition- and Linearity-Aware Rank/Select Dictionaries <i>Paolo Ferragina, Giovanni Manzini, and Giorgio Vinciguerra</i> .....	64:1–64:16
Pattern Masking for Dictionary Matching <i>Panagiotis Charalampopoulos, Huiping Chen, Peter Christen, Grigorios Loukides, Nadia Pisanti, Solon P. Pissis, and Jakub Radoszewski</i> .....	65:1–65:19
Resilient Level Ancestor, Bottleneck, and Lowest Common Ancestor Queries in Dynamic Trees <i>Luciano Gualà, Stefano Leucci, and Isabella Ziccardi</i> .....	66:1–66:17
Computing Shapley Values for Mean Width in 3-D <i>Shuhao Tan</i> .....	67:1–67:17
Simple Envy-Free and Truthful Mechanisms for Cake Cutting with a Small Number of Cuts <i>Takao Asano</i> .....	68:1–68:17
Adaptive Regularized Submodular Maximization <i>Shaojie Tang and Jing Yuan</i> .....	69:1–69:13
$\Gamma$ -Graphic Delta-Matroids and Their Applications <i>Donggyu Kim, Duksang Lee, and Sang-il Oum</i> .....	70:1–70:13
An Approximation Algorithm for Maximum Stable Matching with Ties and Constraints <i>Yu Yokoi</i> .....	71:1–71:16
A Faster Algorithm for Maximum Flow in Directed Planar Graphs with Vertex Capacities <i>Julian Enoch, Kyle Fox, Dor Mesica, and Shay Mozes</i> .....	72:1–72:16
Maximum-Weight Matching in Sliding Windows and Beyond <i>Leyla Biabani, Mark de Berg, and Morteza Monemizadeh</i> .....	73:1–73:16
Quantum Advantage with Shallow Circuits Under Arbitrary Corruption <i>Atsuya Hasegawa and François Le Gall</i> .....	74:1–74:16

## ■ Preface

This volume contains the papers presented at the 32nd International Symposium on Algorithms and Computation (ISAAC 2021). ISAAC 2021 was held in a hybrid manner on December 6–8, 2021 and was organized by Kyushu University, Japan. ISAAC 2021 provided a forum for researchers working in the areas of algorithms, theory of computation, and computational complexity. The technical program of the conference included 72 contributed papers. We received 215 submissions in response to the call for papers. Each submission received at least three reviews. The program committee held electronic meetings using EasyChair. In the end, the Program Committee selected 72 of the submissions for presentation at the symposium.

The conference included two invited presentations, delivered by Prosenjit Bose (Carleton University) and Tatiana Starikovskaya (The École normale supérieure, Paris). Abstracts of their talks are included in this volume. We wish to thank all the authors who submitted extended abstracts for consideration, the program committee members for their scholarly efforts, and all external reviewers who assisted in the evaluation process. We are grateful to Kayamori Foundation of Information Science Advancement, Support Center for Advanced Telecommunications Technology Research (SCAT), KDDI Foundation, Algorithmic Foundations for Social Advancement (AFSA) by Grant-in-Aid for Transformative Research Areas, MEXT, Japan, and Fusion of Computer Science, Engineering and Mathematics Approaches for Expanding Combinatorial Reconfiguration by Grant-in-Aid for Transformative Research Areas, MEXT, Japan, for financial support and the local organizers of ISAAC 2021. Finally, we acknowledge the endorsement from Special Interest Group on Algorithms (SIGAL) of IPSJ.

December 2021

# Streaming Pattern Matching

Tatiana Starikovskaya ✉

DIENS, École normale supérieure, PSL Research University, Paris, France

---

## Abstract

Many classical algorithms for string processing assume that the input can be accessed in full via constant-time random access, which poses a serious limitation in the modern era of data deluge. In this talk, we will focus on the streaming model of computation that allows to overcome this issue. In this model of computation, we assume that the input arrives as a stream, one character at a time, which captures a situation when the data are sequential measurements or an output of an algorithm. The space complexity is defined as all the space used, including the space used to store any information about the input, which allows to develop ultra-efficient algorithms.

The first streaming algorithm for pattern matching was presented in the seminal paper of Porat and Porat in FOCS 2009. For a pattern of length  $m$ , the algorithm uses only  $O(\log m)$  space, while any classical algorithm requires  $\Omega(m)$  space. This result served as a foundation of the area of streaming algorithms for pattern matching. After a brief survey of the area, we will discuss two questions in more details: the  $k$ -mismatch problem and the pattern matching with  $k$ -edits problem. In the  $k$ -mismatch problem, one is given a pattern and a text, and the task is to find all substrings of the text that have at most  $k$  mismatches with the pattern. The current best algorithm for this problem was given by Clifford, Kociumaka, and Porat in SODA 2019, and for a pattern of length  $m$  it uses  $O(k \log m)$  space and  $\tilde{O}(\sqrt{k})$  time per character of the text. In the pattern matching with  $k$ -edits problem, the task is similar, but one must find substrings that can be transformed into the pattern by at most  $k$  edits, i.e. substitutions, insertions, and deletions of a character. For this problem, the first streaming algorithm was presented by Kociumaka, Porat, and Starikovskaya in FOCS 2021. The algorithm takes  $\tilde{O}(\text{poly}(k))$  space and  $\tilde{O}(\text{poly}(k))$  time per character of the text.

**2012 ACM Subject Classification** Theory of computation → Pattern matching; Theory of computation → Sketching and sampling

**Keywords and phrases** Streaming algorithms, Pattern matching, Hamming distance, Edit distance

# Spanning Properties of Variants of the Delaunay Graph

Prosenjit Bose ✉

Carleton University, Ottawa, Canada

---

## Abstract

A weighted geometric graph  $G$  is a graph whose  $n$  vertices are points in the plane and whose  $m$  edges are line segments weighted by the Euclidean distance between their endpoints. A  $t$ -spanner of  $G$  is a connected spanning subgraph  $G'$  with the property that for every pair of vertices  $x, y$ , the shortest path from  $x$  to  $y$  in  $G'$  has weight at most  $t \geq 1$  times the shortest path from  $x$  to  $y$  in  $G$ . The parameter  $t$  is commonly referred to as the spanning ratio or the stretch factor. Typically,  $G$  is a graph with  $\Omega(n^2)$  edges. As such, the goal in this area is to construct a subgraph  $G'$  that possesses several desirable properties such as  $O(n)$  edges and spanning ratio close to 1. In addition, when planarity is one of the desired properties, variants of Delaunay graphs play a vital role in the construction of planar geometric spanners. In this talk, we will provide a comprehensive overview of various results concerning the spanning ratio, among other several other properties, of different types of Delaunay graphs and their subgraphs.

## Abstract

We present subquadratic algorithms in the algebraic decision-tree model for several 3SUM-hard geometric problems, all of which can be reduced to the following question: Given two sets  $A, B$ , each consisting of  $n$  pairwise disjoint segments in the plane, and a set  $C$  of  $n$  triangles in the plane, we want to count, for each triangle  $\Delta \in C$ , the number of intersection points between the segments of  $A$  and those of  $B$  that lie in  $\Delta$ . The problems considered in this paper have been studied by Chan (2020), who gave algorithms that solve them, in the standard real-RAM model, in  $O((n^2/\log^2 n) \log^{O(1)} \log n)$  time. We present solutions in the algebraic decision-tree model whose cost is  $O(n^{60/31+\varepsilon})$ , for any  $\varepsilon > 0$ .

Our approach is based on a primal-dual range searching mechanism, which exploits the multi-level polynomial partitioning machinery recently developed by Agarwal, Aronov, Ezra, and Zahl (2020).

A key step in the procedure is a variant of point location in arrangements, say of lines in the plane, which is based solely on the *order type* of the lines, a “handicap” that turns out to be beneficial for speeding up our algorithm.

## 1 Introduction

Let  $A$  and  $B$  be two sets, each consisting of  $n$  pairwise disjoint line segments in the plane, and let  $C$  be a set of  $n$  triangles in the plane. We study the problem of counting, for each triangle  $\Delta \in C$ , the number of intersection points between the segments of  $A$  and those of  $B$  that lie inside  $\Delta$ . We refer to this problem as *within-triangle intersection-counting*. This is one of four 3SUM-hard problems (among many others) studied by Chan [11], all of which can be reduced to the problem just mentioned.<sup>1</sup> The other three problems are:<sup>2</sup>

- (i) *Intersection of three polygons*. Given three simple  $n$ -gons  $A, B, C$  in the plane, determine whether  $A \cap B \cap C$  is nonempty.
- (ii) *Coverage by three polygons*. Given three simple  $n$ -gons  $A, B, C$  in the plane, determine whether  $A \cup B \cup C$  covers a given triangle  $\Delta_0$ .
- (iii) *Segment concurrency*. Given sets  $A, B, C$ , each consisting of  $n$  pairwise disjoint segments in the plane,<sup>3</sup> determine whether  $A \times B \times C$  contains a concurrent triple.

Chan [11] presents slightly subquadratic algorithms for all four problems, whose running time in the standard real-RAM model (also referred to as the *uniform* model) is  $O((n^2/\log^2 n) \log^{O(1)} n)$ . He has observed that, as already mentioned, all these problems can be reduced in near-linear time to the within-triangle intersection-counting problem, so it suffices to present an efficient subquadratic solution for that problem.

We study the within-triangle intersection-counting problem in the algebraic decision-tree model. In this model only sign tests of polynomial inequalities of constant degree that access explicitly (the endpoint coordinates of) the input segments or vertices of the input triangles count towards the running time. All other operations cost nothing in the model, but are not allowed to access the input segments explicitly. Although originally introduced for establishing lower bounds [7], the algebraic decision-tree model has become a standard model for upper bounds too, used in the study of many problems, including the 3SUM-problem itself [10, 17, 20, 23, 25] and various 3SUM-hard geometric problems [5, 6, 17]. One can interpret the decision-tree model as an attempt to isolate and minimize the cost of the part of the algorithm that explicitly accesses the real representation of the input objects, and ignore the cost of the other purely discrete steps. This has the potential of providing us with an insight about the problem complexity, which might eventually lead to an improved solution also in the uniform real-RAM model.

We show that the within-triangle intersection-counting problem and, hence, also problems (i)–(iii), can be solved in this model with  $O(n^{60/31+\varepsilon})$  sign tests, for any  $\varepsilon > 0$ . Chan [11] also remarks (without providing details) that his algorithm can be implemented in  $O(n^{2-\delta})$  time in the algebraic decision-tree model, for some  $\delta > 0$  that he left unspecified. (With some care, as was communicated to us, one can obtain  $\delta \approx 0.01$ .) Our algorithm is rather

<sup>1</sup> Chan [11] refers to this problem as “triangle intersection-counting.”

<sup>2</sup> The fact that these problems are 3SUM-hard, and the connections between them, are stated in [11].

<sup>3</sup> The segments of one set, say  $C$ , need not be pairwise disjoint. Although not explicitly stated, the technique in [11] for the uniform model can also handle this situation.

different from Chan's, and gives a concrete value for  $\delta$  (any positive  $\delta < 2/31$ ), as mentioned above. Our techniques appear to be of independent interest and to have the potential to apply to other problems, as we demonstrate in the full version [4, Section 4].

If the segments in  $A$  and  $B$  and the triangles in  $C$  were all full lines,<sup>4</sup> then, in general, determining the existence of a concurrent triple of lines in  $A \times B \times C$  (the so-called *concurrency testing* problem) is the dual version of the classical 3SUM-hard *collinearity testing* problem, in which we are given three sets of points in the plane, and wish to determine whether their Cartesian product contains a collinear triple. This problem has recently been studied in the algebraic decision-tree model by Aronov et al. [5], in a restricted version where two of the sets are assumed to lie on two constant-degree algebraic curves, where an algorithm with roughly  $O(n^{28/15})$  comparisons has been presented.

The problems studied here can be regarded as other dual versions of collinearity testing, where restrictions of a different kind are imposed. As noted by Chan [11], the additional disjointness properties that are assumed here make the problem simpler than collinearity testing (albeit by no means simple), and its solution appears to have no bearing on the unconstrained collinearity problem itself. In the full version [4, Section 5] we comment on the substantial differences between this work and the work by Aronov et al. [5].

Our technique is based on hierarchical cuttings of the plane, as well as on tools and properties of segment-intersection range searching. We also use the so-called Fredman's trick in algebraic-geometric settings, in which the problem is mapped into a primal-dual range searching mechanism involving points and surfaces in  $\mathbb{R}^6$ . This reduction exploits the very recent multi-level polynomial partitioning technique of Agarwal et al. [2] (or a similar technique of Matoušek and Patáková [27]). Our range-searching mechanism of points and algebraic surfaces in higher dimensions is a by-product of our analysis, which appears to be broadly applicable in other range-searching contexts, and we thus regard it as a technique of independent interest; see, for example, Proposition 2 and its proof.

**Point location in arrangements.** An additional key ingredient of our approach involves point location in an arrangement of lines in the plane (or an arrangement of curves, or of hyperplanes in higher dimensions). This is of course a well studied problem with several optimal solutions [29], but we adapt and use techniques that are handicapped by the requirement that each operation that examines the real parameters specifying the lines involves at most *three* input lines. In contrast, the persistent data structure of [29], for example, needs to sort the vertices of the arrangement from left to right, thus requiring comparisons of the  $x$ -coordinates of a pair of vertices, which are in general determined by the parameters of *four* input lines. The persistent data structure method has been used in [5, 11] for the study of other 3SUM-hard geometric problems. Here we replace this approach with one that uses solely the relative positions of triples of lines, the so-called *order type* of the arrangement. In this approach each comparison involves only *three* input lines, which, as we show, eventually leads to improved performance of the algorithm.

In standard settings, separating the order-type computation from the rest of the processing makes no sense. This is because obtaining the full order-type information for  $N$  lines already takes  $\Theta(N^2)$  time. This makes the approach based on the order type noncompetitive, as one can just do point location in the line arrangement, in the uniform model, with  $O(N^2)$  preprocessing. Nevertheless, in the applications considered in this paper (see Section 3 and

---

<sup>4</sup> Disjointness then of course cannot be assumed in general, although it might occur when the lines in each set are parallel, as in the dual version of the 3SUM-hard GEOMBASE problem [19].

the full version [4, Section 4]), the input lines have a special representation, which allows us to avoid an explicit construction of their order type and obtain this information implicitly in subquadratic time in the decision-tree model. The rest of the preprocessing, which takes quadratic time and storage in the uniform model, costs nothing in the decision-tree model.

The problem of determining whether and how the order type of an arrangement is sufficient to construct an efficient point-location data structure has, to the best of our knowledge, never been addressed explicitly. As we believe that this kind of “handicapped” point location will be useful for other applications (some of which are mentioned in the full version [4, Section 4]), we present it in some detail in Section 2 and in the full version [4, Section 2.2]. We also present extensions of this technique to arrangements of constant-degree algebraic curves in  $\mathbb{R}^2$ , and to arrangements of planes or hyperplanes in higher dimensions, which will be used in the applications presented in the full version [4, Section 4].

The algorithm for solving the within-triangle intersection-counting problem in the algebraic decision-tree model, and, consequently, also of the other three problems listed at the beginning of this section, is presented in Section 3. Additional applications of our technique are presented in the full version [4, Section 4]; they include: (i) counting intersections between two sets of pairwise disjoint circular arcs inside disks, and (ii) minimum distance problems between lines and two sets of points in the plane.

## 2 Order-type-based point location in arrangements

**Order types.** An arrangement of non-vertical lines in the plane (and, later, curves in the plane, or hyperplanes in higher dimension) can be described in the following combinatorial fashion. We use the notion of an *order type*, defined for a set  $L$  of lines as follows: Given any ordered triple of lines  $(\ell_1, \ell_2, \ell_3)$  from  $L$ , where both  $\ell_2$  and  $\ell_3$  intersect  $\ell_1$ , we record the left-to-right order of the intersections  $\ell_1 \cap \ell_2$  and  $\ell_1 \cap \ell_3$  along  $\ell_1$ ; note that the intersections might coincide. The totality of this information gives, for each line in  $L$ , the left-to-right order of its intersections with every other line it meets. Furthermore, we assume the existence of an “infinitely steep” line  $\ell_\infty$ , placed sufficiently far to the left, the order of whose intersections with the “normal” lines encodes the order of their slopes. This information is dual to the perhaps more familiar notion of an order type for a set of points in the plane (see, e.g., [21]). A higher-dimensional analog of this information involves recording the order in which a line that is the intersection of  $d - 1$  hyperplanes in  $\mathbb{R}^d$  meets the remaining hyperplanes that meet but do not contain it. We also assume a suitable analog of the “infinitely steep line,” recursively defined over the dimension.

Back in the plane, the permutations along each line of the intersection points with the other lines are called *local sequences* [22]. This view allows us to extend the definition of the order type to  $x$ -monotone curves, where each pair of curves is assumed to intersect at most  $s$  points, for some constant  $s$ . In this case the order type gives, for each curve  $\gamma$  in the collection, the labeled left-to-right sequence of intersection points with the other curves, where each intersection point is labeled by the triple  $(i, j, k)$ , where  $i$  and  $j$  are the indices of the two curves that form the intersection, and  $k$  indicates that it is the  $k$ th leftmost intersection point of the two curves. The order type also includes the vertical order of the curves at  $x = -\infty$ . See the full version [4, Section 2.2] for further details.

The significance of the order type is that (a) it only records information for  $(d + 1)$ -tuples of objects, and (b) it contains enough information that lets us construct the arrangement and preprocess it for fast point location, without having to access further the actual parameters that define the objects.

The problem we tackle now is the following: Given the order type of an arrangement, preprocess this information into a point location data structure. The preprocessing stage is not allowed to access the actual geometric description of the objects, such as the coefficients of the equations defining the lines or hyperplanes, but can only exploit the discrete data given by the order type. A query, in contrast, is allowed to examine the coefficients of the few objects that it encounters.

We present two solutions for this problem. First, we show that, for  $d$ -dimensional hyperplane arrangements, for any  $d \geq 2$ , the sampling method of Meiser [28] (see also [16]) can be implemented using only order-type information. Second, we show that for arrangements of  $x$ -monotone curves in the plane, a simple variant of the separating-chain method for point location [15, 26] can be implemented such that only order-type information is used during the preprocessing. We present only the first technique in this version of the paper, and delegate the second one to the full version [4, Section 2.2].

## 2.1 Sampling-based approach for hyperplane arrangements

Let  $H$  be a set of  $N$  non-vertical hyperplanes in  $\mathbb{R}^d$ , where  $d \geq 2$  is a fixed constant. We want to construct a point-location data structure for the arrangement  $\mathcal{A}(H)$  induced by  $H$ , where we are only given the order type of  $H$ . Essentially, we are given, for each intersection line formed by  $d - 1$  hyperplanes, the order of its intersections with the other hyperplanes. (Alternatively, we are given, for each simplex  $\sigma$  formed by  $d + 1$  of the hyperplanes, the  $x_1$ -order of the vertices of  $\sigma$ .) We only require  $H$  not to contain vertical hyperplanes. We do permit more than  $d$  hyperplanes to share a point, as well as other degeneracies. This is indeed a natural scenario for our applications including segment intersection counting and its related problems.

We briefly sketch the randomized method first proposed by Meiser [28] and analyzed in detail by Ezra et al. [16] (see also [10]), and show that the order-type information is sufficient to construct the data structure.

Before considering the point-location structure, we note that the order type suffices to construct a discrete representation of the arrangement  $\mathcal{A}(H)$ , in which each  $j$ -dimensional cell of  $\mathcal{A}(H)$ , for  $j = 1, \dots, d$ , stores the set of all  $(j - 1)$ -dimensional cells that form its boundary (and consequently of all cells, of all dimensions, on its boundary), with respective back pointers from each cell to all higher-dimensional cells that contain it on their boundary. This can be done, e.g., by the Folkman–Lawrence topological representation theorem for oriented matroids [18], which, roughly speaking, implies that, given the order type of  $H$ , one can construct a combinatorial representation for the arrangement  $\mathcal{A}(H)$ , consisting of all *sign conditions*. That is, each face  $f$  of  $\mathcal{A}(H)$  (of any dimension) is encoded by a sign vector  $\{-1, 0, +1\}^{|H|}$  representing the above/below/on relation of  $f$  with respect to each hyperplane in  $H$ ; see [9] for an inductive proof for the planar case, and its generalization to higher dimensions in [8]. Given this property, a naïve actual construction of the combinatorial representation of  $\mathcal{A}(H)$  is easy to derive, and is free of charge in the decision-tree model, once the order type of  $H$  is computed. When we perform a point-location query we report a pointer to the sign vector of the cell of  $\mathcal{A}(H)$  that contains the query point – see below.

**Preprocessing.** Given the arrangement  $\mathcal{A}(H)$  and a fixed  $\varepsilon > 0$ , we first construct a random sample  $S$  of  $O(\frac{d^2}{\varepsilon} \log \frac{d}{\varepsilon})$  hyperplanes of  $H$ ; the size of  $S$  does not depend on  $n$ . We then compute a *canonical* triangulation of the arrangement  $\mathcal{A}(S)$ . For each face of  $\mathcal{A}(S)$ , of any dimension at least 2, we use a fixed rule to designate a *reference vertex*  $p$  of this face. For example, we can take  $p$  to be the lexicographically smallest vertex of the face,

with each vertex represented by the lexicographically smallest  $d$ -tuple of the indices of the hyperplanes that contain it and whose intersection is a single point.<sup>5</sup> We then triangulate each face  $f$  of  $\mathcal{A}(S)$  by the *fan* obtained by adding the vertex  $p$  to each simplex in the triangulations of the lower-dimensional faces composing the boundary of  $f$  and not incident to  $p$ . Next, we construct the *conflict list*  $L(\Delta)$  for each simplex  $\Delta$  of the triangulation, of any dimension, defined as the set of hyperplanes of  $H$  that *cross*  $\Delta$ , i.e., intersect, but not fully contain, it.  $L(\Delta)$  can indeed be constructed using only the order type: Deciding whether a hyperplane  $h \in H$  belongs to  $L(\Delta)$  amounts to testing whether there exist two vertices of  $\Delta$  that lie on different sides of  $h$ , and each such test is an orientation test of the corresponding  $(d + 1)$ -tuple of hyperplanes:  $h$  and the  $d$  hyperplanes forming the vertex.

From standard results on  $\varepsilon$ -nets [24], a suitable choice of the constant of proportionality in the bound on the sample size guarantees that, with high probability, the conflict list size is not larger than  $\varepsilon n$ , for each simplex  $\Delta$ . It remains to recurse, for each simplex  $\Delta$  of the triangulation, with the hyperplanes in  $L(\Delta)$ . (If  $\Delta$  is not full-dimensional, we also record the hyperplanes containing it and the recursive processing involves building a lower-dimensional arrangement within  $\Delta$ .) This leads to a hierarchical data structure in which the number of hyperplanes decreases by a factor  $\varepsilon$  at each level. The construction continues until the number of hyperplanes falls below a suitable constant, at which point we simply store the remaining hyperplanes. Let  $w$  be a leaf in this hierarchy. It will be convenient to further preprocess the set  $H(w)$  of hyperplanes stored at  $w$  into a tree  $\mathcal{T}_w$  that allows us to locate a query point in the arrangement  $\mathcal{A}(H(w))$ . The structure  $\mathcal{T}_w$  is simply a ternary tree of depth  $|H(w)| = O(1)$ , where a node at level  $j$  stores the  $j$ -th hyperplane  $h_j$  of  $H(w)$ , so we can test if a query point is below, on, or above  $h_j$ . Observe that each leaf of  $\mathcal{T}_w$  corresponds to a unique cell in the arrangement  $\mathcal{A}(H(w))$  and, hence, also in  $\mathcal{A}(H)$  – indeed, the sign with respect to every hyperplane in  $H \setminus H(w)$  is determined by the search path to the node  $w$  in the hierarchy.

**Answering queries.** Queries are answered as follows. First, we locate the (open) simplex  $\Delta$  of the canonical triangulation of  $\mathcal{A}(S)$  containing the query point  $q$ . Since  $d$  is assumed to be constant,  $S$  is also of constant size, and so locating  $\Delta$  can be done in  $O(1)$  time. Next, we recurse in the data structure attached to  $\Delta$ . When we reach a leaf  $w$  of the hierarchy, we continue to search in the tree  $\mathcal{T}_w$ . When we reach a leaf in  $\mathcal{T}_w$  we have located  $q$  and can report (a pointer to) the sign vector of the cell containing  $q$ .

The overall number of these recursive steps is  $O(\log n)$ , and thus answering a query costs  $O(\log n)$  arithmetic operations, where the hidden constant<sup>6</sup> is polynomial in  $d$ . As noted, in our applications we only need to determine whether  $q$  lies on a hyperplane of  $H$ .

The following lemma summarizes the result.

► **Lemma 1.** *Let  $H$  be a set of  $n$  hyperplanes in  $\mathbb{R}^d$ , where  $d \geq 2$  is a constant. Using only the order type of  $H$ , we can construct a polynomial-size data structure that guarantees  $O(\log n)$ -time point-location queries in the arrangement  $\mathcal{A}(H)$ ; the implied constant depends polynomially on  $d$ . The (polynomial) preprocessing time and the storage of the data structure cost nothing in the decision-tree model.*

<sup>5</sup> When  $p$  is chosen as the bottommost vertex, the resulting triangulation is referred to as the *bottom-vertex triangulation*, but in general the order type does not provide us with this information.

<sup>6</sup> The value of this constant depends on the storage allocated to the structure. For example, spending  $n^{2d \log d + O(d)}$  on storage guarantees query cost of  $O(d^4 \log n)$  [16].

**Remark.** The query time for  $d = 2$  is better than the time in the second, level-based approach presented in the full version [4, Section 2.2] for curves in the plane (which is  $O(\log^2 n)$ ). However, the sampling-based method does not extend to non-straight curves, since there is no obvious way to extend the notion of a canonical triangulation to the case of curves. The only viable way of doing this seems to use the standard vertical-decomposition technique. Unfortunately (for us), constructing the vertical decomposition requires that we compare the  $x$ -coordinates of vertices defined by different, unrelated pairs of curves. Such a comparison involves *four* input curves and it cannot be resolved from the order-type information alone. For lines in the plane, however, the above technique does yield the improved logarithmic query time.

### 3 The algorithm for within-triangle intersection-counting

Our input consists of two sets  $A, B$ , each of  $n$  pairwise disjoint segments in the plane, and of a set  $C$  of  $n$  triangles in the plane. To simplify the presentation, we assume that the input is in general position, namely that, among the segments of  $A, B$ , and edges of triangles of  $C$ , no two share a supporting line, and no endpoint of one segment lies on another (with the obvious exception of the vertices of a triangle in  $C$ ).<sup>7</sup> These are the only general position assumptions that we need. A triple of segments (one from  $A$ , one from  $B$ , and an edge of a triangle from  $C$ ) are allowed to be concurrent.

**A high-level roadmap of the algorithm.** To avoid various technical issues that complicate the description of our algorithm, we focus in this overview on the simpler segment concurrency problem, where  $C$  is a set of (not necessarily disjoint) segments, and the goal is to determine whether there is a triple  $(a, b, c) \in A \times B \times C$  of concurrent segments. To make the overview even simpler, assume that  $C$  is a set of lines.

We fix a parameter  $g \ll n$  and put  $r := n/g$ . We construct a  $(1/r)$ -cutting  $\Xi(A)$  for the segments of  $A$ , and another such cutting  $\Xi(B)$  for the segments of  $B$ . Since the segments of  $A$  are pairwise disjoint, we can construct  $\Xi(A)$  of size  $O(r)$ , and similarly for  $\Xi(B)$  (see [14]). We overlay the two cuttings and obtain a planar decomposition  $\Xi$ . While the complexity of  $\Xi$  is  $O(r^2)$ , any line of  $C$  crosses only  $O(r)$  of its cells.

For each two-dimensional cell  $\sigma$  of  $\Xi$  (lower-dimensional cells are simpler to handle), we preprocess the sets  $A_\sigma \subseteq A$  and  $B_\sigma \subseteq B$  of those segments that cross  $\sigma$ , each of size at most  $n/r = g$ , into a data structure that supports efficient queries, each specifying a line  $c$  and asking whether  $c$  passes through an intersection point of a segment of  $A_\sigma$  and a segment of  $B_\sigma$ . We pass to the dual plane, obtain sets  $A_\sigma^*$  and  $B_\sigma^*$  of at most  $g$  points (dual to the lines containing the segments) each. (We ignore here “short” segments that have an endpoint inside  $\sigma$ ; see below.) The query is a point  $c^*$  and the task is to determine whether  $c^*$  is collinear with a pair of points  $(a^*, b^*) \in A_\sigma^* \times B_\sigma^*$ . For  $a \in A_\sigma$  and  $b \in B_\sigma$  we define  $\gamma_{a,b}$  to be the line that passes through  $a^*$  and  $b^*$ , and let  $\Gamma_\sigma$  denote the collection of these lines. The query with  $c^*$  then reduces to point location in the arrangement  $\mathcal{A}(\Gamma_\sigma)$ , where we only need to know whether  $c^*$  lies on any of the lines.

We cannot perform this task explicitly in an efficient manner, since the complexity of  $\mathcal{A}(\Gamma_\sigma)$  is  $O(g^2)$  and we have  $O(r^2) = O(n^2/g^2)$  such arrangements, of overall size  $O(n^2)$ . We can do it, though, in the algebraic decision-tree model, in an implicit manner, using the so-called *Fredman’s trick*; see [23] for a simpler yet representative application of Fredman’s

<sup>7</sup> For technical reasons, we also allow a triangle in  $C$  to degenerate to a segment.

trick, as well as [5, 6] for geometric applications of Fredman’s trick. Concretely, we apply the order-type-based machinery of Section 2 to construct  $\mathcal{A}(\Gamma_\sigma)$  and preprocess it for fast point location. More precisely, we first construct the order type of  $\Gamma_\sigma$ : this involves, for each triple of lines  $\gamma_{a_1, b_1}, \gamma_{a_2, b_2}, \gamma_{a_3, b_3}$ , determining the ordering of their intersection points along each of these lines. We express this test, in a straightforward manner, as the sign test of some 12-variate constant-degree polynomial  $G(a_1, a_2, a_3; b_1, b_2, b_3)$ .

We map the triple  $(b_1, b_2, b_3)$  to a point in a six-dimensional parametric space, and  $(a_1, a_2, a_3)$  to an algebraic surface  $\psi_{a_1, a_2, a_3}$  in this space, which is the locus of all triples  $(b_1, b_2, b_3)$  with  $G(a_1, a_2, a_3; b_1, b_2, b_3) = 0$ . We now need to locate the points  $(b_1, b_2, b_3)$  in the arrangement of the surfaces  $\psi_{a_1, a_2, a_3}$ , from which all the sign tests can be resolved, at no extra cost in the algebraic decision-tree model, thereby yielding the desired order type. The subsequent construction of the arrangement  $\mathcal{A}(\Gamma_\sigma)$ , and its preprocessing for fast point location, using the machinery in Section 2, also cost nothing in our model.

To make this process efficient, we group together all the points  $(b_1, b_2, b_3)$ , for  $b_1, b_2, b_3$  in the same cell  $\sigma$ , over all cells  $\sigma$ , into one global set  $P$ , and group the surfaces  $\psi_{a_1, a_2, a_3}$  into another global set  $\Psi$ . We have  $|P|, |\Psi| = O(r) \cdot O(g^3) = O(ng^2)$  (since there are only  $O(r)$  cells of  $\Xi(A)$  (resp., of  $\Xi(B)$ ) from which the triples  $(a_1, a_2, a_3)$  (resp.  $(b_1, b_2, b_3)$ ) are drawn).

Using the recent machinery of Agarwal et al. [2] or of Matoušek and Patáková [27], we can perform this batched point location in 6-space in time

$$O\left(|P|^{6/7+\varepsilon} |\Psi|^{6/7+\varepsilon} + |P|^{1+\varepsilon} + |\Psi|^{1+\varepsilon}\right) = O\left((ng^2)^{12/7+2\varepsilon}\right),$$

for any  $\varepsilon > 0$ . Full details of this step, crucial, albeit rather technical, are given in the full version [4, Section 3.1].

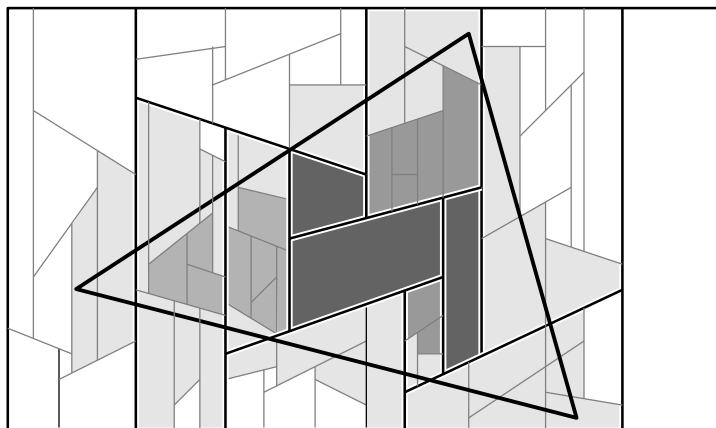

Searching with the dual points  $c^*$  takes  $O\left(\frac{n^2}{g} \log g\right)$  time, because we have  $n$  query lines  $c$ , each line crosses  $O(r) = O(n/g)$  cells  $\sigma$ , and each point location with  $c^*$  in each of the encountered arrangements takes  $O(\log g)$  time. Balancing (roughly) this cost with the preprocessing cost, we choose  $g = n^{2/31}$ , and obtain the total subquadratic running time  $O(n^{2-2/31+\varepsilon}) = O(n^{60/31+\varepsilon})$ .

Quite a few issues were glossed over in this overview. Since the segments of  $A$  and of  $B$  are bounded, a cell  $\sigma$  may contain endpoints of these segments, making the passage to the dual plane more involved. The same applies in the original within-triangle intersection-counting problem, where the triangles of  $C$  may have vertices or more than one bounding edge that lie in or meet  $\sigma$ . We thus need to handle the presence of such “short” segments and/or “short” triangles. Moreover, we need to count intersection points within each triangle, and the number of cells in overlay of the cuttings  $\Xi(A), \Xi(B)$  that a triangle can fully contain is much larger than  $O(r)$ . All these issues require more involved techniques, which are developed below, with some details delegated to the full version [4, Section 3]. Still, the overall runtime of the resulting algorithm remains  $O(n^{60/31+\varepsilon})$ , for any  $\varepsilon > 0$ .

**Hierarchical cuttings.** This ingredient is needed for counting intersection points in cells that are fully contained inside a query triangle. The application of hierarchical cuttings to our problem significantly reduces the query time – see below. Fix a parameter  $g \ll n$  and put  $r := n/g$ . We construct a *hierarchical*  $(1/r)$ -cutting  $\Xi(A)$  for the segments of  $A$ , which is a hierarchy of  $(1/r_0)$ -cuttings, where  $r_0$  is some sufficiently large constant. The top-level cutting  $\Xi_1(A)$  is constructed for  $A$ . Since the segments of  $A$  are pairwise disjoint, we can construct  $\Xi_1(A)$  so that it consists of only  $O(r_0)$  trapezoids (for concreteness, we write this bound as  $br_0$ , for some absolute constant  $b$ ), each of which is crossed by at most

$n/r_0$  segments of  $A$ , which comprise the so-called *conflict list* of the cell  $\sigma$ , denoted as  $A_\sigma$ . The construction time of  $\Xi_1(A)$ , in the real-RAM model, is  $O(n \log r_0) = O(n)$ . See [14, Theorem 1] for details.

For each cell  $\sigma$  of  $\Xi_1(A)$ , we clip the segments in its conflict list  $A_\sigma$  to within  $\sigma$  and apply the cutting-construction step recursively to this set, clipping also the cells of the new cutting to within  $\sigma$  (and ignoring cells, or portions thereof, that lie outside  $\sigma$ , as they are not met by any of the clipped segments of  $A_\sigma$ ). We denote the union of all the resulting  $(1/r_0)$ -cuttings as  $\Xi_2(A)$ . We continue recursively in this manner, until we reach a level  $s$  at which all the cells are crossed by at most  $n/r$  segments. We thus obtain a hierarchy of cuttings  $\Xi_1(A), \Xi_2(A), \dots, \Xi_s(A)$ , for some index  $s = O(\log r)$ . We denote the collective hierarchy as  $\Xi(A)$ . Since we stop the recursion as soon as  $n/r_0^s \leq n/r$ , the overall number of cells of all the levels is  $O((br_0)^s) = O(r^{1+\varepsilon})$ , for any prespecified  $\varepsilon > 0$ , for a suitable choice of  $r_0 = r_0(\varepsilon)$ . Technically, the trapezoids in the cutting are relatively open, and the cutting also includes one- and zero-dimensional cells; as the latter are easier to deal with, we will focus below on the two-dimensional cells of the cutting. At any level  $j$  of the hierarchy, the cells of  $\Xi_j(A)$  are pairwise disjoint. As these cells partition the plane, each intersection point between a segment of  $A$  and a segment of  $B$  lies in precisely one cell of a suitable dimension at each level. See Figure 1 for an illustration.

■ **Figure 1** Interaction of a hierarchical cutting with a triangle. The dark gray cells are the ones inside the triangle at the top level of the hierarchy; the medium gray cells are the ones inside the triangle at the second level (and whose parent cells are not inside the triangle). The light gray cells will be refined and handled at lower levels, since they intersect the triangle boundary.

We apply a similar hierarchical construction for  $B$ , and let  $\Xi(B) = \{\Xi_j(B)\}_{j \leq s}$  denote the resulting hierarchical cutting, which has analogous properties. (We assume for simplicity that the highest index  $s$  is the same in both hierarchies.)

We now overlay  $\Xi(A)$  with  $\Xi(B)$ , that is, at each level  $j$  of the hierarchy, we overlay the cells of  $\Xi_j(A)$  with the cells of  $\Xi_j(B)$ . We denote the  $j$ th level overlay as  $\Xi_j$ , and the entire hierarchical overlay structure as  $\Xi = \{\Xi_j\}_{j \leq s}$ . Since each of  $\Xi_j(A)$  and  $\Xi_j(B)$  consists of at most  $(br_0)^j$  cells, the number of cells of  $\Xi_j$  is at most  $O((br_0)^{2j})$ . Since we have  $r_0^s \approx r$  (up to a factor of  $r_0$ ), it follows that the overall complexity of all the overlays is  $O(r^{2+2\varepsilon})$ , provided that we choose  $r_0$ , as above, to be sufficiently large, as a function of  $\varepsilon$ .

For simplicity of exposition, we ignore lower-dimensional faces of the cuttings, and regard each of the overlays  $\Xi_j$  as a decomposition of the plane into pairwise openly disjoint convex polygons, each of complexity linear in  $j \leq s = O(\log r)$ . Each cell  $\sigma$  of the overlay is

identified by the pair  $(\tau, \tau')$ , where  $\tau$  and  $\tau'$  are the respective cells of  $\Xi_j(A)$  and  $\Xi_j(B)$  whose intersection is  $\sigma$ ; we simply write  $\sigma = (\tau, \tau')$ . Each bottom-level cell  $\sigma$  of the final overlay  $\Xi_s$  is crossed by at most  $n/r = g$  segments of  $A$  and by at most  $g$  segments of  $B$ .

**Classifying the segments and triangles.** Let  $\sigma = (\tau, \tau')$  be a cell of  $\Xi_j$ , for any level  $j$  of the hierarchy. Call a segment  $e$  of  $A$  *long* (resp., *short*) *within*  $\sigma$  if  $e$  crosses  $\sigma$  and neither of its endpoints lies in  $\sigma$  (resp., at least one endpoint lies in  $\sigma$ ). Let  $A_\sigma^l$  (resp.,  $A_\sigma^s$ ) denote the set of long (resp., short) segments of  $A$  within  $\sigma$ . Apply analogous definitions and notations to the segments of  $B$ . Denote by  $C_\sigma$  (resp.,  $C_\sigma^{(0)}$ ) the set of triangles with at least one edge that crosses  $\sigma$  (resp., that fully contain  $\sigma$ ). Call a triangle  $\Delta \in C_\sigma$  *long* (resp., *short*) in  $\sigma$  if  $\sigma$  does not (resp., does) contain a vertex of  $\Delta$ , and denote by  $C_\sigma^l$  (resp.,  $C_\sigma^s$ ) the set of long (resp., short) triangles in  $C_\sigma$ .

For each triangle  $\Delta \in C$ , each of its edges crosses only  $O((br_0)^j)$  cells of  $\Xi_j$ . Indeed, as such an edge crosses from one cell of  $\Xi_j$  to an adjacent cell, it does so by crossing the boundary of either a cell of  $\Xi_j(A)$  or a cell of  $\Xi_j(B)$ , and the total number of such crossings is  $O((br_0)^j)$ . In particular, the edge crosses at most  $O(r^{1+\varepsilon})$  cells of the final overlay  $\Xi_s$ . It follows that  $\sum_{\sigma \in \Xi} |C_\sigma^l| \leq \sum_{\sigma \in \Xi} |C_\sigma| = O(nr^{1+\varepsilon})$ , but clearly  $\sum_{\sigma \in \Xi} |C_\sigma^s|$  is only  $O(n \log r)$ . In contrast,  $\Delta$  can fully contain many more cells of  $\Xi_s$ , perhaps almost all of them, but the hierarchical nature of the construction allows us to deal with a much smaller number of such interior cells, by collecting them at higher levels of the hierarchy; see below for details.

**The algorithm: A quick review.** The high-level structure of the algorithm is as follows (see also the “roadmap” overview given earlier). We construct the hierarchies  $\Xi(A) = \{\Xi_j(A)\}_{j \geq 1}$  and  $\Xi(B) = \{\Xi_j(B)\}_{j \geq 1}$ . For each cell  $\tau$  of  $\Xi_j(A)$  (resp.,  $\tau'$  of  $\Xi_j(B)$ ), we compute its conflict list  $A_\tau$  (resp.,  $B_{\tau'}$ ), which, as we recall, is the set of all segments of  $A$  that cross  $\tau$  (resp., segments of  $B$  that cross  $\tau'$ ). We then form the hierarchical overlay  $\Xi = \{\Xi_j\}_{j \geq 1}$ , and for each cell  $\sigma = (\tau, \tau')$  of any overlay  $\Xi_j$ , we compute the subset  $A_\sigma$  of the segments of  $A_\tau$  that cross  $\sigma$ , and the subset  $B_\sigma$  of the segments of  $B_{\tau'}$  that cross  $\sigma$ . We partition  $A_\sigma$  into the subsets  $A_\sigma^l$  and  $A_\sigma^s$  of long and short segments (within  $\sigma$ ), respectively, and apply an analogous partition to  $B_\sigma$ . The additional overall cost for constructing these sets, over all hierarchical levels, is  $O(r^{2+\varepsilon} \cdot n/r) = O(nr^{1+\varepsilon}) = O(n^{2+\varepsilon}/g)$ . (The cost at the bottom level dominates the entire cost over all levels.)

We also trace each triangle  $c \in C$  through the cells of  $\Xi$  that are crossed by its edges, and form, for each cell  $\sigma$  of the overlay, the list  $C_\sigma$  of triangles of  $C$  with at least one edge that crosses  $\sigma$ . We partition  $C_\sigma$  into the subsets  $C_\sigma^l$  and  $C_\sigma^s$ , as defined earlier. As we show below, we can handle, in a much more efficient way, the short triangles of  $C_\sigma^s$ , as well as the triangles of  $C_\sigma^l$  all three of whose edges cross  $\sigma$ , simply because the overall number of such triangle-cell interactions is small. We therefore focus on the triangles of  $C_\sigma^l$  that have only one or two edges crossing  $\sigma$ . For triangles with two crossing edges we use a standard two-level data structure (where in each level we consider only one crossing edge). This lets us assume, without loss of generality, that each triangle in  $C_\sigma^l$  is a halfplane. Each of these halfplanes can be represented by its bounding line, that is the line supporting the appropriate crossing edge of the triangle. We flesh out the details below.

We also assume, for now, that all the segments of  $A_\sigma$  and of  $B_\sigma$  are long in  $\sigma$  (and so we drop the superscript  $l$ ). This is the hard part of the analysis, requiring the involved machinery presented below. After handling this case, we will address the much simpler situations that involve short segments and/or short triangles (or triangles with three edges crossing  $\sigma$ ). The cost of handling short segments or short triangles within cells is lower, even in the uniform model, since the overall number of short objects within cells is smaller.

**Handling the long segments.** We preprocess each level  $j$  of the overlay, to compute, for each of its cells  $\sigma = (\tau, \tau')$ , the number of intersection points between the (long) segments of  $A_\sigma$  and those of  $B_\sigma$  (which, due to the clipping, lie in  $\sigma$ ). This is a standard procedure that involves computing the number of pairs of segments from  $A_\sigma \times B_\sigma$  whose intersection points with the boundary of  $\sigma$  interleave (these are precisely the pairs of intersecting segments), and can be implemented to take  $O((|A_\sigma| + |B_\sigma|) \log(|A_\sigma| + |B_\sigma|))$  time; see, e.g., [1]. We store the resulting count at  $\sigma$ .

Consider a two-dimensional cell  $\sigma$ , a segment  $a \in A_\sigma$ , a segment  $b \in B_\sigma$ , and a triangle  $\Delta \in C_\sigma$ . By assumption,  $\Delta$  has only one edge  $c$  or two edges  $c_1, c_2$  crossing  $\sigma$ . When  $a$  and  $b$  intersect inside  $\sigma$ , the intersection lies in  $\Delta$  if and only if the triple  $(a, b, c)$ , or each of the triples  $(a, b, c_1)$ ,  $(a, b, c_2)$ , has a prescribed orientation, reflecting the condition that the point  $a \cap b$  lies on the side of  $c$  (or the sides of  $c_1, c_2$ ) that contain  $\Delta$ . This orientation (or orientations) can be positive, negative, or zero, depending on the relative order of the slopes of  $a, b$ , and  $c$  (or of  $c_1$  and  $c_2$ ), and on whether  $\Delta$  lies to the left or to the right of  $c$  (or of  $c_1, c_2$ ).

For each halfplane  $c^+$  that represents a triangle  $\Delta \in C_\sigma$  (the halfplane contains  $\Delta$  and is bounded by the line supporting the single (relevant) edge  $c$  of  $\Delta$  that crosses  $\sigma$ ), we want either (i) to represent the set of pairs  $(a, b) \in A_\sigma \times B_\sigma$  that have a prescribed orientation of the triple  $(a, b, c)$ , as the disjoint union of complete bipartite graphs, or (ii) to count the number of such pairs. The subtask (i) arises in cases where  $\Delta$  has two edges crossing  $\sigma$  and is needed for the first level of the data structure, which we query with the first crossing edge of  $\Delta$ . The subtask (ii) arises in the second level of the structure, which we query with the second crossing edge of  $\Delta$ , and in cases where only one edge of  $\Delta$  crosses  $\sigma$ .

We also count the number of intersections within  $\sigma$ , in  $O((|A_\sigma| + |B_\sigma|) \log(|A_\sigma| + |B_\sigma|))$  time. As a matter of fact, with a simple modification of the procedure, we can, within the same time bound, represent the set of all pairs of segments  $(a, b) \in A_\sigma \times B_\sigma$  that intersect each other (inside  $\sigma$ ) as the disjoint union of complete bipartite graphs, so that the overall size of their vertex sets is  $O((|A_\sigma| + |B_\sigma|) \log(|A_\sigma| + |B_\sigma|))$ . This follows from standard planar segment-intersection range searching machinery; see, e.g., [1]. In what follows we focus on just one such graph, and to simplify the presentation we denote it as  $A_\sigma \times B_\sigma$ , with a slight abuse of notation.

**Preparing for Fredman's trick.** We use the infrastructure developed by Aronov et al. [5], with suitable modifications, but adapt it to the order-type context. We preprocess  $A$  and  $B$  into a data structure that we will then search with the points dual to the lines supporting the edges of the triangles of  $C$ . For each  $a \in A, b \in B$ , we define  $\gamma_{a,b}$  to be the line that passes through  $a^*$  and  $b^*$ , where  $a^*$  (resp.,  $b^*$ ) is the point dual to  $a$  (resp.,  $b$ ). By our general position assumption,  $a^* \neq b^*$ , so  $\gamma_{a,b}$  is well defined. Let  $\Gamma_0$  denote the set of these  $n^2$  lines. Our goal in task (ii) is to count, for each cell  $\sigma$  of any of the overlays, for each point  $c^*$  dual to an edge of a triangle  $\Delta \in C_\sigma$ , the number of lines of  $\Gamma_0$  that lie above  $c^*$ , the number of lines that are incident to  $c^*$ , and the number of lines that lie below  $c^*$ . In task (i), we want to represent each of these sets of lines as the disjoint union of a small number of precomputed canonical sets. This calls for preprocessing the arrangement  $\mathcal{A}(\Gamma_0)$  into a suitable point location data structure, which we will then search with each  $c^* \in C^*$ , and retrieve the desired data from the outcome of each query.

As in, e.g., [5], a naïve implementation of this approach will be too expensive. Instead, we return to the hierarchical partitions  $\Xi(A), \Xi(B)$ , and  $\Xi$ , and iterate, over all cells  $\sigma = (\tau, \tau')$  of the bottom level  $\Xi_s$ , defining  $\Gamma_\sigma := \{\gamma_{a,b} \mid (a, b) \in A_\sigma \times B_\sigma\}$ . In principle, we want to

construct the separate arrangements  $\mathcal{A}(\Gamma_\sigma)$ , over the cells  $\sigma$ , preprocess each of them into a point location data structure, and search, for each triangle  $\Delta \in C$ , in the structures that correspond to the cells of  $\Xi$  that are either crossed by (at most) one or two edges of  $\Delta$ , or fully contained in  $\Delta$ . This is also too expensive if implemented naïvely, so we use instead Fredman’s trick, combined with the machinery developed in Section 2.

We first observe that, for each triangle  $\Delta \in C$ , finding the cells  $\sigma$  (at any level of the hierarchy) that  $\Delta$  fully contains is easy and inexpensive. We go over the hierarchy of the overlays  $\Xi_j$ . At the root we find, by brute force, all the (constantly many) cells of  $\Xi_1$  that  $\Delta$  fully contains, and add their intersection counts to our output counter. We then recurse, in the same manner, in the at most  $br_0$  cells of  $\Xi_1$  that  $\Delta$  crosses. Thus the number of cells we visit is at most  $O(r_0^2) \cdot (1 + br_0 + (br_0)^2 + \dots + (br_0)^s) = O(r^{1+\varepsilon})$ , so the overall cost of this step<sup>8</sup> is  $O(nr^{1+\varepsilon}) = O(n^{2+\varepsilon}/g)$ .

We therefore focus, for each triangle  $\Delta$  of  $C$ , only on the cells that it crosses (at every level of the hierarchy), and restrict the analysis for now to cells at which  $\Delta$  is long, with at most two of its edges crossing the cell. Repeating most of the analysis just given, the number of these cells is  $O(r^{1+\varepsilon})$  (with a smaller constant of proportionality, since we now do not have the factor  $O(r_0^2)$ , as above).

**Constructing  $\mathcal{A}(\Gamma_\sigma)$  in the decision-tree model.** Consider the step of constructing  $\mathcal{A}(\Gamma_\sigma)$  for some fixed bottom-level cell  $\sigma$ . Following the technique in Section 2, we perform this step using only the order type of  $\Gamma_\sigma$ , and we begin by considering the task of obtaining the order-type information. That is, we want to determine, for each ordered triple  $(\gamma_{a_1,b_1}, \gamma_{a_2,b_2}, \gamma_{a_3,b_3})$  of lines of  $\Gamma_\sigma$ , whether the point  $\gamma_{a_1,b_1} \cap \gamma_{a_2,b_2}$  lies to the left or to the right of the point  $\gamma_{a_1,b_1} \cap \gamma_{a_3,b_3}$ . Let  $G(a_1, a_2, a_3; b_1, b_2, b_3)$  denote the 12-variate polynomial (of constant degree) whose sign determines the outcome of the above comparison. (The immediate expression for  $G$  is a rational function, which we turn into a polynomial by multiplying it by the square of its denominator, without affecting its sign; our general position assumption ensures that none of the denominators vanishes.)

Once the signs of all expressions  $G(a_1, a_2, a_3; b_1, b_2, b_3)$  are determined, we can apply Lemma 1. The rest of the preprocessing, which constructs a discrete representation of the arrangement, say, in the DCEL format [13], and turns this representation into an efficient point location data structure, can be carried out at no cost in the algebraic decision-tree model.

We search the structure with each triangle  $\Delta \in C_\sigma$ . We may assume that  $\Delta$  is long in  $\sigma$  and that only one or two edges of  $\Delta$  cross  $\sigma$ , as the other cases are easy to handle. Assuming further that there is only one such edge  $c$ , locating the dual point  $c^*$  in  $\mathcal{A}(\Gamma_\sigma)$  takes  $O(\log g)$  time, as shown in Section 2 (noting that  $\Gamma_\sigma$  consists of only  $g^2$  lines). With suitable preprocessing, locating  $c^*$  gives us, for free in our model, the three sets of the lines that pass above  $c^*$ , are incident to  $c^*$ , or pass below  $c^*$ . The case where two edges of  $\Delta$  cross  $\sigma$  is handled using a two-level version of the structure; see below for details. The point location cost now goes up to  $O(\log^2 g)$ .

Consider then the step of computing the order type of the lines of  $\Gamma_\sigma$ , that is, of computing the sign of  $G(a_1, a_2, a_3; b_1, b_2, b_3)$ , for every triple of segments  $a_1, a_2, a_3 \in A_\sigma$  and every triple of segments  $b_1, b_2, b_3 \in B_\sigma$ . To this end, we play Fredman’s trick. We fix a bottom-level cell  $\tau$  of  $\Xi(A)$ . For each triple  $(a_1, a_2, a_3) \in A_\tau^3$ , we define the surface

$$\psi_{a_1, a_2, a_3} = \{(b_1, b_2, b_3) \in \mathbb{R}^6 \mid G(a_1, a_2, a_3; b_1, b_2, b_3) = 0\},$$

<sup>8</sup> It is for making this step efficient that we use hierarchical partitions. A single-shot partition would have forced the query to visit up to  $\Theta(r^2)$  such cells, which would make it too expensive.

and denote by  $\Psi$  the collection of these surfaces, over all cells  $\tau$ . We have  $N := |\Psi| = O((n/g)^{1+\varepsilon} \cdot g^3) = O(n^{1+\varepsilon}g^2)$ . Similarly, we let  $P$  denote the set of all triples  $(b_1, b_2, b_3)$ , for  $b_1, b_2, b_3 \in B_{\tau'}^3$ , over all cells  $\tau'$  of  $\Xi(B)$ . We have  $M := |P| = O(n^{1+\varepsilon}g^2)$ . These bounds pertain to the bottommost level of the hierarchy; they are smaller at levels of smaller indices.

We apply a batched point-location procedure to the points of  $P$  and the surfaces of  $\Psi$ . The output of this procedure is a collection of complete bipartite subgraphs of  $P \times \Psi$ , so that, for each such subgraph  $P_\alpha \times \Psi_\alpha$ ,  $G(a_1, a_2, a_3; b_1, b_2, b_3)$  has a fixed sign for all  $(b_1, b_2, b_3) \in P_\alpha$  and all  $(a_1, a_2, a_3) \in \Psi_\alpha$ , see, e.g., [3, 12] for the use of such structures in similar contexts. This tells us the desired signs of  $G(a_1, a_2, a_3; b_1, b_2, b_3)$ , for every pair of triples  $(a_1, a_2, a_3) \in A_\tau^3$ ,  $(b_1, b_2, b_3) \in B_{\tau'}^3$ , over all pairs of cells  $(\tau, \tau') \in \Xi(A) \times \Xi(B)$ , and these signs give us the orientation (i.e., the order of the intersection points) of every triple of lines  $\gamma_{a,b}$ . That is, we obtain the order type of the lines. As remarked in Section 2, we may assume that this also includes the sorting of the lines at  $x = -\infty$ , but, for the sake of concreteness, we address this simpler task in the full version [4, Section 3].

The batched point location step proceeds by using the recent multilevel polynomial partitioning technique of Agarwal et al. [2, Corollary 4.8]. We delegate the full, and rather technical, details of the analysis to the full version [4, Section 3.1], and just summarize the result here.

► **Proposition 2.** *Let  $T(M, N)$  denote the maximum possible sum of the sizes of the vertex sets of the complete bipartite graphs produced by the recursive process described above, over all input sets of at most  $M$  points and at most  $N$  surfaces. Then we have*

$$T(M, N) = O\left(M^{6/7+\varepsilon}N^{6/7+\varepsilon} + M^{1+\varepsilon} + N^{1+\varepsilon}\right),$$

for any  $\varepsilon > 0$ , where the constant of proportionality depends on  $\varepsilon$ . The same asymptotic bound also holds for the cost (in the uniform model) of constructing these graphs.

In summary, the information collected so far allows us to obtain the combinatorial structure of each of the arrangements  $\mathcal{A}(\Gamma_\sigma)$ , over all cells  $\sigma$  of  $\Xi$ , and subsequently construct an order-type-based point-location data structure for each of them, at no extra cost in the algebraic decision-tree model. The overall cost of this phase, in this model, is thus  $O((n^{1+\varepsilon}g^2)^{12/7+\varepsilon})$ , for any  $\varepsilon > 0$ . By replacing  $\varepsilon$  by some small multiple thereof, we can write this bound as  $O((ng^2)^{12/7+\varepsilon})$ , for any  $\varepsilon > 0$ .

Fredman’s trick, as applied above, separates the handling of the conflict lists  $A_\tau$ , over the trapezoids  $\tau$  of  $\Xi(A)$ , and the conflict lists  $B_{\tau'}$ , over the trapezoids  $\tau'$  of  $\Xi(B)$ . For a cell  $\sigma = (\tau, \tau')$  of  $\Xi$ , not all the segments in  $A_\tau$  necessarily cross  $\sigma$ , so we have to retain (for  $\sigma$ ) only those that do cross it, and apply a similar pruning to  $B_{\tau'}$ . As we show in the full version [4, Section 3], the cost of this filtering step is  $O(g)$  for each  $\sigma$ , for an overall cost of  $O((n/g)^2 \cdot g) = O(n^2/g)$ .

**Searching with the elements of  $C$ .** We now need to search the structures computed in the preceding phase with the dual features of the triangles of  $C$ . Due to lack of space, we delegate the description to the full version [4, Section 3], where we show that the total searching time, for all the elements of  $C$ , is  $O\left(\frac{n^{2+\varepsilon} \log^2 g}{g}\right)$ , concluding (see once again our high-level roadmap):

► **Theorem 3.** *Let  $A$  and  $B$  be two sets each consisting of  $n$  pairwise disjoint segments in the plane, and let  $C$  be a set of  $n$  triangles in the plane. We can count, for each triangle  $\Delta \in C$ , the number of intersection points of segments of  $A$  with segments of  $B$  that lie inside  $\Delta$ , in the algebraic decision-tree model, at the subquadratic cost  $O(n^{60/31+\varepsilon})$ , for any  $\varepsilon > 0$ .*

► **Corollary 4.** *We can solve, in the algebraic decision-tree model, at the cost of  $O(n^{60/31+\varepsilon})$ , for any  $\varepsilon > 0$ , each of the problems (i) intersection of three polygons, (ii) coverage by three polygons, and (iii) segment concurrency, as listed in the introduction.*

## Abstract

Consider the geometric range space  $(X, \mathcal{H}_d)$  where  $X \subset \mathbb{R}^d$  and  $\mathcal{H}_d$  is the set of ranges defined by  $d$ -dimensional halfspaces. In this setting we consider that  $X$  is the disjoint union of a red and blue set. For each halfspace  $h \in \mathcal{H}_d$  define a function  $\Phi(h)$  that measures the “difference” between the fraction of red and fraction of blue points which fall in the range  $h$ . In this context the maximum discrepancy problem is to find the  $h^* = \arg \max_{h \in \mathcal{H}_d} \Phi(h)$ . We aim to instead find an  $\hat{h}$  such that  $\Phi(h^*) - \Phi(\hat{h}) \leq \varepsilon$ . This is the central problem in linear classification for machine learning, in spatial scan statistics for spatial anomaly detection, and shows up in many other areas. We provide a solution for this problem in  $O(|X| + (1/\varepsilon^d) \log^4(1/\varepsilon))$  time, for constant  $d$ , which improves polynomially over the previous best solutions. For  $d = 2$  we show that this is nearly tight through conditional lower bounds. For different classes of  $\Phi$  we can either provide a  $\Omega(|X|^{3/2 - o(1)})$  time lower bound for the exact solution with a reduction to APSP, or an  $\Omega(|X| + 1/\varepsilon^{2 - o(1)})$  lower bound for the approximate solution with a reduction to 3SUM.

A key technical result is a  $\varepsilon$ -approximate halfspace range counting data structure of size  $O(1/\varepsilon^d)$  with  $O(\log(1/\varepsilon))$  query time, which we can build in  $O(|X| + (1/\varepsilon^d) \log^4(1/\varepsilon))$  time.

## 1 Introduction

Let  $X$  be a set of  $m$  points in  $\mathbb{R}^d$  for constant  $d$  where  $X$  can either be the union of a red,  $R$ , and blue set,  $B$ , of points  $X = R \cup B$  (possibly not disjoint) or a set of weighted points where each point has weight  $w(x)$  for  $x \in X$ . Now let  $(X, \mathcal{H}_d)$  be the associated range space of all subsets of  $X$  defined by intersection with a halfspace.

We are interested in finding the halfspace  $h^*$  and value  $\Phi^*$  that maximizes a function  $\Phi_X(h) : \mathcal{H}_d \rightarrow \mathbb{R}$  for some class of functions  $\Phi$ . We characterize them by reframing it as a function of  $\mu_R$  and  $\mu_B$  so  $\Phi_X(h) = \phi(\mu_R(h), \mu_B(h))$ , where  $\mu_R(h) = |R \cap h|/|R|$  and  $\mu_B(h) = |B \cap h|/|B|$  are the fraction of red or blue points, respectively, in the range  $h$ . In particular, we only consider functions  $\Phi_X(h)$  which can be calculated in  $O(1)$  time from  $\mu_R(h)$  and  $\mu_B(h)$  as  $\phi(\mu_R(h), \mu_B(h))$  (e.g.,  $\phi(\mu_R, \mu_B) = |\mu_R - \mu_B|$ ). Given such a fixed  $\phi$ , or one from a class, we state the two main problems: exact and  $\varepsilon$ -additive error.

- **Problem MAX-HALFSPACE:** *From a given set  $X = R \cup B \subset \mathbb{R}^d$  points where  $|X| = m$  and a Lipschitz constant function  $\Phi_X(h) : 2^X \rightarrow \mathbb{R}$ , find  $h^* = \arg \max_{h \in \mathcal{H}_d} \Phi_X(h)$ .*
- **Problem  $\varepsilon$ -MAX-HALFSPACE:** *From a given set  $X = R \cup B \subset \mathbb{R}^d$  points where  $|X| = m$  and a Lipschitz constant function  $\Phi_X(h) : 2^X \rightarrow \mathbb{R}$  where  $h^* = \arg \max_{h \in \mathcal{H}_d} \Phi_X(h)$ , find  $\hat{h} \in \mathcal{H}_d$  such that  $\Phi_X(h^*) - \Phi_X(\hat{h}) \leq \varepsilon$ .*

## 4:2 Approximate Maximum Halfspace Discrepancy

■ **Figure 1** Plots of common  $\phi$  functions. From left to right:  $\phi_{||}$ ,  $\phi_f$  (for  $f = 0.3$ ), and  $\phi_K$ .

We typically write  $\Phi_X$  as  $\Phi$  when the set  $X$  is clear. Our algorithms will explicitly compute  $\mu_R(h)$  (and  $\mu_B(h)$  separately) for each  $h$  evaluated, and so work with all functions  $\phi$ . Notable useful examples of  $\phi$ , shown in Figure 1, include:

- **discrepancy:**  $\phi_{||}(h) = |\mu_R(h) - \mu_B(h)|$ .  
This measures the maximum disagreement between the proportions of the two sets  $B$  and  $R$ : the central task of building a linear classifier (on training data) in machine learning is often formulated to maximize precisely this function [26, 34, 12, 15]. Given a coloring of  $X$  into  $R$  and  $B$ , this also measures the discrepancy of that coloring [32, 10].
- **$f$ -balancing:**  $\phi_f(h) = 1 - |(\mu_R(h) - \mu_B(h)) - f|$ , for a fraction  $f \in (0, 1)$ .  
This scores how well a halfspaces strikes a balance of  $f$  between the two sets. By minimizing this function (or maximizing  $1 - \phi_f(h)$ ), the goal is to find a range  $h$  that exhibits an imbalance between the sets of  $f$ . Maximizing this function (say with  $f = 1/2$ ) is the problem of finding good ham sandwich cuts [27].
- **Kulldorff:**  $\phi_K(h) = \mu_R(h) \log \frac{\mu_R(h)}{\mu_B(h)} + (1 - \mu_R(h)) \log \frac{1 - \mu_R(h)}{1 - \mu_B(h)}$ .  
This is the Kulldorff discrepancy function [23] which arises in spatial scan statistics [29, 30, 23, 24, 21, 33, 3, 2], for detecting spatial anomalies. This function specifically is derived as the log-likelihood ratio test under a Poisson model, but other similar convex, non-linear functions arise naturally from other models [24, 2]. In this setting the most common range shape model is a disk, and the best algorithms [16, 17, 29] operate by lifting to one-dimension higher where the ranges correspond to halfspaces.

All of these  $\phi$  functions are Lipschitz continuous over  $\mu_B$  and  $\mu_R$ , and thus this extends to a combinatorial notion of Lipschitz over the associated  $\Phi$  with respect to the combinatorial range  $h$ : that is,  $|\Phi_X(h) - \Phi_X(h')| \leq c(|h \cap R| - |h' \cap R|/|R| + |h \cap B| - |h' \cap B|/|B|)$  for constant  $c$ . For  $\phi_{||}$  and  $\phi_f$ ,  $c = 1$ , and for  $\phi_K$  it is bounded in a reasonable range of  $\mu_B, \mu_R$  [2, 28]. This means that approximating each of  $\mu_B(h)$  and  $\mu_R(h)$  up to additive error translates into at most additive error in  $\Phi_X$ .

We also consider the hardness of these problems, and for this we will restrict the classes of functions  $\phi$  considered in these problems. We will show the largest lower bound on *concave* functions  $\phi$  (like  $\phi_f$ ), and this construction will apply to a Lipschitz functions (again like  $\phi_f$ ). However, the class of convex functions (like  $\phi_{||}$  and  $\phi_K$ ) are more prevalent, and we present a smaller lower bound, but which applies to convex Lipschitz functions (including  $\phi_{||}$  and  $\phi_K$ ).

We also note that for all of the above functions and linked challenges, the  $\varepsilon$ -approximate versions are just as relevant and common as the exact ones. For instance in machine learning, typically  $\varepsilon$ -additive error is the baseline, on assumptions that the input  $X$  is drawn from a fixed but unknown distribution [38, 25]. Spatial scan statistics are applicable to data sets containing thousands to 100s of millions of spatial data points, such as census data, disease incidents, geo-located social media posts. The exact algorithms are polynomial in  $m$  and therefore can have massive runtimes, which become infeasible in the full data sets. Usually

the exact algorithms are not even attempted and the set of ranges considered are defined using some heuristic such as disks with centerpoints of a grid or centered at data points. On the other hand the  $\varepsilon$ -additive error versions are scalable with runtimes of  $O(m + \text{poly}(\frac{1}{\varepsilon}))$ , depending only on the accuracy of the solution not the scale of the data or assumptions about the data distribution.

**Our Results.** We connect this problem to the approximate range counting problem for constant  $d \geq 2$  in the additive error model by designing a data structure of size  $O(\frac{1}{\varepsilon^d})$  that can be constructed in time  $O(m + \frac{1}{\varepsilon^d} \log^4 \frac{1}{\varepsilon})$  with constant probability and supports range counting queries in time  $O(\log \frac{1}{\varepsilon})$ . This structure implies a halfspace scanning algorithm that runs in time  $O(m + \frac{1}{\varepsilon^d} \log^4 \frac{1}{\varepsilon})$ . The data structure is closely related to cuttings, but we do not need the set of crossing lines, but only an approximation of their total count.

In the other direction, we show instances where  $\phi$  is linear that are as hard as  $\Omega(m^{3/2-o(1)})$  on the exact problem, reduced from APSP, and instances where  $\phi$  is concave that are as hard as  $\Omega(m + \frac{1}{\varepsilon^{2-o(1)}})$ , reduced from 3SUM. This implies (conditionally) that this class of scanning algorithms requires  $\Omega(m + \frac{1}{\varepsilon^{2-o(1)}})$  time, and any further algorithmic improvements (beyond  $\text{polylog}(1/\varepsilon)$  factors) would either require specific and new assumptions on  $\phi$  or improvement on a classic hard problem.

**Relation to Prior Work.** The best prior algorithms for  $\varepsilon$ -MAX-HALFSPACE required  $O(m + (1/\varepsilon)^{d+1/3} \log^{2/3}(1/\varepsilon))$  time [28] and the best exact algorithm requires  $O(m^d)$  time [16, 17]. Conditioned on 3SUM, without allowing restrictions to  $\phi$  beyond linearity, our lower bound shows the prior exact algorithms are shown tight for  $d = 2$  by setting  $m = 1/\varepsilon$ .

For the related problem of the range space defined by axis-aligned rectangles [39], the story for instance is more complicated with respect to  $\phi$ . For linear  $\phi$  the exact problem can be solved in  $O(m^2)$  time [7] which is tight [6] assuming no subcubic algorithm for MAX-WEIGHT-3-CLIQUE (and hence APSP). The  $\varepsilon$ -approximate version can be solved in  $O(m + \frac{1}{\varepsilon^{2d-2}} + \frac{1}{\varepsilon^2} \log \log \frac{1}{\varepsilon})$  time with constant probability [28], and by the result of Backurs *et al.* [6] this cannot be improved beyond  $\Omega(m + 1/\varepsilon^2)$  in  $\mathbb{R}^2$  under the same assumptions [28]. However, for general functions  $\phi$  the best known runtimes increase to  $O(m^4)$  and  $O(m + 1/\varepsilon^4)$  for the exact and approximate versions, respectively [28]. Although for a big class of convex functions (like  $\phi_K$ ) can be reduced back to  $O(m + 1/\varepsilon^{2.5})$  in the approximate case [28]. Thus, this paper shows the situation appears significantly simpler for the halfspaces case, and we provide a new connection to a (usually) separate [41, 6, 40] class of conditional hardness problems through 3SUM.

Our approximate range counting structure is also new and may be of independent interest, allowing very fast halfspace queries (in  $O(\log 1/\varepsilon)$  time) in moderate dimensions  $d$  where  $1/\varepsilon^d$  may not be too large. For example,  $3d$  disk queries maps to the  $d = 4$  setting, and with  $\varepsilon = 0.01$  (1% error) then  $1/\varepsilon^d = 100$  million – which can fit in the memory of most modern systems, and allow for very fast queries. Similar structures are possible for the exact range counting paradigm [8, 10], and these could be adapted to the approximate setting after constructing an appropriate  $\varepsilon$ -sample of  $X$  [38, 25, 29]. But these would instead use higher  $\tilde{O}(1/\varepsilon^{d+1})$  preprocessing time (where  $\tilde{O}(z)$  hides  $\text{polylog}(z)$  terms). Most effort in approximate range counting has come in the low-space regime. For instance with *relative*  $(1 + \varepsilon)$  error, one can build a data structure of expected size  $O(\text{poly}(1/\varepsilon) \cdot m)$  that answers approximate range counting queries in  $O(\text{poly}(1/\varepsilon) \cdot \log m)$  time in  $\mathbb{R}^3$  [1]. However for  $d > 3$  with linear space, the query time becomes polynomial in  $m$  at  $\tilde{O}(m^{1-1/\lfloor d/2 \rfloor})$  [5, 4, 35].

A related line of work on robust halfspace learning under specific noise models in high dimensions has witnessed significant progress in the last few years [12, 15, 13, 11]. These models and algorithms also start with a sufficiently large iid sample (of size roughly  $1/\varepsilon^2$ ), and ultimately achieve a result with additive  $\varepsilon$  error from the opt. However, they assume a specific noise model, but using this achieve runtimes polynomial in  $d$ , whereas our results grow exponentially with  $d$  but do not require any assumptions on the noise model. A recent focus is on Massart noise, where given a perfect classifier, each point has its sign flipped independently with an assigned probability at most  $\eta < 1/2$ . Only recently [11], in this Massart noise model it was achieved a proper learned function (a halfspace) in time polynomial in  $1/\varepsilon$  and in  $d$ . Recent previous work was not proper (the learned function may not be a halfspace) [12, 15], or takes time exponential in  $1/\varepsilon$  [13]. Indeed, under Gaussian distributed data, the proper halfspace learning requires  $d^{\Omega(1/\varepsilon)}$  time [14], under the statistical query model [36].

## 2 Background and Notation

**Useful Sampling Properties.** An  $\varepsilon$ -sample [19, 38] is a subset  $S \subset X$  so for a range space  $(X, \mathcal{R})$  it preserves the density for all ranges as  $\max_{A \in \mathcal{R}} \left| \frac{|X \cap A|}{|X|} - \frac{|S \cap A|}{|S|} \right| \leq \varepsilon$ . An  $\varepsilon$ -net is a subset  $N \subset X$  so for a range space  $(X, \mathcal{R})$  it hits large ranges, specifically for all ranges  $A \in \mathcal{R}$  such that  $|X \cap A| \geq \varepsilon|X|$  we guarantee that  $N \cap A \neq \emptyset$ . For halfspaces, a random sample  $S \subset X$  of size  $O(\frac{1}{\varepsilon^2}(d + \log \frac{1}{\delta}))$  is an  $\varepsilon$ -sample with probability at least  $1 - \delta$  [38, 25], and a random sample  $N \subset X$  of size  $O(\frac{d}{\varepsilon} \log \frac{1}{\delta})$  is an  $\varepsilon$ -net [20] with probability at least  $1 - \delta$ .

**Enumeration.** Given a set of points  $X \subset \mathbb{R}^d$ , Sauer's Lemma [37] shows that there are at most  $O(|X|^d)$  combinatorially distinct ranges, where each range defined by a halfspace contains the same subset of points. We can always take a halfspace and rotate it until it intersects at most  $d$  boundary points without changing the set of points contained inside. This observation immediately implies a simple algorithm for scanning the point set; we can just enumerate all subsets of at most  $d$  points, compute a halfspace that goes through these points, and count the red and blue points lying underneath to evaluate  $\Phi$ .

Our work builds upon this simple algorithm by dividing it into two steps and optimizing both. We first define a set of prospective ranges  $\hat{\mathcal{H}}_d$  to scan and then secondly compute the function  $\Phi$  on each region. Matheny *et al.* [28] showed that a simple random sample  $X_0 \subset X$  of size  $O(\frac{1}{\varepsilon})$  (for constant  $d$ ) induces a small range space  $(X_0, \mathcal{H}_d)$ . Each range (a subset of  $X_0$ ) maps to a canonical geometric halfspace  $h_0$ , and this geometric halfspace in turn induces a range  $h_0 \cap X$ , an element of  $(X, \mathcal{H}_d)$ . We refer to this subset of  $(X, \mathcal{H}_d)$  as  $(X, \hat{\mathcal{H}}_d)$ , it is of size  $O(1/\varepsilon^d)$ . Now for each range  $h \cap X$  in  $(X, \mathcal{H}_d)$  there is a range  $\hat{h} \cap X \in (X, \hat{\mathcal{H}}_d)$  such that the symmetric difference between them is at most  $\varepsilon|X|$ . So if every range in  $(X, \hat{\mathcal{H}}_d)$  needs to be explicitly checked, and  $f(1/\varepsilon)$  is the time to compute  $\Phi$ , this would imply a  $(1/\varepsilon^d)f(1/\varepsilon)$  lower bound. Note that  $f(1/\varepsilon)$  may take super-constant time because we may need to construct the (approximate)  $\mu_R(h)$  and  $\mu_B(h)$  values.

**Cuttings.** Cuttings are a useful tool to formalize divide and conquer steps in geometric algorithm design. Given  $\mathbb{R}^d$ , a set of halfspaces  $\mathcal{H}_d$  of size  $m$ , and some parameter  $r$  a  $\frac{1}{r}$ -cutting is a partition of  $\mathbb{R}^d$  into a disjoint set of constant complexity cells where each cell is crossed by at most  $m/r$  halfspaces. The set of halfspaces crossing a cell in the cutting is referred to as the conflict list of the cell. It is well established that the number of partitions

is of size  $O(r^d)$  and the partitioning can be constructed in  $O(r^{d-1}m)$  time if the conflict lists are needed [31]. If the crossing information is not needed then faster algorithms can be used. For instance, the arrangement of a  $\frac{1}{r}$ -net over  $\mathcal{H}_d$  defines a partitioning of  $\mathbb{R}^d$  into disjoint cells where each cell is crossed by at most  $m/r$  halfspaces, and since a simple random sample can be used to generate the net, a cutting of size  $O(r^d \log^d r)$  can be computed in  $O(m + r^d \log^d r)$  time with constant probability. For  $r \ll m$ , this can be a substantial runtime improvement with a small increase in size.

When a cutting is restricted to a single cell there are better bounds on the size of the partitioning. We will need this better bound for our proof and we restate it here.

► **Theorem 1** ([9, 8]). *Denote the vertices corresponding to  $d$ -way intersections of  $\mathcal{H}_d$  as  $\mathcal{A}(\mathcal{H}_d)$ . A  $\frac{1}{r}$ -cutting of a cell  $\Delta$  containing  $|\mathcal{A}(\mathcal{H}_d) \cap \Delta| = \eta$  vertices can be constructed with  $O(\eta \left(\frac{r}{m}\right)^d + r^{d-1})$  cells.*

### 3 Approximate Halfspace Range Counting and the Upper Bound

In this section, instead of operating on  $R \cup B = X \in \mathbb{R}^d$ , as is common for halfspace range searching, we work on the set  $H$  of dual halfspaces in  $\mathbb{R}^d$ . In this setting a query halfspace  $h \in \mathcal{H}_d$  in the dual representation is  $q_h \in \mathbb{R}^d$ , and the desired quantity is the number of halfspaces in  $H$  below  $q_h$ . We apply the construction separately for  $R$  and  $B$ , so the halfspaces  $H$  may be weighted, with positive weights.

We will construct  $L$  decompositions of  $\mathbb{R}^d$  into disjoint trapezoidal cells:  $\Delta_0, \Delta_1, \dots, \Delta_L$ . For each level of cells  $\Delta_i$  any cell  $\Delta \in \Delta_i$  has a set of children cells  $S_\Delta$ . The next level of cells  $\Delta_{i+1}$  is the disjoint union of all the  $S_\Delta$  children cells of  $\Delta \in \Delta_i$ ; that is  $\Delta_{i+1} = \bigcup_{\Delta \in \Delta_i} S_\Delta$ . Initially  $\Delta_0 = \mathbb{R}^d$  and therefore contains the entire domain and a corresponding sample of this initial cell will be denoted as  $\hat{H}$ ; we will bound its required size in Lemma 6. Define  $\Delta \cap H$  to be the set of halfspaces in  $H$  that lie completely underneath  $\Delta$  (that is, if  $q \in \Delta$  then  $q \notin h$  for any  $h \in \Delta \cap H$ ), and  $\Delta \cap H$  is the set of halfspaces in  $H$  that cross  $\Delta$ .

Importantly, we maintain an estimate of the weight of each cell  $m_i(\Delta)$ , as we recursively build the decomposition. It depends on a sufficiently large constant  $r$ . For a cell  $\Delta$  we will consider a sample  $H_\Delta \subset H \cap \Delta$  of halfspaces. For each cell  $\Delta' \in \Delta_{i+1}$  where  $\Delta' \in S_\Delta$  we take a sample  $H_{\Delta'} \subset (H_\Delta \cap \Delta')$  of size  $\frac{|H_\Delta \cap \Delta'|}{r}$  with replacement. The value  $\hat{m}_{i+1}(\Delta')$  estimates the number of halfplanes lying below it, and is defined recursively as  $\hat{m}_{i+1}(\Delta') = r^{i+1}|H_\Delta \cap \Delta'| + \hat{m}_i(\Delta)$ ; with  $\hat{m}_0(\Delta) = 0$ . If a cell  $\Delta$  has a small number of lines crossing it, specifically if  $|H_\Delta| \leq \log \frac{1}{\varepsilon}$  then the recursion terminates. Otherwise, we *split* the cell, and create a  $1/t_\Delta$ -cutting of each  $(\Delta, H_\Delta)$ , and let  $S_\Delta$  be its cells; the value  $t_\Delta = \max\left(\frac{|H_\Delta| r^{2i+1}}{|\hat{H}|}, 1\right)$  is 1 if  $|H_\Delta|$  is small, otherwise it is at most  $r$ . We recurse on each cell  $\Delta'$  in each  $S_\Delta$  until each is sufficiently small, which will require  $L = O(\log \frac{|\hat{H}|}{\varepsilon}) = O(\log \frac{1}{\varepsilon})$  levels. See Algorithm 1 for details.

**Complexity analysis.** As cells are subsampled and split the number of lines and vertices lying inside of a cell drops off quickly with the level.

► **Lemma 2.** *A cell  $\Delta \in \Delta_i$  with sample  $H_\Delta$  is of size  $|H_\Delta| \leq |\hat{H}|/r^{2i}$ .*

**Proof.** Consider a cell  $\Delta^* \in \Delta_{i-1}$  where  $\Delta \in S_{\Delta^*}$  then  $|H_\Delta| = \frac{1}{r}|H_{\Delta^*} \cap \Delta|$  by construction, and since  $\Delta$  is a cell in a  $\frac{1}{t_{\Delta^*}}$ -cutting of  $H_{\Delta^*}$  then  $|H_{\Delta^*} \cap \Delta| \leq |H_{\Delta^*}|/t_{\Delta^*} = |\hat{H}|/r^{2i-1}$ ; hence  $|H_\Delta| = |\Delta \cap H_{\Delta^*}|/r \leq |\hat{H}|/r^{2i}$ . ◀

## 4:6 Approximate Maximum Halfspace Discrepancy

■ **Algorithm 1**  $\text{SampleCut}(\Delta_0, \hat{H})$ .

---

**for** levels  $i = [0, L]$  **do**  
  **for** each cell in that level  $\Delta \in \Delta_i$  with  $|H_\Delta| > \log \frac{1}{\varepsilon}$  **do**  
    Set  $t_\Delta = \max(\frac{|H_\Delta| r^{2i+1}}{|\hat{H}|}, 1)$   
    Build  $S_\Delta$ , the cells of a  $\frac{1}{t_\Delta}$ -cutting on  $(\Delta, H_\Delta)$ .  
    **for** each child cell  $\Delta' \in S_\Delta$  **do**  
       $\hat{m}_{i+1}(\Delta') = r^{i+1}|H_\Delta \cap \Delta'| + \hat{m}_i(\Delta)$   
      Sample  $H_{\Delta'} \subset H_\Delta$  where  $|H_{\Delta'}| = |\Delta' \cap H_\Delta|/r$

---

The number of vertices in the cells drops off quickly as well.

► **Lemma 3.** *A cell  $\Delta \in \Delta_i$  with sample  $H_\Delta$  has  $\mathbb{E}[|\mathcal{A}(H_\Delta)|] \leq \frac{|\mathcal{A}(\hat{H}) \cap \Delta|}{r^{di}}$  expected vertices.*

**Proof.** Consider a vertex lying inside of  $\Delta$  induced by the intersection of  $d$  halfspaces  $h_1, \dots, h_d \in H_{\Delta^*}$  in  $\Delta$  (where  $\Delta \subset \Delta^* \in \Delta_{i-1}$ ). The probability that this vertex is in  $H_\Delta$  is  $\Pr(h_1 \in H_\Delta \wedge \dots \wedge h_d \in H_\Delta) \leq \frac{1}{r^d}$ . The probability that a vertex survives through  $i$  samples is then upper bounded by  $\frac{1}{r^{di}}$  and by linearity of expectation  $\mathbb{E}[|\mathcal{A}(H_\Delta)|] \leq \frac{|\mathcal{A}(\hat{H}) \cap \Delta|}{r^{di}}$ . ◀

Combining these results we show the expected number of cells increases as  $O(r^{di})$ . This leverages Theorem 1 using the number of vertex dependent bound for size of the cutting.

► **Lemma 4.** *At a level  $i$  the expected number of cells is  $\mathbb{E}[|\Delta_i|] = O(r^{di})$ .*

**Proof.** The number of cells at a level  $i$  is in expectation

$$\begin{aligned} \mathbb{E}[|\Delta_i|] &= \mathbb{E} \left[ \sum_{\Delta \in \Delta_{i-1}} O(|\mathcal{A}(H_\Delta) \cap \Delta| \frac{t_\Delta^d}{|H_\Delta|^d} + t_\Delta^{d-1}) \right] \\ &= C \cdot \mathbb{E} \left[ \sum_{\Delta \in \Delta_{i-1}} |\mathcal{A}(H_\Delta) \cap \Delta| \frac{t_\Delta^d}{|H_\Delta|^d} + t_\Delta^{d-1} \right] \end{aligned}$$

from Theorem 1, for some sufficiently large constant  $C < r/4$ . Since  $t_\Delta = \max(\frac{|H_\Delta| r^{2i+1}}{|\hat{H}|}, 1)$  we can divide cells in  $\Delta_{i-1}$  into a set  $\Delta_{i-1}^+$  where  $t_\Delta > 1$ , and is therefore split, and a set of cells  $\Delta_{i-1} \setminus \Delta_{i-1}^+$  where  $t_\Delta = 1$ , and is therefore not split. The set of non split cells  $\Delta_{i-1} \setminus \Delta_{i-1}^+$  cannot be larger than  $|\Delta_{i-1}|$ .

$$\begin{aligned} \mathbb{E}[|\Delta_i|] &= C \cdot \mathbb{E} \left[ \sum_{\Delta \in \Delta_{i-1}} |\mathcal{A}(H_\Delta) \cap \Delta| \frac{t_\Delta^d}{|H_\Delta|^d} + t_\Delta^{d-1} \right] \\ &\leq C \cdot \mathbb{E} \left[ |\Delta_{i-1}| + \sum_{\Delta \in \Delta_{i-1}^+} |\mathcal{A}(H_\Delta) \cap \Delta| \frac{r^{2di-d}}{|\hat{H}|^d} + t_\Delta^{d-1} \right] \end{aligned}$$

By Lemma 2 we can bound  $t_\Delta \leq \frac{|H_\Delta| r^{2i+1}}{|\hat{H}|} \leq r$ , to replace the last term.

$$\begin{aligned} \mathbb{E}[|\Delta_i|] &\leq C \cdot \mathbb{E} \left[ |\Delta_{i-1}| + \sum_{\Delta \in \Delta_{i-1}^+} |\mathcal{A}(H_\Delta) \cap \Delta| \frac{r^{2di-d}}{|\hat{H}|^d} + r^{d-1} \right] \\ &\leq C \cdot \frac{r^{2di-d}}{|\hat{H}|^d} \mathbb{E} \left[ \sum_{\Delta \in \Delta_{i-1}^+} |\mathcal{A}(H_\Delta) \cap \Delta| \right] + C \cdot (r^{d-1} + 1) \mathbb{E}[|\Delta_{i-1}|] \end{aligned}$$

By Lemma 3  $\mathbb{E}[|\mathcal{A}(H_\Delta) \cap \Delta|] \leq \frac{|\mathcal{A}(\hat{H}) \cap \Delta|}{r^{di-d}}$ , and this yields

$$\begin{aligned} \mathbb{E}[|\Delta_i|] &\leq C \cdot \frac{r^{2di-d}}{|\hat{H}|^d} \mathbb{E} \left[ \sum_{\Delta \in \Delta_{i-1}^+} \frac{|\mathcal{A}(\hat{H}) \cap \Delta|}{r^{di-d}} \right] + C \cdot (r^{d-1} + 1) \mathbb{E}[|\Delta_{i-1}|] \\ &= C \cdot \frac{r^{di}}{|\hat{H}|^d} \mathbb{E} \left[ \sum_{\Delta \in \Delta_{i-1}^+} |\mathcal{A}(\hat{H}) \cap \Delta| \right] + C \cdot (r^{d-1} + 1) \mathbb{E}[|\Delta_{i-1}|]. \end{aligned}$$

Since a vertex in  $\mathcal{A}(\hat{H}) \cap \Delta$  can only be in one cell  $\sum_{\Delta \in \Delta_{i-1}^+} |\mathcal{A}(\hat{H}) \cap \Delta| \leq |\hat{H}|^d$ , since this quantity upper bounds the number of vertices in  $\mathcal{A}(\hat{H})$ . Hence

$$\mathbb{E}[|\Delta_i|] \leq \dots \text{chain of inequalities} \dots \leq C \cdot (r^{di} + (r^{d-1} + 1) \mathbb{E}[|\Delta_{i-1}|])$$

Now finally we show  $\mathbb{E}[|\Delta_i|] \leq 2C \cdot r^{di}$  by inductively assuming  $\mathbb{E}[|\Delta_{i-1}|] \leq 2C \cdot r^{d(i-1)}$  for  $C < r/4$  and  $r$  sufficiently large

$$\begin{aligned} \mathbb{E}[|\Delta_i|] &\leq C \cdot (r^{di} + (r^{d-1} + 1)(2C r^{d(i-1)})) \\ &\leq C \cdot (r^{di} + r^{di}/2 + r^{di-d+1}/2) \\ &\leq 2C \cdot r^{di} = O(r^{di}). \end{aligned} \quad \blacktriangleleft$$

**Sampling Error.** Consider now that we wish to estimate  $|\hat{H} \cap \Delta|$ , the number of planes crossing under some  $\Delta$ . We will use that  $\Delta$  lies within a nested sequence of cutting cells  $\Delta = \Delta_i \subset \Delta_{i-1} \subset \dots \subset \Delta_0$  with  $\Delta_i \in \mathbf{\Delta}_i, \Delta_{i-1} \in \mathbf{\Delta}_{i-1}, \dots, \Delta_0 \in \mathbf{\Delta}_0$ , where  $i \leq L$ , and with corresponding samples  $\hat{H} = H_{\Delta_0}$  and  $H_{\Delta_1}, \dots, H_{\Delta_\ell}$ . We can also define  $\hat{m}_i(\Delta)$  more generally for a cell  $\Delta$  that is the subset of a cell  $\Delta_i \in \mathbf{\Delta}_i$  (and its ancestors), but not necessary one of those cells. It is defined  $\hat{m}_i(\Delta) = r^i |H_{\Delta_{i-1}} \cap \Delta| + \sum_{j=0}^{i-1} r^j |H_{\Delta_{j-1}} \cap \Delta_j|$ . By this definition  $\hat{m}_0(\Delta) = |\hat{H} \cap \Delta|$ , and we are left to bound  $|\hat{m}_i(\Delta_i) - |\hat{H} \cap \Delta_i||$ .

► **Lemma 5.**  $|\hat{m}_i(\Delta) - |\hat{H} \cap \Delta|| = O(i \sqrt{|\hat{H}| \log \frac{2\ell}{\delta'}})$  with probability  $1 - \delta'$ .

**Proof.** By the triangle inequality we expand

$$\begin{aligned}
 |\hat{m}_i(\Delta) - \hat{m}_0(\Delta)| &\leq \sum_{j=0}^{i-1} |\hat{m}_{j+1}(\Delta) - \hat{m}_j(\Delta)| \\
 &= \sum_{j=0}^{i-1} \left| r^{j+1} |H_{\Delta_j} \cap \Delta| + \sum_{\ell=0}^j r^\ell |H_{\Delta_{\ell-1}} \cap \Delta_\ell| \right. \\
 &\quad \left. - \left( r^j |H_{\Delta_{j-1}} \cap \Delta| + \sum_{\ell=0}^{j-1} r^{\ell-1} |H_{\Delta_{\ell-2}} \cap \Delta_{\ell-1}| \right) \right| \\
 &= \sum_{j=0}^{i-1} |r^{j+1} |H_{\Delta_j} \cap \Delta| + r^j |H_{\Delta_{j-1}} \cap \Delta_j| - r^j |H_{\Delta_{j-1}} \cap \Delta|| \\
 &= \sum_{j=0}^{i-1} r^j |r |H_{\Delta_j} \cap \Delta| - |(H_{\Delta_{j-1}} \cap \Delta_j) \cap \Delta|| \\
 &\leq \sum_{j=0}^{i-1} r^j \cdot r \cdot C_d \sqrt{|H_{\Delta_j}| \log \frac{1}{\delta^\dagger}}.
 \end{aligned}$$

The last inequality follows since  $H_{\Delta_j}$  is a random sample from  $H_{\Delta_{j-1}} \cap \Delta_j$ , and the  $\cap \Delta$  restriction is a constant VC-dimension range [38]; the constant  $C_d$  depends only on  $d$ , and  $\delta^\dagger$  is the probability of failure for each term in the sum. In particular we use  $\left| \frac{|H_{\Delta_j} \cap \Delta|}{|H_{\Delta_j}|} - \frac{|(H_{\Delta_{j-1}} \cap \Delta_j) \cap \Delta|}{|H_{\Delta_{j-1}} \cap \Delta_j|} \right| \leq C_d \sqrt{\frac{1}{|H_{\Delta_j}|} \log \frac{1}{\delta^\dagger}}$  and multiply by  $|H_{\Delta_{j-1}} \cap \Delta_j| = r |H_{\Delta_j}|$ .

Applying Lemma 2 then  $|H_{\Delta_j}| \leq \frac{|\hat{H}|}{r^{2j}}$ . Hence

$$\sum_{j=0}^{i-1} r^j \sqrt{|H_{\Delta_j}| \log \frac{1}{\delta^\dagger}} \leq \sum_{j=0}^{i-1} r^j \sqrt{\frac{|\hat{H}|}{r^{2j}} \log \frac{1}{\delta^\dagger}} \leq \sum_{j=0}^{i-1} \sqrt{|\hat{H}| \log \frac{1}{\delta^\dagger}}.$$

And to ensure a failure probability of  $1 - \delta'$  for the sequence of samples, set  $\delta^\dagger = \delta'/2\ell$ .

$$|\hat{m}_i(\Delta) - |\hat{H} \cap \Delta|| \leq i \cdot C_d \sqrt{|\hat{H}| \log \frac{2\ell}{\delta'}}. \quad \blacktriangleleft$$

Now how large does  $\hat{H}$  need to be to ensure a correct estimate of the cells at the leaves of the arrangement. This largely depends on the number of  $\varepsilon$ -samples taken in total.

► **Lemma 6.** *We can ensure that  $|\hat{m}_i(\Delta) - |\hat{H} \cap \Delta|| \leq \varepsilon |\hat{H}|$  for all  $\Delta \in \mathbf{\Delta}_i$  with probability  $\delta$  by setting  $|\hat{H}| = O(\frac{i^3}{\varepsilon^2} \log \frac{i}{\delta})$ .*

**Proof.** We can set the probability of  $\delta' = \delta/(2|\mathbf{\Delta}_i|)$  in Lemma 5 to ensure a failure probability of  $\delta$  for each cell  $\Delta \in \mathbf{\Delta}_i$  and therefore  $|\hat{m}_i(\Delta) - |\hat{H} \cap \Delta|| = O(i \sqrt{|\hat{H}| \log \frac{2i|\mathbf{\Delta}_i|}{\delta}})$ . So if  $\varepsilon |\hat{H}| = |\hat{m}_i(\Delta) - |\hat{H} \cap \Delta|| = O(i \sqrt{|\hat{H}| \log \frac{2i|\mathbf{\Delta}_i|}{\delta}})$  then  $|\hat{H}| = O(\frac{i^2}{\varepsilon^2} \log \frac{2i|\mathbf{\Delta}_i|}{\delta})$ .

From Lemma 4 we know that  $|\mathbf{\Delta}_i| = O(r^{di})$ , and so  $|\hat{H}| = O(\frac{i^3}{\varepsilon^2} \log \frac{i}{\delta})$ . ◀

**Runtime.** The time to compute an estimate for  $\Delta \in \mathbf{\Delta}_i$  is linear in the number of lines in  $H_\Delta \leq \frac{|\hat{H}|}{r^{2i}}$ . We can then devise the expected runtime for computing estimates for all cells in a level  $i$ , of which there are  $\mathbb{E}[|\mathbf{\Delta}_i|] = O(r^{di})$ , so the total for level  $i$  is  $\sum_{\Delta \in \mathbf{\Delta}_i} O(\frac{|\hat{H}|}{r^{2i}}) = O(\frac{|\mathbf{\Delta}_i| |\hat{H}|}{r^{2i}}) = O(r^{i(d-2)} |\hat{H}|)$ . The total expected runtime over all levels is then  $\sum_{i=0}^L O(r^{i(d-2)} |\hat{H}|)$ . Furthermore, if  $d = 2$  then this will be  $O(\frac{L^4}{\varepsilon^2} \log \frac{L}{\delta})$ . If  $d > 2$

then each layer of the cutting will dominate the previous layers in runtime and so the total time will be bounded by the time to compute the last layer as  $\sum_{i=0}^L O(r^{i(d-2)}|\hat{H}|) = O(r^{(L+1)(d-2)}\frac{L^3}{\varepsilon^2} \log \frac{L}{\delta})$ .

Next we want to achieve that all cells  $\Delta \in \mathbf{\Delta}_L$  are of size  $|H_\Delta| < \log_r \frac{1}{\varepsilon}$ . This can be achieved via  $|H_\Delta| < |\hat{H}|/(r^{2L}) \leq \log_r \frac{1}{\varepsilon}$  by setting the maximum level  $L > \frac{1}{2} \log_r \frac{|\hat{H}|}{\log_r \frac{1}{\varepsilon}} = O(\log \frac{1}{\varepsilon})$ , via Lemma 6. Then a query can at first recursively descend into the structure for  $O(L) = O(\log \frac{1}{\varepsilon})$  steps, and upon reaching a leaf node, can enumerate the leaf node's sample which will take at most  $O(\log \frac{1}{\varepsilon})$  time again. With  $L = O(\log \frac{1}{\varepsilon})$ , the total time to compute the cell division for  $d = 2$  is  $O(\frac{L^4}{\varepsilon^2} \log \frac{L}{\delta}) = O(\frac{1}{\varepsilon^2} \log^4 \frac{1}{\varepsilon} \log \frac{\log \frac{1}{\varepsilon}}{\delta})$ . For  $d > 2$ , then  $O(r^{(L+1)(d-2)}\frac{L^3}{\varepsilon^2} \log \frac{L}{\delta}) = O(\frac{1}{\varepsilon^d} \log^3 \frac{1}{\varepsilon} \log \frac{\log \frac{1}{\varepsilon}}{\delta})$  since  $r^{(L+1)(d-2)} = r r^{(d-2) \log_r \frac{1}{\varepsilon}} = r r^{\log_r \frac{1}{\varepsilon^{d-2}}} = \frac{r}{\varepsilon^{d-2}}$ .

► **Theorem 7.** *We can build an  $\varepsilon$ -approximate halfspace range counting data structure of size  $O(1/\varepsilon^d)$  that for any halfspace  $h \in \mathcal{H}_d$  returns in  $O(\log(1/\varepsilon))$  time returns a count  $\hat{m}(h)$  so that  $|\hat{m}(h) - |h \cap X|| \leq \varepsilon|X|$ . The total expected construction time, with probability  $1 - \delta$ , for  $d = 2$  is  $O(|X| + \frac{1}{\varepsilon^2} \log^4 \frac{1}{\varepsilon} \log \frac{\log \frac{1}{\varepsilon}}{\delta})$ , and for constant  $d > 2$  is  $O(|X| + \frac{1}{\varepsilon^d} \log^3 \frac{1}{\varepsilon} \log \frac{\log \frac{1}{\varepsilon}}{\delta})$ .*

**Finding the Maximum Range.** To query the structure we need a set of viable halfspaces that cover the space well enough to approximately hit the maximum region. We can use a random sample of points from the primal space of size  $O(\frac{1}{\varepsilon})$  to induce a set of  $O(1/\varepsilon^d)$  halfspaces  $\hat{\mathcal{H}}_d$ , as was done in [28], to get a constant probability that at least one halfspace is  $O(\varepsilon)$ -close to the maximum region. Then we repeat the procedure  $\log \frac{1}{\delta}$  times and take the maximum found region to magnify the success probability to  $1 - \delta$  (see [28] for details). For each query hyperplane  $h$  we can query a structure constructed over  $R$  and over  $B$  and then compute the function value from this; we return the  $h$  which maximizes  $\Phi(h)$ .

The set of query hyperplanes from this tactic is of size  $O(\frac{1}{\varepsilon^d})$  for constant  $d$  and at each level we can determine which cell the dual point of the halfspace falls into by testing a constant  $O(r^d)$  number of constant sized cells. At a leaf of the structure we check if the remaining, at most  $\log \frac{1}{\varepsilon}$ , dual halfspaces are below the query dual point, to determine the total count. The query structure has  $O(\log \frac{1}{\varepsilon})$  levels and at each level a constant amount of work is done; it is repeated for each of  $O(\frac{1}{\varepsilon^d})$  halfspaces, and the entire endeavor is repeated  $\log \frac{1}{\delta}$  times to reduce the probability of failure. The full runtime is  $O(\frac{1}{\varepsilon^d} \log \frac{1}{\varepsilon} \log \frac{1}{\delta})$ , plus the construction time of the data structure (from Theorem 7) which dominates the cost.

► **Theorem 8.** *We can solve  $\varepsilon$ -MAX-HALFSPACE with probability  $1 - \delta$ , in expected time  $O(|X| + \frac{1}{\varepsilon^d} \log^4 \frac{1}{\varepsilon} \log \frac{\log \frac{1}{\varepsilon}}{\delta})$  for  $d = 2$  and  $O(|X| + \frac{1}{\varepsilon^d} \log^3 \frac{1}{\varepsilon} \log \frac{\log \frac{1}{\varepsilon}}{\delta})$  for constant  $d > 2$ .*

## 4 Conditional Lower Bounds

Our upper bounds only restrict  $\Phi_X(h) = \phi(\mu_R(h), \mu_B(h))$  to be a Lipschitz function. Next we show that an algorithm that can operate on this entire class of functions for  $d = 2$  has a conditional lower bound of  $O(m + \frac{1}{\varepsilon^{2-o(1)}})$ , depending on 3SUM [18].

However, the first bound requires  $\phi$  is also concave (unlike  $\phi_{||}$  or  $\phi_K$  which are convex). So we consider a different convex function  $\phi(\mu_R, \mu_B) = \mu_R - \mu_B$  on weighted points; solving for it, and again after flipping all signs of weights, corresponds with  $\phi_{||}$  (which can be used to approximate  $\phi_K$ ). We show MAX-HALFSPACE for this  $\phi$  is lower bounded by  $O(m^{3/2-o(1)})$  conditional on APSP [41] requiring  $\Omega(n^{3-o(1)})$  time.

■ **Figure 2** On left converting the POINT-COVERING problem into the dual makes it such that a line contains every ray that it intersects. On right the equivalent bichromatic discrepancy problem where red points have been placed on the lower envelope.

### 4.1 Lower Bounds by 3SUM

Gajentaan and Overmars identified a large class of problems in computational geometry called 3SUM hard [18]. 3SUM can be reduced to each of these problems, so an improvement in any one of them would imply an improvement in 3SUM. While there are some loose lower bounds for this problem, 3SUM is conjectured to **not** be solvable in  $O(m^{2-o(1)})$  time [22, 40]. 3SUM reduces to the following problem in  $O(m \log m)$  time [18].

- **Problem POINT-COVERING:** *From a given set of  $m$  halfspaces determine if there is a point at depth  $k$  ( $k$  halfspaces lie above this point) where  $k \leq m/2$ .*

Through standard point-line duality, we transform this to its equivalent dual problem.

- **Problem LINE-COVERING:** *From a given set of  $m$  rays, oriented upwards or downwards, determine if there is a line cutting through  $k$  rays where  $k \leq m/2$ .*

Define the piecewise linear function (for  $k \leq m/2$ ) on points  $R, B \in \mathbb{R}^2$ :

$$\Phi(h) = \phi_{LC}(\mu_R, \mu_B) = |R| - |\mu_R|R| - \mu_B|B| - k = |R| - ||h \cap R| - |h \cap B| - k|.$$

► **Lemma 9.** *LINE-COVERING is reducible to MAX-HALFSPACE in  $\mathbb{R}^2$  with  $\phi_{LC}$  in  $O(m \log m)$  time.*

**Proof.** Construct the lower envelope of all endpoints of the rays; this takes  $O(m \log m)$  time. Each upwards oriented ray is replaced with a point at its end point, and placed in  $R$ . Each downward oriented ray is replaced with two points: its endpoint generates a point in  $B$ , and where it intersects the lower envelope generates a point in  $R$ . See Figure 2.

Lines now correspond to halfplanes below those lines. Upward ray intersections require lines above them. Downward rays require lines between the corresponding  $B$  and  $R$  points: if a line is above both, they cancel in  $\phi_{LC}$ ; if it is below both, it includes neither; if a line is between them, it only identifies the  $R$  point. But the lines below both are below the lower envelope, and cannot be the optimal halfspace. Thus scanning the generated point set  $R \cup B$ , if it identifies a halfspace  $h$  where  $\Phi(h) > |R|$ , only then is LINE-COVERING satisfied. ◀

We can also reduce the exact version to the approximate version. If we run an  $\varepsilon$ -approximate MAX-HALFSPACE algorithm, and set  $\varepsilon = \frac{1}{2|R|}$  then the approximate range  $h'$  found will be off by at most a count of  $1/2$  from the optimal range, and hence must be the optimal solution.

► **Theorem 10.** *In  $\mathbb{R}^2$ ,  $\varepsilon$ -MAXHALFSPACE for  $\phi_{LC}$  takes  $\Omega(m + 1/\varepsilon^{2-o(1)})$  assuming the full input of size  $m$  needs to be read, and 3SUM requires  $\Omega(n^{2-o(1)})$  time.*

Since  $\phi_{LC}$  is concave and 1-Lipschitz, this implies any algorithm that works for all concave  $\phi$  or all 1-Lipschitz  $\phi$  must also take at least this long.

## 4.2 Lower Bound by All Pairs Shortest Path

We next provide a new construction that directly applies to the  $\phi_{||}$  function on weighted points in  $\mathbb{R}^2$  via a reduction from All Pairs Shortest Path (APSP). We first show the MAX-WEIGHT-3-CLIQUE problem reduces to APSP via another problem NEGATIVE-TRIANGLE.

- **Problem APSP:** *Given an edge-weighted undirected graph with  $n$  vertices, find the shortest path between every pair of vertices.*
- **Problem NEGATIVE-TRIANGLE:** *Given an edge-weighted undirected graph with  $n$  vertices, determine if there is a triangle with negative total edge weight.*
- **Problem MAX-WEIGHT- $K$ -CLIQUE:** *Given an edge-weighted undirected graph with  $n$  vertices, find the  $K$ -clique with the maximum total edge weight.*

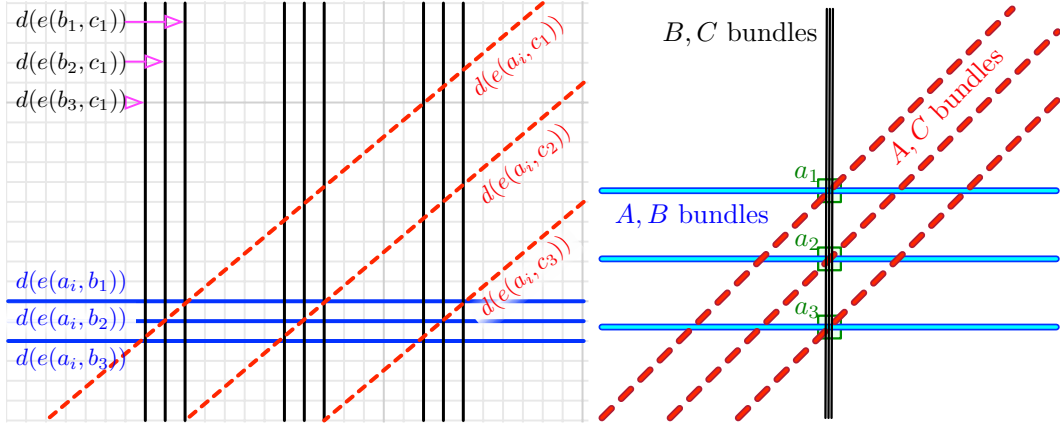

While the APSP is more well-known, Williams and Williams [41] showed it is equivalent to the NEGATIVE-TRIANGLE problem, which will be more useful. Both have well-known  $O(n^3)$  algorithms and are conjectured to not be solvable in less than  $O(n^{3-o(1)})$  time, and improving that bound on one would improve on the other. Moreover, Backurs *et al.* [6] used MAX-WEIGHT- $K$ -CLIQUE as a hard problem, believed to require  $O(n^{K-o(1)})$  time, for which to reduce to several other problems involving rectangles. They note that for  $K = 3$ , MAX-WEIGHT-3-CLIQUE is a special case of NEGATIVE-TRIANGLE. That is, for a guessed max-weight  $\omega$ , one can subtract  $\omega/3$  from each edge weight, then multiply all weights by  $-1$ . If there exists a negative triangle with the new weights, there exists a triangle with weight  $\omega$  in the original. One can resolve the max weight with logarithmically number of steps of binary search. Hence, NEGATIVE-TRIANGLE (and hence also APSP) reduces to MAX-WEIGHT-3-CLIQUE.

For MAX-WEIGHT-3-CLIQUE it is equivalent to assume a 3-partite graph  $G = (V, E)$  [6]; that is, the vertices  $V$  are the disjoint union of three independent sets  $A = \{a_1, a_2, \dots, a_n\}$ ,  $B = \{b_1, b_2, \dots, b_n\}$ , and  $C = \{c_1, c_2, \dots, c_n\}$ . Each independent set will have exactly  $n$  vertices and each vertex, for instance  $a_i$ , will have an edge with every vertex in  $B$  and  $C$ . Denote the edge between  $a_i$  and  $b_j$  as  $e(a_i, b_j)$  and the weight as  $w(e(a_i, b_j))$ . We reduce to a dual of halfspace scanning in  $\mathbb{R}^2$ :

- **Problem MAX-WEIGHT-POINT:** *Given  $m$  weighted lines find a point which maximizes the sum of weights of all lines passing below that point (or intersecting that point).*

Our reduction will rely on a planar geometric realization of any such graph  $G$  with  $m = O(n^2)$  lines, where the lines correspond to edges, and triple configurations of lines correspond with cliques. Given such an instance, if we can solve the MAX-HALFSPACE algorithm (in the dual as MAX-WEIGHT-POINT) in better than  $O(m^{\frac{3}{2}-o(1)})$  time we can recover the solution to the MAX-WEIGHT-3-CLIQUE problem in better than  $O(n^{3-o(1)})$  time.

**The double weighted line gadget.** Our full construction will use a special gadget which will ensure the max weighted point will correspond with a vertex at a triple intersection of a planar arrangement of lines, with each line corresponding with an edge in  $G$ . For this to hold we instantiate each edge as a *double line*  $d(e)$ . This consists of two parallel lines  $\ell_u(e)$  and

■ **Figure 3** MAX-WEIGHT-POINT construction with  $n = 3$ . Left: intersection of  $a_i$  blue and red bundles with all black double lines. Right: relation of the bundles, with 3  $a_i$  intersections marked.

$\ell_l(e)$ , separated vertically by a gap of a small positive value  $\alpha \ll 1$ , with  $\ell_u(e)$  above  $\ell_l(e)$ . In what follows we will refer to a double line as a single line; to be precise this will refer to a line at the midpoint between  $\ell_l$  and  $\ell_u$ . Let  $\bar{w} = 2 \max_{e \in E} |w(e)| + 1$  be a large enough value so for any  $e \in E$  that  $\bar{w} + w(e)$  is strictly positive, and any  $|w(e)| < \bar{w}/2$ . Then we denote the weight of the double line as  $w(d(e)) = w(e) + \bar{w}$ . This is transferred to the lines as  $w(\ell_u(e)) = -w(d(e))$  and  $w(\ell_l(e)) = w(d(e))$ .

Now given a query point  $x \in \mathbb{R}^2$  we say it is *on*  $d(e)$  if it lies between lines  $\ell_l(e)$  and  $\ell_u(e)$ , and *not on* otherwise. This will allow us to control the effect of  $e$  on query  $x$  in a precise way.

► **Lemma 11.** *Any point  $x$  that lies on  $d(e)$  will have weight contributed to it by  $e$  of exactly  $w(e) + \bar{w}$ ; otherwise that contribution will be 0.*

**Reduction to triple intersections.** Our construction will place double lines for each edge in the graph. The edges from  $A$  to  $B$  will be *blue* lines; from  $A$  to  $C$  will be *red* lines, and from  $B$  to  $C$  will be *black* lines. All lines of the same color will be parallel; this will ensure that any query point  $x \in \mathbb{R}^2$  can only be on one double line of each color. For easy of exposition, in our construction description (and illustration; see Figure 3) the black lines will be vertical, which makes ambiguous the “above” relation; so the final step will be to rotate the entire construction clockwise by a small angle (less than  $\pi/4$  radians).

The construction will now lay out the double lines so that every clique  $\{a_i, b_j, c_k\}$  will be realized as a triple intersection of double lines  $d(e(a_i, b_j))$ ,  $d(e(a_i, c_k))$ , and  $d(e(b_j, c_k))$  and so there are no other types of triple intersections. Such a triple intersection will have weight precisely  $w(e(a_i, b_j)) + w(e(a_i, c_k)) + w(e(b_j, c_k)) + 3\bar{w} > (3/2)\bar{w}$ , and any other point (e.g., a double intersection) must have weight strictly less than  $(3/2)\bar{w}$ .

► **Lemma 12.** *The maximum weight point must occur at a triple intersection of three double lines of different colors, and thus must correspond the max weight 3-clique.*

**The full construction.** The blue lines (using  $A$  to  $B$  edges) will all be horizontal. Edge  $e(a_i, b_j)$  will have  $y$ -coordinate  $y_{i,j} = -j - i(5n^2)$  so that  $y_{i,j+1} = y_{i,j} - 1$  and so  $y_{i+1,j} = y_{i,j} - 3n^2$ . Set  $y_{1,1} = -5n^2 - 1$ . This bundles the blue lines associated with the same  $a_i$  point. Figure 3 shows a single bundle (left) and structure of all bundles (right).

The red lines (using  $A$  to  $C$  edges) will be at a 45 degree angle (a slope of 1), similarly clustered by their  $c_k$  values. Double line  $d(e(a_i, c_k))$  will have equation  $\mathbf{y} = \mathbf{x} + o_{i,k}$ . We define the offsets  $o_{i,k} = -k(3n) - i(5n^2)$  so that  $o_{1,1} = -3n - 5n^2$ ;  $o_{i,k+1} = o_{i,k} - 3n$  and  $o_{i+1,k} = o_{i,k} - 5n^2$ . And in particular, double lines  $d(e(a_i, b_j))$  (at horizontal  $y_{i,j}$ ) and  $d(e(a_i, c_k))$  (at offset  $o_{i,k}$ ) will intersect at  $x$ -value  $x_{j,k} = y_{i,j} - o_{i,k}$ .

The black lines (using  $B$  and  $C$ ) will be vertical. Edge  $d(e(b_j, c_k))$  will have  $x$  coordinate  $x_{j,k}$ , defined  $x_{j,k} = y_{i,j} - o_{i,k} = -j + (3n)k$ . Also, these  $x_{j,k}$  values will be distinct for different values of  $j, k$ , but independent of the choice of  $a_i$ . Moreover, these are the same  $x$ -coordinates where the corresponding red and blue lines intersect. Thus each black line  $d(e(b_j, c_k))$  intersects the intersection of blue line  $d(e(a_i, b_j))$  and  $d(e(a_i, c_k))$  for each  $a_i$ .

Finally, note that all black lines are in the  $x$  range  $[-3n^2, 0]$  we can argue that they do not cause any other triple intersections. Because the each red bundle has offsets separated by more than  $3n^2$  then a red bundle associated with  $a_i$  cannot intersect a blue bundle associated  $a_{i'}$  for  $i \neq i'$  since the red lines have linear slope and the blue bundles are also separated by more than  $3n^2$ . Thus the intended triple intersections (of  $d(e(a_i, b_j))$ ,  $d(e(a_i, c_k))$ , and  $d(e(b_j, c_k))$ ) are the only ones in this construction.

In total there are  $n^2$  blue,  $n^2$  blue, and  $n^2$  black double lines, thus  $m = O(n^2)$ . Hence, MAX-WEIGHT-3-CLIQUE on  $n$  vertices reduces to MAX-HALFSPACE in time  $O(n^2)$ . Then reversing the dual mapping, we consider each dual line as two points, one in  $R$  and one in  $B$ , and this corresponds with the MAX-HALFSPACE problem in  $\mathbb{R}^2$  with  $\phi_{||}$ . Then since APSP reduces to MAX-WEIGHT-3-CLIQUE, we obtain the following theorem.

► **Theorem 13.** *In  $\mathbb{R}^2$ , MAX-HALFSPACE for  $\phi_{||}$  on  $m$  points requires  $\Omega(m^{3/2-o(1)})$  time assuming that APSP on  $n$  vertices requires  $\Omega(n^{3-o(1)})$  time.*

## 5 Conclusions and Discussion

We have mostly closed the planar  $\varepsilon$ -MAX-HALFSPACE problem with an  $\tilde{O}(m + 1/\varepsilon^d)$  algorithm in  $\mathbb{R}^d$  and conditional (to 3SUM)  $\Omega(m + 1/\varepsilon^{2-o(1)})$  lower bound in  $\mathbb{R}^2$ . However, the lower bound uses a piecewise-linear function  $\phi_{LC}$ , and while all known algorithmic improvements that depend on  $\phi$  take advantage of this linear structure (e.g., for rectangles [3, 28]), the function  $\phi_{LC}$ , perhaps strangely, is concave. Also surprisingly we can prove another conditional lower bound for MAX-HALFSPACE using a convex (in fact, again linear) function  $\phi$ , but this one is smaller at  $\Omega(m^{3/2-o(1)})$  in  $\mathbb{R}^2$ , and because some point may have very small weight in the construction, does not directly apply to  $\varepsilon$ -MAX-HALFSPACE, which allows  $\varepsilon$  additive error. Moreover, this reduces to APSP, which does not appear to be in the same class as 3SUM [40].

We leave several curious aspects to future work. Is there a real fine-grained complexity difference between the  $\phi$  variants in the problems? That is, can we improve upper bounds for convex  $\phi$ , or improve conditional lower bounds in this case? And can we condition the results on 3SUM in the convex  $\phi$  case? The convex  $\phi$  lower bound construction relies on weighted points, can we obtain improved algorithmic runtime by only allowing  $\{-1, +1\}$  weights? Moreover, are the polynomial terms  $(1/\varepsilon)^d$  in the algorithmic runtime correct in constant dimensions larger than  $d = 2$ ? And can these results help resolve polynomial terms in the high-dimensional robust statistics settings? An anonymous reviewer has suggested to use data structure for relative-error approximate counting on an  $\varepsilon$ -sample of halfspaces, and has argued that this can reduce the space requirements to  $o(1/\varepsilon^d)$ ; given our focus on the runtime of the maximum halfspace problem, we did not pursue this space improvement. If the runtime can be reduced to  $o(1/\varepsilon^d)$  clearly such a reduction in the space complexity would also be required.

## Abstract

Visibility problems are fundamental to computational geometry, and many versions of geometric set cover where coverage is based on visibility have been considered. In most settings, points can see “infinitely far” so long as visibility is not “blocked” by some obstacle. In many applications, this may be an unreasonable assumption. In this paper, we consider a new model of visibility where no point can see any other point beyond a sight radius  $\rho$ . In particular, we consider this visibility model in the context of terrains. We show that the VC-dimension of limited visibility terrains is exactly 7. We give lower bound construction that shatters a set of 7 points, and we prove that shattering 8 points is not possible.

## 1 Introduction

Visibility is fundamental to computational geometry, and in particular, variants of geometric set cover where coverage is determined by what a point “sees” have been widely considered in the literature. One of the most famous such applications is the *art gallery problem* where we are given a simple polygon  $P$  and we wish to place the minimum number of “guard” points  $G$  such that each point inside  $P$  is seen by some guard in  $G$ . Usually, the way that visibility is defined, is that two points  $p$  and  $q$  see each other if the line segment  $\overline{pq}$  does not contain any point outside of  $P$ . The intuition is that  $P$  is modelling some room (or art gallery), and if the line segment connecting the two points exits  $P$ , then there is a wall of the polygon that “blocks” their vision. The geometric set cover problem with respect to this definition of visibility has been considered in many different contexts, for example simple polygons [9, 15, 8, 1, 13], monotone polygons [20, 22, 12, 21, 14], rectilinear polygons [21, 22], staircase polygons [4, 23, 25], and terrains [18, 17, 2, 16, 6, 11, 19].

A *terrain*  $T$  is an  $x$ -monotone polygonal chain defined by a sequence of  $n$  vertices  $p_1, \dots, p_n$ . We let  $x(p_i)$  and  $y(p_i)$  denote the coordinates of  $p_i$ . The  $x$ -monotone property implies that  $x(p_i) < x(p_{i+1})$  for each  $i \in \{1, \dots, n-1\}$ . Note that given this definition, a vertical line intersects  $T$  in at most one point. Consider three vertices of  $T$ ,  $p_i, p_j$ , and  $p_k$  such that  $i < j < k$ . We say  $p_j$  *pierces*  $\overline{p_i p_k}$  if  $p_j$  is strictly above  $\overline{p_i p_k}$ . Similarly, if there is some  $p_j$  that pierces  $\overline{p_i p_k}$  then we say that  $\overline{p_i p_k}$  is *pierced*. Generally visibility in terrains is defined in the following way:  $p_i$  and  $p_k$  see each other if and only if  $\overline{p_i p_k}$  is not pierced.

■ **Figure 1**  $a$  sees  $c$ .  $b$  sees  $d$ . In an LVT,  $a$  may be too far from  $d$  to see it.

## 1.1 A Restricted Model of Visibility

An issue with the usual visibility model for various applications is that points are assumed to be able to see “infinitely far”. That is, a guard that is very far from  $p$  is assumed to see  $p$  just as clearly as another guard that is very close to  $p$ . Distance does not matter so long as the line segment connecting the points is not “blocked”. In many applications, this assumption is not true, and a model that considers the distance between a guard and the points it sees may be desirable. To address this undesirability, there has been some research that has considered restricted visibility models for exploring/guarding polygons or polygonal environments. Much of this past work is motivated by robotics, often times in an online setting where a robot is trying to learn about its surroundings but has restrictions on how far it can see, e.g. [3, 10, 24]. Other past work has considered restricted visibility models when computing an optimal “watchman tour” where a single guard patrols a known polygon, e.g. [26, 7].

In this paper we consider a *limited visibility* model of the terrain guarding problem, where each point has a sight radius  $\rho$  and cannot see any points that are outside of its sight radius. So to contrast with most of the past work with limited visibility models, we are assuming that we have full knowledge of the terrain we wish to guard, we can use multiple guards, and the guards are static. We call an instance of this problem a *limited visibility terrain* (LVT). An LVT can be defined by a set of  $n$ ,  $x$ -monotone vertices and a sight radius  $\rho$ . We say that two points  $p$  and  $q$  see each other if and only if (1)  $\overline{pq}$  is not pierced and (2)  $d(p, q) \leq \rho$ , where  $d(p, q)$  is the Euclidean distance between  $p$  and  $q$ . In this paper, we assume each point has the same sight radius, although it would be interesting to also consider the scenario where each point has its own radius. For any point  $p$ , we denote  $disc(p)$  to be a disc of radius  $\rho$  centered at  $p$ . Then clearly  $p$  cannot see any points that are not inside  $disc(p)$  in this model.

## 1.2 Order Claim Generalization

One of the key properties of (regular) terrains is the order claim.

▷ **Claim 1.** Let  $a, b, c, d$  be four points on a regular terrain such that  $x(a) < x(b) < x(c) < x(d)$ . If (1)  $a$  sees  $c$  and (2)  $b$  sees  $d$ , then  $a$  sees  $d$ .

The intuition here is pretty simple. Since  $a$  sees  $c$ , it must be that  $\overline{ac}$  is not pierced (so  $b$  is “below”  $\overline{ac}$ ). Similarly  $\overline{bd}$  is not pierced (so  $c$  is below  $\overline{bd}$ ). This implies that  $\overline{ad}$  is “above”  $\overline{ac}$  and  $\overline{bd}$ , and therefore  $\overline{ad}$  is not pierced (implying that  $a$  and  $d$  see each other).

For LVTs the order claim does not hold if  $a \notin disc(d)$ . See Figure 1 for an illustration. We can however apply a generalization of the order claim.

▷ **Claim 2.** Let  $a, b, c, d$  be four points on an LVT such that  $x(a) < x(b) < x(c) < x(d)$ . If (1)  $\overline{ac}$  is not pierced and (2)  $\overline{bd}$  is not pierced, then  $\overline{ad}$  is not pierced.

### 1.3 VC-Dimension

An interesting measure of the complexity of a set system is the notion of VC-dimension. To define this, we say that a finite set of points  $G$  in  $T$  is *shattered* if for every subset of  $G' \subseteq G$  there exists some point  $v \in T$  such that  $v$  sees every point in  $G'$  and does not see any point in  $G \setminus G'$ . In this context, we call  $v$  a *viewpoint*. The VC-dimension is the largest  $d$  such that there exists some LVT  $T$  and point set  $G$  of size  $d$  that can be shattered.

Brönnimann and Goodrich give a polynomial-time  $O(\log OPT)$ -approximation algorithm for any set system with constant VC-dimension [5] where  $OPT$  is the size of an optimal cover. For regular terrains, King showed that the VC-dimension is 4 [17]. This result relies heavily on the order claim, which as we mentioned above does not hold in the limited visibility model. One would certainly expect the VC-dimension to increase in this model.

### 1.4 Our Results

We prove the following theorem.

► **Theorem 3.** *The VC-Dimension of limited visibility terrains is 7.*

We show that for any set of 8 points on a LVT, it is not possible to shatter the set, and we show that it is possible to shatter a set of 7 points (thereby proving that our upper bound analysis is tight). We show several key structural lemmas about visibility in a LVT, and then use a computer program to show that there is no permutation of the 8 points and the  $2^8$  needed viewpoints such that there is a LVT with the points in left-to-right order according to the permutation that satisfies all of the visibility requirements. As is often the case with VC-dimension proofs, a direct proof often involves a tedious case analysis, so we use a computer program that is much easier to verify is correct rather than having to analyze each case “manually”. Our proof of Theorem 3 then implies that the algorithm of Brönnimann and Goodrich [5] is a  $O(\log OPT)$ -approximation algorithm for guarding the vertices of a LVT.

## 2 Upper Bound

In this section, we show that the VC-dimension of LVTs is at most 7. We will do this by showing that any set of 8 points cannot be shattered. Suppose that it is possible to shatter 8 points, that is there exists a LVT that shatters a set  $G = \{g_1, \dots, g_8\}$  which are indexed according to increasing x-coordinate without loss of generality. Motivated by the connection to geometric set cover, we sometimes call the points of  $G$  *guards*. For any subset  $S \subseteq \{1, \dots, 8\}$ , let  $vp_S$  denote a point that should see  $g_i$  for each  $i \in S$  and does not see  $g_j$  for any  $j \notin S$ . For example,  $vp_{1,6,8}$  should see  $g_1, g_6$ , and  $g_8$  and should not see any other point of  $G$ . Let  $V$  be the set of all such viewpoints. Clearly  $|V| = 2^8 = 256$ .

We begin with a high-level overview of our proof strategy for showing that  $G$  cannot be shattered. Suppose the contrary, and let  $T$  denote a LVT that does shatter  $G$ . We say the *ordering* of  $T$  is the permutation of  $G \cup V$  when sorting  $G \cup V$  by their x-coordinates (note  $T$  may have vertices that do not correspond with  $G$  or  $V$ ). We say any subsequence of the ordering is a *partial ordering* of  $T$ . The intuition is that an ordering describes the left-to-right order of the points of  $V$  and  $G$  with respect to  $T$ , and a partial ordering describes the left-to-right ordering of *some* of the points of  $V$  and  $G$ . See Figure 2 for an illustration.

■ **Figure 2** The ordering of  $T$  is  $(g_1, vp_{1,2}, g_2, vp_{1,2,3}, vp_{2,3}, g_3, vp_{1,3})$ . Partial orderings of  $T$  include  $(g_1, g_2, vp_{2,3}, g_3)$ ,  $(vp_{1,2}, vp_{1,2,3}, g_3, vp_{1,3})$ , etc.

Now we view the problem in the “opposite direction”; instead of starting with a LVT and considering its order, we start with an order and consider whether there is a LVT that has this order. We call any permutation  $O$  of  $V \cup G$  a *candidate ordering* (CO) of  $V \cup G$ . We say  $O$  is *realizable* if there is a LVT  $T$  that shatters  $G$  such that  $O$  is the ordering of  $T$ . For every subset  $V' \subseteq V$ , we call a permutation of  $V' \cup G$  a *candidate partial ordering* (CPO), and we say it is realizable if it is a partial ordering of any LVT  $T$  that shatters  $G$ .

We obtain our result by showing that there is no realizable CPO. We do this by first proving a set of structural lemmas. Given a CPO  $O$ , the lemmas will imply some properties that must be satisfied by *any* realization of  $O$ . For example, we might be able to argue that any realization of  $O$  must satisfy  $y(g_i) < y(g_j)$ , or we might be able to argue that a point  $v \in V$  that is not supposed to see  $g_i$  must be outside the disc of  $g_i$  or  $\overline{vg_i}$  must be pierced in any realization. If the lemmas contradict each other then we can determine that  $O$  is not realizable.

The proofs of VC-dimension upper bounds are often tedious case analyses. We instead use a computer program that helps to automate this case analysis. Our program, given a CPO  $O$ , determines if our lemmas can be used to show that  $O$  is not realizable. The CPOs we give as inputs to the program are all of the CPOs based off  $G$  and four points of  $V$ . Each of the CPOs can be analyzed in parallel, and therefore picking four points of  $V$  provides a nice tradeoff between the number of CPOs that must be considered and the amount of time it takes to evaluate a single CPO (the time to evaluate all cases on a 3.7 GHz CPU with 6 cores is less than 24 hours).

## 2.1 Structural Lemmas

We now give a set of structural lemmas that will help us argue when a CPO is not realizable. We use the following definitions. Suppose that  $p_i$  and  $p_j$  are two points on an LVT such that  $d(p_i, p_j) \geq \rho$  and  $|x(p_i) - x(p_j)| < \rho$  (note that this implies that  $y(p_i) \neq y(p_j)$ ). Then if  $y(p_i) > y(p_j)$  we say that  $p_i$  is *high outside disc*( $p_j$ ), and similarly we say that  $p_j$  is *low outside disc*( $p_i$ ). See Figure 3.

► **Lemma 4.** *Let  $p_i, p_j, p_k$ , and  $p_l$  be four points on a LVT such that  $x(p_i) < x(p_j) < x(p_k) < x(p_l)$ . If (1)  $p_i$  sees  $p_k$  and (2)  $p_j$  sees  $p_l$ , then  $d(p_j, p_k) \leq \rho$ .*

■ **Figure 3**  $p_j$  is low outside of  $disc(p_i)$ .

■ **Figure 4**  $d(p_j, p_k) \leq \rho$ .

■ **Figure 5**  $y(p_j) < y(p_i)$  and  $y(p_j) < y(p_k)$ .

**Proof.** Without loss of generality, assume that  $y(p_j) \leq y(p_k)$ . Then it must be that  $y(p_k) \leq y(p_l)$ , or else  $p_k$  would pierce  $\overline{p_j p_l}$ . Consider the triangle  $\triangle p_j p_k p_l$ . We have  $\angle p_j p_k p_l > \frac{\pi}{2}$ , thus  $\overline{p_j p_l}$  is the longest side of the triangle. Then we have  $d(p_j, p_k) < d(p_j, p_l) \leq \rho$ . See Figure 4 for illustration. ◀

► **Lemma 5.** Let  $p_i, p_j$ , and  $p_k$  be three points on a LVT such that  $x(p_i) < x(p_j) < x(p_k)$ . If (1)  $p_k$  sees  $p_i$  but does not see  $p_j$  and (2)  $\overline{p_j p_k}$  is not pierced, then  $p_j$  is low outside  $disc(p_k)$ . Moreover, we also have  $y(p_j) < y(p_i)$ .

**Proof.** See Figure 5 for illustration. Since  $\overline{p_j p_k}$  is not pierced and they do not see each other, then clearly  $d(p_j, p_k) > \rho$ . Since  $p_i \in disc(p_k)$ , we must have  $x(p_k) - x(p_i) \leq \rho$ , and since  $x(p_j)$  is “between”  $x(p_i)$  and  $x(p_k)$  it therefore must be that  $x(p_k) - x(p_j) < \rho$ . So it remains to show that  $y(p_j) < y(p_k)$  and  $y(p_j) < y(p_i)$ . For the sake of contradiction, suppose that  $y(p_j) \geq y(p_i)$ , clearly  $y(p_k) > y(p_j)$ , otherwise  $p_j$  will pierce  $\overline{p_i p_k}$ . Consider the  $\triangle p_i p_j p_k$ . We have  $\angle p_i p_j p_k$  is greater than  $\frac{\pi}{2}$ , see Figure 6 for illustration. Therefore  $d(p_i, p_k) > d(p_j, p_k) > \rho$ , contradicting that  $p_i$  sees  $p_k$ . Thus the initial assumption  $y(p_j) \geq y(p_i)$  is wrong. We can derive a contradiction for  $y(p_j) \geq y(p_k)$  similarly. ◀

► **Lemma 6.** Let  $p_i, p_j$ , and  $p_k$  be three points on a LVT such that  $x(p_i) < x(p_j) < x(p_k)$ . If (1)  $y(p_i) < y(p_j)$  and  $d(p_i, p_j) > \rho$ , and (2)  $\overline{p_i p_k}$  is not pierced, then  $y(p_j) < y(p_k)$  and  $d(p_i, p_k) > \rho$ .

**Proof.** Clearly we must have  $y(p_j) < y(p_k)$  or else  $p_j$  would pierce  $\overline{p_i p_k}$ . See Figure 7 for illustration. In  $\triangle p_i p_j p_k$ , clearly the longest edge is  $\overline{p_i p_k}$ , thus  $d(p_i, p_k) > d(p_i, p_j) > \rho$ . ◀

► **Lemma 7.** Let  $p_i$  and  $p_k$  be two points on a LVT that that do not see each other, but  $d(p_i, p_k) \leq \rho$ . Then there must be some point  $p_j \in (p_i, p_k)$  that pierces  $\overline{p_i p_k}$ . If there is some point  $p_l$  such that  $d(p_i, p_l) \leq \rho$  and  $d(p_k, p_l) \leq \rho$ , then either  $d(p_j, p_l) \leq \rho$  or  $p_j$  is high outside  $disc(p_l)$ .

**Proof.** It must be that  $x(p_l) - x(p_i) \leq \rho$ , and since  $p_j$  is “between”  $p_i$  and  $p_k$  then we have  $x(p_l) - x(p_j) < \rho$ . We then complete the lemma by showing that if  $p_j$  is such that  $d(p_j, p_l) > \rho$  and  $y(p_j) < y(p_l)$  then it cannot pierce  $\overline{p_i p_k}$ . In this case,  $p_j$  must be low outside  $disc(p_l)$ . By convexity, we have that  $\overline{p_i p_k}$  is contained inside of  $disc(p_l)$ , and therefore it cannot be that  $p_j$  pierces  $\overline{p_i p_k}$ , see Figure 8 for illustration. ◀

■ **Figure 6** Contradiction with  $p_i$  seeing  $p_k$ .

■ **Figure 7**  $y(p_i) < y(p_k)$ .

■ **Figure 8** Contradiction with  $d(p_j, p_l) > \rho$  and  $y(p_j) < y(p_l)$ .

■ **Figure 9** Contradiction with  $d(v, p_k) \leq \rho$ .

► **Lemma 8.** *Let  $p_i, p_j$ , and  $p_k$  be three points on an LVT such that  $x(p_i) < x(p_j) < x(p_k)$  such that  $p_j$  is low outside  $\text{disc}(p_i)$  and  $d(p_j, p_k) \leq \rho$ . Then there is no point  $v : x(p_j) < x(v) < x(p_k)$  such that  $v$  is low outside  $\text{disc}(p_k)$  and  $d(p_i, v) \leq \rho$ .*

**Proof.** If the lemma is incorrect, then there would be a  $v$  that satisfies the following three properties: (1)  $y(v) < y(p_k)$ , (2)  $d(v, p_k) > \rho$ , and (3)  $d(p_i, v) \leq \rho$ . We will prove the lemma by showing that any point that satisfies conditions (1) and (3) cannot also satisfy condition (2). To that end, let  $v$  be any point satisfying  $y(v) < y(p_k)$  and  $d(p_i, v) \leq \rho$ . We will show that it must be such that  $d(v, p_k) \leq \rho$ . See Figure 9 for illustration. Given  $x(p_i) < x(p_j) < x(v)$ ,  $d(p_i, p_j) > \rho$ ,  $d(p_i, v) \leq \rho$ , from Lemma 5 clearly  $y(v) > y(p_j)$ . Since  $y(v) < y(p_k)$ , then we have  $x(p_j) < x(v) < x(p_k)$  and  $y(p_j) < y(v) < y(p_k)$ . This implies that  $v$  is inside of the axis-parallel rectangle with  $p_j$  as lower-left corner and  $p_k$  as upper-right corner. If  $a$  and  $b$  are any two points in this rectangle, then we have  $d(a, b) \leq d(p_j, p_k) \leq \rho$ , and therefore it must be that  $d(v, p_k) \leq \rho$ . ◀

## 2.2 Procedure

We use a computer program to show that there does not exist a realizable CO of  $G \cup V$ . Our strategy is to consider a starting set of viewpoints  $V_{start} := \{vp_{1,3,5,7,8}, vp_{1,2,4,6,8}, vp_{1,3,6,8}, vp_{1,2,4,5,7,8}\}$ , and to show that every CPO of  $G \cup V_{start}$  is not realizable. This implies there is no realizable CO of  $G \cup V$ . If not, then consider the subsequence of a realizable order when considering the vertices in  $G \cup V_{start}$ . This would be a realizable CPO of  $G \cup V_{start}$ .

Suppose  $O$  is some CPO of  $G \cup V_{start}$  that we are considering. It may be that our lemmas can “directly” show that  $O$  is not realizable, that is we can apply the lemmas to the points in  $O$  to derive a contradiction. In fact, this is true for roughly half of the CPOs of  $G \cup V_{start}$  (which is why we pick this set as a starting point). If we cannot directly show  $O$  is not

realizable, we consider *extensions* of  $O$ . That is, we consider a viewpoint  $v$  that is not in  $O$ , and we consider adding  $v$  to  $O$  in one of the  $|O| + 1$  “gaps” in  $O$ . Intuitively, we add one more viewpoint to  $O$  to obtain a new CPO  $O'$  while ensuring that the order of the points in  $O$  is the same in  $O'$ . Then we say that  $O'$  is an extension of  $O$ . Using this terminology, note that  $O$  is realizable if and only if there is at least one realizable extension of  $O$ . Similarly, if we are considering a CPO  $O$  of  $G \cup V'$  and there is a viewpoint  $v \in V \setminus V'$  such that our lemmas imply a contradiction for *every* extension of  $O$  that includes  $v$ , then we can in turn say that  $O$  is not realizable. When considering viewpoints for extensions, we restrict ourselves to the set  $V_{test}$  which is the set of all 96 viewpoints such satisfies either (1) they see both  $g_1$  and  $g_8$ , or (2) see  $g_2$  and  $g_7$  and exactly one of  $g_1$  and  $g_8$ . The intuition is that  $V_{test}$  consist of the more “difficult” viewpoints to find a spot in an order, so by only considering extensions from  $V_{test}$  we can focus the search to “difficult” viewpoints only, speeding up our program. And indeed it is sufficient to consider only these viewpoints given that our program verifies that no CPO of  $G \cup V_{start}$  is realizable, even if we only needed to extend to  $G \cup V_{test}$ .

Our program consists of two main functions: *isNotRealizable()* (Algorithm 1 and 2 in the paper due to the length of the algorithm) and *candidateOrderingIsExtendable()* (Algorithm 3 in the paper). *isNotRealizable()* takes a CPO as input and returns true if our lemmas can directly show that the order is not realizable, and returns false otherwise. *candidateOrderingIsExtendable()* takes a CPO as input and returns true if there is an extension such that the lemmas cannot directly show it is not realizable, and otherwise returns false. In this paper, we give color-coded pseudocode that explains what our program does. The actual C++ source code that we use as well as a color-coded rich text version of the source code is provided at <https://github.com/utsa-saga/vc8proof> (the colors are used to help with the readability of the code, pairing the “sections” of the source code with the “sections” of the pseudocode from the paper).

Given 4 fixed starting viewpoints  $V_{start}$  and guard set  $G = \{g_1, g_2, \dots, g_8\}$ , we consider all 11,880 CPOs of  $G \cup V_{start}$ . Our program handles each of these 11,880 orderings independently (cases can be tested simultaneously in parallel). Let  $O_1$  denote one such ordering. We pass  $O_1$  to *candidateOrderingIsExtendable()*. This function calls *isNotRealizable()* on  $O_1$ . If we determine that it is not realizable, then *candidateOrderingIsExtendable()* returns false immediately. If we cannot determine that  $O_1$  is not realizable, then we add a new viewpoint from  $V_{test}$  to  $O_1$  to obtain a new candidate ordering and repeat until we find a candidate ordering of  $G \cup V_{test}$  for which *isNotRealizable()* returns false (indicating that it might be realizable) or determine that every candidate ordering of  $G \cup V_{test}$  extending from  $O_1$  is not realizable. In our actual program, we use some heuristics for computing a “good” ordering of the points in  $V_{test} \setminus O_i$  that are not shown in *candidateOrderingIsExtendable()*.

It is not too difficult to see that *candidateOrderingIsExtendable()* is correct given that *isNotRealizable()* is correct. We will formally show that *isNotRealizable()* is correct. That is, we show that if *isNotRealizable()* returns true for some candidate ordering  $O_i$ , then a contradiction about any realization can be derived from our lemmas. To help show the correctness of this function, we define some notation. We use three main variables to detect lemma contradictions: `cannotBlockWithTerrain[{u, v}]`, `tooFarAway[{u, v}]`, and `higherPoint[{u, v}]`.

The first variable is set to true if it must be that every realization must satisfy that  $\overline{uv}$  is not pierced (following from the order claim generalization that we presented in Section 1.2. We consider this variable for all pairs  $u, v \in O$ . The second variable is set to be true when every realization (according to our lemmas) must satisfy that  $d(u, v) > \rho$ , it is set to false if  $d(u, v) \leq \rho$  in every realization, and it is set to unknown if our lemmas do not imply this one

way or the other. We consider this variable for  $u, v$  pairs such that at least one of  $u$  and  $v$  is in  $G$ . As for the third variable, it will be set to either  $u$ ,  $v$ , or unknown depending on if we can determine which point must have the larger y-coordinate in any realization according to our lemmas. This again is defined for all pairs  $u, v$  pairs such that at least one of  $u$  and  $v$  is in  $G$ .

In order to determine the values of variables 2 and 3, we define some extra notation and variables that are used as “helpers”. Let  $O$  be any candidate ordering of  $G \cup V'$ , where  $V'$  is any subset of  $V$ . For ease of description, we add to  $O$  a “dummy” point  $vp_{-\infty}$  to the left of every point of  $O$  and a “dummy” point  $vp_{\infty}$  to the right of every point of  $O$ . Since we have a fixed ordering of the points, we can determine for any two points of  $u, v \in O$  whether or not  $u$  and  $v$  are can be pierced by applying the order claim generalization we presented in Section 1.2. For any guard  $g \in G$ , let  $L(g)$  denote all viewpoints to the left of  $g$  in  $O$ , and similarly let  $R(g)$  denote all viewpoints to the right of  $g$  in  $O$ . Let  $leftMostPointGuardSees(g)$  denote the leftmost point of  $L(g)$  that sees  $g$ . If there is no such point, then we define it to be  $g$ . Similarly we let  $rightMostPointGuardSees(g)$  denote the rightmost point in  $R(g)$  that sees  $g$ , and if no such point exists we set it to be  $g$ . Let  $closestHighOutsideLeft(g)$  denote the rightmost point  $v \in L(G)$  such that  $g$  does not see  $v$ ,  $cannotBlockWithTerrain[\{g, v\}]$  is true, and  $v$  sees some  $g' \in G$  right of  $g$  (our lemmas imply this view point must be high outside  $disc(g)$ ). If no such point exists, we let  $closestHighOutsideLeft(g)$  be  $vp_{-\infty}$ . We similarly define  $closestHighOutsideRight(g)$  to be the leftmost point  $v \in R(g)$  such that  $g$  does not see  $v$ ,  $cannotBlockWithTerrain[\{g, v\}]$  is true, and  $v$  sees some  $g' \in G$  left of  $g$ . If no such point exists, we define  $closestHighOutsideRight(g)$  to be  $vp_{\infty}$ . For any two points  $u, v \in O$ , we say  $u < v$  if  $u$  is to the left of  $v$  in  $O$ .

► **Lemma 9.** *If our function  $isNotRealizable(O)$  returns true, then  $O$  is not realizable.*

**Proof.** We will show a contradiction to realization for each line of  $isNotRealizable()$  that returns true. To this end, we will also show that the assignments for our variables  $cannotBlockWithTerrain$ ,  $tooFarAway$ , and  $highestPoint$  are in fact correct.

**Gold Block.** In the gold block (Line 1), we set the values for the variable  $cannotBlockWithTerrain$ . If for points  $a$  and  $d$  we have  $cannotBlockWithTerrain[\{a, d\}]$  set to true, then it is true that in any realization of  $O$  that  $\overline{ad}$  is not pierced as either they see each other or there are points  $b$  and  $c$  such that  $\overline{ac}$  is not pierced and  $\overline{ad}$  is not pierced (second Claim from Section 1.2). If  $cannotBlockWithTerrain[\{a, d\}]$  is false then we make no assumptions about whether  $\overline{ad}$  is pierced.

**Green Block.** Now consider the green block (Lines 2–3), and in particular suppose we return true in line 3. Without loss of generality assume that it returned true because  $leftMostPointGuardSees(g) < closestHighOutsideLeft(g)$ . Let  $p$  denote  $leftMostPointGuardSees(g)$ , and let  $q$  denote  $closestHighOutsideLeft(g)$ . Then  $g$  does not see  $q$  and  $\overline{qg}$  cannot be pierced which implies that in any realization we must have  $d(q, g) > \rho$ . But we can apply Lemma 4 with  $p_i, p_j, p_k,$  and  $p_l$  as  $p, q, g, g'$  respectively, where  $g'$  is a guard that  $q$  sees to the right of  $g$  (which exists by the definition of  $closestHighOutsideLeft(g)$ ). Then in any realization,  $d(q, g) \leq \rho$  by Lemma 4, a contradiction.

We also remark that  $closestHighOutsideRight(g)$  must indeed be high outside  $disc(g)$  in any realization. This follows from Lemma 5 by letting  $p_k$  be  $closestHighOutsideRight(g)$ ,  $p_j$  be  $g$ , and  $p_i$  be any guard that  $closestHighOutsideRight(g)$  sees to the left of  $g$ . Similarly,  $closestHighOutsideLeft(g)$  must be high outside of  $disc(g)$ .

**Blue Block.** Now consider the blue block of code (Lines 4–23) where we set the `tooFarAway` and `higherPoint` variables for each pair of guards. We claim that if `tooFarAway[{gi, gj}]` is set to true, then the lemmas imply that any realization must have  $d(g_i, g_j) > \rho$ , and if it is set to false then every realization must have  $d(g_i, g_j) \leq \rho$ . Similarly we claim that if we set `higherPoint[{gi, gj}]` to be  $g_i$ , then any realization must have  $y(g_i) > y(g_j)$  and if it is set to be  $g_j$  then any realization must have  $y(g_i) < y(g_j)$ . We initially set both variables to unknown, and then we change them if we detect a reason to change them.

Suppose we set `tooFarAway[{gi, gj}]` to be false in Line 7. Then let  $p$  be `leftMostPointGuardSees(gj)` and let  $q$  be `rightMostPointGuardSees(gi)`. Then from the if-statement, we have that  $p < g_i < g_j < q$  and applying Lemma 4 we have that  $d(g_i, g_j) \leq \rho$  in any realization, therefore our variable setting is correct.

Now suppose that we set `higherPoint[{gi, gj}]` to be  $g_i$  in Line 9. If `closestHighOutsideRight(gj)` and `rightMostPointGuardSees(gi)` are the same point, then we have that  $y(g_i) > y(g_j)$  in any realization by Lemma 5. If they are not the same point, then we have  $g_i < g_j < p < q$  where  $p$  is `closestHighOutsideRight(gj)` and  $q$  is `rightMostPointGuardSees(gi)`. If we had  $y(g_i) \leq y(g_j)$  then it would have to be that  $d(g_i, p) > \rho$  and  $y(g_i) < y(p)$  and therefore we can apply Lemma 6 to  $g_i$ ,  $p$ , and  $q$  to get that  $d(g_i, q) > \rho$ , a contradiction. Therefore it must be that  $y(g_i) > y(g_j)$  in any realization. A symmetric argument holds for Line 13.

Now suppose that we set `higherPoint[{gi, gj}]` to be  $g_j$  in Line 17 (and therefore also set `tooFarAway[{gi, gj}]` to be true in the next line). Then from the if-statement, we can apply Lemma 6 to  $g_i$ , `closestHighOutsideRight(gi)`, and  $g_j$  to see that both assignments must be true in any realization. The argument is symmetric in Line 22.

Note that each of the “return true” statements in this block occur if we get contradictory statements about which of  $g_i$  and  $g_j$  has the larger y-coordinate, and therefore if we return true in this block then  $O$  is indeed not realizable.

**Light Green Block.** Now consider the light green block (Lines 24–26). If we return true in line 26, then we have that  $\overline{g_i g_j}$  cannot be pierced in any realization. But at the same time we would need a  $g_k$  between  $g_i$  and  $g_j$  such that  $y(g_k) > y(g_i)$  and  $y(g_k) > y(g_j)$ . Clearly the latter implies that  $g_k$  pierces  $\overline{g_i g_j}$ , and therefore  $O$  cannot be realized.

**Red Block.** Now consider the red block of code (Lines 27–41). In this block we set the `tooFarAway` and `higherPoint` variables for a guard  $g$  and a viewpoint  $p$ . We will argue that if we set these variables to something other than unknown then any realization must satisfy that assignment. If we set `tooFarAway[{g, p}]` to be false in Line 30 then its either because  $g$  sees  $p$  (in which case they obviously cannot be too far away) or it’s because `leftMostPointGuardSees(g) < p < g < g'` where  $g'$  is a guard that  $p$  sees. In this case we can apply Lemma 4 to see that it must be that  $d(p, g) \leq \rho$  in any realization.

Now suppose we enter the else statement starting at Line 34. In this case we have that  $g$  does not see  $p$  and we have `cannotBlockWithTerrain[{g, p}]` is true. Therefore clearly the reason why  $g$  does not see  $p$  is because  $d(g, p) > \rho$ , and therefore our assignment of `tooFarAway[{g, p}]` to be true is correct. Then further suppose we set `higherPoint[{g, p}]` to be  $g$  in Line 36. Then we can apply to Lemma 5 to `leftMostPointGuardSees(g)`,  $p$ , and  $g$  to see that indeed it must be  $y(p) < y(g)$ . The argument for Line 38 where we set `higherPoint[{g, p}]` to be  $p$  follows symmetrically.

**Yellow Block.** Now consider the yellow block (Lines 42–51). Consider any viewpoint  $vp$  that satisfies the for-loop condition in Line 43. Then we have that  $vp$  does not see  $g_j$ , but  $d(vp, g_j) \leq \rho$ . Therefore any realization must have some point that pierces  $\overline{vp g_j}$ . Moreover

■ **Figure 10**  $x(g') > x(g_k)$  and  $vp$  sees  $g'$ .

we have `cannotBlockWithTerrain`  $\{g_i, g_j\}$  is true from Line 42. Then maybe  $g_i$  is a point that pierces  $\overline{vp g_j}$ , but if it does not pierce it then certainly no point between  $g_i$  and  $g_j$  can pierce  $\overline{vp g_j}$  (as it would also pierce  $\overline{g_i g_j}$ ). This means that if  $g_i$  does not pierce  $\overline{vp g_j}$ , then we would need to find a point between  $vp$  and  $g_i$  (possibly a point not in  $O$ ) to pierce  $\overline{vp g_j}$ . The yellow block first considers if it is possible for  $g_i$  to pierce, and if it cannot, then we consider the possibility of a “blocker” between  $vp$  and  $g_i$ .

First consider the if-statement in Line 44. If this condition is true, then we have that there is some guard  $g_k$  such that  $vp$  and  $g_j$  are inside of  $disc(g_k)$  but  $g_i$  is low outside  $disc(g_k)$ . Lemma 7 implies that any point that pierces  $\overline{vp g_j}$  cannot be low outside  $disc(g_k)$ , and therefore  $g_i$  cannot pierce  $\overline{vp g_j}$ .

Next consider the if-statement in Line 46. If this condition is true, then we have that there is some guard  $g_k$  to the right of  $g_j$  such that  $vp$  is high outside  $disc(g_k)$ ,  $g_i$  is low outside  $disc(g_k)$ , and  $g_j$  is inside  $disc(g_k)$ . Since  $vp$  is high outside  $disc(g_k)$ , we have that a ray shot straight down from  $vp$  will first intersect  $disc(g_k)$  at a point  $I_1$  such that  $y(I_1) > y(g_k)$  (recall that this is true since  $vp$  must see a guard to the right of  $g_k$  in order for `higherPoint`  $\{vp, g_k\}$  to be  $vp$ ). Now consider walking along  $\overline{vp g_j}$  starting at  $g_j$  and walking towards  $vp$ . Let  $I_2$  denote the point that this walk exits  $disc(g_k)$ . Then we have that  $y(I_2) > y(I_1)$ . See Figure 10. Therefore any point that is low outside  $disc(g_k)$  cannot pierce  $\overline{vp g_j}$ , and therefore  $g_i$  cannot pierce  $\overline{vp g_j}$ .

So now suppose that `giCanBeBlocker` was set to false by one of the two cases above. Then indeed  $g_i$  cannot pierce  $\overline{vp g_j}$  and we now need to consider a blocker strictly between  $vp$  and  $g_i$ . There are two potential issues this might cause. The first is that if  $g_i$  does not pierce  $\overline{vp g_j}$  but some point  $b$  between  $vp$  and  $g_i$  does pierce  $\overline{vp g_j}$ , then it must be that  $b$  also pierces  $\overline{vp, g_i}$ . So if we have `cannotBlockWithTerrain`  $\{vp, g_i\}$  set to true, then we cannot use such a blocker  $b$ . But moreover, using a blocker  $b$  in this range may cause us to have to flip `cannotBlockWithTerrain`  $\{vp_2 g_j\}$  from false to true if we use such a blocker  $b$ . Indeed, for any point  $vp_2$  to the left of  $vp$ , if we have `cannotBlockWithTerrain`  $\{vp_2, g_i\}$  is true, then the use of this blocker  $b$  will force us to have `cannotBlockWithTerrain`  $\{vp_2, g_j\}$  to be true by the second claim in Section 1.2. If we previously determined that  $vp_2$  cannot be too far away from  $g_j$ , then this would imply that  $vp_2$  sees  $g_j$ , a contradiction. Therefore in this case we would not be able to use a new blocker  $b$ .

So if we determine that  $g_i$  cannot be a blocker and a new point between  $vp$  and  $g_i$  cannot be the blocker, then it is not possible to pierce  $\overline{vp g_j}$  without changing other visibilities and therefore  $O$  cannot be realized, and the algorithm returns true accordingly.

**Purple Block.** Now consider the purple block (Lines 52–54). If there are guards  $g_i$  and  $g_j$  and viewpoints  $vp_1$  and  $vp_2$  that satisfy the if-statement condition then we have  $vp_2$  sees  $g_j$  and is low outside  $disc(g_i)$ , and we have  $vp_1$  sees  $g_i$  and is low outside  $disc(g_j)$ . The left-to-right order of  $g_i < vp_2 < vp_1 < g_j$  then contradicts Lemma 8, and therefore  $O$  is not realizable and we return true accordingly. ◀

### 3 Lower Bound

In this section, we show that the VC-Dimension of LVTs is at least 7. See Figure 12 for the coordinates of the vertices of our LVT where a set of 7 vertices is shattered. We remark that the main value of this construction is that it shows that our upper bound proof we give in Section 2 is tight. We do not claim that this LVT is particularly interesting outside of the fact that it proves that the upper bound cannot be improved.

Here, we assume that the radius  $\rho$  that each vertex can see is 1. The vertices that are shattered are the vertices  $G = \{g_1, \dots, g_7\}$ . The viewpoints are labeled  $vp$  where the subscript denotes which vertices of  $G$  the viewpoint sees. Some of the vertices are neither a viewpoint nor a vertex in  $G$  and are labeled “-” (their role is simply to block a viewpoint from seeing a vertex in  $G$ ). The table does not contain a viewpoint for the empty set or for the subsets of size 1. It is trivial to add these points: the empty set point can be placed to the right of all points a distance greater than 1 to each vertex in  $G$ , and a viewpoint that should see only one vertex  $g_i$  can be placed in a steep “canyon” just to the left of  $g_i$  so that every other  $g_j$  is blocked from seeing it.

To formally verify that our coordinates are correct, we wrote a computer program that ensures each viewpoint sees exactly which guards they are supposed to see. Our program to verify the problem is available at <https://github.com/utsa-saga/vc7proof>.

The aspect ratio of our construction is very large which makes it difficult to produce a static figure that is helpful in visualizing the construction. Nonetheless, see Figure 11 for a static figure of the LVT. Note that in this figure, we use letters  $A$  through  $G$  to represent the guards instead of  $g_1 - g_7$  (e.g.,  $B$  represents  $g_2$  and  $BEF$  represents  $vp_{2,5,6}$ ). See Figure 11 for the overall the boundary of the LVT, where the viewpoints are listed in blue (many of the labels are not visible because the points are so close together) and the guards in  $G$  are red. There is a dynamic version of the figure that allows zooming in-and-out here: <https://www.geogebra.org/calculator/ybvdrjag>. Finally we have dynamic figures for each guard. They show the disc of the guard so it is possible to see which portions of the LVT are too far away from certain guards. In these figures, green line segments indicate that the guard and viewpoint see each other (their line segment is not pierced, and they are close enough to see each other); red line segments indicate their line segment is pierced; purple viewpoints indicate the viewpoints that are outside of the disc of the guard.

## Abstract

In the standard planar  $k$ -center clustering problem, one is given a set  $P$  of  $n$  points in the plane, and the goal is to select  $k$  center points, so as to minimize the maximum distance over points in  $P$  to their nearest center. Here we initiate the systematic study of the clustering with neighborhoods problem, which generalizes the  $k$ -center problem to allow the covered objects to be a set of general disjoint convex objects  $\mathcal{C}$  rather than just a point set  $P$ . For this problem we first show that there is a PTAS for approximating the number of centers. Specifically, if  $r_{opt}$  is the optimal radius for  $k$  centers, then in  $n^{O(1/\varepsilon^2)}$  time we can produce a set of  $(1 + \varepsilon)k$  centers with radius  $\leq r_{opt}$ . If instead one considers the standard goal of approximating the optimal clustering radius, while keeping  $k$  as a hard constraint, we show that the radius cannot be approximated within any factor in polynomial time unless  $P = NP$ , even when  $\mathcal{C}$  is a set of line segments. When  $\mathcal{C}$  is a set of unit disks we show the problem is hard to approximate within a factor of  $\frac{\sqrt{13}-\sqrt{3}}{2-\sqrt{3}} \approx 6.99$ . This hardness result complements our main result, where we show that when the objects are disks, of possibly differing radii, there is a  $(5 + 2\sqrt{3}) \approx 8.46$  approximation algorithm. Additionally, for unit disks we give an  $O(n \log k) + (k/\varepsilon)^{O(k)}$  time  $(1 + \varepsilon)$ -approximation to the optimal radius, that is, an FPTAS for constant  $k$  whose running time depends only linearly on  $n$ . Finally, we show that the one dimensional version of the problem, even when intersections are allowed, can be solved exactly in  $O(n \log n)$  time.

## 1 Introduction

In the standard  $k$ -center clustering problem, one is given a set  $P$  of  $n$  points in a metric space and an integer parameter  $k \geq 0$ , and the goal is to select  $k$  points from the metric space (or from  $P$  in the discrete  $k$ -center problem), called centers, so as to minimize the maximum distance over points in  $P$  to their nearest center. Equivalently, the problem can be viewed as covering  $P$  with  $k$  balls with the same radius  $r$ , where the goal is to minimize  $r$ . It is well known that it is NP-hard to approximate the optimal  $k$ -center radius  $r_{opt}$  within any factor less than 2 in general metric spaces [21], and that the problem remains hard to approximate within a factor of roughly 1.82 in the plane [12]. For general metric spaces, the standard greedy algorithm of Gonzalez [19], which repeatedly selects the next center to be the point from  $P$  which is furthest from the current set of centers, achieves an optimal 2-approximation to  $r_{opt}$ . An alternative algorithm due to Hochbaum and Shmoys [20] also achieves an optimal approximation ratio of 2 by approximately searching for the optimal radius, observing that if  $r \geq r_{opt}$  then all points will be covered after  $k$  rounds of repeatedly removing points in  $2r$  radius balls centered at any remaining point of  $P$ .

In this paper we consider a natural generalization of  $k$ -center clustering in the plane, where the objects which we must cover are general disjoint convex objects rather than points. Specifically, in the *clustering with neighborhoods* problem the goal is to select  $k$  center points so that balls centered at these points with minimum possible radius intersect all the convex objects. This generalization is natural as real world objects may not be well modeled as individual points. This generalized setting has previously been considered for other classical point based problems in the plane, such as the Traveling Salesperson Problem [10], where the authors referred to these objects as neighborhoods. (We instead typically refer to them as *objects*.) To the best of our knowledge we are the first to consider the general problem of clustering convex objects in this context, though as we discuss below many closely related problems have been considered, some of which equate to special or extreme cases of our problem. We remark that since a point is a convex set, the hardness results for  $k$ -center clustering immediately apply to clustering with neighborhoods.

### Related Work

As clustering is a fundamental data analysis task, countless variants have been considered. Here we focus on variants which share our  $k$ -center objective of minimizing the maximum radius of the balls at the chosen centers. Bandyapadhyay et al. [7] considered the colorful  $k$ -center problem, where the points are partitioned into color classes  $P_1, \dots, P_c$  and the goal is to find  $k$  balls with minimum radius which cover at least  $t_i$  points from each color class  $P_i$ . When our convex objects have bounded diameter our problem can be approximately cast as an instance of colorful  $k$ -center by replacing each object with the set  $P_i$  of grid points it intersects and setting  $t_i = 1$ . General colorful clustering, however, is more challenging as the color classes can be interspersed, which is why [7] assumes the number of color classes is a constant, allowing for a constant factor approximation, which subsequently was improved [5, 23]. Note that colorful  $k$ -center itself generalizes the  $k$ -center with outliers problem [8], corresponding to the case with a single color class  $P$  with  $n - t$  outliers allowed.

Xu and Xu [31] considered  $k$ -center clustering on point sets (KCS) where given points sets  $S_1, \dots, S_n$  the goal is to find  $k$  balls of minimum radius such that each  $S_i$  is entirely contained in one of the balls. Again when our objects have bounded diameter we can relate our problem to KCS by discretizing the objects. Their requirement that all of  $S_i$  be covered by a single ball implies that the optimal radius is at least the radius of the largest object, whereas in our case as only a single point of  $S_i$  needs to be covered the radius can be arbitrarily smaller. In particular, while [31] achieves a  $(1 + \sqrt{3})$ -approximation, we show our problem cannot in general be approximated within any factor in polynomial time unless  $P = NP$ .

For the special case when  $k = 1$  or  $k = 2$ , there are several prior results which closely relate to our problem. When  $k = 1$ , i.e. the one-center problem, the solution can be derived from the farthest object Voronoi diagram, for which Cheong et al. [9] gave a near linear time algorithm for polygon objects. For disk objects, Ahn et al. [4] gave a near quadratic time algorithm for the two-center problem. Several papers have also considered generalizing to higher dimensions, but restricting the convex objects to affine subspaces of dimension  $\Delta$ . Gao et al. [16] introduced the 1-center problem for  $n$  lines, achieving a linear time  $(1 + \varepsilon)$ -approximation, as well as a  $(1 + \varepsilon)$ -approximation for higher dimensional flats or convex sets whose running time depends exponentially on  $\Delta$ . Later in [17] the same authors considered the more challenging  $k = 2$  and  $k = 3$  cases for lines, providing a  $(2 + \varepsilon)$ -approximation in quasi-linear time. Subsequently, [26] considered the problem for axis-parallel flats, where they provide an improved approximation for  $k = 1$ , hardness results for  $k = 2$ , and an

approximation for larger  $k$  where the time depends exponentially on both  $k$  and  $\Delta$ . While our focus is on the  $k$ -center objective, we remark that  $k$ -means clustering for lines was considered by Marom and Feldman [27], who gave a PTAS for constant  $k$ .

The  $k$ -center problem for points in a metric space can also be viewed as clustering the vertices according to the shortest path metric of a positively weighted graph. This allows one to consider specific graph classes, for example, Eisenstat et al. [11] gave a polynomial time bi-criteria approximation scheme for  $k$ -center in planar graphs (i.e. they allow both the number of centers and radius to be violated). We remark, however, that for our problem, and the various others described above where the objects are not points, the complete graph with all pairwise distances between the objects, is not necessarily metric (i.e. it may not be its own metric completion). For example, the triangle inequality would be violated if you had two small convex objects (e.g. points) which are far from one another but both are close to some other large convex object. Note that this non-metric behavior is what allows us to prove a stronger hardness of approximation result than that for points in the plane [12].

Finally, we note that there is a polynomial time algorithm for  $k$ -center when  $k$  is a constant and the objects are points in  $d$ -dimensional Euclidean space, for constant  $d$ . Specifically, Agarwal and Procopiuc [3] gave an  $n^{O(k^{1-1/d})}$  time exact algorithm, as well as a  $O(n \log k) + (k/\varepsilon)^{O(k^{1-1/d})}$  time  $(1 + \varepsilon)$ -approximation. Later Bădoiu et al. [6] removed the bounded dimension assumption, achieving a  $2^{O((k \log k)/\varepsilon^2)} \cdot dn$  time  $(1 + \varepsilon)$ -approximation.

## Our Contribution

In this paper we initiate the systematic study of the NP-hard clustering with neighborhoods problem. While this problem allows centers to be placed anywhere in the plane, in Section 3 we first argue that one can compute a cubic sized set of points  $P$  and a cubic sized set of radii  $R$ , such that for any integer  $k \geq 0$  there is an optimal set  $S \subseteq P$  of  $k$  centers with optimal radius  $r_{opt} \in R$ . This naturally leads to a PTAS for approximating the optimal number of centers by using Minkowski sums to reduce the problem to instances of geometric hitting set, for which there is a well known PTAS [29]. Specifically, if  $r_{opt}$  is the optimal radius for  $k$  centers, then in  $n^{O(1/\varepsilon^2)}$  time we can produce a set of  $(1 + \varepsilon)k$  centers with radius  $\leq r_{opt}$ .

In clustering problems, however, often the emphasis is on approximating the radius, while keeping  $k$  as a hard constraint. In Section 4 we prove this problem is significantly harder, by adapting the hardness proof of [12] for planar  $k$ -center. Specifically, we show that the radius cannot be approximated within any factor in polynomial time unless  $P = NP$ , even when the convex objects are restricted to disjoint line segments. On the other hand, for disjoint unit disks, a more in depth proof shows the problem is APX-hard, and in particular cannot be approximated within  $\frac{\sqrt{13}-\sqrt{3}}{2-\sqrt{3}} \approx 6.99$  in polynomial time unless  $P = NP$ . Complementing this result, in Section 5 we present our main result, showing that when the objects are disjoint disks (of possibly varying radii) there is a  $(5 + 2\sqrt{3})$ -approximation for the optimal radius. Significantly, for the case of disks, our approximation factor of  $5 + 2\sqrt{3} \approx 8.46$  is close to our hardness bound of  $\frac{\sqrt{13}-\sqrt{3}}{2-\sqrt{3}} \approx 6.99$ . Moreover, while our approximation holds for disks of varying radii, interestingly our hardness bound applies even for disks of uniform radii.

Further probing the complexity of clustering with neighborhoods, in Section 6 we show there is an FPTAS for unit disks when  $k$  is bounded by a constant. Specifically, we give an  $O(n \log k) + (k/\varepsilon)^{O(k)}$  time  $(1 + \varepsilon)$ -approximation to the optimal radius, by carefully reducing to the algorithm of [3] for  $k$ -center. Finally in Section 7, by utilizing the searching procedure of [15], we show that in one dimension the problem can be solved exactly in  $O(n \log n)$  time even when intersections are allowed, contrasting our hardness results in the plane.

## 2 Preliminaries

Given points  $x, y \in \mathbb{R}^d$ ,  $\|x - y\|$  denotes their Euclidean distance. Given two closed sets  $X, Y \subset \mathbb{R}^d$ ,  $\|X - Y\| = \min_{x \in X, y \in Y} \|x - y\|$  denotes their distance. For a single point  $x$  we write  $\|x - Y\| = \|\{x\} - Y\|$ . For a point  $x$  and a value  $r \geq 0$ , let  $B(x, r)$  denote the closed ball centered at  $x$  and with radius  $r$ .

Let  $\mathcal{C}$  be a set of  $n$  pairwise disjoint convex objects in the plane. For simplicity, we assume  $\mathcal{C}$  is in general position. We work under the standard assumption that the objects in  $\mathcal{C}$  are semi-algebraic sets of constant descriptive complexity. Namely, the boundary of each object is composed of a set of algebraic arcs where the sum of the degrees of these arcs is bounded by a constant, and any natural standard operation on such objects, such as computing the distance between any pair of objects, can be carried out in constant time. See Agarwal et al. [1] for a more detailed discussion of this model. Our analysis generalizes to the case where  $n$  is the total complexity of  $\mathcal{C}$  and individual objects in  $\mathcal{C}$  are not required to have constant complexity, however, assuming constant complexity simplifies certain structural statements and the polynomial degree of  $n$  in our running time statements.

► **Problem 1** (Clustering with Neighborhoods). *Given a set  $\mathcal{C}$  of  $n$  disjoint convex objects in the plane, and an integer parameter  $k \geq 0$ , find a set of  $k$  points  $S$  (called centers) which minimize the maximum distance to a convex object in  $\mathcal{C}$ . That is,*

$$S = \arg \min_{S' \subset \mathbb{R}^2, |S'|=k} \max_{C \in \mathcal{C}} \|C - S'\|.$$

Let  $S$  be any set of  $k$  points, and let  $r = \max_{C \in \mathcal{C}} \|C - S\|$ . We refer to  $r$  as the *radius* of the solution  $S$ , since  $r$  is the minimum radius such that the set of all balls  $B(s, r)$  for  $s \in S$ , intersect all  $C \in \mathcal{C}$ . If  $S$  is an optimal solution then we refer to its radius  $r_{opt}$  as the optimal radius.

In this paper we will consider two types of approximations.<sup>1</sup> Let  $\mathcal{C}, k$  be an instance of Problem 1 with optimal radius  $r_{opt}$ . For a value  $\alpha \geq 1$ , we refer to a polynomial time algorithm as an  $\alpha$ -size-approximation if it returns a solution  $S$  of radius  $\leq r_{opt}$  where  $|S| \leq \alpha k$ . Alternatively, we refer to a polynomial time algorithm as an  $\alpha$ -radius-approximation if it returns a solution  $S$  of radius  $\leq \alpha r_{opt}$  where  $|S| = k$ . Often we refer to the latter radius case simply as an  $\alpha$ -approximation.

## 3 Canonical Sets and a PTAS for Approximating the Size

In this section we show that while Problem 1 allows centers to be placed anywhere in the plane, we can compute a canonical cubic sized set of points  $P$  and a set of corresponding radii  $R$ , such that for any integer  $k \geq 0$  there is an optimal set  $S \subseteq P$  of  $k$  centers with optimal radius  $r_{opt} \in R$ . We then use this property to give a PTAS for Problem 1 when approximating the size of an optimal solution. Specifically, for any fixed  $\varepsilon > 0$ , we give a  $(1 + \varepsilon)$ -size-approximation with running time  $n^{O(1/\varepsilon^2)}$ . In Section 5, we will again use this canonical set when designing our constant factor radius-approximation for disks.

The *bisector* of two convex objects  $C, C'$  is the set of all points  $x$  in the plane such that  $\|x - C\| = \|x - C'\|$ . Let  $\beta(C, C')$  denote the bisector of  $C$  and  $C'$ . As discussed in [24], any set  $\mathcal{C}$  of  $n$  disjoint constant-complexity convex objects in general position satisfies the conditions of an abstract Voronoi diagram [25]. In particular we can assume the following:

<sup>1</sup> We refrain from using the standard bi-criteria approximation terminology to emphasize that in each case only the size or only the radius is being approximated, not both.

- 1) For any  $C, C' \in \mathcal{C}$  we have that  $\beta(C, C')$  is an unbounded simple curve.
  - 2) The intersection of any two bisectors is a discrete set with a constant number of points.
- We point out that in the following lemma there is a single pair of sets  $P, R$  which works simultaneously for all values of  $k$ .

► **Lemma 2.** *Let  $\mathcal{C}$  be a set of  $n$  disjoint convex objects. In  $O(n^3 \log n)$  time one can compute a set of  $O(n^3)$  points  $P$ , and a corresponding set of  $O(n^3)$  radii  $R$ , such that for any value  $k \geq 0$  for the instance  $\mathcal{C}, k$  of Problem 1 there is an optimal set of  $k$  centers  $S$  with optimal radius  $r_{opt}$  such that  $S \subseteq P$  and  $r_{opt} \in R$ .*

**Proof.** Let  $I(\mathcal{C})$  be a set containing exactly one (arbitrary) point from each convex object in  $\mathcal{C}$ . For any number of centers  $k$ , let  $S$  be any optimal solution, and let  $r_{opt}$  be the optimal radius. Consider an arbitrary center  $s \in S$ . Let  $\mathcal{C}'$  be the subset of objects in  $\mathcal{C}$  which intersect the ball  $B(s, r_{opt})$ . We can assume  $\mathcal{C}'$  is non-empty, as otherwise the center  $s$  does not cover any convex object within radius  $r_{opt}$  and so can be thrown out. Moreover, if  $|\mathcal{C}'| = 1$  then we can assume  $s$  is the point from  $I(\mathcal{C})$  which intersects this one convex object. So assume  $|\mathcal{C}'| > 1$ , and let  $C$  be the convex object in  $\mathcal{C}'$  which lies furthest from  $s$ . Now consider moving  $s$  continuously toward the convex object  $C$ . As we do so the distance from  $s$  to  $C$  monotonically decreases. Thus so long as  $C$  remains the furthest convex object from  $s$  in  $\mathcal{C}'$ , the ball  $B(s, r_{opt})$  still intersects all of  $\mathcal{C}'$  (i.e. we did not increase the solution radius). Now if  $C$  always remains the furthest, when  $s$  eventually reaches and intersects  $C$  then this will imply its distance to all objects in  $\mathcal{C}'$  is zero, which is a contradiction as we assumed the convex objects do not intersect. Otherwise, at some point  $C$  is no longer the furthest, which implies we must have crossed a bisector  $\beta(C, C')$  for some other convex object  $C' \in \mathcal{C}'$ .

So far we have shown one can assume each center  $s$  either is in  $I(\mathcal{C})$ , or lies on the bisector  $\beta = \beta(C, C')$  of the two objects,  $C, C'$ , which lie furthest away from  $s$  among the set of objects  $\mathcal{C}'$  which intersect the ball  $B(s, r_{opt})$ . In the latter case, let  $T_\beta$  denote the set of all points  $p$  on  $\beta$  such that there exists a third object  $X \in \mathcal{C}$  such that  $\|p - X\| = \|p - C\|$  (or equivalently  $\|p - X\| = \|p - C'\|$ ). Note that such points lie at intersections of bisectors and thus from the above discussion before the lemma, we know  $T_\beta$  is a discrete set. As  $\beta$  is a simple curve, we can view points in  $T_\beta$  as being ordered along  $\beta$ . Suppose that  $s \notin T_\beta$ , and let  $p$  and  $q$  be the points of  $T_\beta$  which come immediately before and after  $s$  along  $\beta$ , and let  $[p, q]$  denote the portion of  $\beta$  lying between these points. (This interval may be unbounded to one side if  $s$  comes after or before all points in  $T_\beta$ .) Recall that  $\mathcal{C}'$  is the subset of objects intersecting  $B(s, r_{opt})$ , and  $C$  and  $C'$  are the furthest from  $s$  among those in  $\mathcal{C}'$ . Observe that for any other point  $z$  in  $[p, q]$ ,  $C$  and  $C'$  must also be the furthest objects from  $z$  among those in  $\mathcal{C}'$ , as otherwise as we move continuously along  $\beta$  from  $s$  to  $z$  we must cross another point from  $T_\beta$  before reaching  $z$  and there are no such points in  $(p, q)$ . Thus if we replace  $s$  with the point in  $[p, q]$  minimizing the distance to  $C$  (or equivalently  $C'$ ) then all objects previously intersected by  $B(s, r_{opt})$  will remain intersected by  $B(s, r_{opt})$ .

Let  $M(\mathcal{C})$  be a set containing, for each bisector  $\beta$ , the set  $T_\beta$  and one minimum distance point from each such interval  $[p, q]$ . We thus have argued that the points of  $S$  can be assumed to lie in  $P = I(\mathcal{C}) \cup M(\mathcal{C})$ . As for the running time and size of these sets, first observe that  $I(\mathcal{C})$  has size  $n$  and can be trivially computed in  $O(n)$  time. For the set  $M(\mathcal{C})$ , first observe that there are  $O(n^2)$  bisectors. For any bisector  $\beta$ , the set  $T_\beta$  of intersection points of  $\beta$  with other bisectors that are equidistant at the intersection point, has size  $O(n)$ , since by general position every point is equidistant to at most 3 objects and as mentioned above any pair of bisectors intersect in a constant number of points. (In other words, we ultimately consider all  $O(n^3)$  points equidistant to three objects, as opposed to all  $O(n^4)$  bisector intersections.) Thus the set  $M(\mathcal{C})$ , and correspondingly  $P$ , has size  $O(n^3)$  as claimed. For the running

## 6:6 Clustering with Neighborhoods

time, as the objects in  $\mathcal{C}$  all have constant complexity, so do their bisectors, and thus  $T_\beta$  can be computed in  $O(n)$  time. The minimum points of  $M(\mathcal{C})$  on  $\beta$ , can thus be computed by sorting  $T_\beta$  along  $\beta$ , in  $O(n \log n)$  time, and then computing the minimum point in constant time for each constant complexity interval between consecutive pairs of points from  $T_\beta$  along  $\beta$ . Thus over all  $O(n^2)$  bisectors it takes  $O(n^3 \log n)$  time to compute  $M(\mathcal{C})$ . ◀

We now argue the canonical sets  $P$  and  $R$  from the above lemma naturally lead to a PTAS for size-approximation by using Minkowski sums. For sets  $A, B \subset \mathbb{R}^2$ , let  $A \oplus B = \{a + b \mid a \in A, b \in B\}$  denote their Minkowski sum. Let  $B(r)$  denote the ball of radius  $r$  centered at the origin. Then we write  $\mathcal{C} \oplus B(r) = \{C \oplus B(r) \mid C \in \mathcal{C}\}$ . A set of points  $S$  is called a *hitting set* for a set of objects if every object has non-empty intersection with  $S$ .

► **Observation 3.** *A set  $S$  of  $k$  centers is a solution to Problem 1 of radius  $r$  if and only if  $S$  is a hitting set of size  $k$  for  $\mathcal{C} \oplus B(r)$ . This holds since for any  $C \in \mathcal{C}$  and  $s \in S$ ,  $B(s, r) \cap C \neq \emptyset$  if and only if  $s \in C \oplus B(r)$ .*

In the geometric hitting set problem we are given a set  $\mathcal{R}$  of  $n$  regions and a set  $P$  of  $m$  points in the plane, and the goal is to select a minimum sized hitting set for  $\mathcal{R}$  using points from  $P$ . The above observation implies we can reduce any given instance  $\mathcal{C}, k$  of Problem 1 to multiple instances of geometric hitting set. Specifically, by Lemma 2, in  $O(n^3 \log n)$  time we can compute a set  $R$  of  $O(n^3)$  values, one of which must be the optimal radius  $r_{opt}$ . Then for each  $r \in R$  we construct a hitting set instance where  $\mathcal{R} = \mathcal{C} \oplus B(r)$ , and  $P$  is the set of points from Lemma 2. By the above observation, if  $r < r_{opt}$ , then the hitting set instance requires more than  $k$  points, and if  $r \geq r_{opt}$  then it requires at most  $k$  points. Therefore, given an algorithm for geometric hitting set we can use it to binary search for  $r_{opt}$ .

While hitting set is in general NP-hard to approximate within logarithmic factors [30], in our case there is a PTAS as the regions are nicely behaved. A collection of regions in the plane is called a set of *pseudo-disks* if the boundaries of any two distinct regions in the set cross at most twice. Mustafa and Ray [29] showed that there is an  $nm^{O(1/\varepsilon^2)}$  time PTAS for geometric hitting set when  $\mathcal{R}$  is a collection of  $n$  pseudo-disks and  $P$  is a set of  $m$  points. It is known that if we take the Minkowski sum of a single convex object with each member of a set of disjoint convex objects, then the resulting set is a collection of pseudo-disks (see for example [2]). Thus  $\mathcal{C} \oplus B(r)$  is a collection of pseudo-disks. Therefore, by the above discussion, we have the following theorem. As the decision procedure is now approximate, the binary search must be modified to look at larger radii when the hitting set algorithm returns  $> (1 + \varepsilon)k$  points, and smaller radii otherwise. (This yields an adjacent pair  $r < r'$  such that  $r < r_{opt}$ , implying  $r' \leq r_{opt}$ , and an  $r'$ -cover of the input using  $\leq (1 + \varepsilon)k$  points.)

► **Theorem 4.** *There is a PTAS for Problem 1 for approximating the optimal solution size. That is, for any fixed  $\varepsilon > 0$ , there is a  $(1 + \varepsilon)$ -size-approximation with running time  $n^{O(1/\varepsilon^2)}$ .*

We remark that the PTAS of [29] implicitly assumes the objects are in general position, that is if two objects intersect then they properly intersect (i.e. their interiors intersect). While  $\mathcal{C}$  satisfies this property, it may not after we take the Minkowski sum with a given radius. However, as we can compute distances between our objects, this is easily overcome by computing the smallest non-zero distance  $d$  between two objects in  $\mathcal{C} \oplus B(r)$ , and instead running the hitting set algorithm on  $\mathcal{C} \oplus B(r + \alpha)$ , where  $\alpha$  is some infinitesimal value less than  $d/2$ . This ensures any objects which intersected in  $\mathcal{C} \oplus B(r)$  now properly intersect, and there are no new intersections.

■ **Figure 4.1** Reducing planar Vertex Cover to Problem 1 for segments.

## 4 Radius Approximation Hardness

In this section we argue that for Problem 1 it is hard to approximate the radius within any factor, even when  $\mathcal{C}$  is restricted to being a set of line segments. Moreover, for the case when  $\mathcal{C}$  is a set of disks, i.e. the case considered in Section 5, we argue the problem is APX-Hard. Our hardness results use a construction similar to the one from [12], where they reduce from the problem of planar vertex cover where the maximum degree of a vertex is three, which is known to be NP-complete [18]. We denote this problem as P3VC.

### 4.1 Line Segments

Here we argue that it is hard to radius-approximate Problem 1 within any factor, even when  $\mathcal{C}$  is a set of line segments. We remark that the following reduction works for any instance of planar vertex cover (i.e. regardless of the degree), but the reduction for disks in the next subsection uses that the degree is at most three.

► **Theorem 5.** *Problem 1 cannot in polynomial time be radius-approximated within any factor that is computable in polynomial time unless  $P = NP$ , even when restricting to the set of instances in which  $\mathcal{C}$  is a set of disjoint line segments.*

**Proof.** Let  $G, k$  be an instance of P3VC. Consider a straight line embedding of  $G$ , and let  $d$  denote the distance between the closest pair of non-adjacent segment edges.<sup>2</sup> Let  $\varepsilon > 0$  be a value strictly smaller than  $d/2$  and strictly smaller than half the length of any segment edge. The set  $\mathcal{C}$  of segments in our instance of Problem 1 will be the segment edges from the embedding, but where each segment has an  $\varepsilon$  amount removed from each end, i.e. we remove all portions of segments in  $\varepsilon$  balls around the vertices, see Figure 4.1. We use the same value of  $k$  in our Problem 1 instance as in the P3VC instance.

If there is a vertex cover of size at most  $k$  then if we place balls of radius  $\varepsilon$  at each of the  $k$  corresponding vertices of the embedding, then these balls will intersect all segments in  $\mathcal{C}$ , i.e. we have a solution to Problem 1 of radius  $\varepsilon$ . On the other hand, by the definition of  $d$ , any ball of radius  $< d/2$  cannot simultaneously intersect two segments from  $\mathcal{C}$  if they correspond to non-adjacent edges from  $G$ . (Note when we shrunk the edges by  $\varepsilon$  this could only have made them further apart.) Thus if the minimum vertex cover requires  $> k$  vertices, then our instance of Problem 1 requires  $> k$  centers if we limit to balls with radius  $< d/2$ .

<sup>2</sup> In  $O(n \log n)$  time one can compute a straight line embedding of  $G$  where the vertices are on an  $(2n - 4) \times (n - 2)$  grid [14]. This implies a lower bound on  $d$  with a polynomial number of bits.

Therefore, if we could approximate the minimum radius of our Problem 1 instance within any factor less than  $d/(2\varepsilon)$  then we can determine whether the corresponding vertex cover instance had a solution with  $\leq k$  vertices. However, we are free to make  $\varepsilon > 0$  as small as we want and thus  $d/(2\varepsilon)$  as large as we want, so long as this quantity (or more precisely a lower bound on it) is computable in polynomial time.  $\blacktriangleleft$

## 4.2 Disks

Here we argue that it is hard to radius-approximate Problem 1 within a constant factor when  $\mathcal{C}$  is restricted to be a set of unit disks. The following reduction from P3VC is similar to the one given in [12], which embeds the graph such that edges are replaced by odd length sequences of points. In our case, these odd length sequences of points are instead replaced with odd length sequences of appropriately spaced disks.

**► Theorem 6.** *For the set of instances in which  $\mathcal{C}$  is a set of disjoint unit disks, Problem 1 cannot be radius-approximated to any factor less than  $\frac{\sqrt{13}-\sqrt{3}}{2-\sqrt{3}}$  in polynomial time unless  $P = NP$ .*

**Proof.** To simplify our construction description, instead of requiring the disks be disjoint, we allow them to intersect at their boundaries, but not their interiors. Later we remark how this easily implies the result for the disjoint disk case.

So let  $G = (V, E)$ ,  $k$  be an instance of P3VC. For every edge in  $E$  we create a sequence of an odd number (greater than 1) of unit disks, where consecutive disks in the sequence are spaced  $2(2/\sqrt{3} - 1)$  apart from one another. (Note  $2(2/\sqrt{3} - 1)$  is the distance between the disks, not their centers.) For a vertex  $v$  of degree two, we place the disks corresponding to the  $v$  end of the adjacent edges again at distance  $2(2/\sqrt{3} - 1)$  apart. For a vertex  $v$  of degree three, we place the disks corresponding to the  $v$  end of the adjacent edges such that they all just touch one another at their boundaries, see Figure 4.3. Thus the centers of these disks form an equilateral triangle, and let the center point of this triangle be  $t$ . For any one of the adjacent edges, we further require that the centers of the first two disks (on the  $v$  end of the edge) lie on a straight line containing  $t$ , in other words the edges leaving  $v$  do not bend until several disks away from  $v$ . As  $G$  is a planar graph with maximum degree three such an embedding of polynomial size is possible, similar to the case in [12]. Doing so requires using different numbers of disks for each edge and allowing the edges to bend (i.e. the centers of three consecutive disks of an edge may not lie on a line). However, we will require these bends to be gradual. Specifically, observe that if the centers of three consecutive disks of an edge were on a straight line, the distance between the two non-consecutive disks would be  $2(1 + 2(2/\sqrt{3} - 1)) > 2.6$ , see Figure 4.2. We then require that the bends are shallow enough such that two non-consecutive disks of an edge are more than 2.5 apart. We also require this for disks from edges adjacent to a degree two vertex (when they are not both the disks immediately adjacent at the vertex), or a degree three vertex when neither disk is one of corresponding three touching disks of the vertex. Finally, for disks that come from edges that are not adjacent, we easily enforce that they are again more than 2.5 apart. (This is similar to the value  $d$  from Theorem 5.)

So given an instance  $G, k$  of P3VC, we construct an instance  $\mathcal{C}, \kappa$  of Problem 1 where  $\mathcal{C}$  is determined from  $G$  as described above and  $\kappa = k + (|\mathcal{C}| - |E|)/2$ . We first argue if  $G$  has a vertex cover of size  $k$  then for our instance of Problem 1 there is a solution of radius  $2/\sqrt{3} - 1$ . First, for any vertex  $v$  in the vertex cover we create a center, and roughly speaking place it at the location of  $v$  in the embedding. Namely, if  $v$  had degree two then we place the center at the midpoint of the centers of the disks at the ends of the edges adjacent to  $v$ , which

■ **Figure 4.2** Consecutive disks along an edge.

■ **Figure 4.3** Three touching disks corresponding to a degree three vertex.

by construction are exactly  $2(2/\sqrt{3} - 1)$  apart and thus a ball at the midpoint with radius  $2/\sqrt{3} - 1$  intersects both. If  $v$  has degree three then we place a center at the center point  $t$  of the equilateral triangle determined by three touching disks of the adjacent edges. An easy calculation<sup>3</sup> shows that since our disks have unit radius, that  $B(t, 2/\sqrt{3} - 1)$  intersects the three touching disks. We now cover the remaining disks with  $(|\mathcal{C}| - |E|)/2$  centers. For any edge  $e \in E$  let  $n_e$  be the number of disks used for  $e$  in the above construction. Observe that as we already placed centers at vertices corresponding to a vertex cover of the edges, at least one disk at the end of each edge is already covered, and so there are at most  $n_e - 1$  consecutive disks that need to be covered. (Note  $n_e - 1$  is even.) However, as consecutive disks are exactly  $2(2/\sqrt{3} - 1)$  apart on each edge, these  $n_e - 1$  disks can be covered with  $(n_e - 1)/2$  balls of radius  $(2/\sqrt{3} - 1)$  by covering the disks in pairs. Thus the total number of centers used is  $k + \sum_{e \in E} (n_e - 1)/2 = k + (|\mathcal{C}| - |E|)/2 = \kappa$ .

Now suppose the minimum vertex cover of  $G$  requires  $> k$  vertices. In this case we argue that our instance of Problem 1 requires more than  $\kappa$  centers if we limit to balls with radius  $< \sqrt{13}/3 - 1$ . Call any two disks in  $\mathcal{C}$  neighboring if they are consecutive on an

<sup>3</sup> For an equilateral triangle with edge length 2, the distance from an edge to the center point of the triangle is  $1/\sqrt{3}$ , thus the distance from the center point to any one of the unit balls is  $2/\sqrt{3} - 1$ .

## 6:10 Clustering with Neighborhoods

edge or if they are disks on the  $v$  end of two edges adjacent to a vertex  $v$ . By construction, neighboring disks have distance  $\leq 2/\sqrt{3} - 1$  from each other. For a pair of disks which are not neighboring we now argue their distance is at least  $2\sqrt{13}/3 - 2$ . Specifically, if these disks come from the same edge but are not consecutive along that edge, or if they are from distinct edges that are either non-adjacent or are adjacent to a degree two vertex (but not the two disks of that vertex), then by construction their distance is  $> 2.5 > 2\sqrt{13}/3 - 2$ . The remaining case is when the disks are from distinct edges adjacent to a degree three vertex, but they are not both from the three touching disks of the vertex. It is easy to see that the closest two such disks can be is when one of the disks is one of the three touching disks, and the other is the second disk on another edge. We now calculate the distance between two such disks, see Figure 4.3. Let the three touching disks be denoted  $D_1$ ,  $D_2$ , and  $D_3$ , with centers  $d_1$ ,  $d_2$ , and  $d_3$ , respectively. Let  $D'_2$  denote the second disk on the edge containing  $D_2$ , and let its center be  $d'_2$ . We wish to compute  $\|D_1 - D'_2\| = \|d_1 - d'_2\| - 2$ , as these are unit disks. Let  $m$  denote the midpoint of  $d_1$  and  $d_3$ , and observe that the line through  $d_2$  and  $d'_2$  passes through  $m$  and is orthogonal to the line through  $d_1$  and  $d_3$ , as the points  $d_1$ ,  $d_2$ , and  $d_3$  form an equilateral triangle. Thus by the Pythagorean theorem we have  $\|d_1 - d'_2\|^2 = 1^2 + (1 + 2(2/\sqrt{3} - 1) + 1 + \sqrt{3})^2 = 1 + (4/\sqrt{3} + \sqrt{3})^2 = 52/3$ , where the  $+\sqrt{3}$  term is the height of an equilateral triangle of side length 2. Thus  $\|D_1 - D'_2\| = \|d_1 - d'_2\| - 2 = 2\sqrt{13}/3 - 2$ .

Now we finish the argument that when the minimum vertex cover of  $G$  requires  $> k$  vertices, our instance of Problem 1 requires more than  $\kappa$  centers if we limit to balls with radius  $< \sqrt{13}/3 - 1$ . By the above, limiting to radius  $< \sqrt{13}/3 - 1$  implies that any ball either covers just a single disk, or a pair of neighboring disks. An edge  $e$  with  $n_e$  disks thus requires at least  $\lceil n_e/2 \rceil = 1 + (n_e - 1)/2$  disks to cover it. Moreover, a ball can only cover both a disk of  $e$  and  $e'$  if those disks are on the  $v$  end of two edges adjacent to  $v$ . Let  $E_z$  be the subset of edges with at least one disk covered by such a ball (i.e. a ball corresponding to a vertex), and let  $z$  be the number of such balls. Then the total number of balls required is

$$\begin{aligned} &\geq z + \sum_{e \in E_z} (n_e - 1)/2 + \sum_{e \in E \setminus E_z} (1 + (n_e - 1)/2) \\ &= z + (|\mathcal{C}| - |E|)/2 + |E \setminus E_z| = z + (\kappa - k) + |E \setminus E_z|, \end{aligned}$$

which is more than  $\kappa$  when  $z + |E \setminus E_z| > k$ . Notice, however, there is a vertex cover of  $G$  of size  $z + |E \setminus E_z|$ , consisting of the vertices that  $z$  counted, and one vertex from either end of each edge in  $E \setminus E_z$ . Thus as the minimum vertex cover has size  $> k$ , we have  $z + |E \setminus E_z| > k$  as desired.

Therefore, if we could approximate the minimum radius of our Problem 1 instance within any factor less than  $\frac{\sqrt{13/3}-1}{2/\sqrt{3}-1} = \frac{\sqrt{13}-\sqrt{3}}{2-\sqrt{3}}$  then we can determine whether the corresponding vertex cover instance had a solution with  $\leq k$  vertices. In the above analysis the boundaries of the circles were allowed to intersect, but we can enforce that all disks are disjoint without changing the approximation hardness factor since we showed the problem is hard for any factor that is less than  $\frac{\sqrt{13}-\sqrt{3}}{2-\sqrt{3}}$ . Specifically, rather than having the disks for a degree three vertex touch, we can instead make them arbitrarily close to touching. ◀

## 5 Constant Factor Radius Approximation for Disks

In this section we argue that when  $\mathcal{C}$  is a set of disjoint disks (of possibly differing radii), that there is a constant factor radius-approximation for Problem 1.

► **Lemma 7.** *Let  $\mathcal{C}$  be a set of pairwise disjoint disks such that for all  $C \in \mathcal{C}$ , the radius of  $C$  is  $\geq r$ . If there is a point  $s \in \mathbb{R}^2$  where  $\|s - C\| \leq (2/\sqrt{3} - 1)r$  for all  $C \in \mathcal{C}$ , then  $|\mathcal{C}| \leq 2$ .*

**Proof.** We give a proof by contradiction. So suppose there exists a point  $s$  such that there are three disjoint disks in  $\mathcal{C}$ , each with radius  $\geq r$ , and all of which intersect the ball  $B(s, (\frac{2}{\sqrt{3}} - 1)r)$ . Observe that if any one of these three disjoint disks  $C$  has radius  $> r$ , then it can be replaced by a disk  $C'$  of radius  $r$  such that  $C' \subset C$  and  $C'$  still intersects  $B(s, (\frac{2}{\sqrt{3}} - 1)r)$ . As these new disks are all still disjoint and intersect  $B(s, (\frac{2}{\sqrt{3}} - 1)r)$ , it suffices to argue we get a contradiction when all three disks have radius exactly  $r$ . Let the centers of these three disks be denoted  $x, y$ , and  $z$ . Now, at least one of the angles  $\angle xsy$ ,  $\angle ysz$ , and  $\angle zsx$  is  $\leq 2\pi/3$ . Without loss of generality assume it is  $\angle xsy$ , and let  $\gamma = \angle xsy$ .

Consider the triangle  $\triangle sxy$ , and let its side lengths be denoted  $a = \|x - s\|, b = \|y - s\|, c = \|x - y\|$ . Since  $\gamma \leq 2\pi/3$ , by the Law of Cosines we thus have  $c^2 = a^2 + b^2 - 2ab \cos(\gamma) \leq a^2 + b^2 + ab$ . As the  $r$  radius disks with centers  $x$  and  $y$  are disjoint, we know that  $2r < c$ . Combining these two inequalities we get  $4r^2 < a^2 + b^2 + ab$ . As  $B(s, (\frac{2}{\sqrt{3}} - 1)r)$  intersects the  $r$  radius disks centered at both  $x$  and at  $y$ , we also have that  $a, b \leq (\frac{2}{\sqrt{3}} - 1)r + r = \frac{2r}{\sqrt{3}}$ . Combining this with the previous inequality gives  $4r^2 < a^2 + b^2 + ab \leq 4r^2/3 + 4r^2/3 + 4r^2/3 = 4r^2$ , which is a clear contradiction and thus the number of disks in  $\mathcal{C}$  is at most 2. ◀

For any constant  $c \geq 1$ , we call an algorithm a  $c$ -decider for Problem 1, if for a given instance with optimal radius  $r_{opt}$ , and for any given query radius  $r$ , if  $r \geq r_{opt}$  then the algorithm returns a solution  $S$  of radius  $\leq cr$ , and if  $r < r_{opt}/c$  it returns False (for  $r_{opt}/c \leq r < r_{opt}$  either answer is allowed).

► **Lemma 8.** *There is an  $O(n^{2.5})$  time  $(5 + 2\sqrt{3})$ -decider for Problem 1, when restricted to instances where  $\mathcal{C}$  is a set of disjoint disks.*

**Proof.** Let  $r$  be the given query radius. We build a set  $S$  of centers as follows, where initially  $S = \emptyset$ . Let  $P$  be the set of center points of all disks in  $\mathcal{C}$  with radius  $< (3 + 2\sqrt{3})r$ . Until  $P$  is empty repeatedly add an arbitrary point  $p \in P$  to the set  $S$ , remove all disks from  $\mathcal{C}$  which intersect  $B(p, (5 + 2\sqrt{3})r)$ , and remove all center points from  $P$  corresponding to disks removed from  $\mathcal{C}$ . Let  $S_1$  refer to the resulting set of centers. For the remaining set of disks  $\mathcal{C}'$ , define the subset  $\mathcal{C}'' = \{C \in \mathcal{C}' \mid \exists D \in \mathcal{C}' \setminus \{C\} \text{ s.t. } \|C - D\| \leq 2r\}$ . First, for every disk  $C$  in  $\mathcal{C}' \setminus \mathcal{C}''$  we add an arbitrary point from  $C$  to  $S$ . Let this set of added centers be denoted  $S_2$ . Now for the set  $\mathcal{C}''$  we construct a graph  $G = (V, E)$  where  $V = \mathcal{C}''$  and there is an edge from  $C$  to  $D$  if and only if  $\|C - D\| \leq 2r$ . Let  $\mathcal{E}$  be a minimum edge cover of  $G$ . (Note every vertex in  $G$  has an adjacent edge by the definition of  $\mathcal{C}''$  and thus  $\mathcal{E}$  exists.) For every edge  $(C, D) \in \mathcal{E}$ ,  $\|C - D\| \leq 2r$  and thus there is a point  $p \in \mathbb{R}^2$  such that  $\|p - C\|, \|p - D\| \leq r$ . So finally, for each  $(C, D) \in \mathcal{E}$  we add this corresponding point  $p$  to  $S$ . Let this final set of added centers be denoted  $S_3$ . If  $|S| \leq k$  we return  $S$  (which is the disjoint union of  $S_1, S_2$ , and  $S_3$ ) and otherwise we return False.

To prove the above algorithm is a  $(5 + 2\sqrt{3})$ -decider, first we argue that if  $r < r_{opt}/(5 + 2\sqrt{3})$  then it returns False. To do so we prove the contrapositive. So assume  $|S| \leq k$ . Let  $S_1, S_2$ , and  $S_3$ , and  $\mathcal{C}'' \subseteq \mathcal{C}' \subseteq \mathcal{C}$  be as defined above. As we used balls of radius  $(5 + 2\sqrt{3})r$ , all  $C \in \mathcal{C} \setminus \mathcal{C}'$  are within distance  $(5 + 2\sqrt{3})r$  of points in  $S_1$ . All  $C \in \mathcal{C}' \setminus \mathcal{C}''$  have distance zero to a point in  $S_2$ . Finally, all  $C \in \mathcal{C}''$  have distance  $\leq r$  to a point in  $S_3$ . As  $S$  is the disjoint union of  $S_1, S_2$ , and  $S_3$ , we thus have that all  $C \in \mathcal{C}$  are within distance  $(5 + 2\sqrt{3})r$  to a set  $S$  with  $\leq k$  points, which by the definition of Problem 1 means that  $r_{opt} \leq (5 + 2\sqrt{3})r$ .

Now suppose  $r \geq r_{opt}$ , where  $r_{opt}$  is the optimal radius for the given instance  $\mathcal{C}, k$  of Problem 1. In order to prove the algorithm is a  $(5 + 2\sqrt{3})$ -decider, in this case we must argue it returns a  $\leq (5 + 2\sqrt{3})r$  radius solution. As already shown above, if the algorithm

returns a solution then it has radius  $\leq (5 + 2\sqrt{3})r$ , thus all we must argue is that a solution is returned, namely that  $|S| \leq k$ . So fix an optimal solution  $S^*$  for the original input instance  $\mathcal{C}, k$ . We argue that there are disjoint subsets  $S_1^*, S_2^*$ , and  $S_3^*$  of  $S^*$  such that  $|S_1^*| \geq |S_1|$ ,  $|S_2^*| \geq |S_2|$ , and  $|S_3^*| \geq |S_3|$ , and therefore  $|S| \leq |S^*| = k$ .

Let the points in  $S_1 = \{t_1, \dots, t_{|S_1|}\}$  be indexed in the order they were selected. Consider the point  $t_i$ , which is the center of some disk  $C_i \in \mathcal{C}$  with radius  $\leq (3 + 2\sqrt{3})r$ . Let  $U_i = \cup_{j \leq i} B(t_j, (5 + 2\sqrt{3})r)$ . Define  $S_1^*$  as the centers  $s$  of  $S^*$  such that  $B(s, r) \subseteq U_{|S_1|}$ . To argue  $|S_1^*| \geq |S_1|$ , it suffices to argue that for all  $i$  there exists some  $s \in S^*$  such that  $B(s, r) \not\subseteq U_{i-1}$  while  $B(s, r) \subseteq U_i$  (i.e.  $s$  gets charged uniquely to  $t_i$ ). Now there must be some center  $s \in S^*$  such that  $B(s, r_{opt}) \cap C_i \neq \emptyset$ , as  $S^*$  covers  $\mathcal{C}$  with radius  $r_{opt}$ . Moreover, since  $r \geq r_{opt}$ , we have  $B(s, r) \not\subseteq U_{i-1}$ , since otherwise it implies  $U_{i-1} \cap C_i \neq \emptyset$  and thus  $t_i$  could not have been selected in the  $i$ th round as the algorithm had already removed it from  $P$ . Conversely,  $B(s, r) \subseteq U_i$ , since  $B(s, r)$  intersects  $C_i$  and  $C_i$  has radius  $\leq (3 + 2\sqrt{3})r$ , and thus  $B(s, r) \subseteq B(t_i, (5 + 2\sqrt{3})r) \subseteq U_i$ . Therefore  $|S_1^*| \geq |S_1|$ .

For any  $s \in S_1^*$ ,  $B(s, r) \subseteq U_{|S_1|}$ , and since the disks of  $\mathcal{C}'$  do not intersect  $U_{|S_1|}$ , in the optimal solution  $\mathcal{C}'$  must be  $r_{opt}$ -covered only using centers from  $S^* \setminus S_1^*$ . Let  $S_2^*$  be the subset of centers from  $S^* \setminus S_1^*$  which  $r_{opt}$  covers  $\mathcal{C}' \setminus \mathcal{C}''$ . Since any disk  $C \in (\mathcal{C}' \setminus \mathcal{C}'')$  has distance  $> 2r$  to its nearest neighbor in  $\mathcal{C}' \setminus \{C\}$  and  $r_{opt} \leq r$ , the optimal solution must use a distinct center to cover each disk in  $\mathcal{C}' \setminus \mathcal{C}''$ , i.e.  $|S_2^*| \geq |S_2|$ , and moreover,  $\mathcal{C}''$  must be covered in the optimal solution by  $S^* \setminus (S_1^* \cup S_2^*)$ . So finally, let  $S_3^*$  be the subset of centers from  $S^* \setminus (S_1^* \cup S_2^*)$  which  $r_{opt}$  covers  $\mathcal{C}''$ . By construction, the radius of each  $C \in \mathcal{C}''$  is  $\geq (3 + 2\sqrt{3})r$ . Thus, by Lemma 7 any point from  $S_3^*$  can  $(2/\sqrt{3} - 1) \cdot (3 + 2\sqrt{3})r = r \geq r_{opt}$  cover at most 2 disks from  $\mathcal{C}''$ . Now the graph  $G$ , for which our algorithm computes a minimum edge cover  $\mathcal{E}$ , contains an edge for every pair of disks which can be simultaneously covered with a single  $r$  radius ball. Therefore  $|S_3^*| \geq |\mathcal{E}| = |S_3|$ .

For the running time, computing the set  $P$  takes  $O(n)$  time. Selecting a new point  $p \in P$  and removing all disks from  $\mathcal{C}$  which intersect  $B(p, (5 + 2\sqrt{3})r)$  can be done in  $O(n)$  time, and thus repeating this till  $P$  is empty takes  $O(n^2)$  time. Determining the subset  $\mathcal{C}''$ , and hence the graph  $G$ , can naively be done in  $O(n^2)$  by checking the distances between all pairs in  $\mathcal{C}'$ . Selecting a point from each  $C \in (\mathcal{C}' \setminus \mathcal{C}'')$  takes  $O(n)$  time. Finally, since computing a minimum edge cover can be reduced to computing a maximum matching,  $\mathcal{E}$  can be found in  $O(n^{2.5})$  time (see [28]).  $\blacktriangleleft$

We remark that it should be possible to improve the running time of the above decision procedure, by arguing that the graph  $G$  it constructs is sparse. However, ultimately that will not improve the running time of the following optimization procedure, as it searches over the  $O(n^3)$  sized set of Lemma 2.

► **Theorem 9.** *There is an  $O(n^3 \log n)$  time  $(5 + 2\sqrt{3})$ -radius-approximation algorithm for Problem 1, when restricted to instances where  $\mathcal{C}$  is a set of disjoint disks.*

**Proof.** By Lemma 2, in  $O(n^3 \log n)$  time we can compute an  $O(n^3)$  sized set  $R$  of values, such that  $r_{opt} \in R$ , where  $r_{opt}$  is the optimal radius. So sort the values in  $R$ , and then binary search over them using the  $(5 + 2\sqrt{3})$ -decider of Lemma 8, which we denote `decider`( $r$ ). Specifically, if `decider` returns False we recurse to the right, and if it returns a solution (i.e. True) then we recurse on the left. Note that since our decision procedure is approximate, the values for which it returns True or for which it returns False may not be contiguous in the sorted order of  $R$ . Regardless, however, our binary search allows us to find a pair  $r' < r$  which are consecutive in  $R$  and such that `decider`( $r'$ ) is False, and `decider`( $r$ ) is True. (Unless `decider` always returns True, in which case it returns the smallest value in  $R$ .) By Lemma 8

decider is a  $(5 + 2\sqrt{3})$ -decider, and thus since  $\text{decider}(r')$  is False by definition we have that  $r' < r_{opt}$ . However, as  $r' < r$  are consecutive in the sorted order of  $R$  and since  $r_{opt} \in R$ , this implies  $r_{opt} \geq r$ . On the other hand, again by the definition of a  $(5 + 2\sqrt{3})$ -decider,  $\text{decider}(r)$  outputs a solution with radius at most  $(5 + 2\sqrt{3})r \leq (5 + 2\sqrt{3})r_{opt}$ , thus giving us a  $(5 + 2\sqrt{3})$ -approximation as claimed.

By Lemma 2, computing and sorting the  $O(n^3)$  values in  $R$  takes  $O(n^3 \log n)$  time. By Lemma 8 each call to  $\text{decider}$  takes  $O(n^{2.5})$  time, and since we are binary searching over  $O(n^3)$  values, the time for all calls to  $\text{decider}$  is  $O(n^{2.5} \log(n^3)) = O(n^{2.5} \log n)$ . Thus the total time is  $O(n^3 \log n)$  as claimed.  $\blacktriangleleft$

Our focus in this paper is on the planar case, however, in the full version [22] we remark how the above decision procedure works in higher dimensions. The above optimization procedure does not immediately extend as it makes use of Lemma 2, however, in the full version we informally sketch how one can approximately recover the same result.

## 6 An Efficient FPTAS for Bounded $k$

By Lemma 2, we can compute a set of  $O(n^3)$  points which contains a subset of size  $k$  that is an optimal  $k$ -center solution. Thus, for constant  $k$ , enumerating all  $O(n^{3k})$  possible subsets, and taking the minimum cost found, yields a polynomial time algorithm. In this section, we argue that for constant  $k$ , we can achieve a  $(1 + \varepsilon)$ -radius-approximation for unit disks, whose running time depends only linearly on  $n$ . Contrast this with Theorem 6, where we argued that when  $k$  is not assumed to be constant, that the problem is hard to approximate for unit disks within a given constant factor. We use the following from Agarwal and Procopiuc [3].

► **Theorem 10** ([3]). *Given a set  $P$  of  $n$  points in the plane, there is an  $O(n \log k) + (k/\varepsilon)^{O(\sqrt{k})}$  time  $(1 + \varepsilon)$ -radius-approximation algorithm for  $k$ -center, denoted  $\mathbf{kCenter}(\varepsilon, P)$ .*

► **Theorem 11.** *There is an  $O(n \log k) + (k/\varepsilon)^{O(k)}$  time  $(1 + \varepsilon)$ -radius-approximation algorithm for Problem 1, when restricted to instances where  $\mathcal{C}$  is a set of disjoint unit disks.*

**Proof.** Let  $P$  denote the set of center points of the disks in  $\mathcal{C}$ . For any given set  $S$  of  $k$  points in the plane, let  $r_P(S) = \max_{p \in P} \|p - S\|$  and  $r_{\mathcal{C}}(S) = \max_{C \in \mathcal{C}} \|C - S\|$ . Observe that  $r_{\mathcal{C}}(S) \leq r_P(S) \leq r_{\mathcal{C}}(S) + 1$ . Specifically,  $r_{\mathcal{C}}(S) \leq r_P(S)$  since any ball (in particular one centered at a point from  $S$ ) which contains a center point from  $P$  also intersects the corresponding disk in  $\mathcal{C}$ . On the other hand,  $r_P(S) \leq r_{\mathcal{C}}(S) + 1$  since for any ball intersecting a disk in  $\mathcal{C}$ , if we increase its radius by 1 then it will contain the center point of that disk, as  $\mathcal{C}$  consists of unit disks.

Let  $r_{opt}$  denote the optimum radius for the given instance  $\mathcal{C}, k$  of Problem 1. We consider two cases based on the value of  $r_{opt}$ . First, suppose that  $r_{opt} > 2/\varepsilon$ . Let  $S'$  denote the solution returned by  $\mathbf{kCenter}(\varepsilon/3, P)$ . By the above inequalities and Theorem 10,

$$\begin{aligned} r_{\mathcal{C}}(S') &\leq r_P(S') \leq (1 + \varepsilon/3) \min_{S \subset \mathbb{R}^2, |S|=k} r_P(S) \leq (1 + \varepsilon/3) \left(1 + \min_{S \subset \mathbb{R}^2, |S|=k} r_{\mathcal{C}}(S)\right) \\ &= (1 + \varepsilon/3)(1 + r_{opt}) < (1 + \varepsilon/3)(\varepsilon r_{opt}/2 + r_{opt}) = (1 + \varepsilon/3)(1 + \varepsilon/2)r_{opt} \leq (1 + \varepsilon)r_{opt}, \end{aligned}$$

where the last inequality assumed  $\varepsilon \leq 1$ . Thus  $S'$  is  $(1 + \varepsilon)$ -approximation for Problem 1.

Now suppose that  $r_{opt} \leq 2/\varepsilon$ . In this case observe that for any point  $x \in \mathbb{R}^2$ , the ball  $B(x, r_{opt})$  can intersect only  $O(1/\varepsilon^2)$  disks from  $\mathcal{C}$  as they are disjoint and all have radius 1. Thus any center from the optimal solution can cover at most  $O(1/\varepsilon^2)$  disks within the optimal radius, and so it must be that  $n = O(k/\varepsilon^2)$ .

The algorithm is now straightforward. If  $n \leq \gamma k/\varepsilon^2$ , for some sufficiently large constant  $\gamma$ , then by Lemma 2 in  $O((k/\varepsilon^2)^3 \log(k/\varepsilon))$  time we can compute a set  $P$  of  $O((k/\varepsilon^2)^3)$  points such that  $P$  contains an optimal set of  $k$  centers. We try all possible subsets of  $P$  of size  $k$  and take the best one. There are  $O((k/\varepsilon^2)^{3k})$  such subsets, and for each subset its cost can be determined in  $O(kn) = O((k/\varepsilon)^2)$  time. Thus in this case we can compute the optimal solution in  $O((k/\varepsilon)^2 \cdot (k/\varepsilon^2)^{3k}) = (k/\varepsilon)^{O(k)}$  time.

On the other hand, if  $n > \gamma k/\varepsilon^2$  then the above implies  $r_{opt} > 2/\varepsilon$ . In this case it was argued above that  $\mathbf{kCenter}(\varepsilon/3, P)$  returns a  $(1 + \varepsilon)$ -approximation, and by Theorem 10 it does so in  $O(n \log k) + (k/\varepsilon)^{O(\sqrt{k})}$  time. In either case, we have a  $(1 + \varepsilon)$ -approximation (or better) and the total time is  $\max\{(k/\varepsilon)^{O(k)}, O(n \log k) + (k/\varepsilon)^{O(\sqrt{k})}\}$ . ◀

## 7 One Dimensional Clustering with Neighborhoods

In this section we show that despite clustering with neighborhoods being hard to radius approximate within any factor in the plane, we can solve the one dimensional variant exactly in  $O(n \log n)$  time, even when object intersections are allowed. First, we argue the decision problem can be solved in linear time. Then we argue that we can use a scheme similar to that in [15] to search for the optimal radius.

In one dimension, a convex object is just a closed interval. Thus we have the following one dimensional version of Problem 1, where intersections are no longer prohibited.

► **Problem 12** (One Dimensional Clustering with Neighborhoods). *Given a set  $\mathcal{C}$  of  $n$  closed intervals on the real line, and an integer parameter  $k \geq 0$ , find a set of  $k$  points  $S$  (called centers) which minimize the maximum distance to an interval in  $\mathcal{C}$ . That is,*

$$S = \arg \min_{S' \subset \mathbb{R}, |S'|=k} \max_{C \in \mathcal{C}} \|C - S'\|.$$

The following decision procedure is similar in spirit to various folklore results for interval problems in one dimension (for example, see the discussion in [13] on interval stabbing). The challenge is turning this decision procedure into an efficient optimization procedure, for which as discussed below we make use of [15].

We first sort the intervals in increasing order both by their left and by their right endpoints. We maintain cross links between the two sorted lists so that if we remove an interval from one list, its copy in the other list can be removed in constant time.

► **Lemma 13.** *Given an instance  $\mathcal{C}, k$  of Problem 12, where the intervals have been presorted, for any query radius  $r$ , in  $O(n)$  time one can decide whether  $r \geq r_{opt}$ .*

**Proof.** We build a set  $S$  of centers as follows, where initially  $S = \emptyset$ . Let  $[\alpha, \beta]$  denote the interval with the leftmost right endpoint (i.e.  $\beta$  is smallest among all intervals). We place a center at  $\beta + r$  and add it  $S$ . Next we remove all intervals which intersect the ball  $B(\beta + r, r)$ . Note that these intersecting intervals are precisely those whose left endpoint is  $\leq \beta + 2r$ , as this condition is clearly necessary to intersect  $B(\beta + r, r)$ , but also sufficient as all intervals have right end point  $\geq \beta$ . We then repeat this process until all intervals are removed. If  $|S| \leq k$  we return True and otherwise we return False.

Observe that every time we place a center, we remove intervals it covers within distance  $r$ . Thus the final set  $S$  is a set of centers of radius  $r$ , and so if  $|S| \leq k$ , then  $r \geq r_{opt}$  and the algorithm correctly returns True. Moreover, we now argue that  $S$  is a minimum cardinality set of centers of radius  $r$ , and thus if  $|S| > k$  then the algorithm correctly returns False. Adopting notation from above, let  $[\alpha, \beta]$  be the interval with leftmost right endpoint, and

let  $c$  be the center our algorithm places at  $\beta + r$ . Now in the minimum cardinality solution, there must be at least one center  $c'$  within distance  $r$  from  $[\alpha, \beta]$ , implying the location of  $c'$  is  $\leq \beta + r$ . Thus  $c'$  can only  $r$ -cover intervals with left endpoint  $\leq \beta + 2r$ . However, as described above,  $c$   $r$ -covers all intervals with left endpoint  $\leq \beta + 2r$ , and thus  $c'$   $r$ -covers a subset of those  $c$  does. Conversely, the subset of intervals not  $r$ -covered by  $c$  is a subset of those not  $r$ -covered by  $c'$ . By induction our algorithm uses the smallest possible number of centers to  $r$ -cover the intervals not  $r$ -covered by  $c$ , which therefore is at most the number centers the global minimum solution uses to  $r$ -cover the superset of intervals not  $r$ -covered by  $c'$ . Thus overall our set of centers was an  $r$ -cover of minimum cardinality.

For the running time, observe that determining the location of the next center takes constant time since it only depends on the leftmost right endpoint, and we assumed we have the sorted ordering of the intervals by right endpoint. Moreover, we can remove all of the intervals intersecting the  $r$  radius ball at the new center in time linear in the number of intersecting intervals, since as discussed above these intersecting intervals are a prefix of the sorted ordering by left endpoint. As we spend constant time per interval removed, overall this is an  $O(n)$  time algorithm. ◀

Lemma 13 gives us a decision procedure for Problem 12 which we now wish to utilize to search for the optimum radius. We use the following lemma to reduce the search space, which can be seen as a simplification of Lemma 2 for the one dimensional case, where here we only need to consider distances from bisecting points rather than bisecting curves.

► **Lemma 14.** *Let  $\mathcal{C}$  be a set of closed intervals. Then for any value  $k$ , the optimal radius for the instance  $\mathcal{C}, k$  of Problem 12 is either 0 or  $\|C - C'\|/2$  for some pair  $C, C' \in \mathcal{C}$ .*

**Proof.** For any value  $k$ , let  $S$  be an optimal solution with optimal radius  $r_{opt}$ . Consider an arbitrary center  $s \in S$ , and let  $\mathcal{C}'$  be the subset of  $\mathcal{C}$  which intersects the ball  $B(s, r_{opt})$ . We can assume that  $|\mathcal{C}'| \geq 1$ , as otherwise  $B(s, r_{opt})$  does not intersect any interval and so  $s$  can be thrown out. If  $|\mathcal{C}'| = 1$ , then  $s$  intersects only one interval, and thus without loss of generality  $s$  can be placed inside this interval, i.e. at distance 0 from it. So assume  $|\mathcal{C}'| > 1$ , and let  $C$  be the furthest interval from  $s$  in  $\mathcal{C}'$ . As we move  $s$  towards  $C$ , so long as  $C$  remains the furthest interval from  $s$  in  $\mathcal{C}'$ ,  $B(s, \|s - C\|)$  will continue to intersect all intervals in  $\mathcal{C}'$ . If  $C$  always remains the furthest, when  $s$  eventually reaches  $C$ , its distance to  $C$  and hence all of  $\mathcal{C}'$  will be 0. Otherwise, if before we reach  $C$ ,  $s$  is no longer the furthest from  $s$ , then we must have crossed the bisector point between  $C$  and some other interval in  $\mathcal{C}'$ . In this case, we can place  $s$  on this bisector point and  $B(s, \|s - C\|)$  will intersect all intervals in  $\mathcal{C}'$ , and moreover  $\|s - C\| \leq r_{opt}$  since  $\|s - C\|$  monotonically decreased as we moved  $s$  towards  $C$ . Modifying all centers in  $S$  in this way thus produces a solution whose radius is  $\leq r_{opt}$  and is either 0 or the distance from a bisector point to either interval in the pair it bisects. ◀

Given a set  $\mathcal{C}$  of  $n$  intervals, let  $P(\mathcal{C})$  denote the set of all  $2n$  left and right endpoints of the intervals in  $\mathcal{C}$ . To find the optimal solution to an instance  $\mathcal{C}, k$  of Problem 12, by Lemma 14, we can binary search over the interpoint distances of points in  $P(\mathcal{C})$  using our decider from Lemma 13. (When we call the decider we divide the interpoint distance by two as Lemma 14 actually tells us it is a bisector distance.) As there are  $\Theta(n^2)$  interpoint distances, naively this approach takes  $O(n^2 \log n)$  time. However, [15] previously showed that in the abstract setting where one is given a linear time decider, and the optimal solution is an interpoint distance, one can find the optimal solution in  $O(n \log n)$  time. This is achieved by reducing the problem to searching in an implicitly defined sorted matrix, which we describe in the full version [22]. Below is the summarizing theorem.

► **Theorem 15.** *Problem 12 can be solved in  $O(n \log n)$  time, where  $n = |\mathcal{C}|$ .*

# Approximating Longest Spanning Tree with Neighborhoods

Ahmad Biniáz  

School of Computer Science, University of Windsor, Canada

---

## Abstract

We study the following maximization problem in the Euclidean plane: Given a collection of neighborhoods (polygonal regions) in the plane, the goal is to select a point in each neighborhood so that the longest spanning tree on selected points has maximum length. It is not known whether or not this problem is NP-hard. We present an approximation algorithm with ratio 0.548 for this problem. This improves the previous best known ratio of 0.511.

The presented algorithm takes linear time after computing a diameter. Even though our algorithm itself is fairly simple, its analysis is rather involved. In some part we deal with a minimization problem with multiple variables. We use a sequence of geometric transformations to reduce the number of variables and simplify the analysis.

## 1 Introduction

The spanning tree is a well-studied and fundamental structure in graph theory and combinatorics. The well-known minimum spanning tree (Min-ST) problem asks for a spanning tree with minimum total edge-weight. In contrast, the maximum spanning tree (Max-ST) problem asks for a spanning tree with maximum total edge-weight. In the context of abstract graphs, the two problems are algorithmically equivalent in the sense that an algorithm that finds a Min-ST can also find a Max-ST within the same time bound (by simply negating the edge weights), and vice versa. The situation is quite different in the context of geometric graphs where vertices are points in the plane and edge-weights are Euclidean distances between points. In geometric graphs, an algorithm that exploits geometry for finding a Min-ST is not necessarily useful for finding a Max-ST because there is no known geometric transformation between the “nearest” and “farthest” relations among points [22]. The existing geometric algorithms, for solving these two problems, exploit different sets of techniques.

Problems related to maximum configurations in the plane (also known as *long configurations*) have received considerable attention after the seminal work of Alon, Rajagopalan, and Suri [2]. In this paper we study the *longest spanning tree with neighborhoods* (Max-ST-NB) problem. We are given a collection of  $n$  neighborhoods (polygonal regions) in the Euclidean plane and we want to find a maximum-length tree that connects  $n$  representative points, one point from each neighborhood, as in Figure 1(a). The *length* of the tree is the total Euclidean length of its edges. Each *neighborhood* is the union of simple polygons, and the neighborhoods are not necessarily disjoint. The neighborhoods are assumed to be *colored* by  $n$  different colors. The classical Euclidean Max-ST problem is a special case of the Max-ST-NB in which each neighborhood consists of exactly one point, as in Figure 1(b). Although the Euclidean Max-ST problem can be solved in  $O(n \log n)$  time [22], it is not known whether or

not the Max-ST-NB problem can be solved in polynomial time. The difficulty lies in choosing representative points from neighborhoods; once these points are selected, the problem is reduced to the Euclidean Max-ST problem.

■ **Figure 1** (a) Longest spanning tree with four polygonal neighborhoods that are colored red, green, blue, and purple. (b) Euclidean maximum spanning tree.

It is easily seen (see Section 2) that the longest star (which connects a point in one neighborhood to a point in each of the other neighborhoods) achieves a 0.5-approximate solution for the Max-ST-NB problem. Recently, Chen and Dumitrescu [10] present an approximation algorithm with ratio 0.511, which is the first improvement beyond 0.5.

Although any optimal solution for the Max-ST problem contains a diametral pair (two points with maximum distance) as an edge, an optimal solution for the Max-ST-NB problem does not necessarily contain any bichromatic diametral pair (two points with maximum distance that belong to different neighborhoods). Another result of Chen and Dumitrescu [10] shows that any algorithm, that always includes a bichromatic diametral pair in the solution, cannot achieve an approximation ratio better than  $\sqrt{2} - \sqrt{3} \approx 0.517$ . This somehow breaks the hope of getting a good approximation ratio by using greedy techniques. Thus, to improve the ratio beyond 0.517 one needs to employ some nontrivial ideas.

## 1.1 Our contributions and approach

We present an approximation algorithm for the Max-ST-NB problem with improved ratio  $\frac{\sqrt{7}-1}{3} \approx 0.548$ . Our algorithm is not complicated: We compute a double-star (a tree of diameter 3) centered at a bichromatic diametral pair, and compute up to three stars (trees of diameter 2) centered at points on the smallest enclosing circle, and then report the longest one. Our algorithm takes linear time after computing a bichromatic diameter. Our analysis involves a minimization problem with multiple variables. We employ a sequence of geometric transformations to reduce the number of variables and simplify the analysis. The following theorem summarizes our main contribution.

► **Theorem 1.** *A 0.548-approximation for the longest spanning tree with neighborhoods can be computed in linear time after computing a bichromatic diameter.*

As a minor result we improve the upper bound 0.517 on the approximation ratio of algorithms that always include a bichromatic diameter in their solutions. We show that the ratio of such algorithms cannot be better than 0.5. This upper bound is tight because there exists a 0.5-approximation algorithm that always includes a bichromatic diameter (see Section 2). Therefore, to obtain a ratio of better than 0.5 one should take into account also spanning trees that do not contain any bichromatic diameter.

## 1.2 Related problems and applications

The Max-ST-NB problem has the same flavor as the Euclidean group Steiner tree problem in which we are given  $n$  groups of points in the plane and the goal is to find a shortest tree that contains “at least” one point from each group. The group Steiner tree problem in graphs is NP-hard and cannot be approximated by a factor  $O(\log^{2-\epsilon} n)$  for any  $\epsilon > 0$  [16]. The Max-ST-NB also lies in the concept of *imprecision* in computational geometry where each input point is provided as a region of uncertainty and the exact position of the point may be anywhere in the region; see e.g. [13, 18]. Analogous problems have been studied for other structures, e.g., minimum spanning tree with neighborhoods [8, 13, 25], traveling salesman tour with neighborhoods [3, 20, 21] (which is APX-hard [12]), and convex hulls [18, 23], to name a few. We refer the interested readers to the thesis of Löffler [17].

The maximum spanning tree and related problems, in addition to their fundamental nature, find applications in worst-case analysis of various heuristics in combinatorial optimization [2], and in approximating maximum triangulations [5, pp. 338]. They also appear in clustering algorithms where one needs to partition a set of entities into well-separated and homogeneous clusters [4, 22]. Maximum spanning trees are directly related to computing diameter and farthest neighbors which are fundamental problems in computational geometry, with many applications [1].

## 2 Preliminaries for the algorithm

The output of our algorithm is either a star or a double-star. A *star*, centered at a vertex  $p$ , is a tree in which every edge is incident to  $p$ . A *double-star*, centered at two vertices  $p$  and  $q$ , is a tree that contains the edge  $pq$  and its every other edge is incident to either  $p$  or  $q$ .

Let  $P$  be a set of points in the Euclidean plane. The *smallest enclosing disk* for  $P$  is the smallest disk that contains all the points of  $P$ . A *diametral pair* of  $P$  is a pair of points in  $P$  that attain the maximum distance. If the points in  $P$  are colored, then a *bichromatic diametral pair* of  $P$  is defined as a pair of points in  $P$  with different colors that attain the maximum distance. The *center of mass* of  $P$  (also known as the *centroid*) is a point  $m$  in the plane such that for any arbitrary point  $u$  in the plane we have

$$\sum_{p \in P} \vec{up} = |P| \cdot \vec{um}. \quad (1)$$

The intersection of two disks is called a *lens*. We denote the Euclidean distance between two points  $p$  and  $q$  in the plane by  $|pq|$ . In our context, a *geometric graph* is a graph whose vertices are points in the plane and whose edges are straight line segments. The length of a geometric graph  $G$ , denoted by  $\text{len}(G)$ , is the total Euclidean length of its edges.

### A simple 0.5-approximation algorithm

Chen and Dumitrescu [10] pointed out the following simple 0.5-approximation algorithm for the Max-ST-NB problem (a similar approach was previously used in [2] and [14]). Take a bichromatic diametral pair  $(a, b)$  from the given  $n$  neighborhoods;  $a$  and  $b$  belong to two different neighborhoods. Choose an arbitrary point from each of the other  $n-2$  neighborhoods. Let  $S_a$  be the star obtained by connecting  $a$  to  $b$  and to all chosen points. Define  $S_b$  analogously on the same point set. Every edge of any optimal solution  $T^*$  has length at most  $|ab|$ , and thus  $\text{len}(T^*) \leq (n-1)|ab|$ . By the triangle inequality  $\text{len}(S_a) + \text{len}(S_b) \geq n|ab| \geq \text{len}(T^*)$ . Therefore the longer of  $S_a$  and  $S_b$  is a 0.5-approximate solution for the problem.

### 3 The approximation algorithm

In this section we prove Theorem 1. Put  $\delta = \frac{\sqrt{7}-1}{3} \approx 0.548$ .

To facilitate comparisons we use the same notation as of Chen and Dumitrescu [10]. Let  $\mathcal{X} = \{X_1, X_2, \dots, X_n\}$  be the given collection of  $n$  polygonal neighborhoods of total  $N$  vertices. We assume that each  $X_i$  is colored by a unique color. Our algorithm selects representative points only from boundary vertices of polygonal neighborhoods. Thus, in the algorithm (but not in the analysis) we consider each polygonal neighborhood  $X_i$  as the set of its boundary vertices, and consequently we consider  $\mathcal{X}$  as a collection of  $N$  points colored by  $n$  colors. Define the *longest spanning star* centered at a point  $p \in X_i$  as the star connecting  $p$  to its farthest point in every other neighborhood.

#### The algorithm

The main idea of the algorithm is simple: we compute a spanning double-star  $D$  and (at most) three spanning stars  $S_1, S_2, S_3$ , and then report the longest one.

We compute  $D$  as follows. Let  $(a, b)$  be a bichromatic diametral pair of  $\mathcal{X}$ . After a suitable relabeling assume that  $a \in X_1$  and  $b \in X_2$ . Add the edge  $ab$  to  $D$ . For each  $X_i$ , with  $i \in \{3, \dots, n\}$ , find a vertex  $p_i \in X_i$  that is farthest from  $a$  and find a vertex  $q_i \in X_i$  that is farthest from  $b$  (it might be the case that  $p_i = q_i$ ). If  $|ap_i| \geq |bq_i|$  then add  $ap_i$  to  $D$  otherwise add  $bq_i$  to  $D$ . Observe that  $D$  spans all neighborhoods in  $\mathcal{X}$ , and each edge of  $D$  has length at least  $|ab|/2$ , as in Figure 2(a). Now we introduce the stars. Let  $C$  be the smallest enclosing disk for  $\mathcal{X}$ . Notice that the boundary of  $C$  contains at least two points of  $\mathcal{X}$ . If it contains exactly two points then we define  $S_1$  and  $S_2$  as the two longest spanning stars that are centered at these points (in this case we do not have  $S_3$ ). If it contains three or more points then there exist three of them such that the triangle formed by those points contains the center of  $C$  [11, Chapter 4, Section 4.7]. In this case we define  $S_1, S_2$ , and  $S_3$  as the three longest spanning stars that are centered at those three points, as in Figure 2(b).

■ **Figure 2** Illustration of the algorithm: (a) the double-star  $D$ , and (b) the stars  $S_1, S_2$ , and  $S_3$ .

#### Running time analysis

The smallest enclosing disk  $C$  for  $\mathcal{X}$  can be computed in  $O(N)$  time [9, 19, 24]. The result of [7], that computes a maximum spanning tree on multicolored points, implies that a bichromatic diametral pair  $(a, b)$  for  $\mathcal{X}$  can be found in  $O(N \log N \log n)$  time (the algorithm of Bhattacharya and Toussaint [6] also computes a bichromatic diameter, but only for two-colored points). The rest of our algorithm (finding farthest points from  $a, b$ , and from the points on the boundary of  $C$ ) takes  $O(N)$  time.

### 3.1 Analysis of the approximation ratio

Our main plan for analysis works as follows: we show that if the radius of  $C$  is at least  $\delta$  then one of the stars  $S_i$  is a desired tree, otherwise the double-star  $D$  is a desired tree.

For the analysis we consider  $\mathcal{X}$  as the initial collection of polygonal neighborhoods. Let  $T^*$  denote a longest spanning tree with neighborhoods in  $\mathcal{X}$ . It is not hard to see that for any point in the plane, its farthest point in a polygon  $P$  must be a vertex of  $P$  (see also [11, Chapter 7, Section 7.4]). Thus, any bichromatic diameter of  $\mathcal{X}$  is introduced by two vertices of polygons in  $\mathcal{X}$ . Hence the pair  $(a, b)$ , selected in the algorithm, is a bichromatic diameter of the initial collection  $\mathcal{X}$ . Therefore,  $|ab|$  is an upper bound for the length of edges in  $T^*$ . After a suitable scaling assume that  $|ab| = 1$ . Since  $T^*$  has  $n - 1$  edges,

$$\text{len}(T^*) \leq (n - 1)|ab| = n - 1. \tag{2}$$

Recall the smallest enclosing disk  $C$  from the algorithm. Let  $c$  denote the center of  $C$  and  $r$  denote its radius. If the boundary of  $C$  has exactly two points of  $\mathcal{X}$  then denote them by  $c_1$  and  $c_2$ . In this case the segment  $c_1c_2$  is a diameter of  $C$ ; see [11, Chapter 4, Section 4.7]. If the boundary of  $C$  has three or more points of  $\mathcal{X}$  then denote the three points (that are chosen in the algorithm) by  $c_1, c_2$ , and  $c_3$ . In this case the triangle  $c_1c_2c_3$  is acute and it contains the center  $c$ ; see [11, Chapter 4, Section 4.7]. Recall the longest spanning stars  $S_1, S_2, S_3$  from the algorithm. After a suitable relabeling assume that the star  $S_i$  is centered at the point  $c_i$ .

► **Lemma 2.** *If  $r \geq \delta$  and the boundary of  $C$  contains exactly two points of  $\mathcal{X}$  then*

$$\max\{\text{len}(S_1), \text{len}(S_2)\} \geq \delta \cdot \text{len}(T^*).$$

**Proof.** In this case  $c_1c_2$  is a diameter of  $C$ , and thus  $|c_1c_2| = 2r \geq 2\delta$ . We consider two cases depending on similarity of colors of  $c_1$  and  $c_2$ .

- The points  $c_1$  and  $c_2$  have different colors. This case is depicted in Figure 3(a). After a suitable relabeling assume that  $c_1 \in X_1$  and  $c_2 \in X_2$ . Pick an arbitrary point  $p_i$  from each  $X_i$  with  $i \in \{3, \dots, n\}$ . Let  $S'_1$  be the spanning star with center  $c_1$  that connects  $c_1$  to all  $p_i$ s and to  $c_2$ . Let  $S'_2$  be the spanning star with center  $c_2$  that connects  $c_2$  to all  $p_i$ s and to  $c_1$ . Since  $S_1$  and  $S_2$  are longest spanning stars centered at  $c_1$  and  $c_2$ , it holds that  $\text{len}(S'_1) \leq \text{len}(S_1)$  and  $\text{len}(S'_2) \leq \text{len}(S_2)$ . By bounding the maximum with the average, then using the triangle inequality and (2) we get:

$$\begin{aligned} \max\{\text{len}(S_1), \text{len}(S_2)\} &\geq \max\{\text{len}(S'_1), \text{len}(S'_2)\} \geq \frac{1}{2}(\text{len}(S'_1) + \text{len}(S'_2)) \\ &= \frac{1}{2} \left( |c_1c_2| + |c_1c_2| + \sum_{i=3}^n (|c_1p_i| + |p_ic_2|) \right) \\ &\geq \frac{1}{2} \left( 2|c_1c_2| + \sum_{i=3}^n |c_1c_2| \right) = \frac{|c_1c_2|}{2} \cdot n \geq \delta \cdot n \geq \delta \cdot \text{len}(T^*). \end{aligned}$$

- The points  $c_1$  and  $c_2$  have the same color. Assume that  $c_1, c_2 \in X_1$ . Pick an arbitrary point  $p_i$  from each  $X_i$  with  $i \in \{2, \dots, n\}$ . Let  $S'_1$  be the spanning star that connects  $c_1$  to all  $p_i$ s. Let  $S'_2$  be the spanning star that connects  $c_2$  to all  $p_i$ s. Notice that  $\text{len}(S'_1) \leq \text{len}(S_1)$  and  $\text{len}(S'_2) \leq \text{len}(S_2)$ . Similar to the previous case we have:

$$\max\{\text{len}(S_1), \text{len}(S_2)\} \geq \frac{1}{2} \sum_{i=2}^n (|c_1p_i| + |p_ic_2|) \geq \frac{|c_1c_2|}{2} \cdot (n - 1) \geq \delta \cdot \text{len}(T^*). \quad \blacktriangleleft$$

7:6 Approximating Longest Spanning Tree with Neighborhoods

■ **Figure 3** Illustration of the proofs of (a) Lemma 2, (b) Lemma 3, and (c) Lemma 4.

► **Lemma 3.** *If the boundary of  $C$  contains three or more points of  $\mathcal{X}$  then for any point  $m$  in the plane there exists a point  $c_j \in \{c_1, c_2, c_3\}$  such that  $|c_j m| \geq r$ .*

**Proof.** Let  $C_i$  be the disk of radius  $r$  centered at each  $c_i$ . The boundary of each  $C_i$  passes through the center  $c$  of  $C$ , as in Figure 3(b). Since the triangle  $c_1 c_2 c_3$  contains  $c$  it holds that  $C_1 \cap C_2 \cap C_3 = c$ . Therefore there exists a disk  $C_j$  that does not have  $m$  in its interior, and thus  $|c_j m| \geq r$ . ◀

► **Lemma 4.** *If  $r \geq \delta$  and the boundary of  $C$  contains three or more points of  $\mathcal{X}$  then*

$$\max\{\text{len}(S_1), \text{len}(S_2), \text{len}(S_3)\} \geq \delta \cdot \text{len}(T^*).$$

**Proof.** In this case the triangle  $c_1 c_2 c_3$  contains the center  $c$  of  $C$ . We consider three cases depending on similarity of colors of  $c_1$ ,  $c_2$ , and  $c_3$ .

- The points  $c_1, c_2, c_3$  have pairwise distinct colors. Thus, they belong to three different neighborhoods. After a suitable relabeling assume that  $c_1 \in X_1, c_2 \in X_2$ , and  $c_3 \in X_3$ . Pick an arbitrary point from each  $X_i$  with  $i \in \{4, \dots, n\}$ . Denote the selected points by  $P$ . Let  $m$  be the center of mass of  $P$ . By Lemma 3 there exists a point  $c_j \in \{c_1, c_2, c_3\}$  where  $|c_j m| \geq r$ . After a suitable relabeling assume that  $c_j = c_1$ , and thus  $|c_1 m| \geq r$ . By (1) we get

$$\sum_{p \in P} |c_1 p| \geq |P| \cdot |c_1 m| \geq (n-3) \cdot r \geq (n-3) \cdot \delta.$$

Let  $S'_1$  be the star that connects  $c_1$  to all points of  $P$  and to  $c_2$  and  $c_3$ . Since  $S_1$  is the longest spanning star centered at  $c_1$ , we have that  $\text{len}(S_1) \geq \text{len}(S'_1)$ . Since the triangle  $c_1 c_2 c_3$  contains  $c$ , we have  $|c_2 c_1| + |c_3 c_1| \geq |c_2 c| + |c_3 c| = 2r \geq 2\delta$ . These inequalities and (2) give

$$\text{len}(S_1) \geq \text{len}(S'_1) = |c_1 c_2| + |c_1 c_3| + \sum_{p \in P} |c_1 p| \geq 2\delta + (n-3) \cdot \delta = (n-1) \cdot \delta \geq \delta \cdot \text{len}(T^*).$$

- All points  $c_1, c_2, c_3$  have the same color. Assume that  $c_1, c_2, c_3 \in X_1$ . Pick an arbitrary point from each  $X_i$  with  $i \in \{2, \dots, n\}$ . Denote the selected points by  $P$ . Let  $m$  be the centroid of  $P$ , and let  $c_1$  be the point in  $\{c_1, c_2, c_3\}$  for which  $|c_1 m| \geq r$  (by Lemma 3). Let  $S'_1$  be the star that connects  $c_1$  to all points of  $P$ . Similar to the previous case by using (1) we get

$$\text{len}(S_1) \geq \text{len}(S'_1) \geq \sum_{p \in P} |c_1 p| \geq |P| \cdot |c_1 m| \geq (n-1) \cdot r \geq (n-1) \cdot \delta \geq \delta \cdot \text{len}(T^*).$$

- Only two of  $c_1, c_2, c_3$  have the same color. This case is depicted in Figure 3(c). Assume that  $c_2$  and  $c_3$  have the same color and they belong to  $X_2$ . Also assume that  $c_1 \in X_1$ . We handle this case in a slightly different way; this is because if the point  $c_j$  from Lemma 3 (which would have distance at least  $r$  to the centroid) belongs to  $\{c_2, c_3\}$  then there is no guarantee that  $|c_j c_1| \geq \delta$ , and hence we may not be able to establish the lower bound  $\delta \cdot (n - 1)$ .

Pick an arbitrary point from each  $X_i$  with  $i \in \{3, \dots, n\}$ . Let  $P$  be the set containing all selected points together with the point  $c_1$ . Let  $m$  be the centroid of  $P$ . Consider the point  $c_j$  (from Lemma 3) for which  $|c_j m| \geq r$ . If  $c_j = c_2$  then let  $S'_2$  be the star that connects  $c_2$  to all points of  $P$ . In this case

$$\text{len}(S_2) \geq \text{len}(S'_2) = \sum_{p \in P} |c_2 p| \geq |P| \cdot |c_2 m| \geq (n - 1) \cdot r \geq (n - 1) \cdot \delta \geq \delta \cdot \text{len}(T^*).$$

If  $c_j = c_3$  then by a similar argument we can show that  $\text{len}(S_3) \geq \delta \cdot \text{len}(T^*)$ .

Now assume that  $c_j = c_1$ , and thus  $|c_1 m| \geq r$ . Let  $P' = P \setminus \{c_1\}$ , and let  $m'$  be the centroid of  $P'$ . Using the recursive definition of centroid [15] (based on the Euclidean rule of the lever) the point  $m$  lies on the segment  $c_1 m'$ , as in Figure 3(c). Informally speaking, if we remove  $c_1$  from  $P$  then its (new) centroid moves away from  $c_1$ . Therefore  $|c_1 m'| \geq |c_1 m| \geq r$ . Let  $S'_1$  be the star obtained by connecting  $c_1$  to all points of  $P'$  and to the one of  $c_2$  and  $c_3$  that is farther from  $c_1$ . Assume that  $c_2$  is the farther one, and notice that  $|c_1 c_2| \geq r$ . Then,

$$\begin{aligned} \text{len}(S_1) &\geq \text{len}(S'_1) = |c_1 c_2| + \sum_{p \in P'} |c_1 p| \geq r + |P'| \cdot |c_1 m'| \\ &\geq r + (n - 2) \cdot r \geq \delta \cdot \text{len}(T^*). \end{aligned} \quad \blacktriangleleft$$

Lemmas 2 and 4 take care of our analysis for the case where the radius  $r$  of  $C$  is at least  $\delta$ . The next lemma takes care of the case where  $r \leq \delta$  by showing that in this case the double-star  $D$  is a desired tree. We employ a collection of geometric transformations to simplify the proof.

► **Lemma 5.** *If  $r \leq \delta$  then  $\text{len}(D) \geq \delta \cdot \text{len}(T^*)$ .*

**Proof.** Recall  $(a, b)$  as a bichromatic diametral pair of  $\mathcal{X}$ . Also recall our assumptions that  $a \in X_1$ ,  $b \in X_2$ , and that  $|ab| = 1$ .

One challenge that we face here is that the vertices of our double-star  $D$  could be different from the vertices of the optimal tree  $T^*$ ; this could make it difficult to obtain a lower bound for the length of  $D$  in terms of the length of  $T^*$ . But we know that the vertices of both  $D$  and  $T^*$  come from the same ground sets  $X_1, \dots, X_n$ . Our plan is to compare the length of  $D$  with the length of  $T^*$  by comparing the lengths of their edges separately. For each  $i \in \{1, \dots, n\}$  let  $p_i^*$  and  $p_i$  be the vertices of  $T^*$  and  $D$  that belong to  $X_i$ , respectively (it might be that  $p_i^* = p_i$ ). Notice that  $a = p_1$  and  $b = p_2$ . Direct all edges of  $T^*$  towards  $p_1^*$  and direct all edges of  $D$  towards  $p_1$ . To each vertex of  $T^*$  and  $D$  (except  $p_1^*$  and  $p_1$ ) assign its unique outgoing edge. For each  $i \in \{2, \dots, n\}$  let  $\text{len}(p_i^*)$  and  $\text{len}(p_i)$  be the length of edges that are assigned to  $p_i^*$  and  $p_i$ , respectively. We already know that  $\text{len}(p_2) = |ab| = 1$  and  $\text{len}(p_i^*) \leq |ab| = 1$  for all  $i$ . Thus, in order to show that  $\text{len}(D) \geq \delta \cdot \text{len}(T^*)$  it suffices to show that  $\text{len}(p_i) \geq \delta \cdot \text{len}(p_i^*)$  for each  $i \in \{3, \dots, n\}$ . From the optimization point of view, we are interested in the minimum value of the ratio

$$\frac{\text{len}(p_i)}{\text{len}(p_i^*)} \tag{3}$$

over all pairs  $(p_i, p_i^*)$ . In particular we want this value to be at least  $\delta$ .

## 7:8 Approximating Longest Spanning Tree with Neighborhoods

From now on we consider a fixed value of  $i \in \{3, \dots, n\}$ . For brevity we write  $p$  for  $p_i$ ,  $p^*$  for  $p_i^*$ , and  $X$  for  $X_i$ . In the rest of this section we will show that  $\text{len}(p) \geq \delta \cdot \text{len}(p^*)$ . Recall from the algorithm that  $p$  is connected to the farther of  $a$  and  $b$ , and thus  $\text{len}(p) = \max\{|pa|, |pb|\}$ . Let  $D(a, \delta)$  and  $D(b, \delta)$  be the disks of radii  $\delta$  that are centered at  $a$  and  $b$ , respectively. If  $p$  is outside  $D(a, \delta)$  then  $\text{len}(p) \geq |pa| \geq \delta \geq \delta \cdot \text{len}(p^*)$ . Likewise, if  $p$  is outside  $D(b, \delta)$  then  $\text{len}(p) \geq \delta \cdot \text{len}(p^*)$ , and we are done.

In the rest of this section we assume that  $p$  is in the lens  $L = D(a, \delta) \cap D(b, \delta)$  which is depicted in Figure 4(a). In the current setting, the neighborhood  $X$  (which contains  $p$ ) lies entirely in  $L$  because otherwise our algorithm would have picked a point of  $X$  outside  $L$ . Therefore, the point  $p^*$  (which also belongs to  $X$ ) lies in  $L$ . Moreover  $\max\{|ap|, |bp|\} \geq \max\{|ap^*|, |bp^*|\}$  because otherwise our algorithm would have picked  $p^*$  instead of  $p$ . Thus, in view of (3), it suffices to show that

$$\frac{\max\{|ap^*|, |bp^*|\}}{\text{len}(p^*)} \geq \delta. \quad (4)$$

For any point  $q$  in disk  $C$  let  $q_C$  be the intersection point of the boundary of  $C$  with the ray emanating from  $q$  and passing through the center  $c$ ; Figure 4(a) depicts this for point  $q = p^*$ . The point  $q_C$  is the farthest point of  $C$  from  $q$ . Thus the largest possible length of the edge of  $T^*$  that is assigned to  $p^*$  is  $|p^*p_C^*|$ , that is,  $\text{len}(p^*) \leq |p^*p_C^*|$ . Thus, in view of (4), it suffices to show that

$$\frac{\max\{|ap^*|, |bp^*|\}}{|p^*p_C^*|} \geq \delta. \quad (5)$$

Inequality (5) deals with a minimization problem which has multiple variables, including the coordinates of  $a$ ,  $b$ ,  $p^*$ , and  $c$ . We use a sequence of geometric transformations to reduce the number of variables and simplify the analysis. Our transformations will not increase the ratio in (5).

If we increase the radius of  $C$  (while fixing its center  $c$ ) then  $|p^*p_C^*|$  would increase but  $|ap^*|$  and  $|bp^*|$  remain unchanged. Thus, for the purpose of (5) we can assume that  $C$  has maximum possible radius which is  $\delta$ . Then, for any point  $q \in C$  it holds that  $|qq_C| = |qc| + |cq_C| = |qc| + \delta$ .

Let  $\ell(a, b)$  be the line through  $a$  and  $b$ . If  $p^*$  lies in the same side of  $\ell(a, b)$  as  $c$  does, then let  $\bar{p}^*$  be the reflection of  $p^*$  with respect to  $\ell(a, b)$ . Notice that  $\bar{p}^*$  also lies in lens  $L$ . Moreover  $|\bar{a}\bar{p}^*| = |ap^*|$  and  $|\bar{b}\bar{p}^*| = |bp^*|$ , but  $|p^*p_C^*| \leq |\bar{p}^*\bar{p}_C^*|$ . Thus, in view of (5), the point  $\bar{p}^*$  achieves a smaller ratio than  $p^*$ . Therefore we can assume that  $p^*$  lies in a different side of  $\ell(a, b)$  than  $c$  does.

Let  $\mathcal{L}$  denote the configuration that is the union of the lens  $L$ , the segment  $ab$ , and the point  $p^*$ . Notice that any translation, rotation, and reflection of  $\mathcal{L}$  will not change  $|ap^*|$  and  $|bp^*|$ . Move  $\mathcal{L}$  along the ray, that is emanating from  $c$  and passing through  $p^*$ , and stop as soon as one of  $a$  and  $b$  lies on the boundary of  $C$ . Assume that  $b$  is the point that lies on  $C$ . This translation can only increase  $|p^*p_C^*|$ , but not decrease. Now fix  $\mathcal{L}$  at  $b$  and rotate it in the direction, that moves  $p^*$  away from  $c$ , until  $a$  also lies on the boundary of  $C$ . The lens  $L$  is small enough and does not intersect the boundary of  $C$  after rotation. This rotation can only increase  $|p^*p_C^*|$ , but not decrease. (Such a rotation moves  $p_C^*$  on the boundary of  $C$ , but that does not affect the argument because the value  $|cp_C^*|$ , which is equal to the radius of  $C$ , remains unchanged.) Therefore, above transformations do not increase the ratio in (5). After these transformations assume, without loss of generality, that  $ab$  is horizontal,  $a$  is to the left of  $b$ , and  $c$  lies above  $ab$ . The current setting is depicted in Figure 4(b). Notice that

■ **Figure 4** Illustration of (a) the lens  $L$  and the point  $p_C^*$  associated with  $p^*$ , (b) the configuration  $\mathcal{L}$  after translation and rotation, (c) the points  $q, c_1, c_2$ .

$|p^*p_C^*| = |cp^*| + |cp_C^*| = |cp^*| + \delta$ . Due to symmetry we may assume that  $p^*$  lies to the right side of the vertical line through  $c$ , and thus  $|ap^*| \geq |bp^*|$ , as in Figure 4(c). In view of (5), in the current setting our goal is to show that

$$\frac{|ap^*|}{|cp^*| + \delta} \geq \delta. \tag{6}$$

Let  $q$  be the intersection point of  $ap^*$  with the vertical line through  $c$ , as in Figure 4(c). Then  $|ap^*| = |aq| + |qp^*|$  and  $|cp^*| \leq |cq| + |qp^*|$ . Thus,

$$\frac{|ap^*|}{|cp^*| + \delta} \geq \frac{|aq| + |qp^*|}{|cq| + |qp^*| + \delta} \geq \frac{|aq|}{|cq| + \delta},$$

where the second inequality is valid because we subtract the same amount  $|qp^*|$  from the numerator and denominator of a fraction which is smaller than 1 (notice that  $|aq| < |cq| + \delta$ ). Thus, for showing (6) it suffices to show that

$$\frac{|aq|}{|cq| + \delta} \geq \delta. \tag{7}$$

Recall the definition of  $L$ , and notice that its topmost point lies on the center  $c$ . Let  $c_1$  be the intersection point of  $ab$  with the vertical line through  $c$ , and let  $c_2$  be the lowest point of  $L$ ; see Figure 4(c). Then  $|cc_1| = |c_1c_2|$ ,  $|ac| = |ac_2| = \delta$ , and  $|ac_1| = 1/2$ . Notice that  $q$  lies on the segment  $c_1c_2$ , and  $|cq| = |cc_1| + |qc_1|$ . Denote the length  $|qc_1|$  by  $x$ . Then  $0 \leq x \leq |c_1c_2|$ . Using the Pythagorean theorem we get  $|aq| = \sqrt{x^2 + 1/4}$  and  $|c_1c_2| = \sqrt{\delta^2 - 1/4}$ . Thus we can write the ratio in (7) as a function  $f$  which depends only on  $x$ :

$$f(x) = \frac{|aq|}{|cq| + \delta} = \frac{\sqrt{x^2 + 1/4}}{x + \delta + \sqrt{\delta^2 - 1/4}},$$

where  $x \in [0, \sqrt{\delta^2 - 1/4}]$ . The function  $f(x)$  is decreasing on this interval of  $x$  and thus its minimum value is attained at  $\sqrt{\delta^2 - 1/4}$ . Plugging this into  $f$  we get  $f(\sqrt{\delta^2 - 1/4}) = \frac{\sqrt{7}-1}{3} = \delta$ . This verifies (7) and finishes the proof of the lemma. ◀

The cases considered in Lemmas 2, 4, and 5 ensure that the length of one of  $S_1, S_2, S_3$ , and  $D$  is at least  $\delta \cdot \text{len}(T^*)$ . This concludes our analysis and finishes the proof of Theorem 1.

### 3.2 Inclusion of bichromatic diameter

Here we show that the approximation ratio of an algorithm, that always includes a bichromatic diametral pair in its solution, cannot be larger than 0.5.

■ **Figure 5** Illustration of the upper bound 0.5 for inclusion of a bichromatic diametral pair.

We introduce an input instance with  $n$  neighborhoods. Consider four points  $p_0 = (0, 0)$ ,  $p_1 = (1, 0)$ ,  $p_2 = (2, 0)$ , and  $p_3 = (3 - 2\varepsilon, 0)$  for arbitrary small  $\varepsilon > 0$ , e.g.  $\varepsilon = 1/n$ . Our input consists of neighborhoods  $X_1, \dots, X_n$  where  $X_1 = \{p_0, p_3\}$ ,  $X_2 = \{p_2\}$ , and each of  $X_3, \dots, X_n$  has exactly one point that is placed at distance at most  $\varepsilon$  from  $p_1$ ; see Figure 5. In this setting,  $(p_0, p_2)$  is the unique bichromatic diametral pair. Consider any tree  $T$  that contains the bichromatic diameter  $p_0p_2$  (this means that  $p_3$  is not in  $T$ ). Any edge of  $T$  incident to  $X_3, \dots, X_n$  has length at most  $1 + \varepsilon$ . Therefore  $\text{len}(T) \leq 2 + (1 + \varepsilon)(n - 2) < n + 1$ . Now consider the tree  $T^*$  that does not contain  $p_0p_2$  but connects each of  $X_2, \dots, X_n$  to  $p_3$ . The length of  $T^*$  is at least  $(1 - 2\varepsilon) + (2 - 3\varepsilon)(n - 2) > 2n - 6$ . Then, the ratio

$$\frac{\text{len}(T)}{\text{len}(T^*)} < \frac{n + 1}{2n - 6}$$

tends to  $1/2$  in the limit. This establishes the upper bound 0.5 on the approximation ratio.

## 4 Conclusions

A natural open problem is to further improve the approximation ratio for the Max-ST-NB problem. We believe that our algorithm has better approximation guarantee, however this requires more detailed analysis. We obtained the ratio of 0.548 by analyzing the stars  $S_1, S_2, S_3$  and the double-star  $D$  separately. One might be able to improve the ratio by analyzing the stars and the double-star together and then taking the longest one.

## Abstract

We propose a self-improving algorithm for computing Voronoi diagrams under a given convex distance function with constant description complexity. The  $n$  input points are drawn from a hidden mixture of product distributions; we are only given an upper bound  $m = o(\sqrt{n})$  on the number of distributions in the mixture, and the property that for each distribution, an input instance is drawn from it with a probability of  $\Omega(1/n)$ . For any  $\varepsilon \in (0, 1)$ , after spending  $O(mn \log^{O(1)}(mn) + m^\varepsilon n^{1+\varepsilon} \log(mn))$  time in a training phase, our algorithm achieves an  $O(\frac{1}{\varepsilon} n \log m + \frac{1}{\varepsilon} n 2^{O(\log^* n)} + \frac{1}{\varepsilon} H)$  expected running time with probability at least  $1 - O(1/n)$ , where  $H$  is the entropy of the distribution of the Voronoi diagram output. The expectation is taken over the input distribution and the randomized decisions of the algorithm. For the Euclidean metric, the expected running time improves to  $O(\frac{1}{\varepsilon} n \log m + \frac{1}{\varepsilon} H)$ .

## 1 Introduction

Self-improving algorithms, proposed by Ailon et al. [1], is a framework for studying algorithmic complexity beyond the worst case. There is a *training phase* that allows some auxiliary structures about the input distribution to be constructed. In the *operation phase*, these auxiliary structures help to achieve an expected running time, called the *limiting complexity*, that may surpass the worst-case optimal time complexity.

Self-improving algorithms have been designed for *product distributions* [1, 11]. Let  $n$  be the input size. A product distribution  $\mathcal{D} = (D_1, \dots, D_n)$  consists of  $n$  distributions  $D_i$  such that the  $i$ th input item is drawn independently from  $D_i$ . It is possible that  $D_i = D_j$  for some  $i \neq j$ , but the draws of the  $i$ th and  $j$ th input items are independent. No further information about  $\mathcal{D}$  is given. Sorting, Delaunay triangulation, 2D maxima, and 2D convex hull have been studied for product distributions. For all four problems, the training phase uses  $O(n^\varepsilon)$  input instances, and the space complexity is  $O(n^{1+\varepsilon})$ . The limiting complexities of sorting and Delaunay triangulation are  $O(\frac{1}{\varepsilon} n + \frac{1}{\varepsilon} H_{\text{out}})$  for any  $\varepsilon \in (0, 1)$ , where  $H_{\text{out}}$  is the entropy of the output distribution [1]. The limiting complexities for 2D maxima and 2D convex hull are  $O(\text{OptM} + n)$  and  $O(\text{OptC} + n \log \log n)$  respectively, where  $\text{OptM}$  and  $\text{OptC}$  are the expected depths of the optimal linear decision trees for the two problems [11].

Extensions that allow dependence among input items have been developed. One extension is that there is a *hidden partition* of  $[n]$  into groups. The input items with indices in the  $k$ th group follow some *hidden functions* of a common parameter  $u_k$ . The parameters  $u_1, u_2, \dots$  follow a product distribution. The partition of  $[n]$  is not given though. If the hidden functions

are known to be linear, sorting can be solved in a limiting complexity of  $O(\frac{1}{\varepsilon}n + \frac{1}{\varepsilon}H_{\text{out}})$  after a training phase that takes  $O(n^2 \log^3 n)$  time [8]. If it is only known that each hidden function has  $O(1)$  extrema and the graphs of two functions intersect in  $O(1)$  places (without knowing any of the functions, or any of these extrema and intersections), sorting can be solved in a limiting complexity of  $O(n + H_{\text{out}})$  after an  $\tilde{O}(n^3)$ -time training phase [7]. For the Delaunay triangulation problem, if it is known that the hidden functions are bivariate polynomials of  $O(1)$  degree (without knowing the polynomials), a limiting complexity of  $O(n\alpha(n) + H_{\text{out}})$  can be achieved after a polynomial-time training phase [7].

Another extension is that the input instance  $I$  is drawn from a *hidden mixture* of at most  $m$  product distributions. That is, there are at most  $m$  product distributions  $\mathcal{D}_1, \mathcal{D}_2, \dots$  such that  $\Pr[I \sim \mathcal{D}_a] = \lambda_a$  for some fixed positive value  $\lambda_a$ . The upper bound  $m$  is given, but no information about the  $\lambda_a$ 's and the  $\mathcal{D}_a$ 's is provided. Sorting can be solved in a limiting complexity of  $O(\frac{1}{\varepsilon}n \log m + \frac{1}{\varepsilon}H_{\text{out}})$  after a training phase that takes  $O(mn \log^2(mn) + m^\varepsilon n^{1+\varepsilon} \log(mn))$  time [8].

In this paper, we present a self-improving algorithm for constructing Voronoi diagrams under a convex distance function  $d_Q$  in  $\mathbb{R}^2$ , assuming that the input distribution is a hidden mixture of at most  $m$  product distributions. The convex distance function  $d_Q$  is induced by a given convex polygon  $Q$  of  $O(1)$  size. The upper bound  $m$  is given, and we assume that  $m = o(\sqrt{n})$ . We also assume that for each product distribution  $\mathcal{D}_a$  in the mixture,  $\lambda_a = \Omega(1/n)$ . Let  $\varepsilon \in (0, 1)$  be a parameter fixed beforehand. The training phase uses  $O(mn \log(mn))$  input instances and takes  $O(mn \log^{O(1)}(mn) + m^\varepsilon n^{1+\varepsilon} \log(mn))$  time. In the operation phase, given an input instance  $I$ , we can construct its Voronoi diagram  $\text{Vor}_Q(I)$  under  $d_Q$  in a limiting complexity of  $O(\frac{1}{\varepsilon}n \log m + \frac{1}{\varepsilon}n 2^{O(\log^* n)} + \frac{1}{\varepsilon}H)$ , where  $H$  denotes the entropy of the distribution of the Voronoi diagram output. Note that  $\Omega(H)$  is a lower bound of the expected running time of any comparison-based algorithm. Our algorithm also works for the Euclidean case, and the limiting complexity improves to  $O(\frac{1}{\varepsilon}n \log m + \frac{1}{\varepsilon}H)$ .

For simplicity, we will assume throughout the rest of this paper that the hidden mixture has exactly  $m$  product distributions. We give an overview of our method in the following.

We follow the strategy in [1] for computing a Euclidean Delaunay triangulation. The idea is to form a set  $S$  of sample points and build  $\text{Del}(S)$  and some auxiliary structures in the training phase so that any future input instance  $I$  can be merged quickly into  $\text{Del}(S)$  to form  $\text{Del}(S \cup I)$ , and then  $\text{Del}(I)$  can be split off in  $O(n)$  expected time. Merging  $I$  into  $\text{Del}(S)$  requires locating the input points in  $\text{Del}(S)$ . The location distribution is gathered in the training phase so that distribution-sensitive point location can be used to avoid the logarithmic query time as much as possible. Modifying  $\text{Del}(S)$  efficiently into  $\text{Del}(S \cup I)$  requires that only  $O(1)$  points in  $I$  fall into the same neighborhood in  $\text{Del}(S)$  in expectation.

In our case, since there are  $m$  product distributions, we will need a larger set  $S$  of  $mn$  sample points in order to ensure that only  $O(1)$  points in  $I$  fall into the same neighborhood in  $\text{Vor}_Q(S)$  in expectation. But then merging  $I$  into  $\text{Vor}_Q(S)$  in the operation phase would be too slow because scanning  $\text{Vor}_Q(S)$  already requires  $\Theta(mn)$  time. We need to extract a subset  $R \subseteq S$  such that  $R$  has  $O(n)$  size and  $R$  contains all points in  $S$  whose Voronoi cells conflict with the input points.

Still, we cannot afford to construct  $\text{Vor}_Q(R)$  in  $O(n \log n)$  time. In the training phase, we form a metric  $d$  related to  $d_Q$  and construct a *net-tree*  $T_S$  for  $S$  under  $d$  [15]. In the operation phase, after finding the appropriate  $R \subseteq S$ , we use nearest common ancestor queries [20] to compress  $T_S$  in  $O(n \log \log m)$  time to a subtree  $T_R$  for  $R$  that has  $O(n)$  size. Next, we use  $T_R$  to construct a well-separated pair decomposition of  $R$  under  $d$  in  $O(n)$  time [15], use the decomposition to compute the nearest neighbor graph of  $R$  under  $d$  in  $O(n)$  time, and then

construct  $\text{Vor}_Q(R)$  from the nearest neighbor graph in  $O(n)$  expected time. The merging of  $I$  into  $\text{Vor}_Q(R)$  to form  $\text{Vor}_Q(R \cup I)$ , and the splitting of  $\text{Vor}_Q(R \cup I)$  into  $\text{Vor}_Q(I)$  and  $\text{Vor}_Q(R)$  are obtained by transferring their analogous results in the Euclidean case [1, 6].

We have left out the expected time to locate the input points in  $\text{Vor}_Q(S)$ . It is bounded by  $O(1/\varepsilon)$  times the sum of the entropies of the point location outcomes. We show that  $\text{Vor}_Q(I)$  allows us to locate the input points in  $\text{Vor}_Q(S)$  in  $O(n \log m + n2^{O(\log^* n)})$  time. Then, a result in [1] implies that the sum of the entropies of the point location outcomes is  $O(n \log m + n2^{O(\log^* n)} + H)$ . The expected running time is thus  $O(\frac{1}{\varepsilon}n \log m + \frac{1}{\varepsilon}n2^{O(\log^* n)} + \frac{1}{\varepsilon}H)$ , which dominates the limiting complexity. In the Euclidean case,  $\text{Vor}(I)$  allows us to locate the input points in  $O(n \log m)$  time, so the limiting complexity improves to  $O(\frac{1}{\varepsilon}n \log m + \frac{1}{\varepsilon}H)$ .

Details and proofs that are omitted due to space constraint can be found in the full version of this paper [9].

## 2 Preliminaries

Let  $Q$  be a convex polygon that has  $O(1)$  complexity and contains the origin in its interior. Let  $\partial$  and  $\text{int}(\cdot)$  be the boundary and interior operators, respectively. So  $Q$ 's boundary is  $\partial Q$  and its interior is  $\text{int}(Q)$ . Let  $d_Q$  be the distance function induced by  $Q$ :  $\forall x, y \in \mathbb{R}^2$ ,  $d_Q(x, y) = \min\{\lambda \in [0, \infty) : y \in \lambda Q + x\}$ . As  $Q$  may not be centrally symmetric (i.e.,  $x \in Q \iff -x \in Q$ ),  $d_Q$  may not be a metric.

The bisector of two points  $p$  and  $q$  is  $\{x \in \mathbb{R}^2 : d_Q(p, x) = d_Q(q, x)\}$ , which is an open polygonal curve of  $O(1)$  size. The Voronoi diagram of a set  $\Sigma$  of  $n$  points,  $\text{Vor}_Q(\Sigma)$ , is a partition of  $\mathbb{R}^2$  into interior-disjoint cells  $V_p(\Sigma) = \{x \in \mathbb{R}^2 : \forall q \in \Sigma, d_Q(p, x) \leq d_Q(q, x)\}$  for all  $p \in \Sigma$ . There are algorithms for constructing  $\text{Vor}_Q(\Sigma)$  in  $O(n \log n)$  time [10, 18].

$V_p(\Sigma)$  is simply connected and star-shaped with respect to  $p$  [10]. We use  $N_p(\Sigma)$  to denote the set of Voronoi neighbors of  $p$  in  $\text{Vor}_Q(\Sigma)$ . The Voronoi edges of  $\text{Vor}_Q(\Sigma)$  form a planar graph of  $O(|\Sigma|)$  size. Each Voronoi edge is a polygonal line, and we call its internal vertices *Voronoi edge bends*. We use  $V_\Sigma$  to denote the set of Voronoi edge bends and Voronoi vertices in  $\text{Vor}_Q(\Sigma)$ . For the infinite Voronoi edges, their endpoints at infinity are included in  $V_\Sigma$ .

Define  $Q^* = \{-x : x \in Q\}$ . For any points  $x, y \in \mathbb{R}^2$ ,  $d_{Q^*}(x, y) = d_Q(y, x)$ . At any point  $x$  on a Voronoi edge of  $\text{Vor}_Q(\Sigma)$  defined by  $p, q \in \Sigma$ , there exists  $\lambda \in (0, \infty)$  such that  $d_{Q^*}(x, p) = d_Q(p, x) = d_Q(q, x) = d_{Q^*}(x, q) = \lambda$  and  $d_{Q^*}(x, s) = d_Q(s, x) \geq \lambda$  for all  $s \in \Sigma$ . Hence,  $\{p, q\} \subset \partial(\lambda Q^* + x)$  and  $\text{int}(\lambda Q^* + x) \cap \Sigma = \emptyset$ , i.e., an ‘‘empty circle property’’.

Take a point  $x$ . Consider the largest homothetic<sup>1</sup> copy  $Q_x^*$  of  $Q^*$  centered at  $x$  such that  $\text{int}(Q_x^*) \cap \Sigma = \emptyset$ . If we insert a new point  $q$  to  $\Sigma$ , we say that  $q$  *conflicts with*  $x$  if  $q \in Q_x^*$ . We say that  $q$  *conflicts with* a cell  $V_p(\Sigma)$  if  $q$  conflicts with some point in  $V_p(\Sigma)$ . Clearly,  $V_p(\Sigma)$  must be updated by the insertion of  $q$ . We use  $V_\Sigma|_q$  to denote the subset of  $V_\Sigma$  that conflict with  $q$ . The Voronoi edge bends and Voronoi vertices in  $V_\Sigma|_q$  will be destroyed by the insertion of  $q$ .

We make three general position assumptions. First, no two sides of  $Q$  are parallel. Second, for every pair of input points, their support line is not parallel to any side of  $Q$ . Third, no four input points lie on the boundary of any homothetic copy of  $Q^*$ , which implies that every Voronoi vertex has degree three.

It is much more convenient if all Voronoi cells of the input points are bounded. We assume that all possible input points appear in some fixed bounding square  $\mathcal{B}$  centered at the origin. We place  $O(1)$  dummy points outside  $\mathcal{B}$  so that all Voronoi cells of the input

<sup>1</sup> A homothetic copy of a shape is a scaled and translated copy of it.

■ **Figure 1** The left image shows the bounding square  $\mathcal{B}$  and the large enclosing  $\lambda Q^*$ . In the right image, we slide a copy of  $\lambda Q^*$  around  $\mathcal{B}$  to generate the outer convex polygon. The dashed polygon demonstrates the sliding of  $\lambda Q^*$  around  $\mathcal{B}$ . The bold edges on this convex polygon are translates of the boundary edges of  $\mathcal{B}$ . Every edge of  $\lambda Q^*$  has two translational copies too as labelled.

points are bounded, and their portions inside  $\mathcal{B}$  remain the same as before. Refer to Figure 1. Take  $\lambda Q^*$  for some large enough  $\lambda \in \mathbb{R}$  such that for every point  $x \in \mathcal{B}$ ,  $\lambda Q^* + x$  contains  $\mathcal{B}$ . Refer to the left image in Figure 1. We slide a copy of  $\lambda Q^*$  around  $\mathcal{B}$  to generate the outer convex polygon. The dashed polygon demonstrates the sliding of  $\lambda Q^*$  around  $\mathcal{B}$ . This outer polygon contains a translational copy of every edge of  $\mathcal{B}$  and two translational copies of every edge of  $\lambda Q^*$ . We add the vertices of this outer polygon as dummy points. Any homothetic copy of  $Q^*$  that intersects  $\mathcal{B}$  cannot be expanded indefinitely without containing some of these dummy points. So all Voronoi cells of input points are bounded. For each point  $x \in \mathcal{B}$ , since the dummy points lie outside  $\lambda Q^* + x$  and  $\mathcal{B} \subseteq \lambda Q^* + x$  (i.e.,  $\lambda Q^* + x$  is not empty of the input points), the portion of the Voronoi diagram inside  $\mathcal{B}$  is unaffected by the dummy points.

### 3 Training phase

**Sample set  $\mathcal{S}$ .** Take  $mn \ln(mn)$  instances  $I_1, I_2, \dots, I_{mn \ln(mn)}$ . Define  $x_1, \dots, x_{mn \ln(mn)}$  by taking the  $p_1$ 's in  $I_1, \dots, I_{m \ln(mn)}$  to be  $x_1, \dots, x_{m \ln(mn)}$ ,  $p_2$ 's in  $I_{m \ln(mn)+1}, \dots, I_{2m \ln(mn)}$  to be  $x_{m \ln(mn)+1}, \dots, x_{2m \ln(mn)}$ , and so on. The set  $\mathcal{S}$  of sample points includes a  $\frac{1}{mn}$ -net of the  $x_i$ 's with respect to the family of homothetic copies of  $Q^*$ , as well as the  $O(1)$  dummy points. The set  $\mathcal{S}$  has  $O(mn)$  points and can be constructed in  $O(mn \log^{O(1)}(mn))$  time as homothetic copies of  $Q^*$  are pseudo-disks [1, 19].

**Point location.** Compute  $\text{Vor}_Q(\mathcal{S})$  and triangulate it by connecting each  $p \in \mathcal{S}$  to  $V_S \cap \partial V_p(S)$ , i.e., the Voronoi edge bends and Voronoi vertices in  $\partial V_p(S)$ . For unbounded Voronoi cells, we view the infinite Voronoi edges as leading to some vertices at infinity; an extra triangulation edge that goes between two infinite Voronoi edges also leads to a vertex at infinity, giving rise to unbounded triangles. Figure 2 shows an example.

Construct a point location structure  $L_S$  for the triangulated  $\text{Vor}_Q(\mathcal{S})$  with  $O(\log(mn))$  query time [13]. Take another  $m^\epsilon n^\epsilon$  input instances and use  $L_S$  to locate the points in these input instances in the triangulated  $\text{Vor}_Q(\mathcal{S})$ . For every  $i \in [n]$  and every triangle  $t$ , we compute  $\tilde{\pi}_{i,t}$  to be the ratio of the frequency of  $t$  hit by  $p_i$  to  $m^\epsilon n^\epsilon$ , which is an estimate of  $\Pr[p_i \in t]$ . For each  $i \in [n]$ , form a subdivision  $\mathcal{S}_i$  that consists of triangles with positive  $\tilde{\pi}_{i,t}$ 's, triangulate the exterior of  $\mathcal{S}_i$ , and give these new triangles a zero estimated probability. Set the weight of each triangle in  $\mathcal{S}_i$  to be the maximum of  $(mn)^{-\epsilon}$  and its estimated probability. Construct a distribution-sensitive point location structure  $L_i$  for  $\mathcal{S}_i$  based on the triangle weights [2, 16]. Note that  $L_i$  has  $O(m^\epsilon n^\epsilon)$  size, and locating a point in a triangle  $t \in \mathcal{S}_i$  takes  $O(\log \frac{W_i}{w_t})$  time, where  $w_t$  is the weight of  $t$  and  $W_i$  is the total weight in  $\mathcal{S}_i$ .

■ **Figure 2** Part of the triangulation of a Voronoi diagram induced by the triangle shown with a gray center. The solid edges form the Voronoi diagram. The dashed edges refine it into a triangulation.

For any input instance  $(p_1, \dots, p_n)$  in the operation phase, we will query  $L_i$  to locate  $p_i$  in the triangulated  $\text{Vor}_Q(S)$ , which may fail if  $p_i$  falls into a triangle with zero estimated probability. If the search fails, we query  $L_S$  to locate  $p_i$ .

**Net-tree.** We first define a metric that is induced by a centrally symmetric convex polygon. Define  $\hat{Q} = \{x - y : x, y \in Q^*\}$ , i.e., the Minkowski sum of  $Q^*$  and  $-Q^*$ , or equivalently  $Q^*$  and  $Q$ . It is centrally symmetric by definition. It can be visualized as the region covered by all possible placements of  $Q^*$  that has the origin in the polygon boundary. Since  $\hat{Q}$  is a Minkowski sum, its number of vertices is within a constant factor of the total number of vertices of  $Q^*$  and  $-Q^*$ , which is  $O(1)$ .

Let  $d$  be the metric induced by the centrally symmetric convex polygon  $\hat{Q}$ , which is a *doubling metric* – there is a constant  $\lambda > 0$  such that for any point  $x \in \mathbb{R}^2$  and any positive number  $r$ , the ball with respect to  $d$  centered at  $x$  with radius  $r$  can be covered by  $\lambda$  balls with respect to  $d$  of radius  $r/2$ .

Given a set of points  $P$ , a *net-tree* for  $P$  with respect to  $d$  [15] is an analog of the well-separated pair decomposition for Euclidean spaces [4]. It is a rooted tree whose leaves are the points in  $P$ . For each node  $v$ , let  $\text{parent}(v)$  denote its parent, and let  $P_v$  denote the subset of  $P$  at the leaves that descend from  $v$ . Every tree node  $v$  is given a representative point  $p_v$  and an integer level  $\ell_v$ . Let  $\tau \geq 11$  be a fixed constant. Let  $B(x, h)$  denote the ball  $\{y \in \mathbb{R}^2 : d(x, y) \leq h\}$ . By the results in [15] (Definition 2.1 and the remark that follows Proposition 2.2), the following properties are satisfied by a net-tree:

- (a)  $p_v \in P_v$ .
- (b) For every non-root node  $v$ ,  $\ell_v < \ell_{\text{parent}(v)}$ , and if  $v$  is a leaf, then  $\ell_v = -\infty$ .
- (c) Every internal node has at least two and at most a constant number of children.
- (d) For every node  $v$ ,  $B(p_v, \frac{2\tau}{\tau-1} \cdot \tau^{\ell_v})$  contains  $P_v$ .
- (e) For every non-root node  $v$ ,  $B(p_v, \frac{\tau-5}{2\tau-2} \cdot \tau^{\ell_{\text{parent}(v)}-1}) \cap P \subset P_v$ .
- (f) For every internal node  $v$ , there is a child  $w$  of  $v$  such that  $p_w = p_v$ .

**Clusters.** We construct a *net-tree*  $T_S$  for  $S$  in  $O(mn \log(mn))$  expected time [15]. We define *clusters* as follows. Label all leaves of  $T_S$  as unclustered initially. Select the leftmost  $m$  unclustered leaves of  $T_S$ ; if there are fewer than  $m$  such leaves, select them all. Find the subtree rooted at a node  $v$  of  $T_S$  that contains the selected unclustered leaves, but no child subtree of  $v$  contains them all. We call the subtree rooted at  $v$  a cluster and label all its leaves clustered. Then, we repeat the above until all leaves of  $T_S$  are clustered. By construction, the clusters are disjoint, each cluster has  $O(m)$  nodes, and there are  $O(n)$  clusters in  $T_S$ .

We assign nodes in each cluster a unique cluster index in the range  $[1, O(n)]$ . We also assign each node of a cluster three indices from the range  $[1, O(m)]$  according to its rank in the preorder, inorder, and postorder traversals of that cluster. The preorder and postorder indices allow us to tell in  $O(1)$  time whether two nodes are an ancestor-descendant pair.

We keep an initially empty van Emde Boas tree  $EB_c$  [21] with each cluster  $c$ . The universe for  $EB_c$  is the set of leaves in the cluster  $c$ , and the in-order of these leaves in  $c$  is the total order for  $EB_c$ . We also build a nearest common ancestor query data structure for each cluster [20]. The nearest common ancestor query of any two nodes can be reported in  $O(\log \log m)$  time.

**Planar separator.**  $\text{Vor}_Q(S)$  is a planar graph of  $O(mn)$  size with all Voronoi edge bends and Voronoi vertices as graph vertices. By a recursive application of the planar separator theorem, one can produce an  $m^2$ -division of  $\text{Vor}_Q(S)$ : it is divided into  $O(n/m)$  regions, each region contains  $O(m^2)$  vertices, and the boundary of each region contains  $O(m)$  vertices [14].

Extract the subset  $B \subset S$  of points whose Voronoi cell boundaries contain some region boundary vertices in the  $m^2$ -division. So  $|B| = O(m \cdot n/m) = O(n)$ . Compute  $\text{Vor}_Q(B)$  and triangulate it as in triangulating  $\text{Vor}_Q(S)$ . By our choice of  $B$ , the region boundaries in the  $m^2$ -division of  $\text{Vor}_Q(S)$  form a subgraph of  $\text{Vor}_Q(B)$ . Label in  $O(n)$  time the Voronoi edge bends and Voronoi vertices in  $\text{Vor}_Q(B)$  whether they exist in  $\text{Vor}_Q(S)$ .

We construct point location data structures for every region  $\Pi$  in the  $m^2$ -division as follows. For every boundary vertex  $w$  of  $\Pi$ , let  $Q_w^*$  be the largest homothetic copy of  $Q^*$  centered at  $w$  such that  $\text{int}(Q_w^*) \cap B = \emptyset$ . These  $Q_w^*$ 's form an arrangement of  $O(m^2)$  complexity, and we construct a point location data structure that allows a point to be located in this arrangement in  $O(\log m)$  time. We also construct a point location data structure for the portion of the triangulated  $\text{Vor}_Q(S)$  inside  $\Pi$ . Since the region has  $O(m^2)$  complexity, this point location data structure can return in  $O(\log m)$  time the triangle in the triangulated  $\text{Vor}_Q(S)$  that contains a point inside  $\Pi$ .

**Output and performance.** The following result summarizes the output and performance of the training phase. The proof of Lemma 1(a) is similar to an analogous result for sorting in [8].

► **Lemma 1.** *Let  $\mathcal{D}_a$ ,  $a \in [m]$ , be the distributions in the hidden mixture. The training phase computes the following structures in  $O(mn \log^{O(1)}(mn) + m^\varepsilon n^{1+\varepsilon} \log(mn))$  time.*

- (i) *A set  $S$  of  $O(mn)$  points and  $\text{Vor}_Q(S)$ . It holds with probability at least  $1 - 1/n$  that for any  $a \in [1, m]$  and any  $v \in V_S$ ,  $\sum_{i=1}^n \Pr[X_{iv} | I \sim \mathcal{D}_a] = O(1/m)$ , where  $X_{iv} = 1$  if  $p_i \in I$  conflicts with  $v$  and  $X_{iv} = 0$  otherwise.*
- (ii) *Point location structures  $L_S$  and  $L_i$  for each  $i \in [n]$  that allow us to locate  $p_i$  in the triangulated  $\text{Vor}_Q(S)$  in  $O(\frac{1}{\varepsilon} H(t_i))$  expected time, where  $t_i$  is the random variable that represents the point location outcome, and  $H(t_i)$  is the entropy of the distribution of  $t_i$ .*
- (iii) *A net-tree  $T_S$  for  $S$ , the  $O(n)$  clusters in  $T_S$ , the initially empty van Emde Boas trees for the clusters, and the nearest common ancestor data structures for the clusters.*
- (iv) *An  $m^2$ -division of  $\text{Vor}_Q(S)$ , the subset  $B \subseteq S$  of  $O(n)$  points whose Voronoi cell boundaries contain some region boundary vertices in the  $m^2$ -division,  $\text{Vor}_Q(B)$ , and the point location data structures for the regions in the  $m^2$ -division.*

Lemma 1(a) leads to Lemma 2 below, which implies that for any  $v \in V_S$ , if we feed the input points that conflict with  $v$  to a procedure that runs in quadratic time in the worst case, the expected running time of this procedure over all points in  $V_S$  is  $O(n)$ . The proof of Lemma 2 is just an algebraic manipulation of the probabilities.

► **Lemma 2.** *For every  $v \in V_S$ , let  $Z_v$  be the subset of input points that conflict with  $v$ . It holds with probability at least  $1 - O(1/n)$  that  $\sum_{v \in V_S} \mathbb{E}[|Z_v|^2] = O(n)$ .*

■ **Figure 3** (a) The points  $q$  and  $q'$  define a Voronoi edge, and  $w_1$  and  $w_2$  are two adjacent Voronoi edge bends or Voronoi vertices on this edge. At any point  $x$  between  $w_1$  and  $w_2$ , the polygon  $Q_x^*$  (shown dashed) is a subset of  $Q_{w_1}^* \cup Q_{w_2}^*$ . (b) A triangle  $quv$  in the triangulated Voronoi diagram in Figure 2 is shown. If a point  $p$  conflicts with the white dot (i.e., lies inside the bold dashed triangle), then  $p$  conflicts with  $u$  or  $v$  (i.e., lies inside one of the two light dashed circles).

We state two technical results. Figure 3(a) and (b) illustrate these two lemmas.

► **Lemma 3.** Consider  $\text{Vor}_Q(Y)$  for some point set  $Y$ . For any point  $x \in \mathbb{R}^2$ , let  $Q_x^*$  be the largest homothetic copy of  $Q^*$  centered at  $x$  such that  $\text{int}(Q_x^*) \cap Y = \emptyset$ . Let  $w_1$  and  $w_2$  be two adjacent Voronoi edge bends or Voronoi vertices in  $\text{Vor}_Q(Y)$ . For any point  $x \in w_1 w_2$ ,  $Q_x^* \subseteq Q_{w_1}^* \cup Q_{w_2}^*$ . The same property holds if  $w_1$  and  $w_2$  are Voronoi vertices connected by a Voronoi edge, and  $x$  lies on that Voronoi edge.

► **Lemma 4.** Let  $q$  be a point in some point set  $Y$ . Let  $quv$  be a triangle in the triangulated  $\text{Vor}_Q(Y)$ . If a point  $p \notin Y$  conflicts with a point in  $quv$ , then  $p$  conflicts with  $u$  or  $v$ . Hence, if  $p$  conflicts with  $V_q(Y)$ ,  $p$  conflicts with a Voronoi edge bend or Voronoi vertex in  $\partial V_q(Y)$ .

## 4 Operation phase

Given an instance  $I = (p_1, \dots, p_n)$ , we construct  $\text{Vor}_Q(I)$  using the pseudocode below.

### ■ Algorithm 1 OPERATION PHASE.

1. For each  $i \in [n]$ , query  $L_i$  to find the triangle  $t_i$  in the triangulated  $\text{Vor}_Q(S)$  that contains  $p_i$ , and if the search fails, query  $L_S$  to find  $t_i$ .
2. For each  $i \in [n]$ , search  $\text{Vor}_Q(S)$  from  $t_i$  to find  $V_S|_{p_i}$ , i.e., the subset of  $V_S$  that conflict with  $p_i$ . This also gives the subset of  $S$  whose Voronoi cells conflict with the input points. Let  $R$  be the union of this subset of  $S$  and the set of representative points of all cluster roots in  $T_S$ .
3. Compute the compression  $T_R$  of  $T_S$  to  $R$ .
4. Construct the nearest neighbor graph  $1\text{-NN}_R$  under the metric  $d$  from  $T_R$ .
5. Compute  $\text{Vor}_Q(R)$  from  $1\text{-NN}_R$ .
6. Modify  $\text{Vor}_Q(R)$  to produce  $\text{Vor}_Q(R \cup I)$ .
7. Split  $\text{Vor}_Q(R \cup I)$  to produce  $\text{Vor}_Q(I)$  and  $\text{Vor}_Q(R)$ . Return  $\text{Vor}_Q(I)$ .

We analyze step 1 in Section 4.1, steps 2 and 3 in Section 4.2, steps 4 and 5 in Section 4.3, and steps 6 and 7 in Section 4.4. Step 1 is the most time-consuming; all other steps run in  $O(n)$  expected time.

#### 4.1 Point location

By Lemma 1(b), step 1 runs in  $O(\sum_{i=1}^n \frac{1}{\varepsilon} H(t_i))$  expected time, which is  $O(\frac{1}{\varepsilon} n \log m + \frac{1}{\varepsilon} H(t_1, \dots, t_n))$  as we will show later. By Lemma 5 below, if there is an algorithm that can use  $\text{Vor}_Q(I)$  to determine  $t_1, \dots, t_n$  in  $c(n)$  expected time, then  $H(t_1, \dots, t_n) = O(c(n) + H)$ , implying that step 1 takes  $O(\frac{1}{\varepsilon}(n \log m + c(n) + H))$  expected time. Any preprocessing cost of  $S$  is excluded from  $c(n)$ . We present such an algorithm.

► **Lemma 5** (Lemma 2.3 in [1]). *Let  $\mathcal{D}$  be a distribution on a universe  $\mathcal{U}$ . Let  $X : \mathcal{U} \rightarrow \mathcal{X}$ , and let  $Y : \mathcal{U} \rightarrow \mathcal{Y}$  be two random variables. Suppose that there is a comparison-based algorithm that computes a function  $f : (I, X(I)) \rightarrow Y(I)$  in  $C$  expected comparisons over  $\mathcal{D}$  for every  $I \in \mathcal{U}$ . Then  $H(Y) = C + O(H(X))$ .*

Recall that we have computed in the training phase the subset  $B \subseteq S$  whose Voronoi cell boundaries contain some region boundary vertices in the  $m^2$ -division of  $\text{Vor}_Q(S)$ . Note that  $|B| = O(n)$ . We have also computed  $\text{Vor}_Q(B)$  and point location data structures associated with the regions in the  $m^2$ -division. We use  $\text{Vor}_Q(B)$  and these point location data structures determines  $t_1, \dots, t_n$  as follows.

- Task 1: Merge  $\text{Vor}_Q(B)$  with  $\text{Vor}_Q(I)$  to form the triangulated  $\text{Vor}_Q(B \cup I)$ .
- Task 2: Use  $\text{Vor}_Q(S)$ ,  $\text{Vor}_Q(B)$ , and  $\text{Vor}_Q(B \cup I)$  to find the triangles  $t_1, \dots, t_n$ .

We discuss these two tasks in the following.

**Task 1.** For every point  $p \in B$ , define a polygonal cone surface  $C_p = \{(a, b, d_Q(p, (a, b))) : (a, b) \in \mathbb{R}^2\}$ . Each horizontal cross-section of  $C_p$  is a scaled copy of  $Q$  centered at  $p$ . The triangulated  $\text{Vor}_Q(B)$  is the vertical projection of the lower envelope of  $\{C_p : p \in B\}$ , denoted by  $\mathcal{L}(B)$ . Similarly,  $\mathcal{L}(I)$  projects to  $\text{Vor}_Q(I)$ . We take the lower envelope of  $\mathcal{L}(B)$  and  $\mathcal{L}(I)$  to form  $\mathcal{L}(B \cup I)$  which projects to  $\text{Vor}_Q(B \cup I)$ . We do so in  $O(n2^{O(\log^* n)})$  expected time with a randomized algorithm that is based on an approach proposed and analyzed by Chan [5, Section 4].

**Task 2.** Suppose that for an input point  $p_i \in I$ , we have determined some subset  $B_i$  that satisfies  $B \subseteq B_i \subseteq S$ , and we have computed a Voronoi edge bend or Voronoi vertex  $v_i$  in  $\text{Vor}_Q(B_i)$  that conflicts with  $p_i$  and is known to be in  $V_S$  or not.

If  $v_i \in V_S$ , we search  $\text{Vor}_Q(S)$  from  $v_i$  to find  $V_S|_{p_i}$  (i.e., the subset of  $V_S$  that conflict with  $p_i$ ), which by Lemma 3 also gives the triangle  $t_i$  in the triangulated  $\text{Vor}_Q(S)$  that contains  $p_i$ . By Lemma 2, the expected total running time of this procedure over all input points is  $O(n)$ .

Suppose that  $v_i \notin V_S$ . So  $v_i$  is not a region boundary vertex in the  $m^2$ -division of  $\text{Vor}_Q(S)$ , i.e.,  $v_i$  lies inside a region in the  $m^2$ -division of  $\text{Vor}_Q(S)$ , say  $\Pi$ . For each boundary vertex  $w$  of  $\Pi$ , let  $Q_w^*$  be the largest homothetic copy of  $Q^*$  centered at  $w$  such that  $\text{int}(Q_w^*) \cap B = \emptyset$ . These  $Q_w^*$ 's form an arrangement of  $O(m^2)$  complexity, and we locate  $p_i$  in this arrangement in  $O(\log m)$  time. It tells us whether  $p_i \in Q_w^*$  for some boundary vertex  $w$  of  $\Pi$ . If so, then  $p_i$  conflicts with  $w$ , which belongs to  $V_S$ , and we search  $\text{Vor}_Q(S)$  from  $w$  to find  $V_S|_{p_i}$  and hence the triangle  $t_i$  in the triangulated  $\text{Vor}_Q(S)$  that contains  $p_i$ . Otherwise,  $p_i$  must lie inside  $\Pi$  in order to conflict with  $v_i$  inside  $\Pi$  without conflicting with any boundary vertex of  $\Pi$ . So we do a point location in  $O(\log m)$  time to locate  $p_i$  in the portion of the triangulated  $\text{Vor}_Q(S)$  inside  $\Pi$ . This gives  $t_i$ .

How do we compute  $v_i$  for  $p_i$ ? We discuss this computation and provide more details of Step 2 in the full version [9]. The following lemma summarizes the result that follows from the discussion above.

► **Lemma 6.** *Given  $\text{Vor}_Q(I)$ , the triangles  $t_1, \dots, t_n$  in the triangulated  $\text{Vor}_Q(S)$  that contain  $p_1, \dots, p_n \in I$  can be computed in  $O(n \log m + n2^{O(\log^* n)})$  expected time.*

► **Lemma 7.** *Step 1 of the operation phase takes  $O(\frac{1}{\varepsilon}(n \log m + n2^{O(\log^* n)} + H))$  expected time, where  $H$  is the entropy of the distribution of  $\text{Vor}_Q(I)$ .*

**Proof.** Let  $A \in [1, m]$  be a random variable that indicates which distribution in the mixture generates the input instance. By the chain rule for conditional entropy [22, Proposition 2.23],  $H(t_i) \leq H(t_i) + H(A|t_i) = H(t_i, A) = H(A) + H(t_i|A)$ . It is known that  $H(A) \leq \log_2(\text{domain size of } A) = \log_2 m$  [22, Theorem 2.43]. Thus,  $\sum_{i=1}^n H(t_i) \leq n \log_2 m + \sum_{i=1}^n H(t_i|A)$ . The variables  $t_1|A, \dots, t_n|A$  are mutually independent. So  $\sum_{i=1}^n H(t_i|A) = H(t_1, \dots, t_n|A)$ . Since entropy is not increased by conditioning [22, Theorem 2.38], we get  $\sum_{i=1}^n H(t_i|A) = H(t_1, \dots, t_n|A) \leq H(t_1, \dots, t_n)$ . By Lemma 6, we can determine  $t_1, \dots, t_n$  using  $\text{Vor}_Q(I)$  in  $O(n \log m + n2^{O(\log^* n)})$  expected time. So  $H(t_1, \dots, t_n) = O(n \log m + n2^{O(\log^* n)} + H)$  by Lemma 5, where  $H$  is the entropy of the distribution of  $\text{Vor}_Q(I)$ . ◀

In the Euclidean metric, merging  $\text{Vor}(B)$  and  $\text{Vor}(I)$  into  $\text{Vor}(B \cup I)$  can be reduced to finding the intersection of two convex polyhedra of  $O(n)$  size in  $\mathbb{R}^3$ , which can be solved in  $O(n)$  time [5]. So the expected running time of step 1 improves to  $O(\frac{1}{\varepsilon}(n \log m + H))$ .

## 4.2 Construction of $R$

Step 1 determines the triangle  $t_i$  in the triangulated  $\text{Vor}_Q(S)$  that contains  $p_i \in I$ . We search  $\text{Vor}_Q(S)$  from  $t_i$  to find  $V_S|_{p_i}$ , which takes  $O(|V_S|_{p_i}|)$  time [18]. This search also gives the Voronoi cells that conflict with  $p_i$ . The total time over all  $i \in [n]$  is  $O(\sum_{v \in V_S} |Z_v|)$ , where  $Z_v$  is the subset of input points that conflict with  $v$ . Since  $R$  includes all sites whose cells conflict with the input points and the representative points of all cluster roots in  $T_S$ , we have  $|R| \leq \sum_{v \in V_S} |Z_v| + O(n)$ . The following result follows from Lemma 2.

► **Lemma 8.** *The set  $R$  has  $O(n)$  expected size. Step 2 of the operation phase constructs  $R$  in  $O(n)$  expected time.*

## 4.3 Extraction of $\text{Vor}_Q(R)$

### 4.3.1 Construction of $T_R$

We define a *compression* of a net-tree  $T$ . Select a subset  $U$  of leaves in  $T$ . Let  $T' \subseteq T$  be the minimal subtree that spans  $U$ . Bypass all internal nodes in  $T'$  that have only one child. *The resulting tree is the compression of  $T$  to  $U$ .* The following result is an easy observation.

► **Lemma 9.** *Let  $T$  be a net-tree. Let  $T_1$  be the compression of  $T$  to a subset  $U_1$  of leaves. The compression of  $T_1$  to any subset  $U_2$  of leaves in  $T_1$  can also be obtained by a compression of  $T$  to  $U_2$ .*

Conceptually,  $T_R$  is defined as follows. Select all leaves of  $T_S$  that are points in  $R$ , and  $T_R$  is the compression of  $T_S$  to these selected leaves. Since  $R$  includes the representative points of all cluster roots, all ancestors of the cluster roots in  $T_S$  will survive the compression and exist as nodes in  $T_R$ . The compression affects the clusters only. More precisely, for each

■ **Figure 4** Three different cases in the manipulation of the stack. The tree shown is a part of  $T_S$ . The gray nodes are nodes in  $T_c$ . The gray leaves are leaves in  $R_c$ .

cluster  $c$  in  $T_S$ , we select its leaves that are points in  $R$  and compute the compression  $T_c$  of the cluster  $c$  to these selected leaves. Substituting every cluster  $c$  in  $T_S$  by  $T_c$  gives the desired  $T_R$ . It remains to discuss how to compute the  $T_c$ 's.

We divide  $R$  in  $O(n)$  expected time into sublists  $R_1, R_2, \dots$  such that  $R_c$  consists of the points that are leaves in cluster  $c$ . Recall that every cluster  $c$  has an initially empty van Emde Boas tree  $EB_c$  for its leaves in left-to-right order. For each  $R_c$ , we insert all leaves in  $R_c$  into  $EB_c$  and then repeatedly perform extract-min on  $EB_c$ . This gives in  $O(|R_c| \log \log m)$  time a sorted list  $R'_c$  of the leaves in  $R_c$  according to their left-to-right order in the cluster  $c$ .

If  $|R'_c| = 1$ , then  $T_c$  consists of the single leaf in  $R_c$ . Suppose that  $|R'_c| \geq 2$ . We construct  $T_c$  using a stack. Initially,  $T_c$  is a single node which is the first leaf in  $R'_c$ . The stack stores the nodes on the rightmost root-to-leaf path in the current  $T_c$ , with the root at the stack bottom and the leaf at the stack top. When we scan the next leaf  $q$  in  $R'_c$ , we find in cluster  $c$  the nearest common ancestor  $x$  of  $q$  and  $q$ 's predecessor in  $R'_c$ . This takes  $O(\log \log m)$  time [20]. If we see  $x$  at the stack top, we add  $q$  as a new leaf to  $T_c$  with  $x$  as its parent, and then we push  $q$  onto the stack. Refer to the left image in Figure 4. If we see an ancestor  $z$  of  $x$  at the stack top, let  $y$  be the node that was immediately above  $z$  in the stack and was just popped, we make  $x$  the rightmost child of  $z$  in  $T_c$  (which was  $y$  previously), we also make  $y$  and  $q$  the left and right children of  $x$  respectively, and then we push  $x$  and  $q$  in this order onto the stack. Refer to the middle image in Figure 4. If neither of the two conditions above happens and the stack is not empty, we pop the stack and repeat. Refer to the right image in Figure 4. If the stack becomes empty, we make  $x$  the new root of  $T_c$ , we also make the old root of  $T_c$  and  $q$  the left and right children of  $x$  respectively, and then we push  $x$  and  $q$  in this order onto the stack. The construction of  $T_c$  takes  $O(|R_c| \log \log m)$  time.

► **Lemma 10.** *The compression  $T_R$  of  $T_S$  to  $R$  can be computed in  $O(n \log \log m)$  time.*

### 4.3.2 Construction of the $k$ -nearest neighbor graph

Let  $X$  be any subset of  $S$ . Assume that the compression  $T_X$  of  $T_S$  to  $X$  is available. We show how to use  $T_X$  to construct in  $O(k|X|)$  time the  $k$ -nearest neighbor graph of  $X$  under the metric  $d$ . We denote this graph by  $k\text{-NN}_X$ . We will use the *well-separated pair decomposition* or WSPD for short. For any  $c \geq 1$ , a set  $\{\{A_1, B_1\}, \dots, \{A_s, B_s\}\}$  is a  $c$ -WSPD of  $X$  under  $d$  if the following properties are satisfied:

- $\forall i, A_i, B_i \subseteq X$ .
- $\forall$  distinct  $x, y \in X, \exists i$  such that  $\{x, y\} \in \{\{a, b\} : a \in A_i \wedge b \in B_i\}$ .
- $\forall i$ , the maximum of the diameters of  $A_i$  and  $B_i$  under  $d$  is less than  $\frac{1}{c} \cdot d(A_i, B_i)$ . It implies that  $A_i \cap B_i = \emptyset$ .

It is known that a  $c$ -WSPD has  $O(c^{O(1)}|X|)$  size and can be constructed in  $O(c^{O(1)}|X|)$  time from a net-tree for  $X$  [15]. The same method works for a compression  $T_X$  of  $T_S$  to  $X$ , giving a  $c$ -WSPD of  $O((c+1)^{O(1)}|X|)$  size in  $O((c+1)^{O(1)}|X|)$  time. To compute  $k\text{-NN}_X$ , we transfer a strategy in [4] for constructing a Euclidean  $k$ -nearest neighbor graph using a WSPD.

► **Lemma 11.** *Given the compression  $T_X$  of  $T_S$  to any subset  $X \subseteq S$ , the  $k$ - $\text{NN}_X$  can be constructed in  $O(k|X|)$  time.*

The next result shows that the vertex degree of  $1\text{-NN}_X$  is  $O(1)$ .

► **Lemma 12.** *For any subset  $X \subseteq S$ , every vertex in  $1\text{-NN}_X$  has  $O(1)$  degree, and adjacent vertices in  $1\text{-NN}_X$  are Voronoi neighbors in  $\text{Vor}_Q(X)$ .*

### 4.3.3 $\text{Vor}_Q(R)$ from the nearest neighbor graph

We show how to construct  $\text{Vor}_Q(R)$  in  $O(n)$  expected time using  $1\text{-NN}_R$ . We use the following recursive routine which is similar to the one in [3] for constructing an Euclidean Delaunay triangulation from the Euclidean nearest neighbor graph. The top-level call is  $\text{VorNN}(R, T_R)$ .

■ **Algorithm 2**  $\text{VorNN}(Y, T_Y)$ .

1. If  $|Y| = O(1)$ , compute  $\text{Vor}_Q(Y)$  directly and return.
2. Compute  $1\text{-NN}_Y$  under the metric  $d$  using  $T_Y$ .
3. Let  $X \subseteq Y$  be a random sample such that  $X$  meets every connected component of  $1\text{-NN}_Y$ , and  $\Pr[p \in X] = 1/2$  for every  $p \in Y$ .
4. Compute the compression  $T_X$  of  $T_Y$  to  $X$ .
5. Call  $\text{VorNN}(X, T_X)$  to compute  $\text{Vor}_Q(X)$ .
6. Using  $1\text{-NN}_Y$  as a guide, insert the points in  $Y \setminus X$  into  $\text{Vor}_Q(X)$  to form  $\text{Vor}_Q(Y)$ .

There are two differences from [3]. First, we use a compression  $T_Y$  of  $T_S$  to compute  $1\text{-NN}_Y$  in step 2, which takes  $O(|Y|)$  time by Lemma 11. Second, we need to compress  $T_Y$  to  $T_X$  in step 4. This compression works in almost the same way as described in Section 4.3.1 except that we can afford to traverse  $T_Y$  in  $O(|Y|)$  time to answer all nearest common ancestor queries required for constructing  $T_X$ . Thus, step 4 runs in  $O(|Y|)$  time.

Step 3 is implemented as follows [3]. Form an arbitrary maximal matching of  $1\text{-NN}_Y$ . By the definition of  $1\text{-NN}_Y$ , each connected component of  $1\text{-NN}_Y$  contains at least one matched pair. Randomly select one point from every matched pair. Then, among those unmatched points in  $1\text{-NN}_Y$ , select each one with probability  $1/2$  uniformly at random. The selected points form the subset  $X$  required in step 3. The time needed is  $O(|Y|)$ .

In step 6, for each  $p \in Y \setminus X$  that is connected to some point  $q \in X$  in  $1\text{-NN}_Y$ ,  $p$  and  $q$  are Voronoi neighbors in  $\text{Vor}_Q(Y)$  by Lemma 12. So  $p$  conflicts with a point in  $V_q(X)$ . By Lemma 4,  $p$  conflicts with a Voronoi edge bend or Voronoi vertex in  $\partial V_q(X)$ , which can be found in  $O(|\partial V_q(X)|)$  time. After finding a Voronoi edge bend or Voronoi vertex  $v$  in  $\partial V_q(X)$  that conflicts with  $p$ , we search  $\text{Vor}_Q(X)$  from  $v$  to find all Voronoi edge bends and Voronoi vertices that conflict with  $p$ . In the same search of  $\text{Vor}_Q(X)$ , we modify  $\text{Vor}_Q(X)$  into  $\text{Vor}_Q(X \cup \{p\})$  as in a randomized incremental construction [18]. By the Clarkson-Shor analysis [12], the expected running time of the search of  $\text{Vor}_Q(X)$  and the Voronoi diagram modification over the insertions of all points in  $Y \setminus X$  is  $O(|Y|)$ . We spend  $O(|\partial V_q(X)|)$  time to find  $v$ . It translates to an  $O(1)$  charge at each vertex of  $V_q(X)$ . This charging happens only for  $q$ 's neighbors in  $1\text{-NN}_Y$ . By Lemma 12, there are  $O(1)$  such neighbors of  $q$ , so the charge at each vertex of  $V_q(X)$  is  $O(1)$ . Moreover, if a vertex of  $V_q(X)$  is destroyed by the insertion of a point from  $Y \setminus X$ , that vertex will not reappear. So the  $O(|\partial V_q(X)|)$  cost is absorbed by the structural changes which is already taken care of by the Clarkson-Shor analysis. Unwinding the recursion gives a total expected running time of  $O(|R| + |R|/2 + |R|/4 + \dots) = O(|R|)$ .

► **Lemma 13.**  *$\text{VorNN}(R, T_R)$  computes  $\text{Vor}_Q(R)$  in  $O(|R|)$  expected time.*

#### 4.4 Computing $\text{Vor}_Q(I)$ from $\text{Vor}_Q(R)$ and $I$

Let  $q$  be a point in  $R$ . Let  $v_1, v_2, \dots$  be the vertices of  $V_q(R)$ , in clockwise order, which may be Voronoi edge bends or Voronoi vertices. Let  $Q_{v_i}^*$  denote the largest homothetic copy of  $Q^*$  centered at  $v_i$  such that  $\text{int}(Q_{v_i}^*) \cap R = \emptyset$ . Let  $Z_{v_i} = Q_{v_i}^* \cap I$  where  $I$  is an input instance.

► **Lemma 14.** *The portions of  $\text{Vor}_Q(R \cup I)$  and  $\text{Vor}_Q(\{q\} \cup Z_{v_i} \cup Z_{v_{i+1}})$  inside the triangle  $qv_i v_{i+1}$  are identical.*

**Proof.** Let  $p$  be a point in  $(R \cup I) \setminus \{q\}$  that contributes to  $\text{Vor}_Q(R \cup I)$  inside  $qv_i v_{i+1}$ . As  $qv_i v_{i+1} \subseteq V_q(R)$ ,  $p \notin R$ . So  $p \in I$ . By Lemma 4,  $p$  conflicts with  $v_i$  or  $v_{i+1}$ . ◀

Step 2 of the operation phase has found  $V_S|_{p_i}$  for each  $p_i \in I$ .  $V_S|_{p_i}$  and the portions of the Voronoi edges of  $\text{Vor}_Q(S)$  among the points in  $V_S|_{p_i}$  are preserved in  $\text{Vor}_Q(R)$  because  $R$  includes the subset of  $S$  whose Voronoi cells conflict with the input points. Hence,  $\bigcup_{i=1}^n V_S|_{p_i}$  is the set  $U_R$  of Voronoi edge bends and Voronoi vertices in  $\text{Vor}_Q(R)$  that conflict with the input points. By Lemma 14, we locally compute pieces of  $\text{Vor}_Q(R \cup I)$  and stitch them together. The running time is  $O(\sum_{u,v} (|Z_u| + |Z_v|) \log(|Z_u| + |Z_v|))$ , where the sum is over all pairs  $\{u, v\}$  of adjacent Voronoi edge bends and Voronoi vertices in  $\text{Vor}_Q(R)$  such that  $\{u, v\} \cap U_R \neq \emptyset$ . Since the degrees of Voronoi edge bends and Voronoi vertices are two and three respectively, this running time can be bounded by  $O(\sum_{v \in U_R} |Z_v| \log |Z_v|)$ . Since  $U_R \subseteq V_S$ , by Lemma 2, step 6 of the operation phase computes  $\text{Vor}_Q(R \cup I)$  in  $O(n)$  expected time.

In step 7, the splitting of  $\text{Vor}_Q(R \cup I)$  into  $\text{Vor}_Q(R)$  and  $\text{Vor}_Q(I)$  can be performed in  $O(n)$  expected time by using the algorithm in [6] for splitting a Euclidean Delaunay triangulation. That algorithm is combinatorial in nature. It relies on the Voronoi diagram being planar and of  $O(n)$  size, all points having  $O(1)$  degrees in the nearest neighbor graph, and that one can delete a site from a Voronoi diagram in time proportional to its number of Voronoi neighbors. The first two properties hold in our case, and it is known how to delete a site from an abstract Voronoi diagram so that the expected running time is proportional to its number of Voronoi neighbors [17].

► **Lemma 15.** *Step 6 of the operation phase computes  $\text{Vor}_Q(R \cup I)$  in  $O(n)$  expected time, and step 7 splits  $\text{Vor}_Q(R \cup I)$  into  $\text{Vor}_Q(I)$  and  $\text{Vor}_Q(R)$  in  $O(n)$  expected time.*

In summary, since steps 2-7 of the operation phase take  $O(n)$  expected time, the limiting complexity is dominated by the  $O(\frac{1}{\varepsilon}n \log m + \frac{1}{\varepsilon}n2^{O(\log^* n)} + \frac{1}{\varepsilon}H)$  expected running time of step 1. In the Euclidean case, step 1 runs faster in  $O(\frac{1}{\varepsilon}n \log m + \frac{1}{\varepsilon}H)$  time.

► **Theorem 16.** *Let  $Q$  be a convex polygon with  $O(1)$  complexity. Let  $n$  be the input size. For any  $\varepsilon \in (0, 1)$  and any hidden mixture of at most  $m = o(\sqrt{n})$  product distributions such that each distribution contributes an instance with a probability of  $\Omega(1/n)$ , there is a self-improving algorithm for constructing a Voronoi diagram under  $d_Q$  with a limiting complexity of  $O(\frac{1}{\varepsilon}n \log m + \frac{1}{\varepsilon}n2^{O(\log^* n)} + \frac{1}{\varepsilon}H)$ . For the Euclidean metric, the limiting complexity is  $O(\frac{1}{\varepsilon}n \log m + \frac{1}{\varepsilon}H)$ . The training phase runs in  $O(mn \log^2(mn) + m^\varepsilon n^{1+\varepsilon} \log(mn))$  time. The success probability is at least  $1 - O(1/n)$ .*

## 5 Conclusion

It is open whether one can get rid of the requirement that each distribution in the mixture contributes an instance with a probability of  $\Omega(1/n)$ , which is not needed for self-improving sorting [8]. Eliminating the  $n2^{O(\log^* n)}$  term from the limiting complexity might require solving the question raised in [5] that whether there is an  $O(n)$ -time algorithm for computing

the lower envelope of pseudo-planes. As a Voronoi diagram can be interpreted as the lower envelope of some appropriate surfaces, a natural question is what surfaces admit a self-improving lower envelope algorithm.

## Abstract

We consider the problem of coordinated motion planning for a swarm of simple, identical robots: From a given start grid configuration of robots, we need to reach a desired target configuration via a sequence of parallel, continuous, collision-free robot motions, such that the set of robots induces a connected grid graph at all integer times. The objective is to minimize the *makespan* of the motion schedule, i.e., to reach the new configuration in a minimum amount of time. We show that this problem is NP-hard, even for deciding whether a makespan of 2 can be achieved, while it is possible to check in polynomial time whether a makespan of 1 can be achieved.

On the algorithmic side, we establish simultaneous constant-factor approximation for two fundamental parameters, by achieving *constant stretch* for *constant scale*. Scaled shapes (which arise by increasing all dimensions of a given object by the same multiplicative factor) have been considered in previous seminal work on self-assembly, often with unbounded or logarithmic scale factors; we provide methods for a generalized scale factor, bounded by a constant. Moreover, our algorithm achieves a *constant stretch factor*: If mapping the start configuration to the target configuration requires a maximum Manhattan distance of  $d$ , then the total duration of our overall schedule is  $\mathcal{O}(d)$ , which is optimal up to constant factors.

## 1 Introduction

Coordinating the motion of a set of objects is a fundamental problem that occurs in a large spectrum of theoretical and practical contexts. This problem was also the subject of the 2021 CG Challenge [12], highlighting the high relevance for the algorithmic community.

In this paper, we consider *connected* swarm reconfiguration: transform a set of mobile agents from a given start into a desired target configuration by a sequence of parallel, continuous, collision-free motions that keeps the overall arrangement connected at all integer times. Problems of this type occur for assemblies in space, where disconnected pieces cannot regain connectivity, or for small-scale swarm robots (such as *catoms* in *claytronics* [13]) which need connectivity for local motion, electric power and communication; see Figure 1.

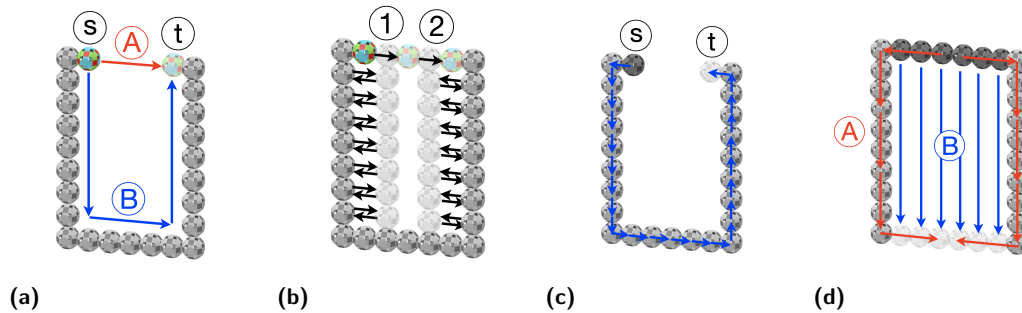

A crucial algorithmic aspect is *efficiency*: How can we coordinate the robot motions, such that a target configuration is reached in timely or energy-efficient manner? Most previous work has largely focused on sequential schedules, where one robot moves at a time, with objectives such as minimizing the number of moves. In practice, however, robots usually move simultaneously, so we desire a *parallel* motion schedule, with a natural objective of minimizing the time until completion, called *makespan*. How well can we exploit parallelism in a robot swarm to achieve an efficient schedule? As illustrated in Figure 2, this is where the connectivity constraints make a tremendous difference.

A critical parameter in self-assembly is the robustness of the involved shapes, corresponding to sufficient local connectivity to prevent fragility. This leads to the concept of *scaled shapes*; intuitively, a scale factor of  $c$  corresponds to replacing each pixel of a polyomino shape by a quadratic  $c \times c$  array of pixels. This has fundamental connections to Kolmogorov and runtime complexity, as shown by Soloveichik and Winfree [22]: “Furthermore, the independence of scale in self-assembly theory appears to play the same crucial role as the independence of running time in the theory of computability. . . [we] show that the running-time complexity, with respect to Turing machines, is polynomially equivalent to the scale complexity of the same function implemented via self-assembly by a finite set of tile types.” As a consequence, limiting scale has received considerable attention, as sketched in the related work section.

As we demonstrate in this paper, achieving optimal makespan for connected reconfiguration is provably hard, even in relatively basic cases. On the positive side, we present methods that are capable of achieving a constant-factor approximation, assuming not more than a generalization of constant scale of configurations. As can be seen from Figure 2, this is considerably more intricate than in a non-connected setting, even in very basic instances.

## 1.1 Our Results

We provide a spectrum of new results for questions arising from efficiently reconfiguring a connected, unlabeled swarm of robots from a start configuration  $C_s$  into a target configuration  $C_t$ , aiming for minimizing the overall makespan and maintaining connectivity in each step.

■ **Figure 2** Reconfiguration with and without connectivity constraints. (a) Relocating the colored particle from  $s$  to  $t$ , without (red trajectory A) and with connectivity constraint (blue trajectory B). (b) Coordinating many particles to quickly deliver a specific particle to a desired location, while preserving connectivity. (c) Reconfiguring an arrangement of *identical* particles in a single, parallel, connected step. (d) Reconfiguring an arch-shaped arrangement of identical particles into a U-shaped one, without (motion plan A, shown in red) and with connectivity (motion plan B, shown in blue).

- Deciding whether there is a schedule with a makespan of 1 transforming  $C_s$  into  $C_t$  can be done in polynomial time, see Theorem 1.
- Deciding whether there is a schedule with a makespan of 2 transforming  $C_s$  into  $C_t$  is NP-hard, see Theorem 2. This implies NP-hardness of approximating the minimum makespan within a constant of  $(\frac{3}{2} - \varepsilon)$ , for any  $\varepsilon > 0$ , see Corollary 3.
- As our main algorithmic result, we show that there is a constant  $c^*$  such that for any pair of start and target configurations with a (generalized) scale of at least  $c^*$ , a schedule with constant stretch can be computed in polynomial time, see Theorem 4 and Corollary 11. This implies that there is a constant-factor approximation for the problem of computing schedules with minimal makespan restricted to pairs of start and target configurations with a scale of at least  $c^*$ , see Corollary 12.

## 1.2 Related Work

In the following, we provide a sketch of the wide spectrum of related work; see the full version of our paper [11] for a more detailed overview, as well as [7].

The basic question of coordinating the motion of many agents in an efficient manner arises in many applications, such as ground swarm robotics [18, 19], aerial swarm robotics [3, 28], air traffic control [5], and vehicular traffic networks [10, 20]. Multi-robot coordination dates back to the seminal work by Schwartz and Sharir [21] from the 1980s. In both discrete and geometric variants of the problem, the objects can be *labeled*, *colored* or *unlabeled*. In the *labeled* case, the objects are all distinguishable and each object has its own, uniquely defined target position. In the *colored* case, the objects are partitioned into  $k$  groups and each target position can only be covered by an object with the right color; see Solovey and Halperin [23]. In the *unlabeled* case, objects are indistinguishable and target positions can be covered by any object; see Kloder and Hutchinson [15], Turpin et al. [27], Adler et al. [1], and Solovey et al. [25]. On the negative side, Solovey and Halperin [24] prove that the unlabeled multiple-object motion planning problem is PSPACE-hard.

For an instance of parallel reconfiguration, a lower bound for the time required for *all* robots to reach their destinations is the maximum distance between a robot's origin and destination. This motivates the *stretch factor*, i.e., the ratio of the makespan of a parallel motion plan divided by the maximum distance. In recent work, Demaine et al. [2, 7] were

able to develop algorithms that can achieve *constant* stretch factors that are independent of the number of robots; however, these approaches do not satisfy the crucial connectivity constraint, so different algorithmic methods are required.

The concept of scale complexity has received considerable attention in self-assembly; achieving constant scale has required special cases or operations. Soloveichik and Winfree [22] showed that the minimal number of distinct tile types necessary to self-assemble a shape, at some scale, can be bounded both above and below in terms of the shape’s Kolmogorov complexity, leading to unbounded scale in general. Demaine et al. [9] showed that allowing to destroy tiles can be exploited to achieve a scale that is only bounded by a logarithmic factor, beating the linear bound without such operations. In a setting of recursive, multi-level *staged* assembly with a logarithmic number of stages (i.e., “hands” for handling subassemblies), Demaine et al. [6] achieved logarithmic scale, and constant scale for more constrained classes of polyomino shapes; this was later improved by Demaine et al. [8] to constant scale for a logarithmic number of stages. More recently, Luchsinger et al. [16] employed repulsive forces between tiles to achieve constant scale in two-handed self-assembly.

## 2 Preliminaries

We consider *robots* at integer grid positions. A set of  $n$  unlabeled robots forms a *configuration*  $C$ , corresponding to a vertex-induced subgraph  $H$  of the infinite integer grid, with an edge between two grid vertices  $v_1, v_2 \in C$  if and only if  $v_1$  and  $v_2$  are on adjacent grid positions, i.e., a distance of 1 apart. A configuration is *connected*, if  $H$  is connected. Two configurations  $C_1$  and  $C_2$  *overlap*, if they have at least one position in common. A configuration  $C$  is *c-scaled*, if it is the union of  $c \times c$  squares of vertices. The *scale* of a configuration  $C$  is the maximal  $c$  such that  $C$  is  $c$ -scaled. This corresponds to objects being composed of pixels at a certain resolution; note that this is a generalization of the uniform pixel scaling studied in previous literature (which considers a  $c$ -grid-based partition instead of an arbitrary union), so it supersedes that definition and leads to a more general set of results. Two robots are *adjacent* if their positions  $v_1, v_2$  are adjacent, i.e.,  $(v_1, v_2) \in E(H)$ ; and *diagonally adjacent* if their positions are adjacent with a common vertex  $v$  such that  $(v_1, v)$  and  $(v, v_2)$  lie orthogonal.

A robot can move in discrete time steps by changing its location from a grid position  $v$  to an adjacent grid position  $w$ ; denoted by  $v \rightarrow w$ . Two moves  $v_1 \rightarrow w_1$  and  $v_2 \rightarrow w_2$  are called *collision-free* if  $v_1 \neq v_2$  and  $w_1 \neq w_2$ . A *transformation* between two configurations  $C_1 = \{v_1, \dots, v_n\}$  and  $C_2 = \{w_1, \dots, w_n\}$  is a set of collision-free moves  $\{v_i \rightarrow w_i \mid i = 1, \dots, n\}$ . Note that a robot is allowed to hold its position. For  $M \in \mathbb{N}$ , a *schedule* is a sequence  $C_1 \rightarrow \dots \rightarrow C_{M+1}$  (also denoted as  $C_1 \rightrightarrows C_{M+1}$ ) of transformations, with a *makespan* of  $M$ . A *stable* schedule  $C_1 \rightrightarrows_{\chi} C_{M+1}$  uses only connected configurations. Let  $C_s, C_t$  be two connected configurations with equally many robots called *start* and *target configuration*, respectively. A *matching* is a one-to-one mapping between vertices from  $C_s$  and  $C_t$ . The *diameter* of a matching is the maximal Manhattan distance between two matched vertices. A *bottleneck matching* is a matching with a minimal diameter. The *diameter*  $d$  of  $(C_s, C_t)$  is the diameter of a bottleneck matching. The *stretch (factor)* of a (stable) schedule is the ratio between the makespan  $M$  of the schedule and the diameter  $d$  of  $(C_s, C_t)$ .

### 3 Makespan 1 and 2

As a first observation we note that it can be decided in polynomial time whether there is a schedule  $C_s \rightarrow C_t$  with a makespan of 1 between a start and a target configuration.

► **Theorem 1.** *For a pair of configurations  $C_s$  and  $C_t$ , each with  $n$  vertices, it can be decided in polynomial time whether there is a schedule with a makespan of 1 transforming  $C_s$  into  $C_t$ .*

**Proof.** Given two connected configurations  $C_s$  and  $C_t$ , each with  $n$  vertices. We compute the bipartite graph  $G_{C_s, C_t} = (V_s \cup V_t, E)$ , where  $V_s$  and  $V_t$  consist of all occupied positions in  $C_s$  and  $C_t$ . For  $E$ , we add an edge if and only if an occupied position in  $C_t$  is adjacent (or identical) to an occupied position in  $C_s$ . Consider a perfect matching in  $G_{C_s, C_t}$ . Because edges only connect positions which are at most one unit step apart, all robots can move along their respective matching edges without crossing the path of another robot. If there is no perfect matching in  $G_{C_s, C_t}$ , at least one robot would have to move to a position further away. Thus, a makespan of 1 would not be achievable. So, there is a schedule of makespan 1 if and only if  $G_{C_s, C_t}$  admits a perfect matching. Because the graph is sparse, this can be checked in  $\mathcal{O}(n^{3/2})$  time, using the method of Hopcroft and Karp [14]. ◀

Note that, because  $C_s$  and  $C_t$  have to be connected, a schedule with a makespan of 1 is always stable. Even for a makespan of 2, the same problem becomes provably difficult.

► **Theorem 2.** *For a pair of configurations  $C_s$  and  $C_t$ , each with  $n$  vertices, deciding whether there is a stable schedule with a makespan of 2 transforming  $C_s$  into  $C_t$  is NP-hard.*

The proof is based on a reduction from the NP-hard problem PLANAR MONOTONE 3SAT [4], which asks to decide whether a Boolean 3-CNF formula  $\varphi$  is satisfiable, for which in each clause the literals are either all unnegated or all negated.

The reduction considers an instance  $\varphi$  of PLANAR MONOTONE 3SAT and constructs an instance  $I_\varphi$  with start configuration  $C_s$  and target configuration  $C_t$ ; see Figure 3, with start configuration (red), target configuration (dark cyan), and positions in both configurations (gray) indicated by colors. We consider a rectilinear planar embedding of the variable-clause incidence graph  $G_\varphi$  of  $\varphi$ , with variable vertices placed horizontally in a row, and clauses with unnegated and negated literals placed above and below, respectively. Variables of  $\varphi$  are represented by horizontal *variable gadgets* (light red). Two additional *auxiliary gadgets* (light blue) are positioned at the top and at the bottom boundary of the instance, connected to the variable gadget via bridges at the right boundary, and a *separation gadget* (yellow) between each adjacent and nested pair of *clause gadgets* (blue). All clause gadgets are connected via bridges to separation gadgets and possibly to the auxiliary gadgets. Further, there are bridges from a clause gadget to the respectively contained variables.

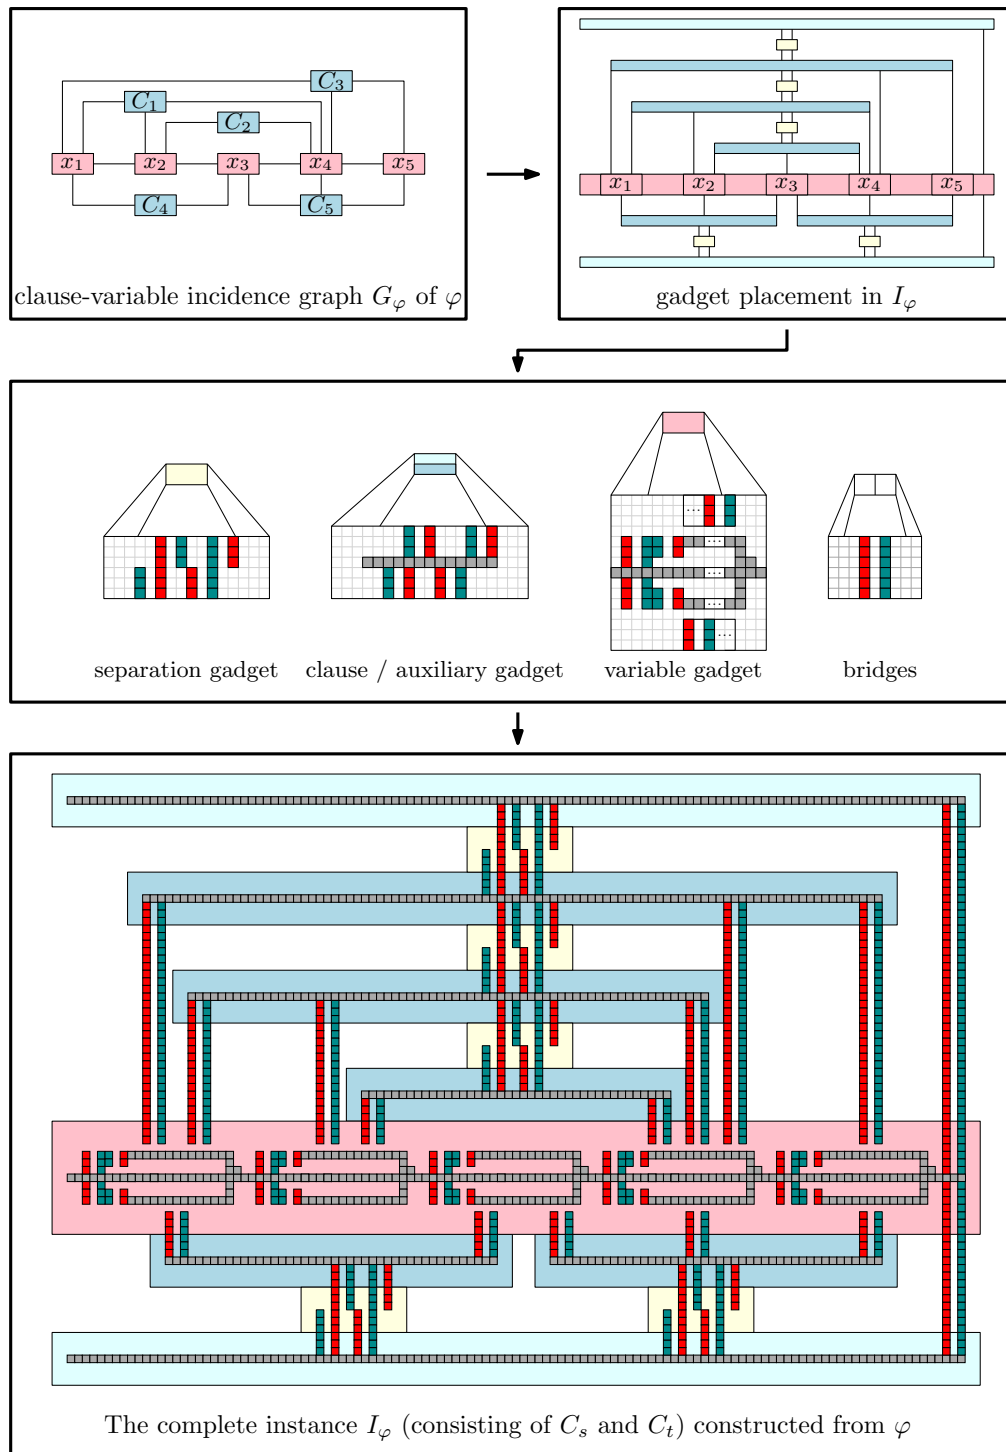

Now a stable schedule for  $I_\varphi$  transforming the start configuration  $C_s$  into the target configuration  $C_t$  with a makespan of 2 requires some robots of the variable gadget to move in a very particular way to ensure connectivity between the variable gadget and the clause gadgets via corresponding bridges. As shown in technical detail in the full paper, this allows variable robots to connect either to the negated or the unnegated literal of involved clauses, inducing a satisfying variable assignment for  $\varphi$ .

Technical details of the proof of Theorem 2 are given in the full version [11].

As a consequence of Theorem 2, even approximating the makespan is NP-hard.

► **Corollary 3.** *It is NP-hard to compute for a pair of configurations  $C_s$  and  $C_t$ , each with  $n$  vertices, a stable schedule that transforms  $C_s$  into  $C_t$  within a constant of  $(\frac{3}{2} - \varepsilon)$  (for any  $\varepsilon > 0$ ) of the minimum makespan.*

9:6 Connected Coordinated Motion Planning with Bounded Stretch

■ **Figure 3** Symbolic overview of the NP-hardness reduction. The depicted instance is due to the PLANAR MONOTONE 3SAT formula  $\varphi = (x_1 \vee x_2 \vee x_4) \wedge (x_2 \vee x_4) \wedge (x_1 \vee x_4 \vee x_5) \wedge (\bar{x}_1 \vee \bar{x}_3) \wedge (x_3 \vee x_4 \vee x_5)$ . We use three different colors to indicate occupied positions in the start configuration (red), in the target configuration (dark cyan), and in both configurations (gray).

## 4 Bounded Stretch for Arbitrary Makespan

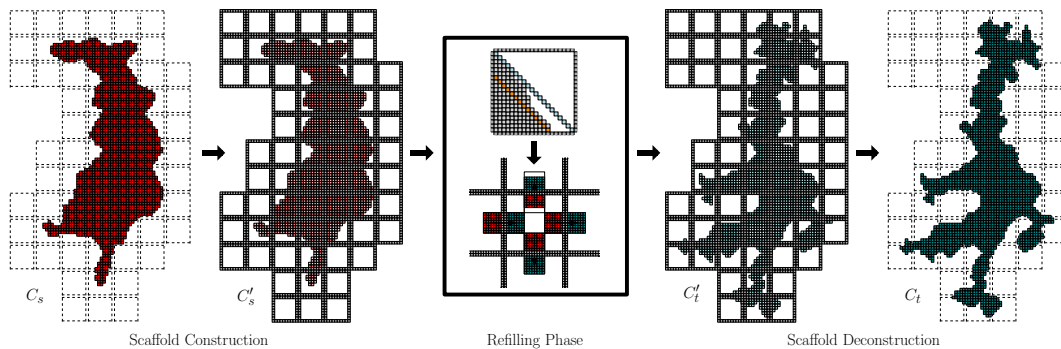

Now we describe our algorithm for computing stable schedules with constant stretch.

► **Theorem 4.** *There is a constant  $c^*$  such that for any pair of overlapping start and target configurations with a scale of at least  $c^*$ , there is a stable schedule of constant stretch.*

For clearer presentation, we do not focus on the specific value of the constant  $c^*$ , but only argue its existence.

### 4.1 Algorithm Overview and Preliminaries

#### 4.1.1 Informal Outline

■ **Figure 4** Overview of the computed schedule: (Left) Constructing the scaffold of  $cd$ -tiles, (middle) the refilling phase, and (right) deconstructing the scaffold.

See Figure 4 for an overview. In two preprocessing phases, we first ensure that the pair  $(C_s, C_t)$  overlaps in at least one position. For this, we move  $C_s$  towards  $C_t$  along a bottleneck matching such that the respective positions that realize the bottleneck distance, coincide. The overlap is necessary to successfully construct the auxiliary structure in the third phase of our approach. Afterwards, we use another bottleneck matching algorithm for mapping the start configuration  $C_s$  to the target configuration  $C_t$ , minimizing the maximum distance  $d$  between a start and a target location. Furthermore, we establish the scale in both configurations, set  $c$  to be the minimum of both scale values, and compute a suitable tiling whose tile size is  $c \cdot d$ , and that contain both  $C_s$  and  $C_t$ .

In a third phase, we build a scaffolding structure around  $C_s$  and  $C_t$ , based on the boundaries of  $cd$ -tiles of the specific tiling, see Figures 4 (left) and 5. This provides connectivity throughout the actual reconfiguration. Restricting robot motion to their current and adjacent tiles also ensures constant stretch. Note that, as the size of the tiles is related to  $d$ , the scaffolding structure is connected.

In a fourth phase, we perform the actual reconfiguration of the arrangement. This consists of refilling the tiles of the scaffold structure, achieving the proper number of robots within each tile, based on elementary flow computations. As a subroutine, we transform the robots inside each tile into a canonical “triangle” configuration, see Figures 4 (middle), 6, and 7.

In a fifth and final phase, we disassemble the scaffolding structure and move the involved robots to their proper destinations, see Figures 4 (right) and 5.

### 4.1.2 Technical Key Components

On a technical level, the five phases can be summarized as follows; again, refer to Figure 4.

- (1) **Guaranteeing Overlap:** Move the configurations towards each other along a bottleneck matching to ensure that the pair  $(C_s, C_t)$  overlaps in at least one position.
- (2) **Preprocessing:** Apply the following three preprocessing steps: (2.1) Set  $c$  to be the minimum of  $c^*$  and the minimum scale values of  $C_s$  and  $C_t$ . (2.2) Compute the diameter  $d$  of  $(C_s, C_t)$ . (2.3) Compute the tiling  $\mathcal{T}$  of  $(C_s, C_t)$ .

The algorithmic core of our algorithm consists of the following three phases.

- (3) **Scaffold Construction:** Reconfigure the start configuration  $C_s$  to a tiled configuration  $C'_s$  such that the interior of  $C'_s$  is a subset of the start configuration  $C_s$ , see Figure 5.
- (4) **Refilling Tiles:** Reconfigure  $C'_s$  to a tiled configuration  $C'_t$ , such that the interior of  $C'_t$  is a subset of the target configuration  $C_t$ , see Figures 6 and 7.
- (5) **Scaffold Deconstruction:** Reconfigure  $C'_t$  to  $C_t$ , see Figure 5.

Note that the scaffold deconstruction is inverse to the scaffold construction.

### 4.1.3 Preliminaries for the Algorithm

Let  $c, d \in \mathbb{N}$  be the scale and the diameter of the pair  $(C_s, C_t)$ , respectively. For  $x, y \in \mathbb{N}$ , a  $cd$ -tile  $T$ , or *tile*  $T$  for short, with *anchor vertex*  $(x \cdot cd, y \cdot cd) \in V(G)$  is a set of  $(cd)^2$  vertices from the grid  $G$  with  $x$ -coordinates from the range between  $x \cdot cd$  and  $x \cdot cd + cd - 1$  and  $y$ -coordinates from the range between  $y \cdot cd$  and  $y \cdot cd + cd - 1$ . The *boundary* of  $T$  is the set of vertices from  $T$  with an  $x$ -coordinate equal to  $x \cdot cd$  or equal to  $x \cdot cd + cd - 1$ , or with a  $y$ -coordinate equal to  $y \cdot cd$  or equal to  $y \cdot cd + cd - 1$ . The *interior* of  $T$  is  $T$  without its boundary. The *right, top, left, and bottom sides* of  $T$  are the sets of vertices from the boundary of  $T$  with maximum  $x$ -coordinates, maximum  $y$ -coordinates, minimum  $x$ -coordinates, and minimum  $y$ -coordinates, respectively. The left and right sides of a tile are *vertical sides* and the top and bottom sides are *horizontal sides*. Two tiles  $T_1, T_2$  are *horizontal (vertical) neighbors* if they have two vertical (horizontal) sides  $s_1 \subset T_1$  and  $s_2 \subset T_2$ , such that each vertex from  $s_1$  is adjacent in  $G$  to a vertex from  $s_2$ . Two tiles  $T_1$  and  $T_2$  are *diagonal neighbors* if there is another tile  $T$ , such that  $T$  and  $T_1$  are horizontal neighbors and  $T$  and  $T_2$  are vertical neighbors. The *neighborhood* of a tile  $T$  is the set of all neighbors of  $T$ . A configuration in the interior of a tile  $T$  is called *monotone*, if and only if for every robot  $r$  in the interior of  $T$  all positions to the left and to the bottom are occupied.

A *start tile* is a tile containing a vertex from the start configuration. A *target tile* is a tile containing a vertex from the target configuration. The *cd-tiling*  $\mathcal{T}$  of  $(C_s, C_t)$  is the union of all start tiles including their neighborhoods and all target tiles. The *scaffold* of  $\mathcal{T}$  is the union of all boundaries of tiles from  $\mathcal{T}$ . A *cd-tiled configuration*  $C$ , or *tiled configuration*  $C$  for short, is a configuration that is a subset of  $\mathcal{T}$  and a superset of the scaffold of  $\mathcal{T}$ . The *interior* of a tiled configuration  $C$  is the set of all vertices from  $C$  not lying on the scaffold. The *filling level* of a tile  $T \in \mathcal{T}$  is the number of robots in the interior of  $T$ . The *filling level* of a tiled configuration  $C$  is the mapping of each tile onto its filling level in  $C$ .

In the following we give the technical description of our algorithm and the corresponding correctness analysis. In particular, we first assume that the start and target configurations overlap in at least one position, resulting in an algorithm guaranteeing constant stretch, and adapt this to the case in that an overlap initially does not exist, afterwards.

## 4.2 Scaffold Construction

► **Lemma 5.** *For any configuration  $C_s$  of scale  $c$  there is a stable schedule of makespan  $\mathcal{O}(d)$ , transforming  $C_s$  into a tiled configuration  $C'_s$ , with the interior of  $C'_s$  being a subset of  $C_s$ .*

**Outline of the Construction.** For the construction we consider  $5 \cdot 5$  different classes, based on  $x$ - and  $y$ -coordinates modulo  $5cd$ ; see Figure 5. We process a single class as follows. For each tile  $T$  we consider its *indirect* neighborhood  $N[T]$  consisting of all neighbors of  $T$  and all neighbors of neighbors of  $T$ , i.e., a  $5 \times 5$  arrangement of tiles centered at  $T$ . For constructing the boundary of  $T$ , we make use of robots from the interior of a tile in  $N[T]$ .

**Constructing the Boundary of  $T$  works in Two Phases.**

(3.1) Constructing the boundaries of all start tiles.

(3.2) Constructing the boundaries of all neighbors of start tiles.

Note that it suffices to construct all boundaries of the start tiles and their neighboring tiles, because each target tile shares a side with a start tile or a side with a tile adjacent to a start tile. Furthermore, the scale condition is only necessary for the construction of the scaffold, i.e., we need to ensure that enough robots are available to build the scaffolding structure. Each additional step of the algorithm works independently from this condition. A very rough estimate on the scale is that  $c^* = 400$  is sufficient.

For details of the construction and the proof, we refer to the full version [11].

■ **Figure 5** Constructing the scaffold. Tiles with currently constructed boundaries are marked in purple. The zoom into the start configuration  $C_s$  shows the indirect neighborhood  $N[T]$  of a tile  $T$  (middle) for which its boundary is currently constructed and a further zoom into  $T$  with an associated robot motion (right). In each transformation step a robot from the interior of a tile  $T' \in N[T]$  is swapped with a free position on the boundary of  $T$  based on a path  $P$  on a BFS-tree.

## 4.3 Refilling Tiles

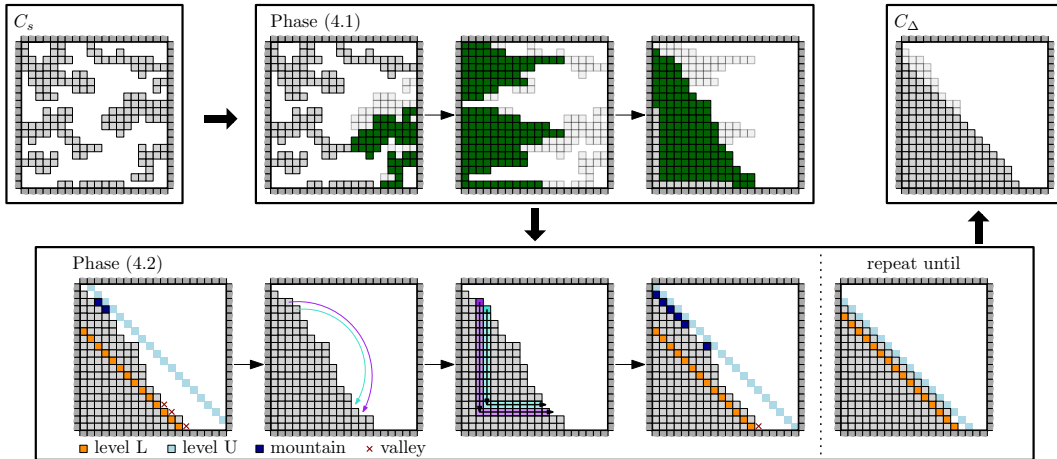

It remains to modify configurations within and between tiles. To this end, we first establish how to efficiently perform reconfigurations between any two tiled configurations *with the same numbers of robots* in the interior of respective tiles; see Section 4.3.1. As a second step, we describe how to relocate robots between tiles such that efficient reconfigurations between any two tiled configurations *with different numbers of robots* in the interior of respective tiles are achieved; see Section 4.3.2.

### 4.3.1 Reconfiguration Maintaining the Number of Robots inside Tiles

► **Lemma 6.** *Let  $C'_s, C'_t$  be two tiled configurations such that for all tiles  $T$ ,  $C'_s$  and  $C'_t$  have the same filling levels, i.e., for any tile, the corresponding start and target configurations consist of the same respective numbers of robots. Then there is a stable schedule transforming  $C'_s$  into  $C'_t$  within a makespan of  $\mathcal{O}(d)$ .*

In the following we describe reconfigurations that leave all robot movements within the interior of their respective tiles  $T$ ; thus, all tiles can be reconfigured in parallel. Therefore, we only have to describe the approach for a start configuration  $C_s$  and a target configuration  $C_t$  within the interior of a single tile  $T$  of a tiled configuration  $C'_s$ .

**Outline of the Reconfiguration.** First compute two stable schedules  $C_s \Rightarrow_\chi C_s^m$  and  $C_t \Rightarrow_\chi C_t^m$ , where  $C_s^m$  and  $C_t^m$  are monotone configurations. These reconfigurations are achieved by a sequence of down and left movements, maintaining connectivity after each move (see Figure 6 (Phase 4.1)). Proceeding from these monotone configurations, the robots are arranged into a triangular configuration  $C_\Delta$  that occupies the lower left positions (defined by a diagonal line with a slope of  $-1$ ) of the interior of  $T$ . This is achieved by swapping pairs of occupied and empty positions within a carefully defined area in several one-step moves along L-shaped paths (see Figure 6 (Phase 4.2)). The property of  $C_\Delta$  is that it is the same for all initial configurations with equally many robots. Thus, to get the stable schedule  $C_s \Rightarrow_\chi C_\Delta \Rightarrow_\chi C_t$ , we can simply revert  $C_t \Rightarrow_\chi C_\Delta$  and combine the result with  $C_s \Rightarrow_\chi C_\Delta$ .

■ **Figure 6** Turning arrangement  $C_s$  (top) into the canonical triangle configuration  $C_\Delta$  (bottom). Phase (4.1) achieves a monotonic arrangement; light gray indicates previous positions of moved robots (shown in green). Phase (4.2) transforms the monotonic configuration into  $C_\Delta$ .

Technically, the approach consists of the following four phases, see Figure 6.

- (4.1) **Monotone Start Configuration:** Reconfigure  $C_s$  into  $C_s^m$ .
- (4.2) **Canonical Triangle:** Reconfigure  $C_s^m$  into  $C_\Delta$ .
- (4.3) **Monotone Target Configuration:** Reconfigure  $C_\Delta$  into  $C_t^m$ .
- (4.4) **Target Configuration:** Reconfigure  $C_t^m$  into  $C_t$ .

Phase (4.4) corresponds to a reversal of Phase (4.1), and Phase (4.3) to one of Phase (4.2), so we only have to describe the first two phases. We analyze them individually, leading to a proof of Lemma 6. Note that we exclude the corners of a tile, so the robots on the tile’s side now form four *non-adjacent* sides. Furthermore, only robots in a tile’s interior move.

**Constructing the Monotone Start Configuration (Phase (4.1)).** In the first step, we only consider robots for which the right side of their tile  $T$  is the only one to which they are connected through the interior of  $T$ . We iteratively move these robots down until further movement is blocked, i.e., any further down move is not collision-free. In the second and third steps, we move all robots left, followed by moving all robots down, each time until further movement is blocked.

For Phase (4.2), we use the following terminology. The *level* of a position in the tile's interior is the sum of its coordinates. A level is *filled*, if all of its positions are occupied by a robot, and *empty*, if none is occupied by a robot. The highest filled level is denoted by  $L$ , the lowest empty level by  $U$ . Let  $\mathcal{M}$  be the set of all positions on level  $U - 1$  occupied by a robot, and  $\mathcal{V}$  be the set of all positions on level  $L + 1$  that are not occupied by a robot (see Figure 6 (Phase 4.2 left)); we call the positions of  $\mathcal{M}$  and  $\mathcal{V}$  *mountains* and *valleys*, respectively.

**Constructing the Canonical Triangle (Phase (4.2)).** Choose two equally sized subsets  $\mathcal{M}' \subseteq \mathcal{M}$  and  $\mathcal{V}' \subseteq \mathcal{V}$  and push each robot from  $\mathcal{M}'$  to a different position in  $\mathcal{V}'$  along an L-shaped path; this can be done simultaneously in one parallel move for all paths. To determine the paths, simply match mountains and valleys, iteratively, in a way that no pair of paths cross each other. This results in reducing  $U$ , and raising  $L$ , i.e., the two levels move towards each other. We distinguish two cases.

- $U - L > 2$ : If  $|\mathcal{M}| \geq |\mathcal{V}|$ , choose an arbitrary subset  $\mathcal{M}' \subset \mathcal{M}$  with  $|\mathcal{M}'| = |\mathcal{V}|$ . Otherwise, choose an arbitrary subset  $\mathcal{V}' \subset \mathcal{V}$  with  $|\mathcal{V}'| = |\mathcal{M}|$ .
- $U - L = 2$ : Note that mountains and valleys are on the same level, and  $|\mathcal{V}| \geq |\mathcal{M}|$  hold. Choose  $\mathcal{V}' \subset \mathcal{V}$  to be the subset of size  $|\mathcal{M}|$  with *smallest*  $x$ -coordinates and set  $\mathcal{M}' = \mathcal{M}$ .

Due to space constraints, the details can be found in the full version [11].

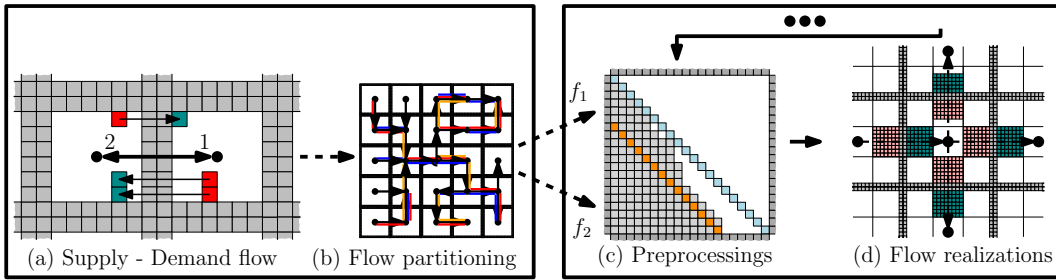

### 4.3.2 Refilling Tiled Configurations

Now we describe the final step for reconfiguring a tiled start configuration  $C'_s$  into a tiled target configuration  $C'_t$ ; because no robots are destroyed or created, this hinges on shifting robots between adjacent tiles, such that the required filling levels are achieved.

► **Lemma 7.** *We can efficiently compute a stable schedule transforming  $C'_s$  into  $C'_t$  within a makespan of  $\mathcal{O}(d)$ .*

**Outline of the Refilling Phase.** To compute the schedule of Lemma 7, we transfer robots between tiles, so that each tile  $T$  contains the desired number in  $C'_t$ . We model this robot transfer by a *supply and demand flow*, see Figure 7, followed by partitioning the flow into  $\mathcal{O}(1)$  subflows, such that each subflow can be realized within a makespan of  $\mathcal{O}(d)$ . For realizing a single subflow, we use the approach of Section 4.3.1 as a preprocessing step, i.e., to rearrange robots participating in a specific subflow and place them at suitable positions.

**Modeling Transfer of Robots via a Supply and Demand Flow.** We model the transfer of robots between tiles as a flow  $F : E(G) \rightarrow \mathbb{N}$ , using the directed graph  $G = (\mathcal{T}, E)$  which is dual to the tiling  $\mathcal{T}$ . Let  $B$  be the bottleneck matching between vertices from the original (non-tiled)  $C_s$  and vertices from the final (non-tiled)  $C_t$ . In  $G$  we have an edge  $(u, v) \in E$ , if there is at least one matching edge  $(r_u, r_v) \in B$ , such that  $r_u$  lies in the interior of the tile  $u$  in configuration  $C'_s$ , and  $r_v$  lies in the interior of the tile  $v$  in configuration  $C'_t$ . The flow value  $F((u, v))$  of  $(u, v)$  is equal to the number of such edges  $(r_u, r_v) \in B$ . A vertex  $v \in V(G)$

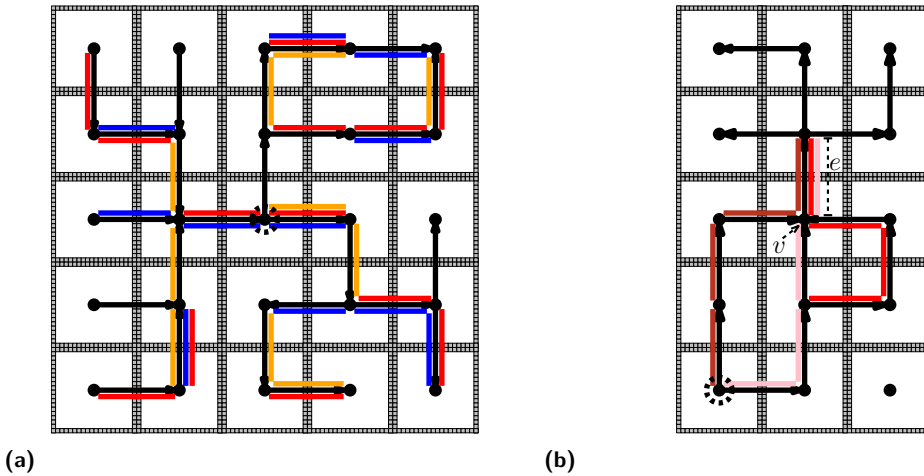

■ **Figure 7** An overview of the schedule refilling tiles: transforming  $C'_s$  into  $C'_t$  by realizing a partition of a supply and demand flow that is computed in advance.

has a *demand* of  $a > 0$  if the sum of the flow values of outgoing edges from  $v$  plus  $a$  is equal to the sum of the flows of incoming edges to  $v$ . Analogously,  $v$  has a *supply* of  $a > 0$  if the sum of flow values incoming to  $v$  plus  $a$  equals the sum of flow values outgoing from  $v$ .

**Flow Partition and Algorithmic Computation.** Now we define a *flow partition* of  $F$ .

► **Definition 8.** For  $k \in \mathbb{N}$ , a  $k$ -subflow of  $F$  is a supply and demand flow  $f : E(G) \rightarrow \mathbb{N}$  on  $G$  with  $f(e) \leq \min\{k, F(e)\}$ . A  $k$ -partition of the flow  $F$  is a set  $\{f_1, \dots, f_\ell\}$  of  $k$ -subflows of  $F$ , such that  $\sum_{i=1, \dots, \ell} f_i(e) = F(e)$  holds for all edges  $e \in E(G)$ .

We describe our approach for computing a  $\phi$ -partition of  $F$ , with  $\phi := \lfloor \frac{(cd-2)^2}{9} \rfloor$ ; the value  $\phi$  arises from partitioning the interior (made up of  $(cd - 2)^2$  pixels) of each tile into 9 almost equally sized *subtiles* that are used for realizing a single set of paths as described below, see Figure 7(d).

■ **Figure 8** (a) We model the movements of robots between tiles as paths forming a tree. By greedily assigning these paths to sets (here highlighted by different colors), such that inside each set each edge is contained in no more than 3 paths, we obtain that at most  $\Theta(d^2)$  sets are needed. (b) An example of a set containing three paths (dark red, pink, and red; assigned in that order to  $S_j$ ) having a common edge  $e$  caused by a vertex  $v$  of  $e$  with an incoming degree of 3.

We compute a 1-partition of  $G$ , with each 1-subflow being either a cycle or a path that connects a supply vertex with a demand vertex. Because the robots are unlabeled, we can simplify  $G$  by eliminating all cyclic 1-subflows, as they are not necessary to realize this

specific transfer of robots; note that this also applies to bidirectional edges. Furthermore, we replace diagonal edges  $(v, w) \in E(G)$  by a pair of adjacent edges  $(v, u), (u, w) \in E(G)$ . After all cyclic subflows are removed,  $G$  is a planar, directed forest consisting of 1-subflows that are paths, see Figure 8(a). We process each tree  $A \subset G$  that is made up of paths  $P_1, P_2, \dots$  separately as follows: We choose an arbitrary vertex of  $A$  as its *root* and consider the *link distance* of  $P_i$  as the minimal length of the path between a vertex from  $P_i$  and the root of  $A$ . Let  $P_1, P_2, \dots \subseteq G$  be sorted by increasing link distances, which is important for our next argument, regarding that we can partition these paths into constant many subflows each of which is realizable in time linear in  $d$ . We greedily assign each path  $P_i = P_1, P_2, \dots$  to a set  $S_j$ , such that the first edge  $e_1$  of  $P_i$  is not part of another path inside  $S_j$ . If no such a set  $S_j$  exists, we create a new set  $S \leftarrow \{P_i\}$ . For each tree we use the same sets  $S_1, S_2, \dots$  of collected paths, because different trees of  $G$  are disjoint. Note, that the construction of the sets  $S_j$  allow that an edge is part of at most three paths inside  $S_j$ . This is due to the fact that the income degree of a head vertex of a directed edge is at most three in the setting of a grid graph, resulting in at most three outgoing edges.

Finally, we greedily partition  $\{S_1, S_2, \dots\}$  into subsets  $G_1, G_2, \dots$  called *groups*, made up of  $\frac{(cd-2)^2}{9 \cdot 3}$  sets. For each group  $G_i$ , we define a subflow  $f_i$  by setting  $f_i(e)$  as the number of paths from  $G_i$  containing the edge  $e$ . As for each set  $S_i$  and each edge  $e$ , there are at most three paths inside  $S_i$  containing  $e$ , each resulting subflow  $f_i$  is a  $\left(\frac{(cd-2)^2}{9 \cdot 3} \cdot 3\right) = \phi$ -subflow. Finally, we have to upper-bound the number of resulting subflows, i.e., the number of groups.

► **Lemma 9.** *The constructed  $\phi$ -partition  $\{f_1, f_2, \dots\}$  consists of at most 28 subflows.*

**Realizing a  $\phi$ -Partition.** Now we describe how to reconfigure a tiled configuration, such that a  $\phi$ -subflow is removed from  $G$ .

► **Definition 10.** *A  $\phi$ -subflow  $f_i$  is realized by transforming the current configuration into another configuration, such that for each edge  $e$  with  $f_i((T, T')) > 0$ , the number of robots in the interior of tile  $T$  is decreased by  $f_i((T, T'))$  and the number of the robots in the interior of tile  $T'$  is increased by  $f_i((T, T'))$ .*

Next we realize a specific  $\phi$ -subflow within a makespan of  $\mathcal{O}(d)$ . In particular, we partition the interior of each tile  $T$  into 9 *subtiles* with equal side lengths (up to rounding), see Figure 7(d). For each subflow  $f_i$ , we place  $f_i((T, T'))$  robots inside the middle subtile of  $T$  that shares an edge with the boundary of  $T$  adjacent to  $T'$ . In particular, robots placed in the same subtile are arranged in layers of width  $\lfloor \frac{cd-2}{9} \rfloor$  as close as possible to the boundary of the tile, see Figure 7(d). The resulting arrangement of robots inside the subtile of  $T$  is a *cluster* and  $T'$  the *target tile* of the cluster. By a single application of the approach from Section 4.3.1, all clusters of all tiles are arranged simultaneously within a makespan of  $\mathcal{O}(d)$ . Finally, simultaneously pushing all clusters of all tiles into the direction of their target tiles realizes  $S_i$ , see Figure 7(d). Note that not all robots are pushed into the target tile  $T'$  but some replace robots on the boundaries between  $T$  and  $T'$ , see Figure 7(d).

Repeating this approach for each subflow  $f_i$  leads to a stable schedule that realizes the entire flow  $F$  within a makespan linear in  $d$ , i.e., transforms  $C'_s$  into  $C'_t$  within  $\mathcal{O}(d)$  transformation steps, see Figure 7.

The omitted proofs can be found in the full version [11].

This concludes the proof of Theorem 4. Finally, we adapt the result to the general case, for which overlap of the start and target configurations is not guaranteed.

► **Corollary 11.** *There is a constant  $c^*$  such that for any pair of start and target configurations with a scale of at least  $c^*$ , there is a stable schedule of constant stretch.*

**Proof.** In case of a pair  $(C_s, C_t)$ , consisting of a start and a target configuration, that does not overlap, our algorithm computes in a first step a minimum bottleneck matching mapping  $C_s$  to  $C_t$  resulting in a bottleneck distance  $\bar{d}$ , and translates  $C_s$  into a configuration  $\bar{C}_s$  overlapping the target configuration within a makespan of  $\bar{d}$ . This results in a bottleneck distance  $d$  between  $\bar{C}_s$  and  $C_t$  which is at most  $2\bar{d}$ . As Theorem 4 guarantees a makespan linear in  $d$ , we obtain a makespan linear in  $\bar{d} + d$ , i.e., linear in  $\bar{d}$  for the overall algorithm. ◀

As the diameter of the pair  $(C_s, C_t)$  is a lower bound for the makespan of any schedule transforming  $C_s$  into  $C_t$ , we obtain the following.

► **Corollary 12.** *There is a constant-factor approximation for computing stable schedules with minimal makespan between pairs of start and target configurations with a scale of at least  $c^*$ , for some constant  $c^*$ .*

## 5 Conclusion

We have shown that connected coordinated motion planning is challenging even in relatively simple cases, such as unlabeled robots that have to travel a distance of at most 2 units. On the other hand, we have shown that (assuming sufficient scale of the swarm), it is possible to compute efficient reconfiguration schedules with constant stretch.

It is straightforward to extend our approach to other scenarios, e.g., to three-dimensional configurations. Other questions appear less clear. Is it possible to achieve constant stretch for arrangements with very small scale factor? We believe that this may hinge on the ability to perform synchronized shifts on long-distance “chains” of robots without delay, which is not a valid assumption for many real-world scenarios. (A well-known example is a line of cars when a traffic light turns green.) As a consequence, the answer may depend on crucial assumptions on motion control; we avoid this issue in our approach. Can we provide alternative approaches with either weaker scale assumptions or better stretch factors? Can we extend our methods to the labeled case? All these questions are left for future work.

# Enclosing Depth and Other Depth Measures

Patrick Schneider   

Department of Mathematical Sciences, University of Copenhagen, Denmark

---

## Abstract

We study families of depth measures defined by natural sets of axioms. We show that any such depth measure is a constant factor approximation of Tukey depth. We further investigate the dimensions of depth regions, showing that the *Cascade conjecture*, introduced by Kalai for Tverberg depth, holds for all depth measures which satisfy our most restrictive set of axioms, which includes Tukey depth. Along the way, we introduce and study a new depth measure called *enclosing depth*, which we believe to be of independent interest, and show its relation to a constant-fraction Radon theorem on certain two-colored point sets.

## 1 Introduction

Medians are an important tool in the statistical analysis and visualization of data. Due to the fact that medians only depend on the order of the data points, and not their exact positions, they are very robust against outliers. However, in many applications, data sets are multidimensional, and there is no clear order of the data set. For this reason, various generalizations of medians to higher dimensions have been introduced and studied, see e.g. [1, 17, 21] for surveys. Many of these generalized medians rely on a notion of *depth* of a query point within a data set, a median then being a query point with the highest depth among all possible query points. Several such depth measures have been introduced over time, most famously Tukey depth [28] (also called halfspace depth), simplicial depth [16], or convex hull peeling depth (see, e.g., [1]). In particular, just like the median, all of these depth measures only depend on the relative positions of the involved points. More formally, let  $S^{\mathbb{R}^d}$  denote the family of all finite sets of points in  $\mathbb{R}^d$ . A depth measure is a function  $\varrho : (S^{\mathbb{R}^d}, \mathbb{R}^d) \rightarrow \mathbb{R}_{\geq 0}$  which assigns to each pair  $(S, q)$  consisting of a finite set of data points  $S$  and a query point  $q$  a value, which describes how deep the query point  $q$  lies within the data set  $S$ . A depth measure  $\varrho$  is called *combinatorial* if it depends only on the order type of  $S \cup \{q\}$ , that is, if it only depends on the orientations of the simplices spanned by the points, but not on their actual positions. In this paper, we consider general classes of combinatorial depth measures, defined by a small set of axioms, and prove relations between them and concrete depth measures, such as *Tukey depth* (TD) and *Tverberg depth* (TvD). Let us first briefly discuss these two depth measures.

► **Definition 1.** *Let  $S$  be a finite point set in  $\mathbb{R}^d$  and let  $q$  be a query point. Then the Tukey depth of  $q$  with respect to  $S$ , denoted by  $\mathbf{TD}(S, q)$ , is the minimum number of points of  $S$  in any closed half-space containing  $q$ .*

■ **Figure 1** The point  $q$  has enclosing depth 5.

Tukey depth, also known as *halfspace depth*, was independently introduced by Joseph L. Hodges in 1955 [11] and by John W. Tukey in 1975 [28] and has received significant attention since, both from a combinatorial as well as from an algorithmic perspective, see e.g. Chapter 58 in [27] and the references therein. Notably, the *centerpoint theorem* states that for any point set  $S \subset \mathbb{R}^d$ , there exists a point  $q \in \mathbb{R}^d$  for which  $\text{TD}(S, q) \geq \frac{|S|}{d+1}$  [22].

In order to define Tverberg depth, we need a preliminary definition: given a point set  $S$  in  $\mathbb{R}^d$ , an  $r$ -partition of  $S$  is a partition of  $S$  into  $r$  pairwise disjoint subsets  $S_1, \dots, S_r \subset S$  with  $\bigcap_{i=1}^r \text{conv}(S_i) \neq \emptyset$ , where  $\text{conv}(S_i)$  denotes the convex hull of  $S_i$ . We call  $\bigcap_{i=1}^r \text{conv}(S_i)$  the *intersection* of the  $r$ -partition.

► **Definition 2.** Let  $S$  be a finite point set in  $\mathbb{R}^d$  and let  $q$  be a query point. Then the Tverberg depth of  $q$  with respect to  $S$ , denoted by  $\text{TvD}(S, q)$ , is the maximum  $r$  such that there is an  $r$ -partition of  $S$  whose intersection contains  $q$ .

Tverberg depth is named after Helge Tverberg who proved in 1966 that any set of  $(d + 1)(r - 1) + 1$  points in  $\mathbb{R}^d$  allows an  $r$ -partition [29]. In particular, this implies that there is a point  $q$  with  $\text{TvD}(S, q) \geq \frac{|S|}{d+1}$ . Just as for Tukey depth, there is an extensive body of work on Tverberg's theorem, see the survey [4] and the references therein.

In  $\mathbb{R}^1$ , both Tukey and Tverberg depth give a very natural depth measure: it counts the number of points of  $S$  to the left and to the right of  $q$  and then returns the minimum of the two numbers. We call this measure the *standard depth* in  $\mathbb{R}^1$ . In particular, for all of them there is always a point  $q \in \mathbb{R}^1$  for which we have  $\varrho(S, q) \geq \frac{|S|}{2}$ , that is, a median.

Another depth measure that is important in this paper is called enclosing depth. For an illustration of this depth measure, see Figure 1. We say that a point set  $S$  of size  $(d + 1)k$  in  $\mathbb{R}^d$   $k$ -encloses a point  $q$  if  $S$  can be partitioned into  $d + 1$  pairwise disjoint subsets  $S_1, \dots, S_{d+1}$ , each of size  $k$ , in such a way that for every transversal  $p_1 \in S_1, \dots, p_{d+1} \in S_{d+1}$ , the point  $q$  is in the convex hull of  $p_1, \dots, p_{d+1}$ . Intuitively, the points of  $S$  are centered around the vertices of a simplex with  $q$  in its interior.

► **Definition 3.** Let  $S$  be a finite point set in  $\mathbb{R}^d$  and let  $q$  be a query point. Then the enclosing depth of  $q$  with respect to  $S$ , denoted by  $\text{ED}(S, q)$ , is the maximum  $k$  such that there exists a subset of  $S$  which  $k$ -encloses  $q$ .

It is straightforward to see that enclosing depth also gives the standard depth in  $\mathbb{R}^1$ . The centerpoint theorem [22] and Tverberg's theorem [29] show that both for Tukey as well as Tverberg depth, there are deep points in any dimension. The question whether a depth

measure enforces deep points is a central question in the study of depth measures. We will show that this also holds for enclosing depth. In fact, we will show that enclosing depth can be bounded from below by a constant fraction of Tukey depth. We will further show that all depth measures considered in this paper can be bounded from below by enclosing depth. From this we get one of the main results of this paper: all depth measures that satisfy the axioms given later are a constant factor approximation of Tukey depth.

Another area of study in depth measures are *depth regions*, also called depth contours. For some depth measure  $\varrho$  and  $\alpha \in \mathbb{R}$ , we define the  $\alpha$ -region of a point set  $S \subset \mathbb{R}^d$  as the set of all points in  $\mathbb{R}^d$  that have depth at least  $\alpha$  with respect to  $S$ . We denote the  $\alpha$ -region of  $S$  by  $D_\varrho^S(\alpha) := \{q \in \mathbb{R}^d \mid \varrho(S, q) \geq \alpha\}$ . Note that for  $\alpha < \beta$  we have  $D_\varrho^S(\alpha) \supset D_\varrho^S(\beta)$ , that is, the depth regions are nested. The structure of depth regions has been studied for several depth measures, see e.g. [20, 32] In particular, depth regions in  $\mathbb{R}^2$  have been proposed as a tool for data visualization [28]. From a combinatorial point of view, Gil Kalai introduced the following conjecture [13]

► **Conjecture 4** (Cascade Conjecture). *Let  $S$  be a point set of size  $n$  in  $\mathbb{R}^d$ . For each  $i \in \{1, \dots, n\}$ , denote by  $d_i$  the dimension of  $D_{T_v D}^S(i)$ , where we set  $\dim(\emptyset) = -1$ . Then*

$$\sum_{i=1}^n d_i \geq 0.$$

The conjecture is known to be true when  $S$  is in so-called *strongly* general position [23], for general position in some dimensions [24, 25, 26] (see also [4] for more information), and without any assumption of general position for  $d \leq 2$  in an unpublished M. Sc thesis in Hebrew by Akiva Kadari (see [15]).

While Kalai's conjecture is specifically about Tverberg depth, the sum of dimensions of depth regions can be computed for any depth measure, and thus the conjecture can be generalized to other depth measures. In fact, in a talk Kalai conjectured that the Cascade conjecture is true for Tukey depth, mentioning on his slides that "this should be doable" [14]. In this work, we will prove the conjecture to be true for a family of depth measures that includes Tukey depth.

## Structure of the paper

We start the technical part by introducing a first set of axioms in Section 2, defining what we call *super-additive* depth measures. For these depth measures, we show that they lie between Tukey and Tverberg depth. In Section 3 we then prove the cascade conjecture for additive depth measures whose depth regions are convex. We then give a second set of axioms in Section 4, defining *central* depth measures, and show how to bound them from below by enclosing depth. Finally, in Section 5, we give a lower bound for enclosing depth in terms of Tukey depth. In order to prove this bound, we notice a close relationship of enclosing depth with a version of Radon's theorem on certain two-colored point sets.

## 2 A first set of axioms

The first set of depth measures that we consider are *super-additive* depth measures<sup>1</sup>. A combinatorial depth measure  $\varrho : (S^{\mathbb{R}^d}, \mathbb{R}^d) \rightarrow \mathbb{R}_{\geq 0}$  is called super-additive if it satisfies the following conditions:

<sup>1</sup> We name both our families of depth measures after one of the conditions they satisfy. The reason for this is that the condition they are named after is the condition which separates this family from the other one.

## 10:4 Enclosing Depth and Other Depth Measures

- (i) for all  $S \in S^{\mathbb{R}^d}$  and  $q, p \in \mathbb{R}^d$  we have  $|\varrho(S, q) - \varrho(S \cup \{p\}, q)| \leq 1$  (sensitivity),
- (ii) for all  $S \in S^{\mathbb{R}^d}$  and  $q \in \mathbb{R}^d$  we have  $\varrho(S, q) = 0$  for  $q \notin \text{conv}(S)$  (locality),
- (iii) for all  $S \in S^{\mathbb{R}^d}$  and  $q \in \mathbb{R}^d$  we have  $\varrho(S, q) \geq 1$  for  $q \in \text{conv}(S)$  (non-triviality),
- (iv) for any disjoint subsets  $S_1, S_2 \subseteq S$  and  $q \in \mathbb{R}^d$  we have  $\varrho(S, q) \geq \varrho(S_1, q) + \varrho(S_2, q)$  (super-additivity).

It is not hard to show that a one-dimensional depth measure which satisfies these conditions has to be the standard depth measure (in fact, the arguments are generalized to higher dimensions in the following two observations) and that no three conditions suffice for this. Further, it can be shown that both Tukey depth and Tverberg depth are super-additive.

We first note that the first two axioms suffice to give an upper bound:

► **Observation 5.** *For every depth measure  $\varrho$  satisfying (i) sensitivity and (ii) locality and for all  $S \in S^{\mathbb{R}^d}$  and  $q \in \mathbb{R}^d$  we have  $\varrho(S, q) \leq \text{TD}(S, q)$ .*

**Proof.** By the definition of Tukey depth,  $\text{TD}(S, q) = k$  implies that we can remove a subset  $S'$  of  $k$  points from  $S$  so that  $q$  is not in the convex hull of  $S \setminus S'$ . In particular,  $\varrho(S \setminus S', q) = 0$  by locality. By sensitivity we further have  $\varrho(S \setminus S', q) \geq \varrho(S, q) - k$ , which implies the claim. ◀

Further, the last two axioms can be used to give a lower bound:

► **Observation 6.** *For every depth measure  $\varrho$  satisfying (iii) non-triviality and (iv) super-additivity and for all  $S \in S^{\mathbb{R}^d}$  and  $q \in \mathbb{R}^d$  we have  $\varrho(S, q) \geq \text{TvD}(S, q)$ .*

**Proof.** Let  $\text{TvD}(S, q) = k$  and consider a  $k$ -partition  $S_1, \dots, S_k$  with  $q$  in its intersection. By non-triviality we have  $\varrho(S_i, q) \geq 1$  for each  $S_i$ . Using super-additivity and induction we conclude that  $\varrho(\bigcup_{i=1}^k S_i, q) \geq \sum_{i=1}^k \varrho(S_i, q) \geq k$ . ◀

Finally, it is not too hard to show that  $\text{TvD}(S, q) \geq \frac{1}{d} \text{TD}(S, q)$ , see e.g. [10] for an argument. Combining these observations, we thus get the following.

► **Corollary 7.** *Let  $\varrho$  be a super-additive depth measure. Then for every point set  $S$  and query point  $q$  in  $\mathbb{R}^d$  we have*

$$\text{TD}(S, q) \geq \varrho(S, q) \geq \text{TvD}(S, q) \geq \frac{1}{d} \text{TD}(S, q).$$

Let us note here that it could be that the factor  $\frac{1}{d}$  in the last inequality could be improved. Indeed, in the plane, we have that  $\text{TvD} = \min\{\text{TD}, \lceil \frac{|S|}{3} \rceil\}$  [23]. This fails already in dimension 3 [3]. It would be interesting to see how much the factor  $\frac{1}{d}$  can be improved.

From Corollary 7 it follows that for any super-additive depth measure and any point set there is always a point of depth at least  $\frac{|S|}{d+1}$ , for example any Tverberg point. On the other hand, there are depth measures which give the standard depth in  $\mathbb{R}^1$  which are not super-additive, for example convex hull peeling depth or enclosing depth.

► **Observation 8.** *Enclosing depth satisfies conditions (i)–(iii) and (v), but not the super-additivity condition (iv).*

**Proof.** It follows straight from the definition that enclosing depth satisfies the conditions (i)–(iii) and (v). To see that the super-additivity condition is not satisfied, consider the example in Figure 2. The point  $q$  has enclosing depth 1 with respect to both the set of blue points and the set of red points. However, it can be seen that the enclosing depth of  $q$  with respect to both the red and the blue points is still 1. ◀

■ **Figure 2** Enclosing depth does not satisfy the super-additivity condition: the point  $q$  has enclosing depth 1 with respect to both the blue and the red points, but its enclosing depth with respect to the union of the two sets is still 1.

### 3 The Cascade Conjecture

In this section we prove the cascade conjecture for super-additive depth measures whose depth regions are convex. In fact, we will prove the cascade conjecture for the case of *weighted point sets*. A weighted point set is a point set  $S$  together with a weight function  $w : S \rightarrow \mathbb{R}_{\geq 0}$  which assigns a weight  $w(p)$  to each  $p \in S$ . We say that a weighted point set  $S'$  is a strict subset of  $S$ , denoted by  $S' \subset S$ , if the underlying point set of  $S'$  is a strict subset of the underlying point set of  $S$ , and  $w'(p) \leq w(p)$  for every  $p \in S'$ , where  $w'$  is the weight function on  $S'$ . In particular, if  $S' \subset S$ , there is a point which is in  $S$  but not in  $S'$ . For two weighted point sets  $A$  and  $B$  with weight functions  $w_A$  and  $w_B$ , respectively, the weight function on their union  $A \cup B$  is defined as the sum of the respective weight functions. That is, we have  $w(p) = w_A(p)$  for  $p \in A \setminus B$ ,  $w(p) = w_B(p)$  for  $p \in B \setminus A$  and  $w(p) = w_A(p) + w_B(p)$  for  $p \in A \cap B$ . Further, for a set  $S$  of points we define the weight of  $S$  as  $w(S) := \sum_{p \in S} w(p)$ . Similarly, by a partition of a weighted point set  $S$  into parts  $A$  and  $B$  we mean two weight functions  $w_A$  and  $w_B$ , such that  $w(p) = w_A(p) + w_B(p)$  for  $p \in S$ , and by a partition into strict subsets  $A$  and  $B$ , we mean that both weighted point sets  $A$  and  $B$  must be strict subsets of  $S$ , that is, there are points  $p_A, p_B$  in  $S$  for which  $w_A(p_A) = 0$  and  $w_B(p_B) = 0$ . The axioms for super-additive depth measures extend to weighted point sets in the following way:

- (i) for all  $S \in S^{\mathbb{R}^d}$  and  $q, p \in \mathbb{R}^d$  we have  $|\varrho(S, q) - \varrho(S \cup \{p\}, q)| \leq w(p)$  (sensitivity),
- (ii) for all  $S \in S^{\mathbb{R}^d}$  and  $q \in \mathbb{R}^d$  we have  $\varrho(S, q) = 0$  for  $q \notin \text{conv}(S)$  (locality),
- (iii) for all  $S \in S^{\mathbb{R}^d}$  and  $q \in \mathbb{R}^d$  we have  $\varrho(S, q) \geq \min\{w(p) : p \in S\}$  for  $q \in \text{conv}(S)$  (non-triviality),
- (iv) for any disjoint subsets  $S_1, S_2 \subseteq S$  and  $q \in \mathbb{R}^d$  we have  $\varrho(S, q) \geq \varrho(S_1, q) + \varrho(S_2, q)$  (super-additivity).

Clearly, each point set can be considered as a weighted point set by assigning weight 1 to each point. On the other hand, by placing several points at the same location, normalizing and using the fact that  $\mathbb{Q}$  is dense in  $\mathbb{R}$ , each depth measure defined on point sets can be extended to weighted point sets. Further, we can again define depth regions  $D_\varrho^S(\alpha) := \{q \in \mathbb{R}^d \mid \varrho(S, q) \geq \alpha\}$ . We will also use a special depth region, called the *median region*,

## 10:6 Enclosing Depth and Other Depth Measures

denoted by  $M_\varrho(S)$ , which is the deepest non-empty depth region. More formally, let  $\alpha_0$  be the supremum value for which  $D_\varrho^S(\alpha_0) \neq \emptyset$ . Then  $M_\varrho(S) := D_\varrho^S(\alpha_0)$ . In the setting of weighted point sets, the cascade condition translates to

$$\int_0^{w(S)} d_\alpha d\alpha \geq 0.$$

Note that the cascade conjecture for a depth measure on weighted point sets implies the cascade conjecture for that depth measure on unweighted point sets. If for a depth measure  $\varrho$  the above integral is non-negative for any weighted point set  $S$ , we say that  $\varrho$  is *cascading*.

In the following, we will show that super-additive depth measures whose depth regions are convex are cascading in two steps. First we will show that if we partition a weighted point set into two parts whose median regions intersect and the cascade condition holds for both parts, then the cascade condition holds for the whole set. In a second step, we prove that we can always partition a point set in such a way, further enforcing that none of the parts contains all points, that is, each part is a strict subset. The claim then follows by induction.

► **Lemma 9.** *Let  $\varrho$  be a super-additive depth measure whose depth regions are convex and let  $S_1$  and  $S_2$  be two weighted point sets in  $\mathbb{R}^d$  whose median regions intersect. Assume that the cascade condition holds for  $S_1$  and  $S_2$ . Then the cascade condition holds for  $S_1 \cup S_2$ .*

Before we prove this, let us describe a way to compute  $\int_0^{w(S)} d_\alpha d\alpha$ . Consider some depth region  $D_\varrho^S(\alpha)$  of dimension  $k$ . Being convex, this depth region lies in some  $k$ -dimensional affine subspace  $H \subset \mathbb{R}^d$ . Considering all depth regions, they lie in a sequence of nested affine subspaces, also known as a *flag*. Assuming that the origin lies in the median region, we can find a basis  $F = \{f_1, \dots, f_d\}$  of  $\mathbb{R}^d$  such that each relevant affine subspace is spanned by a subset of the basis vectors. In fact, there are many choices of bases. Further, we can assign to each basis vector  $f_i$  a *survival time*  $\alpha_i$  defined by the following property: for each  $\alpha \in \mathbb{R}$ , the affine subspace in which  $D_\varrho^S(\alpha)$  lies is spanned by the subset  $\{f_i \in F \mid \alpha_i \geq \alpha\}$ . As above, we let  $\alpha_0$  be the supremum value for which  $D_\varrho^S(\alpha_0) \neq \emptyset$ , that is, we view  $\alpha_0$  as the survival time of the origin. Using this formulation, we note that

$$\int_0^{w(S)} d_\alpha d\alpha = \sum_{i=0}^d \alpha_i - w(S),$$

see Figure 3 for an illustration.

**Proof of Lemma 9.** We may assume without loss of generality that the origin is in both median regions. Further, we can choose a basis  $F = \{f_1, \dots, f_d\}$  of  $\mathbb{R}^d$  such that all relevant affine subspaces both of  $S_1$  and  $S_2$ , and thus also of  $S_1 \cup S_2$ , are spanned by subsets of  $F$ . Let  $\alpha_i$ ,  $\beta_i$  and  $\gamma_i$  denote the survival times of  $f_i$  for  $S_1$ ,  $S_2$  and  $S_1 \cup S_2$ , respectively. It follows from the super-additivity condition that  $\gamma_i \geq \alpha_i + \beta_i$ . Thus we get

$$\begin{aligned} \sum_{i=0}^d \gamma_i - w(S_1 \cup S_2) &\geq \sum_{i=0}^d (\alpha_i + \beta_i) - (w(S_1) + w(S_2)) \\ &\geq \sum_{i=0}^d \alpha_i - w(S_1) + \sum_{i=0}^d \beta_i - w(S_2) \geq 0. \end{aligned} \tag{1}$$

◀

Figure 3  $\int_0^{w(S)} d_\alpha d\alpha = \sum_{i=0}^d \alpha_i - w(S)$ .

► **Lemma 10.** *Let  $\varrho$  be a super-additive depth measure whose depth regions are convex and let  $S$  be a weighted point set in  $\mathbb{R}^d$  with  $|S| \geq d + 2$ . Then there exists a partition of  $S$  into strict subsets  $S_1$  and  $S_2$  whose median regions intersect.*

**Proof.** Assume without loss of generality that  $w(p) = 1$  for every  $p \in S$  (otherwise just multiply the weights of  $p$  in  $S_1$  and  $S_2$  with  $w(p)$  after finding the partition). Consider the barycentric subdivision  $B$  of the boundary  $\partial\Delta$  of the simplex with vertices  $S$ . There is a natural identification of the vertices of  $B$  with strict subsets of  $S$  (see Figure 4). Linearly extending this assignment to  $\partial\Delta$  defines a map which assigns to each point  $b$  on  $\partial\Delta$  a strict weighted subset  $S(b)$  of  $S$ . Further, under the natural antipodality on  $\partial\Delta$ , we get complements of the weighted subsets, that is,  $S(-b) = S(b)^C$ .

We claim that for some point  $b$  on  $\partial\Delta$  we have that the median regions of  $S(b)$  and  $S(-b)$  intersect. If this is true, our claim follows by setting  $S_1 = S(b)$  and  $S_2 = S(-b)$ . Using Proposition 1 from [31], for each  $b$  we may assume that the median region of  $S(b)$  is a single point  $m(b)$  in  $\mathbb{R}^d$  and that the map  $m$  which sends  $b$  to  $m(b)$  is continuous. We thus want to find a point  $b$  for which  $m(b) = m(-b)$ . Further,  $\partial\Delta$  is homeomorphic to the sphere  $S^{|S|-2}$ , and the antipodality on  $\partial\Delta$  corresponds to the standard antipodality on the sphere. As  $|S| \geq d + 2$ , the existence of a point  $b$  for which  $m(b) = m(-b)$  thus follows from the Borsuk-Ulam theorem. ◀

While we have only shown that there is a partition, Bourgin-Yang-type theorems [6, 30] tell us, that the space of possible partitions has to be large. In particular, it has dimension at least  $|S| - d - 2$ . Depending on the application, this might be used to enforce other conditions on the partitions.

► **Theorem 11.** *Let  $\varrho$  be a super-additive depth measure whose depth regions are convex. Then  $\varrho$  is cascading.*

**Proof.** Let  $S$  be a weighted point set in  $\mathbb{R}^d$  and assume without loss of generality that its affine hull is  $\mathbb{R}^d$  (otherwise, we can just consider  $S$  to be a weighted point set in some lower dimensional space). We want to show that the cascade condition holds for  $S$ . We prove this by induction on  $|S|$ . If  $|S| \leq d + 1$ , then  $S$  must be the vertices of a simplex, and in this case it is not hard to check that the cascade condition holds. So, assume now that  $|S| \geq d + 2$ . By Lemma 10, we can partition  $S$  into  $S_1$  and  $S_2$  whose median regions intersect. Note that  $|S_1|, |S_2| < |S|$ , so by the induction hypothesis the cascade condition holds for both  $S_1$  and  $S_2$ . Thus, by Lemma 9, the cascade condition also holds for  $S$ . ◀

■ **Figure 4** Vertices of the barycentric subdivision correspond to strict subsets.

As noted above, an example of a super-additive depth measure with convex depth regions is Tukey depth. Thus, we get the following.

► **Corollary 12.** *Tukey depth is cascading.*

On the other hand, while Tverberg depth is super-additive, its depth regions are in general not convex; in fact, they are not even connected. A weak version of Kalai’s cascade conjecture claims that the cascade condition holds for the convex hull of Tverberg depth regions. These depth regions are convex by definition, but the resulting depth measure is in general not super-additive anymore. So while our approach proves the cascade conjecture for an entire family of depth measures, solving Kalai’s cascade conjecture even in its weak form likely requires additional ideas. As every super-additive depth measure is bounded from below by Tverberg depth, solving the strong version of Kalai’s cascade conjecture would imply that all super-additive depth measures are cascading. Further, it can be seen that any cascading depth measure must enforce deep points. More precisely, if  $\varrho$  is a cascading depth measure and  $S$  is a point set in  $\mathbb{R}^d$ , then there must be a point  $q \in \mathbb{R}^d$  for which  $\varrho(S, q) \geq \frac{|S|}{d+1}$ . Indeed, if there was no such point, we would have  $d_{|S|/(d+1)} = -1$ , and even if  $d_i = d$  for all  $i < \frac{|S|}{d+1}$ , the sum  $\sum_{i=1}^{|S|} d_i$  would still be negative. The existence of deep points is the main feature of the next family of depth measures that we study.

**4 A second set of axioms**

The second family of depth measures we consider are *central* depth measures. A combinatorial depth measure  $\varrho : (S^{\mathbb{R}^d}, \mathbb{R}^d) \rightarrow \mathbb{R}_{\geq 0}$  is called central if it satisfies the following conditions:

- (i) for all  $S \in S^{\mathbb{R}^d}$  and  $q, p \in \mathbb{R}^d$  we have  $|\varrho(S, q) - \varrho(S \cup \{p\}, q)| \leq 1$  (sensitivity),
- (ii) for all  $S \in S^{\mathbb{R}^d}$  and  $q \in \mathbb{R}^d$  we have  $\varrho(S, q) = 0$  for  $q \notin \text{conv}(S)$  (locality),
- (iii’) for every  $S \in S^{\mathbb{R}^d}$  there is a  $q \in \mathbb{R}^d$  for which  $\varrho(S, q) \geq \frac{1}{d+1}|S|$  (centrality).
- (iv’) for all  $S \in S^{\mathbb{R}^d}$  and  $q, p \in \mathbb{R}^d$  we have  $\varrho(S \cup \{p\}, q) \geq \varrho(S, q)$  (monotonicity),

Note that conditions (i) and (ii) are the same as for super-additive depth measures, so by Observation 5 we have  $\varrho(S, q) \leq \text{TD}(S, q)$  for every central depth measure. Further, the centrality condition (iii’) is stronger than the non-triviality condition (iii) for super-additive depth measures. On the other hand, the super-additivity condition (iv) is stronger than

the monotonicity condition (iv'), so at first glance, the families of super-additive depth measures and central depth measures are not comparable. However, we have seen before that any super-additive depth measure indeed satisfies the centrality condition, so central depth measures are a superset of super-additive depth measures. It is actually a strict superset, as for example the depth measure whose depth regions are defined as the convex hulls of Tverberg depth regions is central but not super-additive.

While central depth measures enforce deep points by definition, they might still differ a lot locally. In the following, we will show that we can bound by how much they differ locally, showing that every central depth measure is a constant factor approximation of Tukey depth.

► **Theorem 13.** *Let  $\varrho$  be a central depth measure in  $\mathbb{R}^d$ . Then there exists a constant  $c = c(d)$ , which depends only on the dimension  $d$ , such that*

$$TD(S, q) \geq \varrho(S, q) \geq ED(S, q) - (d + 1) \geq c \cdot TD(S, q) - (d + 1).$$

Here the first inequality is just Observation 5. As for the second inequality, we would like to argue that if  $S$   $k$ -encloses  $q$  then  $\varrho(S, q) = k$ . By centrality, there must indeed be a point  $q'$  with  $\varrho(S, q') = k$  (note that  $|S| = k(d + 1)$  by definition of  $k$ -enclosing), but this point can lie anywhere in the centerpoint region of  $S$  and not every point in the centerpoint region is  $k$ -enclosed by  $S$ . However, by adding  $d + 1$  points very close to  $q$ , we can ensure that  $q$  is the only possible centerpoint in the new point set, and the second inequality then follows from sensitivity and monotonicity after removing these points again.

This argument can be generalized even to a relaxation of central depth measures: We say that a combinatorial depth measure is  $\alpha$ -central if it satisfies conditions (i), (ii) and (iv'), and the following weak version of condition (iii'): for every  $S \in \mathcal{S}^{\mathbb{R}^d}$  there is a  $q \in \mathbb{R}^d$  for which  $\varrho(S, q) \geq \alpha|S|$  ( $\alpha$ -centrality)

► **Lemma 14.** *Let  $\alpha > \frac{1}{d+2}$ , and let  $\varrho$  be an  $\alpha$ -central depth measure. Then there exists a constant  $c_1 = c_1(d)$  such that*

$$\varrho(S, q) \geq c_1 \cdot ED(S, q) - (d + 1).$$

**Proof.** Let  $ED(S, q) = k$  and let  $S'$  be a witness subset. Recall that by monotonicity, we have  $\varrho(S, q) \geq \varrho(S', q)$ . Further, note that  $TD(S', q) = k$  and  $TD(S', q') \leq k$  for all  $q' \in \mathbb{R}^d$ . Let  $\alpha' := (d + 1)\alpha$  and let  $m := \lfloor \frac{1-\alpha'}{\alpha'}k + 1 \rfloor$ . Add  $(d + 1)m$  points very close to  $q$  such that the new point set  $P$   $(k + m)$ -encloses  $q$ . The new point set  $P$  has  $(d + 1)(k + m)$  many points, and we have

$$\alpha|P| = \alpha'(k + m) > \alpha'(k + \frac{1-\alpha'}{\alpha'}k) = \alpha'k + (1 - \alpha')k = k.$$

In particular, the only points  $q'$  for which  $\varrho(P, q') \geq \alpha|P|$  is possible are by construction very close to  $q$ . As they were in the same cell as  $q$  before adding the new points, we can assume without loss of generality that we have  $\varrho(P, q) \geq \alpha|P|$ . By sensitivity we now have

$$\begin{aligned} \varrho(S', q) &\geq \varrho(P, q) - (d + 1)m \\ &\geq \alpha'(k + m) - (d + 1)m \\ &\geq \alpha'k - (d + 1 - \alpha')m \\ &\geq \alpha'k - (d + 1 - \alpha')(\frac{1-\alpha'}{\alpha'} + 1) \\ &= \alpha'k - \frac{(d + 1 - \alpha')(1 - \alpha')}{\alpha'}k - (d + 1) + \alpha \end{aligned}$$

## 10:10 Enclosing Depth and Other Depth Measures

$$\begin{aligned} &\geq (\alpha'^2 - (d+1) + \alpha' + (d+1)\alpha' - \alpha'^2) \frac{k}{\alpha'} - (d+1) \\ &= \frac{(d+2)\alpha' - (d+1)}{\alpha'} k - (d+1). \quad (2) \end{aligned}$$

Plugging in  $\alpha' := (d+1)\alpha$  we get

$$\varrho(S, q) \geq \frac{(d+2)(d+1)\alpha - (d+1)}{(d+1)\alpha} k - (d+1) = (d+2 - \frac{1}{\alpha})k - (d+1).$$

As  $(d+2 - \frac{1}{\alpha}) > 0$  for  $\alpha > \frac{1}{d+2}$ , the claim follows.  $\blacktriangleleft$

The most involved part of Theorem 13 is the last inequality, which we will prove in the next section.

### 5 A lower bound for enclosing depth

In this section, we will prove a lower bound on the enclosing depth in terms of Tukey depth:

► **Theorem 15** ( $E(d)$ ). *There is a constant  $c_1 = c_1(d)$  such that for all  $S \in S^{\mathbb{R}^d}$  and  $q \in \mathbb{R}^d$  we have  $ED \leq c_1 \cdot TD(S, q)$ .*

We will denote this statement in dimension  $d$  by  $E(d)$ . Note that  $E(1)$  is true and  $c_1(1) = 1$ . The general result could be proved using the semi-algebraic same type lemma due to Fox, Pach and Suk [9], combined with the first selection lemma (see e.g. [19]). Here we will give a different proof for two reasons: first, the bounds on  $c_1$  that our proof gives are better than the bounds we would get from the proof using the semi-algebraic same type lemma. Second, our proof shows an intimate relation of enclosing depth to a positive fraction Radon theorem on certain bichromatic point sets.

Let  $P = R \cup B$  be a bichromatic point set with color classes  $R$  (red) and  $B$  (blue). We say that  $B$  *surrounds*  $R$  if for every halfspace  $h$  we have  $|B \cap h| \geq |R \cap h|$ . Note that this in particular implies  $|B| \geq |R|$ . The positive fraction Radon theorem is now the following:

► **Theorem 16** ( $R(d)$ ). *Let  $P = R \cup B$  be a bichromatic point set where  $B$  surrounds  $R$ . Then there is a constant  $c_2 = c_2(d)$  such that there are integers  $a$  and  $b$  and pairwise disjoint subsets  $R_1, \dots, R_a \subseteq R$  and  $B_1, \dots, B_b \subseteq B$  with*

1.  $a + b = d + 2$ ,
2.  $|R_i| \geq c_2 \cdot |R|$  for all  $1 \leq i \leq a$ ,
3.  $|B_i| \geq c_2 \cdot |R|$  for all  $1 \leq i \leq b$ ,
4. for every transversal  $r_1 \in R_1, \dots, r_a \in R_a, b_1 \in B_1, \dots, b_b \in B_b$ , we have

$$\text{conv}(r_1, \dots, r_a) \cap \text{conv}(b_1, \dots, b_b) \neq \emptyset.$$

In other words, the Radon partition respects the color classes. We will denote the above statement in dimension  $d$  by  $R(d)$ .

► **Lemma 17.**  $R(1)$  can be satisfied choosing  $a = 1$ ,  $b = 2$  and  $c_2(1) = \frac{1}{3}$ .

**Proof.** Consider two points  $x_1$  and  $x_2$  such that there are exactly  $\frac{|R|}{3}$  blue points to the left of  $x_1$  and to the right of  $x_2$ , respectively. Define  $B_1$  as the set of blue points left of  $x_1$  and  $B_2$  as the set of blue points right of  $x_2$ . We then have  $|B_1| = |B_2| = \frac{1}{3}|R|$ . Further, as  $B$  surrounds  $R$ , we have at most  $\frac{|R|}{3}$  red points to the left of  $x_1$ , and also to the right of  $x_2$ . In particular, there are at least  $\frac{|R|}{3}$  red points between  $x_1$  and  $x_2$ . Let now  $R_1$  be any subset of  $\frac{|R|}{3}$  red points between  $x_1$  and  $x_2$ . It follows from the construction that  $\text{conv}(R_1) \cap \text{conv}(B_1, B_2) \neq \emptyset$ .  $\blacktriangleleft$

In the following, we will prove that  $R(d - 1) \Rightarrow E(d)$  and that  $E(d - 1) \Rightarrow R(d)$ . By induction, these two claims then imply the above theorems.

► **Lemma 18.**  $R(d - 1) \Rightarrow E(d)$ .

**Proof.** Assume that  $\text{TD}(S, q) = k$  and let  $h$  be a witnessing hyperplane which contains  $q$  but no points of  $S$ . Without loss of generality, assume that  $q$  is the origin and that  $h$  is the hyperplane through the equator on  $S^{d-1} \subseteq \mathbb{R}^d$ , with exactly  $k$  points below. Color the points below  $h$  red and the points above  $h$  blue. Now, for every point  $p \in S$ , consider the line through  $p$  and  $q$  and let  $p'$  be the intersection of that line with the tangent hyperplane to the north pole of  $S^{d-1}$ . Color  $p'$  the same color as  $p$ . This gives a bichromatic point set  $S' = R \cup B$  in  $\mathbb{R}^{d-1}$ . Further, in  $S'$ , we have that  $B$  surrounds  $R$ : Assume there is a hyperplane  $\ell$  (in  $\mathbb{R}^{d-1}$ ) with  $r$  red points and  $b$  blue points on its positive side, where  $r > b$ . In  $\mathbb{R}^d$ , this lifts to a hyperplane containing  $q$  with  $k - r$  red points and  $b$  blue points on its positive side (note that there are exactly  $k$  red points). However,  $k - r + b < k$ , whenever  $r > b$ , thus we would have  $\text{TD}(s, q) < k$ , which is a contradiction.

As we now have a point set in  $\mathbb{R}^{d-1}$ , in which  $B$  surrounds  $R$ , we can apply  $R(d - 1)$  to find families of  $d + 2$  subsets of  $S'$ , each of size  $c_2 \cdot k$ , some red and some blue, such that in each transversal the color classes form a Radon partition. We claim that the corresponding subsets of  $S$   $c_2 \cdot k$ -enclose  $q$ . Pick some transversal (which we call the original red and blue points) and consider the corresponding subset in  $S'$ . Let  $z$  be a point in the intersection of the convex hulls of the two color classes, and let  $g$  be the line through  $z$  and  $q$ . As  $z$  is in the convex hull of the blue points, there is a point  $z^+$  on  $g$  which is in the convex hull of the original blue points, and thus above  $h$ . Similarly, there is a point  $z^-$  on  $g$  which is in the convex hull of the original red points, and thus below  $h$ . As  $q$  is in the convex hull of  $z^+$  and  $z^-$ , it is thus in the convex hull of the original blue and red points. ◀

In particular, this proof shows that  $c_1(d) = c_2(d - 1)$ .

For the proof of the second implication, we need to recall a few results, starting with the *Same Type Lemma* by Bárány and Valtr [5].

► **Theorem 19** (Theorem 2 in [5]). *For every two natural numbers  $d$  and  $m$  there is a constant  $c_3(d, m) > 0$  with the following property: Given point sets  $X_1, \dots, X_m \subseteq \mathbb{R}^d$  such that  $X_1 \cup \dots \cup X_m$  is in general position, there are subsets  $Y_i \subseteq X_i$  with  $|Y_i| \geq c_3 \cdot |X_i|$  such that all transversals of the  $Y_i$  have the same order type.*

From the proof in [5], we get  $c_3(d, m) = 2^{-m^{O(d)}}$ . This bound has been improved in [9] to  $c_3(d, m) = 2^{-O(d^3 m \log m)}$ .

The second result that we will need is the *Center Transversal Theorem*, proved independently by Dol'nikov [8] as well as Zivaljević and Vrećica [31]. We will only need the version for two colors, so we state it in this restricted version:

► **Theorem 20** (Center Transversal for two colors). *Let  $\mu_1$  and  $\mu_2$  be two finite Borel measures on  $\mathbb{R}^d$ . Then there exists a line  $\ell$  such that for every closed halfspace  $H$  which contains  $\ell$  and every  $i \in \{1, 2\}$  we have  $\mu_i(H) \geq \frac{\mu_i(\mathbb{R}^d)}{d}$ .*

Such a line  $\ell$  is called a *center transversal*. By a standard argument (replacing points with balls of small radius, see e.g. [18]), the same result also holds for two point sets  $P_1, P_2$  in general position, where  $\mu_i(H)$  is replaced by  $|P_i \cap H|$ . As we will need similar ideas later, we will briefly sketch a proof of the above Theorem. Consider some  $(d - 1)$ -dimensional linear subspace  $F$ , i.e., a hyperplane through the origin, and project both measures to it.

## 10:12 Enclosing Depth and Other Depth Measures

For each projected measure, consider the centerpoint region (i.e., the region of Tukey depth  $\geq \frac{\mu_i(\mathbb{R}^d)}{(d-1)+1}$ ). This is a non-empty, convex set, so it has a unique center of mass, which we will denote by  $c_i(F)$ . Rotating the subspace  $F$  in continuous fashion, these centers of mass also move continuously, so the  $c_i(F)$  are two continuous assignments of points to the set of all  $(d-1)$ -dimensional linear subspaces. The result then follows from the following Lemma, again proved independently by Dol'nikov [8] as well as Zivaljević and Vrećica [31]:

► **Lemma 21.** *Let  $g_1$  and  $g_2$  be two continuous assignments of points to the set of all  $(d-1)$ -dimensional linear subspaces of  $\mathbb{R}^d$ . Then there exists such a subspace  $F$  in which  $g_1(F) = g_2(F)$ .*

Note that in order to apply this Lemma, we had to choose in a continuous way a centerpoint. If the two measures can be separated by a hyperplane, we can do something similar with the center transversal:

► **Lemma 22.** *Let  $\mu_1$  and  $\mu_2$  be two finite Borel measures on  $\mathbb{R}^d$ , which can be separated by a hyperplane. Then there is a unique canonical choice of a center transversal.*

**Proof.** Let  $x_1, \dots, x_d$  be the basis vectors of  $\mathbb{R}^d$  and assume without loss of generality that the hyperplane  $H : x_d = 0$  separates the two measures  $\mu_1, \mu_2$ . For any  $d-1$ -dimensional linear subspace  $F$ , consider the projection  $\pi_F : \mathbb{R}^d \rightarrow F$ . Note that if  $F$  is orthogonal to  $H$ , then  $\pi_F(H)$  separates  $\pi_F(\mu_1)$  and  $\pi_F(\mu_2)$ , so there is no center transversal parallel to  $H$ . It thus suffices to consider only (oriented) subspaces which point upwards (in the sense that the  $x_d$ -component in their normal vector is  $> 0$ ). The space of these subspaces is homeomorphic to the upper hemisphere  $S^+$  of  $S^{d-1}$ . Let now  $C$  be the set of all such subspaces in which we have  $g_1(F) = g_2(F)$ . We claim that  $C$  is a convex set in  $S^+$ . Consider two subspaces  $F_1$  and  $F_2$  with  $g_1(F_1) = g_2(F_1)$  and  $g_1(F_2) = g_2(F_2)$ . The shortest path between  $F_1$  and  $F_2$  corresponds to a rotation around a  $(d-2)$ -dimensional axis. Rotate from  $F_1$  to  $F_2$  with constant speed and consider a point in the support of a measure. The projection of this point moves along a line in the projection. In fact, all points in move along parallel lines with direction  $\vec{d}$ , and the points in the support of  $\mu_1$  move in the opposite direction of the points in the support of  $\mu_2$ . Further, for any points  $p_1$  in the support of  $\mu_1$  and  $p_2$  in the support of  $\mu_2$ , their projections move towards one another, until they are on a common hyperplane with normal vector  $\vec{d}$ , and the away from one another. The same arguments hold for the centerpoint regions of the projections and their centers of mass, which shows that if  $g_1(F_1) = g_2(F_1)$  and  $g_1(F_2) = g_2(F_2)$  then  $g_1(F) = g_2(F)$  for every subspace  $F$  along the rotation. Thus, the set  $C$  is indeed convex, and we can choose the unique solution corresponding to the center of mass of  $C$ . ◀

Again, the same statement holds for point sets in general position. With these tools at hand, we are now ready to prove the second part of the induction.

► **Lemma 23.**  $E(d-1) \Rightarrow R(d)$ .

**Proof.** Let  $\ell$  be a line through the origin. Sweep a hyperplane orthogonal to  $\ell$  from one side to the other (without loss of generality from left to right). Let  $h_1$  be a sweep hyperplane with exactly  $\frac{|R|}{3}$  blue points to the left, and let  $A_1$  be the set of these blue points. Similarly, let  $A_2$  be a set of exactly  $\frac{|R|}{3}$  blue points to the right of a sweep hyperplane  $h_2$ . Let  $c$  be the unique center transversal of  $A_1$  and  $A_2$  given by Lemma 22 and let  $g$  be the  $(d-1)$ -dimensional linear subspace which is orthogonal to  $c$ . Note that it follows from the proof of Lemma 22 that  $g$  cannot be orthogonal to the sweep hyperplanes. We denote the projection of  $c$  to  $g$  as  $c_A$ . Note that  $c_A$  is a centerpoint of the projections of  $A_1$  and of  $A_2$  to  $g$ . Now, consider the

set  $M$  of all red points between  $h_1$  and  $h_2$  and note that as the blue points surround the red points we have  $|M| \geq \frac{|R|}{3}$ . Project  $M$  to  $g$  and denote by  $c_M$  the center of mass of the centerpoint region of the projected point set. We claim that there exists a choice of a line  $\ell$ , such that  $c_M = c_A$ . Indeed, as  $g$  is not orthogonal to a sweep hyperplane, there is a unique shortest rotation which rotates  $g$  to a hyperplane orthogonal to  $\ell$ , thus the space of all  $g$ 's is homeomorphic to the space of all  $(d - 1)$ -dimensional linear subspaces. Further,  $c_A$  and  $c_M$  are continuous assignments of points, thus the above claim follows from Lemma 21.

So assume now that  $c_M = c_A$ . In particular,  $c$  is a center transversal for  $A_1, A_2$  and  $M$ . Project  $A_1$  to  $g$ . The projection of  $c$  is a centerpoint of the projection of  $A_1$  in  $g$  and  $g$  has dimension  $d - 1$ , thus by the statement  $E(d - 1)$  there are three subsets  $A_{1,1}, \dots, A_{1,d}$  of  $A_1$ , each of size  $c_1 \cdot |A_1|$  whose projections enclose the projection of  $c$ . The analogous arguments gives subsets  $A_{2,1}, \dots, A_{2,d}$  of  $A_2$  and  $M_1, \dots, M_d$  of  $M$ . Consider now these  $3d$  subsets. By Theorem 19 there are subsets  $A'_{1,1}, \dots, M'_d$ , each of size linear in the size of the original subset, such that each transversal of the subsets has the same order type. Consider such a transversal. By construction, the  $d$  points of  $A_1$  contain in their convex hull a point on  $c$  which is to the left of  $h_1$ . Similarly, the  $d$  points of  $A_2$  contain in their convex hull a point on  $c$  to the right of  $h_2$ . Finally, the  $d$  points of  $M$  contain in their convex hull a point on  $c$  between  $h_1$  and  $h_2$ . Thus, the convex hulls of the blue points (from  $A_1$  and  $A_2$ ) and the red points (from  $M$ ) intersect. In particular, there is a subset of  $d + 2$  red and blue points, which form a Radon partition. By choosing the subsets from which these points were selected, we now get the subsets required for  $R(d)$ . ◀

This proof show that  $c_2(d) = \frac{c_3(d,d+2)}{3^d} c_1(d - 1)$ . Using the bound on  $c_3$  from [9] and  $c_1(d) = c_2(d - 1)$ , we thus get  $c_2(d) = \Omega(\frac{c_2(d-2)}{3^d \cdot 2^{d^4 \log d}}) = \dots = \Omega(\frac{1}{3^{d/2} d! \cdot 2^{d^5 \log d}})$ , and as  $c_1(d) = c_2(d - 1)$  we get the same asymptotics for  $c_1$ .

Combining this with the results from Section 4, we get that any central depth measure is an approximation of Tukey depth. In fact, by Lemma 14 this even holds for many  $\alpha$ -central depth measures.

▶ **Corollary 24.** *Let  $\varrho$  be an  $\alpha$ -central depth measure on  $\mathbb{R}^d$  where  $\alpha > \frac{1}{d+2}$ . Then there exists a constant  $c = c(d)$  such that for every point set  $S$  and query point  $q$  in  $\mathbb{R}^d$  we have*

$$TD(S, q) \geq \varrho(S, q) \geq c \cdot TD(S, q).$$

## 6 Conclusion

We have introduced two families of depth measures, called super-additive depth measures and central depth measures, where the first is a strict subset of the second. We have shown that all these depth measures are a constant-factor approximation of Tukey depth.

It is known that Tukey depth is coNP-hard to compute when both  $|S|$  and  $d$  is part of the input [12], and it is even hard to approximate [2] (see also [7]). Our result is thus an indication that central depth measures are hard to compute. However, this does not follow directly, as our constant has a doubly exponential dependence on  $d$ . It is an interesting open problem whether the approximation factor can be improved.

Further, we have introduced a new depth measure called enclosing depth, which is neither super-additive nor central, but still is a constant-factor approximation of Tukey depth. As it turns out, this depth measure is intimately related to a constant fraction Radon theorem on bi-colored point sets. Finally, we have shown that any super-additive depth measure whose depth regions are convex is cascading.

This last result is motivated by Kalai’s cascade conjecture, which, in the terminology of this paper, states that Tverberg depth is cascading. While this conjecture remains open, we hope that our results might be useful for an eventual proof.

There is a depth measure which has attracted a lot of research, which does not fit into our framework: simplicial depth (SD). The reason for this is that while the depth studied in this paper are linear in the size of the point set, simplicial depth has values of size  $O(|S|^{d+1})$ . However, after the right normalization, simplicial depth can be reformulated to satisfy all conditions except super-additivity and centrality. It would be interesting to see whether there is some function  $g$  depending on point sets and query points such that the depth measure  $\frac{SD(S,q)}{g(S,q)}$  is super-additive. Such a function, if it exists, could potentially be used to improve bounds for the first selection lemma (see e.g. [19]).

## Abstract

Given a set  $S$  of regions with piece-wise linear boundary and a positive angle  $\alpha < 90^\circ$ , we consider the problem of computing the locations and orientations of the minimum number of  $\alpha$ -floodlights positioned at points in  $S$  which suffice to illuminate the entire  $x$ -axis. We show that the problem can be solved in  $O(n \log n)$  time and  $O(n)$  space, where  $n$  is the number of vertices of the set  $S$ .

## 1 Introduction

An  $\alpha$ -floodlight is a two-dimensional floodlight whose illumination cone angle is equal to a positive angle  $\alpha$ . We are interested in using the minimum number of  $\alpha$ -floodlights positioned at points of a given set  $S$  in the plane in order to illuminate the entire  $x$ -axis; in particular, we consider that  $S$  is a collection of regions with piece-wise linear boundary which may degenerate into a point. We assume that no point of  $S$  lies on the  $x$ -axis (otherwise, at most two floodlights would suffice for any value of  $\alpha$ ) and that the entire  $S$  lies in the halfplane above the  $x$ -axis (any point of  $S$  below the  $x$ -axis can be equivalently reflected about the  $x$ -axis into the halfplane above the  $x$ -axis). Next, regarding the angle  $\alpha$  of the  $\alpha$ -floodlights, we consider that  $\alpha < 90^\circ$  because for  $\alpha \geq 90^\circ$  the problem admits a trivial solution: if  $90^\circ \leq \alpha < 180^\circ$  then two floodlights are necessary and sufficient to illuminate the entire  $x$ -axis, and if  $\alpha \geq 180^\circ$  then one floodlight is necessary and sufficient. Thus, in this paper we focus on the following problem.

### The Axis $\alpha$ -Illumination Problem

Given a set  $S$  of regions with piece-wise linear boundary above the  $x$ -axis and a positive angle  $\alpha < 90^\circ$ , compute the locations and orientations of the minimum number of  $\alpha$ -floodlights positioned at points in  $S$  which suffice to illuminate the entire  $x$ -axis.

## 11:2 Illuminating the $x$ -Axis by $\alpha$ -Floodlights

As the number of required  $\alpha$ -floodlights can be very large even for a set  $S$  of small descriptive size, we designate that a solution to an instance of the Axis  $\alpha$ -floodlight Problem is a set of pairs  $(t_i, R_i)$  where  $t_i \in S$  and  $R_i$  is a maximal continuous range of the  $x$ -axis to be illuminated by  $\alpha$ -floodlights positioned at  $t_i$  such that (i) the union of all the ranges  $R_i$  is equal to the  $x$ -axis and (ii) over all pairs, the sum  $\sum_i \lceil \frac{\text{angle}(R_i)}{\alpha} \rceil$  is minimized where  $\text{angle}(R_i)$  is the angle subtended by the range  $R_i$  from  $t_i$ ; this sum is precisely the total number of  $\alpha$ -floodlights needed to illuminate the entire  $x$ -axis. We note that there may be more than one pair associated with a location  $t_i \in S$  but if it is so, then the corresponding  $x$ -axis ranges do not intersect; see Figure 1(right). As we show (Corollary 12), the size of such a solution is at most linear in the number of vertices of the given set  $S$ .

■ **Figure 1** (left) An instance of the Axis  $\alpha$ -Illumination Problem for two floodlight locations and  $\alpha = 40^\circ$ ; (middle) A solution with five floodlights; (right) A solution with three floodlights.

Clearly, any instance of the Axis  $\alpha$ -floodlight Problem admits a solution since a single point in the set  $S$  can illuminate the entire  $x$ -axis by using  $\lceil \frac{180^\circ}{\alpha} \rceil$   $\alpha$ -floodlights; see Figure 1(middle) where five  $40^\circ$ -floodlights can be used to illuminate the  $x$ -axis. Yet, the minimum number of needed floodlights may be much smaller; in Figure 1(right), for the given set  $S$  containing two locations, three  $40^\circ$ -floodlights suffice to illuminate the entire  $x$ -axis.

**Our Contribution.** In this paper, we present an algorithm to solve the Axis  $\alpha$ -Illumination Problem. Our algorithm runs in  $O(n \log n)$  time where  $n$  is the number of vertices of the given set  $S$  of potential floodlight locations. Our algorithm can be used to illuminate arbitrary lines as well as line segments.

**Related Work.** Floodlight illumination problems are considered a prominent class in Computational Geometry [14, 20] and find applications in the field of directional sensor networks [19]. The seminal *Stage Illumination Problem* [3] was posed by Urrutia in 1992 and later proved to be NP-complete even with some restrictions by Ito et al. [11]. This problem takes as inputs a line segment and a set of floodlights  $F_i$  with angles  $\alpha_i$  and apexes at predetermined locations  $p_i$  on the same side of the segment, the goal being to rotate the floodlights around their positions in such a way that the segment is completely illuminated. Even more related to our work is the problem of the *Optimal Floodlight Illumination of the Real Line* [5], which takes as inputs a line and a set  $S$  of  $n$  points, with the goal being to determine a finite set of floodlights  $F_j$  of arbitrary angles  $\alpha_j$  and with apexes at  $p_j \in S$  (more than one floodlight can have the same point as apex) such that the line is illuminated and the sum of the angles  $\alpha_j$  is the smallest possible. This problem was shown to be solvable in  $\Theta(n \log n)$  time [5]. Further, the *Optimal Floodlight Illumination of a Stage*, similar to the previous one but considering a segment instead of a line, has also been considered and solved in  $\Theta(n \log n)$  time even if no more than one floodlight are allowed to have the same point as apex [7]. On the other hand, the problem of whether a polygon can be illuminated by a given number of  $\alpha$ -floodlights is NP-hard and APX-hard [1].

■ **Figure 2** (left) A hyperbola with its foci (shown in blue) on a horizontal line; (right) A hyperbola with its foci (shown in blue) on a vertical line. The red lines are the directrices of the hyperbola.

Finally, a wider perspective locates our problem as a variant of the Art Gallery Problem, originally posed by Klee in 1973 as the question of determining the minimum number of guards sufficient to see every point of the interior of a simple polygon; for more details, see the book by O’Rourke [13], the survey article by Shermer [15], and the book chapter by Urrutia [20]. Among all these variants, we only mention just a few, chronologically, those the most related to our problem: the searchlight problem in polygons [18], floodlight illumination of the plane [3], floodlight illumination of polygons [8], the two-floodlight illumination problem [9], floodlight illumination of wedges [17], continuous surveillance of points by rotating floodlights [2], and monitoring the plane with rotating radars [4].

## 2 Preliminaries

Our algorithm relies on the use of hyperbola arcs and of the farthest-point Voronoi diagram of a point set in the plane. So, we present the definition and useful properties of these two notions.

**Hyperbola.** A *hyperbola* with foci  $f_1$  and  $f_2$  is the locus of the points in the plane such that the absolute value of the difference of their distances from  $f_1$  and  $f_2$  is constant (and less than the distance of the foci) [21]; see Figure 2(left). Most commonly, the foci are located at  $(x_0 - c, y_0)$  and  $(x_0 + c, y_0)$ , where  $c > 0$ . Then, if the absolute value of the difference of the distances from the foci is equal to  $2a$  with  $0 < a < c$ , the expression of the hyperbola is

$$\frac{(x - x_0)^2}{a^2} - \frac{(y - y_0)^2}{c^2 - a^2} = 1. \quad (1)$$

Such a hyperbola consists of two branches separated by any vertical line  $x = x_0 + \delta$  where  $-a < \delta < a$ . In fact, these branches can also be defined in terms of the two *directrices* of the hyperbola which, in this case, are vertical lines; the directrices are symmetrically positioned about the *center*  $(x_0, y_0)$  of the hyperbola at distance  $a^2/c$  from it. Then, each *hyperbola branch* is the locus of points whose distance from one of the foci divided by the (perpendicular) distance from the corresponding directrix is greater than 1; for the hyperbola satisfying Equation (1), this ratio of distances is equal to  $c/a > 1$ .

If the foci are located at  $(x_0, y_0 - c)$  and  $(x_0, y_0 + c)$  (i.e., the foci are on a *vertical* line), we have a symmetric case by “exchanging” the  $x$ - and  $y$ -axis, as shown in Figure 2(right).

**Farthest-point Voronoi diagram.** The farthest-point Voronoi diagram of a planar point set will also be exploited in our algorithm. For a given set of points  $S = \{p_1, p_2, \dots, p_n\}$  in the plane, typically called *sites*, the *farthest-point Voronoi diagram* of  $S$  divides the plane into cells such that each cell contains all the points of the plane with the same farthest site among the sites in  $S$  [6]. It is well known that:

## 11:4 Illuminating the $x$ -Axis by $\alpha$ -Floodlights

► **Lemma 1** ([6]).

- (i) A point of a point-set  $S$  has a cell in the farthest-point Voronoi diagram of  $S$  if and only if it is a vertex of the convex hull of  $S$ .
- (ii) The farthest-point Voronoi diagram of  $n$  points in the plane has  $O(n)$  vertices, edges, and cells.

As a result of Lemma 1(i), all cells of a planar farthest-point Voronoi diagram are unbounded and its vertices and edges form a tree-like structure (Figure 9). Additionally, the definition of the farthest-point Voronoi diagram readily implies the following corollary.

► **Corollary 2.** Let  $fVD(S)$  be the farthest-point Voronoi diagram of a planar point-set  $S$  and let  $V(p)$  be the cell of  $p \in S$  in  $fVD(S)$ . Then, a point  $r$  belongs to the closure of  $V(p)$  if and only if the entire  $S$  is enclosed by the circle with center  $r$  and radius the distance of  $r$  to  $p$ .

### 3 Illuminating unbounded and bounded ranges of the $x$ -axis

In this section, we present how to efficiently illuminate unbounded and bounded ranges of the  $x$ -axis and we introduce some useful notation. We first consider unbounded ranges of the  $x$ -axis, i.e., a range  $(-\infty, \chi]$  or a range  $[\chi', +\infty)$ . Then, the definition of an  $\alpha$ -floodlight implies the following observation.

► **Observation 3.** Let  $t$  be a two-dimensional point above the  $x$ -axis. The illumination cone of any  $\alpha$ -floodlight positioned at  $t$  and illuminating the maximum range  $(-\infty, \chi]$  of the  $x$ -axis (i.e.,  $\chi$  is maximized) is delimited by the  $t$ -originating leftward-pointing horizontal ray and the  $t$ -originating downward-pointing ray that forms an angle equal to  $\alpha$  with the positive  $x$ -axis; see Figure 3. Symmetrically, the illumination cone of any  $\alpha$ -floodlight positioned at  $t$  and illuminating the maximum range  $[\chi', +\infty)$  of the  $x$ -axis (i.e.,  $\chi'$  is minimized) is delimited by the  $t$ -originating rightward-pointing horizontal ray and the  $t$ -originating downward-pointing ray that forms an angle equal to  $180^\circ - \alpha$  with the positive  $x$ -axis.

In light of this observation, in the next lemma we show how to efficiently illuminate the unbounded ranges of the  $x$ -axis.

■ **Figure 3** Illuminating a maximum  $x$ -axis range  $(-\infty, \chi]$ .

► **Lemma 4.** For the given set  $S$  of potential floodlight locations, let  $t \in S$  lie on the line supporting  $S$  from below and forming angle  $\alpha$  with the positive  $x$ -axis. Then, the maximum range  $(-\infty, \chi_t]$  of the  $x$ -axis illuminated by an  $\alpha$ -floodlight positioned at  $t$  is no smaller than the maximum range  $(-\infty, \chi]$  of the  $x$ -axis illuminated by an  $\alpha$ -floodlight positioned at any other point in  $S$ ; see Figure 3. A symmetric result holds for the illumination of a range  $[\chi', +\infty)$  of the  $x$ -axis where the points in  $S$  that maximize the illuminated range are those that lie on the line supporting  $S$  from below and forming angle  $180^\circ - \alpha$  with the positive  $x$ -axis.

Next, let  $(-\infty, \chi_{left}]$  and  $[\chi_{right}, +\infty)$  be the maximum such ranges of the  $x$ -axis illuminated by an  $\alpha$ -floodlight positioned at any point in the given location set  $S$ ; the values  $\chi_{left}$  and  $\chi_{right}$  can be computed as described in Lemma 4. Note that  $\chi_{left} < \chi_{right}$  because  $\alpha < 90^\circ$ .

■ **Figure 4** Illuminating a bounded range of the  $x$ -axis with an  $\alpha$ -floodlight positioned at  $t$ .

Now, let us consider the illumination of bounded ranges of the  $x$ -axis. If an  $\alpha$ -floodlight positioned at a point  $t$  above the  $x$ -axis illuminates the range  $[\chi_L, \chi_R]$  of the  $x$ -axis with  $-\infty < \chi_L < \chi_{right}$ , we write that  $illum(t, \chi_L) = [\chi_L, \chi_R]$ ; the range  $illum(t, \chi_L)$  is uniquely defined as the range of the  $x$ -axis swept by the counterclockwise rotation by an angle  $\alpha$  of the  $t$ -originating ray that goes through the point  $(\chi_L, 0)$  on the  $x$ -axis. In addition, we extend this notation and use  $illum(t, -\infty)$  to denote the maximum range of the form  $(-\infty, \chi]$  illuminated by an  $\alpha$ -floodlight at  $t$ ; see Observation 3.

Assuming that  $illum(t, \chi_L) = [\chi_L, \chi_R]$ , let  $p, q$  be the points  $p = (\chi_L, 0)$  and  $q = (\chi_R, 0)$  and let  $r$  be the radius of the circle through  $t, p, q$  (see Figure 4). Then, the distance of the center  $c$  of this circle from the  $x$ -axis is  $r \cos \alpha$ , that is, the ratio of its distance to  $t$  over its distance to the  $x$ -axis is  $1/\cos \alpha$ , which is a constant greater than 1 for any fixed  $\alpha < 90^\circ$ . Therefore, from Section 2, the center  $c$  belongs to a hyperbola branch which we formally define next.

► **Definition 5.** For any positive angle  $\alpha < 90^\circ$  and any point  $t$  above the  $x$ -axis, we define the hyperbola branch  $H_t$  (with the point  $t$  as focus and the  $x$ -axis as directrix) that is the locus of points whose distance from the point  $t$  divided by the (perpendicular) distance from the  $x$ -axis is equal to  $1/\cos \alpha > 1$ .

■ **Figure 5** A set of five point locations and the corresponding hyperbola branches  $H_i$  for  $\alpha = 10^\circ$ .

## 11:6 Illuminating the $x$ -Axis by $\alpha$ -Floodlights

Figure 5 shows the hyperbola branches  $H_t$  for a set of five points and  $\alpha = 10^\circ$ . Then, from the above discussion and from Figure 4, we have:

- **Lemma 6.** *Let  $t$  be a point above the  $x$ -axis and  $\alpha$  a positive angle where  $\alpha < 90^\circ$ . Consider an  $\alpha$ -floodlight positioned at  $t$  which illuminates a range  $[\chi_L, \chi_R]$  of the  $x$ -axis, and let  $p, q$  be the points  $p = (\chi_L, 0)$  and  $q = (\chi_R, 0)$  on the  $x$ -axis. If  $C$  is the circle defined by  $t, p, q$ , then:*
- (i) *The center  $c$  of the circle  $C$  lies on the hyperbola branch  $H_t$  (see Definition 5).*
  - (ii) *The line through  $p$  and  $c$  forms a fixed angle equal to  $90^\circ - \alpha$  with the positive  $x$ -axis. Symmetrically, the line through  $q$  and  $c$  forms a fixed angle equal to  $90^\circ + \alpha$  with the positive  $x$ -axis.*

As we are interested in minimizing the total number of  $\alpha$ -floodlights used, it is important to use floodlights positioned at points of the given set  $S$  of locations such that the illuminated range is maximized. Thus, for  $-\infty \leq \chi < \chi_{right}$ , we denote by  $loc\_max(\chi) \subseteq S$  the set of locations  $t \in S$  such that  $illum(t, \chi)$  is maximized; Lemma 4 implies that if  $\chi = -\infty$ , all these locations belong to a line forming angle  $\alpha$  with the positive  $x$ -axis whereas Figure 4 implies that for  $-\infty < \chi < \chi_{right}$ , they belong to an arc of a circle with endpoints being the endpoints of  $illum(t, \chi)$ .

In order to determine the points in  $loc\_max(\chi)$  for  $\chi$  such that  $\chi_{left} \leq \chi < \chi_{right}$ , we use the properties stated in the following lemma.

- **Lemma 7.** *Let  $t$  be a point in the location set  $S$ . For any real number  $\chi$  such that  $\chi_{left} \leq \chi < \chi_{right}$ , assume that  $illum(t, \chi) = [\chi, \chi_R]$  and let  $p, q$  be the points  $p = (\chi, 0)$  and  $q = (\chi_R, 0)$  on the  $x$ -axis. If  $c$  is the center of the circle  $C$  through  $t, p, q$ , then:*
- (i) *The point  $t$  belongs to  $loc\_max(\chi)$  if and only if the circle  $C$  encloses the entire set  $S$ .*
  - (ii) *The point  $t$  belongs to  $loc\_max(\chi)$  if and only if  $c$  belongs to the upper envelope of the hyperbola branches  $H_u$  for all  $u \in S$ .*
  - (iii) *If  $t$  belongs to  $loc\_max(\chi)$ , then no range  $[\chi'_L, \chi'_R]$  with  $\chi'_L \leq \chi$  and  $\chi'_R > \chi_R$  can be illuminated by an  $\alpha$ -floodlight located at any point of  $S$ .*

### 4 The Algorithm

First, we show that the Axis  $\alpha$ -Illumination Problem admits solutions in which we use one floodlight to illuminate the range  $(-\infty, \chi_{left}]$  and another one to illuminate the range  $[\chi_{right}, +\infty)$  (Figure 6) where  $\chi_{left}, \chi_{right}$  are as defined in Section 3.

- **Lemma 8.** *Let  $S$  be a given set of locations and let  $\alpha < 90^\circ$ . Then, there exists a solution of the Axis  $\alpha$ -Illumination Problem on  $S$  in which one floodlight is used to illuminate the range  $(-\infty, \chi_{left}]$  and another one to illuminate the range  $[\chi_{right}, +\infty)$  of the  $x$ -axis.*

Therefore, next, we concentrate on the illumination of the range  $[\chi_{left}, \chi_{right}]$  of the  $x$ -axis. First, we note that, as is the case in [5], any instance of the Axis  $\alpha$ -Illumination Problem on a (possibly continuous) location set  $S$  can be reduced into an instance on the set of the convex hull vertices of  $S$ , that is, on a discrete location set.

- **Lemma 9.** *The Axis  $\alpha$ -Illumination Problem on a set  $S$  of planar regions with piece-wise linear boundary has the same solution as the Axis  $\alpha$ -Illumination Problem on the vertices of the convex hull  $CH(S)$  of  $S$ .*

Because of Lemma 9, in the following, we can assume that  $S$  is a discrete set, with  $|S| = n$ .

■ **Figure 6** The upper envelope  $H$  of the hyperbola branches in Figure 5 and the  $\alpha$ -floodlights (shown in red) illuminating the ranges  $(-\infty, \chi_{left}]$  and  $[\chi_{right}, +\infty)$  of the  $x$ -axis.

For the illumination of the range  $[\chi_{left}, \chi_{right}]$  of the  $x$ -axis, Lemma 7(iii) suggests that it is advantageous to use locations that belong to the corresponding  $loc\_max(\cdot)$  set. This is what we do in First Algorithm. The algorithm determines a location in the current  $loc\_max(\chi)$  set (for  $\chi_{left} \leq \chi < \chi_{right}$ ) from the intersection of the upper envelope  $H$  of the hyperbola branches with a line forming angle  $90^\circ - \alpha$  with the positive  $x$ -axis that goes through point  $(\chi, 0)$  on the  $x$ -axis (see Lemma 6(ii)); any such line intersects a hyperbola branch  $H_t$  at exactly one point.

#### First Algorithm

*Input:* a positive angle  $\alpha < 90^\circ$ , a set  $S$  of regions with piece-wise linear boundary above the  $x$ -axis, and the range  $[\chi_{left}, \chi_{right}]$  of the  $x$ -axis to be illuminated

*Output:* a set  $F$  of  $\alpha$ -floodlights at points in  $S$  illuminating the entire  $[\chi_{left}, \chi_{right}]$ , and the corresponding illuminated ranges

1.  $F \leftarrow \emptyset$ ;     { $F$  will store a solution}  
 $current\_x \leftarrow \chi_{left}$ ;  
**while**  $current\_x < \chi_{right}$  **do**  
 $p \leftarrow$  the point  $(current\_x, 0)$  on the  $x$ -axis;  
 $v \leftarrow$  a vertex in  $loc\_max(current\_x)$ ;  
 $q \leftarrow$  point on the  $x$ -axis to the right of  $p$  such that the angle  $\widehat{pvq}$  is equal to  $\alpha$ ;  
 $\chi' \leftarrow$  the  $x$ -coordinate of  $q$ ;  
 $F \leftarrow F \cup \{ (v, [current\_x, \chi']) \}$ ;  
 $current\_x \leftarrow \chi'$ ;  
**return** the resulting  $F$ ;

Clearly, the algorithm can be used to illuminate any subset of the range  $[\chi_{left}, \chi_{right}]$  of the  $x$ -axis, and in general any line segment in the plane. First Algorithm places an  $\alpha$ -floodlight at a point in  $loc\_max(\chi_{left})$ , which is computed from the arc in the upper envelope  $H$  that is intersected by the line through the point  $(\chi_{left}, 0)$  and forming angle  $90^\circ - \alpha$  with the positive  $x$ -axis (Lemma 6 and Lemma 7(ii)), and if the illuminated range is  $[\chi_{left}, \chi_1]$ , in a similar fashion, places an  $\alpha$ -floodlight at a point in  $loc\_max(\chi_1)$ , and if the new illuminated range is  $[\chi_1, \chi_2]$ , it places an  $\alpha$ -floodlight at a point in  $loc\_max(\chi_2)$ , and so on so forth until  $\chi_{right}$  gets illuminated. Figure 7 shows how Step 2 of the First Algorithm works in order to illuminate the range  $[\chi_{left}, \chi_{right}]$  of the  $x$ -axis for the set of five point locations of Figure 5.

■ **Figure 7** Illustration of the operation of First Algorithm on the hyperbola branches of Figure 5 and the set of floodlights produced by the algorithm to optimally illuminate the range  $[\chi_{left}, \chi_{right}]$  of the  $x$ -axis.

If the upper envelope  $H$  of the hyperbola branches  $H_t$  of the vertices of the convex hull  $CH(S)$  of the location set  $S$  is given as a left-to-right sequence of hyperbola arcs along with the associated vertices of  $CH(S)$ , First Algorithm takes  $O(n + k)$  time where  $k$  is the number of  $\alpha$ -floodlights that are eventually used. If the output consists of a list of the required floodlights, this algorithm is output-size sensitive. However, the number  $k$  may be very large even for a location set  $S$  of small descriptive size.

In the following, we propose a modified approach which, in one fell swoop, computes a number of illuminated ranges corresponding to many  $\alpha$ -floodlights placed at the same location in  $S$ ; once we reach an arc  $A$  of the upper envelope  $H$ , we determine all consecutive  $\alpha$ -floodlights that need to be placed at the convex-hull vertex corresponding to the arc  $A$  by using the right endpoint of  $A$ . This approach is used in Step 2 of Second Algorithm for the general Axis  $\alpha$ -Illumination Problem, which we give below.

**Second Algorithm**

*Input:* a positive angle  $\alpha < 90^\circ$  and a set  $S$  of regions with piece-wise linear boundary above the  $x$ -axis

*Output:* a set  $F$  of  $\alpha$ -floodlights located at points in  $S$  illuminating the entire  $x$ -axis, and the corresponding illuminated ranges on the  $x$ -axis

1. compute the convex hull  $CH(S)$  of the given location set  $S$ ;  
 compute the upper envelope  $H$  of the hyperbola branches (each defined by a vertex in  $CH(S)$  and the  $x$ -axis as directrix) and store it as a left-to-right sequence of hyperbola arcs, each associated with the corresponding vertex in  $CH(S)$ ;  
 $v_{first} \leftarrow$  a vertex of  $CH(S)$  as described in Lemma 4 in order to place an  $\alpha$ -floodlight to illuminate the range  $(-\infty, \chi_{left}]$  of the  $x$ -axis;  
 $v_{last} \leftarrow$  a vertex of  $CH(S)$  as described in Lemma 4 in order to place an  $\alpha$ -floodlight to illuminate the range  $[\chi_{right}, +\infty)$  of the  $x$ -axis;  
 $F \leftarrow \{ (v_{first}, (-\infty, \chi_{left})) \}; \quad \{F \text{ will store a solution} \}$

*continued on next page...*

### 4.1 Complexity of Second Algorithm

The upper envelope  $H$  of the hyperbola branches  $H_t$  for  $t \in S$  can be efficiently computed by using the farthest-point Voronoi diagram  $fVD(S)$  of the vertices of the convex hull of the set  $S$ , which coincides with the farthest point Voronoi diagram of the vertices of  $S$  (see Lemma 1(i)). The following lemma and the corollary give the relationship of the  $fVD(S)$  with the arcs in the upper envelope  $H$ .

► **Lemma 10.** *Let  $H$  be the upper envelope of the hyperbola branches of all the vertices in the convex hull  $CH(S)$  of  $S$  and let  $fVD(S)$  be the farthest-point Voronoi diagram of the vertices of  $CH(S)$ . Moreover, let  $H_v$  be the hyperbola branch of a vertex  $v$  of the convex hull of  $S$  and let  $t$  be a point of  $H_v$ . Then, the point  $t$  belongs to  $H$  if and only if  $t$  belongs to the closure of the cell of  $v$  in  $fVD(S)$ .*

■ **Figure 9** The upper envelope  $H$  of the five points shown in Figure 5 and their farthest-point Voronoi diagram (shown in red).

Lemma 10 implies the following corollary; see Figure 9.

- **Corollary 11.** *Let  $H$ ,  $fVD(S)$ ,  $v$ , and  $H_v$  be as in Lemma 10. Then, the following hold.*
- (i) *The part of the hyperbola branch  $H_v$  of a vertex  $v \in CH(S)$  that belongs to  $H$  is precisely the intersection of  $H_v$  with the cell of  $v$  in  $fVD(S)$ .*
  - (ii) *A point  $t \in H$  is a vertex of  $H$  if and only if  $t$  either lies on an edge or is a vertex of  $fVD(S)$ .*
  - (iii) *The size (number of vertices or hyperbola arcs) of the upper envelope  $H$  of the hyperbola branches of all the vertices in the convex hull of the set  $S$  is  $O(|CH(S)|)$ .*

Since each arc of the upper envelope  $H$  produces at most one pair in the solution  $F$  in Step 2 of the Second Algorithm (see Figure 8), Corollary 11(iii) implies that:

► **Corollary 12.** *The size of the solution computed by the Second Algorithm is  $O(n)$  where  $n$  is the total number of vertices of the location set  $S$ . Hence, the same holds for any solution to the Axis  $\alpha$ -Illumination Problem as it is described in Section 1.*

Now we are ready to estimate the complexity of the Second Algorithm. Let  $n$  be the number of vertices of the set  $S$ . The computation of the convex hull of the vertices of  $S$ , which coincides with the convex hull of  $S$ , takes  $O(n \log n)$  time [6]. The computation of the upper envelope of  $H$  can be done by computing first the farthest-point Voronoi diagram of the convex hull vertices of  $S$ , and then the vertices of  $H$  by taking advantage of Corollary 11(ii), the proof of Corollary 11(iii), and the appropriate hyperbola arcs of  $H$  in accordance with Corollary 11(i); the farthest point Voronoi diagram of  $O(n)$  points can be computed in  $O(n \log n)$  time [16] and has  $O(n)$  size (see Lemma 1(ii)), while the remaining work can be done in  $O(n)$  time. Finally, computing  $v_{first}$  and  $v_{last}$  takes  $O(n)$  time and the initialization of  $F$  takes constant time. In total, Step 1 can be completed in  $O(n \log n)$  time.

Each iteration of the **while** loop in Step 2 of the algorithm requires constant time for everything but determining the arc  $A$  intersected by the line  $L$ . Finding the arc  $A$  can be done in  $O(\log n)$  time by using binary search on the  $x$ -monotone upper envelope  $H$ ; in fact, all the arcs  $A$  needed in the different iterations of the **while** loop can be found in  $O(n)$  total time by walking along  $H$  from left to right as needed by the algorithm. Because each iteration of the **while** loop involves a different arc in  $H$  and the total number of arcs is  $O(n)$  (Corollary 11(iii)), the total number of iterations is  $O(n)$ . In addition to the **while** loop, Step 2 contains operations that require constant total time; thus, Step 2 can be completed in  $O(n \log n)$  time. Step 3 takes  $O(n)$  time because we can efficiently merge the appropriate pairs in the set  $F$  computed after Step 2 by processing them in the order they are produced.

Overall, the algorithm takes  $O(n \log n)$  time. The space for computing and storing the upper envelope  $H$  of the hyperbola branches, the farthest-point Voronoi diagram (Lemma 1(ii)), and the solution  $F$  (Corollary 12) is  $O(n)$ . Thus, we conclude with the following theorem.

► **Theorem 13.** *The Second Algorithm correctly computes a solution to the Axis  $\alpha$ -Illumination Problem and requires  $O(n \log n)$  time and  $O(n)$  space, where  $n$  is the number of vertices of the given location set.*

## 5 Concluding Remarks

We proved that the Axis  $\alpha$ -Illumination Problem admits an  $O(n \log n)$ -time and  $O(n)$ -space algorithm where  $n$  is the number of vertices of the given location set. The obvious open question is whether there exists a matching lower bound for that problem or if not, to find a faster algorithm.

A natural extension of our Axis  $\alpha$ -Illumination Problem is the case of a set  $S$  of regions (with piece-wise linear boundary) lying in a polygon and we want to illuminate the boundary of that polygon. This problem may be thought of as a variant of the Art Gallery polygon where the purpose is to guard only the boundary of the input polygon [12]. We believe that the Second Algorithm can be extended to the case where  $S$  lies in a circle or in a convex polygon and we want to illuminate the boundary of that circle/polygon. However, in the case of a simple polygon, the problem is NP-hard [13] and APX-hard [10].

## Abstract

We study the priority set cover problem for simple geometric set systems in the plane. For pseudo-halfspaces in the plane we obtain a PTAS via local search by showing that the corresponding set system admits a planar support. We show that the problem is APX-hard even for unit disks in the plane and argue that in this case the standard local search algorithm can output a solution that is arbitrarily bad compared to the optimal solution. We then present an LP-relative constant factor approximation algorithm (which also works in the weighted setting) for unit disks via quasi-uniform sampling. As a consequence we obtain a constant factor approximation for the capacitated set cover problem with unit disks. For arbitrary size disks, we show that the problem is at least as hard as the vertex cover problem in general graphs even when the disks have nearly equal sizes. We also present a few simple results for unit squares and orthants in the plane.

## 1 Introduction

The priority set cover problem is defined as follows. Given a ground set  $X$  and a set  $\mathcal{S}$  of subsets of  $X$ , where each element  $x \in X$  has an associated priority  $\pi(x)$  and each set  $S \in \mathcal{S}$  has an associated priority  $\pi(S)$ , the goal is to pick the smallest cardinality subset  $\mathcal{S}' \subseteq \mathcal{S}$  s.t. for each  $x \in X$ , there is some  $S \in \mathcal{S}'$  contain  $x$  s.t.  $\pi(S) \geq \pi(x)$ .

We study the priority set cover problem for simple geometric regions in the plane. It is a natural generalization of the set cover problem, and is interesting in its own right. It is also related to the capacitated covering problem via the work of Chakarabarty et al. [11]. Another motivation for studying such problems is that it leads to a better understanding of the limitations of the current techniques and forces us to extend them.

By treating the priority as an additional dimension, these problems can be seen as special cases of three dimensional set cover problems. However, these problems turn out to be significantly harder than the corresponding problems without priority. For example, while the set cover problem with disks in the plane admits a PTAS, the same problem with priorities surprisingly turns out to be APX-hard even for unit disks. This is one of the few problems known that is APX-hard for unit disks. One standard technique that yields a constant factor

---

<sup>1</sup> On leave from IIIT-Delhi, India.

approximation for many geometric covering problems is quasi-uniform sampling [28, 13]. However this fails for the priority set cover problem for unit disks since the *shallow cell complexity* (defined in Section 2) of the corresponding set system can be quadratic. Another common technique used to obtain approximation algorithms is *local search*. The analysis of local search requires showing the existence of a *support*, or the existence of a *local search graph* that come from a hereditary family with sublinear size separators (see [26] and the references therein). However, even for the priority set cover problem with unit disks, such graphs do not exist. In fact we show that the standard local search algorithm may produce solutions that are arbitrarily bad compared to an optimal solution.

We develop techniques to obtain the first  $O(1)$ -factor approximation algorithms for the priority set cover problem with unit disks. The algorithm relies on tools we develop to study the priority set cover problem defined by points and *pseudo-halfspaces* in the plane. For the latter problem we show that the shallow cell complexity of the corresponding set system is linear. For the set cover problem without priorities (or equivalently the priority set cover problem with uniform priorities), the problem is known to be solvable in polynomial time [21]. However, we show that the introduction of priorities renders the problem NP-hard.

The proof is non-trivial and uses a novel approach that might be useful in other settings. We also obtain a PTAS for the priority set cover problem for pseudo-halfspaces via local search. For this, we prove that the corresponding set system admits a planar support. Again due to priorities, the proof is much more subtle than for pseudo-halfspaces without priorities.

An identical proof also yields an  $O(1)$ -approximation for the priority set cover problem with unit squares. In this case, we do not know if the problem is APX-hard, and this remains an intriguing open question.

As a consequence of our results for the priority problem, we immediately obtain  $O(1)$ -approximation algorithms for the capacitated covering problems when combined with the results of Bansal and Pruhs [6], and Chakrabarty et al. [11]. We start with the necessary definitions and results in Section 2, and describe related work in Section 3. In Section 4 we present our results for pseudo-halfspaces. We present our results for disks in Section 5. We conclude with open problems in Section 6.

## 2 Preliminaries

Let  $P$  be a set of points and let  $\mathcal{R}$  be a set of regions in the plane and let  $\pi : P \cup \mathcal{R} \rightarrow \mathbb{R}$  be a function that assigns a priority to each point and each region. We say that a region  $R$  *covers* a point  $p$  if  $R$  contains  $p$  and  $\pi(R) \geq \pi(p)$ . We use the notation  $p \prec R$  for “ $R$  covers  $p$ ”. For any region  $R$ , we denote by  $R(P)$ , the set of points in  $P$  covered by  $R$ . We denote the set system  $(P, \{R(P) : R \in \mathcal{R}\})$  by  $(P, \mathcal{R}, \pi)$  and call it the “set system defined by  $P$  and  $\mathcal{R}$ ”. For any point  $p$ , we denote by  $p(\mathcal{R})$  the set of regions in  $\mathcal{R}$  covering  $p$  and we denote the set system  $(\mathcal{R}, \{p(\mathcal{R}) : p \in P\})$  by  $(\mathcal{R}, P, \pi)$  and call it the “dual set system defined by  $P$  and  $\mathcal{R}$ ”.

The *Priority Set Cover problem* defined by  $P$ ,  $\mathcal{R}$  and  $\pi$  is the set cover problem on the set system  $(P, \mathcal{R}, \pi)$ . In other words, the goal is to find the smallest subset  $\mathcal{R}' \subseteq \mathcal{R}$  s.t. each point in  $P$  is covered by at least one of the regions in  $\mathcal{R}'$ . In the *weighted* variant of this problem, we have a weight  $w_R$  with each region  $R$  and the goal is to minimize the total weight of the regions in  $\mathcal{R}'$  instead of its cardinality. We also consider the *Capacitated Set Cover* problem studied by Chakrabarty et al. [11]. In this problem, we are given a set system  $(X, \mathcal{S})$ , where  $X$  is a set of elements,  $\mathcal{S}$  is a collection of subsets of  $X$  with a weight function  $w : \mathcal{S} \rightarrow \mathbb{R}_+$ , and a capacity function  $c : \mathcal{S} \rightarrow \mathbb{R}_+$ . Each element  $x \in X$  has a demand  $d(x) > 0$ . The objective is to select the smallest weight sub-collection  $\mathcal{S}' \subseteq \mathcal{S}$  such that the total capacity of the sets in  $\mathcal{S}'$  containing any element  $x$  is at least  $d(x)$ . A special case of this problem is the *Set Multicover problem* where the capacity of each set in  $\mathcal{S}'$  is 1.

A finite collection of unbounded  $x$ -monotone curves is called a *family of pseudolines* if every pair of curves intersect in at most one point and at this point the curves cross [3]. Pseudoline arrangements have a rich history and a rich combinatorial structure. See the book [20] for further results on pseudolines. A *family of pseudo-halfspaces* is a collection of closed unbounded regions in the plane whose boundaries form a family of pseudolines.

Given a set system  $(X, \mathcal{S})$ , a *support* is a graph  $G = (X, E)$  s.t. any set  $S \in \mathcal{S}$  induces a connected subgraph of  $G$ . A *planar support* is a support that is planar.

A *plane graph* is a drawing of a planar graph in the plane where the vertices are drawn as points and edges are drawn as interior disjoint simple Jordan curves connecting the points corresponding to the incident vertices. A *triangulation* is a plane graph in which all faces have three vertices.

Given a set system  $(X, \mathcal{S})$ , let  $x(\mathcal{S}) = \{S \in \mathcal{S} : x \in S\}$ . The set system  $(X, \mathcal{S})$  has *shallow cell complexity* [13] function  $f(\cdot, \cdot)$  if for any subset  $\mathcal{S}' \subseteq \mathcal{S}$ , and any  $k \in \mathbb{N}$ , the number of sets of size at most  $k$  in  $\{x(\mathcal{S}') : x \in X\}$  is at most  $f(|\mathcal{S}'|, k)$ . If  $f(|\mathcal{S}'|, k) \leq \phi(|\mathcal{S}'|) \cdot k^c$  for some constant  $c$  where  $\phi(\cdot)$  is a linear function of its argument, we say that the shallow cell complexity of the set system is “linear”. Similarly, if  $\phi(\cdot)$  is a quadratic function of its argument, we say that the shallow cell complexity is “quadratic”.

### 3 Related Work

Packing and covering problems are central topics in computational geometry literature, and studied intensively over several decades. Broadly, there are three main algorithmic techniques: LP-rounding, local search and separator based methods.

The technique of Bronimann and Goodrich [9] reduces any covering problem to an  $\epsilon$ -net question so that if the set system admits an  $\epsilon$ -net of size  $\frac{1}{\epsilon} \cdot f(\frac{1}{\epsilon})$ , then we obtain an LP-relative approximation algorithm with approximation factor  $f(\text{OPT})$  where OPT is the size of the optimal solution. Since set systems of finite VC- dimension admit  $\epsilon$ -nets of size  $O(\frac{1}{\epsilon} \log \frac{1}{\epsilon})$ , this implies an  $O(\log \text{OPT})$  approximation algorithm for covering problems involving such set systems. Similarly, for set systems with low shallow cell complexity, we obtain algorithms with correspondingly small approximation factors (see [28, 13]). In particular if the shallow cell complexity is linear, we obtain constant factor approximation algorithms. Varadarajan [28] showed via the *quasi-uniform* sampling technique how these results can be made to work in the weighted setting. His technique was optimized by Chan et al. [13] who also introduced the notion of *shallow cell complexity* generalizing the notion of *union complexity* from geometric set systems to abstract set systems. Some of these algorithms have also been extended to work in the multicover setting (see [15], [6]). One limitation of the approach in [9] is that even for simple set systems with linear shallow cell complexity, the lower bound on the size of the  $\epsilon$ -net may involve a large constant factor which then translates into a lower bound on the approximation ratio of the corresponding rounding algorithm. For simple set systems, such as that for points and halfspaces in the plane, Har-Peled and Lee [21] gave a polynomial time dynamic programming algorithm. Bringmann et al. [8] show a tight  $O(n^{\sqrt{k}})$  exact algorithm to check if there is a set cover of size at most  $k$ , while for dimensions larger than 3, they show that under ETH, it is not possible to improve upon brute force enumeration.

The local search framework, where one starts with any feasible solution and tries to improve the solution by only making constant size *swaps* (i.e., adding/removing a constant number of elements from the solution), yields a PTAS for several packing and covering problems (see e.g. [25, 14, 5, 19, 26, 7]). This framework also has major limitations: it is not as broadly applicable as the LP-rounding technique (in particular it works only for the

unweighted setting so far), often hard to analyse, and the PTASes they yield have a running time like  $n^{O(1/\epsilon^2)}$  with large constants in the exponent, making them irrelevant for practical applications.

The third type of algorithms consists of separator based methods where some kind of *separator* is used to split the problem instance into smaller problems which can be solved independently and combined to obtain an approximate solution. Hochbaum and Maass [22] used this idea to obtain PTASes for several packing and covering problems. More recently, Adamaszek and Wiese [1, 2] have used this kind of idea for obtaining a QPTAS for independent set problems. Mustafa et al. [24] extend the idea of Adamaszek and Wiese to obtain a QPTAS for weighted set cover problem with pseudodisks in the plane and halfspaces in  $\mathbb{R}^3$ . For unit disks, there have also been attempts to obtain better approximation algorithms that run fast. See [17] for an 18-approximation algorithm that runs in  $O(mn)$  for  $m$  points and  $n$  unit disks.

The priority set cover problem was introduced by Chakrabarty et al. [11] as an approach to solve the capacitated set cover problem. In particular, they showed that an LP-relaxation for the capacitated covering problem with *knapsack cover inequalities*, introduced by Carr et al. [10] in the context of approximation algorithms has an  $O(1)$ -approximation algorithm if there is an LP-relative  $O(1)$ -approximation for the set multicovering problem, and an  $O(1)$  LP-relative approximation for the priority set cover problem.

#### 4 Pseudo-halfspaces

In this section we study the priority set cover problem for pseudo-halfspaces in the plane. For the set cover problem without priorities (or equivalently the priority set cover problem with uniform priorities), the problem is known to be solvable in polynomial time [21]. However, in the full version of the paper we show that the introduction of priorities renders the problem NP-hard.

Let  $H = \{h_1, \dots, h_n\}$  be a set of pseudo-halfspaces and let  $P$  be a set of points in  $\mathbb{R}^2$ . We denote the boundary of  $h_i$  by  $\ell_i$ . We assume that curves  $\ell_1, \dots, \ell_n$  lie in general position i.e., no more than two of them intersect at any point in the plane. Each pseudo-halfspace and each point also has an associated priority. We assume without loss of generality that the priorities of all the pseudo-halfspaces are distinct. For any point  $p$ , let  $H(p)$  denote the subset of pseudo-halfspaces covering  $p$ . We define  $depth(p)$  as  $|H(p)|$ .

► **Lemma 1.** *Let  $t$  be a positive integer. Let  $P'$  be any subset of the points in  $P$  s.t. for any point  $p \in P'$ ,  $depth(p) \leq t$  and for any two distinct points  $p, q \in P'$ ,  $H(p) \neq H(q)$ . Then,  $|P'|$  is  $O(nt^2)$ .*

Note that the above lemma implies that the shallow cell complexity of the set system  $(P, \{H(p) : p \in P\})$  is linear.

For any point  $p$ , we can assume without loss of generality that  $p$  is contained in a bounded cell in the arrangement of the boundaries of the pseudo-halfspaces in  $H(p)$ . This can be guaranteed by adding three *dummy* pseudo-halfspaces of priority larger than all the points in  $P$  so that  $P$  is contained in a bounded cell defined by them. The dummy halfspaces increase the depth of each point by 3 but this does not affect the upper bound claimed above.

In order to prove Lemma 1, we define a new set  $Q$  of points as follows. For every triple of pseudo-halfspaces  $h_i, h_j, h_k$  s.t.  $\pi(h_i) < \pi(h_j), \pi(h_k)$  and  $h_i$  contains  $\ell_j \cap \ell_k$ , we define a point  $q = q(i, j, k)$  located at  $\ell_j \cap \ell_k$  with priority  $\pi(h_i)$ . Note that  $Q$  may contain several points with the same location but with different priorities. However no two points in  $Q$  have the same location and priority.

We map each  $p \in P'$  to a point in  $Q$  as follows. We consider the arrangement of the boundaries of all the pseudo-halfspaces whose priority is at least that of  $p$ . As mentioned above, we can assume that  $p$  lies in a bounded cell  $C$  of this arrangement. Let  $h_i$  be the pseudo-halfspace with the lowest priority in  $H(p)$ . Note that the cell  $C$  must have at least three vertices since this is a pseudo-line arrangement. Thus, it must have a vertex defined by the boundaries of two pseudo-halfspaces  $h_j$  and  $h_k$  other than  $h_i$ . Note that  $\pi(h_i) < \pi(h_j), \pi(h_k)$  and  $h_i$  contains  $\ell_j \cap \ell_k$ . We map  $p$  to  $q(i, j, k)$ .

Since  $\ell_j \cap \ell_k$  is adjacent to at most four cells in the arrangement each of which can contain at most one point of  $P'$ , at most four points in  $P'$  are mapped to  $q(i, j, k)$ . Note also that if  $p$  is mapped to  $q(i, j, k)$  then the depth of  $p$  and  $q(i, j, k)$  differ by at most 2 depending on whether  $h_j$  and  $h_k$  contain  $p$ . Thus, in order to prove the upper bound in Lemma 1, it suffices to prove the upper bound on the number of points in  $Q$  of depth at most  $t$ .

▷ **Claim 2.** Let  $t$  be a positive integer. The number of points in  $Q$  of depth at most  $t$  is  $O(nt^2)$ .

*Proof.* First note that any point  $q = q(i, j, k) \in Q$  has depth at least three since it is contained in the three pseudo-halfspaces  $h_i, h_j$  and  $h_k$ . We first prove that the number of points  $q(i, j, k)$  of depth 3 is  $O(n)$ . We then use the Clarkson-Shor technique [16] to prove the lemma.

If a point  $q(i, j, k) \in Q$  has depth 3 then note that  $h_i$  is the pseudo-halfspace of the highest priority below  $\min\{\pi(h_j), \pi(h_k)\}$  containing  $\ell_j \cap \ell_k$ . This means that if we imagine inserting the pseudo-halfspaces into an initially empty arrangement in the decreasing order of their priorities then  $\ell_j \cap \ell_k$  is a vertex on the boundary of the arrangement until  $h_i$  is inserted at which point it is no longer a vertex on the boundary of the arrangement. Since inserting any pseudo-halfspace can create at most two new vertices on the boundary of the arrangement, the total number of vertices that appear on the boundary of the arrangement throughout the process is  $O(n)$  and since only one point of depth 3 in  $Q$  is located at any such point, the number of points in  $Q$  of depth 3 is also  $O(n)$ .

We now bound the number  $N_t$  of points in  $Q$  of depth  $\leq t$  as follows. Imagine picking a sample of the pseudo-halfspaces where each pseudo-halfspace is picked independently with probability  $\rho = 1/t$ . Let  $Q'$  be the subset of points in  $Q$  that are still present and have depth 3 in the sample. The probability that a point  $q(i, j, k)$  is still present in the sample and has depth 3 in the sample is  $\rho^3(1-\rho)^{t-3}$  since this happens iff  $h_i, h_j$  and  $h_k$  are in the sample but none of remaining  $t-3$  pseudo-halfspaces covering  $q(i, j, k)$  are. Thus,  $\mathbb{E}(Q') \geq N_t \cdot \rho^3(1-\rho)^{t-3}$ . On the other hand since the expected number of pseudo-halfspaces in the sample is  $\rho n$ , we also have  $\mathbb{E}(Q') = O(\rho n)$ . Thus,  $N_t = O\left(\frac{n}{\rho^2(1-\rho)^{t-3}}\right) = O(nt^2)$ . ◁

Lemma 1 now follows. The following theorem is an immediate consequence of Lemma 1 and the results in [13].

► **Theorem 3.** *There is a polynomial time  $O(1)$  LP-relative<sup>2</sup> approximation for the weighted priority set cover problem defined by a set of points and a set of pseudo-halfspaces in the plane.*

► **Theorem 4.** *The capacitated set cover problem defined by points and pseudo-halfspaces in the plane has a polynomial time  $O(1)$ -approximation algorithm.*

<sup>2</sup> with respect to the standard LP relaxation for set cover

**Proof.** Since the shallow-cell complexity of the set system defined by points and pseudo-halfspaces (without priorities) is linear, the result of Bansal and Pruhs [6] implies an  $O(1)$  LP-relative approximation for the multicover problem of this set system. Now, Lemma 1 implies that the set system defined by pseudo-halfspaces and points with priorities is linear, and therefore implies an  $O(1)$  LP-relative approximation for the priority problem via the result of Chan et al. [13]. Now, by the result of Chakrabarty et al. [11], the result follows. ◀

Next, we show that the set system  $(P, H, \pi)$  has a planar support. Our result only requires the boundaries of the pseudo-halfspaces and not the direction of the pseudo-halfspace. Therefore, we consider the following problem: the input is a set  $P$  of points and a set  $L$  of pseudolines with priorities. We construct a plane graph  $G$  with vertex set  $P$  such that the subgraphs induced on the points covered by  $h^+(\ell)$  and  $h^-(\ell)$  are connected. Here,  $h^+(\ell)$  and  $h^-(\ell)$  are two pseudo-halfspaces with priority  $\pi(\ell)$  and boundary  $\ell$ . Such a graph  $G$  is called a support on  $P$  with respect to  $L$ .

The proof is constructive: we process the points in increasing order of priority, and maintain a support graph on the processed points with respect to  $L$ . We additionally maintain that this support graph is a triangulation on the processed points and has the property that each edge in the graph is a simple curve that crosses any  $\ell \in L$  at most once. In order to construct the graph, we use the following well known result called the Levi extension lemma.

► **Lemma 5** (Levi extension Lemma [20]). *Given a pseudoline arrangement  $L$  and two points  $p$  and  $q$  not lying on the same pseudoline in  $L$ , there exists a simple curve  $\ell$  through  $p$  and  $q$  such that  $L \cup \ell$  is a pseudoline arrangement.*

Using the Lemma above, we now construct a planar support.

► **Theorem 6.** *Let  $P$  be a set of  $n$  points,  $L$  a family of pseudolines in  $\mathbb{R}^2$ , and  $\pi : P \cup L \rightarrow \mathbb{R}$  be priorities. Then, there exists a graph  $T$  which is a support on  $P$  w.r.t.  $L$  such that each edge in  $T$  crosses any pseudoline  $\ell \in L$  at most once. Further, for any  $n \geq 3$ ,  $T$  is a triangulation.*

**Proof.** Let  $p_1, \dots, p_n$  be an ordering of the points  $P$  in increasing order of priority. We process the points in this order, and for each  $i = 1, \dots, n$ , we maintain a graph  $T_i$  that is a support graph on the points  $p_1, \dots, p_i$  with respect to  $L$  and such that: any edge of  $T_i$  crosses the boundary of any pseudoline in  $L$  at most once. We call such a graph with its embedding a *nice graph*.

For  $i = 1$ , the graph  $T_1$  consisting of  $p_1$  and no edges clearly satisfies both the conditions, and is a nice graph. For  $i = 2$ , by Lemma 5, there is a curve  $\gamma_{12}$  between  $p_1$  and  $p_2$  such that  $L_2 = \gamma_{12} \cup L$  is a pseudoline arrangement. The edge  $e_{12}$  is defined as  $\gamma_{12}[p_1, p_2]$ , i.e., the segment on  $\gamma_{12}$  between  $p_1$  and  $p_2$ . It is clear that  $T_2$  is a nice graph.

For  $i = 3$ , we use Lemma 5 with the pseudoline arrangement  $L_2$  to construct a pseudoline  $\gamma_{13}$  through points  $p_1$  and  $p_3$ , such that  $L_2 \cup \gamma_{13}$  is a pseudoline arrangement. Invoking Lemma 5 again with  $L_2 \cup \gamma_{13}$ , we obtain a pseudoline  $\gamma_{23}$  between  $p_2$  and  $p_3$ , such that  $L_3 = L_2 \cup \gamma_{13} \cup \gamma_{23}$  is a pseudoline arrangement. The new pseudolines added define edges  $e_{13} = \gamma_{13}[p_1, p_3]$  and  $e_{23} = \gamma_{23}[p_2, p_3]$ . Set  $T_3 = T_2 \cup e_{13} \cup e_{23}$ . It is easy to see that  $T_3$  is a nice graph.

Let  $T_{i-1}$  be the graph constructed for the first  $i - 1$  points, and let  $L_{i-1}$  be the union of  $L$  and the additional pseudolines added in the first  $i - 1$  iterations. We construct  $T_i$  as follows: Let  $p_i$  lie in a triangle  $\Delta$  defined by points  $p_a, p_b$ , and  $p_c$  - note that  $p_i$  may lie in the external face. Suppose that  $p_i$  lies in an interior face of  $T_{i-1}$ . Using Lemma 5

with the arrangement  $L_{i-1}$  lets us construct a pseudoline  $\gamma_{ia}$  through  $p_i$  and  $p_a$ , such that  $L_{i-1} \cup \gamma_{ia}$  is a pseudoline arrangement. This gives us the edge  $e_{ia} = \gamma_{ia}[p_i, p_a]$ . Note that the interior of  $e_{ia}$  lies in  $\Delta$ . Otherwise, if  $e_{ia}$  crosses  $\Delta$ , it crosses one of the pseudolines defining the boundaries of  $\Delta$ , which it can not cross again without violating the assumption that  $L_{i-1} \cup \gamma_{ia}$  is a pseudoline arrangement. If  $p_i$  lies in an external face of  $T_{i-1}$ , we first pick a point  $o$  that lies in an internal face of  $T_{i-1}$ , does not lie on any pseudolines in  $L_{i-1}$  and is not one of the points in  $P$ . Let  $C$  be a unit circle centered at  $o$ . We temporarily apply an inversion<sup>3</sup> with respect to  $C$  to turn the external face in which  $p_i$  lies into an internal face. We then proceed as before and apply the inversion again to undo the first inversion.

By a similar argument, we construct edges  $e_{ib}$  and  $e_{ic}$ , and set  $L_i = L_{i-1} \cup \gamma_{ia} \cup \gamma_{ib} \cup \gamma_{ic}$ , and  $T_i = T_{i-1} \cup e_{ia} \cup e_{ib} \cup e_{ic}$ . Since  $p_i$  lies on  $\gamma_{ia}, \gamma_{ib}$  and  $\gamma_{ic}$  it follows that the interiors of  $e_{ia}, e_{ib}$  and  $e_{ic}$  are pairwise internally disjoint. By construction, the edges  $e_{ia}, e_{ib}$  and  $e_{ic}$  lie in the same face of  $T_{i-1}$ , and therefore do not intersect the interiors of edges in  $T_{i-1}$ .

To show that  $T_i$  is a nice graph, we still need to show that  $T_i$  is a support on  $P_i$  with respect to  $L$ . Consider a pseudo-halfspace  $h = h(\ell)$  defined by a pseudoline  $\ell \in L$ . First, we will show that  $h' = h \setminus \cup_{e \in T_i} \text{interior}(e)$  is path connected. If not, let  $p$  and  $q$  be two points in  $h'$  that cannot be connected by a continuous path in  $h'$ . Let  $H_p$  be the set of points reachable from  $p$  i.e.,  $H_p$  is the set of points in  $h$  to which there is path from  $p$  in  $h'$ , and let  $H_q$  be the set of points reachable from  $q$ . Since  $h$  is connected and we have removed only the interiors of the edges that are pairwise non-intersecting, there are no vertices on the boundary of  $H_p$  and  $H_q$ . Since each edge is a simple curve, it implies that there is an edge  $e$  that separates  $H_p$  and  $H_q$ , i.e., the boundary of  $e$  crosses  $\ell$  twice. This leads to a contradiction.

Now, let  $u$  and  $v$  be any two points in  $P_i$  that are contained in  $h$ . We show that there is a path between  $u$  and  $v$  in the subgraph of  $T_i$  induced by  $h \cap P_i$ . Since  $u$  and  $v$  do not lie in the interior of any of the edges in  $T_i$ ,  $u, v \in h'$ . By the previous argument, there is a simple curve  $\sigma$  in  $h'$  joining  $u$  and  $v$ . Observe that adjacent points of  $P_i$  on  $\sigma$  lie in the same face of  $T_i$ , and therefore are adjacent in  $T_i$ , since  $T_i$  is a triangulation. This implies that there is a path in the subgraph of  $T_i$  induced by  $h \cap P_i$  joining  $u$  and  $v$ .

Let  $p_k$  be the point of highest priority that is contained in  $h$ . Then, by the fact that  $T_k$  is a support on  $P_k$  with respect to  $L$  and  $h$  covers exactly the points in  $P_k \cap h$ , we conclude that the subgraph of  $T_k$  induced by the points covered by  $h$  is connected. Since  $T_n$  contains  $T_k$  as subgraph, the subgraph of  $T_n$  induced by the points in  $P = P_n$  covered by  $h$  is also connected. The theorem follows.  $\blacktriangleleft$

An immediate consequence of the above theorem is the following.

► **Corollary 7.** *The set system  $(P, H, \pi)$  admits a planar support.*

► **Corollary 8.** *The set system  $(H, P, \pi)$  admits a planar support if the union of the pseudo-halfspaces in  $H$  do not cover the entire plane.*

**Proof.** If there is a point  $o$  in the plane that is not covered by any of the pseudo-halfspaces in  $H$  then using the duality between points and pseudolines [4], we can map points to pseudo-halfspaces and pseudo-halfspaces to points while maintaining incidences. Then, Corollary 7 implies that the set system  $(H, P, \pi)$  admits a planar support.  $\blacktriangleleft$

<sup>3</sup> [https://en.wikipedia.org/wiki/Inversive\\_geometry](https://en.wikipedia.org/wiki/Inversive_geometry)

The next theorem follows directly from the above result and the results in [26] and [27] which show that the existence of a suitable planar support implies a PTAS.

► **Theorem 9.** *The Set Cover, Hitting Set, Point Packing, and Region Packing problems with priorities defined by a set of points and pseudo-halfspaces in the plane admit a PTAS. The set multi-cover problem defined by a set of points and pseudo-halfspaces with priorities admits a  $(2 + \epsilon)$ -approximation algorithm for any  $\epsilon > 0$ .*

The definitions of the problems mentioned in the theorem above without the priorities can be found in [26] and [27] and naturally extend to the version with priorities.

## 5 Disks

Chan et al. [12] showed that the set cover problem with horizontal and vertical strips in the plane is APX-hard. The input is a set  $P$  of  $n$  points in the plane and a set  $\mathcal{S}$  of vertical or horizontal strips of the form  $V(a, b) = \{(x, y) \in \mathbb{R}^2 : a \leq x \leq b\}$  or  $H(a, b) = \{(x, y) \in \mathbb{R}^2 : a \leq y \leq b\}$ . We show below that the set system defined by axis aligned strips and points in the plane can be implemented using disks and points with priorities. This implies that the set cover problem defined by points and axis aligned strips in the plane can be reduced to the priority set cover problem defined by a set of points and unit disks in the plane in polynomial time.

► **Theorem 10.** *Given a set  $\mathcal{S}$  of horizontal and vertical strips and a set of points  $P$  in the plane, we can map each strip  $S \in \mathcal{S}$  to a unit radius disk  $S'$  and each point  $p \in P$  to another point  $p'$  with appropriate priorities so that  $S'$  covers  $p'$  iff  $S$  contains  $p$ .*

**Proof.** Let  $n$  be the number of points in  $P$ . We can assume without loss of generality that the points in  $P$  lie on an  $n \times n$  grid  $G$  and have cartesian coordinates  $(i, j)$  where  $i, j \in [n]$ . For convenience, we will assume that  $P$  consists of all points in the grid since if the theorem holds for such a  $P$  then it certainly holds for any subset of it. We refer to the point with cartesian coordinates  $(i, j)$  in  $G$  as  $p_{ij}$ .

Let  $D$  be a unit radius disk centered at the origin  $o$ . We first define  $n + 2$  points  $z_0, z_1, \dots, z_{n+1}$  on the boundary of  $D$  as follows. The point  $z_i$  has polar coordinates  $(1, \theta_i)$  i.e., cartesian coordinates  $(\cos \theta_i, \sin \theta_i)$  where  $\theta_i = i \cdot \frac{\pi}{4(n+1)}$ . Let  $\hat{u}$  be a unit vector along the positive  $x$ -axis. We map the point  $p_{ij}$  on the grid to the point  $q_{ij} = z_i + j \cdot \frac{\epsilon}{n} \hat{u}$  where  $\epsilon$  is a sufficiently small constant. We assign priority  $n - j$  to the point  $q_{ij}$ . Note that the points on  $j^{\text{th}}$  column of the grid are mapped to the points  $q_{1j}, \dots, q_{nj}$  that lie on the boundary of a unit radius disk whose center is at  $o + j \cdot \frac{\epsilon}{n} \hat{u}$ . We will call this disk  $C_j$ . The points on the  $i^{\text{th}}$  row of the grid  $G$  are mapped to points on a horizontal segment of length  $\epsilon$  whose left end-point is  $z_i$ . We denote the set of points  $\{q_{ij} : i, j \in [n]\}$  by  $Q$ .

Consider any vertical strip  $S = V(a, b)$  which contains the points in columns  $a, a + 1, \dots, b$  of  $G$ . We map this strip to the disk  $S'$  which is identical to  $C_b$  but has priority  $n - a$ . It can be verified that a point  $q_{ij} \in Q$  is covered by  $S'$  iff the corresponding point  $p_{ij}$  is covered by  $S$ . Now consider any horizontal strip  $S = H(a, b)$  which contains the points in rows  $a, a + 1, \dots, b$  of  $G$ . We map this strip to a disk  $S'$  defined as follows. Let  $u$  be the mid-point on the arc on  $\partial D$  joining  $z_{a-1}$  and  $z_a$ . Similarly, let  $v$  be the mid-point on the arc on  $\partial D$  joining  $z_b$  and  $z_{b+1}$ .  $S'$  is the unique disk of unit radius whose center lies outside  $D$  and whose boundary intersects the boundary of  $D$  at the points  $u$  and  $v$ . For sufficiently small  $\epsilon$ ,  $S'$  contains exactly the subset of points in  $Q$  that correspond to the points in  $P$  contained in  $S$ . We assign a priority of  $n$  to  $S'$  so that it covers all the points it contains. The theorem follows. ◀

The following is an immediate consequence of Theorem 10 and the results in [12].

► **Corollary 11.** *The priority set cover problem defined by a set of points  $P$  and a set of unit radius disks  $\mathcal{D}$  in the plane is APX-hard.*

► **Corollary 12.** *The shallow cell complexity of the set system defined by unit radius disks and points with priority is quadratic.*

**Proof.** This follows from Theorem 10 and the fact that the shallow cell complexity of the set system defined by axis aligned strips and points in the plane is quadratic. To see the latter, consider  $n$  disjoint horizontal strips  $H_1, \dots, H_n$  and  $n$  disjoint vertical strips  $V_1, \dots, V_n$ . Then for every pair of indices  $i, j \in [n]$ ,  $H_i$  and  $V_j$  intersect at a point in the plane that is not contained in any other strip. ◀

► **Remark.** Since the shallow cell complexity is quadratic, the quasi-uniform sampling technique [28, 13] cannot be directly applied to obtain a constant factor approximation for the priority set cover problem defined by points and unit disks in the plane.

The next lemma shows that the standard local search algorithm does not work for the priority set cover problem defined by unit disks and points in the plane. For minimization problems, the standard local search algorithm is the following. It has a fixed parameter  $k$ . The algorithm starts with any feasible solution and tries to decrease the size of the solution by removing at most  $k$  elements from the current solution and adding fewer elements to the solution without violating feasibility. When such improvements are not possible it returns the current solution.

► **Lemma 13.** *For any positive integer  $k$ , there exist instances of the priority set cover problem defined by unit disks and points in the plane such that the standard local search algorithm with parameter  $k$  does not yield a solution with a bounded approximation ratio.*

**Proof.** We will construct an instance of the set cover problem defined by points and axis aligned strips in the plane for which the standard local search algorithm with swap size  $k$  does not yield a solution with a bounded approximation ratio. This along with Theorem 10 implies the statement in the theorem.

Let  $H_1, \dots, H_m$  be  $m$  disjoint horizontal strips and let  $V_1, \dots, V_n$  be  $n$  disjoint vertical strips where  $m \gg n > k$ . For any  $i, j \in [n]$ , let  $p_{ij}$  be a point in  $H_i \cap V_j$ . Consider the set cover problem defined the all the horizontal and vertical strips and the points  $\{p_{ij} : i, j \in [n]\}$ . Then, the horizontal strips form a locally optimal solution i.e., the solution cannot be improved by swapping out at most  $k$  strips from this solution and swapping in fewer strips. This is because if any horizontal strip is dropped, we would need to add all the vertical strips, of which there are more than  $k$ , in order to obtain a feasible solution. Since  $m \gg n$  this solution is arbitrarily large compared to the optimal solution formed by the vertical strips. ◀

We now show that we can construct an arbitrarily set of disks such that every pair intersects at a depth 2. This implies that the shallow-cell complexity of this set system is quadratic.

► **Theorem 14.** *For any positive integer  $n$ , there exist a set of  $n$  disks  $\mathcal{D} = \{D_1, \dots, D_n\}$  whose radii are nearly equal (i.e., the ratio of any two of the radii can be made arbitrarily close to 1) and a set of points  $P$  with  $\binom{n}{2}$  points s.t. for any pair of disks  $i, j \in [n]$  s.t.  $i < j$ , there exists a point  $p_{ij} \in P$  which is covered by only the disks  $D_i$  and  $D_j$  among the disks in  $\mathcal{D}$ .*

## 12:10 On the Geometric Priority Set Cover Problem

■ **Figure 1** Constructing disk  $D_{k+1}$  from disk  $D_k$ . The radius of  $D_{k+1}$  is only slightly bigger than the radius of  $D_k$ , the difference being arbitrarily small. The centers of the two disks are also arbitrarily close to each other.

**Proof.** We show the existence of a family of disks  $\mathcal{D}$  so that for any  $j \in [n]$ , if we consider the arrangement of the disks in  $\mathcal{D}_j := \{D_1, \dots, D_j\}$ , then i) the boundary of every disk in  $\mathcal{D}_j$  contributes at least one arc to the boundary of the union of the disks in  $\mathcal{D}_j$  and ii) the boundary of  $D_j$  intersects the boundary of every other disk non-tangentially on the boundary of the union of the disks in  $\mathcal{D}_j$ .

We show the existence of such disks by induction on the number of disks. The base case is  $n = 1$  and is trivially true. Suppose that we have shown this for  $n = k$  for some  $k \geq 1$ . We now show that we can add a disk  $D_{k+1}$  to the existing collection so that the above properties i) and ii) hold for  $n = k + 1$ . By the inductive hypothesis,  $D_k$  contributes an arc to the boundary of the union of the disks in  $\mathcal{D}_k$ . Let  $p$  be the mid-point of such an arc. Without loss of generality assume that the radius of  $D_k$  is 1. We construct the disk  $D_{k+1}$  in two steps. See Figure 1.

First we tentatively set  $D_{k+1}$  to be a disk of radius  $1 + \delta_{k+1}$  for some  $\delta_{k+1} > 0$  so that  $D_{k+1}$  contains  $D_k$  and the boundaries of  $D_k$  and  $D_{k+1}$  intersect tangentially at  $p$ . We set  $\delta_{k+1}$  to be sufficiently small so that none of the vertices in the arrangement of disks in  $\mathcal{D}_k$  lie in the region  $D_{k+1} \setminus D_k$ . At this point  $D_{k+1}$  almost satisfies the required properties. Since  $\delta_{k+1}$  is very small  $D_{k+1}$  is almost the same as  $D_k$  and is obtained by “growing”  $D_k$  slightly. This means that for each  $j < k$ ,  $D_j$  still contributes an arc to the boundary of the union of disks in  $\mathcal{D}_k$  and the boundary of  $D_{k+1}$  intersects the boundary  $D_j$  on the boundary of the union of the disks in  $\mathcal{D}_{k+1}$ .  $D_{k+1}$  however intersects  $D_k$  tangentially at  $p$  which also means that the boundary of  $D_k$  does not contribute any arc to the boundary of the union of the disks in  $\mathcal{D}_{k+1}$ . To fix these problems, we move the center of  $D_{k+1}$  by a distance  $\epsilon_{k+1} > 0$  in the direction  $c - p$  where  $c$  is the center of  $D_k$ . We choose  $\epsilon_{k+1}$  to be sufficiently small so that during the movement, the boundary of  $D_k$  does not touch any of the vertices in the arrangement of the disks in  $\mathcal{D}_k$ . It can be checked that after this movement the set of disks  $\mathcal{D}_{k+1}$  satisfies the two properties. This concludes the inductive proof. By making  $\epsilon_{k+1}$  and  $\delta_{k+1}$  appropriately small for every  $k$ , we can ensure that the disks have nearly equal radii.

We assign the priority  $n - i$  to the disk  $D_i$ . For any  $i < j$ , we define the point  $p_{ij}$  to be the point located where the boundaries of  $D_i$  and  $D_j$  intersect on the boundary of the union of the disks in  $\mathcal{D}_j$  and having priority  $n - j$ . Note that the point  $p_{ij}$  is covered by both  $D_i$  and  $D_j$ . It is however not contained in any of other disks in  $\{D_1, \dots, D_j\}$  and it is not covered by any of the disks in  $\{D_{j+1}, \dots, D_n\}$  since those disks have a lower priority than that of  $p_{ij}$ . ◀

► **Remark.** It can be shown that the values of  $\epsilon_{k+1}$  and  $\delta_{k+1}$  in the above proof can be chosen so that they can be encoded using  $\text{poly}(n)$  bits. The formal proof of this statement will appear in the extended version of the paper.

► **Corollary 15.** *The priority set cover problem defined by a set of points and nearly equal size disks in the plane does not admit a strongly polynomial time approximation algorithm with approximation factor smaller than 1.36 unless  $P = NP$ . Under the unique games conjecture, this implies that the priority set cover problem does not admit a strongly polynomial time algorithm with approximation factor smaller than 2.*

**Proof.** We give an approximation preserving reduction from vertex cover to priority set cover problem defined by a set of points and a set of nearly equal sized disks in the plane. The corollary then follows from the results known for the vertex cover problem [18, 23]. Given a graph  $G$  with  $n$  vertices  $v_1, \dots, v_n$  and  $m$  edges, we use Theorem 14 to obtain a set  $\mathcal{D}$  of  $n$  disks and a set  $P$  with  $\binom{n}{2}$  points. The disk  $D_i$  corresponds to the vertex  $v_i$  of  $G$ . For each edge  $\{v_i, v_j\}$  in  $G$ , we retain the point  $p_{ij} \in P$ . We remove all other points. Let  $Q$  be the set of points retained. Then, the priority set cover problem defined by the points in  $Q$  and the disks in  $\mathcal{D}$  is equivalent to the vertex cover problem in  $G$ . ◀

We now show that there exists a polynomial time constant factor approximation algorithm for the weighted priority set cover problem defined by a set of points  $P$  and a set of unit disks  $\mathcal{D}$  in the plane. We first define an LP-relaxation for this problem:

$$\text{minimize } \sum_{D \in \mathcal{D}} w_D x_D \quad \text{s.t. for each } p \in P : \sum_{D \in \mathcal{D} : p \in D} x_D \geq 1.$$

We will show that there is a polynomial time algorithm that outputs a solution of size at most a constant times the value  $\text{OPT}_{LP}$  of an optimal solution to the above LP.

► **Theorem 16.** *There is a polynomial time LP-relative  $O(1)$ -approximation algorithm for the weighted priority set cover problem defined by a set of points  $P$  and a set of unit radius disks  $\mathcal{D}$  in the plane.*

**Proof.** We first prove the theorem for disks containing a common point which without loss of generality is assumed to be the origin  $o$ . Let  $x^*$  be an optimal solution to the LP-relaxation. Consider any one of the four quadrants formed by the axes and consider the priority set cover problem restricted to that quadrant. Note that  $x^*$  is also a feasible solution to this problem. Since the boundaries of any two disks containing  $o$  intersect at most once in the quadrant, they behave like pseudo-halfspaces with respect to the quadrant. By Lemma 1, the shallow cell complexity of the corresponding set system is linear and therefore quasi-uniform sampling [13] yields an LP-relative  $O(1)$ -approximation for this problem. Since there are four quadrants, by taking the union of the solutions for each of the quadrants, we obtain an LP-relative  $O(1)$  approximation for the priority set cover problem where all disks contain a common point  $o$ .

Now, we consider the case of a general set of unit disks in the plane. We partition the given set of disks into a constant number of families s.t. each family consists of disjoint groups of disks so that disks in each group intersect at a common point but disks from different groups do not intersect.

An  $O(1)$ -approximation for the priority set cover problem defined by such a family of disks follows from the fact that disks in different groups don't interact and for each group we have an  $O(1)$ -approximation.

The families of the required type are obtained as follows. We place a uniform grid over the plane having cells of size  $\sqrt{2} \times \sqrt{2}$  i.e., each cell is a square with diameter 2. Since there are only a finite number of disks, we can also choose the grid in such a way that the center of each disk lies in the interior of some cell. We associate each unit disk with the cell

## 12:12 On the Geometric Priority Set Cover Problem

containing its center. Note that the disks associated with a cell contain the center of the cell. Next we color the cells with a constant number of colors so that two cells whose centers have distance less than 4 get distinct colors. The disks associated with cells of a single color then is a family of the required type. Each distinct color defines a family. Let  $\mathcal{F}_1, \dots, \mathcal{F}_k$  be the families obtained. As argued above, there is an  $O(1)$ -approximation algorithm for the priority set cover problem defined by any particular family. However, a point can belong to disks of several different families. So, we need a way to assign each point to a particular family. To do this, we consider an optimal solution  $x^*$  to the priority cover problem defined by all disks and points. Since, for any point  $p$ , we have that  $\sum_{D \in \mathcal{D}: p \prec D} x_D \geq 1$ , there is some family  $\mathcal{F}_i$  s.t.  $\sum_{D \in \mathcal{F}_i: p \prec D} x_D \geq 1/k$ . We assign the point  $p$  to one such family.

Let  $P_i$  be the subset of points assigned to family  $\mathcal{F}_i$ . Then note that  $\hat{x}_D = k \cdot x_D^*$ ,  $D \in \mathcal{F}_i$  is a feasible solution to the LP-relaxation for the priority set cover problem defined by the points in  $P_i$  and the disks in  $\mathcal{F}_i$ . Let  $S_i$  be a solution to this problem using an LP-relative  $O(1)$ -approximation. This means that  $S_i$  has weight at most  $O(1) \cdot \sum_{D \in \mathcal{F}_i} w_D \hat{x}_D$ . Note that  $S = \bigcup_{i=1}^k S_i$  is a solution to the weighted priority set cover problem defined by all disks and points and has weight at most

$$O(1) \cdot \sum_{i=1}^k \sum_{D \in \mathcal{F}_i} w_D \hat{x}_D \leq O(1) \cdot \sum_{i=1}^k \sum_{D \in \mathcal{F}_i} k \cdot w_D x_D^* = O(1) \cdot k \cdot \sum_D w_D x_D^* = O(1) \cdot \sum_D w_D x_D^*$$

since  $k$  is a constant.  $S$  is therefore an LP-relative  $O(1)$ -approximation to the weighted priority set cover problem defined by all disks and points. ◀

► **Theorem 17.** *There is a polynomial time LP-relative  $O(1)$ -approximation algorithm for the weighted priority set cover problem defined by a set of points  $P$  and a set of unit squares  $\mathcal{S}$  in the plane.*

**Proof.** The proof is identical to the proof of Theorem 16, except that we have unit squares instead of unit disks. ◀

► **Theorem 18.** *The capacitated set cover problem with unit squares, or unit disks admits an  $O(1)$ -approximation.*

**Proof.** The result of Chakrabarty et al. [11] shows that there exists an  $O(1)$ -approximation for the capacitated set cover problem whenever we have an  $O(1)$ -LP-relative approximation for the multicover problem, and an  $O(1)$ -LP-relative approximation for the priority cover problem. The result of Bansal and Pruhs [6] implies an  $O(1)$ -LP-relative approximation for the multicover problem, and Theorem 16 implies an  $O(1)$ -LP-relative approximation for the priority problem. The result for unit disks follows. For unit squares, the result similarly follows from that of Bansal and Pruhs [6] and Theorem 17. ◀

## 6 Conclusion

We studied the priority set cover problem for several simple geometric set systems in the plane. For pseudo-halfspaces in the plane we were able to obtain a PTAS but for unit disks in the plane the problem is APX-hard and we obtained a constant factor approximation. Obtaining a relatively small approximation factor is an interesting open question. For unit squares in the plane we also obtain a constant factor approximation but it is not clear if the problem is APX-hard. In fact even for orthants in the plane (possibly containing orthants of opposite types), it is not clear if there is a PTAS. In particular, we do not know if the

standard local search yields a PTAS. There are instances showing that the corresponding set system does not admit a planar support. Another interesting open problem is to obtain a constant factor approximation algorithms for disks or square of arbitrary size in the plane.

# The Complexity of Sharing a Pizza

Patrick Schneider   

Department of Mathematical Sciences, University of Copenhagen, Denmark

---

## Abstract

Assume you have a 2-dimensional pizza with  $2n$  ingredients that you want to share with your friend. For this you are allowed to cut the pizza using several straight cuts, and then give every second piece to your friend. You want to do this fairly, that is, your friend and you should each get exactly half of each ingredient. How many cuts do you need?

It was recently shown using topological methods that  $n$  cuts always suffice. In this work, we study the computational complexity of finding such  $n$  cuts. Our main result is that this problem is PPA-complete when the ingredients are represented as point sets. For this, we give a new proof that for point sets  $n$  cuts suffice, which does not use any topological methods.

We further prove several hardness results as well as a higher-dimensional variant for the case where the ingredients are well-separated.

## 1 Introduction

### 1.1 Mass partitions

The study of *mass partitions* is a large and rapidly growing area of research in discrete and computational geometry. It has its origins in the classic *Ham-Sandwich theorem* [44]. This theorem states that any  $d$  mass distributions in  $\mathbb{R}^d$  can be simultaneously bisected by a hyperplane. A mass distribution  $\mu$  in  $\mathbb{R}^d$  is a measure on  $\mathbb{R}^d$  such that all open subsets of  $\mathbb{R}^d$  are measurable,  $0 < \mu(\mathbb{R}^d) < \infty$  and  $\mu(S) = 0$  for every lower-dimensional subset  $S$  of  $\mathbb{R}^d$ . A vivid example of this result is, that it is possible to share a 3-dimensional sandwich, consisting of bread, ham and cheese, with a friend by cutting it with one straight cut such that both will get exactly half of each ingredient. This works no matter how the ingredients lie. In fact, as Edelsbrunner puts it, this even works if the cheese is still in the fridge [19].

But what if there are more ingredients, for example on a pizza? One way to bisect more than  $d$  masses is to use more complicated cuts, such as algebraic surfaces of fixed degree [44] or piece-wise linear cuts with a fixed number of turns [28, 40]. Another option is to use several straight cuts, as introduced by Bereg et al. [8]: Consider some arrangement of  $n$  hyperplanes in  $\mathbb{R}^d$ . The cells of this arrangement allow a natural 2-coloring, where two cells get a different color whenever they share a  $(d - 1)$ -dimensional face. We say that an arrangement bisects a mass distribution  $\mu$  if the cells of each color contain exactly half of  $\mu$ . See Figure 1 for an illustration. It was conjectured by Langerman that any  $nd$  mass distributions in  $\mathbb{R}^d$  can be simultaneously bisected by an arrangement of  $n$  hyperplanes ([30], see also [5]). In a series of papers, this conjecture has been resolved for 4 masses in the

plane [5], for any number of masses in any dimension that is a power of 2 (and thus in particular also in the plane) [26] and in a relaxed setting for any number of masses in any dimension [41]. However, the general conjecture remains open.

There are many other variants of mass partitions that have been studied, see e.g. [27, 38] for recent surveys. In this work, we focus on the algorithmic aspects of the 2-dimensional variant of bisections with hyperplane arrangements, that is, bisections with line arrangements. For this, let us formally define the involved objects.

► **Definition 1** (Partition induced by an arrangement of oriented lines). *Let  $A = (\ell_1, \dots, \ell_n)$  be a set of oriented lines in the plane. For each  $\ell_i$ , define  $R_i^+$  and  $R_i^-$  the part of the plane on the positive and negative side of  $\ell_i$ , respectively. Define  $R^+(A)$  as the part of the plane lying in an even number of  $R_i^+$  and not on any of the  $\ell_i$ . Similarly, define  $R^-(A)$  as the part of the plane lying in an odd number of  $R_i^+$  and not on any of the  $\ell_i$ . Now,  $R^+(A)$  and  $R^-(A)$  are disjoint, and they partition  $\mathbb{R}^2 \setminus \{\ell_1, \dots, \ell_n\}$  into two parts.*

Note that reorienting one line just swaps  $R^+(A)$  and  $R^-(A)$ , so up to symmetry, the two sides are already determined by the underlying unoriented line arrangement. We will thus often forget about the orientations and just say that a mass is bisected by a line arrangement. Hubbard and Karasev [26] have shown the following:

► **Theorem 2** (Planar pizza cutting theorem [26]). *Any  $2n$  mass distributions in the plane can be simultaneously bisected by an arrangement of  $n$  lines.*

From an algorithmic point of view, we want to restrict our attention to efficiently computable mass distributions.

► **Definition 3** (Computable mass distribution). *A computable mass distribution is a continuous function  $\mu$  which assigns to each arrangement of  $n$  oriented lines two values  $\mu(R^+(A))$  and  $\mu(R^-(A))$ , such that  $\mu(R^+(A)) + \mu(R^-(A)) = \mu(R^+(A')) + \mu(R^-(A'))$  for any two arrangements  $A$  and  $A'$ . We further assume that  $\mu$  can be computed in time polynomial in the description of the input arrangement.*

We now have that the following problem always has a solution.

► **Definition 4** (PIZZACUTTING). *The problem PIZZACUTTING takes as input  $2n$  computable mass distributions  $\mu_1, \dots, \mu_{2n}$  and returns an arrangement  $A$  of oriented lines in the plane such that for each  $i$  we have  $\mu_i(R^+(A)) = \mu_i(R^-(A))$ .*

An important special case of masses are point sets with the counting measure. They do not quite fit the above framework of mass distributions, as the number of points on a line can be non-zero. This can however be resolved by rounding: we say that a line arrangement bisects a point set  $P$ , if there are at most  $\lfloor \frac{|P|}{2} \rfloor$  many points of  $P$  in both parts. Note that if the number of points in  $P$  is odd, this implies that at least one point needs to lie on some line. In the following, we will assume that all point sets are in general position, that is, no three points lie on a common line. With this, we can assume that for each point set at most one point lies on a line. Standard arguments (see e.g. [33]) show that the existence of partitions for mass distributions imply the analogous result for point sets with this definition of bisection. Alternatively, we give a direct proof of the following in Section 4.

► **Corollary 5** (Discrete planar pizza cutting theorem). *Any  $2n$  point sets in the plane can be simultaneously bisected by an arrangement of  $n$  lines.*

Thus, also the following discrete version always has a solution.

► **Definition 6** (DISCRETEPIZZACUTTING). *The problem DISCRETEPIZZACUTTING takes as input  $2n$  point sets  $P_1, \dots, P_{2n}$  in general position in the plane and returns an arrangement  $A$  of oriented lines in the plane such that for each  $i$  we have  $|P_i \cap R^+(A)| = |P_i \cap R^-(A)| = \lfloor \frac{|P_i|}{2} \rfloor$ .*

The pizza cutting problem can be viewed as a higher-dimensional generalization of the consensus halving and necklace splitting problems.

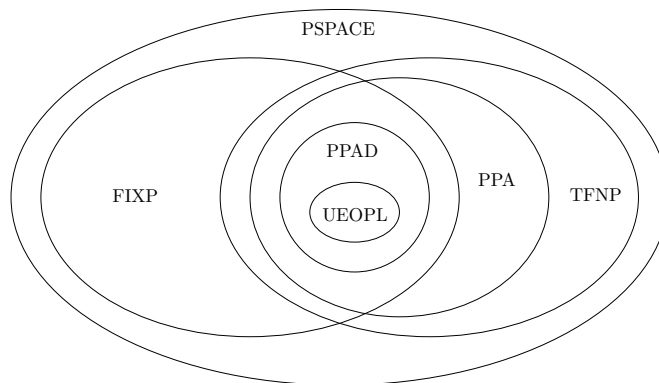

► **Definition 7** (CONSENSUSHALVING/NECKLACESPLITTING). *The problem CONSENSUSHALVING takes as input  $n$  valuation functions  $v_1, \dots, v_n$  on the interval  $[0, 1]$  and returns a partition of  $[0, 1]$  into  $n + 1$  intervals (that is, using  $n$  cuts), each labeled “+” or “−”, such that for each valuation function we have  $v_i(\mathcal{I}^+) = v_i(\mathcal{I}^-)$  (where  $\mathcal{I}^x$  denotes the union of intervals labeled “ $x$ ”). The problem NECKLACESPLITTING is the same, but taking as input  $n$  point sets, again using the above definition of bisections of point sets.*

Again, a solution to the problems is always guaranteed to exist. In the case of mass distributions, this result is known as the *Hobby-Rice theorem* [25]. For necklaces, the statement holds even for the generalized problem of sharing with more than two people [2, 3]. In this work, whenever we refer to the *Necklace splitting theorem*, we mean the version for two people.

Finally, for all above problems, we can also consider the decision version, where we are given one more measure or point set than the number that can always be bisected, and we need to decide whether there still is a bisection. We denote these problems by adding “DECISION” to their name.

## 1.2 Algorithms and complexity

Most proofs of existence of certain mass partitions use topological methods, which, by their nature, are not algorithmic. Thus, there has been quite some effort in developing algorithms that find these promised partitions, ideally efficiently. Arguably the most famous result in this direction are the algorithms for Ham-Sandwich cuts by Lo, Steiger and Matoušek [32, 31]. While in the plane, their algorithm runs in linear time, in general the runtime shows an exponential dependency on the dimension. This curse of dimensionality seems to be a common issue for many algorithmic version of mass partition problems, and most problems have only been studied from an algorithmic point of view in low dimensions, where the constructed algorithms either rely on a relatively small space of solutions or a simplified proof which allows for an algorithmic formulation, see e.g. [1, 6, 37].

■ **Figure 2** Containment relations of some complexity classes for total problems.

The curse of dimensionality was made explicit for the first time by Knauer, Tiwary and Werner, who showed that deciding whether there is a Ham-Sandwich cut through a given point in arbitrary dimensions is  $W[1]$ -hard (and thus also NP-hard) [29]. More recently, in several breakthrough papers, Filos-Ratsikas and Goldberg have shown that computing Ham-Sandwich cuts in arbitrary dimensions is PPA-complete, and so are NECKLACESPLITTING and CONSENSUSHALVING, the latter even in an approximation version [23, 24].

The class PPA was introduced in 1994 by Papadimitriou [36]. It captures search problems, where the existence of a solution is guaranteed by a parity argument in a graph. More specifically, the defining problem is the following search problem in a (potentially exponentially sized) graph  $G$ : given a vertex of odd degree in  $G$ , where  $G$  is represented via a polynomially-sized circuit which takes as input a vertex and outputs its neighbors, find another vertex of odd degree. The class PPA is a subclass of TFNP (Total Function NP), which are total search problems where solutions can be verified efficiently.

A subclass of PPA that is of importance in this work is UEOPPL [22], which is a subclass of PPAD [36]. PPAD is similar to PPA, but instead of an undirected graph, we are given a directed graph in which each vertex has at most one predecessor and at most one successor. We are given a vertex without predecessor, and our goal is to find another vertex without predecessor or successor. If we are further given a potential function which strictly increases on a directed path such that there is a unique vertex with maximal potential, finding this vertex is the defining problem for the class UEOPPL.

The class UEOPPL is related to mass partitions through the fact that finding the unique discrete Ham-Sandwich cut in the case that the point sets are *well-separated* is in UEOPPL [14]. We say that  $k$  point sets  $P_1, \dots, P_k$  in  $\mathbb{R}^d$  are well-separated, if for no  $d$ -tuple of them their convex hulls can be intersected with a  $(d-2)$ -dimensional affine subspace.<sup>1</sup> This definition extends to masses by forbidding intersections of affine subspaces with the convex hulls of their supports. In fact, for well-separated masses and point sets, the  $\alpha$ -Ham-Sandwich theorem states that it is always possible to simultaneously cut off an arbitrary given fraction from each mass or point set with a single hyperplane [4, 43].

The class PPAD has so far mostly been related to the computation of Nash and market equilibria [10, 11, 12, 13, 15, 16, 20, 34, 39, 42, 45].

<sup>1</sup> Admittedly, this would be a very weird pizza.

Finally, the two last classes that are relevant for this work are FIXP and  $\exists\mathbb{R}$ . The class FIXP is the class of problems that can be reduced to finding a Brouwer fixed point [21], whereas  $\exists\mathbb{R}$  is the class of decision problems which can be written in the existential theory of the reals.

In the context of mass partitions, apart from the above mentioned results on Ham-Sandwich cuts, Consensus halvings and Necklace splittings, some of the above classes also appear in the complexity of *Square-Cut Pizza sharing*. In this variant, introduced by Karasev, Roldán-Pensado and Soberón,  $n$  masses in the plane are bisected by a cut which is a union of at most  $n$  axis-parallel segments, or in other words, a piecewise linear cut with at most  $n - 1$   $90^\circ$ -turns [28]. It was recently shown by Deligkas, Fearnley and Melissourgos that finding such a cut even for restricted inputs is PPA-complete, finding a cut where a constant number of additional turns are allowed is PPAD-hard, and that the corresponding decision version is NP-hard [17]. For more general masses, they show the problem to be FIXP-hard and the decision version to be  $\exists\mathbb{R}$ -complete. This work was heavily influenced and motivated by their paper: apart from the different setting, their results are very similar from the results in this work, showing the relation between those two pizza cutting variants. Indeed, in a new version of their paper, the authors of [17] prove some of the same hardness results as this work, and also some stronger hardness results for approximate bisections.

### 1.3 Our contributions

Our main contribution is that DISCRETEPIZZACUTTING is PPA-complete. While the hardness is rather straight-forward, the containment requires some more work. We give a new proof for the existence of pizza cuttings for point sets which, while inspired by the ideas of Hubard and Karasev, uses only elementary geometric techniques which allow us to place the problem in PPA.

We further prove that PIZZACUTTING is FIXP-hard and that PIZZACUTTINGDECISION is  $\exists\mathbb{R}$ -hard and that finding the minimum number of cuts required to bisect an instance of DISCRETEPIZZACUTTING is NP-hard.

Finally, for well-separated masses, we show that the  $\alpha$ -Ham-Sandwich theorem generalizes to pizza cuttings. For point sets in fixed dimensions, we give a linear time algorithm to find such a cut, whereas for arbitrary dimensions we place the problem in UEOPL.

Many of our results are more or less direct applications of known results. In particular, all hardness results follow from a proof of the existence of a Consensus Halving from the existence of a pizza cut. We present this proof and the hardness results in Section 2. In Section 3, we consider the case of well-separated masses and point sets, as some of the ideas are needed for our containment proof. The part where the most new ideas are used is Section 4, where we show the containment of DISCRETEPIZZACUTTING in PPA.

## 2 Hardness results

In this section, we give a proof of existence of Consensus halvings and necklace splittings using the planar pizza cutting theorem. This proof gives a natural reduction to the corresponding algorithmic problems, and thus a variety of hardness results follow.

► **Lemma 8.** *The planar pizza cutting theorem implies the Hobby-Rice theorem.*

**Proof.** Consider the moment curve  $\gamma$  in  $\mathbb{R}^2$ , that is, the curve parametrized by  $(t, t^2)$ . Note that any line  $\ell$  intersects  $\gamma$  in at most two points, call them  $g_1$  and  $g_2$ , with  $g_1$  being to the left of  $g_2$  (in the case of a single or no intersection, we may consider  $g_1 = -\infty$  or  $g_2 = \infty$

## 13:6 The Complexity of Sharing a Pizza

or both). Let  $x_1$  and  $x_2$  be the projections of  $g_1$  and  $g_2$  to the  $x$ -axis under the projection  $\pi(x, y) := x$ . Consider now a half-plane  $h$  bounded by  $\ell$  and consider its intersection with  $\gamma$ . If  $h$  lies below  $\ell$ , then  $h \cap \gamma$  projects to the interval  $[x_1, x_2]$ . If  $h$  lies above  $\ell$ , then  $h \cap \gamma$  projects to  $(-\infty, x_1] \cup [x_2, \infty)$ . Similarly, if  $\ell$  is vertical,  $h \cap \gamma$  projects either to  $(-\infty, x_1]$  or  $[x_2, \infty)$ . Thus, in all cases  $h \cap \gamma$  projects to an interval or the complement of an interval, which, in a slight abuse of notation, we denote by  $\pi(h)$ .

Given a valuation function  $v$ , we now want to define a mass distribution  $\mu$  in the plane. For this, it is enough to just define  $\mu$  on all half-planes. This we can do using the above observations: for any half-plane  $h$ , we define  $\mu(h) := v(\pi(h))$ .

This way, we have defined  $n$  mass distributions. Now, we do the same thing, but shift the interval  $[0, 1]$ , which is the support of the valuation functions, to the interval  $[2, 3]$ . More formally, we consider the projection  $\varphi(x, y) := x - 2$  and, given a valuation function  $v$ , define a mass distribution  $\eta$  as  $\eta(h) := v(\varphi(h))$ .

We have now defined  $2n$  mass distributions. By the pizza cutting theorem, there exists an arrangement  $A = (\ell_1, \dots, \ell_n)$  of  $n$  lines which simultaneously bisect these mass distributions. Consider the intervals  $I_1$  and  $I_2$  on  $\gamma$  defined by  $t \in [0, 1]$  and  $t \in [2, 3]$ . As there are at most  $2n$  intersections of  $A$  and  $\gamma$ , by the pigeonhole principle there are at most  $n$  intersections in one of them, say  $I_1$ . Let  $i_1, \dots, i_n$  be the projections of these intersections under the projection  $\pi$ . We claim that  $i_1, \dots, i_n$  simultaneously bisect  $v_1, \dots, v_n$ .

To show this, consider some valuation function  $v_i$ . By construction, we now have that  $v_i(\mathcal{I}^+) = \mu_i(R^+(A)) = \mu_i(R^-(A)) = v_i(\mathcal{I}^+)$ , which proves the claim. In the case where  $I_2$  has at most  $n$  intersections, we can do the same argument, replacing  $\pi$  with  $\varphi$  and  $\mu$  with  $\eta$ . ◀

Note that all the steps in the proof can be computed in polynomial time. Thus, as CONSENSUSHALVING is FIXP-hard [18], we immediately get the following:

► **Corollary 9.** *PIZZACUTTING is FIXP-hard.*

In the discrete setting, the above proof can be phrased even simpler: for each point  $x$  in  $[0, 1]$ , we just define two points  $(x, x^2)$  and  $(x + 2, (x + 2)^2)$ . As NECKLACESPLITTING is PPA-hard [24], we get that

► **Corollary 10.** *DISCRETEPIZZACUTTING is PPA-hard.*

Clearly, the construction in the proof above also works for more than  $n$  valuation functions. In [18], it was shown that deciding whether  $n + 1$  valuation functions can be bisected with  $n$  cuts is  $\exists\mathbb{R}$ -hard. It thus follows that it is  $\exists\mathbb{R}$ -hard to decide whether  $2n + 2$  masses can be bisected by  $n$  lines. However, in the case where  $n$  is even, we can also only use  $\pi$  and map all valuation functions to a single interval on  $\gamma$ , which analogously proves the Hobby-Rice theorem for even  $n$ . From an asymptotic point of view, this restriction to even values does not matter, so using this reduction, we get the following slightly stronger statement.

► **Corollary 11.** *PIZZACUTTINGDECISION is  $\exists\mathbb{R}$ -hard.*

Finally, it was shown in [9, 35] that finding the minimal number of cuts required to split a necklace is NP-hard. We again get the analogous result for discrete pizza cuttings.

► **Corollary 12.** *Finding the minimal number of lines that simultaneously bisect a family of  $2n$  point sets is NP-hard.*

### 3 Well-separated point sets

In this section we consider well-separated mass distributions and point sets. We generalize the  $\alpha$ -Ham-Sandwich theorem to pizza cuttings.

► **Theorem 13.** *Let  $\mu_1, \dots, \mu_{nd}$  be  $nd$  well-separated mass distributions in  $\mathbb{R}^d$ . Given a vector  $\alpha = (\alpha_1, \dots, \alpha_{nd})$ , with each  $\alpha_i \in [0, 1]$ , there exists an arrangement  $A$  of  $n$  oriented hyperplanes such that for each  $i \in \{1, \dots, nd\}$  we have  $\mu_i(R^+(A)) = \alpha_i \mu_i(\mathbb{R}^d)$ .*

**Proof.** By the  $\alpha$ -Ham-Sandwich theorem [4], for any  $d$  well-separated mass distributions  $\mu_1, \dots, \mu_d$  and any vector  $(\alpha_1, \dots, \alpha_d)$ , there exists a unique single hyperplane cutting each mass distribution in the required ratio. By the definition of well-separatedness, this hyperplane does not intersect the support of any other mass distribution. Partition the point set into  $n$  parts of  $d$  point sets each. For each part, pick some oriented hyperplane which intersects the support of all masses in this part. This defines an arrangement  $B$  of oriented hyperplanes. For each mass  $\mu_i$ , consider the intersection of its support with the positive side of the hyperplane intersecting it, as well as with  $R^+(B)$ . If these two coincide, set  $\alpha'_i := \alpha_i$ , otherwise set  $\alpha'_i := 1 - \alpha_i$ . Now, taking the  $\alpha$ -Ham-Sandwich cut for the vectors  $\alpha'$  gives the required arrangement. ◀

We call such an arrangement an  $\alpha$ -Pizza cut. From the discrete  $\alpha$ -Ham-Sandwich theorem [43], we analogously get the discrete version of the above.

► **Corollary 14.** *Let  $P_1, \dots, P_{nd}$  be  $nd$  well-separated point sets in  $\mathbb{R}^d$ . Given a vector  $\alpha = (k_1, \dots, k_{nd})$ , where each  $k_i$  is an integer with  $0 \leq k_i \leq |P_i|$ , there exists an arrangement  $A$  of  $n$  oriented hyperplanes such that for each  $i \in \{1, \dots, nd\}$  we have  $|P_i \cap R^+(A)| = k_i$ .*

In [14], it was shown that the problem of computing an  $\alpha$ -Ham-Sandwich cut for point sets is in UEOPL. As our  $\alpha$ -Pizza cuts are just a union of  $\alpha$ -Ham-Sandwich cuts, their result generalizes to our setting.

► **Corollary 15.** *The problem of computing an  $\alpha$ -Pizza cut for point sets is in UEOPL.*

► **Remark 16.** The computation of the vector  $\alpha'$  does not directly translate into the setting of UEOPL. However, in [14], they start with an arbitrary hyperplane, and then rotate it in a well-defined fashion to the solution. This immediately translates to our setting: we just start with an arbitrary arrangement, and the choice of the direction of rotation works analogously to the choice in [14].

Further, Bereg [7] has shown that an  $\alpha$ -Ham-Sandwich cut for  $d$  point sets of  $m$  points total in  $\mathbb{R}^d$  can be computed in time  $m2^{O(d)}$ . In particular, if  $d$  is fixed, this algorithm runs in linear time. Again, we get the same result for  $\alpha$ -Pizza cuts.

► **Corollary 17.** *Let  $P_1, \dots, P_{nd}$  be well-separated points sets in  $\mathbb{R}^d$  with  $\sum_{i=1}^{nd} |P_i| = m$ . Then an  $\alpha$ -Pizza cut for  $P_1, \dots, P_{nd}$  can be computed in time  $m2^{O(d)}$ .*

**Proof.** Partition the point sets into parts  $P_{(i-1)d+1}, \dots, P_{id}$ , for  $i \in \{1, \dots, n\}$ . Compute the vector  $\alpha'$  in time  $O(nd)$ . As  $m \geq nd$ , the runtime of the second part dominates the total runtime. For each  $i \in \{1, \dots, n\}$ , use Bereg's algorithm to compute the  $\alpha$ -Ham-Sandwich cut for  $P_{(i-1)d+1}, \dots, P_{id}$ . It follows that the solution is an  $\alpha$ -Pizza cut. The runtime of the algorithm is

$$\sum_{i=1}^n (|P_{(i-1)d+1}| + \dots + |P_{id}|) 2^{O(d)} = \sum_{i=1}^{nd} |P_i| 2^{O(d)} = m 2^{O(d)}. \quad \blacktriangleleft$$

## 4 Containment results

In this section, we prove that DISCRETEPIZZACUTTING is in PPA. We do this by giving a new proof of the discrete planar pizza cutting theorem, which allows for an algorithm in PPA. Before we go into the details of the proof, we briefly sketch the main ideas. The main structure of our proof is similar to and inspired by the original proof of Hubard and Karasev [26], but we replace their topological arguments with easier ones that only use the combinatorics of point sets, but hence do not work for the more general case of mass distributions.

The main idea is that we continuously transform well-separated point sets into the point sets which we want to bisect. In the beginning of this process, we have several bisections, namely one for each partition of the labels of the point sets into pairs, and this number is odd. During the process, we pull these bisecting arrangements along. Every time the orientation of some triple of points changes, it can happen that one of the arrangements is not bisecting anymore. The main step in the proof is, that in these cases, we can always slightly change this arrangement so that it is again bisecting, or that there is a second arrangement that also is not bisecting anymore. In other words, some bisections might vanish during the process, but if they do, then they always vanish in pairs. This step is also where our proof differs from the one by Hubard and Karasev.

Once we have this, the remainder of the proof is rather simple: as we started with an odd number of bisections, and they always vanish in pairs, the number of bisections is always odd, and thus in particular at least 1. Further, we can build a graph where each vertex corresponds to a point set in our process with an arrangement, where the vertices are connected whenever one arrangement is the pulled along version of the other one, or when both point sets are the same and the arrangements are the two arrangements that vanish at this point of the process. (In the end, some of these connections will be paths instead of single edges.) Adding an additional vertex which we connect to all starting arrangements, we get a graph in which the only odd-degree vertices are this additional vertex and the final solutions.

### 4.1 A proof of the discrete planar pizza cutting theorem

We now proceed to give a detailed proof of the discrete planar pizza cutting theorem (Corollary 5). Let  $P_1, \dots, P_{2n}$  be the point sets we wish to bisect. Let further  $m := \sum_{i=1}^{2n} |P_i|$ .

► **Lemma 18.** *We may assume that each  $P_i$  contains an odd number of points.*

**Proof.** For each point set  $P_i$  with an even number of points, add some arbitrary new point  $q_i$  to  $P_i$ , such that the point sets are still in general position. Take some bisecting arrangement  $A$  of the resulting point sets. As all of these point sets consist of an odd number of points in general position, each of them must contain a point  $p_i$  which lies on a line of  $A$ . As each line in  $A$  can pass through at most two points by the general position assumption, there is exactly one such point in each point set. Now, remove  $q_i$  again. If  $p_i = q_i$ , the arrangement still bisects  $P_i$ . Otherwise, one side, without loss of generality  $R^+$ , contains one point too few. Rotate the line through  $p_i$  slightly so that  $p_i$  lies in  $R^+$ . Now the arrangement again bisects  $P_i$ . ◀

So, from now on we may assume that each  $P_i$  contains an odd number of points. Let  $Q_1, \dots, Q_{2n}$  be point sets of the same size, that is,  $|Q_i| = |P_i|$ , that are well-separated. Match each point  $q \in Q_i$  with a point  $p \in P_i$  and consider for each such pair the map  $\varphi(t) := tp + (1-t)q$ . These maps define a map  $\Phi(t)$ , which assigns to each  $t$  the point set defined by the  $\varphi(t)$ 's.

During this process, some orientations of triples of points change. We may assume, that no two triples change their orientation at the same time. Further, as each point crosses each line spanned by two other points at most once, the total number of orientation changes is in  $O(m^3)$ . Thus, the interval  $[0, 1]$  is partitioned into  $O(m^3)$  subintervals, in each of which the orientations of all triples stay the same, that is, the *order type* is invariant. At the boundaries of these subintervals, some three points are collinear.

Taking a representative of each subinterval and the point sets at their boundaries, we thus get a sequence of point sets

$$Q_i = P_i^{(0)}, P_i^{(0.5)}, P_i^{(1)}, \dots, P_i^{(k)}, P_i^{(k.5)}, P_i^{(k+1)}, \dots, P_i^{(C)} = P_i,$$

where  $C \in O(m^3)$  is the number of orientation changes,  $P^{(k)} := \bigcup_{i=1}^{2n} P_i^{(k)}$  is a point set in general position, and  $P^{(k.5)} := \bigcup_{i=1}^{2n} P_i^{(k.5)}$  is a point set with exactly one collinear triple. We will mainly work with the sets  $P^{(k)}$ , the sets  $P^{(k.5)}$  are just used to make some arguments easier to understand.

As argued before, for each  $P^{(k)}$ , any bisecting arrangement  $A$  contains exactly one point  $p_i^{(k)}(A)$  of each  $P_i^{(k)}$  on one of its lines. In particular,  $A$  is defined by a set of pairs of points  $(p_i^{(k)}(A), p_j^{(k)}(A))$ , where each pair defines one line of the arrangement.

► **Lemma 19.** *For  $P^{(0)}$ , the number of bisecting arrangements is odd.*

**Proof.** It is known that for 2 separated point sets, each of odd size, there is a unique Ham-Sandwich cut (see e.g. [43]). We have seen in the proof of Theorem 13, that for well-separated point sets, each bisecting arrangement corresponds to  $n$  Ham-Sandwich cuts, each for a pair of point sets. Thus, the number of bisecting arrangements is the same as the number of partitions of  $2n$  elements into pairs. This number is  $(2n - 1)!! = (2n - 1)(2n - 3) \cdots 3 \cdot 1$ , which is a product of odd numbers, and thus odd. ◀

Let us now follow some arrangement  $A$  through the process. More precisely, Let  $A^{(0)}$  be a bisecting arrangement for  $P^{(0)}$ , defined by pairs of points  $(p_i^{(0)}(A), p_j^{(0)}(A))$ . We now consider the sequence of arrangements  $A^{(k)}$ , where each  $A^{(k)}$  is defined by the corresponding pairs of points  $(p_i^{(k)}(A), p_j^{(k)}(A))$ . Clearly, if  $A^{(k)}$  is bisecting and the orientation change from  $P^{(k)}$  to  $P^{(k+1)}$  is not a point moving over a line in the arrangement  $A^{(k)}$ , then  $A^{(k+1)}$  is still bisecting. For the other changes, we need the following lemma. Here, we say that an arrangement  $A^{(k.5)}$  is *almost bisecting* for  $P^{(k.5)}$ , if it bisects each  $P_i^{(k.5)}$  except for one, for which two points are on a line of the arrangement, and for the remaining points one side contains exactly one point more.

► **Lemma 20.** *Let  $A^{(k)}$  and  $A^{(k+1)}$  be such that  $A^{(k)}$  is bisecting and  $A^{(k+1)}$  is not. Then there either exists a sequence of arrangements*

$$A^{(k)}, A^{(k.5)} = A_0^{(k.5)}, A_1^{(k.5)}, \dots, A_L^{(k.5)} = B^{(k.5)}, B^{(k+1)},$$

where each  $A_i^{(k.5)}$  is almost bisecting,  $B^{(k+1)}$  is bisecting and  $B^{(k)}$  is not bisecting, or there exists a sequence of arrangements

$$A^{(k)}, A^{(k.5)} = A_0^{(k.5)}, A_1^{(k.5)}, \dots, A_L^{(k.5)} = B^{(k.5)}, B^{(k)},$$

where each  $A_i^{(k.5)}$  is almost bisecting,  $B^{(k)}$  is bisecting and  $B^{(k+1)}$  is not bisecting. Further, in the second case, the sequence for  $B^{(k)}$  is the reverse of the sequence for  $A^{(k)}$ .

13:10 The Complexity of Sharing a Pizza

■ **Figure 3** Going from  $A^{(k.5)}$  (left) via  $B^{(k.5)}$  (middle) to  $B^{(k+1)}$  (right). In this example,  $B^{(k+1)}$  does not bisect the blue point set anymore.

In this lemma, the first case corresponds to a bisecting arrangement that can be changed to a new bisecting arrangement, whereas the second case corresponds to two bisecting arrangements disappearing at the same time.

**Proof.** As mentioned above, the situation of the lemma can only occur if the orientation change from  $P^{(k)}$  to  $P^{(k+1)}$  corresponds to a point  $q^{(k)}$  moving over a line  $\ell$  of the arrangement  $P^{(k)}$ . Without loss of generality, let  $\ell$  be defined by the points  $p_1^{(k)} \in P_1^{(k)}$  and  $p_2^{(k)} \in P_2^{(k)}$ . There are two cases we consider: either  $q^{(k)}$  is in the same point set as one of the points on  $\ell$ , without loss of generality  $q^{(k)} \in P_1^{(k)}$ , or it is in a different point set, without loss of generality  $q^{(k)} \in P_3^{(k)}$ . We start with the second case. For an illustration of that case, see Figure 3.

**Case 1:**  $q^{(k)} \in P_3^{(k)}$ . Orient the arrangement in such a way that  $q^{(k)}$  is in  $R^+(A^{(k)})$ . In  $A^{(k.5)}$  the line  $\ell$  contains three points, namely  $p_1^{(k)}$ ,  $p_2^{(k)}$  and  $q^{(k)}$ . Note that  $A^{(k.5)}$  is almost bisecting, and  $R^+(A^{(k.5)})$  is the smaller side for  $P_3^{(k.5)}$ . There exists another line  $\ell'$  in  $A^{(k.5)}$  which contains a second point  $p_3^{(k.5)}$  of  $P_3^{(k.5)}$ . Rotate  $\ell'$  around the other point on it such that  $p_3^{(k.5)}$  is in  $R^+(A^{(k.5)})$ . Note that this direction of rotation is unique. Continue the rotation until  $\ell'$  hits another point  $q_j^{(k.5)} \in P_j^{(k.5)}$  which is not on some line of  $A^{(k.5)}$ . The resulting arrangement is now  $A_1^{(k.5)}$ .

Note that  $A_1^{(k.5)}$  is again almost bisecting, and that the point set which is not exactly bisected is  $P_j^{(k.5)}$ . While  $j \notin \{1, 2, 3\}$ , we can now find another point in  $P_j^{(k.5)}$  lying on a line of the arrangement  $A_l^{(k.5)}$ , rotate this line into the correct direction until a new point is hit, to get a new arrangement  $A_{l+1}^{(k.5)}$ . As all of these arrangements are different, and there are only finitely many possible arrangements, at some point we will have  $j \in \{1, 2, 3\}$ . This gives the arrangement  $B^{(k.5)}$ . There are now several options to consider: there are 3 different ways how  $p_1^{(k)}$ ,  $p_2^{(k)}$  and  $q^{(k)}$  can lie on  $\ell$ ,  $j$  can be 1, 2 or 3, and the smaller side of  $P_j^{(k.5)}$  can be  $R^+(B^{(k.5)})$  or  $R^-(B^{(k.5)})$ . In all of the cases, the only change from the arrangements  $B^{(k)}$  to  $B^{(k+1)}$  are the defining points of  $\ell$ . It follows that exactly one of  $B^{(k)}$  and  $B^{(k+1)}$  can be bisecting, depending on whether the point on  $\ell$  is in  $R^+(B^{(k+1)})$  or not.

**Case 2:**  $q^{(k)} \in P_1^{(k)}$ . In this case, we just have  $A^{(k.5)} = B^{(k.5)}$ .

Finally, the last claim follows from the fact that the directions of rotations from  $A_l^{(k.5)}$  to  $A_{l+1}^{(k.5)}$  are unique. ◀

■ **Figure 4** A schematic drawing of the graph whose leaves correspond to bisecting arrangements.

► **Remark 21.** During the process, it can also happen that two bisecting arrangement appear at the same time. In this case, we immediately get the analogous lemma, just reversing  $k$  and  $(k + 1)$ .

With all these lemmas at hand, we can now finally give a

**Proof of the discrete planar pizza cutting theorem.** Let  $P = (P_1, \dots, P_{2n})$  be in general position. By Lemma 18, we may assume that each  $P_i$  contains an odd number of points. Consider the sequence  $P^{(0)}, P^{(1)}, \dots, P^{(C)} = P$  of point sets. By Lemma 19,  $P^{(0)}$  has an odd number of bisecting arrangements. When going from  $P^{(k)}$  to  $P^{(k+1)}$ , either all bisecting arrangements stay bisecting or, by Lemma 20, one of them can be changed into a new bisecting arrangement or exactly two bisecting arrangements appear or disappear. It follows that for each  $k$ ,  $P^{(k)}$  has an odd number of bisecting arrangements. In particular, also  $P$  has an odd number of bisecting arrangements, and thus at least 1. ◀

## 4.2 Containment in PPA

In order to show that DISCRETEPIZZACUTTING is in PPA, we need to define a graph where the neighborhoods of each vertex can be efficiently computed and all odd-degree vertices, except the starting vertex, correspond to bisecting arrangements. In the following, we describe such a graph. For an illustration of the graph, see Figure 4.

**The vertex set.** Our vertex set consists of a starting vertex  $s$ , as well as vertices of the form  $(P^{(k)}, A^{(k)})$  and  $(P^{(k.5)}, A^{(k.5)})$ . For vertices  $(P^{(k)}, A^{(k)})$ ,  $A^{(k)}$  is an arrangement which is not necessarily bisecting, but whose lines contain exactly one point of each  $P_i^{(k)}$ . Similarly, for vertices  $(P^{(k.5)}, A^{(k.5)})$ , the arrangement  $A^{(k.5)}$  is not necessarily almost bisecting, but its lines contain at least one point of each  $P_i^{(k.5)}$  and exactly 2 for one of them. In particular, one of the lines of  $A^{(k.5)}$  is the line  $\ell$  through the unique three collinear points.

**The edge set.** The starting vertex  $s$  is connected to all vertices  $(P^{(0)}, A^{(0)})$ , for which  $A^{(0)}$  is bisecting. A vertex of the form  $(P^{(k)}, A^{(k)})$ ,  $k < L$  is connected to the vertices  $(P^{((k-1).5)}, A^{((k-1).5)})$  and  $(P^{(k.5)}, A^{(k.5)})$  if and only if  $A^{(k)}$  is bisecting. Otherwise, it is not connected to any other vertex. Similarly, the vertices  $(P^{(C)}, A^{(C)})$  are connected

## 13:12 The Complexity of Sharing a Pizza

to  $(P^{((C-1)\cdot 5)}, A^{((C-1)\cdot 5)})$  if and only if  $A^{(C)}$  is bisecting, and not connected to anything otherwise. Also a vertex of the form  $(P^{(k\cdot 5)}, A^{(k\cdot 5)})$  where  $A^{(k\cdot 5)}$  is not almost bisecting is not connected to any other vertex. For vertices  $(P^{(k\cdot 5)}, A^{(k\cdot 5)})$  with  $A^{(k\cdot 5)}$  almost bisecting we distinguish two cases. If  $\ell$  does not contain a point of the point set which is contained twice in the lines of  $A^{(k\cdot 5)}$ , we connect  $(P^{(k\cdot 5)}, A^{(k\cdot 5)})$  to the two vertices which correspond to the rotations defined in the proof of Lemma 20. Otherwise, we connect  $(P^{(k\cdot 5)}, A^{(k\cdot 5)})$  to the single vertex that we get by such a rotation, as well as to either  $(P^{(k)}, A^{(k)})$  or  $(P^{(k+1)}, A^{(k+1)})$ , depending on which one has the bisecting arrangement (note that we get from Lemma 20 that exactly one of the two arrangements is bisecting).

Note that all vertices have degree 0 or 2, except  $s$  and the vertices  $(P^{(C)}, A^{(C)})$  with  $A^{(C)}$  bisecting, that is, the vertices corresponding to solutions. All the vertices corresponding to solutions have degree 1. The starting vertex has degree  $(2n - 1)!!$ , which is exponential, so we cannot compute its neighborhood in polynomial time. This is however not an issue, as already noted in the paper where PPA is defined [36], provided that we can decide for any two vertices in polynomial time whether they are connected, and there is an efficiently computable *pairing function*, that is, a function  $\phi(v, v')$  which takes as input a vertex  $v$  and an outgoing edge  $\{v, v'\}$  and computes another vertex  $v''$  such that  $\{v, v''\}$  is also an edge. If  $v$  has even degree, then  $\phi(v, v') \neq v'$  for all  $v'$ . If  $v$  has odd degree, then there is exactly one  $v'$  for which  $\phi(v, v') = v'$ . The exact statement from [36] is as follows:

► **Lemma 22** ([36]). *Any problem defined in terms of an edge recognition algorithm and a pairing function is in PPA.*

It remains to show that we have both these ingredients.

► **Lemma 23.** *For any two vertices, we can decide in polynomial time whether they are connected.*

**Proof.** It follows from the construction that for any vertex except the starting vertex  $s$ , the neighborhood can be computed in polynomial time. In particular, it can also be checked whether two such vertices are connected. As for the starting vertex  $s$ , some other vertex can only be connected to it if its point set is  $P^{(0)}$  and its arrangement is bisecting. The first is encoded in the label of the vertex and the second can easily be checked in polynomial time. ◀

► **Lemma 24.** *There is a pairing function  $\phi$  which can be computed in polynomial time.*

**Proof.** As all vertices except  $s$  have degree 0, 1 or 2, and the neighborhoods can be computed in polynomial time, the pairing function follows trivially for these vertices. As for  $s$ , we note that its neighbors correspond to partitions of the  $2n$  point sets into pairs. In other words, its neighbors can be interpreted as perfect matchings in the complete graph  $K_{2n}$  with vertex set  $\{w_1, \dots, w_{2n}\}$ . It is thus enough to describe a pairing function for these perfect matchings. We do this in an algorithmic fashion.

Let  $M$  be some perfect matching. Consider the vertices  $w_1$  and  $w_2$ . Assume first that they are not connected to each other, that is, we have two distinct edges  $\{w_1, w_a\}$  and  $\{w_2, w_b\}$  in  $M$ . In that case, define the pairing  $M' := M \setminus \{\{w_1, w_a\}, \{w_2, w_b\}\} \cup \{\{w_1, w_b\}, \{w_2, w_a\}\}$ , that is, flip the edges incident to  $w_1$  and  $w_2$ . Note that the pairing of  $M'$  is again  $M$ , that is, it indeed is a pairing.

If  $w_1$  and  $w_2$  are connected to each other, repeat the same process with  $w_3$  and  $w_4$ , and so on. This process defines a pairing for each matching except  $\{\{w_1, w_2\}, \dots, \{w_{2n-1}, w_{2n}\}\}$ . Further, the algorithm clearly runs in polynomial time. We thus get a valid pairing function. ◀

We thus get from Lemma 22 that DISCRETEPIZZACUTTING is in PPA. Together with Corollary 10, we can thus conclude our main result.

► **Corollary 25.** *DISCRETEPIZZACUTTING is PPA-complete.*

## 5 Conclusion

We have shown several complexity results related to the pizza cutting problem. Our main result is that DISCRETEPIZZACUTTING is PPA-complete. While we have only considered the planar case, the problem as well as our arguments extend to higher dimensions. More precisely, the proof of the Hobby-Rice theorem using the pizza cutting theorem can be adapted to work for any dimension of the pizza cutting theorem. Further, the proof of the discrete pizza cutting theorem can be adapted to any dimension where the number of initial solutions is odd. This is the case if the dimension is a power of 2 [26]. Thus, in all these dimensions the analogous versions of DISCRETEPIZZACUTTING are also PPA-complete, assuming the dimension is fixed. On the other hand, it is an open problem whether the pizza cutting theorem also holds in other dimensions.

We have also shown that PIZZACUTTING is FIXP-hard. It is an interesting problem whether the problem is in FIXP or even harder. One way to show that the problem is in FIXP is to find a proof for the planar pizza cutting theorem using Brouwer’s fixpoint theorem. Such a proof would have the potential to generalize to any dimension, resolving the above question.

# Dynamic Data Structures for $k$ -Nearest Neighbor Queries

Sarita de Berg 

Department of Information and Computing Sciences, Utrecht University, The Netherlands

Frank Staals 

Department of Information and Computing Sciences, Utrecht University, The Netherlands

---

## Abstract

Our aim is to develop dynamic data structures that support  $k$ -nearest neighbors ( $k$ -NN) queries for a set of  $n$  point sites in  $O(f(n) + k)$  time, where  $f(n)$  is some polylogarithmic function of  $n$ . The key component is a general query algorithm that allows us to find the  $k$ -NN spread over  $t$  substructures simultaneously, thus reducing a  $O(tk)$  term in the query time to  $O(k)$ . Combining this technique with the logarithmic method allows us to turn any static  $k$ -NN data structure into a data structure supporting both efficient insertions and queries. For the fully dynamic case, this technique allows us to recover the deterministic, worst-case,  $O(\log^2 n / \log \log n + k)$  query time for the Euclidean distance claimed before, while preserving the polylogarithmic update times. We adapt this data structure to also support fully dynamic *geodesic*  $k$ -NN queries among a set of sites in a simple polygon. For this purpose, we design a shallow cutting based, deletion-only  $k$ -NN data structure. More generally, we obtain a dynamic  $k$ -NN data structure for any type of distance functions for which we can build vertical shallow cuttings. We apply all of our methods in the plane for the Euclidean distance, the geodesic distance, and general, constant-complexity, algebraic distance functions.

## 1 Introduction

In the  $k$ -nearest neighbors ( $k$ -NN) problem we are given a set of  $n$  point sites  $S$  in some domain, and we wish to preprocess these points such that given a query point  $q$  and an integer  $k$ , we can find the  $k$  sites in  $S$  “closest” to  $q$  efficiently. This static problem has been studied in many different settings [4, 5, 10, 18, 19]. We study the dynamic version of the  $k$ -nearest neighbors problem, in which the set of sites  $S$  may be subject to updates; i.e. insertions and deletions. We are particularly interested in two settings: (i) a setting in which the domain containing the sites contains (polygonal) obstacles, and in which we measure the distance between two points by their geodesic distance: the length of the shortest obstacle avoiding path, and (ii) a setting in which only insertions into  $S$  are allowed (i.e. no deletions).

In many applications involving distances and shortest paths, the entities involved cannot travel towards their destination in a straight line. For example, a person in a city center may want to find the  $k$  closest restaurants that currently have seats available, but since he or she cannot walk through walls, this should be reflected by the distances. This introduces complications, as a shortest path in a polygon with  $m$  vertices may have complexity  $\Theta(m)$ . We wish to limit the resulting dependency on  $m$  in the space and time bounds as much as possible. In particular, we wish to avoid spending  $\Omega(m)$  time every time the availability of the seats in a restaurant changes (which may cause an insertion or deletion of a site in  $S$ ).

The second setting is motivated by classification problems. In  $k$ -nearest neighbor classifiers the sites in  $S$  all have a label, and the label of a query point  $q$  is predicted based on the labels of the  $k$  sites nearest to  $q$  [11]. When this label turns out to be sufficiently accurate, it is customary to then extend the data set by adding  $q$  to  $S$ . This naturally gives an interest in insertion-only data structures that can efficiently answer  $k$ -NN queries.

**The static problem.** If the set of sites is static, and  $k$  is known a-priori, one option is to build the (geodesic)  $k^{\text{th}}$ -order Voronoi diagram of  $S$  [20]. This yields very fast ( $O(\log(n+m) + k)$ ) query times. However it is costly in space, as even in a simple polygon the diagram has size  $O(k(n-k) + km)$ . For the Euclidean plane, much more space efficient solutions have been developed. There is an optimal linear space data structure achieving  $O(\log n + k)$  query time after  $O(n \log n)$  deterministic preprocessing time [1, 10]. Very recently, Liu [19] showed how to achieve the same query time for general constant-complexity distance functions for sites in  $\mathbb{R}^2$ , using  $O(n \log \log n)$  space and roughly  $O(n \log^4 n)$  expected preprocessing time (the exact bound depends on the algebraic degree of the functions). In case the domain is a simple polygon  $\mathcal{P}$ , the problem has not explicitly been studied. The only known solution using less space than just storing the  $k^{\text{th}}$ -order Voronoi diagram is the dynamic 1-NN structure of Agarwal et al. [2]. It uses  $O(n \log^3 n \log m + m)$  space, and answers queries in  $O(k \text{polylog}(n+m))$  time (by deleting and reinserting the  $k$ -closest sites to answer a query).

**Issues when inserting sites.** Since nearest neighbor searching is decomposable, we can apply the logarithmic method [23] to turn a static  $k$ -NN searching data structure into an insertion-only data structure. In the Euclidean plane this yields a linear space data structure with  $O(\log^2 n)$  insertion time. However, since this partitions the set of sites into  $O(\log n)$  subsets, and we do not know how many of the  $k$ -nearest sites appear in each subset, we may have to consider up to  $k$  sites from *each* of the subsets. This yields an  $O(k \log n)$  term in the query time. We will present a general technique that allows us to avoid this  $O(\log n)$  factor.

**Fully dynamic data structures.** In case we wish to support both insertions and deletions, the problem becomes more complicated, and the existing solutions much more involved. When we need to report only one nearest neighbor (i.e. 1-NN searching) in the plane, efficient fully dynamic data structures exist [6, 8, 16]. Actually, all these data structures are variants of the same data structure by Chan [6]. For the Euclidean distance, the current best result uses linear space, and achieves  $O(\log^2 n)$  worst-case query time,  $O(\log^2 n)$  insertion time, and  $O(\log^4 n)$  deletion time [8]. These results are deterministic, and the update times are amortized. The variant by Kaplan et al. [16] achieves similar results for general distance functions. These data structures can also be used to answer  $k$ -NN queries, but when used in this way essentially suffer from the same problem as in the insertion-only case. That is, we get a query time of  $O(\log^2 n + k \log n)$  time [6].

Chan argues that the above data structure for Euclidean 1-NN searching can be extended to answer  $k$ -NN queries in  $O(\log^2 n / \log \log n + k)$  time, while retaining polylogarithmic updates [7]. Chan's data structure essentially maintains a collection of  $k$ -NN data structures built on subsets of the sites. A careful analysis shows that some of these structures can be rebuilt during updates, and that the cost of these updates is not too large. Queries are then answered by performing  $k_i$ -NN queries on several disjoint subsets of sites  $S_1, \dots, S_t$  that together are guaranteed to contain the  $k$  nearest sites. However – perhaps because the details of the 1-NN searching data structure are already fairly involved – one aspect in the query

algorithm is missing: how to determine the value  $k_i$  to query subset  $S_i$  with. While it seems that this issue can be fixed using randomization [9]<sup>1</sup>, our general  $k$ -NN query technique (Section 3) allows us to recover deterministic, worst-case  $O(\log^2 n / \log \log n + k)$  query time.

Very recently, Liu [19] stated that one can obtain  $O(\log^2 n + k)$  query time while supporting  $O(\text{polylog } n)$  expected amortized updates also for general distance functions by using the data structure of Kaplan et al. [16]. However, it is unclear why that would be the case, as all details are missing. Using the Kaplan et al. data structure as is yields an  $O(k \log n)$  term in the query time as with Chan’s original version [6]. If the idea is to also apply the ideas from Chan’s later paper [7] the same issue of choosing the  $k_i$ ’s appears. Similarly, extending the geodesic 1-NN data structure [2] to  $k$ -NN queries yields  $O(k \text{ polylog}(n + m))$  query time.

**Organization and Results.** We develop dynamic data structures for  $k$ -NN queries whose query time are of the form  $O(f(n) + k)$ , where  $f(n)$  is some function of  $n$ . In particular, we wish to avoid an  $O(k \log n)$  term in the query time. To this end, we present a general query technique that given  $t$  disjoint subsets of sites  $S_1, \dots, S_t$ , each stored in a static data structure that supports  $k'$ -NN queries in  $O(Q(n) + k')$  time, can report the  $k$  nearest neighbors among  $\bigcup_{i=1}^t S_i$  in  $O(Q(n)t + k)$  time. Our technique, presented in Section 3, is completely combinatorial, and is applicable to any type of sites. In Section 4, we then use this technique to obtain a  $k$ -NN data structure that supports queries in  $O(Q(n) \log n + k)$  time and insertions in  $O((P(n)/n) \log n)$  time, where  $P(n)$  is the time required to build the static data structure. In the specific case of the Euclidean plane, we obtain a linear space data structure with  $O(\log^2 n + k)$  query time and  $O(\log^2 n)$  insertion time. At a slight increase of insertion time we can also match the query time of Chan’s [7] fully dynamic data structure. For general, constant-complexity, algebraic distance functions, we obtain the same query and insertion times (albeit the insertion time holds in expectation). In the case where the sites  $S$  are points inside a simple polygon  $\mathcal{P}$  with  $m$  vertices, we use our technique to obtain the first *static*  $k$ -NN data structure that uses near-linear space, supports efficient (i.e. without the  $O(k \log n)$  term) queries, *and* can be constructed efficiently. We do get an  $O(\log m)$  factor in the query time, as computing the distance between two sites already takes  $O(\log m)$  time. Our data structure uses  $O(n \log n + m)$  space, can be constructed in  $O(n(\log n \log^2 m + \log^3 m) + m)$  time, and supports  $O((\log(n + m) + k) \log m)$  time queries. In turn, this then leads to a data structure supporting efficient insertions. In Section 5, we argue that our general query algorithm is the final piece of the puzzle for the fully dynamic case. For the Euclidean plane, this allows us to recover the deterministic, worst-case  $O(\log^2 n / \log \log n + k)$  query time claimed before [7, 19]. The amortized update times remain polylogarithmic. We obtain the same query time and similar update times for more general distance functions.

For the geodesic case there is one final hurdle. Chan’s algorithm uses partition-tree based “slow” dynamic  $k$ -NN data structure of linear size in its subroutines. Liu uses a similar trick after linearizing the distance functions into  $\mathbb{R}^c$ , for some constant  $c$  [19]. Unfortunately, these ideas are not applicable in the geodesic setting, as it is unknown if an appropriate partition tree can be built, and the dimension after linearization would depend on  $m$ . Instead, we design a simple, shallow-cutting based, alternative “slow” dynamic (geodesic)  $k$ -NN data structure. This way, we obtain an efficient (i.e.  $O(\text{polylog}(n + m))$  expected updates,  $O(\log^2 n \log^2 m + k \log m)$  queries) fully dynamic  $k$ -NN data structure. Omitted proofs are in the full version of this paper [12].

<sup>1</sup> The main idea is that the data structure as is *can* be used to efficiently report all sites within a fixed distance from the query point (reporting all planes below a query point in  $\mathbb{R}^3$ ). Combining this with an earlier random sampling idea [5] one can then also answer  $k$ -NN queries.

■ **Figure 1** A 2-shallow cutting of a set of lines  $F$  in  $\mathbb{R}^2$  consisting of 3 prisms. The at most  $k$ -level  $L_{\leq k}(F)$  is shown in green for  $k = 0, 1, 2$ .

■ **Figure 2** Example of the dynamic 1-NN data structure. Only one shallow cutting ( $\Lambda_{k_j}$ ) is shown for each tower. The orange planes in  $\mathcal{T}_1$  and  $\mathcal{T}_2$  are pruned when building  $\Lambda_{k_{j-1}}$ , but are not removed from the conflict lists in  $\Lambda_{k_j}$ . When querying for the  $k$ -NN, the green prisms in  $\Lambda_{k_j}$  of each tower are considered. Note that the three orange planes occur in each of the conflict lists.

## 2 Preliminaries

We can easily transform a  $k$ -nearest neighbors problem in  $\mathbb{R}^2$  to a  $k$ -lowest functions problem in  $\mathbb{R}^3$  by considering (the graphs of) the distance functions  $f_s(x)$  of the sites  $s \in S$ . We discuss these problems interchangeably, furthermore we identify a function with its graph.

### 2.1 Shallow cuttings

Let  $F$  be a set of bivariate functions. We consider the arrangement of  $F$  in  $\mathbb{R}^3$ . The *level* of a point  $q \in \mathbb{R}^3$  is defined as the number of functions in  $F$  that pass strictly below  $q$ . The *at most  $k$ -level*  $L_{\leq k}(F)$  is then the set of points in  $\mathbb{R}^3$  that have level at most  $k$ .

A  *$k$ -shallow cutting*  $\Lambda_k(F)$  of  $F$  is a set of disjoint cells covering  $L_{\leq k}(F)$ , such that each cell intersects at most  $O(k)$  functions [21]. When  $F$  is clear from the context we may write  $\Lambda_k$  rather than  $\Lambda_k(F)$ . We are interested only in the case where the cells are (*pseudo-*)*prisms*: constant-complexity regions that are bounded from above by a function, from the sides by vertical (with respect to the  $z$ -direction) planes, and unbounded from below. For example, if  $F$  is a set of planes, we can define the top of each prism to be a triangle. This allows us to find the prism containing a query point  $q$  by a point location query in the downward projection of the cutting. See Figure 1. The subset  $F_{\nabla} \subseteq F$  intersecting a prism  $\nabla$  is the *conflict list* of  $\nabla$ . When, for every subset  $F' \subseteq F$ , the lower envelope  $L_0(F')$  has linear complexity (for example, in the case of planes), a shallow cutting of *size* (the number of cells)  $O(n/k)$  can be computed efficiently [19]. In general, let  $T(n, k)$  be the time to construct a  $k$ -shallow cutting of size  $S(n, k)$  on  $n$  functions, and  $Q(n, k)$  be the time to locate the prism containing a query point. We assume these functions are non-decreasing in  $n$  and non-increasing in  $k$ , and that  $S(n, k) = \frac{n}{k} f(n)$ , for some function  $f(n)$ .

### 2.2 A dynamic nearest neighbor data structure

We briefly discuss the main ideas used in the existing dynamic 1-NN data structures [6, 8, 16], as these also form a key component in our fully dynamic  $k$ -NN data structures. For ease of exposition, we describe the data structure when  $F$  is a set of linear functions (planes). To ensure the analysis is correct for our definition of  $n$  (the current number of sites in  $S$ ), we rebuild the data structure from scratch whenever  $n$  has doubled or halved. The cost of this is subsumed in the cost of the other operations [6].

The data structure consists of  $t = O(\log_b n)$  “towers”  $\mathcal{T}^{(1)}, \dots, \mathcal{T}^{(t)}$ . Each tower  $\mathcal{T}^{(i)}$  consists of a hierarchy of shallow cuttings that is built on a subset of planes  $F^{(i)} \subseteq F$ . For  $\mathcal{T}^{(1)}$  we have  $F^{(1)} = F$ , and a sequence of  $\ell = \lfloor \log(n/k_0) \rfloor$  shallow cuttings, for a fixed constant  $k_0$ . For  $j = 0, \dots, \ell$  we have a  $k_j$ -shallow cutting of a subset of the planes  $F_j \subseteq F^{(1)}$ , where  $k_j = 2^j k_0$ . We set  $F_\ell = F^{(1)}$  and construct these cuttings from  $j = \ell$  to 0. After computing  $\Lambda_{k_j}(F_j)$ , we find the set  $F_j^\times$  of “bad” planes that intersect more than  $c \log n$  prisms in all cuttings computed so far. We *prune* these planes by setting  $F_{j-1} = F_j \setminus F_j^\times$  and removing all planes in  $F_j^\times$  from the conflict lists of the prisms in  $\Lambda_{k_j}(F_j)$ . These bad planes are removed only from the conflict lists of the current cutting, and can still occur in conflict lists of higher level cuttings. In the final  $\Lambda_{k_0}(F_0)$  cutting, each conflict list has a constant size of  $O(k_0)$ . By  $F_{\text{live}}^{(1)}$  we denote the set of planes that have not been pruned during this process. We then set  $F^{(i+1)} = F^{(i)} \setminus F_{\text{live}}^{(i)}$ , and recursively build  $\mathcal{T}^{(i+1)}$  on the functions in  $F^{(i+1)}$ . This partitions  $F$  into sets  $F_{\text{live}}^{(1)}, \dots, F_{\text{live}}^{(t)}$ . Chan [8] recently achieved an overall construction time of  $O(n \log n)$ , by using information of previously computed cuttings to efficiently build the cuttings later in the sequence. Kaplan et al. [16, Lemma 7.1] prove that for any  $\zeta \in (0, 1)$  choosing  $c \geq \frac{2}{\zeta}$ , for a sufficiently large (but constant)  $\gamma$ , ensures that  $|F_{\text{live}}^{(1)}| \geq (1 - \zeta)n$  after building  $\mathcal{T}^{(1)}$ . When  $\zeta = 1/b$ , we get  $O(\log_b n)$  towers, for some fixed  $b \geq 2$  as desired. A plane then occurs  $O(b \log n)$  times in a tower.

**Updates.** When updates take place, planes can move from a set  $F_{\text{live}}^{(i)}$  to some  $F_{\text{live}}^{(i')}$ , but the live sets remain a partition of  $F$ . To insert a plane  $f$  into  $F$ , we create a new tower containing only  $f$ . When  $|F^{(i+1)} \cup \dots \cup F^{(t)}|$  reaches  $3/4 \cdot |F^{(i)}|$  we rebuild the towers  $\mathcal{T}^{(i)}, \dots, \mathcal{T}^{(t)}$ . Such a rebuild occurs only after  $\Omega(|F^{(i)}|)$  insertions, so the amortized insertion time is  $O(\log^2 n)$ .

Deletions are not performed explicitly on the conflict lists. Instead, for each prism  $\nabla$  we keep track of the number of planes in  $F_\nabla$  that have been deleted so far, denoted by  $d_\nabla$ . When deleting a plane  $f$ , we increase  $d_\nabla$  for all prisms with  $f \in F_\nabla$ , and remove  $f$  from the set  $F_{\text{live}}^{(i)}$  that includes  $f$ . When too many planes in a conflict list have been deleted (i.e.  $d_\nabla$  becomes too large), we *purge* the prism. When a prism in  $\mathcal{T}^{(i)}$  is purged, we mark it as such, and we reinsert all planes  $f' \in F_\nabla \cap F_{\text{live}}^{(i)}$ . These planes are effectively moved from  $F_{\text{live}}^{(i)}$  to some other  $F_{\text{live}}^{(i')}$ . Chan [8] shows that each increment of  $d_\nabla$  causes amortized  $O(1)$  reinsertions. This gives an amortized deletion time of  $O(\log^4 n)$ .

**Queries.** We can answer  $k$ -NN queries in  $O(\log^2 n + k \log_b n)$  time, and thus 1-NN queries in  $O(\log^2 n)$  time, as follows. For each tower we consider the prism containing  $q$  in the shallow cutting at level  $j_k := \lceil \log(Ck/n) \rceil$ , for some large enough constant  $C$ . Each such prism has a conflict list of size  $O(k)$ , and thus we can find the  $k$ -lowest *live* planes in each conflict list in  $O(k)$  time. Chan [6] proves that considering only these planes is sufficient.

Liu [19] recently claimed the data structure, in particular the version of Kaplan et al. [16], supports  $k$ -NN queries in  $O(\log^2 n + k)$  time. However, we see an issue with this approach. When a plane is pruned during the preprocessing, or when a prism is purged, the plane is only removed from the conflict lists of the current shallow cutting. It can thus still occur in other shallow cuttings in the hierarchy. This means that we can encounter the same plane multiple times when querying each tower for the  $k$ -lowest planes. See Figure 2 for an illustration. As there are  $O(\log_b n)$  towers, this yields an  $O(k \log_b n)$  term in the query time.

**General distance functions.** Kaplan et al. [16] showed that this data structure is applicable for any set of functions  $F$  for which we can compute small  $k$ -shallow cuttings. The following lemma summarizes the properties of the data structure in this setting.

■ **Figure 3** Example of expansion. Blue elements are included in a clan, orange elements are not. The expansion (building the next subheap) occurs when all elements have been included in a clan.

► **Lemma 1.** Let  $b \geq 2$  be any fixed value, and  $S(n, k)$  be the size of a  $k$ -shallow cutting of  $F$ . There is a dynamic nearest neighbor data structure that has the following properties.

1. The data structure consists of  $O(\log_b n)$  towers.
2. A function occurs  $O(b \log n \cdot S(n, 1)/n)$  times in a conflict list in a single tower.
3. The insertion time is  $O(b \log_b n \cdot P(n)/n)$ , where  $P(n)$  is the preprocessing time.
4. A deletion causes amortized  $O(b \log_b n \log n \cdot S(n, 1)/n)$  reinsertions.
5. To find the  $k$ -NN of a query point  $q$  it is sufficient to consider the prisms containing  $q$  of the shallow cuttings at level  $j_k := \lceil \log(Ck/n) \rceil$ , for some large enough constant  $C$ .

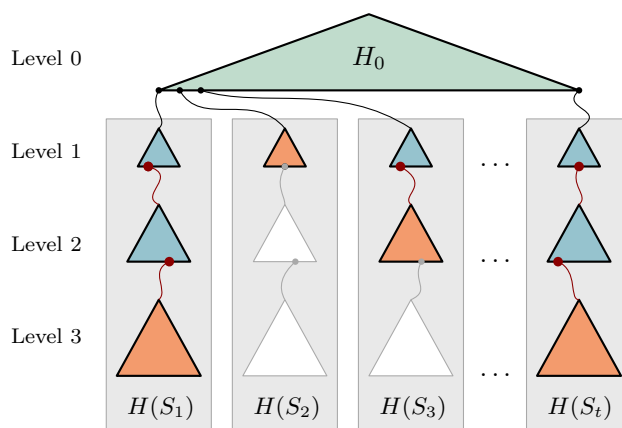

### 3 Querying multiple $k$ -NN data structures simultaneously

We introduce a method to find the  $k$ -nearest neighbors of a query point  $q$  among  $t$  (disjoint)  $k'$ -NN data structures together storing a set of sites  $S$ . Suppose the query time of such a  $k'$ -NN data structure is  $O(Q(n) + k')$ , for a non-decreasing function  $Q$ . Naively, querying each data structure for the  $k$  closest sites would take  $O(Q(n)t + kt)$  time. Our method allows us to find the  $k$ -NN over all these data structures in  $O(Q(n)t + k)$  time instead.

**Query algorithm.** We use the heap selection algorithm of Frederickson [13] to answer  $k$ -NN queries efficiently. This algorithm finds the  $k$  smallest elements of a binary min-heap of size  $N \gg k$  in  $O(k)$  time by forming groups of elements, called *clans*, in the original heap. Representatives of these clans are then added to another heap, and smaller clans are created from larger clans and organised in heaps recursively. For our purposes, we need to consider (only) how clans are formed in the original heap, because we do not construct the entire heap beforehand. Instead, the heap is expanded during the query only when necessary. See Figure 3 for an example. Note that any (non-root) element of the heap will only be included in a clan by the Frederickson algorithm after its parent has been included in a clan.

The heap  $H$ , on which we call the heap selection algorithm, contains all sites  $s \in S$  exactly once, with the distance  $d(s, q)$  as key for each site. Let  $S_1, \dots, S_t$  be the partition of  $S$  into  $t$  disjoint sets, where  $S_i$  is the set of sites stored in the  $i$ -th  $k'$ -NN data structure. For each set of sites  $S_j$ ,  $j \in 1, \dots, t$ , we define a heap  $H(S_j)$  containing all sites in  $S_j$ . We then “connect” these  $t$  heaps by building a dummy heap  $H_0$  of size  $O(t)$  that has the roots of all  $H(S_j)$  as leaves. We set the keys of the elements of  $H_0$  to  $-\infty$ . Let  $H$  be the complete data structure that we obtain this way, see Figure 4. We can now compute the  $k$  sites closest to  $q$  by finding the  $|H_0| + k$  smallest elements in  $H$  and reporting the non-dummy sites.

What remains is how to (incrementally) build the heaps  $H(S_j)$  while running the heap selection algorithm. Each such heap consists of a hierarchy of *subheaps*  $H_1(S_j), \dots, H_{O(\log n)}(S_j)$ , such that every element of  $S_j$  appears in exactly one  $H_i(S_j)$ . Moreover, since the sets  $S_1, \dots, S_j$  are pairwise disjoint, any site  $s \in S$  will appear in exactly one  $H_i(S_j)$ . The *level 1* heaps,  $H_1(S_j)$ , consist of the  $k_1 = Q(n)$  sites in  $S_j$  closest to  $q$ , which we find by querying the static  $k'$ -NN data structure on  $S_j$ . The subheap  $H_i(S_j)$  at level  $i > 1$  is built only

■ **Figure 4** The heap constructed for a  $k$ -NN query. Subheaps of which all elements have been included in a clan are *blue*. Subheaps of which not all elements have been included are *orange*. The *white* subheaps have not been built so far, as not all elements of their predecessor are in a clan yet.

after the last element  $e$  of  $H_{i-1}(S_j)$  is included in a clan. We then add a pointer from  $e$  to the root of  $H_i(S_j)$ , such that the root of  $H_i(S_j)$  becomes a child of  $e$ , as in Figure 3. To construct a subheap  $H_i(S_j)$  at level  $i > 1$ , we query the static data structure of  $S_j$  using  $k_i = k_1 2^{i-1}$ . The new subheap is built using all sites returned by the query that have not been encountered earlier. This ensures that the heap property is preserved.

**Analysis of the query time.** As stated before, finding the  $k$ -smallest non-dummy elements of  $H$  takes  $O(k + |H_0|)$  time [13]. Here, we analyse the time used to construct  $H$ .

First, the level 0 and level 1 heaps are built. Building  $H_0$  takes only  $O(t)$  time. To build the level 1 heaps, we query each of the substructures using  $k_1 = Q(n)$ . In total these queries take  $O((Q(n) + k_1)t) = O(Q(n)t)$  time. Retrieving the next  $k_i$  elements to build  $H_i(S_j)$  for  $i > 1$  requires a single query and thus takes  $O(Q(n) + k_i)$  time. To bound the time used to build all heaps at level greater than 1, we use the following lemma.

► **Lemma 2.** *The size of a subheap  $H_i(S_j)$ ,  $j \in \{1, \dots, t\}$ , at level  $i > 1$  is exactly  $k_1 2^{i-2}$ .*

To pay for building  $H_i(S_j)$ , we charge  $O(1)$  to each element of  $H_{i-1}(S_j)$ . Because we choose  $k_1 = Q(n)$ , Lemma 2 implies that  $|H_{i-1}(S_j)| = \Omega(Q(n))$ , and that  $k_i = k_1 2^{i-1} = 2^2 k_1 2^{i-3} = O(|H_{i-1}(S_j)|)$ . Note that the heap  $H_i(S_j)$ ,  $i > 1$ , is only built when all elements of  $H_{i-1}(S_j)$  have been included in a clan. Thus, we only charge elements of heaps of which all elements have been included in a clan (shown blue in Figure 4). In total,  $O(k)$  elements (not in  $H_0$ ) are included in a clan, so the total size of these subheaps is  $O(k)$ . From this, and the fact that all subheaps are disjoint, it follows that we charge  $O(1)$  to only  $O(k)$  sites.

► **Lemma 3.** *Let  $S_1, \dots, S_t$  be disjoint sets of point sites of sizes  $n_1, \dots, n_t$ , each stored in a data structure that supports  $k'$ -NN queries in  $O(Q(n_i) + k')$  time. There is a  $k$ -NN data structure on  $\bigcup_i S_i$  that supports queries in  $O(Q(n)t + k)$  time. The data structure uses  $O(\sum_i C(n_i))$  space, where  $C(n_i)$  is the space required by the  $k$ -NN structure on  $S_i$ .*

Throughout this section, we used the standard assumption that for any two points  $p, q$  their distance  $d(p, q)$  can be computed in constant time. When evaluating  $d(p, q)$  takes  $T$  time, our technique achieves a query time of  $O(Q(n)t + kT)$  by setting  $k_1 = Q(n)/T$  and charging  $O(T)$  to each site of  $H_{i-1}(S_j)$  to pay for building  $H_i(S_j)$ .

#### 4 An insertion-only data structure

We describe a method that transforms a static  $k$ -NN data structure with query time  $O(Q(n) + k)$  into an insertion-only  $k$ -NN data structure with query time  $O(Q(n) \log n + k)$ . Insertions take  $O((P(n)/n) \log n)$  time, where  $P(n)$  is the preprocessing time of the static data structure, and  $C(n)$  is its space usage. We assume  $Q(n)$ ,  $P(n)$ , and  $C(n)$  are non-decreasing.

To support insertions, we use the logarithmic method [23]. We partition the sites into  $O(\log n)$  groups  $S_1, \dots, S_{O(\log n)}$  with  $|S_i| = 2^i$  for  $i \in \{1, \dots, O(\log n)\}$ . To insert a site  $s$ , a new group containing only  $s$  is created. When there are two groups of size  $2^i$ , these are removed and a new group of size  $2^{i+1}$  is created. For each group we store the sites in the static  $k$ -NN data structure. This results in an amortized insertion time of  $O((P(n)/n) \log n)$ . This bound can also be made worst-case [23]. The main remaining issue is then how to support queries in  $O(Q(n) \log n + k)$  time, thus avoiding an  $O(k \log n)$  term in the query time. Applying Lemma 3 directly solves this problem, and we thus obtain the following result.

► **Theorem 4.** *Let  $S$  be a set of  $n$  point sites, and let  $\mathcal{D}$  be a static  $k$ -NN data structure of size  $O(C(n))$ , that can be built in  $O(P(n))$  time, and answer queries in  $O(Q(n) + k)$  time. There is a  $k$ -NN data structure on  $S$  of size  $O(C(n))$  that supports queries in  $O(Q(n) \log n + k)$  time, and insertions in  $O((P(n)/n) \log n)$  time.*

##### 4.1 Points in the plane

In the Euclidean metric,  $k$ -nearest neighbors queries in the plane can be answered in  $O(\log n + k)$  time, using  $O(n)$  space and  $O(n \log n)$  preprocessing time [1, 10]. Hence:

► **Corollary 5.** *There is an insertion-only data structure of size  $O(n)$  that stores a set of  $n$  sites in  $\mathbb{R}^2$ , allows for  $k$ -NNs queries in  $O(\log^2 n + k)$  time, and insertions in  $O(\log^2 n)$  time.*

If we increase the size of each group in the logarithmic method to  $b^i$ , with  $b = \log^\varepsilon n$  and  $\varepsilon > 0$ , we get only  $O(\log_b n)$  groups instead of  $O(\log n)$ . This reduces the query time to  $O(\log^2 n / \log \log n + k)$ , matching the fully dynamic data structure. However, this also increases the insertion time to  $O(\log^{2+\varepsilon} n / \log \log n)$ . For general constant-complexity distance functions, we achieve the same query time using Liu's data structure [19], using  $O(n \log \log n)$  space and expected  $O(\text{polylog } n)$  insertion time.

##### 4.2 Points in a simple polygon

Next, we consider  $k$ -NN queries on a set  $S$  of  $n$  point sites inside a simple polygon  $\mathcal{P}$  with  $m$  vertices. For any two points  $p$  and  $q$  the (geodesic) distance  $d(p, q)$  is defined as the length of the shortest path  $\pi(p, q)$  between  $p$  and  $q$  fully contained within  $\mathcal{P}$ . Using  $O(m)$  space and preprocessing time, we can store  $\mathcal{P}$  so that  $d(p, q)$  can be computed in  $O(\log m)$  time [15].

To apply Theorem 4, we need a static data structure for geodesic  $k$ -NN queries. As we sketch below, we can obtain such a data structure by combining the approach of Chan [5] and Agarwal et al. [2]. However, building this data structure takes  $O(nm)$  time. We show that using more ideas from Agarwal et al. [2], together with our algorithm from Section 3, we can obtain a static  $k$ -NN data structure that can also be built efficiently. This in turn leads to an efficient insertion-only data structure.

**A static data structure.** The initial data structure consists of a hierarchy of lower envelopes of random samples  $R_0 \subset R_1 \subset \dots \subset R_{\log n}$ . For each sample, we store a (topological) vertical decomposition of the downward projection of the lower envelope and the conflict lists of the

■ **Figure 5** A partial decomposition of  $\mathcal{P}$  and the corresponding heap used in a  $k$ -NN query for  $q$ .

■ **Figure 6** Approximation (in green) of the vertical decomposition of the Voronoi diagram of  $S_\ell$  in  $\mathcal{P}_r$ . To find the trapezoid containing  $q$ , we consider both colored trapezoids.

corresponding (pseudo-)prisms. We can then find a prism in one of the vertical decompositions that contains the query point and whose conflict list has size  $O(k)$  in  $O(\log(n+m) + k \log m)$  time [5, 22]. This allows us to answer  $k$ -NN queries in the same time. The crux in this approach is in how to compute the conflict lists. We can naively compute these in  $O(mn)$  time by explicitly constructing the geodesic distance function for each site [14], and intersecting it with each of the  $O(n)$  pseudo-prisms. It is unclear how to improve on this bound.

► **Theorem 6.** *Let  $S$  be a set of  $n$  sites in a simple polygon  $\mathcal{P}$  with  $m$  vertices. In  $O(n(\log n \log^2 m + \log^3 m))$  time we can build a data structure of size  $O(n \log n \log m)$ , excluding the size of the polygon, that can answer  $k$ -NN queries with respect to  $S$  in  $O(\log(n+m) \log m + k \log m)$  time.*

**Proof Sketch.** To circumvent the issue above, we recursively partition the polygon  $\mathcal{P}$  into two subpolygons  $\mathcal{P}_r$  and  $\mathcal{P}_\ell$  of roughly the same size by a diagonal  $d$  [2]. We denote by  $S_r$  and  $S_\ell$  the sites in  $\mathcal{P}_r$  and  $\mathcal{P}_\ell$ , respectively. Theorem 22 of [2] provides us with a data structure that can find the  $k$ -NN among sites in  $S_\ell$  for a query point in  $\mathcal{P}_r$ . This is essentially the data structure that was described above. However, because the Voronoi diagram of sites in  $S_\ell$  restricted to  $\mathcal{P}_r$  is a Hamiltonian abstract Voronoi diagram [17], we can efficiently compute the conflict lists by only considering the functions intersecting the corners of each prism. We improve the query time of this data structure to  $O(\log(n+m) + k \log m)$  by incorporating the idea of Oh and Ahn [22] to approximate a geodesic Voronoi diagram by a polygonal subdivision, see Figure 6. Storing the points of both  $S_\ell$  and  $S_r$  at each of the  $O(\log m)$  levels of the decomposition in this data structure, and using our technique from Section 3 to query the levels simultaneously, see Figure 5, results in the stated query time. ◀

► **Corollary 7.** *Let  $\mathcal{P}$  be a simple polygon with  $m$  vertices. There is a data structure of size  $O(n \log n \log m + m)$  that stores a set of  $n$  point sites in  $\mathcal{P}$ , allows for geodesic  $k$ -NN queries in  $O(\log(n + m) \log n \log m + k \log m)$  expected time, and inserting a site in  $O(\log^2 n \log^2 m + \log n \log^3 m)$  time.*

## 5 A fully dynamic data structure

In this section, we consider  $k$ -NN queries while supporting both insertions and deletions, building on the results of Chan [7]. We first fill in the part missing from Chan [7]’s query algorithm. We then discuss a simple deletion-only  $k$ -NN structure. This allows us to adapt Chan’s  $k$ -NN data structure to more general distance functions like the geodesic distance.

### 5.1 A dynamic data structure for planes

Chan [7] describes how to adjust his 1-NN data structure to efficiently perform  $k$ -NN queries. There are two main changes: the conflict lists are stored in  $k$ -NN data structures  $\mathcal{D}_0$ , and the number of towers is reduced by using  $b = \log^\varepsilon n$ . Only the *live* planes of the conflict list of each prism  $\nabla$  are stored in the  $\mathcal{D}_0$  data structures. Each such structure uses linear space, can perform  $k'$ -NN queries in  $O(Q_0(|F_\nabla|) + k')$  time and deletions in  $D_0(|F_\nabla|)$  time. A different data structure is used to store small and large conflict lists. After building  $\mathcal{T}^{(i)}$ , each data structure  $\mathcal{D}_0$  of a prism  $\nabla$  is built on  $F_\nabla \cap F_{\text{live}}^{(i)}$ . The total space usage is  $O(n \log n)$ .

The insertions remain unchanged, but deleting a plane  $h$  requires extra work. In addition to increasing  $d_\nabla$  for each prism containing  $h$ ,  $h$  is explicitly removed from the  $\mathcal{D}_0$  data structures. Note that  $\mathcal{T}^{(i)}$  for which  $h \in F_{\text{live}}^{(i)}$  is the only tower whose  $\mathcal{D}_0$  data structures contain  $h$ . When a prism in tower  $\mathcal{T}^{(i)}$  is purged, we also delete its planes from the other  $\mathcal{D}_0$  data structures in  $\mathcal{T}^{(i)}$  to retain this property. This gives an amortized expected update time of  $U(n) = O(\log^{6+\varepsilon} n)$  [7]. The improvement of Kaplan et al. [16] reduces this to  $O(\log^{5+\varepsilon} n)$ . It follows from Lemma 1 and the above modifications that:

► **Lemma 8** (Chan [7]). *Let  $q$  be a query point. In  $O(t \log n)$  time, we can find  $t = O(\log_b n)$  prisms  $\nabla_1, \dots, \nabla_t$ , such that: (i) all prisms contain  $q$ , (ii) the conflict list of each prism has size  $O(k)$ , (iii) the conflict lists are pairwise disjoint and stored in a  $\mathcal{D}_0$  data structure, and (iv) the  $k$  sites in  $S$  closest to  $q$  appear in the union of the conflict lists of those prisms.*

So, to answer  $k$ -NN queries we can use a  $k_i$ -NN query on each  $\mathcal{D}_0$  data structure of the prisms  $\nabla_1, \dots, \nabla_t$ , where  $k_i$  is the number of sites from the  $k$ -nearest neighbours of  $q$  that appear in the conflict list of  $\nabla_i$ . This takes  $O(\sum_{i=1}^t Q_0(k) + k_i) = O(\sum_{i=1}^t Q_0(k) + k)$  time. However, it is unclear how to compute those  $k_i$  values. Fortunately, we can use Lemma 3 to find the  $k$ -nearest neighbors over all of the substructures in  $O(Q_0(k) \log_b n + k)$  time. Plugging in the appropriate query time  $Q_0(k)$  (see Chan [7] and Section 5.3), this achieves a total query time of  $O(\log^2 n / \log \log n + k)$  time as claimed.

### 5.2 A simple deletion-only data structure

Let  $H$  be a set of  $n$  planes, and let  $r \in \mathbb{N}$  be a parameter. We develop a data structure that supports reporting the  $t$  lowest planes above a query point  $q \in \mathbb{R}^2$  in  $O(n/r + \log r + t)$  time, and deletions in  $O(r \log n)$  time. Our entire data structure consists of just  $\ell = O(\log r)$   $k_i$ -shallow cuttings  $\Lambda_{k_0}, \dots, \Lambda_{k_\ell}$  of the planes, where  $k_i = \lfloor 2^i(n/r) \rfloor$ . Hence, this uses  $O(n \log r)$  space. We can compute the shallow cuttings along with their conflict lists in  $O(n \log n)$  time [10]. Note that when  $r > n$ , it can be that  $k_i = 0$  for some  $i$ . In this case, we simply do

not build any of the cuttings that have  $k_i = 0$ . For our application, we are mostly interested in the deletion time of the data structure, and less in the query time. By picking  $r$  to be small, we can make deletions efficient at the cost of making the query time fairly terrible.

**Deletions.** If we delete a plane, we remove it from all conflict lists in all cuttings. Since cutting  $\Lambda_{k_i}$  has size  $O(r/2^i)$ , each plane occurs at most  $O(r/2^i)$  times in this cutting. Hence, the total time to go through all of these prisms is  $\sum_{i=0}^{O(\log r)} r/2^i = O(r)$  time. When more than half of the planes from any conflict list are removed, we rebuild the entire data structure. Because every conflict list contains at least  $n/r$  planes, at least  $\frac{n}{2r}$  deletions take place before a global rebuild. We charge the  $O(n \log n)$  cost of rebuilding to these planes, so we charge  $O(r \log n)$  to each deletion. Deletions thus take amortized  $O(r \log n)$  time.

**Queries.** We report the  $t$ -lowest planes at a query point  $q$  as follows. We consider the cutting for which  $k_i = 2^i(n/r) = O(t)$ , so at level  $i = \lceil \log(ctr/n) \rceil$ , for some large enough constant  $C$ . When  $t < n/r$  there is no such cutting, so we query the lowest level cutting instead. We find the prism containing  $q$  by a point location query. As the largest cutting has size  $O(r)$ , this takes  $O(\log r)$  time. We then simply report the  $t$  lowest planes at  $q$  by going through the entire conflict list. This results in a query time of  $O(\log r + n/r + t)$ .

**Reducing space usage.** When  $n$  is large w.r.t.  $r$ , we can use a similar approach to Chan [6, 7] to achieve linear space usage, by storing only the prisms of the shallow cuttings, and storing the planes in an auxiliary data structure [3]. We then obtain the following result.

► **Lemma 9.** *For any fixed  $r$ , we can construct a data structure of size  $O(n \log r)$ , or  $O(n)$  when  $n \geq r^{1/\varepsilon}$ , in  $O(n \log n)$  time that stores a set of  $n$  planes, allows for  $t$ -lowest planes queries in  $O(\log r + n/r + t)$  time and deletions in  $O(r \log n)$  time.*

**General data structure.** The general idea in the above data structure can be applied to any type of functions for which we have an algorithm to compute  $k$ -shallow cuttings. Note that the “lowest” cutting we use is an  $n/r$ -shallow cutting. It follows that constructing all shallow cuttings takes  $O(T(n, n/r) \log r)$  time. To delete a function, we remove it from the conflict lists in  $\sum_{i=0}^{O(\log r)} S(n, k_i) = O((r/n)S(n, 1))$  time, and we charge  $O((r/n)T(n, n/r) \log r)$  to the deletion to pay for the global rebuild. To answer a query, we simply find the prism containing  $q$  in one cutting, so the query time is  $O(Q(n, n/r) + n/r + t)$ . We thus have:

► **Lemma 10.** *For any fixed  $r$ , we can construct a data structure of size  $O(S(n, 1) \log r)$  in  $O(T(n, n/r) \log r)$  time that stores a set of  $n$  functions, allows for  $t$ -lowest functions queries in  $O(Q(n, n/r) + n/r + t)$  time and deletions in  $O((r/n)(S(n, 1) + T(n, n/r) \log r))$  time.*

### 5.3 A general dynamic data structure

To generalize the dynamic  $k$ -NN data structure from Section 5.1 to other types of distance functions, we replace the  $\mathcal{D}_0$  data structures by the data structure of Section 5.2. Queries and updates are performed as before (see Sections 2.2 and 5.1). This results in a dynamic  $k$ -NN data structure that can be used for any type of distance functions for which we can construct  $k$ -shallow cuttings. Next, we analyze the space usage and the running time in case of the Euclidean distance, as this is somewhat easier to follow, and then generalize to arbitrary distance functions.

## 14:12 Dynamic Data Structures for $k$ -Nearest Neighbor Queries

**Query time.** Our  $\mathcal{D}_0$  data structure has query time  $Q_0(n') = O(\log r + n'/r)$  and deletion time  $D_0(n') = O(r \log n')$ . Because we query the cutting at level  $j_k$ , the size of each conflict list we query is  $O(k)$ . By using our scheme to find the  $k$ -nearest neighbors over the substructures simultaneously, the query time becomes:

$$Q(n) = O([\log n + Q_0(O(k))] \log_b n + k) = O((\log n + (\log r + k/r)) \log_b n + k).$$

If we set  $r = \log n$ , and  $b = \log^\varepsilon n$ , we get  $Q(n) = O(\log^2 n / \log \log n + k)$ , matching the query time of Chan's approach.

**Update time.** Lemma 1 states that insertion time is given by  $I(n) = O(b \log_b n \cdot (P(n)/n))$ , where  $P(n)$  is the preprocessing time of  $\mathcal{D}$ . Our preprocessing time increases w.r.t. to the original data structure, since after building the hierarchy of shallow cuttings for a tower, we additionally need to build the structures  $\mathcal{D}_0$  on each of the conflict lists. As before, building the shallow cuttings takes  $O(n \log n)$  time [8]. Next, we analyse the time to build all data structures  $\mathcal{D}_0$ . Note that the cutting at level  $j$  in the hierarchy consists of  $O(n/k_j)$  prisms, and the size each conflict list in the cutting is  $O(k_j)$ . Let  $\alpha$  be the constant bounding the size of the conflict lists. Using that  $P_0(n') = O(n' \log n')$ , we find the following running time:

$$\begin{aligned} \sum_{j=0}^{\log \frac{n}{k_0}} O\left(\frac{n}{k_j}\right) \cdot P_0(\alpha k_j) &= \sum_{j=0}^{\log \frac{n}{k_0}} O\left(\frac{n}{k_j}\right) \cdot O(\alpha k_j \log(\alpha k_j)) \\ &= \sum_{j=0}^{\log \frac{n}{k_0}} O(n \log(\alpha k_j)) = O(n \log^2 n). \end{aligned}$$

The preprocessing time thus adheres to the recurrence relation  $P(n) \leq P(n/b) + O(n \log^2 n)$ , which solves to  $P(n) = O(n \log^2 n)$ . It follows that  $I(n) = O(b \log_b n \cdot (P(n)/n)) = O(b \log^2 n \log_b n) = O(\log^{3+\varepsilon} n / \log \log n)$ . Note that the improvement of building all shallow cuttings in a tower in  $O(n \log n)$  time does not improve the insertion time to  $O(\log^2 n)$  as in the 1-NN data structure, because building the  $\mathcal{D}_0$  data structures is the dominant term.

When deleting a plane  $h$ , with  $h \in F_{\text{live}}^{(i)}$ , we remove  $h$  from all  $\mathcal{D}_0$  of  $\mathcal{T}^{(i)}$  with  $h \in \mathcal{D}_0$ . There are at most  $O(b \log n)$  such data structures  $\mathcal{D}_0$ . By Lemma 1, deleting a plane causes amortized  $O(b \log n \log_b n)$  reinsertions. Each reinserted plane is also removed from the structures  $\mathcal{D}_0$  of a single tower. We can thus formulate the deletion time as  $D(n) = O(b \log n \log_b n \cdot (b \log n \cdot D_0(n) + I(n)))$ . Plugging in  $D_0(n) = O(\log^2 n)$  and  $I(n) = O(b \log^2 n \log_b n)$ , we find  $D(n) = O(b^2 \log^4 n \log_b n + b^2 \log^3 n \log_b^2 n) = O(\log^{5+\varepsilon} n / \log \log n)$ .

**Space usage.** The space usage of a  $\mathcal{D}_0$  data structure storing  $n'$  planes is  $O(n' \log r)$ . The space usage is thus  $S(n) = \sum_{j=0}^{\log \frac{n}{k_0}} \frac{n}{k_j} \cdot O(k_j \log r) = O(n \log n \log \log n)$ . Note that this can be reduced to  $O(n \log n)$  by using the space reduction idea mentioned in Section 5.2.

We can use the same scheme for any distance measure that allows for constructing a  $k$ -shallow cutting. In the full version of this paper [12], we prove the following lemma (Lemma 11), which we then apply to constant description complexity distance functions and geodesic distance functions (refer to full version [12] for details) to obtain Theorem 12.

► **Lemma 11.** *Given an algorithm to construct a  $k$ -shallow cutting of size  $S(n, k)$  on  $n$  functions in  $T(n, k)$  time, such that locating the prism containing a query point takes  $Q(n, k)$  time, we can construct a data structure of size  $O(S(n, 1)^2/n \cdot \log n \log \log n)$  that maintains a set of  $n$  functions and allows for  $k$ -lowest functions queries in  $O(Q(n, 1) \log n / \log \log n + k)$  time. Inserting a function takes  $O((S(n, 1)T(n, 1)/n^2) \log^{2+\varepsilon} n)$  amortized time, and deleting a function takes  $O((T(n, 1)/\log \log n + T(n, n/\log n)) \cdot S(n, 1)^2 \log^{4+\varepsilon} n/n^3)$  amortized time.*

► **Theorem 12.** *There is a fully dynamic data structure of size  $S(n)$  that stores a set of  $n$  sites and allows for  $k$ -nearest neighbors queries in  $Q(n)$  time, insertions in  $I(n)$  expected amortized time, and deletions in  $D(n)$  expected amortized time.  $\mathcal{P}$  is a simple polygon with  $m$  vertices, and  $\lambda_s(t)$  denotes the maximum length of a Davenport-Schinzel sequence of order  $s$  on  $t$  symbols and  $s$  a constant depending on the functions.*

	Euclidean in $\mathbb{R}^2$	General in $\mathbb{R}^2$	Geodesic in $\mathcal{P}$
$Q(n)$	$O\left(\frac{\log^2 n}{\log \log n} + k\right)$	$O\left(\frac{\log^2 n}{\log \log n} + k\right)$	$O\left(\frac{\log^2 n \log^2 m}{\log \log n} + k \log m\right)$

## Abstract

In a road network with multicriteria edge costs we consider the problem of computing a minimum number of driving preferences such that a given set of paths/trajectories is optimal under at least one of these preferences. While the exact formulation and solution of this problem appears theoretically hard, we show that in practice one can solve the problem exactly even for non-homeopathic instance sizes of several thousand trajectories in a road network of several million nodes. We also present a parameterized guaranteed-polynomial-time scheme with very good practical performance.

## 1 Introduction

It is well observable in practice that drivers' preferences are not homogeneous. If we have two alternative paths  $\pi_1, \pi_2$  between a given source-target pair, characterized by 3 costs/metrics (travel time, distance, and ascent along the route) each, e.g.,  $c(\pi_1) = (27min, 12km, 150m)$ , and  $c(\pi_2) = (19min, 18km, 50m)$ , there are most likely people who prefer  $\pi_1$  over  $\pi_2$  and vice versa. In previous works, people have tried to formalize these preferences. The most common model here assumes a linear dependency on the metrics. While typical real-world trajectories are not necessarily optimal in such a model, they are usually decomposable into very few optimal subtrajectories, see, e.g., [4]. This preference model allows for *personalized route planning*, where a routing query not only consists of source and destination but also a weighting of the metrics in the network.

Since this weighting of the metrics – often called *preference* – is hard to specify as a user of such a personalized route planning system, methods have been developed which infer the preferences from paths that the user has traveled before. The larger a set of paths is, though, the less likely it is that a single preference/weighting exists which explains all paths, i.e., for which all paths are optimal. One might, for example, think of different driving styles/preferences when commuting versus leisure trips through the country side. So a natural question to ask is, what is the minimum number of preferences necessary to explain a set of given paths in a road network with multiple metrics on the edges. This can also be

interpreted as a trajectory clustering task where routes are to be classified according to their purpose. In our example, one might be able to differentiate between commute and leisure. Or in another setting, where routes of different drivers are analyzed, one might be able to cluster them into speeders and cruisers depending on the routes they prefer.

The goal of this paper is the formulation of this natural optimization problem in the context of multicriteria routing and investigate the theoretical and practical challenges of solving this problem.

## Related Work

The linear preference model in the navigation context has been used in numerous works, e.g., [13, 11, 12, 9], to allow for personalized route planning services. Fewer papers deal with the inference of personal preferences like [17, 8]. The latter paper is also most related to this work as it introduced preference inference based on a linear programming formulation, which we will also instrument in our approach. Note, though, that while [8] already talked about the problem of minimizing the number of preferences to explain a set of trajectories, no serious attempt at getting optimal or close-to-optimal solutions has been made.

## Our Contribution

In this paper we show how to mathematically formulate the problem of finding the minimum number of preferences to explain a set of given paths in a road network with multiple edge metrics. We investigate both theoretical challenges as well as practical solvability and provide a guaranteed polynomial-time heuristic as well as an exact (but potentially superpolynomial-time) solution. Our experimental results show that for problem instances based on data from the OpenStreetMap project, we can compute optimal preference sets for thousands of paths within few minutes on road networks with several million nodes and edges.

## 2 Preliminaries

Our work is based on a *linear* preference model, i.e., for a given directed graph  $G(V, E)$  we have for every edge  $e \in E$  a  $d$ -dimensional cost vector  $c(e) \in \mathbb{R}^d$ , where  $c_1(e), c_2(e), \dots, c_d(e) \geq 0$  correspond to non-negative quantities like travel time, distance, non-negative ascent,  $\dots$ , which are to be minimized. A path  $\pi = e_1 e_2 \dots e_k$  in the network then has an associated cost vector  $c(\pi) := \sum_{i=1}^k c(e_i)$ .

A preference to distinguish between different alternative paths is specified by a vector  $\alpha \in [0, 1]^d$ ,  $\sum \alpha_i = 1$ . For example,  $\alpha^T = (0.4, 0.5, 0.1)$  might express that the respective driver does not care much about ascents along the route, but considers travel time and distance similarly important. Alternative paths  $\pi_1$  and  $\pi_2$  are compared by evaluating the respective scalar products of the cost vectors of the path and the preference, i.e.,  $c(\pi_1)^T \cdot \alpha$  and  $c(\pi_2)^T \cdot \alpha$ . Smaller scalar values in our linear model correspond to a preferred alternative. An  $st$ -path  $\pi$  (which is a path with source  $s$  and target  $t$ ) is optimal for a fixed preference  $\alpha$  if no other  $st$ -path  $\pi'$  exists with  $c(\pi')^T \cdot \alpha < c(\pi)^T \cdot \alpha$ .

Of course, this linear model is a bold simplification of actual drivers' preferences, yet it has been observed that real-world trajectories can typically be decomposed into very few optimal subtrajectories [4] (significantly less than for a single metric), so this linear model appears to be a reasonable approximation of reality.

## 2.1 Personalized Route Planning

Using the linear model it is easy to allow for *personalized route planning*, i.e., a query does not only consist of a source  $s$  and a target  $t$ , but also specifies a preference  $\alpha \in [0, 1]^d$ . The expected answer to such a query  $(s, t, \alpha)$  is a path  $\pi$  that is optimal for preference  $\alpha$ . Dijkstra’s algorithm can be instrumented to answer such queries by evaluating the scalar product of the edge cost vector and  $\alpha$  when relaxing an edge in the course of the algorithm.

Since Dijkstra’s algorithm is not really useful for continent-sized road networks people have come up with speed-up schemes, see [13, 12, 11], yet it appears considerably more difficult to achieve the speed-up factors of respective schemes for the single metric case.

## 2.2 Preference Inference

From a practical point of view, it is very unintuitive (or rather: almost impossible) for a user to actually express his driving preferences as such a vector  $\alpha$ , even if he is aware of the units of the cost vectors on the edges. Hence it would be very desirable to be able to *infer* his preferences from paths he likes or which he has traveled before. [8] proposed a technique for preference inference, which essentially instruments linear programming to determine an  $\alpha$  for which a given path  $\pi$  is optimal or certify that none exists. Given an  $st$ -path  $\pi$  in a road network, in principle, their proposed LP has non-negative variables  $\alpha_1, \dots, \alpha_d$  and one constraint for each  $st$ -path  $\pi'$  which states, that “for the  $\alpha$  we are after,  $\pi'$  should not be preferred over  $\pi$ ”. So the LP looks as follows:

$$\begin{array}{llll}
 \max & & \alpha_1 & \\
 \forall st\text{-paths } \pi' : & \alpha^T(c(\pi) - c(\pi')) & \leq 0 & \textit{optimality constraints} \\
 & \alpha_i & \geq 0 & \textit{non-negativity constraints} \\
 & \sum \alpha_i & = 1 & \textit{scaling constraint}
 \end{array}$$

Note, that an objective function is not really necessary, as we only care about feasibility, that is, existence of an  $\alpha$  satisfying all constraints. As such, this linear program is of little use, since typically there is an exponential number of  $st$ -paths, so just writing down the complete LP seems infeasible. Fortunately, due to the equivalence of optimization and separation, it suffices to have an algorithm at hand which – for a given  $\alpha$  – decides in polynomial time whether all constraints are fulfilled or if not, provides a violated constraint (such an algorithm is called a *separation oracle*). In our case, this is very straightforward: we simply compute (using, e.g., Dijkstra’s algorithm) the optimum  $st$ -path for a given  $\alpha$ . If the respective path has better cost (wrt  $\alpha$ ) than  $\pi$ , we add the respective constraint and resolve the augmented LP for a new  $\alpha$ , otherwise we have found the desired  $\alpha$ . Via the Ellipsoid method [14] this approach has polynomial running time, in practice the dual Simplex algorithm has proven to be very efficient.

### 3 Driving Preferences and Geometric Hitting Sets

The approach from Section 2.2 can easily be extended to decide for a *set* of paths (with different source-target pairs) whether there exists a single preference  $\alpha$  for which they are optimal (i.e., which explains this route choice). It does not work, though, if different routes for the same source-target pair are part of the input or simply no single preference can

explain all chosen routes. The latter seems quite plausible when considering that one would probably prefer other road types on a leisure trip on the weekend versus the regular commute trip during the week. So the following optimization problem is quite natural to consider:

Given a set of trajectories  $T$  in a multiweighted graph, determine a set  $A$  of preferences of minimal cardinality, such that each  $\pi \in T$  is optimal with respect to at least one  $\alpha \in A$ .

We call this problem *preference-based trajectory clustering* (PTC).

For a concrete problem instance from the real world, one might hope that each preference in the set  $A$  then corresponds to a driving style like speeder or cruiser. Also note, that a real-world trajectory often is not optimal for a single  $\alpha$  (prime example for that would be a round trip), yet, studies like in [4] show that it can typically be decomposed into very few optimal subtrajectories if multiple metrics are available.

In [8], a sweep algorithm is introduced that computes an approximate solution of PTC. It is, however, relatively easy to come up with examples where the result of this sweep algorithm is by a factor of  $\Omega(|T|)$  worse than the optimal solution. We aim to improve this result by finding practical ways to solve PTC optimally as well as approximately with better quality guarantees. Our (surprisingly efficient) strategy is to explicitly compute for each trajectory  $\pi$  in  $T$  the polyhedron of preferences for which  $\pi$  is optimal and to translate PTC into a geometric hitting set problem.

Fortunately, the formulation as a linear program as described in 2.2 already provides a way to compute these polyhedra. The constraints in the LP from 2.2 exactly characterize the possible values of  $\alpha$  for which one path  $\pi$  is optimal. These values are the intersection of half-spaces described by the optimality constraints and the non-negativity constraints of the LP. We call this (convex) intersection *preference polyhedron*. A preference polyhedron  $P$  of path  $\pi$  is  $d - 1$  dimensional, where  $d$  is the number of metrics. This is because the LP's scaling constraint reduces the dimension by one and we can substitute  $\alpha_d$  by  $1 - \sum_{i < d} \alpha_i$ . In the remainder of this Section, we discuss how to construct preference polyhedra from given paths and reformulate PTC as a minimum geometric hitting set problem.

### 3.1 Exact Polyhedron Construction

A straightforward, yet quite inefficient way of constructing the preference polyhedron for a given path  $\pi$  is to actually determine *all* simple  $st$ -paths and perform the respective half-space intersection. Even when restricting to pareto-optimal paths and real-world networks, their number is typically huge. So we need more efficient ways to construct the preference polyhedron.

#### 3.1.1 Boundary Exploration

With the tool of linear programming at hand, one possible way of exploring the preference polyhedron is by repeated invocation of the LP as in Section 2.2 but with varying objective functions. For sake of simplicity let us assume that the preference polyhedron is full (that is,  $d - 1$ <sup>1</sup>) dimensional. We first determine  $d - 1$  distinct extreme points of the polyhedron to obtain a  $d - 1$ -simplex as first (inner) approximation of the preference polyhedron. We then repeatedly invoke the LP with an objective function corresponding to the normal vectors of

---

<sup>1</sup> after elimination of  $\alpha_d$

the facets of the current approximation of the polyhedron. The outcome is either that the respective facet is part of the final preference polyhedron, or a new extreme point is found which destroys this facet and induces new facets to be investigated later on. If the final preference polyhedron has  $f$  facets, this approach clearly requires  $O(f)$  invocations of the LP solver (and some effort to maintain the current approximation of the preference polyhedron as the convex hull of the extreme points found so far). While theoretically appealing, in practice this approach is not very competitive due to the overhead of repeated LP solving.

### 3.1.2 Corner Cutting Approach

We developed the following *Corner Cutting Approach (CCA)* which in practice turns out to be extremely efficient to compute for a given path  $\pi$  its preference polyhedron, even though we cannot bound its running time in terms of the complexity of the produced polyhedron.

CCA is an iterative algorithm, which computes the feasibility polyhedron via a sequence of half-space intersections. Let  $P_\pi$  be the preference polyhedron of path  $\pi$ . In the  $i$ -th iteration CCA computes a polyhedron  $P_i$  with  $P_\pi \subseteq P_i \subseteq P_{i-1}$ .  $P_0$  is the entire preference space with a number of corners equal to the number of metrics. Each of these corners is initially marked as unchecked.

In iteration  $i$  CCA takes one corner  $\alpha^{(i)}$  of  $P_{i-1}$  that has not been checked before. If no such corner exists, CCA terminates and returns  $P_{CCA} := P_{i-1}$ . Otherwise, it marks the corner  $\alpha^{(i)}$  as checked and computes the optimal path  $\pi(\alpha^{(i)})$ . If  $(\alpha^{(i)})^T (c(\pi) - c(\pi(\alpha^{(i)}))) = 0$ , the corner  $\alpha^{(i)}$  belongs to  $P_\pi$  and there is nothing to do. Otherwise, the constraint  $\alpha^T (c(\pi) - c(\pi(\alpha^{(i)}))) \leq 0$  is violated by a part of  $P_{i-1}$ . We call this part  $P'_i$ . It is clear that  $\alpha^{(i)} \in P'_i$ . Finally, the polyhedron  $P_i := P_{i-1} \setminus P'_i$  is computed by intersecting  $P_{i-1}$  with the half-space  $\alpha^T (c(\pi) - c(\pi(\alpha^{(i)}))) \leq 0$ . This intersection may introduce new corners, which are marked as unchecked. Afterwards, the next iteration starts.

We prove that CCA indeed computes  $P_\pi$ . Let  $P_{CCA}$  be the output of CCA. We first show that  $P_\pi \subseteq P_{CCA}$ .  $P_\pi \subseteq P_0$  is trivially true. Furthermore, in each iteration  $i$  it is clear that  $P'_i \cap P_\pi = \emptyset$ . Hence, for each iteration  $i$ , we have  $P_\pi \subseteq P_i$  and therefore  $P_\pi \subseteq P_{CCA}$ . The other direction  $P_{CCA} \subseteq P_\pi$  follows from the fact that  $P_\pi$  is convex and that all corners of  $P_{CCA}$  belong to  $P_\pi$  as they are marked as checked.

CCA also terminates for finite graphs. Each optimal path  $\pi(\alpha^{(i)})$  can add finitely many corners to  $P_i$  only once. Since the number of optimal paths is finite the number of corners to be considered is finite as well.

The great advantage of CCA compared to the boundary exploration approach is the avoidance of the linear programming solver.

## 3.2 Minimum Geometric Hitting Set

Using the preference polyhedra we are armed to rephrase our original problem as a *geometric hitting set (GHS)* problem. In an instance of GHS we typically have geometric objects (possibly overlapping) in space and the goal is to find a set of points (a *hitting set*) of minimal cardinality, such that each of the objects contains at least one point of the hitting set. Figure 1 shows an example of how preference polyhedra of different optimal paths could look like in case of three metrics. In terms of GHS, our PTC problem is equivalent to finding a hitting set for the preference polyhedra of minimum cardinality, and the “hitters” correspond to respective preferences. In Figure 1 we have depicted two feasible hitting sets (white squares and black circles) for this instance. Both solutions are minimal in that no hitter can be removed without breaking feasibility. However, the white squares (in contrast to the black circles) do not describe a minimum solution as one can hit all polyhedra with less points.

■ **Figure 1** Example of a geometric hitting set problem as it may occur in the context of PTC. Two feasible hitting sets are shown (white squares and black circles).

■ **Figure 2** Inner (yellow) and outer approximation (grey) of the preference polyhedron (black).

While the GHS problem allows to pick arbitrary points as hitters, it is not hard to see that it suffices to restrict to vertices of the polyhedra and intersection points between the polyhedra boundaries, or more precisely vertices in the arrangement of feasibility polyhedra. We describe the computation of these candidates for the hitting sets in Section 3.3.

The GHS instance is then formed in a straightforward manner by having all the hitting set candidates as ground set, and subsets according to containment in respective preference polyhedra. For an exact solution we can formulate the problem as an integer linear program (ILP). Let  $\alpha^{(1)}, \alpha^{(2)}, \dots, \alpha^{(l)}$  be the hitting set candidates and  $\mathcal{U} := \{P_1, P_2, \dots, P_k\}$  be the set of preference polyhedra. We create a variable  $X_i \in \{0, 1\}$  indicating whether  $\alpha^{(i)}$  is picked as a hitter and use the following ILP formulation:

$$\begin{aligned} & \min \sum_i X_i \\ \forall P \in \mathcal{U} : & \sum_{\alpha^{(i)} \in P} X_i \geq 1 \\ \forall i : & X_i \in \{0, 1\} \end{aligned}$$

While solving ILPs is known to be NP-hard, it is often feasible to solve ILPs derived from real-world problem instances even of non-homeopathic size.

### 3.3 Hitting Set Instance Construction via Arrangements of Hyperplanes

To obtain the actual hitting set instance, we overlay the individual preference polyhedra. This can be done via construction of the arrangement of the hyperplanes bounding the preference polyhedra. Each vertex in this arrangement then corresponds to a candidate for the hitting set. If  $N$  is the total number of hyperplanes bounding all preference polyhedra in  $D$ -dimensional space, then this arrangement has complexity  $O(N^D)$  and can be computed by a topological sweep within the same time bound [6]. For  $K$  polyhedra with overall  $N$  bounding hyperplanes we obtain a hitting set instance with  $K$  sets and  $O(N^D)$  potential hitter candidates.

(a) Before inserting new optimal path.

(b) After inserting new optimal path.

■ **Figure 3** Example of preference polyhedra of optimal paths with the same source and target and with equal cost in the third metric.

### 3.4 Challenges

While our proposed approach to determine the minimum number of preferences to explain a set of given paths is sound, it raises two major issues. First, the complexity of a single preference polyhedron might be exponential (or just too large for actual computation), so just writing down the geometric hitting set instance becomes infeasible in practice. Second, solving a geometric hitting set instance to optimality is far from trivial. In the following we will briefly discuss these two issues and then in the next section come up with remedies.

#### 3.4.1 Preference Polyhedron Complexity

In the following, we show that the complexity of preference polyhedra can be arbitrarily high. We proceed in two steps. In the first step we show that if we find  $k$  optimal  $st$ -paths with two metrics we can construct a preference polyhedron with more than  $k$  facets by adding a third metric. In the second step we show that for a single  $st$ -pair there can be arbitrarily many preference polyhedra with non-zero volume with two metrics.

Let us first assume we have two metrics and  $k > 1$  optimal  $st$ -paths  $\pi_1$  to  $\pi_k$ . Furthermore, we assume that each of the  $k$  optimal paths has a preference polyhedron with non-zero volume (a polyhedron is a line in the two-metrics case). We refer to the  $j$ -th entry of cost vector  $c(\pi_i)$  with  $c(\pi_i)_j$ . Let  $x := \max_{1 \leq i \leq k} c(\pi_i)_1 + c(\pi_i)_2$  be the maximum of the sums of the cost vectors.

We now introduce a third metric with a constant cost of  $3x$  for each path. It is clear that each of the  $k$  optimal paths is optimal for the preference  $\alpha_3 = [0, 0, 1]$ . Hence, each preference polyhedron is now a triangle as shown in Figure 3a.

Finally, we create a new optimal path  $\pi_{k+1}$  with the cost vector  $c(\pi_{k+1}) := [2x, 2x, 2x]$ . This path is clearly optimal for the preference  $\alpha_3$ . Since  $\alpha_3^T (c(\pi_{k+1}) - c(\pi_i))$  is strictly less than zero for each  $1 \leq i \leq k$  the volume of the preference polyhedron of  $\pi_{k+1}$  is non-zero. Furthermore, restricted to the first two metrics  $\pi_{k+1}$  is not optimal. This directly follows from the definition of  $x$ . Hence, the preference polyhedron of  $\pi_{k+1}$  shares a constraint with each of the  $k$  other optimal paths as shown in Figure 3b.

We now discuss that with two metrics there can be arbitrarily many shortest paths with the same source and target that have a non-zero volume preference polyhedron.

Let us assume that there are  $k + 1$   $st$ -paths  $\pi_0, \pi_1, \dots, \pi_k$  with cost vectors  $c(\pi_i) := [i^2, (k - i)^2]$ . This could be easily realized with one-edge paths. A preference is in this case a tuple  $[1 - \alpha, \alpha]$  with  $0 \leq \alpha \leq 1$ .

For any  $0 \leq i < k$  we have  $c(\pi_i) - c(\pi_{i+1}) = [-2i - 1, 2(k - i) - 1]$ . With  $\alpha = \frac{2i+1}{2k}$  we get

$$[1 - \alpha, \alpha]^T (c(\pi_i) - c(\pi_{i+1})) = \left[ \frac{2(k-i)-1}{2k}, \frac{2i+1}{2k} \right]^T [-2i-1, 2(k-i)-1] = 0$$

Hence, for  $0 < i < k$  the path  $\pi_i$  is optimal for the range  $\alpha \in \left[ \frac{2i-1}{2k}, \frac{2i+1}{2k} \right]$ . Path  $\pi_0$  is optimal for the range  $\alpha \in \left[ 0, \frac{1}{2k} \right]$  and path  $\pi_k$  is optimal for the range  $\alpha \in \left[ \frac{2k-1}{2k}, 1 \right]$ .

The question remains whether the number of optimal  $st$ -paths can be exponential in the graph size. If this is the case, then it follows with the construction above that there are preference polyhedra with exponential complexity.

### 3.4.2 MGHS Hardness

The minimum hitting set problem (or equivalently the set cover problem) in its general form is known to be NP-hard and even hard to approximate substantially better than a  $\ln n$  factor, see [2]. A simple greedy algorithm yields a  $O(\log n)$  approximation guarantee, which in the general case is about the best one can hope for. For special instances, e.g., when the instance is derived from a geometric setting (as ours), better approximation guarantees can sometimes be achieved. While the exact solution remains still NP-hard even for seemingly simple geometric instances [7], quite strong guarantees can be shown depending on the characteristics of the objects to be hit. Sometimes even PTAS are possible, see, e.g. [16]. Unfortunately, apart from convexity, none of the favourable characterizations seem to be applicable in our case. We cannot even exclude infinite VC dimension in hope for a  $O(\log OPT)$  approximation [5], as the preference polyhedra might have almost arbitrarily many corners.

## 4 Polynomial-Time Heuristics with Instance-based Lower Bounds

The previous section suggests that if we require worst-case polynomial running time, we have to resort to approximation of some kind. Both, generation of the geometric hitting set instance as well as solving of the instance might not be possible in polynomial time. We address both issues in this section.

### 4.1 Approximate Instance Generation

It appears difficult to show polynomial bounds on the size of a single preference polyhedron, so approximation with enforced bounded complexity seems a natural approach. There are well-known techniques like coresets [1] that allow arbitrarily (specified by some  $\epsilon$ ) accurate approximation of convex polyhedra in space polynomial in  $1/\epsilon$  (which is independent of the complexity of the original polyhedron). We follow the coreset approach and also make use of the special provenance of the polyhedron to be approximated.

For  $d$  metrics, our polyhedron lives in  $d - 1$  dimensions, so we uniformly  $\epsilon$ -sample the unit  $(d - 2)$ -sphere using  $O((1/\epsilon)^{d-2})$  samples. Each of the samples gives rise to an objective function vector for our linear program, we solve each such LP instance to optimality. This determines  $O((1/\epsilon)^{d-2})$  extreme points of the polyhedron in equally distributed directions. Obviously, the convex hull of these extreme points is *contained within* and with decreasing  $\epsilon$  converges towards the preference polyhedron. Guarantees for the convergence in terms of  $\epsilon$  have been proven before, but are not necessary for our (practical) purposes. We call the convex hull of these extreme points the *inner approximation* of the preference polyhedron.

What is interesting in our context is the fact that each extreme point is defined by  $d - 1$  half-spaces. So we can also consider the set of half-spaces that define the computed extreme points and compute their intersection. Clearly, this half-space intersection *contains* the preference polyhedron. We call this the *outer approximation* of the preference polyhedron.

Let us illustrate our approach for a graph with  $d = 3$  metrics, so the preference polyhedron lives in the 2-dimensional plane, see the black polygon/polyhedron in Figure 2. Note that we do not have an explicit representation of this polyhedron but can only probe it via LP optimization calls. To obtain inner and outer approximation we determine the extreme points of this implicitly (via the LP) given polyhedron, by using objective functions  $\max \alpha_1, \max \alpha_2, \min \alpha_1, \min \alpha_2$ . We obtain the four solid red extreme points. Their convex hull (in yellow) constitutes the inner approximation of the preference polyhedron. Each of the extreme points is defined by 2 constraints (halfplanes supporting the two adjacent edges of the extreme points of the preference polyhedron). In Figure 2, these are the light green, blue, dark green, and cyan pairs of constraints. The half-space intersection of these constraints form the *outer approximation* in gray.

### 4.1.1 Sandwiching the Optimum Hitting Set Size

If – by whatever means – we are able to solve geometric hitting set instances optimally, our inner and outer approximations of the preference polyhedra yield upper and lower bounds to the solution size for the actual preference polyhedra. That is, if for example the optimum hitting set of the instance derived from the *inner* approximations has size 23 and the optimum hitting set of the instance derived from the *outer* approximations has size 17, we know that the optimum hitting set size of the actual exact instance lies between 17 and 23. Furthermore, the solution for the instance based on the inner approximations is also feasible for the actual exact instance. So in this case we would have an instance-based (i.e., not apriori, but only aposteriori) approximation guarantee of  $23/17 \approx 1.35$ . If for the application at hand this approximation guarantee is not sufficient, we can try improving by refining the inner and outer approximations. In the limit, inner and outer approximations coincide with the exact preference polyhedra.

## 4.2 Approximate Instance Solving

In this section, we discuss approximation algorithms to replace the ILP shown in Section 3.2, which is not guaranteed to run in polynomial time.

The geometric objects to be hit are the preference polyhedra of the given set of paths, the hitter candidates and which polyhedra they hit are computed via the geometric arrangement as described in Section 3.3.

### 4.2.1 Naive Greedy Approach

The standard greedy approach for hitting set iteratively picks the hitter that hits most objects, which have not been hit before. We call this algorithm *Naive Greedy* or short NG. It terminates as soon as all objects have been hit. The approximation factor of this algorithm is  $O(\log n)$ , where  $n$  is the number of objects to be hit, see [15]. The information which preference hits which polyhedron comes from the arrangement described in Section 3.3.

After computing the cover, NG iterates over the picked hitters and removes them if feasibility is not violated. In this way the computed hitting set is guaranteed to be minimal (but not necessarily minimum).

### 4.2.2 LP-guided Greedy Approach

While naive greedy performs quite well in practice, making use of a precomputed optimal solution to the LP relaxation of the ILP formulation from Section 3.2 can improve the quality of the solution. We call this algorithm *LP Greedy* or LPG. It starts with an empty set  $S^*$  and iterates over a random permutation of the cover constraints of the LP. Note that each of these constraints  $C_i$  corresponds to a preference polyhedron  $P_i$ .

At each constraint  $C_i$  LPG checks if  $P_i$  is hit by at least one preference in  $S^*$ . If not, one of its hitters is randomly picked based on the weights of the LP solution and added to  $S^*$ . To be more precise, the probability of a hitter  $\alpha$  to be drawn is equal to its weight divided by the sum of the weights of all hitters of  $P_i$ .

After iterating over all constraints it is clear that  $S^*$  is a feasible solution. Finally, LPG iterates over  $S^*$  in random order removing elements if feasibility is not violated. This ensures that  $S^*$  is minimal. This process is repeated several times and the best solution is returned.

## 5 Experimental Results

In this section, we assess how real-world relevant the theoretical challenges of polyhedron complexity and NP-hardness of the GHS problem are, and compare exact solutions to our approximation approaches.

### 5.1 Experimental Setup

We run our experiments on a server with two intel Xeon E5-2630 v2 running Ubuntu Linux 20.04 with 378GB of RAM. The running times reported are wall clock times in seconds. Some parts of our implementation make use of all 24 CPU threads. We cover two different scenarios by extracting different graphs from OpenStreetMap of the German state of Baden-Württemberg. This first graph is a road network with the cost types *distance*, *travel time for cars* and *travel time for trucks*. It contains about 4M nodes and 9M edges. The second graph represents a network for cyclists with the cost types *distance*, *height ascent*, and *unsuitability for biking*. The latter metric was created based on the road type (big road  $\Rightarrow$  very unsuitable) and bicycle path tagging. The cycling graph has a size of more than double of the road graph with about 11M nodes and 23M edges. The Dijkstra separation oracle was accelerated using a precomputed multi-criteria contraction hierarchy from [9]. For the Sections 5.3 to 5.5, we used a set of 50 preferences chosen u.a.r. per instance and created different quantities of paths with those preferences. We therefore know an apriori upper bound for the size of the optimal hitting set for our instances. In Section 5.6, we show that the number of preferences used does not change the characteristics of our approaches.

### 5.2 Implementation Details

Our implementation consists of multiple parts. The routing and the computation of the (approximate) preference polyhedra of paths is implemented in the rust programming language (compiled with rustc version 1.51) and uses GLPK [3] (version 4.65) as a library for solving LPs. We intentionally refrained from using non-opensource solutions like CPLEX or GUROBI, as they might not be accessible to everyone. The preference polyhedra are processed in a C++ implementation (compiled with g++ version 10.2) which uses the CGAL library [18, 19] (version 5.0.3) to compute the arrangements with exact arithmetic and output the hitting set instances. We transform the hitting set instances into the ILP formulation from Section 3.2

and solve this ILP formulation and its LP relaxation with GLPK. Finally, we implemented the two greedy algorithms described in Section 4.2.1 and 4.2.2 which solve the hitting set instances in C++. Source code and data under <https://doi.org/10.17605/osf.io/4qkvu>.

### 5.3 Geometric Hitting Set Instance Generation

First, we assess the generation of the GHS instances via preference polyhedra construction and computation of the geometric arrangement. In our tables, we refer to the corner cutting approach as “exact” and the approximate approach as “inner- $k$ ”/ “outer- $k$ ” where  $k$  is the number of directions that were approximated. Since the hitter candidates from the geometric arrangement contain a lot of redundancies (which slows down in particular the (I)LP solving), e.g., some hitters being dominated by others, we prune the resulting candidate set in a straightforward set minimization routine. The preference polyhedra construction as well as the set minimization routine are the multithreaded parts of our implementation. Table 1 shows run times and the average polyhedron complexity for a problem instance with 10,000 paths. In this instance, approximating in twelve directions takes more time than the exact calculation with CCA. This is due the polyhedron complexity being very low in practice. It shows that CCA is a valid approach in practice. Set minimizing is particularly expensive for the inner approximations since considerably more candidates are not dominated.

■ **Table 1** Statistics about instance generation: average number of polyhedron corners, polyhedra construction time (multithreaded), construction time for arrangement, time for set minimization (multithreaded). Car graph with 10,000 paths. Time in seconds.

Algo.	Polyh. Compl	Polyh. Time	Arr. Time	SetMin Time
Inner-12	3.8	70.6	352.3	1450.0
Exact	4.7	54.9	356.7	414.8

Outer-4	6.7	5.9	35	11.5

### 5.4 Geometric Hitting Set Solving

We now compare the two greedy approaches from Section 4.2 with the ILP formulation of Section 3.2. For the ILP solver, we set a time limit of 1 hour after which the computation was aborted and the best found solution (if any) was reported. The results for two instances on the bicycle graph are shown in Table 3. The naive greedy approach has by far the smallest run time but it also reports worse results than the LP-based greedy which was able to find the optimal solution for exact and outer approximations of the two instances. The ILP solver always reports the optimal solution but it might take a very long time to do so. Especially, the inner approximations seem to yield hard GHS instances before they converge to the exact problem instance. A state of art commercial ILP solver might improve run time drastically.

■ **Table 3** Comparison of GHS solving algorithms on two instances on the bicycle graph. The times (given in seconds) for the LP-Greedy and ILP algorithm include solving the LP-relaxation first.

Algorithm	Paths	Greedy Solution	Greedy Time	LP-Greedy Solution	LP-Greedy Time	ILP Solution	ILP Time
Inner-12	5000	210	4.2	181	40.8	–	>3600.0
Exact	5000	54	2.9	48	24.8	48	68.4
Outer-12	5000	57	3.1	48	30.5	48	95.5
Inner-12	10000	421	10.9	399	144.6	–	>3600.0
Exact	10000	58	7.6	50	73.5	50	188.9
Outer-12	10000	59	8.1	50	81.1	50	114.6

## 5.5 Varying Polyhedron Approximation

In Table 2 we show that increasing the number of directions in the approximation approach makes its results converge to the exact approach. Interestingly, the outer approximation converges faster than the inner approximation. It typically yields good lower bounds already for four approximation directions and higher. In Table 2 it yields a tight lower bound for eight directions while the inner approximation only achieves a tight upper bound with 128 directions.

## 5.6 Dependence on the number of preferences

So far, we have only considered PTC problem instances that were derived from 50 initial preferences. To ensure that the fixed number of preferences does not bias our results, we also ran instances generated with 10, 20, 100 and 1000 preferences. Tables 4 and 5 hold the results for instances with 1,000 paths on both graphs. As expected, we found larger optimal solutions as the number of preferences increased. Although, the solution size did increase only to 53 and 177 for the car and bicycle graph, respectively. We attribute this to the probably bounded inherent complexity of the graphs and cost types used. We also note a slight increase in ILP run times with spikes when computing the solution to the inner approximation as discussed in Section 5.4. Otherwise, there is no performance difference.

## 6 Conclusions

We have exhibited an example for a real-world application where theoretical complexities and hardness do not prevent the computation of optimal results even for non-toy problem instances. The presented method allows the analysis of large trajectory sets as they are, for example, collected within the OpenStreetMap project. Our results suggest that exact solutions are computable in practice, even more so if commercial ILP solvers like CPLEX or GUROBI are employed. From a theoretical point of view, it would be interesting to prove or disprove our guess that exponentially (in the network size) many optimal paths between one source-target pair exist. Another open problem is to find an explanation for the observed average preference polyhedra complexity, which is surprisingly low. On a more abstract level, our approach of approximating the hitting set problem with increasing precision by refining the inner and outer approximations until an optimal solution can be guaranteed could also be viewed as an extension of the framework of *structural filtering* ([10]), where the high-level idea is to certify exactness of possibly error-prone calculations. It could be interesting to apply this not only to the instance generation step but simultaneously also to the hitting set solution process.

■ **Table 4** Run times and optimal solution of instances generated with varying amount of preferences. The instances each consist of 1.000 paths on the car graph.

# Efficiently Partitioning the Edges of a 1-Planar Graph into a Planar Graph and a Forest

Sam Barr ✉

## Abstract

---

1-planar graphs are graphs that can be drawn in the plane such that any edge intersects with at most one other edge. Ackerman showed that the edges of a 1-planar graph can be partitioned into a planar graph and a forest, and claims that the proof leads to a linear time algorithm. However, it is not clear how one would obtain such an algorithm from his proof. In this paper, we first reprove Ackerman's result (in fact, we prove a slightly more general statement) and then show that the split can be found in linear time by using an edge-contraction data structure by Holm, Italiano, Karczmarz, Łącki, Rotenberg and Sankowski.

## 1 Introduction

In this paper, we study the class of 1-planar graphs: graphs that can be drawn in the plane such that every edge crosses at most one other edge. 1-planar graphs were introduced by Ringel [21], motivated by the problem of coloring the vertices and faces of a planar graph. Since then, there have been many publications concerning 1-planar graphs, both for theoretical results such as coloring, as well as algorithmic results such as solving drawing and optimization problems. The reader may refer to [18] for an annotated bibliography from 2017 and [15] for a more recent book that includes developments since then.

Many of the results for 1-planar graphs are obtained by first converting the 1-planar graph  $G$  into a planar graph  $G'$ , applying results for planar graphs, and then expanding the result from  $G'$  back to  $G$ . (We will give specific examples below.) There are several ways of how to create  $G'$ , e.g., by deleting edges or by replacing crossings with dummy-vertices. Of particular interest to us here is to make a 1-planar graph planar by deleting edges. Put differently, we want an *edge partition*, i.e., write  $E(G) = E' \cup E''$  such that  $E'$  forms a planar graph while  $E''$  has some special structure that makes it possible to expand a solution for  $G'$  to one for  $G$ .

**Previous Work.** The main focus of this paper is a result by Ackerman [1]. He established that the edges of a 1-planar graph can be partitioned such that one partition induces a planar graph and the other induces a forest. This was an extension of an earlier result from Czap and Hudák [8], who proved it for optimal 1-planar graphs (simple 1-planar graphs with the maximum  $4n - 8$  edges). Other partitions of near-planar graphs have also been studied; we list a few here. Lenhart et al. [19] show that optimal 1-planar graphs can be partitioned into a maximal planar graph and a planar graph of maximum degree four (the bound of four

Leibniz International Proceedings in Informatics

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

is shown to be optimal). Bekos et al. [4] provide edge partition results for some  $k$ -planar graphs (graphs that can be drawn in the plane such that any edge crosses at most  $k$  other edges). Di Giacomo et al. [9] prove edge partition results for so-called NIC-graphs, a subclass of 1-planar graphs.

For algorithmic purposes, we need to find such edge partitions in linear time. With one exception, the above papers either explicitly come with a linear-time algorithm to find the edge-partition, or such an algorithm can easily be derived from the proof. The one exception is the paper by Ackerman [1]. He claims that the partition of a 1-planar graph into a planar graph and a forest can be found in linear time, but provides no details. Moreover, while his proof clearly gives rise to a polynomial-time algorithm, it is not clear how one would achieve linear time (or even  $O(n \log n)$  time), since he relies on contracting edges while repeatedly testing whether two vertices share a face and occasionally splitting the graph into subgraphs, and neither of these operations can trivially be done in constant time in planar graphs. (We confirmed this in private communication with Ackerman.)

**Our Results.** In this paper, we show that a partition of a 1-planar graph into a planar graph and a forest can be found in linear time. We were not able to use Ackerman's proof for this directly, so as a first step we re-prove the result in a slightly different way to avoid some problematic situations and so that then a linear-time algorithm can be established. A crucial ingredient for this is a data structure by Holm, Italiano, Karczmarz, Łącki, Rotenberg and Sankowski [14] which allows for efficiently contracting edges of planar graphs. To our knowledge, this data structure has not been implemented. Because of this, we also show that the partition can be computed in  $O(n \log n)$  time using a simpler data structure based on incidence lists.

- As a consequence of our result, a number of related problems can be solved in linear time:
- Angelini et al. [3] studied the problem of finding simultaneous quasi-planar drawings of graphs where some edges are fixed. They used Ackerman's partition result in order to find such a simultaneous drawing of a 1-planar graph and a planar graph and cited its claimed linear runtime; with our result the linear runtime of [3] is established.
  - It is known that every 1-planar graph has *arboricity* 4, i.e., its edges can be partitioned into 4 forests. (This follows from Nash-Williams formula for arboricity [20] since 1-planar graphs have at most  $4n - 8$  edges [6].) The arboricity (and the corresponding edge-partition) of a graph can be computed in polynomial time [11], but to our knowledge not in linear time. For *planar* graphs, a split into 3 forests can be found in linear time [24]. So with our result, the partition of a 1-planar graph into 4 forests can be done in linear time as well, by first partitioning into a forest and a planar graph and then applying [24] onto the planar graph.
  - If  $G$  is a bipartite 1-planar graph, then it has at most  $3n - 8$  edges [16] and hence arboricity 3. With our result we can partition it into a forest and a planar bipartite graph in linear time. The planar bipartite graph can be partitioned into two forests in linear time [22]. In consequence, every 1-planar bipartite graph can be partitioned into three forests in linear time.
  - From a partition into  $d$  forests one easily obtains an edge orientation with in-degree at most  $d$ . For bipartite graphs, such an edge-orientation can be used to prove  $(d+1)$ -list-colorability [13], and this list-coloring can be found in  $O(dn)$  time [5]. Putting everything together, therefore our paper fills the one missing gap to show that 1-planar bipartite graphs can be 4-list-colored in linear time.

Our paper is structured as follows: In Section 2 we go over necessary terminology and present Ackerman’s proof in order to demonstrate that it does not immediately lead to a linear time algorithm. In Section 3 we present our new proof. In Section 4 we use our alternative proof to design an efficient algorithm for finding the partition, before concluding in Section 5.

## 2 Background

We assume basic familiarity with graph theory (see e.g. [10]). All graphs in this paper are finite and connected, but not necessarily simple.

For a (multi)graph  $G$  and a vertex  $x$  of  $G$ ,  $d(x)$  is the number of edges incident to  $x$ .

We recall that a (multi)graph  $G$  is called *planar* if it can be drawn in the plane without edges crossing. Let  $G$  be a planar (multi)graph given with a drawing  $\Gamma$ . The maximal regions of  $\mathbb{R}^2 \setminus \Gamma$  are the *faces* of  $G$ . We add a *chord* to a face  $f$  by adding an edge between two non-adjacent vertices on the boundary of  $f$ , and drawing the edge through the region of  $f$ . For each vertex  $x$  with incident edges  $e_1, \dots, e_k$ , the drawing  $\Gamma$  places these edges in some rotational clockwise order around  $x$ . The space between two edges which are adjacent in this rotational order form an *angle*. The *degree* of a face  $f$  is the number of angles contained in the face. We say that a face  $f$  is a *quadrangle* if it has degree 4. Note that this includes both faces with 4 vertices on their boundary, and some faces with fewer than 4 vertices on their boundary (see Figure 1(a)). If  $f$  is a quadrangle with exactly 4 vertices on its boundary, then we call  $f$  a *simple quadrangle* (the quadrangles of a simple planar graph will all be simple quadrangles). A face of degree 3 is a *triangle*, and a face of degree 2 is a *bigon*.

The *facial cycle* of a quadrangle  $f$  is a 4-tuple  $\langle z_0, z_1, z_2, z_3 \rangle$  such that each  $z_i$  is on the boundary of  $f$  and there are edges  $z_i z_{i+1}$  and  $z_i z_{i-1}$  (arithmetic modulo 4) which form an angle in  $f$ . Note that  $z_0, z_1, z_2, z_3$  need not be distinct if  $f$  has loops or parallel edges, or if it is incident to a bridge. We say that  $z_0$  and  $z_2$  are *opposing vertices in  $f$*  (we will often omit mentioning the face when it is clear from context). Likewise  $z_1$  and  $z_3$  are opposing vertices in  $f$ . Note that it is possible for a vertex to oppose itself in a quadrangle.

*Stellating* a face  $f$  of a planar graph is the process of adding a new vertex  $s$  inside  $f$ , and adding an edge from  $s$  to every vertex on the boundary of  $f$ . Given two vertices  $a$  and  $b$ , we *contract  $a$  and  $b$*  by creating a new vertex  $c$ , adding an edge  $vc$  for each edge  $va$  and  $vb$ , and deleting  $a$  and  $b$  and all their incident edges. If  $a$  and  $b$  were adjacent, then  $c$  has a loop, and if  $a$  and  $b$  were both adjacent to a vertex  $v$ , then  $c$  will have parallel edges to  $v$ . If  $a$  and  $b$  were both on the boundary of some face  $f$  in a planar graph, then we can *contract  $a$  and  $b$  through  $f$*  by placing this new vertex  $c$  inside  $f$ . This preserves planarity, but destroys the face  $f$ .

A *1-planar* graph is a graph  $G$  that can be drawn in the plane such that any edge intersects with at most one other edge. Here “drawing” always means a *good drawing* (see e.g. [23]), in particular this means that no three edges cross in a point, that no edge intersects itself, and that incident edges do not cross. From now on, whenever we speak of a 1-planar graph, we assume that one particular 1-planar drawing has been fixed. A pair of edges that intersect each other are a *crossing pair*, and the point where they intersect is known as the *crossing point*. The *planarization* is the graph  $G^\times$  obtained by replacing each crossing point with a new vertex. A 1-planar graph  $G$  is *planar-maximal* if no *uncrossed edge* (i.e., an edge which does not intersect any other edge) can be added to the fixed drawing of  $G$  without adding a loop or a bigon.

## 16:4 Partitioning the Edges of a 1-Planar Graph

For algorithmic purposes, a drawing of a planar graph can be specified by giving the rotational clockwise order of edges at every vertex; this specifies the circuits bounding the faces uniquely. A drawing of a 1-planar graph can be specified by giving a drawing of its planarization, with the vertices resulting from a crossing point marked as such. Since testing 1-planarity is NP-hard [12], we assume that any 1-planar graph  $G$  is given with such a drawing. We also assume that  $G$  is planar-maximal, because any 1-planar graph can be made planar-maximal in linear time by adding edges [2], and having more edges can only make partitioning more difficult.

For ease of notation, we define a shortcut for our partition problem.

► **Definition 1.** *A graph  $G$  has a PGF-partition if its edge-set  $E(G)$  can be partitioned into two sets  $A$  and  $B$  such that  $G[A]$  is a planar graph and  $G[B]$  is a forest.*

### 2.1 Ackerman's Proof

To establish the difficulties of achieving a linear time algorithm, we briefly review here Ackerman's proof for the existence of a PGF-partition.

Let  $G$  be a (planar-maximal) 1-planar graph without loops drawn in the plane. Remove all crossing pairs of  $G$ . Call the resulting graph  $H$  the (*planar*) *skeleton* of  $G$  [2]. Observe that the faces of  $H$  are either bigons, triangles, or quadrangles, and that there is a 1-1 mapping between the quadrangles of  $H$  and the crossing pairs of  $G$ . Moreover, by this 1-1 mapping and the fact that the two edges forming a crossing pair do not share an endpoint, one can see that the quadrangles of  $H$  are in fact simple quadrangles. Ackerman, similarly to Czap and Hudák [8], establishes the following.

► **Lemma 2** (Ackerman [1]). *Let  $G$  be a 1-planar graph, and let  $H$  be the skeleton of  $G$ . If we can add a chord to every quadrangle of  $H$  such that the chords induce a forest, then  $G$  has a PGF-partition.*

**Proof.** Let  $C$  be the set of chords added to  $H$ . By the 1-1 mapping between quadrangles of  $H$  and crossing pairs of  $G$ , we know that exactly one edge from each crossing pair of  $G$  is contained in  $C$ . In particular, each edge  $e \in C$  forms a crossing pair with some edge  $e'$  of  $G$ . Let  $C'$  be the set of these edges  $e'$ . By assumption  $G[C]$  is a forest. Moreover, the graph  $H \cup C'$  is the graph  $H$  plus a chord added to each quadrangle of  $H$ , and so is a planar graph. As  $H \cup C'$  is also the graph induced by the edge-set  $E(G) \setminus C$ , this gives us the desired partition. ◀

Thus, in order to prove the existence of a PGF-partition, it suffices to show (typically by induction on the number of quadrangles) that such a set of chords can be found. For the induction to go through, Ackerman additionally forbids the chords from containing a path between two adjacent pre-specified vertices  $x, y$ .

► **Theorem 3** (Ackerman [1]). *Let  $H$  be a planar multigraph without loops such that every face has degree at most four and all quadrangles are simple. Let  $x, y$  be a pair of adjacent vertices of  $H$ . Then we can add a chord to every simple quadrangle of  $H$  such that the subgraph induced by the chords is a forest and does not contain a path between  $x$  and  $y$ .*

**Proof.** Proceed by induction on the number of quadrangles in  $H$ . If  $H$  has no quadrangles, then the statement is trivial. Otherwise, let  $f$  be a quadrangle with facial cycle  $\langle z_0, z_1, z_2, z_3 \rangle$ ; by assumption  $f$  is simple.

**Case 1.** The only face containing  $z_0$  and  $z_2$  is  $f$ ; in particular  $z_0$  and  $z_2$  are not adjacent. Contract  $z_0$  and  $z_2$  through  $f$ . Let  $H'$  be the graph resulting from this contraction. Observe that  $H'$  has one fewer quadrangle than  $H$ . All other quadrangles remain simple since  $f$  was the only face containing  $z_0$  and  $z_2$ . Apply induction on  $H'$  with the same pair of adjacent vertices  $x, y$  to receive a set of chords  $C'$ , and then further add the chord  $z_0z_2$ . Chords have now been added to every quadrangle of  $H$ , and it is easy to see that we have not added a cycle, or a path from  $x$  to  $y$ , in the chords.

**Case 2.** There is some face  $f' \neq f$  containing  $z_0$  and  $z_2$ , but the only face containing  $z_1$  and  $z_3$  is  $f$ . Proceed as in Case 1, except contract  $z_1$  and  $z_3$ .

**Case 3.** None of the above. Then there is a face  $f' \neq f$  containing  $z_0$  and  $z_2$ , and there is a face  $f'' \neq f$  containing  $z_1$  and  $z_3$ . Ackerman argues that  $f' = f''$  (see also Lemma 5), and therefore  $f'$  is also a simple quadrangle. Observe that  $G$  can be split into four connected subgraphs  $H_0, H_1, H_2, H_3$ , where  $H_i$  contains  $z_i$  and  $z_{i+1}$  (addition modulo 4) on the boundary (see Figure 1(e)). One of these subgraphs, say  $H_0$ , will contain the adjacent pair  $x, y$ . Apply induction on  $H_0$  with  $x, y$ , and apply induction on the other  $H_i$  with the pair  $z_i, z_{i+1}$ . After induction, add the chords  $z_0z_2$  in  $f$ , and  $z_1z_3$  in  $f'$ . One verifies that the added chords do not add a path between  $x$  and  $y$  and that the chords do not create a cycle. ◀

### 3 An Alternative Existence Proof

While Ackerman's proof clearly leads to a polynomial time algorithm for finding the partition, it is not obviously linear since distinguishing between the cases and contracting are not obviously doable in constant time:

1. We need to test whether a given pair of vertices share more than one face.
2. The graph changes via contractions, and it is not obvious whether the existing data structures for efficiently contracting edges in planar graphs (e.g. [14]) would support (1) in constant time.
3. In Case 3 of Ackerman's proof, we need to identify the four subgraphs  $H_0, H_1, H_2, H_3$ . Furthermore, we need to determine which of these subgraphs contains the pair  $x, y$ . Neither operation is obviously doable in constant time.

We now give a different proof of the existence of a PGF-partition that either avoids these issues or addresses explicitly how to resolve them. The biggest change is how we handle Case 3 of Ackerman's proof. Ackerman used here a split into four graphs, which is necessary in order to maintain that all quadrangles are simple. We prove a more general statement that permits non-simple quadrangles and hence avoids having to split the graph. Moreover, we generalize Ackerman's "forbidden pair"  $x$  and  $y$  by choosing chords in such a way that the chords do not induce a path between *any* pair of vertices that were adjacent in the original graph  $H$ . Doing so simplifies the induction since we no longer need to keep track of where the vertices  $x$  and  $y$  are. Before we state this result we need a few helper-results that hold for all quadrangles (simple or not).

► **Lemma 4.** *Let  $H$  be a plane multigraph without loops, let  $f$  be a quadrangle of  $H$ , and let  $\langle z_0, z_1, z_2, z_3 \rangle$  be the facial cycle of  $f$ . If  $z_i = z_{i+2}$  (addition modulo 4) for some  $i$ , then  $z_{i+1} \neq z_{i+3}$ , and there is no face  $f' \neq f$  that contains  $z_{i+1}$  and  $z_{i+3}$ .*

16:6 Partitioning the Edges of a 1-Planar Graph

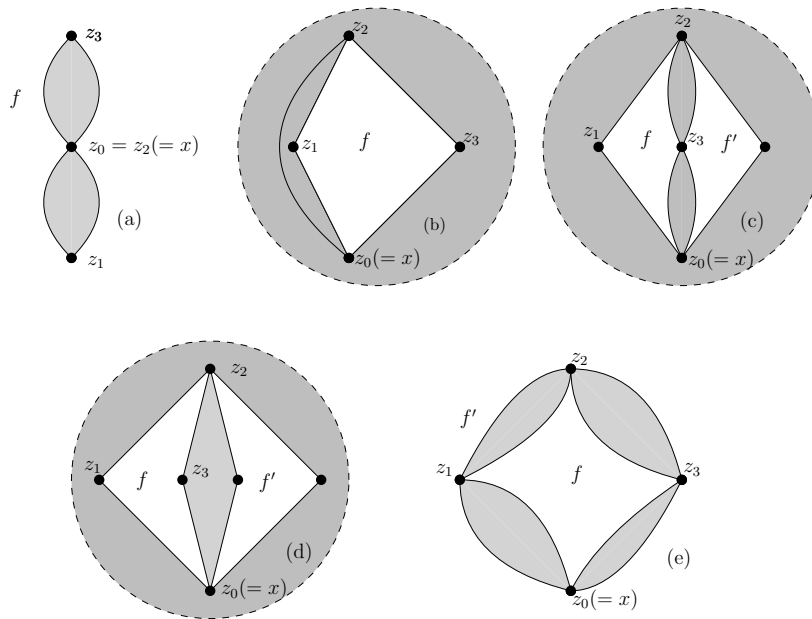

**Proof.** Up to renaming, we may assume that  $i = 0$ , so  $z_0 = z_2$  (see Figure 1(a)). Assume for contradiction that  $z_1 = z_3$ . Then  $f$  consists of several parallel edges between  $z_0 = z_2$  and  $z_1 = z_3$ , and thus  $f$  is not a quadrangle.

Assume by way of contradiction that there is some face  $f' \neq f$  which contains  $z_1$  and  $z_3$ . Subdivide one of the  $z_0z_3$  edges to obtain a new vertex  $y$  adjacent to  $z_0$  and  $z_3$ , and further add an edge  $yz_1$  within  $f$ . We have split  $f$  and attained a simple quadrangle  $f''$  with facial cycle  $\langle z_0, z_1, y, z_3 \rangle$ . Stellate  $f''$  with a new vertex  $c$ , and add an edge  $z_1z_3$  through the face  $f'$ . All these steps maintain the planarity of  $H$ . Moreover, the five vertices  $z_0, z_1, y, z_3, c$  are pairwise adjacent. But this forms a  $K_5$  which is not planar, a contradiction. ◀

The following lemma was shown (without being stated explicitly) in Case 3 of Ackerman’s proof.

► **Lemma 5.** *Let  $H$  be a plane multigraph without loops, let  $f$  be a quadrangle of  $H$ , and let  $\langle z_0, z_1, z_2, z_3 \rangle$  be the facial cycle of  $f$ . If  $z_i$  and  $z_{i+2}$  (addition modulo 4) are both on some face  $f' \neq f$  for some  $i$ , then no face  $f'' \neq f, f'$  contains both  $z_{i+1}$  and  $z_{i+3}$ .*

**Proof.** Up to renaming we may assume that  $i = 0$ , so  $z_0$  and  $z_2$  are on  $f$  and  $f'$  (see Figure 1(b-e)). Suppose for contradiction that such a face  $f''$  exists. By Lemma 4,  $z_1 \neq z_3$  and  $z_0 \neq z_2$ . Stellate  $f$  with a new vertex  $c$ , add an edge  $z_0z_2$  through  $f'$ , and add an edge  $z_1z_3$  through  $f''$ . The original multigraph  $H$  was planar, and all of these operations preserve planarity. However, the five vertices  $z_0, z_1, z_2, z_3$ , and  $c$  are pairwise adjacent and form a  $K_5$ , which is not planar, a contradiction. ◀

■ **Figure 1** Some configurations where we contract  $z_1$  and  $z_3$ .

Now we reprove the existence of quadrangle-chords that form a forest.

► **Theorem 6.** *Let  $H$  be a plane multigraph without loops such that every face has degree at most 4. Then it is possible to add a chord to every quadrangle of  $H$  such that the graph induced by the chords is a forest. Moreover, for all pairs of adjacent vertices  $a$  and  $b$  of  $H$ , there is no path from  $a$  to  $b$  in the chords.*

**Proof.** As in Ackerman’s proof, we prove the claim by induction on the number of quadrangles in  $H$  and remove each quadrangle by contracting an opposing pair of vertices in the quadrangle. If  $H$  has no quadrangles, the claim is trivial. Otherwise, there are quadrangles left. Pick an arbitrary vertex  $x$  that is still incident to some quadrangles (later in our algorithm we will deal with all its incident quadrangles). Let  $f$  be one of its incident quadrangles with facial cycle  $\langle x = z_0, z_1, z_2, z_3 \rangle$ . We first pick two opposing vertices of  $f$  to contract.

**Case 1.** This case covers when we choose to contract  $z_1$  and  $z_3$ , and has three sub-cases. We contract  $z_1$  and  $z_3$  whenever

**Case 1.a**  $x = z_2$  are the same vertex, or

**Case 1.b**  $x$  and  $z_2$  are adjacent, or

**Case 1.c**  $x$  and  $z_2$  are opposing vertices of some quadrangle  $f' \neq f$ .<sup>1</sup>

Figure 1 illustrates possible configurations of face  $f$  where Case 1 applies: Case 1.a applies to (a), Case 1.b applies to (b), and Case 1.c applies to (c,d,e). Note that Case 1.c covers Case 3 of Ackerman’s proof, where  $x, z_1, z_2, z_3$  all belong to two simple quadrangles  $f, f'$  (see also Figure 1(e)). Our contraction turns  $f'$  into a non-simple quadrangle, but our proof can handle this.

**Case 2.** Otherwise, we contract  $x$  and  $z_2$ .

Table 1 demonstrates when we pick Case 1 and when we pick Case 2, and crucially shows cases which are impossible by Lemmas 4 and 5. To see that these lemmas apply in the second row and column, observe that adjacent vertices always share at least one face, and in particular if two opposing vertices are adjacent then they must share two faces other than the quadrangle they are opposing in.

■ **Table 1** All possible cases for the quadrangle  $f$  with facial cycle  $\langle x, z_1, z_2, z_3 \rangle$ . We either indicate which case in the proof of Theorem 6 would be chosen, or indicate the lemma that demonstrates that this case is impossible.

	$x = z_2$	$x \neq z_2;$ $(x, z_2) \in E(H)$	$x \neq z_2;$ $x, z_2$ are opposing in $f'$	Otherwise
$z_1 = z_3$	Impossible (Lemma 4)	Impossible (Lemma 4)	Impossible (Lemma 4)	Case 2
$z_1 \neq z_3;$ $(z_1, z_3) \in E(H)$	Impossible (Lemma 4)	Impossible (Lemma 5)	Impossible (Lemma 5)	Case 2
$z_1 \neq z_3;$ $z_1, z_3$ are opposing in $f''$	Impossible (Lemma 4)	Impossible (Lemma 5)	Impossible if $f' \neq f''$ (Lemma 5), Case 1.c otherwise	Case 2
Otherwise	Case 1.a	Case 1.b	Case 1.c	Case 2

Let  $z_i, z_{i+2}$  be two vertices chosen for contraction and let  $H'$  be the graph resulting from contracting  $z_i$  and  $z_{i+2}$ . By Table 1,  $z_i$  and  $z_{i+2}$  are not adjacent, and they are distinct. Therefore our contraction has destroyed the quadrangle  $f$  and not added any loops, so we can apply induction on  $H'$ . Let  $C'$  be the set of chords added to  $H'$ . By the inductive

<sup>1</sup> In fact, our proof does not require Case 1.c to be separated out; we could equally have contracted  $x$  and  $z_2$  in this case.

## 16:8 Partitioning the Edges of a 1-Planar Graph

hypothesis,  $C'$  induces a forest and for any edge  $ab \in H'$ , there is no path from  $a$  to  $b$  in  $C'$ . Uncontract  $z_i$  and  $z_{i+2}$ , and add a chord  $e := z_i z_{i+2}$  between them. Define  $C := C' \cup \{e\}$ . We now verify that  $C$  satisfies all conditions.

Let  $a, b$  be a pair of adjacent vertices of  $H$ . Assume by way of contradiction that there is a path from  $a$  to  $b$  in  $C$ . By the inductive hypothesis, the path must use  $e$ . Furthermore,  $e$  cannot be the edge  $ab$  since  $z_i$  and  $z_{i+2}$  are not adjacent, so the path must use some edges from  $C'$ . Let  $c_1, \dots, c_{k_1}, e, c_{k_1+1}, \dots, c_{k_2}$  be the edges on this path,  $k_2 \geq 1$ . But then  $c_1, \dots, c_{k_2}$  would be a path from  $a$  to  $b$  within  $C'$  in  $H' = H/e$ , a contradiction.

Assume by way of contradiction that  $C$  induces a cycle in  $H$ . Since  $e$  is not a loop in  $H$ , the cycle must use edges from  $C'$ . Let  $e, c_1, \dots, c_k$  be the cycle,  $k \geq 2$ . Then  $c_1, \dots, c_k$  would induce a cycle within  $C'$  in  $H' = H/e$ , a contradiction. ◀

### 4 Efficient Implementation

It is still not immediately clear how one would implement the above theorem in order to achieve linear runtime, since as in Ackerman's proof we need to repeatedly test how many quadrangles two vertices share. However, if we are more careful about the order in which we contract each quadrangle, an efficient implementation can be achieved. The crucial idea will be to pick some vertex  $x$  and contract all quadrangles incident to  $x$ . This will allow us to store additional information relative to  $x$  and hence speed up testing which case applies. We note that this idea alone would not suffice to make Ackerman's proof run in linear time, as one would still need to find a way to implement Case 3 (where he splits the graph into four subgraphs and determines which subgraph contains a given pair of vertices) of Ackerman's proof efficiently.

#### 4.1 Data Structure Interface

As mentioned earlier, one of the major ingredients to achieve fast run-time is to use the data structure by Holm et al. [14] for contraction in planar graphs, but we will also provide a (simpler but slower) alternative. We will discuss these later (in Subsection 4.4) when we analyze the run-time, but note here the two operations provided by [14] that will be needed:

- $x = \text{contract}(e)$  takes a reference to an edge  $e$ , contracts  $e$ , and returns the vertex resulting from the contraction.

Note that contracting  $e$  creates a loop in the graph, especially if there are multiple copies of this edge, while the proof of Theorem 6 assumed that the graph has no loops. We could remove loops (the data structure by Holm et al. can report newly created loops after `contract`), but this turns out to be unnecessary: We will only contract edges at artificial gadgets inserted into the graph, and the created loops are at quadrangles that are destroyed afterwards and those will not pose problems.

- $\text{neighbors}(x)$  returns an iterator over  $\{\langle xv, v \rangle : xv \in E\}$  where  $E$  is the edge set of the graph. In other words, it returns an iterator to tuples containing each edge incident to  $x$  and the endpoint of this edge. No guarantee is given as to the order of the neighbors.

We assume that  $\text{neighbors}(x)$  has  $O(1)$  runtime and that the returned list can be iterated over in  $O(d(x))$  time (recall that  $d(x)$  denotes the number of edges incident to  $x$ ). Since edge-contraction can create parallel edges, it is possible that  $\text{neighbors}(x)$  contains parallel edges, and hence the second element of the tuple need not be unique. Again this will not pose problems later.

In Subsection 4.2, we will add labels and other meta-data to vertices of our graph. We make no assumptions as to how the meta-data are updated when two vertices are contracted, and so we will maintain those manually.

## 4.2 Preprocessing

We take as input a 1-planar graph  $G$ , given by specifying its planarization via the rotational clockwise order of edges at the vertices, and assuming that vertices of the planarization resulting from crossing points are marked as such.  $G$  need not be simple, but we assume that it has no loops (they can always be added to the planar part) and for ease of stating bounds we assume that it has  $O(n)$  edges. From  $G$ , we can construct a planar-maximal supergraph  $G^+$  in linear time [2], and along the way construct the planarization  $(G^+)^{\times}$  of  $G^+$ . As before we use  $H$  to denote the skeleton of  $G^+$ , but we do not construct it explicitly. Instead, notice that the vertices of  $(G^+)^{\times}$  marked as crossings correspond uniquely to the quadrangles of  $H$ . For this reason, we assume that these vertices are marked with a label *quad* and we call such a vertex a *quadrangle-vertex* (whereas the corresponding face of  $H$  is called a *quadrangle-face*).

Our proof of Theorem 6 relies heavily on having faces, while the data structure of Holm et al. makes no provisions for accessing faces. For this reason, we keep the quadrangle-vertices in the graph as representatives of the quadrangle-faces. This will make it possible to implement the operation of “contract  $z_i$  and  $z_{i+2}$  within quadrangle  $f$ ” used in Theorem 6 via edge-contractions at the corresponding quadrangle-vertex  $f$ . (See Procedure 1 for details.) We also assume that any quadrangle-vertex  $f$  has references to the two original edges in  $G$  that crossed; when doing such a contraction within  $f$  we can hence also record the corresponding edge  $z_i z_{i+2}$  for inclusion in the forest-part of the partition.

### ■ Procedure 1 ContractThrough( $u, v, f$ ).

---

**Result:** Contract two vertices  $u$  and  $v$  in  $H$  through a quadrangle-face  $f$ , and return the resulting vertex  $y$ .

// pre:  $f$  is labelled *quad*

// pre:  $u$  and  $v$  are opposing on face of  $H$  corresponding to  $f$

Find the original edge  $uv$  of  $G$  that is stored with  $f$ .

Record edge  $uv$  as belonging to the forest of the partition.

**for**  $\langle e, w \rangle$  **in** neighbors( $f$ ) **do**

**if**  $v$  equals  $w$  **or**  $v$  equals  $u$  **or**  $w$  has label  $quad_i$  for some  $0 \leq i \leq 3$  **then**  
    |  $y := \text{contract}(e)$

Remove labels  $quad, quad_i$  from  $y$

**return**  $y$

---

Our proof of Theorem 6 also requires knowing the order of vertices along a quadrangle, and the data structures do not support this directly. Therefore at any quadrangle-vertex  $f$  we stellate each of the four incident triangular faces; see Figure 2. Since we have not yet contracted any edges, we have access to the rotational clockwise order of edges at  $f$ ; we can hence label the added vertices with  $quad_i$  (for  $0 \leq i \leq 3$ ) in clockwise order around  $f$ . With this, we can retrieve the clockwise order  $\langle z_0, \dots, z_3 \rangle$  of vertices on the quadrangle-face corresponding to  $f$  in constant time. (See Procedure 2 for details.)

We use  $H^{\diamond}$  for the graph that results after all these modifications (it can be viewed as the planar skeleton  $H$  with a “diamond”-gadget inserted into each quadrangle-face). We also add the following meta-data to each vertex of  $H^{\diamond}$ :

- A boolean `adj`, initialized to **false**.
- A boolean `in_worklist`, initialized to **false**.
- An integer `opposing`, initialized to 0.

## 16:10 Partitioning the Edges of a 1-Planar Graph

### ■ Procedure 2 FacialCycle( $f$ ).

---

```
Result: Reconstruct the facial circuit of a quadrangle-face, given the corresponding
quadrangle-vertex.
// pre:  $f$  is a vertex of  $H^\diamond$  with label  $quad$ 
for vertex  $v$  in neighbors( $f$ ) do
  | for  $i = 0, \dots, 3$  do
  | | if  $v$  has label  $quad_i$  then  $f_i := v$ 
// By construction  $f_i$  has neighbours  $\{z_{i-1}, z_i, f\}$  (indices are mod 4)
for  $i = 0, \dots, 3$  do
  |  $N_i :=$  neighbors( $f_i$ )  $\cap$  neighbors( $f_{i+1}$ )
  | if  $|N_i|$  equals 2 then  $z_i := N_i \setminus \{f\}$ 
// If  $f$  is not simple then  $|N_i| = 3$  for two values of  $i$ , see Fig.2.
  | But then  $z_i$  is determined since we know  $z_{i-1} = z_{i+1}$  already
for  $i = 0, \dots, 3$  do
  | if  $|N_i|$  equals 3 then  $z_i := N_i \setminus N_{i+2}$ 
return  $\langle z_0, z_1, z_2, z_3 \rangle$ 
```

---

The main idea of our algorithm is to iteratively contract all the quadrangles incident to some vertex  $x$ . As we do this, we will use `adj` to mark vertices that are adjacent to  $x$ , `in_worklist` to mark unprocessed quadrangles incident to  $x$ , and `opposing` to keep track of the number of quadrangle-faces where vertex  $y$  is the opposing vertex of  $x$ .

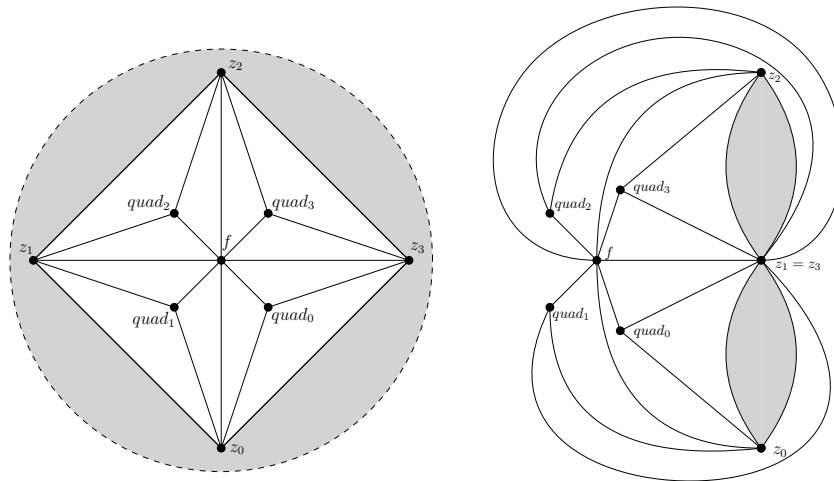

Since  $G$  has  $O(n)$  edges,  $H$  has  $O(n)$  faces, so  $H^\diamond$  has  $O(n)$  edges. All steps in this preprocessing can hence be done in linear time.

### 4.3 Handling the Quadrangles around a Vertex

The main subroutine of our algorithm handles all quadrangles incident to some vertex  $x$  by contracting each of them using the criteria laid out in Theorem 6 to decide which vertices to contract. To do so, we will initialize and maintain a work-list of faces incident to  $x$  that we need to contract (using `in_worklist` to avoid putting duplicate quadrangles into the worklist). We also mark vertices in  $H^\diamond$  as `opposing` and `adj` to  $x$  as needed; this can be done in  $O(d(x))$  time by retrieving all neighbours of  $x$  via `neighbours`. (See Procedure 3 for details.)

Now we iteratively contract all the faces in the worklist according to Theorem 6; with `adj` and `opposing` we can determine the correct case in constant time. (See Procedure 4 for details.) In Case 1, we need to update some values of `opposing`: the vertex  $z_2$  which was opposing  $x$  now no longer opposes  $x$  in  $f$  (since  $f$  was destroyed), so we decrement  $z_2$ .`opposing`. Likewise the new vertex  $v$  resulting from the contraction will be opposing  $x$  in all those quadrangles in which  $z_1$  and  $z_3$  previously opposed  $x$ , so we set  $v$ .`opposing` correspondingly. In Case 2, when we contract some vertex  $z_2$  into  $x$ , we need to add the quadrangles incident to  $z_2$  to our worklist, for which we can re-use Procedure 3.

Lastly, once our worklist is empty (and hence there are no more quadrangles incident to  $x$ ), we reset the meta-data of  $x$  and its neighbors, so that when repeating the procedure with a different vertex as  $x$  there are no stray vertices with meta-data set to erroneous values. (See Procedure 5.)

■ **Figure 2** The gadget added to every quadrangle of  $H$ , shown for both a quadrangle with four vertices on its boundary (left) and one with three vertices on its boundary (right).

■ **Procedure 3** `InitializeAtOneVertex( $y$ ,  $worklist$ )`.

---

**Result:** Adds all quadrangle-vertices incident to a vertex  $y$  to a worklist, taking care not to put duplicates in the worklist.

// pre:  $y$  is a vertex of  $H$

// pre:  $y$  equals  $x$  (the vertex we currently work on), or  $y$  will be contracted into  $x$

**for** vertex  $v \in \text{neighbors}(y)$  **do**

$v.\text{adj} := \text{true}$

**if**  $v$  has label *quad* **and not**  $v.\text{in\_worklist}$  **then**

$v.\text{in\_worklist} := \text{true}$

$\text{worklist.push}(v)$

$\langle z_0, z_1, z_2, z_3 \rangle := \text{FacialCycle}(v)$

relabel  $z_i$  such that  $y$  equals  $z_0$

$z_2.\text{opposing} += 1$

## 4.4 Putting it All Together

The following summarizes our algorithm: after preprocessing, and for as long as there is a quadrangle-face  $f$  left, process all quadrangles at a vertex  $x$  on  $f$  and record all edges that belong to the forest along the way. See Procedure 6 for a detailed description.

It remains to analyze the run-time. For now, we ignore the time required to perform the contractions and analyze the time for handling all quadrangles at one vertex  $x$ . Initialization takes  $O(d(x))$  time, and most other steps take constant time per handled quadrangle, with one notable exception: When we contract some vertex  $z_2$  into  $x$ , we must update the worklist, which takes time  $O(d(z_2))$ . Complicating matters further,  $z_2$  may actually be the result of prior contractions, so its degree may be more than what it was in  $H^\diamond$ , and we must ensure that degrees of vertices are not counted repeatedly.

To handle this, let  $H_f^\diamond$  be the graph that results from  $H^\diamond$  after *all* quadrangle-vertices have been contracted, and let  $s(x)$  be the set of vertices that were contracted into  $x$ , either directly (when handling the quadrangles at  $x$ ) or indirectly (i.e., if they had been contracted

## 16:12 Partitioning the Edges of a 1-Planar Graph

### ■ Procedure 4 HandleQuadsAtOneVertex( $x$ ).

---

**Result:** Contract all the quadrangle-faces incident to a vertex  $x$

```

worklist := []
InitializeAtOneVertex(x, worklist) // see Proc. 3
for quadrangle-vertex f in worklist do
    ⟨z0, z1, z2, z3⟩ := FacialCycle(f) // see Proc. 2
    relabel zi such that x equals z0
    if z2 equals x or z2.adj is true or z2.opposing ≥ 2 then // Case 1
        opposing1 := z1.opposing
        opposing3 := z3.opposing
        v := ContractThrough(z1, z3, f) // see Proc. 1
        v.adj := true
        v.opposing := opposing1 + opposing3
        z2.opposing -= 1
    else // Case 2
        InitializeAtOneVertex(z2, worklist)
        x := ContractThrough(x, z2, f)
CleanupAtOneVertex(x) // see Proc. 5

```

---

### ■ Procedure 5 CleanupAtOneVertex( $y$ ).

---

**Result:** Cleanup the metadata at a vertex  $y$  and its neighbors.

// pre:  $y$  is a vertex of  $H$

```

for vertex v ∈ neighbors(y) ∪ {y} do
    v.adj := false
    v.in_worklist := false
    v.opposing := 0

```

---

### ■ Procedure 6 FindPGFPartition( $G$ ).

---

**Result:** Find a PGF-partition of a graph  $G$ .

Add edges to make  $G$  planar maximal 1-planar

Compute planarization  $G^\times$ , mark vertices of crossings with *quad*

```

foreach vertex f marked quad do
    Insert four vertices in four incident faces of f
    Mark these vertices with quad0, ..., quad3 according to embedding
while there remains a vertex f labeled quad do
    x := some neighbor of f not labeled quadi
    HandleQuadsAtOneVertex(x)

```

Return all edges that were recorded as forest  $F$  and  $G \setminus F$  as planar graph

---

into one of the vertices  $z_2$  that later get contracted into  $x$ ). Crucially, note that if  $x, x'$  are two vertices that are parameters during a call to Procedure 4 (i.e., we contract all quadrangles incident to the vertex), then  $s(x)$  and  $s(x')$  are disjoint. This holds because once we are done with the first of them (say  $x$ ), all vertices in  $s(x)$  have been combined with  $x$  and no longer have any incident quadrangles. Since we only contract vertices into  $x'$  that are incident to quadrangles, none of the vertices in  $s(x)$  becomes part of  $s(x')$ .

Hence for each vertex  $x$  of  $H_f^\diamond$ , the amount of work done in Procedure 4 is proportional to the sum of the degrees  $d_{H^\diamond}(y)$  for each  $y \in s(x)$ . Since  $H^\diamond$  has  $O(n)$  edges, and all other parts of the algorithm take constant time per quadrangle-vertex, the total amount of work done is at most

$$O\left(\sum_{x \in V(H_f^\diamond)} \sum_{y \in s(x)} d_{H^\diamond}(y)\right) = O\left(\sum_{x \in V(H^\diamond)} d_{H^\diamond}(x)\right) = O(|V(H^\diamond)|) = O(|V(G)|)$$

hence the algorithm is linear (ignoring the time for contractions).

Now we consider the run-time of possible data structures for contractions. Our first approach is to represent the graph with incidence lists, where every vertex has a list of incident edges, each edge knows both of its endpoints, and every list knows its length. We can implement `neighbors(x)` in constant time by simply returning an iterator to the incidence list at  $x$ . Contracting two vertices  $u$  and  $v$  can be done in  $O(\min\{d(u), d(v)\})$  time by re-attaching the edges of the vertex with smaller degree to the vertex with larger degree. As with UNION-FIND data structures implemented with linked lists (see e.g. Section 4.6 of [17]), one shows that the amortized time for this is  $O(\log n)$  per contraction. In particular, for graphs with linearly many edges, a set of  $\Theta(n)$  contractions can be done in  $O(n \log n)$  time. With this we have our first result.

► **Theorem 7.** *Let  $G$  be a 1-planar graph implemented with incidence lists and given with a 1-planar embedding. It is possible to find a PGF-partition of  $G$  in  $O(n \log n)$  time.*

To improve this runtime, we appeal to the following result by Holm et al.

► **Theorem 8** (Holm et al. [14]). *Let  $G$  be a planar graph with  $n$  vertices and  $m$  edges. Then there exists a data structure that supports `contract` and `neighbors` and that can be initialized in  $O(n + m)$  time. Any calls to `neighbors` can be processed in worst case constant time, and any sequence of calls to `contract` can be performed in time  $O(n + m)$ .*

Since our graph has  $O(n)$  edges, we have the main result of this paper.

► **Theorem 9.** *Let  $G$  be a 1-planar graph with a given 1-planar embedding. Then in  $O(n)$  time we can find an edge-partition of  $G$  into a forest and a planar graph.*

## 5 Conclusion

In this paper, we reproved a result from Ackerman that all 1-planar graphs admit a partition into a planar graph and a forest. Our proof is more general than Ackerman's: the forest we find is guaranteed to not contain a path between adjacent vertices of the input graph. Using this proof and a data structure from Holm et al. for efficiently contracting the edges of a planar graph, we were able to find this partition in linear time. In consequence, a number of results for 1-planar graphs (such as splitting into 4 forests or 4-list-coloring if the graph is bipartite) can now be achieved in linear time. We also showed that the same algorithm can be implemented in  $O(n \log n)$  time with a simpler data structure that uses only incidence lists.

As for open problems, the most interesting one is whether the partition could be found even *without* being given the 1-planar drawing. (Recall that it is NP-hard to find such a drawing [12], though it is polynomial for optimal 1-planar graphs [7].) All papers listed in the introduction for finding various edge partitions of 1-planar graphs require such an embedding. If this is difficult, could we at least do some of the implications (such as splitting into 4 forests or orienting such that all in-degrees are at most 4) in linear time without a given 1-planar drawing?

## Abstract

Given a digraph  $G$ , a set  $X \subseteq V(G)$  is said to be an *absorbing set* (resp. *dominating set*) if every vertex in the graph is either in  $X$  or is an in-neighbour (resp. out-neighbour) of a vertex in  $X$ . A set  $S \subseteq V(G)$  is said to be an *independent set* if no two vertices in  $S$  are adjacent in  $G$ . A kernel (resp. solution) of  $G$  is an independent and absorbing (resp. dominating) set in  $G$ . The problem of deciding if there is a kernel (or solution) in an input digraph is known to be NP-complete. Similarly, the problems of computing a minimum cardinality kernel, absorbing set (or dominating set) and the problems of computing a maximum cardinality kernel, independent set are all known to be NP-hard for general digraphs. We explore the algorithmic complexity of these problems in the well known class of *interval digraphs*. A digraph  $G$  is an interval digraph if a pair of intervals  $(S_u, T_u)$  can be assigned to each vertex  $u$  of  $G$  such that  $(u, v) \in E(G)$  if and only if  $S_u \cap T_v \neq \emptyset$ . Many different subclasses of interval digraphs have been defined and studied in the literature by restricting the kinds of pairs of intervals that can be assigned to the vertices. We observe that several of these classes, like interval catch digraphs, interval nest digraphs, adjusted interval digraphs and chronological interval digraphs, are subclasses of the more general class of *reflexive interval digraphs* – which arise when we require that the two intervals assigned to a vertex have to intersect. We see as our main contribution the identification of the class of reflexive interval digraphs as an important class of digraphs. We show that all the problems mentioned above are efficiently solvable, in most of the cases even linear-time solvable, in the class of reflexive interval digraphs, but are APX-hard on even the very restricted class of interval digraphs called *point-point digraphs*, where the two intervals assigned to each vertex are required to be degenerate, i.e. they consist of a single point each. The results we obtain improve and generalize several existing algorithms and structural results for reflexive interval digraphs. We also obtain some new results for undirected graphs along the way: (a) We get an  $O(n(n+m))$  time algorithm for computing a minimum cardinality (undirected) independent dominating set in cocomparability graphs, which slightly improves the existing  $O(n^3)$  time algorithm for the same problem by Kratsch and Stewart; and (b) We show that the RED BLUE DOMINATING SET problem, which is NP-complete even for planar bipartite graphs, is linear-time solvable on *interval bigraphs*, which is a class of bipartite (undirected) graphs closely related to interval digraphs.

## 1 Introduction

Let  $H = (V, E)$  be an undirected graph. A set  $S \subseteq V(H)$  is said to be an *independent set* in  $H$  if for any two vertices  $u, v \in S$ ,  $uv \notin E(H)$ . A set  $S \subseteq V(H)$  is said to be a *dominating set* in  $H$  if for any  $v \in V(H) \setminus S$ , there exists  $u \in S$  such that  $uv \in E(H)$ . A set  $S \subseteq V(H)$  is said to be an *independent dominating set* in  $H$  if  $S$  is dominating as well as independent. Note that any maximal independent set in  $H$  is an independent dominating set in  $H$ , and therefore every undirected graph contains an independent dominating set, which implies that the problem of deciding whether an input undirected graph contains an independent dominating set is trivial. On the other hand, finding an independent dominating set of *maximum cardinality* is NP-complete for general graphs, since independent dominating sets of maximum cardinality are exactly the independent sets of maximum cardinality in the graph. The problem of finding a minimum cardinality independent dominating set is also NP-complete for general graphs [12] and also in many special graph classes (refer [18] for a survey). We study the directed analogues of these problems, which are also well-studied in the literature.

Let  $G = (V, E)$  be a directed graph. A set  $S \subseteq V(G)$  is said to be an *independent set* in  $G$ , if for any two vertices  $u, v \in S$ ,  $(u, v), (v, u) \notin E(G)$ . A set  $S \subseteq V(G)$  is said to be an *absorbing (resp. dominating) set* in  $G$ , if for any  $v \in V(G) \setminus S$ , there exists  $u \in S$  such that  $(v, u) \in E(G)$  (resp.  $(u, v) \in E(G)$ ). As any set of vertices that consists of a single vertex is independent and the whole set  $V(G)$  is absorbing as well as dominating, the interesting computational problems that arise here are that of finding a maximum independent set, called INDEPENDENT-SET, and that of finding a minimum absorbing (resp. dominating) set in  $G$ , called ABSORBING-SET (resp. DOMINATING-SET). A set  $S \subseteq V(G)$  is said to be an *independent dominating (resp. absorbing) set* if  $S$  is both independent and dominating (resp. absorbing). Note that unlike undirected graphs, the problem of finding a maximum cardinality independent dominating (resp. absorbing) set is different from the problem of finding a maximum cardinality independent set for directed graphs.

Given a digraph  $G$ , a collection  $\{(S_u, T_u)\}_{u \in V(G)}$  of pairs of intervals is said to be an *interval representation* of  $G$  if  $(u, v) \in E(G)$  if and only if  $S_u \cap T_v \neq \emptyset$ . A digraph  $G$  that has an interval representation is called an *interval digraph* [6]. We consider a loop to be present on a vertex  $u$  of an interval digraph if and only if  $S_u \cap T_u \neq \emptyset$ . An interval digraph is a *reflexive interval digraph* if there is a loop on every vertex. Let  $G$  be a digraph. If there exists an interval representation of  $G$  such that  $T_u \subseteq S_u$  for each vertex  $u \in V(G)$  then  $G$  is called an *interval nest digraph* [26]. If  $G$  has an interval representation in which intervals  $S_u$  and  $T_u$  for each vertex  $u \in V(G)$  are required to have a common left end-point, the interval digraphs that arise are called *adjusted interval digraphs* [9]. Note that the class of reflexive interval digraphs is a superclass of both interval nest digraphs and adjusted interval digraphs. Another class of interval digraphs, called *interval-point digraphs* arises when the interval  $T_u$  for each vertex  $u$  is required to be degenerate (it is a point) [6]. Note that interval-point digraphs may not be reflexive. We call a digraph  $G$  a *point-point digraph* if there is an interval representation of  $G$  in which both  $S_u$  and  $T_u$  are degenerate intervals for each vertex  $u$ . Clearly, point-point digraphs form a subclass of interval-point digraphs and they are also not necessarily reflexive.

In this paper, we show that the reflexivity of an interval digraph has a huge impact on the algorithmic complexity of several problems related to domination and independent sets in digraphs. In particular, we show that all the problems we study are efficiently solvable on reflexive interval digraphs, but are NP-complete and/or APX-hard even on point-point digraphs. Along the way we obtain new characterizations of both these graph classes, which reveal some of the properties of these digraphs.

An undirected graph is a *comparability* graph if its edges can be oriented in such a way that it becomes a partial order. The complements of comparability graphs are called *cocomparability graphs*.

**Our results.** We provide a vertex-ordering characterization for reflexive interval digraphs and two simple characterizations for point-point digraphs including a forbidden structure characterization. Our characterization of point-point digraphs directly yields a linear time recognition algorithm for that class of digraphs (note that Müller's [22] recognition algorithm for interval digraphs directly gives a polynomial-time recognition algorithm for reflexive interval digraphs). From our vertex-ordering characterization of reflexive interval digraphs, it follows that the underlying undirected graphs of every reflexive interval digraph is a cocomparability graph. Also a natural question that arises here is whether the underlying graphs of reflexive interval digraphs is the same as the class of cocomparability graphs. We show that this is not the case by demonstrating that the underlying graphs of reflexive interval digraphs cannot contain an induced  $K_{3,3}$ . This can be used to strengthen a result of Prisner [26] about interval nest digraphs: our results imply that the underlying undirected graphs of interval nest digraphs and their reversals are  $K_{3,3}$ -free weakly triangulated cocomparability graphs. Also, as the INDEPENDENT SET problem is linear time solvable on cocomparability graphs [19], the problem is also linear time solvable on reflexive interval digraphs. This improves and generalizes the  $O(nm)$ -time algorithm for the same problem on interval nest digraphs. In contrast, we prove that the INDEPENDENT SET problem is APX-hard for point-point digraphs.

Domination in digraphs is a topic that has been explored less when compared to its undirected counterpart. Even though bounds on the minimum dominating sets in digraphs have been obtained by several authors (see the book [13] for a survey), not much is known about the computational complexity of finding a minimum cardinality absorbing set (or dominating set) in directed graphs. Even for tournaments, the best known algorithm for DOMINATING-SET does not run in polynomial-time [20, 27]. In [20], the authors give an  $n^{O(\log n)}$  time algorithm for the DOMINATING-SET problem in tournaments and they also note that SAT can be solved in  $2^{O(\sqrt{v})}n^K$  time (where  $v$  is the number of variables,  $n$  is the length of the formula and  $K$  is a constant) if and only if the DOMINATING-SET in a tournament can be solved in polynomial time. Thus, determining the algorithmic complexity of the DOMINATING-SET problem even in special classes of digraphs seems to be much more challenging than the algorithmic question of finding a minimum cardinality dominating set in undirected graphs.

For a bipartite graph having two specified partite sets  $A$  and  $B$ , a set  $S \subseteq B$  such that  $\bigcup_{u \in B} N(u) = A$  is called an *A-dominating set*. Note that the graph does not contain an  $A$ -dominating set if and only if there are isolated vertices in  $A$ . The problem of finding an  $A$ -dominating set of minimum cardinality in a bipartite graph with partite sets  $A$  and  $B$  is more well-known as the RED-BLUE DOMINATING SET problem, which was introduced for the first time in the context of the European railroad network [30] and plays an important role in the theory of fixed parameter tractable algorithms [7]. This problem is equivalent to the well known SET COVER and HITTING SET problems [12] and therefore, it is NP-complete for general bipartite graphs. The problem remains NP-complete even for planar bipartite graphs [1]. The class of *interval bigraphs* are closely related to the class of interval digraphs. These are undirected bipartite graphs with partite sets  $A$  and  $B$  such that there exists a collection of intervals  $\{S_u\}_{u \in V(G)}$  such that  $uv \in E(G)$  if and only if  $u \in A$ ,  $v \in B$ , and  $S_u \cap S_v \neq \emptyset$ .

**Our results.** We observe that the problem of solving ABSORBING-SET on a reflexive interval digraph  $G$  can be reduced to the problem of solving RED-BLUE DOMINATING SET on an interval bigraph whose interval representation can be constructed from an interval representation of  $G$  in linear time. Further, we show that RED-BLUE DOMINATING SET is linear time solvable on interval bigraphs (given an interval representation). Thus the problem ABSORBING-SET (resp. DOMINATING-SET<sup>1</sup>) is linear-time solvable on reflexive interval digraphs, given an interval representation of the digraph as input. If no interval representation is given, Müller’s algorithm [22] can be used to construct one in polynomial time, and therefore these problems are polynomial time solvable on reflexive interval digraphs even when no interval representation of the input graph is known. In contrast, we prove that the ABSORBING-SET (resp. DOMINATING-SET) problem remains APX-hard even for point-point digraphs.

An independent absorbing set in a directed graph is more well-known as a *kernel* of the graph, a term introduced by Von Neumann and Morgenstern [21] in the context of game theory. They showed that for digraphs associated with certain combinatorial games, the existence of a kernel implies the existence of a winning strategy. Most of the work related to domination in digraphs has been mainly focused on kernels. We follow the terminology in [26] and call an independent dominating set in a directed graph a *solution* of the graph. It is easy to see that a kernel in a directed graph  $G$  is a solution in the directed graph obtained by reversing every arc of  $G$  and vice versa. Note that unlike in the case of undirected graphs, a kernel need not always exist in a directed graph. Therefore, besides the computational problems of finding a minimum or maximum sized kernel, called MIN-KERNEL and MAX-KERNEL respectively, the comparatively easier problem of determining whether a given directed graph has a kernel in the first place, called KERNEL, is itself a non-trivial one. In fact, the KERNEL problem was shown to be NP-complete in general digraphs by Chvátal [4]. Later, Fraenkel [10] proved that the KERNEL problem remains NP-complete even for planar digraphs of degree at most 3 having in- and out-degrees at most 2. It can be easily seen that the MIN-KERNEL and MAX-KERNEL problems are NP-complete for those classes of graphs for which the KERNEL problem is NP-complete. A digraph is said to be *kernel-perfect* if every induced subgraph of it has a kernel. Several sufficient conditions for digraphs to be kernel-perfect has been explored [28, 8, 21]. The KERNEL problem is trivially solvable in polynomial-time on any kernel-perfect family of digraphs. But the algorithmic complexity status of the problem of computing a kernel in a kernel-perfect digraph also seems to be unknown [24]. Prisner [26] proved that interval nest digraphs and their reversals are kernel-perfect, and a kernel can be found in these graphs in time  $O(n^2)$  if a representation of the graph is given. Note that the MIN-KERNEL problem can be shown to be NP-complete even in some kernel-perfect families of digraphs that have polynomial-time computable kernels (see Remark 13).

**Our results.** We show that reflexive interval digraphs are kernel-perfect and hence the KERNEL problem is trivial on this class of digraphs. We construct a linear-time algorithm that computes a kernel in a reflexive interval digraph, given an interval representation of

---

<sup>1</sup> Note that the reversal of a reflexive interval digraphs is also a reflexive interval digraph. It is easy to see that the reversal of any digraph can be constructed in linear time. Moreover, an interval representation of the reversal of a reflexive interval digraph  $G$  can be obtained in linear time given an interval representation of  $G$  (if  $\{(S_u, T_u)\}_{u \in V(G)}$  is the interval representation of  $G$ , then  $\{(T_u, S_u)\}_{u \in V(G)}$  is an interval representation of the reversal of  $G$ ). Therefore, all our results about the KERNEL, MIN-KERNEL, MAX-KERNEL, and ABSORBING-SET problems can be adapted to obtain similar results about the SOLUTION, MIN-SOLUTION, MAX-SOLUTION, and DOMINATING-SET problems.

**Figure 1** Forbidden structures for reflexive interval digraphs (possibly  $b = c$  in (i), (ii), (iv) and (v)). A dashed arc from  $u$  to  $v$  indicates the absence of the edge  $(u, v)$  in the graph.

digraph as an input. This improves and generalizes Prisner’s similar results about interval nest digraphs mentioned above. Moreover, we give an  $O((n + m)n)$  time algorithm for the MIN-KERNEL and MAX-KERNEL problems for a superclass of reflexive interval digraphs. As a consequence, we obtain an improvement over the  $O(n^3)$  time algorithm for finding a minimum independent dominating set in comparability graphs that was given by Kratsch and Stewart [17]. Our algorithms for MIN-KERNEL and MAX-KERNEL problems have a better running time of  $O(n^2)$  for adjusted interval digraphs. On the other hand, we show that even the problem KERNEL is NP-complete for point-point digraphs. Moreover, the MIN-KERNEL and MAX-KERNEL problems are APX-hard on point-point digraphs.

### 1.1 Notation

For a closed interval  $I = [x, y]$  of the real line (here  $x, y \in \mathbb{R}$  and  $x \leq y$ ), we denote by  $l(I)$  the left end-point  $x$  of  $I$  and by  $r(I)$  the right end-point  $y$  of  $I$ . We use the following observation throughout the paper: if  $I$  and  $J$  are two intervals, then  $I \cap J = \emptyset \Leftrightarrow (r(I) < l(J)) \vee (r(J) < l(I))$ .

Let  $G = (V, E)$  be a directed graph. For  $u, v \in V(G)$ , we say that  $u$  is an *in-neighbour* (resp. *out-neighbour*) of  $v$  if  $(u, v) \in E(G)$  (resp.  $(v, u) \in E(G)$ ). For a vertex  $v$  in  $G$ , we denote by  $N_G^+(v)$  and  $N_G^-(v)$  the set of out-neighbours and the set of in-neighbours of the vertex  $v$  in  $G$  respectively. When the graph  $G$  under consideration is clear from the context, we abbreviate  $N_G^+(v)$  and  $N_G^-(v)$  to just  $N^+(v)$  and  $N^-(v)$  respectively.

For  $i, j \in \mathbb{N}$  such that  $i \leq j$ , let  $[i, j]$  denote the set  $\{i, i + 1, \dots, j\}$ . Let  $G$  be a digraph with vertex set  $[1, n]$ . Then for  $i, j \in [1, n]$ , we define  $N_{>j}^+(i) = N^+(i) \cap [j + 1, n]$ ,  $N_{>j}^-(i) = N^-(i) \cap [j + 1, n]$ ,  $N_{<j}^+(i) = N^+(i) \cap [1, j - 1]$ , and  $N_{<j}^-(i) = N^-(i) \cap [1, j - 1]$ . We shorten  $N_{>i}^+(i)$  and  $N_{>i}^-(i)$  to  $N_{>}^+(i)$  and  $N_{>}^-(i)$  respectively. Let  $N_{>}(i) = N_{>}^+(i) \cup N_{>}^-(i)$  and  $\overline{N_{>}}(i) = [i + 1, n] \setminus N_{>}(i)$ .

## 2 Ordering characterization

We first show that a digraph is a reflexive interval digraph if and only if there is a linear ordering of its vertex set such that none of the structures shown in Figure 1 are present.

► **Theorem 1** ( $\star$ ).<sup>2</sup> A digraph  $G$  is a reflexive interval digraph if and only if  $V(G)$  has an ordering  $<$  in which for any  $a, b, c, d \in V(G)$  such that  $a < b < c < d$ , none of the structures in Figure 1 occur ( $b$  and  $c$  can be the same vertex in (i), (ii), (iv), (v) of Figure 1).

Now we define the following.

► **Definition 2** (DUF-ordering). A directed umbrella-free ordering (or in short a DUF-ordering) of a digraph  $G$  is an ordering  $<$  of  $V(G)$  satisfying the following properties for any three distinct vertices  $i < j < k$ :

1. if  $(i, k) \in E(G)$ , then either  $(i, j) \in E(G)$  or  $(j, k) \in E(G)$ , and
2. if  $(k, i) \in E(G)$ , then either  $(k, j) \in E(G)$  or  $(j, i) \in E(G)$ .

► **Definition 3** (DUF-digraph). A digraph  $G$  is a directed umbrella-free digraph (or in short a DUF-digraph) if it has a DUF-ordering.

Then the following corollary is an immediate consequence of Theorem 1.

► **Corollary 4.** Every reflexive interval digraph is a DUF-digraph.

Let  $G$  be an undirected graph. We define the *symmetric digraph* of  $G$  to be the digraph obtained by replacing each edge of  $G$  by symmetric arcs.

The following is a characterization of cocomparability graphs due to Kratsch and Stewart [17].

► **Theorem 5** ([17]). An undirected graph  $G$  is a cocomparability graph if and only if there is an ordering  $<$  of  $V(G)$  such that for any three vertices  $i < j < k$ , if  $ik \in E(G)$ , then either  $ij \in E(G)$  or  $jk \in E(G)$ .

Let  $G$  be a DUF-digraph with a DUF-ordering  $<$ . Let  $H$  be the underlying undirected graph of  $G$ . Clearly,  $<$  is an ordering of  $V(H)$  that satisfies the property given in Theorem 5, implying that  $H$  is a cocomparability graph. Thus we have the following corollary.

► **Corollary 6.** The underlying undirected graph of every DUF-digraph is a cocomparability graph.

Note that there exist digraphs which are not DUF-digraphs but their underlying undirected graphs are cocomparability (for example, a directed triangle with edges  $(a, b)$ ,  $(b, c)$  and  $(c, a)$ ). But we can observe that the class of underlying undirected graphs of DUF-digraphs is precisely the class of cocomparability graphs, since the symmetric digraphs of cocomparability graphs are all DUF-digraphs (for any cocomparability graph  $H$ , a vertex ordering of  $H$  that satisfies the property given in Theorem 5 is also a DUF-ordering of the symmetric digraph of  $H$ ). In contrast, the class of underlying undirected graphs of reflexive interval digraphs forms a strict subclass of cocomparability graphs. We prove this by showing that no directed graph that has  $K_{3,3}$  as its underlying undirected graph can be a reflexive interval digraph ( $K_{3,3}$  can easily be seen to be a cocomparability graph). This would also imply by Corollary 4 that the class of reflexive interval digraphs forms a strict subclass of DUF-digraphs.

► **Theorem 7** ( $\star$ ). The underlying undirected graph of a reflexive interval digraph cannot contain  $K_{3,3}$  as an induced subgraph.

---

<sup>2</sup> The proofs of the statements marked with a  $\star$  are omitted due to space constraints. Refer [11] for the omitted proofs.

Prisner [26] proved that the underlying undirected graphs of interval nest digraphs are weakly triangulated graphs. By Corollaries 4, 6 and Theorem 7, we can conclude that the underlying undirected graphs of reflexive interval digraphs are  $K_{3,3}$ -free cocomparability graphs. This strengthens the result of Prisner, since now we have that the underlying undirected graphs of interval nest digraphs are  $K_{3,3}$ -free weakly triangulated cocomparability graphs.

### 3 Algorithms for reflexive interval digraphs

In this section, we present polynomial-time algorithms for the KERNEL, MIN-KERNEL, MAX-KERNEL, ABSORBING-SET, and INDEPENDENT-SET problems on reflexive interval digraphs.

#### 3.1 Kernel

We use the following result of Prisner that is implied by Theorem 4.2 of [26].

► **Theorem 8** ([26]). *Let  $\mathcal{C}$  be a class of digraphs that is closed under taking induced subgraphs. If in every graph  $G \in \mathcal{C}$ , there exists a vertex  $z$  such that for every  $y \in N^-(z)$ ,  $N^+(z) \setminus N^-(z) \subseteq N^+(y)$ , then the class  $\mathcal{C}$  is kernel-perfect.*

► **Lemma 9** (\*). *Let  $G$  be a reflexive interval digraph  $G$  with interval representation  $\{(S_u, T_u)\}_{u \in V(G)}$ . Let  $z$  be the vertex such that  $r(S_z) = \min\{r(S_v) : v \in V(G)\}$ . Then for every  $y \in N^-(z)$ ,  $N^+(z) \setminus N^-(z) \subseteq N^+(y)$ .*

Since reflexive interval digraphs are closed under taking induced subgraphs, by Theorem 8 and Lemma 9, we have the following.

► **Theorem 10.** *Reflexive interval digraphs are kernel-perfect.*

It follows from the above theorem that the decision problem KERNEL is trivial on reflexive interval digraphs. As explained below, we can also compute a kernel in a reflexive interval digraph efficiently, if an interval representation of the digraph is known.

Let  $G$  be a reflexive interval digraph with an interval representation  $\{(S_u, T_u)\}_{u \in V(G)}$ . Let  $G_0 = G$  and  $z_0$  be the vertex in  $G$  such that  $r(S_{z_0}) = \min\{r(S_v) : v \in V(G)\}$ . For  $i \geq 1$ , recursively define  $G_i$  to be the induced subdigraph of  $G$  with  $V(G_i) = V(G_{i-1}) \setminus (\{z_{i-1}\} \cup N^-(z_{i-1}))$  and if  $V(G_i) \neq \emptyset$ , define  $z_i$  to be the vertex such that  $r(S_{z_i}) = \min\{r(S_v) : v \in V(G_i)\}$ . Let  $t$  be smallest integer such that  $V(G_{t+1}) = \emptyset$ . Note that this implies that  $V(G_t) = \{z_t\} \cup N_{G_t}^-(z_t)$ . Clearly  $t \leq n$  and  $r(S_{z_0}) < r(S_{z_1}) < \dots < r(S_{z_t})$ . By Lemma 9, we have that for each  $i \in \{1, 2, \dots, t\}$ ,  $z_i$  has the following property: for any  $y \in N_{G_i}^-(z_i)$  we have  $N_{G_i}^+(z_i) \setminus N_{G_i}^-(z_i) \subseteq N_{G_i}^+(y)$ .

We now recursively define a set  $K_i \subseteq V(G_i)$  as follows: Define  $K_t = \{z_t\}$ . For each  $i \in \{t-1, t-2, \dots, 0\}$ ,

$$K_i = \begin{cases} \{z_i\} \cup K_{i+1} & \text{if } (z_i, z_j) \notin E(G), \text{ where } j = \min\{l : z_l \in K_{i+1}\} \\ K_{i+1} & \text{otherwise.} \end{cases}$$

► **Lemma 11** (\*). *For each  $i \in \{1, 2, \dots, t\}$ ,  $K_i$  is a kernel of  $G_i$ .*

By the above lemma, we have that  $K_0$  is a kernel of  $G$ . We can now construct an algorithm that computes a kernel in a reflexive interval digraph  $G$ , given an interval representation of it. We assume that the interval representation of  $G$  is given in the form of a list of left and

■ **Figure 2** Example of a DUF-digraph that has no kernel.

right endpoints of intervals corresponding to the vertices. We can process this list from left to right in a single pass to compute the list of vertices  $z_0, z_1, \dots, z_t$  in  $O(n + m)$  time. We then process this new list from right to left in a single pass to generate a set  $K$  as follows: initialize  $K = \{z_t\}$  and for each  $i \in \{t-1, t-2, \dots, 0\}$ , add  $z_i$  to  $K$  if it is not an in-neighbor of the last vertex that was added to  $K$ . Clearly, the set  $K$  can be generated in  $O(n + m)$  time. It is easy to see that  $K = K_0$  and therefore by Lemma 11,  $K$  is a kernel of  $G$ . Thus, we have the following theorem.

► **Theorem 12.** *A kernel of a reflexive interval digraph can be computed in linear-time, given an interval representation of the digraph as input.*

The linear-time algorithm described above is an improvement and generalization of a result of Prisner [26], who showed that interval nest digraphs are kernel-perfect, and a kernel can be found in these graphs in time  $O(n^2)$  if an interval representation of the graph is given.

Now it is interesting to note that even for some kernel perfect digraphs with a polynomial-time computable kernel, the problems MIN-KERNEL and MAX-KERNEL turn out to be NP-complete. The following remark provides an example of such a class of digraphs.

► **Remark 13.** Let  $\mathcal{C}$  be the class of symmetric digraphs of undirected graphs. Note that the class  $\mathcal{C}$  is kernel-perfect, as for any  $G \in \mathcal{C}$  the kernels of the digraph  $G$  are exactly the independent dominating sets of its underlying undirected graph. Note that any maximal independent set of an undirected graph is also an independent dominating set of it. Therefore, as a maximal independent set of any undirected graph can be found in linear-time, the problem KERNEL is linear-time solvable for the class  $\mathcal{C}$ . On the other hand, note that the problems MIN-KERNEL and MAX-KERNEL for the class  $\mathcal{C}$  is equivalent to the problems of finding a minimum cardinality independent dominating set and a maximum cardinality independent set for the class of undirected graphs, respectively. Since the latter problems are NP-complete for the class of undirected graphs, we have that the problems MIN-KERNEL and MAX-KERNEL are NP-complete in  $\mathcal{C}$ .

Note that unlike the class of reflexive interval digraphs, the class of DUF-digraphs are not kernel-perfect. Figure 2 provides an example for a DUF-digraph that has no kernel. Since that graph is a semi-complete digraph (i.e. each pair of vertices is adjacent), and every vertex has an out-neighbor which is not its in-neighbor, it cannot have a kernel. The ordering of the vertices of the graph that is shown in the figure can easily be verified to be a DUF-ordering. In contrast to Remark 13, even though DUF-digraphs may not have kernels, we show in the next section that the problems KERNEL, MIN-KERNEL, and MAX-KERNEL can be solved in polynomial time in the class of DUF-digraphs. In fact we give a polynomial time algorithm that, given a DUF-digraph  $G$  with a DUF-ordering as input, either finds a minimum (or maximum) sized kernel in  $G$  or correctly concludes that  $G$  does not have a kernel.

### 3.2 Minimum sized kernel

Let  $G$  be a DUF-digraph with vertex set  $[1, n]$ . We assume without loss of generality that  $\leq = (1, 2, \dots, n)$  is a DUF-ordering of  $G$ .

For any vertex  $i \in \{1, 2, \dots, n\}$ , let  $P_i = \{j : j \in \overline{N_{>}(i)} \text{ such that } [i+1, j-1] \subseteq N^-(i) \cup N^-(j)\}$  and let  $G[i, n]$  denote the subgraph induced in  $G$  by the set  $[i, n]$ . Note that we consider  $[i+1, j-1] = \emptyset$ , if  $j = i+1$ . For a collection of sets  $\mathcal{S}$ , we denote by  $\text{Min}(\mathcal{S})$  an arbitrarily chosen set in  $\mathcal{S}$  of the smallest cardinality. For each  $i \in \{1, 2, \dots, n\}$ , we define a set  $K(i)$  as follows. Here, when we write  $K(i) = \infty$ , we mean that the set  $K(i)$  is undefined.

$$K(i) = \begin{cases} \{i\}, & \text{if } N_{>}^-(i) = \{i+1, \dots, n\} \\ \{i\} \cup \text{Min}\{K(j) \neq \infty : j \in P_i\}, & \text{if } P_i \neq \emptyset \text{ and } \exists j \in P_i \text{ such that } K(j) \neq \infty \\ \infty, & \text{otherwise} \end{cases}$$

Note that it follows from the above definition that  $K(n) = \{n\}$ . For each  $i \in \{1, 2, \dots, n\}$ , let  $OPT(i)$  denote a minimum sized kernel of  $G[i, n]$  that also contains  $i$ . If  $G[i, n]$  has no kernel that contains  $i$ , then we say that  $OPT(i) = \infty$ . We then have the following lemma.

► **Lemma 14** ( $\star$ ). *The following hold.*

1. *If  $K(i) \neq \infty$ , then  $K(i)$  is a kernel of  $G[i, n]$  that contains  $i$ , and*
2. *if  $OPT(i) \neq \infty$ , then  $K(i) \neq \infty$  and  $|K(i)| = |OPT(i)|$ .*

Suppose that  $G$  has a kernel. Now let  $OPT$  denote a minimum sized kernel in  $G$ . Let  $\mathcal{K} = \{K(j) \neq \infty : [1, j-1] \subseteq N^-(j)\}$ . Note that we consider  $[1, j-1] = \emptyset$  if  $j = 1$ . By Lemma 14(1), it follows that every member of  $\mathcal{K}$  is a kernel of  $G$ . So if  $G$  does not have a kernel, then  $\mathcal{K} = \emptyset$ . The following lemma shows that the converse is also true.

► **Lemma 15** ( $\star$ ). *If  $G$  has a kernel, then  $\mathcal{K} \neq \emptyset$  and  $|OPT| = |\text{Min}(\mathcal{K})|$ .*

We thus have the following theorem.

► **Theorem 16**. *The DUF-digraph  $G$  has a kernel if and only if  $K(j) \neq \infty$  for some  $j$  such that  $[1, j-1] \subseteq N^-(j)$ . Further, if  $G$  has a kernel, then the set  $\{K(j) \neq \infty : [1, j-1] \subseteq N^-(j)\}$  contains a kernel of  $G$  of minimum possible size.*

► **Theorem 17** ( $\star$ ). *The MIN-KERNEL problem can be solved for DUF-digraphs in  $O((n+m)n)$  time if the DUF-ordering is known. Consequently, for a reflexive interval digraph, the MIN-KERNEL problem can be solved in  $O((n+m)n)$  time if the interval representation is given as input.*

► **Corollary 18** ( $\star$ ). *An independent dominating set of minimum possible size can be found in  $O((n+m)n)$  time in cocomparability graphs.*

The above corollary is an improvement over the results of Kratsch and Stewart [17], who proved that an independent dominating set of minimum possible size can be computed in  $O(n^3)$  time in cocomparability graphs.

We now show that a minimum sized kernel of an adjusted interval digraph, whose interval representation is known, can be computed more efficiently than in the case of DUF-digraphs.

► **Corollary 19** ( $\star$ ). *The MIN-KERNEL problem can be solved in adjusted interval digraphs in  $O(n^2)$  time, given an interval representation of the digraph.*

► **Remark 20**. Note that the MAX-KERNEL problem can also be solved in  $O((n+m)n)$  time for the class of DUF-digraphs, by a minor modification of our algorithm that solves MIN-KERNEL problem (replace  $\text{Min}\{K(j) \neq \infty : j \in P_i\}$  in the recursive definition of  $K(i)$  by  $\text{Max}\{K(j) \neq \infty : j \in P_i\}$  and follow the same procedure. Then we have that if a kernel exists, then a maximum sized kernel is given by  $\text{Max}(\mathcal{K})$ ). Further, the recursive definition can also be easily adapted to the weighted versions of the problems MIN-KERNEL and MAX-KERNEL to obtain  $O((n+m)n)$  time algorithms for those problems too.

### 3.3 Minimum absorbing set

Given any digraph  $G$ , the splitting bigraph  $B_G$  is defined as follows:  $V(B_G)$  is partitioned into two sets  $V' = \{u' : u \in V(G)\}$  and  $V'' = \{u'' : u \in V(G)\}$ , and  $E(B_G) = \{u'v'' : (u, v) \in E(G)\}$ . Müller [22] observed that  $G$  is an interval digraph if and only if  $B_G$  is an interval bigraph (since if  $\{(S_u, T_u)\}_{u \in V(G)}$  is an interval representation of a digraph  $G$ , then  $\{\{S_u\}_{u' \in V'}, \{T_u\}_{u'' \in V''}\}$  is an interval bigraph representation of the bipartite graph  $B_G$ ).

Recall that for a bipartite graph having two specified partite sets  $A$  and  $B$ , a set  $S \subseteq B$  such that  $\bigcup_{u \in B} N(u) = A$  is called an  $A$ -dominating set (or a red-blue dominating set). If  $G$  is a reflexive interval digraph, then every  $V'$ -dominating set of  $B_G$  corresponds to an absorbing set of  $G$  and vice versa. To be precise, if  $S \subseteq V''$  is a  $V'$ -dominating set of  $B_G$ , then  $\{u \in V(G) : u' \in S\}$  is an absorbing set of  $G$  and if  $S \subseteq V(G)$  is an absorbing set of  $G$ , then  $\{u'' \in V'' : u \in S\}$  is a  $V'$ -dominating set of  $B_G$  (note that this is not true for general interval digraphs). Thus finding a minimum cardinality absorbing set in  $G$  is equivalent to finding a minimum cardinality  $V'$ -dominating set in the bipartite graph  $B_G$ . We show in this section that the problem of computing a minimum cardinality  $A$ -dominating set is linear time solvable for interval bigraphs. This implies that the ABSORBING-SET problem can be solved in linear time on reflexive interval digraphs.

Consider an interval bigraph  $H$  with partite sets  $A$  and  $B$ . Let  $\{I_u\}_{u \in V(H)}$  be an interval representation for  $H$ ; i.e.  $uv \in E(H)$  if and only if  $u \in A$ ,  $v \in B$  and  $I_u \cap I_v \neq \emptyset$ . Let  $|A| = t$ . We assume without loss of generality that  $A = \{1, 2, \dots, t\}$ , where  $r(I_i) < r(I_j) \Leftrightarrow i < j$ . We also assume that there are no isolated vertices in  $A$ , as otherwise  $H$  does not have any  $A$ -dominating set. For each  $i \in \{1, 2, \dots, t\}$ , we compute a minimum cardinality subset  $DS(i)$  of  $B$  that dominates  $\{i, i+1, \dots, t\}$ , i.e.  $\{i, i+1, \dots, t\} \subseteq \bigcup_{u \in DS(i)} N(u)$ . Then  $DS(1)$  will be a minimum cardinality  $A$ -dominating set of  $H$ . We first define some parameters that will be used to define  $DS(i)$ .

Let  $i \in \{1, 2, \dots, t\}$ . We define  $\rho(i) = \max_{u \in N(i)} r(I_u)$  and let  $R(i)$  be a vertex in  $N(i)$  such that  $r(I_{R(i)}) = \rho(i)$ . Since  $A$  does not contain any isolated vertices,  $\rho(i)$  and  $R(i)$  exist for each  $i \in \{1, 2, \dots, t\}$ . Let  $\lambda(i) = \min\{j : \rho(i) < l(I_j)\}$ . Note that  $\lambda(i)$  may not exist.

► **Lemma 21** ( $\star$ ). *Let  $i \in \{1, 2, \dots, t\}$ . If  $\lambda(i)$  exists, then  $R(i)$  dominates every vertex in  $\{i, i+1, \dots, \lambda(i) - 1\}$  and otherwise,  $R(i)$  dominates every vertex in  $\{i, i+1, \dots, t\}$ .*

We now explain how to compute  $DS(i)$  for each  $i \in \{1, 2, \dots, t\}$ . We recursively define  $DS(i)$  as follows:

$$DS(i) = \begin{cases} \{R(i)\} \cup DS(\lambda(i)) & \text{if } \lambda(i) \text{ exists} \\ \{R(i)\} & \text{otherwise.} \end{cases}$$

► **Lemma 22** ( $\star$ ). *For each  $i \in \{1, 2, \dots, t\}$ , the set  $DS(i)$  as defined above is a minimum cardinality subset of  $B$  that dominates  $\{i, i+1, \dots, t\}$ .*

It is not difficult to verify that given an interval representation of the interval bigraph  $H$  with partite sets  $A$  and  $B$ , the parameters  $R(i)$  and  $\lambda(i)$  can be computed for each  $i \in A$  in  $O(n+m)$  time. Also, given a reflexive interval digraph  $G$ , the interval bigraph  $B_G$  can be constructed in linear time. Thus we have the following theorem.

► **Theorem 23**. *The RED-BLUE DOMINATING SET problem can be solved in interval bigraphs in linear time, given an interval representation of the bigraph as input. Consequently, the ABSORBING-SET problem can be solved in linear time in reflexive interval digraphs, given an interval representation of the input digraph.*

Note that even if an interval representation of an interval bigraph is not known, it can be computed in polynomial time using Müller's algorithm [22]. Thus given just the adjacency list of the graph as input, the RED-BLUE DOMINATING SET problem is polynomial-time solvable on interval bigraphs and the ABSORBING-SET problem is polynomial-time solvable on reflexive interval digraphs.

### 3.4 Maximum independent set

We have the following theorem due to McConnell and Spinrad [19].

► **Theorem 24** ([19]). *An independent set of maximum possible size can be computed for cocomparability graphs in  $O(n + m)$  time.*

Let  $G$  be a DUF-digraph. Let  $H$  be the underlying undirected graph of  $G$ . Then by Corollary 6, we have that  $H$  is a cocomparability graph. Note that the independent sets of  $G$  and  $H$  are exactly the same. Therefore any algorithm that finds a maximum cardinality independent set in cocomparability graphs can be used to solve the INDEPENDENT-SET problem in DUF-digraphs. Thus by the above theorem, we have the following corollary.

► **Corollary 25.** *The INDEPENDENT-SET problem can be solved for DUF-digraphs in  $O(n + m)$  time. Consequently, the INDEPENDENT-SET problem can be solved for reflexive interval digraphs in  $O(n + m)$  time.*

The above corollary generalizes and improves the  $O(mn)$  time algorithm due to Prisner's [26] observation that underlying undirected graph of interval nest digraphs are weakly triangulated and the fact that maximum cardinality independent set problem can be solved for weakly triangulated graphs in  $O(mn)$  time [14]. Note that the weighted INDEPENDENT-SET problem can also be solved in DUF-digraphs in  $O(n + m)$  time, as the problem of finding a maximum weighted independent set in a cocomparability graph can be solved in linear time [16].

## 4 Hardness results for point-point digraphs

### 4.1 Characterizations for point-point digraphs

In this section we give a characterization for point-point digraphs which will be further useful for proving our NP-completeness results for this class. Let  $G = (V, E)$  be a digraph. We say that  $a, b, c, d$  is an *anti-directed walk* of length 3 if  $a, b, c, d \in V(G)$ ,  $(a, b), (c, b), (c, d) \in E(G)$  and  $(a, d) \notin E(G)$  (the vertices  $a, b, c, d$  need not be pairwise distinct, but it follows from the definition that  $a \neq c$  and  $b \neq d$ ). Recall that  $B_G = (X, Y, E)$  is a splitting bigraph of  $G$ , where  $X = \{x_u : u \in V(G)\}$  and  $Y = \{y_u : u \in V(G)\}$  and  $x_u y_v \in E(B_G)$  if and only if  $(u, v) \in E(G)$ . We then have the following theorem.

► **Theorem 26.** *Let  $G$  be a digraph. Then the following conditions are equivalent:*

1.  $G$  is a point-point digraph.
2.  $G$  does not contain any anti-directed walk of length 3.
3. The splitting bigraph of  $G$  is a disjoint union of complete bipartite graphs.

**Proof.** (1  $\Rightarrow$  2): Let  $G$  be a point-point digraph with a point-point representation  $\{(S_u, T_u)\}_{u \in V(G)}$ . Suppose that there exist vertices  $a, b, c, d$  in  $G$  such that  $(a, b), (c, b), (c, d) \in E(G)$ . By the definition of point-point representation, we then have  $S_a = T_b = S_c = T_d$ . This implies that  $(a, d) \in E(G)$ . Therefore we can conclude that  $G$  does not contain any anti-directed walk of length 3.

(2  $\Rightarrow$  3): Suppose that  $G$  does not contain any anti-directed walk of length 3. Let  $B_G = (X, Y, E)$  be the splitting bigraph of  $G$ . Let  $x_u y_v$  be any edge in  $B_G$ , where  $u, v \in V(G)$ . Clearly, by the definition of  $B_G$ ,  $(u, v) \in E(G)$ . We claim that the graph induced in  $B_G$  by the vertices  $N(x_u) \cup N(y_v)$  is a complete bipartite graph. Suppose not. Then it should be the case that there exist two vertices  $x_a \in N(y_v)$  and  $y_b \in N(x_u)$  such that  $x_a y_b \notin E(B_G)$ , where  $a, b \in V(G)$ . By the definition of  $B_G$ , we then have that  $(a, v), (u, v), (u, b) \in E(G)$  and  $(a, b) \notin E(G)$ . So  $a, v, u, b$  is an anti-directed walk of length 3 in  $G$ , which is a contradiction to 2. This proves that for every  $p \in X$  and  $q \in Y$  such that  $pq \in E(B_G)$ , the set  $N(p) \cup N(q)$  induces a complete bipartite subgraph in  $B_G$ . Therefore, each connected component of  $B_G$  is a complete bipartite graph. (This can be seen as follows: Suppose that there is a connected component  $C$  of  $B_G$  that is not complete bipartite. Choose  $p \in X \cap C$  and  $q \in Y \cap C$  such that  $pq \notin E(B_G)$  and the distance between  $p$  and  $q$  in  $B_G$  is as small as possible. Let  $t$  be the distance between  $p$  and  $q$  in  $B_G$ . Clearly,  $t$  is odd and  $t \geq 3$ . Consider a shortest path  $p = z_0, z_1, z_2, \dots, z_t = q$  from  $p$  to  $q$  in  $B_G$ . By our choice of  $p$  and  $q$ , we have that  $z_1 z_{t-1} \in E(B_G)$ . But then  $p \in N(z_1)$ ,  $q \in N(z_{t-1})$  and  $pq \notin E(B_G)$ , contradicting our observation that  $N(z_1) \cup N(z_{t-1})$  induces a complete bipartite graph in  $B_G$ .)

(3  $\Rightarrow$  1): Suppose that  $G$  is a digraph such that the splitting bigraph  $B_G$  is a disjoint union of complete bipartite graphs, say  $H_1, H_2, \dots, H_k$ . Now we can obtain a point-point representation  $\{(S_u, T_u)\}_{u \in V(G)}$  of the digraph  $G$  as follows: For each  $i \in \{1, 2, \dots, k\}$ , define  $S_u = i$  if  $x_u \in V(H_i)$  and  $T_v = i$  if  $y_v \in V(H_i)$ . Note that  $(u, v) \in E(G)$  if and only if  $x_u y_v \in E(B_G)$  if and only if  $x_u, y_v \in V(H_i)$  for some  $i \in \{1, 2, \dots, k\}$ . Therefore we can conclude that  $(u, v) \in E(G)$  if and only if  $S_u = T_v = i$  for some  $i \in \{1, 2, \dots, k\}$ . Thus the digraph  $G$  is a point-point digraph.  $\blacktriangleleft$

► **Corollary 27.** *Point-point digraphs can be recognized in linear time.*

## 4.2 Subdivision of an irreflexive digraph

For an undirected graph  $G$ , the  $k$ -subdivision of  $G$ , where  $k \geq 1$ , is defined as the graph  $H$  having vertex set  $V(H) = V(G) \cup \bigcup_{ij \in E(G)} \{u_{ij}^1, u_{ij}^2, \dots, u_{ij}^k\}$ , obtained from  $G$  by replacing each edge  $ij \in E(G)$  by a path  $i, u_{ij}^1, u_{ij}^2, \dots, u_{ij}^k, j$ . The 0-subdivision of an undirected graph  $G$  is defined to be  $G$  itself.

The following theorem is adapted from Theorem 5 of Chlebík and Chlebíková [3].

► **Theorem 28** ([3]). *Let  $G$  be an undirected graph having  $m$  edges.*

1. *The problem of computing a maximum cardinality independent set is APX-complete when restricted to  $2k$ -subdivisions of 3-regular graphs for any fixed integer  $k \geq 0$ .*
2. *The problem of finding a minimum cardinality dominating set (resp. independent dominating set) is APX-complete when restricted to  $3k$ -subdivisions of graphs having degree at most 3 for any fixed integer  $k \geq 0$ .*

Note that the independent sets, dominating sets and independent dominating sets of an undirected graph  $G$  are exactly the independent sets, dominating sets (which are also the absorbing sets), and solutions (which are also the kernels) of the symmetric digraph of  $G$ . Clearly the symmetric digraph of  $G$  is irreflexive. Since the MAX-KERNEL problem is equivalent to the INDEPENDENT-SET problem in symmetric digraphs, we then have the following corollary of Theorem 28.

► **Corollary 29** ( $\star$ ). *The problems INDEPENDENT-SET, ABSORBING-SET, MIN-KERNEL and MAX-KERNEL are APX-complete on irreflexive symmetric digraphs of in- and out-degree at most 3.*

Note that for  $k \geq 1$ , the symmetric digraph of the  $2k$ -subdivision or  $3k$ -subdivision of an undirected graph contains an anti-directed walk of length 3 (unless the graph contains no edges), and therefore by Theorem 26, is not a point-point digraph. Thus we cannot directly deduce the APX-hardness of the problems under consideration for point-point digraphs from Theorem 28.

We define the subdivision of an irreflexive digraph, so that the techniques of Chlebík and Chlebíková can be adapted for proving hardness results on point-point digraphs.

► **Definition 30.** *Let  $G$  be an irreflexive digraph (i.e.  $G$  contains no loops). For  $k \geq 1$ , define the  $k$ -subdivision of  $G$  to be the digraph  $H$  having vertex set  $V(H) = V(G) \cup \bigcup_{(i,j) \in E(G)} \{u_{ij}^1, u_{ij}^2, \dots, u_{ij}^k\}$ , obtained from  $G$  by replacing each edge  $(i, j) \in E(G)$  by a directed path  $i, u_{ij}^1, u_{ij}^2, \dots, u_{ij}^k, j$ .*

Note that the  $k$ -subdivision of any irreflexive digraph is also an irreflexive digraph. We then have the following lemma.

► **Lemma 31.** *For any  $k \geq 1$ , the  $k$ -subdivision of any irreflexive digraph is a point-point digraph.*

**Proof.** Let  $k \geq 1$  and let  $G$  be any irreflexive digraph. By Theorem 26, it is enough to show that the  $k$ -subdivision  $H$  of  $G$  does not contain any anti-directed walk of length 3. Note that by the definition of  $k$ -subdivision, all the vertices in  $V(H) \setminus V(G)$  have both in-degree and out-degree exactly equal to one. Further, for every vertex  $v$  in  $H$  such that  $v \in V(G)$ , we have that  $N^+(v), N^-(v) \subseteq V(H) \setminus V(G)$ . Suppose for the sake of contradiction that  $u, v, w, x$  is an anti-directed walk of length 3 in  $H$ . Recall that we then have  $(u, v), (w, v), (w, x) \in E(H)$ ,  $u \neq w$  and  $v \neq x$ . By the above observations, we can then conclude that  $v \in V(G)$  and further that  $u, w \in V(H) \setminus V(G)$ . Then since  $(w, x) \in E(H)$  and  $v \neq x$ , we have that  $w$  has out-degree at least 2, which contradicts our earlier observation that every vertex in  $V(H) \setminus V(G)$  has out-degree exactly one. This proves the lemma. ◀

Now we have the following theorem.

► **Theorem 32** (★). *The problem INDEPENDENT-SET is APX-hard for point-point digraphs.*

### 4.3 Kernels

As a first step towards determining the complexity of the problems KERNEL, MIN-KERNEL and MAX-KERNEL for point-point digraphs, we show the following.

► **Lemma 33** (★). *Let  $G$  be an irreflexive digraph and let  $k \geq 1$ . Then  $G$  has a kernel if and only if the  $2k$ -subdivision of  $G$  has a kernel. Moreover,  $G$  has a kernel of size  $q$  if and only if the  $2k$ -subdivision of  $G$  has a kernel of size  $q + km$ . Further, given a kernel of size  $q + km$  of the  $2k$ -subdivision of  $G$ , we can construct a kernel of size  $q$  of  $G$  in polynomial time.*

The above lemma can be used to show the existence of a polynomial-time reduction from the KERNEL problem in general digraphs to the KERNEL problem in point-point digraphs. Thus we have the following theorem.

► **Theorem 34** (★). *The problem KERNEL is NP-complete for point-point digraphs.*

Note that KERNEL is known to be NP-complete even on planar digraphs having degree at most 3 and in- and out-degrees at most 2 [10]. The above reduction transforms the input digraph in such a way that every newly introduced vertex has in- and out-degree exactly

## 17:14 Kernels in Interval Digraphs

1 and the in- and out-degrees of the original vertices remain the same. Moreover, if the input digraph is planar, the digraph produced by the reduction is also planar. Thus we can conclude that the problem KERNEL remains NP-complete even for planar point-point digraphs having degree at most 3 and in- and out-degrees at most 2.

An *L-reduction* as defined below is an approximation-preserving reduction for optimization problems.

► **Definition 35** ([23]). *Let  $A$  and  $B$  be two optimization problems with cost functions  $c_A$  and  $c_B$  respectively. Let  $f$  be a polynomially computable function that maps the instances of problem  $A$  to the instances of problem  $B$ . Then  $f$  is said to be an *L-reduction* from  $A$  to  $B$  if there exist a polynomially computable function  $g$  and constants  $\alpha, \beta \in (0, \infty)$  such that the following conditions hold:*

1. *If  $y'$  is a solution to  $f(x)$  then  $g(y')$  is a solution to  $x$ , where  $x$  is an instance of the problem  $A$ .*
2.  *$OPT_B(f(x)) \leq \alpha OPT_A(x)$ , where  $OPT_B(f(x))$  and  $OPT_A(x)$  denote the optimum value of respective instances for the problems  $B$  and  $A$  respectively.*
3.  *$|OPT_A(x) - c_A(g(y'))| \leq \beta |OPT_B(f(x)) - c_B(y')|$ .*

In order to prove that a problem  $P$  is APX-hard, it is enough to show that the problem  $P$  has an L-reduction from an APX-hard problem. Using Lemma 33, one can construct an L-reduction from the MIN-KERNEL and MAX-KERNEL problems for irreflexive symmetric digraphs having in- and out-degree at most 3 to the MIN-KERNEL and MAX-KERNEL problems for  $2k$ -subdivisions of irreflexive symmetric digraphs having in- and out-degree at most 3. Thus, by Corollary 29, we have the following theorem.

► **Theorem 36** ( $\star$ ). *For  $k \geq 1$ , the problems MIN-KERNEL and MAX-KERNEL are APX-hard for  $2k$ -subdivisions of irreflexive symmetric digraphs having in- and out-degree at most 3. Consequently, the problems MIN-KERNEL and MAX-KERNEL are APX-hard for point-point digraphs.*

### 4.4 Minimum Absorbing set

In order to show the approximation hardness of the ABSORBING-SET problem for point-point digraphs, first we prove the following lemma.

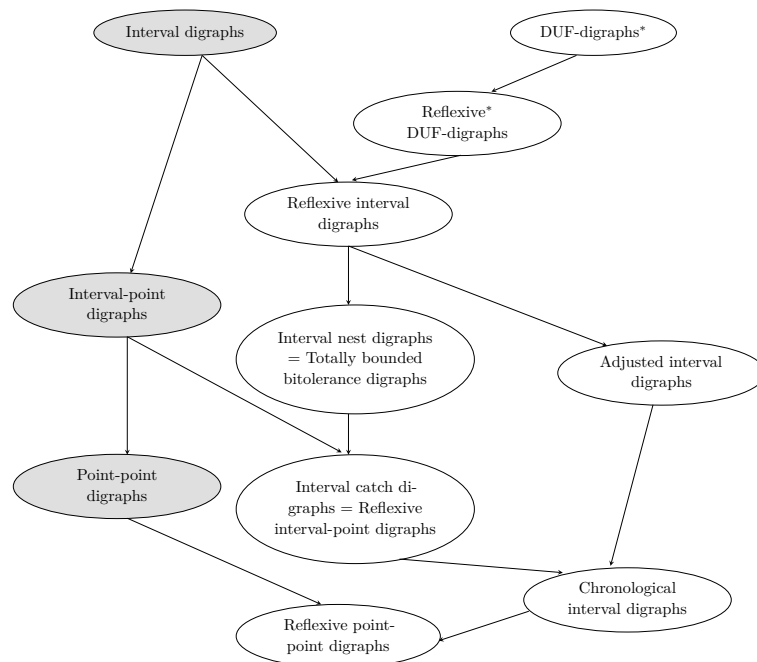

► **Lemma 37** ( $\star$ ). *Let  $G$  be an irreflexive digraph and let  $k \geq 1$ . Then  $G$  has an absorbing set of size at most  $q$  if and only if the  $2k$ -subdivision of  $G$  has an absorbing set of size at most  $q + km$ . Further, given an absorbing set of size at most  $q + km$  in the  $2k$ -subdivision of  $G$ , we can construct in polynomial time an absorbing set of size at most  $q$  in  $G$ .*

The above lemma can be used to construct an L-reduction from the ABSORBING-SET problem for irreflexive symmetric digraphs having in- and out-degree at most 3 to the ABSORBING-SET problem for  $2k$ -subdivisions of irreflexive symmetric digraphs having in- and out-degree at most 3. By Corollary 29, we then have the following theorem.

► **Theorem 38** ( $\star$ ). *For  $k \geq 1$ , the problem ABSORBING-SET is APX-hard for  $2k$ -subdivisions of irreflexive symmetric digraphs having in- and out-degree at most 3. Consequently, the problem ABSORBING-SET is APX-hard for point-point digraphs.*

## 5 Conclusion

The class of interval nest digraphs coincides with the class of totally bounded bitolerance digraphs which was introduced by Bogart and Trenk [2]. Thus totally bounded bitolerance digraphs are a subclass of reflexive interval digraphs, and all the results that we obtain for reflexive interval digraphs hold also for this class of digraphs. Figure 3 shows the inclusion relations between the classes of digraphs that were studied in this paper ( $\star$ ). After work on this paper had been completed, we have been made aware of a recent manuscript of Jaffke, Kwon and Telle [15], in which unified polynomial time algorithms have been obtained for the problems considered in this paper for some classes reflexive intersection digraphs including reflexive interval digraphs. Since their algorithms are more general in nature, their time complexities are much larger than the ones for the algorithms presented in this paper.

■ **Figure 3** Inclusion relations between graph classes. In the diagram, there is an arrow from  $\mathcal{A}$  to  $\mathcal{B}$  if and only if the class  $\mathcal{B}$  is contained in the class  $\mathcal{A}$ . Moreover, each inclusion is strict. The problems studied are efficiently solvable in the classes shown in white, while they are NP-hard and/or APX-hard in the classes shown in gray (\* the complexity of the ABSORBING-SET problem on DUF-digraphs and reflexive DUF-digraphs remain open).

Müller [22] showed the close connection between interval digraphs and interval bigraphs and used this to construct the only known polynomial time recognition algorithm for both these classes. Since this algorithm takes  $O(nm^6(n+m)\log n)$  time, the problem of finding a forbidden structure characterization for either of these classes or a faster recognition algorithm are long standing open questions in this field. But many of the subclasses of interval digraphs, like adjusted interval digraphs [29], chronological interval digraphs [5], interval catch digraphs [25], and interval point digraphs [26] have simpler and much more efficient recognition algorithms. It is quite possible that simpler and efficient algorithms for recognition exist also for reflexive interval digraphs. As for the case of interval nest digraphs, no polynomial time recognition algorithm is known. The complexities of the recognition problem and ABSORBING-SET problem for DUF-digraphs also remain as open problems.

# Interval Query Problem on Cube-Free Median Graphs

Soh Kumabe 

The University of Tokyo, Japan

---

## Abstract

In this paper, we introduce the *interval query problem* on cube-free median graphs. Let  $G$  be a cube-free median graph and  $\mathcal{S}$  be a commutative semigroup. For each vertex  $v$  in  $G$ , we are given an element  $p(v)$  in  $\mathcal{S}$ . For each query, we are given two vertices  $u, v$  in  $G$  and asked to calculate the sum of  $p(z)$  over all vertices  $z$  belonging to a  $u - v$  shortest path. This is a common generalization of range query problems on trees and grids. In this paper, we provide an algorithm to answer each interval query in  $O(\log^2 n)$  time. The required data structure is constructed in  $O(n \log^3 n)$  time and  $O(n \log^2 n)$  space. To obtain our algorithm, we introduce a new technique, named the *staircases decomposition*, to decompose an interval of cube-free median graphs into simpler substructures.

## 1 Introduction

The *range query problem* [18] is one of the most fundamental problems in the literature on data structures, particularly for string algorithms [19]. Let  $f$  be a function defined on arrays. In the range query problem, we are given an array  $P = (p(1), \dots, p(n))$  of  $n$  elements and a *range query* defined by two integers  $i, j$  with  $1 \leq i \leq j \leq n$ . For each query  $(i, j)$ , we are asked to return the value  $f((p(i), \dots, p(j)))$ . The main interest of this problem is the case where  $f$  is defined via a *semigroup operator* [27]. Let  $\mathcal{S}$  be a semigroup with operator  $\oplus$ , and let  $P$  consist of elements in  $\mathcal{S}$ . Then, the function  $f$  is defined as  $f((p(i), \dots, p(j))) = p(i) \oplus \dots \oplus p(j)$ . Typical examples of semigroup operators are sum, max, and min. The fundamental result [27, 28] is that for any constant integer  $k$ , a range query can be answered in  $O(\alpha_k(n))$  time, where  $\alpha_k$  is a slow-growing function related to the inverse of the Ackermann function. The required data structure is constructed in linear time and space. *Range minimum query problem*, i.e.,  $\oplus = \min$ , is one of the well-studied problems in the literature, and it admits a constant-time algorithm with a data structure constructed in linear time and space [1, 4, 5, 18, 20].

This problem is generalized into trees and grids. In these settings, we are given a tree/grid  $G$  and an element  $p(v)$  for each vertex of  $G$ . As a query, given two vertices  $u, v$  in  $G$ , we are asked to calculate the sum<sup>1</sup> of the elements assigned at the vertices on a  $u - v$  shortest path. In particular, we are asked to calculate the sum of the elements on the unique  $u - v$  path for trees and the axis-parallel rectangle with corners  $(u, v)$  on its diagonal for grids. For constant

---

<sup>1</sup> In this paper, for simplicity, we represent the semigroup operation by the terms of summation; that is, we denote  $a \oplus a'$  by the word *sum* of  $a$  and  $a'$  for  $a, a' \in \mathcal{S}$ .

dimensional grids, an almost-constant time algorithm [11] with linear space on semigroup operators and a constant-time algorithm for range minimum query is known [29]. For range query problem on trees, an almost-constant time algorithm [9] with linear space is known on semigroup operators; see [8] for further survey on the problem on trees, particularly for dynamic version.

In this paper, we introduce a common generalization of the two above mentioned cases, named *interval query problem on median graphs*. Let  $G = (V(G), E(G))$  be a connected graph with  $n$  vertices. For two vertices  $u, v \in V(G)$ , let the *interval*  $I[u, v]$  be the set of vertices belonging to a  $u - v$  shortest path, where the length of a path is defined by the number of its edges. The graph  $G$  is called a *median graph* if for all  $u, v, w \in V(G)$ ,  $I[u, v] \cap I[v, w] \cap I[w, u]$  is a singleton [2, 7, 23]. The median graph  $G$  is said to be *cube-free* if  $G$  does not contain a cube as an induced subgraph. Trees and grids are examples of cube-free median graphs. In our problem, we are given a median graph  $G$  and an element  $p(v)$  of a commutative semigroup  $\mathcal{S}$  for each vertex  $v$  of  $G$ . As a query, given two vertices  $u, v$  in  $G$ , we are asked to calculate  $p(I[u, v])$ <sup>2</sup>. The interval query problem on cube-free median graphs is a common generalization of the range query problems on trees and grids.

In this paper, we provide an algorithm to the interval query problem on cube-free median graphs. The main result here is presented as follows:

► **Theorem 1.** *There is an algorithm to answer interval queries on cube-free median graphs in  $O(\log^2 n)$  time. The required data structure is constructed in  $O(n \log^3 n)$  time and  $O(n \log^2 n)$  space, where  $n$  is the number of vertices in a given cube-free median graph.*

The time complexity of answering a query matches the complexity for the two-dimensional *range tree* [21] in the *orthogonal range query problem*, without acceleration via *fractional cascading* [10].

To obtain the algorithm, we introduce a new technique, named the *staircases decomposition*. This technique provides a new method to decompose an interval of cube-free median graphs into a constant number of smaller intervals. Most of the candidates of the smaller intervals, which we refer to as *staircases*, are well-structured, and an efficient algorithm to answer the interval queries can be constructed. The rest are not necessarily staircases; however, each of them are one of the  $O(n \log n)$  candidates, and we can precalculate all the answers of the interval queries on these intervals.

Designing fast algorithms for median graphs is a recently emerging topic. The *distance labeling scheme* [24] is a type of data structure that is defined by the encoder and decoder pair. The encoder receives a graph and assigns a label for each vertex, whereas the decoder receives two labels and computes the distance of the two vertices with these labels. For cube-free median graphs, there is a distance labeling scheme that assigns labels with  $O(\log^3 n)$  bits for each vertex [13]. Very recently, a linear-time algorithm to find the *median* of median graphs was built [6]. This paper continues with this line of research and utilizes some of the techniques presented in these previous studies.

Various applications can be considered in the interval query problem on median graphs. The solution space of a 2-SAT formula forms a median graph, where two solutions are adjacent if one of them can be obtained by negating a set of pairwise dependent variables of the other [3, 22, 26]. For two solutions  $u$  and  $v$ , the interval  $I[u, v]$  corresponds to the set of the solutions  $x$ , such that for each truth variable, if the same truth value is assigned in  $u$  and  $v$ , so does  $x$ . Suppose we can answer the interval queries to calculate sum (resp.

<sup>2</sup> For a vertex subset  $X$ , we denote the sum of  $p(z)$  over all  $z \in X$  by  $p(X)$ .

min) in polylogarithmic time with a data structure of subquadratic time and space. Then, if we have the list of all feasible solutions of the given 2-SAT formula, we can calculate the number (resp. minimum weight) of these solutions in polynomial time of the number of variables for each query, without precalculating the answers for all possible queries. Note that, there is a polynomial-delay algorithm to enumerate all solutions to the given 2-SAT formula [16]. Therefore, if the number of the feasible solutions (and thus the number of vertices in the corresponding median graph) is small, we can efficiently list them. In social choice theory, the structure of median graphs naturally arises as a generalization of *single-crossing preferences* [15, 17] and every closed Condorcet domains admits the structure of a median graph [25]. For two preferences  $u$  and  $v$ , the voters with their preferences in interval  $I[u, v]$  prefer candidate  $x$  to candidate  $y$  whenever both  $u$  and  $v$  prefer  $x$  to  $y$ . Therefore, using interval query, we can count the number of voters  $w$  such that for all pairs of candidates, at least one of  $u$  and  $v$  has the same preference order as  $w$  between these candidates. Although these structures are not necessarily cube-free, we hope that our result will be the first and important step toward obtaining fast algorithms for these problems.

## 1.1 Algorithm Overview

Here we give high-level intuition to our algorithm. More detailed outline is given in Section 3.

Let  $G$  be a cube-free median graph. The first idea for our algorithm is to decompose  $G$  recursively. We recursively divide  $V(G)$  into some parts, called *fibers*. Roughly speaking, a fiber is a set of the vertices located on the similar direction from the special vertex  $m$  (see Figure 1). Each fiber induces a cube-free median graph and, if we take  $m$  properly, has at most  $|V(G)|/2$  vertices; there are at most  $O(\log n)$  recursion steps.

Let  $u, v$  be vertices of  $G$ . Consider calculating  $p(I[u, v])$ . If  $u$  and  $v$  are in the same fiber, we calculate it recursively. Otherwise, we can show that  $I[u, v]$  intersects with only a constant number of fibers and the intersections are intervals with one end on the boundary of the fiber (Section 6, see Figure 8). Thus, it is sufficient to construct an algorithm on such intervals.

To do this, we further decompose such an interval into more well-structured intervals, using our main technique named *staircases decomposition* (Section 4, see Figure 4, 5, and 6). Roughly speaking, we decompose the interval into at most two structured substructures names *staircases* (Figure 2) and a special interval of  $O(n)$  candidates. For special intervals  $I$ , we just use the precalculated  $p(V(I))$ . For staircases  $L$ , we construct an algorithm to calculate  $p(V(L))$  in  $O(\log^2 n)$  time (Section 5), using the fact that the boundary of the fiber is actually a tree [13]. We decompose this tree into paths by heavy-light decomposition and build segment trees to answer the queries.

## 2 Basic Tools for Cube-Free Median Graphs and Trees

In this section, we introduce basic facts about cube-free median graphs and trees.

Let  $G$  be a connected, undirected, finite graph. We denote the vertex set of  $G$  by  $V(G)$ . For two vertices  $u$  and  $v$  in  $G$ , we write  $u \sim v$  if  $u$  and  $v$  are adjacent. For two vertices  $u$  and  $v$  of  $G$ , the *distance*  $d(u, v)$  between them is the minimum number of edges on a path connecting  $u$  and  $v$ , and the *interval*  $I[u, v]$  is the set of vertices  $w$  which satisfies  $d(u, v) = d(u, w) + d(w, v)$ . The graph  $G$  is a *median graph* if for any three vertices  $u, v, w$ ,  $I[u, v] \cap I[v, w] \cap I[w, u]$  contains exactly one vertex, called *median* of  $u, v$  and  $w$ . Median graphs are bipartite and do not contain  $K_{2,3}$  as a subgraph. A median graph is *cube-free* if it does not contain a (three-dimensional) cube graph as an induced subgraph. The followings hold.

## 18:4 Interval Query Problem on Cube-Free Median Graphs

► **Lemma 2** ([14]). *Any interval in a cube-free median graph induces an isometric subgraph of a two-dimensional grid.*

► **Lemma 3** ([13]). *Let  $u, v, w_1, w_2$  be four pairwise distinct vertices of a median graph such that  $v \sim w_1, v \sim w_2$  and  $d(u, v) - 1 = d(u, w_1) = d(u, w_2)$ . Then, there is unique vertex  $z$  with  $w_1 \sim z, w_2 \sim z$  and  $d(u, z) = d(u, v) - 2$ .*

From now on, let  $G$  be a cube-free median graph with  $n$  vertices. Let  $X$  be a subset of  $V(G)$ . For vertex  $z \in V(G)$  and  $x \in X$ ,  $x$  is the *gate* of  $z$  in  $X$  if for all  $w \in X$ ,  $x \in I[z, w]$ . The gate of  $z$  in  $X$  is unique (if it exists) because it is the unique vertex in  $X$  that minimizes the distance from  $z$ .  $X$  is *gated* if all vertices  $z \in V(G)$  have a gate in  $X$ . The following equivalence result is known.

► **Lemma 4** ([12, 13]). *Let  $X$  be a vertex subset of the median graph  $G$ . Then, following three conditions are equivalent.*

- (a)  $X$  is gated.
- (b)  $X$  is convex, i.e.,  $I[u, v] \subseteq X$  for all  $u, v \in X$ .
- (c)  $X$  induces a connected subgraph and  $X$  is locally convex, i.e.,  $I[u, v] \subseteq X$  for all  $u, v \in X$  with  $d(u, v) = 2$ .

An induced subgraph of  $G$  is *gated* (resp. *convex*, *locally convex*) if its vertex set is gated (resp. convex, locally convex). The intersection of two convex subsets is convex. Any interval of median graphs are convex.

For a convex subset  $X$  and a vertex  $x \in X$ , the *fiber*  $F_X(x)$  of  $x$  with respect to  $X$  is the set of vertices in  $G$  whose gate in  $X$  is  $x$ . Two fibers  $F_X(x), F_X(y)$  are *neighboring* if there are vertices  $x' \in F_X(x)$  and  $y' \in F_X(y)$  such that  $x' \sim y'$ , which is equivalent to  $x \sim y$  [13]. Fibers for all  $x \in X$  define a partition of  $V(G)$ . For two adjacent vertices  $x, y \in X$ , the *boundary*  $T_X(x, y)$  of  $F_X(x)$  relative to  $F_X(y)$  is the set of the vertices which have a neighbor in  $F_X(y)$ .  $T_X(x, y)$  and  $T_X(y, x)$  are isomorphic. A vertex in  $T_X(x, y)$  has a unique neighbor in  $T_X(y, x)$ , which is the corresponding vertex under that isomorphism. For vertex  $x \in X$ , a *total boundary*  $T_X(x)$  of  $F_X(x)$  is the union of all  $T_X(x, y)$  for  $y \in X$  with  $x \sim y$ . The subgraph  $H$  is *isometric* in  $G$  if for all  $u, v \in V(H)$ , there is a path in  $H$  with length  $d(u, v)$ . A rooted tree has *gated branches* if any of its root-leaf path is convex. The next lemma exploits the structures of the boundaries of fibers of cube-free median graphs.

► **Lemma 5.** *Let  $X$  be a convex vertex subset of cube-free median graph  $G$ . Let  $x, y \in X$  and assume  $x \sim y$ . Then, the followings hold.*

- (i) ([13])  $T_X(x, y)$  induces a tree, which is convex.
- (ii) ([13])  $T_X(x)$  induces a tree with gated branches, which is isometric in  $G$ .

The following is folklore in a literature of median graphs. A proof is in full version.

► **Lemma 6** (folklore). *Let  $X$  be a convex vertex set of a median graph and let  $Y$  be a convex subset of  $X$ . For  $x \in X$ , let  $F(x)$  be the fiber of  $x$  with respect to  $X$ . Then,  $\bigcup_{y \in Y} F(y)$  is convex.*

Let  $T$  be a tree with gated branches. For a vertex  $v \in V(G)$  and  $w \in T$ ,  $w$  is an *imprint* of  $v$  if  $I[v, w] \cap T = \{w\}$ . If  $T$  is convex, the imprint is equal to the gate and therefore unique. Even if it is not the case, we can state following.

► **Lemma 7.** *Let  $T$  be a tree with gated branches rooted at  $r$ . Let  $u \in V(G)$ . Then, the following statements hold.*

- (i) ([13]) There are at most two imprints of  $u$  in  $T$ .
- (ii) Assume  $u$  has two distinct imprints  $w^1, w^2$  in  $T$ . Then,  $w^1, w^2 \in I[r, u]$ .

**Proof.** We prove (ii). From symmetry, we only prove  $w^1 \in I[r, u]$ . Let  $P_1$  be the root-leaf path of  $T$  that contains  $w^1$ . Then,  $P_1$  is convex and therefore  $d(r, u) = d(r, w^1) + d(w^1, u)$ . ◀

► **Lemma 8.** *Let  $T$  be a tree with gated branches and  $w \in V(T)$ . Then, the set of vertices with an imprint  $w$  in  $T$  is convex.*

**Proof.** Assume the contrary. Then, there are distinct vertices  $z_1, z_2, z_3$  with  $z_1 \sim z_2 \sim z_3$ , such that  $z_1$  and  $z_3$  have an imprint  $w$  but  $z_2$  doesn't. We have  $d(w, z_2) = d(w, z_1) + 1$ ; otherwise,  $d(w, z_2) = d(w, z_1) - 1$  because of bipartiteness of  $G$  holds and in this case,  $I[w, z_2] \subseteq I[w, z_1]$  holds and  $z_2$  has an imprint  $w$ . By the same reason we have  $d(w, z_2) = d(w, z_3) + 1$ . From definition of the imprint, there is a  $z_2 - w$  shortest path that contains a vertex of  $T$  other than  $w$ . Let  $z_4$  be the neighbor of  $z_2$  in this shortest path. Then,  $z_4$  does not have an imprint  $w$  and especially,  $z_1 \neq z_4 \neq z_3$ . Now we have  $d(w, z_4) + 1 = d(w, z_1) + 1 = d(w, z_3) + 1 = d(w, z_2)$  and obtain three squares that all two intersect at an edge from Lemma 3, which contradicts Lemma 2. ◀

For a vertex  $m \in V(G)$ , the *star*  $\text{St}(m)$  of  $m$  is the set of vertices  $x \in V(G)$  such that there is an edge or a square that contains both  $m$  and  $x$ .  $\text{St}(m)$  is convex. The vertex  $m \in V(G)$  is a *median* of  $G$  if it minimizes the sum of distances to all vertices in  $G$ . The following holds.

► **Lemma 9** ([13]). *All the fibers of  $\text{St}(m)$  of a median graph contains at most  $\frac{n}{2}$  vertices.*

For a rooted tree  $T$  that is rooted at  $r$ , a vertex  $u \in V(T)$  is an *ancestor* of  $v$  and  $v$  is a *descendant* of  $u$  if there is a path from  $u$  to  $v$ , only going toward the leaves. The vertex subset  $X$  is a *column* of  $T$  if for any two vertices  $x, y$  in  $X$ ,  $x$  is either an ancestor or a descendant of  $y$ . The vertex  $t$  is the *lowest common ancestor* [20] of  $u$  and  $v$  if  $t$  is an ancestor of both  $u$  and  $v$  that minimizes the distance between  $u$  and  $t$  (or equivalently,  $v$  and  $t$ ) in  $T$ . There is a data structure that is constructed in linear time and space such that, given two vertices on  $T$ , it returns the lowest common ancestor of them in constant time [5].  $u$  is a *parent* of  $v$  and  $v$  is a *child* of  $u$  if  $u$  is an ancestor of  $v$  and  $u \sim v$ . Let  $X \subseteq V(T)$  and  $u \in V(T)$ . The *nearest ancestor* of  $u$  in  $X$  on  $T$  is the vertex  $v \in X$  such that  $v$  is an ancestor of  $u$  and minimizes  $d(u, v)$ .

Let  $T$  be a rooted tree rooted at  $r$ . For a vertex  $v \in V(T)$ , let  $T_v$  be the subtree of  $T$  rooted at  $v$ . An edge  $(u, v)$  in  $G$  such that  $u$  is the parent of  $v$  is a *heavy-edge* if  $|V(T_u)| \leq 2|V(T_v)|$  and a *light-edge* otherwise. Each vertex has at most one child such that the edge between them is a heavy-edge. The *heavy-path* is a maximal path that only contains heavy-edges. The *heavy-light decomposition* is the decomposition of  $T$  into heavy-paths. Note that, there is at most  $O(\log n)$  light-edges on any root-leaf path on  $T$ .

### 3 Outline and Organization

Here we roughly describe our algorithm using the notions in Section 2. Let  $G$  be a cube-free median graph. Let  $m$  be a median of  $G$ ,  $\text{St}(m)$  be the star of  $m$ , and for each  $x \in \text{St}(m)$ , let  $F(x)$  be the fiber of  $x$  in  $\text{St}(m)$  (see Figure 1). Let  $u, v$  be vertices of  $G$ .

Consider calculating  $p(I[u, v])$ . If  $u$  and  $v$  are in the same fiber  $F(x)$  of  $\text{St}(m)$ , we calculate the answer by using the algorithm on  $F(x)$ , which is recursively defined. Lemma 9 ensures that the recursion depth is at most  $O(\log n)$ . Otherwise, we can show that  $I[u, v]$  intersects with only a constant number of fibers, and for each fiber  $F(x)$  that intersects  $I[u, v]$ ,  $I[u, v] \cap F(x)$  can be represented as  $I[u_x, v_x]$  for some vertices  $u_x, v_x \in F(x)$  such that  $v_x$  is on the total boundary of  $F(x)$ . Thus, it is sufficient to construct an algorithm to answer the query on the interval, such that one of the ends is on the total boundary of  $F(x)$ .

■ **Figure 1** A median graph and its decomposition into fibers of  $\text{St}(m)$ .

■ **Figure 2** Staircases with top  $x$  with base starts at  $s$  and ends at  $t$ .

■ **Figure 3** Decomposition of  $I[u, v]$  into an interval  $I[u, w]$  and staircases  $I[e', v]$ . The bold line represents  $P$ .

To do this, we introduce a technique to decompose intervals, which we name the *staircases decomposition*. Let  $T$  be a tree with gated branches and assume  $u \in V(G)$  and  $v \in V(T)$ . We partition an interval  $I[u, v]$  into an interval  $I$  and at most two special structures, which we name a *staircases* (Figure 2), which we describe in Section 4. Such a decomposition can be calculated in  $O(\log n)$  time with appropriate preprocessing. Here, we can take  $I$  as one of the  $O(n)$  candidates of intervals. We just precalculate and store the value  $p(I)$  for each candidate, and recall it when we answer the queries.

Now we just need an algorithm to calculate the value  $p(V(L))$  quickly for a staircases  $L$ . Let  $P$  be a root-leaf path of  $T$ . The segment trees can answer the staircases queries whose base is a subpath of  $P$  in  $O(\log n)$  time. To answer the general queries, we use a heavy-light decomposition of  $T$ .

The rest of the paper is organized as follows. In Section 4, we introduce the staircases decomposition of the intervals with one end on the tree with gated branches. In Section 5, we construct an algorithm and a data structure for the interval queries for the same cases. In Section 6, we prove that we can decompose a given interval into constant number of intervals with one of the ends on the total boundaries of the fibers of  $\text{St}(m)$ . This technique can also be applied to the query that asks the median of given three vertices. Some detailed parts in these sections are found in full version. An algorithm to construct our data structure efficiently is given in full version.

## 4 The Staircases Decomposition of the Intervals with One End on the Boundary

Let  $T$  be a tree with gated branches. In this section, we introduce a technique, *staircases decomposition*, to decompose an interval  $I[u, v]$  such that  $v$  is on  $T$ .

Let  $P = (s = w_0, \dots, w_k = t)$  be a convex path. For a vertex  $x$  with gate  $s$  in  $P$ , the interval  $I[x, t]$  induces *staircases* if for all  $i = 0, \dots, k$ , the set of vertices in  $I[x, t]$  with gate  $w_i$  in  $P$  induces a path.  $P$  is the *base* of  $L$  and the vertex  $x$  is the *top* of  $L$ . The base *starts* at  $s$  and *ends* at  $t$  (see Figure 2). Our staircases decomposition decomposes  $I[u, v]$  into an interval and at most two staircases such that their bases are columns of  $T$ .

### 4.1 The case with One End on a Convex Path

Here we investigate the structure of an interval such that one of the endpoints is on a convex path  $P$ . Consider an interval  $I[u, v]$  such that  $v$  is on  $P$ . Let  $w$  be the gate of  $u$  in  $P$ . The purpose here is to prove that  $I[u, v]$  can be decomposed into the disjoint union of an interval  $I[u, w]$  and a staircases (see Figure 3), if  $w \neq v$ . We assume  $w \neq v$  because otherwise we

■ **Figure 4** Staircases decomposition of  $I[u, v]$  (single imprint, first case).

■ **Figure 5** Staircases decomposition of  $I[u, v]$  (single imprint, second case).

■ **Figure 6** Staircases decomposition of  $I[u, v]$  (double imprints).

have no need of decomposition. Let  $w'$  be the neighbor of  $w$  in  $P$  between  $w$  and  $v$ . We take the isometric embedding of  $I[u, v]$  into a two-dimensional grid (see Lemma 2). We naively introduce a  $xy$ -coordinate system with  $w = (0, 0)$ ,  $w' = (1, 0)$ ,  $u = (x_u, y_u)$  with  $y_u \geq 0$ , and  $v = (x_v, y_v)$  with  $y_v \leq 0$ . Now, we can state the following.

► **Lemma 10.** *If a vertex  $z = (x_z, y_z)$  on  $I[u, v] \cap V(P)$  is not on the  $x$ -axis, there is no vertex other than  $z$  in  $I[u, v]$  with gate  $z$  in  $P$ .*

**Proof.** Assume the contrary and let  $z' = (x_{z'}, y_{z'})$  be a vertex in  $I[u, v]$  with gate  $z$  in  $P$ . Because of the isometricity,  $x_z > 0$  and  $y_z < 0$  holds. Since  $z \in I[w, z']$ , we have  $x_{z'} \geq x_z$ . Since  $z' \in I[u, v]$ ,  $x_v \geq x_{z'}$  holds. Therefore, we can take a vertex  $z''$  in  $P$  with  $x$ -coordinate  $x_{z'}$ , but it means  $z' \in I[w, z'']$  and contradicts to the convexity of  $P$ . ◀

Since such  $z$  does not affect the possibility of decomposition (we can just add such vertices at the end of the staircases), we can assume that  $v = (x_v, 0)$  for  $x_v > 0$ . Moreover, from convexity, we have that all vertices in  $I[u, v]$  have non-negative  $y$ -coordinate. Thus,  $I[u, v] \setminus I[u, w]$  is the set of vertices with positive  $x$ -coordinate and forms staircases (see Figure 3), which is the desired result.

To build an algorithm to calculate  $p(I[u, v])$  as the sum of  $p(I[u, w])$  and  $p(I[u, v] \setminus I[u, w])$ , we should identify the top  $e'$  of the staircases. Instead of direct identification, we rather identify the unique neighbor of it in  $I[u, w]$ , named the *entrance*  $e$  of the staircases: The top  $e'$  can be determined as the neighbor of  $e$  with gate  $w'$  on  $P$ . Here, we have that  $e$  is the gate of  $u$  in the boundary of  $F(w)$  with respect to  $F(w')$ , where  $F(w)$  (resp.  $F(w')$ ) is the fiber of  $w$  (resp.  $w'$ ) with respect to  $P$ . Indeed, this gate should be in  $I[u, w]$  from the definition of the gate and  $e$  is the only candidate for it. We can calculate  $e$  in  $O(\log n)$  time by working on the appropriate data structure on total boundary of the fiber of  $w$  with respect to  $P$ . We discuss this algorithm in full version.

## 4.2 Single Imprint

Here we give the staircases decomposition of the interval  $I[u, v]$ , where  $v$  is on a tree  $T$  with gated branches, rooted at  $r$ . First, we treat the case that there is exactly one imprint  $w$  of  $u$  in  $T$  in  $I[u, v]$ . Let  $t$  be a lowest common ancestor of  $w$  and  $v$  in  $T$ . Note that,  $t$  might coincide with  $w$  or  $v$ . Let  $P$  (resp.  $P'$ ) be the root-leaf path of  $T$  that contains  $w$  (resp.  $v$ ).

Since  $P'$  is convex, we can decompose  $I[u, v]$  into a staircases  $L'$  with base on  $P'$  and an interval  $I[u, t]$ . Since  $P$  is convex, we can further decompose the interval  $I[u, t]$  into a staircases  $L$  with base on  $P$  and an interval  $I[u, w]$ . Now, for fixed  $T$ ,  $I[u, w]$  is one of the  $O(n)$  candidates of the intervals, because it is specified only by a vertex  $u$  and one of at most two imprints of  $u$  on  $T$ . This is the staircases decomposition we obtain here.

To bound the size of the data structure we construct in Section 5, we should ensure that staircases  $L$  and  $L'$  contains only vertices with an imprint on  $P$  and  $P'$ , respectively. Let  $B_L$  (resp.  $B_{L'}$ ) be the base of  $L$  (resp.  $L'$ ). We prove the following.

► **Lemma 11.** *The following statements hold.*

- (i)  $I[u, v]$  contains no vertices in  $T$  other than the vertices on the  $w - v$  path on  $T$ .
- (ii) For a vertex  $z$  in  $L'$ , the gate of  $z$  in  $P'$  is an imprint of  $z$  in  $T$ .
- (iii) For a vertex  $z$  in  $L$ , the gate of  $z$  in  $P$  is an imprint of  $z$  in  $T$ .

**Proof.** (i) Let  $z \in I[u, v] \cap V(T)$ . Then,  $d(u, v) = d(u, z) + d(z, v)$  holds. Since  $w$  is the unique imprint of  $u$  in  $T$ ,  $d(u, z) = d(u, w) + d(w, z)$  and  $d(u, v) = d(u, w) + d(w, v)$  holds. Therefore  $d(w, v) = d(w, z) + d(z, v)$  and it means  $z$  is on the unique path between  $w$  and  $v$  on  $T$ . (ii) Let  $w'_z$  be the gate of  $z$  in  $P'$ . We prove  $I[z, w'_z] \cap V(T) = \{w'_z\}$ . Assume  $x \in (I[z, w'_z] \cap V(T)) \setminus \{w'_z\}$ . From (i),  $x$  is on  $w - t$  path. From isometricity of  $T$ ,  $t \in I[x, w'_z] \subseteq I[z, w'_z]$  holds and it contradicts the definition of  $w'_z$ . (iii) Similar to (ii). ◀

We should also make algorithms to identify the top of the staircases  $L$  and  $L'$ . The top of  $L$  can be found by applying the discussion in previous subsection by precalculating the entrances for all possible patterns of  $u$  and  $w$ , because the start of the base of  $L$  is uniquely determined as a parent of  $w$ , independent of  $v$ . However, we cannot apply it to find the top of  $L'$ , because the start of the base of  $L'$  is a child of  $t$ , not a parent. Instead, we calculate the top of  $L'$  by case-analysis of the positional relation of the staircases. Intuitively, we divide cases by the angle formed by  $B_L$  and  $B_{L'}$ . We have essentially two cases<sup>3</sup> to tract, which this angle is  $\pi/2$  (Figure 4) or  $\pi$  (Figure 5) (we formally define these cases and prove that they cover all cases in full version). In the case in Figure 4, the entrance  $e$  of  $L'$  can be found on  $B_L$ . In the case in Figure 5,  $e$  can be found on the total boundary of the vertex set with imprint  $t$ . In both case, by appropriate data structure given in full version, we can find the entrance in  $O(\log n)$  time.

### 4.3 Double Imprints

Here we consider the staircases decomposition for the case that there are two imprints  $w^1, w^2$  of  $u$  in  $T$  in  $I[u, v]$ . Let  $w$  be the lowest common ancestor of  $w^1$  and  $w^2$  in  $T$ . From (ii) of Lemma 7 and isometricity of  $T$ ,  $d(u, w^1) + d(w^1, w) = d(u, r) - d(w, r) = d(u, w^2) + d(w^2, w)$  holds and particularly we have  $w^1, w^2 \in I[u, w]$ . From isometricity of  $T$ , we have  $w \in I[w_1, w_2] \subseteq I[u, v]$ . Let  $t$  be the lowest common ancestor of  $w$  and  $v$ . Then, from isometricity of  $T$ , we have  $t \in I[w, v] \subseteq I[u, v]$ . Note that, the lowest common ancestor of  $v$  and  $w^1$  (resp.  $w^2$ ) is also  $t$ , because otherwise we have  $w \notin I[u, v]$ . Let  $P$  (resp.  $P'$ ) be any root-leaf path of  $T$  that contains  $w$  (resp.  $v$ ).

Since  $P'$  is convex, we can decompose  $I[u, v]$  into a staircases  $L'$  with base on  $P'$  and an interval  $I[u, t]$ . Since the subpath of  $P$  between  $r$  and  $w$  is convex, we can further decompose the interval  $I[u, t]$  into a staircases  $L$  with base on  $P$  and an interval  $I[u, w]$  (actually, we can prove that  $L$  is a line). Now, for fixed  $T$ ,  $I[u, w]$  is one of the  $O(n)$  candidates of the intervals, because  $w$  is specified only by a vertex  $u$ , as the lowest common ancestor of two imprints of  $u$  in  $T$ . This is the staircases decomposition we obtain here.

Let  $B_L$  (resp.  $B_{L'}$ ) be the base of  $L$  (resp.  $L'$ ). From the same reason as the case with a single imprint, we prove the following lemma. The proof is similar to the proof of Lemma 11.

<sup>3</sup> To explain all cases by these two, we take  $T$  as the maximal tree with gated branches that contains the fiber we consider, rather than the fiber itself.

► **Lemma 12.** *The following statements hold.*

- (i)  $I[u, v]$  contains no vertices in  $T$  other than vertices in  $w^1 - v$  and  $w^2 - v$  path on  $T$ .
- (ii) For a vertex  $z$  in  $L'$ , the gate of  $z$  in  $P'$  is an imprint of  $z$  in  $T$ .
- (iii) For a vertex  $z$  in  $L$ , the gate of  $z$  in  $P$  is an imprint of  $z$  in  $T$ .

**Proof.** (i) Let  $z \in I[u, v] \cap V(T)$ . Then,  $d(u, v) = d(u, z) + d(z, v)$  holds. Let  $w^i$  be the imprint of  $u$  in  $T$  with  $d(u, z) = d(u, w^i) + d(w^i, z)$ . Then,  $d(u, v) = d(u, w^i) + d(w^i, v)$  holds. Therefore  $d(w^i, v) = d(w^i, z) + d(z, v)$  and it means  $z$  is on the unique path between  $w^i$  and  $v$  on  $T$ . (ii) Let  $w'_z$  be the gate of  $z$  in  $P'$ . We prove  $I[z, w'_z] \cap V(T) = \{w'_z\}$ . Assume  $x \in (I[z, w'_z] \cap V(T)) \setminus \{w'_z\}$ . From (i),  $x$  is on  $t - w^1$  or  $t - w^2$  path. From isometricity of  $T$ ,  $t \in I[x, w'_z] \subseteq I[z, w'_z]$  holds and it contradicts the definition of  $w'_z$ . (iii) Similar to (ii). ◀

We should also provide a way to identify the top of the staircases  $L'$ . We have only one case to tract, shown in Figure 6, which we can find the entrance on  $w^1 - t$  or  $w^2 - t$  path on  $T$  (we formally define the case in full version). We can find it in  $O(\log n)$  time in the algorithm in full version.

## 5 Query Processing of the Case with One End on the Tree with Gated Branches

In this section, we construct an algorithm and a data structure that answers the queries with one of the endpoints on the tree with gated branches. That part is the core of our algorithm.

### 5.1 Query Processing for Maximal Staircases with Base on Convex Path

Here we construct an algorithm and a data structure for the staircases whose base is contained in a convex path  $P$ . For simplicity, we assume that  $P$  contains  $2^q$  vertices for some integer  $q$ . We do not lose generality by this restriction because we can safely attach dummy vertices at the end of  $P$ . Let  $P = (w_0, \dots, w_{2^q-1})$ . Our data structure uses a segment tree defined on  $P$ . The information of the vertices with base  $w_i$  in  $P$  are stored by linking to  $w_i$ .

It is convenient to consider the *direction* of  $P$ , as if  $P$  is directed from  $w_0$  to  $w_{2^q-1}$ . The *reverse*  $\bar{P}$  of  $P$  is the same path as  $P$  as an undirected path but has different direction, i.e.,  $\bar{P} = (w_{2^q-1}, \dots, w_0)$ . We represent the path between  $w_x$  and  $w_y$  on  $P$  by  $P[x, y]$ .

Let us formally define the queries to answer here. A query is represented by three vertices  $x, w_a, w_b$  such that the gate of  $x$  on  $P$  is  $w_a$ , and asks to answer the value  $p(L(x, w_a, w_b))$ , where  $L(x, w_a, w_b)$  represents the staircases with top  $x$  and base starts at  $w_a$  and ends at  $w_b$ . We construct two data structures, the first one treats the case  $a \leq b$  and the second one treats the case  $a > b$ . The second data structure is just obtained by building the first data structure on the reverse of  $P$ , therefore we can assume that for all queries,  $w_a \leq w_b$  holds.

For  $i = 0, \dots, 2^q - 1$ , let  $F_i$  be the fiber of  $w_i$  with respect to  $P$ . For  $i = 0, \dots, 2^q - 2$  and  $z \in F_i$ , the *successor*  $\text{succ}_P(z)$  of  $z$  is the gate of  $z$  in  $F_{i+1}$  (see Figure 7). Intuitively,  $\text{succ}_P(z)$  represents the next step of  $z$  in the staircases with base in  $P$ ; more precisely, for  $a < i < b$ , if  $F_i \cap V(L(x, w_a, w_b))$  induces  $z - w_i$  path,  $F_{i+1} \cap V(L(x, w_a, w_b))$  induces  $\text{succ}_P(z) - w_{i+1}$  path.

Here we construct a complete binary tree, which is referred to as *segment tree*, to answer the queries. For each  $d = 0, \dots, q$  and for each  $i = 0, 1, \dots, 2^{q-d} - 1$ , we prepare a node that corresponds to  $P[i \times 2^d, (i+1) \times 2^d - 1]$ . For each node  $v$  that corresponds to  $P[l, r]$  and for each  $z \in F_l$ , we store the vertex  $s(z, l, r) = \text{succ}_P^{r-l}(z)$  and the value  $S(z, l, r) = p(L(z, w_l, w_r)) = p(I[\text{succ}_P^0(z), w_l]) \oplus \dots \oplus p(I[\text{succ}_P^{r-l}(z), w_r])$ , where the  $\text{succ}_P^k(z)$  is recursively defined by  $\text{succ}_P^0(z) = z$  and  $\text{succ}_P^{k+1}(z) = \text{succ}_P(\text{succ}_P^k(z))$  for all  $0 \leq k$ .

## 18:10 Interval Query Problem on Cube-Free Median Graphs

The Algorithm 1 calculates  $p(L(x, w_a, w_b))$ . We call the procedure  $\text{StaircasesQuery}_P(0, 2^q - 1, a, b, x)$  to calculate it, and the algorithm returns the pair of the vertex  $\text{succ}_P^{b-a+1}(x)$  and the value  $p(L(x, w_a, w_b))$ . The time complexity is  $O(q) = O(\log n)$ .

■ **Algorithm 1**  $\text{StaircasesQuery}_P(l, r, a, b, x)$ .

---

```

1: if  $[l, r] \subseteq [a, b]$  then
2:   return  $(s(x, l, r), S(x, l, r))$ 
3:  $med \leftarrow \lfloor \frac{l+r}{2} \rfloor$ 
4: if  $b \leq med$  then
5:   return  $\text{StaircasesQuery}_P(l, med, a, b, x)$ 
6: if  $med < a$  then
7:   return  $\text{StaircasesQuery}_P(med + 1, r, a, b, x)$ 
8:  $(x', S_1) \leftarrow \text{StaircasesQuery}_P(l, med, a, b, x)$ 
9:  $(x'', S_2) \leftarrow \text{StaircasesQuery}_P(med + 1, r, a, b, \text{succ}_P(x'))$ 
10: return  $(x'', S_1 \oplus S_2)$ 

```

---

This data structure is constructed as in Algorithm 2. The correctness is clear and the time complexity is  $O(nq) \leq O(n \log n)$ , assuming that we know the vertex  $\text{succ}_P(x)$  and the value  $p(I[x, w_i])$  for all  $i = 0, \dots, 2^q - 1$  and  $x \in F_i$ . The size of the data structure is clearly  $O(nq) \leq O(n \log n)$ . We give algorithms to calculate  $\text{succ}_P(x)$  and  $p(I[x, w_i])$  in full version.

■ **Algorithm 2** Construction of the Data Structure for Staircases with Base on Convex Path.

**Input:** A cube-free median graph  $G$ , a convex path  $P = (w_0, \dots, w_{2^q-1})$

---

```

1: for  $i = 0, \dots, 2^q - 1$  do
2:   for all  $x \in F_i$  do
3:      $s(x, i, i) \leftarrow x$ 
4:      $S(x, i, i) \leftarrow p(L(x, w_i, w_i)) = p(I[x, w_i])$ 
5:   for  $d = q - 1, \dots, 0$  do
6:     for  $i = 0, \dots, 2^{q-d} - 1$  do
7:        $a \leftarrow i \times 2^d, b \leftarrow (i + \frac{1}{2}) \times 2^d, c \leftarrow (i + 1) \times 2^d$ 
8:       for all  $x \in F_i$  do
9:          $s(x, a, c - 1) \leftarrow s(\text{succ}_P(s, a, b - 1), b, c - 1)$ 
10:         $S(x, a, c - 1) \leftarrow S(x, a, b - 1) \oplus S(\text{succ}_P(s(x, a, b - 1)), b, c - 1)$ 

```

---

## 5.2 Query Processing for Staircases with Base on the Tree with Gated Branches

Let  $T$  be a tree with gated branches. Here we construct an algorithm and a data structure for the staircases whose base is a column of  $T$ . The simplest idea is to prepare the data structure discussed in the previous subsection for all root-leaf paths on  $T$ , but in this case the total size of the data structure can be as bad as  $O(n^2 \log n)$ . To reduce the size, we instead prepare the above data structure on every heavy-path of heavy-light decomposition of  $T$ .

For a vertex  $w \in V(T)$ , let  $F(w)$  be the set of vertices with an imprint  $w$ . For an edge  $(w, w')$  of  $T$  and a vertex  $z \in F(w)$ , we denote  $\text{succ}_{w, w'}(z)$  by the gate of  $z$  in  $F(w')$ . For the staircases  $L$  whose base starts at  $w_1$  and ends at  $w_2$  such that  $w_1, w, w', w_2$  are located on some column of  $T$  in this order, if  $F(w) \cap V(L)$  induces  $z - w$  path,  $F(w') \cap V(L)$  is  $\text{succ}_{w, w'}(z) - w'$  path.

## 18:12 Interval Query Problem on Cube-Free Median Graphs

Now we consider calculating the answer as  $p(L) + p(L') + p(I)$ .  $p(L)$  and  $p(L')$  can be calculated in  $O(\log^2 n)$  time by above algorithm. Furthermore,  $p(I)$  is precalculated in the construction of our data structure and we can take this value in constant time. Therefore we can answer the interval query in the case with one end on the tree with gated branches in  $O(\log^2 n)$  time. We summarize our algorithm in full version.

Here we describe how  $p(I)$  can be precalculated. Recall that, we construct our data structure recursively on each fibers. Therefore, after constructing the smaller data structure on each fiber, we can calculate the value  $p(I)$  in  $O(\log^2 n)$  time by using an interval query on them to complete construction. This is the bottleneck part of our construction algorithm, along with  $O(\log n)$  recursion steps. Note that, this procedure can be implemented during preprocessing because there are only  $O(n)$  candidates of  $I$ . When answering to the queries, we do not need to use the smaller data structure; we have only to refer these precalculated values.

### 6 Decomposing Intervals into intervals with One End on the Boundary

In this section, we consider decomposing an interval with both ends in different fibers into smaller intervals with one end on boundaries (see Figure 8). Specifically, we bound the number of such fibers by 9. Let  $m$  be the median of  $G$ . For  $x \in \text{St}(m)$ , let  $F(x)$  be the fiber of  $x$  with respect to  $\text{St}(m)$ . For  $v \in V(G)$ , let  $r(v)$  be the vertex in  $\text{St}(m)$  that is nearest from  $v$ . From definition of fibers,  $v \in F(r(v))$  holds.

First, we prove that the intersection of an interval and a fiber is indeed an interval. The following lemma holds.

► **Lemma 13.** *Let  $u, v$  be vertices and let  $x \in \text{St}(m)$ . Let  $g_u, g_v$  be the gate of  $u, v$  in  $F(x)$ , respectively. Then,  $I[u, v] \cap F(x)$  coincides with  $I[g_u, g_v]$  if it is nonempty.*

**Proof.** Assume  $z \in I[u, v] \cap F(x)$ . From the definition of the gate, there is a  $u - z$  (resp.  $v - z$ ) shortest path that passes through  $g_u$  (resp.  $g_v$ ). Therefore there is a  $u - v$  shortest path that passes through  $u, g_u, z, g_v, v$  in this order, which means  $z \in I[g_u, g_v]$ . Converse direction is clear from  $I[g_u, g_v] \subseteq I[u, v]$ , which is from the definition of the gate. ◀

Note that, unless  $r(u) = r(v)$ , one of the gates of  $u$  or  $v$  in  $F(x)$  is on the total boundary of  $F(x)$ . Therefore, to obtain the desired structural result, we just need to bound the number of fibers with non-empty intersection with  $I[u, v]$ . We use the following lemma from [13].

► **Lemma 14 ([13]).** *Let  $u, v$  be vertices with  $r(u) \neq r(v)$ . Then, one of the  $m \in I[u, v]$ ,  $r(u) \sim r(v)$ , or  $d(m, r(u)) = d(m, r(v)) = d(r(u), r(v)) = 2$  holds.*

Assume  $m \in I[u, v]$ . Then,  $I[u, v] \cap F(x) \neq \emptyset$  means  $x \in I[u, v]$ . Therefore the number of such fibers  $F(x)$  is same as the number of vertices in  $I[u, v] \cap \text{St}(m)$ . Now, from the fact that  $I[u, v]$  has a grid structure (see Lemma 2) and  $\text{St}(m)$  consists of the vertices in an edge or a square that contains  $m$ , we have that  $|I[u, v] \cap \text{St}(m)| \leq 9$ .

If  $r(u) \sim r(v)$ , from Lemma 6, we have  $I[u, v] \subseteq F(r(u)) \cup F(r(v))$ . If  $d(r(u), r(v)) = 2$ , let  $w$  be the unique common neighbor of  $r(u)$  and  $r(v)$ . Then, from Lemma 6, we have  $I[u, v] \subseteq F(r(u)) \cup F(w) \cup F(r(v))$ . Therefore, in all cases, the number of fibers with nonempty intersection with  $I[u, v]$  is bounded by 9.

In all of these cases, we can list the fibers  $F(x)$  with nonempty intersection with the given interval  $I[u, v]$ ; it is the set of the fibers of the vertices in  $I[r(u), r(v)]$  because  $\bigcup_{x \in I[r(u), r(v)]} F(x)$  is convex, and, we can list them efficiently by using the list of all squares in  $G$ . Now it is sufficient to give a way to calculate the gate of  $u$  and  $v$  in each of these fibers for our algorithm. We give the algorithm in full version.

Above technique can also be applied for the following query. We are given three vertices  $v_1, v_2, v_3$  in a cube-free median graph  $G$  and asked to answer the median  $v$  of these three vertices. Let  $x$  be the median of  $r(v_1)$ ,  $r(v_2)$  and  $r(v_3)$ .  $x$  can be calculated in  $O(\log n)$  time because each of  $I[r(v_1), r(v_2)]$ ,  $I[r(v_2), r(v_3)]$  and  $I[r(v_3), r(v_1)]$  contains at most 9 vertices and  $x$  is the unique vertex in the intersection of these intervals. Now, we can state that  $v \in F(x)$ , because  $F(x)$  is the only fiber that can intersect all of  $I[v_1, v_2]$ ,  $I[v_2, v_3]$  and  $I[v_3, v_1]$ .

Let  $g_{v_1}$  (resp.  $g_{v_2}, g_{v_3}$ ) be the gate of  $v_1$  (resp.  $v_2, v_3$ ) in  $F(x)$ , which can be calculated in  $O(\log n)$  time. Then, from Lemma 13,  $v$  coincides with the median of  $g_{v_1}$ ,  $g_{v_2}$  and  $g_{v_3}$ . Therefore we can reduce the median query on the original graph into the median query on the fiber  $F(x)$  in  $O(\log n)$  time. By recursively working on the fiber, we can calculate  $v$  after  $O(\log n)$  recursion steps. Therefore the query can be answered in  $O(\log^2 n)$  time in total. The data structure required here is constructed in  $O(n \log^2 n)$  time just by taking the necessary parts of the algorithm in full version.

## Abstract

We consider the problem of untangling a given (non-planar) straight-line circular drawing  $\delta_G$  of an outerplanar graph  $G = (V, E)$  into a planar straight-line circular drawing by shifting a minimum number of vertices to a new position on the circle. For an outerplanar graph  $G$ , it is clear that such a crossing-free circular drawing always exists and we define the *circular shifting number*  $\text{shift}^\circ(\delta_G)$  as the minimum number of vertices that need to be shifted to resolve all crossings of  $\delta_G$ . We show that the problem CIRCULAR UNTANGLING, asking whether  $\text{shift}^\circ(\delta_G) \leq K$  for a given integer  $K$ , is NP-complete. Based on this result we study CIRCULAR UNTANGLING for *almost-planar* circular drawings, in which a single edge is involved in all the crossings. In this case we provide a tight upper bound  $\text{shift}^\circ(\delta_G) \leq \lfloor \frac{n}{2} \rfloor - 1$ , where  $n$  is the number of vertices in  $G$ , and present a polynomial-time algorithm to compute the circular shifting number of almost-planar drawings.

## 1 Introduction

The family of outerplanar graphs, i.e., the graphs that admit a planar drawing where all vertices are incident to the outer face, is an important subclass of planar graphs and exhibits interesting properties in algorithm design, e.g., they have treewidth at most 2. Being defined by the existence of a certain type of drawing, outerplanar graphs are a fundamental topic in the field of graph drawing and information visualization; they are relevant to circular graph drawing [28] and book embedding [3, 5]. Several aspects of outerplanar graphs have been studied over the years, e.g., characterization [9, 14, 29], recognition [1, 31], and drawing [15, 21, 27]. Moreover, outerplanar graphs and their drawings have been applied to various scientific fields, e.g., network routing [16], VLSI design [10], and biological data modeling and visualization [20, 32].

In this paper we study the untangling problem for non-planar circular drawings of outerplanar graphs, i.e., we are interested in restoring the planarity property of a straight-line circular drawing with a minimum number of vertex shifts. Similar untangling concepts have been used previously for eliminating edge crossings in non-planar drawings of planar graphs [18]. More precisely, let  $G = (V, E)$  be an  $n$ -vertex outerplanar graph and let  $\delta_G$  be an outerplanar drawing of  $G$ , which can be described combinatorially as the (cyclic) order  $\sigma = (v_1, v_2, \dots, v_n)$  of  $V$  when traversing vertices on the boundary of the outer face counterclockwise. This order  $\sigma$  corresponds to a circular drawing by mapping each vertex  $v_i \in V$  to the point  $p_i$  on the unit circle  $\mathcal{O}$  with polar coordinate  $p_i = (1, 2\pi i/n)$  and drawing each edge  $(v_i, v_j) \in E$  as the straight-line segment between its endpoints  $p_i$  and  $p_j$ . Two edges  $e, e'$  cross in  $\delta_G$  if and only if their endpoints alternate in the order  $\sigma$ . We note that it is sufficient to consider circular drawings since any outerplanar drawing can be transformed into an equivalent circular drawing by morphing the boundary of the outer face to  $\mathcal{O}$ .

Our untangling problem is motivated by the problem of maintaining an outerplanar drawing of a *dynamic* outerplanar graph, which is subject to edge or vertex insertions and deletions, while maximizing the visual *stability* of the drawing [22, 23], i.e., the number of vertices that can remain in their current position. Such problems of maintaining drawings with specific properties for dynamic graphs have been studied before [2, 4, 12, 13], but not for the outerplanarity property.

The notion of untangling is often used in the literature for a crossing elimination procedure that makes a non-planar drawing of a planar graph crossing-free; see [11, 19, 25, 26]. Given a straight-line drawing  $\delta_G$  of a planar graph  $G$ , the problem to decide if one can untangle  $\delta_G$  by moving at most  $k$  vertices, is proved to be NP-hard [18, 30]. Lower bounds on the number of vertices that can remain fixed in an untangling process have also been studied [7, 8, 18]. Bose et al. [7] proved that  $\Omega(n^{1/4})$  vertices can remain fixed when untangling a drawing. Cano et al. [8] on the other hand provide a family of drawings, where at most  $O(n^{0.4948})$  vertices can remain fixed during untangling. Goaoc et al. [18] proposed an algorithm, which allows at least  $\sqrt{(\log n) - 1}/\log \log n$  vertices to be fixed when untangling a drawing. If the graph is outerplanar, the algorithm proposed by Goaoc et al. could eliminate all edge crossings while keeping at least  $\sqrt{n/2}$  vertices fixed. Notice that the drawing obtained by this algorithm is planar but not necessarily outerplanar. In this paper, we study untangling procedures to obtain an outerplanar drawing from a non-outerplanar drawing. To the best of our knowledge, there are no previous studies about untangling circular drawings.

**Preliminaries and Problem Definition.** Given a graph  $G = (V, E)$ , we say two vertices are *2-connected* if they are connected by two internally vertex-disjoint paths. A 2-connected component of  $G$  is a maximal set of pairwise 2-connected vertices. Two subsets  $A, B \subseteq V$  are *adjacent* if there is an edge  $ab \in E$  with  $a \in A$  and  $b \in B$ . A *bridge* (resp. *cut-vertex*) of  $G$  is an edge (resp. vertex) whose deletion increases the number of connected components of  $G$ .

A drawing of a graph is *planar* if it has no crossings, it is *almost-planar* if there is a single edge that is involved in all crossings, and it is outerplanar if it is planar and all vertices are incident to the outer face. A graph  $G = (V, E)$  is *outerplanar* if it admits an outerplanar drawing. In addition, a drawing where the vertices lie on a circle and the edges are drawn as straight-line segments is called a *circular drawing*. Every outerplanar graph  $G$  admits a planar circular drawing, as one can start with an arbitrary outerplanar drawing  $\delta_G$  of  $G$  and transform the outer face of  $\delta_G$  to a circle [28]. In this paper, we exclusively work with circular drawings of outerplanar graphs; we thus simply refer to them as drawings.

Given a non-planar circular drawing  $\delta_G$  of an  $n$ -vertex outerplanar graph  $G$  where vertices lie on the unit circle  $\mathcal{O}$ , we can transform the drawing  $\delta_G$  to an outerplanar drawing by moving the vertices on the circle  $\mathcal{O}$ . We call a sequence of moving operations that results in

an outerplanar drawing an *untangling* of  $\delta_G$ . Formally, given a circular drawing  $\delta_G$ , a vertex move operation (or shift) changes the position of one vertex in  $\delta_G$  to another position on the circle  $\mathcal{O}$  [18]. We define the *circular shifting number*  $\text{shift}^\circ(\delta_G)$  of an outerplanar drawing  $\delta_G$  to be the minimum number of vertices that are required to shift in order to untangle  $\delta_G$ . We say an untangling is *optimal* if the number of vertex moves of this untangling is the minimum over all valid untanglings of  $\delta_G$ . We study the following problems.

► **Problem 1.1** (MINIMUM CIRCULAR UNTANGLING (MINCU)). *Given a circular drawing  $\delta_G$  of an outerplanar graph  $G$ , find a sequence of  $\text{shift}^\circ(\delta_G)$  vertex moves that untangles  $\delta_G$ .*

► **Problem 1.2** (CIRCULAR UNTANGLING (CU)). *Given a circular drawing  $\delta_G$  of an outerplanar graph  $G$  and an integer  $K$ , decide if  $\text{shift}^\circ(\delta_G) \leq K$ .*

**Contributions.** In Section 2, we show that the problem CIRCULAR UNTANGLING is NP-complete. We then consider almost-planar drawings. In this case, we provide a tight upper bound on the circular shifting number in Section 3 and design a quadratic algorithm to compute a circular untangling with the minimum number of vertex moves in Section 4. Details of the omitted/sketched proofs (marked with  $\star$ ) are available in the full version [6] of the paper.

## 2 Complexity of Circular Untangling

The goal of this section is to prove the following theorem.

► **Theorem 2.1.** CIRCULAR UNTANGLING is NP-complete.

Ultimately, the NP-completeness follows by a reduction from the well-known NP-complete problem 3-PARTITION. However, we do not give a direct reduction but rather work via an intermediate problem, called DISTINCT INCREASING CHUNK ORDERING WITH REVERSALS that concerns increasing subsequences. A *chunk* is a sequence  $S = (s_i)_{i=1,\dots,n}$  of positive integers. For a chunk  $C$ , we denote  $C^{-1}$  as its reversal. In the following, we introduce two longest increasing subsequence problems.

► **Problem 2.2** (INCREASING CHUNK ORDERING (ICO)). *Given  $\ell$  chunks  $C_1, \dots, C_\ell$  and a positive number  $M$ , the question is if there exists a permutation  $\pi$  of  $\{1, \dots, \ell\}$  such that the concatenation  $C_{\pi(1)}C_{\pi(2)} \cdots C_{\pi(\ell)}$  contains a strictly increasing subsequence (SISS) of length  $M$ .*

► **Problem 2.3** (INCREASING CHUNK ORDERING WITH REVERSALS (ICOREV)). *Given  $\ell$  chunks  $C_1, \dots, C_\ell$  and a positive integer  $M$ , the question is to determine whether a permutation  $\pi$  of  $\{1, \dots, \ell\}$  and a function  $\varepsilon: \{1, \dots, \ell\} \rightarrow \{-1, 1\}$  exist such that the concatenation  $C_{\pi(1)}^{\varepsilon(1)}C_{\pi(2)}^{\varepsilon(2)} \cdots C_{\pi(\ell)}^{\varepsilon(\ell)}$  contains a SISS of length  $M$ .*

These two problems also come in *distinct* variants, denoted by DISTINCT-ICO and DISTINCT-ICOREV, respectively, where all numbers in all input chunks need to be distinct. In the following, for two problem  $A$  and  $B$ , we write  $A \leq_p B$  if there is a polynomial-time reduction from  $A$  to  $B$ . It is readily seen that CIRCULAR UNTANGLING lies in NP. Therefore, Theorem 2.1 follows immediately from the following two reduction lemmas, whose proofs are given in the next two subsections.

► **Lemma 2.4.**  $\text{DISTINCT-ICOREV} \leq_p \text{CIRCULAR UNTANGLING}$

► **Lemma 2.5.**  $(\star) \text{ 3-PARTITION} \leq_p \text{DISTINCT-ICOREV}$

■ **Figure 1** The reduction from DISTINCT-ICOREV to CIRCULAR UNTANGLING. (a) The circular drawing  $\delta_G$  constructed from a DISTINCT-ICOREV instance with chunk set  $C = \{C_1 = (1, 8, 4), C_2 = (2, 5), C_3 = (6, 7, 9, 3)\}$ . (b) An example drawing obtained by applying an optimum untangling on  $\delta_G$ . Fixed vertices are marked in  $\square$ .

## 2.1 Proof of Lemma 2.4

Let  $I = (C, M)$  be an instance of DISTINCT-ICOREV with chunks  $C_1, \dots, C_\ell$ . By replacing each number with its rank among all occurring numbers, we may assume without loss of generality, that the numbers in the sequence are  $1, \dots, \sum_{i=1}^{\ell} |C_i| =: L$ .

We construct an instance  $I' = (\delta_G, K)$  of CIRCULAR UNTANGLING as follows; see Figure 1a. We create vertices  $v_1, \dots, v_L$  and an additional vertex  $v_0$ . For each chunk  $C_i$ , we create a cycle  $K_i$  that starts at  $v_0$ , visits the vertices that correspond to the elements of  $C_i$  in the given order, and then returns to  $v_0$ . That is,  $G$  consists of  $\ell$  cycles that are joined by the cut-vertex  $v_0$ . The drawing  $\delta_G$  is obtained by placing the vertices in the order  $\sigma_G = v_0, v_1, v_2, \dots, v_L$  clockwise. Finally, we set  $K := L - M$ . Clearly,  $I'$  can be constructed from  $I$  in polynomial time. It remains to prove the following.

► **Lemma 2.6.**  *$I$  is a yes-instance of DISTINCT-ICOREV if and only if  $I'$  is a yes-instance of CIRCULAR UNTANGLING.*

**Proof.** Observe that, since in  $\delta_G$  the vertices are ordered clockwise according to their numbering, the problem of untangling with at most  $L - M$  vertex moves is equivalent to finding a planar circular drawing of  $G$  whose clockwise ordering contains an increasing subsequence of at least  $M$  vertices, which can then be kept fixed; see Figure 1b.

The key observation is that, in every planar circular drawing of  $G$ , the vertices of each cycle  $K_i$  are consecutive, and the order of its vertices is the order along  $K_i$ , i.e., it is fixed up to reversal. Hence the choice of a circular drawing whose clockwise ordering contains an increasing subsequence of at least  $M$  vertices directly corresponds to a permutation and reversal of the chunks  $C_i$ . ◀

## 2.2 Proof of Lemma 2.5

Let  $I = (A, K)$  be an instance of 3-PARTITION. The input to the 3-PARTITION problem consists of a multiset  $A = \{a_1, \dots, a_{3m}\}$  of  $3m$  positive integers and a positive integer  $K$  such that  $\frac{K}{4} < a_i < \frac{K}{2}$ , for  $i = 1, \dots, 3m$ . The question is whether  $A$  can be partitioned into  $m$  disjoint triplets  $T_1, \dots, T_m$  such that  $\sum_{a \in T_j} a = K$ , for all  $j = 1, \dots, m$ . It is well-known

that 3-PARTITION is strongly NP-complete, i.e., the problem is NP-complete even if the integers in  $A$  and  $K$  are polynomially bounded in  $m$ ; see [17]. We show the following simpler lemma and then extend its proof to a proof of Lemma 2.5.

► **Lemma 2.7.** *3-PARTITION  $\leq_p$  INCREASING CHUNK ORDERING.*

**Proof.** Let  $I = (A, K)$  with  $A = \{a_1, \dots, a_{3m}\}$  be an instance of 3-PARTITION. We create for each element  $a_i$  a corresponding chunk  $C_i$  as follows. For two integers  $a < l$ , we denote the consecutive integer sequence  $(a, a + 1, \dots, a + l - 1)$  as the *incremental sequence* of length  $l$  starting at  $a$ .

We say that an incremental sequence *crosses a multiple of  $K$*  if it contains  $cK + 1$  and  $cK$  for some integer  $c$ . We take all the incremental sequences of length  $a_i$  that start at a value in  $\{1, \dots, mK\}$  except for those that cross a multiple of  $K$ . The chunk  $C_i$  is formed by concatenating these sequences in decreasing order of their first number. For example, for  $a_i = 3, m = 2, K = 6$ ,  $C_i$  is the concatenation of sequences  $(10, 11, 12), (9, 10, 11), (8, 9, 10), (7, 8, 9), (4, 5, 6), (3, 4, 5), (2, 3, 4), (1, 2, 3)$ .

We obtain an instance  $I' = (C, M)$  of INCREASING CHUNK ORDERING by setting  $C = \{C_1, \dots, C_{3m}\}$  and  $M := mK$ . We claim that  $I$  is a yes-instance of 3-PARTITION if and only if  $I'$  is a yes-instance of INCREASING CHUNK ORDERING. For the proof, we rely on the following observations:

- (i) every strictly increasing subsequence in  $C_i$  has length at most  $a_i$ .
- (ii) every strictly increasing subsequence in  $C_i$  of length  $a_i$  is consecutive and does not cross a multiple of  $K$ .
- (iii) every incremental sequence of  $\{1, \dots, mK\}$  that has length  $a_i$  and does not cross a multiple of  $K$  is a subsequence of  $C_i$ .

Assume there is a partition of the elements of  $A$  into  $m$  triples, each of which sums to  $K$ . We arbitrarily order these triples, and within each triplet, we order the elements according to their index. This defines a total ordering on the elements, and therefore on the chunks. Let  $T_i = \{a_x, a_y, a_z\}$  with  $x < y < z$  be the  $i$ th triplet and let  $C_x, C_y, C_z$  be the corresponding chunks. By observation (iii)  $C_x, C_y,$  and  $C_z$  contain respectively three incremental subsequences of length  $a_x, a_y,$  and  $a_z$  starting at  $iK + 1, iK + a_x + 1,$  and  $iK + a_x + a_y + 1$ . Concatenating the subsequences for all chunks hence gives the increasing subsequence  $1, \dots, mK$ .

Conversely, assume that there is a chunk ordering so that we obtain the incremental subsequence  $1, \dots, mK$ . By observation (i), each chunk  $C_i$  can contribute a subsequence of at most  $a_i$  elements; therefore each chunk  $C_i$  must contribute an increasing subsequence  $S_i$  of length  $a_i$ . By observation (ii), the subsequence  $S_i$  does not cross a multiple of  $K$ . Therefore, partitioning the sequence  $1, \dots, mK$  into  $k$  incremental sequences  $((c - 1)K + 1, \dots, cK)$  for  $c \in \{1, \dots, m\}$ , each of which corresponds to a triplet of  $A$  with the sum  $K$ . Together, these triplets define a solution of the instance  $I$  of 3-PARTITION. ◀

The proof of the stronger claim of Lemma 2.5 follows the same ideas but requires several additional ingredients. First of all, to achieve distinctness of the elements, we use strings of numbers, called *words*, which we order lexicographically. Then the main information is encoded in the first elements of the sequence, whereas the later entries are used to make the words pairwise distinct. At the end of the construction, each word can be replaced by its rank in a lexicographic ordering of all words that occur in the instance.

A second complication stems from the fact that chunks can be reversed. The chunks we construct in the proof of Lemma 2.7 contain a significantly longer increasing subsequence after reversal, as it may include one element from each incremental subsequence of the chunk,

of which there may be  $mK$  many. To alleviate this, we add a sufficiently long *tailing sequence* of length  $X$  to each increasing subsequence so that one cannot benefit from a reversal. Then chunk  $C_i$  can provide an increasing subsequence of length  $a_i + X$ , and all chunks together shall provide an increasing subsequence of length  $mK + 3mX$ . Implementing this naively by simply adding  $X$  to each element in the 3-PARTITION instance does not work, as the possible starting positions for the increasing subsequences provided by a chunk then grows to  $mK + 3mX$ , thus providing an incremental sequence of length  $mK + 3mX$  after reversal. We can however observe that the only reasonable starting points for the increasing subsequence provided by a chunk  $C_i$  are the original  $mK$ , each of which can be shifted by  $cX$ , where  $c$  is the number of chunks placed before  $C_i$ . This makes for a total of only  $3m^2K$  possible starting values. By choosing  $X > 3m^2K$ , it is then ensured that reversing a chunk only provides a shorter increasing subsequence than  $a_i + X$ .

### 3 A Tight Upper Bound for Almost-Planar Drawings

Let  $G = (V, E)$  be an outerplanar graph, let  $\delta_G$  be an almost-planar circular drawing of  $G$ . In this section, we present an untangling procedure for such almost-planar circular drawings that provides a tight upper bound of  $\lfloor \frac{n}{2} \rfloor - 1$  on  $\text{shift}^\circ(\delta_G)$ .

► **Theorem 3.1.** *Given an almost-planar drawing  $\delta_G$  of an  $n$ -vertex outerplanar graph  $G$  the circular shifting number  $\text{shift}^\circ(\delta_G) \leq \lfloor \frac{n}{2} \rfloor - 1$ , and this bound is tight.*

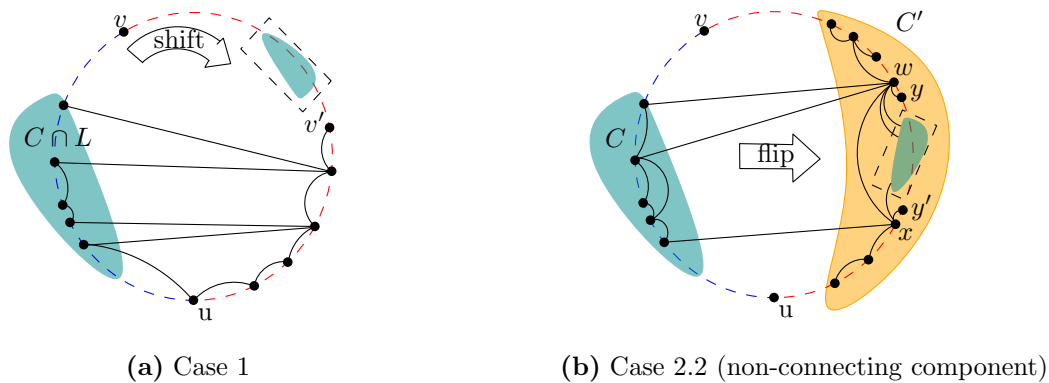

To see that the bound is tight, let  $n \geq 4$  be an even number and let  $G$  be the cycle on vertices  $v_1, \dots, v_n, v_1$  (in this order) and let  $\delta_G$  be a drawing with the clockwise order  $v_2, \dots, v_{2i} \dots, v_n, v_{n-1}, \dots, v_{2i+1}, \dots, v_1$ ; see Figure 2.

■ **Figure 2** An almost-planar drawing  $\delta_G$  with  $\text{shift}^\circ(\delta_G) = \frac{n}{2} - 1$ .

We claim that  $\text{shift}^\circ(\delta_G) \geq \frac{n}{2} - 1$ . Clearly, the clockwise circular ordering of its vertices in a crossing-free circle drawing is either  $v_1, v_2, \dots, v_n$  or its reversal. Assume that we turn it to the clockwise ordering  $v_1, v_2, \dots, v_n$ ; the other case is symmetric. In  $\delta_G$ , the  $\frac{n}{2}$  odd-index vertices  $v_1, \dots, v_{2i+1} \dots, v_{n-1}$  and  $v_n$  are ordered counterclockwise. To reach a clockwise ordering, we need to move all but two of these vertices. Thus, at least  $\frac{n}{2} - 1$  vertices in total are required to move.

The remainder of this section is devoted to proving the upper bound. Let  $e = uv$  be the edge of  $\delta_G$  that contains all the crossings, and let  $G' = G - e$  and  $\delta_{G'}$  be the circular drawing of  $G'$  by removing the edge  $e$  from  $\delta_G$ . The edge  $uv$  partitions the vertices in  $V \setminus \{u, v\}$  into the sets  $L$  and  $R$  that lie on the left and right side of the edge  $uv$  (directed from  $u$  to  $v$ ).

■ **Figure 3** Moving a left component, keeping/reversing the clockwise ordering of its vertices.

► **Theorem 3.2.** *Let  $\delta_G$  be an almost-planar drawing of an outerplanar graph  $G$ . An outerplanar drawing of  $G$  can be obtained by moving only vertices of  $L$  or only vertices of  $R$  to the other side in  $\delta_G$  and fixing all the remaining vertices. The untangling moves only  $\min\{|L|, |R|\}$  vertices and can be computed in linear time.*

This immediately implies the upper bound from Theorem 3.1, since  $|L \cup R| = n - 2$ , and therefore  $\min\{|L|, |R|\} \leq \lfloor \frac{n}{2} \rfloor - 1$ . To prove Theorem 3.2, we distinguish different cases based on the connectivity of  $u$  and  $v$  in  $G'$ .

**Case 1:  $u, v$  are not connected in  $G'$ .** Consider a connected component  $C$  of  $G'$  that contains vertices from  $L$  and from  $R$ .

► **Proposition 3.3.** *Suppose  $u, v$  are not connected in  $G'$ . Let  $C$  be a connected component of  $G'$  that contains vertices from  $L$  and from  $R$ . It is possible to obtain a new almost-planar drawing  $\delta'_G$  of  $G$  from  $\delta_G$  by moving only the vertices of  $C \cap L$  (resp.  $C \cap R$ ) such that  $C$  lies entirely on the right (resp. left) side of  $uv$ .*

**Proof.** Since  $u, v$  are not connected in  $G'$ ,  $C$  contains at most one of  $u, v$ . Without loss of generality, we assume that  $v \notin C$ ; see Figure 3a. Let  $v'$  be the first clockwise vertex after  $v$  that lies in  $C$ . Let  $\delta'_G$  be the drawing obtained from  $\delta_G$  by moving the vertices of  $C \cap L$  clockwise just before  $v'$  without changing their clockwise ordering. Observe that this removes all crossings of  $e$  with  $C$ . The choice of  $v'$  ensures that no edge of  $C$  alternates with an edge whose endpoints lie in  $V \setminus C$ . Finally, the vertices of  $C$  maintain their clockwise order. This shows that no new crossings are introduced, and the crossings between  $e$  and  $C$  are removed. ◀

By applying Proposition 3.3 for each connected component of  $G'$  that contains vertices from  $L$  and from  $R$ , we obtain an outerplanar drawing of  $G$ .

**Case 2:  $u, v$  are connected in  $G'$ .** Let  $C$  be the connected component in  $G'$  that contains both vertices  $u$  and  $v$ . Note that if  $C'$  is another connected component of  $G'$ , then it must lie entirely to the left or entirely to the right of edge  $e$ . Here, we ignore such components as they never need to be moved. We may hence assume that  $G'$  is connected.

**Case 2.1:  $u, v$  are 2-connected in  $G'$ .** We claim that in this case  $\delta_G$  is already planar.

► **Proposition 3.4.** *If  $u$  and  $v$  are 2-connected in  $G'$ , then  $\delta_G$  is planar.*

**Proof.** If vertices  $u, v \in V$  are 2-connected in  $G'$ , then  $G'$  contains a cycle  $C$  that includes both  $u$  and  $v$ . In  $\delta_{G'}$ , this cycle is drawn as a closed curve. Any edge that intersects the interior region of this closed curve therefore has both endpoints on  $C$ . If there exists an edge  $e' = xy$  that intersects  $e = uv$ , then contracting the four subpaths of  $C$  connecting each of  $\{x, y\}$  to each of  $\{u, v\}$  yields a  $K_4$ -minor in  $G$ , which contradicts the outerplanarity of  $G$ . ◀

**Case 2.2:  $u, v$  are connected but not 2-connected in  $G'$ .** In this case  $G'$  contains at least one cut-vertex that separates  $u$  and  $v$ . Notice that each path from  $u$  to  $v$  visits all such cut-vertices between  $u$  and  $v$  in the same order. Let  $f$  and  $l$  be the first and the last cut-vertex on any  $uv$ -path. Additionally, add  $u$  to the set of  $L, R$  that contains  $f$  and likewise add  $v$  to the set of  $L, R$  that contains  $l$ . Let  $X$  denote the set of edges of  $G'$  that have one endpoint in  $L$  and the other in  $R$ . Each connected component of  $G' - X$  is either a subset of  $L$  or a subset of  $R$ , which are called *left* and *right components*, respectively. We call a component of  $G' - X$  *connecting* if it contains either  $u$  or  $v$ , or removing it from  $G'$  disconnects  $u$  and  $v$ . For a left component  $C_L$  and a right component  $C_R$ , we denote by  $E(C_L, C_R)$  the set of edges of  $G'$  that connect a vertex from  $C_L$  to a vertex in  $C_R$ . We can observe that since  $G'$  is connected, for any edge that connects a left and a right component, at least one of the components must be connecting. We use the following observation.

► **Observation 3.5.** *If  $P$  is an  $xy$ -path in a left (right) component  $C$ , then it contains all vertices of  $C$  that are adjacent to a vertex of a right (left) component and lie between  $x$  and  $y$  on the left (right) side.*

■ **Figure 4** The  $K_{2,3}$ -minors we use in the proofs of (a) Lemma 3.6 and (b) Lemma 3.8.

► **Lemma 3.6.** *Every non-connecting component  $C$  of  $G' - X$  is adjacent to exactly one component  $C'$  of  $G' - X$ . Moreover,  $C'$  is connecting, there are at most two vertices in  $C'$  that are incident to edges in  $E(C, C')$ , and if there are two such vertices  $w, x \in C'$ , then they are adjacent and removing  $wx$  disconnects  $C'$ .*

**Proof.** Without loss of generality, we assume that  $C$  is a left component. Since  $C$  is non-connecting, any component adjacent to it must be connecting. Moreover, if there are two distinct such components, they lie on the right side of the edge  $uv$ . Then either there is a path on the right side that connects them (but then they are not distinct), or removing  $C$  disconnects these components, and therefore  $uv$ , contradicting the assumption that  $C$  is a non-connecting component. Therefore  $C$  is adjacent to exactly one other component  $C'$ ,

which must be a right connecting component. Let  $w$  and  $x$  be the first and the last vertex in  $C'$  that are adjacent to vertices in  $C$  when sweeping the vertices of  $G$  clockwise in  $\delta_G$  starting at  $v$ ; see Figure 4a. The lemma holds trivially if  $w = x$ . Suppose  $w \neq x$ . Next we show that  $wx \in E$  and that  $wx$  is a bridge of  $C$ . Let  $P$  be an arbitrary path from  $w$  to  $x$  in  $C$ . If  $P$  contains an internal vertex  $y$ , then the path  $P$  together with a path from  $w$  to  $x$  whose internal vertices lie in  $C$  forms a cycle, where  $x$  and  $w$  are not consecutive. Note that at least one of  $u, v$ , say  $u$ , is not identical to  $w, x$ , otherwise,  $u, v$  are 2-connected. This cycle, together with disjoint paths from  $w$  to  $v$  and  $x$  to  $u$  and the edge  $uv$  yields a  $K_{2,3}$ -minor in  $G$ ; see Figure 4a. Such paths exist, by the outerplanarity of  $\delta_{G'}$  and the fact that  $C'$  is connecting, but  $C$  is not. Since  $G$  is outerplanar, and therefore cannot contain a  $K_{2,3}$ -minor, this immediately implies that  $P$  consists of the single edge  $wx$ , which must be a bridge of  $C'$  as otherwise there would be a  $wx$ -path with an internal vertex. Observation 3.5 implies that  $w$  and  $x$  are the only vertices of  $C$  that are adjacent to vertices in  $C'$ . ◀

► **Proposition 3.7.** *Let  $C$  be a left (right) non-connecting component of  $G' - X$ . It is always possible to obtain a new almost-planar drawing  $\delta'_G$  of  $G$  from  $\delta_G$  by moving only the vertices of  $C \setminus \{u, v\}$  to the right (left) side.*

**Proof.** Without loss of generality, we assume that  $C$  is a left component. Since  $C$  is non-connecting, then by Lemma 3.6, it is adjacent to at most two vertices on the right side. If there are two such vertices, denote them by  $w$  and  $x$  such that  $w$  occurs before  $x$  on a clockwise traversal from  $v$  to  $u$ . Note that  $wx$  is a bridge of a right component  $C'$  by Lemma 3.6; see Figure 3b. Consider the two components of  $C' - wx$  and let  $y$  be the last vertex that lies in the same component as  $w$  when traversing vertices clockwise from  $w$  to  $x$ . If  $C$  is connected to only one vertex, then we denote this by  $y$ . In both cases, let  $y'$  be the vertex of  $L$  that immediately succeeds  $y$  in clockwise direction (If  $y = u$ , let  $y'$  be the vertex that immediately precedes  $y$ ).

We obtain  $\delta'_G$  by moving all vertices of  $C \setminus \{u, v\}$  between  $y$  and  $y'$ , reversing their clockwise ordering. Observe that the choice of  $y$  and  $y'$  guarantees that  $\delta'_G$  is almost-planar and all crossings lie on  $uv$ . ◀

It remains to deal with connecting components.

► **Lemma 3.8.** *The connecting component of  $G' - X$  containing  $u$  or  $v$  is adjacent to at most one connecting component. Every other connecting component is adjacent to exactly two connecting components. Moreover, if  $C$  and  $C'$  are two adjacent connecting components, then there is a vertex  $w$  that is incident to all edges in  $E(C, C')$ .*

**Proof.** The claims concerning the adjacencies of the connecting components follows from the fact that every  $uv$ -path visits all connecting components in the same order. It remains to prove that all edges between two connecting components share a single vertex. If  $u$  and  $v$  are in one component, then this component is the only connecting component and there is nothing to show.

Now let  $C$  and  $C'$  be adjacent connecting components and assume that  $C$  or  $C'$  may contain one of  $u$  or  $v$  but not both. Furthermore, we assume without loss of generality, that  $C$  is a left and  $C'$  is a right component. For the sake of contradiction, assume there exist two edges  $e_1, e_2 \in E(C, C')$  that do not share an endpoint. Let  $e_1 = ab$  and  $e_2 = cd$  where  $a, c \in C$  and  $b, d \in C'$  such that their clockwise order is  $a, b, d, c$ ; see Figure 4b. Note that one of  $u, v$  is not in the set  $\{a, b, c, d\}$ . Otherwise,  $u$  and  $v$  are 2-connected, which contradicts our case assumption. In the following, we assume without loss of generality that  $a, b, c, d, v$

## 19:10 Untangling Circular Drawings: Algorithms and Complexity

are five distinct vertices in  $G'$ . Let  $P$  be a path from  $u$  to  $v$  in  $G'$ . Since  $C$  and  $C'$  are both connecting,  $P$  contains vertices from both components. When traversing  $P$  from  $u$  to  $v$ , let  $s$  and  $t$  denote the first and the last vertex of  $C \cup C'$  that is encountered, respectively. Here, we assume without loss of generality that  $s \in C$  and  $t \in C'$ . Let  $P_L$  be a path in  $C$  that connects  $s$  to  $a$  and let  $P_R$  be a path in  $C'$  that connects  $d$  to  $t$ . By Observation 3.5,  $P_L$  contains  $c$  and  $P_R$  contains  $b$ . We then obtain a  $K_{2,3}$ -minor of  $G$  by contracting each of the paths  $P_L[c, a]$ ,  $P_R[d, b]$ ,  $vuP[u, s]P_L[s, c]$ , and  $P_R[b, t]P[t, v]$  into a single edge. ◀

By Lemma 3.6 and Lemma 3.8, all vertices of a connecting component of  $G' - X$  can be moved to the other side, similarly as in Proposition 3.7.

► **Proposition 3.9.** (★) *Let  $C$  be a left (right) connecting component of  $G' - X$ . It is possible to obtain a new almost-planar drawing  $\delta'_G$  of  $G$  from  $\delta_G$  by moving only the vertices of  $C \setminus \{u, v\}$  to the right (left) side.*

Proposition 3.7 and Proposition 3.9 together imply Theorem 3.2.

## 4 Untangling Almost-Planar Drawings

In this section, we consider how to untangle an almost-planar circular drawing  $\delta_G$  of an  $n$ -vertex outerplanar graph  $G = (V, E)$  with the minimum number of vertex moves. Firstly, we study this problem in several restricted settings (Sections 4.1–4.3), which leads us to the design of an  $O(n^2)$ -time algorithm to compute  $\text{shift}^\circ(\delta_G)$  in Section 4.4. Let  $e = uv$  be the edge of  $\delta_G$  that contains all the crossings, and let  $G' = G - e$  and  $\delta_{G'}$  be the straight-line circular drawing of  $G'$  by removing the edge  $e$  from  $\delta_G$ . The edge  $uv$  partitions the vertices in  $V \setminus \{u, v\}$  into the sets  $L$  and  $R$  that lie on the left and right side of the edge  $uv$  (directed from  $u$  to  $v$ ). Let  $C_u$  and  $C_v$  be the connected components of  $G'$  that contain  $u$  and  $v$ , respectively. Note that  $C_u = C_v$  if  $u, v$  are connected.

### 4.1 Fixed Edge Untangling

Here we consider untangling under the restriction that the positions of  $u$  and  $v$  are fixed. We denote such untangling as *fixed edge untangling*. From very similar arguments as in Section 3, we derive the following statements.

► **Lemma 4.1.** (★) *Let  $C$  be a connected component of  $G'$ . It is always possible to obtain an almost-planar drawing  $\delta'_G$  of  $G$  from  $\delta_G$  by moving all vertices in  $L \cap C$  (resp.  $R \cap C$ ) to the right (resp. left) side.*

► **Theorem 4.2.** (★) *Given an almost-planar drawing  $\delta_G$  of an outerplanar graph  $G$ , a fixed edge untangling of  $\delta_G$  with the minimum number of vertex moves can be computed in linear time.*

### 4.2 Single Component Untangling

Next, we study an untangling variant, called *Single Component Untangling*, which moves vertices of one particular connected component of  $G'$  that contains the vertices  $u$  or  $v$ , while the other components remain fixed. We claim that  $\delta_G$  can always be untangled in this way.

► **Theorem 4.3.** *It is always possible to untangle  $\delta_G$  by moving only the vertices of  $C_u$  or only the vertices of  $C_v$  and such a single component untangling procedure can be found in linear time.*

**Proof.** If  $C_u = C_v$  the claim is trivially true. So let's consider the case that  $u$  and  $v$  are not connected in  $G'$  and assume that  $|C_u| \leq |C_v|$ . We move the vertices of  $C_u$  as follows. Let  $\sigma_u$  be the clockwise order of  $C_u$  in  $\delta_{G'}$ , starting with  $u$ . We insert the vertices of  $C_u$  in the order  $\sigma_u$  clockwise right after  $v$  to obtain a new drawing  $\delta'_{G'}$  of  $G'$ . Since  $C_u$  was crossing-free before and is placed consecutively on the circle, it remains crossing-free. No other edges have been moved. Furthermore,  $u$  and  $v$  are now neighbors on the circle, so we can insert the edge  $uv$  without crossings and have untangled  $\delta_G$  with  $\min\{|C_u|, |C_v|\}$  moves. ◀

### 4.3 Component-Fixed Untangling

An untangling under the restriction that both of  $C_u$  and  $C_v$  must contain fixed vertices, is denoted as *Component-Fixed Untangling*.

We introduce some notions and provide basic observations. Let  $G$  be a connected outerplanar graph. Let  $B$  be a 2-connected component of  $G$  and  $E(B)$  the set of edges in  $B$ . Since  $G$  is connected and  $B$  is 2-connected, each connected component of  $G - E(B)$  contains exactly one vertex in  $B$ . Given a vertex  $b$  in  $B$ , let  $C_b$  be the connected component of  $G - E(B)$  that contains  $b$ . We denote  $C_b$  as the *attachment* of the 2-connected component  $B$  at the vertex  $b$ .

Let  $H(B)$  be the cyclic vertex ordering of  $B$  in the order of its Hamiltonian cycle<sup>1</sup>. We get Observation 4.4; see Figure 5.

► **Observation 4.4.** *Let  $\delta_G$  be an outerplanar drawing of an outerplanar graph  $G$  and  $B$  be a 2-connected component of  $G$ . Then, the clockwise cyclic vertex ordering of  $B$  in  $\delta_G$  is either  $H(B)$  or its reverse. Furthermore, for each attachment of  $B$ , its vertices appear consecutively on the circle in  $\delta_G$ .*

■ **Figure 5** A 2-connected component  $B$  (in blue) and its attachments (gray boxes) in an outerplanar drawing.

Given a connected outerplanar graph  $G$ , a 2-connected component  $B$  of  $G$  and a circular drawing  $\delta_G$ , we say a sequence  $S$  of vertex moves of  $G$  is *canonical*, associated with  $B$ , if in the drawing obtained by applying  $S$  to  $\delta_G$ , the clockwise cyclic vertex ordering of each attachment of  $B$  remains unchanged. Now we are ready to show that an optimal component-fixed untangling with the restriction that fixed vertices exist in both of  $C_u$  and  $C_v$  can be found in  $O(n^2)$  time; see Theorem 4.5.

► **Theorem 4.5.** *A component-fixed untangling procedure  $U$  with the minimum number of vertex moves can be found in  $O(n^2)$  time.*

The remainder of this section is devoted to describing the procedure  $U$ . We distinguish between the following two cases based on the connectivity of  $u, v$  in  $G'$ . In each case, we present a procedure that runs in  $O(n^2)$  time and reports an optimal component-fixed untangling procedure.

<sup>1</sup> In every outerplanar biconnected graph, there is a unique Hamiltonian cycle that visits each node exactly once [29].

**Case 1:  $u$  and  $v$  are connected in  $G'$ .** Let  $C$  be a connected component of  $G'$  that does not contain  $u, v$ . We claim now that  $C$  must lie entirely on one side of  $uv$  in  $\delta_G$ . Otherwise, let  $P$  be a path of  $\delta_{G'}$  that connects  $u$  and  $v$ . Then there would exist crossings between edges of  $P$  and edges of  $C$  in  $\delta_{G'}$  which contradicts the fact that  $\delta_{G'}$  has no crossings. Thus, we can ignore such components as they do not need to be involved in an untangling. Hence, we may assume  $G'$  is a connected graph. If  $u$  and  $v$  are 2-connected in  $G'$ , then  $\delta_G$  is already outerplanar; see Proposition 3.4. Now we consider the case that  $u$  and  $v$  are connected, but not 2-connected in  $G'$ . Note that  $u, v$  are 2-connected in  $G$ . Let  $B$  be the 2-connected component of  $G$  that contains  $u, v$ . We prove that each component-fixed untangling  $U$  can be transformed into a canonical untangling with smaller or the same number of vertex moves; see Lemma 4.6. Thus, we restrict our attention to canonical untanglings. Let  $H(B) = b_1, \dots, b_k$  be the cyclic vertex ordering of the Hamiltonian cycle of  $B$ . Let  $A_i$  be the attachment of  $B$  at the vertex  $b_i$  and let  $\sigma(A_i)$  be the clockwise vertex ordering of  $A_i$  in  $\delta_G$  for  $i \in \{1, \dots, k\}$ . We consider an optimal canonical component-fixed untangling  $U_o$  which orders  $B$  clockwise as  $H(B)$ . Let  $\delta_G''$  be the outerplanar drawing obtained by applying  $U_o$ . Then the clockwise vertex ordering of  $\delta_G''$  is exactly the concatenation of  $\sigma(A_1), \sigma(A_2), \dots, \sigma(A_k)$ . Given  $\delta_G''$ , an optimal untangling transforming  $\delta_G$  to  $\delta_G''$  can be computed in  $O(n^2)$  time; see [24]. Analogously, we obtain an optimal component-fixed untangling  $U_r$  which orders  $B$  counterclockwise as  $H(B)$ . From the two untanglings  $U_o$  and  $U_r$ , we report the one which moves less vertices as the optimal component-fixed untangling.

► **Lemma 4.6.** *Let  $B$  be the 2-connected component of  $G$  that contains  $u, v$ . Each component-fixed untangling  $U$  of  $\delta_G$  can be transformed into a canonical vertex move sequence  $U_c$  (associated with  $B$ ) that untangles  $\delta_G$ . Furthermore, the number of vertex moves in  $U_c$  is not greater than the number of vertex moves in  $U$ .*

**Proof.** Given a component-fixed untangling  $U$  of  $\delta_G$ , let  $\delta_G^U$  be the drawing obtained after applying  $U$  on  $\delta_G$ . In  $\delta_G^U$ , the cyclic vertex ordering of  $B$  (clockwise or counterclockwise) must correspond to its Hamiltonian cycle ordering  $H(B)$ . Furthermore, the vertices of each attachment of  $B$  appear consecutively in  $\delta_G^U$ , including one vertex of  $B$ ; see Observation 4.4. Let  $A_1, \dots, A_k$  be the attachments of  $B$  in  $G$  (indexed in clockwise order as in  $\delta_G^U$ ) and let  $\sigma(A_i)$  be the clockwise vertex ordering of  $A_i$  in  $\delta_G$  for  $i \in \{1 \dots k\}$ . Now consider the vertex ordering  $\sigma'_G = (\sigma(A_1), \dots, \sigma(A_k))$  and let  $\delta'_G$  be an arbitrary circular drawing where the vertices are ordered as  $\sigma'_G$ . Note that the vertex ordering of each attachment is  $\sigma(A_i)$  in  $\delta'_G$  as in the almost-planar drawing  $\delta_G$ , thus each attachment in  $\delta'_G$  is crossing-free. Moreover, in  $\delta'_G$  the vertices of  $B$  are ordered as in the planar drawing  $\delta_G^U$ , thus there is no crossing inside  $B$ . Overall,  $\delta'_G$  is a planar circular drawing. Let  $U_c$  be the untangling of  $\delta_G$  with minimum number of vertex moves such that the clockwise vertex ordering of the resulting drawing is  $\sigma'_G$ .

To see that  $U_c$  does not move more vertices than  $U$ , let  $\sigma_G$  and  $\sigma_G^U$  be the clockwise vertex orderings of  $\delta_G$  and  $\delta_G^U$ , respectively. We can observe that any common subsequence of  $\sigma_G, \sigma_G^U$  is a subsequence of  $\sigma'_G$ . ◀

**Case 2:  $u$  and  $v$  are not connected in  $G'$ .** Note that a connected component of  $G'$  that lies entirely on one side of  $uv$  in  $\delta_G$  can be ignored, since there is no need to move any vertices in such components. After ignoring such components, we can assume that a connected component  $C$  of  $G'$  either contains  $u, v$  or  $C$  contains vertices from  $L$  and also vertices from  $R$ .

► **Observation 4.7.** In  $\delta_{G'}$ , vertices of  $C_u$  (resp.  $C_v$ ) lie consecutively on the cycle.

The first step of our untangling procedure  $U$  deals with the connected components of  $G'$  that neither contain  $u$  nor  $v$ . Let  $U^{\text{fix}}$  be an arbitrary component-fixed untangling of  $\delta_G$ , and let  $\delta_G^{\text{fix}}$  be the outerplanar drawing of  $G$  obtained from  $\delta_G$  by applying  $U^{\text{fix}}$ .

► **Lemma 4.8.** Let  $C$  be a connected component of  $G'$  that does not contain vertices  $u$  or  $v$ . Let  $f_u, f_v$  be two vertices in  $C_u$  and  $C_v$ , respectively, which are fixed in  $\delta_G^{\text{fix}}$ . Then,  $C$  must lie entirely on one side of  $f_u f_v$ <sup>2</sup> in  $\delta_G^{\text{fix}}$ .

**Proof.** In the graph  $G$ , due to the definition of  $f_u$  and  $f_v$ , there exists a path  $P_1$  in  $C_u$  connecting  $f_u$  to  $u$ , and a path  $P_2$  in  $C_v$  connecting  $v$  to  $f_v$ ; see Figure 6. Then, the path  $P = P_1 u v P_2$  in  $G$  connects  $f_u$  to  $f_v$ . In  $\delta_G^{\text{fix}}$ , suppose that the connected component  $C$  is not entirely on one side of  $f_u f_v$ , it implies that at least one edge  $xy$  in  $C$  has endpoints  $x, y$  alternate with  $f_u, f_v$  in clockwise ordering of  $\delta_G^{\text{fix}}$  and then has crossings with  $P$ . It contradicts the outerplanarity of the drawing  $\delta_G^{\text{fix}}$ . ◀

■ **Figure 6** An example illustration for the proof of Lemma 4.8.

Now let  $C$  be a connected component that does not contain  $u, v$ . Vertices  $f_u$  and  $f_v$  partition the vertices of  $C$  in drawing  $\delta_G$  into two sets  $L_C$  and  $R_C$  that are encountered clockwise and counter-clockwise from  $f_u$  to  $f_v$  in  $\delta_G$ , respectively. Observe that,  $L_C = L \cap C$  and  $R_C = R \cap C$ ; see Observation 4.7. Let  $m(C) = \min\{|L \cap C|, |R \cap C|\}$ . By Lemma 4.8,  $m(C)$  is a lower bound of the moved vertices in  $C$  in a component-fixed untangling. By Lemma 4.1, there is a procedure moving  $m(C)$  vertices of  $C$  such that  $C$  lies entirely on one side of  $uv$ . In the first step of our untangling procedure  $U$ , we repeat this step for each component not containing  $u, v$ . After that, an almost-planar drawing of  $G$  remains that has already each component not containing  $u, v$  placed entirely on one side of  $uv$ . We can ignore such components from now on since they never need to be moved again.

Now we assume that  $G'$  has exactly two connected components, namely  $C_u$  and  $C_v$ . Consider an arbitrary outerplanar drawing  $\delta'_G$  of  $G$ . Let  $\sigma(\delta'_G)$  be the circular ordering of vertices in  $\delta'_G$  encountered clockwise. Observe that, in  $\sigma(\delta'_G)$ , the vertices of  $C_u$  (resp.  $C_v$ ) are in a consecutive subsequence  $\sigma(C_u)$  (resp.  $\sigma(C_v)$ ). Otherwise, alternating vertices of two connected components would introduce crossings.

<sup>2</sup> Given a circular drawing of  $G = (V, E)$ , two vertices  $\overrightarrow{a, b}$  partitions the vertices in  $V \setminus \{a, b\}$  into two sets that lie on the left side and right side of the ray  $\overrightarrow{ab}$ .

■ **Figure 7** In any clockwise vertex ordering of an outerplanar drawing,  $u, v$  must be the extreme vertices in the 2-connected components  $B_v$  and  $B_u$ , respectively.

Given an edge  $e'$  in  $C_v$ , we say  $e'$  covers  $v$  if the endpoints of  $e$  alternate with  $u$  and  $v$  in  $\delta_{G'}$ . Note that there is no edge covering  $v$  in  $\sigma(C_v)$ . Otherwise, such an edge would cross with edge  $uv$ . Therefore, in a valid untangling of  $\delta_G$ , it is necessary to move vertices of  $C_v$  in  $\delta_G$  such that no crossing is introduced in  $C_v$  and  $v$  is not covered by any edges in  $C_v$ . Similarly, the same claim holds also for  $C_u$ . We call such vertex moves *vertex unwrapping*. In the following, we consider how to find a valid unwrapping of  $v$  with the minimum number of vertex moves. The same operation will be also applied to  $C_u$ . Observe that, once  $u, v$  are both unwrapped, adding the edge  $e$  into the drawing does not introduce any crossings. The combination of these two unwrappings makes an optimal untangling. Here, we also consider the canonical vertex sequences and get the following Lemma 4.10. The proof is quite similar to the proof of Lemma 4.6 which concerns canonical untanglings.

► **Observation 4.9.** *There exists at least one 2-connected component  $B$  of  $C_v$  such that  $B$  contains  $v$  and no edge in the attachment of  $v$  (associated with  $B$ ) covers  $v$  in  $\delta_G$ .*

The reason for this observation is that either no 2-connected component  $B$  containing  $v$  contains an edge covering  $v$ , in which case  $v$  is already unwrapped and the statement is true for any such  $B$ . Or some 2-connected component  $B$  does contain a covering edge, but then the attachment of  $v$  in  $B$  cannot cover  $v$  due to planarity of  $\delta_{G'}$ .

► **Lemma 4.10.** *Let  $B$  be a 2-connected component of  $C_v$  that contains  $v$  such that the attachment of  $v$  contains no edge covering  $v$ . Each unwrapping  $U$  of  $v$  can be transformed into a canonical unwrapping  $U_c$  (associated with  $B$ ). Furthermore, the number of vertex moves in  $U_c$  is not greater than the number of vertex moves in the original unwrapping  $U$ .*

**Proof.** Given a unwrapping procedure  $U$  of  $v$ , let  $\delta_G^U$  be the drawing obtained after applying  $U$  on  $\delta_G$ . In  $\delta_G^U$ , the cyclic vertex ordering of  $B$  (clockwise or counterclockwise) must correspond to its Hamiltonian cycle ordering  $H(B)$ . Furthermore, the vertices of each attachment of  $B$  appear consecutively in  $\delta_G^U$ , including one vertex of  $B$ ; see Observation 4.4. Let  $A_1, \dots, A_k$  be the attachments of  $B$  in  $C_v$  (in this clockwise order in  $\delta_G^U$ ), let  $\sigma(A_i)$  be the clockwise vertex ordering of  $A_i$  in  $\delta_G$  for  $i \in \{1 \dots k\}$ . Consider the clockwise vertex ordering  $\sigma'_G$  where the vertices of  $B \cup C_u$  are ordered as in  $\delta_G^U$ . Furthermore, for each attachment  $A_i$  the vertices of  $A_i$  appear consecutively in the clockwise ordering  $\sigma(A_i)$ . Let  $\delta'_G$  be an arbitrary circular drawing where the vertices are ordered as  $\sigma'_G$ . Note that the vertex ordering of each attachment of  $B$  is  $\sigma(A_i)$  in  $\delta'_G$  as in the almost-planar drawing  $\delta_G$ , thus each attachment in  $\delta'_G$  is crossing-free. Moreover, in  $\delta'_G$  the vertices of  $B$  are ordered as in the planar drawing  $\delta_G^U$ , thus there is no crossing inside  $B$ . Overall, the vertex  $v$  is unwrapped in  $\delta'_G$ . It remains to prove that the untangling  $U'$ , which transforms  $\delta_G$  to  $\delta'_G$ , moves less than or equally many vertices as  $U$ . By construction each common subsequence of  $\delta_G$  and  $\delta_G^U$  is also a subsequence of  $\delta'_G$ , which implies this fact. ◀

By Lemma 4.10, we restrict our attention to canonical unwrappings. Fixing a 2-connected component  $B_v$  of  $C_v$  containing  $v$  such that no edge in the attachment (associated with  $B_v$ ) of  $v$  covers  $v$ , we consider the two possible canonical unwrappings of  $v$ , which respectively

order vertices of  $B$  clockwise along  $H(B)$  or its reversal, and compute the corresponding resulting clockwise vertex ordering  $\sigma_v$  and  $\sigma_v^{rev}$  of  $C_v$ . With the same idea, we get the clockwise vertex orderings  $\sigma_u$  and  $\sigma_u^{rev}$  of  $C_u$  by the canonical unwrappings of  $u$ . We then get the four optimal unwrappings, each of them transforming  $\delta_G$  to one of the vertex orderings  $(\sigma_v, \sigma_u)$ ,  $(\sigma_v^{rev}, \sigma_u)$ ,  $(\sigma_v, \sigma_u^{rev})$  and  $(\sigma_v^{rev}, \sigma_u^{rev})$ . Such optimal unwrappings can be computed in  $O(n^2)$  time; see [24]. We report the one that moves the minimum number of vertices as an optimal component-fixed untangling.

#### 4.4 Circular Untangling

Given an almost-planar drawing  $\delta_G$ , we claim that it is always possible to compute an optimal untangling procedure for  $\delta_G$  in  $O(n^2)$  time, where  $n$  is the number of vertices of  $G$ . In our approach, we use procedures described in Sections 4.1–4.3 as subroutines.

**The Approach.** *Step 1:* we compute an optimal component-fixed untangling  $U$  by applying the approach described in Section 4.3. An optimal component-fixed untangling  $U$  can be reported in  $O(n^2)$  time (see Theorem 4.5). *Step 2:* let  $m(U)$  be the number of vertex moves in  $U$ . we compare  $m(U)$  with  $\min\{|C_u|, |C_v|\}$ . If  $m(U) \leq \min\{|C_u|, |C_v|\}$ , then we report  $U$ . Otherwise, if  $m(U) > \min\{|C_u|, |C_v|\}$ , we know  $U$  is not an optimal untangling procedure. Because there exists a specific untangling procedure  $U'$  which moves exactly  $\min\{|C_u|, |C_v|\}$  vertices; see its description in the proof of Theorem 4.3. In this case, we compute and report this procedure  $U'$ . The second step takes linear time. In total, the whole procedure needs  $O(n^2)$  time.

**Correctness.** Let  $U_a$  be the untangling reported by our approach. Now, we show that  $U_a$  is indeed an optimal untangling of  $\delta_G$  by contradiction. Note that  $U_a$  has size bounded by  $\min\{|C_u|, |C_v|\}$  (*Step 2*). Suppose there exists an untangling  $U_{a'}$  which moves less vertices than  $U_a$ . Then  $U_{a'}$  moves less vertices than  $\min\{|C_u|, |C_v|\}$ . If so, there are vertices in both of  $|C_u|, |C_v|$  that remain fixed in  $U_{a'}$ . Thus,  $U_{a'}$  is a component-fixed untangling. It leads to a contradiction to the fact that  $U_a$  has its size bounded by the size of optimal component-fixed untangling (*Step 1*). Therefore,  $U_a$  is indeed an untangling of  $\delta_G$  with the minimum number of vertex moves.

► **Theorem 4.11.** *Given an almost-planar drawing  $\delta_G$  of an outerplanar graph  $G$ , an untangling of  $\delta_G$  with the minimum number of vertex moves can be computed in  $O(n^2)$  time, where  $n$  denotes the number of vertices in  $G$ .*

## 5 Conclusions and Discussions

We introduced and investigated the problem of untangling non-planar circular drawings. First from the computational side, we demonstrated the NP-hardness of the problem CIRCULAR UNTANGLING. Second, we studied the almost-planar circular drawings, where all crossings involve a single edge. We gave a tight upper bound of  $\lfloor \frac{n}{2} \rfloor - 1$  on the shift number and an  $O(n^2)$ -time algorithm to compute it. Open problems for future work include: (i) The parameterized complexity of computing the circular shifting, e.g., with respect to the number of crossings or the number of connected components. (ii) Generalization of our results for almost-planar drawings. (iii) Investigation of minimum untangling by other elementary moves such as swapping vertex pairs or moving larger chunks of vertices.

## Abstract

We study the problem of matching a string in a labeled graph. Previous research has shown that unless the *Orthogonal Vectors Hypothesis* (OVH) is false, one cannot solve this problem in strongly sub-quadratic time, nor index the graph in polynomial time to answer queries efficiently (Equi et al. ICALP 2019, SOFSEM 2021). These conditional lower-bounds cover even deterministic graphs with binary alphabet, but there naturally exist also graph classes that are easy to index: E.g. *Wheeler graphs* (Gagie et al. *Theor. Comp. Sci.* 2017) cover graphs admitting a Burrows-Wheeler transform-based indexing scheme. However, it is NP-complete to recognize if a graph is a Wheeler graph (Gibney, Thankachan, ESA 2019).

We propose an approach to alleviate the construction bottleneck of Wheeler graphs. Rather than starting from an arbitrary graph, we study graphs induced from *multiple sequence alignments*. *Elastic degenerate strings* (Bernadini et al. SPIRE 2017, ICALP 2019) can be seen as such graphs, and we introduce here their generalization: *elastic founder graphs*. We first prove that even such induced graphs are hard to index under OVH. Then we introduce two subclasses that are easy to index. Moreover, we give a near-linear time algorithm to construct indexable elastic founder graphs. This algorithm is based on an earlier segmentation algorithm for gapless multiple sequence alignments inducing non-elastic founder graphs (Mäkinen et al., WABI 2020), but uses more involved techniques to cope with repetitive string collections synchronized with gaps. Finally, we show that one of the subclasses admits a reduction to Wheeler graphs in polynomial time.

## 1 Introduction

In string research, many different problems relate to the common question of how to handle a collection of strings. When such a collection contains very similar strings, it can be represented as some “high scoring” *Multiple Sequence Alignment (MSA)*, i.e., as a matrix  $\text{MSA}[1..m, 1..n]$  whose  $m$  rows are the individual strings each of length  $n$ , which may include special “gap” symbols such that the columns represent the aligned positions. While it is NP-hard to find an optimal MSA even under the simplest score of maximizing the number of identity columns (i.e., longest common subsequence length) [21], the central role of MSA as a model of biological evolution has resulted into numerous heuristics to solve this problem in practice [9]. In this paper, we assume an MSA as an input.

A simple way to define the problem of finding a match for a given string in the MSA is to ask whether the string matches a substring of some row (ignoring gap symbols). This leads to the widely studied problem of indexing repetitive text collections, see, e.g., references [24, 29, 30, 28, 27, 14, 15]. These approaches reducing an MSA to plain text reach algorithms with linear time complexities.

One feature worth considering is the possibility to allow a match to jump from any row to any other row of the MSA between consecutive columns. This property is usually referred to as *recombination* due to its connection to evolution, and leads to the graph representation of the MSA [26]. Figure 1a shows a simple solution, which consists in turning distinct characters of each column into nodes, and then adding the edges supported by row-wise connections. In this graph, a path whose concatenation of node labels matches a given string represents a match in the original MSA (ignoring gaps).

Aligning a sequence against a graph is not a trivial task. Only quadratic solutions are known [3, 25, 32], and this was recently proved to be a conditional lower bound for the problem [10]. Moreover, even attempting to index the graph to query the string faster presents significant difficulties. On one hand, indexes constructed in polynomial time still require quadratic-time queries in the worst case [35]. On the other hand, worst-case linear-time queries are possible, but this has the potential to make the index grow exponentially [34]. These might be the best results possible for general graphs and DAGs without any specific structural property, as the need for exponential indexing time to achieve sub-quadratic time queries constitutes another conditional lower bound for the problem [11].

Thus, if we want to achieve better performances, we have to make more assumptions on the structure of the input, so that the problem might become tractable. Following this line, a possible solution consists in identifying special classes of graphs that, while still able to represent any MSA, have a more limited amount of recombination, thus allowing for fast matching or fast indexing. This is the case for *Elastic Degenerate Strings (EDS)* [4, 5, 7, 6, 18], which can represent an MSA as a sequence of sets of strings, in which a match can span consecutive sets, using any one string in each of these (see Figure 1b, graph in the center). The advantage of this structure is that it is possible to perform expected-case subquadratic time queries [5]. However, EDS are still hard to index [16], and there is a lack of results on how to derive a “suitable” EDS from an MSA.

In this context, we propose a generalization of an EDS to what we call an *Elastic Founder Graph (EFG)*. An EFG is a DAG that, as an EDS, represents an MSA as a sequence of sets of strings; each set is called a *block*, and each string inside a block is represented as a labeled node. The difference with EDSes is that the nodes of two consecutive blocks are not forced to be fully connected. This means that, while in an EDS a match can always pair any string of a set with any string of the next set, in an EFG it might be the case that only some of

(a) A column-by-column segmentation of an MSA on the left, leading to the variation graph on the right.

(b) A different segmentation of the MSA, leading to the EDS in the center, and the EFG on the right. Notice that in an EDS every node is connected with all nodes to the right, while in an EFG edges are added only if their endpoints are consecutive in some row of the MSA (as in the case of variation graphs).

(c) A segmentation of the MSA that leads to a repeat-free EFG (i.e. no node label has another occurrence on some path of the EFG).

(d) A segmentation of the MSA that leads to a semi-repeat-free EFG (i.e. no node label has another occurrence on some path of the EFG, except as a prefix of another node in the same segment). An occurrence of query  $Q = \text{CGACTAGTA}$  in EFG is depicted in red. As can be seen, such query does not have an occurrence in a single row of the MSA.

■ **Figure 1** An MSA on the left, and various graph-based representations of it on the right. Notice that in all graphs (except the EDS) edges are added only between nodes that are observed as consecutive in some row of the MSA.

these pairings are allowed. Figure 1b illustrates these differences. Allowing for more selective connectivity between consecutive blocks also means that finding a match for a string in an EFG is harder than in an EDS. This is because EDSes are a special case of EFGs, hence the hardness results for the former carry to the latter. Specifically, a previous work [17] showed that, under the *Orthogonal Vectors Hypothesis* (OVH), no index for EDSes constructed in polynomial time can provide queries in time  $O(|Q| + |\tilde{T}|^\delta |Q|^\beta)$ , where  $|\tilde{T}|$  is the number of sets of strings,  $|Q|$  is the length of the pattern and  $\beta < 1$  or  $\delta < 1$ . Nevertheless, in this work we present an even tighter quadratic lower bound for EFGs, proving that, under OVH, an index built in time  $O(|E|^\alpha)$  cannot provide queries in time  $O(|Q| + |E|^\delta |Q|^\beta)$ , where  $|E|$  is the number of edges and  $\beta < 1$  or  $\delta < 1$ . Notice that  $|\tilde{T}|$  could even be  $o(|E|)$  (e.g. an EFG of two fully connected blocks), hence our lower bound more closely relates to the total size of an EFG. Additionally, the earlier lower bound [17] naturally applies only to indexing EDSes, and is obtained by performing many hypothetical fast queries; ours is derived by first proving a quadratic OVH-based lower bound for the *online* string matching problem in EFGs, and then using a general result [11] to simply translate this into an indexing lower bound.

Then, in order to break through these lower bounds, we identify two natural classes of EFGs, which respect what we call *repeat-free* and *semi-repeat-free* properties. The repeat-free property (Figure 1c) forces each string in each block to occur only once in the entire graph, and the semi-repeat-free property (Figure 1d) is a weaker form of this requirement. Thanks to these properties, we can more easily locate substrings of a query string in repeat-free EFGs and semi-repeat-free EFGs. In particular, (semi-)repeat-free EFGs and EDSes can be indexed in polynomial time for linear time string matching.

One might think that these time speedups come with a significant cost in terms of flexibility. Instead, the special structure of these EFGs do not hinder their expressive power. Indeed, we show that an MSA can be “optimally” segmented into blocks inducing a repeat-free or semi-repeat-free EFG. Clearly, this depends on how one chooses to define optimality. We consider three optimality notions: maximum number of blocks, minimum maximum block width, and minimum maximum block length. In Figure 1d, the first score is 3, second is 3, and the third is 5. The two latter notions stem from the earlier work on segmentations [31, 8], now combined with the (semi-)repeat-free constraint. The first is the simplest optimality notion, now making sense combined with the (semi-)repeat-free constraint.

For each of these optimality notions, we give a polynomial-time dynamic programming algorithm that converts an MSA into an optimal (semi-)repeat-free EFG if such exists. For the first and the third notion combined with semi-repeat-free constraint, we derive more involved solutions with almost optimal  $O(mn \log m)$  and  $O(mn \log m + n \log \log n)$  running time, respectively. In previous work [23], an (optimal)  $O(mn)$  time solution was given for the special case of MSA without gap symbols. Our new solution does not much build on the previous approach, which was based on a monotonicity property not anymore holding with gaps. Instead, we delve into the combinatorial properties of repetitive string collections synchronized with gaps and show how to use string data structures in this setting. The techniques can be easily adapted for other notions of optimality.

Another class of graphs that admits efficient indexing are Wheeler graphs [13], which offer an alternative way to model an EFG and thus a MSA. However, it is NP-complete to recognize if a given graph is a Wheeler graph [17], and thus, to use the efficient algorithmic machinery around Wheeler graphs [1] one needs to limit the focus on indexable graphs that admit efficient construction. Indeed, we show that any EFG that respects the repeat-free property can be reduced to a Wheeler graph in polynomial time. Interestingly, we were not able to modify this reduction to cover the semi-repeat-free case, leaving it open if these two notions of graph indexability have indeed different expressive power, and whether there are more graph classes with distinctive properties in this context.

## 2 Definitions

**Strings.** We denote integer intervals by  $[i..j]$ . Let  $\Sigma = \{1, \dots, \sigma\}$  be an alphabet of size  $|\Sigma| = \sigma$ . A *string*  $T[1..n]$  is a sequence of symbols from  $\Sigma$ , i.e.  $T \in \Sigma^n$ , where  $\Sigma^n$  denotes the set of strings of length  $n$  under the alphabet  $\Sigma$ . A *suffix* of string  $T[1..n]$  is  $T[i..n]$  for  $1 \leq i \leq n$ . A *prefix* of string  $T[1..n]$  is  $T[1..i]$  for  $1 \leq i \leq n$ . A *substring* of string  $T[1..n]$  is  $T[i..j]$  for  $1 \leq i \leq j \leq n$ . The *length* of a string  $T$  is denoted  $|T|$ . The *empty string* is the string of length 0. In particular, substring  $T[i..j]$  where  $j < i$  is the empty string. The *lexicographic order* of two strings  $A$  and  $B$  is naturally defined by the order of the alphabet:  $A < B$  iff  $A[1..i] = B[1..i]$  and  $A[i+1] < B[i+1]$  for some  $i \geq 0$ . If  $i+1 > \min(|A|, |B|)$ , then the shorter one is regarded as smaller. However, we usually avoid this implicit comparison by adding *end marker*  $\mathbf{0}$  to the strings. Concatenation of strings  $A$  and  $B$  is denoted  $AB$ .

**Elastic founder graphs.** As mentioned in the introduction, our goal is to compactly represent an MSA using an elastic founder graph. In this section we formalize these concepts.

A *multiple sequence alignment*  $\text{MSA}[1..m, 1..n]$  is a matrix with  $m$  strings drawn from  $\Sigma \cup \{-\}$ , each of length  $n$ , as its rows. Here  $- \notin \Sigma$  is the *gap* symbol. For a string  $X \in (\Sigma \cup \{-\})^*$ , we denote  $\text{spell}(X)$  the string resulting from removing the gap symbols from  $X$ .

Let  $\mathcal{P}$  be a *partitioning* of  $[1..n]$ , that is, a sequence of subintervals  $\mathcal{P} = [x_1..y_1], [x_2..y_2], \dots, [x_b..y_b]$ , where  $x_1 = 1$ ,  $y_b = n$ , and for all  $j > 2$ ,  $x_j = y_{j-1} + 1$ . A *segmentation*  $S$  of  $\text{MSA}[1..m, 1..n]$  based on partitioning  $\mathcal{P}$  is a sequence of  $b$  sets  $S^k = \{\text{spell}(\text{MSA}[i, x_k..y_k]) \mid 1 \leq i \leq m\}$  for  $1 \leq k \leq b$ ; in addition, we require for a (proper) segmentation that  $\text{spell}(\text{MSA}[i, x_k..y_k])$  is not an empty string for any  $i$  and  $k$ . We call set  $S^k$  a *block*, while  $\text{MSA}[1..m, x_k..y_k]$  or just  $[x_k..y_k]$  is called a *segment*. The *length* of block  $S^k$  is  $L(S^k) = y_k - x_k + 1$  and the *width* of block  $S^k$  is  $W(S^k) = |S^k|$ . Segmentation naturally leads to the definition of a founder graph through the block graph concept:

► **Definition 1** (Block Graph). A block graph is a graph  $G = (V, E, \ell)$  where  $\ell : V \rightarrow \Sigma^+$  is a function that assigns a string label to every node and for which the following properties hold.

1. Set  $V$  can be partitioned into a sequence of  $b$  blocks  $V^1, V^2, \dots, V^b$ , that is,  $V = V^1 \cup V^2 \cup \dots \cup V^b$  and  $V^i \cap V^j = \emptyset$  for all  $i \neq j$ ;
2. If  $(v, w) \in E$  then  $v \in V^i$  and  $w \in V^{i+1}$  for some  $1 \leq i \leq b - 1$ ; and
3. if  $v, w \in V^i$  then  $|\ell(v)| = |\ell(w)|$  for each  $1 \leq i \leq b$  and if  $v \neq w$ ,  $\ell(v) \neq \ell(w)$ .

With *gapless* MSAs, block  $S^k$  equals segment  $\text{MSA}[1..m, x_k..y_k]$ , and in that case the *founder graph* is a block graph induced by segmentation  $S$  [23]. The idea is to have a graph in which the nodes represent the strings in  $S$  while the edges retain the information of how such strings can be recombined to spell any sequence in the original MSA. With general MSAs with gaps, we consider the following extension, with an analogy to EDSes [5]:

► **Definition 2** (Elastic block and founder graphs). We call a block graph *elastic* if its third condition is relaxed in the sense that each  $V^i$  can contain non-empty variable-length strings. An *elastic founder graph* (EFG) is an elastic block graph  $G(S) = (V, E, \ell)$  induced by a segmentation  $S$  as follows: For each  $1 \leq k \leq b$  we have  $S^k = \{\text{spell}(\text{MSA}[i, x_k..y_k]) \mid 1 \leq i \leq m\} = \{\ell(v) : v \in V^k\}$ . It holds  $(v, w) \in E$  if and only if there exists  $k \in [1..b - 1]$  and  $t \in [1..m]$  such that  $v \in V^k$ ,  $w \in V^{k+1}$  and  $\text{spell}(\text{MSA}[t, x_k..y_{k+1}]) = \ell(v)\ell(w)$ .

By definition, (elastic) founder and block graphs are acyclic. For convention, we interpret the direction of the edges as going from left to right. Consider a path  $P$  in  $G(S)$  between any two nodes. The label  $\ell(P)$  of  $P$  is the concatenation of labels of the nodes in the path. Let  $Q$  be a query string. We say that  $Q$  *occurs* in  $G(S)$  if  $Q$  is a substring of  $\ell(P)$  for any path  $P$  of  $G(S)$ . Figure 1 illustrates such a query.

We use the same repeat-free definition as in the non-elastic case [23]:

► **Definition 3.** EFG  $G(S)$  is *repeat-free* if each  $\ell(v)$  for  $v \in V$  occurs in  $G(S)$  only as prefix of paths starting with  $v$ .

We also consider a variant that is relevant due to variable-length strings in the blocks:

► **Definition 4.** EFG  $G(S)$  is *semi-repeat-free* if each  $\ell(v)$  for  $v \in V$  occurs in  $G(S)$  only as prefix of paths starting with  $w \in V$ , where  $w$  is from the same block as  $v$ .

These definitions also apply to general elastic block graphs and to elastic degenerate strings as their special case.

■ **Figure 2** Gadgets  $G_{be}$ ,  $G_0$  and  $G_1$ . Each gadget is organized into three rows, each row encoding a different partitioning of the strings  $bbbb$ ,  $eeee$ ,  $0000$ ,  $1111$ . This ensures that, when combining these gadgets in Figure 3, edges can be controlled to go within the same row, or to the row below.

We note that not all MSAs admit a segmentation leading to a (semi-)repeat-free EFG, e.g. an alignment with rows  $-A$  and  $AA$ . However, our algorithms detect such cases, thus one can build an EFG consisting of just one block with the rows of the MSA (with gaps removed). Such EFGs can be indexed using standard string data structures to support efficient queries.

### 3 Conditional Hardness of Indexing EFGs

We show a reduction from *Orthogonal Vectors* (OV) to the problem of matching a query string in an EFG, continuing the line of research conducted on many related (degenerate) string problems [19, 10, 2, 16]. The OV problem is to find out if there exist  $x \in X$  and  $y \in Y$  such that  $x \cdot y = 0$ , given two sets  $X$  and  $Y$  of  $n$  binary vectors each. We construct string  $Q$  using  $X$  and graph  $G$  using  $Y$ . Then, we show that  $Q$  has a match in  $G$  if and only if  $X$  and  $Y$  form a “yes”-instance of OV. We condition our results on the following OV hypothesis, which is implied by the *Strong Exponential Time Hypothesis* [20].

► **Definition 5** (Orthogonal Vectors Hypothesis (OVH) [36]). *Let  $X, Y$  be the two sets of an OV instance, each containing  $n$  binary vectors of length  $d$ .<sup>1</sup> For any constant  $\epsilon > 0$ , no algorithm can solve OV in time  $O(\text{poly}(d)n^{2-\epsilon})$ .*

**Query String.** We build string  $Q$  by combining string gadgets  $Q_1, \dots, Q_n$ , one for each vector in  $X$ , plus some additional characters. To build string  $Q_i$ , first we place four  $b$  characters, then we scan vector  $x_i \in X$  from left to right. For each entry of  $x_i$ , we place substring  $Q_{i,h}$  consisting of four  $0$  characters if  $x_i[h] = 0$ , or four  $1$  characters if  $x_i[h] = 1$ . Finally, we place four  $e$  characters. For example, vector  $x_i = 101$  results into string

$$Q_i = bbbb Q_{i,1} Q_{i,2} Q_{i,3} eeee, \text{ where } Q_{i,1} = 1111, \quad Q_{i,2} = 0000, \quad Q_{i,3} = 1111.$$

Full string  $Q$  is then the concatenation  $Q = bbbb Q_1 Q_2 \dots Q_n eeee$ . The reason behind these specific quantities will be clear when discussing the structure of the graph.

**Elastic Founder Graph.** We build graph  $G$  combining together three different sub-graphs:  $G_L, G_M, G_R$  (for *left, middle* and *right*). Our final goal is to build a graph structured in three logical “rows”. We denote the three rows of  $G_M$  as  $G_{M1}, G_{M2}, G_{M3}$ , respectively. The

<sup>1</sup> In this section, keeping in line with the usual notation in the OV problem, we use  $n$  to denote the size of  $X$  and  $Y$ , instead of the number of columns of the MSA.

first and the third rows of  $G$ , along with sub-graphs  $G_L$  and  $G_R$  (introduced to allow slack), can match any vector. The second row matches only sub-patterns encoding vectors that are orthogonal to the vectors of set  $Y$ . The key is to structure the graph such that the pattern is forced to utilize the second row to obtain a full match. We present the full structure of the graph in Figure 3, which shows the graph built on top of vector set  $\{100, 011, 010\}$ . In particular,  $G_M$  consists of  $n$  gadgets  $G_M^j$ , one for each vector  $y_j \in Y$ . The key elements of these sub-graphs are gadgets  $G_{be}$ ,  $G_0$  and  $G_1$  (see Figure 2), which allow to stack together multiple instances of strings  $b^4$ ,  $e^4$ ,  $1^4$ ,  $0^4$ . The overall structure mimics the one by Equi et al. [10], except for the new idea from Figure 2.

**Detailed structure of the graph.** **Sub-graph  $G_L$**  (Figure 3a) consists of a starting segment with a single node labeled  $b^4$ , followed by  $n - 1$  sub-graphs  $G_L^1, \dots, G_L^{n-1}$ , in this order. Each  $G_L^i$  has  $d + 2$  segments, and is obtained as follows. First, we place a segment containing only one node with label  $b^4$ , then we place  $d$  other segments, each one containing two nodes with labels  $1^4$  and  $0^4$ . Finally, we place a segment containing two nodes with labels  $b^4$  and  $e^4$ .

The nodes in each segment are connected to all nodes in the next segment, with the exception of the last segment of each  $G_L^i$ : in this case, the node with label  $1^4$  and the one with label  $0^4$  are connected only to the  $e^4$ -node of the next (and last) segment of such  $G_L^i$ .

**Sub-graph  $G_R$**  (Figure 3c) is similar to sub-graph  $G_L$ , and it consists in  $n - 1$  parts  $G_R^1, \dots, G_R^{n-1}$ , followed by a segment with a single node labeled  $e^4$ . Part  $G_R^i$  has  $d + 2$  segments, and is constructed almost identically to  $G_L^i$ . The differences are that, in the first segment of  $G_R^i$ , we place two nodes labeled  $b^4$  and  $e^4$ , while in the last segment we place only one node, which we label  $e^4$ .

As in  $G_L$ , the nodes in each segment are connected to all nodes in the next segment, with the exception of the first segment of each  $G_R^i$ : in this case, the node labeled  $e^4$  has no outgoing edge.

**Sub-graph  $G_M$**  (Figure 3b) implements the main logic of the reduction, and it uses three building blocks,  $G_{be}$ ,  $G_0$  and  $G_1$ , which are organized in three rows, as shown in Figure 2.

Sub-graph  $G_M$  has  $n$  parts,  $G_M^1, \dots, G_M^n$ , one for each of the vectors  $y_1, \dots, y_n$  in set  $Y$ . Each  $G_M^j$  is constructed, from left to right, as follows. First, we place a  $G_{be}$  gadget. Then, we scan vector  $y_j$  from left to right and, for each position  $h \in \{1, \dots, d\}$ , we place a  $G_0$  gadget if the  $h$ -th entry is  $y_j[h] = 0$ , or a  $G_1$  if  $y_j[h] = 1$ . Finally, we place another  $G_{be}$  gadget.

For the edges, we first consider each gadget  $G_M^j$  separately. Let  $G_h$  and  $G_{h+1}$ , be the gadgets encoding  $y_j[h]$  and  $y_j[h + 1]$ , respectively. We fully connect the nodes of  $G_h$  to the nodes of  $G_{h+1}$  row by row, respecting the structure of the segments. Then we connect, row by row, the  $b$ -nodes of the left  $G_{be}$  to the leftmost  $G_h$ , which encodes  $y_j[1]$ , and the nodes of the rightmost  $G_h$ , which encodes  $y_j[d]$ , to the  $e$ -nodes of the right  $G_{be}$ , again row by row. We repeat the same placement of the edges for every vector  $G_h, G_{h+1}$ ,  $1 \leq h \leq d - 1$ ; this construction is shown in Figure 3b.

To conclude the construction of  $G_M$ , we need to connect all the  $G_M^j$  gadgets together. Consider the right  $G_{be}$  of gadget  $G_M^j$ , and the left  $G_{be}$  of gadget  $G_M^{j+1}$ . The edges connecting these two gadgets are depicted in Figure 3b, which shows that following a path we can either remain in the same row or move to the row below, but we cannot move to the row above. Moreover, sub-pattern  $b^8$  can be matched only in the first and second row, while sub-pattern  $e^8$  only in the second and third rows.

In proving the correctness of the reduction, we will refer to graphs  $G_{M1}$ ,  $G_{M2}$  and  $G_{M3}$  as the sub-graphs of  $G_M$  consisting of only the nodes and edges of the first, second and third row, respectively. Formally, for  $t \in \{1, 2, 3\}$ ,  $V_{Mt} \subset V$   $V_{Mt} \subset V$  is the set of

(a) Sub-graph  $G_L$ . The last segment belongs to sub-graph  $G_M$  and shows the connection.

(b) Sub-graph  $G_M$  for vectors  $y_1 = 100$ ,  $y_2 = 011$  and  $y_3 = 010$ . The dashed rectangles highlight the single  $G_M^j$  gadgets.

(c) Sub-graph  $G_R$ . The first segment belongs to sub-graph  $G_M$  and shows the connection.

**Figure 3** An example of graph  $G$ . To visualize the entire graph, watch the three sub-figures from top to bottom and from left to right. We also show two example occurrences of a query string  $Q$  constructed from  $x_1 = 101$ ,  $x_2 = 110$ ,  $x_3 = 100$  (left-most), and from  $x_1 = 101$ ,  $x_2 = 100$ ,  $x_3 = 110$  (right-most), respectively. We highlight each  $Q_i$  with a different color. Any such occurrence must pass through the middle row of  $G_M$ .

nodes placed in the  $t$ -th row of each  $G_{be}$ ,  $G_0$  or  $G_1$  gadget belonging to sub-graph  $G_M$ , and  $E_{Mt} = \{(v, w) \in E \mid v, w \in V_{Mt}\}$ . Thus,  $G_{Mt} = (V_{Mt}, E_{Mt})$ . We will use the notation  $G_{M2}^j$  to refer to the nodes belonging to both  $G_M^j$  and  $G_{M2}$ , excluding the ones in  $G_{M1}$  and  $G_{M3}$ , and the edges connecting them.

**Final graph  $G$**  is obtained by combining sub-graphs  $G_L$ ,  $G_M$  and  $G_R$ . To this end, we connect the nodes in the last segment of  $G_L$  with the  $b$ -nodes in the first and second row of the left  $G_{be}$  gadget of  $G_M^1$ . Finally, we connect the  $e$ -nodes in the second and third row of the right  $G_{be}$  gadget of  $G_M^n$  with both the  $b^4$ -node and  $e^4$ -node in the first segment of  $G_R$ . Figures 3a, 3b and 3c can be visualized together, in this order, as one big picture of final graph  $G$ . In Figures 3a and 3c we placed the adjacent segment of  $G_M$  to show the connection.

**OVH Conditional Hardness.** The proof of correctness is similar to the one by Equi et al. [10], but with adaptations to the elastic founder graph. The following technical lemma (whose proof is deferred to the full version of this paper) summarizes the structure of the possible matches of  $Q$  inside  $G$ . In it, we use the notation  $G_{M2}^j$  to indicate the nodes and edges that belong to the second row of  $G_M^j$ .

► **Lemma 6.**

- If string  $Q_i$  has a match in  $G_{M2}$ , then the path matching  $Q_i$  is fully contained in  $G_{M2}^j$ , for some  $1 \leq j \leq n$ . Moreover, each  $Q_{i,h}$  substring matches a path of two nodes which belong to the  $G_0$  or  $G_1$  gadget encoding  $y_j[h]$ .
- String  $Q_i$  has a match in  $G_{M2}$  if and only if there exist  $y_j \in Y$  such that  $x_i \cdot y_j = 0$ .
- String  $Q$  has a match in  $G$  if and only if a substring  $Q_i$  of  $Q$  has a match in the underlying sub-graph  $G_{M2}$  of  $G_M$ .

Our first lower bound is on matching a query string in an EFG without indexing.

► **Theorem 7.** For any constant  $\epsilon > 0$ , it is not possible to find a match for a query string  $Q$  into an EFG  $G = (V, E, \ell)$  in either  $O(|E|^{1-\epsilon}|Q|)$  or  $O(|E||Q|^{1-\epsilon})$  time, unless OVH fails. This holds even if restricted to an alphabet of size 4.

**Proof sketch.** First, Lemma 6 guarantees that string  $Q$  has a match in  $G$  if and only if there exist orthogonal vectors  $x_i \in X$  and  $y_j \in Y$ . Second, it is easy to check that the reduction requires linear time and space in the size  $O(nd)$  of the OV problem. Third, if we find a match for  $Q$  in  $G$  in  $O(|E|^{1-\epsilon}|Q|)$  or  $O(|E||Q|^{1-\epsilon})$  time, then we can decide if there is a pair of orthogonal vectors in  $O(nd \cdot (nd)^{1-\epsilon}) = O(n^{2-\epsilon}\text{poly}(d))$  time, contradicting OVH. ◀

We obtain the indexing lower bound by proving that the above reduction is a *linear independent-components (lic)* reduction, as defined by [11, Definition 3].

► **Theorem 8.** For any  $\alpha, \beta, \delta > 0$  such that  $\beta + \delta < 2$ , there is no algorithm preprocessing an EFG  $G = (V, E, \ell)$  in time  $O(|E|^\alpha)$  such that for any query string  $Q$  we can find a match for  $Q$  in  $G$  in time  $O(|Q| + |E|^\delta|Q|^\beta)$ , unless OVH is false. This holds even if restricted to an alphabet of size 4.

**Proof.** It is enough to notice that the reduction from OV that we presented is a *lic* reduction. Namely, (1) the reduction is correct and can be performed in linear time and space  $O(nd)$  (recall the proof of Theorem 7), and (2) query string  $|Q|$  is defined using only vector set  $X$  and it is independent from vector set  $Y$ , while elastic founder graph  $G$  is built using only vector set  $Y$  and it is independent from vector set  $X$ . Hence, Corollary 1 in [11] can be applied, proving our thesis. ◀

## 4 Indexing (Semi-)Repeat-Free EFGs

Since indexing a general EFG is hard, we turn our attention to repeat-free and semi-repeat-free EFGs. We show in this section that such EFGs are easy to index.

Let  $G = (V, E)$  be a (semi-)repeat-free founder/block graph. We show that it is sufficient to build an index on a string formed by concatenating labels of neighboring nodes. Namely, consider string  $D = \prod_{i \in \{1, 2, \dots, b\}} \prod_{v \in V^i, (v, w) \in E} \ell(w)^{-1} \ell(v)^{-1} \mathbf{0}$ , where  $X^{-1}$  is the reverse  $x_m x_{m-1} \cdots x_1$  of string  $X = x_1 x_2 \cdots x_m$ . The key feature requiring this reversed direction is that the lexicographic ranges of suffixes of  $D$  starting with  $\ell(v)^{-1}$  for each  $v \in V$  are distinct; this would not (on all inputs) hold on suffixes starting with  $\ell(v)$  in a forward concatenation if  $\ell(v)$  is a prefix of some  $\ell(u)$ , as it can be in the semi-repeat-free case.

As the reader can easily verify, the *expanded backward search* [23] developed for the case of gapless MSAs applied on  $D$  (in place of the forward concatenation therein) works also for repeat-free founder/block graphs; the feature of having variable-length of strings in a block is not used in the correctness analysis. In the following, we give an alternative solution for the semi-repeat-free case using suffix trees.

Let us consider a solution based on the *descending suffix walk*. This search can be supported e.g. by any (compressed) suffix tree [12, 33]. In the following, we assume the reader is familiar with the basic notions on suffix tree [22, Chapter 8]. Consider searching query  $Q[1..q]$  from right to left from the suffix tree of  $D$ . Consider finding a match for  $Q[j..q]$ , but there is no branch with  $Q[j-1]$ . If there is a branch with  $\mathbf{0}$ , there may be  $j'$  such that  $Q[j..j']$  is a label of some node  $v$  of the semi-repeat-free EFG, for some  $j' \leq q$ . To find such  $j'$  (or to find out it does not exist), we can then take suffix links to reach the locus corresponding to  $Q[j..j']$ , and continue the search with  $Q[1..j'-1]$ . This process is repeated until  $Q$  is found, or, if one cannot proceed,  $Q$  does not occur in  $G$ . For this to work, we need to have marked all loci of the suffix tree reached by  $\ell(v)^{-1}$  for all nodes  $v$  of the semi-repeat-free EFG. We stop taking suffix links when reaching a marked loci.

► **Theorem 9.** *A (semi-)repeat-free founder/block graph  $G = (V, E)$  or a (semi-)repeat-free elastic degenerate string can be indexed in polynomial time into a data structure occupying  $O(|D| \log |D|)$  bits of space, where  $|D| = O(L|E|)$  and  $L$  is the maximum length of a node label. Later, one can find out in  $O(|Q|)$  time if a given query string  $Q$  occurs in  $G$ .*

**Proof.** Consider the approach above. If and only if  $Q$  is reported to be found, there is a path in  $G$  that spells  $Q$ : If  $Q$  is found without taking any suffix links, it is a substring of  $D$  and thus a substring of a concatenation of labels of two neighboring nodes of  $G$ . Otherwise, suffix  $Q[j..q]$  is a prefix of a path starting with  $\ell(w) = Q[j..j']$  for some  $w \in V$ . Since  $\ell(w)^{-1}$  occurs in  $D$  only when followed by  $\mathbf{0}$  or  $\ell(v)^{-1}$  for  $(v, w) \in E$ , the search continues only on the in-neighbors of  $w$ . If  $Q$  is found before taking suffix links again,  $Q[1..j-1]$  is a suffix of  $\ell(v)$  for some  $v$  such that  $(v, w) \in E$ , and thus there is a path in  $G$  spelling  $Q$ . Otherwise, suffix  $Q[k..q]$  is a prefix of a path starting with  $\ell(v)\ell(w)$ , for some  $k \leq j-1$ . Continuing this shows that the claim is correct.

Clearly, the length of  $D$  is bounded by  $O(L|E|)$ . Construction of suffix tree on  $D$  can be done in linear time [12]. In polynomial time, the nodes of the suffix tree can be preprocessed with perfect hash functions, such that following a downward path takes constant time per step. Following a suffix link takes amortized constant time. ◀

Observe that  $|D| \leq 2mn$ , where  $m$  and  $n$  are the number of rows and number of columns, respectively, in the MSA from where the elastic founder graph is induced. That is, the index size is linear in the (original) input size. We also note that the index can be modified to report only matches that are (gap-oblivious) substrings of the MSA rows: Short patterns spanning only one edge are already such. Longer patterns can have only one occurrence in  $G$ , and it suffices to verify them with a regular string index on the MSA. Such modified scheme makes the approach functionality equivalent with wide range of indexes designed for repetitive collections [24, 29, 30, 28, 27, 14, 15] and shares the benefit of alignment-based indexes of Na et al. [29, 30, 28, 27] in reporting the aligned matches only once, where e.g. r-index [15] needs to report all occurrences.

Using compressed suffix trees, different space-time tradeoffs can be achieved. We develop an alternative compressed indexing scheme in Section 6 using Wheeler graphs.

## 5 Construction of (Semi-)Repeat-Free EFGs

Now that we have seen that (semi-)repeat-free EFGs are easy to index, it remains to consider their construction.

Consider a segmentation  $S = S^1, S^2, \dots, S^b$  that induces an EFG  $G(S) = (V, E)$ . We call such a segmentation (semi-)repeat-free or simply *valid*, if the resulting EFG is (semi-)repeat-free. A segment  $\text{MSA}[1..m, x_k..y_k]$  corresponding to block  $S^k = \text{spell}(\text{MSA}[1..m, x_k..y_k])$  of

such (semi-)repeat-free  $S$  is then analogously called a (semi-)repeat-free segment. In an earlier work on gapless MSAs [23], it was observed that a sufficient and necessary condition to check if a segment  $\text{MSA}[1..m, x_k..y_k]$  is repeat-free is to check that no string  $\text{MSA}[i, x_k..y_k]$ ,  $1 \leq i \leq m$ , occurs elsewhere in the MSA except at  $\text{MSA}[i', x_k..y_k]$ , for some  $1 \leq i' \leq m$ . Let us refine this condition with gaps. We say that segment  $\text{MSA}[1..m, x_k..y_k]$  is repeat-free (semi-repeat-free) if no string  $\text{spell}(\text{MSA}[i, x_k..y_k])$ ,  $1 \leq i \leq m$ , occurs elsewhere in the MSA except at (as a prefix of, respectively)  $\text{spell}(\text{MSA}[i', 1..n])[g(i', x_k)..g(i', y_k)]$ , for some  $1 \leq i' \leq m$ , where  $g(i', j)$  is  $j$  subtracted with the number of gaps at row  $i'$  of MSA up to column  $j$ . The earlier arguments [23, Sect. 5.1] carry over to showing that these are sufficient and necessary conditions for inducing a repeat-free and semi-repeat-free EFGs, respectively.

We consider three score functions for the valid segmentations, one maximizing the number of blocks, one minimizing the maximum width of a block, and one minimizing the maximum length of a block. The latter two have been studied earlier without the (semi-)repeat-free constraint, and non-trivial linear time solutions have been found [31, 8], while the first score function makes sense only with this new constraint.

Let  $s(j')$  be the optimal score of a semi-repeat-free segmentation  $S^1, S^2, \dots, S^b$  of prefix  $\text{MSA}[1..m, 1..j']$  for a selected scoring scheme. Then

$$s(j) = \bigoplus_{\substack{j' : 0 \leq j' < j, \\ \text{MSA}[1..m, j' + 1..j] \text{ is semi-repeat-free segment}}} w(s(j'), j', j), \quad (1)$$

gives the optimal score of a semi-repeat-free segmentation  $S^1, S^2, \dots, S^b, S^{b+1}$  of  $\text{MSA}[1..m, 1..j]$ , where  $\bigoplus$  is an operator depending on the scoring scheme and  $w(x, j', j)$  is a function on the score  $x$  of the segmentation of  $S^1, S^2, \dots, S^b$  and on the last block  $S^{b+1}$  corresponding to  $\text{MSA}[1..m, j' + 1..j]$ . To fix this recurrence so that  $s(n)$  equals the maximum number of blocks over valid segmentations of  $\text{MSA}[1..m, 1..n]$ , set  $\bigoplus = \max$  and  $w(x, j', j) = x + 1$ . For initialization, set  $s(j) = 0$ . Moreover, when there is no valid segmentation for some  $j$ , set  $s(j) = -\infty$ . To fix this recurrence so that  $s(n)$  equals the minimum of maximum widths of blocks over valid segmentations of  $\text{MSA}[1..m, 1..n]$ , set  $\bigoplus = \min$  and  $w(x, j', j) = \max(x, |\{\text{spell}(\text{MSA}[i, j' + 1..j]) \mid 1 \leq i \leq m\}|)$ . For initialization, set  $s(j) = 0$ . Moreover, when there is no valid segmentation for some  $j$ ,  $s(j) = \infty$ . Finally, to fix this recurrence so that  $s(n)$  equals the minimum of maximum length of blocks over valid segmentations of  $\text{MSA}[1..m, 1..n]$ , set  $\bigoplus = \min$  and  $w(x, j', j) = \max(x, j - j')$ . For initialization, set  $s(j) = 0$ . Moreover, when there is no valid segmentation for some  $j$ , set  $s(j) = \infty$ .

The recurrence fixed for the latter case can be solved in  $O(mn)$  time when the input is a gapless MSA [23]. However, gaps affect most of the more involved techniques [23, 31, 8], so that we only know of a rather straightforward solution working in  $O(mn^2 \log m)$  time for this general case with gaps, for all three score functions and also for the repeat-free case (explicit proof omitted here, but the techniques developed later in this paper are sufficient for deriving such result). In what follows, we develop a different approach that works in  $O(mn \log m)$  time for the first and the last score function in the semi-repeat-free case. We leave it as an open question to obtain a faster algorithm for the second score function, and for the repeat-free case. We start with a simple observation:

► **Observation 10.** *If segment  $\text{MSA}[1..m, j + 1..f(j)]$  is semi-repeat-free, then segment  $\text{MSA}[1..m, j + 1..j']$  is semi-repeat-free for all  $j'$  such that  $f(j) < j' \leq n$ .*

Our goal is to compute for each  $j$  the smallest integer  $f(j)$  such that  $\text{MSA}[1..m, j + 1..f(j)]$  is a semi-repeat-free segment. These values can then be used for efficient evaluation of Eq. (1).

## 20:12 Indexing Elastic Founder Graphs

■ **Figure 4** Illustrating the  $O(m \log m)$  time algorithm to compute value  $f(j)$  for a given  $j$ . Node labels correspond to the string spelled from the root to the node. We assume ACA, AGA, and GCA only appear in the region of the MSA visualized, while GC and A appear also elsewhere.

► **Lemma 11.** *Let  $f(j)$  be the smallest integer such that  $\text{MSA}[1..m, j+1..f(j)]$  is a semi-repeat-free segment. We can compute all values  $f(j)$  in  $O(mn \log m)$  time.*

**Proof sketch.** Full proof is deferred to the full version of this paper. Here we explain the algorithm through the example of Fig. 4. We build a compact trie on the suffixes of the concatenation of MSA rows with gaps removed and special markers added between rows, that is, a *generalized suffix tree* [22, Chapter 8] on set  $\{\text{spell}(\text{MSA}[i, 1..n]) \mid 1 \leq i \leq m\}$ . For each column  $j$ , locate the subset  $W$  of (implicit) suffix tree nodes corresponding to  $\{\text{spell}(\text{MSA}[i, j+1..n]) \mid 1 \leq i \leq m\}$ ; these are the colored nodes in Fig. 4. If the number of leaves covered by the subtrees rooted at  $W$  is greater than  $m$ ,  $f(j)$  remains undefined. Otherwise, we know that  $f(j) \leq n$ , and our aim is to decrease the right boundary, starting with  $n$ , until we have reached column  $f(j)$ . The algorithm picks an arbitrary node in  $W$  and tries to replace it with its parent. This replacement is safe, if the new subtree covers only leaves already covered by  $W$ . Safe replacements are continued as long as possible; these are the black nodes in Fig. 4, while the gray nodes are unsafe replacements. These replacements place the rows into equivalence classes, each sharing the identified common prefix. For row  $i$  in an equivalence class with common prefix length  $k$ , one can then locate the smallest column  $f^i(j)$  with  $|\text{spell}(\text{MSA}[i, j+1..f^i(j)])| = k$ . E.g. for row  $i = 2$  in Fig. 4, we have  $f^2(j) = j + 3$ , as  $|\text{spell}(\text{AC} - \text{A})| = 3 = |\text{ACA}|$ . Finally,  $f(j) = \max_{i:1 \leq i \leq m} f^i(j)$ . At each column, at most  $m$  replacements are required and each replacement can be done in  $O(\log m)$  time, by maintaining the non-overlapping lexicographic intervals corresponding to the suffix tree nodes in a balanced search tree. ◀

Using these precomputed  $f(j)$  values, Algorithms 1 and 2 compute the scores of an optimal semi-repeat-free segmentation under the maximum number of blocks score and minimum of maximum block length score, respectively.

► **Theorem 12.** *After an  $O(mn \log m)$  time preprocessing, Algorithms 1 and 2 compute the scores  $\text{maxblocks}(n) = b$  and  $\text{minmaxlength}(n) = \max_{i:1 \leq i \leq b} L(S^i)$  of optimal semi-repeat-free segmentations  $S^1, S^2, \dots, S^b$  of  $\text{MSA}[1..m, 1..n]$  in  $O(n)$  and  $O(n \log \log n)$  time, respectively.*

**Proof sketch.** Regarding running time, Algorithm 1 and Algorithm 2 clearly take  $O(n)$  and  $O(n \log n)$  time, respectively, when implemented as described in their pseudo-codes. The correctness for Algorithm 1 follows from the fact that when computing the score at column  $j$ , all earlier segmentations that are safe to be extended with a new segment ending at  $j$  are considered. This argument can be formalized analogously for Algorithm 2, whose detailed proof of correctness, as well as running time improvement to  $O(n \log \log n)$  (by using a more efficient data structure for semi-infinite range queries) are given in the full version of this paper. ◀

■ **Algorithm 1** An  $O(n)$  time algorithm for finding an optimal semi-repeat-free segmentation maximizing the number of blocks.

---

**Input:** Right-extensions  $(j, f(j))$  sorted from smallest to largest order by second component:  $(j_1, f(j_1)), (j_2, f(j_2)), \dots, (j_{n-J}, f(j_{n-J}))$ , where  $J$  is such that  $f(j_{n-J+1}), f(j_{n-J+2}), \dots, f(j_n)$  are not defined.

**Output:** Score of an optimal semi-repeat-free segmentation maximizing the number of blocks.

```

1  $x \leftarrow 1$ ;  $\text{maxblocks}(0) \leftarrow 0$ ;  $\text{maxblocks}(j) = \text{maxscore} = -\infty$  for all  $0 < j \leq n$ ;
2 for  $j \leftarrow 1$  to  $n$  do
3   while  $j = f(j_x)$  do
4      $\text{maxscore} \leftarrow \max(\text{maxscore}, \text{maxblocks}(j_x))$ ;
5      $x \leftarrow x + 1$ ;
6    $\text{maxblocks}(j) \leftarrow \text{maxscore} + 1$ ;
7 return  $\text{maxblocks}(n)$ ;
```

---

■ **Algorithm 2** An  $O(n \log n)$  time algorithm for finding an optimal semi-repeat-free segmentation minimizing the maximum segment length. Minimization over an empty set is assumed to return  $\infty$ . Operation **Upgrade** $(k, v)$  sets key  $k$  to value  $v$  if the previous value is larger. Operation **RangeMin** $(a, b)$  returns the smallest value associated with keys in range  $[a..b]$ . Both operations can be supported in  $O(\log n)$  time with standard balanced search trees.

---

**Input:** Right-extensions  $(j, f(j))$  sorted from smallest to largest order by second component:  $(j_1, f(j_1)), (j_2, f(j_2)), \dots, (j_{n-J}, f(j_{n-J}))$ , where  $J$  is such that  $f(j_{n-J+1}), f(j_{n-J+2}), \dots, f(j_n)$  are not defined.

**Output:** Score of an optimal semi-repeat-free segmentation minimizing the maximum segment length.

```

1 Initialize one-dimensional search trees  $\mathcal{T}$  and  $\mathcal{I}$  with keys  $0, 1, 2, \dots, 2n$ , with all keys associated with values  $\infty$ ;
2  $x \leftarrow 1$ ;
3  $\text{minmaxlength}(0) \leftarrow 0$ ;
4 for  $j \leftarrow 1$  to  $n$  do
5   while  $j = f(j_x)$  do
6      $\mathcal{T}.\text{Upgrade}(j_x + \text{minmaxlength}(j_x), \text{minmaxlength}(j_x))$ ;
7      $\mathcal{I}.\text{Upgrade}(j_x + \text{minmaxlength}(j_x), -j_x)$ ;
8      $x \leftarrow x + 1$ ;
9    $\text{minmaxlength}(j) \leftarrow \min(\mathcal{T}.\text{RangeMin}(j + 1, \infty), \mathcal{I}.\text{RangeMin}(-\infty, j) + j)$ ;
10 return  $\text{minmaxlength}(n)$ ;
```

---

## 6 Connection to Wheeler Graphs

Wheeler graphs, also known as Wheeler automata, are a class of labeled graphs that admit an efficient index for path queries [13]. We now give an alternative way to index repeat-free elastic block graphs by transforming the graph into an equivalent Wheeler automaton.

We view a block graph as a nondeterministic finite automaton (NFA) by adding a new initial state and edges from the source node to the starts of the first block, and expanding each string of each block to a path of states. To conform with automata notions, we define that the label of an edge is the label of the destination node.

We denote the repeat-free NFA with  $F$ . First we determinize it with the standard subset construction for the reachable subsets of states. The states of the DFA are subsets of states of the NFA such that there is an edge from subset  $S_1$  to subset  $S_2$  with label  $c$  iff  $S_2$  is the set of states at the destinations of edges labeled with  $c$  from  $S_1$ . We only represent the subsets of states reachable from the subset containing only the initial state. We call the deterministic graph  $G$ . See Figures 5 and 6 for an example.

A DFA is indexable as a Wheeler graph if there exists an order  $<$  on the nodes such that if  $u < v$ , then every incoming path label to  $u$  is colexicographically smaller than every incoming path label to  $v$  (recall that the colexicographic order of strings is the lexicographic order of the reverses of the strings). The repeat-free property guarantees that the nodes at the ends of the blocks can be ordered among themselves by picking an arbitrary incoming path as the sorting key.

To make sure that the rest of the nodes are sortable, we modify the graph so that if a node is not at the end of a block, we make it so that the incoming paths to the node do not branch backward before the backward path reaches the end of a previous block. This is done by turning each block into a set of disjoint trees, where the roots of the trees are the ending nodes of the previous block, in a way that preserves the language of the automaton. The roots may have multiple incoming edges from the leaves of the previous tree. See Figure 7 for an example. The formal definition of the transformation and the proof of sortability are deferred to the full version of this paper. We denote the transformed graph with  $G'$  and obtain the following result:

► **Lemma 13.** *The number of nodes in  $G'$  is at most  $O(NW)$ , where  $W$  is the maximum number of strings in a block of  $F$  and  $N$  is the total number of nodes in  $F$ .*

The Wheeler order  $<$  of the transformed graph can be found by running the XBWT sorting algorithm on a spanning tree of the graph, as shown by Alanko et al. [1]. Finally, we can find the minimum equivalent Wheeler graph by running the general Wheeler graph minimization algorithm of Alanko et al. [1].

With the input graph now converted into a Wheeler graph, one can deploy succinct data structures supporting fast pattern matching [13, Lemma 4], leading to the following result:

► **Corollary 14.** *A repeat-free founder/block graph  $G$  or a repeat-free elastic degenerate string can be indexed in  $O(NW)$  time into a Wheeler-graph-based data structure occupying  $O(NW \log |\Sigma|)$  bits of space, where  $N$  is the total number of characters in the node labels of  $G$ ,  $W$  is the width of  $G$  (maximum number of strings in a block of  $G$ ), and  $\Sigma$  is the alphabet. Later, using the data structure, one can find out in  $O(|Q| \log |\Sigma|)$  time if a given query string  $Q$  occurs in  $G$ .*

Figure 5 Repeat-free block NFA. The last columns of each block are highlighted.

Figure 6 The DFA resulting from the subset construction for the NFA in Figure 5. The numbers above the nodes specify the subset of NFA states corresponding to the DFA state.

Figure 7 The Wheeler DFA resulting from running our Wheeler expansion algorithm on the DFA in Figure 6.

## 7 Discussion

There are many options how to optimize among the valid segmentations [31, 8]. We studied some of these here under the (semi-)repeat-free indexability constraint, but left open how to e.g. minimize the maximum number of distinct strings in a segment (i.e. *width* of the graph) [31], or how to control the over-expressiveness of the graph, in this context.

Other open problems include strengthening the conditional indexing lower bound to cover non-elastic founder graphs, and improving the running time for constructing (semi-)repeat-free elastic founder graphs.

We focused on the theoretical aspects of indexable founder graphs. Our preliminary experiments [23] show that the approach works well in practice on multiple sequence alignments without gaps. In our future work, we will focus on making the approach practical also in the general case.

## Abstract

A natural way of increasing our understanding of NP-complete graph problems is to restrict the input to a special graph class. Classes of  $H$ -free graphs, that is, graphs that do not contain some graph  $H$  as an induced subgraph, have proven to be an ideal testbed for such a complexity study. However, if the forbidden graph  $H$  contains a cycle or claw, then these problems often stay NP-complete. A recent complexity study (MFCS 2019) on the  $k$ -COLOURING problem shows that we may still obtain tractable results if we also bound the diameter of the  $H$ -free input graph. We continue this line of research by initiating a complexity study on the impact of bounding the diameter for a variety of classical vertex partitioning problems restricted to  $H$ -free graphs. We prove that bounding the diameter does not help for INDEPENDENT SET, but leads to new tractable cases for problems closely related to 3-COLOURING. That is, we show that NEAR-BIPARTITENESS, INDEPENDENT FEEDBACK VERTEX SET, INDEPENDENT ODD CYCLE TRANSVERSAL, ACYCLIC 3-COLOURING and STAR 3-COLOURING are all polynomial-time solvable for chair-free graphs of bounded diameter. To obtain these results we exploit a new structural property of 3-colourable chair-free graphs.

## 1 Introduction

Many well-known graph problems are NP-complete in general but become polynomial-time solvable under input restrictions. We focus on problems that partition the vertex set  $V$  of a graph  $G$  into sets  $V_1, \dots, V_k$  such that each  $V_i$  satisfies some property  $\pi_i$  and where  $V_1$  might have the extra condition of being large or being small. For instance, the  $k$ -COLOURING problem is to decide if  $V$  can be partitioned into sets  $V_1, \dots, V_k$ , called *colour classes*, such that each  $V_i$  is an independent set. To give another example, the INDEPENDENT SET problem is to decide if  $V$  can be partitioned into sets  $V_1$  and  $V_2$  where  $V_1$  is independent and  $|V_1| \geq p$  for some given integer  $p$ . Our underlying goal is to understand which graph properties ensure tractability of these problems and which properties cause the computational hardness. In the literature, input is restricted in various ways. In particular, *hereditary* graph classes have been considered.

Hereditary graph classes are the classes of graphs closed under vertex deletion. They form a natural and rich framework that cover many well-known graph classes (see, for example, [7]). Moreover, they enable a systematic study on the computational complexity of graph problems

under input restrictions. The reason is that a graph class  $\mathcal{G}$  is hereditary if and only if  $\mathcal{G}$  can be characterized by a set  $\mathcal{F}_{\mathcal{G}}$  of forbidden induced subgraphs; we also say that  $\mathcal{G}$  is  $\mathcal{F}_{\mathcal{G}}$ -free. A natural starting point for a systematic study is the case where  $\mathcal{F}_{\mathcal{G}}$  has size 1, say  $\mathcal{F}_{\mathcal{G}} = \{H\}$  for some graph  $H$ . In this case the graphs in  $\mathcal{G}$  are said to be  $H$ -free. In other words, no graph  $G \in \mathcal{G}$  can be modified into  $H$  by a sequence of vertex deletions.

In the literature, there are extensive studies on  $H$ -free graphs; for example, on bull-free graphs [11] and claw-free graphs [12, 17]. There also exist several surveys on graph problems or graph parameters for hereditary graph classes that are characterized by a small set of forbidden induced subgraphs, for example, on COLOURING [16, 27] and clique-width [13].

A well-known dichotomy on COLOURING restricted to  $H$ -free graphs is due to Král', Kratochvíl, Tuza, and Woeginger [19]. Namely, COLOURING on  $H$ -free graphs is polynomial-time solvable if  $H$  is an induced subgraph of  $P_4$  (the 4-vertex path) or of  $P_1 + P_3$  (the disjoint union of  $P_1$  and  $P_3$ ) and it is NP-complete otherwise. Recently, similar but almost-complete dichotomies (up to one missing case each) were established for ACYCLIC COLOURING, STAR COLOURING and INJECTIVE COLOURING [4]. In particular, all these problems stay NP-complete if the forbidden induced subgraph  $H$  has a cycle or claw (the 4-vertex star  $K_{1,3}$ ). Moreover, the latter holds even if the number of colours  $k$  is fixed, i.e., not part of the input.

Several other vertex partitioning problems on  $H$ -free graphs stay NP-complete as well if  $H$  has a cycle or claw. Examples of such problems include (INDEPENDENT) FEEDBACK VERTEX SET [6, 23, 26], (INDEPENDENT) ODD CYCLE TRANSVERSAL [6, 10] and EVEN CYCLE TRANSVERSAL [24]. Hence, for all these problems, if  $H$  is a cycle or claw, then we need to add more structure to the class of input graphs in order to find tractable results for  $H$ -free graphs. One way of doing this is to bound the *diameter* of the input graph  $G$  for some problem. Our research question then becomes:

*Does bounding the diameter of an  $H$ -free graph lead to new tractability results?*

We note that graph classes of diameter at most  $d$  are hereditary if and only if  $d \leq 1$ . Many graph problems, such as COLOURING, ACYCLIC COLOURING, STAR COLOURING, CLIQUE and INDEPENDENT SET stay NP-complete even for graphs of diameter 2. The reason is that we can take an arbitrary graph  $G$  from such a problem and add a dominating vertex: the graph  $G$  is a yes-instance if and only if the new graph  $G'$  is a yes-instance.

This approach of adding a dominating vertex does not work if we consider 3-COLOURING. Mertzios and Spirakis [22] proved in a highly nontrivial way that 3-COLOURING is NP-complete even for triangle-free graphs of diameter at most 3. However, determining the complexity of 3-COLOURING for graphs of diameter 2 is a notoriously open problem (see [3, 9, 20, 22, 25]); we refer to [22] and [14] for subexponential-time algorithms for LIST 3-COLOURING on graphs of diameter at most 2. It is also known that ACYCLIC 3-COLOURING and STAR COLOURING, restricted to graphs of diameter at most  $d$ , are polynomial-time solvable if  $d = 2$  or  $d = 3$ , respectively, but NP-complete if  $d = 5$  or  $d = 8$ , respectively [8]. Moreover, the related problems NEAR BIPARTITENESS and INDEPENDENT FEEDBACK VERTEX SET, which we define below, are polynomial-time solvable for  $d = 2$  but NP-complete for  $d = 3$  [5]. These results also show that bounding the diameter on its own (without forbidding any induced graph  $H$ ) does not suffice.

We refer to [20, 21] for a number of results on 3-COLOURING and LIST 3-COLOURING for  $H$ -free graphs of bounded diameter, where  $H$  is a cycle or a *polyad*, which is a tree where exactly one vertex has degree at least 3 (polyads are also known as *subdivided stars*). One crucial observation in [20], based on an application of Ramsey's Theorem, was the starting point of this investigation: for all integers  $d, k$ , the  $k$ -COLOURING problem is constant-time solvable on claw-free graphs of diameter at most  $d$ . In the same paper [20], this result was generalized to the case where  $H$  is the *chair*, which is the graph obtained from the claw after subdividing exactly one of its edges. The chair is also known as the *fork*.

**Our Results.** We first consider the INDEPENDENT SET problem. For this problem we will prove new NP-hardness results that show that bounding the diameter does not help. To explain this, let the graph  $S_{h,i,j}$ , for  $1 \leq h \leq i \leq j$ , be the *subdivided claw*, which is the tree with one vertex  $x$  of degree 3 and exactly three leaves, which are at distance  $h$ ,  $i$  and  $j$  from  $x$ , respectively. Note that  $S_{1,1,1}$  is the claw  $K_{1,3}$ , the graph  $S_{1,1,2}$  is the chair and that every subdivided claw is a polyad. Let  $\mathcal{S}$  be the set of graphs, each connected component of which is a subdivided claw or a path. Alekseev [1] proved that for every finite set of graphs  $\mathcal{F}$ , if no graph from  $\mathcal{F}$  belongs to  $\mathcal{S}$ , then INDEPENDENT SET is NP-complete for the class of  $\mathcal{F}$ -free graphs. In Section 2, we show that exactly the same NP-completeness result holds for the class of  $\mathcal{F}$ -free graphs of diameter 2 if and only if  $|\mathcal{F}| = 1$ .

We then turn to the class of  $H$ -free graphs where  $H$  is a polyad. First, we focus on the case where  $H$  is the chair. In Section 3, we prove that for every integer  $d \geq 1$ , a number of vertex partitioning problems that require yes-instances to be 3-colourable become polynomial-time solvable on chair-free graphs of diameter at most  $d$ . The problems are ACYCLIC 3-COLOURING, STAR 3-COLOURING, NEAR-BIPARTITENESS, INDEPENDENT FEEDBACK VERTEX SET and INDEPENDENT ODD CYCLE TRANSVERSAL. We define these problems below.

Our proof is based on a common strategy. Namely, we determine the following for every chair-free 3-colourable non-bipartite input graph  $G$  of bounded diameter: either  $G$  has a constant number of 3-colourings or there exists a set  $S$  such that  $G - S$  has this property. We prove that we can let  $S$  be the set of private neighbours of some vertex  $u$  of a triangle on vertices  $u, v, w$ , that is, the vertices of  $S$  are adjacent to neither  $v$  nor  $w$ . We then consider each constructed 3-colouring  $c$  and determine in polynomial time if we can extend  $c$  to a solution for the vertex partitioning problem under consideration.

In Section 4 we prove that there is little hope of a full extension from the chair to arbitrary polyads  $H$ . To be more precise, we prove that for ACYCLIC 3-COLOURING, STAR 3-COLOURING and INDEPENDENT ODD CYCLE TRANSVERSAL, there exists a polyad  $H$  and a constant  $d$  such that each of these problems is NP-complete for the class of  $H$ -free graphs of diameter at most  $d$ . In the same section we give some relevant open problems.

**Additional Terminology.** A graph is *acyclic 3-colourable* or *star 3-colourable* if it is 3-colourable and every two colour classes induce a forest or a star forest, respectively (in this context, the  $P_1$  and  $P_2$  are seen as stars). The corresponding decision problems are ACYCLIC 3-COLOURING and STAR 3-COLOURING. A graph  $G$  is *near-bipartite* if its vertex set can be partitioned into an independent set  $I$  and a forest  $F$ ; we also say that  $I$  is an *independent feedback vertex set* of  $G$ . The problems NEAR-BIPARTITENESS and INDEPENDENT FEEDBACK VERTEX SET are to decide if a graph is near-bipartite or has an independent feedback vertex set of size at most  $k$  for some given integer  $k$ . A subset  $S \subseteq V$  of a graph  $G = (V, E)$  is an *independent odd cycle transversal* if  $S$  is independent and  $G - S$  is bipartite. Note that a graph is 3-colourable if and only if it has an independent odd cycle transversal. The INDEPENDENT ODD CYCLE TRANSVERSAL problem is to decide if a given graph has an independent odd cycle transversal of size at most  $k$  for some given integer  $k$ .

Let  $C_r$ ,  $P_r$  and  $K_r$  be the cycle, path and complete graph on  $r$  vertices. The graph  $G + H = (V(G) \cup V(H), E(G) \cup E(H))$  is the disjoint union of graphs  $G$  and  $H$ , and  $sG$  is the disjoint union of  $s$  copies of  $G$ . A graph  $G$  is  $\mathcal{H}$ -free if  $G$  is  $H$ -free for every  $H \in \mathcal{H}$ .

## 2 Independent Set

We let  $\mathcal{S}$  denote the set of graphs, each connected component of which is either a subdivided claw or a path. The following well-known result is due to Alekseev.

► **Theorem 1** ([1]). *Let  $\mathcal{F}$  be a finite set of graphs. If no graph from  $\mathcal{F}$  belongs to  $\mathcal{S}$ , then INDEPENDENT SET is NP-complete for  $\mathcal{F}$ -free graphs.*

We strengthen Theorem 1 to  $\mathcal{F}$ -free graphs of diameter 2 if  $|\mathcal{F}| = 1$ . We need two lemmas. We sketch the proof of the first lemma.

► **Lemma 2.** *For every  $r \geq 3$ , INDEPENDENT SET is NP-complete for  $C_r$ -free graphs of diameter 2.*

**Proof.** First suppose that  $r = 3$ . By Theorem 1, INDEPENDENT SET is NP-complete for  $C_3$ -free graphs. Let  $(G, k)$  be an instance of INDEPENDENT SET, where  $G$  is an  $n$ -vertex  $C_3$ -free graph. We may assume without loss of generality that  $n \geq 2$  and  $k \geq 2$ ; otherwise, the problem is trivial. We also assume that  $G$  has no dominating vertex. Otherwise, if  $u$  is a dominating vertex, then  $G$  has an independent set of size at least  $k \geq 2$  if and only if  $G - u$  has an independent set of size at least  $k$ . Hence, by the iterative deletion of universal vertices, we either solve the problem or obtain an equivalent instance without universal vertices. From  $G$  we now construct a graph  $G'$  as follows:

- Construct a copy of  $G$ .
- For every pair  $\{u, v\}$  of nonadjacent vertices of  $G$ ,
  - construct an arbitrary inclusion maximal independent set  $I_{uv}$  of  $G$  containing  $u$  and  $v$ ,
  - construct a vertex  $x_{uv}$  and make  $x_{uv}$  adjacent to every vertex of  $I_{uv}$ .
 Denote by  $X$  the set of all vertices  $x_{uv}$  constructed for the pairs of nonadjacent  $u$  and  $v$ .
- Construct an independent set of  $n^2$  vertices  $Y$  and make every vertex of  $Y$  adjacent to every vertex of  $X$ .

Observe that for every pair  $\{u, v\}$  of nonadjacent vertices of  $G$ ,  $I_{uv}$  can be constructed by the straightforward greedy procedure starting from the set  $\{u, v\}$ . This implies that  $G$  can be constructed in polynomial time. Our construction immediately implies that  $G'$  is triangle free, because the initial graph  $G$  is triangle-free and the neighbourhood of every vertex from  $X \cup Y$  is an independent set. We claim that the diameter of  $G'$  is at most 2, and moreover that  $G$  has an independent set of size at least  $k$  if and only if  $G'$  has an independent set of size at least  $k'$ . Proof details are omitted. ◀

► **Lemma 3.** *INDEPENDENT SET is NP-complete for  $K_{1,4}$ -free graphs of diameter 2.*

**Proof.** By Theorem 1, INDEPENDENT SET is NP-hard for  $(C_3, K_{1,4})$ -free graphs. Let  $(G, k)$  be an instance of INDEPENDENT SET, where  $G$  is a  $(C_3, K_{1,4})$ -free graph of order  $n$  and size  $m$ . We may assume without loss of generality that  $G$  is connected. Note that  $G$  is subcubic, that is, has maximum degree at most 3. We may assume without loss of generality that  $G$  has no vertices of degree 1 (as we can pick such vertices to be in the independent set and remove their neighbours from  $G$  until this operation can no longer be applied). To  $G$ , we add for every pair of edges  $e_1$  and  $e_2$  of  $G$  that do not share an end-vertex, a new vertex  $x_{e_1, e_2}$  and an edge between  $x_{e_1, e_2}$  and the two end-vertices of both  $e_1$  and  $e_2$ . We also add a new vertex  $y$  and all edges such that  $\{x_{e_1, e_2} : e_1, e_2\} \cup \{y\}$  induces a complete subgraph. Let  $G'$  be the resulting graph and let  $X := \{x_{e_1, e_2} : e_1, e_2\} \cup \{y\}$ . See also Fig. 1.

■ **Figure 1** The graph  $G'$  in the proof of Lemma 3 if  $G = C_5$ . The black vertices are those of  $G$  and the white vertices in the middle are  $x_{e_1e_3}, x_{e_2e_5}, x_{e_1e_4}, x_{e_3e_5},$  and  $x_{e_2e_4}$  from left to right.

For a contradiction, assume that there is some induced  $K_{1,4}$  in  $G'$ , say  $z$  is its centre vertex and  $z_1, z_2, z_3, z_4$  are its leaves. Since  $N_{G'}(x)$  can be partitioned into at most 3 cliques for each  $x \in X$ , we have  $z \in V(G)$ . Furthermore, since  $G$  is subcubic and  $X$  is a clique,  $X$  contains at least and at most one vertex of  $\{z_1, z_2, z_3, z_4\}$ , respectively. As we see now,  $N_G(z) \subseteq \{z_1, z_2, z_3, z_4\}$ . However, each vertex of  $X$  that is adjacent to  $z$ , has a neighbour in  $N_G(z)$ , which contradicts our supposition that  $z$  is the centre vertex of an induced  $K_{1,4}$ .

To show that  $G'$  has diameter 2, first consider an arbitrary vertex  $u$  of  $G$ . As  $G$  is connected, there is a vertex  $v \in N_G(u)$ . As  $G$  has minimum degree at least 2 and  $G$  is triangle-free, there are vertices  $u' \in N_G(u) \setminus \{v\}$  and  $v' \in N_G(v) \setminus \{u, u'\}$ . For  $e_1 = uu'$  and  $e_2 = vv'$ ,  $e_1$  and  $e_2$  do not have a common end-vertex,  $u, x \in N_{G'}[x_{e_1, e_2}]$ , and  $dist_{G'}(u, x) \leq 2$  for each  $x \in X$ . Additionally, if  $w \in V(G) \setminus \{u\}$  is a vertex with  $dist_G(u, w) \geq 3$ , then, since  $G$  is connected, there are edges  $e_3, e_4 \in E(G)$  such that  $u$  is incident to  $e_3$ ,  $w$  is incident to  $e_4$ , and the two edges  $e_3, e_4$  have no common incident vertex. Thus,  $u, w \in N_G(x_{e_3, e_4})$  and so  $dist_{G'}(u, w) \leq 2$ . As  $X$  is a clique, we conclude that  $G'$  has diameter 2.

We observe that  $I \cup \{y\}$  is an independent set of size  $k + 1$  in  $G'$  if  $I$  is an independent set of size  $k$  in  $G$ . Vice versa, given an independent set  $I'$  of size  $k + 1$  in  $G'$ , at most one of its vertices belongs to  $Y$  and  $I' \setminus X$  is an independent set of size at least  $k$  in  $G$ .

The graph  $G'$  can be constructed in time  $\mathcal{O}(m^2)$  and has at most  $n + m^2$  vertices. Vice versa, given an independent set  $I'$  in  $G'$ , the set  $I' \setminus X$  can be constructed in time  $\mathcal{O}(m^2)$ . ◀

We now strengthen Theorem 1, but can only do this for the case where  $|\mathcal{F}| = 1$ . For example, if  $\mathcal{F} = \{C_3, K_{1,4}\}$ , every  $\mathcal{F}$ -free graph has maximum degree 3. Then every  $\mathcal{F}$ -free graph with bounded diameter has constant size. Hence, INDEPENDENT SET is NP-complete for  $\mathcal{F}$ -free graphs by Theorem 1 but constant-time solvable for  $\mathcal{F}$ -free graphs of bounded diameter.

► **Theorem 4.** *Let  $H$  be a graph. If  $H \notin \mathcal{S}$ , then INDEPENDENT SET is NP-complete for  $H$ -free graphs of diameter at most 2. If  $H \in \mathcal{S}$ , then INDEPENDENT SET for  $H$ -free graphs is polynomially equivalent to INDEPENDENT SET for  $H$ -free graphs of diameter at most 2.*

**Proof.** Let  $H$  be a graph. First assume that  $H \notin \mathcal{S}$ . If  $H$  contains an induced cycle  $C_r$  for some  $r \geq 3$ , then the class of  $H$ -free graphs contains the class of  $C_r$ -free graphs, and we use Lemma 2. Otherwise  $H$  is a forest with either an induced  $K_{1,4}$  or a connected component that has at least two vertices of degree 3. In the first case, we use Lemma 3. In the second case, we reduce from INDEPENDENT SET for  $H$ -free graphs, which is NP-complete by Theorem 1. Let  $(G, k)$  be an instance of INDEPENDENT SET, where  $G$  is an  $H$ -free graph. We add a dominating vertex to  $G$  to obtain a graph  $G'$ . As  $H$  has no dominating vertex,  $G'$  is  $H$ -free. We also note that  $(G, k)$  and  $(G', k)$  are equivalent instances.

Now assume that  $H \in \mathcal{S}$ . Any polynomial-time algorithm for INDEPENDENT SET on  $H$ -free graphs can be used on  $H$ -free graphs of diameter 2. As INDEPENDENT SET is polynomial-time solvable for  $K_{1,3}$ -free graphs [28], we may assume that  $H \notin \{K_{1,3}, P_1, P_2, P_3\}$ . Any polynomial-time algorithm for INDEPENDENT SET on  $H$ -free graphs of diameter 2 can be used on  $H$ -free graphs of arbitrary diameter as follows. To the  $H$ -free input graph  $G$  we add a dominating vertex. As  $H \in \mathcal{S} \setminus \{K_{1,3}, P_1, P_2, P_3\}$ , this yields an  $H$ -free graph  $G'$  of diameter 2. We then observe that  $G$  has an independent set of size at least  $k$  if and only if  $G'$  has an independent set of size at least  $k$ . ◀

### 3 Chair-Free Graphs of Bounded Diameter

It follows from Ramsey's Theorem that every  $k$ -colourable  $K_{1,r}$ -free graph of diameter at most  $d$  has order bounded by a function in  $d, k, r$ ; see [20] for a proof of this observation. As a consequence, every problem that has the property that all its yes-instances are  $k$ -colourable for some constant  $k$  is constant-time solvable on  $K_{1,r}$ -free graphs of diameter at most  $d$ . We aim to extend the above observation to  $H$ -free graphs of bounded diameter when  $H$  is obtained from a star after at least one edge subdivision. In [20], a number of results are given for 3-COLOURING for such graph classes. We consider a variety of problems that require all the yes-instances to be 3-colourable. We focus on the first interesting case which is where  $H$  is the chair  $S_{1,1,2}$  (recall that the chair is obtained from the claw after subdividing one edge).

We need the following characterization of bipartite chair-free graphs, due to Alekseev. A *complex* is a bipartite graph that can be obtained by removing the edges of a possibly empty matching from a complete bipartite graph.

► **Theorem 5** ([2]). *If  $G$  is a connected bipartite chair-free graph, then  $G$  is a cycle or a path or a complex.*

It is well-known (cf. [18]) that finding the components of a graph by breadth-first search takes  $O(n + m)$  time. Let  $p$  be the number of components of a graph  $G$ ,  $n$  be its order, and  $m$  be its size. Then  $G$  is a forest if and only if  $p = n - m$ , which implies the following result.

► **Observation 6.** *If  $G$  is a graph, then we can decide if  $G$  is a forest in  $O(n + m)$  time.*

If  $T$  is a tree of order  $n$ , then its diameter is at most 2 if and only if its maximum degree equals  $n - 1$ . Therefore, we can decide whether a given graph is a forest each component of which is of diameter at most 2 in  $O(n + m)$  time. When working with vertex labellings, our findings imply the following observation.

► **Observation 7.** *If  $G$  is a graph and  $\ell$  is a vertex labelling of  $G$  with labels 1, 2, and 3, then we can decide whether  $\ell$  is a 3-colouring, star 3-colouring, or acyclic 3-colouring of  $G$  in  $O(n + m)$  time.*

It is also well-known that we can use breadth-first search for deciding whether a given graph  $G$  is bipartite and, if so, we are in a position to determine its parts in the same time. By this fact, we obtain the following result.

► **Observation 8.** *If  $G$  is a graph,  $k$  is an integer, and  $\ell$  is a vertex labelling of  $G$  with labels 1, 2, and 3, then we can decide whether one colour class of  $\ell$  is an independent feedback vertex set or an independent odd cycle transversal (of size at most  $k$ ) in  $O(n + m)$  time.*

To prove our results we need some more terminology. A *list assignment* of a graph  $G$  is a function  $L$  that gives each vertex  $u \in V(G)$  a (finite) *list of admissible colours*  $L(u) \subseteq \{1, 2, \dots\}$ . A colouring  $c$  *respects*  $L$  if  $c(u) \in L(u)$  for every  $u \in V(G)$ . If  $|L(u)| \leq 2$

for each  $u \in V(G)$ , then  $L$  is a 2-list assignment. The 2-LIST COLOURING problem is to decide if a graph  $G$  with a 2-list assignment  $L$  has a colouring that respects  $L$ . We use the following result.

► **Lemma 9** ([15]). *The 2-LIST COLOURING problem is solvable in  $O(n + m)$  time on graphs with  $n$  vertices and  $m$  edges.*

Let  $G$  be a graph of diameter  $d$  for some  $d \geq 1$  and  $S$  be some set of vertices of  $G$ . A vertex  $u \notin S$  is a *private* neighbour of a vertex  $v \in S$  with respect to  $S$  if  $u$  is adjacent to  $v$  but non-adjacent to any other vertex of  $S$ . We let  $P(v)$  be the set of private neighbours of  $v$  with respect to  $S$ . Let  $N_0 = S$  and, for  $i \in \{1, \dots, d\}$ , let  $N_i$  be the set of vertices that do not belong to  $N_0 \cup N_1 \cup \dots \cup N_{i-1}$  but do have a neighbour in  $N_{i-1}$ . As  $G$  has diameter at most  $d$ , we partition  $V(G)$  into the sets  $N_0, N_1, \dots, N_d$  (where some sets might be empty). We say that we *partition*  $V(G)$  *from*  $S$ . Note that this partitioning takes  $O(n + m)$  time by breadth-first search on the graph  $G'$  which is obtained from  $G$  by adding a new vertex  $u$  and all edges from  $u$  to every vertex of  $S$ .

In [20], it was shown that 3-COLOURING is polynomial-time solvable for chair-free graphs of bounded diameter. The first statement of Theorem 10 below is proven by similar but more precise arguments. The second statement is a new result that requires new arguments.

► **Theorem 10.** *Let  $d \geq 1$  be an integer and  $G$  be a chair-free non-bipartite graph of diameter  $d$  with  $n$  vertices and  $m$  edges.*

1. *We can decide whether  $G$  is 3-colourable in  $O(n + m)$  time.*
2. *If  $G$  is 3-colourable, then we find in  $O(n + m)$  time either all 3-colourings of  $G$ , or a triangle  $xyzx$  in  $G$  with exactly one vertex, say  $x$ , that has private neighbours and all 3-colourings of  $G - P(x)$  that can be extended to 3-colourings of  $G$ . In both cases, we find at most  $3^{9 \cdot 2^d + 8}$  3-colourings.*

**Proof.** We first check in constant time whether  $G$  is of order at most  $2d + 1$ . If so, then we can determine in constant time all 3-colourings of  $G$  and these are at most  $3^{2d+1}$ . Note that  $3^{2d+1} < 3^{9 \cdot 2^d + 8}$ . We proceed by assuming that  $G$  is of order at least  $2d + 2$  and claim that  $G$  contains a triangle. We prove this claim by contradiction: assume that  $G$  is triangle-free. As  $G$  is not bipartite, there is an odd cycle in  $G$ . Let  $x_1 x_2 \dots x_p x_1$  be a shortest one. As  $G$  is triangle-free and of diameter  $d$ , we find  $5 \leq p \leq 2d + 1$ , respectively. Moreover, as  $G$  is of order at least  $2d + 2$ , there is some vertex outside this cycle that has a neighbour on this cycle. Without loss of generality let us assume  $y$  with  $y \notin \{x_1, x_2, \dots, x_p\}$  is adjacent to  $x_1$ . As  $G$  is triangle-free,  $y$  does not have two consecutive neighbours on  $x_1 x_2 \dots x_p x_1$ . As  $G$  is chair-free and  $y$  is neither adjacent to  $x_2$  nor to  $x_p$ , we find that  $y$  must be adjacent to  $x_3$ . We repeat this argument and obtain that  $y$  is adjacent to  $x_{2q+1}$  for every  $0 \leq q \leq \lfloor \frac{p}{2} \rfloor$ . In particular  $y$  is adjacent to the two consecutive vertices  $x_1$  and  $x_p$ , a contradiction. We conclude that our assumption is false and that  $G$  contains a triangle.

We continue and show that we can compute a triangle, say  $T$ , of  $G$  in  $O(n + m)$  time. Let  $u$  be a vertex of  $G$ . We partition  $V(G)$  from  $\{u\}$  and note that breadth-first search computes a breadth-first tree  $F$ , that is,  $F$  is a spanning tree of  $G$  such that each vertex of  $N_i$  has distance  $i$  to  $u$  in  $F$  for any  $i$ . As  $G$  is not bipartite, there has to be an edge  $e$  and an integer  $i$  such that  $e$  is incident to two vertices of  $N_i$ . We can compute such an edge that additionally minimizes  $i$  in  $O(n + m)$  time. By adding this edge to  $F$ , we find an odd cycle  $C$  in  $G$ . As  $F$  is of diameter at most  $2d$ , we find that  $C$  has at most  $2d + 1$  vertices. Hence, we can determine in constant time a shortest induced odd cycle, say  $C'$ , in  $G[V(C)]$ . We check in constant time whether  $C'$  is a triangle. If not, then  $C'$  is of order at least 5. As

$G$  is of order at least  $2d + 2$ , there is a vertex outside  $C'$  that has a neighbour on  $C'$ . We compute such a vertex, say  $y$ , in  $O(n + m)$  time. As shown above,  $y$  has two consecutive neighbours on  $C'$ . As  $C'$  has at most  $2d + 1$  vertices, we can find such two vertices, and thus a triangle in  $G$ , in constant time.

Let  $\{x, y, z\}$  be the vertex set of the triangle  $T$ . We partition  $V(G)$  from  $V(T)$  in  $O(n + m)$  time. We additionally determine all private neighbours of the vertices of  $T$  and all vertices of  $N_1$  that are adjacent to all vertices of  $T$  in linear time. If there is a vertex of the latter type, then  $G$  is not 3-colourable. Thus, we focus on the case where each vertex of  $N_1$  is adjacent to at most two vertices of  $T$ . We compute in linear time the set  $N_1^*$  of all vertices of  $N_1$  that have two neighbours of  $T$ . Clearly,  $S = N_1 \setminus N_1^*$  consists of all private neighbours of the vertices of  $T$ , and its computation takes linear time. We proceed by considering  $G - N_1$ . We check in linear time if this graph has at most  $9 \cdot 2^d + 2$  vertices.

Let us consider the subcase where  $G - N_1$  has at least  $9 \cdot 2^d + 3$  vertices. We claim that  $G$  is not 3-colourable and prove this claim by contradiction: assume that  $G$  is 3-colourable. Hence,  $G$  is  $K_4$ -free. Recall that every vertex of  $N_1$  has at most two neighbours on  $T$ . Let  $i \geq 1$  and  $u$  be a vertex of  $N_i$ . As  $G$  is chair-free, the neighbours of  $u$  in  $N_{i+1}$  form a clique. As  $G$  is  $K_4$ -free, we obtain that  $u$  has at most 2 neighbours in  $N_{i+1}$ . It follows that

$$3 + 9 \cdot 2^d \leq |N_0| + |N_2| + |N_3| + \dots + |N_d| \leq 3 + |N_2| \cdot \sum_{i=2}^d 2^{i-2} < 3 + |N_2| \cdot 2^{d-1}.$$

Hence,  $|N_2| > 18$ . We let  $N_2^*$  be the neighbours of  $N_1^*$  in  $N_2$ . Consider the set  $N_{xy}$  of common neighbours of  $x$  and  $y$  in  $N_1^*$ . The set  $N_{xy}$  is an independent set as  $G$  is  $K_4$ -free. Every vertex  $u \in N_2^*$  with a neighbour  $v$  in  $N_{xy}$  must be adjacent to every vertex in  $N_{xy}$ , as  $G$  is chair-free. For the same reason, no vertex of  $N_1^*$  has two non-adjacent neighbours in  $N_2^*$ . As  $G$  is  $K_4$ -free, this means that there are at most two vertices in  $N_2^*$  that are adjacent to the vertices of  $N_{xy}$ . By applying the same reasoning for every other pair of vertices of  $T$ , we find that  $N_2^*$  has size at most 6. Thus,  $|N_2 \setminus N_2^*| > 12$ . As every vertex of  $N_1$  has at most two neighbours in  $N_2$ , it follows that  $|S| > 6$ . We consider the subcase where at least two vertices, say  $x$  and  $y$ , of  $T$  have a private neighbour. Assume that  $x$  has two non-adjacent private neighbours  $u$  and  $v$  in  $S$ . Then these three vertices, together with  $y$  and a private neighbour  $w \in S$  of  $y$  induce a chair unless  $w$  is adjacent to at least one of  $u$  and  $v$ . If  $w$  is adjacent to  $u$  but not to  $v$ , then  $\{u, v, w, x, z\}$  induces a chair. Hence,  $w$  is adjacent to both  $u$  and  $v$ , but then  $\{u, v, w, y, z\}$  induces a chair. Therefore, the private neighbours of every vertex of  $T$  form a clique. As  $G$  is 3-colourable, we find  $|S| \leq 6$  if at least two vertices of  $T$  have private neighbours. Thus, we obtain that all vertices of  $S$  are adjacent to a common vertex, say  $x$ , of  $T$ . As  $G$  is 3-colourable, we find that  $G[S]$  is bipartite. Therefore, we partition  $S$  into two independent sets  $A$  and  $B$  (one of these two sets might be empty). As  $G$  is chair-free and as  $A$  is independent, the vertices of  $A$  share the same set of neighbours in  $N_2$ . Similarly, the vertices of  $B$  share the same set of neighbours in  $N_2$ . As  $G$  is chair-free and  $K_4$ -free, the neighbourhood of every vertex of  $A \cup B$  is a clique of size at most 2. We conclude that the total number of vertices in  $N_2$  with a neighbour in  $S$  is at most 4, a contradiction as  $|N_2 \setminus N_2^*| > 12$ . We find that  $G$  is not 3-colourable and proceed by assuming that  $G - N_1$  has at most  $9 \cdot 2^d + 2$  vertices.

We consider every vertex labelling of  $G - N_1$  with labels 1, 2, 3 and determine in  $O(n + m)$  time which ones lead to a 3-colouring of  $G$ . We discard those labellings which are not a 3-colouring of  $G - N_1$ . Given a 3-colouring of  $G - N_1$ , each vertex of  $N_1^*$  receives the remaining available label that is not used for its neighbours of  $T$ . Note that this assignment takes linear time. We discard in  $O(n + m)$  time those labellings which do not lead to a

3-colouring of  $G - S$ . Let us take an arbitrary 3-colouring of  $G - S$ . We assign lists to the vertices of  $G$  as follows: we set  $L(u) = \{i\}$ , where  $i$  is the label of  $u$ , if  $u \notin S$  and we set  $L(u) = \{1, 2, 3\} \setminus \{i\}$ , where  $i$  is the label of the unique neighbour of  $u$  on  $T$ , if  $u \in S$ . Thus, checking whether a given 3-colouring of  $G - S$  leads to a 3-colouring of  $G$  takes  $O(n+m)$  time as  $(G, L)$  is an instance of 2-LIST COLOURING (cf. Lemma 9). We discard those 3-colouring of  $G - S$  which do not lead to a 3-colouring of  $G$ . If no 3-colouring of  $G - S$  lead to a 3-colouring of  $G$ , then  $G$  is not 3-colourable. Hence, we proceed by assuming that at least one does, and so we find that  $G$  is 3-colourable. As there are at most  $3^{9 \cdot 2^d + 2}$  vertex labellings of  $G - N_1$ , we can determine all 3-colourings of  $G - S$  that can be extended to 3-colourings of  $G$  in  $O(n+m)$  time, and there are at most  $3^{9 \cdot 2^d + 2}$  such colourings of  $G - S$ .

If  $S = \emptyset$ , then  $G - S$  equals  $G$ . We consider the subcase where at least two vertices of  $T$  have a private neighbour. As shown above, the private neighbours of every vertex of  $T$  form a clique. If  $|S| > 6$ , which we check in constant time, then  $G$  is not 3-colourable. Otherwise, as we have at most  $3^{9 \cdot 2^d + 2}$  3-colourings of  $G - S$ , we find at most  $3^{9 \cdot 2^d + 8}$  3-colourings of  $G$  and their computation takes  $O(n+m)$  time. We finally consider the subcase where all vertices of  $S$  are adjacent to a single vertex, say  $x$ , of  $T$ . We conclude that  $S = P(x)$ , which completes our proof.  $\blacktriangleleft$

We are now in a position to prove our main result of this section.

**► Theorem 11.** *If  $d \geq 1$ , then 3-COLOURING, ACYCLIC 3-COLOURING, STAR 3-COLOURING, INDEPENDENT ODD CYCLE TRANSVERSAL, INDEPENDENT FEEDBACK VERTEX SET, and NEAR-BIPARTITENESS can be solved in  $O(n+m)$  time for chair-free graphs of diameter at most  $d$ .*

**Proof.** Let  $G$  be a chair-free graph of diameter at most  $d$  with  $n$  vertices and  $m$  edges. Note that  $G$  is acyclic 3-colourable or star 3-colourable only if  $G$  is 3-colourable. Moreover, if  $I$  is an independent set of  $G$  for which  $G - I$  is a bipartite graph, then  $G$  is 3-colourable. Hence, our problems require all the yes-instances to be 3-colourable. If  $d = 1$ , then  $G$  is 3-colourable if and only if  $G$  has at most 3 vertices, and so each of our problems can be solved in constant time. We proceed by assuming  $d \geq 2$  and check in  $O(n+m)$  time whether  $G$  is bipartite.

**Case 1.**  $G$  is bipartite.

Note that  $G$  is 3-colourable, near-bipartite, and has an independent odd cycle transversal of size at most  $k$  for any integer  $k$ . We can determine the parts, say  $S_1$  and  $S_2$ , of  $G$  in  $O(n+m)$  time. We may assume without loss of generality that  $|S_1| \geq |S_2|$ . We check in constant time whether  $|S_1| + |S_2| \leq \max\{8, 2d\}$  and if so, then we can solve each of our problems in constant time. Otherwise, we find that  $|S_1| \geq 5$ . As bipartite graphs of maximum degree at most 2 and diameter at most  $d$  are paths or cycles of at most  $2d$  vertices, we find that  $G$  has a vertex of degree at least 3, and so  $G$  is a complex by Theorem 5.

We first claim that in the case where  $G$  is a complex with  $|S_1| \geq 5$ ,  $G$  is star 3-colourable if  $|S_2| \leq 2$  and acyclic 3-colourable only if  $|S_2| \leq 2$ . Note that this claim completes the bipartite case for ACYCLIC 3-COLOURING and STAR 3-COLOURING as we can decide whether  $|S_2| \leq 2$  or not in constant time and as every star 3-colouring of a graph is acyclic. We prove our claim as follows: If  $|S_2| \leq 2$ , then, for any  $s \in S_2$ ,  $G - s$  is a forest each component of which is of diameter at most 2, and thus  $G$  is star 3-colourable with colour classes  $S_1, S_2 \setminus \{s\}$ , and  $\{s\}$ . If  $|S_2| \geq 3$ , then let  $c$  be an arbitrary 3-colouring of  $G$ . By the pigeonhole principle there exists a colour class  $X$  of  $c$  that contains at least two vertices of  $S_1$ , and so  $X \cap S_2 = \emptyset$ . As  $|S_2| \geq 3$ , there are two vertices  $s_2, s'_2 \in S_2$  that are coloured alike. As  $|S_1| \geq 5$ , and as  $s_2$  and  $s'_2$  are of degree at least  $|S_1| - 1$ , we find that  $s_2$  and  $s'_2$  have at least three common

neighbours in  $S_1$  two of which, say  $s_1$  and  $s'_1$ , are coloured alike. Hence,  $s_1 s_2 s'_1 s'_2 s_1$  is a bichromatic 4-cycle. We conclude that every 3-colouring of  $G$  is not acyclic, which completes the proof of our claim.

It remains to consider INDEPENDENT FEEDBACK VERTEX SET for complexes with at least 9 vertices. Let  $k$  be an arbitrary integer. We claim that in the case where  $G$  is a complex with  $|S_1| \geq 5$ ,  $G$  has an independent feedback vertex set of size at most  $k$  if and only if  $k \geq |S_2| - 1$ . Note that the latter can be decided in linear time. We prove our claim as follows: If  $|S_2| \leq 2$ , then  $G - s$  is a forest for any  $s \in S_2$  and  $G$  has an independent feedback vertex set of size at most  $k$ . Hence, we may assume  $|S_2| \geq 3$ . Let  $I$  be a minimum independent feedback vertex set in  $G$ . Such a set exists as  $G$  is bipartite. As  $S_2 \setminus \{s\}$  is independent and as  $G[S_1 \cup \{s\}]$  is a forest for each vertex  $s \in S_2$ , we find  $|I| \leq |S_2| - 1$ . For the sake of a contradiction, let us assume  $|I| \leq |S_2| - 2$ . Hence, any two vertices of  $S_2 \setminus I$  have at least  $|S_1| - 2$  common neighbours in  $S_1$ , and so  $|I \cap S_1| \geq |S_1| - 3 \geq 2$ . Moreover,  $I = I \cap S_1$  as every vertex of  $S_2$  has a neighbour in  $I \cap S_1$  and as  $I$  is independent. As  $I$  is an independent feedback vertex set with  $|I| \leq |S_1| - 2$ , any two vertices of  $S_1 \setminus I$  do not have two common neighbours in  $S_2$  and so  $|S_2| \leq 3$ . Hence,  $5 \leq |S_1| \leq |I| + 3 \leq |S_2| + 1 \leq 4$ , a contradiction. As  $|I| = |S_2| - 1$ , the proof of our claim is complete.

**Case 2.**  $G$  is not bipartite.

*Outline.* As our problems require all the yes-instances to be 3-colourable, we check first whether  $G$  is 3-colourable. If so, then we compute an induced subgraph  $H$  of  $G$  and determine the set  $\mathcal{C}$  of all its 3-colourings that can be extended to 3-colourings of  $G$ . As we compute  $H$  by applying Theorem 10, we find that  $|\mathcal{C}| \leq 3^{9 \cdot 2^d + 8}$ . We then distinguish some subcases. In some of them we further branch by extending our 3-colourings. However, in some of them we find that  $H$  equals  $G$ , and so Observations 7 and 8 imply that our six problems are solvable in  $O(n + m)$  time as  $\mathcal{C}$  is of constant size. As an implicit step, we apply this finding whenever  $H$  is the whole graph  $G$ .

*Full Proof.* We first apply Theorem 10. We continue by assuming that  $G$  is 3-colourable. In fact, the only remaining case is that where the lemma provides a triangle  $T$  on vertex set  $\{x, y, z\}$ , a vertex  $x$  of  $T$  that has private neighbours, and the set of all 3-colourings of  $G - P(x)$  that can be extended to 3-colourings of  $G$ . Note that we have at most  $3^{9 \cdot 2^d + 8}$  such 3-colourings. We partition  $V(G)$  from  $V(T)$ .

We find that  $G[P(x)]$  is bipartite, as  $G$  is 3-colourable, but not necessarily connected. We extend each 3-colouring of  $G - P(x)$  that can be extended to a 3-colouring of  $G$  to some vertices of  $P(x)$ . Let  $c$  be an arbitrary 3-colouring of  $G - P(x)$  that can be extended to a 3-colouring of  $G$ . For  $i \in \{0, 1, 2\}$ , we compute in  $O(n + m)$  time the set  $S_i$  of all vertices of  $P(x)$  which have  $i$  available colours with respect to  $c$ , that is,  $S_i$  is the set of all vertices of  $P(x)$  which have neighbours in  $3 - i$  colours. As  $c$  can be extended to a 3-colouring of  $G$ , we find that  $S_0$  is empty. It takes  $O(n + m)$  time to determine the available colour of each vertex in  $S_1$ . Furthermore, we can extend  $c$  by breadth-first search in the same time to the vertices of those components of  $G[P(x)]$  that contain at least one vertex of  $S_1$ .

Let  $S_c$  be the set of vertices that induce those components of  $G[P(x)]$  that do not contain a vertex of  $S_1$ . Note that  $S_c$  can be computed in  $O(n + m)$  time and that all neighbours of all vertices of  $S_c$  in  $V(G) \setminus S_c$  are coloured alike. Moreover, every vertex of  $S_c$  has its neighbours in  $[N(y) \cap N(z)] \cup N_2 \cup S_c \cup \{x\}$  by definition. As  $c$  can be extended to a 3-colouring of  $G$ , we find that our approach leads to a 3-colouring, say  $c'$ , of  $G - S_c$ . As there are at most  $3^{9 \cdot 2^6 + 2}$  3-colourings of  $G - P(x)$ , we find at most  $3^{9 \cdot 2^6 + 2}$  such triples  $(c, c', S_c)$ . Furthermore, for each 3-colouring  $c_s$  of  $G - P(x)$ , there exists a triple  $(c_s, c'_s, S_{c_s})$  if  $c_s$  can

be extended to a 3-colouring of  $G$ . We proceed by considering the case where  $S_c \neq \emptyset$  as otherwise  $G = G - S_c$ . We continue by distinguishing on the problems we are considering. Recall that  $G$  is 3-colourable.

**Subcase 2.1.** ACYCLIC 3-COLOURING and STAR 3-COLOURING

We check whether for some triple  $(c, c', S_c)$ , the 3-colouring  $c'$  of  $G - S_c$  that can be extended to an acyclic 3-colouring or star 3-colouring of  $G$ . By this approach, we clearly solve ACYCLIC 3-COLOURING and STAR 3-COLOURING.

Let  $(c, c', S_c)$  be an arbitrary triple as defined above. Recall that a star 3-colouring of a graph is acyclic. In time  $O(n + m)$ , we can determine the components of  $G[S_c]$  and check whether  $G[S_c]$  is a forest. If not, then  $G[S_c \cup \{x\}]$ , and thus  $G$ , is not acyclic 3-colourable. We continue and assume that  $G[S_c]$  is a forest. We check in  $O(n + m)$  time if a vertex of  $S_c$  has a neighbour in  $N(y) \cap N(z)$ . If so, say  $s \in S_c$  is adjacent to  $v \in N(y) \cap N(z)$ , then  $c'$  cannot be extended to an acyclic 3-colouring of  $c$  as either  $s$  and  $x$  are coloured alike or one of  $\{svyxs, svzxs\}$  is a bichromatic 4-cycle. We proceed by assuming that  $S_c$  has its neighbours in  $N_2 \cup S_c \cup \{x\}$ . As  $G$  is chair-free, every two non-adjacent vertices of  $S_c$  share the same neighbours in  $N_2$  and, if there exists such a neighbour, then these two vertices have to be coloured differently to avoid a bichromatic 4-cycle. Therefore, in any acyclic extension of  $c'$  to  $G$ , each of the two colour classes in  $S_c$  either has size at most 1 or has no neighbour in  $N_2$ . We check in constant time if  $S_c$  is of size at most 2. If so, then there are at most 4 possibilities to extend  $c'$  to a 3-colouring of  $G$  and for each we apply Observation 7. Hence, we may assume  $|S_c| \geq 3$ . We check in  $O(n + m)$  time if a vertex of  $S_c$  has a neighbour in  $N_2$ .

Let us consider the subcase where  $s \in S_c$  has a neighbour, say  $v$ , in  $N_2$ . Let  $G_s$  be the component of  $G[P(x)]$  that contains  $s$ . Note that there are at most two possibilities to extend  $c'$  to the vertices of  $G_s$ . We check in linear time if  $S_c \setminus V(G_s)$  is of size at least 2. If so, say  $s_1, s_2 \in S_c \setminus V(G_s)$ , then  $v$  is a neighbour of  $s, s_1$ , and  $s_2$ . Thus,  $xs'_1vs'_2x$  is a bichromatic 4-cycle for two vertices  $s'_1$  and  $s'_2$  of  $\{s, s_1, s_2\}$ . We conclude that  $c'$  cannot be extended to an acyclic 3-colouring of  $G$ . Hence, we may assume  $|S_c \setminus V(G_s)| \leq 1$ , and so there are at most four possibilities to extend  $c'$  to a 3-colouring of  $G$  each of which can be obtained in  $O(n + m)$  time. We apply Observation 7 for each. We proceed by assuming that no vertex of  $S_c$  has a neighbour in  $N_2$ . In other words, each vertex of  $S_c$  has its neighbours in  $S_c \cup \{x\}$ .

As  $x$  is a cut-vertex of  $G$ , any extension of  $c'$  to a 3-colouring of  $G$  is acyclic if and only if  $c'$  is acyclic. Hence, we apply Observation 7 on  $G - S_c$  and  $c'$  in order to solve ACYCLIC 3-COLOURING.

We now check in  $O(n + m)$  time if each component of  $G[S_c]$  is of diameter at most 2. If not, then  $G[S_c \cup \{x\}]$ , and thus  $G$  is not star 3-colourable. Let us proceed by assuming that each component of  $G[S_c]$  is of diameter at most 2. We find that every 3-colouring of  $G[S_c \cup \{x\}]$  is a star 3-colouring. In other words, we can restrict ourselves to those 3-colouring extensions of  $c'$  to  $G$  that assign one colour to all vertices of  $S_c$  if  $S_c$  is independent, and an arbitrary 3-colouring extensions of  $c'$  to  $G$  if  $S_c$  is not independent. Note that we can check in  $O(n + m)$  time whether  $S_c$  is independent. We find in both subcases at most two extensions of  $c'$  to  $G$  and apply Observation 7 for each in order to solve STAR 3-COLOURING.

**Subcase 2.2.** INDEPENDENT ODD CYCLE TRANSVERSAL

Let  $k$  be an arbitrary integer. We check whether some triple  $(c, c', S_c)$  consists of a 3-colouring  $c'$  of  $G - S_c$  that can be extended to a 3-colouring of  $G$  whose one colour class is an independent odd cycle transversal of size at most  $k$ . As all the yes-instances require  $G$  to be 3-colourable, this approach clearly solves INDEPENDENT ODD CYCLE TRANSVERSAL.

## 21:12 Partitioning $H$ -Free Graphs of Bounded Diameter

Let  $(c, c', S_c)$  be an arbitrary triple as defined above. Moreover, let  $X, Y, Z$  be the colour classes of  $c'$  with  $x \in X$ ,  $y \in Y$ , and  $z \in Z$ . Clearly,  $X, Y$ , and  $Z$  can be computed in linear time. We decide in linear time which of  $\{Y, Z\}$  is of smaller size, say  $|Y| \leq |Z|$ . Recall that all vertices of  $S_c$  have their neighbours in  $S_c \cup X$ . Note that  $c'$  can be extended to a 3-colouring of  $G$  by 2-colourings of  $G[S_c]$  on the colours that  $c'$  assigns to  $y$  and  $z$ , and these are the only possibilities. We find that the smallest possible colour class of a 3-colouring of  $G$  that extends  $c'$  consists of the vertices either in  $X$  or in  $Y \cup W$ , where  $W$  is the smallest possible colour class of a 2-colouring of  $G[S_c]$ . As we can compute the components of  $G[S_c]$  and its parts in  $O(n + m)$  time, we find  $W$  in the same time. Hence, the smallest possible independent odd cycle transversal of  $G$  that is a colour class of an extension of  $c'$  to a 3-colouring of  $G$  is of size  $\min\{|X|, |Y \cup W|\}$ . We can compare the sizes of  $X$  and  $Y \cup W$  with  $k$  in linear time.

### Subcase 2.3. INDEPENDENT FEEDBACK VERTEX SET and NEAR-BIPARTITENESS

Let  $k$  be an arbitrary integer. We check whether some triple  $(c, c', S_c)$  consists of a 3-colouring  $c'$  of  $G - S_c$  that can be extended to a 3-colouring of  $G$  whose one colour class is an independent feedback vertex set (of size at most  $k$ ). As all the yes-instances require  $G$  to be 3-colourable, this approach clearly solves INDEPENDENT FEEDBACK VERTEX SET and NEAR-BIPARTITENESS.

Let  $(c, c', S_c)$  be an arbitrary triple as defined above. Moreover, let  $X, Y, Z$  be the colour classes of  $c'$  with  $x \in X$ ,  $y \in Y$ , and  $z \in Z$ . Clearly,  $X, Y$ , and  $Z$  can be computed in linear time. We check first whether  $G - X$  is a forest in  $O(n + m)$  time. If so, then we find that  $X$  is an independent feedback vertex set of  $G$  and we can determine its size in linear time. Hence, we proceed by assuming that  $G - X$  contains a cycle or  $|X| > k$ . As we aim to find an extension of  $c'$  to a 3-colouring of  $G$  whose one colour class is an independent feedback vertex set (of size at most  $k$ ), we find that such a set consists of the vertices of  $Y$  or of  $Z$ , and the vertices of some set  $A \subseteq S_c$ . Recall that all vertices of  $S_c$  have their neighbours in  $[N(y) \cap N(z)] \cup N_2 \cup S_c \cup \{x\}$  and their neighbours in  $[N(y) \cap N(z)] \cup N_2 \cup \{x\}$  form an independent set. Note that  $c'$  can be extended to a 3-colouring of  $G$  by 2-colourings of  $G[S_c]$  on the colours that  $c'$  assigns to  $y$  and  $z$ , and these are the only possibilities. If  $G[S_c]$  is connected, which can be tested in  $O(n + m)$  time, then there are at most two such possibilities, and so we apply Observation 8 for each. We proceed by assuming that  $G[S_c]$  is disconnected, and so  $|S_c| \geq 2$ .

We claim that all vertices of  $S_c$  have the same neighbours in  $N_2$ . Let us assume that  $v$  is an arbitrary vertex of  $N_2$  that is adjacent to some vertex of  $S_c$ . Let  $S_v$  be the set of neighbours of  $v$  in  $S_c$ . By definition, we find that  $S_v$  is non-empty. As  $G$  is chair-free, we obtain that every vertex of  $S_v$  is adjacent to every vertex of  $S_c \setminus S_v$  as otherwise  $\{s_1, s_2, v, x, y\}$  would induce a chair for some possible vertices  $s_1 \in S_v$  and  $s_2 \in S_c \setminus S_v$ . As  $G[S_c]$  is disconnected, we find that  $S_c \setminus S_v = \emptyset$ , which completes the proof of our claim as  $v$  is arbitrarily chosen.

We can check if there is a vertex in  $N(y) \cap N(z)$  in  $O(n + m)$  time. First assume there is such a vertex, say  $w$ . As  $\{s_1, s_2, w, x, y\}$  does not induce a chair for each two vertices  $s_1, s_2$  of an independent set  $I$  of  $G[S_c]$ , we find that  $w$  is adjacent to all but at most one vertex of  $I$ . As  $G[S_c]$  is bipartite, it follows that  $w$  has at least  $|S_c| - 2$  neighbours in  $S_c$ . For each  $s \in N(w) \cap S_c$ , we find  $s \in A$  as  $sxyws$  and  $szxws$  are 4-cycles. Note that  $N(w) \cap S_c$  can be computed in  $O(n + m)$  time. As  $|N(w) \cap S_c| \geq |S_c| - 2$ , we find at most eight possibilities to extend  $c'$  to a 3-colouring of  $G$  by a 2-colouring of  $G[S_c]$  in which one colour class contains all the vertices of  $N(w) \cap S_c$ . We apply Observation 8 for each. Hence, we may assume that  $N(y) \cap N(z) = \emptyset$ , and so every two vertices of  $S_c$  share the same neighbours in  $V(G) \setminus S_c$ .

If no vertex of  $N_2$  has a neighbour in  $S_c$ , then  $x$  is a cut-vertex. In this case we find that  $G$  has an independent feedback vertex set of size at most  $k$  if and only if  $G - S_c$  has an independent feedback vertex set (of size at most  $k - |W|$ , where  $W$  is the smallest possible colour class of a 2-colouring of  $G[S_c]$ ). As  $W$  can be computed in  $O(n + m)$  time, we apply Observation 8 for  $G - S_c$  and  $c'$ .

We proceed by considering the situation where  $v \in N_2$  has a neighbour in  $S_c$ . Recall that all vertices of  $S_c$  are adjacent to  $v$ . As  $xs_1vs_2x$  is a 4-cycle for any two vertices  $s_1, s_2 \in S_c$ , we find that  $A$  has size at least  $|S_c| - 1$ . In other words, we aim for such a 2-colouring of  $G[S_c]$  whose one colour class is of size at most 1. If  $S_c$  is not independent, we have at most two such possibilities, and each leads to a 3-colouring of  $G$ . We apply Observation 8 for each. Now suppose that  $S_c$  is independent. We find that any two vertices of  $S_c$  have the same neighbours in  $G$ . Let us fix one vertex, say,  $s$  of  $S_c$ . As there is at most one vertex of  $S_c$  that is not in the independent feedback vertex set, we may assume that  $s$  is that vertex. We have four ways of colouring the vertices of  $S_c$  such that all vertices of  $S_c \setminus \{s\}$  receive the same colour. It remains to apply Observation 8 for each case. ◀

#### 4 A Final Result and Some Open Problems

We showed that bounding the diameter does not help for INDEPENDENT SET for  $H$ -free graphs. We proved that this does help for some problems related to 3-COLOURING if  $H$  is the chair. Whether these results can be extended to larger polyads  $H$  is an interesting but challenging task. For three of these problems, however, we should not seek to extend the theorems from the previous section to omission of arbitrary polyads: in our next result, we give a polyad  $H$  such that these problems are NP-complete for  $H$ -free graphs of diameter  $d$  for some constant  $d$ . We reduce from NOT-ALL-EQUAL 3-SAT, which is well-known to be NP-complete [29]. We omit the proof details.

► **Theorem 12.** *For STAR 3-COLOURING, INDEPENDENT ODD CYCLE TRANSVERSAL and ACYCLIC 3-COLOURING, there exists a polyad  $H$  and integer  $d$  so that the problem remains NP-complete on  $H$ -free graphs of diameter  $d$ .*

Finally, we ask if there exists a polyad  $H$  and an integer  $d$  such that NEAR-BIPARTITENESS and INDEPENDENT FEEDBACK VERTEX SET are NP-complete for  $H$ -free graphs of diameter at most  $d$ . Such a polyad  $H$  was already known to exist for 3-COLOURING of graphs of diameter at most 4 [20].

## Abstract

---

Let  $F$  be a set of  $n$  objects in the plane and let  $\mathcal{G}^\times(F)$  be its intersection graph. A balanced clique-based separator of  $\mathcal{G}^\times(F)$  is a set  $\mathcal{S}$  consisting of cliques whose removal partitions  $\mathcal{G}^\times(F)$  into components of size at most  $\delta n$ , for some fixed constant  $\delta < 1$ . The weight of a clique-based separator is defined as  $\sum_{C \in \mathcal{S}} \log(|C| + 1)$ . Recently De Berg et al. (SICOMP 2020) proved that if  $S$  consists of convex fat objects, then  $\mathcal{G}^\times(F)$  admits a balanced clique-based separator of weight  $O(\sqrt{n})$ . We extend this result in several directions, obtaining the following results.

- Map graphs admit a balanced clique-based separator of weight  $O(\sqrt{n})$ , which is tight in the worst case.
- Intersection graphs of pseudo-disks admit a balanced clique-based separator of weight  $O(n^{2/3} \log n)$ . If the pseudo-disks are polygonal and of total complexity  $O(n)$  then the weight of the separator improves to  $O(\sqrt{n} \log n)$ .
- Intersection graphs of geodesic disks inside a simple polygon admit a balanced clique-based separator of weight  $O(n^{2/3} \log n)$ .
- Visibility-restricted unit-disk graphs in a polygonal domain with  $r$  reflex vertices admit a balanced clique-based separator of weight  $O(\sqrt{n} + r \log(n/r))$ , which is tight in the worst case.

These results immediately imply sub-exponential algorithms for MAXIMUM INDEPENDENT SET (and, hence, VERTEX COVER), for FEEDBACK VERTEX SET, and for  $q$ -COLORING for constant  $q$  in these graph classes.

## 1 Introduction

The famous Planar Separator Theorem states that any planar graph  $\mathcal{G} = (V, E)$  with  $n$  nodes<sup>2</sup> admits a subset  $\mathcal{S} \subset V$  of size  $O(\sqrt{n})$  nodes whose removal decomposes  $\mathcal{G}$  into connected components of size at most  $2n/3$ . The subset  $\mathcal{S}$  is called a balanced<sup>3</sup> *separator* of  $\mathcal{G}$ . The theorem was first proved in 1979 by Lipton and Tarjan [19], and it has been instrumental in the design of algorithms for planar graphs: it has been used to design efficient divide-and-conquer algorithms, to design sub-exponential algorithms for various NP-hard graph problems, and to design approximation algorithms for such problems.

The Planar Separator Theorem has been extended to various other graph classes. Our interest lies in *geometric intersection graphs*, where the nodes correspond to geometric objects and there is an arc between two nodes iff the corresponding objects intersect. If the objects are disks, the resulting graph is called a *disk graph*. Disk graphs, and in particular unit-disk graphs, are a popular model for wireless communication networks and have been studied extensively. Miller et al. [22] and Smith and Wormald [27] showed that if  $F$  is a set of balls in  $\mathbb{R}^d$  of ply at most  $k$  – the *ply* of  $F$  is the maximum number of objects in  $F$  with a common intersection – then the intersection graph of  $F$  has a separator of size  $O(k^{1/d}n^{1-1/d})$ . This was generalized by Chan [4] and Har-Peled and Quanrud [14] to intersection graphs of so-called low-density sets. Separators for string graphs – a string graph is an intersection graph of sets of curves in the plane – have also been considered [13, 18, 21], with Lee [18] showing that a separator of size  $O(\sqrt{m})$  exists, where  $m$  is the number of arcs of the graph.

Even for simple objects such as disks or squares, one must restrict the ply to obtain a separator of small size. Otherwise the objects can form a single clique, which obviously does not have a separator of sublinear size. To design subexponential algorithms for problems such as MAXIMUM INDEPENDENT SET, however, one can also work with a separator consisting of a small number of cliques instead of a small number of nodes. Such *clique-based separators* were introduced recently by De Berg et al. [8]. Formally, a clique-based separator of a graph  $\mathcal{G}$  is a collection  $\mathcal{S}$  of node-disjoint cliques whose union is a balanced separator of  $\mathcal{G}$ . The *weight* of  $\mathcal{S}$  is defined as  $\text{weight}(\mathcal{S}) := \sum_{C \in \mathcal{S}} \log(|C| + 1)$ . De Berg et al. [8] proved that the intersection graph of any set  $F$  of  $n$  convex fat objects in the plane admits a clique-based separator of weight  $O(\sqrt{n})$ , and they used this to obtain algorithms with running time  $2^{O(\sqrt{n})}$  for many classic NP-hard problems on such graphs. This running time is optimal, assuming the Exponential-Time Hypothesis (ETH). The result generalizes to convex fat objects in  $\mathbb{R}^d$ , where the bound on the weight of the clique-based separator becomes  $O(n^{1-1/d})$ .

The goal of our paper is to investigate whether similar results are possible for non-fat objects in the plane. Note that not all intersection graphs admit clique-based separators of small weight. String graphs, for instance, can have arbitrarily large complete bipartite graphs as induced subgraphs, in which case any balanced clique-based separator has weight  $\Omega(n)$ .

The first type of intersection graphs we consider are map graphs, which are a natural generalization of planar graphs. The other types are generalizations of disk graphs. One way to generalize disk graphs is to consider fat objects instead of disks, as done by De Berg et al. [8]. We will study three other generalizations, involving non-fat objects: pseudo-disks, geodesic disks, and visibility-restricted unit disks. Next we define the graph classes we consider more precisely; see Fig. 1 for an example of each graph class.

<sup>2</sup> We use the terms *node* and *arc* when talking about graphs, and *vertex* and *edge* for geometric objects.

<sup>3</sup> For a separator to be balanced it suffices that the components have size at most  $\delta n$  for some constant  $\delta < 1$ . When we speak of separators, we always mean balanced separators, unless stated otherwise.

■ **Figure 1** A map graph, a pseudo-disk graph, a geodesic-disk graph, and a visibility restricted unit-disk graph. For the latter class, the grey disks in the picture have radius  $\frac{1}{2}$ .

In the following, we use  $\mathcal{G}^\times(F)$  to denote the intersection graph induced by a set  $F$  of objects. For convenience, we do not distinguish between the objects and the corresponding nodes, so we use  $F$  to denote the set of objects as well as the set of nodes in  $\mathcal{G}^\times(F)$ . We assume that the objects in  $F$  are connected, bounded, and closed.

**Map graphs.** Let  $\mathcal{M}$  be a planar subdivision and  $F$  be its set of faces. The graph with node set  $F$  that has an arc between every pair of neighboring faces is called the *dual graph* of  $\mathcal{M}$ , and it is planar. Here two faces are neighbors if their boundaries have an edge of the subdivision in common. A *map graph* [6] is defined similarly, except now two faces are neighbors even if their boundaries meet in a single point. Alternatively, we can define a map graph as the intersection graph of a set  $F$  of interior-disjoint regions in the plane. Since arbitrarily many faces can share a vertex on their boundary, map graphs can contain arbitrarily large cliques. If at most  $k$  faces meet at each subdivision vertex, the graph is called a *k-map graph*. Chen [5] proved that any  $k$ -map graph has a (normal, not clique-based) separator of size  $O(\sqrt{kn})$ , which is also implied by Lee’s recent result on string graphs [18].

**Pseudo-disk graphs.** A set  $F$  of objects is a set of pseudo-disks if for any  $f, f' \in F$  the boundaries  $\partial f$  and  $\partial f'$  intersect at most twice. Pseudo-disks were introduced in the context of motion planning by Kedem et al. [15], who proved that the union complexity of  $n$  pseudo-disks is  $O(n)$ . Since then they have been studied extensively. We consider two types of pseudo-disks: polygonal pseudo-disks with  $O(n)$  vertices in total, and arbitrary pseudo-disks.

**Geodesic-disk graphs and visibility-restricted unit-disk graphs.** As mentioned, unit-disk graphs are popular models for wireless communication networks. We consider two natural generalizations of unit-disk graphs, which can be thought of as communication networks in a polygonal environment that may obstruct communication.

- *Geodesic-disk graphs* in a simple polygon  $P$  are intersection graphs of geodesic disks inside  $P$ . (The *geodesic disk* with center  $q \in P$  and radius  $r$  is the set of all points in  $P$  at geodesic distance at most  $r$  from  $q$ , where the geodesic distance between two points is the length of the shortest path between them inside  $P$ .)

- In *visibility-restricted unit-disk graphs* the nodes correspond to a set  $Q$  of  $n$  points inside a polygon  $P$ , which may have holes, and two points  $p, q \in Q$  are connected by an arc iff  $|pq| \leq 1$  and  $p$  and  $q$  see each other (meaning that  $pq \subset P$ ).<sup>4</sup> A more general, directed version of such graphs was studied by Ben-Moshe et al. [2] under the name range-restricted visibility graph. They presented an output-sensitive algorithm to compute the graph.

### Our results: clique-based separator theorems

So far, clique-based separators were studied for fat objects: De Berg et al. [8] consider convex or similarly-sized fat objects, Kisfaludi-Bak et al. [17] study how the fatness of axis-aligned fat boxes impacts the separator weight, and Kisfaludi-Bak [16] studies balls in hyperbolic space. The  $O(\sqrt{n})$  bound on the separator weight is tight even for unit-disk graphs. Indeed, a  $\sqrt{n} \times \sqrt{n}$  grid graph can be realized as a unit-disk graph, and any separator of such a grid graph must contain  $\Omega(\sqrt{n})$  nodes. Since the maximum clique size in a grid graph is two, any separator must contain  $\Omega(\sqrt{n})$  cliques. All graph classes we consider can realize a  $\sqrt{n} \times \sqrt{n}$  grid graph, so  $\Omega(\sqrt{n})$  is a lower bound on the weight of the clique-based separators we consider. We obtain the following results.

In Section 2 we show that any map graph has a clique-based separator of weight  $O(\sqrt{n})$ . This gives the first ETH-tight algorithms for MAXIMUM INDEPENDENT SET (and, hence, VERTEX COVER), FEEDBACK VERTEX SET, and COLORING in map graphs; see below.

In Section 3 we show that any intersection graph of pseudo-disks has a clique-based separator of weight  $O(n^{2/3} \log n)$ . If the pseudo-disks are polygonal and of total complexity  $O(n)$  then the weight of the separator improves to  $O(\sqrt{n} \log n)$ .

In Section 4 we consider intersection graphs of geodesic disks inside a simple polygon. At first sight, geodesic disks seem not much harder to deal with than fat objects: they can have skinny parts only in narrow corridors and then packing arguments may still be feasible. Unfortunately another obstacle prevents us from applying a packing argument: geodesic distances in a simply connected polygon induce a metric space whose doubling dimension depends on the number of reflex vertices of the polygon. Nevertheless, by showing that geodesic disks inside a simple polygon behave as pseudo-disks, we are able to obtain a clique-based separator of weight  $O(n^{2/3} \log n)$ , independent of the number of reflex vertices.

In Section 5 we study visibility-restricted unit-disk graphs. We give an  $\Omega(\min(n, r \log(n/r)) + \sqrt{n})$  lower bound for the separator weight, showing that a clique-based separator whose weight depends only on  $n$ , the number of points defining the visibility graph, is not possible. We then show how to construct a clique-based separator of weight  $O(\min(n, r \log(n/r)) + \sqrt{n})$ .

All separators can be computed in polynomial time. For map graphs and for the pseudo-disk intersection graphs, we assume the objects have total complexity  $O(n)$ . If the objects have curved edges, we assume that basic operations (such as computing the intersection points of two such curves) take  $O(1)$  time.

### Applications

We apply our separator theorems to obtain subexponential algorithms in the graph classes discussed above, for MAXIMUM INDEPENDENT SET, FEEDBACK VERTEX SET, and  $q$ -COLORING for constant  $q$ . The crucial property of these problems that makes our separator

<sup>4</sup> Visibility-restricted unit-disk graphs are, strictly speaking, not intersection graphs. In particular, if  $R_q$  is defined as the region of points within  $P$  that are visible from  $q$  and lie within distance  $1/2$ , then the visibility-restricted unit-disk graph is *not* the same as the intersection graph of the objects  $R_q$ .

■ **Figure 2** (i) A witness graph for the map graph induced by the grey regions. Points in  $P$  are blue, points in  $Q$  are red. (ii) The gadget used to replace a witness point. The edges of  $\mathcal{T}_q$  are black, the cycles connecting nodes at the same level are grey and thick, the edges to triangulate the 4-cycle are grey and thin. (iii) The green paths show an example of how the separator can intersect a gadget. (Note that the tree “wraps around”, as in part (ii) of the figure; see also one of the green paths.) The objects added to the clique  $C_q$  correspond to the leaves indicated by the blue rectangles.

applicable, is that the possible ways in which a solution can “interact” with a clique of size  $k$  is polynomial in  $k$ . We use known techniques (mostly from De Berg et al. [8]) to solve the three problems on any graph class that has small clique-based separators.

All our graph classes are subsumed by string graphs. Bonnet and Rzazewski [3] showed that string graphs have  $2^{O(n^{2/3} \log n)}$  algorithms for MAXIMUM INDEPENDENT SET and 3-COLORING, and a  $2^{n^{2/3} \log^{O(1)} n}$  algorithm for FEEDBACK VERTEX SET, and that string graphs do not have subexponential algorithms for  $q$ -COLORING with  $q \geq 4$  under ETH. One can also obtain subexponential algorithms in some of our classes from results of Fomin et al. [12, 5] or Marx and Philipczuk [20]. The running times we obtain match or slightly improve the results that can be obtained from these existing results. It should be kept in mind, however, that the existing results are for more general graph classes. An exception are our results on map graphs, which were explicitly studied before and where we improve the running time for MAXIMUM INDEPENDENT SET and FEEDBACK VERTEX SET from  $2^{O(\sqrt{n} \log n)}$  to  $2^{O(\sqrt{n})}$ . (But, admittedly, the existing results apply in the parameterized setting while ours don’t.) In any case, the main advantage of our approach is that it allows us to solve MAXIMUM INDEPENDENT SET, FEEDBACK VERTEX SET and  $q$ -COLORING on each of the mentioned graph classes in a uniform manner. Refer to the arXiv version [10] for more details on the state of the art, and the specific results we obtain.

## 2 Map graphs

Recall that a map graph is the intersection graph of a set  $F$  of interior-disjoint objects in the plane. We construct a clique-based separator for  $\mathcal{G}^\times(F)$  in four steps. First, we construct a bipartite plane *witness graph*  $\mathcal{H}_1$  with node set  $P \cup Q$ , where the nodes in  $P$  correspond to the objects in  $F$  and the nodes in  $Q$  (with their incident arcs) model the adjacencies in  $\mathcal{G}^\times(F)$ . Next, we replace each node  $q \in Q$  by a certain gadget whose “leaves” are the neighbors of  $q$ , and we triangulate the resulting graph. We then apply the Planar Separator Theorem to obtain a separator for the resulting graph  $\mathcal{H}_2$ . Finally, we turn the separator for  $\mathcal{H}_2$  into a clique-based separator for  $\mathcal{G}^\times(F)$ . Next we explain these steps in detail.

### Step 1: Creating a witness graph

To construct a witness graph for  $\mathcal{G}^\times(F)$  we use the method of Chen et al. [6]: take a point  $p_f$  in the interior of each object  $f \in F$ , and take a *witness point*  $q \in \partial f \cap \partial f'$  for each pair of touching objects  $f, f' \in F$  and add arcs from  $q$  to the points  $p_f$  and  $p_{f'}$ . Let  $P = \{p_f : f \in F\}$  and let  $Q$  be the set of all witness points added. We denote the resulting

bipartite graph with node set  $P \cup Q$  by  $\mathcal{H}_1$ ; see Figure 2(i) for an example. Observe that points where many objects meet can serve as witness points for many neighboring pairs in  $\mathcal{G}^\times(F)$ . Chen et al. [6, Lemma 2.3] proved that any map graph admits a witness set  $Q$  of size  $O(n)$ . If the objects in  $F$  are polygons with  $O(n)$  vertices in total then  $Q$  can be found in  $O(n)$  time (since the vertices can serve as the set  $Q$ .)

### Step 2: Replacing witness points by gadgets and triangulating

We would like to construct a separator for  $\mathcal{H}_1$  using the Planar Separator Theorem, and convert it to a clique-based separator for  $\mathcal{G}^\times(F)$ . For every witness point  $q \in Q$  in the separator for  $\mathcal{H}_1$ , the conversion would add a clique  $C_q$  to the clique-based separator, namely, the clique corresponding to all objects  $f \in F$  such that  $p_f$  is adjacent to  $q$ . However, the node  $q$  adds 1 to the separator size, but the clique  $C_q$  adds  $\log(|C_q| + 1)$  to the weight of the clique-based separator. To deal with this we modify  $\mathcal{H}_1$ , as follows.

Consider a node  $q \in Q$ . Let  $N(q) \subseteq P$  denote the set of neighbors of  $q$ . For all nodes  $q \in Q$  with  $|N(q)| \geq 3$ , we replace the star induced by  $\{q\} \cup N(q)$  by a gadget  $G_q$ , which is illustrated in Figure 2(ii) and defined as follows.

First, we create a tree  $\mathcal{T}_q$  with root  $q$  and whose leaves are the nodes in  $N(q)$ , as follows. Define the *level*  $\ell(v)$  of a node  $v$  in  $\mathcal{T}_q$  to be the distance of  $v$  to the root; thus the root has level 0, its children have level 1, and so on. All leaves in  $\mathcal{T}_q$  are at the same level, denoted  $\ell_{\max}$ . The root has degree 3, nodes at level  $\ell$  with  $1 \leq \ell < \ell_{\max} - 1$  have degree 2, and nodes at level  $\ell_{\max} - 1$  have degree 2 or 1. For each  $\ell < \ell_{\max}$  we connect the nodes at level  $\ell$  into a cycle. After doing so, all faces in the gadget (except the outer face) are triangles or 4-cycles. We finish the construction by adding a diagonal in each 4-cycle. Define the *height* of a node  $v$  as  $\text{height}(v) := \ell_{\max} - \ell(v)$ . The following observation follows from the construction.

► **Observation 1.** *Let  $v$  be a node at height  $h > 0$  in the gadget  $G_q$ .*

- (i) *The subtree of  $\mathcal{T}_q$  rooted at  $v$ , denoted  $\mathcal{T}_q(v)$ , has at most  $3 \cdot 2^{h-1}$  leaves.*
- (ii) *The distance from  $v$  to any leaf in  $\mathcal{T}_q$  is at least  $h$ .*

To unify the exposition, it will be convenient to also create a gadget for the case where  $q$  has only two neighbors in  $\mathcal{H}_1$ , say  $p_f$  and  $p_{f'}$ . We then define  $\mathcal{T}_q$  to consist of the arcs  $(q, p_f)$  and  $(q, p_{f'})$ . Note that Observation 1 holds for this gadget as well.

By replacing each witness point  $q \in Q$  with a gadget  $G_q$  as above, we obtain a (still planar) graph. We triangulate this graph to obtain a maximal planar graph  $\mathcal{H}_2$ .

### Step 3: Constructing a separator for $\mathcal{H}_2$

We now want to apply the Planar Separator Theorem to  $\mathcal{H}_2$ . Our final goal is to obtain a balanced clique-based separator for  $\mathcal{G}^\times(F)$ . Hence, we want the separator for  $\mathcal{H}_2$  to be balanced with respect to  $P$ . We will also need the separator for  $\mathcal{H}_2$  to be connected. Both properties are guaranteed by the following version of the Planar Separator Theorem, which was proved by Djidjev and Venkatesan [11].

**Planar Separator Theorem.** Let  $\mathcal{G} = (V, E)$  be a maximal planar graph with  $n$  nodes. Let each node  $v \in V$  have a non-negative cost, denoted  $\text{cost}(v)$ , with  $\sum_{v \in V} \text{cost}(v) = 1$ . Then  $V$  can be partitioned in  $O(n)$  time into three sets  $A, B, \mathcal{S}$  such that (i)  $\mathcal{S}$  is a simple cycle of size  $O(\sqrt{n})$ , (ii)  $\mathcal{G}$  has no arcs between a node in  $A$  and a node in  $B$ , and (iii)  $\sum_{v \in A} \text{cost}(v) \leq 2/3$  and  $\sum_{v \in B} \text{cost}(v) \leq 2/3$ .

When applying the Planar Separator Theorem to  $\mathcal{H}_2$ , we set  $\text{cost}(p) := 1/n$  for all nodes  $p_f \in P$  and  $\text{cost}(v) := 0$  for all other nodes. We denote the resulting separator for  $\mathcal{H}_2$  by  $\mathcal{S}(\mathcal{H}_2)$  and the node sets inside and outside the separator by  $A(\mathcal{H}_2)$  and  $B(\mathcal{H}_2)$ , respectively.

#### Step 4: Turning the separator for $\mathcal{H}_2$ into a clique-based separator for $\mathcal{G}^\times(F)$

We convert  $\mathcal{S}(\mathcal{H}_2)$  into a clique-based separator  $\mathcal{S}$  for  $\mathcal{G}^\times(F)$  as follows.

- For each node  $p_f \in \mathcal{S}(\mathcal{H}_2) \cap P$  we put the (singleton) clique  $\{f\}$  into  $\mathcal{S}$ .
- For each gadget  $G_q$  we proceed as follows. Let  $V_q$  be the set of all nodes  $v \in \mathcal{T}_q$  that are in  $\mathcal{S}(\mathcal{H}_2)$ , and define  $C_q := \{f \in F : p_f \text{ is a leaf of } \mathcal{T}_q(v) \text{ that has an ancestor in } V_q\}$ ; see Figure 2(iii). Observe that  $C_q$  is a clique in  $\mathcal{G}^\times(F)$ . We add<sup>5</sup>  $C_q$  to  $\mathcal{S}$ .

The clique-based separator  $\mathcal{S}$  induces a partition of  $F \setminus \bigcup_{C \in \mathcal{S}} C$  into two parts  $A$  and  $B$ , with  $|A|, |B| \leq 2n/3$ , in a natural way, namely as  $A := \{f \in F : f \notin \bigcup_{C \in \mathcal{S}} C \text{ and } p_f \in A(\mathcal{H}_2)\}$  and  $B := \{f \in F : f \notin \bigcup_{C \in \mathcal{S}} C \text{ and } p_f \in B(\mathcal{H}_2)\}$ . The proof that  $\mathcal{S}$  is a valid separator, that is, there are no edges between objects in  $A$  and  $B$ , can be found in the full version [10]. It follows from the fact that for any arc  $(f, f')$  with witness  $q$ , either an ancestor of  $p_f$  or  $p_{f'}$  is in  $V_q$  (and so  $f$  or  $f'$  is in the separator) or  $p_f$  and  $p_{f'}$  (and, hence,  $f$  and  $f'$ ) are in the same component after removing the separator. It remains to prove that  $\mathcal{S}$  has the desired weight.

► **Lemma 2.** *The total weight of the separator  $\mathcal{S}$  satisfies  $\sum_{C \in \mathcal{S}} \log(|C| + 1) = O(\sqrt{n})$ .*

**Proof.** Since  $\mathcal{S}(\mathcal{H}_2)$  contains  $O(\sqrt{n})$  nodes, it suffices to bound the total weight of the cliques added for the gadgets  $G_q$ . Consider a gadget  $G_q$ . Recall that  $V_q$  is the set of all nodes  $v \in \mathcal{T}_q$  that are in  $\mathcal{S}(\mathcal{H}_2)$ . We claim that  $\log(|C_q| + 1) = O(|V_q|)$ , which implies that  $\sum_q \log(|C_q| + 1) = \sum_q O(|V_q|) = O(\sqrt{n})$ , as desired. It remains to prove the claim.

Since  $\mathcal{S}(\mathcal{H}_2)$  is a simple cycle, its intersection with  $G_q$  consists of one or more paths. Each path  $\pi$  enters and exits  $G_q$  at a node in  $N(q)$ . Let  $D_\pi$  denote the set of all descendants of the nodes in  $\pi$ . We will prove that  $\log(|D_\pi| + 1) = O(|\pi|)$ , where  $|\pi|$  denotes the number of nodes of  $\pi$ . This implies the claim since  $\log(|C_q| + 1) \leq \sum_\pi \log(|D_\pi| + 1) = \sum_\pi O(|\pi|) = O(|V_q|)$ .

To prove that  $\log(|D_\pi| + 1) = O(|\pi|)$ , let  $h_{\max}$  be the maximum height of any node in  $\pi$ . Thus  $|\pi| \geq h_{\max}$  by Observation 1(ii). Consider all subtrees of height  $h_{\max}$  in  $\mathcal{T}_q$ . If  $\pi$  visits  $t$  such subtrees, then  $|\pi| \geq t$ . Moreover,  $|D_\pi| \leq 3t \cdot 2^{h_{\max}-1}$  by Observation 1(i). Hence,  $\log(|D_\pi| + 1) \leq \log(3t \cdot 2^{h_{\max}-1} + 1) < h_{\max} + \log(3t) = O(\max(h_{\max}, t)) = O(|\pi|)$ . ◀

By putting everything together we obtain the following theorem.

► **Theorem 3.** *Let  $F$  be a set of  $n$  interior-disjoint regions in the plane. Then the intersection graph  $\mathcal{G}^\times(F)$  has a clique-based balanced separator of weight  $O(\sqrt{n})$ . The separator can be computed in  $O(n)$  time, assuming that the total complexity of the objects in  $F$  is  $O(n)$ .*

### 3 Pseudo-disk graphs

Our clique-based separator construction for a set  $F$  of pseudo-disks uses so-called planar supports, defined as follows. Let  $\mathcal{H}$  be a hypergraph with node set  $Q$  and hyperedge set  $H$ . A graph  $\mathcal{G}_{\text{sup}}$  is a *planar support* [26] for  $\mathcal{H}$  if  $\mathcal{G}_{\text{sup}}$  is a planar graph with node set  $Q$  such that for any hyperedge  $h \in H$  the subgraph of  $\mathcal{G}_{\text{sup}}$  induced by the nodes in  $h$  is connected. In our application we let the node set  $Q$  correspond to a set of points stabbing all pairwise

<sup>5</sup> We tacitly assume that if an object is in multiple cliques in  $\mathcal{S}$ , we remove all but one of its occurrences.

intersections between the pseudo-disks, that is, for each intersecting pair  $f, f' \in F$  there will be a point  $q \in Q$  that lies in  $f \cap f'$ . The goal is to keep the size of  $Q$  small, by capturing all intersecting pairs with few points. The hyperedges are defined by the regions in  $F$ , that is, for every  $f \in F$  there is a hyperedge  $h_f := Q \cap f$ . Let  $\mathcal{H}_Q(F)$  denote the resulting hypergraph.

► **Lemma 4.** *Let  $F$  be a set of  $n$  objects in the plane, let  $Q$  be a set of points stabbing all pairwise intersections in  $F$ , and let  $\mathcal{H}_Q(F)$  denote the hypergraph as defined above. If  $\mathcal{H}_Q(F)$  has a planar support  $\mathcal{G}_{\text{sup}}$  then  $\mathcal{G}^\times(F)$  has a clique-based separator of size  $O(\sqrt{|Q|})$  and weight  $O(\sqrt{|Q|} \log n)$ .*

**Proof.** Let  $\mathcal{S}(\mathcal{G}_{\text{sup}})$  be a separator for  $\mathcal{G}_{\text{sup}}$  of size  $O(\sqrt{|Q|})$ , which exists by the Planar Separator Theorem, and let  $A(\mathcal{G}_{\text{sup}})$  and  $B(\mathcal{G}_{\text{sup}})$  be the corresponding separated parts. To ensure an appropriately balanced separator we use the cost-balanced version of the Planar Separator Theorem, as stated in the previous section. For each object  $f \in F$  we give one point  $q_f \in Q \cap f$  a cost of  $1/n$  and all other points cost 0. We call  $q_f$  the *representative* of  $f$ . (We assume for simplicity that each  $f \in F$  intersects at least one other object  $f' \in F$ , so we can always find a representative. Objects  $f \in F$  not intersecting any other object are singletons in  $\mathcal{G}^\times(F)$  and can be ignored.) For a point  $q \in Q$ , define  $C_q$  to be the clique in  $\mathcal{G}^\times(F)$  consisting of all objects  $f \in F$  that contain  $q$ . Our clique-based separator  $\mathcal{S}$  for  $\mathcal{G}^\times(F)$  is now defined as  $\mathcal{S} := \{C_q : q \in \mathcal{S}(\mathcal{G}_{\text{sup}})\}$ , and the two separated parts are defined as:  $A := \{f \in F : f \notin \mathcal{S} \text{ and } q_f \in A(\mathcal{G}_{\text{sup}})\}$  and  $B := \{f \in F : f \notin \mathcal{S} \text{ and } q_f \in B(\mathcal{G}_{\text{sup}})\}$ . Clearly, the size of  $\mathcal{S}$  is  $O(\sqrt{|Q|})$  and its weight is  $O(\sqrt{|Q|} \log n)$ . Moreover,  $|A|, |B| \leq 2n/3$  because  $\mathcal{S}(\mathcal{G}^*)$  is balanced with respect to the node costs.

We claim there are no arcs in  $\mathcal{G}^\times(F)$  between a node in  $A$  and a node in  $B$ . Suppose for a contradiction that there are intersecting objects  $f, f'$  such that  $f \in A$  and  $f' \in B$ . By definition of  $Q$  there is a point  $q \in Q$  that lies in  $f \cap f'$ . By the planar-support property, the hyperedge  $h_f$  induces a connected subgraph of  $\mathcal{G}_{\text{sup}}$ , so there is a path  $\pi$  that connects  $q$  to the representative  $q_f$  and such that all nodes of  $\pi$  are points in  $f \cap Q$ . No node on the path  $\pi$  can be in  $\mathcal{S}(\mathcal{G}_{\text{sup}})$ , otherwise  $f$  is in a clique that was added to  $\mathcal{S}$ . Similarly, there is a path  $\pi'$  connecting  $q_{f'}$  to  $q$  such that no point on  $\pi'$  is in  $\mathcal{S}(\mathcal{G}_{\text{sup}})$ . But then there is a path from  $q_f$  to  $q_{f'}$  in  $\mathcal{G}_{\text{sup}}$  after the removal of  $\mathcal{S}(\mathcal{G}_{\text{sup}})$ . Hence,  $q_f$  and  $q_{f'}$  are in the same part of the partition, which contradicts that  $f$  and  $f'$  are in different parts.

We conclude that  $\mathcal{S}$  is a clique-based separator with the desired properties. ◀

► **Remark 5.** The witness set  $Q$  in the previous section stabs all pairwise intersections of objects in the map graph, and so  $P \cup Q$  stabs all pairwise intersections as well.  $P \cap Q$  has planar support, so we can get a separator for map graphs using Lemma 4. Its weight would be  $O(\sqrt{n} \log n)$ , however, while in the previous section we managed to get  $O(\sqrt{n})$  weight.

### Polygonal pseudo-disks

We now apply Lemma 4 to obtain a clique-based separator for a set  $F$  of polygonal pseudo-disks. To this end, let  $Q$  be the set of vertices of the pseudo-disks in  $F$ . Observe that whenever two pseudo-disks intersect, one must have a vertex inside the other. Indeed, either one pseudo-disk is entirely inside the other, or an edge  $e$  of  $f$  intersects an edge  $e'$  of  $f'$ . In the latter case, one of the two edges ends inside the other pseudo-disk, otherwise there are three intersections between the boundaries. Furthermore, pseudo-disks have the *non-piercing*

property:  $f \setminus f'$  is connected for any two pseudo-disks  $f, f'$ . Raman and Ray [26] proved<sup>6</sup> that the hypergraph  $\mathcal{H}_Q(F)$  of a set of non-piercing regions has a planar support for any set  $Q$ , so in particular for the set  $Q$  just defined. We can thus apply Lemma 4 to compute a clique-based separator for  $\mathcal{G}^\times(F)$ . The time to compute the separator is dominated by the computation of the planar support, which takes  $O(n^3)$  time [26].

► **Theorem 6.** *Let  $F$  be a set of  $n$  polygonal pseudo-disks in the plane with  $O(n)$  vertices in total. Then the intersection graph  $\mathcal{G}^\times(F)$  has a clique-based balanced separator of size  $O(\sqrt{n})$  and weight  $O(\sqrt{n} \log n)$ , which can be found in  $O(n^3)$  time.*

### Arbitrary pseudo-disks

To construct a clique-based separator using Lemma 4 we need a small point set  $Q$  that stabs all pairwise intersections. Unfortunately, for general pseudo-disks a linear-size set  $Q$  that stabs all intersections need not exist: there is a collection of  $n$  disks such that stabbing all pairwise intersections requires  $\Omega(n^{4/3})$  points. (Such a collection can be derived from a construction with  $n$  lines and  $n$  points with  $\Omega(n^{4/3})$  incidences [23].) Hence, we need some more work before we can apply Lemma 4.

Our separator result for arbitrary pseudo-disks works in a more general setting, namely for sets from a family  $\mathcal{F}$  with linear union complexity. (We say that  $\mathcal{F}$  has union complexity  $U(n)$  if, for any  $n \geq 1$  and any subset  $F \subset \mathcal{F}$  of size  $n$ , the union complexity of  $F$  is  $U(n)$ .) Recall that the union complexity of a family of pseudo-disks is  $O(n)$  [15]. The next theorem states that such sets admit a clique-based separator of sublinear weight. Note that the bound only depends on the number of objects, not on their complexity.

► **Theorem 7.** *Let  $F$  be a set of  $n$  objects from a family  $\mathcal{F}$  of union complexity  $U(n)$ , where  $U(n) \geq n$ . Then  $\mathcal{G}^\times(F)$  has a clique-based separator of size  $O((U(n))^{2/3})$  and weight  $O((U(n))^{2/3} \log n)$ . In particular, if  $F$  is a set of pseudo-disks then  $\mathcal{G}^\times(F)$  has a clique-based separator of size  $O(n^{2/3})$  and weight  $O(n^{2/3} \log n)$ . The separator can be computed in  $O(n^3)$  time, assuming the total complexity of the objects is  $O(n)$ .*

**Proof.** We construct the separator  $\mathcal{S}$  in two steps.

The first step proceeds as follows. For a point  $p$  in the plane, let  $C_p$  denote the set of objects from the (current) set  $F$  containing  $p$ . As long as there is a point  $p$  such that  $|C_p| > n^{1/3}$ , we remove  $C_p$  from  $F$  and put  $C_p$  into  $\mathcal{S}$ ; here  $n$  refers to the size of the initial set  $F$ . Thus the first step adds  $O(n^{2/3})$  cliques to  $\mathcal{S}$  with total weight  $O(n^{2/3} \log n)$ . This step can easily be implemented in  $O(n^3)$  time.

In the second step we have a set  $F^* \subseteq F$  of  $n^*$  objects with ply  $k$ , where  $n^* \leq n$  and  $k \leq n^{1/3}$ . Let  $\mathcal{A}(F^*)$  denote the arrangement induced by  $F^*$ . Since  $F^*$  has ply  $k$ , the Clarkson-Shor technique [7] implies that the complexity of the arrangement  $\mathcal{A}(F^*)$  is  $O(k^2 \cdot U(n^*/k))$ . We can compute this arrangement in  $O(k^2 \cdot U(n^*/k) \log n) = O(n^2 \log n)$  time [9]. Take a point  $q$  in each face of the arrangement, and let  $Q$  be the resulting set of  $O(k^2 \cdot U(n^*/k))$  points. The set  $Q$  stabs all pairwise intersections and the dual graph  $\mathcal{G}^*$  of the arrangement  $\mathcal{A}(F^*)$  is a planar support for the hypergraph  $\mathcal{H}_Q(F)$ . Hence, by Lemma 4 there is a clique-based separator  $\mathcal{S}^*$  for  $\mathcal{G}^\times(F)$  of size  $O\left(k\sqrt{U(n^*/k)}\right)$  and

<sup>6</sup> Raman and Ray assume the sets  $F$  and  $Q$  defining the hypergraph are in general position. Therefore we first slightly perturb the pseudo-disks in  $F$  to get them into general position (while keeping the same intersection graph), then we take  $Q$  to be a point set coinciding with the vertex set of  $F$ , and then we slightly move the points in  $Q$  such that the hypergraph remains the same.

■ **Figure 3** (i) A geodesic disk  $D$  with center  $q$  and radius  $r$ . The set  $\Gamma(D)$  has three pieces,  $\gamma_1, \gamma_2$  and  $\gamma_3$ , shown in blue. (ii) The result of the perturbation. Note that  $|\gamma_1^*| < |\gamma_2^*| < |\gamma_3^*|$  and so  $\varepsilon_{\gamma_1^*} > \varepsilon_{\gamma_2^*} > \varepsilon_{\gamma_3^*}$ . (iii) Illustration for the proof of Theorem 8.

weight  $O\left(k\sqrt{U(n^*/k)}\log n^*\right)$ . Note that  $U(n)$  is a superadditive function [1] which implies that  $U(n/k) \leq U(n)/k$  and therefore  $k\sqrt{U(n^*/k)} \leq \sqrt{k}U(n) \leq (U(n))^{2/3}$ . By adding  $\mathcal{S}^*$  to the set  $\mathcal{S}$  of cliques generated in the first step, we obtain a clique-based separator with the desired properties.  $\blacktriangleleft$

#### 4 Geodesic disks inside a simple polygon

Let  $P$  be a simple polygon. We denote the shortest path (or: *geodesic*) in  $P$  between two points  $p, q \in P$  by  $\pi(p, q)$ ; note that  $\pi(p, q)$  is unique since  $P$  is simple. The *geodesic distance* between  $p$  and  $q$  is defined to be  $\|\pi(p, q)\|$ , where  $\|\pi\|$  denotes the Euclidean length of a path  $\pi$ . For a given point  $q \in P$  and radius  $r > 0$ , we call the region  $D(q, r) := \{p \in P : \|\pi(p, q)\| \leq r\}$  a *geodesic disk*. Let  $\mathcal{D} = \{D_1, \dots, D_n\}$  be a set of geodesic disks in  $P$ . To construct a clique-based separator for  $\mathcal{G}^\times(\mathcal{D})$  we will show that  $\mathcal{D}$  behaves as a set of pseudo-disks so we can apply the result of the previous section.

##### The structure of a geodesic disk

The boundary  $\partial D(q, r)$  of a geodesic disk  $D(q, r)$  consists of circular arcs lying in the interior of  $P$  (centered at  $q$  or at a reflex vertex of  $P$ ) and parts of the edges of  $P$ . We split  $\partial D(q, r)$  into *boundary pieces* at the points where the circular arcs meet  $\partial P$ . This generates two sets of boundary pieces: a set containing the pieces that consist of circular arcs, and a set  $\Gamma(D)$  containing the pieces that consist of parts of edges of  $P$ . An example can be seen in Fig. 3.

A region  $R \subseteq P$  is *geodesically convex* if for any points  $p, q \in R$  we have  $\pi(p, q) \subseteq R$ . Pollack et al. [25] showed that geodesic disks inside a simple polygon are geodesically convex. An immediate consequence is that the intersection of two geodesic disks is connected.

##### Geodesic disks behave as pseudo-disks

Geodesic disks in a simple polygon are not proper pseudo-disks. For example, if  $D_1$  and  $D_2$  are the blue and pink pseudo-disk in the third image in Fig. 1, then  $D_1 \setminus D_2$  has two components, which is not allowed for pseudo-disks. Nevertheless, we will show that  $\mathcal{D}$  behaves as a set of pseudo-disks in the sense that a small perturbation turns them into pseudo-disks, while keeping the intersection graph the same.

As a first step in the perturbation, we increase the radius of each geodesic disk  $D_i \in \mathcal{D}$  by some small  $\varepsilon_i$ . We pick these  $\varepsilon_i$  such that the intersection graph  $\mathcal{G}^\times(\mathcal{D})$  stays the same while all degeneracies disappear. In particular, the boundary pieces of different geodesic disks have different lengths after this perturbation, and no two geodesic disks touch. With a slight abuse of notation, we still denote the resulting set of geodesic disks by  $\mathcal{D}$ .

The second step in the perturbation moves each  $\gamma \in \cup_{i=1}^n \Gamma(D_i)$  into the interior of the polygon over some distance  $\varepsilon_\gamma$ , which is smaller than any of the perturbation distances chosen in the first step. More formally, for each  $\gamma \in \Gamma(D_i)$  we remove all points from  $D_i$  that are at distance less than  $\varepsilon_\gamma$  from  $\gamma$ ; see Fig. 3(ii). To ensure this gives a set of pseudo-disks we choose the perturbation distances  $\varepsilon_\gamma$  according to the reverse order of the Euclidean lengths of the pieces. That is, if  $\|\gamma\| > \|\gamma'\|$  then we pick  $\varepsilon_\gamma < \varepsilon_{\gamma'}$ . The crucial property of this scheme is that whenever  $\gamma_i \subset \gamma_j$  then  $\gamma_i$  is moved more than  $\gamma_j$ .

We denote the perturbed version of  $D_i$  by  $D_i^*$  and define  $\mathcal{D}^* := \{D_i^* : D_i \in \mathcal{D}\}$ . The perturbed versions have the following important property: every connected component of  $D_i^* \setminus D_j^*$  contains a point  $u$  with  $u \in D_i \setminus D_j$ , see [10].

► **Theorem 8.** *Any set  $\mathcal{D}$  of geodesic disks inside a simple polygon  $P$  can be slightly perturbed such that the resulting set  $\mathcal{D}^*$  is a set of pseudo-disks with  $\mathcal{G}^\times(\mathcal{D}) = \mathcal{G}^\times(\mathcal{D}^*)$ .*

**Proof.** Consider the set  $\mathcal{D}^*$  resulting from the perturbation described above. Suppose for a contradiction that there exist two objects  $D_1^*, D_2^* \in \mathcal{D}^*$  such that  $\partial D_1^*$  and  $\partial D_2^*$  cross four or more times. Recall that the intersection of two geodesic disks is connected. This property is not invalidated by the perturbation. Hence, if  $\partial D_1^*$  and  $\partial D_2^*$  cross four or more times then  $D_1^* \setminus D_2^*$  (and, similarly,  $D_2^* \setminus D_1^*$ ) has two or more components.

For  $i = 1, 2$ , let  $q_i$  and  $r_i$  denote the center and radius of  $D_i$ . Without loss of generality assume that  $r_1 \leq r_2$ . Let  $x$  and  $y$  be points in different components of  $D_1^* \setminus D_2^*$ ; see Fig. 3 (iii). We can pick  $x$  and  $y$  such that  $x, y \in D_1 \setminus D_2$ . By concatenating the geodesics  $\pi(x, q_1)$  and  $\pi(q_1, y)$  we obtain a curve that splits  $D_2^*$  into at least two parts – this is independent of where  $q_1$  lies, or whether  $\pi(x, q_1)$  and  $\pi(q_1, y)$  partially overlap. (Note that these geodesics lie in  $D_1$  but not necessarily in  $D_1^*$ . However, they cannot “go around” a component of  $D_2^* \setminus D_1^*$ , because  $D_1$  cannot fully contain such a component. Hence,  $\pi(x, q_1) \cup \pi(q_1, y)$  must indeed go through  $D_2^*$ .) Not all components of  $D_2^* \setminus D_1^*$  can belong to the same part, otherwise  $x$  and  $y$  would not be in different components of  $D_1^* \setminus D_2^*$ . Take a point  $z \in D_2^* \setminus D_1^*$  that lies in a different part than  $q_2$ , the center of  $D_2$ . Again we can pick  $z$  such that  $z \in D_2 \setminus D_1$ . Then the geodesic  $\pi(q_2, z)$  must cross  $\pi(x, q_1) \cup \pi(q_1, y)$ , say at a point  $w \in \pi(q_1, y)$ . Since  $z \notin D_1$  and  $y \notin D_2$  we must have  $\|\pi(q_1, w) \cup \pi(w, z)\| + \|\pi(q_2, w) \cup \pi(w, y)\| > r_1 + r_2$ . But this gives a contradiction because  $y \in D_1$  and  $z \in D_2$  implies  $\|\pi(q_1, w) \cup \pi(w, y)\| + \|\pi(q_2, w) \cup \pi(w, z)\| \leq r_1 + r_2$ .

It remains to show that  $\mathcal{G}^\times(\mathcal{D}) = \mathcal{G}^\times(\mathcal{D}^*)$ . As mentioned earlier, the increase of the radii in the first step of the perturbation is chosen sufficiently small so that no new intersections are introduced. The second step shrinks the geodesic disks, so no new intersections are introduced in that step either. Finally, the fact that the perturbations in the second step are smaller than in the first step guarantees that no intersections are removed. ◀

Theorem 8 allows us to apply Theorem 7. When doing so, we actually do not need to perturb the geodesic disks. We only use the perturbation to argue that the number of faces in the arrangement defined by  $n$  geodesic disks of ply  $k$  is  $O(nk)$ . Computing the geodesic disks (and then computing the separator) can be done in polynomial time in  $n$  and the number of vertices of  $P$ . We obtain the following result.

► **Corollary 9.** *Let  $\mathcal{D}$  be a set of  $n$  geodesic disks inside a simple polygon with  $m$  vertices. Then  $\mathcal{G}^\times(\mathcal{D})$  has a clique-based separator of size  $O(n^{2/3})$  and weight  $O(n^{2/3} \log n)$ , which can be computed in time polynomial in  $n$  and  $m$ .*

■ **Figure 4** (i) Each cluster  $A_i$  sees any of the clusters  $B_j$  completely and all distances are at most 1, so a separator that splits  $\mathcal{G}_{\text{vis},P}^\times(\bigcup A_i \cup \bigcup B_j)$  into two or more components must fully contain  $\bigcup A_i$  or  $\bigcup B_j$ . Since the clusters  $A_i$  (and similarly  $B_j$ ) do not see each other, such a separator has size at least  $r/2$  and weight at least  $((r/2) \log(n/r))$ . (ii) Splitting  $R^*(u)$  into two convex parts.

## 5 Visibility-restricted unit-disk graphs inside a polygon

Let  $P$  be a polygon, possibly with holes, and let  $Q$  be a set of  $n$  points inside  $P$ . We define  $\mathcal{G}_{\text{vis},P}^\times(Q)$  to be the visibility-restricted unit-disk graph of  $Q$ . The nodes in  $\mathcal{G}_{\text{vis},P}^\times(Q)$  correspond to the points in  $Q$  and there is an edge between two points  $p, q \in Q$  iff  $|pq| \leq 1$  and  $p$  and  $q$  see each other. A vertex of  $P$  is *reflex* if its angle within the polygon is more than 180 degrees; note that for a vertex of a hole we look at the angle within  $P$ , not within the hole. Below we sketch a proof of the following theorem; a detailed proof is in the arXiv version of the paper [10].

► **Theorem 10.** *Let  $Q$  be a set of  $n$  points inside a polygon (possibly with holes) with  $r$  reflex vertices. Then  $\mathcal{G}_{\text{vis},P}^\times(Q)$  admits a clique-based separator of size  $O(\min(n, r) + \sqrt{n})$  and weight  $O(\min(n, r \log(n/r) + \sqrt{n}))$ . The bounds on the size and weight of the separator are tight in the worst case, even for simple polygons.*

### The lower bound

Recall that even for non-visibility restricted unit-disk graphs,  $\Omega(\sqrt{n})$  is a lower bound on the worst-case size of the separator. Hence, to prove the lower bound of Theorem 10 it suffices to give an example where the size and weight are  $\Omega(\min(n, r))$  and  $\Omega(\min(n, r \log(n/r)))$ , respectively. This example is given in Fig. 4(i).

### The upper bound

We now sketch our separator construction for the case where  $P$  is a simple polygon. The extension to polygons with holes can be found in the full version [10].

**Step 1: Handling points that see a nearby reflex vertex.** Let  $V_{\text{ref}}$  be the set of reflex vertices of  $P$ , and let  $Q_1 \subseteq Q$  be the set of points that can see a reflex vertex within distance  $\sqrt{2}$ . Consider the geodesic Voronoi diagram of  $V_{\text{ref}}$  within  $P$ . Let  $R(u)$  be the Voronoi region of vertex  $u \in V_{\text{ref}}$  and define  $R^*(u) := R(u) \cap D(u, \sqrt{2})$ . Note that all points in  $R(u)$  can see  $u$  and that all points in  $Q_1$  are in  $S^*(u)$  for some vertex  $u \in V_{\text{ref}}$ . By extending one of the edges of  $P$  incident to  $u$ , we can split  $R^*(u)$  into two convex parts; see Fig. 4(ii). Since  $R^*(u)$  has diameter  $O(1)$ , this means that  $Q_1 \cap R^*(u)$  can be partitioned into  $O(1)$  cliques. We collect all these cliques into a set  $\mathcal{S}_1$ . Since there are  $r$  reflex vertices,  $\mathcal{S}_1$  consists of  $O(r)$  cliques of total weight is  $O(r \log(n/r))$ .

■ **Figure 5** (i) The grid  $G$  defining the chords  $s_i$ . (ii) The points in the top-left cell see a reflex vertex so they are not in  $Q_2(s_i)$ . The points in the top-right cell can be split into  $O(1)$  cliques.

**Step 2: Handling points that do not see a nearby reflex vertex.** Our separator  $\mathcal{S}$  consists of the cliques in  $\mathcal{S}_1$  plus a set  $\mathcal{S}_2$  of cliques that are found as follows. Let  $Q_2 := Q \setminus Q_1$  be the set of points that do not see a reflex vertex within distance  $\sqrt{2}$ . Let  $c$  be a *centerpoint* for  $Q_2$  inside  $P$ , that is, a point such that any (maximal) chord through  $c$  splits  $P$  into half-polygons containing at most  $2|Q_2|/3$  points from  $Q_2$ . Such a point always exists; see [10]. Let  $G$  be a  $\sqrt{n} \times \sqrt{n}$  grid of unit cells centered at  $c$ . For each of the  $\sqrt{n}$  points  $g_i$  in the rightmost column of the grid (even if  $g_i \notin P$ ), we define a chord  $s_i$  by taking the line  $\ell_i$  through  $c$  and  $g_i$  and then taking the component of  $\ell_i \cap P$  that contains  $c$ ; see Fig. 5(i).

For each chord  $s_i$ , we define  $Q_2(s_i)$  to be the set of points  $q \in Q_2$  such that there is a point  $z \in s_i$  that sees  $q$  with  $|qz| \leq 1/2$ . Note that  $\mathcal{G}_{\text{vis},P}^\times(Q)$  cannot have an arc between a point  $p \in Q_2 \setminus Q_2(s_i)$  above  $s_i$  and a point  $q \in Q_2 \setminus Q_2(s_i)$  below  $s_i$ ; otherwise  $p$  and/or  $q$  see a point on  $s_i$  within distance  $1/2$ , and so at least one of  $p, q$  is in  $Q_2(s_i)$ . Since  $s_i$  is a chord through the centerpoint  $c$ , this means that  $s_i$  induces a balanced separator.

It remains to argue that at least one chord  $s_i$  induces a separator of small weight. We will do this by creating a set  $\mathcal{S}(s_i)$  of cliques for each chord  $s_i$ , and prove that the total weight of these cliques, over all chords  $s_i$ , is  $O(n)$ . Since there are  $\sqrt{n}$  chords, one of them has the desired weight.

First, we put all points from  $Q_2(s_i)$  that lie outside the grid  $G$  into  $\mathcal{S}(s_i)$ , as singletons. By definition of the chords  $s_i$ , a point  $q$  outside the grid  $G$  lies at distance at most  $1/2$  from  $O(1)$  chords. Hence, the total number of singleton cliques over all sets  $\mathcal{S}(s_i)$  is  $O(n)$ .

Next, consider a cell  $T$  of the grid  $G$ . Suppose a point  $q \in Q_2(s_i)$  sees a point  $z \in T \cap s_i$  with  $|qz| \leq 1/2$ . Then  $q$  must lie inside one of the nine grid cells surrounding and including  $T$ . Consider such a cell  $T'$ . The points in  $Q_2(s_i) \cap T'$  that can see a point on  $s_i \cap T$  can be partitioned into  $O(1)$  cliques; we prove this by showing that if two such points do not see each other, then they must see a reflex vertex within distance  $\sqrt{2}$  and, hence, be in  $Q_1$ . We thus create  $O(1)$  cliques for  $T'$  and put them into  $\mathcal{S}(s_i)$ . This adds at most  $O(\log(n_{T'} + 1))$  weight to  $\mathcal{S}(s_i)$ , where  $n_{T'} := |Q_2 \cap T'|$ .

Overall, a cell  $T'$  adds  $O(\log(n_{T'} + 1))$  weight for the chords  $s_i$  that cross the nine cells surrounding it. Since there are  $n$  cells in total, this immediately gives a total weight of  $O(n \log n)$  over all sets  $\mathcal{S}(s_i)$ . A more careful analysis shows that the total weight of the cliques is actually  $O(n)$ . Hence, one of the  $\sqrt{n}$  chords induces a separator of the desired weight. This finishes the sketch of the construction of the clique-based separator for  $\mathcal{G}_{\text{vis},P}^\times(Q)$ .

## 6 Concluding Remarks

We showed how clique-based separators with sub-linear weight can be constructed for various classes of intersection graphs which involve non-fat objects. The main advantage of our approach is that we can solve different problems in the graph classes we study in a uniform manner. There are several natural questions that are left open. Some are listed below.

- **Improving the bound for geodesic disks and adding holes.** Our bound on geodesic disks is directly derived by our result on pseudo-disks. However, geodesic disks are much less general than pseudo-disks (and “closer” to regular disks). Hence, one would expect that the optimal weight is closer to  $O(\sqrt{n})$ . If we allow our polygon to have holes, then our approach for geodesic disks no longer works. Indeed, it is easy to see that even after applying our perturbation scheme, the resulting objects can intersect each other more than two times.
- **Improving the bound for pseudo-disks.** Regarding pseudo-disks, an interesting result [24] states that in every finite family of pseudo-disks in the plane one can find a “small” one, in the sense that it is intersected by only a constant number of disjoint pseudo-disks. This property is also shared by, for instance, convex fat objects. Does this mean that the two graph classes are related in some natural way? If yes, could this connection be exploited to construct separators with better bounds?

## Abstract

Given an undirected  $n$ -vertex planar graph  $G = (V, E, \omega)$  with non-negative edge weight function  $\omega : E \rightarrow \mathbb{R}$  and given an assigned label to each vertex, a vertex-labeled distance oracle is a data structure which for any query consisting of a vertex  $u$  and a label  $\lambda$  reports the shortest path distance from  $u$  to the nearest vertex with label  $\lambda$ . We show that if there is a distance oracle for undirected  $n$ -vertex planar graphs with non-negative edge weights using  $s(n)$  space and with query time  $q(n)$ , then there is a vertex-labeled distance oracle with  $\tilde{O}(s(n))^1$  space and  $\tilde{O}(q(n))$  query time. Using the state-of-the-art distance oracle of Long and Pettie [12], our construction produces a vertex-labeled distance oracle using  $n^{1+o(1)}$  space and query time  $\tilde{O}(1)$  at one extreme,  $\tilde{O}(n)$  space and  $n^{o(1)}$  query time at the other extreme, as well as such oracles for the full tradeoff between space and query time obtained in their paper. This is the first non-trivial exact vertex-labeled distance oracle for planar graphs and, to our knowledge, for any interesting graph class other than trees.

## 1 Introduction

Efficiently answering shortest path distance queries between pairs of vertices in a graph is a fundamental algorithmic problem with a wide range of applications. An algorithm like Dijkstra’s can answer such a query in near-linear time in the size of the graph. If we allow for precomputations, we can break this bound, for instance by simply storing the answers to all possible queries in a look-up table. However, a fast query time should preferably not come at the cost of a large space requirement. A *distance oracle* is a compact data structure that can answer a shortest path distance query in constant or close to constant time.

---

<sup>1</sup> We use  $\tilde{O}$ -notation to suppress  $\text{poly}(\log n)$ -factors.

A lot of research has focused on approximate distance oracles which allow for some approximation in the distances output. This is reasonable since there are graphs for which the trivial look-up table approach is the best possible for exact distances. However, for restricted classes of graphs, it may be possible to obtain exact oracles with a much better tradeoff between space and query time. Indeed, for any planar  $n$ -vertex digraph, there is an exact distance oracle with space close to linear in  $n$  and query time close to constant [7, 2, 12].

A related problem is that of obtaining a vertex-labeled distance oracle. Here, we are given a graph with each vertex assigned a label. A query consists of a pair  $(u, \lambda)$  of a vertex  $u$  and a label  $\lambda$  and the output should be the distance from  $u$  to the nearest vertex with label  $\lambda$ . Each vertex is given only one label but the same label may be assigned to multiple vertices. To give some practical motivation, if the graph represents a road network, a label  $\lambda$  could represent supermarkets and the output of query  $(u, \lambda)$  gives the distance to the nearest supermarket from the location represented by  $u$ .

Note that this is a generalization of the distance oracle problem since vertex-to-vertex distance queries can be answered by a vertex-labeled distance oracle if each vertex is given its own unique label. If  $L$  is the set of labels, a trivial vertex-labeled distance oracle with constant query time is a look-up table that simply stores the answers to all possible queries, requiring space  $O(n|L|)$ . This bound can be as high as quadratic in  $n$ .

Our main result, which we shall state formally later in this section, is that for undirected edge-weighted planar graphs, the vertex-labeled distance oracle problem can be reduced to the more restricted distance oracle problem in the sense that up to  $\log n$ -factors, any space/query time tradeoff for distance oracles also holds for vertex-labeled distance oracles. Hence, the tradeoff from [12] translates to vertex-labeled distance oracles, assuming that the planar graph is undirected. To the best of our knowledge, this is the first non-trivial upper bound for vertex-labeled distance oracles in any interesting graph class other than trees [8, 15]. A strength of our result is that any future progress on distance oracles in undirected planar graphs immediately translates to vertex-labeled distance oracles.

## 1.1 Related work on vertex-labeled distance oracles

Vertex-labeled distance oracles have received considerably more attention in the approximate setting. With  $(1 + \epsilon)$  multiplicative approximation, it is known how to get  $\tilde{O}(n)$  space and  $\tilde{O}(1)$  query time both for undirected [11] and directed planar graphs [13] and it has been shown how oracles with such guarantees can be maintained dynamically under label changes to vertices using  $\tilde{O}(1)$  time per vertex relabel.

For general graphs, vertex-labeled distance oracles with constant approximation have been presented [9, 3, 14] with state of the art being an oracle with  $O(kn|L|^{1/k})$  space,  $4k - 5$  multiplicative approximation, and  $O(\log k)$  query time, for any  $k \in \mathbb{N}$ .

## 1.2 Our contributions

We now state our reduction and its corollary:

► **Theorem 1.** *If there is an exact distance oracle for  $n$ -vertex undirected edge-weighted planar graphs with  $s(n)$  space,  $q(n)$  query time, and  $t(n)$  preprocessing time, then there exists an exact vertex-labeled distance oracle for such graphs with  $s(n) + O(n \log^2 n)$  space, and with  $O(q(n) \log n + \log^3 n)$  query time, and  $t(n) + \text{poly}(n)$  preprocessing time.*

Plugging in the distance oracle of Long and Pettie et al. [12] gives the following corollary which can be seen as a generalization of their result:

► **Corollary 2.** *For  $n$ -vertex undirected edge-weighted planar graphs, there exist exact vertex-labeled distance oracles with the following tradeoffs between space and query time:*

1.  $n^{1+o(1)}$  space and  $\tilde{O}(1)$  query time,
2.  $\tilde{O}(n)$  space and  $n^{o(1)}$  query time.

All oracles have preprocessing time polynomial in  $n$ .

Up to logarithmic factors, the full tradeoff between space and query time in their paper similarly extends to vertex-labeled distance oracles in undirected edge-weighted planar graphs.

The rest of the paper is organized as follows. In Section 2, we introduce basic definitions and notation and present tools from the literature that we will need for our oracle. In Section 3 we state the key lemmas but defer their proofs until later sections, and thus immediately present our reduction by describing how to obtain a vertex-labeled distance oracle given a distance oracle as a black box. In Section 4, we present a point location structure similar to [7] but with some important modifications to improve space in our setting.

## 2 Preliminaries

Let  $G = (V, E, \omega)$  be a graph with edge weight function  $\omega : E \rightarrow \mathbb{R} \cup \{\infty\}$ . We denote by  $V(G) = V$  and  $E(G) = E$  the vertex and edge-set of  $G$ , respectively, and by  $n = |V(G)|$  the number of vertices of  $G$ . A graph  $G'$  is said to be a subgraph of  $G$  if  $V(G') \subseteq V(G)$  and  $E(G') \subseteq E(G)$ . We denote by  $u \rightsquigarrow_G v$  a *shortest path* from  $u$  to  $v$  in  $G$ , by  $\mathbf{d}_G(u, v)$  the weight of  $u \rightsquigarrow_G v$ , and write  $u \rightsquigarrow v = u \rightsquigarrow_G v$  and  $\mathbf{d}(u, v) = \mathbf{d}_G(u, v)$  when  $G$  is clear from context. For a shortest path  $p = u \rightsquigarrow v = (u = p_1), p_2, \dots, (p_k = v)$  we define vertex  $p_i$  to occur *before*  $p_j$  on  $p$  if  $i < j$  and similarly for edges  $p_i p_{i+1}$  and  $p_j p_{j+1}$ . Thus statements such as “the first/last vertex/edge on  $p$  satisfying some property  $P$ ” will always be made w.r.t. this ordering. We also write  $p \circ p'$  to denote the concatenation of paths (or edges)  $p$  and  $p'$ , assuming the last vertex of  $p$  equals the first vertex of  $p'$ . Given  $u, v, v' \in V$ ; we say that  $v$  is *closer* than  $v'$  to  $u$  in  $G$  if  $\mathbf{d}_G(u, v) < \mathbf{d}_G(u, v')$  or  $\mathbf{d}_G(u, v) = \mathbf{d}_G(u, v')$  and  $v < v'$ , assuming some lexicographic ordering on vertices. We denote by  $V(p)$ , respectively  $E(p)$ , the set of vertices, respectively edges, on a path  $p$ .

Assume in the following that  $G$  is undirected.  $G$  is said to be connected, respectively biconnected, if any pair of vertices are connected by at least one, respectively two, vertex-disjoint paths. For a rooted spanning tree  $T$  in  $G$  and for any edge  $e = uv$  not in  $T$ , we define *the fundamental cycle* of  $uv$  w.r.t.  $T$  as the cycle obtained as the concatenation of  $uv$  and the two paths of  $T$  from the root to  $u$  and  $v$ , respectively.

### 2.1 Planar graphs and embeddings

An *embedding* of a planar graph  $G$  assigns to each vertex a point in the plane and to each edge a simple arc such that its endpoints coincide with those of the points assigned to its vertices. A *planar embedding* of  $G$  is an embedding such that no two vertices are assigned the same point and such that no pair of arcs coincide in points other than those corresponding to vertices they share. A graph is said to be *planar* if it admits a planar embedding. When we talk about a planar graph we assume that it is *planar embedded* and hence some implicit, underlying planar embedding of the graph. When it is clear from the context we shall refer interchangeably to a planar graph and its embedding, its edges and arcs and its vertices and points. Thus the term graph can refer to its embedding, an edge to its corresponding arc and a vertex to its corresponding point in the embedding.

### Assumptions about the input

Unless stated otherwise, we shall always assume that  $G$  refers to a graph which is weighted, undirected and planar with some underlying embedding. Furthermore, we shall make the structural assumption that  $G$  is triangulated. Triangulation can be achieved by standard techniques, i.e. adding to each face  $f$  an artificial vertex and artificial edges from the artificial vertex to each vertex of  $V(f)$  with infinite weight. This transformation preserves planarity, shortest paths and ensures that the input graph consists only of simple faces. We also assume that shortest paths in the input graph are unique; this can be ensured for any input graph by either randomly perturbing edge weights or with e.g. the deterministic approach in [6] which gives only an  $O(1)$ -factor overhead in running time. Finally, it will be useful to state the following lemma when talking about separators in a graph with unique shortest paths:

► **Lemma 3.** *Let  $u, v, x, y \in V(G)$ . Then  $u \rightsquigarrow v$  and  $x \rightsquigarrow y$  share at most one edge-maximal subpath.*

**Proof.** Assume that  $x \rightsquigarrow y$  intersects  $u \rightsquigarrow v$  and let  $a$  resp.  $b$  be the first resp. last intersection along  $u \rightsquigarrow v$ . Since  $G$  is undirected, uniqueness of shortest paths implies that  $a \rightsquigarrow b$  is a subpath of  $u \rightsquigarrow v$  shared by  $x \rightsquigarrow y$ . ◀

### Edge orderings, path turns and path intersections

For an edge  $e = uv$  of a planar embedded graph  $H$ , we let  $\langle_e^H$  be the clockwise ordering of edges of  $H$  incident to  $v$  starting at  $e$  (ignoring edge orientations). Hence  $\langle_e^H$  is a strict total order of these edges and  $e$  is the first edge in this order.

For vertices  $u, v \in V(H)$ ,  $x \in V(u \rightsquigarrow v) \setminus \{u, v\}$  and  $y \in V(H) \setminus V(u \rightsquigarrow v)$ , let  $pq$  be the last edge shared by  $u \rightsquigarrow v$  and  $x \rightsquigarrow y$ . Furthermore let  $qz$  resp.  $qz'$  be the edge following  $pq$  in the traversal of  $u \rightsquigarrow v$  and  $x \rightsquigarrow y$ , respectively. We say that  $x \rightsquigarrow y$  *emanates from the left* of  $u \rightsquigarrow v$  if  $qz' \prec_{pq}^H qz$ , and otherwise it *emanates from the right*. We dually say that  $y \rightsquigarrow x$  *intersects  $u \rightsquigarrow v$  from the left (right)* if  $x \rightsquigarrow y$  *emanates from the left (right)*.

Given a face  $f$  of  $H$ , vertices  $u \in V(f)$ , and  $v, v' \in V$ , let  $H'_f$  be a copy of  $H$  with an artificial vertex  $f^*$  embedded in the interior of  $f$  along with an additional edge  $f^*u$ . Define the paths  $p_v = f^*u \circ u \rightsquigarrow_{H'_f} v$  and  $p_{v'} = f^*u \circ u \rightsquigarrow_{H'_f} v'$  and assume that neither path is a prefix of the other. By assumption and Lemma 3,  $p_v$  and  $p_{v'}$  share exactly one edge-maximal subpath  $f^* \rightsquigarrow x$ . We say that  $u \rightsquigarrow_H v$  makes a *left turn* w.r.t  $u \rightsquigarrow_H v'$  from  $f$  if  $x \rightsquigarrow v$  emanates from the left of  $p_v$ , and otherwise it makes a *right turn*; we will omit mention of  $f$  when the context is clear. Note that the notion of a turn is symmetric in the sense that  $u \rightsquigarrow_H v$  makes a left turn w.r.t  $u \rightsquigarrow_H v'$  iff  $u \rightsquigarrow_H v'$  makes a right turn w.r.t  $u \rightsquigarrow_H v$ .

## 2.2 Voronoi Diagrams

The definitions in this subsection will largely be made in a manner identical to those of [7], but are included as they are essential to a point location structure which will be presented in Section 4. Given a planar graph  $G = (V, E, \omega)$ ,  $S \subseteq V$ , the *Voronoi diagram of  $S$  in  $G$* , denoted by  $VD(S)$  in  $G$  is a partition of  $V$  into disjoint sets,  $Vor(u)$ , referred to as *Voronoi cells*, with one such set for each  $u \in S$ . The set  $Vor(u)$  is defined to be  $\{v \in V \mid d(u, v) < d(u', v) \text{ for all } u' \in S \setminus \{u\}\}$ , that is the set of vertices that are closer to  $u$  than any other site in terms of  $d(\cdot, \cdot)$ . We shall simply write  $VD$  when the context is clear.

It will also be useful to work with a dual representation of Voronoi diagrams. Let  $VD_0^*$  be the subgraph of  $G^*$  s.t.  $E(VD_0^*)$  is the subset of edges of  $G^*$  where  $uv^* \in VD_0^*$  iff  $u$  and  $v$  belong to different Voronoi cells in  $VD$ . Let  $VD_1^*$  be the graph obtained by repeatedly

contracting edges of  $VD_0^*$  incident to degree 2 vertices until no such vertex remains<sup>2</sup>. We refer to the vertices of  $VD_1^*$  as *Voronoi vertices*, and each face of the resulting graph  $VD_1^*$  can be thought of as corresponding to some Voronoi cell in the sense that its edges enclose exactly the vertices of some Voronoi cell in the embedding of the primal. We shall restrict ourself to the case in which all vertices of  $S$  lie on a single face  $h$ . In particular,  $h^*$  is a Voronoi vertex, since each site is a vertex on the boundary of  $h$  in the primal. Finally, let  $VD^*$  be the graph obtained by replacing  $h^*$  with multiple copies, one for each edge. We note that since there are  $|S|$  Voronoi sites (and thus faces in  $VD^*$ ), the number of Voronoi vertices in  $VD^*$  is  $O(|S|)$  due to Euler's formula. Furthermore, [7] show that when assuming unique shortest paths and a triangulated input graph,  $VD^*$  is a ternary tree. It follows that the primal face corresponding to a Voronoi vertex  $f^*$  consists of exactly three vertices, each belonging to different Voronoi cells. We refer to the number of sites in a Voronoi diagram as its *complexity*.

Finally, they also note that a *centroid decomposition*,  $T^*$ , can be computed from  $VD^*$  s.t. each node of  $T^*$  corresponds to a Voronoi vertex  $f^*$  and the children of  $f^*$  in  $T^*$  correspond to the subtrees resulting from splitting the tree at  $f^*$ , and s.t. the number of vertices of each child is at most a constant fraction of that of the parent. We remark that  $VD^*(S)$  can be computed by connecting all sites to a super-source and running a single-source shortest paths algorithm, and its centroid decomposition in time proportional to  $|V(VD^*(S))|$ .

### 2.3 Separators and decompositions

In the following, we will outline the graph decomposition framework used by our construction. As part of the preprocessing step, we will recursively partition the input graph using balanced fundamental cycle separators until the resulting graphs are of constant size. We shall associate with the recursive decomposition of  $G$  a binary decomposition tree,  $\mathcal{T}$ , which is a rooted tree whose nodes correspond to the regions of the recursive decomposition of  $G$ . We will refer to nodes and their corresponding regions interchangeably. The root node of  $\mathcal{T}$  corresponds to all of  $G$ . The following lemma states the invariants of the decomposition that will be used in our construction:

► **Lemma 4.** *Let  $G = (V, E, \omega)$  be an undirected, planar embedded, edge-weighted, triangulated graph and let  $T$  be a spanning tree<sup>3</sup> of  $G$ . Then there is an  $\tilde{O}(n)$  time algorithm that returns a binary decomposition tree  $\mathcal{T}$  of  $G$  s.t.*

1. *for any non-leaf node  $G' \in \mathcal{T}$ , its children  $G'_l$ , respectively  $G'_r$ , corresponds to the non-strict interior, respectively non-strict exterior of some fundamental cycle in  $G'$  w.r.t.  $T$ ,*
2. *for any child node, it contains at most a constant fraction of the faces of its parent,*
3. *for any leaf node it contains a constant number of faces of  $G$ ,*
4. *for all nodes at depth  $i$ ,  $\mathcal{T}_i$ ,  $\sum_{G' \in \mathcal{T}_i} |V(G')| = O(n)$*

Properties 1-3 follow from recursively applying a classic linear time algorithm for finding fundamental cycles. Property 4 follows from employing standard techniques that involve contracting degree-two vertices of the separators found at each level of recursion and weighting the resulting edges accordingly. This transformation results in a decomposition where the sum of faces of all regions at any level is preserved. We stress that our construction does not rely on the usual sparse simple cycle separators (of size  $O(\sqrt{n})$ ) but rather fundamental cycle separators of size  $O(n)$ .

<sup>2</sup> Formally, given a degree 2 vertex  $v$  with incident edges  $vw, vv'$ , we replace these edges by  $wv'$ , concatenate their arcs and embed  $wv'$  using this arc in the embedding.

<sup>3</sup> For our purposes, the spanning tree will be a shortest path tree.

### 3 The vertex labeled distance oracle

In this section we describe our reduction which shows our main result. The reduction can be described assuming Lemma 4 and the existence of the point location structure which we will state in the following lemma, the proof of which is deferred to Section 4:

► **Lemma 5.** *Let  $G = (V, E, \omega)$  be an undirected, planar embedded, edge-weighted graph with labeling  $l : V \rightarrow L$  and let  $p$  be a shortest path in  $G$ . There is a data structure  $O_{G,p}$  with  $O(|V| \log |V|)$  space which given  $u \in V$  and  $\lambda \in L$  returns a subset  $C \subset V$  of constant size, s.t. if  $v$  is the vertex with label  $\lambda$  closest to  $u$  and  $v \rightsquigarrow u$  intersects  $p$ , then  $v \in C$ . Each such query takes time at most  $O(\log^2 |V|)$ .*

#### 3.1 Preprocessing

Given the input graph  $G = (V, E, \omega)$ , the preprocessing phase initially computes the decomposition tree,  $\mathcal{T}$ , of Lemma 4. Associated with each non-leaf node  $G' \in \mathcal{T}$  is a fundamental cycle separator of  $ab \in E(G')$  w.r.t. the shortest path tree  $T$  rooted at some  $c \in V(G')$ . For such a  $G'$  we shall refer to  $S_1(G') = c \rightsquigarrow_{G'} a$  and  $S_2(G') = c \rightsquigarrow_{G'} b$ . Thus the fundamental cycle separator is given by  $S_1(G') \circ ab \circ S_2(G')$ . The preprocessing phase proceeds as follows: For all non-leaf nodes  $G' \in \mathcal{T}$ , compute and store data structures  $O_{G',S_1(G')}$  and  $O_{G',S_2(G')}$  of Lemma 5. Finally, a distance oracle  $D$  with  $O(s(|V|))$  space capable of reporting vertex-to-vertex shortest path distances in time  $O(t(|V|))$  is computed for  $G$  and stored alongside the decomposition tree and the point location structures.

#### Space complexity

The decomposition tree  $\mathcal{T}$  can be represented with  $O(|V| \log |V|)$  space and  $D$  with  $O(s(n))$  space. For each node  $G' \in \mathcal{T}$ , we store data structures  $S_1(G')$  and  $S_2(G')$ , so by Lemma 4 and 5, we get

$$\sum_{i=0}^{\infty} \sum_{G' \in \mathcal{T}_i} |V(G')| \log |V(G')| = \sum_{i=0}^{c \log n} O(|V| \log |V|) = O(|V| \log^2 |V|)$$

for a total space complexity of  $O(s(|V|) + |V| \log^2 |V|)$ .

#### 3.2 Query

Let  $G' \in \mathcal{T}$  and consider the query  $\mathbf{d}_{G'}(u, \lambda)$ . If  $G'$  is a leaf node, the query is resolved in time  $O(t(n))$  by querying  $D$  once for each vertex of  $G'$ . If  $G'$  is a non-leaf node, the query is handled as follows: First, data structures  $O_{G',S_1(G')}$  and  $O_{G',S_2(G')}$  are queried with  $u$  and  $\lambda$ , resulting in two “candidate sets”,  $C_1$  and  $C_2$ , one for each query. By Lemma 5,  $C_1 \cup C_2$  contains the nearest vertex with label  $\lambda$  for which  $u \rightsquigarrow_{G'} v'$  intersects either  $S_1$  or  $S_2$  if such a vertex exists. Compute  $d_{G'} = \min \{\mathbf{d}_G(u, c) \mid c \in C_1 \cup C_2\} \cup \{\infty\}$  by querying  $D$  once for each vertex of  $C_1 \cup C_2$ . The query then recursively resolves  $d_{G''} = \mathbf{d}_{G''}(u, \lambda)$  where  $G''$  is a child of  $G'$  in  $\mathcal{T}$  containing  $u$ . Finally, the query returns  $\min \{d_{G'}, d_{G''}\}$ .

#### Correctness

Denote by  $v$  the vertex of  $G$  with label  $\lambda$  nearest to  $u$  in  $G'$ , and consider the case in which  $u \rightsquigarrow_{G'} v$  intersects  $S_1(G')$  or  $S_2(G')$ . In this case,  $v \in C$  by Lemma 5 and  $C \neq \emptyset$ , so

$$d_{G'} = \min \{\mathbf{d}_G(u, c) \mid c \in C\} = \mathbf{d}_G(u, v) = \mathbf{d}_{G'}(u, v) = \mathbf{d}_{G'}(u, \lambda) \leq d_{G''}$$

■ **Algorithm 1** Query procedure for the distance oracle.

---

```

1: procedure QUERY( $u, \lambda, G'$ )
2:   if  $G'$  is a leaf node in  $\mathcal{T}$  then
3:     return  $\min \{d_{G'}(u, v) \mid v \in V(G') \text{ and } l(v) = \lambda\}$ 
4:   else
5:      $C_1 \leftarrow O_{G', S_1(G')}(u, \lambda)$ ;  $C_2 \leftarrow O_{G', S_2(G')}(u, \lambda)$ 
6:      $G'' \leftarrow$  A child of  $G'$  in  $\mathcal{T}$  containing  $u$ 
7:      $d_{G'} \leftarrow \min \{d_G(u, c) \mid c \in C_1 \cup C_2\} \cup \{\infty\}$ 
8:      $d_{G''} \leftarrow$  QUERY( $u, \lambda, G''$ )
9:     return  $\min \{d_{G'}, d_{G''}\}$ 

```

---

with the inequality following from definition of  $v$ . Note that in case  $u$  is a vertex of either  $S_1$  or  $S_2$ , the correct estimate is returned at the current level, but for a simpler description, the recursion proceeds anyways. Otherwise  $u \rightsquigarrow_G v$  intersects neither  $S_1$  and  $S_2$  in which case, the path must be fully contained in the (unique) child node,  $G''$ , of  $G'$  containing  $u$ . In this case, the query reports  $d_{G''} = \mathbf{d}_{G''}(u, \lambda) = \mathbf{d}_{G''}(u, v) \leq d_{G'}$ , showing the correctness.

### Time complexity

At each level of the recursion,  $O_{G', S_1(G')}$  and  $O_{G', S_2(G')}$  are queried in time  $O(\log^2 |V|)$ . Furthermore,  $D$  is queried  $|C| = O(1)$  times in total time  $O(1) \cdot O(t(|V|)) = O(t(|V|))$ . By Lemma 4, the query is recursively resolved on a problem instance which is a constant fraction smaller at each level of recursion, giving rise to the recurrence relation  $T(n) = T(n/a) + O(t(n) + \log^2 n)$ . When  $G'$  is a leaf node, then by Lemma 4,  $G'$  consists of a constant number of faces, described by the base case  $T(n) = O(t(n))$  when  $n \leq b$  for sufficiently small  $b$ . It is easily verified that a solution to the recurrence is bounded by  $O(\log^3 n + t(n) \log n)$ . This shows the main theorem, and the rest of this paper is devoted to proving Lemma 5.

## 4 The point location data structure

Our point-location data-structure uses techniques similar to those of [7] for point location in additively weighted Voronoi diagrams, but with some crucial differences in order to save space.

Both structures rely on being able to determine left/right turns of shortest paths in shortest path trees rooted at sites in  $G$ , but to facilitate this, the data structure of [7] explicitly stores an (augmented) shortest path tree rooted at each site as well as a data structure for answering least common ancestor (LCA) queries. The point location structure thus requires  $\Theta(|S|n)$  space where  $S$  is the number of sites, and since  $S$  may be large as  $\Theta(\sqrt{n})$  (corresponding to the size of a sparse balanced separator in a planar graph), this translates to  $\Theta(n^{3/2})$  space for their problem. This will not work in our case since the number of sites can in fact be as high as  $\Theta(n)$ , leading to a quadratic space bound.

The second issue with applying the techniques from [7] directly to our setting, is that it requires us to store a Voronoi diagram for each label, for each shortest path. Each vertex of the path separator would then be a site in the stored Voronoi diagram but as each separator may be large, i.e.  $\Theta(n)$ , we may use as much as  $\Theta(n|L|)$  space over *all* labels of  $L$  for a single separator. What we need is for the number of sites involved for a label  $\lambda$  to be proportional to the number of vertices with label  $\lambda$ ; this would give a near-linear bound on the number of sites when summing over all  $\lambda \in L$  across all levels of the recursive decomposition. We address these issues in the following sections.

## 4.1 MSSP structure

To compactly represent shortest path trees, our point location structure uses an augmented version of the multiple-source shortest-path (MSSP) data structure of Klein [10]. It cleverly uses the persistence techniques of [5] in conjunction with top trees [1] to obtain an implicit representation of shortest path trees rooted at each site. Top-trees allow for shortest path distance queries and least-common ancestor (LCA) queries in time  $O(\log n)$  per query while using  $O(n \log n)$  space, and can easily be augmented to support turn queries, as we shall see shortly. To be used as a black box, the MSSP structure relies on being initialized from a face of  $G$ . In our construction, we wish to use it for querying left/right turns of paths and distances from vertices residing on shortest paths of fundamental cycle separators, and thus some further preprocessing is required. The guarantees of the augmented MSSP structure used for the point location structure are summarized in the following lemma:

► **Lemma 6.** *Let  $G = (V, E, \omega)$  be an edge-weighted planar graph,  $f$  be a face of  $G$  and let  $T_u$  denote the shortest path tree rooted at  $u$ . Then there exists a data structure  $\text{MSSP}(G, f)$  with  $O(n \log n)$  space which given  $u \in V(f)$  and  $c, v \in V$  supports queries*

1.  $\text{DIST}(u, v)$ : report  $\mathbf{d}_G(u, v)$ ,
2.  $\text{LCA}(u, c, v)$ : report the least common ancestor of  $v, c$  in  $T_u$ ,
3.  $\text{TURN}(u, c, v)$ : report whether  $u \rightsquigarrow_{T_u} c$  makes a left or right turn w.r.t.  $u \rightsquigarrow_{T_u} v$  or if one is a prefix of the other.

*in time  $O(\log n)$  per query. The data structure can be preprocessed in  $O(n \log n)$  time.*

Descriptions of  $\text{DIST}$  and  $\text{LCA}$  are available in [10] and [1], and a description of how to implement  $\text{TURN}$  is provided in Appendix A in terms of the vocabulary and interface specified in [1] for completeness. A top-tree representing any shortest path tree rooted at a vertex on  $f$  can be accessed in time  $O(\log n)$  by using persistence in the MSSP structure. Lemma 6 then readily follows from applying the bound of Lemma 13 in Appendix A.

## 4.2 Label sequences

To address the second issue, we first need to make the following definition and state some of its properties when applied in the context of planar graphs:

► **Definition 7.** *Let  $G = (V, E)$  be a graph,  $p = p_1, \dots, p_k$  a sequence of vertices and  $S \subseteq V$ . The label-sequence of  $p$  w.r.t.  $S$  is a sequence  $M_{G,S,p} \in S^k$  satisfying  $M_{G,S,p}(i) = \arg \min_{s \in S} \text{dist}_G(s, p_i)$ . The alternation number on  $p$  w.r.t.  $S$  in  $G$  is defined as  $|M_{G,S,p}| = \sum_{i=1}^{k-1} [M_{G,S,p}(i) \neq M_{G,S,p}(i+1)]$ .*

When  $G$ ,  $S$  and  $p$  are clear from the context, we shall simply write  $M$ , and also note that the sequence is well-defined due the tie-breaking scheme chosen in the preliminaries. The alternation number can be thought of as the number of times consecutive vertices on  $p$  change which vertex they are closest to among  $S$  when “moving along”  $p$ .

When  $G$  is an undirected planar graph and  $p$  is a shortest path in  $G$ , it can be observed<sup>4</sup> that  $M$  is essentially a Davenport-Schinzel sequence of order 2, and it immediately follows that the alternation number is “small” in the sense it is proportional to  $S$  while being agnostic towards the length of  $p$  altogether.

---

<sup>4</sup> We thank the anonymous reviewer for this observation which saved a tedious proof.

■ **Figure 1** Illustration of the proof of Lemma 10. The concatenation of  $u \rightsquigarrow v_{i_1}$ ,  $v_{i_1} \rightsquigarrow v_{i_3}$ , and the reverse of  $u \rightsquigarrow v_{i_3}$  forms a cycle  $C$  and  $v \rightsquigarrow v_{i_2}$  intersects  $u \rightsquigarrow v_{i_3}$  in  $x$ . Note that w.l.o.g.  $C$  is not necessarily simple, that  $v \rightsquigarrow v_{i_2}$  may intersect the cycle more than once and that  $v$  may be a vertex of  $C$ .

► **Definition 8** (Davenport-Schinzel [4]). A sequence  $u_1, u_2, \dots, u_k$  over an alphabet  $\Sigma$  on  $n$  symbols is said to be a  $(n, s)$ -Davenport-Schinzel sequence if

1.  $u_i \neq u_{i+1}$  for all  $1 \leq i < k$  and
2. There do not exist  $s + 2$  indices  $1 \leq i_1 < i_2 < \dots < i_{s+2} \leq k$  for which  $u_{i_1} = u_{i_3} = \dots = u_{i_{s+1}} = u$  and  $u_{i_2} = u_{i_4} = \dots = u_{i_{s+2}} = v$  for  $u \neq v \in \Sigma$ .

► **Lemma 9** (Davenport-Schinzel [4]). Let  $U$  be a  $(n, 2)$ -Davenport-Schinzel sequence of length  $m$ . Then  $|U| \leq 2n - 1$ .

For a sequence of  $\mathcal{S} = u_1, u_2, \dots, u_k$  over an alphabet  $\Sigma$ , the *contraction* of  $\mathcal{S}$  is the subsequence obtained from  $\mathcal{S}$  by replacing every maximal substring  $s, s, \dots, s$  of  $\mathcal{S}$  consisting of identical symbols  $s$  by a single occurrence of  $s$ . As an example with  $\Sigma = \{0, 1, 2\}$ , the contraction of  $0, 0, 1, 2, 2, 1, 1, 0, 1, 0, 0, 2$  is  $0, 1, 2, 1, 0, 1, 0, 2$ .

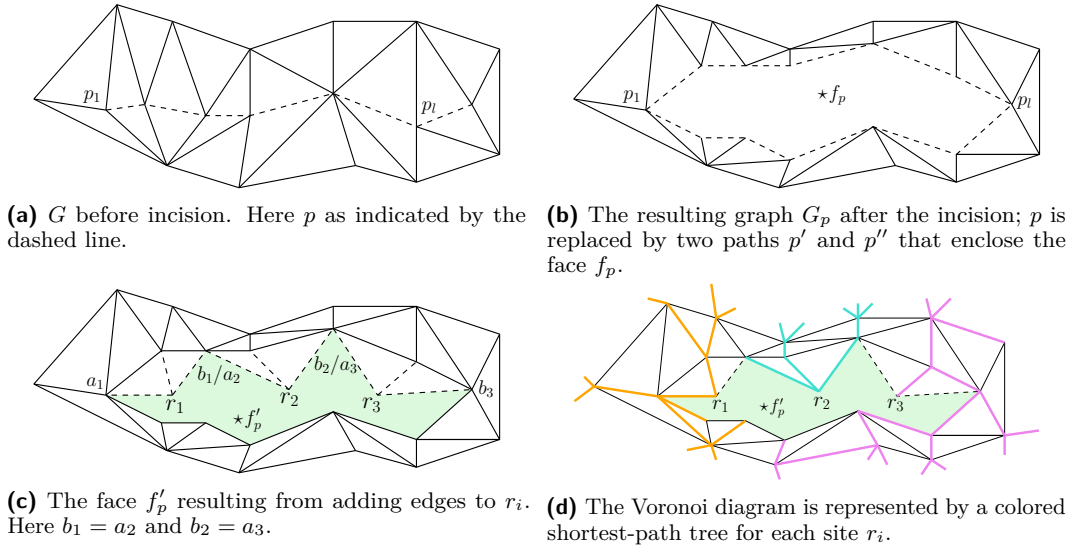

► **Lemma 10.** Let  $G$  be an undirected, weighted planar graph, let  $S \subseteq V$ , and let  $p$  be a shortest path of  $G$  contained in (the boundary of) a face of  $G$ . Then the contraction of  $M$  is a  $(|S|, 2)$ -Davenport-Schinzel sequence.

**Proof.** Define  $v_1, \dots, v_k = p$  and assume for the sake of contradiction that for some  $1 \leq i_1 < i_2 < i_3 < i_4 \leq k$  and  $u, v \in S$  with  $u \neq v$ , it holds that  $u = M(i_1) = M(i_3)$  and  $v = M(i_2) = M(i_4)$ . Then the concatenation of  $u \rightsquigarrow v_{i_1}$ ,  $v_{i_1} \rightsquigarrow v_{i_3}$ , and the reverse of  $u \rightsquigarrow v_{i_3}$  forms a cycle. Thus, either  $v \rightsquigarrow v_{i_2}$  intersects  $u \rightsquigarrow v_{i_1} \cup u \rightsquigarrow v_{i_3}$  or  $v \rightsquigarrow v_{i_4}$  intersects  $u \rightsquigarrow v_{i_1} \cup u \rightsquigarrow v_{i_3}$ ; see Figure 1a and 1b. By symmetry, we only need to consider the former case. If  $v \rightsquigarrow v_{i_2}$  intersects  $u \rightsquigarrow v_{i_3}$  in some vertex  $x$  then  $v \rightsquigarrow x$  has the same weight as  $u \rightsquigarrow x$ . By the “closer than”-relation,  $u = M(i_3) = M(i_2) = v$ , contradicting our assumption that  $u \neq v$ . A similar contradiction is obtained if  $v \rightsquigarrow v_{i_2}$  intersects  $u \rightsquigarrow v_{i_1}$ . ◀

► **Corollary 11.** Let  $G, S$  and  $p$  be as in Lemma 10. Then  $|M_{G,S,p}| = O(|S|)$ .

We remark that  $M$  can be readily computed in polynomial time by adding a super-source connected to each vertex of  $S$  and running an SSSP algorithm. Furthermore  $M$  can be represented with  $O(S)$  space, by storing only the indices for which  $M(i) \neq M(i + 1)$  and  $M(i)$  for each such index.

We will now describe how to achieve  $O(n)$  space for storing Voronoi diagrams for all labels  $\lambda \in L$  at any level of the recursive decomposition. We do so by modifying the preprocessing steps and query scheme of [7] in a manner suitable for application of Lemma 10 and Corollary 11.

■ **Figure 2** Preprocessing steps for the point-location structure.

### 4.3 Preprocessing

Let us briefly recall the statement of Lemma 5; that is, we let  $G$  be an undirected, edge-weighted, planar embedded graph with associated labeling  $l : V \rightarrow L$  and let  $p = p_1 \rightsquigarrow p_k$  be a shortest path in  $G$ . Given a query  $(u, \lambda) \in V \times L$ , we want to identify a small “candidate” set of vertices  $C \subseteq V$  such that if  $v$  is the vertex with label  $\lambda$  closest to  $u$  and  $u \rightsquigarrow v$  intersects  $p$ , then  $v \in C$ .

Here, we first describe how to compute a data structure which provides the guarantees of Lemma 5, but restricts itself to the case only where  $u \rightsquigarrow v$  intersects  $p$  from the left. The description of the data structure for handling paths that intersect  $p$  from the right is symmetric (e.g. by swapping the endpoints of  $p$ ). Lemma 5 thus readily follows from the existence of such structures.

First, a copy,  $G_p$ , of  $G$  is stored and an incision is added along  $p$  in  $G_p$ . This results in a planar embedded graph  $G_p$ , which has exactly one more face than  $G$ . Define by  $p' = p'_1, \dots, p'_l$  and  $p'' = p''_1, \dots, p''_l$  the resulting paths along the incision, where  $p'_1 = p'_l$  and  $p''_1 = p''_l$ . We denote by  $f_p$  the face whose boundary vertices are  $V(p') \cup V(p'')$ . An illustration of this is provided in Figure 2a and 2b.

Next, the MSSP data structure of Lemma 6,  $MSSP(G_p, f_p)$ , is computed and stored as part of the point-location data structure. This structure will be used for the point location query.

#### Centroid decompositions of Voronoi diagrams

The following preprocessing is now done for *each* label  $\lambda \in L$ : First a copy,  $G_p^\lambda$ , of  $G_p$  is made. Next,  $M_{G_p, S_\lambda, p'}$  is computed for  $S_\lambda = \{v \in V \mid l(v) = \lambda\}$ . For convenience we assume that  $M(0) = \text{NIL}$ . The preprocessing phase now consists of modifying  $G_p^\lambda$  before computing the Voronoi diagram and the associated centroid decomposition associated with  $\lambda$  as follows: For  $i \leftarrow 1, \dots, l$ , whenever  $M(i) \neq M(i-1)$ , a new vertex is added to  $G_p^\lambda$  and embedded in  $f_p$  along the curve formed by the deleted arc of the embedding of  $p$ . Denoting by  $r_i$  the most recently added vertex after iteration  $i$ , edge  $p'_i r_i$  with  $\omega(p'_i r_i) = d_G(M(i), p'_i)$  is added to  $G_p^\lambda$

and embedded for all  $i$ . Once again, it is fairly easy to see that  $G_p^\lambda$  is planar embedded. See Figure 2c for an illustration of this. Denote by  $a_i$  and  $b_i$  the endpoints of the first and last edges added incident to  $r_i$  (w.r.t. the order in which they were added). Denote by  $f'_p$  that has  $\{r_i, a_i, b_i \mid 1 \leq i \leq l\} \cup V(p'')$  as its boundary vertices. Now the Voronoi diagram, its dual and subsequently its corresponding centroid decomposition,  $T_{p,\lambda}^*$ , is computed in (the now modified)  $G_p^\lambda$  using  $R = \{r_i \mid 1 \leq i \leq l\}$  as Voronoi sites, see Figure 2d. The intuition is that each site in  $R$  corresponds to a contiguous subsequence  $M(k), \dots, M(l)$  of  $M$  for which  $M(j) = M(j+1) = v$  where  $v$  is the vertex with label  $\lambda$  closest to  $p'_j$  for  $k \leq j < l$ . This implies that the number of sites is proportional to the number of vertices with label  $\lambda$  instead of the length of the original separator  $p$ : By Lemma 11,  $|M| = O(|S_\lambda|)$  and since  $|R| = |M|$  it follows that  $|R| = O(|S_\lambda|)$  bounds the complexity of  $T_{p,\lambda}^*$ , which is stored as part of the data structure. As aforementioned, each centroid  $c \in T_{p,\lambda}^*$  corresponds to some degree three Voronoi vertex,  $f_c^*$ , with vertices,  $\{x_1, x_2, x_3\}$  in the corresponding primal face  $f_c$  s.t. each  $x_j$  belongs to a different Voronoi site  $r_{i_j}$  for  $j \in \{1, 2, 3\}$ . For each such  $j$ , the centroid  $c$  stores a pointer to its corresponding face  $f_c$ , the first vertex  $p_{k_j}$  of  $p'$  on  $r_{i_j} \rightsquigarrow_{G_p'} x_j$  and the weight  $\omega(p_{k_j} r_{i_j})$ .

### Space complexity

The space used for storing the MSSP structure is  $O(|V| \log |V|)$  by Lemma 6. For each centroid, we store a constant amount of data, so the space required for storing the centroid decompositions is

$$\sum_{\lambda \in L} O(1) \cdot |T_{p',\lambda}^*| = \sum_{\lambda \in L} O(|S_\lambda|) = O(V)$$

since  $S_\lambda \cap S_{\lambda'} = \emptyset$  for  $\lambda \neq \lambda' \in L$  as each vertex has exactly one label. The total space used is thus  $O(|V| \log |V|)$ .

## 4.4 Handling a point location query

We now show how to handle a point location query. Note that in the following, we can assume that the vertices of  $p'$  appear in increasing order of their indices when traversing the boundary of  $f_p$  in a clockwise direction. Recall that given  $u \in V$  and  $\lambda \in L$ , we wish to find a subset  $C \subset V$  of constant size, s.t. if  $v$  is the closest vertex with label  $\lambda$  where  $u \rightsquigarrow v$  intersects  $p$  from the left, then  $v \in C$ . The query works by identifying a subset  $P \subseteq V(p')$  s.t. for some  $p'_k \in P$  it holds that  $M_{G_p, S_\lambda, p'}(k) = v$ . We first show how to identify the subset by recursively querying the centroid decomposition  $T_{p,\lambda}^*$  according to the following lemma, which we note is modified version of the query in [7]:

► **Lemma 12.** *Given a query  $(u, \lambda) \in V \times L$ , consider the centroid decomposition tree  $T_{p,\lambda}^*$  computed from  $G_p^\lambda$  in the preprocessing. Let  $c$  be a centroid  $c \in T_{p,\lambda}^*$  corresponding to some Voronoi vertex,  $f_c^*$ , with associated primal triangle containing vertices  $\{x_0, x_1, x_2\} = V(f_c)$  where  $x_j$  belongs to the Voronoi cell of  $r_{i_j}$  for  $j \in \{0, 1, 2\}$  and  $i_0 < i_1 < i_2$ . Furthermore let  $e_j^*$  be the dual edge incident to  $f_c^*$ , s.t.  $e_j = x_j x_{(j+1) \bmod 3}$ , let  $p_{k_j}$  be the successor of  $r_{i_j}$  on  $r_{i_j} \rightsquigarrow_{G_p^\lambda} x_j$ , let  $P_j = p_{k_j} \rightsquigarrow_{G_p} u$ , and let  $T_j^*$  be the subtree of  $T_{p,\lambda}^*$  attached to  $c$  by  $e_j^*$  for  $j \in \{0, 1, 2\}$ . Finally, let  $j^* = \arg \min_{j \in \{0, 1, 2\}} \{\mathbf{d}_{G_p}(p_{k_j}, u) + \omega(r_{i_j} p_{k_j})\} = \arg \min_{j \in \{0, 1, 2\}} \{\mathbf{d}_{G_p^\lambda}(r_{i_j}, u)\}$ . Then*

1. *If  $p_{k_{j^*}} \rightsquigarrow_{G_p} u$  emanates from the left of  $P_{j^*}$  or  $u \in P_{j^*}$ , then the site closest to  $u$  in  $G_p^\lambda$  belongs to  $R^- = \{r_{(i_{(j^*-1) \bmod 3}}, \dots, r_{i_{j^*}})\}$  and the second vertex on the shortest path from that site to  $u$  in  $G_p^\lambda$  belongs to  $P^- = \{p_{(i_{(j^*-1) \bmod 3}}, \dots, p_{i_{j^*}})\}$ ; furthermore,  $T_{j^*}^*$  is the centroid decomposition tree for  $G_p^\lambda$  when restricted to shortest paths from sites in  $R^-$  through successors in  $P^-$ .*

■ **Figure 3** Illustration of Lemma 12. The dashed green lines represent Voronoi edges in the centroid decomposition and the red lines the primal shortest paths to the primal vertices of the centroid. In this case,  $j^* = 1$ , so  $u$  is contained in primal faces spanned by the subtree  $T_1^*$  contained in the region highlighted in yellow.

2. otherwise, the site closest to  $u$  in  $G_p^\lambda$  belongs to  $R^+ = \{r_{i_{j^*}}, \dots, r_{i_{(j^*+1) \bmod 3}}\}$  and the second vertex on the shortest path from that site to  $u$  belongs to  $P^+ = \{p_{i_{j^*}}, \dots, p_{i_{(j^*+1) \bmod 3}}\}$ ; furthermore,  $T_{(j^*+1) \bmod 3}^*$  is the centroid decomposition tree for  $G_p^\lambda$  when restricted to shortest paths from sites in  $R^+$  through successors in  $P^+$ .

**Proof.** By symmetry, we only consider the first case since the second case occurs when  $p_{k_{j^*}} \rightsquigarrow_{G_p} u$  emanates from the right of  $P_{j^*}$  and the first case also includes the case where  $u \in P_{j^*}$ .

By the choice of  $j^*$ ,  $p_{k_{j^*}} \rightsquigarrow_{G_p} u$  cannot intersect any of the paths  $P_{j'}$  with  $j' \in \{(j^* - 1) \bmod 3, (j^* + 1) \bmod 3\}$  since these two paths are subpaths of shortest paths from sites  $r_{i_{j'}} \neq r_{i_{j^*}}$  in  $G_p^\lambda$  and we assume unique shortest paths. Let  $x$  be the first vertex of  $p_{k_{j^*}} \rightsquigarrow_{G_p} u$  such that either  $x = u$  or the path emanates from the left of  $P_{j^*}$  at  $x$ . The rest of  $p_{k_{j^*}} \rightsquigarrow_{G_p} u$  following  $x$  will not intersect  $P_{j^*}$  again due to uniqueness of shortest paths. Thus  $u$  belongs to the region of the plane enclosed by paths  $P_{(j^*-1) \bmod 3}$ ,  $P_{j^*}$ , edge  $e_{(j^*-1) \bmod 3}$ , and path  $p_{k_{(j^*-1) \bmod 3}}, \dots, p_{k_{j^*}}$ . Note that  $T_{j^*}^*$  is the subtree of  $T_{p', \lambda}^*$  spanning the primal faces contained in this region. Hence,  $T_{j^*}^*$  is the centroid decomposition tree for  $G_p^\lambda$  when restricted to shortest paths from sites in  $R^-$  through successors in  $P^-$ . ◀

For an illustration of Lemma 12, see Figure 3. The Lemma implies a fast recursive point location scheme. On query  $(u, \lambda)$ , obtain centroid  $c$  from  $T_{p', \lambda}^*$ . Since weights of edges from sites have been precomputed,  $MSSP(G_p, f_p)$  is applied to find  $j^*$ .  $MSSP(G_p, f_p)$  is also used to determine if  $p_{k_{j^*}} \rightsquigarrow_{G_p} u$  emanates from the left of  $P_{j^*}$  and hence whether the first or second case of the lemma applies. The point location structure now recurses on a subset of sites and vertices of  $p'$  and on a subtree of  $T_{p', \lambda}^*$ , depending on which case applies.

The recursion stops when reaching a subtree corresponding to a bisector for two sites. The vertices of  $V$  with label  $\lambda$  corresponding to these two sites are reported as the set  $C$ , yielding the desired bound.

### Time complexity

The  $O(\log^2 |V|)$  query time bound of Lemma 5 follows since there are  $O(\log |V|)$  recursion levels and in each step, a constant number of queries to  $MSSP(G_p, f_p)$  are executed, each taking  $O(\log |V|)$  time.

## A

 Appendix

A description of how to implement TURN in Lemma 6 is provided here in terms of the terminology and the interface specified in [1]. Readers that are not familiar with the terminology and interface pertaining to top-trees are referred to [1].

► **Lemma 13.** *Let  $G = (V, E, \omega)$  be a weighted planar graph, and let  $\mathcal{T}$  be the root-cluster of a top-tree corresponding to some tree  $T$  in  $G$ . Then in addition to DIST and LCA, we can support TURN queries: For  $u, c, v \in V$ , report whether  $u \rightsquigarrow c$  makes a left or right turn w.r.t.  $u \rightsquigarrow_T v$ , or if one is a prefix of the other in time  $O(\log n)$  per query.*

**Proof.** A description of how to perform LCA queries is found in [1]. Assume that  $u, c, v \in T$  and w.l.o.g. that  $u$  is strictly more rootward in  $T$  than  $v$ . First use  $\mathcal{T}$  to determine the LCA  $c'$  of  $(v, c)$ . If  $c'$  is on both  $u \rightsquigarrow c$  and  $u \rightsquigarrow v$  one path is a prefix of the other. Otherwise invoke EXPOSE( $u, c'$ ) and traverse  $\mathcal{T}$  until a leaf of  $\mathcal{T}$  corresponding to the edge,  $e_v \in E(T)$  is reached, which connects  $c'$  to the subtree containing  $v$  in  $T$ . This can be done in time  $O(\log n)$ . The same is done for  $(u, c')$  and  $(c, c')$ , exposing edges  $e_u, e_c \in T$ . Now, if  $e_c = e_v$  or  $e_c = e_u$ ,  $c$  must be on  $u \rightsquigarrow_T v$ . Otherwise it is easily checked, by maintaining a cyclic order of edges in the adjacency list of  $c'$ , in constant time, whether  $e_c$  emanates to the left or right of the subpath  $e_u e_v$  and hence  $u \rightsquigarrow_T v$ . The total time spent is  $O(\log n)$ . ◀

# A Characterization of Individualization-Refinement Trees

**Markus Anders**

**Pascal Schweitzer**

TU Darmstadt, Germany

---

## Abstract

Individualization-Refinement (IR) algorithms form the standard method and currently the only practical method for symmetry computations of graphs and combinatorial objects in general. Through backtracking, on each graph an IR-algorithm implicitly creates an IR-tree whose order is the determining factor of the running time of the algorithm.

We give a precise and constructive characterization which trees are IR-trees. This characterization is applicable both when the tree is regarded as an uncolored object but also when regarded as a colored object where vertex colors stem from a node invariant. We also provide a construction that given a tree produces a corresponding graph whenever possible. This provides a constructive proof that our necessary conditions are also sufficient for the characterization.

## 1 Introduction

The individualization-refinement (IR) framework is a general backtracking technique employed by algorithms solving tasks related to the computation of symmetries of combinatorial objects [16]. These include algorithms computing automorphism groups, isomorphism solvers, canonical labeling tools used for computing normal forms, and to some extent recently also machine learning computations in convolutional neural networks [1,17]. In fact all competitive graph isomorphism/automorphism solvers, specifically NAUTY/TRACES [15,16], BLISS [11,12], SAUCY [8,9], CONAUTO [13,14], and DEJAVU [3,4] fall within the framework. These tools alternate color-refinement techniques (such as the 1-dimensional Weisfeiler-Leman algorithm) with backtracking steps. The latter perform artificial individualization of indistinguishable vertices. This leads to recursive branching and overall to a tree of recursive function calls, the so called IR-tree.

Using clever invariants and heuristics, the tools manage to prune large parts of the IR-tree. Since the non-recursive work is quasi-linear, it has long been known that the number of traversed nodes of the IR-tree is the determining factor in the running time for all the tools (see for example [20, Theorem 9] and [19]). And in fact, the running times of the various tools closely reflect this [4,16]. Indeed, variation in the traversal strategies among the

tools leads to a different number of traversed nodes which in turn leads to different running times. However, explicit bounds that rigorously show asymptotic advantages of randomized traversals over deterministic ones have only recently been obtained [5]. For this, a specific problem – a search problem in trees with symmetries – is defined. It captures precisely the parameters within which IR-algorithms operate.

While these results are quite general within an abstract model, the bounds proven in [5] apply to the search problem in arbitrary trees with symmetries, independent of whether they originate from actual IR-computations or not. Granted, the vast benchmark library of TRACES [15,16] shows that IR-trees come in an abundance of forms and shapes. However, to date there have been no comprehensive results actually analyzing which trees can arise as an IR-tree.

**Contribution.** In this paper we study which trees are IR-trees. Arising from a branching process, all IR-trees are rooted and all inner vertices have at least 2 children. Such trees are called irreducible (or series reduced). Despite a vast variety of IR-trees arising from benchmark libraries, it turns out that not all irreducible trees are IR-trees. However, we can give a full, constructive characterization of IR-trees.

► **Theorem 1.** *An irreducible tree is an IR-tree if and only if there is no node that has exactly two children of which exactly one is a leaf.*

To prove the theorem we first provide and justify necessary conditions for a tree to be an IR-tree. We then prove that, indeed, these conditions are sufficient by providing graphs on which the execution of an IR-algorithm yields the desired tree. In fact, our proof is constructive, meaning that we obtain an algorithm with the following property. Given a tree  $T$  satisfying the necessary conditions, the algorithm produces a graph whose IR-tree is  $T$ .

As we describe in our definition of IR-trees in Section 2, the trees are naturally associated with a coloring of the vertices. This coloring is a crucial component that is related to the automorphism group structure of the graph. Our characterization also fully describes how color classes may be distributed in a given tree. It turns out that there are several simple restrictions, in particular for vertices that have precisely two children, but apart from that all colorings can be realized and in particular any number of symmetries can be ensured (see Section 4).

Our characterization provides a fundamental argument transferring the analysis of abstract tree traversal strategies performed in [5] to backtracking trees of IR-algorithms on actual instances. Specifically, we may conclude that the abstract trees used for the lower bounds of probabilistic algorithms in [5] indeed appear as IR-trees. However, interestingly, the abstract trees used for the lower bounds of deterministic algorithms (Theorem 13, [5]) are not IR-trees. In fact these trees have nodes with two children, one child that is a leaf and another that is not. This breaks the necessary conditions as laid out by Theorem 1. Fortunately, it also immediately follows from our results that a slight modification can rectify this: by simply replacing the respective leaves with inner nodes that have two attached leaves, the trees become actual IR-trees, due to our characterization. Overall, we therefore prove that the lower bounds of [5] hold true in the IR-paradigm.

**Cell Selectors and Invariants.** Formally, the IR-paradigm allows for different design choices in some of its components. For most of these, competitive practical solvers actually make very similar choices: the refinement is always *color refinement* and solvers commonly choose

as their pruning invariant (essentially) the so-called *quotient graph*. The way in which the actual implementations differ from color refinement and quotient graphs is usually only in minor details and done to achieve practical speed-ups. This only leads to a slightly weaker refinement and invariants in some specific cases. In this paper, we therefore comply with these common design choices.

Many other design choices, such as *how* IR-trees are traversed, have no effect on the characterization of the IR-trees themselves.

There is however one integral design choice where competitive IR-solvers do indeed vary in a way that affects which trees are IR-trees, namely the so-called *cell selectors*. We should emphasize that Theorem 1 only says that for the trees satisfying the necessary conditions there is some cell selector for which the graph is an IR-tree.

However, we can also say something about specific cell selectors. Considering the characterization for a *given* cell selector, there are two possibilities: either, fewer trees turn out to be IR-trees or the same characterization applies. We can use our results to argue that for some cell selectors that are used in practice our necessary conditions are sufficient, while for others they are not (see Section 5 for a discussion).

**Techniques.** Many properties of a graph, e.g. symmetries, are directly tied to properties of its IR-tree. When modeling a graph that is supposed to produce a particular IR-tree, two major difficulties arise, roughly summarized as follows:

1. The effect of color refinement on the graph needs to be kept under control.
2. The shape of the IR-tree may dictate that symmetries must be simultaneously represented in distinct parts of the graph.

We resolve these issues using various gadget constructions specifically crafted for this purpose. We introduce *concealed edges*, which allow us to precisely control the point in time at which the IR-process is able to see a certain set of edges and thus color refinement to take effect (resolving issue (1)). By combining concealed edges with gadgets enforcing particular regular abelian automorphism groups we can synchronize symmetries across multiple branches of the tree (resolving issue (2)).

Here, as the main tool we show the following. As an additional restriction, which stems from the structure of IR-trees, we consider only trees where all leaves can be mapped to the same number of other leaves via symmetries (i.e., under automorphisms all *leaf orbits* have the same size). We show that each such tree  $T$  can be embedded into a graph  $H_T$ , such that  $H_T$  restricts the symmetries of  $T$  in a particular way. Intuitively, we keep just enough symmetries to allow leaves to be mapped to each other whenever this is possible in  $T$ . We thereby effectively couple leaf orbits so that when fixing one leaf, all other leaves are fixed as well. More formally we prove the following theorem.

► **Theorem 2.** *Let  $T$  be a colored tree in which all leaf orbits have the same size. There exists a graph  $H_T$  containing  $T$  as an automorphism invariant induced subgraph so that the action of  $\text{Aut}(H_T)$  is faithful on  $T$  and semiregular on the set of leaves of  $T$ . Moreover,  $\text{Aut}(H_T)$  induces the same orbits on  $T$  as  $\text{Aut}(T)$ .*

Again, we prove the theorem in a constructive manner. All steps can be easily converted into an algorithm that takes as input an admissible (i.e., compatible with our necessary conditions from Section 3) colored tree  $T$  and produces a graph and cell selector with IR-tree  $T$ .

## 2 Individualization-Refinement Trees

Following [16] closely, we introduce the notion of an IR-tree. Algorithms based on the IR-paradigm explore these trees using various traversal strategies to solve graph isomorphism, graph automorphism or canonical labeling problems.

**Colored Graphs.** An undirected, finite graph  $G = (V, E)$  consists of a set of vertices  $V \subseteq \mathbb{N}$  and a set of edges  $E \subseteq V^2$ , where  $E$  is symmetric. Set  $n := |V|$ .

The IR framework relies on coloring the vertices of a graph. A coloring is a surjective map  $\pi: V \rightarrow \{1, \dots, k\}$ . The  $i$ -th *cell* for  $i \in \{1, \dots, k\}$  is  $\pi^{-1}(i) \subseteq V$ . Elements in the same cell are *indistinguishable*. If  $|\pi| = n$ , i.e., whenever each vertex has its own distinct color in  $\pi$ , then  $\pi$  is called *discrete*. A coloring  $\pi$  is *finer* than  $\pi'$  (and  $\pi'$  *coarser* than  $\pi$ ) if  $\pi(v) = \pi(v')$  implies  $\pi'(v) = \pi'(v')$  for all  $v, v' \in V$ . Whenever convenient, we may also view colorings as ordered partitions instead of maps. A colored graph  $(G, \pi)$  consists of a graph and a coloring.

The symmetric group on  $\{1, \dots, n\}$  is denoted  $\text{Sym}(n)$ . An automorphism of a graph  $G$  is a bijective map  $\varphi: V \rightarrow V$  with  $G^\varphi := (\varphi(V), \varphi(E)) = (V, E) = G$ . With  $\text{Aut}(G)$  we denote the automorphism group of  $G$ . For a colored graph  $(G, \pi)$  we require automorphisms to also preserve colors, i.e.,  $\pi(v) = \pi(\varphi(v))$  for all  $v \in V$ . We define the colored automorphism group  $\text{Aut}(G, \pi)$  accordingly.

**Color Refinement and Individualization.** IR-algorithms use a procedure to heuristically refine colorings based on the degree of vertices. The intuition is that if two vertices have different degree, then they can not be mapped to each other by an automorphism. We assign vertices of different degrees distinct colors to indicate this phenomenon. This process is iterated using color degrees: for example, two vertices can only be mapped to each other if they have the same number of neighbors of a particular color  $i$ . Therefore vertices can be distinguished according to the number of neighbors they have in color  $i$ . This gives us a new, refined coloring that (potentially) distinguishes more vertices. This is repeated until the process stabilizes.

The colorings resulting from this process are called equitable colorings. A coloring  $\pi$  is *equitable* if for every pair of (not necessarily distinct) colors  $i, j \in \{1, \dots, k\}$  the number of  $j$ -colored neighbors is the same for all  $i$ -colored vertices. For a colored graph  $(G, \pi)$  there is (up to renaming of colors) a unique coarsest equitable coloring finer than  $\pi$  [16]. We denote this coloring by  $\text{Ref}(G, \pi, \epsilon)$ , where  $\epsilon$  is the empty sequence.

IR-algorithms also use *individualization*. This process artificially forces a vertex into its own cell. We can record which vertices have been individualized in a sequence  $\nu \in V^*$ . We extend the refinement function so that  $\text{Ref}(G, \pi, \nu)$  is the unique coarsest equitable coloring finer than  $\pi$  in which every vertex in  $\nu$  is a singleton with its own artificial color. Specifically, the artificial colors used to individualize  $\nu$  are not interchangeable with colors introduced by the refinement itself and are ordered: the  $i$ -th vertex in  $\nu$  is always colored using the  $i$ -th artificial color.

We require this coloring to be isomorphism invariant (which means that  $\text{Ref}(G, \pi, \nu)(v) = \text{Ref}(G^\varphi, \pi^\varphi, \nu^\varphi)(v^\varphi)$  for  $\varphi \in \text{Sym}(n)$ ). There are efficient *color refinement* algorithms to compute  $\text{Ref}(G, \pi, \nu)$ , for which we refer to [16].

We say two colored graphs  $(G_1, \pi_1)$  and  $(G_2, \pi_2)$  are *distinguishable (by color refinement)*, if with respect to the colorings  $\text{Ref}(G_1, \pi_1, \epsilon)$  and  $\text{Ref}(G_2, \pi_2, \epsilon)$

1. there is a color  $c$  with differently sized cells in  $G_1$  and  $G_2$  (i.e.,  $|\text{Ref}(G_1, \pi_1, \epsilon)^{-1}(c)| \neq |\text{Ref}(G_2, \pi_2, \epsilon)^{-1}(c)|$ ),
2. or there are vertices  $v_1 \in V(G_1)$ ,  $v_2 \in V(G_2)$  of the same color (i.e.,  $\text{Ref}(G_1, \pi_1, \epsilon)(v_1) = \text{Ref}(G_2, \pi_2, \epsilon)(v_2)$ ), such that there is a color  $c$  within which  $v_1$  and  $v_2$  have a differing number of neighbors (i.e.,  $|\{(v_1, w) \in E(G_1) \mid \text{Ref}(G_1, \pi_1, \epsilon)(w) = c\}| \neq |\{(v_2, w) \in E(G_2) \mid \text{Ref}(G_2, \pi_2, \epsilon)(w) = c\}|$ ).

Sequences (or  $t$ -tuples) of vertices  $\nu_1 \in (G_1, \pi_1)^t$  and  $\nu_2 \in (G_2, \pi_2)^t$  are *distinguishable*, if the graphs  $(G_1, \text{Ref}(G_1, \pi_1, \nu_1))$  and  $(G_2, \text{Ref}(G_2, \pi_2, \nu_2))$  are.

**Cell Selector.** In a backtracking fashion, the goal of an IR-algorithm is to reach a discrete coloring using color refinement and individualization. For this, color refinement is first applied. If this does not yield a discrete coloring, individualization is applied, branching over all vertices in one non-singleton cell. The task of the *cell selector* is to isomorphism invariantly pick the non-singleton cell. After individualization, color refinement is applied again and the process continues recursively. Formally, a cell selector is a function  $\text{Sel}: \mathcal{G} \times \Pi \rightarrow 2^V$  (where  $\mathcal{G}$  denotes the set of all graphs and  $\Pi$  denotes the set of all colorings), satisfying:

- Isomorphism invariance, i.e.,  $\text{Sel}(G^\varphi, \pi^\varphi) = \text{Sel}(G, \pi)^\varphi$  for  $\varphi \in \text{Sym}(n)$ .
- If  $\pi$  is discrete then  $\text{Sel}(G, \pi) = \emptyset$ .
- If  $\pi$  is not discrete then  $|\text{Sel}(G, \pi)| > 1$  and  $\text{Sel}(G, \pi)$  is a cell of  $\pi$ .

**IR-Tree.** We describe the IR-tree  $\Gamma_{\text{Sel}}(G, \pi)$  of a colored graph  $(G, \pi)$ , which depends on a chosen cell selector  $\text{Sel}$ . Essentially, IR-Trees simply describe the call-trees stemming from the aforementioned backtracking procedure. Nodes of the search tree are sequences of vertices of  $G$ . The root of  $\Gamma_{\text{Sel}}(G, \pi)$  is the empty sequence  $\epsilon$ . If  $\nu$  is a node in  $\Gamma_{\text{Sel}}(G, \pi)$  and  $C = \text{Sel}(G, \text{Ref}(G, \pi, \nu))$ , then the set of children of  $\nu$  is  $\{\nu.v \mid v \in C\}$ , i.e., all extensions of  $\nu$  by one vertex  $v$  of  $C$ .

By  $\Gamma_{\text{Sel}}(G, \pi, \nu)$  we denote the subtree of  $\Gamma_{\text{Sel}}(G, \pi)$  rooted in  $\nu$ . We omit the index  $\text{Sel}$  when apparent from context.

We recite the following fact on isomorphism invariance of the search tree as given in [16], which follows from the isomorphism invariance of  $\text{Sel}$  and  $\text{Ref}$ :

► **Lemma 3.** *If  $\nu$  is a node of  $\Gamma(G, \pi)$  and  $\varphi \in \text{Aut}(G, \pi)$ , then  $\nu^\varphi$  is a node of  $\Gamma(G, \pi)$  and  $\Gamma(G, \pi, \nu)^\varphi = \Gamma(G, \pi, \nu^\varphi)$ .*

**Quotient Graph.** The IR-tree itself can be exponentially large in the order of  $G$  [18]. To decrease its size IR-algorithms use a pruning mechanism. For this a *node invariant* is used. A node invariant is a function  $\text{Inv}: \mathcal{G} \times \Pi \times V^* \rightarrow I$  that assigns to each sequence of nodes of the tree a value in a totally ordered set  $I$ . It satisfies the following.

- Isomorphism invariance, i.e.,  $\text{Inv}(G, \pi, \nu_1) = \text{Inv}(G^\varphi, \pi^\varphi, \nu_1^\varphi)$  for  $\varphi \in \text{Sym}(n)$ .
- If  $|\nu_1| = |\nu_2|$  and  $\text{Inv}(G, \pi, \nu_1) < \text{Inv}(G, \pi, \nu_2)$ , then for all nodes  $\nu'_1 \in \Gamma(G, \pi, \nu_1)$  and  $\nu'_2 \in \Gamma(G, \pi, \nu_2)$  it holds that  $\text{Inv}(G, \pi, \nu'_1) < \text{Inv}(G, \pi, \nu'_2)$ .

The particular way the node invariant can be exploited depends on the problem to be solved. When solving for graph isomorphism, the algorithm may prune all nodes with an invariant differing from an arbitrary node invariant. However, when algorithms want to compute a canonical labeling, they must find a specific canonical node invariant to continue with. However, in the context of the present work these details are not important.

Most IR-algorithms use a specific invariant, the so-called *quotient graph*, which is naturally produced by color refinement.

■ **Figure 1** Forbidden structures in asymmetric binary IR-trees.

For an equitable coloring  $\pi$  of a graph  $G$ , the quotient graph  $Q(G, \pi)$  captures the information of how many neighbors vertices from one cell have in another cell. Quotient graphs are complete directed graphs in which each vertex has a self-loop. They include vertex colors as well as edge colors. The vertex set of  $Q(G, \pi)$  is the set of all colors of  $(G, \pi)$ , i.e.,  $V(Q(G, \pi)) := \pi(V(G))$ . The vertices are colored with the color of the cell they represent in  $G$ . We color the edge  $(c_1, c_2)$  with the number of neighbors a vertex of cell  $c_1$  has in cell  $c_2$  (possibly  $c_1 = c_2$ ). Since  $\pi$  is equitable, all vertices of  $c_1$  have the same number of neighbors in  $c_2$ .

A crucial fact is that graphs are *indistinguishable by color refinement* if and only if their quotient graphs on the coarsest equitable coloring are equal.

We should also remark that quotient graphs are indeed *complete invariants*, yielding the following property.

► **Lemma 4.** *Let  $\nu, \nu'$  be leaves of  $\Gamma(G, \pi)$ . There exists an automorphism  $\varphi \in \text{Aut}(G, \pi)$  with  $\nu = \varphi(\nu')$  if and only if  $Q(G, \text{Ref}(G, \pi, \nu)) = Q(G, \text{Ref}(G, \pi, \nu'))$ .*

Consistent with the colors of trees used in [5], we may also view quotient graphs as a way to color IR-trees themselves, i.e., where we color a node  $\nu$  with  $Q(G, \text{Ref}(G, \pi, \nu))$ .

### 3 Necessary Conditions for IR-Trees

We collect necessary conditions for the structure of IR-trees. Since IR-trees are the result of a branching process, they are naturally irreducible (no node has exactly one child). Also, indistinguishable leaves can be mapped to each other.

► **Lemma 5.** *IR-trees are irreducible.*

► **Lemma 6.** *Let  $l_1, l_2$  be two leaves of an IR-tree  $(T, \pi)$ . If  $l_1$  and  $l_2$  are indistinguishable, there is an automorphism  $\varphi \in \text{Aut}(T, \pi)$  mapping  $l_1$  to  $l_2$ .*

► **Lemma 7** (see e.g. [4]). *A leaf  $l$  can be mapped to exactly  $|\text{Aut}(G, \pi)|$  leaves in  $\Gamma(G, \pi)$  using elements of the automorphism group  $\text{Aut}(G, \pi)$ .*

It follows that all classes of indistinguishable leaves have equal size.

Since in color refinement, partitionings and hence quotient graphs only ever become finer and more expressive, the following properties hold.

► **Lemma 8.** *Let  $n_1, n_2$  be two nodes of an IR-tree where  $n_i$  is on level  $l_i$ .*

1. *If  $l_1 \neq l_2$ , then  $n_1$  and  $n_2$  are distinguishable.*
2. *Consider the two walks starting in the root and ending in  $n_1$  and in  $n_2$ , respectively. If in these walks two nodes on the same level are distinguishable then  $n_1$  and  $n_2$  are distinguishable.*

Some further restrictions apply specifically in the case of cells of size 2.

► **Lemma 9** (Forbidden Binary Structures).

1. If a node  $n$  has two children  $n_1$  and  $n_2$ , then it cannot be that exactly one of the children  $n_1$  or  $n_2$  is a leaf (see Figure 1, left).
2. If  $n_1, n_2$  are any two nodes and  $n_1$  has exactly 2 children then the multiset of colors of the children of  $n_1$  and  $n_2$  are equal or disjoint (Figure 1, middle and right).

**Proof.** Part 1 follows from the fact that individualizing one vertex in a cell of size 2 also individualizes the other vertex of the cell.

For Part 2 we note that individualization of a child of  $n_1$  also individualizes the other child of  $n_1$  and vice versa. This implies that if a child  $c_2$  of  $n_2$  has the same color as some child  $c_1$  of  $n_1$ , then by definition, individualization of  $c_1$  and  $c_2$ , respectively, produces indistinguishable colorings. So in this case there is a one-to-one correspondence between the colors of the children of  $n_1$  and those of  $n_2$ . ◀

It is easy to see that if at any point the cell selector chooses differently sized cells in different branches, the branches subsequently become distinguishable. However, if we assume cell selectors only base their decision on the quotient graph, this restriction applies earlier. More specifically, we call a cell selector *quotient-graph-based*, whenever the result of the cell selector depends only on the quotient graph rather than other aspects of  $G$  and  $\pi$  (i.e., we have  $\text{Sel}(Q(G, \pi))$  rather than  $\text{Sel}(G, \pi)$ ). Then, we have the following.

► **Lemma 10.** *If two nodes  $n$  and  $n'$  in an IR-tree are indistinguishable, then their parents have the same number of children. If additionally the cell selector is quotient-graph-based then  $n$  and  $n'$  also have the same number of children.*

Restricting the cell selector to quotient graphs thus changes whether we can distinguish nodes with a differing number of children *before* or *after* individualizing one more vertex. We may even distinguish cells *before* individualization in both cases, if we include the decision of the cell selector into the invariant itself (i.e., using  $(Q(G, \pi), \text{Sel}(G, \pi))$  instead of  $Q(G, \pi)$ ), which is clearly only more expressive in case the cell selector is *not* quotient-graph-based).

In the following, we assume cell selectors are indeed quotient-graph-based. Since we only require a less powerful cell selector, our construction becomes more general. However, in the construction, we could alternatively drop the additional restriction above with minor adjustments by allowing a more powerful cell selector.

For the remainder of this paper we say that a tree fulfills the *necessary conditions*, if none of the conditions laid out by this section are violated.

## 4 Graph Constructions

Given a colored tree  $(T, \pi)$  which satisfies the necessary conditions, we describe how to construct a graph  $G(T, \pi)$  and a cell selector  $S(T, \pi)$  for which  $(T, \pi)$  is (up to renaming of colors) the IR-tree  $\Gamma_{S(T, \pi)}(G(T, \pi))$ . We make abundant use of gadget constructions, which we describe first. We give a concise description of the construction, details (i.e., the long version) can be found in the full version of the paper [2] (including omitted correctness arguments).

### 4.1 Gadgets

All our gadgets have multiple *input* and *output gates*. Each gate is a pair of vertices that together form their own color class in the gadget. Vertices in the gates are the only vertices of the gadgets connected to other vertices outside the gadget. We say that vertices labeled

Figure 2 The AND<sub>2</sub> gadget and two variants of directional gadgets.

with  $b_i$  denote the “input”, while  $a_i$  indicates “output”. Gates can be *activated*, by which we mean the process of distinguishing the vertices of the gate pair into distinct color classes, and applying color refinement afterwards. We say activation *discretizes* the gadget if the resulting stable coloring on the gadget vertices is discrete.

Three of the gadgets we present (AND <sub>$i$</sub> , Unidirectional and Dead End gadget) have already been used in other contexts related to color refinement [6, 7, 10].

**AND <sub>$i$</sub>  Gadget [6, 7, 10].** The AND<sub>2</sub> gadget as illustrated in Figure 2a, realizes the logical conjunction of gates with respect to color refinement, and an XOR gadget with respect to automorphisms.

Given  $i > 2$ , we can realize an AND <sub>$i$</sub>  gadget with  $i$  input gates by combining multiple AND<sub>2</sub> gadgets in a tree-like fashion. The AND <sub>$i$</sub>  gadget is constructed by attaching the first and second input gate to an AND<sub>2</sub>, whose output is connected to another AND<sub>2</sub> together with the third input gate, and so on. We use colors to order the input gates, i.e., we color the  $i$ -th input gate with color  $i$ .

We define the special case of the AND<sub>1</sub> gadget to simply consist of a pair of vertices that functions as the input and output gate at the same time.

► **Lemma 11** ([10]). *The AND <sub>$i$</sub>  gadget admits automorphisms that flip the output gate and either one of the input gates while fixing other input gates. As long as some input gate remains unsplit, the output gate is not split but activating all inputs discretizes the gadget.*

**Unidirectional and Dead End Gadget [6, 10].** Next, we describe gadgets through which gate activation can be propagated or blocked depending on the direction of the gadget. Specifically we construct the unidirectional gadget (Figure 2b) and the dead end gadget (Figure 2c). Note that the two gadgets are indistinguishable from each other by color refinement. The smaller vertices depicted in Figure 2 have been included to guarantee that the gadgets become discrete after the input and output gate has been split and can otherwise be ignored.

► **Lemma 12.** *The unidirectional and dead end gadget are indistinguishable by color refinement. In the unidirectional case, activating the input discretizes the gate but activating the output does not split the input gate. In the dead end case, both input and output have to be activated to discretize the gadget.*

**Asymmetry Gadgets.** Our next gadgets only have one gate (see Figure 3,  $\mathcal{F}$  denotes the Frucht graph). The crucial property of the asymmetry gadgets  $A_1$  and  $A_2$  (Figures 3a and 3b) is for the two gate vertices to be initially indistinguishable by color refinement, but to ensure that individualizing one of the gate vertices leads to a different quotient graph than individualizing the other gate vertex.

■ **Figure 3** Asymmetry gadgets and concealed edges based on asymmetry gadgets.

► **Lemma 13.**  $A_1$  and  $A_2$  are asymmetric and stable under color refinement. Activating the input gate discretizes the gadget and we obtain two non-isomorphic colorings depending on which vertex was individualized. Furthermore,  $A_1 \not\cong A_2$ .

**Concealed Edges.** Lastly, we describe the *concealed edge gadget* that is used to hide edges from color refinement. The gadget has two vertices that represent the endpoints of an edge (the blue vertices in Figure 3c). The idea is that instead of an edge connecting the two vertices, we insert a concealed edge gadget. For this the gadget has a pair consisting of two *inner vertices* (the green vertices in Figure 3c), which are both connected to each input vertex. This pair is then connected to an asymmetry gadget. We define two classes of edges, where one type of edge attaches the gadget  $A_1$  (*true edges*) and the other  $A_2$  (*fake edges*).

The crucial property is that as long as inner vertices of the gadgets are not distinguished, color refinement can not distinguish between true edges and fake edges. However, if we distinguish the inner vertices, true edges can indeed be distinguished from fake edges.

We always employ this gadget within the following design pattern. Whenever we want to connect two sets of vertices  $V_1$  and  $V_2$  with edges  $E \subseteq V_1 \times V_2$  in a concealed manner, we first add a concealed edge gadget between *all* pairs  $(v_1, v_2) \in V_1 \times V_2$ . However, only if  $(v_1, v_2) \in E$ , we use a *true edge*, and whenever  $(v_1, v_2) \notin E$  we use a *fake edge*. Finally, we connect all pairs of inner vertices of the concealed edge gadgets to some construction that is used to *reveal* the edges.

The asymmetry gadget prohibits automorphisms from flipping the concealed edge gadget itself. However, care has to be taken when connecting the inner vertices to other constructions: it is imperative to connect the inner vertices of multiple concealed edge gadgets that are on the, say, left side of the asymmetry gadget, in the same manner. Otherwise, once revealed, edges could possibly be distinguished into even more categories than just fake and true edges.

## 4.2 A construction for asymmetric trees

For our construction, we first restrict ourselves to asymmetric trees, i.e., all leaves have different colors. Building on this, the following section takes symmetries into account. Let  $(T, \pi)$  be an *asymmetric*, colored tree that satisfies the necessary conditions (see Section 3). We describe a graph  $G(T, \pi)$  and cell selector  $S(T, \pi)$  such that  $(T, \pi)$  is (up to renaming of colors) the IR-tree  $\Gamma_{S(T, \pi)}(G(T, \pi))$ .

The goal is to model the graph and cell selector in such a way that there is a one-to-one correspondence between paths in  $T$  and sequences of individualizations in  $G(T, \pi)$ . Such sequences are precisely the paths in the IR-tree  $\Gamma_{S(T, \pi)}(G(T, \pi))$ . To guarantee this correspondence, certain properties of paths in  $T$  must translate into specific properties for their respective sequence of individualizations. In particular, when modeling  $G(T, \pi)$ , we ensure the following.

## 24:10 A Characterization of Individualization-Refinement Trees

■ **Figure 4** Connecting levels of the selector tree. Blue/red edges on the right symbolize true/fake edge gadgets.

■ **Figure 5** Colors of  $T$  are encoded in  $G(T)$  by concealed edges to special *color nodes*.

1. Two paths must end in nodes of different color exactly if the corresponding sequences of individualizations result in different quotient graphs.
2. A path must end in a leaf exactly if the corresponding sequence of individualizations (when followed by color refinement) results in a discrete coloring.

**Selector Tree.** We start by describing the part of the graph on which the cell selector operates, i.e., within which cells are chosen. We use a copy of  $T$  itself for this purpose. One of the central difficulties is that color refinement executed on  $T$  may actually result in a coloring that is finer than  $\pi$ .

Hence, the selector tree consists of the nodes of  $T$  but encodes the edges of  $T$  in the selector tree using concealed edges (see Figure 4). This guarantees that our copy of  $T$  is stable under color refinement. At some point, we will need to add another gadget construction to ensure that edges between the levels are actually revealed at the right time. Assuming this for now, the cell selector  $S(T, \pi)$  always chooses as next cell the cell that consists of the children of the node chosen last.

**Colors.** Next, we consider the colors  $\pi$  of  $T$ . Colors indicate whether a sequence of individualizations should lead to differing quotient graphs. We make use of fake edges again to encode this: we encode a one-to-one correspondence between selector tree nodes and their color in  $\pi$  using concealed edges (see Figure 5). We will discuss how edges are revealed further below. Specifically, we will reveal edges incident with node  $n$  at the point in time when node  $n$  is individualized.

**Leaf Detection.** Whenever we individualize a node  $n$  in the selector tree, we want to react to this by revealing a specific set of edges. Therefore, we now add a construction that detects whether a specific node  $n$  in a cell was individualized. Let  $s \geq 2$  be the size of the current cell (in the tree  $T$  the current cell is always the set of children of some node). For each node  $n$  in the cell, consider all  $s - 1$  pairs with other nodes of the cell. We add an  $\text{AND}_{s-1}$  gadget and connect the left node of every input pair to  $n$ , and the other to one of the  $s - 1$  other nodes. An  $\text{AND}_{s-1}$  gadget is not symmetric in its input gates, so in order to keep things symmetrical, we add  $(s - 1)!$  many  $\text{AND}_{s-1}$  gadgets for every possible order of nodes in the input. We connect the output gates of the  $\text{AND}_{s-1}$  gadgets to the *individualization output* of  $n$  (see Figure 6). Crucially, the individualization output is activated (i.e., split) whenever  $n$  is individualized, and not immediately activated if only some other node  $n'$  is individualized.

■ **Figure 6** Leaf detection mechanism for the leftmost node of the cell. If this node is individualized, the  $\text{AND}_3$  gadget is activated. The figure only shows true edges.

We again ensure the construction is stable under color refinement by using concealed edges. We use concealed edges between nodes of level  $i$  and the  $\text{AND}_{s-1}$  of level  $i$  gadgets, using true edges instead of the edges described above.

If a node corresponds to a leaf and its individualization output is activated, we want to propagate discretization to other nodes. We add some control structures for every node  $n$  in the selector tree, namely a *broadcast* and *receiver* gadget as illustrated in Figure 6. We use a dead end gadget instead of a unidirectional as the broadcast gadget whenever  $n$  is not a leaf in  $T$ . Next, we connect the output of the broadcast gadget to the input of *all* receiver gadgets in the graph.

The idea is that if  $n$  is a leaf and individualized, we propagate this split to *all* individualization outputs through the broadcast and receiver gadgets, eventually causing a discretization of the graph, as explained below. If  $n$  is not a leaf, the broadcast gadget is a dead end gadget and no further split occurs.

**Revealing Edges.** We now describe when concealed edges are revealed. Assume we are individualizing a node at level  $i$  of the tree. At this point, we need to reveal the edges in the selector tree connecting level  $i$  to level  $i + 1$ . We use the individualization outputs at level  $i$  to reveal edges of the selector tree to level  $i + 1$ : we connect every individualization output through a unidirectional gadget with the internal nodes of the concealed edges between level  $i$  and level  $i + 1$ .

In order to activate the individualization outputs, we also need to reveal edges from level  $i + 1$  nodes to their  $\text{AND}_{s-1}$  gadgets. Hence, we do the same construction as above, connecting the unidirectional gadgets we added on level  $i$  to reveal these edges on level  $i + 1$ . For the first level of the selector tree (children of the root) we do not use concealed edges, such that the level is initially revealed.

Finally, the same technique is also used to reveal colors. The individualization output of node  $n$  reveals the concealed edges between  $n$  and the color nodes. This reveals the color of  $n$  whenever we individualize  $n$ . Due to broadcasting, *all* colors are revealed whenever a leaf is activated, leading to a discrete coloring.

### 4.3 Generating symmetries

We expand our construction so that it can also handle colored trees  $(T, \pi)$  with prescribed symmetries. As such, the graph  $G(T, \pi)$  can also be build from a tree  $(T, \pi)$  that is not necessarily asymmetric. In this case, sequences of individualizations along root-to-leaf paths still produce the desired tree  $(T, \pi)$  as a subtree of  $\Gamma_{S(T, \pi)}(G(T, \pi))$ . However,  $G(T, \pi)$  is supposed to become discrete after the IR-process reaches a leaf, but at this point the selector tree is only split up to orbits prescribed by  $T$ .

■ **Figure 7** Symmetry cycles couple leaf orbits across multiple branches of the selector tree. The illustration omits fake edges. In the construction, cycles do not contain directed edges, but specially colored nodes that indicate direction.

Discretization of orbits is challenging since we need to make sure that the symmetries are not destroyed by the addition of new gadgets. Once leaf orbits have been discretized, discretization propagates through the selector tree and the whole construction becomes discrete.

Overall we need to construct the graph  $H_T$  mentioned in Theorem 2. To construct  $H_T$ , we introduce *symmetry cycles* and *symmetry couplings*. The basic idea is shown in Fig. 7, a detailed explanation can be found in the full version [2]. This in turn defines a new construction  $\tilde{G}(T, \pi)$  by adding a concealed version of  $H_T$  to the selector tree.

**Discretization of Orbits.** We remark that the way we construct  $H_T$  has additional consequences on color refinement: individualization of a root-to-leaf path in  $H_T$  discretizes all symmetry cycles. In terms of  $\tilde{G}(T, \pi)$ , since different leaf orbits have different colors in  $T$ , this means that individualization of a root-to-leaf path now discretizes the set of leaves as well.

**Concealing Symmetry Couplings.** We hide  $H_T$  from color refinement using concealed edges. In the construction of  $H_T$ , we replace edges with true edge gadgets. All other connections between selector tree nodes and symmetry cycles become fake edges. To reveal the edges whenever a leaf is individualized, we connect the inner nodes of the concealed edges to the output of all broadcast gadgets.

## 5 Conclusion and Future Work

We have shown that every tree that meets some simple necessary conditions is an IR-tree. Regarding invariant pruning we should highlight that of course every pruned tree is a subtree of an unpruned tree, so our techniques extend to IR-algorithms with pruning.

Regarding refinement, we use the standard color refinement used by all IR-algorithms. However regarding cell selectors there is no clear standard. In this paper, we did not optimize the construction for any specific cell selector, but rather used the cell selector as part of the construction.

Let us now assume we are given a fixed cell selector. For a particular cell selector, there are two possibilities: either, fewer trees turn out to be IR-trees or the same necessary conditions apply. For the latter, we suspect that for many natural examples the construction of this paper can be adapted. Consider for example the cell selector that always chooses a smallest non-trivial cell. In this case, by adding more concealed structure enforcing specific cell sizes it can be shown that the same necessary conditions are indeed sufficient again.

In contrast to this, consider the cell selector that always chooses a largest non-trivial cell. Here, the degree of the vertices on root-to-leaf walks in a corresponding IR-tree must monotonically decrease. Hence, fewer trees turn out to be IR-trees and the necessary conditions are not sufficient. If interested in specific cell selectors one might therefore want to refine the necessary conditions.

Another interesting direction of research might be to investigate bounds for the order graphs realizing a given tree since this is related to the running time of IR-tools.

## Abstract

We present a truly subquadratic size distance oracle for reporting, in *constant* time, the exact shortest-path distance between any pair of vertices of an undirected, unweighted planar graph  $G$ . For any  $\varepsilon > 0$ , our distance oracle requires  $O(n^{5/3+\varepsilon})$  space and is capable of answering shortest-path distance queries exactly for any pair of vertices of  $G$  in worst-case time  $O(\log(1/\varepsilon))$ . Previously no truly sub-quadratic size distance oracles with constant query time for answering exact shortest paths distance queries existed.

## 1 Introduction

Efficiently answering shortest path distance queries between pairs of vertices in a graph is a fundamental algorithmic problem. Given an  $n$ -vertex graph  $G = (V, E)$  a *distance oracle* is a compact data-structure capable of efficiently answering shortest path distance queries between pairs of vertices  $u, v \in V$ . Ideally one would like the data structure to be of linear size and the query time to be constant. However, it is well known that there are graphs for which no distance oracle with  $o(n^2)$  bits of space and  $O(1)$  query time exists. In fact, even resorting to approximation, Pătraşcu and Roditty [21] showed that there are sparse graphs on  $O(n \text{ polylog } n)$  edges for which constant query-time distance oracles with stretch less than 2 must be of size  $\Omega(n^2 \text{ polylog } n)$ , assuming the set intersection conjecture. These impossibility results make it natural to consider the problem in restricted classes of graphs.

In this paper we consider exact distance oracles for planar graphs. Distance oracles for planar graphs are well motivated by important real-world applications, notably in routing, navigation of road and sea maps as well as in the context of computational geometry. To the best of our knowledge there are no non-trivial lower bounds for (static) distance oracles for planar graphs, and thus achieving the “holy grail” of a linear-size distance oracle with constant query time may be possible. Indeed, there has been numerous works over at least three decades developing exact distance oracles for planar graph [10, 2, 3, 8, 11, 19, 20]. However, only in 2017, Cohen-Addad et al. [9] gave the first oracle with truly subquadratic

space and polylogarithmic query time. Their result was inspired by Cabello’s [4] breakthrough result, who gave the first truly sub-quadratic time algorithm for computing the diameter of planar graphs by a novel use of Voronoi diagrams. The approach of [9] was subsequently improved by [12, 7, 18], who gave an elegant point-location mechanism for Voronoi diagrams in planar graphs, and combined it with a clever recursive scheme to obtain exact distance oracles for directed weighted planar graphs with  $O(n^{1+o(1)})$  space and  $O(\log^{2+o(1)} n)$  query time. We note that even though the oracles of [7, 18] get quite close to optimal, it remains wide open to support exact queries in *constant time* using truly subquadratic space, even in the most basic case of unweighted undirected planar graphs [26, 5, 25].

Allowing approximate answers does help in planar graphs. Many results reporting  $(1 + \varepsilon)$ -approximate distances with various tradeoffs exist, all with (nearly) linear size and polylogarithmic, or even  $O(1/\varepsilon)$  query-time [24, 15, 14, 27]. Gu and Xu [13] presented a size  $O(n \text{ polylog } n)$  distance oracle capable of reporting  $(1 + \varepsilon)$ -approximate distances in time  $O(1)$ . While their query time is a constant independent of  $\varepsilon$ , the preprocessing time and space are nearly linear, but with an exponential dependency on  $(1/\varepsilon)$ . This exponential dependency can be made polynomial, but then the query time increases to  $O(\log(1/\varepsilon))$  [6].

Thus, despite the large body of work on distance oracles for planar graphs, it has remained an open question to determine whether an exact distance oracle with of size  $O(n^{2-\varepsilon})$  with *constant* query-time can be constructed for some constant  $\varepsilon > 0$ .

## 1.1 Our contributions

We answer this question in the affirmative, and discuss our techniques in the following section. Our result is summarized in the following theorem:

► **Theorem 1.** *Let  $G = (V, E)$  be an undirected unweighted  $n$ -vertex planar graph. For any  $\varepsilon > 0$  there exists a data-structure requiring  $O(n^{5/3+\varepsilon})$  space that, for any  $s, t \in V$ , reports the shortest path distance between  $s$  and  $t$  in  $G$  in time  $O(\log(1/\varepsilon))$ .*

We also present another denser subquadratic distance oracle in Section 4, and remark that it can be distributed into a distance labeling scheme with size  $O(n^{3/4})$  per label, such that the distance between any two vertices  $s, t$  can be computed in  $O(1)$  time given just the labels of  $s$  and  $t$ .

## 1.2 Technical overview

The main concept we use to obtain our result is that of a *pattern* capturing distances between a vertex and a cycle. This concept was used by [26] and by [17] (where it was called a “distance tuple”). Consider a vector storing the distances from a vertex  $u$  to the vertices of a cycle  $\beta$  in their cyclic order. The pattern of  $u$  w.r.t.  $\beta$  is simply the discrete derivative of this vector. That is, the vector obtained by taking the difference between every pair of consecutive values. Li and Parter [17] showed that when the input graph is planar, the number of different patterns w.r.t. a face with  $r$  vertices is  $O(r^3)$ , regardless of the size of the graph. We next outline how this observation can be used to break the quadratic space barrier.

Roughly speaking, any planar graph can be decomposed into  $O(n/r)$  subgraphs, called regions, of size  $r$  each, where the boundary of each region (i.e., the vertices that have neighbors outside the region) is a single cycle  $h$ .<sup>1</sup> Applying Li and Parter’s observation in

<sup>1</sup> In fact, a constant number of cycles. To readers familiar with the concept, this is just an  $r$ -division with a few holes, but *without* the important feature that each region has just  $O(\sqrt{r})$  boundary vertices. This is because one cannot triangulate unweighted graphs without changing the distances.

this setting, the number of different patterns for the hole of each region  $R$  is  $O(r^3)$ . Hence, we can represent the distances from any vertex  $s \notin R$  to  $h$  by just storing the distance from  $s$  to an arbitrarily chosen canonical vertex  $v_h$  of  $h$ , and a pointer to the pattern of  $s$  with respect to  $h$ . This requires just a total of  $O(n)$  space for all vertices not in  $R$  plus  $O(r^3 \cdot r)$  for storing all the patterns for  $h$ . Summing over all  $O(n/r)$  regions, the space required is  $O(n^2/r + nr^3)$ .

We then define the notion of distance from a pattern to a vertex (see Definition 6). While this definition is simple, it is somewhat unnatural because the distance from a pattern to a vertex does not necessarily correspond to the length of any specific path in the graph! However, the distance between  $s$  and any vertex  $t \in R$  is just the sum of the distance between  $s$  and the canonical vertex  $v_h$  and the distance from the pattern of  $s$  with respect to  $h$  to  $t$ .

We therefore store the distances from each of the  $O(r^3)$  possible patterns of  $R$  to each vertex of  $R$ . This requires  $O(r^3 \cdot r)$  space per region, so  $O(nr^3)$  space overall. This way we can report the distance between  $s$  and  $t$  in constant time by (i) retrieving the pattern  $p$  of  $s$  w.r.t.  $h$ , and (ii) adding the distance from  $s$  to the canonical vertex  $v_h$  of  $h$  and the distance from the pattern  $p$  to  $t$ . These ideas alone already imply an oracle with space  $\tilde{O}(n^{7/4})$  and constant query time. Combining these ideas with recursion yields the improved space bound of Theorem 1.

### 1.3 Technical differences from previous oracles

As we previously mentioned, breaking the quadratic space barrier for constant query time has remained a long standing open question and can therefore be considered an important and significant result in its own right. We highlight the following difference between the approach taken in our recursive oracle and the approaches used in all existing distance oracles we are aware of. To the best of our knowledge, all existing distance oracles, both exact and approximate, and both for general graphs and planar graphs, recover the distance from  $s$  to  $t$  by identifying a vertex or vertices on some (possibly approximate) shortest path between  $s$  and  $t$ , for which distances have been stored in the preprocessing stage. These vertices are usually referred to as landmarks, portals, hubs, beacons, seeds, or transit nodes (cf. [23]). Our oracle, on the other hand, reports the exact shortest path without identifying vertices on the shortest path from  $s$  to  $t$ . Instead, it “zooms in” on  $t$  by recovering distances to the canonical vertices of a sequence of subgraphs of decreasing size that terminates at a constant size graph containing  $t$ . We emphasize that *none of these canonical vertices necessarily lies on a shortest path* from  $s$  to  $t$ . This property may be viewed as a disadvantage if we also want to report the shortest path, but when reporting multiple edges on long paths, constant query time is no longer relevant. On the other hand, it may be that just reporting the distance is easier than also reporting an internal vertex on a shortest path. Hence, it may be that developing oracles based on this new approach may lead to further advances on the way to linear size distance oracles for planar graphs with constant query time, and in other related problems.

## 2 Preliminaries

Let  $G$  be a graph. We denote by  $V(G)$  and  $E(G)$  the vertex and edge-set of  $G$ , and denote by  $n = |V(G)|$  the number of vertices of  $G$ .

For a subset  $S$  of edges or vertices we denote by  $G[S]$  the subgraph of  $G$  induced on  $S$ . We denote by  $u \rightsquigarrow_H v$  a *shortest path* from  $u$  to  $v$  in the subgraph  $H$ , by  $\mathbf{d}_H(u, v)$  the length of  $u \rightsquigarrow_H v$ , and define  $u \rightsquigarrow v \equiv u \rightsquigarrow_G v$ .

The following definitions will be useful when talking about decompositions of  $G$ . A *region*  $R$  of  $G$  is an edge-induced subgraph of  $G$ , and its *boundary*  $\partial R$  is the set of vertices of  $R$  that are adjacent to some vertex of  $V(G) \setminus V(R)$  in  $G$ . Vertices of  $V(R) \setminus \partial R$  are called *interior* vertices of  $R$ . Observe that for a region  $R$  and for  $u \in R$  and  $v \in V \setminus V(R)$ , any path from  $u$  to  $v$  in  $G$  must intersect  $\partial R$ .

It will be useful to assume some global strict order on a vertex set  $V$  s.t. for any  $U \subseteq V$  there is a minimum vertex  $\min U \in U$  w.r.t this order. We refer to this as the *canonical vertex* of  $U$ .

We assume the reader is familiar with the the basic definitions of planarity and of planar embeddings.

## 2.1 Faces and holes

The edges of a plane graph induce maximal open portion of the plane that do not intersect any edges. A *face* of the graph is the closure of one such portion of the plane. We refer to the edges bounding a face as the *boundary* of that face. Given a face  $f$ ,  $V(f)$  is the set of vertices on the boundary of  $f$ . We denote by  $w(f)$  the *facial walk* of  $f$  which is the sequence of vertices encountered when walking along  $f$  starting at  $\min V(f)$  and going in the clockwise direction. Note that  $f$  may be non-simple, so some vertices may appear multiple times in  $w(f)$ . A *hole*  $h$  in a region  $R$  of a graph  $G$  is a face of  $R$  which is not a face in  $G$ . We say that a vertex  $u \in V(G) \setminus V(R)$  is *inside* hole  $h$  if  $u$  lies in the region of the plane corresponding to the face  $h$  of  $R$ . We denote by  $V^+(h) = \{u \in V(G) \mid u \text{ is inside } h\}$  all the vertices that are inside  $h$ .

## 2.2 Decompositions of unweighted planar graphs

An  $r$ -division is a widely used decomposition of planar graphs into regions with small boundary. We use the  $r$ -divisions with a few holes as studied in [16], which works for triangulated biconnected graphs:

► **Lemma 2** ( *$r$ -division with few holes for triangulated graphs [16]*). *Let  $G$  be a biconnected, triangulated  $n$ -vertex planar embedded graph, and let  $0 < r \leq n$ .  $G$  can be decomposed into  $\Theta(n/r)$  connected regions, each of which with  $O(r)$  vertices and  $O(\sqrt{r})$  boundary vertices. Each region has a constant number of holes. Every boundary vertex lies on some hole, and each hole has  $O(\sqrt{r})$  vertices.*

The fact that the boundaries of regions are small (only  $O(\sqrt{r})$  boundary vertices for a region with  $r$  vertices) is the basis for many efficient algorithms and data structures for planar graphs. Unweighted planar graphs possess additional structure (in comparison to weighted planar graphs), which may also be useful algorithmically. See for example the unit-Monge property in [1], or the limited number of patterns [26, 17], which we use in this work. However, exploiting such additional structure in conjunction with a decomposition into regions with small boundaries has been elusive because of the seemingly technical requirement in Lemma 2 that the graph be triangulated and biconnected.

Any graph can be triangulated and biconnected by adding to each face  $f$  an artificial vertex and infinitely weighted artificial edges from the artificial vertex to each vertex of  $V(f)$ . This transformation preserves planarity and shortest paths, and ensures that the graph consists only of simple faces of size 3. However, the graph is no longer unweighted. We refer to an *artificial* vertex (edge) of  $G$  as a vertex (edge) which was added in the triangulation step, and a *natural* vertex (edge) of  $G$  as a vertex (edge) which is not artificial. In order to exploit the structure of the unweighted input graph we will remove the artificial edges and

vertices after computing the decomposition using Lemma 2. On the one hand the graph is again unweighted. On the other hand, while the number of boundary vertices in each region remains  $O(\sqrt{r})$ , the holes may now contain new non-boundary vertices, and the total size of the holes in each region may be  $\Theta(r)$ . We note, however, that the deletion of artificial edges and vertices does not disconnect regions [16]. We therefore restate the decomposition lemma for unweighted graphs that are not necessarily triangulated or biconnected.

► **Lemma 3** (*r*-division with few holes for non-triangulated graphs). *Let  $G$  be a  $n$ -vertex planar embedded graph  $G$ , and let  $0 < r \leq n$ .  $G$  can be decomposed into  $\Theta(n/r)$  connected regions, each with  $O(r)$  vertices and  $O(\sqrt{r})$  boundary vertices. Each region has a constant number of holes, and each boundary vertex lies on some hole.*

### 2.3 Recursive $r$ -divisions

Our second construction relies on a *recursive  $r$ -division* which is a recursive decomposition of  $G$  into  $r$ -divisions for varying values of  $r$ . Specifically, for a decreasing sequence  $\mathbf{r} = r_1, r_2, \dots$ , where  $n \geq r_1 > r_2 > \dots \geq 1$ , we want  $r_i$ -divisions for all  $i = 1, 2, \dots$ , such that each region in the  $r_i$  division is the union of regions in the  $r_{i+1}$ -division on the next level. We associate with the recursive  $r$ -division a decomposition tree,  $\mathcal{T}_{\mathbf{r}}$ , which is a rooted tree whose nodes correspond to the regions of the recursive decomposition of  $G$ . We will refer to nodes and their corresponding regions interchangeably. The root node corresponds to all of  $G$ . A node  $x$  of  $\mathcal{T}_{\mathbf{r}}$  at depth  $i$  corresponds to a region of the  $r_i$ -division, and its children are the regions of the  $r_{i+1}$ -division whose union is the region corresponding to  $x$ . We denote by  $\mathcal{T}_{\mathbf{r}}^i$  all the nodes at level  $i$ . It was shown in [16] that recursive  $r$ -divisions can be computed efficiently:

► **Lemma 4** (Recursive  $r$ -division). *Given a biconnected, triangulated  $n$ -vertex planar graph  $G$  and an exponentially decreasing sequence  $\mathbf{r} = n \geq r_1, r_2, \dots \geq 1$ , a decomposition tree,  $\mathcal{T}_{\mathbf{r}}$  can be computed in linear time s.t.  $\mathcal{T}_{\mathbf{r}}^i$  corresponds to an  $r_i$ -division of  $G$  with few holes for each  $i$ .*

## 3 Patterns

Both [26] and [17] introduce a notion of a “distance tuple” which can be thought of as a vector of shortest-path distances from a vertex to consecutive vertices of some hole. We introduce the following similar notion of a *pattern* (See Figure 1 for an illustration):

► **Definition 5** (Pattern). *Let  $G$  be a graph. Let  $H$  be a subgraph of  $G$ . Let  $u$  be a vertex in  $H$ , and let  $\beta = b_0, b_1, \dots, b_k$  be a path in  $H$ . The pattern of  $u$  (w.r.t.  $\beta$  in  $H$ ) is a vector  $p_{\beta, H}(u) \in \{-1, 0, 1\}^k$  satisfying  $p_{\beta, H}(u)[i] = \mathbf{d}_H(u, b_i) - \mathbf{d}_H(u, b_{i-1})$  for  $1 \leq i \leq k$ . When the path  $\beta$  is the boundary walk  $w(h)$  of a hole  $h$  of a region  $R$ , we write  $p_{h, H}(u)$  instead of  $p_{w(h), H}(u)$ .*

► **Definition 6** (pattern to vertex distance). *Let  $R$  be a region in a graph  $G$ . Let  $h$  be a hole of  $R$ . Let  $b_0, b_1, \dots, b_k$  be the vertices of  $w(h)$  in their cyclic order. Let  $p$  be some pattern w.r.t.  $h$  (i.e.,  $p = p_{h, G}(u)$  for some  $u \in V^+(h)$ ). For a vertex  $v \in R$  we define  $\mathbf{d}_G(p, v)$  the distance between  $p$  and  $v$  to be  $\min_{i=0}^k \left\{ \mathbf{d}_G(b_i, v) + \sum_{j=0}^i p[j] \right\}$ .*

► **Lemma 7**. *Let  $R$  be a region of a graph  $G$ . Let  $h$  be a hole of  $R$ . For every  $u \in V^+(h)$  and every  $v \in R$ ,  $\mathbf{d}_G(u, v) = \mathbf{d}_G(u, b_0) + \mathbf{d}_G(p_{h, G}(u), v)$ .*

■ **Figure 1** Illustration of the pattern of the vertex  $s$  w.r.t.  $f^*$  in an undirected graph. In this case  $f^*$  is the external face of the embedding. The numeric labels indicate the shortest path distances from  $s$  to each  $b_i$  where  $b_i \in V(f^*)$  for  $1 \leq i \leq 6$ .

**Proof.** By definition of pattern and by a telescoping sum, for every  $0 \leq i \leq k$ ,  $\mathbf{d}_G(u, b_i) = \mathbf{d}_G(u, b_0) + \sum_{j=0}^i p[j]$ . Let  $b_\ell$  be any vertex of  $w(h)$  on a shortest  $u$ -to- $v$  path ( $b_\ell$  exists since  $u \in V^+(h)$  and  $v \in R$ ). By choice of  $b_\ell$ ,  $\mathbf{d}_G(u, v) = \mathbf{d}_G(u, b_\ell) + \mathbf{d}_G(b_\ell, v) = \min_{0 \leq i \leq k} \{\mathbf{d}_G(u, b_i) + \mathbf{d}_G(b_i, v)\} = \min_{0 \leq i \leq k} \{\mathbf{d}_G(u, b_0) + \sum_{j=0}^i p[j] + \mathbf{d}_G(b_i, v)\} = \mathbf{d}_G(u, b_0) + \mathbf{d}_G(p, v)$ . ◀

### 3.1 Bounding the number of patterns

As mentioned, in a recent paper Li and Parter [17] achieve improved bounds for diameter computation for planar graphs by showing that in unweighted undirected planar graphs the number of patterns is quite small. More specifically, they show that the VC-dimension of a set corresponding to all patterns is at most 3. By the Sauer-Shelah lemma [22], this implies that the number of distinct patterns w.r.t. a sequence  $S$  of consecutive vertices on a face is in  $O(|S|^3)$ . Their result is stated in the following lemma:

► **Lemma 8** (Pattern compression [17]). *Let  $G' = (V, E)$  be an  $n$ -vertex unweighted undirected planar graph, let  $f$  be a face in  $G'$ , and let  $S$  be a sequence of consecutive vertices on  $f$ . Then the number of distinct patterns w.r.t.  $S$ ,  $|\bigcup_{u \in V} \{p_{S, G'}(u)\}|$ , is bounded by  $O(|S|^3)$ .*

We observe that the bound of Lemma 8 also holds for patterns w.r.t. the entire set of vertices on a hole  $h$  of a region  $R$  even when distances are defined in the entire graph  $G$ .

► **Corollary 9.** *Let  $R$  be a region in an  $n$ -vertex unweighted undirected planar graph  $G$ , and let  $h$  be a hole of  $R$ . Then the number of distinct patterns w.r.t.  $h$ ,  $|\bigcup_{u \in V^+(h)} \{p_{h, G}(u)\}|$ , is bounded by  $O(|h|^3)$ .*

**Proof.** For any  $u \in V^+(h)$  and  $v \in h$ , a shortest  $u$ -to- $v$  path in  $G$  can be decomposed into the concatenation of a shortest  $u$ -to- $v'$  path in  $G \setminus (R \setminus h)$ , for some  $v' \in h$ , and a shortest  $v'$ -to- $v$  path in  $G$ . Note that the former depends on  $u$ , but the latter does not. Hence, for every two vertices  $u, u' \in V^+(h)$ ,  $p_{h, G \setminus (R \setminus h)}(u) = p_{h, G \setminus (R \setminus h)}(u')$  implies  $p_{h, G}(u) = p_{h, G}(u')$ . Hence  $|\bigcup_{u \in V^+(h)} \{p_{h, G}(u)\}| = |\bigcup_{v \in V^+[h]} \{p_{h, G \setminus (R \setminus h)}(v)\}|$ .

The corollary now follows since  $h$  is a hole of  $R$  implies that  $h$  is a face of  $G - (R - h)$ , so by Lemma 8,  $|\bigcup_{v \in V^+[h]} \{p_{h, G - (R - h)}(v)\}| = O(|h|^3)$ . ◀

For the remainder of the paper we only deal with distances in  $G$  and with patterns in  $G$ , so we will omit the subscript  $G$ , and write  $\mathbf{d}(\cdot, \cdot)$  and  $p_h(\cdot)$  instead of  $\mathbf{d}_G(\cdot, \cdot)$  and  $p_{h, G}(\cdot)$ .

## 4 $O(n^{7/4})$ space distance oracle

Before presenting our main result, we describe a simpler construction which yields a distance oracle with a larger space requirement of  $O(n^{7/4})$  and  $O(1)$  query time.

### 4.1 Preprocessing

The preprocessing consists of computing an  $r$ -division  $\mathcal{R}$  of  $G$  with a parameter  $r$  to be determined later. For every vertex  $v$  of  $G$  and every region  $R$  of  $\mathcal{R}$ , we store the hole  $h$  of  $R$  s.t.  $v$  is in  $V^+(h)$ . This requires  $O(n \cdot n/r) = O(n^2/r)$  space.

For every region  $R \in \mathcal{R}$ , for every hole  $h$  of  $R$ , we maintain the  $O(r^3)$  patterns of the vertices in  $V^+(h)$  w.r.t.  $h$  as follows. Let  $k$  denote the size of the boundary walk  $w(h)$  of  $h$ . Let  $v_h$  be the canonical (i.e., first) vertex of  $w(h)$ . We maintain the patterns seen so far in a ternary tree  $\mathcal{A}$  whose edges are labeled by  $\{-1, 0, 1\}$ . The depth of  $\mathcal{A}$  is  $k - 1$ , and the labels along each root-to-leaf path correspond to a unique pattern, which we associate with that leaf. For every vertex  $v \in V^+(h)$ , we compute the pattern  $p_h(v)$  and we make sure that  $p_h(v)$  is represented in the tree  $\mathcal{A}$  by adding the corresponding labeled edges that are not yet present in  $\mathcal{A}$ . After all the vertices in  $V^+(h)$  are handled, the tree  $\mathcal{A}$  has  $O(r^3)$  leaves. For each leaf of  $\mathcal{A}$  with an associated pattern  $p$ , we compute and store (i) the distance from  $p$  to each vertex of  $R$ . Storing (i) requires  $O(r^4)$  time and space for all leaves of  $\mathcal{A}$ , so a total of  $O(n/r \cdot r^4) = O(nr^3)$  space for storing all this information over all regions.

For each vertex  $v \in V^+(h)$  we store (ii) a pointer to (the leaf of  $\mathcal{A}$  that is associated with) the pattern  $p_{h,G}(v)$ , as well as (iii) the distance  $\mathbf{d}(v, v_h)$  between  $v$  and the canonical vertex of  $h$ . The total space required to store all these pointers and distances is  $O(n \cdot n/r) = O(n^2/r)$ .

To complete the preprocessing we also store (iv) for each region  $R \in \mathcal{R}$ , the distance  $\mathbf{d}(u, v)$  for all pairs of vertices  $u, v \in R$ . This takes  $O(n/r \cdot r^2) = O(nr)$  additional space, which is dominated by the above terms.

The total space required by the oracle is thus  $O(n^2/r) + O(nr^3)$ . This is minimized for  $r = n^{1/4}$ , resulting in an  $O(n^{7/4})$ -space data structure.

We note that once this information has been computed we no longer need to store the entire tree  $\mathcal{A}$ . Rather, it suffices to store just the list of leaves of  $\mathcal{A}$  and the distances stored with each of them. In particular, we no longer need to remember what is the actual pattern associated with each leaf, we only need to have some identifier for each pattern, and the distances from this pattern to the vertices of the region  $R$ . In the current scheme this has no asymptotic effect on the size of the data structure, since each pattern is of size  $O(r)$ , and we anyway store the  $O(r)$  distances from each pattern to all vertices of  $R$ . However, in the recursive scheme in the next section this observation will become useful.

### 4.2 Handling a query

To answer a query for the distance between vertices  $s$  and  $t$  we proceed as follows. If  $s$  and  $t$  are in the same region, we simply return the distance  $\mathbf{d}(s, t)$  stored in item (iv). Otherwise, let  $R$  be the region containing  $t$ , and let  $h$  be the hole of  $R$  such that  $s \in V^+(h)$ . Let  $v_h$  be the canonical vertex of  $h$ . We return  $\mathbf{d}(s, v_h) + \mathbf{d}(p_{h,G}(s), t)$ . The correctness is immediate from Lemma 7. We note that  $\mathbf{d}(s, v_h)$  is stored in item (iii), a pointer to  $p_{h,G}(s)$  is stored in item (ii), and  $\mathbf{d}(p_{h,G}(s), t)$  is stored in item (i). The query is illustrated in Figure 2.

■ **Figure 2** Illustration of the query in Section 4. By Lemma 7 the query returns  $\mathbf{d}(s, b_0) + \mathbf{d}_R(p, t) = \mathbf{d}(s, b_\ell) + \mathbf{d}_R(b_\ell, t) = \mathbf{d}(s, t)$  where  $b_\ell$  is some boundary vertex of  $R$  on  $s \rightsquigarrow t$ .

### 4.3 Distributed Labels

This oracle can be distributed into a distance labeling scheme of size  $O(n^{3/4})$  per label. Each vertex  $v$  in a region  $R$  stores its distance from each of the patterns of  $R$  (item (i)) using  $O(r^3) = O(n^{3/4})$  space, as well as its part of items (ii) and (iii) in  $O(n/r) = O(n^{3/4})$  space. Finally,  $v$  stores its distance to each other vertex in  $R$  in  $O(r) = O(n^{1/4})$  space. Using the same query algorithm, the distance between any two vertices  $s, t$  can be computed in  $O(1)$  time given just the labels of  $s$  and  $t$ .

## 5 $O(n^{5/3+\epsilon})$ space distance oracle

A bottleneck in the above approach comes from having to store, for each pattern  $p$  of a hole  $h$  of a region  $R$ , the distances from  $p$  to all vertices of  $R$ . Instead, we use a recursive  $r$ -division, in which we store for  $p$ , only the distances to the canonical vertex of a hole  $h'$  of each child region  $R'$  of  $R$  instead of all the vertices in the region. For this information to be useful we also store the pattern induced by  $p$  on the hole  $h'$ , which is defined as follows.

► **Definition 10** (Pattern induced by a pattern). *Let  $R$  be a region in a graph  $G$ . Let  $h$  be a hole of  $R$  and  $p_h$  be a pattern of  $h$  (w.r.t. a vertex or another pattern). Let  $R'$  be a child region of  $R$ . Let  $b_0, b_1, \dots, b_k$  be the vertices of the boundary walk of a hole of  $h'$  of  $R'$ . The pattern induced by  $p_h$  on  $h'$  is the vector  $p_{h'}$  satisfying  $p_{h'}[i] = \mathbf{d}(p_h, b_i) - \mathbf{d}(p_h, b_{i-1})$  for  $1 \leq i \leq k$ .*

► **Lemma 11.** *Consider the settings of Definition 10. If  $p_h = p_h(u)$  for some  $u \in V^+(h)$ , then  $p_{h'} = p_{h'}(u)$ .*

**Proof.** By Lemma 7, for every  $0 \leq i \leq k$ ,  $\mathbf{d}(u, b_i) - \mathbf{d}(u, b_{i-1}) = \mathbf{d}(p_h, b_i) - \mathbf{d}(p_h, b_{i-1})$ . Hence for all  $1 \leq i \leq k$ ,  $p_{h'}[i] = \mathbf{d}(p_h, b_i) - \mathbf{d}(p_h, b_{i-1}) = \mathbf{d}(u, b_i) - \mathbf{d}(u, b_{i-1}) - (\mathbf{d}(u, b_{i-1}) - \mathbf{d}(u, b_i)) = \mathbf{d}(u, b_i) - \mathbf{d}(u, b_{i-1})$ , which is, by definition,  $p_{h'}(u)[i]$ . ◀

### 5.1 Preprocessing

We first compute an  $\mathbf{r} = (r_0, r_1, \dots, r_k, r_{k+1})$ -division of  $G$  for  $\mathbf{r}$  to be determined later, and denote by  $\mathcal{T}_{\mathbf{r}}$  the associated decomposition tree. For convenience, we let  $r_0 = n$ ,  $r_{k+1} = 1$  and define  $C(R) = \{R' \mid R' \text{ is a child of } R \text{ in } \mathcal{T}_{\mathbf{r}}\}$ . In the following we let  $P_h$  denote the set  $\{p_h(u) : u \in V(G)\}$ . We store the following:

1. For each  $u \in V(G)$  we store a list of regions  $R_0 \supset R_1 \supset \dots \supset R_k$  containing  $u$ , where  $R_i \in \mathcal{T}_{\mathbf{r}}^i$ . (Recall that  $\mathcal{T}_{\mathbf{r}}^i$  is the set of all nodes of  $T_{\mathbf{r}}$  at level  $i$ ).

2. For each  $u \in V(G)$ , for each  $0 \leq i \leq k-1$ , for each region  $R \in \mathcal{T}_r^i$  containing  $u$ , for each child region  $R' \subset R$  at level- $(i+1)$ , let  $h$  be the hole of  $R'$  such that  $u \in V^+(h)$ . We associate with the pair  $(u, R')$  (i) a pointer to  $p_h(u)$ , (ii) the canonical vertex  $v_h$ , and (iii) the distance  $\mathbf{d}(u, v_h)$ .
3. For each  $1 \leq i \leq k$ , for each  $R \in \mathcal{T}_r^i$ , for each hole  $h$  in  $R$ , for each  $p \in P_h$  and for each  $R' \in C(R)$ , let  $h'$  be the hole of  $R'$  such that  $v_h \in V^+(h')$ . We associate with the pair  $(p, R')$  (i) a pointer to the pattern  $p_{h'}(p)$  induced by  $p$  on  $h'$ , (ii) the canonical vertex  $v_{h'}$ , and (iii) the distance  $\mathbf{d}(p, v_{h'})$ .

## 5.2 Space analysis

Storing 1 requires space  $O(kn)$ . To bound the space for item 2, we note that the number of regions at level  $i$  to which a vertex  $u$  belongs is bounded by the degree of  $u$ . Since the average vertex degree in a planar graph is at most 6, the average number of regions at level  $i$  to which  $u$  belongs is at most 6. Each such region has  $r_i/r_{i+1}$  subregions at level- $(i+1)$ , so storing 2 requires space  $O(n \sum_{i=0}^{k-1} r_i/r_{i+1}) = O(n^2/r_1) + O(n \sum_{i=1}^{k-1} r_i/r_{i+1})$ . Storing 3 requires space  $O(\sum_{i=1}^k (n/r_i) \cdot r_i^3 \cdot r_i/r_{i+1}) = O(n \sum_{i=1}^k r_i^3/r_{i+1})$ . The total space is thus,  $O(nk + n^2/r_1 + n \sum_{i=1}^k r_i^3/r_{i+1})$ .

## 5.3 Handling a query

Algorithm 1 shows pseudocode describing the query procedure.

■ **Algorithm 1** Query procedure for the  $O(n^{5/3+\varepsilon})$  construction.

---

```

1: procedure QUERY( $s, t$ )
2:    $i \leftarrow$  the largest  $i$  s.t. the region  $R_i$  stored in item 1 for  $t$  contains both  $s$  and  $t$ 
3:    $R_t \leftarrow$  level  $(i+1)$  region stored in item 1 for  $t$ 
4:    $(p, d) \leftarrow$  the tuple associated with  $(s, R_t)$ 
5:    $i \leftarrow i+1$ 
6:   while  $i \leq k$  do
7:      $R'_t \leftarrow$  level  $(i+1)$  subregion of  $R_t$  stored in item 1 for  $t$ 
8:      $(p', d') \leftarrow$  the tuple associated with  $(p, R'_t)$ 
9:      $d \leftarrow d + d'$  ;  $p \leftarrow p'$  ;  $R_t \leftarrow R'_t$  ;  $i \leftarrow i+1$ 
10:  return  $d$ 

```

---

To process a query  $\mathbf{d}(s, t)$  the query procedure first determines the largest value  $i$  for which  $s$  and  $t$  belong to the same region in  $\mathcal{T}_r^i$ . Note that such a region must always exist as the root of  $\mathcal{T}_r$  is all of  $G$ . This level can be found in  $O(k)$  time by traversing  $\mathcal{T}_r$ , starting from a leaf region containing  $s$  and a leaf region containing  $t$ .

Let  $R_t$  be the level- $(i+1)$  region stored for  $t$  in item 1. Note that,  $t \in R_t$ , and, by choice of  $i$ ,  $s \notin R_t$ . Hence,  $s$  is in some hole  $h$  of  $R_t$ . We retrieve the pattern  $p_h(s)$  and the distance  $\mathbf{d}(s, v_h)$  associated with  $(s, R_t)$  in item 2. We then proceed iteratively, “zooming” into increasingly smaller regions containing  $t$ .

We show that the algorithm maintains the invariant that, at the beginning of each iteration, we have a level- $i$  region  $R_t$  containing  $t$ , the variable  $d$  stores  $\mathbf{d}(s, v_h)$ , where  $h$  is the hole of  $R_t$  such that  $s \in V^+(h)$ , and the variable  $p$  stores (a pointer) to the pattern  $p_h(t)$ . Thus, when we reach the singleton region containing  $t$ , the variable  $d$  stores  $\mathbf{d}(s, t)$ .

We have already established that the invariant is maintained just before the loop is entered for the first time. In each iteration of the loop we retrieve  $R'_t$ , a level- $(i+1)$  subregion or  $R_t$  containing  $t$  (available in item 1), and retrieve  $d' \leftarrow \mathbf{d}(p, v_{h'})$  and  $p' \leftarrow p_{h'}(p)$  (associated with the pair  $(p, R'_t)$  in item 3). By Lemma 7,  $d + d' = \mathbf{d}(s, v_h) + \mathbf{d}(p_h(u), v_{h'}) = \mathbf{d}(s, v_{h'})$ . By Lemma 11,  $p' = p_{h'}(t)$ . Hence, after the assignments in Line 9, the invariant is restored.

The time complexity of the query is clearly  $O(k)$ .

#### 5.4 Choosing parameters

Recall that the space requirement is  $O(nk + n^2/r + n \sum_{i=1}^k r_i^3/r_{i+1})$ . Picking each  $r_i$  s.t.  $r_i/r_{i+1} = r_1^\varepsilon$  results in  $r_k = \Theta(1)$  when  $k = \Theta(1/\varepsilon)$ , and in a query time of  $O(1/\varepsilon)$ . Choosing  $r_1 = n^{1/3+\varepsilon}$ , the total space used becomes

$$O\left(n \sum_{i=1}^k r_i^3/r_{i+1}\right) = O(nr_1^2 r_1^\varepsilon) = O(n^{1+2/3+2\varepsilon+\varepsilon/3+\varepsilon^2}) = O(n^{5/3+\varepsilon'})$$

for a suitable choice of  $\varepsilon'$ .

One can decrease the sizes of regions more aggressively to get the query time of  $k = O(\log(1/\varepsilon))$  of Theorem 1. To this end we choose  $\mathbf{r}$  such that  $r_i^3/r_{i+1} = n^{2/3+\varepsilon}$ , and  $r_1 = n^{1/3}$ . Then the space requirement is  $O(n^{5/3} + knn^{2/3+\varepsilon}) = O(kn^{5/3+\varepsilon})$ . It is not hard to verify that one gets  $r_i = O(n^{1/3-\varepsilon \frac{3^i-2^i-1}{2}})$ , so  $r_k = O(1)$  with  $k = O(\log(1/\varepsilon))$ .

As a last remark we note that the smallest interesting choice of  $\varepsilon$  in Theorem 1 is  $\Theta(1/\log n)$ , giving  $O(n^{5/3})$  space and  $O(\log \log n)$  query-time, which is a faster query-time than was previously known for this amount of space [9, 7].

## Abstract

An edge coloring of a graph  $G$  is called *interval edge coloring* if for each  $v \in V(G)$  the set of colors on edges incident to  $v$  forms an interval of integers. A graph  $G$  is *interval colorable* if there is an interval coloring of  $G$ . For an interval colorable graph  $G$ , by the *interval chromatic index* of  $G$ , denoted by  $\chi'_i(G)$ , we mean the smallest number  $k$  such that  $G$  is interval colorable with  $k$  colors. A bipartite graph  $G$  is called  $(\alpha, \beta)$ -biregular if each vertex in one part has degree  $\alpha$  and each vertex in the other part has degree  $\beta$ . A graph  $G$  is called  $(\alpha^*, \beta^*)$ -bipartite if  $G$  is a subgraph of an  $(\alpha, \beta)$ -biregular graph and the maximum degree in one part is  $\alpha$  and the maximum degree in the other part is  $\beta$ .

In the paper we study the problem of interval edge colorings of  $(k^*, 2^*)$ -bipartite graphs, for  $k \in \{3, 4, 5\}$ , and of  $(5^*, 3^*)$ -bipartite graphs. We prove that every  $(5^*, 2^*)$ -bipartite graph admits an interval edge coloring using at most 6 colors, which can be found in  $O(n^{3/2})$  time, and we prove that an interval edge 5-coloring of a  $(5^*, 2^*)$ -bipartite graph can be found in  $O(n^{3/2})$  time, if it exists. We show that every  $(4^*, 2^*)$ -bipartite graph admits an interval edge 4-coloring, which can be found in  $O(n)$  time. The two following problems of interval edge coloring are known to be  $\mathcal{NP}$ -complete: 6-coloring of  $(6, 3)$ -biregular graphs (Asratian and Casselgren (2006)) and 5-coloring of  $(5^*, 5^*)$ -bipartite graphs (Giaro (1997)). In the paper we prove  $\mathcal{NP}$ -completeness of 5-coloring of  $(5^*, 3^*)$ -bipartite graphs.

## 1 Introduction

We use standard definitions and notations of graph theory. In the following, by a graph we mean a nonempty simple graph (i.e., without multiple edges or loops), and by a multigraph we mean a multigraph with possible multiple edges, but without loops.

Let  $G$  be a multigraph with vertex set  $V(G)$  and edge set  $E(G)$ . For some technical reasons, we assume that  $V(G) \cap \mathbb{N} = \emptyset$ . For each vertex  $v \in V(G)$ , by  $N_G(v)$  we mean the set of neighbours of  $v$  in  $G$ , and by  $E_G(v)$  we mean the set of edges incident with  $v$ . The degree of vertex  $v$  in  $G$ , denoted by  $\deg_G(v)$ , is the number  $|E_G(v)|$ . By  $n(G), m(G), \Delta(G)$  and  $\delta(G)$  we denote the number of vertices of  $G$ , the number of edges of  $G$ , the maximum and the minimum degree of a vertex of  $G$ , respectively. By *isolated vertex* we mean a vertex

---

<sup>1</sup> corresponding author

of degree 0, and by *pendant vertex* a vertex of degree 1. The set of all pendant vertices of  $G$  we denote by  $P(G)$ . By  $G[A]$ , where  $A \subset V(G)$ , we denote a subgraph of  $G$  induced by set  $A$ , and by  $G \setminus A$  we mean the graph  $G[V \setminus A]$ . We write  $H \subset G$  if and only if  $H$  is a subgraph of  $G$ , and  $H \sqsubset G$  if and only if  $H$  is an induced subgraph of  $G$ , i.e.,  $H = G[V(H)]$ .

A set of integers  $[a, b] = \{a, a + 1, \dots, b - 1, b\}$ , where  $a, b \in \mathbb{N}$  and  $a \leq b$ , is said to be an *interval* of integers. Let  $X \times Y = \{\{r, s\} : r \in X \wedge s \in Y\}$ .

A bipartite graph  $G$  is called  $(\alpha, \beta)$ -biregular if all vertices in one part of  $G$  have degree  $\alpha$  and all vertices in the other part have degree  $\beta$ . If  $G$  is a subgraph of an  $(\alpha, \beta)$ -biregular graph with the maximum degree in one part  $\alpha$  and the maximum degree in the other part  $\beta$ , it is called an  $(\alpha^*, \beta^*)$ -bipartite graph. If all vertices in the first part of an  $(\alpha^*, \beta^*)$ -bipartite graph have the same degree  $\alpha$ , then it is called an  $(\alpha, \beta^*)$ -bipartite graph. Analogously, we define  $(\alpha^*, \beta)$ -bipartite graphs. If we take the partition  $(A, B)$  of  $V(G)$  of an  $(\alpha^*, \beta^*)$ -bipartite graph  $G$ , we mean that the vertices from set  $A$  are of degree  $\alpha$  or less, and the vertices from set  $B$  are of degree  $\beta$  or less.

### 1.1 Interval coloring and interval $\chi'_i$ -coloring problems

Let  $G$  be a graph. Let  $c: E(G) \rightarrow \mathbb{N}$  be an edge coloring, i.e., a function assigning different colors to adjacent edges. By an *interval edge coloring* we mean an edge coloring  $c$  such that for each  $v \in V(G)$ , the set  $c(E_G(v))$  is an interval of integers. An interval edge coloring  $c$  such that  $c(E(G)) = \{1, 2, \dots, k\}$  is called *interval  $k$ -coloring*. We say that graph  $G$  is *interval colorable* ( *$k$ -colorable*) if there is an interval coloring ( $k$ -coloring) of  $G$ . If  $G$  is interval  $l$ -colorable for some  $l \leq k$ , then we say that  $G$  is interval  $k^*$ -colorable or there is an interval  $k^*$ -coloring of  $G$ . The problem of interval coloring of graphs is the problem of verifying if an arbitrary graph  $G$  is interval colorable. If  $G$  is interval colorable, then by *interval chromatic index* of  $G$ , denoted by  $\chi'_i(G)$ , we mean the smallest number  $k$  such that  $G$  is interval  $k$ -colorable. The problem of interval  $\chi'_i$ -coloring in the class of interval colorable graphs is to find an interval  $\chi'_i(G)$ -coloring for an arbitrary interval colorable graph  $G$ . Let  $\mathcal{A}$  be an interval edge coloring algorithm for some class  $\mathcal{C}$  of interval colorable graphs. We say that  $\mathcal{A}$  is  $k^*$ -algorithm for class  $\mathcal{C}$  if for every graph  $G \in \mathcal{C}$  it gives an interval  $k^*$ -coloring of  $G$ , and we say that  $\mathcal{A}$  is  $(\chi'_i + k)^*$ -algorithm for class  $\mathcal{C}$  if for each graph  $G \in \mathcal{C}$  it gives an interval  $(\chi'_i(G) + k)^*$ -coloring of  $G$  (i.e.,  $\mathcal{A}$  is an additive  $k$ -approximation algorithm for the interval  $\chi'_i$ -coloring problem).

The problem of finding school timetables without idle times for both teachers and classes, which may be modelled by edge colorings of bipartite graphs, probably motivated Asratian and Kamalian to introduce in [2, 3] the concept of interval edge coloring of graphs. The open shop scheduling models with unit time operations, *no wait&idle* criterion, and some special bipartite scheduling graphs were considered in [10, 9], where the authors studied schedules with the minimum makespan which corresponds to the interval  $\chi'_i$ -coloring problem of bipartite scheduling graphs.

In general, not every graph has an interval coloring, since interval colorable graphs are  $\Delta$ -colorable [2]. Moreover, the problem of determining whether a bipartite graph has an interval coloring turned out to be  $\mathcal{NP}$ -complete [19], and the smallest known maximum degree of a bipartite graph without an interval coloring is 11 [16].

Interval colorable graphs, which are known to be interval  $\chi'_i$ -colored in a polynomial time, are regular bipartite graphs (by König theorem) (in  $O(n\Delta \log \Delta)$  time with  $\chi'_i(G) = \Delta(G)$  colors, for a regular graph  $G$ ) [5], trees [14, 15, 11, 3] (in  $O(n)$  time with  $\chi'_i(T) = \Delta(T)$  colors, for a tree  $T$ ) and complete bipartite graphs (in  $O(m)$  time with  $\chi'_i(K_{a,b}) = a + b - \gcd(a, b)$  colors, for a complete bipartite graph  $K_{a,b}$ ) [14, 15, 11, 12]. In [8] the authors constructed an  $O(n)$  time algorithm for interval  $\chi'_i$ -coloring of a grid  $G$  with  $\chi'_i(G) = \Delta(G)$  colors.

In [9] the authors proposed the linear time algorithm for interval coloring of any outerplanar bipartite graph, but the complexity of the interval  $\chi'_i$ -coloring problem of outerplanar bipartite graphs seems to be open. In [10] the authors proposed the linear time algorithm giving an interval coloring of bipartite cacti graph  $G$  with  $\Delta(G) + 1$  colors, which is an  $(\chi'_i + 1)^*$ -algorithm.

In [11] the author proved that any  $(3^*, 3^*)$ -bipartite graph has an interval 4-coloring, which can be constructed in  $O(n)$  time. In [7] the author proved that an interval  $\alpha$ -coloring of  $(\alpha^*, \alpha^*)$ -bipartite graph can be found in  $O(n^{3/2})$  time (if it exists), for  $\alpha \in \{3, 4\}$ .

In [12] the authors proved that if an  $(\alpha, \beta)$ -biregular graph has an interval  $k$ -coloring, then  $k \geq \alpha + \beta - \gcd(\alpha, \beta)$ . In [11] the author proved that every  $(2\alpha, 2)$ -biregular graph admits an interval  $2\alpha$ -coloring (i.e.,  $\chi'_i$ -coloring), for each  $\alpha \geq 1$ , and this construction can be done in  $O(n\Delta \log \Delta)$  time. In [13] the authors proved that every  $(2\alpha + 1, 2)$ -biregular graph admits an interval  $(2\alpha + 2)$ -coloring (i.e.,  $\chi'_i$ -coloring), for every  $\alpha \geq 1$ , and to the best of our knowledge this construction can be done in  $O(n^{3/2}\Delta^2)$  time.

The following problems of interval  $\chi'_i$ -coloring are  $\mathcal{NP}$ -complete: 6-coloring of  $(6, 3)$ -biregular graphs [1] and 5-coloring of  $(5^*, 5^*)$ -bipartite graphs [7].

In [4] the authors proved that every  $(6, 3)$ -biregular graph admits an interval 7-coloring. The problems of interval coloring of  $(4, 3)$ -biregular and  $(5, 3)$ -biregular graphs are still open.

In the paper we solve the interval  $\chi'_i$ -coloring problem for  $(\alpha^*, 2^*)$ -bipartite graphs, for  $\alpha \in \{3, 4, 5\}$ . We show that if  $G$  is a  $(5^*, 2^*)$ -bipartite graph, then  $\chi'_i(G) \leq 6$ , and the interval  $\chi'_i$ -coloring problem for  $(5^*, 2^*)$ -bipartite graphs can be solved in  $O(n^{3/2})$  time. If  $G$  is a  $(4^*, 2^*)$ -bipartite graph, then  $\chi'_i(G) \leq 4$ , and the interval  $\chi'_i$ -coloring problem for  $(4^*, 2^*)$ -bipartite graphs can be solved in  $O(n)$  time. In section 3 we prove  $\mathcal{NP}$ -completeness of the interval 5-coloring of  $(5^*, 3^*)$ -bipartite graphs.

## 1.2 General and interval factor problem

We introduce the *general factor problem* [17, 6] as follows: let  $G$  be a graph and let  $\mathcal{F}: V(G) \rightarrow 2^{\mathbb{N}} \setminus \{\emptyset\}$ , where  $\mathcal{F}(v) \subset \{0, \dots, \deg_G(v)\}$ . Does  $G$  admit an  $\mathcal{F}$ -factor, i.e., a set  $F \subset E(G)$  such that for each vertex  $v \in V(G)$ ,  $|\{e: v \in e \wedge e \in F\}| \in \mathcal{F}(v)$ ? Lóvasz [17] proved that the general factor problem is  $\mathcal{NP}$ -complete for general graphs and mappings taking values  $\{0, 3\}$  for some vertices. In [6] Cornuéjols showed that the general factor problem is  $\mathcal{NP}$ -complete for planar bipartite graphs and mappings taking values  $\{0, 3\}$  for some vertices. A finite set  $A \subset \mathbb{N}$  is said to have a *gap of length*  $k \geq 1$  if  $a, a + k + 1 \in A$  and  $a + 1, \dots, a + k \notin A$ , for some  $a$ . A finite set  $A \subset \mathbb{N}$  has no gaps if and only if it is an interval. Thus, the general factor problem is  $\mathcal{NP}$ -complete for planar bipartite graphs and mappings taking values, i.e., sets, having gaps of length of at least two. In [6] the author proved the conjecture of Lóvasz [17]: there is a polynomial time algorithm for deciding whether a graph  $G$  has an  $\mathcal{F}$ -factor, where the sets  $\mathcal{F}(v)$  have no gap of length of two or more. The complexity of the proposed algorithm is  $O(n^4)$  [6].

If for each  $v \in V(G)$ , set  $\mathcal{F}(v)$  is an interval, then  $\mathcal{F}$ -factor is called an *interval factor*. A special case of interval factors is  $\mathcal{F}$ -factor, where  $\mathcal{F} \equiv \{k\}$ ,  $k \in \mathbb{N}$ , which we denote by  $k$ -factor, e.g., perfect matching is 1-factor.

Let us assume that there is an  $O(\phi(m, n))$  time algorithm ( $\phi(m, n) = \Omega(m + n)$  and  $\phi(m, n) = O(mn^{1/2})$  [18]) solving perfect matching problem in the class of connected bipartite graphs with at most  $m$  edges and  $n$  vertices. Combining the idea of replacing an edge with a complete bipartite graph [6] and the idea of doubling a graph [7] we prove the following theorem.

► **Theorem 1.** *There is an  $O(\phi(m\Delta, m))$  time algorithm solving the interval factor problem in the class of connected bipartite graphs with at most  $m$  edges and the degree bounded by  $\Delta$ .*

**Proof.** Let  $G$  be a connected bipartite graph and let  $\mathcal{F}: V(G) \rightarrow 2^{\mathbb{N}} \setminus \{\emptyset\}$ , such that  $\mathcal{F}(v) = [a_v, b_v]$ ,  $0 \leq a_v \leq b_v \leq \deg_G(v)$ . We construct a bipartite graph  $H$  with  $\Delta(H) \leq \Delta(G) + 1$ ,  $n(H) \leq 8m(G)$  and  $m(H) \leq 4m(G)(\Delta(G) + 1) + n(G)\Delta(G)$  such that there is 1-factor in  $H$  if and only if there is  $\mathcal{F}$ -factor in  $G$ .

For each vertex  $v \in V(G)$ , we denote  $d_v = \deg_G(v)$ ,  $p_v = b_v - a_v$  and  $q_v = d_v - a_v$ . Obviously,  $b_v \leq d_v$  and  $p_v \leq q_v$ . In the first step we construct graph  $H_1$  from graph  $G$ , by replacing each vertex  $v \in V(G)$  with the complete bipartite graph isomorphic to  $K_{d_v, q_v}$  with parts  $A_v^1 = \{v_u^1: u \in N_G(v)\}$  and  $B_v^1 = \{v_1^1, \dots, v_{q_v}^1\}$ , and by replacing each edge  $\{u, v\} \in E(G)$  with an edge  $\{u_v^1, v_u^1\}$ . In the second step, we take the resultant graph  $H_1$  and its isomorphic copy  $H_2$ , where  $v_*^1$  and  $v_*^2$  are corresponding vertices (under isomorphism), and, for each  $v \in V(G)$ , we add edges  $\{v_1^1, v_1^2\}, \dots, \{v_{p_v}^1, v_{p_v}^2\}$ .

Let  $V(H) = V(H_1) \cup V(H_2)$  and  $E(H) = E(H_1) \cup E(H_2) \cup E^*$ , where  $V(H_i) = \bigcup_{v \in V(G)} A_v^i \cup B_v^i$ ,  $E(H_i) = \bigcup_{v \in V(G)} A_v^i \times B_v^i \cup F^i$ , and  $F^i = \bigcup_{\{u, v\} \in E(G)} \{\{u_v^i, v_u^i\}\}$ , for  $i \in \{1, 2\}$ , and  $E^* = \bigcup_{v \in V(G)} \bigcup_{j \in \{1, \dots, p_v\}} \{\{v_j^1, v_j^2\}\}$ .

We prove that there is an  $\mathcal{F}$ -factor in  $G$  iff there is a 1-factor in  $H$ .

( $\Rightarrow$ ) Let  $F$  be  $\mathcal{F}$ -factor in  $G$ .

Let us define  $F_v = \{u \in N_G(v): \{v, u\} \in F\}$ ,  $\hat{F}_v = N_G(v) \setminus F_v$  and  $f_v = |F_v|$ , for each  $v \in V(G)$ . Since  $F$  is  $\mathcal{F}$ -factor, then for each  $v \in V(G)$ ,  $a_v \leq f_v \leq b_v$ . Hence,  $d_v - f_v \leq q_v$  and  $0 \leq f_v - a_v \leq p_v$ . Let  $v \in V(G)$ . Let  $F_v^i = \{v_u^i \in V(H_i): u \in F_v\}$  and  $\hat{F}_v^i = A_v^i \setminus F_v^i$ , for  $i \in \{1, 2\}$ . Observe that  $|\hat{F}_v^i| = d_v - f_v$ , and  $v_u^i \in F_v^i \iff u_v^i \in F_u^i$ . Since  $H_i[A_v^i \cup B_v^i] \simeq K_{d_v, q_v}$ , there is a 1-factor in  $H_i[\hat{F}_v^i \cup \{v_{f_v - a_v + 1}^i, \dots, v_{d_v - a_v}^i\}]$ , denote it by  $\hat{E}_v^i$ . Thus,  $Q = \bigcup_{\{v, u\} \in F} \{\{v_u^1, u_v^1\}, \{v_u^2, u_v^2\}\} \cup \bigcup_{v \in V(G)} \hat{E}_v^1 \cup \hat{E}_v^2 \cup E_v^{12}$ , where  $E_v^{12} = \{\{v_1^1, v_1^2\}, \dots, \{v_{f_v - a_v}^1, v_{f_v - a_v}^2\}\}$ , is a 1-factor in  $H$ . This construction can be done in  $O(m(H))$  time.

From definition of  $H$ ,  $\Delta(H) \leq \Delta(G) + 1$ ,  $n(H) = 2n(H_1) \leq 2 \sum_{v \in V(G)} 2d_v = 8m(G)$ , and  $m(H) \leq 4m(G) + \sum_{v \in V(G)} (2d_v(d_v - a_v) + b_v - a_v) \leq 4m(G) + \sum_{v \in V(G)} (2d_v^2 + d_v) \leq 4m(G) + \Delta(G) \sum_{v \in V(G)} (2d_v + 1) \leq 4m(G)(\Delta(G) + 1) + n(G)\Delta(G)$ . Since  $G$  is bipartite,  $H_1$  and  $H_2$  are bipartite, and hence  $H$  is bipartite. Since there is an  $O(\phi(m(H), n(H)))$  time algorithm finding 1-factor in  $H$ , we get the thesis.

( $\Leftarrow$ ) Let  $Q$  be a 1-factor in  $H$ .

Let  $v \in V(G)$  and  $i \in \{1, 2\}$ . Since  $|\{\{v_1^1, v_1^2\}, \dots, \{v_{p_v}^1, v_{p_v}^2\}\} \cap Q| \leq p_v$ ,  $q_v - p_v \leq |(A_v^i \times B_v^i) \cap Q| \leq q_v$ . Hence,  $a_v \leq |\{u \in N_G(v): \{v_u^i, u_v^i\} \in Q\}| \leq b_v$ . Thus,  $F = \{\{v, u\} \in E(G): \{v_u^1, u_v^1\} \in Q\}$  is an  $\mathcal{F}$ -factor in  $G$ . This construction can be done in  $O(m(H))$  time. ◀

In Fig. 1 there is a graph  $G$  with an interval factor and in Fig. 2 the constructed graph  $H$  with a 1-factor corresponding to the interval factor of  $G$ . White and black vertices form the partition of a bipartite graph.

Since the problem of 1-factor in the class of bipartite graphs with bounded degrees can be solved in  $O(n^{3/2})$  time [18], we have the following corollary.

► **Corollary 2.** *There is an  $O(n^{3/2})$  time algorithm solving the interval factor problem in the class of bipartite graphs with bounded degree.*

■ **Figure 1** A bipartite graph  $G$  with an interval factor (bold edges). ■ **Figure 2** A bipartite graph  $H$  with a 1-factor (bold edges) corresponding to the interval factor of  $G$ .

## 2 Interval $\chi'_i$ -coloring problem of $(\alpha^*, 2^*)$ -bipartite graphs

In this section we construct polynomial time algorithms for the interval  $\chi'_i$ -coloring problem for  $(\alpha^*, 2^*)$ -bipartite graphs, for  $\alpha \in \{3, 4, 5\}$ , and give some other minor results.

### 2.1 Introductory properties

► **Observation 3.** *Let  $G$  be an interval colorable graph, and let  $H$  be an induced subgraph of  $G$  such that for each  $v \in V(H)$ ,  $\deg_H(v) = \deg_G(v)$  or  $\deg_H(v) = 1$ . Then, for any interval edge coloring  $c$  of  $G$ , the coloring  $c' = c|_{E(H)}$  is an interval edge coloring of  $H$ .*

Let  $G$  be an  $(\alpha^*, 2^*)$ -bipartite graph with partition  $(X, Y)$  of  $V(G)$  and let  $P_2(G) = P(G) \cap Y$ . Let  $G'$  be the graph obtained from  $G$  by adding and joining the unique vertex  $x_v$  to each pendant vertex  $v \in Y$ . Formally,  $V(G') = V(G) \cup \{x_v : v \in P_2(G)\}$  and  $E(G') = E(G) \cup \{\{x_v, v\} : v \in P_2(G)\}$ . In the following, this operation (transformation) we denote by  $G \rightarrow_p G'$ . Since the extension of an interval  $k$ -coloring of  $G$  to an interval  $k$ -coloring of  $G'$  is trivial, by Observation 3 we get the properties.

► **Proposition 4.** *Let  $\alpha \in \mathbb{N}, \alpha \geq 1$ . Let  $G$  be an interval colorable  $(\alpha^*, 2^*)$ -bipartite graph and let  $G'$  be the graph obtained by the operation  $G \rightarrow_p G'$ . Then,  $G'$  is an interval colorable  $(\alpha^*, 2)$ -bipartite graph and  $\chi'_i(G) = \chi'_i(G')$ .*

Observe that for each  $(\alpha^*, 2^*)$ -bipartite graph  $G$  we have  $m(G) \leq 2n(G)$ .

► **Proposition 5.** *Let  $k, \alpha \in \mathbb{N}, \alpha \geq 1$ . If there is an  $O(\phi(n))$  time  $k^*$ -algorithm for  $(\alpha^*, 2)$ -bipartite graphs with at most  $n$  vertices, then there is an  $O(\phi(n))$  time  $k^*$ -algorithm for  $(\alpha^*, 2^*)$ -bipartite graphs with at most  $n$  vertices.*

Let  $G$  be an  $(\alpha, 2^*)$ -bipartite graph with the partition  $(X, Y)$  and let  $G'$  be an isomorphic copy of  $G$ . Let us denote by  $v'$  the image of  $v$  under isomorphism. Let  $P_2(G) = P(G) \cap Y$ ,  $q = |P_2(G)|$ , and for each  $v \in P_2(G)$ , let  $p_G(v)$  be the only one neighbour of  $v$  in  $G$ . Let  $W = \{w_v : v \in P_2(G)\}$ , such that  $W \cap (V(G) \cup V(G')) = \emptyset$  and  $|W| = q$ . Let  $H$  be a graph defined as follows:  $V(H) = (V(G) \cup V(G')) \setminus (P_2(G) \cup P_2(G')) \cup W$ , and  $E(H) = E(G \setminus P_2(G)) \cup E(G' \setminus P_2(G')) \cup \bigcup_{v \in P_2(G)} \{\{w_v, p_G(v)\}, \{w_v, p_{G'}(v')\}\}$ . In the following, this operation (transformation) is denoted by  $G \rightarrow_d H$ . Note that  $G \simeq G_W = H[(V(G) \setminus P_2(G)) \cup W]$ , hence  $G_W \simeq G'_W = H[(V(G') \setminus P_2(G')) \cup W]$ . Thus, if  $G_W$  is

an interval colorable graph, then for any interval  $k$ -coloring  $c$  of  $G_W$ , we can extend the coloring  $c$  to the coloring of the whole graph  $H$  by defining a coloring  $c'$  of  $G'_W$  as follows:  $c'(e') = c(e) + 1$ , where  $e$  and  $e'$  are isomorphic edges. Thus, by Observation 3 we get the following properties.

► **Proposition 6.** *Let  $\alpha \in \mathbb{N}, \alpha \geq 1$ . Let  $G$  be an interval colorable  $(\alpha, 2^*)$ -bipartite graph and let  $H$  be the graph obtained by the operation  $G \rightarrow_d H$ . Thus,  $H$  is an interval colorable  $(\alpha, 2)$ -biregular graph and  $\chi'_i(G) \leq \chi'_i(H) \leq \chi'_i(G) + 1$ .*

► **Proposition 7.** *Let  $k, \alpha \in \mathbb{N}, \alpha \geq 1$ . If there is an  $O(\phi(n))$  time  $k^*$ -algorithm for  $(\alpha, 2)$ -biregular graphs with at most  $n$  vertices, then there is an  $O(\phi(n))$  time  $k^*$ -algorithm for  $(\alpha, 2^*)$ -bipartite graphs with at most  $n$  vertices.*

Let us recall that  $\chi'_i(G) = 2\alpha$  if  $G$  is an  $(2\alpha, 2)$ -biregular graph [11], and  $\chi'_i(G) = 2\alpha + 2$  if  $G$  is an  $(2\alpha + 1, 2)$ -biregular graph [13].

► **Corollary 8.** *Let  $\alpha \in \mathbb{N}, \alpha \geq 1$ . If there is an  $O(\phi(n))$  time  $\chi'_i$ -algorithm for  $(2\alpha, 2)$ -biregular graphs with at most  $n$  vertices, then there is an  $O(\phi(n))$  time  $\chi'_i$ -algorithm for  $(2\alpha, 2^*)$ -bipartite graphs with at most  $n$  vertices, and for every  $(2\alpha, 2^*)$ -bipartite graph  $G$ ,  $\chi'_i(G) = 2\alpha$ .*

► **Corollary 9.** *Let  $\alpha \in \mathbb{N}$ . If there is an  $O(\phi(n))$  time  $\chi'_i$ -algorithm for  $(2\alpha + 1, 2)$ -biregular graphs with at most  $n$  vertices, then there is an  $O(\phi(n))$  time  $(\chi'_i + 1)^*$ -algorithm for  $(2\alpha + 1, 2^*)$ -bipartite graphs with at most  $n$  vertices, and for every  $(2\alpha + 1, 2^*)$ -bipartite graph  $G$ ,  $\chi'_i(G) \leq 2\alpha + 2$ .*

## 2.2 Operations on multigraphs and pom-graphs

Let  $H$  be a multigraph. Since  $H$  may have multiple edges incident with the same two vertices, we introduce the notation  $e_i(x, y)$  or  $e(x, y, i)$ , where  $i$  is an identifier, to distinguish two or more edges incident with  $x$  and  $y$ , e.g.,  $e_1(x, y)$  and  $e_2(x, y)$ . Let  $u, v \in V(H)$  such that there is no edge in  $E(H)$  incident with  $u$  and  $v$ . We say that a multigraph  $H'$  is obtained from  $H$  by *contracting* vertices  $v$  and  $u$  if vertices  $v, u$  are replaced by a new vertex  $w(u, v)$  and each edge  $e_i(x, t) \in E(H)$ , where  $x \in \{u, v\}, t \in V(H)$ , is replaced with  $e_i(w(u, v), t)$  (we say further that  $e_i(x, t)$  and  $e_i(w(u, v), t)$  are corresponding edges). Formally,  $H' = ((V(H) \setminus \{v, u\}) \cup \{w(u, v)\}, E(H \setminus \{u, v\}) \cup \{e_i(w(u, v), t) : x \in \{u, v\} \wedge t \in V(H) \wedge e_i(x, t) \in E(H)\})$ .

In the following by a multidigraph we mean a multidigraph without loops. Let  $D$  be a multidigraph. If  $a = (x, y)$  is an arc, then  $y$  is said to be the *head* and  $x$  the *tail* of the arc  $a$ . Since  $D$  may have multiple arcs with the same head and the same tail, we introduce the notation  $a_i(x, y)$  or  $a(x, y, i)$ , to distinguish two or more arcs with the same head and tail, e.g.,  $a_1(x, y)$  and  $a_2(x, y)$ . By  $\text{indeg}_D(v)$  we mean the number of arcs with the head at  $v$ , and by  $\text{outdeg}_D(v)$  we mean the number of arcs with the tail at  $v$  in  $D$ . We say that  $v \in V(D)$  is a pendant vertex in  $D$  if and only if  $\text{indeg}_D(v) + \text{outdeg}_D(v) = 1$ .

Let  $G$  be an  $(\alpha^*, 2)$ -bipartite graph with partition  $(X, Y)$  of  $V(G)$ ,  $\alpha \in \mathbb{N}, \alpha \geq 1$ . Let  $H$  be the multigraph obtained from  $G$  by replacing each two edges  $\{u, v\}$  and  $\{w, v\}$ , where  $v \in Y$ , with one new edge  $e_v(u, w)$  joining  $u$  and  $w$  (we allow multiple edges between  $u$  and  $w$ ). Formally,  $V(H) = X$ , and  $E(H) = \{e_v(u, w) : v \in Y\}$ . In the following, the multigraph  $H$  is said to be the *contraction multigraph* of  $G$ , which we denote by  $G \rightarrow_{cn} H$ . Let  $c$  be an interval  $k$ -coloring of  $G$ . We replace each edge  $e_v(u, w) \in E(H)$  with the arc  $a_v^c$ , where  $a_v^c$  has the tail at  $u$ , if  $c(\{u, v\})$  is an odd number, otherwise  $a_v^c$  has the tail at  $w$ . Since

$c$  is an interval edge coloring and  $\deg_G(v) = 2$ , then only one of  $c(\{u, v\})$  and  $c(\{w, v\})$  is an odd number. Formally,  $D_c(G)$  is the directed multigraph (multidigraph) with vertex set  $V(D_c(G)) = V(H)$  and arc set  $A(D_c(G)) = \{a_v^c : v \in Y\}$ .

By a *partially oriented multigraph* or a *pom-graph*  $P = (V, E \cup A)$  we mean the union of a multigraph  $G = (V, E)$  and a directed multigraph  $D = (V, A)$  on the same vertex set  $V$ , which we denote by  $P = G \cup D$ . In the following, by  $\text{Gr}(P)$  we mean the multigraph  $G$ , by  $\text{Di}(P)$  we mean the multidigraph  $D$ , by  $E(P)$  we mean  $E(G)$ , and by  $A(P)$  we mean  $A(D)$ . The underlying multigraph of a *pom-graph*  $P$ , denoted by  $\text{Un}(P)$ , is the multigraph obtained from  $P$  by replacing each arc  $a_i(x, y) \in A(P)$  with a new edge  $e_i(x, y)$ . Formally,  $\text{Un}(P) = (V(P), E(P) \cup E_A(P))$ , where  $E_A(P) = \{e_i(x, y) : a_i(x, y) \in A(P)\}$ . For each  $e \in E(\text{Un}(P))$ , by  $o(e)$  we mean  $e$ , if  $e \in E(P)$ , or  $a_i(x, y)$ , if  $e \in E_A(P)$  and  $e = e_i(x, y)$ . Let  $H = \text{Un}(P)$  and let  $v \in V(P)$ . By  $EA_P(v)$  we mean  $\{o(e) : e \in E_H(v)\}$ . By  $\deg_P(v)$  we mean  $\deg_H(v)$ , and hence  $\Delta(P) = \Delta(H)$ . Let  $B \subset V(P)$ , by  $P[B]$  we denote a *pom-graph*  $G[B] \cup D[B]$ , and by  $P \setminus B$  we mean the *pom-graph*  $P[V \setminus B]$ . We say that two vertices  $u, v \in V(P)$  are *neighbours* in  $P$  if and only if  $E(\text{Un}(P[\{u, v\}]))$  is a non-empty set.

Let  $P$  be a *pom-graph* and let  $a \leq b \leq \Delta(P)$ ,  $a, b \in \mathbb{N}$ . By  $V_{a,b}(P)$  we denote the set  $\{v \in V(P) : \deg_P(v) \in [a, b]\}$  and by  $G_{a,b}(P)$  we mean  $\text{Gr}(P[V_{a,b}(P)])$ . If  $a = b$ , then we write  $G_a(P)$  instead of  $G_{a,a}(P)$ .

Let  $P'$  be the multigraph obtained from *pom-graph*  $P$  by adding new vertices on each edge and each arc. If we add vertex  $w_e$  on an edge  $e = e_i(x, y)$ , then we add two new edges  $e_i(w_e, x)$  and  $e_i(w_e, y)$ . If we add vertex  $w_a$  on an arc  $a = a_i(x, y)$ , then we add an edge  $e_i(x, w_a)$  and an arc  $a_i(w_a, y)$ . Formally,  $V(P') = V(P) \cup \{w_e : e \in E(P)\} \cup \{w_a : a \in A(P)\}$ ,  $E(P') = \{e_i(w_e, x), e_i(w_e, y) : e \in E(P) \wedge e = e_i(x, y)\} \cup \{e_i(x, w_a) : a \in A(P) \wedge a = a_i(x, y)\}$ ,  $A(P') = \{a_i(w_a, y) : a \in A(P) \wedge a = a_i(x, y)\}$ . In the following, the *pom-graph*  $P'$  is said to be the *subdivision pom-graph* of *pom-graph*  $P$ , which we denote by  $P \rightarrow_{sd} P'$ .

### 2.3 Interval $\chi'_i$ -coloring problem of $(\alpha^*, 2^*)$ -bipartite graphs for $\alpha \in \{3, 4\}$

► **Theorem 10.** *Let  $G$  be a  $(3^*, 2^*)$ -bipartite graph. Then,  $\chi'_i(G) = 3$  if and only if each connected component of  $G$  contains at most one cycle. The construction of interval 3-coloring can be done in linear time.*

**Proof.** Let  $G$  be a  $(3^*, 2^*)$ -bipartite graph with partition  $(X, Y)$  of  $V(G)$ , and let  $P_2(G) = P(G) \cap Y$ . By definition  $\Delta(G) = 3$ .

( $\Rightarrow$ ) Let us assume that  $\chi'_i(G) = 3$ , and let  $G$  contain at least one cycle.

Let  $G'$  be the graph obtained from  $G$  by the operation  $G \rightarrow_p G'$ . By Proposition 4,  $G'$  is  $(3^*, 2)$ -bipartite graph and  $G'$  is interval 3-colorable if and only if  $G$  is interval 3-colorable.

Let  $c$  be an interval 3-coloring of  $G'$ , and let  $D = D_c(G')$ . Obviously,  $\text{indeg}_D(v) \leq 1$ , for each  $v \in V(D)$ . Let  $D'$  be a digraph obtained from  $D$  by successively removing pendant vertices. Hence, for each  $v \in V(D')$ ,  $2 \leq \text{indeg}_{D'}(v) + \text{outdeg}_{D'}(v) \leq 3$ , and  $\text{indeg}_{D'}(v) \leq 1$ . Thus,  $\text{outdeg}_{D'}(v) \geq 1$ . Since  $\sum_{v \in V(D')} \text{indeg}_{D'}(v) = \sum_{v \in V(D')} \text{outdeg}_{D'}(v)$ , each component of  $D'$  is a directed cycle. Thus, each component of  $G$  contains at most one cycle.

( $\Leftarrow$ ) Let us assume that each connected component of  $G$  has at most one cycle. First, we color each cycle with colors 1 and 2, alternately. Next, for each vertex  $v$  of degree 3 that belongs to a colored cycle, color edge  $\{v, u\}$  with 3, where  $u$  does not belong to the colored cycle. In the last step, color the remaining trees in a greedy way using 3 colors, preserving intervals at vertices. Thus, we get an interval 3-coloring of  $G$  in linear time. ◀

► **Theorem 11.** Let  $G$  be a  $(4^*, 2)$ -bipartite graph. Then,  $\chi'_i(G) = 4$ . The construction of an interval 4-coloring of  $G$  can be done in linear time.

**Proof.** Let  $G$  be a  $(4^*, 2)$ -bipartite graph. The construction proceeds in two crucial stages: first, we construct a *pom*-graph  $P$  from graph  $G$ , then we use the structure of  $P$  to build the interval 4-coloring of graph  $G$ . In the first stage we apply to  $G$  the sequence of transformations  $G \rightarrow_{cn} P_0 \dashrightarrow_1 P_1 \dashrightarrow_2 P_2 \rightarrow_{sd} P$ , where  $P_0$  is the contraction multigraph of  $G$ ,  $P_1$  and  $P_2$  are some *pom*-graphs, and  $P$  is the subdivision *pom*-graph of  $P_2$ . In the second stage we start from an edge&arc 4-coloring of  $P$ , preserve this coloring on the underlying graph  $G^* = \text{Un}(P)$ , and in the final step we transform the edge colored graph  $G^*$  to an interval edge colored initial graph  $G$ , by contracting vertices that come from vertices splitted in the transformations  $\dashrightarrow_1$  or  $\dashrightarrow_2$ .

$(P_0 \dashrightarrow_1 P_1)$  Initially, let  $H' = P_0, D' = (V(P_0), \emptyset)$ , and let  $P' = H' \cup D'$  be a *pom*-graph. We proceed with the following successive steps in a loop until there is no cycle in  $G_{3,4}(P')$ .

1. (*find a cycle*) Let  $C$  be a subgraph of  $G_{3,4}(P')$ , which is a cycle. Let  $V(C) = \{v_1, \dots, v_k\}$  and let  $E(C) = \{e(v_1, v_2, i_1), \dots, e(v_{k-1}, v_k, i_{k-1}), e(v_k, v_1, i_k)\}$ . Note that  $C$  may have two vertices.
2. (*orient the cycle*) Remove  $E(C)$  from  $E(P')$  and add  $k$  arcs  $a(v_1, v_2, i_1), \dots, a(v_{k-1}, v_k, i_{k-1}), a(v_k, v_1, i_k)$  to  $A(P')$ .
3. (*split vertices of the cycle*) For each  $v \in V(C)$  such that  $\deg_{P'}(v) = 3$ , or  $\deg_{P'}(v) = 4$  and  $\text{indeg}_{D'}(v) = 2$ , *split*  $v$  into vertices  $v^i$  and  $v^o$  as shown in Fig. 3 and 4. Note that in this case each dashed line is an arc with the tail at  $v$  or  $v^o$ . Formally, add new vertices  $v^i$  and  $v^o$  to  $V(P')$ , for each arc  $a_d(u, v)$  add new arc  $a_d(u, v^i)$ , for each arc  $a_d(v, x)$  add new arc  $a_d(v^o, x)$ , and for each edge  $e_d(v, x)$  add new edge  $e_d(v^o, x)$ , and remove  $v$  from  $V(P')$ .

Knowing that there is no cycle in  $G_{3,4}(P')$ , let  $P_1 = P'$ .

▷ **Claim 12.** For each  $v \in V(P_1)$ ,

- if  $\deg_{P_1}(v) = 1$ , then  $v$  is incident with an edge or an arc with the head at  $v$ ,
- if  $\deg_{P_1}(v) = 2$ , then  $v$  is incident with two edges or an edge and an arc with the tail at  $v$ , or two arcs with tails at  $v$ , or two arcs with heads at  $v$ ,
- if  $\deg_{P_1}(v) = 3$ , then  $v$  is incident with three edges,
- if  $\deg_{P_1}(v) = 4$ , then  $v$  is incident with four edges or two edges and two arcs, one with the tail at  $v$  and one with the head at  $v$ .

■ **Figure 3** Splitting vertex  $v$  of  $\deg_{P'}(v) = 3$ . ■ **Figure 4** Splitting vertex  $v$  of  $\deg_{P'}(v) = 4$ .

$(P_1 \dashrightarrow_2 P_2)$  Let  $P_1 = H_1 \cup D_1$ , where  $H_1$  is a multigraph and  $D_1$  is a multidigraph. Initially, let  $P' = P_1, H' = H_1$  and  $D' = D_1$ . We proceed with the following successive steps in a loop until there is no path in  $G_{3,4}(P')$ . Note that if  $V(G_{3,4}(P')) \neq \emptyset$ , then there is a path in  $G_{3,4}(P')$  with at least one vertex, and by Claim 12,  $\deg_{H'}(v) \geq 2$ , for each  $v \in V(G_{3,4}(P'))$ .

1. (*find a maximal path*) Let  $T$  be a subgraph of  $G_{3,4}(P')$ , which is a maximal path. Let  $V(T) = \{v_1, \dots, v_k\}$  and let  $E(T) = \{e(v_1, v_2, i_1), \dots, e(v_{k-1}, v_k, i_{k-1})\}$ . Note that  $T$  may have one vertex.
2. (*orient the path*) Since  $T$  is a maximal path in  $G_{3,4}(P')$  and  $\deg_{H'}(v) \geq 2$ , for each  $v \in V(G_{3,4}(P'))$ , where  $H' = \text{Gr}(P')$ , there is a vertex  $v \in V(P')$  with  $\deg_{P'}(v) \leq 2$  such that  $e_d(v, v_1) \in E(P')$ . Remove  $E(T) \cup \{e_d(v, v_1)\}$  from  $E(P')$  and add  $k$  arcs  $a(v, v_1, i_1), \dots, a(v_{k-1}, v_k, i_{k-1})$  to  $A(P')$ .
3. (*split vertices of the path*) For each  $v \in V(T)$  such that  $\deg_{P'}(v) = 3$ , or  $\deg_{P'}(v) = 4$  and  $\text{indeg}_{D'}(v) = 2$ , *split*  $v$  into vertices  $v^i$  and  $v^o$  as shown in Fig. 3 and 4. Note that in this case each dashed line may be an edge or an arc with the tail at  $v$  or  $v^o$ . Formally, add new vertices  $v^i$  and  $v^o$  to  $V(P')$ , for each arc  $a_d(u, v)$  add new arc  $a_d(u, v^i)$ , for each arc  $a_d(v, x)$  add new arc  $a_d(v^o, x)$ , and for each edge  $e_d(v, x)$  add new edge  $e_d(v^o, x)$ , and remove  $v$  from  $V(P')$ .

Knowing that there is no path in  $G_{3,4}(P')$ , let  $P_2 = P'$  and let  $P_2 = H_2 \cup D_2$ , where  $H_2$  is a multigraph and  $D_2$  is a multidigraph.

▷ **Claim 13.** For each  $v \in V(P_2)$ ,  $\deg_{P_2}(v) \leq 2$ . If  $\deg_{P_2}(v) = 2$  and there is an arc with the head at  $v$ , then  $v$  is incident with two arcs with heads at  $v$ .

*Proof.* If  $v \in V(P_2)$  is a vertex such that  $v = w^o$  or  $v = w^i$ , for some  $w \in V(P_0)$ , then  $\deg_{P_2}(v) \leq 2$ . Let  $v \in V(P_1)$  and  $\deg_{P_1}(v) > 2$ . Then,  $v \in V(G_{3,4}(P_1))$ , and by Claim 12, there is  $u \in V(P_1)$  such that  $e_d(u, v) \in E(P_1)$ . Thus,  $v \in V(T)$  for some path  $T$  while applying step (1) in the transformation  $P_1 \dashrightarrow P_2$ . After orienting the path  $T$  in step (2), vertex  $v$  is splitted in the next step (3) or its degree is 4 and there are two edges incident with  $v$ . In the latter case,  $v \in V(T')$  for some other path  $T'$  while applying step (1). Thus, after orienting the path  $T'$  in step (2),  $v$  is splitted in the successive step (3).

Let  $\deg_{P_2}(v) = 2$ , for some  $v \in V(P_2)$ , and let us assume that there is an arc with the head at  $v$ . If  $v \in V(P_0)$ , then there is no arc with the head at  $v$  in *pom*-graph  $P_2$ . Thus,  $v = w^i$  for some splitted vertex  $w$ , and  $v$  is incident with two arcs with heads at  $v$ . ◁

Let  $P$  be the *pom*-graph obtained by the transformation  $P_2 \rightarrow_{sd} P$ , and let  $H = \text{Gr}(P)$  and  $G^* = \text{Un}(P)$ . Obviously,  $H$  and  $G^*$  are simple graphs, and by Claim 13,  $\Delta(P) \leq 2$ .

▷ **Claim 14.** Let  $T \sqsubset H$  be a maximal path. Let  $v, u \in V(T)$  such that  $\deg_H(v) = \deg_H(u) = 1$ . If there are arcs  $(v, x), (u, y) \in A(P)$ , then  $|E(T)|$  is even.

▷ **Claim 15.** The graph  $G^*$  is bipartite and each component of  $G^*$  is a path of length of at least 2 or a cycle of length at least 4.

We define  $c': E(P) \cup A(P) \rightarrow \{1, 2, 3, 4\}$  separately for each  $P' \subset P$  such that  $P^*$  is a connected component of  $G^*$ , where  $P^* = \text{Un}(P')$ . By Claim 15,  $P^*$  is a path or a cycle. Let  $V(P') = \{v_1, \dots, v_l\}$  and let  $k = |E(P') \cup A(P')|$ . If  $P^*$  is a cycle, let us denote  $v_{k+1} = v_1$  and  $v_{k+2} = v_2$ . Let us assume that for each  $i \in \{1, \dots, k\}$ ,  $v_i$  and  $v_{i+1}$  are neighbours in  $P'$ . For each  $i \in \{1, \dots, k\}$ , let  $o_i = o(\{v_i, v_{i+1}\})$ , where  $\{v_i, v_{i+1}\} \in E(P^*)$ .

First, color arcs in  $A(P')$ . For each  $i \in \{1, \dots, k\}$ , if  $o_i$  is an arc with the head at  $v_i$ , then let  $c'(o_i) = 1$ , and if  $o_i$  is an arc with head at  $v_{i+1}$ , then let  $c'(o_i) = 4$ . Next, we color edges in  $E(P')$ . If  $o_1$  is an edge, then let  $c'(o_1) = 3$ . For each  $i \in \{1, \dots, k-1\}$  (if  $P^*$  is a cycle, also for  $i = k$ ), if  $o_i$  is an arc and  $o_{i+1}$  is an edge, then by Claim 13,  $o_i$  has the head at  $v_i$ . Since  $c'(o_i) = 1$ , let  $c'(o_{i+1}) = 2$ . We extend  $c'$  to the rest of uncolored edges of  $E(P')$ , coloring them with colors 2 and 3 such that no two adjacent edges have the same color.

## 26:10 Interval Edge Coloring of Bipartite Graphs with Small Vertex Degrees

Observe that if for some  $i \in \{1, \dots, k\}$ ,  $o_i$  is an edge and  $o_{i+1}$  is an arc with the tail at  $v_{i+1}$ , then  $c'(o_{i+1}) = 4$ , and by Claim 14,  $c'(o_i) = 3$ . If  $o_i$  and  $o_{i+1}$  are arcs, then by Claim 13,  $o_i$  and  $o_{i+1}$  have heads at  $v_{i+1}$ , hence  $c'(o_i) = 4$  and  $c'(o_{i+1}) = 1$ .

Let us define  $c^*: E(G^*) \rightarrow \{1, 2, 3, 4\}$  as follows:  $c^*(e) = c'(o(e))$ , where  $o(e) \in E(P) \cup A(P)$ . By the above construction of  $c'$ ,  $c^*$  is an edge 4-coloring.

Now, we define  $c: E(G) \rightarrow \{1, 2, 3, 4\}$ . We contract all the pairs of vertices from  $V(G^*)$  that come from vertices splitted in the transformations  $--\rightarrow_1$  or  $--\rightarrow_2$  and we preserve the colors on the corresponding edges, and thus we get the initial graph  $G$  that is edge colored. Formally, for each  $v^i, v^o \in V(G^*)$ , where  $v \in V(P_0)$  (see Fig. 3 and 4), we contract vertices  $v^i, v^o$  and we preserve the colors on the corresponding edges  $\{v^*, x\}$  and  $\{v, x\}$ , i.e.,  $c(\{v, x\}) = c^*(\{v^*, x\})$ , where  $v^*$  is  $v^i$  or  $v^o$ . Since  $c^*(E_{G^*}(v^i))$  is equal to  $\{1\}$ ,  $\{4\}$  or  $\{1, 4\}$  and  $c^*(E_{G^*}(v^o)) = \{2, 3\}$ , we get  $c(E_G(v)) = \{1, 2, 3\}$  or  $c(E_G(v)) = \{2, 3, 4\}$ , or  $c(E_G(v)) = \{1, 2, 3, 4\}$ . Thus,  $c$  is an interval 4-coloring of  $G$ .

Since the transformation of  $G$  into  $P_2$  can be done in linear time, and the coloring of  $P$  can be done in linear time, the final construction of the coloring of  $G$  can be done in linear time.  $\blacktriangleleft$

By Theorem 11, and Propositions 4 and 5 we get the following theorem.

► **Theorem 16.** *Let  $G$  be a  $(4^*, 2^*)$ -bipartite graph. Then,  $\chi'_i(G) = 4$ . The construction of an interval 4-coloring of  $G$  can be done in linear time.*

### 2.4 Interval $\chi'_i$ -coloring problem of $(5^*, 2^*)$ -bipartite graphs

Let  $G$  be a  $(5^*, 2^*)$ -bipartite graph. Let  $\mathcal{F}_5: V(G) \rightarrow 2^{\mathbb{N}} \setminus \{\emptyset\}$  be defined as follows: if  $\deg_G(v) = 2i + 1$ , for  $i \in \{0, 1\}$ , then let  $\mathcal{F}_5(v) = \{i, i + 1\}$ , if  $\deg_G(v) = 2i$ , for  $i \in \{1, 2\}$ , then let  $\mathcal{F}_5(v) = \{i\}$ , and if  $\deg_G(v) = 5$ , then let  $\mathcal{F}_5(v) = \{2\}$ .

Let  $G$  be a  $(5^*, 2^*)$ -bipartite graph. If  $c$  is an interval 5-coloring of  $G$ , then  $F = \{e \in E(G): c(e) \in \{2, 4\}\}$  is an  $\mathcal{F}_5$ -factor of  $G$ .

► **Theorem 17.** *Let  $G$  be a  $(5^*, 2^*)$ -bipartite graph with  $n$  vertices. Then,  $\chi'_i(G) = 5$  if and only if  $G$  admits an  $\mathcal{F}_5$ -factor. The construction of an interval 5-coloring can be done in  $O(n^{3/2})$  time.*

► **Theorem 18.** *Let  $G$  be a  $(5^*, 2)$ -bipartite graph. Then,  $5 \leq \chi'_i(G) \leq 6$  and the construction of an interval 6\*-coloring of  $G$  can be done in  $O(n^{3/2})$  time.*

By Theorems 17 and 18, and by Propositions 4 and 5 we get

► **Theorem 19.** *Let  $G$  be a  $(5^*, 2^*)$ -bipartite graph. Then,  $\chi'_i(G) \leq 6$  and the construction of an interval  $\chi'_i$ -coloring of  $G$  can be done in  $O(n^{3/2})$  time.*

## 3 $\mathcal{NP}$ -completeness results

► **Theorem 20.** *The problem of interval 5-coloring of  $(5^*, 3^*)$ -bipartite graphs is  $\mathcal{NP}$ -complete.*

The Table 1 contains the state-of-art and our results presented in this paper, and some open problems for further research.

## Abstract

The classical degree realization problem is defined as follows: Given a sequence  $\bar{d} = (d_1, \dots, d_n)$  of positive integers, construct an  $n$ -vertex graph in which each vertex  $u_i$  has degree  $d_i$  (or decide that no such graph exists). In this article, we present and study the related *selected neighbor degree realization* problem, which requires that each vertex  $u_i$  of  $G$  has a *neighbor* of degree  $d_i$ . We solve the problem when  $G$  is required to be acyclic (i.e., a forest), and present a sufficient and necessary condition for a given sequence to be realizable.

## 1 Introduction

**Background and motivation.** Different properties of a given network can be described using “profiles” of the network. As a classical example, the *degree profile* (or *degree sequence*) of an  $n$ -vertex graph  $G$  is the sequence  $\text{DEG}(G) = (d_1, \dots, d_n)$ , where  $d_i = \deg(u_i)$  is the degree of the vertex  $u_i$ .

The extensively studied *degree realization* problem concerns the situation where given a sequence of positive integers  $\bar{d} = (d_1, \dots, d_n)$ , we are asked whether there exists a graph whose degree sequence conforms to  $\bar{d}$ . (If so, then the sequence  $\bar{d}$  is called *graphic*.) Erdős and Gallai [15] gave a necessary and sufficient condition for deciding if a given degree profile is realizable (also implying a  $\Theta(n)$  time decision algorithm), and Havel and Hakimi [18, 19] gave a  $\Theta(\sum_i d_i)$  time algorithm that given a degree profile  $\bar{d}$  computes a realizing graph, or proves that the profile is not realizable. The problem is known to be particularly simple when the realizing graph is required to be acyclic, in which case the necessary and sufficient condition for realizability is simply that  $\sum_i d_i = 2(n - k)$ , where  $k \in \{1, \dots, n\}$  (see [16] for a short analysis for trees). Many extensions and variations of the degree realization problem were studied in the past, cf. [1, 11, 20, 24, 26, 31, 32, 34, 35]. Interesting applications in the context of social networks are studied in [9, 13, 21].

Other aspects of the graph structures may be described using other types of profiles. We focus on profiles that capture aspects of the *vertex neighborhoods* in the given graph. One reason for our interest in neighbor degrees is that in the context of social networks, it is often informative to observe not only the individual degree of each vertex, but also the degrees of nearby vertices, since obtaining a more complete picture of the degree distribution in a given neighborhood may reveal useful information regarding the interrelationships among vertices, and their relative standing in their immediate society.

Let  $N[u]$  denote the closed (inclusive) neighborhood of the vertex  $u$  in  $G$ , namely  $N[u] = \{v \mid (v, u) \in E\} \cup \{u\}$ . Clearly, the profile  $N(G) = \langle N[u_1], \dots, N[u_n] \rangle$  tells us everything we may need to know. However, this profile is costly, or “heavy”, in the sense that storing it requires as much memory as storing the entire graph. Instead, one is often interested in studying “lighter” profiles, storing only a small amount of information per vertex.

For a graph  $G(V, E)$ ,  $V = \{u_1, \dots, u_n\}$ , let  $\text{ctr} : V \rightarrow V$  be a *neighbor selection* function, such that  $\text{ctr}(u) \in N[u]$  for each vertex  $u$ . We refer to the vertex  $\text{ctr}(u)$  as  $u$ 's *selected neighbor* or *center*. For each vertex  $u$ , denote the degree of  $u$ 's selected neighbor by  $\text{snd}(u) = \deg(\text{ctr}(u))$ . Then the sequence  $\text{SND}(G, \text{ctr}) = (\text{snd}(u_1), \dots, \text{snd}(u_n))$  is referred to as the *selected neighbor degree (SND) profile* of the pair  $(G, \text{ctr})$ .

Interesting special cases of the selected neighbor degree profile SND arise when the neighbor selection function  $\text{ctr}$  targets some specific neighbor for each vertex. The ordinary degree profile is obtained by using  $\text{ctr}^{\text{self}}(u) = u$ . Picking the function  $\text{ctr}^{\text{max}}$ , which selects for every vertex  $u$  its neighbor of maximum degree, yields

$$\text{maxnd}(u) = \deg(\text{ctr}^{\text{max}}(u)) = \max\{\deg(w) \mid w \in N[u]\},$$

which gives the *maximum neighbor degree* profile  $\text{MaxND}(G) = (\text{maxnd}(u_1), \dots, \text{maxnd}(u_n))$ . The functions  $\text{ctr}^{\text{min}}$  and  $\text{minnd}$  and the *minimum neighbor degree* profile  $\text{MinND}(G)$  can be defined analogously. Note that the profile  $\text{MaxND}(G)$  (resp.,  $\text{MinND}(G)$ ) is independent of the choice of  $\text{ctr}^{\text{max}}$  (resp.,  $\text{ctr}^{\text{min}}$ ). This is not the case for general SND profiles.

Recently, we studied the realization problem for the  $\text{MinND}$  and  $\text{MaxND}$  profiles. In particular, the *minimum neighbor degree realization* problem, where given a sequence  $\bar{d}$  of  $n$  integers one must decide if there is a graph  $G$  such that  $\text{MinND}(G) = \bar{d}$  and construct such a graph (if exists), was studied in [3]. A complete characterization was given for realization by *forests* (i.e., acyclic graphs), but the problem over general graphs was left open. Surprisingly, when studying the realizability of the *maximum neighbor degree* profile  $\text{MaxND}$  [6], the picture was reversed: we were able to give a complete characterization for the realization problem of maximum neighbor degrees on general graphs, but on forests the problem appears to be harder, and was left open.

It is therefore natural to investigate the problem's behavior when, instead of  $\text{MaxND}$  and  $\text{MinND}$ , we look at general *selected neighbor degree* profiles. The current study addresses this question. We resolve the realizability of SND profiles by forests, although surprisingly even this more relaxed variant turned out to be subtle and considerably more difficult than anticipated initially. Formally, we study the *selected neighbor degree Forest realization (SNDF) problem*. Consider a given  $n$ -integer *SNDF-specification*  $\bar{d}$ . We say that  $\bar{d}$  is a *forest-realizable SNDF-profile* if there exists an  $n$ -vertex forest  $F$ , and a neighbor selection function  $\text{ctr}$ , whose SNDF-profile satisfies  $\text{SND}(F, \text{ctr}) = \bar{d}$ .

**Our Contribution.** We study an optimization version of the SNDF problem. As mentioned earlier, not every SNDF-specification  $\bar{d}$  is realizable. To cope with unrealizable profiles, we define a measure for the deviation of a given profile  $\bar{d}$  from realizability in Sect. 2, where we also introduce the basic elements of the problem, as well as some preliminary notions used in our solution. In Sect. 3 we introduce the framework, give a high-level overview of the general approach and present basic tools for handling SNDF profiles. In Section 4 we present a tight lower bound on the deviation of SNDF-profiles. This lower bound lays the foundation for our algorithm. We also outline our construction algorithm for the problem, which is optimal in the sense that when  $\bar{d}$  is realizable by a forest, the resulting construction  $(F, \text{ctr})$

is a realization of  $\bar{d}$ , and when it is not realizable, the resulting  $(F, \text{ctr})$  has the minimum possible deviation (matching the lower bound). Both the lower bound and the algorithm are rather involved, hence most of the details are omitted for lack of space and can be found in [36]. As a byproduct, our analysis also yields necessary and sufficient conditions for a specification  $\bar{d}$  to be realizable by a forest, as well as a fast algorithm for deciding realizability, thus providing a complete solution for the SNDF problem. Finally, our algorithm can be easily modified into one that minimizes the number of centers.

**Related Work.** Over the years, various extensions of the degree realization problem were studied, cf. [1, 34]. Many studies have addressed related questions such as finding all the (non-isomorphic) graphs that realize a given degree sequence, counting all the (non-isomorphic) realizing graphs of a given degree sequence, sampling a random realization for a given degree sequence as uniformly as possible, or determining the conditions under which a given degree sequence defines a unique realizing graph (a.k.a. the *graph reconstruction* problem), cf. [11, 15, 18, 19, 20, 24, 26, 31, 32, 35]. Interesting applications in the context of social networks are studied in [9, 21, 13]. The somewhat related *shotgun assembly* problem [22] studies graph specifications consisting of a description of the  $r$ -neighborhood (up to radius  $r$ ) of each vertex  $i$ . Realization questions of a similar nature were studied for *other* applications, where given *some* type of information profile specifying the desired vertex properties (concerning distances, connectivity, centrality, or any other property of significance), one may ask whether there exists a graph conforming to the specified profile (see, e.g., [2, 4, 5, 7, 8, 12, 14, 10, 17, 23, 25, 27, 28, 29, 30, 33, 37]). The selected neighbor degree realization problem belongs to this class of problems.

## 2 Preliminaries

Let  $F = (V, E)$  be a forest. For a vertex set  $U \subseteq V$ , let  $N[U] = \bigcup_{u \in U} N[u]$  be the *closed neighborhood* of  $U$ . Let  $\text{ctr} : V \rightarrow V$  be a *neighbor* function on  $F$ 's vertices such that  $\text{ctr}(u) \in N[u]$  for each  $u \in V$ . For every  $u \in V$ , define

$$\text{snd}(u) = \text{snd}_{(F, \text{ctr})}(u) = \deg_F(\text{ctr}(u)) .$$

When  $F$  and  $\text{ctr}$  are clear from the context, we omit them and write  $\text{snd}(u)$ . We refer to  $\text{snd}(u)$  as the *snd value* of  $u$ . The *SND profile* of  $(F, \text{ctr})$  is the sequence

$$\text{SND}(F, \text{ctr}) = (\text{snd}(u))_{u \in V} .$$

It is convenient to represent an SNDF profile in a condensed form as a list of non-negative integers  $(k_i^{n_i})_{i=1}^{\ell}$ , meaning that each value  $k_i$  appears in the list  $n_i$  times and the list contains  $\ell$  distinct values, i.e. there are  $n_i$  vertices that have *snd* value  $k_i$ . We assume  $n - 1 \geq k_1 > \dots > k_\ell \geq 0$ . Overall  $n = \sum_{i=1}^{\ell} n_i$ .

We are interested in the following SNDF realization problem. A given sequence  $\bar{d} = (k_i^{n_i})_{i=1}^{\ell}$  is viewed as an *SNDF profile*. It is realizable if there exists a pair,  $(F, \text{ctr})$ , where  $F$  is a forest, such that  $\text{SND}(F, \text{ctr}) = \bar{d}$ . We call  $(F, \text{ctr})$  an *SNDF realization* of  $\bar{d}$ . (Note that  $\bar{d}$  may or may not be realizable.) The problem concerns finding a realizing  $(F, \text{ctr})$  for a given profile  $\bar{d}$ , if exists. Observe that the *snd* value 0 can only be realized by singleton vertices, independently of the rest of the profile. So hereafter assume that  $k_\ell \geq 1$ .

**Star formations.** When  $k_i + 1$  vertices are required by the profile to have a neighbor of degree  $k_i$ , the requirement can be easily satisfied in a self-sufficient manner by a star composed of a root  $v$  and  $k_i$  leaves, all pointing at the root (i.e., with  $\text{ctr}(u) = v$ ). Likewise,

## 27:4 Selected Neighbor Degree Forest Realization

if the profile contains  $k_i^{n_i}$  where  $n_i = c \cdot (k_i + 1)$  for some integer  $c$ , then this component of the profile can be realized on its own, using  $c$  stars of size  $k_i$  (where by the *size* of a star we refer to the number of leaves). This motivates the following alternative representation for a profile  $\bar{d}$ , using two sequences  $(c_i)_{i=1}^\ell$  and  $(\rho_i)_{i=1}^\ell$  such that

$$n_i = c_i(k_i + 1) - \rho_i \quad \text{and} \quad 0 \leq \rho_i \leq k_i, \quad (1)$$

where  $\rho_i = c_i(k_i + 1) - n_i$  is the  $i$ th *residue*. We refer to the tuple  $(c_i, \rho_i)_{i=1}^\ell$  as the *star formation* of  $\bar{d}$ . Note that

$$n = \sum_{i=1}^{\ell} n_i = \sum_{i=1}^{\ell} (c_i(k_i + 1) - \rho_i).$$

As mentioned before, not every profile  $\bar{d}$  is realizable. We therefore seek approximate solutions to the SNDF realization problem.

**Upper realizations and deviation.** Let  $F = (V, E)$  be a forest and let  $\text{ctr} : V \rightarrow V$ . We say that  $(F, \text{ctr})$  is an *upper realization* (or U-realization) of the profile  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$  if the SNDF profile of  $(F, \text{ctr})$  is of the form  $\text{SND}(F, \text{ctr}) = \bar{d}' = (k_i^{n'_i})_{i=1}^\ell$  (so in particular  $\text{snd}(u) \in \{k_1, \dots, k_\ell\}$  for every  $u$ ) and  $n'_i \geq n_i$  for every  $i$ . Denote  $n(F) = \sum_{i=1}^{\ell} n'_i$ . Denote by  $cc(F)$  the number of connected components in  $F$ . Define the *deviation* of  $(F, \text{ctr})$  from the profile  $\bar{d}$  as

$$\text{Dev}(\bar{d}, (F, \text{ctr})) = \sum_{i=1}^{\ell} (n'_i - n_i) = n(F) - n.$$

**The trivial U-realization.** Observe that there is a straightforward way for constructing a U-realization to a given profile  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$ . Define  $(c_i)_{i=1}^\ell$  and  $(\rho_i)_{i=1}^\ell$  as above. For each  $1 \leq i \leq \ell$  create  $c_i$  stars of size  $k_i$ , and for each leaf  $v$  in a star with center  $u$  define  $\text{ctr}(v) = u$  and  $\text{ctr}(u) = u$ . The resulting forest  $\tilde{F}$  contains  $cc(\tilde{F}) = \sum_{i=1}^{\ell} c_i$  connected components and  $\sum_{i=1}^{\ell} c_i(k_i + 1)$  vertices. We refer to this construction as the *trivial* construction and denote it by  $(\tilde{F}(\bar{d}), \tilde{\text{ctr}}(\bar{d}))$ . Note that

$$\text{Dev}(\bar{d}, (\tilde{F}, \tilde{\text{ctr}})) = \sum_{i=1}^{\ell} (c_i(k_i + 1) - n_i) = \sum_{i=1}^{\ell} \rho_i. \quad (2)$$

While this realization may in some cases be near-optimal, our goal is to construct a U-realization  $(F, \text{ctr})$  whose number of vertices,  $n(F)$ , is as close as possible to  $n$ , the specified number of vertices. Define the *realizable size* of a given profile  $\bar{d}$  as the minimal size of any U-realization for it,

$$n^*(\bar{d}) = \min\{n(F) \mid \exists \text{ctr} : (F, \text{ctr}) \text{ is a U-realization for } \bar{d}\}.$$

Define the deviation of a given profile  $\bar{d}$  as the minimum deviation over all of its U-realizations,

$$\text{Dev}(\bar{d}) = n^*(\bar{d}) - n = \min\{\text{Dev}(\bar{d}, (F, \text{ctr})) \mid (F, \text{ctr}) \text{ is a U-realization for } \bar{d}\}. \quad (3)$$

In this way, we can redefine realizability of SNDF profiles as follows. A given SNDF profile  $\bar{d}$  is realizable if and only if  $n^*(\bar{d}) = n$ , or alternatively,  $\text{Dev}(\bar{d}) = 0$ . Denote by  $(F^*, \text{ctr}^*)$  an optimal U-realization of  $\bar{d}$  (note that  $(F^*, \text{ctr}^*)$  is not necessarily unique), namely, such that  $n(F^*) = n^*(\bar{d})$ , or,  $\text{Dev}(\bar{d}, (F^*, \text{ctr}^*)) = \text{Dev}(\bar{d})$ . Our goal is to find such a realization.

■ **Figure 1** Realization of  $\bar{d}^1 = (6^1, 3^{16})$  using  $\bar{s} = (1, 5)$ . The centers are marked by their degrees.

**Centers and members.** The sets of  $k_i$ -centers and  $k_i$ -members in upper realization  $(F, \text{ctr})$  for a profile  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$  are

$$C_i(F, \text{ctr}) = \{u \in F \mid \deg(u) = k_i, \exists v \in N[u] \text{ s.t. } \text{ctr}(v) = u\},$$

$$M_i(F, \text{ctr}) = \{u \in F \mid \text{snd}(u) = k_i\}.$$

(We may write simply  $C_i$  and  $M_i$  when clear from context.) Clearly,  $C_i \cap C_j = \emptyset$  and  $M_i \cap M_j = \emptyset$  for every  $i \neq j$ , and  $\bigcup_i M_i = V$ , i.e., the sets  $M_i$  form a partition of the vertices of  $F$ . Set  $\sigma_i(F, \text{ctr}) = |C_i(F, \text{ctr})|$ , and let

$$C(F, \text{ctr}) = \bigcup_{i=1}^\ell C_i(F, \text{ctr})$$

and

$$\bar{\sigma}(F, \text{ctr}) = (\sigma_1(F, \text{ctr}), \dots, \sigma_\ell(F, \text{ctr})).$$

**Center specification sequences (CSS).** Clearly, any U-realization  $(F, \text{ctr})$  for  $\bar{d}$  must use at least  $c_i$  centers on layer  $i$ , so  $\sigma_i \geq c_i$  for every  $i$  (see also Lemma 5(1)). Unfortunately, for some profiles, using exactly  $c_i$  centers for every  $i$  yields a suboptimal upper realization (with deviation greater than  $Dev(\bar{d})$ ). A key component of the problem is thus to decide, given  $\bar{d}$ , on the right number of centers for each layer. These numbers are represented as a *center specification sequence* (or *CSS*)  $\bar{s} = (s_1, \dots, s_\ell)$ , which must satisfy  $s_i \geq c_i$  for every  $i$ . A U-realization  $(F, \text{ctr})$  *conforms* to  $(\bar{d}, \bar{s})$  if the number of centers on each layer is as specified by  $\bar{s}$ , i.e.,  $\bar{\sigma}(F, \text{ctr}) = \bar{s}$ . In our construction, we first select a CSS  $\bar{s}$ , and then look for a conforming U-realization  $(F, \text{ctr})$  for it.

For example, the profile  $\bar{d}^1 = (6^1, 3^{16})$  requires at least  $\bar{c} = (1, 4)$  centers, but any U-realization with this many centers has deviation at least 1 (as follows from Thm. 8), whereas using the CSS  $\bar{s} = (1, 5)$  yields the optimal  $Dev(\bar{d}^1) = 0$ , as demonstrated in the Figure 1.

Intuitively, in a conforming U-realization  $(F, \text{ctr})$ , each  $x \in C_i$  acts as the center of a star of degree  $k_i$ , potentially allowing its “clients”  $y \in M_i$  to have  $\text{snd}(y) = k_i$  by setting  $\text{ctr}(y) = x$ . Each center is also a member, possibly for a different  $i$ . Also,  $\text{ctr}(u) \in C_i \cap N[u]$  for every  $i \in [\ell]$  and  $u \in M_i$ , so  $M_i \subseteq N[C_i]$  and  $|M_i| \leq s_i(k_i + 1)$ . Define the *residue* of  $k_i$  w.r.t. a CSS  $\bar{s}$  as

$$\rho_i^s = s_i(k_i + 1) - n_i. \tag{4}$$

Note that Eq. (4) for  $\bar{s} = \sigma(F, \text{ctr}) = (s_1, \dots, s_\ell)$  and  $\bar{\rho}^s = \bar{\rho}^\sigma(F, \text{ctr}) = (\rho_1^s, \dots, \rho_\ell^s)$  is analogous to Eq. (1) for our star formation  $(\bar{c}, \bar{\rho})$ , since

$$n_i = s_i(k_i + 1) - \rho_i^s = c_i(k_i + 1) - \rho_i, \tag{5}$$

which is related to our definition of star formation, since each  $k_i$ -center  $u$  has  $|N[u]| = k_i + 1$ . We break the forest  $F$  into (possibly overlapping) stars centered around the  $k_i$ -centers in  $C_i$ .

The following two assumptions on U-realizations  $(F, \text{ctr})$  are used hereafter without loss of generality.

**Member independence.** In  $(F, \text{ctr})$ , the non-centers are independent, namely,  $F$  contains no edge  $(u, v)$  between any  $u, v \notin C$ . (Such edges can always be removed without changing the profile of  $F$ , and our constructions never use them.)

**No cross-pointing.** In  $(F, \text{ctr})$ , there is no *cross-pointing*, i.e., there are no two centers  $u$  and  $v$  such that  $\text{ctr}(u) = v$  and  $\text{ctr}(v) = u$ . (If cross-pointing occurs, one can change the two ctr values to  $\text{ctr}(u) = u$  and  $\text{ctr}(v) = v$  without changing the profile. Again, our constructions never use cross-pointing.)

### 3 Framework and basic tools

In this section, we describe the basic framework and the tools we use for realizing SNDF profiles.

#### Handling leaf centers

We first show how to handle the cases where  $k_\ell = 1$ . Consequently, in the rest of this article, we consider only SNDF profiles  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$  where  $k_\ell \geq 2$ .

Trivial profiles of the form  $\bar{d} = (1^n)$  for  $n \geq 2$  can be realized by a star  $(F, \text{ctr})$  with  $n - 1$  leaves, such that  $\text{ctr}(u) = u$  for each leaf  $u$ , and for the center,  $v$ ,  $\text{ctr}(v)$  is defined to be one of the leaves.

It remains to handle profiles  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$  where  $\ell \geq 2$  and  $k_\ell = 1$ . This is done by the following approach. Given such a profile  $\bar{d}$ , denote the *truncated profile* (without  $k_\ell$ ) by  $\bar{d}' = (k_i^{n_i})_{i=1}^{\ell-1}$ . We show that the deviation of  $\bar{d}$  is  $\text{Dev}(\bar{d}) = \max\{\text{Dev}(\bar{d}') - n_\ell, 0\}$ , and moreover, there is a polynomial time algorithm that given an optimal U-realization (of a special type, referred to as a *leaf-covered* U-realization) for  $\bar{d}'$ , transforms it into an optimal U-realization for  $\bar{d}$ . Hence the problem is reduced to finding optimal leaf-covered realizations for truncated profiles (with  $k_\ell \geq 2$ ).

#### Leaf-covered U-realizations

Let  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$  be an SNDF profile with U-realization  $(F, \text{ctr})$ . Denote  $e_i = |M_i| - n_i$ , namely, the number of excess vertices with snd value  $k_i$ . Let  $L = \{u \in V(F) \mid \deg(u) = 1\}$  be the set of leaves of  $F$ . We say that  $(F, \text{ctr})$  is a *leaf-covered* U-realization for  $\bar{d}$  if  $|L \cap M_i| \geq e_i$  for every  $i$ .

Intuitively, a leaf-covered U-realization is easy to work with, since we may think of all the excess vertices as being among the leaves.

The reduction and its analysis are deferred to the full paper (see [36]). We get:

► **Proposition 1.** *Let  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$  be a profile with  $\ell \geq 2$  and  $k_\ell = 1$ . Let  $(F', \text{ctr}')$  be an optimal leaf-covered U-realization for  $\bar{d}' = (k_i^{n_i})_{i=1}^{\ell-1}$ , namely,  $\text{Dev}(\bar{d}', (F', \text{ctr}')) = \text{Dev}(\bar{d}')$ . Then  $(F', \text{ctr}')$  can be converted, in polynomial time, into an optimal U-realization  $(F, \text{ctr})$  for  $\bar{d}$ , with  $\text{Dev}(\bar{d}, (F, \text{ctr})) = \text{Dev}(\bar{d})$ .*

By Prop. 1, it suffices to focus on finding optimal leaf-covered U-realizations for profiles without degree 1. Our main result is the following.

► **Theorem 2.** *Let  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$  be an SNDF profile such that  $k_\ell \geq 2$ . There exists an algorithm that constructs an optimal U-realization  $(F^*, \text{ctr}^*)$  for  $\bar{d}$ , namely,  $\text{Dev}(\bar{d}, (F^*, \text{ctr}^*)) = \text{Dev}(\bar{d})$ . In addition,  $(F^*, \text{ctr}^*)$  is leaf-covered. The run-time of the algorithm is  $O(n^*(\bar{d}))$ , which is optimal.*

**Overview of the general approach**

Consider a profile  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$  and let  $(F, \text{ctr})$  be some U-realization of  $\bar{d}$  with center classes  $C_1, \dots, C_\ell$  and  $C = \bigcup_i C_i$ . Consider a collection of stars  $\{S_u\}_{u \in C}$ , where  $S_u$  is centered at  $u$  and contains all of  $u$ 's neighbors in  $F$  and their respective edges. Note that  $S_u$  and  $S_v$  are not necessarily disjoint, but they can share at most two vertices, namely,  $|N[u] \cap N[v]| \leq 2$ , since otherwise, there is a cycle in  $F$ . The trivial U-realization for  $\bar{d}$ ,  $(\tilde{F}, \tilde{\text{ctr}})$  is wasteful, since it employs  $\sum_{i=1}^\ell c_i$  pairwise disjoint stars, resulting in  $\sum_{i=1}^\ell c_i(k_i + 1)$  vertices. To improve it, we construct a realization by starting from disjoint stars and then forcing them to share vertices by performing certain merge operations. The key operation performed by our algorithm involves merging stars. Specifically, the algorithm employs two operations, referred to as *head-merges* and *leaf-merges*.

■ **Figure 2** The forests  $F_2$ ,  $F_3$  and  $F_4$ .

To illustrate these operations, consider the example profile  $\bar{d}^2 = (4^{10})$ . As  $10 = 2 \cdot (4 + 1)$ , an exact realization of this profile is obtained by the trivial U-realization composed of the following pair  $(F_2, \text{ctr}_2)$ , consisting of two stars of size 4 (see Figure 2a). The directional edges represent the value of the ctr pointer of a specific vertex.

A *leaf-merge* of two stars fuses together two leaves, one of each star, into a single vertex, thus creating a single tree. Consider, for example, the profile  $\bar{d}^3 = (4^9)$ . As  $9 = 2 \cdot (4 + 1) - 1$ , the trivial U-realization composed of two stars of size 4, has one excess vertex (namely, a deviation of 1). To overcome this problem, we can leaf-merge vertices 2 and 8 of the forest  $F_2$  into a single vertex denoted  $2 + 8$ , yielding the following pair  $(F_3, \text{ctr}_3)$  (see Figure 2b).

A *head-merge* of two stars is obtained by discarding one leaf of each star and connecting the star roots by a new edge. For example, to realize the profile  $\bar{d}^4 = (4^8)$ , whose trivial U-realization has a deviation of *two* excess vertices, we can head-merge the two stars of forest  $F_2$  by completely removing vertices 2 and 8 and connecting the star heads by a new edge (marked by  $\langle 2, 8 \rangle$  in the figure), yielding the following pair  $(F_4, \text{ctr}_4)$  (see Figure 2c).

Generally, satisfying part  $k_i^{n_i}$  of the profile requires using stars with  $k_i$  leaves, but this will satisfy the profile only if  $n_i$  is a multiple of  $k_i + 1$ . For other  $n_i$  values, using  $c_i = \lceil \frac{n_i}{k_i + 1} \rceil$  stars yields more vertices than needed. We therefore use head and leaf merges to get rid of the excess vertices.

For example, consider the profile  $\bar{d}^5 = (4^{12}, 3^7)$ . As  $12 = 3(4 + 1) - 3$  and  $7 = 2(3 + 1) - 1$ , we start by creating three size 4 stars and two size 3 stars, yielding the pair  $(F_5, \text{ctr}_5)$  shown in Figure 3.

The forest  $F_5$  has three excess vertices with **snd** value 4 and one excess vertex with **snd** value 3. To correct it, we apply a head-merge operation and a leaf-merge operation on the size 4 stars, and a leaf-merge operation on the size 3 stars. This creates the following desired forest  $(F'_5, \text{ctr}'_5)$  depicted in Figure 4, which satisfies  $\bar{d}$ .

27:8 Selected Neighbor Degree Forest Realization

■ Figure 3 ( $F_5, \text{ctr}_5$ ).

■ Figure 4 ( $F'_5, \text{ctr}'_5$ ).

Our algorithm also exploits the fact that the value of  $\text{ctr}$  can be set so as to change the  $\text{snd}$  value of a vertex, by applying head or leaf merge operation to two stars of *different* sizes. To illustrate this point, let us consider the following example. The profile  $\bar{d}^6 = (4^4, 3^4)$  has one excess vertex with  $\text{snd}$  value 4. This profile is realizable in this way by starting from stars of size 3 and 4, and applying a leaf merge, to get the forest  $(F_6, \text{ctr}_6)$  shown in Figure 5.

■ Figure 5 ( $F_6, \text{ctr}_6$ ).

The analysis of our algorithm, and its proof of optimality, are based on the crucial observation that the *only* way to merge two individual stars is by head or leaf merges, namely, discarding one or two vertices, since trying to modify two stars by fusing together three or more vertices will create a cycle. This implies that certain profiles cannot be satisfied. For example, consider the profile  $\bar{d}^7 = (4^7)$ . Again, we must start with a forest  $F_2$ . However, there is no way to discard three vertices from  $F_2$  and end up with a satisfying forest of 7 vertices. Indeed, based on Lemma 5 one can show that  $\text{Dev}(\bar{d}^7) \geq 1$ .

**The  $\mathcal{LM}$  operation and Procedure *Connect***

We now present Procedure  $\mathcal{LM}$ , which reduces the deviation (and the number of connected components in the forest) by 1, by performing a single leaf merge. Formally, given a profile  $\bar{d} = (k_i^{n_i})_{i=1}^{\ell}$  and a U-realization  $(F, \text{ctr})$  of  $\bar{d}$  with  $\text{Dev}(\bar{d}, (F, \text{ctr})) > 0$ , such that  $F$  has  $q = \text{cc}(F) \geq 2$  connected components, the operation constructs a U-realization  $(F', \text{ctr}')$  for  $\bar{d}$  with  $\text{Dev}(\bar{d}, (F', \text{ctr}')) = \text{Dev}(\bar{d}, (F, \text{ctr})) - 1$ , such that  $F'$  has  $\text{cc}(F') = q - 1$  connected components.

While the leaf merge operation is straightforward, applying it to an arbitrary forest raises some subtle points, as discussed next. Let  $i \in [\ell]$  such that  $|M_i(F, \text{ctr})| > n_i$  namely, the  $\text{snd}$  value  $k_i$  appears in  $(F, \text{ctr})$  more than  $n_i$  times. Let  $u \in V(F)$  be a  $k_i$ -center in  $F$ . The procedure aims to remove one of its  $k_i$ -members from  $F$  (possibly,  $u$  itself) in order to reduce

the number of appearances of the  $\text{snd}$  value  $k_i$  in  $F$  (hence reducing the deviation of  $(F, \text{ctr})$  from  $\bar{d}$ ). However, this cannot always be done directly, since removing vertices from  $F$  results in an undesired change in the degree of their neighbors, which might affect the  $\text{snd}$  values of other vertices in  $F$ . Hence, removing vertices from  $F$  needs to be done carefully. The method details, as well as formal code and analysis, are deferred to the full paper (see [36]).

► **Lemma 3.** *Given  $\bar{d}$  and  $(F, \text{ctr})$  such that  $cc(F) \geq 2$  and  $Dev(\bar{d}, (F, \text{ctr})) \geq 1$ ,  $\mathcal{LM}$  returns a U-realization  $(F', \text{ctr}')$  for  $\bar{d}$  such that  $cc(F') = cc(F) - 1$  and  $Dev(\bar{d}, (F', \text{ctr}')) = Dev(\bar{d}, (F, \text{ctr})) - 1$ .*

We now present a simple construction algorithm named *Connect*, based on performing only leaf merges. Given a profile  $\bar{d}$  and a U-realization  $(F, \text{ctr})$ , The algorithm produces a new U-realization  $(F', \text{ctr}')$  by repeatedly invoking  $\mathcal{LM}$  and applying leaf merges as long as possible. It halts when either the forest becomes connected, or the deviation becomes zero, yielding a proper realization.

Note that if the constructed  $(F', \text{ctr}')$  is a U-realization of  $\bar{d}$ , then  $Dev(\bar{d}, (F', \text{ctr}')) = 0$ . Otherwise,  $\mathcal{LM}$  was invoked exactly  $cc(F) - 1$  times, each decreasing the deviation by 1. We thus have the following.

► **Lemma 4.** *Let  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$  be a profile with a U-realization  $(F, \text{ctr})$ . Also, let  $(F', \text{ctr}')$  be the construction returned by Algorithm *Connect*. Then*

$$Dev(\bar{d}, (F', \text{ctr}')) = \max\{Dev(\bar{d}, (F, \text{ctr})) - cc(F) + 1, 0\}.$$

**A basic lower bound on  $Dev(\bar{d})$ .** We next establish preliminary lower bounds on  $Dev(\bar{d})$  and on the number of connected components in specific types of U-realizations.

For a forest  $F$  and a vertex subset  $U \subseteq V(F)$ , denote by  $F[U]$  the induced forest on  $U$ 's vertices, i.e.,  $V(F[U]) = U$  and  $E(F[U]) = E(F) \cap (U \times U)$ . For an SNDF profile  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$  with a U-realization  $(F, \text{ctr})$ , our first lower bound expression involves  $\bar{\rho}$  and  $\rho^\sigma$  as defined in Sect. 2, and  $cc(F[C])$ , the number of connected components in the *centers forest*  $F[C]$  induced by the centers:

$$LB_1^{dev} = LB_1^{dev}(\bar{d}, F, \text{ctr}) = \max \left\{ \sum_{i=1}^{\ell} \rho_i^\sigma - 2 \sum_{i=1}^{\ell} \sigma_i + cc(F[C]) + 1, 0 \right\}. \quad (6)$$

The intuition for the lower bound is as follows. To minimize the deviation, we use head and leaf merges, each of which reduces  $cc(F)$ , the number of connected components, by 1. Hence the total number of both head and leaf merges that can be performed on some U-realization  $(F, \text{ctr})$  is bounded by  $cc(F) - 1$ . However, a head-merge reduces the deviation by 2, whereas a leaf-merge reduces the deviation by 1. Since both of these merges “cost” the same (in the sense that they both decrease  $cc(F)$  by 1), it is desirable to use as many head-merges as possible.

Now consider a given U-realization  $(\tilde{F}, \tilde{\text{ctr}})$  consisting of  $s_i$  stars with  $k_i$  leaves for each  $i \in [\ell]$ , for some predetermined CSS  $\bar{s}$ . This U-realization has deviation  $Dev(\bar{d}, (\tilde{F}, \tilde{\text{ctr}})) = \sum_{i=1}^{\ell} \rho_i^s$  and the number of connected components in  $\tilde{F}$  is  $cc(\tilde{F}) = \sum_{i=1}^{\ell} s_i$ . In the best case, one can perform only head-merges to construct the final  $(F, \text{ctr})$ . Each head-merge reduces the deviation by 2 and  $cc(F)$  by 1, therefore

$$Dev(\bar{d}, (F, \text{ctr})) = \sum_{i=1}^{\ell} \rho_i^s - 2 \sum_{i=1}^{\ell} s_i + 2.$$

## 27:10 Selected Neighbor Degree Forest Realization

However, in many profiles it is not possible to use only head-merges. So assume we used only  $x$  head-merges, and removed  $2x$  excess vertices. Since the total number of merges is bounded by  $cc(F) - 1 = \sum_{i=1}^{\ell} s_i - 1$ , it is now possible to perform up to  $\sum_{i=1}^{\ell} s_i - x - 1$  leaf-merges, removing  $\sum_{i=1}^{\ell} s_i - x - 1$  additional excess vertices, totalling to  $\sum_{i=1}^{\ell} s_i + x - 1$  excess vertices being removed. Note that each head-merge adds an edge  $(u, v)$  for some  $u, v \in C$ , so we have  $x = |E(F[C])|$ , where  $E(F[C])$  is the set of edges in the centers forest  $F[C]$ . Since  $F[C]$  is a forest,

$$|E(F[C])| = |V(F[C])| - cc(F[C]) = \sum_{i=1}^{\ell} s_i - cc(F[C]),$$

and therefore  $x = \sum_{i=1}^{\ell} s_i - cc(F[C])$ . In summary, at most

$$\sum_{i=1}^{\ell} s_i + x - 1 = 2 \cdot \sum_{i=1}^{\ell} s_i - cc(F[C]) - 1$$

out of the  $\sum_{i=1}^{\ell} \rho_i^s$  initial excess vertices were removed.

This lower bound idea is formalized in the following lemma. (Proofs are deferred to the full paper, see [36].)

► **Lemma 5.** *For every profile  $\bar{d}$  and U-realization  $(F, ctr)$ :*

1.  $\sigma_i(F, ctr) \geq c_i$ , for every  $i$ ,
2.  $Dev(\bar{d}, (F, ctr)) \geq LB_1^{dev}$ .

### Reducing the error via head merges

We now present the main idea used later to construct an optimal U-realization  $(F, ctr)$  for a profile  $\bar{d}$ , namely, s.t.  $Dev(\bar{d}, (F, ctr)) = Dev(\bar{d})$ . Our construction has two stages. In the first, we select a CSS  $\bar{s} = (s_1, \dots, s_{\ell})$  specifying the number of  $k_i$ -centers for every  $i$ . The selection ensures  $\bar{s}$  is a CSS and has minimum deviation. The second stage builds a realization  $(F, ctr)$  that conforms to  $(\bar{d}, \bar{s})$ . A key observation, formalized by combining Lemmas 5(2) and 6, is that while  $(\bar{d}, \bar{s})$  has many different conforming realizations  $(F, ctr)$ , with different deviations, their deviations directly depend on  $cc(F[C])$ , the number of connected components in the centers forest  $F[C]$  (where  $C = C(F, ctr)$  is the set of centers). Recall that a head merge is performed by taking two centers  $u, v \in C$ , removing one neighbor with degree 1 from each, and connecting  $u, v$  by an edge, thus it decreases the deviation by 2 while decreasing  $cc(F[C])$  by 1. This means that in order to construct an optimal U-realization (with minimal  $cc(F[C])$ ) that conforms to  $(\bar{d}, \bar{s})$  for a CSS  $\bar{s}$ , we need to perform the maximal number of head merges. Suppose the resulting U-realization  $(F, ctr)$  allows no more head-merges. By Lemma 5(2),  $Dev(\bar{d}, (F, ctr)) \geq LB_1^{dev}(\bar{d}, F, ctr)$ . This bound can be matched by transforming  $(F, ctr)$  using leaf-merges.

► **Lemma 6.** *Consider a profile  $\bar{d} = (k_i^{n_i})_{i=1}^{\ell}$  with a U-realization  $(F, ctr)$ . There exists a U-realization  $(F', ctr')$  with deviation  $Dev(\bar{d}, (F', ctr')) = LB_1^{dev}(\bar{d}, F, ctr)$ .*

We conclude the discussion by stating that, given a profile  $\bar{d}$ , constructing an optimal U-realization for  $\bar{d}$  boils down to

1. Choosing the “right” CSS  $\bar{s}$ .
2. Constructing a U-realization  $(F, ctr)$  that conforms to  $(\bar{d}, \bar{s})$ , such that  $cc(F[C])$  is minimal among all other U-realizations with this property.

To formalize this workplan, we make the following definitions. Let  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$  be a profile with star formation  $(c_i, \rho_i)_{i=1}^\ell$ , and let  $\bar{s}$  be a CSS for  $\bar{d}$ . Define the minimum number of connected components in a centers forest  $F[C]$  for  $F$  that admits a conforming realization for  $\bar{d}$  as

$$cc^*(\bar{d}, \bar{s}) = \min \{cc(F[C]) \mid \exists \text{ctr} : (F, \text{ctr}) \text{ conforms to } (\bar{d}, \bar{s})\}, \quad (7)$$

and define the expression obtained from Eq. (6) by replacing  $cc(F[C])$  with  $cc^*(\bar{d}, \bar{s})$  as

$$LB_3^{dev}(\bar{d}, \bar{s}) = \max \left\{ \sum_{i=1}^{\ell} \rho_i^s - 2 \sum_{i=1}^{\ell} s_i + cc^*(\bar{d}, \bar{s}) + 1, 0 \right\} \quad (8)$$

A CSS  $\bar{s}^*$  is *optimal* for  $\bar{d}$  if  $\bar{s}^*$  minimizes  $LB_3^{dev}(\bar{d}, \bar{s}^*)$  over all CSS's for  $\bar{d}$ . With the above definition, we state the following lemma.

► **Lemma 7.**  $Dev(\bar{d}) = LB_3^{dev}(\bar{d}, \bar{s}^*) = \min \{LB_3^{dev}(\bar{d}, \bar{s}) \mid \bar{s} \text{ is a CSS for } \bar{d}\}$ .

Hereafter, we focus on constructing, for a given profile  $\bar{d}$  and any  $\bar{s}$ , a leaf-covered U-realization  $(F, \text{ctr})$  conforming to  $(\bar{d}, \bar{s})$ . This U-realization has a minimal number of connected components in the centers forest, namely,  $cc(F[C]) = cc^*(\bar{d}, \bar{s})$ . In addition, in Section 4 we show how to find an optimal CSS  $\bar{s}^*$  for  $\bar{d}$ . Combining these results, Theorem 2 follows.

### Layer classification

To construct an optimal solution and analyze the structure of a profile  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$ , we classify each of its  $\ell$  layers according to the values  $s_i$  and the residues  $\rho_i^s$ ; later, the algorithm and analysis treat each class differently.

Consider a profile  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$  with a U-realization  $(F, \text{ctr})$ . Recall that the centers forest  $F[C]$  is the induced forest of  $F$  on  $C$ . Note that for each  $u \in V(F)$ ,  $\text{ctr}(u) \in C$ . For  $\bar{d}$ ,  $(F, \text{ctr})$ , a residue sequence  $(\rho_i^s)_{i=1}^\ell$  and  $I \subseteq [\ell]$ , define the partial residual deviation of  $I$  as  $D_I = \sum_{i \in I} \rho_i^s$ .

For a profile  $\bar{d}$  and a CSS  $\bar{s}$ , define the following four sets of layers, referred to as *very good*, *good*, *bad*, and *very bad* layers.

$$\begin{aligned} VG &= \{i \mid \rho_i^s \leq s_i - 1\}, \\ G &= \{i \mid s_i \leq \rho_i^s \leq 2s_i - 1\}, \\ B &= \{i \mid 2s_i \leq \rho_i^s \leq 3s_i - 1\}, \\ VB &= \{i \mid \rho_i^s \geq 3s_i\}. \end{aligned}$$

As intuition for the terminology, note that a “very good” layer  $i \in VG$  can take care of its deviation on its own (namely, by merging its own stars into a single tree) using leaf-merges alone. A good layer  $i \in G$  can also take care of its deviation on its own, but it must apply some head-merges. In contrast, bad layers (in  $B \cup VB$ ) require the help of other layers in order to reduce their deviation.

In particular, our SNDF problem is easy for *benign profiles*, namely, profiles in which all layers are good or very good w.r.t.  $\bar{c}$ , as well as for profiles in which each layer is either very good for  $\bar{c}$  or  $(c_i = 1$  and  $\rho_i = 2)$ . (See the full paper or [36].) Hereafter, we consider only profiles that are not benign.

**The completion forest**

As described earlier, given a profile  $\bar{d}$  and a CSS  $\bar{s}$ , it is sufficient to construct a U-realization  $(F, \text{ctr})$  conforming to  $(\bar{d}, \bar{s})$ , such that the number of connected components in the centers forest  $cc(F[C])$  is minimal. The completion forest serves as a basic tool in our algorithm for constructing a U-realization for  $\bar{d}$ , where we first construct the centers forest and then add the non-centers. This tool allows us to focus only on the centers forest for some U-realization  $(F, \text{ctr})$ , and use its structure to deduce lower and upper bounds on properties of  $F$ .

Consider a profile  $\bar{d} = (k_i^{n_i})_{i=1}^\ell$  with star formation  $(c_i, \rho_i)_{i=1}^\ell$ , a forest  $\mathcal{F} = (C, E)$  and a neighbor function  $\text{ctr} : C \rightarrow C$  where  $\text{ctr}(u) \in N[u]$  for every  $u \in C$ . (Note that  $(\mathcal{F}, \text{ctr})$  is not a U-realization of  $\bar{d}$ .) Let  $\bar{C} = (C_1, \dots, C_\ell)$  be a partition of  $C$ . The tuple  $(\bar{d}, \mathcal{F}, \text{ctr}, \bar{C})$  is *legal* if  $\deg(u) \leq k_i$  for every  $u \in C_i$ .

The *completion forest for a legal*  $(\bar{d}, \mathcal{F}, \text{ctr}, \bar{C})$  is a pair  $(F, \text{ctr})$  constructed by the following Procedure *CompForest*. For every  $i$  and every  $u \in C_i$ , the procedure adds  $k_i - \deg(u)$  new vertices to the forest, connects them to  $u$  thus increasing its degree to  $k_i$  and making it a proper  $k_i$ -center. For each vertex  $v$  that was connected to  $u$ , the procedure sets  $\text{ctr}(v) = u$ , thus making it a  $k_i$ -member of its center.

Note that the tuple  $(\bar{d}, \mathcal{F}, \text{ctr}, \bar{C})$  is legal if and only if its completion forest is well defined, since it has to satisfy  $\deg(u) \leq k_i$  for each  $u \in C_i$ . Also note that the completion forest  $(F, \text{ctr})$  for  $(\bar{d}, \mathcal{F}, \text{ctr}, \bar{C})$  is not necessarily a U-realization of  $\bar{d}$ , since the number of  $k_i$ -members in  $(F, \text{ctr})$  might happen to be smaller than  $n_i$ . For convenience, we refer to  $(F, \text{ctr})$  as the completion forest for  $\mathcal{F}$ .

For example, consider the profile  $\bar{d} = (4^8, 3^6)$ , where  $k_1 = 4, k_2 = 3$ . Let  $(\mathcal{F} = (C, E), \text{ctr})$ , where the center set  $C = \{1, 2, 3, 4\}$  is partitioned into  $C_1 = \{1, 2\}$  and  $C_2 = \{3, 4\}$ , the sets of  $k_1$  and  $k_2$  centers respectively. The completion forest of the above tuple is defined by “completing” the neighborhoods of  $C$  centers according to  $\bar{d}$  and the layers of  $C$ . See Figure 6.

■ **Figure 6** Completion forest example.

**4 Lower bound and algorithm**

**Tight lower bound for SNDF profiles**

Finally, we derive a tight lower bound on the minimum deviation of a given SNDF profile. To do that, we first lower bound  $cc^*(\bar{d}, \bar{s})$ , defined in Eq. (7), and then combine it with our lower bound on  $LB_3^{dev}(\bar{d}, \bar{s})$  from Lemma 7. Our bound on  $cc^*(\bar{d}, \bar{s})$  depends only on the CSS  $\bar{s}$  and the profile  $\bar{d}$ . Our method of proving the bound is by considering an arbitrary U-realization  $(F, \text{ctr})$ , that conforms to  $(\bar{d}, \bar{s})$ , and proving a lower bound on  $cc(F[C])$ , which

imply a lower bound on  $cc^*(\bar{d}, \bar{s})$ . This is done by decomposing the centers forest  $F[C]$  in a special manner, and then reconstructing  $F[C]$  while keeping track of the number of its connected components. As mentioned earlier, we may assume that the profile  $\bar{d}$  is not benign.

The entire derivation of the lower bound is deferred to the full paper (see [36]). Letting

$$LB_4^{dev}(\bar{d}, \bar{s}) = \max \left\{ 0, 2 + \sum_{i=1}^{\ell} \rho_i^s - 2 \sum_{i=1}^{\ell} s_i \right. \\ \left. + \max \left\{ \sum_{i \in VG} s_i - \left( D_{VG} + \sum_{i \in GUB} \lfloor (\rho_i^s - s_i)/2 \rfloor + \sum_{i \in VB} s_i \right), 0 \right\} \right\}$$

we get the following.

► **Theorem 8.** *Let  $\bar{d} = (k_i^{n_i})_{i=1}^{\ell}$  be an SNDF-profile and let  $\bar{s}'$  be a CSS for  $\bar{d}$ . Assume that  $\bar{s}'$  minimizes  $LB_4^{dev}$  over all choices of CSS  $\bar{s}$  (Note that  $\bar{s}'$  does not necessarily minimize  $LB_3^{dev}$ ). Then  $Dev(\bar{d}) \geq LB_4^{dev}(\bar{d}, \bar{s}')$ .*

### Optimal algorithm

While our algorithm is based on the components introduced above, its actual operation is rather involved, hence its description is deferred to the full paper (see [36]) due to space constraints. It provides an optimal explicit construction of SNDF-realizations, which for a given profile  $\bar{d}$  and sequence  $\bar{s}$  yields a realization with deviation at most  $LB_4^{dev}(\bar{d}, \bar{s})$ , and also show how to select a sequence  $\bar{s}'$  that minimizes  $LB_4^{dev}$ . Combining the above with Theorem 8 yields an explicit construction for optimal realizations. In the full paper (see [36]) we also show a more efficient solution for the decision version of SNDF, namely, decide if a given SNDF-profile  $\bar{d}$  is realizable (i.e.,  $Dev(\bar{d}) = 0$ ).

## 5 Discussion

In this paper we introduced the selected neighbor degree realization problem and solved it when the graph is required to be acyclic. We presented a necessary and sufficient condition for realizability. In addition, we provided an algorithm that given a specification computes an upper realization with minimum deviation from the given specification. In particular, if the specification is realizable, the algorithm computes a realization.

A natural open question is to solve the realization problem on general graphs. One may also consider the problem on other graph families, such as trees or bipartite graphs. (Note that the realization problem is easy in regular graphs.) Finally, another interesting direction for future study is to consider variants of the realization problem on directed graphs.

## Abstract

Let  $V$  be a set of  $n$  vertices,  $\mathcal{M}$  a set of  $m$  labels, and let  $\mathbf{R}$  be an  $m \times n$  matrix of independent Bernoulli random variables with probability of success  $p$ ; columns of  $\mathbf{R}$  are incidence vectors of label sets assigned to vertices. A random instance  $G(V, E, \mathbf{R}^T \mathbf{R})$  of the weighted random intersection graph model is constructed by drawing an edge with weight equal to the number of common labels (namely  $[\mathbf{R}^T \mathbf{R}]_{v,u}$ ) between any two vertices  $u, v$  for which this weight is strictly larger than 0. In this paper we study the average case analysis of WEIGHTED MAX CUT, assuming the input is a weighted random intersection graph, i.e. given  $G(V, E, \mathbf{R}^T \mathbf{R})$  we wish to find a partition of  $V$  into two sets so that the total weight of the edges having exactly one endpoint in each set is maximized.

In particular, we initially prove that the weight of a maximum cut of  $G(V, E, \mathbf{R}^T \mathbf{R})$  is concentrated around its expected value, and then show that, when the number of labels is much smaller than the number of vertices (in particular,  $m = n^\alpha, \alpha < 1$ ), a random partition of the vertices achieves asymptotically optimal cut weight with high probability. Furthermore, in the case  $n = m$  and constant average degree (i.e.  $p = \frac{\Theta(1)}{n}$ ), we show that with high probability, a majority type randomized algorithm outputs a cut with weight that is larger than the weight of a random cut by a multiplicative constant strictly larger than 1. Then, we formally prove a connection between the computational problem of finding a (weighted) maximum cut in  $G(V, E, \mathbf{R}^T \mathbf{R})$  and the problem of finding a 2-coloring that achieves minimum discrepancy for a set system  $\Sigma$  with incidence matrix  $\mathbf{R}$  (i.e. minimum imbalance over all sets in  $\Sigma$ ). We exploit this connection by proposing a (weak) bipartization algorithm for the case  $m = n, p = \frac{\Theta(1)}{n}$  that, when it terminates, its output can be used to find a 2-coloring with minimum discrepancy in a set system with incidence matrix  $\mathbf{R}$ . In fact, with high probability, the latter 2-coloring corresponds to a bipartition with maximum cut-weight in  $G(V, E, \mathbf{R}^T \mathbf{R})$ . Finally, we prove that our (weak) bipartization algorithm terminates in polynomial time, with high probability, at least when  $p = \frac{c}{n}, c < 1$ .

## 1 Introduction

Given an undirected graph  $G(V, E)$ , the MAX CUT problem asks for a partition of the vertices of  $G$  into two sets, such that the number of edges with exactly one endpoint in each set of the partition is maximized. This problem can be naturally generalized for weighted (undirected) graphs. A weighted graph is denoted by  $G(V, E, \mathbf{W})$ , where  $V$  is the set of vertices,  $E$  is the set of edges and  $\mathbf{W}$  is a weight matrix, which specifies a weight  $\mathbf{W}_{i,j} = w_{i,j}$ , for each pair of vertices  $i, j$ . In particular, we assume that  $\mathbf{W}_{i,j} = 0$ , for each edge  $\{i, j\} \notin E$ .

► **Definition 1** (WEIGHTED MAX CUT). *Given a weighted graph  $G(V, E, \mathbf{W})$ , find a partition of  $V$  into two (disjoint) subsets  $A, B$ , so as to maximize the cumulative weight of the edges of  $G$  having one endpoint in  $A$  and the other in  $B$ .*

WEIGHTED MAX CUT is fundamental in theoretical computer science and is relevant in various graph layout and embedding problems [10]. Furthermore, it also has many practical applications, including infrastructure cost and circuit layout optimization in network and VLSI design [20], minimizing the Hamiltonian of a spin glass model in statistical physics [3], and data clustering [19]. In the worst case MAX CUT (and also WEIGHTED MAX CUT) is APX-hard, meaning that there is no polynomial-time approximation scheme that finds a solution that is arbitrarily close to the optimum, unless  $P = NP$  [18].

The average case analysis of MAX CUT, namely the case where the input graph is chosen at random from a probabilistic space of graphs, is also of considerable interest and is further motivated by the desire to justify and understand why various graph partitioning heuristics work well in practical applications. In most research works the input graphs are drawn from the Erdős-Rényi random graphs model  $\mathcal{G}_{n,m}$ , i.e. random instances are drawn equiprobably from the set of simple undirected graphs on  $n$  vertices and  $m$  edges, where  $m$  is a linear function of  $n$  (see also [13, 7] for the average case analysis of MAX CUT and its generalizations with respect to other random graph models). One of the earliest results in this area is that MAX CUT undergoes a phase transition on  $\mathcal{G}_{n,\gamma n}$  at  $\gamma = \frac{1}{2}$  [8], in that the difference between the number of edges of the graph and the Max-Cut size is  $O(1)$ , for  $\gamma < \frac{1}{2}$ , while it is  $\Omega(n)$ , when  $\gamma > \frac{1}{2}$ . For large values of  $\gamma$ , it was proved in [4] that the maximum cut size of  $\mathcal{G}_{n,\gamma n}$  normalized by the number of vertices  $n$  reaches an absolute limit in probability as  $n \rightarrow \infty$ , but it was not until recently that the latter limit was established and expressed analytically in [9], using the interpolation method; in particular, it was shown to be asymptotically equal to  $(\frac{\gamma}{2} + P_* \sqrt{\frac{\gamma}{2}})n$ , where  $P_* \approx 0.7632$ . We note however that these results are existential, and thus do not lead to an efficient approximation scheme for finding a tight approximation of the maximum cut with large enough probability when the input graph is drawn from  $\mathcal{G}_{n,\gamma n}$ . An efficient approximation scheme in this case was designed in [8], and it was proved that, with high probability, this scheme constructs a cut with at least  $(\frac{\gamma}{2} + 0.37613\sqrt{\gamma})n = (1 + 0.75226\frac{1}{\sqrt{\gamma}})\frac{\gamma}{2}n$  edges, noting that  $\frac{\gamma}{2}n$  is the size of a random cut (in which each vertex is placed independently and equiprobably in one of the two sets of the partition). Whether there exists an efficient approximation scheme that can close the gap between the approximation guarantee of [8] and the limit of [9] remains an open problem.

In this paper, we study the average case analysis of WEIGHTED MAX CUT when input graphs are drawn from the generalization of another well-established model of random graphs, namely the *weighted random intersection graphs model* (the unweighted version of the model

was initially defined in [15]). In this model, edges are formed through the intersection of label sets assigned to each vertex and edge weights are equal to the number of common labels between edgepoints.

► **Definition 2** (Weighted random intersection graph). *Consider a universe  $\mathcal{M} = \{1, 2, \dots, m\}$  of labels and a set of  $n$  vertices  $V$ . We define the  $m \times n$  representation matrix  $\mathbf{R}$  whose entries are independent Bernoulli random variables with probability of success  $p$ . For  $\ell \in \mathcal{M}$  and  $v \in V$ , we say that vertex  $v$  has chosen label  $\ell$  iff  $\mathbf{R}_{\ell,v} = 1$ . Furthermore, we draw an edge with weight  $[\mathbf{R}^T \mathbf{R}]_{v,u}$  between any two vertices  $u, v$  for which this weight is strictly larger than 0. The weighted graph  $G = (V, E, \mathbf{R}^T \mathbf{R})$  is then a random instance of the weighted random intersection graphs model  $\overline{\mathcal{G}}_{n,m,p}$ .*

Random intersection graphs are relevant to and capture quite nicely social networking; vertices are the individual actors and labels correspond to specific types of interdependency. Other applications include oblivious resource sharing in a (general) distributed setting, efficient and secure communication in sensor networks [20], interactions of mobile agents traversing the web etc. (see e.g. the survey papers [6, 16] for further motivation and recent research related to random intersection graphs). In all these settings, weighted random intersection graphs, in particular, also capture the strength of connections between actors (e.g. in a social network, individuals having several characteristics in common have more intimate relationships than those that share only a few common characteristics). One of the most celebrated results in this area is equivalence (measured in terms of total variation distance) of random intersection graphs and Erdős-Rényi random graphs when the number of labels satisfies  $m = n^\alpha, \alpha > 6$  [12]. This bound on the number of labels was improved in [23], by showing equivalence of sharp threshold functions among the two models for  $\alpha \geq 3$ . Similarity of the two models has been proved even for smaller values of  $\alpha$  (e.g. for any  $\alpha > 1$ ) in the form of various translation results (see e.g. Theorem 1 in [22]), suggesting that some algorithmic ideas developed for Erdős-Rényi random graphs also work for random intersection graphs (and also weighted random intersection graphs).

In view of this, in the present paper we study the average case analysis of WEIGHTED MAX CUT under the weighted random intersection graphs model, for the range  $m = n^\alpha, \alpha \leq 1$  for two main reasons: First, the average case analysis of MAX CUT has not been considered in the literature so far when the input is drawn from the random intersection graphs model, and thus the asymptotic behaviour of the maximum cut remains unknown especially for the range of values where random intersection graphs and Erdős-Rényi random graphs differ the most. Furthermore, studying a model where we can implicitly control its intersection number (indeed  $m$  is an obvious upper bound on the number of cliques that can cover all edges of the graph) may help understand algorithmic bottlenecks for finding maximum cuts in Erdős-Rényi random graphs.

Second, we note that the representation matrix  $\mathbf{R}$  of a weighted random intersection graph can be used to define a random set system  $\Sigma$  consisting of  $m$  sets  $\Sigma = \{L_1, \dots, L_m\}$ , where  $L_\ell$  is the set of vertices that have chosen label  $\ell$ ; we say that  $\mathbf{R}$  is the *incidence matrix* of  $\Sigma$ . Therefore, there is a natural connection between WEIGHTED MAX CUT and the DISCREPANCY of such random set systems, which we formalize in this paper. In particular, given a set system  $\Sigma$  with incidence matrix  $\mathbf{R}$ , its *discrepancy* is defined as  $\text{disc}(\Sigma) = \min_{\mathbf{x} \in \{\pm 1\}^n} \max_{L \in \Sigma} \left| \sum_{v \in L} x_v \right| = \|\mathbf{R}\mathbf{x}\|_\infty$ , i.e. it is the minimum imbalance of all sets in  $\Sigma$  over all 2-colorings  $\mathbf{x}$ . Recent work on the discrepancy of random rectangular matrices defined as above [1] has shown that, when the number of labels (sets)  $m$  satisfies  $n \geq 0.73m \log m$ , the discrepancy of  $\Sigma$  is at most 1 with high probability. The proof of the main result in [1] is based on a conditional second moment method combined with Stein's

method of exchangeable pairs, and improves upon a Fourier analytic result of [14], and also upon previous results in [11, 21]. The design of an efficient algorithm that can find a 2-coloring having discrepancy  $O(1)$  in this range still remains an open problem. Approximation algorithms for a similar model for random set systems were designed and analyzed in [2]; however, the algorithmic ideas there do not apply in our case.

## 1.1 Our Contribution

In this paper, we introduce the model of weighted random intersection graphs and we study the average case analysis of WEIGHTED MAX CUT through the prism of DISCREPANCY of random set systems. We formalize the connection between these two combinatorial problems for the case of arbitrary weighted intersection graphs in Corollary 4. We prove that, given a weighted intersection graph  $G = (V, E, \mathbf{R}^T \mathbf{R})$  with representation matrix  $\mathbf{R}$ , and a set system with incidence matrix  $\mathbf{R}$ , such that  $\text{disc}(\Sigma) \leq 1$ , a 2-coloring has maximum cut weight in  $G$  if and only if it achieves minimum discrepancy in  $\Sigma$ . In particular, Corollary 4 applies in the range of values considered in [1] (i.e.  $n \geq 0.73m \log m$ ), and thus any algorithm that finds a maximum cut in  $G(V, E, \mathbf{R}^T \mathbf{R})$  with large enough probability can also be used to find a 2-coloring with minimum discrepancy in a set system  $\Sigma$  with incidence matrix  $\mathbf{R}$ , with the same probability of success.

We then consider weighted random intersection graphs in the case  $m = n^\alpha, \alpha \leq 1$ , and we prove that the maximum cut weight of a random instance  $G(V, E, \mathbf{R}^T \mathbf{R})$  of  $\bar{\mathcal{G}}_{n,m,p}$  concentrates around its expected value (see Theorem 5). In particular, with high probability (whp, i.e. with probability tending to 1 as  $n \rightarrow \infty$ ) over the choices of  $\mathbf{R}$ ,  $\text{Max-Cut}(G) \sim \mathbb{E}_{\mathbf{R}}[\text{Max-Cut}(G)]$ , where  $\mathbb{E}_{\mathbf{R}}$  denotes expectation with respect to  $\mathbf{R}$ . The proof is based on the Efron-Stein inequality for upper bounding the variance of the maximum cut. As a consequence of our concentration result, we prove in Theorem 6 that, in the case  $\alpha < 1$ , a random 2-coloring (i.e. bipartition)  $\mathbf{x}^{(rand)}$  in which each vertex chooses its color independently and equiprobably, has cut weight asymptotically equal to  $\text{Max-Cut}(G)$ , with high probability over the choices of  $\mathbf{x}^{(rand)}$  and  $\mathbf{R}$ .

The latter result on random cuts allows us to focus the analysis of our randomized algorithms of Section 4 on the case  $m = n$  (i.e.  $\alpha = 1$ ), and  $p = \frac{c}{n}$ , for some constant  $c$  (see also the discussion at the end of Subsection 3.1), where the assumptions of Theorem 6 do not hold. It is worth noting that, in this range of values, the expected weight of a fixed edge in a weighted random intersection graph is equal to  $mp^2 = \Theta(1/n)$ , and thus we hope that our work here will serve as an intermediate step towards understanding when algorithmic bottlenecks for MAX CUT appear in sparse random graphs (especially Erdős-Rényi random graphs) with respect to the intersection number. In particular, we analyze a Majority Cut Algorithm 1 that extends the algorithmic idea of [8] to weighted intersection graphs as follows: vertices are colored sequentially (each color  $+1$  or  $-1$  corresponding to a different set in the partition of the vertices), and the  $t$ -th vertex is colored opposite to the sign of  $\sum_{i \in [t-1]} [\mathbf{R}^T \mathbf{R}]_{i,t} x_i$ , namely the total available weight of its incident edges, taking into account colors of adjacent vertices. Our average case analysis of the Majority Cut Algorithm shows that, when  $m = n$  and  $p = \frac{c}{n}$ , for large constant  $c$ , with high probability over the choices of  $\mathbf{R}$ , the expected weight of the constructed cut is at least  $1 + \beta$  times larger than the expected weight of a random cut, for some constant  $\beta = \beta(c) \geq \sqrt{\frac{16}{27\pi c^3}} - o(1)$ . The fact that the lower bound on beta is inversely proportional to  $c^{3/2}$  was to be expected, because, as  $p$  increases, the approximation of the maximum cut that we get from the weight of a random cut improves (see also the discussion at the end of Subsection 3.1).

In Subsection 4.2 we propose a framework for finding maximum cuts in weighted random intersection graphs for  $m = n$  and  $p = \frac{c}{n}$ , for constant  $c$ , by exploiting the connection between WEIGHTED MAX CUT and the problem of discrepancy minimization in random set systems. In particular, we design a Weak Bipartization Algorithm 2, that takes as input an intersection graph with representation matrix  $\mathbf{R}$  and outputs a subgraph that is “almost” bipartite. In fact, the input intersection graph is treated as a multigraph composed by overlapping cliques formed by the label sets  $L_\ell = \{v : \mathbf{R}_{\ell,v} = 1\}, \ell \in \mathcal{M}$ . The algorithm attempts to destroy all odd cycles of the input (except from odd cycles that are formed by labels with only two vertices) by replacing each clique induced by some label set  $L_\ell$  by a random maximal matching. In Theorem 11 we prove that, with high probability over the choices of  $\mathbf{R}$ , if the Weak Bipartization Algorithm terminates, then its output can be used to construct a 2-coloring that has minimum discrepancy in a set system with incidence matrix  $\mathbf{R}$ , which also gives a maximum cut in  $G(V, E, \mathbf{R}^T \mathbf{R})$ . It is worth noting that this does not follow from Corollary 4, because a random set system with incidence matrix  $\mathbf{R}$  has discrepancy larger than 1 with (at least) constant probability when  $m = n$  and  $p = \frac{c}{n}$ . Our proof relies on a structural property of closed 0-strong vertex-label sequences (loosely defined as closed walks of edges formed by distinct labels) in the weighted random intersection graph  $G(V, E, \mathbf{R}^T \mathbf{R})$  (Lemma 8). Finally, in Theorem 12, we prove that our Weak Bipartization Algorithm terminates in polynomial time, with high probability, if the constant  $c$  is strictly less than 1. Therefore, there is a polynomial time algorithm for finding weighted maximum cuts, with high probability, when the input is drawn from  $\bar{\mathcal{G}}_{n,n,\frac{c}{n}}$ , with  $c < 1$ . We believe that this part of our work may also be of interest regarding the design of efficient algorithms for finding minimum discrepancy colorings in random set systems.

Due to lack of space, some proofs have been omitted; the full proofs of this paper can be found in our technical report [17].

## 2 Notation and preliminary results

We denote weighted undirected graphs by  $G(V, E, \mathbf{W})$ ; in particular,  $V = V(G)$  (resp.  $E = E(G)$ ) is the set of vertices (resp. set of edges) and  $\mathbf{W} = \mathbf{W}(G)$  is the weight matrix, i.e.  $\mathbf{W}_{i,j} = w_{i,j}$  is the weight of (undirected) edge  $\{i, j\} \in E$ . We allow  $\mathbf{W}$  to have non-zero diagonal entries, as these do not affect cut weights. We also denote the number of vertices by  $n$ , and we use the notation  $[n] = \{1, 2, \dots, n\}$ . We also use this notation to define parts of matrices, for example  $\mathbf{W}_{[n],1}$  denotes the first column of the weight matrix.

A bipartition of the sets of vertices is a partition of  $V$  into two sets  $A, B$  such that  $A \cap B = \emptyset$  and  $A \cup B = V$ . Bipartitions correspond to 2-colorings, which we denote by vectors  $\mathbf{x}$  such that  $x_i = +1$  if  $i \in A$  and  $x_i = -1$  if  $i \in B$ .

Given a weighted graph  $G(V, E, \mathbf{W})$ , we denote by  $\text{Cut}(G, \mathbf{x})$  the weight of a cut defined by a bipartition  $\mathbf{x}$ , namely  $\text{Cut}(G, \mathbf{x}) = \sum_{\{i,j\} \in E: i \in A, j \in B} w_{i,j} = \frac{1}{4} \sum_{\{i,j\} \in E} w_{i,j} (x_i - x_j)^2$ . The maximum cut of  $G$  is  $\text{Max-Cut}(G) = \max_{\mathbf{x} \in \{-1, +1\}^n} \text{Cut}(G, \mathbf{x})$ .

For a weighted random intersection graph  $G(V, E, \mathbf{R}^T \mathbf{R})$  with representation matrix  $\mathbf{R}$ , we denote by  $S_v$  the set of labels chosen by vertex  $v \in V$ , i.e.  $S_v = \{\ell : \mathbf{R}_{\ell,v} = 1\}$ . Furthermore, we denote by  $L_\ell$  the set of vertices having chosen label  $\ell$ , i.e.  $L_\ell = \{v : \mathbf{R}_{\ell,v} = 1\}$ . Using this notation, the weight of an edge  $\{v, u\} \in E$  is  $|S_v \cap S_u|$ ; notice also that this is equal to 0 when  $\{v, u\} \notin E$ . We also note here that we may also think of a weighted random intersection graph as a simple weighted graph where, for any pair of vertices  $v, u$ , there are  $|S_v \cap S_u|$  simple edges between them.

A set system  $\Sigma$  defined on a set  $V$  is a family of sets  $\Sigma = \{L_1, L_2, \dots, L_m\}$ , where  $L_\ell \subseteq V, \ell \in [m]$ . The incidence matrix of  $\Sigma$  is an  $m \times n$  matrix  $\mathbf{R} = \mathbf{R}(\Sigma)$ , where for any  $\ell \in [m], v \in [n]$ ,  $\mathbf{R}_{\ell,v} = 1$  if  $v \in S_\ell$  and 0 otherwise. The discrepancy of  $\Sigma$  with respect to a 2-coloring  $\mathbf{x}$  of the vertices in  $V$  is  $\text{disc}(\Sigma, \mathbf{x}) = \max_{\ell \in [m]} |\sum_{v \in V} \mathbf{R}_{\ell,v} x_v| = \|\mathbf{R}\mathbf{x}\|_\infty$ . The discrepancy of  $\Sigma$  is  $\text{disc}(\Sigma) = \min_{\mathbf{x} \in \{-1, +1\}^n} \text{disc}(\Sigma, \mathbf{x})$ .

It is well-known that the cut size of a bipartition of the set of vertices of a graph  $G(V, E)$  into sets  $A$  and  $B$  is given by  $\frac{1}{4} \sum_{\{i,j\} \in E} (x_i - x_j)^2$ , where  $x_i = +1$  if  $i \in A$  and  $x_i = -1$  if  $i \in B$ . This can be naturally generalized for multigraphs and also for weighted graphs. In particular, the Max-Cut size of a weighted graph  $G(V, E, \mathbf{W})$  is given by

$$\text{Max-Cut}(G) = \max_{\mathbf{x} \in \{-1, +1\}^n} \frac{1}{4} \sum_{\{i,j\} \in E} \mathbf{W}_{i,j} (x_i - x_j)^2. \quad (1)$$

In particular, we get the following Corollary (refer to the full version of our paper [17] for the proof):

► **Corollary 3.** *Let  $G(V, E, \mathbf{R}^T \mathbf{R})$  be a weighted intersection graph with representation matrix  $\mathbf{R}$ . Then, for any  $\mathbf{x} \in \{-1, +1\}^n$ ,*

$$\text{Cut}(G, \mathbf{x}) = \frac{1}{4} \left( \sum_{i,j \in [n]^2} [\mathbf{R}^T \mathbf{R}]_{i,j} - \|\mathbf{R}\mathbf{x}\|^2 \right) \quad (2)$$

and so

$$\text{Max-Cut}(G) = \frac{1}{4} \left( \sum_{i,j \in [n]^2} [\mathbf{R}^T \mathbf{R}]_{i,j} - \min_{\mathbf{x} \in \{-1, +1\}^n} \|\mathbf{R}\mathbf{x}\|^2 \right), \quad (3)$$

where  $\|\cdot\|$  denotes the 2-norm. In particular, the expectation of the size of a random cut, where each entry of  $\mathbf{x}$  is independently and equiprobably either  $+1$  or  $-1$  is equal to  $\mathbb{E}_{\mathbf{x}} [\text{Cut}(G, \mathbf{x})] = \frac{1}{4} \sum_{i \neq j, i,j \in [n]} [\mathbf{R}^T \mathbf{R}]_{i,j}$ , where  $\mathbb{E}_{\mathbf{x}}$  denotes expectation with respect to  $\mathbf{x}$ .

Since  $\sum_{i,j \in [n]^2} [\mathbf{R}^T \mathbf{R}]_{i,j}$  is fixed for any given representation matrix  $\mathbf{R}$ , the above Corollary implies that, to find a bipartition of the vertex set  $V$  that corresponds to a maximum cut, we need to find an  $n$ -dimensional vector in  $\arg \min_{\mathbf{x} \in \{-1, +1\}^n} \|\mathbf{R}\mathbf{x}\|^2$ . We thus get the following (refer to the full version of our paper [17] for the proof):

► **Corollary 4.** *Let  $G(V, E, \mathbf{R}^T \mathbf{R})$  be a weighted intersection graph with representation matrix  $\mathbf{R}$  and  $\Sigma$  a set system with incidence matrix  $\mathbf{R}$ . If  $\text{disc}(\Sigma) \leq 1$ , then  $\mathbf{x}^* \in \arg \min_{\mathbf{x} \in \{-1, +1\}^n} \|\mathbf{R}\mathbf{x}\|^2$  if and only if  $\mathbf{x}^* \in \arg \min_{\mathbf{x} \in \{-1, +1\}^n} \text{disc}(\Sigma, \mathbf{x})$ . In particular, if the minimum discrepancy of  $\Sigma$  is at most 1, a bipartition corresponds to a maximum cut iff it achieves minimum discrepancy.*

Notice that above result is not necessarily true when  $\text{disc}(\Sigma) > 1$ , since the minimum of  $\|\mathbf{R}\mathbf{x}\|$  could be achieved by 2-colorings with larger discrepancy than the optimal.

## 2.1 Range of values for $p$

Concerning the success probability  $p$ , we note that, when  $p = o\left(\sqrt{\frac{1}{nm}}\right)$ , direct application of the results of [5] suggest that  $G(V, E, \mathbf{R}^T \mathbf{R})$  is chordal with high probability, but in fact the same proofs reveal that a stronger property holds, namely that there is no closed vertex-label

sequence (refer to the precise definition in Subsection 4.2) having distinct labels. Therefore, in this case, finding a bipartition with maximum cut weight is straightforward: indeed, one way to construct a maximum cut is to run our Weak Bipartization Algorithm 2 from Subsection 4.2, and then to apply Theorem 11 (noting that Weak Bipartization termination condition trivially holds, since the set  $\mathcal{C}_{\text{odd}}(G^{(b)})$  defined in Subsection 4.2 is empty). Furthermore, even though we consider weighted graphs, we will also assume that  $mp^2 = O(1)$ , noting that, otherwise,  $G(V, E, \mathbf{R}^T \mathbf{R})$  will be almost complete with high probability (indeed, the unconditional edge existence probability is  $1 - (1 - p^2)^m$ , which tends to 1 for  $mp^2 = \omega(1)$ ). In particular, we will assume that  $C_1 \sqrt{\frac{1}{nm}} \leq p \leq C_2 \frac{1}{\sqrt{m}}$ , for arbitrary positive constants  $C_1, C_2$ ;  $C_1$  can be as small as possible, and  $C_2$  can be as large as possible, provided  $C_2 \frac{1}{\sqrt{m}} \leq 1$ . We note that, when  $p$  is asymptotically equal to the upper bound  $C_2 \frac{1}{\sqrt{m}}$ , there is no constant weight upper bound that holds with high probability, whereas, when  $p$  is asymptotically equal to the lower bound  $C_1 \sqrt{\frac{1}{nm}}$ , all weights in the graph are bounded by a small constant with high probability. Our results in Section 3 assume this range of values for  $p$ , and thus graph instances may contain edges with large (but constant) weights. On the other hand, in the analysis of our randomized algorithms in section 4, we assume  $n = m$  and  $p = \Theta\left(\frac{1}{n}\right)$ ; this range of values gives sparse graph instances (even though the distribution is different from sparse Erdős-Rényi random graphs).

### 3 Concentration of Max-Cut

In this section we prove that the size of the maximum cut in a weighted random intersection graph concentrates around its expected value. We note however, that the following Theorem does not provide an explicit formula for the expected value of the maximum cut.

► **Theorem 5.** *Let  $G(V, E, \mathbf{R}^T \mathbf{R})$  be a random instance of the  $\bar{\mathcal{G}}_{n,m,p}$  model with  $m = n^\alpha, \alpha \leq 1$ , and  $C_1 \sqrt{\frac{1}{nm}} \leq p \leq 1$ , for arbitrary positive constant  $C_1$ , and let  $\mathbf{R}$  be its representation matrix. Then  $\text{Max-Cut}(G) \sim \mathbb{E}_{\mathbf{R}}[\text{Max-Cut}(G)]$  with high probability, where  $\mathbb{E}_{\mathbf{R}}$  denotes expectation with respect to  $\mathbf{R}$ , i.e.  $\text{Max-Cut}(G)$  concentrates around its expected value.*

**Proof.** Let  $G = G(V, E, \mathbf{R}^T \mathbf{R})$  be a weighted random intersection graph, and let  $\mathbf{D}$  denote the (random) diagonal matrix containing all diagonal elements of  $\mathbf{R}^T \mathbf{R}$ . In particular, equation (3) of Corollary 3 can be written as

$$\text{Max-Cut}(G) = \frac{1}{4} \left( \sum_{i \neq j, i, j \in [n]} [\mathbf{R}^T \mathbf{R}]_{i,j} - \min_{\mathbf{x} \in \{-1, +1\}^n} \mathbf{x}^T (\mathbf{R}^T \mathbf{R} - \mathbf{D}) \mathbf{x} \right).$$

Furthermore, for any given  $\mathbf{R}$ , notice that, if we select each element of  $\mathbf{x}$  independently and equiprobably from  $\{-1, +1\}$ , then  $\mathbb{E}_{\mathbf{x}}[\mathbf{x}^T (\mathbf{R}^T \mathbf{R} - \mathbf{D}) \mathbf{x}] = 0$ , where  $\mathbb{E}_{\mathbf{x}}$  denotes expectation with respect to  $\mathbf{x}$ . Therefore, by the probabilistic method,  $\min_{\mathbf{x} \in \{-1, +1\}^n} \mathbf{x}^T (\mathbf{R}^T \mathbf{R} - \mathbf{D}) \mathbf{x} \leq 0$ , implying the following bound:

$$\frac{1}{4} \sum_{i \neq j, i, j \in [n]} [\mathbf{R}^T \mathbf{R}]_{i,j} \leq \text{Max-Cut}(G) \leq \frac{1}{2} \sum_{i \neq j, i, j \in [n]} [\mathbf{R}^T \mathbf{R}]_{i,j}, \quad (4)$$

where the second inequality follows trivially by observing that  $\frac{1}{2} \sum_{i \neq j, i, j \in [n]} [\mathbf{R}^T \mathbf{R}]_{i,j}$  equals the sum of the weights of all edges.

By linearity,  $\mathbb{E}_{\mathbf{R}} \left[ \sum_{i \neq j, i, j \in [n]} [\mathbf{R}^T \mathbf{R}]_{i, j} \right] = \mathbb{E}_{\mathbf{R}} \left[ \sum_{i \neq j, i, j \in [n]} \sum_{\ell \in [m]} \mathbf{R}_{\ell, i} \mathbf{R}_{\ell, j} \right] = n(n-1)mp^2 = \Theta(n^2 mp^2)$ , which goes to infinity as  $n \rightarrow \infty$ , because  $np = \Omega\left(\sqrt{\frac{n}{m}}\right) = \Omega(1)$  in the range of parameters that we consider. In particular, by (4), we have

$$\mathbb{E}_{\mathbf{R}}[\text{Max-Cut}(G)] = \Theta(n^2 mp^2). \quad (5)$$

By Chebyshev's inequality, for any  $\epsilon > 0$ , we have

$$\Pr\left(|\text{Max-Cut}(G) - \mathbb{E}_{\mathbf{R}}[\text{Max-Cut}(G)]| \geq \epsilon n^2 mp^2\right) \leq \frac{\text{Var}_{\mathbf{R}}(\text{Max-Cut}(G))}{\epsilon^2 n^4 m^2 p^4}, \quad (6)$$

where  $\text{Var}_{\mathbf{R}}$  denotes variance with respect to  $\mathbf{R}$ . To bound the variance on the right hand side of the above inequality, we use the Efron-Stein inequality. In particular, we write  $\text{Max-Cut}(G) := f(\mathbf{R})$ , i.e. we view  $\text{Max-Cut}(G)$  as a function of the label choices. For  $\ell \in [m], i \in [n]$ , we also write  $\mathbf{R}^{(\ell, i)}$  for the matrix  $\mathbf{R}$  where entry  $(\ell, i)$  has been replaced by an independent, identically distributed (i.i.d.) copy of  $\mathbf{R}_{\ell, i}$ , which we denote by  $\mathbf{R}'_{\ell, i}$ . By the Efron-Stein inequality, we have

$$\text{Var}_{\mathbf{R}}(\text{Max-Cut}(G)) \leq \frac{1}{2} \sum_{\ell \in [m], i \in [n]} \mathbb{E} \left[ \left( f(\mathbf{R}) - f(\mathbf{R}^{(\ell, i)}) \right)^2 \right]. \quad (7)$$

Notice now that, given all entries of  $\mathbf{R}$  except  $\mathbf{R}_{\ell, i}$ , the probability that  $f(\mathbf{R})$  is different from  $f(\mathbf{R}^{(\ell, i)})$  is at most  $\Pr(\mathbf{R}_{\ell, i} \neq \mathbf{R}'_{\ell, i}) = 2p(1-p)$ . Furthermore, if  $L_{\ell} \setminus \{i\}$  is the set of vertices different from  $i$  which have selected  $\ell$ , we then have that  $(f(\mathbf{R}) - f(\mathbf{R}^{(\ell, i)}))^2 \leq |L_{\ell} \setminus \{i\}|^2$ , because the intersection graph with representation matrix  $\mathbf{R}$  differs by at most  $|L_{\ell} \setminus \{i\}|$  edges from the intersection graph with representation matrix  $\mathbf{R}^{(\ell, i)}$ . Also note that, by definition,  $|L_{\ell} \setminus \{i\}|$  follows the Binomial distribution  $\mathcal{B}(n-1, p)$ . In particular,  $\mathbb{E}[|L_{\ell} \setminus \{i\}|^2] = (n-1)p(np - 2p + 1)$ , implying  $\mathbb{E} \left[ \left( f(\mathbf{R}) - f(\mathbf{R}^{(\ell, i)}) \right)^2 \right] \leq 2p(1-p)(n-1)p(np - 2p + 1)$ , for any fixed  $\ell \in [m], i \in [n]$ .

Putting this all together, (7) becomes

$$\begin{aligned} \text{Var}_{\mathbf{R}}(\text{Max-Cut}(G)) &\leq \frac{1}{2} \sum_{\ell \in [m], i \in [n]} 2p(1-p)(n-1)p(np - 2p + 1) \\ &= nmp(1-p)(n-1)p(np - 2p + 1) = O(n^3 mp^3), \end{aligned} \quad (8)$$

Therefore, by (6), we get

$$\Pr\left(|\text{Max-Cut}(G) - \mathbb{E}_{\mathbf{R}}[\text{Max-Cut}(G)]| \geq \epsilon n^2 mp^2\right) \leq \frac{O(n^3 mp^3)}{\epsilon^2 n^4 m^2 p^4} = O\left(\frac{1}{\epsilon^2 nmp}\right),$$

which goes to 0 in the range of values that we consider. Together with (5), the above bound proves that  $\text{Max-Cut}(G)$  is concentrated around its expected value.  $\blacktriangleleft$

### 3.1 Max-Cut for small number of labels

Using Theorem 5, we can now show that, in the case  $m = n^{\alpha}$ ,  $\alpha < 1$ , and  $p = O\left(\frac{1}{\sqrt{m}}\right)$ , a random cut has asymptotically the same weight as  $\text{Max-Cut}(G)$ , where  $G = G(V, E, \mathbf{R}^T \mathbf{R})$  is a random instance of  $\mathcal{G}_{n, m, p}$ . In particular, let  $\mathbf{x}^{(rand)}$  be constructed as follows: for each  $i \in [n]$ , set  $x_i^{(rand)} = -1$  independently with probability  $\frac{1}{2}$ , and  $x_i^{(rand)} = +1$  otherwise.

The proof details of the following Theorem can be found in the full version of our paper [17]. In view of equation (3), the main idea is to prove that, with high probability over random  $\mathbf{x}$  and  $\mathbf{R}$ ,  $\|\mathbf{R}\mathbf{x}\|^2$  is asymptotically smaller than the expectation of the weight of the cut defined by  $\mathbf{x}^{(rand)}$ , in which case the theorem follows by concentration of  $\text{Max-Cut}(G)$  around its expected value (Theorem 5), and straightforward bounds on  $\text{Max-Cut}(G)$ .

► **Theorem 6.** *Let  $G(V, E, \mathbf{R}^T \mathbf{R})$  be a random instance of the  $\bar{\mathcal{G}}_{n,m,p}$  model with  $m = n^\alpha$ ,  $\alpha < 1$ , and  $C_1 \sqrt{\frac{1}{nm}} \leq p \leq C_2 \frac{1}{\sqrt{m}}$ , for arbitrary positive constants  $C_1, C_2$ , and let  $\mathbf{R}$  be its representation matrix. Then the cut weight of the random 2-coloring  $\mathbf{x}^{(rand)}$  satisfies  $\text{Cut}(G, \mathbf{x}^{(rand)}) = (1 - o(1))\text{Max-Cut}(G)$  with high probability over the choices of  $\mathbf{x}^{(rand)}$ ,  $\mathbf{R}$ .*

We note that the same analysis also holds when  $n = m$  and  $p$  is sufficiently large (e.g.  $p = \omega(\frac{\ln n}{n})$ ); more details can be found in our technical report [17]. In view of this, in the following sections we will only assume  $m = n$  (i.e.  $\alpha = 1$ ) and also  $p = \frac{c}{n}$ , for some positive constant  $c$ . Besides avoiding complicated formulae for  $p$ , the reason behind this assumption is that, in this range of values, the expected weight of a fixed edge in  $G(V, E, \mathbf{R}^T \mathbf{R})$  is equal to  $mp^2 = \Theta(1/n)$ , and thus we hope that our work will serve as an intermediate step towards understanding algorithmic bottlenecks for finding maximum cuts in Erdős-Rényi random graphs  $G_{n,c/n}$  with respect to their intersection number.

## 4 Algorithmic results (randomized algorithms)

### 4.1 The Majority Cut Algorithm

In the following algorithm, the 2-coloring representing the bipartition of a cut is constructed as follows: initially, a small constant fraction  $\epsilon$  of vertices are randomly placed in the two partitions, and then in each subsequent step, one of the remaining vertices is placed in the partition that maximizes the weight of incident edges with endpoints in the opposite partition.

■ **Algorithm 1** Majority Cut.

---

**Input:**  $G(V, E, \mathbf{R}^T \mathbf{R})$  and its representation matrix  $\mathbf{R} \in \{0, 1\}^{m \times n}$   
**Output:** Large cut 2-coloring  $\mathbf{x} \in \{-1, +1\}^n$

- 1 Let  $v_1, \dots, v_n$  an arbitrary ordering of vertices;
- 2 **for**  $t = 1$  **to**  $\epsilon n$  **do**
- 3   └ Set  $x_t$  to either  $-1$  or  $+1$  independently with equal probability;
- 4 **for**  $t = \epsilon n + 1$  **to**  $n$  **do**
- 5   └ **if**  $\sum_{i \in [t-1]} [\mathbf{R}^T \mathbf{R}]_{i,t} x_i \geq 0$  **then**
- 6     └  $x_t = -1$ ;
- 7     **else**
- 8     └  $x_t = +1$ ;
- 9 **return**  $\mathbf{x}$ ;

---

Clearly the Majority Algorithm runs in polynomial time in  $n, m$ . Furthermore, the following Theorem provides a lower bound on the expected weight of the cut constructed by the algorithm in the case  $m = n$ ,  $p = \frac{c}{n}$ , for large constant  $c$ , and  $\epsilon \rightarrow 0$ . The full proof details can be found in our technical report [17].

► **Theorem 7.** Let  $G(V, E, \mathbf{R}^T \mathbf{R})$  be a random instance of the  $\bar{\mathcal{G}}_{n,m,p}$  model, with  $m = n$ , and  $p = \frac{c}{n}$ , for large positive constant  $c$ , and let  $\mathbf{R}$  be its representation matrix. Then, with high probability over the choices of  $\mathbf{R}$ , the majority algorithm constructs a cut with expected weight at least  $(1 + \beta) \frac{1}{4} \mathbb{E} \left[ \sum_{i \neq j, i, j \in [n]} [\mathbf{R}^T \mathbf{R}]_{i,j} \right]$ , where  $\beta = \beta(c) \geq \sqrt{\frac{16}{27\pi c^3}} - o(1)$  is a constant, i.e. at least  $1 + \beta$  times larger than the expected weight of a random cut.

**Proof sketch.** Let  $G(V, E, \mathbf{R}^T \mathbf{R})$  be a random instance of the  $\bar{\mathcal{G}}_{n,m,p}$  model, with  $m = n$ , and  $p = \frac{c}{n}$ , for some large enough constant  $c$ . For  $t \in [n]$ , let  $M_t$  denote the constructed cut size just after the consideration of a vertex  $v_t$ , for some  $t \geq \epsilon n + 1$ . By equation (3) for  $n = t$ , and since the values  $x_1, \dots, x_{t-1}$  are already decided in previous steps, we have  $M_t = \frac{1}{4} \left( \sum_{i,j \in [t]^2} [\mathbf{R}^T \mathbf{R}]_{i,j} - \min_{x_t \in \{-1, +1\}} \|\mathbf{R}_{[m],[t]} \mathbf{x}_{[t]}\|^2 \right)$ , and after careful calculation we get the recurrence

$$M_t = M_{t-1} + \frac{1}{2} \sum_{i \in [t-1]} [\mathbf{R}^T \mathbf{R}]_{i,t} + \frac{1}{2} |Z_t|,$$

where  $Z_t = Z_t(\mathbf{x}, \mathbf{R}) = \sum_{i \in [t-1]} [\mathbf{R}^T \mathbf{R}]_{i,t} x_i = \sum_{\ell \in [m]} \mathbf{R}_{\ell,t} \sum_{i \in [t-1]} \mathbf{R}_{\ell,i} x_i$ . Observe that, in the latter recursive equation, the term  $\frac{1}{2} \sum_{i \in [t-1]} [\mathbf{R}^T \mathbf{R}]_{i,t}$  corresponds to the expected increment of the constructed cut if the  $t$ -vertex chose its color uniformly at random. Therefore, lower bounding the expectation of  $\frac{1}{2} |Z_t|$  will tell us how much better the Majority Algorithm does when considering the  $t$ -th vertex.

Towards this end, we note that, given  $\mathbf{x}_{[t-1]} = \{x_i, i \in [t-1]\}$ , and  $\mathbf{R}_{[m],[t-1]} = \{\mathbf{R}_{\ell,i}, \ell \in [m], i \in [t-1]\}$ ,  $Z_t$  is the sum of  $m$  independent random variables, since the Bernoulli random variables  $\mathbf{R}_{\ell,t}, \ell \in [m]$ , are independent, for any given  $t$  (note that the conditioning is essential for independence, otherwise the inner sums in the definition of  $Z_t$  would also depend on the  $x_i$ 's, which are not random when  $i$  is large). By using a domination argument, we can then prove that

$$\mathbb{E}[|Z_t| | \mathbf{x}_{[t-1]}, \mathbf{R}_{[m],[t-1]}] \geq \text{MD}(Z_t^B),$$

where  $Z_t^B$  is a certain Binomial random variable (formally defined in the full proof), and  $\text{MD}(\cdot)$  is the mean absolute difference of (two independent copies of)  $Z_t^B$ , namely  $\text{MD}(Z_t^B) = \mathbb{E}[|Z_t^B - Z_t'^B|]$ . Even though we are aware of no simple closed formula for  $\text{MD}(Z_t^B)$ , we resort to Gaussian approximation of  $Z_t^B - Z_t'^B$  through the Berry-Esseen Theorem, ultimately showing that  $|Z_t^B - Z_t'^B|$  follows approximately the *folded normal distribution*. In particular, we show that  $\text{MD}(Z_t^B) \geq \sqrt{\frac{c(t-1)}{3\pi n}} - o(1)$ , and since the right hand side is independent of  $\mathbf{x}_{[t-1]}, \mathbf{R}_{[m],[t-1]}$ , we get the same lower bound on the expectation of  $|Z_t|$ , namely,  $\mathbb{E}[|Z_t|] \geq \sqrt{\frac{c(t-1)}{3\pi n}} - o(1)$ . Summing over all  $t \geq \epsilon n + 1$ , we get

$$\sum_{t \geq \epsilon n + 1} \mathbb{E}[|Z_t|] \geq \sqrt{\frac{c}{3\pi}} \left( \frac{2}{3} - \epsilon^{3/2} \right) n - o(n),$$

and the result follows by noting that the expected weight of a random cut is equal to  $\frac{1}{4} n(n-1) m p^2 = \frac{c^2}{4} n + o(n)$ , and taking  $\epsilon \rightarrow 0$ . ◀

## 4.2 Intersection graph (weak) bipartization

Notice that we can view a weighted intersection graph  $G(V, E, \mathbf{R}^T \mathbf{R})$  as a multigraph, composed by  $m$  (possibly) overlapping cliques corresponding to the sets of vertices having chosen a certain label, namely  $L_\ell = \{v : \mathbf{R}_{\ell,v}\}, \ell \in [m]$ . In particular, let  $K^{(\ell)}$  denote the

clique induced by label  $\ell$ . Then  $G = \cup_{\ell \in [m]}^+ K^{(\ell)}$ , where  $\cup^+$  denotes union that keeps multiple edges. In this section, we present an algorithm that takes as input an intersection graph  $G$  given as a union of overlapping cliques and outputs a subgraph that is “almost” bipartite.

To facilitate the presentation of our algorithm, we first give some useful definitions. A *closed vertex-label sequence* is a sequence of alternating vertices and labels starting and ending at the same vertex, namely  $\sigma := v_1, \ell_1, v_2, \ell_2, \dots, v_k, \ell_k, v_{k+1} = v_1$ , where the size of the sequence  $k = |\sigma|$  is the number of its labels,  $v_i \in V$ ,  $\ell_i \in \mathcal{M}$ , and  $\{v_i, v_{i+1}\} \subseteq L_{\ell_i}$ , for all  $i \in [k]$  (i.e.  $v_i$  is connected to  $v_{i+1}$  in the intersection graph). We will also say that label  $\ell$  is *strong* if  $|L_{\ell}| \geq 3$ , otherwise it is *weak*. For a given closed vertex-label sequence  $\sigma$ , and any integer  $\lambda \in [|\sigma|]$ , we will say that  $\sigma$  is  $\lambda$ -*strong* if  $|L_{\ell_i}| \geq 3$ , for  $\lambda$  indices  $i \in [|\sigma|]$ . The structural Lemma below is useful for our analysis (refer to the full version of our paper [17] for the proof).<sup>2</sup>

► **Lemma 8.** *Let  $G(V, E, \mathbf{R}^T \mathbf{R})$  be a random instance of the  $\overline{\mathcal{G}}_{n,m,p}$  model, with  $m = n$ , and  $p = \frac{c}{n}$ , for some constant  $c > 0$ . With high probability over the choices of  $\mathbf{R}$ , 0-strong closed vertex-label sequences in  $G$  do not have labels in common.*

The following definition is essential for the presentation of our algorithm.

► **Definition 9.** *Given a weighted intersection graph  $G = G(V, E, \mathbf{R}^T \mathbf{R})$  and a subgraph  $G^{(b)} \subseteq G$ , let  $\mathcal{C}_{odd}(G^{(b)})$  be the set of odd length closed vertex-label sequences  $\sigma := v_1, \ell_1, v_2, \ell_2, \dots, v_k, \ell_k, v_{k+1} = v_1$  that additionally satisfy the following:*

- (a)  $\sigma$  has distinct vertices (except the first and the last) and distinct labels.
- (b)  $v_i$  is connected to  $v_{i+1}$  in  $G^{(b)}$ , for all  $i \in [|\sigma|]$ .
- (c)  $\sigma$  is  $\lambda$ -strong, for some  $\lambda > 0$ .

Algorithm 2 initially replaces each clique  $K^{(\ell)}$  by a random maximal matching  $M^{(\ell)}$ , and thus gets a subgraph  $G^{(b)} \subseteq G$ . If  $\mathcal{C}_{odd}(G^{(b)})$  is not empty, then the algorithm selects  $\sigma \in \mathcal{C}_{odd}(G^{(b)})$  and a strong label  $\ell \in \sigma$ , and then replaces  $M^{(\ell)}$  in  $G^{(b)}$  by a new random matching of  $K^{(\ell)}$ . The algorithm repeats until all odd cycles are destroyed (or runs forever trying to do so).

■ **Algorithm 2** Intersection Graph Weak Bipartization.

---

**Input:** Weighted intersection graph  $G = \cup_{\ell \in [m]}^+ K^{(\ell)}$

**Output:** A subgraph of  $G^{(b)}$  that has only 0-strong odd cycles

- 1 **for** each  $\ell \in [m]$  **do**
  - 2     Let  $M^{(\ell)}$  be a random maximal matching of  $K^{(\ell)}$ ;
  - 3 Set  $G^{(b)} = \cup_{\ell \in [m]}^+ M^{(\ell)}$  ;
  - 4 **while**  $\mathcal{C}_{odd}(G^{(b)}) \neq \emptyset$  **do**
  - 5     Let  $\sigma \in \mathcal{C}_{odd}(G^{(b)})$  and  $\ell$  a label in  $\sigma$  with  $|L_{\ell}| \geq 3$ ;
  - 6     Replace the part of  $G^{(b)}$  corresponding to  $\ell$  by a new random maximal matching  $M^{(\ell)}$ ;
  - 7 **return**  $G^{(b)}$ ;
- 

The following results are the main technical tools that justify the use of the Weak Bipartization Algorithm for WEIGHTED MAX CUT. The proof details for Lemma 10 can be found in our technical report [17].

<sup>2</sup> We conjecture that the structural property of Lemma 8 also holds if we replace 0-strong with  $\lambda$ -strong, for any constant  $\lambda$ , but this stronger version is not necessary for our analysis.

► **Lemma 10.** *If  $\mathcal{C}_{\text{odd}}(G^{(b)})$  is empty, then  $G^{(b)}$  may only have 0-strong odd cycles.*

► **Theorem 11.** *Let  $G(V, E, \mathbf{R}^T \mathbf{R})$  be a random instance of the  $\overline{\mathcal{G}}_{n,m,p}$  model, with  $n = m$  and  $p = \frac{c}{n}$ , where  $c > 0$  is a constant, and let  $\mathbf{R}$  be its representation matrix. Let also  $\Sigma$  be a set system with incidence matrix  $\mathbf{R}$ . With high probability over the choices of  $\mathbf{R}$ , if Algorithm 2 for weak bipartization terminates on input  $G$ , its output can be used to construct a 2-coloring  $\mathbf{x}^{(\text{disc})} \in \arg \min_{\mathbf{x} \in \{\pm 1\}^n} \text{disc}(\Sigma, \mathbf{x})$ , which also gives a maximum cut in  $G$ , i.e.  $\mathbf{x}^{(\text{disc})} \in \arg \max_{\mathbf{x} \in \{\pm 1\}^n} \text{Cut}(G, \mathbf{x})$ .*

**Proof.** By construction, the output of Algorithm 2, namely  $G^{(b)}$ , has only 0-strong odd cycles. Furthermore, by Lemma 8 these cycles correspond to vertex-label sequences that are label-disjoint. Let  $H$  denote the subgraph of  $G^{(b)}$  in which we have destroyed all 0-strong odd cycles by deleting a single (arbitrary) edge  $e_C$  from each 0-strong odd cycle  $C$  (keeping all other edges intact), and notice that  $e_C$  corresponds to a weak label. In particular,  $H$  is a bipartite multi-graph and thus its vertices can be partitioned into two independent sets  $A, B$  constructed as follows: In each connected component of  $H$ , start with an arbitrary vertex  $v$  and include in  $A$  (resp. in  $B$ ) the set of vertices reachable from  $v$  that are at an even (resp. odd) distance from  $v$ . Since  $H$  is bipartite, it does not have odd cycles, and thus this construction is well-defined, i.e. no vertex can be placed in both  $A$  and  $B$ .

We now define  $\mathbf{x}^{(\text{disc})}$  by setting  $x_i^{(\text{disc})} = +1$  if  $i \in A$  and  $x_i^{(\text{disc})} = -1$  if  $i \in B$ . Let  $\mathcal{M}_0$  denote the set of weak labels corresponding to the edges removed from  $G^{(b)}$  in the construction of  $H$ . We first note that, for each  $\ell_C \in \mathcal{M}_0$  corresponding to the removal of an edge  $e_C$ , we have  $\left| \sum_{i \in L_{\ell_C}} x_i^{(\text{disc})} \right| = 2$ . Indeed, since  $e_C$  belongs to an odd cycle in  $G^{(b)}$ , its endpoints are at even distance in  $H$ , which means that either they both belong to  $A$  or they both belong to  $B$ . Therefore, their corresponding entries of  $\mathbf{x}^{(\text{disc})}$  have the same sign, and so (taking into account that the endpoints of  $e_C$  are the only vertices in  $L_{\ell_C}$ ), we have  $\left| \sum_{i \in L_{\ell_C}} x_i^{(\text{disc})} \right| = 2$ . Second, we show that, for all the other labels  $\ell \in [m] \setminus \mathcal{M}_0$ ,  $\left| \sum_{i \in L_{\ell}} x_i^{(\text{disc})} \right|$  will be equal to 1 if  $|L_{\ell}|$  is odd and 0 otherwise. For any label  $\ell \in [m] \setminus \mathcal{M}_0$ , let  $M^{(\ell)}$  denote the part of  $G^{(b)}$  corresponding to a maximal matching of  $K^{(\ell)}$ , and note that all edges of  $M^{(\ell)}$  are contained in  $H$ . Since  $H$  is bipartite, no edge in  $M^{(\ell)}$  can have both its endpoints in either  $A$  or  $B$ . Therefore, by construction, the contribution of entries of  $\mathbf{x}^{(\text{disc})}$  corresponding to endpoints of edges in  $M^{(\ell)}$  to the sum  $\sum_{i \in L_{\ell}} x_i^{(\text{disc})}$  is 0. In particular, if  $|L_{\ell}|$  is even, then  $M^{(\ell)}$  is a perfect matching and  $\left| \sum_{i \in L_{\ell}} x_i^{(\text{disc})} \right| = 0$ , otherwise (i.e. if  $|L_{\ell}|$  is odd) there is a single vertex not matched in  $M^{(\ell)}$  and  $\left| \sum_{i \in L_{\ell}} x_i^{(\text{disc})} \right| = 1$ .

To complete the proof of the theorem, we need to show that  $\text{Cut}(G, \mathbf{x}^{(\text{disc})})$  is maximum. By Corollary 3, this is equivalent to proving that  $\|\mathbf{R}\mathbf{x}^{(\text{disc})}\| \leq \|\mathbf{R}\mathbf{x}\|$  for all  $\mathbf{x} \in \{-1, +1\}^n$ . Suppose that there is some  $\mathbf{x}^{(\text{min})} \in \{-1, +1\}^n$  such that  $\|\mathbf{R}\mathbf{x}^{(\text{disc})}\| > \|\mathbf{R}\mathbf{x}^{(\text{min})}\|$ . As mentioned above, for all  $\ell \in [m] \setminus \mathcal{M}_0$ , we have  $[\mathbf{R}\mathbf{x}^{(\text{disc})}]_{\ell} \leq 1$ , and so  $[\mathbf{R}\mathbf{x}^{(\text{disc})}]_{\ell} \leq [\mathbf{R}\mathbf{x}^{(\text{min})}]_{\ell}$ . Therefore, the only labels where  $\mathbf{x}^{(\text{min})}$  could do better are those corresponding to edges  $e_C$  that are removed from  $G^{(b)}$  in the construction of  $H$ , i.e.  $\ell_C \in \mathcal{M}_0$ , for which we have  $[\mathbf{R}\mathbf{x}^{(\text{disc})}]_{\ell_C} = 2$ . However, any such edge  $e_C$  belongs to an odd cycle  $C$ , and thus any 2-coloring of the vertices of  $C$  will force at least one of the 0-strong labels corresponding to edges of  $C$  to be monochromatic. Taking into account the fact that, by Lemma 8, with high probability over the choices of  $\mathbf{R}$ , all 0-strong odd cycles correspond to vertex-label sequences that are label-disjoint, we conclude that  $\|\mathbf{R}\mathbf{x}^{(\text{disc})}\| \leq \|\mathbf{R}\mathbf{x}^{(\text{min})}\|$ , which completes the proof. ◀

The fact that Theorem 11 is not an immediate consequence of Corollary 4 follows from the observation that a random set system with incidence matrix  $\mathbf{R}$  has discrepancy larger than 1 with (at least) constant probability when  $m = n$  and  $p = \frac{c}{n}$ . Indeed, by a straightforward counting argument, we can see that the expected number of 0-strong odd cycles is at least constant. Furthermore, in any 2-coloring of the vertices at least one of the weak labels forming edges in a 0-strong odd cycle will be monochromatic. Therefore, with at least constant probability, for any  $\mathbf{x} \in \{-1, +1\}^n$ , there exists a weak label  $\ell$ , such that  $x_i x_j = 1$ , for both  $i, j \in L_\ell$ , implying that  $\text{disc}(L_\ell) = 2$ .

We close this section by a result indicating that the conditional statement of Theorem 11 is not void, namely there is a range of values for  $c$  where the Weak Bipartization Algorithm terminates in polynomial time.

► **Theorem 12.** *Let  $G(V, E, \mathbf{R}^T \mathbf{R})$  be a random instance of the  $\overline{\mathcal{G}}_{n,m,p}$  model, with  $n = m$  and  $p = \frac{c}{n}$ , where  $0 < c < 1$  is a constant, and let  $\mathbf{R}$  be its representation matrix. With high probability over the choices of  $\mathbf{R}$ , Algorithm 2 for weak bipartization terminates on input  $G$  in  $O\left((n + \sum_{\ell \in [m]} |L_\ell|) \cdot \log n\right)$  polynomial time.*

The proof of the above theorem uses the following structural Lemma regarding the expected number of closed vertex label sequences.

► **Lemma 13.** *Let  $G(V, E, \mathbf{R}^T \mathbf{R})$  be a random instance of the  $\overline{\mathcal{G}}_{n,m,p}$  model. Let also  $C_k$  denote the number of distinct closed vertex-label sequences of size  $k$  in  $G$ . Then*

$$\mathbb{E}[C_k] = \frac{1}{k} \frac{n!}{(n-k)!} \frac{m!}{(m-k)!} p^{2k}. \quad (9)$$

In particular, when  $m = n \rightarrow \infty$ ,  $p = \frac{c}{n}$ ,  $c > 0$ , and  $k \geq 3$ , we have  $\mathbb{E}[C_k] \leq \frac{c}{2\pi} c^{2k}$ .

**Proof.** Notice that there are  $\frac{1}{k} \frac{n!}{(n-k)!}$  ways to arrange  $k$  out of  $n$  vertices in a cycle. Furthermore, in each such arrangement, there are  $\frac{m!}{(m-k)!}$  ways to place  $k$  out of  $m$  labels so that there is exactly one label between each pair of vertices. Since labels in any given arrangement must be selected by both its adjacent vertices, (9) follows by linearity of expectation.

Setting  $m = n$  and  $p = \frac{c}{n}$ , and using the inequalities  $\sqrt{2\pi} n^{n+\frac{1}{2}} e^{-n} \leq n! \leq e n^{n+\frac{1}{2}} e^{-n}$ ,

$$\begin{aligned} \mathbb{E}[C_k] &= \frac{1}{k} \left( \frac{n!}{(n-k)!} \right)^2 \left( \frac{c}{n} \right)^{2k} \\ &\leq \frac{1}{k} \frac{e^2 n^{2n+1} e^{-2n}}{2\pi (n-k)^{2n-2k+1} e^{2k-2n}} \left( \frac{c}{n} \right)^{2k} = \frac{1}{k} \frac{e^2}{2\pi} \left( \frac{n}{n-k} \right)^{2n-2k+1} \left( \frac{c}{e} \right)^{2k} \\ &\leq \frac{e^2}{2\pi} \frac{n}{k(n-k)} e^{\frac{k}{n-k}(2n-2k)} \left( \frac{c}{e} \right)^{2k} = \frac{e^2}{2\pi} \frac{n}{k(n-k)} c^{2k}. \end{aligned}$$

When  $n$  goes to  $\infty$  and  $k \geq 3$ , then the above is at most  $\frac{c}{2\pi} c^{2k}$  as needed. ◀

We are now ready for the proof of the Theorem.

**Proof of Theorem 12.** We will prove that, when  $m = n \rightarrow \infty$ ,  $p = \frac{c}{n}$ ,  $c < 1$ , and  $k \geq 3$ , with high probability, there are no closed vertex-label sequences that have labels in common. To this end, recalling Definition 9 for  $\mathcal{C}_{\text{odd}}(G^{(b)})$ , we provide upper bounds on the following events:  $A \stackrel{\text{def}}{=} \{\exists k \geq \log n : C_k \geq 1\}$ ,  $B \stackrel{\text{def}}{=} \{|\mathcal{C}_{\text{odd}}(G^{(b)})| \geq \log n\}$  and  $C \stackrel{\text{def}}{=} \{\exists \sigma \neq \sigma' \in \mathcal{C}_{\text{odd}}(G^{(b)}) : \exists \ell \in \sigma, \ell \in \sigma'\}$ .

By the union bound, Markov's inequality and Lemma 13, we get that, whp all closed vertex-label sequences have less than  $\log n$  labels:

$$\Pr(A) \leq \sum_{k \geq \log n} \mathbb{E}[C_k] \leq \sum_{k \geq \log n} \frac{e}{2\pi} c^{2k} = \frac{e}{2\pi} \frac{c^{2 \log n}}{1 - c^2} = O(c^{2 \log n}) = o(1), \quad (10)$$

where the last equality follows since  $c < 1$  is a constant. Furthermore, by Markov's inequality and Lemma 13, and noting that any closed vertex-label sequence in  $\mathcal{C}_{\text{odd}}(G^{(b)})$  must have at least  $k \geq 3$  labels, we get that, whp there less than  $\log n$  closed vertex-label sequences in  $\mathcal{C}_{\text{odd}}(G^{(b)})$ :

$$\Pr(B) \leq \frac{1}{\log n} \sum_{k \geq 3} \mathbb{E}[C_k] \leq \frac{1}{\log n} \sum_{k \geq 3} \frac{e}{2\pi} c^{2k} = \frac{1}{\log n} \frac{e}{2\pi} \frac{c^6}{1 - c^2} = O\left(\frac{1}{\log n}\right). \quad (11)$$

To bound  $\Pr(C)$ , fix a closed vertex-label sequence  $\sigma$ , and let  $|\sigma| \geq 3$  be the number of its labels. Notice that, the probability that there is another closed vertex-label sequence that has labels in common with  $\sigma$  implies the existence of a vertex-label sequence  $\check{\sigma}$  that starts with either a vertex or a label from  $\sigma$ , ends with either a vertex or a label from  $\sigma$ , and has at least one label or at least one vertex that does not belong to  $\sigma$ . Let  $|\check{\sigma}|$  denote the number of labels of  $\check{\sigma}$  that do not belong to  $\sigma$ . Then the number of different vertex-label sequences  $\check{\sigma}$  that start and end in labels from  $\sigma$  is at most  $|\sigma|^2 n^{|\check{\sigma}|+1} m^{|\check{\sigma}|}$ ; indeed  $\check{\sigma}$  in this case has  $|\check{\sigma}|$  labels and  $|\check{\sigma}| + 1$  vertices that do not belong to  $\sigma$ . Therefore, by independence, each such sequence  $\check{\sigma}$  has probability  $p^{2|\check{\sigma}|+2}$  to appear. Similarly, the number of different vertex-label sequences  $\check{\sigma}$  that start and end in vertices from  $\sigma$  is at most  $|\sigma|^2 n^{|\check{\sigma}|-1} m^{|\check{\sigma}|}$  and each one has probability  $p^{2|\check{\sigma}|}$  to appear. Finally, the number of different vertex-label sequences  $\check{\sigma}$  that start in a vertex from  $\sigma$  and end in a label from  $\sigma$  (notice that this also covers the case where  $\check{\sigma}$  starts in a label from  $\sigma$  and ends in a vertex from  $\sigma$ ) is at most  $|\sigma|^2 n^{|\check{\sigma}|} m^{|\check{\sigma}|}$  and each one has probability  $p^{2|\check{\sigma}|+1}$  to appear. Overall, for a given sequence  $\sigma$ , the expected number of sequences  $\check{\sigma}$  described above that additionally satisfies  $|\check{\sigma}| < \log n$ , is at most

$$\sum_{k=0}^{\log n - 1} |\sigma|^2 n^{k+1} m^k p^{2k+2} + \sum_{k=1}^{\log n - 1} |\sigma|^2 n^{k-1} m^k p^{2k} + \sum_{k=1}^{\log n - 1} |\sigma|^2 n^k m^k p^{2k+1} \leq c |\sigma|^2 \frac{\log n}{n}, \quad (12)$$

where in the last inequality we used the fact that  $m = n, p = \frac{c}{n}$  and  $c < 1$ . Since the existence of a sequence  $\check{\sigma}$  for  $\sigma$  that additionally satisfies  $|\check{\sigma}| \geq \log n$  implies event  $A$ , and on other hand the existence of more than  $\log n$  different sequences  $\sigma \in |\mathcal{C}_{\text{odd}}(G^{(b)})|$  implies event  $B$ , by Markov's inequality and (12), we get

$$\Pr(C) \leq \Pr(A) + \Pr(B) + c \frac{(\log n)^4}{n} = O(c^{2 \log n}) + O\left(\frac{1}{\log n}\right) + O\left(\frac{(\log n)^4}{n}\right) = O\left(\frac{1}{\log n}\right).$$

We have thus proved that, with high probability over the choices of  $\mathbf{R}$ , closed vertex-label sequences in  $\mathcal{C}_{\text{odd}}(G^{(b)})$  are label disjoint, as needed.

In view of this, the proof of the Theorem follows by noting that, since closed vertex label sequences in  $\mathcal{C}_{\text{odd}}(G^{(b)})$  are label disjoint, steps 5 and 6 within the while loop of the Weak Bipartization Algorithm will be executed exactly once for each sequence in  $\mathcal{C}_{\text{odd}}(G^{(b)})$ , where  $G^{(b)}$  is defined in step 3 of the algorithm; indeed, once a closed vertex label sequence  $\sigma \in \mathcal{C}_{\text{odd}}(G^{(b)})$  is destroyed in step 6, no new closed vertex label sequence is created. In fact, once  $\sigma$  is destroyed we can remove the corresponding labels and edges from  $G^{(b)}$ , as these will no longer belong to other closed vertex label sequences. Furthermore, to find a closed vertex label sequences in  $\mathcal{C}_{\text{odd}}(G^{(b)})$ , it suffices to find an odd cycle in  $G^{(b)}$ , which can be done by running DFS, requiring  $O(n + \sum_{\ell \in [m]} |L_\ell|)$  time, because  $G^{(b)}$  has at most

$\sum_{\ell \in [m]} |L_\ell|$  edges. Finally, by (11), we have  $|\mathcal{C}_{\text{odd}}(G^{(b)})| < \log n$  with high probability, and so the running time of the Weak Bipartization Algorithm is  $O((n + \sum_{\ell \in [m]} |L_\ell|) \log n)$ , which concludes the proof of Theorem 12.  $\blacktriangleleft$

## 5 Discussion and some open problems

In this paper, we introduced the model of weighted random intersection graphs and we studied the average case analysis of WEIGHTED MAX CUT through the prism of discrepancy of random set systems. In particular, in the first part of the paper, we proved concentration of the weight of a maximum cut of  $G(V, E, \mathbf{R}^T \mathbf{R})$  around its expected value, and we used it to show that, with high probability, the weight of a random cut is asymptotically equal to the maximum cut weight of the input graph, when  $m = n^\alpha$ ,  $\alpha < 1$ . On the other hand, in the case where the number of labels is equal to the number of vertices (i.e.  $m = n$ ), we proved that a majority algorithm gives a cut with weight that is larger than the weight of a random cut by at least a constant factor, when  $p = \frac{c}{n}$  and  $c$  is large.

In the second part of the paper, we highlighted a connection between WEIGHTED MAX CUT of sparse weighted random intersection graphs and DISCREPANCY of sparse random set systems, formalized through our Weak Bipartization Algorithm and its analysis. We demonstrated how our proposed framework can be used to find optimal solutions for these problems, with high probability, in special cases of sparse inputs ( $m = n, p = \frac{c}{n}, c < 1$ ).

One of the main problems left open in our work concerns the termination of our Weak Bipartization Algorithm for large values of  $c$ . We conjecture the following:

► **Conjecture 14.** *Let  $G(V, E, \mathbf{R}^T \mathbf{R})$  be a random instance of the  $\overline{\mathcal{G}}_{n,m,p}$  model, with  $m = n$ , and  $p = \frac{c}{n}$ , for some constant  $c \geq 1$ . With high probability over the choices of  $\mathbf{R}$ , on input  $G$ , Algorithm 2 for weak bipartization terminates in polynomial time.*

We also leave the problem of determining whether Algorithm 2 terminates in polynomial time, in the case  $m = n$  and  $p = \omega(1/n)$ , as an open question for future research.

Towards strengthening the connection between WEIGHTED MAX CUT under the  $\overline{\mathcal{G}}_{n,m,p}$  model, and DISCREPANCY in random set systems, we conjecture the following:

► **Conjecture 15.** *Let  $G(V, E, \mathbf{R}^T \mathbf{R})$  be a random instance of the  $\overline{\mathcal{G}}_{n,m,p}$  model, with  $m = n^\alpha$ ,  $\alpha \leq 1$  and  $mp^2 = O(1)$ , and let  $\mathbf{R}$  be its representation matrix. Let also  $\Sigma$  be a set system with incidence matrix  $\mathbf{R}$ . Then, with high probability over the choices of  $\mathbf{R}$ , there exists  $\mathbf{x}^{\text{disc}} \in \arg \min_{\mathbf{x} \in \{-1, +1\}^n} \text{disc}(\Sigma, \mathbf{x})$ , such that  $\text{Cut}(G, \mathbf{x}^{\text{disc}})$  is asymptotically equal to  $\text{Max-Cut}(G)$ .*

## Abstract

---

Schelling’s classical segregation model gives a coherent explanation for the wide-spread phenomenon of residential segregation. We introduce an agent-based saturated open-city variant, the Flip Schelling Process (FSP), in which agents, placed on a graph, have one out of two types and, based on the predominant type in their neighborhood, decide whether to change their types; similar to a new agent arriving as soon as another agent leaves the vertex.

We investigate the probability that an edge  $\{u, v\}$  is monochrome, i.e., that both vertices  $u$  and  $v$  have the same type in the FSP, and we provide a general framework for analyzing the influence of the underlying graph topology on residential segregation. In particular, for two adjacent vertices, we show that a highly decisive common neighborhood, i.e., a common neighborhood where the absolute value of the difference between the number of vertices with different types is high, supports segregation and, moreover, that large common neighborhoods are more decisive.

As an application, we study the expected behavior of the FSP on two common random graph models with and without geometry: (1) For random geometric graphs, we show that the existence of an edge  $\{u, v\}$  makes a highly decisive common neighborhood for  $u$  and  $v$  more likely. Based on this, we prove the existence of a constant  $c > 0$  such that the expected fraction of monochrome edges after the FSP is at least  $1/2 + c$ . (2) For Erdős–Rényi graphs we show that large common neighborhoods are unlikely and that the expected fraction of monochrome edges after the FSP is at most  $1/2 + o(1)$ . Our results indicate that the cluster structure of the underlying graph has a significant impact on the obtained segregation strength.

## 1 Introduction

Residential segregation is a well-known sociological phenomenon [49] where different groups of people tend to separate into largely homogeneous neighborhoods. Studies, e.g., [18], show that individual preferences are the driving force behind present residential patterns and bear much to the explanatory weight. Local choices therefore lead to a global phenomenon [47]. A simple model for analyzing residential segregation was introduced by Schelling [46, 47] in

the 1970s. In his model, two types of agents, placed on a grid, act according to the following threshold behavior, with  $\tau \in (0, 1)$  as the *intolerance threshold*: agents are *content* with their current position on the grid if at least a  $\tau$ -fraction of neighbors is of their own type. Otherwise they are *discontent* and want to move, either via swapping with another random discontent agent or via jumping to a vacant position. Schelling demonstrated via simulations that, starting from a uniform random distribution, the described process drifts towards strong segregation, even if agents are tolerant and agree to live in mixed neighborhoods, i.e., if  $\tau \leq \frac{1}{2}$ . Many empirical studies have been conducted to investigate the influence of various parameters on the obtained segregation, see [8, 9, 25, 41, 45]. On the theoretical side, Schelling's model started recently gaining traction within the algorithmic game theory and artificial intelligence communities [1, 11, 16, 17, 21, 22, 33], with focus on core game theoretic questions, where agents strategically select locations. Henry et al. [31] described a simple model of graph clustering motivated by Schelling where they showed that segregated graphs always emerge. Variants of the random Schelling segregation process were analyzed by a line of work that showed that residential segregation occurs with high probability [5, 7, 10, 13, 32, 51].

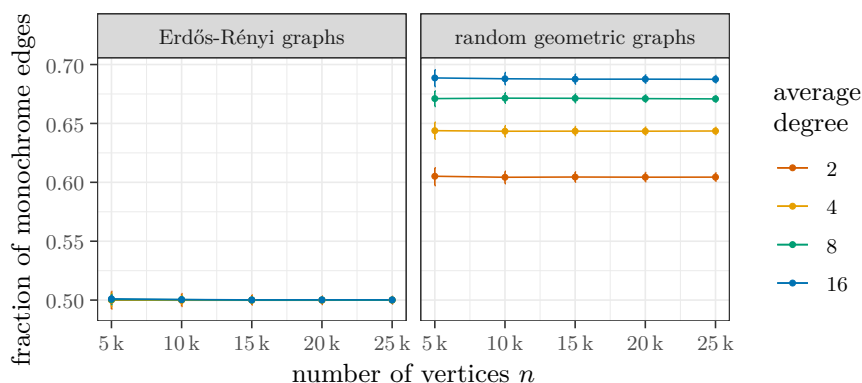

We initiate the study of an agent-based model, called the *Flip Schelling Process (FSP)*, which can be understood as the Schelling model in a *saturated open city*. In contrast to *closed cities* [7, 13, 32, 51], which require fixed populations, open cities [4, 5, 10, 27] allow resident to move away. In saturated city models, also known as voter models [20, 35, 36], vertices are not allowed to be unoccupied, hence, a new agent enters as soon as one agent vacates a vertex. In general, in voter models, two types of agents are placed on a graph. Agents examine their neighbors and, if a certain threshold is of another type, they change their types. Also in this model, segregation is visible. There is a line of work, mainly in physics, that studies the voting dynamics on several types of graphs [3, 14, 37, 43, 50]. Related to voter models, Granovetter [30] proposed another threshold model treating binary decisions and spurred a number of research, which studied and motivated variants of the model, see [2, 34, 38, 44].

In the FSP, agents have binary types. An agent is content if the fraction of agents in its neighborhood with the same type is larger than  $\frac{1}{2}$ . Otherwise, if the fraction is smaller than  $\frac{1}{2}$ , an agent is discontent and is willing to flip its type to become content. If the fraction of same type agents in its neighborhood is exactly  $\frac{1}{2}$ , an agent flips its type with probability  $\frac{1}{2}$ . Starting from an initial configuration where the type of each agent is chosen uniformly at random, we investigate a simultaneous-move, one-shot process and bound the number of monochrome edges, which is a popular measurement for segregation strength [19, 26].

Close to our model is the work by Omidvar and Franceschetti [39, 40], who initiated an analysis of the size of monochrome regions in the so called *Schelling Spin Systems*. Agents of two different types are placed on a grid [39] and a geometric graph [40], respectively. Then independent and identical Poisson clocks are assigned to all agents and, every time a clock rings, the state of the corresponding agent is flipped if and only if the agent is discontent w.r.t. a certain intolerance threshold  $\tau$  regarding the neighborhood size. The model corresponds to the Ising model with zero temperature with Glauber dynamics [15, 48].

The commonly used underlying topology for modeling the residential areas are (toroidal) grid graphs [11, 32, 39], regular graphs [11, 17, 21], paths [11, 33], cycles [4, 6, 7, 13, 51] and trees [1, 11, 22, 33]. Considering the influence of the given topology that models the residential area regarding, e.g., the existence of stable states and convergence behavior leads to phenomena like non-existence of stable states [21, 22], non-convergence to stable states [11, 17, 21], and high-mixing times in corresponding Markov chains [10, 28].

To avoid such undesirable characteristics, we suggest to investigate *random geometric graphs* [42], like in [40]. Random geometric graphs demonstrate, in contrast to other random graphs without geometry, such as *Erdős-Rényi graphs* [23, 29], community structures, i.e.,

■ **Figure 1** The fraction of monochrome edges after the Flip Schelling Process (FSP) in Erdős–Rényi graphs and random geometric graphs for different graph sizes (number of vertices  $n$ ) and different expected average degrees. Each data point shows the average over 1000 generated graphs with one simulation of the FSP per graph. The error bars show the interquartile range, i.e., 50% of the measurements lie between the top and bottom end of the error bar.

densely connected clusters of vertices. An effect observed by simulating the FSP is that the fraction of monochrome edges is significantly higher in random geometric graphs compared to Erdős–Rényi graphs, where the fraction stays almost stable around  $\frac{1}{2}$ , cf. Fig 1.

We set out for rigorously proving this phenomenon. In particular, we prove for random geometric graphs that there exists a constant  $c$  such that, given an edge  $\{u, v\}$ , the probability that  $\{u, v\}$  is monochrome is lower-bounded by  $\frac{1}{2} + c$ , cf. Theorem 6. In contrast, we show for Erdős–Rényi graphs that segregation is not likely to occur and that the probability that  $\{u, v\}$  is monochrome is upper-bounded by  $\frac{1}{2} + o(1)$ , cf. Theorem 17.

We introduce a general framework to deepen the understanding of the influence of the underlying topology on residential segregation. To this end, we first show that a highly decisive common neighborhood supports segregation, cf. Section 3.1. In particular, we provide a lower bound on the probability that an edge  $\{u, v\}$  is monochrome based on the probability that the difference between the majority and the minority regarding both types in the common neighborhood, i.e., the number of agents which are adjacent to  $u$  and  $v$ , is larger than their exclusive neighborhoods, i.e., the number of agents which are adjacent to either  $u$  or  $v$ . Next, we show that large sets of agents are more decisive, cf. Section 3.2. This implies that a large common neighborhood, compared to the exclusive neighborhood, is likely to be more decisive, i.e., makes it more likely that the absolute value of the difference between the number of different types in the common neighborhood is larger than in the exclusive ones. These considerations hold for arbitrary graphs. Hence, we reduce the question concerning a lower bound for the fraction of monochrome edges in the FSP to the probability that, given  $\{u, v\}$ , the common neighborhood is larger than the exclusive neighborhoods of  $u$  and  $v$ , respectively.

For random geometric graphs, we prove that a large geometric region, i.e., the intersecting region that is formed by intersecting disks, leads to a large vertex set, cf. Section 3.3, and that random geometric graphs have enough edges that have sufficiently large intersecting regions, cf. Section 3.4, such that segregation is likely to occur. In contrast, for Erdős–Rényi graphs, we show that the common neighborhood between two vertices  $u$  and  $v$  is with high probability empty and therefore segregation is not likely to occur, cf. Section 4.

Overall, we shed light on the influence of the structure of the underlying graph and discovered the significant impact of the community structure as an important factor on the obtained segregation strength. We reveal for random geometric graphs that already after one round a provable tendency is apparent and a strong segregation occurs.

## 2 Model and Preliminaries

Let  $G = (V, E)$  be an unweighted and undirected graph, with vertex set  $V$  and edge set  $E$ . For any vertex  $v \in V$ , we denote the *neighborhood* of  $v$  in  $G$  by  $N_v = \{u \in V : \{u, v\} \in E\}$  and the degree of  $v$  in  $G$  by  $\delta_v = |N_v|$ . We consider *random geometric graphs* and *Erdős–Rényi graphs* with a total of  $n \in \mathbf{N}^+$  vertices and an *expected average degree*  $\bar{\delta} > 0$ .

For a given  $r \in \mathbf{R}^+$ , a random geometric graph  $G \sim \mathcal{G}(n, r)$  is obtained by distributing  $n$  vertices uniformly at random in some geometric ground space and connecting vertices  $u$  and  $v$  if and only if  $\text{dist}(u, v) \leq r$ . We use a two-dimensional toroidal Euclidean space with total area 1 as ground space. More formally, each vertex  $v$  is assigned to a point  $(v_1, v_2) \in [0, 1]^2$  and the distance between  $u = (u_1, u_2)$  and  $v$  is  $\text{dist}(u, v) = \sqrt{|u_1 - v_1|_0^2 + |u_2 - v_2|_0^2}$  for  $|u_i - v_i|_0 = \min\{|u_i - v_i|, 1 - |u_i - v_i|\}$ . We note that using a torus instead of, e.g., a unit square, has the advantage that we do not have to consider edge cases, for vertices that are close to the boundary. In fact, a disk of radius  $r$  around any point has the same area  $\pi r^2$ . Since we consider a ground space with total area 1,  $r \leq \frac{1}{\sqrt{\pi}}$ . As every vertex  $v$  is connected to all vertices in the disk of radius  $r$  around it, its expected average degree is  $\bar{\delta} = (n-1)\pi r^2$ .

For a given  $p \in [0, 1]$ , let  $\mathcal{G}(n, p)$  denote an Erdős–Rényi graph. Each edge  $\{u, v\}$  is included with probability  $p$ , independently from every other edge. It holds that  $\bar{\delta} = (n-1)p$ .

Consider two different vertices  $u$  and  $v$ . Let  $N_{u \cap v} := |N_u \cap N_v|$  be the number of vertices in the *common neighborhood*, let  $N_{u \setminus v} := |N_u \setminus N_v|$  be the number of vertices in the *exclusive neighborhood* of  $u$ , and let  $N_{v \setminus u} := |N_v \setminus N_u|$  be the number of vertices in the exclusive neighborhood of  $v$ . Furthermore, with  $N_{\overline{u \cup v}} := |V \setminus (N_u \cup N_v)|$ , we denote the number of vertices that are neither adjacent to  $u$  nor to  $v$ .

Let  $G$  be a graph where each vertex represents an agent of type  $t^+$  or  $t^-$ . The type of each agent is chosen independently and uniformly at random. An edge  $\{u, v\}$  is *monochrome* if and only if  $u$  and  $v$  are of the same type. The *Flip Schelling Process* (FSP) is defined as follows: an agent  $v$  whose type is aligned with the type of more than  $\delta_v/2$  of its neighbors keeps its type. If more than  $\delta_v/2$  neighbors have a different type, then agent  $v$  changes its type. In case of a tie, i.e., if exactly  $\delta_v/2$  neighbors have a different type, then  $v$  changes its type with probability  $\frac{1}{2}$ . FSP is a simultaneous-move, one-shot process, i.e., all agents make their decision at the same time and, moreover, only once.

For  $x, y \in \mathbf{N}$ , we define  $[x..y] = [x, y] \cap \mathbf{N}$  and for  $x \in \mathbf{N}^+$ , we define  $[x] = [1..x]$ .

### 2.1 Useful Technial Lemmas

In this section, we state several lemmas that we will use in order to prove our results in the next sections.

► **Lemma 1.** *Let  $X \sim \text{Bin}(n, p)$  and  $Y \sim \text{Bin}(n, q)$  with  $p \geq q$  be independent. Then  $\Pr[X \geq Y] \geq \frac{1}{2}$ .*

**Proof.** Let  $Y_1, \dots, Y_n$  be the individual Bernoulli trials for  $Y$ , i.e.,  $Y = \sum_{i \in [n]} Y_i$ . Define new random variables  $Y'_1, \dots, Y'_n$  such that  $Y_i = 1$  implies  $Y'_i = 1$  and if  $Y_i = 0$ , then  $Y'_i = 1$  with probability  $(p - q)/(1 - q)$  and  $Y'_i = 0$  otherwise. Note that for each individual  $Y'_i$ , we have  $Y'_i = 1$  with probability  $p$ , i.e.,  $Y' = \sum_{i \in [n]} Y'_i \sim \text{Bin}(n, p)$ . Moreover, as  $Y' \geq Y$  for every outcome, we have  $\Pr[X \geq Y] \geq \Pr[X \geq Y']$ . It remains to show that  $\Pr[X \geq Y'] \geq \frac{1}{2}$ .

As  $X$  and  $Y'$  are equally distributed, we have  $\Pr[X \geq Y'] = \Pr[X \leq Y']$ . Moreover, as one of the two inequalities holds in any event, we get  $\Pr[X \geq Y'] + \Pr[X \leq Y'] \geq 1$ , and thus equivalently  $2\Pr[X \geq Y'] \geq 1$ , which proves the claim. ◀

► **Lemma 2.** *Let  $n \in \mathbf{N}^+$ ,  $p \in [0, 1)$ , and let  $X \sim \text{Bin}(n, p)$ . Then, for all  $i \in [0..n]$ , it holds that  $\Pr[X = i] \leq \Pr[X = \lfloor p(n+1) \rfloor]$ .*

**Proof.** We interpret the distribution of  $X$  as a finite series and consider the sign of the differences of two neighboring terms. A maximum of the distribution of  $X$  is located at the position at which the difference switches from positive to negative. To this end, let  $b: [0, n-1] \rightarrow [-1, 1]$  be defined such that, for all  $i \in [0, n-1] \cap \mathbf{N}$ , it holds that

$$b(d) = \binom{n}{d+1} p^{d+1} (1-p)^{n-d-1} - \binom{n}{d} p^d (1-p)^{n-d}.$$

We are interested in the sign of  $b$ . In more detail, for any  $d \in [0, n-2] \cap \mathbf{N}$ , if  $\text{sgn}(b(d)) \geq 0$  and  $\text{sgn}(b(d+1)) \leq 0$ , then  $d+1$  is a local maximum. If the sign is always negative, then there is a global maximum in the distribution of  $X$  at position 0.

In order to determine the sign of  $b$ , for all  $i \in [0..n-1]$ , we rewrite

$$\begin{aligned} b(i) &= \frac{n!}{i!(n-i-1)!} p^i (1-p)^{n-i-1} \frac{p}{i+1} - \frac{n!}{i!(n-i-1)!} p^d (1-p)^{n-i-1} \frac{1-p}{n-i} \\ &= \frac{n!}{i!(n-i-1)!} p^i (1-p)^{n-i-1} \left( \frac{p}{i+1} - \frac{1-p}{n-i} \right). \end{aligned}$$

Since the term  $n! p^i (1-p)^{n-i-1}$  is always non-negative, the sign of  $b(i)$  is determined by the sign of  $p/(i+1) - (1-p)/(n-i)$ .

Solving for  $i$ , we get that

$$\frac{p}{i+1} - \frac{1-p}{n-i} \geq 0 \Leftrightarrow i \leq p(n+1) - 1.$$

Note that  $p(n+1) - 1$  may not be integer. Further note that the distribution of  $X$  is unimodal, as the sign of  $b$  changes at most once. Thus, each local maximum is also a global maximum. As discussed above, the largest value  $d \in [0, n-2] \cap \mathbf{N}$  such that  $\text{sgn}(b(d)) \geq 0$  and  $\text{sgn}(b(d+1)) \leq 0$  then results in a global maximum at position  $d+1$ . Since  $d$  needs to be integer, the largest value that satisfies this constraint is  $\lfloor p(n+1) - 1 \rfloor$ . If the sign of  $b$  is always negative ( $p \leq 1/(n+1)$ ), then the distribution of  $X$  has a global maximum at 0, which is also satisfied by  $\lfloor p(n+1) - 1 \rfloor + 1$ , which concludes the proof. ◀

► **Theorem 3** (Stirling's Formula [24, page 54]). *For all  $n \in \mathbf{N}^+$ , it holds that*

$$\sqrt{2\pi n}^{n+1/2} e^{-n} \cdot e^{(12n+1)^{-1}} < n! < \sqrt{2\pi n}^{n+1/2} e^{-n} \cdot e^{(12n)^{-1}}.$$

► **Corollary 4.** *For all  $n \geq 2$  with  $n \in \mathbf{N}$ , it holds that*

$$n! > \sqrt{2\pi n}^{n+1/2} e^{-n} \quad \text{and} \tag{1}$$

$$n! < e n^{n+1/2} e^{-n}. \tag{2}$$

**Proof.** For both inequalities, we aim at using Theorem 3.

Equation (1): Note that  $e^{(12n+1)^{-1}} > 1$ , since  $\frac{1}{12n+1} > 0$ . Hence,

$$\sqrt{2\pi n}^{n+1/2} e^{-n} < \sqrt{2\pi n}^{n+1/2} e^{-n} \cdot e^{(12n+1)^{-1}}.$$

Equation (2): We prove this case by showing that

$$\sqrt{2\pi} e^{(12n)^{-1}} < e. \tag{3}$$

## 29:6 The Flip Schelling Process on Random Graphs

Note, that  $e^{(12n)^{-1}}$  is strictly decreasing. Hence, we only have to check whether Equation (3) holds for  $n = 2$ .

$$\sqrt{2\pi}e^{(12n)^{-1}} \leq \sqrt{2\pi}e^{\frac{1}{24}} < 2.7 < e. \quad \blacktriangleleft$$

► **Lemma 5.** *Let  $A$ ,  $B$ , and  $C$  be random variables such that  $\Pr[A > C \wedge B > C] > 0$  and  $\Pr[A > C \wedge B \leq C] > 0$ . Then  $\Pr[A > B \wedge A > C] \geq \Pr[A > B] \cdot \Pr[A > C]$ .*

**Proof.** Using the definition of conditional probability, we obtain

$$\Pr[A > B \wedge A > C] = \Pr[A > B \mid A > C] \cdot \Pr[A > C].$$

Hence, we are left with bounding  $\Pr[A > B \mid A > C] \geq \Pr[A > B]$ . Partitioning the sample space into the two events  $B > C$  and  $B \leq C$  and using the law of total probability, we obtain

$$\begin{aligned} \Pr[A > B \mid A > C] &= \Pr[B > C \mid A > C] \cdot \Pr[A > B \mid A > C \wedge B > C] \\ &\quad + \Pr[B \leq C \mid A > C] \cdot \Pr[A > B \mid A > C \wedge B \leq C]. \end{aligned}$$

Note that the condition  $A > C \wedge B \leq C$  already implies  $A > B$  and thus the last probability equals to 1. Moreover, using the definition of conditional probability, we obtain

$$\begin{aligned} \Pr[A > B \mid A > C] &= \Pr[B > C \mid A > C] \cdot \frac{\Pr[A > B \wedge A > C \wedge B > C]}{\Pr[A > C \wedge B > C]} \\ &\quad + \Pr[B \leq C \mid A > C]. \end{aligned}$$

Using that  $\Pr[B > C \mid A > C] \geq \Pr[A > C \wedge B > C]$ , that  $A > B \wedge B > C$  already implies  $A > C$ , that  $\Pr[B \leq C \mid A > C] \geq \Pr[A > B \wedge B \leq C]$ , and finally the law of total probability, we obtain

$$\begin{aligned} \Pr[A > B \mid A > C] &\geq \Pr[A > B \wedge A > C \wedge B > C] + \Pr[B \leq C \mid A > C] \\ &= \Pr[A > B \wedge B > C] + \Pr[B \leq C \mid A > C] \\ &\geq \Pr[A > B \wedge B > C] + \Pr[A > B \wedge B \leq C] \\ &= \Pr[A > B]. \quad \blacktriangleleft \end{aligned}$$

### 3 Monochrome Edges in Geometric Random Graphs

In this section, we prove the following main theorem.

► **Theorem 6.** *Let  $G \sim \mathcal{G}(n, r)$  be a random geometric graph with expected average degree  $\bar{\delta} = o(\sqrt{n})$ . The expected fraction of monochrome edges after the FSP is at least*

$$\frac{1}{2} + \frac{9}{800} \cdot \left( \frac{1}{2} - \frac{1}{\sqrt{2\pi \lfloor \bar{\delta}/2 \rfloor}} \right)^2 \cdot \left( 1 - e^{-\bar{\delta}/2} \left( 1 + \frac{\bar{\delta}}{2} \right) \right) \cdot (1 - o(1)).$$

Note that the bound in Theorem 6 is bounded away from  $\frac{1}{2}$  for all  $\bar{\delta} \geq 2$ . Moreover, the two factors depending on  $\bar{\delta}$  go to  $\frac{1}{2}$  and 1, respectively, for a growing  $\bar{\delta}$ .

Given an edge  $\{u, v\}$ , we prove the above lower bound on the probability that  $\{u, v\}$  is monochrome in the following four steps.

1. For a vertex set, we introduce the concept of *decisiveness* that measures how much the majority is ahead of the minority in the FSP. With this, we give a lower bound on the probability that  $\{u, v\}$  is monochrome based on the probability that the common neighborhood of  $u$  and  $v$  is more decisive than their exclusive neighborhoods.

2. We show that large neighborhoods are likely to be more decisive than small neighborhoods. To this end, we give bounds on the likelihood that two similar random walks behave differently. This step reduces the question of whether the common neighborhood is more decisive than the exclusive neighborhoods to whether the former is larger than the latter.
3. Turning to geometric random graphs, we show that the common neighborhood is sufficiently likely to be larger than the exclusive neighborhoods if the geometric region corresponding to the former is sufficiently large. We do this by first showing that the actual distribution of the neighborhood sizes is well approximated by independent binomial random variables. Then, we give the desired bounds for these random variables.
4. We show that the existence of the edge  $\{u, v\}$  in the geometric random graph makes it sufficiently likely that the geometric region hosting the common neighborhood of  $u$  and  $v$  is sufficiently large.

### 3.1 Monochrome Edges via Decisive Neighborhoods

Let  $\{u, v\}$  be an edge of a given graph. To formally define the above mentioned decisiveness, let  $N_{u \cap v}^+$  and  $N_{u \cap v}^-$  be the number of vertices in the common neighborhood of  $u$  and  $v$  that are occupied by agents of type  $t^+$  and  $t^-$ , respectively. Then  $D_{u \cap v} := |N_{u \cap v}^+ - N_{u \cap v}^-|$  is the *decisiveness* of the common neighborhood of  $u$  and  $v$ . Analogously, we define  $D_{u \setminus v}$  and  $D_{v \setminus u}$  for the exclusive neighborhoods of  $u$  and  $v$ , respectively.

The following theorem bounds the probability for  $\{u, v\}$  to be monochrome based on the probability that the common neighborhood is more decisive than each of the exclusive ones.

► **Theorem 7.** *In the FSP, let  $\{u, v\} \in E$  be an edge and let  $D$  be the event  $\{D_{u \cap v} > D_{u \setminus v} \wedge D_{u \cap v} > D_{v \setminus u}\}$ . Then  $\{u, v\}$  is monochrome with probability at least  $1/2 + \Pr[D]/2$ .*

**Proof.** If  $D$  occurs, then the types of  $u$  and  $v$  after the FSP coincide with the predominant type before the FSP in the shared neighborhood. Thus,  $\{u, v\}$  is monochrome.

Otherwise, assuming  $\bar{D}$ , w.l.o.g., let  $D_{u \cap v} \leq D_{u \setminus v}$  and assume further the type of  $v$  has already been determined. If  $D_{u \cap v} = D_{u \setminus v}$ , then  $u$  chooses a type uniformly at random, which coincides with the type of  $v$  with probability  $\frac{1}{2}$ . Otherwise,  $D_{u \cap v} < D_{u \setminus v}$  and thus  $u$  takes the type that is predominant in  $u$ 's exclusive neighborhood, which is  $t^+$  and  $t^-$  with probability  $\frac{1}{2}$ , each. Moreover, this is independent from the type of  $v$  as  $v$ 's neighborhood is disjoint to  $u$ 's exclusive neighborhood.

Thus, for the event  $M$  that  $\{u, v\}$  is monochrome, we get  $\Pr[M | D] = 1$  and  $\Pr[M | \bar{D}] = \frac{1}{2}$ . Hence, we get  $\Pr[M] > \Pr[D] + \frac{1}{2}(1 - \Pr[D]) = \frac{1}{2} + \Pr[D]/2$ . ◀

### 3.2 Large Neighborhoods are More Decisive

The goal of this section is to reduce the question of how decisive a neighborhood is to the question of how large it is. To be more precise, assume we have a set of vertices of size  $a$  and give each vertex the type  $t^+$  and  $t^-$ , respectively, each with probability  $\frac{1}{2}$ . Let  $A_i$  for  $i \in [a]$  be the random variable that takes the value  $+1$  and  $-1$  if the  $i$ -th vertex in this set has type  $t^+$  and  $t^-$ , respectively. Then, for  $A = \sum_{i \in [a]} A_i$ , the decisiveness of the vertex set is  $|A|$ . In the following, we study the decisiveness  $|A|$  depending on the size  $a$  of the set. Note that this can be viewed as a random walk on the integer line: Starting at 0, in each step, it moves one unit either to the left or to the right with equal probabilities. We are interested in the distance from 0 after  $a$  steps.

Assume for the vertices  $u$  and  $v$  that we know that  $b$  vertices lie in the common neighborhood and  $a$  vertices lie in the exclusive neighborhood of  $u$ . Moreover, let  $A$  and  $B$  be the positions of the above random walk after  $a$  and  $b$  steps, respectively. Then the event

## 29:8 The Flip Schelling Process on Random Graphs

$D_{u \cap v} > D_{u \setminus v}$  is equivalent to  $|B| > |A|$ . Motivated by this, we study the probability of  $|B| > |A|$ , assuming  $b \geq a$ . The core difficulty here comes from the fact that we require  $|B|$  to be strictly larger than  $|A|$ . Also note that  $a + b$  corresponds to the degree of  $u$  in the graph. Thus, we have to study the random walks also for small numbers of  $a$  and  $b$ . We note that all results in this section are independent from the specific application to the FSP, and thus might be of independent interest.

Before we give a lower bound on the probability that  $|B| > |A|$ , we need the following technical lemma. It states that doing more steps in the random walk only makes it more likely to deviate further from the starting position.

► **Lemma 8.** *For  $i \in [a]$  and  $j \in [b]$  with  $0 \leq a \leq b$ , let  $A_i$  and  $B_j$  be independent random variables that are  $-1$  and  $1$  each with probability  $\frac{1}{2}$ . Let  $A = \sum_{i \in [a]} A_i$  and  $B = \sum_{j \in [b]} B_j$ . Then  $\Pr[|A| < |B|] \geq \Pr[|A| > |B|]$ .*

**Proof.** Let  $\Delta_k$  be the event that  $|B| - |A| = k$ . First note that

$$\Pr[|A| < |B|] = \sum_{k \in [b]} \Pr[\Delta_k] \quad \text{and} \quad \Pr[|A| > |B|] = \sum_{k \in [a]} \Pr[\Delta_{-k}].$$

To prove the statement of the lemma, it thus suffices to prove the following claim.

▷ **Claim 9.** For  $k \geq 0$ ,  $\Pr[\Delta_k] \geq \Pr[\Delta_{-k}]$ .

We prove this claim via induction on  $b - a$ . For the base case  $a = b$ ,  $A$  and  $B$  are equally distributed and thus Claim 9 clearly holds.

For the induction step, let  $B^+$  be the random variable that takes the values  $B + 1$  and  $B - 1$  with probability  $\frac{1}{2}$  each. Note that  $B^+$  represents the same type of random walk as  $A$  and  $B$  but with  $b + 1$  steps. Moreover  $B^+$  is coupled with  $B$  to make the same decisions in the first  $b$  steps. Let  $\Delta_k^+$  be the event that  $|B^+| - |A| = k$ . It remains to show that Claim 9 holds for these  $\Delta_k^+$ . For this, first note that the claim trivially holds for  $k = 0$ . For  $k \geq 1$ , we can use the definition of  $\Delta_k^+$  and the induction hypothesis to obtain

$$\begin{aligned} \Pr[\Delta_k^+] &= \frac{\Pr[\Delta_{k-1}]}{2} + \frac{\Pr[\Delta_{k+1}]}{2} \\ &\geq \frac{\Pr[\Delta_{-k+1}]}{2} + \frac{\Pr[\Delta_{-k-1}]}{2} = \Pr[\Delta_{-k}^+]. \end{aligned} \quad \blacktriangleleft$$

Using Lemma 8, we now prove the following general bound for the probability that  $|A| < |B|$ , depending on certain probabilities for binomially distributed variables.

► **Lemma 10.** *For  $i \in [a]$  and  $j \in [b]$  with  $0 \leq a \leq b$ , let  $A_i$  and  $B_j$  be independent random variables that are  $-1$  and  $1$  each with probability  $\frac{1}{2}$ . Let  $A = \sum_{i \in [a]} A_i$  and  $B = \sum_{j \in [b]} B_j$ . Moreover, let  $X \sim \text{Bin}(a, \frac{1}{2})$ ,  $Y \sim \text{Bin}(b, \frac{1}{2})$ , and  $Z \sim \text{Bin}(a + b, \frac{1}{2})$ . Then*

$$\Pr[|A| < |B|] \geq \frac{1}{2} - \Pr\left[Z = \frac{a+b}{2}\right] + \frac{\Pr[X = \frac{a}{2}] \cdot \Pr[Y = \frac{b}{2}]}{2}.$$

**Proof.** Using that  $\Pr[|A| < |B|] \geq \Pr[|A| > |B|]$  (see Lemma 8), we obtain

$$\begin{aligned} &\Pr[|A| < |B|] + \Pr[|A| > |B|] + \Pr[|A| = |B|] = 1 \\ \Rightarrow &2\Pr[|A| < |B|] + \Pr[|A| = |B|] \geq 1 \\ \Leftrightarrow &\Pr[|A| < |B|] \geq \frac{1}{2} - \frac{\Pr[|A| = |B|]}{2}. \end{aligned} \quad (4)$$

Thus, it remains to give an upper bound for  $\Pr[|A| = |B|]$ .

Using the inclusion–exclusion principle and the fact that  $B$  is symmetric around 0, i.e.,  $\Pr[B = x] = \Pr[B = -x]$  for any  $x$ , we obtain

$$\begin{aligned} \Pr[|A| = |B|] &= \Pr[A = B \vee A = -B] \\ &= \Pr[A = B] + \Pr[A = -B] - \Pr[A = B = 0] \\ &= 2\Pr[A = -B] - \Pr[A = B = 0]. \end{aligned} \tag{5}$$

We estimate  $\Pr[A = -B]$  and  $\Pr[A = B = 0]$  using bounds for binomially distributed variables. To this end, define new random variables  $X_i = \frac{A_i+1}{2}$  for  $i \in [a]$  and let  $X = \sum_{i \in [a]} X_i$ . Note that the  $X_i$  are independent and take values 0 and 1, each with probability  $\frac{1}{2}$ . Thus,  $X \sim \text{Bin}(a, \frac{1}{2})$ . Moreover,  $A = 2X - a$ . Analogously, we define  $Y$  with  $Y \sim \text{Bin}(b, \frac{1}{2})$  and  $B = 2Y - b$ . Note that  $X$  and  $Y$  are independent and thus  $Z = X + Y \sim \text{Bin}(a + b, \frac{1}{2})$ . With this, we get

$$\begin{aligned} \Pr[A = -B] &= \Pr[2X - a = -2Y + b] = \Pr\left[Z = \frac{a+b}{2}\right], \text{ and} \\ \Pr[A = B = 0] &= \Pr[A = 0] \cdot \Pr[B = 0] = \Pr\left[X = \frac{a}{2}\right] \cdot \Pr\left[Y = \frac{b}{2}\right]. \end{aligned}$$

This, together with Equations (4) and (5) yield the claim. ◀

The bound in Lemma 10 becomes worse for smaller values of  $a$  and  $b$ . Considering this worst case, we obtain the following specific bound.

► **Theorem 11.** *For  $i \in [a]$  and  $j \in [b]$  with  $0 \leq a \leq b$ , let  $A_i$  and  $B_j$  be independent random variables that are  $-1$  and  $1$  each with probability  $\frac{1}{2}$ . Let  $A = \sum_{i \in [a]} A_i$  and  $B = \sum_{j \in [b]} B_j$ . If  $a = b = 0$  or  $a = b = 1$ , then  $\Pr[|A| < |B|] = 0$ . Otherwise  $\Pr[|A| < |B|] \geq \frac{3}{16}$ .*

**Proof.** Clearly, if  $a = b = 0$ , then  $A = B = 0$  and thus  $\Pr[|A| < |B|] = 0$ . Similarly, if  $a = b = 1$ , then  $|A| = |B| = 1$  and thus  $\Pr[|A| < |B|] = 0$ . For the remainder, assume that neither  $a = b = 0$  nor  $a = b = 1$ , and let  $X, Y$ , and  $Z$  be defined as in Lemma 10, i.e.,  $X \sim \text{Bin}(a, \frac{1}{2})$ ,  $Y \sim \text{Bin}(b, \frac{1}{2})$ , and  $Z \sim \text{Bin}(a + b, \frac{1}{2})$ .

If  $a + b$  is odd, then  $\Pr[Z = \frac{a+b}{2}] = 0$ . Thus, by Lemma 10, we have  $\Pr[|A| < |B|] \geq \frac{1}{2}$ . If  $a + b$  is even and  $a + b \geq 6$ , then

$$\Pr\left[Z = \frac{a+b}{2}\right] = \binom{a+b}{\frac{a+b}{2}} \left(\frac{1}{2}\right)^{a+b} \leq \binom{6}{3} \left(\frac{1}{2}\right)^6 = \frac{5}{16}.$$

Hence, by Lemma 10, we have  $\Pr[|A| < |B|] \geq \frac{1}{2} - \frac{5}{16} = \frac{3}{16}$ .

If  $a + b < 6$  (and  $a + b$  is even), there are four cases:  $a = 0, b = 2$ ;  $a = 0, b = 4$ ;  $a = 1, b = 3$ ;  $a = 2, b = 2$ . If  $a = 0$  and  $b = 2$ , then  $A = 0$  with probability 1 and  $|B| = 2$  with probability  $\frac{1}{2}$ . Thus,  $\Pr[|A| < |B|] = \frac{1}{2}$ . If  $a = 0$  and  $b = 4$ , then  $|A| < |B|$  unless  $B = 0$ . As  $\Pr[B = 0] = \binom{4}{2} \cdot (\frac{1}{2})^4 = \frac{3}{8}$ , we get  $\Pr[|A| < |B|] = 1 - \frac{3}{8} = \frac{5}{8}$ . If  $a = 1$  and  $b = 3$ , then  $|A| = 1$  with probability 1 and  $|B| = 3$  with probability  $\frac{1}{4}$  (either  $B_1 = B_2 = B_3 = 1$  or  $B_1 = B_2 = B_3 = -1$ ). Thus,  $\Pr[|A| < |B|] = \frac{1}{4}$ . If  $a = b = 2$ , then  $|A| = 0$  with probability  $\frac{1}{2}$  and  $|B| = 2$  with probability  $\frac{1}{2}$ . Thus  $\Pr[|A| < |B|] = \frac{1}{4}$ .

We note that the bound of  $\Pr[|A| < |B|] = \frac{3}{16}$  is tight for  $a = b = 3$ . ◀

### 3.3 Large Common Regions Yield Large Common Neighborhoods

To be able to apply Theorem 11 to an edge  $\{u, v\}$ , we need to make sure that the size of their common neighborhood (corresponding to  $b$  in the theorem) is at least the size of the exclusive neighborhoods (corresponding to  $a$  in the theorem). In the following, we give bounds for the probability that this happens. Note that this is the first time we actually take the graph into account. Thus, all above considerations hold for arbitrary graphs.

Recall that we consider random geometric graphs  $\mathcal{G}(n, r)$  and  $u$  and  $v$  are each connected to all vertices that lie within a disk of radius  $r$  around them. As  $u$  and  $v$  are adjacent, their disks intersect, which separates the ground space into four regions; cf. Fig 2a. Let  $R_{u \cap v}$  be the intersection of the two disks. Let  $R_{u \setminus v}$  be the set of points that lie in the disk of  $u$  but not in the disk of  $v$ , and analogously, let  $R_{v \setminus u}$  be the disk of  $v$  minus the disk of  $u$ . Finally, let  $R_{\overline{u \cup v}}$  be the set of points outside both disks. Then, each of the  $n - 2$  remaining vertices ends up in exactly one of these regions with a probability equal to the corresponding measure. Let  $\mu(\cdot)$  be the area of the respective region and  $p = \mu(R_{u \cap v})$  and  $q = \mu(R_{u \setminus v}) = \mu(R_{v \setminus u})$  be the probabilities for a vertex to lie in the common and exclusive regions, respectively. The probability for  $R_{\overline{u \cup v}}$  is then  $1 - p - 2q$ .

We are now interested in the sizes  $N_{u \cap v}$ ,  $N_{u \setminus v}$ , and  $N_{v \setminus u}$  of the common and the exclusive neighborhoods, respectively. As each of the  $n - 2$  remaining vertices ends up in  $N_{u \cap v}$  with probability  $p$ , we have  $N_{u \cap v} \sim \text{Bin}(n - 2, p)$ . For  $N_{u \setminus v}$  and  $N_{v \setminus u}$ , we already know that  $v$  is a neighbor of  $u$  and vice versa. Thus,  $(N_{u \setminus v} - 1) \sim \text{Bin}(n - 2, q)$  and  $(N_{v \setminus u} - 1) \sim \text{Bin}(n - 2, q)$ . Moreover, the three random variables are not independent, as each vertex lies in only exactly one of the four neighborhoods, i.e.,  $N_{u \cap v}$ ,  $(N_{u \setminus v} - 1)$ ,  $(N_{v \setminus u} - 1)$ , and the number of vertices in neither neighborhood together follow a multinomial distribution  $\text{Multi}(n - 2, \mathbf{p})$  with  $\mathbf{p} = (p, q, q, 1 - p - 2q)$ .

The following lemma shows that these dependencies are small if  $p$  and  $q$  are sufficiently small. This lets us assume that  $N_{u \cap v}$ ,  $(N_{u \setminus v} - 1)$ ,  $(N_{v \setminus u} - 1)$  are independent random variables following binomial distributions if the expected average degree is not too large.

► **Lemma 12.** *Let  $X = (X_1, X_2, X_3, X_4) \sim \text{Multi}(n, \mathbf{p})$  with  $\mathbf{p} = (p, q, q, 1 - p - 2q)$ . Then there exist independent random variables  $Y_1 \sim \text{Bin}(n, p)$ ,  $Y_2 \sim \text{Bin}(n, q)$ , and  $Y_3 \sim \text{Bin}(n, q)$  such that  $\Pr[(X_1, X_2, X_3) = (Y_1, Y_2, Y_3)] \geq 1 - 3n \cdot \max(p, q)^2$ .*

**Proof.** Let  $Y_1 \sim \text{Bin}(n, p)$ , and  $Y_2, Y_3 \sim \text{Bin}(n, q)$  be independent random variables. We define the event  $B$  to hold, if each of the  $n$  individual trials increments at most one of the random variables  $Y_1, Y_2$ , or  $Y_3$ . More formally, for  $i \in [3]$  and  $j \in [n]$ , let  $Y_{i,j}$  be the individual Bernoulli trials of  $Y_i$ , i.e.,  $Y_i = \sum_{j \in [n]} Y_{i,j}$ . For  $j \in [n]$ , we define the event  $B_j$  to be  $Y_{1,j} + Y_{2,j} + Y_{3,j} \leq 1$ , and the event  $B = \bigcap_{j \in [n]} B_j$ .

Based on this, we now define the random variables  $X_1, X_2, X_3$ , and  $X_4$  as follows. If  $B$  holds, we set  $X_i = Y_i$  for  $i \in [3]$  and  $X_4 = n - X_1 - X_2 - X_3$ . Otherwise, if  $\overline{B}$ , we draw  $X = (X_1, X_2, X_3, X_4) \sim \text{Multi}(n, \mathbf{p})$  independently from  $Y_1, Y_2$ , and  $Y_3$  with  $\mathbf{p} = (p, q, q, 1 - p - 2q)$ . Note that  $X$  clearly follows  $\text{Multi}(n, \mathbf{p})$  if  $\overline{B}$ . Moreover, conditioned on  $B$ , each individual trial increments exactly one of the variables  $X_1, X_2, X_3$ , or  $X_4$  with probabilities  $p, q, q$ , and  $1 - p - 2q$ , respectively, i.e.,  $X \sim \text{Multi}(n, \mathbf{p})$ .

Thus, we end up with  $X \sim \text{Multi}(n, \mathbf{p})$ . Additionally, we have three independent random variables  $Y_1 \sim \text{Bin}(n, p)$ , and  $Y_2, Y_3 \sim \text{Bin}(n, q)$  with  $(X_1, X_2, X_3) = (Y_1, Y_2, Y_3)$  if  $B$  holds. Thus, to prove the lemma, it remains to show that  $\Pr[B] \geq 1 - 3n \max(p, q)^2$ . For  $j \in [n]$ , the probability that the  $j$ th trial goes wrong is

$$\begin{aligned} \Pr [\overline{B}_j] &= 1 - ((1-p)(1-q)^2) - (p(1-q)^2) - 2(q(1-p)(1-q)) \\ &= 2pq - 2pq^2 + q^2 \leq 2pq + q^2 \leq 3 \cdot \max(p, q)^2. \end{aligned}$$

Using the union bound it follows that  $\Pr [\overline{B}] \leq \sum_{j \in [n]} \Pr [\overline{B}_j] \leq 3n \cdot \max(p, q)^2$ . ◀

As mentioned before, we are interested in the event  $N_{u \cap v} \geq N_{u \setminus v}$  (and likewise  $N_{u \cap v} \geq N_{v \setminus u}$ ), in order to apply Theorem 11. Moreover, due to Lemma 12, we know that  $N_{u \cap v}$  and  $(N_{u \setminus v} - 1)$  almost behave like independent random variables that follow  $\text{Bin}(n-2, p)$  and  $\text{Bin}(n-2, q)$ , respectively. The following lemma helps to bound the probability for  $N_{u \cap v} \geq N_{u \setminus v}$ . Note that it gives a bound for the probability of achieving strict inequality (instead of just  $\geq$ ), which accounts for the fact that  $(N_{u \setminus v} - 1)$  and not  $N_{u \setminus v}$  itself follows a binomial distribution.

► **Lemma 13.** *Let  $n \in \mathbf{N}$  with  $n \geq 2$ , and let  $p \geq q > 0$ . Further, let  $X \sim \text{Bin}(n, p)$  and  $Y \sim \text{Bin}(n, q)$  be independent, let  $d = \lfloor p(n+1) \rfloor$ , and assume  $d = o(\sqrt{n})$ , then  $\Pr [X > Y] \geq (\frac{1}{2} - 1/\sqrt{2\pi d})(1 - o(1))$ .*

**Proof.** By Lemma 1, we get  $\Pr [X \geq Y] \geq \frac{1}{2}$ , and we bound

$$\Pr [X > Y] = \Pr [X \geq Y] - \Pr [X = Y] \geq \frac{1}{2} - \Pr [X = Y],$$

leaving us to bound  $\Pr [X = Y]$  from above. By independence of  $X$  and  $Y$ , we get

$$\Pr [X = Y] = \sum_{i \in [n]} \Pr [X = i] \cdot \Pr [Y = i]. \tag{6}$$

Note that, by Lemma 2, for all  $i \in [0..n]$ , it holds that  $\Pr [X = i] \leq \Pr [X = d]$ . Assume that we have a bound  $B$  such that  $\Pr [X = d] \leq B$ . Substituting this into Equation (6) yields

$$\Pr [X = Y] \leq B \sum_{i \in [n]} \Pr [Y = i] = B,$$

resulting in  $\Pr [X > Y] \geq \frac{1}{2} - B$ . Thus, we now derive such a bound for  $B$  and apply the inequality that for all  $x \in \mathbf{R}$ , it holds that  $1 + x \leq e^x$ , as well as Equation (1). We get

$$\begin{aligned} \binom{n}{d} p^d (1-p)^{n-d} &\leq \frac{n^d}{d!} \left(\frac{d}{n}\right)^d \left(1 - \frac{d}{n}\right)^n \left(1 - \frac{d}{n}\right)^{-d} \\ &\leq \frac{d^d}{d!} e^{-d} \left(1 - \frac{d}{n}\right)^{-d} \\ &\leq \frac{d^d}{\sqrt{2\pi d}^{d+1/2} e^{-d}} e^{-d} \left(1 - \frac{d}{n}\right)^{-d} \\ &= \frac{1}{\sqrt{2\pi d}} \frac{1}{(1 - d/n)^d}. \end{aligned} \tag{7}$$

By Bernoulli's inequality, we bound  $(1 - d/n)^d \geq 1 - d^2/n = 1 - o(1)$  by the assumption  $d = o(\sqrt{n})$ . Substituting this back into Equation (7) concludes the proof. ◀

Finally, in order to apply Theorem 11, we have to make sure not to end up in the special case where  $a = b \leq 1$ , i.e., we have to make sure that the common neighborhood includes at least two vertices. The probability for this to happen is given by the following lemma.

## 29:12 The Flip Schelling Process on Random Graphs

(a) The geometric regions corresponding to the common and exclusive neighborhoods, respectively, with yellow illustrating  $R_{u \cap v}$  and blue illustrating  $R_{u \setminus v}$  and  $R_{v \setminus u}$ .

(b) Let  $\alpha$  be the central angle determined by the intersection points  $i$  and  $j$ , and let  $x$  be the corresponding circular sector (illustrated in yellow).

(c) Let  $y$  be a triangle in the intersection (illustrated in green) determined by the radical axis  $\ell$  and the central angle  $\alpha$ , cf. Fig 2b.

(d) The height  $h$  divides the area  $\mu(y)$  (illustrated in green) of the triangle  $y$ , cf. Fig 2c, into two subareas of equal size, since adjacent and opposite legs have the same length  $r$ .

■ **Figure 2** The neighborhood of two adjacent vertices  $u$  and  $v$  in a random geometric graph.

► **Lemma 14.** Let  $X \sim \text{Bin}(n, p)$  and let  $c = np \in o(n)$ . Then it holds that  $\Pr[X > 1] \geq (1 - e^{-c}(1 + c))(1 - o(1))$ .

**Proof.** As  $X > 1$  holds if and only if  $X \neq 0$  and  $X \neq 1$ , we get

$$\Pr[X > 1] = 1 - \Pr[X = 0] - \Pr[X = 1] = 1 - (1 - p)^n - n \cdot p \cdot (1 - p)^{n-1}.$$

Using that for all  $x \in \mathbf{R}$  it holds that  $1 - x \leq e^{-x}$ , we get

$$\begin{aligned} \Pr[X > 1] &\geq 1 - e^{-pn} - n \cdot p \cdot e^{-p(n-1)} \\ &= 1 - e^{-c} - c \cdot e^{c/n} \cdot e^{-c} \\ &= 1 - e^{-c} \left(1 + c \cdot e^{c/n}\right). \end{aligned}$$

As  $e^{c/n}$  goes to 1 for  $n \rightarrow \infty$ , we get the claimed bound. ◀

### 3.4 Many Edges Have Large Common Regions

In Section 3.3, we derived a lower bound on the probability that  $N_{u \cap v} \geq N_{u \setminus v}$  provided that the probability for a vertex to end up in the shared region  $R_{u \cap v}$  is sufficiently large compared to  $R_{u \setminus v}$ . In the following, we estimate the measures of these regions depending on the distance between  $u$  and  $v$ . Then, we give a lower bound on the probability that  $\mu(R_{u \cap v}) \geq \mu(R_{u \setminus v})$ .

► **Lemma 15.** Let  $G \sim \mathcal{G}(n, r)$  be a random geometric graph with expected average degree  $\bar{\delta}$ , let  $\{u, v\} \in E$  be an edge, and let  $\tau := \frac{\text{dist}(u, v)}{r}$ . Then,

$$\mu(R_{u \cap v}) = \frac{\bar{\delta}}{(n-1)\pi} \left( 2 \arccos\left(\frac{\tau}{2}\right) - \sin\left(2 \arccos\left(\frac{\tau}{2}\right)\right) \right) \text{ and} \quad (8)$$

$$\mu(R_{u \setminus v}) = \mu(R_{v \setminus u}) = \frac{\bar{\delta}}{n-1} - \mu(R_{u \cap v}). \quad (9)$$

**Proof.** We start with proving Equation (8). Let  $i$  and  $j$  be the two intersection points of the disks of  $u$  and  $v$ , let  $\alpha$  be the central angle enclosed by  $i$  and  $j$ , and let  $x$  be the corresponding circular sector, cf. Fig 2b. Moreover, let the triangle  $y$  be a subarea of  $x$  determined by  $\alpha$

and the radical axis  $\ell$ , cf. Fig 2c. Let  $h$  denote the height of the triangle  $y$ , cf. Fig 2d. For our calculations, we restrict the length of  $\ell$  by the intersection points  $i$  and  $j$ . Since we consider the intersection between disks and thus  $\ell$  divides the area  $\mu(R_{u \cap v})$  into two subareas of equal sizes, it holds that  $\mu(R_{u \cap v}) = 2(\mu(x) - \mu(y))$ . Considering the two areas  $\mu(x)$  and  $\mu(y)$ , it holds that

$$\mu(x) = \frac{\alpha}{2}r^2 \quad \text{and} \quad \mu(y) = h \cdot \frac{\ell}{2} = \cos\left(\frac{\alpha}{2}\right)r \cdot \sin\left(\frac{\alpha}{2}\right)r = \frac{\sin(\alpha)}{2}r^2. \quad (10)$$

For the central angle  $\alpha$  we know  $\cos(\alpha/2) = h/r = \tau/2$  and therefore  $\alpha = 2 \arccos(\frac{\tau}{2})$ . Together with Equation (10), we obtain

$$\mu(R_{u \cap v}) = 2(\mu(x) - \mu(y)) = 2 \left( \frac{2 \arccos(\frac{\tau}{2})}{2}r^2 - \frac{\sin(2 \arccos(\frac{\tau}{2}))}{2}r^2 \right). \quad (11)$$

The area of a general circle is equal to  $\pi r^2$ . Since we consider a ground space with total area 1, the area of one disk in the random geometric graph equals  $\frac{\delta}{n-1}$ , i.e.,  $r^2 = \frac{\delta}{(n-1)\pi}$ . Together with Equation (11), we obtain Equation (8).

Equation (9): We get the claimed equality by noting that  $\mu(R_{u \cap v}) + \mu(R_{u \setminus v}) = \pi r^2$ . ◀

► **Lemma 16.** *Let  $G \sim \mathcal{G}(n, r)$  be a random geometric graph, and let  $\{u, v\} \in E$  be an edge. Then  $\Pr[\mu(R_{u \cap v}) \geq \mu(R_{u \setminus v})] \geq (\frac{4}{5})^2$ .*

**Proof.** Let  $\tau = \frac{\text{dist}(u,v)}{r}$ . By Lemma 15 with  $\mu(R_{u \cap v}) \geq \mu(R_{v \setminus u})$ , we get

$$\left( 2 \arccos\left(\frac{\tau}{2}\right) - \sin\left(2 \arccos\left(\frac{\tau}{2}\right)\right) \right) \geq \frac{\pi}{2},$$

which is true for  $\tau \geq \frac{4}{5}$ . The area of a disk of radius  $\frac{4}{5}r$  is  $(\pi(\frac{4}{5}r)^2) / (\pi r^2) = (\frac{4}{5})^2$  times the area of a disk of radius  $r$ . Hence, the fraction of edges with distance at most  $\frac{4}{5}r$  is at least  $(\frac{4}{5})^2$ , concluding the proof. ◀

### 3.5 Proof of Theorem 6

By Theorem 7, the probability that a random edge  $\{u, v\}$  is monochrome is at least  $\frac{1}{2} + \Pr[D]/2$ , where  $D$  is the event that the common neighborhood of  $u$  and  $v$  is more decisive than each exclusive neighborhood. It remains to bound  $\Pr[D]$ .

**Existence of an edge yields a large shared region.** Let  $R$  be the event that  $\mu(R_{u \cap v}) \geq \mu(R_{u \setminus v})$ . Note that this also implies  $\mu(R_{u \cap v}) \geq \mu(R_{v \setminus u})$  as  $\mu(R_{u \setminus v}) = \mu(R_{v \setminus u})$ . Due to the law of total probability, we have

$$\Pr[D] \geq \Pr[R] \cdot \Pr[D | R].$$

Due to Lemma 16, we have  $\Pr[R] \geq (\frac{4}{5})^2$ . By conditioning on  $R$  in the following, we can assume that  $\mu(R_{u \cap v}) \geq \frac{\bar{\delta}}{2n} \geq \mu(R_{u \setminus v}) = \mu(R_{v \setminus u})$ , where  $\bar{\delta}$  is the expected average degree.

**Neighborhood sizes are roughly binomially distributed.** The next step is to go from the size of the regions to the number of vertices in these regions. Each of the remaining  $n' = n - 2$  vertices is sampled independently to lie in one of the regions  $R_{u \cap v}$ ,  $R_{u \setminus v}$ ,  $R_{v \setminus u}$ , or  $R_{\overline{u \cup v}}$ . Denote the resulting numbers of vertices with  $X_1$ ,  $X_2$ ,  $X_3$ , and  $X_4$ , respectively. Then  $(X_1, X_2, X_3, X_4)$  follows a multinomial distribution with parameter  $\mathbf{p} = (p, q, q, 1 - p - 2q)$

## 29:14 The Flip Schelling Process on Random Graphs

for  $p = \mu(R_{u \cap v})$  and  $q = \mu(R_{u \setminus v}) = \mu(R_{v \setminus u})$ . Note that  $N_{u \cap v} = X_1$ ,  $N_{u \setminus v} = X_2 + 1$ , and  $N_{v \setminus u} = X_3 + 1$  holds for the sizes of the common and exclusive neighborhoods, where the  $+1$  comes from the fact that  $v$  is always a neighbor of  $u$  and vice versa.

We apply Lemma 12 to obtain independent binomially distributed random variables  $Y_1$ ,  $Y_2$ , and  $Y_3$  that are likely to coincide with  $X_1 = N_{u \cap v}$ ,  $X_2 = N_{u \setminus v} - 1$ , and  $X_3 = N_{v \setminus u} - 1$ , respectively. Let  $B$  denote the event that  $(N_{u \cap v}, N_{u \setminus v} - 1, N_{v \setminus u} - 1) = (Y_1, Y_2, Y_3)$ . Again, using the law of total probabilities and due to the fact that  $R$  and  $B$  are independent, we get

$$\Pr[D | R] \geq \Pr[B | R] \cdot \Pr[D | R \cap B] = \Pr[B] \cdot \Pr[D | R \cap B].$$

Note that  $p, q \leq \frac{\bar{\delta}}{n}$  for the expected average degree  $\bar{\delta}$ . Thus, Lemma 12 implies that  $\Pr[B] \geq \left(1 - 3\bar{\delta}^2/n\right)$ . Conditioning on  $B$  makes it correct to assume that  $N_{u \cap v} \sim \text{Bin}(n', p)$ ,  $(N_{u \setminus v} - 1) \sim \text{Bin}(n', q)$ ,  $(N_{v \setminus u} - 1) \sim \text{Bin}(n', q)$  are independently distributed. Additionally conditioning on  $R$  gives us  $p \geq \frac{\bar{\delta}}{2n} \geq q$ .

**A large shared region yields a large shared neighborhood.** In the next step, we consider an event that makes sure that the number  $N_{u \cap v}$  of vertices in the shared neighborhood is sufficiently large. Let  $N_1$ ,  $N_2$ , and  $N_3$  be the events that  $N_{u \cap v} \geq N_{u \setminus v}$ ,  $N_{u \cap v} \geq N_{v \setminus u}$ , and  $N_{u \cap v} > 1$ , respectively. Let  $N$  be the intersection of  $N_1$ ,  $N_2$ , and  $N_3$ . We obtain

$$\begin{aligned} \Pr[D | R \cap B] &\geq \Pr[N | R \cap B] \cdot \Pr[D | R \cap B \cap N] \\ &\geq \Pr[N_1 | R \cap B] \cdot \Pr[N_2 | R \cap B] \cdot \Pr[N_3 | R \cap B] \cdot \Pr[D | R \cap B \cap N], \end{aligned}$$

where the last step follows from Lemma 5 as the inequalities in  $N_1$ ,  $N_2$ , and  $N_3$  all go in the same direction. Note that  $N_{u \cap v} \geq N_{u \setminus v}$  is equivalent to  $N_{u \cap v} > N_{u \setminus v} - 1$ . Due to the condition on  $B$ ,  $N_{u \cap v}$  and  $N_{u \setminus v} - 1$  are independent random variables following  $\text{Bin}(n', p)$  and  $\text{Bin}(n', q)$ , respectively, with  $p \geq q$  due to the condition on  $R$ . Thus, we can apply Lemma 13, to obtain

$$\Pr[N_1 | R \cap B] = \Pr[N_2 | R \cap B] \geq \frac{1}{2} - \frac{1}{\sqrt{2\pi[\bar{\delta}/2](1 - o(1))}},$$

and Lemma 14 gives the bound

$$\Pr[N_3 | R \cap B] \geq 1 - e^{-\bar{\delta}/2} \left(1 + \frac{\bar{\delta}}{2} \cdot (1 + o(1))\right).$$

Note that both of these probabilities are bounded away from 0 for  $\bar{\delta} \geq 2$ . Conditioning on  $N$  lets us assume that the shared neighborhood of  $u$  and  $v$  contains at least two vertices and that it is at least as big as each of the exclusive neighborhoods.

**A large shared neighborhood yields high decisiveness.** The last step is to actually bound the remaining probability  $\Pr[D | R \cap B \cap N]$ . Note that, once we know the number of vertices in the shared and exclusive neighborhoods, the decisiveness no longer depends on  $R$  or  $B$ , i.e., we can bound  $\Pr[D | N]$  instead. For this, let  $D_1$  and  $D_2$  be the events that  $D_{u \cap v} > D_{u \setminus v}$  and  $D_{u \cap v} > D_{v \setminus u}$ , respectively. Note that  $D$  is their intersection. Moreover, due to Lemma 5, we have  $\Pr[D | N] \geq \Pr[D_1 | N] \cdot \Pr[D_2 | N]$ . To bound  $\Pr[D_1 | N] = \Pr[D_2 | N]$ , we use Theorem 11. Note that the  $b$  and  $a$  in Theorem 11 correspond to  $N_{u \cap v}$  and  $N_{u \setminus v} + 1$  (the  $+1$  coming from the fact that  $N_{u \setminus v}$  does not count the vertex  $v$ ). Moreover conditioning on  $N$  implies that  $a \leq b$  and  $b > 1$ . Thus, Theorem 11 implies  $\Pr[D_1 | N] \geq \frac{3}{16}$ .

**Conclusion.** The above arguments give us that the fraction of monochrome edges is

$$\frac{1}{2} + \frac{\Pr[D]}{2} \geq \frac{1}{2} + \frac{1}{2} \cdot \underbrace{\Pr[R]}_{\geq (\frac{4}{5})^2} \cdot \underbrace{\Pr[B]}_{1-o(1)} \cdot \underbrace{(\Pr[N_1 | R \cap B])^2}_{\geq \frac{1}{2} - \frac{1}{\sqrt{2\pi \lfloor \bar{\delta}/2 \rfloor}}} \cdot \underbrace{\Pr[N_3 | R \cap B]}_{\geq 1 - e^{-\bar{\delta}/2} (1 + \frac{\bar{\delta}}{2})} \cdot \underbrace{(\Pr[D_1 | N])^2}_{\geq \frac{3}{16}},$$

where we omitted the  $o(1)$  terms for  $\Pr[N_1 | R \cap B]$  and  $\Pr[N_3 | R \cap B]$ , as they are already covered by the  $1 + o(1)$  coming from  $\Pr[B]$ . This yields the bound stated in Theorem 6:

$$\frac{1}{2} + \frac{9}{800} \cdot \left( \frac{1}{2} - \frac{1}{\sqrt{2\pi \lfloor \bar{\delta}/2 \rfloor}} \right)^2 \cdot \left( 1 - e^{-\bar{\delta}/2} \left( 1 + \frac{\bar{\delta}}{2} \right) \right) \cdot (1 - o(1)).$$

#### 4 Monochrome Edges in Erdős–Rényi Graphs

In the following, we are interested in the probability that an edge  $\{u, v\}$  is monochrome after the FSP on Erdős–Rényi graphs. In contrast to geometric random graphs, we prove an upper bound. To this end, we show that it is likely that the common neighborhood is empty and therefore  $u$  and  $v$  choose their types to be the predominant type in their exclusive neighborhood, which is  $t^+$  and  $t^-$  with probability  $\frac{1}{2}$ , each.

► **Theorem 17.** *Let  $G \sim \mathcal{G}(n, p)$  be an Erdős–Rényi graph with expected average degree  $\bar{\delta} = o(\sqrt{n})$ . The expected fraction of monochrome edges after the FSP is at most  $\frac{1}{2} + o(1)$ .*

**Proof.** Given an edge  $\{u, v\}$ , let  $M$  be the event that  $\{u, v\}$  is monochrome. We first split  $M$  into disjoint sets with respect to the size of the common neighborhood and apply the law of total probability and get

$$\begin{aligned} \Pr[M] &= \Pr[M | N_{u \cap v} = 0] \cdot \Pr[N_{u \cap v} = 0] + \Pr[M | N_{u \cap v} > 0] \cdot \Pr[N_{u \cap v} > 0] \\ &\leq \Pr[M | N_{u \cap v} = 0] \cdot 1 + 1 \cdot \Pr[N_{u \cap v} > 0]. \end{aligned}$$

We bound each of the summands separately. For estimating  $\Pr[M | N_{u \cap v} = 0]$ , we note that the types of  $u$  and  $v$  are determined by the predominant type in disjoint vertex sets. By definition of the FSP this implies that the probability of a monochrome edge is equal to  $\frac{1}{2}$ .

We are left with bounding  $\Pr[N_{u \cap v} > 0]$ . Note that  $N_{u \cap v} \sim \text{Bin}(n, p^2)$ . Thus, by Bernoulli's inequality we get  $\Pr[N_{u \cap v} > 0] = 1 - \Pr[N_{u \cap v} = 0] = 1 - (1 - p^2)^n \leq np^2$ . Noting that  $np^2 = o(1)$  holds due to our assumption on  $\bar{\delta}$ , concludes the proof. ◀

## Abstract

Voronoi diagrams induced by distance functions whose unit balls are convex polyhedra are piecewise-linear structures. Nevertheless, analyzing their combinatorial and algorithmic properties in dimensions three and higher is an intriguing problem. The situation turns easier when the farthest-site variants of such Voronoi diagrams are considered, where each site gets assigned the region of all points in space farthest from (rather than closest to) it.

We give asymptotically tight upper and lower worst-case bounds on the combinatorial size of farthest-site Voronoi diagrams for convex polyhedral distance functions in general dimensions, and propose an optimal construction algorithm. Our approach is uniform in the sense that (1) it can be extended from point sites to sites that are convex polyhedra, (2) it covers the case where the distance function is additively and/or multiplicatively weighted, and (3) it allows an anisotropic scenario where each site gets allotted its particular convex distance polytope.

## 1 Introduction

The *Voronoi diagram* of a set of  $n$  geometric objects, called *sites*, is a well-known space partitioning structure with numerous applications in diverse fields of science. In its *closest-site* variant, this diagram partitions the underlying space into maximal regions such that all points within one region have the same closest site. The Euclidean Voronoi diagram of point sites in  $\mathbb{R}^d$  is well studied; see e.g. [4, 7, 11, 15]. It is a piecewise-linear cell complex of worst-case complexity  $\Theta(n^{\lceil \frac{d}{2} \rceil})$  and can be constructed in  $O(n^{\lceil \frac{d}{2} \rceil} + n \log n)$  time. There are many ways to modify this standard diagram, for example, by using different distance measures, by considering sites of more general shape, or by assigning individual weights to them. Adapting to practical needs, such generalizations (among several others) have been studied extensively, and many satisfactory results are available nowadays [4, 18].

For most of these generalized Voronoi diagrams, the partition of space they define is not piecewise linear any more, but is rather composed of curved geometric objects of various dimensions and shapes. This complicates their structural analysis as well as their computational construction, especially in dimensions higher than two (where results are becoming comparatively sparse). For instance, already in three-dimensional space  $\mathbb{R}^3$ , the algebraic description of the edges and facets of the Euclidean Voronoi diagram of straight lines becomes exceedingly complicated [12]. What is more, the combinatorial complexity of

this diagram is a major open problem in computational geometry [17]. There is a gap of an order of magnitude between the  $\Omega(n^2)$  lower bound [1] and the only known upper bound of  $O(n^{3+\epsilon})$ , for any  $\epsilon > 0$  [21].

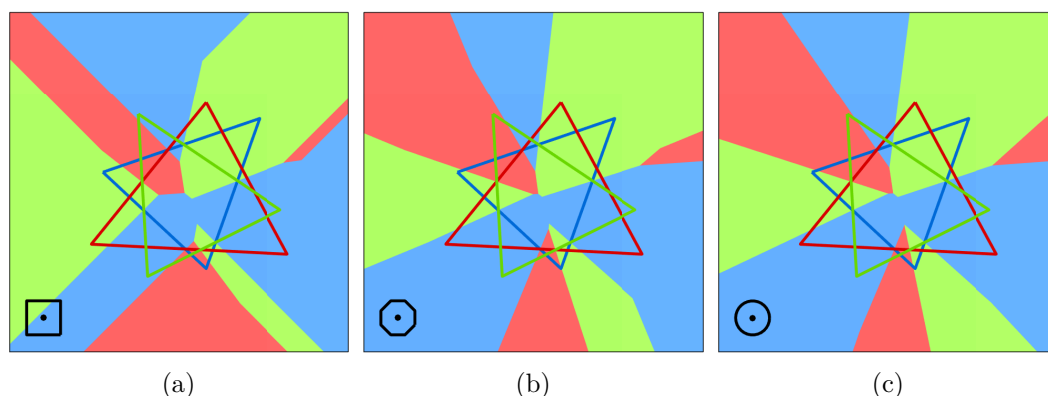

Certain types of Voronoi diagrams retain their piecewise linear structure, however. For example, the so-called power diagram [2] has this property. Another prominent class, and the one of interest in the present note, is induced by (convex) *polyhedral distance functions*. Intuitively speaking, the distance from a point  $x$  to a site  $s$  is now measured as the extent at which a given convex polyhedron  $\mathcal{P}$ , which being centered at  $x$ , has to expand till it starts touching  $s$ .

Several authors succeeded in deriving strong bounds on the combinatorial complexity of such Voronoi diagrams. If the  $n$  sites are points and the distance polytope  $\mathcal{P}$  is a simplex or a cube – the latter just giving the  $L_\infty$  distance – then this complexity in  $\mathbb{R}^d$  is  $\Theta(n^{\lceil \frac{d}{2} \rceil})$ , see [6]. (The dimension  $d$  is considered a constant throughout this paper.) In  $\mathbb{R}^3$ , the same bound still applies when any constant-sized convex polytope is chosen for  $\mathcal{P}$  [13]. For the sites being  $n$  straight lines in  $\mathbb{R}^3$ , with  $\mathcal{P}$  defined as before, near-quadratic bounds of  $\Omega(n^2\alpha(n))$  and  $O(n^2\alpha(n)\log(n))$  can be obtained [9]. Here  $\alpha(n)$  is the extremely slowly growing inverse Ackermann function. If we consider as sites disjoint convex polyhedra with  $n$  faces in total, then the complexity is  $O(n^{2+\epsilon})$ , as has been shown in [16]; this sharpens to  $O(n^2\alpha(n)\log(n))$  if all the sites are line segments.

Though Voronoi diagrams for convex polyhedral distance functions – in comparison to Euclidean Voronoi diagrams – thus proved easier to deal with concerning their combinatorial aspects, this does not seem to carry over to their algorithmic aspects. In fact, the papers cited above do not provide algorithms for computing such diagrams, and we are not aware of any construction algorithm particular to them.

As we shall show in this note, the situation changes if the so-called *farthest-site* variant of the diagram is considered (rather than the closest-site variant as above). The farthest-site Voronoi diagram is a partition of the underlying space into regions, such that the points within one region have the same farthest site (with respect to a given convex polyhedral distance function, in our case). We will show that the complexity of this diagram in  $\mathbb{R}^d$  is  $\Theta(n^{\lceil \frac{d}{2} \rceil})$  in the worst-case, and that it can be computed in optimal time  $O(n^{\lceil \frac{d}{2} \rceil} + n \log n)$ , mainly by using higher-dimensional convex hull algorithms. This result holds under rather general conditions: Sites can be arbitrary convex polyhedra (which may be unbounded or overlapping, having a total of  $n$  faces of various dimensions), the distance polytope  $\mathcal{P}$  may be unbounded (though constant-sized), and the resulting distance function can be additively and/or multiplicatively weighted for each site. Moreover, each site may get allotted a particular distance polytope, in order to generate an anisotropic scenario where sites can influence their surrounding in an individual way.

Farthest-site Voronoi diagrams are useful for performing farthest neighbor queries among the sites, for computing the smallest ball that contacts all sites, and for finding the largest gap to be bridged between any two sites – to name a few of their applications. Unfortunately, Euclidean farthest-site Voronoi diagrams have their peculiarities (unless all sites are points, in which case their combinatorial and computational behavior is much like their closest-point counterparts [20]). Their regions may disconnect into a large number of nonconvex parts, and the close relationship between nonempty regions and the convex hull of the sites is lost; see [3] for line segment sites in  $\mathbb{R}^2$ , and [19] for a generalization to arbitrary  $L_p$ -metrics. The only result for non-point sites in higher dimensions we are aware of is [5], who derive structural and

■ **Figure 1** Two approximations (a) and (b) of a Euclidean farthest-site Voronoi diagram (c). The sites are three overlapping triangles. Their boundaries are visualized in individual colors, and their farthest regions are painted accordingly. The distance polygons used – a square in (a) and a regular 8-gon in (b) – are shown in the bottom-left corner.

combinatorial properties for the farthest-site diagram of lines and line segments in  $\mathbb{R}^d$ . They characterize its unbounded cells, of which there are up to  $\Theta(n^{d-1})$  many in the worst-case, and describe an algorithm to compute these in near-optimal time.

With our results in the present note, a large class of Euclidean farthest-site Voronoi diagrams for convex sites in  $\mathbb{R}^d$ , even in their weighted and/or anisotropic variants, can be approximated in a piecewise-linear manner, and are computable by a simple and uniform approach: In  $\mathbb{R}^3$  for example, being probably the most interesting case, the Euclidean ball can be  $\beta$ -approximated by a convex polytope  $\mathcal{P}$  with  $O(1/\beta)$  vertices [16], such that the convex distance induced by  $\mathcal{P}$  is at most  $1 + \beta$  times the Euclidean distance. As a particularly useful result, a simple method for computing a piecewise-linear approximation of size  $O(n^2)$  of the Euclidean farthest-site Voronoi diagram for lines and/or line segments in  $\mathbb{R}^3$  becomes available. Even the planar instance is interesting: The fastest known algorithm for the Euclidean farthest-site Voronoi diagram for polygonal sites in  $\mathbb{R}^2$  runs in time  $O(n \log^3 n)$  [8], whereas our approximation can be computed in time  $O(n \log n)$  if the polygonal sites are convex. Figure 1 illustrates the similarity between these diagrams.

## 2 Convex polyhedral distance

We define a *polyhedron* in  $\mathbb{R}^d$  as the nonempty and finite (but possibly unbounded) intersection of closed halfspaces of  $\mathbb{R}^d$ . Note that a polyhedron does not need to be full-dimensional: For example lines, line segments, and single points are included as lower-dimensional instances.

Any  $d$ -dimensional polyhedron  $\mathcal{P}$  which contains the origin in its interior can be used to define a so-called *convex polyhedral distance*, from a point  $x \in \mathbb{R}^d$  to a point  $q \in \mathbb{R}^d$ :

$$\delta_{\mathcal{P}}(x, q) = \inf_{t \geq 0} \{ t \mid q \in x + t \cdot \mathcal{P} \}.$$

In other words,  $\delta_{\mathcal{P}}(x, q)$  describes the amount  $t \geq 0$  by which  $\mathcal{P}$ , when being placed at  $x$ , has to be scaled so as to cover  $q$ ; see Figure 2. Note that  $\delta_{\mathcal{P}}$  is a directed distance. We shall call  $\mathcal{P}$  the *distance polytope* that induces the distance function  $\delta_{\mathcal{P}}$ .

Let  $\mathcal{P}^R = \{ -p \mid p \in \mathcal{P} \}$  denote the reflection of the distance polytope about the origin.

► **Observation 1.** We have  $\delta_{\mathcal{P}}(x, q) = \delta_{\mathcal{P}^R}(q, x)$ .

**Proof.** Suppose that  $q \in x + t \cdot \mathcal{P}$ . Then there is a point  $p \in \mathcal{P}$  with  $q = x + t \cdot p$ , that is,  $x = q - t \cdot p$ . Thus we have  $x \in q - t \cdot \mathcal{P}$ , which by the identity  $-t \cdot \mathcal{P} = t \cdot \mathcal{P}^R$  means  $x \in q + t \cdot \mathcal{P}^R$ . ◀

Consider a set  $S$  of point sites in  $\mathbb{R}^d$ , and identify  $\mathbb{R}^d$  with the hyperplane  $x_{d+1} = 0$  in  $(d+1)$ -dimensional space  $\mathbb{R}^{d+1}$ . Observation 1 suggests to associate the distance polytope  $\mathcal{P}$  with a *distance cone*  $C_{\mathcal{P}}$  in  $\mathbb{R}^{d+1}$ , such that  $C_{\mathcal{P}}$  reflects with its height the polyhedral distance induced by  $\mathcal{P}$ .

$$C_{\mathcal{P}} = \bigcup_{t \geq 0} \begin{pmatrix} t \cdot \mathcal{P}^R \\ t \end{pmatrix} \quad (1)$$

$C_{\mathcal{P}}$  is a polyhedral cone obtained from scaling the reflected polytope  $\mathcal{P}^R$ . Its apex is at the origin. Let  $C_{\mathcal{P}}(q_i)$  be the translate of  $C_{\mathcal{P}}$  with its apex at some point site  $q_i \in S$ . Then for any point  $x \in \mathbb{R}^d$ , the  $(d+1)^{\text{st}}$  coordinate (called *height*) of the vertical projection of  $x$  to  $C_{\mathcal{P}}(q_i)$  equals the distance  $\delta_{\mathcal{P}}(x, q_i)$ .

Let now, more generally, the set  $S$  consist of polyhedral sites  $s_i$  in  $\mathbb{R}^d$ . We construct for each site  $s_i \in S$  a distance cone as follows. Take the Minkowski sum  $s_i \oplus C_{\mathcal{P}}$ . (The *Minkowski sum* of point sets  $A$  and  $B$  is defined as  $A \oplus B = \{a + b \mid a \in A \wedge b \in B\}$ .) Because the Minkowski sum of two convex polyhedra is again a convex polyhedron, the object  $s_i \oplus C_{\mathcal{P}}$  is the intersection of halfspaces of  $\mathbb{R}^{d+1}$ . One of them is bounded from below by the hyperplane  $x_{d+1} = 0$  (if the site  $s_i$  is full-dimensional). We ignore this halfspace, and intersecting the remaining ones we obtain an unbounded polyhedron in  $\mathbb{R}^{d+1}$ , which we call the *distance cone* of  $s_i$ , and denote with  $C_{\mathcal{P}}(s_i)$ .

$C_{\mathcal{P}}(s_i)$  exhibits the following useful properties.

- For the special case of  $s_i$  being a point site  $q_i$ , the definition of  $C_{\mathcal{P}}(s_i)$  is consistent with that of  $C_{\mathcal{P}}(q_i)$  before.
- Let  $d_{\mathcal{P}}(x, s_i)$  be the height of the vertical projection of a point  $x \in \mathbb{R}^d$  to  $C_{\mathcal{P}}(s_i)$ . If  $x$  does not lie in the interior of  $s_i$ , then  $d_{\mathcal{P}}(x, s_i)$  is non-negative and equals the polyhedral distance of  $x$  to  $s_i$ , which is commonly defined as

$$\delta_{\mathcal{P}}(x, s_i) = \inf_{t \geq 0} \{ t \mid x + (t \cdot \mathcal{P}) \cap s_i \neq \emptyset \}.$$

- If  $x$  lies in the interior of  $s_i$  then  $d_{\mathcal{P}}(x, s_i)$  is negative, and measures how much  $x$  is inside the (full-dimensional) polyhedral site  $s_i$  by taking the minimum polyhedral distance to its facets; see Figure 1. This is because the part of  $C_{\mathcal{P}}(s_i)$  that lies below the hyperplane  $x_{d+1} = 0$  is determined solely by halfspaces which stem from  $s_i$  (and not from  $C_{\mathcal{P}}$  in Formula (1)). That is,  $d_{\mathcal{P}}$  is related to a generalized medial axis of  $s_i$  in this case.

### 3 Farthest-site Voronoi diagram

The so-called *farthest-site Voronoi diagram* of a set  $S$  of sites in  $\mathbb{R}^d$ , for short FVD( $S$ ), is a partition of  $\mathbb{R}^d$  into regions such that all points within a fixed region have the same farthest site. As before, let the sites  $s_i$  in  $S$  be polyhedra. These may be of any dimension  $k$ , for  $0 \leq k \leq d$ , and are not required to be disjoint or bounded.

■ **Figure 2** Polyhedral distance induced by  $\mathcal{P}$ :  $d_{\mathcal{P}}(x, q) = 2$  and  $d_{\mathcal{P}}(x, q') = 0.7$ .

We are interested in the diagram  $\text{FVD}(S)$  induced by the convex polyhedral distance function  $d_{\mathcal{P}}$  in Section 2, for a given distance polytope  $\mathcal{P}$ . Being a farthest-site diagram,  $\text{FVD}(S)$  corresponds to the pointwise maximum of the functions  $d_{\mathcal{P}}(x, s_i)$ , for  $s_i \in S$ , on  $\mathbb{R}^d$ .  $\text{FVD}(S)$  thus corresponds to the *upper envelope* of the boundaries of the distance cones  $C_{\mathcal{P}}(s_i)$  that define these functions, which, in turn, is given by the common intersection of these cones. Let us formulate this result in the following way.

► **Theorem 2.** *Let  $I$  be the (unbounded) convex polyhedron in  $\mathbb{R}^{d+1}$  that results from intersecting the distance cones  $C_{\mathcal{P}}(s_i)$ , for all sites  $s_i \in S$ . Then  $\text{FVD}(S)$  is the vertical projection of  $I$  onto the hyperplane  $x_{d+1} = 0$  of  $\mathbb{R}^{d+1}$ .*

One of the consequences of Theorem 2 is that  $\text{FVD}(S)$  is a piecewise linear diagram. Each region of  $\text{FVD}(S)$  is pre-partitioned into convex polyhedra (the projected facets of  $I$ ), and these regions define a partition of  $\mathbb{R}^d$ . Let us point out that, in earlier papers on Voronoi diagrams for polyhedral distance functions (e.g. in [16]), the distance of a point  $x$  to a site was set to zero in case  $x$  falls in the interior of that site. As a consequence, when the sites are not chosen to be pairwise disjoint, the part of  $\mathbb{R}^d$  covered by their union does not get partitioned by the diagram. Our more general definition of polyhedral distance, via distance cones, remedies this shortcoming.

The combinatorial complexity of  $\text{FVD}(S)$  is given by that of the projection polyhedron  $I$  in  $\mathbb{R}^{d+1}$ .  $I$  is the intersection of distance cones, and each distance cone  $C_{\mathcal{P}}(s_i)$ , in turn, is the intersection of halfspaces of  $\mathbb{R}^{d+1}$ . It is clear from Section 2 that the number of such halfspaces per cone is bounded by the number of facets of the Minkowski sum  $s_i \oplus \mathcal{P}^R$ , for the reflected distance polytope  $\mathcal{P}^R$ . A single face of  $s_i$ , combined with a single face of  $\mathcal{P}^R$ , can yield at most one facet of  $s_i \oplus \mathcal{P}^R$ ; see e.g. [10]. Therefore, if we assume that  $\mathcal{P}$  (and with it  $\mathcal{P}^R$ ) is of constant size, and that  $s_i$  has a total of  $n_i$  faces of different dimensions, then  $C_{\mathcal{P}}(s_i)$  is defined by  $O(n_i)$  halfspaces of  $\mathbb{R}^{d+1}$ . In conclusion, when putting  $n = \sum_{s_i \in S} n_i$ , the polyhedron  $I$  is the intersection of  $O(n)$  halfspaces of  $\mathbb{R}^{d+1}$ , and its complexity is bounded from above by  $O(n^{\lceil \frac{d}{2} \rceil})$  (provided  $d = O(1)$ ), by the well-known upper bound theorem. We will show in Section 4 that this complexity can be asymptotically attained in the worst case. Observe that  $I$  has  $O(n)$  facets, and that  $\text{FVD}(S)$  thus has this very number of full-dimensional cells.

Concerning computational aspects, the halfspaces defining a particular cone  $C_{\mathcal{P}}(s_i)$  can be singled out by (basically) computing the Minkowski sum  $s_i \oplus \mathcal{P}^R$ . This can be done [10], for instance, by pairwise adding up the  $O(n_i)$  vertices of  $s_i$  and the  $O(1)$  vertices of  $\mathcal{P}^R$ , and computing the convex hull of the resulting  $O(n_i)$  points in  $\mathbb{R}^d$ , spending a total of  $O(n^{\lfloor \frac{d}{2} \rfloor} + n \log n)$  time for all sites  $s_i \in S$ , when the optimal convex hull algorithm in [7]

## 30:6 Piecewise-Linear Farthest-Site Voronoi Diagrams

is applied. The construction of the projection polyhedron  $I$  is more time-consuming and takes  $O(n^{\lceil \frac{d}{2} \rceil} + n \log n)$  time; we use the convex hull algorithm in [7] again, but now for intersecting  $O(n)$  halfspaces in  $\mathbb{R}^{d+1}$ .

We may summarize as follows:

► **Theorem 3.** *Let  $S$  be a set of arbitrary polyhedral sites in  $\mathbb{R}^d$ , with a total combinatorial complexity of  $n$ . The farthest-site Voronoi diagram  $\text{FVD}(S)$  of  $S$  under the convex distance function induced by a polytope of constant size is of complexity  $O(n^{\lceil \frac{d}{2} \rceil})$ , and it can be computed in  $O(n^{\lceil \frac{d}{2} \rceil} + n \log n)$  time. The number of  $d$ -dimensional cells of  $\text{FVD}(S)$  is bounded by  $O(n)$ .*

The dependence on  $d$  of the bounds stated above is the same as for convex hulls of finite point sets.

### 4 More properties of FVD

The maximal size of farthest-site diagrams may be much smaller than that of their closest-site counterparts; several examples can be found in [4]. The question arises whether the upper bound given in Theorem 3 is asymptotically tight.

For special sets of polyhedral sites in  $\mathbb{R}^d$ , the diagram  $\text{FVD}(S)$  is indeed small, namely, when the sites in  $S$  have only a constant number of orientations. Then the halfspaces defining the projection polyhedron  $I$  in  $\mathbb{R}^{d+1}$  will have only a constant number of orientations as well, and all but  $O(1)$  of them will be redundant because their bounding hyperplanes are parallel. Consequently, the polyhedron  $I$  and its projection  $\text{FVD}(S)$  will be of constant size, and can be found in  $O(n)$  time.

Observe that the case of  $S$  being a set of  $n$  point sites in  $\mathbb{R}^d$  is covered above, because each point site can be described by the intersection of  $d+1$  halfspaces of  $\mathbb{R}^d$ , having the same fixed orientations. Not included, however, is the case of  $n$  line segment sites in  $\mathbb{R}^d$ , because the  $d+2$  halfspaces describing a line segment will be of different orientation for different sites, in general. In fact, sites of very simple shape can induce large diagrams, as is shown below.

► **Lemma 4.** *There exists a set  $S$  of  $n$  sites in  $\mathbb{R}^d$  of constant description such that the diagram  $\text{FVD}(S)$  has a complexity of  $\Omega(n^{\lceil \frac{d}{2} \rceil})$ .*

**Proof.** There exist two hyperplanes  $h_1, h_2$  in  $\mathbb{R}^{d+1}$ , and two point sets  $Y_1 \subset h_1$  and  $Y_2 \subset h_2$  each of size  $\frac{n}{2}$ , such that the lower convex hull of  $Y_1 \cup Y_2$  has  $\Theta(n^{\lceil \frac{d+1}{2} \rceil}) = \Theta(n^{\lceil \frac{d}{2} \rceil})$  complexity; this follows from Corollary 12 in [14]. W.l.o.g., we may assume (by applying an affine transformation) that

$$\begin{aligned}
 h_1 : \sum_{i=1}^d x_i = 1, \quad h_2 : \sum_{i=1}^{d-1} x_i - x_d = 1, \quad \text{and} \\
 Y_1 \subset \mathbb{R} \times \left(0, \frac{1}{d}\right]^d, \quad Y_2 \subset \mathbb{R} \times \left(0, \frac{1}{d}\right]^{d-1} \times \left[-\frac{1}{d}, 0\right),
 \end{aligned} \tag{2}$$

which fixes the hyperplanes and guarantees that most coordinates in  $Y_1 \cup Y_2$  are small. We now choose a distance polytope  $\mathcal{P}$  and a set  $S = S_1 \cup S_2$  of sites such that the projection polyhedron  $I$  for  $\text{FVD}(S)$  is dual to the lower convex hull of  $Y_1 \cup Y_2$ .

Let the hypercube  $[-1, 1]^d$  serve as  $\mathcal{P}$ . The set  $S_1 \cup S_2$  will consist of  $n$  halfspace sites in  $\mathbb{R}^d$ . For  $S_1$ , each of its halfspaces  $s$  is constructed from a point  $y = (y_1, \dots, y_{d+1}) \in Y_1$ . In particular, we describe  $s$  by the inequality  $\sum_{i=1}^d a_i x_i \leq b$ , where

$$a_1 = 1, \quad a_i = \frac{y_i}{1 - \sum_{j=2}^d y_j} \quad \text{for } i = 2, \dots, d, \quad \text{and } b = \frac{y_{d+1}}{1 - \sum_{j=2}^d y_j}. \quad (3)$$

Note that all  $a_i$  and  $b$  are positive because of our assumption (2). Moreover, we have  $\mathcal{P}^R = \mathcal{P}$ . Therefore, the Minkowski sum  $s \oplus \mathcal{P}^R$  is just a translate of  $s$  by the vector  $(1, 1, \dots, 1)^T$  in  $\mathbb{R}^d$ , which implies that the distance cone  $C_{\mathcal{P}}(s)$  is a single halfspace in  $\mathbb{R}^{d+1}$ , bounded from below by the hyperplane

$$x_{d+1} = \frac{1}{A} \cdot \left( \sum_{i=1}^d a_i x_i - b \right), \quad \text{where } A = \sum_{j=1}^d a_j. \quad (4)$$

By a well-known duality transform, the hyperplane in (4) is dual to the point

$$q = (q_1, \dots, q_{d+1}) = \frac{1}{A} \cdot (a_1, \dots, a_d, b)$$

in  $\mathbb{R}^{d+1}$ . Substituting the values in (3) and simple calculations give

$$q_i = y_i \quad \text{for } i = 2, \dots, d+1, \quad \text{and } q_1 = 1 - \sum_{j=2}^d y_j. \quad (5)$$

But this implies  $q = y$ , because both points lie in the hyperplane  $h_1$  in (2): We have  $y \in h_1$  by assumption, and  $q \in h_1$  by (5).

In a similar manner, we can construct suitable halfspace sites  $s$  for  $S_2$  from the points  $y$  in  $Y_2$ . (We omit these details here.) In conclusion, the projection polyhedron  $I$ , being the intersection of all the sites' distance cones, is the intersection of the upper halfspaces  $C_{\mathcal{P}}(s)$  for all  $s \in S_1 \cup S_2$ , and thus  $I$  is dual to the lower convex hull of  $Y_1 \cup Y_2$ . ◀

By Lemma 4, the runtime in Theorem 3 is asymptotically optimal in the worst case for  $d \geq 3$ . For  $d = 2$ , a reduction from sorting proves optimality.

Being the projection of  $I$ , the diagram  $\text{FVD}(S)$  is a polyhedral cell complex in  $\mathbb{R}^d$  which is face-to-face. Its *cells* (polyhedra of dimension  $d$ ) are nonconvex in general, as are its *facets* (polyhedra of dimension  $d-1$ ). Since the distance polytope  $\mathcal{P}$  is (more or less) an approximation of the Euclidean ball, quite a few properties of the Euclidean farthest-site diagram of  $S$  carry over to  $\text{FVD}(S)$ ; see e.g. [3, 5]. For example, the *region* of a site  $s_i \in S$  in  $\text{FVD}(S)$  (the set of all points in  $\mathbb{R}^d$  being farthest from  $s_i$ ) is disconnected in general, and it may consist of various cells of  $\text{FVD}(S)$ . Moreover, the following properties of the cells are preserved.

► **Lemma 5.** *All cells of  $\text{FVD}(S)$  are unbounded, and cells cannot contain voids of any dimension.*

**Proof.** Let  $C$  be some cell of  $\text{FVD}(S)$ , and assume that  $C$  is part of the region of the site  $s \in S$ . The assertion of the lemma can be easily derived from the following fact: Let  $x$  be an arbitrary point in  $C$ , and consider the point  $y$  on the boundary of  $s$  that realizes the polyhedral distance  $d_{\mathcal{P}}(x, s)$ . Then the infinite ray  $r$  that starts at  $x$  and is directed away from  $y$  is totally contained in  $C$ .

■ **Figure 3** Illustrations of the proofs of Lemma 5 (left) and Lemma 6 (right).

To prove this fact, refer to Figure 3 (left). Assume first that  $x \notin s$ . Then  $t = d_{\mathcal{P}}(x, s) \geq 0$ , and the homothet  $H = x + t \cdot \mathcal{P}$  touches  $s$  at  $y$ . Since  $s$  is the site in  $S$  farthest from  $x$ ,  $H$  intersects all the other sites. Let now  $x'$  be any point on  $r$  such that  $x$  lies between  $x'$  and  $y$ . Put  $t' = d_{\mathcal{P}}(x', s)$ . Then  $H' = x' + t' \cdot \mathcal{P}$  touches  $s$  at  $y$  too, and  $H$  is covered by  $H'$ , which implies that  $H'$  intersects all other sites as well. This implies that  $x'$  lies in the region of  $s$ .

If  $x \in s$ , on the other hand, then  $t = d_{\mathcal{P}}(x, s) < 0$ , and we have  $t \cdot \mathcal{P} = u \cdot \mathcal{P}^R$  with  $u = -t > 0$ , for the reflected polytope  $\mathcal{P}^R$ . The homothet  $H = x + u \cdot \mathcal{P}^R$  touches  $s$  at  $y$ , and since  $s$  is farthest from  $x$ ,  $H$  is contained in all other sites now. For any point  $x'$  on  $r$  between  $x$  and  $y$ , and  $u' = -d_{\mathcal{P}}(x', s)$ ,  $H' = x' + u' \cdot \mathcal{P}^R$  touches  $s$  at  $y$  again, but is contained in  $H$  now and therefore also in all other sites. So  $x'$  has to lie in the region of  $s$ .

In summary, we conclude that the entire ray  $r$  lies in the cell  $C$  of the region of  $s$ . ◀

Let us define the  $(d-1)$ -skeleton of  $\text{FVD}(S)$  as the union of all the facets of  $\text{FVD}(S)$ . This skeleton can be disconnected, as a simple construction with only two sites shows; see Figure 4(a): Let site  $s_1$  be some polyhedron which approximates a line segment, and take as site  $s_2$  any polyhedron which contains the segment's midpoint but none of its endpoints. Then the region of  $s_1$  disconnects the  $(d-1)$ -skeleton of  $\text{FVD}(\{s_1, s_2\})$ . On the other hand, by the same argument as in [5], the following holds:

► **Lemma 6.** *The  $(d-1)$ -skeleton of  $\text{FVD}(S)$  is connected, provided that the sites in  $S$  are pairwise disjoint.*

**Proof.** Assume that this skeleton is not connected; see Figure 3 (right). Then there exists some cell  $C$  of  $\text{FVD}(S)$  that splits the skeleton into at least two parts. Let  $s$  be the farthest site corresponding to  $C$ . The site  $s$  does not touch the boundary of  $C$ , because of our assumption on the disjointness of the sites. Thus there exists some point  $x \notin C$  which is separated from  $s$  by  $C$ . Let  $y$  be the point on  $s$  that realizes the polyhedral distance from  $x$  to  $s$ . By construction, the line segment  $\overline{xy}$  intersects  $C$ , and we choose a point  $p$  in this intersection. Now, by the reasoning in the proof of Lemma 5, the infinite ray emanating from  $p$  in direction  $x$  is entirely contained in  $C$ . But this implies  $x \in C$ , which is a contradiction. ◀

■ **Figure 4** (a) The  $(d-1)$ -skeleton can be disconnected for non-disjoint sites. (b) A weighted farthest Voronoi diagram of three sites: The blue quadrangle has an additive weight of  $-1$ , and the red pentagon has a multiplicative weight of  $\frac{1}{2}$ .

## 5 Variants

In certain applications, a model of Voronoi diagram is required where the sites are capable of influencing their surrounding in an individual way; see [4, 18] for comprehensive treatments of this topic. One way to achieve this goal is to assign so-called *weights* to the sites, which affect the underlying distance function in an additive and/or multiplicative way.

Let each site  $s_i \in S$  have assigned two real numbers  $a(s_i)$  and  $m(s_i) > 0$ , and consider the weighted polyhedral distance:

$$\frac{d_{\mathcal{P}}(x, s_i)}{m(s_i)} - a(s_i)$$

In contrast to the nearest version, the sites' regions in the farthest Voronoi diagram shrink with increasing weights. Interestingly, and unlike the situation for the Euclidean farthest-site diagram, the FVD( $S$ ) induced by this distance is still a piecewise-linear cell complex. This becomes evident when the respective distance cones are considered: Additive weighting results in a vertical shift of these cones by an amount of  $a(s_i)$ , and multiplicative weighting enlarges by a factor of  $m(s_i)$  the value  $\tan \alpha_j$  of the dihedral angles  $\alpha_j$  of aperture of a cone's facets. In particular, each distance cone still is the intersection of  $O(n_i)$  halfspaces of  $\mathbb{R}^{d+1}$  when site  $s_i$  is of complexity  $n_i$ .

Multiplicative weighting leads to the occurrence of bounded regions in FVD( $S$ ), as simple examples show (Figure 4 (b)). However, purely additive weighting preserves the properties listed in Lemma 5. In particular, all cells are still unbounded: All facets of the projection polyhedron  $I$  for the unweighted FVD( $S$ ) are unbounded, and this fact cannot be altered by vertically shifting any of its defining halfspaces.

We may push things even further, and create an *anisotropic* scenario by allotting an individual distance polytope  $\mathcal{P}_i$  to each site  $s_i$ . In this way, each site is able to “interpret” its surrounding space in its own way – a concept useful in many situations [4]. In fact, the multiplicative weighting scheme is just the special case where  $\mathcal{P}_i = m(s_i) \cdot \mathcal{P}$ .

In all the extensions above, the properties of the distance cones needed for Theorem 3 to hold are preserved. We obtain the following general result:

► **Theorem 7.** *Theorem 3 remains valid for all the weighted and anisotropic variants of  $FVD(S)$  described above.*

Note finally that all these extensions can be combined, and lead to a very general class of easy-to-compute piecewise-linear farthest-site Voronoi diagrams in  $\mathbb{R}^d$ , where the impact of each site can be tuned by its shape, its weights, and its distance polytope including the choice of the polytope's center.

## Abstract

We investigate generalizations of the graph theoretic notions of effective resistance and capacitance to simplicial complexes and prove analogs of formulas known in the case of graphs. In graphs the effective resistance between two vertices is  $O(n)$ ; however, we show that in a simplicial complex the effective resistance of a null-homologous cycle may be exponential. This is caused by relative torsion in the simplicial complex. We provide upper bounds on both effective resistance and capacitance that are polynomial in the number of simplices as well as the maximum cardinality of the torsion subgroup of a relative homology group denoted  $\mathcal{T}_{\max}(\mathcal{K})$ . We generalize the quantum algorithm deciding  $st$ -connectivity in a graph and obtain an algorithm deciding whether or not a  $(d-1)$ -dimensional cycle  $\gamma$  is null-homologous in a  $d$ -dimensional simplicial complex  $\mathcal{K}$ . The quantum algorithm has query complexity parameterized by the effective resistance and capacitance of  $\gamma$ . Using our upper bounds we find that the query complexity is  $O(n^{5/2} \cdot d^{1/2} \cdot \mathcal{T}_{\max}(\mathcal{K})^2)$ . Under the assumptions that  $\gamma$  is the boundary of a  $d$ -simplex (which may or may not be included in the complex) and that  $\mathcal{K}$  is relative torsion-free, we match the  $O(n^{3/2})$  query complexity obtained for  $st$ -connectivity. These assumptions always hold in the case of  $st$ -connectivity. We provide an implementation of the algorithm whose running time is polynomial in the size of the complex and the relative torsion. Finally, we prove a duality theorem relating effective resistance and capacitance when  $\mathcal{K}$  is  $d$ -dimensional and admits an embedding into  $\mathbb{R}^{d+1}$ .

## 1 Introduction

The *effective resistance* between two vertices  $s$  and  $t$  in a graph is a quantity that measures how “well-connected”  $s$  and  $t$  are; specifically, the more, shorter paths connecting  $s$  and  $t$ , the lower the effective resistance between  $s$  and  $t$ . While effective resistance was originally defined in the context of resistor networks, it has since been discovered that effective resistance has many other interpretations. It is a metric on the vertices of a graph [17]; it is proportional to the expected number of steps in a random walk from  $s$  to  $t$  and back to  $s$  [3]; if  $\{s, t\}$  is an edge, it is proportional to the probability  $\{s, t\}$  is in a random spanning tree of  $G$  [15]. Effective resistance also has applications. Sampling edges in a graph with probability proportional to the effective resistance between their endpoints produces a graph that approximates the spectrum of the Laplacian of the original graph [27]. Effective resistance is also a parameter in the running time of a quantum algorithm to decide if  $s$  and  $t$  are connected [1].

Recently, effective resistance has independently been generalized from graphs to simplicial complexes by several groups of authors, although each group defines effective resistance for a different object or objects in a simplicial complex. Kook and Lee [18] and Osting,

Palande, and Wang [23] both define effective resistance as a quantity associated with the boundary of a simplex.<sup>1</sup> This definition is analogous to the graph definition, as a pair of vertices is the boundary of an edge. Hansen and Ghrist [9] give a more general definition and define effective resistance as a quantity between two homologous cycles<sup>2</sup>. Our definition is equivalent to Hansen and Ghrist's, as we define effective resistance as a quantity associated with a null-homologous cycle.

Recent research has shown that some properties of effective resistance in graphs generalize to simplicial complexes. For example, Kook and Lee prove that the effective resistance of the boundary a simplex is the probability that the simplex is in the high-dimensional equivalent of a spanning tree [18]. Osting, Palande, and Wang show that sampling  $d$ -simplices according to the effective resistance of their boundaries approximately preserves the spectrum of the  $(d-1)$ -dimensional up-Laplacian [23].

## 1.1 Our Contributions

In this paper, we continue this trend of investigating effective resistance in simplicial complexes. Our main contribution is to show that there is a quantum algorithm for testing if a cycle is null-homologous in a simplicial complex that is parameterized by the effective resistance and effective capacitance of a cycle. The effective capacitance of a cycle is inspired by a quantity on graphs, and to our knowledge, we are the first to explore effective capacitance in simplicial complexes. Null-homology testing is an important primitive in computational topology. For example, the iterative algorithm for computing Betti numbers works by adding simplices one by one to the complex and testing if the boundary of each is already null-homologous in the previous complex [4].

Motivated by our quantum algorithm, we investigate bounds on the effective resistance and effective capacitance. We prove a negative result. While the effective resistance between a pair of vertices in a graph is bounded above by the number of vertices in the graph, the effective resistance of a  $(d-1)$ -cycle in a simplicial complex can be exponential in the number of the  $d$ -simplices in the complex. The classical algorithm to determine if a cycle is null-homologous is to solve a system of linear equations in the  $d$ th boundary matrix, so the quantum algorithm is slower than the classical algorithm in the worst case. On the positive side, we prove this exponential behavior is the result of relative torsion in dimension  $(d-1)$ , and we prove bounds on effective resistance and effective capacitance in terms of the size of relative torsion groups of the complex.

We also prove a duality result between effective resistance and effective capacitance. For a  $d$ -dimensional simplicial complex  $\mathcal{K}$  embedded in  $\mathbb{R}^{d+1}$ , the effective capacitance of certain  $d$ -cycles in  $\mathcal{K}$  is the effective resistance between a pair of nodes in the dual graph. Our proof relies on a high dimensional generalization of planar graphs with two nodes  $s$  and  $t$  appearing on the same face. Due to space constraints, this result can be found in Appendix C.

## 2 Preliminaries

Given a set of vertices  $V$ , a **simplicial complex**  $\mathcal{K}$  on  $V$  is a subset of the power set  $\mathcal{K} \subseteq P(V)$  with the following property: for each  $\tau \in \mathcal{K}$ , if  $\sigma \subset \tau$ , then  $\sigma \in \mathcal{K}$ . We assume there is a fixed but arbitrary order on the vertices  $V = (v_1, \dots, v_n)$ . A simplex  $\sigma \in \mathcal{K}$  of size

<sup>1</sup> Kook and Lee do not require the simplex to be in the complex.

<sup>2</sup> Hansen and Ghrist define effective resistance on a cellular sheaf, which is a generalization of a simplicial complex.

$|\sigma| = d + 1$  is a **d-simplex**. The set of all  $d$ -simplices of  $\mathcal{K}$  is denoted  $\mathcal{K}_d$ . The **d-skeleton** of  $\mathcal{K}$ , denoted  $\mathcal{K}^d$ , is the simplicial complex of all simplices of  $\mathcal{K}$  of size at most  $d + 1$ . The **dimension** of  $\mathcal{K}$  is the largest  $d$  such that  $\mathcal{K}$  contains a  $d$ -simplex; a 1-dimensional simplicial complex is a **graph**.

The **d<sup>th</sup> chain group**  $C_d(\mathcal{K})$  is the vector space over  $\mathbb{R}$  with orthonormal basis  $\mathcal{K}_d$ . Unless otherwise stated, all vectors and matrices will be in the basis  $\mathcal{K}_d$ . An element of  $C_d(\mathcal{K})$  is a **d-chain**. Let  $\sigma = \{v_{i_0}, \dots, v_{i_d}\}$  be a  $d$ -simplex in  $\mathcal{K}$  with  $v_{i_j} \leq v_{i_k}$  whenever  $j \leq k$ . The **boundary** of  $\sigma$  is the  $(d - 1)$ -chain  $\partial\sigma = \sum_{j=0}^d (-1)^j (\sigma \setminus \{v_{i_j}\})$ . The **d<sup>th</sup> boundary map** is the linear map  $\partial_d : C_d(\mathcal{K}) \rightarrow C_{d-1}(\mathcal{K})$  defined  $\partial_d f = \sum_{\sigma \in \mathcal{K}_d} f(\sigma) \partial\sigma$  where  $f(\sigma)$  denotes the component of  $f$  indexed by the simplex  $\sigma$ . A key property of the boundary map is that  $\partial_{d-1} \circ \partial_d = 0$ . An element in  $\ker \partial_d$  is a **cycle**, and an element in  $\text{im } \partial_d$  is a **boundary** or a **null-homologous cycle**. The boundary maps have the property that  $\partial_d \circ \partial_{d+1} = 0$ , so  $\text{im } \partial_{d+1} \subset \ker \partial_d$ . The **d<sup>th</sup> homology group** is the quotient group  $H_d(\mathcal{K}) = \ker(\partial_d) / \text{im}(\partial_{d+1})$ . The **d<sup>th</sup> Betti number**  $\beta_d$  is the dimension of  $H_d(\mathcal{K})$ . The **d<sup>th</sup> coboundary map** is the map  $\delta_d := \partial_{d+1}^T : C_d(\mathcal{K}) \rightarrow C_{d+1}(\mathcal{K})$ . An element of  $\ker \delta_d$  is a **cocycle**, and an element in  $\text{im } \delta_{d-1}$  is a **coboundary**. We will use the notation  $\partial[\mathcal{K}]$  and  $\delta[\mathcal{K}]$  when we want to specify the complex associated with the (co)boundary operator. For some of our results we will need to consider integral homology. The **integral chain group**  $C_d(\mathcal{K}, \mathbb{Z})$  is the free abelian group generated by the set  $\mathcal{K}_d$  whose elements are formal sums  $\sum_{\sigma_i \in \mathcal{K}_d} \alpha_i \sigma_i$  for  $\alpha_i \in \mathbb{Z}$ . The integral homology groups  $H_d(\mathcal{K}, \mathbb{Z})$  are constructed in the same way as with coefficients over the reals.

The **d<sup>th</sup> up Laplacian**<sup>3</sup> is  $L_d = \partial_{d+1} \delta_d$ . There are two variants of the up Laplacian: the weighted up Laplacian and the normalized up Laplacian. Let  $w : \mathcal{K}_{d+1} \rightarrow \mathbb{R}^+$  be a weight function on the  $(d+1)$ -simplices. Let  $W : C_{d+1}(\mathcal{K}) \rightarrow C_{d+1}(\mathcal{K})$  be the diagonal matrix with  $W_{\tau, \tau} = w(\tau)$ . The **d<sup>th</sup> weighted up Laplacian** is  $L_d^W = \partial_{d+1} W \delta_d$ . The **degree** of a  $d$ -simplex  $\sigma$  is  $\text{deg}(\sigma) = \sum_{\tau \in \mathcal{K}_{d+1} : \sigma \subset \tau} w(\tau)$ . Let  $D : C_d(\mathcal{K}) \rightarrow C_d(\mathcal{K})$  be the diagonal matrix with  $D_{\sigma, \sigma} = \text{deg}(\sigma)$ . The **d<sup>th</sup> normalized up Laplacian** is  $\tilde{L}_d = D^{-1/2} \partial_{d+1} W \delta_d D^{-1/2}$ .

We will make use of the **bra-ket notation** for vectors when discussing the quantum algorithm as this is the convention in the quantum computing literature. A **bra** is a row vector represented by the notation  $\langle v|$ . A **ket** is a column vector represented by the notation  $|v\rangle$ . The inner product of  $u$  and  $v$  is represented as  $\langle u|v\rangle$ .

Finally, we will often want to refer to the set of simplices given a non-zero value by a chain  $f$ . We call this set the **support** of  $f$  and denote it  $\text{supp}(f) = \{\sigma_i \in \mathcal{K}_d : f(\sigma_i) \neq 0\}$ .

### 3 Effective Resistance and Effective Capacitance

Let  $\gamma \in C_{d-1}(\mathcal{K})$  be a cycle in a simplicial complex. We associate two quantities with  $\gamma$ , its *effective resistance* and *effective capacitance*. The effective resistance is finite if and only if  $\gamma$  is null-homologous, and the effective capacitance is finite if and only if  $\gamma$  is not null-homologous. We begin with the definition of effective resistance.

► **Definition 1.** Let  $\mathcal{K}$  be a simplicial complex with weight function  $w : \mathcal{K}_d \rightarrow \mathbb{R}^+$ . Let  $\gamma$  be a  $(d-1)$ -cycle in  $\mathcal{K}$ . If  $\gamma$  is null-homologous, the **effective resistance** of  $\gamma$  is  $\mathcal{R}_\gamma(\mathcal{K}, W) = \gamma^T (L_d^W)^+ \gamma$ , where  $(L_d^W)^+$  is the Moore-Penrose pseudoinverse of  $L_d^W$ ; if  $\gamma$  is not null-homologous, then  $\mathcal{R}_\gamma(\mathcal{K}, W) = \infty$ . When obvious, we drop the weights from the notation and write  $\mathcal{R}_\gamma(\mathcal{K})$ .

<sup>3</sup> There are related operators called the *down Laplacian* and the *Laplacian* (see [8]), but we won't use either in this paper.

## 31:4 Effective Resistance and Capacitance in Simplicial Complexes

This definition of effective resistance is consistent with effective resistance in graphs (see [26]) and other definitions of effective resistance in simplicial complexes [18, 23, 9]. However, this definition gives little intuition about effective resistance. We now prove there is an alternative definition of effective resistance in terms of chains with boundary  $\gamma$ . We begin with two definitions.

► **Definition 2.** *Given a  $d$ -dimensional simplicial complex  $\mathcal{K}$  and a  $(d-1)$ -dimensional null-homologous cycle  $\gamma$ , a **unit  $\gamma$ -flow** is a  $d$ -chain  $f \in C_d(\mathcal{K})$  such that  $\partial f = \gamma$ .*

In the case of graphs a unit  $\gamma$ -flow is a flow sending 1 unit of flow from its source to its sink. We now define the *flow energy* of a unit  $\gamma$ -flow, which quantifies the size of the flow.

► **Definition 3.** *Given a  $d$ -dimensional simplicial complex  $\mathcal{K}$  with weight function  $w : C_d(\mathcal{K}) \rightarrow \mathbb{R}^+$  and a unit  $\gamma$ -flow  $f$ , the **flow energy** of  $f$  on  $\mathcal{K}$  is  $J(f) = \sum_{\sigma \in \mathcal{K}(d)} \frac{f(\sigma)^2}{w(\sigma)} = f^T W^{-1} f$  where  $W$  is the diagonal matrix whose entries are the weights of the  $d$ -simplices.*

We will now relate unit  $\gamma$ -flows and their energy to the definition of effective resistance.

► **Lemma 4.** *Let  $\mathcal{K}$  be a simplicial complex and let  $\gamma$  be a null-homologous  $d$ -cycle. The effective resistance of  $\gamma$  is the minimum flow energy over all unit  $\gamma$ -flows, i.e.  $\mathcal{R}_\gamma(\mathcal{K}) = \min\{J(f) \mid \partial f = \gamma\}$*

**Proof.** We use two well-known properties of the pseudoinverse.

1. If a matrix  $B = AA^T$ , then  $B^+ = (A^T)^+ A^+$ .
2. Let  $B$  be a matrix and  $|v\rangle \in \text{im } B$ . The vector  $B^+v$  is the minimum-norm vector that  $B$  maps to  $v$ , i.e.  $B^+v = \arg \min\{\|u\| : Bu = v\}$ .

Our first observation is that we can factor the weighted Laplacian as

$$\begin{aligned} L_d^W &= \partial_{d+1} W \delta_d \\ &= (\partial_{d+1} W^{1/2})(\partial_{d+1} W^{1/2})^T. \end{aligned}$$

By property 1 above,  $(L_d^W)^+ = ((\partial_{d+1} W^{1/2})^T)^+(\partial_{d+1} W^{1/2})^+$ . Therefore,

$$\begin{aligned} \mathcal{R}_\gamma(\mathcal{K}) &= \gamma^T ((\partial_{d+1} W^{1/2})^T)^+(\partial_{d+1} W^{1/2})^+ \gamma \\ &= \|(\partial W^{1/2})^+ \gamma\|^2. \end{aligned}$$

By property 2 above,  $\mathcal{R}_\gamma(\mathcal{K})$  is the minimum squared-norm of a vector that  $\partial_{d+1} W^{1/2}$  maps to  $\gamma$ . Let  $f = (\partial W^{1/2})^+ \gamma$ ; the vector  $f$  is the unit  $\gamma$ -flow of minimum flow energy, which we now prove. A vector  $v$  is mapped to  $\gamma$  by  $\partial W^{1/2}$  if and only if  $W^{1/2}v$  is mapped to  $\gamma$  by  $\partial$  as  $W^{1/2}$  is a bijection, i.e.  $W^{1/2}v$  is a unit  $\gamma$ -flow. Moreover, the flow energy of  $W^{1/2}v$  is  $J(W^{1/2}v) = (W^{1/2}v)^T W^{-1} (W^{1/2}v) = v^T v = \|v\|^2$ . Therefore, the minimum flow energy of a unit  $\gamma$ -flow is the minimum squared-norm of a vector that  $\partial W^{1/2}$  maps to  $\gamma$ , which we previously saw was  $\mathcal{R}_\gamma(\mathcal{K})$ . ◀

We say that  $(\partial W^{1/2})^+ \gamma$  is the **minimum-energy** unit  $\gamma$ -flow.

The definition of effective capacitance is less intuitive than the definition for effective resistance, both in graphs and simplicial complexes. As well, there are fewer results about effective capacitance in graphs than effective resistance and no previous results about effective capacitance in simplicial complexes. The effective capacitance of  $\gamma$  in a graph is the minimum energy of any *unit  $\gamma$ -potential*, which is analogous to effective resistance that was the minimum energy of any unit  $\gamma$ -flow. Before providing the definition of unit  $\gamma$ -potential in a simplicial complex we will begin by reviewing the definition of a unit *st*-potential in a graph, which can be found in [12].

Let  $G$  be a graph such that  $s$  and  $t$  are connected in  $G$ , and let  $H \subseteq G$  be a subgraph such that  $s$  and  $t$  are not connected in  $H$ . A **unit  $st$ -potential** is a function  $p: V(G) \rightarrow \mathbb{R}$  such that  $p(t) = 1, p(s) = 0$ , and for any two vertices  $u, v$  in the same connected component of  $H$ ,  $p(u) = p(v)$ . Viewing  $p$  as a 0-chain we see by the last property that its coboundary is zero in  $H$ . Intuitively, our definition of a unit  $\gamma$ -potential measures “how far” a cycle  $\gamma$  is from null-homologous in a subcomplex  $\mathcal{L}$  of  $\mathcal{K}$ . The definition of a unit  $\gamma$ -potential is analogous to the definition of a unit  $st$ -potential.

► **Definition 5.** Let  $\mathcal{L} \subset \mathcal{K}$  be simplicial complexes, and let  $\gamma \in C_{d-1}(\mathcal{L})$  be a  $(d-1)$ -cycle such that  $\gamma$  is null-homologous in  $\mathcal{K}$  but not  $\mathcal{L}$ . A **unit  $\gamma$ -potential** in  $\mathcal{L}$  is a  $(d-1)$ -chain  $p$  such that  $\delta[\mathcal{L}]p = 0$  and  $p^T\gamma = 1$ .

► **Definition 6.** Given simplicial complexes  $\mathcal{L} \subset \mathcal{K}$  with weight function  $w: C_d(\mathcal{K}) \rightarrow \mathbb{R}$  and a  $\gamma$ -potential  $p$  in  $\mathcal{L}$ , the **potential energy** of  $p$  on  $\mathcal{K}$  is  $\mathcal{J}(p) = \sum_{\sigma \in \mathcal{K}_d} ((\delta[\mathcal{K}]p)^T \sigma)^2 w(\sigma) = (\delta[\mathcal{K}]p)^T W(\delta[\mathcal{K}]p)$ .

Figure 1 in the appendix shows a  $\gamma$ -potential. It is not obvious from the definition that a unit  $\gamma$ -potential will even exist for  $\gamma$ . We prove this in the following lemma.

► **Lemma 7.** Let  $\mathcal{L} \subset \mathcal{K}$  be simplicial complexes whose  $(d-1)$ -skeletons are equal, and let  $\gamma \in C_{d-1}(\mathcal{L})$  be a cycle. Then there exists a unit  $\gamma$ -potential in  $\mathcal{L}$  if and only if  $\gamma$  is not null-homologous in  $\mathcal{L}$ .

**Proof.** Observe that  $\ker \delta_{d-1}[\mathcal{L}] = (\text{im } \partial_d[\mathcal{L}])^\perp$  as  $\delta_{d-1}[\mathcal{L}] = \partial[\mathcal{L}]^T$ . Assume there is a  $\gamma$ -potential  $p$  in  $\mathcal{L}$ . As  $\delta[\mathcal{L}]p = 0$ , then  $p \in \ker \delta_{d-1}[\mathcal{L}] = (\text{im } \partial_d[\mathcal{L}])^\perp$ . As  $p^T\gamma = 1$  we see that  $\gamma$  has a non-zero component in  $(\text{im } \partial_d[\mathcal{L}])^\perp$ , so  $\gamma \notin \text{im } \partial[\mathcal{L}]$ . Alternatively, suppose that  $\gamma$  is not null-homologous in  $\mathcal{L}$ . Then  $\gamma$  has a non-zero component in  $(\text{im } \partial_d[\mathcal{L}])^\perp = \ker \delta[\mathcal{L}]$ . Let  $q = \Pi_{\ker \delta[\mathcal{L}]} \gamma$ , where  $\Pi_{\ker \delta[\mathcal{L}]}$  is the projection onto  $\ker \delta[\mathcal{L}]$ . Then  $q^T\gamma \neq 0$  and  $\delta[\mathcal{L}]q = 0$ . The vector  $q$  is not necessarily a unit  $\gamma$ -potential as it is not necessarily the case that  $q^T\gamma = 1$ , but the scaled vector  $p = \frac{1}{q^T\gamma} q$  is a unit  $\gamma$ -potential. ◀

Just as the effective resistance of  $\gamma$  was the minimum energy of any unit  $\gamma$ -flow, the effective capacitance of  $\gamma$  is the minimum energy of any unit  $\gamma$ -potential.

► **Definition 8.** Let  $\mathcal{L} \subset \mathcal{K}$  be simplicial complexes, and let  $\gamma \in C_{d-1}(\mathcal{L})$  be a  $(d-1)$ -cycle that is null-homologous in  $\mathcal{K}$ . If  $\gamma$  is not null-homologous in  $\mathcal{L}$ , the **effective capacitance** of  $\gamma$  in  $\mathcal{L}$  is  $\mathcal{C}_\gamma(\mathcal{L}) = \min_p \mathcal{J}(p)$  where  $p$  is a  $\gamma$ -potential. If  $\gamma$  is null-homologous in  $\mathcal{L}$ , then  $\mathcal{C}_\gamma(\mathcal{L}) = \infty$ .

## 4 Basic Properties: Parallel, Series, and Monotonicity Formulas

We now prove there are formulas for effective resistance in simplicial complexes analogous to the series and parallel formulas for effective resistance in graphs. These formulas not only are useful for calculating effective resistance, but they also provide intuition for effective resistance. In particular, they provide justification for the claim that effective resistance measures “how null-homologous” a cycle is in a complex.

► **Theorem 9 (Series Formula).** Let  $\mathcal{K}_1$  and  $\mathcal{K}_2$  be simplicial complexes with  $\gamma \in C_{d-1}(\mathcal{K}_1) \cap C_{d-1}(\mathcal{K}_2)$ ,  $C_d(\mathcal{K}_1) \cap C_d(\mathcal{K}_2) = \emptyset$ , and  $\gamma$  null-homologous in  $\mathcal{K}_1$  and  $\mathcal{K}_2$ . Let  $\mathcal{K} = \mathcal{K}_1 \cup \mathcal{K}_2$ . Then  $\mathcal{R}_\gamma(\mathcal{K}) \leq \mathcal{R}_{\gamma_1}(\mathcal{K}_1) + \mathcal{R}_{\gamma_2}(\mathcal{K}_2)$ . Equality is achieved when  $\gamma_1$  and  $\gamma_2$  are the unique chains in  $\mathcal{K}_1$  and  $\mathcal{K}_2$  that sum to  $\gamma$ .

**Proof.** Let  $\gamma_1$  and  $\gamma_2$  be null-homologous cycles in  $\mathcal{K}_1$  and  $\mathcal{K}_2$  respectively that sum to  $\gamma$ , and let  $f_1$  and  $f_2$  be the minimum-energy unit  $\gamma_1$ - and  $\gamma_2$ -flows, respectively. Then  $f_1 + f_2$  is a unit  $\gamma$ -flow, and we can bound  $\mathcal{R}_\gamma(\mathcal{K}) \leq J(f) = J(f_1) + J(f_2) = \mathcal{R}_{\gamma_1}(\mathcal{K}_1) + \mathcal{R}_{\gamma_2}(\mathcal{K}_2)$ ; the equality  $J(f) = J(f_1) + J(f_2)$  follows from the fact that  $\mathcal{K}_1$  and  $\mathcal{K}_2$  have disjoint sets of  $d$ -simplices.

To prove the other direction, observe that  $\gamma$  can always be written as the sum of two null-homologous chains  $\gamma_1 \in C_{d-1}(\mathcal{K}_1)$  and  $\gamma_2 \in C_{d-1}(\mathcal{K}_2)$ . Any unit  $\gamma$ -flow  $g$  defines null-homologous  $(d-1)$ -cycles  $\gamma_1$  and  $\gamma_2$  that sum to  $\gamma$ ; namely, if  $g_1$  and  $g_2$  are the restriction of  $g$  to  $\mathcal{K}_1$  and  $\mathcal{K}_2$  respectively, then  $\gamma_1 = \partial g_1$  and  $\gamma_2 = \partial g_2$ .

If  $\gamma$  can be uniquely decomposed as  $\gamma = \gamma_1 + \gamma_2$ , then any unit  $\gamma$ -flow  $f$  can be decomposed as a unit  $\gamma_1$ -flow  $f_1$  and a unit  $\gamma_2$ -flow  $f_2$ . It follows that the energy of  $f$  is minimized when the energy of  $f_1$  and  $f_2$  are both minimized. Hence,  $\mathcal{R}_\gamma(\mathcal{K}) = \mathcal{R}_{\gamma_1}(\mathcal{K}_1) + \mathcal{R}_{\gamma_2}(\mathcal{K}_2)$ . ◀

► **Theorem 10 (Parallel Formula).** *Let  $\mathcal{K}_1$  and  $\mathcal{K}_2$  be simplicial complexes with  $\gamma \in C_{d-1}(\mathcal{K}_1) \cap C_{d-1}(\mathcal{K}_2)$ ,  $C_d(\mathcal{K}_1) \cap C_d(\mathcal{K}_2) = \emptyset$ , and  $\gamma$  null-homologous in  $\mathcal{K}_1$  and  $\mathcal{K}_2$ . Let  $\mathcal{K} = \mathcal{K}_1 \cup \mathcal{K}_2$ . Then  $\mathcal{R}_\gamma(\mathcal{K}) \leq \left( \frac{1}{\mathcal{R}_\gamma(\mathcal{K}_1)} + \frac{1}{\mathcal{R}_\gamma(\mathcal{K}_2)} \right)^{-1}$ . Equality is achieved when  $\text{im } \partial[\mathcal{K}_1] \cap \text{im } \partial[\mathcal{K}_2] = \text{span}\{\gamma\}$ .*

**Proof.** Let  $f_1$  and  $f_2$  be the minimum energy unit  $\gamma$ -flows in  $\mathcal{K}_1$  and  $\mathcal{K}_2$  resp. For any real number  $t$ , the chain  $g_t = tf_1 + (1-t)f_2$  is a unit  $\gamma$ -flow in  $\mathcal{K}$ . We can therefore bound the effective resistance as  $\mathcal{R}_\gamma(\mathcal{K}) \leq \min_t J(g_t)$ .

To get the tightest bound of  $\mathcal{R}_\gamma(\mathcal{K})$ , we now derive  $t_{\text{opt}} := \arg \min_t J(g_t)$ . Observe that  $J(g_t) = t^2 J(f_1) + (1-t)^2 J(f_2) = t^2 \mathcal{R}_\gamma(\mathcal{K}_1) + (1-t)^2 \mathcal{R}_\gamma(\mathcal{K}_2)$ ; this follows from the fact that  $\mathcal{K}_1$  and  $\mathcal{K}_2$  have disjoint sets of  $d$ -simplices. The quantity  $J(g_t)$  is a positive quadratic in  $t$ , so  $t_{\text{opt}}$  is the value of  $t$  where the derivative of  $J(g_t)$  with respect to  $t$  is 0. Taking the derivative, we find that  $t_{\text{opt}} = \mathcal{R}_\gamma(\mathcal{K}_2) / (\mathcal{R}_\gamma(\mathcal{K}_1) + \mathcal{R}_\gamma(\mathcal{K}_2))$ . Plugging  $t_{\text{opt}}$  into  $J(g_{t_{\text{opt}}})$ , we find that

$$\begin{aligned} J(g_{t_{\text{opt}}}) &= \left( \frac{\mathcal{R}_\gamma(\mathcal{K}_2)}{\mathcal{R}_\gamma(\mathcal{K}_1) + \mathcal{R}_\gamma(\mathcal{K}_2)} \right)^2 \mathcal{R}_\gamma(\mathcal{K}_1) + \left( 1 - \frac{\mathcal{R}_\gamma(\mathcal{K}_2)}{\mathcal{R}_\gamma(\mathcal{K}_1) + \mathcal{R}_\gamma(\mathcal{K}_2)} \right)^2 \mathcal{R}_\gamma(\mathcal{K}_2) \\ &= \left( \frac{\mathcal{R}_\gamma(\mathcal{K}_2)}{\mathcal{R}_\gamma(\mathcal{K}_1) + \mathcal{R}_\gamma(\mathcal{K}_2)} \right)^2 \mathcal{R}_\gamma(\mathcal{K}_1) + \left( \frac{\mathcal{R}_\gamma(\mathcal{K}_1)}{\mathcal{R}_\gamma(\mathcal{K}_1) + \mathcal{R}_\gamma(\mathcal{K}_2)} \right)^2 \mathcal{R}_\gamma(\mathcal{K}_2) \\ &= \left( \frac{1}{\mathcal{R}_\gamma(\mathcal{K}_1) + \mathcal{R}_\gamma(\mathcal{K}_2)} \right)^2 \left( \mathcal{R}_\gamma(\mathcal{K}_1) + \mathcal{R}_\gamma(\mathcal{K}_2) \right) \mathcal{R}_\gamma(\mathcal{K}_1) \mathcal{R}_\gamma(\mathcal{K}_2) \\ &= \frac{\mathcal{R}_\gamma(\mathcal{K}_1) \mathcal{R}_\gamma(\mathcal{K}_2)}{\mathcal{R}_\gamma(\mathcal{K}_1) + \mathcal{R}_\gamma(\mathcal{K}_2)} \\ &= \left( \frac{1}{\mathcal{R}_\gamma(\mathcal{K}_1)} + \frac{1}{\mathcal{R}_\gamma(\mathcal{K}_2)} \right)^{-1}. \end{aligned}$$

This implies the upper bound on  $\mathcal{R}_\gamma(\mathcal{K})$  in the theorem statement. To get the lower bound, observe that any unit  $\gamma$ -flow  $g$  in  $\mathcal{K}$  can be orthogonally decomposed into chains  $g_1 \in C_d(\mathcal{K}_1)$  and  $g_2 \in C_d(\mathcal{K}_2)$ , so  $\partial[\mathcal{K}]g_1 + \partial[\mathcal{K}]g_2 = \gamma$ . We claim that  $\partial[\mathcal{K}_1]g_1 = t\gamma$  and  $\partial[\mathcal{K}_2]g_2 = (1-t)\gamma$  for some value of  $t$ ; if not, then  $\partial[\mathcal{K}_1]g_1 = t\gamma + \eta$  and  $\partial[\mathcal{K}_2]g_2 = (1-t)\gamma - \eta$  for some non-zero  $\eta \notin \text{span}\{\gamma\}$ , which cannot be the case as  $\text{im } \partial[\mathcal{K}_1] \cap \text{im } \partial[\mathcal{K}_2] = \text{span}\{\gamma\}$ . This proves the chain  $g$  is a linear combination of a unit  $\gamma$ -flow in  $\mathcal{K}_1$  and a unit  $\gamma$ -flow in  $\mathcal{K}_2$ . The chain  $g_t$  is the lowest energy such linear combination. ◀

Figure 2 in the appendix shows examples of unit  $\gamma$ -flows in series and parallel. These formulas justify the claim that the effective resistance of a null-homologous cycle  $\gamma$  is a measure of *how* null-homologous  $\gamma$  is. The more chains with boundary  $\gamma$ , the smaller the effective resistance of  $\gamma$  by the parallel formula. The smaller the chains bounding  $\gamma$ , the lower the effective resistance by the series formula.

A similar result to the series and parallel formula for effective resistance in graphs is *Rayleigh monotonicity*. Rayleigh monotonicity says that adding edges to a graph can only decrease the effective resistance between any pair of vertices; this reinforces the notion that effective resistance measures how well-connected a pair of vertices are, as adding an edge can only make a pair of vertices better connected. We prove a similar result for simplicial complexes.

► **Theorem 11** (Rayleigh Monotonicity). *Let  $\mathcal{K} \subset \mathcal{L}$  be simplicial complexes. Let  $|\gamma\rangle \in C_{d-1}(\mathcal{K}) \cap C_{d-1}(\mathcal{L})$  be a null-homologous cycle in both complexes. Then  $\mathcal{R}_\gamma(\mathcal{L}) \leq \mathcal{R}_\gamma(\mathcal{K})$ .*

**Proof.** As  $C_d(\mathcal{K}) \subset C_d(\mathcal{L})$ , then any unit  $\gamma$ -flow in  $\mathcal{K}$  is also a unit  $\gamma$ -flow in  $\mathcal{L}$ . As the effective resistance is the minimum energy of a unit  $\gamma$ -flow, then clearly  $\mathcal{R}_\gamma(\mathcal{L}) \leq \mathcal{R}_\gamma(\mathcal{K})$ . ◀

## 5 Bounds on resistance and capacitance

In this section, we provide upper bounds on the resistance and capacitance of a cycle  $\gamma$  in an unweighted simplicial complex  $\mathcal{K}$ . Our upper bounds are polynomial in the number of  $d$ -simplices and the cardinality of the torsion subgroup of the relative homology groups. In particular, our bounds on resistance and capacitance are dependent on the maximum cardinality of the torsion subgroup of the relative homology group  $H_{d-1}(\mathcal{L}, \mathcal{L}_0, \mathbb{Z})$ , where  $\mathcal{L} \subset \mathcal{K}$  is a  $d$ -dimensional subcomplex and  $\mathcal{L}_0 \subset \mathcal{L}$  is a  $(d-1)$ -dimensional subcomplex. In the worst case, our upper bounds are exponential in the number of  $d$ -simplices. There exist simplicial complexes such that the torsion subgroup of  $H_{d-1}(\mathcal{K}, \mathbb{Z})$  has cardinality  $n$  while  $\mathcal{K}$  only has  $O(\log^{1/d} n)$  vertices [22]. Note that such a complex contains at most  $O(n^d)$   $d$ -simplices.

In Theorem 17 we provide an example of a simplicial complex containing a cycle  $\gamma$  whose effective resistance is exponential in the number of simplices in the complex. It is important to reiterate that our bounds are in terms of the torsion of the relative homology groups. There exist simplicial complexes with no torsion in their homology groups but that do have torsion in their relative homology groups. An example of this is the Möbius strip. The Möbius strip has no torsion, but it has torsion relative to its boundary [5].

Our results rely on a change of basis on the boundary matrix called the *normal form* which reveals information about the torsion subgroup of  $H_{d-1}(\mathcal{K}, \mathbb{Z})$ . We state the normal form theorem below.

► **Theorem 12** (Munkres, Chapter 1 Section 11 [21]). *There are bases for  $C_d(\mathcal{K}, \mathbb{Z})$  and  $C_{d-1}(\mathcal{K}, \mathbb{Z})$  such that the matrix for the boundary operator  $\partial_d: C_d(\mathcal{K}, \mathbb{Z}) \rightarrow C_{d-1}(\mathcal{K}, \mathbb{Z})$  is in **normal form**, i.e.  $\tilde{\partial}_d = \begin{bmatrix} D & 0 \\ 0 & 0 \end{bmatrix}$  where  $D$  is a diagonal matrix with entries  $d_1, \dots, d_m$  such that each  $d_i$  divides  $d_{i+1}$  and each 0 is a zero matrix of appropriate dimensionality. The normal form of  $\partial_d$  satisfies the following properties:*

1. *The entries  $d_1, \dots, d_m$  correspond to the torsion coefficients of  $H_{d-1}(\mathcal{K}, \mathbb{Z}) \cong \mathbb{Z}^{\beta_d} \oplus \mathbb{Z}_{d_1} \oplus \dots \oplus \mathbb{Z}_{d_m}$  (where  $\mathbb{Z}_1 = 0$ ),*
  2. *The number of zero columns is equal to the dimension of  $\ker(\partial_d)$ .*
- Moreover, the boundary matrix  $\partial$  in the standard basis can be transformed to  $\tilde{\partial}$  by a set of elementary row and column operations. If  $\partial$  is square, these operations multiply  $\det \partial$  by  $\pm 1$ .*

Using Theorem 12, we obtain an upper bound on the determinants of the square submatrices of the boundary matrix  $\partial_d[\mathcal{K}]$  in terms of the *relative homology groups* of  $\mathcal{K}$ . Let  $\mathcal{L}$  be  $d$ -dimensional subcomplex of  $\mathcal{K}$ , and let  $\mathcal{L}_0$  be a  $(d-1)$ -dimensional subcomplex of  $\mathcal{K}$ . The **relative boundary matrix**  $\partial_d[\mathcal{L}, \mathcal{L}_0]$  is the submatrix of  $\partial_d$  obtained by including the columns of the  $d$ -simplices in  $\mathcal{L}$  and excluding the rows of the  $(d-1)$ -simplices in  $\mathcal{L}_0$ . With the relative boundary matrices, one can define the **relative homology groups** as  $H_k(\mathcal{L}, \mathcal{L}_0, \mathbb{Z}) = \ker \partial_k[\mathcal{L}, \mathcal{L}_0] / \text{im } \partial_{k+1}[\mathcal{L}, \mathcal{L}_0]$ . More information on the relative boundary matrix can be found in [5]. We denote the cardinality of the torsion subgroup of the relative homology group  $H_{d-1}(\mathcal{L}, \mathcal{L}_0, \mathbb{Z})$  by  $\mathcal{T}(\mathcal{L}, \mathcal{L}_0)$ . Similarly, we denote the maximum  $\mathcal{T}(\mathcal{L}, \mathcal{L}_0)$  over all relative homology groups as  $\mathcal{T}_{\max}(\mathcal{K})$ .

► **Lemma 13.** *Let  $\partial_d[\mathcal{L}, \mathcal{L}_0]$  be a  $k \times k$  square submatrix of  $\partial_d$  constructed by including columns for the  $d$ -simplices  $\mathcal{L}$  and excluding rows for the  $(d-1)$ -simplices  $\mathcal{L}_0$ . The magnitude of the determinant of  $\partial_d[\mathcal{L}, \mathcal{L}_0]$  is bounded above by the cardinality of the torsion subgroup of  $H_{d-1}(\mathcal{L}, \mathcal{L}_0, \mathbb{Z})$ , i.e.  $|\det(\partial_d[\mathcal{L}, \mathcal{L}_0])| \leq \mathcal{T}(\mathcal{L}, \mathcal{L}_0)$ .*

**Proof.** Without loss of generality, we assume that  $\det(\partial_d[\mathcal{L}, \mathcal{L}_0]) \neq 0$ ; if  $\det(\partial_d[\mathcal{L}, \mathcal{L}_0]) = 0$ , the bound is trivial. Since  $\partial_d[\mathcal{L}, \mathcal{L}_0]$  is a non-singular square matrix, its normal form  $\tilde{\partial}_d[\mathcal{L}, \mathcal{L}_0]$  is a diagonal matrix  $D = \text{diag}(d_1, \dots, d_k)$ . By Theorem 12, the determinant of  $\partial_d[\mathcal{L}, \mathcal{L}_0]$  is equal to  $\pm \det(\tilde{\partial}_d[\mathcal{L}, \mathcal{L}_0]) = \prod_{i=1}^k d_i$ . Also by Theorem 12, the torsion subgroup of  $H_{d-1}(\mathcal{L}, \mathcal{L}_0)$  is  $\mathbb{Z}_{d_1} \oplus \dots \oplus \mathbb{Z}_{d_k}$  which has cardinality  $\mathcal{T}(\mathcal{L}, \mathcal{L}_0) = \prod_{i=1}^k d_i$ . ◀

We are now ready to upper bound the effective resistance of a cycle  $\gamma$  in a simplicial complex  $\mathcal{K}$ .

► **Theorem 14.** *Let  $\mathcal{K}$  be an unweighted  $d$ -dimensional simplicial complex with  $n$   $d$ -simplices. Let  $\gamma$  be a unit-length null-homologous  $(d-1)$ -cycle in  $\mathcal{K}$ . The effective resistance of  $\gamma$  is bounded above as  $\mathcal{R}_\gamma(\mathcal{K}) = O(n^2 \cdot \mathcal{T}_{\max}(\mathcal{K})^2)$ .*

**Proof.** First, we remove  $d$ -simplices from  $\mathcal{K}$  to create a new complex  $\mathcal{L}$  such that  $\ker(\partial_d[\mathcal{L}]) = 0$  and  $\text{im } \partial_d[\mathcal{K}] = \text{im } \partial_d[\mathcal{L}]$ . Theorem 11 proves that removing  $d$ -simplices only increases the effective resistance, so  $\mathcal{R}_\gamma(\mathcal{K}) \leq \mathcal{R}_\gamma(\mathcal{L})$ . As  $\ker(\partial_d[\mathcal{L}]) = 0$ , there is a unique unit  $\gamma$ -flow  $f \in C_{d-1}(\mathcal{L})$ , which implies  $\mathcal{R}_\gamma(\mathcal{L}) = \|f\|^2$ .

The matrix  $\partial_d[\mathcal{L}]$  has full column rank, so we can find a non-singular  $n_d \times n_d$  square submatrix of  $\partial_d[\mathcal{L}]$ ; call this submatrix  $B$ . Let  $\mathcal{L}_0$  be the  $(d-1)$ -dimensional subcomplex that contains the  $(d-1)$ -simplices corresponding to rows excluded from  $B$ ;  $B$  is the relative boundary matrix  $\partial_d[\mathcal{L}, \mathcal{L}_0]$ . We have that  $Bf = c$ , where  $c$  is the restriction of  $\gamma$  to the rows of  $B$ . Observe that  $\|c\| \leq \|\gamma\| = 1$

We will apply Cramer's rule to upper bound the size of  $f$ . Let  $f(\sigma)$  denote the component of  $f$  indexed by the  $d$ -simplex  $\sigma$ . Cramer's rule gives the equality  $f(\sigma) = \frac{\det(B_{\sigma,c})}{\det(B)}$  where  $B_{\sigma,c}$  is the matrix obtained by replacing the column of  $B$  indexed by  $\sigma$  with the vector  $c$ . Since  $\det(B)$  is integral,  $|\det(B)| \geq 1$ , we can drop the denominator and use the inequality  $|f(\sigma)| \leq |\det(B_{\sigma,c})|$ . We bound  $|\det(B_{\sigma,c})|$  by its cofactor expansion on the column  $c$ , specifically  $|\det(B_{\sigma,c})| = |\sum_{i=1}^{n_d} (-1)^{i+j} \cdot c_i \cdot \det(B_{\sigma,c}^{c,i})| \leq \sum_{i=1}^{n_d} |c_i| \cdot t(\mathcal{K}) = O(\sqrt{n} \cdot \mathcal{T}_{\max}(\mathcal{K}))$  where  $B_{\sigma,c}^{c,i}$  denotes the submatrix obtained by removing the column  $c$  and removing the  $i$ th row and  $c_i$  denotes the  $i$ th component of  $c$ . The first inequality comes from Lemma 13, as  $B_{\sigma,c}^{c,i}$  is the relative boundary matrix  $\partial[\mathcal{L} \setminus \{\sigma\}, \mathcal{L}_0 \cup \sigma_i]$ , where  $\sigma_i$  is the  $(d-1)$ -simplex corresponding to the  $i$ th row of  $B$ . The factor of  $\sqrt{n}$  comes from our assumption that  $\|c\| \leq 1$  and the fact that  $\sum_{i=1}^{n_d} |c_i| = \|c\|_1 \leq \sqrt{|\text{supp}(c)|} \cdot \|c\|_2 \leq \sqrt{n} \cdot \|c\|_2$ , which can be shown using the Cauchy-Schwarz inequality. Finally, we compute the flow energy of  $f$  as  $J(f) = \sum_{\sigma \in \mathcal{K}^d} f(\sigma)^2 \leq \sum_{i=1}^{n_d} n \cdot \mathcal{T}_{\max}(\mathcal{K})^2 = O(n^2 \cdot \mathcal{T}_{\max}(\mathcal{K})^2)$ . The effective resistance of  $\gamma$  is the flow energy of  $f$ , so the result follows. ◀

The same argument also applies for any subcomplex  $\mathcal{L} \subset \mathcal{K}$  where  $\gamma$  is null-homologous in  $\mathcal{L}$  which gives us the following corollary.

► **Corollary 15.** *Let  $\mathcal{L} \subset \mathcal{K}$  be an unweighted  $d$ -dimensional simplicial complex and  $\gamma$  a null-homologous  $(d-1)$ -cycle in  $\mathcal{L}$ . The effective resistance of  $\gamma$  in  $\mathcal{L}$  is bounded above by  $\mathcal{R}_\gamma(\mathcal{L}) = O(n^2 \cdot \mathcal{T}_{\max}(\mathcal{K})^2)$ .*

In order to upper bound the effective capacitance of  $\gamma$ , we need to make two additional assumptions. We need to assume that as input  $\gamma$  has integral coefficients and that each coefficient is bound above by a constant. Even though  $\gamma$  is given as input as an integral cycle, we still normalize  $\gamma$  as a preprocessing step. Normalizing  $\gamma$  does not change whether or not  $\gamma$  is null-homologous. We state the theorem but leave the proof to the appendix. The proof idea is similar to that of the bound on effective resistance, but with a few extra technical details.

► **Theorem 16.** *Let  $\mathcal{L} \subset \mathcal{K}$  be an unweighted  $d$ -dimensional simplicial complexes, and let  $\hat{\gamma} \in C_{d-1}(\mathcal{L})$  be a  $(d-1)$ -cycle that is null-homologous in  $\mathcal{K}$  but not in  $\mathcal{L}$ . Assume also that  $\hat{\gamma}$  is integral and each of the coefficients  $|\hat{\gamma}_i| = O(1)$ . The effective capacitance of  $\gamma := \hat{\gamma}/\|\hat{\gamma}\|$  in  $\mathcal{K}(x)$  is bounded above by  $\mathcal{C}_\gamma(\mathcal{L}) = O(n^3 \cdot d \cdot \mathcal{T}_{\max}(\mathcal{K})^2)$ .*

Recall that  $t(\mathcal{K})$  could be exponential in the size of the complex. To end the section, we now provide an example of a simplicial complex containing a cycle  $\gamma$  such that the effective resistance of  $\gamma$  is exponential in the size of the complex.

► **Theorem 17.** *There exists a 2-dimensional simplicial complex with  $\Theta(n)$  triangles and a cycle  $\gamma$  such that the effective resistance of  $\gamma$  is  $\Theta(2^{2n})$ .*

**Proof.** Let  $\mathbb{RP}_\gamma$  denote a simplicial complex homeomorphic to the real projective plane with a disk removed; the cycle  $\gamma$  boundary of the removed disk. Hence, we have that the boundary of the sum of the triangles in the complex is  $\partial_2 \mathbb{RP}_\gamma = 2\alpha + \gamma$  for some 1-cycle  $\alpha$ . We require  $\mathbb{RP}_\gamma$  to be triangulated in such a way that  $|\text{supp}(\alpha)| = |\text{supp}(\gamma)|$ ; that is,  $\alpha$  and  $\gamma$  contain the same number of edges. Let the constant  $c$  denote the number of triangles in  $\mathbb{RP}_\gamma$ . See Figure 3 in the appendix for a triangulation of  $\mathbb{RP}_\gamma$ .

We consider a collection of disjoint complexes  $\mathbb{RP}_{\gamma_0}, \mathbb{RP}_{\gamma_1}, \dots, \mathbb{RP}_{\gamma_{n-1}}, \mathcal{D}_{\gamma_n}$ . Each  $\mathbb{RP}_{\gamma_i}$  is constructed in the same way was  $\mathbb{RP}_\gamma$ , and  $\mathcal{D}_{\gamma_n}$  triangulation of a disk using  $c$  triangles with boundary  $\gamma_n$  such that  $|\text{supp}(\gamma_n)| = |\text{supp}(\gamma)|$ . The sum of the triangles of each  $\mathbb{RP}_{\gamma_i}$  has boundary  $\partial_2 \mathbb{RP}_{\gamma_i} = 2\alpha_i + \gamma_i$ .

We consider the simplicial complex  $\mathcal{K}$  constructed by taking the quotient space under the identification  $\alpha_i \sim \gamma_{i+1}$ . That is, we glue the cycle  $\alpha_i$  in  $\mathbb{RP}_{\gamma_i}$  along the cycle  $\gamma_{i+1}$  in  $\mathbb{RP}_{\gamma_{i+1}}$ . The resulting complex contains a unique unit  $\gamma_0$ -flow  $f$ . The chain  $f$  assigns a value of 1 to each triangle in  $\mathbb{RP}_{\gamma_0}$ , a value of -2 to each triangle in  $\mathbb{RP}_{\gamma_1}$ , and in general, a value of  $(-1)^i 2^{i+1}$  to each triangle in  $\mathbb{RP}_{\gamma_i}$  and  $\mathcal{D}_{\gamma_n}$ . To see that  $f$  is indeed a unit  $\gamma_0$ -flow we compute the boundary

$$\begin{aligned} \partial f &= \left( \sum_{i=0}^{n-1} (-1)^i \cdot 2^i \partial \mathbb{RP}_{\gamma_i} \right) + (-1)^n \cdot 2^n \partial \mathcal{D}_{\gamma_n} \\ &= \left( \sum_{i=0}^{n-1} (-1)^i \cdot 2^i (\gamma_i + 2\gamma_{i+1}) \right) + (-1)^n \cdot 2^n \gamma_n \\ &= \gamma_0. \end{aligned}$$

## 31:10 Effective Resistance and Capacitance in Simplicial Complexes

The chain  $f$  is unique because the value of  $f$  must be equal to 1 on each triangle in  $\mathbb{RP}_{\gamma_0}$ , and the values on the triangles of  $\mathbb{RP}_{\gamma_i}$  determines the values on the triangles of  $\mathbb{RP}_{\gamma_{i+1}}$  and  $\mathcal{D}_{\gamma_n}$  as the  $\gamma_i$  terms must cancel out in  $\partial f$ .

As  $f$  is the unique unit  $\gamma_0$ -flow, the effective resistance of  $f$  is the flow energy of  $\gamma$ . The flow energy of  $f$  is  $J(f) = \sum_{i=0}^n c \cdot (2^i)^2 = \frac{c}{3} (2^{2n+2} - 1) = \Theta(2^{2n})$ . ◀

## 6 A Quantum Algorithm for Null-Homology Testing

In this section we provide an application of effective resistance and capacitance in simplicial complexes. We show that a quantum algorithm based on the *span program* model can be used to decide whether or not a cycle  $\gamma$  is null-homologous in a simplicial complex  $\mathcal{K}$ . An introduction to the span program model can be found in Appendix 6.1. The query complexity of this algorithm is parameterized by the maximum (finite) effective resistance and capacitance of  $\gamma$  over all subcomplexes of  $\mathcal{K}$ .

Our algorithm is a generalization of the quantum algorithm developed by Belovs and Reichardt to decide *st*-connectivity in a graph [1]. Their algorithm is parameterized by the effective resistance and capacitance of the 0-cycle  $|t\rangle - |s\rangle$  in the graph. Upper bounds on the effective resistance and capacitance imply a query complexity of  $O(n^{3/2})$ , where  $n$  is the number of vertices [12].

Our upper bounds on effective resistance and capacitance imply that the query complexity is polynomial in both the number of  $d$ -simplices as well as the cardinality of the largest torsion subgroup of a relative homology group of  $\mathcal{K}$ . In the case that  $\mathcal{K}$  is a graph, we match the  $O(n^{3/2})$  upper bound. Under the assumptions that  $\mathcal{K}$  is relative torsion free and that  $\gamma$  is the boundary of a  $d$ -simplex (which may or may not be included in the complex) we also match the  $O(n^{3/2})$  upper bound. Note that these assumptions are always true for *st*-connectivity in graphs.

### 6.1 A brief introduction to span programs

Span programs were first defined by Karchmer and Wigderson [14] and were first used for quantum algorithms by Reichardt and Špalek [24]. Intuitively, a span program is a model of computation which encodes a boolean function  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  into the geometry of two vector spaces and a linear operator between them. Encoding  $f$  into a span program implies the existence of a quantum query algorithm evaluating  $f$  (Theorem 20.)

► **Definition 18.** A *span program*  $\mathcal{P} = (\mathcal{H}, \mathcal{U}, |\tau\rangle, A)$  over the set of strings  $\{0, 1\}^n$  is a 4-tuple consisting of:

1. A finite dimensional Hilbert space  $\mathcal{H} = \mathcal{H}_1 \oplus \dots \oplus \mathcal{H}_n$  where  $\mathcal{H}_i = \mathcal{H}_{i,0} \oplus \mathcal{H}_{i,1}$ ,
2. a vector space  $\mathcal{U}$ ,
3. a non-zero vector  $|\tau\rangle \in \mathcal{U}$ , called the **target vector**
4. a linear operator  $A: \mathcal{H} \rightarrow \mathcal{U}$ .

For every string  $x = (x_1, \dots, x_n) \in \{0, 1\}^n$  we associate the Hilbert space  $\mathcal{H}(x) = \mathcal{H}_{1,x_1} \oplus \dots \oplus \mathcal{H}_{N,x_n}$  and the linear operator  $A(x) = A\Pi_{\mathcal{H}(x)}: \mathcal{H} \rightarrow \mathcal{U}$  where  $\Pi_{\mathcal{H}(x)}$  is the projection of  $\mathcal{H}$  onto  $\mathcal{H}(x)$ .

The quantum query complexity of evaluating  $\mathcal{P}$  depends on the sizes of the positive and negative witnesses, which we now define.

► **Definition 19.** Let  $\mathcal{P}$  be a span program and let  $x \in \{0, 1\}^N$ . A **positive witness** for  $x$  is a vector  $|w\rangle \in \mathcal{H}(x)$  such that  $A|w\rangle = |\tau\rangle$ . The **positive witness size** of  $x$  is

$$w_+(x, \mathcal{P}) = \min\{\| |w\rangle \|^2 : |w\rangle \in \mathcal{H}(x), A|w\rangle = |\tau\rangle\}.$$

If no positive witness exists for  $x$ , then  $w_+(x, \mathcal{P}) = \infty$ . If there is a positive witness for  $x$ , then  $x$  is a **positive instance**.

A **negative witness** for  $x$  is a linear map  $\langle w| : \mathcal{U} \rightarrow \mathbb{R}$  such that  $\langle w|A\Pi_{\mathcal{H}(x)} = 0$  and  $\langle w|\tau\rangle = 1$ . The **negative witness size** of  $x$  is

$$w_-(x, \mathcal{P}) = \min\{\|\langle w|A\|^2 : \langle w| : \mathcal{U} \rightarrow \mathbb{R}, \langle w|A\Pi_{\mathcal{H}(x)} = 0, \langle w|\tau\rangle = 1\}.$$

If no negative witness exists for  $x$ , then  $w_-(x, \mathcal{P}) = \infty$ . If there is a negative witness for  $x$ , then  $x$  is a **negative instance**.

A string  $x \in \{0, 1\}^N$  will either be a positive or negative instance of  $\mathcal{P}$ . A span program  $\mathcal{P}$  **decides** the function  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  if  $f(x) = 1$  when  $x$  is a positive instance and  $f(x) = 0$  when  $x$  is a negative instance. A span program can also evaluate a partial boolean function  $g: D \rightarrow \{0, 1\}$  where  $D \subset \{0, 1\}^n$  by the same criteria.

Span programs are a popular method in quantum computing because there are upper bounds on the complexity of evaluating span programs in the **query model**. The query model evaluates the complexity of a quantum algorithm by its **query complexity**, the number of times it queries an input oracle. In our case, the input oracle returns the bits of the binary string  $x$ . The **input oracle**  $\mathcal{O}_x$  takes  $\mathcal{O}_x: |i\rangle|b\rangle \rightarrow |i\rangle|b \oplus x_i\rangle$  where  $i \in [N]$ . Observe that the states  $|i\rangle$  can be stored on  $\lceil \log N \rceil$  qubits. Reichardt [25] showed that the query complexity of a span program is a function of the positive and negative witness sizes of the program.

► **Theorem 20** (Reichardt [25]). Let  $D \subset \{0, 1\}^N$  and  $f: D \rightarrow \{0, 1\}$ . Let  $\mathcal{P}$  be a span program that decides  $f$ . Let  $W_+(f, \mathcal{P}) = \max_{x \in f^{-1}(1)} w_+(x, \mathcal{P})$  and  $W_-(f, \mathcal{P}) = \max_{x \in f^{-1}(0)} w_-(x, \mathcal{P})$ . There is a bounded error quantum algorithm that decides  $f$  with query complexity  $O\left(\sqrt{W_+(f, \mathcal{P})W_-(f, \mathcal{P})}\right)$ .

A caveat to the query complexity model is that in general the time complexity of an algorithm can be much larger than the query complexity. We will provide details on bounding the time complexity of our problem in Section A.

## 6.2 A span program to decide if a cycle is null-homologous

In this section we present a span program for testing if a cycle is null-homologous in a simplicial complex. This span program is a generalization of the span program for  $st$ -connectivity defined in [14] and used to develop quantum algorithms in [1, 2, 12, 13]. Let  $\mathcal{K}$  be a  $d$ -dimensional simplicial complex. Let  $|\gamma\rangle \in C_{d-1}(\mathcal{K})$  be a  $(d-1)$ -cycle. Let  $n$  be the number of  $d$ -simplices in  $\mathcal{K}$ . Order the  $d$ -simplices  $\{\sigma_1, \dots, \sigma_n\}$ . Let  $w: \mathcal{K}_d \rightarrow \mathbb{R}$  be a weight function on the  $d$ -simplices. We define a span program over the strings  $\{0, 1\}^n$  in the following way.

1.  $\mathcal{H} = C_d(\mathcal{K})$ , with  $\mathcal{H}_{i,1} = \text{span}\{|\sigma_i\rangle\}$  and  $\mathcal{H}_{i,0} = \{0\}$ .
2.  $\mathcal{U} = C_{d-1}(\mathcal{K})$
3.  $A = \partial_d \sqrt{W}: C_d(\mathcal{K}) \rightarrow C_{d-1}(\mathcal{K})$
4.  $|\tau\rangle = \gamma$

## 31:12 Effective Resistance and Capacitance in Simplicial Complexes

We denote the above span program by  $\mathcal{P}_{\mathcal{K}}$ . Let  $x \in \{0, 1\}^N$  be a binary string. We define the subcomplex  $\mathcal{K}(x) := \mathcal{K}^{d-1} \cup \{\sigma_i : x_i = 1\}$ . That is,  $\mathcal{K}(x)$  contains the  $d$ -simplices  $\sigma_i$  such that  $x_i = 1$ . There exists a solution to the linear system  $\partial_d \sqrt{W} \Pi_{\mathcal{K}(x)} |v\rangle = |\gamma\rangle$  if and only if the cycle  $|\gamma\rangle$  is null-homologous in  $\mathcal{K}(x)$  if and only if  $x$  is a positive instance of  $\mathcal{P}_{\mathcal{K}}$ . The span program  $\mathcal{P}_{\mathcal{K}}$  decides the boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  where  $f(x) = 1$  if and only if  $\gamma$  is a null-homologous cycle in the subcomplex  $\mathcal{K}(x)$ .

Given a string  $x \in \{0, 1\}^n$  we show in the following two lemmas that  $w_+(x, \mathcal{P}_{\mathcal{K}}) = \mathcal{R}_{\gamma}(\mathcal{K}(x))$  and  $w_-(x, \mathcal{P}_{\mathcal{K}}) = \mathcal{C}_{\gamma}(\mathcal{K}(x))$ . The proofs are simple calculations following from the definitions of effective resistance and capacitance.

► **Lemma 21.** *Let  $x \in \{0, 1\}^N$  be a positive instance. There is a bijection between positive witnesses  $|w\rangle$  for  $x$  and unit  $\gamma$ -flows  $|f\rangle$  in  $\mathcal{K}(x)$ . Moreover, the positive witness size is equal to the effective resistance of  $\gamma$  in  $\mathcal{K}(x)$ ; that is,  $w_+(x, \mathcal{P}_{\mathcal{K}}) = \mathcal{R}_{\gamma}(\mathcal{K}(x))$ .*

**Proof.** Let  $|w\rangle \in C_d(\mathcal{K})$  be a positive witness for  $x$ , so  $\partial_d \sqrt{W} |w\rangle = |\gamma\rangle$ . We construct a unit  $\gamma$ -flow  $|f\rangle$  in  $\mathcal{K}(x)$  by  $|f\rangle = \sqrt{W} |w\rangle$ ;  $|f\rangle$  is indeed a unit  $\gamma$ -flow as  $\partial_d |f\rangle = \partial_d \sqrt{W} |w\rangle = |\gamma\rangle$ . Moreover,  $|w\rangle = W^{-1/2} |f\rangle$ . The flow energy of  $\gamma$  is  $J(f) = \langle f | W^{-1} |f\rangle = \langle W^{-1/2} f | W^{-1/2} f \rangle = \langle w | w \rangle = \| |w\rangle \|^2$ . Hence, the flow energy of  $|f\rangle$  equals the witness size of  $|w\rangle$ . Conversely, let  $|f\rangle$  be a unit  $\gamma$ -flow in  $\mathcal{K}(x)$  and define the positive witness for  $x$  as  $|w\rangle = W^{-1/2} |f\rangle$ . The same computation in the above paragraph shows that the flow energy of  $f$  equals the positive witness size of  $|w\rangle$ . ◀

► **Lemma 22.** *Let  $x \in \{0, 1\}^N$  be a negative instance. There is a bijection between negative witnesses  $\langle w |$  for  $x$  and unit  $\gamma$ -potentials  $\langle p |$  in  $\mathcal{K}(x)$ . Moreover, the negative witness size is equal to the effective capacitance of  $\gamma$  in  $\mathcal{K}(x)$ ; that is,  $w_-(x, \mathcal{P}_{\mathcal{K}}) = \mathcal{C}_{\gamma}(\mathcal{K}(x))$ .*

**Proof.** Let  $\langle w |$  be a negative witness for  $x$ . We will verify that  $\langle w |$  is a unit  $\gamma$ -potential. We have by the definition of negative witness that  $\langle w | \gamma \rangle = 1$ . We must show that the coboundary of  $\langle w |$  is zero in  $\mathcal{K}(x)$ . By the definition of a negative witness we have  $\langle w | \partial_d \sqrt{W} \Pi_{\mathcal{K}(x)} = 0$ . Since  $\sqrt{W}$  is a diagonal matrix and  $\Pi_{\mathcal{K}(x)}$  restricts the coboundary to the subcomplex  $\mathcal{K}(x)$ , we see that  $\langle w | \partial_d \sigma = 0$  for any  $\sigma \in \mathcal{K}(x)_d$ . To show that the witness size of  $\langle w |$  is equal to the potential energy, we have

$$\begin{aligned} \|\langle w | \partial_d \sqrt{W}\|^2 &= \langle w | \partial_d \sqrt{W} \sqrt{W} \partial_d^T |w\rangle \\ &= \langle \delta_{d-1} w | W | \delta_{d-1} w \rangle \\ &= \mathcal{J}(w). \end{aligned}$$

Conversely, let  $\langle p |$  be a unit  $\gamma$ -potential for  $\mathcal{K}(x)$ . We will prove that  $\langle p |$  is a negative witness for  $\gamma$ . Since the coboundary of  $\langle p |$  is zero in  $\mathcal{K}(x)$  we have  $\langle \delta p | \sigma \rangle = 0$  for each  $\sigma \in \mathcal{K}(x)_d$ , which implies  $\langle p | \partial_d \sqrt{W} \Pi_{\mathcal{K}(x)} = 0$  by the reasoning in the previous paragraph. Also by the previous paragraph, we have that the potential energy of  $\langle p |$  is equal to the negative witness size of  $\langle p |$  which concludes the proof. ◀

From these two lemmas we obtain the main theorem of the section, the quantum query complexity of the span program.

► **Theorem 23.** *Given a  $d$ -dimensional simplicial complex  $\mathcal{K}$ , a  $(d-1)$ -dimensional cycle  $\gamma$  that is null-homologous in  $\mathcal{K}$ , and a  $d$ -dimensional subcomplex  $\mathcal{K}(x) \subseteq \mathcal{K}$ , there exists a quantum algorithm deciding whether or not  $\gamma$  is null-homologous in  $\mathcal{K}(x)$  whose quantum query complexity is  $O\left(\sqrt{\mathcal{R}_{\max}(\gamma) \mathcal{C}_{\max}(\gamma)}\right)$ , where  $\mathcal{R}_{\max}$  is the maximum effective resistance of  $\gamma$  in any subcomplex  $\mathcal{K}(y)$  and  $\mathcal{C}_{\max}$  is the maximum effective capacitance of  $\gamma$  in any subcomplex  $\mathcal{K}(y)$ .*

**Proof.** By Theorem 20, the span program  $\mathcal{P}_{\mathcal{K}}$  can be converted into a quantum algorithm whose query complexity is  $O\left(\sqrt{W_+(f, \mathcal{P}_{\mathcal{K}})W_-(f, \mathcal{P}_{\mathcal{K}})}\right)$  where  $W_+(f, \mathcal{P}_{\mathcal{K}}) = \max_{x \in f^{-1}(1)} \mathcal{R}_{\gamma}(\mathcal{K}(x)) = \mathcal{R}_{\max}(\gamma)$  and  $W_-(f, \mathcal{P}_{\mathcal{K}}) = \max_{x \in f^{-1}(0)} \mathcal{C}_{\gamma}(\mathcal{K}(x)) = \mathcal{C}_{\max}(\gamma)$ . ◀

By Theorems 14 and 16 we obtain an upper bound on the query complexity parameterized by the number of simplices and the cardinality of the torsion subgroups of the relative homology groups.

► **Theorem 24.** *Let  $\mathcal{K}$  be an unweighted  $d$ -dimensional simplicial complex and  $\mathcal{K}(x)$  a  $d$ -dimensional subcomplex  $\mathcal{K}(x) \subseteq \mathcal{K}$ . Let  $\hat{\gamma} \in C_{d-1}(\mathcal{K})$  be a  $(d-1)$ -cycle such that  $\hat{\gamma}$  is integral and each of the coefficients  $|\hat{\gamma}_i| = O(1)$ . There exists a quantum algorithm deciding whether or not  $\gamma := \hat{\gamma}/\|\hat{\gamma}\|$  is null-homologous in  $\mathcal{K}(x)$  whose quantum query complexity is  $O(n^{5/2} \cdot d^{1/2} \cdot \mathcal{T}_{\max}(\mathcal{K})^2)$ .*

Finally, we state the query complexity under some assumptions that arise in the case of  $st$ -connectivity in graphs. In this case, the input cycle is  $|t\rangle - |s\rangle$ , and the support of  $|t\rangle - |s\rangle$  is equal to 2. A factor of  $n$  in both the upper bounds on resistance and capacitance is actually a factor of  $|\text{supp}(\gamma)|$  as seen in the proofs of these bounds. Under the assumption that the support of  $\gamma$  is bounded above by  $O(d)$ , we can replace a factor of  $n$  from both the flow energy and potential energy of any unit  $\gamma$ -flow and unit  $\gamma$ -potential with a factor of  $d$ . This assumption on the size of  $\text{supp}(\gamma)$  is true when  $\gamma$  is the boundary of a  $d$ -simplex.

Furthermore, graphs do not contain relative torsion<sup>4</sup>, so we make the additional assumption that  $\mathcal{K}$  is relative torsion-free. Under these assumptions our query complexity matches the query complexity arising from the span program deciding  $st$ -connectivity.

► **Corollary 25.** *Let  $\mathcal{K}$  be an unweighted  $d$ -dimensional simplicial complex and  $\mathcal{K}(x) \subseteq \mathcal{K}$  be a  $d$ -dimensional subcomplex. Let  $\hat{\gamma} \in C_{d-1}(\mathcal{K})$  be a  $(d-1)$ -cycle such that  $\hat{\gamma}$  is integral and each of the coefficients  $|\hat{\gamma}_i| = O(1)$ . Further assume that  $\mathcal{K}$  is relative torsion-free and  $|\text{supp}(\gamma)| = O(d)$ . There exists a quantum algorithm deciding whether or not  $\gamma := \hat{\gamma}/\|\hat{\gamma}\|$  is null-homologous in  $\mathcal{K}(x)$  whose quantum query complexity is  $O((dn)^{3/2})$ .*

### 6.3 Time efficient implementations

We have given bounds on the query complexity of null-homology testing; however, this does not imply a bound on the time complexity of evaluating this span program. There are two obstacles to a time-efficient implementation of the span program: the weights and the input cycle  $\gamma$ . The weights on the  $d$ -simplices make it difficult to implement the matrix  $\partial\sqrt{W}$ , as the weights on the simplices can be arbitrary real numbers. The input cycle  $\gamma$  is difficult to create on a quantum computer for the same reason, as the entries of  $\gamma$  can also be arbitrary real numbers. We explore the implementation details of this algorithm in the appendix.

We can give a quantum algorithm of bounded time complexity in one particular instance: when  $\mathcal{K}$  is unweighted and  $\gamma$  is the boundary of a  $d$ -simplex. We do not require said  $d$ -simplex to actually appear in the complex. The time complexity of this case is given in the following theorem.

<sup>4</sup> Graphs do not have relative torsion as the boundary matrix of a graph  $\partial_1[G]$  is *totally unimodular*. See Section 5.1 of the paper [5] for an explanation of the relationship between total unimodularity of the boundary matrix and relative torsion of a simplicial complex.

► **Theorem 26.** Let  $\mathcal{K}$  be a simplicial complex,  $\gamma \in C_{d-1}(\mathcal{K})$  a null-homologous cycle, and  $\mathcal{K}(x) \subset \mathcal{K}$  be a simplicial complex. Furthermore, assume that  $\gamma$  is the boundary of a  $d$ -simplex and the complex is unweighted. There is a quantum algorithm for deciding if  $\gamma$  is null-homologous in  $\mathcal{K}(x)$  that runs in time  $\tilde{O}\left(\frac{(dn)^{3/2} \cdot \mathcal{T}_{\max}(\mathcal{K})^2}{\sqrt{\lambda}} \left(\sqrt{d} + \sqrt{d_{\max}}\right) + \left(\sqrt{\frac{1}{\mathcal{R}_\gamma(\mathcal{K})}} + \sqrt{\mathcal{R}_\gamma(\mathcal{K})}\right) \left(\sqrt{d} + \sqrt{d_{\max}}\right)\right)$  where  $d_{\max}$  is the maximum degree of a  $(d-1)$ -simplex in  $\mathcal{K}$  and  $\lambda$  is the smallest eigenvalue of the normalized up-Laplacian.

The factor of  $\tilde{O}\left(\left(\sqrt{\frac{1}{\mathcal{R}_\gamma(\mathcal{K})}} + \sqrt{\mathcal{R}_\gamma(\mathcal{K})}\right) + \left(\sqrt{d} + \sqrt{d_{\max}}\right)\right)$  comes from the time necessary to create the initial state to the algorithm. Assuming such a state is already provided the running time reduces to  $\tilde{O}\left(\frac{(dn)^{3/2} \cdot \mathcal{T}_{\max}(\mathcal{K})^2}{\sqrt{\lambda}} \left(\sqrt{d} + \sqrt{d_{\max}}\right)\right)$ .

We can get a tighter analysis when  $\mathcal{K}$  is a pseudomanifold. When  $\mathcal{K}$  is a pseudomanifold, the maximum degree  $d_{\max} \leq 2$  and the running time reduces to  $\tilde{O}\left(\frac{d^2 \cdot n^{3/2} \cdot \mathcal{T}_{\max}(\mathcal{K})^2}{\sqrt{\lambda}}\right)$ . Steenbergen, Klivans, and Mukherjee provide a lower bound on  $\lambda$  for pseudomanifolds similar to the Cheeger inequality for graphs [28]. Their lower bound is in terms of the **boundary expansion** of the complex which is defined as  $h_d := \min_{\phi \in C_d(\mathbb{Z}_2)} \frac{\|\partial_d \phi\|}{\min_{\psi \in \text{im } \partial_{d+1}} \|\phi + \psi\|}$ . For pseudomanifolds they prove a lower bound of  $\lambda \geq \frac{h_d^2}{2(d+1)}$ .

Finally, in the case of graphs there is no relative torsion and we can state the running time as  $\tilde{O}\left(\frac{n^{3/2}}{\sqrt{\lambda}}\right)$  where  $\lambda$  is bounded below by the well-known Cheeger inequality.

## A

 Evaluating the span program for null-homology

In this section, we give a quantum algorithm for evaluating the null-homology span program. Our algorithm is inspired by the quantum algorithm for evaluating  $st$ -connectivity span program in graphs. The first quantum algorithm for evaluating the  $st$ -connectivity span program was given by Belovsz and Reichardt in [1]; however, we follow the slightly different algorithm introduced by Ito and Jefferies in [11]. We are also greatly indebted to the presentation of this algorithm given by Jeffery and Kimmel in [13].

The algorithm for evaluating a general span program  $\mathcal{P} = (\mathcal{H}, \mathcal{U}, |\tau\rangle, A)$  is to perform phase estimation of the vector  $|w_0\rangle := A^+|\tau\rangle$  on the unitary operator  $U = R_{\mathcal{H}(x)}R_{\ker A}$  where the notation  $R_S$  denotes the reflection about the subspace  $S$ . (The unitary  $R_S = 2\Pi_S - I$ , where  $\Pi_S$  is the projection onto  $S$ .) Intuitively, if  $x$  is a positive instance, then  $|w_0\rangle$  will be close to an eigenvector of  $U$  with phase 0. If  $x$  is a negative instance, then  $|w_0\rangle$  will be far from any eigenvector of  $U$  of phase 0. If we want to evaluate the function  $f : D \rightarrow \{0, 1\}$ , we need to perform phase estimation to precision  $O\left(1/\sqrt{W_-(f, \mathcal{P})W_+(f, \mathcal{P})}\right)$ . The algorithm for phase estimation of a unitary  $U$  to precision  $O(\delta)$  performs  $O(1/\delta)$  implementations of the unitary  $U$  [16], so the algorithm for evaluating the span program  $\mathcal{P} = (\mathcal{H}, \mathcal{U}, |\tau\rangle, A)$  requires  $O\left(\sqrt{W_-(f, \mathcal{P})W_+(f, \mathcal{P})}\right)$  implementations of  $U$ .

We now analyze the time complexity of implementing the unitary  $U$ . The reflection  $R_{\mathcal{H}(X)}$  can be implemented with one query to  $\mathcal{O}_x$ . This reflection is the same as the reflection across the good states in Grover's Algorithm. The rest of this section is devoted to an implementation of  $R_{\ker \partial}$ .

Recall that  $\ker \partial_d \subset C_d(\mathcal{K})$ . The idea behind the implementation of  $R_{\ker \partial}$  is that instead of reflecting across  $\ker \partial_d$  directly, we can embed  $C_d(\mathcal{K})$  into  $C_{d-1}(\mathcal{K}) \otimes C_d(\mathcal{K})$  by sending  $|\tau\rangle \rightarrow c|\partial\tau\rangle|\tau\rangle$  (where  $c$  is a normalization constant). We can then implement the reflection  $R_{\ker \partial}$  by implementing a series of "local reflections" on the basis  $|\partial\tau\rangle|\tau\rangle$ .

We consider two subspaces  $B$  and  $C$  of  $C_{d-1}(\mathcal{K}) \otimes C_d(\mathcal{K})$ . The spaces  $B$  and  $C$  are defined:

$$B = \text{span} \left\{ |b_\tau\rangle := \frac{1}{\sqrt{d+1}} |\partial\tau\rangle|\tau\rangle : \tau \in \mathcal{K}_d \right\}$$

and

$$C = \text{span} \left\{ |c_\sigma\rangle := \sum_{\sigma \subset \tau} \sqrt{\frac{w(\sigma)}{\deg(\sigma)}} |\sigma\rangle|\tau\rangle : \sigma \in \mathcal{K}_{d-1} \right\}.$$

The space  $C_{d-1}(\mathcal{K}) \otimes C_d(\mathcal{K})$  has basis  $\{|\sigma\rangle|\tau\rangle \mid \sigma \in \mathcal{K}_{d-1}, \tau \in \mathcal{K}_d\}$ . The vector  $|b_\tau\rangle$  is non-zero on a basis element  $|\sigma\rangle|\tau\rangle$  if and only if  $\sigma$  is on the boundary of  $\tau$ . Similarly, a component of  $|c_\sigma\rangle$  is non-zero on  $|\sigma\rangle|\tau\rangle$  if and only if  $\tau$  is on the coboundary of  $\sigma$ . The vector  $|b_\tau\rangle$  can be thought of as being *like* the boundary of  $\tau$ , with the additional property that the set  $\{|b_\tau\rangle \mid \tau \in C_d(\mathcal{K})\}$  is orthonormal. Similarly, the vector  $|c_\sigma\rangle$  is *like* the coboundary of  $\sigma$  but orthonormal.

We also define operators that embed  $C_d(\mathcal{K})$  and  $C_{d-1}(\mathcal{K})$  into  $B$  and  $C$  respectively. We define linear operators  $M_B : C_d(\mathcal{K}) \rightarrow B$  and  $M_C : C_{d-1}(\mathcal{K}) \rightarrow C$  as follows:

$$M_B := \sum_{\tau \in \mathcal{K}_d} |b_\tau\rangle\langle\tau|,$$

and

$$M_C := \sum_{\sigma \in \mathcal{K}_{d-1}} |c_\sigma\rangle\langle\sigma|.$$

As the columns of  $M_B$  and  $M_C$  are orthonormal, both operators are isometries.

We introduce the matrices  $M_C$  and  $M_B$  as they have the property that  $\ker M_C^\dagger M_B = \ker \partial$ , which we prove in the follow lemma. This fact will give us a way to implement  $R_{\ker \partial}$ .

► **Lemma 27.**  $\ker M_C^\dagger M_B = \ker \partial$ .

**Proof.** We first calculate the matrix  $M_C^\dagger M_B$ . We then argue that  $\ker M_C^\dagger M_B = \ker \partial$ . For a  $(d-1)$ -simplex  $\sigma$  and a  $d$ -simplex  $\tau$ , we have that

$$\langle c_\sigma | b_\tau \rangle = \sum_{\tau' \in \mathcal{K}_d: \sigma \subset \tau'} \frac{w(\tau)}{\sqrt{\deg(\sigma)}} \langle \sigma | \partial \tau \rangle \langle \tau' | \tau \rangle = \begin{cases} \sqrt{\frac{w(\tau)}{(d+1)\deg(\sigma)}} \langle \sigma | \partial \tau \rangle & \text{if } \sigma \subset \tau \\ 0 & \text{otherwise} \end{cases}.$$

So  $\langle c_\sigma | b_\tau \rangle$  is non-zero if and only if  $\sigma$  is in the boundary of  $\tau$ . We use this to calculate the product  $M_C^\dagger M_B$ :

$$\begin{aligned} M_C^\dagger M_B &= \sum_{\sigma \in \mathcal{K}_{d-1}} \sum_{\tau \in \mathcal{K}_d} |\sigma\rangle \langle c_\sigma | b_\tau \rangle \langle \tau | \\ &= \frac{1}{\sqrt{(d+1)}} \sum_{\sigma \subset \tau} \frac{\sqrt{w(\tau)} \langle \sigma | \partial \tau \rangle}{\sqrt{\deg(\sigma)}} |\sigma\rangle \langle \tau | \\ &= \frac{1}{\sqrt{(d+1)}} \left( \sum_{\sigma \in \mathcal{K}_{d-1}(\mathcal{K})} \frac{|\sigma\rangle \langle \sigma |}{\sqrt{\deg(\sigma)}} \right) \sum_{\tau \in \mathcal{K}_d} \sqrt{w(\tau)} |\partial \tau\rangle \langle \tau | \\ &= \frac{1}{\sqrt{(d+1)}} \left( \sum_{\sigma \in \mathcal{K}_{d-1}(\mathcal{K})} \frac{|\sigma\rangle \langle \sigma |}{\sqrt{\deg(\sigma)}} \right) \partial \sqrt{W} =: \hat{\partial}. \end{aligned}$$

The term  $\frac{|\sigma\rangle \langle \sigma |}{\sqrt{\deg(\sigma)}}$  is all-zeros matrix except for the  $(\sigma, \sigma)$ -entry, which is  $\frac{1}{\sqrt{\deg(\sigma)}}$ . The sum  $\sum_{\sigma \in \mathcal{K}_{d-1}} \frac{|\sigma\rangle \langle \sigma |}{\sqrt{\deg(\sigma)}}$  is a diagonal matrix. Accordingly, the matrix  $\hat{\partial}$  is  $\partial \sqrt{W}$  with each row scaled. Scaling the rows of a matrix does not change its row space or kernel, so  $\ker M_C^\dagger M_B = \ker \partial$ . ◀

The spaces  $B$  and  $C$  and the matrices  $M_B$  and  $M_C$  are inspired by the follow lemma of Szegedy which is necessary for implementing  $R_{\ker \partial}$ .

► **Lemma 28** (Szegedy [29], Theorem 1). *Let  $M_B$  and  $M_C$  be matrices with the same number of rows and orthonormal columns, and let  $B = \text{span } M_B$  and  $C = \text{span } M_C$ . The matrix  $M_C^\dagger M_B$  has singular values at most 1. Let  $\cos \theta_1, \dots, \cos \theta_k$  be the singular values of  $M_C^\dagger M_B$  in the range  $(0, 1)$ . Let  $U = R_C R_B$ . We can decompose the eigenspaces of  $U$  as*

- The  $(+1)$ -eigenspace of  $U$  is  $(B \cap C) \oplus (B^\perp \cap C^\perp)$ .
- The  $(-1)$ -eigenspace of  $U$  is  $(B \cap C^\perp) \oplus (B^\perp \cap C)$ .
- The remaining eigenvalues of  $U$  are  $e^{\pm 2i\theta_j}$  for  $1 \leq j \leq k$ .

The following lemma gives us a way to implment the  $R_{\ker \partial}$ . Let  $R_{U^-}$  be the rotation about  $(-1)$ -eigenspace of  $U$ , and let  $V = M_B^\dagger R_{U^-} M_B$ . The matrix  $V$  embeds  $C_d(\mathcal{K})$  into  $B$  with  $M_B$ , performs a reflection on  $B$  about the  $(-1)$ -eigenspace of  $U$ , and unembeds with  $M_B^\dagger$ . The following lemma proves that  $V = R_{\ker \partial}$ .

► **Lemma 29.** *The matrix  $V = M_B^\dagger R_{U^-} M_B$  satisfies the equality  $V = R_{\ker \partial}$ .*

**Proof.** We first verify that  $V$  is a reflection; that is, we show the eigenvalues of  $V$  are 1 and  $-1$ . The matrices  $M_B$  and  $M_C$  have orthonormal columns, so we can use Lemma 28 to characterize the eigenspaces of  $U$ . The  $(-1)$ -eigenspace of  $U$  is  $(B \cap C^\perp) \oplus (B^\perp \cap C)$  and the  $(+1)$ -eigenspace of  $U$  is  $(B \cap C) \cap (B^\perp \cap C^\perp)$ . As the spaces  $(B \cap C)$  and  $(B \cap C^\perp)$  span  $B$ ,

then  $R_{U^-}$  restricted to  $B$  has eigenvalues 1 and  $-1$ . As  $B = \text{im } M_B$  and  $V = M_B^\dagger R_{U^-} M_B$ , then we conclude that  $V$  has eigenvalues 1 and  $-1$  as well.

Now that we have determined that  $V$  is a reflection, we need to determine which subspace  $V$  reflects across. A corollary of the previous paragraph is that a vector  $|\psi\rangle \in C_d(\mathcal{K})$  is in the  $(+1)$ -eigenspace of  $V$  if and only if  $M_B|\psi\rangle$  is in the  $(-1)$ -eigenspace of  $U$ . Specifically, a vector  $|\psi\rangle$  is in the  $(+1)$ -eigenspace of  $V$  if and only if  $M_B|\psi\rangle \in C^\perp$ . As  $C^\perp = \ker M_C^\dagger$ , the vector  $|\psi\rangle$  is in the  $(+1)$ -eigenspace of  $V$  if and only if  $|\psi\rangle \in \ker M_C^\dagger M_B$ . We proved in Lemma 27 that  $\ker M_C^\dagger M_B = \ker \partial$ , so we conclude that  $V = R_{\ker \partial}$   $\blacktriangleleft$

We have a matrix  $V$  that implements  $R_{\ker \partial}$ ; next, we analyze the complexity of implementing  $V$ . We start by analyzing the complexity of implementing  $R_{U^-}$ , the reflection across the  $(-1)$ -eigenspace of  $U$ .

We implement the reflection around the  $(-1)$ -eigenspace of  $U$  using phase estimation, an algorithm introduced by Magniez et al. [19]. The algorithm is as follows. We first estimate the phase of  $U$  to some degree of accuracy to be specified shortly. Intuitively, we need to estimate the phase of  $U$  to high enough accuracy to distinguish between  $-1$  eigenvalues of  $U$  and eigenvalues of  $U$  close to  $-1$ . We then perform a reflection controlled on the estimated phase.

The **phase gap** of a unitary  $U$  with eigenvalues  $\{e^{i\theta_1}, \dots, e^{i\theta_k}\}$  is  $\min\{|\theta_i| : \theta_i \neq 0\}$ . The following lemma shows that the phase gap determines the complexity of reflecting across the 1-eigenspace of  $U$ .

► **Lemma 30** (Magniez et al. [19], Paraphrase of Theorem 6). *Let  $U$  be a unitary with phase gap  $\theta$ . A reflection around the 1-eigenspace of  $U$  can be performed to constant precision with  $O(\frac{1}{\theta})$  applications of  $U$ .*

The phase gap measures gap between the 1-eigenspace of a unitary and all other eigenvalues. We are interested in the gap in phase between the  $(-1)$ -eigenspace of  $U$  and the other eigenvalues of  $U$ . This is precisely the phase gap of  $-U$ . The following lemma analyzes the phase gap of  $-U$  and gives the complexity of reflecting about the  $(-1)$ -eigenspace of  $U$ .

► **Lemma 31.** *We can implement  $R_{U^-}$  with  $O\left(\sqrt{\frac{d+1}{\lambda}}\right)$  calls to  $U$ , where  $\lambda$  is the smallest non-zero eigenvalue of the normalized up-Laplacian.*

**Proof.** We need to calculate the phase gap of  $-U$  to determine the precision to which we need to estimate the phase of  $U$ . Observe that if  $\theta$  is the phase of an eigenvalue of  $U$ , then  $\theta + \pi$  is the phase of an eigenvalue of  $-U$ . We can bound the phase gap of  $-U$  using Lemma 28. The non-zero eigenvalues of  $U$  are  $\{e^{\pm i2\theta_j}\}_j$ , where  $\{\cos \theta_j\}_j$  were the singular values of  $M_C^\dagger M_B$ . Therefore, the phases of  $-U$  are  $\{\pm|\pi - 2\theta_j|\}_j$ . Using the inequality that  $\pi/2 - \theta_j \geq \cos \theta_j$  for  $\theta_j \in [0, \pi/2]$ , then the phase gap of  $-U$  is bounded below by

$$|\pi - 2\theta_j| \geq 2 \cos \theta_j \geq 2 \cdot \sigma_{\min}(M_C^\dagger M_B)$$

where  $\sigma_{\min}(M_C^\dagger M_B)$  is the smallest singular value of  $M_C^\dagger M_B$ .

We can actually relate the smallest singular value of  $M_C^\dagger M_B$  to something more meaningful. By the proof of Lemma 27, the matrix  $M_C^\dagger M_B = \frac{1}{\sqrt{d+1}} D^{-1/2} \partial \sqrt{W}$ , where  $D$  is the diagonal matrix with the degrees of the  $(d-1)$ -simplices on the diagonal. Thus,  $(M_C^\dagger M_B)(M_C^\dagger M_B)^\dagger = \frac{1}{d+1} D^{-1/2} \partial W \delta D^{-1/2} = \frac{1}{d+1} D^{-1/2} L D^{-1/2}$ . Recall from Section 2 that the matrix  $D^{-1/2} L D^{-1/2}$  is the normalized up-Laplacian. The singular values of a matrix  $A$  are the square roots of the eigenvalues of  $AA^T$ . Thus, the smallest singular value of  $M_C^\dagger M_B$ ,

and the phase gap of  $-U$ , is  $\Omega\left(\sqrt{\frac{\lambda}{d+1}}\right)$ , where  $\lambda$  is the smallest eigenvalue of  $\Delta$ . Therefore, by Lemma 30, we can implement  $R_{U^-}$  with  $O\left(\sqrt{\frac{d+1}{\lambda}}\right)$  calls to  $U$ . ◀

We are almost ready to give the running time for  $V = R_{\ker \partial}$ , but first, we need to make a delicate distinction. The matrices  $M_B$  and  $M_C$  have orthonormal columns, but they are *not* unitary. We can see this as  $\ker M_B^\dagger \neq 0$  and  $\ker M_C^\dagger \neq 0$ . As  $M_B$  and  $M_C$  are not unitary, they cannot be implemented on a quantum computer. Fortunately, it suffices to implement unitaries  $U_B$  and  $U_C$  such that  $U_B|_{C_d(\mathcal{K})} = M_B$  and  $U_C|_{C_{d-1}(\mathcal{K})} = M_C$ . Now we can give the running time for  $V = R_{\ker \partial}$ .

► **Lemma 32.** *There is an algorithm to perform  $R_{\ker \partial}$  in time  $\tilde{O}\left(\sqrt{\frac{d+1}{\lambda}}(T_B + T_C)\right)$ , where  $T_B$  and  $T_C$  are the times to perform  $U_B$  and  $U_C$  respectively.*

**Proof.** Lemma 29 shows that  $R_{\ker \partial} = V = M_B^\dagger R_{U^-} M_B$ . We can equivalently run  $U_B^\dagger R_{U^-} U_B$ . As  $U_B$  takes  $T_B$  by definition, we only need to show we can implement  $R_{U^-}$  in  $\tilde{O}\left(\sqrt{(d+1)/\lambda}(T_B + T_C)\right)$  time. Lemma 31 shows we can implement  $R_{U^-}$  with  $O(\sqrt{(d+1)/\lambda})$  calls to  $U$ , so we need to show we can implement  $U$  in  $\tilde{O}(T_B + T_C)$ . The unitary  $U = R_C R_B$ , and we claim we can implement  $R_C$  and  $R_B$  in  $\tilde{O}(T_B)$  and  $\tilde{O}(T_C)$  respectively. We can implement  $R_B$  as  $U_B R_{\mathcal{K}_d} U_B^\dagger$ , where  $R_{\mathcal{K}_d}$  reflects across the basis states  $\{|0\rangle|\sigma\rangle \mid \sigma \in \mathcal{K}_d\}$ . We can check if a quantum state is of the form  $|0\rangle|\sigma\rangle$  in  $O(\log n_d)$  gates (specifically, by checking if the basis state is within a certain range), so the unitary  $R_{\mathcal{K}_d}$  takes  $O(\log n_d)$  gates, and  $R_B$  takes  $\tilde{O}(T_B)$  time. The unitary  $R_C$  takes  $\tilde{O}(T_C)$  time by the same argument. ◀

The running time  $T_B$  is dependent on how the boundary maps are loaded into the quantum algorithm. We propose a method of storing the boundary maps in a quantum computer called the **incidence array**. The incidence array is adapted from the *adjacency array* introduced by Durr et al. in [7] to store the adjacency between pairs of vertices in a graph.

For a  $d$ -simplex  $\tau = \{v_0, \dots, v_d\}$ , the **down-incidence array** is the function  $g : |\tau\rangle|j\rangle|0\rangle \rightarrow |\tau\rangle|j\rangle|\tau \setminus \{v_j\}\rangle$  for  $0 \leq j \leq d$ . The simplices in the boundary of  $\tau$  have alternating sign. To address this, we also perform a negation conditioned on the parity of  $|j\rangle$  to compute  $(-1)^j |\tau\rangle|j\rangle|\tau \setminus \{v_j\}\rangle$ .

Durr et al. [7] claim that queries to the incidence array can be performed in logarithmic time. As the down-incidence array is identical to the adjacency array<sup>5</sup>, queries to the down-incidence also take logarithmic time. We can compute the state  $|\partial\tau\rangle|\tau\rangle$  with the down-incidence array and the following lemma.

► **Lemma 33** (Cade, Montanaro, Belovs [2], Implicit in the proof of Lemma 2). *Let  $f : [m] \rightarrow [k]$  be a function, and let  $\mathcal{O}_f$  be an oracle that computes  $\mathcal{O}_f : |i\rangle|0\rangle \rightarrow |i\rangle|f(i)\rangle$ . The state  $\frac{1}{\sqrt{m}} \sum_{i=1}^m |f(i)\rangle$  can be computed with  $O(\sqrt{m})$  queries to  $\mathcal{O}_f$  and  $O(\text{polylog}(m))$  additional gates.*

► **Corollary 34.** *The unitary  $U_B$  can be implemented in  $O(\sqrt{d})$  queries to the down-incidence array and  $\tilde{O}(\sqrt{d})$  time.*

<sup>5</sup> The down-incidence array is actually an adjacency array of a graph related to simplicial complexes, namely, the incidence graph between the  $(d-1)$ - and  $d$ -simplices.

## 31:20 Effective Resistance and Capacitance in Simplicial Complexes

It is harder to produce a generic implementation of  $U_C$  than  $U_B$ . The  $d$ -simplices can have arbitrary weights, so constructing the states  $|c_\sigma\rangle$  in general requires constructing arbitrary quantum states with real coefficients. However, the weights on the simplices do not affect whether or not a cycle is null-homologous. Therefore, we can always run our null-homology test on the unweighted complex; the trade-off is that the effective resistance or effective capacitance might be higher in the unweighted complex. We analyze the running time of this case in Section A.

We now analyze the complexity of constructing the initial state  $|w_0\rangle/||w_0\rangle||$ . To construct the dummy state, we start by adding an additional “ $d$ -cell”  $|\emptyset\rangle$  to the complex with boundary  $|\gamma\rangle$  (really, we just add  $|\gamma\rangle$  as a column to  $\partial$ .) The new cell will have non-trivial overlap with  $|w_0\rangle$ , so we can construct  $|w_0\rangle$  by amplifying this component of  $|\emptyset\rangle$ . We outline this method in the proof of Theorem 36, but first, we state Lemma 35 which is a generalization of the parallel formula for effective resistance; its proof is nearly identical to the proof of Theorem 10.

► **Lemma 35.** *Let  $V = V_1 \oplus V_2$  be a vector space. Let  $A : V \rightarrow U$  be a linear map, and let  $A_1 : U_1 \rightarrow V$  and  $A_2 : U_2 \rightarrow V$  be the restriction of  $A$  to  $U_1$  and  $U_2$ . Let  $|t\rangle \in \text{im } A_1 \cap \text{im } A_2 \subset U$ . If  $|s\rangle = A^+|t\rangle$ ,  $|s_1\rangle = A_1^+|t\rangle$ , and  $|s_2\rangle = A_2^+|t\rangle$ , then*

$$||s||^2 \leq \left( \frac{1}{||s_1||^2} + \frac{1}{||s_2||^2} \right)^{-1}$$

*Equality is achieved when  $\text{im } A_1 \cap \text{im } A_2 = \text{span}\{|t\rangle\}$ . In this case,  $|s\rangle = t|s_1\rangle + (1-t)|s_2\rangle$  where  $t = ||s_2||^2 / (||s_1||^2 + ||s_2||^2)$ .*

► **Theorem 36.** *Let  $\mathcal{O}_\gamma$  be the oracle that takes  $\mathcal{O}_\gamma : |0\rangle \rightarrow |\gamma\rangle$ . Let  $T_\gamma$  be the time it takes to implement  $\mathcal{O}_\gamma$ . The state  $|w_0\rangle = \partial^+|\gamma\rangle$  can be created in  $\tilde{O}((\sqrt{1/\mathcal{R}_\gamma(\mathcal{K})} + \sqrt{\mathcal{R}_\gamma(\mathcal{K})})(T_B + T_C + T_\gamma))$  time.*

**Proof.** We append  $|\gamma\rangle$  as a column to  $\partial$  to create a new matrix  $\hat{\partial}$ . Let  $|\emptyset\rangle$  be index of the new column, so  $\hat{\partial} = \partial + |\gamma\rangle\langle\emptyset|$ . Let  $|w'_0\rangle = \hat{\partial}^+|\gamma\rangle$ . We conclude that  $|\emptyset\rangle = |w'_0\rangle + |w'_0{}^\perp\rangle$  where  $|w'_0{}^\perp\rangle \in \ker \hat{\partial}$ , as the projection  $\Pi_{\ker \hat{\partial}}|\emptyset\rangle = \hat{\partial}^+\hat{\partial}|\emptyset\rangle = \hat{\partial}^+|\gamma\rangle = |w'_0\rangle$ .

We construct  $|w_0\rangle/||w_0\rangle||$  in two steps. First, we use amplitude amplification to amplify the  $|w'_0\rangle$  component of  $|\emptyset\rangle$ . We then use a second amplitude amplification to amplify the  $|w_0\rangle$  component of  $|w'_0\rangle$ . These amplitude amplifications are nested, as we need to perform the first to create the initial state for the second.

If we perform constant time phase estimation of  $|\emptyset\rangle$  on the unitary  $R_{\ker \hat{\partial}}$ , then we can map  $|\emptyset\rangle$  to  $|0\rangle|w'_0\rangle + |1\rangle|w'_0{}^\perp\rangle$ . We can then amplify the amplitude of  $|0\rangle|w_0\rangle$  part arbitrarily close to  $|w_0\rangle/||w_0\rangle||$  using  $O(||w_0\rangle||^{-1})$  calls to  $R_{\ker \hat{\partial}}$ .

We calculate  $||w_0\rangle||$  using the formula from the lemma. The vector  $|\emptyset\rangle$  has length 1, so Lemma 35 shows that

$$||w'_0\rangle||^2 = \left( \frac{1}{\mathcal{R}_\gamma(\mathcal{K})} + 1 \right)^{-1} = \frac{\mathcal{R}_\gamma(\mathcal{K})}{\mathcal{R}_\gamma(\mathcal{K}) + 1}.$$

Thus, we need to perform the reflection  $R_{\ker \hat{\partial}}$  a total of  $O(||w_0\rangle||^{-1}) = O(\sqrt{(\mathcal{R}_\gamma(\mathcal{K}) + 1)/\mathcal{R}_\gamma(\mathcal{K})})$  times to create  $|\hat{w}_0\rangle/||\hat{w}_0\rangle||$ .

The next step in our algorithm is to amplify the  $|w_0\rangle/\|w_0\rangle\|$  component of  $|w'_0\rangle/\|w'_0\rangle\|$ . By Lemma 35, the state  $\|w'_0\rangle\| = t\|w_0\rangle\| + (1-t)\|\emptyset\|$  for  $t = 1/(\mathcal{R}_\gamma(\mathcal{K}) + 1)$ . Therefore, the  $|w_0\rangle/\|w_0\rangle\|$  component of  $|w'_0\rangle/\|w'_0\rangle\|$  has norm

$$\begin{aligned} t\|w_0\rangle/\|w'_0\rangle\| &= \frac{1}{\mathcal{R}_\gamma(\mathcal{K}) + 1} \sqrt{\mathcal{R}_\gamma(\mathcal{K})} \sqrt{\frac{\mathcal{R}_\gamma(\mathcal{K}) + 1}{\mathcal{R}_\gamma(\mathcal{K})}} \\ &= \sqrt{\frac{1}{\mathcal{R}_\gamma(\mathcal{K}) + 1}} \end{aligned}$$

To return the state  $|w_0\rangle/\|w_0\rangle\|$ , we need to perform amplitude amplification again. We can create the state  $|w'_0\rangle$  using the amplitude amplification from the previous two paragraphs with  $O(\sqrt{(\mathcal{R}_\gamma(\mathcal{K}) + 1)/\mathcal{R}_\gamma(\mathcal{K})})$  applications of  $R_{\ker \partial'}$ , and we can reflect across  $|\emptyset\rangle$  in constant time as it is a basis state. To create  $|w_0\rangle/\|w_0\rangle\|$ , we need

$$O\left(\sqrt{(\mathcal{R}_\gamma(\mathcal{K}) + 1)/\mathcal{R}_\gamma(\mathcal{K})} \sqrt{(\mathcal{R}_\gamma(\mathcal{K}) + 1)}\right) = O\left(\sqrt{\mathcal{R}_\gamma(\mathcal{K})} + \sqrt{\frac{1}{\mathcal{R}_\gamma(\mathcal{K})}}\right)$$

applications of  $R_{\ker \hat{\partial}}$ .

We now argue that we can compute  $R_{\ker \hat{\partial}}$  in  $O(T_C + T_B + T_\gamma)$  time. As was the case with  $R_{\ker \partial}$ , we decompose  $R_{\ker \hat{\partial}} = M_B^\dagger R_{\hat{U}} M_B$  for space  $\hat{B}$  and  $\hat{C}$  defined

$$\hat{B} = B \cup \{b_\emptyset := |\gamma\rangle\}$$

$$\hat{C} = \text{span} \left\{ |c_\sigma\rangle := \frac{1}{\sqrt{\deg(\sigma) + 1}} |\sigma\rangle |\emptyset\rangle + \sum_{\sigma \subset \tau} \frac{w(\sigma)}{\sqrt{\deg(\sigma) + 1}} |\sigma\rangle |\tau\rangle : \sigma \in \mathcal{K}_{d-1} \right\}.$$

The unitaries  $M_{\hat{B}}$ ,  $M_{\hat{C}}$ , and  $\mathbb{R}_{\hat{U}}$  are defined analogously to  $M_B$  and  $M_C$ . We can implement the unitary version of these matrices  $U_{\hat{B}}$  in  $O(T_B + T_\gamma)$  and  $U_{\hat{C}}$  in  $O(T_C)$ . ◀

We summarize this section in the following theorem.

► **Theorem 37.** *Let  $\mathcal{K}$  be a simplicial complex,  $\gamma \in C_{d-1}(\mathcal{K})$  a null-homologous cycle, and  $\mathcal{K}(x) \subset \mathcal{K}$  be a simplicial complex. There is a quantum algorithm for deciding if  $\gamma$  is null-homologous in  $\mathcal{K}(x)$  that runs in time*

$$\tilde{O}\left(\sqrt{\frac{(d+1)\mathcal{R}_{\max}(\mathcal{K})\mathcal{C}_{\max}(\mathcal{K})}{\lambda}}(\sqrt{d} + T_C) + \left(\sqrt{\frac{1}{\mathcal{R}_\gamma(\mathcal{K})}} + \sqrt{\mathcal{R}_\gamma(\mathcal{K})}\right)(\sqrt{d} + T_C + T_\gamma)\right)$$

## Special cases

We now consider a few special cases of the null-homology span program. These special cases will allow us to replace the terms  $T_B$  and  $T_\gamma$  in Theorem 37 with concrete running times.

### Unweighted simplicial complexes

We now consider the case where there are no weights on the  $d$ -simplices, or equivalently, when  $w(\tau) = 1$  for each  $d$ -simplex  $\tau$ . While computing  $M_C$  is hard in general, in the unweighted case, we can implement the unitary  $M_C$  using a straightforward oracle. For a  $(d-1)$ -simplex  $\sigma$  that is incident to the  $d$ -simplices  $\{\tau_1, \dots, \tau_m\}$ , the **up-incidence array** is the oracle is the function that maps  $h : |\sigma\rangle |j\rangle |0\rangle \rightarrow |\sigma\rangle |j\rangle |\tau_j\rangle$ . By Lemma 33, the up-incidence array can be used to compute  $|c_\tau\rangle = \frac{1}{\sqrt{m}} |\tau\rangle |\delta\tau\rangle$  in  $O(\sqrt{m})$  time. The unitary  $M_C$  computes the state  $|c_\sigma\rangle$  in parallel, so computing  $M_C$  will take  $\sqrt{d_{\max}}$  queries, where  $d_{\max} = \max_{\tau \in C_{d-1}(\mathcal{K})} \deg(\tau)$  time. This is summarized in the following lemma.

## 31:22 Effective Resistance and Capacitance in Simplicial Complexes

► **Lemma 38.** *If  $\mathcal{K}$  is an unweighted simplicial complex, the unitary  $U_C$  can be implemented in  $O(\sqrt{d_{\max}})$  queries to the up-incidence array and  $\tilde{O}(\sqrt{d_{\max}})$  time.*

### Cycle is the boundary of a $d$ -simplex

We now consider the case that the input cycle  $\gamma$  is the boundary of a  $d$ -simplex. In this case, we can implement the oracle  $\mathcal{O}_\gamma$  with the down incidence array used to implement  $M_B$ . We get the same running time for  $T_\gamma$  as  $T_B$ .

► **Lemma 39.** *If  $\gamma$  is the boundary of a  $d$ -simplex, there is a quantum algorithm implementing  $\mathcal{O}_\gamma$  in  $O(\sqrt{d})$  queries to the down incidence array and  $\tilde{O}(\sqrt{d})$  time.*

## B Omitted proofs

### Proof of Theorem 16

Before obtaining our upper bound on the effective capacitance of a cycle we need to prove one lemma. In the following lemma, we provide an upper bound on the largest singular value of the coboundary matrix.

► **Lemma 40.** *The largest singular value of the coboundary matrix  $\delta_{d-1}$  is  $\sigma_{\max}(\delta_{d-1}) = O(\sqrt{dn})$ .*

**Proof.** Recall that the  $(d-1)$  up-Laplacian is  $L = \delta_{d-1}^T \delta_{d-1}$ . The squared singular values of  $\delta_{d-1}$  are the eigenvalues of  $L$ ; this follows from the generic theorem that the squared singular values of a matrix  $A$  are the eigenvalues of  $A^T A$ . Thus,  $\sigma_{\max}(\delta_{d-1})^2 \leq \sum_i \sigma_i(\delta_{d-1})^2 = \text{trace}(L)$ , where the  $\sigma_i(\delta_{d-1})$  are the singular values of  $\delta_{d-1}$ . We can obtain an upper bound on  $\sigma_{\max}(\delta_{d-1})$  by computing the trace of  $L$ . The diagonal elements of  $L$  are the degrees of the  $(d-1)$ -simplices [8, Proposition 3.3.2]. Each  $d$ -simplex is the coface of  $d+1$   $(d-1)$ -simplices, so summing up the diagonal of  $L$ , we find  $\text{trace}(L) = O(dn)$ . Thus,  $\sigma_{\max}(\delta_{d-1})$  is  $O(\sqrt{dn})$ . ◀

► **Theorem 16.** *Let  $\mathcal{L} \subset \mathcal{K}$  be an unweighted  $d$ -dimensional simplicial complexes, and let  $\hat{\gamma} \in C_{d-1}(\mathcal{L})$  be a  $(d-1)$ -cycle that is null-homologous in  $\mathcal{K}$  but not in  $\mathcal{L}$ . Assume also that  $\hat{\gamma}$  is integral and each of the coefficients  $|\hat{\gamma}_i| = O(1)$ . The effective capacitance of  $\gamma := \hat{\gamma}/\|\hat{\gamma}\|$  in  $\mathcal{K}(x)$  is bounded above by  $\mathcal{C}_\gamma(\mathcal{L}) = O(n^3 \cdot d \cdot \mathcal{T}_{\max}(\mathcal{K})^2)$ .*

**Proof.** Observe that because the coefficients  $\hat{\gamma}_i = O(1)$  then  $\|\hat{\gamma}\| = O(\sqrt{n})$ . We will use this fact later in the proof. Let  $p$  be a  $\gamma$ -potential. By definition,  $\delta[\mathcal{L}]p = 0$  and  $\gamma^T p = 1$ . We can express these constraints as the linear system

$$\begin{bmatrix} \delta[\mathcal{L}] \\ \gamma^T \end{bmatrix} p = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 1 \end{bmatrix}$$

We first remove linearly-dependent columns from this linear system until this system has full column rank. Columns of the matrix correspond to  $(d-1)$  simplices of  $\mathcal{L}$ , and rows correspond to  $d$ -simplices of  $\mathcal{L}$ . Removing columns from  $\delta[\mathcal{L}]$  changes  $\delta[\mathcal{L}]$  to the relative coboundary matrix  $\delta[\mathcal{L}, \mathcal{L}_0]$  where  $\mathcal{L}_0$  is the  $(d-1)$ -subcomplex corresponding to the columns that were removed.

Removing linearly-dependent columns does not change the image of the system of equation, so there is still a solution  $r$ , i.e.

$$\begin{bmatrix} \delta[\mathcal{L}, \mathcal{L}_0] \\ c \end{bmatrix} r = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 1 \end{bmatrix}$$

where  $c$  is the subvector of  $\gamma^T$  after removing the columns. The vector  $r$  is not a  $\gamma$ -potential as it is a vector in  $C_{d-1}(\mathcal{L} \setminus \mathcal{L}_0)$ , not  $C_{d-1}(\mathcal{L})$ . However, we can extend  $r$  to be a  $\gamma$ -potential by adding zeros in the entries indexed by  $\mathcal{L}_0$ . Adding zero-valued entries preserves the length of  $r$ .

We now want to remove rows from this matrix so that it has full row rank. Topologically, removing rows corresponds to removing  $d$ -simplices from the complex  $\mathcal{L}$  to create a new complex  $\mathcal{L}_1$ . Note that we must always include the row  $c$  to have full row rank; otherwise,  $r$  would be a non-zero vector in the kernel of this system, meaning the system does not have full rank. Removing these rows gives the linear system

$$\begin{bmatrix} \delta[\mathcal{L}_1, \mathcal{L}_0] \\ c \end{bmatrix} r = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 1 \end{bmatrix}.$$

Let  $C = [\delta[\mathcal{L}_1, \mathcal{L}_0]^T \quad c^T]^T$  and  $b = [0 \quad 0 \quad \dots \quad 1]^T$ . Note that  $C$  is an square matrix of size (say)  $m \times m$ .

We now use Cramer's rule to bound the size of  $\|r\|$ . By Cramer's rule,  $r_i$ , the  $i$ th entry of  $r$ , is  $r_i = \frac{\det(C_{i,b})}{\det(C)}$ . where  $C_{i,b}$  is the matrix obtained by replacing the  $i$ th column with  $b$ . We first lower bound  $|\det(C)|$ . We can express  $\det(C)$  by its cofactor expansion on the row of  $c$  as  $\det(C) = \sum_{i=1}^m (-1)^i \cdot c_i \cdot \det(\delta[\mathcal{L}_1, \mathcal{L}_0]_i)$  where  $\delta[\mathcal{L}_1, \mathcal{L}_0]_i$  is  $\delta[\mathcal{L}_1, \mathcal{L}_0]$  without the  $i$ th column. Each term  $\delta[\mathcal{L}_1, \mathcal{L}_0]_i$  is integral as  $\delta[\mathcal{L}_1, \mathcal{L}_0]$  is an integral matrix. Moreover, each term  $c_i = \hat{\gamma}_{j_i} / \|\hat{\gamma}\|$  where  $\hat{\gamma}_{j_i}$  is an integer, as  $c$  is a subvector of  $\gamma$ . We can then derive the lower bound

$$\begin{aligned} |\det(C)| &= \left| \sum_{i=1}^m (-1)^i \cdot c_i \cdot \det(\delta[\mathcal{L}_1, \mathcal{L}_0]_i) \right| \\ &= \frac{1}{\|\hat{\gamma}\|} \left| \sum_{i=1}^m (-1)^i \cdot \hat{\gamma}_{j_i} \cdot \det(\delta[\mathcal{L}_1, \mathcal{L}_0]_i) \right| \\ &\geq \frac{1}{\|\hat{\gamma}\|} \quad (\text{as } \sum_{i=1}^m (-1)^i \cdot \hat{\gamma}_{j_i} \cdot \det(\delta[\mathcal{L}_1, \mathcal{L}_0]_i) \text{ is integral}) \\ &= \Omega\left(\frac{1}{\sqrt{|\text{supp}(\hat{\gamma})|}}\right) \quad (\text{as each entry } \hat{\gamma}_i \text{ is } O(1)) \\ &= \Omega\left(\frac{1}{\sqrt{n}}\right). \end{aligned}$$

We now upper bound  $|\det(C_{i,b})|$ . We calculate  $\det(C_{i,b})$  with the cofactor expansion on the column replaced by  $b$ . As  $b$  has 1 in its last entry and 0s elsewhere, the cofactor expansion is  $\det(C_{i,b}) = \det(C_{i,b}^{i,c})$  where  $C_{i,b}^{i,c}$  is the matrix where we dropped the  $i$ th column and the row  $c$  from  $C_{i,b}$ . The matrix  $C_{i,b}^{i,c}$  is a square submatrix of  $\delta[\mathcal{K}]$ , so we can bound

$|\det(C_{i,b})| \leq \mathcal{T}(\mathcal{K})$ . Thus,  $r_i = \det(C_{i,b})/\det(C) \leq \sqrt{n} \cdot \mathcal{T}_{\max}(\mathcal{K})$  and  $\|r\| = \sqrt{\sum_{i=1}^m r_i^2} \leq \sqrt{n^2 \cdot \mathcal{T}_{\max}(\mathcal{K})^2} = n \cdot \mathcal{T}_{\max}(\mathcal{K})$ . The potential energy of  $r$  is  $\|\delta[\mathcal{K}]r\|^2$ . We can bound this using Lemma 40 to obtain  $\|\delta[\mathcal{K}]r\|^2 = O(n^3 \cdot d \cdot \mathcal{T}_{\max}(\mathcal{K})^2)$ . ◀

## C Embedded complexes

In this section, we consider the special case when  $\mathcal{K}$  is a  $d$ -dimensional simplicial complex with a given embedding into  $\mathbb{R}^{d+1}$ . In this case,  $\mathcal{K}$  is an **embedded complex**. Embedded complexes serve as a high dimensional generalization of planar graphs and naturally admit a dual graph. More specifically, we will generalize the special case of planar graphs for which the vertices  $s$  and  $t$  appear on the boundary of the same face. Throughout this section we assume we are given the embedding as input. Computing the dual graph from an embedding can be done in polynomial time [6]. We will show that the effective capacitance of a  $(d-1)$ -dimensional cycle  $\gamma$  in  $\mathcal{K}$  is equal to the effective resistance between a pair of vertices that are “dual” to  $\gamma$ . Hence, we can parameterize the quantum algorithm deciding if  $\gamma$  is null-homologous in terms of the effective resistance in  $\mathcal{K}$  and the effective resistance in the dual graph of  $\mathcal{K}$ . This section generalizes the analysis of planar graphs given by Jeffery and Kimmel [13]. The setup for our analysis has appeared in the author’s previous work [20].

The Alexander duality theorem [10, Corollary 3.45], states that for a  $d$ -dimensional simplicial complex  $\mathcal{K}$  with an embedding into  $\mathbb{R}^{d+1}$  the subspace  $\mathbb{R}^{d+1} \setminus \mathcal{K}$  consists of  $\beta_d + 1$  connected components where  $\beta_d$  is the dimension of  $H_d(\mathcal{K})$ . We call these connected components **voids** and exactly one of these voids is unbounded. We denote the bounded voids as  $V_i$  for  $1 \leq i \leq \beta_d$  and the unbounded void as  $V_\infty$ . Moreover, the boundaries of the bounded voids generate the homology group  $H_d(\mathcal{K})$ . The embedding implies that each  $d$ -simplex is contained on the boundary of at most two voids, and we make the assumption that the  $d$ -simplices are oriented consistently with respect to the voids. That is, if a  $d$ -simplex is on the boundary of two voids it is oriented positively on one void, and negatively on the other. We have a boundary matrix  $\partial_{d+1}$  whose columns are the voids and whose rows are the  $d$ -simplices. From the embedding and the consistent orientation we see that  $\partial_{d+1}$  is the edge-vertex incident matrix of the **directed dual graph**: the directed graph whose vertices are in bijection with the voids and whose edges are in bijection with the  $d$ -simplices of  $\mathcal{K}$ . The direction of the edges are inherited from the orientations of the  $d$ -simplices. For a  $d$ -simplex  $\sigma$  on the boundary of voids  $V_1$  and  $V_2$  we denote the dual edge by  $\sigma^* = (v_1^*, v_2^*)$  and we define the dual weight function by  $w^*(\sigma^*) = 1/w(\sigma)$ .

We construct an additional chain group  $C_{d+1}(\mathcal{K})$  whose basis elements are the bounded voids. This is a purely algebraic construction and gives rise to a new chain complex  $\dots \rightarrow C_{d+1}(\mathcal{K}) \xrightarrow{\partial_{d+1}} C_d(\mathcal{K}) \xrightarrow{\partial_d} \dots \xrightarrow{\partial_1} C_0(\mathcal{K})$ . Since the boundaries of the voids generate the  $d^{\text{th}}$  homology group of  $\mathcal{K}$  and  $C_{d+1}(\mathcal{K})$  is generated by these voids we obtain a valid chain complex. Moreover, we have that  $\dim H_d(\mathcal{K}) = 0$  in our new chain complex. More generally, we define the **dual complex** of  $\mathcal{K}$ , denoted  $\mathcal{K}^*$ , by the isomorphism  $C_{d-k+1}(\mathcal{K}) \cong C_k(\mathcal{K})$ . That is, the  $(d-k+1)$ -simplices of  $\mathcal{K}$  are in bijection with the  $k$ -simplices of  $\mathcal{K}^*$ . The dual graph is the 1-skeleton of  $\mathcal{K}^*$ . Moreover, we define the dual boundary operator  $\partial_k^*: C_k(\mathcal{K}^*) \rightarrow C_{k-1}(\mathcal{K}^*)$  to be the coboundary operator  $\delta_{d-k+1}: C_{d-k+1}(\mathcal{K}) \rightarrow C_{d-k}(\mathcal{K})$  of  $\mathcal{K}$ , and the dual coboundary operator  $\delta_k^*: C_{k-1}(\mathcal{K}^*) \rightarrow C_k(\mathcal{K}^*)$  to be the boundary operator  $\partial_{d-k+1}: C_{d-k+1}(\mathcal{K}) \rightarrow C_{d-k}(\mathcal{K})$  of  $\mathcal{K}$ . In other words the (co)boundary operators commute with the duality isomorphism. We summarize the construction in Figure 4 in the appendix.

We need to make one additional assumption on the location of the input  $(d-1)$ -dimensional cycle  $\gamma$  which makes our setup a generalization of a planar graph with two vertices  $s$  and  $t$  appearing on the same face. To achieve this we assume that there exists a void  $V_i$  with two unit

$\gamma$ -flows  $\Gamma_1$  and  $\Gamma_2$  such that  $\text{supp}(\Gamma_1) \cap \text{supp}(\Gamma_2) = \emptyset$  and  $\text{supp}(\Gamma_1) \cup \text{supp}(\Gamma_2) = \text{supp}(\partial_{d+1} V_i)$ . That is, there exist two unit  $\gamma$ -flows whose supports partition the boundary of the void  $V_i$ . This generalizes the fact in planar graphs that when  $s$  and  $t$  are on the same face we can find two  $st$ -paths which partition the boundary of the face. In planar graphs we are guaranteed to find two such paths, however for an arbitrary  $(d-1)$ -cycle  $\gamma$  we are not guaranteed to find two unit  $\gamma$ -flows partitioning the boundary of some void. More specifically, we take  $\Gamma_2$  to be a unit  $(-\gamma)$ -flow so that  $\partial_d \Gamma_2 = -\gamma$ . In the planar graph analogy this is equivalent as viewing  $\Gamma_1$  as a path from  $s$  to  $t$  and viewing  $\Gamma_2$  as a path from  $t$  to  $s$ . We add an additional basis element  $\Sigma$  to  $C_d(\mathcal{K})$  such that  $\partial_d \Sigma = -\gamma$ . In planar graphs this is equivalent to adding an edge directed from  $t$  to  $s$ . In a planar graphs the addition of this edge splits the face containing  $s$  and  $t$  into two. In higher dimensions the geometry is more complicated, but the addition of  $\Sigma$  allows us to perform a purely algebraic operation makes our chain complex behave as if  $V_i$  has been split into two. We remove  $V_i$  from  $C_{d+1}(\mathcal{K})$  and replace it with two new basis elements  $V_s$  and  $V_t$ . Next, we extend the boundary operator to  $V_s$  and  $V_t$  in the following way:  $\partial_{d+1} V_s = \Gamma_1 - \Sigma$  and  $\partial_{d+1} V_t = \Gamma_2 + \Sigma$ . In the dual complex the vertices dual to  $V_s$  and  $V_t$  are denoted  $s^*$  and  $t^*$ . Dual to  $\Sigma$  is an edge  $\Sigma^* = (t^*, s^*)$ . In the next section we will show that the effective capacitance of  $\gamma$  in a subcomplex  $\mathcal{K}(x)$  is equal to the effective resistance between  $s^*$  and  $t^*$  in the subgraph of the dual graph which is the 1-skeleton of  $\mathcal{K}^*(x)$ . Note that the 1-skeleton of  $\mathcal{K}^*(x)$  contains all of the vertices of  $\mathcal{K}^*$  but only includes the edges dual to the  $d$ -simplices in  $\mathcal{K}(x)$ .

### Effective capacitance is dual to effective resistance

The effective resistance between  $s^*$  and  $t^*$  in  $\mathcal{K}^*(x)$  is determined by the unit  $s^*t^*$ -flows in  $\mathcal{K}^*(x)$ . However, it will be convenient to work with **circulations** instead of flows. A unit  $s^*t^*$ -circulation  $f$  is a cycle; that is, an element of  $\ker \partial_1^*$ , such that  $f(\Sigma^*) = 1$ . Recall that  $\Sigma^*$  is the edge directed from  $t^*$  to  $s^*$ , so a unit  $s^*t^*$ -circulation is just a unit  $s^*t^*$ -flow with the additional edge  $\Sigma^*$  completing the cycle. Clearly, there is a bijection between unit  $s^*t^*$ -flows and unit  $s^*t^*$ -circulations and we define the flow energy of a circulation to be equal to the flow energy of its corresponding flow.

► **Theorem 41.** *Let  $\mathcal{K}$  be a  $d$ -dimensional simplicial complex embedded into  $\mathbb{R}^{d+1}$ , and let  $\gamma$  be a  $(d-1)$ -cycle such that there exist two unit  $\gamma$ -flows  $\Gamma_1$  and  $\Gamma_2$  whose supports partition the boundary of some void  $V_i$ . The effective capacitance  $\mathcal{C}_\gamma(\mathcal{K}(x))$  is equal to the effective resistance  $\mathcal{R}_{s^*t^*}(\mathcal{K}^*(x))$ .*

**Proof.** Let  $p$  be a unit  $\gamma$ -potential in  $\mathcal{K}(x)$  and we define  $f$  to be the image of  $\delta p$  under the duality isomorphism; that is,  $f = \partial_2^* p^*$ , which makes  $f$  a circulation in the 1-skeleton of  $\mathcal{K}^*(x)$ . Further, since  $\Sigma^* = (t^*, s^*)$  the circulation  $f$  corresponds to a unit  $s^*t^*$ -flow by the following calculation:  $f^T \Sigma^* = p^T (\partial_d \Sigma) = p^T \gamma = 1$ . Next, we calculate the flow energy of  $f$  and show it is equal to the potential energy of  $p$ .

$$\begin{aligned}
 J(f) &= \sum_{e^* \in \mathcal{K}^*(x)_1} \frac{f(e^*)^2}{w^*(e^*)} \\
 &= \sum_{e^* \in \mathcal{K}^*(x)_1} f(\sigma^*)^2 w(e) \\
 &= \sum_{\sigma \in \mathcal{K}(x)_d} ((\delta p)^T \sigma)^2 w(\sigma) \\
 &= \mathcal{J}(p)
 \end{aligned}$$

### 31:26 Effective Resistance and Capacitance in Simplicial Complexes

Conversely, let  $f^*$  be a unit  $s^*t^*$ -circulation in  $\mathcal{K}^*(x)$ . By the assumptions outlined in the beginning of the section we have  $\dim H_d(\mathcal{K}) = 0$  which in turn gives us  $\dim H_1(\mathcal{K}^*) = 0$ . Hence,  $f^*$  can be written as a linear combination of boundaries  $f^* = \sum \alpha_i B_i$  where  $B_i \in \text{im } \partial_2^*$ . Let  $p^*$  be the 2-chain in  $\mathcal{K}^*(x)$  with  $\partial_2^* p^* = f^*$ ; we will show that  $p$  is the unit  $\gamma$ -potential in  $\mathcal{K}(x)$  in bijection with  $f^*$ . To see that  $p$  is a unit  $\gamma$ -potential we compute its inner product with  $\gamma$ :

$$\begin{aligned} p^T \gamma &= p^T (\partial_d \Sigma) \\ &= (\delta_{d-1} p)^T \Sigma \\ &= (\partial_2^* p^*)^T \Sigma^* \\ &= (f^*)^T \Sigma^* \\ &= 1. \end{aligned}$$

It remains to show that the potential energy of  $p$  is equal to the flow energy of  $|f^*|$ . We have the following calculation:

$$\begin{aligned} \mathcal{J}(p) &= \sum_{\sigma \in \mathcal{K}(x)_d} ((\delta_{d-1} p)^T \sigma)^2 w(\sigma) \\ &= \sum_{\sigma \in \mathcal{K}(x)_d} \frac{((\delta_{d-1} p)^T \sigma)^2}{w^*(\sigma^*)} \\ &= \sum_{\sigma \in \mathcal{K}(x)_d} \frac{((\partial_2^* p^*)^T \sigma^*)^2}{w^*(\sigma^*)} \\ &= \sum_{\sigma \in \mathcal{K}(x)_d} \frac{f^*(\sigma)^2}{w^*(\sigma^*)} \\ &= \mathcal{J}(f^*). \end{aligned}$$

## Abstract

We consider a multidimensional space partitioning problem, which we call ANONYMITY-PRESERVING PARTITION. Given a set  $P$  of  $n$  points in  $\mathbb{R}^d$  and a collection  $H$  of  $m$  axis-parallel hyperplanes, the hyperplanes of  $H$  partition the space into an arrangement  $\mathcal{A}(H)$  of rectangular cells. Given an integer parameter  $t > 0$ , we call a cell  $C$  in this arrangement *deficient* if  $0 < |C \cap P| < t$ ; that is, the cell contains at least one but fewer than  $t$  data points of  $P$ . Our problem is to remove the minimum number of hyperplanes from  $H$  so that there are no deficient cells. We show that the problem is NP-complete for all dimensions  $d \geq 2$ . We present a polynomial-time  $d$ -approximation algorithm, for any fixed  $d$ , and we also show that the problem can be solved exactly in time  $(2d - 0.924)^k m^{O(1)} + O(n)$ , where  $k$  is the solution size. The one-dimensional case of the problem, where all hyperplanes are parallel, can be solved optimally in polynomial time, but we show that a related INTERVAL ANONYMITY problem is NP-complete even in one dimension.

## 1 Introduction

Consider the following geometric problem. We are given a set  $P$  of  $n$  points and a family  $H$  of  $m$  axis-parallel hyperplanes in  $\mathbb{R}^d$ . The hyperplanes of  $H$  partition the space into an arrangement  $\mathcal{A}(H)$  of rectangular cells. Given an integer parameter  $t > 0$ , we call a cell  $C$  *deficient* if  $0 < |C \cap P| < t$ ; that is, the cell contains at least one but fewer than  $t$  data points of  $P$ . We then ask: What is the minimum number of hyperplanes we must delete so that there are no deficient cells? See Figure 1 for an example. The problem turns out to be nontrivial even in two dimensions and, in fact, also in one dimension under a dual formulation.

While we are mainly interested in this as a natural geometric problem, it can also be relevant in the study of data anonymity. For instance, given a real-valued *scalar* data set, a common technique for *group anonymization* is to partition the domain into *buckets*, defined by a set of boundary values  $\{x_1, x_2, \dots, x_t\}$ . Given an integer target  $t > 0$ , the buckets are chosen to ensure that any bucket  $[x_i, x_{i+1}]$  is either empty or contains at least  $t$  different

data records, thereby ensuring  $t$ -anonymity for each individual data value. Generalizing this to multidimensional data, the buckets are defined independently for each of the  $d$  axes, which geometrically creates a set of axis-parallel hyperplanes – the hyperplanes with normals parallel to the  $i$ -th coordinate axis correspond to the bucketing of the  $i$ -th dimension. Given a set of multidimensional data points and a set of candidate hyperplanes, the problem of discarding the fewest number of hyperplanes to achieve  $t$ -anonymity is precisely our space partitioning problem. For instance, one can imagine points being user locations in a two-dimensional coordinate system, and the problem is to specify those locations to within some “longitude” and “latitude” values so that every user’s location is  $t$ -anonymized. Inspired by these connections, we have chosen to call our problem ANONYMITY-PRESERVING PARTITION for convenience, but our research focus in this work is purely algorithmic, and not related to anonymity.

Space partitioning problems are fundamental to many domains, including computational geometry, databases, robotics, etc. [12, 4, 6, 9, 5, 2]; however, to the best of our knowledge, this particular partition problem has not been studied. In computational geometry, for instance, space partitioning is frequently used for *range query* data structures such as  $kD$ -trees, range trees, etc. [7, 22, 1, 18, 20]. The primary focus in those algorithms is a hierarchical partitioning of the space to represent a set of points so that all points inside a query range can be reported efficiently. In contrast, our goal is to sparsify the (flat) partition induced by a given set of hyperplanes. A different type of multidimensional partitioning is investigated in [15, 21], where the goal is to partition a  $d$ -dimensional array, with nonnegative entries, into a fixed number of subarrays with roughly equal weights. Those approaches are motivated by an interest in constructing a compact *histogram* of the multidimensional data. In contrast, in our anonymizing partition, the goal is not to balance the weight but rather to avoid small-weight regions. In addition, while in the histogram problem the array is partitioned into arbitrarily arranged rectangular boxes, in our setting the partition is induced by full hyperplanes. In [17], LeFevre et al. also consider an anonymity-related partitioning problem, but they compute an arbitrary rectangular subdivision, not an arrangement of hyperplanes. They also show that their problem is NP-complete, but their proof requires the dimension of the space to be unbounded – in particular,  $d \geq n$  in the constructed instances. In contrast, we show our problem is NP-complete even for dimension  $d = 2$ .

## 1.1 Our Contributions

We now discuss the main results of this paper. Given a set  $P$  of  $n$  points in  $\mathbb{R}^d$ , a set  $H$  of  $m$  axis-parallel hyperplanes, and an integer target  $0 < t \leq n$ , we define a *deletion set* to be a subset of hyperplanes so that no cell in the remaining arrangement is deficient. The goal of the ANONYMITY-PRESERVING PARTITION problem is to find a minimum deletion set.

For notational convenience, suppose  $H_i \subseteq H$  is the subset of planes whose normals are parallel to the  $i$ -th coordinate axis, for  $i = 1, 2, \dots, d$ . Then, if the number of nonempty families  $H_i$  is  $p$ , then our problem is essentially a  $p$ -dimensional problem, for  $p \leq d$ . If  $p = 1$ , then it is easy to solve the problem optimally using dynamic programming in time  $O(nm)$ . Surprisingly, we show that the problem is already NP-hard if  $p = 2$ , namely, the input is two-dimensional.

We then propose a polynomial-time  $p$ -approximation algorithm for the problem for any fixed  $p \leq d$ . For this, we reduce the problem to a variant of the well-known HITTING SET problem which we show to have an approximation algorithm using LP rounding. The approximate solution for the reduced HITTING SET instance will yield a  $p$ -approximate solution for our problem. We also give an FPT algorithm for the problem, with running time  $(2d - 0.924)^k m^{O(1)} + O(n)$ . From now on, for convenience of the reader, we assume that  $p = d$  and state the results in terms of  $d$ .

Finally, we also introduce an interval anonymity problem in one dimension which can be viewed as a geometric dual of ANONYMITY-PRESERVING PARTITION when  $d = 1$  – the roles of lines and points are interchanged. Specifically, we are given a set  $P$  of  $n$  points, which we call *markers*, a multiset  $S$  of  $m$  *segments* (intervals) on the real line  $\mathbb{R}$ , and an (integer) anonymity parameter  $0 < t \leq n$ . The set of markers  $P$  partitions  $S$  into equivalence classes, where two segments  $s, s'$  are in the same class if they contain the same set of marker points, namely,  $s \cap P = s' \cap P$ . We say a segment is *nonempty* if it contains at least one marker. We call an equivalence class consisting of nonempty segments *deficient* if it contains less than  $t$  segments. In the INTERVAL ANONYMITY problem, the aim is to remove a minimum number of points from  $P$  so that every nonempty segment of  $S$  belongs to a non-deficient equivalence class. For motivation, one can imagine segments as movement trajectories of  $m$  users, and markers as location sensors, and the goal is to report user locations in such a way that each user has  $t$ -anonymity. Somewhat surprisingly, this one-dimensional problem turns out to be NP-hard.

## 2 NP-Hardness of Anonymity-Preserving Partition

In this section, we prove that ANONYMITY-PRESERVING PARTITION is NP-hard even in two dimensions. This problem is easy to solve in one dimension, which we discuss in Section 3.

Let  $(P, H, t)$  be an instance of ANONYMITY-PRESERVING PARTITION in two dimensions. Without loss of generality, we assume that  $H_1, H_2 \subseteq H$  are the sets of hyperplanes having normals parallel to the  $x$ - and  $y$ -axes, respectively. Furthermore, we denote the hyperplanes  $h_1 \in H_1$  and  $h_2 \in H_2$  by equations of the form  $h_1 = x'$  and  $h_2 = y'$ , respectively, where  $x', y' \in \mathbb{R}$  are constants. To show NP-hardness, we reduce from a structured variant of SAT called LINEAR NEAR EXACT SATISFIABILITY (LNES), which is known to be NP-complete [11]. The main idea here is to associate literals with hyperplanes and clauses with deficient cells, and to make satisfying assignments correspond to deletion sets.

► **Theorem 1.** ANONYMITY-PRESERVING PARTITION is NP-complete for all dimensions  $d \geq 2$ .

**Proof.** Clearly, the decision version of our problem belongs to NP. We now show NP-hardness for just  $d = 2$  as these instances can be easily embedded into any higher dimension. An instance  $J$  of LNES consists of  $5s$  clauses, for  $s \in \mathbb{N}$ , and is denoted by

$$\mathcal{C} = \{U_1, V_1, U'_1, V'_1, \dots, U_s, V_s, U'_s, V'_s\} \cup \{C_1, \dots, C_s\}.$$

(a) This figure shows nine nonempty cells corresponding to an auxiliary clause  $C := (y_1 \vee y_2 \vee y_3 \vee y_4)$ . The middle cell with one point is an *auxiliary cell*, and the four gray cells on its boundary are *shadow auxiliary cells*. The nonempty white cells denote the *helpers*.

(b) This figure shows core cells and variable cells. We consider the following four core clauses:  $U_i := (\bar{y}_1 \vee x_i)$ ,  $V_i := (\bar{y}_2 \vee x_i)$ ,  $U'_i := (\bar{y}_3, \bar{x}_i)$ ,  $V'_i := (\bar{y}_4, \bar{x}_i)$ . Moreover, we assume the literals  $y_1, y_3, y_4$  are associated with the hyperplanes in  $H_2$  forming the auxiliary cells, and  $y_2$  is associated with the hyperplane in  $H_1$ . The *core cells* are colored light gray, and the *variable cell* is colored dark gray.

■ **Figure 2** Example construction of auxiliary, core, and variable cells.

We refer to the first  $4s$  clauses as the *core* clauses, and the remaining  $s$  clauses as the *auxiliary* clauses. The set of variables consists of  $s$  *main variables*  $x_1, \dots, x_s$  and  $4s$  *shadow variables*  $y_1, \dots, y_{4s}$ . Each core clause consists of two literals (one corresponding to a main variable, and the other to a shadow variable) and it has the following structure:  $\forall i \in [s], U_i \cap V_i = \{x_i\}$  and  $U'_i \cap V'_i = \{\bar{x}_i\}$ .

Each main variable  $x_i$  occurs exactly twice as a positive literal and twice as a negative literal. The main variables only occur in the core clauses. Each shadow variable makes two appearances: as a positive literal in an auxiliary clause and as a negative literal in a core clause. Each auxiliary clause consists of four literals, each corresponding to a positive occurrence of a shadow variable.

The LNES problem asks whether, given a set of clauses with the aforementioned structure, there exists an assignment  $\tau$  of truth values to the variables such that *exactly one* literal in every core clause and *exactly two* literals in every auxiliary clause evaluate to TRUE under  $\tau$ .

**Construction.** We construct the set of hyperplanes  $H = H_1 \cup H_2$  by adding hyperplanes placed at integer coordinates starting at one, i.e.,  $H = \{h_1 = x' \mid x' \in \{1, 2, \dots, 3qs\}\} \cup \{h_2 = y' \mid y' \in \{1, 2, \dots, 3qs\}\}$ . These hyperplanes are numbered from left to right and top to bottom. For  $i, j \in \mathbb{N}$ , let  $\square_{(i,j)}$  denote a  $1 \times 1$  cell  $[i, i+1] \times [j, j+1]$  on  $\mathcal{A}(H)$ . We set  $q = 5s + 4$  (recall  $s$  is a parameter from the LNES instance) which is sufficiently larger than the desired size of the deletion set ( $5s$ ). During the construction, we use  $q$  hyperplanes between a cluster of non-empty cells introduced so the sets remain independent, i.e., deleting lines from one cluster does not affect the other. We set the target  $t$  to 4. We associate a hyperplane from  $H$  with each of the  $10s$  literals ( $H$  may contain additional hyperplanes which are not associated with any literal). Of these  $10s$  hyperplanes,  $8s$  are associated with the shadow literals and  $2s$  with the main literals. By default, each cell in  $\mathcal{A}(L)$  is empty. We introduce the nonempty cells and organize them into the following three groups (also, we describe the locations of the  $4s$  hyperplanes associated with the positive shadow literals in the auxiliary cells group, and the locations of the remaining hyperplanes in the core cells group):

- **Auxiliary cells:** We introduce a set of nine nonempty cells for each auxiliary clause. For  $i \in [s]$ , we call  $\square_{(qi, qi)}$  the *auxiliary cell* for clause  $C_i$ . The first two literals in  $C_i$  are associated with the two adjacent hyperplanes  $x = qi$  and  $x = qi + 1$  from  $H_1$ , and the

remaining two literals are associated with the hyperplanes  $y = qi$  and  $y = qi + 1$  from  $H_2$ .<sup>1</sup> We add one point to  $\square_{(qi, qi)}$  (note that  $1 < t/2$ ). Moreover, we add  $t/2$  points to each of  $\square_{(qi-1, qi)}$ ,  $\square_{(qi+1, qi)}$ ,  $\square_{(qi, qi+1)}$ ,  $\square_{(qi, qi-1)}$ , and refer to them as *shadow cells*, while we add  $t$  points to each of  $\square_{(qi-1, qi-1)}$ ,  $\square_{(qi-1, qi+1)}$ ,  $\square_{(qi+1, qi-1)}$ ,  $\square_{(qi+1, qi+1)}$ , and refer to them as *helpers* (see Fig. 2a). Observe that for each  $C_i$ , one needs to remove at least two of the four hyperplanes associated with the shadow literals appearing in  $C_i$  forming the corresponding auxiliary cell  $\square_{(qi, qi)}$ . This is to ensure that we have at least  $t$  points in all the remaining cells among the nine initial cells without exceeding the 5s deletion limit.

- **Core cells:** For each *core clause*, we introduce two nonempty cells. For each *main variable*  $x_i$ , we construct eight cells for the four core clauses  $U_i, V_i, U'_i, V'_i$  together. Without loss of generality, let  $U_i := (\bar{y}_1 \vee x_i)$ , and  $V_i := (\bar{y}_2 \vee x_i)$ . Define  $z_i = q(s + 2i)$  for convenience.<sup>2</sup> We call  $\square_{(z_i, z_i)}$  and  $\square_{(z_i+1, z_i)}$  the *core cells* corresponding to the clauses  $U_i, V_i$ , respectively. We add two points to each of these cells and associate the common hyperplane  $x = z_i + 1$  from  $H_1$  to the literal  $x_i$ . Next, two cases arise according to the orientation of the hyperplanes associated with the literals  $y_1, y_2$ , say  $p(y_1), p(y_2)$  (recall that orientation of these hyperplanes is decided while constructing the *auxiliary cells*):

1.  $p(y_1) \in H_1$ : We associate the hyperplane  $y = z_i$  from  $H_2$  which forms the upper boundary of  $\square_{(z_i, z_i)}$  with  $\bar{y}_1$ , and add four points to  $\square_{(z_i, z_i-1)}$ . Similarly, if  $p(y_2) \in H_1$ , we associate the hyperplane  $y = z_i + 1$  from  $H_2$  which forms the lower boundary of  $\square_{(z_i+1, z_i)}$  with  $\bar{y}_2$ , and add four points to  $\square_{(z_i+1, z_i+1)}$ .
2.  $p(y_1) \in H_2$ : We associate the hyperplane  $x = z_i$  from  $H_1$  which is the left boundary of  $\square_{(z_i, z_i)}$  with  $\bar{y}_1$ , and add four points to  $\square_{(z_i-1, z_i)}$ . Similarly, if  $p(y_2) \in H_2$ , we associate the hyperplane  $x = z_i + 1$  from  $H_1$  which is the right boundary of  $\square_{(z_i+1, z_i)}$  with  $\bar{y}_2$ , and add four points to  $\square_{(z_i+2, z_i)}$ .

The construction above ensures that hyperplanes associated with  $y_i$  and  $\bar{y}_i$  have *orthogonal* normals. We call the two nonempty cells introduced in either of the cases above as *shadow core cells*.

We associate the literal  $\bar{x}_i$  to the hyperplane  $y = z_i + q + 1$  from  $H_2$ , and use a procedure symmetric to the one above to construct four nonempty cells. Here,  $\square_{(z_i+1, z_i+q)}$  and  $\square_{(z_i+1, z_i+q+1)}$  are *core cells* for the clauses  $U'_i, V'_i$ , respectively (note that, here, the two core cells are one below the other as opposed to side-by-side as we did for  $x_i$ ). We complete the rest of the construction as described above. For an example, refer to Fig. 2b. Observe that removal of the hyperplane associated with the positive literal  $x_i$  makes both core cells (corresponding to  $U_i, V_i$ ) non-deficient as these are merged together. Alternatively, removing the hyperplane corresponding to each  $\bar{y}_1, \bar{y}_2$  makes the core cells non-deficient. The case of the literal  $\bar{x}_i$  and the core clauses  $U'_i, V'_i$  is symmetric.

- **Variable cells:** Recall that our construction of core cells ensures that for each main and shadow variable, the two hyperplanes associated with its two literals have orthogonal normals. Next, we introduce three nonempty cells for each of these variables. For each main variable  $x_i$ , the two hyperplanes associated with  $x_i$  and  $\bar{x}_i$  form the top and left boundaries of the cell  $\square_{(z_i+1, z_i+q+1)}$ . We refer to  $\square_{(z_i+1, z_i+q+1)}$  as a *variable cell*, and add two points to it. Furthermore, we add four points each to  $\square_{(z_i, z_i+q+1)}$ ,  $\square_{(z_i+1, z_i+q)}$ , and call them *literal cells*. These cells are adjacent to the left and the upper boundaries of the variable cell. Refer to Fig. 2b.

<sup>1</sup> If for a *main variable*  $x_i$ , the two shadow variables appearing in the core clauses  $U_i, V_i$  are also the first two or the last two literals for some auxiliary clause, then we associate those literals with a pair of orthogonal hyperplanes  $y = qi$  and  $x = qi$  rather than with the default of a pair of parallel hyperplanes described earlier.

<sup>2</sup> Observe that we add an offset of  $qs$  so that the core and auxiliary cells are independent.

Next, we repeat the same procedure of introducing three nonempty cells for each shadow variable at the intersection of the hyperplanes associated with its literals. Notice that it is imperative to remove at least one of the two hyperplanes associated with the two literals for **every** variable so as to merge and make the variable cell non-deficient while staying within the deletion budget of  $5s$  hyperplanes.

For the constructed ANONYMITY-PRESERVING PARTITION instance  $I$ , we ask if there exists a deletion set with size at most  $5s$ . We now turn to the argument of equivalence.

**Forward direction.** Recall that we start with an instance  $J$  of LNES. Let  $\tau$  be a satisfying assignment for  $J$ ; then we claim that the set  $S$  consisting of  $5s$  hyperplanes associated with  $5s$  literals set to TRUE under  $\tau$  gives a valid deletion set for  $I$ . We now show that  $\mathcal{A}(H \setminus S)$  does not contain any deficient cell. First, we observe that  $\tau$  sets exactly one of the two literals associated with each of the  $5s$  variables to TRUE (since  $\tau$  is a valid assignment). Hence, the deficient variable cell introduced for each variable (see the dark gray cell from Fig. 2b) is merged with one of the literal cells and becomes non-deficient. Next, for each auxiliary clause  $C_i$  for  $1 \leq i \leq s$ , exactly two literals are set to TRUE. From the construction of the auxiliary cells group, one can verify that removing exactly two of the four hyperplanes associated with the four literals in  $C_i$  makes the auxiliary cell and the four shadow cells non-deficient (see Fig. 2a). Similarly,  $\tau$  sets exactly one literal from each core clause to TRUE. Hence, we remove exactly one hyperplane on the boundary of each deficient core cell. Due to this, the core cell merges with either a shadow core cell or another core cell, making it non-deficient (see Fig. 2b). This accounts for all the deficient cells in  $I$ ; hence, we conclude our argument for the forward direction.

**Reverse direction.** Let  $S$  be a valid deletion set of size at most  $5s$ ; we construct an assignment  $\tau$  for  $J$  by setting the literals associated with hyperplanes in  $S$  to TRUE. From the construction of the variable cells, we first observe that  $S$  contains exactly one of the two hyperplanes associated with the two literals for each of the  $5s$  variables in  $J$  (since  $|S| \leq 5s$ ). Hence,  $S$  is a valid SAT assignment, i.e., each variable is either set to TRUE or FALSE. Next, using a counting argument, we show that  $\tau$  is a satisfying assignment for  $J$ . Recall that each main variable  $x_i$  occurs twice as a positive literal and twice as a negative literal in the core clauses. Hence, the  $s$  literals associated with the  $s$  main variables set to TRUE under  $\tau$  satisfy exactly  $2s$  core clauses. Next, for the remaining  $2s$  core clauses,  $\tau$  sets exactly one negative shadow literal appearing in each of those clauses to TRUE. This is because from the construction of a core cell corresponding to each core clause, at least one of the two hyperplanes associated with the literals in the clause must be in  $S$  (and literals corresponding to main variables cannot be set to TRUE for this set of core clauses). Similarly,  $\tau$  sets at least two positive shadow literals appearing in each auxiliary clause to TRUE. At this stage, we use a counting argument: Among the  $4s$  shadow literals set to TRUE under  $\tau$ , exactly  $2s$  negative shadow literals and exactly  $2s$  positive shadow literals are TRUE (due to the argument above). Hence, with  $s$  main literals and  $2s$  negative shadow literals set to TRUE, each core clause is satisfied exactly once. With  $2s$  positive shadow literals set to TRUE, each auxiliary clause is satisfied exactly twice. This completes the proof for the reverse direction. ◀

### 3 Approximation and FPT Algorithms

In this section, we present a  $d$ -approximation algorithm for ANONYMITY-PRESERVING PARTITION. We first note that an  $O(d)$ -approximation can be easily achieved using a HITTING SET approximation, since we have a set system of VC dimension  $O(d)$  [13, 8].

Unfortunately, the constant factors in these HITTING SET approximations tend to be large, and in fact a much simpler greedy algorithm can directly give us a  $2d$ -approximation as follows: while there exists a deficient cell  $C$ , we remove all of its (at most)  $2d$  bounding hyperplanes, and iterate until no deficient cell remains. The approximation guarantee follows because for each deficient cell, the optimal solution must remove at least one hyperplane and the greedy algorithm removes  $2d$  hyperplanes. Thus, the main challenge is to improve on this naive bound, which is the main result of this section.

Our algorithm first reduces the ANONYMITY-PRESERVING PARTITION problem to a special case of HITTING SET in which all sets have a small size, and then we design an LP-rounding-based algorithm to obtain a  $d$ -approximation for this problem. We also present a fixed-parameter tractable algorithm running in time  $(2d - 0.924)^k m^{O(1)} + O(n)$  parameterized by the solution size  $k$ .<sup>3</sup>

The one-dimensional case of ANONYMITY-PRESERVING PARTITION can be easily solved in linear time; please see Appendix A for a proof of the following result:

► **Theorem 2.** *The ANONYMITY-PRESERVING PARTITION problem in one dimension can be solved in time  $O(mn)$ , where  $m$  is the number of hyperplanes and  $n$  is the number of points. Further, if every cell in the arrangement is nonempty, then it can be solved in time  $O(m + n)$ .<sup>4</sup>*

### 3.1 A $d$ -Approximation Algorithm

We start by defining a HITTING SET variant. Given a universe of elements  $U$  and a family  $\mathcal{F}$  of subsets of  $U$ , the HITTING SET problem asks us to find a minimum-sized set  $S \subseteq U$  such that  $S$  intersects with every set in  $\mathcal{F}$ . When every set in  $\mathcal{F}$  has size at most  $l$ , we call it the  $l$ -HITTING SET problem.

► **Lemma 3.** *Given an instance  $(P, H, t)$  of the  $d$ -dimensional ANONYMITY-PRESERVING PARTITION problem, we can construct an instance  $(U, \mathcal{F})$  of  $2d$ -HITTING SET such that  $U = H$ ,  $|\mathcal{F}| \leq |H|^{2d}$ , and  $(U, \mathcal{F})$  has a hitting set of size  $k$  if and only if  $(P, H, t)$  has a deletion set of size  $k$ , for any  $k \in \mathbb{N}$ .*

**Proof.** Given an instance  $(P, H, t)$  of ANONYMITY-PRESERVING PARTITION, we construct a  $2d$ -HITTING SET instance with universe  $U = H$  and the family  $\mathcal{F}$  being the set of all nonempty subsets  $X$  of  $H$  such that  $\mathcal{A}(X)$  has a deficient cell and such that  $X$  contains at most two hyperplanes from each  $H_i$  with  $1 \leq i \leq d$ .

▷ **Claim 4.** If  $(P, H, t)$  has a deletion set of size  $k$ , then  $(U, \mathcal{F})$  has a hitting set of size  $k$ .

**Proof.** Let  $H' \subseteq H$  be a deletion set of size  $k$  for  $(P, H, t)$ . Then, there is no deficient cell in  $\mathcal{A}(H \setminus H')$ . Since  $U = H$ , we now show that  $H'$  is also a hitting set of  $(U, \mathcal{F})$ . Suppose not; then there is a set  $X$  in  $\mathcal{F}$  that has no hyperplanes from  $H'$  in it. We know by the construction of  $\mathcal{F}$  that  $X$  has a cell that is deficient in  $\mathcal{A}(X)$ . Observe that even if we add any new hyperplanes to the arrangement  $\mathcal{A}(X)$ , there will still be a deficient cell. Thus,  $\mathcal{A}(H \setminus H')$  will have a deficient cell, which contradicts our assumption that  $H'$  was a deletion set. ◁

<sup>3</sup> Fixed-parameter tractability (FPT) is studied in the realm of parameterized complexity. FPT algorithms admit running time of the form  $f(k)n^{O(1)}$ , where  $k$  is the parameter under consideration and  $n$  is the size of the instance [10].

<sup>4</sup> We assume the points and hyperplanes in the input are sorted.

$$\begin{array}{ll}
\text{minimize} & \sum_{h \in H} x_h \\
\text{s.t.} & \sum_{h \in F} x_h \geq 1 \quad \forall F \in \mathcal{F} \\
& x_h \in [0, 1] \quad \forall h \in H
\end{array}$$

■ **Figure 3** LP for  $2d$ -Hitting Set.

▷ **Claim 5.** If  $(U, \mathcal{F})$  has a hitting set of size  $k$ , then  $(P, H, t)$  has a deletion set of size  $k$ .

*Proof.* Let  $H'$  be a hitting set of  $(U, \mathcal{F})$  of size  $k$ . Since  $U = H$ , we now show that  $H'$  is also a deletion set of  $(P, H)$ . Suppose not; then there is a cell  $C$  that is deficient in  $\mathcal{A}(H \setminus H')$ . Let  $X$  be the set of hyperplanes adjacent to  $C$  in this arrangement. Since all the hyperplanes in  $H$  are axis parallel and we are in the  $d$ -dimensional version of the problem, it follows that  $X$  contains at most two hyperplanes from each  $H_i$  with  $1 \leq i \leq p$ . Also, observe that  $\mathcal{A}(X)$  has the cell  $C$  in it. Since  $C$  is deficient, by construction of the family  $\mathcal{F}$ , we know  $X$  must be in  $\mathcal{F}$ . But since  $H' \cap X = \emptyset$ , this contradicts the fact that  $H'$  is a hitting set. ◁

This completes the proof of Lemma 3. Observe that the  $VC$ -dimension of the constructed set system is  $2d$ , hence, rounding algorithm from [13] would give an  $O(d)$ -approximation. ◀

We now observe the following simple fact:

► **Lemma 6.** For each set  $X \in \mathcal{F}$  of the  $2d$ -HITTING SET instance  $(U, \mathcal{F})$  obtained by applying the reduction in Lemma 3 to  $(P, H, t)$ , it holds that  $|H_i \cap X| \leq 2$ , for  $1 \leq i \leq d$ .

Our approximation algorithm uses LP rounding; see Figure 3. While the integrality gap of this LP is known to be at most  $d$ , the proof is *non-constructive* [3, Theorem 1]<sup>5</sup> and therefore it is not known how to efficiently compute a rounded solution with approximation factor less than  $2d$ . (The size of each set in the LP is  $2d$  and so in any fractional LP solution each set is only guaranteed to have some variable with value at least  $\frac{1}{2d}$ . Thus a straightforward rounding of the LP solution only leads to a  $2d$ -approximation.) Our main contribution, therefore, is to design a polynomial-time rounding algorithm that achieves a  $d$ -approximation for  $2d$ -HITTING SET, and thus also for  $d$ -dimensional ANONYMITY-PRESERVING PARTITION.

► **Theorem 7.** For every fixed dimension  $d \geq 2$ , there exists a polynomial-time algorithm that given a  $d$ -dimensional ANONYMITY-PRESERVING PARTITION instance, computes a deletion set with size at most  $d$  times the optimal size.

**Proof.** We describe our rounding algorithm for  $d = 2$  and defer the general case to Appendix B. We first use Lemma 3 to reduce the 2-dimensional ANONYMITY-PRESERVING PARTITION instance to a HITTING SET instance  $(U = H_1 \cup H_2, \mathcal{F})$ . Observe that by Lemma 6, for each set  $X \in \mathcal{F}$ , we have  $|H_1 \cap X| \leq 2$  and  $|H_2 \cap X| \leq 2$ . We now give a 2-approximation algorithm for  $(U, \mathcal{F})$  by extending the integrality gap result for the LP in [3] (see Figure 3).

<sup>5</sup> Note that in [3], Theorem 1 shows the integrality gap for a variant of hypergraph Vertex Cover. It is fairly straightforward to see that the Hitting Set instances obtained by applying the reduction in Lemma 3 can be equivalently expressed as instances of that same hypergraph Vertex Cover variant; hence, Lemma 3 also gives a reduction to hypergraph Vertex Cover.

For completeness, we first include the proof that the integrality gap is at most 2, and then describe our algorithm.

Let  $g : U \rightarrow [0, 1]$  be an optimal fractional hitting set of  $(U, \mathcal{F})$  with value  $\tau^*(U, \mathcal{F})$ . Also, let  $\tau(U, \mathcal{F})$  be the size of an optimal integral hitting set of  $(U, \mathcal{F})$ . Let  $B = \{(x_1, x_2) \in [0, \frac{1}{2}] \times [0, \frac{1}{2}] : x_1 + x_2 = \frac{1}{2}\}$ , and for each  $x = (x_1, x_2) \in B$ , let

$$T(x) = \{h \in H_1 : g(h) \geq x_1\} \cup \{h \in H_2 : g(h) \geq x_2\}.$$

In other words,  $B$  can be viewed as the set of all points on the line segment  $x_1 + x_2 = \frac{1}{2}$  for  $x_1, x_2 \in [0, \frac{1}{2}]$ , and  $T(x)$  can be viewed as the set obtained by rounding  $g$  using  $x_i$  as the threshold for each  $H_i$ .

We now prove that for any  $x \in B$ ,  $T(x)$  is a hitting set of  $(U, \mathcal{F})$ . Suppose not; then there must be a set  $X \in \mathcal{F}$  such that  $X \cap T(x) = \emptyset$ . By the definition of  $T(x)$ , for each hyperplane  $h \in X \cap H_i$ ,  $i \in \{1, 2\}$ , it holds that  $g(h) < x_i$ . Combining this with the fact that  $|X \cap H_1| \leq 2$  and  $|X \cap H_2| \leq 2$ , we get  $\sum_{h \in X} g(h) < 2(x_1 + x_2) = 1$ . This contradicts the fact that  $g$  is a feasible fractional hitting set of  $(U, \mathcal{F})$ , and thus  $T(x)$  is a hitting set.

Observe that for any given  $a, b \in [0, 1/2]$  with  $a \leq b$ , for a uniformly random  $x = (x_1, x_2) \in B$ , we have  $Pr(a \leq x_i \leq b) = \frac{b-a}{1/2}$  for  $i \in \{1, 2\}$ , i.e.,  $x_1$  and  $x_2$  have a uniform distribution over the interval  $[0, 1/2]$ . We will now use a probabilistic argument to prove that the integrality gap is bounded by 2. If we choose a uniformly random  $x = (x_1, x_2)$  from  $B$ , and let  $E(\cdot)$  denote the expected value, then we have

$$\begin{aligned} \tau(U, \mathcal{F}) \leq E(|T(x)|) &= \sum_{h \in H_i, i \in \{1, 2\}} Pr(g(h) \geq x_i) = \sum_{h \in U} \min\left(1, \frac{g(h)}{1/2}\right) \\ &\leq \sum_{h \in U} 2g(h) = 2\tau^*(U, \mathcal{F}). \end{aligned}$$

Let  $T := \{T(x) : x \in B\}$ . By the above argument, there exists  $x \in B$  such that  $T(x)$  is a hitting set of size at most  $2\tau^*(U, \mathcal{F})$ . Thus, to get a 2-approximation we will show that  $|T| \leq 2m + 2$  and that  $T$  can be constructed in polynomial time (see Appendix B, Algorithm 1 for pseudocode). We now build a set  $B' \subset B$  of size at most  $2m + 2$  such that  $T' := \{T(x) : x \in B'\} = T$ . We include one point for each hyperplane  $h \in H_i$  with  $g(h) \leq 1/2$ , and we include an arbitrarily chosen point between each consecutive pair of these points on the line  $x_1 + x_2 = 1/2$ .

Formally, define  $B_1$  and  $B_2$  as follows: For each  $h \in H_1$ , add  $(g(h), 1/2 - g(h))$  to  $B_1$  if  $g(h) \leq 1/2$ , and for each  $h \in H_2$ , add  $(1/2 - g(h), g(h))$  to  $B_1$  if  $g(h) \leq 1/2$ . Finally, add the point  $(1/2, 0)$  to  $B_1$ . Choose a value  $\varepsilon > 0$  such that for any distinct  $(x_1, x_2), (x'_1, x'_2) \in B_1$ , we have  $\varepsilon < |x'_1 - x_1|$ . For each  $x = (x_1, x_2) \in B_1$  such that  $x_1 \neq 1/2$ , add  $(x_1 + \varepsilon, 1/2 - x_1 - \varepsilon)$  to  $B_2$ . Finally, add  $(0, 1/2)$  to  $B_2$ . Now let  $B' = B_1 \cup B_2$ .

We now prove that  $T' = T$ . We only need to argue that for all  $x \in B \setminus B'$ ,  $T(x) \in T'$ . Given  $x = (x_1, x_2) \in B \setminus B'$ , let  $x' = (x'_1, x'_2)$  be the pair in  $B_1$  having the largest  $x'_1$  such that  $x'_1 < x_1$ . If such an  $x'$  does not exist, then it is easy to see that  $T(y = (0, 1/2)) = T(x)$ . If  $x'$  exists, then  $T(y = (x_1 + \varepsilon, 1/2 - x_1 - \varepsilon)) = T(x)$  since  $x \notin B'$ . In both cases  $y$  is in  $B'$  and thus  $T(y) = T(x)$  is in  $T'$ . This proves that  $T' = T$  and that  $|T| \leq 2m + 2$ . Our approximation algorithm constructs  $T$  and outputs the set in  $T$  having the smallest size. This completes the proof for  $d = 2$ . The complete algorithm as well as the details of the general case for dimensions  $d > 2$  are presented in Appendix B. ◀

The approximation ratio in Theorem 7 is the best possible that can be obtained using the particular LP formulation from Fig. 3 because it has an integrality gap of  $d$  for the constructed hitting set instances [3].

### 3.2 Fixed-Parameter Tractable Algorithm

Given the equivalence of  $2d$ -HITTING SET and ANONYMITY-PRESERVING PARTITION (refer to Lemma 3), an FPT algorithm follows easily (when  $d$  is a constant). This is because the  $l$ -Hitting Set problem is known to admit an exact algorithm running in time<sup>6</sup>  $(l - 0.924)^k |U|^{O(1)}$  [14], where  $k$  is the size of the hitting set.

► **Theorem 8.** *The ANONYMITY-PRESERVING PARTITION problem in  $d$  dimensions can be solved in time  $(2d - 0.92)^k (m)^{O(1)} + O(n)$ , where  $k$  is the size a minimum deletion set,  $m$  is the number of hyperplanes, and  $n$  is the number of points.*

## 4 An NP-hard Anonymity Problem on the Line

In this section, we show that the INTERVAL ANONYMITY problem is NP-complete and give an exact algorithm running in time  $3.08^k n^{O(1)} + O(m)$ , where  $k$  is the solution size. Recall that here we are given a set  $P$  of  $n$  points, which we call *markers*, a multiset  $S$  of  $m$  segments (intervals) on the real line  $\mathbb{R}$ , and an integral anonymity parameter  $t > 0$ . For convenience, when we consider any set of points, we consider them to be ordered from left to right according to their relative positions on the line. The set of markers  $P$  partitions  $S$  into equivalence classes, where two segments  $s$  and  $s'$  are in the same class if they contain the same set of marker points, namely,  $s \cap P = s' \cap P$ . We call an equivalence class consisting of nonempty segments *deficient* if it contains less than  $t$  segments. The INTERVAL ANONYMITY problem asks us to remove a minimum number of points from  $P$  so that every segment of  $S$  belongs to a non-deficient equivalence class. We now show that INTERVAL ANONYMITY is NP-complete.

► **Theorem 9.** *INTERVAL ANONYMITY is NP-complete, and is NP-hard to approximate within a factor of  $(2 - \varepsilon)$ , for any  $\varepsilon > 0$ , assuming the unique games conjecture (UGC).*

**Proof.** Clearly, the decision version of INTERVAL ANONYMITY belongs to NP. We give a polynomial-time approximation-preserving reduction from VERTEX COVER, which is NP-hard to approximate within a factor less than 2, assuming UGC [16].

**Construction.** Let  $G$  be a graph for which we seek a vertex cover of size at most  $k$ , and let  $n = |V(G)|$ . We can assume  $k \leq n$ . We construct an instance  $(P, S, t)$  of INTERVAL ANONYMITY having  $|P| = n + (n - 1)k$  and  $t = 2$ , where we seek the same solution size  $k$ . Let  $v_1, \dots, v_n$  be the vertices of  $G$ . For each vertex  $v_i$ , we create  $k + 2$  markers labeled as  $v_i, v_i^{(1)}, v_i^{(2)}, \dots, v_i^{(k+1)}$ , with one exception: the last vertex corresponds to just one marker,  $v_n$ . These markers occur in the following order:

$$v_1, v_1^{(1)}, \dots, v_1^{(k+1)}, \quad \dots, \quad v_{n-1}, v_{n-1}^{(1)}, \dots, v_{n-1}^{(k+1)}, v_n.$$

For each  $(v_i, v_j) \in E(G)$  with  $i < j$ , we add the following five (closed) intervals to  $S$ :  $[v_i, v_j]$ , two copies of  $[v_i, v_{j-1}^{(k+1)}]$ , and two copies of  $[v_i^{(1)}, v_j]$ . Since  $t = 2$ , we can see that the deficient intervals are exactly the ones of the form  $[v_i, v_j]$ .

<sup>6</sup> When  $2d \geq 15$ , there is an algorithm that runs in time  $O(c^k + m)$ ,  $c = d - 1 + \frac{1}{d-1}$  [19].

**Proof of equivalence.** For any vertex cover  $\mathcal{S}$  of  $G$ , if we remove the markers (without superscripts) corresponding to the vertices in  $\mathcal{S}$ , we obtain a solution for the Interval Anonymity instance. For the reverse direction, suppose we have a deletion set  $\overline{\mathcal{S}}$  for  $(P, S, t)$  of size at most  $k$ . Since our segments only have endpoints of the form  $v_i, v_i^{(1)},$  or  $v_i^{(k+1)}$ , we would have had to include in  $\overline{\mathcal{S}}$  all of the  $(k+1)$ -superscripted markers between two consecutive vertices if we wished for these to affect feasibility. Therefore, we can remove from  $\overline{\mathcal{S}}$  any superscripted markers and still maintain a feasible solution. Now,  $\overline{\mathcal{S}}$  naturally corresponds to a vertex cover for  $G$ . ◀

We now turn to a 4-approximation and an exact algorithm for the Interval Anonymity problem. Since this problem only cares about segments  $s$  such that  $s \cap P \neq \emptyset$ , we will from now on assume that for all segments  $s \in S$ ,  $s \cap P \neq \emptyset$ . Given an instance  $(P, S, t)$  of the Interval Anonymity problem, we now associate a set of at most four markers from  $P$  to every equivalence class  $X$ . We denote this set by  $M_X$ . Let  $s$  be a segment in  $X$ , and let  $l$  and  $r$  be the leftmost and the rightmost markers in the set  $s \cap P$ . Also, let  $l'$  and  $r'$  be the markers in  $P$  to the left of  $l$  and to the right of  $r$ , respectively, if they exist. Then,  $M_X = \{l', l, r, r'\}$  is the set containing these markers. Note that  $l$  might be equal to  $r$  and  $l'$  and  $r'$  might not exist, and thus  $M_X$  is a set of size at most four.

**4-Approximation.** The idea that each equivalence class can be associated with a set of at most four markers immediately gives us a polynomial-time 4-approximation algorithm and an exact algorithm running in time  $4^k(m+n)^{O(1)}$ , where  $k$  is the size of a minimum deletion set. The key here is to observe that (i) All segments in an equivalence class will remain in the same equivalence class in the final solution, and (ii) In order to make a deficient equivalence class  $X$  non-deficient, we need to remove at least one of the markers from  $M_X$ .

Then, the 4-approximation algorithm is as follows: (i) Initialize the deletion set  $D = \emptyset$ ; (ii) Repeatedly pick an arbitrary deficient equivalence class  $X$  and add all the markers in  $M_X$  to  $D$ , as long as there is a deficient equivalence class; (iii) Finally, output  $D$ . For the exact algorithm, instead of adding all of the markers from  $M_X$  to the deletion set, we guess which one of these markers to add to the deletion set (branching).

We obtain a better exact algorithm for this problem, similarly to the ANONYMITY-PRESERVING PARTITION problem, by reducing to 4-Hitting Set.

► **Theorem 10.** *The INTERVAL ANONYMITY problem can be solved in time  $3.08^k n^{O(1)} + O(m)$ , where  $k$  is the size a minimum deletion set.*

**Proof.** We first reduce our problem to 4-HITTING SET and then use the known  $(3.08)^k |U|^{O(1)}$  time algorithm [14] for 4-HITTING SET to solve our problem. Our focus now is to describe the reduction. Given an instance  $(P, S, t)$  of the INTERVAL ANONYMITY problem, we construct a 4-HITTING SET instance with universe  $U = P$  and family  $\mathcal{F}$  being the set of all nonempty subsets  $Q$  of  $P$  of size at most four such that the instance  $(Q, S, t)$  contains some deficient equivalence class.

Now we prove the forward direction: If  $(P, S, t)$  has a deletion set of size  $k$ , then  $(U, \mathcal{F})$  has a hitting set of size  $k$ . Let  $P' \subseteq P$  be a deletion set of size  $k$  of  $(P, S, t)$ . Then, there is no equivalence class in  $(P \setminus P', S, t)$  that is deficient. Since  $U = P$ , we now show that  $P'$  is also a hitting set of  $(U, \mathcal{F})$ . Suppose not; then there is a set  $Q \in \mathcal{F}$  that contains no markers from  $P'$ . We know by construction of  $\mathcal{F}$  that there is some deficient equivalence class  $X$  in  $(Q, S, t)$ . Let  $s$  be a segment in  $X$ , and let  $X'$  be the equivalence class that  $s$  belonged to in  $(P \setminus P', S, t)$ . Since segments in  $X'$  always remain together in their resulting equivalence class even after removing additional markers, it is easy to see that if  $X'$  is not deficient in  $(P \setminus P', S, t)$ , then  $X$  is not deficient in  $(Q, S, t)$ . This contradicts the fact that  $X$  is deficient and thus completes the forward direction.

Next, we show the reverse direction: If  $(U, \mathcal{F})$  has a hitting set of size  $k$ , then  $(P, S, t)$  has a deletion set of size  $k$ . Let  $P'$  be a hitting set of  $(U, \mathcal{F})$  of size  $k$ . Since  $U = P$ , we now show that  $P'$  is also a deletion set of  $(P, S, t)$ . Suppose not; then there is a deficient equivalence class  $X$  in  $(P \setminus P', S, t)$ . We show that  $M_X$  from  $(P \setminus P', S, t)$  belongs to  $\mathcal{F}$ , thus contradicting the fact that  $P'$  is a hitting set of  $(U, \mathcal{F})$  since  $M_X$  does not have any marker from  $P'$ . To satisfy an equivalence class  $E$ , at least one of the markers in  $M_E$  must be deleted. Therefore, deleting all markers from  $P \setminus P'$  except those from  $M_X$  will make  $X$  a deficient equivalence class in  $(M_X, S, t)$ . Thus, by construction,  $M_X$  belongs to  $\mathcal{F}$ . ◀

## 5 Conclusion

We considered a natural multidimensional space partitioning problem, showed that it is NP-complete in all dimensions  $d \geq 2$ , and designed a  $d$ -approximation algorithm and an FPT algorithm parameterized by solution size. Although we described our results for the case  $p = d$ , it is easy to see that the algorithm in fact guarantees a  $p$ -approximation for the more general case, where  $p \leq d$  is the number of nonempty families of hyperplanes. We also showed that a simple INTERVAL ANONYMITY problem is NP-complete even in one dimension, and gave approximation and FPT algorithms for that as well. Improving our approximation factors is an interesting open problem.

## A Proof of Theorem 2

We show that the Anonymity-Preserving Partition problem is easy to solve in the one-dimensional case in time  $O(mn)$ . Furthermore, this special case can be solved in time  $O(m + n)$  if every cell in the arrangement is nonempty. In both cases, we assume the points and hyperplanes in the input are pre-sorted.

**Proof (of Theorem 2).** We design a dynamic-programming algorithm to solve the problem in the one-dimensional case. Let  $i$  be the dimension in which we have a nonempty set of hyperplanes. We have  $m = |H_i| = |H|$ . We will denote the cells by  $f_1, \dots, f_{m+1}$  and the hyperplanes by  $h_1, \dots, h_m$ , so that they occur in the following order in space:

$$f_1, h_1, f_2, h_2, \dots, h_m, f_{m+1}.$$

Let  $n_i$  be the number of points in the cell  $f_i$ . We will think of hyperplanes and cells with smaller indices in this ordering as being “to the left.”

For each  $1 \leq i \leq m + 1$ , let  $L_i$  be the set of hyperplanes to the left of the cell  $f_i$ . We have  $L_1 = \emptyset$ . For a set of hyperplanes  $H'$ , let  $f_i(H')$  denote the cell containing  $f_i$  in the arrangement  $\mathcal{A}(H \setminus H')$ . For example, if  $H' = \{h_1\}$ , then  $f_2(H')$  is the cell formed by the union of  $f_1$  and  $f_2$ . For every  $1 \leq i \leq m + 1$  and every  $0 \leq s \leq t$ , we define the following value:

$f(i, s) =$  minimum possible size of a set  $H' \subseteq L_i$  such that in the arrangement  $\mathcal{A}(H \setminus H')$ , any nonempty cell to the left of  $f_i(H')$  contains at least  $t$  points, and the cell  $f_i(H')$  contains at least  $s$  points.

## 32:14 Anonymity-Preserving Space Partitions

The value we need to compute is  $f(m+1, t)$ . We compute  $f(m+1, t)$  using the following recursive formula:

$$f(i, s) = \begin{cases} 0 & \text{if } i = 1 \text{ and } s \leq n_1 \\ \infty & \text{if } i = 1 \text{ and } s > n_1 \\ \min(f(i-1, 0) + 1, f(i-1, t)) & \text{if } i > 1 \text{ and } s \leq n_i \\ f(i-1, s - n_i) + 1 & \text{if } i > 1 \text{ and } s > n_i. \end{cases}$$

The return value  $f(m+1, t)$  is always finite since we assume  $n \geq t$ . This concludes the algorithm – we leave the formal proof of correctness to the reader. It is easy to see that the running time is  $O(mt + n)$ , which is bounded by  $O(mn)$ .

We now proceed to the case when the instance is not only one-dimensional, but also has the property that every cell in the arrangement is nonempty. In this case, the problem can be solved by a greedy algorithm, which proceeds as follows:

- Initially, set  $q = 1$  and set  $S = \emptyset$ .
- Repeat the following steps while  $q \leq m + 1$ :
  - Set  $j$  to be the smallest  $j$  such that  $\sum_{i=q}^j n_i \geq t$ . Set  $S' = \{h_q, \dots, h_{j-1}\}$ . (If  $j = q$ , then  $S'$  is empty.) If there is no such  $j$ , this means we have reached the last of the cells. In that case, set  $j$  to be the largest  $j$  such that  $\sum_{i=j}^{m+1} n_i \geq t$ , set  $S' = \{h_j, \dots, h_m\}$ , and break once this iteration is complete.
  - Set  $S = S \cup S'$ .
  - Set  $q = j + 1$ .
- Return  $S$ .

Note that there always exists a  $j$  such that  $\sum_{i=j}^{m+1} n_i \geq t$  since we assume  $\sum_{i=1}^{m+1} n_i = n \geq t$ . The formal proof of correctness is straightforward, and we leave it to the reader. ◀

### B Proof of Theorem 7 for $d \geq 3$

In this section, we prove Theorem 3 for  $d \geq 3$  and provide the pseudocode for the  $d = 2$  case. Recall that Theorem 7 promises a  $d$ -approximation algorithm for the  $d$ -dimensional Anonymity-Preserving Partition problem.

**Proof (of Theorem 3 – for  $d \geq 3$ ).** Given an instance  $(P, H, t)$  of the  $d$ -dimensional Anonymity-Preserving Partition problem, we use the reduction in Lemma 3 to obtain a  $2d$ -Hitting Set instance  $(U, \mathcal{F})$ . Recall that  $U = H = \bigcup_{1 \leq i \leq d} H_i$ , i.e.,  $U$  is a union of  $d$  disjoint sets of hyperplanes  $H_i$ .

Next, we partition  $U$  into three sets  $S_1, S_2, S_3$  such that for all  $X \in \mathcal{F}$ ,  $|X \cap S_i| \leq d$  for  $1 \leq i \leq 3$ . When  $d$  is even, we let

$$S_1 = \bigcup_{1 \leq i \leq \frac{d}{2}} H_i, \quad S_2 = \bigcup_{\frac{d}{2} + 1 \leq i \leq d} H_i, \quad S_3 = \emptyset.$$

When  $d$  is odd, we let

$$S_1 = \bigcup_{1 \leq i \leq \lfloor \frac{d}{2} \rfloor} H_i, \quad S_2 = \bigcup_{\lfloor \frac{d}{2} \rfloor + 1 \leq i \leq d-1} H_i, \quad S_3 = H_d.$$

We define  $s_i = \max_{X \in \mathcal{F}} |X \cap S_i|$ , for  $i \in \{1, 2, 3\}$ . From Lemma 2, we know that for all  $X \in \mathcal{F}$ ,  $|X \cap H_i| \leq 2$ ; hence,  $s_1 + s_2 + s_3 \leq 2d$ . We now describe a  $d$ -approximation algorithm for  $(U, \mathcal{F})$ . To this end, we first use a result from [3] which bounds the integrality gap for the

LP from Fig. 3 on the instance  $(U, \mathcal{F})$  by  $d$ . For completeness, we include the proof from [3], and then build upon it to give an approximation algorithm.

Let  $g : U \rightarrow [0, 1]$  be an optimal fractional hitting set of  $(U, \mathcal{F})$  with value  $\tau^*(U, \mathcal{F})$ . Furthermore, let  $\tau(U, \mathcal{F})$  be the size of an optimal integral hitting set. We now construct a set  $B \subseteq [0, 1/d]^3$ . Fix four points:

$$q_1 = \left( \frac{s_1 + s_2 - s_3}{2ds_1}, 0, \frac{1}{d} \right), \quad q_2 = \left( \frac{1}{d}, \frac{s_2 + s_3 - s_1}{2ds_2}, 0 \right)$$

$$q_3 = \left( \frac{s_1 + s_3 - s_2}{2ds_1}, \frac{1}{d}, 0 \right), \quad q_4 = \left( 0, \frac{s_1 + s_2 - s_3}{2ds_2}, \frac{1}{d} \right)$$

and let

$$B^{(1)} = [q_1, q_2], \quad B^{(2)} = [q_3, q_4], \quad B^{(3)} = [q_1, q_3], \quad B^{(4)} = [q_2, q_4],$$

where  $[q_i, q_j]$  denotes the line segment between the points  $q_i$  and  $q_j$ . We define  $B = B^{(1)} \cup B^{(2)} \cup B^{(3)} \cup B^{(4)}$ .

Notice that the coordinates of  $q_1, q_2, q_3, q_4$  all satisfy the equation  $s_1x_1 + s_2x_2 + s_3x_3 = 1$ , and hence, this equation is satisfied by all tuples  $x = (x_1, x_2, x_3) \in B$ . Hence, using an argument similar to that used for  $d = 2$ , the sets  $T(x)$  constructed as follows are indeed hitting sets:

$$T(x) = \{h \in S_1 : g(h) \geq x_1\} \cup \{h \in S_2 : g(h) \geq x_2\} \cup \{h \in S_3 : g(h) \geq x_3\}.$$

Let  $T = \{T(x) : x \in B\}$ . Next, we define a probability measure  $\mu$  over  $B$  such that for any given  $a, b \in [0, 1/d]$  with  $a \leq b$ , for a randomly chosen tuple  $(x_1, x_2, x_3) \in B$ , we have  $\Pr(a \leq x_i \leq b) = \frac{b-a}{1/d}$  for  $1 \leq i \leq 3$ , i.e., the  $x_i$ 's have a uniform distribution over the interval  $[0, 1/d]$ . For  $1 \leq i \leq 4$ , let  $\mu_i$  be the uniform measures on the line segments  $B^{(i)}$  such that

$$\mu_1(B^{(1)}) = \mu_2(B^{(2)}) = \frac{(s_1 + s_3 - s_2)(s_2 + s_3 - s_1)}{2s_3(s_1 + s_2 - s_3)},$$

$$\mu_3(B^{(3)}) = \frac{(s_2 - s_3)(s_2 + s_3 - s_1)}{s_3(s_1 + s_2 - s_3)},$$

$$\mu_4(B^{(4)}) = \frac{(s_1 - s_3)(s_1 + s_3 - s_2)}{s_3(s_1 + s_2 - s_3)}.$$

We set  $\mu = \mu_1 + \mu_2 + \mu_3 + \mu_4$ . It can be verified that  $\sum_{i=1}^4 \mu_i(B^{(i)}) = 1$ , and hence,  $\mu(B) = 1$ . At this stage, to argue as in the case  $d = 2$  in order to show the bound on the integrality gap, it remains to show that  $x_i$  indeed has a uniform distribution on  $[0, 1/d]$  for all  $1 \leq i \leq 3$ .

It is easy to see that for a randomly chosen  $x = (x_1, x_2, x_3) \in B$ ,  $x_3$  has a uniform distribution over  $[0, 1/d]$ . This is because each  $\mu_i$  is a uniform measure over  $B^{(i)}$ , and  $x_3$  takes all values from  $[0, 1/d]$  on each  $B^{(i)}$  with  $1 \leq i \leq 4$ . It is easy to see that  $x_1$  is uniform over  $B^{(4)}$  using the same argument. Next, we observe that  $x_1$  is uniform on

## 32:16 Anonymity-Preserving Space Partitions

each of the line segments  $\left[0, \frac{s_1+s_3-s_2}{2ds_1}\right]$ ,  $\left[\frac{s_1+s_3-s_2}{2ds_1}, \frac{s_1+s_2-s_3}{2ds_1}\right]$ ,  $\left[\frac{s_1+s_2-s_3}{2ds_1}, \frac{1}{d}\right]$ . Recall that  $\mu_1(B^{(1)}) = \mu_2(B^{(2)})$ ; hence, the situation for the first and the third line segment is the same. Without loss of generality, assume that  $0 \leq s_3 \leq s_2 \leq s_1 \leq d$ . Hence, we only need to check

$$\frac{\mu_3(B^{(3)})}{\mu_2(B^{(2)})} = \frac{\frac{s_1+s_2-s_3}{2ds_1} - \frac{s_1+s_3-s_2}{2ds_1}}{\frac{s_1+s_3-s_2}{2ds_1}},$$

which indeed holds. Hence,  $x_1$  is uniformly distributed. With a similar argument, it can be shown that  $x_2$  is uniformly distributed. At this stage, similarly to the  $d = 2$  case, we can compute the expected size of  $T(x)$  to obtain the desired bound  $d$  on the integrality gap.

Next, we show that there are only  $O(m)$  distinct rounded hitting sets  $T(x)$  constructed using  $x \in B$ . Observe that while traversing on any line segment  $B^{(i)}$  for  $1 \leq i \leq 4$ , the hitting set  $T(x)$  may change at points  $x \in B^{(i)}$  for which there exists  $1 \leq j \leq 3$  such that  $g(h) = x_j$  for some  $h \in S_j$ , i.e., when the plane  $x_j = g(h)$  intersects  $B$ . Note that the hitting set  $T(x)$  does not change for the points on the open line segment between two consecutive intersection points on  $B^{(i)}$  obtained from the aforementioned planes (here, the open line segment  $(x_i, x_j)$  is the set of all points on the line segment  $[x_i, x_j]$  except for the endpoints). Since each such plane can have at most four intersection points with  $B$ , the number of distinct rounded solutions is  $O(m)$ , where  $m = |U|$ .

We iterate through all distinct rounded solutions and return a hitting set with minimum cardinality. This completes the proof of Theorem 7.  $\blacktriangleleft$

# Impatient PPSZ – A Faster Algorithm for CSP

Shibo Li ✉ 

Shanghai Jiao Tong University, China

Dominik Scheder ✉ 

Shanghai Jiao Tong University, China

---

## Abstract

PPSZ is the fastest known algorithm for  $(d, k)$ -CSP problems, for most values of  $d$  and  $k$ . It goes through the variables in random order and sets each variable randomly to one of the  $d$  colors, excluding those colors that can be ruled out by looking at few constraints at a time.

We propose and analyze a modification of PPSZ: whenever all but 2 colors can be ruled out for some variable, immediately set that variable randomly to one of the remaining colors. We show that our new “impatient PPSZ” outperforms PPSZ exponentially for all  $k$  and all  $d \geq 3$  on formulas with a unique satisfying assignment.

## 1 Introduction

A Constraint Satisfaction Problem, or CSP for short, consists of a finite set of variables  $x_1, \dots, x_n$ , a domain  $[d] := \{1, \dots, d\}$  of potential values, called *colors*, and a set of constraints. A constraint is of the form  $(x_{i_1}, \dots, x_{i_k}) \in S$ , where  $S \subseteq [d]^k$ . In analogy to CNF-SAT, we assume in this paper that  $|S| = d^k - 1$ , i.e., all but one possible assignments satisfy the constraint. We speak of a  $(d, k)$ -CSP if all constraints are over  $k$  variables. In a slight abuse of notation, we also use  $(d, k)$ -CSP to denote the associated *decision problem*: is there a way to assign values in  $[d]$  to the variables that satisfies all constraints? This is NP-complete except when  $d = 1$  or  $k = 1$  or  $k = d = 2$ , so researchers focus on finding *moderately exponential-time algorithms*: algorithms of running time  $c^n$  for  $c < d$ . Examples include Beigel and Eppstein’s randomized algorithm for  $(d, 2)$ -CSP with running time  $O((0.4518d)^n)$  [1]; Schönning’s random walk algorithm of running time  $O^*((\frac{d(k-1)}{k})^n)$  [11]; Paturi, Pudlák, and Zane encoding-based randomized algorithm called PPZ [7] for  $k$ -SAT (i.e.,  $d = 2$ ), which runs in time  $O(2^{(1-1/k)n})$ . Paturi, Pudlák, Saks and Zane [6] improved PPZ by introducing a pre-processing step using small-width resolution. Both PPZ and PPSZ can be easily modified to work for  $(d, k)$ -CSP as well, as done by Scheder [8] for PPZ and Hertli et al. [4] for PPSZ. In both cases, several subtleties and technical difficulties arise, which are not present for  $k$ -SAT. Furthermore, [4] is the currently fastest algorithm for  $(d, k)$ -CSP when  $k \geq 4$ .

## 1.1 The PPSZ Algorithm

Let us give an informal description of PPSZ, first for SAT, and then for CSP. In either case, it chooses a random ordering  $\pi$  on the variables  $x_1, \dots, x_n$ . Then it goes through the variables one by one, in the order of  $\pi$ ; when processing  $x_i$ , it fixes  $x_i$  randomly to **true** or **false**, unless there is a set of up to  $D$  clauses that logically implies  $x_i = b$  for some  $b \in \{0, 1\}$ ; in the latter case, we fix  $x_i$  to  $b$  and say that  $x_i$  has been inferred by  $D$ -implication. For CSP, the only difference is that when processing  $x_i$ , it checks (with brute force) for which colors  $c \in [d]$  the statement  $[x_i \neq c]$  can be inferred by a set of up to  $D$  constraints; if so, we say  $[x_i \neq c]$  is  $D$ -implied, and color  $c$  is obviously ruled out. It then fixes  $x_i$  randomly to one of the colors not yet ruled out (or declares failure if all colors have been ruled out).

**Unique-SAT versus general-SAT.** A peculiar feature of PPSZ, as analyzed in the seminal paper [6], is that it performs better if the input instance  $F$  has a *unique* satisfying assignment. Certain properties, such as the existence of critical clause trees, break down once  $F$  has multiple solutions. In [6], the authors proposed a clever but technical workaround, which incurred an exponential overhead for  $k = 3, 4$ . In his 2011 breakthrough paper, Hertli [3] showed that this peculiarity is in fact an artifact of the analysis, and gave a very abstract and high-level proof that PPSZ on formulas with many solutions is indeed no worse. His proof was later simplified by Scheder and Steinberger [10]. The proofs in [3] and [10] work only provided that the internal machinery of the PPSZ algorithm (e.g., checking  $D$ -implication) is “not too good”. Curiously, in [4] it turned out that, for  $k = 2, 3$  and certain values of  $d$ , the PPSZ machinery is indeed “too good”, and consequently their time complexity for the general case (multiple solutions) is worse than for the unique case (exactly one solution). For formulas with a unique solution, their analysis gives a running time of  $O(d^{nS_{d,k} + o(n)})$ , for  $S_{d,k}$  defined below. This is the best known running time for all  $d, k$  except for  $(d, k) = (3, 2)$  and  $(d, k) = (4, 2)$ .

**Improvements to PPSZ for  $k$ -SAT.** Two recent results improve PPSZ. Hansen, Kaplan, Zamir, and Zwick [2] define a *biased* version of PPSZ and show that it achieves an improvement for all  $k \geq 3$ . Scheder [9] shows that PPSZ itself performs exponentially better than in the analysis of [6]. We would not be surprised if both improvements carry over to  $(d, k)$ -CSP, although to our knowledge, this has not been analyzed so far. The improvement presented in this work is of a different quality: it is not a generalization of some idea for  $k$ -SAT; in fact, the main idea only makes sense for  $d \geq 3$  and thus is particular to  $(d, k)$ -CSP problems.

**The time complexity of PPSZ for Unique  $(d, k)$ -CSP.** A main result of [4] is that PPSZ solves Unique  $(d, k)$ -CSP in time  $O(2^{S_{d,k} n + o(n)})$ , where  $S_{d,k}$  is defined by the following random experiment: let  $T^\infty$  be the infinite rooted tree in which each node on even depth (which includes the root at depth 0) has  $k - 1$  children and every node on odd depth has  $d - 1$  children. Let  $T_1, \dots, T_{d-1}$  be disjoint copies of  $T^\infty$ , sample  $p \in [0, 1]$  uniformly, and delete every odd-level node with probability  $p$ , independently. Let  $J_c$  be the indicator variable that is 1 if the root of  $T_c$  is contained in an infinite component after this deletion step. Then

$$S_{d,k} := \mathbb{E}[\log_2(J_1 + \dots + J_{d-1} + 1)] . \quad (1)$$

Approximate values of  $S_{d,k}$  for small values of  $d, k$  can be found in Hertli et al. [4]<sup>1</sup> To understand  $S_{d,k}$  for large values  $d$ , it is most advantageous to write  $c_{d,k} := \log_2(d) - S_{d,k}$ . Intuitively,  $\log_2(d)$  is the number of bits required to specify a color and  $S_{d,k}$  is the number of coin tosses used by PPSZ to determine it, so  $c_{d,k}$  is the number of coin tosses per variable saved by PPSZ. Theorem 1.4 of [4] states that  $\lim_{d \rightarrow \infty} c_{d,k} = -\int_0^1 \log_2(1 - r^{k-1})$ .

Thus, for large  $d$ , PPSZ saves a *constant number of bits* per variable; this is somewhat unsatisfactory; we would like to save a *constant fraction of bits*, i.e., an algorithm of running time  $d^{(1-c_k)n}$  for some  $c_k > 0$  for arbitrary  $d$ . The existence of such an algorithm is posed as an open problem by Koucký, Rödl, and Talebanfard [5]. In the same paper, they give such an algorithm for CSP formulas where every variable appears in a constant number of constraints. Formally, their algorithm runs in time  $d^{(1-c_{k,r})n}$  on  $(d, k)$ -CSP formulas  $F$  where each of the  $n$  variables occurs in at most  $r$  constraints.

## 1.2 Our Contribution

In this work, we focus on the case that  $F$  has a unique satisfying assignment  $\alpha^*$ , without loss of generality  $\alpha^* := (d, d, \dots, d)$ . The idea behind our improvement is as follows: suppose  $x, y, z$  are variables appearing in the order  $y, x, z$  in  $\pi$ . Focus on the point in time when PPSZ processes  $x$ , and assume every assignment prior to  $x$  has been correct. For example, the variable  $y$  has already been replaced by the constant  $d$ . In other words, when PPSZ tries to infer statements like  $[x \neq c]$  from small sets of constraints, it can use the information  $[y = d]$ . It cannot use  $[z = d]$ , however. Or can it? Maybe PPSZ can already infer  $[z \neq 1], \dots, [z \neq d - 1]$ ; in this case, it can also infer  $[z = d]$ , and it would be safe to fix  $z$  to  $d$ . Let us propose the following rule:

**Rule of One.** Whenever  $[z = c]$  can be inferred by  $D$ -implication, fix  $z$  to  $c$ .

This rule is “uncontroversial” in the sense that it will never make a mistake. Indeed, the reader who is familiar with the literature about PPSZ, in particular with its original version using small-width resolution, will notice that resolution implicitly implements the above rule. We propose the following more aggressive rule:

**Rule of Two.** Whenever  $[z = c_1 \vee z = c_2]$  can be inferred by  $D$ -implication, i.e., if all but 2 colors can be ruled out, pick  $c \in \{c_1, c_2\}$  uniformly at random and fix  $z$  to  $c$ .

Obviously, this rule can introduce mistakes. On the plus side, it might be very unlikely that the range of plausible (i.e., not ruled out) colors for  $z$  further decreases from 2 to 1. Better to bite the bullet now, decide on a value for  $z$ , hope that it is correct, and use that information for subsequent  $D$ -implications. For example, it might be that using the information  $[z = d]$  lets us rule out additional colors for  $x$ , the variable currently being processed by PPSZ. Unfortunately, this rule does more bad than good: consider the variables coming towards the very end of  $\pi$ . For each of them, it is very likely that all but one color can be ruled out; thus, PPSZ would set them correctly with high probability; using our Rule of Two, this probability would go down from (almost) 1 to (roughly) 1/2 since we decide on a value once only two values are left. We propose a less impatient rule:

<sup>1</sup> In [4] they define  $S_{d,k}$  with  $\log_d$  instead of  $\log_2$ . We prefer the binary logarithm for purely cosmetic reasons: otherwise some of our expressions would contain the expression “ $\log_d(2)$ ”, but “1” is undoubtedly nicer.

**Conservative Rule of Two.** Apply the Rule of Two only to variables  $z$  that are among the first  $\theta n$  in  $\pi$ ; don't apply it to the last  $(1 - \theta)n$  variables.

We will show that for those early variables, it is extremely unlikely that the set of plausible colors gets narrowed down to only one color; and that it is somewhat more likely that the Rule of Two helps us rule out one additional colors for a variable. In particular, we prove the following theorem:

► **Theorem 1.** *For every  $d \geq 3$  and  $k \geq 2$ , there is some  $\epsilon > 0$  and a randomized algorithm solving  $(d, k)$ -CSP in time  $2^{n(S_{d,k} - \epsilon)} \text{poly}(n)$ , where  $S_{d,k}$  is as defined in (1).*

Note that the Rule of Two does not make any sense in the Boolean context. For every variable  $z$  we can trivially 0-imply  $[z = 0 \vee z = 1]$ , and thus every variable immediately qualifies for impatient assignment. We thus lose all control over the ordering  $\pi$  in which we process the variables. The Rule of One does of course make sense in the Boolean setting and is implicitly implement if you are running “strong” PPSZ, i.e., with small-width resolution.

### 1.3 Notation

Let  $V = \{x_1, \dots, x_n\}$  be a set of variables and  $[d] = \{1, \dots, d\}$  be the set of possible colors. A *literal* is an expression  $(x \neq c)$ , where  $x \in V, c \in [d]$ . A *clause* is a disjunction of literals:  $(v_1 \neq c_1 \vee v_2 \neq c_2 \vee \dots \vee v_k \neq c_k)$ . A  $(d, k)$ -CSP is a conjunction of clauses of size  $k$  each. An assignment  $\alpha$  is a function  $V \rightarrow [d]$ . It satisfies a literal  $(x \neq c)$  if  $\alpha(x) \neq c$ ; it satisfies a clause if it satisfies at least one literal therein; it satisfies a  $(d, k)$ -CSP  $F$  if it satisfies all clauses in  $F$ . If  $V' \subseteq V$  and  $\alpha : V' \rightarrow [d]$ , we call  $\alpha$  a *partial assignment*;  $\text{vbl}(\alpha)$  denotes its domain, i.e.,  $V'$ .  $F^{[\alpha]}$  is the simplified formula after setting all variables in  $V'$  according to  $\alpha$ . We will write partial assignments like this:  $[x \mapsto 2, y \mapsto 3, \dots]$  and therefore  $F^{[x \mapsto 2]}$  will denote the formula after replacing  $x$  with 2. For a set  $V' \subseteq V$  of variables, we take the liberty to write  $F^{[V' \mapsto d]}$ , where  $[V' \mapsto d]$  is the partial assignment  $[x \mapsto d \text{ for each } x \in V']$ . For a clause  $C$  and a  $(d, k)$ -CSP  $F$ ,  $\text{vbl}(C)$  and  $\text{vbl}(F)$  denote the sets of variables in  $C$  and  $F$ , respectively. For a rooted tree  $T$  and a node  $v$  therein, the *subtree of  $T$  rooted at  $v$*  is the tree containing  $v$  (as root) and all its descendants. We use the notation  $[\text{statement}]$ , which evaluate to 1 if **statement** holds, and to 0 otherwise.

### 1.4 PPSZ and impatient PPSZ

► **Definition 2** (*D-implication* [4]). *Let  $F$  be a  $(d, k)$ -CSP formula and  $u$  be a literal of  $F$ . We say  $F$  implies  $u$  and write  $F \models u$  if all assignment satisfying  $F$  also satisfy  $u$ . We say  $F$   $D$ -implies  $u$  and write  $F \models_D u$  if there is some  $G \subseteq F$  with  $|G| \leq D$  and  $G \models u$ .*

For the rest of the paper,  $D = D(n)$  will be some slowly growing function in  $n$ , so  $F \models_D u$  can be checked in time  $O(|F|^D \text{poly}(n))$ , which is subexponential in  $n$ .

► **Definition 3** (*Plausible values*). *Let  $F$  be a  $(d, k)$ -CSP formula and  $x$  a variable. We say color  $c \in [d]$  is  $D$ -plausible for  $x$  in  $F$  if  $F$  does not  $D$ -imply  $(x \neq c)$ . Let  $\text{Plaus}(x, F, D)$  denote the set of all colors that are  $D$ -plausible for  $x$ . We will drop the parameter  $D$  if it is understood from the context.*

Note that our code specifies  $\pi$  as an explicit input parameter; it is the responsibility of the “user” to make sure  $\text{PPSZ}(F, \pi)$  is called with a random  $\pi$ ; furthermore, we implicitly assume that PPSZ declares failure if the set  $\text{Plaus}(x, F^{[\alpha]})$  in Line 4 is empty.

---

**Algorithm 1** PPSZ algorithm.
 

---

```

1: procedure PPSZ( $F, \pi$ )
2:    $\alpha \leftarrow$  the empty assignment
3:   for  $x \in \text{vbl}(F)$  in the order of  $\pi$  do
4:     choose  $\iota \in \text{Plaus}(x, F^{[\alpha]})$  uniformly at random
5:      $\alpha := \alpha \cup [x \mapsto \iota]$ 
6:   end for
7:   return  $\alpha$  if it satisfies  $F$ , else failure
8: end procedure

```

---

From now on, we view  $\pi$  not as a permutation of the variables but as a *placement*, i.e., a function  $V \rightarrow [0, 1]$ ; note that if  $\pi : V \rightarrow [0, 1]$  is sampled uniformly at random, it will be an injection with probability 1; sorting  $V$  in ascending order by their  $\pi$ -value will give a permutation of  $V$ . Additionally, we fix two parameters  $\theta$  (to be determined later) and  $\zeta := 2 - \log_2(3)$ , and mark every variable  $x$  as *eligible for impatient assignment* as follows:

► **Definition 4** (Eligible for impatient assignment). *For each variable  $x$ , define  $\mathbb{I}_x \in \{0, 1\}$  as follows. (1) If  $\pi(x) \geq \theta$ , set  $\mathbb{I}_x := 0$ ; (2) if  $\pi(x) < \theta$ , set  $\mathbb{I}_x := 1$  with probability  $\zeta$  and to 0 with probability  $1 - \zeta$ , independently of all other choices. If  $\mathbb{I}_x = 1$  we say  $x$  is eligible for impatient assignment.*

The reasoning behind condition (1) is that a “late” variable  $x$  (one with  $\pi(x) \geq \theta$ ) is likely to end up with a unique plausible value when PPSZ reaches it; setting it prematurely will do more bad than good; our decision to mark “early” variables with  $\pi(x) < \theta$  as eligible only with probability  $\zeta$  (and not with probability 1) has technical reasons: we want a certain function to become concave, and our choice of  $\zeta$  is the largest value for which this happens.

---

**Algorithm 2** Impatient PPSZ.
 

---

```

1: procedure IMPATIENTPPSZ( $F, \pi$ )
2:    $\alpha :=$  the empty assignment
3:   for  $x \in \text{vbl}(F)$  in ascending order of  $\pi$  do
4:     while  $\exists y \in \text{vbl}(F) \setminus \text{vbl}(\alpha)$  with  $\mathbb{I}_y = 1$  and  $|\text{Plaus}(y, F^{[\alpha]})| \leq 2$  do
5:       choose  $\iota \in \text{Plaus}(y, F^{[\alpha]})$  uniformly at random
6:        $\alpha := \alpha \cup [y \mapsto \iota]$ 
7:     end while
8:     if  $x \notin \text{vbl}(\alpha)$  then
9:       choose  $\iota \in \text{Plaus}(x, F^{[\alpha]})$  uniformly at random
10:       $\alpha := \alpha \cup [x \mapsto \iota]$ 
11:    end if
12:  end for
13:  return  $\alpha$  if it satisfies  $F$ , else failure
14: end procedure

```

---

**Proof sketch of Theorem 1.** As the analysis of PPSZ, our proof relies heavily on the concept of *critical clause trees*. Intuitively, those trees are a neat and tidy way to describe all ways how  $[x = c]$  can be ruled out. For PPSZ, this can be described as an extinction event in a Galton-Watson process; for ImpatientPPSZ however, we need a more complicated notion. To make matters worse, while [6] and [4] showed that the worst case for their PPSZ analysis

happens if all trees are “nice”, this fails for our algorithm. We have to come up with a (short) list of non-niceties, and for each of them show that  $[x = c]$  is a bit more likely to be ruled out; we can then finally analyze the “nice” case. ◀

## 2 Conceptual Framework

**Notation for sets of variables coming before variable  $x$ :  $V_x$  and  $V_x^{\text{imp}}$ .** To analyze PPSZ and our variant ImpatientPPSZ, we need to talk about the point in time where the algorithm processes a variable  $x$ , and in particular, we need to talk about the set of variables that have already been assigned a value at this point. For PPSZ, this is easy: we define  $V_x := \{y \in \text{vbl}(F) \mid \pi(y) < \pi(x)\}$ . For ImpatientPPSZ, it’s a bit more complicated: imagine we run ImpatientPPSZ but feed it the “correct” values in every assignment; that is, whenever a color  $c$  is chosen, make sure that  $c = d$  (we manipulate this random source to always choose the correct color); pause the algorithm in the iteration when variable  $x$  is being processed, just after line 7, and look at the partial assignment  $\alpha$  built so far. We set  $V_x^{\text{imp}} := \text{vbl}(\alpha) \setminus \{x\}$ . We remove  $x$  for purely technical reasons; if  $x$  happens to be already set at that time, then line 9 and 10 will be skipped by the algorithm anyway.

► **Observation 5.** *If line 9 is executed then  $c$  is chosen uniformly at random from the set  $\text{Plaus}(x, F^{[V_x^{\text{imp}} \mapsto d]})$ .*

We define the following indicator variables:

$$A_{x,c} := \begin{cases} 1 & \text{if } c \in \text{Plaus}(x, F^{[V_x \mapsto d]}, D) \\ 0 & \text{else.} \end{cases}$$

$$A_{x,c}^{\text{imp}} := \begin{cases} 1 & \text{if } c \in \text{Plaus}(x, F^{[V_x^{\text{imp}} \mapsto d]}, D) \\ 0 & \text{else.} \end{cases}$$

and  $A_x := \sum_c A_{x,c}$  and  $A_x^{\text{imp}} := \sum_c A_{x,c}^{\text{imp}}$ . These are random variables in our random placement  $\pi$ . Note that  $A_{x,d} = A_{x,d}^{\text{imp}} = 1$  because color  $d$  is always plausible; also,  $A_{x,c}^{\text{imp}} \leq A_{x,c}$  simply because  $V_x \subseteq V_x^{\text{imp}}$ , i.e., ImpatientPPSZ has at least as much information as PPSZ.

► **Lemma 6 ([4]).** *For a fixed permutation  $\pi$ ,  $\Pr[\text{PPSZ}(F, \pi) \text{ finds } \alpha^*] = \prod_x \frac{1}{A_x(\pi)}$ . For a random permutation,  $\Pr_\pi[\text{PPSZ}(F, \pi) \text{ finds } \alpha^*] \geq 2^{-\sum_x \mathbb{E}_\pi[\log_2 A_x(\pi)]}$ .*

The second statement follows from the first by Jensen’s inequality. To obtain a similar formula for ImpatientPPSZ, we need to take into account that a variable  $x$  might be assigned in line 6 or in line 10.

► **Lemma 7.** *For a fixed permutation  $\pi$ , we have  $\Pr[\text{ImpatientPPSZ}(F, \pi) \text{ finds } \alpha^*] \geq \prod_x \frac{1}{\max(1 + \mathbb{I}_x, A_x^{\text{imp}}(\pi))}$ . For a random permutation, the probability that ImpatientPPSZ succeeds is at least*

$$\Pr_\pi[\text{ImpatientPPSZ}(F, \pi) \text{ finds } \alpha^*] \geq 2^{-E_\pi[\sum_x \log_2(\max(1 + \mathbb{I}_x, A_x^{\text{imp}}(\pi)))]}.$$

**Proof.** If  $\mathbb{I}_x = 0$  then  $x$  will be assigned in line 10 and thus its value will be correct with probability  $1/A_x^{\text{imp}}(\pi)$ , conditioned on all prior assignments being correct. If  $\mathbb{I}_x = 1$  then either it is assigned in line 6, and is correct with probability  $1/2$ ; or it is still assigned regularly in line 10, and is correct with probability  $1/A_x^{\text{imp}}(\pi)$ . This proves the first inequality. The second inequality in the lemma follows from the first by Jensen’s inequality. ◀

## 2.1 Independence between colors

The crucial quantity in the analysis of ImpatientPPSZ is the random variable  $A_x^{\text{imp}} = \sum_c A_{x,c}^{\text{imp}}$ . The next lemma states that we can focus on analyzing the indicator variables  $A_{x,c}^{\text{imp}}$  individually; that is, if we condition on  $\pi(x) = p$ , then the  $d$  indicator variables are independent in the worst case. More formally:

► **Lemma 8** (Independence between colors). *Let  $\pi : V \rightarrow [0, 1]$  be uniformly random and set  $p := \pi(x)$ . We sample  $d$  random variables  $\tilde{A}_{x,c}^{\text{imp}} \in \{0, 1\}$ ,  $c = 1, \dots, d$  by setting each  $\tilde{A}_{x,c}^{\text{imp}}$  to 1 with probability  $\Pr[A_{x,c}^{\text{imp}} = 1 \mid \pi(x) = p]$ , independently. Set  $\tilde{A}_x^{\text{imp}} := \sum_c \tilde{A}_{x,c}^{\text{imp}}$ . Then*

$$\mathbb{E}_{\pi} [\log_2 (\max (1 + \mathbb{I}_x, A_x^{\text{imp}}(\pi)))] \leq \mathbb{E}_{\pi} [\log_2 (\max (1 + \mathbb{I}_x, \tilde{A}_x^{\text{imp}}(\pi)))] \quad (2)$$

**Proof idea.** We would like to prove this along the lines of Lemma 3.5 of [4]. The additional problem here is that although the function  $f : t \mapsto \log(t)$  is concave, the function  $g : t \mapsto \log(\max(2, t))$  isn't. This is why, if  $\pi(x) < \theta$ , we set  $\mathbb{I}_x$  to 1 with probability  $\zeta$  and to 0 with probability  $1 - \zeta$ . The convex combination  $(1 - \zeta) \cdot f + \zeta \cdot g$  is concave<sup>2</sup> and the proof goes through just as for Lemma 3.5 in [4]. See Lemma 24 in the appendix for a complete proof. ◀

The upshot is that it is sufficient to bound  $\Pr[A_{x,c}^{\text{imp}} = 1 \mid \pi(x) = p]$  from above, for each variable  $x$  and color  $c$ , individually.

## 2.2 Critical Clause Trees and Brief Analysis of PPSZ

In this section, we define critical clause trees and review some results from [4]. We assume that  $\mathbf{d} = (d, \dots, d)$  is our unique satisfying assignment. Note that every unsatisfied literal is of the form  $(y = d)$  and every satisfied literal is of the form  $(y \neq c)$  for some  $c \neq d$ . Let  $x \in \text{vbl}(F)$  and  $c \in \{1, \dots, d - 1\}$ . The *critical clause tree*  $T_{x,c}^h$  of height  $h$  has two types of nodes: a node  $u$  on an even level (which includes the root at level 0) is a *clause node*, has a *clause label*  $\text{clauselabel}(u)$  and an *assignment label*  $\beta_u$ ; it has at most  $k - 1$  children (in fact, one for each unsatisfied literal in  $\text{clauselabel}(u)$ ). A node  $v$  on an odd level is a *variable node* and has a *variable label*  $\text{varlabel}(v)$ ; it has exactly  $d - 1$  children. An edge  $(v, w)$  from a variable node  $v$  to a clause node  $w$  has an edge color  $EC(e) \in [d - 1]$ . Thus, if  $\text{varlabel}(v) = y$  and  $(v, w)$  edge color  $EC(v, w) = i$ , then this edge represents the alternative assignment  $[y \mapsto i]$ . The critical clause tree  $T_{x,c}^h$  is constructed as in algorithm 3.

Let us assume  $h$  is always odd, so the lowest layer of  $T_{x,c}^h$  consists of variable nodes.  $T_{x,c}^h$  has two types of leaves: those variable nodes at height  $h$ ; we call them *safe leaves*; and clause nodes whose clause label does not contain any literal of the form  $(y \neq d)$ ; we call them *unsafe leaves*.

► **Proposition 9** ([4]).

1. *Suppose  $v$  is a clause node in  $T_{x,c}^h$  with clause label  $C$  and  $(y \neq i)$ ,  $i \in [d]$  is a literal in  $C$ . Then if  $i = d$ ,  $v$  has a child whose variable label is  $y$ . If  $i < d$  and  $y \neq x$  then  $v$  has an ancestor node whose variable label is  $y$ .*
2. *No variable appears more than once as variable label on a path from root to a leaf.*

<sup>2</sup> The attentive reader might notice: it's not concave; however, if we change the definition of "log" in the definition of  $f$  and  $g$  from the usual log to "log on  $\mathbb{N}$  and linear between integers, then it is concave, provided that  $\zeta \leq 2 - \log_2 3$ .

---

**Algorithm 3** BuildCCT( $F, x, c, h$ ).

---

```

1: Create a root node and set  $\beta_{\text{root}} := \alpha[x = c]$ 
2: while  $\exists$  clause node  $u$  of height less than  $h - 1$  without a clause label do
3:   Find a clause  $C$  which is not satisfied by  $\beta_u$ 
4:   Set  $\text{clauselabel}(u) := C$ 
5:   for each unsatisfied literal  $(y \neq d)$  in  $C$  do
6:     Create a new child  $v$  of  $u$ 
7:      $\text{varlabel}(v) := y$ 
8:     for  $i \in [d - 1]$  do
9:       Create a new child  $w$  of  $v$ 
10:      Set  $\beta_w := \beta_v[y = i]$ 
11:      Set  $EC(v, w) = i$ 
12:     end for
13:   end for
14: end while
15: remove clause nodes at height  $h + 1$

► **Definition 10** (labeled tree). *A labeled tree is a possibly infinite tree such that: (1) every node is either a variable node or a clause node; (2) a variable node  $u$  has a label  $\text{varlabel}(u) \in \mathbb{L}$  in some label space  $\mathbb{L} \supseteq V$ ; (3) they alternate, i.e., if a variable node has children, they are all clause nodes, and vice versa; (4) its degree is bounded: there is some  $\Delta \in \mathbb{N}$  such that every node has at most  $\Delta$  children. A leaf in a labeled tree is a safe leaf if it is a variable node; Otherwise, it is an unsafe leaf.*

Note that each subtree of a critical clause tree is a labeled tree. A *safe path* in a labeled tree is a path that starts at the root and is either infinite or ends at a safe leaf.

► **Definition 11** ( $\text{Cut}_p$  and  $\text{Cut}$ ). *Let  $T$  be a labeled tree. The event  $\text{Cut}_p(T)$  is an event in the probability space of all placements  $\pi : \mathbb{L} \rightarrow [0, 1]$  that happens if every safe path in  $T$  contains a node  $v$  with  $\pi(\text{varlabel}(v)) < p$ . Let  $x$  be the label of the root of  $T$ . We define  $\text{Cut}(T) := \text{Cut}_{\pi(x)}(T)$ .*

Suppose  $T$  is a labeled tree, and let  $T_1, \dots, T_l$  be the subtrees rooted at the  $l$  children of the root of  $T$ . Note that the  $T_i$  are themselves labeled trees. If the root of  $T$  is a clause node then  $\text{Cut}_p(T) = \bigwedge_{i=1}^l \text{Cut}_p(T_i)$ . If it is a variable node, let  $y := \text{varlabel}(\text{root}(T))$ , and observe that  $\text{Cut}_p(T) = [\pi(y) < p]$  if  $\text{root}(T)$  itself is a safe leaf (i.e., if  $l = 0$ ) and  $\text{Cut}_p(T) = [\pi(y) < p] \vee \bigwedge_{i=1}^l \text{Cut}_p(T_i)$  else .

Next, we connect the notion of cuts to our notion of being a plausible color. For this, set  $L := (d - 1)(k - 1)$  and observe that  $T_{x,c}^h$  has at most  $L^i$  clause nodes at depth  $2i$ . Choose  $\tilde{h}$  to be the largest integer for which  $1 + L + L^2 + \dots + L^{\tilde{h}} \leq D$  (recall  $D$ , our strength parameter in the definition of  $D$ -implication), and set  $h := 2\tilde{h} + 1$ . Then  $T_{x,c}^h$  has at most  $D$  clause nodes and  $h$  is also a slowly growing function in  $n$ .

► **Lemma 12** ([4]). *Let  $p = \pi(x)$ . If  $\text{Cut}_p(T_{x,c}^h)$  happens then  $A_{x,c} = 0$ .*

Recall the infinite trees  $T^\infty$  and  $T_1, \dots, T_{d-1}$  and the indicator variables  $J_1, \dots, J_{d-1}$  defined above, just before (1), and observe that  $J_c = 1$  iff  $\text{Cut}_p(T_c)$  does *not* happen. Let  $T_\infty$  be the subtree of  $T^\infty$  rooted at the first child of the root. Define  $Q(p) := \Pr[\text{Cut}_p(T^\infty)]$  and  $R(p) := \Pr[\text{Cut}_p(T_\infty)]$ . The next proposition is from [4], adapted for our purposes.

► **Proposition 13** ([4]). Set  $L = (k - 1)(d - 1)$ . If  $p \geq 1 - \frac{1}{L}$  then  $Q(p) = R(p) = 1$ ; otherwise,  $Q(p)$  and  $R(p)$  are the unique roots in  $[0, 1]$  of the equations  $Q = (p + (1 - p)Q^{d-1})^{k-1}$  and  $R = p + (1 - p)R^L$ , respectively. Furthermore,  $Q(p) = R(p)^{k-1}$ .

As our height parameter  $h$  grows (roughly logarithmic with our strength parameter  $D$ ), the critical clause trees  $T_{x,c}^h$  will look more and more like  $T^\infty$ , and thus the cut probability will converge to  $Q(p)$ . Formally, let  $\text{error}(d, k, h, p)$  and  $\text{error}(d, k, h)$  stand for any functions that converge to 0 as  $h \rightarrow \infty$ .

► **Proposition 14** (Lemma 3.6 in [4]).  $\Pr[\text{Cut}_p(T_{x,c}^h)] \geq \Pr[\text{Cut}_p(T_c)] - \text{error}(d, k, p, h)$ .

To summarize: conditioned on  $\pi(x) = p$ , the sum  $A_x = A_{x,1} + \dots + A_{x,d}$  has the worst behavior if all  $A_{x,c}$  are independent (Lemma 8); furthermore,  $A_{x,c} \leq J_c$  except with probability  $\text{error}(d, k, p, h)$ , for all  $c \leq d - 1$ , and therefore:

► **Lemma 15** ([4]).  $\mathbb{E}_\pi[\log_2(A_x)] \leq \mathbb{E}[\log_2(J_1 + \dots + J_{d-1} + 1)] + \text{error}(d, k, h) = S_{d,k} + \text{error}(d, k, h)$ .

### 3 The Probability of Inferring $x \neq c$

Just as [4] analyzes PPSZ by studying the random variables  $A_{x,c}$ , we have to study  $A_{x,c}^{\text{imp}}$ . We can always resort to the “old” analysis via  $A_{x,c}^{\text{imp}} \leq A_{x,c}$ . However, the whole point of this work is to show that this inequality is often strict. To understand how and when this might happen, we discuss an example for  $d = 3$ .

This is  $T_{x,1}^3$ , the critical clause tree for  $x$  and 1 built up to height 3. The formula  $F$  in question contains the constraints shown as clause labels, but of course contains many more constraints. Suppose that  $u, v, a, b, z$  come before  $x$  in  $\pi$ , and  $e, w, r, s, y$  come later. In the normal PPSZ, we have already set  $u, v, a, c, z \mapsto 3$  when considering  $x$ , and thus the clauses of  $F$  will have shrunk:

- $(yuv \neq 133)$  shrinks to  $(y \neq 1)$ ;
- $(yab \neq 233)$  shrinks to  $(y \neq 2)$ ;
- $(zew \neq 133)$  and  $(zrs \neq 233)$  don't shrink but disappear: they are satisfied by  $z \mapsto 3$ ;
- $(xyz \neq 133)$  shrinks to  $(xy \neq 13)$ .

Together, the three shrunk clauses  $(y \neq 1)$ ,  $(y \neq 2)$ , and  $(xy \neq 13)$  imply  $(x \neq 1)$ ; since  $D \geq 3$  this means that  $x = 1$  can be ruled out, i.e.,  $A_{x,1} = 0$ . Next, suppose  $\pi$ , viewed as a placement  $\pi : V \rightarrow [0, 1]$ , looks like this:

### 33:10 Impatient PPSZ

and assume for simplicity that all variables  $l$  with  $\pi(l) < \theta$  in  $\text{vbl}(F)$  are eligible for impatient assignment (i.e., have  $\mathbb{I}_l = 1$ ). Note that  $\text{Cut}(T_{x,1}^3)$  does not happen. Namely, the path from root to  $c$  contains two variable labels,  $y$  and  $b$ , and  $\pi(y), \pi(b) \geq \pi(x)$ . Analogously, the alternative assignment  $\alpha^*[x \mapsto 1, y \mapsto 2, b \mapsto 2]$  satisfies all clauses in the figure above, and thus the algorithm cannot infer  $x \neq 1$  from those clauses alone, and  $A_{x,1} = 1$ . Observe now what happens in ImpatientPPSZ:

- $r, s, u, v \mapsto 3$  before  $x$  is even considered;
- $(yuv \neq 133)$  shrinks to  $(y \neq 1)$ , and thus  $\text{Plaus}(y, F^{[\alpha]})$  shrinks to  $\{2, 3\}$ ;
- $y$  is assigned a value in line 6;
- the analogous thing happens to  $z$ ;
- $r, s, u, v \in V_x$ , and  $r, s, u, v, y, z \in V_x^{\text{imp}}$ ;
- $(xyz \neq 133)$  shrinks to  $(x \neq 1)$  and thus  $A_{x,1}^{\text{imp}} = 0$ .

We can now try to work out a formula for the probability that  $x = c$  is ruled out in this manner; however, our above example and analysis contains two silent assumptions that cannot be taken for granted in general:

1. All variable labels in  $T_{x,c}^3$  are distinct.
  2. All clause labels of  $T_{x,c}^3$  are critical clauses, i.e.,  $k - 1$  of its literals are of the form  $y \neq d$ .
- The original PPSZ paper [6] addresses Point 1 by using the FKG inequality to show that having multiple labels can never hurt us. But now we are talking about a more complicated event; it is not clear whether an FKG-like result applies. Point 2 is more troublesome. Consider the alternative scenario that  $T_{x,c}^3$  looks like this:

and consider the same  $\pi$  as above:  $r, s, u, v, x, z, y, \theta, e, w, a, b$ . After setting  $r, s, u, v \mapsto 3$ , the shrunk clauses are  $(yx \neq 11)$ ,  $(yab \neq 233)$ ,  $(zew \neq 133)$ , and  $(zx \neq 21)$ . Neither for  $y$  nor for  $z$  can we rule out any color, and therefore our impatient mechanism will not kick in. We will have  $V_x = V_x^{\text{imp}} = \{r, s, u, v\}$ . In other words, non-critical clauses seem useless for ImpatientPPSZ. But looking at the above example tree, we see what comes to the rescue: the right-most clause node is missing a child; it has at most  $k - 2$  children instead of  $k - 1$ . This alone will be enough to improve our success probability by a bit. It is time for some formal definitions.

► **Definition 16** (Privileged variables). *A variable  $x$  is privileged if there is some color  $c \in \{1, \dots, d - 1\}$  such that*

1.  $T_{x,c}^h$  has fewer than  $(k - 1)^2(d - 1)$  variable nodes at level 3 or
2.  $T_{x,c}^3$  has two variable nodes  $u$  and  $w$  with  $\text{varlabel}(u) = \text{varlabel}(w)$ .

► **Proposition 17.** *There is an  $\epsilon_{\text{privileged}} > 0$  for variable  $x$  which is privileged, depending only on  $d$  and  $k$ , such that*

$$\mathbb{E}[\log_2(A_x)] \leq S_{d,k} - \epsilon_{\text{privileged}} + \text{error}(d, k, h),$$

for every privileged variable  $x$  in  $F$ .

See Proposition 25 in the appendix for a proof.

► **Corollary 18.** *For every privileged variable  $x \in \text{vbl}(F)$  it holds that  $\mathbb{E}[\log_2(\max(1 + \mathbb{I}_x, A_x^{\text{imp}}))] \leq S_{d,k} - \epsilon_{\text{privileged}} + c\theta + \text{error}(d, k, h)$*

**Proof.** Since  $\max(a, b) \leq a \cdot b$  when  $a, b \geq 1$ , we get

$$\mathbb{E}[\log_2(\max(1 + \mathbb{I}_x, A_x^{\text{imp}}))] \leq \frac{\mathbb{E}[\log_2(1 + \mathbb{I}_x)]}{\pi} + \frac{\mathbb{E}[\log_2(A_x^{\text{imp}})]}{\pi}.$$

The first term equals  $\Pr[\mathbb{I}_x = 1] = c\theta$ ; the second is at most  $\mathbb{E}[\log_2(A_x)]$ , which by Proposition 17 is at most  $S_{d,k} - \epsilon_{\text{privileged}} + \text{error}(d, k, h)$ . This concludes the proof. ◀

► **Lemma 19.** *There is a constant  $\epsilon > 0$ , depending only on  $d$  and  $k$ , such that*

$$\mathbb{E}[\log_2(\max(1 + \mathbb{I}_x, A_x^{\text{imp}}))] \leq S_{d,k} - 0.1699 \left( \frac{c}{L+1} \theta^{L+1} + O(\theta^{L+2}) \right) + \text{error}(d, k, h).$$

for all non-privileged variables  $x$ . The constant factor hidden in the  $O(\cdot)$  depends only on  $d$  and  $k$ .

By choosing  $\theta$  sufficiently small, we can make sure that the bounds in Lemma 19 and Corollary 18 are both at most  $S_{d,k} - \epsilon_{d,k} + \text{error}(d, k, h)$ , for some  $\epsilon_{d,k}$  depending only on  $d$  and  $k$ . Together with Lemma 7, this proves Theorem 1.

**Proof of Lemma 19.** For a color  $1 \leq c \leq d - 1$ , fix the critical clause tree  $T_{x,c}^h$  and let us introduce a bit of notation. The root of  $T_{x,c}^h$  has a label

$$C_{\text{root}} = (x \neq c \vee y_1 \neq d \cdots \vee y_{k-1} \neq d).$$

It has  $k - 1$  children  $v_1, \dots, v_{k-1}$ , whose respective variable labels are  $y_1, \dots, y_{k-1}$ . Let  $T_i$  denote the subtree of  $T_{x,c}^h$  rooted at  $v_i$ . Each  $y_i$  in turn has  $d - 1$  children; each such level-2 node  $v$  has a clause label  $C_v$ ; note that  $C_v$  is a *critical clause*, i.e.,  $k - 1$  of its literals are of the form  $(z \neq d)$ , since otherwise it would have fewer than  $k - 1$  children, and  $T_{x,c}^h$  would have fewer than  $(k - 1)^2(d - 1)$  nodes at level 3; in other words,  $x$  would be privileged.

We need to define an event  $\text{ImpCut}_p(T_{x,c}^h)$  which, analogous to  $\text{Cut}_p(T_{x,c}^h)$ , describes the event  $A_{x,c}^{\text{imp}} = 0$  in terms of  $T_{x,c}^h$  only. Going for a full such characterization is possible but messy, and it is not clear what the worst-case structure of such  $T_{x,c}^h$  will be; this is the reason why we, when considering our impatient assignment mechanism, will look only up to depth 3 in  $T_{x,c}^h$ . For each node  $w$  of  $T_{x,c}^h$  at level 1, 2, or 3, we define event  $\text{LocalImpCut}_p(v)$  as follows:

1. If  $v$  is at level 3 of  $T_{x,c}^h$  then  $\text{LocalImpCut}_p(v)$  happens if  $\pi(\text{varlabel}(v)) < p$ .
2. If  $v$  is at level 2 of  $T_{x,c}^h$  then  $\text{LocalImpCut}_p(v)$  happens if  $\text{LocalImpCut}_p(w)$  happens for the  $k - 1$  children  $w$  of  $v$  (recall that  $\text{clauselabel}(v)$  is a critical clause and therefore  $v$  has exactly  $k - 1$  children);
3. If  $v$  is at level 1, set  $y := \text{varlabel}(v)$ ;  $\text{LocalImpCut}_p(v)$  happens if
  - a.  $\pi(y) < p$  or
  - b.  $\mathbb{I}_y = 1$  and  $\text{LocalImpCut}_p(v)$  happens for at least  $d - 2$  of the  $d - 1$  children of  $v$ .

Finally, we define

$$\text{ImpCut}_p(T_{x,c}^h) := \bigwedge_{i=1}^{k-1} (\text{Cut}_p(T_i) \vee \text{LocalImpCut}_p(v_i)) \quad (3)$$

The next lemma is the “impatient analog” of Lemma 12.

► **Lemma 20.** *Let  $p = \pi(x)$ . If  $\text{ImpCut}_p(T_{x,c}^h)$  happens then  $A_{x,c}^{\text{imp}} = 0$ .*

The proof is very similar to that of Lemma 12, just taking into account the impatient assignment mechanism. We restate and prove it as Lemma 26 in the appendix. Next, we prove a lower bound on  $\Pr[\text{ImpCut}_p(T_{x,c}^h)]$ . For  $q \in [0, 1]$  and  $l \in \mathbb{N}$ , define

$$\text{abamo}(q, l) := q^l + l(1 - q)q^{l-1} . \quad (4)$$

The name abamo is the acronym of “all but at most one” and is indeed the probability that, among  $l$  independent events of probability  $q$  each, all or all but one happen. Recall the definition of  $Q(p) := \Pr[\text{Cut}_p(T^\infty)]$  just before Proposition 13.

► **Lemma 21.** *If  $p < \theta$  then  $\Pr[\text{ImpCut}_p(T_{x,c}^h) \mid \pi(x) = p]$  is at least*

$$(p + c(\theta - p)\text{abamo}(p^{k-1}, d - 1) + (1 - p - c(\theta - p))Q(p)^{d-1})^{k-1} - \text{error}(d, k, h) .$$

*If  $p \geq \theta$  then it is at least  $Q(p) - \text{error}(d, k, h)$ .*

**Proof sketch.** For each subtree  $T_i$  of  $T_{x,c}^h$ , either  $\text{Cut}_p(T_i)$  or  $\text{LocalImpCut}_p(v_i)$  must happen. Now this happens if either (1)  $\pi(y) < p$ , which explains the first term of the sum in the parentheses; (2)  $\pi(y) \geq p$  and  $\mathbb{I}_{y_i} = 1$  and  $\text{LocalImpCut}_p(v_i)$ , which is the second term; or (3)  $\pi(y) \geq p$  and  $\mathbb{I}_{y_i} = 0$  and  $\text{Cut}_p(T_i)$ , which is the third term. See Lemma 27 for a complete proof. ◀

Let us summarize our reasoning so far. Define an ensemble  $J_1^{\text{imp}}, \dots, J_{d-1}^{\text{imp}}$  of random variables in  $\{0, 1\}$  as follows: set  $p := \pi(x)$ ; then independently set each  $J_c^{\text{imp}}$  to 0 with probability  $W^{k-1}$  and 1 with probability  $1 - W^{k-1}$ , where

$$W = W(p) := \begin{cases} p + c(\theta - p)\text{abamo}(p^{k-1}, d - 1) + (1 - p - c(\theta - p))Q(p)^{d-1} & \text{if } p < \theta \\ R(p) & \text{else.} \end{cases}$$

One checks that  $W(p)$  is continuous at  $p = \theta$  since  $R(p) = p + (1 - p)R(p)^{(k-1)(d-1)} = p + (1 - p)Q(p)^{d-1}$ . Set  $J^{\text{imp}} := J_1^{\text{imp}} + \dots + J_{d-1}^{\text{imp}} + 1$ . We have shown so far that

$$\begin{aligned} \mathbb{E} [\log_2 \max(1 + \mathbb{I}_x, A_{x,c}^{\text{imp}})] &\leq \mathbb{E} [\log_2 \max(1 + \mathbb{I}_x, J^{\text{imp}})] + \text{error}(d, k, h) \\ &= \Pr[J^{\text{imp}} = 1 \wedge \mathbb{I}_x] + \mathbb{E} [\log_2(J^{\text{imp}})] + \text{error}(d, h, k) . \end{aligned} \quad (5)$$

► **Proposition 22.**  $\Pr[J^{\text{imp}} = 1 \wedge \mathbb{I}_x] \leq \frac{c}{L+1}\theta^{L+1} + O(\theta^{L+2})$ .

► **Proposition 23.**  $\mathbb{E} [\log_2(J^{\text{imp}})] - S_{d,k} \leq (d - 1) \log_2(1 - 1/d) \cdot \left( \frac{c}{L+1}\theta^{L+1} + O(\theta^{L+2}) \right)$ .

We prove the two propositions in Section E in the appendix. Together with (5), they imply that  $\mathbb{E} [\log_2 \max(1 + \mathbb{I}_x, A_{x,c}^{\text{imp}})] - S_{d,k}$  is at most

$$\left( \frac{c}{L+1}\theta^{L+1} + O(\theta^{L+2}) \right) (1 + (d - 1) \log_2(1 - 1/d)) + \text{error}(d, k, h) .$$

The expression in the first parenthesis is positive for sufficiently small  $\theta$ ; in fact, we have to choose  $\theta$  small enough to beat the hidden constant in the  $O(\cdot)$ , which in turn depends only on  $d$  and  $k$ . The expression in the second parenthesis,  $1 + (d - 1) \log_2(1 - 1/d)$ , is negative for all  $d \geq 3$ . It is maximized for  $d = 3$ , where it becomes  $2 - 2 \log_2(3) < -0.1699$ . Thus, we can choose  $\theta$  such that the whole expression is at most  $S_{d,k} - \epsilon_{d,k} + \text{error}(d, k, h)$  for some  $\epsilon_{d,k} > 0$  depending only on  $d$  and  $k$ . This concludes the proof of Lemma 19. ◀

## 4 Future Work

In the analysis of PPSZ, the worst case happens if all everything looks “nice”: all variable nodes in  $T_{x,1}, \dots, T_{x,d-1}$  have different labels; all clause labels are critical clauses.

In this scenario, our analysis for impatient assignment could go deeper than level 3; we could define a more powerful event ImpCut and obtain much better bounds on the running time. Indeed, future work hopefully will identify the worst-case shape of the  $T_{x,c}^h$  and allow us to analyze the full power impatient assignment.

The condition  $|\text{Plaus}(y, F^{[\alpha]})| \leq 2$  in Line 4 in Algorithm 2 is arbitrary. Why “ $\leq 2$ ”? Why not “ $\leq 3$ ”? For large  $d$ , what would the optimal cut-off value be?

## A Independence between colors

► **Lemma 24** (Lemma 8, restated). *Let  $\pi : V \rightarrow [0, 1]$  be uniformly random and set  $p := \pi(x)$ . We sample  $d$  random variables  $\tilde{A}_{x,c}^{\text{imp}} \in \{0, 1\}$ ,  $c = 1, \dots, d$  by setting each  $\tilde{A}_{x,c}^{\text{imp}}$  to 1 with probability  $\Pr[A_{x,c}^{\text{imp}} = 1 \mid \pi(x) = p]$ , independently. Set  $\tilde{A}_x^{\text{imp}} := \sum_c \tilde{A}_{x,c}^{\text{imp}}$ . Then*

$$\mathbb{E}_{\pi} \left[ \log_2 \left( \max \left( 1 + \mathbb{I}_x, A_x^{\text{imp}}(\pi) \right) \right) \right] \leq \mathbb{E}_{\pi} \left[ \log_2 \left( \max \left( 1 + \mathbb{I}_x, \tilde{A}_x^{\text{imp}}(\pi) \right) \right) \right] \quad (6)$$

**Proof.** We prove (6) conditioned on  $\pi(x) = p$ . Let  $\mathbf{Z} \in \{0, 1\}^{V \setminus \{x\}}$  be defined by  $Z_y := [\pi(y) \geq p]$ . Note that each  $Z_y$  is 1 with probability  $1 - p$ , independently. Next, observe that each  $A_{x,c}^{\text{imp}}$  is a monotone increasing Boolean function  $f_c(Z)$ : moving some  $\pi(y)$  above  $p$  can only increase  $A_{x,c}^{\text{imp}}$ . Let  $\mathbf{Z}^{(1)}, \dots, \mathbf{Z}^{(d)}$  be  $d$  independent copies of  $\mathbf{Z}$ ; that is, each has the same distribution as  $\mathbf{Z}$  but they are independent. Conditioned on  $\pi(x) = p$ , we have  $(f_1(\mathbf{Z}), \dots, f_d(\mathbf{Z})) \sim (A_{x,1}^{\text{imp}}, \dots, A_{x,d}^{\text{imp}})$  and  $(f_1(\mathbf{Z}^{(1)}), \dots, f_d(\mathbf{Z}^{(d)})) \sim (\tilde{A}_{x,1}^{\text{imp}}, \dots, \tilde{A}_{x,d}^{\text{imp}})$ , where  $A \sim B$  means that the random variables  $A$  and  $B$  have the same distribution.

Now if  $p > \theta$  and therefore  $\mathbb{I}_x = 0$ , then the function  $\log_2(\max(1 + \mathbb{I}_x, \cdot))$  in (6) becomes  $\log_2(\cdot)$  and we can directly apply the Concave Correlation Lemma (Lemma A.1 of the full version of [4]).

If  $\mathbb{I}_x = 1$ , the trouble is that the function  $t \mapsto \log_2(\max(2, t))$  is not concave anymore. However, note that if  $\pi(x) < \theta$ , we set  $\mathbb{I}_x$  to 1 with probability  $\zeta$  and 0 with probability  $1 - \zeta$ . Conditioned on  $\pi(x) = p$ , the randomness in (6) comes from two sources: (1) the choice of  $\mathbb{I}_x$ ; (2) the randomness in  $\mathbf{Z}$  (or  $\mathbf{Z}^{(1)}, \dots, \mathbf{Z}^{(d)}$  for the right-hand side). We can break down both sides of (6) as follows:

$$\mathbb{E}_{\mathbf{Z}, \mathbb{I}_x} [\log_2(\max(1 + \mathbb{I}_x, A_x^{\text{imp}}))] = \mathbb{E}_{\mathbf{Z}} [\zeta \log_2(\max(2, A_x^{\text{imp}})) + (1 - \zeta) \log_2(A_x^{\text{imp}})] , \quad (7)$$

where  $\zeta = 2 - \log_2(3)$ . Now the function  $t \mapsto \zeta \log_2(\max(2, t)) + (1 - \zeta) \log_2(t)$  is still not concave. However, note that the arguments of  $\log_2(t)$  in (6) and (7) are integers; define  $g(t)$  to be the function that equals  $\log_2(t)$  if  $t$  is an integer, and is linear between integers. Now  $g$  is concave and  $t \mapsto \zeta g(\max(2, t)) + (1 - \zeta)g(t)$  is concave, too. In fact, this function is linear on  $[1, 3]$  and agrees with  $g$  for  $t \geq 3$ . Now the lemma again follows by the Concave Correlation Lemma (Lemma A.1 of [4]).  $\blacktriangleleft$

## B PPSZ for privileged variables

► **Proposition 25** (Proposition 17, restated). *Suppose  $x \in \text{vbl}(F)$  is a privileged variable. Then there is an  $\epsilon_{\text{privileged}} > 0$ , depending only on  $d$  and  $k$ , such that*

$$\mathbb{E} [\log_2(A_x)] \leq S_{d,k} - \epsilon_{\text{privileged}} + \text{error}(d, k, h) ,$$

for every privileged variable  $x$  in  $F$ .

**Proof.** This proof is similar in spirit and also technical details to the proof of Lemma 19 in [9], except that the latter is concerned with SAT (i.e., the case  $d = 2$ ).

Note that a variable  $x$  can be privileged for two reasons: first, there is some color  $c$  such that the critical clause tree  $T_{x,c}^h$  has fewer than  $(k - 1)L$  leaves at level 3; in other words, some clause node  $v$  at level 2 has fewer than  $k - 1$  children (note that the nodes at level 0 and 1 have the “right” number of children; the clause label of 0 is a critical clause, and therefore the root has always  $k - 1$  children; an odd-level node always has  $d - 1$  children). The second reason would be that, for some color  $c$ , level 1 and 3 of the critical clause tree  $T_{x,c}^h$  contain nodes  $u$  and  $v$  with  $\text{varlabel}(u) = \text{varlabel}(v)$ .

It is easy to see that the first kind of privilege is stronger: let  $v$  be the level-2 node with fewer than  $k - 1$  children. We can add “fictitious” subtrees until  $v$  has  $k - 1$  children, and make sure that one of the added children shares its variable label with an already-existing level-3 node. The result of this operation,  $T'_{x,c}$ , exhibits a privilege of the second kind, and  $\text{Cut}_p(T_{x,c}^h) \supseteq \text{Cut}_p(T'_{x,c})$ .

Thus, let us assume that  $x$  is privileged because  $T_{x,c}^h$  contains two nodes  $v$  and  $w$  with  $\text{varlabel}(v) = \text{varlabel}(w) = z$  and the depths of  $v$  and  $w$  are in  $\{1, 3\}$ . Analogous to the proof of Proposition 14 (Lemma 3.5 in [4]), we start with iteratively assign fresh labels to variable

nodes; as shown in [4], this never increases  $\Pr[\text{Cut}_p(T_{x,c}^h)]$ . We apply this to all variable nodes except  $v$  and  $w$ , and obtain a new tree  $T$ . We make sure that there are no “missing children” in  $T$ , i.e., that every clause has  $k - 1$  children; this can be achieved by attaching fictitious subtrees, which does not increase  $\Pr[\text{Cut}_p(T)]$ . Also, we will for convenience assume that  $T$  is infinite, i.e., has no safe leaves (and no unsafe leaves, either). This does increase  $\Pr[\text{Cut}_p]$ , but by at most  $\text{error}(d, k, h)$ . In  $T$  we still have  $\text{varlabel}(v) = \text{varlabel}(w) = z$ , but all other labels are distinct. Let  $T'$  be the tree where  $v$  and  $w$  receive fresh labels  $z_v, z_w$ . We already know that  $\Pr[\text{Cut}_p(T')] = Q(p)$ . It remains to show that  $\Pr[\text{Cut}_p(T)]$  is substantially larger than  $\Pr[\text{Cut}_p(T')]$ . For this, let  $\mathbb{L}$  be the set of variable labels appearing in  $T$  and  $T'$ , and let  $\tau : \mathbb{L} \setminus \{z, z_v, z_w\} \rightarrow [0, 1]$ . We will analyze the difference

$$\Pr[\text{Cut}_p(T) \mid \tau] - \Pr[\text{Cut}_p(T') \mid \tau] \tag{8}$$

for fixed  $\tau$ . Introduce the three Boolean variables  $a := [\pi(z) < p]$ ,  $a_v := [\pi(z_v) < p]$ , and  $a_w := [\pi(z_w) < p]$ . Note that under  $\tau$ , the event  $\text{Cut}_p(T')$  reduces to  $f_\tau(a_v, a_w)$  for some monotone Boolean function and  $\text{Cut}_p(T)$  reduces to  $f_\tau(a, a)$ , for the same function  $f_\tau$ . There are only six possible such functions:  $f_\tau(a_v, a_w)$  is either 0, 1,  $a_v$ ,  $a_w$ ,  $a_v \wedge a_w$ , or  $a_v \vee a_w$ . If it is one of the first four, then  $\Pr[f_\tau(a_v, a_w)] = \Pr[f_\tau(a, a)]$  and (8) is 0. It cannot be  $a_v \vee a_w$ : the nodes  $v$  and  $w$  are not ancestors of each other. Finally, if  $f_\tau(a_v, a_w) = a_v \wedge a_w$  then we call  $\tau$  *pivotal* and observe that (8) becomes  $p - p^2$ .

From here on, our plan is to lower bound the probability that  $\tau$  is pivotal. We give a necessary and sufficient criterion for  $\tau$  to be pivotal.<sup>3</sup> It is best illustrated with a figure.

Squares are the clause nodes and circles are the variable nodes. Note that we assume that  $v$  and  $w$  are both on level 3, and their lowest common ancestor is the root. In the other cases, the picture and the subsequent calculation will be slightly different. To ease notation, we adopt the notation  $\text{Cut}_p(u) := \text{Cut}_p(T_u)$ , where  $T_u$  is the subtree of  $T'$  rooted at  $u$  (note that  $T'$  and  $T$  have the same node set, only some labels differ). In the case depicted in the figure,  $\tau$  is pivotal if and only if

1.  $\text{Cut}_p(u)$  happens for all aunts and uncles  $u$ ;
2.  $\text{Cut}_p(u)$  does not happen for all children  $u$  of  $v$ ; neither for all children  $u$  of  $w$ .
3.  $\pi(\text{grandparent of } v), \pi(\text{grandparent of } w) \geq p$ .

<sup>3</sup> Actually, it is sufficient for our purposes that the criterion be sufficient, and not necessary that it be necessary.

### 33:16 Impatient PPSZ

Furthermore, note that  $\Pr[\text{Cut}_p(u)]$  equals  $Q(p)$  if  $u$  is an uncle and  $R(p)$  if  $u$  is an aunt. Therefore,

$$\begin{aligned} \Pr[\text{Cut}_p(T)] - \Pr[\text{Cut}_p(T')] &\geq (p - p^2) \cdot \Pr[\tau \text{ is pivotal}] = \\ &(p - p^2)Q(p)^{\text{uncles}} \cdot R(p)^{\text{aunts}} \cdot (1 - Q(p)^{d-1})^2 (1 - p)^2 \\ &=: \delta(p) . \end{aligned}$$

It is clear that  $\delta(p) > 0$  for  $0 < p < 1 - 1/N$  and  $\delta(p) = 0$  for  $p \geq 1 - 1/N$ . Recalling the definition of  $S_{d,k} = \mathbb{E}[\log(J_1 + \dots + J_{d-1} + 1)]$  comparing it to  $\mathbb{E}[\log_2(A_x)] = \mathbb{E}[\log_2(A_{x,1} + \dots + A_{x,d-1} + 1)]$ , we can couple the ensembles  $\mathbf{A} := (A_{x,c})_{c=1}^{d-1}$  and  $\mathbf{J} := (J_c)_{c=1}^{d-1}$  such that  $\mathbf{A} \leq \mathbf{J}$  except with probability error( $d, k, p, h$ ), and  $A_{x,c} = 0, J_c = 1$ , conditioned on  $\pi(x) = p$ , happens with probability at least  $\delta(p) - \text{error}(d, k, p, h)$ . In fact, let us ignore the term error( $d, k, h$ ) for now and simply assume that  $\mathbf{A} \leq \mathbf{J}$  (more rigorously, we would have to replace every  $T_{x,c}^h$  by the appropriate infinite version; we decide to simply ignore error( $d, k, h$ ) in the following, lest we overload the reader with our notation). Set  $\Delta := J - A_x$ , and observe that  $\Delta \geq 0$  and  $\Pr[\Delta \geq 1 \mid \pi(x) = p] \geq \delta(p)$ .

$$\begin{aligned} \mathbb{E}[\log_2(J)] - \mathbb{E}[\log_2(A_x)] &= -\mathbb{E}\left[\log_2\left(\frac{J - \Delta}{J}\right)\right] \\ &= -\mathbb{E}\left[\log_2\left(1 - \frac{\Delta}{J}\right)\right] \\ &\geq -\mathbb{E}\left[\log_2\left(1 - \frac{\Delta}{d}\right)\right] \\ &\geq \frac{\log_2(e)}{d} \mathbb{E}[\Delta] \\ &\geq \frac{\log_2(e)}{d} \int_0^1 \delta(p) dp =: \epsilon_{\text{privileged}} . \end{aligned}$$

This is some positive number, and it depends only on  $d$  and  $k$ . ◀

## C Local reasoning for ImpatientPPSZ

► **Lemma 26** (Lemma 20, restated). *Suppose  $x \in \text{vbl}(F)$  is non-privileged. Let  $p = \pi(x)$ . If  $\text{ImpCut}_p(T_{x,c}^h)$  happens then  $A_{x,c}^{\text{imp}} = 0$ .*

**Proof.** We will prove the contrapositive: assume that  $A_{x,c}^{\text{imp}} = 1$  and show that  $\text{ImpCut}_p(T_{x,c}^h)$  does not happen. Let  $F(T_{x,c}^h)$  denote the set of clause labels appearing in  $T_{x,c}^h$ . Since  $A_{x,c}^{\text{imp}} = 1$  by assumption, the formula  $F^{[V_x^{\text{imp}} \mapsto d]}$  does not  $D$ -imply  $(x \neq c)$ . In particular,  $|F(T_{x,c}^h)| \leq D$  and therefore  $F(T_{x,c}^h)^{[V_x^{\text{imp}} \mapsto d]}$  does not imply  $(x \neq c)$ . This means that there is an assignment  $\gamma$  that (1) satisfies  $F(T_{x,c}^h)$ , (2)  $\gamma(x) = c$ , (3)  $\gamma(y) = d$  for all  $y \in V_x^{\text{imp}}$ .

As a first step, we will show that  $\text{Cut}_p(T_{x,c}^h)$  does not happen. For this, we will construct a sequence of clause nodes  $u_0, u_1, \dots$ , with  $u_0$  being the root and  $u_{i+1}$  being a grandchild of  $u_i$ , keeping the following invariant:

**Invariant.** For every clause node  $u$  in the sequence,  $\beta_u(y) \neq d \Rightarrow \gamma(y) = \beta_u(y)$ .

Note that the invariant is satisfied for the root:  $x$  is the only variable with  $\beta_{\text{root}}(x) \neq d$ , and  $\gamma(x) = c = \beta_{\text{root}}(x)$ . To find  $u_{i+1}$  from  $u_i$ , let  $C_i$  be the clause label of  $u_i$ , and write  $C_i$  as

$$C_i = (y_1 \neq c_1 \vee \dots \vee y_l \neq c_l \vee z_{l+1} \neq d \vee \dots \vee z_{k-1} \neq d) ,$$

where  $c_1, \dots, c_l \neq d$ . By construction,  $\beta_{u_i}$  violates  $C_i$ , and therefore  $\beta_{u_i}(y_j) = c_j$  for  $1 \leq j \leq l$ ; by the invariant,  $\gamma(y_j) = c_j$ , too. But  $\gamma$  satisfies  $C_i$  (it satisfies every clause label in  $T_{x,c}^h$ ), and therefore  $\gamma(z_j) = c \neq d$  for some  $l+1 \leq j \leq k-1$ . In particular,  $u_i$  has children. Let  $v$  be the child of  $u_i$  with variable label  $z_j$ . If  $v$  is a leaf (a safe leaf), terminate the process and call the path from root to  $v$  the *witness path*. Otherwise, and let  $u_{i+1}$  be the child of  $v$  with  $EC(v, u_{i+1}) = c$ . Note that  $u_{i+1}$  satisfies the invariant.

Since  $T_{x,c}^h$  is finite, this process terminates with a witness path. Note that  $\gamma(y) \neq d$  for all variable labels  $y$  appearing on that path. In particular, this means that  $y \notin V_x^{\text{imp}}$ , thus  $y \notin V_x$ , thus  $\pi(y) \geq \pi(x)$ . In other words,  $\text{Cut}_p(T_{x,c}^h)$  does not happen.

Without loss of generality, let  $v_1$  be the level-1-node on the witness path, and  $T_1$  be the tree rooted at  $v_1$ , and  $y_1 := \text{varlabel}(v_1)$ . Observe that  $\text{Cut}_p(T_1)$  does not happen. We will now show that  $\text{LocalImpCut}_p(v_1)$  does not happen, either. Assume, for the sake of contradiction, that  $\text{LocalImpCut}_p(v_1)$  happens. Does it happen because of Point 3a in the definition? Certainly not:  $\gamma(y_1) \neq d$  since  $v_1$  is on the witness path, and thus  $\pi(y_1) \geq p$ . So it happens because of Point 3b, and  $\mathbb{I}_{y_1} = 1$ ; without loss of generality, this means that  $\text{LocalImpCut}_p(v_1)$  happens for the first  $d-2$  children  $w_1, \dots, w_{d-2}$  of  $v_1$ ; let  $C_1, \dots, C_{d-2}$  be the respective clause labels. All those  $C_i$  are critical clauses ( $x$  is non-privilegeded, remember), and have  $k-1$  children each. So  $\text{LocalImpCut}_p$  happens for the first  $(k-1)(d-2)$  of the  $(k-1)(d-1)$  grandchildren of  $v_1$ . In other words, all their variable labels  $z$  have  $\pi(z) < p$  and thus  $z \in V_x$ . Under the assignment  $[V_x \mapsto d]$ , each of  $C_i$  reduces to a unit clause; this unit clause is still violated by  $\beta_{w_i}$  and is therefore either  $(y_1 \neq i)$  or  $(x \neq c)$ . If it was  $(x \neq c)$  then  $F(T_{x,c}^h)^{[V_x \mapsto d]}$  would imply  $(x \neq c)$  and therefore  $A_{x,c} = A_{x,c}^{\text{imp}} = 0$ , contradicting our assumption. So it is  $(y_1 \neq i)$ . In other words,  $F(T_{x,c}^h)^{[V_x \mapsto d]}$  contains the unit clauses  $(y_1 \neq 1), \dots, (y_1 \neq d-2)$ ; thus, when  $x$  is being processed by ImpatientPPSZ, the set of plausible values for  $y$  has been reduced to at most two values:  $d-1$  and  $d$ ; since  $\mathbb{I}_{y_1} = 1$ , the algorithm will assign  $y_1$  a value in Line 6, and  $y_1 \in V_x^{\text{imp}}$ . This is again a contradiction:  $\gamma(y_1) \neq d$  since  $v_1$  is on the witness path;  $\gamma(y_1) = d$  since  $y_1 \in V_x^{\text{imp}}$ . This concludes the proof.  $\blacktriangleleft$

## D ImpCut probability

Suppose  $x \in \text{vbl}(F)$  is non-privilegeded and  $T_{x,c}^h$  is a critical clause tree for  $x$  and  $c \in [d]$ .

► **Lemma 27** (Lemma 21, restated). *If  $p < \theta$  then  $\Pr[\text{ImpCut}_p(T_{x,c}^h) \mid \pi(x) = p]$  is at least*

$$(p + c(\theta - p)\text{abamo}(p^{k-1}, d-1) + (1 - p - c(\theta - p))Q(p)^{d-1})^{k-1} - \text{error}(d, k, h) .$$

*If  $p \geq \theta$  then it is at least  $Q(p) - \text{error}(d, k, h)$ .*

**Proof.** If  $p \geq \theta$  then this is obvious since already  $\text{Cut}_p(T_{x,c}^h)$  has probability at least  $Q(p) - \text{error}(d, k, h)$ , by Proposition 14. Thus we assume  $p < \theta$ . The root of  $T_{x,c}^h$  has  $k-1$  children  $v_1, \dots, v_{k-1}$ , whose respective variable labels are  $y_1, \dots, y_{k-1}$ . Let  $T_i$  denote the subtree of  $T_{x,c}^h$  rooted at  $v_i$ .

$$\begin{aligned} \Pr [\text{ImpCut}_p(T_{x,c}^h)] &= \Pr \left[ \bigwedge_{i=1}^{k-1} (\text{Cut}_p(T_i) \vee \text{LocalImpCut}_p(v_i)) \right] \\ &\geq \prod_{i=1}^{k-1} (\Pr[\text{Cut}_p(T_i) \vee \text{LocalImpCut}_p(v_i)]) . \quad (\text{FKG inequality}) \end{aligned}$$

We can apply the FKG inequality because each event  $\text{Cut}_p(T_i) \vee \text{LocalImpCut}_p(v_i)$  is a monotone increasing Boolean function in the variables  $[\pi(z) < p]$  and  $\mathbb{I}_{y_i}$ . It remains to show that, for each  $1 \leq i \leq k-1$ , the event  $\text{Cut}_p(T_i) \vee \text{LocalImpCut}_p(v_i)$  happens with probability at least

$$p + c(\theta - p)\text{abamo}(p^{k-1}, d-1) + (1 - p - c(\theta - p))Q(p)^{d-1} - \text{error}(d, k, h) \quad (9)$$

For this, let us abbreviate  $T := T_i$ ,  $v := v_i$  its root, and  $y := \text{varlabel}(v) = y_i$ ; also, we define the events  $A := \text{LocalImpCut}_p(v)$  and  $B := \text{Cut}_p(T)$ . We distinguish three cases:

- (i) if (1)  $\pi(y) < p$  then the desired event  $A \vee B$  happens;
- (ii) if  $\pi(y) \geq p$  and  $\mathbb{I}_y = 1$  (which implies  $\pi(y) < \theta$ ) then we ignore  $B$  and focus on  $A$ ;
- (iii) if  $\pi(y) \geq p$  and  $\mathbb{I}_y = 0$ , then  $A$  does not happen, so focus on  $B$ .

Formally,

$$\Pr[A \vee B] \geq \Pr[(i)] + \Pr[(ii)] \cdot \Pr[A \mid (ii)] + \Pr[(iii)] \cdot \Pr[B \mid (iii)]$$

Next, let us look at each case.

1.  $\Pr[(i)] = p$ ; this explains the first term in (9).
2.  $\Pr[(ii)] = c(\theta - p)$ . Furthermore, if (ii) happens, then  $A$  happens if and only if for at least  $d-2$  of the children  $w_1, \dots, w_{d-1}$ , the event  $A_j := \text{LocalImpCut}_p(w_j)$  happens. Each  $A_j$  happens with probability  $\rho := p^{k-1}$ ; they are independent since all  $(d-1)(k-1)$  grandchildren of  $v$  have distinct labels. Therefore,

$$\begin{aligned} \Pr[A \mid (ii)] &= \Pr[A_1 \wedge \dots \wedge A_{d-1}] + \sum_{j^*=1}^{d-1} \Pr[\neg A_{j^*} \wedge \bigwedge_{j \neq j^*} A_j] \\ &= \rho^{d-1} + (d-1)(1-\rho)\rho^{d-2} = \text{abamo}(p^{k-1}, d-1). \end{aligned}$$

This explains the second term in (9).

3.  $\Pr[(iii)] = 1 - p - c(\theta - p)$ . If (iii) happens, then  $B$  happens if and only if  $\text{Cut}_p(T)$  happens for each of the  $d-1$  subtrees of  $T$ . By Proposition 14, this happens with probability  $(Q(p) - \text{error}(d, k, h))^{d-1}$ . This explains the third and fourth term in (9).

This concludes the proof.  $\blacktriangleleft$

## E Bounding losses and gains. Proofs of Propositions 22 and 23

First, we need some good-enough estimates for our probabilities  $R(p)$ ,  $Q(p)$ , and  $W(p)$ . Note that  $R(p)$  and  $Q(p)$  are the roots of certain polynomials, and we do not have an explicit formula for them. The bounds in Proposition 28 are somewhat crude but sufficient for our purposes.

► **Proposition 28.**  $R(p) \leq p + 4p^L$ ;  $Q(p) \leq (p + 4p^L)^{k-1}$ ; and  $W(p) \leq p + O(\theta p^{(d-2)(k-1)})$ . The hidden constant in the  $O$  depends on  $d$  and  $k$  only.

**Proof.** One checks that  $R(p)$  is convex on the interval  $[0, 1 - 1/L]$ . To see this, note that for  $p \leq 1 - 1/L$ ,  $R(p)$  is the unique solution in  $[0, 1]$  of the equation

$$R = p + (1 - p)R^L,$$

by Proposition 13. We can solve explicitly for  $p$  and check that  $p(R)$  is concave, by elementary calculus. Since  $R$  is convex,  $R(0) = 0$ , and  $R(1 - 1/L) = 1$ , the graph of  $R(p)$  is below the line from  $(0, 0)$  to  $(1 - 1/L, 1)$ , and therefore  $R(p) \leq \frac{L}{L-1}p$ . This is not enough yet, but applying the equation of  $R$  to this estimate gives

$$R = p + (1-p)R^L \leq p + (1-p) \left( \frac{L}{L-1} p \right)^L \leq p + 4p^L.$$

The upper bound for  $Q$  follows directly from  $Q(p) = R(p)^{k-1}$ . It remains to prove the upper bound on  $W(p)$ :

$$\begin{aligned} W(p) &= p + c(\theta - p)\text{abamo}(p^{k-1}, d-1) + (1-p - c(\theta - p))Q(p)^{d-1} \\ &\leq p + \theta\text{abamo}(p^{k-1}, d-1) + Q(p)^{d-1} \\ &= p + \theta p^{(k-1)(d-1)} + \theta(d-1)(1-p^{k-1})p^{(k-1)(d-2)} + Q(p)^{d-1} \\ &\leq p + (d-1)\theta p^{(d-2)(k-1)} + R^L \\ &\leq p + (d-1)\theta p^{(d-2)(k-1)} + (p + 4p^L)^L \\ &\leq p + O\left(\theta p^{(d-2)(k-1)}\right). \end{aligned}$$

► **Proposition 29** (Proposition 22, restated).  $\Pr[J^{\text{imp}} = 1 \wedge \mathbb{I}_x] \leq \frac{c}{L+1}\theta^{L+1} + O(\theta^{L+2})$ .

**Proof.** Recall that if  $\pi(x) < \theta$  then  $\mathbb{I}_x$  is 1 with probability  $c$  and 0 with probability  $1 - c$ . If  $\pi(x) \geq \theta$  then  $\mathbb{I}_x = 0$ . Also,  $J^{\text{imp}} = 1$  if and only if  $J_1^{\text{imp}} = \dots = J_{d-1}^{\text{imp}} = 0$ . Therefore,

$$\begin{aligned} \Pr[J^{\text{imp}} = 1 \wedge \mathbb{I}_x] &= c \cdot \int_0^\theta \Pr[J^{\text{imp}} = 1 \mid \pi(x) = p] dp = c \cdot \int_0^\theta W^{(d-1)(k-1)} dp \\ &= c \cdot \int_0^\theta (p + O(\theta p^{(d-2)(k-1)}))^L dp \leq c \cdot \int_0^\theta p^L (1 + O(\theta)) dp \\ &\hspace{15em} (\text{since } (d-2)(k-1) \geq 1) \\ &= \frac{c}{L+1}\theta^{L+1} + O(\theta^{L+2}) \end{aligned}$$

This proves the proposition. ◀

► **Proposition 30** (Proposition 23, restated).  $\mathbb{E}[\log_2(J^{\text{imp}})] - S_{d,k} \leq (d-1)\log_2(1-1/d) \cdot \left( \frac{c}{L+1}\theta^{L+1} + O(\theta^{L+2}) \right)$ .

**Proof.** Recall the definition of  $S_{d,k}$ : sample random variables  $J_1, \dots, J_{d-1}$  by setting  $p := \pi(x)$  and setting each  $J_c$  to 0 with probability  $Q(p)$  and to 1 with probability  $1 - Q(p)$ , and  $J = J_1 + \dots + J_{d-1} + 1$ . So the  $J_c$  are independent conditioned on  $\pi(x) = p$ . Then  $S_{d,k} = \mathbb{E}[\log_2(J)]$ . Set  $\Delta_c := J_c - J_c^{\text{imp}}$  and  $\Delta = \sum_c \Delta_c$ . Note that all  $\Delta_c$  have the same distribution.

► **Proposition 31.**  $\mathbb{E}[\Delta_1 \mid \pi(x) = p] \geq c(\theta - p)L(p^{L-1} - O(p^L))$  for all  $1 \leq c \leq d-1$ .

In particular, if  $p < \theta$  and  $\theta$  is sufficiently small then  $\mathbb{E}[\Delta_1] \geq 0$ . Therefore,  $\mathbb{E}[J_c] \leq \mathbb{E}[J_c^{\text{imp}}]$  and we can couple the ensemble  $(J_1, \dots, J_{d-1})$  and  $(J_1^{\text{imp}}, \dots, J_{d-1}^{\text{imp}})$  on a common probability space on which  $J_c \leq J_c^{\text{imp}}$ , always, and thus  $\Delta \geq 0$ . We therefore see that

### 33:20 Impatient PPSZ

$\mathbb{E}[\log_2(J^{\text{imp}})] - S_{d,k}$  is

$$\begin{aligned} \mathbb{E}[\log_2(J^{\text{imp}}) - \log_2(J)] &= \mathbb{E}\left[\log_2\left(1 - \frac{\Delta}{J}\right)\right] \\ &\leq \mathbb{E}\left[\log_2\left(1 - \frac{\Delta}{d}\right)\right] \leq \mathbb{E}\left[\log_2\left(\left(1 - \frac{1}{d}\right)^\Delta\right)\right] \\ &= \mathbb{E}[\Delta] \log_2\left(1 - \frac{1}{d}\right). \end{aligned}$$

Conditioned on  $\pi(x) = p$  and using Proposition 31, this is at most

$$c(\theta - p)L(p^{L-1} - O(p^L))(d-1)\log_2\left(1 - \frac{1}{d}\right).$$

We integrate this over  $p$  to get rid of the condition  $\pi(x) = p$  and see that

$$\mathbb{E}[\log_2(J^{\text{imp}})] - S_{d,k} \leq (d-1)\log_2\left(1 - \frac{1}{d}\right) \cdot \left(\frac{c}{L+1}\theta^{L+1} + O(\theta^{L+2})\right).$$

This concludes the proof of Proposition 30. ◀

It remains to prove Proposition 31.

#### Proof of Proposition 31.

$$\begin{aligned} \mathbb{E}[\Delta_1 \mid \pi(x) = p] &= \mathbb{E}[J_c - J_c^{\text{imp}} \mid \pi(x) = p] = (1 - Q) - (1 - W^{k-1}) = W^{k-1} - R^{k-1} \\ &\geq (k-1)(W - R)R^{k-2}, \end{aligned}$$

where the last inequality follows because  $W^{k-1} = (R + W - R)^{k-1} = R^{k-1} \left(1 + \frac{W-R}{R}\right)^{k-1} \geq R^{k-1} \left(1 + \frac{(k-1)(W-R)}{R}\right) = R^{k-1} + (k-1)(W-R)R^{k-2}$ . Now let us bound  $W - R$  from below. If  $p \geq \theta$  then  $W(p) = R(p)$  and  $W - R = 0$ . If  $p < \theta$ , we expand  $R(p)$  as follows:

$$R = p + (1-p)Q^{(d-1)} = p + c(\theta - p)Q^{d-1} + (1-p - c(\theta - p))Q^{d-1}$$

and therefore

$$\begin{aligned} W - R &= c(\theta - p) \left(\text{abamo}(p^{k-1}, d-1) - Q^{d-1}\right) \\ &= c(\theta - p) \left(p^{(k-1)(d-1)} + (d-1)(1-p^{k-1})p^{(k-1)(d-2)} - Q^{d-1}\right) \\ &\geq c(\theta - p) \left(p^L + (d-1)p^{(k-1)(d-2)} - (d-1)p^L - (p + O(p^2))^L\right) \\ &\geq c(\theta - p)(d-1) \left(p^{(k-1)(d-2)} - O(p^L)\right). \end{aligned}$$

Next, combining the previous two calculations, we see that

$$\begin{aligned} \mathbb{E}[\Delta_1 \mid \pi(x) = p] &\geq (k-1)(W - R)R^{k-2} \geq (k-1)(W - R)p^{k-2} \\ &\geq (k-1)c(\theta - p)(d-1) \left(p^{(k-1)(d-2)} - O(p^L)\right) p^{k-2} \\ &\geq c(\theta - p)L(p^{L-1} - O(p^L)). \end{aligned} \quad \blacktriangleleft$$

# Fine-Grained Meta-Theorems for Vertex Integrity

## Abstract

---

Vertex Integrity is a graph measure which sits squarely between two more well-studied notions, namely vertex cover and tree-depth, and that has recently gained attention as a structural graph parameter. In this paper we investigate the algorithmic trade-offs involved with this parameter from the point of view of algorithmic meta-theorems for First-Order (FO) and Monadic Second Order (MSO) logic. Our positive results are the following: (i) given a graph  $G$  of vertex integrity  $k$  and an FO formula  $\phi$  with  $q$  quantifiers, deciding if  $G$  satisfies  $\phi$  can be done in time  $2^{O(k^2q + q \log q)} + n^{O(1)}$ ; (ii) for MSO formulas with  $q$  quantifiers, the same can be done in time  $2^{2^{O(k^2+kq)}} + n^{O(1)}$ . Both results are obtained using kernelization arguments, which pre-process the input to sizes  $2^{O(k^2)}q$  and  $2^{O(k^2+kq)}$  respectively.

The complexities of our meta-theorems are significantly better than the corresponding meta-theorems for tree-depth, which involve towers of exponentials. However, they are worse than the roughly  $2^{O(kq)}$  and  $2^{2^{O(k+q)}}$  complexities known for corresponding meta-theorems for vertex cover. To explain this deterioration we present two formula constructions which lead to fine-grained complexity lower bounds and establish that the dependence of our meta-theorems on  $k$  is best possible. More precisely, we show that it is not possible to decide FO formulas with  $q$  quantifiers in time  $2^{o(k^2q)}$ , and that there exists a constant-size MSO formula which cannot be decided in time  $2^{2^{o(k^2)}}$ , both under the ETH. Hence, the quadratic blow-up in the dependence on  $k$  is unavoidable and vertex integrity has a complexity for FO and MSO logic which is truly intermediate between vertex cover and tree-depth.

## 1 Introduction

An algorithmic meta-theorem is a general statement proving that a large class of problems is tractable. Such results are of great importance because they allow one to quickly classify the complexity of a new problem, before endeavoring to design a fine-tuned algorithm. In the domain of parameterized complexity theory for graph problems, possibly the most well-studied type of meta-theorems are those where the class of problems in question is defined using a language of formal logic, typically a variant of First-Order (FO) or Monadic Second-Order (MSO) logic, which are the logics that allow quantification over vertices or sets of vertices respectively<sup>1</sup>. In this area, the most celebrated result is Courcelle’s theorem [6], which states

---

<sup>1</sup> Note that the version of MSO logic we use in this paper is sometimes also referred to as  $\text{MSO}_1$  to distinguish from the version that also allows quantification over sets of edges.

that all properties expressible in MSO logic are solvable in linear time, parameterized by treewidth and the size of the MSO formula. In the thirty years since the appearance of this fundamental result, numerous other meta-theorems in this spirit have followed (we give an overview of some such results below).

Despite its great success, Courcelle’s theorem suffers from one significant weakness: the algorithm it guarantees for deciding an MSO formula  $\phi$  on a graph  $G$  with  $n$  vertices and treewidth  $k$  has running time  $f(k, \phi) \cdot n$ , where  $f$  is, in the worst case, a tower of exponentials whose height can only be bounded as a function of  $\phi$ . Unfortunately, it has been known since the work of Frick and Grohe [20] that this terrible parameter dependence cannot be avoided, even if one only considers FO logic on trees (or MSO logic on paths [40]). This has motivated the study of the complexity of FO and MSO logic with parameters which are more restrictive than treewidth. In the context of such parameters, fixed-parameter tractability for all MSO-expressible problems is already given by Courcelle’s theorem, so the goal is to obtain more “fine-grained” meta-theorems which achieve a better dependence on  $\phi$  and  $k$ .

The two results from this line of research which are most relevant to our paper are the meta-theorems for vertex cover given in [39], and the meta-theorem for tree-depth given by Gajarský and Hliněný [21]. Regarding vertex cover, it was shown in [39] that FO and MSO formulas with  $q$  quantifiers can be decided on graphs with vertex cover  $k$  in time roughly  $2^{O(kq+q \log q)}$  and  $2^{2^{O(k+q)}}$  respectively. Both of these results were shown to be tight, in the sense that improving their dependence on  $k$  would violate the Exponential Time Hypothesis (ETH). For tree-depth, it was shown in [21] that FO and MSO formulas with  $q$  quantifiers can be decided on graphs with tree-depth  $k$  with a complexity that is roughly  $k$ -fold exponential. Hence, for fixed  $k$ , the complexity we obtain is elementary, but the height of the tower of exponentials increases with  $k$ , and this cannot be avoided under the ETH [40].

Vertex cover and tree-depth are among the most well-studied measures in parameterized complexity. In all graphs  $G$  we have  $\text{vc}(G)+1 \geq \text{td}(G) \geq \text{pw}(G) \geq \text{tw}(G)$ , so these parameters form a natural hierarchy with pathwidth and treewidth, with vertex cover being the most restrictive. As explained above, the distance between the performance of meta-theorems for vertex cover (which are double-exponential for MSO) and for tree-depth (which give a tower of exponentials of height  $\text{td}$ ) is huge, but conceptually this is perhaps not surprising. Indeed, one could argue that the structural distance between graphs of vertex cover  $k$  from the class of graphs of tree-depth  $k$  is also huge. As a reminder, a graph has vertex cover  $k$  if we can delete  $k$  vertices to obtain an independent set; while a graph has tree-depth  $k$  if there exists  $k' \leq k$  such that we can delete  $k'$  vertices to obtain a disjoint union of graphs of tree-depth  $k - k'$ . Clearly, the latter (inductive) definition is more powerful and covers vastly more graphs, so it is natural that model-checking should be significantly harder for tree-depth.

The landscape of parameters described above indicates that there should be space to investigate interesting structural parameters *between* vertex cover and tree-depth, exactly because the distance between these two is large in terms of generality and complexity. One notion that has recently attracted attention in this area is *Vertex Integrity* [11], denoted as  $\iota(G)$ . A graph has vertex integrity  $k$  if there exists  $k' \leq k$  such that we can delete  $k'$  vertices and obtain a disjoint union of graphs of *size* at most  $k - k'$ . Hence, the definition of vertex integrity is the same as for tree-depth, except that we replace the inductive step by simply bounding the size of the components that result after deleting a separator of the graph. This produces a notion that is more restrictive than tree-depth, but still significantly more general than vertex cover (where the resulting components must be singletons). In all graphs  $G$ , we have  $\text{vc}(G) + 1 \geq \iota(G) \geq \text{td}(G)$ , so it becomes an interesting question to investigate the complexity trade-off associated with these parameters, that is, how the complexity of various

problems deteriorates as we move from vertex cover, to vertex integrity, to tree-depth. This type of study was recently undertaken systematically for many problems by Gima et al. [29]. In this paper we make an investigation in the same direction from the lens of algorithmic meta-theorems.

**Our results.** We consider the problem of verifying whether a graph  $G$  satisfies a property given by an FO or MSO formula with  $q$  quantifiers, assuming  $\iota(G) \leq k$ . Our goal is to give a fine-grained determination of the complexity of this problem as a function of  $k$ . We obtain the following two positive results:

1. FO formulas with  $q$  quantifiers can be decided in time  $2^{O(k^2q + q \log q)} + n^{O(1)}$ .
2. MSO formulas with  $q$  vertex and set quantifiers can be decided in time  $2^{2^{O(k^2 + kq)}} + n^{O(1)}$ .

Hence, we obtain meta-theorems stating that any problem that can be expressed in FO or MSO logic can be solved in the aforementioned times. Both of these results are obtained through a kernelization argument, similar in spirit to the arguments used in the meta-theorems of [21, 39]. To describe the main idea, recall that if  $\iota(G) \leq k$ , then there exists a separator  $S$  of size at most  $k$ , such that removing it will disconnect the graph into components of size at most  $k$ . The key now is that these components can be partitioned into  $2^{k^2}$  equivalence *types*, where components of the same type are isomorphic. We then argue that if we have a large number of isomorphic components, it is always safe to delete any one of them from the graph, as this does not change whether the given formula holds (Lemmas 12 and 14). We then complete the argument by applying the standard brute-force algorithms for FO and MSO logic on the kernels.

We complement the results above by showing that the approach of kernelizing and then executing the brute-force algorithm is best possible. More precisely, we show that, under the ETH, it is not possible to obtain a model-checking algorithm for FO logic running in time  $2^{o(k^2q)}n^{O(1)}$ ; while for MSO we construct a constant-sized formula which cannot be model-checked in time  $2^{2^{o(k^2)}}$ . Hence, the quadratic dependence on  $k$ , which distinguishes our meta-theorems from the corresponding meta-theorems for vertex cover, cannot be avoided.

**Related work.** The study of structural parameters which trade off the generality of treewidth for improved algorithmic properties is by now a standard topic in parameterized complexity. The most common type of work here is to consider a problem that is intractable parameterized by treewidth and see whether it becomes tractable parameterized by vertex cover or tree-depth [2, 10, 13, 16, 17, 31, 32, 35, 34, 36, 42, 41]. See [1] for a survey of results of this type. In this context, vertex integrity has only recently started being studied as an intermediate parameter between vertex cover and tree-depth, and it has been discovered that fixed-parameter tractability for several problems which are W-hard by tree-depth can be extended from vertex cover to vertex integrity [4, 12, 25, 27, 29]. Note that some works use a measure called *core fracture* number, which is an equivalent notion to vertex integrity.

Algorithmic meta-theorems are a well-studied topic in parameterized complexity (see [30] for a survey). Courcelle's theorem has been extended to the more general notion of clique-width [7], and more efficient versions of these meta-theorems have been given for the more restricted parameters twin-cover [22], shrub-depth [24, 23], neighborhood diversity and max-leaf number [39]. Meta-theorems have also been given for even more general graph parameters, such as [5, 14, 19, 18], and for logics other than FO and MSO, with the goal of either targeting a wider class of problems [26, 37, 38, 44], or achieving better complexity [43]. Meta-theorems have also been given in the context of kernelization [3, 15, 28] and

approximation [9]. To the best of our knowledge, the complexity of FO and MSO model checking parameterized by vertex integrity has not been explicitly studied before, but since vertex integrity is a restriction of tree-depth and a generalization of vertex cover, the algorithms of [21] and the lower bounds of [39] apply in this case.

## 2 Definitions and Preliminaries

First, let us formally define the notion of vertex integrity of a graph.

► **Definition 1.** *A graph  $G$  is said to have vertex integrity  $\iota(G)$  when there exists a set  $S \subset V(G)$  such that, if  $S' \subset V(G)$  is the set of vertices of the largest connected component of  $G \setminus S$  then  $|S| + |S'| \leq \iota(G)$ .*

We recall that Drange et al. [11] have shown that deciding if a graph has  $\iota(G) \leq k$  admits a kernel of order  $O(k^3)$ . Hence, given a graph  $G$  that is promised to have vertex integrity  $k$ , we can execute this kernelization algorithm and then look for the optimal separator  $S$  in the kernel. As a result, finding a separator  $S$  proving that  $\iota(G) \leq k$  can be done in  $k^{O(k)} + n^{O(1)}$ . Since this running time is dominated by the running times of our meta-theorems, we will always silently assume that the separator  $S$  is given in the input when the input graph has vertex integrity  $k$ .

A main question that will interest us is whether a graph satisfies a property expressible in First-Order (FO) or Monadic Second-Order (MSO) logic. Let us briefly recall the definitions of these logics. We use  $x_i, i \in \mathbb{N}$  to denote vertex (FO) variables and  $X_i, i \in \mathbb{N}$  to denote set (MSO) variables. Vertex variables take values from a set of vertex constants  $U = \{u_i, i \in \mathbb{N}\}$ , whereas vertex set variables take values from a set of vertex set constants  $D = \{D_i, i \in \mathbb{N}\}$ .

Now, given a graph  $G$ , in order to say that the assignment of a vertex variable  $x_i$  or a vertex set variable  $X_i$  to a constant corresponds to a particular vertex or vertex set of  $G$ , we make use of a *labeling* function  $\ell$  that maps vertex constants to vertices of  $V(G)$  and of a *coloring* function  $\mathcal{C}$  that maps vertex set constants to vertex sets of  $V(G)$ . More formally,  $\ell, \mathcal{C}$  are partial functions  $\ell : U \rightarrow V(G)$  and  $\mathcal{C} : D \rightarrow 2^{V(G)}$ . The functions may be undefined for some constants, for example, if  $\ell$  is not defined for the constant  $u_i$  we write  $\ell(u_i) \uparrow$ .

► **Definition 2.** *Given a triplet  $G, \ell, \mathcal{C}$ , a vertex  $v \in V(G)$  is said to be unlabeled if  $\nexists u_i \in U$  such that  $\ell(u_i) = v$ . A set of vertices  $C_1 \subseteq V(G)$  is unlabeled if all the vertices of  $C_1$  are unlabeled.*

► **Definition 3.** *We say that two labeling functions  $\ell, \ell'$  agree on a constant  $u_i$  if either they are both undefined on  $u_i$  or  $\ell(u_i) = \ell'(u_i)$ . Similarly, two coloring functions  $\mathcal{C}, \mathcal{C}'$  agree on  $D_i$  if they are both undefined or  $\mathcal{C}(D_i) = \mathcal{C}'(D_i)$ .*

► **Definition 4.** *Given two triplets  $G_1, \ell_1, \mathcal{C}_1$  and  $G_2, \ell_2, \mathcal{C}_2$  and a bijective function  $f : V(G_1) \rightarrow V(G_2)$ . For  $C_1 \subseteq V(G_1)$ , we define  $f(C_1) = \bigcup_{v \in C_1} \{f(v)\}$ . We say that  $V(G_1)$  and  $V(G_2)$  have the same labelings for  $f$  if  $\forall u_i \in U$ , either both  $\ell_1(u_i), \ell_2(u_i)$  are undefined or  $f(\ell_1(u_i)) = \ell_2(u_i)$ ; we say that  $V(G_1)$  and  $V(G_2)$  have the same colorings for  $f$  if  $\forall D_i \in D$ , either both  $\mathcal{C}_1(D_i), \mathcal{C}_2(D_i)$  are undefined or  $f(\mathcal{C}_1(D_i)) = \mathcal{C}_2(D_i)$ .*

► **Definition 5.** *An isomorphism between two triplets  $G_1, \ell_1, \mathcal{C}_1$  and  $G_2, \ell_2, \mathcal{C}_2$  is a bijective function  $f : V(G_1) \rightarrow V(G_2)$  such that (i) for all  $v, w \in V(G_1)$  we have  $(v, w) \in E(G_1)$  if and only if  $(f(v), f(w)) \in E(G_2)$ , (ii)  $V(G_1)$  and  $V(G_2)$  have the same labelings and colorings for  $f$ . Two triplets  $G_1, \ell_1, \mathcal{C}_1$  and  $G_2, \ell_2, \mathcal{C}_2$  are isomorphic if there exists an isomorphism between them.*

► **Definition 6.** Given a triplet  $G, \ell, \mathcal{C}$ . We say that two sets  $C_1 \subseteq V(G)$  and  $C_2 \subseteq V(G)$  have the same type if there exist  $\ell', \mathcal{C}'$  and an isomorphism  $f : V(G) \rightarrow V(G)$  between the triplets  $G, \ell, \mathcal{C}$  and itself such that  $f$  maps elements of  $C_1$  to  $C_2$  and vice versa and elements from  $V(G) \setminus (C_1 \cup C_2)$  to themselves.

Notice that only for vertices that don't belong in the sets  $C_1$  and  $C_2$  (which  $f$  maps to themselves) we can have that  $f(\ell(u_i)) = \ell(u_i)$ . This leads to the following observation:

► **Observation 7.** In order for two disjoint sets  $C_1$  and  $C_2$  to have the same type, they should necessarily be unlabeled (that is,  $\forall u_i, \ell(u_i) \notin C_1 \cup C_2$ ).

► **Definition 8.** Given a triplet  $G, \ell, \mathcal{C}$  and a set  $C_1 \subset V(G)$ . The restriction of  $\mathcal{C}$  to  $G \setminus C_1$  is a function  $\mathcal{C}' : D \rightarrow V(G) \setminus C_1$  such that  $\mathcal{C}'(D_i) = \mathcal{C}(D_i) \setminus C_1$  for all  $D_i \in D$  for which  $\mathcal{C}(D_i) \cap C_1 \neq \emptyset$  and  $\mathcal{C}, \mathcal{C}'$  agree on the rest of  $D_i$ .

An MSO formula is a formula produced by the following grammar, where  $X$  represents a set variable,  $x$  a vertex variable,  $y$  a vertex variable or vertex constant, and  $Y$  a set variable or constant:

$$\phi \rightarrow \exists X.\phi \mid \exists x.\phi \mid \phi \vee \phi \mid \neg\phi \mid y \sim y \mid y = y \mid y \in Y$$

The operations above are vertex set quantification, vertex quantification, disjunction, negation, edge relation, vertex equality, and set inclusion respectively. Their semantics are defined inductively in the usual way: given a triplet  $G, \ell, \mathcal{C}$  and an MSO formula  $\phi$ , we say that the graph satisfies the property described by  $\phi$ , or simply that  $G, \ell, \mathcal{C}$  models  $\phi$ , and write  $G, \ell, \mathcal{C} \models \phi$  according to the following rules:

- $G, \ell, \mathcal{C} \models u_i \in D_j$  if  $\ell(u_i)$  is defined and  $\ell(u_i) \in \mathcal{C}(D_j)$ .
- $G, \ell, \mathcal{C} \models u_i = u_j$  if  $\ell(u_i), \ell(u_j)$  are defined and  $\ell(u_i) = \ell(u_j)$ .
- $G, \ell, \mathcal{C} \models u_i \sim u_j$  if  $\ell(u_i), \ell(u_j)$  are defined and  $(\ell(u_i), \ell(u_j)) \in E(G)$ .
- $G, \ell, \mathcal{C} \models \phi \vee \psi$  if  $G, \ell, \mathcal{C} \models \phi$  or  $G, \ell, \mathcal{C} \models \psi$ .
- $G, \ell, \mathcal{C} \models \neg\phi$  if it is not the case that  $G, \ell, \mathcal{C} \models \phi$ .
- $G, \ell, \mathcal{C} \models \exists x_i.\phi$  if there exists  $v \in V(G)$  such that  $G, \ell', \mathcal{C} \models \phi[x_i \setminus u_i]$ , where  $\ell(u_i) \uparrow$ ,  $\phi[x_i \setminus u_i]$  is the formula obtained from  $\phi$  if we replace every occurrence of  $x_i$  with the (new) constant  $u_i$  and  $\ell' : U \rightarrow V(G)$  is a partial function for which  $\ell'(u_i) = v$ , and  $\ell', \ell$  agree on all other values  $u_j \neq u_i$ .
- $G, \ell, \mathcal{C} \models \exists X_i.\phi$  if there exists  $S \subseteq V(G)$  such that  $G, \ell, \mathcal{C}' \models \phi[X_i \setminus D_i]$ , where  $\mathcal{C}(D_i) \uparrow$ ,  $\phi[X_i \setminus D_i]$  is the formula obtained from  $\phi$  if we replace every occurrence of  $X_i$  with the (new) constant  $D_i$  and  $\mathcal{C}' : D \rightarrow 2^{V(G)}$  is a partial function for which  $\mathcal{C}'(D_i) = S$  and  $\mathcal{C}', \mathcal{C}$  agree on all other values  $D_j \neq D_i$ .

If none of the above applies then  $G, \ell, \mathcal{C}$  does not model  $\phi$  and we write  $G, \ell, \mathcal{C} \not\models \phi$ . Observe that, from the syntactic rules presented above, a formula can have free (non-quantified) variables. However, we will only define model-checking for formulas without free variables (also called sentences). Slightly abusing notation, we will write  $G \models \phi$  to mean  $G, \ell, \mathcal{C} \models \phi$  for the nowhere defined functions  $\ell, \mathcal{C}$ . Note that our definition does not contain conjunctions or universal quantifiers, but these can be obtained from disjunctions and existential quantifiers using negations in the usual way, so we will use them freely when constructing formulas.

An FO formula is defined as an MSO formula that uses no set variables  $X_i$ . In the remainder, we will assume that all formulas are given to us in prenex form, that is, all quantifiers appear in the beginning of the formula. We call the problem of deciding whether  $G, \ell, \mathcal{C} \models \phi$  the model-checking problem.

We recall the following basic fact:

► **Lemma 9.** *Let  $G_1, \ell_1, \mathcal{C}_1$  and  $G_2, \ell_2, \mathcal{C}_2$  be two isomorphic triplets. Then, for all MSO formulas  $\phi$  we have  $G_1, \ell_1, \mathcal{C}_1 \models \phi$  if and only if  $G_2, \ell_2, \mathcal{C}_2 \models \phi$ .*

**Proof.**  $G_1, \ell_1, \mathcal{C}_1$  and  $G_2, \ell_2, \mathcal{C}_2$  are isomorphic. Thus there exists a bijective function  $f : V(G_1) \rightarrow V(G_2)$  such i)  $f$  preserves in  $G_2$  the (non-)edges between the pairs of images of vertices in  $G_1$  and ii)  $V(G_1)$  and  $V(G_2)$  have the same labelings and colorings for  $f$ .

We proceed by induction on the structure of  $\phi$ .

- For  $\phi := u_i \in D_j$ .  $G_1, \ell_1, \mathcal{C}_1 \models \phi$  iff  $\ell_1(u_i) \in \mathcal{C}_1(D_j)$  iff  $f(\ell_1(u_i)) \in f(\mathcal{C}_1(D_j))$  iff  $\ell_2(u_i) \in \mathcal{C}_2(D_j)$  iff  $G_2, \ell_2, \mathcal{C}_2 \models \phi$
- For  $\phi := u_i = u_j$ .  $G_1, \ell_1, \mathcal{C}_1 \models \phi$  iff  $\ell_1(u_i) = \ell_1(u_j)$  iff  $f(\ell_1(u_i)) = f(\ell_1(u_j))$  iff  $\ell_2(u_i) = \ell_2(u_j)$  iff  $G_2, \ell_2, \mathcal{C}_2 \models \phi$
- For  $\phi := u_i \sim u_j$ .  $G_1, \ell_1, \mathcal{C}_1 \models \phi$  iff  $(\ell_1(u_i), \ell_1(u_j)) \in E(G_1)$  iff  $(f(\ell_1(u_i)), f(\ell_1(u_j))) \in E(G_2)$  iff  $(\ell_2(u_i), \ell_2(u_j)) \in E(G_2)$  iff  $G_2, \ell_2, \mathcal{C}_2 \models \phi$
- For  $\phi := \phi' \vee \phi''$ , or  $\phi := \neg \phi'$  By the inductive hypothesis,  $G_1, \ell_1, \mathcal{C}_1 \models \phi'$  iff  $G_2, \ell_2, \mathcal{C}_2 \models \phi'$  and  $G_1, \ell_1, \mathcal{C}_1 \models \phi''$  iff  $G_2, \ell_2, \mathcal{C}_2 \models \phi''$ . Thus the statement also holds for  $\phi$ .
- For  $\phi := \exists x_i. \phi'$ . We prove the one direction, the other is identical if we use  $f^{-1}$  instead of  $f$  in our arguments.

$G_1, \ell_1, \mathcal{C}_1 \models \exists x_i. \phi'$  if there exists  $v \in V(G_1)$  such that  $G_1, \ell'_1, \mathcal{C}_1 \models \phi[x_i \setminus u_i]$ , where  $\ell_1(u_i) \uparrow$ ,  $\ell'_1(u_i) = v$ , and  $\ell'_1, \ell_1$  agree on all other values  $u_j \neq u_i$ . We define a partial labeling function  $\ell'_2 : U \rightarrow V(G_2)$ , such that  $\ell'_2(u_i) = f(\ell'_1(u_i)) = f(v)$  and  $\ell'_2, \ell_2$  agree on all other values. It is easy to see that  $G_1, \ell'_1, \mathcal{C}_1$  and  $G_2, \ell'_2, \mathcal{C}_2$  are isomorphic, thus by the inductive hypothesis  $G_2, \ell'_2, \mathcal{C}_2 \models \phi[x_i \setminus u_i]$ . Since  $\exists f(v) \in V(G_2)$  such that  $G_2, \ell'_2, \mathcal{C}_2 \models \phi[x_i \setminus u_i]$  and  $\ell_2(u_i) \uparrow$  (since  $\ell_1(u_i) \uparrow$  and  $V(G_1)$  and  $V(G_2)$  have the same labelings for  $f$ ), therefore  $G_2, \ell_2, \mathcal{C}_2 \models \exists x_i. \phi'$ .

- For  $\phi := \exists X_i. \phi'$ . The proof is similar with the above case. Once again we will only show the one direction.

$G_1, \ell_1, \mathcal{C}_1 \models \exists X_i. \phi'$  if there exists  $S \subseteq V(G_1)$  such that  $G_1, \ell_1, \mathcal{C}'_1 \models \phi[X_i \setminus D_i]$ , where  $\mathcal{C}_1(D_i) \uparrow$ ,  $\mathcal{C}'_1(D_i) = S$  and  $\mathcal{C}'_1, \mathcal{C}_1$  agree on all other values  $D_j \neq D_i$ .

We define a partial coloring function  $\mathcal{C}'_2 : D \rightarrow 2^{V(G_2)}$  such that  $\mathcal{C}'_2(D_i) = f(\mathcal{C}'_1(D_i)) = f(S)$  and  $\mathcal{C}'_2, \mathcal{C}_2$  agree on all other values. Once again,  $G_1, \ell_1, \mathcal{C}'_1$  and  $G_2, \ell_2, \mathcal{C}'_2$  are isomorphic, thus by the inductive hypothesis  $G_2, \ell_2, \mathcal{C}'_2 \models \phi[X_i \setminus D_i]$ . Since  $\exists f(S) \subseteq V(G_2)$  such that  $G_2, \ell_2, \mathcal{C}'_2 \models \phi[X_i \setminus D_i]$  and we have that  $\mathcal{C}_2(D_i) \uparrow$ , therefore  $G_2, \ell_2, \mathcal{C}_2 \models \exists X_i. \phi'$ . ◀

### 3 FPT algorithms for FO and MSO Model-Checking parameterized by vertex integrity

In this section we prove Theorems 10 and 11. The statements appear right below.

► **Theorem 10.** *Given a graph  $G$  with  $\iota(G) \leq k$  and an FO formula  $\phi$  in prenex form having at most  $q$  quantifiers. Then deciding if  $G \models \phi$  can be solved in time  $(2^{O(k^2)} \cdot q)^q + \text{poly}(|G|)$ .*

► **Theorem 11.** *Given a graph  $G$  with  $\iota(G) \leq k$  and an MSO formula  $\phi$  in prenex form having at most  $q_1$  vertex variable quantifiers and at most  $q_2$  vertex set variable quantifiers. Then deciding if  $G \models \phi$  can be solved in time  $(2^{2^{O(k^2+kq_2)}} \cdot q_1)^{q_1} + \text{poly}(|G|)$ .*

The proofs are heavily based on Lemmata 12 and 14. The first, which is about FO Model-Checking, says that if we have at least  $q+1$  components of the same type then we can erase one such component from the graph. The reason essentially is that, if  $G, \ell, \mathcal{C}$  models  $\phi$

by labeling a vertex  $v$  that belongs to the component to be removed, we can replace that vertex by a corresponding vertex in another component having the same type. Notice that the formula has  $q$  quantifiers and thus the graph will have  $q$  labels after the assignment. Since we have  $q + 1$  components of the same type, for one of these components the vertex that corresponds to  $v$  will be unlabeled.

The second, which is about MSO Model-Checking, says that since we can quantify over sets of vertices, unlike the case for FO, each set quantification can potentially affect a large number of components that originally had the same type (by coloring its intersection with each of them). However, since each component has size at most  $k$ , we have  $2^k$  ways that the quantified set can overlap with the components. Thus, if we originally had a sufficiently large number of same type components, even after the coloring, we will still have a sufficient number of components that are of the same type, such that even if we remove one such component the answer of the problem won't change.

Lemmata 12 and 14, together with the fact that there exist a bounded number of types of components, give the kernels (Lemma 13 for FO and Lemma 15 for MSO).

► **Lemma 12.** *Given a triplet  $G, \ell, \mathcal{C}$  having  $q + 1$  vertex sets  $C_1, C_2, \dots, C_{q+1}$  of the same type and  $\phi$  an FO formula in prenex form having  $q$  quantifiers. Then  $G, \ell, \mathcal{C} \models \phi$  if and only if  $G \setminus C_1, \ell, \mathcal{C}' \models \phi$ , where  $\mathcal{C}'$  is the restriction of  $\mathcal{C}$  to  $V(G) \setminus C_1$ .*

**Proof.** We proceed by induction on the structure of the formula  $\phi$ .

1. For  $\phi := u_i \in D_j$ ,  $\phi := u_1 = u_2$ , or  $\phi := u_1 \sim u_2$ . From Observation 7 the sets are unlabeled. Thus  $\nexists v \in C_1$  for which  $\ell(u_1) = v$  or  $\ell(u_2) = v$ . Thus the statement of the lemma holds for the base case.
2. For  $\phi := \phi_1 \vee \phi_2$  or  $\phi := \neg \phi_1$ . From the inductive hypothesis, we have that  $G, \ell, \mathcal{C} \models \phi_1$  if and only if  $G \setminus C_1, \ell, \mathcal{C}' \models \phi_1$  and that  $G, \ell, \mathcal{C} \models \phi_2$  if and only if  $G \setminus C_1, \ell, \mathcal{C}' \models \phi_2$ . It is easy to see that the statement of the lemma holds also for  $\phi$ .
3. The most interesting case is for  $\phi := \exists x_i. \phi'$ . If  $G, \ell, \mathcal{C} \models \phi$  then from the definition of the semantics of  $\phi$  there exists  $v \in V(G)$  such that  $G, \ell', \mathcal{C} \models \phi[x_i \setminus u_i]$  with  $\ell(u_i) \uparrow$  and  $\ell' : U \rightarrow V(G)$  being a partial function for which  $\ell'(u_i) = v$ , and  $\ell'$  agrees with  $\ell$  on all other values  $u_j \neq u_i$ .

First we prove that without loss of generality  $v \notin C_1$ . Suppose that  $v \in C_1$ . Since  $C_1$  and  $C_2$  have the same type on  $G, \ell, \mathcal{C}$ , by Definition 6 there exists an isomorphism  $f : C_1 \rightarrow C_2$ . Consider now a labeling function  $\ell'' : U \rightarrow V(G)$  where  $\ell''(u_i) = f(\ell'(u_i)) = f(v)$ , otherwise  $\ell', \ell''$  agree on  $u_j \neq u_i$ . Observe that  $G, \ell', \mathcal{C}$  and  $G, \ell'', \mathcal{C}$  are isomorphic, thus from Lemma 9 we have that  $G, \ell', \mathcal{C} \models \phi$  iff  $G, \ell'', \mathcal{C} \models \phi$ . In that case, instead of  $v \in C_1$  we shall consider  $f(v) \in C_2$ . Thus, from now on we can assume that  $v \notin C_1$ .

For the triplet  $G, \ell', \mathcal{C}$   $q$  of the sets  $C_1, C_2, \dots, C_{q+1}$  are still unlabeled and have the same type ( $C_1$  is among them). Also  $\phi'$  has  $q - 1$  quantifiers. Thus, by the inductive step,  $G, \ell', \mathcal{C} \models \phi'$  if and only if  $G \setminus C_1, \ell', \mathcal{C}' \models \phi'$ . Since  $v \in V(G) \setminus C_1$ , we have that  $G \setminus C_1, \ell, \mathcal{C}' \models \phi$ .

For the other direction, observe that  $v \in V(G) \setminus C_1$  implies that  $v \in V(G)$ . Thus the statement holds with similar reasoning as above. ◀

► **Lemma 13.** *For a triplet  $G, \ell, \mathcal{C}$  with vertex integrity  $\iota(G) \leq k$  and with  $\ell, \mathcal{C}$  everywhere undefined and for a formula  $\phi$  with  $q$  quantifiers, FO MODEL CHECKING has a kernel of size  $O(2^{k^2} \cdot q \cdot k)$ , assuming we are given in the input  $S \subseteq V(G)$  such that the largest component of  $G \setminus S$  has size at most  $k - |S|$ .*

**Proof.** We give a polynomial-time algorithm to calculate an upper bound on the number of components of  $G \setminus S$  having the same type. Observe that types are only specified by the neighborhoods of the vertices of the components ( $\ell$  and  $\mathcal{C}$  are everywhere undefined thus there are no labels or colors on  $G$ ).

First, we arbitrarily number the vertices of  $S$  and of each component. In order to classify the components into types, we map each component  $C_i$  to a vector  $[N_1, N_2, \dots, N_{|C_i|}]$ , where  $N_j$  is an ordered set containing the (numbered) neighbors of the  $j^{\text{th}}$  vertex of  $C_i$  (starting from the neighbors in  $S$ ). Clearly, two components having the same vectors also have the same type, using the isomorphism that maps the  $i$ -th vertex of one to the  $i$ -th vertex of the other.

Since each component has at most  $k$  vertices and each vertex has at most  $2^k$  different types of neighborhoods  $N_j$ , we can have at most  $2^{k^2}$  vectors, thus at most  $2^{k^2}$  types of components. Furthermore, since we are given  $S$ , we can test in polynomial time if two components have the same type under the arbitrary numbering we used. From Lemma 12, if more than  $q$  components have the same type we can remove one such component without changing the answer of the problem, thus we can in polynomial time either reduce the graph or conclude that each component type appears at most  $q$  times. In the end we will have at most  $2^{k^2} \cdot q$  components, each having at most  $k$  vertices, thus the result.  $\blacktriangleleft$

By applying the straightforward algorithm which runs in time  $|V(G)|^q \cdot \text{poly}(|G|)$  for FO MODEL CHECKING, together with Lemma 13 we get the complexity promised by Theorem 10.

In order to prove Theorem 11 we need a stronger version of Lemma 12.

► **Lemma 14.** *Given a triplet  $G, \ell, \mathcal{C}$  with at least  $q' = 2^{k \cdot q_2} \cdot q_1 + 1$  vertex sets  $C_1, C_2, \dots, C_{q'}$  having the same type and sizes at most  $k$  and an MSO formula  $\phi$  in prenex form with  $q_1$  FO quantifiers and  $q_2$  MSO quantifiers. Then  $G, \ell, \mathcal{C} \models \phi$  if and only if  $G \setminus C_1, \ell, \mathcal{C}_1 \models \phi$ , where  $\mathcal{C}_1$  is the restriction of  $\mathcal{C}$  to  $V(G) \setminus C_1$ .*

**Proof.** We proceed by induction on the structure of  $\phi$ . We can reuse the arguments of Lemma 12, except for the case where  $\phi := \exists X_i. \phi'$ , so we focus on this case.

For the one direction, if  $G, \ell, \mathcal{C} \models \phi$ , from the definition of the semantics of  $\phi$ , then there exists  $S \subseteq V(G)$  such that  $G, \ell, \mathcal{C}' \models \phi[X_i \setminus D_i]$  with  $\mathcal{C}(D_i) \uparrow$  and  $\mathcal{C}' : D \rightarrow 2^{V(G)}$  being a partial function for which  $\mathcal{C}'(D_i) = S$ , and  $\mathcal{C}'$  agrees with  $\mathcal{C}$  on all other values  $D_j \neq D_i$ .

Since each of the vertex sets  $C_1, C_2, \dots, C_{q'}$  has size at most  $k$ , there are at most  $2^k$  possible ways for  $S$  to intersect with each of them. Therefore, by pigeonhole principle, one such intersection appears in at least  $\lceil \frac{q'}{2^k} \rceil = 2^{k(q_2-1)} \cdot q_1 + 1$  sets, call that group  $M$ . In order to be able to apply the inductive hypothesis, we need to prove that, without loss of generality,  $C_1 \in M$ .

Suppose that  $C_1 \notin M$ . We will do a “swapping” of  $C_1$  with a vertex set (say  $C_2$  without loss of generality) that does belong in the group  $M$ . Since  $C_1$  and  $C_2$  have the same type, that means that there exists an isomorphism  $f : C_1 \rightarrow C_2$ .

We consider a new coloring function  $\mathcal{C}''$  that agrees with  $\mathcal{C}'$  everywhere but on the constant  $D_i$ . This new coloring function will map  $D_i$  to the set of vertices  $S'$  (instead of  $S$ ), where we have replaced every  $v \in S \cap C_1$  with  $f(v)$  and every  $v \in S \cap C_2$  with  $f^{-1}(v)$  (see Figure 1). More formally,  $\mathcal{C}''(D_i) = S'$  where  $S' = (S \setminus (C_1 \cup C_2)) \cup f(C_1 \cap S) \cup f^{-1}(C_2 \cap S)$ . Then the triplets  $G, \ell, \mathcal{C}'$  and  $G, \ell, \mathcal{C}''$  are isomorphic and from Lemma 9 we have that  $G, \ell, \mathcal{C}' \models \phi$  iff  $G, \ell, \mathcal{C}'' \models \phi$ . From now on we assume that  $C_1$  belongs in  $M$ .

For the triplet  $G, \ell, \mathcal{C}'$ , the sets in  $M$  have all the same type and  $|M| \geq 2^{k(q_2-1)} \cdot q_1 + 1$ . Furthermore, the function  $\phi'$  has  $q_1$  FO and  $q_2 - 1$  MSO quantifiers. Therefore, by the inductive hypothesis we can remove a set from  $M$  and the answer of the problem won't change, in other words we have that  $G, \ell, \mathcal{C}' \models \phi'$  iff  $G \setminus C_1, \ell, \mathcal{C}'_1 \models \phi'$ , where  $\mathcal{C}'_1$  is the restriction of  $\mathcal{C}'$  on  $V(G) \setminus C_1$ . From the semantics of  $\phi$  we have that  $G \setminus C_1, \ell, \mathcal{C}_1 \models \phi$ .

■ **Figure 1** The way the vertex set  $S'$  intersects the vertex sets  $C_1$  and  $C_2$ .

For the other direction, if  $G \setminus C_1, \ell, \mathcal{C}_1 \models \phi$  then there exists  $S_1 \subseteq V(G) \setminus C_1$  such that  $G \setminus C_1, \ell, \mathcal{C}'_1 \models \phi[X_i \setminus D_i]$  with  $\mathcal{C}_1(D_i) \uparrow$  and  $\mathcal{C}_1$  being a partial coloring function for which  $\mathcal{C}'_1(D_i) = S_1$ , and  $\mathcal{C}'_1$  agrees with  $\mathcal{C}_1$  on all other values  $D_j \neq D_i$ .

As previously,  $S_1$  partitions  $C_2, \dots, C_{q'}$  into  $2^k$  equivalence classes, depending on the intersection of each set with  $S_1$ , such that sets placed in the same class (i.e. having isomorphic intersection with  $S_1$ ) have the same type in  $G \setminus C_1, \ell, \mathcal{C}'_1$ . Hence, one of these classes has size at least  $\frac{q'-1}{2^k} = 2^{k(q_2-1)} \cdot q_1$ , call this class  $M'$ . We construct a triplet  $G, \ell, \mathcal{C}^*$  as follows: let  $C_j \in M'$  and  $f'$  be the isomorphism from  $C_j$  to  $C_1$ ; We set that  $\mathcal{C}^*$  agrees with  $\mathcal{C}$  on all sets except  $D_i$ ; and for  $D_i$  we have  $\mathcal{C}^*(D_i) = \mathcal{C}'_1(D_i) \cup f'(S_1 \cap C_j)$ . In other words, we define  $\mathcal{C}^*$  in such a way that the set  $C_1$  has the same type as all sets of the class  $M'$ . But then we have  $|M' \cup \{C_1\}| \geq 2^{k(q_2-1)} \cdot q_1 + 1$  sets of the same type and by inductive hypothesis we have  $G, \ell, \mathcal{C}^* \models \phi[X_i \setminus D_i]$ . Therefore, by the semantics of MSO we have  $G, \ell, \mathcal{C} \models \phi$ . ◀

▶ **Lemma 15.** *For a triplet  $G, \ell, \mathcal{C}$  with vertex integrity  $\iota(G) \leq k$  and with  $\ell, \mathcal{C}$  everywhere undefined and for a formula  $\phi$  with  $q_1$  FO quantifiers and  $q_2$  MSO quantifiers, MSO MODEL CHECKING has a kernel of size  $O(2^{k^2+kq_2} \cdot q_1 \cdot k)$ , assuming we are given in the input  $S \subseteq V(G)$  such that the largest component of  $G \setminus S$  has size at most  $k - |S|$ .*

**Proof.** The proof is the same as for Lemma 13. The only thing that changes is the number of same-type components required to have before removing one such component ( $q'$  required by Lemma 14 versus  $q + 1$  required by Lemma 12). ◀

Applying the straightforward algorithm for MSO Model-Checking that runs in  $2^{q_2 \cdot V(G)} \cdot V(G)^{q_1} \cdot \text{poly}|G|$  and Lemma 15 gives the complexity promised by Theorem 11.

## 4 Lower Bounds

In this section we show that the dependence of our meta-theorems on vertex integrity cannot be significantly improved, unless the ETH is false. Our strategy will be to present a unified construction which, starting from an arbitrary graph  $G$  with  $n$  vertices, produces a new graph  $H(G)$ , with small vertex integrity, such that we can deduce if two vertices of  $G$  are connected using appropriate constant-sized FO formulas of  $H$ . This will, in principle, allow us to express an FO or MSO-expressible property of  $G$  as a corresponding property of  $H(G)$ , and hence, if the original property is hard, to obtain a lower bound on model-checking on  $H$ . Let us describe this construction in more details.

**Construction.** We are given a graph  $G$  on  $n$  vertices, say  $V(G) = \{v_1, \dots, v_n\}$ , and  $m$  edges. Let  $k = \lceil \sqrt{\log n} \rceil$ . We construct a graph  $H$  as follows:

1. We begin constructing  $V(H)$  by forming  $n + m + 1$  sets of vertices, called  $S, W_1, \dots, W_n$ , and  $Y_1, \dots, Y_m$ . We have  $|S| = 2k, |W_i| = k$  for all  $i \in [n]$ , and  $|Y_j| = 2k + 1$  for all  $j \in [m]$ . The vertices of  $S$  are numbered arbitrarily as  $s_1, s_2, \dots, s_{2k}$ .

■ **Figure 2** The connection between  $S$  and the set  $W_{47}$ . For this example  $k = 3$ , we can represent up to  $2^9$  numbers in binary. In order to represent  $47_{10} = 000101111_2$ , we shall connect  $w_{(47,1)}$  with  $s_4, s_5$  and  $s_6$  in order to represent the three least significant bits (which are all 1), and  $w_{(47,2)}$  with  $s_4$  and  $s_6$  to represent the next triad of bits. The three most significant bits are all 0.

2. Internally,  $S$  induces an independent set, each  $W_i$ , for  $i \in [n]$  induces a clique, and each  $Y_j$ , for  $j \in [m]$  induces a graph made up of two disjoint cliques of size  $k$ , denoted  $Y_j^1, Y_j^2$ , and a vertex connected to all  $2k$  vertices of the cliques  $Y_j^1, Y_j^2$ .
3. For each  $i \in [n]$ , we attach a leaf to each vertex of  $W_i$ . For each  $j \in [m]$ , we attach two leaves to each vertex of  $Y_j^1$ , three leaves to each vertex of  $Y_j^2$ , and four leaves to the remaining vertex of  $Y_j$ .
4. For each  $i \in [n]$ , number the vertices of  $W_i$  arbitrarily as  $w_{(i,1)}, w_{(i,2)}, \dots, w_{(i,k)}$ . For each  $\beta \in [k]$  we connect  $w_{(i,\beta)}$  to  $s_\beta$ . Furthermore, let  $b_1 b_2 \dots b_{k^2}$  be the binary representation of  $i - 1$  with the least significant digit first, that is, a sequence of bits such that  $\sum_\beta b_\beta 2^{\beta-1} = i - 1$ . Note that  $k^2 \geq \log n$ , therefore  $k^2$  bits are sufficient to represent all numbers from 0 to  $n - 1$ . We partition this binary representation into  $k$  blocks of  $k$  bits. For  $\beta \in [k]$  we consider the bits  $b_{(\beta-1)k+1} \dots b_{\beta k}$  and we use these bits to determine the connections between  $w_{(i,\beta)}$  and the vertices  $s_{k+1}, \dots, s_{2k}$ . More precisely, for  $\beta, \gamma \in [k]$ , we set that  $w_{(i,\beta)}$  is connected to  $s_{k+\gamma}$  if and only if  $b_{(\beta-1)k+\gamma}$  is equal to 1.
5. For each  $j \in [m]$  we do the following. Suppose the  $j$ -th edge of  $G$  has endpoints  $v_{i_1}, v_{i_2}$ . We number the vertices of  $Y_j^1$  as  $y_{(j,1)}^1, \dots, y_{(j,k)}^1$ , and the vertices of  $Y_j^2$  as  $y_{(j,1)}^2, \dots, y_{(j,k)}^2$  in some arbitrary way. Now for all  $\beta \in [k]$  we set that  $y_{(j,\beta)}^1$  has the same neighbors in  $S$  as  $w_{(i_1,\beta)}$  and  $y_{(j,\beta)}^2$  has the same neighbors in  $S$  as  $w_{(i_2,\beta)}$ .

The construction of our graph is now complete. The intuition behind this construction is that each clique  $W_i$  represents a vertex  $v_i \in V(G)$ . In order to distinguish the vertices, we use the  $k^2 \geq \log n$  possible edges between vertices in  $W_i$  and the second part of  $S$ , that is  $\{s_{k+1}, \dots, s_{2k}\}$ . These edges should represent the binary representation of  $i$ . See Figure 2 for an example.

Vertices of  $H$  may be (arbitrarily) labeled for the purpose of the construction but for the purpose of Model-Checking the graph  $H$  is unlabeled. In order to give a numbering to the vertices of  $W_i$ , we use the matching between  $W_i$  and the first  $k$  vertices of the set  $S$  (the first vertex of  $W_i$  connects to the first vertex of  $S$ , etc).

The sets  $Y_j$  represent edges in  $G$ . If the  $j^{\text{th}}$  edge in  $E(G)$  is the edge  $(v_{i_1}, v_{i_2})$ , then  $Y_j^1$  should have the same connections with  $S$  as the set  $W_{i_1}$  (similarly  $Y_j^2, W_{i_2}$ ). In order to check in  $H$  whether  $(v_{i_1}, v_{i_2})$  is an edge, we shall check if there exists a set  $Y_j$  such that each vertex of  $Y_j^1$  has the same neighborhood in  $S$  as a vertex of  $W_{i_1}$  and each vertex of  $Y_j^2$  has the same neighborhood in  $S$  as a vertex of  $W_{i_2}$ .

It is crucial here that the construction is such that  $W_i, W_{i'}$  are distinguishable for  $i \neq i'$  in terms of their neighborhoods in  $S$ , that is, there always exists  $w \in W_i$  for which no  $w' \in W_{i'}$  has  $N(w) \cap S = N(w') \cap S$ . We will show that it is not hard to express this property in FO logic. Furthermore, the leaves we have attached to various vertices will allow us to distinguish in FO logic whether a vertex belongs in a set  $W_i, Y_j^1$ , or  $Y_j^2$ .

We now establish some basic properties about  $H$  and what can be expressed about its vertices in FO logic:

- **Lemma 16.** *The graph  $H$  satisfies the following properties, for any coloring function  $\mathcal{C}$ .*
1. *We have  $\iota(H) = O(\sqrt{\log n})$  and  $|V(H)| = O(n^2\sqrt{\log n})$ .*
  2. *For each  $i, i' \in [n]$  with  $i \neq i'$ , there exists a vertex  $w \in W_i$  such that for all  $w' \in W_{i'}$  we have  $N(w) \cap S \neq N(w') \cap S$ .*
  3. *There exist constant-sized FO formulas  $\phi_W(x_1), \phi_{Y_1}(x_1), \phi_{Y_2}(x_1), \phi_S(x_1)$  using one free variable  $x_1$ , such that  $H, \ell, \mathcal{C} \models \phi_W[x_1 \setminus u_1]$  (respectively  $H, \ell, \mathcal{C} \models \phi_{Y_1}[x_1 \setminus u_1]$ ,  $H, \ell, \mathcal{C} \models \phi_{Y_2}[x_1 \setminus u_1]$ ,  $H, \ell, \mathcal{C} \models \phi_S[x_1 \setminus u_1]$ ) if and only if  $\ell(u_1) \in W_i$  for some  $i \in [n]$  (respectively  $\ell(u_1) \in Y_j^1$ ,  $\ell(u_1) \in Y_j^2$ , for some  $j \in [m]$ ,  $\ell(u_1) \in S$ ).*
  4. *There exists a constant-sized FO formula  $\phi_{WY}$  using only two free variables  $x_1, x_2$  such that  $H, \ell, \mathcal{C} \models \phi_{WY}[x_1 \setminus u_1][x_2 \setminus u_2]$  if and only if  $\ell(u_1) \in W_i$  for some  $i \in [n]$ ,  $\ell(u_2) \in Y_j^\alpha$  for some  $j \in [m], \alpha \in \{1, 2\}$ , and for all  $\beta \in [k]$  we have  $N(w_{(i,\beta)}) \cap S = N(y_{(j,\beta)}^\alpha) \cap S$ .*
  5. *There exists a constant-sized FO formula  $\phi_{adj}$  using only two free variables  $x_1, x_2$  such that  $H, \ell, \mathcal{C} \models \phi_{adj}[x_1 \setminus u_1][x_2 \setminus u_2]$  if and only if  $\ell(u_1) \in W_i$  and  $\ell(u_2) \in W_{i'}$  for some  $i, i' \in [n]$  such that  $(v_i, v_{i'}) \in E(G)$ .*

**Proof.** For the first property, we observe that the largest component of  $H \setminus S$  has size at most  $10\sqrt{\log n} + 2$ , while  $|S| \leq 2\sqrt{\log n} + 2$ . Furthermore, we have at most  $m + n = O(n^2)$  components after removing  $S$ .

For the second property, since  $i \neq i'$ , their binary representations differ in some bit. Let  $\beta, \gamma \in [k]$  be such that if  $b_1 \dots b_{k-2}$  is the binary representation of  $i - 1$  and  $b'_1 \dots b'_{k-2}$  is the binary representation of  $i' - 1$ , we have  $b_{(\beta-1)k+\gamma} \neq b'_{(\beta-1)k+\gamma}$ . But then, exactly one of  $w_{(i,\beta)}, w_{(i',\beta)}$  is connected to  $s_{k+\gamma}$ . Furthermore,  $w_{(i,\beta)}$  is connected to  $s_\beta$ , but the only neighbor of  $s_\beta$  in  $W_{i'}$  is  $w_{(i',\beta)}$ . Hence,  $w_{(i,\beta)}$  is the claimed vertex.

For the third property, observe that, in  $H$ , vertices of  $S$  have no leaves attached, vertices of each  $X_i$  have one leaf attached, vertices of  $Y_j^1$  have two leaves attached, vertices of  $Y_j^2$  have three leaves attached, and the remaining vertices have four leaves attached. Hence, it suffices to be able to express in FO, with a constant-sized formula, the property “ $x_1$  has exactly  $c$  leaves attached”, where  $c \in \{0, 1, 2, 3\}$ . This is not hard to do. For example, the formula  $\phi_2(x_1) := \exists x_2 \exists x_3 \forall x_4 ((x_2 \sim x_1) \wedge (x_3 \sim x_1) \wedge (x_2 \neq x_3) \wedge ((x_4 = x_1) \vee (\neg(x_4 \sim x_2) \wedge \neg(x_4 \sim x_3))))$  expresses the property that  $x_1$  has at least two leaves attached to it. Using the same ideas we can construct  $\phi_c(x_1)$ , for  $c \in \{1, 2, 3, 4\}$  and then  $\phi_S(x_1) := \neg\phi_1(x_1)$ ,  $\phi_W(x_1) := \phi_1(x_1) \wedge \neg\phi_2(x_1)$ ,  $\phi_{Y_1} := \phi_2(x_1) \wedge \neg\phi_3(x_1)$ ,  $\phi_{Y_2}(x_1) := \phi_3(x_1) \wedge \neg\phi_4(x_1)$ .

For the fourth property, we set  $\phi_{WY}(x_1, x_2) := \phi_{WY_1}(x_1, x_2) \vee \phi_{WY_2}(x_1, x_2)$ , where we define two formulas  $\phi_{WY_\alpha}$  depending on whether  $\alpha = 1$  or  $\alpha = 2$ . We have

$$\begin{aligned} \phi_{WY_\alpha}(x_1, x_2) &:= \phi_W(x_1) \wedge \phi_{Y_\alpha}(x_2) \wedge \forall x_3 ((\neg\phi_W(x_3)) \vee (\neg(x_3 \sim x_1) \wedge \neg(x_3 = x_1))) \vee \\ &\quad \exists x_4 (\phi_{Y_1}(x_4) \wedge (x_4 \sim x_2 \vee x_4 = x_2) \wedge \forall x_5 (\phi_S(x_5) \rightarrow (x_5 \sim x_3 \leftrightarrow x_5 \sim x_4))) \end{aligned}$$

What we are saying here is that  $\phi_{WY_1}[x_1 \setminus u_1][x_2 \setminus u_2]$  is satisfied if  $\ell(u_1) \in W_i, \ell(u_2) \in Y_j^1$ , for some  $i \in [n], j \in [m]$ , and for every  $x_3 \in W_i$  there exists  $x_4 \in Y_j^1$  such that  $N(x_3) \cap S = N(x_4) \cap S$ . Therefore, if this property holds, then  $W_i$  and  $Y_j^1$  represent the same vertex of  $V$  (similarly for  $\phi_{WY_2}$ ).

For the last property, we set

$$\begin{aligned} \phi_{adj}(x_1, x_2) &:= \phi_W(x_1) \wedge \phi_W(x_2) \wedge \exists x_3 \exists x_4 ((\phi_{Y_1}(x_3) \wedge \phi_{Y_2}(x_4)) \vee (\phi_{Y_1}(x_4) \wedge \phi_{Y_2}(x_3))) \wedge \\ &\quad \phi_{WY}(x_1, x_3) \wedge \phi_{WY}(x_2, x_4) \wedge \exists x_5 (\neg\phi_S(x_5) \wedge x_3 \sim x_5 \wedge x_4 \sim x_5) \end{aligned}$$

## 34:12 Fine-Grained Meta-Theorems for Vertex Integrity

In other words,  $H, \ell, \mathcal{C} \models \phi_{adj}[x_1 \setminus u_1][x_2 \setminus u_2]$  if (i)  $\ell(u_1) \in W_i$  and  $\ell(u_2) \in W_{i'}$ , for some  $i, i' \in [n]$  (ii) there exist  $x_3, x_4$  such that  $x_3 \in Y_j^1$  and  $x_4 \in Y_j^2$  for the same  $j$ ; this is verified because  $x_3, x_4$  have a common neighbor  $x_5$  that does not belong in  $S$  (iii)  $W_i, W_{i'}$  correspond to the same pair of vertices as the set  $Y_j = Y_j^1 \cup Y_j^2$ , which means that  $(v_i, v_{i'}) \in E(G)$ .  $\blacktriangleleft$

We are now ready to prove our lower bounds.

► **Theorem 17.** *If there exists an algorithm which, given a graph  $G$  with  $n$  vertices and  $\iota(G) = k$  and an FO formula  $\phi$  with  $q$  quantifiers, decides whether  $G \models \phi$  in time  $2^{o(k^2q)}n^{O(1)}$ , then the ETH is false.*

**Proof.** We perform a reduction from  $q$ -CLIQUE. It is well-known that, given a graph  $G$  on  $n$  vertices it is not possible to decide if  $G$  contains a clique of size  $q$  in time  $n^{o(q)}$ , unless the ETH is false [8]. We claim that we will construct the graph  $H(G)$ , as previously described, and an FO formula  $\phi_C$  such that  $\phi_C$  will contain  $O(q)$  quantifiers and  $H, \ell, \mathcal{C} \models \phi_C$  for the nowhere defined functions  $\ell, \mathcal{C}$  if and only if  $G$  has a  $q$ -clique. If we achieve this, then, since by Lemma 16 we have  $k = O(\sqrt{\log n})$ , and the size of  $H$  is polynomially related to the size of  $G$ , the stated running time would become  $2^{o(q(\sqrt{\log n})^2)}n^{O(1)} = n^{o(q)}$  and we refute the ETH. Our goal is then to define such an FO formula  $\phi_C$ . We define

$$\begin{aligned} \phi_C := & \exists x_1 \exists x_2 \dots \exists x_q \bigwedge_{i \in [q]} \phi_W(x_i) \wedge \bigwedge_{i, i' \in [q], i \neq i'} (x_i \neq x_{i'}) \\ & \forall x_{q+1} \forall x_{q+2} \bigwedge_{i \in [q]} (\neg(x_{q+1} = x_i)) \vee \bigwedge_{i \in [q]} (\neg(x_{q+2} = x_i)) \vee (x_{q+1} = x_{q+2}) \vee \\ & \phi_{adj}(x_{q+1}, x_{q+2}) \end{aligned}$$

We now claim that by the construction of  $H$ , we have that  $H, \ell, \mathcal{C} \models \phi_C$  if and only if  $G$  has a clique. If  $G$  has a clique  $\{v_{i_1}, v_{i_2}, \dots, v_{i_q}\}$ , we map  $x_1, x_2, \dots, x_q$  to arbitrary vertices of  $W_{i_1}, \dots, W_{i_q}$ . For the next part of the formula, either  $x_{q+1}, x_{q+2}$  correspond to some (different)  $x_i, x_{i'}$  or the formula is true. Last, we claim that  $H, \ell', \mathcal{C} \models \phi_{adj}[x_{q+1} \setminus u_i][x_{q+2} \setminus u_{i'}]$ , where  $x_i, x_{i'}$  are substituted by  $u_i, u_{i'}$  and  $\ell'(u_i) \in W_i, \ell'(u_{i'}) \in W_{i'}$ . Indeed, because we have a clique in  $G$ , by construction there exists a  $Y_j$  such that each vertex of  $Y_j^1$  has the same neighborhood in  $S$  as  $W_i$  and each vertex of  $Y_j^2$  has the same neighborhood in  $S$  as  $W_{i'}$  (or the same with the roles of  $Y_j^1, Y_j^2$  reversed). Hence,  $\phi_{adj}$  is satisfied.

For the converse direction, suppose that  $H, \ell, \mathcal{C} \models \phi_C$  for the nowhere defined labeling function  $\ell$ . Then there exists a labeling function  $\ell'$  that assigns  $\ell'(u_1), \ell'(u_2), \dots, \ell'(u_q)$  to some vertices of  $\bigcup_{i \in [n]} W_i$  and is undefined everywhere else such that  $\ell'(u_i) \neq \ell'(u_{i'})$  for  $i \neq i'$  and  $H, \ell', \mathcal{C} \models \phi_C$  where

$$\phi_{C'} := \forall x_{q+1} \forall x_{q+2} \bigwedge_{i \in [q]} (\neg(x_{q+1} = u_i)) \vee \bigwedge_{i \in [q]} (\neg(x_{q+2} = u_i)) \vee (x_{q+1} = x_{q+2}) \vee \phi_{adj}(x_{q+1}, x_{q+2})$$

We extract a multi-set  $S$  of  $q$  vertices of  $G$  as follows: for  $\beta \in [q]$ , if  $\ell'(u_\beta) \in W_i$ , then we add  $v_i$  to  $S$ . We claim that for any two elements  $v_i, v_{i'}$  of  $S$  we have  $(v_i, v_{i'}) \in E$ . If we prove this, then the vertices of  $S$  are distinct and form a  $q$ -clique in  $G$ .

Since we have universal quantifications for  $x_{q+1}, x_{q+2}$ , we can define a new labeling function  $\ell''$ , with  $\ell''(u_{q+1}) = \ell'(u_i)$  and  $\ell''(u_{q+2}) = \ell'(u_{i'})$ , for any  $i, i' \in [q], i \neq i'$ , with  $\ell'', \ell'$  agreeing everywhere else. Observe that this selection imposes that  $H, \ell'', \mathcal{C} \models \phi_{adj}[x_{q+1} \setminus u_i][x_{q+2} \setminus u_{i'}]$  and from property 5 of Lemma 16 we get that  $\ell'(u_i), \ell'(u_{i'})$  belong to two different  $W_j, W_{j'}$  that correspond to the endpoints of an edge of  $G$ .  $\blacktriangleleft$

► **Theorem 18.** *If there exists an algorithm which, given a graph  $G$  with  $n$  vertices and  $\iota(G) = k$  and an MSO formula  $\phi$  with constant size, decides whether  $G \models \phi$  in time  $2^{2^{o(k^2)}} n^{O(1)}$ , then the ETH is false.*

**Proof.** Our strategy is similar to that of Theorem 17, except that we will now reduce from 3-COLORING, which is known not to be solvable in  $2^{o(n)}$  on graphs on  $n$  vertices, under the ETH [33]. We will produce a constant-sized formula  $\phi_{Col}$  with the property that  $H, \ell, \mathcal{C} \models \phi_{Col}$  for the nowhere defined functions  $\ell, \mathcal{C}$  if and only if  $G$  is 3-colorable. Since  $k = O(\sqrt{\log n})$  an algorithm running in  $2^{2^{o(k^2)}}$  would imply a  $2^{o(n)}$  algorithm for 3-coloring  $G$ , contradicting the ETH. We define

$$\phi_{Col} := \exists X_1 \exists X_2 \exists X_3 \forall x_1 \forall x_2 (x_1 \in X_1 \vee x_1 \in X_2 \vee x_1 \in X_3) \wedge \bigwedge_{i=1,2,3} \phi_{adj}(x_1, x_2) \rightarrow (x_1 \in X_i \rightarrow \neg(x_2 \in X_i))$$

Assume that  $G$  has a proper 3-coloring  $c : V \rightarrow [3]$ . Then we define, for  $\alpha \in [2]$   $S_\alpha = \bigcup_{i:c(v_i)=\alpha} W_i$  and  $S_3 = V(H) \setminus (S_1 \cup S_2)$ . Let  $\mathcal{C}'$  be a coloring function such that  $\mathcal{C}'(D_\alpha) = S_\alpha$  for  $\alpha = 1, 2, 3$  and  $\mathcal{C}'(D_{\alpha'}) \uparrow$  for  $\alpha' \notin [3]$ . We claim that  $H, \ell, \mathcal{C}' \models \phi_{Col}[X_1 \setminus D_1][X_2 \setminus D_2][X_3 \setminus D_3]$ . Indeed, for any labeling function  $\ell'$  that defines only  $\ell'(u_1)$  and  $\ell'(u_2)$  we have (i)  $H, \ell', \mathcal{C}' \models u_1 \in D_1 \vee u_1 \in D_2 \vee u_1 \in D_3$  (since  $\mathcal{C}'(D_1), \mathcal{C}'(D_2), \mathcal{C}'(D_3)$  is a partition of  $V(H)$ ); (ii) If  $H, \ell', \mathcal{C}' \models \phi_{adj}[x_1 \setminus u_1][x_2 \setminus u_2]$  then  $\ell'(u_1) \in W_i, \ell'(u_2) \in W_{i'}$  for some  $i, i' \in [n], i \neq i'$  with  $(v_i, v_{i'}) \in E(G)$  (from property 5 of Lemma 16). Therefore  $c(v_i) \neq c(v_{i'})$  so for  $\alpha \in [3]$   $H, \ell', \mathcal{C}' \models u_1 \in D_\alpha \rightarrow \neg u_2 \in D_\alpha$ .

For the converse direction, suppose that  $H, \ell, \mathcal{C} \models \phi_{Col}$  for the nowhere defined  $\ell, \mathcal{C}$ . Then there exists a coloring function  $\mathcal{C}'$  such that  $\mathcal{C}'(D_\alpha) = S_\alpha$ , for  $\alpha \in [3]$  and  $H, \ell, \mathcal{C}' \models \phi_{Col}[X_1 \setminus D_1][X_2 \setminus D_2][X_3 \setminus D_3]$ . We extract a coloring of  $V(G)$  as follows: for  $i \in [n]$  we set  $c(v_i)$  to be the minimum  $\alpha$  such that  $W_i \cap S_\alpha \neq \emptyset$ . We show that the coloring  $c : V(G) \rightarrow [3]$  defined in this way is proper. Consider  $i, i' \in [n]$  such that  $(v_i, v_{i'}) \in E(G)$ . Let  $\ell'$  be a labeling function such that  $\ell'(u_1) \in W_i \cap S_{c(v_i)}$  and  $\ell'(u_2) \in W_{i'} \cap S_{c(v_{i'})}$ . Observe that  $W_i \cap S_{c(v_{i'})} \neq \emptyset$  by the definition of  $c(v_i)$ . Then  $H, \ell', \mathcal{C}' \models \phi_{adj}[x_1 \setminus u_1][x_2 \setminus u_2]$ . Therefore we have that for  $\alpha \in [3]$ ,  $H, \ell', \mathcal{C}' \models u_1 \in D_\alpha \rightarrow \neg(u_2 \in D_\alpha)$ . Therefore  $S_{c(v_i)} \neq S_{c(v_{i'})}$ , which means that  $c(v_i) \neq c(v_{i'})$ . ◀

## Abstract

We study kernelization of classic hard graph problems when the input graphs fulfill triadic closure properties. More precisely, we consider the recently introduced parameters closure number  $c$  and weak closure number  $\gamma$  [Fox et al., SICOMP 2020] in addition to the standard parameter solution size  $k$ . The weak closure number  $\gamma$  of a graph is upper-bounded by the minimum of its closure number  $c$  and its degeneracy  $d$ . For CAPACITATED VERTEX COVER, CONNECTED VERTEX COVER, and INDUCED MATCHING we obtain the first kernels of size  $k^{\mathcal{O}(\gamma)}$ ,  $k^{\mathcal{O}(\gamma)}$ , and  $(\gamma k)^{\mathcal{O}(\gamma)}$ , respectively. This extends previous results on the kernelization of these problems on degenerate graphs. These kernels are essentially tight as these problems are unlikely to admit kernels of size  $k^{\mathcal{O}(\gamma)}$  by previous results on their kernelization complexity in degenerate graphs [Cygan et al., ACM TALG 2017]. For CAPACITATED VERTEX COVER, we show that even a kernel of size  $k^{\mathcal{O}(c)}$  is unlikely. In contrast, for CONNECTED VERTEX COVER, we obtain a problem kernel with  $\mathcal{O}(ck^2)$  vertices. Moreover, we prove that searching for an induced subgraph of order at least  $k$  belonging to a hereditary graph class  $\mathcal{G}$  admits a kernel of size  $k^{\mathcal{O}(\gamma)}$  when  $\mathcal{G}$  contains all complete and all edgeless graphs. Finally, we provide lower bounds for the kernelization of INDEPENDENT SET on graphs with constant closure number  $c$  and kernels for DOMINATING SET on weakly closed split graphs and weakly closed bipartite graphs.

## 1 Introduction

A main tool for coping with hard computational problems is to shrink large input data to a computationally hard core by removing easy parts of the instance in polynomial time. Parameterized algorithmics provides the framework of *kernelization* for analyzing the power and limits of polynomial-time data reduction algorithms. In addition to the input instance  $I$ ,

a parameterized problem comes equipped with a parameter  $k$  which describes the structure of the input or is a bound on the solution size. A *kernelization* for a parameterized problem  $L$  is an algorithm that replaces every input instance  $(I, k)$  of  $L$  in polynomial time by an equivalent instance  $(I', k')$  of  $L$  (the kernel) whose size depends only on the parameter  $k$ , that is,  $|I'| + k' \leq g(k)$  for some computable function  $g$ . The kernel is guaranteed to be small if  $k$  is small and  $g$  grows only modestly. A particularly important special case is thus a kernelization where  $g$  is a polynomial function. Such kernels are referred to as *polynomial kernelizations*.

Many problems do not admit a kernel simply because they are believed to be not *fixed-parameter tractable*. That is, it is assumed that they are not solvable in  $f(k) \cdot |I|^{\mathcal{O}(1)}$  time. A classic example is DOMINATING SET parameterized by the solution size  $k$ . Moreover, even problems that do admit kernels are known to not admit polynomial kernels [2, 7, 21, 22]<sup>1</sup>; a classic example is CONNECTED VERTEX COVER parameterized by the solution size  $k$  [7].

To devise kernelization algorithms for such problems, one considers either additional parameters or restricted classes of input graphs. One example for this approach is kernelization in degenerate graphs [4, 5, 24]. A graph  $G$  is  $d$ -degenerate if every subgraph of  $G$  contains at least one vertex with degree at most  $d$ . DOMINATING SET, for example, admits a kernel of size  $k^{\mathcal{O}(d^2)}$  where  $d$  is the degeneracy of the input graph [24]. Thus, the exponent of the kernel size depends on  $d$ ; we will say that DOMINATING SET admits a polynomial kernel on  $d$ -degenerate graphs. This kernelization was shown to be tight in the sense that there is no kernel of size  $k^{\mathcal{O}(d^2)}$  [4]. The situation is different for INDEPENDENT SET which admits a trivial problem kernel with  $\mathcal{O}(dk)$  vertices: here the kernel size is polynomial in  $d + k$ .

Real-world networks have small degeneracy  $d$ , making  $d$  an interesting parameter from an application point of view. Moreover, bounded degeneracy imposes combinatorial structure that can be exploited algorithmically as evidenced by the discussion above. Recently, Fox et al. [13] discovered two new parameters that share these two features; they are well-motivated from a practical standpoint and describe interesting and useful combinatorial features of graphs. The first parameter is the *closure* of a graph, defined as follows.

► **Definition 1.1** ([13, Definition 1.1]). Let  $\text{cl}_G(v) := \max_{w \in V(G) \setminus N[v]} \{|N(v) \cap N(w)|, 0\}$  denote the closure number of a vertex  $v$  in a graph  $G$ . A graph  $G$  is  $c$ -closed if  $\text{cl}_G(v) < c$  for all  $v \in V(G)$ .

In other words, a graph is  $c$ -closed if every pair of nonadjacent vertices has at most  $c - 1$  common neighbors. The parameter models triadic closure in social networks, the observation that people with many common acquaintances are likely to know each other. Fox et al. [13] devised another parameter, the *weak closure* which relates to  $c$ -closure as degeneracy relates to maximum degree: instead of demanding a bounded closure number for every vertex, one demands that every induced subgraph has some vertex with bounded closure number.

► **Definition 1.2** ([13, Definition 1.3]). A graph  $G$  is weakly  $\gamma$ -closed if

- there exists a weak closure ordering  $\sigma := v_1, \dots, v_n$  of the vertices of  $G$  such that  $\text{cl}_{G_i}(v_i) < \gamma$  for all  $i \in [n]$  where  $G_i := G[\{v_i, \dots, v_n\}]$ , or, equivalently, if
- every induced subgraph  $G'$  of  $G$  has a vertex  $v \in V(G')$  such that  $\text{cl}_{G'}(v) < \gamma$ .

The weak closure number of a graph  $G$  is the minimum integer  $\gamma$  such that the graph  $G$  is weakly  $\gamma$ -closed.

<sup>1</sup> All kernelization lower bounds mentioned in this work are based on the assumption  $\text{coNP} \not\subseteq \text{NP/poly}$ .

Let  $G$  be a graph and let  $d, c$ , and  $\gamma$  be the degeneracy, the closure number and the weak closure number of  $G$ . The three parameters  $d, c$ , and  $\gamma$  are related as follows:

1. The weak closure number  $\gamma$  is at most  $\max(d + 1, c)$ .
2. The weak closure number  $\gamma$  can be arbitrarily smaller than  $d$  as witnessed by large complete graphs.
3. The degeneracy  $d$  and the closure number  $c$  are incomparable as witnessed by large complete graphs (these have large degeneracy and are 1-closed) and large complete bipartite graphs where one part has size two (these are 2-degenerate and have large closure number).
4. The latter example also shows that  $\gamma$  can be much smaller than the closure number  $c$  which is very often the case in real-world data [13, 19].

Akin to degeneracy,  $c$ -closure and weak  $\gamma$ -closure have proven to be very useful parameters. In particular, all maximal cliques of a graph can be enumerated in  $3^{\gamma/3} \cdot n^{\mathcal{O}(1)}$  time [13]. By the above discussion on the relation of  $\gamma$  and  $d$ , this result thus extends the range of tractable clique enumeration instances from the class of bounded-degeneracy graphs [9] to the larger class of graphs with bounded weak closure. The clique enumeration algorithm for weak closed graphs [13] has also been extended to the enumeration of other clique-like subgraphs [16, 19]. Concerning kernelization, in previous work, we showed that INDEPENDENT SET and INDUCED MATCHING admit polynomial kernels with respect to the parameter  $k + c$  and that DOMINATING SET admits a polynomial kernel on  $c$ -closed graphs [20]. Later, we extended the kernelization result for INDEPENDENT SET to parameterization by weak closure. More generally, we showed that  $\mathcal{G}$ -SUBGRAPH, where one wants to find a subgraph on at least  $k$  vertices belonging to  $\mathcal{G}$  admits a kernel with  $\mathcal{O}(\gamma k^2)$  vertices if  $\mathcal{G}$  is closed under taking subgraphs [19]. To the best of our knowledge, this is the only known kernelization result for the weak closure parameterization.

In this work we study the kernelization of several further hard graph problems on weakly closed graphs. In a nutshell, we provide kernels for a range of problems that have not been considered on weakly closed graphs so far. Our kernels are based on several combinatorial observations on the structure of weakly closed graphs that might be of more general interest.

**Our Results.** Building on a combinatorial lemma of Frankl and Wilson [14], we obtain a general lemma (Lemma 2.2) which can be used to bound the size of graphs in terms of their vertex cover number and weak closure number. More precisely, we show that in a graph  $G$  with vertex cover  $S$  of size  $k$  and weak closure  $\gamma$ , the number of different neighborhoods in the independent set  $I := V(G) \setminus S$  is  $k^{\mathcal{O}(\gamma)}$ . Lemma 2.2 gives a general strategy for obtaining kernels in weakly closed graphs: Devise reduction rules that 1) bound the size of the vertex cover and 2) decrease the size of neighborhood classes. We also show that Lemma 2.2 can be extended to a more general notion of neighborhood types (Lemma 2.4).

We then show that this strategy helps in obtaining kernels on weakly closed graphs for CAPACITATED VERTEX COVER, CONNECTED VERTEX COVER, CONNECTED  $\ell$ -COMPONENT ORDER CONNECTIVITY (CONNECTED  $\ell$ -COC), and INDUCED MATCHING all parameterized by the natural parameter solution size  $k$ . For these problems, polynomial kernels in degenerate graphs are known [4, 5, 11, 17]. Our results thus extend the class of graphs for which polynomial kernels are known for these problems. The kernels have size  $k^{\mathcal{O}(\gamma)}$  and  $(\gamma k)^{\mathcal{O}(\gamma)}$ , respectively, and by previous results on degenerate graphs the dependence on  $\gamma$  in the exponent cannot be avoided [4, 5]. We complement these findings with a study of CAPACITATED VERTEX COVER and CONNECTED VERTEX COVER on  $c$ -closed graphs. Interestingly, the kernelization complexity of the problems differs: CAPACITATED VERTEX COVER does not admit a kernel of size  $\mathcal{O}(k^{\frac{c-1}{2}-\epsilon})$  for all  $\epsilon > 0$  whereas CONNECTED VERTEX COVER admits a kernel with  $\mathcal{O}(ck^2)$  vertices.

Next, we study the kernelization complexity of INDEPENDENT SET on  $c$ -closed graphs. We show that INDEPENDENT SET does not admit a kernel of size  $\mathcal{O}(k^{2-\epsilon})$  on  $c$ -closed graphs for constant  $c$ . This complements previous kernels of size  $\mathcal{O}(c^2 k^3)$  [20] and  $\mathcal{O}(\gamma^2 k^3)$  [19], narrowing the gap between upper and lower bound for the achievable kernel size on (weakly) closed graphs. We also obtain a lower bound of  $\Omega(k^{4/3-\epsilon})$  on the number of *vertices* in the graph in case of constant  $c$  and show that at least a linear dependence on  $c$  is necessary in any kernelization of INDEPENDENT SET in  $c$ -closed graphs: under standard assumptions, there is no kernel of size  $c^{(1-\epsilon)} \cdot k^{\mathcal{O}(1)}$ . Some of our results also hold for Ramsey-type problems where one wants to find a large subgraph belonging to a class  $\mathcal{G}$  containing all complete and all edgeless graphs. In this context, we observe that weakly  $\gamma$ -closed graphs fulfill the Erdős–Hajnal property [10] with a linear dependence on  $\gamma$ : There is a constant  $q$  such that every weakly  $\gamma$ -closed graph on  $k^{q\gamma}$  vertices has either a clique of size  $k$  or an independent set of size  $k$ . We believe that this observation is of independent interest and that it will be useful in the further study of weakly  $\gamma$ -closed graphs.

Finally, we consider DOMINATING SET which admits a kernel of size  $k^{\mathcal{O}(c)}$  [20]. It is open whether DOMINATING SET admits a kernel of size  $k^{f(\gamma)}$  for some function  $f$ , which would extend the class of kernelizable input graphs from degenerate to weakly closed. We make partial progress towards answering this question by showing that there is a kernel of size  $k^{\mathcal{O}(\gamma^2)}$  on graphs with constant clique number (such as bipartite graphs) and a kernel of size  $(\gamma k)^{\mathcal{O}(\gamma)}$  in split graphs. In both cases these bounds are tight in the sense that kernels of size  $k^{\mathcal{O}(d^2)}$  and of size  $k^{\mathcal{O}(c)}$  are unlikely to exist [4, 19].

Due to lack of space, several proofs (marked with (\*)) and all results for DOMINATING SET on bipartite and split graphs are deferred to the full version of this article.

**Preliminaries.** By  $[n]$  we denote the set  $\{1, \dots, n\}$  for some  $n \in \mathbb{N}$ . For a graph  $G$ , let  $V(G)$  denote its *vertex set*,  $E(G)$  its *edge set*, and  $n := |V(G)|$  the number of vertices. Let  $X \subseteq V(G)$  be a vertex set. By  $G[X]$  we denote the *subgraph induced* by  $X$  and by  $G - X := G[V(G) \setminus X]$  we denote the graph obtained by removing the vertices of  $X$ . If the vertices of  $X$  are pairwise adjacent (nonadjacent), then  $X$  is a *clique* (an *independent set*, respectively). We denote by  $N_G(X) := \{y \in V(G) \setminus X \mid xy \in E(G), x \in X\}$  the *open neighborhood* of  $X$  and by  $N_G[X] := N_G(X) \cup X$  the *closed neighborhood* of  $X$ . The maximum degree of  $G$  is  $\Delta_G := \max_{v \in V(G)} \deg_G(v)$ . In the remainder of this paper we fix a weak closure ordering  $\sigma$ . Note that such an ordering can be computed in polynomial time [13]. We define  $P_G^\sigma(v) := \{u \in N_G(v) \mid u \text{ appears before } v \text{ in } \sigma\}$  and  $Q_G^\sigma(v) := \{u \in N_G(v) \mid u \text{ appears after } v \text{ in } \sigma\}$ . We say that  $P_G^\sigma(v)$  are *prior neighbors* of  $v$  and  $Q_G^\sigma(v)$  are *posterior neighbors* of  $v$ . A *matching*  $M$  is a set of vertex-disjoint edges. By  $V(M)$  we denote the union of all endpoints of edges in  $M$ . We omit the superscripts and subscripts when they are clear from the context. The following observation follows from the definition of weak closure.

► **Observation 1.3.** *For nonadjacent vertices  $u, v \in V(G)$ , it holds that  $|Q(u) \cap Q(v)| \leq |Q(u) \cap N(v)| \leq \gamma - 1$ .*

**Proof.** Let  $G_u$  and  $G_v$  be the graph induced by the vertices that appear after  $u$  and  $v$ , respectively. We have two cases based on whether  $u$  or  $v$  appears first in the weak closure ordering  $\sigma$ .

- $u$  precedes  $v$ . By the definition of  $Q$ -neighbors, we have  $Q_G(u) \cap Q_G(v) \subseteq Q_G(u) \cap N_G(v)$  and  $Q_G(u) \cap N_G(v) = N_{G_u}(u) \cap N_{G_u}(v)$ . Since  $|N_{G_u}(u) \cap N_{G_u}(v)| \leq \text{cl}_{G_u}(u)$ , it follows from the definition of weak closure that  $|N_{G_u}(u) \cap N_{G_u}(v)| \leq \gamma - 1$ .

- $v$  precedes  $u$ . Clearly,  $Q_G(u) \cap P_G(v) = \emptyset$ . We then have  $Q_G(u) \cap N_G(v) = Q_G(u) \cap (P_G(v) \cup Q_G(v)) = Q_G(u) \cap Q_G(v)$ . It follows from the definition of  $Q$ -neighbors that  $|Q_G(u) \cap Q_G(v)| = |N_{G_u}(u) \cap N_{G_v}(v)| \leq |N_{G_v}(u) \cap N_{G_v}(v)| \leq \text{cl}_{G_v}(v) \leq \gamma - 1$ . We have shown that  $|Q(u) \cap Q(v)| \leq |Q(u) \cap N(v)| \leq \gamma - 1$  for both cases. ◀

A parameterized problem is *fixed-parameter tractable* if every instance  $(I, k)$  can be solved in  $f(k) \cdot |I|^{\mathcal{O}(1)}$  time for some computable function  $f$ . An algorithm with such a running time is an *FPT algorithm*. A *kernelization* is a polynomial-time algorithm which transforms every instance  $(I, k)$  of a parameterized language  $Q$  into an equivalent instance  $(I', k')$  of  $Q$  such that  $|I'| + k' \leq g(k)$  for some computable function  $g$ . A *compression* of a parameterized language  $Q$  into a language  $R$  is an algorithm that takes as input an instance  $(x, k) \in \Sigma^* \times \mathbb{N}$  and returns a string  $y$  in time polynomial in  $|x| + k$  such that  $|y|$  is bounded by some polynomial in  $k$ , and  $y \in R$  if and only if  $(x, k) \in Q$ . It is widely believed that  $W[t]$ -hard problems ( $t \in \mathbb{N}$ ) do not admit an FPT algorithm. For more details on parameterized complexity, we refer to the standard monographs [3, 8].

## 2 Bounding the Size of Weakly Closed Graphs with Small Twin Sets

Frankl and Wilson [14] proved the following bound on the size of set systems where the number of different intersection sizes is bounded.

► **Proposition 2.1** ([14, Theorem 11]). *Let  $\mathcal{F}$  be a collection of pairwise distinct subsets of  $[n]$  and let  $L \subseteq \{0\} \cup [n]$  be some subset. If  $|S \cap S'| \in L$  for all distinct  $S, S' \in \mathcal{F}$ , then  $|\mathcal{F}| \in \mathcal{O}(n^{|L|})$ .*

We now use this proposition to achieve a bound on the size of weakly closed graphs when every vertex has few false twins and the size of the vertex cover is small. Herein, two vertices  $u$  and  $v$  are *false twins* if  $N(u) = N(v)$ .

► **Lemma 2.2.** *Let  $G$  be a weakly  $\gamma$ -closed graph and let  $I$  be an independent set of  $G$ . Suppose that each vertex  $v \in I$  has at most  $t - 1$  false twins. Then,  $|I| \in t \cdot \mathcal{O}(3^{\gamma/3} \cdot k^{2\gamma+3})$ , where  $k := n - |I|$ .*

**Proof.** We say that two vertices  $v, v' \in I$  are *P-equivalent*, *Q-equivalent*, and *N-equivalent* if  $P(v) = P(v')$ ,  $Q(v) = Q(v')$ , and  $N(v) = N(v')$ , respectively. Let  $\mathcal{P}$ ,  $\mathcal{Q}$ , and  $\mathcal{N}$  denote the collection of *P*-equivalence, *Q*-equivalence, and *N*-equivalence classes, respectively. We extend the notation of *P*, *Q*, and *N* to an equivalence classes  $A$  by defining  $P(A) := P(v)$ ,  $Q(A) := Q(v)$ , and  $N(A) := N(v)$  for some  $v \in A$ . Since there is at most one *N*-equivalence class for every pair of *P*-equivalent and *Q*-equivalent classes, we have  $|\mathcal{N}| \leq |\mathcal{P}| \cdot |\mathcal{Q}|$ . By the assumption that there are at most  $t$  vertices in each *N*-equivalence class, we also have  $|I| \leq t \cdot |\mathcal{N}|$ . Thus, it suffices to show suitable bounds on  $|\mathcal{P}|$  and  $|\mathcal{Q}|$ .

First, we prove that  $|\mathcal{Q}| \in \mathcal{O}(k^\gamma)$ , using the result of Frankl and Wilson (Proposition 2.1 [14]). Since  $I \supseteq A$  is an independent set,  $Q(A) \subseteq S := V(G) \setminus I$ . Moreover, for two distinct *Q*-equivalence classes  $A$  and  $A'$ , we have  $|Q(A) \cap Q(A')| < \gamma$  by Observation 1.3, and equivalently,  $|Q(A) \cap Q(A')| \in L$  for  $L := \{0\} \cup [\gamma - 1]$ . By Proposition 2.1 we obtain  $|\mathcal{Q}| \in \mathcal{O}(|S|^{|L|}) = \mathcal{O}(k^\gamma)$ .

Next, we bound the size of  $\mathcal{P}$ . Let  $I_0 := \{v \in I \mid \exists u, w \in P(v): uw \notin E(G)\}$  be the set of vertices in  $I$  with nonadjacent prior neighbors. By the definition of weak  $\gamma$ -closure, there are at most  $\gamma - 1$  vertices of  $I_0$  for every pair of nonadjacent vertices in  $S$ . Thus, we have  $|I_0| < \gamma \binom{|S|}{2} \in \mathcal{O}(\gamma k^2)$ .

Let  $I_1 := I \setminus I_0$  and let  $\mathcal{P}_1$  be the collection of  $P$ -equivalence classes in  $I_1$ . Note that for every  $A \in \mathcal{P}_1$ , its neighborhood  $P(A)$  is a clique. Since a weakly  $\gamma$ -closed graph on  $n$  vertices has  $\mathcal{O}(3^{\gamma/3}n^2)$  maximal cliques [13], there are  $\mathcal{O}(3^{\gamma/3}k^2)$  equivalence classes  $A$  such that  $P(A)$  constitutes a maximal clique in  $G[S]$ . Consider an equivalence class  $A$  such that  $P(A) \subset C$  for some maximal clique  $C$  in  $G[S]$ . We will show that there are  $k^{\mathcal{O}(\gamma)}$  such equivalence classes. Let  $u$  be the first vertex of  $C \setminus P(A)$  in the weak closure ordering  $\sigma$ . Since  $P(A) \subset C \subseteq N(u) = P(u) \cup Q(u)$ , we have  $P(A) = (P(A) \cap P(u)) \cup (P(A) \cap Q(u))$ . As  $P(A) \cap P(u) = C \cap P(u)$  by the choice of  $u$ , we can rewrite  $P(A) = (C \cap P(u)) \cup B$ , where  $B := P(A) \cap Q(u)$ . Thus, there is at most one equivalence class of  $\mathcal{P}_1$  for every maximal clique  $C$  in  $G[S]$ , vertex  $u \in S$ , and vertex subset  $B \subseteq S$ , and thereby, we have  $|\mathcal{P}_1| \in \mathcal{O}(3^{\gamma/3}k^2 \cdot k \cdot b)$ , where  $b$  denotes the number of choices for  $B$ . Observe that  $P(A) = P(v)$  for some vertex  $v \in I_1$  and thus that  $B = Q(u) \cap P(v) \subseteq Q(u) \cap N(v)$ . Recall that  $u$  and  $v$  are not adjacent by the choice of  $u$ . It follows that  $|B| \leq |Q(u) \cap N(v)| \leq \gamma - 1$  by Observation 1.3, and hence  $b \in \mathcal{O}(k^\gamma)$  and  $|\mathcal{P}_1| \in \mathcal{O}(3^{\gamma/3} \cdot k^3 \cdot k^\gamma) = \mathcal{O}(3^{\gamma/3} \cdot k^{\gamma+3})$ . Overall, we have  $|\mathcal{P}| \leq (|I_0| + |\mathcal{P}_1|) \in \mathcal{O}(3^{\gamma/3} \cdot k^{\gamma+3})$ . The total number of  $N$ -equivalence classes is thus at most  $|\mathcal{Q}| \cdot |\mathcal{P}| \in \mathcal{O}(3^{\gamma/3} \cdot k^{2\gamma+3})$ . ◀

We now show that Proposition 2.1 can be also applied to bound the graph size in terms of the  $\ell$ -COC number, which is the smallest size of a vertex set  $S$  such that every connected component in  $G - S$  has size at most  $\ell$ , where  $\ell$  is a fixed constant. The 1-COC number is the vertex cover number. To obtain this generalization, we extend the notion of twins.

► **Definition 2.3.** *Let  $G = (V, E)$  be a graph and let  $A, B \subseteq V(G)$  such that  $|A| = |B| = \ell$ . The sets  $A$  and  $B$  are  $\ell$ -twins if there exists an ordering  $a_1, \dots, a_\ell$  of  $A$  and an ordering  $b_1, \dots, b_\ell$  of  $B$  such that  $N(a_i) \setminus A = N(b_i) \setminus B$  for each  $i \in [\ell]$ .*

Note that  $u$  and  $v$  are false twins if and only if  $\{u\}$  and  $\{v\}$  are 1-twins.

► **Lemma 2.4 (\*)**. *Let  $G$  be a graph and let  $D \subseteq V(G)$  be such that each connected component in  $G[D]$  has size at most  $\ell$ . Suppose that for every connected component  $Z$  in  $G[D]$ , there are at most  $t - 1$  other connected components  $Z'$  in  $G[D] - Z$  such that  $Z$  and  $Z'$  are  $|Z|$ -twins. Then,  $|D| \in \mathcal{O}(t \cdot k^{\mathcal{O}(\gamma)})$ , where  $k = n - |D|$ .*

### 3 Applications of our Framework

We now apply Lemma 2.2 and Lemma 2.4 to obtain kernels for several well-known problems.

#### 3.1 Capacitated Vertex Cover

The first problem to which we apply Lemma 2.2 is CAPACITATED VERTEX COVER.

CAPACITATED VERTEX COVER

**Input:** A graph  $G$ , a capacity function  $\text{cap}: V(G) \rightarrow \mathbb{N}$ , and  $k \in \mathbb{N}$ .

**Question:** Is there a set  $S$  of at most  $k$  vertices and a function  $f$  mapping each edge of  $E(G)$  to one of its endpoints in  $S$  such that  $|\{e \in E(G) \mid f(e) = v\}| \leq \text{cap}(v)$  for all  $v \in S$ ?

CAPACITATED VERTEX COVER admits a kernel with  $\mathcal{O}(k^{d+1})$  vertices. Furthermore, this kernel is essentially tight: a kernel with  $\mathcal{O}(k^{d-\epsilon})$  vertices would imply  $\text{coNP} \subseteq \text{NP/poly}$  [4]. We will show that the reduction rule used to obtain a kernel in degenerate graphs also leads to a kernel in graphs with bounded weak closure. One may view this result as a way of showing that the rules are more powerful than what was previously known. The kernel uses the following rule.

► **Reduction Rule 3.1** ([4, Rule 3]). *If  $S \subseteq V(G)$  is a subset of false twin vertices with a common neighborhood  $N(S)$  such that  $|S| = k + 2 \geq |N(S)|$ , then remove a vertex with minimum capacity in  $S$  from  $G$ , and decrease all the capacities of vertices in  $N(S)$  by one.*

We omit the proof for the correctness of Reduction Rule 3.1, referring to Cygan et al. [4, Lemma 20]. One can easily verify that it does not increase the weak  $\gamma$ -closure. In the following theorem, we show that Reduction Rule 3.1 indeed gives us a kernel with  $k^{\mathcal{O}(\gamma)}$  vertices.

► **Theorem 3.2.** *CAPACITATED VERTEX COVER has a kernel of size  $k^{\mathcal{O}(\gamma)}$ .*

**Proof.** We show that a Yes-instance which is reduced with respect to Reduction Rule 3.1 has size  $k^{\mathcal{O}(\gamma)}$ . Let  $S$  be a capacitated vertex cover of size at most  $k$  of  $(G, \text{cap})$ . Let  $I := V(G) \setminus S$ . By definition,  $I$  is an independent set and  $N(v) \subseteq S$  for all  $v \in I$ . Moreover, since  $(G, \text{cap})$  is reduced with respect to Reduction Rule 3.1 there is no set of  $k + 2$  vertices in  $I$  that have the same neighborhood. Hence,  $I$  fulfills the condition of Lemma 2.2 with  $t = k + 2$ . Thus,  $|I| \in k \cdot k^{\mathcal{O}(\gamma)}$  which implies  $|V(G)| = |S| + |I| \in k^{\mathcal{O}(\gamma)}$ . ◀

We also show that this kernel is essentially tight even if  $\gamma$  is replaced by  $c$ .

► **Theorem 3.3 (\*)**. *For  $c \geq 4$ , CAPACITATED VERTEX COVER has no kernel of size  $\mathcal{O}(k^{\frac{c-1}{2}-\epsilon})$  unless  $\text{coNP} \subseteq \text{NP/poly}$ .*

## 3.2 Connected Vertex Cover

We now provide kernels for CONNECTED VERTEX COVER, a well-studied variant of VERTEX COVER which is notoriously hard and does not admit a polynomial kernel when parameterized  $k$  [7].

CONNECTED VERTEX COVER

**Input:** A graph  $G$  and  $k \in \mathbb{N}$ .

**Question:** Is there a vertex cover  $S$  of size at most  $k$  in  $G$  such that  $G[S]$  is connected?

We will show that by applying Lemma 2.2 we obtain a kernel of size  $k^{\mathcal{O}(\gamma)}$ . We may use the following known rule.

► **Reduction Rule 3.4** ([4, Rule 2]). *If  $S \subseteq V(G)$  is a set of at least two twin vertices with a common neighborhood  $N(S)$  such that  $|S| > |N(S)|$ , then remove one vertex  $v$  of  $S$  from  $G$ .*

After exhaustive application of Reduction Rule 3.4 we have, again by Lemma 2.2, that every Yes-instance has size  $k^{\mathcal{O}(\gamma)}$ . The proof is completely analogous to that of Theorem 3.2.

► **Theorem 3.5.** *CONNECTED VERTEX COVER admits a kernel of size  $k^{\mathcal{O}(\gamma)}$ .*

This kernel is essentially tight, because there is no kernel of size  $k^{o(d)}$  [4]. We now show a polynomial kernel for  $k + c$ .

► **Theorem 3.6 (\*)**. *CONNECTED VERTEX COVER has a kernel with  $\mathcal{O}(ck^2)$  vertices.*

This result stands in contrast to CAPACITATED VERTEX COVER, which has no kernel of size  $k^{o(c)}$  unless  $\text{coNP} \subseteq \text{NP/poly}$  (Theorem 3.3).

**An Extension to Connected  $\ell$ -COC.** In CONNECTED  $\ell$ -COC the task is to find a set  $S$  of at most  $k$  vertices such that  $G[S]$  is connected and every connected component of  $G - S$  has size at most  $\ell$ , where  $\ell$  is a fixed constant. We show that this problem also admits a kernel of size  $k^{\mathcal{O}(\gamma)}$ . The main idea lies in the extension of Reduction Rule 3.4:

► **Reduction Rule 3.7.** *Let  $T_1, \dots, T_x \subseteq V(G)$  be a set of  $x$  many  $r$ -twins, for some  $r \in [\ell]$ . If  $x \geq k + \ell + 2$ , then remove all vertices in  $T_x$  from  $G$ .*

Note that Reduction Rule 3.7 can be exhaustively performed in polynomial time since the  $r$ -twin relation can be computed in  $n^{2r+\mathcal{O}(1)}$  time. We then obtain the following theorem from Lemma 2.4.

► **Theorem 3.8 (\*).** *CONNECTED  $\ell$ -COC has a kernel of size  $k^{\mathcal{O}(\gamma)}$  for constant  $\ell$ .*

### 3.3 Induced Matching

In this section, we provide a kernel of size  $(\gamma k)^{\mathcal{O}(\gamma)}$  for INDUCED MATCHING:

INDUCED MATCHING

**Input:** A graph  $G$  and  $k \in \mathbb{N}$ .

**Question:** Is there a set  $M$  of at least  $k$  edges such that the endpoints of distinct edges are pairwise nonadjacent?

INDUCED MATCHING is W[1]-hard for the parameter  $k$  on general graphs. For  $c$ -closed graphs, we developed a kernel with  $\mathcal{O}(c^7 k^8)$  vertices [20]. For  $d$ -degenerate graphs, Kanj et al. [17] and Erman et al. [11] independently presented kernels of size  $k^{\mathcal{O}(d)}$ . Later, Cygan et al. [4] provided a matching lower bound  $k^{\mathcal{O}(d)}$  on the kernel size. Note that this also implies the nonexistence of  $k^{\mathcal{O}(\gamma)}$ -size kernels unless  $\text{coNP} \subseteq \text{NP/poly}$ .

It turns out that Lemma 2.2 is again helpful in designing a  $k^{\mathcal{O}(\gamma)}$ -size kernel for INDUCED MATCHING. In a nutshell, we show that the application of a series of reduction rules results in a graph with a  $(\gamma k)^{\mathcal{O}(1)}$ -size vertex cover. We do so by combining the kernelization of Erman et al. [11] for degenerate graphs with our previous one for  $c$ -closed graphs [20]. Lemma 2.2 and the reduction rule which removes twin vertices then give us a kernel of size  $(\gamma k)^{\mathcal{O}(\gamma)}$ .

Erman et al. [11] use the following observation for degenerate graphs.

► **Lemma 3.9** ([11, Proof of Theorem 2.10]). *Any graph  $G$  with a matching  $M$  has an induced matching of size  $|M|/(4d_G + 1)$ .*

Ideally, we would like to prove a lemma analogous to Lemma 3.9 on weakly  $\gamma$ -closed graphs. Note, however, that a complete graph on  $n$  vertices (which is weakly 1-closed) has no induced matching of size 2, although it contains a matching of size  $\lfloor n/2 \rfloor$ . So we follow a different route, and prove an analogous lemma on weakly  $\gamma$ -closed bipartite graphs (there exist bipartite 2-closed graphs whose degeneracy is unbounded; see e.g. Eschen et al. [12]). As we shall see, this serves our purposes.

► **Lemma 3.10.** *Suppose that  $G$  is a bipartite graph with a bipartition  $(A, B)$ . If  $G$  has a matching  $M$  of size  $f_\gamma(k) := 4\gamma k^2 + 3k$ , then  $G$  has an induced matching of size  $k$ .*

**Proof.** Recall that  $Q^\sigma(v) := \{u \in N(v) \mid u \text{ appears after } v \text{ in } \sigma\}$ . Let  $S \subseteq V(G)$  be the set of vertices  $v$  such that  $|Q(v)| \geq \gamma k$ . Suppose that  $|S| \geq 2k$ . Then, we may assume that  $|A \cap S| \geq k$ . Let  $A' \subseteq A \cap S$  be an arbitrary vertex set of size exactly  $k$  and consider

some vertex  $v \in A'$ . Since  $|Q(v) \cap N(v')| < \gamma$  for every  $v' \in A' \setminus \{v\}$  by Observation 1.3, we have  $|Q(v) \setminus \bigcup_{v' \in A' \setminus \{v\}} N(v')| > 0$  for each  $v \in A'$ . Consequently, there is at least one vertex  $q_v \in Q(v) \setminus \bigcup_{v' \in A' \setminus \{v\}} N(v')$ . Then, the edge set  $\{vq_v \mid v \in A'\}$  forms an induced matching of size  $k$  in  $G$ .

Now, consider the case  $|S| < 2k$ . By the definition of  $S$ , it holds that  $|Q_{G-S}(v)| \leq |Q_G(v)| \leq \gamma k$  for each vertex  $v \in V(G) \setminus S$ . Hence, the degeneracy of  $G - S$  is at most  $\gamma k$ . Since  $G - S$  has a matching  $M_{G-S}$  of size at least  $|M| - |S| \geq f_\gamma(k) - 2k = 4\gamma k^2 + k$ , Lemma 3.9 yields an induced matching of size  $|M_{G-S}|/(4d_{G-S} + 1) \geq k$ . ◀

We use the following reduction rule to sparsify the graph  $G$  so that every sufficiently large vertex set contains a large independent set (see Lemma 3.13).

► **Reduction Rule 3.11.** *If for some vertex  $v \in V(G)$ , there is a maximum matching  $M_v$  of size at least  $2\gamma k$  in  $G[Q(v)]$ , then delete  $v$ .*

► **Lemma 3.12.** *Reduction Rule 3.11 is correct.*

**Proof.** Let  $G' := G - v$ . Suppose that  $G$  has an induced matching  $M$  of size  $k$ . If  $v \notin V(M)$ , then  $M$  is also an induced matching in  $G'$ . So assume that  $vv' \in V(M)$  for some vertex  $v' \in V(G)$ . Then, we have  $|N(u) \cap Q(v)| < \gamma$  for any vertex  $u \in V(M \setminus \{vv'\})$  by Observation 1.3 and thus  $|V(M_v) \setminus \bigcup_{u \in V(M \setminus \{vv'\})} N(u)| \geq 2|M_v| - (\gamma - 1)(2k - 2) > |M_v|$ . By the pigeon-hole principle, this implies that there is an edge  $e \in M_v$  not incident with any vertex in  $V(M)$  and no endpoint of  $e$  is adjacent to any vertex in  $V(M \setminus \{vv'\})$ . Then,  $(M \setminus \{vv'\}) \cup \{e\}$  is an induced matching of size  $k$  in  $G'$ . ◀

► **Lemma 3.13.** *Suppose that  $G$  is a graph in which Reduction Rule 3.11 is applied on every vertex. Then, every vertex set  $S \subseteq V(G)$  of size at least  $g_\gamma(k) := 4\gamma k^2 + k^2$  contains an independent set  $I \subseteq S$  of size  $k$ .*

**Proof.** Suppose that there is no independent set of size  $k$  in  $G' := G[S]$  for some vertex set  $S$  of size  $g_\gamma(k)$ . For every vertex  $v \in S$ , let  $M_v$  be a maximum matching in  $Q_{G'}(v)$  and let  $I_v := Q_{G'}(v) \setminus V(M_v)$ . By Reduction Rule 3.11, we have  $|V(M_v)| = 2|M_v| \leq 4\gamma k$ . Since  $I_v$  is an independent set, we then have  $|Q_{G'}(v)| = |M_v| + |I_v| < 4\gamma k + k$  for every vertex  $v \in S$ , and thus  $d_{G'} < 4\gamma k + k$ . Note, however, that  $G'$  has an independent set of size  $|S|/(d_{G'} + 1) \geq k$ , which is a contradiction. ◀

To identify a part of the graph with a sufficiently large induced matching, we rely on the LP relaxation of VERTEX COVER, following our approach [20] to obtain a polynomial kernel on  $c$ -closed graphs. Recall that VERTEX COVER can be formulated as an integer linear program as follows, using a variable  $x_v$  for each  $v \in V(G)$ :

$$\min \sum_{v \in V(G)} x_v \quad \text{subject to} \quad \begin{array}{l} x_u + x_v \geq 1 \quad \forall uv \in E(G), \\ x_v \in \{0, 1\} \quad \forall v \in V(G). \end{array}$$

We will refer to the LP relaxation of VERTEX COVER as VCLP. We use the well-known facts that VCLP always admits an optimal solution in which  $x_v \in \{0, 1/2, 1\}$  for each  $v \in V(G)$  and that such a solution can be found in polynomial time. Suppose that we have such an optimal solution  $(x_v)_{v \in V(G)}$ . Let  $V_0 := \{v \in V(G) \mid x_v = 0\}$ ,  $V_1 := \{v \in V(G) \mid x_v = 1\}$ , and  $V_{1/2} := \{v \in V(G) \mid x_v = 1/2\}$ . Also, let  $\text{opt}(G)$  be the optimum of VCLP. We show that we can immediately return Yes, whenever  $\text{opt}(G)$  is sufficiently large:

► **Reduction Rule 3.14.** *If  $\text{opt}(G) \geq 2g_\gamma(g_\gamma(f_\gamma(k)))$ , then return Yes.*

## 35:10 Essentially Tight Kernels for (Weakly) Closed Graphs

Here, the functions  $f_\gamma$  and  $g_\gamma$  are as specified in Lemmas 3.10 and 3.13, respectively.

► **Lemma 3.15.** *Reduction Rule 3.14 is correct.*

**Proof.** We show that  $G$  has an induced matching of size  $k$  whenever  $\text{opt}(G) \geq 2g_\gamma(g_\gamma(f_\gamma(k)))$ . Let  $M$  be an arbitrary maximal matching in  $G$ . Since  $V(M)$  is a vertex cover, we have  $\text{opt}(G) \leq |V(M)| = 2|M|$ , and hence  $|M| \geq \text{opt}(G)/2 \geq g_\gamma(g_\gamma(f_\gamma(k)))$ . Let  $M := \{a_1b_1, \dots, a_{|M|}b_{|M|}\}$  and let  $A := \{a_1, \dots, a_{|M|}\}$  and  $B := \{b_1, \dots, b_{|M|}\}$ . By Lemma 3.13, there exists an independent set  $A' \subseteq A$  of size  $s' := g_\gamma(f_\gamma(k))$ . Without loss of generality, suppose that  $A' = \{a'_1, \dots, a'_{s'}\}$  and let  $B' := \{b'_1, \dots, b'_{s'}\}$  be the set of vertices matched to  $A'$  in  $M$ . Again by Lemma 3.13, we obtain an independent set  $B'' \subseteq B'$  of size  $s'' := f_\gamma(k)$ . We assume without loss of generality that  $B'' = \{b''_1, \dots, b''_{s''}\}$ . Let  $A'' := \{a''_1, \dots, a''_{s''}\}$  be the set of vertices matched to  $B''$  in  $M$ . Then,  $G[A'' \cup B'']$  is a bipartite graph with a matching of size at least  $s'' = f_\gamma(k)$ . By Lemma 3.10,  $G[A'' \cup B'']$  has an induced matching of size  $k$ . ◀

Since  $\text{opt}(G) = |V_{1/2}|/2 + |V_1|$ , it holds that  $|V_{1/2}|/2 + |V_1| \leq 2g_\gamma(g_\gamma(f_\gamma(k))) \in \mathcal{O}(\gamma^7 k^8)$  after the application of Reduction Rule 3.14. Hence, it remains to bound the size of  $V_0$ . To do so, it suffices to remove twins:

► **Reduction Rule 3.16.** *If  $N(u) = N(v)$  for some vertices  $u, v \in V(G)$ , then delete  $v$ .*

Since an induced matching contains at most one of  $u$  and  $v$ , the rule is obviously correct. We are finally ready to utilize Lemma 2.2 to derive an upper bound on  $V_0$ : Since  $V_0$  is an independent set, Lemma 2.2 gives us  $|V_0| \in |V_{1/2} \cup V_1|^{\mathcal{O}(\gamma)} \in (\gamma k)^{\mathcal{O}(\gamma)}$ . Thus, we have the following result.

► **Theorem 3.17.** *INDUCED MATCHING has a kernel of size  $(\gamma k)^{\mathcal{O}(\gamma)}$ .*

## 4 Independent Set and Ramsey-Type Problems

We now investigate the kernelization complexity of INDEPENDENT SET, where we are given a graph  $G$  and an integer  $k$ , and ask whether  $G$  has an independent set of size  $k$ . INDEPENDENT SET admits a kernel with  $\mathcal{O}(ck^2)$  vertices and  $\mathcal{O}(c^2k^3)$  edges [20] and a kernel with  $\mathcal{O}(\gamma k^2)$  and  $\mathcal{O}(\gamma^2 k^3)$  edges [19]. We show a lower bound for these parameterizations: unless  $\text{coNP} \subseteq \text{NP/poly}$ , INDEPENDENT SET admits no kernel of size  $k^{2-\epsilon}$  and no kernel with  $k^{4/3-\epsilon}$  vertices even if the  $c$ -closure is constant. We also show a kernel lower bound of size  $c^{1-\epsilon} k^{\mathcal{O}(1)}$  for any  $\epsilon$ . We also consider the following related problem where  $\mathcal{G}$  is a hereditary graph class containing all complete graphs and edgeless graphs.

$\mathcal{G}$ -SUBGRAPH

**Input:** A graph  $G$  and  $k \in \mathbb{N}$ .

**Question:** Is there a set  $S$  of at least  $k$  vertices such that  $G[S] \in \mathcal{G}$ ?

Khot and Raman [18] showed that  $\mathcal{G}$ -SUBGRAPH is FPT when parameterized by  $k$ , using Ramsey's theorem: for any  $k \in \mathbb{N}$ , any graph  $G$  on at least  $R(k) \in 2^{\mathcal{O}(k)}$  vertices contains a clique of size  $k$  or an independent set of size  $k$ . RAMSEY, the special case where  $\mathcal{G}$  is the family of all complete and edgeless graphs, admits no polynomial kernel unless  $\text{coNP} \subseteq \text{NP/poly}$  [21]. Similarly,  $\mathcal{G}$ -SUBGRAPH admits no polynomial kernel for several graph classes  $\mathcal{G}$ , such as cluster graphs [23]. Our contribution for  $\mathcal{G}$ -SUBGRAPH is two-fold: First, we observe that the lower bounds for INDEPENDENT SET on graphs with constant  $c$ -closure also

■ **Figure 1** An illustration of  $P_r^i$  and  $P_r^{i+1}$  for  $t = 5$ .

hold for RAMSEY. This complements a kernel for  $\mathcal{G}$ -SUBGRAPH with  $\mathcal{O}(ck^2)$  vertices [20].<sup>2</sup> Second, we provide a kernel of size  $k^{\mathcal{O}(\gamma)}$ . To show our kernel lower bounds, we will use *weak  $q$ -compositions*. Weak  $q$ -compositions exclude kernels of size  $\mathcal{O}(k^{q-\varepsilon})$  for  $\varepsilon > 0$ .

► **Definition 4.1** ([6, 15]). *Let  $q \geq 1$  be an integer, let  $L_1 \subseteq \{0, 1\}^*$  be a decision problem, and let  $L_2 \subseteq \{0, 1\}^* \times \mathbb{N}$  be a parameterized problem. A weak  $q$ -composition from  $L_1$  to  $L_2$  is a polynomial-time algorithm that on input  $x_1, \dots, x_{t^q} \in \{0, 1\}^n$  outputs an instance  $(y, k') \in \{0, 1\}^* \times \mathbb{N}$  such that:*

- $(y, k') \in L_2 \Leftrightarrow x_i \in L_1$  for some  $i \in [t^q]$ , and
- $k' \leq t \cdot n^{\mathcal{O}(1)}$ .

► **Lemma 4.2** ([3, 6, 15]). *Let  $q \geq 1$  be an integer, let  $L_1 \subseteq \{0, 1\}^*$  be an NP-hard problem, and let  $L_2 \subseteq \{0, 1\}^* \times \mathbb{N}$  be a parameterized problem. If there is a weak  $q$ -composition from  $L_1$  to  $L_2$ , then  $L_2$  has no compression of size  $\mathcal{O}(k^{q-\varepsilon})$  for any  $\varepsilon > 0$ , unless  $\text{coNP} \subseteq \text{NP/poly}$ .*

**Weak Composition.** We give a weak composition from the following problem:

MULTICOLORED INDEPENDENT SET

**Input:** A graph  $G$  and a partition  $(V_1, \dots, V_k)$  of  $V(G)$  into  $k$  cliques.

**Question:** Is there an independent set of size exactly  $k$ ?

A standard reduction from a restricted variant of 3-SAT (for instance, each literal appears exactly twice [1]) shows that MULTICOLORED INDEPENDENT SET is NP-hard even when  $\Delta_G \in \mathcal{O}(1)$  and  $|V_i| \in \mathcal{O}(1)$  for all  $i \in [k]$ . Let  $[t]^q$  be the set of  $q$ -dimensional vectors whose entries are in  $[t]$ . Suppose that  $q \geq 2$  is a constant and that we are given  $t^q$  instances  $\mathcal{I}_x = (G_x, (V_x^1, \dots, V_x^k))$  for  $x \in [t]^q$ , where  $\Delta_{G_x} \in \mathcal{O}(1)$  and  $|V_x^i| \in \mathcal{O}(1)$  for all  $x \in [t]^q$  and  $i \in [k]$ . We construct an INDEPENDENT SET instance  $(H, k')$ . The kernel lower bound of size  $k^{2-\varepsilon}$  will be based on the special case  $q = 2$ . To obtain the lower bound of  $c^{1-\varepsilon} k^{\mathcal{O}(1)}$ , however, we need the composition to work for all  $q \in \mathbb{N}$ . Hence, we give a generic description in the following. First, we construct a graph  $H_i$  as follows for every  $i \in [k]$ :

- For every  $x \in [t]^q$ , include  $V_x^i$  into  $V(H_i)$ .
- For every  $r \in [q]$ , introduce a path  $P_r^i$  on  $2t - 2$  vertices. We label the  $(2j - 1)$ -th vertex as  $p_{r,j,1}^i$  and the  $2j$ -th vertex as  $p_{r,j+1,2}^i$  (see Figure 1 for an illustration). Note that  $V(P_r^i) = \{p_{r,j,1}^i, p_{r,j+1,2}^i \mid j \in [t - 1]\}$ . For every  $j \in [t]$ , we now define the set  $P_{r,j}^i$ : let  $P_{r,1}^i = \{p_{r,1,1}^i\}$ ,  $P_{r,t}^i = \{p_{r,t,2}^i\}$ , and  $P_{r,j}^i = \{p_{r,j,1}^i, p_{r,j,2}^i\}$  for  $j \in [2, t - 2]$ .
- For every  $r \in [q]$  and  $j \in [t]$ , add edges such that  $P_{r,j}^i \cup \bigcup_{x \in [t]^q, x_r = j} V_x^i$  forms a clique (see Figure 1 for an illustration).

<sup>2</sup> Any  $c$ -closed  $n$ -vertex graph contains a clique or an independent set of size  $\Omega(\sqrt{n/c})$  [20].

## 35:12 Essentially Tight Kernels for (Weakly) Closed Graphs

Now, construct  $H$  by taking the disjoint union of the  $H_i$ ,  $i \in [k]$ , and adding the following:

- For every  $x \in [t]^q$ , add edges such that  $H[V(G_x)] = G_x$ .
- For every  $i \in [k-1]$ ,  $r \in [q]$ , and  $j \in [t-1]$ , add edges  $p_{r,j,1}^i p_{r,j+1,2}^{i+1}$  and  $p_{r,j,1}^{i+1} p_{r,j+1,2}^i$ .

This concludes the construction of  $H$ . Let  $k' := qkt - qk + k$ .

We call the vertices of  $\bigcup_{x \in [t]^q, i \in [k]} V_x^i$  the *instance vertices*. The other vertices, which are on  $P_r^i$  for some  $i \in [k]$  and  $r \in [q]$ , serve as *instance selectors*: As we shall see later, any independent set  $J$  of size  $k'$  in  $H$  contains exactly  $t-1$  vertices of  $P_r^i$  for every  $i \in [k]$  and  $r \in [q]$ . In fact, there is exactly one  $j \in [t]$  such that  $J \cap P_{r,j}^i = \emptyset$  and  $|J \cap P_{r,j'}^i| = 1$  for all  $j' \in [t] \setminus \{j\}$ . Consequently,  $J$  contains no instance vertex in  $V_x^i$  for  $x_r \neq j$ , and thereby,  $j$  is *selected* for the  $r$ -th dimension. We bound the  $c$ -closure of  $H$  and prove the correctness.

► **Lemma 4.3 (\*)**. *It holds that  $\text{cl}_H \in \mathcal{O}(t^{q-2})$ .*

► **Lemma 4.4 (\*)**. *The graph  $G_x$  has a multicolored independent set of size  $k$  for some  $x \in [t]^q$  if and only if the graph  $H$  has an independent set  $I$  of size  $k'$ .*

For  $q = 2$ , we have a weak 2-composition from MULTICOLORED INDEPENDENT SET to INDEPENDENT SET on  $\mathcal{O}(t^{q-2}) = \mathcal{O}(1)$ -closed graphs by Lemmas 4.3 and 4.4. Since the constructed graph  $H$  has no clique of size  $k'$ , the construction also constitutes a weak 2-composition to RAMSEY on  $\mathcal{O}(1)$ -closed graphs. Thus, Lemma 4.2 implies the following:

► **Theorem 4.5**. *For any  $\varepsilon > 0$ , neither INDEPENDENT SET nor RAMSEY has a kernel of size  $k^{2-\varepsilon}$  on graphs of constant  $c$ -closure, unless  $\text{coNP} \subseteq \text{NP/poly}$ .*

By Theorem 4.5, neither INDEPENDENT SET nor RAMSEY admit a kernel of  $k^{1-\varepsilon}$  vertices. We improve this bound on the number of vertices, taking advantage of the fact that any  $n$ -vertex  $c$ -closed graph can be encoded using  $\mathcal{O}(cn^{1.5} \log n)$  bits in polynomial time [12]. Assume for a contradiction that INDEPENDENT SET or RAMSEY admit a kernel of  $k^{4/3-\varepsilon'}$  vertices for constant  $c$ . Using the above-mentioned encoding, we obtain a string with  $\mathcal{O}(k^{(4/3-\varepsilon')1.5} \log k) = \mathcal{O}(k^{2-\varepsilon})$  bits. So a kernel of  $k^{4/3-\varepsilon'}$  vertices implies that there is a compression of INDEPENDENT SET or RAMSEY with bitsize  $\mathcal{O}(k^{2-\varepsilon})$ , a contradiction. Thus, we have the following:

► **Theorem 4.6**. *For any  $\varepsilon > 0$ , neither INDEPENDENT SET nor RAMSEY has a compression of  $k^{4/3-\varepsilon}$  vertices on graphs of constant  $c$ -closure, unless  $\text{coNP} \subseteq \text{NP/poly}$ .*

We also obtain another kernel lower bound for INDEPENDENT SET; this bound excludes the existence of polynomial kernels (in terms of  $c+k$ ) whose dependence on  $c$  is sublinear.

► **Theorem 4.7**. *For any  $\varepsilon > 0$ , INDEPENDENT SET has no kernel of size  $c^{1-\varepsilon} k^{\mathcal{O}(1)}$  unless  $\text{coNP} \subseteq \text{NP/poly}$ .*

**Proof.** We show that INDEPENDENT SET admits no kernel of size  $c^{1-\varepsilon} k^i$  for any  $\varepsilon, i > 0$ , unless  $\text{coNP} \subseteq \text{NP/poly}$ . Let  $q$  be a sufficiently large integer with  $\frac{q-\varepsilon-i}{q-2} > 1-\varepsilon$  (that is,  $q > \frac{i+3\varepsilon-2}{\varepsilon}$ ). Recall, that in the constructed instance we have  $c \in \mathcal{O}(t^{q-2})$  and  $k' := qkt - qk + k$ . A straightforward calculation shows that  $\ell := c^{\frac{1}{q-2}(1-\frac{i}{q-\varepsilon})} k'^{\frac{i}{q-\varepsilon}} \in \mathcal{O}(t)$ , and hence INDEPENDENT SET admits a weak  $q$ -decomposition for the parameterization  $\ell$ . Thus, Lemma 4.2 implies that there is no kernel of size  $\ell^{q-\varepsilon} = c^{\frac{q-\varepsilon-i}{q-2}} k'^i > c^{1-\varepsilon} k^i$ . ◀

Finally, we show that  $\mathcal{G}$ -SUBGRAPH has a kernel of size  $k^{\mathcal{O}(\gamma)}$  for any graph class  $\mathcal{G}$  containing all complete graphs and empty graphs.

► **Proposition 4.8.** *Any graph  $G$  on at least  $R_\gamma(a, b) \in (a \cdot b)^{\gamma + \mathcal{O}(1)}$  vertices has a clique of size  $a$  or an independent set of size  $b$ .*

**Proof.** The Ramsey number  $R(a, b)$  denotes the smallest number such that every graph on  $R(a, b)$  vertices contains a clique of size  $a$  or an independent set of size  $b$ . It is known that  $R(a, b) \leq \binom{a+b}{b}$ . So whenever  $a \leq \gamma$  or  $b \leq \gamma$ , we have  $R_\gamma(a, b) \leq \binom{a+b}{\gamma} \in \mathcal{O}((a+b)^\gamma)$ . For  $a, b > \gamma$ , let  $R_\gamma(a, b)$  be some number greater than  $ab \binom{b}{\gamma} + b \binom{a}{\gamma} \sum_{b' \in [b]} \binom{b'-1}{\gamma}$ .

Let  $n = |V(G)|$  and let  $v_1, \dots, v_n$  be a weak closure ordering  $\sigma$  of  $G$ . Divide  $V(G)$  into  $b$  subsets  $V_1, \dots, V_b$  of equal size<sup>3</sup>: let  $V_i = \{v_{((b-i)n/b)+1}, \dots, v_{(b-i+1)n/b}\}$  for each  $i \in [b]$ . Notably,  $V_1$  is the set of  $n/b$  vertices occurring last in  $\sigma$  and  $V_b$  is the set of  $n/b$  vertices occurring first in  $\sigma$ . Moreover, let  $G_i := G[\{v_{(b-i)n/b+1}, \dots, v_n\}]$  be the subgraph induced by  $\bigcup_{i' \in [i]} V_{i'}$  for each  $i \in [b]$ . Suppose that  $G$  contains no clique of size  $a$ . We show that  $G$  contains an independent set of size  $b$ . More precisely, we prove by induction that  $G_i$  contains an independent set of size  $i$  for each  $i \in [b]$ .

This clearly holds for  $i = 1$ . For  $i > 1$ , assume that there is an independent set  $I$  of size  $i - 1$  in  $G_{i-1}$  by the induction hypothesis. In the following, we consider subsets  $X$  of size at most  $\gamma$  of  $I$  to obtain an independent set  $I'$  of size at least  $i$ .

First, consider vertex sets  $X \subseteq I$  of size  $\gamma$  and  $V_X := \{v \in V_i \mid N_G(v) \supseteq X\}$ . Note that  $X \subseteq Q(v)$  for each  $v \in V_X$ . Hence, since  $G$  is weakly  $\gamma$ -closed,  $V_X$  is a clique. It follows that  $|V_X| < a$ . Therefore, less than  $a \binom{b}{\gamma}$  vertices of  $V_i$  are adjacent to at least  $\gamma$  vertices in  $I$ .

Second, consider vertex sets  $X \subseteq I$  with  $X \neq \emptyset$  and  $|X| < \gamma$ . Furthermore, let  $V'_X = \{v \in V_i \mid N_G(v) \cap I = X\}$ . Since  $n > R_\gamma(a, b)$ , there exists  $X \subseteq I$  of size at most  $\gamma - 1$  such that  $|V'_X| > R(a, \gamma)$ . By Ramsey's theorem, we then find an independent set  $I' \subseteq V'_X$  of size  $\gamma$  (recall that  $G$  has no clique of size  $a$ ). It follows that  $(I \setminus X) \cup I'$  is an independent set of size at least  $i$  in  $G_i$ . ◀

Now, we directly obtain to a kernel for  $\mathcal{G}$ -SUBGRAPH where  $\mathcal{G}$  contains all cliques and all independent sets since each graph on  $k^{\mathcal{O}(\gamma)}$  vertices contains either a clique or an independent set of size at least  $k$  by the bound on the Ramsey number in weakly closed graphs shown in Proposition 4.8.

► **Corollary 4.9.** *Let  $\mathcal{G}$  be a class of graphs containing all cliques and independent sets.  $\mathcal{G}$ -SUBGRAPH has a kernel of size  $k^{\mathcal{O}(\gamma)}$ .*

## 5 Conclusion

We have provided several kernelization algorithms and kernelization lower bounds for classic graph problems on (weakly) closed graphs. How far can our results for CONNECTED VERTEX COVER and CAPACITATED VERTEX COVER be extended to other cases of connected or capacitated vertex deletion problems? We did show that CONNECTED  $\ell$ -COC admits a kernel of size  $k^{\mathcal{O}(\gamma)}$ . In contrast, CONNECTED FEEDBACK VERTEX SET does not admit a polynomial kernel for the solution size  $k$  even in 2-closed graphs [5]. Drawing a borderline between those desired graph properties where connected and capacitated vertex deletion problems do admit a kernel on (weakly) closed graphs and those where they do not would improve our understanding when (weak) closure can be exploited algorithmically. It is also open whether the Ramsey number of weakly closed graphs can be bounded by  $(a + b + \gamma)^{\mathcal{O}(1)}$ , such a bound would immediately improve some of our kernels. The most important open

<sup>3</sup> For ease of presentation we assume that  $|V(G)|$  is divisible by  $b$ .

problem is arguably whether DOMINATING SET parameterized by the solution size  $k$  admits a polynomial kernel on weakly closed graphs. We made partial progress by showing that DOMINATING SET admits a kernel on weakly closed bipartite graphs and on weakly closed split graphs. Answering this question positively would need further insights into the structure of weakly closed graphs, however.

## Abstract

We revisit a classical crossword filling puzzle which already appeared in Garey&Jonhson’s book. We are given a grid with  $n$  vertical and horizontal slots and a dictionary with  $m$  words and are asked to place words from the dictionary in the slots so that shared cells are consistent. We attempt to pinpoint the source of intractability of this problem by carefully taking into account the structure of the grid graph, which contains a vertex for each slot and an edge if two slots intersect. Our main approach is to consider the case where this graph has a tree-like structure. Unfortunately, if we impose the common rule that words cannot be reused, we discover that the problem remains NP-hard under very severe structural restrictions, namely, if the grid graph is a union of stars and the alphabet has size 2, or the grid graph is a matching (so the crossword is a collection of disjoint crosses) and the alphabet has size 3. The problem does become slightly more tractable if word reuse is allowed, as we obtain an  $m^{\text{tw}}$  algorithm in this case, where  $\text{tw}$  is the treewidth of the grid graph. However, even in this case, we show that our algorithm cannot be improved to obtain fixed-parameter tractability. More strongly, we show that under the ETH the problem cannot be solved in time  $m^{o(k)}$ , where  $k$  is the number of horizontal slots of the instance (which trivially bounds  $\text{tw}$ ).

Motivated by these mostly negative results, we also consider the much more restricted case where the problem is parameterized by the number of slots  $n$ . Here, we show that the problem does become FPT (if the alphabet has constant size), but the parameter dependence is exponential in  $n^2$ . We show that this dependence is also justified: the existence of an algorithm with running time  $2^{o(n^2)}$ , even for binary alphabet, would contradict the randomized ETH. Finally, we consider an optimization version of the problem, where we seek to place as many words on the grid as possible. Here it is easy to obtain a  $\frac{1}{2}$ -approximation, even on weighted instances, simply by considering only horizontal or only vertical slots. We show that this trivial algorithm is also likely to be optimal, as obtaining a better approximation ratio in polynomial time would contradict the Unique Games Conjecture. The latter two results apply whether word reuse is allowed or not.

## 1 Introduction

Crossword puzzles are one-player games where the goal is to fill a (traditionally two-dimensional) grid with words. Since their first appearance more than 100 years ago, crossword puzzles have rapidly become popular. Nowadays, they can be found in many newspapers

■ **Figure 1** Place valid words in this grid. In a possible instance, letters S, U, I, V, R, E, and T have weight 7, 5, 4, 2, 6, 1, and 3, respectively. Any other letter has null weight. Try to obtain at least 330 points.

and magazines around the world like the *New York Times* in the USA, or *Le Figaro* in France. Besides their obvious recreational interest, crossword puzzles are valued tools in education [2] and medicine. In particular, crossword puzzles participation seems to delay the onset of memory decline [14]. They are also helpful for developing and testing computational techniques; see for example [16]. In fact, both the design and the completion of a puzzle are challenging. In this article, we are interested in the task of solving a specific type of crossword puzzle.

There are different kinds of crossword puzzles. In the most famous ones, some clues are given together with the place where the answers should be located. A solution contains words that must be consistent with the given clues, and the intersecting pairs of words are constrained to agree on the letter they share. *Fill-in* crossword puzzles do not come with clues. Given a list of words and a grid in which some slots are identified, the objective is to fill all the slots with the given words. The list of words is typically succinct and provided explicitly.

In a variant of fill-in crossword puzzle currently proposed in a French TV magazine [12], one has to find up to 14 words and place them in a grid (the grid is the same for every instance, see Figure 1 for an illustration). The words are not explicitly listed but they must be *valid* (for instance, belong to the French language). In an instance of the game, some specified letters have a positive weight; the other letters have weight zero. The objective is to find a solution whose weight – defined as the total sum of the letters written in the grid – is at least a given threshold.

The present work deals with a theoretical study of this fill-in crossword puzzle (the grid is not limited to the one of Figure 1). We are mainly interested in two problems: Can the grid be entirely completed? How can the weight of a solution be maximized? Hereafter, these problems are called CROSSWORD PUZZLE DECISION and CROSSWORD PUZZLE OPTIMIZATION (CP-DEC and CP-OPT in short), respectively.

CP-DEC is not new; see GP14 in [5]. The proof of NP-completeness is credited to a personal communication with Lewis and Papadimitriou. Thereafter, an alternative NP-completeness proof appeared in [4] (see also [10]). Other articles on crossword puzzles exist and they are mostly empirically validated techniques coming from Artificial Intelligence and Machine Learning; see for example [6, 13, 11, 1, 16, 15] an references therein.

**Our Results.** Our goal in this paper is to pinpoint the relevant structural parameters that make filling crossword puzzles intractable. We begin by examining the structure of the given grid. It is natural to think that, if the structure of the grid is tree-like, then the problem should become easier, as the vast majority of problems are tractable on graphs of small treewidth. We only partially confirm this intuition: by taking into account the structure of a graph that encodes the intersections between slots (the grid-graph) we show in Section 3

that CP-OPT can be solved in polynomial time on instances of constant treewidth. However, our algorithm is not fixed-parameter tractable and, as we show, this cannot be avoided, even if one considers the much more restricted case where the problem is parameterized by the number of horizontal slots, which trivially bounds the grid-graph's treewidth (Theorem 4). More devastatingly, we show that if we also impose the natural rule that words cannot be reused, the problem already becomes NP-hard when the grid graph is a matching for alphabets of size 3 (Theorem 6), or a union of stars for a binary alphabet (Theorem 5). Hence, a tree-like structure does not seem to be of much help in rendering crosswords tractable.

We then go on to consider CP-OPT parameterized by the total number of slots  $n$ . This is arguably a very natural parameterization of the problem, as in real-life crosswords, the size of the grid can be expected to be significantly smaller than the size of the dictionary. We show that in this case the problem does become fixed-parameter tractable (Corollary 9), but the running time of our algorithm is exponential in  $n^2$ . Our main result is to show that this disappointing dependence is likely to be best possible: even for a binary alphabet, an algorithm solving CP-DEC in time  $2^{o(n^2)}$  would contradict the randomized ETH (Theorem 12). Note that all our positive results up to this point work for the more general CP-OPT, while our hardness results apply to CP-DEC.

Finally, in Section 5 we consider the approximability of CP-OPT. Here, it is easy to obtain a  $\frac{1}{2}$ -approximation by only considering horizontal or vertical slots. We are only able to slightly improve upon this, giving a polynomial-time algorithm with ratio  $\frac{1}{2} + O(\frac{1}{n})$ . Our main result in this direction is to show that this is essentially best possible: obtaining an algorithm with ratio  $\frac{1}{2} + \epsilon$  would falsify the Unique Games Conjecture (Theorem 15).

## 2 Problem Statement and Preliminaries

We are given a dictionary  $\mathcal{D} = \{d_1, \dots, d_m\}$  whose words are constructed on an alphabet  $\mathcal{L} = \{l_1, \dots, l_\ell\}$ , and a two-dimensional grid consisting of horizontal and vertical slots. A slot is composed of consecutive cells. Horizontal slots do not intersect each other; the same goes for vertical slots. However horizontal slots can intersect vertical slots. A cell is *shared* if it lies at the intersection of two slots. Unless specifically stated,  $n$ ,  $m$  and  $\ell$  denote the total number of slots, the size of  $\mathcal{D}$ , and the size of  $\mathcal{L}$ , respectively. Finally, let us mention that we consider only instances where the alphabet is of constant size, i.e.,  $\ell = O(1)$ .

In a feasible solution, each slot  $S$  receives either a word of  $\mathcal{D}$  of length  $|S|$ , or nothing (we sometimes say that a slot receiving nothing gets an *empty word*). Each cell gets at most one letter, and the words assigned to two intersecting slots must agree on the letter placed in the shared cell. All filled horizontal slots get words written from left to right (across) while all vertical slots get words written from top to bottom (down).

There is a weight function  $w : \mathcal{L} \rightarrow \mathbb{N}$ . The weight of a solution is the total sum of the weights of the letters placed in the grid. Observe that, for a given solution, the total weight of all filled-in words is not the same as the weight of this solution as, in the latter, the letters of the shared cells are counted only once.

The two main problems studied in this article are the following. Given a grid, a dictionary  $\mathcal{D}$  on alphabet  $\mathcal{L}$ , and a weight function  $w : \mathcal{L} \rightarrow \mathbb{N}$ , the objective of CROSSWORD PUZZLE OPTIMIZATION (CP-OPT in short) is to find a feasible solution of maximum weight. Given a grid and a dictionary  $\mathcal{D}$  on alphabet  $\mathcal{L}$ , the question posed by CROSSWORD PUZZLE DECISION (CP-DEC in short) is whether the grid can be completely filled or not?

Two cases will be considered: whether each word is used at most once, or if each word can be assigned multiple times. In this article, we will sometimes suppose that some cells are pre-filled with some elements of  $\mathcal{L}$ . In this case, a solution is feasible if it is consistent with the pre-filled cells. Below we propose a first result when all the shared cells are pre-filled.

► **Proposition 1.** *CP-DEC and CP-OPT can be solved in polynomial time if all the shared cells in the grid are pre-filled, whether word reuse is allowed or not.*

**Proof.** If word reuse is allowed, then for each combination of letters placed in these cells, we greedily fill out the rest of each slot with the maximum value word that can still be placed there. This is guaranteed to produce the optimal solution. On the other hand, if word reuse is not allowed, we construct a bipartite graph, with elements of  $\mathcal{D}$  on one side and the slots on the other, and place an edge between a word and a slot if the word can still be placed in the slot. If we give each edge weight equal to the value of its incident word reduced by the weight of the letters imposed by the shared cells of the slot, then an optimal solution corresponds to a maximum weight matching. ◀

One can associate a bipartite graph, hereafter called the *grid graph*, with each grid: each slot is a vertex and two vertices share an edge if the corresponding slots overlap. The grid (and then, the grid graph) is not necessarily connected.

Let us also note that so far we have been a bit vague about the encoding of the problem. Concretely, we could use a simple representation which lists for each slot the coordinates of its first cell, its size, and whether the slot is horizontal or vertical; and then supplies a list of all words in the dictionary and an encoding of the weight function. Such a representation would allow us to perform all the basic operations needed by our algorithms in polynomial time, such as deciding if it is possible to place a word  $d$  in a slot  $S$ , and which letter would then be placed in any particular cell of  $S$ . However, one drawback of this encoding is that its size may not be polynomially bounded in  $n + m$ , as some words may be exponentially long. We can work around this difficulty by using a more succinct representation: we are given the same information as above regarding the  $n$  slots; for each word we are given its total weight; and for each slot  $S$  and word  $d$ , we are told whether  $d$  fits exactly in  $S$ , and if yes, which letters are placed in the cells of  $S$  which are shared with other slots. Since the number of shared cells is  $O(n^2)$  this representation is polynomial in  $n + m$  and it is not hard to see that we are still able to perform any reasonable basic operation in polynomial time and that we can transform an instance given in the simple representation to this more succinct form. Hence, in the remainder, we will always assume that the size of the input is polynomially bounded in  $n + m$ .

We will rely on the Exponential Time Hypothesis (ETH) of Impagliazzo, Paturi, and Zane [8], which states the following:

► **Conjecture 2.** *Exponential Time Hypothesis: there exists an  $\epsilon > 0$ , such that 3-SAT on instances with  $n$  variables and  $m$  clauses cannot be solved in time  $2^{\epsilon(n+m)}$ .*

Note that it is common to use the slightly weaker formulation which states the ETH as the assumption that 3-SAT cannot be solved in time  $2^{o(n+m)}$ . This is known to imply that  $k$ -INDEPENDENT SET cannot be solved in time  $n^{o(k)}$ [3]. We use this fact in Theorem 4. In Section 4 we will rely on the randomized version of the ETH, which has the same statement as Conjecture 2 but for randomized algorithms with expected running time  $2^{\epsilon(n+m)}$ .

### 3 When the Grid Graph is Tree-like

In this section we are considering instances of CP-DEC and CP-OPT where the grid graph is similar to a tree. First, we give an algorithm for both problems in cases where the grid graph has bounded treewidth and we are allowed to reuse words and we show that this algorithm is essentially optimal. Then, we show that CP-DEC and CP-OPT are much harder to deal

with, in the case where we are not allowed to reuse words, by proving that the problems are NP-hard even for instances where the grid graph is just a matching. For the instances such that CP-DEC is NP-hard, we know that CP-OPT is NP-hard. That happens because we can assume that all the letters have weight equal to 1 hence a solution for CP-DEC is an optimal solution for CP-OPT.

### 3.1 Word Reuse

We propose a dynamic programming algorithm for CP-OPT and hence also for CP-DEC. Note that it can be extended to the case where some cells of the instance are pre-filled.

► **Theorem 3.** *If we allow word reuse, then CP-OPT can be solved in time  $(m+1)^{tw(n+m)}O(1)$  on inputs where  $tw$  is the treewidth of the grid graph.*

**Proof.** As the techniques we are going to use are standard we are sketching some details. For more details on tree decomposition (definition and terminology) see [3, Chap. 7]. Assuming that we have a rooted nice tree decomposition of the grid graph, we are going to perform dynamic programming on the nodes of this tree decomposition. For a node  $B_t$  of the given tree decomposition of the grid graph we denote by  $B_t^\downarrow$  the set of vertices of the grid graph that appears in the nodes of the subtree with  $B_t$  as a root. Since each vertex of the grid graph corresponds to a slot, we interchangeably mention a vertex of the grid graph and its corresponding slot. In particular, we say that a solution  $\sigma$  assigns words to the vertices of the grid graph, and  $\sigma(v)$  denotes the word assigned to  $v$ .

For each node  $B_t$  of the tree decomposition we are going to keep all the triplets  $(\sigma, W, W_t)$  such that:

- $\sigma$  is an assignment of words to the vertices of  $B_t$ ;
- $W$  is the weight of  $\sigma$  restricted to the vertices appearing in  $B_t$ ;
- and  $W_m$  is the maximum weight, restricted to the vertices appearing in  $B_t^\downarrow$ , of an assignment consistent with  $\sigma$ .

In order to create all the possible triplets for all the nodes of the tree decomposition we are going to explore the nodes from leaves to the root. Therefore, each time we visit a node we assume that we have already created the triplets for all its children. Let us explain how we deal with the different types of nodes.

In the Leaf nodes we have no vertices so we keep an empty assignment ( $\sigma$  does not assign any word) and the weights  $W$  and  $W_m$  are equal to 0.

For an Introduce node  $B_t$  we need to take in consideration its child node. Assume that  $u$  is the introduced vertex; for each triplet  $(\sigma, W, W_m)$  of the child node we are going to create all the triplets  $(\sigma', W', W'_m)$  for the new node as follows. First we find all the words  $d \in \mathcal{D}$  that fit in the corresponding slot of  $u$  and respect the assignment  $\sigma$  (i.e., if there are cells that are already filled under  $\sigma$  and  $d$  uses these cells then it must have the same letters). We create one triplet  $(\sigma', W', W'_m)$  for each such a  $d$  as follows:

- We set  $\sigma'(u) := d$  and  $\sigma'(v) := \sigma(v)$  for all  $v \in B_t \setminus \{u\}$ .
- We can easily calculate the total weight,  $W'$ , of the words in  $B_t$  where the shared letters are counted only once under the assignment  $\sigma'$ .
- For the maximum weight  $W'_m$  we know that it is increased by the same amount as  $W$ ; so we set  $W'_m = W_m + W' - W$ .

Observe that we do not need to consider the intersection with slots whose vertices appear in  $B_t^\downarrow \setminus B_t$  as each node of a tree decomposition is a cut set.

Finally, we need to take in consideration that we can leave a slot empty. For this case we create a new word  $d_*$  which, we assume that, fits in all slots and  $d_*$  has weight 0. Because the empty word has weight 0,  $W'$  and  $W'_m$  are identical to  $W$  and  $W_m$  so for each triplet of

the child node, we only need to extend  $\sigma$  by assigning  $d_*$  to  $u$ . In the case we assign the empty word somewhere we will consider that the cells of this slot are empty unless another word  $d \neq d_*$  uses them.

For the Forget nodes we need to restrict the assignments of the child node to the vertex set of the Forget node, as it has been reduced by one vertex (the forgotten vertex), and reduce the weight  $W$  (which we can calculate easily). The maximum weight is not changed by the deletion.

However, if we restrict the assignments we may end up with several triplets  $(\sigma, W, W_m)$  with identical assignments  $\sigma$ . In that case we are keeping only the triplet with maximum  $W_m$ . Observe that we are allowed to keep only triplets with the maximum  $W_m$  because each node of a tree decomposition is a cut set so the same holds for the Forget nodes. Specifically, the vertices that appear in the nodes higher than a Forget node  $B_t$  of the tree decomposition do not have edges incident to vertices in  $B_t^{\downarrow} \setminus B_t$  so we only care for the assignment in  $B_t$ .

Finally, we need to consider the Join nodes. Each Join node has exactly two children. For each possible assignment  $\sigma$  on the vertices of this Join node, we create a triplet iff this  $\sigma$  appears in a triplet of both children of the Join node.

Because  $W$  is related only to the assignment  $\sigma$ , it is easy to see that it will be the same as in the children of the Join node. So we need to find the maximum weight  $W_m$ . Observe that between the vertices that appear in the subtrees of two children of a Join node there are no edges except those incident to the vertices of the Join node. Therefore, we can calculate the maximum weight  $W_m$  as follows: first we consider the maximum weight of each child of the Join node reduced by  $W$ , we add all these weights and, in the end, we add again the  $W$ . It is easy to see that this way we consider the weight of the cells appearing in each subtree without those of the slots of the Join node and we add the weight of the words assigned to the vertices of the Join node in the end.

For the running time we need to observe that the number of nodes of a nice tree decomposition is  $O(\text{tw} \cdot n)$  and all the other calculations are polynomial in  $n + m$  so we only need to consider the different assignments for each node. Because for each vertex we have  $|\mathcal{D}| + 1$  choices, the number of different assignments for a node is at most  $(|\mathcal{D}| + 1)^{\text{tw}+1}$ . ◀

It seems that the algorithm we propose for CP-DEC is essentially optimal, even if we consider a much more restricted case.

► **Theorem 4.** *CP-DEC with word reuse is  $W[1]$ -hard parameterized by the number of horizontal slots of the grid, even for alphabets with two letters. Furthermore, under the ETH, no algorithm can solve this problem in time  $m^{o(k)}$ , where  $k$  is the number of horizontal slots.*

**Proof.** We perform a reduction from  $k$ -INDEPENDENT SET, where we are given a graph  $G = (V, E)$  with  $|V|$  vertices and  $|E|$  edges and are looking for an independent set of size  $k$ . This problem is well-known to be  $W[1]$ -hard and not solvable in  $|V|^{o(k)}$  time under the ETH [3]. We assume without loss of generality that  $|E| \neq k$ . Furthermore, we can safely assume that  $G$  has no isolated vertices.

We first describe the grid of our construction which fits within an area of  $2k - 1$  lines and  $2|E| - 1$  columns. We construct:

1.  $k$  horizontal slots, each of length  $2|E| - 1$  (so each of these slots is as long horizontally as the whole grid). We place these slots in the unique way so that no two of these slots are in consecutive lines. We number these horizontal slots  $1, \dots, k$  from top to bottom.
2.  $|E|$  vertical slots, each of length  $2k - 1$  (so each of these slots is long enough to cover the grid top to bottom). We place these slots in the unique way so that no two of them are in consecutive columns. We number them  $1, \dots, |E|$  from left to right.

Before we describe the dictionary, let us give some intuition about the grid. The main idea is that in the  $k$  horizontal slots we will place  $k$  words that signify which vertices are selected from the original graph. Each vertical slot represents an edge of  $E$ , and we will be able to place a word in it if and only if we have not placed words representing two of its endpoints in the horizontal slots.

Our alphabet has two letters, say 0, 1. In the remainder, we assume that the edges of the original graph are numbered, that is,  $E = \{e_1, \dots, e_{|E|}\}$ . The dictionary is as follows:

1. For each vertex  $v$  we construct a word of length  $2|E| - 1$ . For each  $i \in \{1, \dots, |E|\}$ , if the edge  $e_i$  is incident on  $v$ , then the letter at position  $2i - 1$  of the word representing  $v$  is 1. All other letters of the word representing  $v$  are 0. Observe that this means that if  $e_i$  is incident on  $v$  and we place the word representing  $v$  on a horizontal slot, the letter  $i$  will appear on the  $i$ -th vertical slot. Furthermore, the word representing  $v$  has a number of 1s equal to the degree of  $v$ .
2. We construct  $k + 1$  words of length  $2k - 1$ . One of them is simply  $0^{2k-1}$ . The remaining are  $0^{2j-2}10^{2k-2j}$ , for  $j \in \{1, \dots, k\}$ , that is, the words formed by placing a 1 in an odd-numbered position and 0s everywhere else. Observe that if we place one of these  $k$  words on a vertical slot, a 1 will be placed on exactly one horizontal slot.

This completes the construction. We now observe that the  $k$  horizontal slots correspond to a vertex cover of the grid-graph. Therefore, if the reduction preserves the answer, the hardness results for  $k$ -INDEPENDENT SET transfer to our problem, since we preserve the value of the parameter.

We claim that if there exists an independent set of size  $k$  in  $G$ , then it is possible to fill the grid. Indeed, take such a set  $S$  and for each  $v \in S$  we place the word representing  $v$  in a horizontal slot. Consider the  $i$ -th vertical slot. We will place in this slot one of the  $k + 1$  words of length  $2k - 1$ . We claim that the vertical slot at this moment contains the letter 1 at most once, and if 1 appears it must be at an odd position (since these are the positions shared with the horizontal slots). If this is true, clearly there is a word we can place. To see that the claim is true, recall that since  $S$  is an independent set of  $k$  distinct vertices, there exists at most one vertex in  $S$  incident on  $e_i$ .

For the converse direction, recall that  $|E| \neq k$ . This implies that if there is a way to fill out the whole grid, then words representing vertices must go into horizontal slots and words of length  $2k - 1$  must go into vertical slots. By looking at the words that have been placed in the horizontal slots we obtain a collection of  $k$  (not necessarily distinct) vertices of  $G$ . We will prove that these vertices must actually be an independent set of size exactly  $k$ . To see this, consider the  $i$ -th vertical slot. If our collection of vertices contained two vertices incident on  $e_i$ , it would have been impossible to fill out the  $i$ -th vertical slot, since we would need a word with two 1s. Observe that the same argument rules out the possibility that our collection contains the same vertex  $v$  twice, as the column corresponding to any edge  $e_i$  incident on  $v$  would have been impossible to fill. ◀

### 3.2 No Word Reuse

If a word cannot be reused, then CP-DEC looks more challenging. Indeed, in the following theorem we prove that if reusing words is not allowed, then the problem becomes NP-hard even if the grid graph is acyclic and the alphabet size is 2. (Note that if the alphabet size is 1, the problem is trivial, independent of the structure of the graph).

► **Theorem 5.** *CP-DEC is NP-hard, even for instances where all of the following restrictions apply: (i) the grid graph is a union of stars (ii) the alphabet contains only two letters (iii) words cannot be reused.*

**Proof.** We show a reduction from 3-PARTITION. Recall that in 3-PARTITION we are given a collection of  $3n$  distinct positive integers  $x_1, \dots, x_{3n}$  and are asked if it is possible to partition these integers into  $n$  sets of three integers (triples), such that all triples have the same sum. This problem has long been known to be strongly NP-hard [5] and NP-hardness when the integers are distinct was shown by Hulett et al. [7]. We can assume that  $\sum_{i=1}^{3n} x_i = nB$  and that if a partition exists each triple has sum  $B$ . Furthermore, we can assume without loss of generality that  $x_i > 6n$  for all  $i \in \{1, \dots, 3n\}$  (otherwise, we can simply add  $6n$  to all numbers and adjust  $B$  accordingly without changing the answer).

Given an instance of 3-PARTITION as above, we construct a crossword instance as follows. First, the alphabet only contains two letters, say the letters  $*$  and  $!$ . To construct our dictionary we do the following:

1. For each  $i \in \{1, \dots, 3n\}$ , we add to the dictionary one word of length  $x_i$  that begins with  $!$  and  $n - 1$  words of length  $x_i$  that begin with  $*$ . The remaining letters of these words are chosen in an arbitrary way so that all words remain distinct.
2. For each  $i, j, k \in \{1, \dots, 3n\}$  with  $i < j < k$  we check if  $x_i + x_j + x_k = B$ . If this is the case, we add to the dictionary the word  $*^{2i-2}!_*^{2j-2i-1}!_*^{2k-2j-1}!_*^{6n-2k}$ . In other words, we constructed a word that has  $*$  everywhere except in positions  $2i - 1, 2j - 1$ , and  $2k - 1$ . The length of this word is  $6n - 1$ . Let  $f$  be the number of words added to the dictionary in this step. We have  $f \leq \binom{3n}{3} = O(n^3)$ .

We now also need to specify our grid. We first construct  $f$  horizontal slots, each of length  $6n - 1$ . Among these  $f$  slots, we select  $n$ , which we call the “interesting” horizontal slots. For each interesting horizontal slot, we construct  $3n$  vertical slots, such that the  $i$ -th of these slots has length  $x_i$  and its first cell is the cell in position  $2i - 1$  of the interesting horizontal slot. This completes the construction, which can clearly be carried out in polynomial time. Observe that the first two promised restrictions are satisfied as we have an alphabet with two letters and each vertical slot intersects at most one horizontal slot (so the grid graph is a union of stars).

We claim that if there exists a partition of the original instance, then we can place all the words of the dictionary on the grid. Indeed, for each  $i, j, k \in \{1, \dots, 3n\}$  such that  $\{x_i, x_j, x_k\}$  is one of the triples of the partition, we have constructed a word of length  $6n - 1$  corresponding to the triple  $(i, j, k)$ , because  $x_i + x_j + x_k = B$ . We place each of these  $n$  words on an interesting horizontal slot and we place the remaining words of length  $6n - 1$  on the non-interesting horizontal slots. Now, for every  $i \in \{1, \dots, 3n\}$  we have constructed  $n$  words, one starting with  $!$  and  $n - 1$  starting with  $*$ . We observe that among the interesting horizontal slots, there is one that contains the letter  $!$  at position  $2i - 1$  (the one corresponding to the triple containing  $x_i$  in the partition) and  $n - 1$  containing the letter  $*$  at position  $2i - 1$ . By construction, the vertical slots that begin in these positions have length  $x_i$ . Therefore, we can place all  $n$  words corresponding to  $x_i$  on these vertical slots. Proceeding in this way we fill the whole grid, fulfilling the third condition.

For the converse direction, suppose that there is a way to fill the whole grid. Then, vertical slots must contain words that were constructed in the second step and represent integers  $x_i$ , while horizontal slots must contain words constructed in the first step (this is a consequence of the fact that  $x_i > 6n$  for all  $i \in \{1, \dots, 3n\}$ ). We consider the  $n$  interesting horizontal slots. Each such slot contains a word that represents a triple  $(i, j, k)$  with  $x_i + x_j + x_k = B$ .

We therefore collect these  $n$  triples and attempt to construct a partition from them. To do this, we must prove that each  $x_i$  must belong to exactly one of these triples. However, recall that we have exactly  $n$  words of length  $x_i$  (since all integers of our instance are distinct) and exactly  $n$  vertical slots of this length. We conclude that exactly one vertical slot must have  $!$  as its first letter, therefore  $x_i$  appears in exactly one triple and we have a proper partition. ◀

Actually, the problem remains NP-hard even in the case where the grid graph is a matching and the alphabet contains three letters. This is proved for grid graphs composed of  $\mathcal{T}$ s, where a  $\mathcal{T}$  is a horizontal slot solely intersected by the first cell of a vertical slot.

► **Theorem 6.** *CP-DEC is NP-hard, even for instances where all of the following restrictions apply: (i) each word can be used only once (ii) the grid is consisted only by  $\mathcal{T}$ s and (iii) the alphabet contains only three letters.*

► **Remark 7.** Theorem 4 can be adjusted to work also for the case where word reuse is not allowed. We simply need to add a suffix of length  $\log m$  to all words of length  $2k - 1$  and add rows to the grid accordingly. Hence, under the ETH, no algorithm can solve this problem in time  $m^{o(k)}$ , where  $k$  is the number of horizontal slots.

Finally, observe that by filling the slots of a vertex cover of the grid graph, all the shared cells are pre-filled. Since there are at most  $m^k$  (where  $k$  is the size of the vertex cover) ways to assign words to these slots, by Proposition 1, we get the following corollary.

► **Corollary 8.** *Given a vertex cover of size  $k$  of the grid graph we can solve CP-DEC and CP-OPT in time  $m^k(n + m)^{O(1)}$ . Furthermore, as vertex cover we can take the set of horizontal slots.*

Therefore, the bound given in Remark 7 for the parameter vertex cover is tight.

## 4 Parameterized by Total Number of Slots

In this section we consider a much more restrictive parameterization of the problem: we consider instances where the parameter is  $n$ , the total number of slots. Recall that in Theorem 4 (and Remark 7) we already considered the complexity of the problem parameterized by the number of *horizontal* slots of the instance. We showed that this case of the problem cannot be solved in  $m^{o(k)}$  and that an algorithm with running time roughly  $m^k$  is possible whether word reuse is allowed or not.

Since parameterizing by the number of horizontal slots is not sufficient to render the problem FPT, we therefore consider our parameter to be the total number of slots. This is, finally, sufficient to obtain a simple FPT algorithm.

► **Corollary 9.** *There is an algorithm that solves CP-DEC and CP-OPT in time  $O^*(\ell^{n^2/4})$ , where  $n$  is the total number of slots and  $\ell$  the size of the alphabet, whether word reuse is allowed or not.*

Even though the running time guaranteed by Corollary 9 is FPT for parameter  $n$ , we cannot help but observe that the dependence on  $n$  is rather disappointing, as our algorithm is exponential *in the square* of  $n$ . It is therefore a natural question whether an FPT algorithm for this problem can achieve complexity  $2^{o(n^2)}$ , assuming the alphabet size is bounded. The main result of this section is to establish that this is likely to be impossible.

## 36:10 Filling Crosswords Is Very Hard

**Overview.** Our hardness proof consists of two steps. In the first step we reduce 3-SAT to a version of the same problem where variables and clauses are partitioned into  $O(\sqrt{n+m})$  groups, which we call SPARSE 3-SAT. The key property of this intermediate problem is that interactions between groups of variables and groups of clauses are extremely limited. In particular, for each group of variables  $V_i$  and each group of clauses  $C_j$ , at most one variable of  $V_i$  appears in a clause of  $C_j$ . We obtain this rather severe restriction via a randomized reduction that runs in expected polynomial time. The second step is to reduce SPARSE 3-SAT to CP-DEC. Here, every horizontal slot will represent a group of variables and every vertical slot a group of clauses, giving  $O(\sqrt{n+m})$  slots in total. Hence, an algorithm for CP-DEC whose dependence on the total number of slots is subquadratic in the exponent will imply a sub-exponential time (randomized) algorithm for 3-SAT. The limited interactions between groups of clauses and variables will be key in allowing us to execute this reduction using a *binary* alphabet.

Let us now define our intermediate problem.

► **Definition 10.** *In SPARSE 3-SAT we are given an integer  $n$  which is a perfect square and a 3-SAT formula  $\phi$  with at most  $n$  variables and at most  $n$  clauses, such that each variable appears in at most 3 clauses. Furthermore, we are given a partition of the set of variables  $V$  and the set of clauses  $C$  into  $\sqrt{n}$  sets  $V_1, \dots, V_{\sqrt{n}}$  and  $C_1, \dots, C_{\sqrt{n}}$  of size at most  $\sqrt{n}$  each, such that for all  $i, j \in [\sqrt{n}]$  the number of variables of  $V_i$  which appear in at least one clause of  $C_j$  is at most one.*

Now, we are going to prove the hardness of SPARSE 3-SAT, which is the first step of our reduction.

► **Lemma 11.** *Suppose the randomized ETH is true. Then, there exists an  $\epsilon > 0$  such that SPARSE 3-SAT cannot be solved in time  $2^{\epsilon n}$ .*

We are now ready to prove the main theorem of this section.

► **Theorem 12.** *Suppose the randomized ETH is true. Then, there exists an  $\epsilon > 0$  such that CP-DEC on instances with a binary alphabet cannot be solved in time  $2^{\epsilon n^2} \cdot m^{O(1)}$ . This holds also for instances where all slots have distinct sizes (so words cannot be reused).*

**Proof.** Suppose for the sake of contradiction that for any fixed  $\epsilon > 0$ , CP-DEC on instances with a binary alphabet can be solved in time  $2^{\epsilon n^2} \cdot m^{O(1)}$ . We will then contradict Lemma 11. In particular, we will show that for any  $\epsilon'$  we can solve SPARSE 3-SAT in time  $2^{\epsilon' N}$ , where  $N$  is the upper bound on the number of variables and clauses. Fix some  $\epsilon' > 0$  and suppose that  $\phi$  is an instance of SPARSE 3-SAT with at most  $N$  variables and at most  $N$  clauses, where  $N$  is a perfect square. Recall that the variables are given partitioned into  $\sqrt{N}$  sets,  $V_1, \dots, V_{\sqrt{N}}$  and the clauses partitioned into  $\sqrt{N}$  sets  $C_1, \dots, C_{\sqrt{N}}$ . In the remainder, when we write  $V(C_j)$  we will denote the set of variables that appear in a clause of  $C_j$ . Recall that the partition satisfies the property that for all  $i, j \in [\sqrt{N}]$  we have  $|V_i \cap V(C_j)| \leq 1$ . Suppose that the variables of  $\phi$  are ordered  $x_1, x_2, \dots, x_N$ .

We construct a grid as follows: for each group  $V_i$  we construct a horizontal slot and for each group  $C_j$  we construct a vertical slot, in a way that all slots have distinct lengths. More precisely, the  $i$ -th horizontal slot, for  $i \in [\sqrt{N}]$  is placed on row  $2i - 1$ , starts in the first column and has length  $2\sqrt{N} + 2i$ . The  $j$ -th vertical slot is placed in column  $2j - 1$ , starts in the first row and has length  $5\sqrt{N} + 2j$ . (As usual, we number the rows and columns top-to-bottom and left-to-right). Observe that all horizontal slots intersect all vertical slots; in particular, the cell in row  $2i - 1$  and column  $2j - 1$  is shared between the  $i$ -th horizontal and  $j$ -th vertical slot, for  $i, j \in [\sqrt{N}]$ . We define  $\mathcal{L}$  to contain two letters  $\{0, 1\}$ .

What remains is to describe the dictionary.

- For each  $i \in [\sqrt{N}]$  and for each assignment function  $\sigma : V_i \rightarrow \{0, 1\}$  we construct a word  $w_\sigma$  of length  $2\sqrt{N} + 2i$ . The word  $w_\sigma$  has the letter 0 in all positions, except positions  $2j - 1$ , for  $j \in [\sqrt{N}]$ . For each such  $j$ , we consider  $\sigma$  restricted to  $V_i \cap V(C_j)$ . By the properties of SPARSE 3-SAT, we have  $|V_i \cap V(C_j)| \leq 1$ . If  $V_i \cap V(C_j) = \emptyset$  then we place letter 0 in position  $2j - 1$ ; otherwise we set in position  $2j - 1$  the letter that corresponds to the value assigned by  $\sigma$  to the unique variable of  $V_i \cap V(C_j)$ .
- For each  $j \in [\sqrt{N}]$  and for each *satisfying* assignment function  $\sigma : V(C_j) \rightarrow \{0, 1\}$ , that is, every assignment function that satisfies all clauses of  $C_j$ , we construct a word  $w'_\sigma$  of length  $5\sqrt{N} + 2j$ . The word  $w'_\sigma$  has the letter 0 in all positions, except positions  $2i - 1$ , for  $i \in [\sqrt{N}]$ . For each such  $i$ , we consider  $\sigma$  restricted to  $V_i \cap V(C_j)$ . If  $V_i \cap V(C_j) = \emptyset$  then we place letter 0 in position  $2i - 1$ ; otherwise we set in position  $2i - 1$  the letter that corresponds to the value assigned by  $\sigma$  to the unique variable of  $V_i \cap V(C_j)$ .

The construction is now complete. We claim that if  $\phi$  is satisfiable, then it is possible to fill out the grid we have constructed. Indeed, fix a satisfying assignment  $\sigma$  to the variables of  $\phi$ . For each  $i \in [\sqrt{N}]$  let  $\sigma_i$  be the restriction of  $\sigma$  to  $V_i$ . We place in the  $i$ -th horizontal slot the word  $w_{\sigma_i}$ . Similarly, for each  $j \in [\sqrt{N}]$  we let  $\sigma'_j$  be the restriction of  $\sigma$  to  $V(C_j)$  and place  $w'_{\sigma'_j}$  in the  $j$ -th vertical slot. Now if we examine the cell shared by the  $i$ -th horizontal and  $j$ -th vertical slot, we can see that it contains a letter that represents  $\sigma$  restricted to (the unique variable of)  $V_i \cap V(C_j)$  or 0 if  $V_i \cap V(C_j) = \emptyset$ , and both the horizontal and vertical word place the same letter in that cell.

For the converse direction, if the grid is filled, we can extract an assignment  $\sigma$  for the variables of  $\phi$  as follows: for each  $x \in V_i$  we find a  $C_j$  such that  $x$  appears in some clause of  $C_j$  (we can assume that every variable appears in some clause). We then look at the cell shared between the  $i$ -th horizontal and the  $j$ -th vertical slot. The letter we have placed in that cell gives an assignment for the variable contained  $V_i \cap V(C_j)$ , that is  $x$ . Having extracted an assignment to all the variables, we claim it must satisfy  $\phi$ . If not, there is a group  $C_j$  that contains an unsatisfied clause. Nevertheless, in the  $j$ -th vertical slot we have placed a word that corresponds to a *satisfying* assignment for the clauses of  $C_j$ , call it  $\sigma_j$ . Then  $\sigma_j$  must disagree with  $\sigma$  in a variable  $x$  that appears in  $C_j$ . Suppose this variable is part of  $V_i$ . Then, this would contradict the fact that we extracted an assignment for  $x$  from the word placed in the  $i$ -th horizontal slot.

Observe that the new instance has  $n = 2\sqrt{N}$  slots. If there exists an algorithm that solves CP-DEC in time  $2^{\epsilon n^2} m^{O(1)}$  for any  $\epsilon > 0$ , we set  $\epsilon = \epsilon'/8$  (so  $\epsilon$  only depends on  $\epsilon'$ ) and execute this algorithm on the constructed instance. We observe that  $m \leq 2\sqrt{N} \cdot 7^{\sqrt{N}}$ , and that  $2^{\epsilon n^2} \leq 2^{\epsilon' N/2}$ . Assuming that  $N$  is sufficiently large, using the supposed algorithm for CP-DEC we obtain an algorithm for SPARSE 3-SAT with complexity at most  $2^{\epsilon' N}$ . Since we can do this for arbitrary  $\epsilon'$ , this contradicts the randomized ETH. ◀

## 5 Approximability of CP-Opt

This section begins with a  $(\frac{1}{2} + O(\frac{1}{n}))$ -approximation algorithm which works when words can, or cannot, be reused. After that, we prove that under the unique games conjecture, an approximation algorithm with a significantly better ratio is unlikely.

► **Theorem 13.** *CP-OPT is  $(\frac{1}{2} + \frac{1}{2(\epsilon n + 1)})$ -approximable in polynomial time, for all  $\epsilon \in (0, 1]$ .*

## 36:12 Filling Crosswords Is Very Hard

**Proof.** Fix some  $\varepsilon \in (0, 1]$ . Let  $k_v := \min(\lceil \frac{1}{\varepsilon} \rceil, n - h)$  and  $r_v := \lceil \frac{n-h}{k_v} \rceil$ , where  $h$  is the number of horizontal slots in the grid. Create  $r_v$  groups of vertical slots  $G_1, \dots, G_{r_v}$  such that  $|G_i| \leq k_v$  for all  $i \in [r_v]$  and  $G_1 \cup \dots \cup G_{r_v}$  covers the entire set of vertical slots. For each  $G_i$ , guess an optimal choice of words, i.e., identical to a global optimum, and complete this partial solution by filling the horizontal slots (use the aforementioned matching technique where the words selected for  $G_i$  are excluded from  $\mathcal{D}$ ). Each slot of  $\bigcup_{j \neq i} G_j$  gets the empty word.

Since  $|G_i| \leq k_v$ , guessing an optimal choice of words for  $G_i$  by brute force requires at most  $m^{k_v}$  combinations. This is done  $r_v$  times (once for each  $G_i$ ). The maximum matching runs in time  $O((m+n)^2 \cdot mn)$ . In all, the time complexity of the algorithm is  $O(m^{k_v} \cdot r_v \cdot (m+n)^2 \cdot mn) \leq O(m^{1/\varepsilon} \cdot \varepsilon n \cdot (m+n)^2 \cdot mn)$ .

Assume that, given an optimal solution,  $W_H^*$  and  $W_V^*$  are the total weight of the words assigned to the horizontal and vertical slots, respectively, both including the shared cells. Furthermore, let  $W_S^*$  be the weight of the letters assigned to the shared cells in the optimal solution. Observe that the weight of the optimal solution is  $W_H^* + W_V^* - W_S^*$  and the weight of our solution is at least  $W_H^* + \frac{1}{r_v}(W_V^* - W_S^*)$ .

We repeat the same process, but the roles of vertical and horizontal slots are interchanged. Fix a parameter  $k_h := \min(\lceil \frac{1}{\varepsilon} \rceil, h)$ . Create  $r_h := \lceil \frac{h}{k_h} \rceil$  groups of horizontal slots  $G_1, \dots, G_{r_h}$  such that  $|G_i| \leq k_h$  for all  $i \in [r_h]$  and  $G_1 \cup \dots \cup G_{r_h}$  covers the entire set of horizontal slots. For each  $G_i$ , guess an optimal choice of words and complete this partial solution by filling the vertical slots. Each slot of  $\bigcup_{j \neq i} G_j$  gets the empty word.

Using the same arguments as above, we can conclude that the time complexity is  $O(m^{1/\varepsilon} \cdot \varepsilon n \cdot (m+n)^2 \cdot mn)$  and that we return a solution of weight at least  $W_V^* + \frac{1}{r_h}(W_H^* - W_S^*)$ .

Finally, between the two solutions, we return the one with the greater weight. It remains to argue about the approximation ratio. We need to consider two cases:  $W_H^* \geq W_V^*$  and  $W_V^* > W_H^*$ .

Suppose  $W_H^* \geq W_V^*$ . The first approximate solution has value  $W_H^* + \frac{1}{r_v}(W_V^* - W_S^*) \geq \frac{1+1/r_v}{2}(W_H^* + W_V^* - W_S^*)$ . If  $k_v = n - h$  then  $r_v = 1$  and our approximation ratio is 1. Otherwise,  $k_v = \lceil \frac{1}{\varepsilon} \rceil$  and  $r_v = \lceil \frac{n-h}{\lceil 1/\varepsilon \rceil} \rceil \leq \frac{n-h}{\lceil 1/\varepsilon \rceil} + 1 = \frac{n-h + \lceil 1/\varepsilon \rceil}{\lceil 1/\varepsilon \rceil}$ . It follows that  $\frac{1}{r_v} \geq \frac{\lceil 1/\varepsilon \rceil}{n-h + \lceil 1/\varepsilon \rceil}$ . Use  $n - h + \lceil 1/\varepsilon \rceil \leq n + \frac{1}{\varepsilon}$  and  $\lceil 1/\varepsilon \rceil \geq 1/\varepsilon$  to get that  $\frac{1}{r_v} \geq \frac{1/\varepsilon}{n+1/\varepsilon} = \frac{1}{\varepsilon n + 1}$ . Our approximation ratio is at least  $\frac{1+1/(\varepsilon n + 1)}{2}$ .

Suppose  $W_V^* > W_H^*$ . The second approximate solution has value  $W_V^* + \frac{1}{r_h}(W_H^* - W_S^*) > \frac{1+1/r_h}{2}(W_H^* + W_V^* - W_S^*)$ . If  $k_h = h$ , then our approximation ratio is 1. Otherwise,  $k_h = \lceil \frac{1}{\varepsilon} \rceil$  and, using the same arguments, our approximation ratio is at least  $\frac{1+1/(\varepsilon n + 1)}{2}$ .

Note that  $\frac{1+1/(\varepsilon n + 1)}{2} \leq 1$ . In all, we have a  $\frac{1+1/(\varepsilon n + 1)}{2}$ -approximate solution in  $O(m^{1/\varepsilon} \cdot \varepsilon n \cdot (m+n)^2 \cdot mn)$  for all  $\varepsilon \in (0, 1]$ . ◀

The previous approximation algorithm only achieves an approximation ratio of  $\frac{1}{2} + O(\frac{1}{n})$ , which tends to  $\frac{1}{2}$  as  $n$  increases. At first glance this is quite disappointing, as someone can observe that a ratio of  $\frac{1}{2}$  is achievable simply by placing words only on the horizontal or the vertical slots of the instance. Nevertheless, we are going to show that this performance is justified, as improving upon this trivial approximation ratio would falsify the Unique Games Conjecture (UGC).

Before we proceed, let us recall some relevant definitions regarding Unique Games. The UNIQUE LABEL COVER problem is defined as follows: we are given a graph  $G = (V, E)$ , with some arbitrary total ordering  $\prec$  of  $V$ , an integer  $R$ , and for each  $(u, v) \in E$  with  $u \prec v$  a 1-to-1 constraint  $\pi_{(u,v)}$  which can be seen as a permutation on  $[R]$ . The vertices of  $G$  are

considered as variables of a constraint satisfaction problem, which take values in  $[R]$ . Each constraint  $\pi_{(u,v)}$  defines for each value of  $u$  a unique value that must be given to  $v$  in order to satisfy the constraint. The goal is to find an assignment to the variables that satisfies as many constraints as possible. The Unique Games Conjecture states that for all  $\epsilon > 0$ , there exists  $R$ , such that distinguishing instances of UNIQUE LABEL COVER for which it is possible to satisfy a  $(1 - \epsilon)$ -fraction of the constraints from instances where no assignment satisfies more than an  $\epsilon$ -fraction of the constraints is NP-hard. In this section we will need a slightly different version of this conjecture, which was defined by Khot and Regev as the Strong Unique Games Conjecture. Despite the name, Khot and Regev showed that this version is implied by the standard UGC. The precise formulation is the following:

► **Theorem 14** (Theorem 3.2 of [9]). *If the Unique Games Conjecture is true, then for all  $\epsilon > 0$  it is NP-hard to distinguish between the following two cases of instances of UNIQUE LABEL COVER  $G = (V, E)$ :*

- (Yes case): *There exists a set  $V' \subseteq V$  with  $|V'| \geq (1 - \epsilon)|V|$  and an assignment for  $V'$  such that all constraints with both endpoints in  $V'$  are satisfied.*
- (No case): *For any assignment to  $V$ , for any set  $V' \subseteq V$  with  $|V'| \geq \epsilon|V|$ , there exists a constraint with both endpoints in  $V'$  that is violated by the assignment.*

Using the version of the UGC given in Theorem 14 we are ready to present our hardness of approximation argument for the crossword puzzle.

► **Theorem 15.** *Suppose that the Unique Games Conjecture is true. Then, for all  $\epsilon$  with  $\frac{1}{4} > \epsilon > 0$ , there exists an alphabet  $\Sigma_\epsilon$  such that it is NP-hard to distinguish between the following two cases of instances of the crossword problem on alphabet  $\Sigma_\epsilon$ :*

- (Yes case): *There exists a valid solution that fills a  $(1 - \epsilon)$ -fraction of all cells.*
- (No case): *No valid solution can fill more than a  $(\frac{1}{2} + \epsilon)$ -fraction of all cells.*

*Moreover, the above still holds if all slots have distinct lengths (and hence reusing words is trivially impossible).*

**Proof.** Fix an  $\epsilon > 0$ . We will later define an appropriately chosen value  $\epsilon' \in (0, \epsilon)$  whose value only depends on  $\epsilon$ . We present a reduction from a UNIQUE LABEL COVER instance, as described in Theorem 14. In particular, suppose we have an instance  $G = (V, E)$ , with  $|V| = n$ , alphabet  $[R]$ , such that (under UGC) it is NP-hard to distinguish if there exists a set  $V'$  of size  $(1 - \epsilon')n$  that satisfies all its induced constraints, or if all sets  $V'$  of size  $\epsilon'n$  induce at least one violated constraint for any assignment. Throughout this proof we assume that  $n$  is sufficiently large (otherwise the initial instance is easy). In particular, let  $n > \frac{20}{\epsilon}$ .

We construct an instance of the crossword puzzle that fits in an  $N \times N$  square, where  $N = 4n + n^2$ . We number the rows  $1, \dots, N$  from top to bottom and the columns  $1, \dots, N$  from left to right. The instance contains  $n$  horizontal and  $n$  vertical slots. For  $i \in [n]$ , the  $i$ -th horizontal slot is placed in row  $2i$ , starting at column 1, and has length  $2n + n^2 + i$ . For  $j \in [n]$ , the  $j$ -th vertical slot is placed in column  $2j$ , starts at row 1 and has length  $3n + n^2 + j$ . Observe that all horizontal slots intersect all vertical slots and in particular, for all  $i, j \in [n]$  the cell in row  $2i$ , column  $2j$  belongs to the  $i$ -th horizontal slot and the  $j$ -th vertical slot. Furthermore, each slot has a distinct length, as the longest horizontal slot has length  $3n + n^2$  while the shortest vertical slot has length  $3n + n^2 + 1$ .

We define the alphabet as  $\Sigma_\epsilon = [R] \cup \{*\}$ . Before we define our dictionary, let us give some intuition. Let  $V = \{v_1, \dots, v_n\}$ . The idea is that a variable  $v_i \in V$  of the original instance will be represented by both the  $i$ -th horizontal slot and the  $i$ -th vertical slot. In particular, we will define, for each  $\alpha \in [R]$  a pair of words that we can place in these slots to represent

## 36:14 Filling Crosswords Is Very Hard

the fact that  $v_i$  is assigned with the value  $\alpha$ . We will then ensure that if we place words on both the  $i$ -th horizontal slot and the  $j$ -th horizontal slot, where  $(v_i, v_j) \in E$ , then the assignment that can be extracted by reading these words will satisfy the constraint  $\pi_{(v_i, v_j)}$ . The extra letter  $*$  represents an indifferent assignment (which we need if  $(v_i, v_j) \notin E$ ).

Armed with this intuition, let us define our dictionary.

- For each  $i \in [n]$ , for each  $\alpha \in [R]$  we define a word  $d_{(i, \alpha)}$  of length  $2n + n^2 + i$ . The word  $d_{(i, \alpha)}$  has the character  $*$  everywhere except at position  $2i$  and at positions  $2j$  for  $j \in [n]$  and  $(v_i, v_j) \in E$ . In these positions the word  $d_{(i, \alpha)}$  has the character  $\alpha$ .
- For each  $j \in [n]$ , for each  $\alpha \in [R]$  we define a word  $d'_{(j, \alpha)}$  of length  $3n + n^2 + j$ . The word  $d'_{(j, \alpha)}$  has the character  $*$  everywhere except at position  $2j$  and at positions  $2i$  for  $i \in [n]$  and  $(v_i, v_j) \in E$ . In position  $2j$  we have the character  $\alpha$ . In position  $2i$  with  $(v_i, v_j) \in E$ , we place the character  $\beta \in [R]$  such that the constraint  $\pi_{(v_i, v_j)}$  is satisfied by assigning  $\beta$  to  $v_i$  and  $\alpha$  to  $v_j$ . (Note that  $\beta$  always exists and is unique, as the constraints are permutations on  $[R]$ , that is, for each value  $\alpha$  of  $v_j$  there exists a unique value  $\beta$  of  $v_i$  that satisfies the constraint).

This completes the construction. Suppose now that  $V = \{v_1, \dots, v_n\}$  and that we started from the Yes case of UNIQUE LABEL COVER, that is, there exists a set  $V' \subseteq V$  such that  $|V'| \geq (1 - \epsilon')n$  and all constraints induced by  $V'$  can be simultaneously satisfied. Fix an assignment  $\sigma : V' \rightarrow [R]$  that satisfies all constraints induced by  $V'$ . For each  $i \in [n]$  such that  $v_i \in V'$  we place in the  $i$ -th horizontal slot (that is, in row  $2i$ ) the word  $d_{(i, \sigma(v_i))}$ . For each  $j \in [n]$  such that  $v_j \in V'$  we place in the  $j$ -th vertical slot the word  $d'_{(j, \sigma(v_j))}$ . We leave all other slots empty. We claim that this solution is valid, that is, no shared cell is given different values from its horizontal and vertical slot. To see this, examine the cell in row  $2i$  and column  $2j$ . If both of the slots that contain it are filled, then  $v_i, v_j \in V'$ . If  $(v_i, v_j) \notin E$  and  $i \neq j$ , then the cell contains  $*$  from both words. If  $i = j$ , then the cell contains  $\sigma(v_i)$  from both words. If  $i \neq j$  and  $(v_i, v_j) \in E$ , then the cell contains  $\sigma(v_i)$ . This is consistent with the vertical word, as the constraint  $\pi_{(v_i, v_j)}$  is assumed to be satisfied by  $\sigma$ . We now observe that this solution covers at least  $2(1 - \epsilon')n^3$  cells, as we have placed  $2(1 - \epsilon')n$  words, each of length at least  $n^2 + 2n$ , that do not pairwise intersect beyond their first  $2n$  characters.

Suppose now we started our construction from a No instance of UNIQUE LABEL COVER. We claim that the optimal solution in the new instance cannot cover significantly more than half the cells. In particular, suppose a solution covers at least  $(1 + \epsilon')n^3 + 10n^2$  cells. We claim that the solution must have placed at least  $(1 + \epsilon')n$  words. Indeed, if we place at most  $(1 + \epsilon')n$  words, as the longest word has length  $n^2 + 4n$ , the maximum number of cells we can cover is  $(1 + \epsilon')n(n^2 + 4n) \leq (1 + \epsilon')n^3 + 4(1 + \epsilon')n^2 < (1 + \epsilon')n^3 + 10n^2$ . Let  $x$  be the number of indices  $i \in [n]$  such that the supposed solution has placed a word in both the  $i$ -th horizontal slot and the  $i$ -th vertical slot. We claim that  $x \geq \epsilon'n$ . Indeed, if  $x < \epsilon'n$ , then the total number of words we might have placed is at most  $(n - x) + 2x < (1 + \epsilon')n$ , which contradicts our previous observation that we placed at least  $(1 + \epsilon')n$  words. Let  $V' \subseteq V$  be defined as the set of  $v_i \in V$  such that the solution places words in the  $i$ -th horizontal and vertical slot. Then  $|V'| \geq \epsilon'n$ . We claim that it is possible to satisfy all the constraints induced by  $V'$  in the original instance, obtaining a contradiction. Indeed, we can extract an assignment for each  $v_i \in V'$  by assigning to  $v_i$  value  $\alpha$  if the  $i$ -th horizontal slot contains the word  $d_{(i, \alpha)}$ . Note that the  $i$ -th horizontal slot must contain such a word, as these words are the only ones that have an appropriate length. Observe that in this case the  $i$ -th vertical slot must also contain  $d'_{(i, \alpha)}$ . Now, for  $v_i, v_j \in V'$ , with  $(v_i, v_j) \in E$  we see that  $\pi_{(v_i, v_j)}$  is satisfied by our assignment, otherwise we would have a conflict in the cell in position  $(2i, 2j)$ . Therefore, in the No case, it must be impossible to fill more than  $(1 + \epsilon')n^3 + 10n^2$  cells.

The only thing that remains is to define  $\epsilon'$ . Let  $C$  be the total number of cells in the instance. Recall that we proved that in the Yes case we cover at least  $2(1 - \epsilon')n^3$  cells and in the No case at most  $(1 + \epsilon')n^3 + 10n^2$  cells. So we need to define  $\epsilon'$  such that  $2(1 - \epsilon')n^3 \geq (1 - \epsilon)C$  and  $(1 + \epsilon')n^3 + 10n^2 \leq (\frac{1}{2} + \epsilon)C$ . To avoid tedious calculations, we observe that  $2n^3 \leq C \leq 2n^3 + 8n^2$ . Therefore, it suffices to have  $2(1 - \epsilon')n^3 \geq 2(1 - \epsilon)(n^3 + 4n^2)$  and  $(1 + \epsilon')n^3 + 10n^2 \leq (1 + 2\epsilon)n^3$ . The first inequality is equivalent to  $(\epsilon - \epsilon')n \geq 4(1 - \epsilon)$  and the second inequality is equivalent to  $(2\epsilon - \epsilon')n \geq 10$ . Since we have assumed that  $n \geq 20/\epsilon$ , it is sufficient to set  $\epsilon' = \epsilon/2$ . ◀

## 6 Conclusion

We studied the parameterized complexity of some crossword puzzles under several different parameters and we gave some positive results followed by proofs which show that our algorithms are essentially optimal. Based on our results the most natural questions that arise are: What is the complexity of CP-DEC when the grid graph is a matching and the alphabet has size 2? Can Theorem 12 be strengthened by starting from ETH instead of randomized ETH? Can we beat the 1/2 approximation ratio of CP-OPT if we restrict our instances? Can Theorem 14 be strengthened by dropping the UGC? Furthermore, it would be interesting to investigate if there exist non trivial instances of the problem that can be solved in polynomial time. Finally, we could consider a variation of the crossword puzzle problems where each word can be used a given number of times. This would be an intermediate case between word reuse and no word reuse.

## Abstract

Grid graphs, and, more generally,  $k \times r$  grid graphs, form one of the most basic classes of geometric graphs. Over the past few decades, a large body of works studied the (in)tractability of various computational problems on grid graphs, which often yield substantially faster algorithms than general graphs. Unfortunately, the recognition of a grid graph (given a graph  $G$ , decide whether it can be embedded into a grid graph) is particularly hard – it was shown to be NP-hard even on trees of pathwidth 3 already in 1987. Yet, in this paper, we provide several positive results in this regard in the framework of parameterized complexity (additionally, we present new and complementary hardness results). Specifically, our contribution is threefold. First, we show that the problem is fixed-parameter tractable (FPT) parameterized by  $k + \text{mcc}$  where  $\text{mcc}$  is the maximum size of a connected component of  $G$ . This also implies that the problem is FPT parameterized by  $\text{td} + k$  where  $\text{td}$  is the treedepth of  $G$ , as  $\text{td} \leq \text{mcc}$  (to be compared with the hardness for pathwidth 2 where  $k = 3$ ). (We note that when  $k$  and  $r$  are unrestricted, the problem is trivially FPT parameterized by  $\text{td}$ .) Further, we derive as a corollary that strip packing is FPT with respect to the height of the strip plus the maximum of the dimensions of the packed rectangles, which was previously only known to be in XP. Second, we present a new parameterization, denoted  $a_G$ , relating graph distance to geometric distance, which may be of independent interest. We show that the problem is para-NP-hard parameterized by  $a_G$ , but FPT parameterized by  $a_G$  on trees, as well as FPT parameterized by  $k + a_G$ . Third, we show that the recognition of  $k \times r$  grid graphs is NP-hard on graphs of pathwidth 2 where  $k = 3$ . Moreover, when  $k$  and  $r$  are unrestricted, we show that the problem is NP-hard on trees of pathwidth 2, but trivially solvable in polynomial time on graphs of pathwidth 1.

## 1 Introduction

Geometrically, a *grid graph* is a graph that can be drawn on the Euclidean plane so that all vertices are drawn on points having positive integer coordinates, and all edges are drawn as axis-parallel straight line segments of length 1;<sup>1</sup> when the maximum  $x$ -coordinate is at most  $r$  and the maximum  $y$ -coordinate is at most  $k$ , we may use the term  $k \times r$  *grid graph* (see Figure 2). Grid graphs form one of the simplest and most intuitive classes of geometric graphs. Over the past few decades, algorithmic research of grid graphs yielded a large body of works on the tractability or intractability of various computational problems when restricted to grid graphs (e.g., see [14, 15, 3, 37, 48, 17, 4] for a few examples). Even for problems that remain NP-hard on grid graphs, we know of practical algorithms for instances of moderate size (e.g., the STEINER TREE problem on grid graphs is NP-hard [27], but admits practical algorithms [25, 49]). Thus, the recognition of a graph as a grid graph unlocks highly efficient tools for its analysis. In practice, grid graphs can represent layouts or environments, and have found applications in several fields, such as VLSI design [45], motion planning [32] and routing [46]. Indeed, grid graphs naturally arise to represent entities and the connections between them in *existing* layouts or environments. However, often we are given just a (combinatorial) graph  $G$  – i.e., we are given entities and the connections desired to have between them, and we are to construct the layout or environment; specifically, we wish to test whether  $G$  can be embedded into a grid graph (where if it can so, realize it as such a graph). Equivalently, the recognition of a grid graph can be viewed as an embedding problem, where a given graph is to be embedded within a rectangular solid grid.

Accordingly, the problem of recognizing (as well as realizing) grid graphs is a basic recognition problem in Graph Drawing. In what follows, we discuss only recognition – however, it would be clear that all of our results hold also for realization (with the same time complexity in case of algorithms). Formally, in the GRID EMBEDDING problem, we are given a (simple, undirected)  $n$ -vertex graph  $G$ , and need to decide whether it can be embedded into a grid graph. In many cases, taking into account physical constraints, compactness or visual clarity, we would like to not only have a grid graph, but also restrict its dimensions. This yields the  $k \times r$ -GRID EMBEDDING problem, where given an  $n$ -vertex graph  $G$  and positive integers  $k, r \in \mathbb{N}$ , we need to decide whether  $G$  is a  $k \times r$  grid graph. Notice that GRID EMBEDDING is the special case of  $k \times r$ -GRID EMBEDDING where  $k = r = n$  (which virtually means that no dimension restriction is posed).

The GRID EMBEDDING problem has been proven to be NP-hard already in 1987, even on trees of pathwidth 3 [9]. Shortly afterwards, it has been proven to be NP-hard even on binary trees [29]. On the positive side, there is research on practical algorithms for this problem [7]. The related upward planarity testing and rectilinear planarity testing problems are also known to be NP-hard [28], as well as HV-planarity testing even on graphs of maximum degree 3 [20]. We remark that when the embedding is fixed, i.e., the clockwise order of the edges is given for each vertex, the situation becomes drastically easier computationally; then, for example, a rectangular drawing of a plane graph of maximum degree 3, as well as an orthogonal drawing without bends of a plane graph of maximum degree 3, were shown to be computable in linear time in [43] and [44], respectively.

In this paper, we study the classical and parameterized complexity of the GRID EMBEDDING and  $k \times r$ -GRID EMBEDDING problems. To the best of our knowledge, this is the first time that these problems are studied from the perspective of parameterized complexity. Let

---

<sup>1</sup> Some papers in the literature use the term grid graphs to refer to *induced* grid graphs, where we require also that every pair of vertices at distance 1 from each other have an edge between them.

$\Pi$  be an NP-hard problem. In the framework of parameterized complexity, each instance of  $\Pi$  is associated with a *parameter*  $k$ . We say that  $\Pi$  is *fixed-parameter tractable (FPT)* if any instance  $(I, k)$  of  $\Pi$  is solvable in time  $f(k) \cdot |I|^{\mathcal{O}(1)}$ , where  $f$  is an arbitrary computable function of  $k$ . Nowadays, Parameterized Complexity supplies a rich toolkit to design FPT algorithms as well as to prove that some problems are unlikely to be FPT [22, 16, 24]. In particular, the term para-NP-hard refers to problems that are NP-hard even when the parameter is fixed, which implies that they are not FPT unless  $P=NP$ .

Research at the intersection of graph drawing and parameterized complexity (and parameterized algorithms in particular) is in its infancy. Most (in particular, the early efforts) have been directed at variants of the classic CROSSING MINIMIZATION problem, introduced by Turán in 1940 [47], parameterized by the number of crossings (see, e.g., [30, 38, 23, 35, 36, 39]). However, in the past few years, there is an increasing interest in the analysis of a variety of other problems in graph drawing from the perspective of parameterized complexity (see, e.g., [1, 10, 2, 31, 13, 34, 6, 19, 18, 11, 21, 41, 40]).

## Our Contribution and Main Proof Ideas

**I. Parameterized Complexity: Maximum Connected Component Size.** Our contribution is threefold. First, we prove that  $k \times r$ -GRID EMBEDDING is FPT parameterized by  $\text{mcc} + k$ . Here, the idea of the proof is first to recognize all possible embeddings of any choice of connected components or parts of connected components of  $G$  into  $k \times \text{mcc}(G)$  grids, called blocks. These blocks then serve as vertices of a new digraph, where there is an arc from one vertex to another if and only if the corresponding blocks can be placed one after the other. After that, we also guess which blocks should occur at least once in the solution, as well as a spanning tree of the underlying undirected graph of the graph induced on them. This then leads us to a formulation of an Integer Linear Program (ILP), where we ensure that each connected component is used as many times as it is in the input, and that overall we get an Eulerian trail in the graph – having such a trail allows us to place the blocks one after the other, so that every pair of consecutive blocks are compatible. The ILP can then be solved using known tools.

► **Theorem 1.1.**  $k \times r$ -GRID EMBEDDING is FPT parameterized by  $\text{mcc} + k$  where  $\text{mcc}$  is the maximum size of a connected component in the input graph.

One almost immediate corollary of this theorem concerns the 2-STRIP PACKING problem. In this problem, we are given a set of  $n$  rectangles  $S$ , and positive integers  $k, W \in \mathbb{N}$ , and the objective is to decide whether all the rectangles in  $S$  can be packed in a rectangle (called a *strip*) of dimensions  $k \times W$ . In [5], it was shown that if the maximum of the dimensions of the input rectangles, denoted by  $\ell$ , is fixed, then the problem is FPT by  $k$ . Thus, the question whether the problem is FPT parameterized by  $k + \ell$  remained open. By a straightforward reduction, we resolve this question as a corollary of our theorem.

► **Corollary 1.2.** 2-STRIP PACKING is FPT parameterized by  $\ell + k$  where  $\ell$  is the maximum of the dimensions of the input rectangles.

We remark that in case  $k$  and  $r$  are unrestricted, the problem is trivially FPT with respect to  $\text{mcc}$ , since one can embed each connected component (using brute-force) individually. This implies that GRID EMBEDDING is FPT parameterized by  $\text{mcc}$ .

As a corollary of Theorem 1.1 and the above observation, we obtain that  $k \times r$ -GRID EMBEDDING is FPT parameterized by  $\text{td} + k$ , and GRID EMBEDDING is FPT parameterized by  $\text{td}$ , where  $\text{td}$  is the treedepth of the input graph. This finding is of interest when contrasted with the hardness of these problems when pathwidth equals 2 and  $k = 3$  or unrestricted. Thus, this also charts a tractability border between pathwidth and treedepth.

## II. Parameterized Complexity: Difference Between Graph and Geometric Distances.

Secondly, we introduce a new parameterization that relates graph distance to geometric distance, and may be of independent interest. Roughly speaking, the rationale behind this parameterization is to bound the difference between them, so that graph distances may act as approximate indicators to geometric distances. In particular, vertices that are close in the graph, are to be close in the embedding, and vertices that are distant in the graph, are to be distant in the embedding as well. Specifically, with respect to an embedding  $f$  of  $G$  in a grid, we define the *grid distance* between any two vertices as the distance between them in  $f$  in L1 norm. Then, we define the measure of *distance approximation* of  $f$  as the maximum of the difference between the graph distance (in  $G$ ) and the grid distance of two vertices, taken over all pairs of vertices in  $G$ . Here, it is implicitly assumed that  $G$  is connected. Then, the parameter  $a_G$  is the minimum distance approximation  $a_f$  of any embedding  $f$  of  $G$  in a (possibly  $k \times r$ ) grid, defined as  $|V(G)|$  if no such embedding exists. A more formal definition as well as motivation is given in Section 2.

We first prove that the problems are para-NP-hard parameterized by  $a_G$ . This reduction is quite technical. On a high level, we present a construction of “blocks” that are embedded in a grid-like fashion, where we place an outer “frame” of the form of a grid to guarantee that the boundary (which is a cycle) of each of these blocks must be embedded as a square. Each variable is associated with a column of blocks, and each clause is associated with a row of blocks. Within each block, we place two gadgets, one which transmits information in a row-like fashion, to ensure that the clause corresponding to the row has at least one literal that is satisfied, and the other (which is very different than the first) transmits information in a column-like fashion, to ensure consistency between all blocks corresponding to the same variable (i.e., that all of them will be embedded internally in a way that represents only truth, or only false). For clarity, in the full version we split the reduction into two, and use as an intermediate problem a new problem that we call the BATTERIES problem.

► **Theorem 1.3.** GRID EMBEDDING (and hence also  $k \times r$ -GRID EMBEDDING) is para-NP-hard parameterized by  $a_G$ .

When we enrich the parameterization by  $k$ , then  $k \times r$ -GRID EMBEDDING problem becomes FPT. (Recall that parameterized by  $k$  alone, the problem is para-NP-hard). The idea of the proof is to partition a rectangular solid  $k \times r$  grid in which we embed our graph into blocks of size  $k \times (a_G + k)$ , and “guess” one vertex that is to be embedded in the leftmost column of the leftmost block. Then, the crux is in the observation that, for every vertex, the block in which it should be placed is “almost” fixed – that is, we can determine two consecutive blocks in which the vertex may be placed, and then we only have a choice of one among them. This, in turn, leads us to the design of an iterative procedure that traverses the blocks from left to right, and stores, among other information, which vertices were used in the previous block.

► **Theorem 1.4.**  $k \times r$ -GRID EMBEDDING is FPT parameterized by  $a_G + k$ .

Lastly, we prove that when restricted to trees, the problems become FPT parameterized by  $a_G$  alone. Here, a crucial ingredient is to understand the structure of the tree, including a bound on the number of vertices of degree at least 3 in the tree that split it to “large” subtrees. For this, one of the central insights is that, with respect to an internal vertex  $v$  and any two “large” subtrees attached to it (there can be up to four subtrees attached to it), in order not to exceed the allowed difference between the graph and geometric distances, one of the subtrees must be embedded in the “opposite” direction of the other (so, both

■ **Figure 1** Example of a path  $P$  on 8 vertices with three different grid graph embeddings  $f_1$ ,  $f_2$  and  $f_3$ . Since  $a_{f_2} = a_{f_3} = 0$ , we get that  $a_P = 0$ .

are embedded roughly on the same vertical or horizontal line in opposite sides). Now, for an internal vertex of degree at least 3, there must be two attached subtrees that are not embedded in this fashion (as a line can only accommodate two subtrees), which leads us to the conclusion that all but two of the attached subtrees are small. Making use of this ingredient, we argue that a dynamic programming procedure (somewhat similar to the one mentioned for the previous theorem but much more involved) can be used.

► **Theorem 1.5.**  $k \times r$ -GRID EMBEDDING (and hence also GRID EMBEDDING) on trees is FPT parameterized by  $a_G$ .

**III. Classical Complexity.** Lastly, we extend current knowledge of the classical complexity of GRID EMBEDDING and  $k \times r$ -GRID EMBEDDING at several fronts. Here, we begin by developing a refinement of the classic reduction from NOT-ALL-EQUAL 3SAT in [9] (which asserted hardness on trees of pathwidth 3) to derive the following result. While the reduction itself is similar, our proof is more involved and requires, in particular, new inductive arguments.

► **Theorem 1.6.** GRID EMBEDDING is NP-hard even on trees of pathwidth 2. Thus, it is para-NP-hard parameterized by  $\text{pw}$ , where  $\text{pw}$  is the pathwidth of the input graph.

In particular, now the hardness result is *tight* with respect to pathwidth due to the simple observation that GRID EMBEDDING is polynomial time solvable on graphs of pathwidth 1. Because GRID EMBEDDING is a special case of  $k \times r$ -GRID EMBEDDING, the above theorem has the following result as an immediate corollary:  $k \times r$ -GRID EMBEDDING is NP-hard even on trees of pathwidth 2.

Additionally, we show that  $k \times r$ -GRID EMBEDDING is NP-hard on graphs of pathwidth 2 even when  $k = 3$ . Here, we give a relatively simple reduction from 3-PARTITION (whose objective is to partition a set of numbers encoded in unary into sets of size 3 that sum up to the same number), where the idea is to encode “containers” by special identical connected components whose embedding is essentially fixed, and then each number as a simple path on a corresponding number of vertices.

► **Theorem 1.7.**  $k \times r$ -GRID EMBEDDING is NP-hard even on graphs of pathwidth 2 when  $k = 3$ . Thus, it is para-NP-hard parameterized by  $k + \text{pw}$ , where  $\text{pw}$  is the pathwidth of the input graph.

## 2 Preliminaries

Definitions of various standard concepts can be found in the full version. For every  $k \in \mathbb{N}$ , denote  $[k] = \{1, 2, \dots, k\}$ , and for  $i, j \in \mathbb{N}$ , denote  $[i, j] = \{i, i + 1, \dots, j\}$ . Given a set  $W$  of integers,  $\sum W$  denotes the sum of its elements. Given a function  $g$  defined on a set  $W$ , we denote the set of images of its elements by  $g(W)$ . Given a graph  $G$ , we denote its vertex set and edge set by  $V(G)$  and  $E(G)$ , respectively. For a vertex  $v \in V(G)$ , we denote the degree of  $v$  in  $G$  by  $\deg_G(v)$ . Given a set  $V' \subseteq V(G)$ , the subgraph of  $G$  induced by  $V'$  is denoted by  $G[V']$ . Given  $u, v \in V(G)$ , the distance  $d(u, v)$  between  $u$  and  $v$  in  $G$  is the length of a shortest path between them. The *pathwidth* of a graph  $G$  is denoted by  $\text{pw}(G)$ .

We now define basic notions related to grids and grid embeddings. Let  $f : V(G) \rightarrow \mathbb{N} \times \mathbb{N}$  be a function that maps each vertex  $v$  of  $G$  to a point  $(i, j)$  of an integer grid; then,  $i$  and  $j$  are also denoted as  $f_{\text{row}}(v)$  and  $f_{\text{col}}(v)$ , respectively, that is,  $f(v) = (f_{\text{row}}(v), f_{\text{col}}(v))$ . Let  $u, v \in V(G)$  be two vertices. The *grid graph distance of  $u$  and  $v$  induced by  $f$* , denoted by  $d_f(u, v)$ , is defined to be  $d_f(u, v) = |f_{\text{row}}(u) - f_{\text{row}}(v)| + |f_{\text{col}}(u) - f_{\text{col}}(v)|$ . A  $k \times r$  *grid graph embedding* of  $G$  is an injection  $f : V(G) \rightarrow [k] \times [r]$  such that for every  $\{u, v\} \in E(G)$  it follows that  $d_f(u, v) = 1$ . Moreover, a *grid graph embedding* of  $G$  is a  $|V(G)| \times |V(G)|$  grid graph embedding of  $G$ . We say that  $G$  is a (*resp.*  $k \times r$ ) *grid graph* if there exists a (*resp.*  $k \times r$ ) grid graph embedding of  $G$ . Now, the  $k \times r$ -GRID EMBEDDING and GRID EMBEDDING problems are defined as follows. Given a graph  $G$  and two positive integers  $k, r$ , the  $k \times r$ -GRID EMBEDDING and GRID EMBEDDING problems ask whether  $G$  is a  $k \times r$  grid graph or a grid graph, respectively.

We now define the distance approximation parameter formally and discuss some of the motivation behind it. Towards this, we first present the following simple observation. Let  $G$  be a connected grid graph with a grid embedding  $f$ , and let  $u, v \in V(G)$ . Then,  $d_f(u, v) \leq d(u, v)$ . Keeping this in mind, we drop the absolute value notation from the following definition: For any  $k \times r$  grid graph embedding  $f$  of  $G$ , define  $a_f = \max_{u, v \in V(G)} (d(u, v) - d_f(u, v))$ . Then, if  $G$  is a  $k \times r$  grid graph, let  $a_G(k, r) = \min\{a_f \mid f \text{ is a } k \times r \text{ grid graph embedding of } G\}$ ; otherwise,  $a_G(k, r) = |V(G)|$ . When  $k$  and  $r$  are clear from context, we write “distance approximation parameter” and  $a_G$  rather than “ $k \times r$  distance approximation parameter” and  $a_G(k, r)$ , respectively. When  $k$  and  $r$  are unrestricted,  $a_G(k, r) = a_G(|V(G)|, |V(G)|)$ . See Figure 1. We also remark that whenever  $G$  is a  $k \times r$  grid graph, then  $a_G(k, r) \leq |V(G)| - 2$  (because for any grid graph embedding  $f$  of  $G$  and two different vertices  $u, v \in V(G)$ ,  $d(u, v) \leq |V(G)| - 1$  and  $d_f(u, v) \geq 1$ ).

This rationale behind this parameter makes sense in various scenarios. Suppose that vertices represent utilities, factories or organizations, or, very differently, components to be placed on a chip. On the one hand, those that are closer to each other in the graph might need to cooperate more often: they have direct and indirect (through other entities on the path) connections between them; the more “links on the chain”, the less is directed interaction required. On the other hand, we may have a competitive constraint – we may want these entities to also be “as far as possible”. In particular, if they are far in the graph, we will take advantage of this to place them far in the embedding (proportionally). For example, these entities may cause pollution, radiation or heat [8, 26]. Alternatively, in the case of utilities, we may want to cover as large area as we can. Recently, due to the COVID-19 pandemic, many governments around the world have introduced social distancing. Briefly, social distancing means that people should be physically away from each other, if possible. According to experts, one of the most effective ways to reduce the spread of coronavirus is social distancing [12, 33, 42]. Suppose that the vertices represent people, the edges represent

social (or other) relations between them, and we want to find a seating arrangement. In order to preserve the social distancing, we would like that people who do not need to be close to each other, to be relatively far away from each other. In another example, suppose that the vertices represent some facilities that “attract” people, like stores. Placing the stores far away from each other, if possible, contributes to social distancing. More intuition is given in the full version. We remark that the embeddings that our algorithms compute satisfy the conditions of being a grid graph embedding, in particular, the embeddings are planar. Furthermore, we do not need to know the value of  $a_G$  in advance, in order to use our algorithm, as we iterate over all the potential values for  $a_G$ .

### 3 FPT Algorithm on General Graphs

In this section, we show that  $k \times r$ -GRID EMBEDDING is FPT parameterized by  $\text{mcc}(G) + k$ . We first give the definition of a  $k \times r$  rectangular grid graph and some related terms. An undirected graph  $H$  is a  $k \times r$  rectangular grid graph if there exists a bijection  $f : V \rightarrow [k] \times [r]$ , such that for every pair of vertices  $u, v \in V(H)$ ,  $\{v, u\} \in E(H)$  if and only if  $d_f(u, v) = 1$ . Given a  $k \times r$  rectangular grid graph  $H$  and a corresponding bijective function  $f$ , we define the columns of  $H$  as follows: For every  $j \in [r]$ , let  $C_j(H) = \{u \in V(H) \mid f_{\text{col}}(u) = j\}$ . Clearly,  $V(H) = \bigcup_{j=1}^r C_j(H)$ . We refer to  $C_1(H)$  and  $C_r(H)$  as the left boundary column and right boundary column, respectively, of  $H$ .

Given a subgraph  $S$  of a  $k \times r$  rectangular grid graph  $H$ , we denote by  $\mathcal{FC}(S)$  the set of fully contained connected components of  $S$  defined as all the connected components of  $S$  that either do not intersect the boundary columns of  $H$  or intersect both boundary columns of  $H$ . Moreover, we denote by  $\mathcal{LC}(S)$  ( $\mathcal{RC}(S)$ ) the set of left contained (right contained) connected components of  $S$  defined as all the connected components of  $S$  that intersect the left (right) boundary column of  $H$  but do not intersect the right (left) boundary column of  $H$ . Note that the three sets  $\mathcal{FC}(S)$ ,  $\mathcal{LC}(S)$  and  $\mathcal{RC}(S)$  are pairwise disjoint and  $S = \mathcal{FC}(S) \cup \mathcal{LC}(S) \cup \mathcal{RC}(S)$ . See Figure 2. We now prove that  $k \times r$ -GRID EMBEDDING is FPT.

**Proof Sketch of Theorem 1.1.** The FPT algorithm is based on ILP. To this end, let  $G$  be an instance of the  $k \times r$ -GRID EMBEDDING problem. Due to lack of space, we only give a sketch of the algorithm. For completeness, please refer to the full version.
